hand, in the distorted $Si(2)S_4$ tetrahedron, the partial substitution of the indium atom for the Si(2) site seems to have no influence on the Si(2)-S bond lengths, which range from 2.111 to 2.191 Å. The mean Si(2)-S bond length of 2.133 Å is closely related to the mean bond lengths observed in other thiosilicates, e.g., Fe_2SiS_4 (2.130 Å),[18] Ba_2SiS_4 (2.17 Å),[1] $Na_4Si_4S_{10}$ (2.107 Å; bridge, 2.144 Å; terminal, 2.035 Å),[8] and SiS_2 (2.13 Å).[19] The S(terminal)-Si-S(bridge) bond angles are in the 108.7—115.3° range; also, the S(terminal)-Si-S(terminal) bond angles are 113.8° for Si(1) and 114.4° for Si(2). These bond angles are larger than the regular tetrahedral angle of 109.28′. On the other hand, the S(bridge)-Si-S(bridge) bond angles within the four-membered ring, 89.1° for Si(1) and 100.6° for Si(2), are significantly smaller than those in the regular tetrahedron. The distortion from the regular tetrahedral angle must be due to the repulsion between the two positively charged silicon atoms. The formation of such dimers is, therefore, attributable to the tendency of the configuration of the four-membered ring to minimize repulsions by electrostatic force: the repulsions between the two positively charged silicon atoms and those between the two negatively charged sulfur atoms. This unexpected atomic configuration of the Si_2S_6 group, which is novel for thio- and oxo-anions, is similar to the structure of Al_2Cl_6 (in the gas phase) and Al_2Br_6, and is very similar to configurations of, *e.g.*, the $Ge_2S_6^{4-}$ anions in $Tl_4Ge_2S_6$[6] and $Na_4Ge_2S_6 \cdot 14H_2O$,[7] the $Ge_2Se_6^{4-}$ anion in $Na_4Ge_2Se_6 \cdot 16H_2O$,[20] and the $Sn_2S_6^{4-}$ anion in $Na_4Sn_2S_6 \cdot 14H_2O$.[7] On the contrary, taking into account the substitution of the indium atom for the Si(1) site, it appears that the SiS_4 tetrahedron combines with the InS_4 tetrahedron by means of a common edge to form a dimeric (SiS_3-InS_3) group. This is the first example of a dimer composed of both silicon and indium tetrahedra.

The indium atom is bonded to the four nearest sulfur atoms, thus forming an almost regular tetrahedron, as is shown in Fig. 3. The S-In-S bond angles range from 104.1 to 113.4°, with an average value of 109.5°. These values are in agreement with the regular tetrahedral angle of 109°28′. The In-S bond lengths in the range from 2.296 to 2.379 Å are significantly less than the values found in β-In_2S_3 (tetrahedron: 2.44—2.48 Å; octahedron: 2.54—2.68 Å).[21] These values are in accord with the value for the sum of the covalent radii, 2.32 Å, calculated on the basis of the occupancies of the indium atom and the silicon atom in the In site. The sharing of two sulfur atoms for each InS_4 tetrahedron may result in simple infinite chains with the formula of $(InS_3)_n$, as is shown in Fig. 1-(b). The In-S(1) and In-S(2) bond lengths, 2.346 and 2.379 Å, are somewhat longer than the In-S(3) and In-S(4) bond lengths, 2.296 and 2.331 Å. The dimeric Si_2S_6 groups hold the parallel chains by sharing two edges to form a two-dimensional sheet-like network (see Fig. 1).

Two thallium atoms which are nonequivalent in the cell are located between these sheets, bonded weakly to their nearest neighbours. One of them, Tl(1), forms a 7+2 irregular coordination polyhedron (Fig. 4). Seven sulfur atoms are closer to the thallium atom at distances from 3.410 to 3.734 Å, while two sulfur atoms are further away, at distances of 3.957 Å. The average Tl-S distance for Tl(1) is 3.641 Å in the nine-fold coordination polyhedron. The arrangement of sulfur atoms around the other thallium atom, Tl(2), shows no systematic coordination geometry (Fig. 5), with nine Tl-(2)-S contacts ranging from 3.293 to 3.780 Å, with the mean of 3.574 Å.

The mean Tl-S bond distances for the Tl(1) and Tl(2) atoms in the nine-fold coordination polyhedron are considerably longer than the mean bond distances for the similar coordination polyhedra found in $Tl_4Ge_4S_{10}$ (Tl-S: 3.43 Å)[10] and in thallium sulfosalts, *e.g.*, simo-

nite, $TlHgAs_3S_6$ (Tl-S: 3.43 Å)[22] and synthetic parapierrotite, $TlSb_5S_8$ (Tl-S: 3.39 Å).[23] Because those long bond distances represent relatively weak bonding interactions, such substances might be expected to cleave most readily in directions parallel to the sheets, as is observed in micas. In fact, this expectation is confirmed in a series of quaternary chalcogenides having the formulae of $TlInSiS_4$, $TlInGeS_4$, $TlGaSiS_4$, $TlGaGeS_4$, and $TlAlGeS_4$.[13]

The authors are grateful to Professors Masaaki Ohmasa and Shigeho Sueno, the University of Tsukuba, for their helpful advice and for reading the paper.

Excited-state Reactions of Coumarins in Aqueous Solutions. II. The Fluorescence Quenching of 7-Ethoxycoumarins by Halide Ions

Tetsuo MORIYA

Electrotechnical Laboratory, 1-1-4 Umezono, Sakura-mura, Niihari-gun, Ibaraki, 305

(Received November 2, 1983)

The fluorescence yield and the fluorescence lifetime of 7-ethoxycoumarins in aqueous solutions are reduced with the increase in the temperature and in the concentration of the quenching agents. The radiationless deactivation of the excited state in the absence of quenchers is temperature-dependent; its activation energy has been determined to be 32.5—34.8 kJ mol^{-1}. The quenching reaction due to halide ions proceeds *via* both a diffusional and a static process. The rate constant for the diffusional process has a value of $(9.7—10.2)\times10^9$ mol^{-1} dm^3 s^{-1} in the case of I^- as a quencher. The static quenching component can be approximately described by the $V[Q]$ expression, with the static quenching constant, V, being 1.6—1.8 mol^{-1} dm^3. The quenching efficiencies that represent the probability leading to real quenching reactions by an encounter of the molecule and the halide ion are unity for I^-, 0.39—0.42 for Br^-, and almost zero for Cl^-. The possible physical interpretation of the quenching mechanism is discussed in relation to the electron transfer between colliding species.

Although a considerable volume of data has been accumulated on the luminescence properties of various coumarin derivatives,[1] few works have appeared on the fluorescence-quenching of the molecule in solution by unlike molecules or by inorganic ions. We have already examined in detail the fluorescent behavior of 7-hydroxycoumarins,[2] and our study has revealed that the molecules have several molecular species in the optically excited state, depending on the pH of the solution. This situation has made it very difficult to investigate the fluorescence-quenching effects of these molecules because of the complexity of the fluorescence spectrum itself in the absence of quenchers. If the hydroxyl group of 7-hydroxycoumarins is replaced by the ethoxyl group, then the neutral species becomes the only species existing in the excited state as well as in the ground state, and the fluorescence spectrum becomes a very simple one over a wide pH range in aqueous solutions, in contrast to the case of 7-hydroxy-substituted coumarins. Accordingly, 7-ethoxy-substituted coumarins are a convenient group for a fundamental study of fluorescence-quenching reactions of coumarins.

The quantum yield of molecules in solution is known to be affected by a variety of factors, such as the temperature, the viscosity, and the concentration of the quenching agents. In this paper, halide ions have been chosen as quenchers, and the fluorescence intensities of 7-ethoxycoumarin (**1**) and 7-ethoxy-4-methylcoumarin (**2**) in aqueous solutions have been measured as a function of the concentration of the quencher and the temperature of the solution. The reaction-rate constant for fluorescence quenching by halide ions and the several activation energies related to it will be derived by means of the obtained data, and the quenching mechanism will be discussed in detail.

Experimental

Materials. The high-purity-grade reagents of 7-ethoxycoumarin (**1**) and 7-ethoxy-4-methylcoumarin (**2**) were obtained from Molecular Probes, Inc., and used as purchased. Their melting points were determined distinctly by means of differential thermal analysis (DTA); the purity was revealed to be very high by the measured DTA curves:[3] **1**, mp 84.8 °C **2**, mp 115.5 °C. The sodium chloride, sodium bromide, sodium iodide, and sodium thiosulfate were pure and were obtained from Wako Pure Chemical Ind. The water was permeated and distilled.

Methods. The UV absorption spectra at the ambient temperature were obtained on a Hitachi 323 spectrophotometer. The fluorescence-intensity measurements were done on a Hitachi MPF 4 spectrofluorometer with an S-5 type photomultiplier tube. For the temperature-dependence studies, we used a hollow cell holder, through which water from a constant-temperature bath was circulated. The temperature in the cuvette could be controlled to within ±0.5° between 10 and 50 °C, and was monitored directly by means of a thermocouple immediately after the fluorescence measurement.

The wavelengths of the excitation light were chosen to be 324 nm for **1** and 321 nm for **2**, which corresponded to the absorption maxima. The concentrations of the fluorescent molecules in the aqueous solution were $\approx5\times10^{-5}$ mol dm^{-3} for **1** and $\approx4\times10^{-5}$ mol dm^{-3} for **2**, with which the reliable and stable recording of the fluorescence spectra was ensured.[4] Since the shape and position of the emission spectrum were not noticeably altered by either the change in the temperature or by the addition of a quencher, the fluorescence intensity was usually determined by the measurement of the relative intensity at the emission maxima, which were found at 390 nm and 382 nm for **1** and **2** respectively.

In the quenching experiment, the fluorescence of a series of samples, containing a constant amount of a fluorescent compound and a graduated amount of a quencher, was measured. The stocked solutions of quenchers used to vary the concentration of the halide ions were 4M NaCl, 2M NaBr, and 0.2M NaI (containing $\approx10^{-4}$ M $Na_2S_2O_3$ to prevent I_3^- formation; 1 M=1 mol dm^{-3}). The quenchers had no disturbing absorption in the wavelength region of interest.

The fluorescence lifetime measurements were performed by using a time-correlated single-photon-counting fluorometer similar to the one described in Ref. 5. Because the determined lifetime becomes less accurate for lifetimes shorter than 2 ns when our apparatus was used, the supplemental relationship:

$$\tau_0(t) = \tau_0^{20}\frac{I_0(t)}{I_0^{20}}, \tag{1}$$

was used to obtain the temperature dependence of the lifetime at higher temperatures, where τ_0^{20} and $\tau_0(t)$, I_0^{20} and $I_0(t)$ are the lifetimes and the emission intensities at 20 °C and t °C in the absence of a quencher. The viscosity of water was taken from

the literature.

Results and Discussion

Temperature Dependence of the Fluorescence Lifetime. A frequently postulated kinetic scheme for the fluorescence-quenching process is as follows:

$$A + h\nu_A \xrightarrow{I_{abs}} A^*$$

$$A^* + Q \underset{k_2}{\overset{k_1}{\rightleftharpoons}} (AQ)^* \xrightarrow{k_3} A + Q$$

$$(AQ)^* \xrightarrow{n_1} A + h\nu_F \qquad (AQ)^* \xrightarrow{n_2} A$$

Here, A, Q, and $h\nu$ represent the fluorophore, the quencher, and the light quantum; A* and (AQ)* are the excited states of the fluorophore and of the encounter complex between A and Q respectively; the k's are the reaction-rate constants, and the n's are the transition probabilities. When the quencher is absent, the lifetime, τ_0, and the quantum yield, ϕ_0, of the excited molecule at t °C are given by:

$$\tau_0(t) = \frac{1}{n_1+n_2(t)} \text{ and } \phi_0(t) = \frac{n_1}{n_1+n_2(t)}, \qquad (2)$$

where n_1 and n_2 are the radiative and radiationless transition probabilities respectively. The temperature dependence of the lifetime or the quantum yield of **1** and **2** in an aqueous solution is quite large, as may be seen from Fig. 1. Because of the effect of the slight broadening of the emission spectra at higher temperatures, the integrated area of the spectrum was used to estimate the rigorous quantum yield. No shift in the wavelength of the emission maximum was observed upon raising the temperature, suggesting that the fluorescing state itself is not altered at all.

If the reasonable assumptions are made that n_1 is independent of the temperature (at least in the region between 10 to 50 °C) and that only one radiationless deactivation process is significant, then the temperature dependence of the lifetime may be expressed by:

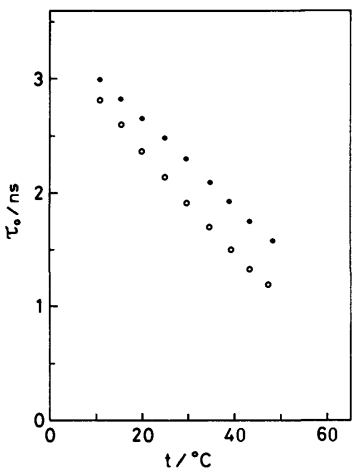

Fig. 1. Temperature dependence of the fluorescence lifetimes of 7-ethoxycoumarins in aqueous solution. ○, 7-ethoxycoumarin (**1**); ●, 7-ethoxy-4-methylcoumarin (**2**).

$$\frac{1}{\tau_0(t)} - n_1 = n_2(t) = n_2^0 \exp\left(-\frac{E_2}{RT}\right), \qquad (3)$$

where n_2^0 is the frequency factor for the deactivation process and involves the entropic component of the corresponding free energy of activation, E_2 is the activation energy for the deactivation process, R is the gas constant, and T is the absolute temperature. By means of the numerical fitting of Eq. 3 with the data in Fig. 1, the value of n_1 can be determined; Fig. 2 shows the logarithmic plots of $(1/\tau_0)-n_1$ *vs.* $1/T$, from the slope of which we have obtained the E_2 of Eq. 3. The actual lifetime, τ_0, at 20 °C, the radiative lifetime, $\tau_1(=1/n_1)$, and the activation energy, E_2, are listed in Table 1. It is known from the obtained values that the radiative and radiationless transition probabilities are of the same order at around 20 °C. The activation energies of 32.5—34.8 kJ mol^{-1} are similar to those for tryptophan derivatives in water;[6] this similarity may be related to the activation of a "tunneling" process from the excited to the ground state or, alternatively, of an electron-ejecting process of the molecule to the solvent. It may be noted here that the assumption of only one deactivation process is an expedient one because the examined temperature range is not so wide as to exclude completely the existence of the temperature-independent term or other types of temperature-dependent terms. In contrast to the case of an organic solvent,[7] the quenching by dissolved dioxygen in an aqueous solution has been shown by the lifetime measurement to be unimportant.

Fluorescence Quenching by Halide Ions. In the quenching reaction between an excited state of a fluoro-

2	2.2_5	3.2_2	32.5

a) The values at 20 °C.

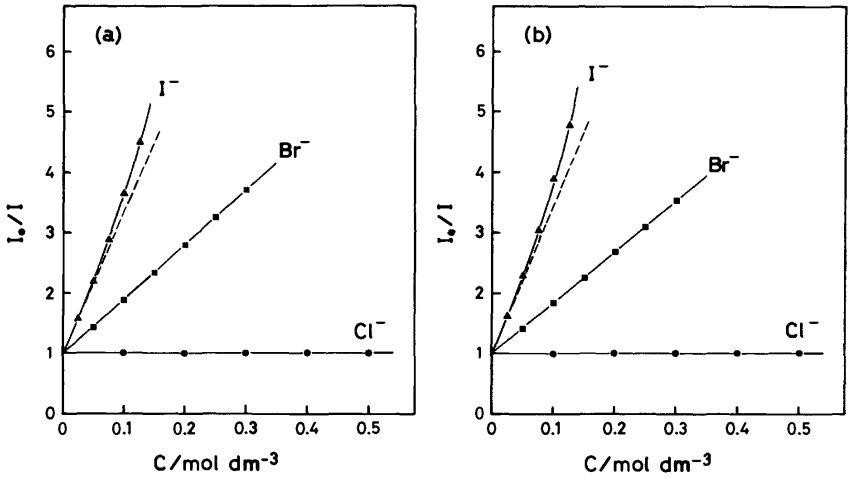

Fig. 3. Stern-Volmer plots for the fluorescence quenching by I^- (▲), Br^- (■), and Cl^- (●) in aqueous solution at 20°C. (a), 7-ethoxycoumarin (**1**); (b), 7-ethoxy-4-methylcoumarin (**2**).

phore, A*, and a quencher, Q, the encounter complex, (AQ)*, that is formed with a diffusion-controlled rate constant, k_1, reacts to dissipate the electronic energy by some internal-mechanism rate constant, k_3. For such a case, the Stern-Volmer relationship under steady-state conditions is described by:[8]

$$\frac{\phi_0}{\phi} = 1 + K_{sv}[Q] = \frac{I_0}{I}, \tag{4}$$

where ϕ_0 and ϕ, I_0 and I, are the quantum yields and the emission intensities in the absence and in the presence of Q, respectively. K_{sv} is the collisional quenching constant, which is equal to $k_q\tau_0$; k_q is the apparent rate constant for the collisional quenching process; it is given by:

$$k_q = \gamma k_1 \text{ and } \gamma = \frac{k_3}{k_2+k_3}. \tag{5}$$

Here, γ represents the efficiency of the quenching reaction, which approaches unity if $k_2 \ll k_3$. When not every encounter between Q and A* results in quenching, the efficiency of the reaction becomes less than unity, and k_q is approximately equal to k_1k_3/k_2 if $k_2 \gg k_3$.

The data in Figs. 3(a) and 3(b) are the Stern-Volmer plots obtained when Cl^-, Br^-, and I^- were used as quenchers. Cl^- had no effect on the fluorescence intensity when $[Cl^-] \lesssim 0.5$ mol dm^{-3}. Br^- and I^- drastically quenched the fluorescence of both **1** and **2**. When I^- is used as a quencher, it may be seen from Fig. 3 that the plots are apparently curved upwards in a fashion similar to those found in many other detailed quenching studies.[9] This type of deviation from the expected linear plot can be explained by the fact that only a certain fraction, W, of the excited state is actually quenched by the collisional mechanism. Some molecules in the excited state, the fraction of which is $1-W$, are deactivated almost instantaneously after being formed because a quencher happens to be randomly positioned in the proximity at the time the molecules are excited and interacts very strongly with them. Several models can be employed to describe this instantaneous or "static" quenching process, all leading to the following modified form of the Stern-Volmer equation:

$$\frac{\phi_0}{\phi} = \frac{1+K_{sv}[Q]}{W} = \frac{I_0}{I}. \tag{6}$$

Model 1. The complete Smolchowski equation for diffusion-controlled reactions contains an often neglected transient term:[10,11]

$$k_1 = 4\pi N'RD + 4R^2(\pi D)^{1/2}t^{-1/2}$$
$$= (\text{steady state term}) + (\text{transient term}) \tag{7}$$

where N′ is Avogadro's number per millimole, R is the encounter distance between the reactants, D is the sum of the individual diffusion coefficients of the reactants, and t is the time. The retention of the latter term leads to an additional factor, W, in the Stern-Volmer equation which is approximately equal to $\exp(-V[Q])$, where V is the static quenching constant.[10]

Model 2. Frank and Vavilov[12] have suggested that instantaneous quenching results at those instances in a randomly distributed system when a quencher happens to reside within a "sphere of action" with a volume of V/N' and a radius of r, *i.e.*, $V/N' = 4\pi r^3/3$, surrounding a fluorophore at the time of excitation. In this case, W is also given by this expression: $\exp(-V[Q])$.

Model 3. In the model of Moon *et al.*,[13] instantaneous quenching follows the excitation of the ground-state complex, (AQ). Such a situation can be described by adding the following reactions to the primary scheme:

$$\begin{array}{ccc} A + h\nu_A & \xrightarrow{I_{abs}\delta} & A^* \\ {\scriptstyle K^0}\Big\| & & \\ (AQ) + h\nu_A & \xrightarrow{I_{abs}(1-\delta)} & (AQ) \end{array}$$

where:

$$\delta = \frac{1}{1+(\varepsilon_{AQ}/\varepsilon_A)K^0[Q]} \text{ and } K^0 = \frac{[AQ]}{[A][Q]}, \tag{8}$$

ε_{AQ} and ε_A being the molar extinction coefficients of (AQ) and A respectively at the excitation wavelength. Then the fraction, W, is given by:

$$W = \frac{\delta+k_2/k_3}{1+k_2/k_3} = \gamma\left(\delta+\frac{k_2}{k_3}\right). \tag{9}$$

If the dark complex, (AQ), is really formed in the solution, δ decreases from unity and, therefore, W decreases, leading to the decrease in the quantum yield.

Because the fraction, W, depends on the concentration of Q in all the cases mentioned above, the Stern-Volmer plots for a quencher with high quenching ability generally deviate from a linear plot. In order to extract more tractable information from these models, it is sensible to calculate the value of $\{1-(I/I_0)\}/[Q]$, that is:

$$\frac{1-(I/I_0)}{[Q]} = K_{sv}\frac{I}{I_0} + \frac{1-W}{[Q]}. \quad (10)$$

For Models 1 and 2, when $V[Q] \ll 1$ is satisfied, $W \approx 1-V[Q]$ and Eq. 10 is written as:

$$\frac{1-(I/I_0)}{[Q]} = K_{sv}\frac{I}{I_0} + V. \quad (11)$$

For Model 3, when $(\varepsilon_{AQ}/\varepsilon_A)K^0[Q] \ll 1$ is satisfied, $W \approx 1-\gamma(\varepsilon_{AQ}/\varepsilon_A)K^0[Q]$ and Eq. 10 is written as:

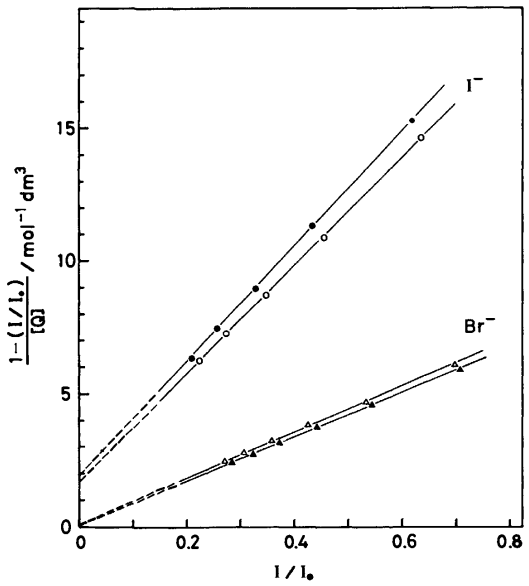

Fig. 4. Plots of $[1-(I/I_0)]/[Q]$ *vs.* I/I_0 at 20°C. I^- as a quencher: ○, **1**; ●, **2**. Br^- as a quencher: △, **1**; ▲, **2**.

$$\frac{1-(I/I_0)}{[Q]} = K_{sv}\frac{I}{I_0} + \gamma\frac{\varepsilon_{AQ}}{\varepsilon_A}K^0. \quad (12)$$

In any case, $\{1-(I/I_0)\}/[Q]$ is described by the form of $a(I/I_0)+b$ when the concentration of quenchers is relatively low. Naturally, the second term, b, of Eq. 10 becomes strictly zero if the linear condition, *i.e.*, $W=1$, is satisfied. The plot of $\{1-(I/I_0)\}/[Q]$ *vs.* I/I_0, therefore, becomes linear in this approximation, the slope, a, of which is K_{sv}, and the intercept, b, of which at $I/I_0 \to 0$ becomes V or $\gamma(\varepsilon_{AQ}/\varepsilon_A)K^0$, depending upon the model being used.

Fig. 4 shows the plots of $\{1-(I/I_0)\}/[Q]$ *vs.* I/I_0 for Compounds **1** and **2** in an aqueous solution at 20 °C. The quenching effects by two halide ions, *i.e.*, Br^- and I^-, have been examined. As can readily be seen from Fig. 4, the effect of varying the fluorescent molecule on the slope and intercept is rather small, but that of varying the quenching ion from Br^- to I^- is large; the values of K_{sv} ($=k_q\tau_0$) and b at 20 °C are listed in Table 2. As for the case of Br^-, the deviation from the linear Stern-Volmer relation is small, because b is very small; this is also known from the plots in Fig. 3. On the other hand, b is much larger for I^-, and the deviation becomes quite large. It may be noted that, in spite of such a deviation from the Stern-Volmer plot, the approximations made in Eqs. 11 and 12 are fully appropriate, as the expansion inacuracy is less than 4% over the concentration range of the quencher used. Accordingly, the newly derived relation of Eqs. 11 and 12 turns out to be a more powerful equation for the analysis of strongly quenching processes than the usual Stern-Volmer equation.

Table 2. Values of the quenching constant K_{sv} and the constant b at 20 °C

Substance	Quencher	K_{sv}/mol^{-1} dm^3	b/mol^{-1} dm^3 a)
1	Br^-	8.5_9	0.1
	I^-	20.3_0	1.7
2	Br^-	8.4_6	0.0_4
	I^-	21.7_2	1.9

a) b is the value for the second term of Eq. 11 or 12.

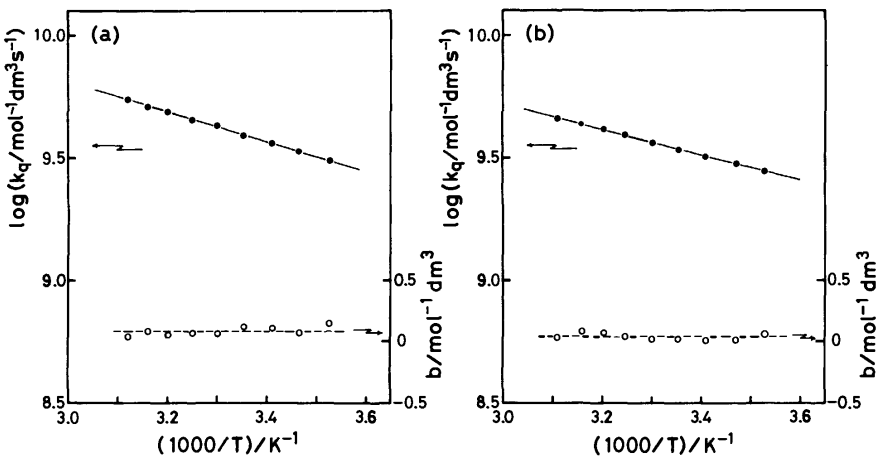

Fig. 5. Arrhenius plots of the rate constants for the collisional quenching, and plots of the static quenching constants *vs.* $1/T$. Br^- as a quencher: (a), **1**; (b), **2**.

Temperature Dependence of the Rate Constant. The collisional quenching constant, K_{SV}, depends, of course, on the temperature through the temperature dependence of the quenching-rate constant, k_q, and the lifetime, τ_0. The values of K_{SV} and τ_0 at temperatures between 10 and 50 °C could be known by independent measurements, so that the temperature dependence of k_q was readily estimated from these values; the logarithm of k_q is plotted against the inverse of the absolute temperature in Figs. 5 and 6. It is clear that the plots of log k_q *vs.* $1/T$ are linear in the temperature range measured. Assuming $k_q \propto \exp(-E_q/RT)$, the activation energy, E_q, for the collisional quenching process was obtained from the slope of this plot; it is listed in Table 3. It seems that E_q is dominated mainly by the species of quenchers, since Compounds **1** and **2** have very similar values of E_q for Br^- and I^- respectively.

Concerning the case of I^-, E_q has been found to be 16.3 and 15.6 kJ mol^{-1} for **1** and **2** respectively; these values are very similar to the value obtained for indole derivatives in water, *i.e.*, 15.5 kJ mol^{-1}.[14] As will be mentioned later, these values are also very near the activation energy for the viscosity of water; this suggests that the rate of reaction is limited only by the diffusion of the reactants through the aqueous solution. E_q for Br^- is somewhat less than these values; the reason for such a difference will be discussed below.

The plots of b in Figs. 5 and 6 show no indication of the temperature dependence in any case. Model 3 predicts that b is temperature-dependent, for the equilibrium constant, K^0, contained in the expression of b varies with the temperature. This fact would contradict the experimental result, although the small possibility that K^0, as well as b, varies very slowly with the temperature cannot be denied. Furthermore, no trace of the ground-state complex, (AQ), could be found by means of the absorption measurement, even if the concentration of a halide ion was set extremely high. Therefore, the deviation from the linear Stern-Volmer relation is not due to the process described by Model 3. Model 1 also predicts the dependece of b on the temperature through the temperature dependence of the diffusion coefficient, which is contained in the transient term of Eq. 7.

On the other hand, Model 2 uses only the statistical nature of the quenchers distributed around the fluorescent molecule, so that no dependence on the temperature is predicted in accordance with the experimental result. For these reasons, it seems most reasonable, in the case of the coumarin derivatives in an aqueous solution, to discuss the quenching phenomena in terms of Model 2, *i.e.*, the sphere-of-action model. By equating b with V, the values of V averaged over temperatures shown in Table 3 are obtained. Using the relation: $V/N' = 4\pi r^3/3$, the radius of the sphere of action for the quenching by I^- is estimated to be 8.6 Å for **1** and 9.0 Å for **2**. These radii are slightly larger than the value, 6—7 Å, which can be estimated as the sum of the radii of the coumarin and the iodide ion. This clearly shows that the instantaneous quenching can occur if the quencher is very near to, or in contact with, the fluorescent molecule at the exact moment that it becomes excited. In the case of Br^-, the active volume element,

TABLE 3. RATE CONSTANTS FOR THE COLLISIONAL QUENCHING PROCESS AT 20 °C, ACTIVATION ENERGIES FOR THE COLLISIONAL QUENCHING, STATIC QUENCHING CONSTANTS, AND RADII OF THE SPHERE OF ACTION

Substance	Quencher	$k_q \times 10^{-9}$ / mol^{-1} dm^3 s^{-1}	E_q / kJ mol^{-1}	V / mol^{-1} dm^3	r / Å
1	Br^-	4.3_0	11.7	0.0_8	3.2
	I^-	10.1_5	16.3	1.6_2	8.6
2	Br^-	3.7_6	9.9	0.0_4	2.5
	I^-	9.6_5	15.6	1.8_1	9.0

V/N', is much smaller and r is less than 4 Å (see Table 3). This is attributable to the weakness in the quenching ability of Br^-, in comparison with that of I^-, because the contact of the quencher with the fluorophore does not always lead to subsequent fluorescence quenching.

Quenching Efficiency. If the values of R and D are reasonably assigned as 7 Å and 1.5×10^{-5} cm^2 s^{-1}, based on the molecular and ionic volumes and the Stokes-Einstein relation,[8] the diffusion-limited value of the quenching-rate constant, k_1, can be calculated to be 7.9×10^9 mol^{-1} dm^3 s^{-1} by using the steady-state portion of Eq. 7, *i.e.*, $k_1=4\pi N'RD$. It was previously mentioned that the actual quenching rate, k_q, is given by $k_q=\gamma k_1$, where γ is the efficiency of the quenching reaction. Although the value obtained above is only a rough estimation, it is close to the experimental values for I^- which are shown in Table 3; the quenching-rate constants for Br^- are somewhat smaller. This indicates that the efficiency of the quenching reaction by I^- is almost unity, while that of the reaction by Br^- is less than unity. The diffusion coefficients of Br^- and I^- in water do not differ very much; therefore, assuming $\gamma=1$ for I^-, the value of γ for Br^- is estimated by means of Eq. 5 to be 0.42 for **1** and 0.39 for **2**, which means more than half of the encounter events between the coumarin and Br^- do not result in the fluorescence quenching. In other words, the encounter distance, R, is shortened effectively to γR for inefficient quenchers such as Br^-.

It has become clear that the efficiency of the collisional deactivation depends on the strength of the quenching ability of each quencher, which is represented by the value "γ". For an efficient quencher like I^-, the efficiency of the quenching reaction is unity, and the magnitude of k_q can be interpreted as the frequency of the collisional encounter between A* and Q. In the case of $\gamma=1$, the temperature behavior of k_q coincides with that of the diffusion-controlled rate constant, k_1 ($=4\pi N'RD$); the temperature dependence of k_1 is due to that of the diffusion coefficient, D. When a relatively narrow region of temperature is considered, D is approximately written as:[15]

$$D = D'\exp(-E_d/RT), \tag{13}$$

where E_d is the activation energy of diffusion and D' is the value at $T=\infty$. Therefore, the obtained value of E_q is equivalent to the activation energy of diffusion.

If γ happens to be less than unity, as in the case of Br^-, the expression for k_q becomes more complicated; in particular, the magnitudes of k_2 and k_3, which may depend on the temperature, become significant. Nevertheless, if the dependence of γ on the temperature is roughly represented by an activation energy, E_γ, *i.e.*, $\gamma\propto\exp(E_\gamma/RT)$, the discussion proceeds parallel to that for the case of $\gamma=1$. The activation energy of k_q for Br^- is smaller than that for I^- by 4.6—5.7 kJ mol^{-1}, as may be seen in Table 3. Considering $k_q\propto\gamma D$, the activation energy of k_q for Br^- may be said to correspond with E_d-E_γ. If such an idea of "efficiency" is also applicable to the radius of the sphere of action, and if r is replaced by γr, then the value of V for Br^- becomes smaller by an order of magnitude than that for I^- due to the factor of γ^3. This prediction agrees well with the experimental results shown in Table 3.

Relation between the Rate Constant and the Viscosity. As has been mentioned previously, $k_1\propto D$, and, as a first approximation, D is obtained by the Stokes-Einstein relation, $D=kT/6\pi R\eta$, where η is the viscosity of water; the plot of k_q *vs.* T/η should be linear if $\gamma=1$. Fig. 7 shows such plots for Br^- and I^-. In reality, k_q for I^- is linearly dependent on T/η, as is to be expected from a diffusion-controlled reaction; in addition, the plot for Br^- is also linear, but the slope is more gentle than that for I^-. Although linear dependence is obtained for both cases, a curious point remains that k_q at a low T/η does not go exactly to zero, which contradicts the simple Stokes-Einstein relation. The deviation from this relationship is due to the inapplicability of the Stokes coefficients of viscous friction, which are introduced by the assumption that the solute molecules are moving in a solvent continuum. Taking proper account of the relative size of the solute and solvent molecules, the expression for the diffusion coefficient sufficient to describe experiments is given by:[8]

$$D = A\frac{T}{\eta} + b\eta^x\frac{T}{\eta}, \tag{14}$$

where A, b and x are constants and the rate constant of diffusional quenching is written as:

$$k_q = \gamma k_1 = \gamma\cdot 4\pi N'RD$$
$$= A'\gamma\frac{T}{\eta} + b'\gamma\eta^x\frac{T}{\eta}. \tag{15}$$

By using the activation energy of the quenching efficiency and of the fluidity, γ and η can be described by:

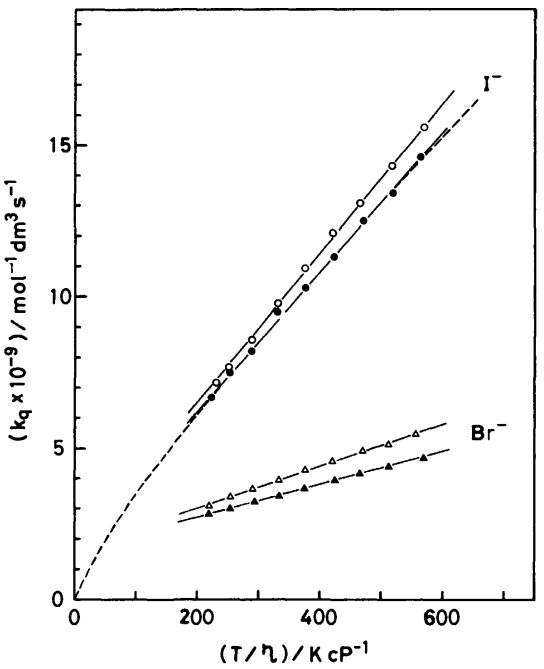

Fig. 7. Dependence of the rate constants for the collisional quenching upon T/η. I^- as a quencher: ○, **1**; ●, **2**. Br^- as a quencher: △, **1**; ▲, **2**. The dashed curve indicates the variation of k_q according to Eq. 17 without any approximation.

Table 4. Parameters obtained for the modified Stokes-Einstein relation and for the quenching efficiency

Substance	Quencher	$A' \times 10^{-7}$ / mol^{-1} dm^3 s^{-1} cP K^{-1}	$B' \times 10^{-4}$ / mol^{-1} dm^3 s^{-1} cP K^{-1}	E_γ / kJ mol^{-1}	$\gamma' \times 10^2$
1	Br^-	2.6_0	8.5_4	4.6_0	6.6_8
	I^-			0	1
2	Br^-	2.3_9	8.4_9	5.7_3	3.8_4
	I^-			0	1

$$\gamma = \gamma' \exp(E_\gamma/RT) \text{ and } \eta = \eta' \exp(E_\eta/RT), \quad (16)$$

in the temperature range of 10—50 °C used; in the case of water, $\eta' \approx 1.2 \times 10^{-3}$ cP and $E_\eta \approx 16.4$ kJ mol^{-1} in the neighborhood of 30 °C, the mean temperature of the measured region; the values of E_γ are already known as $E_\gamma \approx 0$ ($\gamma' = 1$) in the case of I^- and 4.60 and 5.73 kJ mol^{-1} for **1** and **2** respectively in the case of Br^-. The value of x was presumed to be 0.7 by plotting $k_q\eta/T$ *vs.* η^x in the case of I^- for various values of x and by searching for a linear dependency. Then, Eq. 15 is rewritten as:

$$k_q = A'\gamma' \exp(E_\gamma/RT)\frac{T}{\eta} + B'\gamma' \exp\{(E_\gamma + xE_\eta)/RT\}\frac{T}{\eta}, \quad (17)$$

where A', B' and γ' are constants. Regarding $\exp(E_\gamma/RT)$ and $\exp\{(E_\gamma+xE_\eta)/RT\}$ as functions of η/T, and by expanding them around $(\eta/T)_{30}$, the value of η/T at 30 °C, we obtain approximately this relation:

$$\begin{aligned} k_q = {} & \gamma' \exp(E_\gamma/RT_0)\left\{A'\frac{E_\eta + RT_0 - E_\gamma}{E_\eta + RT_0}\right. \\ & \left. + B' \exp(xE_\eta/RT_0)\frac{E_\eta + RT_0 - (E_\gamma + xE_\eta)}{E_\eta + RT_0}\right\}\frac{T}{\eta} \\ & + \gamma' \exp(E_\gamma/RT_0)\left(\frac{T}{\eta}\right)_{30}\left\{A'\frac{E_\gamma}{E_\eta + RT_0}\right. \\ & \left. + B' \exp(xE_\eta/RT_0)\frac{E_\gamma + xE_\eta}{E_\eta + RT_0}\right\}, \end{aligned} \quad (18)$$

where $T_0 = 303.15$ K. Eq. 18 is valid in the neighborhood of 30 °C; this explains very well the experimental relationship of $k_q = a(T/\eta) + b$. By substituting all known parameters and by using the data in Fig. 7, the unknown constants, A', B', and γ', can be obtained as listed in Table 4. It can be recognized from Fig. 7 that the k_q values for both Br^- and I^- have a linear dependence on T/η in the measured region, as is to be expected from Eq. 18. The difference in the slopes for Br^- and I^- is due to the lower quenching efficiency of Br^-; it is interesting that the intercepts at $T/\eta = 0$ are unexpectedly nearly equal in all cases.

In conclusion, the quenching-rate constant of the coumarin derivatives by halide ions is reasonably well described by means of the diffusion-controlled mechanism of the quenching reaction. I^- has been shown to be an "efficient" quencher; Br^- is rather an "inefficient" quencher; Cl^- is a very weak quencher and has no effect on the fluorescence under the conditions examined. Such an order of quenching ability is parallel with the order of the ionization energies of halide anions.[16] Therefore, the initiation of the quenching process is perhaps related with the electron transfer from the ion to the fluorescent molecule in the excited

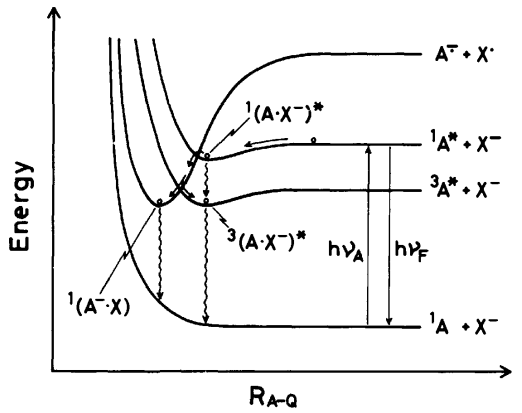

Fig. 8. Schematic potential energy curves of the colliding species and presumable pathways for the fluorescence quenching. R_{A-Q} is the distance between the fluorescent molecule and the halide anion. $^1A^*$ and $^3A^*$ are the singlet and triplet state of the excited molecule, and A^- is the anion radical generated by the electron transfer from the halide anion, X^-. The upward and downward arrows describe the radiative transition, and the downward wavy arrows represent the radiationless transition caused by the collisional reaction.

state.[18] Fig. 8 shows a schematic drawing of the energy levels of the interacting species; it takes account of all the results discussed so far. At an infinite distance, the energy differences between the singlet ground and excited states of 7-ethoxycoumarins are 338—343 kJ mol^{-1}, and the ionization energies of Cl^-, Br^-, and I^- in an aqueous solution are 678, 623, and 544 kJ mol^{-1}.[16] If the crossing of the energy curves of $^1A^*+X^-$ and $A^-+X\cdot$ resides near the encounter distance, the electron transfer from a halide anion to an excited molecule will easily occur, which results in an efficient conversion of the singlet state of the encounter complex, $^1(AX^-)^*$, to its triplet state or, alternatively, to the charge-transferred singlet state, $^1(A^-X\cdot)$. Because the stability of the charge-transferred complex, $(A^-X\cdot)$, is altered by the magnitude of the ionization energy of halide anions, and because its energy position goes lower as the ionization energy decreases, the above-mentioned conversion induced by the electron-transfer process may become a main quenching pathway for I^- and Br^-, but not for Cl^-. However, from a consideration of only the information obtained here, the so-called heavy-atom effect of halide anions, which directly converts the singlet state of the encounter complex to its triplet state, *i.e.*, $^1(AX^-)^* \rightarrow {}^3(AX^-)^*$, cannot be excluded completely. This point is dis-

cussed fully in Refs. 17 and 18, where it is concluded that the main pathway for the fluorescence quenching by diamagnetic inorganic anions is strongly related to the electron-transfer process. It is also revealed that the Stokes-Einstein relation must be somewhat modified in order to explain the dependence of the quenching-rate constants on the viscosity and temperature of the solution.

The author wish to thank Dr. Hiroyuki Anzai of this laboratory for his helpful advice and stimulating discussions during the course of this work.

Saw-toothed Distributions of Deuterium in Butenes Formed by 1,3-Butadiene Deuteration on a Pt/Al_2O_3 Catalyst in D_2SO_4

Katsuaki SHIMAZU and Hideaki KITA*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received November 28, 1983)

Saw-toothed distributions of deuterium are observed in butenes produced by the deuteration of 1,3-butadiene on Pt/Al_2O_3 catalysts suspended in 0.5 M D_2SO_4. The nature of the saw-tooth is sensitive to the purity of the solution and to the deuterium content of the solution. On the basis of the N-profiles (the distributions of hydrogen equilibrated with surface H/D pool) deduced from the observed distributions of deuterium in butenes, the saw-tooth distribution is explained by the reaction mechanism where *cis*- and *trans*-1-methyl-π-allyls are reaction intermediates for the formation of *cis*-2-butene and the other isomers of 1-and *trans*-2-butenes respectively.

The heterogeneous catalytic hydrogenation of 1,3-butadiene in the gas phase has widely been studied on various transition-metal catalysts from the 1960's, for example, on Pt,[1-4] Pd,[1-3,5] other noble metals,[1-4] Co[6-8], and Ni.[6,8,9] However, only a few of these studies have used an isotopic tracer method. The deuteration of 1,3-butadiene on Pt catalysts has been reported only by Bates *et al.*[3] Their reaction mechanism includes mono- and di-π-bonded butadiene as the raction intermediates. 1,3-Butadiene is first chemisorbed in the mono-π-bonded form and then some of the adsorbed 1,3-butadiene becomes the di-π-bonded one in an irreversible way. Thereafter, these adsorbed butadienes, in equilibrium with the corresponding adsorbed butenyl intermediates, are converted to butenes. Their discussion was based on the N-profiles calculated from the distribution of the deuterium in the products.

One must mention that in gaseous catalytic deuteration, deuterium up-take is limited to a lower extent because of the lower deuterium-fraction in adsorbed hydrogen atoms, f_D, due to both the slow rate of the exchange reaction of the adsorbed hydrogen with D_2[3,10] and the smaller ratio, D in D_2 gas/H in butadiene. This limitation is entirely removed in the case of the reaction in a deuterated acid solution.[11] That is, f_D is raised nearly to unity through the fast equilibrium step; $D(a) \rightleftharpoons D^+ + e^-$ on Pt, and the ratio of D in solution/H in butadiene is extremely large. Thus, the reaction products in a solution of deuterated acid are expected to acquire many more deuterium atoms and to provide more concrete information for the elucidation of the reaction mechanism. We have already reported the deuteration of 1,3-butadiene on Pt/graphite[11] and Pt-net,[12] of ethylene[13] and propene[14] on Pt in a 0.5 M D_2SO_4 solution. The deuteration of cyclopentene in solutions of tetrahydrofuran (THF) containing D_2O with and without 5% D_2SO_4 or in the other solutions of CH_3COOD, CH_3OD, $(CH_3)_3COD$, and $DOCH_2CH_2ND_2$-CH_3OD has been studied by Phillipson and Burwell,[15] but here the f_D's are lower than that in a deuterated acid solution, and hence the average number of deuterium atoms taken up in the product cyclopentane was much smaller, even though the addition of D_2O to THF accelerated the deuterium-exchange reaction.

In the present investigation, the deuteration of 1,3-butadiene on a Pt/Al_2O_3 catalyst was conducted in 0.5 M D_2SO_4 purified by the preelectrolysis. We will present a new saw-toothed distribution of deuterium in butenes and discuss the reaction mechanism.

Experimental

Catalysts. The Pt/Al_2O_3 (0.5 wt% Pt) used in this study was a *reference catalyst* supplied by the Catalysis Society of Japan and was prepared as follows.[16] The γ-alumina (BET surface area, 174 m^2/g; pore volume, 0.66 ml/g) was impregnated in an aqueous solution of H_2PtCl_6 and then dried overnight. After calcination at 450 °C for 3 h in O_2, the catalyst was reduced in a H_2 stream at 300 °C for 3 h and then recalcinated at 600 °C for 3 h. The dispersion of Pt has been measured by means of the CO, H_2, and O_2 adsorption methods by several investigators and found to be *ca.* 0.6, though slightly scattered.[16]

Reaction Procedure. The catalyst (0.1—0.2 g), heated at 250 °C for 1 h in a H_2 stream, was suspended in 0.5 M D_2SO_4 and rereduced by bubbling D_2 (Showa Denko, 7N-purity, 99.97D%, P_D=13 mmHg, 1 mmHg=133.3 $N \cdot m^{-2}$) through the solution. The reaction gas was mixture of 1,3-butadiene (4N-purity, P_R=14 mmHg), D_2(P_D=7 or 28 mmHg) and He (7N-purity) at a total pressure of 1 atm. The reaction was conducted by circulating the reaction gas through the solution at 20±1 °C. Our previous work has shown that, under these conditions, the diffusion of D_2 to the catalyst surface is rate-determining.[11,12] No reaction occurred under these conditions without the catalyst.

Solution. The solution of 0.5 M D_2SO_4 was prepared from D_2O (Showa Denko, 99.75D%) and sulfuric acid-d_2 (Merck 99D%). The deuterium content of the solution was estimated from its specific gravity. Unless otherwise stated, the solution was subjected to preelectrolysis overnight (anodically and then cathodically, several mA). The AES and XPS of the Pt electrode used for the preelectrolysis were run on an ESCA 3 Electron Spectrometer (VG Scientific, Ltd.) to detect any impurity picked up from the solution. Both the purity and the deuterium content of the solution greatly influenced the results. These effects will be discussed in the text.

Analysis. The analyses of the products were conducted gas-chromatographically and mass-spectrometerically, as has been described previously.[11]

† 1 M=1 mol dm^{-3}.

Results and Discussion

Saw-toothed Distribution. Table 1 presents the saw-toothed distributions of deuterium in butenes produced from 1,3-butadiene on 0.5 wt%Pt/Al_2O_3 in pre-electrolyzed 0.5 M D_2SO_4 with a high deuterium content (99.7D%). The saw-toothed shape is most clear in *trans*-2-butene and least clear in *cis*-2-butene, while the latter product shows the most enhanced deuterium-exchange among the three isomers. Such saw-toothed distributions are independent of the conversion, at least up to 20%. As has been stated above, each butene takes up much more deuterium atoms than it does in gaseous deuteration on Pt catalysts. For example, the average deuterium number, DN, ($\sum_{i=1}^{8} i \cdot X_i$, X_i is the fraction of the d_i-species) of *cis*-2-butene in Table 1 is 5.2, while, it is 2.1 in the gaseous deuteration.[3] However, the product distributions are very close to each other; butane: 1-butene: *trans*-2-butene: *cis*-2-butene=44:34:11:12 in this work and 44:36:10:10 at 15 °C in a gaseous reaction.[1] This fact indicates that the reaction mechanism is almost the same for both systems. The present saw-toothed distributions have also been observed in our separate experiments on such other catalysts as 5 wt% Pt/Al_2O_3, 0.5 wt% Pt/SiO_2, Pt/TiO_2, and Pt/Nb_2O_5 in a deuterated solution.[17] Therefore, it is concluded that the kind of supports and the amount of doped Pt have no effect on the reaction mechanism.

The saw-toothed shape is sensitive to the solution purity and the deuterium content of the solution. When the solution is used repeatedly without the pre-electrolysis (this was the case in our previous work on Pt/graphite[11]), the saw-tooth becomes less clear. Such a situation is reproduced in the present catalyst as exemplified by the distribution of deuterium in *trans*-2-butene in Fig. 1 (-○-). The overnight pre-electrolysis of the same solution makes the saw-toothed shape clearer, as is shown in Fig. 1 (-△-), indicating that a trace of impurity interferes with the appearance of the saw-toothed shape. In order to check on the impurities removed, the surface of the Pt electrode used for the preelectrolysis was examined by means of the AES and XPS. Both spectra show the peaks of carbon, oxygen, and sulfur. Since the peak intensity of carbon and oxygen is much the same as that on clean Pt foil, neither kind of atom comes from the solution. The presence of sulfur is easily understood, as it comes from SO_4^{2-} in the solution, not from the impurity. The complete absence of the other kinds of atoms in the spectra leads us to assume organic compounds as the impurities in the solution, since organic compounds will be decomposed during the anodic polarization, while inorganic compounds will be deposited through discharge during the cathodic polarization. However, a possibility would remain that the impurity is so small an amount of the inorganic compound that it cannot be detected by means of the AES and XPS. Further

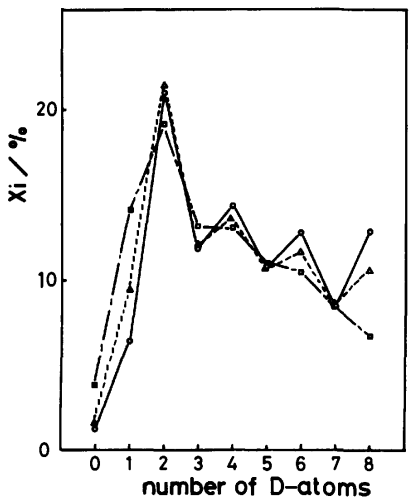

Fig. 2. Distribution of deuterium in *trans*-2-butene formed by the deuteration of 1,3-butadiene on Pt/Al_2O_3 in 0.5M D_2SO_4 of 99.7 D% (○), 97.6 D% (△), and 94.2 D% (□). All the solutions were subjected to the preelectrolysis overnight. P_R=14 mmHg, P_D= 7 mmHg. Total conversions are 2.0% for ○ and 2.5 % for △ and □.

examination is required for the solution of this problem.

The saw-tooth also tends to be smoothed by decreasing the deuterium content of the solution (Fig. 2). In the solution of 94.2 D%, only the shoulders can be seen at butene-d_4 and -d_6. Though both factors - the solution purity and deuterium content of the solution- influence the saw-toothed shape very much, the lack of the saw-toothed shape in the previous work is taken predominantly as being due to the impurity factor, for the decrease in the deuterium content upon repeated use is not large enough to smoothen out the saw-toothed shape.

Isotopically exchanged 1,3-butadiene was not detected after the reaction. Therefore, it is concluded that there is an irreversible adsorption of 1,3-butadiene on the Pt surface.

Simulation by N-profile. The N-profiles of butenes were calculated in order to discuss the reaction mechanism. The N-profile consists of N_0, N_1, ···, N_8, where N_i represents the fraction of the butene in which i hydrogen positions have been equilibrated with the surface H/D pool. The fraction of molecules in which m out of i equilibrated atoms are deuterium, $X_m(i)$, is given by the standard binomial formula as;

$$X_m(i) = {}_iC_m f_D^m (1-f_D)^{i-m}$$

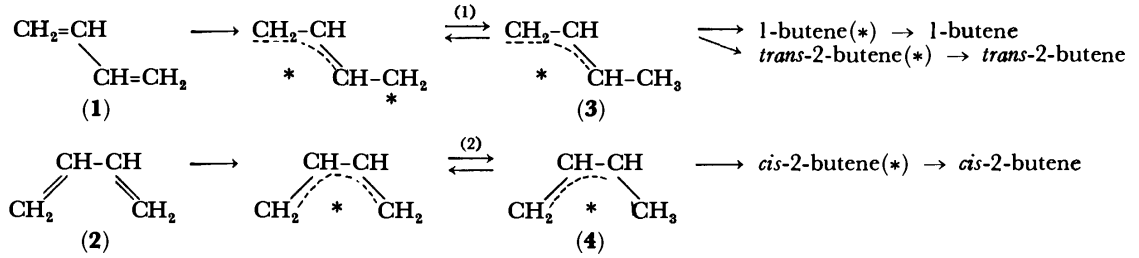
Thus, the fraction of d_m-species, X_m, is calculated as;

$$X_m = \sum_{i=m}^{8} X_m(i) \cdot N_i$$

The N-profile is determined so that X_m, m=0, 1, ···, 8, can best fit the observed distribution of deuterium by adjusting N_2, N_3, ···, N_8 (N_0=N_1=0 because the two hydrogen or deuterium atoms are necessarily taken up in butenes).

The N-profiles thus calculated are shown in Table 1, together with the experimental and the calculated X_m distributions of deuterium. The first thing to notice is that each experimental distribution is satisfactorily reproduced by the X_m calculated based on the N-profile listed in the third row for each butene. The N-profiles of 1-butene and *trans*-2-butene resemble each other. Maxima appear at N_2, N_4, and N_8. N_6 appears as a clear maximum for *trans*-2-butene, but only as a shoulder for 1-butene. N_7 is exceptionally small in both cases. Thus, the N-profiles of 1-butene and *trans*-2-butene also reflect the characteristic features of the maxima (or shoulder) at N_2, N_4, N_6, and N_8. On the other hand, the N-profile of *cis*-2-butene presents three maxima, at N_2, N_6, and N_8, without N_4.

N-profile and Reaction Mechanism. The above features of N-profiles are explained by the following reaction mechanism including the reaction intermediates, **3** and **4** proposed by Bates *et al.*[3] for the same reaction, but on Pd/Al_2O_3 in the gas phase;

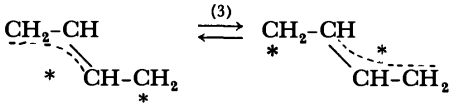


A molecule of 1,3-butadiene in the gas phase which exists in the *s-trans* **1** or *s-cis* **2** form is adsorbed irreversibly on the surface by delocalizing its π-electrons with the same geometrical configuration. The adsorbed *s-trans*-butadiene is converted to either 1-butene or *trans*-2-butene through *trans*-1-methyl-π-allyl **3**, whereas the *s-cis*-butadiene is converted only to *cis*-2-butene through *cis*-1-methyl-π-allyl **4**. Interconversions between the two kinds of adsorbed butadienes and between *trans*- and *cis*-1-methyl-π-allyls are not allowed because of the double-bond-like nature of the internal C-C bond. The lack of these interconversions is in accordance with the clear difference in the distribution of deuterium between *trans*- and *cis*-2-butene. This difference can not be accounted for by either σ- or π-bonded butadiene, since these adsorbed butadienes allow a rotation of the other vinyl group around the axis of the internal C-C bond and, hence, mutual interconversion between the *trans* and *cis* forms. The σ-bonded butadiene is not likely to be present, as is seen from the negative shift of the work function caused by the butadiene adsorp-

tion on Pt(100) and Pt(111).[18]

It must be expected on the basis of the above mechanism that a good correlation exists between the molar fraction of *cis*-2-butene in the products and that of *s-cis*-1,3-butadiene in the gas phase, because *cis*-2-butene is the only product from *s-cis*-1,3-butadiene (butane comes from the *s-trans via* 1-butene[11]). The former molar fraction is 12%, while the latter has been reported to be 3—7%.[19] The correlation is not bad if one takes into account the small modification in the stability of *s-cis*-1, 3-butadiene at the adsorption.

In the above mechanism, the *s-trans* route produces d_4 species by H/D exchange only through Step (1) and d_6 species through Step (1) and also the following Step (3), first proposed by Bates *et al.*[3];

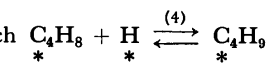


The relative rate of the hydrogenation of species **3** to the reverse of Step (1) for 1-butene formation is somewhat faster than the case of *trans*-2-butene formation. Thus, no distinct maximum is observed at N_6 for 1-butene.

On the other hand, the *s-cis* route gives the N_6-species of *cis*-2-butene through the single step of the reversible Step (2), because the two terminal methylenes in the adsorbed *s-cis*-butadiene are equivalent. Thus, the maximum at N_4 for *cis*-2-butene is diminished.

In addition to N_4 and N_6, considerable amounts of N_3 and N_5 are obtained. This can be readily explained by the slowness of the reverse rates of Steps (1) and (2).

The high fraction of N_8 and the zero amounts of N_7 for all the butenes suggest the presence of another sequence which causes an extremely fast H/D exchange over a molecule. The above mechanism can not explain the formation of N_8-species. One possible explanation could be that the butyl intermediate accelerates the H/D exchange by the following, reversible step;



where $\overset{*}{C_4H_9}$ includes the two possible butyls bonded at either of the carbon atoms of the double bond. Thus, all the hydrogen atoms in the molecule become H/D exchangeable through Steps (1) to (4). The admission of the adsorbed butyl, however, will undoubtedly cause the hydroisomerization of butenes, which is not the case in the hydrogenation of 1,3-butadiene.[11] Further investigation of the details will be required.

The above mechanism is different from that on Pt/Al_2O_3 in the gas phase proposed by Bates *et al.*[3], where *mono-* and *di-*π-bonded butadienes were proposed. Interconversion between these two π-bonded butadienes was taken not to be readily reversible. Their discussion was based on the N-profiles, which differed for the respective butenes, though the observed distribution of deuterium in 1-butene was very similar to that of *trans*-2-butene, but different from that of *cis*-2-butene, as in our results. Therefore, their N-profiles had to lead to a different mechanism. Since the f_D in the gas-phase deuteration is rather low, it is essentially difficult to calculate the N-profile accurately from the distribution of deuterium in less deuterated products, though a somewhat saw-toothed figure can be noticed in their N-profile calculated for *trans*-2-butene. On the other hand, the present system can provide highly deuterium-exchanged products which ensure an accurate N-profile, and it enables us to elucidate the reaction mechanism more precisely.

The authors wish to thank Professor I. Toyoshima of Hokkaido University for the measurements of the XPS and AES. The present work was partly supported by a Grant-in-Aid for Scientific Research, No 57470001, from the Ministry of Education.

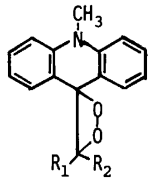
A Kinetic Study on the Chemiluminescence of 9-Alkylacridines upon Air Oxidation in Alkaline Aprotic Solvents

Isao KAMIYA,* Takashi SUGIMOTO, and Kuniaki YAMABE†
Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464
†*Department of Industrial Chemistry, Sasebo Technical College, Sasebo 857-11*
(Received November 28, 1983)

9-Methyl- (**1a**), 9-benzyl- (**1b**), 9-(diphenylmethyl)- (**1c**), and 9-ethylacridine (**1d**) were employed to obtain luminescent features of the acridines. The decay of chemiluminescence (CL) exhibits a pseudo-first order behavior with apparent rate constants 0.10, 3.30, 4.10, and 0.07 min^{-1} at 312 K for **1a**, **1b**, **1c**, and **1d**, respectively. A relatively high CL quantum yield (6.3×10^{-3}) is provided for **1a**, in contrast to low yields for **1b**, **1c**, and **1d** (1.5×10^{-6}, 1.1×10^{-5}, and 1.3×10^{-4}, respectively). A reaction mechanism involving a cleavage of a dioxetane intermediate to give excited singlet acridone anion is plausible for the luminescent reaction. In view of the fact that several dioxetanes decompose to give excited singlet products in high yields, the CL appears to arise from a minor reaction.

A number of acridines and acridinium salts have been reported to chemiluminesce in various reactions.[1] However, there exists little information as to the chemiluminescence (CL) of 9-alkylacridines on base-catalyzed air oxidation except a short description by White and Harding.[2] They observed a CL of 9-methylacridine (**1a**) on reaction with potassium *t*-butoxide (*t*-BuOK) and oxygen in dimethyl sulfoxide and proposed a reaction scheme involving a cleavage of a dioxetane intermediate to give the excited singlet acridone anion. Recently, such 1,2-dioxetanes as **2a**, **2b**, and **2c** have been derived and shown to decompose



2a: $R_1=R_2=H$
2b: $R_1=H$, $R_2=C_6H_5$
2c: $R_1=R_2=C_6H_5$

thermally to give excited singlet 10-methylacridone.[3] According to Lee and Singer,[3c] the chemiexcitation yield for the generation of excited singlet 10-methylacridone changes with a structural variation at R_1 and R_2 in the dioxetanes, increasing in the order **2a**<**2b**<**2c**. Thus, we anticipated that if dioxetane intermediates like **2b** and **2c** were generated, the CL from air oxidation of 9-benzyl- (**1b**) or 9-(diphenylmethyl)acridine (**1c**) would be more intense than that from **1a**. A preliminary experiment, however, showed that the pattern of the substituent effect was contrary to our expectation; only feeble emission could be detected from **1b** and **1c** in spite of a high yield of ground state of acridone anion being obtained.

In order to study the effect of 9-alkyl substituents on the CL intensity of 9-alkylacridines **1a**—**1c** and 9-ethylacridine (**1d**), we investigated the kinetics for the luminescent air oxidation and determined the CL quantum and chemiexcitation yields for the generation of the excited singlet acridone anion.

Results and Discussion

The luminescent reaction was initiated by adding 0.3 cm^3 of a solution of *t*-BuOK in *t*-butyl alcohol (*t*-BuOK/*t*-BuOH solution, 2×10^{-2} mol/dm^3) to 2.0 cm^3 of an aerated solution of **1a**, **1b**, **1c**, or **1d** in DMF (1×10^{-4} mol/dm^3). CL emissions from each acridine show the same spectral distribution, matching the fluorescence (FL) spectra of the spent reaction mixtures and the FL spectrum of acridone anion under the identical experimental conditions,[4] as shown in Fig. 1. Actually, 9-acridone was detected and identified by a comparison with an authentic sample (Tokyo Kasei, guaranteed reagent) by means of thin layer chromatography on silica gel.

Under the experimental conditions employed, CL decays showed a pseudo-first order behavior to about 3 half-lives. From the decays, apparent rate constants at several different temperatures were determined. Rates of reactions were also determined by following the increase in the concentration of acridone anion through measurement of its FL-emission intensity at 465 nm. The FL-increasing curves obtained from **1a** and **1b** are illustrated together with the corresponding CL-decay curves in Fig. 2. The rate constants determined from the FL-increasing curves and those from CL-decay curves are shown in Table 1. A fairly good

321 K			0.14	0.16

TABLE 2. APPARENT ACTIVATION ENERGIES (E_a) AND PREEXPONENTIAL FACTORS (A) FOR THE CHEMILUMINESCENT REACTIONS OF **1a**, **1b**, AND **1d**

Acridine	E_a / kJ mol^{-1}	A / min^{-1}
1a	65.2	8.8×10^{10}
1b	58.9	2.4×10^{10}
1d	70.8	4.2×10^{10}

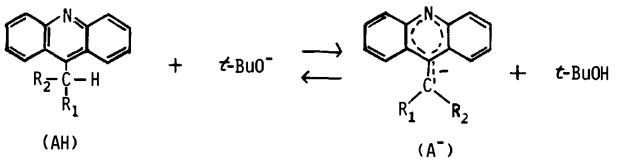
agreement is found between the two, which indicates that the rate of the luminescent reaction is parallel to the rate of generation of acridone anion. The rate constants yield rather good Arrhenius plots, from which apparent activation energies and preexponential factors for **1a**, **1b**, and **1d** were determined. These kinetic data are tabulated in Table 2.

When *t*-BuOK/*t*-BuOH solution was added to a degassed solution of **1a** or **1b** *in vacuo*, no CL emission was observed and an orange-red intermediate was found, which was stable in the absence of oxygen. The absorption and FL spectra of this intermediate in a system with **1b** are shown Fig. 3. An admission of air to the system caused CL to appear progressively. Mason and Roberts[5] observed a similar orange-red intermediate when they added aqueous sodium hydroxide to a degassed solution of 4,5-dihydropyrazino[2,1-a:3,4-a']diisoquinolinediium dibromide in methanol, which chemiluminesced on reaction with oxygen due to generation of excited singlet 1,2-di[2-(1-isoquinolonyl)]-ethane. Heller and coworkers[6] reported that the orange-red color is attributable to a formation of electron-rich olefin *via* a cation radical, which reacts with oxygen to produce excited singlet 1,2-di[2-(1-isoquinolonyl)]ethane, and that the initial step of the change is the abstraction of a proton from the pyrazinodiisoquinolinediium salt.

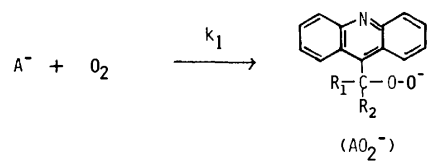
On the analogy of the luminescent reaction of the pyradinodiisoquinolinediium salt, it seems likely that an electron-rich olefin is generated at the initial stage by loss of a proton from acridines. The extremely low magnitude of reaction rate for **1d** is probably due to low concentration of the olefin since no appreciable formation of the orange-red intermidiate was observed.

In view of the experimental results described above, the following reaction scheme, analogous to the one outlined by White and Harding,[2] would be plausible for the luminescent reaction.

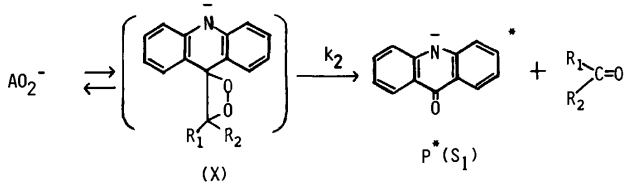
(1) Proton transfer from acridine (AH) to *t*-BuO$^-$ to form an electron-rich olefin (A$^-$):



(2) Reaction of A$^-$ with oxygen to produce a peroxide anion (AO_2^-):



(3) Of the decomposition processes of AO_2^-, one is a cleavage *via* a dioxetane intermediate (X) to give excited singlet acridone anion ($P^*(S_1)$):



or to give the ground state of acridone anion ($P(S_0)$):

$$AO_2^- \rightleftarrows (X) \xrightarrow{k_3} P(S_0) + R_1R_2C{=}O.$$

(4) The cleavage processes of AO_2^- *via* acyclic pathways to give $P(S_0)$ and other products (Q) will compete with the above processes:

$$AO_2^- \xrightarrow{k_4} P(S_0),$$

$$AO_2^- \xrightarrow{k_5} Q.$$

(5) FL emission from $P^*(S_1)$:

$$P^*(S_1) \xrightarrow{k_6} P(S_0) + h\nu.$$

(6) Radiationless deactivation of $P^*(S_1)$:

$$P^*(S_1) \xrightarrow{k_7} P(S_0).$$

(7) Intersystem crossing to excited triplet acridone anion ($P^*(T_1)$) followed by radiationless deactivation:

$$P^*(S_1) \xrightarrow{k_8} P^*(T_1) \longrightarrow P(S_0).$$

According to the scheme, the intensity of CL emission is given by

$$I_{CL} = k_6[P^*(S_1)].$$

Using the steady-state approximation formulations $d[P^*(S_1)]/dt=0$ and $d[AO_2^-]/dt=0$, I_{CL} can be written as

$$I_{CL} = (k_2/(k_2+k_3+k_4+k_5))\Phi_F k_1[A^-][O_2],$$

where Φ_F is the apparent FL quantum yield of acridone anion in aerated DMF-*t*-BuOK systems and is given by

$$\Phi_F = k_6/(k_6+k_7+k_8).$$

If $[O_2]$ and $[t\text{-BuO}^-]$ are assumed to be maintained constant during the CL emission, I_{CL} is given by

$$I_{CL} = (k_2/(k_2+k_3+k_4+k_5))\Phi_F k_{obsd}[AH],$$

where

$$k_{obsd} = k_1[O_2]K[t\text{-BuO}^-]/[t\text{-BuOH}]$$

and

$$K = [A^-][t\text{-BuOH}]/[AH][t\text{-BuO}^-].$$

Figure 4 shows plots of the logarithm of emission intensity *vs.* time for the CL of **1a** (1.0×10^{-4} mol/dm^3) for different concentrations of *t*-BuOK, which indicates that the apparent first-order rate constant for the CL decay (k_{obsd}) is a function of $[t\text{-BuO}^-]$ as assumed above.

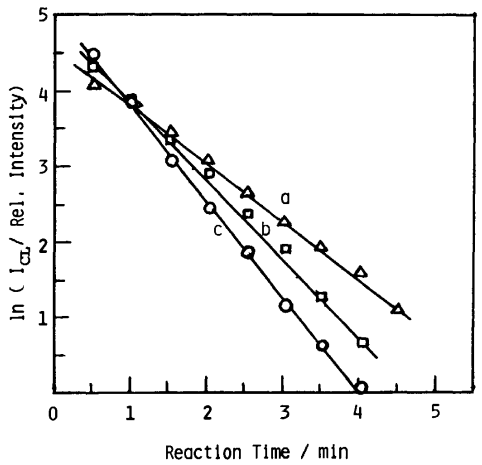


Fig. 4. The plots of ln (CL intensities of **1a** with different *t*-BuOK concentrations) *vs.* reaction time at 321K.
a: $[t\text{-BuOK}]=2.5\times10^{-3}$ mol/dm^3, $k_{obsd}=0.28$ min^{-1}; b: 4.0×10^{-3} mol/dm^3, 1.00 min^{-1}; c: 5.0×10^{-3} mol/dm^3, 1.30 min^{-1}.

The scheme further gives the following relation:

$$d[P(S_0)]/dt = ((k_2+k_3+k_4)/(k_2+k_3+k_4+k_5))k_{obsd}[AH].$$

Because of the low concentration of A^-, $d[P(S_0)]/dt$ is approximately written as

$$d[P(S_0)]/dt = ((k_2+k_3+k_4)/(k_2+k_3+k_4+k_5)) \times(-d[AH]/dt),$$

so that $[AH]=[AH]_0\exp(-k_{obsd}t)$, where $[AH]_0$ is the initial concentration of acridine.

Thus, I_{CL} is given by

$$I_{CL} = (k_2/(k_2+k_3+k_4+k_5))\Phi_F k_{obsd}[AH]_0 \exp(-k_{obsd}t), \quad (1)$$

and the concentration of acridone anion at reaction time *t* is given by

$$[P(S_0)]_t = ((k_2+k_3+k_4)/(k_2+k_3+k_4+k_5))[AH]_0 \times(1-\exp(-k_{obsd}t)). \quad (2)$$

From Eqs. 1 and 2, the overall CL quantum yield defined by

$$\Phi_{CL} = \int_0^{t_e} I_{CL}dt/[AH]_0$$

is given by

$$\Phi_{CL} = \Phi^*\Phi_F\Phi_r,$$

where t_e is the duration of CL emission, Φ^* is the chemiexcitation yield for the generation of excited singlet acridone anion from acridine, given by

$$\Phi^* = k_2/(k_2+k_3+k_4+k_5),$$

and Φ_r is the yield of acridone anion from acridine, given by

$$\Phi_r = [P(S_0)]_{t_e}/[AH]_0.$$

Φ_{CL} was determined from the ratio of the total light emitted from the CL of acridine to that from a standard luminol solution in dimethyl sulfoxide containing *t*-BuOK ($\Phi^S_{CL}=1.28\times10^{-2}$)[7] by the same method as described in our previous paper.[8] Φ_r was determined from

TABLE 3. CHEMILUMINESCENCE QUANTUM YIELD (Φ_{CL}), YIELDS OF ACRIDONE ANION FROM ACRIDINES (Φ_r), AND CHEMIEXCITATION YIELDS FOR THE GENERATION OF EXCITED SINGLET ACRIDONE ANION FROM DIOXETANE INTERMEDIATES (Φ^*) AT SEVERAL DIFFERENT TEMPERATURES

	Φ_{CL}	Φ_r	Φ^*	Φ_{CL}	Φ_r	Φ^*
	1a			**1b**		
293 K	6.3×10^{-3}	0.40	7.5×10^{-2}	1.6×10^{-6}	0.625	1.2×10^{-6}
298 K	6.8×10^{-3}	0.43	7.5×10^{-2}	1.5×10^{-6}	0.63	1.1×10^{-6}
303 K	6.9×10^{-3}	0.43	7.6×10^{-2}	1.5×10^{-6}	0.66	1.1×10^{-6}
307 K	6.3×10^{-3}	0.40	7.5×10^{-2}	1.5×10^{-6}	0.62	1.1×10^{-6}
312 K	6.3×10^{-3}	0.425	7.1×10^{-2}	1.4×10^{-6}	0.625	1.1×10^{-6}
	1c			**1d**		
312 K	1.1×10^{-5}	0.60	7.8×10^{-5}	1.1×10^{-4}	0.21	2.5×10^{-3}
316 K				1.3×10^{-4}	0.24	2.6×10^{-3}
321 K				1.45×10^{-4}	0.34	2.2×10^{-3}

($\Phi_F=0.21$ over the temperature range)

FL assay with known concentrations of acridone anion as internal standard by the method reported by Lee and coworkers (the method of standard addition).[9] Φ_F was determined by comparison of the FL emission of acridone anion in basic DMF[4] with that from a standard solution of quinine sulfate in 0.50 mol/dm^3 H_2SO_4 ($\Phi_F^S=0.50$)[10] and obtained to be 0.21, which was maintained almost constant over the temperature range of 289—321 K. The values of Φ_{CL} and Φ_r at several different temperatures and of Φ^* calculated from Eq. 3 are tabulated in Table 3. The results indicate that neither k_{obsd} nor Φ_r but Φ^* contributes to Φ_{CL}, which means that the ratio of k_2 to $k_3+k_4+k_5$ governs the CL quantum yield. The little dependence of Φ^* (and thus Φ_{CL}) on temperature may be interpreted in terms of the little dependence of k_2, k_3, k_4, and k_5 on temperature due to the low activation energy for the decomposition of unstable peroxide anion (AO_2^-). Our present experimental data do not allow us to decide whether k_3 or k_4+k_5 contributes predominantly to the lowering of the value of Φ_{CL} since the net chemiexcitation yield from dioxetane intermediate, $k_2/(k_2+k_3)$, cannot be determined. In view of the fact that several isolated dioxetanes decompose to give excited singlet product in high yields,[3a,c] it seems likely that the decomposition path *via* the dioxetane intermediate is a minor one, and thus, the extremely high magnitude of k_4 or k_5 lowers the Φ_{CL}-values of **1b** and **1c**.

Two other possibilities to lower the Φ_{CL}-values of **1b** and **1c** are conceivable. One is the direct generation of excited triplet acetophenone (from **1b**) or benzophenone (from **1c**), and the other is the generation of some quenching products. These, however, seem unlikely because neither indirect CL with 9,10-dibromoanthracence (one of triplet monitors) nor cis isomerization of added *trans*-stilbene could be observed, and because the CL of **1a** was not quenched by the addition of **1b** or **1c**. Further investigation is required to clarify the reason why the CL emissions from **1b** and **1c** are by far lower than the one from **1a**.

Experimental

Preparation of 9-Alkylacridines. The acridines were synthesized by heating a mixture of a carboxylic acid and diphenylamine with zinc chloride. The following procedure is representative of the syntheses. A mixture of diphenylamine (5.0 g), acetic acid (5.0 g), and zinc chloride (2.0 g) was heated at 210—220 °C for 10 h. While warm, the mixture was mixed with water (200 cm^3) and the product was extracted with benzene (3×200 cm^3). Evaporation of the extract and subsequent crystallization from benzene gave 9-methylacridine (**1a**) as pale yellow needles (49% yield): mp 117.5—118.5 °C [O. Blum, *Chem. Ber.*, **62**, 881 (1929): mp 117—118 °C]; MS *m/z* 193 (M^+). Found: C, 87.05; H, 5.68; N, 7.20. Calcd for $C_{14}H_{11}N$: C, 87.01; H, 5.74; N, 7.25. In a similar way, the following compounds were synthesized. 9-ethylacridine (**1d**) (58% yield): mp 115.5—116.5 °C [O. Tsuge, M. Nishinohara, and K. Sadano, *Bull. Chem. Soc. Jpn.*, **38**, 2037 (1965): mp 116 °C]; MS *m/z* 207 (M^+). Found: C, 86.59; H, 6.38; N, 6.62. Calcd for $C_{15}H_{13}N$: C, 86.92; H, 6.32; N, 6.76. 9-benzylacridine (**1b**) (58% yield): mp 173—174 °C [E. H. Huntress and E. N. Show, *J. Org. Chem.*, **13**, 674 (1948): mp 173 °C]; MS *m/z* 269 (M^+). Found: C, 88.93; H, 5.59; N, 5.27. Calcd for $C_{20}H_{15}N$: C, 88.18; H, 5.61; N, 5.20. 9-(diphenylmethyl)acridine (**1c**) (30% yield): mp 195—197 °C (from a 1.1 mixture of benzene and hexane); MS *m/z* 345 (M^+). Found: C, 89.95; H, 5.60; N, 4.15. Calcd for $C_{26}H_{19}N$: C, 90.39; H, 5.55; N, 4.06.

Measurements of Intensity and Spectra of CL and FL Emissions. The reactions were conducted in a quartz cell (1.0×1.0×4.5 cm), which was kept at a constant temperature by means of thermostated cell holder. The intensity and spectrum of CL emission were measured on a Hitachi MPF-2A fluorescence spectrophotometer, with the excitation source off. The intensity and spectrum of FL emission were also measured on the same apparatus.

The Effect of 4-Hydroxyl Substituent on the Singlet Chemiexcitation Yield in Base-catalyzed Air Oxidation of 3,5-Dichlorophenylpyruvic Acids

Isao KAMIYA,* Shizuaki MURATA, and Kuniaki YAMABE†
Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464
†*Department of Industrial Chemistry, Sasebo Technical College, Sasebo 857-11*
(Received January 20, 1984)

In base-catalyzed air oxidation of substituted phenylpyruvic acids, an excited singlet product is generated from 3,5-dichloro-4-hydroxyphenylpyruvic acid (**1**) but excited triplet products from 3,5-dichlorophenyl- (**2**) and 3,5-dichloro-4-methoxyphenylpyruvic acid (**3**). According to the reaction scheme proposed, the singlet chemiexcitation yield from **1** and the triplet yields from **2** and **3** are 1.2×10^{-4}, 8.3×10^{-4}, and 6.7×10^{-4}, respectively. A discussion is made on the difference in spin state selectivity between **1** and **2** or **3**.

By studying the chemiluminescence (CL) in air oxidation of -CO-CH- containing molecules, we have revealed that excited triplet products are generated from simple molecules such as 3-methyl-2-butanone and isopropyl phenyl ketone.[1] We have further observed a direct CL due to generation of excited singlet products in similar air oxidations of 9, 10-diacylanthracenes[2] and 3-acyl-9-methylcarbazoles.[3]

In view of the evidence that simple isolated 1,2-dioxetanes predominantly give excited triplet products by homolytic cleavage,[4] whereas several 1,2-dioxetanes bearing easily oxidizable substituents decompose to give excited singlet products in high yield by intramolecular electron-transfer mechanism,[5] it seemed likely that the difference in spin states of products is attributable to different decomposition paths of 1,2-dioxetane intermediates.

In the present study on the chemiexcitation in base-catalyzed air oxidation of substituted phenylpyruvic acids,[6] a remarkable difference in spin state selectivity has been found between 3,5-dichloro-4-hydroxyphenyl- (**1**) and 3,5-dichlorophenyl- (**2**) or 3,5-dichloro-4-methoxyphenylpyruvic acid (**3**); an excited singlet product is generated from **1** but excited triplet products from **2** and **3**. Details of the experimental results and a discussion based on the results will be presented in this paper.

Results and Discussion

The reaction was initiated at 40 °C by adding 0.1 cm^3 of a solution of potassium *t*-butoxide in *t*-butyl alcohol (*t*-BuOK/*t*-BuOH solution, 2×10^{-2} mol/dm^3) to 2.0 cm^3 of an aerated solution of **1**, **2**, or **3** (5.0×10^{-4} mol/dm^3) in *N*,*N*-dimethylformamide (DMF). Direct CL was exhibited from **1**, whose spectral distribution has a peak at 390 nm and is similar to the fluorescence (FL) spectrum of 3,5-dichloro-4-hydroxybenzaldehyde (**4**) (Fig. 1(a,c)). This finding indicates that the emitting species is excited singlet **4**. Upon adding 9,10-diphenylanthracence (DPA) or 9,10-dibromoanthracence (DBA), there appeared indirect CL, whose spectrum comprises a peak at 430 nm (FL from DPA or DBA) and a shoulder at 390 nm (emission from **4**) as shown in Fig. 1 (b,d).

In contrast to **1**, neither direct CL nor indirect CL with DPA could be detected from **2** or **3** to any significant degree, whereas indirect CL with DBA was exhibited. These results strongly suggest a generation of excited triplet products (presumably, 3,5-dichlorobenzaldehyde (**5**) from **2**, and 3,5-dichloro-4-methoxybenzaldehyde (**6**) from **3**) since DBA is more capable of accepting the energy of excited triplet species than DPA due to the heavy-atom effect, the energy being released in the form of FL emission.[7]

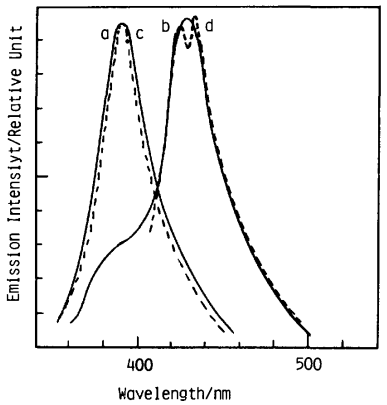

Fig. 1. Emission spectra: direct CL of **1** (—— a), indirect CL with DPA (—— b), FL of **4** (---- c), FL of DPA (----d).

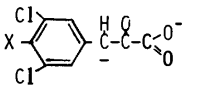
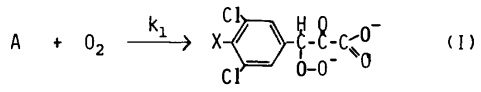
The base-catalyzed air oxidation of such enolizable carbonyl compounds as **1**, **2**, and **3** would follow the same reaction pathways as the one proposed for the luminescent air oxidation of simple ketones,[1] 9,10-diacylanthracences,[2] and 3-acyl-9-methylcarbazoles,[3] which is quite similar to the mechanism for the base-catalyzed autoxidation of carbonyl compounds.[8]

(1) Anion A could be formed from pyruvic acid, **1**, **2**, or **3** by the action of strong basic *t*-BuOK.



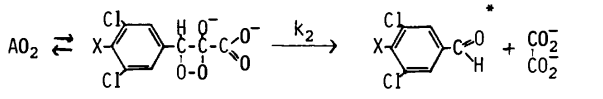
A X = O^- (from 1)
X = H (from 2)
X = OCH_3 (from 3)

(2) Reaction of A with oxygen produce peroxides AO_2:



AO_2 (I)

(3) Of decomposition processes of AO_2, one is a cleavage *via* 1,2-dioxetane intermediates (M) to give excited singlet **4** ($P^*(S_1)$) from **1** or excited triplet **5** and **6** ($P(T_1)$) from **2** and **3**, respectivey:



M $P^*(S_1)$: X=O⁻ $P^*(T_1)$: X=H, OCH_3 (II)

or to give the ground state of **4**, **5**, or **6** ($P(S_0)$):

$$AO_2 \rightleftarrows M \xrightarrow{k_3} P(S_0). \quad \text{(III)}$$

(4) The cleavage of AO_2 *via* acyclic pathways to give $P(S_0)$) and other products Q will compete with the above processes:

$$AO_2 \xrightarrow{k_4} P(S_0), \quad \text{(IV)}$$

$$AO_2 \xrightarrow{k_5} Q. \quad \text{(V)}$$

(5) FL emission from $P^*(S_1)$:

$$P^*(S_1) \xrightarrow{k_6} P(S_0) + h\nu_0. \quad \text{(VI)}$$

(6) Radiationless deactivation of $P^*(S_1)$:

$$P^*(S_1) \xrightarrow{k_7} P(S_0). \quad \text{(VII)}$$

(7) Intersystem crossing to excited triplet state ($P^*(T_1)$) followed by radiationless deactivation:

$$P^*(S_1) \xrightarrow{k_8} P^*(T_1) \longrightarrow P(S_0). \quad \text{(VIII)}$$

According to the scheme, the intensity of direct CL of **1** is given by

$$I^0_{CD} = \Phi^*_S \Phi^0_F k_1 [A][O_2],$$

where Φ^*_S is the singlet chemiexcitation yield for the generation of $P^*(S_1)$ from **1** and Φ^0_F is the apparent FL quantum yield of **4**, which are respectively given by

$$\Phi^*_S = k_2/(k_2+k_3+k_4+k_5) \text{ and } \Phi^0_F = k_6/(k_6+k_7+k_8).$$

Assuming that $\Phi^*_S \Phi^0_F$ is maintained constant during the reaction, the total light emission is given by

$$\int I^0_{CL} dt = \Phi^*_S \Phi^0_F k_1 \int [A][O_2] dt.$$

From the reaction scheme, the following relation is obtained:

$$k_1 \int [A][O_2] dt = [\mathbf{1}]_0,$$

where $[\mathbf{1}]_0$ is the initial concentration of **1**. The same relations are also obtained for **2** and **3**.

Thus, the overall CL quantum yield of direct CL of **1** is given by

$$\Phi^0_{CL} = \int I^0_{CL} dt / [\mathbf{1}]_0 = \Phi^*_S \Phi^0_F. \quad (1)$$

When fluorescer D (DPA or DBA) is added, the following steps IX—XI are to be taken into account.

Singlet-singlet energy transfer from $P^*(S_1)$ to D:

$$P^*(S_1) + D(S_0) \xrightarrow{k_{SS}} P(S_0) + D^*(S_1). \quad \text{(IX)}$$

FL emission from $D^*(S_1)$:

$$D^*(S_1) \xrightarrow{k_F} D(S_0) + h\nu_1, \quad \text{(X)}$$

Radiationless deactivation processes:

$$D^*(S_1) \xrightarrow{\Sigma k_Q} D(S_0). \quad \text{(XI)}$$

Taking all of the steps into account allows us to formulate the quantum yield of indirect CL of **1** with D as

$$\Phi^D_{CL} = \frac{\Phi^0_F + (k_{SS}/(k_6+k_7+k_8))\Phi^D_F[D]}{1+(k_{SS}/(k_6+k_7+k_8))[D]} \Phi^*_S, \quad (2)$$

where Φ^D_F is the apparent FL quantum yield of *D*, given by

$$\Phi^D_F = k_F/(k_F + \Sigma k_Q).$$

From Eqs. **1** and **2**, we obtain

$$\frac{\Phi^0_{CL}}{\Phi^D_{CL}-\Phi^0_{CL}} = \frac{\Phi^0_F}{\Phi^D_F-\Phi^0_F}\left(1+\frac{k_6+k_7+k_8}{k_{SS}} \cdot \frac{1}{[D]}\right). \quad (3)$$

Φ^0_{CL} and Φ^D_{CL} for several different concentrations of DPA were evaluated by a comporison of the total light emission from the systems with that from a standard luminol solution in dimethyl sulfoxide containing *t*-BuOK ($\Phi^S_{CL}=1.28\times10^{-2}$)[9] by the same method as that described in our previous peper.[3] The results are tabulated in Table 1. The quantum yield of indirect CL of **1** when [DBA] is 5×10^{-4} mol/dm³ ($\Phi^{DBA}_{CL}(\mathbf{1})$) was determined to be 1.3×10^{-6}. By a comparison of the FL-emission intensities of **4**, DPA, and DBA with that of a standard solution of quinine sulfate in 0.50

Table 1. Values of Φ^0_{CL} and Φ^{DPA}_{CL} for different concentrations of DPA

[DPA] / 10^{-4} mol dm^{-3}	20	10	5.0	1.1	0.65	0
Φ^{DPA}_{CL} / 10^{-6}	18.9	9.3	6.6	1.8	1.1	0.8 (Φ^0_{CL})

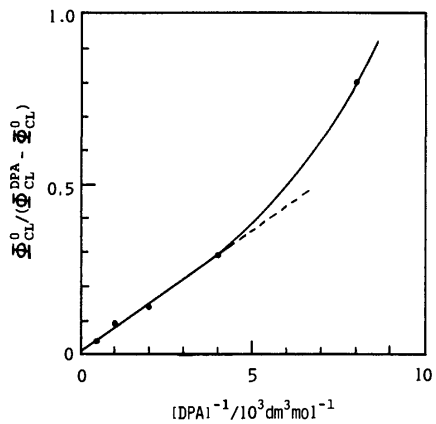


Fig. 2. Plot of $\Phi^0_{CL}/(\Phi^{DPA}_{CL}-\Phi^0_{CL})$ *vs.* 1/[DPA].

mol/dm³ H_2SO_4 (Φ_F^S=0.50),[10] the values of Φ_F^0, Φ_F^{DPA}, and Φ_F^{DBA} were determined to be 6.7×10^{-3}, 1.0, and 0.12, at 40 °C, respectively.

As shown in Fig. 2, linear plots of $\Phi_{CL}^0/(\Phi_{CL}^{DPA}-\Phi_{CL}^0)$ *vs.* 1/[DPA] can be obtained except for the systems with dilute concentrations of DPA, indicating that Eq. 3 is plausible when [DPA] is higher than 2.5×10^{-4} mol/dm³. The value of the *abscissa* intercept in Fig. 3, $\Phi_F^0/(\Phi_F^{DPA}-\Phi_F^0)$ is 7×10^{-3}. A direct calculation with the values of Φ_F^0 (6.7×10^{-3}) and Φ_F^{DPA}(1.0) gives a similar value of 6.7×10^{-3}. From the ratio of the line slope to the *abscissa* intercept, the magnitude of $k_{SS}/(k_6+k_7+k_8)$ is estimated to be 95 dm³/mol. If it is assumed that only P*(S_1) is generated from **1** and the magnitude of $k_{SS}/(k_6+k_7+k_8)$ for DBA is comparable to that for DPA, the value of Φ_{CL}^{DBA}(**1**) when [DBA] is 5.0×10^{-4} mol/dm³ may be calculated by the equation (see Eq. 3)

$$\frac{8\times10^{-7}}{\Phi_{CL}^{DBA}(\mathbf{1})-8\times10^{-7}} = \frac{6.7\times10^{-3}}{0.12-6.7\times10^{-3}}\left(1+\frac{1}{95}\frac{1}{5\times10^{-4}}\right),$$

from which Φ_{CL}^{DBA}(**1**) is obtained to be 1.4×10^{-6}. The calculated value is in fairly good agreement with the observed value (1.3×10^{-6}).

From Eq. 1 and the values of Φ_{CL}^0 (8×10^{-7}) and Φ_F^0 (6.7×10^{-3}), the singlet chemiexcitation yield (Φ_S^*) from **1** is estimated to be 1.2×10^{-4}.

In the systems of **2** and **3**, where excited triplet **5** and **6** (P*(T_1)) may be generated from phenylpyruvate anion, the steps I—V and the following steps VI′—XI′ will be taken into account.

Radiationless deactivation of P*(T_1):

$$P^*(T_1) \xrightarrow{k_6'} P(S_0), \qquad \text{(VI′)}$$

Quenching of P*(T_1) by oxygen:

$$P^*(T_1) + O_2 \xrightarrow{k_7'} P(S_0) + O_2(\Delta), \qquad \text{(VII′)}$$

Triplet-singlet energy transfer from P*(T_1) to DBA:

$$P^*(T_1) + DBA(S_0) \xrightarrow{k_{TS}} P(S_0) + DBA^*(S_1), \qquad \text{(VIII′)}$$

Triplet-triplet energy transfer:

$$P^*(T_1) + DBA(S_0) \xrightarrow{k_{TT}} P(S_0) + DBA^*(T_1), \qquad \text{(IX′)}$$

FL emission from DBA*(S_1):

$$DBA^*(S_1) \xrightarrow{k_F'} DBA(S_0) + h\nu_2, \qquad \text{(X′)}$$

Radiationless deactivation of DBA*(S_1):

$$DBA^*(S_1) \xrightarrow{\Sigma k_Q'} DBA(S_0). \qquad \text{(XI′)}$$

Then, the quantum yield of indirect CL of **2** (or **3**) with DBA is written by

$$\Phi_{CL}^{DBA}(\mathbf{2}) = \int I_{CL}^{DBA}(\mathbf{2})dt/[\mathbf{2}]_0 = \frac{\Phi_T^*k_{TS}\Phi_F^{DBA}[DBA]}{(k_{TS}+k_{TT})[DBA]+k_6'+k_7'[O_2]}$$

or

$$\frac{1}{\Phi_{CL}^{DBA}(\mathbf{2})} = \frac{1}{\Phi_F^{DBA}\Phi_T^*\Phi_{TS}}\left(1+\frac{k_6'+k_7'[O_2]}{(k_{TS}+k_{TT})[DBA]}\right), \qquad (4)$$

where $\Phi_F^{DBA}=k_F'/(k_F'+\Sigma k_Q')$, $\Phi_{TS}=k_{TS}/(k_{TS}+k_{TT})$, and $\Phi_T^*=k_2/(k_2+k_3+k_4+k_5)$. The observed values of Φ_{CL}^{DBA}(**2**) and Φ_{CL}^{DBA}(**3**) are shown in Tables 2 and 3, respectively. The plots of $1/\Phi_{CL}^{DBA}$(**2**) *vs.* 1/[DBA] and of $1/\Phi_{CL}^{DBA}$(**3**) *vs.* 1/[DBA] are shown in Figs. 3 and 4, respectively. The results indicate that Eq. 4 is plausible except for the systems with low concentrations of DBA. From the values of the *abscissa* intercepts in Figs. 3 and 4 and the values of Φ_F^{DBA}(0.12) and

Table 2. Values of Φ_{CL}^{DBA}(**2**) for different concentrations of DBA

[DBA] / 10^{-4} mol dm^{-3}	20	10	5.0	3.3	2.5	1.3
Φ_{CL}^{DBA}(**2**) / 10^{-6}	11	7.2	4.3	2.5	1.5	0.4

Table 3. Values of Φ_{CL}^{DBA}(**3**) for different concentrations of DBA

[DBA] / 10^{-4} mol dm^{-3}	20	10	5.0	2.5	1.3
Φ_{CL}^{DBA}(**3**) / 10^{-6}	5.9	3.3	1.8	0.9	0.4

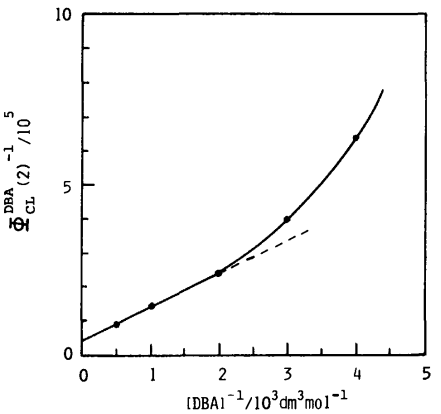

Fig. 3. Plot of $1/\Phi_{CL}^{DBA}$(**2**) *vs.* 1/[DBA].

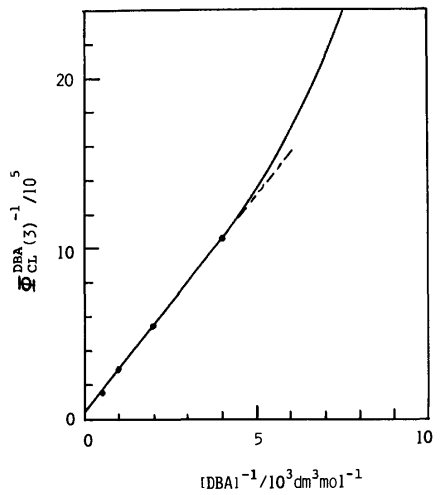

Fig. 4. Plot of $1/\Phi_{CL}^{DBA}$(**3**) *vs.* 1/[DBA].

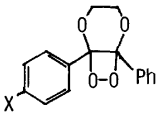
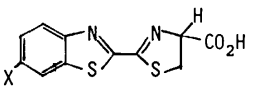
Φ_{TS} (0.25),[11] the triplet chemiexcitation yields from **2** and **3** are estimated to be 8.3×10^{-4} and 6.7×10^{-4}, respectively.

Schaap and Gagnon[12] have reported noticeable chemiexcitation features about the spin state selectivity in the thermolysis of 1,2-dioxetanes **7a—7d**. Hy-



7 a: X = OH; b: X = OCH_3; c: X = H; d: X = O^-

droxy-substituted (**7a**), methoxy-substituted (**7b**), and unsubstituted one (**7c**) decomposed to give excited triplet products, which are typical of most simple 1,2-dioxetanes, while the very unstable phenoxide one (**7d**) decomposed with high singlet chemiexitation yield. Moreover, the deprotonation of **7a** to give **7d** with a base resulted in a flash of brilliant luminescence. White *et al.*[13] also showed that only the cases of the



8 a: X = OCH_3; b: X = $NHCOCH_3$; c: X = NH_2; d: X = O^-

natural oxido-substituted luciferin (**8d**) and amino-substituted luciferin (**8c**) exhibited bioluminescence, although the luciferins **8a—8d** were oxidized to give carbonyl products *via* the corresponding 1,2-dioxetanes. The high singlet chemiexcitation yields have nicely been explained by the intramolucular electron-transfer mechanism.[14]

On the analogy of the chemiexcitation features of the 1,2-dioxetanes, the cleavage of an oxido-substituted 1,2-dioxetane intermediate by the intramolecular electron-transfer mechanism would be plausible for the generation of an excited singlet product from **1**. The low values of both Φ_S^* and Φ_T^* are presumably due to the fact that the chemiexcitation *via* the 1,2-dioxetane intermediate arises from a minor reaction.

More examples of -CO-CH- containing molecules as this type should be investigated to confirm this trend.

Experimental

Instruments. IR spectra were recorded on a JASCO A-102 spectrophotometer in the noted phase. ^1H NMR and ^{13}C NMR spectra were determined on a JEOL FX-90 spectrometer. Chemical shifts are reported as δ values in parts per million relative to the central signal of DMSO-d_6 (2.43 for ^1H and 29.50 for ^{13}C). The intensity and specta of CL emission were determined by measuring the output of R44 photomutiplier-photometer (Opelecs CLS-1 spectrophotometer). The intensity and spectra of FL emission were measured on a Hitachi MPF-2A fluorescence spectrophotometer.

Materials. For the preparation of **1**, **2**, and **3**, 4-hydroxy- and 4-methoxybenzaldehyde, *N*-acetylglycine (Nakarai Kagaku), sulfonyl chloride (Wako Junyaku), 3,5-dichlorobenzaldehyde (Aldrich), and various solvents were used without further purification. For the measurement of CL and FL emissions, *t*-BuOK (Merck, for synthesis), *t*-BuOH (Tokyo Kasei, extra pure grade), DPA (Nakarai Kagaku, specially prepared reagent), and quinine sulfate (Nakarai Kagaku, extra pure reagent) were used as received. DBA (Tokyo Kasei, guaranteed reagent) and luminol (Nakarai Kagaku, guaranteed reagent) were purified by recrystallization from xylene and dilute hydrochloric acid, respectively. DMF (Wako Junyaku, extra pure reagent) was distilled prior to use.[15]

Preparation of 3,5-Dichloro-4-hydroxyphenylpyruvic Acid (1). Following reported procedures,[16] **1** was prepared from 4-hydroxybenzaldehyde *via* chlorination, condensation with *N*-acetylglycine, and acid hydrolysis. Recrystallization from acetic acid gave pure **1** as colorless crystals (mp 208—210 °C decomp. uncorr.).

Preparation of Dichlorophenylpyruvic Acid (2). A mixture of 3,5-dichlorobenzaldehyde (1 g), *N*-acetylglycine (0.8 g), and sodium acetate (0.6 g) in acetic anhydride (7 cm^3) was heated under reflux for 4 h, and then allowed to stand overnight in a refrigerator. The crystals were filtered, washed with boiling water, and dried under vacuum. The crude product was heated under reflux with 3 cm^3 of 30% hydrochloric acid and 10 cm^3 of acetic acid for 4 h. The solvents were removed off on a rotary evaporator. Recrystallization from acetic acid with activated carbon gave a pale brown powder (0.33 g). The crude product was purified by a column of C_{18} reversed phase silica (10 g, Silica Gel ODS-Q3, 75 Å, 30—50 μm, purchased from Fuji Gel Co.) with a mixture of methanol, water, and acetic acid (50:50:1) as an eluant. Pure **2** (0.27 g, 23% overall yield) was obtained as colorless crystals (mp 153—155 °C, uncorr.): IR (KBr disk) 3500(OH) and 1695 (C=O) cm^{-1}; ^1H NMR (CD_3SOCD_3) 7.72 (2H, d, J=2.0 Hz, H-C(2) and H-C(6) of arom.), 7.32 (1H, t, J=2.0 Hz, H-C(4) of arom.), and 6.30 (1H, s, ArCH= enol form); ^{13}C NMR (CD_3SOCD_3) 165.52 (COOH), 144.28 (C(1) of arom.), 138.60 (C(4) of arom.), 133.83 (C(3) and C(5) of arom.), 127.11 (C(2) and C(6) of arom.), 125.97 (=COH enol from), and 106.30 (ArC= enol form). Found: C, 46.31; H, 2.51. Calcd for $C_9H_6Cl_2O_3$: C, 46.38; H, 2.59.[17]

Preparation of 3,5-Dichloro-4-methoxyphenylpyruvic Acid (3). To 13.6 g of 4-methoxybenzaldehyde, 122 g of sulfonyl chloride was added by distillation and the mixture was allowed to stand for 3 d at room temperature. After the sulfonyl chloride was removed by evaporation, the residue was distilled under reduced pressure (2 Torr, 140°C) (1 Torr= 133.322 Pa). The yellow oil obtained, which solidfied into white powder by cooling, was recrystallized from methanol. Pure 3,5-dichloro-4-methoxybenzaldehyde (15 g, 73% yield, mp 58—61 °C) was obtained as colorless crystals. A mixture of 3,5-dichloro-4-methoxybenzaldehyde (4.3 g), *N*-acetylglycine (4.3 g), and sodium acetate (3.1 g) was dissolved in 35 cm^3 of acetic anhydride, and the solution was warmed on a water bath for 2 h, and then cooled. A 1:1 mixture of water and petroleum (10 cm^3) was added and the resulting precipitate was triturated, filtered, and dried. Recrystallization from chloroform gave 1.98 g (18.3% yield) of pale yellow crystals of 4-(4-methoxy-3,5-dichlorobenzylidene)-2-methyl-5-oxazolone (mp 190—195 °C). The oxazolone (1.5 g) obtained was dissolved in a mixture of acetic acid (40 cm^3) and 6 mol/dm^3 hydrochloric acid (14 cm^3), and the solution was heated at 140—160 °C under reflux for 2 h, and then the mixture was allowed to stand overnight at room temperature. The resulting white precipitate was

filtered, washed with water, and dried. Recrystallization from acetic acid gave 0.89 g (64.5% yield) of **3** (mp 190 °C): IR (KBr disk) 3460(OH), and 1685(C=O) cm^{-1}: ^1H NMR (CD_3SOCD_3) 9.80 (2H, br, OH), 7.84 (2H, s, arom.), 6.33 (1H, s, ArCH= enol form), and 3.79 (3H, s, OCH_3); ^{13}C NMR (CD_3SOCD_3) 165.7 (COOH), 149.9 (C(1) of arom.), 143.3 (C(3) and C(5) of arom.), 133.2 (C(4) of arom.), 129.2 (=C-OH enol form), 128.1 (C(2) and C(5) of arom.), 106.3 (ArCH= enol form and 60.6 (CH_3O). Found: C, 45.54; H, 3.30. Calcd for $C_{10}H_8Cl_2O_4$: C, 45.63; H, 3.04.[18]

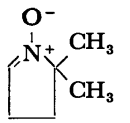
Flash Photolysis Study for Substituent and Solvent Effects on Spin-trapping Rates of Phenylthiyl Radicals with Nitrones

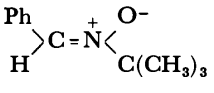
Osamu ITO* and Minoru MATSUDA
Chemical Research Institute of Nonaqueous Solutions, Tohoku University, Katahira, Sendai, Miyagi, 980
(Received December 10, 1983)

The spin-trapping rates for the reactions of para-substituted phenylthiyl radicals with nitrones have been determined by flash photolysis. For the phenylthiyl radical, the rate constant (in $mol^{-1}\,dm^3\,s^{-1}$) in benzene for a cyclic nitrone, 5,5-dimethyl-1-pyrroline *N*-oxide, is 5.2×10^8, which is greater than that for acyclic one, *N*-*t*-butyl-α-toluenimine *N*-oxide (1.1×10^7). The rates decrease with the solvent polarity and with the hydrogen-bonding ability; the maximum ratio of *ca.* 30 is observed for the rates between cyclohexane and methanol. Combined with the observed substituent effects, the mechanisms of the reactions and properties of the transition states are discussed.

The spin-trapping rates can be relatively determined from the stationary ESR signal intensities of the stable spin adducts,[1-4] while, for the reactions producing the unstable spin adducts, the time dependences of decays of the attacking radicals or formations of the spin adducts must be directly followed.[5-7] In the previous paper we have shown that the absolute rates for spin trapping of the thiyl radicals with nitroso spin-traps were determined from decay of the thiyl radicals generated by flash photolysis;[8] however, in these reaction rates we could not find the solvent effects which were reported in the literature.[4b] We can expect the solvent effects in polar and hydrogen-bonding solvents for more polar spin traps, nitrones ($-C{=}N^+{-}O^-$). In this study we investigate the thiyl radical-trapping reactions with 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO) as a cyclic nitrone and *N*-*t*-butyl-α-toluenimine *N*-oxide (PBN, α-phenyl-*N*-*t*-butylnitrone) as an acyclic nitrone. From both solvent and substituent effects, the property and structure of the transition state are discussed.



DMPO



PBN

Experimental

Commercially available DMPO (Aldrich) and PBN (Aldrich) were used without further purification. Diphenyl disulfides were purified by recrystallization from ethanol. Solvents were distilled when spectrophotometric grade ones were not available. Samplings and measurements were made in the dark to prevent inadvertent photolysis.

The ESR spectra of the spin adducts were measured with a Varian E4 ESR spectrometer during the photolysis of disulfides (*ca.* 10^{-3} mol dm^{-3}) with the light between 350 and 450 nm (500 W high pressure Hg lamp) in the presence of nitrones (*ca.* 10^{-3} mol dm^{-3}) in degassed solution (*ca.* 10^{-1} Pa). Decay of the ESR signals after cutting off the light was followed by a fast recorder or by a transient memory.

The xenon flash photolysis apparatus was of standard design;[8] input energy was 150 J and the half-duration of xenon flash lamp (Xenon Corp. N-851 C) was *ca.* 10 μs. By the use of light filter, disulfides were flash photodecomposed with the light between 350 and 450 nm so as to avoid the photolysis of nitrones.

Results and Discussion

ESR Measurements. ESR spectra were observed during the photolysis of disulfides in the presence of nitrones as shown in Fig. 1. The hyperfine splitting constants of the nitrogen atom (a_N) and the α-hydrogen atom (a_H) are summarized in Table 1. The spin adducts with PBN can be ascribed to the nitroxides, **1**, as shown in Scheme 1, since both a_N and a_H are in good agreement

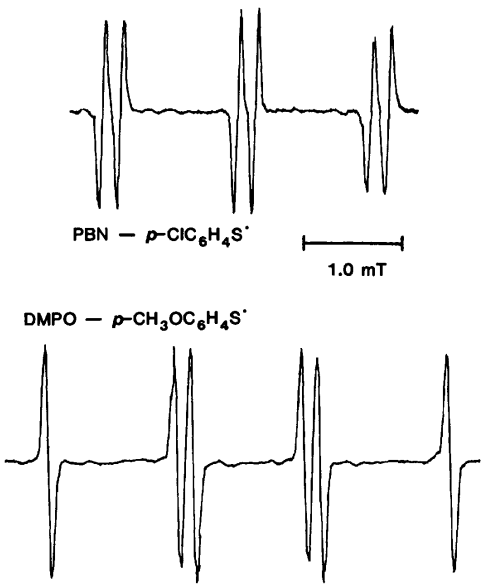


Fig. 1. ESR spectra of spin adducts produced by light illumination of diphenyl disulfides (*ca.* 10^{-3} mol dm^{-3}) in the presence of nitrones (*ca.* 10^{-3} mol dm^{-3}) in degassed benzene.

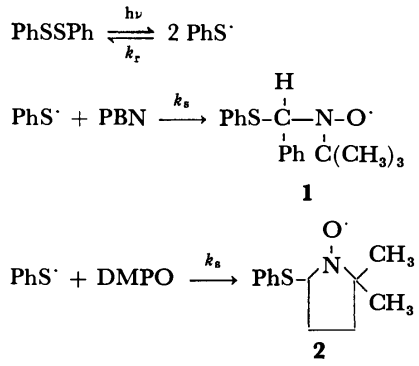
	DMPO			PBN		
	a_N / mT	a_H / mT	$\tau_{1/2}$ / s	a_N / mT	a_H / mT	$\tau_{1/2}$ / s
p-ClC_6H_4S·	1.36	1.43	3.3	1.38	0.18	0.38
p-$CH_3OC_6H_4S$·	1.33	1.45	1.7	1.39	0.18	0.15



Scheme 1.

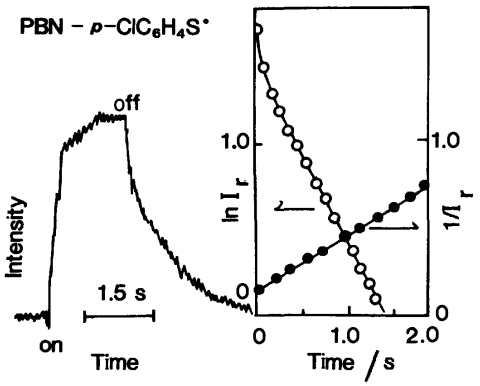


Fig. 2. Time dependence of ESR signal of the spin adduct produced by light illumination of disulfide in the presence of PBN at 23°C. The decay is plotted with the first-order (ln I_r *vs.* time; I_r refers to the relative signal intensity) and with the second-order ($1/I_r$).

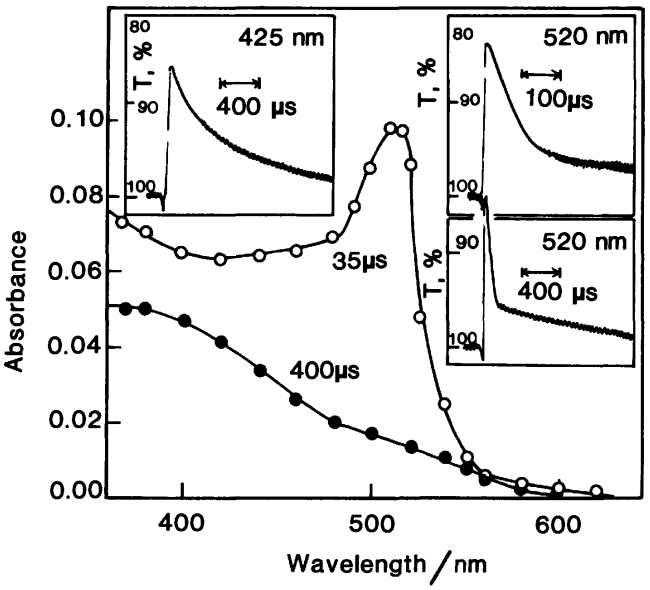

Fig. 3. Transient absorption spectra observed by flash photolysis of bis (*p-t*-butylphenyl) disulfide (*ca.* 10^{-4} mol dm^{-3}) in the presence of PBN (3.0×10^{-3} mol dm^{-3}) in benzene. The absorption band at 510 nm observed 35 μs after flash is ascribed to the *p-t*-butylphenylthiyl radical and the band of 400 μs after flash is ascribed to the spin adduct. Insert: The fast decay and the slow decay at 520 and 425 nm.

with the reported ones.[9] The spin adducts with DMPO have large a_H value characteristic to cyclic nitroxides, **2**; such large a_H values come from both conformational and electronic reasons.[10]

Figure 2 shows that the growth of the ESR signal intensity reaches at the maximum within *ca.* 1 s and that the signal decays rapidly after cutting off the light. The decay curves seem to obey either one second-order kinetics or two first-order kinetics. The half-life of the spin adduct is approximately estimated from the initial part of the decay curves (Table 1). The spin adducts with DMPO are more stable than those with PBN. The substituent effects of the phenylthiyl moiety on a_N, a_H, and half-life of the nitrone adducts are smaller than those of the nitroso adducts;[8] this finding is reasonably interpreted because the C-S bond is formed at the α-carbon in the former, whereas the S atom bonds directly to the nitrogen atom in the latter.

Transient Absorption Spectra. Figure 3 shows transient absorption spectra observed by the flash photodecomposition of bis(*p-t*-butylphenyl) disulfide in the presence of PBN. The absorption band at *ca.* 510 nm observed immediately after flash (35 μs) is attributed to the *p-t*-butylphenylthiyl radical.[8] Similar absorption bands were observed for other phenylthiyl radicals. The decay rate of the thiyl radical in the presence of PBN (decay curve at 520 nm of Fig. 3) is faster than that without PBN. The decay curve at 520 nm is composed of the fast and slow decay parts; the slow part yielded a spectrum which is depicted with the absorbances at 400 μs after flash. This spectrum may be attributed to the spin adduct. The decay profile at 425 nm shown in a long time scale in Fig. 3 seems to obey second-order kinetics rather than first-order kinetics. The half-life evaluated from the decay at 425 nm is *ca.* 1 ms which is considerably shorter than that evaluated from the ESR signal. This suggests the presence of the fast decay process which did not appear in the decay of the ESR signal; otherwise, there may be inadvertent photolysis of the spin adducts with the monitoring light of the flash photolysis experiment. The second-order decay of the spin adducts indicates that the decomposition mechanism of the spin adducts may include the dimerization process to the diamagnetic dimers before the fission of the bonds as Grillan and Ingold suggested.[11] Similar phenomena were observed for DMPO.

Determination of Rate Constants. The decay rate of the thiyl radical can be evaluated from the first order plots for the decay of the absorption band of the thiyl radical by the addition of nitrones (Fig. 4). The rate can be expressed as Eq. 1:

$$-d[PhS^{\cdot}]/dt = 2k_r[PhS^{\cdot}]^2 + k_s[PhS^{\cdot}][\text{nitrone}] \quad (1)$$

The processes for the reproduction of the thiyl radical with the decomposition of the adduct and the reaction of the thiyl radical with the spin adduct are omitted from the rate expression because of their small contribution.[8] By the addition of nitrones in large excess

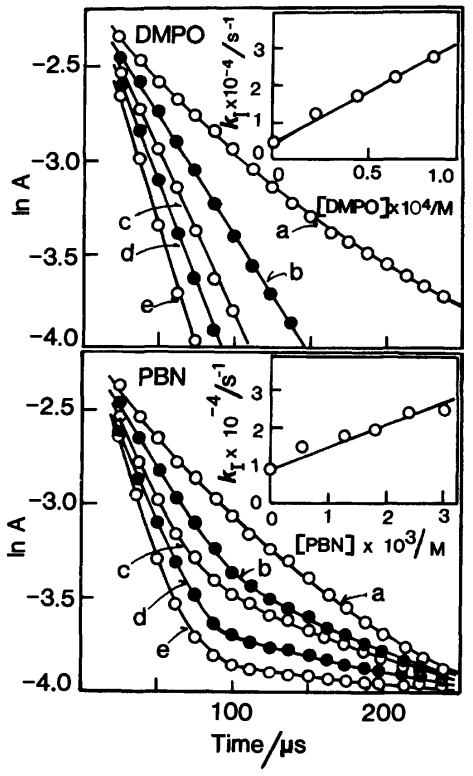

Fig. 4. The first-order plots for decay of *p*-t-butylphenylthiyl radical. [DMPO] × 10^5 mol dm^{-3}: a, 0; b, 2.2; c, 4.4; d, 6.6; and e, 8.8. [PBN] × 10^3 mol dm^{-3}: a, 0; b, 0.55, c, 1.3; d, 2.4; and e, 3.0. Insert: Pseudo-first-order plots; 1 M = 1 mol dm^{-3}.

compared with the concentration of the thiyl radical generated by one flash exposure which was estimated to be *ca.* 10^{-6} mol dm^{-3},[8] decay kinetics approaches first order (Fig. 4). In Fig. 4, the slopes of the first-order plots (k_1) are plotted against [nitrone]; fairly good pseudo-first-order relationships are found. The slopes yield the rate constants for spin trapping (k_S). In the case of PBN, although the slow decay part disturbs the analysis, the k_S values can be estimated from the slopes of the initial parts.

Substituent Effect. In order to clarify the contribution of the polar transition state to the reactivity, we at first examined the substituent effect of the phenylthiyl radicals. In Table 2 the rate constants for the phenylthiyl radicals with both electron-donating and withdrawing substituents are summarized. For each nitrone, the electron-withdrawing substituents accelerate the rates and *vice versa*. The Hammett plots *vs.* σ^+ (Fig. 5) yielded straight lines, whereas the plots *vs.* σ yielded curves. This suggests that the resonance factors contribute to the reactivities in addition to the inductive effects and that, in the Yukawa-Tsuno equation, $\log(k/k_0)=\rho(\sigma^\circ+r\Delta_{R^+})$, the r value is about 1.[12] The slopes for the k_S values in benzene yielded $\rho^+=0.98\pm0.02$ for DMPO and $\rho^+=1.14\pm0.02$ for PBN. The observed interval between both lines is the difference in the reactivities of two nitrones.

Although the rates decrease in methanol (Table 2), a straight line is also found in the Hammett plot for DMPO (Fig. 5); $\rho^+=1.15\pm0.02$ which is slightly greater

Table 2. Substituent effect on spin-trapping rate constants (k_S) of *p*-$XC_6H_4S^\cdot$ with DMPO and PBN in benzene or in methanol at 23 °C

X	$k_S \times 10^{-6}$ / $mol^{-1}\,dm^3\,s^{-1}$ DMPO[a] In benzene	DMPO[a] In methanol	PBN[b] In benzene
Br	750	72	17
Cl	700	60	12
H	520	54	11
t-C_4H_9	260	26	5.6
CH_3	300	19	5.0
CH_3O	110	5.4	1.1

a) Estimation error is *ca.* 10%. b) Estimation error is *ca.* 20%.

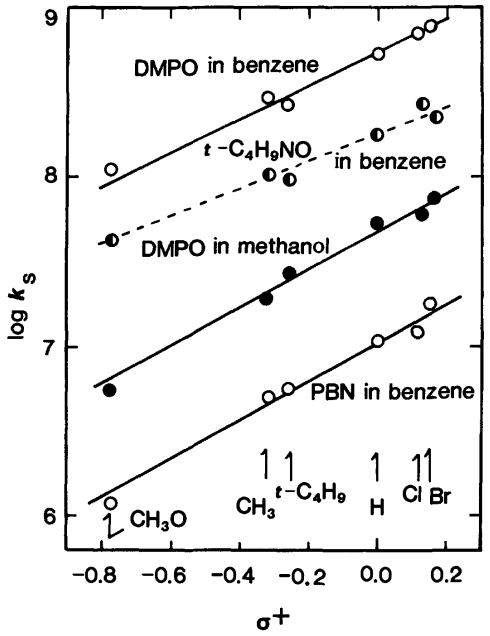

Fig. 5. The Hammett plots of $\log k_S$ *vs.* σ^+. Data for *t*-C_4H_9NO are cited from ref. 8.

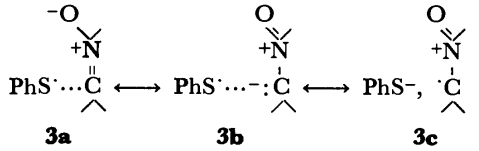
than that in benzene. Positive ρ^+ values, in general, indicate that there is a contribution of the polar resonance structures to the transition state such as [PhS^-, $nitrone^{+}\cdot$]. In the case of the phenylthiyl radicals, however, since the thermodynamic stabilities vary with the change of the para substituents,[13] some parts of the observed ρ^+ value for the reactivities may come from the linear free-energy relationship and remaining parts can be attributable to the polar transition state.

The slope of the Hammett plot for 2-methyl-2-nitrosopropane (Fig. 5)[8] is less than those for nitrones; this indicates that the contribution of the polar resonance structure for nitrones is greater than that for nitroso compounds. The polar structures anticipated for nitrones are shown below (**3a**—**3c**), in which **3c** reasonably represents the charge transfer from nitrone to the thiyl radical. On the other hand, the polar resonance structures for the nitroso spin-trapping reactions are not so stable as nitrones. For a highly electro-

philic benzoyloxyl radical-trapping with PBN, a similar tendency was reported,[1a] whereas the opposite tendency was reported for less electrophilic attacking radicals such as *t*-butoxyl radical and primary radical.[1c,4a]



3a **3b** **3c**

Solvent Effect. The k_S values for the reaction of *p*-*t*-butylphenylthiyl radical with DMPO in nonpolar, polar, and alcoholic solvents are summarized in Table 3. The k_S values decrease with the solvent polarity; the ratio of k_S in cyclohexane to k_S in 1,2-dichloroethane is *ca.* 5. Alcoholic solvents reduce the k_S values in a great extent; the ratio of k_S in cyclohexane to that in methanol is *ca.* 30. A similar tendency was found for the reaction system with PBN. Figure 6 shows a plot of log k_S *vs.* the Kirkwood parameter, $(\varepsilon-1)/(2\varepsilon+1)$, which is one of solvent polarity parameters.[14] The points are divided into two groups; the upper group includes nonpolar and polar solvents and the lower one includes alcoholic solvents. The upper group shows a linear correlation with a slope of −2.48, which corresponds to the coefficient of the following equation derived by Steam and Eyring.[15]

$$\ln k_s = \ln k_s^\circ - \frac{1}{kT}\cdot\frac{\varepsilon-1}{2\varepsilon+1}\cdot\left(\frac{\mu_s^2}{r_s^3}+\frac{\mu_n^2}{r_n^3}-\frac{\mu_{\neq}^2}{r_{\neq}^3}\right) \qquad (2)$$

where k_s° refers to the rate constant at $\varepsilon=1$; μ and r refer to the dipole moment and radius, respectively. Subscripts s, n, and $\neq$ refer to the thiyl radical, nitrone, and activated complex, respectively. The component of the dipole moment of the thiyl radical parallel to the C-N-O bonds of nitrone can be assumed to be zero when the thiyl radical approaches perpendiculary the C-N-O bonds as shown in **3**. Thus, by substituting $r_s=r_n=3.0$ Å, $r_{\neq}=3.5$ Å, and $\mu_n=3.55$ D,[16] we can calculated $\mu_{\neq}$ to be 3.1 D. The activated complex becomes less polar than nitrone in the reactant; this suggests that there is a contribution of the resonance structures as would be anticipated from the substituent effect, **3b** and **3c**, which do not play any important role in nitrone alone in the reactant.

Table 3. Solvent effect on spin-trapping rate constants (k_s) of t-$C_4H_9C_6H_4S^\cdot$ with DMPO at 23 °C

Solvent	$k_s\times10^{-7}$	Solvent	$k_s\times10^{-7}$
c-C_6H_{12}	79	C_5H_5N	21
CCl_4	52	CH_3CN	23
(*n*-$C_3H_7)_2O$	43	$(CH_3)_2SO$	19
(*i*-$C_3H_7)_2O$	42	CH_2ClCH_2Cl	16
$CH_3CO_2C_2H_5$	30	$(C_2H_5)_2CHOH$	4.3
FC_6H_5	23	C_2H_5OH	3.0
$(CH_2)_4O$	22		

Unit of k_s; $mol^{-1}\,dm^3\,s^{-1}$.

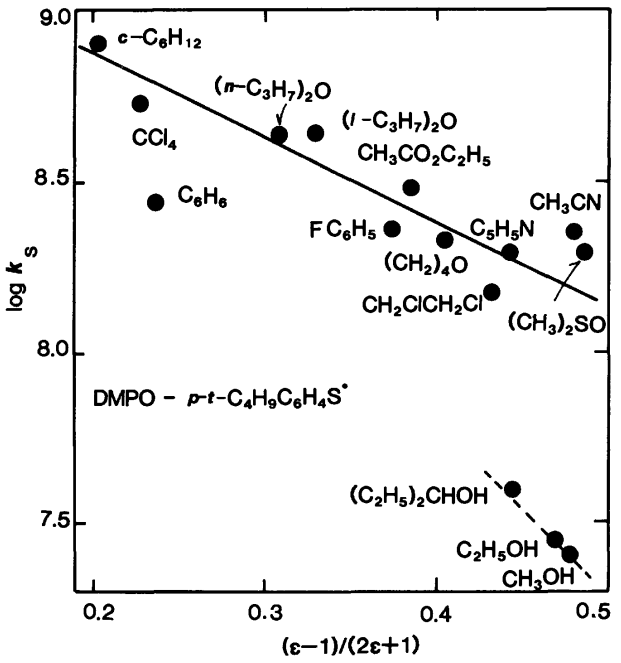


Fig. 6. Plots of log k_s *vs.* the Kirkwood parameter, $(\varepsilon-1)/(2\varepsilon+1)$.

On the other hand, the thiyl radical-trapping rates with nitroso compounds did not show appreciable solvent polarity effect,[8] although the dipole moments of nitroso compounds (*ca.* 3.2 D)[17] are only slightly smaller than those of nitrones (*ca.* 3.6 D).[16] One of the reasons is that the resonance structure ($-\ddot{N}^+-O^-$) in the reactant can not be changed by the approach of the thiyl radical in the transition state.

Alcoholic solvents reduce the rates more than the rates expected only from the solvent polarity (Fig. 6). Since such a decrease in the rates was not observed for nitroso compounds,[8] this can be attributd to the strong hydrogen bonding with nitrone, not but with the thiyl radical. Hydrogen bonding may stabilize nitrone in the reactant more than that in the activated complex, because the interaction of hydrogen atom of alcohols with the anionic oxygen atom of nitrone in the former is greater than that with the neutral oxygen atom in the latter (**3b** and **3c**). The order of a decrease in the rates among three alcoholic solvents seems to correlate with the Kirkwood parameter as seen in Fig. 6, suggesting that such interaction is cooperating with the solvent polarity effect. On the other hand, the solvent effect was not observed for the rates of nitroso spin-trapping reactions even in methanol;[8] this suggests that the hydrogen-bonding ability of the nitroso group is considerably smaller than that of nitrone.

Relative Reactivity. Since the solvent effect on the rates was observed for nitrones but not for nitroso compounds, the order of the reactivities among various spin traps depends upon solvents. In benzene, the order toward each thiyl radical is DMPO>nitrosobenzene>*t*-C_4H_9NO>PBN, whereas in methanol the order changes as nitrosobenzene>*t*-C_4H_9NO>DMPO>PBN. The order may also change with the electrophilicity of the attacking radical; *i.e.*, the slopes of the Hammett plots for nitrones are steeper than that of nitroso compound. For less electrophilic radicals such as the primary alkyl radical, the reported order differs from that of the thiyl radical (in benzene, nitroso-

benzene>t-C_4H_9NO>DMPO>PBN).[4b] The ratio of the rates for DMPO to PBN for the thiyl radical (*ca.* 50) varies with the attacking radicals; the ratio increases with the electrophilicity of the attacking radicals (primary alkyl radical (*ca.* 20)[1b] and t-butoxyl radical (*ca.* 90)).[4a] The higher reactivity of DMPO can be attributed to the strain energy released with the change from cyclic double bond to cyclic single bond.[18,19]

We would like to thank Professor Y. Ikegami and Dr. S. Tero-Kubota of Tohoku University for helpful discussion.

Corrections for Intensity Data in Energy-dispersive X-Ray Diffractometry of Liquids. Application to Carbon Tetrachloride

Keiko NISHIKAWA* and Takao IIJIMA
Department of Chemistry, Faculty of Science, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171
(Received December 13, 1983)

The procedure of the analysis of the diffraction intensity of liquids obtained by the energy-dispersive method has been revised and improved. A new method for determining the energy spectrum of the primary beam is presented. The escape correction, the slit correction and the correction for multiple scattering have been newly applied. Scattering of X-rays from liquid CCl_4 has been measured and its structure function has been obtained by an improved procedure.

The intensity measurement of scattered X-rays by the use of energy-dispersive method has been carried out in various experiments since it was introduced by Giessen and Gordon.[1] In the energy-dispersive method, white X-rays are used as the primary beam and the scattered photons are detected and energy-analyzed by a solid state detector (SSD) connected with a multichannel pulse height analyzer (MCA). The energies of detected photons are distributed over the whole energy-region of the primary beam, so the scattering intensities of a certain range of the scattering parameters s, ($s=(4\pi\sin\theta/hc)E$, 2θ: scattering angle, E: photon energy), are accumulated in parallel.

This method has various advantages[2-4] over the conventional angle-dispersive method. However, the rather complex procedure of the data analysis is a drawback. The problems in the data analysis for quantitative intensity studies are as follows:

1) the determination of the properties of the primary beam, namely, the energy spectrum and the energy dependence of polarizaion of the primary beam,

2) the corrections for the effects originating from the detector, the slit system and the sample, namely, the escape correction when pure Ge or Ge(Li) detector is used, the slit correction and the absorption correction,

3) the correction for multiple scattering and the theoretical estimation of the intensity of Compton scattering.

Prober and Schultz performed the first quantitative measurement of the diffraction intensity from a sample which gives a halo pattern by the use of the energy-dispersive technique.[5] Three years later, Murata and one of the present authors (K. N.),[2] and Egami[3] reported the construction of their energy-dispersive diffractometers and the procedures of data analysis. In recent years, the energy-dispersive technique was also applied to the measurement of scattering intensities from gases.[6]

Prober and Schultz determined the energy spectrum of the primary beam by comparing the observed scattering intensity of the sample itself at high s-values, where the curve of the diffraction intensity is smooth without any particular structure, with the theoretical scattering intensity of mercury atoms.[5] However, they neglected the Compton shift in this procedure. This negligence seems to lead to a serious error. Egami followed the method by Prober and Schultz in determination of the primary energy spectrum, and developed this method considering the Compton shift.[3] For the determination of not only the primary energy spectrum but also the absorption coefficient of the sample, Egami proposed a self-consistent analysis.[3,4,7] However, it seems unreliable because too many parameters have to be determined simultaneously. Egami did not make the escape correction and the slit correction.

Murata and Nishikawa directly observed the energy spectrum of the primary beam by the use of the same slit system as in the measurement of scattered X-rays from samples, reducing the radiation intensity by decreasing the tube current to a few micro-amperes.[2] However, there has been anxiety about whether or not the decrease of the tube current produces distortion of the energy spectrum of the primary beam. In the data analysis of Ref. 2, the recoil factor for free electrons was used and the band-width ratio in the Compton shift was ignored. The polarization of the primary beam was neglected. Actually the effect has been found to be small in the energy region they used.

In the present paper, we report a procedure of improved data analysis of the energy-dispersive method and the structure function of liquid CCl_4 obtained by the improved procedure.

Experimental

Diffractometer. Since the main constitution of the apparatus is the same as that in Ref. 2, only the outline is given in the following. The geometry of the diffractometer is shown in Fig. 1. A horizontal goniometer system is adopted, in which an X-ray source and a detector are set in a horizontal plane. Although measurement by the energy-dispersive tech-

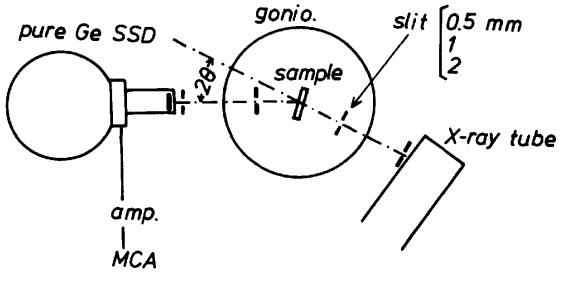

Fig. 1. Schematic diagram of the energy-dispersive diffractometer.

nique is carried out at a fixed scattering angle, such measurement must be repeated at different angles in order to cover a sufficiently wide region of s-space. To change the scattering angle, the X-ray tube is rotated around the vertical axis of the goniometer, which has a θ-2θ scanning system, while the detector (SSD) with a heavy cryostat is fixed.

A fine focus Phillips tube with a tungsten target is used, because strong white X-rays can be obtained without disturbance by characteristic X-rays, and the applicable power is large. The high voltage power supply for X-rays (Rigaku Denki Co.) is used. The stability of the high voltage is better than 0.1%. The X-ray tube is usually operated at 47.5 kV and 30 mA. The scattered X-rays are detected by a pure Ge SSD (ORTEC, Model 1513-10190). A pair of slits made of lead is used for both the incident and the detecting collimators. The separation of the two slits is about 150 mm. The width of the slit is varied: 0.5, 1, and 2 mm, and the height is 6 mm. The sample holder reported previously[8] is attached at the center of the goniometer. The transmission geometry is employed in order to make absorption correction easier.

Measurement of CCl_4. The diffracted X-ray photons from liquid CCl_4 at room temperature were collected at the scattering angles of 2θ=2.5, 4, 6, 10, 16, 28, 40, and 56°, by operating the X-ray tube at 47.5 kV and 30 mA. The spectrum in the energy-region 12—38 keV (λ=1.03—0.326 Å) is used for the analysis. The settings of 2θ=2.5, 4, 6, 10, 16, 28, 40, and 56° correspond to the regions of s=0.27—0.84, 0.42—1.34, 0.64—2.02 1.06—3.36, 1.69—5.36, 2.94—9.32, 4.16—13.18 and 5.71—18.09 Å^{-1}, respectively. In usual structure studies it is not necessary to measure the intensities at so many scattering angles. However, in the present experiment it is desired to obtain justification of a procedure of an analysis that includes several corrections. This is ascertained by checking the consistency of the data in the same s-regions which have been collected at different settings of the scattering angles and analyzed independently.

The scattering from Myler films, 5 μm thick, of the windows of the sample holder, was also measured. The measurement includes the scattering intensity from air, too. The thickness of the sample was 0.50 mm.

In order to obtain the relation of the photon energy *vs.* the channel number in the MCA, the fluorescent X-rays from Ba, Ag, Mo, Cu, and Cr were observed. The channel numbers of these peaks in the MCA were fitted to the energies of the corresponding characteristic X-rays by using a table by Bearden.[9] The linear relationship between the photon energy and the channel number is good.

The Properties of the Primary Beam

The Energy Spectrum of the Primary Beam. The energy spectrum of the primary beam was determined by measuring the scattering from air at low scattering angle with the same slit system and the same operating conditions of the tube as in the measurement of the sample. This method requires no particular preparation, because the diffraction measurement without the sample holder gives the scattering intensity from air. The scattering intensity of air at low scattering angles is strong enough to measure by the use of a usual sealed-off tube, because the effective volume of air which scatters X-rays is fairly large. In the analysis of the data of low scattering angles, it is permissible to neglect the Compton shift and the polarization of the primary beam. Moreover, the scattering amplitudes of light atoms such as N and O can be theoretically calculated with high accuracy.[10]

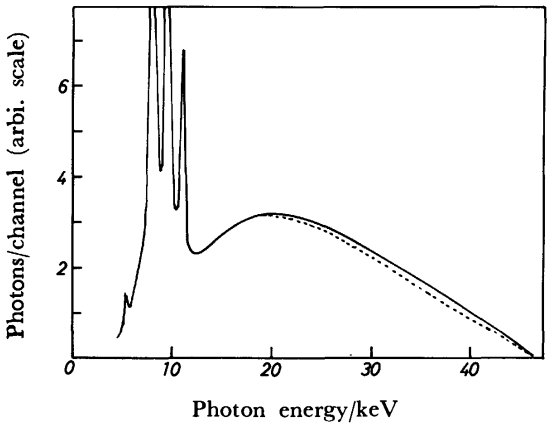

Fig. 2. The energy spectra of the primary beam. The solid curve is the spectrum determined by measuring scattering intensities of air. The broken curve is the one obtained by direct measurement by decreasing the tube current to a few micro-amperes.

The spectrum of the primary beam obtained from the scattering intensity of air is shown in Fig. 2, where it is compared with the spectrum measured directly at a tube current of a few micro-amperes. As is shown in Fig. 2, the intensity at high energy region obtained from air is stronger than that from the direct measurement. This seems to be caused by the difference between the amplitude of the ripples of the imperfectly smoothed voltage applied to the X-ray tube for the tube current of milli-amperes and that for the tube current of micro-amperes. In the former case the amplitude of the ripples is greater than that in the latter. The number of photons of radiated X-rays in a channel is not simply proportional to the applied voltage. So the intensity at the high energy region may become stronger in the case of the operation at milli-amperes. Another origin of the difference in the energy spectrum of the primary beam may be the difference of the size of the focus of the electron beam on the target.

The Polarization of the Primary Beam. It is known that the white X-ray radiation is polarized in the direction parallel to the electron beam at the high energy limit of the Bremsstrahlung spectrum.[11] The polarization $\Pi(E)$ of the primary beam is defined by

$$\Pi(E) = (I_{p,n}(E) - I_{p,p}(E))/(I_{p,n}(E) + I_{p,p}(E)), \quad (1)$$

where $I_{p,n}$ and $I_{p,p}$ are the intensities of the normal and parallel polarization components, respectively, with respect to the scattering plane. It is known that the polarization $\Pi(E)$ of white X-rays from a thin target is very large, and some experiments of such samples have been reported. However, there have been very few measurements for the polarization $\Pi(E)$ from such thick targets as those used in commercial sealed-off tubes. One recent example was the experiment carried out by Olsen *et al.*[12]

We also measured the polarization $\Pi(E)$ of our X-ray tube with a tungsten target (Phillips fine focus) at 47.5 kV. Two scattering intensities from silica glass were measured at a fixed scattering angle with

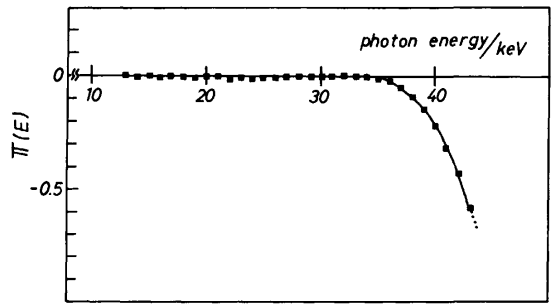

Fig. 3. The measured polarization $\Pi(E)$ of the used tungsten tube at 47.5 kV.

point focus collimators. One of them was the intensity measured in the ordinary condition where the X-ray tube was set on the scattering plane, and the other was that where the X-ray tube was set perpendicular to the scattering plane. From these two intensities, the polarization $\Pi(E)$ was obtained as shown in Fig. 3. The result is in fairly good agreement with that of Olsen *et al.*[12] However, the present result contains large uncertainties, because $\Pi(E)$ is computed from the differences of the two intensities which are nearly equal.

The $\Pi(E)$ amounts to almost -0.5 at the high energy limit, but up to the energy of 38 keV which is 0.8× (incident electron energy), absolute value of $\Pi(E)$ is below 0.1. So, in order to make the error caused by the polarization of the primary beam small, it is preferable to use the data whose energy region is below 0.8×(incident electron energy). By the use of this energy region, the errors due to the polarization contained in the data which are obtained at the scattering angle below 25° are less than 1%. But at high angles, for example, 2θ=56°, they amount to 5% if the polarization correction is not made. In our data, which are corrected by the use of the measured polarization, $\Pi(E)$, the estimated uncertainties are about 1% even at high scattering angles (2θ=40 and 56°).

In order to cancel the effect of polarization, Olsen *et al.*[12] and Egami[3] proposed the use of a diffractometer with an X-ray tube tilted away from the diffraction plane by 45°. In aperture collimator systems, this method may be used. However, it is not suitable in the case of slit systems, because the projection of the slit height on the scattering plane becomes large and the resolution of the scattering angle becomes low.

Correction for the Effects Originating from the Detector, the Slit System and the Sample

The Escape Correction. When a pure Ge or Li drifted Ge SSD is used, escape peaks are observed.[13] Some photons which come into the detector excite K electrons of Ge atoms and produce $K\alpha$ or $K\beta$ fluorescent X-rays characteristic of Ge. If the fluorescent X-ray photon is instantly re-absorbed in the crystal of the SSD, the output pulse height from the detector has a value corresponding to the energy of the original photon that entered the detector. However, if the fluorescent X-ray photon escapes from the detector

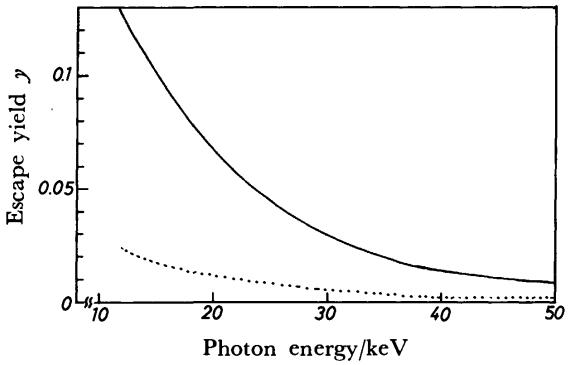

Fig. 4. The escape yield, $y(E)$, of the Ge SSD.[14] The solid curve is the yield for $K\alpha$ photons, and the broken curve for $K\beta$ photons.

crystal, the pulse height from the detector decreases to the value corresponding to the original photon energy minus E_k, the energy of Ge $K\alpha$ or $K\beta$ photons. Thus the number of photons counted at the energy E becomes less, and that at the energy $E-E_k$ becomes more, than the values they shoud be, where E_k is about 10 keV.

The yield of the escape, $y(E)$, of the Ge SSD used in the present work was measured by Mitsuhashi *et al.*, by the use of a single crystal of Si.[6,14] It is shown in Fig. 4.

With a little manipulation, we obtain the following formula for the true intensity I_0 at energy E:

$$I_0 = J_0 - \frac{y_1}{1-y_1}J_1 + \frac{y_1y_2}{(1-y_1)(1-y_2)}J_2 - \frac{y_1y_2y_3}{(1-y_1)(1-y_2)(1-y_3)}J_3 + \cdots\cdots \quad (\text{for } E<E_k) \quad (2)$$

and

$$I_0 = \frac{1}{1-y_0}\left[J_0 - \frac{y_1}{1-y_1}J_1 + \frac{y_1y_2}{(1-y_1)(1-y_2)}J_2 - \frac{y_1y_2y_3}{(1-y_1)(1-y_2)(1-y_3)}J_3 + \cdots\cdots\right] \quad (\text{for } E\geq E_k) \quad (3)$$

where J_n is the apparent intensity observed by the Ge SSD at the energy $E+nE_k$; y_n is the escape yield at the energy $E+nE_k$. The progression in Eq. 2 or 3 is terminated at the n-th term where the energy of $(E+(n+1)E_k)$ becomes for the first time greater than the high energy limit which is determined by the applied tube voltage. By the use of the measured values of y_n and J_n, we can make the escape correction with sufficient accuracy.

Slit Correction. The peaks and valleys of the observed intensity curve are smeared by the convolution due to the dispersion of the scattering angle, which is determined by the geometrical arrangement and widths of the slits. For liquid CCl_4, which gives a sharp peak at small s-values, the reduction of the peak height caused by this convolution is a serious problem.

According to the method of the slit correction in the experiment of small angle scattering[15] the deconvoluted intensity $I(s)$ is approximately given by

$$I(s) = 2\tilde{I}(s) - [\tilde{I}(s+\Delta s)+\tilde{I}(s-\Delta s)]/2, \quad (4)$$

where $\tilde{I}(s)$ is the observed intensity at s and Δs is the dispersion of the scattering parameter s, which is related to the angle dispersion ξ by the following formula:

$$\Delta s = \frac{4\pi}{hc} E \sin(\theta+\xi) - \frac{4\pi}{hc} E \sin\theta. \quad (5)$$

The parameter ξ is the dispersion of the angle caused by the width of slits. The values of ξ are estimated to be 0.125, 0.250, and 0.50° for the slits with the widths of 0.5, 1, and 2 mm, respectively, in the geometrical arrangement of the present work. The details of the estimation of ξ are given in Appendix 1. The first peak at $s \simeq 1.3 \text{Å}^{-1}$ for liquid CCl_4 becomes 5% higher than that without the slit correction, when the data were obtained at the scattering angle of $2\theta=6°$ and 0.5 mm slit systems with 150 mm separation were used.

Absorption Correction. The most important correction in energy-dispersive diffractometry is the absorption correction, because the linear absorption coefficient, μ, changes to a great extent with the energy of the X-rays. The values of $\mu(E)$ were experimentally determined from the measurements of the transmittance of the sample at $\theta=0°$ with the primary beam. The tube was operated at a few micro-amperes, after being stabilized well before the measurement. The observed values are shown in Fig. 5, together with the calculated ones. The calculation of $\mu(E)$ was performed according to the International Tables.[16] A good agreement was obtained except in the high-energy region and the low-energy region. In the former region, the calculated absorption coefficients are somewhat smaller than the observed ones, while in the latter region, the calculated absorption coefficients are larger. The observed absorption coefficients were used for the data analysis.

In the present work, the transmission geometry is adopted and the absorption factor $A_{coh}(E,\theta)$ is given simply by

$$A_{coh}(E,\theta) = \exp(-\mu(E) l \sec\theta), \quad (6)$$

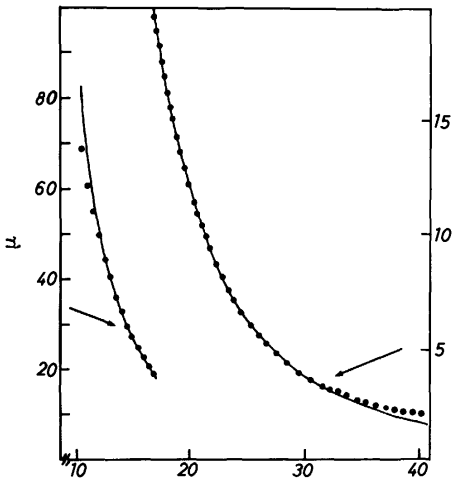

Fig. 5. The observed (dots) and calculated (solid curve) linear absorption coefficient, μ, of liquid CCl_4.

where l is the thickness of the sample.[2] The incoherent absorption factor $A_{inc}(E,E',\theta)$ is given by

$$A_{inc}(E,E',\theta) = \int_0^l \exp[-\mu(E)x\sec\theta - \mu(E')(l-x)\sec\theta]dx/l$$
$$= \frac{\exp(-\mu(E')l\sec\theta)}{l\mu(E)\sec\theta(1-\mu(E')/\mu(E))} \times [1-\exp\{-\mu(E)l\sec\theta(1-\mu(E')/\mu(E))\}], \quad (7)$$

if Compton scattering is assumed to occur with equal probability at any place inside the sample.

Egami proposed the reflection geometry as the optical system,[7] because the absorption factor $A(E,\theta)$ is proportional to $\mu(E)^{-1}$ in this arrangement. However, this is valid only when the incident beam is completely absorbed by the sample and when all the X-rays scattered at a particular angle from the sample are collected by the detector. In order to satisfy these conditions, it is necessary to use a wide detector slit on the side of the sample. This results in loss of angular resolution, which causes a serious error, as mentioned in the section of the slit correction. Moreover, the reflection geometry makes it difficult to measure scattering intensities at low angles.

Problems in the Scattering Process

Multiple Scattering. We have considered the kinematical double scattering, following the method by Warren and Mozzi,[17] who reported the correction for the double scattering of an amorphous sample in the case of reflection geometry and for the angle-dispersive method. We have calculated the effect of the double scattering for the transmission geometry and for the used region of the photon energy. The details are given in Appendix 2. In the case of the reflection method, Warren and Mozzi[17] and Egami[7] reported that the ratio of the double scattering intensity to the single scattering intensity amounts to 8% and 10%, respectively. However, in the case of transmission method, the maximum value of this ratio is 1.5%. This is because the sample is very thin (0.5 mm in the present experiment) in the transmission method. The energy-dependence of the ratio is rather small, but the ratio becomes larger as the scattering angle increases, as is shown in Appendix 2 (Fig. 13).

Compton Scattering. In the energy-dispersive method, the observed intensities are the sum of the intensities of incoherent scattering or Compton scattering and coherent scattering. The accumulated counts at a certain channel corresponding to the photon energy E contain the counts of incoherently scattered photons which have the incident energy E'. E' is larger than E by the Compton shift ΔE, which is given by

$$\Delta E = \frac{2E^2\sin^2\theta}{mc^2} \frac{1}{\left(1-\frac{2E}{mc^2}\sin^2\theta\right)}. \quad (8)$$

Since it is difficult to measure the incoherent scattering of the sample separately, we used the sum of

atomic incoherent scattering factors of the constituent atoms for the stoichiometric unit of the sample, denoted by I_{inc} multiplied by the recoil factor K, in the analysis. The atomic incoherent scattering factors are calculated by Cromer.[18] The Breit-Dirac recoil factor K is $(E/E')^2$ in the case of free electrons, and the ratio of the band width, $(dE'/dE)=(E'/E)^2$, cancels out the recoil factor, as pointed out by Egami[3] (see Eq. 9). However, for a system with bound electrons, the recoil factor is (E/E'),[19] and accordingly the product $K(dE'/dE)$ becomes (E'/E). Compton scattering has a profile with a width due to the momentum distribution of electrons, but it is permissible to neglect this width in the analysis.

Reduction to the Structure Function

After we measured the energy spectrum of X-rays from the sample, the structure function is obtained according to the following processes.

First the escape correction and the slit correction are performed. After these corrections, the observed spectrum $I_{obsd}(E,\theta)$ is expressed as

$$\begin{aligned} I_{obsd}(E,\theta) = k[&A_{coh}(E,\theta)P(E,\theta)I_p(E)I_{coh}(E,\theta) \\ &+ K(dE'/dE)A_{inc}(E,E',\theta)P(E',\theta)I_p(E')I_{inc}(E',\theta) \\ &+ A_{coh}(E,\theta)P(E,\theta)I_p(E)D(E,\theta)] \\ &+ A_{coh}(E,\theta)I_{back}(E,\theta) \end{aligned} \quad (9)$$

In Eq. 9, A is the absorption factor, P the polarization factor, I_{coh} and KI_{inc} are the coherent and incoherent scattering intensities of the sample, respectively. D is the double scattering intensity. I_{back} is the experimentally obtained background intensity, which includes the scattering from windows of the sample holder and that from air, and the intensity of parasitic scattering. $I_p(E)$ is the energy spectrum of the primary beam, obtained experimentally as mentioned in previous Chapter, including the attenuation due to the X-ray absorption by air and the detector efficiency. For I_p and I_{back} described in Eq. 9, the escape correction and the slit correction are already performed. The scale factor k normalizes the observed intensity to the absolute scale of the stoichiometric unit of the liquid. E' is the initial photon energy which is reduced to E after Compton scattering. The polarization factor, P, in Eq. 9 is given by

$$P(E,\theta) = (1+\cos^2 2\theta)/2 + (1-\cos^2 2\theta)\Pi(E)/2, \quad (10)$$

in terms of the polarization $\Pi(E)$, which has been determined experimentally as mentioned in the previous section.

Second, with the use of the absorption factor $A_{coh}(E,\theta)$ calculated by the use of the measured values of $\mu(E)$ and Eq. 6, the fourth term in Eq. 9 is subtracted easily. Dividing the remaining term by the factor $A_{coh}(E,\theta)P(E,\theta)I_p(E)$, we obtain the following quantity:

$$\begin{aligned} I'_{obsd}(E,\theta) = k\Big\{&I_{coh}(E,\theta) + \frac{(E'/E)A_{inc}(E,E',\theta)P(E',\theta)I_p(E')}{A_{coh}(E,\theta)P(E,\theta)I_p(E)} \\ &\times I_{inc}(E',\theta) + D(E,\theta)\Big\} \end{aligned} \quad (11)$$

The product $K(dE'/dE)$ has been replaced by (E'/E) as discussed in the preceding section. All the factors in the second term in Eq. 11 are known. The double scattering intensity, $D(E,\theta)$ has been estimated as described in Appendix 2.

Next, we should determine the scale factor k as in the following process. The total coherent intensity I_{coh} is composed of three terms; that is,

$$I_{coh}(E,\theta) = \sum_n f_n(s)^2 + i_1 + i_2 \quad (12)$$

where the first term is the self-scattering intensity from the constituent atoms, the second term i_1 represents the molecular term which is the result of the interference from each atom pair within a molecule, and the third term i_2 represents the interference from atom pairs between different molecules. Since the term i_2 in Eq. 12 vanishes at large s-values, I_{coh} is given by the first and second terms in Eq. 12. The scale factor k to normalize the experimental intensity to the absolute intensity is obtained by comparing the experimental intensity with the calculated absolute intensity, which is composed of I_{coh} and the second and third terms in Eq. 11. The scale factor k was easily obtained for the data at 2θ=28, 40, and 56°.

For the data which are obtained at smaller scattering angles, the approximation of $i_2 \simeq 0$ is not valid. Utilizing the values of $I_{coh}(s)$ obtained by the data at 2θ=28° for the overlapping s-region of 2θ=28° and the next lower angle 2θ=16°, we can calculate the absolute intensity for 2θ=16°, because $I_{coh}(E,\theta)$ is simply a function of s, and the second and the third terms of Eq. 11 are known. By comparing the calculated absolute intensity and $I'_{obsd}(E,2\theta=16°)$, the scale factor k for 2θ=16° is determined. This procedure is repeated for the data obtained at lower scattering angles, and both k and $I_{coh}(s)$ can be determined.

The obtained total coherent intensity $I_{coh}(s)$ for liquid CCl_4 at room temperature is shown in Fig. 6 by a solid curve, together with the calculated values of the self-scattering intensity from the individual atoms, *i.e.*, $\sum_n f_n(s)^2$ by broken curve. The weighted structure function, $si(s)$, is shown in Fig. 7, where $i(s)$

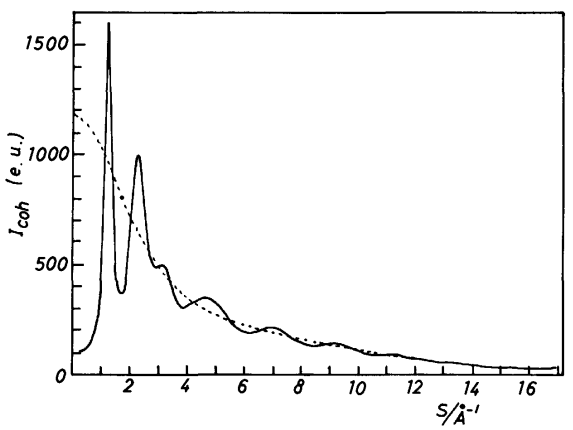

Fig. 6. The observed total coherent intensity $I_{coh}(s)$ for liquid CCl_4 (solid curve) and self-scattering intensity from the constituent atoms (broken curve).

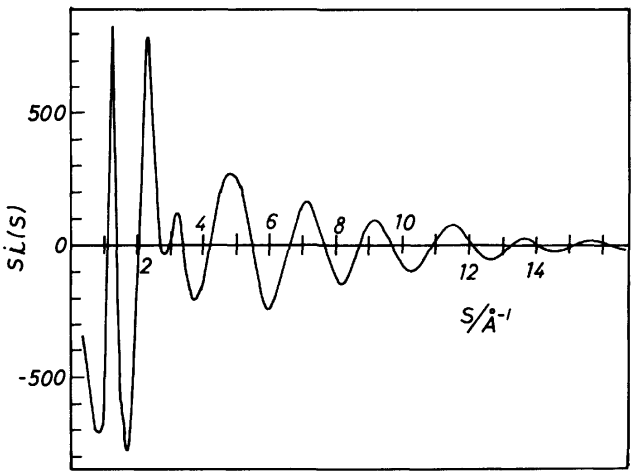

Fig. 7. Weighted structure function $si(s)$ for liquid CCl_4 at room temperature.

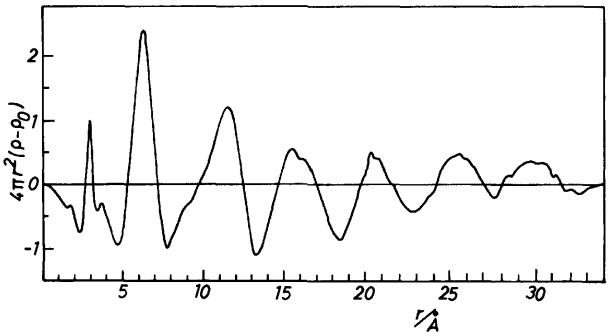

Fig. 8. The electronic distribution function of liquid CCl_4 containing the distribution of electron cloud, $4\pi r^2(\rho-\rho_0)$.

is the reduced intensity defined by

$$i(s) = I_{\text{coh}} - \sum_n f_n(s)^2 = i_1 + i_2. \quad (13)$$

The weighted structure function contains the information on the molecular structure and on the arrangement of molecules in the liquid.

The distribution function containing the distribution of electron cloud is shown in Fig. 8. It is defined by the Fourier transform of the weighted structure function, $si(s)$,

$$4\pi r^2(\rho-\rho_0) = \frac{2r}{\pi\sum_n Z_n^2}\int si(s)\sin sr ds, \quad (14)$$

where ρ_0 is the bulk number density of the liquid and Z_n is the atomic number of the n-th component atom.

Discussion

We have enumerated many factors which affect the accuracy of the intensity data obtained by the energy-dispersive method and taken them into account in the analysis. Whether or not the corrections have improved the experimental results is ascertained in the following two ways. First, we can check the consistency of the data in the same s-region which

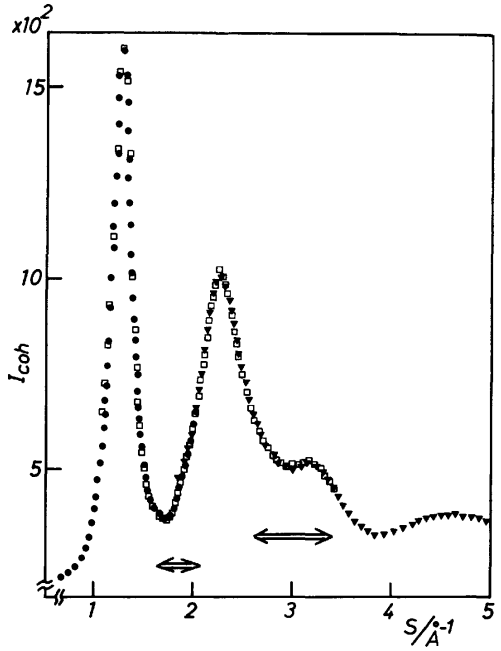

Fig. 9. The total coherent intensity for liquid CCl_4 to show the consistency of the data obtained by different angle-setting. The marks such as ●, □, and ▼ show the data obtained by the angle-setting at $2\theta = 6$, 10, and 16°, respectively. The arrows show the region used for determining the scale factor k.

are collected at different scattering angles and analyzed independently. This consistency is very good as is shown in Fig. 9, when the energy region ranging from 10 to 38 keV is used. In the energy region lower than 10 keV, the absorption by liquid is very strong, and the uncertainty of the observed transmittance becomes large. In the energy region higher than 38 keV, the uncertainty of the polarization of the primary beam becomes large. In the case of liquid CCl_4, the energy region of 10—38 keV is suitable to use for the measurement of scattering intensities.

Second, in order to evaluate the procedure of the present work, the intensity data obtained by the present experiment may be compared with data obtained by the angle-dispersive method. The diffraction intensity of this sample (liquid CCl_4) has been measured by several authors.[20-23] However, only Narten presented the numerical values of the intensity data in the table.[23] Our experiment has been carried out at room temperature and Narten reported the data at 20°C. So, our data obtained by energy-dispersive method have been compared with those of Narten in the form of the molecular structure function $H(s)$, where $H(s)$ is defined by

$$H(s) = i(s)/(\sum_n f_n(s))^2. \quad (15)$$

As is shown in Fig. 10, the present structure function is in fairly good agreement with the one by Narten[23] except for the small s-region. In Fig. 10, our data are shown by a solid curve and Narten's data by dots. A large difference is observed at the small s-region (s= 0—1.3 Å^{-1}). For the region of s less than 1 Å^{-1}, the values of $H(s)$ by Narten are too small, because for

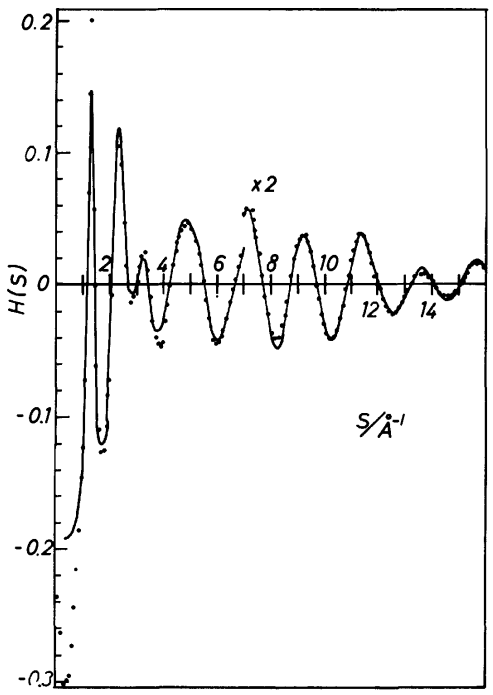

Fig. 10. The comparison of the structure function $H(s)$ of the present work and Narten's.[23] Solid curve is the present data and dots show Narten's.

liquid CCl_4 the structure function $H(s)$ can never be less than -0.217, even if the total coherent intensity I_{coh} were equal to zero at $s\simeq 0$ Å^{-1}. For the peak-height at $s\simeq 1.3$ Å^{-1}, Narten's value is much higher than our data. We can not understand why these discrepancies in $H(s)$ exist in the small s-region, because the total coherent intensity obtained by Narten[23] shows very good agreement with ours (Fig. 6) in the region $s\simeq 0$ Å^{-1} and also for the peak-height at $s\simeq 1.3$ Å^{-1}.

The results mentioned above seem to show the need of the corrections discussed in the present paper.

The diffraction intensity of liquid CCl_4 was also measured as the first sample when Murata and Nishikawa constructed an energy-dispersive diffractometer.[2] The main difference between the previous and the present data is the peak-height of the first peak at $s\simeq 1.3$ Å^{-1}. The first peak of the present data is much higher than that of the previous data, because in the previous analysis the slit correction was not made. In the data corrections which we have newly made, the effect of the slit correction is the largest. Especially for liquid CCl_4, whose diffraction pattern has a very sharp peak at small s-region, the divergence of the scattering angle in the experimental condition is very sensitive to the peak-height.

We believe that solutions have been given to the problems in the analysis of the diffraction data obtained by the energy-dispersive method. One of the remaining problems may be the anomalous dispersion. In the case of CCl_4, this effect is rather small in the energy range used in the experiment. However, this effect should be taken into account for samples containing heavier atoms.

By the revision and improvement of the analysis for the data obtained by the energy-dispersive method, the intensity data of liquid CCl_4 have been improved, but the structure model is unchanged. The model of the bcc local structure[24] has turned out to be still valid with better agreement between the observed and the simulated curves of the structure function. The discussion on the structure of liquid CCl_4 will be reported in detail in a succeeding paper.

The authors wish to express their thanks to Messrs. Masayoshi Hamano, Hiroshi Miyagi, and Yuzi Shimokawa of the machine shop of Gakushuin University for the construction of the vertical tube holder to measure the polarization of the primary beam. Their thanks are also due to Professor Hideki Morikawa of Tokyo Institute of Technology for offering the sample of silica glass. The present work is a continuation to the research project initiated by Professor Yoshitada Murata of the Institute for Solid State Physics, the University of Tokyo.

Appendix 1

Slit Correction. For middle or large angle scattering experiments, the widths of the slits which are ordinarily used have a smearing effect on the observed intensity data. It is also permissible to neglect the effect of the finite slit height. We describe the slit correction for the diffraction data which are smeared due to the width of the slits.

The experimental scattered intensity $\tilde{I}(E,\theta)$ for a scattering angle 2θ is related to the scattered intensity of the perfect collimation, $I(E,\theta)$, by the equation

$$\begin{aligned}\tilde{I}(E,\theta) &= \iiint I(E,\theta+\delta\theta)W(w,z,u)\mathrm{d}w\mathrm{d}z\mathrm{d}u \\ &\quad / \iiint W(w,z,u)\mathrm{d}w\mathrm{d}z\mathrm{d}u \\ &= \iiint [I(E,\theta)+I'(E,\theta)\delta\theta+\tfrac{1}{2}I''(E,\theta)\delta\theta^2] \\ &\quad \times W\mathrm{d}w\mathrm{d}z\mathrm{d}u / \iiint W\mathrm{d}w\mathrm{d}z\mathrm{d}u. \qquad \text{(A1.1)}\end{aligned}$$

where $W(w,z,u)$ is a weight function, the form of which depends on the collimation system. The parameters w, z, and u are the deviations of a path of X-rays from the central line (chained line in Fig. 11) in the collimator, on the side of the incident slit, on the sample and on the detector slit, respectively, as is shown in Fig. 11. The central lines

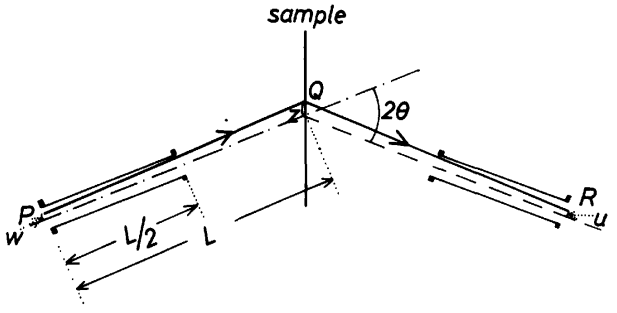

Fig. 11. Geometry of the slit system. We consider the angle dispersion for the X-rays which pass through P, Q and R.

determine the scattering angle 2θ. The notations I' and I'' show the first and second derivatives of the intensity I. In Eq. A1.1, the angular deviation $\delta\theta$ is a function of w, z, and u. Equation A1.1 is rewritten as

$$\tilde{I}(E,\theta) = I(E,\theta) + I'(E,\theta)\iiint \delta\theta W \mathrm{d}w\mathrm{d}z\mathrm{d}u \Big/ \iiint W \mathrm{d}w\mathrm{d}z\mathrm{d}u + \frac{1}{2}I''(E,\theta)\iiint \delta\theta^2 W \mathrm{d}w\mathrm{d}z\mathrm{d}u \Big/ \iiint W \mathrm{d}w\mathrm{d}z\mathrm{d}u \quad \text{(A1.2)}$$

The second term in Eq. A1.2 vanishes, because it is possible to assume that the function $(\delta\theta W)$ is an odd function of the parameters w, z, and u. Let us define the angle dispersion ξ by the following relation:

$$\xi = (\overline{\delta\theta^2})^{1/2} = \left[\iiint \delta\theta^2 W \mathrm{d}w\mathrm{d}z\mathrm{d}u \Big/ \iiint W \mathrm{d}w\mathrm{d}z\mathrm{d}u\right]^{1/2}. \quad \text{(A1.3)}$$

We have

$$\tilde{I}(E,\theta) = I(E,\theta) + \frac{1}{2}I''(E,\theta)\xi^2. \quad \text{(A1.4)}$$

On the other hand,

$$\tilde{I}(E,\theta+\xi) = \tilde{I}(E,\theta) + \tilde{I}'(E,\theta)\xi + \frac{1}{2}\tilde{I}''(E,\theta)\xi^2 \quad \text{(A1.5)}$$

$$\tilde{I}(E,\theta-\xi) = \tilde{I}(E,\theta) - \tilde{I}'(E,\theta)\xi + \frac{1}{2}\tilde{I}''(E,\theta)\xi^2 \quad \text{(A1.6)}$$

By the summation of Eq. A1.5 and Eq. A1.6, we obtain

$$\tilde{I}''(E,\theta)\xi^2 = \tilde{I}(E,\theta+\xi) + \tilde{I}(E,\theta-\xi) - 2\tilde{I}(E,\theta). \quad \text{(A1.7)}$$

Now, we make an appriximation,

$$\tilde{I}''(E,\theta) = I''(E,\theta), \quad \text{(A1.8)}$$

then we have

$$I(E,\theta) = 2\tilde{I}(E,\theta) - \frac{1}{2}[\tilde{I}(E,\theta+\xi) + \tilde{I}(E,\theta-\xi)], \quad \text{(A1.9)}$$

from Eq. A1.4 and Eq. A1.7. This equation corresponds to Eq. 4 in the text. With enough accuracy, we can approximate the intensity $\tilde{I}(E,\theta+\xi)$ by $\tilde{I}(E+\delta E,\theta)$, where the pair of parameters $E+\delta E$ and θ gives the same s-value as the pair of E and $\theta+\xi$.

The angle dispersion must be estimated for a particular optical geometry. Let us consider a path of X-rays which pass through the points P, Q, and R (see Fig. 11). Let the incident collimator be placed symmetrically to the detecting collimator. For low scattering angles, we have

$$\delta(2\theta) = (z-w)/L + (z-u)/L$$

or

$$\delta\theta = [2z-(w+u)]/2L \quad \text{(A1.10)}$$

where L is the distance between the slit on the side of the X-ray tube (or the detector) and the sample, and $\cos\theta$ is approximated by unity. For the gentle peaks obtained at large scattering angles, the angle dispersion causes little smearing effect. We consider the slit correction only for the case of low scattering angles. Let us derive the expressions of ξ for some optical systems.

Case 1: The incident beam is perfectly parallel and u is fixed to zero. In this case,

$$\delta\theta = z/2L$$
$$W(w,z,u)\mathrm{d}w\mathrm{d}z\mathrm{d}u = Q(z)\mathrm{d}z.$$

where $Q(z)$ is simply a constant for the slit system, and is given by

$$Q(z) = 1/2d. \quad \text{(A1.11)}$$

Accordingly,

$$\xi^2 = \int_{-d}^{d}\left(\frac{z}{2L}\right)^2\frac{1}{2d}\mathrm{d}z \Big/ \int_{-d}^{d}\left(\frac{1}{2d}\right)\mathrm{d}z = d^2/12L^2 \quad \text{(A1.12)}$$

Case 2: The incident beam is perfectly parallel and u is not fixed to zero. This case gives the following relations:

$$\delta\theta = (z-u)/2L$$
$$W(w,z,u)\mathrm{d}w\mathrm{d}z\mathrm{d}u = V(z,u)\mathrm{d}z\mathrm{d}u$$

where

$$\text{if } |z| \geq |u|, \quad \text{then } V(z,u) = Q(z)$$

and

$$\text{if } |z| < |u|, \quad \text{then } V(z,u) = Q(u).$$

Considering the symmetrical property of the beam around the central lines, we can omit the cross term of u and z, and we have

$$\begin{aligned}\xi^2 &= \iint\left(\frac{z-u}{2L}\right)^2 V(z,u)\mathrm{d}z\mathrm{d}u \Big/ \iint V(z,u)\mathrm{d}z\mathrm{d}u \\ &= \frac{1}{4L^2}\iint(z^2+u^2)V(z,u)\mathrm{d}z\mathrm{d}u \Big/ \iint V(z,u)\mathrm{d}z\mathrm{d}u \\ &= \frac{1}{4L^2}\left\{2\left[\int_{z=0}^{d}\int_{u=0}^{z}\left(\frac{z^2+u^2}{2d}\right)\mathrm{d}u\mathrm{d}z + \int_{u=0}^{d}\int_{z=0}^{u}\left(\frac{z^2+u^2}{2d}\right)\mathrm{d}z\mathrm{d}u\right]\right. \\ &\quad \left./2\left[\int_{z=0}^{d}\int_{u=0}^{z}\mathrm{d}uQ(z)\mathrm{d}z + \int_{u=0}^{d}\int_{z=0}^{u}\mathrm{d}zQ(u)\mathrm{d}u\right]\right\} \\ &= d^2/6L^2 \end{aligned} \quad \text{(A1.13)}$$

Case 3: Let the length of the collimator be L; namely, there is no separation between the collimators and the sample. In this case, we find

$$\delta\theta = [2z-(\omega+u)]/2L$$
$$W(w,z,u)\mathrm{d}w\mathrm{d}z\mathrm{d}u = Q(q)\mathrm{d}w\mathrm{d}z\mathrm{d}u$$

where q is the maximum among $|u|$, $|z|$, and $|w|$. By the same reason as in Case 2, the cross terms of w, z, and u vanish, and we obtain the following relation:

$$\begin{aligned}\xi^2 &= \iiint\left[\frac{2z-(w+u)}{2L}\right]^2 Q(q)\mathrm{d}w\mathrm{d}z\mathrm{d}u \Big/ \iiint Q(q)\mathrm{d}w\mathrm{d}z\mathrm{d}u \\ &= \frac{1}{4L^2}\iiint(4z^2+w^2+u^2)Q(q)\mathrm{d}w\mathrm{d}z\mathrm{d}u \\ &\quad \Big/ \iiint Q(q)\mathrm{d}w\mathrm{d}z\mathrm{d}u.\end{aligned}$$

The integration can be analytically performed to give

$$\xi^2 = d^2/2L^2 \quad \text{(A1.14)}$$

Case 4: In the optical geometry of the present work the length of the collimator is $L/2$. In this most realistic case,

$$\delta\theta = [2z-(w+u)]/2L$$
$$W(w,z,u)\mathrm{d}w\mathrm{d}u\mathrm{d}z = Q(q)\mathrm{d}w\mathrm{d}z\mathrm{d}u$$

where q is the maximum among $|w|$, $|w+z|/2$, $|u+z|/2$, and $|u|$. By the consideration of the symmetrical property of W, the region of the integration is reduced to

$$-d \leq w \leq d,$$
$$0 \leq u \leq d,$$

and

$$-3d \leq z \leq 2d.$$

TABLE 1. THE MEAN SQUARES OF ANGLE DISPERSION, ξ^2, FOR SLIT AND APERTURE SYSTEMS

L is the distance between the detector and the sample. The notations d and r refer to half of the slit width and the radius of the aperture, respectively.

	Slit	Aperture
Case 1	$d^2/12L^2$	$r^2/16L^2$
Case 2	$d^2/6L^2$	$2r^2/15L^2$
Case 3	$d^2/2L^2$	$5r^2/12L^2$
Case 4	$1.706\times d^2/L^2$	$1.404\times r^2/L^2$

In this case, we can not integrate Eq. A1.3 analytically. The result obtained by numerical integration is

$$\xi^2 = \iiint\left[\frac{2z-(w+u)}{2L}\right]^2 Q(q)\mathrm{d}w\mathrm{d}z\mathrm{d}u \Big/ \iiint Q(q)\mathrm{d}w\mathrm{d}z\mathrm{d}u = 1.706\times d^2/L^2 \quad \text{(A1.15)}$$

For the aperture systems with the radius r, the weight function becomes

$$Q_A(x) = 2\sqrt{r^2-x^2}/\pi r^2 \quad \text{(A1.16)}$$

in place of Eq. A1.11, and ξ^2 can be calculated by replacing $Q(x)$ by $Q_A(x)$. For comparison, the expressions of ξ^2 for both slit systems and aperture systems are listed in Table 1, for cases 1 to 4.

Appendix 2

Multiple scattering. The following calculation was made with reference to the work by Warren and Mozzi.[17] Let us consider the double scattering from the sample for the transmission geometry. The power of the primary beam is given by I_0S_0, where I_0 is the intensity of the primary beam per unit area and S_0 is the cross section area of the primary beam. Let n be the number density of the units of composition, and $J(2\theta)$ be the intensity of the single scattering per unit of composition for the scattering angle 2θ. Let $\mathrm{d}I_r$ be the intensity at distance r from the volume element $\mathrm{d}V_1$ due to the scattering of the primary beam by $\mathrm{d}V_1$, then

$$\mathrm{d}I_r = A_1P_1I_0\frac{e^4}{m^2c^4r^2}J(2\theta_1)nS_0\mathrm{d}t \quad \text{(A2.1)}$$

where A_1 is the absorption factor, P_1 the polarization factor and r is the distance between volume element $\mathrm{d}V_1$ and $\mathrm{d}V_2$. Let $\mathrm{d}I(2)$ be the intensity at the point of observation at distance R from the sample, due to the scattering of the intensity $\mathrm{d}I_r$ by the volume element $\mathrm{d}V_2$.

$$\mathrm{d}I(2) = A_2P_2\mathrm{d}I_r\frac{e^4}{m^2c^4R^2}J(2\theta_2)n\mathrm{d}V_2. \quad \text{(A2.2)}$$

Here, the volume element $\mathrm{d}V_2$ is given by

$$\mathrm{d}V_2 = r^2\cos\varepsilon\,\mathrm{d}\varepsilon\mathrm{d}\varphi\mathrm{d}r, \quad \text{(A2.3)}$$

(see Fig. 12 for the definitions of the angles θ, $2\theta_1$, $2\theta_2$, ε, and φ and of the distances t and r). By Eq. A2.1 for $\mathrm{d}I_r$, we have

$$\mathrm{d}I(2) = I_0S_0AP\left(\frac{e^4}{m^2c^4}\right)^2\frac{n^2}{R^2}J(2\theta_1)J(2\theta_2)\cos\varepsilon\,\mathrm{d}\varepsilon\mathrm{d}\varphi\mathrm{d}t\mathrm{d}r. \quad \text{(A2.4)}$$

The absorption factor A in Eq. A2.4 is given by

$$A = \exp(-\mu f(r))$$

where μ is the linear absorption coefficient and $f(r)$ is the path length of the X-ray beam in the sample and given by

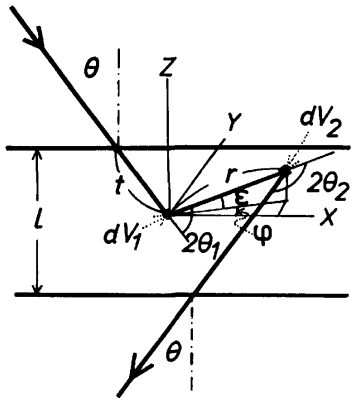

Fig. 12. Geometry of the double scattering process for the transmission method.

$$f(r) = r + l/\cos\theta + r\sin\varepsilon/\cos\theta \quad \text{(A2.5)}$$

where l is the thickness of the sample. The polarization factor P is given by

$$P = \cos^2 2\theta_1 + \cos^2 2\theta_2 + (\cos 2\theta_1\cos 2\theta_2 - \cos 2\theta)^2/2. \quad \text{(A2.6)}$$

The polarization of the primary beam is neglected, because it is small in the energy region we used. The double scattering $I(2)$ is given by the integration of Eq. A2.4 by the parameters t, r, ε, and φ.

First let us consider the integration by the parameters t and r. In the integrand in Eq. A2.4 only the absorption factor A is a function of the parameters t and r. We define A' by

$$A' = \iint \exp(-\mu f(r))\mathrm{d}r\mathrm{d}t.$$

The region of the integration by r for the case of forward scattering ($\varepsilon\leq 0$) is different from that for back scattering ($\varepsilon>0$). For the former, r goes from 0 to $(l-t\cos\theta)/(-\sin\varepsilon)$ and for the latter, r goes from 0 to $t\cos\theta/\sin\varepsilon$. The region of the integration for t is the same for the two cases and becomes from 0 to $l\sec\theta$. For the forward scattering, we obtain

$$A' = \int_{t=0}^{l\sec\theta}\int_{r=0}^{\frac{-l+t\cos\theta}{\sin\varepsilon}} \exp\{-\mu f(r)\}\mathrm{d}r\mathrm{d}t = \exp(-\mu l\sec\theta)\left[\frac{\cos\theta\cdot\sin\varepsilon}{\mu^2(\cos\theta+\sin\varepsilon)^2} \times\{1-\exp[\mu l(\sec\theta+\operatorname{cosec}\varepsilon)]\}+\frac{l}{\mu(\cos\theta+\sin\varepsilon)}\right] \quad \text{(A2.7)}$$

For the back scattering, we have

$$A'' = \int_{t=0}^{l\sec\theta}\int_{r=0}^{\frac{t\cos\theta}{\sin\varepsilon}} \exp\{-\mu f(r)\}\mathrm{d}r\mathrm{d}t = \exp(-\mu l\sec\theta)\left[\frac{\cos\theta\sin\varepsilon}{\mu^2(\cos\theta+\sin\varepsilon)^2} \times\{\exp[-\mu l(\sec\theta+\operatorname{cosec}\varepsilon)]-1\}+\frac{l}{\mu(\cos\theta+\sin\varepsilon)}\right] \quad \text{(A2.8)}$$

Next, we relate the scattering angles $2\theta_1$ and $2\theta_2$ to the angles θ, ε, and φ. By a simple calculation, we obtain

$$\cos 2\theta_1 = \cos\varepsilon\cos\varphi\sin\theta - \sin\varepsilon\cos\theta$$

and

$$\cos 2\theta_2 = -\cos\varepsilon\cos\varphi\sin\theta - \sin\varepsilon\cos\theta. \quad \text{(A2.9)}$$

We have

$$I(2) = I_0 S_0 \left(\frac{e^4}{m^2c^4}\right)^2 \frac{n^2}{R^2} \times \left[\int_{\varphi=-\pi}^{\pi}\int_{\varepsilon=-\frac{\pi}{2}}^{0} A'\cdot P\cdot J(2\theta_1)J(2\theta_2)\cos\varepsilon\, d\varepsilon d\varphi + \int_{\varphi=-\pi}^{\pi}\int_{\varepsilon=0}^{\frac{\pi}{2}} A''\cdot P\cdot J(2\theta_1)J(2\theta_2)\cos\varepsilon\, d\varepsilon d\varphi\right]$$
$$= I_0 S_0 \left(\frac{e^4}{m^2c^4}\right)^2 \frac{n^2}{R^2} \times 2\left[\int_{\varphi=0}^{\pi}\int_{\varepsilon=\frac{\pi}{2}}^{0} A'\cdot P\cdot J(2\theta_1)J(2\theta_2)\cos\varepsilon\, d\varepsilon d\varphi + \int_{\varphi=0}^{\pi}\int_{\varepsilon=0}^{\frac{\pi}{2}} A''\cdot P\cdot J(2\theta_1)J(2\theta_2)\cos\varepsilon\, d\varepsilon d\varphi\right] \quad \text{(A2.10)}$$

On the other hand, the corresponding intensity of the single scattering is given by

$$I(1) = I_0\left(\frac{e^4}{m^2c^4}\right)\frac{nl\sec\theta S_0}{R^2}\left(\frac{1+\cos^2\theta}{2}\right)J(2\theta)\exp(-\mu l\sec\theta) \quad \text{(A2.11)}$$

The double scattering ratio to the single scattering is $I(2)/I(1)$ and is calculated by Eq. A2.10 and A2.11. In the calculation of Eq. A2.10, numerical integration is made for the parameters ε and φ. The intensity $J(2\theta)$ (and $J(2\theta_1)$, $J(2\theta_2)$) is approximated by

$$J(2\theta) = \sum_n f_n(E,\theta)^2 + I_{inc}(E,\theta). \quad \text{(A.12)}$$

This approximation is good enough because the double scattering is averaged over all directions and shows a smooth change for the scattering parameter s.

For each energy used for the experiment, we have calculated the ratio of the double scattering intensity to the single scattering intensity. The result is shown in Fig. 13 for the scattering angles 2θ=2.5, 28, and 55°. The double scattering intensity $D(E,\theta)$ in the text is estimated by $(I(2)/I(1))\,J(2\theta)$.

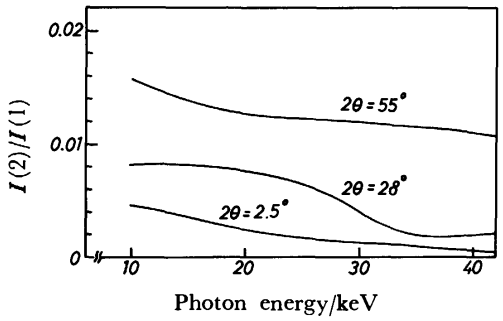

Fig. 13. The double scattering ratios to the single scattering *vs.* photon energies. The ratios are shown for the scattering angles 2θ=2.5, 28, and 55°.

†*Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606*

(Received December 22, 1983)

The ESR spectra of the cation radicals of TTF and its related compounds in which two 1,3-dithiole rings are connected by conjugated carbon and cumulene chains are measured. The spin distributions obtained from the *hfcc* due to the protons and sulfur atoms agree well with the results of the MINDO/3 calculations. The spin densities on the sulfur and central carbon atoms decreases as the central chain length increases. A linear relationship, $g=2.00379+0.00108\ a(S)$, between the *g*-values and the sulfur *hfcc* is noted and explained in terms of the Stone's theory. The *g*-values of the cation radicals with cumulene chains deviate from this relation and a possible cause is suggested.

The cation radical states of π electron donors play essential roles in making the organic metals such as tetrathiafuluvalene-tetracyanoquinodimethan(TTF-TCNQ) highly conductive[1] or in producing superconductivity in the salts of tetramethyltetraselenafuluvalene $(TMTSF)_2^{+\cdot}X^-(X^-=PF_6^-, ClO_4)$.[2] In order to understand the electronic band structures and the conduction mechanisms of these salts, it is desirable to know the details of the wave function and the orbital energies of the highest occupied molecular orbitals (HOMO). Electron spin resonance (ESR) and cyclic voltammetry measurements can provide information about them.

We have synthesized the compounds **2** to **5** shown in Fig. 1 in order to find electron donors better than TTF (**1**) and investigated their properties with various experimental techniques.[3] From the cyclic voltammetry measurements it was found that all these compounds have oxidation potentials ($E_{1/2}^{ox}$) lower than TTF and that they can be novel electron donors. Here we have studied the cation radicals of these compounds by ESR and examined the results in comparison with those predicted by the MINDO/3 calculation.

In this paper we first describe the results of the ESR investigation on the cation radicals of these compounds **1** to **5** in solution. From the hyperfine coupling constants (*hfcc*) of protons and sulfur atoms (^{33}S isotopes), the spin density distributions of the HOMO are determined in detail. The ESR spectra of the cation radicals of the several derivatives of **1**—**5** shown in Fig. 1 are also studied to examine the effects of substitution on the spin distributions.

Secondly, we compare the spin distributions obtained by ESR measurements with those calculated by the MINDO/3 method. We discuss how the HOMO changes as the central carbon chain in TTF becomes longer with conjugated or cumulene groups. In the case of **3**, there is an ambiguity whether the structure is *cis*- or *trans*-conformer. We investigated the compounds **6** and **7** shown in Fig. 1 in order to answer this question.

Finally, we discuss the relationship between the *g*-values and the sulfur *hfcc* noted for a series of compounds **1** to **3** using the Stone's theory. The *g*-values of **4** and **5**, however, deviate from this relationship. The origin of this deviation is discussed.

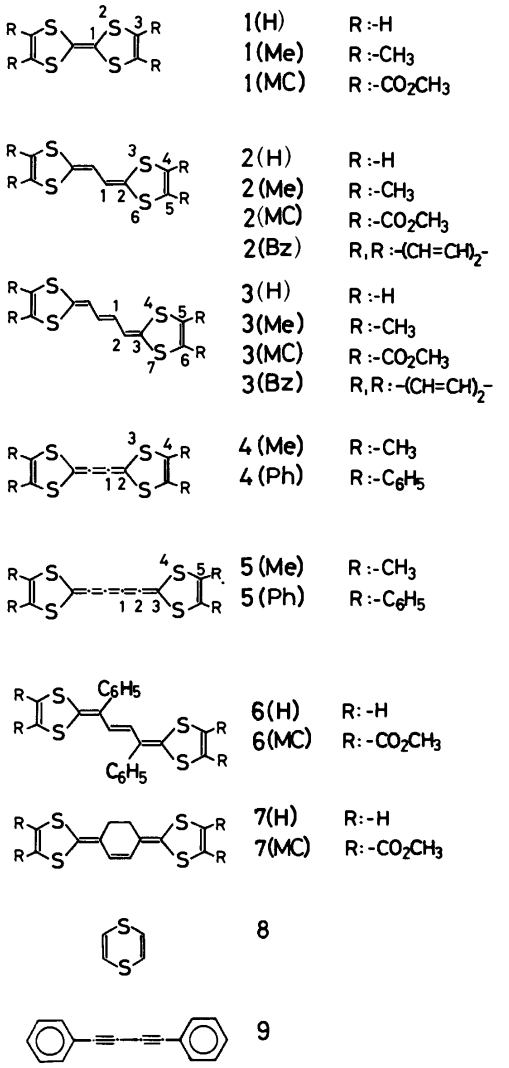

Fig. 1. Molecular structures investigated. The numbers distinguish the π-system and its derivatives are denoted by their abbreviations in last parenthes.

Experimental

The synthesis of the compounds **2**, **3**, and their derivatives was described elsewhere.[3] The series of compounds with cumulene skeletons are very unstable in the neutral states and we have not yet succeeded in synthesis. However the dication states of their tetramethyl and tetraphenyl derivatives are stable enough to be obtained in the form of perchlorate salts $\mathbf{4}^{2+}$ $2ClO_4^-$ and $\mathbf{5}^{2+}$ $2ClO_4^-$.[4] The generation of the cation radicals and the ESR measurements were carried out by using an electrochemical ESR system based on a JEOL-FE3X spectrometer.[5] The cation radicals of **1**, **2**, and **3** were generated by one-electron oxidation, while those of **4** and **5** were obtained by one-electron reduction of corresponding dications. Dry dichloromethane of spectroscopic grade was used as the solvent and tetrabutylammonium tetrafluoroborate was used as the supporting electrolyte. Potassiumn nitrosilbis(sulfate) was used as a standard sample for calibration of the magnetic field, the accuracy being within ±0.005 G†. *g*-Values were measured in reference to the signal of Cr(III) diluted in MgO (g=1.9800), the accuracy being within ±0.0001.

Results and Discussion

The ESR Spectra of $\mathbf{1}^{+\cdot}$, $\mathbf{2}^{+\cdot}$, *and* $\mathbf{3}^{+\cdot}$. The cation radicals of **1**(H), **2**(H), and their derivatives are stable but that of **3**(H) is a little unstable when it is oxidized at room temperature. The ESR spectra of these compounds do not change over the entire range of the temperature from −80 °C to room temperature. The proton *hfcc* and *g*-values of the cation radicals of **1**(H) and **1**(Me) are very close to those reported previously.[6] The ESR spectra of compounds $\mathbf{2}(H)^{+\cdot}$ and $\mathbf{3}(H)^{+\cdot}$ are shown in Figs. 2a and 3a, respectively, as examples. All of these ESR spectra have the linewidths of about 0.2 G and are easily analyzed and reconstructed by computer simulation (Figs. 2b and 3b).

The *hfcc* due to the isotopic sulfur atoms, ^{33}S (I=3/2) were observed as satellite lines in some cases. Especially, in the case of tetrakis (methoxycarbonyl) derivatives of $\mathbf{2}(MC)^{+\cdot}$ and $\mathbf{3}(MC)^{+\cdot}$, it was easy to observe the ^{33}S satellites because of the simplification of the ESR spectra by methoxycarbonyl substitution. As a typical example, the satellite lines of $\mathbf{2}(MC)^{+\cdot}$ are shown in Fig. 4. Two kinds of ^{33}S satellites are expected for **2** and **3** from the molecular symmetries, but only one is expected in **1** because four sulfur atoms are equivalent. Two kinds of ^{33}S satellites were observed for most of **2** and **3** as expected. In the spectrum of $\mathbf{2}(H)^{+\cdot}$, however, only one ^{33}S satellite (3.98 G) was resolved because the ^{33}S satellite due to the *hfcc* smaller than 3.98 G overlapps with the other lines.

In Table 1 are listed the obtained *g*-values and the *hfcc* of the protons and ^{33}S. The assignment of the

hfcc due to protons and ^{33}S is based on the results of MINDO/3 calculation. Comparing the *hfcc* due to the central protons and the ^{33}S and the *g*-values of derivatives with those of the parent compounds, it is found that there is no substantial effect of substitution by tetramethyl, tetrakis(methoxycarbonyl), and dibenzo groups on the spin distribution. This is because the spin densities on the carbon atoms attached by substituent groups are relatively small. It is also noticeable that both the *g*-values and ^{33}S *hfcc* decrease in the order of **1**, **2**, and **3**. The same trend holds for the *hfcc* of the side protons and the central protons in **2** and **3**.

The ESR Spectra of $4^{+\cdot}$ *and* $5^{+\cdot}$. **4**(Me)$^{+\cdot}$ and **5**(Me)$^{+\cdot}$ are stable when they are generated by one-electron reduction at the temperature below −40 °C. The ESR spectrum of **4**(Me)$^{+\cdot}$ shown in Fig. 5a indicates a clear splitting of 0.69 G due to the twelve methyl protons, while in the spectrum of **5**(Me)$^{+\cdot}$ shown in Fig. 5b only a sign of about 0.5 G splitting due to the methyl protons is observed. The satellite ^{33}S splittings of **4**(Me)$^{+\cdot}$ and **5**(ph)$^{+\cdot}$ were observed but that of **5**(Me)$^{+\cdot}$ was not observed because of low intensity of the ESR signal. The four sulfur atoms are all equivalent in **4** and **5**.

Comparing the *hfcc* due to the methyl protons of **4**(Me)$^{+\cdot}$ and **5**(Me)$^{+\cdot}$ and the *hfcc* due to ^{33}S of **4**(Me)$^{+\cdot}$ and **5**(Ph)$^{+\cdot}$ with those of **1**(Me)$^{+\cdot}$, it is seen that the *hfcc* also decrease in the order of **1**, **4**, and **5**, as observed in the series of **2** and **3**. On the other hand, the *g*-value does not follow the same order. This point will be discussed later in detail.

Comparison with MO Calculation. We calculated the spin density distributions of these compounds using the MINDO/3 method which is capable of handling sulfur atoms.[7] The atomic coordinates of **1** were taken from the crystallographic data of **1**(H)[8] and those of the other compounds **2** to **5** were obtained based on the structure of **1** by using the bond lengths and bond angles adopted widely. For the methyl derivatives we carried out the calculation by fixing configurations of the methyl groups.

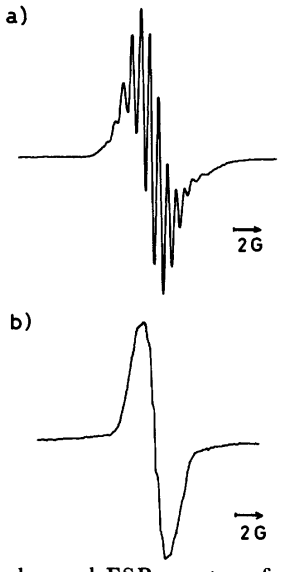

Fig. 5. The observed ESR spectra of **4**(Me)$^{+\cdot}$ (a) and **5**(Me)$^{+\cdot}$ (b).

The *hfcc* of the protons and ^{33}S obtained by the ESR study are compared with those estimated from the spin densities calculated by MINDO/3 method by using the following equations;

$$a(\mathrm{H}) = -24.0 \cdot \rho(C) \quad \text{for aromatic protons,} \tag{1}$$

$$a(\mathrm{Me}) = 507 \cdot \rho(H) \quad \text{for methyl protons,} \tag{2}$$

$$a(^{33}\mathrm{S}) = 33.0 \cdot \rho(S) \quad \text{for } ^{33}S, \tag{3}$$

here $\rho(C)$ is the $2p\pi$ spin densities on the carbon atoms attached by the aromatic protons. For methyl protons a(Me) are obtained from the averaged spin densities on the 1*s* orbitals of three methyl protons $\rho(H)$ by Eq. (2). The ^{33}S *hfcc* is estimated from the spin densities of $3p\pi$ of sulfur atoms $\rho(S)$ by using Eq. (3) proposed previousely.[9]

The calculated *hfcc* are also listed in Table 1. The correlation between the observed and calculated *hfcc* is shown in Fig. 6. From this figure it is seen that the agreement between the observed and calculated *hfcc* is satisfactory. We also note that there is a fair linear relationship between the calculated energy of the HOMO and the $E_{1/2}^{\circ}$ measured by the cyclic voltammetry as shown in Fig. 7. Based on these results it is concluded that the HOMO calculated by the MINDO/3 method represents the actual orbital quite well.

The trend that the *hfcc* of ^{33}S and protons decrease in the order of **1**, **2**, and **3** is reproduced by this calculation. This trend is seen clearly from Fig. 8, which indicates the HOMO schematically. It is also seen from this picture that the spin is localized on the four sulfur atoms and central conjugated carbon chains. In the compounds with cumulene chains the situation is similar (Fig. 8), though the spin densities on the cumulene chains are slightly different from those on the normal conjugated chains.

The Structure of **3**. There are two possibilities for the structure of **3**, namely, *trans* and *cis* conformers. According to the chromatographic study, there is only one species for **3**. We tried to determine the structure of **3** by comparing the NMR and UV spectra of **3** with those of **6** and **7**, which are regarded as the rigid model compounds for the *trans* and *cis* forms of **3**, respectively. However, this attempt was in failure because there were no significant differences in the spectra between **6** and **7**. Then we compared the ESR parameters. It is also interesting to examine whether the spin density distribution changes by conformational change of *cis* and *trans* form, since the spin distribution in stilbene is known to depend on the conformation.[10]

The *hfcc* of both the central and side protons listed in Table 2 are almost the same for *trans* **6**(H)$^{+\cdot}$ and *cis* **7**(H)$^{+\cdot}$ (the difference between the two groups of the side protons was not seen in spectra). However the *g*-value of **6**(H)$^{+\cdot}$ is larger than that of **7**(H)$^{+\cdot}$ by 0.0004, which agree with the difference between **6**-(MC)$^{+\cdot}$ and **7**(MC)$^{+\cdot}$. The *g*-value of **3**(H)$^{+\cdot}$ is very close to that of **6**(H)$^{+\cdot}$. Therefore, **3**(H)$^{+\cdot}$ is likely to be the *trans* form.

The Relationship Between The g-values and The ^{33}S

hfcc. As was described before, both the *g*-value and ^{33}S *hfcc* of the compounds **1**, **2**, and **3** decrease in the order of **1**, **2**, and **3**. Figure 9 shows the plots of the *g*-value *vs.* ^{33}S *hfcc* for all the compounds containing only C, H, and S atoms for which the ^{33}S splittings was observed in this study. The solid straight line obtained by a least square fit to the experimental points of five compounds is expressed by

$$g = 2.00379 + 0.00108 \cdot a(^{33}S) \quad (4)$$

The above relationship indicates that there is a linear

relation between the *g*-values and the π spin densities on the sulfur atoms. This means that the variation of the spin density on the sulfur atoms is the main cause of the *g* shift. In the following, we discuss this correlation by using the Stone's theory.[11]

One of the principal components of the *g* tensor can be derived by using the second order perturbation theory as

$$g^{\alpha\alpha} = g_e - 2\Sigma_n \frac{\langle \Psi_0 | \Sigma_\mu \zeta_\mu l_{\alpha\mu} | \Psi_n \rangle \langle \Psi_n | \Sigma_\nu l_{\alpha\nu} | \Psi_0 \rangle}{E_n - E_0}, \quad (5)$$

where the notations in Eq. 5 have usual meanings.[12] Stone[11] has shown that the deviation of *g*-value from the free electron *g*-value $\Delta g = g - g_e$ for the radicals of

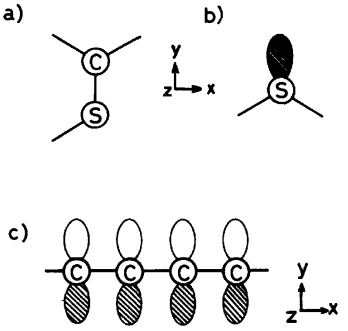

Fig. 10. The local axes for a) C-S bond, b) non-bonding orbital on sulfur atom, and c) cumulene or acetylene carbon chain. π orbital is along to z axis.

conjugated aromatic hydrocarbons can be expressed by the sum of the contributions from the σ-orbitals localized on C-C and C-H fragments. We formulate the contributions to Δg from the C-S fragment and nonbonding orbital on the sulfur atom in a similar way.

We first consider the contribution from the C-S bond. If the local axes are chosen as shown in Fig. 10a, bonding and antibonding orbitals of the C-S bond, $\psi(\sigma)$ and $\psi(\sigma^*)$, with the energy of E_σ and E_{σ^*}, respectively, can be written by linear combinations of two sp^2 orbitals belonging to the C and S atoms as

$$\psi(\sigma) = c_1\{\sqrt{1/3}\, S(\mathrm{C}) - \sqrt{2/3}\, P_y(\mathrm{C})\} + c_2\{\sqrt{1/3}\, S(\mathrm{S}) + \sqrt{2/3}\, P_y(\mathrm{S})\} \quad (6)$$

$$\psi(\sigma^*) = c_2\{\sqrt{1/3}\, S(\mathrm{C}) - \sqrt{2/3}\, P_y(\mathrm{C})\} - c_1\{\sqrt{1/3}\, S(\mathrm{S}) + \sqrt{2/3}\, P_y(\mathrm{S})\}. \quad (7)$$

Here, c_1 and c_2 are the normalization constants. On the other hand, the π orbital $\psi(\pi)$ (HOMO) with the energy E_π on the C-S fragment is expressd by

$$\psi(\pi) = c_C P_z(C) + c_S P_z(S), \quad (8)$$

where c_C and c_S are the coefficients of the singly occupied π orbital normalized over all atoms in the molecule. By substituting Eqs. (6), (7), and (8) to Eq. (5), we obtain

$$\Delta g^{xx} = \frac{4}{3}\frac{(c_1c_C - c_2c_S)(c_1\zeta_C c_C - c_2\zeta_S c_S)}{E_\pi - E_\sigma} + \frac{4}{3}\frac{(c_2c_C + c_1c_S)(c_2\zeta_C c_C + c_1\zeta_S c_S)}{E_\pi - E_{\sigma^*}}. \quad (9)$$

In order to simplify Eq. (9), we assume that $c_1 = c_2 = 1/\sqrt{2}$ and that the spin-orbit coupling constant of carbon atom ($\zeta_C = 29\ \mathrm{cm}^{-1}$) can be neglected compared with that of sulfur atom ($\zeta_S = 382\ \mathrm{cm}^{-1}$). Taking into account that c_C is the same order of magnitude as c_S and has an opposite sign to c_S in HOMO as seen in Fig. 8, we obtain the following simple relation between Δg^{xx} and c_S^2;

$$\Delta g^{xx} = \frac{4}{3}\frac{c_S^2\zeta_S}{E_\pi - E_\sigma} \quad (10)$$

Next, we treat the contribution from the non-bonding orbital on the S atom (Fig. 10b) in a similar way.

The non-bonding orbital on S atom, $\psi(n)$, with the energy of E_n is given by one of the three sp^2 orbitals;

$$\psi(n) = \sqrt{1/3}\,S(S) + \sqrt{2/3}\,P_y(S), \quad (11)$$

and we obtain the contribution for Δg^{xx} as well;

$$\Delta g^{xx} = \frac{4}{3}\frac{c_S^2\zeta_S}{E_\pi - E_n} \quad (12)$$

where, c_S^2 is the coefficient of $P_z(S)$ π orbital. The Δg due to the S atom is given after averaged for the three principal values as,

$$\Delta g = \frac{4}{9}\zeta_S\left(\frac{n_{C-S}}{E_\pi - E_\sigma} + \frac{n_S}{E_\pi - E_n}\right)c_S^2, \quad (13)$$

where n_{C-S} and n_s represent the number of C-S bond and the number of non-bonding orbital, respectively.

Consequently, the g-value is expected to correlate with the spin density on the sulfur atom by Eq. (13). Here, the coefficient of c_S^2 corresponds to the slope of the straight line of Eg. (4). We can roughly estimate this coefficient to be 0.00136 by taking the energy differences to be 3 eV and 10 eV for $(E_\pi - E_n)$ and $(E_\pi - E_\sigma)$, respectively, and by converting the c_S^2 to $a(^{33}S)$ by Eg. (3). This value is in reasonable agreement with the value of 0.00108 obtained experimentally. On the other hand, the intercept of the line at $a(^{33}S)=0$ corresponds to the total contribution from the residual C-C and C-H fragments. The obtained intercept 2.00379 is close to the g-values of the radicals of aromatic hydrocarbons. Therefore, it is concluded that the main cause of the g shift in our case is attributed to the variation of the spin densities on the sulfur atom.

To examine the validity of our formulation further we plot the data for the cation radical of dithin (**8**) (g=2.0089; $a(^{33}S)$=9.84 G),[13] which has a very different π system from that of TTF. When we take account of the fact that there are only two sulfur atom in **8** instead of four in TTF, the correlation between g and $a(^{33}S)$ agrees with that predicted by the line in Fig. 9. This indicates that Eq. (13) is also applicable to other compounds with similar sigma structure.

The Anomaly in g*-Value of* $4^{+\cdot}$ *and* $5^{+\cdot}$. The plots of g-value *vs.* ^{33}S *hfcc* for $4(Me)^{+\cdot}$ and $5(ph)^{+\cdot}$ shown in Fig. 9 deviate from the correlation line; the g-value of $4(Me)^{+\cdot}$ is larger than the line by 0.0004 and that of $5(ph)^{+\cdot}$ is smaller by 0.0027. A similar decrease of the g-value was reported by Goldberg and Bard[14] in the case of the anion radical of 1,4-diphenyl-1,3-butadiyne (**9**); g=2.00216 is smaller than that of 1,4-diphenyl-1,3-butadiene anion radical by 0.00054 and smaller than g_e. They suggested that the cause of this decrease can be attributed to the decrease of the energy difference between the π_z-orbital and the lowest unoccupied π_y-orbital, the latter being localized on the central acetylene carbons and perpendicular to the π_z-orbital shown in Fig. 10c. The anomalous g shift in our case may also be explained in a similar way.

The contribution of the acetylene or cumulene carbon chain to the g shift can be calculated by Eq. (5) as follows. The π_y-orbitals are expressed by the linear combination of P_y orbitals;

$$\phi^{(n)}(\pi_y) = \sum_i b_i^{(n)} P_{yi}(C), \quad (14)$$

and the π_z-orbital (HOMO) is also expressed by

$$\phi(\pi_z) = \sum_i c_i P_{zi}(C) \quad (15)$$

Substituting Egs. (14) and (15) to Eg. (5), we obtain

$$\Delta g = \frac{2}{3}\zeta_C \sum_n \frac{\{\sum_i c_i b_i^{(n)}\}^2}{E_{\pi z} - E_{\pi y}^{(n)}}. \quad (16)$$

Small energy denominators in Eq. (16) lead to a large Δg.

Therefore, the anomaly in g-value of $4^{+\cdot}$ and $5^{+\cdot}$ are likely due to the closeness of π_y and π_z orbitals. We estimate the energy differences by using Eq. (16). If the Hückel orbitals of butadiene with β=2.5 eV are used for the energies and the coefficients $b_i^{(n)}$ of π_y-orbitals, the energy differences between the π_z-orbital and the lowest unoccupied π_y-orbital are estimated to be 0.026 eV and 0.26 eV for $5(ph)^{+\cdot}$ and $9^{-\cdot}$, respectively.

On the other hand, when the energy of the π_z-orbital is very close to the energy of the doubly occupied orbital of π_y-orbital, the g-value becomes large. The slightly large g-value of $4(Me)^{+\cdot}$ is considered to be due to this effect. The energy difference in $4(Me)^{+\cdot}$ is estimated to be 0.30 eV by a similar argument.

Investigation on the electronic conductivities of the organic metals containing radical cations of the present compounds are in progress.

Kinetic Studies of Fast Equilibrium by Means of High-performance Liquid Chromatography. VI. Separation of Rotamers of Formanilide

Masataka MORIYASU,* Kazuko KAWANISHI, Atsushi KATO, and Yohei HASHIMOTO
Kobe Women's College of Pharmacy, Motoyamakita-machi, Higashinada-ku, Kobe 658
(Received December 26, 1983)

The restricted rotation about the carbon-nitrogen bond of formanilide has been investigated by high-performance liquid chromatography. At lower temperatures, two peaks corresponding to two dynamic rotamers (*E*- and *Z*-form) have appeared on chromatograms, whereas at higher temperatures they have not been separated and a single peak has appeared on chromatograms, due to rapid bond rotation. The equilibrium concentration ratio of *E*- to *Z*-form has been found to vary in different solvents, suggesting the presence of solute-solvent and solute-solute interactions such as hydrogen bond formation. Determination of kinetic characteristics such as rate constant and activation energy of fast reactions has been established by high-performance liquid chromatography. The authors have named the present method "dynamic high-performance liquid chromatography," in imitation of "dynamic nuclear magnetic resonance spectroscopy" which traces fast equilibrium.

In this research series[1-5] a method has been devised to investigate fast equilibrium by means of high-performance liquid chromatography(HPLC). In part IV of this series,[4] the restricted rotation about carbon-nitrogen bonds of unsymmetrical palladium(II) dithiocarbamate chelates was examined. The carbon-nitrogen bonds of these compounds have the double-bond character shown in the following cannonical forms, and these compounds gave two peaks in

HPLC chromatograms at lower temperatures due to the separation of two labile rotamers. On the other hand, at higher temperatures rotamers were not separated and only one peak appeared.

There exist numerous substances which have a partially double-bond character on carbon-nitrogen bonds. Amides fall under this category. The present report deals with a kinetic study of intramolecular bond rotation of formanilide.

Experimental

Reagents. Formanilide was purchased commercially and was recrystallized from hexane-diethyl ether. Acetanilide was also obtained commercially and was used without further purification.

Apparatus. The HPLC apparatus described in our previous report[4] was modified as depicted in Figs. 1 and 2. Bathcooler (Model Cryocool CC-80f, Neslab Instrument Inc.), thermoregulator, heater, stirrer and HPLC column were plunged into the bath filled with methanol. The temperature of the bath was controlled from 25 to −60 °C. HPLC was possible up to −60 °C with a gradual decrease of column efficiency. Satisfactory separation of two rotamers was attained when temperature was below −30 °C. Two injectors (both Model 7125, Rheodyne), a six-way valve (Model 7010, Rheodyne), and a three-way valve (Model 7010, Rheodyne) were fixed on the plastic board which was placed on the upper part of the bath. Thus, most of the flow paths in stainless steel tubes were immersed in the cooled bath.

In order to obtain kinetically unstable species and to observe its change into other species, the following procedures were carried out. The equilibrated solution of two isomers (X⇌Y) was supplied to HPLC from injector I, and the portion corresponding to the retention time of X (or Y) was collected into the reservoir, which was controlled at various temperatures(−30—0 °C) by a freezing mixture composed of methanol-water. The collected portion was stirred and then kept standing for a few minutes. After the flow paths were changed by the six-way valve, the solution in the reservoir was sucked in from injector II. The injection was repeated for a definite interval. With the lapse of time, the peak of Y (or X) grew, while that of X (or Y) fell. Thus, the progress of the reaction X→Y (or Y→X) at lower temperatures was traced by HPLC.

Nuclear magnetic resonance (NMR) spectra were measured on a Varian Model XL-200 instrument, using tetramethylsilane as an internal reference.

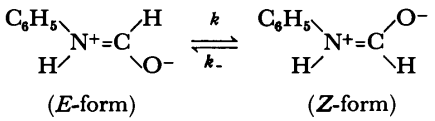
Results and Discussion

HPLC of Formanilide at Lower Temperatures. The theoretical treatment for analyzing a fast unimolecular reaction by HPLC was detailed in our previous report.[4]

Figure 3 shows chromatograms of the mixture of formanilide and acetanilide on silica gel packings at various temperatures. A slight broad peak of formanilide at room temperature splits into two sharp peaks at −30 °C *via* complicated chromatograms at intermediate temperatures. Contrary to this, acetanilide gives only one peak at all temperatures. This phenomenon is explained as follows. It has been established from NMR study that amide compouds can exist as the equilibrated mixture of two dynamic rotamers.[6] Thus, the NMR study[7] has demonstrated that formanilide exists as the mixture of two rotamers (*E*- and *Z*-form), while acetanilide exists exclusively as the *Z*-form.



(1)

Since the carbon-nitrogen bond has a strong double-bond character, the intramolecular bond rotation around this carbon-nitrogen bond is seriously restricted. Figure 3 suggests that this bond rotation does not occur during chromatography at lower temperatures and then two rotamers are separated. On the other hand, at higher temperatures, since partial or complete bond rotation occurs during chromatography, two rotamers are not separated.

Equilibrium Ratio of Two Rotamers. Since the bond rotation practically does not occur during chromatography when HPLC is operated under −30 °C, it follows that chromatograms obtained at this temperature directly indicate the equilibrium concentrations of two isomers prior to HPLC. Thus, when samples of formanilide dissolved in different conditions, such as concentration, solvent and temperature, are submitted to HPLC, chromatogram patterns will vary due to the differences of the equilibrium ratios of the two isomers.

Formanilide was dissolved in 22 different solvents and these solutions were submitted to HPLC at −30 °C. Figure 4 exemplifies chromatograms of 0.5% formanilide solutions in different solvents. Here the temperatures of the sample solutions were controlled to be 25 °C. The ratio of two peak heights was found to vary markedly. Now, since it was elucidated that the equilibrium ratio of two isomers really varied in different solvents, an attempt was made to determine the equilibrium ratio of two isomers in different conditions; the procedure was carried out as follows, similar to that described in our previous report.[4] The equilibrated sample solution was submitted to HPLC and the portions corresponding to the former and the latter peaks were collected. The solution was then diluted to a definite volume by HPLC solvent. Each solution reached equilibrium promptly at room temperature according to Eq. 1. Thus, when the aliquot of these solutions was submitted to HPLC once more, two equilibrated peaks appeared on chromatograms again. Thus, from the measurements of two peak heights (or areas), the ratio of two isomers was determined. It should be noted here that direct measurements of two peak areas in Fig. 4 do not give the ratio of two isomers due to the difference in their absorption coefficients.

In order to identify the peaks which appeared on chromatograms, we compared present HPLC results with NMR results reported by other authors.[7] It was demonstrated in Ref. 7 that in chloroform the ratio of *Z*-form of formanilide increased with increase of form-

anilide concentration. Formanilide was dissolved in chloroform at various concentrations to be submitted to HPLC. The ratio of the two peak areas was found to vary according to the concentration of formanilide, and the ratio of the latter peak was large when concentration of formanilide was high. The latter peak was thus identified as *Z*-form by NMR study, as shown in Table 1.

Now that the method to determine the ratio of two isomers was established and the problem of peak identification was resolved, equilibrium ratios of two isomers in 22 different solvents were determined; the results are summarized in Table 2. Interesting is the fact that when formanilide is dissolved in polar solvents such as methanol and water, the percentage of *Z*-form is high, while in nonpolar solvents such as chloroform and carbon tetrachloride, *E*-form is the predominant species. The latter phenomenon will be interpreted in terms of solute-solute hydrogen bond formation; *E*-form of formanilide exists as a ring dimer in chloroform or carbon tetrachloride.[7-10] This effect seems to result in a more stable structure of *E*-form in these solvents. In the former, polar solvents such as methanol and water will interact with formanilide strongly by solute-solvent hydrogen bond formation. When *Z*-form of formanilide enters into the tetrahedral lattice in solvent water, this species will be stabilized by hydrogen bond formation, as shown in the following

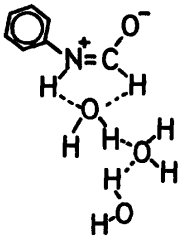

chart. A similar discussion will hold for several other polar solvents, such as methanol and ethanol.

Rate of Interconversion and Energy Barrier for Bond Rotation. The rate constant k in Eq. 1 was determined by HPLC with similar procedures as described in our previous report.[4] The equilibrated solution of formanilide was supplied to HPLC through injector I, and the portion corresponding to the former peak (*E*-form) was collected into a reservoir thermostated at low temperatures. The collected portion was stirred and then left standing for a few minutes. After changing the flow path by the six-way valve, the solution in the reservoir was sucked into the column from injector II repeatedly at a definite intervals. With the lapse of time, the peak of *Z*-form appeared and grew gradually, while the peak of *E*-form fell. The rate constant k was calculated according to the following equation assuming a unimolecular process:[4]

$$k = \{y_e/x_0(t'+\Delta t)\}\ln\{y_e/(y_e-y'-\Delta y)\}, \quad (2)$$

where x_o, y_e and $y'+\Delta y$ were the initial concentration of *E*-form, the equilibrium concentration of *Z*-form and the concentration of *Z*-form at a definite time, $t'+\Delta t$, respectively. Thus, from the growth of peak height of *Z*-form, k was calculated. The value at −27.6 °C was determined to be $(1.27\pm0.05)\times10^{-3}$ s^{-1}.

In order to determine the energy barrier(E_a) for the

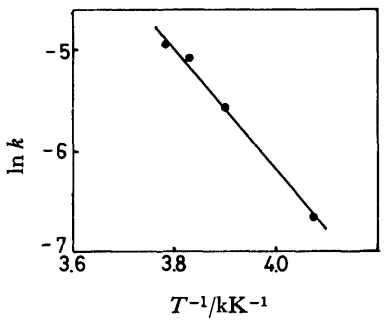

Fig. 5. Activation energy of the carbon–nitrogen bond rotation. Chromatographic conditions were similar to those shown in Fig. 4. The values of k were determined at various temperatuers according to Eq. 3. The value E_a was determined from the follwoing equation: $k=A_0\exp(-E_a/RT)$

carbon-nitrogen bond rotation, k was measured at different temperatures. Thus, from Arrhenius' plot shown in Fig. 5, E_a was determined to be (54.2±5.0) kJ mol^{-1}. From this plot the rate constant k at room temperature was estimated to be 9.5×10^{-2} s^{-1} (at 25 °C). Thus, it follows that the bond rotation occurs several times in a minute at room temperature.

Comparison of HPLC and NMR Results. The ^{1}H NMR spectra of formanilide were measured in deuterated dimethyl sulfoxide at various temperatures. A part of the spectra concerning the C-H protons near 8.3 and 8.8 ppm, assigned as *Z*- and *E*-form, respectively, is depicted in Fig. 6. The lower field band of *E*-form gave triplet-like signals at room temperature, which were analyzed as a mixture of doublet and singlet signals; the former was coupled with N-H proton (J=11.2 Hz) and the latter was not because of being replaced by deuteron in the solvent. When the temperature was increased to 60 °C, the "triplet" signals coalesced into a broad signal. A similar discussion will hold for the *Z*-form signal of C-H (8.3 ppm), though due to small spin-spin coupling constant, this band gave a singlet peak with deuteron exchanged partially. The spectral pattern from 60 to 150 °C shown in Fig. 6 resembles that of HPLC chromatograms depicted in Fig. 3, though the temperature range differs. This can reasonably be interpreted as follows. NMR has been well known to be a powerful tool for investigating fast equilibrium in solution, because two conformers which undergo interconversion promptly can be detected as different two species. Thus, two isomers of formanilide can be distinguished by NMR at room temperature. With increasing temperature, since the rate of interconversion increases rapidly, the two signals will commence to coalesce. A similar phenomenon should also occur in HPLC. Since a kinetically unstable species whose lifetime is a few seconds cannot be distinguished by HPLC, only one peak appears on chromatograms at room temperature. With decreasing temperature, lifetimes of two rotamers are prolonged and consequently two peaks corresponding to each rotamer appear on chromatograms. Thus, both Figs. 3 and 6 reflect identical phenomenon, *i.e.*, carbon-nitrogen bond rotation.

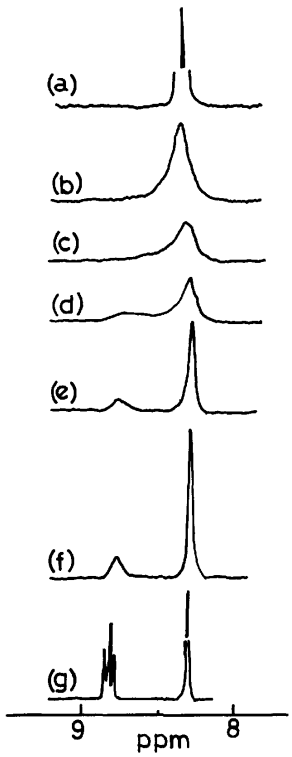

Fig. 6. The ^{1}H NMR spectra of formanilide in dimethylsulfoxide at different temperatures.
(a) 150 °C, (b) 100 °C, (c) 90 °C, (d) 80 °C, (e) 70 °C, (f) 60 °C, (g) 24 °C

The method has been well established for examining fast equilibrium of two dynamic isomers by means of NMR, which has been called dynamic nuclear magnetic resonance spectroscopy (DNMR). The energy barrier of carbon-nitrogen bond rotation has been well examined on various amides by DNMR. This method is based on the measurements of signal width at different temperatures, which is broadened due to fast interconversion of two conformers. Thus, from the signal shape analysis, the energy barrier has been determined to be from 13 to 30 kcal mol^{-1} (1 kcal mol^{-1}=4.18 kJ mol^{-1}) for various amides, mainly for *N*,*N*-disubstituted amides.[6] Determination of the energy barrier for *N*-monosubstitutued amides by ^{1}H NMR is difficult because intermolecular hydrogen bond formation complicates signal shape. Two isomers of *o*-methylformanilide were separated with careful treatment[11] and their ^{1}H NMR spectra were measured at low temperatures;[12] the E_a and k for this amide were 15.7 kcal mol^{-1} and $(2.7—4.4)\times10^{-3}$ s^{-1}, respectively, at −40 °C. Since two isomers of nonsubstitutued formanilide would rotate rapidly, while the *o*-methyl-substitutued one would not due to steric hindrance, the present value of E_a (54.2 kJ mol^{-1}=13.0 kcal mol^{-1}) of the former seems to be a reasonable one. DNMR study of ^{13}C NMR of formanilide demonstrated[13] that E_a was about 20 kcal mol^{-1} at high temperatures under the assumption that the effect of hydrogen-bond formation on signal shape was negligible in ^{13}C NMR study. The discrepancy between the ^{13}C NMR and present HPLC results might be interpreted at least partially in terms of the temperature difference of the measurements.

Conclusions

In this rsearch series, it has been demonstrated that rather fast equilibria can be traced by means of HPLC based on conventional principles. For this purpose, DNMR method has been used exclusively. The present HPLC method is comparable with the DNMR method. Since the time scale of detection for HPLC differs from that for NMR, kinetic data obtainable by DNMR method are not always obtained by HPLC method. The authors, however, consider that the HPLC method have some advantages over the DNMR method. First, undesirable effects such as hydrogen-bond formation, which tends to broaden the signal shape in NMR, can be neglected in HPLC. Second, in HPLC method, kinetically unstable species can be obtained, so determination of physicochemical properties of labile species will be possible by combining HPLC

with other suitable apparatus. The authors propose here to call this HPLC method dynamic high-performance liquid chromatography, in imitation of DNMR which traces fast equilibria in solution.

This work was partially supported by a Grant-in-Aid for scientific research from the Ministry of Education, Science and Culture. The authors are grateful to Miss T. Sai, Kobe Women's College of Pharmacy, for NMR measurements.

Far Ultraviolet Electric Linear Dichroism. II. Pulsed Electric Dichroism Apparatus and Dichroic Spectra of Collagen in Aqueous Solution in the 230—187 nm Wavelength Region

Kiwamu YAMAOKA,* Manabu ASATO, Koichiro MATSUDA, and Kazuyoshi UEDA
Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received January 17, 1984)

A Pulsed electric linear dichroism (ELD) apparatus is described for studying the optical properties and solution conformation of biologically important macromolecules whose chromophores absorb light in the far ultraviolet region. This apparatus is capable of generating a rectangular-wave electric pulse field with a duration of 5 μs—5 ms and an amplitude of 0.2—8 kV over the 360—185 nm region. A special feature to this apparatus is its ability to record both parallel and perpendicular dichroism signals simultaneously and independently. To prove the instrumental performance, some dichroic spectra of calfskin collagen solution (pH 3.16 and concentration 0.03 g dm^{-3}) in 0.001 mol dm^{-3} H_3PO_4 were measured in the 230—187 nm region, where the peptide chromophore shows a broad absorption spectrum. The reduced dichroism of collagen was positive but not constant throughout the wavelength region. A detailed analysis revealed that the peptide spectrum contains three overlapping absorption bands centered at 219, 200, and 189 nm. These transition moments were found to be inclined at ±(50.6—51.0°) (219 nm), ±(48.8—49.5°) (200 nm), and ±(56.0—55.8°) (189 nm) relative to the orientation axis of a triple-stranded collagen helix.

When a homogeneous electric field is externally applied to a macromolecular solution, the solute molecules tend to orient toward the direction of the electric field. If these molecules contain chromophoric groups, they absorb linearly-polarized light selectively. The difference in absorbances $\Delta A(=A_{/\!/}^{E}-A_{\perp}^{E})$ between the light component polarized parallel ($A_{/\!/}^{E}$) and perpendicular ($A_{\perp}^{E}$) to the direction of the electric field is a negative or positive quantity, which is termed the electric linear dichroism (ELD).[1-3] By examining the wavelength dependence of reduced dichroism, $\Delta A/A$, inside an absorption band, where A is the isotropic absorbance in the absence of electric field, useful information may be extracted on the relative arrangement between a particular chromophore and the polymer backbone chain and on the overall polymer conformation in solution.

Although natural and synthetic polymers often contain characteristic chromophores in the ultraviolet and far ultraviolet regions, the dependence of $\Delta A/A$ on wavelength has been studied only in a few cases.[1-13] (Related subjects have been reviewed prior to 1973 in Refs. 1—5.) This is mostly because technical difficulties are involved in measuring the electric dichroism spectra; for instance, no commercial instruments are available as yet. The instrumentation of electric dichroism in the visible and near ultraviolet regions has been reported with particular emphasis on a fast and high-voltage square-wave pulse, a widely covered wavelength region, and a high spectral resolution.[6,14] With such a pulsed electric field, the transient dichroic signal of an ionic solution can be measured. This in turn makes it possible to determine the relaxation time and to estimate the overall macromolecular shape.

Such vital biopolymers as nucleic acids, polypeptides, proteins, and polysaccharides all have intrinsic chromophores in the far ultraviolet region. Hence, for the purpose of clarifying the optical properties and solution conformation of these biopolymers, we initiated a series of the far ultraviolet ELD studies. In this paper, we will briefly describe a new ELD apparatus, which can cover 360—185 nm and allow an independent and simultaneous detection of both parallel and perpendicular signals. This procedure is essential to detect any anomalous electrochromic effect,[15] although it has been often ignored. With this apparatus, we will demonstrate some important features associated with ELD spectra of collagen in an acid solution, together with an analytical procedure for observed data.

Apparatus and Data Analysis

Apparatus. A transient ELD apparatus consists of four major parts; the electric, optical, signal-detecting, and measuring-cell systems. The principles and design procedure for such an apparatus have been discussed elsewhere.[1,2,6,14] A new feature was added to the present far ultraviolet ELD apparatus, in such a way that both parallel and perpendcular signals can be recorded by applying a single high-voltage pulse to a sample cell. Figure 1 shows the block diagram of this apparatus. The electric system is unchanged from that previously described in detail.[14] It consists of a pulse generator, a homemade pulse amplifier, a 10 kV DC high-voltage power supply, and a homemade high-voltage pulse discharge network. The single square-wave pulse applied to a measuring "Kerr" cell was attenuated with a Tektronix 1000:1 P6013A probe and fed to a 7A18 plug-in amplifier of a Sony-Tektronix 7844 dual beam oscilloscope. The rise and decay times of a high voltage pulse were confirmed to be less than 1 μs under optimum conditions.[14]

Figure 2 shows the optical system schematically; this was newly designed and constructed for the present purpose. The light source is a water-cooled 200 watt deuterium discharge arc lamp D_2 (D-200F, Original Hanau, West Germany) operated on a 100 volt DC power in the 400—185 nm region. This lamp is about four times as intense as the conventional 40—30 watt deuterium lamp. The monochromatic light from a 25 cm grating double monochromator with low stray light and high wavelength accuracy (0.1 nm) (Japan

Spectroscopic Co. Model CT-25ND) is collimated by the first double-convex lens L_1 to the center of a "Kerr" cell K. The diverging beam is again converged onto the front of photomultipliers $P_{m,//}$ and $P_{m,\perp}$ by the second double-convex lens L_2. These lenses are made of strain-free far ultraviolet transmitting quartz (Extrasil grade), the focal length and the diameter being 55 mm and 33 mm respectively. A screen with a 4×10 mm rectangular aperture is placed behind L_1 and another with a 2×8 mm aperture is in front of L_2. A Rochon-type

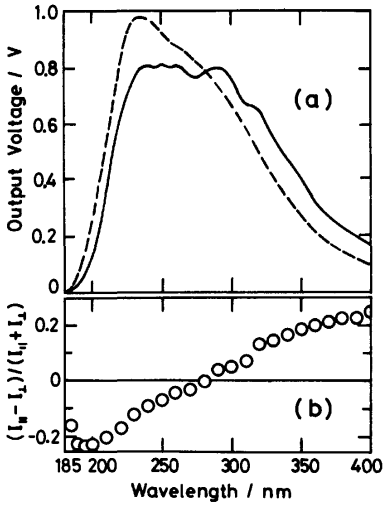

Fig. 3. The overall spectral intensity distribution of deuterium lamp in the ELD apparatus (a) and the wavelength dependence of the degree of polarization p (b). In (a), the light intensities, $I_{//}$ (——) and $I_\perp$ (----), were detected as the photomultiplier output voltage. In (b), $p=(I_{//}-I_\perp)/(I_{//}+I_\perp)$, where $I_{//}$ and $I_\perp$ are the intensities of light polarized parallel and perpendicular to the direction of electric field in the absence of a "Kerr" cell assembly.

magnesium fluoride beam-splitting polarizer Pol (MFR-9, Karl Lambrecht, Inc., Chicago, USA) is inserted. This prism is set in such a way that the emerging light is separated into two components; one, polarized parallel to the pulsed electric field, traveling straight and the other, polarized perpendicular to the field, traveling obliquely at an angle of 4.5° at 200 nm. Thus, both parallel- and perpendicularly-polarized emerging light beams can be detected *independently* and *simultaneously* without rotating the prism. Each of these beams is further separated and converged by placing a rectangular concave mirror M_p (11×42 mm) with a focal length of 60 mm, which reflects light from the front surface coated with aluminum and protected with magnesium fluoride.

The signal-detecting system consists of two matched side-on type R106UH photomultipliers (Hamamatsu TV Co.), each detecting the linearly polarized beam. The voltage generated by each P_m tube is led to either of the separate channels of the dual beam oscilloscope. Two signals and an attenuated pulse are all displayed simultaneously on a cathode-ray tube (CRT) and photographed with a Tektronix C-53 oscilloscope camera. Figure 3a shows the spectral characteristics of the photomultiplier output voltage with a 200 watt deuterium lamp in the 400—185 nm region. In the present optical system, the transmitted light intensity is both wavelength- and polarization-dependent. Figure 3b shows the degree of polarization for the overall optical system. In practice, however, these features do not interfere with the signal measurement at discrete wavelengths, since the instrument is operated manually.

A cylindrical high-voltage-resistant "Kerr" cell was made of either Kel-F or Acrylite plastics for the far ultraviolet region. The design of the cell is essentially

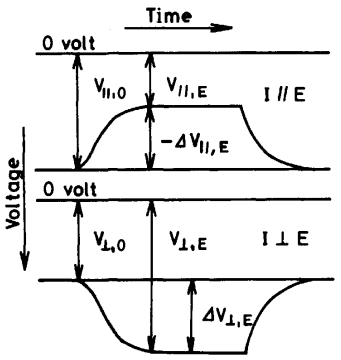

Fig. 4. Parallel- and perpendicular-polarized dichroism signals for data analysis. Notations are given in Eqs. 1–3 in text.

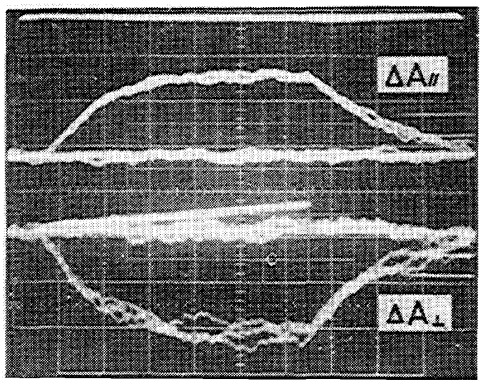

Fig. 5. Simultaneous display of transient dichroism signals for a collagen solution. Wavelength, 200 nm; field strength, 12.8 kV/cm; sweep timp, 100 μs/division.

the same as the one described previously;[6,14] the gap between two highly polished electrode plates (stainless steel) is 0.327 cm and the optical path length is 0.60 cm. The volume of a sample solution is 0.2—0.3 ml. The Kerr cell is set inside the blackened brass block, through which a temperature-controlled fluid circulates with an accuracy of ±0.05 °C. The temperature of a sample is recorded with a small thermistor probe which is in direct contact wih the solution.

Data Analysis. Figure 4 schematically shows the dichroic signals displayed on a CRT screen. Let $I_{//,E}$ and $I_{//,0}$ be the parallel-polarized light intensities transmitting through the solution and the polarizer and falling onto a detecting tube in the presence and the absence of an external electric field. The difference in absorbances $\Delta A_{//}(=A^E_{//}-A)$ is given as[13,14]

$$\Delta A_{//} = \Delta\varepsilon_{//}Cl = (\varepsilon^E_{//}-\varepsilon)Cl = -\log\left(1+\frac{\Delta I_{//,E}}{I_{//,0}}\right) = -\log\left(1+\frac{\Delta V_{//,E}}{V_{//,0}}\right), \quad (1)$$

where C is the molar concentration of solute, l is the path length in cm, $\varepsilon^E_{//}$ and ε are the molar absorption coefficients of the solute, and $V_{//,E}$ and $V_{//,0}$ are the voltages generated across a load resistor in the presence and the absence of the external field. $\Delta V_{//,E}(=V_{//,E}-V_{//,0})$ should be determined within the range, in which the light intensity is linearly proportional to the voltage generated.[14] Similarly, for the perpendicularly-polarized light,

$$\Delta A_{\perp} = \Delta\varepsilon_{\perp}Cl = (\varepsilon^E_{\perp}-\varepsilon)Cl = -\log\left(1+\frac{\Delta I_{\perp,E}}{I_{\perp,0}}\right) = -\log\left(1+\frac{\Delta V_{\perp,E}}{V_{\perp,0}}\right). \quad (2)$$

The reduced dichroism is given from Eqs. 1 and 2 as

$$\frac{\Delta A}{A} = \frac{A^E_{//}-A^E_{\perp}}{A} = \frac{1}{A}\log\left(\frac{1+\dfrac{\Delta V_{\perp,E}}{V_{\perp,0}}}{1+\dfrac{\Delta V_{//,E}}{V_{//,0}}}\right). \quad (3)$$

If the applied electric pulse field orients solute molecules, but does not deform the molecular shape, then the following relation should hold:[15]

$$\frac{\Delta A_{//}}{A} = -\frac{2\Delta A_{\perp}}{A} \quad \text{and} \quad 3A = A^E_{//} + 2A^E_{\perp}. \quad (4)$$

Experimental

Materials and Measurements. Collagen (type III, acid soluble from calfskin) was purchased from Sigma Co. The sample was kindly purified by Dr. K. Gekko of Nagoya University by dissolving it in 0.5 M (1 M=1 mol dm^{-3}) acetic acid and centrifuging at 4 °C to remove precipitates. After repeating this procedure, the supernatant was dialyzed against distilled water and then freeze-dried. The collagen solution was prepared by dissolving the dried sample in 1 mM H_3PO_4 aqueous solution (pH=3.16), the concentration being 0.28 mM (=0.03 g dm^{-3}).[16,17] The isotropic spectrum was measured on a Hitachi EPS-3T spectrophotometer with a pair of 0.5 cm quartz cells. The electric dichroism was measured on the present apparatus with two Kerr cells; one (l=2.00 cm with a gap of 0.330 cm[14]) the 230—208 nm region and the other (l=0.60 cm with a gap of 0.327 cm) in the 206.5—187 nm region. The slit widths were adjusted manually, so that the half-intensity width was less than 2 nm at 200 nm. All measurements were performed at 20 °C under nitrogen gas purge (3 L/min).

Figure 5 shows an oscillogram of a collagen solution. Both $\Delta A_{//}$ and $\Delta A_{\perp}$ were traced three times to illustrate the reproducibility.

Results and Discussion

Dependence of Electric Dichroism on Field Strength. Figure 6 shows the dependence of the observed dichroism of collagen on the applied electric field at 200 nm. Parallel and perpendicular specific dichroic signals ($\Delta A_{//}/A$ and $\Delta A_{\perp}/A$) are plotted against the square of the field strength, E^2, together with the reduced dichroism ($\Delta A/A$) which was calculated with the aid of Eq. 3. The first relation in Eq. 4 holds up to 19 kV/cm, which indicates that no anomalous effect is induced by the applied field. The $\Delta A/A$ values tend to saturate at high fields. By extrapolating these values to infinitely high field, the saturated value, $(\Delta A/A)_s$, was estimated with due consideration for curvature.[18,19] This procedure is shown in Fig. 7, where $\Delta A/A$ values at 200 nm were plotted against E^{-1} and E^{-2} and the intercepts were determined to be 0.333 and 0.291 by linear least-square fitting. These values correspond to the upper and lower limits for the true value of $(\Delta A/A)_s$; the value of 0.333

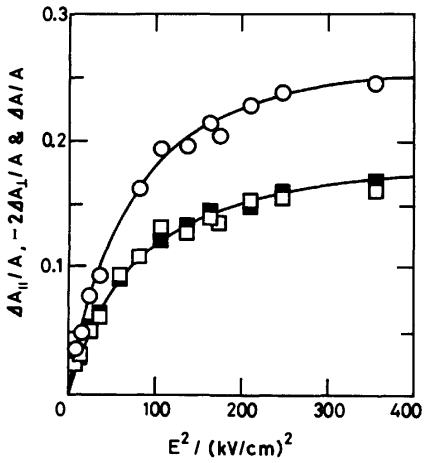

Fig. 6. Dependence of dichroism for a collagen solution on applied electric field. $\Delta A_{//}/A$ (□), $-2\Delta A_\perp/A$ (■), and $\Delta A/A$ (○) at 200 nm.

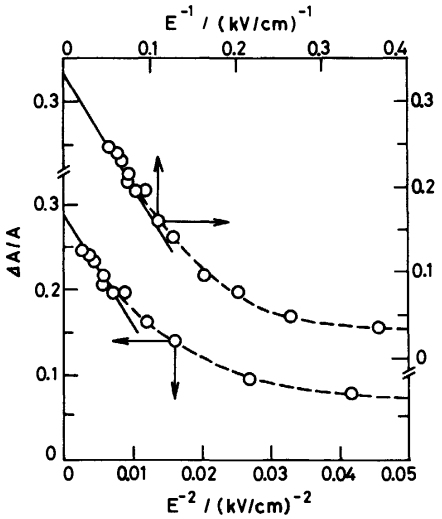

Fig. 7. Extrapolation of reduced dichroism to infinitely high field strength. The data were the same as those in Fig. 6. Solid lines represent the least-square fitting. Other details are given in text.

would be reached if the orientation of the collagen helices results from the pure permanent dipole moment, while the estimated value would be 0.291 if the orientation is solely due to the polarizability anisotropy.[18,19]

Dependence of Electric Dichroism on Wavelengh. Figure 8 shows the dependence of dichroism on wavelength (upper half) and the anisotropic spectra, $A_{//}^E$ and $A_\perp^E$, at a constant field strength of 16.3 kV/cm, together with the isotropic spectrum of collagen, A, in the absence of the field (lower half). The reduced dichroism is positive but not constant throughout the 230—187 nm region, indicating that the broad single-peaked isotropic spectrum is only apparent and contains several transition moments directed at different angles relative to the orientation axis of a collagen molecule. These dichroic spectra of the peptide chromophore of collagen in solution could be determined, for the first time, with the present ELD apparatus. The $A_{//}^E$-spectrum with the maximum at 192 nm is always more

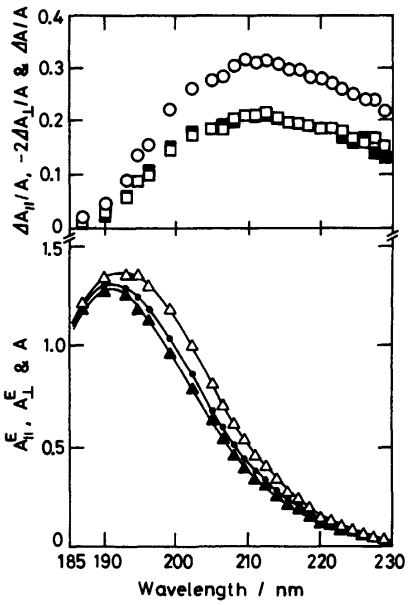

Fig. 8. The dependence of reduced dichroism on wavelength (upper half)and the anisotropic spectra (lower half) of collagen in an acid solution at 16.3 kV/cm. Upper half: $\Delta A_{//}/A$ (□), $-2\Delta A_\perp/A$ (■), and $\Delta A/A$ (○). Lower half: $A_{//}^E$ (-△-), $A_\perp^E$ (-▲-); the observed isotropic spectrum (——) and the isotropic absorbance calculated with $3A=A_{//}^E+2A_\perp^E$ (●). The path lengths are normalized to 0.60 cm in all cases.

intense than the $A_\perp^E$-spectrum with the maximum at 190 nm, both spectra coinciding with each other below 188 nm. It should be noted that these absorption maxima are shifted relative to the maximum of the isotropic spectrum at 191 nm. A similar trend was observed for a stroked collagen film.[20] Equation 4 holds over the entire wavelength region; the isotropic spectrum calculated with the relation, $3A=A_{//}^E+2A_\perp^E$, was indicated with dots (lower half).

Simulation of Reduced Dichroism. Collagen in a triple-stranded helix conformation is known to be oriented by a pulsed electric field, owing to the interaction predominantly with the permanent dipole moment borne on the polypeptide chains.[21-23] The orientation axis of collagen toward the electric field is the longitudinal axis of the triple helix. The degree of orientation (denoted as Φ) of collagen molecules in solution at a given orienting field strength of E is related to the reduced dichroism observed at E and the saturated dichroism as $\Delta A/A=(\Delta A/A)_s\times\Phi$,[15] Φ being independent of wavelength inasmuch as the value of E is specified. For example, $\Phi=0.72$ at $E=16.3$ kV/cm, since at 200 nm $\Delta A/A=0.240$ and $(\Delta A/A)_s=0.333$ (the last was estimated from the extrapolation of $\Delta A/A$ against E^{-1}). The value of $(\Delta A/A)_s$ may be calculated at any wavelength, once the value of Φ is known. It is related to the absorption transition moment by the following expression:[13]

$$\left(\frac{\Delta A}{A}\right)_s=\left(\frac{\Delta A}{A}\right)\left(\frac{1}{\Phi}\right)=\frac{3}{2}\frac{\sum_i(3\cos^2\theta_i-1)A_i}{\sum_i A_i}, \qquad (5)$$

where θ_i is the angle between the transition dipole

moment direction of the ith absorption band with absorbance A_i and the orientation axis of a collagen molecule, *i. e.*, the long axis of the triple-stranded helix.

From the variation of $\Delta A/A$ with wavelength in Fig. 8, at least three overlapping component bands must be present in the peptide band; approximately the first is at 230—210 nm, the second at 210—200 nm, and the third at 200—185 nm. In order to simulate the wavelength dependence of $\Delta A/A$ with these bands, the isotropic spectrum must be decomposed into these three component bands. In this work, the profile of each band was assumed to be Gaussian as

$$A_i(\tilde{\nu}) = A_{i,\max}\exp\left[-(4\ln 2)\left(\frac{\tilde{\nu}-\tilde{\nu}_{i,\max}}{\delta_i(\tilde{\nu})}\right)^2\right], \quad (6)$$

where $A_i(\tilde{\nu})$ is the absorbance at a given wave number $\tilde{\nu}$, $A_{i,\max}$ is the maximum absorbance at the peak position $\tilde{\nu}_{i,\max}$, and $\delta_i(\tilde{\nu})$ is the half-intensity band width where $A_i/A_{i,\max}=0.5$.

Figure 9 shows a decomposition of the observed isotropic spectrum (circles) into three component bands (dashed lines) centered at 219 nm, 200 nm, and 189 nm. The resultant spectrum (solid line), composed of these three bands, is in excellent agreement with the observed spectrum. With the characteristic parameters for $A_{i,\max}$ (i=1—3) given in Table 1, the experimentally obtained values of $\Delta A/A$ were fitted by adjusting the angle θ_i with the aid of Eq. 5. The best values of θ_i (i=1—3) are given in Table 1. The agreement between the experimental and simulated values of $\Delta A/A$ is good throughout the 230—187 nm region. Since collagen is a complex protein consisting of many different amino acid residues, it would not be relevant further to refine the simulated

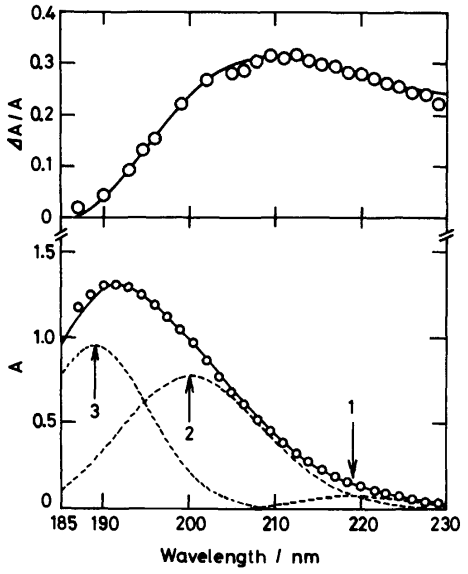

Fig. 9. Decomposition and simulation of the isotropic spectrum and the wavelength dependence of $\Delta A/A$ of collagen. Upper half: observed values of $\Delta A/A$ (O) and the simulated dependence of $\Delta A/A$ (——) on wavelength. Lower half: observed (O) and simulated (——) isotropic spectra, together with three component bands (----). These are: (1) the 219 nm band, (2) the 200 nm band, and (3) the 189 nm band. The experimental data are taken from Fig. 8.

wavelength dependence of $\Delta A/A$ values by decomposing the isotropic spectrum into four or more component bands.

The Peptide Chromophore in Collagen. There have been two reports, one by Mandel and Holzwarth[20] and the other by Jenness *et al.*,[17] in which the optical properties of collagen were quantitatively studied in solutions and in stroked films. These workers, however, failed to identify the first component band at 219 nm that was detected in this work. This transition may be assigned to the n-π^* transition on the carbonyl oxygen because of its weak intensity and long wavelength peak.[17,20] It is the wavelength dependence of the reduced dichroism, but not of the dichroism, $\Delta A_{/\!/}$ or $\Delta A_{\perp}$,[20] itself that reveals the hidden features in an isotropic spectrum, such as the number of transition moments and the angles, in a tangible fashion. Since Eq. 5 yields only the absolute magnitude for the angle θ_i, it may be said that the direction of the n-π^* transition makes an angle +(50.6—51.0°) or −(50.6—51.0°) (θ_1) with respect to the orientation axis of a collagen molecule.

The second component band at 200 nm is associated with a positive dichroism with an angle +(48.8—49.5°) or −(48.8—49.5°) (θ_2), while the third band at 189 nm is associated with a negative dichroism with an angle of +(56.0—55.8°) or −(56.0—55.8°) (θ_3). The presence of these bands has been noted both in the isotropic spectrum and in the anisotropic spectra of collagen films.[20] On the basis of Moffitt's prediction,[24] Mandel and Holzwarth have assigned these bands to the exciton-split π-π^* transitions which are expected for a single-stranded helix.[20,24] The allowed exciton bands are polarized parallel and perpendicular to the axis of the helix. According to the prediction, the positive 200-nm band is the parallel (//) band, while the negative 189-nm band is the perpendicular (⊥) band. As mentioned above, the wavelength dependence of $\Delta A/A$ can afford the angle relative to the orientation axis which is the axis of the triple-stranded helix of collagen. The estimated angles are about ±49°, but not 0°, for the "//-band" and about ±56°, but not 90°, for the "⊥-band". This discrepancy between the observed and theoretically expected values for angles θ_2 and θ_3 may be

attributed to three possibilities which remain to be resolved.

The first possibility is that the exciton band is not formed over the collagen helix which consists of three intermolecular hydrogen-bonded helix chains. The second is that the exciton splitting does occur, but it is limited only to each single-stranded helix chain which is coiled around the collagen axis. The third is that the Moffitt-type splitting does not actually occur, and the observed component bands all belong to the intrinsic peptide chromophore. These are interesting poins for future investigations, which must be deferred until the geometry of the collagen helix and the optical property of small-molecular-weight amide compounds are more thoroughly clarified.

Conclusion

We have constructed a high-voltage pulsed electric linear dichroism apparatus with the aim of unraveling the optical properties of the chromophores involved in biologically important macromolecules, which absorb light in the far ultraviolet region. Using this apparatus, we have measured the dichroic spectra of collagen in an acid solution over the 230—187 nm region, in which the reduced dichroism was found to be wavelength-dependent. We have presented a detailed, analytical procedure for electric dichroism data. On the basis of this analysis, we concluded that the isotropic absorption spectrum of collagen contains at least three transition moments, which make different angles with respect to the orientation axis of the collagen helix.

We are deeply indebted to Dr. E. Charney of the National Institutes of Health (Bethesda, Md., USA) for kindly lending us a magnesium fluoride polarizer in the initial stage of this work. This work was in part supported by a Grant-in-Aid for Scientific Research (No. 347009) from the Ministry of Education, Science, and Culture.

Dispersibility of Magnetic and Nonmagnetic Iron(III) Oxides in Cyclohexane and Effect of Water on the Stability

Kazuhiko KANDORI,* Akio KAZAMA, Kijiro KON-NO, and Ayao KITAHARA
Department of Industrial Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received January 24, 1984)

The dispersion stability of needlelike and octahedral iron(III) oxides of magnetic or nonmagnetic particles in cyclohexane solutions of sodium 1,2-bis(2-ethylhexyloxycarbonyl)ethanesulfonate (Aerosol OT or AOT) was studied on anhydrous and hydrous systems. The dispersion stability of the anhydrous system was examined for seven kinds of oxides. The sedimentation velocity of dispersions, the histograms of particle distribution, the adsorption of Aerosol OT on the particles and zeta potential were measured. Potential energies of the interaction between a pair of particles were calculated for the anhydrous system. It was suggested from the calculation of potential energies that the magnetic attractive force, which is a function of the strength of the saturation magnetization and the volume of particle, is a main factor affecting the flocculation of the magnetic particles in cyclohexane as well as in 2-butanone reported in the previous papers. The study of the dispersion stability of the hydrous system was done for three kinds of needlelike oxides. The relatively stable region appeared in the lower concentration range of water. The stability decreased at the fixed water concentration followed by marked flocculation ("floc formation" region). It was considered that the appearance of the "floc formation" is caused by the formation of thick hydration layer on the oxide surface and the decrease of zeta potential.

Many data on the stability of colloidal dispersions in nonpolar organic media as well as in water have been accumulated. The stability of colloidal dispersions discussed in water by the DLVO theory[1] has been extended to that in nonpolar organic media.[2-5] The effect of zeta potential of carbon black and titanium oxides on the dispersibility in nonpolar organic media has been discussed.[4,6,7]

The important role of a small quantity of water had also been indicated in nonpolar media. For example, the effect of water on the dispersion of TiO_2 in surfactant solutions in nonpolar media has been reported by Parfitt *et al.*.[7] The effect of water on the dispersibility and the zeta potential for carbon black particles has been also shown in Aerosol OT/cyclohexane solution.[8,9]

On the other hand, the dispersion stability of pigments in polar organic media has recently drawn much attention as seen in paints used for magnetic tapes in the industrial field. However, the fundamental studies of pigment in polar organic media are very rare.[10] The authors have reported the dispersibility of the magnetic particles by two kinds of copolymer dispersants for the anhydrous and the hydrous systems[11-13] and that of the carbon black particles by Aerosol OT[14] in 2-butanone. Hence it seems to be interesting that the dispersibility of the magnetic particles in nonpolar organic media is compared with that in polar organic media published already.[11-13]

In this paper, the dispersions of needlelike and octahedral iron(III) oxides of the magnetic or nonmagnetic particles are prepared in cyclohexane. The sedimentation experiments of dispersions and measurements of adsorption and zeta potential are carried out to study the dispersibility. The characteristic behavior of the sedimentation experiment in the anhydrous system is compared with the calculated data of the potential energies and with the results of the dispersibility in polar organic media. Further study is mainly focussed the effect of water on the stability. Interesting behavior of the dispersibility is compared with the system of the dispersion of carbon black in cyclohexane in the previous paper.

Experimental

Materials. Seven kinds of iron(III) oxides were prepared according to the references.[15-17] Each property of these iron(III) oxides is shown in Table 1. The oxides of Nos. 1—5 were the same samples as used in the previous papers[11-13] and purified similarly.

Cyclohexane used as a solvent was purified and dried from GR-grade material as usual and treated finally with Molecular Sieve 4A to remove any trace of water. Aerosol OT used as a dispersant was commercial grade and was purified according to the previous method.[18]

Preparation of Dispersions. The dispersion was prepared by mixing the particles (0.2 wt%) and the solution of a fixed concentrations of the dispersant(AOT) and water under irradiation with ultrasonic apparatus (Kaijo Denki Co. Model TA-4015, Power Supply 150 W, 20 kHz) for 5 min. No precipitation was observed immidiately after this procedure.

Estimation of Dispersion Stability. The stability of the dispersion was estimated for the anhydrous and hydrous systems by two kinds of sedimentation experiments stated in the previous papers.[11-13] One was the experiment to obtain the sedimentation velocity in sedimentation tubes of the diameter of 1 cm. The other was done with a sedimentation balance in order to verify the dispersion stability obtained by sedimentation tube. The particles were almost distributed over the range of the diameter 0—1 μm in the particle distribution histograms obtained by the latter. So that the median diameter, which seems to be the most partinent parameter to indicate the dispersion stability, was determined from the histograms.[12]

Measurements of Adsorption of Aerosol OT or Water and Zeta Potential. The dispersions of the oxides involving a fixed amount of AOT and/or water(the molar ratio of water to AOT, R=[water]/[AOT], was fixed; that was R=0.5, 1, 2, 3) were shaken for 16 hr at 30±0.1 °C. The concentration of the oxide was 4 wt% for the adsorption of AOT and 0.2 wt% for that of water. The equilibrium concentrations of AOT and water in the supernatant after centrifugation were determined

TABLE 1. PROPERTIES OF IRON(III) OXIDES

No.	Class	Specific surface area (m^2/g)	Saturation magnetization (emu/g)	Saturation magnetization (gauss)	Size Å	Density (g/cm^3)	Volume of a particles (m^3)
1	γ-Fe_2O_3	37.6	68	3674	1470×160	4.3	2.96×10^{-23}

a) α-Fe_2O_3 keeps its magnetization.

by an ultraviolet spectrometer (UV-200 S, Shimadzu Co.) and a Karl-Fischer apparatus, respectively, to calculate the amount of adsorption.

Electrophotoretic mobility was measured by microelectrophoresis with Laser Zee TM Model 500 (PEN KEM Co.) as stated in the previous papers.[11,13,14]

Calculation of Potential Energy. Potential energies between particles were calculated in the anhydrous system according to the methods published in previous paper[12] in order to evaluate the result of the dispersibility of seven kinds of oxides. The octahedral and needlelike particles used in this paper were assumed to be spherical and cylindrical, respectively. The parallel interaction was only considered for the needlelike particles, because it is clear from the previous paper that the parallel interaction is more predominant than the head-tail interaction between the needlelike particles.[12]

Four kinds of potential energies of the interaction between a pair of particles were considered: Steric repulsion between adsorbed layers(V_R^{en}), electrostatic double layer repulsion(V_R^{el}), van der Waals attraction (V_A^{δ} or V_A^{L}) and magnetic attraction (V_A^{M}). They are expressed in following equations (1)—(8).

For Octahedral Particles: i) Steric repulsion between adsorbed layers; Here Ottewill-Walker's equation was utilized:[19]

$$V_R^{en} = \frac{4\pi kTC_v^2}{3v_1^2\rho_2^2}\cdot(\psi_1-\kappa_1)\left(\delta-\frac{H}{2}\right)^2\left(3a+2\delta+\frac{H}{2}\right) \quad (1)$$

where C_v is the concentration of AOT in the adsorbed layer, v_1 is the molecular volume of a solvent, δ is the thickness of an adsorbed layer, ρ_2 is the density of AOT, a is the radius of a particle, H is the shortest distance between the particle surfaces and ψ_1 and κ_1 are entropic and enthalpic parameters of mixing proposed Flory.

ii) Electrostatic double layer repulsion:[20]

$$V_R^{el} = \frac{\varepsilon a^2\zeta^2}{2a+H} \quad (2)$$

where ε is the dielectric constant of a medium and ζ is zeta potential.

iii) Van der Waals attraction; Here Vold's equation was used, considering the effect of adsorbed layer:[21]

$$V_A^{\delta} = -\frac{1}{12}\left\{(\sqrt{A_{22}}-\sqrt{A_{33}})^2\cdot\frac{a+\delta}{H}+(\sqrt{A_{33}}-\sqrt{A_{11}})^2\cdot\frac{a}{H+2\delta}+4a(\sqrt{A_{22}}-\sqrt{A_{33}})(\sqrt{A_{33}}-\sqrt{A_{11}})\cdot\frac{a+\delta}{(H+\delta)(2a+\delta)}\right\} \quad (3)$$

where A_{11}, A_{22} and A_{33} are the Hamaker constants of the oxide, a solvent and AOT adsorbed, respectively.

iv) Magnetic attraction:[22]

$$V_A^{M} = -2\left(\frac{M}{4\pi}\right)^2\frac{v^2}{(2a+H)^3} \quad (4)$$

where M is the saturation magnetization (gauss) and v is the volume of a particle.

For Needlelike Particles: i) Steric repulsion between adsorbed layers:[19]

$$V_R^{en} = \frac{2kTC_v^2}{v_1\rho_2^2}\cdot(\psi_1-\kappa_1)\cdot V \quad (5)$$

where V is the total volume of the overlapping zone of the adsorbed layer.

ii) Electrostatic double layer repulsion:[12]

$$V_R^{el} = \frac{\varepsilon\sqrt{h\kappa}\psi_0^2}{2\pi}\left[\frac{2}{3}\left(\frac{1}{\exp(\kappa H+1)+1}\right)-\frac{1}{\exp(\kappa H)+1}\right)\cdot\times(1+3\kappa H)+2\left\{\left(\frac{1}{\exp(\kappa H)+1}-\frac{1}{\exp(\kappa H+1)+1}\right)\kappa H+\frac{1}{\exp(\kappa H)+1}\right\}+1.142\exp(-\kappa H)-2\exp(-\kappa H-1)\right] \quad (6)$$

where h is the radius of the cylinder of a needlelike particle, H is the shortest distance between the particle surface and κ is the reciprocal Debye length expressed as follows:

$$\kappa = \sqrt{\frac{8\pi nz^2e^2}{\varepsilon kT}} \quad (6')$$

The equation (6) introduced under an assumption of $\kappa h>1$ in the previous paper[12] was approximately used for the cyclohexane system($\kappa h<1$). This approximation can be allowed, because the contribution of this repulsion is comparatively small as seen in Table 3-2.

iii) Van der Waals attraction:[1]

$$V_A^{L} = -\frac{A}{48}\left\{\frac{1}{(H/2)^2}+\frac{1}{(H/2+h)^2}-\frac{2}{(H/2+h/2)^2}\right\} \quad (7)$$

where A is the Hamaker constant of the oxide in cyclohexane. Here the effect of adsorbed layer was neglected.

iv) Magnetic attraction:[12]

$$V_A^{M} = -\left(\frac{M}{4\pi}\right)^2\frac{v^2}{(2h+H)^3} \quad (8)$$

Total potential energy (V_T) of the octahedral and the needlelike particles are calculated by summing the contributions of Eqs. (1)—(4) and Eqs. (5)—(8), respectively.

Results

Effect of AOT on the Stability. The change of the boundary lines between the supernatant and the dispersion (the sediment height) in the sedimentation tube are shown as a function of time for seven kinds of oxides in Fig. 1. Here AOT of 20 mM was used as a dispersant. In

the absence of AOT, all of the dispersions sedimented rapider than Nos. 4, 5, 6 in Fig. 1. This shows the effectiveness of AOT on the stability of iron oxides in cyclohexane. The sedimentation velocity, that is, the gradient of the lines in Fig. 1 was used to discussed the dispersion stability.

In order to examine the effect of AOT concentration on the dispersibility and zeta potential, measurements of the sedimentation and zeta potential were carried out for the magnetic needlelike particle (No. 1). The dependence of the sedimentation velocity and zeta potential on the AOT concentration is indicated in Fig. 2. The amount of adsorbed AOT is also shown in Fig. 2. The dispersion stability is markedly improved by the addition of a small amount of AOT (2—3 mM), as seen in Fig. 2. This concentration is the similar order to the critical micellar concentration of AOT in cyclohexane (1.4 mM).[23] Moreover, at this concentration of AOT, the adsorption reaches approximately the saturation. This correspondence illustrates the effect of AOT molecules adsorbed on the dispersibility of the oxide.

Comparison of the Dispersibility of Seven Kinds of Oxides in Anhydrous System. The following result is seen from Fig. 1. The effect of AOT on the stabilization of the dispersions is remarkable in the system of the needlelike nonmagnetic oxide(No. 2). The dispersibility of the needlelike and magnetic oxides (Nos. 1 and 3) and needlelike and nonmagnetic oxide (No. 7) is considerably improved by the addition of AOT of 20 mM. On the other hand, the dispersibility of the octahedral oxides(Nos. 4 and 5) and the needlelike and magnetic oxide in which particles have large volume(No. 6) is scarcely improved.

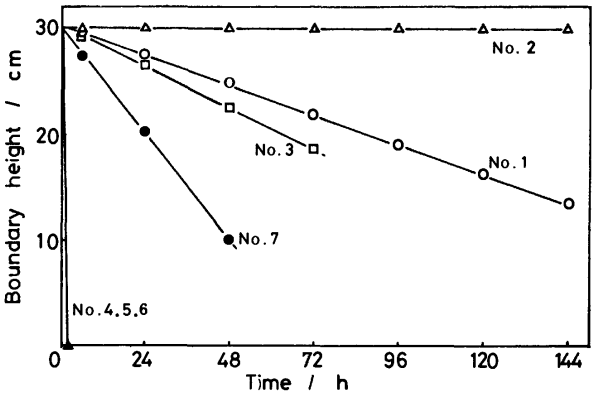

Fig. 1. Plots of Boundary height *vs.* Time. [AOT]=20 mM

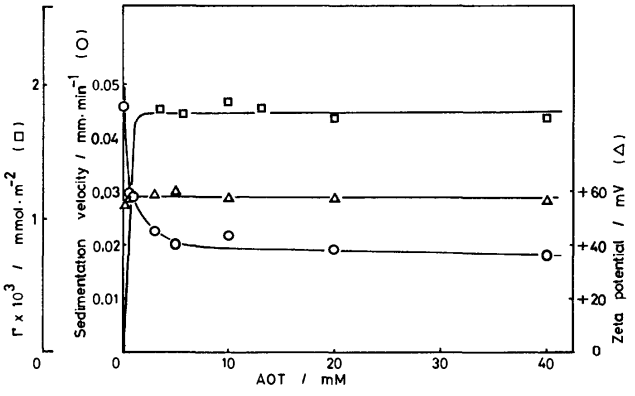

Fig. 2. Relation of the sedimentation velocity (○), zeta potential (△) and amount of adsorbed AOT (□) with Aerosol OT concentration for No. 1 sample.

The result of each measurement for seven kinds of oxides was listed in Table 2 to estimate the dispersibility. Here adsorption isotherms were the Langmuirian type and their Langmuir plots were linear in all cases. The saturation values of adsorption (Γ_m) listed in Table 2 for seven kinds of oxides were obtained from these Langmuir plots. Table 2 shows that the order of the magnitude of the sedimentation velocity is as follows;

$$\text{No. } 6 \simeq 4 > \text{No. } 5 \gg \text{No. } 7 > \text{No. } 3 > \text{No. } 1 > \text{No. } 2 \qquad \text{(A)}$$

The result of (A) agrees with the result of the dispersibility in 2-butanone for Nos. 1—5 oxides stabilized by two kinds of copolymer dispersants,[11] except for the order between No. 3 and No. 1, though the difference between them is minor.

The order of the magnitude of the median diameter in Table 2 obtained by the sedimentation balance is as follows;

$$\text{No. } 6 > \text{No. } 4 > \text{No. } 5 > \text{No. } 3 > \text{No. } 7 > \text{No. } 1 > \text{No. } 2 \qquad \text{(B)}$$

The result of (B) agrees with the result of (A) except for the order between No. 3 and No. 7, though the difference between them is minor.

It is seen in Table 2 that there are not so much differences among the zeta potential of each particle, and the order of the value does not agree with that of the sedimentation velocity. Moreover, the order of the saturation amount of adsorbed AOT does not also agree with that of the sedimentation velocity.

Potential Energy in Anhydrous System. The dispersibility of seven kinds of oxides might be evaluated quantitatively from the magnitude of the total potential energy consisting of repulsive (V_R^n, V_R^l) and attractive (V_A^δ or V_A^L, V_A^M) energies between particles which were expressed by Eqs. (1)—(8).

Numerical values used for each equation were as follows: In Eqs. (1) and (5), $\psi_1-\kappa_1=0.1$[24], $a=1000$ Å, $\rho_1=$

Table 2. Results of each measurement of iron(III) oxides

No.	Sedimentation velocity (mm/min)	ζ-potential (mV)	$\Gamma_m \times 10^3$ (mmol/m²)	D_{med} (μm)
1	0.019	+55.7	1.74	0.898

6	3.00	+53.7	1.74	23.5
7	0.068	+57.7	1.44	1.06

1.0 g/cm^3 [25] and C_v was calculated from the following equation for each particle, $C_v=\Gamma_m/\delta \cdot So$, where Γ_m is the saturation amount of adsorbed AOT, δ is the thickness of the adsorbed surfactant molecules(15 Å)[25] and So is the specific surface area of each particle.

In Eqs. (2) and (6), ε=2.02[26] and ζ was listed in Table 2. κ=3132 cm^{-1} was calculated for 20 mM AOT/cyclohexane solution from Eq. (6)′ with the ion concentration(n) obtained by the electric conductivity method described before.[27] In Eqs. (3) and (7), the Hamaker constants were as follows: A_{11}= 2.1×10^{-19} J for particles,[12] A_{22}=5.9×10^{-20} J for solvent,[12] A_{33}=2.5×10^{-20} J for adsorbed layer.[24] The value of A, 4.6×10^{-20} J, in Eg. (7) was calculated from the following equation, $A=(\sqrt{A_{11}}-\sqrt{A_{22}})^2$.

In Eqs. (4) and (8), the values in Table 1 (gauss) were used for the saturation magnetization(M).

The results of the calculation for the octahedral particles obtained from Eqs. (1)—(4) and for the needlelike Eqs. (5)—(8) are listed in Tables 3-1 and 3-2, respectively. The dispersibility of the seven kinds of oxides can be discussed quantitatively from the results.

As seen in Table 3-1 for the octahedral particles (Nos. 4, 5), the orders of the energy of the magnetic attractive force(V_A^M) are about -10^4kT, though the orders of the energy of steric repulsion(V_R^{st}) and electric repulsion(V_R^{el}) are about 2×10^2—$5\times10kT$ and below $5kT$, respectively. Therefore, it can be considered that the total potential energies(V_T) are mainly dominated by the magnetic attractive force.

As seen in Table 3-2 for the needlelike particles, the orders of the energy of magnetic attractive force(V_A^M) are about -10^2—-10^3kT for No. 1 and No. 3 oxides. The energy of van der Waals attractive force(V_A^L) is also high, similarly to the magnetic attractive force in the range of the short distance. But it drastically decreases with increase of the distance. The energies of steric repulsion(V_R^{st}) and electric repulsion(V_R^{el}) are relatively low. Hence the total potential energies(V_T) for the highly magnetic and needlelike particles(Nos. 1, 3 and 6) are dominated by both the energies of magnetic attractive force and those of van der Waals attractive force in the region of the short distance between two particles. But they are only dominated by the energy of the magnetic attractive force in the region of the long distance. Fig. 3 shows the potential energy curves for Nos. 1, 2 and 3 oxides as examples.

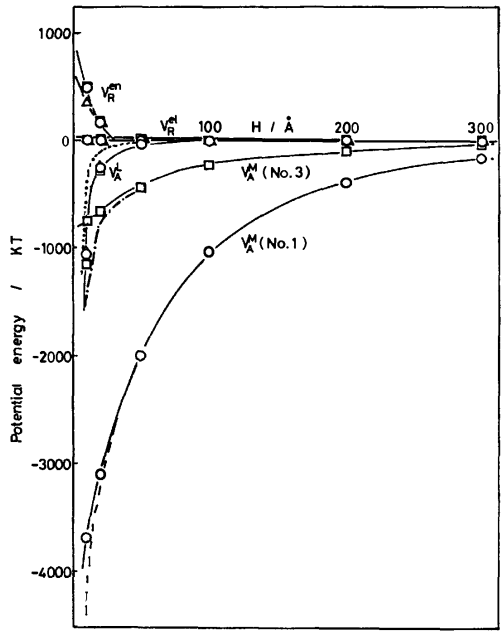

Fig. 3. The potential energy curves of the parallel interaction for three kinds of needlelike particles.

Sample	V_T
○; No. 1	— — — — —
△; No. 2	—— - —— -
□; No. 3	- - - - - - - -

On the other hand, the energy of the magnetic attractive force(V_A^M) for nonmagnetic and needlelike particles(Nos. 2 and 7) is low. So that they are only dominated by the van der Waals attractive force.

Effect of Water on Dispersibility. The effect of water on the stability of dispersions in cyclohexane was investigated in the presence of 20 mM of AOT. The needlelike particles of Nos. 1, 2 and 7 were selected for the study.

The sedimentation velocity, zeta potential and the amount of water adsorbed on the oxide surface are shown as a function of water concentration for Nos. 1, 2 and 7 oxides in Fig. 4. As shown in Fig. 4 the stable region(lower sedimentation velocity) appeared in the lower concentration range of water and the sedimentation velocity suddenly increases in a fixed concentration range. The latter behavior shows the occurrence of rapid flocculation for three kinds of oxides. The concentration region is named the "floc formation" region. Water concentrations of about 60, 100 and 80 mM are the "floc formation" regions for Nos. 1, 2 and 7 oxides, respectively. The similar "floc formation" due to the presence of water was already observed for the hydrophobic carbon black particles [9] and for the iron oxide particles. [13] Zeta potential gradually decreases with increase of the concentration of water.

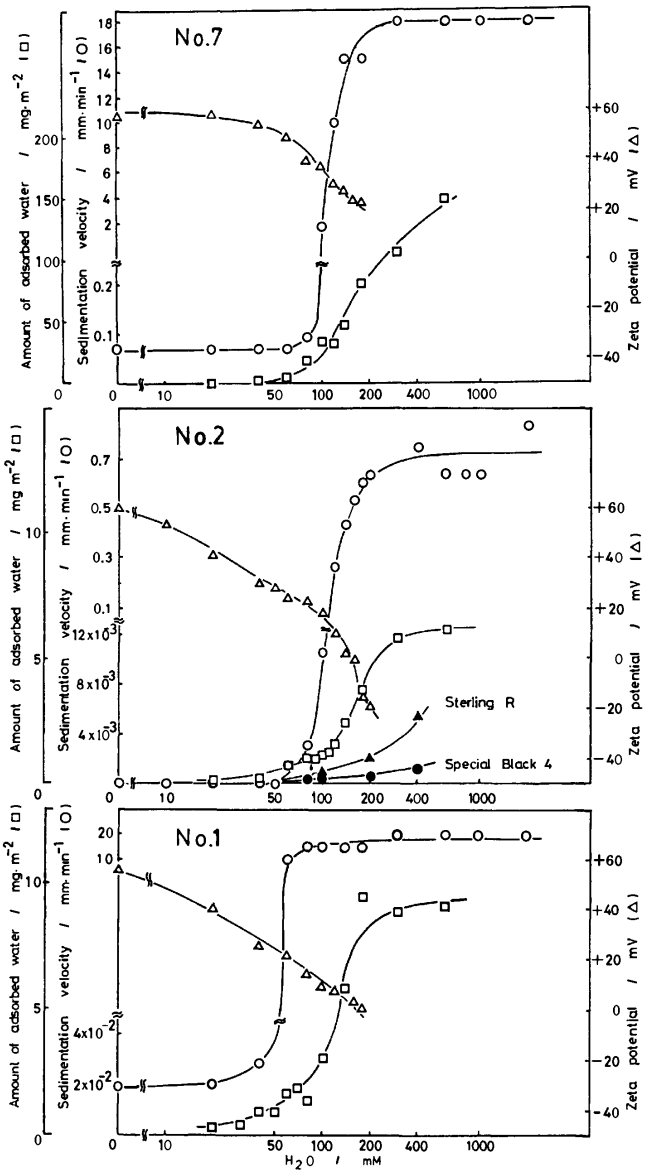

Fig. 4. Change of the sedimentation velocity (○), zeta potential (△) and amount of adsorbed water (□) of Nos. 1,2 and 7 samples with water concentration. [AOT]=20 mM. Fulled mark in the figure is expressing the amount of adsorbed water of carbon black particles (Sterling R and Special Black-4) from Ref. (9). Sterling R: Cabot Co. pH=5.5, Specific surface area=25 m²/g. Special black-4: Degussa Co. pH=2.0, Specific surface area=180 m²/g.

The median diameter(D_{med}), determined from the particle distribution histograms, was shown in Fig. 5 as a function of concentration of water for three kinds of oxides. These results are well correspondent with the results of Fig. 4, though the increase of the median diameter of No. 2 oxide is relatively low.

The amount of adsorbed AOT was shown in Fig. 6 as a function of concentration of water under the constant concentration of AOT(20 mM). The amount of adsorbed AOT gradually decrease with increase of water concentration.

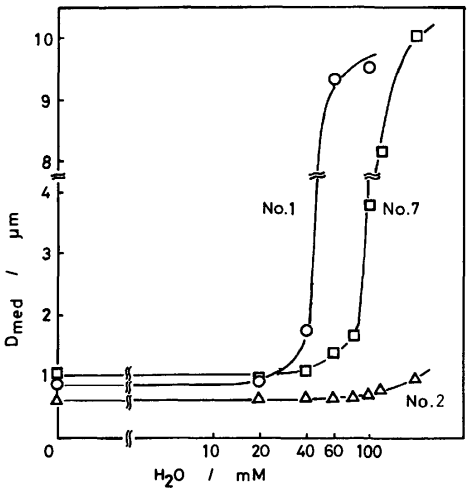

Fig. 5. Change of the median diameter of No. 1, 2 and 7 samples with water concentration.

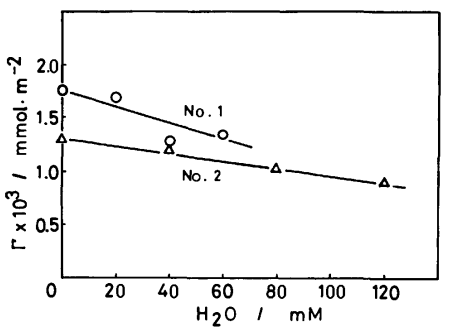

Fig. 6. Change of the amount of adsorbed Aerosol OT for No. 1 and No. 2 samples with water concentration. [AOT]=20 mM.

Discussion

Dispersibility of the Anhydrous Systems. The dispersibility of iron oxides in cyclohexane is stabilized by the addition of AOT as shown in Figs. 1 and 2. However, the difference in the dispersibility of seven kinds of oxides as seen in series (A) or (B) does not correspond with the difference of zeta potential and the amount of adsorbed AOT of each particle in Table 2. This fact was seen in the dispersibility in 2-butanone.[11] It was discussed from the difference in the saturation magnetization and the size of particles. In order to check the applicability of the discussion to this study, the potential energies between the particles were calculate.

The order of the magnitude of the total potential energy, by comparison at the same distance(*i.e.* H=20 Å) in Table 3-1 and 3-2, is as follows:

No. 6>No. 4>No. 5>No. 7>No. 1>No. 3>No. 2 (C)

It is clear that this result of (C) agrees with the results of (A) and (B) expressing the order of the dispersibility except for the No. 3 oxide. This fact shows that the magnetic attractive force, which depends on the strength of the magnetization and the volume of particle, is the main factor affecting the dispersibility of the iron oxides in cyclohexane similarly in 2-butanone.[11,12]

Effect of Water on the Dispersibility. The amount of adsorbed water, as shown in Fig. 4, remarkably increased from a fixed concentration range of water which is approximately coincident with the region of the "floc formation". Hence the occurrence of the "floc formation" is discussed as follows: The thickness of water molecules in hydration layer was calculated from Fig. 4, under an assumption that water molecules would be uniformly adsorbed on the particle surface. The thickness was above 6 molecules for all systems in the region of the "floc formation" from the calculation. So that it can be estimated that the water forms thick hydration layer above this region. The hydration layers formed at the oxide surface would work as a binder between the particles by the strong hydrogen bond among water molecules and would cause the "floc formation". The occurrence of the "floc formation" would be also due to the decrease of the energy of the electric repulsive force, because zeta potential decreases with increase of water concentration as shown in Fig. 4.

The mechanism of the effect of water on the dispersibility as seen in Fig. 4 is considered from the following discussion. In the anhydrous system, AOT molecules would be adsorbed on the oxide surface orienting nonpolar group outside and at the same time excess counter ions(Na^+) are prefferentially adsorbed on the oxide surface to cause the zeta potential positive. On the addition of a small amount of water, a part of water molecules would be adsorbed on the oxide surface and the others would be solubilized in AOT micelles in the bulk solution. With increase of the concentration of water, AOT on the oxide surface would be desorbed and transferred to the swollen micelles due to their strong ion-dipole interaction with water molecules as shown in Fig. 6. The counter ions would be also transferred to the water solubilized in reversed micelles to decrease the zeta potential. Further increase of the concentration of water increases the adsorption of water on the particle surface as well as the increase of the water core in reversed micelles. Zeta potential furthermore decreases by the shift of the slipping plane from the particle surface caused by the formation of the thick hydration layer. So that the dispersion is destabilized by the thick hydration layer and the decreased zeta potential to form "floc formation" region.

It is considered that the difference in "floc formation" regions of Nos. 1 and 2 which was seen in Fig. 4 is caused by the difference of the degree of hydrophilicity. It was described in the previous paper that the degree of hydrophilicity of No. 1 particle is higher than No. 2 particle.[13] The formation of the thicker hydration layer on No.1 particle at lower water concentration is also evidently seen in Fig. 4 for cyclohexane system. This hydration layer works as the attractive force between particles. Moreover, it was also described in the previous papers[12,13] that the energy of magnetic attractive force would not be influenced by the kind of solvents. Hence the magnetic attractive force would operate between No. 1 particles in cyclohexane as well as in 2-butanone. So that No. 1 paticle having higher saturation magnetization will be also causes the strong magnetic attractive forces between the particles in cyclohexane as shown in Fig. 3. Therefore, No. 1 particle flocculate at the lower water concentration than No. 2 particle.

It was reported in the previous paper[9] that carbon black particles (Sterling R and Special Black-4) are restabilized in the water concentration of 800—1000 mM by formation of the weak network structure among carbon black particles and AOT microemulsion. This behavior was not observed for the iron oxide particles in this study. This difference would be due to the difference of the amount of the adsorbed water, the density and the size of each particle. The amount of adsorbed water on the oxide surface is much higer than that on carbon black surface as seen in Fig. 4, due to the difference of the hydrophilicity. This may lead restabilization of the iron oxide difficult.

Photoelectron Angular Distribution and Assignment of Photoelectron Spectrum of Ozone

Shunji KATSUMATA,* Haruo SHIROMARU, and Toshiaki KIMURA
Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo 060
(Received February 3, 1984)

For the first three ionized states of ozone the ordering of $^2A_1$, $^2B_2$ and $^2A_2$ states has so far been controversial both experimentally and theoretically. The present work establishes assignment of the $^2A_2$ state by using the characteristic of electron energy dependence of an asymmetry parameter (β) of photoelectron angular distribution measured with NeI, HeI, and NeII resonance radiation. From measurements of photoelectron spectra of ozone with NeI, HeI, and HeII radiation, we newly find that two bands centered at 16.50 and 17.6 eV exhibit vibrational structures with the spacings of about 850 and about 1000 cm^{-1}, respectively. Furthermore abnormally weak bands are also confirmed at 22.7, 24.1, and 26.8 eV in the HeII spectrum.

Three studies of ozone by a high resolution VUV photoelectron (PE) spectroscopy have so far been reported in the literature,[1-3] except a work performed at a low resolution.[4] There appears disagreement concerning the identification of PE bands and vibrational spacings and orbital assignment of bands. For example, Frost *et al.*[1] and Brundle[2] reported four and five bands in the HeI spectrum, respectively, but Dyke *et al.*[3] identified eight bands including weak bands. Furthermore, Dyke *et al.* estimated the adiabatic ionization energy (IE) of the first band to be 12.44 eV, whereas other workers assigned it to 12.53,[1] 12.56[2] and 12.519 eV[5] as the corresponding value, respectively. For a vibrational structure of the third band at 13.57 eV, Frost *et al.* and Dyke *et al.* suggested that the bending mode is excited, but their values for the vibrational spacing are not equal. Brundle, on the other hand, concluded that the stretch mode is excited in the band.

We suppose that sources inducing the disagreement may be as follows; i) the sample of ozone was mainly contaminated with oxygen, ii) some PE bands due to ozone are weak and diffuse, and iii) the π biradical nature (predicted to be about 23% theoretically[6,7]) of the ground state of ozone makes the orbital assignment of bands difficult.

In order to explain the PE spectrum of ozone, various theoretical calculations[8-15] which go beyond the single-configuration SCF approximation have so far been carried out, but the calculated results are not always consistent, as described by Cederbaum *et al.*[13] Particularly for the first two PE bands at 12.75 and 13.02 eV,[3] the energy difference is so small that the assignment of the ionic states could not be deduced definitely even if the most reliable theoretical calculation is carried out. Therefore, Cederbaum *et al.*[13] and Maloquist *et al.*[15] calculated each vibrational structure of the first three PE bands to assign by comparison with the experimental PE bands. However, the calculated vibrational structures by them disagree for the $^2A_1$ and $^2B_2$ states and the proposed assignments also differ. In addition to the first three PE bands, observation of some shake-up or CI bands is predicted from the theoretical calculations taking account of configuration interaction (CI).

In the present study, we measured NeI, HeI, and HeII PE spectra at a high resolution using a very pure sample of ozone in order to establish the PE bands of ozone. For the first three PE bands, measurements of the photoelectron angular distribution parameter (β) were also carried out at NeI, HeI, and NeII radiation in order to determine the nature of their bands unambiguously by using the characteristics of the photon energy dependence of β.

Experimental

The photoelectron angular distribution of free molecules for unpolarized radiation is given by

$$J(\theta) \propto 1 + \frac{1}{2}\beta\left(\frac{3}{2}\sin^2\theta - 1\right) \quad (1)$$

where $J(\theta)$ is the photoelectron intensity, θ is the angle between the incoming photons and the outgoing photoelectrons, and β is the asymmetry parameter ranging between -1 and 2. In order to obtain β values, the photoelectron spectra were measured at θ=90° and 135° using NeI, HeI, and NeII radiation, with a photoelectron spectrometer (VG Scientific Ltd., model ADES-400), as described previously.[16,17] The energy resolution of about 120 meV was used to increase photoelectron counts and to measure in the short time for avoiding a variation of a sample pressure. On the other hand, NeI, HeI, and HeII spectra of ozone were recorded using a PE spectrometer (JASCO Ltd., model PE-1A) described elsewhere.[18] An energy resolution was about 25 meV for NeI and HeI spectra and about 70 meV for HeII spectrum. A full spectrum was usually measured with a scan voltage of 5 or 7 mV per one channel. Each of two PE spectrometers mentioned above was connected to a microcomputer system in order to control a scan voltage, a sample pressure and rotation of a turn table putting an analyzer for angular distribution measurement, automatically. Data were stored in a multichannel scaler and processed by use of a microcomputer (NEC COMPO BS/80) equipped with a floppy disk drive, an X-Y plotter and a printer. The multichannel scaler and the controller for driving pulse motors were home-made.

The ozone used in this work was produced from oxygen in a commercial ozonizer (NIPPON OZONE Ltd., type 0-1-2), stored by adsorbing on nonindicating silica gel at −196 °C (liq. N_2) and purified by pumping off oxygen. The glass vessel containing the adsorbed ozone, equipped with a teflon needle valve, was then connected to the spectrometer. The ozone was introduced into the spectrometer at the required pressure through the teflon needle valve, by raising the temperature of the vessel to about −80 °C by ethanol-liq. N_2. In the case of using the JASCO spectrometer, the ozone encounters no metal except for an ionization chamber coated

by an aquadag, but little amount of the residual oxygen was measured all the time. In the case of using the VG spectrometer equipped with a stainless steel needle valve and a copper inlet tube, the decomposition of ozone was also found not to affect the value. Argon was used for the energy calibration.

Results

Figure 1A shows the HeI photoelectron spectrum of ozone obtained here which is partially contaminated by a little amount of the residual oxygen. The oxygen contamination was easily identified since more amount of oxygen was observed at early stage of measurement. Fig. 1C exhibits the PE spectrum of pure ozone obtained by subtracting the pure oxygen spectrum (Fig. 1B) from Fig. 1A. We tentatively classified the PE bands into two types by their intensities. Individual ionization bands in Fig. 1C are indicated by solid lines with the numerals or alphabet at their band maxima which correspond to vertical ionization energies. Numerals are used for the bands with normal intensity in the spectrum while alphabet is used for the abnormally weak band which must be shake-up or CI band.

The first three bands in the 12—14 eV region are known to exhibit complex vibrational structures. The interpretation of the vibrational spacing and the orbital assignmet for these bands have so far been controversial. Figure 2 shows the first three bands measured with a scan voltage of 1 mV per one channel. Then, analyses of the vibrational separations elucidate that there are three ionized states in the 12—14 eV region. Furthermore, the adiabatic IE value of the first ionized state is confirmed to be 12.43 eV as shown in Fig. 2, in agreement with the value of Dyke *et al.*[3] The vibrational structures will be discussed in detail later.

It should be noted that the vibrational structure centered at 16.5 eV (band 4) is fairly resolved in this work, which was not reported in the previous papers.[1-4] Figure 3 exhibits the expanded PE bands measured with a scan voltage of 1 mV, and there the two vibrational structures are identified with the spacings

a) The adiabatic IE is 16.09 eV. b) The adiabatic IE is 17.10 eV. c) Shoulders of band 6. d) The ionic states and the I_v's (eV) are shown with the monopole intensities multiplied by one hundred in the parentheses.

of about 850 and 1000 cm^{-1}, respectively. The NeI spectrum shown in Fig. 4 also displays the vibrational structure near 16.5 eV although the spectrum is complicated by NeI (16.67 and 16.85 eV) resonance lines. The weak and diffuse band at 15.6 eV (band A) indicated by Dyke *et al.* could be also certified in the NeI and HeI spectra in this work. Concerning other bands, our HeI and NeI spectra are in good agreement with the previous ones.

The HeII spectrum of ozone shown in Fig. 5 is in fair agreement with that reported by Dyke *et al.*[3] They however suggested only a very weak band at 24.7 eV (corresponding to the band C) in the region between 21 and 28 eV. As can be seen in Fig. 5, the bands B and D were found as well as the band C. The ionization energies determined in this work are listed in Tables 1 and 2.

Concerning photoelectron angular distribution, the experimental NeI and HeI β values for the first three bands are plotted against ionization energy in Fig. 6, together with the HeI spectrum obtained at θ=90°. The HeI β values for the three vertical IE peaks are commonly about 0.1, and the NeI β values for the first and second peaks are also about 0.3 similarly. However,

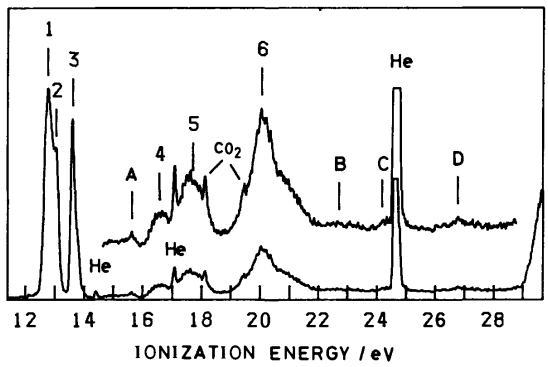

Fig. 5. HeII photoelectron spectrum of ozone.

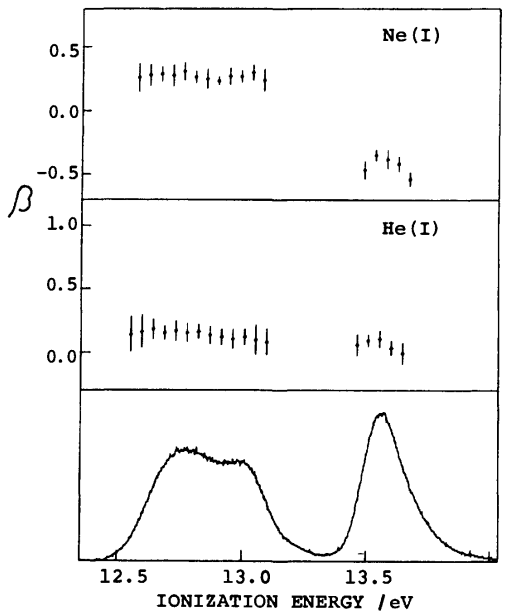

Fig. 6. Plots of experimental β values of ozone obtained for NeI and HeI radiation in the first three bands, and HeI photoelectron spectrum obtained at θ=90°.

the NeI β value (−0.31) for the third peak is quite different from those of them.

Discussion

The PE Bands in the 12—14 eV Region. It is of no doubt from the PE spectra mentioned above that there are three bands in the 12—14 eV region. The assignment for the first three ionic states of ozone presents an interesting problem for theoretical

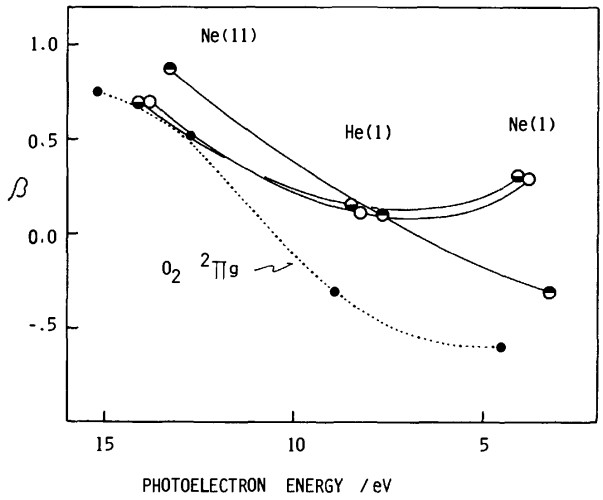

Fig. 7. Photoelectron energy dependence of β for (◒) band 1, (○) band 2 and (◓) band 3 of ozone and for (●) the $^2\Pi_g$ band of oxygen.

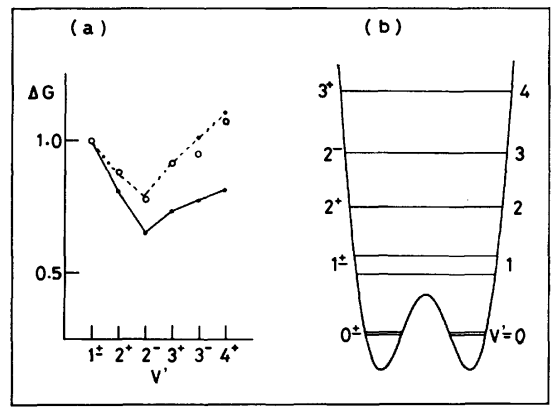

Fig. 8. (a) Plots of the relative vibrational spacing against vibrational quantum number for the first ionized state. Open circle shows the experimental value; solid line, the theoretical value taken from Ref. 23 in the case of $\rho=0.6$ and $B=1.2$; dotted line, corrected with anharmonicity. treatments of correlation and/or reorganization effects. If Koopmans' theorem[19] is assumed, the order of increasing ionization energy would be $1a_2$ (13.24 eV), $6a_1$ (15.01 eV) and $4b_2$ (15.39 eV) from *ab initio* SCF MO calculation.[14] However, the order of the ionic states suggested previously by both experimental and theoretical studies is either the $^2A_1$, $^2B_2$, and $^2A_2$ state or the $^2A_1$, $^2A_2$, and $^2B_2$ state, predicting a breakdown of Koopmans' theorem because of the π biradical nature of the initial state.

The a_2 orbital of ozone consists of a simple combination of the p_π terminal oxygen orbitals and it is very similar to the $1\pi_g$ orbital of oxygen molecule. Our aim is to determine the a_2 orbital by using the characteristic of the photoelectron energy dependence of β. Fig. 7 shows plots of β values obtained at NeI, HeI, and NeII radiation for the three vertical IE peaks, together with that of β for the $v'=1$ peak of the $1\,^2\Pi_g$ ionic state of oxygen molecule.[20,21] The peak of $v'=1$ for oxygen involves no autoionization effect at NeI radiation.[20] It is found from Fig. 7 that the β curve for the third peak of ozone has higher slope than those for others and is quite similar to that for the $^2\Pi_g$ state of oxygen molecule. Therefore, the third ionized state of ozone must be assigned to the $^2A_2$. Next problem is the order of the first two ionized states which should be either the $^2A_1$ and $^2B_2$ or the $^2B_2$ and $^2A_1$. It should be determined by analysis of the vibrational spacing.

Concerning the vibrational structure of the two bands in the 12—13.4 eV region, Fig. 2 exhibits easily distinguishable two vibrational progressions which consist of seven peaks in the low region of 12.43 up to 12.91 eV and three peaks in the high region of 13.00 to 13.34 eV. For the first progression, the relative vibrational spacing (ΔG) between the adjacent peaks from $v'=0$ up to 6 is irregular as shown by open circle in Fig. 8a, which exhibits the minimum value of 540 cm^{-1} at the third spacing and gradually increases toward higher quanta. The averaged separation is about 640 cm^{-1} and assigned to the bending mode, ν_2, which is 719 cm^{-1} in neutral ozone.[22] The irregular spacing obtained in this work is in good agreement with that reported by Dyke *et al.*[3] who suggested that the Renner-Teller effect contributes to the irregularity.

We investigated the irregular spacing on the basis of the double-minimum potential method proposed by Coon *et al.*[23] If parameters $\rho=0.6$ and $B=1.2$ are used, individual spacings are displayed by a solid line in Fig. 8a according to the notation of v' by Coon *et al.* Furthermore, the experimental spacings are better reproduced by taking account of an anharmonicity of $2X'h\nu(v'+1)$, as shown by dotted line in Fig. 8a. Then the estimated separation, $h\nu$, is 690 cm^{-1} and assigned to the bending mode ν_2. Figure 8b shows the double-minimum potential and the vibrational levels obtained here by use of $\rho=0.6$ and $B=1.2$. The barrier height at $\phi=180°$ (linear ozone) is about 830 cm^{-1} corresponding to about one vibrational energy. The positions of the minima give the angle of an equilibrium geometry of the ionized state of ozone. The angle was obtained as about 170° and is very different from that (116.8°) of the neutral ozone.[22] This fact clearly predicts that Franck-Condon factors between the ionized state and the neutral ground state do not reproduce the experimental results at all, in spite of the satisfactory reproducibility of vibrational spacing. As the result, we must conclude that the irregular spacing can not be explained by the model such as the Renner-Teller effect but possibly results from an anharmonicity such as some potential change near an equilibrium geometry of the cation.

For the second band, the peak at 13.00 eV displaying a shoulder in the high energy side allows us to predict the partial overlap of the progression belonging to the first band. The first two spacings between the adjacent peaks at 13.00 up to 13.34 eV are 1380 and 1330 cm^{-1}, respectively, and assigned to the symmetric stretch mode, ν_1 (1124 cm^{-1} in neutral[22]). The vertical IE value of the second ionic state is naturally assigned to be 13.00 eV. The adiabatic IE value however seems not to be the same as the vertical one because the spectral pattern of the first band exhibits such change as an

increase of the background in the region above the peak of $v'=5$.

Concerning the third band at 13.54 eV, the vibrational structure is badly broadened but is still resolved as a faint structure. The broadening may be brought about by a predissociation[5] as one of some possibilities. The averaged separation is about 900 cm^{-1}, being in better agreement with the value (900 cm^{-1}) of Brundle[2] than that (800 cm^{-1}) of Dyke *et al.*[3] The vibration may be assigned to the ν_1.

Considering the vibrational structure of the first three ionic states, the excitation of the bending mode must be due to ionization from the angle-determining a_1 orbital, so that the first band may be assigned to the $^2A_1$ state. Since the third band is assigned to the $^2A_2$ state from the result of the photoelectron angular distribution, the second band must be the $^2B_2$ state. Experimental asymmetry parameters and assignment for these bands are summarized in Table 1 in comparison with theoretical assignments.

The PE Bands in the 14—28 eV Region. The bands observed in the region above 14 eV can be classified into two types by their intensities. First, the bands 4—6 with normal intensity are obtained at 16.5, 17.6, and 20.0 eV, respectively, and secondly, the CI bands *A*—*D* with abnormally weak intensity appear at 15.6, 22.7, 24.1, and 26.8 eV, respectively. In order to interpret these bands, we consider it most useful to refer to available theoretical results calculated by *ab initio* CI methods.[10,14] Their results are compared in Table 2. The theoretical calculations by Basch[10] and Kosugi *et al.*[14] presented both the ionization energies and the monopole intensities which wholly seem to be in good agreement with the experimental results.

Let's consider the bands 4 and 5. According to the calculated results by Refs. 10 and 14, the band 4 corresponds to the $^2B_1$ ionic state. As can be seen from Fig. 3, this band has the vibrational spacing of about 850 cm^{-1} of which value is almost constant over the eight vibrational peaks. Hence, the vibration may be predicted to be the stretch mode ν_1 weakened by ionization from the strong bonding orbital of $1b_1$, rather than a bending mode. The band 5 exhibits a faint vibrational structure of about 1000 cm^{-1} associated with stretch mode in the low energy region, as shown in Fig. 3. The band seems to consist of overlapping bands due to two ionized states at least since it is broad and intense. This expectation is in good agreement with the theoretical results, one of which predicts two ionized states of $^2A_1$ and $^2B_2$, as listed in Table 2.

The band 6 centered at 20.00 eV exhibits two shoulders at 19.4 and 20.8 eV. According to the theoretical results, this band must correspond to many ionized states. Two theoretical results available are not consistent with each other and definite assignment of this band will be also impossible experimentally.

Concerning the abnormally weak CI bands, the band A at 15.6 eV may be assigned to the $^2B_2$ state as predicted by the theoretical results.[10,14] The other CI bands B—D must be interpreted by some theoretical calculations involving configuration interaction.

We would like to thank Mr. Y. Shindo in this Institute for his cooperation in constructing controllers and interfaces for the micro computer system. We also thank Professor S. Iwata in Keio University for drawing our attention to this work.

Simple Estimation of Ionization Energies. An Improvement of Koopmans' Approximation by Scaling

Makoto ISIHARA
Department of General Education, Shotoku-Gakuen Women's Junior College, Nakauzura 1-38, Gifu 500
(Received February 13, 1984)

A simple method of estimating ionization energies is proposed, formulation being made for atomic systems. The method aims at improving Koopmans' approximation by incorporating a scale factor into Koopmans' variation problem for the hole state in the space built of the occupied Hartree-Fock manifold of the parent state. The shrinking of the electronic cloud through ionization is effectively taken into account with the scale factor; the scaling makes the hole state fulfil the virial theorem. Numerical examples are given for valence-shell and core ionizations of several atomic systems. The results are encouraging on the whole. The attendant concepts, the quasiparticle ejection energy and the global correction, seem to be helpful in understanding the electronic behavior through ionization.

The ionization energy can be obtained, in principle, by subtracting the parent state energy from the hole state one calculated separately;[1] the problem is thus ascribed to the calculation of state energies with sufficient accuracy. Surely this way of thinking is orthodox, but we have to endure two disadvantages. One is not essential but practical; the laboriousness to keep high accuracy through subtraction of two nearly equal large numbers. The other is conceptual; the loss of intuitive and intimate understanding of the ionization energy as a physical quantity. Here it is neither suitable nor possible to give an adequate bibliography of state energy calculations;[2] we only list a few interesting devisals[3,4] and a practical approximate method based on the Rayleigh-Schrödinger perturbation theory[5] in references.

Nowadays we already have several elaborate methods of directly evaluating ionization energies of atoms and molecules, the Green's function methods,[6-10] the equation-of-motion methods,[11,12] and so on.[13,14] The perturbation analysis has arrived at a fairly high stage.[13,15,16] All of these elaborate methods, however, require relevant knowledge of unoccupied orbitals in order to display their own superior abilities; the knowledge is almost exclusively unavailable from the Hartree-Fock (HF) calculation for the parent state.

As a standard method without use of explicit knowledge of unoccupied orbitals we have what is called ΔSCF method.[17,18] Subtraction of two nearly equal large numbers being avoided in its variant the transition operator method for the ΔSCF calculation,[19] we must still perform separate self-consistent-field (SCF) calculations for each hole state of interest besides the parent state. Though ΔSCF method is a natural approximation to "separate energy calculations for individual states" mentioned above, its essential consists in meticulous consideration of the electronic reorganization effect with complete neglect of the correlation energy change; we can sometimes obtain rather comfortable estimates from Koopmans' relation[20] because of fortunate cancellation between the reorganization and correlation corrections.

Of course, we should rely on elaborate methods to reproduce or to predict experimental values accurately.[10] Simple or, in another word, handy estimations are, nevertheless, not to be despised from both practical and conceptual points of view. Especially, those of clear physical grounds advance our knowledge of both the quantity and the system under consideration.

Koopmans' relation results from the variation problem within the hole state space built of the occupied HF manifold of the parent state.[20-22] An extension to the case of the correlated parent state has been attempted[22] and analyzed.[23] Now cannot we effectively enrich Koopmans' variation problem only by introducing some additional variation parameter?

In this paper, confining ourselves to atomic systems, we propose a simple method of estimating ionization energies, where a scale factor[24] is incorporated into Koopmans' variation problem as an additional variation parameter. The motivation stems from the observation that the hole state in Koopmans' treatment does not fulfil the virial theorem[24,25] which we think a fundamental requisite for approximate states to be well-behaved. The scaling to make the virial theorem hold in the hole state is a key of the present method. Our confinement to atomic systems should not be regarded as an intrinsic restriction but is a setting for the compact presentation of the essential of the method.

Method

Throughout this section we work within the spin unrestricted picture, calling spinorbitals merely orbitals. Let $\{\phi_p\}$ be canonical orbitals obtained from the HF calculation for the parent state. The scaled orbitals $\{\phi_p^\lambda\}$ are constructed with a real scale factor λ as

$$\phi_p^\lambda(\boldsymbol{r}) = \lambda^{3/2}\phi_p(\lambda\boldsymbol{r}), \tag{1}$$

where $\boldsymbol{r}$ stands for the spatial coordinate. The orthonormality is preserved in the sense that

$$\int \phi_p^{\lambda *}\phi_q^\lambda \mathrm{d}\tau = \delta_{pq}, \tag{2}$$

the integration running over the spin and spatial coordinates. Denoting the creation and annihilation operators for ϕ_p^λ as $a_p^{\lambda\dagger}$ and a_p^λ, respectively, we can write the electronic Hamiltonian in the second quantized form as

$$H = \sum_{pq} (\lambda^2 t_{pq} + \lambda v_{pq}) a_p^{\lambda\dagger} a_q^{\lambda} + \frac{\lambda}{2} \sum_{pqrs} v_{qs}^{pr} a_p^{\lambda\dagger} a_r^{\lambda\dagger} a_s^{\lambda} a_q^{\lambda}, \tag{3}$$

where

$$t_{pq} = \int \phi_p^*(-\Delta/2)\phi_q d\tau, \tag{4}$$

$$v_{pq} = \int \phi_p^*(-Z/|\boldsymbol{r}|)\phi_q d\tau, \tag{5}$$

and

$$v_{qs}^{pr} = \iint \phi_p^*(\boldsymbol{r})\phi_r^*(\boldsymbol{r}')(1/|\boldsymbol{r}-\boldsymbol{r}'|)\phi_s(\boldsymbol{r}')\phi_q(\boldsymbol{r}) d\tau d\tau'. \tag{6}$$

Here Z is the atomic number.

Let us label the occupied orbitals in the parent state with the indices $\{i, j, k, l\}$ and introduce the notation for the scaled HF state

$$|N,\lambda\rangle = \prod_j a_j^{\lambda\dagger} |\text{vacuum}\rangle. \tag{7}$$

The parent state, written in the above notation as $|N,1\rangle$, has the energy

$$E_N = \langle N,1|H|N,1\rangle = T + V \tag{8}$$

with

$$T = \sum_j t_{jj} \tag{9}$$

and

$$V = \sum_j (v_{jj} + \sum_k (v_{jk}^{jk} - v_{kj}^{jk})/2). \tag{10}$$

We postulate that the parent state already satisfies the virial theorem;[25]

$$2T + V = 0. \tag{11}$$

On the other hand, our trial hole state is prepared in the form

$$|N-1,\lambda,\boldsymbol{C}\rangle = \sum_j c_j^* a_j^{\lambda} |N,\lambda\rangle, \tag{12}$$

where $\boldsymbol{C}$ stands for $\{c_j\}$. This trial state is, of course, orthogonal to the parent state $|N,1\rangle$, since they are different eigenstates of the number of electrons. Regarding λ and $\boldsymbol{C}$ as variation parameters, we would like to minimize the expectation value

$$\begin{aligned} E_{N-1}(\lambda,\boldsymbol{C}) &= \langle N-1,\lambda,\boldsymbol{C}|H|N-1,\lambda,\boldsymbol{C}\rangle \\ &= \lambda^2(T - \sum_{jk} c_j^* c_k t_{jk}) + \lambda(V - \sum_{jk} c_j^* c_k u_{jk}) \end{aligned} \tag{13}$$

with

$$u_{jk} = v_{jk} + \sum_i (v_{ki}^{ji} - v_{ik}^{ji}) \tag{14}$$

under the normalization constraint

$$\langle N-1,\lambda,\boldsymbol{C}|N-1,\lambda,\boldsymbol{C}\rangle = \sum_j c_j^* c_j = 1. \tag{15}$$

This conditional extremum problem can be treated easily as an unconditional one by Lagrange's undetermined multiplier method. Noting that $\{t_{jk}\}$ and $\{u_{jk}\}$ are hermitian, we resultantly arrive at the following system of equations with a real multiplier ω.

$$\begin{cases} \lambda = \left(-\frac{1}{2}\right)(V - \sum_{jk} c_j^* c_k u_{jk})/(T - \sum_{jk} c_j^* c_k t_{jk}) & (16) \\ \sum_k (\lambda^2 t_{jk} + \lambda u_{jk}) c_k = \omega c_j & (17) \end{cases}$$

together with the normalization condition given by Eq. 15.

Because λ contains $\boldsymbol{C}$, Eq. 17 does not form a genuine eigenvalue problem. It is, however, impractical to work out the problem by substituting Eq. 16 into Eq. 17. We had better solve the system of Eqs. 16 and 17 iteratively, treating Eq. 17 as an eigenvalue problem with λ given:

[0] For certain i, assume the mixing coefficients as

$$c_j = \delta_{ji}. \tag{18}$$

[1] Compute λ by Eq. 16 with the assumed $\boldsymbol{C}$.

[2] Solve the eigenvalue problem Eq. 17 for the computed λ, obtaining the computed $\boldsymbol{C}$ through the normalization of Eq. 15.

[3] Go back to the process 1 with the computed $\boldsymbol{C}$ as the assumed $\boldsymbol{C}$ until the computed $\boldsymbol{C}$ coincides with the assumed $\boldsymbol{C}$.

As to usual ionization energies we may choose the index of the highest occupied orbital as i in the initial setting (Eq. 18). Other choices of i lead us to inner valence-shell and core ionization energies.

Our hole state thus obtained fulfils the virial theorem; Eq. 16 is nothing other than the virial condition.[25] After substitution of the determined λ and $\boldsymbol{C}$, Eq. 13 gives the hole state energy

$$E_{N-1} = \lambda^2 T + \lambda V - \omega \tag{19}$$

by virtue of Eq. 17. From Eqs. 8 and 19, using the virial theorem for the parent state (Eq. 11), we have the ionization energy

$$I = E_{N-1} - E_N = -\omega + \Lambda \tag{20}$$

with

$$\Lambda = -(\lambda-1)^2 E_N. \tag{21}$$

In the form of Eq. 20 a characteristic of our method is clearly seen. Our ionization energy consists of two parts: $-\omega$, the ejection energy of the quasiparticle for the ionization considered, literally of quasiparticle nature, and Λ, the residual correction, of global nature. It may be suitable and convenient to refer to the former as the quasiparticle ejection energy and to the latter as the global correction. Note that the scaling affects not only Λ of the explicit λ-dependence but also ω. Roughly speaking, the scale factor greater than unity shrinks the electronic cloud closer to the nucleus. This contraction conserves the "shape" of the electronic cloud for the constituent hole state $a_j^{\lambda}|N,\lambda\rangle$ individually, but the image of the shape-conservative contraction fails in the hole state $|N-1,\lambda,\boldsymbol{C}\rangle$ in general, because λ and $\boldsymbol{C}$ interrelate to each other.

Without scaling, that is, in Koopmans' treatment, we have Eq. 17 with $\lambda=1$, which is just the canonical HF equation in the canonical orbital representation; ω becomes the canonical orbital energy and Λ vanishes. Still Koopmans' approximation is not to be confused with a "limiting case" of making λ tend to unity in our method. The approximation inherently violates the virial theorem for the hole state.

Numerical Examples

The present method has been applied to valence-shell and core ionizations of several atomic systems of which parent states have single configurations in Roothaan's

a) The case of Bagus' bases: B_N=2,2,1[4] for Na^+ and 1,2,4[3,2,2] for Cl^-. b) Both of Bagus' and CR's bases give E_N^{SCF}/a.u. = −161.677 for Na^+ and −459.577 for Cl^-. c) The case of CR's bases: B_N=2,3[4] for Na^+ and 2,2,3[2,4] for Cl^-. d) Koopmans' value.

HF calculation.[26] The results are summarized in Tables 1—5.

Tables 1 and 2 concern preliminary examination of the basis set dependence. The dependence on the size of a basis set is examined in Table 1 using Clementi and Roetti (CR)'s bases.[27] As the result of SCF calculation settles down, that of our calculation also does. There is an obvious gap between the single and double zeta results; the former seems of no use. Table 2 compares the cases using CR's and Bagus'[17] bases of the similar size. The results are almost identical. As the SCF calculation tends to the HF limit, this identity is expected to become complete. What is shown in Tables 1 and 2 is rather natural, since our method does not work upon basis functions themselves but work upon occupied HF orbitals.

Table 3 presents the results for usual valence-shell ionizations. CR's occupied SCF orbitals are used as a starting point of our calculation. Koopmans' and the ΔSCF values for the sake of comparison are quoted also from CR's SCF calculation. For the closed-shell systems, that is, for He-, Ne-, and Ar-isoelectronic systems, our values of ionization energies are variously lower than Koopmans' ones, nearing the experimental; the lowering ranges from about eighty to a few percent of that attained by ΔSCF method. On the other hand, for what we call the semiclosed-shell systems, Be- and Mg-isoelectronic systems, our values are only little depressed from and remain approximately equal to Koopmans' values in spite of the obvious lowering of the ΔSCF values. The ionization energies of these systems are, as is well known, rather considerably larger than Koopmans' estimates; our method can be said to work fairly well. The results for the open-shell systems, N and O^+, are moderate and we may draw no outstanding feature from them; our estimates are a little more agreeable than Koopmans' ones.

Tables 4 and 5 show the results for core ionizations.

a) The valence-shell ionization concerning the highest occupied orbital is meant. b) The ^4S state is used as the parent state. c) The number of the basis functions for the hole state SCF calculation in ΔSCF method. d) The hydrogen-like orbital. e) Δ and X stand for the ΔSCF and experimental values, respectively. f) All values are taken from the table in Ref. 28 except for the values with a dagger, which are from the data of electron affinities (Ref. 29). g) The percentage of the lowering from Koopmans' value by the present method in that by ΔSCF method; $R=100(K-I)/(K-\Delta)$. h) The deviations from the experimental value; $D\Delta=\Delta-X$, $DK=K-X$, and $DI=I-X$.

Occupied orbitals for our calculation as well as Koopmans' and the ΔSCF values are taken from Bagus' SCF calculation. Certainly ΔSCF method gives much more excellent results than Koopmans' relation as to core ionizations in which the reorganization effect is primary.[17,18] The present method works satisfactorily as well for inner core ionizations. For outer core ionizations,[18] however, our values are not so favorable, being better than Koopmans' to some extent.

The global correction is generally small and about few percent or less of the ionization energy, yet the magnitude is usually comparable with the difference between Koopmans' and experimental values of the ionization energy. We have the slight global corrections due to the scale factors very close to unity for the valence-shell ionizations of the semiclosed-shell systems. This seems, so to speak, to represent the "stiffness" of the electronic cloud characteristic of these systems. Another general feature is observed in the results of the isoelectronic sequence: While the quasiparticle ejection energy changes distinctly according to the atomic number in a sequence, the global correction as well as the scale factor varies comparatively slowly. As the atomic number increases, the scale factor becomes small little by little remaining similar. This may be well understood from the image that the larger nuclear charge forms the tighter electronic cloud with the similar shape in the parent

state. The scale factor and the global correction reflect a nature of the electronic cloud of the system considered.

Concluding Remarks

The method proposed is a natural improvement of Koopmans' approximation but stands on a much more sound ground. The numerical examples in the previous section show the usefulness of the method in both qualitative and quantitative aspects. Though the method, intended for a handy estimation, should not be expected to reproduce experimental values accurately, the obtained values are almost always better than Koopmans' and sometimes surprisingly appropriate. The method allows us to get some feel about the electronic behavior through ionization. Above all it should be emphasized that our method requires little additional work to the parent state HF calculation, the laboriousness being incomparable with that of the HF calculation for each hole state of interest. We believe that the present method is promising as a simple estimation in place of Koopmans' relation.

The idea of the present work has two obvious direction of development: One is, of course, an extension to molecular systems. We have somewhat more to be done, but there seems to exist no essential difficulty. The other is an application to estimating electron affinities, which is straightforward in principle. Still the virtual orbitals supplied by the parent state HF calculation are unphysical or poor-physical; we must improve the virtual orbitals[31] relevantly at a time.

References

1) There is some semantic problem about the usage of the terms: ground, ionic, hole states, and so on. The definition of the ground state is arbitrary depending on whether or not the number of electrons are specified (Specified: The usual ionization $He \rightarrow He^+$ is the process from the two-electron ground state to the one-electron ground state. Nonspecified: In the process $Be^+ \rightarrow Be^{++}$ we cannot call Be^+ the ground state, the ground state being Be.), but the tractable N-electron state may be referred to as the ground state concerning the transition to the $N-1$-electron state. When the N-electron state is ionic, the $N-1$-electron state is not necessarily ionic. Though the "ionized" state matches the word "ionization", it is suitable to call the $N-1$-electron state the ionized state only if the N-electron state is neutral. We use "parent" for "N-electron" and "hole" for "$N-1$-electron"; the word "hole" does not always fit literally into the $N-1$-electron state. The term "ionization energy" is undoubtedly inappropriate for the ionic parent state, yet it has been used traditionally too long to be replaced by others. Here we use it reluctantly.

Carbon-13 Nuclear Magnetic Relaxation Studies of Benzene Molecules Adsorbed on the Pillar Interlayered Montmorillonite

Mutsuyoshi MATSUMOTO,*,† Sumio SHINODA, (the late) Hiroshi TAKAHASHI, and Yasukazu SAITO
Institute of Industrial Science, The University of Tokyo,

(Received February 14, 1984)

Carbon-13 nuclear magnetic relaxation times of ^{13}C-enriched benzene have been determined in order to elucidate the adsorption properties of PILM (pillar interlayered montmorillonite) by varying temperatures and coverages. The activation energy of diffusion as small as 6.5 kJ mol^{-1} indicates that the majority of PILM adsorption sites exhibits a weak interaction with benzene. The pre-exponential factor of correlation time was exceptionally large, probably because the two-dimensional pore structure of PILM, in contrast to the three-dimentional zeolite or the open surfaces of graphitized carbon black and silica gel, restricts the chance for the adsorbate to diffuse. In the spin-lattice relaxation spectra at low temperatures, the internal and the external surfaces of PILM were discriminated, since the two adsorbed states on these surfaces give different T_1 and chemical shift values.

In recent years, there has been a growing interest in sheet silicates or aluminosilicates such as montmorillonite, vermiculite, kaolinite, and halloysite. The advantage of using montmorillonite is the easiness to accept an intercalating substance and to control the size of the generated interlayer (micropore) compared with the other clay minerals. Thus organic reactant molecules introduced into the interlayer space may undergo novel types of chemical reactions.[1]

The basic layer structure of montmorillonite is threefold, consisting of a gibbsite Al_2O_3 layer (the octahedral layer) sandwiched by two $Si_2O_5^{2-}$ sheets (the tetrahedral layer). In the octahedral layer a part of the Al^{3+} ions are randomly substituted with Fe^{3+} or Mg^{2+} ions, the lack of the lattice charge being balanced with exchangeable cations (usually Na^+).

Thermal stability is endowed by substituting the exchangeable Na^+ with $[Al_{13}O_4(OH)_{24+x}(OH_2)_{12-x}]^{7-x}$ followed by a calcination treatment, since this polynuclear inorganic cation acts as a pillar substance and forms an interlayer network. Extensive investigations have been made on catalytic[2] and adsorption[3] properties of this new type of compound, *i.e.*, pillar interlayered montmorillonite (PILM).

As well established by the diffusion and shape-selective properties of zeolite,[4] the mobility of molecules inside the pore is essentially important for catalysis and adsorption. Not only the mobility of molecules but also various interactions of the adsorbed molecules with the surfaces and other neighboring molecules are well elucidated by NMR relaxation measurements.[5–9] In the present work ^{13}C nuclear magnetic relaxation study has been performed for the molecular dynamics of benzene adsorbed on PILM in order to gain a deeper insight into the characteristics of intercalation compounds.

Experimental

Montmorillonite. Otay montmorillonite, supplied from Ward's Natural Science Establishment, Inc., was used; the fraction less than 2 μm in diameter was separated by gravity sedimentation in water dispersion.

Intercalation. An aqueous solution of $AlCl_3$ (0.3 mol dm^{-3}) was vigorously stirred under reflux, followed by a slow dropwise addition of NaOH (1.0 mol dm^{-3}), until the OH/Al ratio of the solution became 2.37;[10–12] by this procedure the polynuclear cation, $[Al_{13}O_4(OH)_{24}(OH_2)_{12}]^{7+}$,[13] was formed. The resultant solution was added dropwise to the refluxing water suspension of montmorillonite (3%) upto about five times as much as the total cation exchange capacity (*ca.* 1 meq. g^{-1}) of montmorillonite. The boiling slurry was aged for 2 h, filtered, and washed with distilled water until Cl^- ions were undetected by the $AgNO_3$ test. The product was dried in an oven overnight at 393 K, calcined in air at 673 K for 2 h, and then kept in a desiccator containing the saturated aqueous solution of NH_4Cl. A schematic view of pillar interlayered montmorillonite (PILM) is shown in Fig. 1.

Nitrogen adsorption isotherm obeyed the Langmuir-type equation at 77 K for PILM, which was pretreated overnight under vacuum (<10^{-1} pa) at 393 K. The surface area of 290 m^2 g^{-1} thus obtained was much larger than the external surface area of 40 m^2 g^{-1}, determined with the α_s-plot.[14] The d-spacing (c_0) of PILM was 1.80 nm, whereas the interlayer spacing was 0.84 nm.[3] This magnitude is acceptable because the pillar diameter is *ca.* 0.9 nm.[10] These results support the view of PILM microporosity, with the structure shown in Fig. 1.

NMR Measurements. 0.4 g (dry basis) of PILM was placed in a Pyrex NMR sample tube (10 mm O. D.) and fixed with a Teflon plug. After the heat treatment at 393 K under vacuum (<10^{-3} Pa) overnight, a given amount of gaseous dosage of ^{13}C-enriched (89%) benzene, supplied from Molécules Marquées France, was introduced to the sample at room temperature; the monolayer capacity of benzene on PILM (1.81 mmol g^{-1} at θ=1) was determined from the adsorption isotherm at 298 K. In order to seal off the sample tube without losing any benzene molecule present in the vapor phase, the sample was frozen with liquid nitrogen.

^{13}C-NMR measurements were carried out at 15.04 MHz using a pulsed Fourier-transform spectrometer (Jeol JNX-FX60Q). The spectra of phisically adsorbed benzene were obtained as easily as liquid benzene with, however, about 100 times broader line width. Spin-lattice relaxation times T_1 were determined by the inversion recovery method following a π-t-$\pi/2$ pulse sequence.[15] Spin-spin relaxation times T_2 were measured by means of the Carr-Purcell-Meiboom-Gill method under conditions of non-spinning and non-^1H-decoupling, which are required for this type of measurements.[16] The absolute value spectra, $(u^2+v^2)^{1/2}$, instead of the conventional absorption ones, v,

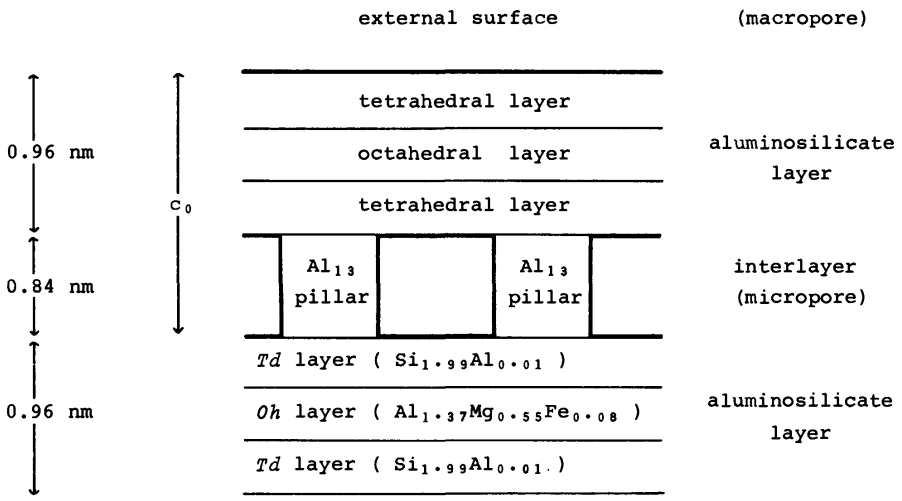

Fig. 1. Schematic view of pillar interlayered montmorillonite (PILM).

were adopted in determining T_2.[17] If not otherwise stated, the longitudinal and transversal relaxation were treated as purely exponential. The sample temperature was stabilized within the range of ±1 K (181—327 K).

Results and Discussion

NOE and Relaxation Mechanism. It was confirmed that the NOE (nuclear Overhauser enhancement) was unity (no enhancement of signal intensity under conditions of ^1H decoupling) for all the studied samples of benzene adsorbed on PILM. This fact clearly indicates that the ^1H-^{13}C dipolar interaction is completely ineffective[18] for the ^{13}C relaxation of the adsorbed benzene. Although high ^{13}C-enrichment in benzene (89%) may bring about the ^{13}C-^{13}C dipolar interaction, this interaction is much weaker than the ^1H-^{13}C dipolar interaction owing to a lower gyromagnetic ratio and a longer internuclear distance. Thus, the dominant mechanism for the relaxation is ascribed to the dipolar interaction with paramagnetic species. This view is supported by the quite high level of Fe^{3+} impurities in the aluminosilicate layer of PILM (13,000 ppm); it was pointed out for propene adsorbed on cation-exchanged X and Y type zeolites that NOE fell down to unity, when the Fe^{3+} content became beyond 700 ppm.[19]

Chemical Shift and Line Width. Figure 2 shows typical temperature dependence of the spectra (θ=0.23) for benzene adsorbed on PILM. Small resonance shift for the adsorbed benzene (about 1 ppm to higher field referred to the liquid) was observed for the adsorption coverage of $0.016 \leqq \theta \leqq 1.0$ within the limits of experimental error (±0.5 ppm). Since the order of magnitude of this shift is covered within the range of necessary corrections for medium effects, no further remarks will be given. It is apparent from Fig. 2 that the higher the temperature is, the narrower the width of the ^{13}C resonance is. This phenomenon is in accord with "motional narrowing",[18] and commonly observed for all other samples (θ=0.016, 1.0, and 1.9).

Figure 3 presents the effect of adsorption coverage (θ) on the spectra at 302 K.

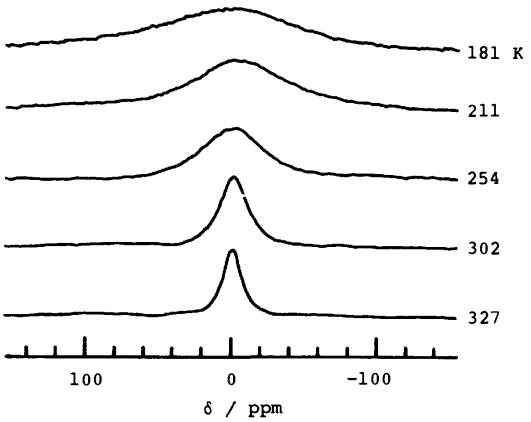

Fig. 2. ^{13}C-NMR spectra of benzene adsorbed on PILM (θ=0.23) as a function of temperature. Resonance frequency: 15.04 MHz. Standard for δ: liquid benzene.

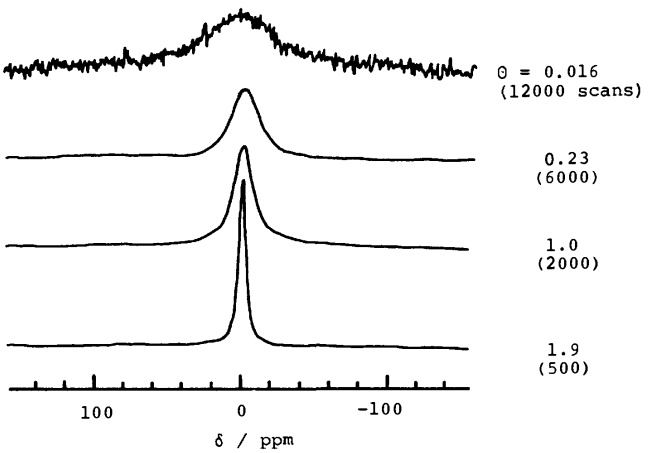

Fig. 3. ^{13}C-NMR spectra of benzene adsorbed on PILM as a function of coverage. Temperature: 302 K. Resonance frequency: 15.04 MHz. Standard for δ: liquid benzene.

The trend of marked broadening of the resonance peak caused by the decrease of θ was noticed at all the

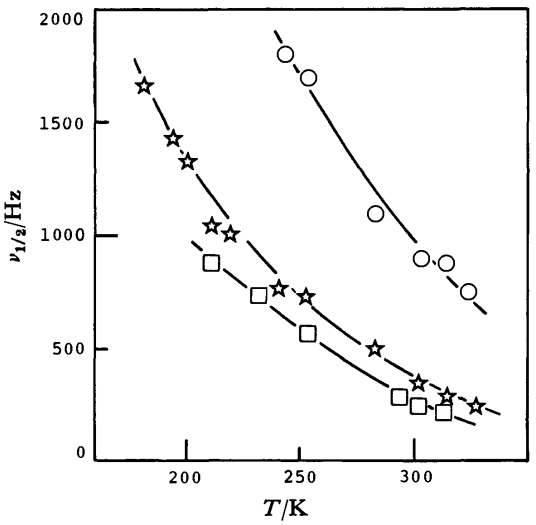

Fig. 4. Temperature dependence of ^{13}C-NMR half-height width ($\nu_{1/2}$) for benzene adsorbed on PILM. ○: θ=0.016, ☆: θ=0.23, □: θ=1.0.

temperature studied. Referred to the temperature dependence described above, the translational motion is considered to become more restricted as θ decreases (*vide infra*). The half-height width data are shown in Fig. 4.

Longitudinal and Transverse Relaxation Times. In order to consider the motional behavior of benzene adsorbed on PILM more precisely, we measured T_1 and T_2 varying both temperature and adsorption coverage θ. At higher coverage (θ=1.0, 1.9) T_1's were determined from the beginning of the decay ($0 \leqq t \leqq 2T_1$), since the relaxation functions were deviated from the exponential type at the later stage of the decay. The results of these measurements are summarized in Fig. 5.

Longitudinal and transverse relaxation times for the dipolar relaxations of ^{13}C near a paramagnetic center are given by[5,6,20,21]

$$\frac{1}{T_1} = \frac{\gamma_I^2\gamma_S^2\hbar^2 S(S+1)}{15r_{IS}^6}\left(\frac{6\tau_c}{1+\omega_I^2\tau_c^2}\right) \quad (1)$$

$$\frac{1}{T_2} = \frac{\gamma_I^2\gamma_S^2\hbar^2 S(S+1)}{15r_{IS}^6}\left(4\tau_c+\frac{3\tau_c}{1+\omega_I^2\tau_c^2}\right) \quad (2)$$

where γ is gyromagnetic ratio, $\omega_I=\gamma_I H_0$ resonance frequency of nuclear spin I, r_{IS} distance between the spins I and S, and τ_c correlation time for the diffusion of the adsorbate (the time between molecular jumps). Eqs. (1) and (2) imply $\omega_S \gg \omega_I$ and $\tau_{Si}(\simeq 10^{-6}\ \mathrm{s}) \gg \tau_c$ (i=1,2), where $\omega_S=\gamma_S H_0$ is resonance frequency of electron spin S and τ_{Si} means the electron spin relaxation time.

Scalar interaction is prohibited, because Fe^{3+} ions are included only in the octahedral layer which is separated from the interlayer (micropore) by the tetrahedral layer.

As revealed in the systematic change of T_1 with adsorption coverage (Fig. 5), the mobility of benzene molecule is more restricted at a given temperature as the coverage is lowered, indicating the presence of strong adsorption sites on PILM. The amount of this site is

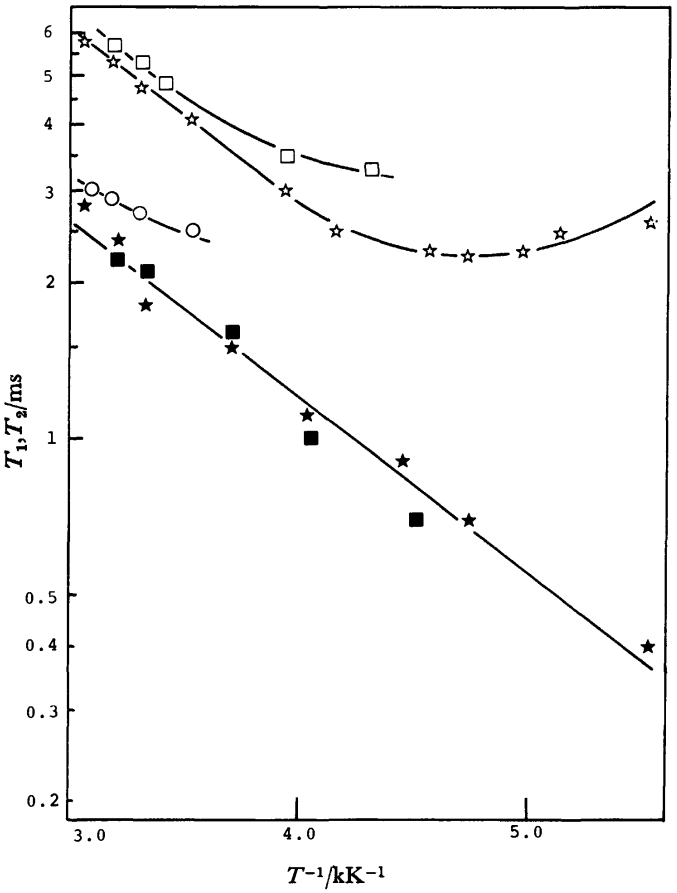

Fig. 5. Temperature dependence of ^{13}C relaxation times of benzene adsorbed on PILM; T_1 and T_2 indicated by open and solid symbols, respectively. ○: θ=0.016, ☆,★: θ=0.23, □,■: θ=1.0.

certainly limited, since the change of T_1 is larger for θ=0.23→0.016 than for θ=1.0→0.23.

A similar behavior was reported for benzene adsorbed on silica gel.[22] However, an inverse trend was pointed out for cyclohexane adsorbed on NaY-zeolite, where intermolecular hindrance between cyclohexane molecules became dominant rather than particular interactions with adsorption sites, as the pore filling factor increased.[21]

Low-temperature T_1 measurements for θ=0.016 and θ=1.0 were encountered with experimental difficulties due to severe line broadening and peak separation (*vide infra*), respectively. However, a rather flat minimum of T_1 is clearly seen for θ=0.23 (Fig. 5), which suggest a distribution of correlation times.[6] Resing showed that many experimental data were put in order by the assumption of correlation times with a logarithmic Gaussian distribution:[5]

$$\tau_c' = \tau_c \exp\{(E'-\langle E\rangle)/RT\}$$

with

$$\tau_c = \tau_0 \exp(\langle E\rangle/RT)$$

and

$$\beta = [2\langle\{(E'-\langle E\rangle)/RT\}^2\rangle]^{1/2}$$

where E' is the activation energy of the motional pro-

cess, $\langle E\rangle$ is the average value of E', R is the gas constant, and T is the absolute temperature. A theoretical curve was given for the relationship between β and the ratio T_1/T_2 at the minimum of T_1.[6] $T_1/T_2=1.83$ corresponds to $\beta=0$ with one correlation time. On the other hand, the value of 3.3 observed in this case leads to $\beta=1.3$, which supports the view that the correlation times are distributed within a certain range. On the basis of $\omega_I\tau_c=1$ at the minimum of T_1, τ_c was obtained as 1.1×10^{-8} s at 210 K.

As shown in Fig. 5, a linear relationship was observed between T_1 or T_2 and the reciprocal absolute temperature in the high temperature range ($\omega_I^2\tau_c^2\ll1$). Since T_1 and T_2 are inversely proportional to τ_c in this region, the activation energy for diffusion $\langle E\rangle$ ($=E$) is therefore able to be determined from the temperature dependence of the relaxation times. From the T_1 measurements for $\theta=0.23$, the value of 6.5 kJ mol^{-1} was obtained. The validity of this value was confirmed, for the same value was obtained from the T_2 measurements in the whole temperature range studied.

Translational Mobilities of Benzene Molecules in the Adsorbed and the Liquid States. Table 1 summarizes translational mobilities of benzene molecules in the adsorbed and the liquid states. Benzene molecules adsorbed on the graphitized carbon black ($\theta=1$) are as mobile as liquid, probably due to the geometrical and electronic similarities between benzene and graphite.[23] Difference in the pre-exponential factor τ_0 may reflect the spatial limitation of motion in the adsorbed state.

Benzene molecules adsorbed in the supercage of NaY-zeolite are known to be extremely restricted in mobility. The adsorption center for benzene has been ascribed to the sodium ions at the S_{II}-sites (maximam number of 4 per supercage).[8,24] As a consequence of mutual hindrance between the adsorbed molecules, E increases with θ, exhibiting the largest E value of 23 kJ mol^{-1} at $\theta=0.83$.[25]

The activation energy of 6.5 kJ mol^{-1} for PILM at $\theta=0.23$ is small, probably because the interaction of benzene with the surface sites is weak comparable to those for B and C sites of silica gel.[27]

On the contrary, the observed pre-exponential factor τ_0 for benzene molecules absorbed on PILM was exceptionally larger than those on silica gel and NaY-zeolite. With regard to NaY-zeolite, a similar value was obtained for cyclohexane (1.5×10^{-12} s) as small as benzene (4.9×10^{-12} s), reflecting its geometrical structure.

The activation energy and the pre-exponential factor of diffusion for benzene adsorbed on NaX-zeolite were reported as 25 ± 7 kJ mol^{-1} and 8.2×10^{-4} cm^2 s^{-1}, respectively.[28]

The pre-exponential factor of the correlation time τ_0 is known to be related to that of diffusion D_0 by

$$\tau_0 = \langle l^2\rangle/6D_0$$

where $\langle l^2\rangle$ is the mean square jump length in diffusion. From the references of τ_0[25] and D_0[28], the value of $(\langle l^2\rangle)^{1/2}$ was deduced to be 1.5 nm, which is reasonable in magnitude from the geometrical viewpoint of NaX and NaY-zeolites. Provided that the magnitude of $\langle l^2\rangle$ of benzene on PILM is similar to that on NaY (NaX)-zeolite, the value of D_0 would become obviously smaller for PILM than for the zeolite. The two-dimensional lamellar structure of PILM seems to afford less chance for the adsorbed molecules to diffuse in contrast to the three-dimensional framework structure of NaY-zeolite.

Adsorption Sites on PILM. Besides the silanol and the abundant siloxane groups, possible candidates to be mentioned as the surface adsorption sites of PILM are as follows: (i) the exchangeable cations such as Na^+ and Ca^{2+} in the interlayer, (ii) the hydroxyl groups on the alumina pillar surface, (iii) the Al^{3+} ions as the substituting elements of the $Si_2O_5^{2-}$ network in the tetrahedral layer, and (iv) Lewis acid sites generated as the oxygen vacancies on the alumina pillar surface. The amounts of the exchangeable cations (i) and the hydroxyl groups on the pillar surface (ii) were estimated as 0.19 and 5 mmol g^{-1}, respectively, whereas the Al^{3+} ions in the tetrahedral layer (iii) amounted only to 0.049 mmol g^{-1}.[3] Since the amount of the strong adsorption sites is a little larger or smaller than $\theta=0.016$ (0.029 mmol g^{-1}) and at least far smaller than $\theta=0.23$ (0.42 mmol g^{-1}) (*vide ante*), the Al^{3+} ions in the tetrahedral layer as well as the oxygen vacancies on the alumina pillar surface introduced by the heat treatment could be the candidates of the strong adsorption sites. It is also highly probable that all these adsorption sites on PILM are related to the distribution pattern of the observed E and τ_c values.

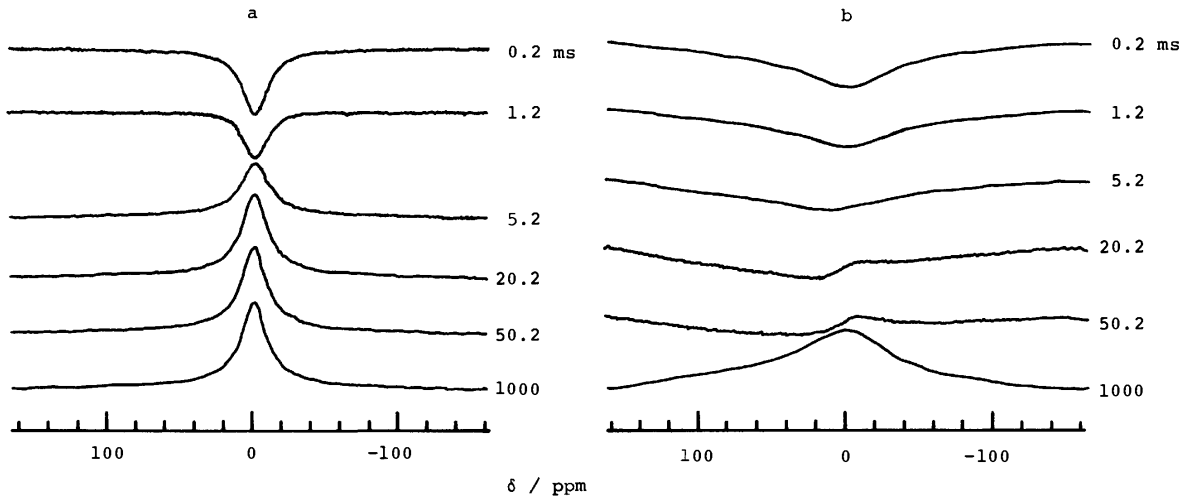

Fig. 6. ^{13}C spin-lattice relaxation spectra of benzene adsorbed on PILM (θ=1.9) at the temperatures of 282 K (a) and 220 K (b).
Resonance frequency: 15.04 MHz. Pulse sequenne: π-t-$\pi/2$. Standard for δ: liquid benzene.

Discrimination of Internal and External Surfaces. For lamellar adsorbents, discrimination of internal surface (micropore) and external surface (macropore) under dynamic conditions is important especially in relation to catalytic properties. Difference in T_1 between the adsorbed states enables peak discrimination in the spin-lattice relaxation spectra, which were observed for the samples with θ=1.0 under 203 K and θ=1.9 under 234 K. Illustrative spectra are presented in Fig. 6 (θ=1.9). It is apparent from Fig. 6 that there exist two peaks with different relaxation rates at 220 K, and that they are coalesced at 282 K into a single peak at the middle position. Accurate chemical shifts were determined from the absolute-value display of the spectra.

The high-field peak ($\delta\simeq-2$ ppm) exhibited shorter T_1 ($\simeq$7 ms) and narrower $\nu_{1/2}$ ($\simeq$1000 Hz) than the low-field peak ($\delta\simeq$8 ppm, $T_1>$100 ms, $\nu_{1/2}\simeq$1700 Hz). We assign the former to benzene molecules adsorbed in the micropore, and the latter to those adsorbed on the external surface on the basis of the following results. In the case of θ=1.0, the intensity of the low-field peak were very similar to those obtained for θ=0.23, whereas the pattern of exceedingly long T_1 and large $\nu_{1/2}$ exhibited in the low-field peak was quite exceptional.

Since long T_1 is indicative of high mobility, the low-field peak is naturally assigned to the external surface adsorption. At higher temperature than 254 K, discrimination of the two adsorbed states became difficult due to the onset of free exchange.

We consider that the NMR spin-lattice relaxation spectra of adsorbed molecules on intercalation compounds are useful to characterize the adsorbate mobility as well as the adsorption sites.

The Theory of Liquid Ion-exchange Membrane Ion-selective Electrodes Based on the Concept of the Mixed Ion-transfer Potential**

Takashi KAKIUCHI and Mitsugi SENDA*
Department of Agricultural Chemistry and Research Center for Cell and Tissue Culture, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606
(Received October 17, 1983)

The theory of liquid ion-exchange membrane ion-selective electrodes has been developed on the basis of the concept of the zero-current potential, or the mixed potential in the presence of interfering ions, of ion transfer at the interface between a liquid membrane and a sample solution. Under the assumptions of the reversible ion transfer at the interface, the presence of supporting electrolytes in both phases, and the monovalency of all relevant ions, theoretical equations for the mixed potential are derived for two cases; the primary and interfering ions have 1) the same charge sign and 2) the opposite sign. The selectivity coefficients of the ion-selective electrodes can be expressed as a function of the difference between the standard ion-transfer potentials of the primary and interfering ions, the ratios of the mass-transfer coefficients of the ions, and the ratios of the concentrations of the ions. The theoretical prediction has been shown to be applicable to an interpretation of the response of liquid-membrane ion-selective electrodes.

The theory of the ion transport in liquid ion-exchange membrane proposed by Sandblom *et al.*[1] has been widely used for the interpretation of the response of ion-selective electrodes with the liquid ion-exchange membrane. This theory can predict the observed linear relationship between the selectivity coefficient of the ion-selective electrodes and the ion-distribution coefficients. However, the theory seems unsuccessful in explaining the observed fact that the experimental selectivity coefficients vary with the experimental conditions under which the selectivity coefficients are determined.[2-5] Such variation of the selectivity coefficients is one of the puzzles in the field of ion-selective electrodes which have not yet been fully solved.[6] Several attempts have been made to interpret this fact in terms of the concentration polarization of the ions in the solution just outside the membrane.[5,7-12] Most of these treatments presume the validity of the basic assumption implied in the Sandblom *et al.* theory,[1] that of the steady state of the ion transport throughout the liquid-membrane. This assumption, however, is not realistic when the membrane is not thin enough, *e.g.*, in the case of the experiments using a U-shaped cell.[13] Moreover, this theory is obviously not applicable to the ion-selective electrodes with a blocked interface, *e.g.*, coated wire electrodes.[14]

When a relatively thick membrane is brought into contact with a sample solution, the compositions of the inner solution and of the membrane in the vicinity of the membrane-inner solution interface or membrane-electronic conductor interface would remain unchanged unless a sufficiently long time elapses, while the compositions in the vicinity of the membrane-sample solution interface generally change with the time due to the ion-transfer reactions across the interface, resulting in the concentration polarization on both sides of the interface. Therefore, it seems necessary to examine the ion-transfer processes occurring at the membrane-sample solution interface for the understanding of the response of the liquid-membrane ion-selective electrodes.

In the last decade, ion transfer processes between two immiscible electrolyte solutions have been intensively studied using various electrochemical techniques.[15] Since the solvents used for liquid membranes are usually only poorly miscible with aqueous solutions and since the interface between them can be considered as an interface between two immiscible electrolyte solutions, the electrochemistry of the ion transfer at such interfaces has an immediate significance in elucidating the ion-transfer processes occurring at the membrane-solution interface of ion-selective electrodes of the liquid-membrane type. Cammann[16] first suggested the importance of the mixed potential concept[17] at the membrane-solution interface. Koryta[18] has pointed out that the current *vs.* potential curves of the ion transfer at the membrane-solution interface are of fundamental importance in interpreting the response of the ion-selective electrodes and showed that the Nernstian, sub-Nernstian, and super-Nernstian responses can be deduced from the zero current potential of the appropriate "anodic and cathodic waves" of the ion transfers of the relevant ions. Fujinaga and his co-workers[19,20] have advanced this approach and applied it to several types of ion-selective electrodes.

The aim of this study is to present a quantitative theory of the zero-current potential of ion transfer, which we call the mixed potential of ion-transfer in the case of the presence of interfering ions, at the interface between a liquid membrane and a sample solution, and to apply the theory to the interpretation of the response of the ion-selective electrodes with the liquid ion-exchange membrane. The mixed ion-transfer potential can be easily formulated using the current *vs.* potential curves for the transfer of primary and interfering ions when the supporting electrolytes exist in both the liquid membrane and the sample solution. The model system consisting of a liquid membrane and a sample solution, both containing supporting electrolytes, provides us with the characteristics of the ion distribution

** The main results of the present paper were presented at the 28th Annual Meeting on Polarography, November 11—12, 1982, Sapporo.[31]

processes with mass transfer *per si* at the membrane-solution interface, knowledge which seems essential for understanding the response of the liquid-membrane ion-selective electrodes to various ionic species. The ion-transfer processes at the membrane-sample solution interface should play an essential role in determining the potential response also in the liquid-membrane ion-selective electrode of the type with no such supporting electrolyte, like most of the ion-selective electrodes with liquid ion-exchangers so far studied. The ion-transfer processes are also important in the solid-membrane ion-selective electrodes.

Theoretical

We consider a liquid-membrane ion-selective electrode immersed in a sample solution. The electrochemical cell thus formed may be represented by:

Ref. 1	Liquid Membrane	Sample Solution	Ref. 2	(I)

where Ref. 1 and Ref. 2 are the reference electrodes. Ref. 2 may be a conventional reference electrode, whereas Ref. 1 may consist of an internal solution with a conventional reference electrode, or it may be an electronic conductor in the case of a coated wire electrode. Below, we assume that the potential difference between Ref. 1 and the membrane and that between the sample solution and Ref. 2 are invariant, irrespective of the composition of the membrane and of the sample solution.

When a liquid membrane and a sample solution, both containing electrolytes, are brought into contact to form a membrane-solution interface, ions will generally move across the interface according to the difference in their electrochemical potentials in the two phases. The transfer of ions across the interface is associated with the flow of the current. The net ion-transfer current I across the interface is the sum of the partial ion-transfer currents, I_j, due to the transfer of the j ion across the interface:

$$I = \sum_j I_j \tag{1}$$

The potential of an ion-selective electrode is usually measured under zero-current conditions:

$$I = \sum_j I_j = 0 \tag{2}$$

The inner potential of the sample solution phase, referred to that of the membrane phase, *i.e.*, the liquid junction potential between the two phases, at zero current, $\Delta_O^W\varphi(I=0)$, may generally be composed of an interfacial potential and two diffusion potentials:

$$\Delta_O^W\varphi(I=0) = \Delta\varphi_{diff}^0(I=0) + \Delta_O^W\varphi_{Interfacial}(I=0) + \Delta\varphi_{diff}^W(I=0) \tag{3}$$

In Eq. 3, $\Delta_{diff}^\alpha\varphi(I=0)$ is the diffusion potential in the α phase(α=O or W), where the superscripts O and W denote the membrane and solution phases respectively, and where $\Delta_O^W\varphi_{interfacial}(I=0)$ is the interfacial potential, which is also called the "phase-boundary potential"[21] or the "Donnan potential".[22] The interfacial potential is determined by the kinetics of ion transfer, which is represented by I_j and which is generally different from the interfacial potential at the distribution equilibrium at which all I_j's are zero and the interfacial potential is identical with the distribution potential.[23] When the partial ion-transfer current is not zero, the diffusion potentials are generally present, even at I=0.

The potential of an ion-selective electrode in the cell(I) at zero current, $E(I=0)$, is related to the liquid-junction potential, $\Delta_O^W\varphi(I=0)$, by:

$$E(I=0) = E_{mix} = \Delta_O^W\varphi(I=0) + \Delta E_{ref} \tag{4}$$

where $E(I=0)$ is the potential of Ref. 2 with respect to Ref. 1 in the cell(I) at I=0 and is identical with the mixed ion-transfer potential, E_{mix}, in the presence of interfering ions, and where ΔE_{ref} is the potential difference associated with the reference electrodes in the cell(I), which may include possible liquid-junction potentials at the sample solution-reference electrode and the membrane-reference electrode junctions. We will confine the following treatment to the cases where both the membrane and the sample solution contain a sufficient amount of the supporting electrolytes, so that the migration of the ions becomes negligible. This condition also ensures that the two diffusion potential terms in Eq. 3 are negligibly small;[24] hence:

$$\Delta_O^W\varphi(I=0) \fallingdotseq \Delta_O^W\varphi_{Interfacial}(I=0) \tag{5}$$

We assume that the rate of the transfer of ions across the interface is so fast that the Nernst equation:

$$\Delta_O^W\varphi_{Interfacial} = \Delta_O^W\varphi_j^0 + \frac{RT}{z_jF}\ln\frac{\gamma_j^{W,0}}{\gamma_j^{O,0}} + \frac{RT}{z_jF}\ln\frac{c_j^{W,0}}{c_j^{O,0}} \tag{6}$$

holds for every ion passing through the interface, *i.e.*, that the ion-transfer processes are reversible or Nernstain. In Eq. 6, $\Delta_O^W\varphi_j^0$ is the standard potential of the ion transfer of the ion j from the membrane phase to the sample solution phase;[23] z_j is the electric charge of the ion j; $c_j^{\alpha,0}$(α=O or W) is the surface concentration of the ion j, which is usually considered as the concentration of the ion j just outside the diffuse double layer in the phase α,[25] and $\gamma_j^{\alpha,0}$(α=O or W) is the corresponding activity coefficient of the ion j. R, T, and F have the usual meanings. We also assume that the diffusion coefficients of the ions are independent of the ion concentrations.

When the membrane is so thick that the ion transfer in the membrane phase as well as that in the solution phase meet the condition of semi-infinite mass transfer, the partial current I_j due to the transfer of the ion j through the interface can be written as:

$$\frac{I_j}{z_jFA} = \frac{D_j^W}{\delta_j^W}(c_j^W - c_j^{W,0}) = k_j^W(c_j^W - c_j^{W,0}) \tag{7}$$

$$= -\frac{D_j^O}{\delta_j^O}(c_j^O - c_j^{O,0}) = -k_j^O(c_j^O - c_j^{O,0}) \tag{8}$$

where A is the surface area of the interface; D_j^α, δ_j^α and k_j^α are the diffusion coefficient, the diffusion layer thickness, and the mass-transfer coefficient of the ion j in the phase α(α=O or W) respectively, and c_j^α is the concentration of the ion j in the bulk of the phase α(α=O or W) δ_j^O and δ_j^W have the forms of $1/(\pi D_j^O t)^{1/2}$ and $1/(\pi D_j^W t)^{1/2}$ respectively in the case of a semi-infinite linear diffu-

sion of the ions at a stationary planar interface, where t is the time elapsed from the instant of the contact of the membrane with the sample solution. In Eqs. 7 and 8, the sign of the current is taken as positive(negative) when the positively(negatively) charged ion transfers from the sample solution to the membrane. Equations 7 and 8 hold also in the presence of the convective transport of ions if one chooses appropriate expressions for δ_j^0 and δ_j^W. From Eqs. 6—8 we obtain the equation of a current *vs.* potential curve for the reversible transfer of the ion j through the interface:

$$I_j = \frac{I_{j,\mathrm{lim}}^{\mathrm{o}} + I_{j,\mathrm{lim}}^{\mathrm{w}} \exp(f_j)}{1+\exp(f_j)} \tag{9}$$

where

$$f_j = \frac{z_j F}{RT}(E - E_{1/2,j}^{\mathrm{r}}) \tag{10}$$

and where $I_{j,\mathrm{lim}}^{\alpha}(\alpha = \mathrm{W}$ or $\mathrm{O})$ is the limiting current for the transfer of the ion j from the phase α to the other; it is defined by

$$\frac{I_{j,\mathrm{lim}}^{\mathrm{w}}}{z_j F A} = k_j^{\mathrm{w}} c_j^{\mathrm{w}} \tag{11}$$

and

$$\frac{I_{j,\mathrm{lim}}^{\mathrm{o}}}{z_j F A} = -k_j^{\mathrm{o}} c_j^{\mathrm{o}} \tag{12}$$

In Eq. 10, E is the potential of Ref 2 with respect to Ref 1 in the cell(I), while $E_{1/2,j}^{\mathrm{r}}$ is the reversible half-wave potential of the transfer of the ion j and is defined by

$$E_{1/2,j}^{\mathrm{r}} = \Delta_{\mathrm{o}}^{\mathrm{w}}\varphi_j^0 + \frac{RT}{z_j F} \ln \frac{\gamma_j^{\mathrm{w},0} k_j^{\mathrm{w}}}{\gamma_j^{\mathrm{o},0} k_j^{\mathrm{o}}} + \Delta E_{\mathrm{ref}} \tag{13}$$

By substituting Eq. 9 into Eq. 2, we obtain:

$$\sum_j \frac{I_{j,\mathrm{lim}}^{\mathrm{o}} + I_{j,\mathrm{lim}}^{\mathrm{w}} \exp(f_j^0)}{1+\exp(f_j^0)} = 0 \tag{14}$$

where f_j^0 is the f_j at $I=0$. The potential which satisfies Eq. 14, *i.e.*, $E(I=0)$, gives the zero-current ion-transfer potential, or the mixed ion-transfer potential in the case of simultaneous ion transfers of more than two ions.

Below we will consider the mixed ion-transfer potential and the selectivity coefficient for two cases, *i.e.*, the primary and interfering ions have (1) the same charge sign and (2) the opposite charge sign. It is assumed that the electrolytes are completely dissociated in both the membrane and the sample solution, that all the ions are monovalent, and that $\gamma_j^{\mathrm{o},0} = \gamma_j^{\mathrm{w},0} = 1$.

Primary and Interfering Ions with the Same Charge Sign. Consider the case where the membrane that contains three cations, K1, K2, and K4, and an anion, A4, is brought into contact with a sample solution containing two cations, K1 and K3, and an anion, A3. Then, the electrochemical cell can be represented by

Ref. 1	K1 K3, A3	K1, K2 K4, A4	Ref. 2	(II)
	Membrane	Sample solution		

Suppose also that, among these ions, only K1 and K2 ions can pass through the interface. Such a condition may be fulfilled when the values of the standard ion-transfer potentials for K3 and A4, $\Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K3}}^0$ and $\Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K4}}^0$, are very negative, while those of K4 and A3, $\Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K4}}^0$ and $\Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K3}}^0$, are very positive, compared with those of K1 and K2, $\Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K1}}^0$ and $\Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K2}}^0$. If we regard K1 and K2, as a primary ion and an interfering ion respectively, the electrolytes, K3A3 in the membrane and K4A4 in the sample solution, may be considered to be supporting electrolytes.

The current *vs.* potential curve for the transfer of K1 is schematically represented by Curve 1 in Fig. 1. If $\Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K2}}^0 \gg \Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K1}}^0$, the partial ion-transfer current of K2, I_{K2}, is negligibly small around the equilibrium potential of K1, as is shown by Curve 2 in Fig. 1. Then, the potential where the current I becomes zero corresponds to the equilibrium potential for the distribution of K1 between the two phases:

$$E(I=0) = \Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K1}}^0 - \frac{RT}{F} \ln (c_{\mathrm{K1}}^{\mathrm{W}}/c_{\mathrm{K1}}^{\mathrm{O}}) + \Delta E_{\mathrm{ref}} \tag{15}$$

When the value of the standard ion-transfer potential of K2 is close to that of K1, as shown by Curve 3 in Fig. 1, the potential at zero current deviates from the equilib-

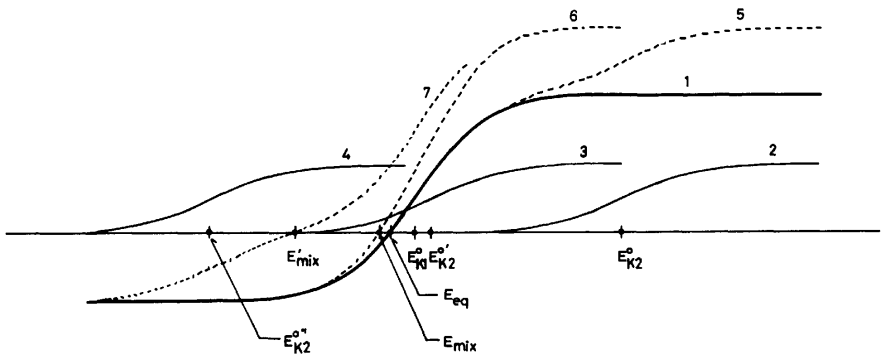

Fig. 1. Schematic representation of current *vs.* potential curves for the ion transfers between a liquid membrane and a sample solution for a primary ion K1 (curve 1), for an interfering ion K2 when $\Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K2}}^0 \gg \Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K1}}^0$(2), for K2 when $\Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K2}}^0 \fallingdotseq \Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K1}}^0$(3), and for K2 when $\Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K2}}^0 \ll \Delta_{\mathrm{O}}^{\mathrm{W}}\varphi_{\mathrm{K1}}^0$(4). Curves 5, 6, and 7 show the total current *vs.* potential curves when the partial currents for K2 are given by (2), (3), and (4), respectively. Standard ion transfer potentials and the mixed ion transfer potentials are indicated on the potential axis.

rium potential of Eq. 15 to the negative direction because of the deformation of the total current *vs.* potential curve (Curve 6 in Fig. 1). Accordingly, the potential at zero current is not the equilibrium potential, but an mixed ion-transfer potential, E_{mix}, in which the ion transfers of both K1 and K2 participate. When $\Delta^{W}_{O}\varphi^{0}_{K2} \ll \Delta^{W}_{O}\varphi^{0}_{K1}$, the interference by the K2 ion becomes enormous, as is shown by Curve 7 in Fig. 1.

From Eq. 14, the mixed ion-transfer potential for the cell(II) is given by

$$E_{mix} = E^{0}_{K1} + \frac{RT}{F}\ln J \tag{16}$$

where

$$J = \frac{1}{2}[-(A+B\xi)+\{(A+B\xi)^2+C\xi\}^{1/2}] \tag{17}$$

$$\xi = \exp\left[\frac{F}{RT}\Delta E^{0}_{K2,K1}\right] \tag{18}$$

$$A = \left(\frac{k^{W}_{K2}}{k^{O}_{K1}}\frac{c^{W}_{K2}}{c^{W}_{K1}} - \frac{c^{O}_{K1}}{c^{W}_{K1}}\right)\Big/\left(1+\frac{k^{W}_{K2}}{k^{W}_{K1}}\frac{c^{W}_{K2}}{c^{W}_{K1}}\right) \tag{19}$$

$$B = \frac{k^{W}_{K2}}{k^{O}_{K2}}\Big/\left(1+\frac{k^{W}_{K2}}{k^{W}_{K1}}\frac{c^{W}_{K2}}{c^{W}_{K1}}\right) \tag{20}$$

$$C = 4\frac{k^{W}_{K2}}{k^{O}_{K2}}\frac{c^{O}_{K1}}{c^{W}_{K1}}\Big/\left(1+\frac{k^{W}_{K2}}{k^{W}_{K1}}\frac{c^{W}_{K2}}{c^{W}_{K1}}\right) \tag{21}$$

and

$$E^{0}_{K1} = \Delta^{W}_{O}\varphi^{0}_{K1} + \Delta E_{rlf}$$

In Eq. 18, $\Delta E^{0}_{K2,K1}$ is defined by

$$\Delta E^{0}_{K2,K1} = \Delta^{W}_{O}\varphi^{0}_{K2} - \Delta^{W}_{O}\varphi^{0}_{K1} \tag{22}$$

Usually, the selectivity of ion-selective electrodes for the ion i over the ion j is evaluated through the selectivity coefficient, $k^{pot}_{i,j}$, defined by the Nicolsky equation,[26] which may be written for the present case as:

$$E = E^{0}_{K1} - \frac{RT}{F}\ln\frac{c^{W}_{K1}+k^{pot}_{K1,K2}c^{W}_{K2}}{c^{O}_{K1}} \tag{23}$$

We have introduced the c^{O}_{K1} term in the denominator of the argument of the logarithm in Eq. 23 in order for the limiting behavior of E at infinitely small $k^{pot}_{K1,K2}$ values or at infinitely small c^{W}_{K2} values to coincide with that of Eq. 15. By equating E of Eq. 23 with E_{mix} of Eq. 16, one obtains

$$k^{pot}_{K1,K2} = (c^{W}_{K1}/c^{W}_{K2})(c^{O}_{K1}/c^{W}_{K1}-J)/J \tag{24}$$

Equations 16—24 are applicable to the cases where the primary ion as well as the interfering ion are anions, A1 and A2, in place of K1 and K2 in the cell(II), if one replaces, respectively, the subscripts K1 and K2 with A1 and A2, and if

$$\xi=\exp[(F/RT)\Delta E^{0}_{K2,K1}] \text{ and } \Delta E^{0}_{K2,K1} = \Delta^{W}_{O}\varphi^{0}_{K2}-\Delta^{W}_{O}\varphi^{0}_{K1}$$

with

$$\xi=\exp[(F/RT)\Delta E^{0}_{A1,A2}] \text{ and } \Delta E^{0}_{A1,A2} = \Delta^{W}_{O}\varphi^{0}_{A1}-\Delta^{W}_{O}\varphi^{0}_{A2}$$

in these equations.

Primary and Interfering Ions with the Opposite Charge Sign. When the interfering ion has a charge whose sign is opposite to that of the primary ion, the response of the ion-selective electrodes is significantly different from the cases described above. Let us first consider the case in which the primary ion and the interfering ion are a cation K1 and an anion A2 respectively. In this case, the cell may be represented by:

Ref. 1	K1 / K3, A3 (Membrane)	K1, A2 / K4, A4 (Sample solution)	Ref. 2	(III)

Figure 2 schematically represents the effect of the interfering anion A2 on the current *vs.* potential curve of the primary ion K1. When $\Delta^{W}_{O}\varphi^{0}_{A2} \ll \Delta^{W}_{O}\varphi^{0}_{K1}$ (Curve 2), there is no significant interference. The interference becomes appreciable, however, when $\Delta^{W}_{O}\varphi^{0}_{A2}$ is close to $\Delta^{W}_{O}\varphi^{0}_{K1}$, as is shown by Curve 5 in Fig. 2. In contrast to

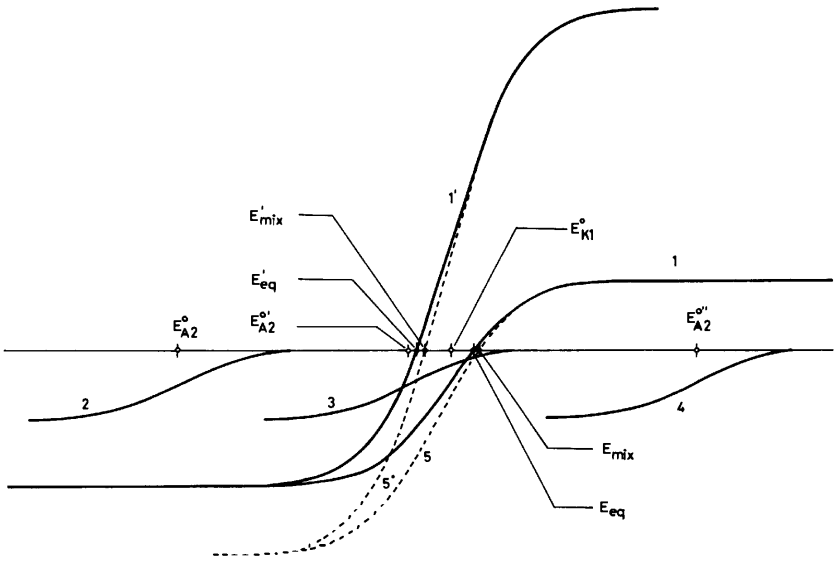

Fig. 2. Schematic representation of current *vs.* potential curves when an interfering ion is an anion A2: the curves for K1 (curves 1 and 1'), for A2 when $\Delta^{W}_{O}\varphi^{0}_{A2} \ll \Delta^{W}_{O}\varphi^{0}_{K1}$(2), $\Delta^{W}_{O}\varphi^{0}_{A2} \fallingdotseq \Delta^{W}_{O}\varphi^{0}_{K1}$(3), and $\Delta^{W}_{O}\varphi^{0}_{A2} \gg \Delta^{W}_{O}\varphi^{0}_{K1}$(4). Curves 1' represents the current potential curve when c^{W}_{K1} is four times larger than that of curve 1. Curves 5 and 5' are the total current *vs.* potential curves for these two cases.

the interference by a cation K2, the presence of the interfering anion shifts the zero-current ion-transfer potential to the positive direction (Curve 5 in Fig. 2). Another distinctive feature of the anion interference is that the degree of the interference becomes greater with the increase in c^{W}_{K1} at a given concentration of A2 in the sample solution, as can be seen from a comparison of Curve 5 with 5′ and of E_{mix} with E'_{mix} in Fig. 2.

Equations 16 and 17 are also valid for the mixed ion-transfer potential for the cell (III), if one defines the terms ξ, A, B, and C in Eqs. 16 and 17 as follows:

$$\xi = \exp\left[\frac{F}{RT}\Delta E^{0}_{A2,K1}\right] \tag{25}$$

$$A = -\frac{c^{O}_{K1}}{c^{W}_{K1}} \tag{26}$$

$$B = \frac{k^{O}_{A2}}{k^{W}_{A2}}\left(1-\frac{k^{W}_{A2}}{k^{W}_{K1}}\frac{c^{W}_{A2}}{c^{W}_{K1}}\right) \tag{27}$$

$$C = 4\left(\frac{k^{O}_{A2}}{k^{O}_{K1}}\frac{c^{W}_{A2}}{c^{W}_{K1}}+\frac{k^{O}_{A2}}{k^{W}_{A2}}\frac{c^{O}_{K1}}{c^{W}_{K1}}\right) \tag{28}$$

where

$$\Delta E^{0}_{A2,K1} = \Delta^{W}_{O}\varphi^{0}_{A2} - \Delta^{W}_{O}\varphi^{0}_{K1} \tag{29}$$

Equations 16, 17, and 25—29 are applicable to the cases where the primary ion is an anion A1 and the interfering ion is a cation K2, in place of K1 and A2 in the cell (III), if one replaces, respectively, the subscripts K1 and A2 with A1 and K2, and if $\xi=\exp[(F/RT)\Delta E^{0}_{A2,K1}]$ and $\Delta E^{0}_{A2,K1}=\Delta^{W}_{O}\varphi^{0}_{A2}-\Delta^{W}_{O}\varphi^{0}_{K1}$ with $\xi=\exp[(F/RT)\Delta E^{0}_{A1,K2}]$ and $\Delta E^{0}_{A1,K2}=\Delta^{W}_{O}\varphi^{0}_{A1}-\Delta^{W}_{O}\varphi^{0}_{K2}$ in these equations.

Discussion

Equations 16—22 explicitly relate the mixed ion-transfer potential with the various parameters: the difference between the standard ion-transfer potentials for K1 and K2, $\Delta E^{0}_{K2,K1}$; the ratios of the mass-transfer coefficients, k^{O}_{K1}/k^{W}_{K1}, k^{O}_{K2}/k^{W}_{K2}, and k^{W}_{K2}/k^{W}_{K1}, and the ratios of the concentrations, c^{W}_{K2}/c^{W}_{K1} and c^{O}_{K1}/c^{W}_{K1}. E_{mix} is solely determined by the properties of the primary and interfering ions as well as by those of the two solvents and has nothing to do with the nature of the A3 ion, which is usually called the liquid "ion-exchanger" in the membrane. Therefore, for the ion-selective electrode of the type represented by the cell (II) (and also (III)), the term liquid "ion-exchanger" membrane is obviously inadequate.

Figure 3 shows the mixed ion-transfer potentials as a function of c^{W}_{K2}/c^{W}_{K1} at different values of $\Delta E^{0}_{K2,K1}$ and at $c^{O}_{K1}/c^{W}_{K1}=1$, $k^{W}_{K1}/k^{O}_{K1}=k^{W}_{K2}/k^{O}_{K2}=\sqrt{2}$, and $k^{W}_{K2}/k^{W}_{K1}=1$. This figure indicates that E_{mix} shows a Nernstian response to c^{W}_{K1} at the higher values of c^{W}_{K1} at given values of c^{W}_{K2} and c^{O}_{K1}, but E_{mix} deviates from the Nernstian slope at the lower values of c^{W}_{K1}. The interference of K2 becomes significant as the difference between the standard ion-transfer potentials for K1 and K2 becomes negative.

Equation 24 expresses $k^{pot}_{K1,K2}$ as a function of the difference between the standard ion-transfer potentials of the ions K1 and K2, $\Delta E^{0}_{K2,K1}$; the concentration ratios, c^{W}_{K2}/c^{W}_{K1} and c^{O}_{K1}/c^{W}_{K2}, and the ratios of the mass-transfer

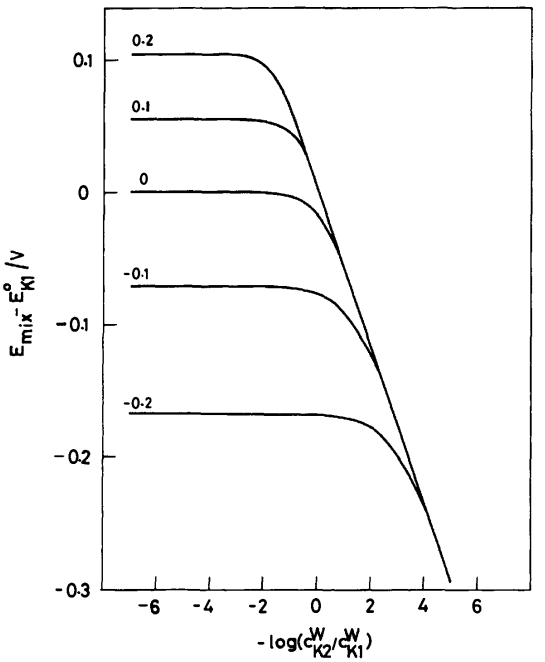

Fig. 3. Dependence of mixed ion transfer potentials on $\log(c^{W}_{K2}/c^{W}_{K1})$ at $k^{W}_{K1}/k^{W}_{K1}=k^{O}_{K2}/k^{W}_{K2}=\sqrt{2}$, $k^{W}_{K2}/k^{W}_{K1}=1$ and $c^{O}_{K1}/c^{W}_{K1}=1$ calculated from Eq. 16. Labels indicate the values of $\Delta E^{0}_{K2,K1}$.

coefficients, k^{O}_{K1}/k^{W}_{K1}, k^{O}_{K2}/k^{W}_{K2}, and k^{W}_{K2}/k^{W}_{K1}; the selectivity coefficient depends upon these parameters. Among these factors, the difference in the standard ion-transfer potentials $\Delta E^{0}_{K2,K1}$ is intrinsic for a given set of ions and solvents, whereas the ratios of the maas-transfer coefficients and of the concentrations vary with the experimental conditions. When there is no convective transport of the ions, the ratio of the mass-transfer coefficients is reduced to the square root of the ratio of the diffusion coefficients, for example, $k^{O}_{K1}/k^{W}_{K1}=(D^{O}_{K1}/D^{W}_{K1})^{1/2}$; then the ratios of the mass-transfer coefficient are also constants for a given set of ions and solvents.

The values of $k^{pot}_{K1,K2}$ were calculated from Eq. 24 and are plotted in Fig. 4 as a function of $\Delta E^{0}_{K2,K1}$ at different values of k^{W}_{K2}/k^{W}_{K1} when $k^{O}_{K1}/k^{W}_{K1}=k^{O}_{K2}/k^{W}_{K2}=\sqrt{2}$ and $c^{O}_{K1}/c^{W}_{K1}=c^{W}_{K2}/c^{W}_{K1}=1$. When the value of k^{W}_{K2}/k^{W}_{K1} is larger than unity, the logarithm of $k^{pot}_{K1,K2}$ changes almost linearly with $\Delta E^{0}_{K2,K1}$. On the other hand, when k^{W}_{K2}/k^{W}_{K1} is less than unity, the plots deviate from the straight lines at large negative values of $\Delta E^{0}_{K2,K1}$. The approximate linear relationship between $\log k^{pot}_{K1,K2}$ and $\Delta E^{0}_{K2,K1}$ in the positive range of $\Delta E^{0}_{K2,K1}$ at the lower values of k^{W}_{K2}/k^{W}_{K1} and in both the positive and negative ranges of $\Delta E^{0}_{K2,K1}$ at higher values of k^{W}_{K2}/k^{W}_{K1} is in line with the experimental finding that the logarithm of the selectivity coefficients of the liquid ion-exchange membrane electrodes correlates linearly with the logarithm of the ion-exchange equilibrium constants.[11]

Figure 4 shows that the selectivity coefficient depends markedly on the value of k^{W}_{K2}/k^{W}_{K1}, especially at the

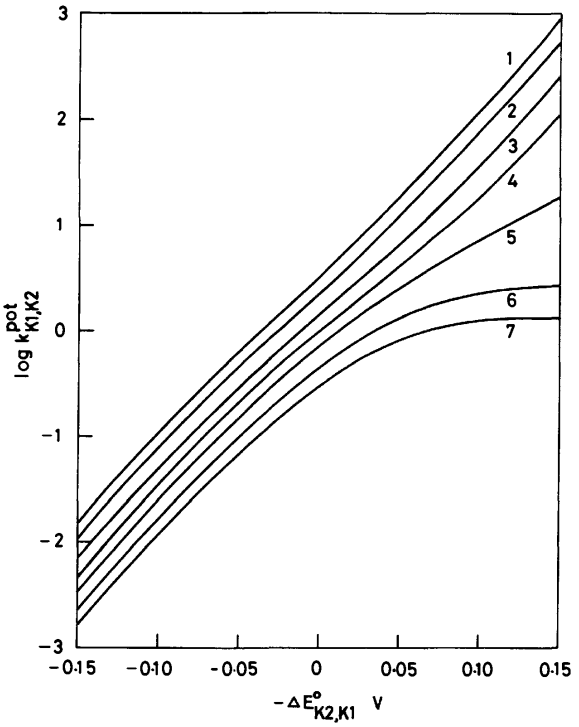

Fig. 4. $\log(k^{pot}_{K1,K2})$ *vs.* $\Delta E^{0}_{K2,K1}$ curves at $k^{w}_{K2}/k^{w}_{K1}=\sqrt{10}$ (curve 1), $\sqrt{5}$ (2), $\sqrt{2}$ (3), 1(4), $\sqrt{0.5}$(5), $\sqrt{0.2}$(6), and $\sqrt{0.1}$(7), when $k^{o}_{K1}/k^{w}_{K1}=k^{o}_{K2}/k^{w}_{K2}=\sqrt{2}$ and $c^{w}_{K2}/c^{w}_{K1}=c^{o}_{K1}/c^{w}_{K1}=1$, calculated from Eq. 24.

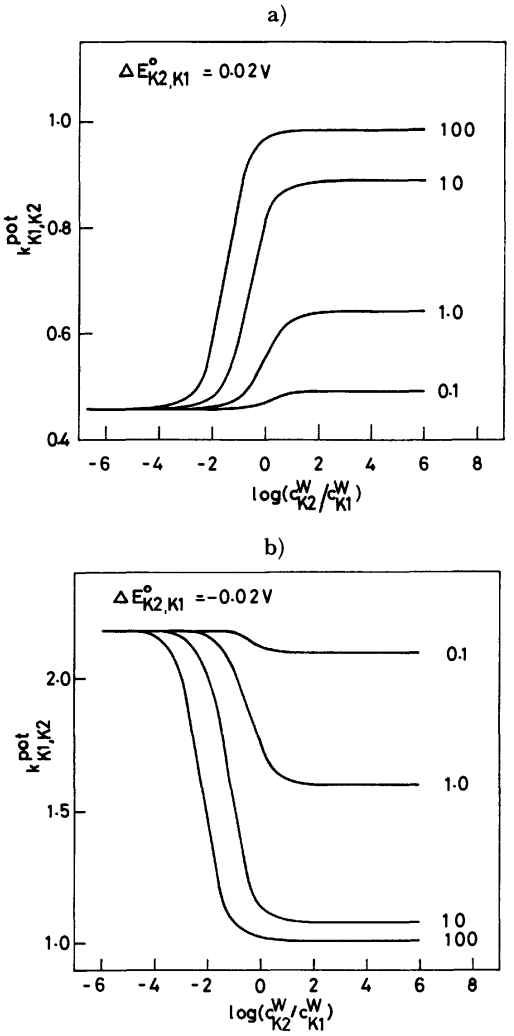

Fig. 5. Change of $k^{pot}_{K1,K2}$ with $\log(c^{w}_{K2}/c^{w}_{K1})$ calculated from Eq. 24 for $\Delta E^{0}_{K2,K1}=0.02$ V (Fig. 5a) and -0.02 V (Fig. 5b). Labels indicate the values of c^{o}_{K1}/c^{w}_{K2}.

negative extreme of $\Delta E^{0}_{K2,K1}$. This means that, in the absence of convection in both the membrane and the sample solution, the selectivity coefficient depends upon the relative magnitude of the diffusion coefficients of the primary and interfering ions. The dependence of the mixed potential and the selectivity coefficient on the ratio of the mass-transfer coefficients accounts for the effect of the convection on the potential response and the value of the selectivity coefficient of the ion-selective electrodes. The effect of stirring the sample solutions on the potential response of the ion-selective electrodes has been reported.[27] The often observed irreproducible values of the experimental selectivity coefficients may be attributed to such an effect of the mass-transfer coefficients on the selectivity coefficients, since the mass-transfer coefficient is generally not well reproducible under natural convection, which can be caused by the density gradient, accompanied by ion transfers across the membrane-solution interface.

The dependence of $k^{pot}_{K1,K2}$ on the concentration ratios, c^{w}_{K2}/c^{w}_{K1} and c^{o}_{K1}/c^{w}_{K2}, at several values of c^{o}_{K1}/c^{w}_{K2} was calculated from Eq. 24 for $\Delta E^{0}_{K2,K1}=0.02$ V (Fig. 5a) and -0.02 V (Fig. 5b). These conditions correspond to those in experiments for the determination of the selectivity coefficients using the procedure in which the concentration of the primary ion in the sample solution is changed while keeping the concentration of the primary ion in the membrane and that of the interfering ion in the sample solution constant.[26] Figures 5a and 5b show that the value of $k^{pot}_{K1,K2}$ depends markedly upon both c^{w}_{K2}/c^{w}_{K1} and c^{o}_{K1}/c^{w}_{K2}, except at the small extreme of c^{w}_{K2}/c^{w}_{K1}. The trend of the change in the $k^{pot}_{K1,K2}$ value depends upon the sign of $\Delta E^{0}_{K2,K1}$. For a positive value of $\Delta E^{0}_{K2,K1}$, $k^{pot}_{K1,K2}$ increases with the increae in c^{w}_{K2}/c^{w}_{K1}, whereas it decreases with the increase in c^{w}_{K2}/c^{w}_{K1} for a negative value of $\Delta E^{0}_{K2,K1}$. In both cases, the larger the value of c^{o}_{K1}/c^{w}_{K2}, the greater the change in $k^{pot}_{K1,K2}$ with the change in c^{w}_{K2}/c^{w}_{K2}. At the large extreme of c^{w}_{K2}/c^{w}_{K1}, $k^{pot}_{K1,K2}$ reaches a constant value whose magnitude depends upon c^{o}_{K1}/c^{w}_{K2}. These figures clearly illustrate that the experimental $k^{pot}_{K1,K2}$ values can vary with the experimental conditions.[2-6] For example, the selectivity coefficients are often determined from the intersection of the extrapolation of the two linear portions of a curve similar to those shown in Fig. 3.[28] This $k^{pot}_{K1,K2}$ value corresponds to the limiting value of $k^{pot}_{K1,K2}$ at the large extreme of c^{w}_{K2}/c^{w}_{K1} in Figs. 5a and 5b, that is, at the infinitely small concentration of the primary ion. This means that, at a given value of c^{o}_{K1}, the selectivity coefficient depends on the concentration level of the interfering ion in the sample solution.[6] The theoretical prediction of the dependence of the selectivity coefficient

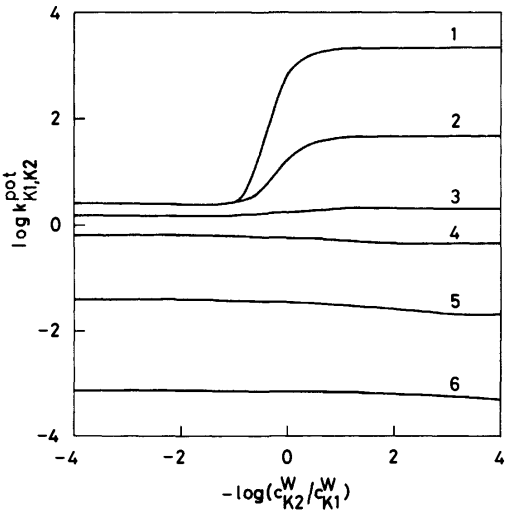

Fig. 6. $\log(k^{pot}_{K1,K2})$ *vs.* $\log(c^W_{K2}/c^W_{K1})$ curves calculated from Eq. 24 at $\Delta E^0_{K2,K1}=-0.2(1)$, $-0.1(2)$, $-0.02(3)$, $0.02(4)$, $0.1(5)$, and $0.2\,V(6)$, when $k^W_{K1}/k^0_{K1}=\sqrt{2}$, $k^W_{K2}/k^W_{K1}=1$ and $c^0_{K1}/c^W_{K1}=1$.

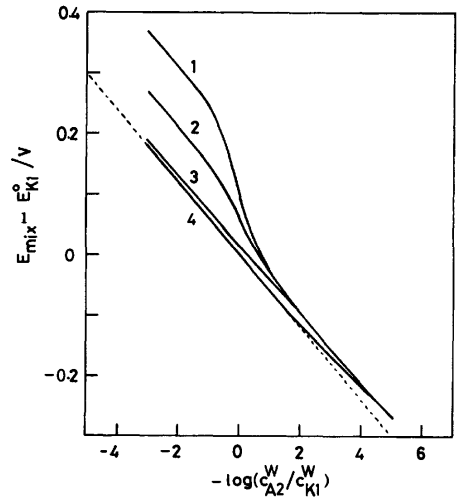

Fig. 7. Variation of E_{mix} with $\log(c^W_{A2}/c^W_{K1})$ at $\Delta E^0_{A2,K1}=0.2(1)$, $0.1(2)$, $0(3)$, and $-0.1\,V(4)$, when $k^W_{K1}/k^0_{K1}=k^W_{A2}/k^0_{A2}=\sqrt{2}$, $k^W_{A2}/k^W_{K1}=1$ and $c^0_{K1}/c^W_{A2}=1$.

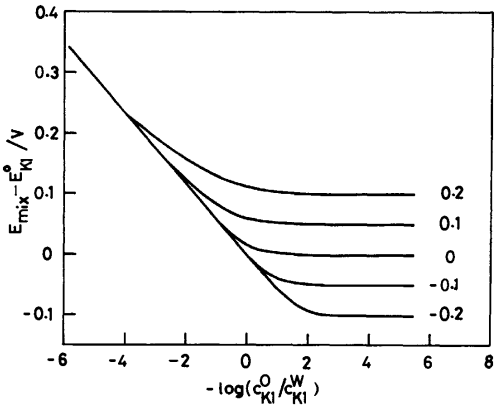

Fig. 8. Variation of E_{mix} with $\log(c^0_{K1}/c^W_{K1})$ at $\Delta E^0_{A2,K1}=0.2(1)$, $0.1(2)$, $0(3)$, $-0.1(4)$, and $-0.2\,V(5)$, when $k^W_{K1}/k^0_{K1}=k^W_{A2}/k^0_{A2}=\sqrt{2}$, $k^W_{A2}/k^W_{K1}=1$ and $c^W_{A2}/c^W_{K1}=1$.

on the concentrations of the ions, as exemplified in Figs. 5a and 5b, apparently conforms to the trends of the experimental observations found by Srinivasan and Rechnitz[2] for several anion-selective electrodes.

The selectivity coefficient is sometimes determined using the procedure in which the concentration of an interfering ion in a sample solution is changed, while the primary ion concentrations both in the sample solution and in the membrane are kept constant.[3,29] The selectivity coefficients corresponding to such experimental conditions were calculated from Eq. 24 at several different values of $\Delta E^0_{K2,K1}$; they are shown in Fig. 6 as a function of $\log(c^W_{K2}/c^W_{K1})$ at $c^O_{K1}/c^W_{K1}=1$. For the large positive values of $\Delta E^0_{K2,K1}$, $\log k^{pot}_{K1,K2}$ is almost independent of $\log(c^W_{K2}/c^W_{K1})$, whereas it varies drastically at the large negative values of $\Delta E^0_{K2,K1}$. In the small values of c^W_{K2}/c^W_{K1}, $k^{pot}_{K1,K2}$ reaches a constant value whose magnitude is dependent on the value of $\Delta E^0_{K2,K1}$. Such behavior of $k^{pot}_{K1,K2}$ has also been found experimentally for anion-selective electrodes of the liquid-membrane type.[3,9,11] Senkyr and Petr[9] and Morf[11] have suggested that the selectivity coefficients of anion-selective electrodes with respect to several different interfering ions converge to unity with the decrease in the activity of the interfering ions. However, this is not in conformity with the present theory, as is shown in Fig. 6.

Figure 7 shows the mixed ion-transfer potentials of the cell(III) for several different values of $\Delta E^0_{A2,K1}$ when c^W_{A2}/c^W_{K1} is changed, while keeping the c^O_{K1}/c^W_{A2} ratio constant. The effect of anion interference is quite different from that of cation interference. When $\Delta E^0_{A2,K1}$ has a large positive value, E_{mix} shows a so-called "super-Nernstian" response in the middle range of c^W_{A2}/c^W_{K1}. At the large extreme of c^W_{A2}/c^W_{K1}, E_{mix} *vs.* $\log(c^W_{A2}/c^W_{K1})$ curves exhibit the Nernstian response. At the small extreme of c^W_{A2}/c^W_{K1}, all the curves merge into a single curve with a sub-Nernstian slope.

Figure 8 shows the mixed ion-transfer potential of the cell(III) as a function of $\log(c^O_{K1}/c^W_{K1})$ at $c^W_{A2}/c^W_{K1}=1$ for several different values of $\Delta E^0_{A2,K1}$. Experimentally, such conditions may be met when the concentrations of K1 and A2 in the sample solution are changed by adding a salt K1A2 to the sample solution, *i.e.*, in the case of the so-called co-ion interference.[30] In such cases, the deviation of the potential from the Nernstian behavior becomes significant at the lower values of c^O_{K1}/c^W_{K1}, *i.e.*, at the larger values of c^W_{K1} at a constant c^O_{K1} value. A similar change in the potential has been found for a co-ion interference with the nitrate-selective electrodes.[30]

The present theory is limited to the case of the presence of supporting electrolytes in both membrane and solution phases and of the semi-infinite mass-transport of ions. However the above results indicate that the ion transfer across the membrane-sample solution interface plays an essential role in determining the potential of ion-selective electrodes through the interfacial potential and that the concepts of the zero-current potential

and the mixed ion-transfer potential are satisfactorily applicable for interpreting the behavior of the ion-selective electrodes with liquid membranes and also with solid membranes.

The present treatment can also be extended to more general cases, *e.g.*, simultaneous ion transfers of more than two ions and arbitrary valencies of the ions, and also to the presence of association between ions and between ions and ligands(ionophores).

(Received November 28, 1983)

Two types of lanthanoid(III) *m*-hydroxybenzoates, indicated in the title, have been synthesized, and the crystal and molecular structures of four representative complexes, where M=La (**1**), Nd (**2**), Sm (**3**), and Er (**4**), were determined by the single-crystal X-ray diffraction method. They are all triclinic, space group $P\bar{1}$, and the cell constants are as follows: (**1**) a=12.351(11), b=15.533(10), c=9.250(4) Å, α=109.86(4), β=101.40(6), γ=62.95(6)°; (**2**) a=12.287(4), b=15.542(7), c=9.194(3) Å, α=109.64(3), β=101.46(3), γ=62.83(3)°; (**3**) a=10.580(1), b=12.006(5), c=10.105(2) Å, α=111.14(2), β=90.27(1), γ=97.16(2)°; (**4**) a=10.586(4), b=11.943(6), c=10.027(5) Å, α=111.11(3), β=90.53(4), γ=97.26(4)°. The final R values obtained were (**1**) 0.039, (**2**) 0.038, (**3**) 0.030, and (**4**) 0.039. The central metal atoms of both types of complexes are octa-coordinated, and each is in a square-antiprism geometry. In **1** and **2**, one free acid molecule is present, and the molecule is hydrogen-bonded to the oxygen atoms of the coordinated water molecules through its carboxyl oxygen atoms. **1** and **2** have linear polymeric structure, and each pair of the metal atoms is bridged by a pair of the carboxylate ligands, while **3** and **4** have a dimeric structure, where metal atoms are bridged by two carboxylate ligands.

Several examples of the complicated structures of lanthanoid(III) carboxylates have already been elucidated.[1-7] Among them, the tetraacetato complex of cerium(III) has the most interesting structure; four acetate ions are coordinated to the central metal atom by both of the carboxyl oxygen atoms, forming four-membered chelate rings.[1] Although the structures of lanthanoid(III) aromatic carboxylates are expected to be different from those of the aliphatic ones, only a few results have been published thus far.[5,8-10] This is probably due to the difficulty in obtaining good crystals for the X-ray analysis, as their solubilities are generally low. To raise the solubility of the complexes, it is thought to be effective to introduce hydroxyl groups on the phenyl group of the ligand; however, *o*- and *p*-hydroxybenzoates of lanthanoids(III) are hardly soluble in water. On the other hand, *m*-hydroxybenzoates of lanthanoid(III) are soluble enough into water, and their crystals were obtained easily. Indeed, their tetracarboxylato complexes of some lanthanoid(III), with the formula of $HML_4 \cdot 4H_2O$ (where M=La, Ce, and Nd, HL=*m*-hydroxybenzoic acid) have been reported,[11] though their structure has not been solved. We could obtain the tetracarboxylates of La, Ce, Pr, and Nd from an aqueous solution containing an excess of the acid: moreover, new tricarboxylate-type complexes were obtained for the heavier lanthanoids: Sm, Gd, Dy, Er, and Yb, under similar experimental conditions.

It was found, from the results of the preliminary structural studies, that the coordination geometry of both types of complexes resemble each other. It was thought to be interesting to check the variation in the bond lengths and some detailed structures of the complexes, depending on the change in the atomic number of the central metal atom. Therefore, the lanthanum(III) (**1**) and neodymium(III) (**2**) complexes of the tetracarboxylate type, as well as the samarium(III) (**3**), and erbium(III) (**4**) complexes of the tricarboxylate type, were chosen, and their structures were fully determined by the single-crystal X-ray diffraction method.

Experimental

*Synthesis of Diaquatris(*m*-hydroxybenzoato)lanthanum(III)-(*m*-hydroxybenzoic acid) dihydrate polymer (**1**).* About 1.3 g (9.4 mmol) of *m*-hydroxybenzoic acid and fresh lanthanum(III) hydroxide, prepared from 0.75 g (2.0 mmol) of lanthanum(III) chloride heptahydrate, were mixed in hot water (about 20 cm^3). The solution was then cooled and left standing in a silica-gel desiccator overnight; the crystalline product was thus obtained. The product was washed with water and diethyl ether successively to remove the excess free acid. The crude product thus obtained could be recrystallized from the aqueous solution by leaving it in a silica-gel desiccator for several days. The yield was about 0.9 g (about 60%).

A similar synthetic technique is applicable to obtain the isomorphous cerium(III), and praseodymium(III) complexes; their yields were about the same. In the case of neodymium(III) **2**, as the tetracarboxylate is hardly precipitated at all, a little more free acid was added to the more dilute aqueous solution, and it was left standing in the desiccator longer. The coprecipitated free acid was removed by washing the product with diethyl ether repeatedly.

*Synthesis of Di-*μ*-(*m*-hydroxybenzoato)bis{triaquabis-(*m*-hydroxybenzoato)erbium(III)} Dihydrate (**4**).* When the

procedure used for the former type of complexes was applied to erbium(III) hydroxide, the titled complex was obtained as single crystals; even when the mole ratio of the added acid to the metal salt was increased, the precipitate obtained was a mixture of the titled tricarboxylate complex and the free acid. Similarly, this type of tricarboxylate complex was obtained for samarium(III) (**3**), gadolinium(III), dysprosium(III), and ytterbium(III). The yields were all about 60%.

The results of the elemental analyses of the products are shown in Table 1.

a) The chemical formulae of the complexes: Type 1: $[LnL_3(H_2O)_2]\cdot HL\cdot 2H_2O$; Type 2: $[LnL_3(H_2O)_3]_2\cdot 2H_2O$ (where HL = *m*-hydroxybenzoic acid).

Single-crystal X-Ray Analysis. Crystals 0.4×0.3×0.3 mm³ in size were used as the samples of **1**, **2**, and **3**, while a crystal 0.3×0.3×0.3 mm³ in size was used as the sample of **4**. The reflections were collected on a Rigaku AFC-6A automated four-circle diffractometer with graphite monochromated Mo $K\alpha$ radiation (0.7107 Å), the θ-2θ scan technique being employed (scan speed 4° min^{-1}; scan width 1.03+0.5tanθ°). These crystals are all triclinic, space group $P\bar{1}$; their crystallographic data are shown in Table 2. The intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption and extinction. All the calculations were carried out on a HITAC M-200H computer of the Computer Center of the University of Tokyo, using the local version of the UNICS program.[12] The atomic-scattering factors were taken from the tables.[13]

Structure Determination. The structure of each complex was solved by the heavy-atom method. In the case of the **1** and **4** complexes, the central metal and some oxygen atoms were deduced from the three-dimensional Patterson maps, while all the other non-hydrogen atoms were located by means of successive Fourier syntheses and refined by the block-diagonal least-squares method. The final R values obtained by applying the anisotropic temperature factors are shown in Table 2.[14] As **2** and **3** were found to be isomorphous with **1**, and **4** respectively, from their X-ray crystallographic data, the positional and thermal parameters of the latter complexes were tentatively applied to the former ones as the starting data, and they were then refined as usual.

Other Measurements. The X-ray powder patterns of these complexes were obtained by the use of a diffractometer, Model DX-GO-F JEOL, using Cu $K\alpha$ radiation, in the range from 6° to 50° in 2θ. The infrared absorption spectra of the samples were obtained by means of a JASCO A-202 grating infrared spectrophotometer, using Nujol and hexachloro-1,3-butadiene mull. The simultaneous thermogravimetric(TG) and differential thermal analyses(DTA) were carried out with a Rigaku Denki "Thermoflex" M-8075, using a sample of about 10 mg in each run, referring to Al_2O_3, at the heating rate of 2.5 K min^{-1}. The pH of the titrated solution was measured by the use of a Toa-Dempa glass electrode pH meter, model HM-5A.

a) The equivalent isotropic temperature factors were computed using the following expression: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{12}ab\cos\gamma+B_{13}ac\cos\beta+B_{23}bc\cos\alpha)$. The B_{ij}'s are defined by: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})]$.

The Structure of Lanthanum(III) Complex (1). The central lanthanum(III) atom of **1** is octa-coordinated and is in a square-antiprism geometry, being coordinated to eight oxygen atoms. The La atom is bridged to La^{i} as well as to La^{ii} with a couple of the respective carboxylate ligands, to form a linear polymeric structure (where the keys to the symmetry operations are: i: 1.0−*x*, 1.0−*y*, 1.0−*z*; ii: 1.0−*x*, 1.0−*y*, −*z*). Therefore, the zig-zag chain of the polymeric complex is parallel to *z*-axis. The center of symmetry of **1** exists at the mid-point of La and La^{i}, as well as of La and La^{ii}. Each oxygen atom of the carboxylate ligand, which bridge La and La^{i} atoms, is coordinated to a respective metal atom, forming a La-O-C-O-La^{i}-type bridge. In the case of the ligand, which bridges La and La^{ii}, O(21) and O(22) are coordinated to La^{ii} and La respectively; moreover, the O(22) takes a position not very far from La^{ii} (3.074(8) Å). Taking this additional weak bonding, La···O(22^{ii}), into consideration, the La atom can be said to be ennea-coordinated and to be in a capped square-antiprism geometry. Another carboxylate ligand forms a four-membered chelate ring, coordinated to the metal atom through both of the carboxylate oxygen atoms, O(31) and O(32). Two water oxygen atoms, O(W1) and O(W2), are also coordinated to the metal atom, and the fourth acid molecule forms hydrogen bondings with the water oxygen atoms O(W1)···O(42), 2.698(8) Å, and O(W2)···O(41), 2.860(7) Å, where the former bonding is

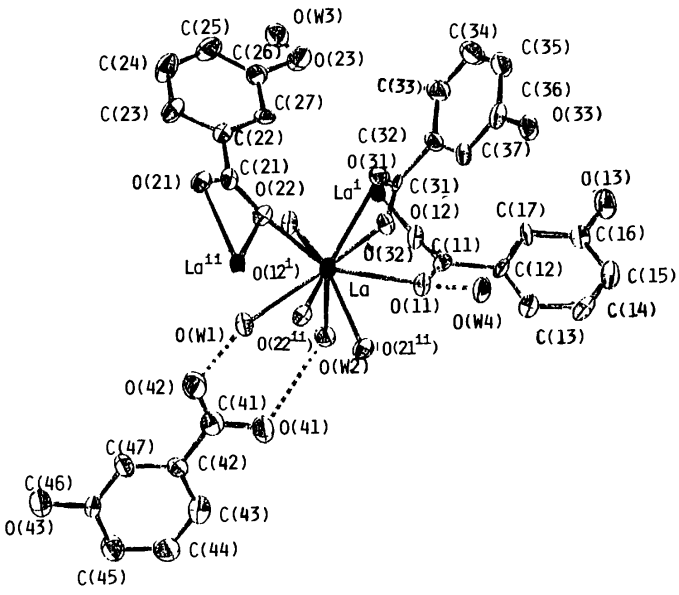

Fig. 1. A perspective drawing of diaquatris(*m*-hydroxybenzoato)lanthanum(III)(*m*-hydroxybenzoic acid)·dihydrate, and the numbering scheme of atoms.

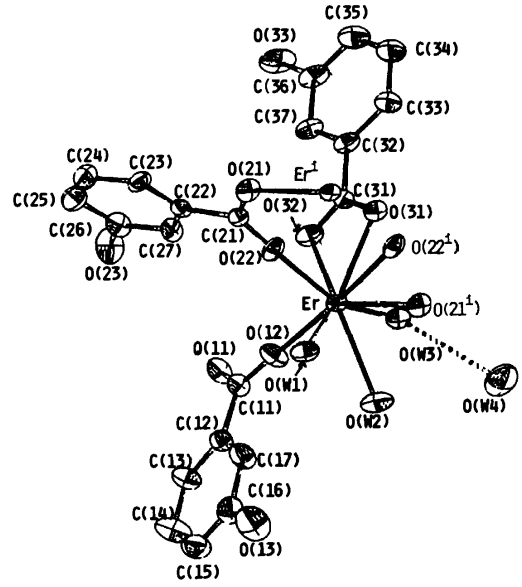

Fig. 2. A perspective drawing of di-μ-(*m*-hydroxybenzoato) bis{triaquabis(*m*-hydroxybenzoato) erbium(III)}·dihydrate, and the numbering scheme of atoms.

through the water hydrogen and the latter one through the acid hydrogen atom. The other water oxygen atoms, O(W3) and O(W4), are not coordinated to the lanthanoid atom. The phenol hydroxyl oxygen atoms of the ligands are not coordinated to the metal atom, either. Possible hydrogen bondings between the oxygen atoms are summarized in Table 4 (less than 2.95 Å). Thus, a polymer chain of the complex is weakly bonded to other chains.

The two C-O bond lengths of each carboxyl group which acts as a ligand are not very different from each other; the differences are O(11), O(12)-C(11), 0.056; O(21), O(22)-C(21), 0.043; and O(31), O(32)-C(31), 0.013 Å. However, that of the fourth acid molecule is a

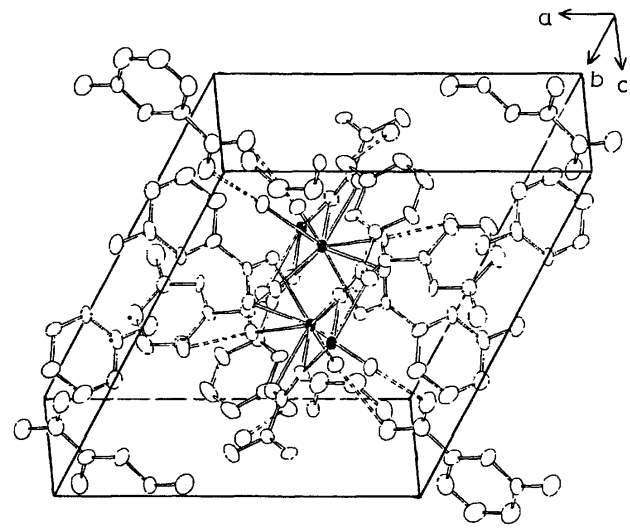

Fig. 3. Crystal packing diagram of the lanthanum(III) complex.

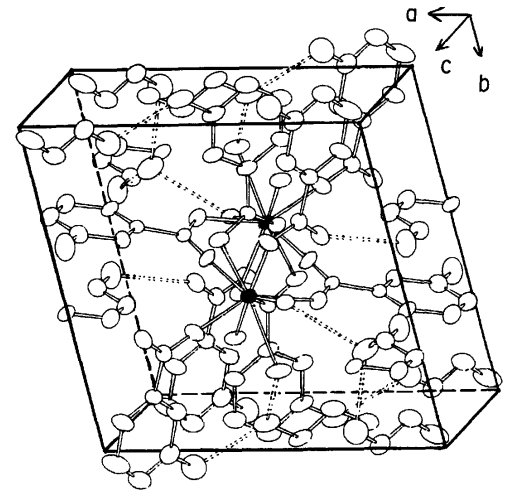

Fig. 4. Crystal packing diagram of the erbium(III) complex.

little large, 0.130 Å, like that of a free acid molecule.

The Structure of the Neodymium(III) Complex (2). The **2** complex is isomorphous with **1**, and both structures resemble each other. Every Nd-O length in **2** (2.491 Å in average) is shorter than the corresponding La-O ones in **1** (2.606 Å in average) by about 0.11 Å, and among them, M-O(12^{i}), M-O(22^{ii}), and M-O(21^{ii}) are especially shortened; the reductions of the above-mentioned distances are much larger than those to be expected from the decrease in the central-metal-atom radius (the atomic radii are: La, 1.877; Nd, 1.821 Å[16a]). They are all bridging ligand ones, and the inter-metal-atom distances, M···M^{i} as well as M···M^{ii}, also decrease, as is shown in Table 4. The hydrogen bond lengths, O(W1)···O(42) and O(W2)···O(41), of **2** are slightly shorter than the respective ones of **1**.

The Structure of the Samarium(III) Complex (3). The central samarium(III) atom of **3** is octa-coordinated and is in a square-antiprism geometry, being coordi-

a) The central metal atom of each complex is shown. The chemical formulae of the first two differ from those of the latter two (see Table 1, footnoot).
Keys to the symmetry operations: For the lanthanum(III) and neodymium(III) complexes: i: $1.0-x$, $1.0-y$, $1.0-z$; ii: $1.0-x$, $1.0-y$, $-z$; iii: x, y, $1.0+z$; iv: $-x$, $1.0-y$, $1.0-z$; v: $-x$, $1.0-y$, $-z$; vi: $2.0-x$, $1.0-y$, $1.0-z$. For the samarium(III) and erbium(III) complexes: i: $1.0-x$, $1.0-y$, $1.0-z$; ii: $1.0-x$, $1.0-y$, $-z$; iii: x, $-1.0+y$, z; iv: $1.0-x$, $-y$, $-z$; v: x, $1.0+y$, z; vi: $-x$, $1.0-y$, $-z$.

nated to eight oxygen atoms, as is shown in Fig. 2 (Er-(III) analogue). The metal atom Sm is bridged to Sm^{i} with a couple of the carboxylato ligands (where the keys to the symmetry operations are: i: $1.0-x$, $1.0-y$, and $1.0-z$, and Sm···Sm^{i} is 4.625 Å). As the shortest interatomic distance from an oxygen atom of the complex around Sm to Sm^{ii} is O(II)···Sm^{ii}=4.451(5) Å, there is no bridging between Sm and Sm^{ii} (where the keys to the symmetry operations are: ii: $1.0-x$, $1.0-y$, $-z$, and Sm···Sm^{ii} is 5.959 Å). Therefore, **3** should be regarded as having a dimeric structure, but the complex molecules are approximately lined to the *z*-axis, as in the case of **1**. Between Sm and Sm^{i}, there are two Sm-O-C-O-Sm^{i}-type bridges, where O(21)-Sm^{i} and O(22)-Sm are 2.364(5) and 2.322(4) Å respectively. As O(22)···Sm^{i} is 3.273(5) Å, it is too far to be considered as a-bonding. The eight Sm-O coordination bond distances are in the range of 2.273(4) and 2.594(4) Å (2.431 Å on the average). The difference between a pair of C-O bond lengths of each carboxyl group of the ligands are: O(11), O(12)-C(11), 0.037; O(21), O(22)-C(21), 0.014; O(31), O(32)-C(31), 0.004 Å. They are not large, not even the first one, where the ligand is in a unidentate form. As in the case of **1**, the short O···O distances around O(W4), and the phenyl hydroxyl oxygen atoms are summarized in Table 4; some of them are expected to form the hydrogen bonds.

The Structure of the Erbium(III) Complex (4). The **4** complex is isomorphous with **3**, although the bond distances around the central metal atom are a little different. As the Er-O bond lengths are in the range of 2.198(5) and 2.534(5) Å (2.359 Å on the average), the difference in the average M-O lengths of **3** and **4** is a little longer than that in the metal atomic radii (the atomic radii are: Sm, 1.802; Er, 1.757 Å [16a]). The interatomic distance, Er···$O(22^{i})$, is 3.382(6) Å, which is longer than the corresponding Sm···$O(22^{i})$ distance, 3.273(5) Å, in spite of the fact that the former metal atomic radius is smaller than the latter. The interatomic distances, Er···Er^{i} or Er^{ii}, are not much different from those of the corresponding distances of **3**; the differences are smaller than those between **1** and **2**.

The comparison of 1,2-Type and 3,4-Type Complexes. The respective interatomic distances and the bond angles of **1**, **2**, **3**, and **4** are shown in Table 4, while their atomic coordination geometries are shown in Fig. 5.

There are some similarities between **1** and **3**-type complexes. They are triclinic, with the space group $P\bar{1}$; the central metal atom is octa-coordinatated and is in a square-antiprism geometry. Both types of complexes are lined almost parallel to the *z*-axis, although the **3**-type is discrete between M and M^{ii} and is dimer. In the **1**-type, the M···M^{i} distance is about 0.5 Å longer than that of the M···M^{ii}; and therefore, the long and short M···M′ distances appear alternatively in the polymeric chain of the **1**-type complexes. In the **3**-type complexes, an additional water oxygen atom, O(W3), is coordinated to the metal atom in place of one bridging oxygen atom, O(11), of the **1**-type complexes. The positions of the other ligating atoms are almost the same as in both types of complexes.

The differences between **1** and **3** may be summarized as follows:

1) The **3**-type complexes do not have the free acid molecule in the crystal.

2) The **3**-type complexes are in the dimeric structure.

3) The interatomic distances, M···$O(22^{i})$, of **3** is much longer than the corresponding one of **2**, M···$O(22^{ii})$, and the former complex can not be considered as having the ennea-coordination.

4) When are compared **3** and **2**, the Sm-O(22) and Sm-$O(21^{i})$ (2.322(4) and 2.364(5) Å) distances are much

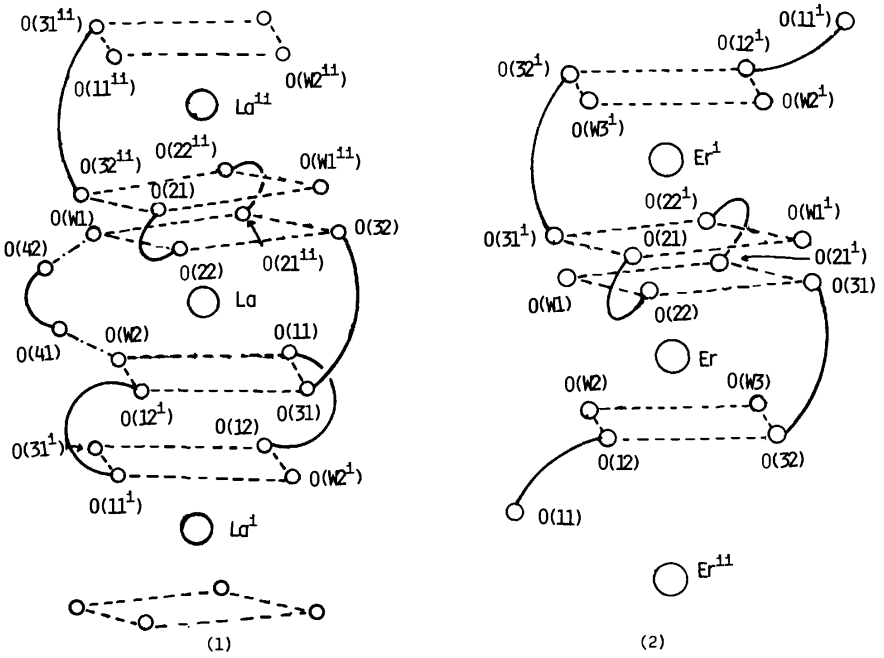

Fig. 5. Arrangement of the coordinating atoms around the central metal atoms of (1) the lanthanum(III) and (2) the erbium(III) complexes. (Key to the symmetric operations: i: 1.0—x, 1.0—y, 1.0—z; ii: 1.0—x, 1.0—y, —z.)

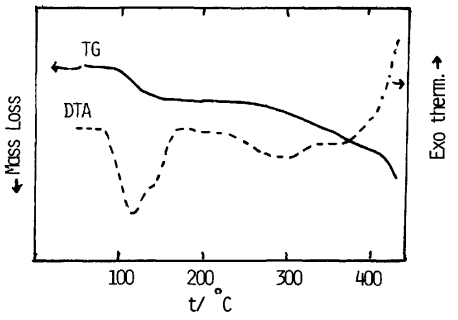

Fig. 6. TG(——) and DTA (----) curves of the lanthanum (III) complex. Mass loss of TG was taken downwards, and the exothermal change of DTA was taken upwards.

shorter than the corresponding Nd-O(22) and Nd-O(21^{ii}) (2.479(7) and 2.488(6) Å) distances of **2**, even the difference of their metal atomic radii is considered (Sm, 1.802 and Nd, 1.821 Å). Nevertheless, the interatomic distance, Sm···Sm^{i} of **3** is longer than the Nd···Nd^{ii} distance of **2** by 0.15 Å.

Although it was already known that the complexes of light and heavy lanthanoid(III) with the same ligand are sometimes different from each other in their chemical compositions,[16b,17,18] only a few comparisons of their structures have been published.[18]

The radii of lanthanoid atoms decrease with the increase in their atomic number. When the reduction of the radius is not large, only the bond lengths between the central metal and the coordinated atoms decrease, and the crystal is kept in an isomorphous state. However, when the radius decreases more, the ligand molecules must approach too near each other if the same configuration in the crystal is kept. Then they are rearranged to another structure, as in the present case.

Results of Other Measurements. As the four water molecules in **1** are divided into two groups, the coordinated ones and the crystalline ones, they can be expected to be distinguished by the thermal analysis. However, as is shown in Fig. 6, even when a relatively slow temperature-raising speed was applied (2.5 K min^{-1}), the dehydration peak of the DTA curve did not show any clear separation. Only a shoulder was found on the higher-temperature side of the peak, which means that there are two different types of water molecules and that they are removed at slightly different temperatures.

The fourth acid molecule in **1** is bonded only indirectly to the lanthanoid atom in the solid. This molecule can be expected to be liberated in its aqueous solution; this was ascertained by the measurement of the pH variation in the solution during titration with sodium hydroxide. The concentration of the complex used was [La^{III}]=3.01×10^{-3} mol dm^{-3}, and that of NaOH was 0.1 mol dm^{-3}. The results are shown in Fig. 7. An inflection point was observed when an equimol of NaOH was added, and the metal hydroxide began to precipitate after that point.

The infrared absorption spectra of the free acid, **1**, and of **4** are shown in Fig. 8. The spectra of the other lanthanoid complexes are almost the same as those of the two representative complexes. Although the free acid has two peaks in the ν_{as}(COO) region, at 1675 and 1598 cm^{-1}, the latter one is likely to be mixed with those of the phenyl group or of the hydroxyl group vibration. As the spectra of **1** has a peak at 1690 cm^{-1}, the fourth acid molecule in the complex is expected to act almost as a free acid. Although they may be overlapped, or mixed with other vibrations, the peaks at 1590 and 1502 cm^{-1} are expected to contain the ν_{as}(COO) mode of the coordinated ligand. In the spectra of **4**, one strong

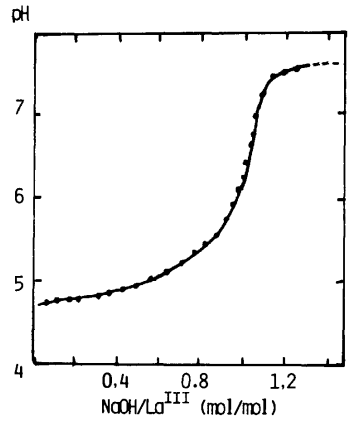

Fig. 7. The titration curve of the lanthanum(III) complex, using sodium hydroxide. ([La^{III}]=3.01×10^{-3} mol dm^{-3}; [NaOH]=0.1 mol dm^{-3}, in aqueous solution).

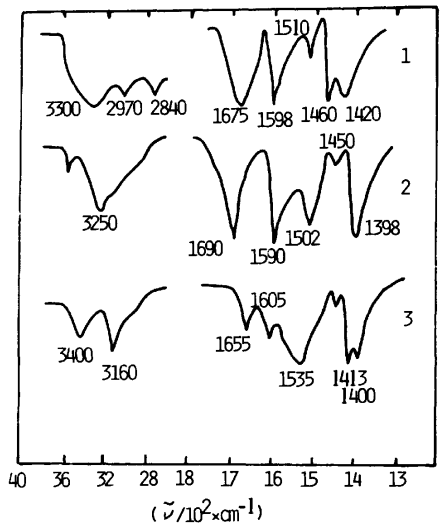

Fig. 8. Infrared absorption spectra of 1) *m*-hydroxybenzoic acid, 2) the lanthanum(III) complex (**1**), and 3) the erbium(III) copmlex (**4**).

peak is found at 1535 cm^{-1}, which is thought to be the ν_{as}(COO) mode of the coordinated ligand. The other peaks in the region, 1655 and 1605 cm^{-1}, may correspond with some modes of the other coordinated ligands in the complex; however, the exact assignment is difficult.

The authors wish to thank heartily The Shin-Etsu Chemical Co., Ltd., for aiding this study by presenting the highly pure lanthanoid oxides. The present work was partly supported by a Grant-in-Aid for Scientific Researches (No. 57430011) from the Ministry of Education, Science, and Culture. The helpful discussions about this research by Mr. Kiyofumi Nagai and Miss Reiko Nakamura are also deeply acknowledged.

Kinetic and Thermodynamic Characterization of Thermal Pyridine Liberation-Anation Reactions of Bis(2,3-alkanedione dioximato)dipyridinecobalt(III) Iodide in the Solid State

Setsuko KINOSHITA,* Hisanobu WAKITA, and Isao MASUDA
Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814-01
(Received November 29, 1983)

Thermodynamic and kinetic characterizations were carried out on the thermal, pyridine liberation-anation reactions, $[Co^{III}(R,CH_3\text{-dioxH})_2(py)_2]I \xrightarrow{\Delta} [Co^{III}(R,CH_3\text{-dioxH})_2(py)I]+py\uparrow$.* These occurred endothermally in the solid state of the complexes. The ΔH values of the reactions were determined. A large increment in the entropy was found to be indispensable for the progress of the reactions; it could be brought about by the liberation of gaseous pyridine from the solid system of the complexes. The kinetic analyses revealed that the reaction rates were increased by the substitution of R with the longer-carbon-chain alkyl groups. The activation enthalpies and activation free energies were shown to be decreased by the above substitutions. The Co^{III}-pyridine bond was observed to be weakened by the electron-donating inductive effect of R to the central cobalt atom and by the steric interference of R toward axial pyridine coordination.

Tsuchiya *et al.* have revealed that the complexes, $[Ni(H_2O)_2(N,N'\text{-deen})_2]Cl_2$* and $[Cr(NH_3)_6]X_3$ ($X=Cl^-$, Br^-), thermally liberate the volatile ligands in the coordination sphere such as H_2O or NH_3 accompaning anation reactions, in the solid state.[1] Analogous anation reactions which occur in the solid state were investigated by Zsakó *et al.* using complexes of the type, $[Co(DH)_2B_2]X$ [DH=dimethylglyoximato and (*E,E*)-(benzil dioximato); B=pyridine, aniline and their derivatives; $X=Cl^-$, Br^-, I^-, and SCN^-]; these thermally eliminated B to produce complexes of the type, $[Co(DH)_2(B)X]$.[2] Although they carried out kinetic analyses on these reactions, they only achieved ambiguous conclusions, probably due to their indiscriminate choice of the compounds.

In the present article, complexes of 2,3-alkanedione dioximes, $[Co(R,CH_3\text{-dioxH})_2(py)_2]I$,* with a series of extended alkyl groups R on the dioximato moiety, have been subjected to thermal investigation. The steric effect on the reactions arising from the alkyl groups will be discussed. In our previous investigation, it was revealed that the thermally induced one-electron transfer reactions from ligand L to Co^{III} in the solid $[Co^{III}(salen)L]$ complexes (L=2,4-alkanedionato ligand) were controlled dominantly by the activation entropies which were increased by the substitution of alkyl groups on the carbon atom at the 4-position of L.[3]

Experimental

Materials. The ligands, $R,CH_3\text{-dioxH}_2$, were prepared as described elsewhere.[4] The series of $[Co(R,CH_3\text{-dioxH})_2(py)_2]I$ complexes, including newly prepared ones with R= C_2H_5, n-C_3H_7, and n-C_4H_9, were prepared by following the method reported in the literature.[5] The complexes were recrystallized from dichloromethane solution by addition of petroleum ether to the solution. The analytical data of the complexes are given in Table 1. As Table 1 shows, the complexes were obtained in an anhydrous state when they included R=CH_3 and C_2H_5, but were obtained dihydrate and tetrahydrate when they included R=n-C_3H_7 and n-C_4H_9, respectively.

Table 1. Analytical data of the complexes, $[Co(R, CH_3\text{-dioxH})_2(py)_2]I$[a]

R	C %	H %	N %	Co %
CH_3	37.61	4.14	14.48	10.38
	(37.66)	(4.18)	(14.65)	(10.26)
C_2H_5	40.04	4.53	13.94	9.89
	(39.87)	(4.32)	(13.96)	(9.79)
n-C_3H_7; dihydrate	39.65	5.41	12.62	8.84
	(39.46)	(5.79)	(12.15)	(8.80)
n-C_4H_9; tetrahydrate	39.46	6.03	11.51	8.07
	(39.76)	(5.94)	(11.19)	(8.03)

a) Calculated values are given in parentheses.

The ^1H NMR spectra in DMSO-d_6 solution showed that all the complexes obtained here have a peak at 18.18 ppm which could be ascribed to the hydrogen atom in the =N-O-H-O-N= group formed by an intramolecular hydrogen bond in the complex molecules.[6] This is consistent with the assumption that the two dioximate monoanion molecules are coordinated symmetrically in the equatorial plane and the two pyridine molecules, in the axial positions.

Measurements. TG-DSC and powder X-ray diffraction measurements were carried out as described previously.[4] The kinetic analyses under isothermal conditions were carried out on the TG curves. The particle size of the samples provided for the thermal analyses was under 200 mesh.

Results

Pyrolysis. The TG-DSC curves are shown in Fig. 1. For the $[Co(CH_3,CH_3\text{-dioxH})_2(py)_2]I$ complex, an endothermic DSC peak appeared with a maximum at 158 °C, and a weight-loss corresponded to this change was 13.7%, being in agreement with calculated 13.8% for the elimination of one mole of pyridine per mole of complex. The powder X-ray diffraction of the product which was left behind after the above weight-loss was coincident with that of authentic $[Co(CH_3,CH_3$-

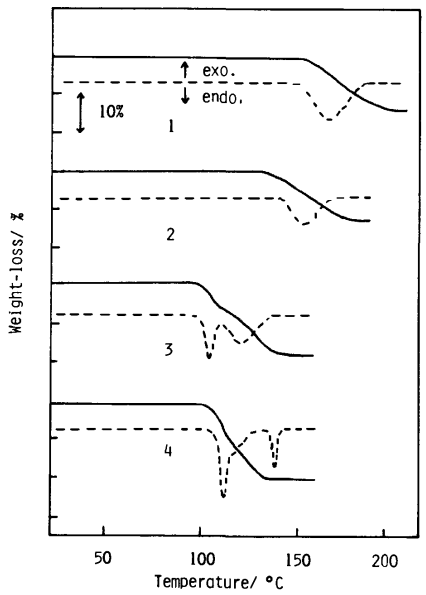

Fig. 1. TG(——) and DSC(----) curves of the complexes, $[Co(R,CH_3\text{-dioxH})_2(py)_2]I$, in a flowing N_2 atmosphere. Heating rate: 10 °C/min.
1, R=CH_3; 2, R=C_2H_5; 3, R=n-C_3H_7 (dihydrate); 4, R=n-C_4H_9 (tetrahydrate).

dioxH)$_2$(py)I].[7] Similarly, $[Co(C_2H_5,CH_3\text{-dioxH})_2(py)_2]I$ released pyridine leaving behind $[Co(C_2H_5, CH_3\text{-dioxH})_2(py)I]$. The observed weight-loss, 13.1%, corresponded to the calculated value, 13.1%. For $[Co(n\text{-}C_3H_7,CH_3\text{-dioxH})_2(py)_2]I\cdot 2H_2O$, dehydration occurred at *ca.* 100 °C, the weight-loss was 5.7% (Calcd, 5.4%). Then, pyridine was liberated; the weight-loss was 12.8% (Calcd, 12.5%). In the case of $[Co(n\text{-}C_4H_9,CH_3\text{-dioxH})_2(py)_2]I\cdot 4H_2O$, dehydration occurred accompanied by subsequent pyridine liberation; the total weight-loss was 21.2% (Calcd, 20.7%). A DSC peak at 143 °C is due to the melting of the resulting $[Co(n\text{-}C_4H_9,CH_3\text{-dioxH})_2(py)I]$. The results of the above thermal analyses are consistent with the following reaction scheme:

$$[Co(R, CH_3\text{-dioxH})_2(py)_2]I \xrightarrow{\Delta} [Co(R, CH_3\text{-dioxH})_2(py)I] + py\uparrow. \quad (1)$$

The reactions all proceeded endothermally. The enthalpy changes, ΔH values, determined by means of the DSC peak area measurement,[4] are given in Table 2.

Kinetic Analysis. As seen in Fig. 1, the pyridine liberation-anation reactions (Eq. 1) tend to occur at lower temperatures when the complexes include R having longer-carbon-chains. In order to reveal the kinetic character of the reactions, the kinetic analyses were carried out under isothermal conditions. It was found that the rate plots were linear. This is exemplyfied in Fig. 2 by the results obtained for $[Co(CH_3,CH_3\text{-dioxH})_2(py)_2]I$; similar linear relations were also obtained for the other complexes. These rate plots indicated that the reactions proceeded following the Avrami-Erofeev equation (Eq. 2),[8] for all the complexes.

$$\alpha/1-\alpha = kt^n \quad (n=1) \quad (2)$$

Table 2. Thermodynamic data of pyridine liberation-anation reactions of the complexes, $[Co(R, CH_3\text{-dioxH})_2(py)_2]I$

R	DSC peak maximum temp/K	ΔH kJ mol^{-1}	ΔS JK^{-1} mol^{-1}
CH_3	431	50±2	>116±5
C_2H_5	427	47±3	>110±7
n-C_3H_7	393	39±2	> 99±5

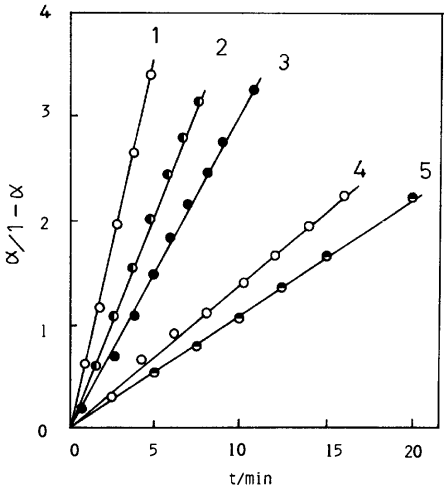

Fig. 2. Rate plots for pyridine liberation-anation reactions of $[Co(R,CH_3\text{-dioxH})_2(py)_2]I$; R=$CH_3$, under isothermal conditions.
1, 422.7 K; 2, 419.0 K; 3, 416.7 K; 4, 413.9 K; 5, 411.6 K.

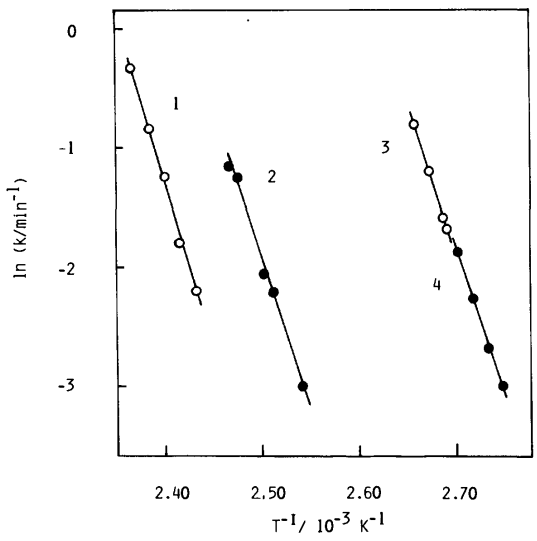

Fig. 3. Arrhenius plots for pyridine liberation-anation reactions of $[Co(R,CH_3\text{-dioxH})_2(py)_2]I$.
1, R=CH_3; 2, R=C_2H_5; 3, R=n-C_3H_7; 4, R=n-C_4H_9.

In Eq. 2, α is the molar fraction of $[Co(R,CH_3\text{-dioxH})_2(py)I]$ produced in the system by the reaction (Eq. 1); k, the rate constant; t, the reaction time. The k values at several different temperatures were determined from the slopes of the straight lines in the rate plots. Then, the Arrhenius plots gave good linear relations as shown in Fig. 3. According to the Arrhenius

equation, $k=A\exp(-E/RT)$, the activation energies, E values, and the pre-exponential factors, A valuse, were calculated from these Arrhenius plots. In order to disclose the reaction character more extensively, the activation enthalpies, ΔH^* values, and the activation entropies, ΔS^* values, were calculated by Eqs. 3 and 4, respectively:[3]

$$\Delta H^* = E - RT \quad (3)$$

$$\Delta S^* = R[\ln(Ah/kT) - 1]. \quad (4)$$

The E value, 266±9 kJ mol^{-1}, obtained for [Co(CH$_3$,CH$_3$-dioxH)$_2$(py)$_2$]I is larger as compared with E=227 kJ mol^{-1} reported by Zsacó *et al.*,[2] who determined it under non-isothermal conditions.

Discussion

Thermodynamics. As described in the results section, the [Co(R,CH$_3$-dioxH)$_2$(py)$_2$]I complexes thermally liberated pyridine in the solid state to produce the [Co(R,CH$_3$-dioxH)$_2$(py)I] complexes (*cf.* Eq. 1). A thermodynamic cycle regarding the reactions is delineated in Fig. 4. As is seen in Fig. 4, the observed ΔH value is composed of those due to the three energy terms given in Eq. 5:

$$\Delta H = \Delta H_{\text{subst}} + (\Delta H_{\text{lattice}} - \Delta H'_{\text{lattice}}). \quad (5)$$

The ΔH_{subst} values are expected to be positive because the basicity of iodide ion is appreciably weaker than pyridine. And $\Delta H_{\text{lattice}} - \Delta H'_{\text{lattice}}$ values are also expected to be positive, as the $\Delta H_{\text{lattice}}$ values of the ionic crystals of [Co(R,CH$_3$-dioxH)$_2$(py)$_2$]I are considered to be larger than those of the molecular crystals of [Co(R,CH$_3$-dioxH)$_2$(py)I]. Hence, it is reasonable that ΔH values are found to be positive as given in Table 2.

Furthermore, judging from the positive ΔH values and with $\Delta G=\Delta H-T\Delta S<0$ for the occurrence of reaction, large increases in the S values are indispensable in the present reactions. The ΔS values calculated for the present reactions are given in Table 2. Such large increments in the S values, as seen in Table 2, would be brought about by elimination of gaseous pyridine from the solid system. An evaluated ΔS value of the reaction, pyridine(solid)→pyridine(gas) at 431 K was *ca.* 125 J K^{-1} mol^{-1} when C_p (molar heat capacity at constant pressure) was assumed to be 106 J K^{-1} mol^{-1} in the gas phase and 133 J K^{-1} mol^{-1} in the liquid and solid phases.

Kinetics. The reactions (Eq. 1) fitted well the Avrami-Erofeev equation, Eq. 2, wherein n=1; it would be interpreted as that the reactions proceeded one-dimensionally after nucleation had occurred. For comparison, the rate constants, k values, of the reactions are normalized to those at 400 K. These values, as seen in Table 3, increase in the following order of R; CH$_3$<C$_2$H$_5$<n-C$_3$H$_7$<n-C$_4$H$_9$. Therefore, it is generally expected that the activation enthalpies ΔH^* values, increase in the inverse order of R in the above. In fact, this trend is seen in Table 3. If the ΔH^* value were considered to reflect mostly the strength of the Co^{III}-pyridine bonding, the increase in the ΔH^* value could be explained as follows: the electron donating alkyl groups behave to increase the electron density on the dioximato moiety, and hence, to decrease the Lewis acidity of the cobalt atom; these resulted in a weakening of the Co^{III}-pyridine bonding. A longer-carbon-chain alkyl group may weaken the Co^{III}- pyridine bonding more extensively.

The activation entropies, ΔS^* values, are positive and rather large, as given in Table 3. This fact is in line with the assumption that the reaction follows the S_N1 mechanism, that is, the reaction rate is controlled not by the anation, but by the pyridine dissociation process.[3] The fact that the k values increase in the above order of R also supports the S_N1 reaction mechanism.

n-C$_4$H$_9$	210± 7	27.1±1.0	(4.16±0.40)×10^{-1}	207± 7	263±19

As mentioned above, when the complexes included R groups with longer-carbon-chains, they underwent reaction with smaller ΔH^* values. In order to disclose the contribution of the entropic term to the reactions, the ΔG^* values are calculated by the relation, $\Delta G^* = \Delta H^* - T\Delta S^*$, and are plotted against the ΔH^* values in Fig. 5-A. The relation in Fig. 5-A indicates that the ΔG^* values decrease with decreasing ΔH^* values, *i.e.*, ΔG^* values decrease in the order of R as CH_3> C_2H_5>*n*-C_3H_7>*n*-C_4H_9. This relation indicates that the ΔS^* values are almost definite for the reactions of the series of the complexes examined here. By taking into account the relation, $k = \frac{kT}{h}\exp(-\Delta G^*/RT)$, it is expected that the k values increase in the above order of R. The relation between ΔG^* and ΔH^* values, disclosed above, is in contrast to that known for the thermal, [Co^{III}(salen)L]→[Co^{II}(salen)] reactions; in the latter case, the extended alkyl groups on L resulted in the decrease in the ΔG^* values and the increase in the ΔH^* values, indicating that the reaction is dominated by the entropy term.[3] It is demonstrated in Fig. 5-B.

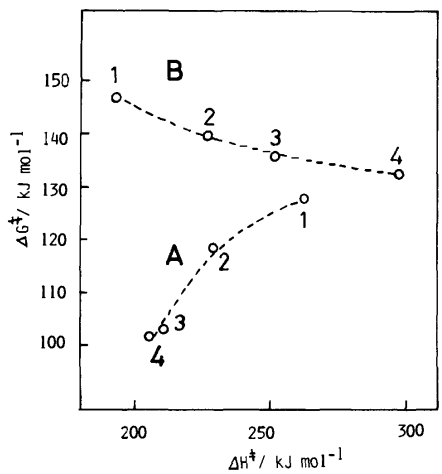

Fig. 5. Relation between ΔG^* and ΔH^* values.

B; Taft's plots for pyridine liberation-anation reactions of [Co(R,CH_3-dioxH)$_2$(py)$_2$]I: 1, R=CH_3; 2, R=C_2H_5; 3, R=*n*-C_3H_7; 4, R=*n*-C_4H_9.

For the thermal pyridine liberation reactions of Ni[*N*-(R-C_6H_4)salam]$_2$(py)$_2$* (R=H, *p*-F, *p*-Cl and *p*-Br),[9] Hammett's plots of the log k/k_0 (400 K) against σ_p are shown in Fig. 6-A. The linear relation, seen in Fig. 6-A, indicates that the rate constant k is controlled dominantly by the electron-donating inductive effect of the substituent, R. Similar plots were attempted for the present series of the complexes. However, no linear relation was found. An inspection of a stereo model of these complex molecules implies steric interference which might exist beween the extended R groups and the axial pyridine ligands. Evidence for the above type of interference can be obtained by applying the following Taft's relation for the analyses of the reactions:

$$\log k/k_0 = \rho^*\sigma^* + \delta E_s = \rho^*\left(\sigma^* + \frac{\delta}{\rho^*}E_s\right). \quad (6)$$

In Eq. 6, σ^* and E_s are, as have been defined by Taft, polar and steric substituent constants, respectively; ρ^* and δ are definite value with respect to a series of analogous reactions and these are parameters susceptible, respectively, to the polar and steric effects of the substituents. The relation given by Eq. 6 has been observed extensively for the organic reactions; for example, the methanolysis reactions of 1-mentyl esters of a series of aliphatic carboxylic acid, $RCO_2C_{10}H_{19}$, are clearly shown to be affected by both steric and electronic effects of R groups with extended-carbon-chains.[10] The fact that the ΔS^* values are nearly definite for the reactions of the present complexes is considered to support the application of the Taft equation. For, if the ΔS^* values were remarkably differed from each other in the series of reactions, the ρ^* and δ values would vary appreciably with temperature. As Fig. 6-B shows, a good linear relation is observed when log k/k_0 is plotted against $\sigma^*+1.2\,E_s$; ρ^* and δ are calculated to be −5.7 and −7.0, respectively. This result indicates that a steric effect due to the R groups as well as the electronic one, can contribute to the pyridine liberation reaction. That is, the Co^{III}-pyridine bonding can be weakened both by steric interference between the R and pyridine groups and by the inductive effect due to R. Thus, the substitution of the R groups having longer-carbon-chains into the complexes causes the decrease both in the ΔH^* and ΔG^* values, hence it causes the increase in the k value.[11]

In summary, the [Co(R,CH_3-dioxH)$_2$(py)$_2$]I complexes tend to liberate pyridine at lower temperature by including the R groups with longer-carbon-chain; this is in line with the case of the reactions, [Co^{III}-

(salen)L]→[Co^{II}(salen)]. However, it is noticeable that in the former case, the R groups behave to decrease the activation enthalpy ΔH^*, whereas in the latter case, the R groups substituted on L behave to increase activation entropy ΔS^*.

11) When 2,3-alkanedione dioxime with R=$CH_2CH(CH_3)_2$ was used, only the mono(pyridine) adduct of [Co{$CH_2CH(CH_3)_2$,CH_3-dioxH}$_2$(py)I] was isolated. It is speculated that if the bis(pyridine) adduct were isolated, its pyridine liberation-anation reaction in the solid state would be very fast; the rate constant k(400 K) is evaluated to be 1.7×10^7 times larger than that of [Co(CH_3,CH_3-dioxH)$_2$(py)$_2$]I.

Kinetic Studies of Fast Equilibrium by Means of High-performance Liquid Chromatography. V. Stepwise Complex Formation of the Nickel(II) Ion with 2,2′-Bipyridine and 1,10-Phenanthroline

Masataka MORIYASU* and Yohei HASHIMOTO
Kobe Women's College of Pharmacy, Motoyamakita-machi, Higashinada-ku, Kobe 658
(Received December 6, 1983)

The stepwise complex formation of the nickel(II) ion (M^{2+}) with 2,2′-bipyridine(bpy) and 1,10-phenanthroline(phen) ($M_{n-1}^{2+}+L \rightleftharpoons ML_n^{2+}$ with $K_n=[ML_n^{2+}]/[ML_{n-1}^{2+}][L]$, where $n=1-3$), has been investigated by means of high-performance liquid chromatography. Peaks of the labile partially ligand substituted complexes, ML^{2+} and ML_2^{2+}, have appeared on chromatograms, along with peaks of the ML_3^{2+} and excess free ligands, on reverse phase ion-pair chromatography using sodium dodecyl sulfate in acidic media. Each labile species has been found to be eluted without any noticeable change, such as ligand addition, dissociation, or disproportionation, during chromatography. Thus, the chromatograms obtained have directly indicated the equilibrium concentrations of each species in the solutions prior to chromatography. The stepwise complex formation constants of nickel(II) with bpy or phen have been determined by means of high-performance liquid chromatography.

In this series of papers[1-4] it has been demonstrated that a considerably fast reaction can be traced by means of high-performance liquid chromatography(HPLC) based on conventional principles. The present report deals with the complex formation of the nickel(II) ion (M^{2+}) with 2,2′-bipyridine(bpy) and 1,10-phenanthroline(phen) in aqueous media.

The representative stepwise complex formation of M^{2+} with these *N,N*-coordinates chelating reagents(L) is expressed by the following equations:

$$M^{2+} + L \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ML^{2+} \quad (1)$$

$$ML^{2+} + L \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} ML_2^{2+} \quad (2)$$

$$ML_2^{2+} + L \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} ML_3^{2+} \quad (3)$$

$$K_1 = [ML^{2+}]/[M^{2+}][L] \quad (4)$$

$$K_2 = [ML_2^{2+}]/[ML^{2+}][L] \quad (5)$$

$$K_3 = [ML_3^{2+}]/[ML_2^{2+}][L] \quad (6)$$

The rate constant k_1, which was determined by several authors by means of the stopped-flow method,[5-10] is a bimolecular rate constant of the order of 10^3 mol^{-1} dm^3 s^{-1}, suggesting that mono-complex formation proceeds promptly. In strongly acidic conditions, since bpy and phen exist as the protonated form HL^+, another path for complex formation has been proposed:[8]

$$L + H^+ \underset{k_-}{\overset{k}{\rightleftharpoons}} HL^+ \quad (7)$$

$$K = [HL^+]/[H^+][L] \quad (8)$$

$$M^{2+} + HL^+ \underset{k'_{-1}}{\overset{k'_1}{\rightleftharpoons}} ML^{2+} + H^+ \quad (9)$$

$$ML^{2+} + HL^+ \underset{k'_{-2}}{\overset{k'_2}{\rightleftharpoons}} ML_2^{2+} + H^+ \quad (10)$$

$$ML_2^{2+} + HL^+ \underset{k'_{-3}}{\overset{k'_3}{\rightleftharpoons}} ML_3^{2+} + H^+ \quad (11)$$

The rate constant k'_1 has been reported to be of the order of 10^0—10^1 mol^{-1} dm^3 s^{-1},[8-10] much smaller than k_1. When M^{2+} and L are mixed, the complex formation reaches equilibrium almost instantaneously, except in strong acidic conditions. If the equilibrated solution is supplied to HPLC, it seems that the equilibrium prior to HPLC is displaced rapidly and that each labile species undergoes some reactions in the column promptly. This, however, is not always true for the following reasons. Among the various equilibrium equations mentioned above, the acid-base equilibrium shown in Eq. 7 will reach the equilibrium fastest. Thus, the rate constants k and k_- will be large, and when L (or HL^+) is chromatographed, it will reach equilibrium ($L^+ + H^+ \rightleftharpoons HL^+$) in the eluent almost instantaneously. The progress of other reactions in the column is not so fast. Since the forward reaction of Eq. 1 is a bimolecular one, the progress of the reaction is retarded during chromatography because of the decrease in the probability of collision between M^{2+} and L. Furthermore, mono-complex formation will be suppressed in an acidic eluent because, in acidic media, almost all ligands exist as the protonated form HL^+, which reacts with M^{2+} only slowly. The backward reaction of Eq. 1 is also slow. The dissociation rate constant, k_{-1}, of the $[Ni(bpy)]^{2+}$ complex has been reported to be of the order of 10^{-4} s^{-1}.[11] Our previous report[4] demonstrated that the progress of a unimolecular reaction during chromatography could be suppressed when the rate constant was of the order of 10^{-4} s^{-1}.

A similar discussion might hold for the second and the third steps of complex formation described in Eqs. 2, 3, 10, and 11. Aside from the reactions mentioned above, another type of reaction of ML^{2+} and ML_2^{2+} should be taken into consideration.

$$2ML^{2+} \underset{k_{-d}}{\overset{k_d}{\rightleftharpoons}} ML_2^{2+} + M^{2+} \quad (12)$$

This type of "disproportionation" reaction is not always negligible because the "reactants" are not separated by HPLC. We ourselves have previously described the disproportionation reaction for the sys-

tem of nickel(II) dithiocarbamate chelates[1] and demonstrated that the disproportionation did not occur during chromatography. Similarly, it might safely be concluded that disproportionation can also be neglected in the present case.

When all the above premises are fulfilled, each labile species is eluted without any change in the column. In this case, since the concentrations of each species prior to HPLC can be determined from the peak height (or area) appearing on chromatograms, the equilibrium constants, K_1, K_2, and K_3 in Eqs. 4, 5, and 6 will be determined.

Experimental

Reagents. A standard solution of nickel(II) was prepared by dissolving $NiCl_2 \cdot 6H_2O$ in water. The chelating reagents (bpy and phen) were also dissolved in water.

Apparatus. The HPLC apparatus used in this study is similar to the one described previously.[1] Several reverse phase packings (Nucleosil 5C18 (5 μm), LiChrosorb RP 18 (5 μm), Hypersil ODS (5 μm), Nucleosil 5C8 (5 μm), and LiChrosorb RP 8 (5 μm)) were slurry packed into stainless steel columns. A digital pH meter (Model 225, Iwaki Glass Co., Ltd.) was used to measure the accurate pH of the equilibrated solutions prior to HPLC.

Results and Discussion

Optimum Conditions of Reverse Phase Ion-pair Chromatography. The separation of some heavy metal chelates of bpy[12] and phen[13,14] has been reported by several authors using a proper ion-pair reagent such as sodium 1-pentanesulfonate. We here chose sodium dodecyl sulfate as an ion-pair reagent. The ion-pair reagent was dissolved in the mixed solvent system of water-acetonitrile, and the pH of the solution was controlled by adding a suitable quantity of salt. A satisfactory separation was attained when the solvent system was strongly acidic. Among the several acids tested, tartaric acid gave best results, and so we here chose this solvent system. The elution behavior varied markedly when different packings were used. Among these, Nucleosil 5C18 gave satisfactory results. Other packings gave a poor resolution due to either serious tailing or the overlap of two peaks. When free bpy or phen was injected into the column, a peak corresponding to red-colored $[Fe(bpy)_3]^{2+}$ or $[Fe(phen)_3]^{2+}$ appeared on chromatograms, along with the peak of free bpy or phen because of the contamination of iron ion from the HPLC apparatus. In order to eliminate the contamination, a minute amount of ethylenediaminetetraacetic acid(EDTA,H_4edta) was added to the eluent.[15] Thus treated, the peak of $[Fe(bpy)_3]^{2+}$ or $[Fe(phen)_3]^{2+}$ disappeared and the enlarged peak of free bpy or phen alone appeared on chromatograms. This treatment, which permits the quantitative elution of free bpy (or phen), is not always preferred because there exists some possibility that coordinated bpy (or phen) might be substituted for edta during chromatography. As will be shown in the following section, this ligand exchange is negligible when the concentration of EDTA added is small. Therefore, the content of EDTA should be so chosen that free bpy (or phen) may be eluted quantitatively and the peak heights of ML^{2+}, ML_2^{2+}, and ML_3^{2+} may not be affected by EDTA addition.

The best conditions for HPLC were as follows: solvent system: acetonitrile: 0.05 mol dm^{-3} tartaric acid: 0.001 mol dm^{-3} EDTA: sodium dodecyl sulfate =80: 50:0.3:0.5 g; Column: Nucleosil 5C18 (4.6 mm×15 cm); Column temperature: 25 °C (for phen chelate) or 10 °C (for bpy chelate); Flow rate: 1.5 cm^3 min^{-1}; Detector: UV 254 nm. Hereafter, the experiments were carried out under these conditions.

HPLC of Ni^{2+}-bpy System. Two solutions of Ni^{2+} and bpy were mixed, and after the pH had been adjusted to 1.9—2.0 by $HClO_4$-$NaClO_4$, the solutions were made up to a definite volume. The concentrations of the total nickel(II) ion [M_t] and ClO_4^- were chosen to be 1.0×10^{-3} mol dm^{-3} and 1.0×10^{-1} mol dm^{-3}. The ratio of the [M_t] to the total bpy [L_t] was changed from 0.25 to 3.5 consecutively in the molar ratio. Then, the aliquots of these samples was submitted to HPLC; the chromatograms are shown in Fig. 1. Several peaks appeared on the chromatograms. Peak 2, which was

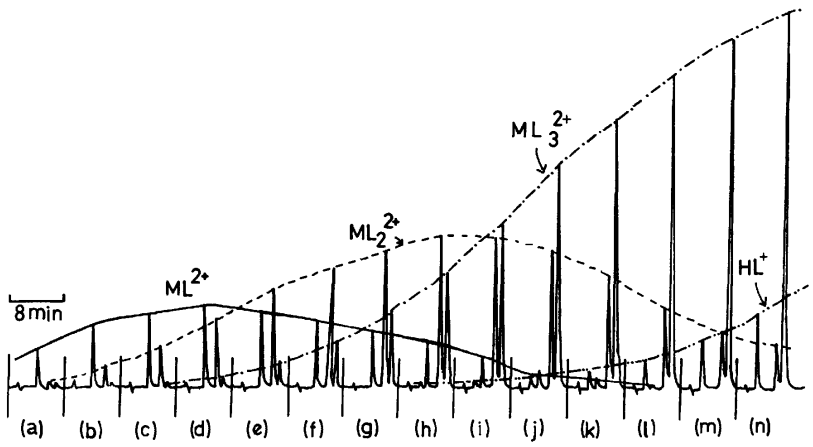

Fig. 1. Chromatograms of nickel(II)-bpy system in acidic media. For chromatographic conditions, see text.
[M_t]=1.0 mM, pH=1.93—1.99($HClO_4$-$NaClO_4$, ClO_4^-=0.1 M)
[L_t]/[M_t] 0.25(a), 0.50(b), 0.75(c), 1.00(d), 1.25(e), 1.50(f), 1.75(g), 2.00(h), 2.25(i), 2.50(j), 2.75(k), 3.00(l), 3.25(m), 3.50(n).

relatively large when the $[L_t]/[M_t]$ ratio was small and which reached the maximum under the condition $[L_t]/[M_t]=1.0$, corresponds to the 1:1 complex ML^{2+}. Peak 3, which gave highest peak when $[L_t]/[M_t]$ was equal to 2.0, is the peak of the 1:2 complex ML_2^{2+}. The last peak (Peak 4), which increased gradually with the increase in $[L_t]$, corresponds to the 1:3 complex ML_3^{2+}. When $[L_t]/[M_t]$ exceeded 2.0, a new peak (Peak 5) appeared on chromatograms. This peak, which grew with the increase in $[L_t]/[M_t]$ is attributed to the peak of free bpy. Near the present HPLC conditions, free ligands should be chromatographed as the protonated form HL^+, because the eluent is strongly acidic. In Fig. 1, the peak of the aquanickel(II) ion M^{2+} did not appear on chromatograms because the aqua ion does not have any absorption in the UV range. When the portion corresponding to the solvent front was collected and sodium diethyldithiocarbamate was added to the portion, a brownish yellow color of nickel(II) diethyldithiocarbamate chelate appeared, suggesting that the aquanickel(II) ion was eluted without retention.

It seems that the elution sequence, M^{2+}, ML^{2+}, ML_2^{2+}, and ML_3^{2+}, is reasonable for the following reason. With an increase in the coordination number of the hydrophobic bulky bpy ligand, the hydrophobicity of the chelate increases. Thus, the 1:3 complex will form a very hydrophobic ion pair with the dodecyl sulfate ion, which has a strong affinity with the hydrophobic ODS stationary phase. Thus, the retention time of the 1:3 complex will be the longest, and the elution sequence described above will result. Since the aquanickel(II) ion is very hydrophilic, it is not retained on the stationary phase at all.

The addition of EDTA to the eluent was necessary for the quantitative elution of free ligands. In order to investigate the effect of EDTA on other peaks, HPLC was carried out in the presence and absence of EDTA. Each peak height was found to be indifferent to the addition of EDTA, with the exception of the peak of free bpy. This result suggests that the bpy ligand coordinated with ML^{2+}, ML_2^{2+}, and ML_3^{2+} is not replaced by edta during chromatography when the EDTA concentration is low.

Determination of the Stepwise Complex Formation Constants of the Ni^{2+}-bpy System. Two solutions of Ni^{2+} and bpy were mixed so that $[L_t]/[M_t]$ was equal to 2.0. Then the pH of the solution was changed from 1 to 8 by the use of $HClO_4$-$NaClO_4$ or $NaClO_4$-NaOH. The concentration of $[M_t]$ was chosen as 1.0×10^{-3} mol dm^{-3}. Figures 2(a) and (b) depict examples of chromatograms near acidic and almost neutral conditions. These two chromatograms suggest that some difference in chromatograms exists when the pH values of the sample solutions are different. This can be explained in terms of the "protonation reaction" of bpy. The concentration of ligands effective on complex formation is smaller in acidic media than in basic or neutral media, because in acidic conditions most of the bpy exists as the protonated form HL^+. Thus, the ratio of the 1:3 complex is smaller in acidic media than in neutral media because of the low effective concentration of bpy available for complex formation.

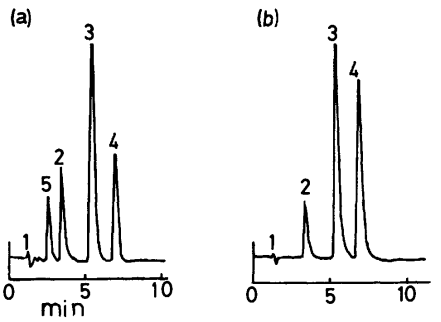

Fig. 2. Chromatograms of nickel(II)-bpy system at $[L_t]/[M_t]=2.0$. For chromatographic conditions, see text.
$[M_t]=1.0$ mM, $[L_t]=2.0$ mM, pH=1.2(a), 5.1(b) ($HClO_4$-$NaClO_4$, $ClO_4^-=0.1$ M)
1 M^{2+}(solvent front), 2 ML^{2+}, 3 ML_2^{2+}, 4 ML_3^{2+}, 5 HL^+.

Now peaks of HL^+, ML_3^{2+}, ML_2^{2+}, ML^{2+}, and possibly M^{2+} appeared on chromatograms in acidic conditions, as is shown in Fig. 2(a), the determination of the stepwise complex formation constants, K_1, K_2, and K_3, is, therefore, possible provided that the equilibrium concentrations of each species are known. For this purpose, the following facts are noteworthy: (1) The chromatograms shown in Fig. 2 should directly indicate the equilibrium concentration of each species prior to HPLC. The ion-pair formation of these metal chelates with the dodecyl sulfate ion might result in a displacement of the equilibrium. If this phenomenon really occurs, the reaction proceeds instantaneously in the column. The fast separation speed of HPLC and the moderate lability of these chelates suggest that this reaction is unlikely to occur. Furthermore, when the content of SDS in the eluent was chosen as 0.1 and 1.0 g instead of 0.5 g, the percentage of ML_3^{2+} in the sample shown in Fig. 2(a) was not changed. (2) Calibration graphs of each species are necessary, the procedure being carried out as follows: First, a linear calibration graph of bpy is obtained. Second, a calibration graph of ML_3^{2+} is obtained by mixing nickel(II) and bpy so that the $[L_t]/[M_t]$ ratio is 4.0 or higher near neutral pH conditions and by supplying the sample to HPLC. This sample gave only two peaks of ML_3^{2+} and excess free ligands, suggesting the complete 1:3 complex formation. The calibration graph of ML_3^{2+} was also linear. Calibration curves of other species could not be obtained directly because of either the lack of absorption(M^{2+}) or the lability of the chelates(ML^{2+} and ML_2^{2+}). It is noteworthy here that the measurements of each peak area in Fig. 2(a) do not give the concentrations of each species because of the difference in the absorption coefficients of the species. The absorption coefficients were found to decrease in this order: $ML_3^{2+}>ML_2^{2+}>ML^{2+}$, which was parallel to the coordination numbers of bpy. Calibration graphs of these labile species were obtained by the following procedures. Fractions corresponding to M^{2+}, ML^{2+}, and ML_2^{2+} were collected, and a slight excess of bpy was added. After the pH was adjusted to approximately neutral, each portion was diluted to a definite volume

Table 1. Stepwise complex formation constants of the nickel(II)-bpy system at 25 °C

$\log K_1$	$\log K_2$	$\log K_3$	Ref.
6.92±0.11	6.81±0.07	6.25±0.06	This work*
6.80	6.46	5.20	17
7.13	6.88	6.53	18
7.07	6.86	6.20	19
6.9	6.8	5.9	20
6.95	6.83	6.35	21

* Chromatograms are shown in Fig. 2(a).
The concentrations of each species are as follows: $[M]_t=1.00$ mM (1M=1 mol dm^{-3}); $[L]_t=2.00$ mM; $[M^{2+}]=(0.16\pm0.02)$ mM; $[ML^{2+}]=(0.29\pm0.01)$ mM; $[ML_2^{2+}]=(0.41\pm0.01)$ mM; $[ML_3^{2+}]=(0.16\pm0.005)$ mM; $[L]+[HL^+]\fallingdotseq[HL^+]=(0.35\pm0.03)$ mM; pH=1.21.
From the measurements of the peak height, the total concentration of $[M_t]$ was calculated to be (1.02±0.045) mM.

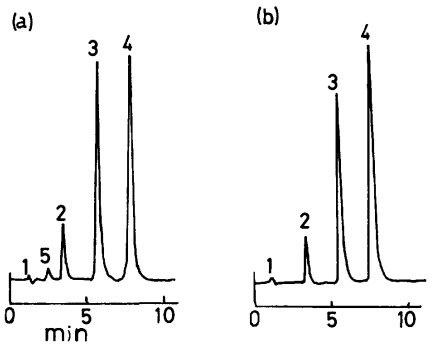

Fig. 3. Chromatograms of nickel(II)-phen system at $[L_t]/[M_t]=2.0$. For chromatographic conditions, see text.
$[M_t]=0.5$ mM, $[L_t]=1.0$ mM, pH=1.3(a), 6.2(b) (HCl–NaCl, $Cl^-=0.05$ M)
1 M^{2+} (solvent front), 2 ML^{2+}, 3 ML_2^{2+}, 4 ML_3^{3+}, 5 HL^+.

by the use of the HPLC solvent. Each sample solution was left to stand at least 2 h and then submitted to HPLC. From the peak heights (or areas) of ML_3^{2+} which then appeared on chromatograms, the initial concentrations of ML_2^{2+}, ML^{2+}, and M^{2+} were calculated. In order to confirm that each species was converted into the 1:3 complex thoroughly, the following experiments were carried out. The aquanickel(II) ion (M^{2+}) was dissolved in the HPLC solvent in the presence and absence of EDTA and tartaric acid. A slight excess of bpy was added to these solutions and pH was adjusted to be almost neutral. These two solutions were then diluted to a definite volume and were submitted to HPLC. The peak heights of ML_3^{2+} were similar for these two sample solutions, suggesting the complete 1:3 complex formation.

Now, the concentrations of M^{2+}, ML^{2+}, ML_2^{2+}, ML_3^{2+}, and HL^+ were determined by HPLC, K_1, K_2, and K_3 can be determined if the dissociation constant of bpy (K in Eq. 8) is known. Table 1 indicates these values by assuming log K=4.4.[16] The stepwise complex formation constants reported by other authors[17–21] are also included in this table. The present values agree very well with the results of other authors, suggesting the reliability of the present HPLC method.

Table 2. Stepwise complex formation constants of the nickel(II)-phen system at 25 °C

$\log K_1$	$\log K_2$	$\log K_3$	Ref.
8.97±0.35	8.82±0.16	8.40±0.15	This work*
8.60	8.10	7.55	22
8.80	8.30	7.70	23
8.8	8.3	7.7	18
8.0	8.0	7.9	19
8.65	8.43	7.83	24

* Chromatograms are shown in Fig. 3(a).
The concentrations of each species are as follows: $[M]_t=0.50$ mM; $[L]_t=1.00$ mM; $[M^{2+}]=(0.03\pm0.01)$ mM; $[ML^{2+}]=(0.10\pm0.01)$ mM; $[ML_2^{2+}]=(0.21\pm0.01)$ mM; $[ML_3^{2+}]=(0.17\pm0.01)$ mM; $[L]+[HL^+]\fallingdotseq[HL^+]=(0.015\pm0.003]$ mM; pH=1.33.
The concentration of $[M_t]$ was calculated to be (0.51±0.04) mM.

Ni^{2+}-phen System. Similar experiments were carried out for the Ni^{2+}-phen system. The chromatogram patterns obtained resembled those for the Ni^{2+}-bpy system. The results at $[L_t]/[M_t]=2.0$ are exemplified in Figs. 3(a) and (b) under acidic and almost neutral conditions. The equilibrium concentrations of M^{2+}, ML^{2+}, ML_2^{2+}, ML_3^{2+}, and HL^+ were determined by HPLC with similar procedures; thus, the stepwise complex formation constants were calculated. The results are tabulated in Table 2, assuming that log K=5.0.[16] The results reported by other authors[18,19,22–24] are also appended in this table. The present results agree fairly well with those of other authors, though the present data are slightly larger. A comparison of Table I and Table II indicates that the ratio of HL^+ and ML^{2+} is smaller in the Ni^{2+}-phen system than in the Ni^{2+}-bpy system. This may be attributed to the fact that the stepwise complex formation constants are larger for the Ni^{2+}-phen system than for the Ni^{2+}-bpy system.

The Color Reaction of Purine Bases by Ternary-complex Formation with Eosin and Silver(I)†

Yoshikazu FUJITA, Itsuo MORI,* Shoko KITANO,
Hiroshi KAWABE, and Yoshiyuki KAMADA
Osaka College of Pharmacy, 2-10-65, Kawai, Matsubara, Osaka 580
(Received December 7, 1983)

A color reaction of purine bases utilizing a ternary-complex system among a purine base, a metal ion, and a xanthene dye was studied, and the fundamental conditions for the spectrophotometric determination of purine bases(as adenine) with eosin and silver(I) were established. The absorption maxima of the ternary-complexes lie at 550—560 nm against water. The optimum pH ranges for the color formation of the complexes are pH 4.8—5.4. Beer's law is obeyed over the range of 1—10 μg/10 cm³ of adenine, and the apparent molar absorptivity is 1.1×10^5 dm³ mol⁻¹ cm⁻¹ at 560 nm. In the determination of adenine, the coexistence of pyrimidine bases, such as uracil and cytosine, and nucleotides containing adenine, such as 5′-adenosine triphosphate(ATP) and β-nicotinamide-adenine dinucleotide(NAD), scarcely interfere.

Various photometries and fluorometries of ions and substances utilizing the ternary-complex system (metal ion-electronegative ligand-organic base system) have been reported[1-8]; for example, the ionic-association complex system between a metal ion-1,10-phenanthroline(phen) cation and the anion of a dyestuff such as a xanthene derivative have been studied.

Eosin(2,4,5,7-tetrabromofluorescein) as a xanthene derivative is already used for the determination of such metal ions as silver(I), cadmium(II), iron(III), and cobalt(II).[9-15] However, the method for the determination of organic compounds by using eosin and a metal ion have not been reported entirely.

On the other hand, we recognized that the addition of a purine base to an eosin-silver(I) solution (Solution C) showed a red shift compared with that of Solution C or eosin solution (Solution B), and that the magnitude of the increase in the absorbance of this mixed solution at around 550—560 nm was proportional to the concentration of a purine base.

In this paper, therefore, the fundamental conditions for a new color reaction of purine bases by ternary-complex formation with eosin and silver(I) were studied, and the spectrophotometric determination of purine bases(as adenine) using this color reaction has been established.

Experimental

Reagents and Materials. Stock solutions (1.0×10^{-2} mol dm⁻³) of purine bases were prepared by dissolving proper quantities of purine bases in 2 cm³ of 10% sulfuric acid and diluting the mixtures to 100 cm³ with water. The working solution was made up to the suitable dilution by the use of this stock solution as required. A stock solution (1.0×10^{-1} mol dm⁻³) of silver(I) was prepared by dissolving silver nitrate in water, and then corrected by potentiometry. The working solution (1.0×10^{-3} mol dm⁻³) was made by the suitable dilution of this stock solution. A solution (1.0×10^{-3} mol dm⁻³) of eosin was prepared by dissolving eosin ($C_{20}H_6O_5Br_4Na_2$, Tokyo Kasei Kogyo Co., Ltd., Tokyo) in water. A 2.0% poly(*N*-vinylpyrrolidone)(PVP) solution was prepared by dissolving PVP (K-15, Tokyo Kasei Kogyo, Co., Ltd.) in water. A buffer solution (pH 5.0) was prepared by mixing 0.2 mol dm⁻³ acetic acid and 0.2 mol dm⁻³ sodium acetate solutions. All the other reagents and materials were of an analytical grade and were used without further purification. Doubly distilled water was used.

Apparatus. A Shimadzu Model UV-240 recording spectrophotometer with 1.0-cm quartz cells was used for the absorption spectra and absorbance measurements. A Hitachi-Horiba Model F-7 AD glass electrode pH meter was used for the pH measurements. A Metrohm Model E336A potentiograph was employed for the potentiometric titrations.

Standard Procedure for the Determination of Adenine. A solution containing 1—10 μg adenine was transferred to a 10 cm³ volumetric flask; to this solution 1.0 cm³ of a 2.0% PVP solution, 3.0 cm³ of the buffer (pH 5.0) solution, 0.5 cm³ of a 1.0×10^{-3} mol dm⁻³ eosin solution and 1.0 cm³ of a 1.0×10^{-3} mol dm⁻³ silver(I) solution were added. The mixture was diluted to 10 cm³ with water, kept at 45 °C for 20 min, and then cooled for 10 min in water. The absorbance of the eosin-silver(I)-adenine solution (Solution A) was measured at 560 nm against a eosin solution (Solution B).

Results and Discussion

Color Reaction and Absorption Spectra. On the addition of adenine, a purine base, to the eosin-silver(I) solution (Solution C), the maximum absorption of the eosin-silver(I)-adenine ternary complex solution (Solution A) at around 560 nm was distinctly observed; its absorbance was proportional to the concentration of adenine. Solution A without a surfactant was unstable, and it gradually precipitated on standing. The use of a nonionic surfactant was effective as a dispersion agent. By the way, no difference in absorption spectra between Solution C and the eosin solution (Solution B) in the absence of adenine was observed. The absorption spectra of Solutions A, B, and C in the presence of PVP at pH 5.0 are shown in Fig. 1.

On the other hand, other purine bases, such as guanine or phen, also formed the colored complexes, but the difference in absorbance between Solution B and its ternary complex solution was small as compared with that of the adenine complex solution. The absorption spectrum of the eosin-silver(I)-guanine solution or the eosin-silver(I)-phen solution under the same condi-

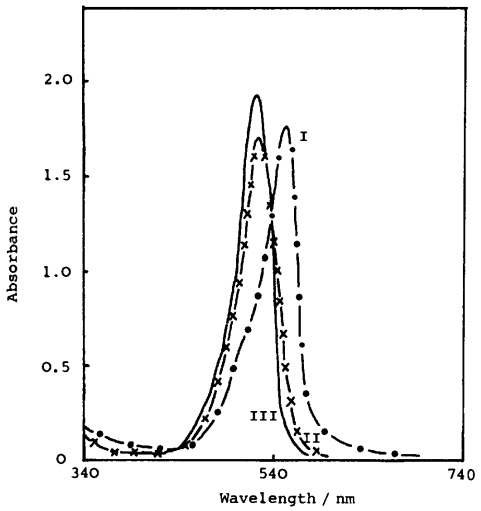

Fig. 1. Absorption spectra of eosin, eosin-silver(I), eosin-silver(I)-adenine, eosin-silver(I)-guanine, and eosin-silver(I)-phen solutions at pH 5.0.
Eosin: 2.5×10^{-5} mol dm^{-3}; silver(I): 5.0×10^{-5} mol dm^{-3}; adenine, guanine, and phen: 5.0×10^{-5} mol dm^{-3}; PVP: 1.0 cm^3 of 2.0% PVP solution/10 cm^3; Reference: water; curve I: eosin-silver(I)-adenine solution; curve II: eosin-silver(I)-guanine and eosin-silver(I)-phen solutions; curve III: eosin-silver(I) and eosin solution.

tions is also shown in Fig. 1.

The effect of dyes was studied by measuring the absorbance of Solution A against a dye solution. Eosin was superior to the other dyes tested in terms of sensitivity. The results are given in Table 1.

Only silver(I) was effective among the various metal ions: silver(I), cadmium(II), copper(II), zinc(II), iron (III), manganese(II), cobalt(II), cerium(III), lanthanum(III), thorium(IV), paladium(II), *etc.* The eosin-silver(I)-purine base ternary complex solution was fairly stable and was scarcely affected by any metal ions.

In the ternary complex systems among eosin, silver(I), and purine bases, the color reactions of various purine bases were examined. The difference in absorbance between the eosin-silver(I)-adenine solution and Solution B was larger than that of the other purine bases tested. The results are given in Table 2.

From the results described above, adenine was chosen for the purpose of fundamental investigations of the determination of purine bases, and the absorbance of Solution A at 560 nm against Solution B was measured in order to allow the determination of adenine.

Effect of pH. The effect of the pH on the color development was investigated with a solution containing 6.8 μg/10 cm^3 adenine. As is shown in Fig. 2, the ranges in which the maximum and nearly constant absorbance was observed at pH 4.8—5.4. Hence, the pH value of 5.0 with a 0.2 mol dm^{-3} acetic acid —0.2 mol dm^{-3} sodium acetate buffer solution was used for the pH adjustment.

Effect of Surfactants. Among the various surfactants tested, PVP(K-15), a nonionic surfactant, was best as a dispersion agent; the maximum and constant absorbance of Solution A was observed upon the addition of more than 0.75 cm^3 of a 2.0% PVP solution to the final volume of 10 cm^3. The results are given in Table 3.

Effect of Eosin and Silver(I) Concentrations. The effect of the amounts of eosin and silver(I) was exam-

Adenine taken: 6.8 μg/10 cm^3; eosin: 5.0×10^{-5} mol dm^{-3}; silver(I): 1.0×10^{-4} mol dm^{-3}; surfactant: 1.0 cm^3 of 2.0% surfactant solution/10 cm^3; pH: 5.0; Reference: Solution B.

ined by varying the molar ratio of eosin to silver(I), the amount of adenine being kept constant. A maximum and almost constant absorbance was observed upon the addition of a 0.5—1.5 cm^3 of 1.0×10^{-3} mol dm^{-3} silver(I) solution. The molar ratio of silver(I) to eosin in the complex was found by the molar-ratio method to be 2:1 in the presence of adenine.

Accordingly, all further work was carried out with 5.0×10^{-5} mol dm^{-3} eosin and 1.0×10^{-4} mol dm^{-3} silver(I) in the final volume.

Sequence of Addition and Stability. The maximum absorbance was obtained when silver(I) was finally added to an eosin-adenine solution. The color formation of the ternary complex did not occur instantaneously at room temperature (15—25 °C), about more than 120 min being required for a complete color reaction. The effect of the temperature on the color formation was examined by heating the mixed solution for 10—60 min at various temperature (30°, 45°, or 60 °C); the maximum and constant absorbance was obtained by heating for 20 min at 45 °C and cooling for 10 min in water. The absorbance was constant for at least 2 h at room temperature.

Calibration Curve. The calibration curve for adenine was constructed according to the standard procedure. It was found that Beer's law held in the concentration range of 1—10 μg of adenine in the final volume of 10 cm^3. The apparent molar absorptivity at 560 nm was estimated to be 1.1×10^5 dm^3 mol^{-1} cm^{-1}. The sensitivity, according to Sandell's scale, was 0.0013 μg cm^{-2} for adenine. The relative standard deviation for five replicate determinations was 0.68% for 6.8 μg of adenine.

Effects of Foreign Substances. The effects of foreign substances on the determination of adenine were also examined. The coexistence of most metal ions did not interfere in a 100-fold excess over adenine. Among the various anions tested, the coexistence of small amounts of thiosulfate, thiocyanate, cyanide, and iodide, and the presence of large amounts of chloride gave negative errors because of reacting with silver(I). These anions could be conveniently eliminated by the addition of a silver nitrate solution as a preliminary step. Anions such as phosphate, nitrate, and organic acid ions did not interfere. The presence of small amounts of such purine bases as guanine, hypoxanthine, 6-mercaptopurine, and 6-iodopurine, and the coexistence of large amounts of such purine bases as purine, 1-methyladenine, and uric acid did interfere, though, xanthine derivatives such as caffeine and theophilline, and pyrimidine bases such as uracil and cytosine, did not affect the determination of adenine. Moreover, nucleosides and nucleotides, such as adenosine, 5′-adenine triphosphate (ATP), β-nicotinamide-adenine dinucleotide (NAD) and adenosine cyclic 3′,

Silver(I): 2.0×10^{-5} mol dm^{-3}; eosin: 2.0×10^{-4} mol dm$^{-3}\times$X cm^3/10 cm^3; adenine: 1.0×10^{-4} mol dm^{-3}; PVP: 1.0 cm^3 of 2.0% PVP solution/10 cm^3; pH: 5.0; Reference: Solution B.

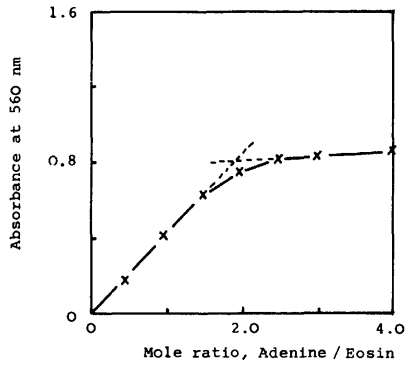

Fig. 4. Composition of [adenine: eosin] in the presence of silver(I) obtained by the molar-ratio method. Silver(I): 2.0×10^{-5} mol dm^{-3}; eosin: 1.0×10^{-5} mol dm^{-3}; adenine: 1.0×10^{-4} mol dm$^{-3}\times$X cm^3/10 cm^3; PVP: 1.0 cm^3 of 2.0% PVP solution/10 cm^3; pH:5.0; Reference: Solution B.

5′-monophosphate (cyclic AMP), also did not interfere in a 100-fold excess. Though such amines as putrescine, spermidine and tryptamine interfered in large amounts, amino acids, D-glucose, L-ascorbic acid, *etc.* did not interfere. The results are summarized in Table 4.

The Composition of the Complex. The mole ratio of silver(I) to eosin was established by the molar-ratio and continuous-variation methods. The results indicated that the mole ratio of silver(I) to eosin was 2:1. The results obtained by the molar-ratio method are shown in Fig. 3.

It was found that the adenine-to-eosin ratio obtained by the molar-ratio method was 2:1, as is shown in Fig. 4.

From these results, it is deduced that the ternary complex formed in this reaction system may be expressed as (adenine)$_2$(Ag)$_2$(eosin).

Color Reaction between Substances Containing Adenine and Solution C. The color reactions between some substances containing adenine and Solution C were also studied. No difference in color between these substances containing adenine and Solution C was observed. Therefore, liberated adenine was determined by the standard procedure after these substances containing adenine had been treated with acid-hydrolysis as a preliminary step. The results are given in Table 5.

Though further investigation is necessary, this proposed method may also be useful in the determination of nucleosides and nucleotides.

Conclusion

The fundamental conditions for the color reaction of purine bases by ternary-complex formation with eosin and silver(I) have been discussed, and a spectrophotometric method for the determination of adenine, a purine base, utilizing this ternary complex has been established. This method could be used in the concentration range of 1—10 μg/10 cm^3 adenine at 560 nm. The apparent molar absorptivity in this procedure was estimated to be 1.1×10^5 dm^3 mol^{-1} cm^{-1} for adenine. The method is inferior to the fluorometric methods[16,17] in sensitivity, but it is about 10 times more sensitive than the method[18] utilizing the diazo-coupling reaction with the Brotton-Marshall reagent. This method is superior to those methods in terms of rapidity, simplicity, and reproducibility. In addition, this proposed method for the determination of adenine is scarcely affected by the coexistence of pyrimidine bases, such as uracil and cytosine, and the substances containing adenine, such as adenosine, ATP and NAD. The application to the determination of these nucleosides or nucleotides with a suitable preliminary treatment may be feasible. Therefore, the application to high-performance liquid chromatography for purine bases can also be expected.

(Received January 24, 1984)

The synthesis and crystal structure of the complex [Ni(en)(L-sor-en)]$Cl_2 \cdot 1/2CH_3OH$ which was derived from the reaction of tris(ethylenediamine)nickel(II) dichloride dihydrate with L-sorbose are described. Crystallographic details for the complex are follows: space group C2 (monoclinic); a=17.862(2) Å, b=8.212(1) Å, c=12.644(2) Å, β=90.89(1)°; Z=4; D_{calcd}=1.53 gcm^{-3}. The structure was solved by heavy atom methods, and the structure parameters including almost all hydrogen atoms were refined by least-squares methods. The final R factor was 0.032 for 2680 independent reflections. The nickel atom is octahedrally coordinated with a bidentate ethylenediamine and a tetradentate glycosylamine ligand of L-sor-en. L-Sorbose moiety adopts the six-membered α-$^2C_5$ chair conformation. In addition to the synthesis and structure of this complex, we report the results of absorption and circular dichroism spectroscopy.

Carbohydrates have long been known to form complexes with metal ions. The interactions between metal and carbohydrates in solution have been much studied; by potentiometric titration,[1] electrophoresis,[2] circular dichroism,[3] NMR spectroscopy,[4] ESR spectroscopy,[5] and chromatography,[6] *etc.* There are many complexes of alkaline earth metals with carbohydrates, some of which were analyzed by X-ray crystallography,[7] however only a few transition metal complexes, which were confirmed to have sugar chelates, have been reported.[8]

Recently the structure of both complexes [Ni(en)(D-fru-en)]$CL_2 \cdot CH_3OH$[9] (**1**) and [Ni(L-rham-tn)$_2$]$Br_2 \cdot 2H_2O \cdot CH_3OH$[10] (en=ethylenediamine, D-fru-en=2-[(2-aminoethyl)amino]-2-deoxy-D-fructose, tn=trimethylenediamine, L-rham=tn=1-[(3-aminopropyl)amino]-1-deoxy-L-rhamnose) was determined by X-ray crystallography. The crystal structure of complex **1** suggested that an *N*-glycoside derived from a ketose and a diamine coordinates to the nickel atom through the two oxygen atoms of the hydroxyl groups on C-1 and C-3 of the sugar moiety and through the two nitrogen atoms of the diamine. It also indicated that the coordination structure of a ketose will depend on the orientation of the C-3 hydroxyl group and this makes a significant contribution to the circular dichroism.

In the course of our study to clarify the interactions between transition metals and carbohydrates,[9,10] we have prepared and characterized a new nickel(II) complex containing an *N*-glycoside which was derived from the reaction of tris(ethylenediamine)nickel(II) ion with L-sorbose. Since L-sorbose is C-5 epimer of D-fructose, the absolute configurations around other asymmetric carbon atoms are the same as those of D-fructose in the pyranose form (Fig. 1). Consequently the coordination behaviour of *N*-glycosides derived from L-sorbose, and the circular dichroism of their complexes are expected to be similar to those for complexes

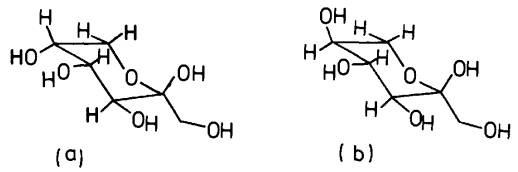

Fig. 1. The structure of ketohexoses in the pyranose form: (a) α-L-sorbose and (b) β-D-fructose.

of D-fructose. However, the CD curves of the complexes are different, as is shown later in this report. To clarify the stereochemistry of this complex, we have undertaken a crystal and molecular structure determination. A preliminary account of this work has already appeared.[11]

Experimental

All materials were reagent grade. L-Sorbose was purchased from Tokyo Kasei Co., [Ni(en)$_3$]$Cl_2 \cdot 2H_2O$[12] was prepared by the ordinary method.

Preparation of [Ni(en)(L-sor-en)]$Cl_2 \cdot 1/2CH_3OH$ (2)

This complex was prepared from tris(ethylenediamine)-nickel(II) complex and L-sorbose by a similar method described previously[9] with slight modifications, as follows. To a solution of 8.8 mmol [Ni(en)$_3$]$Cl_2 \cdot H_2O$ in 80 mL of methanol was added 17.6 mmol of L-sorbose and 8.8 mmol of NH_4Cl, and heated to reflux for 1 h. The color of the solution changed from violet to blue. Then it was concentrated to about 30 mL by a rotary evaporator and poured on to a column of Sephadex LH-20 gel (4 cm×90 cm), and the material was eluted with methanol. The colored material was separated into violet, blue, yellow, and orange bands. The blue fractions were collected and concentrated to about 15 mL and kept at 5 °C. Blue crystals (520 mg) were obtained, they were recrystallized from a minimum amount of hot methanol. Found: Ni, 14.3; C, 29.19; H, 6.86; N, 13.36; Cl, 16.56; Calcd. for $C_{10.5}H_{28}N_4O_{5.5}Cl_2Ni$: Ni, 13.7; C, 29.46;

H, 6.61; N, 13.09; Cl, 16.56.

Measurements Visible and near infrared absorption spectra were measured with a Hitachi model 340 recording spectrophotometer. Reflectance spectra were recorded on this instrument equipped with a reflectance attachment. Circular dichroism spectra were recorded on a Jasco J-500 recording spectropolarimeter. Magnetic susceptibility was measured at room temperature using a Shimadzu MB-100 magnetic balance (Faraday method). Diamagnetic corrections were calculated from Pascal's constants.[13]

Crystal Data and Intensity Data Collection of [Ni(en)(L-sor-en)]Cl$_2$·1/2CH$_3$OH. A block-shaped blue crystal (0.56×0.50×0.35 mm), which was coated with epoxy cement, was used to collect diffraction data on a Rigaku AFC-5 four-circle automated diffractometer controlled by a Facom U-100 computer and the Rigaku FOS program system, equipped with Mo $K\alpha$ radiation (λ=0.71073 Å). The accurate unit cell dimentions were determined by least-squares methods from θ values for 40 reflections in the range of 25°—31° measured on the diffractometer. Crystal data are as follows.

[Ni(en)(L-sor-en)]Cl$_2$·1/2CH$_3$OH, $C_{10.5}H_{28}N_4O_{5.5}Cl_2Ni$, M.W.=428.02, Monoclinic, space group C2, a=17.862(2), b=8.212(1), c=12.644(2) Å, β=90.89(1)°, D(obsd)=1.55 g cm^{-3} (by flotation in 1,2-dichloroethane and 1,2-dibromoethane mixture), D(calcd)=1.53 g cm^{-3}, Z=4.

Intensity data were collected by θ-2θ method (2$\theta \leqq 60°$), scan speed=3°/min, scan width=(1.2+tanθ)°. Backgrounds were measured both at the beginning and the end of the scan, each for half time of the scan. Three standard reflections were monitored for every fifty reflections, and no significant changes were found. Of the 2997 reflections collected, 2680 independent reflections with $|F_o|>3\sigma(|F_o|)$ were used in the structure analysis. The intensity data were corrected for standard Lorentz-polarization effects. An absorption correction with a numerical integration procedure was applied; μ=13.92 cm^{-1} (Mo $K\alpha$).

Structure Solution and Refinement. All calculations were carried out on a HITAC M-200H system of The Computer Center of The Institute for Molecular Science with a universal computing program UNICS-III.[14] The initial coordinates of the nickel atom were determined by a three dimensional Patterson synthesis. The positions and isotropic temperature factors of other nonhydrogen atoms were determined by means of mutual cycles of Fourier synthesis and block-diagonal least squares refinement. Atomic scattering factors were taken from Ref. 15. A methanol molecule was found to be located close to a special position on the twofold axis. A weighting scheme $1/w=\sigma_{count}^2+(0.015|F_o|)^2$ was employed and anomalous scattering factors[16] for non hydrogen atoms were introduced in F_c. Least-squares refinement of the atomic parameters with isotropic temperature factors of the nonhydrogen atoms gave convergence at R=10.16%. ($R=\sum||F_o|-|F_c||/\sum|F_o|$). The absolute configuration of this complex was determined from the known configuration of L-sorbose. When the f'' values of Ni, Cl, O, N, and C atoms were reversed in sign to test the structure, the convergence was reached to R=10.34%. At this stage, anisotropic temperature factors were introduced for all nonhydrogen atoms. Difference Fourier synthesis made clear the locations of all hydrogen atoms of the complex cation except for H(C9)1, the coordinates of this H(C9)1 were calculated by assuming a tetrahedral coordination with C-H bond distance of 1.08 Å. The positional parameters and isotropic temperature factors of all hydrogen atoms are also refined. The final R factor was 0.032, and R_w was 0.042 ($R_w=[\sum w(|F_o|-|F_c|)^2/\sum w\cdot|F_o|^2]^{1/2}$). The final difference Fourier synthesis revealed no unusual features with the highest peak being 0.71 Å^{-3}. The anisotropic thermal parameters and complete list of the $|F_o|$ and $|F_c|$ values have been preserved by the Chemical Society of Japan (Document No. 8425).

Results and Discussion

Synthesis. The reaction of L-sorbose with [Ni(en)$_3$]Cl$_2$·H$_2$O was studied and the new complex containing glycosylamine ligand (L-sor-en) was isolated. The method of preparation was almost the same as described previously to prepare the glycosylamine complex containing another monosaccharides.[9] When tris diamine nickel(II) complex and L-sorbose are refluxed in methanol, the solution becomes blue. This solution is separated into four bands by gel permeation chromatography. The first violet band consists of the starting nickel-diamine complex, the second blue band contains glycosylamine complex, and the contents of the third and the fourth fractions (yellow and orange) are not clear. Blue crystals are obtained from blue fractions. When NH_4Cl is not added to the reactant, more reaction time is necessary and about half of the yield of glycosylamine complex is obtained. Consequently NH_4Cl appears to act as a general acid base catalyst similar to the formation of glycosylamine without metal.[17] Analytical data indicated that this complex has a glycosylamine and a diamine similar to [Ni(en)(D-fru-en)]Cl$_2$·CH$_3$OH.[9] This complex is soluble in methanol and water, but it decomposes in a few days in water.

Magnetic Moments and Absorption Spectra. Magnetic moments and absorption spectra were measured to investigate the coordination geometry of the nickel complex. The effective magnetic moment at room temperature of this complex **2** is 3.17 μ_B, which is normal for octahedral nickel(II) complexes.[18] Near-infrared and visible absorption spectra and CD spectra of this complex together with complex **1** in methanolic solution are given in Fig. 2. Table 1 lists their spectral data. Both of these absorption spectra possess three peaks in the near-infrared and visible region

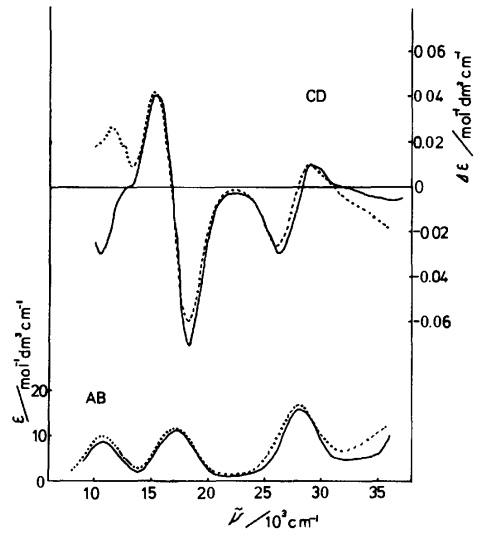

Fig. 2. Absorption and circular dichroism spectra of complexes: [Ni(en)(L-sor-en)]$^{2+}$ (——) and [Ni(en)-(D-fru-en)]$^{2+}$ (----).

and the molar absorption coefficient of these peaks are comparatively small. These spectral features are typical for octahedral nickel(II) complexes.[19] The $10D_q$ value of complex **2**, which is equal to the energy of the first absorption peak in the case of d^8 octahedral complex, is 10.7 kcm^{-1}, that is normal for N_4O_2 nickel(II) octahedral complex.[19] The absorption spectra of the complexes **1** and **2** are almost identical, so it is deduced that these complexes have similar ligand fields around the nickel atoms.

Crystal and Molecular Structure of [Ni(en)(L-sor-en)]-$Cl_2 \cdot 1/2CH_3OH$. Since this structure analysis yielded a high degree of convergence of parameters for a sugar-containing complex (R=0.032), the coordinates of all atoms including hydrogen atoms of the complex cation were determined. The final atomic coordinates, bond distances, and bond angles are listed in Tables 2, 3, and 4, respectively.

Fig. 3 shows an ORTEP drawing[20] of the complex cation $[Ni(en)(L\text{-sor-en})]^{2+}$. The nickel atom is coordinated with four nitrogen atoms and two oxygen atoms. The coordination geometry of this complex resembles that of the D-fructose complex **1**. The nickel atom is coordinated with a tetradentate glycosylamine (L-sor-en) and a bidentate diamine (en).

The glycosylamine coordinates to the nickel atom at four points through the two hydroxyl groups on carbon 1, and carbon 3 of the sugar moiety, and the two nitrogen atoms of the ethylenediamine residue. In the glycosylamine, L-sorbose moiety has the usual α-$^2C_5$ pyranose form. This form is the most stable in the solution of L-sorbose alone,[21] and it is known that crystalline α-L-sorbose also takes this form.[22] This anomeric structure is equivalent to the case of the D-fru-en complex **1**, although the nomenclature of the anomeric form in the complex **1** is β because the nomenclature of the anomeric form is reversed whether the absolute configuration of the ketose is D or L. In the tetradentate glycosylamine ligand, five membered chelate ring of the ethylenediamine moiety adopts a symmetrical gauche conformation, but other five membered chelates (Ni-N(1)-C(2)-C(3)-O(3)) and

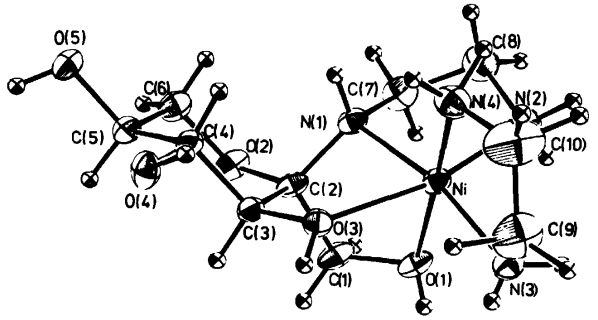

Fig. 3. A perspective drawing of the complex cation $[Ni(en)(L\text{-sor-en})]^{2+}$.

(Ni-N(1)-C(2)-C(1)-O(1)) are in the asymmetrical ones. The absolute configuration of the secondary nitrogen atom is *S*. These structural features around the nickel atom are common to complex **1** and **2**. The bidentate ethylenediamine chelate has the δ-gauche conformation (Fig. 4), although the corresponding ethylenediamine chelate ring of the complex **1** has the λ-gauche conformation. This is the most conspicuous difference of the structure around the nickel atom between complex **1** and **2**.

The coordination geometry around the nickel atom of the complex **2** is distorted octahedral symmetry. The least cis angle around the nickel atom is 76.1° (O(1)-Ni-N(1)), and the largest cis angle is 105.5° (N(1)-Ni-N(4)). Furthermore, the least trans angle around the nickel atom is 162.8° (Table 4). This tendency for distortion from an octahedron is similar to the

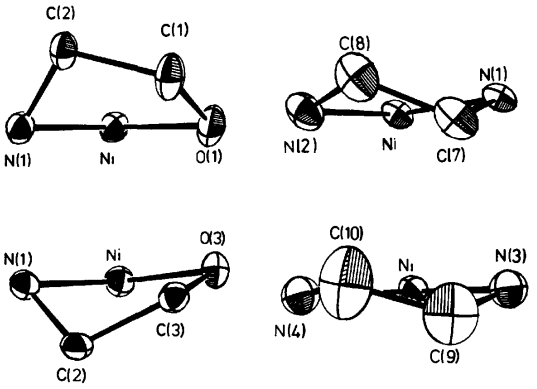

Fig. 4. Perspective drawings of the chelate rings.

case of complex **1**. The bite angle of the five membered chelate rings are smaller than ninety degrees, and they are normal.[24] The conformation of L-sorbose moiety is the typical chair form. The angles of C-C-C and C-O-C in the pyranose ring are within 110°±2.1° similar to α-L-sorbose crystals.[22]

The average nickel-nitrogen bond distance of 2.08 Å is very close to that in the complex **1** (2.07 Å), and they are normal values in comparison with the reported nickel-nitrogen bond distances. The average nickel-oxygen bond distance of 2.13 Å is slightly shorter than that in the complex **1** (2.17 Å), however these values are considerably longer compared with the reported nickel-oxygen distances of carboxylate complexes.[23] These results show that the coordinate bond between the nickel and the hydroxyl groups is comparatively weak. In this structure analysis the coordinates of all hydrogen atoms of the complex cation were refined by least squares methods. The average oxygen-hydrogen bond distance of the coordinated hydroxyl groups is 0.76(4) Å, which is shorter than that of free hydroxyl groups (0.88(4) Å). The average angle around the coordinated oxygen atoms is 114(2)°. As mentioned above, the coordination structure of the hydroxyl groups to the nickel ion is revealed. This is one of the important results of this structure analysis, since the orientation of hydroxyl groups can not be estimated by geometric considerations. This is a rare sample to clarify the coordination geometry of hydroxyl groups to the nickel ion.

The unit cell contains four complex cations, eight Cl^- anions and two methanol molecules of solvation. The carbon atom of this methanol molecule is located at a special position on the twofold axis, so that the oxygen atom of this methanol is disordered to two positions, each of which has a population of 0.5. The stereoview of the unit cell is shown in Fig. 5. Hydrogen bonds of the type O-H···Cl and N-H···Cl probably exist between O(4)···Cl(2), O(5)···Cl(2), N(1)···Cl(1), and N(3)···Cl(1). Since the interatomic distance of O(3)···O(4) between two molecules is short (2.68 Å), they are probably linked by hydrogen bonding. The hydrogen bonding distances are listed in Table 5.

Circular Dichroism. In the octahedral ligand field, only the lowest energy transition $^3A_{2g} \rightarrow {}^3T_{2g}$ is magnetic dipole allowed in the case of nickel(II) com-

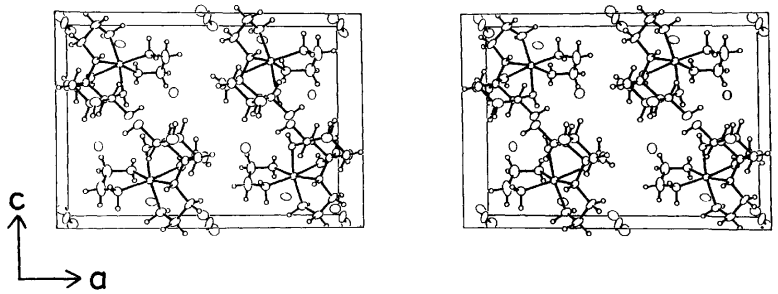

Fig. 5. A stereo view of the unit cell.

TABLE 5. INTERATOMIC DISTANCES<3.5 Å OUTSIDE THE COMPLEX CATION AND ESTIMATED STANDARD DEVIATIONS: A-H···B

Atom A	Atom B	A-H Distance l/Å	A···B Distance l/Å	Symmetry of Atom B
O(4)	Cl(2)	0.90(5)	3.032(2)	x, y, z
O(5)	Cl(2)	0.86(3)	2.980(3)	$1.5-x$, $-0.5+y$, $1-z$
O(3)	O(4)	0.90(5)	2.678(4)	$1.5-x$, $0.5+y$, $1-z$
N(3)	Cl(1)	0.88(4)	3.275(3)	$1.5-x$, $-0.5+y$, $1-z$
N(3)	Cl(1)	0.93(5)	3.316(3)	$1.5-x$, $-0.5+y$, $1-z$

plex. The two higher energy spin allowed transitions are magnetic dipole forbidden and are expected for CD bands significantly weaker than the allowed transitions. It is often observed that the CD pattern of the first transition band is too much influenced by stereochemical features of dissymmetric nickel(II) complexes.[25] The CD spectra of $[Ni(en)(D\text{-fru-en})]^{2+}$ and $[Ni(en)(L\text{-sor-en})]^{2+}$ in methanol are shown in Fig. 2. They have CD curves of opposite sign in the first absorption region. The X-ray crystal structure analysis for both the complexes revealed that the structure of the two complex cations are similar except for the orientation of each C-5 atom and the conformation of each bidentate ethylenediamine. In this case the contributions of these stereochemical differences mentioned above can be ruled out, since each C-5 atom is far from the central metal atom to effect the circular dichroism in the d-d bands, and an ethylenediamine chelate makes a rapid interconversion between δ and λ in solution. Therefore it is an unusual fact that the CD curves of the complexes are dissimilar. On the other hand it is interesting to note that their CD spectra are nearly identical in the second and third absorption region. These results indicate that detailed stereochemical examinations using many kinds of diamines and ketoses are necessary to establish the relationships between the structure of the complexes and their CD spectra.

The results obtained in this study revealed that L-sorbose reacts with $[Ni(en)_3]^{2+}$ to yield the octahedral nickel(II) complex which is surrounded with a bidentate ethylenediamine and a tetradentate *N*-glycoside. The X-ray crystallographic study of this complex revealed the coordination structures of hydroxyl groups to the nickel atom. The results of the crystal structure of $[Ni(en)(D\text{-fru-en})]Cl_2 \cdot CH_3OH$[9] and $[Ni(en)(L\text{-sor-en})]Cl_2 \cdot 1/2CH_3OH$ confirmed that the coordination geometry of these complexes is almost the same, and that the coordination pattern of an *N*-glycoside ligand derived from a ketose and a diamine depends on the orientation of the C-3 hydroxyl groups of the sugar. Unusual features were observed in the CD spectra of these complexes.

The authors wish to thank Prof. Kozo Sone and Dr. Yutaka Fukuda of Ochanomizu University for help in obtaining the magnetic data. The present work was partially supported by a Grant-in-aid for Scientific Research (No. 58540380) from the ministry of Education, Science and Culture.

Inductively Coupled Plasma Atomic Emission Spectrometry Utilizing a Direct Graphite Cup Insertion Technique

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received January 18, 1984)

A preliminary study on analytical performances of graphite sample cups is described for an instrumental assembly to carry out microliter volumes of liquid sample analysis. The graphite cup with a graphite rod and an insulating handle is inserted axially *via* the injector tube of a quartz torch into a low power operated inductively coupled argon plasma. Univariate search method has been employed for optimization of cup size, rod height and plasma operating parameters for manganese ionic line at 257.6 nm to obtain the most favorable net signal-to-background ratio. Detection limits, reproducibilities and dynamic ranges are also reported for manganese, zinc, lead, chromium, and nickel in solution.

In addition to conventional pneumatic nebulization, sample introduction into an inductively coupled plasma (ICP) for atomic emission spectrometry has been concerned with external vaporization using electrothermal heating,[1,2] spark excitation,[3] or laser ablation.[4] In these introduction techniques, the generated aerosol is transported into the plasma with a stream of the carrier gas.

Recently, Salin and Horlick[5] described a method in which samples were introduced directly into a 2.5 kW argon ICP using a graphite electrode inserted axially *via* the injector tube of a Fassel type torch. In their experiments, the plasma had to be ignited and extinguished on each insertion. Continuous operation of the plasma was achieved by Sommer and Ohls[6] who inserted samples into a Greenfield type torch supporting an argon-nitrogen ICP at a continuous RF power of 3 kW. Kirkbright and Walton[7] as well as Kirkbright and Zhang Li-Xing[8] were also able to introduce sample solutions into a low power (<1.5 kW), continuously running argon ICP supported on a demountable torch described by Bombelka.[9] Kirk-bright and his coworkers used an axial flat-ended graphite rod onto which only 5 μl of sample solution could be applied with a micropipet.

The present study reports an attempt to develop a technique for direct insertion of the graphite cup into a continuously running argon ICP with low power *via* the injector tube of a quartz torch. In these experiments, the graphite rod with graphite sample cup into which 10 μl of sample solution can be applied with a micropipet are designed to overcome the limitations encountered by the previous papers.[5-8]

Experimental

Chemicals and Materials. All standard solutions for calibration curves were prepared by diluting the standard stock solutions (1000 μg/ml) of the respective elements with 1% nitric acid. The sample solution (5—10 μl) was transferred in the graphite sample cup with a micropipet, and dried by an IR lamp prior to its insertion into the plasma.

The graphite rods (Tokai H. P. G. Spectroscopic Electrodes) were obtained from Tokai Carbon Co., Ltd., and the graphite sample cups and graphite rods of required dimensions were constructed in our laboratory. The graphite cup was burnt 5 times in the plasma to minimize the impurity levels prior to analyte vaporization. One graphite cup was available more than 20 times for sample insertion into the plasma.

Instrumentation. An ICP atomic emission spectrometer (Model Plasma Atomcomp Mk II) and a standard quartz torch from Jarrell-Ash Co. were used in our experiments. The instrumental components and operating conditions are summarized in Table 1. The central injector tube of the ICP quartz torch with 20 mm o. d. was replaced with a 3.7 mm i. d. quartz tube, which had no constriction at the tip. The torch was supported with a magnetic stand and a clamp.

The schematic diagram of the torch assembly is shown in Fig. 1. The insertion device consisted of a graphite sample cup with a graphite rod and a Teflon insulating handle, all of which were of 3.3 mm o.d. The inner diameter and the depth of the graphite cup were 2.5 mm and 2 mm, respectively. An adjustable Teflon stopper, which was equipped at the bottom end of the Teflon insulating handle, controlled the final position of the cup in the plasma.

Both of the polychromator (Paschen-Runge type) and the monochromator (Ebert type) were available for the emission

Table 1. Instrumentations and operating conditions

ICP spectrometer	Jarrell-Ash model Plasma Atomcomp Mk II
RF generator	Plasma Therm Inc. model HFP 2000 D

Multipen Recorder	Rikadenki model R-10.

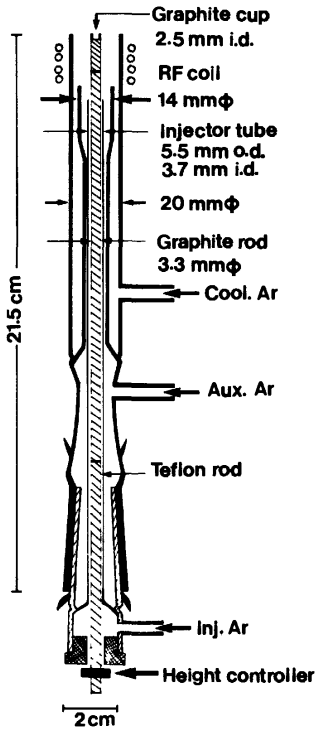

Fig. 1. A schematic diagram of the plasma torch assembly for direct graphite cup insertion device.

signal detection. The analog signal measurements were performed by using a dc amplifier (Model 472 from Keithley) and a strip chart recorder.

Procedure. For simplicity of the experimental procedure, no carrier argon gas was used in the injector tube. The plasma was ignited well with closing the bottom of the injector tube. When the plasma was ignited, the flow rate of the auxiliary argon gas was initially about 1 l/min, and then it was increased at the optimum flow rate of 1.4 l/min. Under these conditions, the plasma was kept sustained even when the graphite sample cup was inserted and taken out, although Salin and Horlick extinguished the plasma during the sample cup operation. Thereafter the plasma could be sustained with the injector tube of the open bottom.

The sample solution of 5—10 μl was applied in the graphite sample cup and dried with an IR lamp prior to insertion. The sample cup assembled with the graphite rod and insulating handle was manually raised through the injector tube until it was fixed at the final position in the plasma. A spark-like discharge occurred momentarily near the load coil when the graphite sample cup was inserted along the injector tube. No change of background signal level was observed at this time. Immediately after the graphite sample cup was inserted into the plasma, the brightness of the plasma decreased. This may be due to the coupling change of RF power with the graphite cup, *i.e*, matching shift of RF power, which was accompanied by significant baseline drift on the recorder. The cup was held in the plasma for 30 s, and after a few seconds the emission signal of the element was observed.

Results and Discussion

Optimization of Experimental Parameters and Conditions. After the preliminary operating conditions of the ICP instrument and the graphite cup insertion device were examined, the following experimental conditions for the ICP-AES measurements were optimized

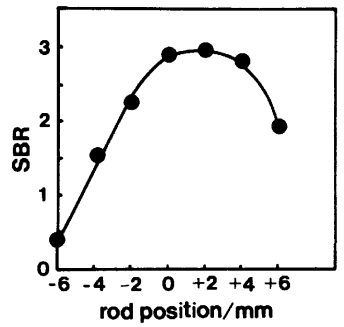

Fig. 2. Optimization of rod position in the plasma relative to the top of the load coil. Power 1.09 kW, observation height 16 mm, coolant argon flow rate 19 l/min, auxiliary argon flow rate 2 l/min, lateral viewing position plasma central channel.

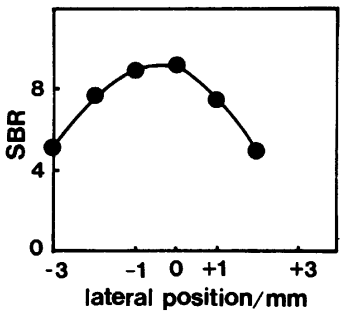

Fig. 3. Variation of net SBR with lateral viewing position of the plasma. Rod position 2 mm above the load coil, power 1.09 kW, observation height 16 mm, coolant argon flow rate 19 l/min, auxiliary argon flow rate 2 l/min.

by using an univariate search method; cup position relative to the top of the load coil, depth of the recess in the graphite cups, RF power, observation height above the load coil, viewing position in the plasma, and flow rates of coolant and auxiliary argon gases. According to the univariate search method, the experimental conditions are optimized by obtaining the maximum signal-to-background ratio (SBR) when one variable is change at a time. Net SBR for manganese ionic line at 257.6 nm obtained from the recorder signals were taken as response. In the following experiments, 5 μl aliquot of 50 ng/ml manganese solution is applied on the graphite sample cup, if no statement is given.

The rod position (from the bottom of the cup) relative to the top of the load coil was optimized under the operating conditions of RF power 1.09 kW, observation height 16 mm, coolant argon flow rate 19 l/min, and auxiliary argon flow rate 2 l/min. The graphite cups used were 1 mm in depth. The optimum rod (cup) height for best SBR was found to be 2 mm (Fig. 2) above the load coil. Under the same operating conditions, a lateral scan was carried out at a rod height of 2 mm to ensure the observation area of the plasma tail flame. The result is shown in Fig. 3. The region of best SBR was almost near the plasma central channel.

Effect of depth in the graphite sample cups on SBR at a rod height of 2 mm is shown in Fig. 4. In the experi-

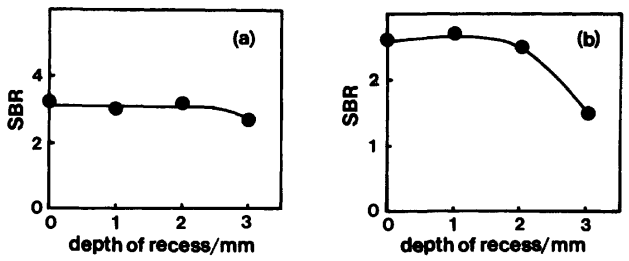

Fig. 4 a) Variation of net SBR with depth of recess in graphite sample cups (rod height was taken from the bottom of the cup). b) Variation of net SBR with depth of recess in graphite sample cups (rod height was taken from the top rim of the cup). Rod position 2 mm above the load coil, power 1.09 kW, observation height 16 mm, coolant argon flow rate 19 l/min, auxiliary argon flow rate 2 l/min, lateral viewing position plasma central channel.

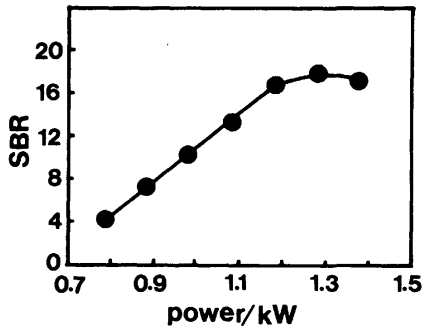

Fig. 5. Univariate search for power of operation. Rod position 2 mm, observation height 16 mm, lateral position plasma central channel, coolant argon flow rate 19 l/min, auxiliary argon flow rate 2 l/min.

ments, the cups of different depths were used, and the rod height of 2 mm was maintained in two different ways: The first one was taken from the bottom of the cup relative to the top of the load coil (Fig. 4a), in which SBR was almost constant up to 2 mm depth in the cup. The second one was taken from the top rim of the cup relative to the top of the load coil (Fig. 4b), in which SBR gradually decreased with increasing the depths of the cups. Consequently, the graphite cup of 2 mm depth was used in the subsequent experiments. Ten μl of solution can be also applied to this cup.

For optimization of RF power (Fig. 5), it was necessary to stabilize the system at least for 30 min after each increase of RF power. Here RF power was defined as "the forward power minus the reflected power." As for RF power, the optimun power of operation for the best SBR appeared to be 1.18 kW.

Effect of observation height above the load coil on SBR of manganese ionic line at 257.6 nm is shown in Fig. 6. It was clearly observed that the optimum observation height was 16 mm above the load coil.

The flow rates of coolant and auxiliary argon gases were also optimized, and they were 18 l/min and 2 l/min, respectively. These gas flow rates provided little effect on SBR compared to other plasma operating parameters. It should be noted that in the present system continuous operation of the plasma with the

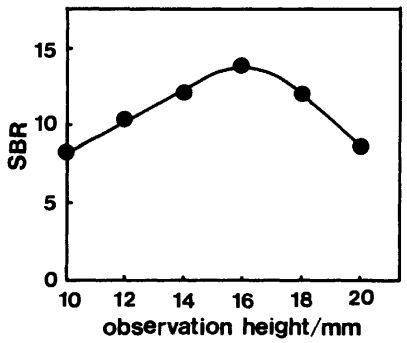

Fig. 6. Univariate search for optimum observation height above the load coil. Rod position 2 mm, power 1.18 kW, coolant argon flow rate 19 l/min, auxiliary argon flow rate 2 l/min, lateral position plasma central channel.

Table 2. Optimum operating conditions for ICP-AES utilizing direct graphite cup insertion technique

Graphite sample cup	Inner diameter 2.5 mm depth 2 mm
Rod position in the plasma	4 mm above load coil
RF Power	0.9 kW
Observation height	16 mm above load coil
Lateral viewing position	Plasma center
Coolant Ar-flow rate	17 l/min
Auxiliary Ar-flow rate	1.4 l/min.

injector tube of opened bottom required the coolant argon gas flow rate more than 15 l/min, and the auxiliary argon gas flow rate more than 1.4 l/min.

The optimum operating conditions for the best SBR obtained for manganese ionic line at 257.6 nm after 5 times repeats of the optimization procedure cycle are summarized in Table 2. Precise establishment of optimum plasma operating conditions by univariate search method is rather difficult because of the interdependent and complex plasma parameter variables. So the optimum operating conditions shown in Table 2 are the compromized ones among all the variables examined for stable operation of the plasma with the injector tube of open bottom.

Time-dependent Signal Profile. Under the optimum operating conditions shown in Table 2, some typical time-dependent emission signal profiles, obtained with 10 μl aliquot of each element utilizing the direct graphite cup insertion technique are shown in Figs.7 and 8. As can be seen in these figures, immediately after insertion of the graphite cup into the plasma, large baseline drift occurred with Pb, Cr, and Ni, while as for Mn and Zn the baseline drift was not so significant. The baseline drift and the emission signal peak are well separated for all the elements studied. In addition, after insertion of the cup into the plasma, the elements are completely vaporized within 10 s with an exception of Zn an Pb which complete vaporization within 4 s.

Durability of Graphite Cup. A single graphite cup could be used up to 20 times of insertion into the

plasma without deteriorating the emission intensity of the analyte. After then the emission intensity (peak height as well as integrated intensity) was gradually decreased with repeated use of the cup, and diffusion of analyte vapor took place through the side wall of the porous graphite cup, resulting in lower emission intensity. Due to this short durability of the graphite cup, multicups were used throughout the experiments.

Detection Limits, Reproducibilities and Linear Dynamic Ranges. Although the system was optimized for manganese ionic line at 257.6 nm, detection limits, relative standard deviations (RSDs) and linear dynamic ranges were evaluated for manganese, zinc, lead, chromium, and nickel with each of the elements in 1% nitric acid solution by using multicups under the same operating conditions. The results are summarized in Table 3. In the experiments, ten integrated signals (each 10 s integration) were measured for each of these elements using 10 μl aliquot of the analyte (50 ng/ml) with the detection system of a polychromator. Corresponding ten integrated background signals were also measured for 1% nitric acid as a blank. The detection limit was then calculated as the concentration of the analyte which was equivalent to three times of the standard deviation(3σ) of the background signals. RSD is expressed in percent. The linear dynamic ranges obtained were linear over the concentration range of 4.0—5.7 orders of magnitude. The detection limits and RSD from peak height measurement are also presented in the same table. As can be seen from Table 3, the detection limits obtained are comparable to those reported by Kirkbright *et al.*[7,8]

Conclusion

The sensitivity, precision and linear dynamic ranges obtained by ICP-AES utilizing direct graphite cup insertion technique are comparable to those obtained

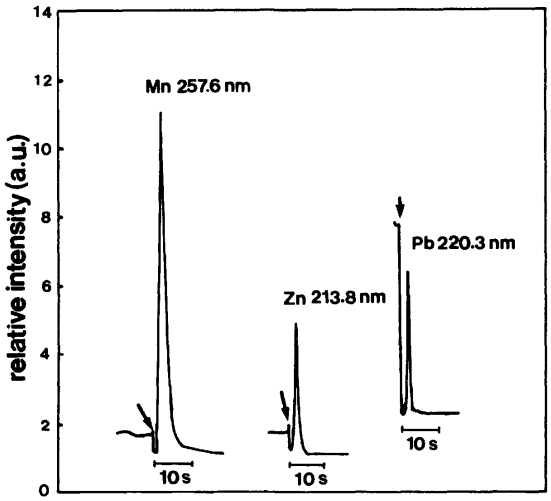

Fig. 7. Time-dependent emission signal profiles obtained for 0.1 μg/ml of manganese, zinc, and lead by ICP-AES utilizing direct graphite cup insertion technique. The arrow lines indicate insertion of the cup into the plasma.

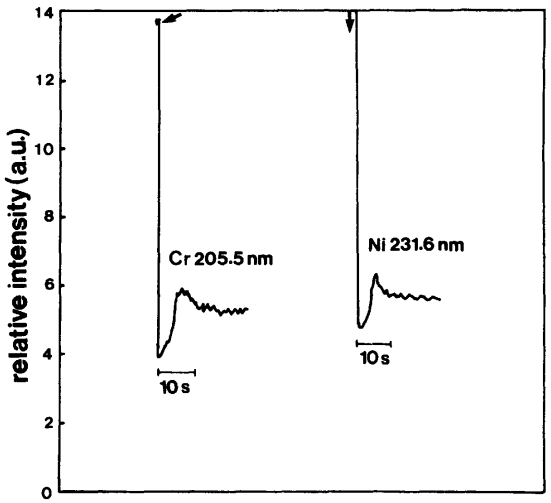

Fig. 8. Time-dependent emission signal profiles obtained for 0.1 μg/ml of chromium, and nickel by ICP-AES utilizing direct graphite cup insertion technique. The arrow lines indicate insertion of the cup into the plasma.

Table 3. Detection limits, relative standard deviations and linear dynamic ranges obtained by ICP-AES utilizing the direct graphite cup insertion technique

Element	Wavelength[a] (nm)	Detection limit (3σ) concentration (ng/ml)	Detection limit (3σ) absolute amount (pg)	RSD[c] (%)	log(LDR)[d]	Detection limit (2σ)[e] (ng/ml)
Mn	257.6 II	0.84	8.4	4.1	5.0	—
		0.40[b]	4.0[b]	11.0[b]		1.2[b]
Zn	213.8 I×2	18.0	180	15.4	4.0	
		1.8[b]	18.0[b]	13.0[b]		0.7[b]

Ni	231.6 II×2	14.8	148	12.0	5.7	12.7[b]

a) I and II indicate the atomic and ionic lines, respectively, and (×2) shows the use of the second order lines. b) Peak height measurement. c) Relative standard deviation. d) Linear dynamic range in log unit. e) Reported by Kirkbright and Walton[7], and Kirkbright and Zhang Li-Xing.[8]

by any other sample introduction techniques. In addition the system is almost free from the interferences due to variation in sample transport efficiency which is known for sample introduction through tubing by eletrothermal vaporization. Further, the use of a polychromator for signal detection and integration for direct graphite cup insertion technique shows its potential feasibility for multielement analysis of trace elements in small volume liquid samples. Optimization for individual element, use of more sensitive analytical lines, and automation of the rod insertion device using a stepping motor may improve the analytical figures of merit such as the detection limits and precision.

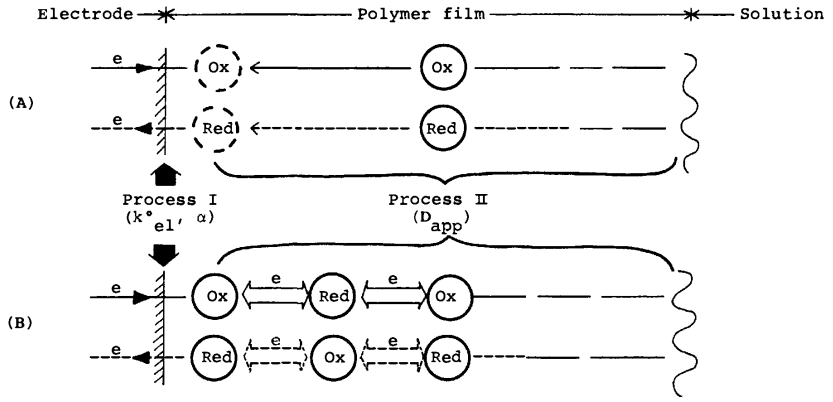
(Received January 20, 1984)

A "heterogeneous" electron-transfer process of three kinds of viologen polymers, *i.e.*, *N,N'*-dimethyl-4,4'-bipyridinium (methylviologen, MV)-Nafion®, poly(xylylviologen) (PXV)-poly(*p*-styrenesulfonate) (PSS) and poly(methylviologen) (PMV), in which MV and PXV were electrostatically trapped in Nafion and PSS, respectively, on a basal-plane pyrolytic graphite (BPG) electrode and PMV was directly attached to the BPG electrode surface, was examined by normal pulse voltammetry. The relevant kinetic parameters (*i.e.*, the standard rate constant, k°_{el} and the cathodic transfer coefficient, α) of the electrode reaction and the apparent diffusion coefficients, D_{app}, for the "homogeneous" charge transport within these polymer films were determined at the various surface concentrations ($\Gamma_{MV^{2+}}$ in units of mol cm^{-2}) of viologen dication site. With the PMV and PXV-PSS systems, both k°_{el} and D_{app} were independent of $\Gamma_{MV^{2+}}$, while with the MV-Nafion system both k°_{el} and D_{app} decreased with an increase in $\Gamma_{MV^{2+}}$ under the constant concentration of Nafion. The values of α were independent of $\Gamma_{MV^{2+}}$ and constant (*i.e.*, 0.56, 0.58, and 0.20 for the PMV, MV-Nafion and PXV-PSS systems, respectively).

In a series of papers concerning the "polymer-coated electrodes,"[1-4] we have examined the "heterogeneous" electron-transfer reactions between the electrode and the electroactive species confined to the polymer films on the electrode surfaces as well as the "homogeneous" charge transport process within the polymer films incorporating the electroactive species by means of the normal pulse voltammetry (Scheme 1). It has become apparent that the "heterogeneous" electron-transfer reaction (process I) at the electrode/film interface obeys the conventional Butler-Volmer equation[5] which characterizes the electrode reaction at an uncoated, ordinary electrode in a solution and that the "homogeneous" charge transport process (process II) within the films obeys the Fick's law relations which are the same as those in thin layer electrochemistry[6] except that the polymer film is *ca.* 10^3 thinner than the usual thin layer electrochemical cell. The process II can be treated as a semi-infinite diffusion process when the distance of charge transport δ ($\approx 2(D_{app} \cdot t)^{1/2}$) is smaller than the thickness of the film (ϕ) (D_{app}: the apparent diffusion coefficient for the diffusion-like charge transport process within the film, t: time). Furthermore, from the previous data with respect to the $[Mo(CN)_8]^{4-/3-}$,[1,2] $[Fe(CN)_6]^{4-/3-}$,[3] $[W(CN)_8]^{4-/3-}$ and $[IrCl_6]^{3-/2-}$ [4] incorporated electrostatically into the protonated poly(4-vinylpyridine) (PVP) films and the $[Fe(CN)_5]^{3-/2-}$ [3] coordinated to the unprotonated PVP films, we have also found that the kinetic parameters (*i.e.*, the standard rate constant, k°_{el}, and the transfer coefficient, α) of "heterogeneous" electron transfer reaction and D_{app} depend upon the molar ratio of the incorporated



Scheme 1. Schematic depiction of charge transfer process on electrodes coated with polymers containing electroactive species.
Processes I and II represent heterogeneous electron transfer process and homogeneous charge transfer process, respectively. k°_{el} and α are the standard rate constant and the transfer coefficient respectively, of process I. D_{app} is the apparent diffusion coefficient for process II. Overall electrode reaction: (——) reduction, (----) oxidation. Charge can be transported through polymer films *via* (A) physical diffusion of electroactive species itself and (B) electron self-exchange between the redox couples. Note that process II (A and B) is associated with charge-compensating counter ion motion.

electroactive species to pyridine group of PVP. Such a concentration dependence of k°_{el}, α and D_{app} is worthy of remark, since this behavior has been rarely observed in the case of ordinary electrode reaction with an uncoated electrode and the physical diffusion in the solution phase except for special cases.[7-9]

In this paper, we will extend the normal pulse voltammetric study concerning "heterogeneous" electron-transfer reaction and "homogeneous" charge transport process on polymer-coated electrodes for the *N,N'*-dimethyl-4,4'-bipyridinium (methylviologen, MV)-Nafion (perfluorinated ion exchange polymer), poly(xylylviologen) (PXV)-poly(*p*-styrenesulfonate) (PSS) and poly(methylviologen) (PMV) systems. The MV and PXV are electrostatically trapped in the anionic polymer coatings, *i.e.*, Nafion and PSS, respectively, on a basal-plane pyrolytic graphite (BPG) electrode and PMV is directly attached to the BPG electrode surfaces owing to the water insolubility of PMV itself (Fig. 1). In these three systems, the viologen dication group is the common electroactive site. In each system, the dependence of k°_{el}, α and D_{app} upon the concentration of viologen dication site in polymer coatings will be examined and compared with the previous results[1-4] obtained with the highly charged anionic redox species confined in cationic polymer films on electrodes.

Experimental

Materials. *N,N'*-Dimethyl-4,4'-bipyridinium dichloride (methylviologen, $MVCl_2$) (Wako Chemical Co.) was recrystallized twice from methanol-acetone. The polymer pendant methylviologen (PMV) and poly(xylylviologen) (PXV) with average molecular weight 9.8×10^3 and 8×10^3, respectively, were prepared as described elsewhere.[10-13] Nafion membrane 125^R which was obtained from Du Pont de Nemours and Company (Wilmington, DE) was used as an electrode-coating film of polyelectrolyte. The stock solution of Nafion was prepared as described previously[10-13] and the concentration was 2.55 mg ml^{-1}. The preparation of sodium poly(*p*-styrenesulfonate) (PSS) was carried out according to the same procedure as described previously.[13] The average molecular weight of the PSS was 5×10^4. The concentration of styrenesulfonate as PSS was 2.4 mM (1M=1 mol dm^{-3}). The basal-plane pyrolytic graphite (BPG) (Union Carbide Co.) disk electrodes (area: 0.17 cm^2) were prepared and mounted into glass tube with heat-shrinkable polyolefin tube.[14,15] Sodium perchlorate was used as a supporting electrolyte in sample solution (pH 3.4). All other chemicals were reagent grade and were used without further purification.

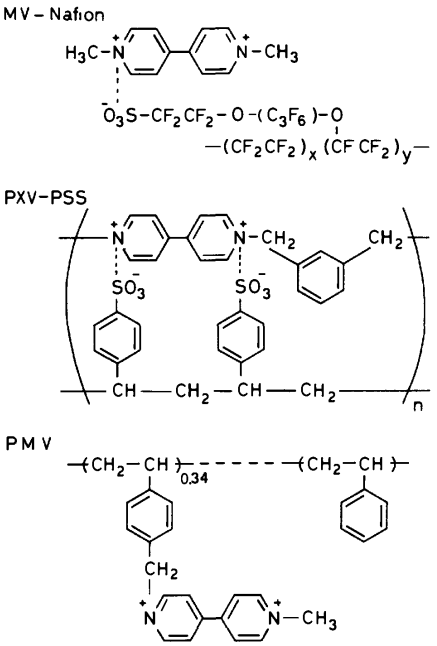


Fig. 1. Structures of the viologen polymers used.

Apparatus and Procedures. Aliquots of the stock solution of Nafion were spread by a microsyringe on the freshly cleaved electrode surface of BPG and then the solvent was evaporated at room temperature. The resulting electrode was soaked in a 0.2 to 10 mM solution of MV for 1 to 60 min in order to achieve the incorporation of desired quantities of MV in Nafion coatings. Adherent coatings of intermolecular complex of PXV and PSS (PXV-PSS) were produced by transferring aliquots (1—6 μl) of an aqueous stock solution containing 1.2 mM of viologen as PXV and of an aqueous stock solution containing 2.4 mM styrenesulfonate as PSS to the surface of a freshly cleaved BPG electrode, mixing them on it, and then evaporating the solvent at room temperature. With PMV film coating, aliquots of methanolic solution containing 3 mM methylviologen as PMV were spread by a microsyringe on the freshly cleaved BPG surface and air-dried to remove methanol. The quantity of the electroactive reactants (*i.e.*, viologen dication) existing in polymer coatings on electrodes was determined by measuring the charge required in a potential-step experiment[15] to quantitatively reduce the dications (MV^{2+}) of MV, PXV of PMV to the corresponding radical monocations (MV^{+}) and/or measuring the area of cyclic voltammograms (for the oxidation-reduction reaction of the $MV^{2+/+}$ redox couple) obtained at slow potential scan rates. The quantity of incorporated reactant estimated by two procedures was the same within an experimental error.

Normal pulse voltammograms were obtained with instruments which were constructed in our laboratory and were recorded with an X-Y recorder (Watanabe Corp.). Positive feedback circuitry was employed to provide as much compensation as possible of the additional resistance (20—80Ω) associated with the polymer coatings. Measurements were confined to times sufficiently short to ensure that semi-infinite linear diffusion prevailed.[1-4,16] Solutions were deaerated with prepurified nitrogen and experiments were conducted at 25 °C. Potentials were measured and are quoted with respect to a sodium chloride saturated calomel electrode (SSCE).

Results and Discussion

Homogeneous Charge Transport Process within the Coatings Incorporating Electroactive Species. A set of normal pulse voltammograms for the reduction of MV^{2+} (to MV^{+}) as PXV-PSS complex or PMV coated on BPG or as MV incorporated into Nafion film on BPG at various sampling times is shown in Fig. 2. The electrode was scanned only over the first of the two reduction waves (*i.e.*, MV^{2+} to MV^{+} and MV^{+} to MV^{0}), because the salt of the PXV-PSS, MV in Nafion and PMV become water soluble when the charge of the viologen is reduced to zero.[13] Thus, the responses observed arise from reduction of the viologen dication

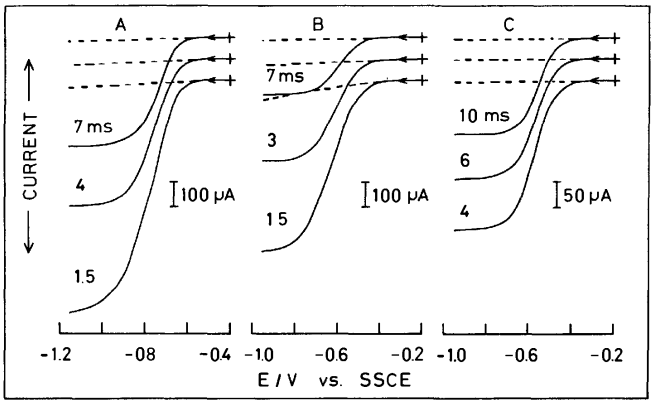

Fig. 2. Typical normal pulse voltammograms for the reduction of viologen dication as (A) MV incorporated into Nafion film on BPG electrodes and (B) PXV-PSS and (C) PMV coated on BPG electrodes at various sampling times in a 0.2 M $NaClO_4$ solution (pH= 3.4). (A): $\Gamma_{MV^{2+}}=9.2\times10^{-9}$ mol cm^{-2}, $\Gamma_{Nafion}=1.5\times10^{-7}$ mol cm^{-2}, (B): $\Gamma_{MV^{2+}}=5.6\times10^{-8}$ mol cm^{-2}, $\Gamma_{PSS}=1.1\times10^{-7}$ mol cm^{-2}, (C): $\Gamma_{MV^{2+}}=7.3\times10^{-9}$ mol cm^{-2}. Sampling times (ms) are given on each voltammogram. Dotted lines show residual current.

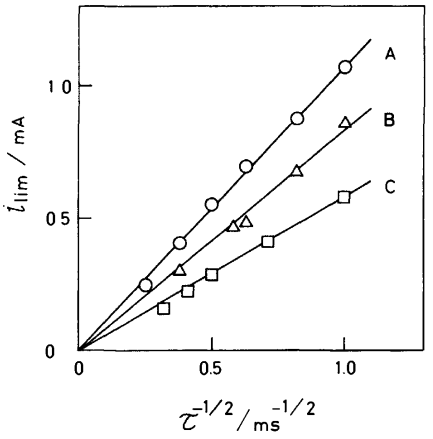

Fig. 3. Plots of limiting current, i_{lim}, *vs.* (sampling time)$^{-1/2}$ for the reduction of viologen dication as (A) MV-Nafion, (B) PXV-PSS, and (C) PMV on BPG electrodes. Other experimental conditions are the same as in Fig. 2.

to the radical cation.

The wave shapes are similar to those observed for solution-phase redox species at an uncoated electrode.[17-19] The half-wave potentials of the first waves obtained with MV-Nafion, PXV-PSS and PMV coated BPG electrodes are observed at −0.74, −0.52, and −0.57 V *vs.* SSCE, respectively at sampling time of 6 ms. This indicates differences in the spatial distribution and the electrostatic interaction of the redox centers and differences in the degree of porosity and hydrophobic nature of the coating film (*i.e.*, changes in the chemical environment of the coating film).[13,20,21] At any rate, the half-wave potential of the normal pulse voltammograms shifted to more positive values with increasing sampling times. Plots of the cathodic limiting current (i_{lim}) of these normal pulse voltammograms against the inverse square root of the sampling time (τ) were found to be linear as expected for the diffusion-controlled limiting current (Fig. 3).[1-4,17-19] Thus, the values of the apparent diffusion coefficients, D_{app}, for the process of the charge transport within the films were obtained from the slopes of the i_{lim} *vs.* $\tau^{-1/2}$ plots by using the Cottrell equation:[22]

$$(i_d)^C_{Cott} = nFAC^\circ\sqrt{D_{app}/\pi\tau} \quad (1)$$

where $(i_d)^C_{Cott}$ denotes the cathodic limiting diffusion current, n the number of electrons involved in the "heterogeneous" electron transfer reaction, F the Faraday constant, A the electrode area and C° the bulk concentration of the redox sites confined in polymeric coatings.

It has been generally recognized that the values of the apparent diffusion coefficients for the charge transport process within the polymeric films depend upon the kind and the concentration of the incorporated redox species, the kind of the film confining the redox species, the kind of the soaking solution, *etc.*[1-4,16,23-32] So far, the three types of dependences of D_{app} on the volume concentration (C°_M in units of mol cm^{-3}) of the incorporated electroactive species in polymeric films, that is, (1) D_{app} decreases with an increase in C°_M,[1-4,16,26-29] (2) D_{app} increases with an increase in C°_M,[29] and (3) D_{app} is independent of C°_M[28,30-32] have been reported and some possible models of the physical meaning of the D_{app} obtained have been ever proposed for the individual cases. In this study, the dependence of D_{app} upon the surface concentration of electroactive sites in polymer films (*i.e.*, $\Gamma_{MV^{2+}}$ in units of mol cm^{-2}) was examined. The results obtained are shown in Fig. 5, together with the dependence of k°_{el} and α upon $\Gamma_{MV^{2+}}$. With PMV and PXV-PSS systems, D_{app} is independent of $\Gamma_{MV^{2+}}$, while with MV-Nafion system D_{app} decreases with increasing $\Gamma_{MV^{2+}}$.

When the "homogeneous" charge transport process within the coatings follows the electron-exchange mechanism which was originally proposed by Kaufman and Engler,[33,34] electrons are removed from MV^{2+} sites that are remote from the BPG electrode by successive electron transfers between neighbor MV^{2+} and MV^{+} sites in the coating. D_{app} will be determined by the process limiting charge transport, which may be the intrinsic electron-transfer rate between adjacent sites, the rate of charge compensating counter ion motion which is necessarily coupled to electron transfer, or the rate of segmental motions of the polymer backbone. Translation of D_{app} into an electron transfer rate constant is of interest. If every "collision" in fact results in electron self-exchange, then the reaction is truly diffusion-controlled, D_{app} represents the diffusion rate, and D_{app} can be converted to an effective electron-transfer rate constant, k^{diff}_{ex}, by using a conventional formula for collision-controlled reaction rates:[4,29,35]

$$k^{diff}_{ex} = \frac{4\pi NRD}{10^3} \quad (2)$$

where N is Avogadro's number, R and D are the sum of the radii and of the diffusion coefficients, respectively, of the reactants. For $D_{app}=1\times10^{-9}$ cm^2

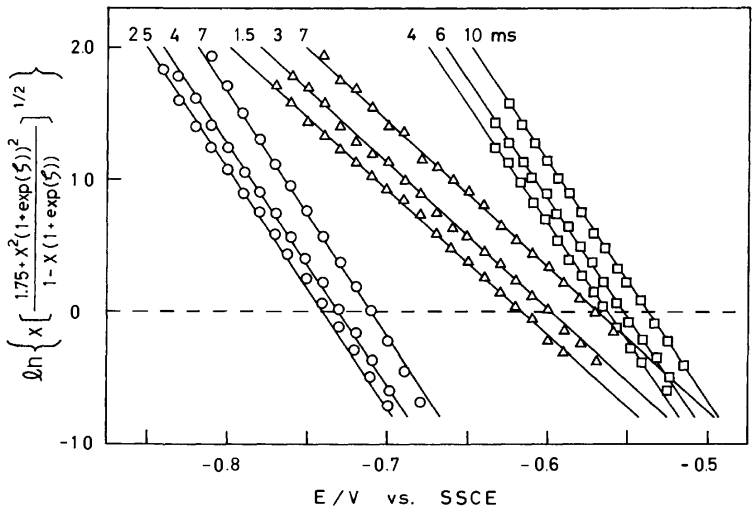

Fig. 4. Modified log plots of normal pulse voltammograms for the reduction of viologen dication as MV-Nafion, PXV-PSS and PMV on BPG electrodes. (○): MV-Nafion, (△): PXV-PSS, (□): PMV. Sampling times (ms) are indicated on each straight line. Other experimental conditions are the same as in Fig. 2.

s^{-1} and R=10Å,[29] with the assumption of $D=2\,D_{app}$, $k_{ex}^{diff}=1.5\times10^{6}\,M^{-1}\,s^{-1}$ which is ~5 times smaller than the self-exchange rate constant of the $MV^{2+/+}$ redox couple ($k_{ex}=8\times10^{6}\,M^{-1}\,s^{-1}$).[36] If we assume that the electron transfer is itself the slow step, then $D_{app}\approx\pi k_{ex}^{act}\,\delta^{2}C/4$ (δ: the distance between the centers of the reactants when the electron transfer occurs, C: the sum of the volume concentrations of the oxidized and reduced forms of the redox couple, k_{ex}^{act}: the second-order self-exchange rate constant for the redox couple).[7,8,28-30,32] In this case, for $D_{app}=1\times10^{-9}\,cm^{2}\,s^{-1}$, δ=10Å[29,32] and $C_{MV^{2+}}=\Gamma_{MV^{2+}}/\phi$ (film thickness)$=1.1\times10^{-4}$ mol cm^{-3}, $k_{ex}^{act}=1.1\times10^{6}\,M^{-1}\,s^{-1}$. This is also smaller than the self-exchange rate constant of the $MV^{2+/+}$ couple.[36] From these calculations, it is likely that the process limiting charge transport may be the rate of charge compensating counter ion motion and/or the rate of segmental motions of the polymer film.[1-4,15,16,23-26,33,34]

Heterogeneous Electron-transfer Reactions between the Electrodes and Electroactive Sites Confined in the Polymer Coatings on Electrode Surfaces. An analysis of the rising part of the current-potential curves shown in Fig. 2 allows us to estimate the kinetic parameters (*i.e.*, the standard rate constant and the cathodic transfer coefficient) of the heterogeneous electron-transfer reaction. The relevant current-potential relationship[1-4,17-19] for normal pulse voltammograms for the simple electrode process, Red⇌Ox+ne, has already been derived and is given for the reduction by

$$E = E_{1/2}^{r} + \frac{RT}{\alpha nF}\ln\left\{\frac{4}{\sqrt{3}}\frac{k^{\circ}_{el}\sqrt{\tau}}{\sqrt{D}}\right\} - \frac{RT}{\alpha nF}\ln\left\{x\left[\frac{1.75+x^{2}(1+\exp(\zeta))^{2}}{1-x(1+\exp(\zeta))}\right]^{1/2}\right\} \qquad (3)$$

where E is the electrode potential, $E_{1/2}^{r}$ the reversible half-wave potential, α the cathodic transfer coefficient, k°_{el} the standard rate constant, τ the sampling time, R the gas constant, T the absolute temperature, ζ the dimensionless parameter expressed as $\{(nF/RT)(E-E_{1/2}^{r})\}$, and D the diffusion coefficient expressed as $\{(D_{app}$(for cathodic process))$^{\alpha}(D_{app}$(for anodic process))$^{1-\alpha}\}$. The x is the ratio of the current at potential E to the cathodic limiting diffusion current, $(i_d)_{Cott}^{C}$, expressed by the Cottrell equation (Eq. 1).

Figure 4 shows the typical examples of the modified log plots of normal pulse voltammograms in which the logarithm of the third term on r.h.s. of Eq. 3 is plotted against E for the reduction of viologen dications to the corresponding radical monocations in polymer coatings. These plots gave the straight lines the slopes of which were constant at the different sampling times ranging from 1 to 10 ms in each system. From the slope of the straight lines shown in Fig. 4 and the intersect of these lines with the zero-line the values of k°_{el} and α were estimated by using the known values of $E_{1/2}^{r}$, D*1, and τ. For doing this, the values of $E_{1/2}^{r}$ were estimated as the average of the anodic and cathodic peak potentials of the cyclic voltammograms for the oxidation-reduction of the $MV^{2+/+}$ redox couple in coatings on BPG electrodes in a solution containing only supporting electrolyte.

Figure 5 shows the dependence of k°_{el} and α upon $\Gamma_{MV^{2+}}$. With the PMV and PXV-PSS systems, the values of k°_{el} were independent of $\Gamma_{MV^{2+}}$ and were $(3.9\pm0.4)\times10^{-5}$ and $(1.1\pm0.3)\times10^{-4}$ cm s^{-1}, respectively. The difference in k°_{el} values may be primarily attributed to the difference in the molecular polymer-structure of PMV and PXV-PSS and their overall film-morphology. On the other hand, with the MV-Nafion system the values of k°_{el} decreased gradually with increasing $\Gamma_{MV^{2+}}$. The similar dependence of k°_{el} upon the concentration of electroactive species in coatings has been previously observed for several other systems (*e.g.*, the $[Mo(CN)_8]^{4-/3-}$, $[Fe(CN)_6]^{4-/3-}$, and $[IrCl_6]^{3-/2-}$ redox couples incorporated into the proto-

*1 With the assumption that D_{app} (for cathodic process)$\approx D_{app}$ (for anodic process), the values of D were estimated as those of D_{app} (for cathodic process).

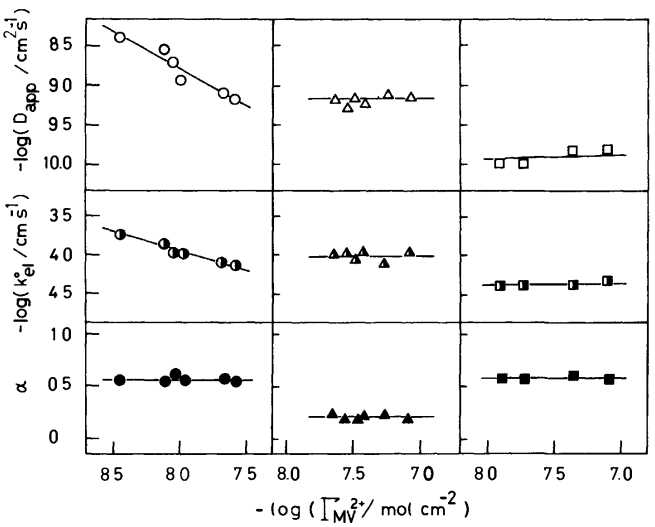

Fig. 5. Dependence of k°_{el}, α and D_{app} upon $\Gamma_{MV^{2+}}$. (○,◑,●): MV-Nafion ($\Gamma_{Nafion}=1.5\times10^{-7}$ mol cm^{-2}), (△,◭,▲,): PXV-PSS ($C_{MV^{2+}}=1.1\times10^{-4}$ mol cm^{-3} and $C_{pss}=2.2\times10^{-4}$ mol cm^{-3}), (□,◨,■): PMV ($C_{MV^{2+}}=1.1\times10^{-4}$ mol cm^{-3}). Other experimental conditions are the same as in Fig. 2.

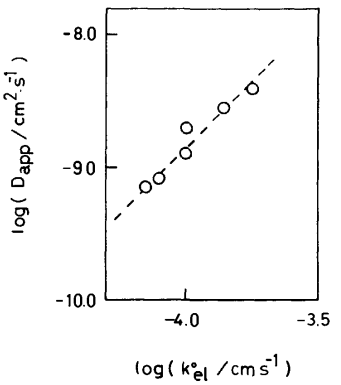

Fig. 6. Linear relationship between log k°_{el} and log D_{app} in the MV-Nafion system. The values of k°_{el} and D_{app} were taken from Fig. 5.

nated poly(4-vinylpyridine) (PVP) film on BPG electrodes.[1-4]

In the case of the PMV and PXV-PSS systems, the volume concentration ($C_{MV^{2+}}$) of MV^{2+} is constant ($C_{MV^{2+}}=1.5\times10^{-4}$ and 1.1×10^{-4} mol cm^{-3} for the PMV and PXV-PSS systems, respectively), because the thickness of the coating film can be assumed to be proportional to the amount of coating on the electrode surfaces. The independence of D_{app} against $\Gamma_{MV^{2+}}$ indicates that the degree of the solvent swelling and the porosity of the coating film, the spatial distribution of the viologen sites and the supporting electrolytic ions, the electrostatic interaction of the viologen sites, *etc.* do not change substantially with the thickness (ϕ) of coatings in the range examined of ϕ (1.9×10^{-4} to 7.5×10^{-4} cm). On the other hand, in the case of the MV-Nafion system, the values of $\Gamma_{MV^{2+}}$ were changed deliberately (see Experimental Section) under the constant amount coated of Nafion ($\Gamma_{Nafion}=1.5\times10^{-7}$ mol cm^{-2}), so that $C_{MV^{2+}}$ increases with an increase in $\Gamma_{MV^{2+}}$. As can readily be seen from the essential ground (*i.e.*, electrostatic interaction[1-4,16,26]) of the incorporation of methylviologen dication (MV) into anionic Nafion film, MV is strongly interacting with its surroundings. As the $\Gamma_{MV^{2+}}$ increases, the degree of electrostatic cross-linking of the film by the dication, *i.e.*, multiple ion pairing of dications with the sulfonyl groups of Nafion becomes to be large. It is thus thought that the free energy required to reorganize the surrounding medium prior to the electron transfer becomes to be large with an increase in $\Gamma_{MV^{2+}}$.[3,4] On the basis of such a consideration, the dependence of k°_{el} on $\Gamma_{MV^{2+}}$ shown in Fig. 5 appears to arise from the change of the solvent reorganization energy by changing $\Gamma_{MV^{2+}}$.

The values of cathodic transfer coefficient (α) were independent of $\Gamma_{MV^{2+}}$ in the systems studied. Note that the values (0.56 and 0.58) of α obtained with PMV and MV-Nafion coated BPG electrodes are almost the same and largely different from that (0.20) obtained with PXV-PSS coated BPG electrode. Such a significant small value of α has been obtained in the PMV system when the polyelectrolyte such as sodium poly(*p*-styrenesulfonate) was used as a supporting electrolyte.[37] Such different α-values may reflect the different reaction positions of the viologen dication sites (*e.g.*, with respect to the outer Helmholtz plane) in the transition state of the electron-transfer reaction and/or the existence of the potential-independent chemical reaction preceding the electron-transfer reaction proper.[4,38-41]

Comparison with Previous Results. As mentioned above, in the MV-Nafion system, the values of both D_{app} and k°_{el} decreased with increasing concentration of viologen dication in Nafion coatings. A similar dependence of both D_{app} and k°_{el} upon the concentration of the incorporated species has been previously observed with the $[Fe(CN)_6]^{4-/3-}$, $[Mo(CN)_8]^{4-/3-}$, and $[IrCl_6]^{3-/2-}$ incorporated into the protonated PVP film coated on BPG electrodes.[1-4] Furthermore, it has been found in these redox systems that there is a linear relationship between log k°_{el} and log D_{app}, even though the theoretical explanation for this relationship has not been given yet. For the MV-Nafion system also, we can see the establishment of this linear relationship (see Fig. 6). Such a linear relationship may suggest that the increase of the concentration of the redox sites (or species) confined in polymer coatings causes an increase in the degree of electrostatic cross-linking[1-4,16,26,42] and/or the electrostatic repulsions[4,43] between the highly charged redox sites (or species) and these result in the decrease in the rates of both heterogeneous electron transfer reaction at the electrode/film interfaces and homogeneous charge transfer process within the coatings. Additional work is required to make this point clearer.

This work was partly supported by the Grant of the Shimadzu Foundation for Science and Technology.

Some Palladium(II) Complexes Containing Both the *O*-Unidentate β-Diketonato and 2-, 3-, or 4-Pyridyl Ligands. Dynamic Behaviors of *trans*-[Pd(β-dik-*O*)-(C_5H_3(6-Cl)N-C^2)(PEt_3)$_2$] in Solution

(Received February 2, 1984)

Palladium(II) complexes of the [Pd(β-dik-*O*)(pyridyl)(PEt_3)$_2$] type containing an *O*-unidentate acetylacetonate, trifluoroacetylacetonate, or hexafluoroacetylacetonate anion and a 2-, 3-, 4-pyridyl or 6-chloro-2-pyridyl group as ligands were prepared and characterized mainly by ^{1}H and ^{13}C NMR spectroscopy. The acetylacetonate and hexafluoroacetylacetonate ligands in the [Pd(β-dik-*O*)(C_5H_3(6-Cl)N-C^2)(PEt_3)$_2$] complexes undergo the head-to-tail donor-atom exchange reaction, to which an intramolecular mechanism is proposed.

In a previous paper[1] a number of palladium(II) complexes containing an *O*,*O*′-chelating β-diketonate anion and a 2-, 3-, or 4-pyridyl group as ligands were prepared and characterized mainly by ^{1}H and ^{13}C NMR spectroscopy. Among these complexes [Pd(acac)-(C_5H_3(6-Cl)N-C^2)(PPh_3)] was found to undergo coordination site exchange catalyzed not only by usual free ligands such as tertiary phosphines, pyridine and its derivatives, but also by various donor solvents. Although the 6-chloro-2-pyridyl complex is stereochemically rigid by itself, the corresponding 2-pyridyl complex [Pd(acac)(C_5H_4N-C^2)(PPh_3)] partially dissociates in solution to liberate triphenylphosphine, which catalyzes the coordination-site exchange reaction of the parent complex, averaging the environments of two methyl groups of the acetylacetonate ligand (autocatalysis). Furthermore molecules of [Pd(acac)(C_5H_4N-C^3 or -C^4)(PPh_3)] were found to catalyze mutually their own coordination-site exchange (self-catalysis).

In the course of this investigation various pyridylpalladium(II) complexes containing an *O*-unidentate β-diketonate anion as a ligand were obtained. This paper reports on the preparation and characterization of these interesting compounds as well as dynamic behaviors of some of them in solution.

Experimental

Preparation of Complexes. The starting complexes [Pd(β-dik)(pyridyl)(PPh_3)] (β-dik=chelating anion of β-diketone (β-dikH) such as acetylacetone (acacH), trifluoroacetylacetone (tfacH), and hexafluoroacetylacetone (hfacH); pyridyl=C_5H_4N-C^2, C_5H_4N-C^3, C_5H_4N-C^4, or C_5H_3(6-Cl)-N-C^2) were prepared according to the methods reported previously.[1] Preparation of [PdBr(pyridyl)(PEt_3)$_2$] was also reported.[2] The present complexes [Pd(β-dik-*O*)(pyridyl)-(PEt_3)$_2$] containing an *O*-unidentate β-diketonate anion were prepared by two methods both in dichloromethane: (A) reactions of [Pd(β-dik)(pyridyl)(PPh_3)] with excess triethylphosphine, and (B) reactions of [PdBr(pyridyl)(PEt_3)$_2$] with Tl(β-dik). Here is described only a favorable method for each complex.

*[Pd(acac-O)(C_5H_4N-C²)(PEt_3)$_2$] (**a1**): (Method A)*; Triethylphosphine (0.087 cm³, 0.596 mmol) was added to a solution of [Pd(acac)(C_5H_4N-C^2)(PPh_3)] (0.109 g, 0.199 mmol) in dichloromethane (5 cm³) and the mixture was stirred at room temperature for 30 min. After concentration to *ca.* 1 cm³ by evaporation under reduced pressure, diethyl ether was added to the concentrate to deposit a white precipitate, which was filtered, washed with the ether and dried *in vacuo*. The product was purified by dissolution in dichloromethane followed by reprecipitation on addition of diethyl ether. The yield was 0.075 g (71.9%).

*[Pd(tfac-O)(C_5H_4N-C²)(PEt_3)$_2$] (**a2**): (Method A)*; Complex **a2** was obtained in a 76.4% yield by the reaction between [Pd(tfac)(C_5H_4N-C^2)(PPh_3)] and PEt_3.

*[Pd(hfac-O)(C_5H_4N-C²)(PEt_3)$_2$](**a3**): (Method B)*; A mixture of [PdBr(C_5H_4N-C^2)(PEt_3)$_2$] (0.309 g, 0.616 mmol) and Tl(hfac) (0.262 g, 0.636 mmol) in dichloromethane (10 cm³) was stirred at room temperature for 50 min. After separation of thallium(I) bromide by filtration, the filtrate was concentrated to *ca.* 1 cm³. On addition of petroleum ether (bp<60 °C) to the concentrate a precipitate appeared, which was filtered, washed with petroleum ether, and dried *in vacuo*. The yield was 0.272 g (68.1%).

*[Pd(acac-O)(C_5H_4N-C³)(PEt_3)$_2$] (**b1**), [Pd(tfac-O)(C_5H_4N-C³)(PEt_3)$_2$] (**b2**), and [Pd(hfac-O)(C_5H_4N-C³)(PEt_3)$_2$] (**b3**)*: These complexes were similarly prepared by methods A, A, and B in 88.5, 88.0, and 37.7% yields, respectively. Complex **b3** is insoluble in usual organic solvents and precludes purification.

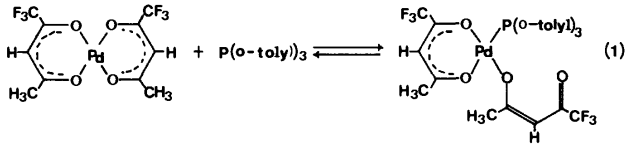
*[Pd(acac-O)(C_5H_4N-C⁴)(PEt_3)$_2$] (**c1**), [Pd(tfac-O)(C_5H_4N-C⁴)(PEt_3)$_2$] (**c2**), and [Pd(hfac-O)(C_5H_4N-C⁴)(PEt_3)$_2$] (**c3**)*: Methods A, A, and B gave these complexes in 84.9, 91.9, and 42.6% yields, respectively.

*[Pd(acac-O)(C_5H_3(6-Cl)N-C²)(PEt_3)$_2$] (**d1**), [Pd(tfac-O)(C_5H_3-(6-Cl)N-C²)(PEt_3)$_2$](**d2**), and [Pd(hfac-O)(C_5H_3(6-Cl)N-C²)-(PEt_3)$_2$](**d3**)*: Complexes **d1** and **d2** were obtained by method A in 72.3 and 75.1% yields, respectively, while method B is preferable for compound **d3**. After filtration of thallium(I) chloride produced by the reaction between [PdCl(C_5H_3(6-Cl)N-C^2)PEt_3)$_2$] (0.269 g, 0.549 mmol) and Tl(hfac) (0.248 g, 0.603 mmol) in dichloromethane (10 cm³) at room temperature, the solvent was vaporized *in vacuo* as far as possible. The residual mass was extracted with heptane. On standing the extract deposited a small additional amount of thallium(I) chloride, which was separated by filtration. The solvent was evaporated to dryness and the residue was dried at 50 °C *in vacuo*. The yield of **d3** was 0.261 g (71.8%).

Measurements. Infrared spectra were obtained in Nujol mull on a JASCO DS 701G spectrophotometer. The NMR spectra were recorded with JEOL JNM-MH100 (for ^{1}H) and FX 60Q (for ^{13}C and ^{31}P) spectrometers. Molecular weight was determined by vapor pressure osmometry with an instrument manufactured by Knauer in West Berlin, West Germany.

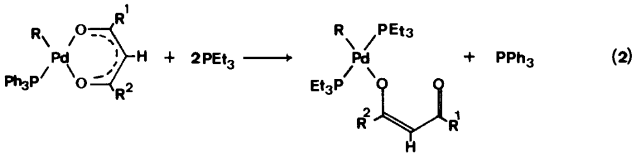
Results and Discussion

In recent years two of the present authors (S. K. and S. O.) and their coworkers studied extensively the reactions of [M(β-dik)$_2$] (M=Pd and Pt) with a variety of nitrogen bases,[3] tertiary phosphines,[4] and arsines.[4c] Among many kinds of products, some palladium(II) and platinum(II) complexes, [M(β-dik)(β-dik-*O*)L][4a] and [Pt(β-dik-*O*)$_2$L$_2$],[3c,4a] containing the *O*-unidentate β-diketonate ligand were obtained. Kinetics and equilibrium of the reaction between [Pd(tfac)$_2$] and P(*o*-tolyl)$_3$ to form [Pd(tfac)(tfac-*O*){P(*o*-tolyl)$_3$}] (Eq. 1)[5] and the crystal and molecular structure of the product[6] were also reported.



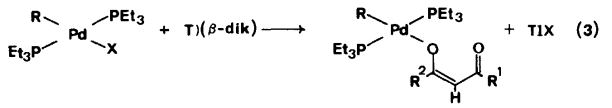
(1)

Now triethylphosphine reacted with [Pd(β-dik)(pyridyl)(PPh$_3$)] to convert the *O*,*O*′-chelated β-dik ligand into the *O*-unidentate state besides displacement of triphenylphosphine (Eq. 2, where R=pyridyl).

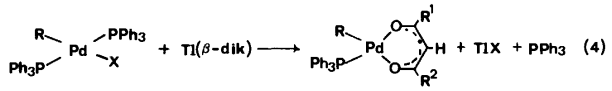


(2)

Although triethylphosphine was used in excess, other products such as [Pd(pyridyl)(PEt$_3$)$_3$](β-dik) and [Pd(pyridyl)(β-dik-*C*^{3})(PEt$_3$)$_2$] were not produced, but only the *O*-unidentate β-diketonato complexes were obtained in good yields. These complexes were also prepared by the reactions of [PdX(pyridyl)(PEt$_3$)$_2$] with Tl(β-dik) (Eq. 3), whereas the corresponding triphenylphosphine complexes [PdX(pyridyl)(PPh$_3$)$_2$] reacted with Tl(β-dik) to afford the β-dik chelates (Eq. 4).

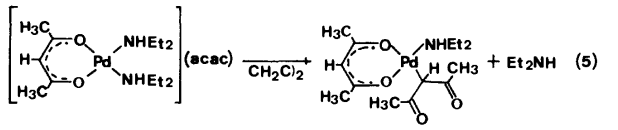


(3)

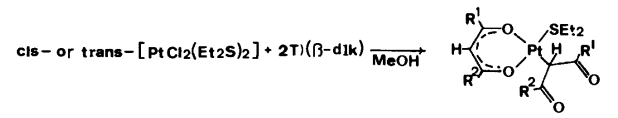


(4)

The Pd-PEt$_3$ bond seems to be stronger than Pd-PPh$_3$ and not cleaved by the intramolecular attack of the dangling carbonyl end of the *O*-unidentate β-diketonate ligand. It is worth noting that the β-diketonate anion is accepted as an *O*-unidentate ligand in the substitution reaction 3 irrespective of the nature of β-diketone (β-dik=acac, tfac, and hfac), whereas the central carbon bonding is prefered in many other reactions such as those exemplified by Eqs. 5[7] and 6 (β-dik=acac, tfac, or hfac).[8]



(5)



(6)

In the case of reaction 3 the carbon-bonded pyridyl ligand may exert trans influence to favor the *O*-bonding over the *C*-bonding of the β-diketonate anion. The PEt$_3$ ligands positioned mutually trans (*vide infra*) may also exert a steric influence on the entering β-diketonate ligand to favor the less bulky *O*-bonding. Results of elemental analysis and molecular weight determination of the newly prepared complexes are listed in Table 1.

^{1}H and ^{13}C NMR Spectra. The ^{1}H and ^{13}C{^{1}H} NMR data are collected in Tables 2 and 3, respectively. The latter data were obtained only for the 6-

Table 1. Analytical data for complexes [Pd(β-dik-*O*)(pyridyl)(PEt$_3$)$_2$]

a) Chemical shifts in ppm from internal Me_4Si. Figures in parentheses and brackets give N(C-P) and J(C-F) in Hz, br=broad. b) Measured in $CDCl_3$ at room temperature. c) Measured in CD_2Cl_2 at −30 °C. d) Indiscernible because of a weak intensity and overlapping with signals from C(2).

chloro-2-pyridyl complexes which are sufficiently soluble in chloroform to allow the ^{13}C NMR measurements. The methyl-proton signal from the PEt_3 ligands in each complex appears as a 1:4:6:4:1 quintet and the methylene protons resonate as a multiplet. This spectral pattern is characteristic of the PEt_3 ligands situated mutually trans.[9)] The methylene carbons of the PEt_3 ligands in each of complexes **d1**, **d2**, and **d3** exhibit a triplet signal owing to coupling to the phosphorus atoms which are situated trans to each other and virtually coupling. In fact the $^{31}P\{^1H\}$ NMR spectra of **d1** and **d2** in $CDCl_3$ and of **d3** in CD_2Cl_2 show a singlet at 11.9, 12.0, and 9.5 ppm, respectively, downfield from external 85% H_3PO_4. The signal from **d3** is broad at room temperature (half-height width *ca.* 7 Hz) and becomes broader at higher temperature (half-height width at 60 °C *ca.* 14 Hz), while it sharpens at lower temperatures (half-height width at −30 °C *ca.* 2 Hz).

Figures 1, 2, and 3 compare the ^1H and $^{13}C\{^1H\}$ signals from the β-diketonate ligands in **d1**, **d2**, and **d3**. Of the two methyl-proton signals from complex **d1**, the lower-field one (δ2.36) is assigned to the methyl adjacent to the coordinated carbonyl group by reference to the data for $[Pt(acac\text{-}O)_2(piperidine)_2]$ which exhibits two methyl signals, one at 2.25 ppm[3c)] and the other flanked by ^{195}Pt satellites at 2.34 ppm.[3c)] The ^{13}C NMR data for the acac ligand in this platinum(II) complex (C^1 23.9, C^2 188.7, C^3 103.3, C^4 196.8, and C^5 30.6 ppm) are quite helpful for assignment of ^{13}C signals from **d1** (Table 3). The ^1H and ^{13}C NMR spectra of the *O*-unidentate tfac in **d2** (Fig. 2) also bear a close resemblance to those of the tfac-*O* ligands in $[Pt(\beta\text{-dik})(tfac\text{-}O)L]$ (β-dik=acac or tfac, L=PPh_3, P(*o*-tolyl)$_3$, or PEt_3), $[Pd(tfac)(tfac\text{-}O)L]$ (L=P(*o*-tolyl)$_3$ or P(cyclohexyl)$_3$), and $[Pt(tfac\text{-}O)_2(PEt_3)_2]$.[4a)]

Head-to-Tail Intramolecular Donor Atom Exchange of the O-Unidentate β-dik Ligands. Although the NMR spectra of **d1** and **d2** are satisfactorily interpreted on the basis that these complexes are stereochemically rigid in solution, complex **d3** shows only one set of signals from CF_3 and CO carbons (Fig. 3), indicating that **d3** is fluxional and the environments of both halves

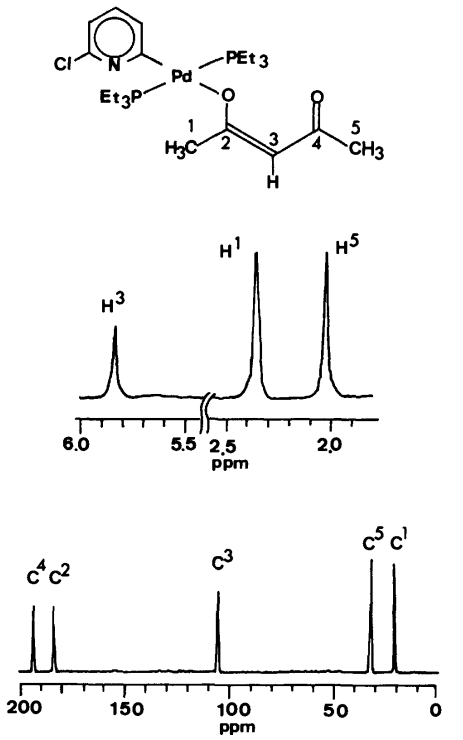

Fig. 1. ^{1}H and $^{13}C\{^{1}H\}$ NMR signals from the acetylacetonate ligand in [Pd(acac-*O*)(C_5H_3(6-Cl)N-*C*^{2})-(PEt_3)$_2$] (**d1**) in $CDCl_3$ at room temperature. Chemical shifts are shown in ppm from internal Me_4Si.

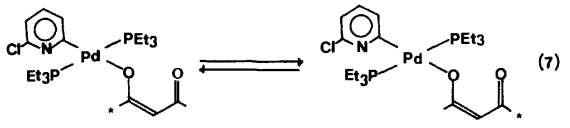
of the *O*-unidentate hfac ligand are averaged rapidly on the NMR time scale. Unfortunately solubility of **d3** in dichloromethane is so poor at lower temperatures as to preclude the spectral determination below −30 °C, but the ^{13}C signals from the hfac-*O* ligand become broader with decreasing temperature and the carbonyl carbon signals show some indication of splitting.

As is seen in Fig. 4, the methyl-proton signals from the acac ligand in **d1** become sharper at 0 °C and broader at 50 °C, suggesting fluxional motion similar to that exhibited by **d3**. Complex **d1** as well as **d3** seems to undergo the head-to-tail intramolecular donor-atom exchange (Eq. 7), since no other change in spectrum is observed in this temperature range.



(7)

In order to study the fluxional motion of **d1** at higher temperatures *o*-dichlorobenzene was employed as solvent. A minor methyl signal appeared at 1.92 ppm besides the 2.11 and 2.56 ppm ones in this solvent at room temperature (Fig. 4). The chemical shift of this additional signal corresponds to average of methyl signals (1.90 and 1.94 ppm) of complex **d4**[1)] in Eq. 8. In a previous paper triphenylphosphine was found to be a very effective catalyst for the coordination-site exchange reaction of [Pd(acac)(C_5H_3(6-Cl)N-*C*^{2})(PPh_3)].[1)] Triethylphosphine liberated by the chelate ring closure reaction (Eq. 8) seems to catalyze the coordination-site exchange of **d4**.

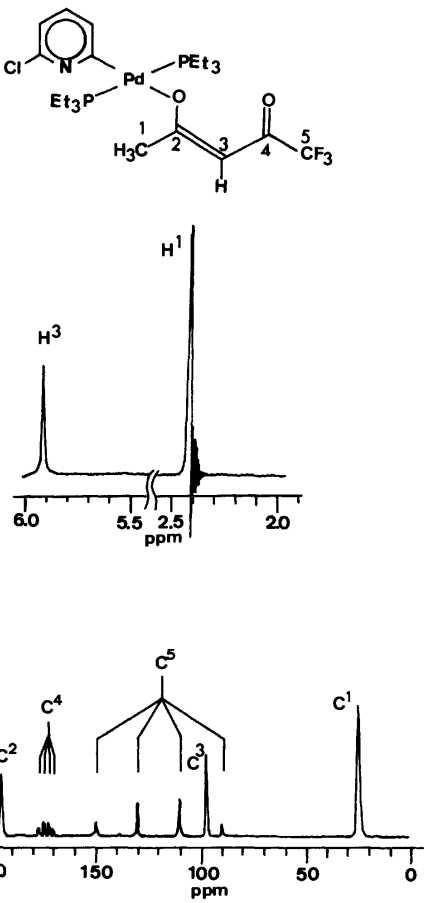


Fig. 2. ^{1}H and $^{13}C\{^{1}H\}$ NMR signals from the trifluoroacetylacetonate ligand in [Pd(tfac-*O*)(C_5H_3-(6-Cl)N-*C*^{2})(PEt_3)$_2$] (**d2**) in $CDCl_3$ at room temperature. Chemical shifts are shown in ppm from internal Me_4Si.

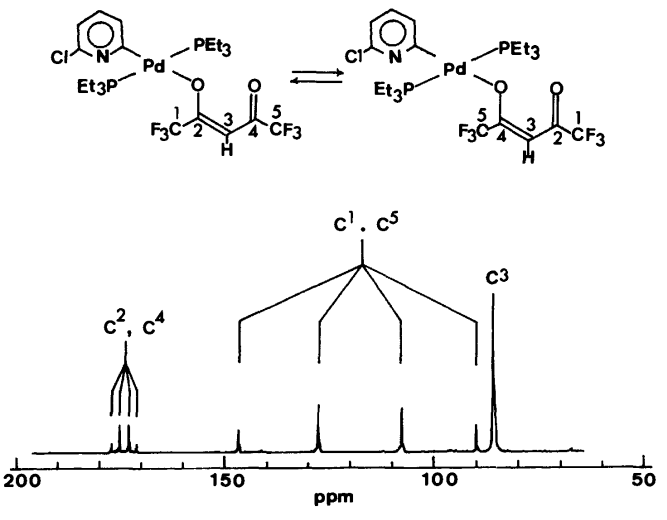

Fig. 3. $^{13}C\{^{1}H\}$ NMR signals from the hexafluoroacetylacetonate ligand in [Pd(hfac-*O*)(C_5H_3(6-Cl)N-*C*^{2})-(PEt_3)$_2$] (**d3**) in $CDCl_3$ at room temperature. Chemical shifts are shown in ppm from internal Me_4Si.

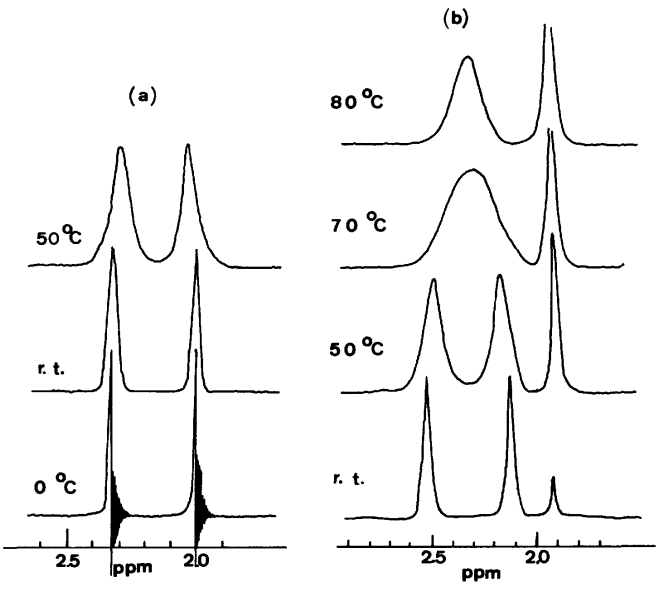

Fig. 4. ^{1}H NMR signals from the acetylacetonate ligand in [Pd(acac-*O*)(C_5H_3(C_5H_3(6-Cl)N-*C*^{2})(PEt_3)$_2$] (**d1**) in $CDCl_3$ (a) and *o*-dichlorobenzene (b) at several temperatures.

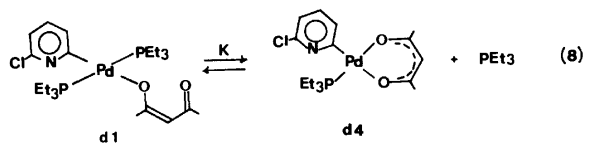
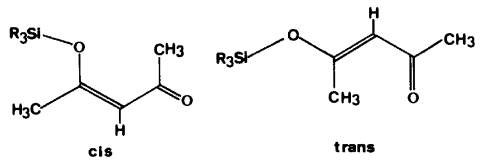


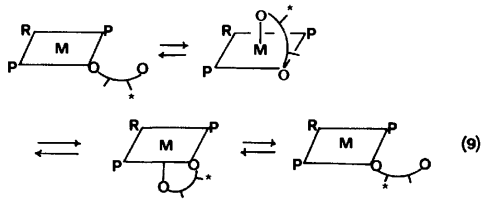
The equilibrium quotient K of reaction 8 was determined from the signal-area ratio to be 7.0×10^{-3} mol dm^{-3} at 33 °C. As is seen in Fig. 4, the δ1.92 signal becomes larger remarkably with temperature, K being 1.7×10^{-2}, 4.5×10^{-2}, 1.0×10^{-1}, and 2.2×10^{-1} mol dm^{-3} at 60, 70, 90, and 120 °C, respectively, and ΔH was obtained as 40.2 kJ mol^{-1}. Reaction 8 does not occur appreciably in chloroform and dichloromethane.

The ^{1}H NMR spectrum of R_3Si(acac-*O*) was found by Pinnavaia and his collaborators to be composed of signals from both cis and trans isomers.[10]



The trans isomer exhibits two methyl doublets and a methine multiplet owing to the spin-spin coupling between the methine and methyl protons, while the cis isomer shows a methyl singlet and a methine singlet without coupling. Equivalence of the two methyl groups in the cis isomer was thought to be caused by the intramolecular rearrangement *via* a trigonal-bipyramidal transition state involving the *O,O'*-chelated acetylacetonate anion.[10]

Complex **d1** shows only one methine singlet and two methyl signals with no sign of coupling indicating that the dangling acetyl group of the acac ligand is positioned cis to the coordinating oxygen atom with respect to the C=C bond. The same structure was also assigned to *trans*-[Pt(acac-*O*)$_2$(PEt_3)$_2$].[11] As is seen in Fig. 4 methyl signals become broader with increasing temperature and collapse at 70 °C. Above 80 °C one broad signal is observed. As a mechanism for the head-to-tail donor-atom exchange of the *O*-unidentate β-diketonate ligand in the present case, a simple oscillatory motion of the β-diketonate ligand spanning the apical and basal coordination sites in the square-pyramidal intermediate (Eq. 9) is proposed.



This kind of motion of a potentially bidentate ligand was previously assumed to explain the environmental equivalence of both halves of the essentially unidentate 1,10-phenanthroline in *cis*-[PtCl(phen)(PEt_3)$_2$]BF_4.[12] The X-ray molecular structures and solution behaviors of square-pyramidal complexes [Pt(hfac)$_2$(PCy_3)] and [Pd(hfac)$_2${P(*o*-tolyl)$_3$}] were reported and the oscillatory motion depicted above was proposed as one of the two fluxional modes to average the environments of four CF_3 groups involved in the palladium(II) complex.[13]

Although the hfac anion gives these stable square-pyramidal platinum(II) and palladium(II) complexes in which one hfac anion spans the apical and basal coordination sites, the analogous reaction between [Pd(tfac)$_2$] and P(*o*-tolyl)$_3$ proceeds reversibly to afford [Pd(tfac)(tfac-*O*){P(*o*-tolyl)$_3$}] (Eq. 1), exhibiting no spectral evidence for the five-coordinate intermediate.[5] No examples of square-pyramidal platinum(II) and palladium(II) complexes containing the acac ligand have been obtained either. These results suggest that the five-coordinate square-pyramidal intermediate as postulated in Eq. 9 will be most favorable for the hfac complex. It may be the reason why complex **d3** undergoes the fluxional motion much more readily than **d1** does.

We wish to thank Mr. Junichi Gohda for elemental analyses.

Comparison of the Experimental Zone Mobility-pH Curves of the Bases of Nucleic Acid on the Pure Cellulose Paper with the Calculated Ones[1)]

Yoshinori KITAOKA

Research Reactor Institute, Kyoto University, Kumatori-cho, Sennan-gun, Osaka 590-04

(Received February 2, 1984)

Comparison of the experimental zone mobility-pH curves of nucleic acid bases with the calculated ones was made over acidic and basic regions using a pure cellulose paper as a support after correction of the capillary action and the endoosmotic flow. The mobilities in the acid region agreed with the calculated ones but those in the basic region did not. Some unknown factors affect the mobilities in the basic region.

Paper electrophoretic behavior of weak acids or bases is strongly affected by the pH-value of a supporting solution, which controls the ratios of ionization of a migrant.[2)] Several workers have studied the mobilities and the pH-values of the supporting solution. Smith[3,4)] discussed the relationship between the mobility and the dissociations of amino and phosphonoxy groups of nucleotides. Wade and Morgan[5)] separated nucleoside and bases using a borate buffer. Kiso and coworkers[6)] derived an equation for the relationship between mobility and pH-value and applied it to phosphorus compounds. If we know the mobility of each species and the dissociation constant of a given compound, the zone mobility-pH curves[6)] could be drawn theoretically. However, in the actual electrophoresis using a support, the observed mobilities are affected by electroosmosis, capillary action, and so on of the support in addition to the chemical nature of the supporting solution.[7)] Thus, the good agreement between the observed and the calculated mobilities will be made only under well defined conditions. In this experiment, in order to lessen the chemical effect of a support on the mobility, a pure cellulose paper was used as a support. Although electrophoretic separation at fixed and narrow pH-range has often been reported, this is not so for the electrophoretic behavior over an extended acid and alkaline range in the same experiment. In this experiment, the pH-values were continuously varied over a range of pH=2.0—13 in the same system. The theoretical mobility-pH curves were calculated by a microcomputer.

In this report, we discuss the differences between the observed and the calculated mobilities of nucleic acid bases on pure cellulose paper (A=adenine, G=guanine, T=thymine, U=uracil, and C=cytosine). The observed mobilities of the bases were found to be in good agreement with the calculated ones in the acid region, but not in the alkaline region.

Reagent and Procedures

The procedures and apparatus used were similar to those described previously.[8)] All the nucleic acid bases (A, G, T, U, C) were purchased from Sigma (St. Louis, Mo., U. S. A.). Sørensen's buffer solutions[9)] were used as a supporting solution: citrate buffer; pH=2.0—6.0, phosphate buffer; pH6.0—8.0, glycine buffer; pH=9.0—13.0. A 5 μl volume of sample solution (10^{-2} M (1 M=1 mol dm^{-3})) was spotted at the center of the filter paper (Toyoroshi, No. 51A, pure cellulose paper) wetted with a supporting solution. The spotting paper was immersed in hexane and a constant voltage (1000 V/30 cm) applied to it for 30 min at 20 °C. The position of the bases on the paper was detected by irradiation with ultraviolet light (253 nm). In order to estimate the electroosmotic flow, glucose was migrated under the same electrophoretic conditions as for the bases. The glucose was detected by spraying with *o*-aminophenol solution.[10)]

Results and Discussion

The observed electrophoretic behaviors of the bases against pH-values are shown in Fig. 1. The migration distances shown were not corrected for the electroosmotic flow which was estimated from the movement of glucose under conditions similar to those of electrophoresis. Thus, the observed migration distances include the movements by the electroosmotic flow. The average electroosmotic flow (-1.0 ± 0.3 cm, pK_i=4.0) in this experiment is shown in Fig. 2. The effects of a capillary action on the migrations are negligible because the sample solutions were spotted at the center of the filter paper.[7)]

Generally, the zone mobility is the weighted mean value of the mobility of each species present in a given solution. In an ideal solution where only C_i and C_{i+1} species are present, the zone mobility U_{zi} is expressed by the Eq. 1

$$U_{zi} = (U_i[C_i] + U_{i+1}[C_{i+1}])/([C_i] + [C_{i+1}]), \quad (1)$$

where U_i and U_{i+1} are the mobility of C_i and C_{i+1} ions, and $[C_i]$ and $[C_{i+1}]$ the concentration of C_i and C_{i+1} ions in a given system. The concentration of each chemical species is related to the dissociation constant (K_i)

$$K_i = [C_{i+1}][H^+]/[C_i]. \quad (2)$$

Then, by substituting Eq. 2 into Eq. 1, we obtain

$$U_{zi} = \frac{U_i + U_{i+1} \cdot K_i/[H^+]}{1 + K_i/[H^+]}. \quad (3)$$

Thus, if we know the values of U_i, U_{i+1}, and K_i respectively, the value of U_{zi} against the pH value will be calculated. The curves in Fig. 2 are drawn by substituting the most suitable values obtained by the actual

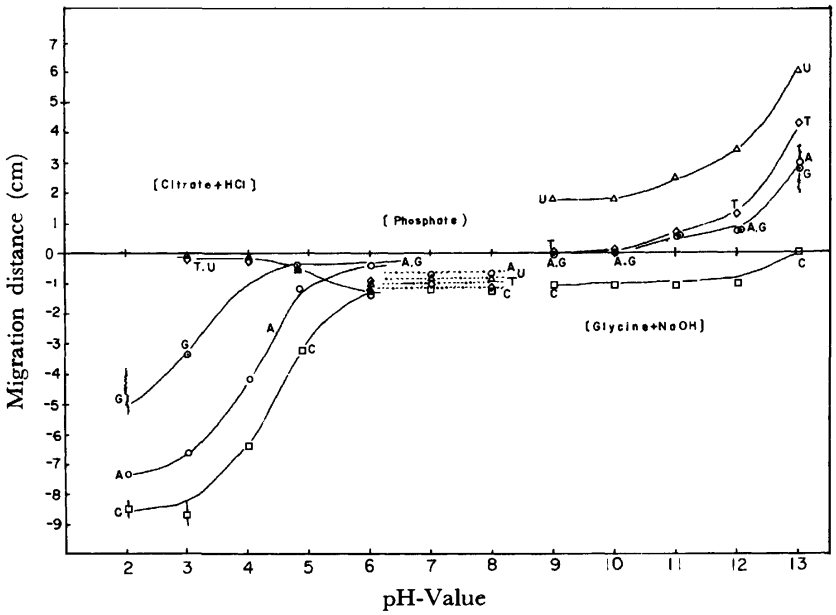

Fig. 1. Observed electrophoretic behaviors of the bases of the nucleic acid against pH-values.
Sample solutions: ○, adenine (A); ⊙, guanine (G); △, uracil (U); ◇, thymine (T); □, cytosine (C). Electrophoresis conditions: 1000 V per 30 cm, 30 min, at 20 °C. Supporting solutions, citric acid buffer (pH=2.0—6.0); phosphoric acid buffer (pH=6.0—8.0); glycine+NaOH buffer (pH=9.0—13.0). Support, pure cellulose paper (Toyoroshi No. 51 A). Spotting position, the centre of a support. Positive movement is towards the anode, negative movement towards the cathode.

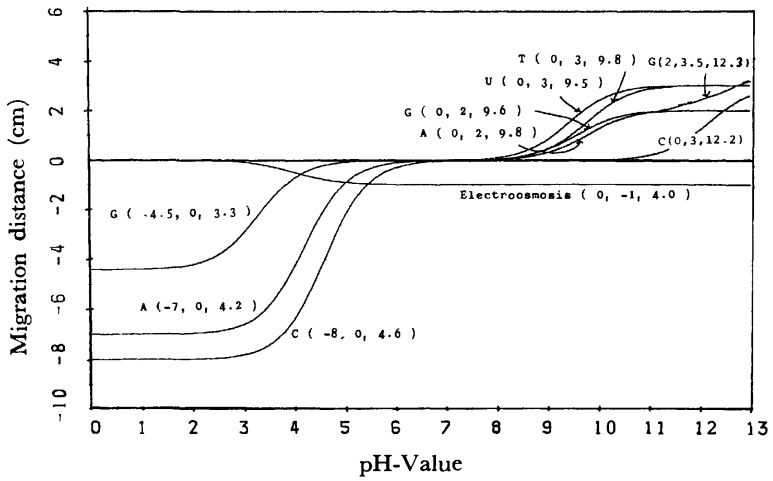

Fig. 2. Calculated migration curves of the bases of the nucleic acid.
Electrophoresis conditions and symbols used are the same as in Fig. 1. The three figures in the parenthesis are migration distances (cm) of C_i, C_{i+1}, and pK_i-value in this order.

experiment for equation 3. The zone mobility-pH curves shown in Fig. 2 are drawn by a microcomputer (Model, NEC PC-9801) equipped with a plotter (Watanabe multi myplot).* The three figures in the parenthesis in Fig. 2 show U_i, U_{i+1}, and pK_i (negative logarithm of K_i) in this order. U_i and U_{i+1} are the mobilities of each species, they varies with the charge, the molecular weight, the hydration, the shape, the size etc. The U_i and U_{i+1} in Fig. 2 were taken from this experiment. The pK_i values were referred to the data[11] which are determined by the chemical methods other than the electrophoresis. The electroosmotic flows were measured by the movement of glucose. The main cause of the flows seems to be due to the carboxyl groups in cellulose paper introduced during the manufacturing of the filter paper.[12] As the inflection point of the electroosmotic flow was estimated to be around pH=4.0 from this experiment, the pK_i value are assumed to be 4.0, and the calculated curve was drawn by the microcomputer. In acid region, movements due to the protonated amino groups of the bases are expected. Three bases (A, G, C) moved towards the cathode while two bases (T, U) having no amino group did not. Compar-

* The computer program is available on application to the author.

ing the actual results with the calculated ones in the acid region, we find a good agreement. In the neutral region, as all the bases have no charge on the molecule, it is assumed that they do not migrate. The observed small migrations of all the bases towards the cathodic side were within the range of the electroosmotic flow. In alkaline region, the dissociation of the hydrogen of the phenolic hydroxyl groups or of the imino group is expected. The p$K$is of the phenolic groups of U, G, and T or of the imino group of A are reported to be within pH=9—10.[11] In this experiment, no inflextion point was found within pH=9—10. Furthermore, the movement of U at pH=9.0 is too large, comparing with that of G or T. In the strongly alkaline region (pH=12—13), the dissociation of the hydrogen atom of the imino groups of G or of phenolic hydroxyl group of C is expected. The high migration distances of U and T may be due to the dissociation (pK>13[13]) of the hydrogen of the second phenolic hydroxy group. Although we tried to select the most appropriate mobility for the anions obtained from actual experiment, agreement between observed and calculated values were never obtained. The inflection points of the experimental curves were not definite and the inflection point seemed to be shifted to a more alkaline region. The data for migration at pH=13 may not be reliable because of the possibility of partial decomposition of the sample and the support. The migration of C in the cathodic side is due to the electroosmosis. The discrepancy between the calculated and observed curves are much large in alkaline region. The cause of the discrepancy seems to be some unknown factors other than electroosmosis and capillary action. Some chemically specific interaction between a migrant and a supporting solution or the structual change of a filter paper in alkaline region might be considered. Further studies on the cause of the discrepancy in alkaline region is needed.

From the chemical isolation point of view, A, G, and C could be separated from T and U in acid region, and U and T could be separated from each other in alkaline region. The neutral region is not good for the separation of any bases.

In conclusin, it is found that the electrophoretic behavior in the acid region could be explained satisfactorily but not in the alkaline region.

Cation Ordering in (NaLa)(MgW)O_6 with the Perovskite Structure

Tadashi Sekiya, Tetsuo Yamamoto, and Yasuyoshi Torii*
Government Industrial Research Institute, Nagoya Hirate-machi, Kita-ku, Nagoya 462
(Received November 11, 1983)

The title compound with an ordered monoclinic (pseudotetragonal) perovskite structure has been prepared. The lattice constants are a=5.5239(5), b=5.5253(4), c=7.8936(6) Å, β=90.16(1)°, and Z=2. The superstructure was found to be due to a layer-like ordering of Na^+ and La^{3+} ions along alternate c-planes as well as a NaCl-type ordering of Mg^{2+} and W^{6+} ions in the octahedral sites. This new compound is the first example for the occurence of cation ordering in the A site. The origin of the superstructure was discussed.

There are many examples of ABO_3-type perovskites where cation ordering occurs in the B site when ions of different size and charge substitute for a single B atom. Generally, cation ordering is unlikely to occur in the A site. An ordering of A-site vacancies, however, has been found only in some compounds such as $La_{0.33}NbO_3$[1,2] and $La_{0.67}TiO_3$[3]. Recently we have reported that $La_{1.33}(MgW)O_6$ crystallized in an orthorhombically distorted perovskite structure, showing a NaCl-type ordering of B ions as well as an ordering of A-site vacancies along alternate c-planes.[4] Our attempt to prepare a new perovskite of (NaLa)(MgW)O_6 composition was successful. The X-ray diffraction pattern was highly similar to that of $La_{1.33}(MgW)O_6$ in general features. This new compound is therefore considered having a layer-like ordering of Na^+ and La^{3+} ions in the A site. This remarkable ordering phenomenon at the larger cation sublattice has been observed in the perovskite-related compounds (NaLn)TiO_4 (Ln=lanthanoids.[5] The superstructure of Na^+ and La^{3+} ions may result in a poor charge compensation in the octahedral surroundings. The new compound (NaLa)-(MgW)O_6 is challenging for a crystal chemical investigation. The purpose of the present work is to examine the cation distribution in this compound and to interpret the origin of the superstructure.

Experimental

The title compound was prepared from Na_2CO_3, La_2O_3, MgO and WO_3 of high purity. 2.5 Mol% of excess Na_2CO_3 was added to a stoichiometric composition for vaporization of Na_2O at elevated temperatures. The weighed batch was heated at 950 °C for 4 h in air. The reacted mixture was further ground, pressed into disks and reheated twice at 1100 °C for 6 hrs on a Pt foil in a closed alumina crucible. As shown in Fig. 1(a), the X-ray diffraction analysis of the product showed that the phase crystallized well and that it did not contain any additional compound. The reflections were measured at a scanning speed of (1/8)° 2θ/min and the Bragg angles were corrected with a silicon standard. The lattice constants were refined by the least-squares method.[6] The observed intensities were measured by cutting out and weighing tracings of the peaks. Infrared absorption measurements between 1200—250 cm^{-1} were made for powder specimens dispersed in a pressed KBr disk, using a Perkin-Elmer infrared spectrophotometer model 180.

Results and Discussion

The title compound (NaLa)(MgW)O_6 shows an X-ray powder pattern characteristic of the perovskite

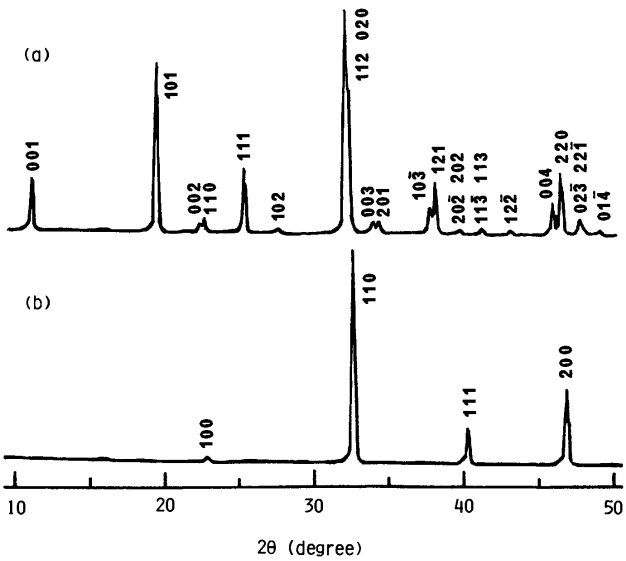

Fig. 1. X-Ray powder patterns of perovskites (NaLa)(MgW)O_6 (a) and (NaLa)Ti_2O_6 (b).

structure, as can be seen by comparison with that of a simple perovskite (NaLa)Ti_2O_6[7] in Fig. 1(b). The X-ray diffraction data for (NaLa)(MgW)O_6 are given in Table 1. The superstructural reflections marked by an asterisk arise from a NaCl-type ordering of Mg^{2+} and W^{6+} ions in the oxygen-octahedral sites. In addition to their reflections, extra reflections marked by double asterisks are observed in the X-ray powder pattern of (NaLa)(MgW)O_6. Various kinds of line-splitting phenomena indicate appreciable distortion from ideally cubic symmetry. All the reflections in Table 1 could be satisfactorily indexed on the basis of a monoclinic unit cell with β close to 90°. Its lattice constants were refined for selected 41 observed reflections by the least-squares method. This gave a=5.5239(5), b=5.5253(4), c=7.8936(6) Å, and β=90.16(1)°. The cell-edges are approximately $\sqrt{2}a'$ for the a- and b-axis and $2a'$ for the c-axis, where a' is the length of the perovskite-like subcell edge. Since the a and b dimensions are very nearly equal, the monoclinic unit cell is considered to be pseudotetragonal. The pycnometrically measured density of 6.46 g/cm^3 was in good agreement with the calculated value of 6.42 g/cm^3 for two formula units of (NaLa)(MgW)O_6 per cell. This result supports that the new compound has the chemical formula of (NaLa)-(MgW)O_6.

The reflections given in Table 1 show no systematic

* Superstructural reflection due to a NaCl-type ordering of B-site ions. ** Superstructural reflection due to a layer-like ordering of A-site ions.

absences for general reflections of *hkl* type, and the monoclinic cell is therefore primitive. This X-ray pattern, except the additional reflections marked by double asterisks, obeys a body-centered absence rule. On the other hand, the additional reflections marked by double asterisks occur with only $h+k=2n$ for (hkl) planes, if a few reflections of very weak intensity are ignored. This indicates that (NaLa)(MgW)O_6 has a C-face-centered lattice for special atoms. Especially, the appearance of relatively strong *001* reflection at about 7.88 Å, which can not be assigned to the NaCl-type ordering of the B ions, points to a doubling of the c'-axis in the small perovskite subcell, as found in $La_{0.33}NbO_3$[2] and $La_{0.67}TiO_3$.[3] In the compound (NaLa)(MgW)O_6, a cation ordering of Na^+ and La^{3+} ions is therefore considered to occur along alternate c-planes. Thus a superstructure model based on cation ordering is proposed as shown in Fig. 2. The perovskite subcell is designated by dotted outlines.

The extinction rule deduced from the observed reflections in Table 1 is as follows; *0k0*: ($k=2n$). So two space groups, $P2_1$ (No. 4) and $P2_1/m$ (No. 11), satisfy the extinction rule and simultaneously give

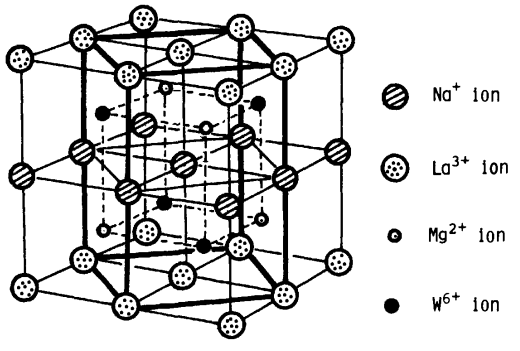

Fig. 2. Superstructure of (NaLa)(MgW)O_6, where oxygen ions are not shown.
Monoclinic unit cell: heavy solid line. Perovskite-like subcell: dotted line,

the monoclinic crystal system[8]. The space group of monoclinic (NaLa)(MgW)O_6 probably belongs to $P2_1$, judging from the three-dimensional symmetry of the B ions in the NaCl-type ordering. The c-axis in (NaLa)(MgW)O_6 is regarded as a characteristic axis of the pseudotetragonal (actually monoclinic) cell.

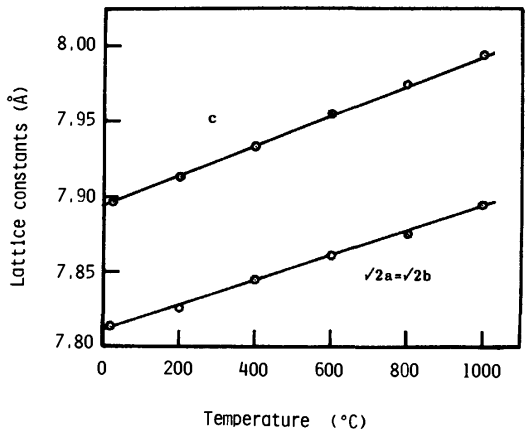

Fig. 3. Temperature dependence of lattice constants for (NaLa)(MgW)O_6.

Figure 3 shows the variation of the lattice constants of monoclinic (NaLa)(MgW)O_6 with temperature. The unit cell was tetragonal at 200 °C, and phase transitions were absent up to 1000 °C. The marked change in the cell dimensions with temperature is not accompanied by any appreciable change in the degree of tetragonality, and the superstructural reflections marked by double asterisks did not disappear even at 1000 °C. This result shows a crystallographic tendency similar to $La_{0.33}NbO_3$,[9] $La_{0.67}TiO_3$,[3] and $La_{1.33}(MgW)O_6$,[10] in which the A-site vacancies are ordered along alternate c-planes. Generally, the low symmetry of ordinary perovskites is expected to improve at high temperatures. The title compound (NaLa)(MgW)O_6 also differs from ordinary perovskites in the nature of tetragonal distortion. Hence the basic cell distortion in this compound is concluded to be tetragonal. The monoclinic distortion deviated from the tetragonal symmetry probably arises from atomic displacements in the neighboring perovskite subcells.

In order to confirm the proposed superstructure (Fig. 2), the theoretical intensities for (NaLa)(MgW)O_6 were calculated using ideal position parameters on the assumption of a tetragonal cell and were compared with the observed intensities in Table 1. In intensity calculations, the effects of atomic displacements and crystal distortion (actually monoclinic) on reflection intensity were neglected to avoid troublesome position parameters. In such a rough test, however, a qualitatively good agreement between the observed and calculated intensities was obtained as shown on the right side of each reflection in Table 1. The reliability factor R for the intensities of 36 peaks was 28%. This result gives good evidence for the general correctness of the proposed structure. Consequently the basic superstructure of (NaLa)(MgW)O_6 is concluded to arise from the NaCl-type ordering of the B ions as well as the layer-like ordering of the A ions, although cation ordering is unlikely to occur among the A-site ions in the perovskite structure. In this respect, the new compound (NaLa)(MgW)O_6 is an exceptional case.

Figure 4 gives the infrared absorption spectra of perovskites (NaLa)(MgW)O_6 and (NaLa)Ti_2O_6. In the case of cubic (NaLa)Ti_2O_6, two strong absorption band

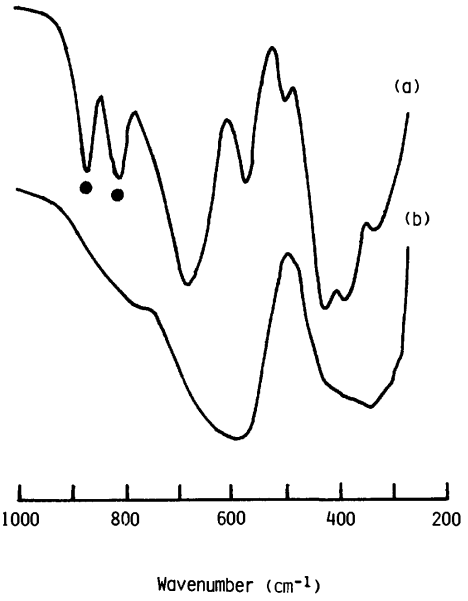

Fig. 4. Infrared absorption spectra of perovskites (NaLa)(MgW)O_6 (a) and (NaLa)Ti_2O_6 (b).

peaks were observed at 600 and about 340 cm^{-1}. On the basis of Last's mode assignment[11] on the perovskites, the high frequency band corresponds to the Ti-O stretching mode, while the lower frequency band does to the Ti-O bending mode. On the other hand, the spectrum of monoclinic (NaLa)(MgW)O_6 is more complicated. Two strong absorption bands at 685 and about 400 cm^{-1} are assigned to the internal modes of oxygen octahedra. The extra bands probably arises from the monoclinic distortion from ideal cubic symmetry, which would split degenerate modes to give additional frequencies as mentioned by some investigators.[12–14] However, it should be noted that two strong bands (marked a black circle) were found at 870 and 820 cm^{-1}. In view of the spectral positions, the two bands must be due to the B-O vibrational mode. The strong bands at very high wavenumbers, which are not expected for a regular octahedron, indicate a strong deviation from cubic symmetry. Such a remarkable spectrum[15] has been found in perovskite-related compounds (NaLn)TiO_4, where the Na^+ and Ln^{3+} ions are ordered on the larger cation sublattice. In the case of (NaLn)TiO_4, a strong band is located around 900 cm^{-1} in addition to the normal vibrations. This striking band is absent in Sr_2TiO_4. This fact that this mode was observed at very high wavenumbers has been concluded to be due to the superstructure of Na^+ and Ln^{3+} ions which results in a poor charge compensation in the octahedral surroundings. Consequently the infrared spectrum of (NaLa)(MgW)O_6 supports that a layer-like ordering of Na^+ and La^{3+} ions occurs on the A site.

Our attempt to prepare the corresponding Ni and Zn compounds to (NaLa)(MgW)O_6 was unsuccessful. A similar result[4] has been obtained for the replacements of Ni^{2+} and Zn^{2+} ions for Mg^{2+} ion in cation-deficient perovskite $La_{1.33}(MgW)O_6$. Since these three cations are roughly equal in size, the failure of the preparation is not thought to be mainly due to the ionic size effect.

Thus the Mg/W combination not only contributes to the framework as constituent ions, but also plays an important role in the stabilization of the perculiarly ordered perovskite structure.

According to the X-ray structure analysis[2] of orthorhombic (pseudotetragonal) $La_{0.33}NbO_3$, the Nb^{5+} ions are displaced from the centers of the oxygen octahedra which themselves suffer distortion so as to retain only one of their four-fold axes. The particular displacement of the Nb^{5+} ions must be connected with the ordering of A-site vacancies along alternate c-planes. Recently we have reported that A-site vacancies are randomly distributed in the cubic $La_{0.33}NbO_3$ phase crystallized by rapid quenching of its melt.[16] Further, the pseudotetragonal perovskites $La_{0.33}NbO_3$ and $(NaLa)(MgW)O_6$ show the temperature-independent tetragonality, in addition to the layer-like ordering of A-site ions. Consequently, $(NaLa)(MgW)O_6$ is also considered to have similar off-centered octahedra to $La_{0.33}NbO_3$. This conclusion is supported by the infrared data of $(NaLa)(MgW)O_6$. Such a severly distorted octahedral-site seems to be unfavorable surroundings for Ni^{2+} and Zn^{2+} ions owing to strong crystal field effect of Ni^{2+} ($3d^8$) ion and tetrahedral site-preference of Zn^{2+} ($3d^{10}$) ion. This situation is reflected in the nonexistence of $NiSiO_3$ and $ZnSiO_3$ pyroxenes (the existence of $MgSiO_3$ pyroxene), since the pyroxene structure[17] consists of severely distorted octahedra and single chains of SiO_4 tetrahedra. Thus the Mg^{2+} ion makes no small contribution to the stabilization of this type of superstructure. The origin of the superstructure is represented as follows: The difference in charge between the Na^+ and La^{3+} ions is enough to cause cation ordering to occur among the A-site ions. The electrostatic imbalance due to the layer-like ordering of Na^+ and La^{3+} ions is compensated by the particular displacement of the Mg^{2+} and W^{6+} ions for the c direction, and such an electrostatic interaction gives rise to the pseudotetragonal distortion. In consequence, two strong absorption bands at very high wavenumbers were observed in the infrared spectrum of $(NaLa)(MgW)O_6$. The temperature-independent tetragonality shown in Fig. 3 is closely related with the layer-like ordering of A-site ions along alternate c-planes.

(Received August 6, 1983)

An improved procedure for the preparation of 1-(methylthio- and phenylthio)vinyllithium reagents utilizing 2-methoxyalkyl sulfides was developed and their reactions with ketones, aldehydes, oxiranes, and alkyl halides were studied.

The utilization of various heteroatom-stabilized vinyl anions in organic synthesis has become increasingly important in recent years.[1] The α-lithiated alkenyl sulfide (**3**) is one of these anions, and usefulness of **3** in the synthesis of certain organic compounds has well been demonstrated. For example, Oshima *et al.* showed that **3**, which are useful intermediates for the synthesis of ketones,[2] could be considered as acyl anion equivalents. It was also reported that the adducts of **3** with aldehydes might be valuable intermediates for the preparation of furans and 1,4-dicarbonyl compounds.[3]

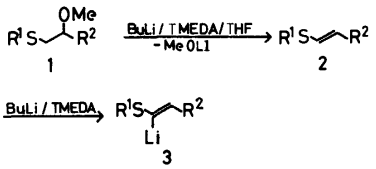
Since **3** is generally prepared by the treatment of alkenlyl sulfide (**2**) with strong base, such as *s*-butyllithium, *t*-butyllithium, or lithium diisopropylamide (LDA), the preparation of alkenyl sulfides (**2**) is required at the first step of the aforementioned synthesis. However, the synthesis of **2** may not be straightforward in some cases.[4] We have thus investigated an improved procedure for the preparation of **3**. Recently, we found that the reaction of 2-methoxyalkyl sulfides (**1**) with two molar butyllithium in the presence of *N,N,N′,N′*-tetramethylethylenediamine (TMEDA) directly produced **3**, probably *via* **2**.[5]

Concerning the formation of alkenyl sulfide from 2-methoxyalkyl sulfide and subsequent lithiation, Corey *et al.* reported that 1,3-bis(methylthio)propene (**4**) was obtained by the reaction of 1,3-bis(methylthio)-2-methoxypropane (**5**) with an equimolar amount of LDA, and 1,3-bis(methylthio)allyl anion (**6**) was directly produced when **5** was treated with two equivalents of LDA.[6] Unlike the above-mentioned result of us, the formation of vinyllithium (**3**) was not observed in the lithiation of **4** with LDA. This selective formation of the allyl anion (**6**) is apparently due to the presence of methylthio group attached to the allylic position of **4**.

In this paper, we wish to report the scope and limitation for the generation of **3** with our method, and the results obtained in the reaction of **3** with carbonyl compounds, oxiranes, and alkyl halides are described.

Results and Discussion

1-(Methylthio- and phenylthio)vinyllithiums (**3**) were prepared by the reaction of the corresponding 2-methoxyalkyl sulfides (**1**) with butyllithium or LDA as indicated in Eq. 1. The yield of **3** was estimated on the basis of the isolated yield of adduct with benzaldehyde (Table 1). Satisfactory results were obtained when **1** was treated with butyllitium at −30 °C or higher for 1 to 3 h in the presence of TMEDA. At −78 °C, the yield of **3a**



1a R¹=Me R²=H
1b R¹=Me R²=Ph(CH₂)₂
1c R¹=Me R²=(CH₃)₂CHCH₂
1d R¹=Me R²=Ph

a) The reaction was carried out at −50 °C without HMPA.

was only 11% after 1 h. In the absence of TMEDA, only a trace amount of **3a** was produced under similar reaction conditions. In contrast to the reactions of **1a**, **1e**, and **1f**, the treatment of 2-methoxy-2-phenylethyl sulfide (**1d**) with butyllithium did not afford **3**, but produced the Michael type adduct of the intermediate alkenyl sulfide (**2**). When LDA was used as a base, however, this side reaction was suppressed.

The reaction of **3** with various aldehydes and ketones proceeded smoothly and produced β-methylthio and phenylthio β,γ-unsaturated alcohols (**7**) in good yields (Table 2). When allylic hydrogen was present in the intermediate methl alkenyl sulfide (**2**), **7** was contaminated by some by-products. Since the purification of **7** was not successful in these cases, a mixture of the products was treated with hydrochloric acid in CH_3CN,[7] and the formation of **7** was proved by the isolation of the α-methylthio ketone (**8**) (Table 3). The NMR spectra of the by-products produced along with **7** suggested that not only α-lithiation but also lithiation of γ-position and the methylthio group proceeded in this case. In fact 2-hydroxyalkyl vinyl sulfide (**9**), which originated from the lithiation of methylthio group, was isolated in 14% yield in addition to α-adduct (**7c-1**) in the reaction of **1c** with cyclohexanone.

The alkylation of 1-(pheylthio)vinyllithium (**3**) was also examined. When **3f** was allowed to react with octyl iodide at −30 °C, the alkylated product (**10f-2**) was isolated only in 15% yield. On the other hand, **10f-2** was obtained in 67% yield by the reaction carried out at −78 °C. Furthermore, it was found that the yield of **10f-2** increased by the use of hexamethylphosphoric triamide (HMPA) as an additive. Accordingly, the reactions of **3** with various alkyl halides were performed in the presence of HMPA (Table 4).

When primary alkyl halides were employed, the corresponding 1-alkyl-1-alkenyl sulfides (**10**) were produced in good yields. On the other hand, the reactions with benzyl bromide or allyl bromide resulted in the formation of **10** only in moderate yields. The coupl-

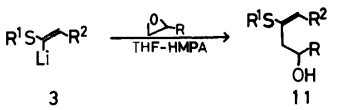
a) The reaction was carried out without HMPA.

ing reactions of halides appeared to reduce the yield of **10**. Finally, it should be pointed out that the reaction of **3** with *s*-alkyl halide, such as isopropyl iodide or *s*-butyl bromide, gave no alkylated product.

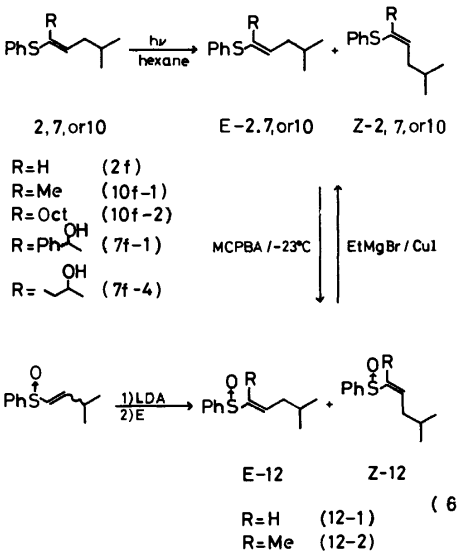
The reaction of **3** with oxiranes also took place smoothly and γ-alkylthio γ,δ-unsaturated alcohols (**11**) were obtained in good yields (Table 5). In this reaction, the addition of HMPA markedly increased the yield of **11** as well.



(5)

The first step of the present preparation of **3** may be the formation of alkenyl sulfide (**2**). In fact, the corresponding alkenyl sulfide (**2**) were isolated in high yields (**2e**; 90%, **2f**;95%, **2g**; 85%) when 2-methoxyalkyl sulfides (**1**) were treated with an equimolar amount of butyllithium in the presence of TMEDA. The NMR spectra of the isolated alkenyl sulfides (**2**) suggested that they were *E*-isomers. In order to check the stereochemical purity of the resultant **2g**, we synthesized the authentic (*Z*)-**2f** by the following procedures. The alkenyl sulfide (**2f**) prepared by the present reaction was photoisomerized by the irradiation with high pressure mercury lamp to yield a mixture of (*Z*)- and (*E*)-**2f**. Although the separation of stereoisomers of **2f** was unsuccessful, the corresponding sulfoxides (**12-1**) were separated by TLC. The oxidation of **2f** was carried out by the treatment with *m*-chloroperbenzoic acid (MCPBA) in CH_2Cl_2 at −23 °C. The stereochemically pure alkenyl sulfoxides ((*E*)- and (*Z*)-**12-1**) were reduced with ethylmagnesium bromide in the presence of CuI[8] to give the authentic (*E*)- and (*Z*)-**2f**. The examination of the ^1H NMR spectra of these alkenyl sulfides showed that **2f** of the *E*-configuration was produced stereoselectively by the reaction of **1f** with butyllithium. Further, it was confirmed that **12-1** prepared by the oxidation of **2f** without photolysis contained no *Z*-isomer by its NMR spectrum.

Since alkenyl anions generally exhibit very high degree of retention of configuration,[9] we expected that the present reactions gave the 1-substituted alkenyl sulfides (**7**, **10**, and **11**) stereoselectively. Actually, the obtained alkenyl sulfides seemed to be pure *E*-isomers on the basis of their NMR spectra. In order to determine the configuration of alkenyl sulfides, we prepared several authentic *E*-alkenyl sulfides ((*E*)-**7f-1**, (*E*)-**7f-4**, (*E*)-**10f-1**, and (*E*)-**10f-2**) from the alkenyl sulfoxide (**12-1**) by the method reported by Takei *et al.*[10] The NMR spectra of the authentic alkenyl sulfides were identical with those of the alkenyl sulfides obtained by the present reactions. Further, we concluded that the alkenyl sulfides (**7f-1**, **7f-4**, **10f-1**, and **10f-2**) contained no *Z*-isomer on the basis of the following experimental results. The alkenyl sulfides (**7f-1**, **7f-4**, **10f-1**, and **10f-2**) prepared by the reaction of **3f** with electrophiles were irradiated with high pressure mercury lamp to give the mixtures of two stereoisomers. The two isomers were separated each other by TLC with exception of **7f-4**. The structures of the stereoisomers produced by the photolysis were determined to be *Z*-alkenyl sulfides by the comparison of their IR and NMR spectra with those of the authentic *E*-isomers. It was confirmed that NMR signals characteristic to the *Z*-isomers were absent in the NMR spectra of the starting alkenyl sulfides. (*E*)- and (*Z*)-**10f-1** obtained by the above-mentioned procedure were oxidized with MCPBA to the corresponding sulfoxides (**12-2**). The NMR signal of vinyl proton of (*E*)-**12-2** appeared at δ=6.40 and that of (*Z*)-**12-2** appeared at δ=5.94. On the other hand, the NMR spectrum of the sulfoxide derived from **10f-1** without photolysis showed only one signal for the vinyl proton at δ=6.40.



(6)

In conclusion, it is demonstrated that various alkenyl sulfides with β-substituents were easily synthesized in good to high yields by the use of 1-(methylthio- and phenylthio)vinyllithium reagents (**3**) prepared by the treatment of 2-methoxyalkyl sulfides (**1**) with two molar butyllithium in the presence of TMEDA and the reactions of **3** with some electrophiles proceeded stereoselectively to give the *E*-isomers in all cases examined. The present method for the preparation of **3** would extend the applicability of α-lithiated alkenyl sulfides in organic synthesis.

Experimental

Measurements. The boiling points and melting point

were uncorrected. NMR spectra were recorded with JEOL JNM-C-60HL spectrometer. IR spectra were measured with a JASCO DS-403G spectrometer.

2-Methoxyalkyl Sulfide (1). Phenyl (or methyl) 2-methoxyalkyl sulfides (**1b, c, d, e, f,** and **g**) were synthesized by the methylation (MeI/NaH/THF) of the corresponding 2-hydroxyalkyl sulfides prepared from aldehydes by the methods reported by Corey and Seebach,[11] and Peterson.[12] The boiling points, spectral data, and overall yields from aldehydes were as follows: 2-Methoxy-4-phenylbutyl methyl sulfide (**1b**); 45%, 102—105 °C/1 Torr (1 Torr=133.322 Pa), IR (neat): 3040, 2920, 1603, 1496, 1455, 1100, 744, and 700 cm^{-1}. ^1H NMR (CCl_4): δ=1.59—2.11 (2H, m), 2.02 (3H, s), 2.38—2.80 (4H, m), 3.03—3.37 (1H, m), 3.27 (3H, s), and 7.08 (5H, s). 2-Methoxy-4-methylpentyl methyl sulfide (**1c**); 52%, 89—92 °C/30 Torr, IR (neat): 2960, 1467, 1368, and 1096 cm^{-1}. ^1H NMR (CCl_4): δ=0.92 (6H, d, J=6 Hz), 1.15—1.88 (3H, m), 2.10 (3H, s), 2.28—2.52 (2H, m), 2.98—3.34 (1H, m), and 3.31 (3H, s). 2-Methoxy-2-phenylethyl methyl sulfide (**1d**); 64%, 85—87 °C/2 Torr, IR (neat): 2900, 1602, 1495, 1455, 1105, 742, and 702 cm^{-1}. ^1H NMR (CCl_4): δ=1.98 (3H, s), 2.58 and 2.69 (2H, 2d, J=6 and 7 Hz), 3.18 (3H, s), 4.09 and 4.21 (1H, 2d, J=6 and 7 Hz), and 7.24 (5H, s). 2-Methoxy-4-phenylbutyl phenyl sulfide (**1e**); 84%, 150—152 °C/0.6 Torr, IR (neat): 3030, 2930, 1583, 1480, 1438, 1097, 1026, 737, and 695 cm^{-1}. ^1H NMR (CCl_4): δ=1.54—2.06 (2H, m), 2.38—3.33 (5H, m), 3.24 (3H, s) and 6.72—7.37 (10H, m). 2-Methoxy-4-methylpentyl phenyl sulfide (**1f**); 69%, 98 °C/0.7 Torr, IR (neat): 2960, 1586, 1481, 1438, 1027, 737, and 692 cm^{-1}. ^1H NMR (CCl_4): δ=0.89 (6H, d, J=6 Hz), 1.13—1.97 (3H, m), 2.67 and 2.94 (2H, 2d, J=8 and 5 Hz), 3.03—3.41 (1H, m), 3.23 (3H, s), and 6.86—7.41 (5H, m). 2-Methoxyheptyl phenyl sulfide (**1g**); 83%, 94 °C/0.2 Torr, IR (neat): 2940, 1586, 1481, 1439, 1097, 1026, 738, and 692 cm^{-1}. ^1H NMR (CCl_4): δ=0.60—1.73 (11H, m), 2.72—3.00 (2H, m), 3.12—3.36 (1H, m), 3.24 (3H, s), and 6.83—7.40 (5H, m). 2-Methoxyethyl methyl sulfide (**1a**) (70%, bp 129—131 °C, lit.[13], 132 °C) was prepared by the alkylation of 2-mercaptoethanol.

Preparation of 1-(Alkylthio)vinyllithium (3). 1-(Methylthio)vinyllithium (3a): To a THF (5 ml) solution of **1a** (212 mg, 2 mmol) and TMEDA (511 mg, 4.4 mmol) was added dropwise a hexane solution of butyllithium (4.4 mmol) at −30 °C. After stirring for 1 h, the resultant pale yellow solution of **3a** was used for the subsequent reactions.

1-Methylthio-2-phenylvinyllithium (3d). To a THF (0.5 ml) solution of LDA prepared from diisopropylamine (101 mg, 1 mmol) and butyllithium (1 mmol) was added a THF (1 ml) solution of **1d** (182 mg, 1 mmol) at −30 °C. After stirring for 40 min, HMPA (0.6 ml) and an additional THF (0.5 ml) solution of LDA (diisopropylamine; 121 mg, 1.2 mmol, butyllithium; 1.2 mmol) were successively added to the reaction mixture at −60 °C and stirring was continued for 2.5 h. The resultant dark green solution of **3d** was used in the subsequent steps.

4-Phenyl-1-phenylthio-1-butenyllithium (3e). To a THF (1 ml) solution of TMEDA (244 mg, 2.1 mmol) were added a hexane solution of butyllithium (2.1 mmol) and a THF (1 ml) solution of 2-methoxy-4-phenylbutyl phenyl sulfide (**1e**) (272 mg, 1 mmol) successively at −30 °C. After stirring for 2 h, the reddish purple solution of **3e** was obtained. By a similar procedure, the THF solutions of other vinyllithiums (**3b** and **c**; 0 °C, 30 min, **3f** and **g**; −23 °C, 3 h) were prepared.

The Reaction of 1-(Methylthio)vinyllithium (3a) with Benzaldehyde. To a THF solution of **3a** prepared from **1a** (212 mg, 2 mmol) by the above-mentioned procedure was added a THF (2 ml) solution of benzaldehyde (233 mg, 2.2 mmol) at −30 °C and the reaction mixture was allowed to warm up to r.t. The reaction was quenched by the addition of a phosphate buffer solution (pH 7). The organic material was extracted with AcOEt and dried over Na_2SO_4. The extract was condensed under reduced pressure. The residue was chromatographed on silica gel (AcOEt–hexane) and 2-methylthio-1-phenyl-2-propen-1-ol (**7a-1**) was isolated (289 mg) in 80% yield. **7a-1**; a viscous oil. IR (neat): 3420, 1602, 1494, 1040, 861, 755, and 702 cm^{-1}. ^1H NMR (CCl_4): δ=2.12 (3H, s), 2.54 (1H, br s), 4.70 (1H, s), 5.08 (1H, s), 5.31 (1H, s), and 7.21 (5H, s). Found: C, 66.50; H, 6.70; S, 17.61%. Calcd for $C_{10}H_{12}OS$: C, 66.62; H, 6.71; S, 17.79%.

In a similar manner, the following β-alkylthio β,γ-unsaturated alcohols (**7**) and 2-hydroxyalkyl vinyl sulfide (**9**) were obtained. 2-Methylthio-5-phenyl-1-penten-3-ol (**7a-2**); a viscous oil. IR (neat): 3420, 1604, 1497, 1047, 861, 754, and 704 cm^{-1}. ^1H NMR (CCl_4): δ=1.63—2.10 (3H, m), 2.17 (3H, s), 2.44—2.89 (2H, m), 3.84—4.26 (1H, m), 4.56 (1H, s), 5.20 (1H, s), and 7.08 (5H, s). Found: C, 69.23; H, 7.77; S, 15.19%. Calcd for $C_{12}H_{16}OS$: C, 69.19; H, 7.74; S, 15.39%. 2-Methylthio-5-phenyl-1,4-pentadien-3-ol (**7a-3**); a viscous oil. IR (neat): 3410, 1601, 1497, 1030, 967, 863, 757, and 698 cm^{-1}. ^1H NMR (CCl_4): 2.18 (3H, s), 2.18—2.40 (1H, br s), 4.47 (1H, s), 4.47—4.83 (1H, br s), 5.31 (1H, s), 6.06 (1H, dd, J=16 and 6 Hz), 6.57 (1H, d, J=16 Hz), and 6.97—7.42 (10H, m). Found: C, 69.64; H, 6.84; S, 15.29%. Calcd for $C_{12}H_{14}OS$: C, 69.86; H, 6.84; S, 15.54%. 2-Methylthio-1-penten-3-ol (**7a-4**); a viscous oil. IR (neat): 3420, 1602, 1100, 983, and 859 cm^{-1}. ^1H NMR (CCl_4): δ=0.70—1.11 (3H, m), 1.36—1.80 (2H, m), 2.02—2.15 (1H, m), 2.20 (3H, s), 3.98 (1H, t, J=6 Hz), 4.67 (1H, s), and 5.20 (1H, s). Found: C, 54.39; H, 9.17; S, 24.11%. Calcd for $C_6H_{12}OS$: C, 54.51; H, 9.14; S, 24.25%. 5-Methyl-2-methylthio-1-hexen-3-ol (**7a-5**); a viscous oil. IR (neat): 3400, 2960, 1600, 1063, and 855 cm^{-1}. ^1H NMR (CCl_4): δ=0.94 (6H, d, J=6 Hz), 1.27—1.93 (3H, m), 1.93—2.15 (1H, m), 2.19 (3H, s), 4.11 (1H, t, J=6 Hz), 4.53 (1H, s), and 5.21 (1H, s). Found: C, 59.57; H, 10.09; S, 19.64%. Calcd for $C_8H_{16}OS$: C, 59.96; H, 10.06; S, 20.00%. 3-Methylthio-1-phenyl-3-buten-2-ol (**7a-6**); a viscous oil. IR (neat): 3450, 1597, 1496, 1070, 864, 718, and 701 cm^{-1}. ^1H NMR (CCl_4): δ=1.69 (3H, s), 2.13 (3H, s), 2.31 (1H, s), 4.78 (1H, s), 5.39 (1H, s), and 7.01—7.54 (5H, m). Found: C, 67.90; H, 7.30; S, 16.26%. Calcd for $C_{11}H_{14}OS$: C, 68.00; H, 7.26; S, 16.50%. 1-(4-Methyl-1-methylthio-2-pentenyl)-1-cyclohexanol (**7c-1**); a viscous oil. IR (neat): 3460, 2940, 1605, 1447, 1060, 982, and 913 cm^{-1}. ^1H NMR (CCl_4): δ=0.94 (6H, d, J=6 Hz), 1.14—2.14 (12H, m), 2.15 (3H, s), 2.14—2.60 (2H, m), and 5.18 (1H, t, J=7 Hz). Found: C, 67.97; H, 10.51; S, 13.66%. Calcd for $C_{13}H_{24}OS$: C, 68.37; H, 10.59; S, 14.04%. 1-[(4-Methyl-1-pentenylthio)methyl]-1-cyclohexanol (**9**); a viscous oil. IR (neat): 3450, 2940, 1613, 1448, 1056, 978, and 948 cm^{-1}. ^1H NMR (CCl_4): δ=0.88 (6H, d, J=6 Hz), 1.10—2.26 (14H, m), 2.68 (2H, s), 5.58 (1H, dt, J=15 and 6 Hz), and 5.93 (1H, d, J=15 Hz). Found: C, 68.40; H, 10.70; S, 13.95%. Calcd for $C_{13}H_{24}OS$: C, 68.37; H, 10.59; S, 14.04%. 2-Methylthio-1,3-diphenyl-2-propen-1-ol (**7d-1**); mp 63—64 °C (hexane-benzene). IR (neat): 3400, 1599, 1494, 1030, 753, and 698 cm^{-1}. ^1H NMR (CCl_4): δ=2.10 (3H, s), 2.85—3.27 (1H, br s), 5.65—5.95 (1H, br s), 6.32 (1H, s), and 6.88—7.42 (10H, m). Found: C, 74.81; H, 6.29; S, 12.50%. Calcd for $C_{16}H_{16}OS$: C, 74.96; H, 6.29; S, 12.51%. 2-Methylthio-1,5-diphenyl-1-penten-3-ol (**7d-2**); a viscous oil. IR (neat): 3400, 1602, 1497, 1053, 787, 756, and 699 cm^{-1}. ^1H NMR (CCl_4): δ=1.61—2.14 (2H, m), 2.18 (3H, s), 2.31—2.82 (3H, m), 4.51—4.84 (1H, m), 6.05 (1H, s), and 7.07 (10H, s). Found: C, 76.19; H, 7.11; S, 10.51%. Calcd for $C_{18}H_{20}OS$: C, 76.01; H, 7.09; S, 11.27%. 2-Methylthio-1,5-diphenyl-1,4-pentadien-3-ol (**7d-3**); a viscous oil. IR (neat): 3400, 1599, 1495, 1068, 964, 784, 750, and 694 cm^{-1}. ^1H NMR (CCl_4): δ=1.94—2.17 (1H, br s), 2.32 (3H, s), 5.21—5.47 (1H, br s), 6.30 (1H, s), 6.13 (1H, dd, J=16 and 4 Hz), 6.61 (1H, d, J=16 Hz), and 6.77—7.46 (10H, m). Found: C, 75.97; H, 6.51;

S, 11.02%. Calcd for $C_{18}H_{18}OS$: C, 76.56; H, 6.42; S, 11.35%. 2-Methylthio-1-phenyl-1-penten-3-ol (**7d-4**); a viscous oil. IR (neat): 3390, 2950, 1598, 1493, 1028, 753, and 697 cm^{-1}. ^1H NMR (CCl_4): δ=0.85 (3H, t, J=7 Hz), 1.38—1.90 (2H, m), 2.25 (3H, s), 4.17—4.73 (1H, m), 6.10 (1H, s), and 7.13 (5H, s). Found: C, 69.08; H, 7.82; S, 14.90%. Calcd for $C_{12}H_{16}OS$: C, 69.19; H, 7.74; S, 15.39%. 5-Methyl-2-methylthio-1-phenyl-1-hexen-3-ol (**7d-5**); a viscous oil. IR (neat): 3380, 2950, 1600, 1029, 755, and 694 cm^{-1}. ^1H NMR (CCl_4): δ=0.59—1.03 (6H, m), 1.13—1.84 (3H, m), 1.97—2.22 (1H, br s), 2.25 (3H, s), 4.52—4.90 (1H, m), 6.09 (1H, s), and 7.16 (5H, s). Found: C, 71.15; H, 8.58; S, 13.15%. Calcd for $C_{14}H_{20}OS$: C, 71.14; H, 8.53; S, 13.56%. 1,5-Diphenyl-2-phenylthio-2-penten-1-ol (**7e-1**); a viscous oil. IR (neat): 3430, 3020, 1601, 1582, 1496, 1479, 1025, 743, and 698 cm^{-1}. ^1H NMR (CCl_4): δ=2.19—2.97 (4H, m), 2.78 (1H, s), 5.52 (1H, s), 5.76 (1H, t, J=7 Hz), and 6.59—7.70 (15H, m). Found: C, 79.70; H, 6.33; S, 9.22%. Calcd for $C_{23}H_{22}OS$: C, 79.73; H, 6.40; S, 9.25%. 7-Phenyl-4-phenylthio-4-hepten-3-ol (**7e-2**); a viscous oil. IR (neat): 3420, 1602, 1582, 1496, 1478, 1086, 1024, 743, and 697 cm^{-1}. ^1H NMR (CCl_4): δ=0.84 (3H, t, J=7 Hz), 1.20—1.78 (3H, m), 2.26—2.83 (4H, m), 4.02—4.45 (1H, m), 5.74 (1H, t, J=7 Hz), and 6.97—7.38 (10H, m). Found: C, 76.38; H, 7.49; S, 10.52%. Calcd for $C_{19}H_{22}OS$: C, 76.47; H, 7.43; S, 10.74%. 2-Methyl-8-phenyl-5-phenylthio-5-octen-4-ol (**7e-3**); a viscous oil. IR (neat): 3420, 2960, 1603, 1583, 1497, 1480, 1068, 1026, 744, and 698 cm^{-1}. ^1H NMR (CCl_4): δ=0.84 and 0.88 (6H, 2d, J=6 and 7 Hz), 1.03—1.92 (4H, m), 2.33—2.86 (4H, m), 4.39 (1H, dd, J=8 and 5 Hz), 5.60 (1H, t, J=8 Hz), and 6.80—7.33 (10H, m). Found: C, 76.91; H, 8.15; S, 9.45%. Calcd for $C_{21}H_{26}OS$: C, 77.25; H, 8.03; S, 9.82%. 2,6-Diphenyl-3-phenylthio-3-hexen-2-ol (**7e-4**); a viscous oil. IR (neat): 3450, 1597, 1580, 1495, 1477, 1024, 743, and 696 cm^{-1}. ^1H NMR (CCl_4): δ=1.64 (3H, s), 2.08 (1H, s), 2.15—2.38 (4H, m), 5.64 (1H, t, J=7 Hz), and 6.58—7.48 (15H, m). Found: C, 79.94; H, 6.71; S, 8.77%. Calcd for $C_{24}H_{24}OS$: C, 79.96; H, 6.71; S, 8.89%. 5-Methyl-1-phenyl-2-phenylthio-2-hexen-1-ol (**7f-1**); a viscous oil. IR (neat): 3420, 2950, 1581, 1479, 1025, 740, and 697 cm^{-1}. ^1H NMR (CCl_4): δ=0.91 (6H, d, J=7 Hz), 1.17—1.92 (1H, m), 2.16 (2H, t, J=8 Hz), 2.59 (1H, d, J=7 Hz), 5.54 (1H, d, J=7 Hz), 5.79 (1H, t, J=8 Hz), and 6.70—7.37 (10H, m). Found: C, 76.60; H, 7.51; S, 10.51%. Calcd for $C_{19}H_{22}OS$: C, 76.47; H, 7.43; S, 10.74%. 7-Methyl-1-phenyl-4-phenylthio-4-octen-3-ol (**7f-2**); a viscous oil. IR (neat): 3420, 2950, 1601, 1581, 1497, 1478, 1024, 744, and 697 cm^{-1}. ^1H NMR (CCl_4): δ=0.85 (6H, d, J=7 Hz), 1.11—2.12 (6H, m), 2.60 (2H, t, J=7 Hz), 4.14—4.56 (1H, m), 5.69 (1H, t, J=8 Hz), and 6.77—7.38 (10H, m). Found: C, 77.01; H, 8.10; S, 9.52%. Calcd for $C_{21}H_{26}OS$: C, 77.25; H, 8.03; S, 9.82%. 7-Methyl-1-phenyl-4-phenylthio-1,4-octadien-3-ol (**7f-3**); a viscous oil. IR (neat): 3400, 2950, 1580, 1478, 1024, 966, 750, and 692 cm^{-1}. ^1H NMR (CCl_4): δ=0.95 (6H, d, J=6 Hz), 1.20—1.92 (1H, m), 2.19 (2H, t, J=7 Hz), 4.93—5.27 (1H, m), 5.88 (1H, t, J=7 Hz), 5.97 (1H, dd, J=16 and 5 Hz), 6.48 (1H, d, J=16 Hz), and 6.96—7.43 (10H, m). Found: C, 77.49; H, 7.47; S, 9.58%. Calcd for $C_{21}H_{24}OS$: C, 77.73; H, 7.46; S, 9.88%. 7-Methyl-4-phenylthio-4-octen-3-ol (**7f-4**); a viscous oil. IR (neat): 3420, 2960, 1582, 1480, 1024, 739, and 690 cm^{-1}. ^1H NMR (CCl_4): δ=0.68—1.11 (3H, m), 0.91 (6H, d, J=7 Hz), 1.11—2.30 (6H, m), 4.18—4.66 (1H, m), 5.81 (1H, t, J=8 Hz), and 6.98—7.57 (5H, m). Found: C, 71.45; H, 8.77; S, 12.42%. Calcd for $C_{15}H_{22}OS$: C, 71.96; H, 8.85; S, 12.80%. 2,8-Dimethyl-5-phenylthio-5-nonen-4-ol (**7f-5**); a viscous oil. IR (neat): 3420, 2950, 1579, 1477, 1022, 736, and 687 cm^{-1}. ^1H NMR (CCl_4): δ=0.93 (12H, d, J=7 Hz), 1.16—2.25 (7H, m), 4.28—4.62 (1H, m), 5.69 (1H, t, J=8 Hz), and 6.89—7.41 (5H, m). Found: C, 73.38; H, 9.48; S, 11.14%. Calcd for $C_{17}H_{26}OS$: C, 73.33; H, 9.41; S, 11.51%. 1-(4-Methyl-1-phenylthio-1-pentenyl)-1-cyclohexanol (**7f-6**); a viscous oil. IR (neat): 3480, 2940, 2870, 1582, 1479, 1024, 738, and 690 cm^{-1}. ^1H NMR (CCl_4): δ=0.93 (6H, d, J=7 Hz), 1.06—2.03 (12H, m), 2.39 (2H, t, J=7 Hz), 5.81 (1H, t, J=7 Hz), and 7.00—7.50 (5H, m). Found: 74.23; H, 8.98; S, 10.84%. Calcd for $C_{18}H_{26}OS$: C, 74.43; H, 9.02; S, 11.04%. 6-Methyl-2-phenyl-3-phenylthio-3-hepten-2-ol (**7f-7**); a viscous oil. IR (neat): 3450, 1598, 1580, 1495, 1478, 1066, 1024, 743, and 694 cm^{-1}. ^1H NMR (CCl_4): δ=0.65 and 0.70 (6H, 2d, J=7 Hz), 1.10—2.00 (3H, m), 1.70 (3H, s), 2.31 (1H, s), 5.70 (1H, t, J=8 Hz), and 6.84—7.51 (10H, m). Found: C, 76.86; H, 7.83; S, 10.09%. Calcd for $C_{20}H_{24}OS$: C, 76.88; H, 7.74; S, 10.26%. 1-Phenyl-2-phenylthio-2-octen-1-ol (**7g-1**); a viscous oil. IR (neat): 3400, 3020, 2880, 1575, 1470, 1430, 1015, 725, and 685 cm^{-1}. ^1H NMR (CCl_4): δ=0.55—1.61 (9H, m), 1.96—2.50 (2H, m), 2.93 (1H, s), 5.61 (1H, s), 5.84 (1H, t, J=7 Hz), and 6.88—7.49 (10H, m). Found: C, 76.91; H, 7.84; S, 9.96%. Calcd for $C_{20}H_{24}OS$: C, 76.88; H, 7.74; S, 10.26%. 1-(1-Phenylthio-1-heptenyl)-1-cyclohexanol (**7g-2**); a viscous oil. IR (neat): 3490, 2930, 1584, 1482, 1432, 1028, 742, and 693 cm^{-1}. ^1H NMR (CCl_4): δ=0.70—2.03 (20H, m), 2.25—2.73 (2H, m), 5.84 (1H, t, J=7 Hz), and 7.00—7.48 (5H, m). Found: C, 74.95; H, 9.42; S, 10.44%. Calcd for $C_{19}H_{28}OS$: C, 74.95; H, 9.27; S, 10.53%. 2-Phenyl-3-phenylthio-3-nonen-2-ol (**7g-3**); a viscous oil. IR (neat): 3460, 2920, 1598, 1580, 1493, 1478, 1439, 1024, 739, and 699 cm^{-1}. ^1H NMR (CCl_4): δ=0.53—1.40 (9H, m), 1.68 (3H, s), 1.60—2.30 (2H, m), 2,56 (1H, s). 5.80 (1H, t, J=7 Hz) and 7.03—7.67 (10H, m). Found: C, 77.47; H, 8.13; S, 9.58%. Calcd for $C_{21}H_{26}OS$: C, 77.25; H, 8.03; S, 9.82%. The following α-methylthio ketones were obtained by the reaction of **3b** and **3c** with aldehydes followded by the isomerization by hydrochloric acid. 2-Methylthio-1,5-diphenyl-1-pentanone (**8b-1**); a viscous oil. IR (neat): 3020, 2920, 1673, 1498, 1449, 742, and 699 cm^{-}. ^1H NMR (CCl_4): δ=1.41—2.06 (4H, m), 1.81 (3H, s), 2.41—2.78 (2H, m), 3.94 (1H, t, J=7 Hz), 7.09 (5H, s), 7.17—7.48 (3H, m), and 7.67—8.02 (2H, m). Found: C, 76.04; H, 7.18; S, 11.18%. Calcd for $C_{18}H_{20}OS$: C, 76.01; H, 7.09; S, 11.27%. 4-Methylthio-1,7-diphenyl-3-heptanone (**8b-2**); a viscous oil. IR (neat): 3020, 2920, 1700, 1453, 746, and 697 cm^{-1}. ^1H NMR (CCl_4): δ=1.30—1.87 (4H, m), 1.70 (3H, s), 2.27—3.12 (7H, m), and 7.12 (10H, s). Found: C, 76.49; H, 7.70; S, 10.07%. Calcd for $C_{20}H_{24}OS$: C, 76.88; H, 7.74; S, 10.26%. 4-Methylthio-7-phenyl-3-heptanone (**8b-3**); a viscous oil. IR (neat): 3020, 2940, 1703, 1453, 747, and 698 cm^{-1}. ^1H NMR (CCl_4): δ=1.04 (3H, t, J=8 Hz), 1.35—1.88 (4H, m), 1.82 (3H, s), 2.10—2.79 (4H, m), and 7.11 (5H, s). Found: C, 71.32; H, 8.61; S, 13.14%. Calcd for $C_{14}H_{20}OS$: C, 71.14; H, 8.53; S, 13.56%. 5-Methyl-2-methylthio-1-phenyl-1-hexanone (**8c-1**); a viscous oil. IR (neat): 3020, 2940, 1672, 1448, 739, and 695 cm^{-1}. ^1H NMR (CCl_4): δ=0.92 (6H, d, J=6 Hz), 1.03—2.13 (5H, m), 1.85 (3H, s), 3.92 (1H, t, J=7 Hz), 7.08—7.51 (3H, m), and 7.73—8.02 (2H, m). Found: C, 71.20; H, 8.55; S, 13.38%. Calcd for $C_{14}H_{20}OS$: C, 71.14; H, 8.53; S, 13.56%.

Reaction of 4-Phenyl-1-phenylthio-1-butenyllithium (3e) with Octyl Iodide. To a THF solution of **3e** prepared from **1e** (272 mg, 1 mmol) was added an HMPA (0.6 ml) solution of octyl iodide (360 mg, 1.5 mmol) at −78 °C. After stirring for 30 min at −78 °C, the reaction mixture was warmed up to r.t. The reaction was quenched by the addition of aqueous NH_4Cl. The usual work up gave 1-phenyl-4-phenylthio-3-dodecene (**10e-2**) (439 mg, 64%). **10e-2**; an oil. IR (neat): 2930, 1602, 1598, 1583, 1480, 1455, 1440, 1027, 742, and 699 cm^{-1}. ^1H NMR (CCl_4): δ=0.60—1.67 (15H, m), 1.82—2.90 (6H, m), 5.77 (1H, t, J=7 Hz), and 7.17 (10H, s). Found: C, 81.55; H, 9.25; S, 8.90%. Calcd for $C_{24}H_{32}S$: C, 81.76; H, 9.15; S, 9.09%. In a similar manner, the following alkenyl sulfides (**10**) were obtained. 2-Methylthio-1-decene (**10a-1**); an oil. IR (neat): 2920, 1710, 1598, and 840 cm^{-1}. ^1H NMR (CCl_4): δ=0.62—1.88 (15H, m),

1.92—2.40 (2H, m), 2.16 (3H, s), 4.50 (1H, s), and 4.94 (1H, s). Found: C, 70.92; H, 11.87; S, 16.80%. Calcd for $C_{11}H_{22}S$: C, 70.90; H, 11.90; S, 17.20%. 5-Phenyl-2-phenylthio-2-pentene (**10e-1**)[10]; an oil. IR (neat): 2920, 1601, 1582, 1496, 1478, 1453, 1439, 1026, 745, and 697 cm^{-1}. ^{1}H NMR (CCl_4): δ=1.72 (3H, s), 2.08—2.85 (4H, m), 5.81 (1H, t, J=6 Hz), and 7.15 (10H, s). Found: C, 80.41; H, 7.26; S, 12.27%. Calcd for $C_{17}H_{18}S$: C, 80.27; H, 7.13; S, 12.60%. 1,5-Diphenyl-2-phenylthio-2-pentene (**10e-3**); an oil. IR (neat): 3020, 2920, 1600, 1582, 1497, 1476, 1453, 1438, 1024, 742, and 698 cm^{-1}. ^{1}H NMR (CCl_4): δ=2.22—2.86 (4H, m), 3.36 (2H, s), 5.85 (1H, t, J=7 Hz), and 6.74—7.41 (15H, m). Found: C, 83.52; H, 6.80; S, 9.51%. Calcd for $C_{23}H_{22}S$: C, 83.59; H, 6.71; S, 9.70%. 5-Methyl-2-phenylthio-2-hexene (**10f-1**); an oil. IR (neat): 2950, 1581, 1476, 1437, 1023, 737, and 688 cm^{-1}. ^{1}H NMR (CCl_4): δ=0.95 (6H, d, J=6 Hz), 1.07—2.43 (3H, m), 1.88 (3H, br s), 5.79 (1H, br t, J=7 Hz), and 7.21 (5H, s). Found: C, 75.81; H, 8.96; S, 15.36%. Calcd for $C_{13}H_{18}S$: C, 75.67; H, 8.79; S, 15.54%. 2-Methyl-5-phenylthio-4-tridecene (**10f-2**); an oil. IR (neat): 2920, 1582, 1479, 1467, 1439, 1025, 737, and 690 cm^{-1}. ^{1}H NMR (CCl_4): δ=0.65—2.44 (20H, m), 0.93 (6H, d, J=6 Hz), 5.79 (1H, t, J=7 Hz), and 7.26 (5H, s). Found: C, 78.81; H, 10.65; S, 10.34%. Calcd for $C_{20}H_{32}S$: C, 78.88; H, 10.59; S, 10.53%. 5-Methyl-1-phenyl-2-phenylthio-2-hexene (**10f-3**); an oil. IR (neat): 2950, 1598, 1581, 1495, 1475, 1452, 1438, 1024, 740, and 695 cm^{-1}. ^{1}H NMR (CCl_4): δ=0.93 (6H, d, J=6 Hz), 1.43—2.28 (3H, m), 3.47 (2H, s), 5.88 (1H, t, J=7 Hz), and 6.81—7.38 (10H, m). Found: C, 80.94; H, 7.98; S, 11.19%. Calcd for $C_{19}H_{22}S$: C, 80.80; H, 7.85; S, 11.35%. 7-Methyl-4-phenylthio-1,4-octadiene (**10f-4**); an oil. IR (neat): 2900, 1647, 1593, 1490, 1037, 922, 752, and 702 cm^{-1}. ^{1}H NMR (CCl_4): δ=0.92 (6H, d, J=6 Hz), 1.43—2.25 (3H, m), 2.93 (2H, d, J=6 Hz), 4.76—5.22 (2H, m), 6.13—5.45 (2H, m), and 7.05—7.47 (5H, m). Found: C, 77.50; H, 8.80; S, 13.67%. Calcd for $C_{15}H_{20}S$: C, 77.52; H, 8.68; S, 13.80%. 4-Methyl-1-phenylthio-1-trimethylsilyl-1-pentene (**10f-5**); an oil. IR (neat): 2960, 1582, 1477, 1440, 1249, 841, 740, and 692 cm^{-1}. ^{1}H NMR (CCl_4): δ=0.11 (9H, s), 0.93 (6H, d, J=6 Hz), 1.35—1.89 (1H, m), 2.16 (2H, t, J=7 Hz), 6.42 (1H, t, J=7 Hz), and 6.93—7.42 (5H, m). Found: C, 68.46: H, 9.21; S, 12.32%. Calcd for $C_{15}H_{24}SSi$: C, 68.11; H, 9.15; S, 12.12%. 2-Phenylthio-2-octene (**10g-1**); an oil. IR (neat): 2960, 1593, 1487, 1449, 1035, 750, and 701 cm^{-1}. ^{1}H NMR (CCl_4): δ=0.60—1.72 (9H, m), 1.82—2.01 (3H, m), 2.01—2.60 (2H, m), 5.63—6.02 (1H, m), and 7.01—7.62 (5H, m). Found: C, 76.25; H, 9.25; S, 14.34%. Calcd for $C_{14}H_{20}S$: C, 76.30; H, 9.15; S, 14.55%. 3-Phenylthio-3-nonene (**10g-2**); an oil. IR (neat): 2980, 1593, 1489, 1474, 1449, 1036, 748, and 701 cm^{-1}. ^{1}H NMR (CCl_4): δ=0.67—1.70 (9H, m), 1.04 (3H, t, J=7 Hz), 1.88—2.45 (4H, m), 5.81 (1H, t, J=7 Hz), and 6.92—7.53 (5H, m). Found: C, 76.83; H, 9.65; S, 13.39%. Calcd for $C_{15}H_{22}S$: C, 76.86; H, 9.46; S, 13.68%. 7-Phenylthio-6-pentadecene (**10g-3**); an oil. IR (neat): 2930, 1583, 1480, 1468, 1441, 1027, 762, 740, and 692 cm^{-1}. ^{1}H NMR (CCl_4): δ=0.50—1.75 (24H, m), 1.85—2.48 (4H, m), 5.78 (1H, t, J=7 Hz), and 6.95—7.42 (5H, m). Found: C, 79.33; H, 10.81; S, 10.06%. Calcd for $C_{21}H_{34}S$: C, 79.18; H, 10.76; S, 10.06%. 1-Phenyl-2-phenylthio-2-octene (**10g-4**); an oil. IR (neat): 3030, 2930, 1600, 1582, 1498, 1476, 1453, 1440, 1026, 742, and 695 cm^{-1}. ^{1}H NMR (CCl_4): δ=0.68—1.64 (9H, m), 1.96—2.48 (2H, m), 3.52 (2H, s), 5.93 (1H, t, J=7 Hz), and 7.16 and 7.25 (10H, 2s). Found: C, 81.07; H, 8.20; S, 10.76%. Calcd for $C_{20}H_{24}S$: C, 81.03; H, 8.16; S, 10.81%.

*The Reaction of 1-Phenylthio-1-heptenyllithium (**3g**) with 1,2-Epoxybutane.* To a THF solution of **3g** prepared from **1g** (477 mg, 2 mmol) was added an HMPA (0.6 ml) solution of 1,2-epoxybutane (216 mg, 3 mmol) at −78 °C. After stirring for 30 min, the reaction mixture was warmed up to r.t. The reaction was quenched by the addition of a phosphate buffer solution (pH 7). The usual work up gave 5-phenylthio-5-undecen-3-ol (**11g-2**) (301 mg, 54%). **11g-2**; a viscous oil. IR (neat): 3420, 3070, 2930, 1584, 1477, 1440, 1105, 744, and 692 cm^{-1}. ^{1}H NMR (CCl_4): δ=0.62—1.70 (14H, m), 1.90—2.43 (5H. m), 3.53—3.90 (1H, m), 5.96 (1H, t, J=7 Hz), and 6.94—7.45 (5H, m). Found: C, 73.02; H, 9.43; S, 11.36%. Calcd for $C_{17}H_{26}OS$: C, 73.33; H, 9.41; S, 11.51%. In a similar manner, the following γ-phenylthio γ,δ-unsaturated alcohols (**11**) were obtained. 3-Methylthio-1-phenyl-3-buten-1-ol (**11a-1**); a viscous oil. IR (neat): 3400, 1600, 1582, 1053, 854, 757, and 700 cm^{-1}. ^{1}H NMR (CCl_4): δ=2.16 (3H, s), 252 (2, d, J=6 Hz), 2.64—2.87 (1H, br s), 4.53 (1H, s), 4.80 (1H, t, J=6 Hz), 5.01 (1H, s), and 7.28 (5H, s). Found: C, 68.10; H, 7.20; S, 16.49%. Calcd for $C_{11}H_{14}OS$: C, 68.00; H, 7.26; S, 16.50%. 6-Methyl-1-phenyl-3-phenylthio-3-hepten-1-ol (**11f-1**); a viscous oil. IR (neat): 3400, 1600, 1582, 1053, 854, 757, and 700 cm^{-1}. ^{1}H NMR (CCl_4): δ=0.80 and 0.85 (6H, 2d, J=6 Hz), 1.24—2.09 (4H, m), 2.43 and 2.53 (2H, 2d, J=5 and 7 Hz), 4.90 (1H, dd, J=5 and 7 Hz), 5.94 (1H, t, J=7 Hz), and 6.93—7.45 (10H, m). Found: C, 76.86; H, 7.79; S, 10.14%. Calcd for $C_{20}H_{24}OS$: C, 76.88; H, 7.74; S, 10.26%. 8-Methyl-5-phenylthio-5-nonen-3-ol (**11f-2**); a viscous oil. IR (neat): 3390, 2950, 1584, 1480, 1072, 1028, 743, and 696 cm^{-1}. ^{1}H NMR (CCl_4): δ=0.60—1.08 (3H, m), 0.93 (6H, d, J=6 Hz), 1.13—1.77 (3H, m), 1.86—2.63 (5H, m), 3.48—3.97 (1H, m), 5.96 (1H, t, J=7 Hz), and 7.29 (5H, s). Found: C, 72.46; H, 9.12; S, 12.15%. Calcd for $C_{16}H_{24}OS$: C, 72.68; H, 9.15; S, 12.12%. 1-Phenyl-3-phenylthio-3-nonen-1-ol (**11g-1**); a viscous oil. IR (neat): 3410, 3050, 3020, 2920, 1582, 1478, 1050, 1024, 742, and 699 cm^{-1}. ^{1}H NMR (CCl_4): δ=0.66—1.53 (9H, m), 1.60—2.34 (3H, m), 2.46 and 2.56 (2H, 2d, J=5 and 8 Hz), 4.94 (1H, dd, J=5 and 8 Hz), 5.97 (1H, t, J=8Hz), and 7.23 and 7.28 (10H, 2s). Found: C, 76.64; H, 8.02; S, 9.68%. Calcd for $C_{21}H_{26}OS$: C, 77.25; H, 8.03; S, 9.80%.

*Preparation of (E)-4-Methyl-1-phenylthio-1-pentene (**2f**) and (Z)-**2f**.* A hexane (4 ml) solution of **2f** (364 mg, 1.9 mmol) prepared by the reaction of **1f** with an equimolar amount of butyllithium was irradiated by high pressure mercury lamp (400 W) for 40 min. After evaporation of the solvent, the residue was dissolved in CH_2Cl_2 (6 ml) and was added to a CH_2Cl_2 (6 ml) solution of MCPBA (327 mg, 1.9 mmol) at −23 °C. The reaction mixture was stirred for 1 h. Then, the reaction was quenched by the addition of 5% aqueous $NaHCO_3$ and the crude sulfoxides were extracted with CH_2Cl_2. The extract was dried over Na_2SO_4 and condensed under reduced pressure. The residue was chromatographed on silica gel (AcOEt-hexane) and (*E*)-4-methyl-1-phenylsulfinyl-1-pentene (**12-1**) (136 mg, 34%) and (*Z*)-**12-1** (96 mg, 24%) were obtained. The reduction of the sulfoxides were carried out by the method reported by Posner and Tang.[8] To a suspension of CuI (37 mg, 0.19 mmol) in ether (0.7 ml) was added an ethereal solution of ethylmagnesium bromide (1.9 mmol) at 0 °C. After stirring for 1 h, (*E*)-**12-1** (135 mg, 0.65 mmol) in ether (0.7 ml) was added to the solution and the reaction mixture was stirred for 1 h. The reaction was quenched by the addition of aqueous NH_4Cl and the organic substance was extracted with ether. The extract was dried over Na_2SO_4 and condensed under reduced pressure. The crude sulfide was purified by TLC (hexane) and (*E*)-**2f** (61 mg) was isolated in 49% yield. In a similar manner, (*Z*)-**2f** was also obtained by the reduction of (*Z*)-**12-1** in 33% yield. (*E*)-**12-1**; a viscous oil. IR (neat): 2950, 1623, 1580, 1466, 1444, 1086, 1047, 968, 746, and 690 cm^{-1}. ^{1}H NMR (CCl_4): δ=0.90 (6H, d, J=6 Hz), 1.43—2.28 (3H, m), 6.18 (1H, d, J=15 Hz), 6.57 (1H, dt, J=15 and 7 Hz), and 7.37—7.82 (5H, m). (*Z*)-**12-1**; a viscous oil. IR (neat): 2950, 1614, 1580, 1465, 1443, 1083,

1040, 745, 715, and 690 cm^{-1}. ^1H NMR (CCl_4): δ=1.00 (6H, d, J=6 Hz), 1.47—2.07 (1H, m), 2.36—2.68 (2H, m), 5.86—6.42 (2H, m), and 7.35—7.73 (5H, m). (*E*)-**2f**; an oil. IR (neat): 2950, 1582, 1480, 1440, 1080, 1025, 953, 738, and 689 cm^{-1}. ^1H NMR (CCl_4): δ=0.93 (6H, d, J=6 Hz), 1.07—1.93 (1H, m), 1.93—2.20 (2H, m), 5.83 (1H, dt, J=14 and 6 Hz), 6.15 (1H, d, J=14 Hz), and 7.21 (5H, s). (*Z*)-**2f**; an oil. IR (neat): 2940, 1584, 1479, 1438, 1080, 1023, 762, 733, and 685 cm^{-1}. ^1H NMR (CCl_4): δ=0.97 (6H, d, J=6 Hz), 1.37—2.02 (1H, m), 2.16 (2H, t, J=7 Hz), 5.77 (1H, dt, J=10 and 7 Hz), 6.20 (1H, d, J=10 Hz), and 7.23 (5H, s).

*Photoisomerization of 5-Methyl-2-phenylthio-2-hexene (**10f-1**).* A hexane (2.8 ml) solution of **10f-1** (305 mg, 1.47 mmol) was irradiated with high pressure mercury lamp (400 W) for 2 h. After evaporation of the solvent, the residue was chromatographed on silica gel (hexane) and (*E*)-**10f-1** (100 mg) and (*Z*)-**10f-1** (164 mg) were obtained in 33% and 54% yields, respectively. (*Z*)-**10f-1**; an oil. IR (neat): 2960, 1583, 1479, 1441, 1026, 739, and 690 cm^{-1}. ^1H NMR (CCl_4): δ=0.93 (6H, d, J=7 Hz), 1.09—2.42 (3H, m), 1.86 (3H, br s), 5.83 (1H, br t, J=7 Hz), and 7.25 (5H, s). In a similar manner, the photoisomerization of **7f-1** (0.7 h, *E*; 16%, *Z*; 33%), **7f-4** (0.7 h, 78%, *E*:*Z*=40:60), and **10f-2** (2 h, *E*; 35%, *Z*; 38%) were carried out and the following *Z*-isomers were obtained. (*Z*)-5-Methyl-1-phenyl-2-phenylthio-2-hexene-1-ol (**7f-1**); a viscous oil. IR (neat): 3380, 2950, 1582, 1479, 1025, 740, and 698 cm^{-1}. ^1H NMR (CCl_4): δ=0.91 (6H, d, J=7 Hz), 1.20—1.98 (1H, m), 2.26 (3H, br t, J=7 Hz), 5.08 (1H, br s), 6.33 (1H, t, J=7 Hz), 7.21 and 7.27 (10H, 2s) (*E* and *Z*)-7-methyl-4-phenylthio-4-octen-3-ol (**7f-4**); a viscous oil. IR (neat): 3400, 2960, 1583, 1480, 1024, 739, and 690 cm^{-1}. ^1H NMR (CCl_4): δ=0.91 (6H, d, J=7 Hz), 0.68—1.12 (3H, m), 1.12—2.46 (6H, m), 3.99 and 4.44 (1H, 2t, J=7 Hz), 5.81 and 6.33 (1H, 2t, J=7 Hz), and 6.99—7.56 (5H, m). (*Z*)-2-Methyl-5-phenylthio-4-tridecene (**10f-2**); an oil. IR (neat): 2920, 1582, 1479, 1438, 1027, 739, and 690 cm^{-1}. ^1H NMR (CCl_4): δ=0.64—2.48 (20H, m), 0.93 (6H, d, J=6 Hz), 5.85 (1H, t, J=7 Hz), and 7.22 (5H, s).

*Preparation of (Z)-5-Methyl-2-phenylsulfinyl-2-hexene (**12-2**).* To a CH_2Cl_2 (3 ml) solution of MCPBA (134 mg, 0.78 mmol) was added a CH_2Cl_2 (3 ml) solution of (*Z*)-5-methyl-2-phenylthio-2-hexene (**10f-1**) (160 mg, 0.78 mmol) at −23 °C. After stirring for 1 h, 5% aqueous $NaHCO_3$ was added to the reaction mixture and the usual work up gave (*Z*)-**12-2** (102 mg) in 59% yield. (*Z*)-**12-2**; a viscous oil. IR (neat): 2950, 1580, 1464, 1443, 1083, 1041, 748, and 693 cm^{-1}. ^1H NMR (CCl_4): δ=1.03 (6H, d, J=5 Hz), 1.45—2.86 (3H, m), 1.64 (3H, br s), 5.94 (1H, br t, J=8 Hz), and 7.49 (5H, m). In a similar manner, (*E*)-**12-2** was obtained by the oxidation of (*E*)-**10f-1**. (*E*)-5-Methyl-2-phenylsulfinyl-2-hexene (**12-2**) (55%); a viscous oil. IR (neat): 2950, 1580, 1466, 1443, 1086, 1043, 749, and 692 cm^{-1}. ^1H NMR (CCl_4): δ=0.97 (6H, d, J=5 Hz), 1.16—2.28 (3H, m), 1.56 (3H, br s), 6.40 (1H, br t, J=8 Hz), and 7.25—7.72 (5H, m).

(Received August 31, 1983)

On irradiation in benzene under oxygen atmosphere *cis*- and *trans*-4-flavanols gave flavanones with significant structural effects on the yield: A high cis/trans selectivity and enhancement effect by electron-donating substituents. A series of benzylic-type alcohols showed similar substituent effects. The structure-reactivity relationships were explained in terms of the stereoelectronic requirements for favorable overlapping of intermediates. In order to infer the active oxidant species, the above photoreactions were compared with the oxidations by singlet oxygen and superoxide ion. The involvement of superoxide ion or its related species such as electron transfer complex $R^{+\cdot}\cdots O_2^{-\cdot}$ was suggested. The effects of additives and solvents were also investigated.

A detailed study has been reported on the photooxidation reaction of a series of benzylic-type alcohols in DMSO under oxygen atmosphere, showing a special effects of DMSO or the formation of a charge transfer complex.[1] On the other hand, a high stereoselectivity has been observed for the thermal oxidations of secondary alcohols[2] and a series of 4-chromanols[3] with chromium trioxide, which has been attributed to both the stereoelectronic effect and the strain relief. A significant cis/trans selectivity has also been observed in the oxidation of cis and trans isomers of 4-flavanols with the triplet state benzophenone, which has been explained in terms of the stereoelectronic requirements or favorable overlapping of the radical intermediates.[4]

The present paper reports on the structural effects in the photooxygenation reactions of 4-flavanols **1**—**3** and the related benzylic-type alcohols **4**—**11** (Chart 1).

Results and Discussion

Photooxygenation Reactions. Table 1 summarizes the yields of flavanones formed in the photooxidations of 4-flavanols under oxygen atmosphere, in benzene (benzene/O_2), in benzene-diphenyl sulfone (benzene-DPSO/O_2), and in dimethyl sulfoxide (DMSO/O_2), respectively. No reaction products were detected from a benzene solution of **1a** after bubbling through with oxygen gas for 8.5 h in the dark, while only a trace amount of flavanone was detected by TLC analysis on irradiation under nitrogen atmosphere in place of oxygen.

In the above photoreactions two points may be noted as to the structural effects of the substrates: (i) the cis isomers (**1a**, **2a**, **3a**) show higher reactivities compared with the corresponding trans isomers (**1b**, **2b**, **3b**), (ii) electron donating substituents at the 7-position facilitate the reaction. The latter (ii) implies the electrophilic nature of the intermediates while the former (i) suggests the conformational requirements for the substrates and/or intermediates.

Table 2 shows relative reactivities of a series of benzylic-type alcohols (hereafter denoted as benzylic alcohols) in the photooxidations in benzene/O_2, in benzene-DPSO/O_2, and in DMSO/O_2, respectively.

Table 1. Photooxidations of 4-flavanols under different conditions

4-Flavanol	Percent yield of flavanone		
	Benzene/O_2[a]	Benzene-DPSO/O_2[b]	DMSO/O_2[c]
1a	22	34	20
1b	Trace	Trace	Trace
2a	35	44	22
2b	4	Trace	Trace
3a	53	d)	71
3b	12	d)	11

a) 4-Flavanol 0.04 mol dm^{-3} in benzene, under O_2 atomsphere, irradiation time 8 h. b) 4-Flavanol 0.04 mol dm^{-3}, diphenyl sulfone (DPSO) 0.04 mol dm^{-3} in benzene, under O_2 atmosphere, irradiation time 8 h. c) 4-Flavanol 0.025 mol dm^{-3} in dimethyl sulfoxide, under O_2 atmosphere, irradiation time 15 h. d) Photolyzed mixture solutions were too complex to analyze.

Table 2. Photooxidations of benzylic alcohols

Photooxidation system	Benzylic alcohol	Consumption of alcohol/%	Yield of acetophenone/%
Benzene/O_2[a]	**4**	12	12
	5	20	10
	6	32	29
	7	16	8
	8	10	8
	9	19	10
Benzene-DPSO/O_2[b]	**4**	51	45
	5	58	27
	6	98	19
DMSO/O_2[c]	**4**	10	10
	10	29	23[d]
	11	0	0

a) Benzylic alcohol 0.04 mol dm^3 in benzene, under O_2 atmosphere, irradiation time 10 h. b) Benzylic alcohol 0.04 mol dm^{-3}, diphenyl sulfone (DPSO) 0.04 mol dm^3 in benzene, under O_2 atmosphere, irradiation time 10 h. c) Benzylic alcohol 0.025 mol dm^{-3} in dimethyl sulfoxide, under O_2 atmosphere, irradiation time 15 h. d) Benzoic acid was also formed in 6% yield.

Relative reactivities of the *p*-substituted benzylic alcohols in benzene/O_2 show similar tendency (**4**<**5**<**6**) to that of 4-flavanols (**1a**<**2a**<**3a**). Although relative consumption rates in benzene-DPSO/O_2 also show similar tendency, the large gaps between the consumption of the substrates and the yield of acetophenones prevent detailed inspection.

On the other hand, ortho and meta substituents tend to lower the reactivity (**8**, **9** compared with **4**, **6**). Comparison of **4**, **10**, and **11** in DMSO/O_2 shows that bulky groups on the benzylic carbon depress the reaction in spite of the electron-donating ability, implying predominant role of steric factors over the stabilities of intermediates (*e.g.*, benzylic radicals).

Oxidations with Singlet Oxygen and Superoxide Ion. In order to infer the active oxidant species involved in the photooxygenation reactions, it seemed reasonable to compare the reactivities with those in the oxidations by singlet oxygen and superoxide ion, respectively. Oxidation of 4-flavanols by singlet oxygen gave the corresponding flavanones with high cis/trans selectivities (Table 4) which are comparable with those in Table 1. However, the substituent effect of the reactiviy order (**1a**>**2a**>**3a**) is the reverse to that in Table 1, thus suggesting different mechanisms. In the oxidation of 4-flavanols (R) with singlet oxygen in *t*-butyl alcohol, which is fairly polar solvent, superoxide ion may be generated from singlet oxygen *via* CT interaction[5,6] and act as the oxidant species, *e.g.*,

$$R + {}^1O_2 \rightleftharpoons R^{+\cdot} + O_2^{-\cdot} \longrightarrow RO_2 \rightarrow \rightarrow \text{products.}$$

Then, the difference in the reactivity order (Tables 1 and 4) may be due to the difference in the active oxidant species between superoxide ion (in *t*-butyl alcohol) and polar CT complexes (in benzene).

No sufficient data were available for the oxidation of 4-flavanols with superoxide ion (Table 4); the reaction in benzene gave mixtures too complex to analyze, except for **1a** and **1b** which show rather low cis/trans selectivity. In addition, reactions weie complicated by the concomitant rearrangement reaction (ring opening). Thus, **1a**, **1b**, **2a**, and **2b** gave the corresponding 2′-hydroxychalcones stoichiometrically while **3a** and **3b** led to highly complex mixtures incapable of analysis.

As alternatives to the 4-flavanols, a series of benzylic alcohols may serve to see the structure-reactivity relationships in the superoxide ion oxidation. Table 3 illustrates the yields of acetophenone produced in the superoxide oxidation in benzene, showing that the reaction is fairly clean. The substituent effects on the reactivity are comparable to those in the photooxygenation reaction in benzene (Table 2). Thus, electron-donating substituents at the *p*-position facilitate the reaction (**4**—**6** and **5**/**6**), whereas the substituents at the ortho or meta position retard (**7**—**9**). From the similarities in the structure-reactivity relationships (Tables 1—3), it seems probable that the active oxidant species,

Table 3. Yields of acetophenones in the oxidation of benzylic alcohols with $O_2^{-\cdot}$[a]

a) 4-Flavanol 0.025 mol dm^{-3}, KO_2 0.25 mol dm^{-3}, 18-Crown-6 0.025 mol dm^{-3} in benzene, for 2 h at room temperature. b) 4-Flavanol 0.025 mol dm^{-3}, KO_2 0.08 mol dm^{-3}, 18-Crown-6 0.025 mol dm^{-3} in dimethyl sulfoxide, for 3 h at room temperature. c) 4-Flavanol 0.13 mol dm^{-3}, Rose Bengal 3.3×10^{-4} mol dm^{-3} in *t*-butyl alcohol, irradiated with a W-lamp (300 W) for 5 h. Similar results were obtained with thionine sensitizer in place of Rose Bengal.

Table 5. Photooxidation of **4** in the presence of DPSO[a]

DPSO added $\times10^3$ mol dm^{-3}	Consumption of alcohol/%	Yield of acetophenone/%
0	4	4
2	9	9
4	11	11
8	17	17
10	22	19
20	20	20
40	25	25
80	40	32

a) 1-Phenylethanol 0.04 mol dm^{-3} in benzene, under O_2 atmosphere, irradiated for 10 h. A fairly worn-out light source (100-W Hg lamp) was employed in this irradiation and the intensity was much lower than that of the one used elsewhere in the present study.

Table 6. Effects of additives on the yield of flavanone in the photooxidation of **1a** under oxygen atmosphere[a]

Additive mol dm^{-3}	Percent yield of flavanone[b] at 2 h	4 h	6 h	8 h	10 h
Nil	Trace	10	19	29	41
		12	24	30	
DABCO/0.02	0	0	0	Trace	
DTBP/0.02	Trace	22	37	58	
DMB/0.02	Trace	Trace	13	26	
TNM/0.02	76	100	100		
DPSO/0.04	24	43			
DPSO/0.04+DTBP/0.02	47				
DPSO/0.04+DMB/0.02	38				

a) In benzene solution of **1a** 0.02 mol dm^{-3}. DABCO: 1,4-diazabicyclo[2.2.2]octane, DTBP: 2,6-di-*t*-butylphenol, DMB: *p*-dimethoxybenzene, TNM: tetranitromethane, DPSO: diphenyl sulfone. b) Determined from the ^{1}H-NMR signal intensities at $\delta=5$.

involved in the photooxygenation reaction in benzene, is superoxide ion or its related species such as CT complexes. In fact 4-flavanols (**1a**, **3a**, and **3b**) in methanol under oxygen atmosphere showed broad enhancements of the UV-absorption in the region of 220—350 nm, which are ascribable to the charge transfer absorption.

Effects of Solvent and Additives. Photooxygenation of **1a** in different solvents under comparable conditions showed a wide variation in the yield of flavanone (%); ethyl acetate (100%), acetonitrile (61%), benzene (54%), DMSO (45%), 1,2-dimehoxyethane (13%), *t*-butyl alcohol (8%), DMF (trace).

Solvent polarity has been shown to play the key role in partitioning active species between the types of ion pairs and CT cmplexes present in solution.[6-9] The reactivity order shown here is not in the order of solvent polarity, hence superoxide ion mechanism is of minor importance at least in less polar solvents.

Photooxidation of **4** in benzene/O_2 was significantly facilitated by the addition of small amounts of diphenyl sulfone (DPSO). Both the consumption of **4** and the yield of acetophenone were increased with increasing addition of DPSO (Table 5). The enhancement effect may be relevant to charge transfer phenomena as has been implied earlier in the photooxidation of benzylic alcohols in DMSO/O_2.[1]

The effects of other additives were also examined including 1,4-diazabicyclo[2. 2. 2]octane (DABCO) as a powerful detector for singlet oxygen,[5] 2,6-di-*t*-butylphenol (DTBP) for free radicals,[10] tetranitromethane (TNM) for superoxide ion,[11] and *p*-dimethoxybenzene (DMB) as a competitor for the presumed CT complex formation of **1a** with O_2.[6] Table 6 shows the additive effects on the percent yield of flavanone formed in the photooxidation of **1a** in O_2-saturated benzene. Insufficient supply of O_2 during photolysis gave somewhat different results. Thus, comparable irradiation

of **1a** in sealed ampuls, after bubbling through with O_2 gas for 30 min, gave flavanone in 19% (additive/nil), 16% (DABCO/0.02 mol dm^{-3}), a trace (DMB/0.02 mol dm^{-3}), a trace (DTBP/0.02 mol dm^{-3}), respectively. Further, irradiation under air, in place of O_2 gas, led to no significant amount of the product.

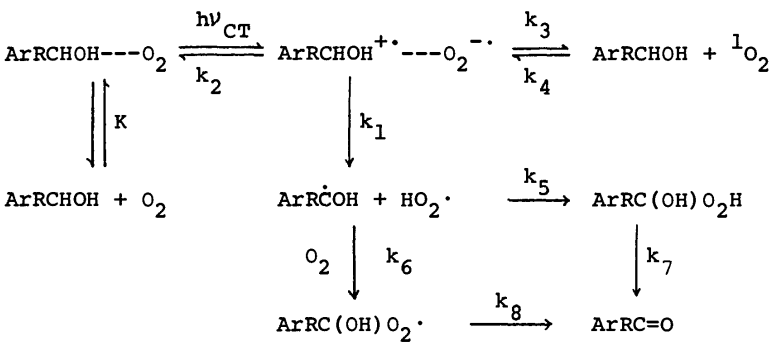
The remarkable enhancement effect by TNM implies the important role of CT interaction, while the strong depression by DABCO suggests the involvement of singlet oxygen. However, the photoreaction in sealed ampuls (O_2-insufficient conditions) was little subject to DABCO, hence singlet oxygen does not necessarily act as the oxidant species in its own form. The presence or absence of the depression by DABCO, depending on excess or deficiency of O_2, also implies that singlet oxygen is formed indirectly, *via* equilibria including complex formation which would become significant only in the presence of a large excess of O_2 (Scheme 1). The depression effect by DMB can be explained in terms of the competitive complex formation with oxygen species, which would be more significant in O_2-insufficient solution (Scheme 2). Also, it is notable that the photoreaction was enhanced by the combined addition of DPSO and DMB, as compared to the single addition of either, suggesting electron transfer sensitization by the additives.

Speculation on the Mechanism. Direct evidence has been reported for the generation of radical ions in electron transfer photooxygenation reactions in highly polar solvents.[7] In nonpolar solvents such as benzene, however, no such ion pair formation seems to occur but highly polar CT complexes are often formed.[6,12] The present photooxygenation reactions in benzene/O_2 can be explained in terms of Scheme 1, which is essentially similar to those proposed for the electron transfer photooxygenations of ethers,[13] amines,[12,14] and alkylbenzenes,[14,15] except for the inefficient generation of ion pairs in the present photoreaction. Here, ArRCHOH $\cdots O_2$ represents a contact pair between the substrate and oxygen in their ground states which is implied by the enhanced UV-absorption(250—300 nm). On excitation this will lead to a CT complex ($ArRCHOH^{+\cdot}\cdots O_2^{-\cdot}$), which will then undergo back electron transfer (k_2), proton transfer (k_1) to give the substrate radicals ArRĊOH, or the reversible formation of singlet oxygen (k_3, k_4). In the presence of DABCO efficient quenching of $^1O_2$ would occur to depress the photoreaction. The overall reaction efficiency will be governed by the ratio k_1/k_2 which in turn depends on the structure of the relative stability of ArRĊOH, if the subsequent processes (k_5, k_6) occur irreversibly. The in-cage radical coupling reaction (k_5) would proceed rapidly and little scavenged by added radical inhibitors such as DTBP.

In the presence of excess O_2 the out-of-cage reaction (k_6) would also occur efficiently before scavenged by DTBP. Disproportionation of the peroxyl radical (k_8) and decomposition of the hydroperoxide (k_7) will lead to the final products. The reactivity ratio of **3a**/**1a** or **4**/**6** is in the range of 2-3 (Tables 1 and 2), which corresponds to the Hammet reaction constant of $-0.6 \leqq \rho \leqq 1.4$, being consistent with the intermediacy of the substrate radicals.

The structure-reactivity relationships may be explained in terms of the stereoelectronic effects of the radical intermediates, assuming that the reaction efficiency is mainly determined by the ratio k_1/k_2 or the stability of the radical intermediate. Since the hydrogen atom on the 4-position is assigned to quasi-axial for the *cis*-4-flavanols **1a—3a** and quasi-equatorial for the trans isomers **1b—3b**,[16] the transition states or the 4-hydroxy-4-flavanyl radical intermediates would have conformations as [A] and [B], respectively (Chart 2). For the conformer [A] the *p*-type orbital on the 4-position is capable of overlapping with both the hydroxyl and phenoxyl groups. The conformer [B] is incapable of such coplanar overapping and less stable. Thus the cis/trans selectivity in Table 1 can be explained by the stereoelectronic effects of the intermediates. The substituent effects of benzylic alcohols (Table 2) may be explained in a similar manner. Thus, in the absence of ortho substituents the benzylic radicals can have the coplanar configuration [C] to allow favorable overapping with both the aryl and the hydroxyl groups. In the presence of ortho substituents such coplanarity would be sterically hindered, leading to unstable intermediates [D]. The methoxyl group at the meta position would destabilize the benzylic radicals due to its inductive effect while incapable of resonance effect, resulting in the slight depression of the product formation (**7** in Table 2). Photooxidations in DMSO/O_2 and in benzene-DPSO/O_2 show structure-reactivity relationships apparently similar to those in benzene/O_2, suggesting similar intermediates, ArRĊOH.

Highly complicated features are suggested for the



Scheme 1.

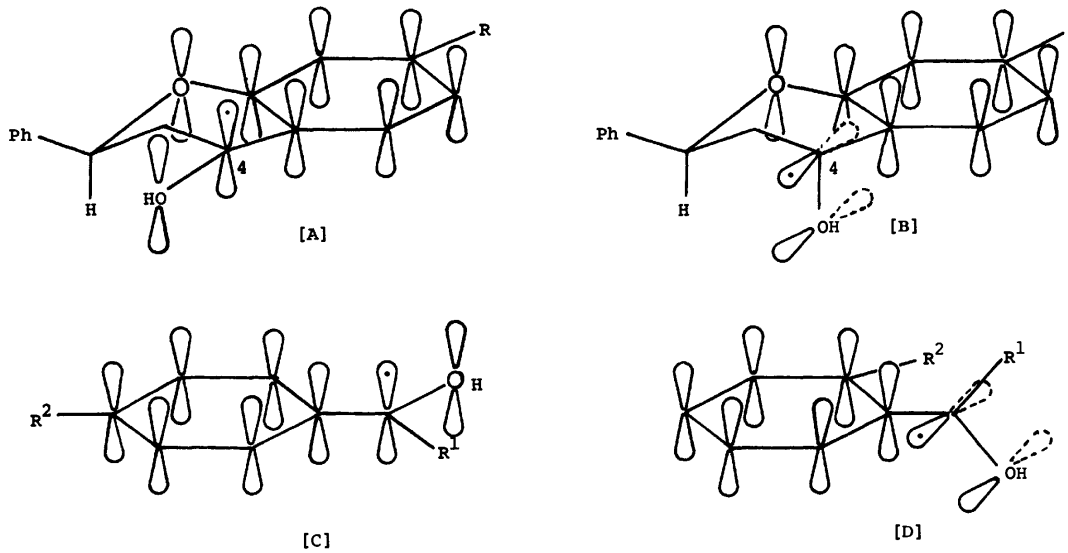


Chart 2.

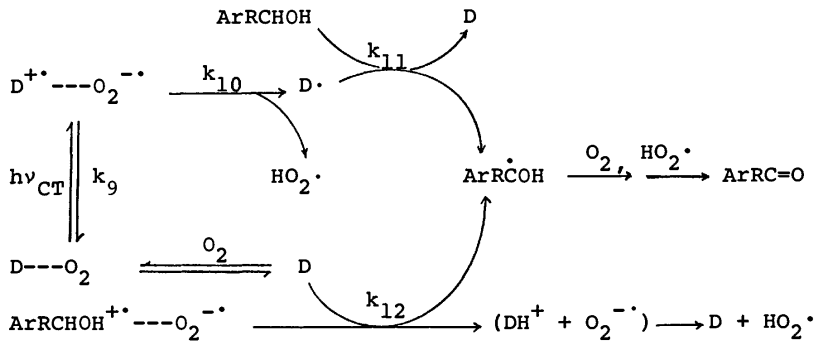
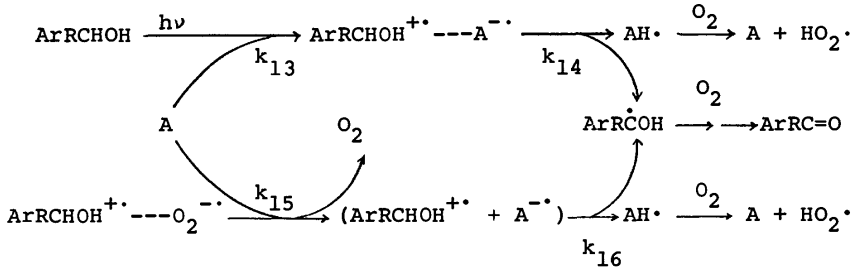


Scheme 2.



Scheme 3.

effects of additives, since many of the additives can act on the various species present in the systems. For example, DTBP can be a good competitor for electron transfer interaction as well as a powerful scavenger of free radicals. It may also act as a carrier and/or initiator in free radical reactions.

Crude mechanisms are tentatively proposed for the effects of electron donors (Scheme 2) and electron acceptors (Scheme 3), respectively. In the presence of a good electron donor (D) such as DMB or DTBP, a CT complex of D ($D^{+\cdot}\cdots O_2^{-\cdot}$) may be formed on CT excitation of a contact pair ($D\cdots O_2$). These processes would not seriously affect the formation of $ArRCHOH\cdots O_2$ and $ArRCHOH^{+\cdot}\cdots O_2^{-\cdot}$, in the presence of excess O_2.

Subsequent proton transfer (k_{10}) will give radical D· which may undergo hydrogen abstraction from the substrates (k_{11}) to give the radical ArRĊOH. Alternatively, proton transfer from $ArRCHOH^{+\cdot}\cdots O_2^{-\cdot}$ to D may proceed (k_{12}) to facilitate the formation of ArRĊOH, thus eventually enhancing the product formation. The enhancement effects of D may be also due to the increased solubility or concentration of O_2 gas *via* contact pair formation.

In the presence of a good electron acceptor (A) such as TNM or DPSO, on the other hand, another type of CT complex ($ArRCHOH^{+\cdot}\cdots A^{-\cdot}$) may be formed ($k_{13}$), followed by proton transfer (k_{14}) to give ArRĊOH (Scheme 3). Alternatively, electron transfer from $ArRCHOH^{+\cdot}\cdots O_2^{-\cdot}$ to A may occur (k_{15}).

Subsequent proton transfer (k_{16}) will lead to ArRĊOH, thus eventually facilitating the photoreaction.

Experimental

Apparatus and Procedure. The light source for irradiation was a 100-W high pressure mercury lamp (Rico). The UV absorption and proton NMR spectra were measured with a Hitachi 200-10 UV-spectrophotometer and a Hitachi R-24 NMR spectrometer (60 MH_z), respectively. The product mixtures were chromatographed over Caster wax or PEG-20 M on 60—80 mesh Chromosorb WAW (3 mm×3 m), by the use of a Shimadzu GC-4CM-PF with a FID deteactor and nitrogen carrier gas. All melting points and boiling points were uncorrected.

Materials. While 2,4-*cis*-4-flavanols **1a**, **2a**, and **3a** were prepared by the reduction of the corresponding flavanones with sodium borohydride,[17,18] 2,4-*trans*-4-flavanols **1b**, **2b**, and **3b** were obtained from **1a**, **2a**, and **3a**, respectively, by treatment with phosphorous tribromide followed by alkaline hydrolysis.[18] **1a**: Colorless needles from methanol, mp 147.5—148 °C; **1b**: colorless needles from benzene-petroleum benzine, mp 115—116 °C; **2a**: colorless needles from ethanol-water, mp 103—103.5 °C; **2b**: colorless needles from hexane-benzene, mp 49.5—51.5 °C; **3a**: colorless needles from methanol, mp 100—101 °C; **3b**: colorless needles from benzene-petroleum benzine, mp 110—111 °C. 1-Phenylethanol **4** was of guaranteed grade commercially available (Wako Chemicals), while **5**—**9** were prepared by the reduction of the corresponding *p*-substituted acetophenones with sodium borohydride.[9] The purities were confirmed by GLC analysis. **5**: Bp 96.5—97 °C/5 mmHg†; **6**: bp 110.5 °C/4 mmHg; **7**: bp 94 °C/2.5 mmHg; **8**: bp 100 °C/5 mmHg; **9**: colorless needles from ether-petroleum ether, mp 41.5—42.5°C. Diphenyl sulfone, acetophenone, DABCO and DTBP were of the purest grade commercially available. Benzene and other solvents were distilled before use.

Photooxygenation Reactions. Typical procedures will be described below. A 25 ml benzene solution containing 0.04 mol dm^{-3} substrate was bubbled through with oxygen gas for 30 min, then irradiated at room temperature while stirring with a magnetic stirrer under oxygen atmosphere for 8—10 h. The photolyzed mixtures from 4-flavanols were analyzed by ^1H NMR spectroscopy after the removal of the solvent. Relative yields of flavanones and 4-flavanols recovered were calculated from the relative intensities of the protons at the C-2 position of flavanones and those at the C-4 or C-2 positions of 4-flavanols. Besides flavanones, trace amounts of 2′-hydroxychalcones were detected by TLC analysis on silica gel-benzene. The photoproducts from benzylic alcohols (**4**—**11**) were determined on GLC by comparing with corresponding acetophenones commercially available (acetophenone, 4′-chloro- and 4′-methoxyacetophenones) or prepared by known methods.[20] 3′-Methoxyacetophenone: Bp 134—135.5 °C/24 mmHg; 2′,4′-dimethoxyacetophenone: Colorless needles from benzene, mp 39—40 °C; 2′-methoxyacetophenone: Bp 132—135 °C/25 mmHg.

Oxidation by Superoxide Ion. A 30 ml benzene solution containing 18-Crown-6 (0.25 g, 1.0 mmol) and a benzylic alcohol (1.0 mmol) was mechanically stirred while bubbling through with nitrogen gas, then added potassium peroxide (0.40 g, 5.3 mmol) and continued stirring until the color changed into orange (*ca.* 15 h). Water was added and shaken, then the organic layer was condensed and analyzed on GLC as described above. Similarly, 4-flavanols were oxidized under nitrogen atmosphere in a 20 ml benzene solution containing a 4-flavanol (1.0 mmol), 18-Crown-6 (1.0 mmol), and potassium peroxide (10 mmol) for 2 h, or in a 20 ml DMSO solution containing a 4-flavanol (1.0 mmol), 18-Crown-6 (0.76 mmol), and potassium peroxide (2.8 mmol) for 3—5 h. The products were analyzed by NMR spectroscopy as described above.

Oxidation of 4-Flavanols by Singlet Oxygen. A 15 ml solution of *t*-butyl alcohol containing a 4-flavanol (2 mmol) and Rose Bengal or thionine (5 mg) as a sensitizer was irradiated with a 300-W tungsten lamp for 5 h while stirring with magnetic stirrer under oxygen atmosphere.

The authors would like to express their thanks to Mr. Jiro Amano and Tsukasa Uei for discussion.

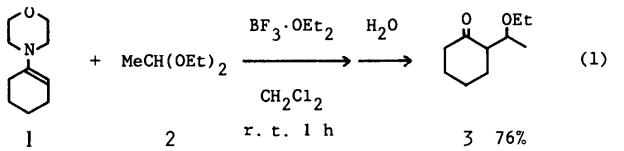
Reaction of Enamines with Acetals or Trialkyl Orthoformates Activated by Lewis Acids

Osamu TAKAZAWA,* Kunio KOGAMI, and Kazuo HAYASHI
Kawasaki Research Laboratories, T. Hasegawa Co., Ltd., 335 Kariyado, Nakahara-ku, Kawasaki 211
(Received October 13, 1983)

Enamines, prepared readily from various carbonyl compounds, react with acetals or trialkyl orthoformates in the presence of Lewis acids such as $BF_3 \cdot OEt_2$ to give corresponding β-alkoxy carbonyl compounds or α-dialkoxymethyl carbonyl compounds in good yields. The reaction of dienamines with acetals or trialkyl orthoformates also selectively gives corresponding β,γ-unsaturated α-(α-alkoxyalkyl) carbonyl compounds or β,γ-unsaturated α-diakoxymethyl carbonyl compounds in good yields.

The reaction of enamines with trialkyl orthoformates was briefly reported in our previous paper.[1] In this report, the above reaction is investigated in detail.

In the preceding paper,[2] it was shown that the β-alkoxy carbonyl compounds or α-dimethoxymethyl carbonyl compounds are obtained by the reaction of enol silyl ethers with acetals or trimethyl orthoformate in the presence of $TiCl_4$. In the present investigation, it has been found that enamines react with acetals or trialkyl orthoformates in the presence of Lewis acids similarly to enol silyl ethers. For example, to a dichloromethane solution of a 1.2 molar amount of acetaldehyde diethyl acetal (**2**) was added a 1.3 molar amount of $BF_3 \cdot OEt_2$ at −40 °C in argon atmosphere. Then 1-morpholino-1-cyclohexene (**1**) was added and the reaction mixture was stirred for 1 h at room temperature. After hydrolysis, the resulting organic layer was concentrated. The reaction product, 2-(1-ethoxyethyl)-1-cyclohexanone (**3**), was obtained in 76% yield after distillation under reduced pressure, the reaction concerned being summarized as:



1 2 3 76%

(Erythro and threo mixture)

In order to investigate the effect of Lewis acids, reactions of **1** with **2** in the presence of various Lewis acids were tried according to the procedure mentioned above (Table 1). The results described in Table 1 demonstrate that, of the Lewis acids examined, $BF_3 \cdot OEt_2$ exhibits a remarkable effect as compared with the others. In case $TiCl_4$ was employed, 2-ethylidenecyclohexanone was obtained as a major product along with **3**.

The effect of the amount of $BF_3 \cdot OEt_2$ upon the yield of **3** was then investigated by using the reaction between **1** and a 1.2 molar amount of **2** at room temperature for 1 h as a reference reaction. It was found that the product **3** was obtained in the highest yield when a 1.3 or 1.5 molar amount of $BF_3 \cdot OEt_2$ was applied (Table 2).

Furthermore, the effect of amines used in enamine synthesis was studied by treating enamines derived from various amines and cyclohexanone with a 1.2 and 1.3 molar amount of **2** and $BF_3 \cdot OEt_2$, respectively, under similar conditions as described above. The results shown herein indicate that morpholine enamine (**1**) is significantly favored in this reaction to afford the best yield (Table 3).

Reactions of **1**, 3,7-dimethyl-1-morpholino-1,6-octadiene (**11**), or 1-piperidino-1-hexene (**14**) with a variety of acetals were tried in the presence of $BF_3 \cdot OEt_2$ according to the typical procedure, and the corresponding β-alkoxy carbonyl compounds were obtained in good yields as shown in Table 4.

The reaction of crotonaldehyde dimethyl acetal with **1** gave a Michael type adduct (**18**) in 13% yield

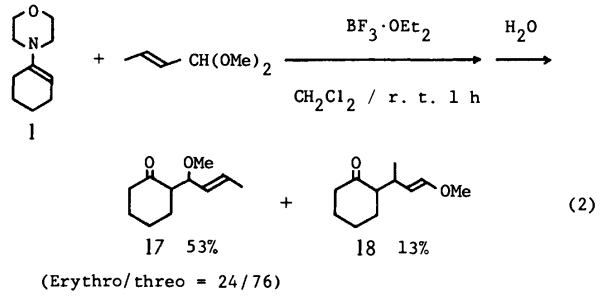
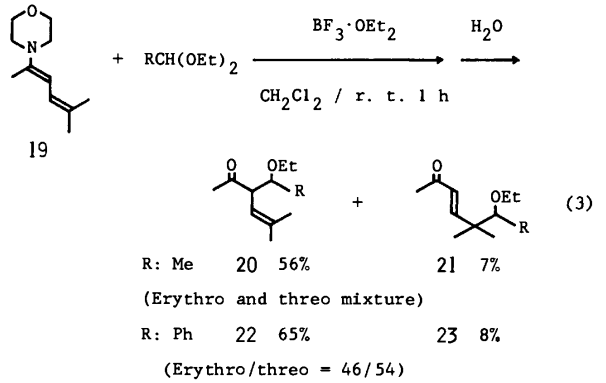
together with β-methoxy ketone (**17**) in 53% yield:[3]

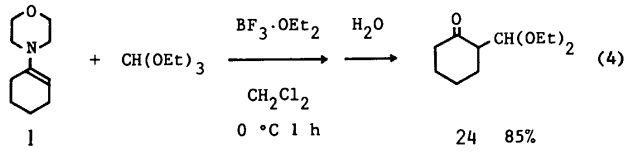


In contrast to the result[4] that the reaction of dienyloxysilanes with acetals gave α,β-unsaturated γ-(α-alkoxyalkyl) carbonyl compounds, the present reaction of a dienamine, 2-methyl-5-morpholino-2,4-hexadiene (**19**), with acetals selectively afforded β,γ-unsaturated α-(α-alkoxyalkyl) carbonyl compounds, **20**, or **22**, as shown by the following equation:



It is known that the reaction of enamines with alkyl halomethyl ethers affords α-alkoxymethyl carbonyl compounds.[5] In contrast to this finding, the present reaction gives α-(1-alkoxyalkyl) carbonyl compounds in good yields.

On the other hand, α-dialkoxymethyl carbonyl compounds are obtained by the reaction of enamines with trialkyl orthoformates. For example, to a dichloromethane solution of **1** and a 1.3 molar amount of triethyl orthoformate was added a 1.3 molar amount of $BF_3 \cdot OEt_2$ at −40 °C in argon atmosphere. Then the reaction mixture was stirred for 1 h at 0 °C. After hydrolysis, the resulting organic layer was concentrated. The reaction product, 2-diethoxymethyl-1-cyclohexanone (**24**), was obtained in 85% yield after distillation under reduced pressure, the reaction concerned being summarized as:



In a similar manner, the reaction of enamines derived from various carbonyl compounds with trialkyl orthoformates afforded the corresponding α-dialkoxymethyl carbonyl compounds as listed in Table 5.

Table 4. Synthesis of β-alkoxy carbonyl compounds from enamines and acetals in the presence of $BF_3 \cdot OEt_2$

Enamine	Acetal		Product	Isolated yield/%	Isomer ratio[a] a/b
 1	$MeCH(OBu^n)_2$	7		81	-
	$PhCH(OEt)_2$	8		89	38/62[b]
		9		57	59/41[c]
		10		70	55/45[c]
 11	$PhCH(OEt)_2$	12		81	48/52[b]
		13		79	54/46[c]
 14	$PhCH(OEt)_2$	15		56	30/70[b,d]
		16		12	-

a) Erythro and threo isomers. Determined by GLC analysis. b) a/b = erythro/threo. c) The stereochemistries of a and b are not determined. d) Determined by NMR analysis.

Since the reactivity of trialkyl orthoformates toward enamines is higher than that of acetals, α-dialkoxymethyl carbonyl compounds were obtained in good yields in the presence of $TiCl_4$, $SnCl_4$, or $ZnCl_2$.

In contrast to the result that the reaction of dienoxysilanes with trialkyl orthoformates gave α,β-unsaturated γ-dialkoxymethyl carbonyl compounds,[4] the present reaction of dienamine **19** with trimethyl orthoformate afforded β,γ-unsaturated α-dimethoxymethyl ketone (**28**).

It is known that the reaction of enamines with a mixed anhydride of formic acid and acetic acid[5c] or the Vilsmeier reagent ($POCl_3$-DMF)[6] affords 2-formyl ketones. In comparison with the above reaction, the present reaction has an advantage in that α-dialkoxymethyl carbonyl compounds, having the protected formyl and carbonyl groups in the same molecule, is exclusively formed by a one-step procedure.

Experimental

Spectra. ^1H NMR spectra were recorded on a Hitachi R-24A spectrometer. Chemical shifts are reported on the δ scale relative to tetramethylsilane as an internal standard. IR spectra were taken with a JASCO IRA-2 spectrometer. Products were identified by NMR and IR spectra and elemental analyses.

Materials. Commercially available $BF_3 \cdot OEt_2$, $TiCl_4$,

and $SnCl_4$ were distilled in argon atmosphere before use. Anhydrous $AlCl_3$, $ZnCl_2$, $ZnBr_2$, $FeCl_3$, and $MgCl_2$ were used without purification. Enamines of carbonyl compounds, 1-morpholino-1-cyclohexene (**1**), 1-pyrrolidino-1-cyclohexene (**5**), and *N*-(1-cyclohexenyl)-*N*-methylaniline (**6**), were prepared according to literature procedures[5c,7] and purified by distillation. **1**: bp 116—117 °C/10 mmHg (1 mmHg≈133.322 Pa) (lit,[7] 118—120 °C/10 mmHg); **5**: bp 103—104 °C/10 mmHg (lit,[5c] 105—107 °C/13 mmHg); **6**: bp 95—97 °C/1 mmHg (lit,[5c] 148—153 °C/12 mmHg). In a similar manner, 1-piperidino-1-cyclohexene (**4**), 3,7-dimethyl-1-morpholino-1,6-octadiene (**11**), 1-piperidino-1-hexene (**14**), 5-methyl-2-morpholino-2,4-hexadiene (**19**), 3,4-dimethyl-1-morpholino-1,3-cyclohexadiene (**26**), and 6,10-dimethyl-1-morpholino-1,5,9-undecatriene (5*E*:5*Z*=1:1) (**30**) were prepared from the corresponding carbonyl compounds and amines, and the physical data are as follows. **4**: bp 109—110 °C/10 mmHg; NMR ($CDCl_3$) δ=1.52 (10H, m), 2.04 (4H, m), 2.74 (4H, m), and 4.66 (1H, t, J=3.0 Hz). **11**: bp 113 °C/2 mmg; NMR ($CDCl_3$) δ=1.00 (3H, d, J=6.0 Hz), 1.2—2.3 (5H, m), 1.61 (3H, s), 1.70 (3H, s), 2.75 (4H, m), 4.30 (1H, dd, J=14.5 and 8.5 Hz), 5.10 (1H, t, J=7.0 Hz), and 5.75 (1H, d, J=14.5 Hz). **14**: bp 103 °C/13 mmHg; NMR ($CDCl_3$) δ=0.90 (3H, t, J=5.5 Hz), 1.1—1.8 (10H, m), 1.97 (2H, q, J=7.0 Hz), 2.75 (4H, m), 4.38 (1H, dt, J=14.0 and 7.0 Hz), and 5.80 (1H, d, J=14.0 Hz). **19**: bp 125—127 °C/9 mmHg; NMR ($CDCl_3$) δ=1.72 (3H, s), 1.80 (3H, s), 1.88 (3H, s), 2.88 (4H, m), 3.75 (4H, m), 5.30 (1H, d, J=11.5 Hz), and 5.96 (1H, d, J=11.5 Hz). **26**: bp 97—98 °C/0.6 mmHg; NMR ($CDCl_3$) δ=1.70 (6H, s), 2.15 (4H, s), 2.82 (4H, m), 3.69 (4H, m), and 4.76 (1H, s). **30**: NMR ($CDCl_3$) δ=1.60 and 1.68 (9H, s), 1.8—2.2 (8H, m), 2.70 (4H, m), 3.65 (4H, m), 4.45 (1H, m), 5.10 (2H, m), and 5.80 (1H, d, J=14.0 Hz).

Reaction of 1-Morpholino-1-cyclohexene (1) with Acetaldehyde Diethyl Acetal (2) in the Presence of $BF_3 \cdot OEt_2$. To a dichloromethane (50 ml) solution of 7.08 g (60 mmol) of acetaldehyde diethyl acetal (**2**) was added 9.23 g (65 mmol) of $BF_3 \cdot OEt_2$ at −40 °C in argon atmosphere. Then 8.35 g (50 mmol) of 1-morpholino-1-cyclohexene (**1**) was added immediately and the reaction mixture was stirred for 1 h at room temperture. The mixture was quenched with water and stirred for 1 h at room temperature. After hydrolysis, the organic layer was washed with a saturated solution of $NaHCO_3$ and dried over $MgSO_4$. After removal of the solvent, the residue was distilled under reduced pressure to give a mixture of diastereomers (**3a** and **3b**) of 2-(1-ethoxyethyl)cyclohexanone (**3**) (6.50 g, 93—94 °C/10 mmHg, 76%). **3a** and **3b** were in the ratio 46:54 as found by means of gas chromatography (PEG-20 M). Analytically pure samples of **3a** and **3b** were prepared by preparative gas chromatography (20% PEG-20 M).

Reactions of enamines, such as 1-morpholino-1-cyclohexene (**1**), 1-piperidino-1-cyclohexene (*4*), 1-pyrrolidino-1-cyclohexene (**5**), *N*-(1-cyclohexenyl)-*N*-methylaniline (**6**), 3,7-dimethyl-1-morpholino-1,6-octadiene (**11**), and 1-piperidino-1-hexene (**14**), with various acetals were carrid out according to the same procedure, and the yields of the corresponding β-alkoxy carbonyl compounds are listed in Tables 3 and 4. The physical properties and analytical data of the products are shown in Table 6.

Reaction of 1-Morpholino-1-cyclohexene (1) with Acetaldehyde Diethyl Acetel (2) in the Presence of Various Lewis Acids. To a dichloromethane (50 ml) solution of 7.08 g (60 mmol) of acetaldehyde diethyl acetal (**2**) was added a Lewis acid (65 mmol) at −40 °C in argon atmosphere. Then 8.35 g (50 mmol) of 1-morpholino-1-cyclohexene (1) was added immediately. The reaction mixture was worked up as described above and purified by distillation. The reaction conditions and the yields of **3** are listed in Table 1.

Reaction of 1-Morpholino-1-cyclohexene (1) with Crotonaldehyde Dimethyl Acetal. Into a mixture of 8.35 g (50 mmol) of **1** and 6.96 g (60 mmol) of crotonaldehyde dimethyl acetal in dichloromethane (50 ml) was added 8.52 g (60 mmol) of $BF_3 \cdot OEt_2$ at −40°C in argon atmosphere and the reaction mixture was stirred for 1 h at room temperature. The reaction mixture was worked up as described above and the resulting residue was distilled under reduced pressure to give a mixture of diastereomers (**17a** and **17b**) of 2-(*trans*-1-methoxy-2-butenyl)-1-cyclohexanone (**17**) and 2-(*trans*-3-

a) Erythro and threo isomers. b) An erythro and threo mixture. c) e stands for erythro and t for threo.

methoxy-1-methyl-2-propenyl)-1-cyclohexanone (**18**) (6.00 g, 77—84 °C/2.0 mmHg, 66%). **17a** (erythro), **17b** (threo), and **18** were found to be in the ratio 13:40:13 by means of gas chromatography (PEG 20 M). Analytically pure samples of products were prepared by silica-gel column chromatography (hexane-ether) and preparative gas chromatography (20% PEG-20 M).

Reaction of 5-Methyl-2-morpholino-2,4-hexadiene (19) with Acetals. To a dichloromethane (50 ml) solution of 10.8 g (60 mmol) of benzaldehyde diethyl acetal was added 9.23 g (65 mmol) of $BF_3 \cdot OEt_2$ at −40 °C in argon atmosphere. Then 9.05 g (50 mmol) of 5-methyl-2-morpholino-2,4-hexadiene (**19**) was added immediately and the reaction mixture was stirred for 1 h at room temperature. The reaction mixture was worked up as described above and purified by silica-gel column chromatography. Elution with hexane and ether afforded 8.01 g (65%) of a mixture of diastereomers (**22a** and **22b**) of 3-(α-ethoxybenzyl)-5-methyl-4-hexen-2-one (**22**) and 0.98 g (8%) of 5-(α-ethoxybenzyl)-5-methyl-3-hexen-2-one (**23**). **22a** (erythro) and **22b** (threo) were in the ratio 46:54 as

Table 7. NMR signals of methylene protons in β-alkoxy carbonyl compounds

Product			Ha/δ	Jab/Hz	Solvent
8	a	(erythro)	4.84	4.4 (2.5)[a]	$CDCl_3$
	b	(threo)	4.67	8.0 (9.0)[a]	$CDCl_3$
12	a	(erythro)	4.66	8.0	$CDCl_3$
	b	(threo)	4.72	9.3	$CDCl_3$
15	a	(erythro)	4.58	5.7	$CDCl_3$
	b	(threo)	4.42	9.0	$CDCl_3$
17	a	(erythro)	3.99	4.4 (3.7)[a]	$CDCl_3$
	b	(threo)	3.92	8.0 (7.0)[a]	$CDCl_3$
22	a	(erythro)	4.67	5.6	$CDCl_3$
	b	(threo)	4.46	10.0	$CDCl_3$

a) The value of the corresponding aldol.

found by means of NMR.

Similarly, the reaction of **19** (9.05 g, 50 mmol) and acetaldehyde diethyl acetal (7.08 g, 60 mmol) in the presence of $BF_3 \cdot OEt_2$ (9.23 g, 65 mmol) gave 5.15 g (56%) of a mixture of diastereomers of 3-(1-ethoxyethyl)-5-methyl-4-hexen-2-one (**20**) and 0.65 g (7%) of *trans*-5-(1-ethoxyethyl)-5-methyl-3-hexen-2-one (**21**).

Stereochemistry of β-Alkoxy Carbonyl Compounds. The diastereomers **8a** and **8b** were stereospecifically converted into the corresponding *O*-methyloximes **33a** and **33b** by treatment with *O*-methylhydroxylamine (1.5 equiv., H_2O–MeOH, r. t, quant.). Then, it was found that **33a** and **33b** were erythro and threo isomers, respectively, by comparison with authentic samples prepared stereospecifically from the corresponding aldols[8] by treatment with *O*-methylhydroxylamine (1.5 equiv., H_2O–MeOH, r. t.) and NaH–EtI (THF, reflux, 30—50% yields). Therefore, it was determined that **8a** and **8b** were erythro and threo isomers, respectively. The stereochemistry of the diastereomers **17a** and **17b** was determined in a similar manner as above.

The stereochemistry of the diastereomers of **12**, **15**, and **22** was assigned on the basis of NMR spectra (shown in Table 7). Each of the diastereomers of **12**, **15**, and **22** has an absorption due to the proton (Ha) of the O–CH group or the other tertiary hydrogen (Hb), and a comparison of the coupling constant (*J*ab) of the isomers suggests the assigned stereochemistry.

Reaction of 1-Morpholino-1-cyclohexene (1) with Triethyl Orthoformate in the Presence of $SnCl_4$. To a mixture of 8.35 g (50 mmol) of 1-morpholino-1-cyclohexene (**1**) and 9.62 g (65 mmol) of triethyl orthoformate in dichloromethane (50 ml) was added 16.9 g (65 mmol) of $SnCl_4$ at −40 °C in argon atmosphere. Then the reaction mixture was stirred for 1 h at 0 °C. The mixture was quenched with water and stirred for 1 h at room temperature. After hydrolysis, the resulting organic layer was washed with a saturated solution of $NaHCO_3$ and dried over $MgSO_4$. After removal of the solvent, the residue was distilled to afford 9.00 g (90%) of 2-diethoxymethyl-1-cyclohexanone (**24**) (76 °C/0.9 mmHg).

The reaction of enamines, such as **1**, **11**, **14**, **19**, 3,4-dimethyl-1-morpholino-1,3-cyclohexadiene (**26**), and 1-morpholino-6,10-dimethyl-1,5,9-undecatriene (5*E*:5*Z*=1:1) (**30**), with triethyl or trimethyl orthoformate in the presence of various Lewis acids were carried out according to the same procedure, and the yields of the corresponding α-dialkoxymethyl carbonyl compounds are listed in Table 5. The physical properties and analytical data of the products are shown in Table 6.

The authors wish to express their thanks to Professor Teruaki Mukaiyama, the University of Tokyo for his helpful discussions.

Atmosphere Dependent Photoreaction of 4-Pyridinecarboxylic Ester in Acidic Methanolic Solutions

Toru SUGIYAMA,* Yukari KUSANO, Kazuya YAGI,
Yoko ITO, and Akira SUGIMORI*
Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7-1, Chiyoda-ku, Tokyo 102
(Received October 26, 1983)

The UV-irradiation of methyl 4-pyridinecarboxylate (**1**) in methanol under oxygen in the presence of sulfuric acid brings about methoxylation at the 3-position of the pyridine ring, while under nitrogen methoxylation and hydroxymethylation occur at the 2-position. The change of photoreactions of **1** caused by oxygen can not be explained either by the promotion of intersystem crossing by O_2 or by the charge transfer interactions between **1** and O_2.

The UV-irradiation of pyridinecarboxylic acid derivatives in acidic alcoholic solutions generally leads to alkylation, hydroxyalkylation, and alkoxylation at the α-and γ-positions of the pyridine ring.[1-5] In the course of our studies on the photoreactions of pyridinecarboxylic acid derivatives, we have observed a remarkable effect of oxygen in the photoreaction of 4-pyridinecarboxylic ester in alcohols in the presence of sulfuric acid.[6]

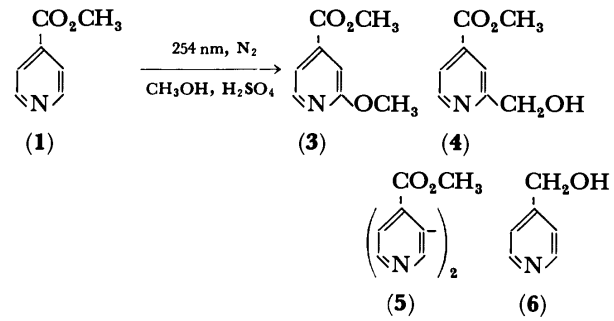
Although the photoreactions in the presence of oxygen have been extensively investigated, the roles of oxygen in the photoreactions have not yet been fully clarified. Besides the well-investigated reactions *via* singlet oxygen, the interest in the effects of oxygen *via* electron transfer interactions is increasing.[7] Pac *et al.* reported a marked increase in the quantum yields by oxygen on the sensitized retro-cycloaddition of dimethylthymine dimers.[8] Mizuno *et al.* have recently reported that the photoisomerization of 1,2-diarylcyclopropanes in the presence of 9,10-dicyanoanthracene is promoted by the addition of air.[9] The acceleration by oxygen in these photoreactions has been ascribed to the electron transfer interactions between the excited substrates and oxygen.

There remain, however, several interesting effects of oxygen, the roles of which have not yet been elucidated. Among them is promotion of the photochemical alcoholysis of organic halides by oxygen.[10]

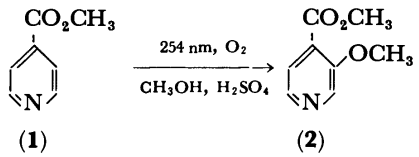
In this paper we report the analysis of the effects of oxygen in the photoreactions of methyl 4-pyridinecarboxylate in acidic methanolic solutions.

Results and Discussion

Types of Photoreactions under N_2 and O_2 Atmosphere. The UV-irradiation of methyl 4-pyridinecarboxylate(**1**) in methanol under nitrogen atmosphere in the presence of sulfuric acid brings about methoxylation and hydroxymethylation at the 2-position of the pyridine ring accompanied by the formation of trace amounts of dimethyl 3,3′-bipyridine-4,4′-dicarboxylate and 4-pyridylmethanol (Table 1).



Under oxygen atmosphere, these reactions are inhibited and **1** gives the methoxylation product at the 3-position selectively (Table 1).



The photoreaction of **1** is characterized by the fact that the presence of oxygen causes a dramatic change in the position of the methoxylation Such a remarkable oxygen effect was not observed in the photoreactions of 2- and 3-pyridinecarboxylic esters.

Photoreactions under N_2. The photoreactions of methyl 4-pyridinecarboxylate (**1**) in an acidic methanolic solution under nitrogen are essentially similar to those of 2- and 3-pyridinecarboxylic esters:[3,4] ionic methoxylation and hydroxymethylation in radical reaction occur in parallel. The difference of the photo-

[**1**]=0.01 mol dm^{-3}, [H_2SO_4]=0.05 mol dm^{-3}, —○—: **3**, —△— — —: **4**.

reactions of 4-pyridinecarboxylic ester from those of 2- and 3-isomers are: 1) the occurrence of hydroxymethylation in place of methylation which occurs in 2- and 3-pyridinecarboxylic esters and 2) the formation of dimethyl 3,3′-bipyridine-4,4′-dicarboxylate (dimerization) and 4-pyridylmethanol (reduction).

The photoreaction of **1** is dependent on the concentration of added sulfuric acid and on the concentration of the substrate itself.

Figure 1 shows the effect of the concentration of sulfuric acid on the photoreaction. In the lower concentrations of sulfuric acid, hydroxymethylation occurs exclusively. As the concentration of sulfuric acid increases, hydroxymethylation is suppressed and methoxylation becomes dominant. This shows that non-protonated **1** undergoes only hydroxymethylation and protonated **1** undergoes methoxylation and hydroxymethylation.

The photo-methoxylation of **1** shows a remarkable concentration dependence of the substrate (Fig. 2). A similar concentration dependence was observed in the photo-methoxylation of methyl 2-pyridinecarboxylate and a kinetic analysis revealed that the photo-methoxylation of 2-pyridinecarboxylic ester proceeds *via* an excimer of the substrate.[3] The similarity of the concentration dependences in the photo-methoxylations of 2- and 4-pyridinecarboxylic esters suggests the participation of an excited dimer in the formation of **3**.

The inhibition of photo-methoxylation of **1** by aromatic hydrocarbons is very similar to that of 2-pyridinecarboxylic ester.[3] Photo-methoxylation at the 2-position under nitrogen atmosphere is inhibited by anthracene effectively as is shown in a Stern-Volmer plot in Fig. 3.[11] Similar inhibitions are observed for *trans*-1,3-pentadiene, naphthalene, triphenylene, azulene, and even for benzene which is considered as a triplet sensitizer. The efficiencies for the quenching of the formation of **3** by the additives correlate very well with the ionization potentials of the additives (Fig. 4). These facts can be explained by the quenching of an excimer *via* an electron transfer (from aromatic hydrocarbons to **1**) mechanism proposed by Caldwell *et al.*[12]

Hydroxymethylation should originate from an excited monomer in the singlet excited state, because it is not inhibited by anthracene as is shown in Fig. 3.

Photo-hydroxymethylation should be initiated by the hydrogen abstraction by an excited **1** from methanol. The radical pair thus formed combines to give an addition product which is converted to 4-pyridylmethanol either *via* disproportionation or *via* a kind of oxidation.

Mechanism for the photo-methoxylation and the hydroxymethylation of **1** is summarized in Scheme 1.

Although the bipyridine formation (a kind of dimerization) and the reduction of the ester carbonyl to alcohol are characteristic for the photoreaction of **1**, the detailed analyses of the mechanism for the formation of these products could not be done, because their yields are very low.

Photo-methoxylation at the 3-Position under O_2. The UV-irradiation of **1** in methanol in the presence of sulfuric acid under O_2 gives methyl 3-methoxy-4-pyridinecarboxylate (**2**) selectively. The results summarized in Table 2 indicate that the yields of the products are changed by the addition of oxygen. When the solution is deoxyganated by bubbling nitrogen, the methoxylation at the 2-position becomes dominant. As the partial pressure of oxygen becomes higher, the methoxylation at the 3-position remarkably increases, while the methoxylation and the hydroxymethylation at the 2-position as well as the rate of decomposition of **1** are suppressed.

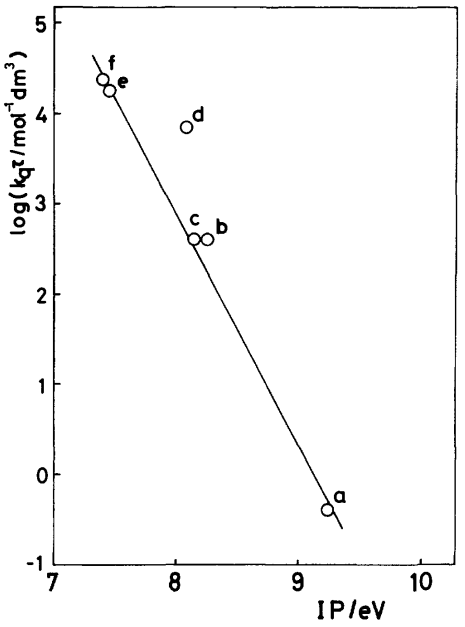

Fig. 4. Relation between $k_q\tau$ for the quenching of photo-methoxylation at the 2-position and ionization potentials of quenchers. a) benzene, b) *trans*-1,3-pentadiene, c) naphthalene, d) triphenylene, e) anthracene, f) azulene.

Oxygen does not serve as an oxidizing agent of a precursor of **2**, because the addition of $K_3[Fe(CN)_6]$ as an oxidizing agent after the irradiation of **1** under N_2 does not increase the yield of **2** (Table 2). The bubbling of oxygen through the solution which has been irradiated under N_2 causes no increase in the yield of **2**.

Such a dramatic change of photoreactions by oxygen has not been observed in the cases of 2- and 3-pyridinecarboxylic esters for which oxygen only inhibits the photoreactions.[3,4]

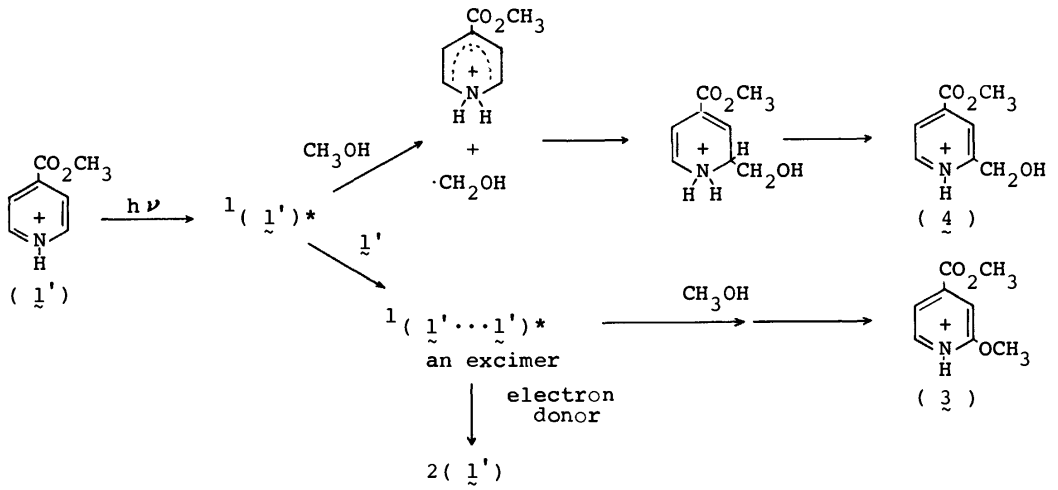
As is shown on Figs. 1 and 2 the methoxylation at the 3-position under O_2 shows dependence on the concentrations of sulfuric acid and **1**. These facts are somewhat similar to the methoxylation at the 2-position under N_2 described in the preceeding section.

However, the effects of additives on the methoxylation at the 3-position are different from those of the methoxylation at the 2-position under N_2. Methoxylation under O_2 is not inhibited by anthracene and by *trans*-1,3-pentadiene, while that under N_2 are inhibited by aromatic hydrocarbons. This fact indicates that the excited states responsible for the two kinds of methoxylation are different in character.

Role of Oxygen in the Photo-methoxylation at the 3-Position. In order to explore the role of oxygen in the promotion of the photo-methoxylation at the 3-position, we have tested the following possibilities for the role of oxygen: 1) the acceleration of intersystem crossing and 2) charge transfer interaction between **1** and oxygen resulting in the electron transfer.

Unexpectedly, no evidence in support of the role of oxygen is observed as described in the following sections.

Possibility of Acceleration of Intersystem Crossing. Oxygen could accelerate intersystem crossing of an excited singlet state of **1** to a triplet state and the triplet would give the methoxylation product at the



Scheme 1. Mechanism of photoreactions of **1** under N_2.

a) [**1**]=0.01 mol dm^{-3}; [H_2SO_4]=0.25 mol dm^{-3}; Irradiation time, 1 h; Temp., 20 °C. b) The solution was purged with gas for 50 min before irradiation. c) O_2 was bubbled after irradiation. d) $K_3[Fe(CN)_6]$ was added after irradiation. e) [**1**]=5×10^{-3} mol dm^{-3}; [H_2SO_4]=1×10^{-1} mol dm^{-3}; Irradiation time, 48 h; Temp., 25.5 °C; Irradiated with monochromatic light of 365 nm.

3-position (**2**). This possibility can be tested by examining the contribution of a triplet state of **2** for the formation of **2**.

Triplet quenchers such as anthracene and *trans*-1,3-pentadiene have little effect on the formation of **2**, as mentioned before. When the irradiation is carried out in the presence of benzophenone, no reaction occurs under either O_2 or N_2. The irradiation is carried out under NO, a paramagnetic gas, but no reaction occurs, as is shown in Table 2.

Possibility of Effect via Charge Transfer Interaction between Substrate and Oxygen. Oxygen is an efficient electron acceptor and can affect the photoreactions *via* charge transfer interaction either in the ground[13-16] or in the excited state. Oxygen could abstract an electron from the substrate and the irradiation of **1** under O_2 may give an electron-deficient intermediate (the postulated intermediate formed in the above process should easily undergo the necleophilic methoxylation). If this process actually occurs, electron acceptors other than oxygen could show the same effect as oxygen. To test this possibility, the irradiation in the presence of several typical electron acceptors in place of oxygen (reduction potential, $E_{1/2}$=−0.94 V *vs.* SCE in CH_3CN)[7] are carried out under N_2 atmosphere. *p*-Dicyanobenzene ($E_{1/2}$=−1.97 V *vs.* Ag/$AgClO_4$ (0.1 mol dm^{-3}) in DMF)[17] and 1,2,4,5-tetracyanobenzene ($E_{1/2}$=−1.02 V *vs.* Ag/$AgClO_4$ (0.1 mol dm^{-3}) in DMF)[17] have almost no effect on the photoreaction of **1**: the electron acceptors neither promote the methoxylation at the 3-position nor inhibit the methoxylation at the 2-position (Table 3).[11]

The above results indicate that the remarkable change of the photoreactivity of **1** by oxygen is not due to the charge transfer interactions between the substrate and oxygen.

Since the concentration dependence curves of the methoxylations under N_2 and O_2 are somewhat different as shown in Fig. 2, it seems that the excimer leading to the methoxylation at the 3-position under O_2 is different in character from that leading to the methoxylation at the 2-position under N_2.

The present study revealed that the oxygen effect observed in the photoreaction of **1** in acidic methanolic solutions can not be categorized as types of oxygen effect which have been generally accepted. The processes of the photo-methoxylation of 4-pyridinecarboxylic ester at the 3-position should contain a novel type of the interaction between oxygen and the excited molecule.

Table 3. Effects of electron acceptors on the photo-methoxylations of **1** under N_2[a]

Experimental

Materials. Commercial methly 4-pyridinecarboxylate (GR grade reagent of Tokyo Kasei Co) was purified by vacuum distillation; bp, 94—95 °C/16.5 mmHg (1 mmHg≈133.322 Pa). Anthracene (standard reagent for elemental analysis made by E. Merck Co.), triphenylene (GR grade reagent of Tokyo Kasei Co.), *trans*-1,3-pentadiene (GR grade reagent of Wako Junyaku Co.), and azulene (GR grade reagent of Tokyo Kasei Co.) were used without further purification. Commercial *p*-dicyanobenzene was purified by recrystallization; mp, 228—229 °C. 1,2,4,5-tetracyanobenzene was kindly supplied by Mr. Haruhiko Tomoda of Shibaura Institute of Technology.

UV-Irradiation for Preparation of Products. Through the solutions of **1** (0.02 mol dm^{-3}, 50 cm^3) containing sulfuric acaid (0.25 mol dm^{-3}) oxygen or nitrogen were bubbled for 50 min before irradiation. The solutions were irradiated with a 17 W low pressure mercury lamp for 25 min at 30 °C.

UV-Irradiation for Study of Mechanism. The solutions of **1** (20 cm^3) containing sulfuric acid and the additives, if necessary, were purged with a gas (O_2, air, or N_2) for 50 min before irradiation. The solutions were irradiated with a 17 W low pressure mercury lamp in a merry-go-round type ap-

paratus at 20°C.

For wavelength effect experiments the irradiation was carried out by using a Shimadzu-Bausch-Lomb Co. monochrometer equipped with a 200 W super high pressure mercury lamp.

Isolation and Identification of Photo-products. After the irradiation the solution was concentrated with a rotary evaporator and neutralized with sodium carbonate solution. The neutralized solution was extracted with ethyl acetate. The products were separated by means of TLC (Plate, GF_{254} Type 60 of E. Merck Co.; developing solvent, ethyl acetate-dichloromethane 3:7 v/v).

Methyl 3-methoxy-4-pyridinecarboxylate (**2**): Mp 55—56.5 °C; IR (KBr disk) 1720 (ester C=O) and 1220 cm^{-1} (C-O-C); ^1H NMR ($CDCl_3$) δ=8.44 (1 H, s), 8.29 (1 H, d, J=4 Hz), 7.55 (1 H, d, J=4 Hz), 4.02 (3H,s), and 3.91 (3H,s); MS (70 ev), m/z (rel intensity) 167 (M^+; 77), 152 (14), 138 (18), 137 (9), 136 (100), 135 (18), 134 (79), 106 (31), 93 (36), and 78 (74), Found: m/z 167.0585. Calcd for $C_8H_9NO_3$: M, 167.0583.

Methyl 2-methoxy-4-pyridinecarboxylate (**3**) was identified by the accordance of its ^1H NMR spectra with those obtained by Deady *et al.*[18]

Methyl 2-hydroxymethyl-4-pyridinecarboxylate(**4**) (mp 67.5—68 °C; lit,[19] 68—69 °C) was identified by means of spectral analyses.

Dimethyl 3,3′-bipyridine-4,4′-dicarboxylate(**5**): Mp 184—187 °C(sub); IR (KBr disk), 1720 cm^{-1} (ester C=O); ^1H NMR ($CDCl_3$) δ=8.95 (1 H, d. J=1.6 Hz), 8.85 (1 H, d, J=5 Hz), 7.87 (1 H, dd, J=1.6 and 5 Hz), and 4.00 (3H, s); Found: C, 61.7; H, 4.7; N, 10.2% M^+, 272. Calcd for $C_{14}H_{12}N_2O_4$: C, 61.76; H, 4.44; N, 10.29%; M, 272.

4-Pyridylmethanol (**6**) was identified by the accordance of gas-chromatographic and spectral properties with those of authentic sample.

Quantitative Analyses of Photo-products. The yields of the products were determined by means of GLC (1.5 m column of 10% PEG 20M on 60—80 mesh Celite 545) with a Shimadzu gas chromatograph model GC 6A and/or by means of HPLC with Shimadzu liquid chromatograph model LC 1 and LC 3A (4.6 mm×25 cm column of Zorbax ODS; eluent, H_2O-MeOH 4:6 v/v).

Spectral Measurments. IR spectra were measured on a Hitachi 215 spectrometer, and ^1H NMR spectra were determined with Hitachi R 22 NMR spectrometer (90M Hz) with tetramethylsilane as an internal standard. MS spectra were recorded on a JEOL D-300 spectrometer.

The authors wish to thanks to Professor L. W. Deady of La Trobe University in Australia and Professor Ichiya Ninomiya of Kobe Women's College of Pharmacy for sending them the spectral data of pyridinecarboxylic esters and Mr. Haruhiko Tomoda of Shibaura Institute of Technology for a gift of 1,2,4,5-tetracyanobenzene.

Ni(0)-Trialkylphosphine Complexes. Efficient Homo-coupling Catalyst for Aryl, Alkenyl, and Heteroaromatic Halides

Kentaro TAKAGI,* Naomi HAYAMA, and Ken SASAKI†

College of Liberal Arts and Science, Okayama University, Tsushima, Okayama 700

†*Department of Polymer Science and Engineering, Kyoto Technical University, Matsugasaki, Kyoto 606*

(Received October 29, 1983)

Bis(trialkylphosphine)nickel(0) generated *in situ* from bis(trialkylphosphine)nickel(II) chloride was found to be an effective catalyst for a homo-coupling of aryl, alkenyl, or heteroaromatic halides with zinc powder. The catalytic reaction proceeded very well in NMP or HMPA solvent under mild conditions to afford dehalogenative-coupling products in good yields.

It has been shown recently that several zerovalent nickel complexes exhibit specific ability in a reductive coupling of aryl or alkenyl halides.[1] These nickel (0) complexes may be divided into two groups according to the kinds of coordinated ligands: One group is characterized by the presence of phosphorus ligands, especially triphenylphosphine, while another is characterized by the absence of them.

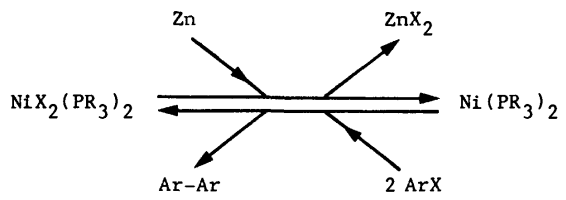
$$2\,ArX + NiL_n \longrightarrow Ar\text{-}Ar + NiX_2L_m$$

L=PPh_3,[2-5] 1,5-COD,[2,6] none (or solvent)[7-9] n,m= 2—4

Although the reactivities of nickel(0) complexes containing trialkylphosphine ligands in the coupling reaction have been little reported,[1] the complexes are much more reactive than triarylphosphine analogs in certain organometallic reactions, such as oxidative additions of aryl or alkenyl halides.[10] It is also known that trialkylphosphine ligands impart better thermal stability to some organometallics than triarylphosphine ligands do.[11] Thus, nickel(0) complexes containing trialkylphosphine ligands are expected to show interesting reactivities in the title reaction. In this paper, we will describe a facile homo-coupling of aryl, alkenyl, and heteroaromatic halides with zinc powder in the presence of catalytic amounts of bis(trialkylphosphine)nickels(0) which are generated *in situ* by a reduction of bis(trialkylphosphine)nickel(II) chlorides, with zinc powder.

Results and Discussion

General Survey of Reaction Conditions and Homo-coupling of Aryl Halides. All zerovalent nickel used in this study were prepared *in situ* by the reduction of divalent nickel complexes with zinc powder.[12] 2—10 mol% of the nickel(II) precursor was used together with an excess of zinc powder intending to render the reaction catalytic in nickel as shown in Scheme 1 (*vide infra*).



Scheme 1.

Following this convenient method, bis(triphenylphosphine)-, bis(triethylphosphine)-, or metallic nickel(0) was generated *in situ*, and their catalytic activities in the homo-coupling of bromobenzene with zinc powder were compared with one other. Hexamethylphosphoric triamide (HMPA) was used as a solvent since *in situ* generated metallic nickel is known to work in the solvent.[7] Runs 1—3 in Table 1 clearly show that bis(triethylphosphine)nickel(0) is the most favorable judging from the turnover number of the catalyst. Encouraged by this result, the catalytic activities of nickel(0)-trialkylphosphine complexes toward various organic halides containing an otherwise inert sp^2-carbon-halogen bond were investigated in detail.

Among the bis(trialkylphosphine)nickel(II)-chloride precursors examined, both triethylphosphine (PEt_3) and tributylphosphine (PBu_3) complexes gave biphenyl in better yields than either 1,2-bis(diethylphosphino)ethane ($Et_2PCH_2CH_2PEt_2$) or tricyclohexylphosphine (PCy_3) complex (Runs 7, 12, 14—16). The addition of two molar equivalents of tributylphosphine retarded the reaction with bis(tributylphosphine)nickel(II) chloride considerably (Runs 12 and 13).[13] As solvent for this reaction, *N*-methyl-2-pyrrolidone (NMP) as well as HMPA were effective, whereas other solvents like 1,1,2,2-tetramethylurea (TMU), *N*,*N*-dimethylformamide (DMF), acetonitrile (AN), or tetrahydrofuran (THF) were less effective (Runs 3, 7—11). Throughout the entire research, we prefered to use NMP unless otherwise noted since no special care need in the handling of this solvent in contrast with HMPA.[14] The addition of potassium iodide was effective for a smooth catalytic reaction (Runs 5 and 6).

The reaction of iodobenzene proceeded more readily than that of bromobenzene (Runs 5 and 7), whereas that of chlorobenzene did not react to completion even at elevated temperatures like 80 °C (Runs 17 and 18). Several functional groups such as ester, ketone, or alkyl were compatible with this reaction and a bulky substituent did not much alter the total reactivity (Runs 19—21). Thus, 2,2′-dibenzoylbiphenyl was readily obtained from 2-iodobenzophenone at 30 °C in a good yield.

Homo-coupling of Alkenyl Halides. The reaction of alkenyl bromides also proceeded very well under mild conditions to afford conjugated alkadienes in good yields as shown in Table 2. Interesting stereochemistry was observed in the reaction of (*E*)- or (*Z*)-β-bromostyrene: Only one of the two double bonds in the produced alkadiene retained the configuration of the

alkenyl halide (Runs 26 and 27). Thus, for example, (*E*)-β-bromostyrene afforded (*E,E*)-1,4-diphenyl-1,3-butadiene mainly with a small amount of (*E,Z*)-isomer, but no (*Z,Z*)-isomer. The fact that third isomers ((*E,E*)-isomer from (Z)-alkenyl halide and (*Z,Z*)-isomer from (*E*)-alkenyl halide) were obtained from neither (*E*)- nor (*Z*)-β-bromostyrene seems to indicate that cis,trans-isomerization of the alkenyl group does not occur on nickel. Therefore, it may be speculated that the isomerization happened on the transfered-alkenyl ligand at

33	3-Iodopyridine	HMPA	40	4	0
34	2-Iodopyridine	HMPA	40	4	0

a) In the presence of 0.25 mmol (Runs 22, 24—28, 32—34) or 2 mmol (Runs 23, 29—31) of organic halide in 0.3 ml (Runs 22, 24—28, 32—34) or 4 ml (Runs 23, 29—31) of solvent under nitrogen. The molar ratio of the component was as follows: RX/$NiCl_2(PEt_3)_2$/Zn/KI=1.0/0.04/1.0/2.0 (Runs 22—27) or 1.0/0.1/1.5/2.0 (Runs 28—34). b) Yields were determined by GLC using internal standards. Yields in parentheses were isolated ones. c) *Z*/*E*=98/2. d) (*E,E*) : (*E,Z*) : (*Z,Z*). e) *Z*/*E*<1/99.

the stage of disproportionation between two oxidative-addition adducts to produce a diorganonickel species (*vide infra*).

Homo-coupling of Heteroaromatic Halides. The homo-coupling of 2- or 3-bromofuran proceeded well in HMPA solvent to afford the corresponding dimer in good yield (Runs 28 and 29). On the other hand, neither reactions of 2- nor 3-bromothiophene proceeded to completion under conditions similar to those adopted above; however both iodothiophenes afforded dimers in good yields (Runs 30—32). In the case of 2- or 3-halopyridine, neither bromo nor iodo compounds afforded any of the corresponding dimers (Runs 33 and 34). Thus, the order of decreasing reactivities of heteroaromatic halides in the nickel(0)-catalyzed homo-coupling with zinc powder is 3-furyl≧2-furyl>2-thienyl, 3-thienyl>2-pyridyl, 3-pyridyl. Since, in a series of substituted halobenzenes, electron-withdrawing substituents usually enhance the reactivities in the nickel(0)-promoted homo-coupling,[2,4,7,9] the least reactivities of halopyridines were unexpected judging from the fact that halopyridines have the most electron deficient heterocycles among the examined compounds.[15] The observed difference in reactivities might suggest that not only a term of electron density but also other terms such as coordinating abilities of hetero atoms to nickel(0) and/or -(II) species must be considered as well when the reactivities of a series of heteroaromatic halides are compared.

Reaction Path. The results presented above lead to the following equations as the most plausible sequences of the reaction. The bis(trialkylphosphine)-nickel(0) which comes from the reduction of bis(trialkylphosphine)nickel(II) chloride with zinc powder

$$NiCl_2(PR'_3)_2 + Zn \longrightarrow Ni(PR'_3)_2 + ZnCl_2 \quad (1)$$

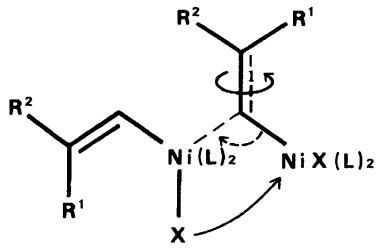
$$Ni(PR'_3)_2 + RX \rightleftarrows \underset{\mathbf{1}}{NiX(R)(PR'_3)_2} \quad (2)$$

$$2\,NiX(R)(PR'_3)_2 \longrightarrow \underset{\mathbf{2}}{Ni(R)_2(PR'_3)_2} + NiX_2(PR'_3)_2 \quad (3)$$

$$Ni(R)_2(PR'_3)_2 \longrightarrow R_2 + Ni(PR'_3)_2 \quad (4)$$

(Eq. 1) readily reacts with aryl, alkenyl, or some heteroaromatic halides to give an oxidative-addition adduct (**1**) (Eq. 2). Following this, the disproportionation between the two adducts occurs to give a nickel(II)-halide complex and a diorganonickel(II) species (**2**) (Eq. 3) which subsequently yields a dimer (Eq. 4). This type of decomposition is well-established and is not catalytic by nature.[16] To ensure the catalytic cycle, the original nickel(0) must be regenerated from the nickel(II) thus formed, and zinc powder in at least a stoichiometric quantity is required.

It is well-known that oxidative addition of alkenyl halides towards various low valent transition metal complexes proceeds with retention of configuration[17] and it is also believed that reductive elimination from various organometallic compounds proceeds again with retention of configuration of the alkenyl ligands.[18] Thus, observed partial cis,trans-isomerization in the reaction of alkenyl halides probably happened at the stage of disproportionation on the trans-



fered alkenyl ligand (*vide ante*).[19]

Experimental

All reagents including zinc powder (purchased from Kanto Chemicals) were used directly as obtained commercially, unless otherwise noted. The solvents were distilled and were dried over a Molecular Sieve (3A). The bis(trialkylphosphine)-nickel(II) chlorides were prepared by previously reported method.[20] 2-Iodobenzophenone,[21] (*E*)-,[22] or (*Z*)-β-bromostyrene,[23] 2-bromo-1,1-diphenylethene,[24] 2-,[25] or 3-iodopyridine,[26] and 3-iodothiophene[27] were prepared according to procedures in the literatures. A Hitachi 160 gas chromatograph was used for the GLC analysis. ^{1}H NMR spectra were obtained on a JOEL PMX 60 spectrometer.

General Procedure for Homo-coupling. Preparation of Dimethyl 3,3′-Biphenyldicarboxylate: A mixture of methyl *m*-bromobenzoate (430 mg, 2 mmol), bis(triethylphosphine)-nickel(II) chloride (29.3 mg, 0.08 mmol), zinc powder (134 mg, 2 mmol), potassium iodide (664 mg, 4 mmol), and NMP (4 ml) was evacuated, flushed with nitrogen, and kept at 30 °C for 3 h with stirring. To the resulting mixture, dilute hydrochloric acid (0.1 mol dm^{-3}, 30 ml) was added. The organic materials were extracted with two 20 ml portions of ether, washed with three 30 ml portions of aqueous sodium chloride, and dried over anhydrous sodium sulfate. Evaporation of the solvent gave 247 mg of dimethyl 3,3′-biphenyldicarboxylate (91%) which was proved to be essentially pure and not contaminated by triethylphosphine by NMR and GLC analysis. Mp 99.5—101 °C (lit,[28] 104 °C). Recrystallization from ethanol gave 217 mg (80%) of the biaryl. Mp 102—103 °C. Found: C, 71.03; H, 5.26%. Calcd for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22%.

4,4′-Dimethylbiphenyl: Mp 121—121.5 °C (lit,[29] 121 °C). Found: C, 92.36; H, 7.82%. Calcd for $C_{14}H_{14}$: C, 92.26; H, 7.74%.

2,2′-Dibenzoylbiphenyl: Mp 169.5—170.5 °C (lit,[30] 171 °C). Found: C, 86.15; H, 5.18%. Calcd for $C_{26}H_{18}O_2$: C, 86.15; H, 5.02%.

1,1,4,4-Tetraphenyl-1,3-butadiene: Mp 198.5—199.5 °C (lit,[31] 207—210 °C). Found: C, 93.96; H, 6.31%. Calcd for $C_{28}H_{22}$: C, 93.81; H, 6.19%

Dimethyl 2,2′-Bifuryl-5,5′dicarboxylate: Mp 228—229 °C (lit,[32] 233—234 °C). Found: C, 57.42; H, 3.98%. Calcd for $C_{12}H_{10}O_6$: C, 57.61; H, 4.03%.

3,3′-Bithienyl: Mp 133—134 °C (lit,[33] 130—132 °C). Found: C, 58.17; H, 3.69%. Calcd for $C_8H_6S_2$: C, 57.80; H, 3.64%.

2,2′-Bithienyl: Mp 28—29 °C (lit,[34] 33 °C). Found: C, 57.68; H, 3.67%. Calcd for $C_8H_6S_2$: C, 57.80; H, 3.64%.

Differential Scanning Calorimetric Studies on the Thermal Denaturation of Ribonuclease A in Aqueous 2-Methyl-2,4-pentanediol

Yukihisa FUJITA* and Yukinao NODA

Department of Chemistry, Hyogo College of Medicine, Mukogawa, Nishinomiya, Hyogo 663

(Received October 31, 1983)

The thermal denaturation of ribonuclease A in aqueous solutions of 2-methyl-2,4-pentanediol(MPD) was investigated by differential scanning calorimetry at pH 5.8, *i.e.*, conditions similar to those used to crystallize the protein, and also at pH 3. A two-state reversible denaturation occurred in aqueous MPD up to 50%(v/v) MPD. Under both conditions the denaturation temperature, T_d, decreased almost linearly with increasing MPD concentration; there was a slightly greater effect at pH 5.8. The calorimetric enthalpy, ΔH_d, first increased with increasing MPD concentration and then decreased slightly at MPD concentrations above 20—30%. This behavior is analogous to that observed for organic additives, such as ethanol and dimethyl sulfoxide, with denaturing agents. The plot of ΔH_d against ΔS_d, the denaturation entropy at T_d, gave a linear correlation between these parameters, indicating a close relationship between the MPD-induced unstabilization of the protein and the water structure around the protein molecule. The standard thermodynamic parameters for denaturation, $\Delta G°$, $\Delta H°$, and $\Delta S°$, were calculated from T_d and ΔH_d, assuming a constant heat capacity change. The unstabilizing effect of MPD on the thermal stability of the protein results from that the increase in $\Delta H°$, induced by MPD, is compensated by a large increase in $\Delta S°$, with a resulting decrease in $\Delta G°$; it is in accord with an effect on solvent ordering around the exposed nonpolar groups of the protein. It also indicates a temperature dependence of the MPD effect on the protein stability.

Differential scanning calorimetry(DSC)** is a useful tool for measuring the thermally induced conformational transition of biopolymers such as proteins and nucleic acids. Application of DSC to the study of protein denaturation has increased the available thermodynamic information on the unfolding process of protein; this has been recently reviewed by Biltonen and Freire[1] and Privalov.[2] The thermogram can be used to calculate the van't Hoff enthalpy[3] or an effective enthalpy[4] for comparison with the calorimetric enthalpy to determine the cooperativity and nature of the denaturation. Furthermore, the other thermodynamic parameters for denaturation, as well as the denaturation temperature and enthalpy, can be calculated without any ambiguous assumptions.[2,5] These studies may lead to an understanding of the nature and magnitude of the forces that stabilize the native conformation of proteins, which has been a major focus of protein research.

Organic solvents such as alcohols and sulfoxides alter the conformation of proteins when added to aqueous protein solutions as result of solvent effects on the local Gibbs energy of conformational stability of the amino acid residues exposed to the surface.[6,7] 2-Methyl-2,4-pentanediol(MPD) is well known as a crystallizing reagent for proteins. For the purpose of X-ray crystal-structure analysis, bovine pancreatic ribonuclease A(RNase A) was crystallized from a mixture of 55% MPD and 45%(v/v) water and the crystals equilibrated with 75% MPD were used.[8] The water-MPD solvent system has a partially hydrophobic character, since the MPD molecule contains six methylene groups, and one might expect it to unstabilize the native structure of a protein. Indeed, monohydric alcohols depress the denaturation temperature of RNase A, a reflection of their unstabilizing action on the native structure, and the unstabilizing effect becomes more effective with an increase in their hydrophobic character.[9] We have observed that ethylene glycol also lowers the denaturation temperature of RNase A at pH 5.[10] In addition, solubility measurements of amino acids in 55% MPD have shown a favorable Gibbs energy of transfer of most amino acid side chains to this medium.[11] This suggests that MPD has a denaturing rather than a crystallizing action.

On the other hand, Bello and Nowoswiat[12,13] have reported that RNase A crystals in 75% MPD possess enzymatic activity and that the same histidine residues are carboxymethylated in the crystal as in aqueous solution, suggesting that the structure of crystalline RNase A appears to be similar to that in aqueous solution. They have further shown from the solubility data of amino acids that the unfolding of RNase A in 55% MPD would have a positive Gibbs energy change at 25 °C.[11] The CD spectra of RNase A in water and 50% MPD are indistinguishable in the far-and near-UV regions.[11,14] Pittz and Timasheff[14] have reported that RNase A is preferentially hydrated in mixtures of water and MPD. According to Bull and Breese,[15] any substance which trends to maintain or increase the hydration of proteins stablize a protein. Indeed, sugars and polyhydric alcohols which induce the preferential hydration of proteins stabilize them against thermal denaturation.[16-19] Therefore, it is of interest to study the effect of MPD on the thermal stability of RNase A.

In this paper, the thermal denaturation of ribonuclease A in aqueous MPD solutions at MPD concentrations up to 50%(v/v) was investigated by DSC at pH 5.8, *i.e.*, conditions similar to those used to crystallize the protein, and at pH 3 and the results are reported.

** Abbreviations used: DSC,differential scanning calorimetry; MPD, 2-methyl-2,4-pentanediol; RNase A, ribonuclease A(bovine pancreatic, EC 3.1.4.22).

Experimental

Materials. Bovine pancreatic ribonuclease A (EC 3.1.4.22) was purchased from Sigma Chemical Co.(type I-A,five-times recrystallized). 2-Methyl-2,4-pentanediol was purified by the method of Bello and Nowoswiat.[12] Other chemicals were reagent grade products from Wako Pure Chemical Industries. The experiments were carried out in either 0.05 mol dm^{-3} acetate or glycine buffer adjusted respectively to pH 5.8 and 3 with 1 mol dm^{-3} HCl. Protein concentrations were determined spectrophotometrically on a Hitachi 323 automatic recording spectrophotometer. The extinction coefficient was assumed to be 7.1 at 277 nm for a 10 mg cm^{-3} RNase A solution.[20] The same value was used at all solvent compositions, since it has been shown that variation of solvent composition from water to 50% MPD does not significantly affect the position of the absorption maximum nor the extinction coefficient of this protein.[21]

DSC Measurements. The thermal denaturation of RNase A was measured on a Seiko Instruments & Electronics SSC-560U differential scanning calorimeter(conduction type) at a heating rate of 1 K min^{-1} and at protein concentrations of 5—10 mg cm^{-3}. The sample solutions were extensively dialyzed at 4 °C against the solvent which was used as reference material, and then hermetically sealed in a silver vessel (0.06 cm^3). The DSC apparatus was calibrated using gallium, benzophenone, palmitic acid, and naphthalene. The area between the transition peak and a base line fitted by inspection was measured with a planimeter and converted to the calorimetric enthalpy of denaturation, ΔH_d, using the calibration constant, 2.29 mJ $mV^{-1}s^{-1}$, and the molecular weight of 13700 for RNase A. The denaturation temperature, T_d, was estimated from the temperature at which the area of the transition peak was divided into halves by assuming that the area under the peak was proportional to the amount denatured. The difference between the obtained T_d and the temperature of maximal heat flow, T_p, did not exceed 0.5 K in every measurement because of the nearly symmetrical nature of the transition peak. Privalov and Khechinashivili[4] have reported that T_d was lower than T_p by approximately 0.7 K. For each solvent composition, these thermodynamic parameters were evaluated as the averaged value of five or more experiments. Temperatures have experiment errors of ±0.1 °C. The ΔH_d values have maximum expected errors of ±5% including errors in sample preparation, calibration constant, and reproduciblity.

Results and Discussion

Representative DSC scans for the thermal denaturation of RNase A in aqueous MPD solutions at pH 5.8 are shown in Fig. 1. The DSC curves shown correspond to denaturation of a protein solution of 8 mg cm^{-3} and MPD concentrations of 0, 20, and 50%(v/v). In every measurement, a reproducible endothermic peak was observed occurring over a temperature width of 19—22 K. The increase in MPD content leads to a shift of the transition peak towards lower temperature and variation of the peak area. The endothermal slope of the base line in the pre- and post-transition regions which was observed in the DSC curves obtained at MPD concentrations below 40% were typical features of globular proteins, indicating that the temperature coefficients of the heat capacities of the native and denatured states are positive. As can be seen from this figure, the DSC curve obtained at 50% MPD exhibited only a slightly exothermal slope

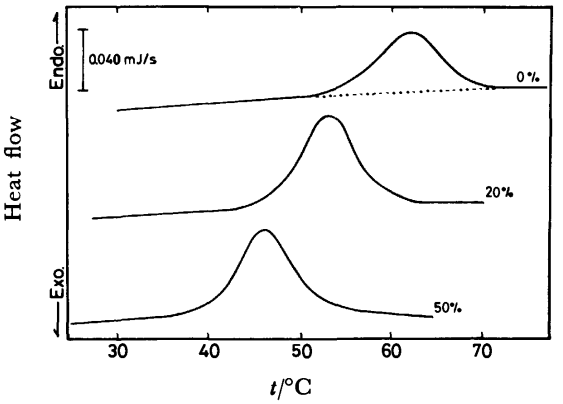

Fig. 1. DSC curves for the thermal denaturation of RNase A in aqueous MPD solutions at pH 5.8. Protein concentration is a 8 mg cm^{-3} and MPD concentrations are 0, 20, and 50% (v/v). The dotted line in the top figure shows the base line assumed in the transition region for the determination of the thermodynamic parameters of denaturation.

of the base line in the post-transition region; this was probably a reflection of partial aggregation of the denatured protein. A further addition of MPD brought about a remarkable increase in the exothermal slope of the base line and an extreme decrease in the solubility of the protein. At MPD contents more than 50%, therefore, the thermodynamic parameters for denaturation could not be estimated exactly.

The reversibility of the thermal denaturation of RNase A in MPD-water mixtures was confirmed by reheating the protein solution after rapidly cooling from the first scan, although the reversible nature of the denaturation of RNase A in aqueous solution has been well established.[4,22-25] The thermal denaturation was almost completely reversible, 98±5%, in aqueous MPD solutions at MPD concentrations up to 50%. The denaturation temperature was scarcely influenced by heating rates slower than 1 K min^{-1}, allowing equilibrium analysis of the data. The ΔH_d values obtained in aqueous buffer solutions were 370±9 kJ mol^{-1} at pH 3 and 428±17 kJ mol^{-1} at pH 5.8. These values are in very good agreement with those reported by Tsong *et al.*[24] and Privalov *et al.*[25] from calorimetric experiments at similar pH values. However, the T_d value in glycine buffer at pH 3, 53.5±0.1 °C, is considerably higher compared to the data of Tsong *et al.*[24] and Privalov *et al.*[25] The value obtained in acetate buffer at pH 5.8, 61.5±0.1 °C, is in good accord with those obtained by Tsong *et al.*,[24] Crescenzi and Delben[26] from DSC measurements, and Konishi and Scheraga[27] from spectrophotometric measurements at similar pH, but it is slightly lower than those reported by Privalov *et al.*[25] at pH 5.5 and Jacobson and Turner[28] from DSC measurements at pH 5. Although the reason for the differences in T_d is not clear, a number of factors such as protein concentration, ionic strength, specific buffer effect, purity of the protein sample (contamination), and heating rate could contribute to the differences. For example, Tsong *et al.*[24] have shown that the T_d of RNase A in aqueous buffer at pH 2.8 increases by 4.2 K when the protein con-

centration is increased from 0.1 to 2.7%(w/w).

The calorimetric transition profile permits assessment of the validity of the two-state theory of denaturation for this protein. If the transition does not involve the formation of thermodynamically stable intermediates, the shape of the transition profile is dictated by the van't Hoff equation. In this case, the effective enthalpy of denaturation, ΔH_{eff}, was evaluated by applying an approximated expression,[25]

$$\Delta H_{eff} = 4RT_d^2/\Delta T_{1/2}$$

where $\Delta T_{1/2}$ is the half-width of the transition peak. The ratio of calorimetric to effective enthalpies of denaturation, $\Delta H_d/\Delta H_{eff}$, showed near-unity value, 1.02±0.04, meaning that the thermal denaturation of RNase A in aqueous MPD solutions is very nearly a two-state process.

Figure 2 shows the dependence of the denaturation temperature on the MPD concentration at pH 3 and at pH 5.8. Under both conditions the T_d decreases monotonously with an increase in the MPD concentration. It is evident that MPD unstabilizes RNase A against thermal denaturation. This is consistant with the expectation based on the hydrophobic character of MPD and on the results of our investigation with ethylene glycol.[10] Therefore, the thermal unstabilization of RNase A by MPD appears to be responsible for the hydrophobic character of solvent induced by the addition of MPD. Needless to say, the T_d values at pH 5.8 which is the pH near the isoelectric point of this protein are higher than those at pH 3. The lowering of T_d by MPD is slightly larger at pH 5.8 than at pH 3, suggesting the temperature dependence of the thermally unstabilizing effect of MPD on the protein. The dependence of the calorimetric enthalpy of denaturation on the MPD concentration is shown in Fig. 3. The error bar shown in the figure is the standard deviation of the data. The denaturation enthalpy exhibits a maximum, that is, the ΔH_d first increases with increasing the concentration of MPD and then decreases slightly at MPD concentrations above approximately 30%(v/v), corresponding to about 2.3 mol dm^{-3}. A similar trend of ΔH_d has been observed for the thermal denaturation of RNase A with dimethylsulfoxide[28] and lysozyme with monohydric alcohols[3,29] and with sulfoxides.[30] These organic solvents strongly unstabilize these proteins against thermal denaturation.

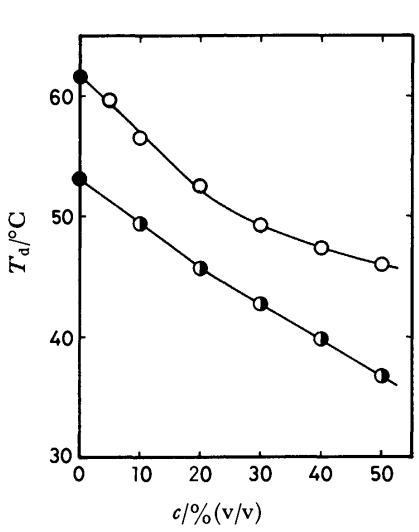

Fig. 2. Variation of the denaturation temperature, T_d, with the concentration of MPD at pH 5.8 (○) and at pH 3 (◑).
The symbol ● refers to the buffer solution without MPD.

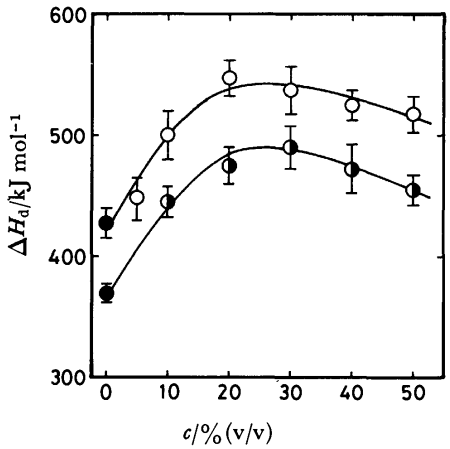

Fig. 3. Variation of the calorimetric enthalpy of denaturation, ΔH_d, with the concentration of MPD. The symbols used are identical with those in Fig. 2. The error bar shows the standard deviation of the data.

As is evident from Figs. 2 and 3, the dependence of ΔH_d on T_d is analogous to each other under both conditions; ΔH_d passes through a maximum with increasing temperature. The similarity of the temperature dependences of ΔH_d under both conditions, pH 5.8 and 3, suggests that the thermal unstabilization of RNase A induced by MPD is not directly dependent on the pH. Furthermore, the dependence of ΔH_d on T_d in the presence of MPD differs drastically from that described by Privalov[2] for variation of T_d induced by variation of the pH and addition of guanidine hydrochloride. He has shown that the denaturation enthalpy is a linear function of the denaturation temperature under all conditions. This means that the mechanism of the MPD-induced unstabilization is different, at least, from that induced by denaturants such as guanidine hydrochloride and urea.

In Fig. 4, the denaturation enthalpy is plotted against the denaturation entropy at the denaturation temperature, $\Delta S_d(=\Delta H_d/T_d)$. A linear correlation between these thermodynamic parameters suggests that the unstabilization by MPD on the thermal stability of RNase A is closely related to the water structure around the protein molecule.[31] The compensation temperature, which is defined as the slope of the graph, is about 300 K. This value is within the temperature range of 250 to 320 K observed for many processes.

The equilibrium constant of denaturation can also be obtained directly from the thermogram, since the area under the transition peak is proportional to the amount of the protein denatured. The equilibrium constant, K, at temperature T may be taken as $Q_T/(Q-Q_T)$, where Q is the total area of the transition peak and Q_T is the partial area up to temperature T. For

the present three-component system, the dependence of the equilibrium constant of denaturation on the solvent variables is ascribed to the difference in the preferential binding of solvent compositions between the native and denatured states.[32,33] The logarithm of K obtained at pH 5.8 thus is plotted against the logarithm of the MPD concentration in Fig. 5. The molarity unit was used instead of activity on the assumption that the activity coefficient is unity, since there is no activity datum for MPD in water. The slope of the lines is a positive, 3.09±0.07, and nearly temperature independent within the experiment error. This indicates that the binding of MPD to the protein increases upon denaturation. In fact, the increase in the protein surface on denaturation is generated by exposing the nonpolar residues buried in the interior of the native protein and by breaking peptide-peptide hydrogen bonds in the native state and replacing them by peptide-water hydrogen bonds. The resultant increase in the surface area of the denatured protein probably contributes to an increase in the extent of the hydrophobic interactions between the nonpolar groups of the protein and the nonpolar moiety of MPD.

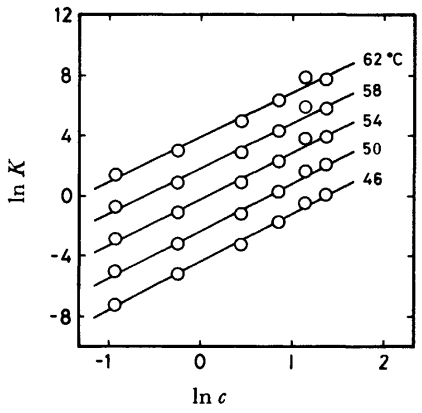

Fig. 5. Wyman plots of the effect of MPD on the thermal denaturation of RNase A at several temperatures.
The number at the right end of each line shows the temperature.

A more quantitative estimation of the MPD effect on the thermal stability of RNase A may be given by comparison of the thermodynamic parameters of denaturation, $\Delta G°$, $\Delta H°$, and $\Delta S°$, at identical temperatures. These have not been reported previously for this solvent system. Assuming that the heat capacity change of denaturation, ΔC_p, is independent of temperature, standard thermodynamic parameters at any temperature, T, can be calculated by the equations.[3,4]

$$\Delta H° = \Delta H_d - \Delta C_p(T_d - T)$$
$$\Delta S° = \Delta H_d/T_d - \Delta C_p \ln(T_d/T)$$
$$\Delta G° = \Delta H° - T\Delta S°$$

For the calculation, ΔC_p in MPD-water mixtures was assumed to be identical with that in aqueous buffer, 5.02 kJ K^{-1} mol^{-1}, since, unfortunately it can not be determined accurately in the present study. This assumption will not cause significant error in the standard thermodynamic parameters when T is close to T_d. Using the data obtained at pH 5.8, therefore, the standard thermodynamic parameters of denaturation were calculated at 53 °C, which is near the midpoint of the range, 46.0 to 61.5 °C, of the T_d obtained at pH 5.8 and were plotted as a function of the MPD concentration in Fig. 6. It is evident that $\Delta G°$ decreases monotonously with increasing MPD concentration. On the other hand, $\Delta H°$ and $\Delta S°$ increase gradually with an increase in the MPD content and tend to flatter at the MPD concentrations above 20%(v/v). In the thermal denaturation of RNase A, the increase in $\Delta H°$ induced by MPD is compensated by a large increase in $\Delta S°$, with a resulting decrease in $\Delta G°$. Therefore, the thermal unstabilization of RNase A by MPD seems to be dominantly produced by an entropic rather than an enthalpic effect, suggesting the possibility of some kind of solvent-disordering effect around the protein. These

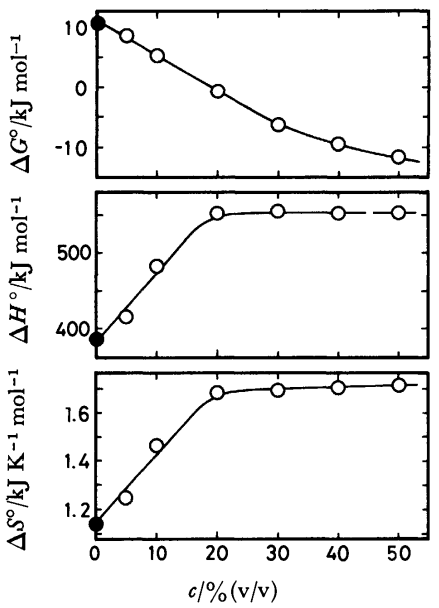

Fig. 6. Variation of the standard thermodynamic parameters of denaturation, $\Delta G°$, $\Delta H°$, and $\Delta S°$, with the concentration of MPD at 53°C.
The symbols ● and ○ refer to the aqueous and the mixed solvents at pH 5.8, respectively.

results are similar to the observation by Brandts[34] that, at a given temperature, $\Delta H°$ and $\Delta S°$ are much larger for the denaturation of chymotrypsinogen in ethanol -water mixtures than in water. Brandts and Hunt[22] have also shown that $\Delta H°$ of the thermal denaturation of RNase in the same solvent system increases with increasing ethanol content, with a maximum around an ethanol concentration of 20%(v/v). At present, the unstabilization of proteins by the addition of alcohols has been explained in terms of their effect on the structure of the water in contact with the nonpolar residues and the direct interaction of alcohol with the protein, which cause weakening the hydrophobic interactions between the nonpolar residue of protein.[7,22] Although RNase A is preferentially hydrated in MPD-water mixtures at low temperature near room temperature,[14] it is not clear at present whether MPD is preferentially bound to the protein or not at elevated temperatures which the thermal denaturation occurs, but, at least, the binding of MPD to the protein increases upon denaturation. A decrease in solvent ordering around the protein and the consequent reduction of the hydrophobic effect when MPD is added to the medium would render more favorable the exposure to solvent of hydrophobic groups buried in the interior of the native protein.

The unstabilizing effect of MPD is consistent with our expectation based on previous studies of the thermal denaturation of lysozyme in aqueous solutions of monohydric alcohols[29] and ethylene glycol[19] and RNase A in aqueous ethylene glycol.[10] However, Pittz and Bello[11] have concluded from the solubility data of amino acids that the unfolding of RNase A in 55% MPD has a positive Gibbs energy change at 25 °C, that is, a stabilizing effect of MPD on the protein. The study of the interactions between RNase A and solvent components in MPD-water mixtures at pH 5.8 by differential refractometry and light scattering has shown that the protein is preferentially hydrated at all solvent compositions up to 50%(v/v) MPD.[14] According to Bull and Breese,[15] any substance which trends to increase the hydration of proteins stabilize a protein. These findings suggests the stabilization of the native protein by MPD at low temperatures near room temperature and the temperature dependence of the MPD effect on solvent ordering around the protein. Thus, in order to examine the temperature dependence of the MPD effect on the thermal stability of RNase A, the $\Delta G°$ at each solvent composition was calculated at several temperatures in the transition region. As expected, it was found that the $\Delta G°$ value increased with a decrease in temperature and further that the decrease in $\Delta G°$ by MPD became reduced with decreasing temperature. Therefore, the temperature dependence of $\Delta G°$ at each MPD content was extrapolated to 25 °C and the resulting value of $\Delta G°$ was plotted against the MPD concentration in Fig. 7. At high temperature, as shown in Fig. 6, MPD is quite effective in decreasing the Gibbs energy change of denaturation. However, at low temperature, MPD acts differently even at a qualitative level, *i.e.*, it behaves as a rather stabilizing agent for native RNase A at low MPD concentrations, almost independent of the pH. Although this conclusion depends to some extent on the validity of the extrapolation, this qualitative

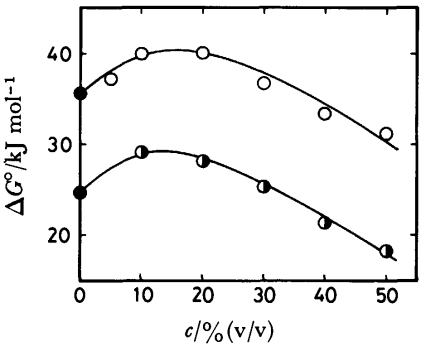

Fig. 7. Variation of $\Delta G°$ with MPD concentration at 25°C.
The symbols used are identical with those in Fig. 2.

conclusion appears to be justified, as the temperature range of extrapolation is short and the effect is large. Moreover, the native protein is too stable at 25 °C and pH 3 to permit direct measurement of the denaturation. Such behavior of $\Delta G°$ has also been found for the denaturation of RNase A in aqueous ethanol solution.[22] This implies that relatively nonpolar organic additives, which have hitherto been considered to be only denaturing agents, might show somewhat the same behavior at low temperature. Indeed, we observed for the thermal denaturation of RNase A in aqueous solutions of ethylene glycol at different pH values that ethylene glycol decreased the denaturation temperature at high temperature, near 60 °C, but increased it at lower temperature, near 40 °C.

These results may be explained on the basis of solvent ordering effect, similarly to that proposed by Brandts and Hunt[22] for the stabilizing effect of ethanol at low temperature and at low ethanol concentration. According to their hypothesis, ethanol replaces ordered water molecules around exposed hydrophobic groups, both solvent components becoming part of the solvent sheath which surrounds the nonpolar side chains of the protein.[34-36] In the case of ethanol, this structure is disrupted at temperatures near room temperature, permitting the formation of hydrophobic contacts between the nonpolar moiety of the alcohol and the nonpolar groups of the protein and leading to the unstabilization of the protein. In the case of MPD, such a solvation sheath around the exposed nonpolar groups of the protein should remain intact up to relatively high temperature, at least, near 25 °C, since the hydrophobicity of MPD appears to be smaller than that of ethanol.

Asymmetric Hydrogenation of Dehydroamino Acids and Dehydrodipeptides with Rhodium(I)-modified DIOP Catalysts

Takamichi YAMAGISHI,* Masanobu YATAGAI, Hidetoshi HATAKEYAMA, and Mitsuhiko HIDA
Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received November 9, 1983)

(−)-DIOP was modified in two ways: i), Introduction of a large aromatic substituent at the dioxolane ring of (-)-DIOP and ii), replacement of one diphenylphosphino group by diarylphosphino group to give unsymmetrical DIOPs. Modification at the dioxolane ring had a small effect on the asymmetric induction by DIOP in the hydrogenation. Modification at the phosphino group affected the stereocontrol by the ligand and the unsymmetrical DIOP with di-2-naphthylphosphino group gave higher optical yields than (−)-DIOP for the hydrogenation of α-acetamidocinnamic acid and dehydrodipeptides.

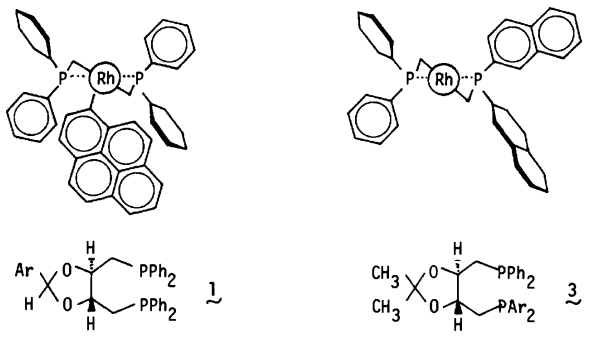
Asymmetric hydrogenation of dehydroamino acid derivatives has been intensively studied using many chiral diphosphine or diphosphinite ligands. DIOP, the first chiral diphosphine reported in the literature,[1] has been widely used because of its ease of preparation and its effectiveness for asymmetric hydrogenation of various substrates, but the optical yields of hydrogenation reported are about 80% e.e. at most.[1,2] Many modifications of DIOP have been reported;[2a,3] only a few ligands could give a little higher stereoselectivity than the DIOP in the hydrogenation of α-acetamidocinnamic acid.

The authors have modified (−)-DIOP in two ways (Scheme 1):

i) Introduction of a large aromatic substituent on the dioxolane ring of (−)-DIOP (compound **1**).

ii) Modification at the phosphino group of (−)-DIOP (compound **3**). The former would cause a change in face and edge conformation of the phenyl groups on phosphorus atoms of the ligand by steric repulsion between the aromatic substituent and the methylene unit adjacent to the phosphino group. The latter affords unsymmetrical DIOPs with a diphenylphosphino group at one side and a diarylphosphino group at the other side. This modification would provide a significant change in the steric and electronic factors of the bidentate ligand. The unsymmetrical DIOP coordinated onto Rh(I) would provide different degrees of congestion at two apical sites of the complex,[4] while prochiral substrates will generally coordinate unsymmetrically onto rhodium. Therefore, the unsymmetrical DIOP may allow more preferable fitting of the prochiral substrate than symmetrical DIOP[5] at the step of face-selection of the substrate.

Using two types of modifiefd DIOPs, the asymmetric hydrogenation of dehydroamino acid derivatives and dehydrodipeptides was studied. The effect of modification was large in the case of unsymmetrical DIOP with 2-naphthyl substituent.



Scheme 1.

Results and Discussion

The modified DIOPs examined in this paper are listed in Table 1. As DIOP derivatives modified at the dioxolane ring, two derivatives (**1a** and **1b**) were prepared by the phosphination of acetals derived from corresponding aromatic aldehydes and 1,4-di-*O*-tosyl-L-threitol. In the hydrogenation, cationic rhodium(I) complexes, [Rh(diphosphine)(nbd)]$^+BF_4^-$ (nbd: norbornadiene), were used as catalysts.

Unsymmetrical DIOPs (**3a—3d**) were prepared by two-step phosphination of 2,3-*O*-isopropylidene-1,4-di-*O*-tosyl-L-threitol (ditosylate) using $LiPPh_2$ and $LiPAr_2$ successively (Scheme 2). For the monophosphination of ditosylate, lithium diphenylphosphide was

used in 0.5 molar excess to ditosylate in order to consume ditosylate completely. Extraction of by-products such as (−)-DIOP or tetraphenyldiphosphane (Ph_2P-PPh_2) from the reaction products with hot hexane left monophosphine **2** as a viscous oil. Monophosphine **2** was phosphinated by lithium diarylphosphide to give unsymmetrical DIOPs. As these DIOPs were viscous oil, they were converted to cationic rhodium(I) complexes and purified by recrystallization.

Circular Dichroism Spectra. The circular dichroism (CD) spectra for [Rh(diphosphine)(nbd)]$^+BF_4^-$ complexes are shown in Figs. 1 and 2. Though modification at the dioxolane ring of (−)-DIOP gave a relatively small change in the CD spectra (Fig. 1), CD spectra of unsymmetrical DIOP complexes were strongly dependent on the aryl substituent in the phosphino group. The intensity of CD spectra near 350 nm

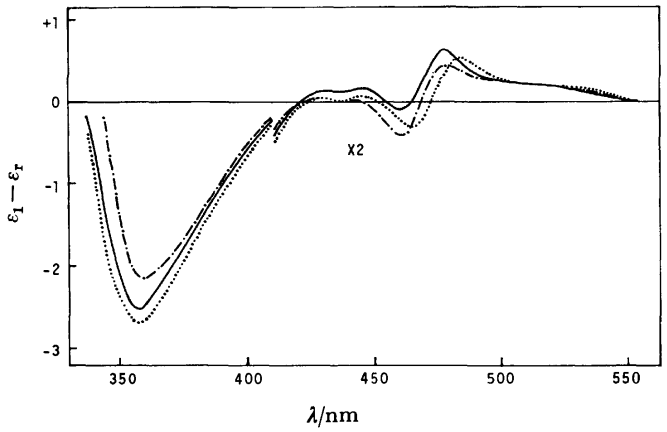

Fig. 1. CD spectra of cationic Rh(I) complexes of DIOP derivatives modified at the dioxolane ring in methanol solution.
——: [Rh((−)-DIOP)(nbd)]$^+BF_4^-$; ·····: [Rh(**1a**)(nbd)]$^+BF_4^-$; —·—: [Rh(**1b**)(nbd)]$^+BF_4^-$.

of the complexes of **3a**—**3d** was strongest for the complex of **3c** and least strong for the complex of **3d**, thus suggesting a different stereoelectronic effect of the aryl substituent in the ligands.

Hydrogenation with Modified DIOPs. Asymmetric hydrogenations of dehydroamino acid derivatives using cationic complex of **1a** or **1b** were compared with those by (−)-DIOP complex. As for the reaction rate, no apparent difference was observed between (−)-DIOP and **1a** or **1b**. The optical yields were decreased slightly in the order of (−)-DIOP, **1a** and **1b** (for example, optical yields for the reaction of α-acetamidocinnamic acid were 79, 79, and 70% e.e., respectively). A CPK model of the cationic complex coordinated by **1a** or **1b** suggested a steric repulsion between the aromatic substituent and the methylene unit adjacent to the phosphino group. It will cause a change of the face and edge conformation of phenyl groups of the ligand to alter the steric control, but the obtained results would indicate that the change in the face and edge conformation was not so large even in the case of **1b** with a pyrene ring. In the reactions of methyl esters of α-acetamidocinnamic acid and α-benzamidocinnamic acid, however, **1a** gave higher optical yields than those by DIOP.

In the case of cationic rhodium complexes, modification at the dioxolane ring of DIOP gave generally a small negative effect on the stereoselection. On the other hand, neutral rhodium(I) complexes prepared from $[Rh(cod)Cl]_2$ and modified DIOPs (**1a** and **1b**) *in situ* gave higher optical yields in the reaction of α-acetamidocinnamic acid than the catalyst from $[Rh(cod)Cl]_2$ and (−)-DIOP (Optical yields were 77, 77 and 72% e.e., respectively). This result would indicate that the structures of neutral chlororhodium-diphosphine complexes are different from the square planar cationic complexes.[6] Cationic rhodium(I)-**1a**-α-acetamidocinnamic acid and neutral chlororhodium(I)-**1a**-α-acetamidocinnamic acid systems showed different absorption maxima corresponding to d-d transition in ethanol-benzene(2:1) solution (Fig. 3).

The introduction of aromatic substituent on the dioxolane ring of DIOP had a small effect on the steric control by DIOP in the hydrogenation of dehydroamino

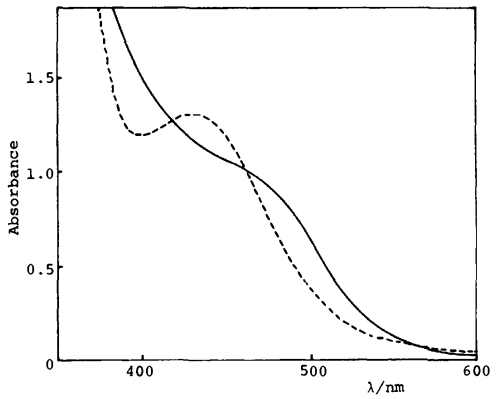

Fig. 3. Absorption spectra of Rh(I)-**1a**-α-acetamidocinnamic acid in ethanol-benzene(2/1).
——: cationic Rh(I)-**1a**-α-acetamidocinnamic acid; ----: neutral Rh(I)Cl-**1a**-α-acetamidocinnamic acid.

acid derivatives. Therefore, it will be necessary to introduce larger ring systems to cause a significant change in the face and edge conformation of the phenyl groups of the ligand.[7]

Results of hydrogenation of dehydroamino acids using unsymmetrical DIOPs (**3a—3d**) are summarized in Table 2. As shown in the Table, modification at the phosphino group influenced the optical yields depending on the combination of the ligand and substrate, though the (*R*)-selectivity held for all ligands. As for α-acetamidocinnamic acid, **3a** and **3d** afforded higher optical yields than DIOP did; **3d** gave an especially high yield about 90% e.e., suggesting the increased stereocontrol by the 2-naphthyl group. For isopropyl α-acetamidocinnamate, however, **3d** was less effective than (−)-DIOP. It is likely that the less electron-donating di-2-naphthylphosphino group favors the coordination of carbonyl oxygen in amido group of the substrate in the trans position on the rhodium complex, thus olefinic double bond occupying the cis position to the di-2-naphthylphosphino group.[4] So, bulky isopropyl group of ester would lower the stereoselectivity by the steric repulsion between naphthyl substituent of **3d** and isopropyl group of ester. For α-acetamidoacrylic acid **3d** gave only low optical yield. **3b** with *p*-methoxyphenyl group gave generally low optical yields, though the hydrogenation itself proceeded faster than the reaction with DIOP or **3a**. Using Rh(I)-DIOP catalysts, α-benzamidocinnamic acid was reduced with much lower optical yields than α-acetamidocinnamic acid, and the decrease in optical yields was large with **3a** or **3b** catalysts. In the case of **3a** or **3b** with an electron-donating substituent carbonyl oxygen in amido group of the substrate would occupy the cis position to the diarylphosphino group of **3a** or **3b**. Thus, substituent on the phenyl group of **3a** or **3b** would increase the steric repulsion with benzoyl group of the substrate. In the case of α-acetamidoacrylic acid, the difference between the steric factors by **3a** and **3b** seems to be not so large. Therefore, the large difference in optical yields between **3a** and **3b** for α-acetamidoacrylic acid would suggest that not only the steric effect but also the electronic effect by electron-donating substituent on the phenyl group played a role in the stereoselection.

Table 2. Asymmetric hydrogenation of dehydroamino acid derivatives with Rh(I)-unsymmetrical DIOP catalysts[a]

Substrate[b]	% e.e.[c]				
	(−)-DIOP	**3a**	**3b**	**3c**	**3d**
C_6H_5, $NHCOCH_3$, H, $COOH$	79	83	68	63	88
C_6H_5, $NHCOCH_3$, H, $COOCH(CH_3)_2$	85	84	71	59	78
C_6H_5, $NHCOC_6H_5$, H, $COOH$	62	55	40	—	—
H, $NHCOCH_3$, H, $COOH$	77	64	55	—	47

a) Hydrogenations were performed with cationic Rh(I) complexes in ethanol-benzene (2/1) under atmospheric hydrogen pressure at 20 °C. b) Substrate/Rh=200. c) Optical yields (% e.e.) were determined from the specific rotation of the product and that of optically pure substance.[2e,9] Absolute configuration of the products was (*R*) in every case.

In the CD spectra of the Rh(I)-unsymmetrical DIOP complexes, **3c** with 1-naphthyl groups showed the strongest CD spectra, suggesting a large stereoelectronic effect by 1-naphthyl substituent on the rhodium complex, but the rate of hydrogenation using **3c** was slow and the stereoselectivity was poor, presumably because of a very crowded structure around the phosphorus atom of the ligand.

The results of dehydrodipeptide reductions using modified DIOPs (**1a**, **1b**, and **3a—3d**) are shown in Table 3. In the reaction of Ac-ΔPhe-(*S*)-Phe-OH, which has a large steric factor, **1b** with a pyrene ring at the dioxolane ring gave a higher optical yield (64% d.e.) than DIOP (58% d.e.) and the reaction with **1b** pro-

Table 3. Asymmetric hydrogenation of dehydrodipeptides with Rh(I)-modified DIOP catalysts[a]

Dehydrodipeptide[b]	Diphosphine	Time / min	Conv. / %	(*S,S*)/(*R,S*) or (*S,R*)/(*R,R*)	% d.e.
Ac-ΔPhe-(*S*)-Phe-OH	(−)-DIOP	10	100	21/79	58
	1a	10	100	24/76	52
	1b	8	100	18/82	64
	3a	10	100	22/78	56

	3d	5	100	3/97	94
Ac-ΔPhe-(*R*)-Phe-OMe	(−)-DIOP	5	100	6/94	88
	3d	5	100	3/97	94

a) Hydrogenations were performed with cationic Rh(I) complexes in ethanol under atmospheric hydrogen pressure at 20 °C. b) Dehydrodipeptide/Rh=50.

ceeded faster than that with DIOP or **1a**, though **1b** was less effective than DIOP or **1a** for the reactions of dehydroamino acid derivatives. In the case of dehydrodipeptides, carboxyl group in the substrate would weakly occupy the apical site of the complex, and this will favor the stereoselection.[8] For Ac-ΔPhe-(*R*)-Phe-OH, DIOP and **1b** gave almost the same optical yields (92 and 90% d.e., respectively). Unsymmetrical **3a** and **3b** showed similar stereoselectivities to that by DIOP. It is noted that **3d** with 2-naphthyl groups afforded a higher optical yield (72% d.e.). We think that the di-2-naphthylphosphino group caused different congestions at two apical sites of the complex and had a different electronic effect on rhodium from that caused by the diphenylphosphino group. This would affect the fitting of dehydrodipeptide onto rhodium and the succeeding reactions on the complex. The effectiveness of **3d** was observed also in the cases of Ac-ΔPhe-(*S*)-Ala-OMe and Ac-ΔPhe-(*R*)-Phe-OMe to give high optical yields, more than 90% d.e..

Among the modified DIOPs, unsymmetrical DIOPs affected the stereocontrol in the asymmetric hydrogenation and the unsymmetrical DIOP with 2-naphthyl groups was effective for the hydrogenation of α-acetamidocinnamic acid and dehydrodipeptides. It will be possible to widen the applicability of the unsymmetrical ligands for other catalytic asymmetric reactions by selecting the diarylphosphino group.

Experimental

General Procedures. ^{1}H NMR spectra were recorded on a HITACHI R-24 spectrometer. Absorption spectra and CD spectra were recorded on a HITACHI 220A spectrophotometer and on a JASCO J-40A spectropolarimeter, respectively. Optical rotations were measured with a UNION P 101 automatic digital polarimeter.

Materials. α-Acetamidoacrylic and α-acetamidocinnamic acids were commercial products. α-Acylaminocinnamic acid derivatives and *N*-acetyldehydrodipeptides were prepared according to the literature.[2e,11-13] Chlorodiarylphosphines (aryl=*p*-tolyl, *p*-methoxyphenyl, 1-naphthyl, and 2-naphthyl) were prepared by the reaction of sodium diethyl phosphonite with corresponding Grignard reagent[14] followed by the reaction with PCl_3.[15] 2,3-*O*-Isopropylidene-1,4-di-*O*-tosyl-L-threitol,[16] 1,4-di-*O*-tosyl-L-threitol,[17] and (−)-DIOP[1b] were prepared by the methods reported. [Rh(nbd)(acac)] was prepared according to the literature.[18]

*Preparation of DIOP Derivatives Modified at the Dioxolane Ring (**1a** and **1b**).* 1,4-Di-*O*-tosyl-L-threitol was reacted with aromatic aldehyde (2-formylnaphthalene or 1-formylpyrene) in the presence of *p*-toluenesulfonic acid in dry benzene under reflux using a Dean-Stark trap.[17] Recrystallization of the product gave the acetal as white crystals. Phosphination of the acetal was performed in a THF solution using lithium diphenylphosphide. Solvent was evaporated and the residue was recrystallized from THF-ethanol after washing with ethanol to give white needles.

2,3-O-(2-Naphthylmethylene)-1,4-di-O-tosyl-L-thretiol: White crystals from THF-ethanol (42% yield). Mp 120.0—120.8 °C (corr.). ^{1}H NMR($CDCl_3$) δ=7.1—7.9 (15H, m, aromatic H), 5.1 (1H, s, CH), 4.3 (6H, bs, CH and CH_2), 2.36 (3H, s, CH_3), 2.31 (3H, s, CH_3).

2,3-O-(1-Pyrenylmethylene)-1,4-di-O-tosyl-L-threitol: White crystals from benzene-ethanol (55% yield). Mp 54.2—55.0 °C (corr.). ^{1}H NMR($CDCl_3$) δ=6.7—8.1 (22H, m, aromatic H and CH), 4.3 (6H, m, CH and CH_2), 2.3 (3H, s, CH_3), 2.2 (3H, s, CH_3).

*(−)-2,3-O-(2-Naphthylmethylene)-1,4-bis(diphenylphosphino)-2,3-butanediol (**1a**)*: White needles (66% yield). Mp 122—123 °C (corr., sealed tube). $[\alpha]_D^{25}$ −48.8° (*c* 0.48, C_6H_6). ^{1}H NMR($CDCl_3$) δ=7.2—7.9 (27H, m, aromatic H), 6.0 (1H, s, CH), 4.0—4.4 (2H, m, CH), 2.55 (4H, d, CH_2).

*(−)-2,3-O-(1-Pyrenylmethylene)-1,4-bis(diphenylphosphino)-2,3-butanediol (**1b**)*: White needles (66% yield). Mp 158.5—159.1 °C (corr., sealed tube). $[\alpha]_D^{25}$ −70.0° (*c* 0.55, C_6H_6). ^{1}H NMR($CDCl_3$) δ=7.8—8.3 (9H, m, aromatic H), 7.1—7.6 (20H, m, aromatic H), 6.8 (1H, s, CH), 4.1—4.6 (2H, m, CH), 2.5—2.7 (4H, q, CH_2).

*Preparation of Unsymmetrical DIOPs (**3a**—**3d**).* *(−)-2,3-O-Isopropylidene-4-diphenylphosphino-1-O-tosyl-1,2,3-butanetriol (**2**)*: To a THF solution of 2,3-*O*-isopropylidene-1,4-di-*O*-tosyl-L-threitol (ditosylate), 0.5 molar excess of lithium diphenylphosphide in THF was added slowly over 8 h and the mixture was stirred for another 12 h. Evaporation of solvent and extraction of the residue with dry benzene gave an oily crude product. Extraction of by-products (DIOP and tetraphenyldiphosphane) from the oily product with hot hexane gave monophosphine **2** as a very viscous oil containing a small amount of ditosylate (less than 5 mol%). 49% yield. ^{1}H NMR($CDCl_3$) δ=7.2—7.9 (14H, m, aromatic H), 3.6—4.2 (4H, m, CH and CH_2), 2.3—2.5 (5H, d, CH_2 and CH_3), 1.4 (3H, s, CH_3), 1.2 (3H, s, CH_3).

Phosphination of **2** was performed by adding a THF solution of **2** slowly to 0.2—0.4 molar excess of lithium diarylphosphide in THF. Solvent was evaporated and the residue was extracted with ether. The ether extract was concentrated. After removing tetraaryldiphosphane (Ar_2P-PAr_2) and unreacted **2** by cooling at −20 °C, unsymmetrical DIOP was precipitated by adding hexane to the ethereal mother liquor and cooling at −20 °C.

*(−)-2,3-O-Isopropylidene-1-diphenylphosphino-4-(di-p-tolylphosphino)-2,3-butanediol (**3a**)*: Viscous oil (68% yield). $[\alpha]_D^{25}$ −6.6° (*c* 0.7, C_6H_6). ^{1}H NMR($CDCl_3$) δ=6.9—7.6(18H, m, aromatic H), 3.7—4.2 (2H, m, CH), 2.2—2.5 (10H, m, CH_2 and CH_3), 1.3 (6H, s, CH_3).

*(−)-2,3-O-Isopropylidene-1-diphenylphosphino-4-[bis(p-methoxyphenyl)phosphino]-2,3-butanediol (**3b**)*: Viscous oil (*ca.* 40% yield). ^{1}H NMR ($CDCl_3$) δ=6.8—7.7 (18H, m, aromatic H), 3.7—4.0 (2H, m, CH), 3.8 (6H, s, OCH_3), 2.9 (4H, m, CH_2), 1.35 (3H, s, CH_3), 1.25 (3H, s, CH_3).

*(−)-2,3-O-Isopropylidene-1-diphenylphosphino-4-(di-1-naphthylphosphino)-2,3-butanediol (**3c**)*: Pale yellow solid (*ca.* 25% yield). ^{1}H NMR($CDCl_3$) δ=7.0—8.8 (25H, m, aromatic H), 4.0—4.3 (2H, m, CH), 2.4—2.6 (4H, m, CH_2), 1.35 (6H, bs, CH_3).

*(−)-2,3-O-Isopropylidene-1-diphenylphosphino-4-(di-2-naphthylphosphino)-2,3-butanediol (**3d**)*: Viscous oil (*ca.* 25% yield). ^{1}H NMR($CDCl_3$) δ=7.0—8.2 (25H, m, aromatic H), 4.0—4.3 (2H, m, CH), 2.4—2.5 (4H, m, CH_2), 1.4 (3H, s, CH_3), 1.3 (3H, s, CH_3).

TLC analysis and NMR spectra showed that **3c** and **3d** contained corresponding tetranaphthyldiphosphane (about 10%).

Preparation of Cationic Rhodium(I) Complexes. Cationic Rh(I) complexes [Rh(diphosphine)(nbd)]$^+BF_4^-$ were prepared from [Rh(nbd)(acac)], modified DIOP and $NaBF_4$ in CH_2Cl_2-H_2O two phase system,[19] and the complexes were recrystallized from methanol-ether.

*[Rh(**1a**)(nbd)]$^+BF_4^-$*: Orange-red crystals (60% yield). ^{1}H NMR($CDCl_3$) δ=7.3—7.8 (27H, m, aromatic H), 5.9 (1H, s, CH), 4.5 (4H, m, olefinic H), 3.9—4.1 (4H, m, CH), 2.8—3.1 (4H, m, CH_2), 1.5 (2H, m, CH_2).

*[Rh(**1b**)(nbd)]$^+BF_4^-$*: Bright red crystals (82% yield). ^{1}H NMR($CDCl_3$) δ=7.2—8.0 (29H, m, aromtic H), 6.8 (1H,

s, CH), 4.4—4.6 (4H, m, olefinic H), 3.8—4.1 (4H, m, CH), 2.9—3.2 (4H, m, CH_2), 1.4 (2H, m, CH_2).

[Rh(3a)(nbd)]$^+BF_4^-$: Orange-red crystals (60% yield). ^1H NMR($CDCl_3$) δ=7.2—7.8 (18H, m, aromatic H), 4.4—4.7 (4H, m, olefinic H), 3.5—4.2 (4H, m, CH), 2.4—3.0 (4H, m, CH_2), 2.45 (3H, s, CH_3), 2.50 (3H, s, CH_3), 1.55 (2H, m, CH_2), 1.2 (6H, s, CH_3).

[Rh(3b)(nbd)]$^+BF_4^-$: Orange crystals (69% yield). ^1H NMR($CDCl_3$) δ=7.0—7.8 (18H, m, aromatic H), 4.3—4.6 (4H, m, olefinic H), 3.7—4.0 (4H, m, CH), 3.85 (3H, s, OCH_3), 3.90 (3H, s, OCH_3), 2.2—2.8 (4H, m, CH_2), 1.5 (2H, m, CH_2), 1.2 (6H, s, CH_3).

[Rh(3c)(nbd)]$^+BF_4^-$: Orange crystals (39% yield). ^1H NMR($CDCl_3$) δ=7.0—8.5 (24H, m, aromatic H), 4.3—4.8 (4H, m, olefinic H), 3.8—4.2 (4H, m, CH), 2.5 (4H, m, CH_2), 1.4 (2H, m, CH_2), 1.2 (3H, s, CH_3), 1.1 (3H, s, CH_3).

[Rh(3d)(nbd)]$^+BF_4^-$: Orange crystals (32% yield). ^1H NMR($CDCl_3$) δ=7.2—8.2 (24H, m, aromatic H), 4.5—4.9 (4H, m, olefinic H), 3.8—4.2 (4H, m, CH), 2.3—2.4 (4H, m, CH_2), 1.6 (2H, m, CH_2), 1.3 (3H, s, CH_3), 1.2 (3H, s, CH_3).

Hydrogenations. Typically, dehydroamino acid derivatives (2 mmol) was hydrogenated using 0.01 mmol of cationic Rh(I) catalyst in 10 cm^3 benzene-ethanol(2/1). Optical yields were determined polarimetrically. In the case of dehydrodipeptides, 1 mmol of dehydrodipeptide was hydrogenated with 0.02 mmol of Rh(I) catalyst in 3 cm^3 ethanol. Diastereomeric excess and the chirality, newly formed, were determined by ^1H NMR with shift reagent.

Absorption Spectra Measurements. Hydrogen was introduced to a 10 mm cell containing [Rh(**1a**)(nbd)]$^+BF_4^-$ or neutral chlororhodium complex from $[Rh(nbd)Cl]_2$ and **1a** (**1a**/Rh=1.1) in ethanol-benzene. The cell was shaken until the absorption of coordinated olefin disappeared. Then the cell was evacuated and α-acetamidocinnamic acid solution was added under nitrogen (Rh: 0.5 mmol/dm^3).

CD Spectra Measurements. CD spectra of cationic Rh(I) complexes [Rh(diphosphine)(nbd)]$^+BF_4^-$ were recorded in methanol solution (0.5 mmol/dm^3) using a 10 mm cell under nitrogen.

The authors express their gratitude to Professor M. Kobayashi and Dr. N. Kamigata, Tokyo Metropolitan University, for CD spectroscopy.

Total Synthesis of Racemic and Optically Active Coronafacic Acids

Susumu OHIRA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received November 17, 1983)

(±)-Methyl 3-ethyl-4-oxotricyclo[4.3.0.0^{1,5}]nonane-5-carboxylate (**4**), prepared by the stereoselective alkylation of methyl 4-oxotricyclo[4.3.0.0^{1,5}]nonane-5-carboxylate, was reduced with zinc borohydride, and the resultant hydroxy ester was treated with *p*-toluenesulfonyl chloride to give a mixture of α,β-unsaturated esters, having hydrindan skeletons. The mixture was submitted to hydroboration-oxidation to afford a keto ester, which was hydrolyzed to (±)-coronafacic acid (**2**). A diastereomeric mixture of *l*-menthyl 3-ethyl-4-oxotricyclo-[4.3.0.0^{1,5}]nonane-5-carboxylates, prepared by a modification of the synthesis of (±)-**4**, was resolved by column chromatography on silica gel, and each diastereomer was converted into (+)-**2** and (−)-**2** in a similar way as (±)-**2**.

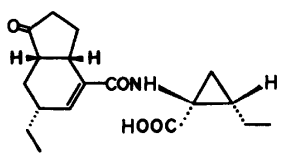
Coronatine (**1**), a phytotoxin produced by *Pseudomonas syringae pv. atropurpurea*, induces chlorosis on the leaves of Italian ryegrass and a hypertrophy on potato tuber tissues at a very low concentration.[1] The structure of **1** was established by the combination of a single-crystal X-ray analysis of coronafacic acid (**2**)[2a] and partial synthesis of **1**, which was achieved from natural **2** and synthesized coronamic acid (**3**).[2b] Determination of the absolute configuration of **1** was based on the ORD measurement of **2**[2b] and X-ray diffraction analysis of the *N*-acetyl derivative of the enantiomer of **3**.[2c] The first synthesis of (±)-**2**,[3a] which means the total synthesis of coronatine in a formal sense, was reported by Ichihara *et al.* in 1977. Since then many different syntheses have been accomplished constructing the hydrindan skeleton by characteristic methods, namely the intermolecular or intramolecular Diels-Alder reaction,[3,4b] the anionic oxy-Cope rearrangement,[4a] and the palladium-catalyzed cyclization followed by the Dieckmann condensation.[5] In this paper, I describe the total synthesis of racemic and optically active coronafacic acids,[6] including the transformation of the tricyclo[4.3.0.0^{1,5}]nonane system to the hydrindan skeleton *via* the cleavage of the cyclopropane ring.

Synthesis of (±)-Coronafacic Acid.[6a] As C_{7a}-epimer of **2** is easily convertible to **2**,[2-4] the major stereochemical problem in the synthesis of (±)-**2** was the introduction of the C_6-ethyl group *trans* to the C_{3a}-proton. A tricyclo[4.3.0.0^{1,5}]nonane derivative (**4**) appeared to be a suitable synthetic intermediate, because (±)-**4** was expected to be thermodynamically more stable than its C_3-epimer (**5**), which may have a significant interaction between the ethyl group and the cyclopropane ring. Transformation of the similar tricyclic compound to the fused bicyclic one was reported by Ruppert and White,[7] although there has been no application to the synthesis of the natural product.

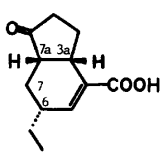
1-Cyclopentenecarbaldehyde (**6**)[8] was reduced with lithium aluminium hydride to give an alcohol (**7**). Treatment of **7** with *p*-toluenesulfonyl chloride (TsCl) under the phase-transfer catalyzed conditions (benzene-aqueous sodium hydroxide)[9] gave a sensitive sulfonate (**8**), which was not obtainable in the standard way (TsCl–pyridine). Without purification, **8** was subjected to reaction with the dianion of methyl acetoacetate, giving a β-keto ester (**9**)[10] in 66% yield from **6**. Treatment of **9** with *p*-toluenesulfonyl azide in acetonitrile in the presence of triethylamine afforded a diazo compound, which was heated in refluxing toluene with a catalytic amount of trimethyl phosphite-copper(I) iodide complex to give a 60% yield of the cycloadduct (±)-**10**.

Alkylation of (±)-**10** with 1 equiv of lithium diisopropylamide (LDA) and ethyl bromide in tetrahydrofuran provided a mixture of the monoalkylation product (±)-**4** and the dialkylation product (±)-**11** in various ratios depending on the reaction conditions. Although (±)-**5** was not produced as was expected, the yield of (±)-**4** was generally unsatisfactory due to production of (±)-**11** and recovery of (±)-**10**. After some considerable investigation, a 68% yield of (±)-**4** was obtained using a small excess of LDA, 4 equiv of hexamethylphosphoric triamide (HMPA) as a cosolvent, and 5 equiv of ethyl iodide in place of the bromide. The stereochemistry of (±)-**4** was confirmed by single-crystal X-ray analysis as shown in Fig 1.[11]

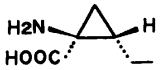
(±)-**4** was reduced with sodium borohydride in methanol to give an epimeric mixtur (*a* 3:1 ratio) of the hydroxy ester (±)-**12** and (±)-**13**; these were separated by chromatography on silica gel. The major product was assumed to be (±)-**12**, produced by the attack of the hydride from the less hindered side. Evidently, the ^{1}H NMR spectrum of the minor product (**13**) showed the CHOH proton at δ 4.06 as a double doublet, coupled with the adjacent methine proton (J= 3.5 Hz) and the OH proton (J=6.5 Hz), suggesting the intramolecular hydrogen bonding between the hydroxyl group and the ester carbonyl group. On



(1)



(2)



(3)

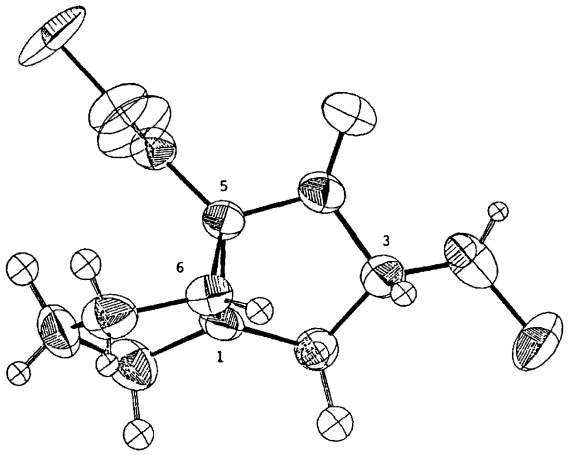


Fig. 1. Computer-generated perspective drawing of compound **4**.

the other hand, the ^{1}H NMR spectrum of the major product (**12**) showed the CHOH proton at δ 4.16 as a doublet with a larger coupling (J=6.5 Hz) than that of the minor product. Reduction of (±)-**4** with zinc borohydride gave a 86% yield of (±)-**12** as a single isolated product by the attack of the hydride from the same side as the ester carbonyl group.[11]

Transformation of (±)-**12** to the fused bicyclic system was attempted using HMPA or TsCl. Treatment with refluxing HMPA for a few minutes, or a large excess of TsCl for a few days at room temperature, afforded an unseparable mixture of α,β-unsaturated esters (±)-**14a—c**, contaminated with the aromatized product (**15**). Their structures were determined by GC-MS spectra and the ^{1}H NMR spectrum of the mixture, which showed the C_1-proton of (±)-**14a** and the C_7-proton of (±)-**14b** at δ 5.17 and 5.40 (each bs), the C_5-proton of (±)-**14a—c** at δ 6.5—6.9 (m), and two aromatic protons of **15** at δ 7.15 and 7.56 (each bs). After standing for a week at room temperature, almost all of the (±)-**14a—c** changed to **15**. When (±)-**12** was treated with 2—3 equiv of TsCl in pyridine at 90 °C for 1 h, a 1:1:1 mixture (glc analysis) of (±)-**14a—c** was obtained without **15**.

The unseparable mixture was then submitted to hydroboration and subsequent oxidation with pyridinium chlorochromate to give a complex mixture, from which a methyl ester of (±)-coronafacic acid (**16**) was isolated in 8% yield based on (±)-**12**. The ^{1}H NMR spectrum of (±)-**16** was identical with that of the methyl ester derived from the natural product. The hydroboration-oxidation process was investigated under various reaction conditions; but the yield of (±)-**16** could not be improved. Epoxidation of (±)-**14a—c** with *m*-chloroperbenzoic acid and subsequent treatment with boron trifluoride etherate afforded an undesired mixture, from which (±)-**16** could not be isolated.

Hydrolysis of (±)-**16** with refluxing aqueous hydrochloric acid[4] gave an 80% yield of (±)-**2**, whose spectral and analytical properties were identical with those of the natural product.[12]

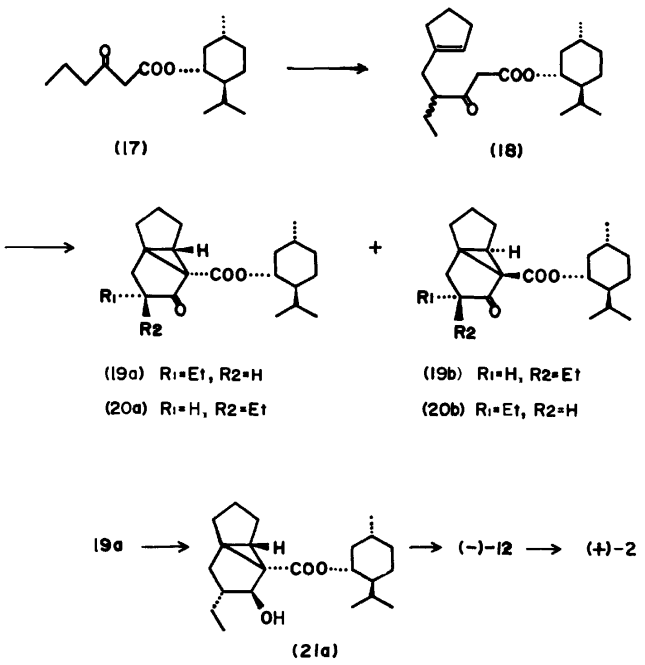
Synthesis of Optically Active Coronafacic Acids.[6b] Although the overall yield of (±)-**2** (0.9% from **6**) was not very satisfactory, the short process fror. (±)-**4** was attractive for the synthesis of optically active coronafacic acids, as there has been no approach to (+)- and/or (−)-**2** in contrast to (+)- and (−)-**3** which were prepared by resolution of the racemate.[2b] It was decided to try the resolution of the *l*-menthyl ester derivative[14] corresponding to (±)-**4**.

To circumvent the late alkylation step (**10**→**4**) in this study, the dianion of *l*-menthyl acetoacetate was first alkylated with 1 equiv of ethyl bromide to give the 3-oxohexanoate (**17**) in 88% yield. Reaction of **8** with the dianion of **17** afforded a 75% yield of a β-keto ester (**18**), whose diazotization and subsequent carbenoid addition gave a stereoisomeric mixture of the desired diastereomers (**19**) and its isomers (**20**) in 56% yield. Isolation of each isomer was difficult; however treatment of the mixture with sodium methoxide in refluxing methanol caused epimerization of **20** to afford only **19**. Fortunately, it could be resolved cleanly by column chromatography on silica gel and recrystallization from methanol gave **19a** and **19b** in a 1:1 ratio. The absolute configurations of **19a** and **19b** became clear after completion of the synthesis of (+)- and (−)-**2**.

Although **19a** could be converted to *l*-menthyl ester of (+)-**2** in three steps as described above, the ester resisted hydrolysis under mild acidic conditions (aqueous hydrochloric acid, aqueous sulfuric acid-acetic acid. To avoid the possibility of epimerization at the C_6-



position under vigorous conditions of hydrolysis, the hydroxy ester (**21a**), which was obtained by reduction of **19a** with zinc borohydride in 90% yield, was converted beforehand into the corresponding methyl ester. Hydrolysis of **21a** was not achieved by refluxing in aqueous sodium hydroxide-methanol or ethanol, but was effected on refluxing with aqueous sodium hydroxide-dimethyl sulfoxide. The resultant carboxylic acid was esterified with ethereal diazomethane to give (−)-**12** in 88% yield from **21a**. By a similar transformation as described for the synthesis of (±)-**2**, (−)-**12** was led to (+)-**2** ($[\alpha]_D^{20}$+109°, lit,[2a] +119°) whose optical rotation showed the same sign as the natural product. (−)-**2** ($[\alpha]_D^{20}$−119°) was obtained from **19b** on a similar four-step process.

Experimental

All melting points were uncorrected. IR spectra were recorded on a Hitachi EPI-G3 spectrometer. The ordinary mass spectra were determined on a Hitachi RMU-6L mass spectrometer, using a direct inlet system with a prove temperature of 60—100 °C, an ionizing energy 70 eV and an accelerating voltage 3.2 kV. The high resolution mass spectra were taken using a Hitachi RMU-7L double focussing mass spectrometer. ^{1}H NMR spectra were recorded on Varian T-60 (60 MHz) and Hitachi R-22 (90 MHz), employing tetramethylsilane as an internal standard. Optical rotations were measured on a Yanako OR-50 polarimeter. Column chromatography and preparative TLC were performed on Merck silica gel 60 (70—230 mesh ASTM) and 60 PF_{254}, respectively.

*Methyl 3-Oxo-5-(1-cyclopentenyl)pentanoate (**9**).* 1-Cyclopentenecarbaldehyde (**6**)[8] (6.79 g, 70.6 mmol) was added to a suspension of lithium aluminium hydride (1.0 g, 26.4 mmol) in anhydrous ether (100 ml), and the reaction mixture was stirred at room temperature for 2 h. After the excess reagent was destroyed with ethyl acetate, aqueous sodium hydroxide was added to the mixture until aluminium oxide separated. The organic layer was washed with brine, and dried ($MgSO_4$). Removal of the solvent gave **7** (6.59 g) as a colorless oil, which was used directly in the next reaction: IR ($CHCl_3$) 3620, 3420 (OH), and 1670 cm^{-1} (-CH=C-); ^{1}H NMR (CCl_4) δ=3.76 (1H, bs, OH), 4.07 (2H, bs, $C\underline{H}_2OH$), and 5.55 (1H, bs, -CH=C-); MS *m/z* (rel intensity) 98 (M^+; 64), 80 (29), 70 (86), 67 (100), 57 (63), and 31 (85).

To a solution of **7** (6.59 g, 67.1 mmol) and *p*-toluenesulfonyl chloride (15.4 g, 80.6 mmol) in benzene (100 ml), was added 30% aqueous sodium hydroxide (100 ml) and benzyltriethylammonium chloride (0.8 g), with vigorous stirring at 20 °C (water bath). After the heterogeneous mixture was stirred for 5 h, the organic layer was washed with water, dil hydrochloric acid and brine, and dried (Na_2SO_4). The solvent was carefully evaporated *in vacuo* at *ca.* 30 °C to give the sensitive *p*-toluenesulfonate **8** as a colorless oil, which was used immediately in the next reaction: ^{1}H NMR (CCl_4) δ=2.43 (3H, s, CH_3), 4.54 (2H, bs, $C\underline{H}_2OTs$), and 5.65 (1H, bs, -CH=C-).

To a suspension of 55% sodium hydride (4.85 g, 111 mmol) in tetrahydrofuran (100 ml), was added a solution of methyl acetoacetate (11.7 g, 101 mmol) in tetrahydrofuran (300 ml) at 0—20 °C, and subsequently 1.6 M (1M=1 mol dm^{-3}) butyllithium in hexane (69 ml, 110 mmol) under nitrogen at −5—0 °C (ice-ethanol bath). To the yellow solution of the dianion, was added a solution of the sulfonate **8** in tetrahydrofuran (200 ml) at 0 °C, and the reaction mixture was stirred for 3 h. After quenching with aqueous ammonium chloride, the solvent was evaporated and the residue was extracted with ether. The organic layer was dried (Na_2SO_4) and evaporated *in vacuo* to give a crude product. Purification of the mixture by column chromatography on silica gel (300 g) using ethyl acetate-hexane (1:3) as eluent, gave **9** (9.09 g, 66% yield from **6**) as an oil: IR ($CHCl_3$) 1740 (ester C=O) and 1710 cm^{-1} (C=O); ^{1}H NMR (CCl_4) δ=3.33 (2H, s, $COCH_2CO$), 3.71 (3H, s, $COOCH_3$), and 5.32 (1H, bs, -CH=C-); MS *m/z* (rel intensity) 196 (M^+; 17), 178 (26), 122 (60), 95 (80), 94 (70), 80 (97), and 79 (100). Found: C, 67.14; H, 8.44%. Calcd for $C_{11}H_{16}O_3$: C, 67.32; H, 8.22%.

*(±)-Methyl 4-Oxoticyclo[4.3.0.0^{1,5}]nonane-5-carboxylate (**10**).* The keto ester **9** (3.39 g, 17.3 mmol) was dissolved in acetonitrile (70 ml) and mixed with triethylamine (2.62 g, 25.9 mmol) and *p*-toluenesulfonyl azide (3.57 g, 19.0 mmol) at room temperature. After standing overnight, the solvent was removed and the residue was treated with ether and water. The organic layer was washed with aqueous sodium hydroxide, water, and brine, and dried (Na_2SO_4). Removal of the solvent gave a crude product as an oil which was dissolved in toluene (200 ml) and refluxed for 5 h with trimethyl phosphite-copper (I) iodide complex (0.5 g). After cooling, the mixture was filtered and evaporated *in vacuo* to give a dark brown oil. Purification of the mixture by column chromatography on silica gel (160 g) using ethyl acetate-hexane (1:3) as eluent, gave (±)-**10** (2.02 g, 60% yield), which was recrystallized from ether-hexane as colorless prisms: Mp 68.5—69.5 °C; IR ($CHCl_3$) 1735 (ester C=O) and 1710 cm^{-1} (C=O); ^{1}H NMR (CCl_4) δ=0.6—1.4 (1H, brm, -CH-) and 3.68 (3H, s, $COOCH_3$); MS *m/z* (rel intensity) 194 (M^+; 10), 166 (36), 162 (100), 152 (48), 135 (28), and 93 (77). Found: C, 67.81; H, 7.38%. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27%.

*(±)-Methyl 3-Ethyl-4-oxotricyclo[4.3.0.0^{1,5}]nonane-5-carboxylate (**4**).* To a solution of lithium diisopropylamide in tetrahydrofuran (20 ml), prepared from diisopropylamine (450 mg, 4.38 mmol) and 1.6 M butyllithium in hexane (2.0 ml, 3.2 mmol) at 0 °C, was added a solution of (±)-**10** (567 mg, 2.93 mmol) and hexamethylphosphoric triamide (2.1 g, 11.7 mmol) in tetrahydrofuran (5 ml). The mixture was stirred for 15 min and ethyl iodide (2.3 g, 16 mmol) was

added to the solution. After stirring at 0 °C for 3 h, the reaction mixture was quenched with aqueous ammonium chloride. The solvent was evaporated *in vacuo* and the residue was extracted with ether. The organic layer was dried (Na_2SO_4) and evaporated *in vacuo* to give a crude product. Purification by column chromatography on silica gel (30 g) using ethyl acetate–hexane (1:5) as eluent, gave (±)-**4** (442 mg, 68% yield), which was recrystallized from ether–hexane as colorless prisms: Mp 71.5—73 °C; IR ($CHCl_3$) 1740 (ester C=O) and 1715 cm^{-1} (C=O); ^1H NMR (CCl_4) δ=0.87 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$) and 3.66 (3H, s, $COOCH_3$); MS *m/z* (rel intensity) 222 (M^+; 12), 194 (80), 166 (100), 152 (54), 134 (36), and 93 (70). Found: C, 69.96; H, 8.12%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

A mixture from less polar fractions was purified by preparative TLC, using ethyl acetate–hexane (1:10) as solvent, to give the dialkylation product (±)-**11** (99 mg) as a colorless oil: IR ($CHCl_3$) 1735 (ester C=O) and 1710 cm^{-1} (C=O); ^1H NMR (CCl_4) δ=0.78 (3H, t, J=6.5 Hz, $CH_2C\underline{H}_3$), 0.83 (3H, t, J=6.5 Hz, $CH_2C\underline{H}_3$), and 3.67 (3H, s, $COOCH_3$); MS *m/z* (rel intensity) 250 (M^+; 3), 222 (19), 190 (10), 166 (100), and 98 (78). Found: C, 72.00; H, 9.10%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

X-Ray Analysis of (±)-4. (±)-**4** crystallized as a monoclinic crystal with a=8.617(2), b=9.737(3), c=15.070(6) Å, β=103.19(3)°. All unique diffraction intensities with $2\theta<50.0°$ were collected in a variable speed ω-scan mode on a Syntex R3 four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation (0.7107 A). 1420 were judged to be observed after correction for Lorentz, polarization, and background effects. A phasing model which was obtained from the program MALTAN[14] was defined using Syntex XTL program system. Full-matrix least-squares refinements with anisotropic temperature factors for the nonhydrogen atoms and isotropic ones for the hydrogen atoms converged to a final R factor of 0.082 for 1420 reflections.

Reduction of (±)-4 with Sodium Borohydride. A stirred solution of (±)-**4** (78 mg, 0.35 mmol) in methanol (3 ml) was treated with sodium borohydride (67 mg, 1.8 mmol) for 2 h at room temperature. After the solvent was removed *in vacuo*, the residue was taken up in ether, washed with dil hydrochloric acid, aqueous sodium hydrogencarbonate and brine, and dried (Na_2SO_4). Removal of the solvent *in vacuo* gave a crude product, which was purified by preparative TLC, developed twice, using ethyl acetate–hexane (1:5) as solvent, to give (±)-**12** (47 mg, 60% yield) and (±)-**13** (17 mg, 22% yield). (±)-**12**: a colorless oil; R_f 0.45 (ethyl acetate–hexane=1:2); IR ($CHCl_3$) 3600 (OH) and 1710 cm^{-1} (ester C=O); ^1H NMR (CCl_4) δ=0.90 (3H, t, J=6 Hz, $CH_2C\underline{H}_3$), 2.61 (1H, bs, OH), 3.71 (3H, s, $COOCH_3$), and 4.16 (1H, d, J=6.5 Hz, $-C\underline{H}OH$); MS *m/z* (rel intensity) 224 (M^+; 14), 206 (18), 191 (25), 177 (43), 165 (48), 147 (56), and 136 (100). Found: C, 69.33; H, 9.16%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%. (±)-**13**: a colorless oil; R_f 0.52 (ethyl acetate–hexane=1:2); IR ($CHCl_3$) 3600 (OH) and 1710 cm^{-1} (C=O); ^1H NMR (CCl_4) δ=2.57 (1H, d, J=6.5 Hz, OH), 3.70 (3H, s, $COOCH_3$), and 4.06 (1H, dd, J=6.5, 3.5 Hz, $-C\underline{H}OH$). Found: C, 69.23; H, 9.12%. Calcd for $C_{13}H_{20}O_3$: C, 69.01; H, 8.99%.

Reduction of (±)-4 with Zinc Borohydride. To a solution of (±)-**4** (155 mg, 0.697 mmol) in ether (5 ml), was added 0.33 M zinc borohydride in ether (2.1 ml, 0.69 mmol) at 0 °C. After stirring for 2 h, the reaction mixture was quenched with ice and dil hydrochloric acid. The organic layer was washed with aqueous sodium hydrogencarbonate and brine, and dried (Na_2SO_4). Removal of the solvent gave a crude product which was purified by preparative TLC, developed twice, using ethyl acetate–hexane (1:5) as solvent, to give (±)-**12** (135 mg, 86% yield).

Methyl Ester of (±)-Coronafacic Acid (16). A solution of (±)-**12** (135 mg, 0.602 mmol) and *p*-toluenesulfonyl chloride (344 mg, 1.80 mmol) in pyridine (2 ml) was stirred at 90 °C under nitrogen for 1 h. The solvent was removed *in vacuo*, and the residue was treated with ether and water. The organic layer was washed with dil hydrochloric acid and brine, and dried (Na_2SO_4). Removal of the solvent gave a crude product, which was purified by preparative TLC, using ethyl acetate–hexane (1:5) as solvent, to give the unseparable mixture of (±)-**14a—c** (93 mg) as a colorless oil: IR ($CHCl_3$) 1710 (ester C=O) and 1630 ($-CH=\overset{1}{C}-$); ^1H NMR (CCl_4) δ=3.66, 3.67 (3H totally, each s, $COOCH_3$), 5.17, 5.40 (each *ca.* 0.3H, bs, C_1-or C_7-olefin proton), and 6.5—6.9 (1H, m, C_5-olefin proton).

To a solution of (±)-**14a—c** (93 mg, 0.46 mmol) in tetrahydrofuran (5 ml) was added 2.6 M borane in tetrahydrofuran (0.6 ml, 1.56 mmol) at 0 °C under nitrogen. The reaction mixture was stirred for 1 h at 0 °C and excess borane was destroyed with a small portion of water. Dichloromethane (10 ml) and pyridinium chlorochromate (0.8 g, 3.6 mmol) was added to the mixture succesively at 0—20 °C, and the mixture was stirred at room temperature for 2 h. The dark brown solution was passed over silica gel using ethyl acetate as eluent. After removal of the solvent, the residue was treated with ether and water. The organic layer was dried (Na_2SO_4) and evaporated *in vacuo* to give a complex mixture of many products. Isolation by preparative TLC, developed three times, using ethyl acetate–hexane (1:8) as solvent, and further purification by preparative TLC, developed twice, using ether–hexane (1:5) as solvent, provided (±)-**16** (11 mg, 8% yield from (±)-**12**), as a colorless oil: IR ($CHCl_3$) 1740 (ester C=O), 1710 (C=O), and 1640 cm^{-1} ($-CH=\overset{1}{C}-$); ^1H NMR ($CDCl_3$: 90 MHz) δ=0.99 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), and 6.93 (1H, bs, $-CH=\overset{1}{C}-$); MS *m/z* (rel intensity) 222 (M^+; 100), 193 (14), 190 (26), 145 (20), 133 (28), and 119 (74). Found: *m/z* 222.1272. Calcd for $C_{13}H_{18}O_3$: M, 222.1255. The ^1H NMR spectrum of (±)-**16** was identical with that of the methyl ester of natural coronafacic acid.

(±)-Coronafacic Acid (2). A suspension of (±)-**16** (12 mg, 0.054 mmol) in 2.4 M hydrochloric acid (10 ml) was refluxed for 2 h with vigorous stirring. After cooling, the mixture was extracted with dichloromethane and the organic layer was dried (Na_2SO_4). The solvent was removed *in vacuo* and the residue was purified by preparative TLC, developed twice, using ethyl acetate–hexane (1:2) as solvent, to give (±)-**2** (9 mg, 80% yield), which was recrystallized from diisopropyl ether as colorless prisms: mp 130—132 °C (lit,[3b] 115—127 °C); IR ($CHCl_3$) 3400—2500 (COOH), 1735 (C=O), 1685 (COOH), and 1635 cm^{-1} ($-CH=\overset{1}{C}-CO$); ^1H NMR ($CDCl_3$: 90 MHz) δ=0.99 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 2.96—3.23 (1H, m, $-\overset{1}{C}=CHC\underline{H}-$), 7.11 (1H, bs, $-\overset{1}{C}=CH-$), and 10.28 (1H, bs, COOH); MS *m/z* (rel intensity) 208 (M^+; 100), 190 (20), 163 (29), 151 (33), 133 (48), 119 (71), 105 (47), 91 (64), and 79 (88). Found: C, 69.13; H, 7.66%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%. The ^1H NMR spectrum of (±)-**2** was identical with that of the natural product. The IR spectrum of (±)-**2** was identical with that of an authentic sample.[12]

l-Menthyl 3-Oxohexanoate (17). A similar procedure to the preparation of **9**, using *l*-menthyl acetoacetate[13] (13.94 g, 58 mmol), 55% sodium hydride (3.04 g, 70 mmol), 1.6 M butyllithium in hexane (40 ml, 64 mmol), and ethyl bromide (7.6 g, 69.7 mmol), gave a crude product, which was chromatographed on silica gel (400 g), using ethyl acetate–hexane (1:30) as eluent, to give **17** (13.7 g, 88% yield) as an oil; $[\alpha]_D^{20}$ −63.5 ° (*c* 0.85, $CHCl_3$); IR ($CHCl_3$) 1730 (ester C=O) and 1705 cm^{-1} (C=O); ^1H NMR (CCl_4) δ=2.47 (2H, t, J=7 Hz, $CH_2C\underline{H}_2CO$), 3.28 (2H, s, $COCH_2CO$), and 4.64 (1H, dt,

J=10, 4 Hz, COOCH–); MS m/z (rel intensity) 268 (M^+; 1), 155 (5), 138 (76), 123 (30), 113 (15), 95 (68), 71 (72), and 43 (100). Found: C, 71.67; H, 10.73%. Calcd for $C_{16}H_{28}O_3$: C, 71.60; H, 10.52%.

1-Menthyl 3-Oxo-4-(1-cyclopentenylmethyl)hexanoate (18). A similar procedure to the preparation of **9**, using **17** (1.29 g, 4.81 mmol), 55% sodium hydride (230 mg, 5.27 mmol), 1.6 M butyllithium in hexane (3.3 ml, 5.3 mmol), and **8** prepared from **7** (380 mg, 3.88 mmol) gave a crude product, which was chromatographed on silica gel (60 g), using ethyl acetate-hexane (1:50) as eluent, to give **18** (1.016 g, 75% yield from **7**) as an oil: IR ($CHCl_3$) 1735 (ester C=O), 1710 (C=O), and 1645 cm^{-1} (–CH=C–), ^1H NMR (CCl_4) δ=2.70 (1H, m, COCH–), 3.27 (2H, s, $COCH_2CO$), 4.67 (1H, m, COOCH–), and 5.35 (1H, bs, –CH=C–); MS m/z (rel intensity) 348 (M^+; 3), 210 (56), 192 (33), 130 (40), 123 (87), 83 (65), and 81 (100). Found: C, 75.51; H, 10.53%. Calcd for $C_{22}H_{36}O_3$: C, 75.81; H, 10.41%.

Preparation of 1-Menthyl 3-Ethyl-4-oxotricyclo[4.3.0.0^{1,5}]-nonane-5-carboxylates (19) and (20). A similar procedure to the preparation of (±)-**10**, using **18** (8.21 g, 23.6 mmol), triethylamine (2.86 g, 28.3mmol), *p*-toluenesulfonyl azide (4.88 g, 24.8 mmol), and a catalytic amount of trimethyl phosphite-copper(I) iodide complex, gave a crude product, which was chromatographed on silica gel (300 g), using ethyl acetate-hexane (1:15) as eluent, to give a mixture of cycloadducts **19** and **20** (4.54 g, 56% yield).

Epimerization of 20 and Resolution of 19. To a solution of sodium methoxide in methanol, prepared by addition of sodium (0.5 g, 22 mmol) into methanol (200 ml), was added the mixture of **19** and **20** (4.20 g, 12.1 mmol), and refluxed for 2 h. After cooling, aqueous ammonium chloride was added to the mixture and the methanol was evaporated *in vacuo*. The residue was extracted with ether and the organic layer was dried (Na_2SO_4). Removal of the solvent gave the mixture of **19a** and **19b**, which was chromatographed on silica gel (200 g) using ether-hexane (1:10) as eluent. Repeated column chromatography on silica gel and final purification by recrystallization from methanol gave pure **19a** (1.65 g, 21% yield from **18**) and **19b** (1.61 g, 21% yield from **18**). **19a**: Mp 70—71 °C (colorless prisms); R_f 0.26 (ether-hexane=1:5); $[\alpha]_D^{20}$ −86.7° (c 4.65, $CHCl_3$); IR (CCl_4) 1740 (ester C=O) and 1720 cm^{-1} (C=O); ^1H NMR (CCl_4) δ=4.65 (1H, dt, J=10, 4 Hz, COOCH–); MS m/z (rel intensity) 346 (M^+; 1), 209 (52), 191 (100), 180 (21), 164 (44), 152 (20), 138 (40), 123 (19), and 95 (45). Found: C, 76.54; H, 10.19%. Calcd for $C_{22}H_{34}O_3$: C, 76.26; H, 9.89%. **19b**: mp 100—101.5 °C (colorless prisms); R_f 0.31 (ether-hexane=1:5); $[\alpha]_D^{20}$ +5.4° (c 3.68, $CHCl_3$); IR (CCl_4) 1740 (ester C=O) and 1715 cm^{-1} (C=O); ^1H NMR (CCl_4) δ=4.62 (1H, dt, J=10, 4 Hz, COOCH–). Found: C, 76.54; H, 9.96%. Calcd for $C_{22}H_{34}O_3$: C, 76.26; H, 9.89%.

Reduction of 19 with Zinc Borohydride. A similar procedure to the reduction of (±)-**4**, using **19a** (1.016 g, 2.93 mmol) and 0.33 M zinc borohydride in ether (6.8 ml, 2.24 mmol), gave a crude product, which was chromatographed on silica gel (50 g), using ethyl acetate-hexane (1:8) as eluent, to give **21a** (0.918 g, 90% yield) as a colorless oil: $[\alpha]_D^{20}$ −67.5° (c 1.53, $CHCl_3$); IR (CCl_4) 3600 (OH) and 1705 cm^{-1} (ester C=O); ^1H NMR (CCl_4) δ=2.26 (1H, s, OH), 4.05 (1H, d, J=6.5 Hz, –CHOH), and 4.68 (1H, dt, J=10, 4 Hz, COOCH–); Found: C, 75.64; H, 10.69%. Calcd for $C_{22}H_{36}O_3$: C, 75.82; H, 10.41%.

Hydrolysis of 21a and Subsequent Esterification. A solution of **21a** (769 mg, 2.21 mmol) in 2.5 M aqueous sodium hydroxide (15 ml) and dimethyl sulfoxide (30 ml) was refluxed for 3 h. After addition of water, the mixture was extracted with ether. The aqueous layer was acidified with crashed ice and 6 M hydrochloric acid, and extracted with ether. The organic layer was washed with brine and dried (Na_2SO_4). Removal of the solvent gave a crude carboxylic acid, which was treated with ethereal diazomethane. After evaporation of the solvent, the residue was purified by column chromatography on silica gel (60 g), using ethyl acetate-hexane (1:5) as eluent, to give (−)-**12** (436 mg, 88% yield) as a colorless oil: $[\alpha]_D^{20}$ −43.5° (c 1.82, $CHCl_3$); the physical data (IR, ^1H NMR, and TLC analysis) of (−)-**12** were identical with those of (±)-**12**. Found: C, 69.72; H, 9.08%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%.

(+)-Coronafacic Acid (2). A similar three-step procedure to the preparation of (±)-**2** from (±)-**12**, using (−)-**12** (1.22 g), gave (+)-**2** (15 mg), which was recrystallized from diisopropyl ether: Mp 142—143 °C (colorless prisms) (authentic sample[12]: 142—143 °C, mmp 142—143 °C, lit,[2a] 125—126 °C); $[\alpha]_D^{20}$ +109° (c 0.75, MeOH, lit,[2a] +119.1°); IR and ^1H NMR spectra were identical with those of the natural product and (±)-**2**. Found: C, 69.09; H, 7.81%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

(−)-Coronafacic Acid (2). A similar five-step procedure to the preparation of (+)-**2** from **19a**, using **19b** (1.151 g), gave (−)-**2** (17 mg), which was recrystallized from diisopropyl ether: Mp 142—143 °C (colorless prisms); $[\alpha]_D^{20}$ −119° (c 0.86, MeOH); IR and ^1H NMR spectra were identical with those of the natural product and (±)-**2**. Found: C, 69.31; H, 7.93%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

The author wishes to express his hearty thanks to Associate Professor Mitsuru Nakayama of Hiroshima University for his encouragement and guidance during the course of this research. The author is grateful to his laboratory staff, for useful suggestions and continual encouragement, and also to Professor Akitami Ichihara, Hokkaido University, for kindly providing him with an authentic sample, as well as spectral data of natural coronafacic acid and its methyl ester. Thanks are also due to Dr. Shizuko Eguchi (MS) and Dr. Sachihiko Imai (NMR), Hiroshima University, for the spectral measurement. The author is grateful to Dr. Hiroshi Nozaki, Okayama University of Science, for the help and advice with X-ray analysis.†

(Received November 17, 1983)

Heteropoly acid (HPA) was used as an oxidant in the Wacker catalyst system. Among the catalyst systems examined, the $PdSO_4$-$H_3PMo_6W_6O_{40}$ catalyst system showed the highest activity with regard to the oxidation of cycloolefins, particularly cyclopentene and cyclohexene, to the corresponding cyclic ketones. The largest total turnover number with respect to Pd^{2+} was found to be 85 in water containing 20% *N*-methylformamide by volume. The initial rate of cyclohexene oxidation was expressed as

$$V_0 = k[\text{Cyclohexene}]^{1.0}[PdSO_4]^{1.0}[\text{HPA}]^0[O_2]^0.$$

The rate-determining step was suggested as being where cyclohexene was oxidized to cyclohexanone by Pd(II) salt. The apparent activation energy was 7.8 kcal mol^{-1} (1 cal=4.18 J). In the catalytic oxidation of cycloolefins (C_nH_{2n-2}: n=5, 6, 7, and 8), the yield of alicyclic ketone decreased as the carbon number n increased. Methyl-substituted cyclohexenes exhibited lower reactivities than cyclohexene.

The Wacker catalyst ($PdCl_2$-$CuCl_2$) is the well-established homogeneous catalyst for olefin oxidation. But there is still the need to improve the conventional Wacker catalyst, because the Cl^- anion in aqueous media causes reactor corrosion and the undesirable formation of chlorinated by-products, particularly from higher olefins. An improvement could be attained by replacing $CuCl_2$ with an oxidant which is easily reoxidized under the reaction conditions.

One candidate for the oxidant is 12-heteropoly acid, because the electrochemical reduction and oxidation of the 12-heteropolyanion proceed reversibly in acidic solutions. They are accompanied by transfer of 2,4,or 6 electrons and retention of the Keggin structure.[1] It has been reported that the redox potential of the 12-heteropoly acid which can play the role of the oxidant in the Wacker catalyst system must be in the range of 0.59—1.229 V[2] or 0.19—1.116 V[3] (*vs.* NHE); *i.e.*, the redox potential of the 12-heteropolyanion should be higher than that of the palladium redox couple Pd^{2+}/Pd^0 and lower than that of the oxygen redox couple O_2/H_2O. The highest redox potentials were measured to be 0.3 V[1] or 0.32 V[3,4] (*vs.* SCE) for $PMo_{12}O_{40}^{3-}$, and 0.50 V[3] (*vs.* SCE) for $PMo_6W_6O_{40}^{3-}$, and 0.28 V[5] (*vs.* SCE) for $PMoW_{11}O_{40}^{3-}$. These values suggest that one can substitute one of the above heteropolyanions for $CuCl_2$ as the oxidant in the Wacker catalyst system.

Recently, it was found that the 12-heteropoly acids can oxidize palladium atoms and that Pd(II) salt-heteropoly acid systems can be used as catalysts for the oxidation of ethylene[2] and 1-butene.[6] We have reported a successful attempt to obtain alicyclic ketones from cycloolefins using a $PdSO_4$-$H_3PMo_6W_6O_{40}$ catalyst system under mild conditions.[7] In this paper, details of the results are described.

Results and Discussion

Catalyst System. Figure 1 shows the initial rates of cyclohexene oxidation and amounts of cyclohexanone produced after 20 h from the start of the reaction as a function of Mo content in the $PdSO_4$-$H_3PMo_nW_{12-n}O_{40}$ catalyst series. The mixed-coordinated heteropoly acid, $H_3PMo_6W_6O_{40}$, was found to be the most active oxidant judging from the initial rate and the amount of cyclohexanone produced.

Figure 2 shows the changes of IR absorption spectra of the heteropoly acid during the oxidation. Each band is assigned according to the literature[8] as follows: 1070 cm^{-1} to P-O stretching (O_p band), 970 cm^{-1} to M=O (M: Mo and W) stretching (O_t band), and 790, 870 cm^{-1} to M-O-M vibration (O_b band). After the reaction proceeded for 20 h, the intensities of the O_p band and the O_b band decreased significantly, while the intensity of the O_t band was almost unchanged. Similar behavior in IR absorption was reported by other wokers[9-11] who concluded that these decreases in intnsity were caused by the reduction of the heteropoly compounds but the Keggin structure was still retained. The IR spectrum of the heteropoly acid used for the reaction is clearly different from those

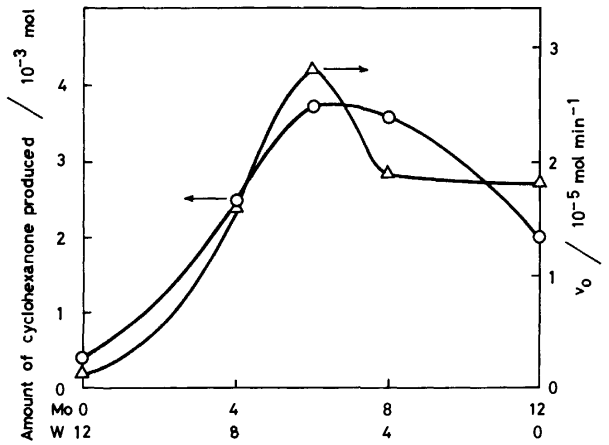

Fig. 1. Activity of $PdSO_4$-$H_3PMo_nW_{12-n}O_{40}$ catalyst system for cyclohexanone production. Each experiment was carried out at 303K for 20h under oxygen at 1 atm using cyclohexene (2.9×10^{-2} mol), $PdSO_4$ (8.3×10^{-3} mol), $H_3PMo_nW_{12-n}O_{40}$ (2.0×10^{-4} mol), and H_2O (10 ml).

of WO_3 and MoO_3. It is unlikely that the heteropoly acid decomposed to the WO_3 and MoO_3 units.

Various Pd(II) salts were tested in the oxidation of cyclohexene and 3-methylcyclohexene using $H_3PMo_6W_6O_{40}$ as the oxidant. Yields of cyclic ketones and total turnover numbers with respect to Pd^{2+} are listed in Table 1. The reaction time in Table 1 means the period of time after which no further oxidation occurred. From the standpoint of the total turnover number and the initial rate, $PdSO_4$ is the most active salt among the Pd(II) salts tested. The amount of cyclohexanone produced decreased in the following order depending upon the kind of counter anion of Pd^{2+};

$$SO_4^{2-} > NO_3^- > CH_3COO^- \geqslant Cl^-.$$

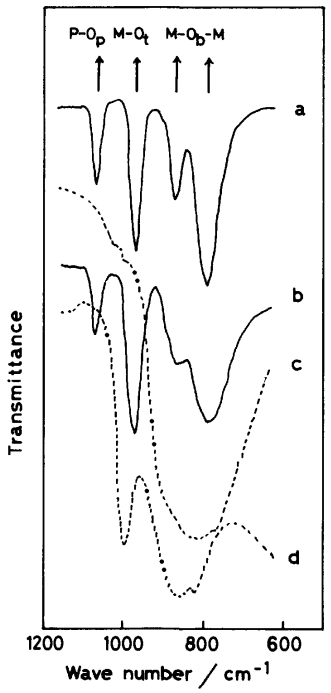

Fig. 2. IR spectra of heteropoly acid and related oxides:
a, Synthesized $H_3PMo_6W_6O_{40}$; b, $H_3PMo_6W_6O_{40}$ after 20 h of reaction; c, authentic WO_3; d, authentic MoO_3.

A similar order was observed in the oxidation of 1-butene.[6] We then adopted $PdSO_4$-$H_3PMo_6W_6O_{40}$ as a pertinent catalyst system for the oxidation of various cycloolefins.

Rate Expression. The amount of cyclohexanone produced was equal to that of cyclohexene consumed and to half of the oxygen uptake. The material balance indicates that the overall reaction is written as

$$\text{Cyclohexene} + 1/2\ O_2 = \text{Cyclohexanone}.$$

From the temperature dependence of the initial rate, the apparent activation energy was found to be 7.8 kcal·mol.$^{-1}$ The dependence of the initial rate of cyclohexanone production on the concentrations of cyclohexene and $PdSO_4$ is shown in Figs. 3 and 4, respectively. The slopes of the lines indicate that the oxidation of cyclohexene was first-order in both cyclohexene and $PdSO_4$. Under the present conditions, the initial rate was independent of the concentration of the heteropoly acid (see Fig. 5) and the partial pressure of oxygen. Accordingly, the following rate expression was obtained:

$$V_o = k[\text{Cyclohexene}]^{1.0}[PdSO_4]^{1.0}[HPA]^0[O_2]^0.$$

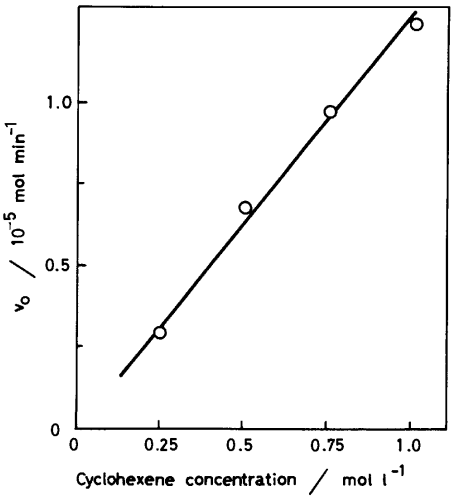

Fig. 3. Dependence of the initial rate of cyclohexanone production on cyclohexene concentration. Reaction conditions: $PdSO_4$ (5.0×10^{-5} mol) and $H_3PMo_6W_6O_{40}$ (2.0×10^{-4} mol) in H_2O (10 ml); and cyclohexene-cyclohexane solution (6 ml).

Table 1. Activity of Pd(II) salt-$H_3PMo_6W_6O_{40}$ catalyst[a)]

	$Pd(CH_3COO)_2$	24	12.1	4	0.05

a) All oxidations were carried out at 303 K under 1 atm oxygen using both cyclohexane (3 ml) and H_2O (10 ml) as solvents. b) With respect to Pd^{2+}. c) 3-Methylcyclohexene (6.6×10^{-3} mol), Pd(II) salt (8.3×10^{-5} mol), and $H_3PMo_6W_6O_{40}$ (2×10^{-4} mol). d) Cyclohexene (1.5×10^{-3} mol), Pd(II) salt (5×10^{-5} mol), and $H_3PMo_6W_6O_{40}$ (2×10^{-4} mol).

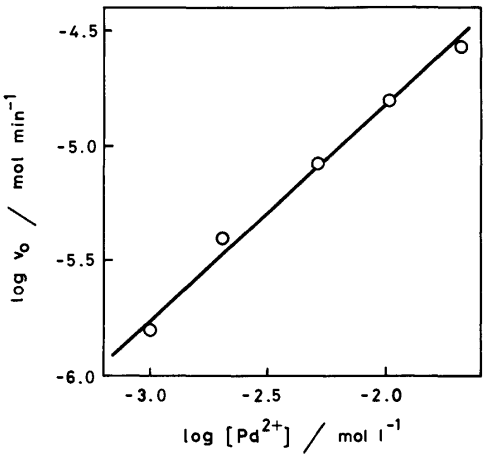

Fig. 4. Dependence of the initial rate of cyclohexanone production on $PdSO_4$ concentration. Reaction conditions: $PdSO_4$ in H_2O (10 ml), $H_3PMo_6W_6O_{40}$ (2.0×10^{-4} mol), cyclohexene (3.0×10^{-3} mol) in cyclohexane (6 ml).

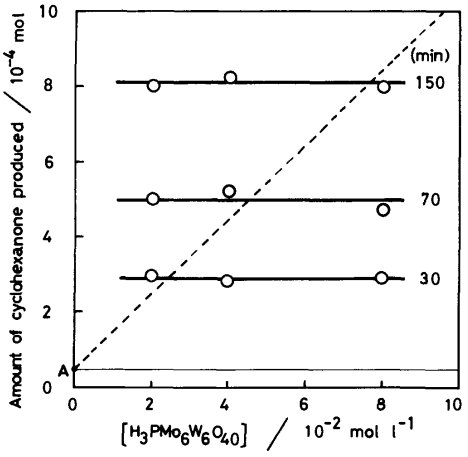

Fig. 5. Dependence of cyclohexanone production on heteropoly acid concentration. Reaction conditions: cyclohexene (3.0×10^{-3} mol) in cyclohexane (3 ml), heteropoly acid and $PdSO_4$ (5.0×10^{-5} mol) in H_2O (10 ml).

Redox Cycle in the Catalyst System. In order to clarify the role of the heteropoly acid and oxygen in the oxidation of cyclohexene, the reaction was carried out under nitrogen at atmospheric pressure. The aqueous reaction mixture was degassed by bubbling nitrogen gas through it for 15 min. The reaction was then conducted for 3 h at room temperature. As shown in Fig. 6, 0.27×10^{-3} mol of cyclohexanone was produced. The amount is very close to the amount (0.25×10^{-3} mol) calculated under the assumption that all heteropoly acid molecules act as oxidants which accept two electrons each from a Pd^0 atom. When nitrogen gas was replaced by oxygen gas at this reaction stage, the oxidation started again. These facts indicate that a heteropoly acid molecule of the oxidized form oxidized a Pd^0 atom to a Pd^{2+} ion and was accompanied by transfer of two electrons. A heteropoly acid molecule of the reduced form was then easily reoxidized by molecular oxygen. From the measurements of the redox potential

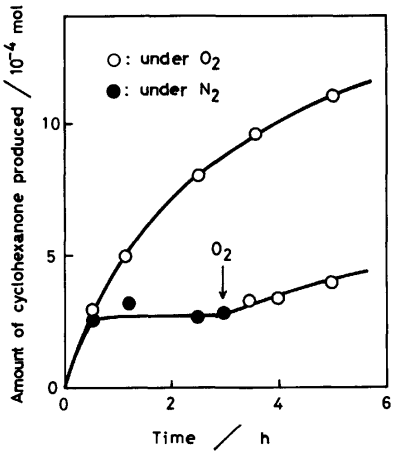

Fig. 6. Oxidation of cyclohexene under O_2 or N_2 at 1 atm. Reaction conditions cyclohexene (3.0×10^{-3} mol), $PdSO_4$ (5.0×10^{-5} mol), and $H_3PMo_6W_6O_{40}$ (2.0×10^{-4} mol) in H_2O (10 ml); cyclohexane (3 ml).

of $H_3PMo_6W_6O_{40}$, Izumi *et al.* concluded that two electrons were transferred in the oxidation and reduction processes.[3]

The oxidation of cyclohexene can be written as follows:

$$\text{Cyclohexene} + Pd^{2+} + H_2O \rightarrow \text{Cyclohexanone} + 2H^+ + Pd^0 \quad (1)$$

$$Pd^0 + HPA_{ox} \longrightarrow Pd^{2+} + HPA_{red} \quad (2)$$

$$HPA_{red} + 1/2O_2 + 2H^+ \longrightarrow HPA_{ox} + H_2O, \quad (3)$$

the subscripts ox and red stand for the oxidized and reduced forms, respectively. The oxidation proceeds catalytically through the redox cycles consisting of processes (1), (2), and (3).

One can confirm the passage through the redox cycles using the data shown in Fig. 5. The horizontal line through point A indicates the amount of cyclohexanone (0.05×10^{-3} mol) expected from the stoichiometric oxidation by $PdSO_4$ alone according to process (1). The dotted line indicates the amount of cyclohexanone expected from the amount of the oxidant heteropoly acid added under the assumption that processes (1) and (2) are operating. Figure 5 clearly shows that the amounts of cyclohexanone produced were above the horizontal line and exceeded the dotted line as the reaction proceeded when smaller amounts of heteropoly acid were used. These observations evidence that the redox cycles consisting of the processes (1), (2), and (3) were all operating effectively under the present conditions.

The system, $PdSO_4$(0.05×10^{-3} mol)-$H_3Mo_6W_6O_{40}$-(0.2×10^{-3} mol), gave about 0.8×10^{-3} mol of cyclohexanone after 150 min of reaction. It was deduced from the values that the redox cycle of $H_3PMo_6W_6O_{40}$,

turned at least 3 times. In a H_2O-*N*-methylformamide solvent, the cycle turned at least 21 times (see Table 3).

a) Each experiment was carried out at 303 K using a mixture of cyclohexane (3 ml) and H_2O (10 ml) under 1 atm oxygen. b) With respect to Pd^{2+}. c) Cyclohexene (1.5×10^{-3} mol), $H_3PMo_{12}O_{40}$ (2×10^{-4} mol), and concd. H_2SO_4 were added to the aqueous solution in order to make the pH similar to that for the conditions of footnote e (pH 1.3). d) No oxygen was absorbed during the reaction. e) Cyclohexene (1.5×10^{-3} mol), $H_3PMo_6W_6O_{40}$ (2×10^{-4} mol), and concd. H_2SO_4 (trace). f) Olefin (1.5×10^{-3} mol), $PdSO_4$ (5×10^{-5} mol), and $H_3PMo_6W_6O_{40}$ (2×10^{-4} mol). g) Olefin (6.6×10^{-3} mol), $PdSO_4$ (8.3×10^{-5} mol), and $H_3PMo_6W_6O_{40}$ (2×10^{-4} mol). h) 2-Methylcyclohexanone, 7.6%; 3-methylcyclohexanone, 12.9%. i) 3-Methylcyclohexanone, 1.7%; 4-methylcyclohexanone, 0.8%. j) 2-Hexanone, 75%; hexanal, 10.9%.

Oxidation of Cycloolefins. The results of the oxidation of cycloolefins were listed in Table 2. The yields of ketones in an H_2O-cyclohexane mixture decreased in the following order:

Cyclopentene > Cyclohexene > Cycloheptene > Cyclooctene,

Cyclohexene > 3-Methylcyclohexene > 4-Methylcyclohexene > 1-Methylcyclohexene.

The increase in the carbon number of the cycloolefins caused the yield of the cyclic ketones to decrease. Relative reactivities of the cycloolefins were measured by their competitive oxidation. Figure 7 shows the result of the competitive oxidation of a cyclopentene-cyclohexene equimolar mixture together with the results of the individual oxidation of cyclopentene and cyclohexene. The production of cyclopentanone was not affected by the presence of cyclohexene; while the production of cyclohexanone was inhibited by cyclopentene. After an induction period of about 3 h, cyclohexanone began to form. Competitive reactions of a cyclohexene-cycloheptene equimolar mixture and a cyclohexene-cyclooctene equimolar mixture behaved similarly; *i.e.*, the oxidation of olefin having a smaller number of carbon atoms was not retarded by the higher olefin, while the oxidation of olefin having a larger number of carbon atoms was retarded by the lower olefin.

Rate-determining Step. In the oxidation of 1-butene, Izumi *et al.*[3] suggested that process(3)determines the rate in the $PdSO_4$-$H_3PMo_6W_6O_{40}$ catalyst system. The rate expression for the cyclohexene oxidation described before suggests that process (1) is rate-determining. The shift of the rate-determining process from (3) to (1) may be due to the very low reactivities of the cycloolefins toward Pd^{2+}. This consideration is supported by the facts that the rate of process (1) decreases as the carbon number of the straight-chain olefins[12] increases and that the oxidation rate of cyclohexene was slower than that of 1-hexene (see Table 2).

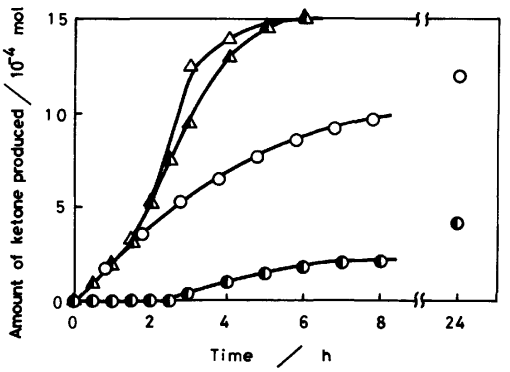

Fig. 7. Reaction profiles of oxidation of cyclopentene and cyclohexene and competive oxidation of a cyclopentene-cyclohexene equimolecular mixture: △, cyclopentanone; ○, cyclohexanone; ▲ and ◐, cyclopentanone and cyclohexanone produced in the competitive oxidation, respectively. Reaction conditions; olefin (1.5×10^{-3} mol), $PdSO_4$ (5.0×10^{-5} mol), and $H_3PMo_6W_6O_{40}$ (2.0×10^{-4} mol) in H_2O (10 ml); cyclohexane (3 ml).

Cyclohexene Oxidation in Various Solvents. The oxidation of olefin with the Wacker catalyst is affected by solvating forces. Clement and Selwitz[13] described a convenient synthesis of 2-dodecanone from 1-dodecene using aqueous *N,N*-dimethylformamide solvent, and suggested that *N,N*-dimethylformamide provided more intimate contact between the olefin and the catalyst solution and also might exert a solvent effect which promoted reaction. Lloyd *et al.*[14] reported that the oxidation of cyclohexene with $PdCl_2$-$CuCl_2$ catalyst proceeded more readily in alcoholic media and most readily in media containing little or no water because of

Table 3. Oxidation of cyclohexene in various solvents[a)]

Solvent system	Catalyst	Time/h	Yield/%	Total turnover number[b)]
H_2O-cyclohexane[c)]	$PdSO_4$-$H_3PMo_6W_6O_{40}$	10	70.3	21

Ethanol[d)]	$PdCl_2$-$CuCl_2$	22	73.8	74

a) Each experiment was carried out at 303 K, except at 293 K in H_2O-Et_2O solvent, using Pd(II) salt (5×10^{-5} mol) and $H_3PMo_6W_6O_{40}$ (2×10^{-4} mol) or Cu(II) salt (2×10^{-4} mol) under 1 atm oxygen. b) With respect to Pd^{2+}. c) Cyclohexene (1.5×10^{-3} mol), H_2O (10 ml), and organic solvent (3 ml). d) Cyclohexene (5×10^{-3} mol) and ethanol (10 ml). e) Cyclohexene (5×10^{-3} mol), H_2O (8 ml), and *N*-methylformamide (2 ml).

the greater reactivity of the alcohol-solvated Pd(II) species.

Various solvents were used for the oxidation of cyclohexene with $PdSO_4$-$H_3PMo_6W_6O_{40}$ catalyst in order to obtain cyclohexanone in good yields. The results are shown in Table 3. Each run was stopped after the time denoted in Table 3 because no further oxidation occurred thereafter. Methanol, ethanol, 2-propanol, and *t*-butyl alcohol were examined, but oxidation took place only in ethanol giving a low yield of 7.3 %. Alcohols are not suitable solvents for the present catalyst system, although $PdCl_2$-$CuCl_2$ catalyst prefers ethanol as a solvent.

In H_2O-ether solvent systems, the oxidation proceeded readily in the following order:

diethyl ether>diisopropyl ether>dibutyl ether.

Interestingly, the larger the dielectric constant of solvent is, the higher the yield of cyclohexanone becomes.

In the H_2O-formamide solvent systems examined, the H_2O-*N*-methylformamide system was the most efficient. Figure 8 shows the effect of the addition of *N*-methylformamide to water on the yield of cyclohexanone. The best yield was obtained with water containing 20% *N*-methylformamide (by volume) and the total turnover number with respect to Pd^{2+} reached 85 after 24 h of reaction. When equal volumes of *N*-methylformamide and water were employed, the yield dropped drastically. Tetrahydrofuran, sulfolane, and dimethyl sulfoxide, which are not listed in Table 3, were highly inferior to *N*-methylformamide.

Life of the $PdSO_4$-$H_3PMo_6W_6O_{40}$ Catalyst. The oxidation proceeded catalytically within a certain reaction period. The reaction was inhibited by deposition of palladium metal. $PdSO_4$ or $H_3PMo_6W_6O_{40}$ was added to the reaction mixture after the inhibition, but the reaction did not proceed any more. To start the oxidation again, simultaneous addition of both $PdSO_4$ and $H_3PMo_6W_6O_{40}$ was required. The change of the IR spectra in Fig. 2 suggests that the $H_3PMo_6W_6O_{40}$ was in the reduced state after the inhibition. Calcination of the heteropoly acid in air at 673 K for 1 h restored about half of its activity. To produce a longer life for the present catalyst system, it is required that the reoxidation of the reduced heteropoly acid be activated in the course of the reaction.

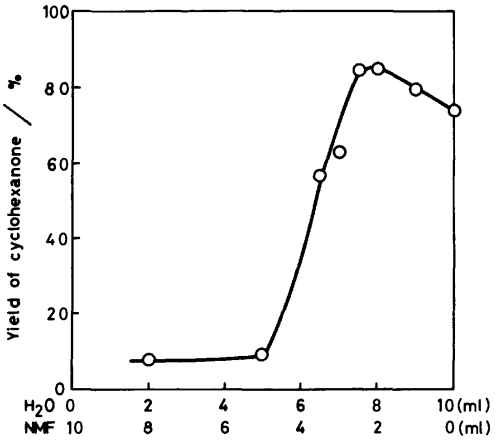

Fig. 8. Effect of addition of *N*-methylformamide (NMF) to water on the yield of cyclohexanone. Each experiment was carried out at 303K using cyclohexene (1.5×10^{-3} mol), $PdSO_4$ (5.0×10^{-4} mol), and $H_3PMo_6W_6O_{40}$ (2.0×10^{-4} mol) under oxygen at 1 atm over a 24 h period.

Experimental

Materials. *Catalysts*: Pd(II) salts were used as received; $PdSO_4$ (Mitsuwa Chemicals; assay(Pd) 52.5%), Pd-$(NO_3)_2$ (Wako Chemicals; assay(Pd) 45.5%) and $PdCl_2$ (Wako Chemicals; assay(Pd) 59.0%).

$H_3PMo_{12}O_{40}$ and $H_3PW_{12}O_{40}$ were purchased from Ventron Alfa Products, and used as received. Various mixed-coordinated heteropoly acids, $H_3PMo_nW_{12-n}O_{40}$ were synthesized according to the method reported.[15] It was confirmed by thermogravimetric analysis that a $H_3PMo_6W_6O_{40}$ molecule contained 10.8 molecules of water of crystallization.

Cycloolefins: Reagent grade cyclopentene, cyclohexene, cycloheptene, cyclooctene, 1-methylcyclohexene, 3-methyl-

cyclohexene, 4-methylcyclohexene, and 1-hexene were purchased from Wako Chemicals and Tokyo Kasei, and used without further purification.

Solvent: Organic solvents were all guaranteed grade except ethers (reagent grade) and were used as received.

Apparatus and Procedure. The oxidation was carried out under oxygen at atmospheric pressure using a 20 ml glass vessel reactor surrounded by a jacket in which thermostated water at 303±0.1 K was circulated. A wrist-action shaker was used to achieve vigorous agitation of the reaction solution. A typical example of the oxidation of cycloolefin is illustrative. $PdSO_4$ (0.05×10^{-3} mol) and heteropoly acid (0.2×10^{-3} mol) were dissolved in water (10 ml) and the resulting mixture was allowed to settle for a day at room temperature to obtain a homogeneous solution. The solution was stirred with a magnetic stirrer under oxygen at atmospheric pressure and 303 K for 1 h in order to activate the catalyst in the solution. After the treatment, cyclohexene (1.5×10^{-3} mol) in cyclohexane (3 ml) which contained *trans*-decalin (0.3×10^{-3} mol) as an internal standard was injected into the reaction solution. The oxidation was then carried out with vigorous agitation.

Analysis of Reaction Products and Catalysts. The reaction mixtures were analyzed with a Yanagimoto Model G80 gas chromatograph. The progress of reaction was followed by glc analysis of aliquot samples and by oxygen-uptake measurements. Reaction products were identified by comparing their retention times with those of the authentic samples. To confirm the identification, gas chromatographically separated samples of the reaction products were analyzed with a JASCO infrared spectrometer, a Hitachi RMS-4 mass spectrometer, and a JEOL FX-90Q ^1H NMR spectrometer. Spectroscopic data are listed as below: Cyclopentanone; IR (neat) ν=1745 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=2.07 (8H, m, cyclopentyl); MS (8 ev) *m/z* (rel intensity), 84 (M^+;100), 85 (5.2), 56 (4.3). Cyclohexanone; IR (neat) ν=1703 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.74 (6H, m, cyclohexyl), δ=2.30 (4H, m, cyclohexyl); MS (8 ev) *m/z* (rel intensity), 98 (M^+;100), 99 (6.4), 80 (3.7). Cycloheptanone; IR (neat) ν=1703 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.63 (8H, m, cycloheptyl), δ=2.46 (4H, m, cycloheptyl).

Synthesized heteropoly acids were analyzed with the IR spectrometer and a Rigaku-Denki 8076D TG-DTA analyzer.

(Received November 18, 1983)

The reaction of biphenylene with $Pb(OAc)_4$ gave 2-substituted biphenylenes and 2,3-biphenylenedione. The reaction of 2-methylbiphenylene and 2,3-dimethylbiphenylene with $Mn(OAc)_3$ yielded products in which the methyl substituent had been oxidized. The reaction of 2-methoxybiphenylene with $Pb(OAc)_4$ gave 2-acetoxy-3-methoxybiphenylene and *r*-2,*c*-3-diacetoxy-2-methoxy-2,3-dihydrobiphenylene, which is the first example of a 2,3-dihydrobiphenylene. The reactions of 2-carboxy-, 2-methoxycarbonyl- and 2,7-dibromobiphenylene with $Mn(OAc)_3$ and (in part) with $Pb(OAc)_4$ yielded nuclear acetoxymethylated products. The conversion of *r*-2,*c*-3-diacetoxy-2-methoxy-2,3-dihydrobiphenylene into 5,10-diacetoxy-7(8*H*)-benzocyclooctenone was observed.

A previous study on the oxidation of biphenylene (**1**) with $Mn(OAc)_3$ resulted in the formation of a propellane, 7-oxa-10,11-benzotricyclo[4.3.2.$0^{1,6}$]undeca-2,4,10-triene-8-one.[1] This led us to investigate the reactions of mono- and disubstituted biphenylenes in the hope of obtaining further evidence on the anomalous reactivity of biphenylene towards $Mn(OAc)_3$. The reaction of biphenylene with $Pb(OAc)_4$ was also studied, since this reagent should show a similar reactivity under certain reaction conditions,[2] although one of the authors has already reported that the reaction of biphenylene (**1**) with $Pd(OAc)_4$, followed by hydrolysis gave 2-hydroxybiphenylene.[3]

Results

When biphenylene (**1**) was oxidized with $Pb(OAc)_4$ in a 1:2 molar ratio, it gave 2-acetoxybiphenylene (**2**) and 2,3-biphenylenedione (**3**) (Table 1, Entry 2). When the molar ratio of the oxidant to substrate was increased, the yields were not very much affected, but a third product, 2-formylbiphenylene (**4**), was obtained (Entries 3 and 4). 2-Acetoxymethylbiphenylene (**5**) was detected by its CH_2 and CH_3 peaks in the ^{1}H-NMR spectrum of the crude product.

When 2-methylbiphenylene[4] (**7**) was oxidized with $Mn(OAc)_3$ and with $Pb(OAc)_4$, the products were found to be **4** and **5**. When acetic anhydride was added to the reaction mixture of $Mn(OAc)_3$, **5** was the major product, while the yield of **4** decreased, and compounds **6**, **8a**, and **8b** were isolated. The structures of **8a** and **8b** were determined by comparison with the corresponding authentic samples (see Experimental). The results are summarized in Table 2. It was shown that the recovery of **7** was much less than that of **1** in the oxidation with $Pb(OAc)_4$.

When the reaction of 2-methoxybiphenylene[5] (**11**) with $Mn(OAc)_3$ was examined in molar ratios of 1:2 and 1:4 in acetic acid at room temperature, it gave a complex mixture which could not be separated. The reaction of **11** with $Pb(OAc)_4$, in a molar ratio of 1:1 under similar reaction conditions gave two com-

c) Acetic anhydride (10 ml) was added.

pounds; **12** (5%) and **13** (9%). Spectroscopic properties of **13** indicate that the structure of **13** could be either 2,3-diacetoxy-2-methoxy-2,3-dihydrobiphenylene (**13a**) or 2,4a-diacetoxy-3-methoxy-2,4a-dihydrobiphenylene (**13b**). However, the structure **13a** is preferred because compound **13** showed a symmetrical A_2B_2 pattern due to aromatic protons in the ^{1}H-NMR spectrum. Also, the δ values calculated[6] for H-1 and H-4 in **13a** are the same (6.0) and they agree with the experimental value (6.0), whereas the values calculated for H-1 and H-4 in **13b** (4.95 and 6.0 respectively) differ by about 1 ppm. The compound **13** was stable in $CDCl_3$ solution, but when the solution contained HCl (or DCl), it was converted to a new compound, **14**, which showed a new carbonyl carbon at δ 197.722 and a methylene carbon at δ 41.164 in its ^{13}C-NMR spectrum. The ^{1}H-NMR spectrum indicated the presence of =CH-CO-CH_2-CH=unit. These spectroscopic properties suggest the structure of 5,10-diacetoxy-7(8*H*)-benzocyclooctenone (**14**) (Scheme 1).

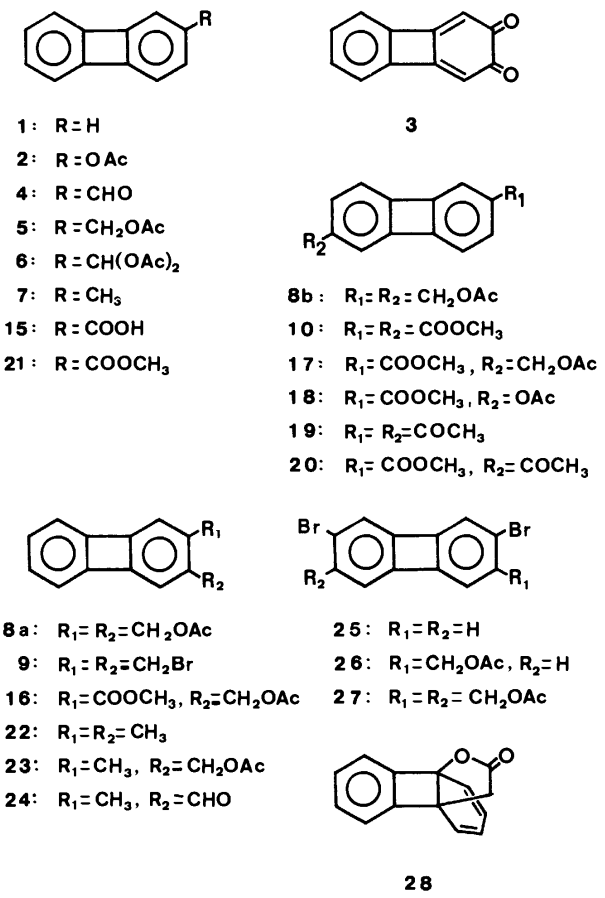

Fig. 1.

When 2-carboxybiphenylene[3] (15) was oxidized with $Pb(OAc)_4$ and $Mn(OAc)_3$, followed by treatment with diazomethane, three compounds, **16**, **17**, and **18**, were obtained (Table 3, Entries 1—4). The structures of these compounds were elucidated by spectroscopic evidence, by conversion to a known compound, and by synthesis. The structure of **16** was confirmed by reducing it with $LiAlH_4$ and then acetylating it to give a bis(acetoxymethyl)biphenylene which was identical with **8a**. In the same way, the structure of compound **17** was confirmed by converting it into the bis(acetoxymethyl) compound **8b**. The structure of **18**, which could not be obtained as a pure substance, was confirmed by an unambiguous synthesis. The Baeyer-Villiger oxidation of 2-acetyl-6-(methoxycarbonyl)biphenylene (**20**) which was obtained from 2,6-diacetylbiphenylene (**19**) gave **18**. When 2-(methoxycarbonyl)biphenylene[3] (**21**) was oxidized with $Pb(OAc)_4$ and with $Mn(OAc)_3$, it gave again **16**, **17**, and **18** in slightly modified yields (Table 3, Entries 5 and 6).

Oxidation of 2,3-dimethylbiphenylene[4] (**22**) with $Mn(OAc)_3$ in the molar ratio of 1:2 gave 2-acetoxymethyl-3-methylbiphenylene (**23**) and 2-formyl-3-methylbiphenylene[4] (**24**) (Table 4, Entry 1). When the molar ratio was increased to 1:4, the products were **23**, **24**, and **8a** together with very small amounts of the other substitution products which could not be separated. The structure of **23** was proved by its ^{1}H-NMR spectrum which showed the presence of six aromatic protons, one $ArCH_2$ and $ArCH_3$ group.

Bromination of biphenylene with *N*-bromosuccinimide (molar ratio 1:2) in *N*,*N*-dimethylformamide gave a mixture of dibromobiphenylenes. 2,7-Dibromobiphenylene (**25**) (the less soluble isomer) was obtained by fractional crystallization of the mixture. However, it is easier to isolate **25** if the bromination of biphenylene is carried out in two steps, *i.e. via* monobromobiphenylene. The orientation of **25** was proved by treatment with butyllithium and then with methyl iodide, which gave 2,7-dimethylbiphenylene. Oxidation of 2,7-dibromobiphenylene (**25**) with $Mn(OAc)_3$ gave mono(acetoxymethyl) compound **26** and a much lower yield of the bis(acetoxymethyl) compound **27** (Table 4, Entry 3). The structures of **26** and **27** were

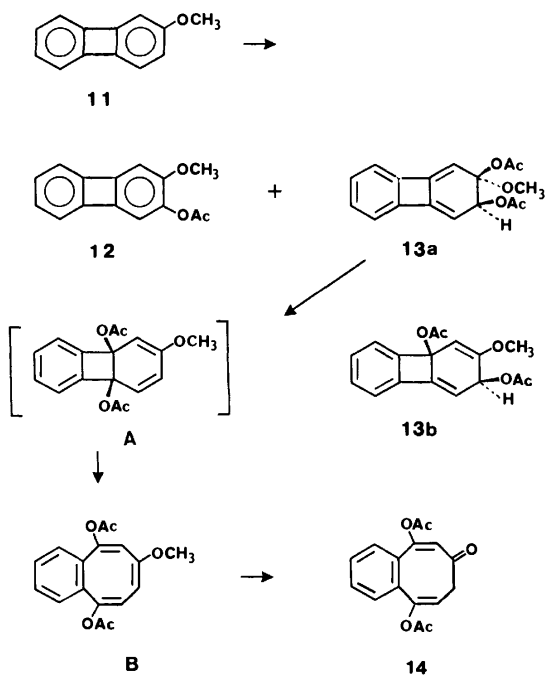
determined by their ^{1}H-NMR spectra. In each experiment, there were many unidentified products which could not be separated.

Discussion

The oxidation of biphenylene (**1**) with $Mn(OAc)_3$ gives a mixture of 2-substituted biphenylenes and an addition product, namely the propellane **28** (0—10% yield).[1] The latter is presumably formed by attack of the $^{\cdot}CH_2COOH$ radical at position 4a of biphenylene, followed by cyclization. The formation of **4** and **5** in the reaction of **1** with $Pb(OAc)_4$ indicates that this acetate also yielded the $^{\cdot}CH_2COOH$ radical in minor quantity, but it could not afford any of the propellane **28**. The reaction of **5** with $Pb(OAc)_4$ gave **4** in a 35% yield, together with 2-(diacetoxymethyl)biphenylene **6** (14%). It seemed that **2** might be a precursor for **3**; therefore, the reaction of **2** with $Pb(OAc)_4$ was also carried out, but it gave **3** (3%) and unchanged **2** (19%). The result indicates that **2** cannot be the major precursor because of the poor yield of **3** from **2**. We hoped that $Mn(OAc)_3$ oxidation of biphenylene containing either electron-donating (CH_3) or electron-withdrawing substituents (COOH, $COOCH_3$, and Br) would give higher yields of propellane. However, we were not able to detect any propellane type of products from the substituted biphenylenes, but we obtained acetoxymethylated-biphenylenes as the major product in each case. Our results show that the incoming groups, OAc and CH_2COOH (and thence CH_2OAc, $CH(OAc)_2$, CHO),[7] always enter at β-positions (2,3,6,7) of the biphenylene nucleus. This is further evidence of the unreactivity of the α-positions (1,4,5,8) towards substitution by free radicals, by electron-transfer mechanism, and by electrophilic reagents. On the other hand, the reactions of **7** and **22** with $Mn(OAc)_3$ occurred at the methyl group rather than in the biphenylene nucleus, giving acetoxymetyl- and formyl-derivatives.

Several reactions have been reported in which X-Y reagents add to biphenylene and give products with ring-enlargement, for example in the reaction of biphenylene with HNO_3 and Ac_2O[8] and in the reaction of methoxybiphenylene with Br_2.[9] However, as far as we know, compound **13a** is the first example of a stable 2,3-adduct isolated from an addition reaction of biphenylene. It has been reported that aliphatic vinyl ether, CH_2=CHOR, reacts with $Pb(OAc)_4$ at room temperature to give diacetate, *e.g.* CH_2=CHOR gives $AcOCH_2CH(OR)OAc$.[10] In 2-methoxybiphenylene (**11**), the $C_{(2)}$-$C_{(3)}$ bond is more like a double-bond than the $C_{(1)}$-$C_{(2)}$ bond is, and the CH_3O-$C_{(2)}$-$C_{(3)}$ system may behave like a vinyl ether. The proposed rearrangement of **13a** to A involves the 1,3-migration of two acetoxyl groups. Similar [3,3] sigmatropic changes have been recorded, *e.g.* the reversible isomerization of 6-acyloxy-2,4-cyclohexadienes into 4-acyloxy-2,5-cyclohexadienes by heating them in chloroform or pyridine.[11] Now the thermal [3,3] sigmatropic rearrangement of allylic acetates proceeds suprafacially *via* a 6-membered transition state;[11] hence the two acetoxyl groups in **13a** must be *cis* as shown.[12] The rearrangement of **13a** into A could take place either in two-steps, *e.g.* *via* **13b**, or in one step *via* simultaneous 1,3-migration of two acetoxyl groups. However both paths (one-step and two-step) have the same stereochemical requirements and lead to the same conclusion concerning the relative stereochemistry of **13a** and A. The intermediate, B, is an enol ether and, as expected,[8] undergoes very rapid acid-catalyzed hydrolysis to the ketone **14**. In conclusion, it was shown that the reaction of biphenylenes having electron-withdrawing groups



Scheme 1.

with $Mn(OAc)_3$ and $Pb(OAc)_4$ yielded acetoxymethylated derivatives, whereas the methyl group was oxidized in the reaction of methyl substituted biphenylenes. The reaction of 2-methoxybiphenylene with $Pb(OAc)_4$ provided the first example of a stable 2,3-adduct in the addition reaction of biphenylene.

Experimental

The ^{1}H-NMR spectra at 60 MHz and 200 MHz were recorded with a Hitachi-Perkin-Elmer R 24 (or JEOL PMX 60) and with a JEOL FX 200 spectrometer, respectively, with TMS as internal reference. The ^{13}C-NMR spectra at 22.5 MHz were obtained on a JEOL FX 90Q spectrometer. The IR spectra were taken on a JASCO IR A-1 grating spectrometer. The high-resolution Mass spectra were recorded on an A.E.I. MS 902 spectrometer (VG2AB electronics and ion source) with direct inlet at 75 ev. The melting points were determined with a Yanagimoto micro-melting point apparatus and were not corrected.

Oxidation with $Pb(OAc)_4$. The typical procedure for the oxidations of biphenylene[13] and its derivatives was as follows. A mixture of a biphenylene (1 mmol) and $Pb(OAc)_4$ in acetic acid (15 ml) was heated or stirred until the solution became negative to a wet KI-starch paper. The reaction mixture was then diluted with water (15 ml) and extracted with chloroform. After removal of the chloroform *in vacuo*, the resulting mixture was separated on TLC (Wakogel B10) with chloroform as the developing solvent. In the case of the oxidation of 2-carboxybiphenylene, the products were treated with diazomethane in diethyl ether and then separated. Yields are summarized in Tables 1, 2, 3, and 4.

Oxidation Products of Biphenylene (1). 2-Acetoxybiphenylene (**2**), mp 91—92 °C (lit,[5] mp 91—92 °C), 2,3-biphenylenedione (**3**), mp 213—216 °C (from light petroleum) (lit,[14] 216—217 °C), and 2-formylbiphenylene (**4**), mp 80—82 °C (light petrolem) (lit,[15] mp 78—79 °C). The ^{1}H-NMR and IR spectra were identical with those of authentic samples.[1,16]

Oxidation Products of 2-Acetoxymethylphenylene[1] (5). *2-Formylbiphenylene (4)*: **4** (35%) was obtained as a mixture with **5** (28%); the yields were estimated from its ^{1}H-NMR spectrum.

2-(Diacetoxymethyl)biphenylene (6): Mp 154—155 °C (CCl_4); 14%; IR($CHCl_3$) 1760 cm^{-1} (OAc); ^{1}H-NMR ($CDCl_3$) δ=2.00 (6H, s, 2×OAc), 6.5—6.7 (7H, m, aromatic), and 7.42 (1H, s, -CH<); MS *m/z* (rel intensity) 43 (40), 151 (37), 179 (48), 180 (78), 181 (100), 223 (3), and 282.0890 (64, M^+). Calcd for $C_{17}H_{14}O_4$: M, 282.0892.

Oxidation Products of 2-Methylbiphenylene[4] (7). 2-Formylbiphenylene (**4**) and 2-acetoxymethylbiphenylene (**5**) were obtained as a mixture.

Oxidation Products of 2-Methoxybiphenylene[3] (11). *2-Acetoxy-3-methoxybiphenylene (12)*: Mp 125.4—126.4 °C (hexane) (lit,[17] mp 111—112 °C); 5%; IR ($CHCl_3$) 1760 cm^{-1} (OAc); ^{1}H-NMR ($CDCl_3$) δ=2.23 (3H, s, OAc), 3.77 (3H, s, OCH_3), 6.26 (1H, s, $H_{(1)}$ or $H_{(4)}$), 6.40 (1H, s, $H_{(4)}$ or $H_{(1)}$), and 6.2—6.7 (4H, m, $H_{(5)}$-$H_{(8)}$); MS *m/z* (rel intensity) 126.0476 (22), 180.0443 (91), 198.9746 (100), 240.0834 (28, M^+). Calcd for $C_{15}H_{12}O_3$: M, 240.0774.

r-*2*,c-*3-Diacetoxy-2-methoxy-2,3-dihydrobiphenylene (13a)*: Mp 137.5—138.5 °C (methanol); 9%; IR ($CHCl_3$) 1640 (C=C) and 1760 cm^{-1} (OAc); ^{1}H-NMR ($CDCl_3$) δ=2.15 (6H, s, 2×OAc), 3.50 (3H, s, OCH_3), 4.95 (1H, d, *J*=6.0 Hz, -CH<), 6.0 (2H, m, 2×-CH=), and 7.2—7.4 (4H, m, aromatic). The doublet at δ 4.95 collapsed to a singlet on irradiation of the signals at δ 6.0; ^{13}C-NMR ($CDCl_3$) δ=21.126 (2×$OCO\underline{C}H_3$), 55.281 (OCH_3), 96.615 (-CH<), 116.789 (=CH-), 119.000 (=CH-), 127.709 (=CH-), 127.913 (=CH-), 128.594 (=CH-), 128.866 (=CH-), 135.874, 136.044, 145.672, 149.218 153.394, 168.941 ($O\underline{C}OCH_3$), and 169.723 ($O\underline{C}OCH_3$); MS *m/z* (rel intensity, formula) 182.0413 (20, $C_{12}H_6O_2$), 183.0433 (32, $C_{12}H_7O_2$), 197.0589 (30, $C_{13}H_9O_2$), 198.0637 (100, $C_{13}H_{10}O_2$), 199.0704 (20, $C_{13}H_{11}O_2$), 201.0507 (16, $C_{12}H_9O_3$), 215.0721 (35, $C_{13}H_{11}O_3$), 216.0789 (27, $C_{13}H_{12}O_3$), and 258.0941 (10, $C_{15}H_{14}O_4$). Found: C, 67.86; H, 5.41%. Calcd for $C_{17}H_{16}O_5$: C, 67.99; H, 5.37%.

5,10-Diacetoxy-7(8H)-benzocyclooctenone (14): IR (CH_2Cl_2) 1670, 1690, 1725, and 1775 cm^{-1} (OAc); ^{1}H-NMR (200 MHz, $CDCl_3$) δ=2.192 (6H, s, 2×OAc), 2.769 (1H, dd, *J*=12.94 and 10.36 Hz, -$\underline{H}$CH-), 3.019 (1H, ddd, *J*=12.94, 7.42, and 1.71 Hz, -$\underline{H}$CH-), 5.813 (1H, dd, *J*=10.36 and 7.42 Hz, $H_{(9)}$), 6.290 (1H, d, *J*=1.71 Hz, $H_{(6)}$), and 7.492 (4H, m, aromatic); ^{13}C-NMR ($CDCl_3$) δ=20.956 (q, $OCO\underline{C}H_3$), 21.160 (q, $OCO\underline{C}H_3$), 41.162 (t, $-CH_2-$), 115.700 (d, =CH-), 123.457 (d, =CH-), 126.859 (d, =CH-), 128.492 (d, =CH-), 129.206 (d, =CH-), 130.023 (d, =CH-), 133.527 (s, =$\underline{C}$-), 134.071 (s, =$\underline{C}$-), 147.815 (s, =$\underline{C}$-), 156.422 (s, =$\underline{C}$-), 168.125 (s, $O\underline{C}OCH_3$), 169.111 (s, $O\underline{C}OCH_3$), and 197.722 (s, >C=O); MS *m/z* (rel intensity) 43 (100), 128 (17), 156 (23), 157 (20), 159 (86), 160 (76), 174 (22), 184 (24), 202.0622 (51, calcd for $C_{12}H_{10}O_3$: 202.0630), and 244.0738 (25, calcd for $C_{14}H_{12}O_4$: 244.0735).

Oxidation Products of 2-Carboxy-[3] (15) and 2-(Methoxycarbonyl)biphenylene[3] (21). *2-Acetoxymethyl-3-(methoxycarbonyl)biphenylene (16)*: Mp 96.7—97.7 °C (methanol); IR ($CHCl_3$) 1710 (-$COOCH_3$) and 1725 cm^{-1} (OAc); ^{1}H-NMR ($CDCl_3$) δ=2.10 (3H, s, OAc), 3.82 (3H, s, OCH_3), 5.33 (2H, s, $-CH_2O-$), 6.75 (5H, m, $H_{(4)}$-$H_{(8)}$), and 7.12 (1H, s, $H_{(1)}$); MS *m/z* (rel intensity) 43 (11), 151 (18), 179 (17), 207 (100), 239 (10), 282.0899 (37, M^+). Calcd for $C_{17}H_{14}O_4$: M, 282.0892.

2-Acetoxymethyl-6-(methoxycarbonyl)biphenylene (17): Mp 95.5—96.6 °C (methanol); IR ($CHCl_3$) 1710 (-$COOCH_3$) and 1735 cm^{-1} (OAc): ^{1}H-NMR ($CDCl_3$) δ=2.05 (3H, s, OAc), 3.80 (3H, s, OCH_3), 4.88 (2H, s, $-CH_2O-$), 6.5—6.9 (4H, m, $H_{(4)}$, $H_{(5)}$, $H_{(7)}$, and $H_{(8)}$), 7.20 (1H, d, *J*=1.0 Hz, $H_{(1)}$), and 7.52 (1H, dd, *J*=6.0 and 1.0 Hz, $H_{(3)}$); MS *m/z* (rel intensity) 43 (14), 223 (70), 240 (25), and 282.0894 (100, M^+). Calcd for $C_{17}H_{14}O_4$: M, 282.0892.

2-Acetoxy-6-(methoxycarbonyl)biphenylene (18): Mp 134—137 °C (metanol); IR ($CHCl_3$) 1725 (-$COOCH_3$) and 1760 cm^{-1} (OAc); ^{1}H-NMR ($CDCl_3$) δ=2.25 (3H, s, OAc), 3.80 (3H, s, OCH_3), 6.5—6.8 (4H, m, $H_{(4)}$, $H_{(5)}$, $H_{(7)}$, and $H_{(8)}$), 7.20 (1H, d, *J*=1.0 Hz, $H_{(1)}$), and 7.60 (1H, dd, *J*=6.0 and 1.0 Hz, $H_{(3)}$); MS *m/z* (rel intensity) 167 (14), 195 (22), 226.0642 (100, M^+ −42, calcd for $C_{14}H_{10}O_3$: 226.0630), and 268.0733 (13, M^+). Calcd for $C_{16}H_{12}O_4$: M, 268.0735.

Oxidation of 2-Methylbiphenylene (7) with $Mn(OAc)_3$. A mixture of **7** (1 mmol) and $Mn(OAc)_3\,2H_2O$[18] in acetic acid (20 ml) was heated under reflux for the time shown in Table 2 until the color of the Mn(III) ions disappeared. The reaction mixture was worked up in a manner similar to that described in the oxidation with $Pb(OAc)_4$. 2-Formylbiphenylene (**4**) and 2-acetoxymethylbiphenylene (**5**) were obtained as a mixture, yields of which were estimated from the ^{1}H-NMR as shown in Table 2.

2-(Diacetoxymethyl)biphenylene (6): Mp 154—155 °C

2,3-Bis(acetoxymethyl)biphenylene (8a): Mp 88—89 °C (ethanol); IR (CCl_4) 1742 cm^{-1} (OAc); ^{1}H-NMR ($CDCl_3$) δ=2.00 (6H, s, 2×OAc); 4.91 (4, s, 2×$-CH_2O-$), and 6.62 (6H, br. s, aromatic); MS *m/z* (rel intensity) 43 (22), 165 (26), 194 (100), 296.1038 (17, M^+). Calcd for $C_{18}H_{16}O_4$: M, 296.1048.

2,6-Bis(acetoxymethyl)biphenylene (8b): Mp 104—105.5 °C (ethanol); IR ($CHCl_3$) 1742 cm^{-1} (OAc); ^{1}H-NMR (CCl_4) δ=2.00 (6H, s, 2×OAc), 4.74 (4H, s, 2×$-CH_2O-$), 6.56 (6H, m, aromatic); MS *m/z* (rel intensity) 43 (23), 152 (10), 165 (28), 178

(19), 195 (12), 237 (77), 254 (11), and 296.1030 (100, M^+). Calcd for $C_{18}H_{16}O_4$: M, 296.1048.

Preparation of 2,3-Bis(acetoxymethyl)biphenylene (8a). *a) From 2,3-bis(bromomethyl)biphenylene (9)*: A mixture of 2,3-bis(bromomethyl)biphenylene[17] (258 mg) and anhydrous sodium acetate (205 mg) in acetic acid was refluxed for 3 h, then allowed to stand for 60 h. Water (50 ml) was added and the mixture was extracted with toluene (2×25 ml). The toluene was evaporated and the residue was separated by TLC on silica gel with chloroform as eluent. The major component was collected and recrystallized from aqueous ethanol. The product (162 mg, 55%), mp 88—89 °C was identical (IR, ^{1}H-NMR and Mass) with compound **8a**.

b) From 2-acetoxymethyl-3-(methoxycarbonyl)biphenylene (16): A mixture of **16** (60 mg), anhydrous tetrahydrofuran (10 ml), and lithium aluminium hydride (200 mg) was stirred at room temperature for 2 h. After ethyl acetate (1 ml) and 3M (1M=1 mol dm^{-3}) hydrochloric acid (100 ml) had been added to the mixture, it was extracted with ethyl acetate. After removal of the ethyl acetate, the resulting liquid was treated with acetic anhydride (1 ml) in pyridine (1 ml) overnight. The mixture was poured into water and the precipitate was collected, and recrystallized from methanol, giving **8a** (45 mg, 72%), mp 89—90 °C.

Oxidation of 2,6-Diacetylbiphenylene (19) by King's Method.[19] A mixture of 2,6-diacetylbiphenylene[20] (**19**) (460 mg, 2 mmol), iodine (1.1 g, 4 mmol), and pyridine (30 ml) was heated on a steam bath for 1 h, then kept at room temperature for 12 h. The brown precipitate was collected by filtration and washed with water. The solid was boiled for 2 h with water (10 ml) and 10% sodium hydroxide (15 ml), then poured into water (50 ml). The mixture was extracted with diethyl ether to remove non-acidic material. The aqueous solution was acidified with hydrochloric acid and the yellow precipitate was collected and dried at 100 °C. This solid (275 mg) did not melt below 350 °C. A mixture of the solid (250 mg) and boron trifluoride-methanol complex (14% BF_3, 12 ml) in methanol (20 ml) was refluxed for 6 h. The solution was cooled, poured into a saturated aqueous solution of sodium hydrogencarbonate, then extracted with diethyl ether. Evaporation of the ethereal solution gave a yellow solid (130 mg) which was separated by preparative TLC (silica gel) in benzene, the plate being eluted four times to achieve good separation. The band with lowest R_f value gave a yellow solid (6 mg, 1.5%) mp 256 °C identified as 2,6-diacetylbiphenylene (mixed mp and IR spectrum). The middle band gave 2-acetyl-6-(methoxycarbonyl)biphenylene (**20**) as a yellow solid (93 mg, 20% overall), mp 180—181 °C; IR (Nujol mull) 1670 and 1722 cm^{-1}; UV (C_2H_5OH) λ_{max} (log ε) 216 (3.76), 266 (4.32), 279 (4.42), 326^{sh} (3.04), 339^{sh} (3.34), 342 (3.34), 354^{sh} (3.61), 357 (3.62), and 374 nm (3.87); ^{1}H-NMR ($CDCl_3$) δ=2.42 (3H, s, $COCH_3$), 3.79 (3H, s, OCH_3), 6.69 (2H, d, $H_{(4)}$ and $H_{(8)}$), 7.19 (1H, d, $H_{(1)}$), 7.24 (1H, d, $H_{(5)}$), 7.45 (1H, dd, $J_{1,3}$=1.0 and $J_{4,5}$=7.5 Hz, $H_{(3)}$), and 7.58 (1H, dd, $J_{5,7}$=1.0 and $J_{7,8}$=7.5 Hz, $H_{(7)}$). Found: C, 75.98; H, 4.68%. Calcd for $C_{16}H_{12}O_3$: C, 76.19; H, 4.76%. The band with the highest R_f value gave 2,6-bis(methoxycarbonyl)biphenylene (**10**) (30 mg, 6% overall) as a yellow solid, mp 210—212 °C (lit,[21] mp 223—225 °C); IR (Nujol mull) 852, 902, and 1715 cm^{-1}; UV (C_2H_5OH) λ_{max} log ε) 216 (4.16), 262^{sh} (4.67), 269 (4.75), 277^{sh} (4.62), 322^{sh} (3.25), 330^{sh} (3.38), 334 (3.51), 338 (3.52), 347 (3.78), 3.52 (3.79), and 369 nm (3.98); ^{1}H-NMR ($CDCl_3$) δ=3.77 (6H, s, 2×OCH_3), 6.76 (2H, d, $H_{(4)}$ and $H_{(8)}$), 7.31 (2H, d, $H_{(1)}$ and $H_{(5)}$), and 7.65 (2H, dd, $J_{1,3}$=1.0 and $J_{3,4}$=7.5 Hz, $H_{(3)}$ and $H_{(7)}$).

Preparation of 2,6-Bis(acetoxymethyl)biphenylene (8b). *a) From 2,6-bis(methoxycarbonyl)biphenylene[21] (10)*: 2,6-Bis-(methoxycarbonyl)biphenylene (100 mg), when reduced and acetylated in a manner similar to the above, yielded **8b** (86 mg, 78%), mp 105—106.4 °C.

b) From 2-acetoxymethyl-6-(methoxycarbonyl)biphenylene (17): 2-Acetoxymethyl-6-(methoxycarbonyl)biphenylene (**17**) (80 mg) was similarly treated with lithium aluminium hydride and then acetic anhydride to give **8b** (40 mg, 47%), mp 104—106 °C.

Preparation of 2-Acetoxy-6-(methoxycarbonyl)biphenylene (18) from 2-Acetyl-6-(methoxycarbonyl)biphenylene (20). A mixture of **20** (10.4 mg) and *m*-chloroperbenzoic acid (22 mg) in deuteriochloroform (0.3 ml) was kept at 36 °C for 6.5 h. The reaction mixture was passed through a short alumina column eluting with chloroform. After removal of the chloroform, the resulting solid was recrystallized from methanol, giving **18** (7.6 mg, 69%), mp 147—148 °C.

Oxidation of 2,3-Dimethylbiphenylene[4] (22) with Mn(OAc)$_3$. A mixture of **22** (170 mg, 0.94 mmol) and $Mn(OAc)_3 2H_2O$ (500 mg, 1.86 mmol) in acetic acid (20 ml) and acetic anhydride (10 ml) was heated under reflux until the brown color of the solution had changed to yellow. Water (150 ml) was added and the mixture was allowed to stand overnight. The mixture was extracted with toluene (2×100 ml). The toluene extracts were evaporated to dryness. TLC on silica gel, with chloroform as eluent, showed two components, whose R_f values were 0.75 and 0.59, and a third component, R_f 0.55 (visible under UV light), which overlapped the component with R_f value 0.59. The mixture was partially separated on a column of silica gel (35 g) using chloroform as eluent. The fractions corresponding to R_f values 0.59—0.55 were separated by chromatography several times on TLC plates (0.5 mm thickness of silica gel). The compound with R_f value 0.75 was unchanged compound **22**.

When the experiment was repeated using 1.01 g instead of 500 mg of $Mn(OAc)_3$, a new component (with R_f value 0.38) was obtained. The results are summarized in Table 4.

2-Acetoxymethyl-3-methylbiphenylene (23): R_f value 0.59; mp 62—64 °C (from aqueous ethanol); ^{1}H-NMR ($CDCl_3$) δ= 2.02 (3H, s, OAc), 2.10 (3H, s, CH_3), 4.82 (2H, s, -CH_2O-), and 6.30—6.80 (6H, m, aromatic); MS *m/z* (rel intensity) 165 (12), 178 (100), 179 (60), 238.0976 (45, M^+). Calcd for $C_{16}H_{14}O_2$: M, 238.0994.

2-Formyl-3-methylbiphenylene (24): R_f value 0.55; mp 141—143 °C (lit,[4] 136—138 °C), identified by its ^{1}H-NMR spectrum.[4]

2,3-Bis(acetoxymethyl)biphenylene (8a): R_f value 0.38; This was not obtained pure, but its ^{1}H-NMR spectrum (apart from impurities) was identical with that of an authentic sample.

Preparation of 2,7-Dibromobiphenylene (25). (In collaboration with Dr. M. E. Cracknell) A mixture of biphenylene (4.57 g) and *N*-bromosuccinimide (4.50 g) in dry *N,N*-dimethylformamide (50 ml) was stirred at room temperature for 3 h. The mixture was diluted with water (100 ml) and stirred for 3 h more. The crude product was collected, dried, and sublimed at 90 °C/0.5 mmHg (1 mmHg≈133.322 Pa) and gave 2-bromobiphenylene (5.55 g, 80%) as yellow crystals, mp 63—65 °C (lit,[20] mp 64—65 °C). A mixture of 2-bromobiphenylene (2 g) and *N*-bromosuccinimide (1.54 g) in *N,N*-dimethylformamide (50 ml) was stirred at room temperature for 20 h. The mixture was poured into ice water, and the solid was collected and dried in a vacuum desiccator. The crude product was fractionally crystallized from methanol and gave 2,7-dibromobiphenylene (**25**) (0.28 g, 10%) as yellow plates, mp 137—138 °C; ^{1}H-NMR ($CDCl_3$) δ=6.37 (2H, dd, $H_{(4)}$ and $H_{(5)}$), 6.65 (2H, m, $J_{1,3}$=1.2 and $J_{1,4}$= 0.8 Hz, $H_{(1)}$ and $H_{(8)}$), and 6.83 (2H, dd, $J_{3,4}$=6.8 Hz, $H_{(3)}$, $H_{(6)}$). Found: C, 46.39; H, 2.13%. Calcd for $C_{12}H_6Br_2$: C, 46.49; H, 1.95%.

Conversion of 2,7-Dibromobiphenylene (25) into 2,7-Dimethylbiphenylene. 2,7-Dibromobiphenylene (1 g) was dissolved in sodium-dried diethyl ether (40 ml) and cooled to 0

°C under an atmosphere of nitrogen. Butyllithium (10 ml) was added and the solution was stirred for 5 min. Methyl iodide (4.6 g) was added to the solution, giving some precipitates. The uncovered reaction mixture was left stirring overnight. Water was added and the solution was extracted with diethyl ether. The organic layer was washed with a saturated solution of sodium chloride and dried over anhydrous sodium sulfate. The solution was filtered and then the solvent was evaporated off. The resulting solid was recrystallized from ethanol to give 2,7-dimethylbiphenylene (197 mg, 34%), mp 113—114 °C (lit,[22] mp 115 °C). The ^{1}H-NMR spectrum was identical with that reported.

Oxidation of 2,7-Dibromobiphenylene (25) with Mn(OAc)$_3$. A mixture of **25** (340 mg) and $Mn(OAc)_32H_2O$ (1.08 g) in acetic acid (20 ml) and acetic anhydride (9.3 ml) was heated under reflux until the color of the solution had changed from brown to yellow. The products were isolated and separated as described for the oxidation of 2,3-dimethylbiphenylene. The experiment was repeated using 1.62 g in place of 1.08 g $Mn(OAc)_32H_2O$. The yields for both experiments are shown in Table 4.

2-Acetoxymethyl-3,6-dibromobiphenylene (26): Mp 133—134 °C (ethanol); ^{1}H-NMR δ=2.14 (3H, s, CH_3), 5.01 (2H, s, -CH_2O-), 6.55 (1H, dd, $H_{(8)}$), 6.72 (1H, d, $J_{1,4}$=0.4 Hz, $H_{(1)}$), 6.79 (1H, dd, $J_{5,7}$=1.5 and $J_{5,8}$=0.7 Hz, $H_{(5)}$), 6.87 (1H, br. s, $H_{(4)}$), and 6.97 (1H, dd, $J_{7,8}$=7.4 Hz, $H_{(7)}$). Found: C, 47.59; H, 2.82: Br, 41.56%. Calcd for $C_{15}H_{10}Br_2O_2$: C, 47.16; H, 2.64; Br, 41.83%.

2,7-Bis(acetoxymethyl)-3,6-dibromobiphenylene (27): Mp153—154 °C (ethanol); ^{1}H-NMR ($CDCl_3$) δ=2.08 (6H, s, 2×CH_3), 4.97 (4H, s, 2×-CH_2O-), 6.67 (2H, s, $H_{(1)}$ and $H_{(8)}$), and 6.77 (2H, s, $H_{(4)}$ and $H_{(5)}$); MS *m/z* (rel intensity) 43 (27), 163 (11), 209 (11), 331 (98), 332 (19), 333 (100), 334 (18), 395 (18), 452 (18, M^+), 453.9235 (45, M^+), and 456 (19, M^+). Calcd for $C_{18}H_{14}O_4$ $^{79}Br^{81}Br$: M, 453.9238.

We are indepted to Dr. B. E. Ayres for performing the oxidation of 2,6-diacetylbiphenylene.

(Received November 28, 1983)

Chiral tertiary amines with a secondary amide group at α- or β-carbon were prepared, and an asymmetric hydrogenation of methyl 2-(acetylamino)acrylate and *N,N'*-dimethyl-5-benzylidenehydantoin catalyzed by achiral base-coordinated bis(dimethylglyoximato)cobalt(II)-chiral cocatalyst system was examined by using each of them as the cocatalyst. The enantiomeric excess of *N,N'*-dimethyl-5-benzylhydantoin reached 79.1% with (*S*)-*N*-[(*R*)-1-phenylethyl]-2-quinuclidinecarboxamide as the cocatalyst. Remarkable differences were observed in the enantioselectivities between the two substrates for the same cocatalysts. Discussion about the conformations of the cocatalysts and substrates led to proposed models of chirality-recognizing transition states.

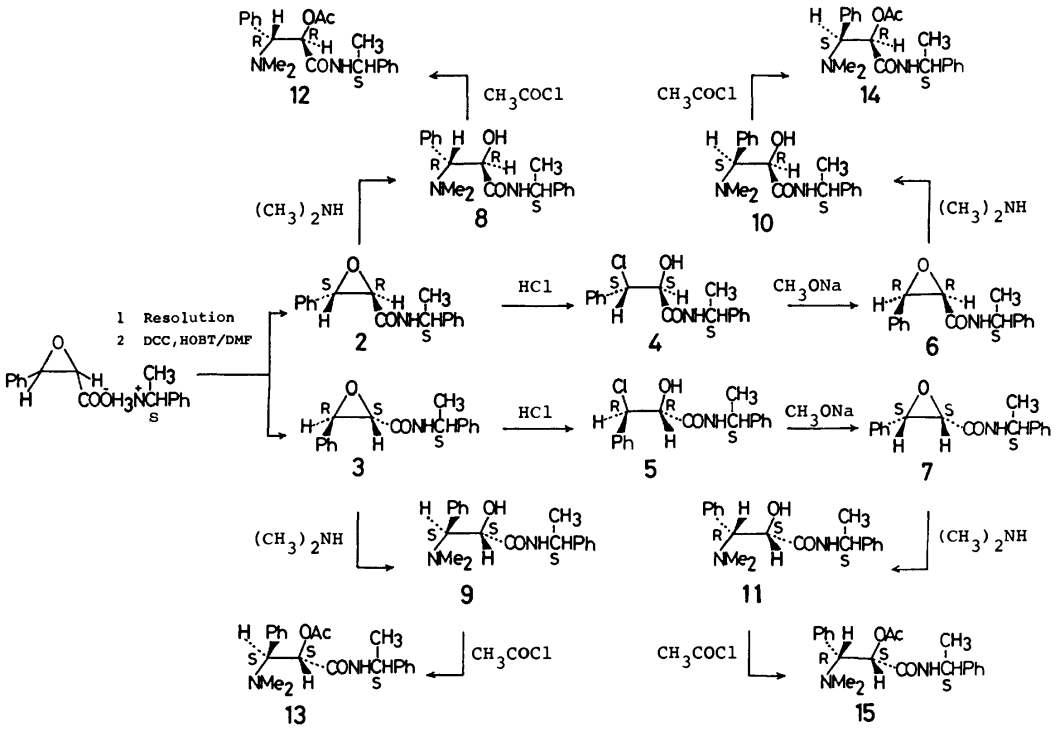
The authors have previously reported the asymmetric hydrogenation catalyzed by the achiral base-coordinated bis(dimethylglyoximato)cabalt(II)-chiral base(cocatalyst) system(hereafter abbreviated as Co(dmgH)$_2$·B-B*; B and B* are achiral and chiral bases respectively). Co(dmgH)$_2$·B-quinine resulted in high optical yields (up to 78%) for α-diketones such as benzil, but in low optical yields (up to 19%) for dehydro amino acid derivatives. A hydrogen bond between the hydroxyl group of cocatalyst(quinine) and the carbonyl group of substrate(benzil) in the chirality-recognizing transition state extremely enhances the enantioselectivity of this system.[2)]

In the preceding paper, the authors reported the asymmetric hydrogenation of methyl 2-(acetylamino)-acrylate with 34.5%ee(enantiomeric excess) using (2*S*, 3*S*)-2-acetoxy-3-dimethylamino-3-pheny-*N*-[(*R*)-1-phenylethyl]propionamide as the cocatalyst and deduced that the hydrogen bond between the amide groups of the substrate and cocatalyst acts as an attractive force to enhance the enantioselectivity.[3)]

Here, we would like to describe the preparation of other new cocatalysts and the asymmetric hydrogenation of 2-(acetylamino)acrylate and *N,N'*-dimethyl-5-benzylidenehydantoin using them as the cocatalysts.

Results and Discussion

Preparation of Cocatalysts. Four diastereoisomers of 2-acetoxy-3-dimethylamino-3-phenyl-[(*S*)-1-phenylethyl]propionamide [**12**(DHP-*OAc*-(2*R*,3*R*)*S*), **13**(DHP-*OAc*-(2*S*,3*S*)*S*), **14**(DHP-*OAc*-(2*R*,3*S*)*S*), and **15**(DHP-*OAc*-(2*S*,3*R*)*S*)] were prepared from (*S*)-1-phenylethylammonium 2,3-epoxy-3-phenylpropionate by the route shown in Scheme 1. Four enantiomers of them [**12'**(DHP-*OAc*-(2*S*,3*S*)*R*), **13'**(DHP-*OAc*-(2*R*, 3*R*)*R*), **14'**(DHP-*OAc*-(2*S*,3*R*)*R*), and **15'**(DHP-*OAc*-(2*R*,3*S*)*R*)] were prepared from (*R*)-1-phenylethyl-



Scheme 1.

ammonium 2,3-epoxy-3-phenylpropionate by the same procedures (each enantiomer of the compounds in Scheme 1 is expressed as the same number with prime). O-Benzoyl derivative DHP-*OBz*-(2*S*,3*S*)*R* was obtained by benzoylation of **8′**.

Two diastereoisomers of *N*-[(*R*)-1-phenylethyl]-2-quinuclidinecarboxamide [**18**(QC-(*S*)*R*) and **19**(QC-(*R*)*R*)] were prepared from (*S*)- and (*R*)-2-quinuclidinecarboxylic acids (**16** and **17**, respectively) by the route shown in Scheme 2.

(Details are described in the Experimental section).

Asymmetric Hydrogenation of Methyl 2-(acetylamino)-acrylate and N,N′-Dimethyl-5-Benzylidenehydantoin with $Co(dmgH)_2$·B-chiral Amino Amides. The asymmetric hydrogenation of methyl 2-(acetylamino)acrylate and *N,N′*-dimethyl-5-benzylidenehydantoin with $Co(dmgH)_2$·B-B* was carried out in benzene under an atmospheric pressure of hydrogen at room temperature.

The chiral α- and β-amino amides prepared above were used as the cocatalysts(B*), and quinine and (*S*)-

a) The molar ratio of substrate to cobalt was 9.3 : 1, while those of PPh_3, BA, the chiral bases and their hydrochlorides to cobalt were all 1 : 1. Solvent was benzene. b) Configuration. c) Optical purity. d) $PhCH_2$-$\overset{S}{C}H(N(CH_3)_2)$-CONH$\overset{R}{C}H(CH_3)$Ph.

N^{α},N^{α}-dimethyl-*N*-[(*R*)-1-phenylethyl]phenylalaninamide(Pha-*S*,*R*) were also used as B* for comparison in the case of *N*,*N*′-dimethyl-5-benzylidenehydantoin. Benzylamine(BA) and triphenylphosphine(PPh_3) were used as the achiral bases(B).

As the specific rotation of enantiomerically pure *N*,*N*′-dimethyl-5-benzylhydantoin was unknown, the enantiomeric excesses shown in Table 2 were determined by the method described in the Experimental section.

The results of the asymmetric hydrogenation are summarized in Table 1 and Table 2.

As can be seen in Table 1, the enantiomeric excesses[4] in runs 5—9 are much higher than those in runs 1—4, and the enantioselectivities are affected by the configurations of the C-2 and C-3 chiral centers of DHP-*OAc* and DHP-*OBz* (the cocatalysts are erythro isomers in runs 5—9 and threo isomers in runs 1—4) but are little affected by that of the chiral center of 1-phenylethylamine moiety.

The most stable conformations of the erythro and the threo isomers may exist as shown in Fig. 1.

In the chirality-recognizing step (*i.e.*, the protonation by the protonated chiral cocatalyst to the carbanion formed through the hydrogenation with $Co(dmgH)_2 \cdot B$[2]), a hydrogen bonding between the amide group of cocatalyst and the functional group of carbanion is possible in the erythro isomer but not in the threo isomer, since in the threo isomer the protonated dimethylamino group and the amide group exist in anti position and cannot interact with the carbanion simultaneously. This explains the difference between enantioselectivity in runs 5—9 and runs 1—4.

As can be seen in Table 2, the enantiomeric excess of *N*,*N*′-dimethyl-5-benzylhydantoin reached 79.1% (run 11), which is the highest value so far attained in the asymmetric hydrogenation of olefinic compounds with $Co(dmgH)_2 \cdot B$-B* system. The configuration of the predominant isomer in every case coincides with that of the chiral center bearing a tertiary amino group of the cocatalyst and the enantioselectivity is not so largely affected by the configuration of the 1-phenylethylamine moiety.

A comparison of Tables 1 and 2 shows that the configurations of *N*,*N*′-dimethyl-5-benzylhydantoin in runs 7, 8, 9, 11 and 12 of Table 2 are opposite to those of methyl *N*-acetylalaninate in runs 6, 8, 9, 10 and 11 of Table 1, respectively, and the enantioselectivities are remarkably increased in runs 11 and 12 of Table 2. The reason for the difference in the enantioselectivity

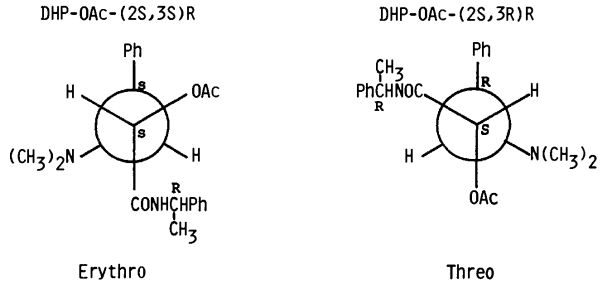

Fig. 1. Conformations of DHP-*OAc*.

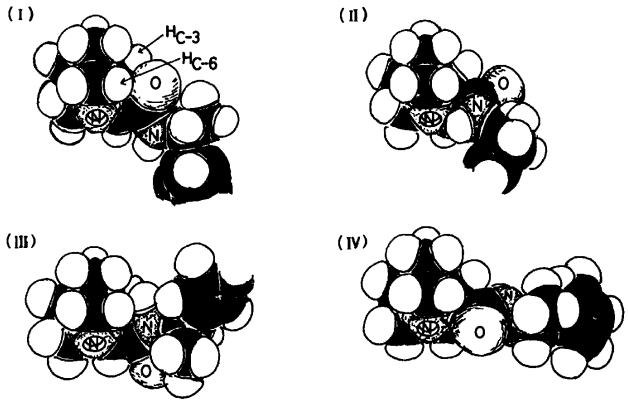

Fig. 2. Conformations of QC-(*S*)*R*.

between the two substrates will be discussed below in the cases of run 10 of Table 1 and run 11 of Table 2.

As the enantioselective recognition is made through the protonation to the carbanions formed from the two substrates by the protonated QC-(*S*)*R*, it is necessary to discuss the interactions between the conformers of the protonated QC-(*S*)*R* and the carbanions. The conformations of QC-(*S*)*R* and the carbanions were considered with CPK's space-filling models.

As C=O and N-H of amide group lie in coplanar anti position, the possible conformers of QC-(*S*)*R* are shown in Fig. 2.

The conformer **III** is very unstable because of a large steric repulsion between the hydrogen atoms attached to C-3 and C-6 of the quinuclidine ($H_{C\text{-}3}$ and $H_{C\text{-}6}$, respectively) and that of N-H of amide group (N-**H**). The conformer **II** and the protonated conformer **IV** are stable because of intramolecular hydrogen bonds (between N-**H** and the nitrogen atom of quinuclidine, and between the carbonyl oxygen and the hydrogen attached to the nitrogen atom of quinuclidine, respectively) and because of small steric repulsions between $H_{C\text{-}3}$, $H_{C\text{-}6}$ and the amide group. Their stabilities, however, will decrease their proton-accepting and proton-donating activities respectively, and will moreover lower their abilities to make an intermolecular hydrogen bond. The protonated conformer **I** (HQC-(*S*)*R*-I) is relatively stable because the steric repulsion between $H_{C\text{-}3}$, $H_{C\text{-}6}$ and the carbonyl oxygen is not so large, and thus can make an intermolecular hydrogen bond between N-**H** of HQC-(*S*)*R*-I and the carbonyl oxygen of the carbanions (the intramolecular hydrogen bonding is impossible).

Therefore, HQC-(*S*)*R*-I is regarded as the best conformer with which to determine the chirality of the carbanions through the intermolecular hydrogen bond in the protonation step.

The possible conformations of the carbanions of (*S*)-*N*,*N*′-dimethyl-5-benzylhydantoin ((*S*)-$DMBH_a$ and (*S*)-$DMBH_b$) and methyl (*R*)-*N*-acetylalaninate ((*R*)-AA) are shown in Fig. 3.

The conformer (*S*)-$DMBH_a$ is more stable irrespective of the relatively large steric repulsion between the hydantoin and benzene rings and is more likely to react with HQC-(*S*)*R*-I than (*S*)-$DMBH_b$, because the electrostatic repulsion between the lone pair on the asym-

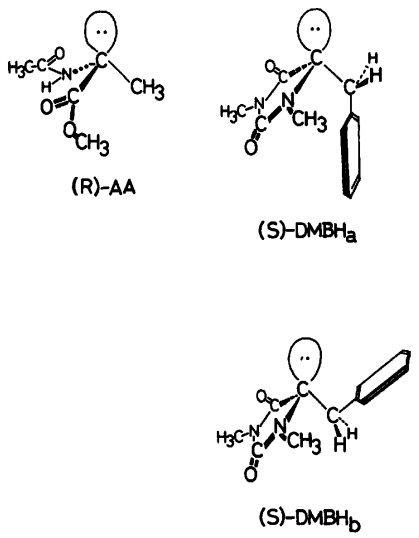

Fig. 3. Conformations of (*R*)-*N*-acetylalaninate and (*S*)-*N*,*N*′-dimethyl-5-benzylhydantoin.

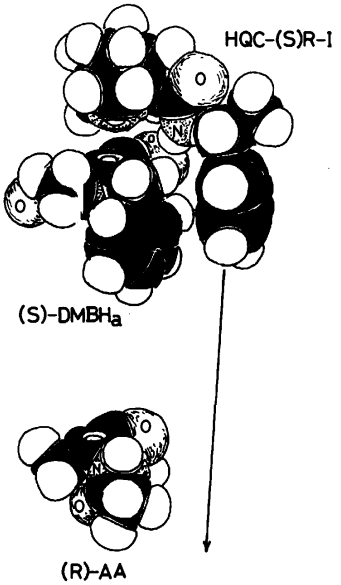

Fig. 4. Models of the protonation by HQC-(*S*)*R*-I to (*S*)-$DMBH_a$ and (*R*)-AA.

metric carbon atom of (*S*)-$DMBH_b$ and the π-electron on the benzene ring is more serious and/or the benzene ring of (*S*)-$DMBH_b$ prevents HQC-(*S*)*R*-I from approaching to the reaction center of (*S*)-$DMBH_b$.

As shown in Fig. 4, HQC-(*S*)*R*-I can approach (*S*)-$DMBH_a$ to make the intermolecular hydrogen bond between N-**H** of HQC-(*S*)*R*-I and the C-4 carbonyl oxygen of (*S*)-$DMBH_a$ without any substantial overlap of their substituents (in Fig. 4, the hydrogen atom attached to the nitrogen atom of quinuclidine and the lone pair on the asymmetric carbon atom of (*S*)-$DMBH_a$ and (*R*)-AA are not depicted for convenience).

On the other hand, if HQC-(*S*)*R*-I approaches (*R*)-$DMBH_a$ without the overlap of their substituents, the intermolecular hydrogen bonding becomes impossible.

Consequently, HQC-(*S*)*R*-I can selectively protonate (*S*)-$DMBH_a$ to give (*S*)-*N*,*N*′-dimethyl-5-benzylhydantoin predominantly with relatively high enantioselectivity.

As can be seen in Fig. 4, HQC-(*S*)*R*-I can approach (*R*)-AA to make the intermolecular hydrogen bond between N-**H** of HQC-(*S*)*R*-I and the carbonyl oxygen of ester group of (*R*)-AA without any substantial overlap of their substituents (if HQC-(*S*)*R*-I in Fig. 4 is shifted in the direction of the arrow and is so placed as to make the hydrogen bond, a plausible model of the transition state of protonation to (*R*)-AA by HQC-(*S*)*R*-I will be made). HQC-(*S*)*R*-I can also approach (*S*)-AA to make the hydrogen bond without a significant overlap of their substituents. However, the approach of HQC-(*S*)*R*-I may occur preferentially to (*R*)-AA rather than to (S)-AA, since the space between $COOCH_3$ and $NHCOCH_3$ is larger than that between CH_3 and $COOCH_3$.

This may explain the opposite and lower enantioselectivity in run 10 of Table 1 in comparison with that of run 11 of Table 2.

Experimental

The melting points were determined by Yanagimoto micro-melting point apparatus and were uncorrected. The IR spectra were recorded on a JASCO A-3 spectrometer. The ^1H NMR spectra were obtained on JEOL-FX 200 spectrometer. The optical rotations were measured with a Perkin Elmer 241 polarimeter.

Preparation of Stereoisomers of DHP-OAc and DHP-OBz. As the preparations of **12** and **12′** were described in the preceding paper,[3] the preparation procedures of the other three diastereoisomers and their enantiomers are described below.

*(2R,3S)-2,3-Epoxy-3-phenyl-*N*-[(R)-1-phenylethyl]propionamide (3′) and Its Enantiomer (3).* Starting from 72.1 g of ethyl 2,3-epoxy-3-phenylpropionate, 40.0 g of crystalline (*R*)-1-phenylethylammonium (2*S*,3*R*)-2,3-epoxy-3-phenylpropionate was obtained by Harada's method.[5] The filtrate which contained (*R*)-1-phenylethylammonium (2*R*,3*S*)-2,3-epoxy-3-phenylpropionate(**1′**) was concentrated to dryness *in vacuo* to afford 34.0 g of sirupy residue. This was dissolved in DMF (200 ml) and to the solution was added a solution of DCC (24.6 g, 119 mmol) and 1-hydroxybenzotriazole (16.0 g, 119 mmol) in DMF (150 ml) during 1.5 h on ice-cooling with stirring. Stirring was continued overnight at room tempetature. After filtration of the precipitate, the filtrate was concentrated *in vacuo* at 30—40 °C. The residue was dissolved in ethyl acetate (*ca.* 1300 ml), and the solution was washed successively with a 10% citric acid solution (200 ml), a 4% sodium hydrogencarbonate solution (200 ml), and a sodium chloride solution (300 ml) and then dried (Na_2SO_4). The solution was concentrated to 150—200 ml and the crystals which separated out were dissolved thoroughly on heating. To the solution petroleum ether was added carefully. Crystals (prisms, 17.1 g) were obtained: $[\alpha]_D^{17.5}$ −2.1°; $[\alpha]_{365}^{17.5}$ +46.2° (*c* 0.999, $CHCl_3$).

Its enantiomer(**3**) was likewise prepared from the sirupy residue (33.8 g) containing **1** to give 12.7 g of crystals (prisms): $[\alpha]_D^{25.5}$ +1.6°; $[\alpha]_{365}^{25.5}$ −47.9° (*c* 0.988, $CHCl_3$).

*(2S,3S)-3-Dimethylamino-2-hydroxy-3-phenyl-*N*-[(S)-1-phenylethyl]propionamide (9) and Its Enantiomer (9′).* A suspension of **3** (5.0 g) in a 50% aqueous dimethylamine solution (200 ml) was stirred for 2.5 h at room temperature. The homogeneous solution obtained was evaporated *in vacuo*. A crystalline mass was separated out when water began to evaporate and then was filtered off after water was

added to the solution. After drying, the crystals (5.7 g) were recrystallized from benzene to give 4.2 g of needles: $[\alpha]_D^{20.0}$ −56.1° (*c* 1.016, $CHCl_3$).

Its enantiomer was likewise prepared from **3′** (7.0 g) to give 2.47 g (first crop) and 4.36 g (second crop) of crystals (needles): $[\alpha]_D^{26.0}$ +54.2° (*c* 0.994, $CHCl_3$) and $[\alpha]_D^{21.0}$ +56.1° (*c* 1.007, $CHCl_3$), respectively.

(2S,3S)-2-Acetoxy-3-dimethylamino-3-phenyl-N-[(S)-1-phenylethyl]propionamide (13) and Its Enantiomer (13′). To a solution of **9** (3.8 g, 12.2 mmol) in dry ethyl acetate (200 ml) was added acetyl chloride (1.0 g, 12.2 mmol). The solution was allowed to stand overnight at room temperature. The amorphous solid which separated out was dissolved in water after ethyl acetate was decanted. The aqueous solution was washed with ether, and the aqueous layer was made basic with a sodium hydrogencarbonate solution. The solution was extracted with ethyl acetate. The ethyl acetate layer was dried(Na_2SO_4) and concentrated to yield 3.7 g of crystalline material. This was recrystallized from ethyl acetate-petroleum ether to give 3.23 g of needles: $[\alpha]_D^{27.5}$ −66.8° (*c* 1.003, $CHCl_3$).

Its enantiomer was likewise prepared from **9′** (5.0 g) to give 3.97 g of needles: $[\alpha]_D^{27.0}$ +66.6° (*c* 0.998, $CHCl_3$).

(2S,3S)-3-Chloro-2-hydroxy-3-phenyl-N-[(S)-1-phenylethyl]propionamide (4) and Its Enantiomer (4′). Into a solution of **2** (1.2 g) in 1000 ml of dry benzene was bubbled dry hydrogen chloride gas for 30 min at room temperature with stirring. Stirring was continued for 1 h and then concentrated to dryness to yield 1.2 g of crystalline material.[6] 14.4 g of the crystalline material thus obtained was recrystallized from ethyl acetate (150 ml)- petroleum ether (158 ml) to give 7.7 g of needles: $[\alpha]_D^{20.0}$ +40.8° (*c* 0.500, $CHCl_3$).

Its enantiomer was likewise prepared from **2′** *via* 10.7 g of crystalline material to give 6.1 g of needles: $[\alpha]_D^{27.0}$ −41.1° (*c* 0.506, $CHCl_3$).

(2R,3R)-2,3-Epoxy-3-phenyl-N-[(S)-1-phenylethyl]propionamide (6) and Its Enantiomer (6′). 6.45 g (21.2 mmol) of **4** was dissolved in ethanol (200 ml) while heating. After cooling, 2.12 mol dm^{-1} sodium methoxide solution (10.0 ml) was added dropwise to the solution during 2—3 min with stirring. The solution was allowed to stand for 1.5 h at room temperature and then concentrated. The residue was extracted with chloroform. The chloroform layer was dried (Na_2SO_4) and concentrated to yield 5.5 g of crystalline material. This was recrystallized from ethyl acetate-petroleum ether to give 4.3 g of needles: $[\alpha]_D^{24.0}$ −59.7° (*c* 1.003, $CHCl_3$).

Its enantiomer was likewise prepared from **4′** (5.0 g) to give 4.4 g of needles: $[\alpha]_D^{24.0}$ +60.6° (*c* 1.019, $CHCl_3$).

(2R,3S)-3-Dimethylamino-2-hydroxy-3-phenyl-N-[(S)-1-phenylethyl]propionamide (10) and Its Enantiomer (10′). A suspension of 4.2 g of **6** in a 50% aqueous dimethylamine solution (140 ml) was stirred for 1.5 h at room temperature. The homogeneous solution was treated and purified by the same procedure as **9** to give 4.28 g of needles: $[\alpha]_D^{21.0}$ −125.6° (*c* 1.022, $CHCl_3$).

Its enantiomer was likewise prepared from **6′** (3.5 g) to give 3.2 g of needles: $[\alpha]_D^{20.0}$ +127.1° (*c* 1.036, $CHCl_3$).

(2R,3S)-2-Acetoxy-3-dimethylamino-3-phenyl-N-[(S)-1-phenylethyl]propionamide (14) and Its Enantiomer (14′). These were prepared from **10** (3.6 g) and **10′** (2.9 g) by the same procedure as **13** to give needles (3.4 g and 2.5 g): $[\alpha]_D^{25.0}$ −12.0° (*c* 1.002, $CHCl_3$) and $[\alpha]_D^{27.5}$ +11.9° (*c* 1.003, $CHCl_3$), respectively.

(2R,3R)-3-Chloro-2-hydroxy-3-phenyl-N-[(S)-1-phenylethyl]propionamide (5) and Its Enantiomer (5′). This was prepared from **3** by the same procedure as **4**. The crystalline material (14.5 g) thus obtained was recrystallized from ethyl acetate (100 ml)-petroleum ether (126 ml) to give 5.56 g of prisms. This was again recrystallized from ethyl acetate (25 ml)-petroleum ether (43 ml) to give 4.4 g of prisms: $[\alpha]_D^{20.0}$ −158.3° (*c* 0.504, $CHCl_3$).

Its enantiomer was likewise prepared from **3′**. The product (12.5 g) was recrystallized from ethyl acetate-petroleum ether to give 4.4 g of prisms: $[\alpha]_D^{20.0}$ +156.6° (*c* 0.516, $CHCl_3$).

(2S,3S)-2,3-Epoxy-3-phenyl-N-[(S)-1-phenylethyl]propionamide (7) and Its Enantiomer (7′). These were prepared from **5** (4.1 g) and **5′** (4.0 g) by the same procedure as **6** to give needles (2.5 g and 2.5 g): $[\alpha]_D^{20.5}$ −0.0°; $[\alpha]_{365}^{20.5}$ −16.3° (*c* 1.003, $CHCl_3$) and $[\alpha]_D^{20.5}$ +0.0°; $[\alpha]_{365}^{20.5}$ +15.8° (*c* 1.006, $CHCl_3$), respectively.

(2S,3R)-3-Dimethylamino-2-hydroxy-3-phenyl-N[(S)-1-phenylethyl]propionamide (11) and Its Enantiomer (11′). These were prepared from **7** (3.2 g) and **7′** (3.0 g) by the same procedure as **10** except for recryatallization from ethyl acetate-petroleum ether to give needles (1.82 g and 2.5 g): $[\alpha]_D^{21.0}$ −81.6° (*c* 1.000, $CHCl_3$) and $[\alpha]_D^{20.0}$ +81.6° (*c* 1.002, $CHCl_3$), respectively.

(2S,3R)-2-Acetoxy-3-dimethylamino-3-phenyl-N-[(S)-1-phenylethyl]propionamide (15) and Its Enantiomer (15′). These were prepared from **11** (2.0 g) and **11′** (2.1 g) by the same procedure as **13** except for recrystallization from ether to give needles (1.37 g and 1.25 g): $[\alpha]_D^{27.0}$ −109.8° (*c* 1.001, $CHCl_3$) and $[\alpha]_D^{26.0}$ +110.0° (*c* 1.003, $CHCl_3$), respectively.

(2S,3S)-2-Benzoyloxy-3-dimethylamino-3-phenyl-N-[(R)-1-phenylethyl]propionamide. To a solution of **8′** (1.2 g, 3.8 mmol) in dry ethyl actate (200 ml) was added benzoyl chloride (0.59 g, 4.2 mmol). The solution was allowed to stand for 2 d and then concentrated. The residue was solidified with ether. The solid material was filtered off and recrystallized from methanol-ether to give 0.69 g of prisms: $[\alpha]_D^{15.0}$ +103.3° (*c* 1.002, CH_3OH); IR(KBr) 3500, 3200, 3100, 2800—2400 (amide NH and N^+–H), 1720 (ester C=O) and 1690 cm^{-1} (amide C=O). Found: C, 66.31; H, 6.63; N, 5.95%. Calcd for $C_{26}H_{29}N_2O_3Cl \cdot H_2O$: C, 66.17; H, 6.68; N, 5.80%.

Melting points, elemental analyses, IR spectra and ^1H NMR spectra of the compounds **2**—**15** and their enantiomers **2′**—**15′** are summarized in Tables 3, 4, 5 and 6.

Preparation of QC-(S)R and QC-(R)R. 2-Quinuclidinecarboxylic acid was prepared from 4-pyridinecarbaldehyde and diethyl malonate by the method reported by Långström.[7] Optical resolution of ethyl 2-quinuclidinecarboxylate was caried out by the method reported by Pracejus and Kohl.[8] (*S*)- and (*R*)- quinuclidinecarboxylic acid hydrochlorides, whose optical rotations were $[\alpha]_D^{21.0}$ −96.5° (1.073, water) and $[\alpha]_D^{24.0}$ +97.5° (*c* 1.012, water), respectivety (literature[7]: $[\alpha]_D$ −96.2° (*c* 1, water)) were obtained by hydrolysis of their ethyl esters. QC-(*S*)*R* and QC-(*R*)*R* were prepared by a condensation of **16** and **17** with (*R*)-1-phenylethylamine by the following procedures.[9]

(S)-N-[(R)-1-Phenylethyl]-2-quinuclidinecarboxamide (18).[10] Thionyl chloride (31.5 ml) and **16** (2.95 g, 15.4 mmol) were refluxed for 20 min and the homogeneous solution was concentrated to remove the excess thionyl chloride. To the residue was added dry ether (60 ml) and (*R*)-1-phenylethylamine (8.0 ml, 62 mmol) on ice cooling with stirring. Stirring was continued for 3 h and to the solution was added 50% aqueous potassium carbonate solution untill the water layer became basic. The water layer was extracted with ether three times (300 ml). The ether layer was dried(Na_2SO_4) and concentrated to remove also the excess (*R*)-1-phenylethylamine and to give 3.1 g of oily material which soon crystallized. This was recrystallized from petroleum ether to give 2.33 g of plates: mp 97.0—99.0 °C; $[\alpha]_D^{22.5}$ −3.5°, $[\alpha]_{365}^{22.5}$ +41.1° (*c* 1.004, $CHCl_3$); IR (KBr) 3350 (NH) and 1650 cm^{-1} (amide C=O); ^1H NMR ($CDCl_3$) δ=1.47 (3H, d, *J*=7.1 Hz, $C\underline{H}_3$), 1.47 (4H, m), 1.82 (3H, m), 2.62 (2H, q), 2.88 (2H, m), 3.31 (1H, t, *J*= 8.8 Hz, C-2 methine proton), 5.14 (1H, quintet, *J*=7.1 Hz, CH_3-$C\underline{H}$) and 7.30 (6H, m, Ph and $N\underline{H}$). Found: C, 74.38;

H. 8.58; N, 10.84%. Calcd for $C_{16}H_{22}N_2O$: C, 74.26; H, 8.81; N, 10.76%.

(R)-N[(R)-1-Phenylethyl]-2-quinuclidinecarboxamide (19).[10] This was prepared from **17** (2.3 g) by the procedure used for **20** to yield 2.6 g of oily material which did not crystallize. *p*-Toluenesulfonic acid (1.54 g, 8.1 mmol) and 2.1 g (8.1 mmol) of the oily material were dissolved in methanol (20 ml) and then the solution was concentrated to dryness. To the residue was added dry benzene and the mixture was concentrated (this was repeated 2—3 times). The crystalline material obtained was recrystallized from ethyl acetate (1200 ml) to give 2.2 g of thin plates, which were further recrystallized from ethyl acetate (700 ml) to give 1.8 g of thin plates. These crystals were dissolved in a small amount of water and to the solution was added enough 50% potassium carbonate solution to make the water layer basic. The solution was extracted with ether 2—3 times. The ether layer was dried (Na_2SO_4) and concentrated to give 1.1 g of oil: $[\alpha]_D^{21.5}$ +121.6° (*c* 1.017, $CHCl_3$); IR (NaCl) 3350 (NH) and 1770 cm^{-1} (amide C=O); ^1H NMR ($CDCl_3$) δ=1.49 (3H, d, *J*= 6.84 Hz, CH_3), 1.49 (4H, m), 1.78 (3H, m), 2.75 (2H, t), 2.88 (2H, q), 3.27 (1H, t, *J*=7.8 Hz, C-2 methine proton), 5.51 (1H, quintet, *J*=6.84 Hz, CH_3-CH), 7.30 (6H, m, Ph and NH).

Asymmetric Hydrogenation of Methyl 2-(acetylamino)acrylate and N,N'-Dimethyl-5-benzylidenehydantoin with Co(dmgH)$_2$·B-B.* As the procedures of the hydrogenation of methyl 2-(acetylamino)acrylate and the isolation of the hydrogenated product were described in the preceding paper,[3] only those of *N,N'*-dimethyl-5-benzylidenehydantoin in run 11 of Table 2 are given below.

To a methanol solution (10 ml) of $CoCl_2·6H_2O$ (0.25 g, 1.05 mmol) was added a hot solution of dimethylglyoxime (0.24 g, 1.05 mmol) in methanol (15 ml) under nitrogen atmosphere with stirring. The solution was stirred for 2—3 min and then 1.0 ml of 2.12 mol dm^{-1} sodium methoxide solution was added to the solution. After 1—2 min, triphenylphosphine (0.275 g, 1.05 mmol) in hot methanol (15 ml) and a methanol solution of equimolar mixture of **18** (0.27 g, 1.05 mmol) and its hydrochloride were added to the solution.

Methanol in the resulting catalyst solution was evaporated *in vacuo*; stirring was continued untill the sample became a wet paste. To this paste 15 ml of degassed benzene was added by a syringe under atmospheric pressure of hydrogen, and the mixture was then evaporated again to wet paste *in vacuo*. To the resulting catalyst was added a degassed benzene solution (60 ml) of *N,N'*-dimethyl-5-benzylidenehydantoin (2.0 g, 9.26 mmol) again with a syringe.

After a theoretical amount of hydrogen was absorbed (for about 3 d), 100 ml of benzene was added to the reaction mixture. Then the solution was washed successively with water, sodium chloride solution, 3 mol dm^{-1} hydrochloric acid solution (100 ml), sodium chloride solution and sodium hydrogencarbonate solution. The benzene layer was dried (Na_2SO_4) and concentrated to give an oily material.

The oily material was adsorbed on a silica-gel column (Wako Gel C-300, 20 g, 1.8ϕ×23 cm), and eluted by benzene (100—150 ml) and then by a mixture of benzene and ethyl acetate (10:1, 200 ml; and then 5:1, 100 ml). Triphenylphosphine was eluted out with 100—150 ml of benzene and 1.89 g of oily material was obtained from the eluates of the mixture of benzene and ethyl acetete (10:1 and 5:1, 300 ml). The oily material was soon crystallized.

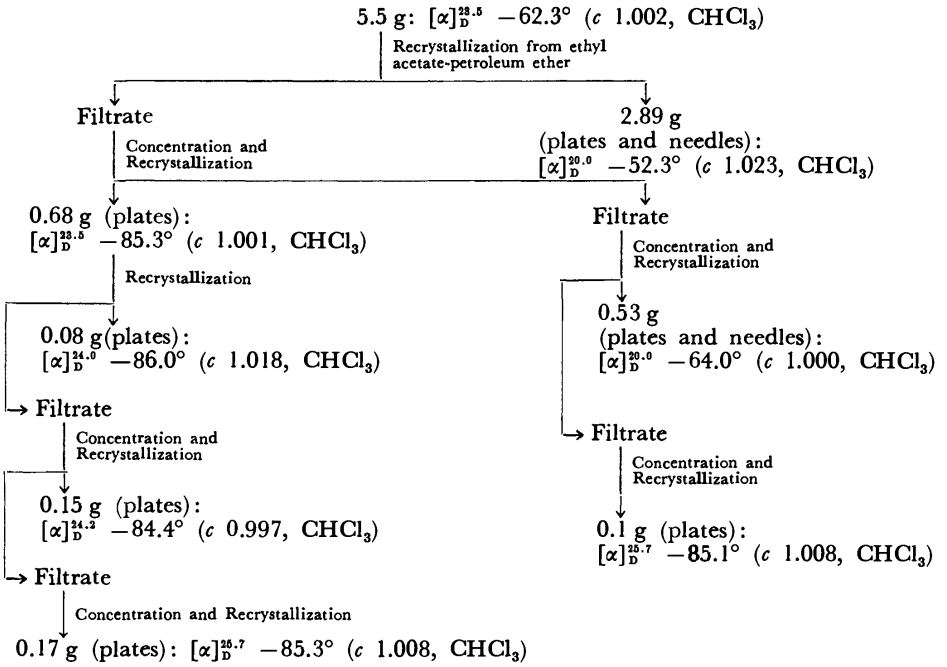
When benzylamine was used as the achiral base, the purification of the product through silica-gel column was not necessary.

Determination of the Specific Rotation of an Enantiomerically Pure (S)-N,N'-Dimethyl-5-benzylhydantoin. (*S*)-5-benzylhydantoin[$[\alpha]_D^{21.0}$ −102.2° (*c* 0.508, 50% C_2H_5OH), literature[11]: $[\alpha]_D$ −96.3° (50% C_2H_5OH)] prepared from (*S*)-phenylalanine was dimethylated by Shin's method[12] as follows.

To a mixture of (*S*)-5-benzylhydantoin (6.0 g) and potassium carbonate (43.8 g) in DMF (180 ml) was added methyl iodide (33 ml) with vigorous stirring; the stirring was continued for 2 d at room temperature. The reaction mixture was poured into water (200 ml) and the solution was extracted with ethyl acetate twice (400 ml). The ethyl acetate layer was washed with sodium chloride solution (200 ml) three times, dried(Na_2SO_4) and then concentrated to give oily material.

The oily material was adsorbed on a silica-gel column (Wako Gel C-300, 60 g, 3.5ϕ×20 cm), and eluted by benzene (600 ml) and then by a mixture of benzene and ethyl acetate (5:1, 700 ml). The eluate of the mixture of benzene and ethyl

TABLE 7. RECRYSTALLIZATION OF *N,N'*-DIMETHYL-5-BENZYLHYDANTOIN OF $[\alpha]_D$ −62.3°



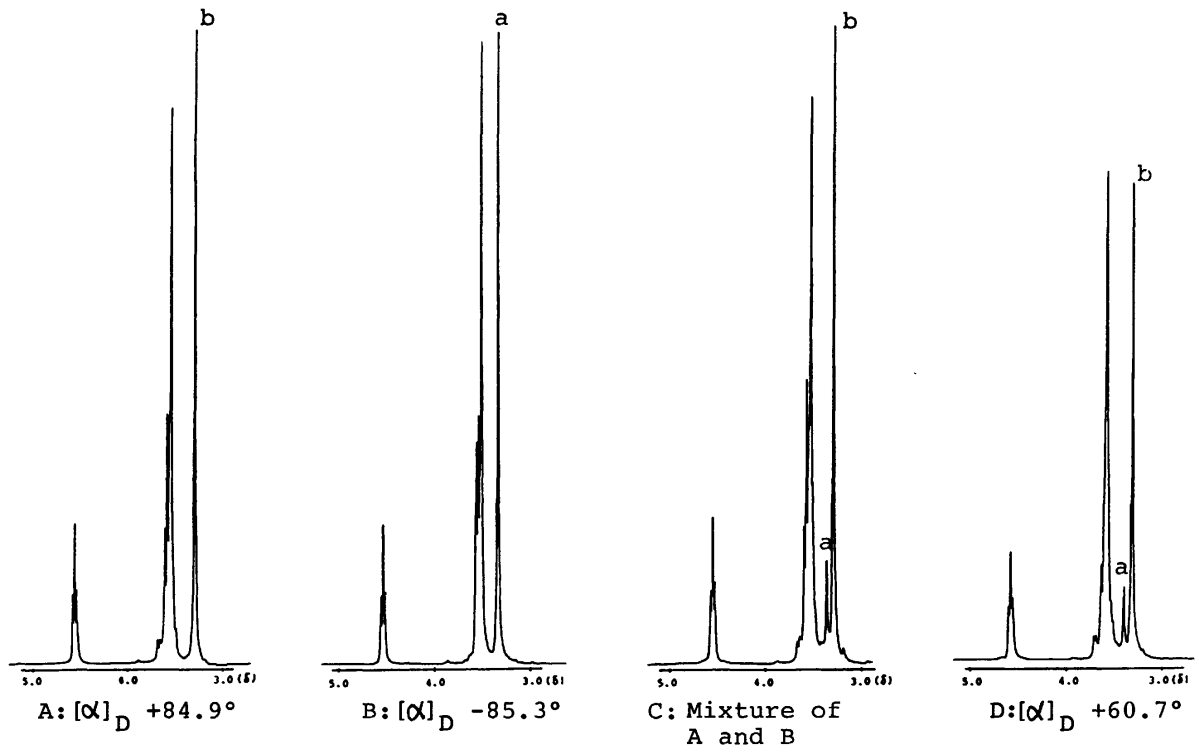


Fig. 5. ^1H NMR spectra of *N,N'*-dimethyl-5-benzylhydantoin in the presence of chiral shift reagent. In each case 45.0—46.0 mg of the sample was dissolved in 860—875 mg of $CDCl_3$ and to the solution 16.0—17.0 mg of the chiral shift reagent was added.

acetate was concentrated to give 5.78 g of oily material which crystallized gradually: $[\alpha]_D^{23.5}$ −62.3° (*c* 1.022, $CHCl_3$).

This was recrystallized from ethyl acetate-petroleum ether to give 2.89 g of crystals in which plates were covered with needles: $[\alpha]_D^{20.0}$ −52.3° (*c* 1.004, $CHCl_3$). The filtrate was concentrated and the crystals obtained were recrystallized from ethyl acetate-petroleum ether to give 0.68 g of long plates: $[\alpha]_D^{23.5}$ −85.3° (*c* 1.001, $CHCl_3$). The long plates were recrystallized repeatedly, as shown in Table 7.

The highest value thus obtained was $[\alpha]_D^{24.0}$ −86.0° (*c* 1.018, $CHCl_3$).

N,N'-dimethyl-5-benzylhydantoin (1.5 g) in run 12 of Table 2 ($[\alpha]_D^{24.0}$+60.7° (*c* 1.004, $CHCl_3$)) was similarly recrystallized from ethyl acetate-petroleum ether to give 0.19 g of long plates as a second crop: $[\alpha]_D^{22.0}$ +84.9° (*c* 1.002, $CHCl_3$).

The ^1H NMR spectra of the samples of $[\alpha]_D$ +84.9° (A), $[\alpha]_D$ −85.3° (B), $[\alpha]_D$ +60.7° (D; of run 12 in Table 2) and the mixture (C) of (A, 39.1 mg) and (B, 6.6 mg) in the presence of tris(3-trifluoroacetyl-d-camphorato)europium(III)[13] are shown in Fig. 5. These ^1H NMR spectra show that signals a and b of each spectrum are those of *S* and *R* enantiomers respectively and that the samples (A) and (B) are approximately enantiomerically pure.[14] Therefore, the highest value detected above ($[\alpha]_D$ −86.0°) must be the one of the enantiomerically pure sample; the enantiomeric excesses in Table 2 were thus calculated from this value.

The authors wish to express their thanks to Professor Chung-gi Shin, Kanagawa University, for his valuable discussions; to Miss Tatsuko Sakai, Meijho University, for her elemental analyses; and to Mr. Katsuhiko Sotomaru, Gasukuro Kogyo Co. Ltd., for his GLC analyses. We also would like to thank Mr. Akira Ohtaki and Miss Satoko Ohkura for the preparation of 2-quinuclidinecarboxylic acid and its derivatives.

(Received December 1, 1983)

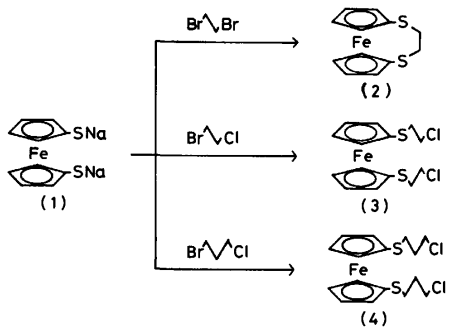
1,1′-Bis(2-chloroethylthio)ferrocene reacted with disodium 1,2-ethanedithiolate to give 1,4,7,10-tetrathia-[10]ferrocenophane and 1,4,7,10,22,25,28,31-octathia[10.10]ferrocenophane, along with unexpected 1,4,7-trithia-[7]ferrocenophane, 1,4,7,10,13-pentathia[13]ferrocenophane and 1,4,7,10,13,25,28,31,34-nonathia[10.13]ferrocenophane. The reaction of 1,1′-bis(2-chloroethylthio)ferrocene with disodium 1,3-propanedithiolate gave 1,4,-8,11-tetrathia[11]ferrocneophane. 1,1′-Bis(3-chloropropylthio)ferrocene reacted with disodium 1,2-ethanedithiolate and 1,3-propanedithiolate to afford 1,5,8,12-tetrathia[12]ferrocenophane and 1,5,8,12,24,27,31,34-octathia-[12.12]ferrocenophane, and 1,5,9,13-tetrathia[13]ferrocenophane, respectively. The structural features of the above polythia[*n*]ferrocenophanes are also discussed on the bases of their spectral data.

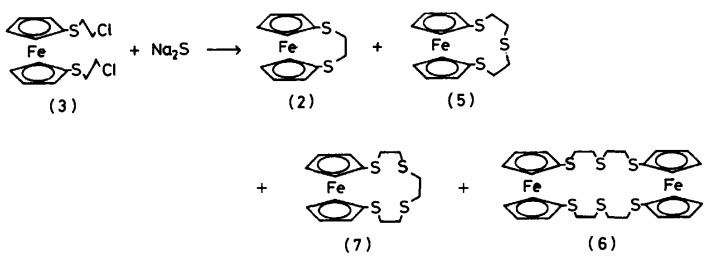
Various types of crown ethers have been prepared and their functionalities investigated.[1] The first thia-crown ether was synthesized in 1934[2] and thereafter some thia-macrocyclic compounds have been prepared[3-6] and shown to have a high affinity toward transition metal cations.[3,7-9] Especially, the complex with a copper atom has attracted much attention as a model of the blue copper protein,[8] nevertheless, the modified thia-crown ethers have scarcely been reported. Polythiaferrocenophanes, in which a ferrocene nucleus is incorporated in the framework of a thia-crown ether ring, is a new type of these modified thia-crown compounds. We now report on the preparation of several polythia[*n*]ferrocenophanes and polythia[*n.n*]-ferrocenophanes.[10]

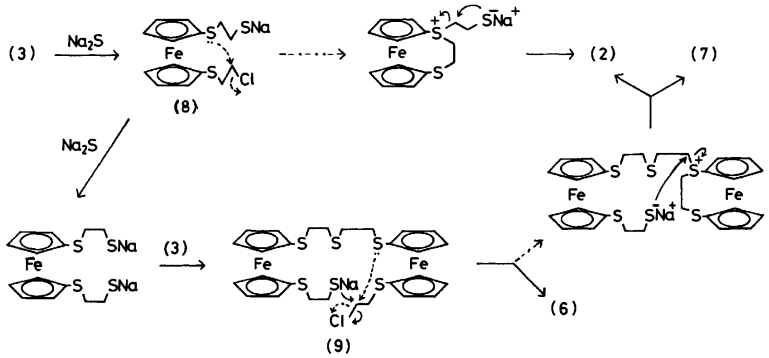
Disodium 1,1′-ferrocenedithiolate (**1**), which was prepared from 1,1′-ferrocenedithiol[11] and sodium hydroxide in ethanol, reacted with 1,2-dibromoethane in ethanol at room temperature to give 1,4-dithia[4]-ferrocenophane (**2**) as orange crystals in 37% yield. Although a polymeric compound was produced, no dimer of **2** was isolated. In the ^{1}H-NMR spectrum of **2**, the α- and β-protons of ferrocene rings appeared as two well-separated doublets at δ 4.41 and 4.19, suggesting the presence of a little tilt-deformation in the two cyclopentadienyl rings of the ferrocene nucleus.[12] The bridging methylene protons resonated downfield, δ 3.33; this would be explained by the fact that they are rigidly held in a deshielding zone between two cyclopentadienyl rings.[13]

Compound **1** reacted with 1-bromo-2-chloroethane in ethanol to give 1,1′-bis(2-chloroethylthio)ferrocene (**3**) as yellow crystals in 67% yield, along with a small amount of **2**. The ^{1}H-NMR spectrum of **3** showed the methylene protons as a A_2X_2 pattern at δ 2.86 (t, 4H, J=8.7 Hz) and 3.57 (t, 4H, J=8.7 Hz), supporting the assigned structure. Similarly, **1** reacted with 1-bromo-3-chloropropane to give 1,1′-bis(3-chloropropylthio)ferrocene (**4**) as an orange oil in 71% yield. The ^{1}H-NMR spectrum, which showed the methylene protons as two triplets at δ 2.71 (4H, J=6.5 Hz, CH_2S) and 3.61 (4H, J=6.5 Hz, CH_2Cl) and a pentuplet at δ 1.94 (4H, $CH_2C\underline{H}_2CH_2$) and the ring protons as a multiplet at δ 4.24, confirmed the proposed structure.

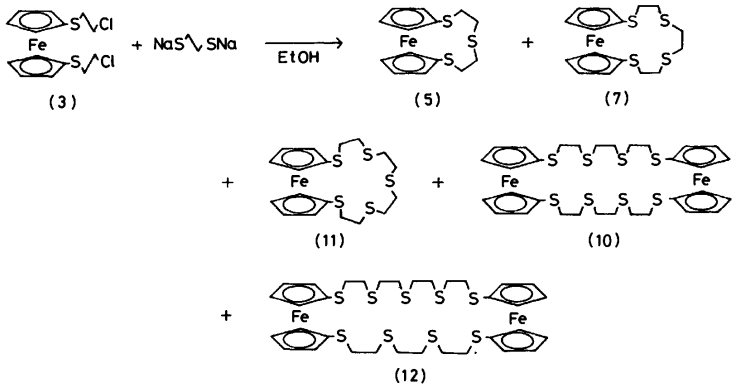
A solution of dichloride **3** in dry tetrahydrofuran (THF) was added all at once to a solution of sodium sulfide nonahydrate in ethanol and the resulting solution was refluxed for 10 h. After the usual work-up, the reaction mixture was chromatographed on silica gel to give a moderate yield (27.5%) of 1,4,7-trithia[7]-ferrocenophane (**5**) and a trace amount of the dimer, 1,4,7,19,22,25-hexathia[7.7]ferrocenophane (**6**), along with unexpected 1,4-dithia[4]ferrocenophane (**2**) (5.0%)





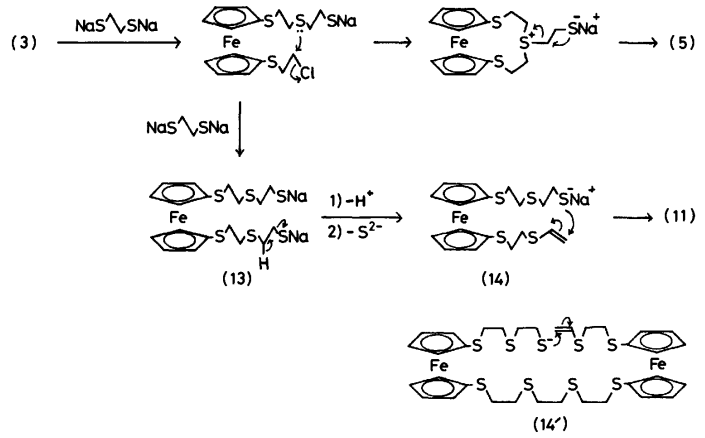


Scheme 1.

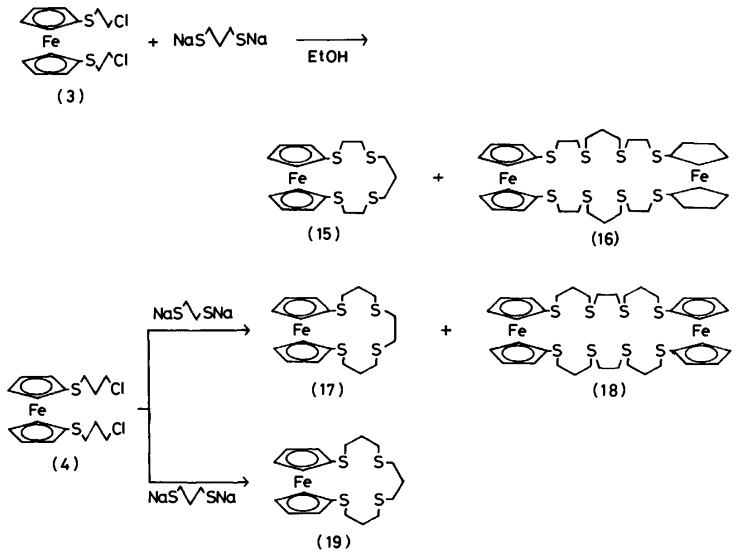


and 1,4,7,10-tetrathia[10]ferrocenophane (**7**) (3.1%). The formation of the abnormal products **2** and **7** may be rationalized in terms of the formation of the intermediate monochloride (**8**) or the dimeric monochloride (**9**) and the following cyclic sulfonium ions as shown in Scheme 1. Similar propagation products are reported in the reaction of bis(2-chloroethyl) ether with sodium sulfide.[14] The replacement of the reaction solvent from ethanol to *N*,*N*-dimethylformamide caused no enhancement of the yield of **5** and **6**. The structure of **5** was confirmed by its ^{1}H-NMR and mass spectra [*m*/*z* 336 (M^+)]. In the ^{1}H-NMR spectrum of **5**, the ring protons and the methylene protons appeared as a pair of triplets at δ 4.25 (4H) and 4.33 (4H), and as a multiplet at δ 2.9—3.5 (8H), respectively. The close appearance of the α- and β-ring protons suggests little tilt-deformation caused by the seven-membered (three sulfur and four carbon atoms) bridging chain. The structure of the dimer **6** was similarly assigned by its mass spectrum [*m*/*z* 672 (M^+)] and ^{1}H-NMR spectrum [δ 4.28 (s, 8H) and δ 2.6—3.2 (m, 8H)]. The methylene protons of the former were observed at somewhat lower field than that of the latter; this is probably because the former methylene portons were held in a deshielding zone between the two cyclopentadienyl rings as described above.

The dichloride **3** reacted with four equivalents of disodium 1,2-ethanedithiolate by refluxing in ethanol-tetrahydrofuran for 2 h. After the usual work-up, the reaction mixture was chromatographed on silica gel by elution with hexane-toluene to give 1,4,7,10-tetrathia[10]-ferrocenophane (**7**) and 1,4,7,10,22,25,28,31-octathia[10.10]-ferrocenophane (**10**) in 50.4 and 3.6% yields, respectively. Moreover, the unexpected products, 1,4,7-trithia[7]ferrocenophane (**5**) (1.7%), 1,4,7,-10,13-pentathia[13]ferrocenophane (**11**) (11.6%), and 1,-4,7,10,13,25,28,31,34-nonathia[10.13]ferrocenophane (**12**) (1.6%) were isolated. Treatment of **3** with one equivalent of disodium 1,2-ethanedithiolate under similar conditions gave all compounds described above (**5**, **7**, **10**, **11**, and **12**) in yields slightly different from the above experiment. The structure of these compounds was assigned by their elemental analyses, mass, and ^{1}H-NMR spectra. For example, **11** showed the molecular ion (M^+) at *m*/*z* 456 in the mass spectrum. The ^{1}H-NMR spectrum of **11** had the resonances at δ 4.26 (m, 8H) and 2.7—3.2 (m, 16H). The formation of **5** can be rationalized by the intermediate formation of a monochloride followed by a cyclic sulfonium ion as described above (Scheme 2). A similar process was presumed in the reaction of bis(2-chloroethyl) sulfide with the sodium salt of 1,2-ethanedithiol.[5] A possible mechanism for the unexpected formation of **11** and **12** is proposed in Scheme 2. A similar type of reaction has been observed only in the reaction of 1,1′-bis-(2-chloroethoxy)ferrocene with disodium 1,2-ethanedithiolate.[15] The initial reaction would be a nucleophilic attack of two moles of disodium 1,2-ethanedithiolate on the halogenated carbons of **3** to form the dithiolate (**13**). Subsequently, one proton elimination from the methylene carbon next to a sulfur atom takes place and is followed by elimination of S^{2-} to give a vinyl sulfide intermediate (**14**). Thus, the formation of **11** can be interpreted by an intramolecular attack of $-S^-$ to the double bond of **14** followed by addition of proton to the resulting sulfur-stabi-



Scheme 2.



lized anion. The formation of **12** can be similarly explained *via* the intermediate (**14'**). The driving force of the unusual propagation reaction may be an easy formation of the sulfur-stabilized carbanion from **13**.

The chloride **3** was treated with four equivalents of disodium 1,3-propanedithiolate in refluxing ethanol-tetrahydrofuran for 2 h under nitrogen. After the usual work-up, the reaction mixture was chromatographed on silica gel to give 1,4,8,11-tetrathia[11]ferrocenophane (**15**) in 57% yield. The ^{1}H-NMR spectrum of **15** showed ferrocene ring protons as a singlet at δ 4.27 (8H), the methylene protons next to a sulfur atom as multiplets at δ 2.7—3.0 (8H) and 3.0—3.2 (4H), and the methylene protons as a quintet at δ 2.02, confirming the assigned structure. On addition to **15**, the compound (**16**), assumed to be the dimer of **15** by its mass and ^{1}H-NMR spectra, was isolated, although the final assignment was unsuccessful because of insufficient product.

1,1'-bis(3-chloropropylthio)ferrocene (**4**) reacted with four molar equivalents of disodium 1,2-ethanedithiolate in similar conditions to those described above, affording 1,5,8,12-tetrathia[12]ferrocenophane (**17**) and 1,5,8,12,24,28,31,35-octathia[12.12]ferrocenophane (**18**) in 47.8% and 11.2% yields, respectively. The reaction with one equivalent of the sodium salt gave considerably decreased yields of the products and no dimer **18**. The reaction of **4** with one equivalent of disodium 1,3-propanedithiolate gave 1,5,9,13-tetrathia[13]ferrocenophane (**19**) in 64.6% yields. The reaction with 4 equivalents of the sodium salt resulted in no increase of the yield of **19** and no isolation of the corresponding dimer.

The electronic and ^{13}C-NMR spectral data of the mononuclear derivatives **2**, **5**, **7**, **11**, **15**, **17**, and **19** were summarized in Tables 1 and 2. As shown in Table 1, 1,4,7-trithia[7]ferrocenophane (**5**) showed an abnormally bathochromic shift ($\Delta\lambda$ *ca.* 20 nm) and an increase in the absorbance ($\Delta\varepsilon$ *ca.* 40) of an absorption band near 440 nm characteristic of ferrocene, which was assigned to d-d transition from the HOMO to the LUMO.[16] In its ^{13}C-NMR spectrum, **5** showed a

down-field shift of the bridgehead carbon resonance ($\Delta\delta$ *ca.* 4 ppm) and an up-field shift of the α- and β-ring carbon resonances ($\Delta\delta$ 0.6—2.3 ppm) of the ferrocene necleus, compared with those of other cyclophanes. There seems to be no tilting strain of the two cyclopentadienyl rings in this molecule, since only a slight splitting of the chemical shifts of the α- and β-ring protons was observed as described previously. The stereomolecular model also evidenced the absence of a tilting strain in **5**. The abnormal shifts observed in the electronic and ^{13}C-NMR spectra therefore may be interpreted by an interaction either between a ferrocene nucleus and a sulfur atom in the 4-position or between a ferrocene nucleus and sulfur atoms in the 1- and 7-positions of **5**. The former possibility, however, is excluded by the fact that such an abnormal shift was not observed in the electronic and ^{13}C-NMR spectra of 1,7-dioxa-4-thia[7]ferrocenophane.[17] From consideration of the stereomolecular model of **5**, the hybrid orbital of the lone pair of the sulfur atom attached to the cyclopentadienyl rings is held to be perpendicular to the plane of cyclopentadienyl rings. Two possible interactions, therefore, remain to explain the spectroscopic characteristics observed in **5**: an interaction between the nonbonding d-orbital on the iron atom and the lone pair of a sulfur atom and an interaction between the lone pair of a sulfur atom and the Fe-C bond connecting a cyclopentadienyl ring to an iron atom (σ-π conjugation).[18] The detailed study on this phenomena will be discussed in another paper.[19]

Experimental

Materials. 1,1′-Ferrocenedithiol was prepared from 1,2,3-trithia[3]ferrocenophane.[11] 1,2-Dibromoethane, 1-bromo-2-chloroethane, 1-bromo-3-chloropropane, 1,2-ethanedithiol and 1,3-propanedithiol were all commercially available; the purity of the last two was checked by GLC. All reactions were done under an atmosphere of nitrogen.

1,4-Dithia[4]ferrocenophane (2). To a suspension of 1,1′-ferrocenedithiol (0.34 g, 1.4 mmol) in ethanol (50 ml) was added a 40% aq solution of sodium hydroxide (0.23 ml) under stirring. The resulting red solution of disodium 1,1′-ferrocenedithiolate (**1**) and a solution of 1,2-dibromoethane (0.12 ml, 1.4 mmol) in ethanol (50 ml) were added dropwise at the same rate to N_2-saturated ethanol (100 ml) for a period of 3 h under stirring at room temperature, and then further stirred overnight. After the reaction had been completed, the mixture was evaporated under vacuum, the residue was dissolved in benzene and the undissolved material was filtered off. Chromatography of the condensed filtrate on silica gel gave 1,4-dithia[4]ferrocenophane (**2**) (0.14 g, 37%) as orange cubes, mp 138—139 °C. Found: C, 52.18; H, 4.34%. Calcd for $C_{12}H_{12}S_2Fe$: C, 52.18; H, 4.38%. MS (75 eV); *m/z* 276 (M^+, 100%) and 248 ($M^+-CH_2CH_2$, 57%). IR (KBr): 3080, 1410, 1160, 1020, 890, and 810 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=3.33 (s, 4H, CH_2CH_2), 4.19 (t, 4H, J= 1.9 Hz, H_α), and 4.41 (t, 4H, J=1.9 Hz, H_β).

1,1′-Bis(2-chloroethylthio)ferrocene (3). To a solution of disodium 1,1′-ferrocenedithiolate (**1**), prepared from 1,1′-ferrocenedithiol (0.50 g, 2 mmol) and 40% aq sodium hydroxide (0.4 ml) in ethanol (40 ml), was all at once added a solution of 1-bromo-2-chloroethane (0.63 g, 4.4 mmol) in ethanol (2 ml). The solution was stirred for 4 h at room temperature. After the reaction mixture had been evaporated under vacuum, the residue was chromatographed on silica gel by elution of hexane-toluene (2:1), giving 1,1′-bis(2-chloroethylthio)ferrocene (**3**) as orange crystals (0.45 g, 61%), mp 90.5—91 °C, along with a trace amount (4%) of 1,4-dithia[4]-ferrocenophane (**2**). Found: C, 45.05; H, 4.10%. Calcd for $C_{14}H_{16}Cl_2S_2Fe$: C, 44.82; H, 4.30%. MS (75 eV):*m/z* 375 (M^+, 100%) and 276 ($M^+-C_2H_4Cl_2$, 32%). IR (KBr): 3080, 1438, 1210, 1020, 983, 828, and 690 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ= 2.86 (t, 4H, J=8.7 Hz, CH_2S), 3.57 (t, 4H, J=8.7 Hz, CH_2Cl) 4.29 (t, 4H, J=1.7 Hz), 4.35 (t, 4H, J=1.7 Hz).

1,1′-Bis(3-chloropropylthio)ferrocene (4). A similar reaction of 1,1′-ferrocenedithiol (3.83 g, 15.3 mmol), 40% aq sqlution of sodium hydroxide (2.3 ml), and 1-bromo-3-chloropropane (5.78 g, 36.7 mmol) gave 1,1′-bis(3-chloropropylthio)ferrocene (**4**) (4.36 g, 70.7%) as an orange oil. Found: C, 47.59; H, 5.00%. Calcd for $C_{16}H_{20}Cl_2S_2Fe$: C, 47.66; H, 5.01%. MS (75 eV): *m/z* 402 (M^+, 100%). IR (Neat): 3080, 2950, 1440, 1420, 1268, 1020, and 825 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ= 1.94 (m, 4H, CH_2), 2.71 (t, 4H, J=6.8 Hz, CH_2S), 3.61 (t, 4H, J=6.4 Hz, CH_2Cl), 4.24 (t, 4H, J=1.8 Hz), and 4.30 (t, 4H, J=1.8 Hz).

Reaction of 1,1′-Bis(2-chloroethylthio)ferrocene (3) with Sodium Sulfide. To a solution of sodium sulfide nonahydrate (0.54 g, 2.2 mmol) in anhyd. ethanol (250 ml) was added a solution of 1,1′-bis(2-chloroethylthio)ferrocene (**3**) (0.67 g, 1.8 mmol) in tetrahydrofuran (THF) (45 ml). The solution was refluxed for 10 h under nitrogen. After the reaction had been completed, the reaction mixture was evaporated under vacuum, the residue was dissolved in benzene and the yellow precipitate was filtered off. The filtrate was condensed and chromatographed on silica gel by elution with hexane-toluene, the following products being separated and purified by recrystallization. 1,4-Dithia[4]ferrocenophane (**2**) (0.025 g, 5%). 1,4,7-Trithia[7]ferrocenophane (**5**) (0.17 g, 28%) as red plates, mp 120 °C. Found: C, 50.10; H, 4.89%. Calcd for $C_{14}H_{16}S_3Fe$: C, 50.00; H, 4.80%. MS (75 ev): *m/z* 336 (M^+, 100%), 280 ($M^+-2C_2H_4$, 44%), 248 (24%), and 184 (44%). IR (KBr): 3080, 1418, 1160, 1020, and 806 cm^{-1}.

^{1}H-NMR ($CDCl_3$): δ=3.0—3.5 (m, 8H, CH_2S), 4.28 (m, 8H, ring-H). 1,4,7,10-Tetrathia[10]ferrocenophane (**7**) (0.22 g, 3.1%) (See later.). 1,4,7,19,22,25-Hexathia-[7.7]ferrocenophane (**6**) (0.039 g, 6.5%) as yellow orange crystals, mp 185—185.5 °C. Found: 50.13; H, 4.79%. Calcd for $C_{28}H_{32}S_6Fe_2$: C, 50.00; H, 4.80%. MS (75 eV): *m/z* 672 (M^+, 14%), 336 ($M^+/2$, 23%), and 304 ($M^+/2$-S, 100%). IR (KBr) 3080, 1418, 1190, 1022, and 810 cm^{-1}. ^{1}H-NMR ($CDCl_3$):δ=2.6—3.2 (m, 16H, CH_2S) and 4.28 (s, 16H).

The same reaction was carried out using *N,N*-dimethylformamide in the place of ethanol-THF as a solvent to give **5** and **6** in 27.2 and 9.1% yields, respectively.

Reaction of 1,1′-Bis(2-chloroethylthio)ferrocene (3) with Disodium 1,2-Ethanedithiolate. To a solution of sodium hydroxide (1.2 g, 30 mml) in anhyd ethanol (400 ml) was added 1,2-ethanedithiol (1.0 ml, 12 mmol), and then all at once a solution of 1,1′-bis(2-chloroethylthio)ferrocene (**3**) (1.12 g, 3 mmol) in anhyd THF (75 ml). The resulting solution was gently refluxed for 2 h and then evaporated under vacuum. Water was added, the mixture was extracted with benzene and the benzene extract was dried over anhyd. sodium sulfate and evaporated. The residue was chromatographed on silica gel to give the following products: 1,4,7-Trithia[7]ferroceneophane (**5**) (0.017 g, 1.7%). 1,4,7,10-Tetrathia[10]ferrocenophane (**7**) (0.60 g, 50.5%) as orange crystals, mp 116 °C. Found: C, 48.61; H, 4.97%. Calcd for $C_{16}H_{20}S_4Fe$: C, 48.48; H, 5.09%. MS (75 eV): *m/z* 396 (M^+, 100%), 272 (M^+—124, 61%) and 184 (18%). IR (KBr): 3075, 1420, 1268, 1020, 800, and 688 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=2.7—3.0 (m, 4H, CH_2S), 3.0—3.3 (m, 4H, CH_2S), 3.10 (s, 4H, SCH_2-CH_2S), and 4.25 (m, 8H, ring-H).

1,4,7,10,13-Pentathia[13]ferrocenophane (**11**)(0.159 g, 11.6%) as orange needles, mp 100.5—102 °C. Found: C, 47.49; H, 5.44%. Calcd for $C_{18}H_{24}S_5Fe$: C, 47.36; H, 5.30%. MS (75 eV): *m/z* 456 (M^+, 100%), 332 (M^+—124), 272 (13%), and 184 (11%). IR (KBr): 3070, 1420, 1195, 1025, and 820 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=2.7—3.2 (m, 16H, CH_2S) and 4.26 (s, 8H, ring-H).

1,4,7,10,22,24,27,30-Octathia[10,10]ferrocenophane (**10**) (0.043 g, 3.6%) as reddish orange crystals, mp 152.5—153.5 °C. Found: C, 48.48; H, 5.25%. Calcd for $C_{32}H_{40}S_8Fe_2$: C, 48.48; H, 5.09%. MS (25 eV): *m/z* 792 (M^+, 100%) and 272 (59%). IR (KBr): 3080, 2920, 1422, 1200, 1020 and 820 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=2.5—3.0 (m, 16H, CH_2S), 2.66 (s, 8H, SCH_2CH_2S), and 4.34 (m, 16H, ring-H).

1,4,7,10,13,25,28,31,34-nonathia[10.13]ferrocenophane (**12**) (0.022 g, 1.6%) as orange crystals, mp 114.5 °C. Found: C, 47.74; H, 5.53%. Calcd for $C_{34}H_{44}S_9Fe_2$: C, 47.88; H, 5.20%. MS (35 eV): *m/z* 852 (M^+, 7%) and 272 (100%). IR (KBr): 3080, 2920, 1424, 1188, 1018, and 805 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ= 2.5—3.0 (m, 28H, CH_2S) and 4.35 (m, 16H, ring-H).

When one equivalent of disodium 1,2-ethanedithiolate was used in the above reaction, the yields of **5**, **7**, **11**, **10**, and **12** were 6.0, 32.7, 8.6, 2.6, and 1.4%, respectively.

Reaction of 1,1′-Bis(2-chloroethylthio)ferrocene (3) with 1,3-Propanedithiol. To a solution of sodium hydroxide (0.855 g) in anhydrous ethanol (280 ml) was added 1,3-propanedithiol (0.84 ml, 8.4 mmol) and then a solution of 1,1′-bis(2-chloroethylthio) ferrocene (0.748 g, 2 mmol) in anhyd. THF (50 ml) under an atmosphere of nitrogen. The solution was refluxed for 2 h and then evaporated. The residue was chromatographed on silica gel to give two products: 1,4,8,11-tetrathia[11]ferrocenophane (**15**) (0.462 g, 56.3%) as orange plates, mp 75 °C. Found: C, 49.79; H, 5.15%. Calcd for $C_{17}H_{22}S_4Fe$: C, 49.75; H, 5.40%. MS (75 eV): m/z 410 (M^+, 96%), 286 (M^+ —124, 100%), 248 (35%), and 184 (16%). IR (KBr): 3080, 2895, 1432, 1262. 1160, 1024, 886, and 805 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=2.02 (p, 2H, J=7.5 Hz, CH_2), 2.7—3.0 (m, 8H, CH_2S), 3.0—3.2 (m, 4H, CH_2S), and 4.27 (s, 8H, ring-H).

1,4,8,11,23,26,30,33-Octathia[11.11]ferrocenophane (**16**) as yellow crystals, mp 132 °C. MS (35 eV): *m/z* 820 (M^+, 4%), 410 ($M^+/2$, 14%), and 286 (100%). IR (KBr): 3085, 2930, 1622, 1430, 1204, 1025, 895, and 835 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=1.75 (p, 4H, J=7.3 Hz, CH_2), 2.56 (t, 8H, J=7.3 Hz, SCH_2), 3.0—2.5 (m, 16H, SCH_2), and 4.34 (m, 16H, ring-H).

Reaction of 1,1′-Bis(3-chloropropylthio)ferrocene(4) with 1,2-Ethanedithiol. To a solution of disodium 1,2-ethanedithiolate, prepared from 1,2-ethanedithiol (1.0 ml, 12 mmol) and sodium hydroxide (1.2 g, 30 mmol) in anhyd. ethanol (400 ml) was added a solution of 1,1′-bis(3-chloropropylthio) ferrocene (**4**) (1.21 g, 3 mmol) in anhyd THF (75 ml) under an atmosphere of nitrogen. After being refluxed for 2 h, the solution was evaporated under vacuum, the residue was dissolved in water, the mixture was extracted with benzene, the extract was dried over anhyd. sodium sulfate and then evaporated. From the residue, two crystalline products were isolated by chromatography on silica gel:

1,5,8,12-Tetrathia[12]ferrocenophane (**17**) (0.608 g, 47.8%) as orange crystals, mp 98 °C. Found: C, 51.25; H, 5.70%. Calcd for $C_{18}H_{24}S_4Fe$: C, 50.93; H, 5.70%. MS (75 eV): *m/z* 424 (M^+, 100%) and 184 (19%). IR (KBr): 3080, 2900, 1410, 1248, 1165, 1020, and 812 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=1.91 (m, 4H, CH_2), 2.7—3.0 (m, 8H, CH_2S), 2.80 (s, 4H, SCH_2CH_2S), and 4.25 (s, 8H, ring-H).

1,5,8,12,24,28,31,35-Octathia[12.12]ferrocenophane (**18**) (0.143 g, 11,2%) as yellow fine needles, mp 82—83 °C. Found: 51.17; H, 5.79%. Calcd for $C_{36}H_{48}S_8Fe_2$: C, 50.93; H, 5.70%. MS(35 eV): *m/z* 848 (M^+, 18%) and 424 ($M^+/2$, 100%). IR (KBr): 2900, 1422, 1240, 1020, and 830 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=1.82 (p, 8H, J=7.3 Hz, CH_2), 2.66 (t, 8H, J= 7.5 Hz, CH_2S), 2.69 (s, 8H, SCH_2CH_2S), 2.73 (t, 8H, J=7.1 Hz, CH_2S), 4.2—4.37 (m, 16H, ring-H).

When one equivalent of disodium 1,2-ethanedithiolate was used in the above reaction, **17** was obtained in 35% yield and the dimer **18** was not isolated.

1,5,9,13-Tetrathia[13]ferrocenophane (19). To a solution of disodium 1,3-propanedithiolate, prepared from 1,3-propanedithiol (0.10 ml, 1 mmol) and sodium hydroxide (0.089 g, 2.2 mmol) in anhyd. ethanol (125 ml), was all at once added a solution of 1,1′-bis(3-chloropropylthio)ferrocene (**4**) (0.403 g, 1.0 mmol) in anhyd. THF (26 ml) under nitrogen. The solution was gently refluxed for 5 h and then evaporated under vacuum. The residue was chromatographed on silica gal by elution with hexane-toluene (3:1) to give 1,5,9,13-tetrathia[13]ferrocenophane (**19**) (0.283 g, 64.6%) as orange needles, mp 60 °C. Found: C, 52.20; H, 5.81%. Calcd for $C_{19}H_{26}S_4Fe$: C, 52.04; H, 5.98%. MS (75 eV): *m/z* 438 (M^+, 100%) and 184 (5%). IR (KBr): 3100, 2900, 1415, 1255, 1168, 1020, and 818 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ= 1.7—2.2 (m, 6H, CH_2), 2.5—3.0 (m, 12H, SCH_2), and 4.25 (s, 8H, ring-H).

Application of 4 equivalents of disodium 1,3-propandithiolate in the above reaction resulted in no increase in the yield of the monomer **19** and no detection of the corresponding dimer.

1-Bromo-2-ethoxycyclopropyllithium: A Synthetic Equivalent of 2-Lithio- or 3-Lithiopropenal. Application to the Synthesis of Juvenile Hormone (JH-II), β-Sinensal, and Jasmonoids

Yoshitomi MORIZAWA, Akihiro KANAKURA, Hajime YAMAMOTO, Tamejiro HIYAMA,*,† and Hitosi NOZAKI

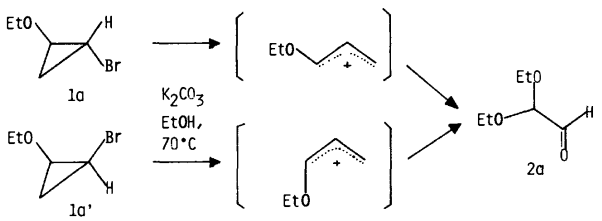
(Received December 2, 1983)

The ethyl vinyl ether-dibromocarbene adduct was lithiated with butyllithium at −95 °C in tetrahydrofuran. The resulting lithium carbenoid **3** was allowed to react with various electrophiles to give 1-substituted *trans*-1-bromo-2-ethoxycyclopropanes (**1**) in good yields. The trans relationship of Br and OEt groups was found particularly pertinent to the ethanolysis of **1** producing 2-substituted propenal diethyl acetal derivatives. The reaction has been applied to 1-methoxycyclohexene-dibromocarbene adducts, giving rise hereby 2-substituted 2-cyclohepten-1-one dimethyl acetals under ring enlargement. The transformation has been utilized in the synthesis of a homoterpenoid (JH-II) or a terpenoid (β-sinensal) structure by S_N2' substitution of allylic acetates with lithium dimethylcuprate(I) or iron pentacarbonyl respectively. The reaction products of **3** with aldehydes are oxidized with dimethyl sulfoxide to give cyclopropyl ketones whose ethanolysis in the presence of boron trifluoride ether complex gives β-bromo γ-keto aldehyde acetals. Debromination followed by acidic hydrolysis produces γ-keto aldehydes serving as precursors of dihydrojasmone and *cis*-jasmone.

Cyclopropane ring cleavage provides highly efficient methods for stereoselective and often stereospecific transformation.[1] The synthetic application heavily depends on the accessibility of appropriately substituted cyclopropanes, which are often prepared *via* lithium carbenoids.[2] Lithium-halogen exchange reaction of *gem*- dihalocyclopropanes at low temperature provides the requisite carbenoids. The present paper deals with the chemistry of a lithium carbenoid derived from the ethyl vinyl ether-dibromocarbene adduct as applied to the synthesis of some terpenoids and related compounds.[3]

Reaction of 1-Bromo-2-ethoxycyclopropyllithium. Thermal rearrangement of 1,1-dihalo-2-alkoxycyclopropanes to 2-halopropenal derivatives is well-documented,[4] although the stereo-electronic aspect of the ring opening still remains unsolved. *trans*- and *cis*-1-Bromo-2-ethoxycyclopropanes (**1a**), (**1a'**) are prepared by reducing 1,1-dibromo-2-ethoxycyclopropane (**1b**) with tributyltin hydride.[5] As shown in Scheme 1 each isomer (1 mol dm^{-3}) was dissolved in ethanol and heated at 70 °C in the presence of potassium carbonate. The reaction was monitored by GLC assay. Pseudo first order rate constant for the trans isomer (**1a**) was 9.2×10^{-2} min^{-1}, whereas that for the cis isomer (**1a'**) was 7.8×10^{-4} min^{-1}. Thus, the transformation of **1a** to propenal diethyl acetal (**2a**) (93% GLC yield) proceeded about 100 times faster than the cis isomer (**1a'**). The difference of the reaction rate is attributed to the one of the energy-barrier of the ring-opening to give ethoxyallyl cation of W-form and sickle one, since the cyclopropyl halide-allyl cation transformation proceeds under orbital control.[11]



Scheme 1.

The favored isomers **1**[6] (Scheme 2) are prepared by means of the carbenoid **3** obtained by bromine–lithium exchange reaction of 1,1-dibromo-2-ethoxycyclopropane[7] **1b** with butyllithium. Treatment of the resulting carbenoid **3** at −95 °C with an electrophile gave the corresponding adduct **1**, which was successively heated in ethanol in the presence of potassium carbonate to afford a diethyl acetal **2**. Acidic hydrolysis gave the aldehyde **4**. The results are summarized in Table 1. According to the present two-step procedure, the carbenoid **3** is synthetically equivalent to 2-lithiopropenal[8] and provides 2-substituted propenal derivatives which themselves are potentially useful synthetic intermediates.[9]

The methodology described herein has been applicable to cyclic enol ether-dibromocarbene adducts (Scheme 3). For example, lithiation of 1-methoxy-7,7-dibromonorcarane **5** with butyllithium at −95 °C and treatment of the resulting carbenoid **6**[10] with an electro-

phile afforded **7** whose substituents were appropriately disposed for the subsequent rearrangement.[11] Solvolysis of **7** in methanol in the presence of potassium carbonate gave cycloheptenone dimethyl acetal (**8**) under ring-enlargement. Although the reaction of **6** with trimethylsilyl chloride and heptanal took place with no difficulty, alkylation of the carbenoid turned out rather arduous. By employing hexamethylphosphoric triamide (HMPA) as the cosolvent,[1b] the alkylated products **9c—9e** were obtained. The results are shown in Table 2.

Synthesis of JH-II and β-Sinensal. The allylic acetate of type **10** is useful for the synthesis of α, β-unsaturated aldehyde moiety of homoterpenoid and terpenoid structure, such as **11** and **13** as shown in Scheme 4. For example, the allylic acetate **10** derived from **2e** was treated with lithium dimethylcuprate(I) in ether at −18 °C[12] to give, after acid-hydrolysis, (*E*)-2-ethyl-2-nonenal (**11**).[13] Selective S_N2' type methyl introduction is the key of the present synthesis.

As shown in Scheme 5, this result has been successfully applied to the synthesis of juvenile hormone (JH-II).[14] The aldehyde **20** (Scheme 6) was allowed to react with the carbenoid **3**, and the adduct was subjected to the two-step transformation of Scheme 2 to afford the acetal which was isolated as the acetate **14** in 84% overall

yield. Treatment of **14** with lithium dimethylcuprate(I) and then with 5% aq sulfuric acid in THF gave an aldehyde **15** in 83% yield. Deoxygenation of **15** was accomplished by sodium borohydride reduction followed by removal of the produced allylic hydroxyl group[15] to afford **16** (78% yield). Cleavage of the protecting trityl group[14c] and the subsequent route[14a] to the target molecule are already established.

As Shown in Scheme 4, the aldehyde **12** is also transformed into (*E*)-α,β-unsaturated aldehyde **13** by a formal S_N2' type introduction of hydride and elimination of acetoxyl group. For example, when **12** was mixed with 0.5 mol of sodium cyanotrihydroborate in metha-

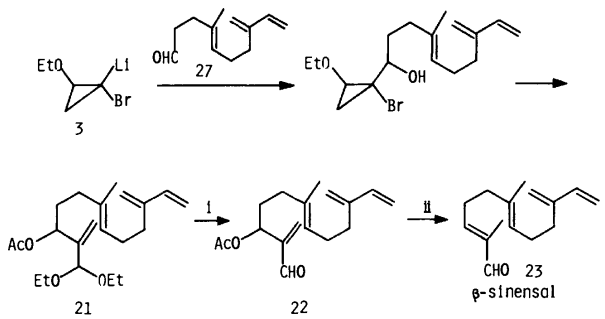

Scheme 7.

nol-acetic acid 10:1 at 0 °C, saturation of the olefinic bond occurred preferentially to afford the aldehyde **13** in 61% yield. The reduction is much more efficiently performed by means of iron pentacarbonyl and 1,4-diazabicyclo[2.2.2]octane (DABCO) in wet *N,N*-dimethylformamide (DMF) (96% yield).[16] It should be noted that the incipient 1,1-disubstituted ethylenic linkage is reduced to produce a new, triply substituted one which remains intact under the conditions.

The applicability of the new method has been demonstrated in the synthesis of β-sinensal (**23**) (Scheme 7), an important constituent of the odor and taste of Chinese orange oil (*Citrus sinensus L.*).[17] A triene aldehyde **27** (Scheme 8) was subjected to the carbenoid reaction as described in Scheme 2 to give the acetal acetate **21**. Deprotection of the aldehyde group with 5% aq sulfuric acid in THF resulted in polymerization of the large part of the product due to the acid-sensitive 1,3-diene moiety. The hydrolysis with silica gel-10% aq oxalic acid (10:1) suspended in dichloromethane[18] at room temperature gave the aldehyde **22** in 87% yield. Reductive removal of the acetoxyl group was selectively attained with iron pentacarbonyl-DABCO in wet DMF and β-sinensal (**23**) was produced in 95% yield.

Transformation of the Adducts of the Carbenoid 3 with Aldehydes into γ-Keto Aldehydes. Synthesis of Dihydrojasmone and cis-Jasmone. Ring-cleavage reaction of cyclopropyl ketone derivatives[19] has been also applicable to the homologation of carbon skeleton as shown in Scheme 9. Oxidation of **1e** type adducts of Scheme 2 was best carried out to give acid-lable *r*-1-bromo-*t*-2-ethoxy-1-heptanoyl-cyclopropane (**28a**) by the Swern's method.[20] Without isolation, **28a** was treated with

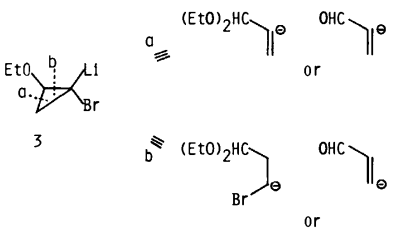
catalytic amount of boron trifluoride ether complex at room temperature to give a bromo acetal ketone **29a**. Reductive debromination with $CrCl_3$-$LiAlH_4$[21] followed by hydrolysis gave 4-oxodecanal (**30a**)[22], which was readily transformed into dihydrojasmone (**31a**)[23].

Starting with (*Z*)-4-heptenal,[24] *cis*-jasmone was prepared by the similar sequence of reactions. The ring-opening of the cyclopropyl ketone **28b** with BF_3-OEt_2 proceeded very slowly and gave complex mixture. On treatment with a catalytic amount of acetic acid, however, **28b** was converted to a bromo acetal ketone **29b** at room temperature in fairly good yield. The compound **29b** was reduced to give the γ-keto aldehyde **30b**,[22] a key precursor of *cis*-jasmone (**31b**).[25]

Acid hydrolysis of **29a** resulted in the formation of an α, β-unsaturated γ-keto aldehyde **32** (56% yield) (Scheme 10).

In conclusion, 1-bromo-2-ethoxycyclopropyllithium (**3**) is found to be a useful C_3 homologation reagent. The sequence shown in Scheme 2 clearly demonstrates that the lithium carbenoid **3** is a synthetic equivalent of 2-lithiopropenal or its acetal. In contrast, Scheme 9



together with Scheme 10 shows that **3** is attached to an aldehyde at the carbon (3) of propenal or 3-bromopropanal. This ambient reactivity of **3** is controlled by the ring-opening operation (*a* or *b*) of **1** derived from **3**, and the applicability of the reagent has been illustrated in the synthesis of terpenoids and jasmonoids.

Experimental

All temperatures recorded are uncorrected. Distillation of small amount of samples (less than 1 g) was carried out with Kugelrohr. ^{1}H-NMR spectra (tetramethylsilane as an internal standard unless otherwise noted) were obtained on a Varian EM 390 spectrometer or JOEL PMX-60 spectrometer, chemical shifts being given in ppm unit. IR spectra of neat liquid film samples (unless otherwise noted) on a Shimadzu IR-27G spectrometer, MS on a Hitachi RMU-6L spectrometer, and exact mass on a Hitachi M-80 spectrometer, Gas-liquid phase chromatography (GLC) analyses were performed with a Yanagimoto GCG-550F chromatograph. Preparative TLC plates were prepared with Merck Kiesel-gel PF_{254}. Column chromatography was carried out with silica gel (Wakogel C-100) at atmospheric pressure.

*Synthesis of 2-(Diethoxymethyl)-1-nonen-3-ol (**2e**) and 3-Hydroxy-2-methylenenonanal (**4e**). A Typical Procedure for the Reaction of 1-Bromo-2-ethoxycyclopropyllithium (**3**) with an Electrophile*: Butyllithium (1.67 M† hexane solution, 7.2 ml, 12.0 mmol) was added to a THF (50 ml) solution of 1,1-dibromo-2-ethoxycyclopropane (2.93 g, 12.0 mmol) at −95 °C over a period of 5 min. After stirring for 10 min heptanal (1.12 g, 9.8 mmol) was added at −95 °C, and the reaction mixture was stirred at −95 °C for 30 min, then at room temperature for 20 min. Workup gave **1e** which was dissolved in ethanol (15 ml), and the mixture was stirred with potassium carbonate (6.90 g, 50 mmol) for 1 h under reflux. Workup and purification by column chromatography (hexane-ether=3:1) gave **2e** (1.84 g, 77% yield): bp 100—105 °C (bath temperature)/14 Torr**; ^{1}H-NMR (CCl_4) δ=0.6—1.6 (m+t, 19 H), 2.20 (br s, 1H), 3.2—3.8 (m, 4H, $CH_3C\underline{H}_2O$), 4.05 (t, J=5 Hz, 1H, C$\underline{H}$-OH), 4.80 (br s, 1H), 5.17 (br s, 2H, =C$\underline{H}_2$); IR 3450, 2940, 2870, 1460, 1365, 1105, 1050, 923 cm^{-1}; MS *m/z* (rel intensity) 199 (9), 154 (4), 115 (56), 103 (53), 85 (100), 55 (47), 43 (69).

A mixture of the acetal **2e** in THF (5 ml) and 5% aq sulfuric acid (5 ml) was stirred at room temperature for 5 min. Workup followed by purification by column chromatography gave **4e** (1.32 g, quantitative yield): bp 115—120 °C (bath temperature)/20 Torr; ^{1}H-NMR δ=0.7—1.6 (m. 13H), 2.20 (br s, 1H), 4.37 (t, J=6 Hz, 1H), 5.95 (d, J=1 Hz, 1H), 6.38 (d, J=1 Hz, 1H), 9.52 (s, 1H); IR 3450, 1685, 955, 908, 790 cm^{-1}; MS *m/z* (rel intensity) 170 (M$^+$, 2), 123 (7), 100 (13), 85 (100), 55 (40), 43 (80). Found: C, 70.63; H, 10.86%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

r-*1-Bromo-t-2-ethoxy-1-trimethylsilylcyclopropane (**1c**)*: Bp 61—63 °C (bath temperature)/2 Torr; ^{1}H-NMR (CCl_4, internal standard CH_2Cl_2) δ=0.15 (s, 9H), 1.04—1.26 (m+t(δ=1.15, J=7.1 Hz), 5H), 3.52 (q, J=7.1 Hz, 2H), 3.68 (dd, J=6.5, 4.5 Hz, 1H); IR 2980, 2890, 1335, 1240, 1120. 1050, 840 cm^{-1}; MS *m/z* (rel intensity) 209 (4), 207 (4), 157 (24), 139 (10), 137 (10), 113 (45), 75 (24), 73 (100).

*2-Bromo-3,3-diethoxypropene (**2b**)*[26]: Bp 120—130 °C (bath temperature)/20 Torr; ^{1}H-NMR (CCl_4, internal standard, $CHCl_3$) δ=0.95 (t, J=7 Hz, 6H), 3.1—3.5 (m, 4H), 4.57 (br, s, 1H), 5.43 (br, s, 1H), 5.87 (br, s, 1H); IR 2980, 2880, 1630, 1370, 1050, 905 cm^{-1}; MS *m/z* (rel intensity) 165 (32), 163 (34), 137 (88), 135 (99), 109 (21), 108 (26), 103 (100), 75 (52).

*2-Trimethylsilyl-3,3-diethoxypropene (**2c**)*: Bp 88—90 °C/26 Torr; ^{1}H-NMR (CCl_4, $CHCl_3$ internal standard) δ=0.03 (s, 9H), 1.10 (t, J=6.5 Hz, 6H), 3.2—3.7 (m, 4H), 4.80 (br s, 1H), 5.45 (m, 1H), 5.80 (m, 1H); IR 2980, 2880, 1240, 1110, 940, 840 cm^{-1}; MS *m/z* (rel intensity) 157 (17), 113 (28), 103 (100), 75 (51), 73 (44). Hydrolysis of **2c** with aq sulfuric acid gave 2-trimethylsilylpropenal (*4c*) which was characterized as the 2,4-dinitrophenylhydrazone: mp 153.5—154 °C (orange needle, 95% ethanol-ethyl acetate); ^{1}H-NMR ($CDCl_3$, $CHCl_3$ internal standard); δ=0.12 (s, 9H), 5.88 (d, J=1.8 Hz, 1H), 6.03 (d, J=1.8 Hz, 1H), 7.70 (d, J=10 Hz, 1H), 7.79 (br s, 1H), 8.21 (dd, J=10, 3 Hz, 1H), 9.00 (d, J=3 Hz, 1H), 11.0 (br s, 1H); IR 3280, 2930, 2850, 1615, 1595, 1510, 1315, 1130, 1080, 840 cm^{-1}; MS *m/z* (rel intensity) 308 (M$^+$, 1), 148 (17), 147 (100), 75 (24), 73 (26), 66 (12). Found: C, 46.94; H, 5.23, N, 18.36%. Calcd for $C_{12}H_{16}N_4O_4$: C, 46.74; H, 5.23; N, 18.17%.

*2-Phenylthio-3,3-diethoxypropene (**2d**)*: Bp 115—125 °C (bath temperature)/0.06 Torr; ^{1}H-NMR (CCl_4) δ=1.16 (t, J=7 Hz, 6H), 3.3—3.7 (m, 4H), 4.85 (s, 2H), 5.51 (s, 1H), 7.2—7.5 (m, 5H); IR 3060, 2980, 2880, 1610, 1480, 1445, 1380, 1110, 1010, 880, 750 cm^{-1}; MS *m/z* (rel intensity) 238 (M$^+$, 11), 194 (25), 147 (25), 185 (31), 103 (100), 91 (29), 75 (74); Found: C, 65.54; H, 7.50%. Calcd for $C_{13}H_{18}O_2S$: C, 65.51; H, 7.61%.

*2-Trimethylsilyl-2-cyclohepten-1-one (**9a**)*. A hexane solution (1.7 M) of butyllithium (1.64 ml, 2.8 mmol) was added drop by drop to 7,7-dibromo-1-methoxynorcarane[27] (0.71 g, 2.5 mmol) in THF (10 ml) at −95 °C. After 10 min's aging chlorotrimethylsilane (1 ml, *ca.* 8 mmol) was added and the reaction mixture was stirred for 2 h at −95 °C, allowed to warm up to room temperature and treated with water. The organic layer was extracted with ether, dried (sodium sulfate) and concentrated *in vacuo*. The residue was heated in methanol (7 ml) to reflux with potassium carbonate (2.1 g, 15 mmol) for 2 h. Usual workup gave **8a**, which was dissolved in a mixture of THF (5 ml) and 5% aq sulfuric acid (5 ml) and stirred at room temperature for 20 min. Workup followed by purification by column chromatography gave **9a** (0.31 g, 57% yield): bp 147—150 °C (bath temperature)/15 Torr; ^{1}H-NMR (CCl_4, CH_2Cl_2 internal standard) δ=0.07 (s, 9H), 1.6—1.8 (m, 4H), 2.4—2.6 (m, 4H), 6.58 (t, J=6 Hz, 1H); IR 2940, 2865, 1660, 1595, 1450, 1235, 945, 840 cm^{-1}; MS *m/z* (rel intensity) 182 (M$^+$, 82), 167 (1), 155 (4), 137 (3), 75 (11), 73 (8), 40 (100). Found: C, 65.93; H, 10.09%. Calcd for $C_{10}H_{18}OSi$: C, 65.87; H, 9.95%.

*2-(1-Hydroxyheptyl)-2-cyclohepten-1-one (**9b**)*: Bp 90—110 °C (bath temperature)/1 Torr; ^{1}H-NMR (CCl_4) δ=0.88 (t, J=6 Hz, 3H), 1.1—1.6 (m, 10H), 1.6—2.0 (m. 4H), 2.3—3.0 (m, 5H), 4.0—4.3 (m, 1H), 6.52 (t, J=6 Hz, 1H); IR 3450, 2930, 2860, 1660, 1460, 1370, 900 cm^{-1}; MS *m/z* (rel intensity) 224 (M$^+$, 2), 206 (9), 149 (16), 139 (100), 121 (10), 111 (13), 97 (17), 93 (15), 83 (14), 79 (16). Found: C, 74.78; H, 10.86%. Calcd for $C_{14}H_{24}O_2$: C, 74.95; H, 10.78%.

*2-(3-Methyl-2-butenyl)-2-cyclohepten-1-one (**9c**)*: Bp 115—125 °C (bath temperature)/0.15 Torr; ^{1}H-NMR (CCl_4) δ=1.6—1.9 (m+s (δ=1.60)+s (δ=1.70), 10H), 2.2—2.6 (m, 4H), 2.83 (d, J=7.8 Hz, 2H), 5.02 (t, J=7.8 Hz, 1H), 6.30 (t,

† 1 M=1 mol dm^{-3}; ** Torr=133.322 Pa.

J=6.3 Hz, 1H); IR 2920, 2850, 1665, 1455, 1370, 850 cm^{-1}; MS m/z (rel intensity) 178 (M^+, 33), 163 (100), 135 (53), 107 (33), 95 (40), 93 (45), 79 (47). Found: C, 81.05; H, 10.44%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

*2-Pentyl-2-cyclohepten-1-one (**9d**)*: Bp 160—170 °C (bath temperature)/0.3 Torr; ^{1}H-NMR (CCl_4) δ=0.90 (t, J=6 Hz, 3H), 1.0—1.5 (m, 6H), 1.5—2.0 (m, 4H), 2.0—2.6 (m, 6H), 6.33 (t, J=6 Hz, 1H); IR 2970, 1665, 1270, 885 cm^{-1}; MS m/z (rel intensity) 180 (M^+, 14), 151 (40), 133 (30), 112 (40), 95 (100), 81 (37), 67 (100). Found: C, 79.89; H, 11.44%. Calcd for $C_{12}H_{20}O$: C, 79.94; H, 11.18%.

*2-Methyl-2-cyclohepten-1-one (**9e**)*[28]: Bp 135—140 °C (bath temperature)/12 Torr; ^{1}H-NMR (CCl_4) δ=1.6—1.8 (m+d (δ=1.76, J=1.5 Hz), 7H), 2.2—2.6 (m, 4H), 6.44 (tq, J=1.5, 6 Hz, 1H); IR 2950, 1660, 1050, 850, 790 cm^{-1}; MS m/z (rel intensity) 125 (M^++1, 7), 124 (M^+, 53), 95 (58), 81 (46), 67 (100), 55 (31).

*3-Acetoxy-2-diethoxymethyl-1-nonene (**10**).* Acetal alcohol **2e** was acetylated with excess acetic anhydride and pyridine at room temperature for 12 h: bp 110—116 °C (bath temperature)/0.5 Torr; ^{1}H-NMR (CCl_4) δ=0.7—1.8 (m, 19H), 1.98 (s, 3H), 3.2—3.6 (m, 4H), 4.80 (br s, 1H), 5.0—5.3 (m, 3H); IR 2950, 2880, 1740, 1360, 1226, 1050 cm^{-1}; MS m/z (rel intensity) 181 (52), 103 (100), 85 (20), 75 (45), 43 (82). Found: C, 67.09; H, 10.51%. Calcd for $C_{16}H_{30}O_4$: C, 67.09; H, 10.56%.

*(E)-2-Ethyl-2-nonenal (**11**).* To lithium dimethylcuprate(I) (1.2 mmol) in ether (5 ml), **10** dissolved in ether (1 ml) was added at −18 °C and stirred for 30 min. The reaction mixture was poured into aq ammonium chloride and extracted with ether. The organic layer was concentrated and treated with aq 5% sulfuric acid (5 ml)-THF (5 ml) at room temperature for 5 min. Workup and purification by preparative TLC (hexane-ether=5:1) gave (*E*)-2-ethyl-2-nonenal (**11**) (82 mg, 61% yield) along with the (*Z*)-isomer (less than 5%). **11** gave: bp 118—120 °C (bath temperature)/18 Torr; ^{1}H-NMR (CCl_4) δ=0.90 (t, J=6.0 Hz, 3H), 0.94 (t, J=7.6 Hz, 3H), 1.1—1.8 (m, 7H), 2.0—2.6 (m, 4H), 6.28 (t, J=7.6 Hz, 1H), 9.28 (s, 1H); IR 2950, 2875, 2730, 1685, 1640, 1460, 1080, 792 cm^{-1}; MS m/z (rel intensity) 168 (M^+, 8), 149 (6), 139 (12), 111 (33), 85 (37), 79 (33), 55 (74), 41 (100). Found: m/z 168.1540. Calcd for $C_{11}H_{20}O$: M^+ 168.1514. (*Z*)-2-Ethyl-2-nonenal gave ^{1}H-NMR (CCl_4) δ=0.6—1.8 (m, 13H), 1.9—2.8 (m, 4H), 6.30 (t, J=8.0 Hz, 1H), 10.06 (s, 1H).

*Hydrolysis of **10** to 3-Acetoxy-2-methylenenonenal (**12**).* Diethyl acetal **10** (1.43 g, 5.0 mmol) was treated with THF (15 ml)-aq 5% sulfuric acid (15 ml) at room temperature for 80 min. Workup gave pure aldehyde **12** (1.06 g, quantitative yield): ^{1}H-NMR (CCl_4) δ=0.87 (t, J=5.9 Hz, 3H), 1.1—1.8 (m, 10H), 2.00 (s, 3H), 5.47 (t, J=7.5 Hz, 1H), 5.98 (s, 1H), 6.25 (s, 1H), 9.48 (s, 1H).

*Synthesis of (E)-2-Methyl-2-nonenal (**13**).*[29] *Procedure A*: To the compound **12** (50 mg, 0.23 mmol) dissolved in methanol (1 ml)-acetic acid (0.1 ml), sodium cyanotrihydroborate (11 mg, 0.18 mmol) was added at room temperature for 2 h. Workup with brine and purification by preparative TLC gave **13** (22 mg, 61% yield).

Procedure B: Iron pentacarbonyl (0.25 ml, 1.9 mmol) was added to DABCO (0.11 g, 0.94 mmol) in wet *N,N*-dimethylformamide (DMF:H_2O=98:2) (1 ml). To the resulting dark-brown solution, the compound **12** (0.10 g, 0.46 mmol) was added and allowed to react for 1 h. Quenching was effected by addition of satd ethereal solution of iodine and water. Workup and purification by preparative TLC (hexane-ether=7:1, R_f 0.40—0.55) gave **13** (67 mg, 96% yield): ^{1}H-NMR (CCl_4) δ=0.90 (t, J=6.0 Hz, 3H), 1.2—1.7 (m, 8H), 1.71 (s, 3H), 2.32 (q, J=7.0 Hz, 2H), 6.34 (t, J=7.5 Hz, 1H), 9.31 (s, 1H), IR 2940, 2730, 1685, 1640, 1465, 1225, 1070, 820, 790, 725 cm^{-1}; MS m/z (rel intensity) 154 (M^+, 5), 135 (5), 97 (50), 84 (46), 71 (68), 55 (75), 43 (100).

*Synthesis of (E)-4-Methyl-8-methylene-4,9-decadienal (**27**).* Myrcene (10.0 g, 73 mmol) was transformed with *m*-chloroperbenzoic acid (15.9 g, 73.5 mmol) in chloroform (150 ml) at 0 °C for 5 h into 6,7-epoxy-7-methyl-3-methylene-1-octene (**24**) (6.7 g, 60% yield): bp 79—81 °C/9 Torr; ^{1}H-NMR (CCl_4) δ=1.22 (s, 3H), 1.26 (s, 3H), 1.63 (dt, J=6.0, 7.6 Hz, 2H), 2.34 (dt, J=4.5, 7.6 Hz, 2H), 2.57 (t, J=6.0 Hz, 1H), 4.9—5.4 (m, 4H), 6.33 (dd, J=11.4, 18.0 Hz, 1H); IR 3090, 2930, 1595, 1465, 1240, 1115, 990, 895 cm^{-1}; MS m/z (rel intensity) 152 (M^+, 5), 137 (8), 134 (8), 119 (16), 109 (18), 93 (29), 79 (100), 71 (57), 59 (57). Found: C, 78.99; H, 10.76%. Calcd for $C_{10}H_{16}O$: C, 78.90; H, 10.59%. The epoxide **24** (0.16 g, 1.05 mmol) was added to lithium diisopropylamide (1.5 mmol) in ether (4 ml) at 0 °C, and the reaction mixture was stirred for 15 h. To this solution, acetic anhydride (1 ml) and pyridine (0.5 ml) were added and stirred at room temperature for 2 h. Workup and purification by preparative TLC (hexane-ethyl acetate=5:1, R_f 0.55—0.65) gave an acetate **25** (0.13 g, 70% yield): bp 75—85 °C (bath temperature)/11 Torr; ^{1}H-NMR (CCl_4) δ=1.6—2.3 (m+d (δ=1.72, J=0.9 Hz), 7H), 1.99 (s, 3H), 4.8—5.3 (m, 7H), 6.27 (dd, J=11.4, 17.4 Hz, 1H); IR 3030, 2935, 1735, 1650, 1595, 1225, 1020, 900 cm^{-1}; MS m/z (rel intensity) 194 (M^+, 0.3), 152 (4), 134 (8), 119 (17), 105 (11), 93 (14), 91 (16), 79 (17), 43 (100). Found: C, 74.30; H, 9.45. Calcd for $C_{12}H_{18}O_2$: C, 74.19: H, 9.34%.

The acetate **25** (3.37 g, 17.3 mmol) was added to lithium diisopropylamide (34.7 mmol) at −78 °C and stirred for 1 h at −78 °C. To this solution, *t*-butylchlorodimethylsilane (5.22 g, 34.7 mmol) dissolved in THF (10 ml)-hexamethylphosphoric triamide (3 ml) was added, and the reaction mixture was warmed up gradually to room temperature, then heated at 70 °C for 2.5 h, after cooling poured into water and extracted with ether. The organic layer was concentrated. The residue was dissolved in methanol (20 ml) and treated with aq trimethylbenzylammonium fluoride (*ca.* 0.5 ml). Workup and purification by column chromatography gave a carboxylic acid **26** (2.76 g, 82% yield): bp 70—80 °C (bath temperature)/1 Torr; ^{1}H-NMR (CCl_4) δ=1.62 (br s, 3H), 2.1—2.5 (m, 8H), 4.9—5.3 (m, 5H), 6.27 (dd, J=11.4, 17.4 Hz, 1H), 11.10 (br s, 1H); IR 3100, 2650, 1710, 1595, 1450, 990, 895 cm^{-1}; MS m/z (rel intensity) 194 (M^+, 4), 134 (7), 121 (9), 109 (12), 93 (100), 81 (46), 67 (24). Found: C, 73.93; H, 9.49%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

The carboxylic acid **26** (0.075 g, 0.38 mmol) was reduced with lithium aluminum hydride (0.026 g, 0.67 mmol) in ether. Workup and purification by preparative TLC (hexane-ether=1:2, R_f 0.40—0.50) gave an alcohol (0.058 g, 84% yield): bp 70—80 °C (bath temperature)/1 Torr; ^{1}H-NMR (CCl_4) δ=1.60 (br s, 3H), 1.9—2.3 (m, 8H), 2.70 (br s, 1H), 3.50 (t, J=6.5 Hz, 2H), 4.8—5.3 (m, 5H), 6.27 (dd, J=11.4, 17.4 Hz, 1H); IR 3350, 3090, 2980, 1595, 1445, 1060, 990 cm^{-1}; MS m/z (rel intensity) 180 (M^+, 3), 121 (9), 119 (9), 93 (100), 75 (100).

The alcohol (1.57 g, 8.7 mmol) was converted into the aldehyde **27** with pyridinium chlorochromate (PCC)[30] (5.65 g, 17.5 mmol) in 77% yield. Bp 95—105 °C (bath temperature)/15 Torr; ^{1}H-NMR (CCl_4) δ=1.61 (br s, 3H), 2.1—2.5 (m, 8H), 4.8—5.3 (m, 5H), 6.27 (dd, J=11.4, 17.4 Hz, 1H), 9.65 (s, 1H); IR 3090, 2910, 2730, 1725, 1595, 990, 895 cm^{-1}; MS m/z (rel intensity) 178 (M^+, 2), 160 (2), 145 (4), 134 (10), 119 (16), 93 (100), 85 (37). Found: C, 81.13; H, 10.33%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

*(E)-3-Acetoxy-2-diethoxymethyl-6-methyl-10-methylene-1,6,11-dodecatriene (**21**).* The lithium carbenoid was produced from 1,1-dibromocyclopropane (0.85 g, 3.5 mmol) and allowed to react with the aldehyde **27** (0.36 g, 2.0 mmol) to give cyclopropylmethanol, which was without purification treated with ethanol (10 ml) in the presence of potassium carbonate (1.4 g, 10 mmol). The resulting alcohol was directly acetylated to give **21** (0.59 g, 83% yield): bp 132—134

°C (bath temperature)/1 Torr; ^{1}H-NMR (CCl_4) δ=1.18 (t, J=7.4 Hz, 6H), 1.60 (br s, 3H), 1.7—2.2 (m+s (δ=1.99), 11H), 3.2—3.7 (m, 4H), 4.7—5.3 (m, 7H), 6.27 (dd, J=11.4, 17.4 Hz, 1H); IR 2990, 1740, 1595, 1450, 1230, 1115, 1050, 890 cm^{-1}; MS m/z (rel intensity) 244 (21), 217 (23), 198 (14), 183 (11), 151 (22), 149 (23), 131 (28), 123 (31), 105 (33), 93 (75), 79 (38), 43 (100). Found: C, 71.88; H, 9.96%. Calcd for $C_{21}H_{34}O_4$: C, 71.96; H, 9.78%.

(E)-3-Acetoxy-2,10-dimethylene-6-methyl-6,11-dodecadienal (22). The diethyl acetal (**21**) (0.45 g, 1.29 mmol) dissolved in dichloromethane (1 ml) was treated with silica gel (Wakogel C-100) (1.36 g) and 10% aq oxalic acid (0.14 ml) in dichloromethane (3 ml) at room temperature for 1 h. The reaction mixture was neutralized with sodium hydrogencarbonate (0.045 g), and then filtered. Concentration of the filtrate and purification by column chromatography gave the desired aldehyde (**22**) (0.31 g, 87% yield): bp 120 °C (bath temperature)/1 Torr; ^{1}H-NMR (CCl_4) δ=1.60 (br s, 3H), 1.6—2.3 (m+s (δ=2.03), 11H), 4.9—5.6 (m, 6H), 5.97 (br s, 1H), 6.21 (dd, J=11.4, 17.4 Hz, 1H), 6.24 (br s, 1H), 9.50 (s, 1H); IR 3080, 2700, 1740, 1690, 1595, 1440, 1220, 1050, 1020, 895 cm^{-1}; MS m/z (rel intensity) 221 (5), 188 (6), 173 (5), 145 (8), 133 (19), 119 (19), 105 (20), 93 (100), 79 (37). Found: C, 73.99; H, 8.84%. Calcd for $C_{17}H_{24}O_3$: C, 73.88; H, 8.75%.

Transformation of 22 into β-Sinensal (23). Iron pentacarbonyl (0.91 ml, 1.45 mmol) was added to **22** (90 mg, 0.33 mmol) dissolved in a mixture of DABCO (81 mg, 0.72 mmol) and DMF-water (98:2, 1 ml), and the whole was stirred at room temperature for 1 h. Workup gave **23**[17] in 95% yield: ^{1}H-NMR (CCl_4) δ=1.63 (br s, 3H), 1.71 (br s, 3H), 1.9—2.6 (m, 8H), 4.8—5.3 (m, 5H), 6.1—6.5 (m, 2H), 9.28 (s, 3H); IR 2940, 2740, 1680, 1655, 1595, 990, 893 cm^{-1}; MS m/z (rel intensity) 218 (M^+, 5), 203 (3), 190 (10), 133 (26), 93 (100), 81 (39).

Preparation of (4E,8E)-4,8-Dimethyl-10-triphenylmethoxy-4,8-decadienal (20). A pyridine (100 ml) solution of geraniol (15.4 g, 0.10 mol) and triphenylmethyl chloride (35.0 g, 0.12 mol) was refluxed for 15 h. Evaporation of the pyridine under reduced pressure followed by column chromatography gave the geranyl triphenylmethyl ether in 33% yield: ^{1}H-NMR (CCl_4) δ=1.46 (s, 3H), 1.61 (s, 3H), 1.67 (s, 3H), 1.9—2.1 (m, 4H), 3.52 (d, J=6 Hz, 2H), 4.9—5.1 (m, 1H), 5.2—5.5 (m, 1H), 7.0—7.5 (m, 15H); IR 3080, 3050, 2950, 1670, 1600, 1495, 1455, 1050, 900, 765, 748, 710 cm^{-1}.

The geranyl triphenylmethyl ether (13.0 g, 32.7 mmol) was treated with *m*-chloroperbenzoic acid (7.1 g, 32.7 mmol) in chloroform (30 ml) at 0 °C for 2.5 h. Purification by column chromatography gave the epoxide **17** (7.9 g, 58% yield): ^{1}H-NMR (CCl_4) δ=1.22 (s, 3H), 1.25 (s, 3H), 1.47 (s, 3H), 1.5—1.6 (m, 2H), 2.13 (d, J=8 Hz, 2H), 2.50 (t, J=6 Hz, 1H), 3.53 (d, J=6 Hz, 2H), 5.42 (t, J=7 Hz, 1H), 7.0—7.5 (m, 15H); IR 3080, 2980, 1672, 1598, 1495, 1454, 1050, 900, 765, 750, 710 cm^{-1}.

The epoxide **17** (8.0 g, 19 mmol) was isomerized with lithium diethylamide (20 mmol) in ether for 48 h to an allylic alcohol (4.5 g, 57% yield) which showed: ^{1}H-NMR (CCl_4) δ=1.3—1.8 (m+s (δ=1.47, 3H)+d (δ=1.70, J=1.2 Hz, 3H), totally 9H), 1.9—2.2 (m, 2H), 3.53 (d, J=6 Hz, 2H), 3.93 (t, J=6 Hz, 1H), 4.74 (t, J=2 Hz, 1H), 4.87 (quintet, J=1.2 Hz, 1H), 5.41 (t, J=6 Hz, 1H), 7.0—7.5 (m, 15H); IR 3400, 3080, 1650, 1600, 1495, 1453, 1045, 900, 765, 712 cm^{-1}.

The alcohol (4.0 g, 9.8 mmol) was treated with acetic anhydride (10 ml) and pyridine (10 ml) at room temperature for 12 h to give **18** in 93% yield: ^{1}H-NMR (CCl_4) δ=1.47 (s, 3H), 1.5—1.8 (m+d (δ=1.72, J=1.2 Hz), 5H), 1.8—2.1 (m+s (δ=1.97), 5H), 3.53 (d, J=6 Hz, 2H), 4.83 (t, J=2 Hz, 1H), 4.91 (quintet, J=1.2 Hz, 1H), 5.09 (t, J=6 Hz, 1H), 5.39 (t, J=6 Hz, 1H), 7.0—7.5 (m, 15H); IR 3070, 2940, 1738, 1649, 1595, 1490, 1450, 1225, 1042, 895, 763 cm^{-1}.

The acetate **18** was converted into a carboxylic acid **19** in 85% yield as described for the transformation of **25** into **26**. ^{1}H-NMR ($CDCl_3$) δ=1.45 (s, 3H), 1.61 (s, 3H), 1.9—2.1 (m, 4H), 2.2—2.5 (m, 4H), 3.53 (d, J=6 Hz, 2H), 5.0—5.2 (m, 1H), 5.33 (t, J=6 Hz, 1H), 7.0—7.5 (m, 15H), 10.0—10.2 (m, 1H); IR 3080, 2950, 1710, 1598, 1494, 1453, 1045, 765, 710 cm^{-1}.

The carboxylic acid **19** was reduced with lithium aluminum hydride to give an alcohol, which was converted into the aldehyde **20** with pyridinium chlorochromate in 80% yield: ^{1}H-NMR (CCl_4) δ=1.43 (s, 3H), 1.61 (s, 3H), 1.9—2.0 (m, 4H), 2.1—2.4 (m, 4H), 3.56 (d, J=6 Hz, 2H), 5.0—5.2 (m, 1H), 5.40 (t, J=6 Hz, 1H), 7.0—7.5 (m, 15H), 9.53 (t, J=0.6 Hz, 1H); IR 3080, 2940, 2740, 1725, 1672, 1596, 1492, 1450, 1048, 900, 765, 750, 710 cm^{-1}. Found: C, 85.02; H, 7.96%. Calcd for $C_{31}H_{34}O_2$: C, 84.89; H, 7.81%.

(6E,10E)-3-Acetoxy-2-diethoxymethyl-6,10-dimethyl-12-triphenylmethoxy-1,6,10-dodecatriene (14): ^{1}H-NMR (CCl_4) δ=1.17 (t, J=7.2 Hz, 6H), 1.46 (s, 3H), 1.5—2.1 (m+s (δ=1.60, 3H)+s (δ=1.93, 3H), totally 14H), 3.2—3.6 (m, 6H), 4.78 (s, 1H), 5.0—5.5 (m, 5H), 7.0—7.5 (m, 15H); IR 2990, 1740, 1452, 1230, 1115, 1050, 765, 710 cm^{-1}.

(2E,6E,10E)-2-Ethyl-6,10-dimethyl-12-triphenylmethoxy-2,6,10-dodecatrienal (15). To lithium dimethylcuprate(I) (0.6 mmol) in ether (3 ml), allylic acetate (**14**) (0.12 g, 0.20 mmol) was added at −18 °C and the resulting mixture was stirred for 30 min at −18 °C. Workup followed by hydrolysis with aq 5% sulfuric acid-THF (1:1) and isomerization with potassium carbonate (8 mg) in methanol (12 ml) at 40 °C for 15 h gave **15** (0.072 g, 73% yield): ^{1}H-NMR (CCl_4) δ= 0.92 (t, J=7.5 Hz, 3H), 1.47 (s, 3H), 1.63 (s, 3H), 2.0—2.5 (m, 10H), 3.52, (d, J=7.2 Hz, 2H), 5.0—5.2 (m, 1H), 5.37 (t, J=7.0 Hz, 1H), 6.22 (t, J=7.2 Hz, 1H), 7.0—7.5 (m, 15H), 9.23 (s, 1H); IR 3080, 3000, 2950, 2740, 1688, 1644, 1598, 1494, 1453, 1046 710 cm^{-1}.

(2E,6E,10E)-2-Ethyl-6,10-dimethyl-12-triphenylmethoxy-2,6,10-dodecatrien-1-ol. The aldehyde **15** was reduced with sodium borohydride (quantitative yield): ^{1}H-NMR (CCl_4) δ= 0.97 (t, J=7 Hz, 3H), 1.47 (s, 3H), 1.62 (s, 3H), 1.8—2.2 (m, 10H), 3.52 (d, J=6 Hz, 2H), 3.88 (s, 2H), 5.0—5.5 (m, 3H), 7.0—7.5 (m, 15H); IR 3320, 3080, 2930, 1665, 1596, 1494, 1452, 1050, 900, 750, 710 cm^{-1}. Found: C, 85.15; H. 8.72%. Calcd for $C_{35}H_{42}O_2$: C, 84.97; H, 8.56%.

(2E,6E,10Z)-3,7,11-Trimethyl-2,6,10-tridecatriene-1-ol triphenyl methyl Ether (16). To the above alcohol (77 mg, 0.16 mmol) dissolved in THF (2 ml), sulfur trioxide-pyridine complex (49 mg, 0.31 mmol) was added at 0 °C. After 3 h, lithium aluminum hydride (*ca.* 50 mg) was added and the reaction was heated to reflux for 3 h. Workup and purification by preparative TLC (hexane-ether=5:1, R_f 0.80) gave **16**[31] 58 mg, 78% yield): ^{1}H-NMR (CCl_4) δ=0.94 (t, J=7.5 Hz, 3H), 1.48 (s, 3H), 1.61 (s, 3H), 1.64 (s, 3H), 1.7—2.1 (m, 10H), 3.52 (d, J=6.0 Hz, 2H), 4.9—5.1 (m, 2H), 5.39 (d, J=6.0 Hz, 1H), 7.0—7.5 (m, 15H); IR 3080, 2990, 2940, 1665, 1596, 1494, 1453, 1050, 900, 745, 710 cm^{-1}.

Preparation of 3-Bromo-1,1-diethoxy-4-decanone (29a). To dimethyl sulfoxide (DMSO) (1.56 g, 20.0 mmol) dissolved in dichloromethane (20 ml), trifluoroacetic anhydride (3.15 g, 15.0 mmol) in dichloromethane (5 ml) was added over 10 min at −78 °C. After 10 min, a dichloromethane solution (5 ml) of the alcohol **1e** (prepared from **3** (15 mmol) and heptanal (9.65 mmol), and used without purification) was added over a period of 10 min at −78 °C, and the resulting solution was stirred for 70 min before quenching with triethylamine (4 ml), then warmed up and stirred for 70 min at room temperature. Workup gave a crude cyclopropyl ketone **28a** which was dissolved in ethanol (15 ml) containing a catalytic amount of boron trifluoride ether complex (*ca.* 50 mg) for 2 h at room temperature. Workup and purification by column chromatography (hexane-ether=10:1) gave **29a** (2.32g, 74% yield): ^{1}H-NMR (CCl_4) δ=0.89 (t, J=5.6 Hz, 3H), 1.13 (t,

J=7.1 Hz, 3H), 1.17 (t, J=7.1 Hz, 3H), 1.3—1.8 (m, 8H), 1.9—2.9 (m, 4H), 3.2—4.1 (m, 4H), 4.27 (t, J=7.4 Hz, 1H), 4.47 (dd, J=4.7, 6.3 Hz, 1H); IR 2940, 1715, 1460, 1360, 1120, 1155 cm^{-1}; MS m/z (rel intensity) 280 (5), 279 (4), 278 (5), 277 (5), 197 (24), 113 (17), 103 (100), 97 (33), 85 (70), 75 (43).

Synthesis of 4-Oxodecanal (30a). Lithium aluminum hydride (48 mg, 1.25 mmol) was added to the suspension of chromium(III) chloride (0.40 g, 2.50 mmol) in THF (2 ml) at 0 °C. To the resulting dark brown reagent[21], the α-bromo ketone **29a** (0.17 g, 0.52 mmol) was added, and the whole was stirred for 1 h at room temperature. Workup gave a crude keto acetal (0.13 g) which was stirred in a mixture of THF (3 ml) and aq 15% sulfuric acid (1 ml) at room temperature for 1.5 h. Workup and purification by column chromatography (hexane-ether=3:1) gave **30a**[22] (70 mg, 80% yield): ^{1}H-NMR (CCl_4) δ=0.7—1.1 (m, 3H), 1.1—1.8 (m, 8H), 2.38 (t, J=7.4 Hz, 2H), 2.63 (s, 4H), 9.72 (s, 1H); IR 2940, 2740, 1705, 1460, 1405, 1125, 865 cm^{-1}; MS m/z (rel intensity) 170 (M^+, 1), 113 (35), 100 (24), 85 (79), 72 (52), 57 (47), 43 (100).

Preparation of (Z)-3-Bromo-1,1-diethoxy-7-decen-4-one (29b). The lithium carbenoid **3** was prepared from 1,1-dibromo-2-ethoxycyclopropane (0.44 g, 1.79 mmol), butyllithium (1.98 M hexane solution, 0.88 ml, 1.75 mmol) and allowed to react with (Z)-heptenal (0.12 g, 1.04 mmol). The produced alcohol was oxidized without purification by the Swern's method as described for the oxidation of **1e** to give **28b** which was stirred in ethanol (5 ml) containing acetic acid (*ca.* 15 mg) at room temperature for 4 h. Workup gave **29b** (0.26 g, 77% yield): ^{1}H-NMR (CCl_4) δ=0.98 (t, J=8.4 Hz, 3H), 1.16 (t, J=6.6 Hz, 3H), 1.19 (t, J=6.6 Hz, 3H), 1.9—3.0 (m, 8H), 3.3—3.8 (m, 4H), 4.33 (t, J=6.6 Hz, 1H), 4.52 (dd, J=9.6, 15.6 Hz, 1H), 5.1—5.5 (m, 2H); IR 2980, 1720, 1450, 1380, 1125, 1160, 790 cm^{-1}; MS m/z (rel intensity) 277 (8), 275 (8), 195 (66), 167 (22), 149 (22), 103 (98), 85 (61), 75 (88), 55 (88), 47 (100). Found: m/z 275.0616. Calcd for $C_{12}H_{20}O_2Br$ (M-OEt): M 275.0646.

Synthesis of (Z)-4-Oxo-7-decenal (30b). Reduction of **29b** with the $CrCl_3$-$LiAlH_4$ reagent[21] gave **30b** in 91% yield: ^{1}H-NMR (CCl_4) δ=0.97 (t, J=7.2 Hz, 3H), 1.7—2.8 (m+s (δ=2.65, 4H), totally 10H), 5.0—5.5 (m, 2H), 9.73 (s, 1H); IR 3055, 2960, 1720, 1415, 1095, 1020, 865, 720 cm^{-1}; MS m/z (rel intensity) 168 (M^+, 3), 149 (7), 123 (35), 95 (37), 85 (91), 69 (51), 68 (53), 55 (86), 41 (100).

(E)-4-Oxo-2-decenal (32). The bromo acetal **29a** (0.17 g, 0.52 mmol) was treated with THF (3 ml)-aq 15% sulfuric acid (2 ml) at room temperature for 5 h. Workup and purification by preparative TLC (hexane-ethyl acetate=10:1, double development) gave **32** (56 mg, 64% yield): ^{1}H-NMR (CCl_4) δ=0.91 (t, J=5.7 Hz, 3H), 1.1—1.9 (m, 8H), 2.65 (t, J=6.9 Hz, 2H), 6.7—6.9 (m, 2H), 9.75 (dd, J=1.8, 5.4 Hz, 1H); IR 2950, 2750, 1700, 1625, 1115, 1080, 980 cm^{-1}; MS m/z (rel intensity) 168 (M^+, 6), 139 (47), 125 (15), 111 (20), 98 (83), 83 (77), 70 (58), 55 (94), 43 (100). Found: m/z 168.1158. Calcd for $C_{10}H_{16}O_2$: M 168.1149.

10) The configuration of the carbenoid is discussed by Taylor (ref 6a) and lithium ion is found to occupy the exo position cis to methoxyl group. The intramolecular coordination effect by the adjacent methoxyl group seems extremely remarkable to reverse the configuration of the carbenoid predominating in the absence of the methoxyl group. See Ref. 2b.

11) Orbital symmetry rule suggests 7-*endo*-halonorcarane is amenable to ring opening reaction under solvolytic conditions, while 7-*exo*-halo isomer remains unchanged. See R. B. Woodward and R. Hoffmann, "The Conservation of Orbital Symmetry," Verlag Chemie GmbH, Weinheim, Germany, 1970, p 56.

13) The cuprate reactions are explained (Ref. 12) to proceed through one-electron transfer yielding an allyl radical i of the thermodynamically favorable W form. Subseqent methyl transfer, therefore, should give (Z)-olefin ii and hence iii. In fact iii [NMR (CCl_4): δ=6.30 (t, J=8 Hz, 1H), 10.06 (s, 1H)] was the major product when deacetalization was performed carefully, but isomerization to **11** occurred rapidly and completely upon purification on silica gel. Formation of an S_N2 type product iv was less than 5%.

The Asymmetric Ullmann Coupling Reaction of Chiral Diol Diesters of 1-Bromo-2-naphthoic Acid and 2-Halo-3-nitrobenzoic Acids: Highly Diastereoselective Synthesis of Atropisomeric 6,6'-Dinitrodiphenic Acids[1)]

Sotaro MIYANO,* Shigeru HANDA, Kunitoshi SHIMIZU,
Katsuya TAGAMI, and Harukichi HASHIMOTO

(Received December 5, 1983)

The copper-promoted Ullmann reaction of chiral diol diesters of 1-bromo-2-naphthoic acid induced axial dissymmetry into the newly formed 1,1'-binaphthyl bond: chiral diol, apparent net optical yield for the joining of two naphthyl units, and axial chirality induced are as follows: (*S*)-1,1'-binaphthyl-2,2'-diol, 71%, *S*; (1*S*,2*S*)-1,2-diphenyl-1,2-ethanediol, 32%, *S*; (1*R*,2*R*)-1,2-bis(ethoxycarbonyl)-1,2-ethanediol, 33%, *S*; (4*S*,5*S*)-bis(hydroxymethyl)-2,2-dimethyl-1,3-dioxolane, 3.7%, *R*. The reaction of (*R*)-1,1'-binaphthyl-2,2'-diol esters of 2-halo-3-nitrobenzoic acids gave up to 85% net optical yield for the coupling; the intramolecular cyclization proceeded with virtually complete diastereoselectivity to give cyclic diester of *R*,*R*-configuration in a 42% isolated yield. This remarkable stereocontrol is ascribed to the steric requirement of the 12-membered cyclic diester structure containing rigid 1,1'-binaphthyl and 1,1'-biphenyl moiety.

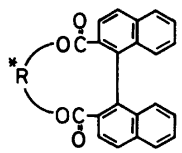
Although axially dissymmetric biaryl skeletons have been successfully utilized in the asymmetric recognition,[2)] direct route to the requisite chiral biaryls are limited.[3)] Thus, the construction of atropisomeric biaryls by asymmetric induction represents a potential value. Recently two groups disclosed elegant synthesis of chiral binaphthyls through nucleophilic aromatic displacement using oxazolines as the activating substituents for the naphthalene nucleus.[4,5)]

In the previous paper,[1)] we have reported asymmetric synthesis of atropisomeric 1,1'-binaphthyl derivatives (**3** and **4**) *via* the Ullmann reaction of chiral 1,1'-binaphthyl-2,2'-diol esters (**1a**) of 1-bromo-2-naphthoic acid followed by cleavage of the ester linkage (Scheme 1).

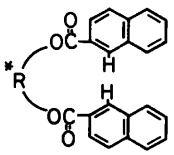
Herein we wish to report the effects of the diol structure on the induction of axial dissymmetry in the asymmetric Ullmann reaction, and an extention to a highly diastereoselective synthesis of chiral 6,6'-dinitrodiphenic acids.

Results and Discussion

Induction of Axial Dissymmetry into 1,1'-Binaphthyl Bond. Chiral diols (**2a—2d**) were converted into respective diesters **1a—1d** by the reaction with 1-bromo-2-naphthoyl chloride in benzene-pyridine. These bifunctional substrates were treated with activated copper powder in gently-refluxing DMF to give thoroughly debrominated products. As evidenced by TLC and HPLC, these mixtures were comprised of many components containing intramolecularly coupled cyclic diester **7**, the reduction product **8**, and various oligomers formed *via* intermolecular reactions. The ester linkage of the reaction products was reductively cleaved to hydroxymethyl function by the treatment with lithium aluminum hydride (LAH). The apparent net optical yields for the induction of axial dissymmetry in joining two naphthyl units by the asymmetric Ullmann reaction were estimated from the optical rotations of the 2,2'-bis(hydroxymethyl)-1,1'-binaphthyls **4** thus obtained (Table 1).

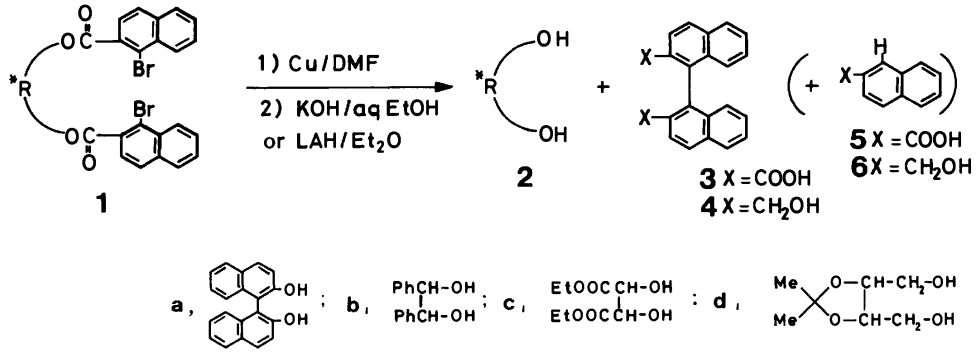


7



8

It is noted that axially dissymmetric 1,1'-binaphthyl-2,2'-diol (*S*)-**2a** gave relatively high optical yields of up to 71% under dilution conditions. In the previous paper,[1)] we reported that the intramolecular coupling of (*S*)-**1a** proceeds with complete diastereoselectivity to



Scheme 1.

Table 1. Asymmetric ullmann coupling of chiral diol diesters of 1-bromo-2-naphthoic acid[a)]

1	Reaction conditions: 1 (mmol)	Cu (g)	DMF (ml)	Addn time/h	4: Optical purity/%[b)]	Config
(*S*)-**1a**	0.401	1.0	10	—[c)]	45	*S*
	1.25	2.0	80	5	57	*S*
	0.864	2.0	60	8	71	*S*
(*S*)-**1b**	2.92	2.0	60	1	23	*S*
	2.78	2.0	100	5	32	*S*
(*R*)-**1c**	2.86	2.0	80	5	33	*S*
(*S*)-**1d**	1.99	3.0	50	5	3.7	*R*

a) A solution of **1** in DMF was added to a gently-refluxing suspension of copper powder in DMF. After the addition, the reaction was continued for another 2 h. b) Calculated on the basis of the value for optically pure (*S*)-**4**; $[\alpha]_{546}^{23}$ —86.0° (*c* 1.43, acetone). See Ref. 1. c) Result from Ref. 1 where a mixture of diester and copper powder in DMF was heated at 120—130 °C for 10 h.

give cyclic diester (*S,S*)-**7a** with no detectable amount of (*S,R*)-isomer. This remarkable stereocontrol is ascribed to the steric requirement in assembling 12-membered cyclic diester which contains two sets of 1,1′-binaphthyl residues. However, competing intermolecular coupling of **1** to oligomeric products seems hardly to induce axial dissymmetry in the joining of two naphthyl moieties,[1,6] thus reducing the overall optical yield for the synthesis of chiral binaphthyls *via* the route depicted in Scheme 1. Thus, the substantial improvement of the optical yields under dilution reaction conditions should be attributed to the enhancement of the unimolecular process.

C-Chiral 1,4-diol (*S*)-**2d** was almost ineffective to cause asymmetric induction, while 1,2-diols such as (1*S*,2*S*)-1,2-diphenyl-1,2-ethanediol ((*S*)-**2b**) and (1*R*, 2*R*)-1,2-bis(ethoxycarbonyl)-1,2-ethanediol ((*R*)-**2c**) induced *S* chirality into the binaphthyl linkage with moderate optical yields. As was stated above, intermolecular coupling of chiral 1-bromo-2-naphthoates seems not so effective in asymmetric induction, the monocyclization step to **7** is critical for determining the overall optical yield in Scheme 1. In this respect, 1,2-ethanediol **2b** and **2c** seem not so strictly control the stereochemistry of monocyclization as binaphthol **2a**. Actually, (*S*)-**1b** gave the cycle **7b** as a mixture of (*S,S*)- and (*S,R*)-isomer in a ratio of 5.2:1 (*i.e.* 68% diastereomeric excess) based on HPLC of the crude reaction mixture (5-h addition reaction in Table 1).

Examination of CPK molecular models does not show so much difference in steric distortions between the diastereomeric cycles (*S,S*)- and (*S,R*)-**7b**, showing sharp contrast to the possible cycles (*S,S*)- and (*S,R*)-**7a** from (*S*)-**1a**.[1] In the case of (*S,R*)-**7b**, however, the lone pair electrons on one of the ester oxygen seem to strongly interact with one naphthalene ring plane. Another explanation for the preferential formation of (*S,S*)-**7b** over (*S,R*)-counterpart may involve the inspection of plausible conformers of (*S*)-**1b** which may lead

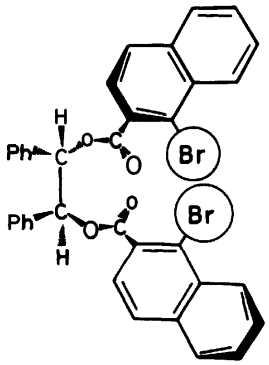


Fig. 1. Conformer (*S*)-**1b**-*S* to (*S,S*)-**7b**.

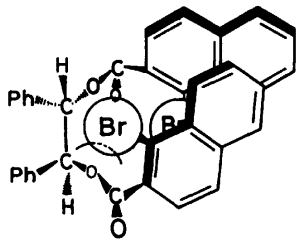

Fig. 2. Conformer (*S*)-**1b**-*R* to (*S,R*)-**7b**.

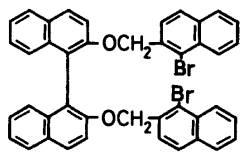
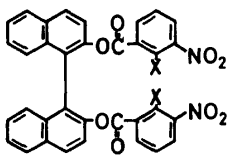
to the coupling stages and thus may reflect transition states. As schematically shown in Figs. 1 and 2, the conformer (*S*)-**1b**-*S* which may lead to *S,S*-coupling will be significantly favored over (*S*)-**1b**-*R* conformer to *S,R*-coupling because of the severe steric distortion in the latter caused by inwardly directed bromine and one ester oxygen atom. This reasoning is based on the assumption that the central mechanistic feature of the Ullmann coupling reaction involves intermediary of organocopper species and free radicals do not play critical role, thus imposing relatively high steric requirements in the coupling process.[7,8]

Although we have been unable to resolve reaction products from (*R*)-**1c**, similar rationalization as above may be applied to explain the preferential formation of (*S*)-binaphthyl (*S*)-**4**: Phenyl and ethoxycarbonyl substituents do not exert meaningful differences on the plausible conformers depicted in Fig. 1 and 2. This may explain the similarity of the magnitudes of asymmetric induction and the sense of chirality with (*S*)-**2b** and (*R*)-**2c**.

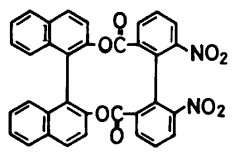
Highly Asymmetric Synthesis of Chiral 6,6′-Dinitrodiphenic Acids. Knowing that 1,1′-binaphthyl-2,2′-diol is the best chiral auxiliary among the diols examined, we tried the reaction of diether **9**, but did not observe any sign of debromination after an elongated treatment with activated copper powder at reflux in DMF.[9]



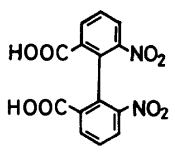
9



10 X = I
11 X = Cl
12 X = H



13



14

It is well known that electron-withdrawing substituents activate aromatic nucleus toward the Ullmann reaction.[8] Hoping to enhance the key unimolecular coupling, we tried the reaction of 2-halo-3-nitrobenzoic acid esters (**10** and **11**). A reaction of (*R*)-2,2′-bis(2-iodo-3-nitrobenzoyloxy)-1,1′-binaphthyl ((*R*)-**10**) was carried out as above. HPLC of the reaction mixture showed the presence of, in the order of elution, the cyclic diester (*R,R*)-**13** as the major component as expected (*ca.* 70% of the HPLC peak area by UV absorption at 254 nm), the reduction product (*R*)-**12** (*ca.* 10%), and others. It has been our general experience that monomeric cyclic diesters **7** are more mobile than the open chain counterparts **8** on chromatography. After a hydrolytic treatment and standard extractive workup followed by TLC, a sample of (*R*)-6,6′-dinitrodiphenic acid ((*R*)-**14**) was recovered in *ca.* 50% chemical yield, with $[\alpha]_D^{22}$+116° in 95% EtOH, indicating a 85% optical yield based on the rotation of enantiomerically pure (*R*)-**14** (*vide infra*). It should be noted that the chiral source (*R*)-**2a** was recovered without appreciable loss of optical activity. Similarly, (*S*)-diacid ((*S*)-**14**) was obtainable by the reaction of (*S*)-**10**.

The dichloro ester (*R*)-**11**, prepared from commercially available 2-chloro-3-nitrobenzoic acid, gave analogous results but with slightly reduced overall optical yield (80%). The Ullmann product was subjected to a silica-gel chromatography to give a pure sample of (*R,R*)-**13** as an yellow-orange powder in a 42% isolated yield, $[\alpha]_D^{22}$+226° in $CHCl_3$. The enantiomeric purity of the sample was confirmed by the optical rotations of the recovered (*R*)-**2a** and (*R*)-**14** obtained after hydrolytic cleavage of the ester linkage. The specific rotation of the recovered diacid (*R*)-**14** was $[\alpha]_D^{22}$ +136.6° (95% EtOH), while that claimed for enantiomerically pure (*R*)-**14** is $[\alpha]_D$ +133.7° (95% EtOH).[10]

Here again, high steric requirement in assembling 12-membered cyclic diester **13** which contains rigid binaphthyl and biphenyl skeleton explains the exclusive formation of (*R,R*)-**13** without (*R,S*)-isomer. Moreover, two sets of nitro substituents in (*R,S*)-**13** can not lie on the attaching benzene planes, further disfavoring the formation of it (Figs. 3 and 4).

Although the scope and limitations of the asymmetric Ullmann coupling reaction remains to be examined,[11] the method presented here, that is the intramolecular coupling of two aryl moieties attached to a chiral 1,1′-binaphthyl residue, is likely to provide an entry into the asymmetric synthesis of chiral biaryls.

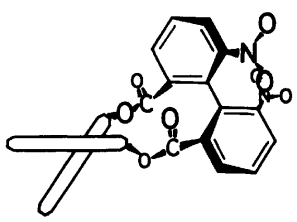


Fig. 3. (*R,R*)-**13**.

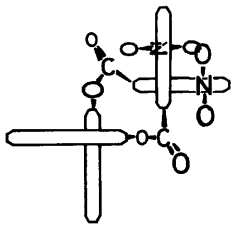

Fig. 4. (*R,S*)-**13**.

Experimental

Melting points are uncorrected. Measurements and materials were similar to those described in the previous paper unless otherwise noted.[1]

The following compounds were prepared as described in the literature; 2-iodo-3-nitrobenzoic acid,[12,13] mp 205—209 °C (lit,[13] 210—212 °C), IR (KBr) 1710, 1540, and 1370 cm^{-1}; (4*S*,5*S*)-4,5-bis(hydroxymethyl)-2,2-dimethyl-1,3-dioxolane ((*S*)-**2d**),[14] bp 112 °C/1.5 mmHg.†

Racemic 1,2-diphenyl-1,2-ethanediol was resolved into *R*- and *S*-isomer by direct crystallization from ether solution.[15] Crystals which showed levorotation in $CHCl_3$ were collected[16]; mp 148—149 °C (lit,[16b] 148—149 °C), $[\alpha]_D^{22}$ −95.0° (*c* 1.00, EtOH) (lit,[16b] $[\alpha]_D^{22}$−94.5° (*c* 0.998, EtOH)). Commercial 2-chloro-3-nitrobenzoic acid and (1*R*,2*R*)-1,2-bis(ethoxycarbonyl)-1,2-ethanediol were used as received. 2-Halo-3-nitrobenzoic acids were converted to acid chlorides by the treatment with thionyl chloride.

Synthesis of Diol Diesters. To a stirred, water-chilled solution of a chiral diol **2** (5—6 mmol) in PhH(100 ml)-pyridine(10 ml) was slowly added slightly excess amount of an acid chloride (12—14 mmol). The mixture was stirred overnight at ambient temperature and finally heated under reflux for 3 h. The reaction mixture was diluted with PhH (50 ml), and then 50 ml of 2 M†† HCl was added. The aqueous layer was extracted with PhH (30 ml×3). The combined organic extracts were washed successively with 2 M HCl, 1 M Na_2CO_3, and water, and then dried over Na_2SO_4 in the presence of activated charcoal. After volatiles were removed under a reduced pressure, the crude diester was purified by column chromatography and/or recrystallization. Yields were generally good to excellent (65—95%).

*(S)-2,2′-Bis(1-bromo-2-naphthoyloxy)-1,1′-binaphthyl ((S)-**1a**)*: This compound was the same as was used in the previous work.[1]

*(1S,2S)-1,2-Bis(1-bromo-2-naphthoyloxy)-1,2-diphenylethane ((S,S)-**1b**)*: The crude material was chromatographed on a silica-gel column with toluene as the eluent to yield white solids: mp 177—179 °C; $[\alpha]_D^{22}$ +12.3° (*c* 1.63, $CHCl_3$); IR (KBr) 3500—3300, 3050—2950, 1730, 1260, 1220, 1110, 960, 808, 750, and 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.47, (2H, s, -CH<×2), 7.20 (10H, s, $-C_6H_5$×2), 7.30—7.80 (10H, m), and 8.15—8.45 (2H, m). Found: C, 63.60; H, 3.43; Br, 23.27%. Calcd for $C_{36}H_{24}Br_2O_4$: C, 63.55; H, 3.56; Br, 23.49%.

*Diethyl (2R,3R)-2,3-Bis(1-bromo-2-naphthoyloxy)-1,4-butanedioate ((R,R)-**1c**)*: The crude material was chromatographed on a silica-gel column with $CHCl_3$ (1% EtOH) as the eluent, and then recrystallized from MeOH: mp 127—129 °C; $[\alpha]_D^{22}$

† 1 mmHg≈133.322 Pa.

†† 1 M=1 mol dm^{-3}.

−79.1° (*c* 0.923, $CHCl_3$); IR (KBr) 3500—3300, 3000—2850, 1765—1740, 1250, 1220—1195, 1110, 805, and 755 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.1—1.33 (6H, t, *J*=7 Hz, $-CH_3\times2$), 4.06—4.41 (4H, q, *J*=7 Hz, $-CH_2-\times2$), 6.03 (2H, s, $-CH<\times2$), 7.33—7.80 (10H, m), and 8.15—8.40 (2H, m). *(R)-2,2′-Bis(2-iodo-3-nitrobenzoyloxy)-1,1′-binaphthyl ((R)-**10**)*: The crude material was chromatographed on a silica-gel column with toluene as the eluent: mp 99—106 °C; $[\alpha]_D^{22}$ +22.3° (*c* 1.03, $CHCl_3$); IR (KBr) 3500—3300, 1750, 1530, 1350, 1250, 1190, 1110, 1090, 805, 760—720, and 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.55—8.00 (m). Found: C, 49.15; H, 2.04; N, 3.19; I, 29.98%. Calcd for $C_{34}H_{18}I_2N_2O_8$: C, 48.83; H, 2.17; N, 3.35; I, 30.35%.

*(S)-**10***: $[\alpha]_D^{22}$ −23.1° (*c* 0.997, $CHCl_3$). Found: C, 49.18; H, 2.08; N, 3.35; I, 29.82%.

*(R)-2,2′-Bis(2-chloro-3-nitrobenzoyloxy)-1,1′-binaphthyl ((R)-**11**)*: The crude material was chromatographed on a silica-gel column with toluene as the eluent: mp 77—80 °C; $[\alpha]_D^{22}$ +43.2° (*c* 1.46, $CHCl_3$); IR (KBr) 1755, 1535, 1350, 1280—1240, 1190, 1120—1080, 805, 735, and 680 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.90—8.00 (m). Found: C, 62.58; H, 2.73; N, 4.13; Cl, 10.43%. Calcd for $C_{34}H_{18}Cl_2N_2O_8$: C,62.50; H, 2.78; N, 4.29; Cl, 10.85%.

*(±)-2,2′-Bis(3-nitrobenzoyloxy)-1,1′-binaphthyl (**12**)*: The crude material was chromatographed on a silica-gel column with toluene as the eluent: mp 174—177 °C; IR (KBr) 3500—3300, 1750—1740, 1530, 1345, 1240, 1200, 1100, 805, 750, and 705 cm^{-1}; MS (70 eV), *m/z* (%) 584 (M^+, 18.4), 268 (4.32), 150 (44.9), and 104 (12.3). Found: C, 70.06; H, 3.31; N, 4.44% Calcd for $C_{34}H_{20}N_2O_8$: C, 69.86; H, 3.45; N, 4.79%.

*(±)-2,2′-Bis(1-bromo-2-naphthylmethoxy)-1,1′-binaphthyl (**9**)*: (±)-1,1′-Binaphthyl-2,2′-diol (5.74 g, 20.0 mmol) was added to a sodium methoxide (prepared from 1.1 g (48 mmol) of sodium) in 50 ml of DMF. To the mixture was slowly added 1-bromo-2-bromomethylnaphthalene (12.0 g, 40 mmol), and the mixture was diluted with 50 ml of toluene. The reaction was stirred overnight at room temperature, and worked up as usual. The crude material was recrystallized from $CHCl_3$-EtOH (2/1), 8.8 g (61%): mp 177—178 °C; IR (KBr) 1620, 1590, 1500, 1340, 1290, 1235, 1120, 1100, 840, 830, and 765 cm^{-1}; ^1H NMR (CCl_4) δ=5.6(4H, s, $-CH_2-\times2$), and 7.2—8.0 (24H, m). Found: C, 69.89; H, 3.77; Br, 22.31%. Calcd for $C_{42}H_{28}O_2Br_2$: C, 69.63; H, 3.90; Br, 22.06%.

Ullmann Reaction of Bifunctional Substrates. The reaction of (*S*)-**1a** is representative. See Table 1 for the reaction conditions.

*Ullmann Reaction of (S)-**1a***: In a 200-ml, two-necked, round-bottomed flask, copper powder (2.0 g) was pretreated for activation just prior to use.[1] Under a nitrogen atmosphere, to the flask were attached a reflux condenser topped with nitrogen inlet and a pressure-equilibrating Hershberg-type dropping funnel.[17] The funnel was charged with 0.650 g (0.864 mmol) of (*S*)-**1a**, which was then dissolved in 30 ml of DMF. The copper powder was stirred vigorously in 30 ml of DMF and heated to a gentle reflux. To the suspension was added the ester over 8 h period. After the addition had been completed, the reaction mixture was stirred under reflux for another 2 h. After the reaction, the mixture was allowed to cool to room temperature, diluted with 50 ml of PhH, and then filtered. Solids were washed well with portions of PhH. Combined organic layer was washed successively with 2 M HCl and then water (×3), and dried over Na_2SO_4 in the presence of activated charcoal. Evaporation of the solvent *in vacuo* left a pale yellow residue (0.482 g); $[\alpha]_D^{22}$ −201° (*c* 1.03, PhH). A portion of the residue (0.30 g) was boiled with 0.2 g of LAH in ether (40 ml) for 4 h. The reaction was quenched with cautious addition of ethyl acetate and then water, and worked up as usual. Preparative TLC on silica gel with $CHCl_3$-ethyl acetate (4/1) afforded (*S*)-**4** (80 mg), $[\alpha]_{546}^{22}$ −61.1° (*c* 0.973, acetone), and (*S*)-**2a** (127 mg), $[\alpha]_D^{22}$ −35.0° (*c* 1.06, THF).

When the addition time of (*S*)-**1a** was reduced to 5 h, the Ullmann product showed $[\alpha]_D^{22}$ −170° (*c* 1.30, PhH), and the optical rotation of recovered **4** was reduced to $[\alpha]_{546}^{22}$ −49.2° (*c* 0.955, acetone).

*Ullmann Reaction of (S)-**1b***: The addition time of (*S*)-**1b**, optical rotation of the Ullmann product, and that of recovered **4** were as follows; 1 h, $[\alpha]_D^{22}$ +10.1° (*c* 1.19, $CHCl_3$), $[\alpha]_{546}^{22}$ −19.7° (*c* 1.02, acetone); 5 h, $[\alpha]_D^{22}$ −42.3° (*c* 1.40, $CHCl_3$), $[\alpha]_{546}^{22}$ −27.5° (*c* 1.16, acetone).

Among the products of these Ullmann reactions, the component eluted third on HPLC (ODS column, CH_3CN-H_2O (20/1)) was assigned as the reduction product **8b** by comparing the retention volume with that of authentic sample. The most mobile component was assigned as (*S,R*)-**7b**, and the second as (*S,S*)-**7b** on the basis of the peak areas of these two components on HPLC (UV absorption at 254 nm) and optical purity of the **4** obtained after LAH reduction of mixtures of these two components. The HPLC peak areas were calibrated to mole fractions of (*S,S*)- and (*S,R*)-**7b** using the formula

$$\text{O.P.} \times (1/100) \approx (fP_{S,S}-P_{S,R})/(fP_{S,S}+P_{S,R}) = (M_{S,S}-M_{S,R})/(M_{S,S}+M_{S,R})$$

where O.P.=% optical purity of the recovered **4**, $M_{S,S}$=moles of (*S,S*)-**7b**, $M_{S,R}$=moles of (*S,R*)-**7b**, $P_{S,S}$=peak area of (*S,S*)-**7b** on HPLC, $P_{S,R}$=peak area of (*S,R*)-**7b**, and f= a correspondence factor (2.86, r=0.995) experimentally determined from different mixtures of (*S,S*)- and (*S,R*)-**7b** and the optical rotations of recovered **4**.

In an example, a fraction from the column chromatography which contained (*S,R*)- and (*S,S*)-**7b** (0.170 g, HPLC peak area ratio $P_{S,R}/P_{S,S}$=0.202) was treated with LAH to give (*S*)-**4**, 89 mg (86%), $[\alpha]_{546}^{22}$ −73.7° (*c* 1.02, acetone) and (*S*)-**2b**, 68 mg (97%), $[\alpha]_D^{22}$ −91.3° (*c* 1.03, EtOH).

*Ullmann Reaction of (R)-**1c***: The Ullmann product showed $[\alpha]_D^{22}$ −1.9° (*c* 1.08, $CHCl_3$), and the optical rotation of recovered **4** was $[\alpha]_{546}^{23}$ −28.1° (*c* 1.27, acetone).

*Ullmann Reaction of (S)-**1d***: The Ullmann product showed $[\alpha]_D^{23}$ +13.7° (*c* 1.69, acetone), and the optical rotation of recovered **4** was $[\alpha]_{546}^{22}$ +3.2° (*c* 1.89, acetone).

*Attempted Ullmann Reaction of (±)-2,2′-Bis(1-bromo-2-naphthylmethoxy)-1,1′-binaphthyl (**9**)*: A mixture of **9** (2.50 g, 3.45 mmol) and activated copper powder (prepared from 2.0 g of Cu) in 30 ml of DMF was refluxed for 10 h with vigorous stirring under nitrogen. HPLC showed the presence of only starting material; the organic residue weighed 2.20 g (88%), and the IR absorption spectra (KBr) were superimposable to those of **9**.

When an intimate mixture of **9** (2.40 g, 3.31 mmol) and copper powder (1.5 g) was heated to 250 °C for 4 h in a sand bath, an intractable tarry matter resulted.

*Ullmann Reaction of (R)-2,2′-Bis(2-iodo-3-nitrobenzoyloxy)-1,1′-binaphthyl ((R)-**10**)*: A solution of (*R*)-**10** (1.26 g, 1.51 mmol) in 40 ml of DMF was added to a gently-refluxing suspension of copper powder (1.5 g) in 60 ml of DMF over 5 h period, and then the reaction was continued for another 2 h. The organic residue weighed 0.824 g, $[\alpha]_D^{22}$ +166° (*c* 1.37, $CHCl_3$).

Part of the residue (0.787 g) was refluxed with KOH (1.5 g) in EtOH(80 ml)-H_2O (10 ml) for 3 h. After solvents were removed *in vacuo*, the mixture was diluted with H_2O (20 ml) and 2 M HCl (10 ml), and then extracted with ethyl acetate (30 ml×3). Combined organic layer was extracted with 1 M Na_2CO_3 (30 ml×3) and then H_2O (30 ml×3), and dried over Na_2SO_4. Removal of the solvent left (*R*)-**2a**, 0.323 g (84%), $[\alpha]_D^{22}$ +36.3° (*c* 1.85, THF). The combined aq extracts were made acidic with conc. HCl, and then extracted with ethyl acetate (30 ml×3). The organic extracts were treated as usual. Evaporation of the solvent left a mixture of *m*-nitrobenzoic acid and 6,6'-dinitrodiphenic acid **14**, 0.381 g, *ca.* 85% yield. A preparative TLC with PhH-ethyl acetate-acetic acid (5/2/trace) gave (*R*)-**14**, 0.211 g (55.4%); $[\alpha]_D^{22}$+116° (*c* 1.18, 95% EtOH); IR (KBr) 3500—2500, 1730, 1690, 1530, 1340, 1260, 1105, 890, 770, 740, and 690 cm^{-1}; ^1H NMR (acetone-d_6) δ= 7.48—7.77 (2H, m), 8.15—8.30 (4H, m), and 10.85 (2H, s, -COOH×2).

Ullmann Reaction of (S)-10: Similar reaction of (*S*)-**10** (0.972 g, 1.16 mmol) with copper powder (1.5 g) in 100 ml of DMF gave the Ullmann product, 0.573 g, $[\alpha]_D^{22}$ −164° (*c* 0.923, $CHCl_3$). The diacid (*S*)-**14** was recovered in a 50% yield and showed $[\alpha]_D^{22}$ −114° (*c* 1.08, 95% EtOH).

Ullmann Reaction of (R)-2,2'-Bis(2-chloro-3-nitrobenzoyloxy)-1,1'-binaphthyl ((R)-11): The chloro ester (*R*)-**11** (1.24 g, 1.90 mmol) was allowed to react with copper powder (2.5 g) using 100 ml of DMF. The organic residue weighed 1.05 g (*ca.* 95%), $[\alpha]_D^{22}$ +159° (*c* 1.24, $CHCl_3$). From the residue, a 0.483 g of sample was chromatographed on a silica-gel column with toluene as the eluent to give (*R,R*)-**13**, 0.213 g (42% yield based on the (*R*)-**11** used); $[\alpha]_D^{22}$ +226° (*c* 0.989, $CHCl_3$); mp 211—215 °C; MS (70 eV), *m/z* (%) 582 (M^+, 34.6), 283 (6.02), 282 (3.69), 269 (6.21), 268 (25.9), 255 (4.85), 239 (4.56), 226 (3.20), 198 (3.10), 138 (4.17), and 134 (3.69); IR (KBr) 3500—3300, 3000—2850, 1755, 1530, 1345, 1260, 1210, 1190, 1090, 850, 805, 745, and 700 cm^{-1}. Found: C, 69.92; H, 3.29; N, 4.88%. Calcd for $C_{34}H_{18}N_2O_8$: C, 70.10; H, 3.11; N, 4.81%.

The cyclic diester (0.189 g, 0.324 mmol) was treated with KOH in aq EtOH as above, affording (*R*)-**14**, 70 mg (65%), $[\alpha]_D^{22}$ +136.6° (*c* 0.915, 95% EtOH), mp 222—225 °C (lit,[9] 231—231.5 °C), and (*R*)-**2a**, 68 mg (73%), $[\alpha]_D^{22}$ +34.6° (*c* 1.10, THF).

We thank Associate Professor Junzo Yamashita and Dr. Yoshio Inoue of our laboratory for their encouragement for this work. We are also grateful to Professor Shozo Yamaguchi of our university for kind gift of 2-chloro-3-nitrobenzoic acid. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 57550526 from the Ministry of Education, Science and Culture.

Practical Procedure for the Chemoselective Reduction of Esters by Sodium Borohydride. Effect of the Slow Addition of Methanol[1)]

Kenso SOAI,* Hidekazu OYAMADA, Masako TAKASE, and Atushiro OOKAWA
Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received December 8, 1983)

The effect of solvents on the reduction of esters was examined with readily available sodium borohydride which is known to be incapable of reducing such functional groups. In mixed solvents of *t*-butyl alcohol-methanol or tetrahydrofuran-methanol, various carboxylic esters and lactones were found to be reduced by sodium borohydride to the corresponding alcohols or diols in high yields. Slow addition of methanol to the refluxing mixture of ester and sodium borohydride in *t*-butyl alcohol or tetrahydrofuran was essential to achieve effective reduction. On the other hand, each individual solvent, methanol or *t*-butyl alcohol, was not effective for the reduction. The procedure provided a practical method for the functional group selective reduction of esters in the presence of chloro, cyano, carboxylato, carbamoyl, carboxy or nitro groups, which can not usually be performed by lithium aluminium hydride.

We wish to report here a practical and selective reduction of esters and lactones with sodium borohydride ($NaBH_4$) in mixed solvent of *t*-butyl alcohol(*t*-BuOH)-methanol(MeOH), and in tetrahydrofuran(THF)-MeOH.

$NaBH_4$, since its discovery by Schlesinger, Brown and co-workers,[2)] has enjoyed extensive use in the reduction of ketones and aldehydes. $NaBH_4$ is presently one of the most easily available among many complex metal hydrides, it is easier to manipulate than lithium aluminium hydride($LiAlH_4$) and lithium borohydride because of its lower sensitivity towards moisture.[3)]

Though selective reduction of esters is an important method in organic synthesis,[4)] $LiAlH_4$ can not usually be used for the purpose because of its excessive reducing power.[3)] On the other hand, it is generally accepted that $NaBH_4$, a mild reducing agent, does not effectively reduce carboxylic esters.[5)] If the reduction of esters with $NaBH_4$ is realized, the procedure may open the route to the reduction of esters with excellent functional group selectivities. Reduction of esters with $NaBH_4$ in ethanol(EtOH)[6)] or MeOH[7)] result in the formation of alcohols only in low yields. High reaction temperature (300 °C),[8)] use of polyethylene glycol (PEG 400) of high boiling point[9)] or metal salt additive[10)] is required for the reduction of esters with $NaBH_4$.

We recently reported that $NaBH_4$ in mixed solvent of THF and a protic solvent shows much higher stereoselectivity than in each individual solvent in asymmetric reduction of chiral α-keto amides.[11)] We describe in this paper the details of the study on solvents and the scope and limitations of the selective reduction of esters with $NaBH_4$ in mixed solvents.

Results and Discussion

In order to study the effect of mixed solvents (solvent A and solvent B) on the reduction of esters by $NaBH_4$, methyl benzoate (**1**) was chosen as a model compound. Solvent B (0.8 ml) was added slowly (1 h) to the mixture of **1** (1 mmol) and $NaBH_4$ (2.1—2.6 mmol) in solvent A (4 ml) at various temperatures. The reactions were quenched by the addition of water or dil. HCl,[12)] and the yields of the resulting benzyl alcohol (**2**) were determined by GLC. For comparison, reductions in single solvents, MeOH or *t*-BuOH, were also run. The results are summarized in Table 1.

$$\underset{(1)}{PhCO_2Me} \xrightarrow[\text{solvent A and solvent B}]{NaBH_4} \underset{(2)}{PhCH_2OH}$$

The following conclusions and comments may be drawn from the data in Table 1: (1) Reduction in a single solvent of MeOH afforded **2** in only 11% yield (Entry 1) and vigorous evolution of gas (probably hydrogen) was observed when $NaBH_4$ and MeOH were mixed. This low yield of the alcohol was in accord with the previously reported result of the reduction of ester with $NaBH_4$ in MeOH.[7)] (2) The yield of **2** was only 6% when reaction was run in a single solvent of *t*-BuOH (Entry 2). *t*-BuOH seemed to be almost inert to $NaBH_4$.[10c)] (3) A dramatic result was obtained when MeOH was added to the refluxing mixture of $NaBH_4$ and **1** in *t*-BuOH. The yield of **2** increased 88% (Entry 3).[13)] (4) Furthermore, combination of THF and MeOH was found to be more effective. The yield of **2** reached 97% (Entry 6). (5) Reduction at refluxing

Table 1. Effect of solvent and temperature on the reduction of methyl benzoate (**1**) by sodium borohydride[a)]

temperature (88%, Entry 3) afforded a higher yield of **2** than that at room temperature (3%, Entry 4). (6) As co-solvent, MeOH (88%, Entry 3) was more effective than 2-propanol (20%, Entry 5). (7) $NaBH_4$ is known to be soluble in diglyme.[3c] Reduction at 50 °C gave a moderate yield (60%) of **2** (Entry 10). However there remains a possibility of a higher yield in the reduction run at a higher temperature. (8) $NaBH_4$ was not soluble in the mixed solvent of benzene and MeOH and the yield of **2** was low (Entry 9). (9) Low yield (38%) of **2** in ether and MeOH (Entry 8) was probably due to the lower reaction temperature than that of THF–MeOH (Entry 6). (10) *t*-BuOH was more effective than 2-propanol (Entries 3 and 7).

As described, the addition of MeOH to the refluxing mixture of methyl benzoate (**1**) and $NaBH_4$ in *t*-BuOH or THF was very effective for the conversion of **1** to benzyl alcohol (**2**). It is also of interest that the mixed solvent of *t*-BuOH and MeOH (Table 1, Entry 3) was much more effective than the separate individual solvents, *t*-BuOH (Entry 2) or MeOH (Entry 1).

From the standpoint of synthesis, the present method has the following advantages over the procedure using PEG 400[9] (1) High yields using lesser amount of $NaBH_4$. (2) Shorter reaction time. (3) An easier working-up procedure because of the use of solvents of lower boiling points (MeOH, *t*-BuOH, THF). (4) Easier control of the rate of evolution of the hydrogen formed by the reaction between MeOH and $NaBH_4$. In the case of PEG 400, evolution of hydrogen, formed by reaction between PEG and $NaBH_4$, is reported during the warming of the reaction mixture.[9] On the other hand, the present procedure includes the slow addition of MeOH to the refluxing mixture of $NaBH_4$ and ester in THF or *t*-BuOH. Therefore, the rate of the evolution of gas by the reaction of MeOH and $NaBH_4$ is limited by the amount of MeOH added (reaction between *t*-BuOH and $NaBH_4$ is negligible,[10c] Table 1, Entry 2).

We then examined if the present procedure of the reduction of **1** is applicable to other esters and lactones. In a similar manner, reduction of various esters and lactones by $NaBH_4$ was performed either in mixed solvents of *t*-BuOH–MeOH or THF–MeOH. As clearly seen from the data summarized in Table 2, aliphatic, aromatic, heterocyclic mono- and diesters, in all cases, gave the corresponding alcohols in high yields. Diesters such as diethyl phthalate gave 1,2-benzenedimethanol in 91% yield and phthalide in 8% yield (Entry 14). Lactones afforded the corresponding diols in high yield, too (Entries 15 and 16). Even esters of sterically hindered carboxylic acids such as methyl 2-ethylbutanoate and methyl 2,2-dimethylpropanoate were reduced in high yields (Entries 3 and 4). The effect of the structure of the alcohol moiety of the esters was examined using various kinds of benzoates (Entries 5—12). Methl and ethyl benzoates were reduced in high yields (Entries 5, 6 and 7), and isopropyl benzoate afforded a moderate yield of **2** (Entries 8 and 9). However *t*-butyl benzoate was reduced only in low yield (Entries 10 and 11) Reduction of an α,β-unsaturated ester was accompanied by the reduction of the carbon-carbon double bond (Entry 17).[6] Methyl *p*-hydroxybenzoate was not reduced and was recovered unchange (Entry 18).[14]

The results of the preceding paragraphs suggested the possibility of a selective reduction of esters by the reducing system used. In fact, when compounds other than esters such as benzamide, *N,N*-dimethylbenzamide or 1-chlorodecane (**3**) were treated with $NaBH_4$ in refluxing *t*-BuOH–MeOH, no reduction products were obtained and all the substrates were recovered in 100%, 98%, and 93% yield respectively. In order to establish the synthetic utility of the reduction of esters by $NaBH_4$ in mixed solvents, we examined the competitive or selective reduction of esters in the presence of other groups.[15] The results are shown in Table 3.

A mixture of equimolar amounts of methyl benzoate (1) and 1-chlorodecane (**3**) was treated with $NaBH_4$ in refluxing *t*-BuOH–MeOH. **1** was reduced selectively to afford benzyl alcohol(2) in the yield of 82%, whereas 88% of **3** was recovered (Entry 1). Similarly, in the competitive reduction carried out in THF–MeOH, **2** was obtained in 88% yield and the recovery of **3** was 88% (Entry 2). Similarly, in the competitive reduction of esters in the presence of benzonitrile (Entries 3 and 4), sodium benzoate (Entry 5) benzamide (Entry 6) or benzoylglycine (Entry 9), esters were reduced selectively in moderate to high yields (49—97%). Whereas substrates other than esters were recovered in high yields (84—97%). Sodium benzoate was recovered as benzoic acid (85%, Entry 5). The ethoxycarbonyl group of ethyl *p*-nitrobenzoate was reduced selectively to afford *p*-nitrobenzyl alcohol in high yields (Entries 7 and 8). As described above, reduction by $NaBH_4$ in mixed solvents is useful for the selective reduction of esters in the presence of other functional groups such as chloro, cyano, carboxylato, carbamoyl, carboxy or nitro.

It is reported that hydroxylic solvents play an important role in the reduction of ketones with $NaBH_4$.[16] Hydroxylic solvents are incorporated in the mechanism of the reduction.[16] In inert solvents such as diglyme, reductions of ketones by $NaBH_4$ do not proceed to any appreciable extent.[17] Though it is not yet clear, we tentatively assume the following possibilities, (1) and/or (2), for the unusually high yields of the reduction of esters by the addition of MeOH to the refluxing mixture of $NaBH_4$ and esters in *t*-BuOH or THF. (1) MeOH as a protic solvent may play the same role as in the reductions of ketones by $NaBH_4$ in hydroxylic solvent.[16] (2) When MeOH reacts with $NaBH_4$, various alkoxyhydroborate(−1) are formed, *i.e.* $BH_3(OMe)^-$, $BH_2(OMe)_2^-$, $BH(OMe)_3^-$. These species or their aggregated form may show higher reducing power than $NaBH_4$, and may be capable of reducing esters.[18,22] Detailed discussion of the mechanistic aspects of the reduction of esters with $NaBH_4$ in mixed solvents must await further investigation. Low yields of the reduction of esters with $NaBH_4$ in single solvents of MeOH(Table 1, Entry 1) or EtOH[6] may be attributed to the high concentration of protic solvents. When a large amount of MeOH or EtOH exists, hydrides of $NaBH_4$ are rapidly consumed by the reaction with hydroxylic solvents especially at reflux temperatures. On the other hand, slow addition of MeOH to the mixture of $NaBH_4$ and ester in the present study may suppress this side reaction because the concentration of MeOH is much

a) Molar ratio (ester : A : $NaBH_4$ = 1.0 : 1.0 : 2.5), at refluxing temperature. b) Isolated yields unless otherwise noted. c) Isolated recovery. d) Determined by GLC. e) Recovered as benzoic acid after acidic treatment.

lower than that in single solvent of MeOH.

Conclusion

The addition of MeOH to a refluxing mixture of $NaBH_4$ and esters or lactones in *t*-BuOH or THF enabled the reduction of carboxylic esters or lactones to the corresponding alcohols or diols in high yields. The method provided synthetically useful selective reduction of esters in the presence of other reducible groups. Advantages of the method are the availability and easy manipulation of the reagents ($NaBH_4$, *t*-BuOH, THF, MeOH) and easy working-up because of the low boiling points of the solvents.

Experimental

Melting points were not corrected. IR spectra were recorded with a Hitachi 260-10 spectrophotometer. ^{1}H-NMR spectra (60 MHz) were recorded by using either a Varian EM-360A NMR spectrometer or a JEOL JNM- PMX-60 NMR spectrometer. GLC analyses were carried out with a Shimadzu Gas Chromatograph either model GC-4C or model GC-4A. All of the reaction were run under an atmosphere of argon.

Materials. 2-Propanol and benzene were stored over 4 Å molecular sieves. Methanol was stored over 3Å molecular sieves. *t*-Butyl alcohol was purchased from Kanto and was used without further purification. Tetrahydrofuran and diglyme were distilled from lithium aluminum hydride prior to use.

$NaBH_4$ (Nakarai) was used without further purification. Its activity (99%) was determined following a similar procedure described in the literature.[22] Most of the organic compounds utilized in this study were commercial products of high purity (Tokyo Kasei, Nakarai), but they were further purified by distillation when necessary. Methyl 2-ethylbutanoate was synthesized from the corresponding acid and MeOH using a catalytic amount of sulfuric acid according to the standard procedure: bp. 131—132 °C, lit,[23] bp. 135—137 °C (736 mm) .

Procedure for The Study of The Effect of Mixed Solvents and Temperature on The Reduction of Methyl Benzoate (1) by $NaBH_4$ (Table 1) Solvent B (0.8 ml) was added over a period of 1 h to the refluxing mixture of **1** (0.136 g, 1 mmol) and $NaBH_4$ (0.079—0.098 g, 2.1—2.6 mmol) in solvent A (4 ml). The reaction mixture was refluxed for an additional 1 h or more, and then 1—2 ml of diluted HCl or water was added. Most of the organic solvents of A and B were evaporated on a rotary evaporator. Naphthalene in ether was added to the residue. The yields of benzyl alcohol (**2**) were determined by GLC using naphthalene as internal standard (2 m glass column of 10% PEG 20M (1 M=1 mol dm^{-3}) on Chromosorb W AW, column temperature 140—170 °C, carrier gas He, TC detector).

General Procedure for The Reduction of Esters or Lactones by $NaBH_4$ in Mixed Solvents of t-BuOH-MeOH or THF-MeOH (Table 2). Methanol (0.8 ml) was added over a period of 1 h to the refluxing mixture of $NaBH_4$ (1 mmol) and ester or lactone (1 mmol) in *t*-BuOH (4 ml) or THF (4 ml). After the addition of MeOH, the reaction mixture was refluxed for an appropriate period. The reaction was quenched by the addition of diluted HCl or H_2O.

(1) The resulting alcohols were isolated according to the following procedure. Most of the organic solvents were evaporated on a rotary evaporator, and the residue was extracted with dichloromethane (6×5 ml). The combined extracts were dried over anhydrous sodium sulfate. After the evaporation of the solvent under reduced pressure, the residue was purified on preparative silica gel TLC. The NMR and IR spectra were identical with those of authentic samples.[24]

1,4-Undecanediol (Entry 15): NMR ($CDCl_3$) 0.6—1.8 (m, 19H), 3.3—3.75 (m, 3H), 4.0 (broad, 2H); IR (neat) 3320, 2950, 2870, 1470, 1070 cm^{-1}. Found: C, 70.12; H, 12.81%. Calcd for $C_{11}H_{24}O_2$: C, 70.16; H, 12.85%.

1,5-Dodecanediol (Entry 16): Mp 43.5—44.2 °C; NMR ($CDCl_3$) 0.6—1.9 (m, 21H), 3.0 (s, 2H), 3.4—3.8 (m, 3H); IR (KBr) 3280, 2920, 2850, 1460, 1380, 1138, 1108, 1065, 920 cm^{-1}. Found: C, 71.27; H, 12.88%. Calcd for $C_{12}H_{26}O_2$: C, 71.23; H, 12.95%.

(2) In the determination of the yields by gas chromatography, appropriate internal standards were added to the quenched reaction mixture and GLC analyses then carried out. The conditions of GLC analyses were as follows: for benzyl alcohol (**2**) (Entries 5—12), 2-m glass column of 10% PEG 20M on Chromosorb W AW, column temp. 145 °C, internal standard: naphthalene, TC detector; for 2-ethyl 1-butanol (Entry 3), capillary column SE-30, column temp. 45 °C, 2,2-dimethyl 1-propanol (internal standard), FI detector; for 2,2-dimethyl 1-propanol (Entry 4), capillary column SE-30, column temp. 45 °C, 2-ethyl 1-butanol (internal standard), FI detector.

Competitive Reduction of The Mixture of Methyl Benzoate (1) and 1-Chlorodecane or Benzonitrile (Table 3, Entry 1—4). Equimolar mixtures of methyl benzoate (**1**) (1 mmol) and 1-chlorodecane (1 mmol) or benzonitrile (1 mmol) were reduced with $NaBH_4$ in *t*-BuOH-MeOH or THF-MeOH according to the procedure described in the preceding paraph. Benzyl alcohol (**2**) (81—82%) and 1-chlorodecane (88%) (Entries 1 and 2) were purified on preparative silica gel TLC using dichloromethane as developing solvent. Yield of **2** (61—72%) and recoveries of benzonitrile (84—87%) (Entries 3 and 4) were determined by GLC analyses (2-m glass column of 10% PEG 20M on Chromosorb W AW, column temperature 140 °C, FI detector, with naphthalene as internal standard).

Competitive Reduction of The Mixture of Methyl Decanoate and Sodium Benzoate (Table 3, Entry 5). An equimolar mixture of methyl decanoate (1 mmol) and sodium benzoate (1 mmol) was reduced with $NaBH_4$ in *t*-BuOH-MeOH as described above. The reaction was quenched with water, and the solution made alkaline by adding 1M aq NaOH. The mixture was extracted with dichloromethane. The extracts were dried over anhydrous sodium sulfate, and evaporated on a rotary evaporator. Purification on silica gel TLC [developing solvent dichloromethane:ether (6:1)] gave 1-decanol in 74% yield. The 1-decanol synthesized was identical with an authentic sample in GLC analysis. Benzoic acid was recovered according to the following procedure. The water layer was acidified by diluted HCl, and extracted with dichloromethane and evaporated on a rotary evaporator. Purification on silica gel TLC [developing solvent dichloromethane:ether (6:1)] gave benzoic acid in 85% recovery.

Competitive Reduction of The Mixture of Methyl Decanoate and Benzamide (Table 3, Entry 6). An equimolar mixture of methyl decanoate and benzamide was reduced with $NaBH_4$ in t-BuOH-MeOH as described above. Purification on silica gel TLC [developing solvent CH_2Cl_2:MeOH (20:1)] afforded 1-decanol in 75% yield and benzamide in 97% recovery.

Reduction of Ethyl p-Nitrobenzoate (Table 3, Entries 7, 8). Ethyl *p*-nitrobenzoate was reduced with $NaBH_4$ in *t*-BuOH-MeOH or THF-MeOH. Silica gel TLC purification [developing solvent CH_2Cl_2:MeOH (10:1)] gave *p*-nitrobenzyl alcohol in 88—89% yield. mp 90—91 °C (lit,[22] mp 92—93 °C); ^{1}H NMR ($CDCl_3$) 2.15 (s, 1H, OH), 4.8 (s, 2H, CH_2), 7.4—8.3 (dd, 4H, aromatic protones); IR (KBr) 3540, 1610, 1518, 1345, 1065, 748 cm^{-1}.

Effect of The Molar Ratio of $NaBH_4$ and Methyl Benzoate (1) **1** was reduced in THF-MeOH using various amounts of $NaBH_4$ according to the procedure described in preceding paragraphs. Yields are those of the benzyl alcohol (**2**) isolated.

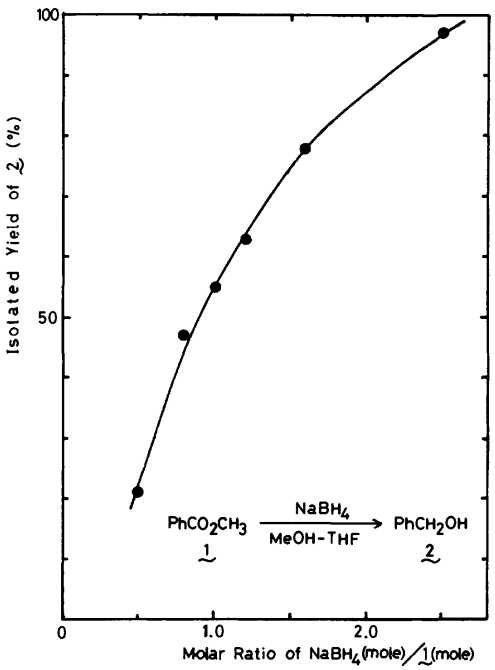

Fig. 1. Effect of Molar Ratio.

12) No significant difference in the yield of benzyl alcohol (**2**) was observed between the methods of quenching. Yields of **2** by the addition of water or dil. HCl were 63% and 62% respectively in comparative reductions of **1**.

13) Slow addition of MeOH was more effective than rapid addition. When MeOH (12 mmol) was added to the mixture of ($NaBH_4$ 2.5 mmol) and **1** (1 mmol) before heating, the yield of **2** dropped to 64%. Interestingly, hydride of the reagent remained even after reflux. Despite this molar ratio of $NaBH_4$ and MeOH (1.0:4.8), evolution of gas (hydrogen) was observed when the reaction was quenched with dil. HCl.

14) Methyl *p*-hydroxybenzoate is known to resist reduction. See ref. 9.

15) When different groups are attached to the same molecule, the selectivity may be changed by neighbouring group participation. On the other hand, even pairs of groups of the same type have been differentiated by virtue of their steric environment in the molecule which has a rather rigid skeleton. Therefore we assume that competitive reduction is on a suitable scale for the functional group selectivity of the reaction. a) F. C. Huang, L. F. H. Lee, R. S. D. Mittal, P. R. Ravikumar, J. A. 18) Sodium hydrotrimethoxyborate [$NaBH(OCH_3)_3$] is known to undergo rapid disproportionation into $NaBH_4$ and sodium tetramethoxyborate in THF.[19]

$$4\,NaBH(OCH_3)_3 \xrightarrow[THF]{} NaBH_4 + 3\,NaB(OCH_3)_4$$

Though reduction of esters with $NaBH(OCH_3)_3$ is reported, $NaBH(OCH_3)_3$ reduces the esters only slowly in ether at reflux or in dibutyl ether at high temperatures(100—140 °C)[20] with the exception of the reduction in dimethoxyethane at reflux.[15b]

To clarify whether all the reducing species are formed *in situ* $NaBH(OCH_3)_3$ in the reduction of esters by $NaBH_4$ in THF-MeOH, effect of the molar ratio of $NaBH_4$ and ethyl benzoate (**1**) was studied in the mixed solvent of THF and MeOH. Results are shown in Fig. 1. The yield of benzyl alcohol (**2**) increased with increase of $NaBH_4$. It become clear that $NaBH(OCH_3)_3$ is not the only reducing species, at least when the molar ratio of $NaBH_4$ to ester (**1**) is between 0.8—1.2. The reason is as follows: $NaBH(OCH_3)_3$ has only one active hydride[21] and one ester needs two active hydrides to be reduced to the corresponding alcohol. If $NaBH(OCH_3)_3$ were the only reducing species and if the reduction proceeded quantitatively, the yield of **2** could not exceed 50% when equimolar amounts of $NaBH_4$ and **1** were used. However, the actual isolated yield of **2** was 55% using equimolar amounts of $NaBH_4$ in mixed solvent of THF and MeOH.

Syntheses of the Sex-Attractant of Pine Sawflies

Tadashi KIKUKAWA, Motomasa IMAIDA, and Akira TAI*
Institute for Protein Research, Osaka University, Yamada-oka, Suita, Osaka 565
(Received December 15, 1983)

In order to establish the stereochemistry of the sex attractant of various species of pine sawflies, (2*S*,3*R*,7*R*)-, (2*S*,3*R*,7*S*)- and (2*S*,3*S*,7*S*)-2-acetoxy- and 2-propionyloxy-3,7-dimethylpentadecane were synthesized. The alcohol moiety of each pheromone was prepared by the coupling of Grignard reagent of C_{12} block with tosylate of C_5 block. The C_{12} blocks, (*R*)- and (*S*)-1-bromo-2-methylundecane, were prepared from (*R*)-(+)-pulegone. The C_5 blocks, (2*R*,3*S*)- or (2*S*,3*S*)-2-methyl-3-tetrahydropyranyloxy-1-(tosyloxy)butane, were derived from (2*S*,3*S*)- or (2*R*,3*S*)-2-methyl-3-hydroxybutyric acid prepared by the enantio-differentiating hydrogenation of methyl 2-methyl-3-oxobutyrate over the asymmetrically modified nickel catalyst.

Virgin females of pine sawflies (*Hymenoptera, Diprionidae*) utilize a powerful sex pheromone to attract males. In 1967, Jewett *et al.*[1] reported that the chemical structure of *N. lecontei* (red headed pine sawfly) was an acetate of (2*R**,3*R**)-3,7-dimethyl-2-pentadecanol (*erythro*-**1**). At the same time, it was proposed that the pheromones of various sawflies were either acetates or propionates of **1**.

The acetate or propionate of the synthesized racemic **1**[2] (a mixture of all possible isomers) was, however, much less active than the natural pheromone and could not discriminate a difference among species. These data suggested that not only a sort of ester moiety but also stereochemistry of **1** were essential factors to distinguish the many sympatric species of sawflies.

In order to clarify the stereochemistry of the pheromones, we have synthesized optically active *erythro*-isomers, (2*S*,3*S*,7*R*/*S*)- and (2*R*,3*R*,7*R*/*S*)-**1**, and *threo*-isomers, (2*S**,3*R**,7*R*/*S*)-, (2*S*,3*R*,7*R*/*S*)- and (2*R*,3*S*,7*R*/*S*)-**1**.[3,4] The field assay of these compounds against *N. lecontei* clearly showed that the natural pheromone must be erythro (2*S*,3*S*)-configuration.[5,6] Later, K. Mori *et al.*[7] synthesized the four *erythro*-isomers: (2*R*,3*R*,7*R*)-, (2*R*,3*R*,7*S*)-, (2*S*,3*S*,7*R*)- and (2*S*,3*S*,7*S*)-**1**. The field assay carried out by Kraemer *et al.*[8] showed that only the acetate of (2*S*,3*S*,7*S*)-1 was highly active against *N. lecontei*. Thus the pheromone of *N. lecontei* was expected to be a single component and its structure was established to be (2*S*,3*S*,7*S*)-**1**. Although (2*S*,3*S*)- or (2*S*,3*S*,7*S*)-**1** attracted many other *Neodiprion* families in the field, its potency for attraction was very weak compared to that of the natural pheromone of each species.

In the course of the field assay by using *erythro*-and *threo*-isomers, we have found that the pheromone of various species other than *N. lecontei* was not a single component but a mixture of *threo*-and *erythro*-isomers. For example, a mixture of (2*S*,3*S*,7*S*)- and (2*S*,3*R*,7*R*/*S*)-**1** in a different ratio functioned for the discrimination of two closely related species, *N. sertifer* and *N. banksianae*.[9] On carrying out the stereochemical studies of this pheromone in detail, the syntheses of optically pure *threo*-isomer as well as *erythro*-isomer were absolutely necessary. Although the synthetic methods of four possible *erythro*-isomers have been reported,[7,10,11] the methods were not applicable for the synthesis of the optically pure *threo*-isomers. This report describes the method for the syntheses of optically pure three essential stereoisomers for the biological study of the pheromone of sawfly: (2*S*,3*R*,7*R*)-, (2*S*,3*R*,7*S*)- and (2*S*,3*S*,7*S*)-**1**.

Results and Discussion

The most reliable procedure to prepare an optically pure stereoisomer is to assemble optically pure building blocks by a method which does not involve the bond breaking and bond forming process at the chiral center of each block. Our synthetic procedure was designed in line with the above mentioned policy. The procedure consists of the preparation of optically pure C_{12} blocks and C_5 blocks and their couplings,as shown in Fig. 1.

Optically pure C_{12} blocks, (*R*)- and (*S*)-1-bromo-3-methylundecane (**9**), were prepared from (*R*)-(+)-citronellic acid (**3**) ($[\alpha]_D^{20}$+8.89° (neat), lit,[12] $[\alpha]_D^{25}$+8.48° (neat)) derived from (*R*)-(+)-pulegone (**2**) ($[\alpha]_D^{20}$+21.97° (neat)) supplied by courtesy of Takasago Perfume Industry Co. The resulting (*R*)-3 was determined to be essentially optically pure by the GLC method developed in this study. A diastereomeric mixture of amides

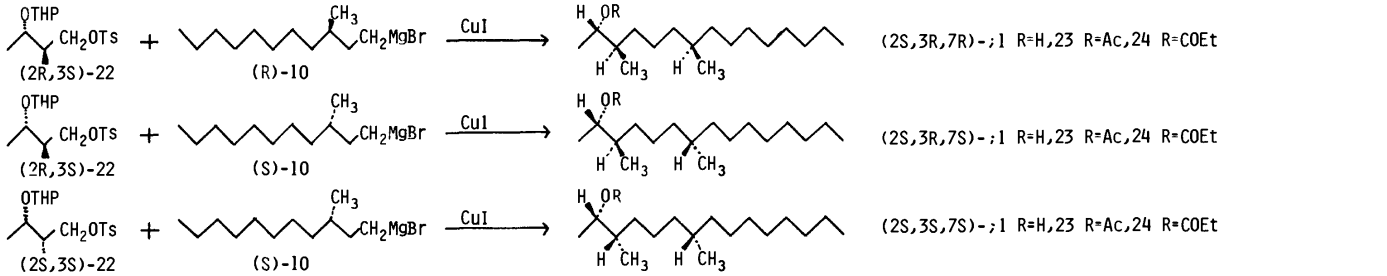

Fig. 1. Preparation of 3,7-dimethyl-2-pentadecanol (**1**) and its derivatives, (**23**) and (**24**).

from citronellic acid and α-methylbenzylamine was found to be completely resolved by capillary GLC (OV-101, 50 m (L)×0.25 mm (I.D)). When the **3** used for this study was converted to its amide with (*S*)-α-methylbenzylamline ($[\alpha]_D^{20}$ −39° (neat), Aldrich Co.), the diastereomeric excess (d.e.) of the resulting amide was 98%. However, the (*S*)-α-methylbenzylamine[13] was found to be not optically pure. The GLC analysis with a chiral capillary column (OA-500, 40 m (L)×0.25 mm (I.D)) indicated that the enantiomeric excess (e.e.) of this amine was 98%. If our citronellic acid had been contaminated with some antipode, the d.e. value of amide would have been less than 98%.

From the fact that the d.e. value of amide and the e.e. value of amine were identical, and that the optical rotation of our citronellic acid was slightly higher than the reported value[12], it was concluded that the (*R*)-citronellic acid must be optically pure.

The procedure for the preparation of (*R*)-**9** is shown in Fig. 2. (*R*)-Ethyl citronellate (**4**) prepared by the esterification of (*R*)-**3** was ozonized in methanol.[14] The hydrogenolysis of the ozonide over Pd/C gave ethyl (*R*)-3-methyl-6-oxohexanoate (**5**). The reaction of (*R*)-**5** with Wittig reagent[15] prepared from pentyltriphenylphosphonium bromide and butyllithium gave ethyl (*R*)-3-methyl-6-undecenoate (**6**). Hydrogenation of (*R*)-**6** over Pt(Adam's) gave ethyl (*R*)-3-methylundecanoate (**7**), which was reduced with lithium aluminum hydride to give (*R*)-3-methyl-1-undecanol (**8**). The bromination[16] of (*R*)-**8** gave (*R*)-**9**: $[\alpha]_D^{20}$ −4.07° (*c* 4.9, hexane). The (*R*)-**9** was converted to Grignard reagent ((*R*)-**10**) ((*R*)-C_{12} block) in ether right before the use for the coupling reaction.

The procedure for the preparation of (*S*)-**9** is shown in Fig. 3. The reduction of (*R*)-**4** with lithium aluminum hydride gave the corresponding alcohol(**11**), which was then converted to a tosylate ((*R*)-**12**). The coupling of (*R*)-**12** with hexylmagnesium chloride in the presence of copper(I) iodide[17] gave (*R*)-2,6-dimethyl-2-tetradecene (**13**). The ozonolysis of (*R*)-**13** in dichloromethane and oxidative cleavage of the ozonide with hydrogen peroxide in formic acid[14] gave (*S*)-4-methyldodecanoic acid (**14**). The Hunsdiecker reaction[18] of (*S*)-**14** gave (*S*)-**9**: $[\alpha]_D^{20}$ +4.04° (*c* 4.5, hexane). The (*S*)-**9** was converted to Grignard reagent ((*S*)-**10**) ((*S*)-C_{12} block) in ether right before the use for the coupling reaction.

As the optical rotations of (*R*)-and of (*S*)-**9** were the same value within experimental error, it was concluded that no racemization took places in each step of the reaction process. Therefore, these bromides (**9**) must be optically pure.

The preparation of C_5 blocks is shown in Fig. 4.

The hydrogenation of methyl 2-methyl-3-oxobutyrate (**15**) over the nickel catalyst modified with (*S,S*)-tartaric acid, ((*S,S*)-TA-MHNi) gave a mixture of methyl *threo*-and *erythro*-3-hydroxy-2-methylbutyrate (**16**) in a ratio of 25 to 75[19,20]. The effective isolation of *threo*-and *erythro*-isomer on a practical scale was successfully achieved by the crystallization method. The procedure shown in Fig. 4 enabled us to isolate *threo*-isomer with 55% recovery and *erythro*-isomer with 54% recovery. The advantage of this method is that *threo*-and *erythro*-isomers were obtained at once; furthermore the optical purity of each diastereomer was approximately 60%.

The mixture of *threo*-and *erythro*-**16** was saponified to sodium 3-hydroxy-2-methylbutyrate (**17**). The sodium salt thus obtained was dissolved in a minimum amount of methanol. By the slow addition of acetone to the solution, sodium salt of *threo*-isomer was preferentially precipitated as crystals. The recrystallization of the sodium salt from methanol-acetone gave pure *threo*-**17** (optical purity 60%, (2*S*,3*S*) in excess). *Erythro*-isomer enriched in the mother liquid of the first crystallization converted to cyclohexylammonium salt (**19**). Three succesive recrystallizations from EtOH gave pure *erythro*-**19** (optical purity 60%, (2*R*,3*S*) in excess).

Enrichments of optical purity of *threo*-and *erythro*-2-

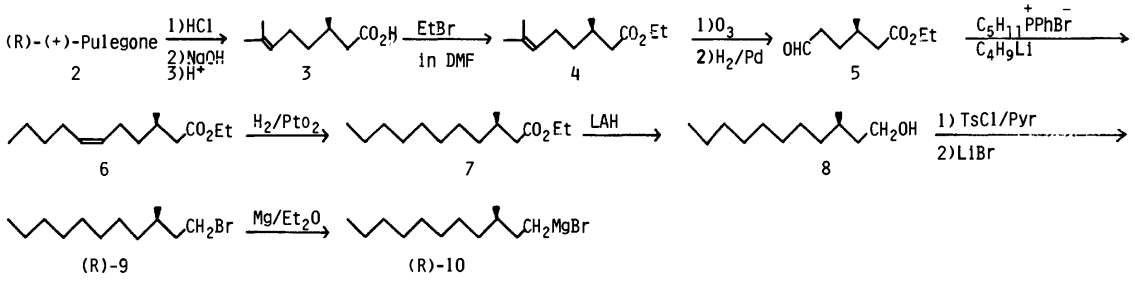

Fig. 2. Preparation of (R)-C_{12} building block.

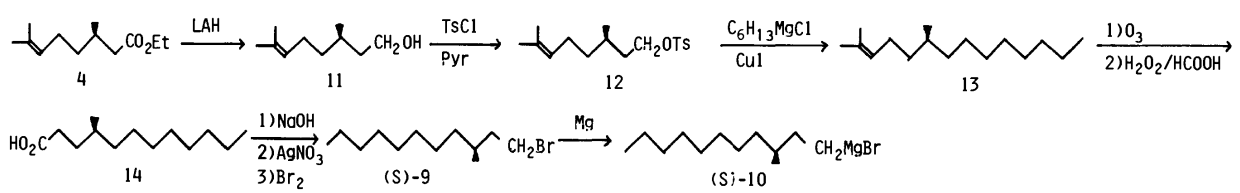

Fig. 3. Preparation of (*S*)-C_{12} building block.

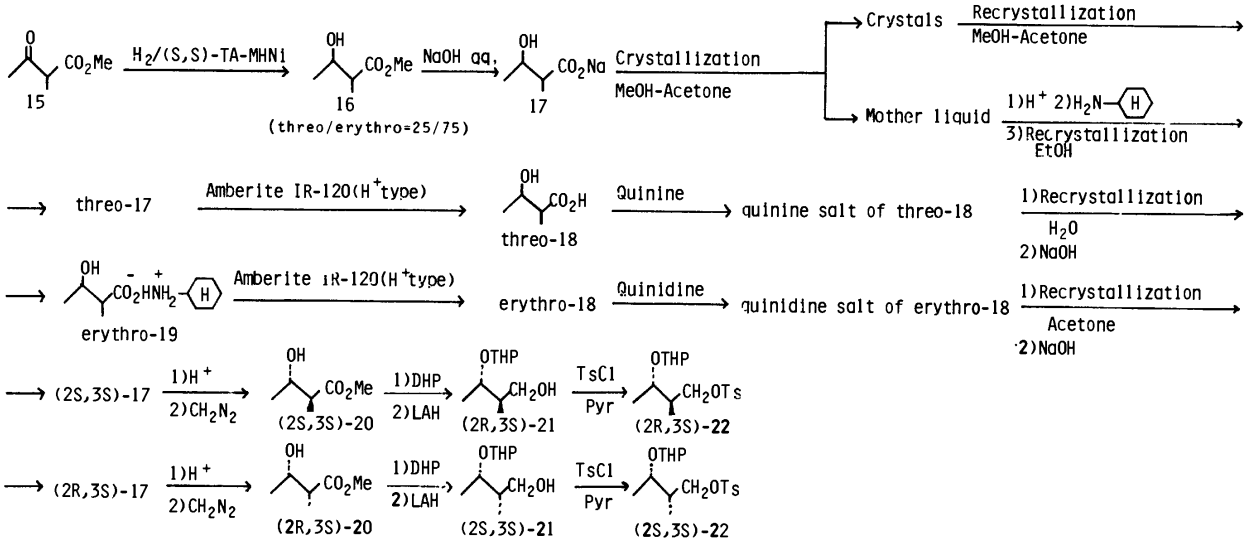

Fig. 4. Preparation of C_5 building blocks.

hydroxy-3-methylbutyric acid (**18**) were carried out by the recrystallization of quinine (*threo*-) and quinidine (*erythro*-) salt respectively. Removal of base by sodium hydroxide gave pure (2*S*,3*S*)-and (2*R*,3*S*)-**17**. The **17** was esterified to the corresponding methyl ester (**20**). After the protection of hydroxyl group of **20** by the treatment of dihydropyran, the resulting compounds were reduced with lithium aluminum hydride to give 2-methyl-3-tetrahydropyranyloxy-1-butanol (**21**). Tosylation of **21** by the conventional procedure gave 2-methyl-3-tetrahydropyranyloxy-1-(tosyloxy)butane (**22**), as shown in Fig. 4.

The coupling reaction of **22** with **10** was carried out by the reported method[17] to give the corresponding alcohol, as shown in Fig. 1. The stereochemical purity at the 2 and 3 position of the resulting (2*S*,3*S*, 7*S*)-, (2*S*,3*R*,7*S*)- and (2*S*,3*R*,7*R*)-**1** were determined by the analytical GLC (Capillary column PEG 20M, 50 m (L)×0.25 mm (I.D)) which can detect at least 0.2% of contaminated epimer. The optical purity of these compounds were also proved by the ^{1}H-NMR.

Each alcohol was converted to the acetate and propionate by the conventional procedure and the resulting esters were employed for the field assays. The synergistic effect of the acetate of (2*S*,3*R*,7*R*)-**1** on the acetate of (2*S*,3*S*,7*S*)-**1** in *N. sertifer* was clearly demonstrated.[21] For other species, the highly biological activity of the mixture of the acetate of (2*S*,3*R*,7*R*)- or (2*S*,3*R*,7*S*)-**1** and acetate of (2*S*,3*S*,7*S*)-**1** has been observed.[9] Details of the biological studies will be published elsewhere.

Experimental

All melting and boiling points are uncorrected. IR spectra were recorded on a Shimadzu IR-420 spectrometer. ^{1}H-NMR spectra were recorded in $CDCl_3$ solution at 200 MHz with TMS as an internal standard on a JOEL FX-200 spectrometer. Optical rotations were measured on a Perkin-Elmer 241 polarimeter. The analytical GLC and preparative GLC were carried out on a Shimadzu GC-6A gas chromatograph.

(R)-(+)- *Citronellic Acid (3).* This was prepared from (*R*)-(+)-pulegone (**2**), $[\alpha]_D^{20}$ +21.97° (neat), supplied by Takasago Perfume Industry Co., in 80% yield by the reported method[12]: bp 98.5 °C/1.5 mmHg†; $[\alpha]_D^{20}$ +8.89° (neat), lit,[12] $[\alpha]_D^{20}$ +8.48° (neat); GLC (3% OV-17 on Chromosorb W, 2 m×3 mm, at 150—220°, temperature gradient, 8 °C/min, carrier gas N_2, 1.4 kg/cm^{-2}), Rt 11 min (a single peak).

Determination of the Optical Purity of (R)-(+)-citronellic Acid. To the (*R*)-**3** (0.1 ml) in a test tube was added dicyclohexylcarbodiimide (DCC) (0.2 g) in ethyl acetate (0.5 ml) and then (*S*)-α-methylbenzylamine (0.2 ml) (Aldrich Co. $[\alpha]_D^{20}$—39° (neat), the e.e. was 98%, which was determined by the method described in the following section). After the mixture was allowed to stand for 1 h, acetic acid was added to this to decompose excess DCC. The white crystals which precipitated were removed by using a centrifuge. The supernatant was subjected to GLC analysis (capillary column OV-101, 50 m (L)×0.25 mm (I.D), at 160 °C, carrier gas N_2, 1.4 kg/cm^2). Under these conditions, (*R**,*S**)- and (*R**,*R**)-amide were completely resolved at the retention times of 69.4 min and 71.4 min respectively at 160 °C. The d.e. of the (*R*,*S*)-amide obtained above was calculated to be 98% from the ratio of the two peaks. The d.e. value was identical with the e.e. value of the (*S*)-α-methylbenzylamine employed. When the same **3** as above was allowed to react with (*R*)-α-methylbenzylamine (Aldrich Co. $[\alpha]_D^{20}$+38° (neat), the e.e. was determined to be 97%), the d.e. of (*R*,*R*)-amide was calculated to be 97% from the ratio of the two peaks. Since the d.e. values of these amides corresponded to the e.e. values of the α-methylbenzylamine employed for analyses, (*R*)-**3** was expected to be optically pure.

Determination of Optical Purity of (R)- and (S)-α-Methylbenzylamine. To (*R*)- or (*S*)-amine (0.1 ml) dissolved in ether (2 ml), trifluoroacetic anhydride (2 ml) was added. After removing the water soluble matter by washing with water, the ether solution was dried over $MgSO_4$. The resulting ethereal solution of *N*-trifluoroacetyl-α-methylbenzylamine was subjected to GLC analysis on OA-500 (Sumitomo Chemical Co. Ltd; capillary column coated with chiral compound, 40 m (L)×0.25 mm (I.D), at 150 °C, carrier gas N_2, 1.4 kg/cm^2). The (*R*)- and (*S*)-*N*-trifluoroacetamide were completely resolved at the retention time of 17.9 and 19.3 min at 150 °C respectively.

† 1 mmHg≈133.322 Pa.

Ethyl Citronellate (4). This was prepared from sodium salt of (*R*)-**3** and ethyl bromide in DMF. From 150 g of 3, 166 g (94.4%) of **4** was obtained: bp 66—68°C/1.5 mmHg; $[\alpha]_D^{20}$+2.6° (*c* 4.5, hexane); GLC(3% OV-17 on Chromosorb W, 2 m×3 mm, at 140 °C, carrier gas N_2, 1.4 kg/cm²), Rt 7 min (a single peak).

Ethyl (R)-3-Methyl-6-oxohexanoate (5). Ozone (4% in carrier gas) was introduced into 25 g of **4** dissolved in methanol (20 ml) in a carrier gas (O_2) (flow rate 0.2 l/min) at −70 °C. After the excess ozone in the reaction mixture was blown off by N_2 gas, the residue was transferred into a flask which contained a suspension of the preactivated Pd/C (100 mg) in methanol (20 ml). The reaction was continued until the theoretical amount of hydrogen was absorbed under atmospheric pressure at room temperature. After removal of Pd/C by filtration, and evaporation of methanol from the filtrate, the residue was distilled *in vacuo* to give 14.5 g (67%) of **5**: bp 124 °C/20 mmHg; $[\alpha]_D^{20}$ +4.0° (*c* 5.1, hexane); GLC (2.5% PEG 20M+3% $AgNO_3$ on Uniport B, 2 m×3 mm, at 150 °C, carrier gas N_2, 1.4 kg/cm²), Rt 5 min (a single peak); NMR ($CDCl_3$, TMS), δ=9.79 (1H for -CHO, s); IR (neat), 1720 and 1740 cm⁻¹ for aldehyde and ester groups. Found: C, 61.31; H, 9.48%. Calcd for $C_9H_{16}O_3$: C,62.76; H, 9.36%.

Ethyl (R)-3-Methyl-6-undecenoate (6). Pentyltriphenylphosphonium bromide was prepared from triphenylphosphine and 1-bromopentane in dry benzene.[15]

Butyllithium (4.28 g in 40 ml of hexane) was added dropwise into a suspension of the above pentyltriphenylphosphonium bromide (27.6 g) in anhydrous ether (200 ml) under nitrogen at room temperature. Into the solution of the ylide thus obtained, a solution of (*R*)-**5** (11.5 g) in ether (20 ml) was added dropwise at room temperature. The mixture was refluxed for 2 h and allowed to stand overnight at room temperature. After removal of insoluble matter by filtration, the ether in the filtrate was evaporated under reduced pressure. The residue was eluted with a 1 to 1 mixture of hexane and ether on a silica gel column (Wakogel C-100). The eluate was concentrated *in vacuo* and the residue was distilled to give 9.6 g (63.6%) of **6**: bp 91—92 °C/1.5 mmHg; $[\alpha]_D^{20}$+0.24° (*c* 5.4, hexane). Found: C, 72.34; H, 11.34%. Calcd for $C_{14}H_{26}O_2$: C, 74.28; H, 11.58%.

Ethyl (R)-3-Methylundecanoate (7). The **6** (9.6 g) was hydrogenated over Pt-black (60 mg) in methanol (20 ml). The distillation of the reaction product gave 9.3 g of (*R*)-**7**: bp 107—109 °C/5 mmHg; $[\alpha]_D^{20}$ +1.83° (*c* 5, hexane); GLC (2.5% PEG-20M+3% $AgNO_3$ on Uniport B, 2 m×3 mm, at 180 °C, carrier gas N_2, 1.4 kg/cm²), Rt 3.8 min (a single peak); IR (neat), 1738 cm⁻¹ for ester group.

(R)-3-Methyl-1-undecanol (8). The **7** (9.3 g) in dry ether (20 ml) was reduced with lithium aluminum hydride (2.3 g) in dry ether (100 ml). The reaction mixture was worked up by conventional procedures to give 7.6 g (>99%) of (*R*)-**8**: bp 137—140 °C/15 mmHg; $[\alpha]_D^{20}$ +4.8° (*c* 5.1, hexane); GLC (3% OV-17 on Chromosorb W, 2 m×3 mm, at 160 °C, carrier gas N_2, 1.4 kg/cm²), Rt 8 min (a single peak); IR (neat), 3300, 2900, 2840, 1450, 1380, 1050 cm⁻¹; NMR ($CDCl_3$, TMS), δ=0.92 (6H, overlapped t and d, 2×C<u>H</u>$_3$-), 1.26 (17H, br s, -(C<u>H</u>$_2$)$_8$- and -C<u>H</u>-), 3.69 (2H, t, -C<u>H</u>$_2$OH). Fond: C, 77.26; H, 14.15%. Calcd for $C_{12}H_{26}O$: C, 77.35; H, 14.07%.

(R)-1-Bromo-3-methylundecane (9). *p*-Toluenesulfonyl chloride (11.7 g) was added to (*R*)-**8** (7.6 g) in dry pyridine (40 ml) under stirring and ice-cooling. The mixture was stirred for 2 h and allowed to stand overnight in a refrigerator. Then it was poured onto ice-water and extracted with ether. The extract was washed with water, aqueous $CuSO_4$, $NaHCO_3$ and brine, dried over $MgSO_4$ and concentrated *in vacuo* to give the tosylate of **8** as viscous oil: IR (neat), 2900, 1600, 1450, 1360, 1180, 1100, 940 cm⁻¹. Anhydrous lithium bromide (3.6 g) was added to a stirred solution of the tosylate (7 g) in acetone (20 ml) at once. The reaction mixture was kept at around 40 °C for 1 h. The resulting insoluble matter was separated by filtration and washed with ether. The filtrate and washing were combined and concentrated *in vacuo*. The residue was chromatographed over silica gel (Wacogel C-100). Elution with hexane gave 7.2 g (70.6%) of (*R*)-**9**: bp 99—105 °C/5 mmHg; GLC (3% OV-17 on Chromosorb W, 2 m×3 mm, at 170 °C, carrier gas N_2, 1.4 kg/cm²), Rt 9 min (96% purity with 4% unidentified impurity, Rt 7 min). The analytical sample is purified by a preparative GLC (10% OV-17 on Chromosorb W , 5 m×4 mm, at 210 °C), $[\alpha]_D^{20}$ −4.07° (*c* 4.9,hexane); IR (neat), 2900, 2850, 1450, 1370, 1255, 720, 645 cm⁻¹; NMR ($CDCl_3$, TMS), δ=0.89 (6H, overlapped t and d, 2×C<u>H</u>$_3$-), 1.27 (14H, s, -(C<u>H</u>$_2$)$_7$-), 1.5—1.93 (3H, m, BrCH$_2$C<u>H</u>$_2$C<u>H</u>(CH$_3$)-), 3.41 (2H, t, BrC<u>H</u>$_2$-). Found: C, 57.95; H, 10.21%. Calcd for $C_{12}H_{25}Br$: C, 57.83; H, 10.11%.

(R)-Citronellol (11). The reduction of (*R*)-**4** with lithium aluminum hydride gave (*R*)-**11** in 96% yield: bp 117 °C/18 mmHg; $[\alpha]_D^{20}$ +6.16° (*c* 4.9, hexane); GLC (3% OV-17 on Chromosorb W, 2 m×3 mm, at 150 °C, carrier gas N_2, 1.4 kg/cm²), Rt 2.5 min (a single peak).

(R)-Citronellyl Tosylate (12). This was prepared by the reaction between **11** and *p*-toluenesulfonyl chloride in dry pridine. From 31.5 g of (*R*)-**11**, 55 g (87.8%) of crude (*R*)-**12** was obtained as a viscous oil. The product was used for the next step without further purification.

(R)-2,6-Dimethyl-2-tetradecene (13). Grignard reagent was prepared from Mg (10.7 g) and 1-chlorohexane (53 g) in dry ether (200 ml). To this reagent, cooled at −70 °C, a solution of (*R*)-**12** (55 g) in ether (100 ml) was added gradually. Then well pulverized CuI (4.2 g) was added to the mixture at once. The temperature of the reaction mixture was kept at −70 °C for 1 h, then gradually raised to room temperature. The mixture was allowed to stand over night, refluxed for 1 h and then poured into aqueous NH_4Cl, and extracted three times with ether. The combined extract was washed with aqueous NH_4Cl, $NaHCO_3$ and brine and dried over $MgSO_4$. After removal of the ether *in vacuo*, the residue was chromatographed over silica gel (Wakogel C-100). The fraction eluted with 1% ether in hexane (150 ml) was concentrated *in vacuo* and distilled to give 35 g (80.1% from **12**) of the pure **13**: bp 134—140 °C/13 mmHg; $[\alpha]_D^{20}$−1.67° (*c* 5.5, hexane); GLC (3% OV-17 on Chromosorb W, 2 m×3 mm, at 160 °C, carrier gas N_2, 1.4 kg/cm²), Rt 9 min (a single peak); IR (neat), 2900, 2840, 1450, 1370, 820 720 cm⁻¹; NMR ($CDCl_3$, TMS), δ=0.87 (6H, overlapped t and d, 2×C<u>H</u>$_3$-), 1.26 (17H, br s, -(C<u>H</u>$_2$)$_8$- and -C<u>H</u>-), 1.64 (6H, d, =C(C<u>H</u>$_3$)$_2$), 1.9 (2H, m, -C<u>H</u>$_2$-CH=C-), 5.11 (1H, t, -C<u>H</u>=C-).

(S)-4-Methyldodecanoic Acid (14). The ozonolysis of **13** (35 g) in CH_2Cl_2 (50 ml) at −70 °C and the oxidative cleavage of the resulting ozonide with 35% H_2O_2/HCOOH by the reported procedur[14] gave 25 g (89.5%) of **14**: bp 130—140 °C/1.5 mmHg; $[\alpha]_D^{20}$−0.6° (*c* 5.3, hexane); IR (neat), 3000, 2890, 2840, 2600, 1710, 1700, 1450, 1420, 1280, 1210, 915 cm⁻¹. Found: C, 72.00; H, 12.58%. Calcd for $C_{13}H_{26}O_2$: C, 72.84; H, 12.23%. A small portion of the product was converted to methyl ester. NMR ($CDCl_3$, TMS) of the ester showed signals as follows: δ=0.88 (6H, overlapped t and d, 2×C<u>H</u>$_3$-), 1.26 (17H, br s, -(C<u>H</u>$_2$)$_8$ -and -C<u>H</u>-), 2.38 (2H, m, -C<u>H</u>$_2$CO$_2$-), 3,66 (3H, s, -COOC<u>H</u>$_3$).

(S)-Bromo-3-methylundecane (9). To a solution of potassium hydroxide (6.6 g) in water (300 ml) was added (*S*)-**14** (25 g) with stirring. The solution of potassium salt of **14** thus obtained and the solution of $AgNO_3$ (19.9 g) were added simultaneously into 100 ml of hot water (60 °C) at about the same rate. The resulting white precipitate was filtered, washed with water and acetone, and dried over P_2O_5 to give 33.6 g of silver salt of **14**. To a suspension of silver salt of **14**

(33.6 g) in CCl_4 (200 ml, dried over molecular sieves) was slowly added dried bromine (16.75 g) in CCl_4 (50 ml) with stirring and cooling. The mixture was kept under ice-cooling for 1 h and allowed to stand for 2 h at room temperature. After that, the temperature of the mixture was gradually increased to refluxing temperature. The reaction was continued until no more generation of carbon dioxide was observed. The insoluble matter in the reaction mixture was filtered off and washed with hexane (200 ml). The combined filtrate and washing were concentrated *in vacuo*. The residue was distilled to give 22 g (84.6%) of (*S*)-**9**: bp 90—93 °C/3 mmHg; GLC (3% OV-17 on Chromosorb W, 2 m×3 mm, at 165 °C, carrier gas N_2, 1.4 kg/cm²), Rt 13 min (95% purity with unidentified impurity, Rt 8 min). The analytical sample is purified by a preparative GLC (10% OV-17 on Chromosorb W, 5 m×4 mm, at 210 °C: $[\alpha]_D^{20}$ +4.04° (*c* 4.5, hexane); Found: C, 57.45; H, 10.01%. Calcd for $C_{12}H_{25}Br$: C, 57.83; H, 10.11%. The IR and NMR spectra were identical with those of (*R*)-**9**.

Methyl threo-*and* erythro-*3-Hydroxy-2-methylbutyrate (16).* Methyl 2-methyl-3-oxobutyrate (**15**) (120 g) dissolved in THF (300 ml) was hydrogenated over reduced nickel (7.6 g) modified with (*S,S*)-tartaric acid (MHNi) in an autoclave (1000 ml capacity) by the procedure reported before[19,20] to give 116 g (95%) of crude methyl 3-hydroxy-2-methylbutyrate (**16**): bp 79—81 °C/18 mmHg. GLC (5% NPGS on Chromosorb W, 2 m×3 mm, at 90 °C, carrier gas N_2, 1.4 kg/cm²) indicated that the products consisted of 25% of *threo*-**16** (retention time 12.8 min) and 75% of *erythro*-**16** (retention time 14.1 min). Seven repeated runs gave 833 g of crude **16**.

The Separation of threo-*and erythro-3-Hydroxy-2-methylbutyric Acid (18).* The **16** obtained above was saponified with 30% aqueous sodium hydroxide at 0 °C to give sodium 3-hydroxy-2-methylbutyrate (**17**). The aqueous solution of **17** was concentrated *in vacuo* at 40 °C to give 800 g of white crystalline **17**. A 200 g part of the crystals was dissolved in hot methanol (*ca.* 800 ml), and acetone (*ca.* 600 ml) was gradually added to the solution at room temperature until crystals of the sodium salt appeared. The crystals thus obtained were filtered to give 56.4 g of crude *threo*-**17**. Four repeated runs of this procedure gave 216 g of the salt. Three recrystallizations from methanol–acetone gave 108.8 g (13.6% from **16**) of pure *threo*-**17**. A small portion of the salt was acidified and the resulting acid was converted to methyl ester by the treatment of diazomethane. The GLC (5% NPGS on Chromosorb W, 2 m×3 mm, at 90 °C, carrier gas N_2, 1.4 kg/cm²) of the methyl ester showed a single peak of the *threo*-isomer; Rt 12.8 min: $[\alpha]_D^{20}$ +22.4° (*c* 5, MeOH). The optical purity of the ester was calculated to be 61% based on the reported value ($[\alpha]_D^{20}$ +36.80° (*c* 5, MeOH)) for optically pure (2*S*,3*S*)-**20**.[22]

The mother liquids obtained from the original crystallization and the first recrystallization, as mentioned before, were combined and concentrated to dryness. The residue (534 g) was acidified with hydrochloric acid and was extracted with three 150 ml portions of ether. The evaporation of the extracts under reduced pressure gave 448.4 g (95% recovery from **17**) of 3-hydroxy-2-methylbutyric acid (**18**) enriched with *erythro*-isomer. The resulting **18** was dissolved in ethanol (650 ml) and then the solution was mixed with cyclohexylamine (380 g) under nitrogen. The mixture was allowed to stand overnight in a refrigerator. The crystals which precipitated were collected and recrystallized twice from ethanol to give 494.4 g (40% from **16**) of pure cyclohexylammonium salt (*erythro*-**19**). A small portion of the salt was acidified, and the free acid was converted to methyl ester with diazomethane. The GLC (5% NPGS on Chromosorb W, 2 m×3 mm, at 90 °C, carrier gas N_2, 1.4 kg/cm²) of the ester showed a single peak corresponding to the *erythro*-isomer; Rt 14.1 min: $[\alpha]_D^{20}$ −8.5° (*c* 5, MeOH). The optical purity of the ester was calculated to be 60% based on the reported value ($[\alpha]_D^{20}$ +14.32° (*c* 5, MeOH)) for optically pure (2*S*, 3*R*)-**20**.[22]

Enrichment of Optical Purity of threo-*18.* *Threo*-**17** (90 g) dissolved in water (1000 ml) was passed through the column of Amberlite IR-120 (H^+ type) and the resulting solution of acid was converted to quinine salt with quinine (210 g) by the procedure reported before.[22] The quinine salt was recrystallized from water three times to give 144 g (51% from *threo*-**17**) of pure crystals of quinine salt: mp 154 °C; $[\alpha]_D^{20}$ −163° (*c* 2, 50% aq EtOH). The crystals were dissolved in water (200 ml) and the solution was mixed with 5% aqueous solution of NaOH until the pH of the mixture became 10. After removal of quinine precipitated by filteration, the filtrate was concentrated to dryness. Crystallization of the residue from ethanol–acetone gave 45 g (98% from quinine salt) of (2*S*,3*S*)-**17**: $[\alpha]_D^{20}$ +10.6° (*c* 10, H_2O).

Enrichment of Optical Purity of erythro-*18.* *Erythro*-**19** (100 g) in water (1000 ml) was passed through the column packed with Amberlite IR-120 (H^+ type) and the eluted acid was treated with 149 g of quinidine. The resulting quinidine salt was recrystallized three times from acetone.[22]

The purified quinidine salt thus obtained amounted to 101.8 g (58% from *erythro*-**19**): mp 100 °C; $[\alpha]_D^{20}$ +172° (*c* 1, H_2O). The quinidine salt dissolved in water was treated with 5% aqueous solution of NaOH while stirring. After removal of the quinidine which precipitated, the filtrate was concentrated to dryness. Crystallization of the residue from ethanol–acetone gave 30.0 g (93.2% from quinidine salt) of (2*R*,3*S*)-**17** as crystals: $[\alpha]_D^{20}$ +7.5° (*c* 10, H_2O).

Methyl (2S,3S)-3-Hydroxy-2-methylbutyrate ((2S,3S)-20). The **18** liberated from (2*S*,3*S*)-**17** (20 g) by the treatment with 12M[††] HCl (48 ml) was extracted with three 40 ml portions of ether. After the extract was concentrated to *ca.* 80 ml, an excess amount of ethereal diazomethane was added to the solution. After removal of the ether, the residue was distilled *in vacuo* to give 17.6 g (95.2%) of (2*S*,3*S*)-**20**: bp 75 °C/13 mmHg; $[\alpha]_D^{20}$ +36.80° (*c* 5, MeOH); GLC (5% NPGS on Chromosorb W, 2 m×3 mm, at 90 °C, carrier gas N_2, 1.4 kg/cm²), Rt 12.8 min. (a single peak); NMR ($CDCl_3$, TMS), δ=1.17 (3H, d, J=7.1 Hz, $C\underline{H}_3$- at C-2), 1.24 (3H, d, J=6.4 Hz, $C\underline{H}_3$- at C_3), 2.47 (1H, quintet, -C$\underline{H}$(CH_3)-CO_2-CH_3), 2.64—2.72 (1H, br, -O$\underline{H}$), 3.72 (3H, s, -$CO_2C\underline{H}_3$), 3.85 (1H, quintet, $CH_3C\underline{H}$(OH)-). Found: C, 54.45; H, 9.16%. Calcd for $C_6H_{12}O_3$: C, 54.53; H, 9.15%. In the NMR, methyl protons of ester group of (2*S*,3*S*)-**20** and that of (2*R*,3*R*)-**20** showed different chemical shift in the presence of chiral shift reagent. As for the sample of (2*S*,3*S*)-**20**, no detectable signals of antipode was observed when the spectra was measured with 17.5 mg of the sample and 45 mg of Eu(hfc)₃ in $CDCl_3$ (0.4 ml).

Methyl (2R,3S)-3-Hydroxy-2-methylbutyrate ((2R,3S)-20). By the procedure mentioned above, 20 g of (2*R*,3*S*)-**17** was converted into 17 g (92%) of (2*R*,3*S*)-**20**: bp 75 °C/15 mmHg; $[\alpha]_D^{20}$ −14.3° (*c* 5, MeOH); GLC (5% NPGS on Chromosorb W, 2 m×3 mm, at 90 °C, carrier gas N_2, 1.4 kg/cm²), Rt 14.0 min. (a single peak); NMR ($CDCl_3$, TMS), δ=1.18 (3H, d, J=6.4 Hz, $C\underline{H}_3$- at C_3), 1.19 (3H, d, J=7.6 Hz, $C\underline{H}_3$- at C_2), 2.3—2.7 (2H, m, -C$\underline{H}$(CH_3)CO_2CH_3 and -O$\underline{H}$), 3.71 (3H, s, $-CO_2C\underline{H}_3$), 3.2—4.2 (1H, m, $CH_3C\underline{H}$(OH)-). Found: C, 54.60; H, 9.46%. Calcd for $C_6H_{12}O_3$: C, 54.53; H, 9.15%. In the NMR, methyl protons of ester group of (2*R*,3*S*)-**20** and that of (2*S*,3*R*)-**20** showed different chemical shifts in the presence of chiral shift reagent. As for the present sample, no detectable signals of antipode was observed when the spectra were measured with the sample (19.2 mg) and Eu(hfc)₃ (100 mg) in $CDCl_3$ (0.4 ml).

(2R,3S)-2-Methyl-3-tetrahydropyranyloxy-1-butanol ((2R,3S)-21). To the solution (2*S*,3*S*)-**20** (13.5 g) and dihydro-

[††] 1M=1 mol dm^{-3}.

pyran (7.8 g) in dry ether (20 ml) was added *p*-toluenesulfonic acid (0.1 g) with stirring at room temperature. The reaction mixture was allowed to stand overnight at room temperature and washed with aqueous $NaHCO_3$, and dried over K_2CO_3. This material was employed for the next step without further purification. To a stirred and ice-cooled suspension of lithium aluminum hydride (5.7 g) in dry ether (200 ml) was added dropwise the above ester in dry ether (30 ml). The mixture was refluxed for 3 h, cooled down to room temperature and hydrolyzed with the theoretical amount of water (10.8 g). The white precipitate was filtered on Celite and washed with ether. The combined filtrate was concentrated *in vacuo*. The distillation of the residue gave 12.2 g (83.7%) of (2*R*,3*S*)-**21**: bp 86.6 °C/2 mmHg; IR (neat), 3600—3800, 2800, 2700, 1430—1450, 1370, 1110—1120, 1010, 970, 930, 900, 870, 800 cm^{-1}. Found: C, 64.00; H, 10.91%. Calcd for $C_{10}H_{20}O_3$: C, 63.79; H, 10.71%.

(2S,3S)-2-Methyl-3-tetrahydropyranyloxy-1-butanol ((2*S*,3*S*)-**21**). By the same method as discribed above, (2*R*,3*S*)-**20** (20 g) was converted to 15.1 g (68%) of (2*S*,3*S*)-**21**: bp 93 °C/3 mmHg. Found: C, 63.60; H, 10.82%. Calcd for $C_{10}H_{20}O_3$: C, 63.79; H, 10.71%.

(2R,3S)-2-Methyl-3-tetrahydropyranyloxy-1-(tosyloxy)butane ((2R,3*S*)-**22**). The (2*R*,3*S*)-**21** (12.2 g) was added dropwise to the solution of *p*-toluenesulfonyl chloride (14.9 g) in dry pyridine (50 ml) cooled on an ice bath. After the reaction mixture was allowed to stand in a refrigerator overnight, it was poured into ice-water (100 ml), and extracted with three 20 ml portions of ether. The combined extract was washed with water, aqueous $CuSO_4$, $NaHCO_3$, and then brine, dried over $MgSO_4$ and concentrated *in vacuo* to give 21 g (95.4%) of crude (2*R*,3*S*)-**22**.

(2S,3S)-2-Methyl-3-tetrahydropyranyloxy-1-(tosyloxy)butane ((2*S*,3*S*)-**22**). The (2*S*,3*S*)-**21** (12.2 g) was treated with 14.9 g of *p*-toluenesulfonyl chloride. The reaction product was worked up by the same procedure as before to give 18.3 g (83%) of crude (2*R*,3*S*)-**22**.

(2S,3R,7R)-3,7-Dimethyl-2-pentadecanol ((2*S*,3R,7R)-**1**). Grignard reagent, (*R*)-**10** was prepared from magnesium (0.43 g) and (*R*)-**9** (4.4 g) in well dried ether (30 ml). After the solution of (*R*)-**10** was cooled down to −70 °C in a Dry Ice-acetone bath, (2*R*,3*S*)-**21** (3 g) dissolved in ether (10 ml) and CuI (0.2 g) were added to the solution with stirring. The temperature of the reaction mixture was gradually raised to 5 °C and kept at 5 °C for 3 h and then overnight at room temperature. After the reaction mixture was refluxed and cooled down, the resulting ether solution was poured into ice-cooled NH_4Cl and the ethereal layer separated out. The aqueous layer was extracted with three 10 ml portions of ether. The combined ethereal solution was washed with aqueous NH_4Cl, $NaHCO_3$ and brine and then evaporated *in vacuo*. The remaining material was treated with *p*-toluenesulfonic acid (0.2 g) in methanol (20 ml) to give crude (2*S*,3*R*,7*R*)-**1**. The crude **1** was purified on a column (Wacogel C-100) with hexane (120 ml) and then 50% ether in hexane (100 ml). The (2*S*,3*R*,7*R*)-**1** was eluted in the second fraction. After removal of the solvent *in vacuo*, the distillation of the residue gave 1.9 g (84.4% from (2*R*,3*S*)-**22**) of (2*S*,3*R*,7*R*)-**1**: bp 116 °C/0.5 mmHg; $[\alpha]_D^{20}$ +16.03° (*c* 5.2, hexane); GLC (capillary column PEG 20M, 50 m (L)×0.25 mm (I.D), at 140 °C, carrier gas N_2, 1.2 kg/cm^2), Rt 15.5 min (a single peak); IR (neat) 3300, 2900, 2850, 1465, 1377, 1095 cm^{-1}; NMR ($CDCl_3$, TMS), δ=0.85 (9H, overlapped t and d, CH_3- at C-3, C-7 and terminal), 1.12 (3H, d, *J*=6.4 Hz, CH_3- at C-2), 1.26 (22H, br s, -$(CH_2)_{10}$-and 2×-CH-), 3.6 (1H, m, -CH(OH)-). Found: C, 79.04; H, 14.30%. Calcd for $C_{17}H_{36}O$: C, 79.61; ,H, 14.15%. (2*S*,3*R*)-**1** and (2*S*,3*S*)-**1** can be distinguished in the capillary GLC and ^{1}H-NMR. The capillary GLC (PEG 20M) results showed that the retention times of the former and the later were 15.5 min and 15.2 min, respectively. The present sample showed a single peak (Rt 15.5) and no peak of (2*S*,3*S*)-**1** (Rt. 15.2 min) was observed. By NMR, only doublet splitting of C-1 methyl signals was observed. Those analyses indicated that the sample was completely free from (2*S*,3*S*)-**1**.

(2S,3R,7S)-3,7-Dimethyl-2-pentadecanol ((2*S*,3R,7*S*)-**1**). This was obtained from (*S*)-**10** and (2*R*,3*S*)-**22** in 80% yield by the procedure mentioned before: bp 106.5—108 °C/0.4 mmHg; $[\alpha]_D^{20}$ +16.36° (*c* 3.5, hexane), GLC (capillary column PEG 20M, 50 m (L)×0.25 mm (I.D), at 130 °C, carrier gas N_2, 1.2 kg/cm^2), Rt 15.5 min (a single peak); IR (neat), 3300, 2900, 2850, 1465, 1377, 1095 cm^{-1}; NMR ($CDCl_3$, TMS), δ=0.85 (9H, overlapped t and d, CH_3-at C-3, C-7 and terminal), 1.16 (3H, d, *J*=6.4 Hz, CH_3- at C-2), 1.26 (22H, br s, -$(CH_2)_{10}$- and 2×-CH-), 3.6 (1H, m, -CH(OH)-). Found: C, 78.76; H, 14.29%. Calcd for $C_{17}H_{36}O$: C, 79.61; H, 14.15%. It was shown that the product was completely free from (2*S*,3*S*)-**1** in the capillary GLC and NMR analyses of this sample under the same conditions as mentioned before.

(2S,3S,7S)-3,7-Dimethyl-2-pentadecanol ((2*S*,3*S*,7*S*)-**1**). This was obtained from (*S*)-**10** and (2*S*,3*S*)-**22** in 52% yield by the method mentioned before: bp 110—117 °C/0.5 mmHg; $[\alpha]_D^{20}$ −10.4° (*c* 3.7, hexane); GLC (capillary column PEG 20M, 50 m (L)×0.25 mm (I.D), at 130 °C, carrier gas N_2, 1.2 kg/cm^2), Rt 15.2 min (a single peak); IR (neat) 3300, 2900, 2850, 1450, 1370, 1400, 920, 715 cm^{-1}; NMR ($CDCl_3$, TMS), δ=0.86 (9H, overlapped t and d, CH_3- at C-3, C-7 and terminal), 1.15 (3H, d, *J*=6.4 Hz, CH_3- at C-2), 1.26 (22H, br s, -$(CH_2)_{10}$- and 2×-CH-), 3.6 (1H, m, -CH(OH)-). Found: C, 78.95; H, 14.32%. Calcd for $C_{17}H_{36}O$: C, 79.61; H, 14.15%.

It was shown that the sample was completely free from (2*R*,3*S*)-isomer in the capillary GLC and NMR analyses

Table 1. Analytical date of (2*S*,3*R*,7*R*)-, (2*S*,3*R*,7*S*)-, or (2*S*,3*S*,7*S*)-2-acetoxy- and 2-propionyloxy-3,7-dimethylpentadecane

3,5-Dinitro-1-(4-nitrophenyl)-4-pyridone, A Novel and Convenient Protecting Reagent for Primary Amines[1)]

Eizo MATSUMURA,† Hironori KOBAYASHI, Tomomi NISHIKAWA, Masahiro ARIGA, Yasuo TOHDA, and Toshihide KAWASHIMA*

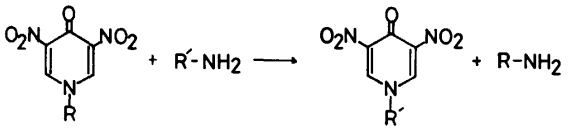
Department of Chemistry, Osaka Kyoiku University, Minamikawahori-cho 4-88, Tennoji-ku, Osaka 543

(Received December 19, 1983)

Crystalline derivatives of the following L-amino acids modified by 3,5-dinitro-4-pyridone have been prepared: glycine, alanine, valine, leucine, isoleucine, phenylalanine, serine, threonine, tyrosine, aspartic acid, asparagine, glutamic acid, glutamine, tryptophan, histidine, arginine, methionine and lysine. The modified L-amino acids (DNPY-L-amino acids) could be purified by recrystallization and were characterized by ^{1}H-NMR, IR and UV spectral data. The molar rotation of the DNPY-L-amino acids varied from 2 to 100 times those of the parent amino acids. The effectiveness of 3,5-dinitro-1-(4-nitrophenyl)-4-pyridone as an amino-protecting reagent of L-amino acids is described.

We have previously reported that 1-substituted 3,5-dinitro-2- and 4-pyridones reacted with some carbon nucleophiles. In the reaction, a new ring transformation was found by action of alkali salts of β-keto esters and vinyl ethers.[2)]

We have recently shown that the treatment of the 4-pyridone with a primary amine leads to another type of ring transformation reaction. Thus 3,5-dinitro-1-(4-nitrophenyl)-4-pyridone(DNPY[3)]-C_6H_4-NO_2-4) and 1.1 equimolar amounts of propylamine in pyridine medium gave 3,5-dinitro-1-propyl-4-pyridone and 4-nitroaniline in nearly quantitative yields at room temperature.[4)] The reaction involves the nucleophilic attack of the amine in sequence at C-2 and C-6 positions on the 4-pyridone and exchanges of the amine moiety in the pyridone ring, as shown in Scheme 1.



Scheme 1.

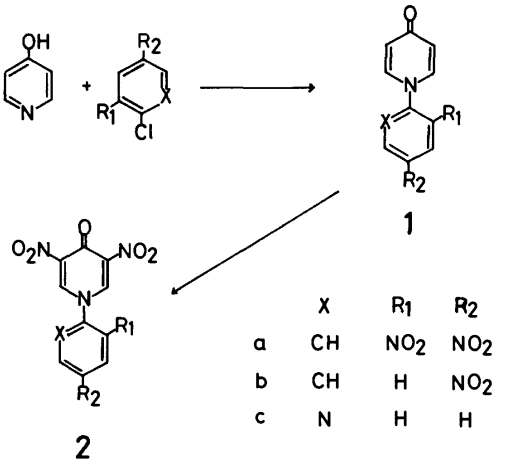
The reaction may be referred to the difference in nucleophilicity between the introduced amines and the liberated ones. Therefore the 4-pyridone derivative with an electron-withdrawing substituent at the 1-position should be one of the best protecting reagents for primary amines.

In synthetic organic chemistry, a variety of protective reagents (*e.g.*, urethane-type, acyl-type and alkyl-type), have been developed and utilized.[5)] Here we propose the 1-substituted 3,5-dinitro-4-pyridone as a novel reagent for blocking of the amino function, since the 4-pyridone reacts easily under very mild conditions.

The present paper describes the first application of the reagent to amino acids and the properties of the resulting modified amino acids(DNPY-L-amino acids).

Results and Discussion

Preparation of 1-Substituted 3,5-Dinitro-4-Pyridones. 1-Substituted 3,5-dinitro-4-pyridones (**2a**—**2c**) were prepared by two step reactions from 4-pyridinol, as shown in Scheme 2.



Scheme 2.

Table 1. Yield of 1-substituted 3,5-dinitro-4-pyridones

4-Pyridone	**2a**	**2b**	**2c**
Overall yield[a)]	13%	70%	24%

a) Based on 4-pyridinol.

As has been pointed out, the 4-pyridone with a stronger electron-withdrawing group at the 1-position would be more favorable for a protective reagent. However, the strongest electron-withdrawing group does not always make the pyridone the best reagent for protecting. Tetranitro compound, **2a** is indeed the most electron-deficient, but its precursor **1a** is too electron-poor to give the nitration product **2a** in good yield, as Table 1 shows. Among the three pyridones, **2b** was chosen as the suitable substrate for our purpose in view of the yield obtained and the cost for preparation.

Syntheses of Modified L-Amino Acids (DNPY-L-Amino Acids). In aqueous pyridine, **2b** reacted with eighteen kinds of L-amino acids in high yield, as follows.

The reaction was accomplished in 2—24 h at room

† Emeritus professor of Osaka Kyoiku University.

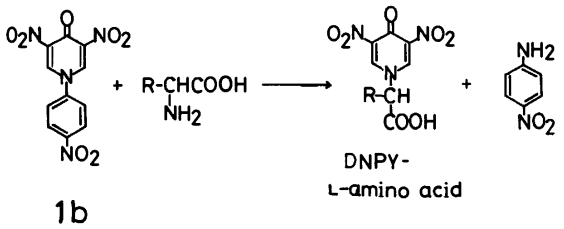
a) Bis-DNPY-L-Lys



Scheme 3.

temperature when all reactants had been dissolved completely.

The solvent was evaporated *in vacuo* and then the residue was extracted with chloroform to remove 4-nitroaniline. The aqueous layer was condensed to give a DNPY L-amino acid. All the L-amino acids except L-lysine could be converted to α-amino-protected compounds. In the case of L-lysine, which had two amino functions, it reacted with an equimolar amount of **2b** to give a mixture of mono-DNPY-L-lysine, bis-DNPY-L-lysine and L-lysine. From L-arginine, on the other hand, α-amino-protected product was only obtained in 77% yield. The results can be explained by the suggestion that the latter's ω-amino function is a part of the amidine structure and is less nucleophilic to **2b** under the conditions used. In the former, however, its ω-amino function reacts easily with **2b** because its p*K*a value is 10.28.[6] Thus treatment of L-lysine with 2 equimolar amounts of **2b** gave bis-DNPY-L-lysine in good yield. In both cases, the reactions under nitrogen atmosphere led to better results.

All of the modified L-amino acids were yellow solids because of the DNPY-protection and could be purified by recrystallization from aqueous ethanol. The DNPY-protection caused the amino function to become tertiarized and the modified L-amino acids to become less hygroscopic. Thus the DNPY-L-amino acids could be handled more easily. Their structures were determined based upon the spectroscopic data, as follows.

The Spectroscopic Properties of the DNPY-L-amino Acids. The spectral characteristics of the DNPY-L-amino acids are summarized in Table 3. In the ^{1}H-NMR spectrum, the aromatic protons on the pyridone ring appear as a sharp singlet at *ca.* δ=9.1. In addition, the α-methine proton of the modified L-amino acid moiety is shifted downfield compared with that of the parent L-amino acid, due to the electron-withdrawing effect of the DNPY group. The infrared spectra of the DNPY-L-amino acids show the stretching vibration of the pyridone carbonyl at *ca.* 1670 cm^{-1} characteristically. Furthermore, the asymmetrical and the symmetrical stretching vibration of the nitro group are present at about 1510 and 1340 cm^{-1}, respectively.

In the ultraviolet spectrum, the absorption identified as the π-π* transition of the pyridone ring appears at *ca.* 340 nm with ε=*ca.* 4.5×10^3 characteristically.

The Optical Property of The DNPY-L-amino Acids. The values of the optical rotation have been used as a quantification of the modified amino acids, so those of the DNPY-L-amino acids determined in DMF are listed in Table 4.

The molar rotation of the DNPY-L-amino acids, $[M]_D$ are in general higher and in some cases very much higher than those of the parent L-amino acids. Furthermore, the values are comparable with or superior to those of well-known DNP-L-amino acids, of which the molar rotations vary from 2 to 100 times those of the parent amino acids.[7] The results may permit the identification and the optical characterization of a small quantity of an amino acid enantiomorph, so the DNPY group would be useful for amino-protection.

Removal of the DNPY Group. For the removal

of the DNPY group from the modified L-amino acid, a deblocking reagent must be more nucleophilic than the corresponding L-amino acid, of which the α-amino function generally has a p*K*a value of 9.1—9.8.[6] In addition, on the deblocking reaction, the liberated L-amino acid has to be easily separated from the DNPY-derivative formed. Thus hexylamine, whose p*K*a value was 10.64[8] was selected as a deblocking reagent. The removal reaction also proceeded in aqueous pyridine medium at room temperature for 0.5—2.5 h similar to the blocking process. The liberated L-amino acid was recovered in good yield after the same post-treatment as used for the blocking procedure. The results are shown in Table 5, along with the specific

rotation.

No change in specific rotation of the L-amino acid throughout the DNPY-modification was found, within an uncertainty of about four percent. The results indicate that racemization does not occur; this is an important advantage of the DNPY-modification.

Subsequently, the DNPY-modification is very utilizable for amino-protection of amino acids in following aspects.

(1) 3,5-Dinitro-1-(4-nitrophenyl)-4-pyridone, the protecting reagent is easily prepared from pyridine with a sequence of only three reactions.

(2) The blocking and deblocking processes proceed under very mild conditions, in aqueous pyridine and at room temperature with stirring.

(3) The tertiarization by DNPY-protection makes an amino acid less hygroscopic and the modified L-amino acid can be handled more easily.

(4) The DNPY-L-amino acids are identified very easily by the spectroscopic data of the characteristic DNPY group.

(5) No racemization takes place throughout the modification.

The DNPY-modification tertiarized the nitrogen of the α-amino group on every L-amino acids like phthaloyl-masking.

The latter, however, has not been applied to tryptophan.[9] Furthermore, its blocking-deblocking processes are more complicated and drastic than the DNPY-method. In these aspects, the DNPY-protecting is superior to the phthaloyl-modification.

Further work is in progress, and the data of esterification and of peptide synthesis with the DNPY-L-amino acid will be reported elsewhere.

Experimental

Measurements. All melting points were determined on a Yanako Melting Point Apparatus and are uncorrected. ^{1}H-NMR, IR and UV spectra were obtained on a HITACHI R-20B High Resolution Spectrometer, a HITACHI 225 Grating Infrared Spectrophotometer, and a HITACHI EPS-3 Recording Spectrophotometer, respectively. Optical rotation was determined on a Jasco DIP-180 automatic polarimeter.

*3,5-Dinitro-(4-nitrophenyl)-4-pyridone (**2b**).* Two and a half grams of sodium metal was dissolved in 100 ml of absolute ethanol and then 10 g of 4-pyridinol was added gradually. After 30 min, the mixture was evaporated and the residue was dissolved in 50 ml of DMF.

To the solution, a DMF (50 ml) solution of 18 g of 1-chloro-4-nitrobenzene was added dropwise and the resulting mixture was heated at 150 °C for 10 h. After cooling, the mixture was evaporated *in vacuo*, and water was added to the residue. The aqueous solution was acidified till pH 5. Yellow crystalline precipitates were collected and recrystallized from water to give 1-(4-nitrophenyl)-4-pyridone (**1b**) quantitatively, mp 191—192 °C; IR (as Nujol mulls): 1675 cm^{-1} (C=O), 1530, 1350 (NO_2); ^{1}H-NMR (DMSO-d_6): δ=6.29 (2H, d, J=8 Hz, β-protons of pyridone ring), 8.13 (2H, d, J=8 Hz, α-protons of pyridone ring), and 7.86 and 8.37 (4H, AA'BB', J=9 Hz, aromatic protons of 1,4-disubstituted benzene ring).

One gram of 1-(4-nitrophenyl)-4-pyridone (**1b**) was dissolved in 20 ml of concentrated sulfuric acid (d=1.84), and then 5.8g of fuming nitric acid (d=1.52) was added gradually with ice cooling. The mixture was poured over crushed ice. The yellow crystalline solid was collected and washed with cold water. The solid was recrystallized from aqueous acetic acid (*ca.* 50%) to give **2b** as yellow needles in 70% yield; mp 264—265 °C; IR (as Nujol mulls): 1680 cm^{-1} (C=O), 1600, 1540, 1500, 1345, 850; ^{1}H-NMR (DMSO-d_6): δ=9.36 (2H, sharp s, α-protons of pyridone ring), and 8.47 and 8.06 (4H, AA'BB', J=9 Hz, aromatic protons of 1,4-disubstituted benzene ring); Found: C, 42.84; H, 2.15; N, 18.39%. Calcd for $C_{11}H_6N_4O_7$: C, 43.15; H, 1.98; N, 18.30%.

The other 1-substituted 3,5-dinitro-4-pyridones, **2a** and **2c** were prepared in a way similar to that used for **2b**.

L-Amino acids were supplied by Wako Pure Chemical Industries, Ltd. The protecting reaction by **2b** was carried out as follows.

In a round-bottomed flask were placed **2b** (2.0 mmol), L-amino acid (2.2 mmol) and 60 ml of water–pyridine (3:1). The mixture was stirred with a magnetic stirrer at room temperature. (In the cases of L-Arg and L-Lys, under nitrogen stream.) After all reactants had dissolved, the solvent was removed below 30 °C *in vacuo*. A yellow residue was obtained, to which water was added. The resulting mixture was extracted with chloroform to remove 4-nitroaniline. The aqueous layer was acidified with dilute hydrochloric acid till pH 1—2 and then evaporated under reduced pressure to give a yellow crystalline solid. The crude product was collected and washed with water, and recrystallized from aqueous ethanol.

The purified DNPY-L-amino acid was dried over phosphorus pentaoxide at 100 °C for 5—6 h *in vacuo*.

Deblocking Reaction of The DNPY-L-amino Acid. In a round-bottomed flask were placed DNPY-L-Ala (1 mmol), hexylamine (1.1 mmol) and 15 ml of pyridine. The mixture was stirred at room temperature for 1.5 h. The solvent was evaporated *in vacuo* and water was added to the residue. The mixture was extracted with chloroform. The water layer was neutralized and condensed to give L-Ala in 92% yield. After dryness, L-Ala was identified by the spectroscopic data and its specific rotation. The organic layer was evaporated to give 1-hexyl-3,5-dinitro-4-pyridone[4] quantitatively, which was identified by comparing with an authentic sample. The other DNPY-L-amino acids were treated similarly to give the parent L-amino acids.

The authors are grateful to the Ministry of Education, Science and Culture for Grant-in-Aid for Scientific Research No. 56740212 for partial support of this work.

Liquid Crystal Materials with Sulfur Atoms Incorporated in the Principal Structure 1. New Liquid Crystal Compounds with 1,3-Dithiane Ring

Yuichiro HARAMOTO,* Atushi NOBE, and Hiroyoshi KAMOGAWA
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400
(Received December 19, 1983)

2-(*p*-Substituted phenyl)-5-alkyl-1,3-dithianes, new liquid crystals, were synthesized by the thioacetalization of the corresponding aldehydes and dithiols. These compounds have characteristic supercooling states, exhibit monotropic liquid crystal phases even in the case of long terminal alkyl substituents. The mesomorphic characteristics of these compounds were different from those of the corresponding 1,3-dioxanes, this must originate in the difference in the molecular width caused by the difference in the atomic volume between sulfur and oxygen.

In a previous communication,[1] 2,5-disubstituted 1,3-dithianes and 1,3-oxathianes as novel types of liquid crystal were reported. Since only 2,5-disubstituted 1,3-dioxanes are known as structurally related liquid crystal materials,[2] we wish to report here in more detail the synthesis and properties of these novel 1,3-dithiane type liquid crystals prepared by us.

Results and Discussion

2-(*p*-Substituted phenyl)-5-alkyl-1,3-dithianes were synthesized *via* the following route.

Compounds **2** and **3** were obtained in good yields. In step **3**→**4**, the reaction temperature was crucial. If the reaction temperature was 70—75 °C, the main product was a mono substituted bromide contrary to our purpose. Therefore, the reaction temperature must be kept at 95—100 °C. As compound **5** was susceptible to oxidation, step **4**→**5** required a nitrogen atomosphere. In **5**→**7**, both axial (cis) and equatorial (trans) isomers were produced differing at the C-5 position of the 1,3-dithiane ring. Repeated recrystallization was necessary to obtain the purified equatorial isomers. In the case of 2-(*p*-cyanophenyl)-5-alkyl-1,3-dithianes, the production ratios of the axial isomers were higher than those for other 1,3-dithianes, so that purification of the equatorial isomers by recrystallization was unsuccessful.

Centrifugal liquid chromatography and T.L.C. were used to purify these compounds. As the axial and equatorial isomers exhibited different patterns of ^{1}H-NMR, the existance of the axial isomer can be detected by the examination of proton signals at δ=2.3—3.5: proton signals of the equatorial isomer are located only in a narrow range of ^{1}H-NMR chemical shift (δ=2.6—2.9), whereas those of the axial isomer cover a wide range (δ=2.3—3.5). Synthesized compounds **7** are all colorless and odorless crystals or powders, which are soluble in common organic solvents. They all exhibited remarkable supercooled states (about 15—70 °C below the melting point). This property seems to originate from the steric structure of the 1,3-dithiane ring bearing bulky sulfur and its dominant role in the lateral interactions between molecules, since the corresponding 1,3-dioxane-type compounds mostly indicate enantiotropic liquid crystal behavior. (Table 1)

Mesomorphic ranges determined for compounds **7** are given in Table 1, together with those for the corresponding 1,3-dioxanes.

Measurement of the mesomorphic ranges and assignment of the mesophases were carried out by means of a differential scanning calorimeter (D.S.C.) and a micro melting point apparatus equipped with polarizers.

In the alkyl-chain length ranging from R=C_2 to C_4 (**7-1**—**7-17**), any mesomorphic phases could not be observed under the polarization microscope. These compounds only exhibited the supercooled state. In the alkyl chain length from R=C_5 to C_7 (**7-18**—**7-32**), monotropic nematic phases were observed under the

polarization microscope. In compounds of R=C_8 (**7-33—7-35**), monotropic smectic phases were observed.

In the case of 2-(*p*-alkoxyphenyl)-5-butyl-1,3-dithianes (**7-9—7-15**), increasing the carbon number of the *p*-alkoxyl group (R′) did not afford any mesophases, but in 2-(*p*-butoxyphenyl)-5-alkyl-1,3-dithianes, increasing the length of the alkyl group (R) brought about the appearance of mesophases (**7-20**, **-25**, **-30**, **-34**). Therefore, the effect of the chain length of the alkyl substituent (R) at the C-5 position of the 1,3-dithiane ring on the appearance of mesophases is more marked than that of the *p*-alkoxyl substituent (R′) of the 2-phenyl group.

While, for R=C_5 to C_8, all 1,3-dithiane compounds indicated monotropic liquid crystal behavior, the corresponding 1,3-dioxane compounds became enantiotropic liquid crystals.

This suggests that the increased width of the 1,3-dithiane molecule caused by the bulky sulfur atoms decreases attractive interactions between the molecules. This strong tendency to exhibit monotropic mesophases is a feature of this 2-(*p*-substituted phenyl)-5-alkyl-1,3-dithiane liquid crystal group.

Experimental

IR, ^{1}H-NMR, ^{13}C-NMR, and mass spectra were obtained with a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, a JNM FX 90Q FT-NMR spectrometer, and a Hitachi RMU-6 MG spectrometer, respectively. Elemental analyses were carried out with a Perkin-Elmer 250 instrument. Centrifugal liquid chromatography was made with a Hitachi CLC-5 apparatus. Mesomorphic phases and transition temperatures were determined more precisely and in detail than in the communication[1] by means of both a Mitamura Riken micro melting point apparatus equipped with polarizers and D.S.C., with satisfactory coincidences of the results. The rate of cooling was fixed to 1 °C/min.

Diethyl n-*Alkylmalonates (2).* A conventional procedure[3] was used for the syntheses of **2**. Yields ranged from 80 to 90%. Bp: 82—84 °C/3—5 mmHg† (R=C_2H_5), 90—92 °C/3—5 mmHg (R=C_3H_7), 94—97 °C/3—5 mmHg (R=C_4H_9), 110—113 °C/4—6 mmHg (R=C_5H_{11}), 113—115 °C/3—5 mmHg (R=C_6H_{13}), 120—123 °C/3—5 mmHg (C_7H_{15}), 124—128 °C/3—5 mmHg (R=H_8H_{17}). IR ($CHCl_3$) 2800—3000 (Alkyl), 1740 (C=O) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=0.7—2.1 (m, Alkyl), 3.25 (t, 1H, CH), 4.2 (q, 4H, $2CH_2$-O).

2-*Alkyl*-1,3-*propanediol (3).* $LiAlH_4$-reduction of 2 in ether at 35 °C for 18 h provided **3**. Yields ranged from 90 to 95%. IR ($CHCl_3$) 3600 (OH), 2800—3000 (Alkyl) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=0.6—2.1 (m, R-CH), 3.1—4.3 (m, 6H, $2CH_2$-OH).

2-*Alkyl*-1,3-*dibromopropane (4).* To a solution of 48% HBr (50g) and conc. H_2SO_4 (15 g) cooled in an ice bath were added successively compound **3** (0.1 mol) and conc. H_2SO_4 (25g). The solution was kept at 95—100 °C, for 18 h. The reaction mixture was then poured into ice water (200g). The mixture was stirred and extracted twice with ether (each 400 ml). The extract was washed with cold 10% aq $NaHCO_3$, and concentrated on a rotary evaporator at 30 °C. The residue was distilled *in vacuo* to afford transparent liquid in a 30—50% yield. Bp: 60—65 °C/1—2 mmHg (R=C_2H_5), 65—69 °C/1—2 mmHg (R=C_3H_7), 73—74 °C/1—2 mmHg (R=C_4H_9), 76—79 °C/1—2 mmHg (R=C_5H_{11}), 91—92 °C/2—3 mmHg (R=C_6H_{13}), 97—100 °C/1—2 mmHg (R=C_7H_{15}), 105—108 °C/1—2 mmHg (R=C_8H_{17}). IR ($CHCl_3$) 2800—3000 (Alkyl) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=0.7—2.1 (m, R-CH), 3.45—3.75 (m, 4H, $2CH_2$-Br).

2-Alkyl-1,3-propanedithiol (5). To a solution of thiourea (0.064 mol, 4.9 g) in triethylene glycol (8 ml) kept at 75 °C was added compound **4** (0.016 mol) in a nitrogen atmosphere, followed by stirring at 75 °C for 18 h.

Tetraethylenepentamine (0.016 mol, 3.03 g) was then added, and the mixture was stirred at 75 °C for 2 h under a nitrogen atmosphere. The reaction mixture was fractionated *in vacuo* to afford a transparent oily product in a 70—80% yields. Bp: 55—57 °C/1—2 mmHg (R=C_2H_5), 64—66 °C/1—2 mmHg (R=C_3H_7), 82—85 °C/1—2 mmHg (C_4H_9), 95—98 °C/1—2 mmHg (R=C_5H_{11}), 108—110 °C/1—2 mmHg (R=C_6H_{13}), 109—113 °C/1 mmHg (R=C_7H_{15}, 116—121 °C/1—2 mmHg (R=C_8H_{17}). IR ($CHCl_3$) 2800—3000 (Alkyl) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=0.7—2.1 (m, R-CH, 2SH), 2.5—2.9 (m, 4H, $2CH_2$-S).

*2-(*p*-Substituted phenyl)-5-alkyl-1,3-dithiane (7).* To a solution of compound **5** (0.004 mol) and *p*-substituted benzaldehyde **6** (0.004 mol) in anhyd. $CHCl_3$ (200 ml) cooled in an ice bath were added $BF_3 \cdot (C_2H_5)_2O$ (0.5 g) and molecular sieves (3A, 1/5; 3g). The mixture was stirred at 0—5 °C for 8 h and then at 20—25 °C for 18 h. The solution was washed with 10% $NaHCO_3$(400 ml), then with water (400 ml), dried over anhyd. Na_2SO_4, and evaporated *in vacuo* at 40 °C. The crude product was purified by recrystallizations from hexane-ether (5:1, v/v), then if necessary, by centrifugal liquid chromatography to separate the trans isomers.

*2-(*p*-Alkoxyphenyl)-5-Alkyl-1,3-dithianes.* IR ($CHCl_3$) 2800—3000 (Alkyl), 1600 (Ar), 1240 (Ether) cm^{-1}. ^{1}H-NMR ($CDCl_3$) 7-1, 7-5, 7-9: δ=0.7—2.1 (m, R-CH), 2.6—2.9 (m, 4H, CH_2-S), 3.8 (s, 3H, OCH_3), 5.05 (s, 1H, $\overset{S}{S}$>CH-), 6.7—7.5 (q, 4H, ArH); Others: δ=0.7—2.1 (m, R-CH, O-CH_2-C_n-$\underline{H}_{2n+1}$), 2.6—2.9 (m, 4H, $2CH_2$-S), 3.9 (t, 2H, OCH_2, 5.05 (s, 1H, $\overset{S}{S}$>CH-), 6.7—7.6 (q, 4H, ArH).

*[2-(*p*-Methoxyphenyl)-5-ethyl-1,3-dithiane (7-1)]*: Yield, 49%.

Restricted Rotation Involving the Tetrahedral Carbon. LIV. The Effects of 1-Substituents on the Barriers to Rotation in 9-(2-Methyl-1-naphthyl)fluorenes[1,2]

Shigeru MURATA, Teruo MORI, and Michinori ŌKI*
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received December 20, 1983)

A series of 1-substituted 9-(2-methyl-1-naphthyl)fluorenes, where the substituent is fluoro, chloro, bromo, or methyl, has been prepared and barriers to rotation in these compounds have been examined to investigate the substituent effects. The barrier is enhanced generally, if we go from the 1-substituent of a small size to that of a large size with an exception of the fluorine case: the 1-fluoro compound exhibits a lower barrier to rotation than the unsubstituted compound by *ca.* 0.5 kcal mol^{-1}. X-Ray crystallographic analysis suggests that, in the fluoro compound, the C_9(fluorene)-to-C_1(naphthalene) bond is abnormally long, although other compounds possess bonds of normal lengths. The low barrier to rotation in the fluoro compound relative to the unsubstituted is thus attributed to the raise of the ground state energy and insufficient raise of the transition state energy in the former compound.

Although various stable rotamers of 9-arylfluorenes are isolated at room temperature, their barriers to rotation are usually less than 30 kcal mol^{-1} (1 cal=4.184 J).[3,4] The only exceptions to these are the reports by Ford *et al.*[5] and by Kajigaeshi and associates.[6] The former authors pointed out that the barrier to rotation in 1-methyl-9-(2-methyl-1-naphthyl)-fluorene (**2b**) was 33.3±0.3 kcal/mol at 166 °C, and the latters that of 32.8 kcal mol^{-1} at 170 °C in 1,2-benzoannelated 9-(2-methyl-1-naphthyl)fluorene. These reports certainly suggest that the transition state for rotation about the C_9(fluorene)-to-C_1(naphthalene) bond is raised relative to the ground state because the substituent in the 1-position of the fluorene ring interacts strongly with the 2-methyl-1-naphthyl group in the transition state for rotation.

In this context, it will be of interest to see the effect of the 1-substituent in the fluorene ring on the barrier to rotation. At the outset, we prepared 1-fluoro-9-(1-naphthyl)fluorene and surprisingly found that the introduction of the fluoro substituent into the 1-position of the fluorene moiety reduced the barrier to rotation. This finding prompted us to reexamine the barriers to rotation in the parent compound, 9-(1-naphthyl)fluorene. The results shown in Table 1 clearly indicate that the barriers reported by others[7,8] were reproducible and confirm that the introduction of a fluorine atom to the 1-position of fluorene reduces the barrier height in the system of 9-(1-naphthyl)-fluorene.

In order to find generality of the trend in the barrier heights, we examined the barrier to rotation in 1-fluoro-9-(2-methyl-1-naphthyl)fluorene (**2c**). The barrier to rotation in **2c** was again lower than that reported for the parent compound.[7] Thus the reduction of the barrier height on introduction of a fluorine atom to the 1-position of fluorene seems to be a general practice.

Then it became of interest to examine the barriers in a series of 1-substituted 9-(2-methyl-1-naphthyl)fluorenes (**2**): what is the general tendency in affecting the barrier heights due to the presence of a 1-substituent in these compounds? This paper reports the results of the investigation and discusses the origin of the anomalous barrier heights in the fluoro compounds from the X-ray crystallographic data of **2c** and two related compounds.

The syntheses of the compounds in question were straightforward. 1-Substituted 9-fluorenones (**1**) were treated with 2-methyl-1-naphthyllithium or the corresponding Grignard reagent and the products were reduced to the desired compound (**2**). The rotational isomers of **2** were separated by chromatography. The stereochemistry of each rotamer was assigned by considering the chemical shifts of the methyl protons which is

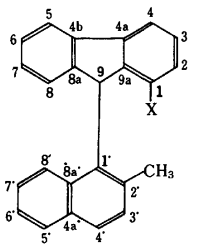
attached to the naphthalene nucleus in ^{1}H NMR spectra as are customarily done in other cases.

The rates of rotation in **2** together with equilibrium constants at various temperatures are summarized in Table 2 and activation parameters with relative rates of rotation in Table 3.

The equilibrium constants are very close to unity when **2** is a hydrocarbon irrespective of the substituent (H or methyl) in the 1-position of the fluorene ring. In contrast, if the 1-substituent is a halogen, a rotamer in which the 2-methyl group (in naphthalene) is over the fluorene ring is disfavored to some extent. This tendency is the largest when X is fluorine and equilibrium constants become closer to unity as the halogens become larger. The reason for this phenomenon is not well understood at the moment but could be a repulsive interaction between the 2-methyl (in naphthalene) and the fluorene groups and consequently the large deformation, as discussed in the crystal structure section.

The barriers to rotation about the C_9(fluorene)-to-C_1(naphthalene) bond indicate that they are enhanced as the bulkiness of the 1-substituent in the fluorene ring increases, except the case of fluorine. Therefore, the series of X=H, Cl, Br, and CH_3 is quite normal in the sense that the bulkier 1-substituent in the fluorene ring affects more the transition state of rotation than the ground state.

To shed light to the reason for the anomaly in the fluorine compound (**2c**), X-ray crystallography of *ac**(*S**)-**2c**[9] was carried out. The X-ray structures of **2a** and **2b** were also examined for comparison. Unfortunately, however, only *sc**(*S**) form of **2b** gave suitable crystals for the X-ray investigation, whereas *sp*-**2a** and *ac**(*S**)-**2c**, in which the 2-methyl groups are over the fluorene moiety, gave suitable crystals. Therefore, we may have to discuss with some reservations if we really compare the structures. The results are given in Tables 4 through 7. The nonhydrogen atoms are numbered or designated as shown below.



The first feature in the structures which we wish to discuss is the dihedral angles made by the naphthyl group and the C_9-H bond. Since we neglect the positions of hydrogens, the dihedral angles are given by the C-C-C planes in Table 6. The most apparent feature is that the naphthyl group does not bisect the C(8a)-C(9)-C(9a) angle, thus does not eclipse the C_9-H. This is interesting because, in solution chemistry, the eclipsing conformation about a C_{ar}-C_{aliph} bond is supposed to be often the energy minimum due to the fact that two equivalent groups in the geminal position give equivalent ^{1}H NMR chemical shifts when the internal rotation is frozen.[10] Although we have to discuss the difference carefully, because the conformation in the solid state is not nec-

Table 2. Rate constants of rotation and equilibrium constants in 1-substituted 9-(2-methyl-1-naphthyl)-fluorenes (**2**) in *o*-dichlorobenzene

1-substituent	Temp/°C	k_1/s^{-1}	K[a]
H	69.6	1.48×10^{-6}	1.14±0.02
	81.3	5.47×10^{-6}

essarily retained in solution, it is possible that, by ^{1}H NMR, the rapid exchange $+ap \rightleftharpoons -ap$ *or* $+sp \rightleftharpoons -sp$ cannot be detected.[11] Another common feature of interest in the structures is concerned with C(9) and its vicinity: the C(8a)-C(9) and C(9)-C(9a) distances are very long and the C(8a)-C(9)-C(9a) bond angle is very small relative to those in fluorene.[12] These must be the results of steric strain which is eased by lengthening the bonds and by sharpening the angle.

The conformations about the C(9)-C(1') bond in *ac**(*S**)-**2c** are interesting. The methyl group which is over the fluorene ring is close to C(1), which bears the 1-substituent, rather than to C(8a). The cause for this phenomenon is not clear at the moment.

The molecular structures of *sp*-**2a** and *sc**(*S**)-**2b** are quite normal, except the atomic positions close to C(9), as pointed out above. The bond distances and bond angles are very close to those reported for fluorene[12] and 1,5-dimethylnaphthalene[13] except some points discussed above and below. The abnormality is caused because of the presence of the 2'-methyl group over the fluorene ring and also because of the fact that the naphthyl group does not eclipse the C(9)-H bond. The steric congestion in *sp*-**2a** is relieved by lengthening the C(9)-C(9a) bond which is close to the 2'-methyl group. Thus the C(9)-C(9a) bond in *sp*-**2a** is longer than the C(8a)-C(9) (Table 5). This explanation is partially supported by the fact that the lengths of C(8a)-C(9) and C(9)-C(9a) bonds in *sc**(*S**)-**2b** are close to each other. Due to the small size of the π-system relative to the methyl, the congestion in *sc**(*S**)-**2b** must be small.

Table 7. Some distances (Å) between nonbonded atoms in proximity of steric crowding

Atom 1	Atom 2	*sp*-**2a**	*sc**(*S**)-**2b**	*ac**(*S**)-**2c**

CH_3[a]	C(8)	4.108(21)	4.026(5)	4.188(21)

a) Atom 1 is C(8a') in the case of *sc**(*S**)-**2b**.

Some nonbonded distances between atoms in the congested sites are compiled in Table 7. The X-C(1') distances in *sc**(*S**)-**2b** and *ac**(*S**)-**2c** are shorter than or very close to the sum of the van der Waals radii of the atom and/or the groups concerned. This strain seems to be distributed widely over the molecules. The small difference in distances CH_3-C(8a) and CH_3-C(9a) together with the same trend in the dihedral angle in *sc**(*S**)-**2b** relative to others is a reflection of the fact that a π-system is smaller in size than a methyl. As far as these nonbonded distances concern, *sp*-**2a** and *ac**(*S**)-**2c** take similar structures.

The structure of the fluoro compound, *ac**(*S**)-**2c**, shows some interesting features. The bond distance of C(1)-C(9a) is abnormally short, compared with those in other compounds, and that of C(9)-C(1') abnormally long, although the latter involves a large error. It is tempting to consider that, due to the electronic effect of the fluorine substituent, the bond C(1)-C(9a) is shortened and this effect also restricts the lengthening of the C(9)-C(9a) bond: the latter bond is very long in *sp*-**2a** because of the steric effect but is almost normal in *ac**(*S**)-**2c**. The strain caused by these bond distances seems to be released by lengthening the C(9)-C(1') bond together with widening the C(9)-C(1')-C(2') and C(1')-C(2')-CH_3 angles and contracting the C(9)-C(1')-C(8a') and C(3')-C(2')-CH_3 angles. We therefore conclude that the relatively low barrier to rotation in **2c** is caused by the strain in the ground state, whereas the transition state energy is not raised to a great extent.

Experimental

9-(2-Methyl-1-naphthyl)fluorene (2a). Rotamers were obtained as reported in a previous paper.[14]

1-Fluoro-9-(2-methyl-1-naphthyl)fluorene (2c). To a stirred solution of 2-methyl-1-naphthylmagnesium bromide, prepared from 1.3 g (5.9 mmol) of 1-bromo-2-methylnaphthalene, 0.14 g (5.8 mmol) of magnesium, and 9 mL of dry tetrahydrofuran under a nitrogen atmosphere, 0.97 g (4.9 mmol) of 1-fluoro-9-fluorenone (**1**:X=F)[15] was added at room temperature. The mixture was heated under reflux for 1.5 h with stirring, cooled and decomposed with

Table 6. Dihedral angles (degree) involving the naphthyl group in **2**

Plane 1	Plane 2	*sp*-**2a**	*sc**(*S**)-**2b**	*ac**(*S**)-**2c**
C(2')-C(1')-C(9)	C(1')-C(9)-C(8a)	71.7	67.7	71.3

18 mL of 25% aqueous ammonium chloride. The organic layer was separated and the aqueous layer was extracted with ether. The combined organic layer was washed with water and dried over magnesium sulfate. After evaporation of the solvent, the residue was submitted to chromatography on silica gel (3:1 hexane-benzene eluent). The product was dissolved in 35 mL of acetic acid and heated with 8.7 mL of 57% hydriodic acid for 3 h at 60 °C. The mixture was poured into a cold solution of sodium hydrogensulfite. The organic product was extracted with dichloromethane. The extract was washed with aqueous sodium hydrogencarbonate and dried over magnesium sulfate. After evaporation of the solvent, the product was separated by silica gel chromatography (hexane eluent). The *ac**(*S**) form was eluted first and then *sc**(*R**) form followed. The combined yield of the both forms was 0.91 g (57% based on the amount of 1-fluoro-9-fluorenone).

*ac**(*S**), mp 159—160 °C. Found: C, 89.02; H, 5.16%. Calcd for $C_{24}H_{17}F$: C, 88.86; H, 5.28%. ^{1}H NMR ($CDCl_3$) δ =1.38 (3H, s), 6.27 (1H, s), 6.9—7.9 (12H, m), 8.53 (1H, d, J=8 Hz). ^{19}F NMR ($CDCl_3$, ppm from C_6F_6): 44.2 (dd, J=9.3 and 4.5 Hz).

*sc**(*R**), mp 140—141 °C. Found: C, 89.15; H, 5.07%. Calcd for $C_{24}H_{17}F$: C, 88.86; H, 5.28%. ^{1}H NMR ($CDCl_3$), δ=2.86 (3H, s), 5.86 (1H, s), 6.44 (1H, d, J=9 Hz), 6.8—8.0 (12H, m). ^{19}F NMR ($CDCl_3$, ppm from C_6F_6): 42.7 (dd, J=9.3 and 4.5 Hz).

*1-Chloro-9-(2-methyl-1-naphthyl)fluorene (**2d**).* A solution of 2-methyl-1-naphthyllithium was prepared from 3.71 g (16.8 mmol) of 1-bromo-2-methylnaphthalene and 0.29 g of lithium in 16.8 mL of ether by stirring the mixture for 1 h at room temperature. To a 7.3 mL portion of the solution was added 1.25 g (5.8 mmol) of 1-chloro-9-fluorenone (**1**:X=Cl)[16] and the mixture was heated under reflux for 1 h with stirring. After the mixture was coold, it was treated similarly as above. The product was reduced with hydriodic acid by stirring a solution prepared as above for 15 h at room temperature. The total yield of **2d** was 57% based on the amount of 1-chloro-9-fluorenone used.

*ac**(*S**), mp 197—198 °C. Found: C, 84.29; H, 4.79; Cl, 10.49%. Calcd for $C_{24}H_{17}Cl$: C, 84.57; H, 5.03; Cl, 10.40%. ^{1}H NMR ($CDCl_3$) δ=1.35 (3H, s), 6.22 (1H, s), 7.0—7.9 (12H, m), 8.55 (1H, d, J=8 Hz).

*sc**(*R**), mp 186—187 °C. Found: C, 84.82; H, 4.79; Cl, 10.29%. Calcd for $C_{24}H_{17}Cl$: C, 84.57; H, 5.03; Cl, 10.40%. ^{1}H NMR ($CDCl_3$): δ=2.91 (3H, s), 5.80 (1H, s), 6.42 (1H, d, J=9 Hz), 6.8—8.0 (12H, m).

*1-Bromo-9-(2-methyl-1-naphthyl)fluorene (**2e**)* was prepared similarly as described in the preparation of the 1-chloro compound (**2d**). The yield was 32% based on the amount of 1-bromo-9-fluorenone (**1**:X=Br).[16]

*ac**(*S**), mp 192—193 °C. Found: C, 74.96; H, 4.39; Br, 21.06%. Calcd for $C_{24}H_{17}Br$: C, 74.82; H, 4.45; Br, 20.74%. ^{1}H NMR ($CDCl_3$) δ=1.34 (3H, s), 6.16 (1H, s), 6.9—8.0 (12H, m), 8.57 (1H, d, J=9 Hz).

*sc**(*R**), mp 189—190 °C. Found: C, 74.88; H, 4.36; Br, 21.02%. Calcd for $C_{24}H_{17}Br$: C, 74.82; H, 4.45; Br, 20.74%. ^{1}H NMR ($CDCl_3$) δ=2.74 (3H, s), 5.74 (1H, s), 6.42 (1H, d, J=9 Hz), 6.8—8.0 (12H, m).

*1-Methyl-9-(2-methyl-1-naphthyl)fluorene (**2b**)* rotamers were already prepared by Ford *et al.*[5] with a different method from that described above. These were also prepared as above in 56% yield based on 1-methyl-9-fluorenone (**1**:X=CH_3)[5,17] used.

*ac**(*R**), mp 152—153 °C (lit,[5] 152—153.5 °C). Found: C, 93.63; H, 6.03%. Calcd for $C_{25}H_{20}$: C, 93.71; H, 6.29%. ^{1}H NMR ($CDCl_3$) δ=1.28 (3H, s), 1.72 (3H, s), 6.12 (1H, s), 6.9—7.9 (12H, m), 8.58 (1H, d, J=9 Hz).

*sc**(*S**), mp 195—196 °C (lit,[5] 189—191 °C). Found: C, 93.77; H, 6.11%. Calcd for $C_{25}H_{20}$: C, 93.71; H, 6.29%. ^{1}H NMR ($CDCl_3$) δ=1.71 (3H, s), 2.84 (3H, s), 5.70 (1H, s), 6.47 (1H, d, J=8 Hz), 6.8—8.0 (12H, m).

1-Fluoro-9-(1-naphthyl)fluorene, mp 109.0—110.5 °C, was prepared similarly as described in the preparation of **2c**. Found: C, 89.27; H, 4.71%. Calcd for $C_{23}H_{15}F$: C, 89.01; H, 4.87%. ^{1}H NMR ($CDCl_3$) δ=5.40 (2/3H, s), 6.06 (1/3H, s), 6.5—7.9 (13 1/3H, m), 8.43 (2/3H, br d).

9-(1-Naphthyl)fluorene was prepared according to the published method.[7]

Kinetic Measurement of Internal Rotation by Dynamic NMR. A sample was dissolved in hexachlorobutadiene to make up a *ca.* 5% solution. The temperature was read by the chemical shift differences of the ethylene glycol protons. The free energy of activation was calculated by the graphical method.[18]

Kinetic Measurement of Internal Rotation by Classical Method. Each pure rotamer (25—30 mg), *sp*-**2a** and other corresponding forms, was dissolved in 0.45 mL of *o*-dichlorobenzene. The solution was placed in an NMR sample tube and oxygen was purged from the solution by bubbling dry nitrogen gas for some time. The tube was sealed and was heated by immersing the tube in an appropriate boiling-solvent bath. The ratio of rotational isomers was determined by ^{1}H NMR spectroscopy at appropriate intervals and the equilibrium constant was obtained by heating the solution for a long enough time. The rate constants were calculated by assuming reversible first order kinetics. Activation parameters were obtained by putting these rate constants into the Eyring equation.

Spectral Measurement. ^{1}H NMR spectra were recorded either on a Hitachi R-20B, which operates at 60 MHz, or a Varian EM-390 spectrometer which operates at 90 MHz. ^{19}F NMR spectra were obtained with the Varian EM-390 spectrometer operating at 84.67 MHz.

X-Ray Crystallography. Crystals of *sp*-9-(2-methyl-1-naphthyl)fluorene (**2a**), *ac**(*S**)-1-fluoro-9-(2-methyl-1-naphthyl)fluorene (**2c**), and *sc**(*S**)-1-methyl-9-(2-methyl-1-naphthyl)fluorene (**2b**) were grown from hexane-benzene. The suitable crystals were mounted on a Rigaku AFC-M diffractometer and the intensity data of $|F_o| \geq 3\sigma|F_o|$ were collected using Cu $K\alpha$ radiation of 1.54180 Å wave length within the range of $2\theta \leq 57°$. Total reflections used for the analysis were 2011, 2335, and 2352 for *sp*-**2a**, *sc**(*S**)-**2b**, and *ac**(*S**)-**2c**, respectively.

The crystal data were as follows. *sp*-9-(2-Methyl-1-naphthyl)fluorene: $C_{24}H_{18}$, F. W. 306.41, monoclinic, space group $P2_1/N$, a=9.264(2) Å, b=8.621(2) Å, c=21.083(7) Å, β=91.53(2)°, z=4, D_C=1.21 g/cm^3.

*ac**(*S**)-1-Fluoro-9-(2-methyl-1-naphthyl)fluorene: $C_{24}H_{17}F$, F. W.=324.40, monoclinic, space group $P2_1/C$, a=9.438(4) Å, b=15.514(6) Å, c=12.032(6) Å, β=107.79(2)°, z=4, D_C= 1.28 g/cm^3.

*sc**(*S**)-1-Methyl-9-(2-methyl-1-naphthyl)fluorene: $C_{25}H_{20}$, F. W. 320.41, primitive orthorhombic, space group Pbcn, a=18.164(4) Å, b=7.414(2) Å, c=26.431(6) Å, z=8, D_C= 1.20 g/cm^3.

The structures were solved by the direct method. All the positional and thermal parameters were refined by the least-squares method. The final R values for *sp*-**2a**, *sc**(*S**)-**2b**, and *ac**(*S**)-**2c** were 7.6, 6.5, and 7.0%, respectively.

We wish to thank Rigaku Denki Company for the rent of an AFC-M machine which made this study possible. We also thank Mr. Toshihiko Hori and Miss Yukiko Takagi of the same company for the technical assistance.

11) Ōki briefly commented that a ^{1}H NMR signal due to the methylene protons in a 9-(2-bromomethyl-6-methylphenyl)fluorene rotamer became broad at low temperatures.[3] This must mean that the eclipsing form of the C_9–H with the 2-bromomethyl-6-methylphenyl group is not the energy minimum but there are two potential minima within the *sp* or the *ap* zone. The ^{1}H NMR spectra of these compounds in 1:1 CF_2ClH–$CFCl_2H$ are now reexamined at 250 MHz. The *sp* form showed broadening of the methylene proton signal at 120 K whereas the *ap* form showed no significant broadening at the temperature. The results at least support the assumption that the potential is of the double-minimum type. We wish to thank Professor C. H. Bushweller, The University of Vermont, for the measurement of the ^{1}H NMR spectra at 250 MHz at low temperatures.

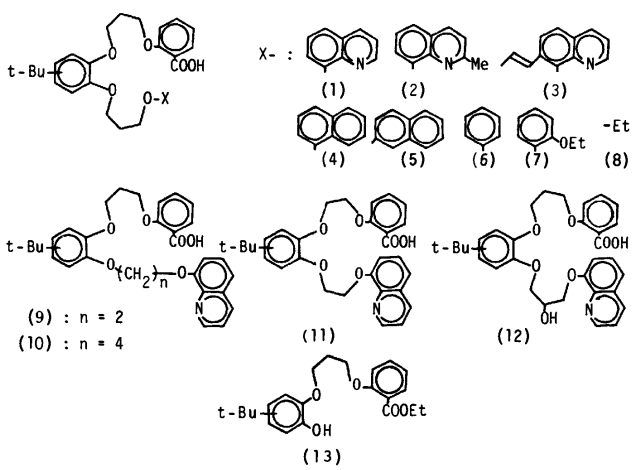
The Synthesis of Li^+-selective Polyether Carriers and Thier Behavior in Cation Transport through Liquid Membranes[1)]

Kazuhisa HIRATANI,* Kazuhiro TAGUCHI, Hideki SUGIHARA, and Kokoro IIO
Industrial Products Research Institute, Higashi 1-chome, Yatabe-machi, Tsukuba-gun, Ibaraki 305
(Received November 18, 1983)

Noncyclic polyethers exhibiting lithium ion selectivity have been synthesized. Their competitive alkali-metal-ion transport through liquid membranes has been investigated, and the influence of their structures on the rates and selectivities of cation transport has been demonstrated. It has been found that the introduction of the oxytrimethylene chain on the polyethers is significant for the appearance of a high selectivity for the lithium ion, and also that the kind of terminal group might play an important role either in determining the rates of cation transport or the selectivity for the lithium ion. The introduction of a methyl group at the 2-position on the quinolyl terminal group of the polyether increased largely the selectivity for the lithium ion compared with that of the polyether having an unsubstituted quinolyl group. The cause of this was discussed on the basis of the NMR spectroscopic method and the CPK-model building.

The lithium ion has the smallest naked ionic radius (0.66 Å) among the alkali metal ions, whereas it has the largest hydrated one (3.40 Å) and also the strongest hydrated energy (ΔH=124 kcal/mol) among them.[2)] Therefore, it is not easy to design a compound with lithium ion-selectivity, and there have been few reports about available compounds which exhibit lithium ion-selective transport through liquid membranes or which extract the lithium ion into organic solvents, compared with the cases of other alkali metal ions.[3)] In addition, the lithium is an important cation practically, and its selective separation and concentration from a diluted aqueous solution will become of significance in the future. For example, there is a possibility that large amounts of lithium are required for the production of tritium, which is used as a reactant in the nuclear-fusion reaction. Thus, the synthesis of lithium ion-selective compounds is a very interesting target.

In a previous paper, one of the present authors has reported that 1-[3-(*o*-carboxyphenoxy)propoxy]-2-[3-(8-quinolyloxy)propoxy]-4(or 5)-*t*-butylbenzene (**1**) can transport the lithium ion selectively through liquid membranes and against its concentration gradient.[4)] So far, there has been no report of a noncyclic polyether carrier exhibiting uphill transport for the lithium ion selectively.[5)] Though some cyclic polyethers, *e.g.*, 12-crown-4 and its derivatives, and cryptand[211], can take up the lithium ion selectively, they do not always transport it selectively and efficiently.[6)]



In this paper, we wish to report that analogues of **1**, **2**—**12**, were newly synthesized in order to investigate the effects of their structural modification on the transport rates and selectivities. In the cation-transport experiments, the competitive cation transport of alkali metal ions from an alkaline aqueous solution (source phase) through a chloroform phase to an acidic aqueous solution (receiving phase) by these noncyclic polyethers was examined.

Results and Discussion

Dependence of the Cocentration of Cations in Aqueous Phases on the Li^+-Selectivity of 1. The competitive ion transport of alkali metal ions (Li^+, Na^+, and K^+) by **1** against their concentration gradient was examined by changing the concentration of cations in both aqueous solutions under a constant concentration (1.5×10^{-4} mol in 30 ml of chloroform) of polyether (**1**) and a constant pH gradient. The results are shown in Figs. 1,2, and 3. Table 1 shows the amounts of cation transported after 2 d and the selectivities. Under these conditions, no cation could be transported without a carrier. In the membrane system (0.15 M† LiOH+0.15 M NaOH+0.15 M KOH+0.175 MH_2SO_4, 15 ml/1.5×10^{-4} mol of **1**, 30 ml of chloroform/0.15 M LiOH+0.15 M NaOH+0.15 M KOH+0.275 M H_2SO_4, 15 ml), which initially contained a sufficient cation concentration in comparison with the magnitude of the pH gradient between the two aqueous phases, the selectivity for the lithium ion was much higher than in the system which had an initial concentration of 0.1 M for each cation. That is, the transport ratios, Li/Na and Li/K, reach 6.6 and >10 respectively in this system, and the amount of the lithium ion transported reaches 0.795 mmol after 2 d. On the other hand, when the initial concentration of each cation was 0.033 M and the magnitude of the initial pH gradient was the same as above, 82% of the lithium ion in the source phase was trans-

† 1 M=1 mol dm^{-3}.

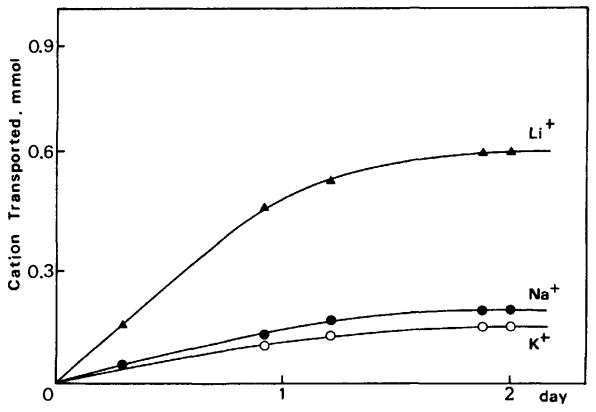


Fig. 1. Cation transport by (**1**) for lithium, sodium, and potassium ion species existing together. Initial transport conditions (25 °C) ; Source phase : 15 ml of 0.1M LiOH+0.1 M NaOH+0.1 M KOH+0.1 M H_2SO_4 aqueous solution, Chloroform membrane : 30 ml of chloroform containing 1.5×10^{-4} mole of (**1**), Receiving phase : 15 ml of 0.1 M LiOH+0.1 M NaOH+0.1 M KOH+0.2 M H_2SO_4 aqueous solution.

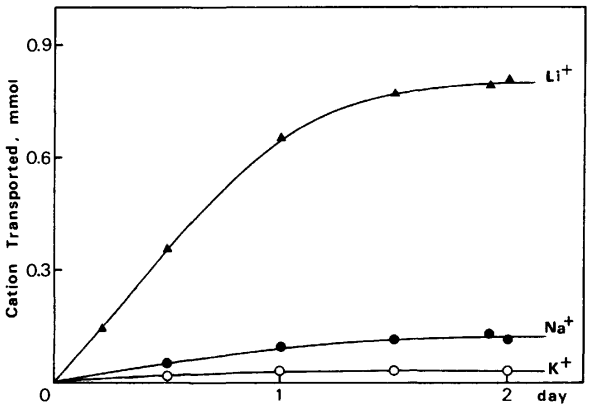

Fig. 2. Cation transport by (**1**) for lithium, sodium, and potassium ion species existing together. Initial transport conditions (25 °C); Sourcephase: 15 ml of 0.15 M LiOH+0.15 M NaOH+0.15 M KOH+0.175 M H_2SO_4 aqueous solution, Chloroform membrane: 30 ml of chloroform containing 1.5×10^{-4} mole of (**1**), Receiving phase: 15 ml of 0.15 M LiOH+0.15 M NaOH+0.15 M KOH+0.275 M H_2SO_4 aqueous solution.

ported by **1** after 2 d, although the selectivity (Li/Na) became fairly low. In this system, both sodium and potassium ions were transported gradually with the time, as is shown in Fig. 3, making a sigmoidal shape. This could be attributed to the excessive pH gradient, which is not exhausted by the transport of the lithium ion, between the two aqueous phases. Interestingly, this trend is in line with the results observed in the case of the potassium ion-selective polyether, 1-[2-[2-(8-quinolyloxy)-ethoxy]ethoxy]-2[2-[2-(*o*-carboxyphenoxy)ethoxy]ethoxy]-4(or 5)-*t*-butylbenzene, as has been reported recently.[7] These results mean that the selectivity for a cation can be changed greatly by changing the con-

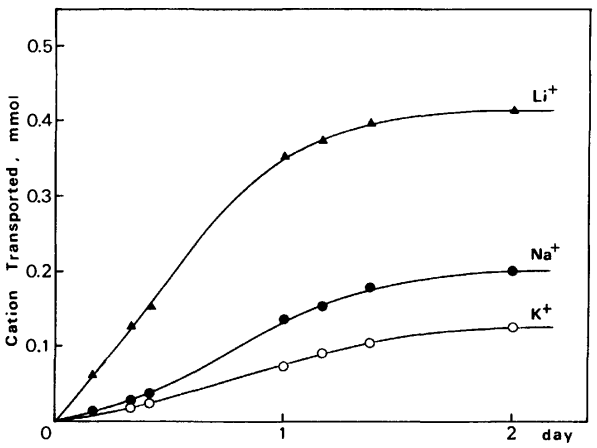

Fig. 3. Cation transport by (**1**) lithium, sodium, and potassium ion species existing together. Initial transport conditions (25 °C); Source phase: 15 ml of 0.033 M LiOH+0.033 M NaOH+0.033 M KOH aqueous solution, Chloroform membrane : 30 ml of chloroform containing 1.5×10^{-4} mole of (**1**), Receiving phase : 15 ml of 0.033 M LiOH+0.033 M NaOH+0.033 M KOH+0.1 M H_2SO_4 aqueous solution.

Table 1. Influence of initial cation concentration on the amounts of cation transported by (**1**)

Initial conc. of each cation*	Cation transported after 2 d (mmol)			Selectivity	
	Li	Na	K	Li/Na	Li/K
0.033 M	0.410	0.205	0.125	2.0	3.3
0.10 M	0.615	0.180	0.120	3.4	5.1
0.15 M	0.795	0.120	0.030	6.6	$\gg$10

* Other conditions: see the footnotes in Figures 1,2, and 3 respectively.

centration of cations in the aqueous phases under a constant pH gradient. Therefore, it is suggested that the lithium ion can be separated and concentrated with a high selectivity from other alkali ions against their concentration gradient when adequate transport conditions are chosen in the system.

Effects of the Kind of Oxyalkylene Chain on the Selectivity. As has been described above, we have found that the noncyclic polyether (**1**), with both *o*-carboxyphenyl and 8-quinolyl terminal groups, exhibits the ability of the selective uphill transport of the lithium ion. Then, what structure of the noncyclic polyethers which exhibit lithium ion-selectivity is essentially required? In order to clarify this question, firstly, the effects of the kind of oxyalkylene chain on the selectivity were examined.

Some noncyclic polyethers which contain oxyethylene, oxytrimethylene, and/or oxytetramethylene chains were prepared and used as carriers in the cation transport through liquid membranes. The results are shown in Table 2. In Table 2, polyether (**1**) which contains two oxytrimethylene chains, exhibits the best selectivity for the lithium ion between them. The selectivity is lowered when the oxyalkylene chain

TABLE 2. INFLUENCE OF KINDS OF ALKYLENE CHAIN ON THE CATION-SELECTIVE TRANSPORT

Polyether	Cations transported after 2 d (%)				Selectivity		
	Li	Na	K	Total	Li/Na	Li/K	Na/K
(**1**)	41	12	8	61	3.4	5.1	1.5
(**9**)	34	17	11	62	2.0	3.1	1.5
(**10**)	36	16	11	63	2.2	3.3	1.5
(**11**)	28	21	13	62	1.3	2.1	1.6

Initial transport conditions (25 °C):

(Source phase)	(Chloroform membrane)	(Receiving phase)
0.1 M LiOH 0.1 M NaOH 0.1 M KOH 0.1 M H_2SO_4 15 ml	Polyether 1.5×10^{-4} mol $CHCl_3$ 30 ml	0.1 M LiOH 0.1 M NaOH 0.1 M KOH 0.2 M H_2SO_4 15 ml

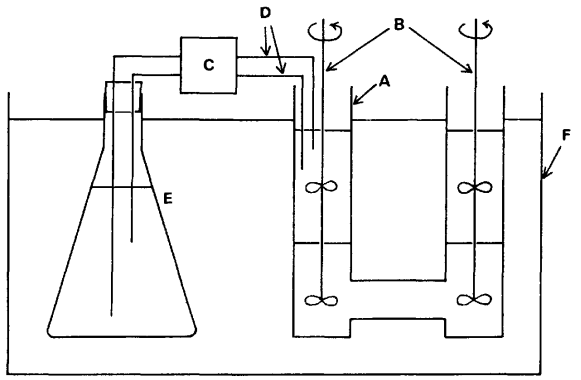

Fig. 4. Apparatus for measuring cation transport ; (A) U-type glass tube, (B) glass stirrer (200 min^{-1}.), (C) circulating pump, (D) polypropylene tube (diameter 2 mm) for circulating aqueous solution in the source phase, (E) 100-ml Erlenmeyer flask, (F) water bath controlled temperature (25 °C).

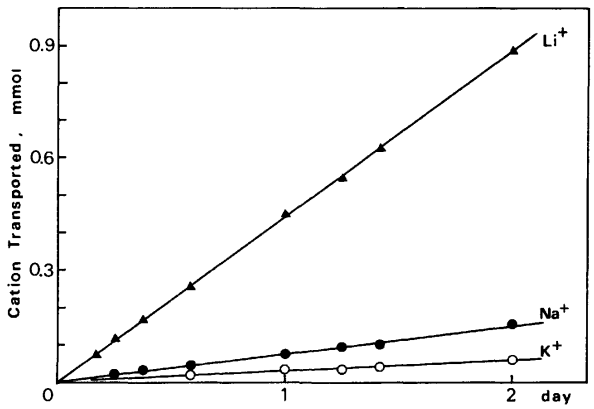

Fig. 5. Cation transport by (**2**) for lithium, sodium, and potassium ion species existing together. Initial transport conditions (25 °C) ; Source phase : 115 ml of 0.1 M LiOH+0.1 M NaOH+0.1 M KOH+0.1 M H_2SO_4 aqueous solution, Chloroform membrane : 30 ml of chloroform containing 1.5×10^{-4} mole of (**2**), Receiving phase : 15 ml of 0.05 M H_2SO_4 aqueous solution.

of polyether is either longer or shorter than oxytrimethylene. The structural significance of the oxytrimethylene-chain unit is noted for the appearance of a high selectivity for the lithium ion.

Effects of Terminal Groups on the Selectivity. Next, the effects of the kind of terminal groups on the selectivity were examined using polyethers containing other substituent groups in place of the 8-quinolyl terminal group of **1**. The other groups of **1** are not changed because the two trimethylene groups are important for the appearance of the high selectivity for the lithium ion and the other terminal group, the *o*-carboxyphenyl group, is required for cation-catching. In this study, as is shown in Fig. 4, a large amount of the solution in the source phase is circulated to keep the concentration of the cations constant, and the receiving phase contains only 15 ml of the 0.05 M sulfuric acid solution. Under these transport conditions, the amounts of each cation transported increased linearly with the running time for 2 d at least. Figure 5 summarizes the results obtained in the case of polyehter (**2**), while Table 3 shows the results of the transport rates (μmol/hr), which were calculated from the linear slopes of the amounts of each cation transported *vs.* the running time, and the selectivities of polyethers, (**1**)—(**8**) and (**12**). The values of the selectivities of **1** in Table 3 are a little different from those in Table 2 because of the different transport conditions. The values in Tables 1 and 2 were calculated from the amounts of the cation transported after 2 d, whereas the values in Table 3 were calculated from the transport rates of the cations. Here, it may be noted that the selectivity ratios, Li/Na and Li/K, change greatly with the change in the position of the substituent group introduced to the quinoline skelton. Polyether (**2**), which contains the 2-methyl-8-quinolyl group, gives a selectivity for the lithium ion superior to the (**1**) and (**3**) polyethers, whereas the (**3**) polyether which contains the 7-(1-propenyl)-8-quinolyl group,[8] gives a worse selectivity for the lithium ion than **1**. It is suggested that the structure of the terminal group and the position of the group introduced into the terminal group are important in order to increase the selectivity for the lithium ion. Furthermore, although there is little difference of selectivity for the lithium ion between **1** and the polyethers, (**4**) and (**5**), the significance of the heteroatom on the terminal

Table 3. Influence of substituents of the carriers on the cation-selective transport

Polyether	Transport rate (μ mol/hr)			Selectivity		
	Li	Na	K	Li/Na	Li/K	Na/K
(**1**)	20	6.2	3.4	3.2	5.9	1.8
(**2**)	18	3.1	1.3	5.8	14	2.5
(**3**)	18	6.9	5.6	2.6	3.2	1.2
(**4**)	19	6.3	5.3	3.0	3.6	1.2
(**5**)	19	6.1	5.0	3.1	3.8	1.2
(**6**)	19	6.9	5.0	2.8	3.8	1.4
(**7**)	19	5.3	4.1	3.6	4.7	1.3

(**12**)	13	11	10	1.2	1.3	1.1

Initial transport conditions (25 °C):

(Source phase)	(Chloroform membrane)	(Receiving phase)
0.1 M LiOH 0.1 M NaOH 0.1 M KOH 0.1 M H_2SO_4 115 ml	Polyether 1.5×10^{-4} mol $CHCl_3$ 30 ml	0.05 M H_2SO_4 15 ml

group may be presumed from the enhancement of the selectivity in the case of **7** containing the *o*-ethoxyphenyl terminal group compared with that of **6** containing the phenyl group.[9] In the case of **8**, which contains an ethyl terminal group, the selectivity is not much different from that in the case of the polyethers containing a phenyl or naphthyl group, but the transport rates of each cation using **8** as a carrier decrease apparently in spite of stirring mechanically at 200 min^{-1} in every case, in comparison with those in the case of the polyethers containing aromatic substituents. The transport rates may depend on the difference in hydrophobicity between them. Thus, no large difference in selectivities between polyethers, (**4**)—(**6**) and (**8**), is observed. These results suggest that the more important factor affecting the selectivities for a cation is the introduction of the oxytrimethylene chain, as is shown in Table 2, rather than the kinds of terminal group. By the way, polyether (**12**), with the 2-hydroxy-1,3-propanediyl group, with which 8-quinolyloxy and *t*-butyl-*o*-phenyleneoxy groups are bound, exhibits a much lower selectivity for the lithium ion than **1**. The cause of this will be discussed later.

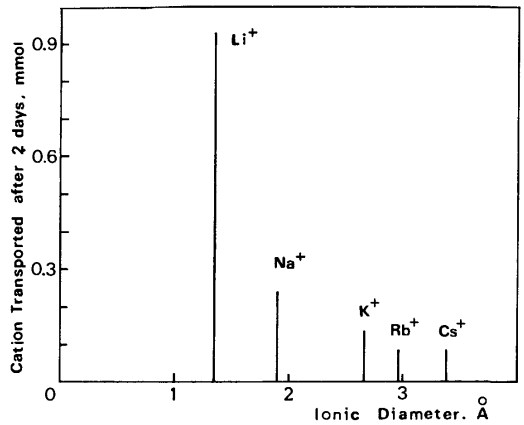

Fig. 6. Dependence of ionic diameter on the amounts of cation transported by (**1**) after 2 d. Initial transport conditions (25 °C) ; Source phase : 115 ml of 0.1 M LiOH+0.1 M NaOH+0.1 M KOH+0.1 M RbOH+0.1 M CsOH+0.2 M H_2SO_4 aqueous solution, Chloroform membrane : 30 ml of chloroform containing 1.5×10^{-4} mole of (**1**), Receiving phase : 15 ml of 0.05 M H_2SO_4 aqueous solution.

Structures of the Polyethers with Li^+-Selective Transport. From the results obtained, the structural significance of noncyclic polyethers may be pointed out. How can these polyethers exhibit Li^+-selective transport through liquid membranes?

Figure 6 shows the results of cation transport by **1** for five alkali metal ion species existing together in the source phese. Apparently, the smaller the ionic diameter, the larger the transport rates: $Li^+ \gg Na^+ > K^+ > Rb^+ \approx Cs^+$. Although the ionic diameter of a naked lithium ion is the smallest (1.32 Å) among alkali metal ions, its hydrated diameter (total hydration number =25) is the largest (6.80 Å) among them. The uptake of hydrated lithium ions by the polyethers does not occur, probably because the proton signal assigned to water does not appear in the NMR spectrum of Li-salt of **1** in $CDCl_3$. Furthermore, if the hydrated lithium ion can be transported, it can not be explained why the transport rates decrease in the order of the naked ionic diameter from the smallest Li^+ to the largest Cs^+. Additionally, in the case of the polyether containing the *p*-carboxyphenyl terminal group substituted for the *o*-carboxyphenyl one, its alkali salt can not be soluble in chloroform and can not be mobile through liquid membranes.[10] This means that the hydrated lithium ion is insoluble in chloroform. Therefore, it is reasonable to consider that the naked lithium ion becomes incorporated into the polyether carrier by means of the electrostatic interaction between ether-oxygens of the polyether and the lithium ion in a manner similar to cyclic polyethers, the so-called crown ethers.[11]

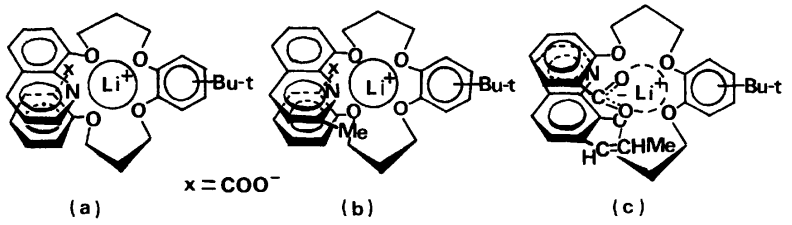

Fig. 7. Pseudocyclic structures Li-salts of polyethers on the basis of the CPK model; (a) Li—(**1**), (b) Li—(**2**), (c) Li—(**3**).

Here, if one looks at the molecular models of the carboxylate salt of the polyether with the lithium ion, it can be understood that these polyethers can transport the lithium ion selectively. As is shown in Fig. 7, the polyether (**1**) can form a pseudocyclic structure (a), the cavity of which has a diameter of 1.4—1.6 Å, and then the terminal aromatic rings overlap one another plainly to form a stacking structure,[12] when both ether-oxygen and nitrogen atoms are spatially directed to the inside. This indicates that the lithium ion best fits the size of the cavity formed. The other compounds with two oxytrimethylene chains, (**2**)—(**8**), also form the size of cavity which the lithium ion best fits among alkali metal ions. The stacking structure between terminal aromatic rings is suggested on the basis of the CPK-model building when the lithium ion becomes incorporated into the cavity of the polyethers.

The NMR spectra of polyether (**1**)-cation salts have been measured in order to get information concerning the stacking structure. Figure 8 shows the NMR spectra of the polyether (**1**), its Li^+ salt, and its K^+ salt. Especially notable is the proton at the 2-position of the quinolyl group; the proton (δ=8.96 ppm) in the case of Li^+ salt shifts to a higher magnetic field than that (δ=9.09 ppm) of the free polyether, while the proton (δ=9.08 ppm) in the case of the K^+ salt shifts hardly at all. It is presumed that the shift to the higher magnetic field in the case of Li^+ salt is to be attributed to the shielding effect (ring-current effect) of the aromatic rings on account of the stacking structure between them. If the nitrogen atom on the quinolyl group participates in the coordination to cations, the proton at the 2-position of the quinolyl group should shift to the lower magnetic field rather than that of free polyether (**1**). On the other hand, the size of the potassium ion is large, so that the terminal aromatic rings can not completely overlap each other. This can be confirmed from the CPK-model building.

The (**2**) polyether exhibits the most excellent selectivity for the lithium ion among the polyethers, whereas the (**3**) polyether exhibits a worse selectivity for it than even **1**. The difference in selectivity among the polyethers, (**1**)—(**3**), can not be explained by their lipophilicity because it increases in the following order: **1**<**2**<**3**. The difference in selectivity between **2** and **3** was also inferred on the basis of the CPK-model building (Fig. 7-b and 7-c). The CPK model indicates that the methyl moiety of **2** fills a space of the hydrophobic exterior which the (**1**) polyether forms around the cavity when aromatic terminal groups are stacked parallel to each other, playing a

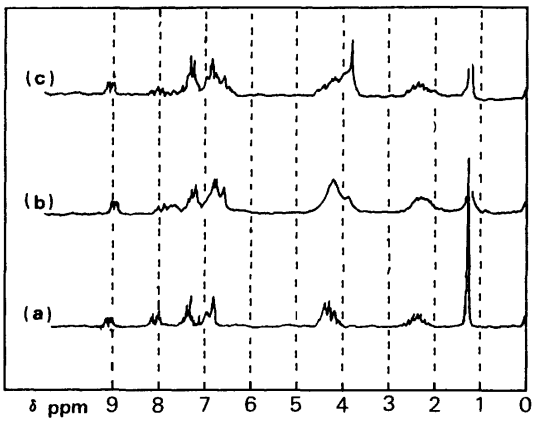

Fig. 8. NMR spectrum of (**1**) and its alkali salts ; (a) (**1**), (b) the Li salt, (c) the K salt.

part in the hydrophobic wall around the cavity (see, Fig. 7-b), whereas the 1-propenyl moiety of **3** can not act as a hydrophobic wall around the cavity, unlike the methyl moiety of **2**, but 1-propenyl and carboxylato groups on the two terminal aromatics could, rather, collide with each other when the complex with the lithium ion forms,to interfere a little with the favorable structure for the lithium ion (Fig. 7-c).

The small difference in selectivity for the lithium ion between **1** and **4** is not always reflected by the participation of the nitrogen atom,[9] which may be suggested from the CPK-model building, in the uptake of the lithium ion. On the contrary, the difference in selectivity dependent on the length of the oxyalkylene chain is reflected by the size of the cavity formed on the basis of the CPK-model building. The selective transport for the lithium ion by **12** is greatly lowered compared with that by **1**. It is presumed that the ability to wrap favorably around the lithium ion is decreased because the hydrophilic OH group on the trimethylene chain tends to be oriented inside the cavity in a nonpolar solvent (liquid membranes), resulting in the deformation of the cavity. From these considerations, we can reach the conclusion that the essential point in the structure of a noncyclic polyether for exhibiting lithium ion-selective transport is to contain the 1,2-bis(3-oxytrimethyleneoxy)phenyl group.

The schematic mechanism of cation transport by **1** as an example is proposed in Fig. 9. Thus, when the structure of the polyether can enoughly satisfy every process as follows: i) a selective uptake of cations at the boundary between phases (a) and (b), ii) solubility into the chloroform liquid membrane (b) and mobility

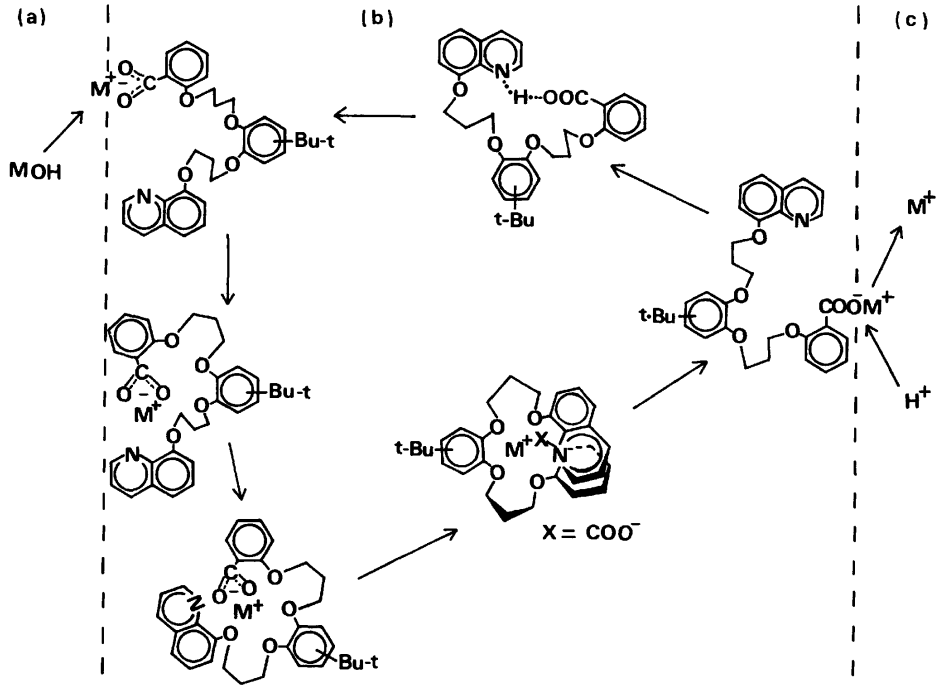

Fig. 9. Posturated cation transport sheme; (a) Source phase, (b) Chloroform membrane, (c) Receiving phase.

through it, and a smooth and rapid release of cations at the boundary between phases (b) and (c), the cation transport by the polyether is considered to proceed most effectively and selectively.

Experimental

General. The IR spectra were recorded with a JASCO A-3 Infrared spectrophotometer. The ^{1}HNMR (60 MHz) spectra were recorded with a Varian EM-360 spectrometer. The chemical shifts for $CDCl_3$ solutions are reported from internal tetramethylsilane.

1-[3-(o-Carboxyphenoxy)propoxy]-2-[3-(8-quinolyloxy)propoxy]-4-(or 5)-t-butylbenzene (1). *Method 1*: Under a nitrogen atmosphere, to a solution of 33.2 g (0.2 mol) of 4-*t*-butylcatechol in 150 ml of DMF was added 55.2 g of powdered potassium carbonate, after which the reaction mixture was stirred at 70 °C for 2 h. Then, 40 g (0.21 mol) of 3-chloro-1-propanol and a small amount of KI were added to it, and the mixture was stirred at 70 °C for 24 h. The solvent was evaporated under reduced pressure, and the residue was added to an aqueous hydrochloric acid solution to neutralize it and then extracted with chloroform. The chloroform extract was washed with water, dried with anhydrous magnesium sulfate, and evaporated to give an oily residue. The residue was purified by Kugelrohr distillation at 190 °C (0.3 mmHg[††]) to give 43 g (76%) of 1,2-bis(3-hydroxypropoxy)-4-*t*-butylbenzene as a colorless liquid.

To the solution of 31.7 g of 1,2-bis(3-hydroxypropoxy)4-*t*-butylbenzene and 30 g of pyridine in 150 ml of benzene was added dropwise 20 g of thionyl chloride. After refluxing for 10 h, the benzene solution was washed twice with water, then with diluted aqueous K_2CO_3 and with water. After the solution had been dried with anhydrous $MgSO_4$, the benzene was removed and the residue was purified by Kugelrohr distillation at 186 °C (1.3 mmHg) to give 27 g (76%) of 1,2-bis(3-chloropropoxy)-4-*t*-butylbenzene as a colorless liquid.

The reaction mixture of 3.4 g (0.02 mol) of ethyl salicylate and 2.3 g (0.02 mol) of *t*-BuOK in 50 ml of DMF was stirred until it became homogeneous. To the solution was then added 15 g (0.047 mol) of 1,2-bis(3-chloropropoxy)-4-*t*-butylbenzene, and the mixture was stirred at 70 °C for 42 h. After cooling to room temperature, the reaction mixture was poured into water and extracted with benzene. The benzene layer was washed with water three times and dried with anhydrous $MgSO_4$. After the solvent and the excess reactants had been removed under reduced pressure, the residue was submitted to column chromatography on activated alumina (Wako gel, 300 mesh) with a chloroform eluent to give 5.1 g (57%) of 1-[3-(*o*-ethoxycarbonylphenoxy)propoxy]-2-(3-chloropropoxy)-4(or 5)-*t*-butylbenzene as a colorless liquid.

The reaction mixture of 2.0 g of 8-quinolinol and 0.30 g of NaH in 30 ml of DMF was stirred until it became homogeneous. To the solution was then added 4.8 g (0.011 mol) of 1-[3-(*o*-ethoxycarbonylphenoxy)propoxy]-2-(3-chloropropoxy)-4(or 5)-*t*-butylbenzene, and the mixture was stirred at 70 °C for 48 h. After cooling to room temperature, the reaction mixture was poured into water and extracted with benzene. The benzene layer was washed with water three times and dried with $MgSO_4$. After the solvent had been evaporated, the residue was submitted to column chromatography on activated alumina (Wako gel, 300 mesh) with a chloroform eluent to give 3.7 g (62%) of 1-[3-(*o*-ethoxycarbonylphenoxy)-propoxy]-2-[3-(8-quinolyloxy)propoxy]-4(or 5)-*t*-butylbenzene. This ethyl ester (2.8 g) and 1 g of KOH in 30 ml of ethanol were refluxed under stirring overnight. After the ethanol had been evaporated, water was added to the residue, and the solution was slightly acidified with glacial acetic acid and extracted with chloroform two times. The chloroform layer was washed with water two times and dried with $MgSO_4$. After the removal of chloroform, the residue was submitted to column chromatography on silica gel (Wako gel, 300 mesh)

[††] 1 mmHg≈133.322 Pa.

with a chloroform eluent to give 2.1 g (79%) of **1** as a pale yellow glassy solid. ^{1}H NMR ($CDCl_3$) δ=1.27 (9H, s, $C(CH_3)_3$), 2.0—2.8 (4H, m, $OCH_2C\underline{H}_2CH_2O$), 4.1—4.7 (8H, m, $OC\underline{H}_2$-$CH_2C\underline{H}_2O$), 6.8—7.7 (10H, m, aromatic), 8.1—8.4 (2H, m, aromatic), 9.09 (1H, m, aromatic), *ca.* 8—9 (1H, broad, COOH); IR(KBr): 3280 and 2500 (COOH), 1705 (C=O), 1600 and 1580 cm^{-1} (aromatic C=C). Found: C 72.03, H 6.51, N 2.55%. Calcd for $C_{32}H_{35}NO_6$: C 72.57, H 6.66, N 2.64%.

Method 2: The reaction mixture of 33 g (0.2 mol) of ethyl salicylate and 5 g (0.2 mol) of NaH in 150 ml of DMF was stirred until it became homogeneous. To the solution was added 40 g of 2-(3-chloropropoxy)tetrahydropyran, which had been obtained quantitatively by the reaction of 3-chloro-1-propanol with 3,4-dihydro-2*H*-pyran, and the mixture was stirred at 70 °C for 24 h. After it was cooled to room temperature, the reaction mixture was poured into water and extracted with benzene. The benzene layer was washed with water and dried with $MgSO_4$. After the benzene had been removed, 100 ml of ethanol and a few drops of conc. HCl were added to the residue, and the solution was stirred at room temperature overnight. After the removal of the solvent, water was added to the residue, and the solution was extracted with chloroform. The chloroform layer was washed with water and dried with $MgSO_4$. After the removal of the chloroform, the residue was purified by Kugelrohr distillation at 180 °C (0.5 mmHg) to give 36.0 g (80%) of ethyl 2-(3-hydroxypropoxy)benzoate. To the reaction mixture of 33 g (0.15 mol) of ethyl 2-(3-hydroxypropoxy)benzoate and 15 g of pyridine in 300 ml of benzene was then added 20 g of thionyl chloride, drop by drop, and then the mixture was refluxed under stirring for 17 h. After cooling to room temperature, the solution was washed with water three times, then with diluted aqueous K_2CO_3 and with water, and dried with $MgSO_4$. After the removal of the benzene, the residue was purified by Kugelrohr distillation at 150 °C (0.4 mmHg) to give 30 g (83%) of ethyl 2-(3-chloropropoxy)benzoate.

The reaction mixture of 50 g (0.3 mol) of 4-*t*-butylcatechol and 6.0 g (0.054 mol) of *t*-BuOK in 150 ml of DMF was stirred under a nitrogen atmosphere until it became homogeneous. To the solution was added 13 g (0.054 mol) of ethyl 2-(3-chloropropoxy)benzoate, and the mixture was stirred at 70 °C for 48 h. After cooling to room temperature, 200 ml of benzene was added to the solution, and it was washed with water three times and dried with $MgSO_4$. After the removal of the benzene, the excess *t*-butylcatechol was removed from the residue at 130 °C under reduced pressure (0.5 mmHg). The residue was submitted to column chromatography on activated alumina with a chloroform eluent to give 14.5 g (76%) of 2-[3-(*o*-ethoxycarbonylphenoxy)propoxy]-4(or 5)-*t*-butylphenol (**13**) as a colorless liquid. ^{1}H NMR ($CDCl_3$) δ=1.30 (9H, s, $C(CH_3)_3$), 1.37 (3H, t (7.2 Hz), $OCH_2C\underline{H}_3$), 2.0—2.6 (2H, m, $OCH_2C\underline{H}_2CH_2O$), 4.05—4.60 (4H, m, $OC\underline{H}_2CH_2C\underline{H}_2O$), 4.35 (2H, q (7.2 Hz), $OC\underline{H}_2CH_3$), *ca.* 5.7 (1H, broad, OH), 6.8—8.0 (7H, m, aromatic); IR (neat): 3440 (OH), 1720 (C=O), 1600 and 1580 cm^{-1} (aromatic C=C). Found: C 71.28, H 7.65%. Calcd for $C_{22}H_{28}O_5$: C 70.94, H 7.58%.

The mixture of 36 g (0.25 mol) of 8-quinolinol and 28 g (0.25 mol) of *t*-BuOK in 70 ml of DMSO was stirred until it became homogeneous. To the solution 24 g (0.25 mol) of 3-chloro-1-propanol was added, and the mixture was stirred at 70 °C for 38 h. The solution was then poured into 500 ml of water, and the solid, which was precipitated in water, was separated from the solution by filtration, washed with water three times, and dried under a vacuum to give 33 g (66%) of 3-(8-quinolyloxy)-1-propanol. To the solution of 23 g (0.11 mol) of 3-(8-quinolyloxy)-1-propanol in 100 ml of benzene was added 16 g (0.13 mol) of thionyl chloride, drop by drop, after which the solution was refluxed for 5 h under stirring. After cooling to room temperature, diluted aqueous K_2CO_3 was slowly added to the solution until it became slightly basic. The benzene layer was washed with water two times and dried with $MgSO_4$. After the removal of the benzene, the crude product was purified by recrystallization from hexane to give 17 g (68%) of 1-chloro-3-(8-quinolyloxy)propane as a white solid; mp 68—69 °C.

The reaction mixture of 7.3 g (0.02 mol) of **13** and 2.2 g (0.02 mol) of *t*-BuOK in 50 ml of DMSO was stirred until it became homogeneous. To the solution was then added 4.4 g (0.02 mol) of 1-chloro-3-(8-quinolyloxy)propane and a small amount of KI, and the mixture was stirred at 70 °C for 4 d. Then, benzene and water were added to the solution, and the benzene layer was washed with water and dried with $MgSO_4$. After the removal of the benzene, the residue was submitted to column chromatography on activated alumina with a chloroform eluent to give 9.4 g (85%) of 1-[3-(*o*-ethoxycarbonylphenoxy)propoxy]-2-[3-(8-quinolyloxy)propoxy]-4(or 5)-*t*-butylbenzene as a pale yellow liquid. The polyether (**1**) was obtained in a manner similar to that described in Method 1.

The polyethers, (**2**)—(**8**) and (**10**), were obtained by the reaction of **13** with the corresponding 3-substituted 1-chloropropane in a manner similar to that described in Method 2.

1-[3-(o-Carboxyphenoxy)propoxy]-2-[3-(2-methyl-8-quinolyloxy)-propoxy]-4(or 5)-t-butylbenzene (2). The above procedure was followed, using **13** and 1-chloro-3-(2-methyl-8-quinolyloxy)propane; a pale yellow glassy solid. ^{1}H NMR ($CDCl_3$) δ=1.27 (9H, s, $C(CH_3)_3$), 2.0—2.7 (4H, m, OCH_2-$C\underline{H}_2CH_2O$), 2.77 (3H, s, CH_3-Ar), 4.05—4.65 (8H, m, $OC\underline{H}_2$-$CH_2C\underline{H}_2O$), 6.8—7.6 (10H, m, aromatic), 7.9—8.3 (2H, m, aromatic), *ca.* 8.9 (1H, broad, COOH); IR (KBr): 3280 and 2550 (COOH), 1710 (C=O), 1605, 1580, and 1575 cm^{-1} (aromatic C=C). Found: C 72.26, H 6.81, N 2.49%. Calcd for $C_{33}H_{37}NO_6$: C 72.91, H 6.86, N 2.57%.

1-[3-(o-Carboxyphenoxy)propoxy]-2-[3-[7-(1-propenyl)-8-quinolyloxy]propoxy]-4(or 5)-t-butylbenzene (3). The above procedure was followed, using **13** and 1-chloro-3-[7-(1-propenyl)-8-quinolyloxy]propane, which had been obtained by the reaction of 7-allyl-8-quinolinol with 3-chloro-1-propanol, followed by treatment with thionyl chloride. 7-Allyl-8-quinolinol was obtained in a good yield by the Claisen rearrangement of 8-(allyloxy)quinoline. Polyether (**3**): a pale yellow glassy solid. ^{1}H NMR ($CDCl_3$) δ=1.32 (9H, s, C (CH_3)$_3$), 1.78 (3H, d, $C\underline{H}_3$-CH=CH-Ar), 2.0—2.6 (4H, m, $OCH_2C\underline{H}_2CH_2O$), 4.0—4.6 (8H, m, $OC\underline{H}_2CH_2C\underline{H}_2O$), 6.0—6.6 (1H, m, CH_3-C$\underline{H}$=CH-Ar), 6.7—7.8 (10H, m, aromatic and CH_3-CH=C$\underline{H}$-Ar), 8.10 (2H, m, aromatic), 8.87 (1H, m, aromatic), *ca.* 8.8 (1H, broad, COOH); IR (KBr): 3270 and 2450 (COOH), 1725 and 1700 (C=O), 1645 (CH=CH), 1600 and 1580 cm^{-1} (aromatic C=C). Found: C 73.07, H 6.71, N 2.38%. Calcd for $C_{35}H_{39}NO_6$: C 73.79, H 6.90, N 2.46%.

1-[3-(o-Carboxyphenoxy)propoxy]-2-[3-(1-naphthyloxy)propoxy]-4(or 5)-t-butylbenzene (4). The above procedure was followed, using **13** and 1-chloro-3-(1-naphthyloxy)propane, which had been obtained by the reaction of 1-naphthol with 1,3-dichloropropane: colorless liquid. ^{1}H NMR ($CDCl_3$) δ=1.28 (9H, s, C (CH_3)$_3$), 2.0—2.7 (4H, m, OCH_2-$C\underline{H}_2CH_2O$), 4.0—4.55 (8H, m, $OC\underline{H}_2CH_2C\underline{H}_2O$), 6.7—8.5 (14H, m, aromatic), *ca.* 9—10 (1H, broad, COOH); IR (neat): 3300 (COOH), 1740 and 1700 (C=O), 1630, 1605, and 1580 cm^{-1} (aromatic C=C). Found: C 75.40, H 6.72%. Calcd for $C_{33}H_{36}O_6$: C 74.98, H 6.86%.

1-[3-(o-Carboxyphenoxy)propoxy]-2-[3-(2-naphthyloxy)propoxy]-4(or 5)-t-butylbenzene (5). The above procedure was followed, using **13** and 1-chloro-3-(2-naphthyloxy)propane: colorless liquid. ^{1}H NMR ($CDCl_3$) δ=1.31 (9H, s, $C(CH_3)_3$), 2.0—2.6 (4H, m, $OCH_2C\underline{H}_2CH_2O$), 4.05—4.55 (8H, m, $OC\underline{H}_2CH_2C\underline{H}_2O$), 6.83—7.97 (13H, m, aromatic),

8.22 (1H, m, aromatic), *ca.* 9—10 (1H, broad, COOH); IR (neat): 3300 (COOH), 1740 and 1700 (C=O), 1630, 1600, and 1580 cm^{-1} (aromatic C=C). Found: C 74.41, H 6.95%. Calcd. for $C_{33}H_{36}O_6$: C 74.98, H 6.86%.

1-[3-(o-Carboxyphenoxy)propoxy]-2-(3-phenoxypropoxy)-4(or 5)-t-butylbenzene (6). The above procedure was followed using **13** and 1-chloro-3-phenoxypropane: colorless liquid. ^1H NMR ($CDCl_3$) δ=1.30(9H, s, $C(CH_3)_3$), 2.0—2.6 (4H, m, $OCH_2C\underline{H}_2CH_2O$), 3.95—4.65 (8H, m, $OC\underline{H}_2CH_2$-$C\underline{H}_2O$), 6.7—7.7 (1H, m, aromatic), 8.05—8.30 (1H, m, aromatic), *ca.* 9—10 (1H, broad, COOH); IR (neat): 3290 (COOH), 1740 and 1695 (C=O), 1605 and 1590 cm^{-1} (aromatic C=C). Found: C 73.56, H 7.03%. Calcd for $C_{29}H_{34}O_6$: 72.78, H 7.16%.

1-[3-(o-Carboxyphenoxy)propoxy]-2-[3-(o-ethoxyphenoxy)propoxy]-4(or 5)-t-butylbenzene (7). The above procedure was followed, using **13** and 1-chloro-3-(*o*-ethoxyphenoxy)-propane which was obtained by the reaction of *o*-ethoxyphenol with 1,3-dichloropropnane: pale yellow liquid. ^1H NMR ($CDCl_3$) δ=1.30 (9H, s, $C(CH_3)_3$), 1.40 (3H, t, OCH_2-$C\underline{H}_3$), 2.0—2.6 (4H, m, $OCH_2C\underline{H}_2CH_2O$), 4.06 (2H, q, $OC\underline{H}_2CH_3$), 4.1—4.7 (8H, m, $OC\underline{H}_2CH_2C\underline{H}_2O$), 6.93 (4H, s, aromatic), 6.8—7.8 (6H, m, aromatic), 8.22 (1H, m, aromatic), *ca.* 9—10 (1H, broad, COOH); IR (neat): 3300 (COOH), 1740 and 1700 (C=O), 1605 and 1580 cm^{-1} (aromatic C=C). Found: C 70.73, H 7.02%. Calcd for $C_{31}H_{38}O_7$: C 71.26, H 7.33 %.

1-[3-(o-Carboxyphenoxy)propoxy]-2-(3-ethoxypropoxy)-4(or 5)-t-butylbenzene (8). The above procedure was followed, using **13** and 1-chloro-3-ethoxypropane, which had been obtained by the reaction of 3-ethoxypropionic acid with $LiAlH_4$ following chlorination: colorless liquid. ^1H NMR ($CDCl_3$) δ=1.17 (3H, t, $OCH_2C\underline{H}_3$), 1.31 (9H, s, $C(CH_3)_3$), 1.75—2.65 (4H, m, $OCH_2C\underline{H}_2CH_2O$), 3.47 (2H, q, $OC\underline{H}_2CH_3$), 3.59 (2H, t, $OCH_2CH_2C\underline{H}_2O$-$CH_2CH_3$), 3.95—4.70 (6H, m, $OC\underline{H}_2CH_2C\underline{H}_2O$), 6.87—7.80 (6H, m, aromatic), 8.22 (1H, m, aromatic), *ca.* 9 (1H, broad, COOH); IR (neat): 3290 (COOH), 1740 and 1700 (C=O), 1605 and 1580 cm^{-1} (aromatic C=C). Found: C 70.30, H 7.63%. Calcd for $C_{25}H_{34}O_6$: C 69.74, H 7.96%.

1-[3-(o-Carboxyphenoxy)propoxy]-2-[4-(8-quinolyloxy)butoxy]-4(or 5)-t-butylbenzene (10). The above procedure was followed, using **13** and 1-chloro-4-(8-quinolyloxy)butane, which had been obtained by the reaction of 8-quinolinol with 4-chloro-1-butanol, following chlorination: a pale yellow glassy solid. ^1H NMR ($CDCl_3$) δ=1.28 (9H, s, $C(CH_3)_3$), 1.9—2.5 (6H, m, $OCH_2C\underline{H}_2CH_2O$ and $OCH_2C\underline{H}_2C\underline{H}_2$-$CH_2O$), 3.85—4.65 (8H, m, $OC\underline{H}_2CH_2C\underline{H}_2O$ and $OC\underline{H}_2$-$CH_2CH_2C\underline{H}_2O$), 6.85—7.65 (10H, m, aromatic), 8.0—8.3 (2H, m, aromatic), 9.00 (1H, m, aromatic), *ca.* 8—9 (1H, broad, COOH); IR (KBr): 3290 and 2500 (COOH), 1710 (C=O), 1600 and 1580 cm^{-1} (aromatic C=C) Found: C 72.11, H 7.05, N 2.43%. Calcd for $C_{33}H_{37}NO_6$: 72.91, H 6.86, N 2.58%.

1-[3-(o-Carboxyphenoxy)propoxy]-2-[2-(8-quinolyloxy)ethoxy]-4(or 5)-t-butylbenzene (9). The reaction mixture of 3.7 g (0.01 mol) of **13** and 1.2 g of *t*-BuOK in 50 ml of DMSO was stirred until it became homogeneous. To the solution was then added 3.0 g of 2-(2-chloroethoxy)tetrahydropyran, and the mixture was stirred at 70 °C for 90 h. The solution was then poured into water and extracted with benzene. The benzene layer was washed with water three times and dried with $MgSO_4$. After the removal of the benzene, 50 ml of EtOH and a few drops of conc. HCl were added to the residue and the mixture was stirred overnight at room temperature. After the removal of the ethanol, the residue was extracted with chloroform, washed with water, and dried with $MgSO_4$. After the removal of the chloroform, the residue was submitted to column chromatography on activated alumina with $CHCl_3$–EtOH (9:1) eluents to give 2.9 g (70%) of 1-[3-(*o*-ethoxycarbonylphenoxy)propoxy]-2-(2-hydroxyethoxy)-4(or 5)-*t*-butylbenzene as a colorless liqued.

To the solution of 2.8 g of 1-[3-(*o*-ethoxycarbonylphenoxy)-propoxy]-2-(2-hydroxyethoxy)-4(or 5)-*t*-butylbenzene and 0.60 g of pyridine in 30 ml of benzene was added 0.9 g of thionyl chloride, and the mixture was refluxed overnight. The benzene layer was washed with water and then with aqueous K_2CO_3, and dried with $MgSO_4$. After the removal of the benzene, the residue was submitted to column chromatography on activated alumina with a chloroform eluent to give 2.3 g (78%) of 1-[3-(*o*-ethoxycarbonylphenoxy)propoxy]-2-(2-chloroethoxy)-4(or 5)-*t*-butylbenzene as a colorless liquid.

The reaction mixture of 1.0 g of 8-quinolinol and 0.65 g of *t*-BuOK in 15 ml of DMSO was stirred until it became homogeneous. To the solution was then added 2.3 g of 1-[3-(*o*-ethoxycarbonylphenoxy)propoxyl-2-(2-chloroethoxy)-4(or 5)-*t*-butylbenzene, and the mixture was stirred at 70 °C for 4 h. After it had cooled to room temperature, 100 ml of benzene was added to the solution, and it was washed with water three times and dried with $MgSO_4$. After the removal of the benzene, the residue was submitted to column chromatography on activated alumina with a chloroform eluent to give 1.9 g (66%) of 1-[3-(*o*-ethoxycarbonylphenoxy)propoxy]-2-[2-(8-quinolyloxy]ethoxy]-4(or 5)-*t*-butylbenzene as a pale yellow liquid. The solution of 1.1 g of this ethyl ester and 0.5 g of KOH in 30 ml of ethanol was refluxed overnight. After the removal of the ethanol, water was poured into the residue, and the solution was slightly acidified with glacial acetic acid and extracted with chloroform two times. The chloroform layer was washed with water two times and dried with $MgSO_4$. After the removal of the chloroform, the residue was submitted to column chromatography on silica gel (300 mesh) with a chloroform eluent to give 0.8 g (80%) of **9**: a pale yellow glassy solid. ^1H NMR ($CDCl_3$) δ=1.28 (9H, s, $C(CH_3)_3$), 2.0—2.5 (2H, m, $OCH_2C\underline{H}_2CH_2O$), 4.25 (2H, t, $OC\underline{H}_2CH_2CH_2O$-$C_6H_4$(*o*-COOH)), 4.37 (2H, t, $OCH_2CH_2C\underline{H}_2O$-$C_6H_4$(*o*-COOH)), 4.63 (4H, s, $OC\underline{H}_2C\underline{H}_2O$), 6.8—7.65 (10H, m, aromatic), 8.0—8.3 (2H, m, aromatic), 8.3 (1H, broad, COOH), 9.03 (1H, m, aromatic); IR (KBr): 3260 and 2500 (COOH), 1705 (C=O), 1600 and 1580 cm^{-1} (atomatic C=C). Found: C 71.88, H 6.62, N 2.85%. Calcd for $C_{31}H_{33}NO_6$: C 72.21, H 6.45, N 2.71%.

1-[2-(o-Carboxyphenoxy)ethoxy]-2-[2-(8-quinolyloxy)ethoxy]-4(or 5)-t-butylbenzene (11). A procedure similar to that described above (Method 1 for **1**) was used for the preparation of **11**: a pale yellow glassy solid. ^1H NMR ($CDCl_3$) δ= 1.30 (9H, s, $C(CH_3)_3$), 4.43 (4H, s, $OC\underline{H}_2C\underline{H}_2O$-quinolyl), 4.65 (4H, m, $OC\underline{H}_2C\underline{H}_2O$-$C_6H_4$(*o*-COOH)), 6.7—7.7 (10H, m, aromatic), 7.9—8.3 (2H, m, aromatic), 9.07 (1H, m, aromatic), 10.07 (1H, broad, COOH); IR (KBr): 3280 and 2500 (COOH), 1730 and 1710 (C=O), 1605 and 1580 cm^{-1} (aromatic C=C). Found: C 71.88, H 6.49, N 2.76%. Calcd for $C_{30}H_{31}NO_6$: C 71.98, H 6.24, N 2.80%.

1-[3-(o-Carboxyphenoxy)propoxy]-2-[3-(8-quinolyloxy)-2-hydroxypropoxy]-4(or 5)-t-butylbenzene (12). The reaction mixture of 7.4 g 0.02 mol) of **13** and 2.3 g (0.02 mol) of *t*-BuOK in 30 ml of benzene was stirred at room temperature until it became homogeneous. After the removal of the benzene, 24 g of epichlorohydrin was added to the residue, and then the mixture was stirred at 70 °C for 19 h. After cooling to room temperature, the mixture was poured into water and extracted with benzene. The benzene layer was washed with water three times and dried with $MgSO_4$. After the removal of the benzene and excess epichlorohydrin under a vacuum, 7.9 g (93%) of the crude product, 1-[3-(*o*-ethoxycarbonylphenoxy)-propoxy]-2-glycidyl-4(or 5)-*t*-butylbenzene, was obtained. This product was used for the following reaction without further purification.

After the reaction mixture of 3.0 g (0.02 mol) of 8-quinolinol and 2.0 g (0.018 mol) of *t*-BuOK in 50 ml of dioxane had been stirred at 70 °C for 2 h, 7.5 g (0.018 mol) of 1-[3-(*o*-ethoxycarbonylphenoxy)propoxy]-2-glycidyl-4(or 5)-*t*-butylbenzene was added to it, and the mixture was stirred at 70 °C for 46 h. Then, after the removal of the dioxane, to the residue was added water and the solution was slightly acidified with glacial acetic acid and extracted with benzene. The benzene layer was washed with water three times and dried with $MgSO_4$. After the removal of the benzene, the residue was submitted to column chromatography on activated alumina with a chloroform eluent to give 5.6 g (53%) of 1-[3-(*o*-ethoxycarbonylphenoxy)propoxy]-2-[3-(8-quinolyloxy)-2-hydroxypropoxy]-4(or 5)-*t*-butylbenzene as a pale yellow liquid. The solution of 2.0 g of this ethyl ester and 1.0 g of KOH in 50 ml of ethanol was refluxed overnight. After the removal of the ethanol, water was poured into the residue, and the solution was slightly acidified with glacial acetic acid and extracted with chloroform. The chloroform layer was washed with water two times and dried with $MgSO_4$. After the removal of the chloroform, the residue was submitted to column chromatography on silica gel (300 mesh) with chloroform-ethanol (9:1) eluents to give 1.1 g (58%) of **12**: a pale yellow glassy solid. ^{1}H NMR ($CDCl_3$) δ=1.26 (9H, s, $C(CH_3)_3$), 2.0—2.6 (2H, m, $OCH_2C\underline{H}_2CH_2O$), 4.0—4.7 (9H, m, $OC\underline{H}_2$-$CH_2C\underline{H}_2O$ and $OC\underline{H}_2C\underline{H}(OH)C\underline{H}_2O$), 6.8—7.7 (12H, m, aromatic, $OCH_2CH(O\underline{H})CH_2O$, and $COO\underline{H}$), 7.94—8.40 (2H, m, aromatic), 9.06 (1H, m, aromatic); IR (KBr): 3450 (OH), 3290 and 2500 (COOH), 1720 (C=O), 1605 and 1580 cm^{-1} (aromatic C=C). Found: C 71.09, H 6.31, N 2.77%. Calcd for $C_{32}H_{35}HO_7$: C 70.44, H 6.47, N 2.57%.

General Procedure of Cation Transport. Reagents: Chloroform (extra-pure grade) was used without further purification. Each aqueous solution which was used in either the source or receiving phase was prepared by the dilution of one normal alkali hydroxide and/or one normal acid.

Procedure: A U-type glass tube as previously reported[7] was used for measuring the transport of the alkali-metal ions. In the first case (*cf.* Table 1 and Table 2), the same volumes of an aqueous solution which initially contained the same amounts of alkali-metal ions were used as both aqueous phases. First, 30 ml of chloroform containing 1.5×10^{-4} mol of a carrier was placed in the tube. Two kinds of the aqueous solution used for the source phase and the receiving phase were subsequently poured into both sides. The tube was then placed in a water bath whose temperature was kept at 25±0.2 °C. Each phase was agitated at 200 min^{-1} mechanically with a pair of glass stirrers.

In the second case (*cf.* Table 3), a large amount of the aqueous solution (115 ml) was used for the source phase, while 15 ml of a 0.05 M sulfuric acid solution was used for the receiving phase. As is shown in Fig. 4, the solution for the source phase was circulated by means of a circulating pump (circulating velocity, 2.5 ml/ min.). Under these conditions, the concentration of each cation in the receiving phase was confirmed to increase linearly with the running time (less than 2 d), and the apparent transport rates of cations were calculated.

The transport of alkali-metal ions was initiated by the addition of the aqueous solutions. At each time point, 50 μl of the solution was withdrawn from each aqueous phase, and the concentration of the cation was adjusted by using a measuring flask and determined by means of a Shimadzu AA-646 atomic absorption spectrometer. The transport of cations in the blank systems was negligible. The detailed conditions are shown in the tables.

Crystal and Molecular Structure of 4-*t*-Butyl-5-cyano-2-phenyl-1-thioxo-7-thia-1-phosphabicyclo[2.2.1]hept-2-ene

Tokiko UCHIDA,* Kozo KOZAWA, Takao SAITO,† and Shinichi MOTOKI†

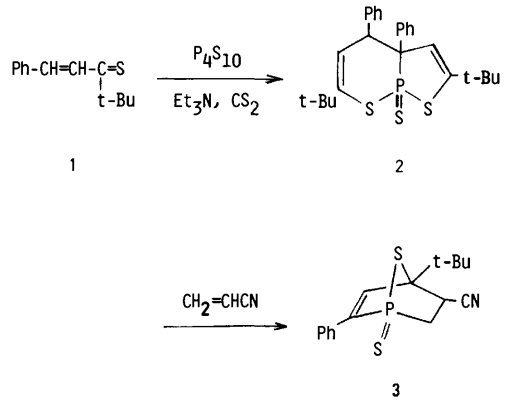
Department of Industrial and Engineering Chemistry, Faculty of Science and Technology, Science University of Tokyo, Noda, Chiba 278

†*Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162*

(Received December 22, 1983)

The crystal and molecular structures of the title compound were determined by means of X-ray diffraction. Crystal data: $C_{16}H_{18}NS_2P$, M_r=319.4, triclinic, a=12.731(2), b=13.143(1), c=12.483(1) Å, α=102.39(1), β=104.34(1), γ=117.96(1)°, V=1648.6 Å^3, space group P$\bar{1}$, D_m=1.30, D_x=1.287 g cm^{-3}, Z=4, μ=4.02 cm^{-1} (Mo $K\alpha$). The structure was solved by the direct method and refined by the block-diagonal least-squares method to R=0.082 for 4495 observed reflections. The bond distances and angles are in good agreement with the ordinary values except for the P-S-C bridged angle of 82.5°. An asymmetric unit contains two crystallographically independent molecules, which are rotational isomers along the P-C bond.

The title compound (**3**) was formed by the reaction of acrylonitrile and 3,8-di-*t*-butyl-5,6-diphenyl-1-thioxo-2,9-dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene (**2**) prepared from 4,4-dimethyl-1-phenyl-1-pentene-3-thione (**1**).[1,2] Compound **3** has a unique norbornene-like skeleton in which one of the sulfur atoms bridges between phosphorus and carbon atoms. The present study was performed to confirm the structure and establish the total geometry of the molecule.



Experimental

The compound was prepared by the method described previously.[1] Colorless crystals were obtained by recrystallization from chloroform with a well-developed (112) face.

After determining preliminary cell constants and space group from Weissenberg photographs, a crytal with dimensions of 0.40×0.25×0.15 mm was mounted with the (112) face perpendicular to the ϕ axis on a Hilger & Watts diffractometer with Zr-filtered Mo$K\alpha$ radiation. Lattice constants were determined by a least-squares procedure for setting angles of 12 reflections with $16.5° < \theta < 21.4°$. The intensities were recorded with an θ-2θ step scan mode at every 0.01° of θ step up to $2\theta \leqq 55°$. The scan width of θ was 0.8° for all the reflections. Counting time was 1 s per step for peak measurements, and backgrounds were measured for 10 s at both ends of a scan.

Three standard reflections, monitored every 50 measurements, showed no significant change throughout the data collection. Of the 7545 independent reflections measured, 4495 with $F_o \geqq 3\sigma(F)$ were used for further calculations. Lorentz and polarization corrections were applied but no absorption correction was made. No systematical absent spectra was observed. Density was determined by the flotation method with K_2HgI_4 aqueous solution.

Crystal Data: $C_{16}H_{18}NS_2P$, M_r=319.4, triclinic, a=12.731(2), b=13.143(1), c=12.483(1) Å, α=102.39(1), β=104.34(1), γ=117.96(1)°, V=1648.6 Å^3, space group P$\bar{1}$, D_m=1.30, D_x=1.287 g cm^{-3}, Z=4, μ=4.02 cm^{-1} (Mo $K\alpha$).

Solution and Refinement of the Structure

The structure was solved by the direct method.[3] After several cycles of block-diagonal least-squares refinement, all the H atoms were located on the difference Fourier map. The final cycle was calculated with the anisotropic thermal parameters for non-H atoms, a fixed isotropic thermal parameter for H atoms, B=4.0 Å^2, and anomalous scattering factors for S and P atoms. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$, where $w=[\sigma^2(F)+0.0011|F_o|^2]^{-1}$. In the final cycle, the maximum parameter shift/error was less than 0.07. Final R and R_w were 0.082 and 0.084, respectively. A final difference Fourier synthesis showed no significant features. The atomic scattering factors were adopted from "International Tables for X-ray Crystallography."[4] All the computations were carried out on a HITAC M-200H computer at the Computer Center of Tokyo University with the *UNICS* program system.[5]

Results and Discussion

The asymmetric unit contains two crystallographically independent molecules, hereafter referred to as molecule A and molecule B. Table 1 lists the final fractional coordinates and the equivalent thermal parameters.[6] The bond distances with the numbering scheme of atoms are given in Fig. 1, and the bond angles in Table 2. The bond distances and angles including P and S atoms almost agree with the literature values[7] except for the P-S(2)-C(3) angle. Differences between corresponding bond distances and bond angles in molecules A and B are not so significant. Figure 2 shows an *ORTEP* drawing of molecule A.[8] Each of two five-membered rings takes an envelope conformation, commonly possessing the P-S(2)-C(3) bridge. A

Table 1. The final fractional coordinates and equivalent isotropic thermal parameters
Estimated standard deviations are given in parentheses. The equivalent isotropic thermal parameters for non-hydrogen atoms are calculated using the expression: $B_{eq}=4/3\Sigma_i\Sigma_j\mathbf{a}_i\mathbf{a}_j\beta_{ij}$, where the $\mathbf{a}_i$'s are the unit cell edges in direct space. The isotropic thermal parameter of hydrogen atoms is fixed, $B=4.0$ Å^2.

considerable decrease in bond angle is observed at the bridged S atom [P-S(2)-C(3) of average 82.5°], which indicates the steric strain about the bicyclo skeleton. Table 3 gives bond angles of bridged S atom in several bicyclo compounds,[9-12] though the value of the P-S-C bridge angle has not been reported other than in the present study. As expected, the more the number of ring atoms increases, the larger the bridge C-S-C angle changes.

Figure 3, the Newman projection along the P-C(1) bond, shows that the torsion angles of S(1)-P-C(1)-C(61) are appreciably different for molecule A and molecule B. The conformational difference between molecules A and B is obviously illustrated in Fig. 4, which is the projection of phenyl group and its neighboring atoms onto the plane perpendicular to the C(1)=C(2) double bond. Although the S(1)···H(62) and H(2)···H(66) separations keep the van der Waals distances, their relative orientations are distinct from one another in the two molecules. In other words, molecule A and molecule B are rotational isomers to each other, because the C(1)-C(61) bond is kept from free rotation by the steric hindrance of ortho hydrogens, H(62) and H(66).

Planarity of the plane defined by atoms around the C(1)=C(2) double bond [C(1), C(2), C(3), C(61) and P] is

not so good: the maximum deviation from the least-squares plane reaches to 0.09 Å of C(1) in molecule B.[6] That is because of the strain of bicyclo skeleton and the overcrowding effect of bulky substituents, namely *t*-

Table 2. Bond angles of molecule A and molecule B with their estimated standard deviations in parentheses

butyl and phenyl groups. Similar effects were observed in several substituted ethylenes, in which the ethylenic C=C double bonds were twisted owing to the steric interactions.[13] The dihedral angles between the above-mentioned plane and phenyl group, that composes a faily good plane, are 26.9° and −29.6° for molecule A and molecule B, respectively.[6] Figure 5 shows the packing arrangement of the molecules in a unit cell.[8] There is no particular interaction, for example hydrogen bonding between molecules, since all the intermolecular atomic distances are considered to be van der Waals contacts.

The authors express their hearty thanks to Mr. Hiroshi Taguchi for his technical assistance.

(Received December 22, 1983)

The crystal and molecular structures of the title compound were determined by means of X-ray diffraction. Crystal data: $C_{26}H_{31}S_3P$, M_r=470.68, orthorhombic, a=17.116(4), b=19.798(4), c=14.898(3) Å, V=5048.4 Å^3 (21 °C), space group Pbca, D_m=1.23, D_x=1.239 g cm^{-3}, Z=8, μ=3.58 cm^{-1} (Mo $K\alpha$). The structure was solved by the direct method and refined by the full-matrix least-squares method to R=0.083 for 3318 observed reflections. The bicyclo skeleton is so highly strained that abnormal bond distances [P-C of 1.895(5) and C-C of 1.594(6) Å] were observed. Conformation of six-membered ring is a boat-form.

Previously, we found that treatment of α,β-unsaturated thioketones (**1**) with P_4S_{10} gave 1-thioxo-2,9-dithia-1-phosphabicyclo[4.3.0]nona-3,7-dienes (**2**).[1,2] They possess a characteristic heterocyclic skeleton, and are useful starting materials of the synthesis of various new heterocycles. The X-ray analysis of the title compound (**3**) has been performed to confirm its exact structure, since the arrangement of phosphorus and sulfur atoms in the molecule are difficult to elucidate by spectroscopic methods (IR, ^{1}H-, and ^{13}C-NMR spectra).

3 : Ar = Ph

Experimental

The synthesis of the compound was described previously.[1] Crystals were obtained from chloroform as colorless hexagonal platelets with a well-developed(010) cleavage plane.

After determining preliminary cell parameters and space group from Weissenberg photographs, a crystal with dimensions of 0.35×0.40×0.50 mm was mounted with the c axis parallel to the ϕ-axis on a Hilger & Watts diffractometer. Lattice parameters were determined by a least-squares procedure with setting angles of 12 reflections with $20.9°<\theta<25.9°$ (Zr-filtered Mo $K\alpha$ radiation, λ=0.7107 Å). The intensities were recorded with a θ-2θ step scan mode at every 0.02° of θ step up to $2\theta\leq55°$. The scan width of θ was 0.8° for all the reflections. Counting time was 1 s count at each 40 steps of 0.04° in 2θ, background count of 5 s at each end of the scan range. Three standard reflections, (040, 021, and 210) monitored every 50 measurements, showed changes within ±3% of $|F|$'s throughout the data collection. Of the 6408 independent reflections measured, 3320 with $F_o\geq3\sigma(F)$ were used for further calculations. Lorentz and polarization corrections were applied as usual, but the absorption correction was not made. Density was observed by the flotation method with K_2HgI_4 aqueous solution.

Crystal Data: $C_{26}H_{31}S_3P$, M_r=470.68, orthorhombic, a=17.116(4), b=19.798(4), c=14.898(3) Å, V=5048.4 Å^3 (21 °C); absent spectra: $0kl$ k odd, $h0l$ l odd, $hk0$ h odd; Space group Pbca; D_m=1.23, D_x=1.239 g cm^{-3}; Z=8; μ=3.58 cm^{-1} (Mo $K\alpha$).

Solution and Refinement of the Structure

The structure was solved by the direct method.[3] After several cycles of block-diagonal least-squares refinement, 19 H atoms were located on a difference Fourier map. The next cycles with anisotropic non-H atoms and isotropic 19 H atoms reduced R to 0.090. Then, difference Fourier map revealed the remaining 12 H atoms. The final refinement was carried out with the full-matrix least-squares with the anisotropic thermal parameters for non-H atoms, a fixed isotropic thermal parameter for H atoms, B=4.0 Å^2, and anomalous dispersion corrections for S and P atoms. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$, where $w=[\sigma^2(F_o)]^{-1}$ and $\sigma(F_o)$ is the standard deviation in the observed amplitudes based on counting statistics.

In the final cycle, the maximum parameter shft/error was less than 0.5. Final R and $R_w=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}$ were 0.083 and 0.038, respectively, where two reflections (040 and 021) were given zero weight because they were seriously affected by extinction. A final difference synthesis showed no significant feature. The atomic scattering factors with anomalous corrections were adopted from "International Tables for X-ray Crystallography."[4] All the computations were performed on a HITAC M-200H computer at the Compurter Center of Tokyo University with the *UNICS* program system.[5]

Discussion

The final atomic coordinates and equivalent temperature parameters are listed in Table 1. The numbering scheme is given in Fig. 1 with the bond distances, and Table 2 shows the bond angles.[6] Figure 2 gives the stereoscopic view of the molecule drawn by *ORTEP*.[7]

The bicyclo skeleton has a shallow envelope thiaphosphacyclopentene ring and a boat-form thiaphosphacyclohexene ring, which are cis-fused together with the bridging P-C(4) bond that is the side of the boat of the six-membered ring.

The molecule possesses three stereochemically char-

TABLE 1. THE FINAL FRACTIONAL COORDINATES AND EQUIVALENT ISOTROPIC THERMAL PARAMETERS

Estimated standard deviations are given in parentheses. The equivalent isotropic thermal parameters for non-hydrogen atoms are calculated using the expression: $B_{eq}=4/3\sum_i\sum_j \mathbf{a}_i\mathbf{a}_j\beta_{ij}$, where the $\mathbf{a}_i$'s are the unit cell edges in direct space. The isotropic thermal parameter of hydrogen atoms is fixed, $B=4.0$ Å^2.

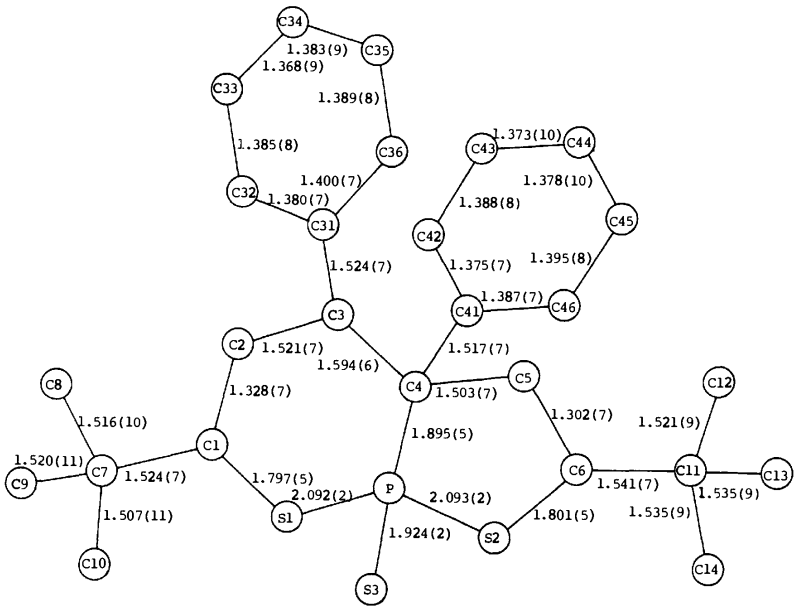

Fig. 1. Atom numbering and bond distaces (Å) of **3**. E.s.d.'s are in parentheses.

acteristic features. (i) The conformation of six-membered ring is a boat-form, as mentioned above. (ii) Several abnormal bond distances and bond angles are observed about the bridgehead P and C(4) atoms. The C(3)-C(4) bond distance of 1.594(6) Å is apparently longer than the commonly accepted C-C bond distance, and the observed P-C(4) bond distance of 1.895 (5)Å is longer than the average P-C bond distance of 1.832(7) Å in 4-*t*-butyl-5-cyano-2-phenyl-1-thioxo-7-thia-1-phosphabicyclo[2.2.1]hept-2-ene,[2] which was synthesized by using **3** as the starting material.[1] (iii) Though C(3) is a chiral atom, the conformational isomer has not been found in the present study.

These features can be elucidated by positing the existence of two double bonds in the ring system and the four bulky substituents, especially two neighboring phenyl groups. *cis*-8-Azabicyclo[4.3.0]non-3-ene methiodide[8] possesses a boat-form cyclohexene ring, which consists of six ring carbon atoms with no substituents except for hydrogen atoms. It has a similar bicyclo skeleton to that of **3** and has no abnormal bond distances in the ring system. So, if both bridgehead atoms are tetrahedrally bonded, the most stable conformation of *cis*-fused bicyclo[4.3.0]non-3-ene ring must be a boat-form. In the case of the present compound (**3**), moreover, the second ethylenic group in the five-membered ring, makes the *trans*-fusing of two rings impossible. The elongation of P-C(4) and C(3)-C(4) bonds are due to the strain caused by the neighboring phenyl groups: such a situation is often observed in fused ring systems with bulky substituents.[9] The phenyl group attached to the C(3) takes a position eclipsed to the H(2), while it is staggered (gauche) to the other phenyl group attached to

	C (44)	−0.008		

Average e.s.d.'s are 0.04 Å for Planes E1 and E2, and 0.007 Å for Planes P1 and P2. Orthogonal coordinates X, Y, and Z (Å) are parallel to the crystal axes a, b and c.

Atoms marked with asterisk were excluded from the calculations.

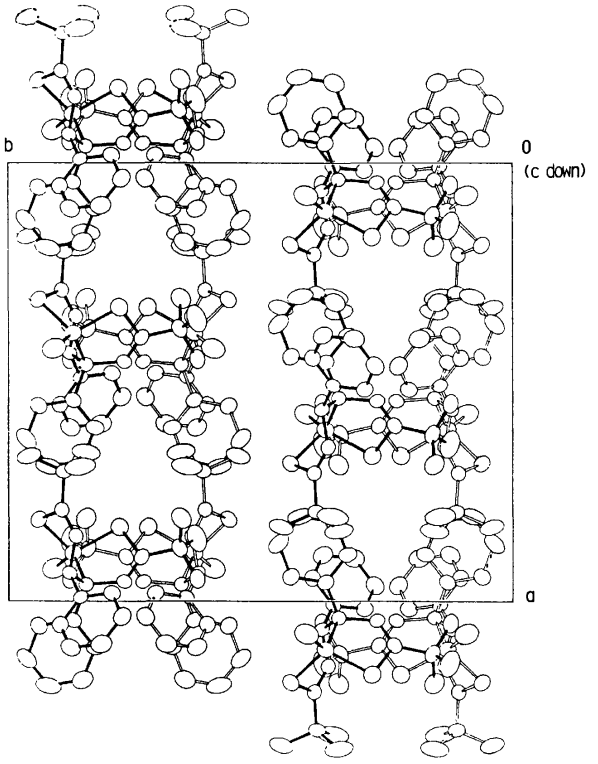

Fig. 3. Crystal structure of **3** projected along the *c* axis. The thermal ellipsoids for non-H atoms are at the 50% probability level. H atoms are omitted.

the C(4). Since this stereochemical feature gives the minimum Pitzer strain, the formation of a conformational isomer about C(3) must be difficult. Several torsion angles related to the six-membered ring are listed in Table 3.

The two ethylenic groups and the two phenyl groups each form fairly good planes. Table 4 gives their least-squares planes with deviations of atoms from them. The dihedral angles between the planes are as follows: E1-P1, 44.2°; E2-P2, 45.3°, and P1-P2, 48.9°.

The crystal structure of **3** is shown in Fig. 3.[7] There are no special interactions between the molecules, since all the intermolecular atomic distances are considered to be van der Waals contacts.

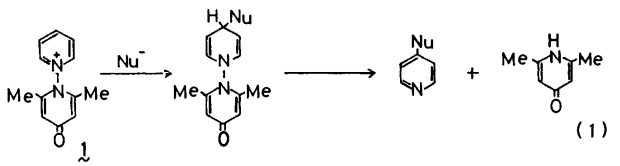
A Convenient Method for the Regioselective Synthesis of 4-Alkyl(aryl)pyridines Using Pyridinium Salts

Kin-ya AKIBA,* Yūji ISEKI, and Makoto WADA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730
(Received December 24, 1983)

$RCu \cdot BF_3$ reacted with 1-ethoxycarbonylpyridinium chloride at the 4-position with almost complete regioselectivity (>99%) to afford the corresponding 1,4-dihydropyridine derivatives in high yields (81—94%). The dihydropyridines were oxidized by oxygen to give 4-alkyl(aryl)pyridines (38—68%). Grignard reagents also reacted with 1-*t*-butyldimethylsilylpyridinium triflate with almost complete regioselectivity (>99%) to afford the corresponding 1,4-dihydropyridines, which were easily oxidized by oxygen to give 4-substituted pyridines in higher yields than above (58—70%).

Considerable efforts have been directed at the introduction of substituents directly onto pyridine using organometallic reagents.[1] Organolithiums were shown to add to the 2-position selectively in high yields[2] and Grignard reagents to the 2- and 4-positions under forceful conditions in low yields.[3] 2-Lithio-1,3-dithiane adds to the 4-position and 4-formylpyridine is obtained after hydrolysis and air-oxidation.[4] However, it is necessary to activate pyridine as the pyridinium salt for facile reaction with organometalloids. Grignard and organocadmium reagents afford 2-substituted 1-acyl-1,2-dihydropyridines in good yields under mild conditions.[5]

Lithium dialkylcuprate (I) is the only organometallic reagent known which adds to the 4-position of a pyridinium salt predominantly,[6] but one half of the alkyl group of the reagent is inevitably wasted. Therefore, it still remains to devise some pertinent method to introduce substituents selectively into the 4-position of pyridine. Recently, Katritzky and co-workers challenged this problem successfully and reported the synthesis of 4-substituted pyridines in good yields starting with 1-(2,6-dimethyl-4-oxo-1,4-dihydro-1-pyridyl)pyridinium salt (**1**), where the 2,6-positions of the pyridinium moiety is sterically shielded.[7]

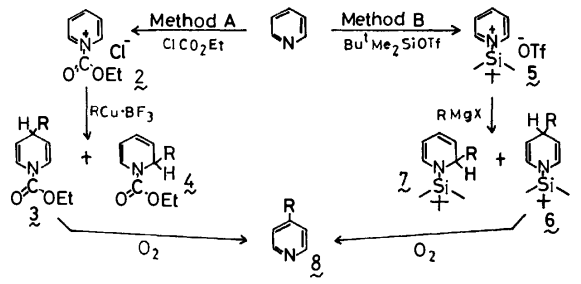


(1)

In order to circumvent the preparation of the special starting material **1** and to start with pyridine itself, we investigated successfully the following two methods (Scheme 1) with the objective to, *i.e.*, i) use softer and maybe bulkier nucleophiles to increase the regioselectivity of attack at the 4-position of 1-ethoxycarbonylpyridinium chloride (Method A), ii) use the most versatile nucleophile, Grignard reagents, and choose bulky quaternizing reagents to shield the 2- and 6-positions sterically, which can readily be eliminated to give the pyridine nucleus (Method B).

Both methods showed better than a 99% selective nucleophilic attack at the 4-position relative to the 2-position.[8]

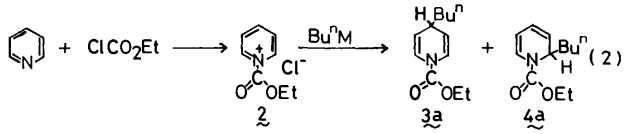
Quite recently after our research had been completed, we became aware of the results of Comins and Abdullah[9] which is closely related to Method A. This fact prompted us to publish our results in full.



Scheme 1.

Results and Discussion

Regioselective Synthesis of 4-Alkyl(aryl)pyridines by Method A. We examined the reaction of ethoxycarbonylpyridinium chloride with butylmagnesium bromide in tetrahydrofuran (THF) at 0 °C first in order to find a convenient procedure to convert the 1,2-dihydropyridine into the 2-substituted pyridine. While Fraenkel *et al.* obtained only 1,2-dihydropyridine (**4a**) in a moderate yield,[5a] a mixture (80% total yield) of 1,2-dihydropyridine (**4a**) and 1,4-dihydropyridine (**3a**) was obtained in a ratio of 65 to 35. A similar result was obtained with hexylmagnesium bromide. Furthermore, our result was confirmed recently by Comins *et al.*[9] and Yamaguchi *et al.*[10]



(2)

We then examined the reaction of **2** with butyllithium in ether, in which case the corresponding dihydropyridine was not obtained but the original pyridine was recovered. On the other hand, the reaction of **2** with $Bu^nLi \cdot BBu^n_3$ in ether afforded a mixture of **3a** and **4a** in a ratio of 75 to 25 with a total yield of 42%. Accordingly, we investigated the reaction of $Bu^nMgBr \cdot BBu^n_3$, Bu^nCu, and $Bu^nCu \cdot BF_3$[11] with **2** and the results are summarized in Table 1. Exclusive attack at the 4-position was achieved with Bu^nCu and $Bu^nCu \cdot$

Table 1. Reaction of various organometallic reagents with **2**

Nucleophile		Yield of **3a** and **4a**(%)[3]	Ratio=1,4-(**3a**)/1,2-(**4a**)[4]	Solvent
Bu^nMgBr		80	35/65	THF
HexMgBr		90	30/70	THF
Bu^nLi		0	—	ether
$Bu^nLi \cdot BBu^n_3$ [1]		42	75/25	ether
$Bu^nMgBr \cdot BBu^n_3$ [1]		58	62/38	THF
Bu^nCu	(Bu^nLi+CuI)	35	—	ether
	(Bu^nMgBr+CuI)	78	99.5/0.5	THF
$Bu^nCu \cdot BF_3$[2]	(Bu^nLi+CuI)	48	98.0/2.0	ether
	(Bu^nMgBr+CuI)	59	99.2/0.8	ether
	(Bu^nMgBr+CuI)	89	99.5/0.5	THF

1) Tributylborane complex was prepared by addition of the borane to Bu^nLi or Bu^nMgBr at −78 °C. 2) This reagent was prepared following the procedure of Maruyama and Yamamoto.[11] 3) Isolated yield by Kugelrohr distillation. 4) Product ratio was determined by GLC analysis (5% Apiezon Grease L on Chromosorb WAW DMCS, 100 °C→230 °C).

Table 2. Regioselective synthesis of **3** and **8**

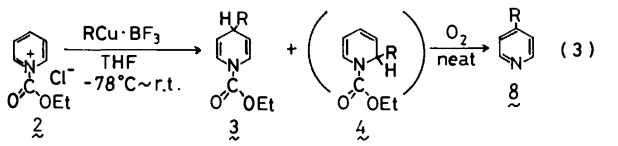
	R	Total yield of **3** and **4**[1](%)	Ratio: 1,4-(**3**)/1,2-(**4**)[2]	Oxidation time (h)	Yield of **8**[3] (%)	Overall yield from Py (%)
a	$CH_3(CH_2)_3$-	89	99.5/0.5	1	68	61
b	$CH_3(CH_2)_5$-	85	99.7/0.3	1	66	56
c	$PhCH_2CH_2$-	81	100/0	19	55[4]	45
d	CH_3CH_2(CH$_3$)CH-	83	99.7/0.3	7	38[4]	32
e	Ph-	94	99.0/1.0	12	59	55

1) Isolated yield by Kugelrohr distillation. Satisfactory IR and ^1H NMR data were obtained for these compounds and satisfactory MS data was obtained for **3a**. 2) By GLC analysis (5% Apiezon Grease L on Chromosorb WAW DMCS, 100 °C⟶230 °C). 3) Isolated yield by Kugelrohr distillation. Identified by IR and ^1H NMR spectroscopy and MS. 4) Lower yields may be due to over-oxidation.

BF_3 in high yield in THF (**3a**:**4a**=~99.5:~0.5). The total yields were about 10% higher with $Bu^nCu \cdot BF_3$ than with Bu^nCu under the same conditions as shown in Table 1. This can probably be ascribed to the relative stability of the copper reagents.

It was also found that the yield of **3a** was higher when butylmagnesium bromide was used as a source of organocopper reagent compared with that using butyllithium.

Therefore, we examined the reaction of various $RCu \cdot BF_3$ reagents with **2** in THF and some of the results are summarized in Table 2. Evidently this method is superior to that with lithium dialkylcuprate (I),[6] because one equivalent of an alkyl group is transferred to the pyridine nucleus stoichiometrically. Moreover, the ratio (99.0:1.0) remains high even with $PhCu \cdot BF_3$, whereas it lowered to 90:10 with lithium diphenylcuprate (I).

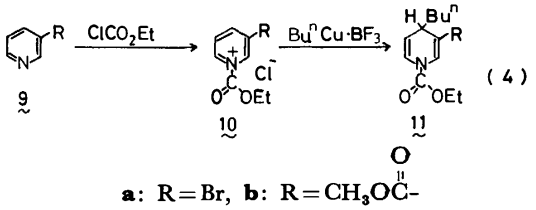


(3)

It is noteworthy that 1,4-dihydropyridines (**3**) can be obtained pure and stable by distillation with quick work-up in the air. 1,4-Dihydropyridines (**3**) were fully characterized as described in Experimental Section. The ^1H NMR of **3a** in $CDCl_3$ (δ) showed the 4-H at 2.72—3.10 as a multiplet, the 3-H and 5-H at 4.77 as a broad double of doublet (J=8 and 3 Hz), and the 2-H and 6-H at 6.79 as a broad doublet (J=8 Hz). The characteristic ^1H NMR signals are almost identical to all **3**.

On the other hand, it is well known that dihydropyridine derivatives are susceptible to oxidation and a small amount of oxidized product **8** was often detected by ^1H NMR. Therefore, oxidation of **3a** in solution (CH_2Cl_2 and THF) was effected by bubbling dry air or oxygen during 10—15 h, but the yield of **8a** was 40—50%. The product **8a** was obtained in 68% yield by oxidation of the neat liquid **3a** under an oxygen atmosphere with stirring for 1 h followed by distillation. Others were oxidized similarly as shown in Table 2. Oxidation of **3e** proceeds sluggishly. The lower yield of **8c** and **8d** may be ascribed to overoxidation. Other oxidations of **3a** were less successful, *i.e.*, i) with H_2O_2-NaOH in THF for 3 d at r.t., 24%; ii) with MCPBA in CH_2Cl_2 for 12 h at r.t., 9%; iii) MCPBA in CH_2Cl_2 for 3 h at reflux, 10%; iv) with *p*-benzoquinone in CH_2Cl_2 at r.t., no reaction took place and at reflux for 3 h, only a tarry residue was obtained. Although oxidation of **3a** to **8a** was performed with silver nitrate in THF at r.t. in 67% yield and that with sulfur has been reported,[12] we adopted the above mentioned procedure mainly due to its simplicity.

We next demonstrated the utility of this method to some of substituted pyridines to investigate the limitation of this method. First, reaction of the 3-bromopyridinium salt (**10a**) with $Bu^nCu \cdot BF_3$ was carried out by the same procedure as described above where 3-bromo-4-butyl-1-ethoxycarbonyl-1,4-dihydropyridine (**11a**) was obtained in 42% yield after Kugelrohr distillation. In a similar manner, reaction of the 3-methoxycarbonylpyridinium salt (**10b**) was tried, however, the reaction mixture was very complicated. Purification of the mixture by flash column chromatography afforded 4-butyl-1-ethoxycarbonyl-3-methoxycarbonyl-1,4-dihydropyridine (**11b**, 19%) and its oxidized product, 4-butyl-3-methoxycarbonylpyridine (12%).



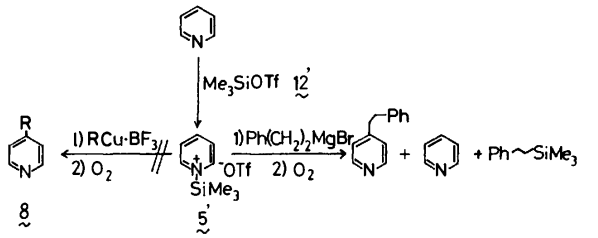
(4)

a: R=Br, **b**: R=CH_3OC(=O)-

On the other hand, when α-picoline was used the desired product was not obtained because the α-picolinium salt was not prepared in a pure state at 0 °C with or without solvent and a dark brown viscous oil was gradually produced. It was reported that the α-picolinium salt can be prepared below −20 °C and used for the reaction with a Grignard reagent in the presence of CuI, although the yields were low.[9]

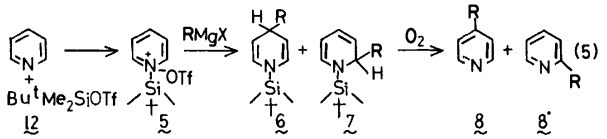
Regioselective Synthesis of 4-Alkylpyridines by Method B. In the regioselective synthesis of 4-alkylpyridines *via* Method A, the total yield was not so high as desired due to the moderate yield in the oxidation step. We now describe a more facile and handy method for the regioselective synthesis of 4-alkylpyridines using Grignard reagents as the nucleophile and a silyl triflate as a quaternizing reagent. The silyl group is electron-donating and the resulting 1,4-dihydropyridines can be oxidized more easily.

The reaction of pyridine with trimethysilyl chloride was carried out first, however, the corresponding pyridinium salt was not obtained under several conditions since the chloride anion seemed to attack the silicon to dissociate the pyridinium salt. Trimethylsilyl trifluoromethanesulfonate (**12′**) was then used as a quaternizing reagent because trifluoromethanesulfonate anion has a low nucleophilicity. The reaction of pyridine with **12′** in CH_2Cl_2 at 0 °C afforded the trimethylsilylpyridinium triflate (**5′**) as a white solid after removal of the solvent. When **5′** was allowed to react with a couple of $RCu \cdot BF_3$ in THF, no desired product was obtained after the oxidation procedure and pyridine was recovered. This result suggests that the trimethylsilyl group does not activate the pyridinium moiety sufficiently, compared to the ethoxycarbonyl group, for $RCu \cdot BF_3$ to add to **5′**. Phenethylmagnesium bromide in THF was then added to a suspension of **5′** in THF at room temperature. After oxidative work-up phenethylpyridine was obtained in 29% yield where the ratio of the 4- to 2-derivative was 99 to 1. Trimethylphenethylsilane and pyridine were the major products.



Scheme 2.

Since reaction of *t*-butyldimethylsilyl chloride with nucleophiles is 10^4 times slower relative to trimethylsilyl chloride,[13] we used *t*-butyldimethylsilyl triflate (**12**) as a quaternizing reagent. When *t*-butyldimethylsilylpyridinium triflate (**5**), prepared from **12** and pyridine, was reacted with phenethylmagnesium bromide followed by oxidation of **6** and **7** using oxygen, 4- and 2-phenethylpyridines were obtained (67%, **8c**:**8′c**= 98.9:1.1). The reaction of various Grignard reagents with **5** was attempted and some of results are summarized in Table 3.



(5)

When the entire process is carried out in one-pot, *i.e.*, oxygen was bubbled through a mixture of THF and aq $NaHCO_3$ solution, the yields of 4-alkylpyridines were 10—20% lower than the results shown in Table 3.

It should be noted that there is definitely a limitation to this method depending on the nature of the nucleophiles. When butyllithium was used instead of butylmagnesium bromide, the total yield of butylpyridine was 58% according to the standard procedure and the ratio of 4- to 2-substitution was 85 to 15, showing poorer selectivity. The lithium enolate of acetophe-

Table 3. Regioselective synthesis of 4-alkylpyridines (**8**)

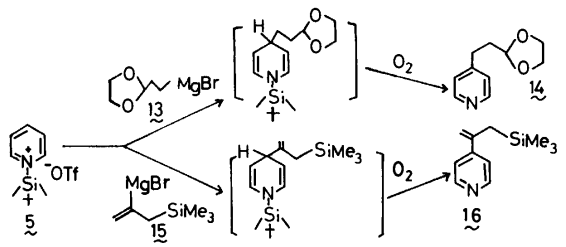
1) Isolated yield based on pyridine after Kugelrohr distillation. 2) Isolated yield after TLC (SiO_2, $MeCO_2Et$) purification. 3) Yield after ether extraction (pure by ^1H NMR). 4) Determined by GLC (5% Apiezon Grease L on Chromosorb WAW DMCS, 150—200 °C).

none and Grignard type reagent of 2-mercaptoacetate attacked the silicon of **5** almost exclusively. On the other hand, no reaction took place with **5** when dibutylboron enolate and trimethylsilyl enol ether of acetophenone and the Reformatzky reagent of ethyl bromoacetate were used.

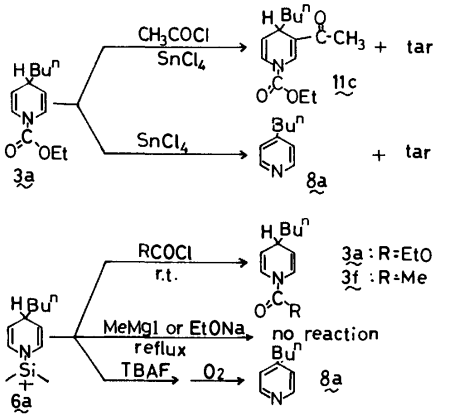
We also applied this reaction to introduce functional groups other than alkyl and aryl groups into the 4-position of the pyridine ring. First, the reaction of **5** with the Grignard reagent **13**, prepared from 2-bromopropionaldehyde ethylene acetal, afforded 3-(4-pyridyl)propionaldehyde ethylene acetal (**14**) in 50% yield after oxidation under a stream of oxygen followed by purification. In a similar fashion, **5** reacted with 1-(trimethylsilylmethyl)vinylmagnesium bromide[14] (**15**) to give **16** in 38% yield after standard work-up. Thus, it was demonstrated that almost any Grignard reagent containing some functional group can be introduced selectively at the 4-position of pyridine.



Scheme 3.

Attempted Reactions of 1,4-Dihydropyridines as Enamines. Since 1-ethoxycarbonyl-1,4-dihydropyridines (**3**) can be obtained easily after distillation and 1-*t*-butyldimethylsilyl-1,4-dihydropyridines (**6**) can be generated *in situ* in high yield, we investigated their use as enamines to introduce a second substituent into the 3-position. There is only one such a report by Shōno *et al.* where the Vilsmeier reaction of 1-methoxycarbonyl-1,4-dihydropyridine gave 3-formyl-1-methoxycarbonyl-1,4-dihydropyridine in 75% yield.[15] When acetylation of **3a** was carried out in dichloromethane at −78 °C in the presence of a ten molar excess of acetyl chloride and tin tetrachloride, the expected **11c** was obtained in 21% yield after separation by flash column chromatography. Although **11c** gave correct ^{1}H NMR and IR spectra, it gradually deteriorated under careful handling. At r.t., **3a** was oxidized by tin tetrachloride to **8a** in low yield (*ca.* 30%) together with tarry material.

Since the silyl group is electron-donating, acylation of **6a** generated *in situ* by Method B was attempted. However, exchange of the silyl group for the acyl group occurred unexpectedly in moderate yield (R=EtO, 57%; R=Me, 65%).[16] Although the mechanism of this exchange is not clear, electron transfer from **6a** to the acylating reagent may take place at the initial stage of the reaction, because nucleophilic attack at the N-Si bond should not take place due to the steric effects of the silyl group as exemplified by the inertness of the bond to methylmagnesium iodide and sodium ethoxide. Desilylation by TBAF (tetrabutylammonium fluoride) took place to give **8a** in high yield after usual work-up in the air.



Scheme 4.

Experimental

Infrared spectra were recorded with a Hitachi 215 spectrophotometer. ^{1}H NMR spectra were recorded with a Varian T-60 spectrometer and chemical shifts (δ) were reported in ppm using internal tetramethylsilane. Mass spectra were measured with a Hitachi RMU-6L spectrometer. Boiling points quoted for products distilled in a Kugelrohr apparatus refer to the oven temperature. Melting points were measured using a Yanagimoto micro melting point apparatus and are uncorrected. GLC was performed with a Yanagimoto gas chromatograph G-180 equipped with a 3.0 m×4 mm column, packed with 5% Apiezon Grease L on Chromosorb WAW DMCS. Merck 230—400 mesh silica gel (art 9385) was used for flash column chromatography. All reactions were carried out under a nitrogen atmosphere using syringe and septum techniques.[17] THF and diethyl ether were freshly distilled from Na/benzophenone. Pyridine, α-picoline, and alkyl halides were distilled from CaH_2 under nitrogen. Ethyl chloroformate and boron trifluoride etherate were used after simple distillation under nitrogen. Trimethylsilyl chloride was used after distillation in the presence of a small amount of quinoline. Trimethylsilyl triflate and *t*-butyldimethylsilyl triflate were prepared according to the literature.[18] Butyllithium in hexane was carefully standardized prior to use.

Preparation of 4-Alkyl-1-ethoxycarbonyl-1,4-dihydropyridines (3) by the Reaction of 1-Ethoxycarbonylpyridinium Chloride (2) with RCu·BF$_3$. Method A. 4-Butyl-1-ethoxycarbonyl-1,4-dihydropyridine (3a). General Procedure: Butylmagnesium bromide, prepared from butyl bromide (1.90 ml, 17.6 mmol) and magnesium (0.43 g, 17.6 mmol) in THF (30 ml), was added to a suspension of CuI (3.36 g, 17.6 mmol) in THF (60 ml) at −20 °C under nitrogen through a double-ended needle and the mixture was stirred for 10 min at that temperature. The mixture was then cooled to −78 °C and $BF_3 \cdot OEt_2$ (2.17 ml, 17.6 mmol) was added slowly. After stirring for 10 min at −78 °C, the resulting dark brown mixture was transferred through a double-ended needle to a suspension of the pyridinium salt, which was prepared from pyridine (1.22 ml, 15.0 mmol) and ethyl chloroformate (1.44 ml, 15.0 mmol) in THF (60 ml) at 0 °C, and the mixture was allowed to warm to room temperature with stirring. The color changed from dark brown to dark gray. After the reaction mixture was stirred for 3 h at room temperature, aq 5% $NaHCO_3$ (100 ml) was added and the THF was evaporated under reduced pressure. The following procedure must be carried out quickly because the 1,4-dihydropyridine is easily oxidized. The product was extracted with ether (30 ml×3) and the solvent was evaporated under reduced pressure after drying ($MgSO_4$). The

crude product was purified by Kugelrohr distillation to afford 4-butyl-1-ethoxycarbonyl-1,4-dihydropyridine (2.80 g) in 89% yield. bp 125—135 °C/1.0 mmHg (by Kugelrohr distillation); ^{1}H NMR ($CDCl_3$) δ=0.60—1.50 (m, 12H), 2.72—3.10 (m, 1H), 4.19 (q, 2H, J=7 Hz), 4.77 (br. dd, 2H, J=8, 3 Hz), and 6.79 (br. d, 2H, J=8 Hz); IR (neat) 2940, 1720, 1690. 1635, 1470, 1415, 1400, 1375, 1335, 1310, 1210, 1120, 970, 950, 760, and 740 cm^{-1}; MS (m/z) 209 (M^+, 14.7%), 152 (100), 135 (32.2), 108 (58.0), and 83 (76.7); Ratio: **3a**/**4a**=99.5/0.5 (by GLC analysis); Calcd for $C_{12}H_{19}NO_2$: C, 68.86; H, 9.15; N, 6.69%; Found: C, 68.60; H, 9.45; N, 6.61%.

*1-Ethoxycarbonyl-4-hexyl-1,4-dihydropyridine (**3b**).* Yield 81%; bp 140—165 °C/0.15 mmHg (by Kugelrohr distillation); ^{1}H NMR ($CDCl_3$) δ=0.90—1.70 (m, 16H), 2.76—3.10 (m, 1H), 4.11 (q, 2H, J=7 Hz), 4.81 (br. dd, 2H, J=8, 3 Hz), and 6.74 (br. d, 2H, J=8 Hz); IR (neat) 2930, 1720, 1690, 1635, 1465, 1415, 1395, 1375, 1335, 1310, 1205, 1110, 955, 760, 740 cm^{-1}; Ratio: **3b**/**4b**=99.7/0.3 (by GLC analysis).

*1-Ethoxycarbonyl-4-phenethyl-1,4-dihydropyridine (**3c**).* Yield 81%; bp 140—150 °C/0.50 mmHg (by Kugelrohr distillation); ^{1}H NMR ($CDCl_3$) δ=1.28 (t, 3H, J=7 Hz), 1.50—1.90 (m, 2H), 2.40—2.80 (m, 2H), 2.80—3.20 (m, 1H), 4.22 (q, 2H, J=7 Hz), 4.84 (br. dd, 2H, J=8, 3 Hz), 6.79 (br. d, 2H, J=8 Hz), and 7.17 (s, 5H); IR (neat) 2940, 1730, 1635, 1400, 1380, 1340, 1315, 1215, 1120, 960, 740, and 700 cm^{-1}; Ratio: **3c**/**4c**=100/0 (by GLC analysis).

*4-s-Butyl-1-ethoxycarbonyl-1,4-dihydropyridine (**3d**).* Yield 83%; bp 115—125 °C/0.35 mmHg (by Kugelrohr distillation); ^{1}H NMR ($CDCl_3$) δ=0.60—1.60 (m, 12H), 2.85—3.13 (m, 1H), 4.21 (q, 2H, J=7 Hz), 4.77 (br. dd, 2H, J=8, 3 Hz), and 6.80 (br. d, 2H, J=8 Hz); IR (neat) 2950, 1720, 1690, 1635, 1465, 1415, 1330, 1310, 1210, 1110, 975, 760, and 730 cm^{-1}; Ratio: **3d**/**4d**=99.7/0.3 (by GLC analysis).

*1-Ethoxycarbonyl-4-phenyl-1,4-dihydropyridine (**3e**).* Yield 94%; bp 185—195 °C/0.70 mmHg (by Kugelrohr distillation); ^{1}H NMR ($CDCl_3$) δ=1.29 (t, 3H, J=7 Hz), 4.25 (q, 2H, J=7 Hz), 4.10—4.30 (m, 1H), 4.89 (br. dd, 2H, J=8, 3 Hz), 6.85 (br. d, 2H, J=8, 3 Hz), and 7.10—7.60 (m, 5H); IR (neat) 2980, 1720, 1690, 1630, 1415, 1375, 1335, 1310, 1205, 1115, 980, 840, 725, and 695 cm^{-1}; Ratio: **3e**/**4e**=99.0/1.0 (by GLC analysis).

*The Conversion of **3** into 4-Alkylpyridine (**8**). 4-Butylpyridine (**8a**). General Procedure*: The dihydropyridine (**3a**: 0.338 g, 1.62 mmol) was placed in a flask under an atmosphere of oxygen without solvent. Stirring was continued until TLC analysis indicated that the starting material was consumed (*ca.* for 6 h). Aqueous 5 M HCl (1 M=1 mol dm^{-3}) was added to the mixture until a pH of 2 was obtained and the organic layer was extracted with water (20 ml×3). The acidic solution was then treated with aqueous 3M NaOH until a pH of 11 was obtained. The product was extracted with CH_2Cl_2 (50 ml×2) and the extracts were dried over anhydrous $MgSO_4$, filtered, concentrated under reduced pressure, and distilled by Kugelrohr to give 0.149 g (68%) of 4-butylpyridine (**8a**), which gave correct elemental analysis. Bp 90—100 °C/12 mmHg (lit,[20] bp 98 °C/20 mmHg).

*4-Hexylpyridine (**8b**).* Yield 66%; bp 120—140 °C/18 mmHg (by Kugelrohr distillation) (lit,[9] bp 130—132 °C/16 mmHg).

*4-Phenethylpyridine (**8c**).* Yield 55%; mp 68.5—70.0 °C (from hexane); (lit,[21] mp 70—71 °C).

*4-s-Butylpyridine (**8d**).* Yield 38%; bp 125—145 °C/25 mmHg (by Kugelrohr distillation) (lit,[22] bp 90—150 °C/20 mmHg; bp 194—195 °C/740 mmHg).

*4-Phenylpyridine (**8e**).* Yield 59%; mp 75.5—76 °C (lit,[9]mp 73—74 °C).

*Preparation of 4-Alkylpyridines (**8**) by the Reaction of the N-Silylpyridinium Salts (**5**) with Grignard Reagent: Method B. 4-Butylpyridine (**8a**). General Procedure*: A solution of pyridine (0.38 ml, 4.70 mmol) in CH_2Cl_2 (5 ml) was cooled to 0 °C and *t*-butyldimethylsilyl triflate (**12**) (1.24 ml, 4.69 mmol) was added. After stirring for 5 min, the solvent was evaporated under reduced pressure to give the pyridinium salt as a white solid. The pyridinium salt can be also prepared without solvent. THF (7 ml) was added to the pyridinium salt and then cooled to ice bath temperature. Butylmagnesium bromide, prepared from butyl bromide (0.62 ml, 5.77 mmol) and magnesium (0.14 g, 5.76 mmol) in THF (20 ml), was added to a suspension of the pyridinium salt and the mixture was stirred for 2—3 h at room temperature under a nitrogen atmosphere. The crude product, which contained 20—40% of 4-butylpyridine due to air-oxidation, was obtained by ether extraction (15 ml×3) after quenching the mixture with 5% aq $NaHCO_3$ (30 ml). The mixture of crude product was placed in a flask and stirred for 3 h under an atmosphere of oxygen. The method of purification was the same as described for the synthesis of 4-alkylpyridine from 4-alkyl-1-ethoxycarbonyl-1,4-dihydropyridine (**3**). 4-Butylpyridine was obtained in 68% yield (**8a**:**8′a**=97.6:0.4, by GLC analysis). Overall yields of 4-alkylpyridines and ratios (4-alkylpyridine/2-alkylpyridine) were

*Hexylpyridine (**8b**).* :62% :99.5/0.5
*Phenethylpyridine (**8c**).* :64% :98.9/1.1
s-*Butylpyridine (**8d**).* :58% :98.8/1.2
*Phenylpyridine (**8e**).* :59% :99.7/0.3
*Propylpyridine (**8f**).* :61% :99.4/0.6

bp 70—85 °C/18 mmHg (by Kugelrohr distillation) (lit,[20] bp 80 °C/20 mmHg).

s-*Propylpyridine (**8g**).* :65% :99.0/1.0

bp 170 °C (by Kugelrohr distillation) (lit,[23] bp 173 °C).

*Pentylpyridine (**8h**).* :63% :99.5/0.5

bp 110—122 °C/15 mmHg (by Kugelrohr distillation) (lit,[20] bp 114 °C/20 mmHg).

*Octylpyridine (**8i**).* :69% :99.7/0.3

bp 103—115 °C/1 mmHg (by Kugelrohr distillation) (lit,[20] bp 91 °C/0.1 mmHg).

*3-(4-Pyridyl)propionaldehyde Ethylene Acetal (**14**).* Yield 50%; ratio: 4-substituted pyridine (**14**)/2-substituted pyridine (**14′**)=98.3/1.7; ^{1}H NMR (CCl_4) δ=1.69—2.12 (m, 2H), 2.52—2.88 (m, 2H), 3.68—4.03 (m, 4H), 4.76 (t, 1H, J=4.5 Hz), 7.01 (dd, 2H, J=4, 2 Hz), and 8.33 (dd, 2H, J=4, 2 Hz); IR (neat) 1605, 1410, 1135, and 1025 cm^{-1}.

*2-(4-Pyridyl)-3-trimethylsilyl-1-propene (**16**).* Yield 38%; ^{1}H NMR (CCl_4) δ=−0.07 (s, 9H), 1.98 (s, 2H), 4.95 (d, 1H, J=1 Hz), 5.25 (d, 1H, J=1 Hz), 7.17 (dd, 2H, J=5, 1.5 Hz), and 8.43 (dd, 2H, J=5, 1.5 Hz); IR (neat) 2960, 1595, 1405, 1245, 845, and 825 cm^{-1}.

Introduction of a Butyl Group into the 4-Position of 3-Substiteud Pyridines (3-Bromopyridine, Methyl nicotinate). The procedure for the synthesis of these compounds was the same as described above in the synthesis of 4-alkylpyridines by Method A.

*3-Bromo-4-butyl-1-ethoxycarbonyl-1,4-dihydropyridine (**11a**).* Attempts to purify **11a** by Kugelrohr distillation was not so successful as much residue was produced by polymerization during distillation. Almost pure **11a** was obtained after extraction as indicated by ^{1}H NMR in which case the yield was about 80%.

Yield 42%; bp 150—160 °C/0.5 mmHg (by Kugelrohr distillation); ^{1}H NMR ($CDCl_3$) δ=0.70—1.72 (m, 12H), 3.04—3.36 (m, 1H), 4.22 (q, 2H, J=7 Hz), 4.77 (dd, 1H, J=8, 4 Hz), 6.73 (d, 1H, J=8 Hz), and 7.07 (s, 1H).

*4-Butyl-1-ethoxycarbonyl-3-methoxycarbonyl-1,4-dihydropyridine (**11b**).* A portion of **11b** was oxidized to 4-butyl-3-methoxycarbonylpyridine during purification by flash

† 1 mm Hg≈133.322 Pa.

column chromatography.

Yield 19% (purified by flash column chromatography, SiO_2: hexane/AcOEt=9/1): ^1H NMR ($CDCl_3$) δ=0.65—1.90 (m, 12H), 3.04—3.36 (m, 1H), 3.77 (s, 3H), 4.34 (q, 2H, J=7 Hz), 5.10 (dd, 1H, J=8, 5 Hz), 6.87 (d, 1H, J=8 Hz), and 7.95 (s, 1H); IR (neat) 2960, 1730, 1710, 1625, 1470, 1400, 1375, 1330, 1230, 1175, 765, and 735 cm^{-1}.

4-Butyl-3-methoxycarbonylpyridine. Yield 12% (purified by flash column chromatography, SiO_2: hexane/AcOEt=9/1): ^1H NMR ($CDCl_3$) δ=0.75—1.85 (m, 7H), 2.98 (t, 2H, J=8 Hz), 3.94 (s, 3H), 7.17 (d, 1H, J=5 Hz), 8.42 (d, 1H, J=5 Hz), and 8.88 (s, 1H); IR (neat) 2950, 1720, 1585, 1275, and 1100 cm^{-1}.

*Reaction of 4-Butyl-1-t-butyldimethylsilyl-1,4-dihydropyridine (**6a**) with Acetyl Chloride and Ethyl Chloroformate. 1-Acetyl-4-butyl-1,4-dihydropyridine (**3f**)*: To the reaction mixture containing **6a**, prepared from **5** (2.47 mmol) and butylmagnesium bromide, was added acetyl chloride (0.23 ml, 3.23 mmol) at room temperature with stirring. After stirring for 2 h, the reaction mixture was quenched with 20 ml of 5% aqueous sodium hydrogencarbonate. The crude product was extracted with ether (15 ml×3), dried over anhydrous $MgSO_4$, filtered, and the solvent was removed under reduced pressure. Flash column chromatography (SiO_2, hexane/AcOEt=9/1) afforded 1-acetyl-4-butyl-1,4-dihydropyridine (**3f**) in a 65% yield (0.288 g). This compound is susceptible to be oxidized by oxygen.

^1H NMR (CCl_4) δ=0.87—1.55 (m, 9H), 2.11 (s, 3H), 2.80—3.07 (m, 1H), 4.60—5.00 (m, 2H), 6.30—6.60 (m, 1H), and 6.87—7.17 (m, 1H); IR (neat): 2920, 1670, 1375, 1325, and 1310 cm^{-1}.

*4-Butyl-1-ethoxycarbonyl-1,4-dihydropyridine (**3a**).* Yield 57% (flash column chromatography: SiO_2 hexane/AcOEt=9/1), spectral data were identical to those described before.

Partial support of this work was provided by Grant-in-Aid for Scientific Research (No. 554139) and that for Special Project Research (No. 56109002) administered by Ministry of Education, Science and Culture. Kind gift of silylating reagents is sincerely acknowledged for Chisso Co. Ltd.

(Received December 1, 1983)

Coal liquefaction experiments were carried out by using seven catalysts with different pore structures. As for the unimodal catalysts, the total conversion increased with the pore radius of the catalyst because of the lesser pore-diffusional limitation. However, the ratio of oil to oil-plus-asphaltene decreased with the pore radius. In the case of a large-pore catalyst, heavy components with a large molecular size and a low reactivity can approach the intra-particle active sites and occupy them to prevent the hydrocracking of asphaltene to oil. Bimodal catalysts with micropores ($r<10$ nm) and macropores ($r>300$ nm) gave higher values of both the coal liquefaction and the oil yields than did the unimodal catalysts. The presence of macropores seems to enhance the pore diffusion and increase the efficiency of the micropore use, while mesopores with radii between 10 nm and 300 nm did not make such a high contribution to the pore diffusion as was shown for the macropores. For the removal of heteroatoms, there was little difference in the performance among the catalysts with different pore structures. It is suggested that the active sites for the heteroatom removal are deactivated easily by the heavy components.

Molybdenum alumina catalysts have long been used for the hydrodesulfurization (HDS) of gas oil and the refining of the petroleum residue. Recently serious attention has been paied to the use of these catalysts for the direct liquefaction of coal in a fixed bed or an ebullated bed. However, since there are many differences in properties between coal (or coal derived liquids) and petroleum, MoO_3/Al_2O_3 catalysts designed for petroleum refining cannot show a high activity or favorable selectivity for the direct liquefaction of coal. Further, the catalytic activity, especially the hydrogenation activity, declines rapidly during the hydrotreatment of coal because of coke build-up and metal deposition on the surface of the catalyst.[1,2]

During the course of the development of molybdenum catalysts for coal liquefaction, a deliberate designing of the catalyst is absolutely necessary. For this purpose, it is necessary to clarify the effects of the properties of the catalyst on its activity, selectivity, and life. The present paper will describe the effects of the pore size distribution (PSD) on the activity and selectivity of the supported catalyst.

Recently, in the petroleum hydrotreating process the feedstocks have become heavier, and many kinds of functions besides HDS and hydrocracking activity, such as asphaltene conversion and demetallation, have come to be required for the catalyst. Furthermore, large amounts of poisoning materials contained in heavy feedstocaks deactivate the conventional HDS catalysts rapidly. One of the solutions to these problems can be found in designing the proper pore structure of catalyst support. Numerous catalysts with different pore structures have been tested and reported in many patents[3-10] and papers.[11-13] As a result of these investigations, some effects of the PSD on the catalytic activity and life have become obvious. They are;

1. The pore-diffusional limitation of the reaction rates is serious in the hydrotreating of heavy feedstocks than in the light gas oil.
2. The optimal pore structure may not be the same for every hydrotreating reaction, desulfurization, denitrogenation, asphaltene conversion, and demetallation.
3. Carbonaceous and metal deposition from the feedstocks on the catalysts varies as a function of the pore structure.

On the contrary, a few fundamental studies have been undertaken on the effects of the PSD of the catalyst used for coal liquefaction. Weller and his co-workers[14-16], by using several kinds of supports which have different average pore diameters, demonstrated that the catalysts with large pores showed a higher performance than those with small pores. Bertolacini *et al.*[17,18] indicated that a bimodal PSD is required for high performance, especially in terms of aging. As has been shown above, it has become somewhat clear that the PSD of the catalyst support plays an important role in the performance of the catalyst for coal liquefaction. However, the proper PSD of the catalyst for coal liquefaction will differ with the starting materials and with the products aimed at. Process conditions, such as the type of reactor, will also change the most favorable PSD. Accordingly, further practical studies have to be undertaken on the effects of the PSD on the catalytic activity, selectivity, and life in order to develop practical catalysts with high performance.

In the present study, the effects of the PSD on the activity and selectivity of the catalyst will be investigated by using both unimodal and bimodal catalysts. Moreover, the roles of micro-, meso-, and macropores in the catalytic activity will also be clarified. Seven catalysts with different PSD values, with the same weight loading of molybdenum, were prepared and screened for coal liquefaction in a batch autoclave. From the results of the product distribution and the removal of nitrogen and sulfur, the proper pore structure for each reaction will be discussed.

Experimental

Equipment. A 500-cm^3 autoclave with a magnedrive stirrer was used for all runs of coal liquefaction. The auto-

clave was equipped with a wire basket to prevent the catalysts from being crushed. The hydrogenation of 1-methylnaphthalene (1-MN) was carried out using a 50-cm³ autoclave in order to examine the activity of the catalysts.

Catalysts. Seven kinds of Al_2O_3 (sphere with a diameter of 1.6 mm) with different PSD values were chosen as catalyst supports (prepared by Sumitomo Aluminum Smelting Co., Ltd.). Figures 1—3 show the PSD curves of the catalyst supports (before impregnation with active components) as measured by using a mercury porosimeter (AMINCO 60,000 psi). The MoO_3/Al_2O_3 catalysts were prepared by impregnating the Al_2O_3 supports with an ammoniacal solution of ammonium heptamolybdate, and the $NiO-MoO_3/Al_2O_3$ catalysts with an ammoniacal solution of ammonium heptamolybdate and nickel nitrate. All the operations of the impregnation procedure were performed at pH values over 9.0 for 42 h (at 27 °C) using the equilibrium adsorption method.[19] The samples were subsequently dried (at 110 °C, 16 h) and calcined (at 300 °C, 50 min; subsequently at 500 °C, 3 h).

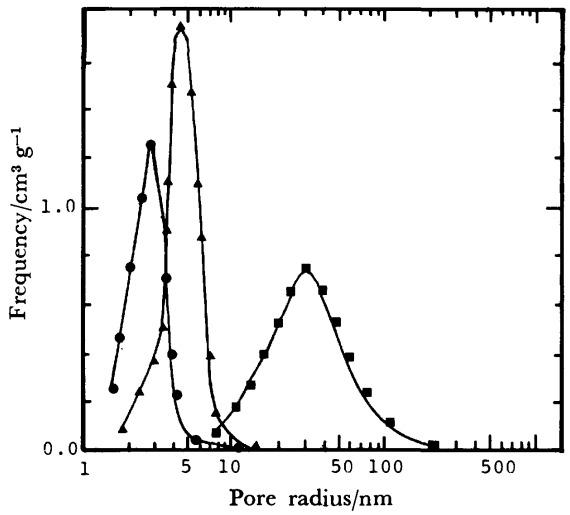

Fig. 1. Pore size distributions of catalysts.
●: Catalyst A, ▲: catalyst B, ■: catalyst C

The loading of molybdenum was determined by chemical analysis, and that of nickel, by the use of an X-ray fluorescence analyzer (Rigaku, Ultra Trace System). The specific surface areas and pore volumes of all the catalysts were measured by using the mercury porosimeter. The properties and the chemical components of the catalysts are summarized in Tables 1 and 2. Reductive sulfiding was carried out in a stream of 10 vol% of H_2S (balance H_2) at 350 °C for 2 h before liquefaction.

Procedures. *Coal Liquefaction*: The coal used was a subbituminous Taiheiyo coal containing 16.1% ash (dry base). The rersults of the elemental analysis of the coal were: C, 74.9; H, 6.2; N, 1.3; S, 0.4; O, 17.2% (moisture and ash free base). The powdered coal with a diameter smaller than 150 μm was dried at 110 °C in a nitrogen atmosphere before use. The solvent used was hydrogenated anthracene oil (HAO), which contained: C, 91.8; H, 7.0; N, 0.6; S, 0.1; O, 0.5%.

The autoclave was charged with coal (60 g), a solvent (140 g), and a catalyst (5 g), and then pressurized with H_2 to an initial pressure of 100 kg cm^{-2} at room temperature. The temperature of the unit was increased to 400 °C over a period of 2 h and then held at this temperature for 1 h. The stirring rate was 900 min^{-1} for all runs.

After cooling to room temperature, the gas was slowly discharged through a wet gas meter. During this letdown, a sample of the gas was collected in a syringe in order to determine the gas composition. The liquid and solid products were separated into "toluene insolubles," "asphaltene (toluene soluble and hexane insoluble)," and "oil (hexane soluble)" portions using a Soxhlet extractor. The nitrogen and sulfur contents in the liquid products were determined by means of a nitrogen and sulfur analyzer (Mitsubishi Kasei, MCI-TN-02).

Hydrogenation of 1-Methylnaphthalene (1-MN): The hydrogenation activity of the catalysts was examined using 1-MN as a reactant. The autoclave was charged with 10 cm^3 of 1-MN and 0.5 g of a catalyst, and then pressurized with H_2 to an initial pressure of 70 kg cm^{-2}. The unit was then heated to 375 °C over a 10-min period and then held at this temperature for 90 min. The analysis of the liquid product was done using a gas chromatograph equipped with a FFAP fused silica capillary column (25 m).

Results and Discussion

Conversion and Oil Yields. The results of the coal liquefaction and hydrogenation of 1-MN on molybdenum catalysts are summarized in Table 3. In the liquefaction of coal, the total conversion (oil-plus-asphaltene yields) and the oil yields for a blank run were much lower than those for runs with a catalyst. 1-MN did not react without a catalyst. These results made it clear that the catalysts accelerated the reaction rates.

In the liquefaction test, the gas composition for the blank run was: CO_2, 5.9; CO, 1.3; CH_4, 4.0; C_2H_6, 1.1% (in addition, trace amounts of H_2S and NH_3 were detected), whereas that for the runs with a catalyst was: CO_2, 6.0—6.4; CO, 1.5—1.6; CH_4, 4.0—4.2; C_2H_6, 1.5%. There was little difference in gas composition among runs with a catalyst. A small difference in the gas composition was found between runs with and without a catalyst. In catalytic runs the concentrations of CH_4 and C_2H_6 (hydrocarbons) were a little higher than those in the run without a catalyst. The hydrocracking activity of the catalyst seems to result in this difference.

Unimodal Catalysts: The total conversion increased with the pore size of the catalyst (A<B<C) despite the smaller surface area of the large-pore catalysts. In the case of the catalyst C, which has an eminently small surface area, the loading of MoO_3 exceeded the monolayer coverage. Therefore, the catalyst C showed a much lower activity for the hydrogenation of 1-MN. However, a higher total conversion was given for coal liquefaction by the catalyst C than by the catalysts A and B. This tendency shows that the production of asphaltene from coal was greatly affected by the pore structure of the catalyst because the pore diffusion limited the reaction rates seriously. On the other hand, with an increase in the pore diameter of the catalyst, the production of oil remained constant, or even decreased, the ratio of oil to oil-plus-asphaltene decreasing obviously.

Ho *et al.*[16] also reported that the total coal liquefaction was seriously limited by the pore diffusion, and that the ratio of oil to oil-plus-asphaltene decreased with an increase in the diameter of the catalyst pore. They explained that this phenomenon was due to the low reaction temperature (400 °C) when the oil production rate was small. In the present study, however, a high oil yield was given by some catalysts (D and E) in spite of a low reaction temperature. This result suggests that the pore structure of the catalyst also affected the production rate of oil from asphaltene.

It has been known that the molecular weight of the asphaltene derived from coal, although always much lower than that from petroleum, ranges from 400 to 800.[20-22] Considering the fact that the coal-derived asphaltene has a polyaromatic ring structure, its molecular size might be larger than 1 nm. In addition, large molecules with polyaromatic rings are known to have a tendency to aggregate with each other and to give a micell-like structure. It may thus be assumed that there exists a pore-diffusional limitation in the production of oil from asphaltene.

Mass-transfer theory for porous catalysts indicates that, in a series reaction, poor yields of intermediate

products are obtained for a catalyst with a low effectiveness factor.[23] In the case of coal liquefaction, asphaltene is an intermediate product, when coal is the starting material and oil is the final product of a series reaction, indicating that a small-pore catalyst with a low effectiveness factor gives a higher ratio of oil to asphaltene than dose a large-pore catalyst.

On the other hand, it is considered that heavy components with a low reactivity (heavier than preasphaltene) can reach the intra-particle active sites of large-pore catalysts and occupy them easily, thus preventing the hydrocracking of asphaltene to oil. In fact, the analysis of the aged catalyst showed that the carbonaceous materials deposited on the catalyst were heavy components with a lower H/C ratio than asphaltene.[24]

The contribution of the catalyst to coal liquefaction is considered to be smaller than that of the hydrogen-donor solvent at the first stage of liquefaction.[25,26] The effects of catalysts on the product distribution are reflected in the increase in light components, such as the oil or distillate fraction, especially in the case of molybdenum catalysts.[27,28] In the present study, all of the catalysts gave a higher ratio of oil to oil-plus-asphaltene than was observed in the blank run. This result shows that the production of oil was more accelerated by the catalysts than that of asphaltene. However, as has been shown above, the product distribution changes with the pore size distribution of the catalyst. This result suggests that an elaborate designing of the proper pore size distribution of the catalyst is required to get a desirable product distribution.

Bimodal Catalysts: Bimodal catalysts with micropores with radii smaller than 10 nm and macropores with radii larger than 300 nm (D and E) gave a much higher value in both total conversion and oil yields than did the unimodal catalysts (Table 3). When the physical properties of bimodal catalysts were compared with those of unimodal catalysts, the pore volume of the former was found to be approximately twice as large as that of the latter in spite of the small difference in surface area between them (Table 1). This fact suggests that the macropores did not increase the number of the active sites, but enhanced the diffusion rates of the molecules inside the catalyst particle. In fact, in the case of the hydrogenation of 1-MN, which has a small molecular size, no effect of the macroporosity was observed.

A higher total conversion and lower oil yields were given in the catalyst E, with large micropores, than in the catalyst D, with small micropores. Micropores with small radii were favorable for the production of light components, even in the case of the bimodal catalysts, this result being in keeping with that obtained for the unimodal catalysts.

The catalysts with large micropores ($r \sim 7$ nm) and mesopores ($10\text{ nm} < r < 300\text{ nm}$) (F and G) gave lower values both in total conversion and oil yields than the catalysts D and E. The catalyst G, with a large volume of mesopores with a large diameter, gave a higher total conversion and higher oil yields than the catalyst F. However, even in the case of the catalyst G, mesoporosity did not enhance the catalytic activity as compared with the macroporosity.

Table 4. Coal liquefaction with nickel molybdenum catalysts

Catalyst	P	Q	R
Pore radius[a]/nm	2.5	30	4.5, 450
Total conversion/wt%[b]	87.9	95.9	95.1
Oil yields/wt%	59.5	71.8	78.1
Oil/(oil+asp.)[c]	0.68	0.75	0.81

a) Most probable pore radius. b) Oil plus asphaltene yields (toluene solubles). c) Oil yields/total conversion.

Nickel Molybdenum Catalysts: The results of coal liquefaction with nickel molybdenum catalysts are shown in Table 4. Higher oil yields were given for the catalysts Q and R as compared with the catalysts C and E. This result is due to the high loading of molybdenum and the additional loading of nickel. However, the catalyst P, with only microporosity, gave a lower total conversion and lower oil yields than the catalyst A. This result indicates that the high loading of the active components decreased the effective pore size of the catalyst if the catalyst has only microporosity.

The effects of the pore structure observed for NiO–MoO_3/Al_2O_3 catalysts were similar to those obtained for MoO_3/Al_2O_3 catalysts; a high total conversion was given by the large-pore or bimodal catalysts, and high oil yields, by the bimodal catalyst. These results support our previous discussion and show that, in the case of industrial catalysts, the pore size distribution of the support also affects the activity and selectivity of the catalyst. It may also be suggested that a high loading of active metal components cannot enhance the performance of the small-pore catalyst because of the pore-diffusional limitation.

Heteroatom Removals. The contents of nitrogen and sulfur in each fraction of the products are given in Table 5. Excepet for the catalysts F and G, higher contents of nitrogen were given in the runs with a catalyst than in the run without a catalyst. In most cases, the hexane-soluble fraction gave a higher concentration of nitrogen compounds than the toluene-soluble fraction. These results suggest that the catalysts do not very much accelerate the hydrodenitrogenation (HDN) of light components during the hydrogenation of coal. One reason for this phenomenon is that the strong adsorption of heavy components on the catalyst reduced the catalytic activity for HDN. As has been mentioned above, coal derived oil obtained by the catalytic hydrogenation of coal contains fairly large amounts of heteroatoms. However, it may be useful as a liquefaction solvent because of its polar interaction with coal molecules.[29,30]

In the runs with catalysts having meso- or macropores, lower nitrogen contents were given in spite of the high total conversion and oil yields, as compared with the runs with micropore catalysts or without a catalyst. This suggests that large pores are preferable to small pores for nitrogen-removal reaction from coal molecules.

In terms of HDS, although the sulfur contents in the products of the runs with catalysts were smaller than those without a catalyst, there was little difference

TABLE 5. CONTENTS OF NITROGEN AND SURFUR IN LIQUEFACTION PRODUCTS

Catalyst	None	A	B	C	D	E	F	G

Toluene solubles/wt%	0.64	0.73	0.70	0.64	0.62	0.62	0.47	0.50
Sulfur								
Hexane solubles/wt. ppm.	1210	750	850	760	730	620	830	820
Toluene solubles/wt. ppm.	1200	810	710	790	720	820	740	730

among catalysts. Plumail *et al.*[13] reported that smaller pores were more favorable for HDS than asphaltene conversion in the case of petroleum refining, while Ho *et al.*[16] indicated that in the case of coal liquefaction the bimodal PSD, which was most favorable for a total conversion, also gave the highest HDS performance. In the present study, the concentration of sulfur in the starting material was extremely low. Therefore, it may be difficult to discuss the HDS activity of the catalyst.

As has been described above, the pore size distribution has great effects on the activity and the selectivity of the catalyst, because the pore diffusion limits the reaction rates seriously. Large pores are more advantageous in the production of asphaltene than small pores. On the other hand, small pores are required for the production of light components. In fact, mesopores are superior to micropores in terms of total conversion, while inferior in the production of oil. Bimodal catalysts with macroporosity ($r>300$ nm) and microporosity ($r<10$ nm) performed excellently in terms of both total conversion and oil yields. Macropores enhance the efficiency of the catalyst, while micropores are useful for the production of oil. Mesopores, as compared with macropores, have no great effect on the increase in the pore-diffusional limitation.

Finally, these results show that the design of the pore structure is very important in getting a favorable product distribution. On the other hand, the pore structure of the catalyst support is also known to have great effects on the life of the catalyst. The effects of the pore size distribution of the support on the aging behavior of the catalyst during coal liquefaction will be discussed in the following work.

(Received January 5, 1984)

Synopsis. The surface tension of the aqueous solutions of six dyes have been measured as a function of dye concentration at 298.15 K under atmospheric pressure. The adsorbed films of four azo dyes have been found to transform from the gaseous phase to the expanded phase. The relation between the molecular structure of dye and the state of the adsorbed film has been discussed by making use of the surface pressure *vs.* mean area curve.

It is necessary to have a detailed knowledge of the adsorption behavior of dyes at interfaces in order to understand the dyeing process on fibers. Properties of the adsorbed films of dyes, however, have been scarcely clarified. The purpose of this paper is to obtain information about the adsorption behavior of dyes at their aqueous solution/air interface and about the effect of the molecular structure of dyes on it. The surface tension of the aqueous solutions of dyes, which have different molecular structures, was measured and analyzed by making use of thermodynamic equations.

Experimental

The dyes used in the present study are summarized in Table 1. The commercially available dyes, except for Ethyl Orange and 2,4-diamino-4′-methylazobenzene chloride (DAM), were used by the recrystallization from distilled water and then ethanol several times. Ethyl Orange was prepared by coupling diazotized sulfanilic acid with *N*,*N*-diethylaniline and then recrystallized from distilled water and ethanol. DAM was synthesized by the coupling of *m*-phenylenediamine and diazotized *p*-toluidine according to the usual way and recrystallized from the aqueous solution of 1% hydrochloric acid. Water was twice distilled from alkaline permanganate solution.

The surface tension was measured by the drop volume method with a precision better than 0.05 mN m^{-1}.[1] The drop was stood for about 15 min to reach the adsorption equilibrium.

a) 2,4-Diamino-4′-methylazobenzene monohydrochloride.

Results and Discussion

The surface tension γ *vs.* molality of dye m_1 curves are shown in Fig. 1. It is seen that γ decreases with increasing m_1. However, it should be noted that the γ *vs.* m_1 curves of Ethyl Orange, C. I. Basic Orange 2, DAM, and C. I. Acid Yellow 36 consist of two portions, *i.e.*, the linear one with a small slope and the curved one with a relatively large slope. Such a break point on the curve has been observed in the cases of various surfactants.[1,2] It has been proved thermodynamically that the adsorbed film of the surfactant transforms from a gaseous to an expanded phase at the concentration of the break point.[1,2] It may be said, therefore, that the phase transition takes place in the adsorbed films of these azo dyes.

On the other hand, the γ values of the aqueous solutions of C. I. Basic Green 1 and C. I. Basic Violet 10 decrease monotonously with increase in m_1. Moreover, the γ *vs.* m_1 curve of C. I. Basic Violet 10 seems to approach a constant value. Taking into account that a large number of dyes associate to form aggregates in their aqueous solution,[3-6] the shape of the γ *vs.* m_1 curves can be attributed to the formation of aggregates. It is concluded, therefore, that the adsorbed films of C. I. Basic Green 1 and C. I. Basic Violet 10 are not attended by the phase transition within the present concentration range.

To clarify the state of adsorbed films, it is advantageous to evaluate the surface density of dye molecules. According to the thermodynamics,[1] the surface excess number of moles per unit area of a dye Γ_1^H can be

calculated by the following equation:

$$\Gamma_1^H = -m_1(\partial\gamma/\partial m_1)_{T,p}/2RT, \quad (1)$$

where R is the gas constant. Shown in Fig. 2 are the surface density *vs.* molality curves at 298.15 K under atmospheric pressure. It is seen that the values of Γ_1^H increase with increasing m_1 except for C. I. Basic Violet 10. The fact that the Γ_1^H *vs.* m_1 curve of C. I. Basic Violet 10 has a maximum is explicable by the nonideality of its aqueous solution,[7] which results from the formation of the aggregates. As is expected, the discontinuous change in Γ_1^H is observed for the dye which has the break point on γ *vs.* m_1 curve in Fig. 1. This fact confirms that the phase transition takes place in the adsorbed films and, taking into account that the surface tension is equivalent to the Gibbs free energy, it is the first order. The surface pressure π *vs.* the area per adsorbed molecule A curve is useful to elucidate the state of adsorbed film. Here, $\pi=\gamma^0-\gamma$ and $A=1/N_A\Gamma_1^H$, where γ^0 is the surface tension of pure water and N_A Avogadro's number. The results are shown in Fig. 3. It is seen that the π *vs.* A curves of the azo dyes are a typical one attended by the phase transition. Taking into account that the values of the transition pressure and area are comparable to those of the surfactants,[1,2] the phase transition can be said to take place from a gaseous state to an expanded state. On the other hand, the π *vs.* A curves of C. I. Basic Green 1 and C. I. Basic Violet 10 at 298.15 K are found to be a two-dimensional isotherm at a temperature higher than the critical temperature of the phase transition between gaseous and expanded states.

It should be noted that the azo dyes differ significantly from one another in the A value of the expanded film. However, the order of the A value is found to be the same as that of the transition pressure value except for Ethyl Orange. Taking into account that the molecules of these dyes are linear and similar in cross sections, this order represents that of the strength of the intermolecular interaction in the adsorbed film. A large value of A for Ethyl Orange may be attributable to the bulky diethylamino substituent. On the other hand, since the molecules of C. I. Basic Green 1 and C. I. Basic Violet 10 have nonlinear structures, their intermolecular interactions at the surface are too weak to cause the phase transition from the gaseous film to the expanded film.

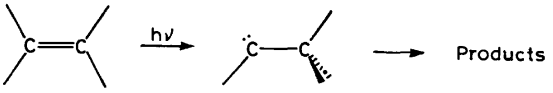
Ab Initio MO Study on the 1,2-Hydrogen Migration from the Twisted Propene

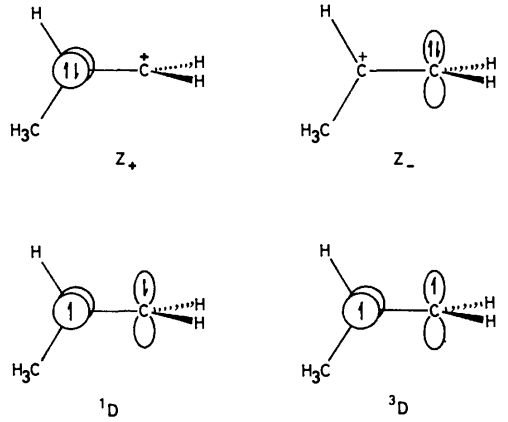
Osamu KIKUCHI
Department of Chemistry, The University of Tsukuba, Sakura, Ibaraki 305
(Received January 21, 1984)

Synopsis. The 1,2-hydrogen migration from the 90°-twisted propene to the corresponding carbenes was examined on the basis of *ab initio* MO CI calculations. It was predicted that, in the polarized zwitterionic states of the twisted propene, the 1,2-hydrogen migration occurs from the negatively-charged carbon atom to the positively-charged one.

There is experimental evidence[1] that photochemical reactions of olefins involve the carbene intermediates.

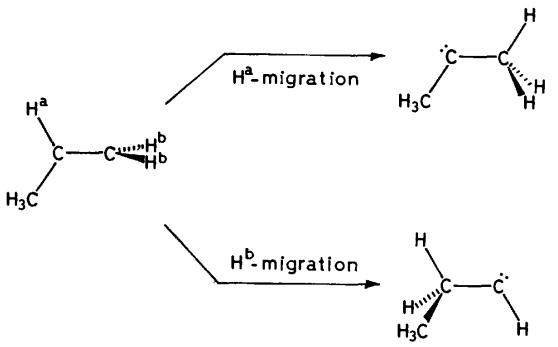


Also, it is well known that the excited state of an olefin is stabilized by a double-bond rotation which gives the twisted structure.[2] Thus a working hypothesis is used that the intermediate carbene is formed by the 1,2-hydrogen migration from the twisted structure.[3] Evleth and Sevin[4] have investigated theoretically the photodecomposition processes of ethylene and have shown that the 1,2-hydrogen migration occurs from the zwitterionic state of the 90°-twisted ethylene.



In the case of the 90°-twisted propene, there are two lower-lying zwitterionic states, Z_+ and Z_-, which have different polarizations. In each zwitterionic state, two different 1,2-hydrogen migrations are possible: the H^a-migration to form isopropylidene and the H^b-migration to form propylidene. This note intends to compare these two reaction paths on the basis of *ab initio* MO CI calculations and to predict the reactivity of the twisted unsymmetric olefins.

First, the 1,2-hydrogen migration of the twisted ethylene is described. The energy diagrams for the twisted ethylene, ethylidene, and the half-reacted species are shown in Fig. 1. Each energy level in Fig. 1 was calculated by means of the closed-shell or restricted open-shell SCF method with the 4-31G basis set[5] by using the molecular structure which was optimized with the STO-3G basis set.[6] The overall shape of Fig. 1



is similar to that observed in the energy variations reported by Evleth and Sevin.[3]

In the calculation of the propene system, the molecular structures of the twisted propene, propylidene, isopropylidene, and the half-reacted species were obtained by introducing a methyl group into the optimized structure of the ^1D state of the ethylene–ethylidene system. Moreover, the intermediate structures were estimated by interpolation. The MO basis set used in the CI calculation[7] was the open-shell SCF solution for the ^1D state. In the CI calculation, 41 singly- and doubly-excited configurations were selected. The potential energy curves obtained with the 4-31G basis set are shown in Fig. 2.

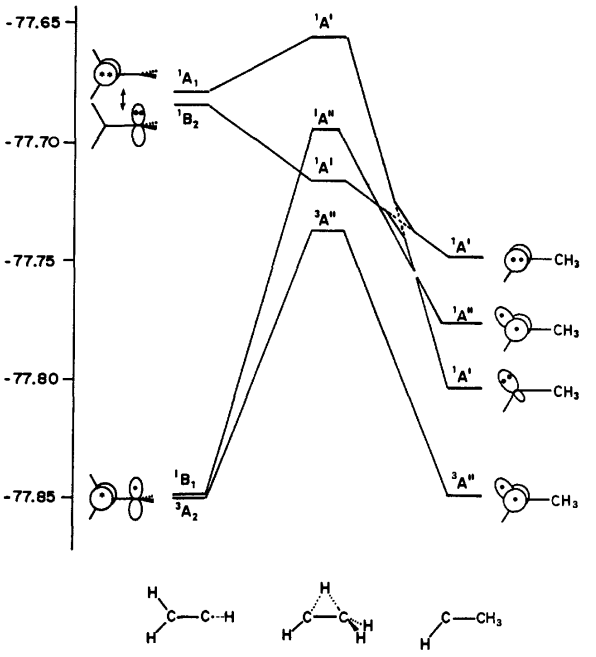


Fig. 1. Energy diagrams for the twisted (D_{2h}) ethylene, the half-reacted species, and ethylidene. The electronic structures of the twisted ethylene and ethylidene are shown schematically on both sides of the diagrams. The energies are in a.u.

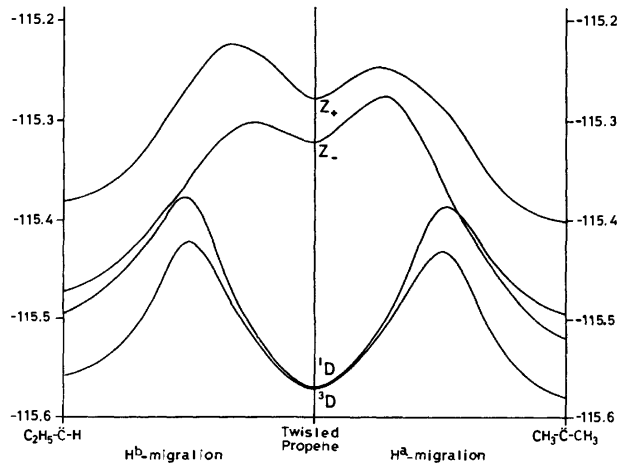

Fig. 2. Potential energy (in a.u.) curves along the hydrogen migrations from the twisted propene. The electron configurations of the twisted propene are shown in the text. The electron configurations at the carbene centers in four electronic states of propylidene and isopropylidene are same as those of ethylidene which are shown in Fig. 1.

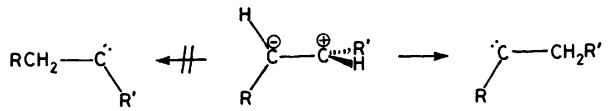
The Z_+ and Z_- zwitterionic states of propene are largely polarized. In the Z_- state, for example, the negative charge on the C^- atom was calculated to be -1.04 and the positive charge on the C^+ atom to be $+0.69$. The Z_- state was found to be lower in energy than the Z_+ state. This may be understood simply from the electron-donating character of the methyl group.

Figure 2 indicates the preferable path for the hydrogen migration from the zwitterionic states. From the Z_- state, the H^b-migration is expected to occur easily more than the H^a-migration, while the H^a-migration is expected to occur from the Z_+ state. These two different results give a common conclusion that the 1,2-hydrogen migration from the zwitterionic states of the twisted non-symmetric olefins occurs from the negatively-charged carbon atom to the positively-charged carbon atom. Figure 2 also indicates that the singlet diradical (^1D) and the triplet diradical (^3D) of twisted olefins might not undergo the 1,2-hydrogen



migration, since the activation energy is very large.

The preferential migration, which occurs to the positive center, involves 2 electrons (4N+2) in the C···H···C bond of the transition state, while the migration to the negative center involves 4 electrons (4N) in it. This is quite parallel to the ground state 1,2-migrations in carbonium ions and carbanions: the 1,2-migration occurs very easily in carbonium ions (2 electron transition state), while it is absent in carbanions (4 electron transition state).[8] Although the present study treats the excited states, the conclusion obtained is equivalent to the ground state reactivity which is widely accepted.

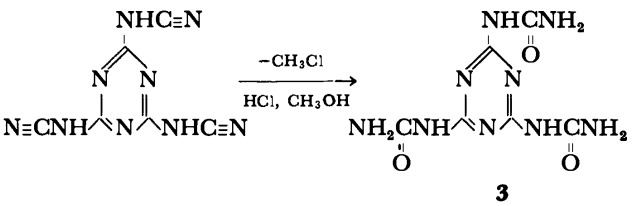
(Received December 24, 1983)

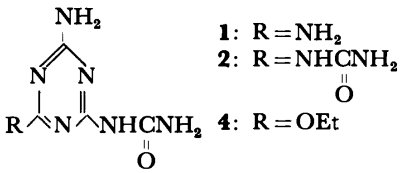
Synopsis. 2,4,6-Triureido-1,3,5-triazine and 2-amino-4,6-diureido-1,3,5-triazine were readily synthesized in high yields, 94 and 85% respectively, by the alcoholysis of 2,4,6-tris(cyanoamino)-1,3,5-triazine and 2-amino-4,6-bis(cyanoamino)-1,3,5-triazine in the presence of hydrogen chloride.

There are numerous reports[1-7] on preparations and uses of ureido-1,3,5-triazines such as 2,4-diamino-6-ureido-1,3,5-triazine (**1**), 2-amino-4,6-diureido-1,3,5-triazine (**2**), and 2,4,6-triureido-1,3,5-triazine (**3**). However, there are still problems with the preparations of these compounds.[8,9] In our previous paper,[10,11] we reported the preparation of **1** and its properties. This paper will describe a facile method of synthesizing **2** and **3** from the corresponding cyanoamino-1,3,5-triazines and will clarify their properties in acidic and alkaline aqueous solutions.

An attempted cyclotrimerization of linear cyanoureido compounds such as cyanourea and *N*-cyano-*O*-ethylisourea did not give **3**. Cyanourea, however, gave 1-carbamoyl-3-cyanoguanidine and 1-cyanobiuret,[12] and *N*-cyano-*O*-ethylisoures gave 2-amino-4-ethoxy-6-ureido-1,3,5-triazine (**4**) in the presence of hydrogen chloride, using sulfolane as a solvent. The isoureido group attached to 1,3,5-triazine ring might be converted into the ureido group by the action of hydrogen chloride. Furthermore, acid hydration of cyanoamino-1,3,5-triazines failed to give the corresponding ureido-1,3,5-triazines, except for **1**.[10]

Alcoholysis of 2,4,6-tris(cyanoamino)-1,3,5-triazine in the presence of hydrogen chloride gave **3** hydrochloride. During the reaction, methyl chloride was evolved and identified by its mass spectrum. The free **3** was given in 94% yield by the treatment of its hydrochloride with a dilute sodium hydroxide solution. **3** was slightly soluble in water and ordinary organic solvents, but could be recrystallized from a hot dilute nitric acid solution as the nitrate.





1: R = NH_2
2: R = $NHCNH_2$ (O)
4: R = OEt

In a similar manner, **2** was synthesized from 2-amino-4,6-bis(cyanoamino)-1,3,5-triazine in 85% yield. **2** was also slightly soluble in water and organic solvents, but could be recrystallized from a hot dilute sulfuric acid solution as the sulfate.

It was reported[10] that the alkaline hydrolysis of **1** gave melamine, carbon dioxide, and ammonia in high yields. The similar alkaline hydrolysis of **3**, however, gave ammeline instead of melamine, along with carbon dioxide and ammonia. In the case of **2**, melamine, ammeline, carbon dioxide, and ammonia were all obtained.

Acid hydrolyses of **2** and **3** with 2 mol dm^{-3} of hydrochloric acid were examined. The reaction was followed by the IR spectrum of the reaction mixture. Small amounts of the solution were taken out at 30 min intervals and evaporated to dryness. In the case of **3**, cyanuric acid was readily detected after 30 min refluxing the solution. Cyanuric acid and urea were obtained in 95 and 26% yields respectively after 4 h. In the case of **2**, cyanuric acid was detected after 1 h. Cyanuric acid, ammelide and urea were obtained in 74, 2 and 34% yields respectively after 2 h. These results suggest that the hydrolysis of **2** and **3** is liable to take place on the carbon atom of the 1,3,5-triazine ring attached with ureido group, and that the preparation of **2** and **3** by the acid hydration of corresponding cyanoamino-1,3,5-triazines is very difficult.

Experimental

The melting points are uncorrected. The IR spectra were taken with a Hitachi EPI-2 spectrometer. The UV spectra were taken with a Hitachi 624 spectrometer. The NMR spectra were measured with a Hitachi R-24A spectrometer using TMS as an internal standard. The mass spectra were taken with a JEOL JMS-D100 mass spectrometer.

2-Amino-4-ethoxy-6-ureido-1,3,5-triazine (4). Hydrogen chloride (1.82 g, 0.05 mol) was introduced into a stirred solution on *N*-cyano-*O*-ethylisourea (5.66 g, 0.05 mol) in 20 mol of sulfolane at room temperature. After 2 h at 70 °C, the solution was poured into a large amount of water. The precipitate of **4** was filtered and recrystallized from water. The yield was 2.52 g (51%). Mp 220 °C. Found: C, 36.10; H, 4.99; N, 42.10%; M^+, 198. Calcd for $C_6H_{10}N_6O_2$: C, 36.36; H, 5.09; N, 42.42%; M^+, 198. IR (KBr) 1700 (C=O) and 815 cm^{-1} (1,3,5-triazine ring). UV (H_2O) 212.4 nm (log ε 4.55). NMR (DMSO-d_6) δ=1.24 (3H, CH_3), 4.25 (2H, CH_2), 7.10, 7.36, 8.60, and 9.67 (5H, m).

2,4,6-Triureido-1,3,5-triazine (3). Hydrogen chloride (7.29 g, 0.2 mol) was introduced into a suspension of the trisodium salt of 2,4,6-tris(cyanoamino)-1,3,5-triazine[13] (5.34 g, 166 mmol) in 40 ml of methanol under cooling below 5 °C. The reaction mixture was stirred for 2 h at room temperature, and then heated to reflux for 2 h, evolving methyl

chloride, which was identified by the mass spectrometer, MS m/z 52 and 50 (M^+). After cooling, the precipitate was filtered and washed with a dilute sodium hydroxide solution and water. The yield of **3** was 4.52 g (94%). **3** was recrystallized from a hot dilute nitric acid solution (0.50 g of **3**/4 mol dm^{-3} HNO_3 180 ml) as the nitrate: mp>360 °C; Found: C, 21.19; H, 3.56; N, 41.62; H_2O, 5.87%. Calcd for $C_6H_9N_9O_3 \cdot HNO_3 \cdot H_2O$: C, 21.43; H, 3.60; N, 41.66; H_2O, 5.36%. IR (KBr) 1720, 1700 (C=O), and 795 cm^{-1} (1,3,5-triazine ring). UV (H_2O) 215.5 (log ε 4.86) and *ca.* 247.0 nm (sh, 4.08).

2-Amino-4,6-diureido-1,3,5-triazine (2). **2** was synthesized from 2-amino-4,6-bis(cyanoamino)-1,3,5-triazine[14] by the same method as above, in 85% yield. **2** was recrystallized from the hot dilute sulfuric acid solution (0.50 g of **2**/10% H_2SO_4 100 ml) as the sulfate: mp>360 °C; Found: C, 19.07; H, 3.43; N, 36.40%. Calcd for $C_5H_8N_8O_2 \cdot H_2SO_4$: C, 19.36; H, 3.23; N, 36.12%. IR (KBr) 1715 (C=O) and 790 cm^{-1} (1,3,5-triazine ring). UV (H_2O) 216.0 (log ε 4.62) and *ca.* 242.5 nm (sh, 3.86).

Alkaline Hydrolysis. According to the previously reported method,[10] **3** gave ammeline (43%), barium carbonate (83%), and ammonia (82%).

Similarly **2** gave melamine (33%), ammeline (9%), barium carbonate (62%), and ammonia (57%).

Acid Hydrolysis. **3** (0.97 g, 1/300 mol) was refluxed in 40 ml of 2 mol dm^{-3} of hydrochloric acid for 4 h. After the reaction mixture had been evaporated to dryness under reduced pressure, the residue was washed with a small amount of water to give 3.30 g (77%) of cyanuric acid. The filtrate was neutralized with dilute sodium hydroxide solution and the saturated melamine solution was added to give 0.13 g (18%) of melamine cyanurate. The filtrate was evaporated and extracted with ethanol to give 0.32 g (26%) of urea as the nitrate. Ammonia was detected in the solution.

In a similar manner, **2** was refluxed in 2 mol dm^{-3} of hydrochloric acid for 2 h, and gave cyanuric acid (70%), melamine cyanurate (4%), urea nitrate (34%), and ammelide (2%). Ammonia was also detected in the solution. Products were confirmed by comparing their IR spectrum and melting points with those of an authentic sample.

Reaction of *N*-Aroyl-*N*-*t*-butylhydroxylamines with Thionyl Chloride. Synthesis of Substituted Benzohydroximoyl Chlorides

Yuzuru UCHIDA* and Seizi KOZUKA†

Department of Applied Chemistry, Osaka Institute of Technology, Asahi-ku, Osaka 535

†*Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558*

(Received December 28, 1983)

Synopsis. The reaction of *N*-benzoyl-*N*-*t*-butylhydroxylamine with thionyl chloride in carbon tetrachloride gave *O*-chlorosulfinylbenzohydroximoyl chloride as the main product. On treating with ethanol, the compound gave benzohydroximoyl chloride in good yield. The reaction was applied to the synthesis of substituted benzohydroximoyl chlorides.

We have previously shown that *N*-[2-(methylthio)-benzoyl]-*N*-alkylhydroxylamines gave 2-substituted 1,2-benzisothiazol-3(2*H*)-ones in good yields on treating with thionyl chloride and pyridine.[1] In the course of our study on the reaction of the hydroxylamine derivatives, the reaction of *N*-benzoyl-*N*-*t*-butylhydroxylamine with thionyl chloride was found to give benzohydroximoyl chloride in good yield. Benzohydroximoyl chloride and its derivatives have been exensively used for the synthesis of heterocyclic compounds as precursors of benzonitrile oxides.[2] We wish to report here an efficient method for the synthesis of substituted benzohydroximoyl chlorides.

Results and Discussion

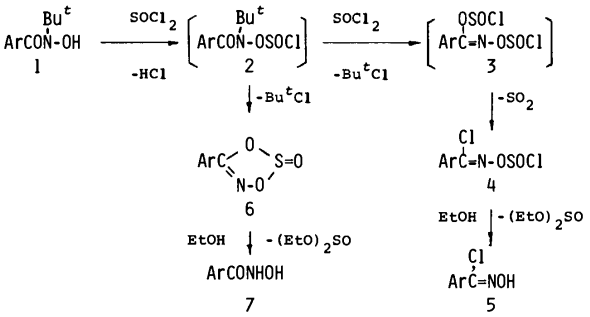
N-Aroyl-*N*-*t*-butylhydroxylamines (**1**) were prepared by hydrolysis of *N*-aroyl-*O*-benzoyl-*N*-*t*-butylhydroxylamines with sodium hydroxide in methanol, as reported previously.[3] The reaction of **1** with thionyl chloride was carried out at −30 °C. A detailed product analysis was performed for the reaction of **1a** with thionyl chloride in carbon tetrachloride. After removal of the solvent and the excess thionyl chloride, the IR spectrum of the reaction product showed the characteristic bands of *O*-chlorosulfinylbenzohydroximoyl chloride (**4a**) together with weak bands at 1770 cm^{-1} and 1330 cm^{-1}. On treating with ethanol, the product gave benzohydroximoyl chloride (**5a**) (78%), benzohydroxamic acid (**7a**) (8%) ethyl benzoate (**8a**) (4%), and diethyl sulfite. The results suggest that the reaction product is a mixture of **4a**, 5-phenyl-1,3,2,4-dioxathiazole 2-oxide (**6a**), and benzoyl chloride. *t*-Butyl chloride was detected by ^{1}H-NMR spectrum of the reaction mixture. Chloride **4a** was difficult to isolate from the reaction mixture, because **4a** was sensitive to heat and moisture. The compound **4a** and **6a**[4] were prepared by the reactions of **5a** and **7a** with thionyl chloride, respectively, and the reactions of **4a** were examined. On heating of **4a** in boiling toluene, benzonitrile was formed in 82% yield. When **4a** was treated with aqueous acetone, benzohydroximoyl chloride was obtained in 90% yield. On treating **4a** with ethanol, **5a** and diethyl sulfite were formed in 90 and 70% yields, respectively.

The reaction of **1a** with thionyl chloride was carried out in various solvents, and the reaction mixture was treated with ethanol. Benzohyxroximoyl chloride (**5a**) was obtained as the main product, together with small amounts of **7a**, **8a**, and diethyl sulfite. No significant difference was observed in the yields of **5a**, except for the reaction in acetonitrile. When the reaction of **1a** with thionyl chloride was carried out in acetonitrile, **5a** and **7a** were formed in 20 and 45% yields, respectively after treatment of the reaction mixture with ethanol. Ethyl phenylcarbamate (**9a**) and 3-phenyl-5-methyl-1,2,4-oxadiazole (**10a**) were also obtained in 9 and 27% yields, respectively, by the reaction in acetonitrile.

Similarly, the reaction of *N*-aroyl-*N*-*t*-butylhydroxylamines (**1b—h**) with thionyl chloride in carbon tetrachloride gave *m*- and *p*-substituted benzohydroximoyl chlorides (**5b—h**) after treatment with ethanol. The results are summarized in Table 1. On the other hand, *N*-(*o*-methoxybenzoyl)-*N*-*t*-butylhydroxylamine (**1i**) and *N*-(*o*-chlorobenzoyl)-*N*-*t*-butylhydroxylamine (**1j**) did not give the corresponding benzohydroximoyl chlorides under the same reaction conditions.

Although benzohydroximoyl chlorides are usually prepared by chlorination of benzaldehyde oximes,[5-8] *p*-methoxybenzohydroximoyl chloride is difficult to obtain by chlorination of *p*-methoxybenzaldehyde oxime. In the chlorination, the strong electron-donating substituent facilitates chlorination on the aromatic ring, giving a mixture of chlorinated products.[9,10] As given in Table 1, the present reaction is successfully applied to the synthesis of *m*- and *p*-substituted benzohydroximoyl chlorides bearing both electron-donating and electron-withdrawing substituents. In addition, the present method is useful for the synthesis of **5e**, which has a sulfide group which is usually oxidized during the chlorination.

The most probable mechanism for the present reaction is shown in Scheme 1. The reaction proceeds through intermediates, *N*-aroyl-*O*-chlorosulfinyl-*N*-*t*-



Scheme 1.

Table 1. Yields of substituted benzohydroximoyl chlorides

Substrate 1	Ar	Solvent	Product	Yield[a] %	Mp θ_m/°C
1a	C_6H_5	CCl_4	**5a**	78	51—52 (lit,[5] 48—52)
1a		CH_2Cl_2	**5a**	66

1g	*m*-ClC_6H_4	CCl_4	**5g**	74	68—69 (lit,[7] 69—70)
1h	*p*-$NO_2C_6H_4$	CCl_4[d]	**5h**	87	125.5—126.5 (lit,[7] 124—125)

a) Isolated yields. b) The reaction was carried out at 5 °C for 5 h and allowed to stand overnight. c) Compounds **7a**, **8a**, and **10a** were obtained in 45, 9, and 27% yields, respectively. d) The reaction was carried out at 25 °C for 15 h.

butylhydroxylamines (**2**), and bis(chlorosulfinyl) compound (**3**). The intermediates **2** and **3** are transformed to **6** and **4** by the subsequent eliminations of *t*-butyl chloride and sulfur dioxide, respectively. In the reaction of **1** with thionyl chloride in acetonitrile, oxadiazole **10** would be formed by cycloaddition of acetonitrile and benzonitrile oxides.

Experimental

Preparation of N-*Aroyl*-N-*t*-*butylhydroxylamines (1).* *N*-Aroyl-*N*-*t*-butylhydroxylamines (**1**) were prepared by hydrolysis of the corresponding *N*-aroyl-*O*-benzoyl-*N*-*t*-butylhydroxylamines with sodium hydroxide in methanol, as reported previously.[3]

Reaction of N-*Aroyl*-N-*t*-*butylhydroxylamines (1) with Thionyl Chloride.* A typical run was as follows: Thionyl chloride (10 g, 84 mmol) was added to a stirred mixture of *N*-benzoyl-*N*-*t*-butylhydroxylamine (**1a**) (1.932 g, 10 mmol) and carbon tetrachloride (30 cm³) at −30 °C. The mixture was stirred at −30 °C for 5 h, and allowed to stand overnight at room temperature. The solvent and excess thionyl chloride were evaporated under reduced pressure. Ethanol (10 cm³) was added to the residue, and the mixture was stirred at room temperature for 2 h. After removal of the ethanol, the residue was separated by column chromatography on silica gel, using dichloromethane and ethyl acetate as the eluents. The fractions obtained by dichloromethane as the eluent gave **5a** (1.218 g, 78%) and **8a** (0.062 g, 4%). Benzohydroxamic acid (**7a**) (0.110 g, 8%) was obtained with the chromatography with ethyl acetate as the eluent. Similarly, the reaction of **1b**—h with thionyl chloride gave **5b**—h. **5d**; Found: C, 51.78; H, 4.24; N, 7.54%. Calcd for $C_8H_8ClNO_2$: C, 51.77; H, 4.34; N, 7.55%. **5e**; Found: C, 47.64; H, 3.84; N, 6.87%. Calcd for C_8H_8ClNOS: C, 47.64; H, 4.00; N, 6.95%.

Preparation of O-Chlorosulfinylbenzohydroximoyl Chloride (4a). Thionyl chloride (5.0 g, 42 mmol) was added to a solution of benzohydroximoyl chloride (1.555 g, 10 mmol) in dichloromethane (30 cm³) and the mixture was allowed to stand overnight. Removal of the solvent and excess thionyl chloride *in vacuo* gave *O*-chlorosulfinylbenzohydroximoyl chloride (**4a**) (2.303 g, 97%) as a colorless oil. IR (neat) 1590, 1580, 1240, 880, 760, 690, and 600 cm⁻¹.

Preparation of 5-Phenyl-1,3,2,4-dioxathiazole 2-oxide (6a). A mixture of benzohydroxamic acid (**7a**) (2.742 g, 20 mmol) and thionyl chloride (10 g, 84 mmol) in dichloromethane (30 cm³) was allowed to stand for 6 h at 30 °C. The excess thionyl chloride and the solvent were evaporated under reduced pressure to give (**6a**) (3.554 g, 97%). IR (neat) 1605, 1325, 1240, 1060, 850, and 720 cm⁻¹.

Thermal Decomposition of 4a A solution of **4a** (0.246 g, 1.03 mmol) in toluene (10 cm³) was refluxed for 4 h. The products were analyzed by GLC.

Hydrolysis of 4a. A solution of **4a** (0.463 g, 1.95 mmol) in acetone (8 cm³) and water (2 cm³) was allowed to stand overnight. After evaporation of acetone, the residue was extracted with diethyl ether. The extract was washed with water and dried over anhydrous calcium chloride. Removal of the ether gave **5a** (0.272 g, 90%).

Alcoholysis of 4a. A solution of **4a** (0.463 g, 1.95 mmol) in ethanol (10 cm³) was allowed to stand for 2 h. The reaction mixture was subjected to GLC analysis, and the remainder was chromatographed on silica gel to isolate the products. Diethyl sulfite (70%, GLC) and **5a** (0.272 g, 90%) were obtained.

Shinjulactones G and H, New Bitter Principles of *Ailanthus altissima* SWINGLE

Masami ISHIBASHI, Shin YOSHIMURA, Takahiko TSUYUKI, Takeyoshi TAKAHASHI,* and Kazuhiro MATSUSHITA†

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

†*Application Center, Scientific Instrument Project, JEOL Ltd., Nakagami, Akishima, Tokyo 196*

(Received February 3, 1984)

Synopsis. Two bitter quassinoids, shinjulactones G and H were isolated from *Ailanthus altissima* SWINGLE and their structures were determined to be 1β,11β,12α,20-tetrahydroxypicras-3-ene-2,16-dione and 2α,12β-dihydroxypicrasane-1,11,16-trione, respectively, by spectral and chemical means.

In the continuation of our studies on the bitter principles of Simaroubaceous plants, the structure determination of six quassinoids isolated from *Ailanthus altissima* SWINGLE (Japanese name: Shinju or Niwaurushi) has been reported.[1] Two new bitter principles named shinjulactones G and H (**1** and **2**), have been isolated from the same plant. This paper describes the structure determination of **1** and **2**.

Aqueous extract of the root bark of *A. altissima* was continuously extracted with dichloromethane. The organic layer was subjected to separation by a silica-gel column chromatography and then further purified by a partition column chromatography on silicic acid to afford two minor bitter quassinoids, shinjulactone G (**1**, *ca.* 0.0003% yield) and shinjulactone H (**2**, *ca.* 0.001% yield) together with other quassinoids.

Shinjulactone G (**1**), mp 274—277 °C, gave a weak molecular ion peak in high resolution mass spectrum, leading to the molecular formula, $C_{20}H_{28}O_7$, for **1**. IR and ^{1}H NMR spectra of **1** revealed the presence of a vinyl methyl, a tertiary methyl, a secondary methyl, a hydroxymethyl, and an α,β-unsaturated carbonyl, and a lactone grouping. ^{1}H NMR decoupling experiment suggested that the structure of shinjulactone G (**1**) might be formulated as 20-hydroxyklaineanone. Configuration of the hydroxyl groups at C-11 and C-12 was determined by coupling constants ($J_{11,12}$=3 and $J_{12,13}$=2.5 Hz). The structure of shinjulactone G (**1**) was further confirmed by chemical conversion of **1** into chaparrinone triacetate (**3**).[2] According to the procedure described for klaineanone[2] and 15-hydroxyklaineanone,[3] shinjulactone G (**1**) was acetylated to give a triacetate (**4**), which showed an IR absorption band at 3450 cm^{-1} and a doublet signal at δ 7.84 (J=5 Hz) due to a hydroxyl group in the ^{1}H NMR of **4**. Since the doublet signal coupled with a broad singlet signal due to $C_{(11)}$-H at δ 5.05 with the coupling constant J=5 Hz, the hydroxyl group was concluded to exist at C-11. Jones oxidation of **4** afforded chaparrinone triacetate (**3**), which was completely identical with an authentic sample. Thus, the structure of shinjulactone G (**1**) was determined to be 1β,11β,12α,20-tetrahydroxypicras-3-ene-2,16-dione.

Shinjulactone H (**2**), mp 135—139 °C, was shown to have a molecular formula, $C_{20}H_{28}O_6$, by high resolution mass spectrum. ^{1}H (Table 1) and ^{13}C NMR spectra indicated the presence of two tertiary methyls, two secondary methyls, two isolated carbonyls, and a lactone grouping. The IR absorption band at 3450 cm^{-1} and two doublet signals at δ 81.9 and 69.9 in the ^{13}C NMR spectrum of **2** indicated that the remaining two oxygen atoms are ascribed to hydroxyl groups. These spectral features are very similar to those of amarolide (**5**).[4,5] Acetylation of shinjulactone H (**2**) gave a diacetate (**6**) which was not identical with amarolide diacetate (**7**).[5] The ^{1}H NMR spectral comparison between shinjulactone H (**2**) and amarolide (**5**) could reveal a difference in the relative position of hydroxyl and carbonyl groups in ring C. Shinjulactone H (**2**) showed a double doublet at δ 4.01 with coupling constants J=11 and 3 Hz and a multiplet at δ 2.16, assignable to $C_{(12)}$-H and $C_{(13)}$-H, respectively. On irradiation at δ 4.01, the multiplet signal resulted in a change of its shape. When D_2O was added, the double doublet was changed into a doublet with a coupling constant J=11 Hz, which implies the protons at C-12 and C-13 are in trans-diaxial relationship and the former was coupled with the hydroxyl proton at C-12. From these observations together with a singlet signal at δ 2.94 due to $C_{(9)}$-H, the structure (**2**) was proposed for shinjulactone H. The proposed structure (**2**) was firmly established by a preparation of shinjulactone H diacetate (**6**) from known chaparrolide (**8**).[6] Acetylation of chaparrolide (**8**) afforded two diacetates (**9** and **10**) and a known triacetate, 1,2,12-tri-*O*-acetylchaparrolide (**11**).[6] From the ^{1}H NMR spectra, the diacetates (**9** and **10**) were assigned to be 2,12- and 1,2-di-*O*-acetyl derivatives, respectively. 2,12-Di-*O*-acetylchaparrolide (**9**) was oxidized with Jones reagent to give a keto acetate (**6**), which was completely identical with the diacetate (**6**) derived from shinjulactone H (**2**). The structure of shinjulactone H (**2**) was, therfore, concluded to be 2α,12β-dihydroxypicrasane-1,11,16-trione.[7]

a) δ and J are expressed in ppm and Hz, respectively. b) Measured in C_5D_5N for **1** and in $CDCl_3$ for **2**. c) Signals were overlapped. d) Coupling constants were determined by decoupling experiment; $J_{9,11}=2.5$, $J_{11,12}=3$, $J_{12,13}=2.5$, and $J_{13,14}=4.5$ Hz. e) Signals may be reversed.

Experimental[8]

Shinjulactone G (1). Mp 274—277 °C; $[\alpha]_D^{26}$ +6.5° (*c* 1.2, pyridine); IR (KBr) 3470, 1730, 1700, 1675, and 1280 cm^{-1}; UV (ethanol) 237 nm (ε 5300); ^{1}H NMR (Table 1); ^{13}C NMR (pyridine-d_5) δ 12.4q, 15.5q, 22.4q, 26.4t, 27.9d, 29.4t, 36.2d, 41.7d, 42.4s, 43.3d, 48.8s, 61.8t, 74.2d, 77.7d, 79.7d, 85.0d, 124.8d, 165.1s, 172.2s, and 199.6s; MS *m/z* (%) 380 (M$^+$), 362 (100), 347 (27), and 151 (50); Found: *m/z* 380.1824. Calcd for $C_{20}H_{28}O_7$: M, 380.1834.

1,12,20-Tri-O-acetylshinjulactone G (4). Shinjulactone G (**1**; 7 mg) was acetylated in the usual manner to afford **4** (8 mg), mp 130—134 °C, IR (film) 3450, 1735, 1680, and 1235 cm^{-1}; ^{1}H NMR (pyridine-d_5) δ 0.94 (3H, d, J=7 Hz), 1.65 (3H, s), 1.80 (3H, br s), 1.90, 2.07, and 2.18 (each 3H, s), 5.05 (1H, br s), 5.73 (1H, s), 5.96 (1H, d, J=13 Hz), 6.10 (1H, br s), and 7.84 (1H, d, J=5 Hz); MS *m/z* (%) 506 (M$^+$; 7), 488 (9), 446 (70), and 404 (100); Found: *m/z* 506.2104. Calcd for $C_{26}H_{34}O_{10}$: M, 506.2150.

Oxidation of 4 with Jones Reagent. 1,12,20-Tri-*O*-acetylshinjulactone G (**4**; 7.5 mg) was treated with Jones reagent (in excess) in acetone (6 mL) at room temperature for 8 h. The usual work-up afforded chaparrionone triacetate (**3**; 5 mg), which was identified with an authentic sample by TLC, ^{1}H NMR, IR, and mass spectra.

Shinjulactone H (2). Mp 135—139 °C; $[\alpha]_D^{21}$ −14° (*c* 3.9, ethanol); IR (KBr) 3450, 1720, and 1230 cm^{-1}; ^{1}H NMR (Table 1); ^{13}C NMR ($CDCl_3$) δ 15.2q, 15.2q, 18.2q, 23.8q, 26.7t, 27.6t, 27.9d, 39.2s, 39.4d, 45.3d, 46.6t, 46.8d, 47.0d, 48.8s, 69.9d, 76.2d, 81.9d, 169.3s, 208.2s, and 213.0s; MS *m/z* (%) 364 (M$^+$; 23), 346 (43), 321 (46), and 57 (100); Found: *m/z* 364.1877. Calcd for $C_{20}H_{28}O_6$: M, 364.1884.

2,12-Di-O-acetylshinjulactone H (6). Acetylation of shinjulactone H (**2**; 10 mg) gave **6** (12 mg), mp 146—150 °C; IR (KBr) 1745, 1730, and 1230 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 0.96 (3H, d, J=6.5 Hz), 1.04 (3H, d, J=6 Hz), 1.17 (3H, s), 1.60 (3H, s), 2.11 and 2.17 (each 3H, s), 4.26 (1H, t, J=3 Hz), 5.12 (1H, d, J=12.5 Hz), and 5.77 (1H, dd, J=13 and 7 Hz); MS *m/z* (%) 448 (M$^+$; 9), 406 (10), 388 (100), and 328 (21); Found: *m/z* 448.2089. Calcd for $C_{24}H_{32}O_8$: M, 448.2096.

Acetylation of Chaparrolide (8). Chaparrolide (**8**; 61 mg) was acetylated with acetic anhydride (1 mL) in pyridine (2 mL) at room temperature for 6 h. After the usual work-up, the reaction mixture was separated by a column chromatography (silica gel; 30 g). Elution with benzene–acetone (9:1) afforded **11** (*ca.* 30 mg), **10** (*ca.* 25 mg), and **9** (16 mg) in succession. **9**: mp 152—154 °C; IR (KBr) 3450, 1735, and 1250 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 0.88 (3H, d, J=6.5 Hz), 1.06 (3H, d, J=6 Hz), 1.15 (3H, s), 1.36 (3H, s), 2.03 and 2.16 (each 3H, s), 3.17 (1H, dd, J=9 and 5 Hz), 4.31 (1H, t, J=3 Hz), 4.87 (1H, m), and 4.89 (1H, d, J=11.5 Hz); MS *m/z* (%) 450 (M$^+$; 7), 390 (100), 348 (43), and 330 (54); Found *m/z* 450.2226. Calcd for $C_{24}H_{34}O_8$: M, 450.2253. **10**: mp 167—168 °C; IR (KBr) 3450, 1735, and 1235 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 0.90 (3H, d, J=6 Hz), 1.06 (3H, s), 1.12 (3H, d, J=6.5 Hz), 1.46 (3H, s), 1.86 and 1.97 (each 3H, s), 3.27 (1H, d, J=5 Hz), 3.80 (1H, dd, J=10.5 and 5 Hz), 4.28 (1H, t, J=2.5 Hz), 4.62 (1H, d, J=10 Hz), and 5.06 (1H, m); MS *m/z* (%) 450 (M$^+$; 24), 390 (84), 348 (57), and 330 (100); Found: *m/z* 450.2238. Calcd for $C_{24}H_{34}O_8$: M, 450.2253.

Oxidation of 9 with Jones Reagent. 2,12-Di-*O*-acetylchaparrolide (**9**; 16 mg) was treated with Jones reagent (in excess) at 0 °C for 1.5 h. After the usual work-up, a keto acetate (**6**; 12.5 mg) was obtained and was identified with 2,12-di-*O*-acetylshinjulactone H (**6**) by TLC, ^{1}H NMR, IR, and mass spectra.

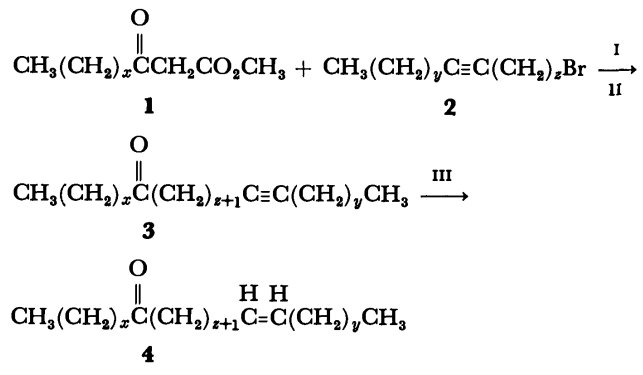
(Received January 5, 1984)

Synopsis. A convenient synthesis of *cis*-12-nonadecen-9-one (**4a**), *cis*-13-icosen-10-one (**4b**), the pheromone of peach fruit moth, and *cis*-15-henicosen-11-one (**4c**), the pheromone of Douglas fir tussock moth, is described. **4a** was synthesized from methyl 3-oxoundecanoate and 1-bromo-2-nonyne (**2a**) *via* 12-nonadecyn-9-one. The higher homolog **4b** could be obtained from methyl-3-oxododecanoate and **2a**. Similarly, **4c** was prepared from methyl 3-oxotridecanoate and 1-bromo-3-nonyne (**2b**).

cis-12-Nonadecen-9-one (**4a**) and *cis*-13-icosen-10-one (**4b**) have been recognized as the principles of sex pheromone of Japanese peach fruit moth (*Carposina niponensis* Walsingham), a major economic pest of peach, apple and other fruits in Japan.[1] It is pointed out that a mixture of **4a** and **4b** in a ratio 1:20 shows the strongest biological activity.[1,2] On the other hand, *cis*-15-henicosen-11-one (**4c**) is known as the sex pheromone of Douglas fir tussock moth (*Orgyia pseudotsugata* McDunnough), a severe defoliator of Douglas fir and other fir forests in western North America.[3] These three compounds are unusual in that most lepidopterous sex pheromones are characterized as unsaturated fatty alcohols, acetates or aldehydes of C_{12}, C_{14}, or C_{16} chain length.[4]

Since above mentioned pheromones are potent male attractants, and might be of practical interests, a variety of synthetic methods of **4a**, **4b**,[1,5] and **4c**[6] have been reported. However no example for the preparation of these unsaturated ketones by the same technique has been explored.

Recently general and practical methods for the synthesis of arbitrary β-keto esters, versatile intermediates in organic synthesis, have been developed.[7] Thus we wish to report here a convenient synthesis of **4a**, **4b**, and **4c** starting from β-keto esters (**1**) which could be obtained easily accoding to Yonemitsu *et al.*[7a]



1 a: $x=7$, b: $x=8$, c: $x=9$; **2** a: $y=5$, $z=1$, b: $y=4$, $z=2$; **3,4** a: $x=7$, $y=5$, $z=1$, b: $x=8$, $y=5$, $z=1$, c: $x=9$, $y=4$, $z=2$
I: NaH in Toluene; II: wet DMSO; III: H_2/Pd-$BaSO_4$

Scheme 1.

The high stereoselectivity and chemical yield anticipated for the reduction of acetylenic bond to corresponding *cis*-olefin suggested 12-nonadecyn-9-one (**3a**), 13-icosyn-10-one (**3b**) and 15-henicosyn-11-one (**3c**) as the primary synthetic goal.[8] Thus the synthesis of title compounds **4a**, **4b**, and **4c** was carried out according to Scheme 1.

Methyl 3-oxoundecanoate (**1a**) was alkylated with 1-brom-2-nonyne (**2a**) in toluene in the presence of sodium hydride. The porduct, without isolation, was then heated in wet dimethyl sulfoxide (DMSO)[9] to be demethoxycarbonylated to 12-nonadecyn-9-one (**3a**) in a good yield (80%). **3b** was also prepared in the same manner from methyl 3-oxododecanoate (**1b**). **3c** could be obtained by the same procedure from methyl 3-oxotridecanoate (**1c**) and 1-bromo-3-nonyne (**2b**) in a low yield (≈40%). However, the yield of **3c** was improved upon (78%) by carrying out the alkylation in the presence of *N*,*N*-dimethylformamide (DMF). These acetylenic ketones were partially hydrogenated over palladium/barium sulfate catalyst to give desired compounds in 89—91% yields. The resulting products, **4a**, **4b**, and **4c** showed no infrared absorption band in the neighborhood of 970 cm^{-1} due to disubstituted *trans*-alkene. The structure of these products were identified by comparing IR and NMR spectra with those of reported data.[5,6]

Experimental

The IR and NMR spectra were recorded on Hitachi 285 and JEOL/FX-100 spectrometer respectively.

12-Nonadecyn-9-one (3a), 13-Icosyn-10-one (3b), and *15-Henicosyn-11-one (3c).* To a stirred suspension of sodium hydride (50% mineral oil dispersion 1.49 g, 31 mmol) in dry toluene (150 ml) a solution of methyl 3-oxoundecanoate (**1a**) (6.42 g, 30 mmol) in dry toluene (20 ml) was added dropwise over a period of 20 min at room temperature. Stirring was continued for 1 h. Then 1-bromo-2-nonyne (**2a**)[10] (6.7 g, 32 mmol) and powdered sodium iodide (2 g) were added. The mixture was refluxed for 11 h and then poured onto cold hydrochloric acid. The toluene layer was separated and the solvent was distilled off *in vacuo*. The residue was dissolved in a mixture of DMSO (50 ml) and water (5 ml) then the solution was heated (150 °C, bath temp) for 3.5 h. The mixture was poured onto ice water and extracted with ether (100 ml×2). The ether solution was washed with brine and dried over anhydrous magnesium sulfate, concentrated *in vacuo* to give crude **3a** as a pale yellow liquid. This crude **3a** was chromatographed over silicagel with hexane-benzene (6:4) as eluent to give 6.66 g (80%) of **3a**. IR (neat): 2940, 2860, 1720, 1460, 1090 cm^{-1}. NMR ($CDCl_3$): δ 0.87 (6H, distored t, J=6 Hz), 1.08—

1.66 (20H, br s), 1.97—2.23 (4H, m), 2.25—2.63 (4H, m). *13-Icosyn-10-one (3b)* was obtained from methyl 3-oxododecanoate (**1b**) and **2a** by the same procedure in 78% yield. IR (neat): 2960, 2860, 1720, 1460, 1090 cm^{-1}. NMR ($CDCl_3$): δ 0.90 (6H, distored t, J=6 Hz), 1.05—1.73 (22H, br s), 1.96—2.22 (4H, m), 2.27—2.63 (4H, m). *15-Henicosyn-11-one (3c)* could be prepared from methyl 3-oxotridecanoate (**1c**) and 1-bromo-3-nonyne (**2b**)[11] in 78% yield by using a mixture of toluene and DMF (10—15% of toluene)[12] as the solvent of the alkylation. IR (neat): 2920, 2840, 1715, 1460, 1090 cm^{-1}. NMR ($CDCl_3$): δ 0.93 (6H, distored t, J=6 Hz), 1.10—1.80 (24H, br s), 1.98—2.23 (4H, m), 2.26—2.60 (4H, m).

cis-*12-Nonadecen-9-one (4a)*, cis-*13-Icosen-10-one (4b)*, and cis-*15-Henicosen-11-one (4c)*. A methanol solution (35 ml) of **3a** (1.60 g, 5.8 mmol) containing two drops of quinoline was hydrogenated over 5% Pd-$BaSO_4$ (120 mg) under atmospheric pressure for 3 h. The solid was filtered off and the filtrate was concentrated *in vacuo*. The residue was dissolved in ether and washed with 5% hydrochloric acid, brine, dried over magnesium sulfate. Concentration of ether gave crude **4a** which was chromatographed over silica gel with hexane-benzene (6:4) as eluent to obtain 1.48 g (91%) of **4a**. IR (neat): 2960, 1710, 1460, 1370 cm^{-1}. NMR ($CDCl_3$): δ 0.88 (6H, distored t, J=6 Hz), 1.10—1.70 (20H, br s), 1.90—2.12 (2H, m), 2.20—2.42 (6H, m), 5.17—5.40 (2H, m). cis-*13-Icosen-10-one (4b)* was obtained by the same manner from **3b** in 89% yield. IR (neat): 2930, 1710, 1470, 1370 cm^{-1}. NMR ($CDCl_3$): δ 0.90 (6H, distored t, J=6 Hz), 1.10—1.70 (22H, br s), 1.90—2.10 (4H, m), 2.20—2.40 (6H, m), 5.15—5.40 (2H, m). cis-*Henicosen-11-one (4c)* was prepared from **3c** by the same procedure in 91% yield. IR (neat): 3000, 1715, 1460, 1370 cm^{-1}. NMR ($CDCl_3$): δ 0.98 (6H, distored t, J=6 Hz), 1.05—1.75 (24H, br s), 1.90—2.15 (4H, m), 2.35 (4H, t, J=7 Hz), 5.26—5.32 (2H, m).

12) When a large quantity of DMF was used the yield of **3c** was lower (≈66%).

Studies on Nucleosides and Nucleotides. XI.[1] Synthesis of 5′-Deoxypyrimidine Nucleosides

Junji KIMURA, Yoshiyuki NISHIKUBO, and Oyo MITSUNOBU
College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157
(Received January 14, 1984)

Synopsis. When 2′,3′-*O*-(triphenylphosphoranediyl)-O^2,5′-cyclouridine and N^4-benzoyl-2′,3′-*O*-(triphenylphosphoranediyl)-O^2,5′-cyclocytidine were allowed to react with tributyltin hydride in the presence of azobisisobutyronitrile under reflux, 5′-deoxyuridine (84% yield) and N^4-benzoyl-5′-deoxycytidine (71% yield) were obtained.

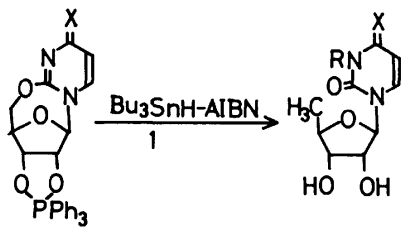
Tributyltin hydride (**1**) has been widely used as a reducing agent for organic compounds which include alkyl halides,[2a] nitro compounds,[2b] and xanthates.[2c]

In this paper we wish to report the reaction of 2′,3′-*O*-(triphenylphosphoranediyl)cyclonucleosides with **1**.

When 2′,3′-*O*-(triphenylphosphoranediyl)-O^2,5′-cyclouridine (**2**) was allowed to react with two molar amounts of **1** in the presence of azobisisobutyronitrile (AIBN) in THF under reflux for 6 h, 5′-deoxyuridine (**3**)[3] was obtained in 84% yield. When three molar amounts of **1** were used, a minor, more polar product was isolated by preparative layer chromatography ($CHCl_3$:MeOH=10:1). Based on ^{1}H-NMR spectroscopy, the structure of the side product was assigned to be N^3-methyl-5′-deoxyuridine (**4**) which would be formed during work-up. Thus, **2** was first reacted with **1** in THF as above, followed by addition of methanol, and the resulting solution was refluxed for 8 h. Compound **4** was expectedly isolated in 40% yield along with **3** (60%). Reduction of N^4-benzoyl-2′,3′-*O*-(triphenylphosphoranediyl)-O^2,5′-cyclocytidine (**5**) by the use of two molar amounts of **1** in the presence of AIBN afforded N^4-benzoyl-5′-deoxycytidine (**6**) in 71% yield. Products **3**, **4**, and **6** were readily converted into the corresponding acetonides, indicating that the 2′- and 3′-hydroxyl groups have the original cis configuration.

Contrary to the case of pyrimidine nucleosides, 3′,5′-*O*-(triphenylphosphoranediyl)adenosine or 2′,3′-*O*-(triphenylphosphoranediyl)-N^3,5′-cycloguanosine did not react with **1**.

From these results, it is proved that **1** does not react at the phosphoranediyl group but induces cleavage of the O^2,5′-anhydro bond of **2** or **5**.



2 X=O
5 X=NBz

3 X=O R=H
4 X=O R=Me
6 X=NBz R=H

We next examined the reaction of 2′,3′-*O*-isopropylidene-O^2,5′-cyclouridine (**7**) under the same conditions where 5′-deoxy-2′,3′-*O*-isopropylideneuridine was obtained in only 31% yield with 63% recovery of **7**. On the other hand, O^2-methyluridine, 5′-*O*-benzoyl-O^2,2′-cyclouridine, and O^2,2′-cyclocytidine hydrochloride were not reduced by **1** and starting materials were quantitatively recovered.

It is generally known that the O^2,2′-anhydro bond of pyrimidine nucleosides is more stable than the O^2,5′-anhydro bond.[4] The difference of reactivity between **2** and **7** might be due to 2′,3′-*O*-protecting group which exerts influence on the stability of O^2,5′-anhydro bond. Thus the phosphoranediyl group activate the O^2,5′-anhydro bond of **2** or **5** to some extent compared to isopropylidene group.

Experimental

5′-Deoxyuridine (3) and N³-Methyl-5′-deoxyuridine (4). A suspended solution of **2** (486 mg, 1 mmol),[5] **1** (582 mg, 2 mmol), and AIBN (40 mg) in THF (15 ml) was refluxed under nitrogen atmosphere for 6 h. As the reaction proceeded, the solution became homogeneous. The reaction solution was evaporated and 191 mg (84% yield) of the product **3** was obtained by column chromatography (Merck Kieselgel 60, solvent; $CHCl_3$: MeOH=5:1), followed by recrystallization from CH_3CN and had mp 187—189 °C (lit,[3] mp 182—184 °C); UV_{max}^{MeOH} 264 (ε 9800) nm; UV_{min} 232 nm. Found: C, 47.32; H, 5.30; N, 12.29%. Calcd for $C_9H_{12}O_5N_2$: C, 47.37; H, 5.30; N, 12.28%. NMR (DMSO-d_6) δ=1.28 (d, 3H, C$_5$′H), 5.63 (d, 1H, C$_5$H), 5.69 (d, 1H, C$_1$′H), and 7.55 ppm (d, 1H, C$_6$H).

Similarly, the reaction of **2** with three molar amounts of **1** in the presence of AIBN in THF was carried out under reflux for 6 h and methanol (20 ml) was added to the resulting mixture. The solution was successively refluxed for 8 h and evaporated. The products were separated by column chromatography (solvent; $CHCl_3$: MeOH=10:1) to give **3** and **4** in 60% and 40% yields, respectively. Compound **4** recrystallized from benzene had mp 107—109 °C; UV_{max}^{MeOH} 263 nm; UV_{min} 234 nm. Found: C, 49.48; H, 5.81; N, 11.55%. Calcd for $C_{10}H_{14}O_5N_2$: C, 49.48; H, 5.83; N, 11.57%. NMR ($CDCl_3$) δ=1.43 (d, 3H, C$_5$′H), 3.30 (s, 3H, CH_3), 5.65 (d, 1H, C$_1$′H), 5.78 (d, 1H, C$_5$H), and 7.43 ppm (d, 1H, C$_6$H).

N⁴-Benzoyl-5′-deoxycytidine (6). The reaction of **5**[5] with two molar amounts of **1** in the presence of AIBN in THF under reflux for 6 h gave **6** in 71% yield. The **6** recrystallized from methanol had mp 201—202 °C; UV_{max}^{MeOH} 261 (ε 22200); 306 nm, UV_{min} 232, 287 nm. Found; C, 57.66; H, 5.12; N, 12.61%. Calcd for $C_{16}H_{17}O_5N_3$: C, 58.00; H, 5.17; N, 12.68%. NMR (DMSO-d_6) δ=1.39 (d, 3H, C$_5$′H) and 5.81 ppm (d, 1H, C$_1$′H).

N³-Methyl-5′-deoxy-2′,3′-O-isopropylideneuridine. A solution of **4** in 2,2-dimethoxypropane-acetone in the presence of *p*-toluenesulfonic acid was stirred at room temperature for 5 h. The title compound was quantitatively iso-

lated as an oil by preparative TLC (developing solvent; ethyl acetate). NMR ($CDCl_3$) δ=1.38 (d, 3H, $C_{5'}H$), 1.32, 1.55 (s, 6H, $(CH_3)_2C$), 3.30 (s, 3H, CH_3), 5.56 (d, 1H, $C_{1'}H$), 5.70 (d, 1H, C_5H), and 7.20 ppm (d, 1H, C_6H).

N^4-*Benzoyl-5'-deoxy-2',3'-O-isopropylidenecytidine.* A solution of **6** in 2,2-dimethoxypropane-acetone in the presence of *p*-toluenesulfonic acid was stirred at room temperature for 2 h. The product was isolated in 61% yield by preparative TLC ($CHCl_3$:MeOH=10:1) and had mp 184—186 °C. NMR (DMSO-d_6) δ=1.38 (d, 3H, $C_{5'}H$), 1.31, 1.45 (s, 6H, $(CH_3)_2C$), and 5.83 ppm (d, 1H, $C_{1'}H$).

Pyridinium Fluorochromate or Benzyltrimethylammonium Chlorochromate for Selective Oxidation of Alcohols

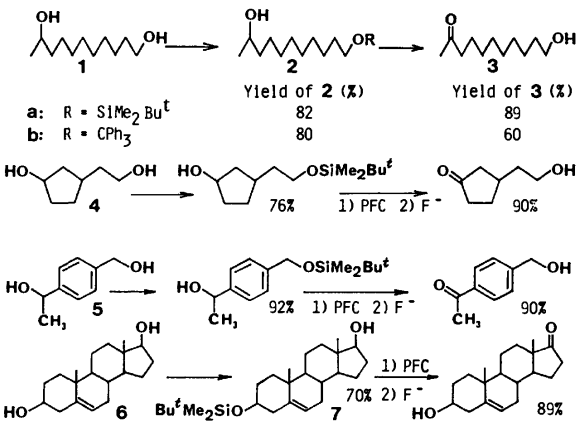
Tsuyoshi NONAKA, Shigekazu KANEMOTO, Koichiro OSHIMA,* and Hitosi NOZAKI
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606
(Received January 20, 1984)

Synopsis. Selective oxidation of secondary alcohols in the presence of primary ones has been achieved by the following sequences, (1) selective protection of primary alcohols with *t*-BuMe$_2$SiCl, (2) oxidation of secondary alcohols with title reagents, and (3) deprotection of primary hydroxyls.

The reagents containing the chromium(VI) as a key atom are most commonly used for the oxidation of alcohols to carbonyl compounds because of their ready accessibility and operational simplicity.[1] A large number of them, however, cannot be applied to modern organic synthesis and there still exists a need for new methods for the oxidation of complex or highly sensitive substrates. Here we wish to describe the preparation and reaction of several chromium(VI) reagents which oxidize alcohols under slightly acidic or neutral conditions.

Among many reagents examined, only pyridinium fluorochromate (PFC)[2] was as reactive as pyridinium chlorochromate (PCC) and oxidation took place at 25 °C. The reaction with benzyltrimethylammonium chlorochromate (BTMACC) proceeded very sluggishly at 25 °C and the completion of oxidation required heating at 80 °C in 1,2-dichloroethane. Tetrabutylammonium chlorochromate (TBACC) was marginal and tetramethylammonium chlorochromate, tetramethylammonium fluorochromate, and tetrabutylammonium fluorochromate were inert for the oxidation of alcohols. The results of representative experiments by means of PFC together with those by BTMACC and TBACC are summarized in Table 1.

It is worth noting that PFC is less acidic than PCC, thus even such acid-labile compounds as SiMe$_2$Bu^t ethers or trityl ethers survive without buffering the reaction mixture with bases. Combination of this oxidation procedure with selective protection of primary hydroxyl groups provides us with a simple route to the selective oxidation of primary, secondary diols at the secondary positions.[3]



Treatment of 1,10-undecanediol with Bu^{t}Me$_2$SiCl and Et$_3$N in the presence of a catalytic amount of 4-dimethylaminopyridine gave monosilyl ether **2a** in 82% yield. Similarly, the diols **4** and **5** could be transformed into their monoethers. Oxidation of monosilyl ether **2a** with PFC or BTMACC followed by desilylation (Bu$^n_4$NF) provided 11-hydroxy-2-undecanone (**3**) in 89% or 90%, respectively. In contrast, the reaction of **2a** with PCC gave *t*-butyldimethylsilyl ether of keto alcohol (**3**) (68%) along with 10-oxoundecanal (20%). Trityl ether **2b** was also converted into the ketone **3** with PFC followed by deprotection (*p*-TsOH).[4] As exemplified below, the selective oxidation of secondary, secondary

Table 1. Oxidation of alcohols with PFC, BTMACC, or TBACC

Alcohol	Oxidant	Conditions		Yield/%[a] of carbonyl compound
		Temp °C	Time h	
4-*t*-Butylcyclohexanol	PFC[b]	25	6	92

	PFC	25	4	78[h]

a) Yields represent isolated purified products. b) 2 mmol of alcohols and 4 mmol of PFC were employed. c) 2 mmol of alcohols and 6 mmol of BTMACC or TBACC were employed. d) A mixture of *cis* and *trans* citral was obtained. The ratio of *cis*:*trans* was 15:85. e) *cis*:*trans*=29:71. f) *cis*:*trans*=13:87. g) *cis*:*trans*=68:32. h) THP ether remained untouched.

diol, 5-androstene-3β,17β-diol to the 17-keto steroid, has been also achieved.

Experimental

Distillation was carried out in Kugelrohr (Büchi) and boiling points were determined by mesuring the bath temperature. All mp and bp are not corrected. All ^{1}H-NMR spectra (tetramethylsilane as an internal standard) were obtained in ppm units. The IR spectra of neat liquid film samples were measured on a Shimadzu IR-27 or Hitachi IR-215 spectrometer. Microanalysis was performed at the Elemental Analyses Center of Kyoto University. Preparative TLC plates were prepared with Merck Kiesel-gel PF_{254}. Column chromatography was carried out with silica gel (Wakogel C-200) at atmospheric pressure.

Preparation of Benzyltrimethylammonium Chlorochromate (BTMACC). Anhydrous chromium trioxide (5.0 g, 50 mmol) was dissolved in 6 M† HCl (9.0 ml, 55 mmol) at 0 °C. After stirring for 5 min, a solution of benzyltrimethylammonium hydroxide (40% in H_2O, 23 g, 55 mmol) was carefully added over 10 min to give an orange solid which was collected, washed, and dried for 5 h *in vacuo* (yield 13.1 g, 96%, mp 85 °C (decomp)). Found: C, 41.69; H, 5.43; N, 4.80%. Calcd for $C_{10}H_{16}ClNO_3Cr$: C, 42.11; H, 5.61; N, 4.91%. Other chromium(VI) reagents were prepared in a similar fashion.

Oxidation of 4-t-Butylcyclohexanol to 4-t-Butylcyclohexanone. A Typical Procedure for the Oxidation of Alcohols with PFC, BTMACC, or TBACC: A solution of 4-*t*-butylcyclohexanol (0.31 g, 2.0 mmol) in CH_2Cl_2 (2.0 ml) was added in one portion to the CH_2Cl_2 (8.0 ml) suspension of PFC (0.80 g, 4.0 mmol). After stirring for 6 h at 25 °C, the resulting mixture was diluted with ether (20 ml) and the supernatant was decanted. The residue was washed twice with 10 ml portions of ether. The combined organic solution was washed with $NaHSO_3$ and brine. Purification by silica gel column chromatography gave 4-*t*-butylcyclohexanone (0.28 g) in 92% yield.

General Procedure for the Preparation of Mono Ethers. According to the reported method,[5] diols **1**, **4**, and **5** were transformed into their monosilyl ethers on treatment with Bu^tMe_2SiCl and Et_3N in the presence of 4-dimethylaminopyridine. Similarly, trityl ether **2b** was prepared from diol **1** and Ph_3CCl instead of Bu^tMe_2SiCl.[6]

11-(t-Butyldimethylsiloxy)-2-undecanone. A dichloromethane solution of 11-(*t*-butyldimethylsiloxy)-2-undecanol (0.6 g, 2.0 mmol) was combined with PFC (0.8 g, 4.0 mmol) and the whole was stirred for 3 h at 25 °C. Workup (Et_2O, $NaHSO_3$) and purification by preparative TLC gave the title compound (0.53 g, 89% yield) as an oil: Bp 116—118 °C (bath temp, 1 Torr‖); IR (neat) 2890, 2820, 1705, 1250, 1090, 830 cm^{-1}; NMR ($CDCl_3$) δ 0.03 (s, 6H), 0.91 (s, 9H), 1.2—1.4 (m, 10H), 1.4—1.6 (m, 4H), 2.13 (s, 3H), 2.40 (t, *J*=7.4 Hz, 2H), 3.57 (t, *J*=6.5 Hz, 2H). Found: C, 67.78; H, 12.32%. Calcd for $C_{17}H_{36}O_2Si$: C, 67.94; H, 12.07%.

11-Hydroxy-2-undecanone (3). A THF solution of siloxyl ketone (0.30 g, 1.0 mmol) was treated with Bu^n_4NF (1.0 M THF solution, 1.1 ml) for 30 min at 25 °C to give the hydroxy ketone (0.30 g) quantitatively: Mp 42—43 °C; IR (neat) 3424, 1709, 1358, 1042 cm^{-1}; NMR (CCl_4) δ 1.1—1.8 (m, 14H), 2.09 (s, 3H), 2.36 (t, *J*=6.6 Hz, 2H), 3.58 (t, *J*=6.8 Hz, 2H), 3.78 (b, 1H). Found: C, 70.65; H, 11.90%. Calcd for $C_{11}H_{22}O_2$: C, 70.92; H, 11.90%.

3-[2-(t-Butyldimethylsiloxy)ethyl]cyclopentanone: Bp 137 °C (bath temp, 1 Torr); IR (neat) 1730, 1250, 1100, 830, 770 cm^{-1}; NMR ($CDCl_3$) δ 0.03 (s, 6H), 0.85 (s, 9H), 1.2—2.5 (m, 11H), 3.62 (t, *J*=5.8 Hz, 2H). Found: C, 64.51; H, 10.96%. Calcd for $C_{13}H_{26}O_2Si$: C, 64.46; H, 10.74%.

p-[(t-Butyldimethylsiloxy)methyl]phenyl Methyl Ketone: Bp 103 °C (bath temp, 1 Torr); IR (neat) 2900, 1670, 1600, 1266, 1092 cm^{-1}; NMR ($CDCl_3$) δ 0.05 (s, 6H), 0.85 (s, 9H), 2.44 (s, 3H), 4.64 (s, 2H), 7.2—7.9 (m, 4H). Found: C, 68.10; H, 9.35%. Calcd for $C_{15}H_{24}O_2Si$: C, 68.18; H. 9.09%.

Conversion of 5-Androstene-3β,17β-diol (6) to 3β-Hydroxy-5-androsten-17-one. Following the Hosoda's prodcedure,[7] diol **6** was converted into monosilyl ether **7** in 70% yield. This compound (0.20 g, 0.5 mmol) was treated successively with PFC (0.20 g, 1.0 mmol) and Bu^n_4NF (5.5 mmol) to give 17-keto steroid (0.13 g, 89% yield) which was identifical with an authentic sample.

Equilibria in Aqueous Ternary System Containing Na^+, $CH_3CO_2^-$, and HPO_4^{2-} between 38 and 75 °C

Takahiro WADA,* Fumiko YOKOTANI, and Yoshihiro MATSUO
Central Research Laboratory, Matsushita Electric Industrial Co., Ltd., 1006 Kadoma, Osaka 571
(Received September 1, 1983)

Synopsis. Ternary system CH_3CO_2Na–Na_2HPO_4–H_2O was investigated between 38 and 75 °C. No double salt formation occurs in this temperature range. Saturated CH_3CO_2Na solution has a strong dehydrating influence on $Na_2HPO_4 \cdot 2H_2O$ and $Na_2HPO_4 \cdot 7H_2O$. The lowest formation temperature for anhydrous Na_2HPO_4 is about 57 °C.

Recently, Kimura[1] reported that addition of a small amount of a mixture of disodium hydrogenphosphate and anhydrous sodium acetate to a sodium acetate solution is very effective for the crystal nucleation of sodium acetate trihydrate from the solution. Wada and Matsuo[2] have studied the influence of preheating on the crystallization of sodium acetate trihydrate from its aqueous solution with a small amount of disodium hydrogenphosphate added, proposing an adsorption model to account for the crystal nucleation catalytic effect. To complete the investigation, knowledge is required of the ternary system, sodium acetate–disodium hydrogenphosphate–water. Phase diagrams of the binary systems, sodium acetate–water and disodium hydrogenphosphate–water, based on data from Seidell's compilation,[3] are shown in Fig. 1. In this figure, W_a and W_b are the mass fractions of sodium acetate and disodium hydrogenphosphate, respectively.

This paper reports results from an investigation using disodium hydrogenphosphate together with sodium acetate aqueous solution.

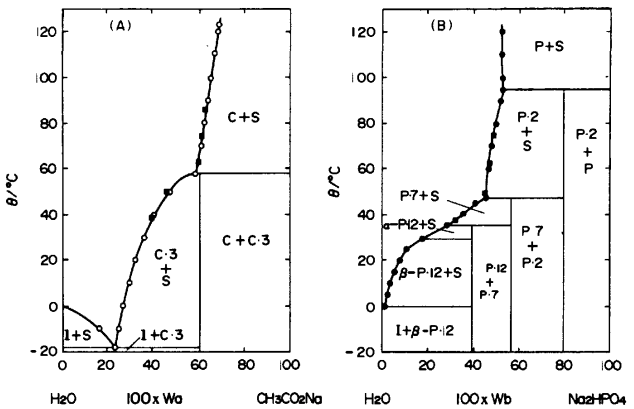

Fig. 1. Phase diagrams of the binary systems, CH_3CO_2Na–H_2O (A) and Na_2HPO_4–H_2O (B). Symbols: I = ICE, C = CH_3CO_2Na, C·3 = $CH_3CO_2Na \cdot 3H_2O$, P = Na_2HPO_4, P·2 = $Na_2HPO_4 \cdot 2H_2O$, P·7 = $Na_2HPO_4 \cdot 7H_2O$, P·12 = $Na_2HPO_4 \cdot 12H_2O$, S = Solution.
○: the data obtained by Green,[4] ●: the average of the reported data (the transition temperature between α-P·12 and β-P·12 in the presence of P·7 is not unkown),[3] ■: the data obtained by the present experiment.

Experimental

Sodium acetate trihydrate, anhydrous sodium acetate, and disodium hydrogenphosphate were guaranteed grade reagents. Experiments were conducted as previously described.[5] Phosphate ion was analyzed colorimetrically. The concentration of dissolved total salts was determined by drying the supernatant solution. The sodium acetate concentration was calculated from the difference in concentration between total salts and disodium hydrogenphosphate. The redidual solid existing in equilibrium with the saturated solution was separated out and identified by the X-ray diffraction. The solution in equilibrium with two solid phases was confirmed by analyzing the solution with those solids added.

Results

For the ternary system sodium acetate–disodium hydrogenphosphate–water, four sets of data for isotherms between 38 and 75 °C are shown in Table 1. Solubilities of the binary systems, sodium acetate–water and disodium hydrogenphosphate–water, determined by the present experiment, are plotted in Fig. 1. From Fig. 1, it is clear that the solubilities determined here are in good agreement with the reported data.

There is no formation of double salt in the present system between 38 and 75 °C. It is noteworthy that the saturated sodium acetate solutions contain only a small amount of disodium hydrogenphosphate and that they have a very strong dehydrating influence on the disodium hydrogenphosphate hydrates. The outline of the ternary system below 75 °C is given in Fig. 2, with

Effect of M-series PRBS Modulation on the Time Resolution in Correlation Photoacoustics

Yoshinori SUGITANI* and Akinori UEJIMA
Institute of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305
(Received September 5, 1983)

Synopsis. Time resolution in the first kind correlation photoacoustics using the M-series PRBS mechanical light modulator was experimentally checked. It was found that the time resolution limited by the mechanical chopper was more determinative than that by the microphone detector or the time delay unit in the experimental system used.

It has been demonstrated[1,2] that the introduction of the cross-correlation technique into photoacoustic spectroscopy enables a new kind of experiment such as measuring the delay time of photoacoustic output signal with respect to the exciting light, or recording the absorption spectra of a definite layer lying deep in a layered material. The delay time measurement is conducted by the correlation photoacoustics of the first kind, where the spectra are obtained from the measurement of cross-correlation function $C(\tau)$ between an exciting input and the resultant photoacoustic output as a function of delay time τ. The measurement of the absorption spectra of a layer is referred to as the correlation photoacoustics of the second kind, where the cross-correlation function is recorded as a function of the exciting wavelength λ at the fixed delay time τ_0 of the reference signal.

In the first kind correlation photoacoustics we are interested in the shortest limit of the delay time measurable by the present experimental system. A similar problem occurs in the measurement of the second kind correlation spectra in the sense that one would be interested in the shortest distance between layers which can be resolved from each other by the present system. Both of these problems are reduced to the same term of "time resolution", since the distance between layers can be converted into time scale if the thermal conductivity of the material is known, and *vice versa*.

Experimental

A block diagram for the first and second kind correlation photoacoustics is shown in Fig. 1. In the present work only the first kind correlation spectra have been measured. The exciting light from the He-Ne laser source(NEC, 50 mw) was mechanically modulated by the chopper which gives a pseudo random binary sequence(PRBS) modulaton based on the M-series (maximum-length linear shift register) binary sequence. The modulated light was introduced into a photoacoustic cell to irradiate the carbon black sample. The output was detected by a microphone (SONY, electret condenser type, FET buffer included, No. 8-814-196-50) and was fed into a correlator, essentially an integral circuit. The reference signal detected by a photo-diode was delayed by the variable amount of τ at T. D. U. (Time Delay Unit) and led into the correlator, the output of which was recorded as a function of τ.

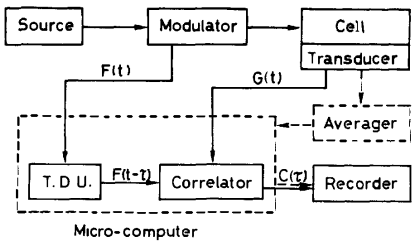

Fig. 1. Block diagram showing the experimental setup for the measurement of the first kind correlation photoacoustic spectra.

Results and Discussion

There are many factors which will influence the limit of experimental time resolution. Some are concerned with the characteristics of the sample measured. One of the major factors coming from the measuring system would be the way of modulating input signal.

Figure 2 shows the power spectrum of the input signal produced by a PRBS chopper with $63(=2^6-1)$ binary bit in a sequence, when rotated at 390 rpm. The upper limit of the modulation frequency contained in the spectrum is around 410 Hz neglecting the higher order components, so that the time resolution attainable by this chopping system would be about 2.5 ms(=1/400 s) at highest. To improve time resolution, or to increase the highest component of modulating frequecy contained, one has to either raise the rotating speed of the chopper or use other choppers which have larger number of binary bits of the M-series. Figure 3 shows the first kind correlation spectra by the use of the $31(=2^5-1)$ bit and $127(=2^7-1)$ bit PRBS choppers at the rotating speed of 396 rpm. The delay time of about 0.5 ms obtained from the peak position of curve A is considerably smaller than that

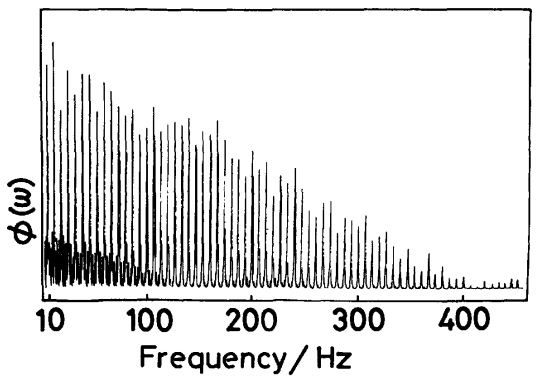

Fig. 2. Power spectrum of the M-series 63 bit PRBS chopper rotated at 396 rpm. Higher frequency part of the spectrum starting from about 410Hz is omitted in the figure.

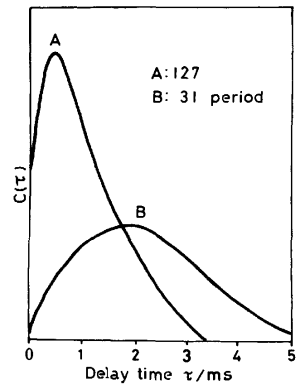

Fig. 3. The first kind correlation photoacoustic spectra of carbon black sample with the use of the 127 bit (A) and 31 bit (B) choppers rotated at 396 rpm.

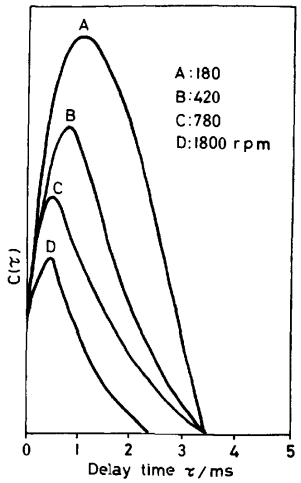

Fig. 4. The first kind correlation photoacoustic spectra of the carbon black sample recorded at the different rotating speeds of the 127 bit PRBS chopper; A: 180, B: 420, C: 780, and D: 1800rpm.

from curve B(about 2 ms), showing that the 127 bit chopper gives much closer value to the delay time of carbon black. Similar experiments using the 255 bit PRBS chopper showed the same line shape and peak position as curve A, indicating that the delay time 0.5ms obtained by the 127 bit chopper gives the lowest τ value when the choppers are rotated at 396 rpm.

Figure 4 shows the change of the first kind correlation spectra of the carbon black at different rotating speeds of the 127 bit PRBS chopper. The peak position of curve D agrees with that of curve C within the experimental error. Similar results have been obtained with the use of a 255 bit chopper at lower rotating speeds (approximately at half speeds). A 511 ($=2^9-1$) bit chopper which comes next to the 255 bit one would be the biggest possible one in view of manufacturing and/or stability of rotation at high speeds. We are not yet successful in driving the 511 bit chopper at a sufficient stability probably due to the lack of driving power. The time resolution practically obtainable with the use of the 127 bit chopper would be $(1/127\times1/30)s\fallingdotseq260\ \mu s$ at highest when rotated at 1800 rpm.

The ways of signal detection and signal processing are other important factors which determine the limit of time resolution. The microphone used in the present experiment has the working range up to about 15 kHz. Consequently the time resolution with the use of this microphone could reach to 70 μs which is sufficiently shorter than 260 μs, the time resolution limited by the 127 bit chopper.

The slowest part of the signal processing of the present system lies in the time delay unit(T. D. U., Fig.1) which digitally delays the reference signal by certain amount of τ by a microcomputer(NEC, TK-80) program. The limit of time resolution of this unit is determined by the speed of the microprocessor(D8080-AFC) of TK-80 as tens of microseconds[3], which is a comparable order of magnitude to that limited by the microphone. The correlator in our system is made by the analog unit which works much faster than the TK-80 digital unit, so that no limit of time resolution from the correlator unit will be put in the present system of signal processing.

Great improvements in time resolution would be expected by the use of a laser source in place of the xenon lamp source, an acousto-optic modulating system in place of the mechanical PRBS chopping system, or a piezoelectric detecting system in place of the microphonic detection. Effect of these replacements will be studied on conditions developed.

Authors wish to thank Professor Kozo Nagashima, The University of Tsukuba, Institute of Chemistry, for his kind support and encouragement during the course of this work.

The Crystal Structure of $(TMTTF)_2ReO_4$

Hayao KOBAYASHI,* Akiko KOBAYASHI,† Yukiyoshi SASAKI,† Gunzi SAITO,†† and Hiroo INOKUCHI††
Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274
†*Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*
Institute for Molecular Science, Okazaki 444
(Received October 19, 1983)

Synopsis. The crystal of $(TMTTF)_2ReO_4$ is isomorphous with the other $(TMTTF)_2X$ compounds($X=ClO_4$, PF_6, Br,···). TMTTF molecules are stacked face-to face to form a zig-zag column. Although the structure of $(TMTTF)_2ReO_4$ closely resembles that of the analogous compound, $(TMTSF)_2ReO_4$, the loose intermolecular contacts in $(TMTTF)_2ReO_4$ suggest that the intermolecular interaction appears to be much weaker than that in $(TMTSF)_2ReO_4$.

It is well-known that tetramethyltetraselenafulvalene(TMTSF) forms a number of 2:1 salts with a variety of monovalent inorganic anions (Bechgaard salt). They exhibit a superconducting-phase transition and the charge (or spin)-density wave instability characteristic of one-dimensional metal systems.[1] Although the Bechgaard salts are isomorphic with each other, their physical properties are different from salt to salt and are sensitive to the small structural change induced by the variation in the anions. The sulfur analog, tetramethyltetrathiafulvalene (TMTTF), also form the isostructural series of $(TMTTF)_2X$ salts ($X=ClO_4$, PF_6, Br,···).[2] The band-structure calculation[3] shows that the Fermi surface of $(TMTTF)_2X$ is composed of distorted planes, quite similar to that of $(TMTSF)_2X$.[4] However, unlike $(TMTSF)_2X$, $(TMTTF)_2X$ undegoes a metal-insulator transition at a comparatively high temperature.[5] Recent studies have shown that $(TMTTF)_2Br$ and $(TMTTF)_2SCN$ take the antiferromagnetic ground states.[6,7]

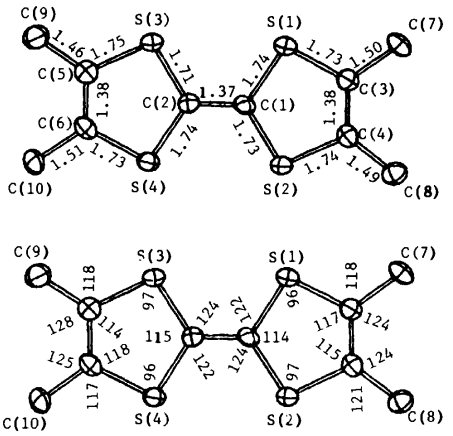

Fig. 2. The bond lengths (Å) and angles (°) of TMTTF. The averaged standard deviations of the bond lengths and angles are 0.02 Å and 1.3 °, respectively.

We also made structure analyses of $(TMTTF)_2X$ ($X=ClO_4$, ReO_4) and $(TMTSF)_2X$ ($X=BF_4$, ReO_4), $(TMTSF)_2BF_4$ structure of which has been previously reported.[8] However, we found that the structural description has been made on $(TMTSF)_2ReO_4$ and $(TMTTF)_2ClO_4$.[2,9] In this paper, we wish to report on the crystal structure of $(TMTTF)_2ReO_4$.

The black needle crystals were prepared electrochemically. The crystal data are: $(TMTTF)_2ReO_4$, $(C_{10}H_{12}S_4)_2ReO_4$, F.W.=771.1, triclinic, $P\bar{1}$, a=7.166(2), b=7.621(2), c=13.230(3) Å, α=86.62(2), β=95.56(2), γ=108.20(2)°, U=679.5(3) Å^3, Z=1, d_c=1.88 gcm^{-3}. The intensities were measured on a Rigaku automated diffractometer with Mo $K\alpha$ radiation up to 2θ=60°. The structure refinement gave a conventional R value of 0.066. The structure is shown in Fig. 1. The bond lengths and angles are given in Fig. 2. The atomic coordinates are given in Table 1. The table of the anisotropic temperature factors and F_o-F_c table are kept at the Chemical Society of Japan (Document No. 8421).

As has been mentioned before, $(TMTTF)_2ReO_4$ is isostructural with the other compounds of the $(TMTTF)_2X$ and $(TMTSF)_2X$ series. The planar TMTTF molecules are stacked face-to-face to from a zig-zag column along the a axis. Two independent interplanar distances are 3.57 (A···B) and 3.59 Å (A···C) (see Fig. 1). These values are somewhat larger than those of the other $(TMTTF)_2X$ salts:[2] 3.50, 3.53 Å (x=Br); 3.50, 3.57 (NO_3); 3.50, 3.54 (I); 3.54, 3.56 (BF_4); 3.49, 3.56 (SCN); 3.52, 3.59 (ClO_4); 3.53, 3.62 (PF_6). There appears to be a good correlation between the size of the anions and the interplanar distances. Although the $(TMTTF)_2X$ compound is considred to be a one-dimensional metal around room temperature, there is no short intermolecular contact along the columns. The shortest S···S distance in $(TMTTF)_2ReO_4$ (3.74 Å) is longer than the van der Waals distance of S···S (3.70 Å). Similarly, in the perchrolate salt, the shortest S···S distance is 3.73 Å.[10]

The short contact between Se stoms and the atoms of the anions is a common structural feature in $(TMTSF)_2X$ systems.[11] The shortest Se···O distance in $(TMTSF)_2ReO_4$ is 3.10 Å,[10] indicating a strong coupling between the TMTSF columns and the ReO_4 anions. This is consistent with the occurence of a sharp metal-insulator transition in $(TMTSF)_2ReO_4$, where the distortion of TMTSF columns and the displacement of ReO_4 anions take place cooperatively.[12] However, the shortest S···O contact in $(TMTTF)_2ReO_4$ is 3.12 Å, which is only slightly shorter than the corresponding van der Waals distance. The generous metal-insulator transition in $(TMTTF)_2X$[5] ($X=BF_4$, ClO_4, SCN,···) may be attributable to the loose contact between TMTTF columns and the anions. The preliminary resistivity measurement of $(TMTTF)_2ReO_4$ suggests the existence of a metal-insulator transition around 230 K, with the room-temperature resistivity of 0.03 Ω cm.

The Partial Molar Volume of 1-Alkanols in a Sodium Dodecylsulfate Solution around Its Critical Micelle Concentration

Masahiro MANABE,* Sumiyoshi KIKUCHI, Shingo KATAYAMA, Susumu TOKUNAGA, and Masaharu KODA
Department of Industrical Chemistry, Niihama Technical College Niihama, Ehime 792
(Received October 20, 1983)

Synopsis. The partial molar volume (V_a) of 1-alkanols (C_6–C_8) was determined at 25 °C in a solution of sodium dodecylsulfate up to its critical micelle concentration in water. The V_a in micellar solutions is higher than that in non-micellar ones. This increase in V_a has been explained in terms of the promotion of micellization by the addition of alkanol.

The partial molar volume of 1-alkanols[1,2] and alkanes[3,4] in a micellar solution of surfactants has been reported to be higher than that in water. The higher value has been attributed to the incorpotation of the solubilizate in micelles, their inside having an oil-like character.

On the other hand, the higher value can possibly be explained in terms of the transformation of the monomer surfactant species into a micellar one on the addition of the solubilizate, judging from the following well-known facts. One is the lowering of the critical micelle concentration (cmc) of the surfactants in the presence of alkanols.[5] Another is the higher partial molar volume of the micellar surfactant species than that of the monomer one in water.[6] No quantitative explanation derived from the viewpoint of micellization has, however, been proposed until now.

In order to confirm the validity of this explanation, the partial molar volume of 1-alkanols (C_6–C_8) was determined in solutions of sodium dodecylsulfate (SDS), up to 8 mmol kg^{-1}, just around cmc_0 (cmc in water) at 25 °C. The method of determination was the same dilatometric one as was used in previous studies[1,7]: a small amount of alkanol was successively injected into a dilatometer filled with a SDS solution.

The dependence of the experimentally determined partial molar volume (V_a) on the concentration of alkanol (C_a) for heptanol is illustrated in Fig. 1. In SDS solutions with very low concentrations as well as in water, V_a continues to be constant up to the solubility of the alkanol, followed by higher constant V_a values obtained in a turbid solution. When the SDS concentration (C_s) exceeds a certain value (C_s=2 mmol kg^{-1} for heptanol), an abrupt increase in V_a from a lower constant value to a higher one appears, without turbidity, at an alkanol concentration (C_a^*). Thereafter, the solution is saturated with the alkanol. The trend is obvious that C_a^* decreases and the solubility increases as C_s increases. As may be seen in Fig. 1, the respective concentrations, C_a^*, and the solubility coincide reasonably well with the alkanol concentration at the cmc of SDS, as determined by a surface-tension method.[8] The consistency shows that the abrupt increase in V_a at C_a^* is due to the beginning of micelle formation upon the addition of alkanol.

As for each SDS solution, the values of V_a below C_a^*, between C_a^* and the solubility, and above the solubility are averaged to give the respective mean values, V_a^f, V_a^m, and V_a^s, which are then plotted in Fig. 2 against C_s, together with the literature data.[1] It may be seen that each value has little dependence on C_s. V_a^f is close to the V_a in water: V_a^f corresponds to the partial molar volume of monomerically dissolving alkanol. V_a^m reflects the partial molar volume of alkanol in the presence of micelles, and V_a^s corresponds to that of alkanol in the separated phase. The values for each state of alkanol are averaged again, denoted by $\overline{V}_a^f$, $\overline{V}_a^m$, and $\overline{V}_a^s$, and listed in Table 1. It may be noticed that $\overline{V}_a^m$ is in agreement with the partial molar volume of each alkanol determined above the cmc_0 of SDS (Fig. 1). This fact suggests that the partial molar volume of alkanol at just cmc_0 must be equal to $\overline{V}_a^m$. $\overline{V}_a^s$ is close to the molar volume of pure liquid alkanol[1] (see Table 1), although the alkanol in the separated phase is not pure, but saturated with water.

In order to simplify the discussion, we will consider the volumetric behavior under the particular condition that the concentrations of both the micelle and the added alkanol are extremely low. If a small amount of alkanol (ΔC_a mol) is added to such a SDS solution (1 dm^3) with a very low concentration of the micelle (at cmc_0), it is probable that almost the entire amount of the added alkanol will dissolve monomerically in the aqueous bulk phase and cause the volume-increase by

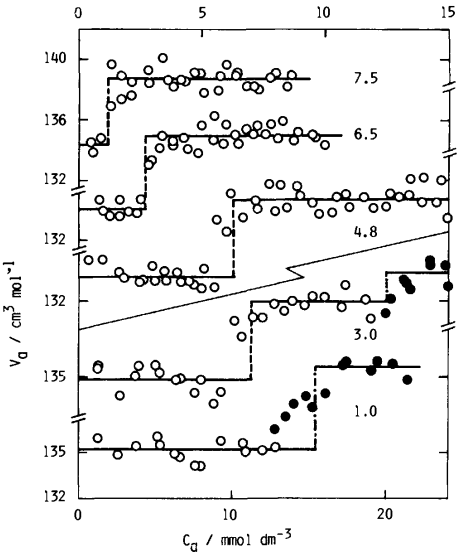

Fig. 1. The dependence of partial molar volume of 1-heptanol on its concentration in SDS solution at 25 °C. Closed circle indicates appearance of turbidity. Broken line and chain one indicate the concentration of the alkanol at cmc of SDS and solubility of the alkanol, respectively, taken from Ref. (1). Number represents C_s (mmol kg^{-1}).

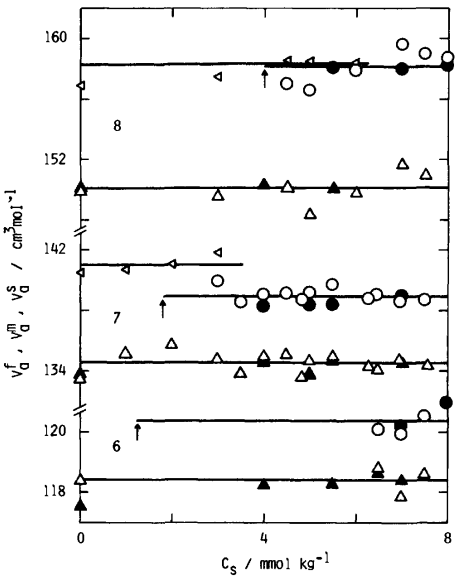

Fig. 2. The dependence of partial molar volume of 1-alkanols on the concentration of SDS at 25 °C. Large triangle, circle, and small triangle represent V_a^f, V_a^m, and V_a^s, respectively. Closed mark is from Ref.(1). Number indicated the number of carbon atoms in the alkanol molecule. Arrow indicates C_s below which micelle formation is impposible, described in Ref. (8).

Table 1. Partial molar volume of 1-alkanols in an SDS solution at 25 °C

	Partial molar volume/cm^3 mol^{-1}				
	$\overline{V}_a^f$	$\overline{V}_a^m$		$\overline{V}_a^s$	Molar volume[b]
		Below cmc_0	Above cmc_0[b]		
N[a]	—	—	—	—	—
6	118.36	120.38	120.93		124.70
7	134.50	138.87	139.04	141.02	141.59
8	150.12	158.11	157.53	158.21	157.91

a) Number of carbon atoms in an alkanol molecule.
b) Taken from Ref. (1).

$\Delta\overline{V}_s$ ($-\Delta$cmc) resulting from the micellization of Δcmc mol of SDS, since the increase in the concentration of alkanol (ΔC_a mol dm^{-3}) leads to the decrease in cmc (Δcmc mol dm^{-3}), where $\Delta\overline{V}_s$ indicates the partial molar volume increment of SDS on its micellization. Therefore, the total volume increment of the whole solution is $\overline{V}_a^f\,\Delta C_a+\Delta\overline{V}_s$ ($-\Delta$cmc). On the basis of the general definition of the partial molar volume, the volume increment per mole of alkanol added to the micellar solution, $\overline{V}_a^m$, corresponds to $\overline{V}_a^f+\Delta\overline{V}_s$ ($-\Delta$cmc/ΔC_a) *i.e.* $\overline{V}_a^m-\overline{V}_a^f=\Delta\overline{V}_s$ ($-\Delta$cmc/ΔC_a). The validity of the equation can be checked in Fig. 3, by using the literature data of the rate of cmc-lowering, Δcmc/ΔC_a, of 1-alkanols in an SDS solution[5] and of the $\Delta\overline{V}_s$ for SDS in water (11 cm^3 mol^{-1}).[6] It can be recoginzed that the point ($\overline{V}_a^m-\overline{V}_a^f$, $-\Delta$cmc/ΔC_a) for each alkanol falls on a straight curve with a slope of unity and passing through 11 cm^3 mol^{-1} ($\Delta\overline{V}_a$) at the unity of $-\Delta$cmc/ΔC_a, taking the experimental errors of each term into account. The result gives the conclusion that the gain in the partial molar volume, $V_a^m-V_a^f$, is essentially to be attributed, no to the solubilization of the added alkanol,[1,2] but to the promotion of the micellization of SDS alone.

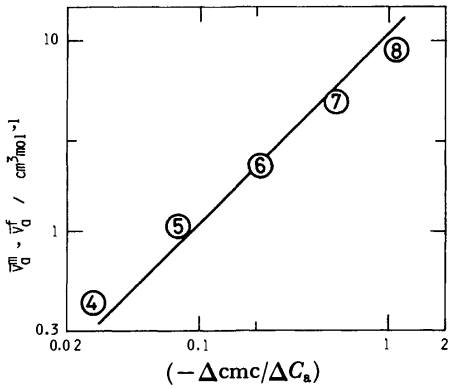

Fig. 3. The relation between log ($\overline{V}_a^m-\overline{V}_a^f$) and log ($-\Delta$cmc/$\Delta C_a$) in 1-alkanol $-$SDS system at 25 °C. Number indicates the number of carbon atoms in alkanol molecule. For the straight curve, see in text. $\overline{V}_a^m$ and $\overline{V}_a^f$ of 1-butanol and 1-pentanol are taken from Ref.(1).

Above cmc_0, V_a^m must be correlated in a complicated manner with the amount of solubilized alkanol. If we can estimate the quantity corresponding to Δcmc/ΔC_a at any concentration of the surfactant, the further analysis of V_a^m will be possible.

(Received November 1, 1983)

Synopsis. The dimer yields in the radiolysis of the *neo*-C_5H_{12}-*cyclo*-C_5H_{10} (1 mol%) mixtures at 77 and 4 K have been measured by capillary gas chromatography. Analysis of the results indicates that cyclopentyl radicals are produced selectively at 77 K, while their selective formation is suppressed at 4 K. This result coincides well with the data obtained by ESR spectroscopy.

When neopentane containing a small amount of other alkane is γ-irradiated at 77 K, solute alkyl radicals are formed selectively.[1] H atoms, produced by the radiolysis of neopentane, abstract hydrogen atoms much more efficiently from the alkane solute than the neopentane solvent to form the solute radicals selectively.[2] This phenomenon was also found in several solid alkanes.[3] The selective formation of radicals was studied by ESR spectroscopy which can only detect trapped reaction intermediates. Since it has been generally accepted that the radiation effect is not selective, the selective formation of the solute radicals should be verified by the product analysis which gives information about overall radiation effects.

Recently the selective formation of the $C_{10}H_{21}$ radicals in the radiolysis of the n-$C_{10}D_{22}$-n-$C_{10}H_{22}$ mixtures was verified by the analysis of dimer products.[4]

Here, we report the results on dimer products in the radiolysis of the neopentane-cyclopentane mixtures as measured by a capillary gas chromatography, and compare them with the results of ESR measurement.

Experimental

The details of the experimental procedure were described in a previous paper.[5] Neopentane and cyclopentane were the same as those used previously.[5] In order to cool the sample completely, helium gas at 400 mmHg was sealed in a cell for the γ-irradiation at 4 K. The total dose for experiments on product analysis at 4 and 77 K was fixed at 0.24 Mrad. The dose rate of γ-rays was 0.14 Mrad h^{-1}.

Product analysis was performed by means of Varian Aerograph 1440 and 3700 gas chromatographs with a FID detector. The capillary column (25 m×1.25 mm) was coated with squalane. A typical chromatogram of the heavy products in the radiolysis of neopentane was shown in a previous paper.[5]

The radicals produced in the irradiated samples were measured with a JEOL ESR spectrometer at microwave power levels of 200 μW at 77 K and 10 μW at 4 K.

Results and Discussion

When pure neopentane is γ-irradiated at 77 K, neopentyl radicals are the main radicals observed by ESR spectroscopy.[2] Figure 1A shows the ESR spectrum of the *neo*-C_5H_{12}-*cyclo*-C_5H_{10} (1 mol%) mixture γ-irradiated at 77 K. The spectrum consists of the spectrum of cyclopentyl radicals, denoted by arrows (↑), and that of neopentyl radicals, denoted by arrows (↑). The relative yield of the cyclopentyl radicals, measured by a double integration of the spectrum, amounts to 26% of the total radical yields, which is much higher than the concentration (1 mol%) of cyclopentane in the mixture. The selective formation of the solute radicals was reported previously by Miyazaki *et al.*[1] Figure 1B shows the ESR spectrum of the *neo*-C_5H_{12}-*cyclo*-C_5H_{10} (1 mol%) mixture containing He, γ-irradiated at 4 K and measured at 4 K. It is seen that cyclopentyl radicals are not observed at all, but neopentyl radicals, denoted by arrows (↕), are formed, exclusively.[6,7]

In order to measure the dimer products in the radiolysis of the *neo*-C_5H_{12}-*cyclo*-C_5H_{10} mixture by gas chromatography, 2,2,5,5-tetramethylhexane (bineopentyl), neopentylcyclopentane, and bicyclopentyl were synthesized and their structures were determined by ^{13}C NMR spectroscopy. The chromatographic retention of the radiolysis products was compared with that of the

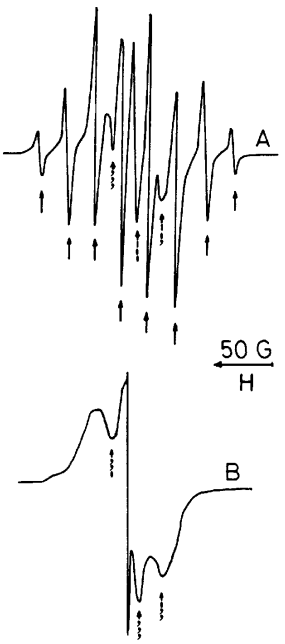

Fig. 1. ESR spectra of γ-irradiated *neo*-C_5H_{12}-cyclo-C_5H_{10} (1 mol%). A, Spectrum measured at 77 K after γ-irradiation at 77 K; B, Spectrum measured at 4 K after γ-irradiation at 4 K. Total doses at 77 and 4 K are 0.24 and 0.06 Mrad, respectively.

Table 1. Relative yields of dimer products in the radiolysis of neopentane at 77 K and 4 K[a]

Product[b]		*neo*-C_5H_{12}	*neo*-C_5H_{12}-*cyclo*-C_5H_{10} (1 mol%)	
		77 K	77 K	4 K
2233TeMC$_4$		—	—	0.23
2244TeMC$_5$		0.03	0.04	—
225TMC$_6$		0.05		0.02
C_9H_{18}[c]		0.19	0.20	0.15
bineopentyl		1.0	1.0	1.0
$C_{10}H_{22}$		0.08	0.07	0.08
neopentyl-cyclopentane		—	0.63	0.07
bicyclopentyl		—	0.13	0.003

a) Yield of bineopentyl is taken as 1. *G*-values of bineopentyl at 77 and 4 K are approximately 0.3. b) T, Te, and M represent tri, tetra, and methyl, respectively. For example, 2233TeMC$_4$ means 2,2,3,3-tetramethylbutane. c) C_9H_{18} represents a mixture of isomers. (*cf.* Ref. 5)

synthesized one. The relative yields of dimer products are shown in Table 1. Bineopentyl, neopentylcyclopentane and bicyclopentyl are all formed in the radiolysis of the *neo*-C_5H_{12}-*cyclo*-C_5H_{10}(1 mol%) mixture at 77 K. In the radiolysis at 4 K, however, the formation of neopentylcyclopentane and bicyclopentyl is suppressed drastically, but bineopentyl is still a main product.

The relative yields of neopentyl and cyclopentyl radicals can be estimated from the dimer yields by the following assumptions: (1) the dimer formation is due to the recombination of radicals; (2) neopentyl and cyclopentyl radicals have the same dispropotionation-combination rate constant ratio, k_d/k_c. Then, the relative yields of neopentyl and cyclopentyl radicals can be obtained as follows:[8]

$$\text{Yield of } \textit{neo}\text{-}C_5H_{11} = 2 \times (\text{bineopentyl yield}) + (\text{neopentylcyclopentane yield})$$

$$\text{Yield of } \textit{cyclo}\text{-}C_5H_9 = 2 \times (\text{bicyclopentyl yield}) + (\text{neopentylcyclopentane yield})$$

The relative yields of neopentyl and cyclopentyl radicals in the radiolysis of the *neo*-C_5H_{12}-*cyclo*-C_5H_{10} (1 mol%) mixture at 77 and 4 K are summarized in Table 2. Since k_d/k_c for secondary radicals, such as cyclopentyl radicals, may be larger than that for primary radicals, such as neopentyl radicals,[9] the relative yields of the cyclopentyl radicals may be somewhat underestimated. The radical yields obtained by the product analysis coincide well with those by ESR spectroscopy. The yields of cyclopentyl radicals at 77 K are much higher than expected from the mole fraction of cyclopentane in the mixture. Thus, it has been confirmed from product analysis as well as ESR measurement that the cyclopentyl radicals, *i.e.*, solute radicals, are selectively formed in the radiolysis of the *neo*-C_5H_{12}-*cyclo*-C_5H_{10} (1 mol%) mixture at 77 K.

Table 2. Relative yields of neopentyl and cyclopentyl radicals in the radiolysis of *neo*-C_5H_{12}-*cyclo*-C_5H_{10} (1 mol%) at 77 and 4 K[a]

Radicals	77 K		4 K	
	Prod. Anal.[b]	ESR[c]	Prod. Anal.[b]	ESR[c]
neo-C_5H_{11}	1.00	1.00	1.00	1.00
cyclo-C_5H_9	0.33	0.35	0.03	<0.05

a) Yield of *neo*-C_5H_{11} radicals is taken as 1.00. b) Yield of radicals were obtained by analysis of dimer products. c) Yield of radicals were obtained by ESR measurements. The ratio of concentration of *cyclo*-C_5H_9 radicals to that of *neo*-C_5H_{11} radicals did not change after annealing the γ-irradiated sample to 77 K.

Interionic Charge Transfer Enhanced by Hydrophobic Interaction

Koichi HIRANO* and Masahiko TOKUHARA
Department of Chemistry, Miyagi University of Education, Aramaki-aoba, Sendai 980
(Received November 10, 1983)

Synopsis. A water solution containing Rhodamine 6G and Na-tetraphenylborate exhbits a new absorption band at 540 nm, which has the characteristics of a charge-transfer (CT) band. In organic solvents, however, such a CT band is not found. This indicates that hydrophobic interactions enhance the charge transfer interaction.

Spectroscopic studies on the charge transfer interaction in water solution have been made in connection with the biological interest.[1-6] However, very little has been reported about the effect of hydrophobic interactions on the charge transfer interaction.

In the present report we show evidence to support the view that hydrophobic interactions play an important role in the formation of the charge transfer (CT) complex.

Experimental and Results

When the sodium salts of tetraphenylborate (BPh_4^-) is added to a water solution of Rhodamine 6G (Rhod $6G^+$), a purple color appears instantaneously. At the same time, the characteristic fluorescence of the Rhod $6G^+$ ion decreases on adding the BPh_4^- solution. On the contrary, no evidence of any CT interactions with BPh_4^- was found for Rhod $6G^+$ in organic solvents such as ethanol, acetonitrile, and *N*-methylformamide. These results indicate that water enhances the CT interaction between the organic ions both possessing large hydrophobic groups.

The UV/VIS absorption spectra of the water solutions of mixtures of Rhod 6G and Na-tetraphenylborate were examined on a Shimadzu UV 200S double beam spectrophotometer at 25 C°. The results are shown in Fig. 1. The appearance of isosbestic points confirms the presence of a new complex. The absorption maximum of the new band was determined as λ=540 nm from the concentration dependence of the peak position of the spectra. We analysed the spectra on the basis of a modified Rose-Drago equation[7]:

$$\frac{ab}{d-d_0} = \left(a+b-\frac{d-d_0}{\varepsilon_C-\varepsilon_A}\right)\frac{1}{\varepsilon_C-\varepsilon_A} + \frac{1}{K(\varepsilon_C-\varepsilon_A)} \qquad (1)$$

where d_0, d, ε_A, ε_C, a, b and K denote the absorbances of Rhod $6G^+$ and mixtures, the molar absorptivites of Rhod $6G^+$ and complex, the initial concentrations of Rhod $6G^+$ and BPh_4^-, and the equilibrium constant for the complex. By means of an iterative method, the constant was determined as $K=1.02\times10^5$ l/mol at 25 C°. This is fairly comparable with the K values of the ion pair of $[(i\text{-}C_5H_{11})_3(n\text{-}C_4H_9)N]^+BPh_4^-$ determined by conductometry[8] or of fluorenylsodium by spectrophotometry.[9] These facts strongly suggest the new entity to be an interionic CT complex with 1:1 stoichiometry. Therefore, equlibrium (2) should be considered;

$$\text{Rhod } 6G^+ + BPh_4^- \rightleftharpoons \text{Rhod } 6G^+ \leftarrow BPh_4^- \qquad (2)$$

Thus the new absorption at 540 nm is ascribable to the CT band arising from the excitation of the complex.

Discussion

From Table 1, it is evident that the CT interaction between Rhod $6G^+$ and BPh_4^- is not affected by the solvent polarity, but it is storongly dependent upon the nature of the solvent, the lipophilicity or hydrophobic solvation capability. In organic solvents, the solvent-solute pairs must be formed predominantly in comparison with the solute-solute pairs, because of their relatively strong hydrophobicity. Hence, it is difficult to form the tight binding donor-acceptor ion pairs. This leads to the interuption of the subsequent charge

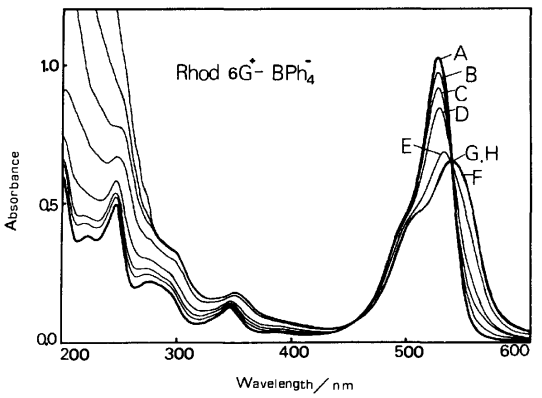

Fig. 1. Absorption spectra of Rhod $6G^+$ (1.12×10^{-5} mol/l) in water with various amounts of BPh_4^- at 25 °C. A none, B 1.06×10^{-6} mol/l, C 0.19×10^{-5} mol/l, D 0.38×10^{-5} mol/l, E 0.76×10^{-5} mol/l, F 1.52×10^{-5} mol/l, G 3.42×10^{-5} mol/l, H 6.83×10^{-5} mol/l.

TABLE 1. SOLVENT DEPENDENCE ON THE CT-COMPLEX FORMATION BETWEEN Rhod $6G^+$ AND BPh_4^- IONS

Solvent	Dielectric constant	Spectral evidence	Complex formation
Water	78.54[a]	A new band appears at 540 nm.	yes
Ethanol	24.30[b]	A shift in the Rhod $6G^+$ spectrum is observed.	no
Acetonitrile	37.45[b]	A shift in the Rhod $6G^+$ spectrum is observed.	no
N-Methylformamide	182.4[b]	A shift in the Rhod $6G^+$ spectrum is observed.	no

a) The Chemical Society of Japan, Ed. "Kagaku Binran, Kiso-hen II", Maruzen (1957) p. 1166. b) A. J. Bard, Ed. "Electroanalytical Chemistry", Marcel Dekker, Inc., New York (1969) Vol. 3, Appendix 1.

transfer since CT interaction involves short range forces, so that the formation of the CT complex is reduced. This explains why the CT band is not found in solvents such as ethanol, acetonitrile and *N*-methylformamide. On the contrary, when water is used as a solvent the stacking between the donor and acceptor ions must be promoted, for solvent water enhances the hydrophobic interactions between the two ions.[10-11] Once stacking take place between two pi-elctron systems, the charge transfer from donor to acceptor occurs easily, because intermolecular charge transfer is most strongly favored in the case where "active orbital" overlapping between donnor and scceptor is possible.[12] This is the main reason why Rhod $6G^+$ forms a CT complex with BPh_4^- in water solution.

Subsequently, we have estimated the overall free energy change on complex formation as $\Delta G=-26$ kJ/mol. Let ΔG_{HI} be the free energy change due to the hydrophobic interaction we can split ΔG into two contributions;

$$\Delta G = \Delta G_{E,C} + \Delta G_{HI} \quad (3)$$

where $\Delta G_{E,C}$ is the contributions from electrostatic and CT interactions. Sheraga[13] calculated ΔG_{HI} values for various types of hydrophobic interactions; $\Delta G_{HI}=-1.3\sim-6.3$ kJ/mol were determined. These values are relatively small in comparison with the ΔG. In spite of the fact, the hydrophobic effect on the CT interaction must be significant, because ΔG_{HI} describes the tendency to form the tight binding ion pairs, and only a fraction of the pairs yield the CT complex.

Dependence of Efficiency of Photoinduced Electron Transfer from Pyrene to Copper(II) Ion on Copper(II)-Ion Fraction on Dodecyl-Sulfate-Micelle Surface

Takashi NAKAMURA, Akira KIRA,* and Masashi IMAMURA
The Institute of Physical and Chemical Research Wako-shi, Saitama 351-01
(Received November 24, 1983)

Synopis. In quenching of the pyrene fluorescence by copper(II) ions in dodecyl sulfate micelles whose surface is covered by sodium and copper(II) ions, the pyrene-cation quantum yield decreases, after reaching a certain maximum yield, with increasing copper(II)-ion fraction. The decrease suggests that the micellar structure becomes unfavorable for electron transfer quenching as copper(II) ions displace sodium ions on the micellar surface.

Pyrene cations are produced in quenching of the pyrene singlet excited state by copper(II) ions in sodium dodecyl sulfate (SDS) micelle solutions.[1] Previous studies of fluorescence measurement[2] as well as our early laser photolysis study[1] have been made at low concentrations of both surfactant and quencher in order to avoid possible complexities caused by the change in the micellar size and shape. Recently, remarkable surfactant-concentration effects have been found in this electron transfer at SDS concentrations of 0.05—1 M (1 M=1 mol dm^{-3}).[3] The present note deals with the seemingly unusual dependence of the pyrene-cation quantum yield on the fraction of copper(II) dodecyl sulfate (CUDS) in mixed solutions of SDS and CUDS. This mixture provides dodecyl sulfate micelles covered by sodium and copper(II) ions. Considering the importance of comparison of the data for the same total dodecyl sulfate (DS^-) concentration, it is convenient to define the copper(II)-ion fraction on the micellar surface, $F(Cu^{2+})$, by

$$F(Cu^{2+}) = 2[CUDS]/(2[CUDS]+[SDS]) \quad (1)$$

where the denominator represents the total dodecyl sulfate concentration, and the value of $F(Cu^{2+})$ thus defined equals unity for CUDS solutions without SDS.

Experimental

Deaerated solutions containing 0.2 mM pyrene were subjected to laser photolysis, where a 20-ns pulse of a frequency-doubled ruby laser (347 nm) was used for excitation.[1,3] In order to prevent biphotonic ionization, the excitation intensity was adjusted so that the sample absorbed an energy of about 2 mJ cm^{-2} per pulse. The numbers of absorbed photons were estimated using the anthracene T-T absorption as a reference.[1]

Results

The pyrene fluorescence lifetime in the presence of 10 mM CUDS is 43 ns for an SDS concentration of 1.0 M and becomes shorter with decreasing SDS concentration.[3] In CUDS micelles the pyrene fluorescence vanishes within the duration of the laser pulse, indicating a lifetime shorter than 20 ns. These lifetimes are much shorter than the natural fluorescence lifetime in SDS micelles, 340 ns for SDS concentrations of 0.05 to 1.0 M. Thus, practically all the excited pyrene molecules were quenched by copper(II) ions under the present experimental conditions. The absorption spectra of pyrene cations with a peak at 450 nm were practically unchanged in shape and position under various conditions used in the experiments. The cation quantum yield, Φ, was determined from the absorbance at 450 nm where the molar absorption coefficient is 20500 $M^{-1}\,cm^{-1}$.[4]

Figure 1A exhibits the cation quantum yield as a function of the copper(II)-ion fraction in SDS/CUDS mixture solutions where the total dodecyl sulfate concentraion was kept at 0.5 M. The cation yield increases as expected with the CUDS concentration up to Φ=0.56 at a copper(II)-ion fraction of 0.2 (the data in such a region are presented elsewhere[3]) but then decreaes to converge finally to about 0.45. Such decrease in the cation yield with increasing reactant concentration is rather unusual in the chemical-kinetic point of view. The cation quantum yields in CUDS solutions containing no SDS are plotted in Fig. 2A for several CUDS concentrations. The dependence of the yield on the CUDS concentration in this plot cannot be ascribed to the difference in the copper(II)-ion fraction on the micellar surface, for $F(Cu^{2+})$=1 for all these solutions, but to the change in the micellar size, as has been discussed in our preceding paper.[3] The cation quantum yields in mixture solutions of SDS (0.05—1.0 M) and

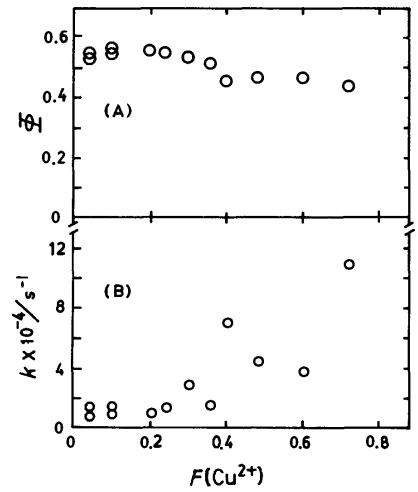

Fig. 1. The pyrene cation quantum yields (A) and the decay rate constants (B) plotted as a function of the copper(II)-ion fraction in CUDS/SDS mixture solutions where the total DS^- concentration is kept at 0.5 M.

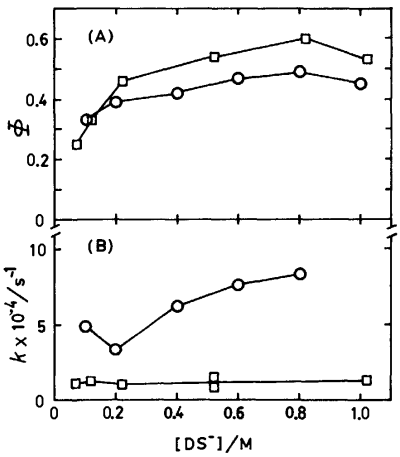

Fig. 2. The pyrene cation quantum yields (A) and the cation decay rate constants (B) in CUDS solutions (○) and in SDS solutions containing 10 mM CUDS (□) plotted as a function of the DS^- concentration.

CUDS (10 mM) are also plotted, for comparison, as a function of the total dodecyl sulfate concentration in Fig. 2A. When the two plots are compared at the same DS^- concentration, the yield for a CUDS solution is lower than that for a SDS/10 mM-CUDS mixture solution, that is, the decrease in the cation yield in the region of high copper(II)-ion fraction occurs, except in the low DS^- concentration region near 0.05 M.

The decay of pyrene cations obeyed the first-order rate law in contrast to a previous result for *N*-methylphenothiazine ions in CUDS micelles.[5] The apparent decay rate constants as plotted in Fig. 1B and 2B indicate that the decay is too slow to compete with the cation formation whose apparent rate constants exceed $2\times10^7\ s^{-1}$ (=1/(43 ns)) and that it does not affect the observed cation yield. It is interesting that the cation decay is not affected by sodium ions but enhanced by copper(II) ions, as suggested by the results shown in Fig. 2B, although this finding will not be subjected to discussion in this note.

Discussion

Phenomenologically, the pyrene cation quantum yield is given by

$$\Phi = \frac{k_{qe}[\mathrm{CUDS}]}{k_s + (k_{qe}+k_{qd})[\mathrm{CUDS}]} \qquad (2)$$

where k_s is the rate constant for the spontaneous fluorescence decay in the absence of copper(II) ions, k_{qe} is the one for electron transfer on quenching, and k_{qd} is the one for quenching processes other than the electron transfer. The electron-transfer efficiency defined by $k_{qe}/(k_{qe}+k_{qd})$ practically equals the observed cation yield, if $k_s \ll (k_{qe}+k_{qd})[\mathrm{CUDS}]$. The fluorescence decay data indicate that this condition is met in CUDS solutions. In SDS/10-mMCUDS mixture solutions, certain portions, which is less than 13% (=43 ns/340 ns), of the singlet excited pyrene molecules fail to react with copper(II) ions; therefore, the electron-transfer efficiency is higher than the observed cation yield. Thus, the decrease in the cation yield observed at high CUDS concentrations indicates the decrease in the electron-transfer efficiency. The concentration dependence of the electron-transfer efficiency is most likely connected with the change in the micellar structure, as will be discussed below.

In our preceding paper on surfactant concentration effects on electron transfer,[3] we have proposed a hypothesis that the electron-transfer efficiency is larger for a densely packed structure of the surfactant layer than for a porous structure. According to this hypothesis, the decrease in the cation yield in the region of high copper(II)-ion fraction is interpreted as that the increase in the copper(II)-ion fraction disturbs a densely packed structure attained in SDS micelles. The densely packed structure is probably peculiar to large rod-like micelles which are believed to exist in solutions of high (above about 0.5 M for SDS) surfactant concentrations.[6] The finding that the decrease in the cation yield at high copper(II)-ion fractions occurs for DS^- concentrations above 0.2 M supports the above explanation based on the densely packed structure of rod-like micelles. The exceptional agreement in the cation yield between a 50 mM-SDS/10 mM-CUDS solution and a 50 mM CUDS solution as shown in Fig. 2A is understood, if it is assumed that porous spherical micelles which lack the densely packed structure are mainly involved in the reaction at these low surfactant concentrations. Incidentally, spherical micelles of CUDS and SDS are similar in size, as suggested by the aggregation numbers (of dodecyl sulfate ions): 85 for CUDS[7] and 62 for SDS.[8]

Reactions of Dipyridylacetylenes and Carbon Disulfide under High Pressure. Synthesis of Tetra-2-pyridyltetrathiafulvalene

Takahiro NAGAWA, Yoshiaki ZAMA, and Yoshiyuki OKAMOTO*

Department of Chemistry, Polytechnic Institute of New York, Brooklyn, New York 11201, U.S.A.

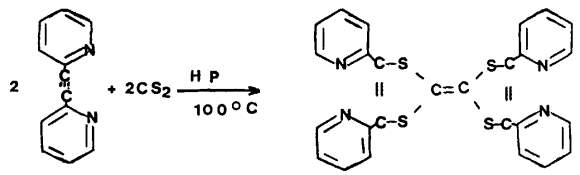
(Received August 23, 1983)

Synopsis The reaction of di-2-pyridylacetylene with CS_2 at 100 °C under 4500 atm for 12 h. gave tetra-2-pyridyltetrathiafulvalene in 80% yield.

Electron-rich tetrathiafulvalene (TTF) reacts with tetra cyanoquinodimethan (TCNQ) to form a charge transfer complex which has unusually high electrical conductivity.[1] Recently certain planar transition metal organic macrocyclic solids were also found to be conductive.[2] Thus, it would be interesting to couple the electron-rich TTF π-systen with a metal complex into a single conjugated and repeating framework. Engler and his coworkers recently synthesized polymers based on TTF and a metal 1,3-dithiolene complex and found they were highly conductive.[3]

We have shown previously that TTF derivatives can be readily synthesized by the reactions between acetylenic compounds substituted with strong electron-withdrawing groups and CS_2 under high pressure.[4] In exploring a simple synthetic route for the TTF compounds which are capable of forming metal complexes, we have initiated the preparation of pyridyl-substituted TTF compounds from the reaction between a corresponding acetylene compound and CS_2 under high pressure.

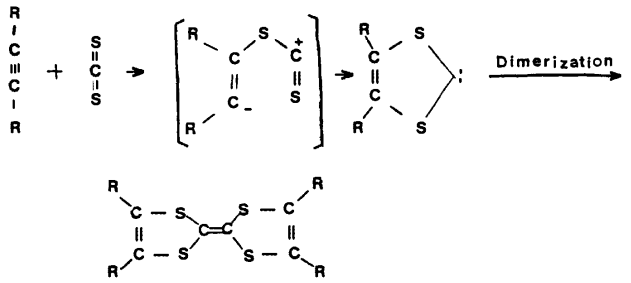
Di-2-, 3- and 4-pyridylacetylenes were synthesized according to the reported methods[5-7] and reactions of these pyridyl compounds with CS_2 under pressure were carried out. Di-2-pyridylacetylene was dissolved in CS_2 and the solution was pressurized to 4500 atm and heated at 100 °C for 12 h. Tetra-2-pyridyltetrathiafulvalene was obtained in 80% yield based on the dipyridylacetylene used.



The reactions of di-3- and 4-pyridylacetylene with CS_2 were carried out using similar and more severe conditions (~6000 atm, at 110 °C). However, the corresponding TTF derivatives were not obtained and most of the starting dipyridyl compounds were recovered.

The mechanism for the formation of TTF derivatives under high pressure was proposed to be the dimerization of the 1,3-dithiolium carbene formed from the reaction between an acetylenic compound and CS_2.[4]

Apparently the electronegative nitrogens of di-2-pyridylacetylene make the acetylenic carbon more reactive to CS_2 as compared with those of di-3- and 4-pyridyl compounds. Since pyridinium compounds are highly electron-withdrawing, reactions of di-3- and 4-pyridylacetylenes with CS_2 in the presence of excess



CH_3COOH or CF_3COOH were carried out at a pressure of 5000 atm for 12 h at 100 °C. The reactions yielded a brown solid which was found to contain several components, but the corresponding TTF derivatives could not be isolated.

The charge transfer complexes of the tetra-2-pyridyl-TTF synthesized with I_2 and TCNQ were prepared and the electrical conductivities were in the range of 10^{-5}—10^{-4} Ω^{-1} cm^{-1}.

Experimental

Infrared spectra were recorded on a Perkin-Elmer Model 457 grating infrared spectrophotometer. Nuclear Magnetic Resonance spectra were recorded on a Varian A-60 NMR spectrometer or a JEOL JNM-FX 90Q. Ultraviolet spectra were recorded on a Cary 15 UV-VIS spectrophotometer. Mass spectra were obtained at the Rockefeller University Mass Spectrometric Lab. using chemical ionization. Melting points were measured on an electrothermal apparatus and are uncorrected. Elemental analyses were performed by Schwarzkopf Microanalytical Laboratory, New York.

High pressure experiments were performed in Teflon capsules (3 ml capacity) in a stainless steel die and compressed *via* a piston with a Clifton 200 ton hydraulic press.

Materials. Di-2-pyridylacetylene was prepared in a manner identical to that described in the literature[5] in 90% yield, mp 70—73 °C (lit,[5] mp 69—70 °C). Di-3-pyridylacetylene was synthesized in a manner similar to that reported, mp 61—62 °C (lit,[6] mp 60—62 °C). Di-4-pyridylacetylene was also prepared by the method reported, mp 115—116 °C (lit,[7] mp 114 °C).

Synthesis. A typical reaction procedure at high pressure is as follows: Di-2-pyridylacetylene (1.0 g, 5.7 mmol) was dissolved in carbon disulfide (3 ml) and then placed in a Teflon capsule. Pressure was applied at 4500—5000 atm and the capsule was heated at 100 °C for 12 h. Pressure was controlled within 200 atm. After cooling, the capsule was opened and a dark red material was isolated (1.1 g). A brown solid was recrystallized from tetrahydrofuran, mp 287—290 °C. (0.80 g, yield 56%) IR (KBr) 1572, 1442, 1258, 1020, 962, 935 cm^{-1}; λ_{max} 355 nm (ε 8000), 385 (9150), 425 (2000) *m/z* 512. Calcd for $C_{26}H_{16}N_4S_4$: C, 60.94; H, 3.10; N, 10.94%. Found: C, 61.10; H, 3.40; N, 11.10%.

TCNQ and I_2 Complexes. To the acetonitrile solution, 20 ml of tetra-2-pyridyl-TTF (1.0 g, 0.02 mol) was added 1 equiv mol of a TCNQ solution (20 ml) in acetonitrile. Upon evaporating the solvent, a dark brown complex was

obtained. Tetra-2-pyridyl-TTF powder was exposed to I_2 vapor for 2—4 h and the complex obtained (mol ratio of the TTF to I_2 was 1:0.3, respectively). The electrical conductivities of these compounds were measured on compressed pellets using nickel electrodes with a Keithley electrometer.

This research was partly supported by a generous grant from Koppers Company, Inc.

Adsorption Measurements during Catalytic Isomerization of Pentenes and 2-Methyl-1-pentene over KC_{24}

Susumu TSUCHIYA,* Shinji YAMAMOTO, and Hayao IMAMURA
Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755
(Received June 1, 1983)

The catalytic isomerization of pentenes over KC_{24} has been investigated. The double-bond-migration and the *cis-trans* isomerization took place over KC_{24}, but the skeletal isomerization was not observed. From the rates of reactions and the selectivity ratios, all six of the relative rate constants and the activation energies of reactions were determined. The reaction paths on the triangular graph calculated from the rate constants show the *cis*-convex type profile. The competitive isomerization of 1-pentene and 2-methyl-1-pentene has also been investigated. The rate of isomerization of 1-pentene was greater than that of 2-methyl-1-pentene, which can be explained on the basis that the amount of chemisorption of 1-pentene during the competitive reaction is greater than that of 2-methyl-1-pentene.

Great attention has been paid to all the characteristic properties of graphite intercalation compounds, and the catalytic properties of the compounds have been extensively investigated in various reactions.[1-2] In heterogeneous catalysis, adsorption plays an important role, and measuring the adsorption during the reaction has been fruitful in many investigations.[3] In this work, the interest has centered on the catalytic characteristics of KC_{24} for the isomerization of pentenes; the adsorption during the course of reaction was measured.

Experimental

Materials. The KC_{24} samples used as catalysts were prepared in the manner described elsewhere.[4] Graphite (1.25 g of Union Carbide Spectroscopic Grade powder) and 0.44 g of potassium metal were used for each preparation. The preparation vessel was heated in a electric heater for 24 h under *ca.* 10^{-3} Pa at 620 K to form KC_{24}, and then evacuated for 30 min. The X-ray diffraction data of the samples formed agreed quite well with those reported by Rüdorff and Schultze.[5] The color of the KC_{24} obtained was deep blue.

Pentenes used as the reactants were obtained from Tokyo Kasei Co., Ltd., and were purified by repeated distillation *in vacuo*. The purity was confirmed by gas chromatography to be more than 99%.

Helium (99.995%) and nitrogen (99.99%) were obtained from the Seitetsu Kagaku Co., Ltd.

Procedure. The apparatus used for the present study was essentially the same as that used previously.[6] A closed circulating system with greaseless stopcocks and with a U-shaped reactor, connected to a conventional vacuum line and a gas chromatograph, was used to follow the reaction. The volume of the reaction system corresponded to about 288 cm^3 at a reaction temperature of 373 K.

Known amounts of reactant and an inert gas, *e.g.* nitrogen, were introduced into the reaction system, and the reaction was started by circulating. The ambient pressure and the composition of circulating gas were measured at suitable time intervals by a gas chromatograph with a column of 2,4-dimethylsulfolane on Uniport C. Inert gases were useful for effective circulation and accurate analysis.

The amounts of adsorption were obtained from the material balance. When 1-pentene was the reactant, amounts of adsorption were estimated from the amount of 1-pentene introduced and the pressure and the composition of the circulating gas at the suitable time. The sum of pentenes adsorbed could only be estimated.

Before each run, the catalyst was evacuated under *ca.* 10^{-3} Pa for 3 h at 573 K, and helium was introduced into the reactor. The evacuation temperature was selected as about 50 K lower than the preparation temperature of the catalyst; care was taken to avoid changes of KC_{24}. The reactor was then cooled to the reaction temperature and evacuated for a few minutes. The experimental results were well reproducible.

Results and Discussion

Isomerization of Pentenes. The double-bond-migration and the *cis-trans* isomerization of pentenes took place over KC_{24}, of which BET surface area was 50 m^2/g. The graphite did not show any catalytic activity for the reaction under the same experimental conditions. No skeletal isomerization occurred. No gase-

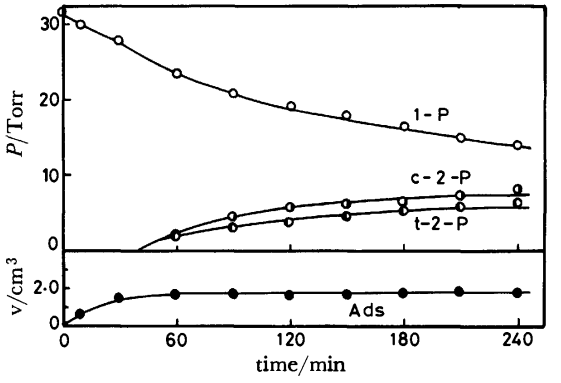

Fig. 1. Adsorption measurement during the isomerization of 1-pentene over KC_{24} at 440 K. (1 Torr= 133.322 Pa)

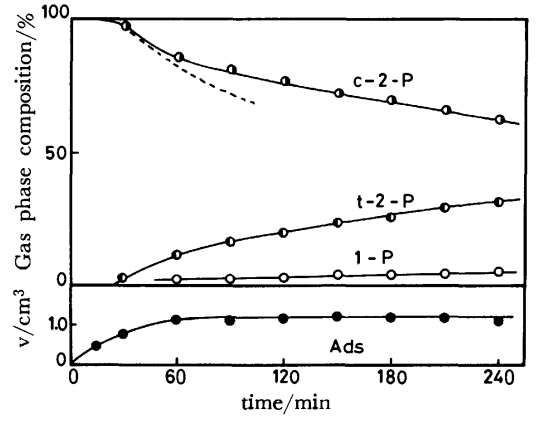

Fig. 2. Adsorption measurement during the isomerization of *cis*-2-pentene over KC_{24} at 513 K.

ous hydrocarbon other than pentenes was detected in the reaction mixtures under the present experimental conditions.

Figure 1 shows a typical result for the isomerization of 1-pentene over KC_{24} at 440 K, together with those of adsorption measurements. The adsorption measured appears to be chemical in nature, in view of the high adsorption temperature as 440 K. An induction period is observed at the initial stage of reaction. This may arise from the fact that at the initial stage the rate of adsorption of the reactant is much higher than that of desorption of the reactant as well as of the product. Accordingly, the decrease in the pressure of the reactant observed after the induction period is attributable to the progress of isomerization alone.

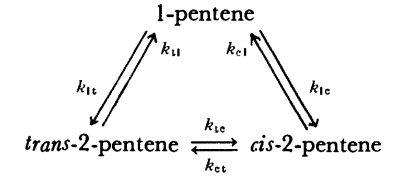
Figure 2 shows a typical result of the isomerization of *cis*-2-pentene over KC_{24} at 513 K. A similar induction period of the reaction is also observed. Instead of pressure, the composition in the gas phase is shown, as a function of time. The rate of the isomerization of *cis*-2-pentene is lower than that of 1-pentene (the broken line) under the same initial pressure.

The amounts of pentenes adsorbed appear to be almost constant; at the later stage of the reaction, the sums of the amount of reactant adsorbed and that of product adsorbed are constant. If the adsorption of reactant were the rate-determining step, the amounts of adsorption of reactant and of product would increase with increasing the pressure of product. If the desorption of product were the rate-determining step, the amounts of adsorption of reactant and of product would decrease with decreasing the pressure of reactant. In both cases, the sums of the adsorption of the reactant and product are not constant. The present result can be explained on the basis that the surface reaction is the rate-determining step. After the induction period the amount of reactant adsorbed depends on the ambient pressure of reactant, and will decrease with time. The rate of isomerization may be proportional to the amount of adsorbed reactant, since the surface reaction in the rate-determining step. Thus, the decrease in the rate of isomerization with its progress is explicable.

Ottmers *et al.*[7] reported that the catalytic activity of KC_n (n=8, 24, 36) for the isomerization of 1-pentene sharply declined with time on stream. The activity was estimated from the per pass conversion in the flow system. In the closed circulating system, a conversion is integrated with reaction time. Therefore, if the initial rapid decrease in catalytic activity actually takes place, the effect would be diluted. It was accordingly impossible in the present experiment to observe the clear deactivation process. As Ottmers *et al.*[7] suggested, the deactivation process might be due to traces of oxygen in the flow system.

The good reproducibility of the experimental results in the present work, however, suggests that the deactivation process during the course of the reaction, if it exists, is not permanent, and that the catalytic activity can be easily regenerated by evacuation.

The isomerization of pentenes was almost first order with respect to the pressure of reactant, ranging from 2×10^3 to 1.3×10^4 Pa, after the induction period. From the rates of reaction and the selectivity ratios: *cis/trans*, *trans*/1, and 1/*cis*, all six of the relative rate constants expressed by Scheme 1 and the activation energies of reaction were determined.



Scheme 1.

The relative rate constants at 440 K and the activation energies (bracketed) are shown in Fig. 3.

When the isomerization of 1-pentene takes place with the allyl anion mechanism, the initial *cis/trans* ratio is greater than unity.[8,9] The selectivity ratios obtained in the present study satisfy the condition of the allyl anion mechanism.

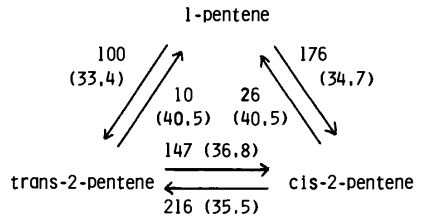


Fig. 3. Relative rate constants at 440 K and activation energies (kJ/mol) bracketed.

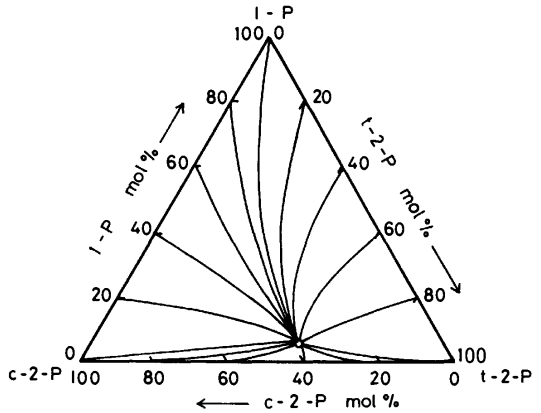

Fig. 4a. Reaction profile of isomerization of pentenes over KC_{24} at 440 K.

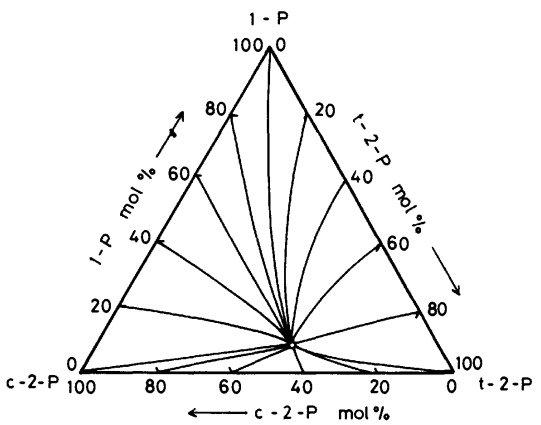

Fig. 4b. Reaction profile of isomerization of pentenes over KC_{24} at 513 K.

When the isomerization of pentenes proceeds, the composition of pentenes in the gas phase varies with time. The mol% of 1-pentene, *cis*-2-pentene, and *trans*-2-pentene corresponding to reaction time can be calculated from the relative rate constants, k_{ij}.[4,10,11] Figures 4a and 4b show the reaction paths calculated at 440 K and 513 K, respectively. These triangular graphs thus represent one of the catalytic characteristics of KC_{24} for the isomerization of pentenes. The curves, which originate from the left side of the triangle, bend in a convex manner to the left. The *cis*-convexity increased at a lower temperature, as shown in Fig. 4. These characteristics of pentenes are similar to those of butenes previously reported.[4]

Competitive Isomerization of 1-Pentene and 2-Methyl-1-Pentene. The reactivities of 1-pentene and 2-methyl-1-pentene have been studied. Figure 5 shows a typical result of the competitive isomerization of 1-pentene and 2-methyl-1-pentene over KC_{24} at 440 K. *cis*-2-Pentene, *trans*-2-pentene, and 2-methyl-2-pentene were observed as the products. The induction period is also observed both for 1-pentene and 2-methyl-1-pentene. The rate of adsorption of 1-pentene at initial state is larger than that of 2-methyl-1-pentene, which may be due to the structure effect of KC_{24}. 2-Methyl-1-pentene has a larger cross-sectional area than 1-pentene, and finds it more difficult to penetrate into the KC_{24} lattice. The amount of adsorption of 1-pentene at a later time is more than that of 2-methyl-1-pentene. The rate of isomerization of 1-pentene after the induction period is also more than that of 2-methyl-1-pentene. These results suggest that the higher rate of isomerization of 1-pentene than 2-methyl-1-pentene is due to either the larger rate of adsorption or the larger amount of adsorption of 1-pentene or both.

The degree of adsorption of 1-pentene in the presence of 2-methyl-1-pentene shown in Fig. 1 is less than that in the absence of 2-methyl-1-pentene shown in Fig. 5. This suggests that the adsorption of 1-pentene is disturbed by the presence of 2-methyl-1-pentene, and that 1-pentene is more strongly adsorbed on the same kind of sites than is 2-methyl-1-pentene in the competitive adsorption during the reaction.

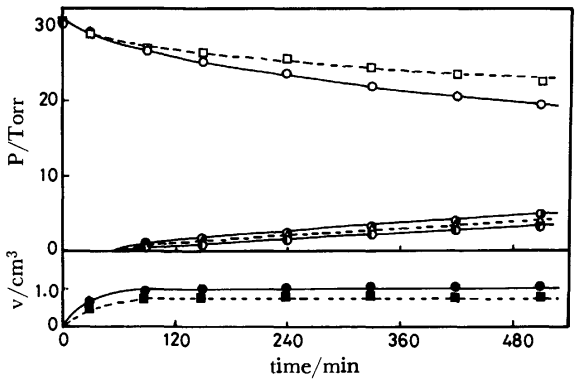

Fig. 5. Adsorption measurement during the competitive isomerization of 1-pentene and of 2-methyl-1-pentene over KC_{24} at 440 K.
Gaseous olefins: 1-pentene (-○-), 2-methyl-1-pentene (--□--), *cis*-2-pentene (-◑-), *trans*-2-pentene (-◐-), 2-methyl-2-pentene (--△--), Adsorbed olefins: *n*-pentenes adsorbed (-●-), methylpentenes adsorbed (--■--).

Conclusion

The catalytic selectivity of KC_{24} for the isomerization of pentenes is similar to that of butenes. The initial *cis/trans* ratio can be explained on the basis that the reaction may proceed *via* an allyl anion mechanism. One of the catalytic characteristics is thus shown in Fig. 5. Competitive isomerization revealed that 1-pentene is more reactive than 2-methyl-1-pentene over KC_{24}. This fact can be explained on the basis that the rate and/or the amount of adsorption of 1-pentene during the competitive reaction are larger than those of 2-methyl-1-pentene.

The authors are grateful to Professor T. Mizota of the Department of Mining and Mineral Engineering of this faculty for his X-ray analysis. This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, for which the authors' thanks are due.

Vibrational Level Populations of Hydrogen Fluoride Produced in Infrared Multiple-photon Decompositon of C_2H_5F

Yo-ichi ISHIKAWA* and Shigeyoshi ARAI
The Institute of Physical and Chemical Research, Wako-shi, Saitama 351-01
(Received July 30, 1983)

CO_2 TEA laser-induced photolysis of C_2H_5F was studied by using a time-resolved infrared fluorescence technique. Molecular elimination of vibrationally excited hydrogen fluoride (HF*) from C_2H_5F* occurs in the process. Rotational temperatures and vibrational level populations of HF* are estimated from observed fluorescence spectra by computational fitting. Higher vibrational levels are populated to a less extent in the decomposition under a collisionless condition. When the pressure of C_2H_5F is increased, however, population inversion is allowed among some levels. Possible reaction mechanism is discussed for the production of HF* at extraordinarily high vibrational levels.

Infrared multiple-photon decomposition (IRMPD) is usually considered to be a unimolecular decomposition of a molecule excited vibrationally above its decomposition threshold under a collisionless condition. However, it has been pointed out that the decomposition induced by collisions between highly vibrationally excited molecules occurs significantly even in a relatively low pressure region.[1-3] Previous time-resolved luminescence studies show that both instantaneous and delayed emissions are observable in IRMPD.[1,3,4] The latter has been ascribed to radiative species produced in collisions between highly vibrationally excited molecules. The collision-induced decomposition was estimated to contribute over 90% to the total decomposition at a pressure as low as 0.07 Torr (1 Torr≈133.322 Pa), where excited molecules can not collide with each other at least within a laser pulse duration.[3] On the other hand, Danen and Jang[5] have suggested that the decomposition *via* collisional V-V ladder climbing is not significant in IRMPD of large molecules.

The time-resolved infrared spectroscopic technique has been applied to UV photolysis by an excimer laser[6] or IRMPD by a CO_2 TEA laser.[7-9] This method affords dynamic information on rotation-vibration states of decomposition fragments and parent molecules. Quick and Wittig[8] measured infrared fluorescence spectra of HF* produced in IRMPD of fluorinated ethanes and ethylenes and estimated the rotational temperatures and vibrational distributions from spectral simulation. They found $N_v/N_{v+1}>1$ under a collisionless condition, where N_v and N_{v+1} denote the vibrational level populations at levels v and $v+1$, respectively. The addition of inert gas does not influence the vibrational distribution, while it lowers the rotational temperature.

Our previous study has shown that the energy transfer from highly vibrationally excited molecules is a main cause for isotope scrambling in IRMPD of mixtures of trifluoromethane-d_1 and -d_0 (CDF_3 and CHF_3).[9] However, the kinetic behavior of highly vibrationally excited molecule has not yet been well understood except for its unimolecular decomposition channel.[4,10] In this paper, we report time-resolved infrared fluorescence spectra observed in IRMPD of C_2H_5F, where the pressure of reactant is varied from 0.025 Torr, a collisionless condition, to 10 Torr. The fluorescence in the wavelength region of 2.2—3.2 μm is due to the HF* produced in a molecular elimination process. The role of highly vibrationally excited parent molecule in IRMPD will be discussed on the basis of the estimate of rotational temperatures and vibrational distributions of HF*.

Experimental

The experimental apparatus and procedure are similar to the previous ones.[9] The laser used for irradiation was a CO_2 TEA laser (Lumonics 103-2). The pulse duration was about 80 ns fwhm when the laser was operated without nitrogen gas in the cavity. All samples were irradiated with the P(20) line (1046.85 cm^{-1}) of the 9.6 μm CO_2 band at a repetition rate of 0.7 Hz. Laser energy was measured with a pyroelectric detector. The laser beam was truncated through a 9.9 mm diameter iris and focused onto the center of irradiation cell with a BaF_2 lens ($f.l.$=20 cm). The beam area at focus was estimated to be 5×10^{-3} cm^2 from a beam divergence of about 2 mrad. Laser fluences at focus were calculated from the beam area and laser energies. The cell with two KBr windows at both ends was 36 cm in length in the laser beam direction and 2 cm in inner diameter. The infrared fluorescence light at a focal regime, *i.e.*, in the vicinity of the center of cell, was made parallel by a parabolic mirror and then focused on the entrance slit of the infrared spectrometer (Ritsu Oyo Kogaku, MC-20L) by a CaF_2 lens ($f.l.$=20 cm). The focal point of laser beam was adjusted to fit the focal point of the parabolic mirror in the optical arrangement. More than 70% of the emission light at focus is converted into a parallel beam by reflection on the parabolic mirror. The maximum field of view of the detection system is limited to a 2 cm range along the laser beam within the enclosure of mirror. The fluence variation may be milder than 40% of the fluence at focus because the optical setup was designed to pick up most efficiently the emission in the vicinity of the focus. The infrared light was detected with an InSb detector mounted behind the exit slit of spectrometer. The current signal from the detector, after converted into a voltage signal, was amplified by a preamplifier (PAR Model 115) and then averaged by a boxcar system (a PAR Model 162 boxcar averager and a PAR Model 155 gated integrator). The aperture duration τ_g, aperture delay τ_d,, and time constant τ_c used for the boxcar averager will be described in the table and figure legends. The overall rise time was about 2 μs. The signal picked up by a photon drag detector was used as the trigger for the boxcar averager. The flow rate of a reactant gas in the cell was set between 1 and 10 Torr ml min^{-1} according to the pressure used. Pressures were measured with a capacitance-type manometer (MKS Baratron Model 220 BH).

Fluoroethane was synthesized through reaction of potassium fluoride with ethyl tosylate and purified by low temperature distillation.[11] Its purity was found to be higher

than 99% in an infrared absorption measurement. Argon purchased from Takachiho Kagaku Kogyo Co. (research grade) was used without further purification.

Results

The laser irradiation of 9.0 Torr C_2H_5F at a fluence of 40 J cm^{-2} yielded infrared fluorescence in a wide wavelength region of 2.2—3.8 μm. The spectrum of Fig. 1 (a) in the region of 2.2—3.2 μm (solid curve) is attributed to vibrationally excited HF*. The observed spectrum was simulated according to the method reported by Quick and Wittig.[8] The rotation-vibration terms of HF* were calculated by using the equation[12]

$$F_{vJ} = \sum_{lm} Y_{lm}(v+1/2)^l[J(J+1)]^m, \quad (1)$$

where Y_{lm} is a constant related to the molecular constants of HF; J and v are a rotational quantum number and a vibrational quantum number, respectively. On the other hand, the emission intensity of the v', $J'\rightarrow v''$, J'' transition I_{em} was calcualted by using the equation

$$I_{em} \propto \frac{C_{em}\,\nu^4\,F\,S_{J'}}{Q_r}\exp\left[-(F_{v'J'} - F_{v'0})(hc)/(kT)\right], \quad (2)$$

where $S_{J'}$ is $J'+1$ for P branch, *i.e.* $\Delta J = J'-J'' = -1 (J' = 0, 1, 2, \cdots)$ and J' for R branch, *i.e.*, $\Delta J = +1$ ($J' = 1, 2, 3, \cdots$); C_{em} is a constant proportional to the square of a transition dipole moment, values for various vibrational transitions being given in the paper by Herblin and Emanuel;[13] the symbol ν is a transition frequency; Q_r is the rotational partition function defined by a certain rotational temperature T; the Boltzmann distribution being assumed for the rotational level populations; F is a relative vibrationa level population, which may be regarded as a fitting parameter in this simulation; the symbols h and k are the Planck and Boltzmann constants, respectivery; and c is the light speed. Finally, each profile of emission line was determined from the slit function and the simulation spectrum was constructed by superposing the emission lines. The

a) Laser line, 9.6 μm P(20) at 1046.85 cm^{-1}; laser fluence, approximately 40 J cm^{-2} (E_{in}=0.23 J pulse^{-1} and focal length=20 cm); τ_d=1 μs; τ_g=10 μs. b) Ref. 8.

calculated intensity distributions of the rotational lines due to the rotation-vibration transitions ($\Delta v=1$ and $v' \leqq 5$) with a common rotational temperature of 1800 K are illustrated in the upper part of Fig. 1(a), where each vibrational level has the same total population. Then, the fluorescence intensities through the actual slit function, which had a triangular shape with 0.016 μm fwhm, were calculated at wavelength intervals of 0.01 μm, as shown by the open circles in Fig. 1(a). The vibrational level populations were selected so that the simulated spectrum gave the best fit. The dotted curve represents a smooth connection of the calculated points. Figure 1(b) is the fluorescence spectrum in the region of 3.0—3.8 μm, which may originate from vibrationally excited parent molecules $C_2H_5F^*$ because the emission center at about 3.4 μm coincides in wavelength with the $v'=1 \leftarrow v''=0$ transition in the C-H stretching mode of C_2H_5F. The ratio of the emission peak intensity of HF* (at 2.35 μm) to that of $C_2H_5F^*$ (at 3.4 μm) is about 1.3.

The variation in pressure influences the rotational temperature T_{rot} and vibrational level populations N_{vib} of HF*; the pressure effects on T_{rot} and N_{vib} are summarized in Table 1. These data were obtained from the spectral simulation where N_{vib} ($v'=1$) was always normalized to unity in each case. Both T_{rot} and N_{vib} are fitting parameters in the present treatment. T_{rot} can be estimated directly from the spectral shape in the wavelength region below 2.36 μm since the rotational lines of the $v'=1 \rightarrow v''=0$ transition are isolated from those of the other transitions. For 5.0-Torr C_2H_5F the simulation was performed for four spectra observed independently under the same experimental conditions. The error limit in Table 1 shows the range of the scatter of T_{rot} or N_{vib} in the simulation. In practice, we could not satisfactorily reproduce the spectrum obtained with 5.0-Torr C_2H_5F by using the values out of the error limits. Quick and Wittig[8] gave error limits, which are included in Table 1 for the vibrational level populations calculated in a similar manner. The rotational temperature increases with an increase in C_2H_5F pressure. When the partial pressure of C_2H_5F was lower than 0.17 Torr, argon approximately 60 times was added to the system. The addition of argon to a reaction mixture lowers T_{rot} to room temperature and enhances the signal intensity, *i.e.*, the dissociation probability, while N_{vib} at each vibrational level is scarcely affected by the addition of argon. The effect of argon is also shown in Table 1, where $N_{v/b}$ at each vibrational level has similar values for C_2H_5F at 0.025—0.50 Torr with and without argon, although T_{rot} changes between 300 and 900 K. For comparison, the populations reported by Quick and Wittig[8] are included in the same table; their result is consistent with ours.

Figure 2 presents four typical HF* fluorescence spectra obtained at different pressures, where open circles are calculated in the above-mentioned method. The wavelength resolution was sacrificed for the measurements at low pressures because the emission intensity decreased with decreasing pressure. The spectrum apparently becomes broader with increasing pressure above 0.5 Torr. The relative fluorescence intensities due to HF* at $v'=2$ and 3 decrease with increasing pressure, while those due to $v'=4$ and 5 increase. T_{rot} also increases with pressure. It is worth noting that the absolute fluorescence intensities due to HF* and $C_2H_5F^*$ increase markedly with an increase in C_2H_5F pressure. However, the intensity due to $C_2H_5F^*$ grows more rapidly as compared with that due to HF*.

The infrared fluorescence spectra determined at 3, 10, 20, 30, and 50 μs after the laser pulse are shown in

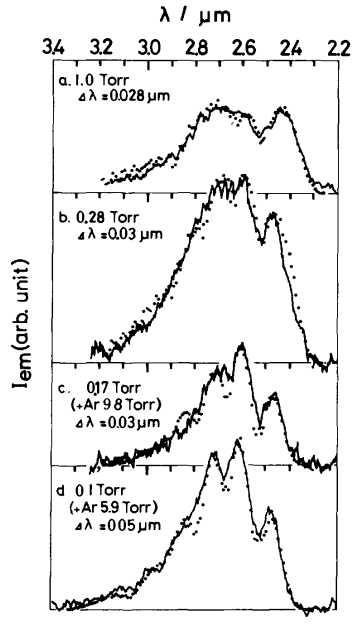

Fig. 2. Infrared fluorescence spectra obtained with 1.0-Torr (a), 0.28-Torr (b), 0.17-Torr (c), and 0.1-Torr (d) C_2H_5F. Argon was added in (c) and (d). Laser fluence, 40 J cm^{-2}; τ_d, 1 μs; τ_g, 10 μs; O, calculated point. Wavelength resolution Δλ is shown in the figure.

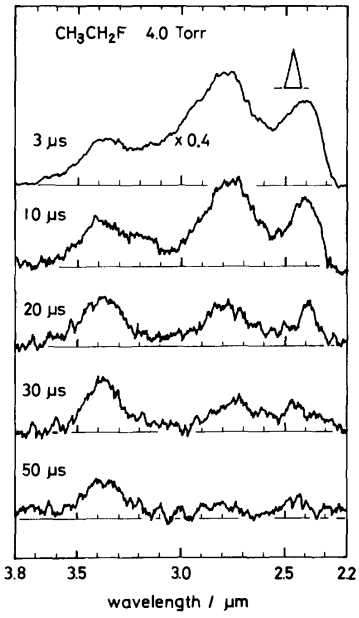

Fig. 3. Infrared fluorescence spectra obtained with 4.0-Torr C_2H_5F. The spectra were determined at 3, 10, 20, 30, and 50 μs after the laser pulse. Wavelength resolution is shown in the figure. Laser fluence, 40 J cm^{-2}; τ_d, 1 μs; τ_g, 10 μs.

TABLE 2. TRANSIENT VIBRATIONAL POPULATIONS OF HF* PRODUCED IN IRMPD OF C_2H_5F[a)]

τ_d	T_{rot}	N_{vib}				
μs	K	$v'=1$	2	3	4	5
2	1800	1	0.4	0.2	0.2	0.3
3	1800	1	0.4	0.2	0.1	0.3
6	1200	1	0.3	0.05	0.4	0.1
10	1200	1	0.2	0.05	0.3	0.05
15	1200	1	0.2	0.05	0.15	0.05
20	1200	1	0.2	0.05	0.15	0.05

a) Laser line, 9.6 μm P(20) (1046.85 cm^{-1}); laser fluence, about 40 J cm^{-2}; τ_g=1 μs; C_2H_5F pressure, 5.0±0.1 Torr.

Fig. 3. The pressure of C_2H_5F is 4.0 Torr. The time dependences of the vibrational level populations obtained with 5.0-Torr C_2H_5F are summarized in Table 2. The vibrational level populations at v'=2, 3, and 5 decrease with a lapse of time; the higher the level is, the larger is the decrease. The population at v'=4 reaches a maximum at 6 μs and then decreases.

Table 3 presents the fluence effect on the fluorescence. The production of HF* at high vibrational levels tends to increase with increasing fluence. This tendency can be seen with 5-Torr C_2H_5F alone and with the mixture of 0.17-Torr C_2H_5F and 9.83-Torr Ar. However, the change in vibrational level population is not evident in the present study because a possible fluence variation is restricted within a narrow range.

Figure 4 shows the fluorescence intensity *vs.* time curve observed at 2.4, 2.8, and 3.4 μm for 4-Torr C_2H_5F. The fluorescence monitored at 2.4 μm corresponds mainly to the R branch of the HF* ($v'=1\rightarrow HF(v''=0)$ transition, while that at 2.8 μm includes several transitions of $\Delta v=1$ from various vibrational levels. Parent molecules fluoresce at the vicinity of 3.4 μm. The fluoresce due to HF* grows almost completely within the response time of the detection system, *i.e.*, 3 μs. The following decay consists of the rapid component with a lifetime of 10 μs and the slow component lasting for 30—40 μs. The whole temporal behavior is invariant against C_2H_5F pressure if it is higher than 0.5 Torr. In contrast, only the slow component is observed for the decay curve if the pressure is lower than 0.2 Torr. Moreover, the decay rate tends to decrease with decreasing pressure in the low pressure region.

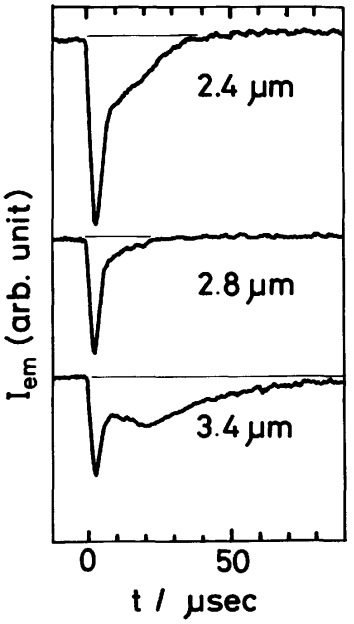

Fig. 4. Fluorescence intensity *vs.* time curves obtained with 4.0-Torr C_2H_5F. Laser fluence, 40 J cm^{-2}.

Discussion

Setser and coworkers[14)] and Quick and Wittig[8)] have reported that the molecular elimination of HF occurs in IRMPD of C_2H_5F:

$$C_2H_5F + nh\nu \longrightarrow C_2H_4 + HF \qquad \Delta H = 10 \text{ kcal mol}^{-1}. \quad (4)$$

The activation energy of this reaction has been found to be approximately 57 kcal mol^{-1}. The dissociation energies of bonds C-C, C-H, and C-F in ethane-type molecules are estimated to be 85, 100, and 100 kcal mol, respectively. Therefore, the molecular elimination of HF should be the most favorable reaction channel in IRMPD of C_2H_5F. When 4.0 Torr C_2H_5F was irradiated with a CO_2 TEA laser (1000 pulses), three new bands attributable to products appeared near 1030, 950, and 730 cm^{-1} in the infrared absorption spectrum. The first band corresponds to the ν_3 mode (SiF deg. stretch) of SiF_4,[15)] the second to the ν_7 mode (CH_2 wag) of C_2H_4,[16)] and the third to the ν_5 mode (CH bend) of C_2H_2.[16)] Acetylene may be formed secondarily by the

decomposition of ethylene.[17] The production of SiF_4 implies that hydrogen fluoride reacts with the glass wall. These results support the previous conclusion that Reaction (4) proceeds most efficiently in IRMPD of C_2H_5F. We could not find the infrared emission due to vibrationally excited DF* in IRMPD of a mixture of 1-Torr C_2H_5F and 2-Torr D_2. This fact suggests that no fluorine atom is produced in the primary process of IRMPD of C_2H_5F.

Vibrational level populations have been estimated for hydrogen halides produced from halogenated hydrocarbons activated in various processes. Steady-state infrared fluorescences of hydrogen halides were measured in chemical activation[18] and mercury sensitized photolysis.[19] Transient fluorescences were measured in UV laser photolysis.[20] Throughout these measurements, N_v was always larger than N_{v+1}. In the present study, however, we found the extraordinary population distribution of HF* at C_2H_5F pressures higher than 1.0-Torr. The extraordinary population distribution might be explained in the following ways: (a) some vibrational levels of HF* are overpopulated in the so-called Treanor distribution *via* collisional V-V ladder climbing;[21] (b) the energy transfer from highly vibrationally excited C_2H_5F* yields preferentially HF* at some particular vibrational levels. Fürsich and Kompa[22] could not observe any inverted vibrational population when hydrogen fluoride at 30—60 Torr was directly excited with pulses from a high power HF laser. This result denies item (a) above as a reasonable cause for the extraordinary population distribution. In our experiment, pressures of C_2H_5F are lower than 10 Torr. Since HF is produced from excited C_2H_5F*, the partial pressure of vibrationally excited hydrogen fluoride HF* should be much lower than 10 Torr. It is highly improbable that the Treanor distribution of HF* is accomplished at low partial pressures of HF. Vibrationally excited C_2H_5F* was found to fluoresce in the wavelength region of 3.1—3.6 μm. As shown in Figs. 3 and 4, the fluorescence was observed over 100 μs after the pulse, although the fluorescence due to HF* terminated within 40 μs. The clear difference between the transient behavior of C_2H_5F* and HF* seems to rule out item (b) above for the production of HF*.

The fluorescence intensity *vs.* time curve observed at 2.4 μm for 0.17-Torr of C_2H_5F exhibits only one decay component, which fits a first-order kinetic low. The origin of HF* at such a low pressure may be the laser-induced multiple-photon decomposition of C_2H_5F. The collision-induced process can be ignored for the production of HF*. Assuming that HF* is fully produced within the pulse duration, one can estimate the rate constant for the collisional deactivation of HF* to be $3\times10^5\,s^{-1}\,Torr^{-1}$. The fluorescence monitored at 2.4 μm is due to HF* in a vibrational state of $v'=1$. Hancock and Green[23] have measured rate constants of deactivation of HF* ($v'=1$) by several hydrocarbons by use of the laser-induced vibrational fluorescence technique. Of the rate constants, cyclopropane has the same value as C_2H_5F.

The HF* fluorescence intensity *vs.* time curves obtained with C_2H_5F at pressures higher than 0.5 Torr show a fast rise followed by fast and slow decays. The qeunching lifetime of HF* is expected to be shorter than 1 μs if the pressure of C_2H_5F is higher than 3 Torr. The initial fluorescence spike is mainly due to the HF* molecules produced in IRMPD of C_2H_5F. The fast rise is limited by the response time of the detection system since the production of HF* in IRMPD terminates at the end of pulse. The fast decay is caused by the collisional deactivation of the fraction of HF* produced in IRMPD. The slow decay suggests that HF* is also produced in a slow process after the termination of pulse. One possible mechanism for the slow formation of HF* is the decomposition of excited C_2H_5F molecules produced in the collision induced process. The direct IRMPE of C_2H_5F results in the distribution of excited molecules over a wide range of internal energy. Those C_2H_5F molecules which have energies much higher than the threshold energy undergo immediate decomposition. On the other hand, those molecules which have energies almost euqal to or a little higher than the threshold energy persist for a long time after the laser pulse irradiation. It should be noted that the reaction zone in IRMPD is limited to a small volume around a focal point and that most molecules in the reaction zone are in highly vibrationally excited states. Collisions among vibrationally excited molecules with long lifetimes may produce excited molecules above the dissociation threshold. The excited HF* molecules formed in the subsequent decomposition may show the inverted vibrational level populations. The energy distribution of excited C_2H_5F molecules approaches the Boltzmann distribution defined by temperature with a lapse of time. However, the fraction of excited molecules produced above the threshold during the relaxation process undergoes the decomposition leading to the formation of HF*. The temperature inside a reaction zone is usually high enough to induce thermal decomposition in IRMPD at high fluences or high pressures. However, the temperature gradually decreases as excited molecules diffuse from the reaction zone or cold molecules diffuse into the reaction zone.

A pressure is expected to affect IRMPD through hole filling and energy transfer. These phenomena couple together to influence the absorption and decomposition processes. Richardson and Setser[14] have studied IRMPD of binary mixtures, where one component does not absorb the laser energy but does possess the decomposition channel with the threshold energy comparable to that of the other component. The decomposition yields of both components were measured as a function of total pressure. They found that for pressures $\geq$1 Torr the intermolecular energy transfer is sufficiently rapid that the collision-induced decomposition of the non-absorbing molecule is prominent. In our experiment, the collision-induced decomposition seems to become important for pressures $\geq$1 Torr.

The response time and sensitivity of the present detection system are not satisfactory for transient infrared fluorescence observation. Therefore, it is exceedingly difficult to separate out the effects of the collision-induced process on the observed vibrational level populations from those arising from the laser-induced multiple-photon excitation process itself. However, we observed the distribution of HF* with $N_v/N_{v+1}\geq1$ at low pres-

sures of C_2H_5F where IRMPD occurs mainly. The extraordinary distribution becomes more prominent with increasing pressure or a lapse of time. These facts are consistent with the above-mentioned mechanism.

(Received August 12, 1983)

The disproportionation reaction of NO was investigated on CaHY-type zeolite. The relation between pretreatment temperature and activity was determined by the pulse reaction technique, and the dependence of the initial formation rate of N_2O on NO pressure was investigated with a gas circulation system. The rate of initial formation of N_2O is third order in NO pressure in the lower pressure region (*ca.* 30 Torr, 1 Torr≈133.322 Pa) and 2.2th order in NO pressure in the higher pressure region (*ca.* 200 Torr). TPD spectra are composed mainly of three peaks: The first peak is assigned to the unreactive adsorbed NO, the second to the NO produced by the decomposition of N_2O_3 and left on the zeolite surface, and the third to the N_2O remaining. On the basis of the reaction mechanism proposed by Chao and Lunsford, the rate equation for the initial formation of N_2O has been derived as $\alpha=\bar{k}_2K_1P^3/(1+K_1P^2)$, where P, K_1, and $\bar{k}_2$ are the pressure of NO, an equilibrium constant, and a rate constant, respectively. This equation is in good agreement with experimental results obtained with the gas circulation system.

In a study on sorption and reactivity of NO, Addison and Barrer[1] found that the disproportionation reaction of NO, $4NO=N_2O+N_2O_3$, occurs on chabazite, faujasite, and A-type zeolites at 0 °C or lower temperatures; the resulting N_2O can be removed quantitatively, whereas the N_2O_3 stays occluded in the zeolites. Later, Alekseyev *et al.*[2] studied infrared spectra of NO adsorbed on A- and X-type zeolites. Chao and Lunsford[3] also studied those on NaY- and CaY-type zeolites and proposed a mechanism for the disproportionation reaction.

Recently, the disproportionation reaction on MgHY-type zeolites with different degrees of ion exchange was studied by use of a pulsed microreactor, and it was revealed that active sites for this reaction are Mg^{2+} located on Site II.[4] This reaction on alkaline earth metal oxides[5,6] has further been investigated, with a result that the activity order is MgO>CaO>SrO>BaO. Pulse technique studies[7–9] of this reaction on Y-type zeolites with various metal ions exchanged disclosed that alkaline earth Y-type zeolites possess higher activities, whereas the zinc family, alkali metals, and LaY-type zeolites possess lower activities, as detailed by the activity sequence: CaY>CdY>MgY>ZnY>LaY>BeY>NaY>LiY>KY≫SrY>BaY, AgY, HgY, FeY, AlY=0.

Understanding the reactivity of NO, on the other hand, is of great value for studies on the transformation and elimination of atmospheric pollutants.[10–18] The disproportionation reaction, therefore, is important not only from a fundamental viewpoint but also from a practical aspect.

The present study has been carried out to collect kinetic information on the disproportionation reaction of NO. Measurements for activity and TPD chromatogram were made on CaHY-type zeolites.

Experimental

Materials and Reagents. A synthetic Y-type zeolite (Union Carbide Co.) in the sodium form (SK-40) was ion-exchanged 16 times at 90 °C with 10 wt% solution of ammonium nitrate. A $CaNH_4Y$-type zeolite was prepared *via* ion-exchange of the resultant NH_4Y-type zeolite with a solution of calcium nitrate at 90 °C. The resultant $CaNH_4Y$-type zeolite was washed 3 times with 0.05 mol dm^{-3} calcium nitrate solution and dried overnight at 110 °C. The composition of the $CaNH_4Y$-type zeolite prepared in this way corresponds to $Ca_{24}(NH_4)_8Na(AlO_2)_{57}(SiO_2)_{135}\cdot nH_2O$ per unit cell. A chemical analysis of samples was done by flame spectrophotometry (Na^+) and atomic absorption spectrophotometry (Ca^{2+} and Al^{3+}); the sample was pressed at about 10 ton/cm^2 and ground into pieces of 32 to 60 mesh and of 1 to 2 mm.

Powder X-ray diffraction patterns and values of specific surface area measured with a BET apparatus confirmed that no structual damages were caused during the sample preparation. Prior to various measurements, a CaHY-type zeolite was prepared by a treatment for ammonia removal of the $CaNH_4Y$-type zeolite. Details of the treatment will be described in the following section. The helium used (for the pulsed microreactor and TPD experiment) was passed through a Yanagimoto RT003 purifier. NO was obtained from a commercial cylinder (Takachiho Chemical Industry, Ltd.) and purified first by passage through a dry NaOH-packed column (for the pulse method and TPD experiment) and then by a repetition of distillations at −196 °C (for the closed gas circulation system).

Apparatus and Procedure. *1. Pulsed Microreactor*: After a treatment at 150 °C for 3 h in a stream of dry CO_2-free air, the temperature of a sample of *ca.* 10 mg was increased up to the desired temperature (this temperature will be called the pretreatment temperature) at a constant rate of 0.5 °C/min, where the sample was kept for 4 h before being annealed in a stream of He for 2 h. After the temperature of the sample was lowered down to the reaction temperature, 2.26 cm^3 of NO was injected onto the zeolite in a stream (10.0 cm^3/min) of He.

2. Temperature-programmed Desorption: TPD studies were carried out as follows: After a run of the pulsed reaction described above was finished, the temperature of reaction vessel was raised at a constant rate of 7.14 °C/min in a stream of He (10 cm^3/min). The effluent gas was periodically analyzed with a gas chromatograph, equipped with a Porapak T and Molecular Sieve 13X column at 50 °C and using He as carrier gas, for contents of NO, N_2O, O_2, and N_2.

3. Closed Gas Circulation System: A closed gas circulation system (*ca.* 705 cm^3) equipped with a pyrex reaction vessel was used to study the kinetics of the disproportionation reaction of NO. A zeolite (*ca.* 2 cm^3) was treated at 500 °C in acoordance with the procedure described above under the heading in

"Pulsed Microreactor" and was evacuated (10^{-6} Torr) at a constant temperature (500 °C) for 2 h. After a series of these treatments, the temperature of vessel was adjusted to the reaction temperature and NO gas was introduced into the reaction system. The amount of products was measured by gas chromatography.

Results

Activity and Pretreatment Temperature. The activity was measured at 15 °C with a pulsed microreactor. Since the activity decreased markedly with increasing number of pulses, it is expressed by the rate of N_2O formation in the first pulse, which is taken to indicate the activity for the disproportionation reaction of NO. The gas analysis showed that the only gaseous product is N_2O, in agreement with the result of Addison and Barrer.[1]

Figure 1 shows the relation between activity and pretreatment temperature in the range 400—900 °C. The activity increases with an increase in pretreatment temperature, reaches a broad maximum at 700 °C, and decreases gradually with a further increase in pretreatment temperature. A powder X-ray diffraction examination of zeolites activated at each pretreatment temperature revealed that this gradual decrease in activity is caused by a collapse of the crystalline structure of zeolite pretreated at 800 or 900 °C.

TPD Profile. Addison and Barrer[7] insisted that the N_2O_3 produced by the disproportionation reaction of NO would be stabilized in the zeolite. On the other hand, Chao and Lunsford[2] suggested that the adsorbed N_2O_3 will decompose to give NO and NO_2 when the excess NO gas is removed by evacuation from the reaction mixture. In the procedure described above for temperature-programmed desorption, therefore, the NO_2 gas desorbed by raising temperature was removed by a dry NaOH-packed column in order to avoid complexity. TPD profiles were measured after the first pulse reaction. The change in TPD profile with pretreatment temperature was disclosed. Figure 2 shows the TPD profile of zeolites treated at 700 °C, the numerical values indicating the desorption temperature.

The TPD profile is composed of five signals α, β, γ, δ, and ε arranged in parallel with the increasing temperature scale, of which signals δ and ε are negligibly small. One can consider that peaks α, β, and γ offer information about adsorbed species staying on the zeolite surface after the disproportionation reaction of NO. According to an analysis of desorbed gases, peak α consists of NO, *ca.* 90% of peak β is composed of NO with the residual portion as N_2O, and *ca.* 90% of peak γ is N_2O with the rest as NO.

TPD profiles of zeolites treated at various pretreatment temperatures are also composed of five signals and the area of each peak (α, β, γ) varied independently of the others. In spite of the low resolution of TPD peaks (α, β, γ), the area of each peak (α, β, γ) was determined by drawing a supplementary line in order to separate the three peaks. Figure 3 shows the relation between the area of each peak (α, β, γ) and the pretreatment temperature. The plot breadth in Fig. 3 indicates the experimental error range in connection with the arbitrariness of the method to draw the supplementary lines. The area of peak α decreases gradually with an increase in pretreatment temperature, and those of peaks β and γ increase with increasing pretreatment temperature, reach a broad maximum at *ca.* 700 °C, and decrease with a further increase in pretreatment temperature. The variation in peak areas of β and γ showed a tendency similar to the variation in the activity illustrated in Fig. 1, hence it follows that peaks β and γ reflect the activity. The desorption temperatures for peaks α, β, and γ were approximately constant in all experiments, indicating that the respective adsorp-

tion states are almost independent of pretreatment temperature.

Reaction Kinetics. The desorption peak of N_2O was recognized in the TPD experiment after a pulse reaction, indicating that readsorption of N_2O formed by the disproportionation of NO will occur. However, we assume for convenience in this paper that irreversible adsorption of N_2O should occur only in the initial stage of reaction, so that the formation rate of N_2O may be expressed as the rate of Reaction 2, specified in the following section, for a comparatively prolonged stage of reaction pass time.

The Elovich equation in wide use is one of the most convenient ways of describing chemisorption kinetics, especially when the chemisorption is slow. The Elovich equation is written in its differential form as $dQ/dt=\alpha \exp(-\beta Q)$ where Q (mol g^{-1}) is the amount of N_2O produced at a reaction pass time t (min) and α and β are constants for each system at a fixed temperature. In its integrated form, the equation can be written as $Q=(1/\beta)\ln(t+t_o)-(1/\beta)\ln t_o$, $t_o=1/\alpha\beta$ (constant) where α (mol g^{-1} min^{-1}) is the initial formation rate of N_2O, *i.e.*, the formation rate of N_2O taken when the reaction pass time t approaches zero.

The dependence of the initial formation rate of N_2O on NO pressure was studied on zeolites pretreated at 500 °C by using a closed gas circulation system at reaction temperature 0 °C. Figure 4 shows the relation

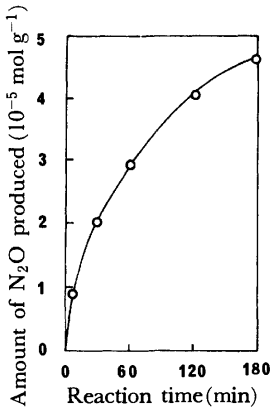

Fig. 4. Amount of N_2O produced plotted against reaction time.
P_0=110.2 Torr: Reaction temp. 0 °C

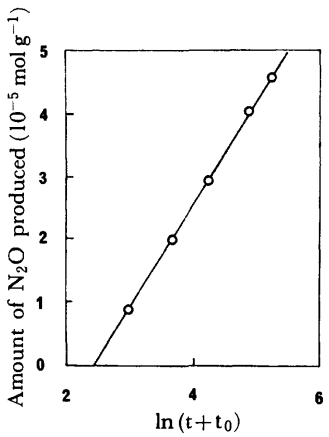

Fig. 5. Relationship between Q and $\ln(t+t_0)$.
$Q=1/\beta \ln(t+t_0)-1/\beta \ln t_0$, $t_0=1/\alpha\beta$, t_0=9.87 min

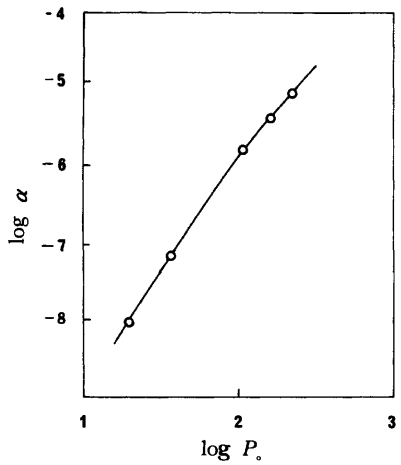

Fig. 6. Relationship between $\log\alpha$ and $\log P_o$.

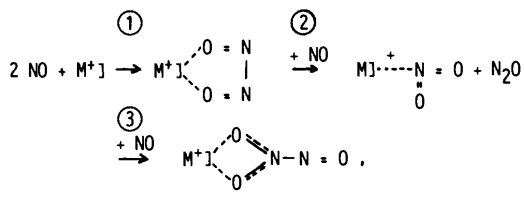
between the amount of N_2O produced and the reaction pass time t obtained when the pressure P_o of introduced NO is equal to 110 Torr. The curve in Fig. 4 shows an initial rapid upturn, in good correspondence to the Elovich equation. The best-fit value of t_o as obtained by using the integrated formula of Elovich equation is given in Fig. 5 as 9.87 min, which in turn evaluates α as 1.58×10^{-6} mol g^{-1} min^{-1}. In accordance with this procedure, the relation between the introduced-NO pressure P_o and the initial formation rate α was determined. Figure 6 shows the relation between log P_o and log α. The reaction order of the initial formation rate of N_2O was determined from the slope of the curve in Fig. 6; α is proportional to the third order of P_o in the lower pressure region (*ca.* 30 Torr). In an intermediate pressure region, the slope of the curve in Fig. 6 gradually decreases with an increase in NO pressure and α obeys the 2.2th order of P_o in the higher pressure region (*ca.* 200 Torr). Therefore, it is concluded that the initial formation rate of N_2O is third order with respect to NO pressure, and that the reaction order gradually decreases with an increase in NO pressure.

Discussion

Rate Equation for Initial Formation of N_2O. The mechanism proposed by Chao and Lunsford for the disproportionation reaction of NO,[3] is



(from Chao and Lunsford's model[3])

where M^+ refers to Na^+ and Ca^{2+} for NaY- and CaY-type zeolites, respectively. For derivation of the initial formation rate of N_2O, we assume that the backward reaction of step ② is negligible. On this assumption, *i.e.*, the rate determining step is step ②, we have the following effective reaction sequence for the initial formation of N_2O:

$$[\quad] + 2NO \overset{K_1}{=} [N_2O_2], \qquad (1)$$

$$[N_2O_2] + NO \xrightarrow{\vec{k}_2} [NO_2] + N_2O, \quad (2)$$

$$[N_2O_2] + [\quad] = 1, \quad (3)$$

where [ ] denotes vacant adsorption sites, $[N_2O_2]$ denotes N_2O_2 adsorption sites, K_1 is the equilibrium constant for Eq. 1, and $\vec{k}_2$ is the rate constant for Eq. 2. By using Eqs. 1, 2, and 3, the initial formation rate α is formulated as

$$\alpha = \vec{k}_2[N_2O_2]\,P = \vec{k}_2K_1P^3/(1+K_1P^2), \quad (4)$$

where P is the pressure of NO. Therefore, the reaction order n is given by

$$n = \partial \ln \alpha/\partial \ln P = 3 - 2K_1P^2/(1+K_1P^2). \quad (5)$$

Equations 4 or 5 indicates that the initial formation rate of N_2O is expected to obey a third-order relation with respect to NO pressure at the lower pressure region if K_1P^2 is negligibly smaller than 1, and that the reaction order will decrease with an increase in NO pressure. On the other hand, a first-order relation is available if K_1P^2 is so large as to make 1 negligible. These characteristics may interpret the relation between log P_o and log α shown in Fig. 6.

Active Sites. Figure 1 shows that the activity increases with an increase in pretreatment temperature. In a study on the relation between the cation destribution and the residual water content in faujasites with metal cations exchanged, Dempsey and Olson[19] found that the occupancy of Sites I′ and II′[20] increase with an increase in the residual water content. Yamada *et al.*[21] studied chemisorptions of two kinds of gases having different adsorption properties, CO and NO, on NiHY-type zeolites, and concluded that the distribution of Ni^{2+} in the cation Site II increase with an increase in pretreatment temperature. From a study on the disproportionation reaction of NO on MgHY-type zeolites with different degrees of ion exchange, we derived[4] that the concentration of Mg^{2+} serving as active sites increases with an increase in pretreatment temperature. Thus, the effect of pretreatment temperature, shown in Fig. 1,may be considered to originate from an increase in Ca^{2+} distributed in Site II on Y-type zeolite.

In relation to activity and pretreatment temperature, we have described that the activity decreases markedly with increasing number of pulses. This drastic decrease in activity may be interpreted as follows: Most of the active sites or Ca^{2+} distributed in Site II are covered with N_2O_3 produced by the disproportionation reaction immediately after the NO in the first pulse has been introduced onto a CaHY-type zeolite, so that the resulting drastic decrease in the number of active sites will lead to the disappearance of catalytic activity. We[6] formerly reported that the apparent activation energy for the disproportionation of NO on CaY-type zeolite in the temperature range between −24 and 45 °C is −6.9 kcal/mol. Therefore, even if the disproportionation reaction of NO were carried out at 200 °C where NO, N_2O_3, and N_2O once adsorbed are desorbed, it would be most probable that nobody should be able to get a steady state activity of catalyst.

Reaction Mechanisms. On the basis of infrared spectra relating to NO adsorbed on CaY-type zeolite, Chao and Lunsford[3] deduced that the infrared peak assignable to N_2O disappears after the reaction mixture has been pumped out. In our study, however, peak γ of TPD profile has been assigned to N_2O. This discrepancy seems to be due to the fact that the TPD experiment was carried out in a He carrier gas flow with no pumping applied after the activity had been measured according to the pulse method. In addition, an experiment in which N_2O instead of NO was pulsed into the reactor has led to a conclusion that most of induced N_2O molecules remain adsorbed on a CaHY-type zeolite, without being allowed to desorb out into the gas phase. This experimental information is in support of the idea that the adsorptive power of N_2O is stronger than that of NO.

In accordance with the reaction mechanism proposed by Chao and Lunsford,[3] an N_2O_2 adsorbed at a cationic active site causes a rearrangement by reaction with a gas phase NO molecule to produce N_2O and NO_2, and the resulting NO_2 reacts rapidly with an NO molecule in the gas phase, leaving the spieces N_2O_3 on the zeolite surface. This reaction stage is step③ in Chao and Lunsford's model.

A comparison of Figs. 1 and 3 leads us to notice that peaks β and γ have a certain relation in activity. The results can be explained as follows: As is well known, N_2O_3 dissociates easily into NO and NO_2 and thus, the N_2O_3, formed by the disproportionation reaction and left on the surface, is caused to dissociate into NO and NO_2 when heated in the TPD experiment, the resulting NO corresponding to peak β in the TPD profile, whereas the resulting NO_2 is removed during passage through the dry NaOH-packed column before entering the detector.

Peak γ in the TPD profile is expected to be composed of a part of the N_2O formed by disproportionation and still remaining in the zeolite. The diameter of N_2O molecule is larger than that of NO molecule, hence it may follow that N_2O molecule is harder to desorb than NO molecule. This may be the reason for the observation that peak γ appears in a higher temperature region than peak β. On the other hand, peak α may be regarded as corresponding to the unreactive NO which is weakly adsorbed on the zeolite surface.

As seen from Fig. 3 for the pretreatment temperature range 600—700 °C, the areas of TPD peaks β and γ are *ca.* 1.5 and 4 times as large as those for the pretreatment temperature 400 °C. On the basis of these facts, the effect of pretreatment temperature on the area of TPD peak may be deduced as follows: As the pretreatment temperature is increased, *i.e.*, the number of water molecules in the zeolite structure is decreased, the amount of empty sites increases so that the N_2O produced by the disproportionation reaction of NO is made liable to adsorb on empty sites.

Adsorptions of Organic Compounds in Basic Solutions

Kohei URANO* and Hisanao KANO
Department of Safety and Environmental Engineering, Yokohama National University, 156 Tokiwadai, Hodogaya-ku, Yokohama 240
(Received October 12, 1983)

The adsorption isotherms of various aromatic compounds on an activated carbon or a polystyrene adsorbent in aqueous solutions and basic solutions were investigated. The adsorption isotherms of nonionic compounds and strong anionic electrolytes in the basic solutions were equal to the isotherms in the aqueous solutions. However, the adsorbed amounts of weak anionic electrolytes decreased with ionization in the basic solutions, and the adsorption isotherms of the non-ionized form and the ionized form of all these compounds except phenol could be expressed by the Freundlich equations with the same values of n. The amounts of those weak anionic electrolytes adsorbed at a desired pH could be calculated from the adsorption isotherms of the non-ionized form and the ionized form and the ionization constants.

Applications of adsorption from solutions on solid adsorbents have been considerably developed and become very important in many fields, such as in purification processes, water-treatment processes, and analytical methods.[1]

Adsorptions are now carried out at various pH values in those adsorption processes, and regenerations by desorption with a basic solution are applied in several processes. However, the influence of the pH on the adsorptions of organic compounds in water has not been made clear.[2] In this study, the adsorption isotherms of 7 aromatic compounds on an activated carbon or a polystyrene adsorbent were obtained in basic solutions, and they were compared with the isotherms in aqueous solutions.

Experimental

Three nonionic and four anionic compounds, whose properties are shown in Table 1, were tested as adsorbates in this study. A granular activated carbon and a polystyrene adsorbent whose properties are shown in Table 2 were used as adsorbents.

The adsorption isotherms at 25 °C were obtained by means of a batch-adsorption method as same in the previous paper.[3]

Results and Discussion

The adsorption isotherms in the aqueous solutions are shown in Figs. 1 and 2 as the Freundlich expression, logarithmic relationships between the adsorbed amount Q(mol g^{-1}) and the equilibrium concentration C(mol dm^{-3}). Most of them show linearity, and most could be expressed by the Freundlich equation; $Q = kC^{1/n}$. However, the isotherms for several anionic compounds, such as benzoic acid and nitrobenzoic acid fell lower in the concentration range than about 10^{-4} mol dm^{-3}. Further, the amount of the benzenesulfonic acid adsorbed for the activated carbon was much smaller than those of the other compounds, and it was negligibly small for the polystyrene adsorbent. Since benzoic acid and nitrobenzoic acid are ionized partially in the concentration range lower than about 10^{-4} mol dm^{-3} and since benzensulfonic acid is ionized completely throughout the concentration range, it can be presumed that the adsorbed amounts decrease with the ionization of the adsorbates.

Then the adsorption isotherms in sodium hydroxide solutions were obtained. The adsorption isotherms of the nonionic compounds and benzenesulfonic acid in the 1 mol dm^{-3} sodium hydroxide solution are shown

TABLE 1. PROPERTIES OF THE ADSORBATES TESTED

Adsorbate	Molecular weight	Solubility / mol dm^{-3}	Ionization constant K_a
Nitrobenzene	123.1	1.6×10^{-2}	—
Benzaldehyde	106.1	2.8×10^{-2}	—
Benzonitrile	103.1	2.1×10^{-2}	—
Benzoic acid	122.1	2.8×10^{-2}	6.1×10^{-5}
m-Nitrobenzoic acid	167.1	2.1×10^{-2}	3.6×10^{-4}
Phenol	94.1	9.2×10^{-1}	1.0×10^{-10}
Benzenesulfonic acid	158.2	∞	2×10^{-1}

in Figs. 3 and 4. The adsorption isotherms for these compounds in the basic solutions were almost equal to those in the aqueous solutions. Therefore, sodium hydroxide did not influence the adsorptions of the nonionic compounds and the strong anionic electrolytes.

(Symbols are same as in Fig. 5)

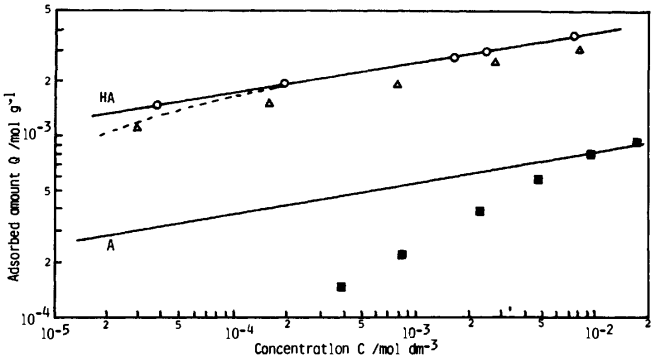

Fig. 7. Adsorption isotherms of phenol on activated carbon in sodium hydroxide solutions at 25°C.
(Symbols are same as in Fig. 5)

The adsorption isotherms of the weak anionic electrolytes in sodium hydroxide solutions from 10^{-4} to 1 mol dm^{-3} are shown in Figs. 5—10. The amounts of these weak anionic electrolytes adsorbed in the 1 mol dm^{-3} sodium hydroxide solutions, in which those compounds were completely ionized, were much smaller than those in the aqueous solutions for the activated carbon. Their amounts adsorbed on the polystyrene adsorbent were negligibly small in the solutions of 1 mol dm^{-3} sodium hydroxide.

However, the adsorption isotherms of the completely ionized form for the activated carbon were parallel to their isotherms of the non-ionized form in the aqueous solutions, except for phenol. That, the values of n of the Freundlich equation were equal to one another. Urano *et al.*[3] reported that the distribution function of the adsorption energy could be obtained from the modified Freundlich isotherm equation; $Q=k'(C/C_s)^{1/n}$, and that the values of k' and n related, respectively, to adsorption space and mechanism, where C_s is the saturated concentration of the adsorbate. The fact that the values of n for the non-ionized form and the ionized form were equal to one another shows that the adsorption mechanisms of both forms are equal and that only the solubilities C_s are different. That, it can be thought that the adsorption amounts for those compounds except phenol decrease with the ionization in the basic solutions, because the apparent solubilities C_s of the ionized forms increase much more than those of the non-ionized forms.

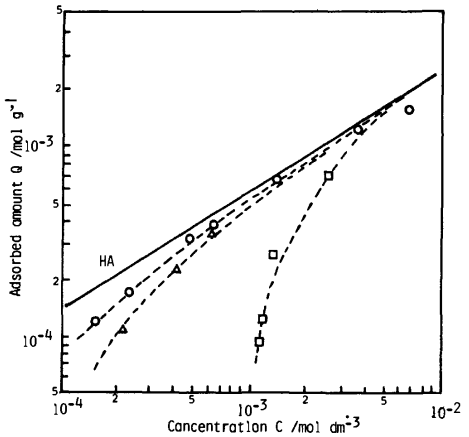

Fig. 8. Adsorption isotherms of benzoic acid on polystyrene adsorbent in sodium hydroxide solutions at 25 °C.
(Symbols are same as in Fig. 5)

The adsorptions of those weak anionic electrolytes in a basic solution seem to be examples of the adsorption of the dual-components, the non-ionized form (HA) and the ionized form (A). Getzen and Ward[4] reported a method of estimating the adsorption of several substituted benzoic acids by the application of the Langmuir equation for dual-components. However, it is difficult to determine the parameters of the Langmuir equation for application over a wide concentration range. Radke and Prausnitz[5] also proposed a method of predicting the adsorption of multi-components by means of a thermodynamic consideration. The total amounts Q of benzoic acid adsorbed under several conditions were calculated by the Radke-Prausnitz method for the forms of HA and A; they are compared with the observed data in Table 3. The calculated values are different from the observed data. Therefore, the Radke-Prausnitz method cannot be applied for the adsorption of the ionic compounds.

Now, assuming that the adsorptions of the non-ionized and the ionized forms are independent of one another, the total adsorbed amounts Q can be calculated as follows from the sum of the two Freundlich equations for HA and A;

$$Q = Q_{HA} + Q_A = k_{HA}C_{HA}^{1/n} + k_AC_H^{1/n} \quad (1)$$

The values of k_{HA}, k_A, and n can be obtained from the adsorption isotherms in aqueous solutions and sodium hydroxide solutions of 1 mol dm^{-3}; they are summarized in Table 4. The concentrations of the non-ionized and the ionized forms, C_{HA} and C_A, can be calculated from

1.0×10^{-2}	2.6×10^{-2}	1.6×10^{-2}	1.0×10^{-2}	1.4×10^{-3}	5.2×10^{-3}

TABLE 4. PARAMETERS OF FREUNDLICH EQUATION FOR THE NON-IONIZED FORM AND THE IONIZED FORM

	Activated Carbon			Polystyrene		
	k_{HA}	k_A	n	k_{HA}	k_A	n
Nitrobenzene	1.9×10^{-2}	—	4.0	9.1×10^{-2}	—	1.7
Benzaldehyde	1.6×10^{-2}	—	3.9	6.2×10^{-2}	—	1.7
Benzonitrile	1.7×10^{-2}	—	3.7	4.5×10^{-2}	—	1.8
Benzoic acid	9.4×10^{-3}	1.8×10^{-3}	4.8	6.7×10^{-2}	$<10^{-4}$	1.5
m-Nitrobenzoic acid	7.9×10^{-3}	1.2×10^{-3}	5.7	2.8×10^{-2}	$<10^{-4}$	1.8
Phenol	8.3×10^{-3}	—	5.7	1.9×10^{-2}	$<10^{-4}$	1.5
Benzenesulfonic acid	—	1.6×10^{-3}	6.7	—	$<10^{-4}$	—

the total concentration of the organic compound C, the concentration of the sodium ion C_{Na}, and the ionization constant K_a by means of the following equations;

$$C = C_{HA} + C_A \quad (2)$$

$$C_H + C_{Na} = C_A + C_{OH} = C_A + 10^{-14}/C_H \quad (3)$$

$$K_a = C_H C_A / C_{HA} \quad (4)$$

The adsorption isotherms in 10^{-4}, 10^{-3}, and 10^{-2} mol dm^{-3} of sodium hydroxide solutions were calculated by means of Eqs. 1—4; they all shown as broken lines in Figs. 5—10. The calculated lines approximately fit the observed plots for the various systems of a weak anionic compound and an adsorbent except for the adsorption of phenol on the activated carbon. Therefore, the adsorptions of the non-ionized form and the ionized form of those compounds seem to be practically independent of one another.

Consequently, the total adsorbed amount at a desired pH (or C_H) for the weak anionic electrolytes, except for several phenolic compounds,[6] can be predicted by the use of Eq. 1 from the adsorption isotherms of the non-ionized form and the ionized form and the ionization constant, because the concentrations of both forms, C_{HA} and C_A, can be given as Eqs. 5 and 6 from Eqs. 2—4 at the desired pH;

$$C_{HA} = 10^{-pH}C/(10^{-pH} + K_a) \quad (5)$$

$$C_A = K_a C/(10^{-pH} + K_a) \quad (6)$$

The amounts of phenol adsorbed on the activated carbon decreased much in the lower concentration ranges in basic solutions, as shown in Fig. 7. It was shown in previous papers[3,6] that several phenolic compounds combined with the carbon surface by means of the π-electron combination. Therefore, the deviation of phenol for the activated carbon may be due to the combination of the hydroxide ion with the electrophilic groups on the surface of activated carbon.[3,6]

Applicability of a New Adsorption Isotherm Equation and Adsorption Abilities of Commercial Chelating Resins for Single Metal Ions in Acidic Solution

Kohei URANO,* Veerapan CHANYASAK, Nobuhiko FUJII, and Toshiaki YUKAWA
Department of Safety and Environmental Engineering, Yokohama National University, 156 Tokiwadai, Hodogaya-ku, Yokohama 240
(Received December 8, 1983)

Adsorption isotherms for single metal ions (Ca^{2+}, Fe^{3+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, or Pb^{2+}) in acidic solutions at 25 °C on 9 types of commercial chelating resins were obtained. The results could all be expressed by the isotherm equation, $Q=Q_{max}/(1+AC_M^{-\alpha}C_H^{\beta})$, reported in the preceding paper. The parameters α and β, which indicate respectively the influences of concentrations of metal ion (C_M) and hydrogen ion (C_H) on the adsorption capacities (Q), were discussed in relation to the properties of the chelating resins and the metal ions.

Chelating resins have been used for the removal and the recovery of metals from water and also for the concentration and analysis of trace metals.[1-4] Conventional studies on chelating resins, however, related only to those involving syntheses and examples of application under specific conditions.[5] In a previous study,[6] competitive adsorptions of metal ion and of hydrogen ion on chelating resin were investigated, and it was shown that the adsorption isotherms of single heavy metal ion in acidic solution on several systems of metal ion and chelating resin could be represented by the following equation;

$$Q = Q_{max}/(1+AC_M^{-\alpha}C_H^{\beta}). \quad (1)$$

Here Q is an adsorption amount (m mol/g-dry resin), Q_{max} is the maximum adsorption amount which can be determined from the total ion-exchange capacity of the resin, A is a correction factor, C_M is the concentration (mol dm^{-3}) of metal ion, and C_H is the concentration (mol dm^{-3}) of hydrogen ion. α and β are parameters such that the values of $1-\alpha$ and β show the exponents of the distribution function of ligands which have various dissociation constants. However, this isotherm equation is semi-theoretical and its applicability to many systems of chelating resin and metal ion over wide concentration ranges of metal ion and hydrogen ion needs to be confirmed experimentally.

The objectives of this study are to establish the validity of the above equation for various systems of commercial chelating resins and heavy metal ions, and to estimate the adsorption abilities of commercial chelating resins for various metal ions by the values of α and β in Eq.1.

Experimental

Nine types of chelating resins were employed in this study. They were UR-10, UR-20, UR-30, UR-40, UR-50, which are

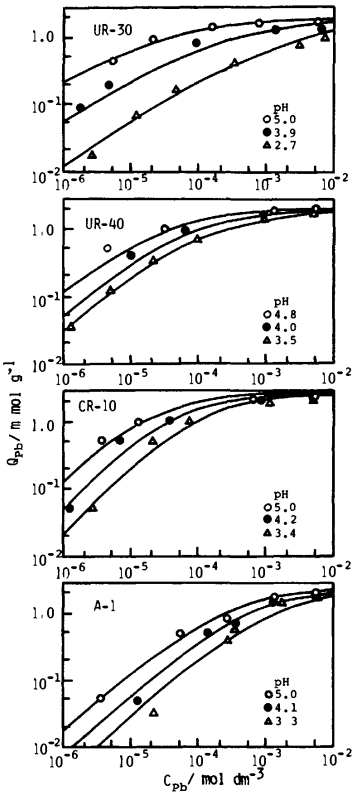

Fig. 8. Adsorption isotherms of Pb^{2+} for various resins and pH.

are shown in Figs.1 and 2. The swelling ratio corresponds to the degree of crosslinkage of the resin. Three types of UR-20 and UR-30, namely H, Ca, and Na types, were used in the experiments, but only the H type of the other resins was used.

Metal salts employed for adsorption tests were nitrates of Ca(II), Fe(III), Cu(II), Zn(II), Cd(II), and Pb(II) of reagent grade.

The methods for the pretreatments of the resins and the batchwise adsorption tests have been described in the previous paper.[6] The pH was controlled at about 3, 4, 5, 8, or 9 for the adsorption tests of Ca^{2+} about 1 or 2 for Fe^{3+}, and about 3, 4, or 5 for Cu^{2+}, Zn^{2+}, Cd^{2+}, and Pb^{2+}. The concentrations of Ca^{2+} and Fe^{3+} were measured by an atomic absorption flame spectrophotometer, Model AA-610 of Shimadzu Co., and the concentrations of Cu^{2+}, Zn^{2+}, Cd^{2+}, and Pb^{2+} were measured by an anodic stripping voltametric analyzer, Model AS-01 of Mitsubishi Chemical Industry Ltd.

Results and Discussion

Applicability of the Adsorption Isotherm Equation. Adsorption isotherms of each metal at 25 °C are shown in Figs. 3—8, respectively. The curves in these figures were calculated from Eq.1, and the plots show the measured data. All the measured data fitted approximately on the calculated curves. Consequently, it is confirmed that the isotherm Eq.1 can be applied generally for the various systems of commercial chelating resin and metal ion over a wide ranges of pH and concentration of the metal ion. The values of the parameters of Eq.1 for all the tested systems are listed in Table 2.

Variation of α and β with Systems of Chelating Resin and Metal Ion. Variations of the values of α and β, which show respectively the influences of C_M and C_H on Q, with the chelating resins, are discussed for each metal ion.

Calcium Adsorption: The α values of UR-10, UR-20, and UR-30 which have many phenolic OH groups are 0.66 ± 0.03 for Ca^{2+}, whereas for UR-40, UR-50, CR-10, and Dowex A-1 which have few or no phenolic OH group, the α values are 0.81 ± 0.06. The influence of the phenolic OH group on the adsorption of Ca^{2+} was greater than on the adsorption of the other heavy metal ions. This difference may be attributed to the high ionization ratio of the phenolic OH group at the higher pH values in the adsorption tests of Ca^{2+}. The β values for Ca^{2+} show only a small variation among the chelating resins. However, resins with higher degrees of crosslinkage tend to have smaller β values.

Iron (III) Adsorption: Fe^{3+} adsorbed slightly on CR-20 and CR-40 which have amino groups. For all the other resins, the α values for Fe^{3+} are 0.60 ± 0.06. Except for Dowex A-1 whose β value is 0.30, the β values of Fe^{3+} are 0.57 ± 0.09. The reason for the small β for Dowex A-1 may be because Dowex A-1 has various functional groups. Compared to CR-10, which has similar resin matrix to Dowex A-1 but only iminodiacetate functional group, Dowex A-1 has also smaller β values for other metals. In other words, more metals adsorbed on Dowex A-1 at low pH, though less adsorbed on Dowex A-1 than on CR-10 at normal pH.

Copper Adsorption: The adsorption of Cu^{2+} was specific and different from those of the other heavy metal ions. Many chelating resins could adsorb much Cu^{2+} at concentration higher than 10^{-3} mol dm^{-3}, but the adsorptions at the lower concentration range varied

	A-1	2.5	9.0×10^{-2}	0.84	0.38

widely with different resins. Therefore, the α values for Cu^{2+} vary widely with the chelating resins. The β values for Cu^{2+} are very small for most of the resins except for CR-20 and CR-40 which have amino functional groups. Two resins, CR-20 and CR-40, adsorb Cu^{2+} selectively, because N-O ligands form complexes with Cu^{2+} easily. However, the values of the parameters A, α, and β for CR-20 and CR-40, which have different a resin matrix but similar functional group, are very different form each other. Further, it was found that the α values of UR-20 for Cu^{2+}, Zn^{2+}, Cd^{2+}, and Pb^{2+} were larger than those of the other resins of the UR series. The reason is unknown, though the pore-size distribution of UR-20 was different from those of the other resins.

Zinc Adsorption: The α and β values for Zn^{2+} show

large variations with the chelating resins. The α values of the UR series resins for Zn^{2+} do not depend on the amount of phenolic OH group. The α values of UR-20 or UR-30 of different ion types, namely H, Na, and Ca types, for Zn^{2+} are slightly different, but the β values of these different type resins decreased in the following order: H type>Na type>Ca type. In the cases of the Ca type resins, Ca^{2+} ion which was released with adsorption of H^+ might be adsorbed competitively with Zn^{2+}, as a result, the apparent β values are smaller than those of the other types. However, in the cases of the Na type resins, the released Na^+ might be adsorbed much less than Zn^{2+}. The reason for the smaller β values of the Na type resins than the H type resins might be that Na^+ in the resins became difficult to release due to shrinking of the Na type resins with the adsorption of H^+. It was also found that the β values for Cd^{2+} and Pb^{2+} of different type resins varied in the same order as in the case of Zn^{2+}.

Cadmium Adsorption: The α values of the UR series resins for Cd^{2+} do not depend on the amounts of phenolic OH group, but the α values of UR-40 having no phenolic OH group are larger than the other resins of UR series. The β values of CR-20 and CR-40, which have amino group, for Cd^{2+} are smaller than those of the other resins. The β value of UR-10 with high degree of crosslinkage for Cd^{2+} is slightly smaller than those of the other resins of UR series.

Lead Adsorption: As is in the case of Cd^{2+}, the α values for Pb^{2+} can be divided into two groups; (1) UR-10, UR-30, and UR-50 and (2) the other resins. The β value of UR-10 for Pb^{2+} is also smaller than the values of the other resins, this is similar to the case of Cd^{2+}. As mentioned previously, the β value of UR-20 is larger than the values of the other resins.

Order of β Values: The β values of various chelating resins increase in the order: $Cu^{2+}<Ca^{2+}<Pb^{2+}<Fe^{3+}<Zn^{2+}<Cd^{2+}$. This order, except for Ca^{2+} whose adsorption tests were carried out at higher pH than the others, is in opposite order to the stability constants of ethylenediaminetetraacetate with these metal ions. The reason for the deviation of Ca^{2+} adsorption may be that the phenolic OH group of the resins of UR series influences the adsorption at the higher pH range.

Adsorption Isotherm Equation for Coexistence of Two Kinds of Metal Ions in Acidic Solution on Chelating Resin

Kohei URANO* and Nobuhiko FUJII
Department of Safety and Environmental Engineering, Yokohama National University, 156 Tokiwadai, Hodogaya-ku, Yokohama, 240
(Received December 8, 1983)

Adsorption isotherms for the coexistence of two metal ions (combinations of Zn^{2+}, Cd^{2+}, and Pb^{2+}) in acidic solutions on chelating resins were measured at 25 °C. They were analyzed in relation to the adsorption isotherm equation of a single metal ion, $Q=Q_{max}/(1+AC_M^{-\alpha}C_H^{\beta})$, as was reported in the preceding paper. It is found that the adsorption isotherms of two metal ions (i and j) in acidic solution on chelating resins can be generally expressed by the equation;

$$Q_{i,j}=Q_{max}/\{1+A_iC_i^{-\alpha_i}C_H^{\beta_i}(1+K_{i,j}C_j^{\alpha_j}C_H^{-\beta_j})\}$$

over wide ranges of concentrations of the metal ion, C, and the hydrogen ion, C_H (mol dm^{-3}). Where Q_i and $Q_{i,j}$ are the adsorption amounts (m mol/g-dry resin) of i metal ion in the absence and in the coexistence of j metal ion. Q_{max} is the maximum adsorption amount, α and β are parameters in the adsorption of single metal solution, A and K are correction factors, and subscripts i and j identifing i and j metal ions. The adsorption capacities of two metal ions in acidic solution can be obtained from the isotherms parameters A_i, α_i, α_j, β_i and β_j for an individual single metal ion and only one additional parameter $K_{i,j}$ is needed.

Chelating resins are used to separate a specific metal ion from many coexisting ions in water for removal and analysis of the ion. However, there are few studies on selective adsorption of metal ions on chelating resins under various conditions. In the previous papers,[1,2] the general adsorption isotherm equation and its parameter were given for many systems of chelating resin and single-component heavy metal ion in acidic solution, but no general isotherm equation has been reported for the competitive adsorption of three adsorbates, two metal ions and hydrogen ion. In this study, adsorption isotherms for coexistence of two metal ions (combinations of Zn^{2+}, Cd^{2+}, and Pb^{2+}) in acidic solution on several chelating resins, which have iminodiacetate groups, were measured. They were analyzed by using the adsorption isotherm equation of each single-component heavy metal ion to give a general isotherm equation for selective adsorption of a heavy metal ion in competition with another coexisting metal ion and hydrogen ion.

Experimental

The tested systems of chelating resin and metal ions are shown in Table 1. The chelating resins of UR-40, CR-10, and Dowex A-1 are products of Unitika Ltd., Mitsubishi Chemical Industry Ltd., and Dow Chemical Ltd., respectively. Their properties were described in the preceding paper.[2] The methods for the pretreatments of the resins and the batchwise adsorption tests were similar to those described in the previous paper.[1]

Solutions containing two metal nitrates of various concentrations ranging from 5×10^{-4} to 1×10^{-2} mol dm^{-3} and at constant pH were used for the adsorption tests. The analytical method for determining the metal ions was also similar to that described in the previous papers.[1,2]

TABLE 1. TESTED SYSTEMS OF CHELATING RESIN, METALS, AND pH

Resin	Metals	pH
UR-40	Cd^{2+}-Pb^{2+}	5.1, 3.6
CR-10	Zn^{2+}-Cd^{2+}	5.0, 3.6
CR-10	Zn^{2+}-Pb^{2+}	5.0, 3.6
A-1	Zn^{2+}-Pb^{2+}	5.0, 3.4

Results and Discussion

The adsorbed amount of single i metal ion in acidic solution, Q_i, can be given by the following equation reported in the previous paper.[1]

TABLE 2. PARAMETERS OF Eq. (1) FOR TESTED SYSTEMS

Resin	Metal	Q_{max}	A_i	α_i	β_i
UR-40	Cd^{2+}	2.0	24	0.86	1.0
UR-40	Pb^{2+}	2.0	5.0×10^{-2}	0.80	0.48
CR-10	Zn^{2+}	2.5	6.0	0.76	0.87
CR-10	Cd^{2+}	2.5	20	0.86	1.0
CR-10	Pb^{2+}	2.5	8.4×10^{-3}	0.94	0.46
A-1	Zn^{2+}	2.5	8.6	0.65	0.69
A-1	Pb^{2+}	2.5	9.0×10^{-2}	0.84	0.38

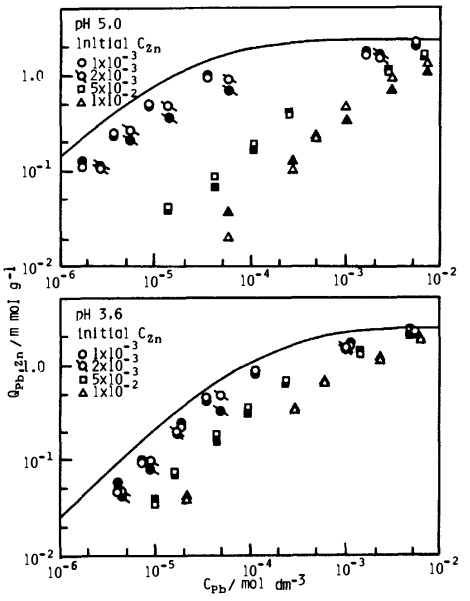

Fig. 1. Adsorption equilibria of Pb^{2+} under coexistence of Zn^{2+} on CR-10 at 25 °C (In all Figs. 1 and 3—9, curves show adsorption isotherms of single metal ion i by Eq. [1], open marks show observed data, and black marks show calculated $Q_{i,j}$ by Eq. [6] for the observed C_i and C_j).

$$Q_i = Q_{max}/(1+A_iC_i^{-\alpha_i}C_H^{\beta_i}) \quad (1)$$

Here, Q_{max} is the maximum adsorption amount which can be given by total ion-exchange capacity of the resin, and C_i and C_H are the concentrations of the i metal ion and hydrogen ion. α_i and β_i are parameters which indicate the degree of influences of C_i and C_H on Q_i. In other words, they show adsorbabilities of i metal ion and hydrogen ion, hence $A_iC_i^{-\alpha_i}C_H^{\beta_i}$ actually means an interfering factor for Q_i. The values of A_i, α_i, and β_i for all the tested systems of chelating resin and metal ion had been obtained in the preceding study.[2] They are listed again in Table 2 because they are needed for the analyses of the results in this study.

Adsorption equilibria of Pb^{2+} under the coexistence of Zn^{2+} on CR-10 at a pH of 5.0 and 3.6 are shown in Fig.1. The adsorbed amount of Pb^{2+} under the coexistence of Zn^{2+} in the acidic solution, $Q_{Pb,Zn}$, was smaller at higher initial concentration of Zn^{2+} and approached Q_{Pb} for a single Pb^{2+} solution at lower concentration of Zn^{2+}.

The interferences of the j metal ion and hydrogen ion to the adsorption of i metal ion were assumed to be represented by Eq. 2 as in the case of the adsorption of a single metal ion.

$$Q_{i,j} = Q_{max}/\{1+A_iC_i^{-\alpha_i}C_H^{\beta_i}(1+K_{i,j}C_j^{\gamma}C_H^{-\delta})\} \quad (2)$$

The interfering factor $K_{i,j}C_j^{\gamma}C_H^{-\delta}$ could be expressed by Eq. 3 from Eq. 2.

$$K_{i,j}C_j^{\gamma}C_H^{-\delta} = (Q_{max}-Q_{i,j})/Q_{i,j}A_iC_i^{-\alpha_i}C_H^{\beta_i} - 1 \quad (3)$$

Therefore, both logarithmic relationships between the values of the righthand side of Eq. 3 and C_j at a constant pH (C_H) and between the values of the righthand side of Eq. 3 and C_H at a constant C_j should be linear. For the adsorption of Pb^{2+} under the coexistence of Zn^{2+} at the constant pH, the former relationships were plotted on a log-log graph as shown in Fig. 2. Straight parallel lines with a slope, γ, of 0.76 were obtained. Also, the log-log plots of the latter relationship at fixed C_{Zn} for the same system showed straight lines with a slope, $-\delta$, of -0.87 as is also shown in Fig. 2. Therefore, the following equation can be obtained for the system of CR-10, Pb^{2+} and Zn^{2+}.

$$Q_{Pb,Zn} = 2.5/\{1+8.4\times10^{-3}C_{Pb}^{-0.94}C_H^{0.46} \times(1+0.44C_{Zn}^{0.76}C_H^{-0.87})\} \quad (4)$$

The calculated values of $Q_{Pb,Zn}$ by Eq. 4 for the same C_{Pb} and C_{Zn} as the observed data were plotted also in the Fig. 1 as black marks, and they are approximately equal to the observed data as open marks. Consequently, the adsorption amount of Pb^{2+} under the coexistence of Zn^{2+} could be obtained by Eq. 4.

The values of $\gamma=0.76$ and $\delta=0.87$ for this system were equal to the values of α_i and β_i for Zn^{2+} adsorption in the single solution on CR-10. Furthermore, the adsorption amount of Zn^{2+}, $Q_{Zn,Pb}$, for the same system could be given by Eq. 5.

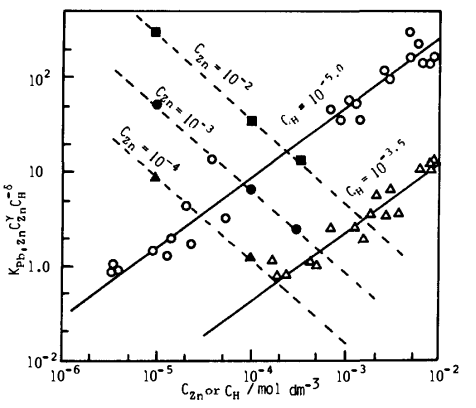

Fig. 2. Logarithmic plots of $K_{Pb,Zn}C_{Zn}{}^{\gamma}C_H{}^{-\delta}$ against C_{Zn} at constant C_H or against C_H at constant C_{Zn} for adsorption of Pb^{2+} on CR-10 under coexistence of Zn^{2+}.

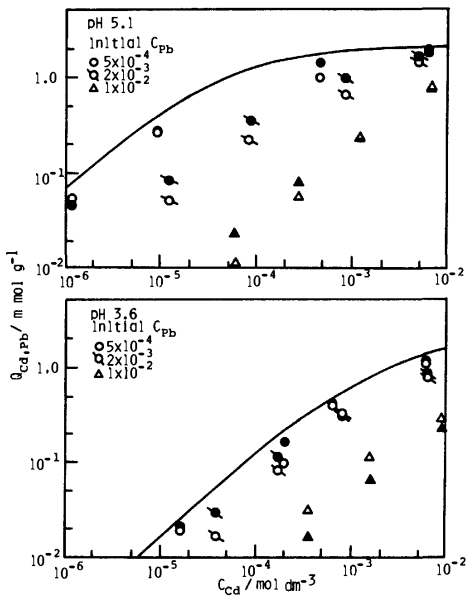

Fig. 3. Adsorption equilibria of Cd^{2+} under coexistence of Pb^{2+} on UR-40 at 25°C.

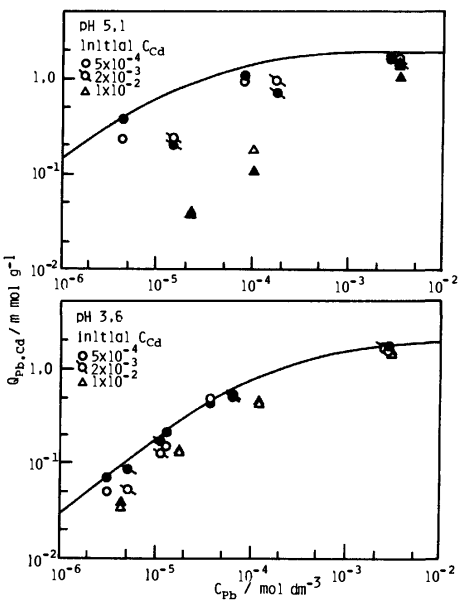

Fig. 4. Adsorption equilibria of Pb^{2+} under coexistence of Cd^{2+} on UR-40 at 25°C.

$$Q_{Zn,Pb} = 2.5/\{1+6.0C_{Zn}^{-0.76}C_H^{0.87}(1+50C_{Pb}^{0.94}C_H^{-0.46})\} \quad (5)$$

The values of $\gamma=0.94$ and $\delta=0.46$ were also equal to the values of α_i and β_i for Pb^{2+} adsorption in the single solution on CR-10.

Therefore, the following equation seems to be valid over a wide concentration range for two metal ions and hydrogen ion.

$$Q_{i,j} = Q_{max}/\{1+A_iC_i^{-\alpha_i}C_H^{\beta_i}(1+K_{i,j}C^{\alpha_j}C_H^{-\beta_j})\} \quad (6)$$

For the other tested systems of chelating resin and metal ions, the calculated values of $Q_{i,j}$ by Eq. 6 are compared with the observed data in Figs. 3—9. In these figures, curves show the adsorption isotherms of a single i ion by Eq. 1, open marks show the observed data, and black marks show the calculated $Q_{i,j}$ for the observed C_i and C_j. The computed values of $K_{i,j}$ for all the system are shown in Table 3. Almost all the observed data for the various systems were closely equal to the calculated values over a wide range of conditions. The small deviations of a few data from the calculat-

TABLE 3. PARAMETER $K_{i,j}$ OF EQ. (6) OBTAINED BY EXPERIMENTS

Resin	Metal i-j	$K_{i,j}$
UR-40	Cd^{2+}-Pb^{2+}	2.7×10^{-2}
	Pb^{2+}-Cd^{2+}	44
CR-10	Zn^{2+}-Cd^{2+}	0.47
	Cd^{2+}-Zn^{2+}	4.3×10^{-2}
	Zn^{2+}-Pb^{2+}	50
	Pb^{2+}-Zn^{2}	0.44
A-1	Zn^{2+}-Pb^{2+}	0.29
	Pb^{2+}-Zn^{2+}	18

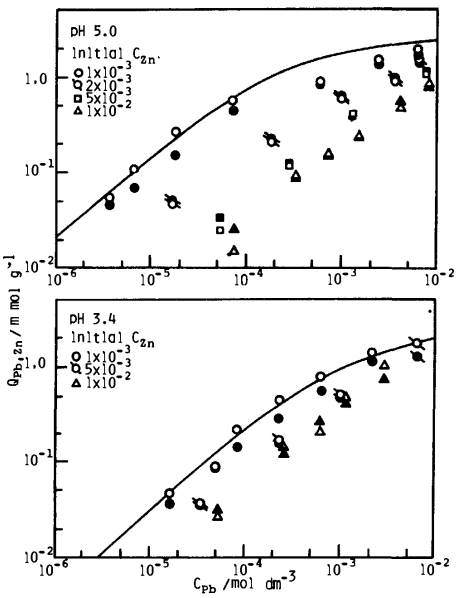

Fig. 9. Adsorption equilibria of Pb^{2+} under coexistence of Zn^{2+} on Dowex A-1 at 25°C.

ed values will be due to errors of analysis of C_i and of the values of α and β. Consequently, it was confirmed that the selective adsorption isotherm of i ion under coexistence of j ion and hydrogen ion is given by Eq. 6 which contained only one additional correction parameter $K_{i,j}$ with the parameters of the adsorption isotherms for single i and j metal ions. The fact that the adsorption isotherm equation for dual metal ions could be generally expressed by application of the adsorption isotherm equation of single metal ion proves that those adsorption isotherm equations well describe adsorption phenomena on chelating resins.

The Volume, Adiabatic Compressibility, and Viscosity of Amino Acids in Aqueous Alkali-chloride Solutions

Toshio OGAWA, Kiyoshi MIZUTANI, and Motoo YASUDA*
Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464
(Received January 5, 1984)

The apparent molal volumes (ϕ_V), apparent molal adiabatic compressibilities (ϕ_{KS}), and relative viscosities (n_r) at 25 °C have been obtained for the following amino acids in aqueous alkali-chloride solutions from measurements of the density, the ultrasonic velocity, and the flow time: glycine, L-alanine, β-alanine, α-aminoisobutyric acid, L-serine, and L-threonine. Viscosity measurements were also carried out in water for reference. The alkali chlorides used were lithium, sodium, and potassium chlorides. The limiting values ϕ_V°, ϕ_{KS}°, and the extended Jones-Dole viscosity coefficients, B and D, were calculated by a linear extrapolation using the least-squares method. All the ϕ_V°, ϕ_{KS}°, and B values obtained in the mixed solvents were larger than the corresponding ones in water, except in a few cases of the B coefficient. The results are discussed in terms of the dehydration effect of the electrolytes upon the amino acids.

Much attention has been given recently to the effects of electrolytes and nonelectrolytes on the structure of water. A quantitative interpretation of the factors which govern the structure remains difficult notwithstanding numerous remarkable investigations. We ourselves carried out volume and compressibility measurements of several amino acids in urea–water mixtures in order to understand the effect of urea upon the hydration of the amino acids.[1] The results showed that both the apparent molal volumes and the apparent molal adiabatic compressibilities of the amino acids increased upon the addition of urea in aqueous amino-acid solutions. This was explained in terms of the dehydration effect of urea upon the amino-acid molecules. Although the influence of salts on the activity coefficients of nonelectrolytes in aqueous solutions and on kinetic problems was examined carefully for a long time, there was no systematic study of the influence of salts upon the volume, compressibility, and viscosity of nonelectrolytes. Recently, as with cyclic amino acids, proline and hydroxyproline, we carried out a volume, compressibility, and viscosity study in aqueous alkali-chloride solutions.[2] For a better understanding of the behavior of the amino acids in mixed aqueous solvents, the densities, ultrasonic velocities, and viscosities were measured at 25 °C for six amino acids in amino acid-water-alkali chloride ternary systems at various concentrations. The apparent molal volumes and apparent molal adiabatic compressibilities, and the viscosity B- and D-coefficients were calculated from these data.

Experimental

The amino acids and alkali chlorides used in this study were guaranteed reagents from Wako Chemical Industries, Ltd., and were used without further purification except the lithium chloride, which was used after having been dried for several hours at *ca.* 150 °C. The densities and efflux times were measured in 1 and 2 mol kg^{-1} aqueous alkali-chloride solutions. Viscosity measurements in water were also carried out. The ultrasonic velocities were determined in 2 mol kg^{-1} alkali-chloride solutions.

All the amino-acid solutions were prepared by weight in the concentration range of 0.2—1 mol kg^{-1} (the number of moles of amino acid per kg of the mixed solvent whenever the mixed solvents were used) ; the highest concentration of the respective amino acid depended on the solubility of the amino acid.

The density and ultrasonic velocity measurements have been described previously.[1] The viscosities were measured by means of two Cannon-Fenske capillary viscometers with efflux times of *ca.* 210 and 240 s for distilled water; the kinetic-energy correction needed was negligibly small. The temperature control of the thermostated bath systems regulating the densimeter, ultrasonic interferometer, and viscometers was better than ±0.005 °C.

The pH values of all the amino-acid solutions, both in water and in aqueous alkali-chloride solutions, were very close to the isoelectric point of the respective amino acid; thus, no appreciable change in the structure of dipolar molecules can be considered.

Results

The densities, ultrasonic velocities, and efflux times were measured at 25 °C for the following amino-acid solutions; glycine (Gly), L-alanine (Ala), β-alanine (β-Ala), α-aminoisobutyric acid (Me-ala), L-serine (Ser), and L-threonine (Thr). The apparent molal volumes were obtained from Eq. 1:

$$\phi_V = \frac{M}{d} + \frac{1000(d_\circ - d)}{m\, d_\circ\, d}, \tag{1}$$

where M is the molecular weight of the amino acid; m, its molal concentration, and $d_\circ$ and d, the densities of the solvent and the solution respectively. The adiabatic compressibilities, β_S, and the apparent molal adiabatic compressibilities, ϕ_{KS}, were obtained using Eq. 2 and Eq. 3 respectively, where β_S is expressed in bar^{-1}:

$$\beta_S = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_s = \frac{100}{d\,u^2}, \tag{2}$$

and:

$$\phi_{KS} = -\left(\frac{\partial \phi_V}{\partial P}\right)_s = \frac{\beta_S M}{d} + \frac{1000(\beta_S d_\circ - \beta_S^\circ d)}{m\, d_\circ\, d}, \tag{3}$$

where u is the velocity of sound (m s^{-1}) and where β_S° is the adiabatic compressibility of the solvent. The limiting values of the apparent molal volumes and the apparent molal adiabatic compressibilities were calculated by a linear extrapolation using the least-squared fit to these equations:

$$\phi_V = \phi_V^\circ + S_V m, \tag{4}$$

and:

$$\phi_{KS} = \phi_{KS}^{\circ} + S_K m, \quad (5)$$

where ϕ_V° and ϕ_{KS}° are the infinite dilution apparent molal volume and the apparent molal adiabatic compressibility respectively, and where S_V and S_K are the experimental slopes. At an infinite dilution, $\phi_V^{\circ}=\overline{V}^{\circ}$ (the infinite dilution partial molal volume) and $\phi_{KS}^{\circ}=\overline{K}_S^{\circ}$ (infinite dilution partial molal adiabatic compressibility). The derived values for ϕ_V° are summarized in Table 1, with the literature data on proline and hydroxyproline.[2] The standard deviations are mostly less than 0.02 $cm^3 mol^{-1}$. The values for ϕ_{KS}° and the standard deviations, σ, in water and 2 mol kg^{-1} aqueous alkali-chloride solutions are listed in Table 2.

The viscosity, η, of dilute solutions of nonelectrolytes is represented by:[3]

$$\eta = \eta_0(1+Bc), \quad (6)$$

a) Ref. 2.

where η_0 is the viscosity of the solvent, c is the molar concentration of the solute, and B is an empirical constant which is called usually the Jones-Dole viscosity B-coefficient. This is known to depend on the size of the solute particle and also on the interaction between the solute and solvent molecules. The B-coefficient is expressed in molar concentration units; thus, the molar concentrations were calculated using the density data. For the more concentrated solutions of the amino acid used in this study, the relative viscosity is given by Eq. 7, in which D is an another empirical constant.[4] Desnoyers and Perron examined the D-coefficients and concluded that they cannot be interpreted unambiguously.[5]

$$\eta_r = 1 + Bc + Dc^2 \quad (7)$$

By rearranging this equation, we obtain:

$$(\eta_r - 1)/c = B + Dc. \quad (8)$$

The viscosity coefficients, B and D, were calculated by linear extrapolation using the least-squares fit to Eq. 8. Table 3 shows the viscosity in terms of the parameters of Eq. 7.

Discussion

Volume Results. The volume behavior of a solute in an infinite dilution is independent of the solute-solute interactions and thus can provide information concerning solute-solvent interactions. As may be seen from Table 1, the limiting apparent molal volumes of the amino acids in mixed solvents are larger than those of the corresponding ones in water. This was also observed for the data in aqueous urea solutions and was discussed in terms of the dehydration effect of urea upon the amino acids.[1] In order to ascertain the influence of the sodium-chloride concentration on the ϕ_V° of the amino acids, the transfer volumes, $\Delta\bar{V}_{tr}^\circ$, are plotted *vs.* the concentration of sodium chloride in Fig. 1;

$$\Delta\bar{V}_{tr}^\circ = \phi_V^\circ(\mathrm{NaCl}) - \phi_V^\circ(\mathrm{water}). \quad (9)$$

The transfer functions increase with the concentration, as in aqueous urea solutions.[1,6]

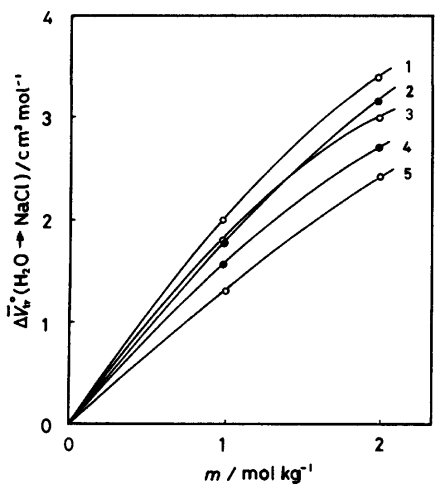

Fig. 1. Plot of $\Delta\bar{V}_{tr}^\circ$ *vs.* m for NaCl.
1: Ser, 2: Thr, 3: Gly, 4: Ala, 5: Me-ala.

The transfer volumes of the six amino acids studied decrease in the following order:

$$\mathrm{Ser} > \mathrm{Thr} > \beta\text{-Ala} > \mathrm{Gly} > \mathrm{Ala} > \mathrm{Me\text{-}ala},$$

for both water→aq NaCl and water→aq KCl transfers. The water→aq LiCl transfer volumes are in the same sequence except the Thr, which occurs between Gly and Ala. Our earlier study of the water→aqueous urea-transfer volumes gave a similar sequence:

$$\mathrm{Ser} > \mathrm{Thr} > \mathrm{Gly} > \beta\text{-Ala} \approx \mathrm{Ala} > \mathrm{Me\text{-}ala}.$$

The positive sign of the transfer volumes can be ascribed mainly to the fact that the hydration number of the amino acids is reduced by the addition of alkali chloride or urea: *i.e.*, the electrostriction effect which brings about the diminution in the volume of the solvent caused by the electrical fields of the dipolar solutes is reduced in the mixed solvents as compared with that in pure water. Ser and Thr, which contain an OH group, have larger transfer volumes; this was also observed in the case of hydroxyproline, *i.e.*, it has the larger transfer volume than proline, as may be seen from Table 1. In water-urea mixtures, the transfer volume of β-alanine was almost the same as that of alanine and less than that of glycine at a particular urea concentration.[1] In aqueous alkali-chloride solutions, β-Ala has a larger transfer volume than that of Gly. This may result from the fact that β-Ala has a larger dipole moment than that of Ala; thus, the former interacts more with the alkali and chloride ions than does Ala, which has a smaller dipole moment. The more the ion-dipole interaction, the more the dehydration effect. On the other hand, there may be no difference, or a very small one, as with the interaction of the amino acids with urea.

Compressibility Results. The infinite-dilution data for the compressibility can also give information concerning solute-solvent interactions. The limiting partial molal adiabatic compressibilities of the amino acids can be expressed by a simple model:[7]

$$\bar{K}_S^\circ = \bar{K}_S^\circ(\mathrm{int}) + \bar{K}_S^\circ(\mathrm{elect}), \quad (10)$$

where $\bar{K}_S^\circ$ (int) is the intrinsic partial molal adiabatic compressibility of the amino acid and where $\bar{K}_S^\circ$ (elect) is the electrostriction partial molal adiabatic compressibility due to the hydration of the amino acid. As has been noted by Millero *et al.*, as a first approximation, one can assume that $\bar{K}_S^\circ$ (int)≈0, since one would expect $\bar{K}_S^\circ$ (int) to be very small.[7] Thus, $\bar{K}_S^\circ$ may be thought to represent $\bar{K}_S^\circ$ (elect). The $\bar{K}_S^\circ$ values of the amino acids in water are all negative; this must come from the hydration of the charged centers of the amino acids, as the hydrated water molecules are already compressed and thus less compressible than that in the bulk. For the amino acids, the order of increasing (less negative) $\bar{K}_S^\circ$ values in water is:

$$\mathrm{Thr} < \mathrm{Ser} < \mathrm{Gly} < \beta\text{-Ala} < \mathrm{Ala} < \mathrm{Me\text{-}ala}.$$

This sequence may be considered to show a decreasing order of hydration, as a first approximation, particularly for the amino acids without the OH group, as will be mentioned below. If all the amino acids

were subjected to the dehydration effect by the addition of alkali chloride in the same proportion, the $\overline{K}_S^\circ$ (MCl)/$\overline{K}_S^\circ$ (water) ratios of the amino acids may be almost the same. The ratios decrease in the following order in 2*m* NaCl:

$$\text{Ser} > \text{Gly} > \beta\text{-Ala} \approx \text{Thr} > \text{Ala} > \text{Me-ala},$$

and in 2*m* KCl:

$$\text{Gly} \approx \text{Ser} > \beta\text{-Ala} > \text{Thr} \approx \text{Ala} > \text{Me-ala}.$$

The order in 2*m* LiCl differs a little compared with those in NaCl and in KCl, but the difference in ratios is rather small; therefore, the series is probably less reliable. The ratios in 3*m* aqueous urea show almost the same order as in NaCl and in the KCl solutions.[1] Thr and Ser are the amino acids with an OH group. As has been noted by Mathieson and Conway, ions which hydrogen-bond with water have unusual compressibilities.[8] Some have anomalously high compressibilities, while the OH^- ion exhibits a low compressibility. Thus, these two amino acids may be assumed to behave differently with the four other amino acids with no OH group. At any rate, however, Ser has a larger compressibility ratios than Thr in all the solvents studied. Of the four amino acids with no OH group, Gly has the largest value, and Me-ala , the smallest; β-Ala and Ala are in between in each solvent. This corresponds to the order of increasing absolute values of $\overline{K}_S^\circ$ in water, which answers to the order of increasing hydration numbers. Thus, the less hydrated amino acid in water has the lower compressibility ratio in the mixed solvent and then loses the hydrated water molecules more easily in the transfer from water to the mixed solvent. In this connection, it is very interesting to note that the compressibility ratios of proline and hydroxyproline with cyclic secondary amine group are very small (Table 2). These two amino acids must be supposed to lose their hydrated water molecules very easily in the transfer from water to the mixed solvent. However, from another point of view, as seen from the volume data, the number of dehydrated water molecules involved in the transfer increase in the order of increasing hydration number in water; in general, the more hydrated amino acid loses the more hydrated water molecules are involved in the transfer.

Viscosity Results. The viscosity coefficients of several amino acids at 25 °C have been reported by Devine and Lowe;[4] the *B*-coefficients of Gly and β-Ala were 0.143 and 0.220 respectively, while the *D*-coefficients were 0.010 and 0.040 respectively. However, the viscosity datum for the lowest concentration for each amino acid appears to be rather erroneous. If it is omitted, the recalculated coefficients were B= 0.139 and D=0.020 for Gly and B=0.216 and D= 0.051 for β-Ala. These values are in good agreement with the respective data listed in Table 3. In Table 3, though the solvent concentration is indicated in the molal concentration, the viscosity coefficients were calculated in molar concentration units, as has been mentioned above. The *B*-coefficients in the mixed solvents are larger than the corresponding values in water, particularly in 2*m* alkali-chloride solutions. However, the *B* values of Thr in 1*m* LiCl and 1*m* NaCl are almost the same as those in water and are rather small in 1*m* KCl. The reason for this is not clear at present. Concerning the effects of the salts on the *B*-coefficient of each amino acid, there seems to exist no regularity. The *D*-coefficients in the mixed solvents have almost the same value as the corresponding values in water.

For a dilute solution of unsolvated spherical colloidal suspensions, Einstein has derived this relation:

$$\eta_r = 1 + 2.5\phi, \tag{11}$$

where ϕ is the volume fraction of the solute.[9] If this equation is valid for the amino acids, Eq. 11 becomes:

$$\eta_r = 1 + 0.0025\, V_h\, c, \tag{12}$$

where V_h is the hydrodynamic volume in $cm^3 mol^{-1}$. Since the Dc^2 term in Eq. 7 can be assumed to be negligible in a dilute solution, the following relation holds:

$$B = 0.0025\, V_h. \tag{13}$$

As has been noted by Desnoyers and Perron, V_h may be assumed to be the partial molal volume of the unsolvated solute particle in a continuum solvent.[5] Thus, if the amino-acid molecule has no interaction with the solvent molecules, the larger *B* value in the mixed solvent might mean a larger hydrodynamic volume in the mixed solvent. However, as has been mentioned above, judging from both the volume and the compressibility data, it must be concluded that, in the mixed solvents, the amino-acid molecules are less hydrated than in water. One possible explanation may be as follows: the hydrated amino-acid molecules interact with the solvent molecules, reducing the structure of water and thus bringing about a dimunution of the *B* value; this effect must be larger in water than in the mixed solvents, for in the mixed solvents the structure of water is already broken to some extent by the cosolvent alkali chloride. Another explanation may be the ion-dipolar pair formation between the amino-acid molecule and the ions. However, since there is no definite relationship among the effects of ions upon the *B* values of the amino acids, it is not possible at present to conclude the reason why the *B* coefficients in the mixed solvents are larger than in water, notwithstanding the less hydration.

Alkali-metal-cation Effects. As may be seen from Tables 1 and 2, for the alkali-metal ions the order of decreasing dehydration effect is:

$$Na^+ > K^+ > Li^+.$$

This sequence is not that of either the increasing or decreasing crystal ionic radii of the alkali metals. The main factor determining the order may be the difference in the interaction of the alkali cations with the amino-acid molecules. Having a rather large dipole moment, the amino-acid molecules should have a rather large interaction with the ions. According to Frank and Wen, a small ion in aqueous solutions is surrounded by three concentric regions.[10] The innermost (Region A) is immobilized; the second (Region B) one is a less ice-like water structure, and the third (Region C) contains normal water. If some hydrated water molecules are lost by the interaction, the electrostric-

tion effect should decrease, and the volume and also the compressibility of the amino acid should increase, in the mixed solvent. Li^+ should have water molecules firmly bounded in Region A because of its small crystal radius. On the other hand, Na^+ and K^+ have larger radii; thus, they should have the water molecules held less firmly than Li^+. If only Na^+ and K^+ ions lose their water molecules in Region A when these three alkali cations interact strongly with the amino acid, this order of increasing effective radius: $Na^+ > K^+ > Li^+$ may result. This accounts for this order of decreasing dehydration effect $Na^+ > K^+ > Li^+$. However, for a further discussion the difference in the hydration number of the alkali cations must be taken into consideration.

The Electrical and Structural Features of Vanadium-oxide Films as Formed by the Thermal Decomposition of Vanadium Naphthenate

Yoshiya KERA,* Hisateru IMORI, Shigeharu KIDA, and Katsumi DEGAWA
Department of Applied Chemistry, Faculty of Science and Engineering, Kinki University, Higashiosaka, Osaka 577
(Received January 17, 1984)

Vanadium-oxide thin film, which was amorphous, brownish, and transparent, was prepared more conveniently by improving Sekiya-Matsushita's method by, for instance, decomposing vanadium naphthenate thermally; that is, 10 wt% of a 1-butanol solution of vanadium naphthenate was dropped on slide glass, dried in air, decomposed at 600 °C for 20 min under 0.5 l/min of a N_2 stream which was equilibrated with water at 21.5 °C, and then taken out rapidly into the air for cooling. The VO thin film thus prepared usually showed an abrupt change in electric conductivity from 2×10^{-5} to 1×10^{-4} Ω^{-1} at about 60 °C. The electrical feature was greatly affected by the addition of other metal oxides, such as Na_2O, TiO_2, Cr_2O_3, MoO_3, and ZrO_2. Both the conductivity and the gap tended to decrease in the cases of TiO_2, Cr_2O_3, and MoO_3, and to increase in ZrO_2. On the addition of Na_2O, however, the conductivity increased only at temperatures lower than the transition point; thus, the gap decreased greatly, almost disappearing. It was concluded from these facts that the electrical feature of the vanadium-oxide film must be controlled to a great extent by the addition of some compounds of vanadium oxide with the other metal oxides formed at the grain boundary of the VO_2 amorphous particles. That is, the larger the conductivity of the compound in the boundary layer, the more clearly the intrinsic feature of the VO_2 particles appears, and *vice versa*.

Many vanadium-oxide compounds show a metal insulator or semiconductor transition, accompanied by a small change in the crystal structure.[1] Because big changes in not only the electrical property, but also the magnetic and optical properties, occur at the transition point, many solid-state physicists and chemists have worked on these subjects.[2-9] In order to investigate in detail such solid-state properties, the single crystal[10,11] and the thin film of the compounds have been prepared. With respect to the preparation of those thin films, the methods of the chemical deposition of the compounds from the vapor phase and the oxidation of the metal particles sputtered on substrates have mainly been applied,[12-16] but the procedures seem to be too complicated and it seems to be difficult to obtain a good film constantly. Recently, Sekiya and Matsushita[17] have reported a convenient method for the preparation of a vanadium-oxide thin film with a conductivity gap of one order of magnitude at about 60 °C. We have taken notice of the Sekiya-Matsushita method because the film may be used for studying the catalytic property of vanadium-oxide compounds in connection with their solid-state properties. In the present experiment, the method of preparing the vanadium-oxide thin film (VO thin film) was re-examined in order to make the procedure of Sekiya-Matsushita more convenient; further, the method of preparing VO thin films containing other metal oxides, such as Na_2O, TiO_2, Cr_2O_3, MoO_3, and ZrO_2, was examined. The electrical and structural features of the VO thin films thus prepared were discussed.

Experimental

1) Materials and Procedures. Vanadium naphthenate (containing *ca.* 3 wt% of the vanadium(IV) ion, Harima Kasei Co., Ltd.) was dissolved in 1-butanol to prepare 10 wt% of the solution. A thin film of vanadium oxide (VO thin film) was formed on a Pyrex glass plate by the following procedures. The glass plate was cut in the size of 11×24 mm^2; on both ends there had previously been deposited gold film (7 mm in width) as an electrode in order to keep a good ohmic contact during the conductivity measurements. Three droplets of the vanadium-naphthenate solution were placed on the plate, and it was dried at 20 °C in air for 1 h. The plate was then inserted into a furnace kept at 600 °C for 20 min to decompose the vanadium naphthenate and then rapidly taken out into the air for cooling. A nitrogen gas stream, bubbled in water kept exactly at 21.5 °C, was introduced into the furnace during the decomposition.

Upon the preparation of the VO thin films containing other metal oxides, such as Na_2O, TiO_2, Cr_2O_3, MoO_3, and ZrO_2, these oxides (CH_3ONa in the case of Na_2O) were weighed exactly and were then ground well with 10 wt% of a 1-butanol solution of vanadium naphthenate in an agate mortar in order to dissolve them fully. Then, the solution containing the metal oxides was dropped on the glass plate with the gold electrodes and subsequently decomposed by the procedures used in the case of the pure VO thin film. The concentrations of these metal oxides added to vanadium oxide were changed in the range of 10—60 atom%; (M)/(V).

2) Measurements. The electric conductivity was measured by the usual two-probe method. In the measurements of the conductivity, the temperature was elevated from 20 to 200 °C at the constant speed of 4.5 °C/min by the use of a programable controller, Yokogawa Model PC-182. In order to determine exactly the relationship between the conductivity and the temperature, an automatic-measurement system was constructed; both the potential difference between the ends of the VO thin film and the thermoelectric power generated in the CA-thermocouple attached to the film were amplified simultaneously by means of microvoltmeters, Ookura Denki Model AM-2002, and then introduced, at intervals of 1 °C into a microcomputer, Sharp Model MZ-80K2E, *via* a 12-bit A/D-convertor, Hoowa Sangiyo Model ADL-1224. The X-ray analyses of the thin films were done in the range of $2\theta=4$—60° by setting the glass plate with the VO thin film deposited directly in the sample holder. The diffractometer used was Rigaku Denki Model GF-Rad-γA. Cu $K\alpha$ radiation and nickel filter were used.

Results

1) Preparation Conditions of Vanadium-oxide Thin

Film. The VO thin films were prepared by decomposing the vanadium naphthenate for 10—20 min at 600 °C in a nitrogen stream equilibrated with water kept exactly at 21.5 °C. As a result, the VO thin film, transparent, was found to be formed only by decomposition for 20 min; its conductivity and the conductivity gap at the transition point were similar in extent with those shown in Fig. 1. In the VO thin films formed by decomposition for 10 and 15 min, however, both the conductivity and the gap were quite small. The VO thin films were also prepared by decomposing the vanadium naphthenate in a nitrogen stream equilibrated with water kept at 20—25 °C at 600 °C for 20 min. In the VO thin films formed in the N_2 stream equilibrated with water kept at 21 and 22 °C, an electrical feature similar to that shown in Fig. 1 was found. However, in the films formed in the stream equilibrated with water kept at 20 °C, both the conductivity and the gap became very small, and in those formed at 23—25 °C the transparency disappeared completely. Therefore, it was make clear that the VO thin film, which is transparent and which, further, shows the conductivity change of one order of magnitude accompanied by a phase transition at about 60 °C, could easily be prepared under the following conditions: vanadium-naphthenate film formed by dropping 10 wt% of the 1-butanol solution on a Pyrex glass plate and then by drying should be decomposed at 600 °C for 20 min in a nitrogen stream equilibrated with water kept at exactly at 21.5 °C.

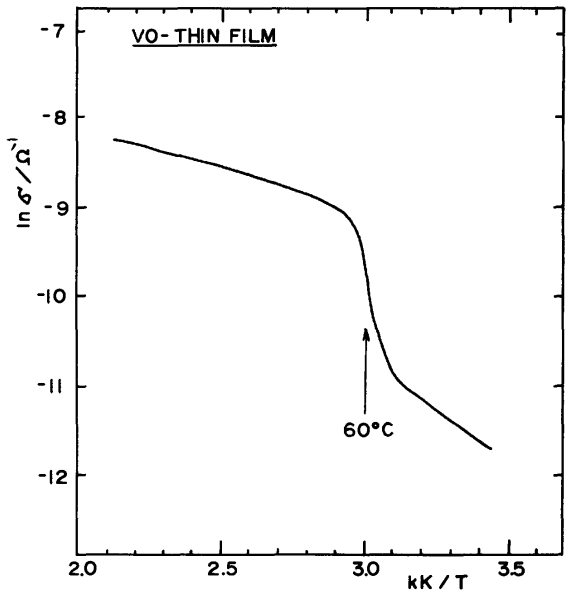

Fig. 1. The electric conductivity-temperature relation for the vanadium oxide thin film prepared by thermal decomposition of vanadium naphthenate solution; The plot of $\ln\sigma$ against $1/T$.

The thickness of the VO thin film thus prepared was evaluated roughly as 1—2 μm from the amounts of the vanadiun-naphthenate solution dropped on the substrate. The activation energies for the conductivity were estimated as 0.08 and 0.21 eV for above and below the transition temperature respectively, as shown in Table 1. Furthermore, the larger the conductivity, the smaller the activation energy tended generally to become, especially at temperatures above the transition point.

2) The Lnσ-1/T Curves of the VO Thin Films Containing Other Metal Oxides. With respect to the VO thin films formed from the vanadium-naphthenate solution, in which 10 and 40 atom% of sodium to vanadium were mixed, the conductivity-temperature curves ($\ln\sigma$-$1/T$) are shown in Figs. 2-a and b respectively. The conductivity of the film at 10 atom% was kept at the same level with that of the pure VO thin film above the transition temperature, but it became much higher than the pure VO film below that temperature. Thus, the conductivity gap at the transition point apparently decreased; further, in the film at 40 atom%, the conductivity gap almost disappeared. With respect to the VO thin films containing TiO_2, at 10 atom%, the $\ln\sigma$-$1/T$ curve was sim-

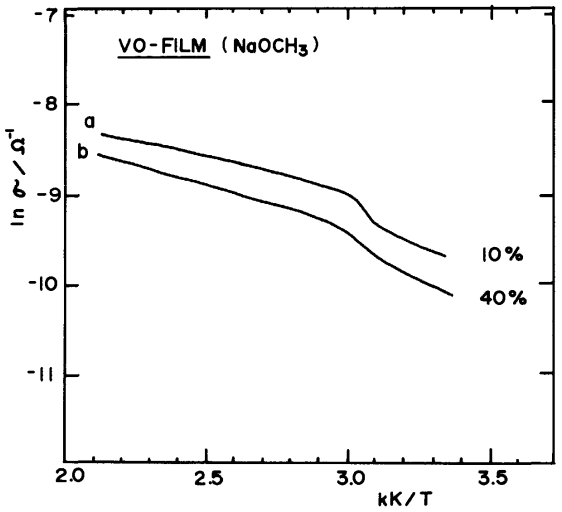

Fig. 2. The $\ln\sigma$-$1/T$ curves for the VO thin films containing 10 and 40 atom% of Na_2O.

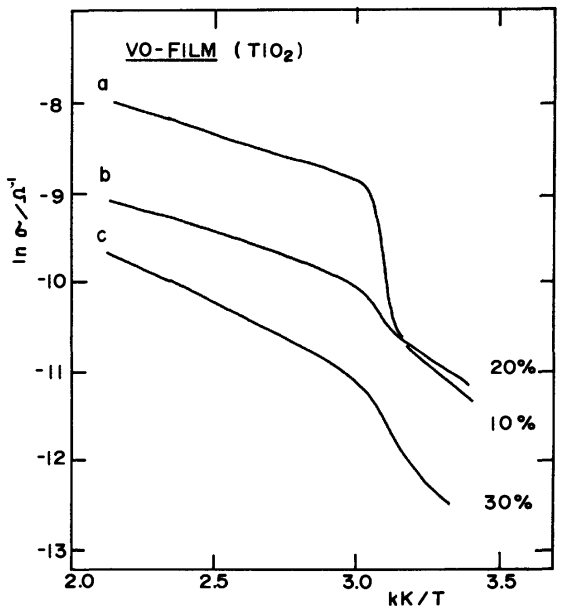

Fig. 3. The $\ln\sigma$-$1/T$ curves for the VO thin films containing 10, 20, and 30 atom% of TiO_2.

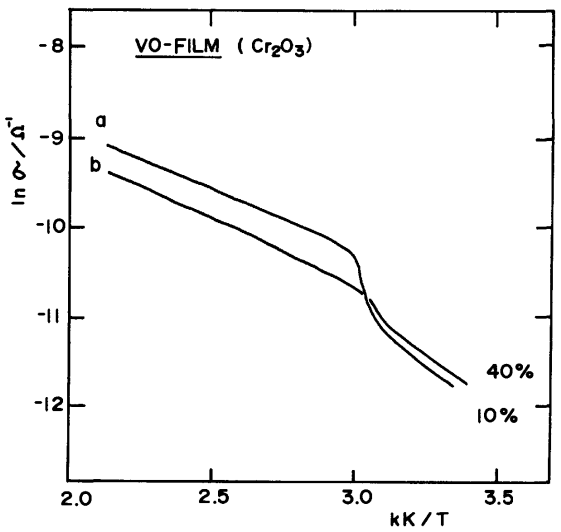

Fig. 4. The $\ln\sigma$-$1/T$ curves for the VO thin films containing 10 and 40 atom% of Cr_2O_3.

ilar to that of the pure VO thin film, as can be seen by comparing Fig. 3-a with Fig. 1, but at 20 atom% the σ-values considerably decreased only above the transition temperature, and thus the conductivity gap almost disappeared, as can be seen in Fig. 3-b. At 30 atom%, however, the conductivity decreased throughout the temperature region, as is shown in Fig. 3-c. With the VO thin films containing Cr_2O_3, both the conductivity and the gap considerably decreased at 10 atom%, and the gap almost disappeared at 40 atom%, as Fig. 4 shows. With the VO thin films containing MoO_3, the feature of the $\ln\sigma$-$1/T$ curve did not change, even at 20 atom%, but both the conductivity and the gap decreased considerably at 40 atom%,

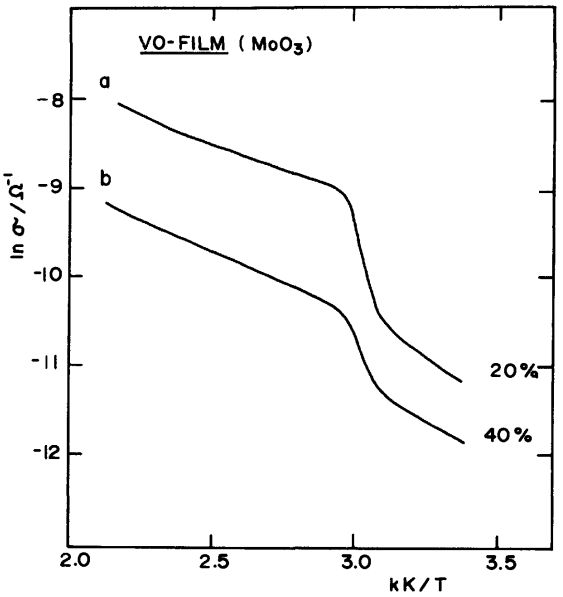

Fig. 5. The $\ln\sigma$-$1/T$ curves for the VO thin films containing 20 and 40 atom% of MoO_3.

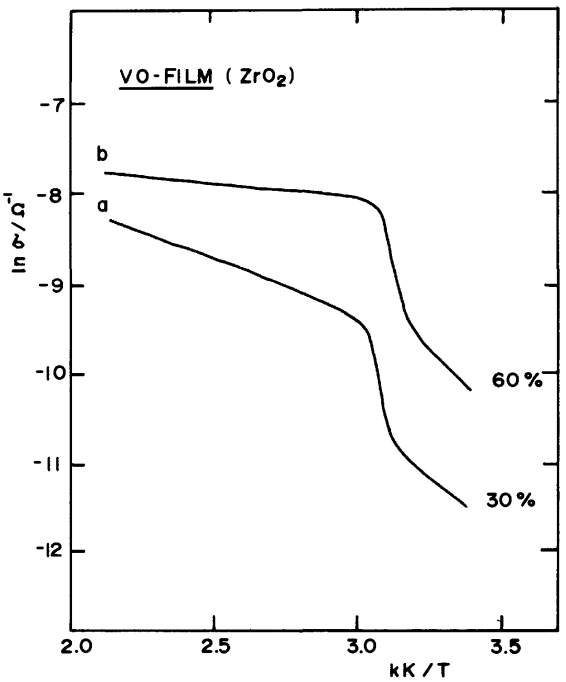

Fig. 6. The $\ln\sigma$-$1/T$ curves for the VO thin films containing 30 and 60 atom% of ZrO_2.

as Fig. 5 shows. With respect to the VO thin film containing ZrO_2, however, the conductivity and the gap tend to increase with an increase in the content of ZrO_2, especially at 60 atom%. Furthermore, it is known form Fig. 6-b and Fig. 1 and in Table 1 that the inclination of the $\ln\sigma$–$1/T$ curve increases greatly above the transition temperature, while it decreases below that temperature.

3) X-Ray Analyses of the VO Thin Films. The X-ray diffraction patterns of the pure VO thin film are shown in Fig. 7-a, where the strong lines at 2θ=38.65 and 44.95° are those caused by the gold electrodes deposited on both ends of the glass plate. Only rather weak peaks are seen at 2θ=12.2, 19.3, 28.0, and 29.2° in Fig. 7-a, except for a very broad unsplit line. These data suggest that the pure VO thin film is composed of very small crystalline particles or amorphous particles. X-Ray diffraction patterns similar to those of the pure VO thin film were also found in all the VO thin films containing TiO_2, Cr_2O_3, and MoO_3 except for the very weak peaks which appeared at angles differing a little from sample to sample, as Figs. 7-b—f show. However, no compounds corresponding to those weak peaks were found in any ASTM card. On the other hand, many sharp peaks were found in the X-ray diffraction patterns for the VO thin film containing ZrO_2, as Fig. 7-f shows; they are summarized in Fig. 8. Thus, it has to be emphasized that, only in ZrO_2 is the VO thin film composed of rather large crystalline particles. However, no compounds corresponding to those peaks were found in the ASTM cards.

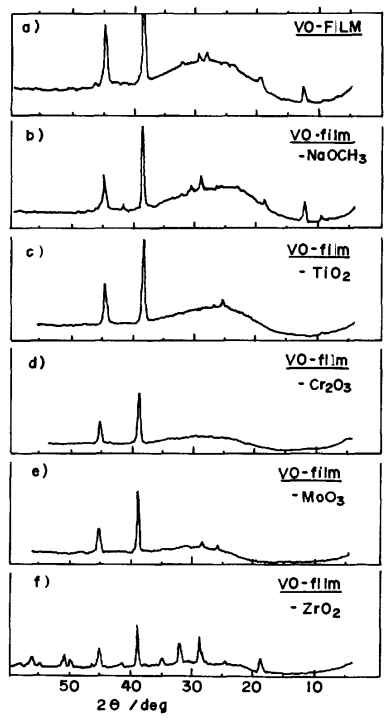

Fig. 7. X-Ray powder diffraction spectra for the vanadium oxide films: a) The pure VO-film, b) the VO-film containing 40 atom% of Na_2O, c) 30 atom% of TiO_2, d) 40 atom% of Cr_2O_3, e) 40 atom% of MoO_3, and f) 60 atom% of ZrO_2.

Discussion

1) Preparation Conditions of the Vanadium-oxide Thin Film. Sekiya and Matsushita successfully prepared a vanadium-oxide thin film by the thermal decomposition of vanadium naphthenate on a slide glass and a quartz plate.[17] The VO thin film showed a crystalline state and a conductivity change of about one order of magnitude at about 60 °C. To obtain a conductivity gap of such an extent, a thermal decomposition procedure must be repeated four times while the temperature is elevated at the speed of 5 °C/min from 25 up to 600 °C. The present paper proposes a more convenient procedure for the preparation of a VO thin film which showed a conductivity and a gap almost identical in extent with those of Sekiya and Matsushita; that is, the vanadium-naphthenate film formed by drying 10 wt% of the 1-butanol solution on a Pyrex glass plate needs to be decomposed thermally only once at 600 °C for 20 min under 0.5 l/min of a nitrogen stream equilibrated with water kept

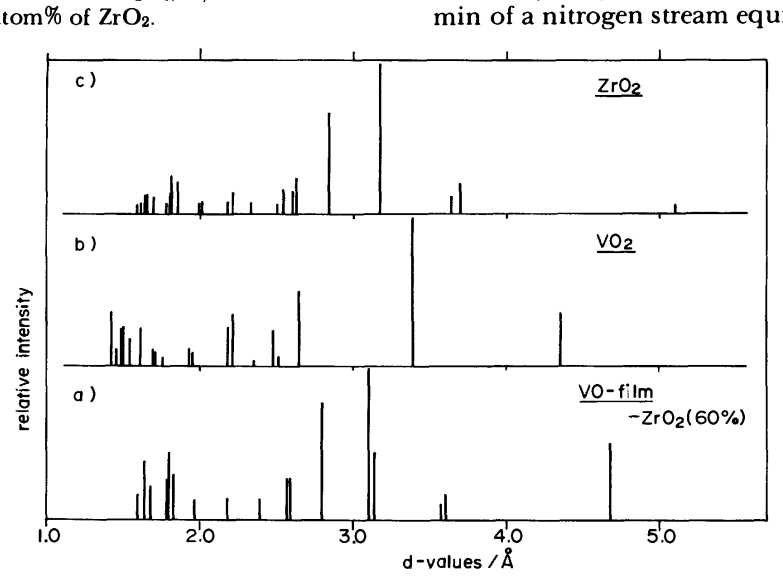

Fig. 8. X-Ray powder diffraction patterns for a) the VO-film, containing 60 atom% of ZrO_2, b) VO_2 crystalline powder,[19] and c) the original ZrO_2 powder.

at 21.5 °C and then to be rapidly taken out into the air. Sekiya and Matsushita suggested that the water vapor contained in the N_2 stream might affect the hydrolysis process of the vanadium naphthenate during the decomposition and might thus be an important factor in the formation of the VO thin film.[17] In the present study, the water vapor was confirmed to play a very important role in the formation process of the VO thin film; that is, under saturated water vapor at 21.0 and 22.0 °C, a favorable conductivity was obtained, but under that at 20.0 °C, both the conductivity and the gap became quite small, and under that at 23—25 °C, the transparency disappeared completely and the color changed to dark blue, as has been mentioned above. These results suggest that, under a rather high vapor pressure, the rates of the decomposition and the growth of the vanadium-oxide particles are accelerated to a great extent, and that thus, the VO_2 particles grown become so large as to block the transmission of visible light, while, on the contrary, under a lower vapor pressure, the decomposition and the growth of the particles cannot occur rapidly, so that both the conductivity and the gap become small.

2) The Conductivity Changes in the VO Thin Films Containing Other Metal Oxides. The VO_2 single crystal showed a metal semiconductor phase transition at 340±2 K (67±2 °C), and the specific conductivity changed abruptly from 10^{-3} to 10^{1} $\Omega^{-1}cm^{-1}$ at the transition point.[1,18] In fact, the inclination of the ln σ–$1/T$ curve changed from a positive to a negative value in the VO_2 single crystal. The conductivities, σ_l and σ_h, which were estimated by extrapolating the ln σ–$1/T$ curves from the temperatures below and above the transition point to the transition temperature in Fig. 1, were 2.2×10^{-5} and 1.2×10^{-4} Ω^{-1} respectively, as Table 1 shows. In the vanadium-oxide film of Sekiya and Matsushita,[17] 6.7×10^{-5} and 1×10^{-3} Ω^{-1} have been obtained as the values corresponding to σ_l and σ_h respectively. The conductivities of the thin films prepared by Sekiya *et al.* and by us at the transition point are very small relative to those of the VO_2 single crystal. Such a large difference in the conductivity is probably caused by the difference in dimensions. The difference might also arise from the difference in the extent of the contribution of the grain boundary to the conductivity; the conductivity is affected by the boundary layer to a much greater extent in the polycrystalline and amorphous films than in the single crystal. The VO thin film of Sekiya *et al.* is probably thicker than the present film because the former has been prepared repeatedly and is composed of rather large crystalline particles, while the present film is composed of amorphous or polycrystalline particles too small to be detected by X-ray diffraction analysis. In fact, both the conductivity and the gap are larger in Sekiya and Matsushita's film rather than in the present one. It can be expected, therefore, that the properties would be affected by those in the boundary layer to a much lesser extent in the former film than in the latter. Based on such an understanding with regard to the the apparent conductivity of the VO thin film, the electrical and structural features of the VO thin films containing the other metal oxides will be discussed below.

The conductivity gap at the transition point almost disappeared in the ln σ–$1/T$ curves of the VO thin films, containing 10 and 40 atom% of Na, as shown in Figs. 2-a and b. These films, brown and transparent, are composed of amorphous particles, as is known from the X-ray diffraction paterns in Fig. 7-b, although several minor peaks are seen in the patterns. By comparing the ln σ–$1/T$ curves of the VO thin film containing Na_2O with that of the pure VO thin film, the conductivity gap can apparently be seen to decrease because the conductivity increases considerably below the transition temperature upon the addition of Na_2O. Such changes may be caused by some sodium vanadium oxides formed in the grain boundary of the vanadiun-oxide particles. Upon the addition of TiO_2, the ln σ–$1/T$ curve was not affected at such rather low contents as 10 atom%, but at a high content, such as 20 or 30 atom%, it decreases as a whole, and also the conductivity gap becomes small, as shown in Figs. 3-a—c and in Table 1. These result might also be caused by the change in the conductivity of the grain boundary, accompanied by the formation of some titanium vanadium oxides. The additions of Cr_2O_3 and MoO_3 similarly affected the ln σ–$1/T$ curves, as shown in Figs. 4-a and b Figs. 5-a and b, and also in Table 1, although the effects seem to be relatively small upon the addition of MoO_3.

On the other hand, the conductivities of the VO thin films containing ZrO_2, especially at 60 atom%, generally increase relative to the pure VO thin film. Furthermore, the conductivity gap becomes large, and the inclination of the ln σ–$1/T$ curve tends to decrease above the transition point, while, on the contrary, it increases below the transition. That is, the activation energies for the electron conduction were estimated from the inclinations as 0.03 eV above the transition and as 0.33 eV below the transition, while the corresponding values for the pure VO thin film were similarly estimated as 0.08 and 0.21 eV respectively, as shown in Table 1. By comparing these corresponding values, therefore, we can make it clear that the activation energies decrease about 1/3 times at higher temperatures, while, on the contrary, they increase about 1.6 times at lower temperatures, upon the addition of ZrO_2. The change in the electrical property is probably connected with the facts that only in the addition of ZrO_2 did the transparency disappear completely, that the color changed dark blue from brown, and, further, that the crystalline part increased considerably relative to the amorphous part, as is shown by the X-ray powder patterns in Fig. 7-f.

3) The Electrical and Structural Features of the VO Thin Films. The X-ray diffraction patterns of the VO thin film containing 60 atom% of Zr are given in Fig. 8-a, while those of the pure VO_2 crystalline powder[19] and of the original ZrO_2 powder are shown in Figs. 8-b and c respectively for the sake of comparison. Since no peaks in Fig. 8-a are consistent with those in Fig. 8-b, the VO thin film containing ZrO_2 may not be composed of VO_2 crystalline particles, but of amorphous particles. On the other hand, the main peaks in Fig. 8-a, for instance, d=3.100, 2.797, 1.800, and 1.791 A, correspond well to those in Fig.

8-c: d=3.165, 2.842, 1.848, and 1.818 A respectively, although the d-values always shift a little relative to one another. Therefore, the diffraction peaks may be ascribed to some ZrO_2 crystallines, dissolving a little of the vanadium oxide, which are growing at the grain boundary. Thus, a large increase in the conductivity gap and a large decrease in the activation energy above the transition temperature can be understood if this Zr-V-O coumpound formed at the boundary layer has a large conductivity relative to the grain boundary of the pure VO thin film. The findings that the conductivities of the VO thin films containing TiO_2, Cr_2O_3, and MoO_3 became apparently smaller than that of the pure VO thin film, could similarly be understood if some compounds of vanadium oxide with the metal oxides were formed in the boundary layer and if, further, their conductivities were quite small. In the addition of Na_2O, the conductivity increased to a great extent below the transition temperature, while it changed almost not at all above the transition point, as has been mentioned above. This would suggest that the conductivities of some compounds of sodium vanadium oxide formed at the boundary layer are quite large.

Only in the addition of ZrO_2, did both the conductivity and the gap increase greatly; that is, the electrical feature of the VO_2 particle itself appeared more clearly, because the compounds of the vanadium oxide with ZrO_2 formed at the boundary showed quite a high conductivity. Upon the addition of Na_2O and ZrO_2, the corresponding compounds formed at the grain boundary of the vanadium-oxide particles showed a high conductivity relative to the boundary of the pure vanadium oxide itself, but the conductivity gap decreased greatly in the former and increased in the latter. Therefore, it can be expected that, upon the addition of Na_2O, almost no pure VO_2 particles are formed, but, rather, some sodium oxide particles are, while, on the contrary, almost all the pure VO_2 particles remain, without mixing with ZrO_2, on the addition of ZrO_2, except the boundary layer.

The authors wish to express their appreciation to Drs. Tadashi Sekiya and Osamu Kondo for their gift of the vanadium naphthenate and to Mr. Hideji Yonekawa for his help in the construction of the automatic measurement system by means of a microcomputer.

(Received March 8, 1984)

The three-dimensional structure of plasminostreptin, a bacterial protein protease inhibitor from *Streptomyces antifibrinolyticus*, was determined at 2.8Å resolution by the multiple isomorphous replacement technique. A dimer with the molecular weight of 11,402×2 was included in an asymmetric unit of the crystal. The monomer, composed of 109 amino acid residues, consisted of an antiparallel twisted β-sheet with five strands, two short helices, and irregular polypeptide-chain segments. The reactive site of plasminostreptin belonged to one of these irregular polypeptide-chain segments. The two monomers in the dimer were related by a non-crystallographic pseudo-two-fold axis, and the two β-sheets were arranged face-to-face with each other. The averaged angle between the strands of the two β-sheets was approximately 30° clockwise. In spite of 37 amino acid substitutions including the reactive site residues, the tertiary and quaternary structures of plasminostreptin were similar to those of *Streptomyces* subtilisin inhibitor (SSI). The main-chain conformations of the reactive site of plasminostreptin were similar to those of SSI and other protease inhibitors analysed previously. Moreover, the conformations of the side chain of the evolutionarily conservative asparagine in the so-called "secondary contact region" resembled those found in the inhibitors of the pancreatic secretory trypsin inhibitor family.

Plasminostreptin is a bacterial protein protease inhibitor, isolated from a culture fluid of *Streptomyces antifibrinolyticus* IFO** 13298; it was crystallized by Kakinuma *et al.*[1] It inhibits the proteolytic activities of plasmin, trypsin, and several microbial alkaline proteases (for example, subtilisin) by forming enzyme-inhibitor complexes with the inhibition constants of approximately 10^{-8}M (1M=1 mol dm^{-3}).[1] Two identical monomers are dimerized in a solution. The sequence of 109 amino acid residues comprising the monomer was determined by Sugino *et al.*[2] (Fig. 1), and the molecular weight of the monomer was calculated to be 11,402. The scissile peptide bond of the reactive site was located at Lys69-Gln70.[3] On the basis of the fact that 66% of the amino acid residues, and also the disulfide bonds, are identical with those of *Streptomyces* subtilisin inhibitor (SSI***),[4] plasminostreptin was classified in the SSI family of protein protease inhibitors by Laskowski and Kato.[5] However, the inhibition spectra of plasminostreptin are markedly different from those of SSI.[1,6] Compared with SSI, a total of 37 out of 109 amino acid residues are substituted in plasminostreptin, and Mitsui *et al.*[7] pointed out that some of these residues were inside the SSI molecule. From the preliminary X-ray work for the crystal of plasminostreptin, two monomers were expected in an asymmetric unit. In the case of SSI, however, only one monomer is included in the asymmetric unit. The crystallographic studies of plasminostreptin might reveal the similarities and differences between the structures of plasminostreptin and SSI.

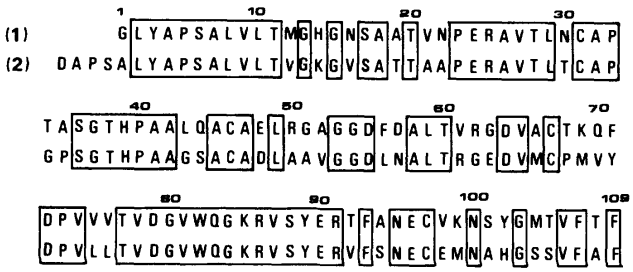

Fig. 1. The amino acid sequences of plasminostreptin[2] and SSI.[4] The residues enclosed by squares are identical between plasminostreptin (1) and SSI (2). To get the sequence number of SSI, four should be added to the number shown here. The scissile peptide bond of plasminostreptin is between Lys69 and Gln70.

The three-dimensional structures of the proteinaceous inhibitors of serine proteases have been studied about the bovine pancreatic trypsin inhibitor [Kunitz] (BPTI),[8] the complex of trypsin with BPTI,[9] and that of trypsin with the soybean trypsin inhibitor [Kunitz] (STI).[10] In addition, the structures of SSI and its complex with subtilisin BPN′ have been determined.[7,11] Recently, three inhibitors of the pancreatic secretory trypsin inhibitor [Kazal] (PSTI) family have also been analysed. These are the third domain of the Japanese quail ovomucoid inhibitor (OMJPQ3),[12] the third domain of the ovomucoid inhibitor from turkey (OMTKY3) complexed with *Streptomyces griseus* protease B,[13] and PSTI complexed with trypsin.[14] In this paper, we wish to report the three-dimensional structure of plasminostreptin at 2.8Å resolution and to compare it with those of SSI and other inhibitors previously analysed.

Experimental

The Crystals of Plasminostreptin. Plasminostreptin was purified by the method of Kakinuma *et al.*[1] The elongated octahedral crystals of plasminostreptin were prepared at 4°C in a solution in the absence of any buffer reagent. The typical dimensions of the crystals were 0.6×1.0×1.2 mm^3. The preliminary X-ray photographs revealed that the crystals belonged to the orthorhombic

*** Hereafter, the abbreviations for the proteins will be shown in parentheses on their first appearances.

TABLE 1. THE DATA SETS OF THE CRYSTALS OF PLASMINOSTREPTIN

Crystal	Condition	Resolution	Number of reflections	R_M
Native	Non-buffered	2.0Å	14,964(2σ)	0.040
	Phosphate-buffered	2.8Å	6,102(3σ)	0.024
Heavy-atom	0.5 mM $K_2[PtCl_4]$ for 7 days	2.8Å	6,000(3σ)	0.031
Derivatives	1.0 mM $HgBr_2$(2KBr) for 7 days	2.8Å	5,988(3σ)	0.033
	5.0 mM $K[Au(CN)_2]$ for 7 days	2.8Å	5,542(3σ)	0.023

There are two kinds of native crystals. One of them, non-buffered, was grown by the method of Kakinuma *et al.*[1], while the other, phosphate-buffered, was transferred into the phosphate-buffer solution for the MIR technique. The three heavy-atom derivatives were soaked in phosphate-buffer solutions containing the heavy-atom compounds. The reflections whose intensities were more than the values in parentheses (σ was the standard deviation of the reflection intensity) were taken into account in this analysis. The merging R factor, R_M, is defined as follows: $R_M=\sum||F^+|-|F^-||/\sum||F^+|+|F^-||$, where $|F^+|$ and $|F^-|$ are the amplitudes of a Friedel pair.

TABLE 2. THE HEAVY-ATOM PARAMETERS

Derivative	Atom	Occupancy	x	y	z	B
$K_2[PtCl_4]$	Pt1	32e	0.0204	−0.0145	0.1349	23 Å^2
	Pt2	26	−0.0149	0.2392	0.2540	27
$HgBr_2$	Hg1	26	0.0546	−0.0232	0.1293	31
	Hg2	18	−0.0166	0.2492	0.2690	41
$K[Au(CN)_2]$	Au1	19	−0.0598	0.1606	0.2316	19
	Au2	11	0.0639	0.1493	0.2486	8

The occupancies are converted to the electron unit by using the absolute scale factor, which was calculated through a Wilson plot.[21] (x, y, z) are the fractional coordinates of the atom. The isotropic temperature factors, B, of the Pt and Hg atoms are calculated from the anisotropic temperature factors.

system and that the space group was $P2_12_12_1$. The unit cell dimensions were a=56.88 Å, b=88.87 Å, and c=46.40 Å. Two monomers were expected in an asymmetric unit, which would give the packing density[15] of 2.6 Å^{3}u^{-1}. The crystals were transferred into a phosphate buffer (1.0 M, pH 6.8) for the structure determination by means of the multiple isomorphous replacement (MIR) technique[16] at 2.8 Å resolution. These crystals were regarded as the native crystals. Some of them were soaked in phosphate buffer solutions containing heavy-atom compounds at room temperature. The three heavy-atom derivatives listed in Table 1 were useful in this structure determination.

Data Collection. The X-ray diffraction intensities, including their Friedel pairs, were measured by the use of a computer-controlled four-circle diffractometer, Rigaku AFC-V, set on a rotating anode X-ray generator, Rigaku RU-200. The focus size on the anode was 0.3×3.0 mm^2, and the take-off angle was 6°. The incident X-ray beam was Cu$K\alpha$ radiation monochromatized with a graphite plate, and it was passed through a collimator with the diameter of 0.3 or 0.5 mm. The distance from the crystal to the receiving aperture (3×3 mm^2) was 40 cm. An evacuated beam tunnel was used to avoid X-ray absorption by the air. One of the computer programs for the data collection was modified by Associate Prof. Kyoyu Sasaki of Nagoya University to allow for ordinate analysis.[17] The continuous ω-scan was carried out at a scan speed of 0.04 degree s^{-1} over an angle of 0.72°. The counting time for each reflection was divided into 18 steps. In the ordinate analysis, the extreme three steps on both sides of the scan were regarded as the background, and the remaining twelve steps, as the reflected X-ray peak. In order to monitor the X-ray damage to the crystals, the intensities of four standard reflections were measured every 200 reflection measurements; the damages remained less than 10%. Two crystals were consumed for the data collection of each of the native and heavy-atom derivatives in the MIR technique. Another set of 2.0 Å -resolution data were collected with five original non-buffered crystals and used for the systematic checking of the molecular models.

The Structure Determination. Lorentz-polarization factors, the X-ray-absorption[18] factor, and the damage factor upon X-ray exposure were applied to each of the data sets. The scales between the two or five crystals were calculated using the intensities of the overlapped reflections. The intensity data are summerized in Table 1. After the Kraut scaling,[19] the difference Patterson maps of the derivatives were computed with the coefficients of $(|F_{PH}|-|F_P|)^2$.**** The coordinates of the heavy-atom sites were estimated from these maps. The parameters of these heavy atoms were refined by the phase-refinement procedure[20] (Table 2). The anomalous terms of the heavy atoms contributed only to the inner reflections. The handedness of the heavy-atom parameters were consistent with the calculation of the negative correlation coefficients[22] between the observed and calculated anomalous differences. The refined parameters were used for the calculation of the MIR phases.[23] The averaged figure of merit was 0.61 for the 6,102 reflections. The statistics for the phasing are shown in Table 3.

The MIR electron-density map was calculated at 2.8 Å resolution. The preliminary models of the two independent monomers in an asymmetric unit were built according to the Diamond procedure.[24] The corresponding C$^\alpha$ atoms of each monomer were superposed,[25] and the two monomers could be related by a linear transformation. In order to reduce possible errors in the MIR electron-density map, the electron densities of the two independent monomers were averaged according to the following procedures. (1) Summations of the squared differences between the electron densities at the grid points in one monomer and those at the corresponding points in the other monomer were calculated around the translational vector elements and the angular values estimated from the rotational matrix. (2) Based on the matrix and vector which gave the minimum value of the summation, the MIR electron densities of the two monomers could be averaged. Into this

**** F_{PH} and F_P are structure factors of the heavy-atom derivatives and the native crystal in the MIR technique respectively.

TABLE 3. STATISTICS IN THE MIR PHASING AT 2.8Å RESOLUTION

			RMS E	68	34	40	41	34	32	28	30

A total of 6,102 reflection data was divided into eight shells by the range of $4\sin^2\theta/\lambda^2$. The definitions are as follows:
$\langle|F_P|\rangle$; the averaged observed reflection amplitude of the native crystal. ⟨f.o.m⟩; the averaged figure of merit. R_F; $\sum||F_{PH}|-|F_P||/\sum|F_P|$. $\langle|f_H|\rangle$; the averaged calculated structure factor amplitudes of the heavy atoms in the derivative. Rc; $\sum|F_{PH}-F_P|-|f_H||/\sum|F_{PH}-F_P|$ for the centric data. Rk; $\sum||F_{PH}|-|F_P+f_H||/\sum|F_{PH}|$ for all of the reflections whose f.o.m. values are more than 0.85. RMS E; $\{\sum(|F_{PH}|-|F_P+f_H|)^2/n\}^{1/2}$ where n is the number of reflections.

averaged electron-density distribution, a Nicholson model (on a scale of 1 cm/ Å) of one monomer was fitted by using the half-mirror device of Richards.[26] A set of the atomic coordinates was measured on this device. The coordinates for the other monomer in the asymmetric unit were calculated with the linear transformation obtained by the procedure mentioned above. For the systematic checking of the atomic coordinate sets thus obtained, "removed maps"[27] ($|F_o|\exp^{i\alpha c}$) were calculated. The structure factor amplitudes ($|F_o|$) used were the observed 2.0 Å data, and the phases (αc) were those of the structure factors calculated from the atomic-coordinate sets where some atoms were systematically subtracted from the total atoms of the two independent monomers. Some parts of the models were fitted into the electron-density distributions of the "removed maps." The corrected atomic coordinates were refined energetically,[28] and the molecular models were more accurately adjusted to the electron-density distribution according to the Diamond real-space refinement procedure.[29] We believe that the resolution of this structure determination should be regarded as 2.8 Å, since the refinement of the structure with the 2.0 Å resolution data has not yet been completed. Hereafter we will describe the structure of plasminostreptin based on the corrected models.

Results and Discussion

The Monomer Structure. Figure 2 is a schematic illustration of the main chain of the plasminostreptin monomer. The monomer is composed of an antiparallel twisted β-pleated sheet with five strands and two short helices. The five strands of the β-sheet are those of Pro5–Gly15, Arg25–Cys31, Ser36–Thr38, Pro73–Gln83, and Lys85–Phe93. The two helices are defined as the α_1-helix (Ala42–Gly53) and the α_2-helix (Asn95–Gly103), like those of SSI.[7] These helices in the same side of the β-sheet are almost parallel to the sheet and are nearly perpendicular to each other. These secondary structural units are connected by the two disulfide bonds and irregular polypeptide-chain segments. One of the disulfide bonds (Cys31–Cys46) links the α_1-helix to the β-sheet, and the other (Cys67–Cys97) links a part of one of the irregular polypeptide-chain segments to the α_2-helix. The irregular polypeptide-chain segments are in the regions of the N-terminus (Gly1–Ala4), two loops (Asn16–Glu24, Gly54–Asp72), and the C-terminus (Gly103–Phe109). All these regions exist on the surface of the monomer, except for the C-terminal region, which is a part of the hydrophobic core of the monomer. One of the loops (Asn16–Glu24) protrudes from the β-sheet to the interspace between the monomers of the dimer structure (see the following section). The reactive site (Cys67–Phe71) belongs to the other loop (Gly54–Asp72). The site is proximate to the β-sheet and is linked to the α_2-helix by the disulfide bond (Cys67–Cys97). The four residues of Cys31–Thr34 constitute a β-turn, and Pro33 in this turn is in the *cis*-form.[30]

The Dimer Structure. The non-crystallographic relationship between the two monomers in the asymmetric unit is determined by the superposing procedure[25] of the corrected coordinates of the corresponding C^α atoms of each monomer. The rotational matrix and translational vector which relate the two monomers are listed in Table 4. Hereafter, the two monomers will be denoted as the I and II monomers. The centers of gravity calculated from the coordinates of the C^α atoms in angstrom units are (42.2 Å, 25.6 Å, 14.2 Å) and (31.5 Å, 42.4 Å, 25.9 Å) for the I and II monomers respectively. The spherical polar coordinates[31] of the

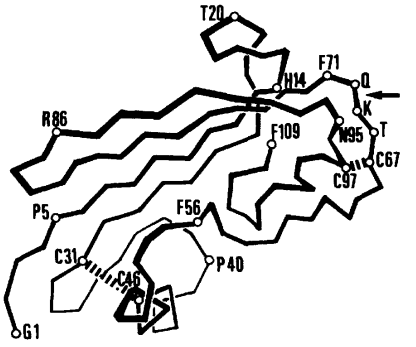

Fig. 2. A schematic drawing of the main chain of the monomer of plasminostreptin. The C^α atoms of 109 amino acid residues are at the creases, and the important positions are identified by open circles together with one letter codes of amino acid residues followed by the sequence number. The arrow represents the scissile peptide bond. The marks (IIIIII) denote the disulfide bonds.

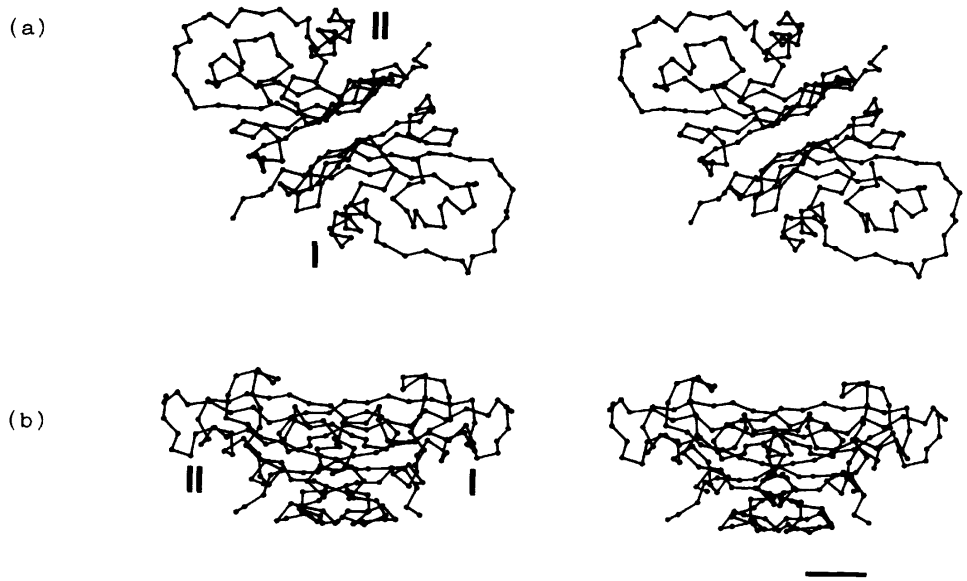

Fig. 3. Stereographic drawings of the plasminostreptin dimer.
The dimer is viewed parallel (a) and perpendicular (b) to the non-crystallographic pseudo-two-fold axis. The models are drawn with the C^{α} atoms. In (a), the lower-right model is the I monomer, and the upper-left is the II monomer. The scale bar in the bottom-right represents 10 Å.

TABLE 4. THE ROTATIONAL MATRIX AND THE TRANSLATIONAL VECTOR OF THE NON-CRYSTALLOGRAPHIC RELATIONSHIP BETWEEN THE I AND II MONOMERS

Rotational matrix			Translational vector
−0.038	−0.133	0.990	22.4
−0.079	−0.988	−0.136	73.0
0.996	−0.083	0.027	−14.4

The atomic coordinates (X, Y, Z) of the II monomer in angstrom units are related to those of the I monomer by this rotational matrix and translational vector: $X = 56.88 \times x$, $Y = 88.87 \times y$, and $Z = 46.40 \times z$, where (x, y, z) are the fractional coordinates.

rotation axis, calculated from the rotational matrix, are 83.7° (from the $-y$-axis of the unit cell in the x-y plane), 44.2° (from the z-axis), and 182.2° (rotational angle around the rotation axis). The root-mean-square (RMS) deviation is 1.4 Å between the superposed C^{α} atoms. Figure 3 shows the stereo-drawings viewed parallel and perpendicular to the rotational axis. It is possible to conclude that the I and II monomers may be related by a pseudo-two-fold symmetry and may form a dimer. The β-sheet of the I monomer is faced to that of the II monomer in the dimer structure. The topology of stacking β-sheets has been studied by several workers.[32-36] Cohen *et al.*[36] have pointed out that the averaged angle between the strands of the two twisted β-sheets (inter-sheet angle) is from 20° to 50° anticlockwise for the fragments of the immunoglobulin, the Bence-Jones protein, human prealbumin, CuZn superoxide dismutase, and Jack-bean concanavalin A, and that the nonpolar side chains are packed in the interspace between the β-sheets. In the dimer structure of plasminostreptin, the inter-sheet angle was about 30° clockwise, as shown in Fig. 3, and the direction of the rotation is opposite from those studied by Cohen *et al.* Figure 4 shows schematically the arrangement of side chains in between the two β-sheets. In the amino

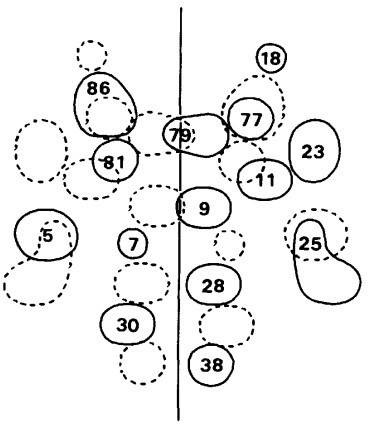

Fig. 4. The arrangement of the side chains between the β-sheets in the dimer. The vertical solid line represents the pseudo-two-fold axis. The side chains which belong to the I monomer are enclosed by the solid lines, and their sequence numbers are given in the circles. The side chains which belong to the II monomer are indicated by the broken circles. The broken circles are related to the solid circles by the pseudo-two-fold symmetry.

acid residues which are in the interspace between the two monomers, the side chains of Pro5, Val9, and Val81 are nonpolar, while those of Asp79 and Arg86 are polar. The side chains of Thr11, Thr28, Asn30, Thr38, and Thr77 are intermediate and can contribute to hydrogen bonds. The Thr11, Thr28, Asn30, Thr38, Thr77, Asp79, and Arg86 of both of the monomers either can be formally charged or can contribute to hydrogen bonds. The side chains of Val9 and Thr28 are close to the pseudo-two-fold axis which related the I and II monomers, and these side chains of the two monomers were in contact with each other. The side chain of Arg86 in one monomer could be expected to interact with the side chains of Thr11, Thr77, and

Asp79 in the other monomer. The side chain of Arg86 would not, however, interact with those of Thr11, Thr77, and Asp79 in an orientation of β-sheets where the inter-sheet angle was 20° to 50° anticlockwise, as in the proteins studied by Cohen *et al.*,[36] but it could interact with them in the orientation of the two monomers of plasminostreptin where the inter-sheet angle was about 30° clockwise.

Comparisons between the Main Chains of Plasminostreptin and SSI. According to the superposing procedure[25] of the corresponding C^{α} atoms, the RMS deviations are 1.4 Å for all the following combinations: the I monomer and the SSI subunit, the II monomer and the SSI subunit, and dimeric plasminostreptin and dimeric SSI. Therefore, the overall structure of plasminostreptin resembles that of SSI not only in the tertiary structure of the monomer, but also in the quaternary structure of the dimer. Compared with the sequence of SSI, a total of 37 out of 109 amino acid residues of plasminostreptin are substituted (see Fig. 1). Eight of these substituted residues are Met12, Val21, Ala52, Phe56, Val75, Val76, Lys99, and Thr108, whose side chains are buried in the monomer. The side chains of the other substituted residues are exposed to the solvent. Mitsui *et al.*[7] expected that the buried side chains could be accommodated in the SSI structure. Their expectations are, in fact, confirmed in the plasminostreptin structure. The residue of Phe56 may be noteworthy in these substitutions, since the total volume of the side chain is considerably larger than that of the corresponding residue, Leu60, of SSI. In the plasminostreptin structure, the benzene moiety of the phenylalanine is packed between the β-sheet and the α_1-helix, and it is nearly parallel to the β-sheet. The torsion angle around the C^{α}–C^{β} bond, χ_1, is similar to that of SSI. This kind of substitution is also found between the structures of the complexes of *Streptomyces griseus* protease A with Ac-Pro-Ala-Pro-Phe-H or -Phe-OH[37] and of *Streptomyces griseus* protease B with OMTKY3.[13] The P_1 residue is substituted from the phenylalanine of the tetrapeptides to the leucine residue in OMTKY3. The side chains are inserted between a β-sheet and a polypeptide chain, and they exist at almost the same position as the specific binding pocket of the enzyme. The substitution only slightly affects the conformations around them. Between the structures of plasminostreptin and SSI, no significant movement of the α_1-helix could be detected. However, the substitution might cause small conformational changes in the side chains around the phenylalanine residue.

Comparisons of the Reactive Site Region with the Inhibitors Already Analysed by X-Ray Crystallography. According to the classification of Laskowski and Kato[5], the six inhibitors which have already been analysed by X-ray crystallography may be classified into four families: the BPTI [Kunitz], STI [Kunitz], PSTI [Kazal], and SSI families. These four families are genetically different, and their main-chain foldings are also different from each other. It is, however, noticeable that the main-chain conformations of the reactive sites (the residues from P3 to P2′[38]) are homologous.[7] Their main-chain torsion angles, phi and psi, are listed in Table 5. The angles of the reactive site of plasminostreptin are similar, in spite of the differences in the amino acid sequences and their inhibitory specificities. These similarities can be expected as examples of convergent evolution.[39] Figure 5 shows the structures around the reactive site regions of plasminostreptin, SSI, and OMJPQ3. The structure of OMJPQ3 can be deemed as representing the inhibitors of the PSTI [Kazal] family, since the three inhibitors, OMJPQ3, OMTKY3, and PSTI, belonging the same inhibitor family turned out to have very similar overall structures.[12–14] The structure around the reactive site of plasminostreptin closely resembles those of SSI and OMJPQ3. (The benzene moiety of Phe71 in plasminostreptin extends to a different direction from those of the phenol moieties of Tyr75 in SSI and Tyr20 in OMJPQ3. This difference may be caused by the crystal packing, because the side chains of Phe71 and Asp72 are in close contact with the residues of Phe71 and Asn16 respectively of a neighboring monomer in the present crystal.) It is interesting to note that an asparagine residue in the secondary contact region[39] is evolutionarily conservative. The residues are Asn95 in plas-

Table 5. The main-chain conformations of the reactive sites of BPTI,[8] STI,[10] SSI,[a] OMJPQ3,[12] and plasminostreptin, and their residues

	P3		P2		P1		P1′		P2′	
	phi	psi	phi	psi	phi	psi	phi	psi	phi	psi
BPTI	−86°	−7°	−89°	165°	−127°	32°	−77°	178°	−134°	88°
STI	−46	−21	−77	136	−89	85	−135	−115	−175	−179
SSI	−123	144	−55	130	−74	76	−103	170	−117	96
OMJPQ3	−121	153	−64	160	−102	18	−61	138	−105	92
Plasminostreptin (tentative)	−120	168	−78	166	−127	29	−78	133	−95	72

BPTI	Pro	Cys	Lys(15)	Ala	Arg
STI	Ser	Tyr	Arg(63)	Ile	Arg
SSI	Cys	Pro	Met(73)	Val	Tyr
OMJPQ3	Cys	Pro	Lys(18)	Val	Tyr
Plasminostreptin	Cys	Thr	Lys(69)	Gln	Phe

The angles of plasminostreptin are those of the I monomer and should be regarded as tentative, since the structure refinement is not yet finished. a) The angles of SSI are those partially refined with the 2.3Å resolution data (R=27%; private communication from Dr. Yukio Mitsui).

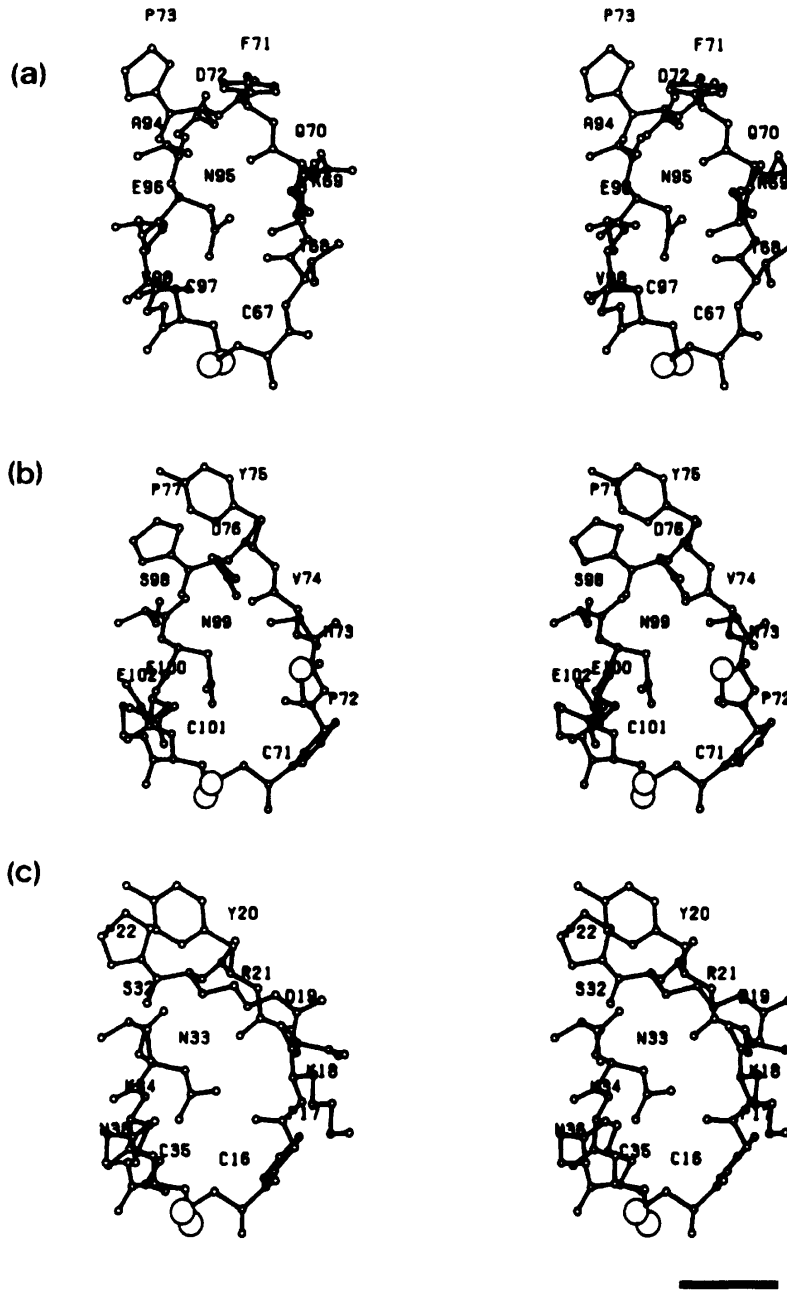

Fig. 5. Similarities of the structures around the reactive sites of plasminostreptin (a), SSI (b), and OMJPQ3 (c).
The reactive site of plasminostreptin is drawn with the coordinate set of the I monomer. The coordinate set of SSI was taken from the Protein Data Bank. The structure of OMJPQ3 is based on the coordinates kindly provided by Prof. Dr. Robert Huber. These structures are viewed from the nearly equivalent direction which was determined by means of the superpositions of the corresponding C^{α} atoms. The large open circles are the sulfur atoms. The residue names are represented by one letter codes followed by the sequence numbers. The scale bar in the bottom-right corner represents 5 Å.

minostreptin, Asn99 in SSI, and Asn33 in OMJPQ3. In all of the three inhibitors of the PSTI [Kazal] family, the side chain of the asparagine residue exists between the reactive site loop and the inner α-helix, connecting them with hydrogen-bonding networks.[12-14] Such a network in the OMJPQ3 structure consists of three hydrogen bonds between the N^{δ} atom of Asn33 and the main-chain carbonyl oxygen atoms of Pro17 and Asp19 in the reactive site, and between the O^{δ} atom of Asn33 and the peptide nitrogen atom of Asn36 in the α-helix.[12] Fujinaga *et al.*[13] considered this network to be essential for the inhibitory mechanism. It resists the formation of the tetrahedral intermediate of the proteolysis at the carbonyl-carbon atom of the scissile peptide bond.

This network has not been found in the SSI structure[7], but it seems likely to exist in the plasminostreptin structure, as shown in Fig. 5. The structure of plasminostreptin is being refined, and the conformations of Asn95 can be defined more precisely after the refinements.

The authors wish to thank Associate Professor Noriyoshi Sakabe, Dr. Kiwako Sakabe, and Associate Professor Kyoyu Sasaki of Nagoya University for their helpful suggestions in studying this structure and their critical advice in the preparation of this manuscript. We are also greatly thankful for the help of Professor Dr. Robert Huber of the Max-Planck-Institut für Biochemie in kindly informing us of the OMJPQ3 and PSTI structures. We also wish to thank Drs. Masao Nishikawa and Atsushi Kakinuma of Takeda Chemical Industries, Ltd., for their support and encouragement throughout this work. One of us (M. M.) is especially grateful to Professor Takashi Kihara of Osaka Medical College for his great encouragement during this study, and one of us (N. K.) is a holder of a scholarship from the Toyoda Physical and Chemical Research Institute. The computations were done at the Nagoya University Computation Center and Computer Center of the Institute for Molecular Science.

(Received August 25, 1983)

The oxidation of iron(II) sulfate with SO_2/O_2 (sulfur dioxide and oxygen mixtures) was carried out using an air-lift percolator in the temperature range of 25—50 °C and over the pH range of 0—3. Under conditions in which sulfur dioxide is immediately oxidized, the rate of the oxidation of iron(II) is proportional to the flow rate of sulfur dioxide and independent of the flow rate and partial pressure of oxygen, and the concentration of iron(II). The molar ratio of Fe^{2+} oxidized/SO_2 oxidized is 1.3—2 in the pH range of 0.5—2.0. A free-radical chain reaction in which HSO_5^- oxidizes iron(II) is proposed as the reaction mechanism.

Although the oxidation of iron(II) with oxygen according to Eq. (1):

$$Fe^{2+} + 1/4\,O_2 + 1/2\,H_2O \longrightarrow Fe^{3+} + OH^-, \quad (1)$$

is thermodynamically possible, practical rates of oxidation are so slow in acidic solutions that the oxidation is frequently performed with the aid of manganese dioxide, hydrogen peroxide, pressurized oxygen, iron-oxidizing bacteria, *etc.* Recently, it was reported that, although sulfur dioxide by itself reduces iron(III) to iron(II), a mixture of sulfur dioxide with oxygen oxidizes iron(II) to iron(III).[1,2] It was suggested that this reaction might be used for the separation of iron from a zinc-containing solution,[1] the selective recovery of zinc and copper from iron-containing lead slags,[3] and the leaching of metal-sulfide concentrates.[2] However, no systematic study of this reaction has yet been made, and the details are not clear. In the present study, a series of tests was carried out to investigate specifically the oxidation behavior of iron(II) with SO_2/O_2 in acidic solutions.

Experimental

Materials. All the chemicals were of an analytical reagent grade and were used without further purification.

Apparatus and Procedure. The apparatus used for the oxidation study is shown diagramatically in Fig. 1. In each test, 400 cm^3 of redistilled water was transferred to a Pyrex-glass air-lift percolator (50 $mm^{\phi} \times 650\,mm^{H}$) fitted with an unglazed pottery gas-ditributor plate. After the removal of the dissolved oxygen by passing nitrogen gas through for 20 min, a known quantity of iron(II) sulfate, sodium perchlorate, and 10 mol/dm^3 perchloric acid were added to adjust the concentration of iron(II), the ionic strength, and the pH, and then SO_2/O_2 was introduced to start the reaction. The pH of the solution was maintained at a preselected value by the addition of a 0.5 mol/dm^3 sodium hydroxide solution by means of a peristaltic pump; the temperature was maintained at a set temperature ± 0.5 °C by circulating temperature-controlled water through the jacket.

Unless otherwise stated, the general experimental conditions used were: temperature, 25 °C; pH, 1.7; ionic strength, 1.0 mol/dm^3; flow rate of oxygen, 200 cm^3/min; flow rate of sulfur dioxide, 5 cm^3/min; initial iron(II) concentration, 0.08 mol/dm^3.

Analysis. The concentration of iron(II) was determined by the modified 1,10-phenanthroline method proposed previously.[4] The concentration of sulfurous acid was determined iodimetrically after the addition of an acidified sodium cyclo-hexaphosphate solution to mask the iron(II) and iron(III), while the sulfate and dithionate concentrations were estimated gravimetrically as barium sulfate. The concentration of sulfur dioxide in the outlet gas was determined by the back-titration of the excess iodine with a sodium thiosulfate solution after the absorption of the sulfur dioxide in the iodine solution for 15 min.

Results and Discussion

Oxidation of Iron(II) with Oxygen. Experiments were conducted at two different temperatures, 25 and 50 °C, in the presence of 0.02 mol/dm^3 of different foreign substrates. The results of these tests are shown in Fig. 2. The oxidation of iron(II) with oxygen at both temperatures was very slow. However, in the presence of ethylenediaminetetraacetic acid (EDTA=H_4edta) and sodium triphosphate, the oxidation proceeded rapidly until the amount of resulting iron(III) reached about 0.02 mol/dm^3, the rates then fell, and the reaction stopped essentially. Copper(II) sulfate, known as a catalyst for iron(II) oxidation with oxygen,[5,6] increased the reaction rate, but the catalytic effect was substantially less than that seen with the complex-forming species, EDTA and triphosphate. On the other hand, the addition of catechol ($C_6H_4(OH)_2$) show-

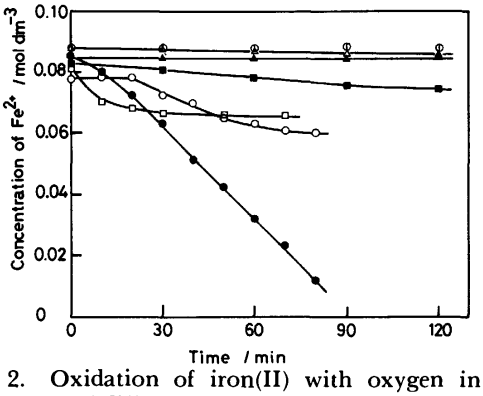

Fig. 2. Oxidation of iron(II) with oxygen in the presence of different foreign substrates.
■: 0.02 mol/dm^3 $CuSO_4$, ○: 0.02 mol/dm^3 $Na_5P_3O_{10}$, □: 0.02 mol/dm^3 EDTA-2Na, Φ: 0.02 mol/dm^3 $C_6H_4(OH)_2$, ●: SO_2 was introduced at a rate of 5 cm^3-NTP/min, △ ▲: None, Temperature (°C)---- ○, ●, □, ▲, Φ: 25, ■, △: 50.

ed no effect. These results indicated that the increase in the oxidation rate with EDTA and triphosphate was probably due to the reduction in redox potentials. The redox potentials of the metal ion and metal-complex ion couples are related through Eq. (2):

$$E^\circ_{ML} = E^\circ_M + \frac{RT}{nF} \ln \frac{K_{M(R)L}}{K_{M(O)L}}, \quad (2)$$

where E°_M and E°_{ML} are the standard redox potentials of metal aquaions and metal-complex ions, and where $K_{M(R)L}$ and $K_{M(O)L}$ are the stability constants of the reduced form and the oxidized form of metal-complex ions respectively. If $K_{M(O)L}$ is larger than $K_{M(R)L}$, E°_{ML} is smaller than E°_M, and the metal-complex ion is thermodynamically less stable than the aquaion under oxidizing conditions. Such an effect was in accord with the test results. When iron was complexed with EDTA and triphosphate ligands with large values of $K_{M(O)L}$, the oxidation rate of iron(II) was increased, whereas the rate was not affected in the presence of catechol, which has a smaller value. The fall-off in the reaction rate observed in the presence of EDTA and triphosphate (Fig. 2) seemed to be due to the consumption of the complex-forming species:[7]

$$Fe^{3+} + edta^{4-} = Fe(edta)^-, \quad (3)$$

$$Fe^{3+} + H_2P_3O_{10}^{3-} = FeH_2P_3O_{10}, \quad (4)$$

$$Fe^{3+} + H_3P_3O_{10}^{2-} = FeH_3P_3O_{10}^+. \quad (5)$$

When sulfur dioxide was introduced together with oxygen, iron(II) was rapidly oxidized at a constant rate. In addition, more than 99% of the sulfur dioxide introduced was converted in the solution to be oxidized to sulfate. The yield of dithionate was less than 1%, so that the reaction of iron(III) and hydrogen sulfite shown as Eq. (6)[8-10] was not significant under the reaction conditions used.

$$2Fe^{3+} + 2HSO_3^- \longrightarrow 2Fe^{2+} + S_2O_6^{2-} + 2H^+, \quad (6)$$

Therefore, the reactions occurring in the presence of SO_2 may be represented by Eqs. (1), (7), and (8):

$$SO_2 + H_2O = HSO_3^- + H^+, \quad (7)$$

$$HSO_3^- + 1/2\,O_2 \longrightarrow SO_4^{2-} + H^+. \quad (8)$$

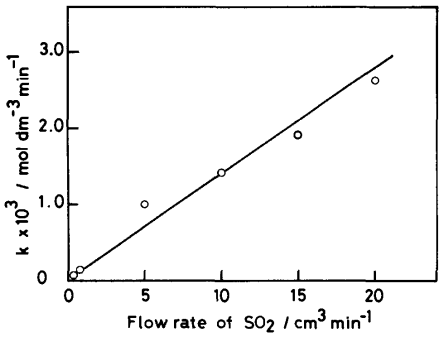

Fig. 5. Rate of oxidation as a function of sulfur dioxide flow rate.

Oxidation of Different Concentrations of Iron(II) with SO_2/O_2. A series of experiments was conducted in which the initial concentration of iron(II) was varied from 0.08 to 0.44 mol/dm^3. As is shown in Fig. 3, the plots of the concentration of iron(II) *versus* the time were all linear, with the same gradient. The reaction rate, therefore, was zeroth-order with respect to the iron(II) concentration. The lag period found in all experiments seems to be attributable to the time necessary for the sulfur dioxide to get to the solution from the cylinder rather than to some induction period.

In addition, a constant rate of oxidation was found even when the oxygen-flow rate and the partial pressure were varied over the ranges of 100—300 cm^3-NTP/min and 0.14—0.98 atm respectively. The mass transfer of oxygen, therefore, does not control the reaction under these experimental conditions.

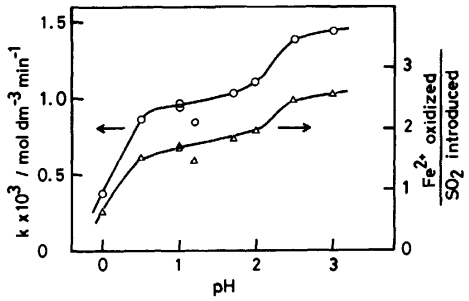

Fig. 6. Oxidation of iron(II) with SO_2/O_2 at different solution pH.

Oxidation of Iron(II) with SO_2/O_2 at Different Flow Rates of SO_2. The effect of changes in the flow rate of sulfur dioxide on the rate of oxidation of iron(II) is shown in Figs. 4 and 5. It is significant to note that the rate of oxidation increased linearly with the flow rate of sulfur dioxide over the range of 0.38—20 cm^3-NTP/min. The average value of the molar ratio of Fe^{2+} oxidized/SO_2 oxidized, calculated from the slope of the straight line shown in Fig. 5, is 1.3.

Oxidation of Iron(II) with SO_2/O_2 at Different Solution pHs. A series of oxidation experiments was carried out in which the solution pH was varied from 0 to 3.0. The results, shown in Fig. 6, indicated that there was no significant pH effect in the pH range of 0.5—2.0 with values of 1.3—2.0 for the molar ratio of Fe^{2+} oxidized/SO_2 introduced. However, the oxidation rate decreased dramatically below pH 0.5 and increased appreciably above pH 2.5. Since a significant amount of SO_2 was detected in the outlet gas at low-pH experiments, the reduction in the rate at low pHs may be due to the decreases in the solubility of sulfur dioxide[11] and in the oxidation rate of sulfurous acid with oxygen.[12,13] On the other hand, the rate increase at higher pHs seems to be attributable to the reduction of the oxidation potential of iron by the formation of a complex between iron and the hydroxide ions, as shown in Eqs. (9)—(14):[14]

$$Fe^{2+} + OH^- = FeOH^+, \quad (9)$$

$$Fe^{2+} + 2OH^- = Fe(OH)_2, \quad (10)$$

$$Fe^{3+} + OH^- \overset{K_I}{=} FeOH^{2+} \qquad pK_I = 11.1, \quad (11)$$

$$Fe^{3+} + 2OH^- \overset{K_{II}}{=} Fe(OH)_2^+ \qquad pK_{II} = 21.69, \quad (12)$$

$$2Fe^{3+} + 2OH^- \overset{K_d}{=} Fe_2(OH)_2^{4+} \qquad pK_d = 25.10, \quad (13)$$

$$Fe^{3+} + 3OH^- \overset{K_{sp}}{=} Fe(OH)_3 \qquad pK_{sp} = 37.20, \quad (14)$$

It has been reported that the reactive species of iron(II) with oxygen is Fe^{2+} in an acidic solution but $FeOH^+$ above a pH of about 3.[15] Further, the main iron(III) species above pH 2.5 is insoluble $Fe(OH)_3$; under these conditions, iron(II) becomes more easily oxidized.[15] Therefore, the direct oxidation of iron(II) with oxygen also proceeds at high pHs.

Oxidation of Iron(II) with SO_2/O_2 in the Presence of Different Foreign Substrates. A series of experiments was conducted in which different foreign substrates were added. Specifically, EDTA, sodium triphosphate, copper(II) sulfate, and catechol were used as these materials, all were known as accelrators or inhibitors for the oxidation of iron(II) and sulfite with oxygen, as shown in Table 1. Since the same reaction behavior was observed when the concentration of additives were changed from 0.01 to 0.03 mol/dm^3, the results of the tests using 0.02 mol/dm^3 of additives are given in Figs. 7 and 8. There was no noticeable influence on the reaction rate with the addition of copper(II) sulfate. In the presence of catechol, the oxidation did not proceed at all. On the other hand, EDTA and sodium triphosphate showed a limited inhibition; that is, the inhibition continued until the amount of iron(III) formed rose to about 0.02 mol/dm^3, but thereafter the rate was constant. When those results are compared with those shown in Fig. 2, it can be said that, while inhibition persists, the rates of oxidation in the presence of EDTA and triphosphate were

almost the same as those found when oxygen alone was used with those compounds. It is of interest to note that the oxidation of sulfite did not proceed during this inhibition period, but that afterwards sulfurous acid and iron(II) both were rapidly oxidized (Fig. 8). It is considered, therefore, that complex-forming species, such as EDTA, triphosphate, and catechol, inhibit the oxidation of sulfurous acid with oxygen by masking iron(III), which acts as an oxidation catalyst. Such a process is known to inhibit sulfite oxidation.[16] It is also considered that some reactive intermediate produced in the reaction of sulfurous acid and oxygen plays a significant role in the oxidation of iron(II) to iron(III). The anions of HSO_5^-[17] and SO_5^{2-}[18] have, in fact, been postulated as intermediates in the oxidation of sulfite with oxygen, and SO_5^{2-} is known to be a strong oxidant in alkaline media.[19]

Oxidation of Iron(II) with SO_2/O_2 at Various Temperatures. The effect on the oxidation of the temperature over the 25—50 °C range at two different pHs, pH 1.0 and pH 2.0, is shown in Fig. 9. The Fe^{2+} oxidized/SO_2 oxidized molar ratio increased slightly with the increase in the temperature at pH 2.0, but there was no appreciable temperature effect at pH 1.0. The results obtained at pH 1.0 are not inconsistent with the idea that iron(II) is oxidized by an intermediate produced in the oxidation of sulfurous acid with oxygen. On the other hand, the results obtained at pH 2.0 showed that the direct oxidation of iron(II) with oxygen also occurred at higher temperatures.

General Discussion

The experimental results presented above have shown that; (a) the rate of the oxidation of iron(II) with SO_2/O_2 mixtures is independent of the concentrations of oxygen and iron(II), but is directly proportional to the amount of sulfurous acid oxidized; (b) the effects of changes in the pH and the temperature on the reaction rate are not significant; (c) the value of the Fe^{2+} oxidized/SO_2 oxidized molar ratio is 1.3—2.0; (d) some reactive intermediate produced in the reaction of sulfurous acid and oxygen plays a significant role in the oxidation of iron(II), and (e) the reaction between iron(III) and hydrogen sulfite does not occur under the reaction conditions used.

There have been many studies of the oxidation of sulfite with oxygen, and the free-radical-chain reactions shown by Eq. (A), proposed by Bäckstrom,[18] are the accepted oxidation mechanism for diluted sulfite solutions in the neutral and alkaline regions:

$$\left.\begin{aligned} &SO_3^{2-} + Cu^{2+} \longrightarrow \cdot SO_3^- + Cu^+,\\ &\cdot SO_3^- + O_2 \longrightarrow \cdot SO_5^-,\\ &\cdot SO_5^- + SO_3^{2-} \longrightarrow \cdot SO_3^- + SO_5^{2-},\\ &SO_5^{2-} + SO_3^{2-} \longrightarrow 2SO_4^{2-} + O_2,\\ &2\cdot SO_5^- \longrightarrow 2SO_4^{2-} + O_2. \end{aligned}\right\} \quad (A)$$

On the other hand, Schroeter has postulated the anion of HSO_5^- as an intermediate in the oxidation of a sulfite solution.[16] Since the tetravalent sulfur exists as $SO_2 \cdot H_2O$ and HSO_3^- below pH 4.5,[15] the postulation of HSO_5^- as an oxidation intermediate seems reasonable. Therefore, the following mechanism containing free-radical-chain reactions similar to that proposed for sulfite oxidation by Bäckstrom[18] was considered to be in reasonable agreement with the reaction results:

Equilibria:

$$SO_2 + H_2O \overset{K_1}{=} HSO_3^- + H^+, \quad (7)$$

$$Fe^{2+} + HSO_3^- \overset{K_2}{=} FeHSO_3^+, \quad (15)$$

$$Fe^{3+} + HSO_3^- \overset{K_3}{=} FeSO_3^+ + H^+. \quad (16)$$

Initiation:

$$FeHSO_3^+ + 1/4\, O_2 \xrightarrow{k_1} FeSO_3^+ + 1/2\, H_2O, \quad (17)$$

$$FeSO_3^+ \xrightarrow{k_2} \cdot SO_3^- + Fe^{2+}. \quad (18)$$

Propagation:

$$\cdot SO_3^- + O_2 \xrightarrow{k_3} \cdot SO_5^-, \quad (19)$$

$$\cdot SO_5^- + HSO_3^- \xrightarrow{k_4} HSO_5^- + \cdot SO_3^-. \quad (20)$$

Termination:

$$HSO_5^- + HSO_3^- \xrightarrow{k_5} 2SO_4^{2-} + 2H^+, \quad (21)$$

$$HSO_5^- + 2Fe^{2+} + H^+ \xrightarrow{k_6} SO_4^{2-} + 2Fe^{3+} + H_2O, \quad (22)$$

$$\cdot SO_5^- + \cdot SO_5^- \xrightarrow{\text{slow}} 2SO_4^{2-} + O_2. \quad (23)$$

The derived Fe^{2+} oxidized/SO_2 oxidized molar ratio based on this postulated mechanism is:

$$\frac{d[Fe^{3+}]/dt}{d[SO_4^{2-}]/dt} = \frac{2k_6[Fe^{2+}]^2[H^+]}{2k_5[HSO_3^-] + k_6[Fe^{2+}]^2[H^+]}$$

which would approach 2, since $2k_5[HSO_3^-]$ should be very small; this value is in agreement with the experimentally determined values of between 1.3—2.0 at pH 0.5—2.0. The assumption of a small value for $2k_5[HSO_3^-]$ seems reasonable because the sulfur dioxide introduced into the solution is immediately oxidized under the experimental conditions used. If the effect of the concentration of HSO_3^- on the oxidation of iron(II) could be investigated, it should be quite useful in confirming the propriety of this oxidation mechanism. However, it is important to remember that, in the presence of appreciable amounts of sulfurous acid, iron(III) reacts with HSO_3^- to form dithionate according to Eq. (6). In order to prevent this side reaction, the oxidaiton with SO_2/O_2 needs to be conducted in the absence of hydrogen sulfite ions in high concentrations at all time. Further, this mecha-

nism may also elucidate the strong oxidation power of SO_2/O_2 mixtures that was shown for the leaching of ZnS.[2)]

The Synthesis and Thermal Decomposition of Magnesium Phosphoramidate

Makoto WATANABE,* Yoshio MORII, and Shoji SATO
Department of Industrial Chemistry, Chubu University, Matsumoto-cho, Kasugai, Aichi 487
(Received January 23, 1984)

Magnesium phosphoramidate-water (1/7) was made by adding an aqueous magnesium chloride solution to an aqueous potassium hydrogenphosphoramidate solution at pH 9.0—9.5. The product was stable at room temperature, while it decomposed on heating. The product decomposed to produce polyphosphates when it was heated in air. The decomposition product heated above 600 °C was magnesium diphosphate. A small amount of imidodiphosphate was made when the phosphoramidate was heated in dried N_2.

Phosphoramidates with P-N covalent bonds have potential as new chemical fertilizers and as flame-proof materials because they produce polyphosphates containing imino and amino groups when they are heated. There have been many papers on phosphoric triamide and several papers concerning synthesis, thermal decomposition, or hydrolysis of ammonium and alkali-metal salts of phosphoramidic or phosphorodiamidic acid have been published.[1] Other salts of these phosphoramidic and phosphorodiamidic acids have not been studied. The present authors investigated the syntheses and thermal decompositions of magnesium and calcium bis(hydrogenphosphoramidate).[2,3] This paper describes the synthesis and thermal decomposition of magnesium phosphoramidate.

Experimental

Materials and Procedure. Potassium hydrogenphosphoramidate was prepared by the method described in a textbook.[4] About 0.1 mol of the phosphoramidate was dissolved in 100 cm^3 of water. Magnesium chloride hexahydrate was dissolved in 100 cm^3 of water by 0.1 mol. The magnesium chloride solution was added slowly to the phosphoramidate solution below 5 °C to prevent the hydrolysis of the latter. The resulting mixture was stirred for about 15 min. The pH of the solution was kept at 9.0—9.5 with aqueous ammonia during the treatment. A white precipitate was produced and was filtered off, washed with cooled water, ethanol, and then acetone. The product was dried under 5330 Pa at 20—25 °C for 2 d.

Chemical Analysis. About 0.2 g of the product was dissolved in 20 cm^3 of 6-mol dm^{-3} nitric acid and the solution was heated on a water bath for 1 h. The orthophosphate in the solution was determined to be $Mg_2P_2O_7$ by the gravimetric method.[5] Nitrogen and magnesium in the product were determined by the Kjeldahl method and by the EDTA (disodium dihydrogen ethylenediaminetetraacetate dihydrate) titration technique respectively.

Paper Chromatography and Colorimetry of Phosphates. One-dimensional paper chromatographic separation was run for the separation of the phosphate species in a sample with acidic (for the separation of chain phosphates) and basic (for the separation of ring phosphates) solvents.[6] A sample was dissolved in a 2% EDTA aqueous solution and the pH of the solution was adjusted to about 7 with an aqueous sodium hydroxide solution. The resulting solution was spotted on Toyo No. 51A filter paper (2 by 50 cm). The development was run at 5 °C for 2 d. Phosphates on the chromatogram were extracted with a 0.1-mol dm^{-3} aqueous ammonia and determined colorimetrically by means of the molybdenum-blue method with Lucena-Conde and Prat's reagent.[7]

X-Ray Diffractometry. An X-ray diffraction pattern of a powder sample was taken with nickel-filtered Cu $K\alpha$ radiation by using a Toshiba X-ray diffractometer, ADG-102.

IR Measurement. An IR spectrum of a sample was recorded on a JASCO IR spectrophotometer, model A-3, using a KBr disc method.

DTA and TG. A sample was heated at the heating rate of 5 °C min^{-1} in air and in dried N_2 by using a Cho Balance TRDA$_1$-H-type apparatus.

^{31}P NMR. A sample was dissolved in a 6% EDTA deuterated-water solution. The ^{31}P NMR spectrum of the solution was taken by a JEOL-FX-60-FT-NMR instrument.

Determination of Bound Water. The amount of bound water in a sample was determined by the Karl Fisher method with an MK-AII apparatus made by Kyoto Denshi.

Results and Discussion

Composition of the Product. The yield of the product was about 18 g. Found: P, 12.5; N, 5.7; Mg, 9.8%. Calcd for $MgPO_3NH_2 \cdot 7H_2O$: P, 12.6; N, 5.7; Mg, 9.9%. Accordingly, the product is magnesium phosphoramidate heptahydrate. The product was stable in air at room temperature.

DTA and TG in Air. DTA and TG curves of $MgPO_3NH_2 \cdot 7H_2O$ are shown in Fig. 1. The samples as numbered on Fig. 1 were removed from a furnace, cooled in a silica-gel desiccator, and then subjected to further analysis. The results are presented in Table 1 and Fig. 2. As Table 1 shows, the first large endo-

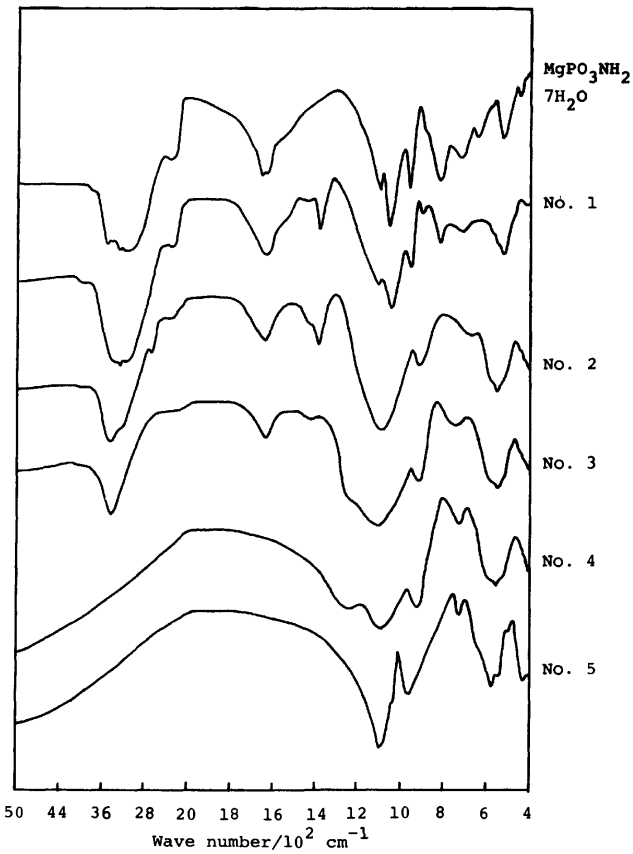

Fig. 2. IR spectra of the thermal decomposition products of $MgPO_3NH_2 \cdot 7H_2O$ in air.

thermic peak, with an accompanying rapid weight loss, seemed to be due to the elimination of bound water, and the endothermic reaction between 120 and 250 °C also included the elimination of ammonia. IR spectra of Nos. 1 and 2 showed the absorption of NH_4^+ at 1400 cm^{-1} and those of a P-O-P or a P-NH-P linkage at 940 and 740 cm^{-1}. Sample No. 1 gave X-ray diffraction peaks of $MgPO_3NH_2 \cdot 7H_2O$. Samples Nos. 2—4 were X-ray diffractometrically amorphous. After the large endothermic peaks, the weights of the samples gradually decreased until about 600 °C. The IR spectra of Nos. 3 and 4 had a large absorption due to a $(PO_3)^{2-}$ group at 1100 cm^{-1}. The absorptions of the two samples at 940 and 720 cm^{-1} seemed to be associated with a P-O-P linkage because, as Table 1 shows, the samples contained only a slight amount of nitrogen or did not contain any nitrogen at all. The two samples also exhibited an absorption at around 1250 cm^{-1}. Table 1 shows that sample No. 3 involves tri- and higher polyphosphates. So the absorption at 1250 cm^{-1} may be caused by the middle-PO_4 group of these polyphosphates. Samples Nos. 4 and 5 were insoluble in water or an aqueous EDTA solution and it was impossible to check the composition of the phosphates in the samples by the paper chromatography. The absorption of No. 4 at 1250 cm^{-1} may be due to a middle-PO_4 group of polyphosphates with chain lengths longer than that of diphosphate. The sample No. 5 did not show the absorption of a middle-PO_4 group and exhibited an X-ray diffraction diagram of $Mg_2P_2O_7$ (ASTM card, No. 8—38). So the exothermic peak at about 670 °C seemed to be due to crystallization of the amorphous phosphates to the diphosphate. According to stoichiometric considerations and the results obtained above, one can write the following thermal decomposition and condensation equations for the product:

$$O\text{-}P(=O)(Mg_{1/2})\text{-}NH_2 + H_2O \longrightarrow O\text{-}P(=O)(Mg_{1/2})\text{-}ONH_4, \quad (1)$$

$$2\ O\text{-}P(=O)(Mg_{1/2})\text{-}ONH_4 \longrightarrow O\text{-}P(=O)(Mg_{1/2})\text{-}O\text{-}P(=O)(Mg_{1/2})\text{-}O + 2NH_3 + H_2O. \quad (2)$$

The above equations show it is unreasonable for tri- and higher polyphosphates to be produced as intermediates of the thermal decomposition products. The following condensation reaction is considered to be difficult to occur at the relatively low temperature range of 100—600 °C; it has not been known to take place in this temperature range:

$$O\text{-}P(=O)(Mg_{1/2})\text{-}O\text{-}P(=O)(Mg_{1/2})\text{-}O + NH_4O\text{-}P(=O)(Mg_{1/2})\text{-}O \longrightarrow O\text{-}P(=O)(Mg_{1/2})\text{-}O\text{-}P(=O)(Mg_{1/2})\text{-}O\text{-}P(=O)(Mg_{1/2})\text{-}O + 1/2Mg(OH)_2 + NH_3. \quad (3)$$

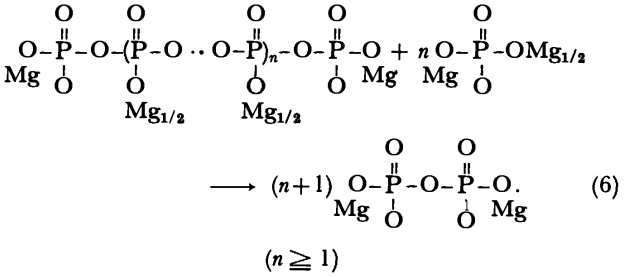
The conflict can be resolved by the consideration that the following disproportionation reaction is taking place in the amorphous thermal decomposition products:

$$2\ O\text{-}P(=O)(Mg_{1/2})\text{-}ONH_4 \longrightarrow Mg_{1/2}O\text{-}P(=O)(NH_4)\text{-}O + O\text{-}P(=O)(Mg_{1/2})\text{-}OMg_{1/2}. \quad (4)$$

The species, $Mg_{1/2}(NH_4)_2PO_4$, is bifunctional for thermal condensation and can produce tri- and higher polyphosphates. As the final thermal decomposition product of $MgPO_3NH_2 \cdot 7H_2O$ showed an X-ray diffraction diagram of magnesium diphosphate and did not show an IR absorption of a $(PO_2)^-$ group, the following overall-thermal decomposition reaction can be written for the phosphoramidate:

$$2MgPO_3NH_2 \cdot 7H_2O \longrightarrow Mg_2P_2O_7 + 2NH_3 + 13H_2O. \quad (5)$$

The experimental final weight loss of the product showed a value very close to the calculated one for this decomposition reaction. The disappearance of polyphosphates with chain lengths longer than that of diphosphate in the thermal product can be explained by the following reorganization or degradation of the amorphous phosphates to diphosphate:



$$\longrightarrow (n+1)\ \text{Mg}\left[\text{O-P(=O)(O)-O-P(=O)(O)-O}\right]\text{Mg} \quad (6)$$

$$(n \geqq 1)$$

According to these results, it is not definitive yet that P-NH_2 linkages thermally decompose to form P-NH-P linkages by the elimination of ammonia. To obtain the data about this point, ^{31}P NMR spectrum of No. 2 was taken, because the thermal reaction seemed active at the temerature range and the sample still contained 3.5% of nitrogen. The sample indicated the ^{31}P NMR peaks of orthophosphate, phosphoramidate, and diphosphate, and did not show any peak of phosphates with an imino group. Therefore, magnesium phosphoramidate-water (1/7) did not decompose to make P-NH-P linkages thermally in air.

Isothermal Reaction at 150 °C. To obtain more detailed data about the thermal decomposition of the phosphoramidate, the isothermal decomposition of the phosphoramidate was carried out in air at 150 °C. This temperature is suitable for the analysis because the thermal reaction of the product was active and the elimination of ammonia from the decomposition product was not so rapid at this temperature. IR spectra of the isothermal decomposition products are presented in Fig. 3. With the passage of heating time, the

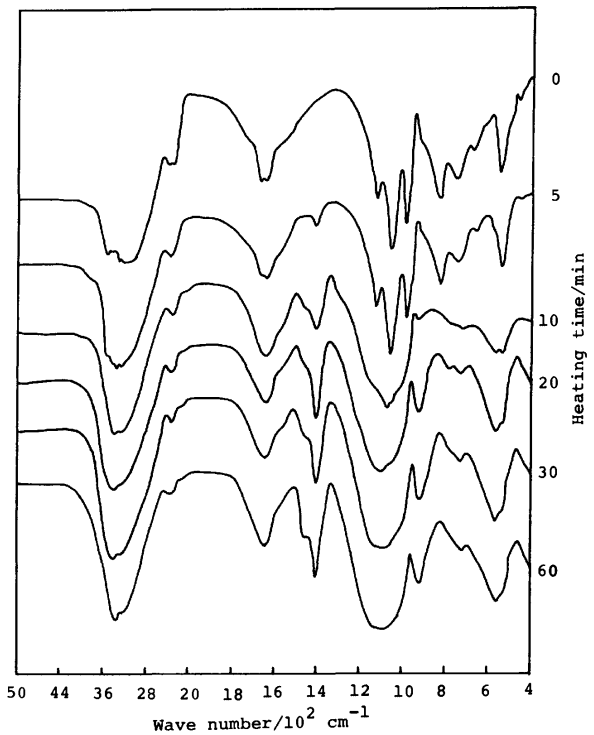


Fig. 3. IR spectra of the thermal decomposition products in air at 150 °C.

absorption of NH_4^+ at 1400 cm^{-1} and of a P-O-P or a P-NH-P linkage at 940 and 740 cm^{-1} appeared and their intensity increased, while the intensity of the absorption of a P-N linkage at 820 cm^{-1} decreased and disappeared after 10 min. These data show that Reactions 1 and 2 are taking place in the isothermal reaction of the phosphoramidate. The result listed in Table 2 well explains the change in the IR spectra of the decomposition products. The separation between orthophosphate and phosphoramidate and between di- and imidodiphosphate was not clear, but the result well agrees with the appearance of a P-O-P or a P-NH-P linkage in the IR spectra of the decomposition products. The above results do not indicate clearly that P-NH_2 linkages thermally decompose to form P-NH-P linkages with the elimination of ammonia at 150 °C. The ^{31}P NMR spectrum of the isothermal decomposition product at the reaction time of 30 min was taken. The sample did not show any peaks other than those of ortho-, monoamido-, and diphosphates. Therefore, magnesium phosphoramidate-water (1/7) may isothermally decompose at 150 °C according to

Table 2. Weight loss of the product and composition of the thermal decomposition products in air at 150 °C

Reaction time/min	Total N/%	N/% as NH_4^+	Water/%	Wt. loss/%	Phosphates/P%		
					Ortho & Amido	Di & Imidodi	Tri
0	5.7	—	51.4	—	100	0.0	0.0
5	5.6	1.2	40.4	8.3	84.1	12.4	3.5
10	5.5	2.2	31.2	19.9	70.8	22.9	6.3
20	5.4	2.3	15.5	37.7	68.7	26.4	4.9
30	5.2	2.5	8.9	44.8	68.2	27.4	4.4
60	4.4	2.8	5.9	48.4	68.1	28.2	3.7
120	3.8	2.7	4.6	49.3	66.1	30.2	3.7

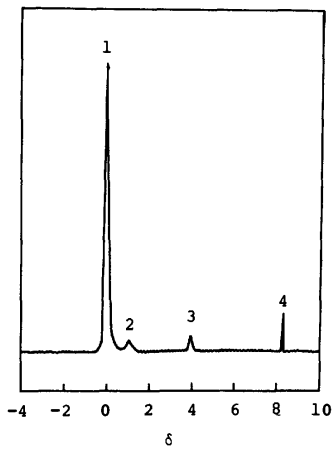

Fig. 4. ^{31}P NMR spectrum of the thermal decomposition product in dried N_2.
1: Orthophosphate, 2: imidodiphosphate, 3: phosphoramidate, 4: diphosphate.[10]

Reactions 1 and 2, and does not decompose to form a P-NH-P linkage. The result in Table 2 also seems to show that Reaction 4 and a condensation reaction of the product made by the disproportionation are taking place at the same time.

DTA and TG in Dried N_2. In dried N_2, $MgPO_3NH_2 \cdot 7H_2O$ gave quite similar DTA and TG curves to those in air and the decomposition products showed the same IR and X-ray diffraction data as those in air. It could be concluded that the product decomposes in dried N_2 according to a process analogous to that in air. A ^{31}P NMR spectrum of the decomposition product which was produced by heating the phosphoramidate by 250 °C by the DTA-TG instrument in dried N_2 is shown in Fig. 4. The small peak at 1.1 ppm was considered to be caused by imidodiphosphate. A small amount of the phosphoramidate may decompose in dried N_2 to make a P-NH-P linkage by the elimination of ammonia according to the following reaction:

$$2\ \mathrm{O{-}\overset{\overset{\mathrm{O}}{\|}}{P}{-}NH_2} \longrightarrow \mathrm{O{-}\overset{\overset{\mathrm{O}}{\|}}{P}{-}NH{-}\overset{\overset{\mathrm{O}}{\|}}{P}{-}O} + NH_3. \qquad (7)$$

Hydrophobic Vitamin B_{12}. III. Incorporation of Hydrophobic Vitamin B_{12} Derivatives into Single-Compartment Vesicles and Their Alkylation in Various Molecular Aggregates†

Yukito MURAKAMI,* Yoshio HISAEDA, and Teruhisa OHNO
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received February 16, 1984)

The incorporation of hydrophobic vitamin B_{12} derivatives into the single-compartment vesicles of *N,N*-didodecyl-N^{α}-[6-(tyimethylammonio)hexanoyl]-L-alaninamide bromide ($N^+C_5Ala2C_{12}$) was found to be primarily concerned with the extent of insolubility of the cobalt complexes in the aqueous bulk phase, while such incorporation into the single-walled vesicles of *N,N*-ditetradecyl-N^{α}-[6-(trimethylammonio)hexanoyl]-L-histidinamide bromide ($N^+C_5His2C_{14}$) was enhanced by the coordination interaction between the cobalt complex and the imidazolyl group of the lipid. In molecular aggregates formed with hexadecyltrimethylammonium bromide, α-[4-(1,1,3,3-tetramethylbutyl)phenyl]-ω-hydroxypoly(oxyethylene), or $N^+C_5Ala2C_{12}$, the alkylation rates of a hydrophobic vitamin B_{12} with 1-bromo-2-methylpropane and methyl 2-methyl-3-bromopropanoate were much enhanced relative to those in methanol. In the $N^+C_5Ala2C_{12}$ vesicle, a two-step mechanism was observed for the alkylation with the latter reagent. The possible origin of such rate enhancement was discussed.

It is of great interest to evaluate the microenvironmental effects on reactions of vitamin B_{12} in order to simulate the functions of apoproteins concerned in biological systems. Such enzymatic microenvironments for vitamin B_{12} seem to be concerned with the extents of integrated mode of hydrogen-bonding, hydrophobic, and other weak interactions effective in the active sites of enzymes. On the other hand, the physicochemical properties of hydrophobic vitamin B_{12} are subjected to change by the nature of reaction media as reported previously.[1,2] On the basis of the above viewpoints, the association behavior between micelles and the base-on and base-off methylcobalamin,[3] the interactions of vitamin B_{12a} with cysteine and *N*-alkanoylcysteines,[4] the formation of glycine, imidazole, and azide adducts of vitamin B_{12a},[5] and the methyl transfer reaction between methylcobalamin and mercuric acetate[6] have been investigated in aqueous and/or reversed micellar phases. The extents of these interactions and reactions have been discussed in connection with microenvironmental properties of the reaction sites concerned.

We have reported previously that amphiphiles involving an amino acid residue interposed between a polar head group and an aliphatic double-chain segment constitute stable single-compartment vesicles in aqueous media due to formation of the hydrogen-belt domain in the intramembrane region.[7] In this regard, these stable single-compartment vesicles have been utilized as media for various reactions to mimic the functions of apoproteins.[8] Futhermore, we have investigated the binding behavior of bilayer vesicles, formed with $N^+C_5Ala2C_{12}$, toward a hydrophobic cobalt complex, dicyano(8,12-diethyl-1,2,3,7,13,17,18,19-octamethyltetradehydrocorrinato)cobalt(III), and clarified that the bilayer vesicles may provide two binding sites which are largely different from each other in microenvironmental polarity.[9] Such previous studies prompted us to carry out various reactions of hydrophobic vitamin B_{12} derivatives in single-compartment vesicles of the peptide amphiphiles in order to obtain a clue to understanding microenvironmental effects characteristic of apoproteins. In this work, we investigated incorporation of the hydrophobic vitamin B_{12} derivatives into single-compartment vesicles formed with $N^+C_5Ala2C_{12}$ and $N^+C_5His2C_{14}$ and alkylation of the vitamin B_{12s} analogs in aqueous molecular aggregates as well as in methanol.

Experimental

General Analyses and Measurements. Elemental analyses were performed at the Microanalysis Center of Kyushu University. IR spectra were taken on a JASCO DS-

†Contribution No. 724 from this Department.

403G grating spectrophotometer, while electronic absorption spectra were recorded on a Hitachi 340 or a Hitachi 220A spectrophotometer. pH-Measurements were carried out with a Beckman expandomatic SS-2 pH meter equipped with a Metrohm EA-125 combined electrode after calibration with a combination of appropriate standard aqueous buffers. A JEOL JEM-200B electron microscope, installed at the Research Laboratory for High Voltage Electron Microscopy of Kyushu University, was used for morphological measurements of the aggregates.[7b] Circular dichroism (CD) spectra were recorded on a JASCO J-500C spectropolarimeter.

Materials. Cyanocobalamin was purchased from Nakarai Chemicals and used for its modifications without further purification. Hexadecyltrimethylammonium bromide (CTAB) was purchased from Nakarai Chemicals and recrystallized from ethanol. Sodium dodecyl sulfate (SDS) of Nakarai Chemicals and α-[4-(1,1,3,3-tetramethylbutyl)phenyl]-ω-hydroxypoly(oxyethylene) (n=9—10) (Triton X-100) of Rohm and Haas were used without further purification. 1-Bromo-2-methylpropane was obtained commercially from Nakarai Chemicals as extra pure grade and fractionally distilled just before use. Methyl 2-methyl-3-bromopropanoate was synthesized from the corresponding carboxylic acid: bp 73.0 °C/2.53×10³ Pa; IR (neat) 1735 cm^{-1} (ester C=O); ^{1}H-NMR ($CDCl_3$, TMS) δ=1.28 (3H, d, CH_3), 2.84 (1H, m, CH), 3.47 (2H, dd, CH_2) and 3.66 (3H, s, $COOCH_3$). These alkyl bromides were confirmed to be sufficiently pure by GLC. *N,N*-Didodecyl-*N*$^{\alpha}$-[6-trimethylammonio)hexanoyl]-L-alaninamide bromide ($N^+C_5Ala2C_{12}$) was synthesized according to the method described previously.[7b] *N,N*-Ditetradecyl-*N*$^{\alpha}$-[6-(trimethylammonio)-hexanoyl]-L-histidinamide bromide ($N^+C_5His2C_{14}$) was prepared in a manner similar to that reported previously by utilizing the benzyl group in place of the tosyl as an imidazole-protecting moiety.[8c]

Preparation of heptamethyl dicyanocobyrinate, $(CN)_2$-Cob(III)C$_1$ester, and heptamethyl cobyrinate perchlorate, [Cob(II)C$_1$ester]ClO_4, has been described previously.[1] Heptaethyl dicyanocobyrinate, $(CN)_2$Cob(III)C$_2$ester, heptapropyl dicyanocobyrinate, $(CN)_2$Cob(III)C$_3$ester, and heptabutyl dicyanocobyrinate, $(CN)_2$Cob(III)C$_4$ester, were prepared from cyanocobalamin according to the method of Werthemann *et al.*,[10] adopted for the preparation of $(CN)_2$Cob(III)C$_1$ester, with some modification as typically described below.

Heptapropyl Dicyanocobyrinate, $(CN)_2$Cob(III)C$_3$ester. Cyanocobalamin (500 mg, 0.37 mmol) in 333 ml of dry 1-propanol was mixed with 33 ml of cold conc. sulfuric acid and 167 ml of dry 1-propanol. The solution was deoxygenated by bubbling nitrogen gas through it for 1 h, and heated to 60—62 °C for 250 h in the dark under nitrogen atmosphere.[11] The solution was concentrated to *ca.* 100 ml, diluted with 250 ml of cold water, and quickly neutralized with sodium carbonate. After addition of 2.5 g of potassium cyanide, the reaction mixture was extracted with carbon tetrachloride (70 ml×3) and dichloromethane (70 ml×3). The dichloromethane extract, which contained partially esterified corrins, was used for the above esterification reaction. The carbon tetrachloride extract was evaporated to dryness, and the residue was purified by TLC on silica gel (Kiesel gel 60H) with dichloromethane–methanol (10:1 v/v). The TLC analysis showed the presence of 5 components: A purple one with the highest R_f was collected and dissolved in carbon tetrachloride. This solution was treated with aqueous potassium cyanide and evaporated to dryness to afford a dark purple solid: yield 190 mg (40%); λ_{max} (C_6H_6) 316, 372, 426, 520 sh, 550, and 590 nm; IR (neat) 2130 (C≡N) and 1730 cm^{-1} (ester C=O).

Found: C, 63.38; H, 7.98; N, 6.32. Calcd for $C_{68}H_{101}CoN_6O_{14}$: C, 63.53; H, 7.92; N, 6.54.

Heptaethyl Dicyanocobyrinate. Found: C, 61.31; H, 7.43; N, 6.83. Calcd for $C_{61}H_{87}CoN_6O_{14}$: C, 61.71; H, 7.39; N, 7.08.

Heptabutyl Dicyanocobyrinate. Found: C, 65.19; H, 8.40; N, 5.62. Calcd for $C_{75}H_{115}CoN_6O_{14}$: C, 65.10; H, 8.38; N, 6.07.

Heptapropyl Cobyrinate Perchlorate, [Cob(II)C$_3$ester]ClO_4. This complex was prepared after the method employed for the preparation of [Cob(II)C$_1$ester]ClO_4.[1] Found: C, 59.17; H, 7.70; N, 4.42. Calcd for $C_{66}H_{101}ClCoN_4O_{18}$: C, 59.47; H, 7.64; N, 4.20.

Equilibrium Measurements for Incorporation of $(CN)_2$Cob(III)C$_n$ester into Single-compartment Vesicles. A dichloromethane solution (1.1 ml) containing $N^+C_5Ala2C_{12}$ (1.0×10^{-5} mol) and $(CN)_2$Cob(III)C$_n$ester (n=1,2,3,4; 1.0×10^{-7} mol) was evaporated *in vacuo* to remove the solvent completely, and an aqueous potassium cyanide solution (1 ml, 5.0×10^{-4} mol dm^{-3}) was added to the residue. The resulting mixture was sonicated for 30 s with a probe-type sonicator at 30 W to give a clear solution. An extent of incorporation of a hydrophobic vitamin B_{12} into single-compartment vesicles was examined by gel-filtration chromatography on a column of Sephadex G-50 with an aqueous potassium cyanide solution (5.0×10^{-4} mol dm^{-3}) as an eluant; the bound complex was eluted first in the column void volume. An amount of the incorporated complex was determined by electronic spectroscopy.

Kinetic Measurements. A 3-ml sample of an aqueous buffer (5.00×10^{-3} mol dm^{-3} phosphate–4.75×10^{-2} mol dm^{-3} borate, pH 9.18) containing CTAB (5.0×10^{-3} mol dm^{-3}) was placed in a spectrophotometric cell thermostated at 21.5± 0.1 °C. The sample was deoxygenated by bubbling argon gas through it for 10 min. To this solution were added 10 µl of a methanol solution of [Cob(II)C$_3$ester]ClO_4 (final concentration, *ca.* 2×10^{-5} mol dm^{-3}) and 10 µl of the aqueous buffer containing sodium tetrahydroborate (final concentration, *ca.* 1—2×10^{-4} mol dm^{-3}) under argon atmosphere. The reduction of the complex to the cobalt(I) state took place instantaneously. A methanol solution of an alkyl bromide was injected into the medium containing the cobalt(I) complex under argon atmosphere to initiate the reaction. The mixture was quickly shaken, and the decrease in absorbance at 392 nm, characteristic of Cob(I)C$_3$ester, was monitored. In all kinetic runs, an alkyl bromide was used in excess to assure the pseudo-first-order conditions and clear isosbestic points were observed along the progress of conversion of the cobalt(I) complex to the corresponding alkylated complex. All the kinetic runs under the pseudo-first-order conditions provided linear correlations for ln (OD_t-OD_∞) *vs.* time, and the slopes (pseudo-first-order rate constants) were divided by the initial concentrations of alkyl bromides to give the corresponding second-order rate constants. The resulting alkylated complexes were confirmed by means of identification of their photolysis products obtained under aerobic conditions. The kinetic measurements in aqueous single-compartment vesicles were carried out as follows: an amphiphile (2.0×10^{-3} mol dm^{-3}) dispersed in the aqueous buffer was sonicated for 1 min with a probe-type sonicator at 30 W; [Cob(II)C$_3$ester]-ClO_4, sodium tetrahydroborate, and an alkyl halide were added to the resulting clear vesicle solution in a manner as stated above.

Results and Discussion

Incorporation of Hydrophobic Vitamin B_{12} into Single-compartment Vesicles. As shown in Table 1, the hydrophobic vitamin B_{12} derivatives, $(CN)_2$Cob(III)C$_n$ester, are readily incorporated into the $N^+C_5Ala2C_{12}$ vesicle when the n-value of C$_n$ is equal to 2 or larger.

Table 1. Incorporation of hydrophobic vitamin B_{12} derivatives into single-compartment vesicles[a]

Vesicle[b]	Complex[c]	Incorporated amount,[d] mol
$N^+C_5Ala2C_{12}$	$(CN)_2Cob(III)C_1ester$	0
$N^+C_5Ala2C_{12}$	$(CN)_2Cob(III)C_2ester$	2.4×10^{-7}
$N^+C_5Ala2C_{12}$	$(CN)_2Cob(III)C_3ester$	5.0×10^{-7}
$N^+C_5Ala2C_{12}$	$(CN)_2Cob(III)C_4ester$	5.0×10^{-7}
$N^+C_5His2C_{14}$	$[Cob(II)C_1ester]ClO_4$[e]	4.5×10^{-7}

a) Incorporation was examined by gel-filtration chromatography on a column (ϕ0.9×21 cm) of Sephadex G-50 with aqueous KCN solution (5×10^{-4} mol dm^{-3}) as an eluant. b) Quantity used, 1.0×10^{-5} mol. c) Qunatity used, 5.0×10^{-7} mol. d) Incorporated quantity was determined by electronic spectroscopy. e) Aqueous $NaClO_4$ solution (5×10^{-4} mol dm^{-3}) was used as an eluant.

$(CN)_2Cob(III)C_1ester$ is slightly soluble in water (*ca.* 10^{-4} mol dm^{-3}), but $(CN)_2Cob(III)C_3ester$ and $(CN)_2Cob(III)C_4ester$ are almost insoluble. Thus, the partitioning trend of $(CN)_2Cob(III)C_nester$ to the membrane phase is subjected to change by the hydrophobicity of the ester groups placed in the peripheral positions of the corrinoid skeleton. On the other hand, when a membrane-forming amphiphile involves a functional group capable of coordinating to the cobalt complex, such a coordination effect acts to enhance the incorporation of $[Cob(II)C_1ester]ClO_4$ having some limited solubility in water (*ca.* 10^{-3} mol dm^{-3}); this cobalt complex is largely incorporated into the $N^+C_5His2C_{14}$ vesicle (Table 1). The stability constant (K) for the coordination of the imidazolyl moiety of $N^+C_5His2C_{14}$ to the nuclear cobalt of $[Cob(II)C_1ester]ClO_4$ at one of its axial sites was measured in dichloromethane at 26.5 °C by the method described previously:[1] $\log K=5.5$. Consequently, the incorporation of $[Cob(II)C_1ester]ClO_4$ into the vesicles of $N^+C_5His2C_{14}$ originates in the axial coordination of the amphiphile to the complex. The experimental method for the equilibrium measurements (see Experimental) was not applied to the evaluation of an extent of incorporation of $[Cob(II)C_1ester]ClO_4$ into the $N^+C_5His2C_{14}$ vesicle since the complex was converted into the corresponding cobalt(III) complex during the sonication (see Fig. 1). Alternatively, a methanol solution of $[Cob(II)C_1ester]ClO_4$ was added to the single-compartment vesicles of $N^+C_5His2C_{14}$, and the cobalt(II) complex was confirmed to be bound to the vesicle in the base-on form in the light of our previous study[1] (Fig. 1). This clearly indicates that the imidazolyl moiety of $N^+C_5His2C_{14}$ in the vesicular state coordinates to the nuclear cobalt of $Cob(II)C_1ester$. The microenvironmental polarity for $(CN)_2Cob(III)C_3ester$ was evaluated when the complex was incorporated into the micelles or the vesicle in reference to the α- and γ-bands of the complex measured in various organic media (Table 2 and Fig. 2). The CTAB and Triton X-100 micelles provide a microenvironment comparable to acetonitrile, while the $N^+C_5Ala2C_{12}$ vesicle provides one equivalent to dichloromethane.

The structure of molecular aggregates composed of $N^+C_5Ala2C_{12}$, when $(CN)_2Cob(III)C_3ester$ was incorporated into them, was measured directly by electron

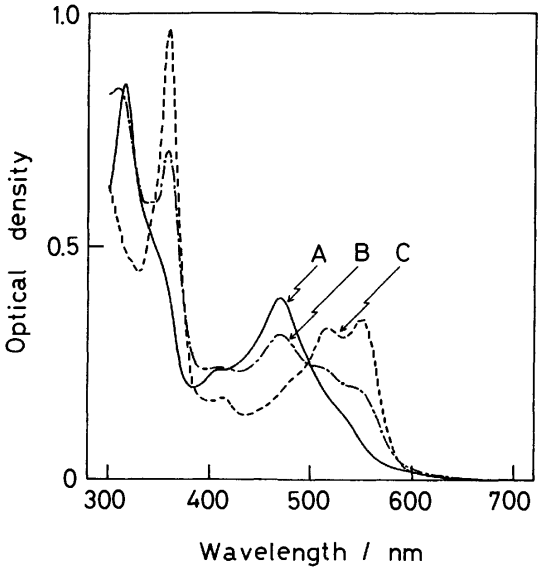

Fig. 1. Electronic spectra of $[Cob(II)C_1ester]ClO_4$ in aqueous phosphate (5.00×10^{-3} mol dm^{-3})-borate (4.75×10^{-2} mol dm^{-3}) buffer (pH 9.18) at 19.6±0.1 °C: A, $[Cob(II)C_1ester]ClO_4$, 3.16×10^{-5} mol dm^{-3}: B, $[Cob(II)C_1ester]ClO_4$, 3.16×10^{-5} mol dm^{-3}; $N^+C_5His2C_{14}$, 2.0×10^{-3} mol dm^{-3} (sonicated for 1 min at 30 W): C, sample B was sonicated for 1 min at 30 W.

Table 2. Characteristic absorption bands of $(CN)_2Cob(III)C_3ester$ in various media

Medium	Solvent parameters		α-Band,[c] nm	γ-Band,[c] nm
	Z[a]	$E_T(30)$[b]		
Benzene	54.0	34.5	590.4	372.0
Dichloromethane	64.2	41.1	588.8	371.0
Acetonitrile	71.3	46.0	587.2	370.2

Triton X-100 micelle	71[d]	46[d]	587.2	370.5
$N^+C_5Ala2C_{12}$ vesicle	64[d]	41[d]	588.8	372.0

a) E. M. Kosower, "An Introduction to Physical Organic Chemistry," John Wiley and Sons, New York (1968), Part 2. b) C. Reichardt, "Solvent Effects in Organic Chemistry," Verlag Chemie, Weinheim (1979). c) Electronic absorption bands characteristic of the corrinoid complex are named α-, β-, and γ-bands by going from lower to higher energy regions. d) Numerical value was evaluated approximately in reference to the correlations given in Fig. 2.

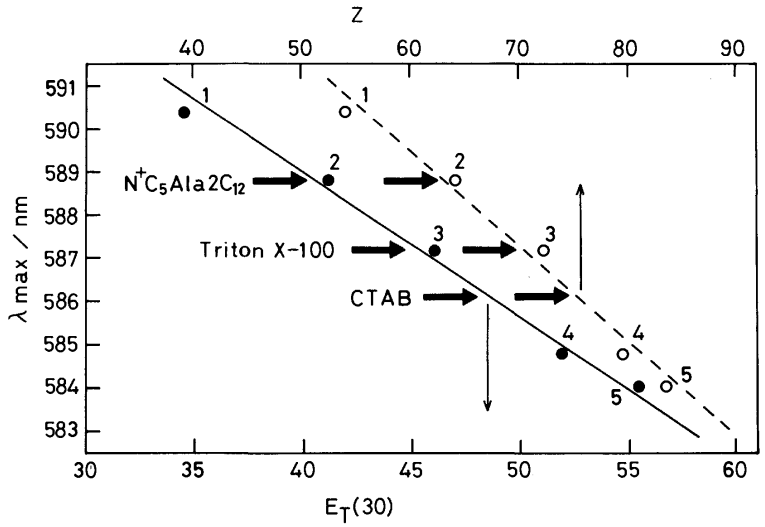

Fig. 2. Correlation of α-band of $(CN)_2$Cob(III)C_3ester with solvent polarity parameters, Z and $E_T(30)$: 1, benzene; 2, dichloromethane; 3, acetonitrile; 4, ethanol; 5, methanol. α-Bands of $(CN)_2$Cob(III)C_3ester in molecular aggregates are shown by arrows.

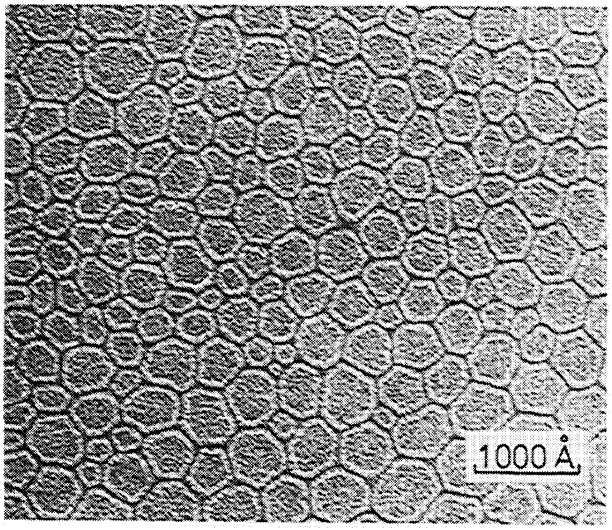

Fig. 3. Electron micrograph of single-compartment vesicles of N^+C_5Ala2C_{12} entrapping $(CN)_2$Cob(III)C_3ester: N^+C_5Ala2C_{12}, 5.0×10^{-3} mol dm^{-3}; $(CN)_2$Cob(III)C_3ester, 1.0×10^{-4} mol dm^{-3}: negatively stained with uranyl acetate, sonicated for 1 min with a probe-type sonicator at 30 W, and allowed to stand for 10 min at 5 °C.

microscopy (Fig. 3). A large number of single-compartment vesicles ranging from 200 through 700 Å in diameter are observable, and the layer thickness is evaluated to be 40—50 Å, approximately twice the length of the hydrophobic double-chain segment. This means that the incorporation of a hydrophobic vitamin B_{12}, does not disturb the aggregate morphology of such peptite lipid.

The CD spectra of $(CN)_2$Cob(III)C_1ester and [Cob(II)C_1ester]ClO_4 are shown in Fig. 4 as typical examples. The spectral pattern of $(CN)_2$Cob(III)C_1ester is comparable to that of cyanocobalamin.[12] [Cob(II)C_1ester]ClO_4 was gradually oxidized upon addition of potassium cyanide under aerobic conditions and finally converted to $(CN)_2$Cob(III)C_1ester as confirmed by CD spectroscopy. In the light of these observations, $(CN)_2$Cob(III)$C_n$ester and [Cob(II)$C_n$ester]ClO_4 prepared in the present study retain the same enantiomeric configurations as the naturally occurring vitamin B_{12}'s even after the hydrophobic modifications.

Alkylation of Hydrophobic Vitamin B_{12} in Various Media. The alkylation reactions of hydrophobic vitamin B_{12} derivatives with alkyl halides in various media were followed by the spectrophotometric method. Figure 5 shows a typical spectral change observed along the progress of alkylation in the CTAB micelle under the conditions: in the aqueous phosphate–borate buffer at pH 9.18 and 21.5±0.1 °C under argon. Pseudo-first-order plots for these reactions gave satisfactory straight lines, and the corresponding second-order rate constants for the reaction of Cob(I)C_3ester with 1-bromo-2-methylpropane and methyl 2-methyl-3-bromopropanoate in various media are summarized in Table 3.

The same kinetic runs were also carried out in the anionic micelles of sodium dodecyl sulfate (SDS). However, Cob(I)C_3ester was not formed instantaneously, different from the above runs. The electrostatic repulsion between the anionic micellar surface and the tetrahydroborate ion does not seem to allow the effective permeation of the latter into the micellar interior and acts to lower the reactivity of the reductant toward Cob(II)C_3ester.

In order to characterize the reactivity of the hydrophobic vitamin B_{12} derivatives toward alkyl halides relative to that of cobalamin in the cobalt(I) state, the second-order rate constants for the reactions of some hydrophobic vitamin B_{12}'s with 1-bromo-2-methylpropane were obtained in the same medium, methanol, as summarized in Table 4. The reactivity of the hydrophobic vitamin B_{12}'s in the alkylation decreases by 1/4- to 1/5-fold as compared with that of cobalamin. The reactivity of corrinoid complexes must be subjected to change by the nature of intramolecular cage, provided

with the peripheral substituents, at the axial sites of the nuclear cobalt(I). Since the axial sites of the hydrophobic vitamin B_{12}'s containing ester groups are apolar as compared with those of cobalamin bearing the amide moieties as well as the nucleotide group, the nucleophilicity of the present hydrophobic complexes is lowered relative to that of the latter natural complex in the light of the solvent effect on the Co^{II}/Co^{I} redox potential observed for Cob(II)C$_1$ester.[2] Furthermore, the transition state of alkylation becomes polar relative to the original state, so that the microenvironmental property of cobalamin provided at the cobalt(I) site would be in favor of such reaction. This environmental effect is reflected on the large stability of Cob(II)-

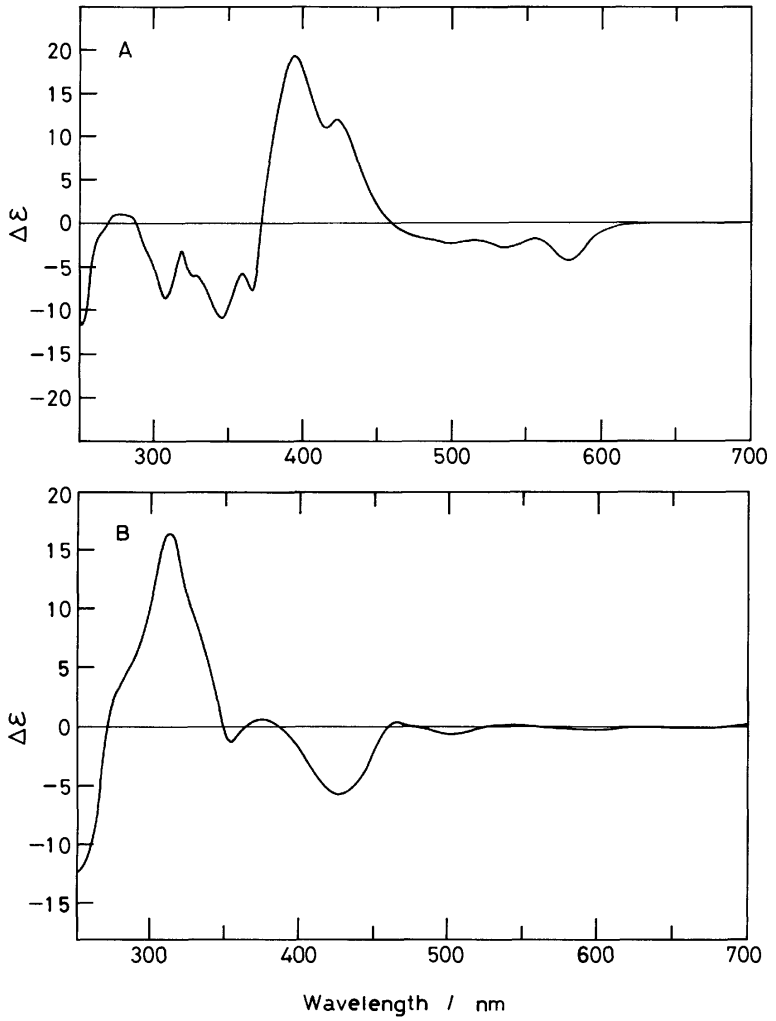

Fig. 4. CD spectra of $(CN)_2$Cob(III)C$_1$ester (A) and [Cob(II)C$_1$ester]-ClO_4 (B) in methanol at 20.0±0.1 °C.

Table 3. Second-order rate constants for the reactions of Cob(I)C$_3$ester with alkyl bromides in various media at 21.5±0.1 °C

Medium[a,b]	k_2/mol^{-1} dm^3 s^{-1}	
	$(CH_3)_2CHCH_2Br$	$(CH_3OOC)(CH_3)CHCH_2Br$
Methanol	0.21±0.03	0.87±0.05
Triton X-100 micelle	5.50±0.13	9.30±0.20
CTAB micelle	12.6±0.3	24.2±0.4
$N^+C_5Ala2C_{12}$ vesicle	10.8±0.2	39.0±0.8[c] (two steps)[d]

a) [Cob(I)C$_3$ester]=2.0×10^{-5} mol dm^{-3}. b) Amphiphile concentrations for molecular aggregates in phosphate (5.00×10^{-3} mol dm^{-3})-borate (4.75×10^{-2} mol dm^{-3}) buffer: Triton X-100,5.0×10^{-3} mol dm^{-3}; CTAB, 5.0×10^{-3} mol dm^{-3}; $N^+C_5Ala2C_{12}$, 2.0×10^{-3} mol dm^{-3}. c) Rate constant for the first step of two-step kinetics. d) Pseudo-first-order rate constants (k_{obsd}) for the two steps were measured by changing the concentration of the alkyl bromide (RX): first step, k_{obsd}=(2.46±0.15)×10^{-2} s^{-1} with [RX]=6.31×10^{-4} mol dm^{-3}; second step, k_{obsd}=(2.41±0.16)×10^{-2} s^{-1} with [RX]=5.32×10^{-3} mol dm^{-3} (k_{obsd} for the first step under this condition was too large to evaluate accurately and the stopped-flow technique was not applicable due to the foam-forming property of $N^+C_5Ala2C_{12}$).

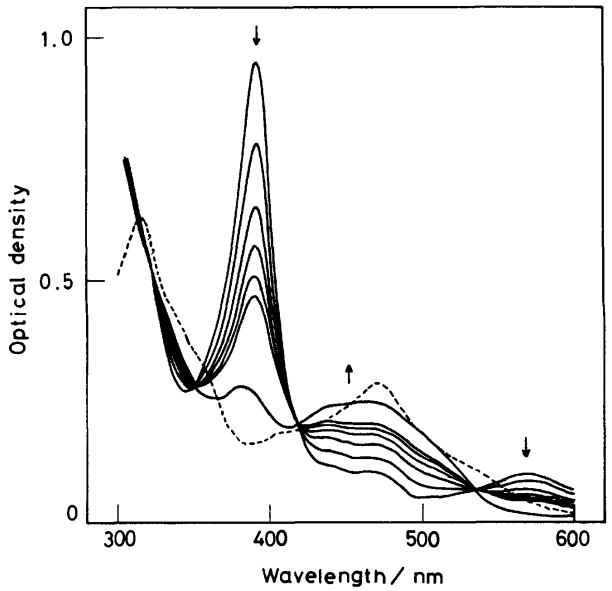

Fig. 5. Spectral change for the reaction of Cob(I)C3ester (2.1×10^{-5} mol dm^{-3}) with 1-bromo-2-methylpropane (2.1×10^{-4} mol dm^{-3}) in the presence of CTAB micelles (5.0×10^{-3} mol dm^{-3}) in aqueous phosphate-borate buffer (pH 9.18) at 21.5±0.1 °C. Trends of spectral change with time are shown by arrows. Broken line represents the spectrum for [Cob(II)C3ester]ClO_4 before reduced with $NaBH_4$.

Table 4. Second-order rate constants for the reactions of corrinoid Co^I complexes with 1-bromo-2-methylpropane[a] in methanol at 21.5±0.1 °C

Corrinoid complex[b]	k_2/mol^{-1} dm^3 s^{-1}
Cob(I)alamin	1.12±0.12
Cob(I)C1ester	0.27±0.08
Cob(I)C3ester	0.21±0.04

a) Concentration range for the alkyl bromide: 1.0×10^{-3}—2.1×10^{-3} mol dm^{-3}. b) Aquacobalamin, [Cob(II)C1ester]ClO_4, and [Cob(II)C3ester]ClO_4 were used as starting materials and reduced with sodium tetrahydroborate (*ca.* 6×10^{-4} mol dm^{-3}) to the corresponding cobalt(I) complexes under argon atmosphere.

$C_n$ester under aerobic conditions, while Cob(II)alamin is readily oxidized under the identical conditions. Even though the dioxygen adduct of Cob(II)$C_n$ester is formed to a limited extent, the oxidation of the hydrophobic vitamin B_{12r} does not take place readily. This is plausibly due to the following effect. In order that the electron transfer from Cob(II)$C_n$ester to dioxygen takes place, the coordinated oxygen molecule needs to be much polarized in the transition state. The apolar microenvironment provided at the cobalt site of Cob(II)$C_n$ester would not be favorable for the formation of such polarized structure.

The second-order rate constants for the reactions in the micellar and vesicular phases are 10—60 times greater than the corresponding values in methanol (Table 3). When methyl 2-methyl-3-bromopropanoate having an electron-withdrawing ester group is used as a substrate, the second-order rate constants are somewhat larger than the corresponding values for the reactions with 1-bromo-2-methylpropane. On the other hand, the rate enhancements in the molecular aggregates, relative to the reactivity in methanol, are much larger for the reaction with 1-bromo-2-methylpropane than those for the reaction with methyl 2-methyl-3-bromopropanoate. This would be due to the difference in hydrophobicity between the two substrates. The former substrate is to be more favorably incorporated into the hydrophobic interior of the molecular aggregates.

When 1-bromo-2-methylpropane is used as substrate, the second-order rate constant measured in the N^+C_5Ala2C_{12} vesicle is comparable to or even slightly less than that in the CTAB micelle, while the rate constant in the nonionic Triton X-100 micelle is smaller than both of the above values. This must originate in the difference in polarizing power, acting on the transition state, between the cationic and nonionic molecular aggregates; *i.e.*, the transition state is more effectively stabilized in the cationic aggregates.

In the single-compartment vesicles of N^+C_5Ala2C_{12}, the reaction behavior between Cob(I)C3ester and methyl 2-methyl-3-bromopropanoate was somewhat different from that in the micelles or in methanol. The reaction proceeded through a two-step mechanism; a faster step was followed by a slow one. The substrate-binding property of single-walled vesicles formed with *N,N*-ditetradecyl-N^{α}-[6-(trimethylammonio)hexanoyl]-L-alaninamide bromide has been investigated previously from both static and dynamic viewpoints, hexyl *p*-nitrophenyl ether being used as a pseudo-substrate. The substrate-binding equilibrium was achieved through a two-step mechanism: the substrate molecules located in the bulk phase are incorporated readily into the surface area as the first step and such incorporated guest molecules penetrate rather slowly from the surface area into the hydrophobic interior of vesicular assembly.[7g] This feature is consistent with the presence of a potential barrier between the surface and interior hydrophobic regions of the vesicular system for translocation of such a substrate. This barrier must be identical with the so-called hydrogen-belt domain located in the intramembrane region which has been identified by the use of dicyano(8,12-diethyl-1,2,3,7,13,17,18,19-octamethyltetradehydrocorrinato)cobalt(III) as a probe.[9] In the light of these previous studies, the two kinetic steps observed for the alkylation with methyl 2-methyl-3-bromopropanoate may be defined as follows: (i) The first-step reaction takes place quite readily in the relatively polar domain near the vesicular surface; (ii) the second-step reaction occurs in the hydrophobic domain after permeation of the substrate into it. Under the experimental conditions for measurements of the first step ([RX]=6.31×10^{-4} mol dm^{-3}, RX being methyl 2-methyl-3-bromopropanoate), the absorbance at 392 nm characteristic of Cob(I)C3ester decayed to about a 40% level of the initial one by following the pseudo-first-order kinetics; a further decay was extremely slow for accurate evaluation of the rate. Under the experimental conditions for measurements of the second step ([RX]=5.32×10^{-3} mol dm^{-3}), the 392 nm absorbance instantaneously decreased to about a 40% level of the initial one, followed by a slow decay in the pseudo-first-order kinetics. This result clearly indicates that the

molar ratio of Cob(I)C_3ester distributing between the relatively polar and apolar domains is approximately 6:4. The second-order rate constant for the reaction of Cob(I)C_3ester with 1-bromo-2-methylpropane in the $N^+C_5Ala2C_{12}$ vesicle is more or less comparable to that measured in the CTAB micelle, while the rate constant for the reaction of the same complex with methyl 2-methyl-3-bromopropanoate in the former vesicle is significantly larger than that in the CTAB micelle. The rate enhancement would originate in the effective entrapment of the latter substrate into the hydrogen-belt domain of the vesicle due to the hydrogen-bonding interaction of the methoxycarbonyl group with the domain.

The net volume occupied by the CTAB micelle is determined on the basis of the partial molar volume of the surfactant monomer in the micellar state; $\bar{V}=0.32-0.37\ dm^3\ mol^{-1}$.[13] The intrinsic volume occupied by the $N^+C_5Ala2C_{12}$ vesicle is assumed to be approximately equal to that by egg phosphatidylcholine; $\bar{V}=0.75\ dm^3\ mol^{-1}$.[14] Thus, the molecular aggregates under the present experimental conditions hold about 1/600 of the total solution volume. Since Cob(I)C_3ester, being insoluble in water, is completely encapsulated in the aggregates, the micro-concentration effect exercised by the molecular aggregates on Cob(I)C_3ester is undoubtedly responsible for the rate enhancement. Since the extents of incorporation of the alkyl bromides were not determined by the gel-filtration chromatography applied to the hydrophobic vitamin B_{12}'s for their chemical instability, a conventional extraction method was employed here to evaluate them;[15] at least 25% of the total amount of the substrates was entrapped into the aggregates. In conclusion, multiple hydrophobic materials can be incorporated into the hydrophobic intramembrane region, the extents being dependent on their hydrophobic properties. The entrapped substances may undergo reactions in the significantly small compartments of molecular aggregates, and the apparent rate enhancement is attained at least by the micro-concentration effect.

The present work was supported in part Grant-in-Aid for Scientific Research No. 58430016 from the Ministry of Education, Science and Culture.

15) Diethyl ether ($E_T(30)=34.6$) was used as an extractant in the present work for technical reasons. $N^+C_5Ala2C_{12}$ in the vesicular state is hardly extracted with diethyl ether, while the present alkyl bromides present in the bulk aqueous phase were readily extracted. The extracted bromides were analyzed quantitatively by GLC. The fraction of the entrapped bromides was evaluated under consideration that those bromides bound to the vesicle are not readily extracted with diethyl ether.

Synthesis, Spectral and Magnetic Properties and Crystal Structures of Alkoxo-oxygen Coordinated Copper(II) Complexes of *N,N'*-Disubstituted Malonamide and Oxamide Derivatives

Takashi Toki, Masahiro Mikuriya,* Hisashi Ōkawa, Ichiro Murase,† and Sigeo Kida
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
†*Laboratory of Chemistry, College of General Education, Kyushu University 01, Ropponmatsu, Chuo-ku, Fukuoka 810*
(Received February 25, 1984)

1:1 Copper(II) complexes with *N,N'*-bis(2-hydroxyethyl)malonamide (abbreviated as H_4maae), MCu(maae) (M=Ca, Sr, Ba), and 2:1 copper(II) complexes with *N,N'*-bis(5-amino-3-hydroxypentyl)malonamide and *N,N'*-bis(5-amino-3-hydroxypentyl)oxamide (abbreviated as H_4madpl and H_4oxdpl, respectively),[Cu_2(madpl)]·$3H_2O$ and [Cu_2(oxdpl)]·$2H_2O$, were prepared and characterized by elemental analyses, infrared and electronic spectra, and magnetic susceptibilities. The 2:1 complexes exhibit a band at 23.3—27.0×10^3 cm^{-1} characteristic of alkoxo-oxygen bridged structure and show a very strong antiferromagnetic interaction, whereas the 1:1 complexes show no such band and their magnetic moments fall in the range of those for ordinary mononuclear copper(II) complexes. The crystal structures of [Cu_2(madpl)]·$3H_2O$ and BaCu(maae)·$7H_2O$ were determined by the single-crystal X-ray diffraction method. The structure of [Cu_2(madpl)]·$3H_2O$ consists of alkoxo-oxygen bridged binuclear molecules, where $madpl^{4-}$ functions as a sexadentate binucleating ligand with an $N_2O_2N_2$ donor set. In BaCu(maae)·$7H_2O$, the basic unit is a hetero-metal tetranuclear entity $(H_2O)_2${Ba$(H_2O)_4$Cu(maae)}$_2$ in which the two Ba^{2+} are linked sharing two H_2O and are also bound to alkoxo oxygens of $Cu(maae)^{2-}$. On the basis of the crystal structures, their spectral properties were discussed.

Although a great number of binuclear copper(II) complexes have been prepared, only few examples containing amide nitrogen coordination are known. Recently, we reported the preparation, crystal structure, spectra and magnetic properties of binuclear copper(II) complexes of amides derived from 3-amino-1-propanol and various amino acids.[1] The deprotonated amide coordination resulted in a marked increase in the planarity of the molecule. The magnetic and spectral properties of these complexes are consistent with the planar structure. As the continuation, in this study, we have prepared new sexadentate binucleating ligands derived from the reaction of 1,5-diamino-3-pentanol and diethyl malonate or diethyl oxalate (abbreviated as H_4madpl and H_4oxdpl, respectively) and isolated their 2:1 copper(II) complexes,[Cu_2(madpl)] (**1**) and [Cu_2(oxdpl)] (**2**), respectively. We have also prepared 1:1 copper(II) complexes with *N,N'*-bis(2-hydroxyethyl)malonamide (abbreviated as H_4maae),[2] MCu(maae) (M=Ca, Sr, Ba) (**3**). These complexes were characterized by spectral and magnetic measurements. The determination of X-ray crystal structures have been carried out for [Cu_2(madpl)]·$3H_2O$ and BaCu(maae)·$7H_2O$. The former complex has been found to have an alkoxo-oxygen bridged binuclear structure as expected. On the other hand, the latter has been revealed to be composed of novel type linearly linked Cu–Ba–Ba–Cu tetranuclear entities.

Experimental

Preparation of the Ligands. 1,5-Diamino-3-pentanol was prepared according to the method reported by Murase *et al.*[3] The preparative methods for H_4maae,[2] H_4madpl, and H_4oxdpl are all similar and exemplified by that for H_4oxdpl.

A 2:1 mixture of 1,5-diamino-3-pentanol and diethyl oxalate in ethanol was refluxed for 2 h. A white precipitate resulted was collected by filtration and washed with ethanol. This was used for synthesis of the complex without further purification.

Preparation of the Complexes. BaCu(maae)·$7H_2O$: To a mixture of copper(II) hydroxide (250 mg), H_4maae (500 mg) and sodium hydroxide (410 mg) in 100 ml of water was added 630 mg of barium chloride dihydrate under nitrogen atmosphere. The resulting reddish purple solution was filtered and allowed to stand overnight at room temperature. Red crystals separated were collected by filtration and dried in an open air. Anal. Found: C, 16.47; H, 4.62; N, 5.56%. Calcd for BaCu(maae)·$7H_2O$: C, 16.38; H, 4.71; N, 5.46%. The crystals lost all of the crystal water in a P_2O_5 desiccator under reduced pressure. Found: C, 21.57; H, 2.76; N, 7.16; Cu, 16.84%. Calcd for BaCu(maae): C, 21.72; H, 2.60; N, 7.24; Cu, 16.42%.

SrCu(maae): This complex was obtained as purple powder in the same way as that of BaCu(maae) except for using strontium chloride hexahydrate in place of barium chloride dihydrate. Found: C, 24.63; H, 3.07; N, 8.20; Cu, 19.12%. Calcd for SrCu(maae): C, 24.92; H, 2.99; N, 8.30; Cu, 18.84%.

CaCu(maae)·$3H_2O$: This complex was obtained as purple powder in the same way as that of BaCu(maae) except for using calcium chloride dihydrate instead of barium chloride dihydrate. The product was dried in a P_2O_5 desiccator under reduced pressure for two days. Found: C, 24.47; H, 4.74; N, 8.17; Cu, 20.50%. Calcd for CaCu(maae)·$3H_2O$: C, 24.45; H, 4.69; N, 8.15; Cu, 20.38%.

[Cu_2(madpl)]·$3H_2O$: To a mixture of copper(II) hydroxide (510 mg) and H_4madpl (800 mg) in 40 ml of water was added 840 mg of sodium hydroxide to give a reddish brown solution.

The solution was filtered and concentrated under reduced pressure to precipitate a red solid. It was recrystallized from ethanol to give red plates. Found: C, 32.45; H, 6.23; N, 11.48%. Calcd for $[Cu_2(madpl)]\cdot 3H_2O$: C, 32.43; H, 6.28; N, 11.64%.

$[Cu_2(oxdpl)]\cdot 2H_2O$: This complex was obtained as brown powder in a similar manner to the above but could not be recrystallized because of its low solubility in conventional solvents. Found: C, 31.99; H, 5.77; N, 12.39; Cu, 28.16%. Calcd for $[Cu_2(oxdpl)]\cdot 2H_2O$: C, 32.07; H, 5.83; N, 12.47; Cu, 28.28%.

Measurements. Cabon, hydrogen, and nitrogen analyses were carried out at the Service Center of Elemental Analysis, Kyushu University. Copper analysis was carried out with a Shimadzu Atomic Absorption-Flame Spectrophotometer Model AA-610. Infrared spectra were measured with a Hitachi Grating Infrared Spectrophotometer Model 215 in the region 4000—650 cm^{-1} on a KBr disk. Electronic spectra were measured with a Shimadzu Multipurpose Spectrophotometer Model MSP-5000 at room temperature. Magnetic susceptibility was measured by the Faraday method over the temperature range 80—300 K. The apparatus was calibrated by the use of $[Ni(en)_3]S_2O_3$. The susceptibilities were corrected for the diamagnetism of the constituent atoms by the use of Pascal's constants. Effective magnetic moments were calculated from the equation, $\mu_{eff}=2.828\sqrt{(\chi_A-N\alpha)T}$, where χ_A is the atomic magnetic susceptibility and $N\alpha$ is the

temperature-independent paramagnetism in cgs emu.

X-Ray Crystal Structure Analysis. *[Cu₂(madpl)]·3H₂O*: A crystal with dimensions of 0.37×0.31×0.09 mm was used for the X-ray analysis. The unit-cell parameters and intensities were measured on a Rigaku AFC-5 automated four-circle diffractometer with graphite-monochromated Mo *Kα* radiation (λ=0.71069 Å) at 19±1°C. Intensity data were collected by the 2θ-ω scan technique with a scan rate of 8°min^{-1}. For weak reflections the peak scan was repeated up to four times depending on their intensities. Three standard reflections were monitored after every 100 reflections, and their intensities showed a good stability. The intensity data were corrected for the Lorentz and the polarization effects, but not for absorption.

Crystal Data: $Cu_2(C_{13}H_{24}N_4O_4)\cdot 3H_2O$, F. W.=481.5, monoclinic, space group $P2_1/n$, a=22.613(21), b=8.890(7), c=9.496(5) Å, β=93.00(8)°, D_m=1.66, D_c=1.68 g cm^{-3}, Z=4.

A total of 4200 reflections with $2\theta \leq 52°$ were collected, of

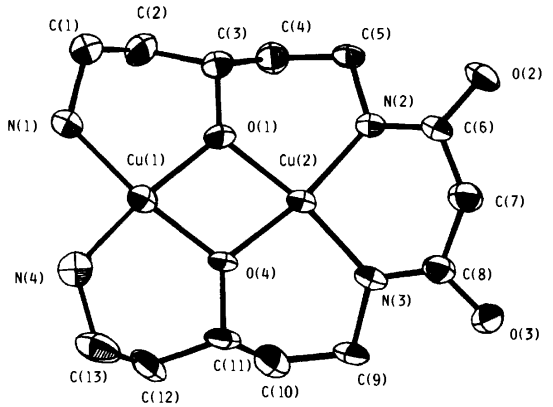

Fig. 1. Molecular structure of $[Cu_2(madpl)]\cdot 3H_2O$ with thermal ellipsoids (50% probability level). Water molecules are not shown.

which independent 2596 reflections had $|F_o| \geq 3\sigma(F_o)$ and were employed in the solution and refinement of the structure.

The structure was solved by the heavy-atom method. Refinement was carried out by the block-diagonal least-squares method. All the hydrogen atoms except for those of the water molecules were located from the difference Fourier map and included in the refinement. The final R value was 0.067.

BaCu(maae)·7H₂O: Data collection from a crystal of dimensions of 0.40×0.30×0.28 mm was carried out in a fashion similar to that employed for $Cu_2(madpl)\cdot 3H_2O$.

Crystal Data: $BaCu(C_7H_{10}N_2O_4)\cdot 7H_2O$, F. W.=513.2, triclinic space group $P\bar{1}$, a=9.642(3), b=11.374(3), c=8.761(3) Å, α=96.93(2), β=112.27(2), γ=102.83(2)°, D_m=2.02, D_c=2.02 g cm^{-3}, Z=2.

A total of 3746 reflections with $2\theta \leq 52°$ were collected, of which independent 3184 reflections had $|F_o| \geq 3\sigma(F_o)$ and were used in the solution and refinement of the structure. The structure was solved by the heavy-atom method and refined by the block-diagonal least-squares method. All the hydrogen atoms except for those bound to the water oxygen atoms, OW(2), OW(3), OW(4), and OW(5), were located from the difference Fourier map and included in the refinement. The final R value was 0.080.

All the calculations were carried out on the FACOM M-200 computer in the Computer Center of Kyushu University by the use of a local version[4] of the UNICS-III and the ORTEP programs. The final positional and thermal parameters with their estimated standard deviations are given in Table 1. The coordinates and isotropic temperature factors of the hydrogen atoms, the anisotropic thermal parameters of the nonhydrogen atoms, and the F_o-F_c tables have been deposited as a Document No. 8428 at the Office of the Editor.

Results and Discussion

Description of the Structure. *[Cu_2(madpl)]·3H_2O*: The crystal consists of alkoxo-oxygen bridged binuclear molecules, [Cu_2(madpl)], and crystal water. A perspective drawing of the binuclear molecule and the numbering system are illustrated in Fig. 1. Bond lengths and angles are listed in Table 2.

The two copper atoms, Cu(1) and Cu(2), are bridged by two alkoxo-oxygen atoms of madpl, O(1) and O(4). The N_2O_2 donor sets are planar and Cu(1) and Cu(2) deviate from the relevant N_2O_2 planes only by 0.081 and 0.018 Å, respectively. The dihedral angle of the planes is 7.4°. The Cu–O bond lengths (1.910—1.940 Å) and the Cu–N (amine) bond lengths (1.978(8) and 1.990(8) Å) are normal for in-plane coordination.[5-7] The Cu–N (amide) distances (1.930(7) and 1.940(6) Å) are substantially shorter than the Cu–N (amine) distances and fall in the range of those of deprotonated amide complexes (1.89—1.99 Å, average 1.92 Å).[8]

In the madpl moiety, the C–N bond lengths of the amide bonds (1.306(11) and 1.292(11) Å) are shorter than the other C–N bond distances (1.469—1.511 Å) as found in many copper(II) complexes with deprotonated amides.[8] The madpl ligand forms five six-membered chelate rings with two copper atoms. All these chelate rings assume a boat conformation (Table 3). The bonds attached to the bridging oxygen atom are almost coplanar (sums of the bond angles subtended at O(1) and O(3) are 358.3 and 357.5°, respectively).

The water molecules are located in the vicinity of

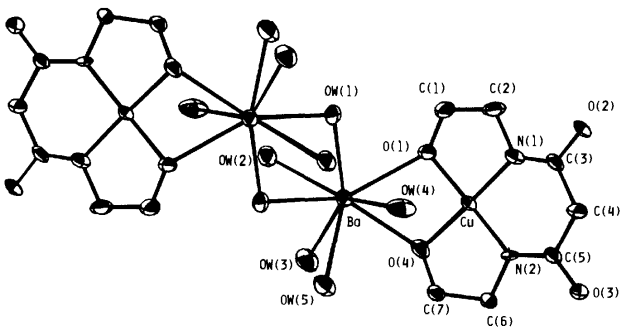

Fig. 2. A perspective view of $BaCu(maae)\cdot 7H_2O$ with thermal ellipsoids (50% probability level).

the amino and carbonyl groups of the madpl ligand by hydrogen bonding (Table 2) and do not coordinate to the copper atoms.

$BaCu(maae)\cdot 7H_2O$: The molecular structure of $BaCu(maae)\cdot 7H_2O$ is shown in Fig. 2. The unit cell contains two $BaCu(maae)\cdot 5H_2O$ units and crystal water molecules. Two water molecules intervene between two barium atoms to form a Cu-Ba-Ba-Cu tetranuclear entity as shown in Fig. 2. This unit is located at the crystallographic inversion center.

Each copper atom is coordinated by two alkoxo-oxygen and two amide nitrogen atoms in a square-planar geometry. These donor atoms are almost coplanar with the largest deviation of 0.042 Å, and the copper atom deviates from this plane by 0.001 Å. The Cu-O bond lengths (1.918(11) and 1.955(14) Å) fall in the range of those of the alkoxo-oxygen bridged binuclear copper(II) complexes.[1,5-7] The Cu-N (1.943(17) and 1.923(13) Å), C=O (1.289(24) and 1.265(20) Å) and C-N 1.254(20) and 1.292(20) Å) distances of the amide bonds are normal for the bond lengths of copper(II) complexes with deprotonated amides.[8] In the IR spectrum, the amide I (at≈1630 cm^{-1}) and amide II[9] (at≈1560 cm^{-1}) bands of the H_4maae are replaced by the band at≈1595 cm^{-1} on coordination. This is in accord with the general rule for the deprotonated amide coordination.[1]

The six-membered Cu-N(1)-C(3)-C(4)-C(5)-N(2) chelate ring is planar, the maximum deviation from the least-squares plane being 0.044 Å. The two five-membered Cu-O(1)-C(1)-C(2)-N(1) and Cu-O(4)-C(7)-C(6)-N(2) chelate rings assume a gauche conformation as is usually observed for saturated five-membered chelate rings.

The coordination around the barium atom is a distorted square antiprism with two alkoxo-oxygen atoms from the maae ligand and six water oxygen atoms. The barium-oxygen distances vary from 2.741 to 2.960 Å. These values are in the normal range for an eight-coordinated barium ion.[10] The Ba-O(1) and Ba-O(4) bond lengths are substantially shorter than the Ba-O (water oxygen) distances. The barium atom is not in the coordination plane of Cu(maae), the deviation from the O(1)-O(4)-N(1)-N(2) plane being 1.37 Å (Table 3). The geometries around the alkoxo-oxygen atoms considerably deviate from planar arrangement (sums of the bond angles subtended at O(1) and O(4) are 340.3 and 331.1 °, respectively).

Electronic Spectra. Some examples of the electronic spectra in nujol mull are shown in Fig. 3. The band maxima are given in Table 4.

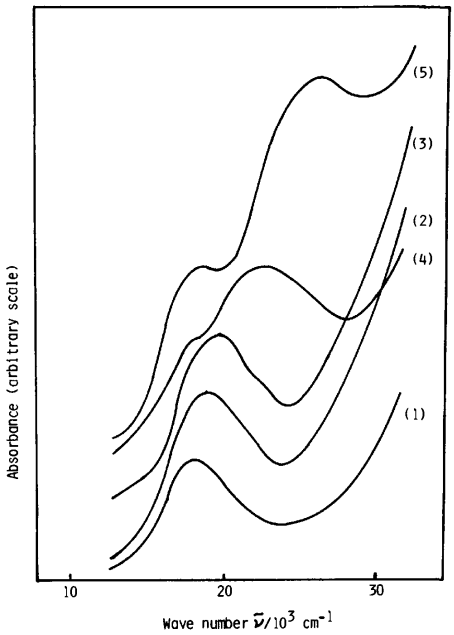

Fig. 3. Electronic spectra of (1) $CaCu(maae)\cdot 3H_2O$, (2) SrCu(maae), (3) BaCu(maae), (4) $[Cu_2(oxdpl)]\cdot 2H_2O$, and (5) $[Cu_2(madpl)]\cdot 3H_2O$ in nujol mull.

Table 4. Spectral data

Complex	Nujol mull spectra $\tilde{\nu}_{max}/10^3$ cm^{-1}

$CaCu(maae)\cdot 3H_2O$	18.5	

a) Absorption spectra in aqueous solution($\tilde{\nu}_{max}/10^3$ cm^{-1} (ε)). b) sh=shoulder.

All the complexes show a band assignable to d-d transitions at 18.5—19.8×10^3 cm^{-1}. The relatively high values of $\tilde{\nu}_{max}$ considered from the N_2O_2 coordination environment may be attributed to the square-planar coordination free from the axial perturbation.[1] More intense bands were observed at 27.0×10^3 and 23.3×10^3 cm^{-1} for $[Cu_2(madpl)]\cdot 3H_2O$ and $[Cu_2(oxdpl)]\cdot 2H_2O$, respectively. On the other hand, in the MCu(maae) complexes, no such bands were observed in this region. It is known that alkoxo-oxygen bridged binuclear copper(II) complexes always show an absorption at 22—29×10^3 cm^{-1}. This band is characteristic of alkoxo-oxygen bridged structure and may be assigned to $p_\pi(O)\rightarrow d(Cu)$ charge transfer transition.[11-13] The absence and presence of the characteristic CT band in the present complexes are understandable in terms of their bonding mode of the bridging oxygen atoms. The X-ray structure analyses of $[Cu_2(madpl)]\cdot 3H_2O$ and $BaCu(maae)\cdot$

Table 5. Magnetic data

Complex	μ_{eff}/B.M. (T/K)	θ/K	$2J$/cm^{-1} [a]	$N\alpha\times10^6$/cgs emu	P
$[Cu_2(madpl)]\cdot3H_2O$	0.36 (293)		−1075	27	0.017
$[Cu_2(oxdpl)]\cdot2H_2O$	0.55 (298)		−855	60	0.020
BaCu(maae)	1.71 (291)	−5			
SrCu(maae)	1.75 (288)	−5			
$CaCu(maae)\cdot3H_2O$	1.83 (295)	−12			

a) For all the complexes g=2.10 was assumed.

$7H_2O$ show that both complexes have alkoxo-oxygen bridged structures, but the two structures differ in their bridging mode: in $[Cu_2(madpl)]\cdot3H_2O$ the bonds attached to the bridging oxygen are almost coplanar as found for alkoxo-oxygen bridged binuclear copper(II) complexes so far reported,[1,5-7] whereas in BaCu(maae)·$7H_2O$ the geometry around the alkoxo-oxygen atom considerably deviates from planar arrangement. This fact suggests that a planar structure of the bridging oxygen may be responsible for the appearence of the characteristic band. Kida *et al.* interpreted the $p_\pi(O)\rightarrow$ d(Cu) charge transfer band in the visible region in the following way.[12] Usually the nonbonding orbital on the alkoxo-oxygen atom should be regarded to be sp^3 hybridized orbital rather than a p_z orbital. However, in the case of the bridging oxygen in a planar binuclear-structure, the good planarity of the Cu O Cu bond would

result in a pure p-character of the nonbonding orbital of the alkoxo-oxygen atom. Since optical electronegativity of the nonbonding electrons is dependent on the degree of hybridization of 2s and 2p orbitals, the O→Cu charge transfer band for the planar binuclear-structure would be lower in frequency compared with those of the usual nonplanar alkoxo complexes such as BaCu(maae)·$7H_2O$.

Magnetic Susceptibilities. The magnetic moments of the MCu(maae) complexes are 1.71—1.83 B. M. at room temperature. These complexes obey the Curie-Weiss law, $\chi_A=C/(T-\theta)$, in the temperature range 80—300 K. The Weiss constants, θ, are given in Table 5. The small negative θ values indicate that a weak antiferromagnetic interaction is operative between the copper(II) ions.

The magnetic moments per copper atom of $[Cu_2(madpl)]\cdot3H_2O$ and $[Cu_2(oxdpl)]\cdot2H_2O$ are 0.36 and 0.55 B. M., respectively, at room temperature, indicating a strong antiferromagnetic interaction is operating between the copper (II) ions. The temperature dependence of magnetic susceptibilities for these complexes can be interpreted by the modified Bleaney-Bowers equation[14]

$$\chi_A=\frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1}(1-P)+\frac{0.45P}{T}+N\alpha \quad (1)$$

where χ_A is a susceptibility per copper atom, P is the mole fraction of the mononuclear copper(II) impurity, and other symbols have the usual meanings. The second term in Eq. 1 was added to account for the presence of a small amount of paramagnetic impurity. The parameters, $-2J$, $N\alpha$, and P were evaluated from the best fit of the experimental data to Eq. 1 and are listed in Table 5. It is notable that the $-2J$ values, the energy separation between the spin-singlet ground state and the lowest spin-triplet state, for the present binuclear complexes are very large. Generally an antiferromagnetic spin-exchange interaction between two copper(II) ions becomes stronger when the tetragonal planes of the two copper(II) ions become more coplanar. In $[Cu_2(madpl)]\cdot3H_2O$, the two copper(II) ions and the donating atoms are almost coplanar, and there is no axial coordination which is a factor of depressing the antiferromagnetic interaction. Therefore, the very strong antiferromagnetic interaction observed for the present binuclear copper(II) complexes is attributable to the planar skeleton.[1]

Photochemistry of Dihalogenobis(diamine)chromium(III) Complexes in Methanol

Masanori SAWANO, Hideki YOSHIFUJI, Akira UEHARA,* and Ryokichi TSUCHIYA
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received February 29, 1984)

The photochemical reactions of *trans*- and *cis*-$[CrX_2(AA)_2]X$ in methanol were investigated under the ligand-field band irradiation, where X is Cl^- or Br^- ion and AA is en, pn or tn. In the earlier step of irradiation, only trans-to-cis photoisomerization was observed irrespective of diamines. The process of the photoisomerization was reasonably explained in terms of the bond indices calculated on the basis of VC theory. The quantum yields for dichloro complexes were larger than those for dibromo complexes, and the yields increased in the order of pn<en<tn complexes. The photochemistry of *cis*-$[CrCl_2(pn)_2]Cl$ was also studied and the difference of the photochemical reactions from the thermochemical reactions was discussed.

We have systematically studied the thermal cis-trans isomerization of $[CrX_2(AA)_2]X$ type complexes in a solid phase since ten years ago, where X is Cl^- or Br^- ion and AA is a diamine selected from ethylenediamine (en), *dl*-1,2-propanediamine (pn) and 1,3-propanediamine (tn).[1-4] In these studies, cis-to-trans isomerization was detected in the complexes containing tn which forms six-membered chelate ring with chromium(III) ion, whereas trans-to-cis isomerization was recognized in the complexes containing en or pn which forms five-membered chelate ring. The mechanism of the thermal isomerization was verified to be bond rupture.[1c,4]

The isomerization takes place not only in thermal environment, but also under sunlight. We have actually noticed that the exposure of *trans*-$[CrCl_2(pn)_2]Cl$ to sunlight readily causes trans-to-cis isomerization in a solid state. However, the photochemical reaction is difficult to be traced quantitatively in the solid because the reaction takes place just on the surface of the compound. Therefore, few studies have been devoted to the photochemistry in a solid state.[5]

In recent years, on the other hand, the photochemistries of transition metal complexes have extensively been investigated in solution.[6] Whether photochemical reactions are allowed or forbidden have reasonably been discussed on the basis of the orbital symmetries of reactants, products and intermediates.[7]

In the present study, the isomerization and subsequent reactions of $[CrX_2(AA)_2]X$ type complexes in methanol were investigated under the ligand-field band irradiation, where X is Cl^- or Br^- ion and AA is en, pn, or tn.

Experimental

Preparation of Complexes. *trans*-$[CrCl_2(en)_2]Cl$,[8] *cis*-$[CrCl_2(en)_2]Cl$,[9] *trans*-$[CrCl_2(pn)_2]Cl\cdot 1.5H_2O$,[10] *cis*-$[CrCl_2(pn)_2]Cl$,[11] *cis*- and *trans*-$[CrCl_2(tn)_2]Cl$,[12] *trans*-$[CrBr_2(en)_2]Br$,[13] *cis*-$[CrBr_2(en)_2]Br$,[14] *cis*- and *trans*-$[CrBr_2(pn)_2]Br$,[1b] and *cis*- and *trans*-$[CrBr_2(tn)_2]Br$[2b] were prepared by the known methods partially modified. The crude products were purified by the recrystallization from dry methanol and ether several times.

Isolation of Products during Photochemical Reactions. *fac-*$[CrCl_2(CH_3OH)(pn)_2]Cl\cdot H_2O$ *and cis-*$[CrBr(CH_3OH)(pn)_2]Br_2$: They were isolated during photochemical reaction of *cis*-$[CrCl_2(pn)_2]Cl$ and *cis*-$[CrBr_2(pn)_2]Br$, respectively. The light of 400 nm was irradiated for more than 600 min on the solution (methanol) containing appropriate amounts of *cis*-$[CrCl_2(pn)_2]Cl$ or *cis*-$[CrBr_2(pn)_2]Br$. The resulting solutions were evaporated to about a half of its volume, and thereto an appropriate amount of ether was added to precipitate the desired materials. The precipitates thus obtained were recrystallized from dry methanol–ether (1:1). The products were identified by means of elemental analyses, TLC, UV- and far-IR spectrophotometry, and molar conductivity measurements. Details will be mentioned in the later section.

Found for the former complex: C, 23.57; H, 7.61; N, 15.25%. Calcd for *fac*-$[CrCl_2(CH_3OH)(pn)_2]Cl\cdot H_2O$: C, 23.87; H, 7.34; N, 15.71%. Found for the latter complex: C, 17.61; H, 4.95; N, 11.36; Cr^{3+}, 11.03%. Calcd for *cis*-$[CrBr(CH_3OH)(pn)_2]Br_2$: C, 17.81; H, 5.12; N, 11.87; Cr^{3+}, 11.02%.

Preparation of Materials Used as Actinometer. Potassium tris(oxalato)ferrate(III), $K_3[Fe(C_2O_4)_3]$ was prepared by the literature method,[15] and Reinecke's salt, $K[Cr(NCS)_4(NH_3)_2]$ was derived from the corresponding ammonium salt[16] by metathesis.

Measurements. The apparatus used for the photochemical reactions was the lamp house (Model UI-501C) by Ushio Denki Co., Ltd. The light source was a 500 W Ushio short arc xenon lamp (Model UXL-500D-O). The monochromatized beams of 400, 530, and 580 nm were obtained with Toshiba interference filters, KL-40, KL-53 and KL-58, respectively.

The sample solution for photochemical reactions was prepared by dissolving either one of the complexes in absolute methanol. The solution was irradiated in a thermostated spectrophotometric cell of 10 cm length with a continuous mechanical stirring. A part of the beam for irradiation to the sample was simultaneously reflected by quartz plate and introduced into the cell setting the actinometer. The wavelengths used for irradiation were 400 and 580 nm for trans-complexes and 400 and 530 nm for cis-complexes. As the actinometer potassium tris(oxalato)ferrate(III)[17] was used for 400 nm, and Reinecke's salt, for 530 and 580 nm.[18] The temperature applied were 22 and 32 °C. The change in absorbances of the sample solution was measured at each relevant wavelength and the extents of photoconversion were determined. They were corrected by measuring the dark reaction under the same conditions as those for the sample solution.

The photochemical products were identified by measuring electronic spectra, far-IR spectra and molar conductivities, and by means of TLC and thermal analyses. The instruments used for the measurement of spectra were a JASCO UVIDEC-505 UV/VIS recording digital spectrophotometer and a JASCO Model IR-F far infrared spectrophotometer. The measurement of molar conductivities was carried out with a Yokogawa Universal Bridge BV-Z-12A. The plates used for TLC were those of silica gel G 250 made by Merck Ltd. Thermal analyses were performed with a MOM Typ-OD-102 Derivatograph and with a Chyo

Thermobalance.

Results

First, it should be noted for clarification of the following discussion that only trans-to-cis isomerization was detected for all the trans complexes, and no isomerization was found for the cis complexes, but instead the coordination of solvent was recognized.

Photochemical Reactions. trans-*[CrCl$_2$(pn)$_2$]Cl·1.5H$_2$O*: The photochemical behavior of the complex was basically the same irrespective of the irradiation wavelengths (580 and 400 nm) used for excitation. Figure 1 shows the electronic spectral changes with time on 580 nm irradiation in methanol at 22 °C. As seen from the figure, the absorption peaks of the complex shift with time toward those of the corresponding cis complex. Any isosbestic point is not detectable in the spectra. However, the application of TLC to the sample solution after irradiation for about thirty minutes evidenced the presence of *trans-* and *cis-*[$CrCl_2(pn)_2$]Cl. Table 1 summarized the R_f values. The R_f's (0.54 and 0.33) for the sample solution are quite close to those of the reference trans-form (0.54) and cis-form (0.34). Thus, the first photochemical reaction within thirty minutes is trans-to-cis photoisomerization.

Further irradiation brought about subsequent spectral changes, suggesting that a secondary photochemical reaction occurs besides the trans-to-cis isomerization. The secondary photochemical reaction was found to be parallel to the reaction of *cis-*[$CrCl_2(pn)_2$]Cl as described later.

trans-*[CrCl$_2$(en)$_2$]Cl*, trans-*[CrBr$_2$(en)$_2$]Br*, trans-*[CrBr$_2$(pn)$_2$]Br*, trans-*[CrCl$_2$(tn)$_2$]Cl and* trans-*[CrBr$_2$(tn)$_2$]Br*: The photochemical behaviors of the complexes were monitored on 580 and 400 nm irradiations in methanol at 22 and 32 °C. In all cases, the absorption spectra of the trans complexes shifted to those of the corresponding cis complexes. After the irradiation for about thirty minutes, the sample solutions were checked by TLC. Inspection of the R_f values in Table 1 reveals that all the sample solutions contain both trans and cis complexes. Thus, the photochemical reaction within 30 min is trans-to-cis isomerization. Interesting is that the direction of photo-isomerization (trans-to-cis) of the tn complexes is contrast to that of the thermal isomerization (cis-to-trans).

Further irradiation on the solution of *trans-*[$CrBr_2(pn)_2$]Br causes an additional reaction other than iso-

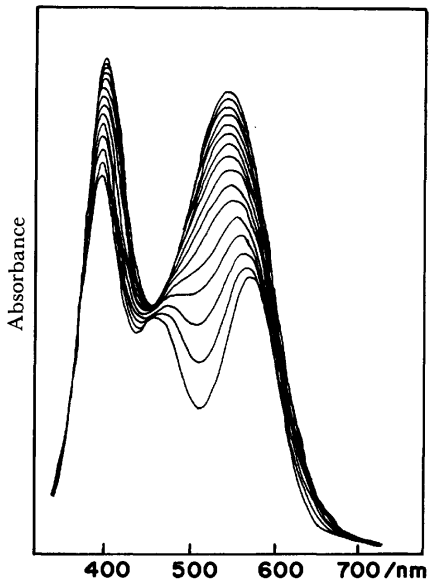

Fig. 1. Electronic spectral changes with time of *trans-*[$CrCl_2(pn)_2$]Cl·1.5H$_2$O in methanol on 580 nm irradiation at 22 °C. The spectra were monitored every ten minutes.

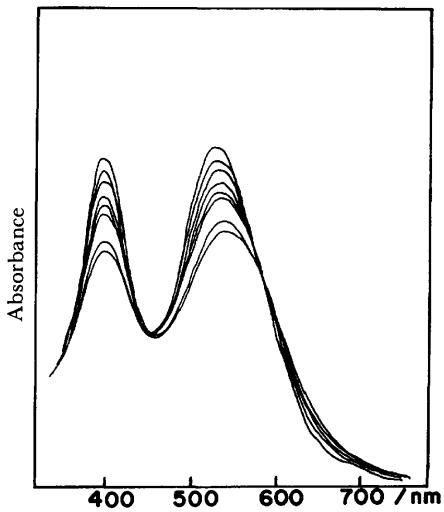

Fig. 2. Electronic spectral changes with time of *cis-*[$CrCl_2(pn)_2$]Cl in methanol on 530 nm irradiation at 22 °C. The spectra were monitored every twenty minutes.

Table 1. R_f Values by thin layer chromatography(TLC)[a]

Starting complex	Sample solution[b]		Reference complex	
			trans-form	*cis*-form
trans-[$CrCl_2(pn)_2$]Cl·1.5H$_2$O	0.54	0.33	0.54	0.34
trans-[$CrCl_2(en)_2$]Cl	0.60	0.41	0.60	0.40
trans-[$CrCl_2(tn)_2$]Cl	0.47	0.17	0.47	0.18
trans-[$CrBr_2(pn)_2$]Br	0.63	0.43	0.63	0.43
trans-[$CrBr_2(en)_2$]Br	0.70	0.34	0.70	0.33
trans-[$CrBr_2(tn)_2$]Br	0.55	0.22	0.55	0.22
cis-[$CrCl_2(pn)_2$]Cl	0.32	0.09[c]		0.34
cis-[$CrBr_2(pn)_2$]Br		0.13[c]		0.32

a) The mixture of 1-butanol, methanol, and acetic acid (7:2:1) was used as the developer. b) The sample solutions were irradiated for about 30 min and checked by TLC. c) The value is that for the secondary photochemical product.

merization, which is a reaction similar to that of *cis*-$[CrBr_2(pn)_2]Br$ as mentioned later.

cis-[CrCl₂(pn)₂]Cl: When the cis complex is irradiated, an isosbestic point appears at 587 nm in the spectra irrespective of the irradiation wavelengths (530 and 400 nm). Figure 2 shows the spectral changes with time on 530 nm irradiation at 22 °C. After appropriate irradiation times, aliquot of the sample solution was taken out to be analyzed by TLC. Two R_f values were obtained: one (0.32) is due to the cis complex and the other (0.09) may come from another product. We then tried to isolate the product as mentioned in Experimental section.

The molar conductivity of the product was 80.78 $\Omega^{-1}cm^{-1}$ in methanol at 25 °C, suggesting that the compound is 1-1 valence type. Far-IR spectra of the product showed the absorption peaks due to Cr–O (530 and 395 cm^{-1}), Cr–N (575 cm^{-1}) and Cr–Cl (490 and 290 cm^{-1}) stretching vibrations. The weight loss (13.9%) observed upon heating the compound at 180 °C corresponds to the evolution of one mole of H_2O (5.1%) plus one mole of CH_3OH (8.9%). These results support that the photoproduct has the formula of $[CrCl_2(CH_3OH)(pn)_2]Cl$. Two isomers are feasible for the configuration of the product: one is facial and the other, meridional with respect to the position of two chloride ions and methanol. The electronic spectrum of the product is illustrated in Fig. 3 together with those of *fac*- and *mer*-$[CrCl_2(H_2O)(dien)]^+$ (dien: diethylenetriamine). Comparison of these spectra readily reveals that the products has *fac*-configuration.

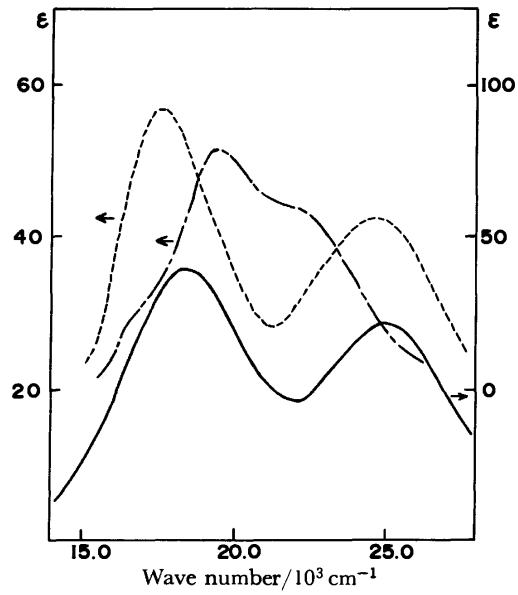

Fig. 3. Electronic spectra of *fac*-$[CrCl_2(CH_3OH)(pn)_2]$-Cl in methanol (——), *fac*-$[CrCl_2(H_2O)(dien)]^+$ in 0.6 M $HClO_4$ (1 M=1 mol dm^{-3}) (----), and *mer*-$[CrCl_2(H_2O)(dien)]^+$ in 1 M $HClO_4$ (——).

cis-[CrBr₂(pn)₂]Br: The spectral changes with time under 530 and 400 nm irradiations gave isosbestic points at 593, 483, and 442 nm for about 200 min. The first photoproduct giving these isosbestic points is assumed to be *fac*-$[CrBr_2(CH_3OH)(pn)_2]^+$, but the complex were unable to be isolated. After the irradiation for more than 600 min, the isosbestic points disappeared because of the formation of the secondary photoproduct. Details of the product are still unkown. We tentatively speculate from the electronic spectrum that the product is *fac*-$[CrBr(CH_3OH)_2(pn)_2]^{2+}$. Attempt to isolate the product was carried out as mentioned in Experimental section. However, the material isolated was always identified to be *cis*-$[CrBr(CH_3OH)(pn)_2]Br_2$ by TLC, elemental analysis, molar conductivity, far-IR spectra and thermal analysis. This is probably because upon crystallization, a unidentate pn contained in *fac*-$[CrBr(CH_3OH)_2(pn)_2]^{2+}$ functions as bidentate accompanied by the expulsion of one mole of CH_3OH from coordination sphere.

Quantum Yields. The photochemical product of each trans complex was the corresponding cis complex in the earlier step of irradiation. The ratios of the starting trans- to the cis-isomers produced were calculated from the absorbances of the resulting solution and those of the reference trans- and cis-isomers as reported previously.[1] The quantum yields were estimated by the use of those of the actinometers. Table 2 summarizes the quantum yields.

Discussion

Photochemistry of trans Complexes. (1) Labilization Mode: Gaussian analyses of the electronic spectra of the trans complexes gave four resolved curves. Figure 4 shows four Gaussian curves obtained for *trans*-$[CrCl_2$-

Table 2. Quantum yields (ϕ) for trans-to-cis isomerization of *trans*-$[CrX_2(AA)_2]X$

Starting complex AA	Irradiation wavelength (nm)	Temp. /°C	Quantum yield (ϕ) X=Cl	Quantum yield (ϕ) X=Br

		32	0.403±0.002	0.169±0.002
	400	22	0.308±0.008	0.0565±0.0004
		32	0.390±0.008	0.0721±0.0003

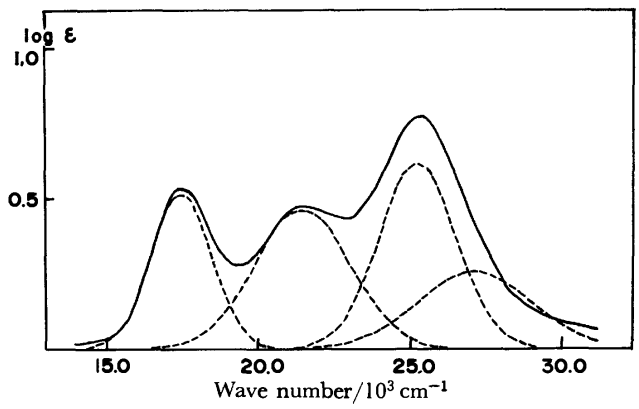

Fig. 4. Electronic spectrum of *trans*-$[CrCl_2(pn)_2]Cl \cdot 1.5H_2O$ with four Gaussian curves.

$(pn)_2]Cl \cdot 1.5H_2O$. These four peaks are assigned to the transition to excited states, $^4E_g{}^a$, $^4B_{2g}$, $^4A_{2g}$ and $^4E_g{}^b$ from the ground state $^4B_{1g}$ in D_{4h} symmetry of the trans complexes; the irradiation at 580 nm populates $^4E_g{}^a$ state, while the irradiation at 400 nm populates $^4A_{2g}$ state.[19]

Adamson *et al.* reported that the quartet excited state is inherently short-lived, but the state is labile enough for reaction to take place because it is in nearly pentagonal pyramid with a lengthened metal-ligand bond.[20]

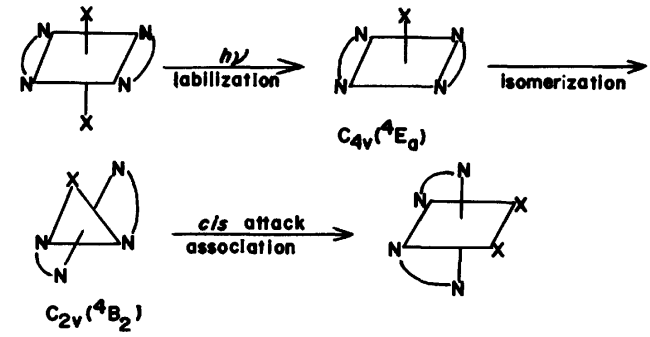
The ratios of quantum yields at 580 and 400 nm are approximately constant for chlorides (*ca.* 1.1) and the bromides (2.4—2.8). This suggests that the photochemical reactions are related to either one of two excited states, $^4E_g{}^a$ and $^4B_{2g}$.

Table 3. Bond indices I* (Cr-L)(μm^{-1}) in the excited state for *trans*-$[CrX_2(AA)_2]X$

State	I*	X=Cl	X=Br
$^4E_g{}^a$	Cr-X	0.90	0.81
	Cr-N	1.21	1.22
$^4B_{2g}$	Cr-X	1.39	1.27
	Cr-N	0.90	0.90

The bond indices I* in the excited $^4E_g{}^a$ and $^4B_{2g}$ states were estimated according to VC theory[21], which are listed in Table 3. It may be deduced from the table that the bond Cr-X is ruptured in $^4E_g{}^a$ state and the bond Cr-N is ruptured in $^4B_{2g}$ state. MO theory gives the same results for the trans complexes.[22] In $^4E_g{}^a$ state, the axial π bond is strengthened and the σ bond is weakened; so the bond Cr-X is relatively activated. On the other hand, in $^4B_{2g}$ state, the equatorial π bond is weakened and σ bond, strengthened, the bond Cr-N being activated. It may therefore be concluded that the bond labilized in the trans complexes is Cr-X rather than Cr-N and the photoactive state which can undergo photoisomerization is $^4E_g{}^a$. The energies of 580 and 400 nm (206 and 299 kJ mol^{-1}) are enough to rupture the coordination bond.

(2) Photochemical Processes: Assuming that the photoactive state is ^4E_a and the reaction proceeds *via* five-coordinated intermediate, the allowed processes can be expressed as follows:



Scheme 1.

The first process is photolabilization expelling a halogeno ligand to form a five-coordinated intermediate of tetragonal pyramid (TP) with C_{4v} symmetry in ^4E_a state. The second process involves isomerization from TP to trigonal bipyramid (TBP) with X^- in equatorial position (C_{2v}) which is more energetically favored than with X^- in axial position (C_{3v}) d_{yz} is empty in the $^4B_2$ state of TBP, making cis attack easy. Therefore, exclusive production of the cis complexes from the corresponding trans complexes is reasonably explained by VC theory using five-coordinated intermediate.[22,23]

(3) Comparison of Quantum Yields: The quantum yields of the trans-dichloro complexes are larger than those of the trans-dibromo complexes as seen in Table 2. This may depend upon the small ionic radius of Cl^- (1.81 Å) compared with that of Br^- (1.96 Å). The yields increase in the following order of the diamines contained, pn<en<tn. The difference may depend upon the isomerization step in Scheme 1. Above all, the intermediate in the tn complexes is more stereomobile than those in the en or pn complexes, since the six-membered chelate ring in the tn complexes can be more easily elongated in the intermediates than the five-membered chelate ring in the en and pn complexes.

(4) Activation Energies: The quantum yields exhibit temperature dependence at two wavelengths at 22 and 32 °C. The apparent activation energies (E_a) were estimated from the plots of log ϕ *vs.* $1/T$, which are listed in Table 4. The values for each complex are roughly the same for both wavelengths. Thus, the photochemical reactions may occur from the same excited state, *i. e.*, the thermally equilibrated excited state (thexi state) $^4E_g{}^\circ$.[20]

Table 4. Apparent activation energies (Ea) for photoisomerization of *trans*-$[CrX_2(AA)_2]X$

AA	Irradiation wavelength(nm)	Ea (kJ mol^{-1})	
		X=Cl	X=Br
pn	580	−12.6±3.8	−10.4±1.7
	400	−22.5±1.7	−19.6±4.4
en	580	11.2±1.4	10.8±1.3
	400	11.9±1.8	13.2±2.5
tn	580	11.3±1.7	16.8±2.0
	400	17.6±3.3	18.2±0.8

The negative activation energies in the pn complexes are explainable by assuming that the electrons excited under irradiation relax to the $^4E_g{}^\circ$ state, but a part of the electrons are excited to the $^4E_g{}^a$ state by thermal energy to be deactivated instantly. Thus, the energy difference between $^4E_g{}^a$ and $^4E_g{}^\circ$ states may be small in the

Table 5. Quantum yields (ϕ) for the photochemical reaction of *cis*-$[CrCl_2(pn)_2]Cl$

Irradiation wavelength (nm)	Temp./°C	Quantum yield (ϕ)
530	22	0.049±0.001
	32	0.052±0.001
400	22	0.051±0.001
	32	0.050±0.001

Table 6. Bond indices I* (Cr–L)(μm^{-1}) in the excited state for *cis*-$[CrX_2(AA)_2]X$

State	I*	X=Cl	X=Br
$^4B_2$	Cr–N_{ax}	1.44	1.44
	Cr–N_{eq}	0.90	0.90
	Cr–X	0.97	0.89
^4E_a	Cr–N_{ax}	0.95	0.97
	Cr–N_{eq}	1.14	1.13
	Cr–X	1.11	1.01

case of the pn complexes. On the other hand, the activation energies in the en and tn complexes are positive because of the energy difference between $^4E_g{}^a$ and $^4E_g{}^\circ$ states being large, and so the energy enough for reaction to occur is thermally supplied.

Photochemistry of cis Complexes. The excited energy levels become higher in the following order: $^4B_2 < {}^4E_a < {}^4E_b < {}^4A_2$ in C_{2v} symmetry for the cis complexes. Since the quantum yields under 530 and 400 nm irradiations are nearly the same as seen in Table 5, the reaction is considered to take place from either one of $^4B_2$ and ^4E_a states.[24] On the basis of VC theory, the bond indices were estimated as listed in Table 6. Comparison of the bond indices reveals that the bond Cr–N_{eq} may be ruptured in the $^4B_2$ state and the bond Cr–N_{ax}, in the ^4E_a state. However, it is not so easy to determine from which excited state the photochemical reaction of *cis*-$[CrX_2(AA)_2]X$ takes place.

Comparison of Photochemical Reaction with Thermochemical Reaction. The mechanisms in the photochemical and thermochemical reactions can not be discussed on the same basis because the photochemical reaction occurs at the excited state, whereas the thermochemical reaction occurs at the ground state. However, the apparent difference was found in the direction of the isomerization. In thermal environment, the complexes containing five-membered chelate diamines such as en and pn undergo trans-to-cis isomerization and the complexes containing six-membered chelate diamine tn undergo cis-to-trans isomerization.[1c] In the ligand-field photochemistry, on the other hand, only trans-to-cis isomerization was observed irrespective of the diamines contained. Accordingly, in the case of $[CrX_2(tn)_2]X$, the direction of the isomerization is mutually reverse between photochemical and thermochemical reactions as follows:

$$trans\text{-}[CrX_2(tn)_2]X \underset{\triangle}{\overset{h\nu}{\rightleftharpoons}} cis\text{-}[CrX_2(tn)_2]X$$

Bromochlorination of Alkenes with Dichlorobromate(1−) Ion. I

Takeshi NEGORO* and Yoshitsugu IKEDA
Department of Chemistry, Faculty of Education, Wakayama University, Fukiage, Wakayama 640
(Received October 12, 1983)

In the reaction of styrene with chlorine, the added bromide ions were mostly incorporated into the adduct, giving a bromo chloro compound. Tetrabutylammonium dichlorobromate(1−) was found to be an efficient bromochlorinating agent. The reactions of 2-butenes and stilbenes were completely *anti* stereospecific.

The reactions of alkenes with *N*-chlorosuccinimide (NCS) in the presence of a bromide ion have been know to proceed by prior formation of bromine chloride (BrCl) and its addition to alkenes.[1] Bromine chloride (BrCl) may presumably be produced from the reaction of molecular chlorine and a bromide ion.[2] On the other hand, quaternary ammonium dichlorobromate(1−) (R_4NBrCl_2) was prepared by treatment of quaternary ammonium bromide with chlorine.[3,4] The structure of R_4NBrCl_2 have been confirmed by IR and other spectral evidence.[4] No chemical reaction with R_4NBrCl_2, however, has been tried although a dichlorobromate(1−) ion has been accepted as an intermediate of the bromochlorination of alkenes.[1,5]

The reaction of alkene with R_4NBrCl_2 may proceed *via* BrCl as a possible intermediate, on assuming the following equilibrium (Scheme 1):

$$R_4N^+Br^- + Cl_2 \rightleftharpoons R_4N^+BrCl_2^- \rightleftharpoons R_4N^+Cl^- + BrCl$$

Scheme 1.

We investigated the reactions of alkenes with chlorine in the presence of tetrabutylammonium bromide and found that this system would be a convenient new bromochlorinating agent. We describe here the details of the reaction products obtained from reaction with styrene, the synthetic utility for bromochlorination, and also the mechanistic aspects of this reaction.

Results and Discussion

A solution of an excess amount of styrene (**1a**) in chloroform was treated at 15 °C with a chloroform solution of chlorine containing various amounts of tetrabutylammonium bromide. The reaction mixture was directly subjected to GLC analysis. The reaction products were a mixture of 1-chloro-2-phenylethylene (**2**), 1,2-dichloro-1-phenylethane (**3**), 2-bromo-1-chloro-1-phenylethane (**4a**), and 1,2-dibromo-1-phenylethane (**5**) with recovery of **1a**.

$$\underset{\mathbf{1a}}{C_6H_5CH{=}CH_2} \xrightarrow{Cl_2/Br^-} C_6H_5CH{=}CHCl\ (\mathbf{2}) + C_6H_5CHClCH_2Cl\ (\mathbf{3}) + C_6H_5CHClCH_2Br\ (\mathbf{4a}) + C_6H_5CHBrCH_2Br\ (\mathbf{5})$$

Scheme 2.

As was expected, the formation of the bromo chloro compound (**4a**) was markedly dependent on the amount of a bromide ion added (Table 1). The amount of **4a** increased proportionally with the increase of bromide ions until the number of bromide ions reached that of chlorine. Further addition of bromide ions moderately decreased the amount of **4a** with the formation of the dibromoalkane (**5**). Consequently, it is apparent that almost all the added bromide ions were incorporated into the adduct up to the equimolar amounts of bromide ions to that of chlorine. It is important to note that the ratios of **2** to **3** were nearly constant regardless of the numbers of bromide ions, and pretty close to that of the addition product of chlorine in the absence of bromide ions (Entry 1, Table 1).[6] In addition, only the bromo chloro adduct (**4a**) was formed in a regiospecific manner without contamination with 1-bromo-2-chloro-1-phenylethane, regardless of the number of bromide ions. The structure of the adduct (**4a**) was identified by comparison of its ^{13}C- and ^1H-NMR spectra with those of an authentic sample prepared from 1,2-dibromo-1-phenylethane and $SnCl_4$.[7]

If the bromochloroalkane (**4a**) was formed by the initial attack of chlorine, giving dichloride (**3**), and

followed by either subsequent attack of a bromide ion on **3** or a 2-chloro-1-phenylethyl cation[8] as an intermediate, the ratios of **2** to **3** would be dependent on the amount of ammonium bromide. The present observations are inconsistent with the above mechanism and strongly suggest that the formation of **4a** is through a quite different mechanism from that of the process giving **2** and **3**. The most plausible process giving **4a** would involve an electrophilic attack of BrCl or dichlorobromate(1−) ion ($BrCl_2^-$) instead of chlorine. In fact, the reaction of BrCl to the same alkene has been found to yield only **4a** in a regiospecific manner.[9]

On the other hand, it is well known that the addition of molecular BrCl to alkene gives bromochloroalkane together with considerable amounts of dibromo and dichloro adducts formed by the attacks of Br_2 and Cl_2, which are in equilibrium with BrCl.[9,10] No dibromo and dichloro adducts were found in the present reaction by using an equimolar mixture of chlorine and bromide ion (Entry 7, Table 1). The results suggest that this reaction involves a different attacking species, not molecular BrCl. A similar result was also observed for the reaction of 3-β-trifluoroacetoxy-5-cholestene with BrCl in the presence of tetraphenylarsonium chloride, which gave the bromo chloro adduct in good yields without the formation of the dibromo and dichloro adducts.[11] In addition, kinetic data for the addition reaction of bromine to alkenes in the presence of a chloride ion have suggested a dichlorobromate(1−) ion as the reacting species.[5] Thus, a dichlorobromate(1−) ion would be the reactant and bromine chloride would not be involved in the process giving **4a**. A dichlorobromate(1−) ion was also suggested to be involved in the bromochlorination of cyclohexene with NCS and a bromide ion.[1]

As mentioned above, an equimolar mixture of chlorine and bromide ions would be a very effective and convenient bromochlorinating agent. Furthermore, several quaternary ammonium dichlorobromates(1−) were found to be easily isolable. The bromochlorinations of alkenes were also tried with the isolated salts. The reaction of styrene (**1a**) with tetrabutylammonium dichlorobromate(1−) (**6**) in chloroform completed within a few minutes at 0 °C, giving **4a** in nearly quantitative yield. Tetramethylammonium and phenyltrimethylammonium dichlorobromates(1−) (**7** and **8**) were also useful for the bromochlorination of alkenes, regardless of their lower solubilities. The reaction of **1a** with **6** was examined in several different solvents with a wide variety of polarities. Reactions in dioxane, carbon tetrachloride, ethyl acetate, dichloromethane, 1,2-dichloroethane, and acetic anhydride gave **4a** in similar yields. Thus, the usual aprotic solvents can be employed as the reaction medium. On the other hand, the reaction of **1a** in acetic acid gave **4a** (65%) and 1-acetoxy-2-bromo-1-phenylethane (**9**, 35%). In methanol, the major product was 2-bromo-1-methoxy-1-phenylethane (**10**, 80%). These results have also been found in the reaction of 1-hexene with BrCl in methanol.[12]

In order to obtain some information on the mechanistic aspects, the reactions of **6** with a variety of alkenes were examined. The results are given in Table 2. In analogy with the reaction of **1a**, reactions with methyl *trans*-cinnamate (**1b**) and vinyl acetate (**1c**) gave the corresponding regiospecific products. Addition to such alkenes as propene (**1d**) and 3-chloropropene (**1e**) gave both Markownikoff and *anti*-Markownikoff adducts. The reason for the formation of *anti*-Markownikoff adducts is uncertain; however, it may be attributed to the combined effects of polar and steric effects. Similar orientation have also been found in the reactions of these alkenes with other bromochlorinating agents.[13,14]

The additions to *cis*- and *trans*-2-butenes (**1f** and **1f'**), cyclohexene (**1g**), and methyl *trans*-cinnamate (**1b**) with **6** gave completely *anti* stereospecific products. Similarly, *anti* stereospecific products, *threo*- and *erythro*-1-bromo-2-chloro-1,2-diphenylethanes (**4h** and **4h'**) were obtained from *cis*- and *trans*-stilbenes (**1h** and **1h'**), respectively. The solvent effect on *anti*

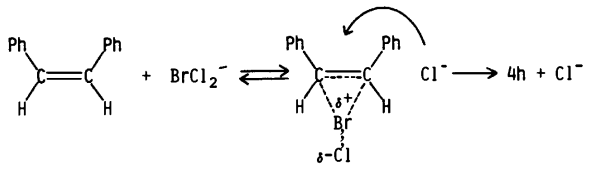
stereospecific addition was examined. The reactions of **1h** in dichloromethane, 1,2-dichloroethane, acetic anhydride, and nitromethane gave *threo* isomer (**4h**) free from *erythro* isomer (**4h'**). In contrast, it has previously been reported that the addition of molecular BrCl to **1h'** in chloroform is *anti* stereospecific, while that of **1h** gives considerable amounts of **4h'**.[9] Furthermore, the stereochemistry of bromine addition to **1h** has been known to be dependent on the solvents.[15] Thus, the mode of the reaction is very different in the additions to **1h** with **6** and with BrCl (and Br_2). Therefore, the present results cannot be explained on the basis of any accepted mechanism for the additions of bromine and bromine chloride.[15,16] The completely *anti* stereospecific addition with **6** can be explained by assuming an $AdEC_2$-type mechanism involving a rate- and product-determining attack of a chloride ion to a three-center bound π complex-type intermediate (**11**)[17], as shown in Scheme 3. A similar mechanism has been suggested for the additions of Br_3^- and Br_2Cl^- to alkenes and dienes.[16,18]



11

Scheme 3.

The product obtained from diethyl maleate (**1i**) and fumarate (**1i'**) was the same compound, diethyl *erythro*-2-bromo-3-chlorosuccinate (**4i'**). The reactions with these electron-deficient alkenes proceeded only on heating and the maleate (**1i**) was found to isomerize to the fumarate (**1i'**) under the reaction conditions. On the other hand, fumaric and maleic acids have been known to react with BrCl, yielding *erythro*- and *threo*-2-bromo-3-chlorosuccinic acids, respectively.[19] The difference would be additional evidence to support the conclusion that the reactant in the reaction of **6** is not BrCl but $BrCl_2^-$.

When compared with other bromochlorinating agents, the merits of ammonium dichlorobromate(1−) become evident. Although the formation of bromochloroalkanes by the use of a mixture of Br_2 and Cl_2 has been well known,[9] the yields appeared to be lower due to contaminations of dichloro and dibromoalkanes. Certain olefinic substances with BrCl prepared *in situ* from *N*-bromoacetamide and hydrogen chloride also give undesired by-products,[7] as was the case for a mixture of NCS and a bromide ion.[1] Although pyridine-BrCl complex[16,20] and a mixture of Br_2 and $SbCl_5$ (or $SbCl_3$)[13] were reported to be effective bromochlorinating agents, the products were usually complex. Tetraalkylammonium dichlorobromate(1−) can be handled easily and can be used as a very convenient bromochlorinating agent. Simple purification of the product provides pure bromochloroalkane in nearly quantitative yield.

Experimental

All the melting points and boiling points are uncorrected. NMR spectra were recorded on a JEOL JNM FX-60Q and a JEOL C-60HL spectrometer, using TMS as an internal standard. Mass spectra were recorded on a JMS-D-300 Mass spectrometer. The GLC analyses were performed on a Yanako GCG-550T with a Silicon DC 550 (25%)-Celite 545 (2 m) column (A) or Yanako G-180 Gas Chromatograph with a High vacuum silicon grease (25%)-Celite 545 (2 m) column (B). All the organic starting materials, including the solvents, were distilled or recrystallized before use. Chlorine was passed through water and sulfuric acid. Tetrabutylammonium dichlorobromate(1−) (**6**), tetramethylammonium dichlorobromate(1−) (**7**), and phenyltrimethylammonium dichlorobromate(1−) (**8**) were prepared by the literature procedure.[3]

The Reaction of Styrene (1a) with Chlorine in the Presence of Tetrabutylammonium Bromide. Experiments were carried out by adding 20 ml of chlorine solution in chloroform (0.16 mol dm^{-3}) in the presence of various amounts of tetrabutylammonium bromide (0.55—4.73 mmol) to 6.4 mmol of **1a** (in 30 ml of the same solvent) at 15 °C with stirring for 10 min. After the reaction completed, the mixture was washed with aq Na_2CO_3 and water, and dried over $MgSO_4$. The solvent was removed by evaporation. The relative amounts of products were determined by the peak areas of GLC on the column (A) at 100 °C with hydrogen as a carrier gas (50 ml/min). Retention times (in minutes) were: **1a**, 1; **2**, 3.2; **3**, 7.8; **4a**, 12.8; **5**, 14. The results are given in Table 1.

The Reaction of Styrene (1a) with 6. General Procedure: To a solution of **1a** (3.12 g, 30 mmol) in chloroform (100 ml), was added **6** (11.8 g, 30 mmol) at 0 °C over 20 min with stirring. The mixture was stirred for an additional 10—20 min, then washed with five 100-ml portions of water to remove the ammonium salt, dried over Na_2SO_4, and the solvent was evaporated. Distillation afforded 5.6 g (85%) of pure **4a**: bp 80—81 °C/1 mmHg (1 mmHg≈133.322 Pa) (lit,[7] 106—107 °C/6 mmHg); ^1H NMR ($CDCl_3$) δ=3.82, 3.83 (2H, 2d, J=8.3 and 6.6 Hz, CH_2Br), 5.03 (1H, q, J=8.3 and 6.6 Hz, CHCl), 7.36 (5H, s, C_6H_5); ^{13}C NMR ($CDCl_3$) δ=35.9, 61.3, 127.2, 128.6, 129.0, 138.3; MS M^+ at m/z=218, 220, 222 (100: 129:34); Found: m/z 217.9494. Calcd for C_8H_8BrCl: M, 217.9499. Yields in other aprotic solvents were: in dioxane, 78%; CCl_4, 80%; $CH_3COOC_2H_5$, 79%; CH_2Cl_2, 85%; CH_2ClCH_2Cl, 83%; $(CH_3CO)_2O$, 80%.

In Acetic Acid as the Solvent. To a solution of **1a** (1.04 g, 10 mmol) in acetic acid (30 ml) was added **6** (3.93 g, 10 mmol) at 20 °C over 5 min with stirring. The product was isolated by pouring the reaction mixture into cold saturated aq NaCl, followed by extraction with ether (200 ml) and washing with aq $NaHCO_3$ and water. The ethereal extract was dried over $MgSO_4$ and concentrated. The residue (2.00 g) was analyzed by GLC and ^1H-NMR. The composition analyzed by GLC was: **4a**, 65.4 and 1-acetoxy-2-bromo-1-phenylethane (**9**), 34.6%. ^1H-NMR shows 67:33 mixture of **4a** and **9**, respectively (by integration of methine protons). The ^1H-NMR spectrum of **9** corresponds well with that reported in the literature.[21]

In Methanol as the Solvent. To a solution of **1a** (1.04 g, 10 mmol) in methanol (30 ml) was added **6** (3.93 g, 10 mmol) at 0 °C over 5 min with stirring. The solvent was removed by evaporation, and ether (150 ml) was added to the residue. The ether solution was washed with aq $NaHCO_3$ and water. The ethereal extract was dried over $MgSO_4$ and concentrated. ^1H-NMR spectrum of the residue shows a 80:20 mixture of 2-bromo-1-methoxy-1-phenylethane (**10**) and **4a**, respectively (by integration of methine protons). Column chromatography of the residual oil (1.85 g) on silica gel with hexane as the eluent gave 1.10 g of pure **10** and 0.2 g of **4a**. The data for **10** are as follows: bp 65—66 °C/2 mmHg (lit,[22] 57 °C/0.40 mmHg); ^1H NMR ($CDCl_3$) δ=3.32 (3H, s, CH_3), 3.49,

3.50 (2H, 2d, J=5.7 and 7.0 Hz, CH_2Br), 4.37 (1H, approx. triplet, CH), 7.35 (5H, s, C_6H_5); ^{13}C NMR ($CDCl_3$) δ=36.2, 57.2, 83.4, 126.7, 128.4, 128.6, 139.0; MS M^+ at m/z=214, 216 (100:96); Found: m/z 213. 9981. Calcd for $C_9H_{11}BrO$: M, 213.9994.

Syntheses of Bromochloroalkanes by 6 in Chloroform. The procedure was the same as that described for that of **1a**, except for the reaction temperature and period. The results are given in Table 2.

Methyl erythro-*2-bromo-3-chloro-3-phenylpropanate (4b).* Mp 118—120 °C (from pentane). ^1H NMR ($CDCl_3$) δ=3.89 (3H, s, CH_3), 4.62 (1H, d, J=11.3 Hz, CHBr), 5.27 (1H, d, J=11.3 Hz, CHCl), 7.39 (5H, s, C_6H_5). Found: C, 43.51; H, 3.37%. Calcd for $C_{10}H_{10}BrClO_2$: C, 43.27; H, 3.63%.

1-Acetoxy-2-bromo-1-chloroethane (4c). Bp 80—81 °C/25 mmHg (lit,[13] 64—65 °C/10 mmHg). ^1H NMR ($CDCl_3$) δ=2.17 (3H, s, CH_3), 3.70 (2H, d, J=6.0 Hz, CH_2Br), 6.53 (1H, t, J=6.0 Hz, CHCl). ^{13}C NMR ($CDCl_3$) δ=20.6, 32.7, 80.0, 168.0.

1-Bromo-2-chloropropane (4d) and 2-Bromo-1-chloropropane (4d'). Gaseous propene (**1d**) from a cylinder was passed through the chloroform solution of **6** at 0 °C until the yellow color disappeared. After the usual work-up procedure, mixed bromochloroalkanes (**4d** and **4d'**) were obtained: bp 53—55 °C/70 mmHg. ^1H-NMR shows a 56:44 mixture of **4d** and **4d'**, respectively. ^1H NMR ($CDCl_3$) (an asterisk indicates **4d**) δ=1.65* (d, J=6.35 Hz, CH_3), 1.79 (d, J=6.34 Hz, CH_3), 3.3—4.4 (m). ^{13}C NMR ($CDCl_3$) (an asterisk indicates **4d**) δ=23.2, 37.5*, 46.3, 49.6, 55.4*. Although attempts to separate two regioisomers were unsuccessful, these assignments were supported for dibromo and dichloro analogs.[23]

1-Bromo-2,3-dichloropropane (4e) and 2-Bromo-1,3-dichloropropane (4e'). A mixture of two isomeric bromodichloropropanes (**4e** and **4e'**) was obtained from 3-chloropropene (**1e**): bp 60—62 °C/22 mmHg. ^{13}C NMR shows a 31:69 mixture of **4e** and **4e'**, respectively. The ratio was obtained by comparison of the spectra of each pure sample as follows: **4e**, ^{13}C NMR ($CDCl_3$) δ=33.1, 46.0, 57.9; **4e'**, ^{13}C NMR ($CDCl_3$) δ=45.2, 49.1.

threo-*2-Bromo-3-chlorobutane (4f).* Bp 45—48 °C/30 mmHg (lit,[24] 50—52 °C/30 mmHg). ^1H NMR ($CDCl_3$) δ=1.60 (3H, d, J=6.6 Hz, CH_3), 1.74 (3H, d, J=6.6 Hz, CH_3), 4.0—4.8 (2H, m, CHCl and CHBr). ^{13}C NMR ($CDCl_3$) δ=20.3, 20.4, 52.5, 60.5. MS M^+ at m/z=170, 172, 174 (100:129:31). Found: m/z 169.9490. Calcd for C_4H_8BrCl: M, 169.9498.

erythro-*2-Bromo-3-chlorobutane (4f').* Bp 51—52 °C/50 mmHg (lit,[24] 50—52 °C/51 mmHg). ^1H NMR ($CDCl_3$) δ=1.65 (3H, d, J=6.3 Hz, CH_3), 1.80 (3H, d, J=6.5 Hz, CH_3), 4.0—4.3 (2H, m, CHBr and CHCl). ^{13}C NMR ($CDCl_3$) δ=23.5, 53.8, 61.8. MS M^+ at m/z=170, 172, 174 (100:131:33). Found: m/z 169.9495. Calcd for C_4H_8BrCl: M, 169.9498.

trans-*1-Bromo-2-chlorocyclohexane (4g).* Bp 91—92 °C/18 mmHg (lit,[13] 90—95 °/17 mmHg). ^{13}C NMR ($CDCl_3$) δ=22.5, 23.3, 32.8, 33.3, 55.5, 62.9. MS M^+ at m/z=196, 198, 200 (100:129:32). Found: m/z 195.9640. Calcd for $C_6H_{10}BrCl$: M, 195.9655. The ^1H-NMR spectrum corresponds well with that reported in the literature.[25]

threo-*1-Bromo-2-chloro-1,2-diphenylethane (4h).* Mp 102.5—103 °C (from 95% ethanol) (lit,[9] 99—100 °C). ^1H NMR ($CDCl_3$) δ=5.34 (2H, s, CHBr and CHCl), 7.18 (10H, s, $2C_6H_5$). MS M^+ at m/z=294, 296, 298 (100:127:32). Found: m/z 293.9819. Calcd for $C_{14}H_{12}BrCl$: M, 293.9811.

erythro-*1-Bromo-2-chloro-1,2-diphenylethane (4h').* Mp 218—221 °C (from ligroine) (lit,[9] 220—221 °C). ^1H NMR ($CDCl_3$) δ=5.32 (2H, s, CHBr and CHCl), 7.42 (10H, m, $2C_6H_5$). MS M^+ at m/z=294, 296, 298 (100:132:34). Found: m/z 293.9809. Calcd for $C_{14}H_{12}BrCl$: M, 293.9811.

The Reactions of Diethyl Fumarate (1i') and Maleate (1i) with 6. The mixture of **6** (11.8 g, 30 mmol) and **1i'** (5.16 g, 30 mmol) in 100 ml of $CHCl_3$ was stirred at refluxing temperature for 50 h. The reaction mixture was washed with aq Na_2SO_3 and water. After the usual work-up procedure, the solid residue was recrystallized from ligroine to give 6.15 g (71%) of diethyl *erythro*-2-bromo-3-chlorosuccinate (**4i'**, mp 56—57 °C). The structure was confirmed by comparison of the ^1H-NMR spectra with that reported in the literature.[13]

In a similar way, analysis of the residue from the reaction of **1i** with **6** by ^1H-NMR revealed a mixture of **4i'** and unreacted alkenes. The solid residue was recrystallized from ligroine to give 5.7 g (66%) of product (mp 56—57 °C) (not depressed on admixture with the product obtained from **1i'**). ^1H-NMR analysis of the recovered alkene indicated 77% of **1i'** and 23% of **1i** on the basis of relative areas of the signals at δ=6.84 and 6.25 for olefinic protons, respectively.

Reaction of cis-*Stilbene (1h) with 6 in Various Solvents.* The reactions were carried out by the addition of 2 mmol of **6** to 2 mmol of **1h** in 50 ml of the solvents at 20 °C with stirring. After the yellow color disappeared, the reaction mixture was washed with water and dried over Na_2SO_4. The product of the reaction in acetic anhydride was isolated by extraction with ether. After the solvent was removed under reduced pressure, the residue was analyzed by GLC and ^1H-NMR. Reactions in $CHCl_3$, CH_2Cl_2, CH_2ClCH_2Cl, $(CH_3CO)_2O$, and CH_3NO_2 gave *threo* isomer (**4h**) free from *erythro* isomer (**4h'**). Yields in the solvents were: in $CHCl_3$, 95%; CH_2Cl_2, 98%; CH_2ClCH_2Cl, 96%; $(CH_3CO)_2O$, 95%; CH_3NO_2, 95%. The GLC analysis was performed on the column (B) at 150 °C with helium as a carrier gas (50 ml/min).

The authors wish to thank Dr. Seizi Kozuka of Osaka City University for helpful discussions.

Bromochlorination of Alkenes with Dichlorobromate(1−) Ion. II.[1] Regio- and Stereochemistry for the Bromochlorination of 1-Phenylpropenes with Dichlorobromate(1−) Ion

Takeshi NEGORO* and Yoshitsugu IKEDA

(Received October 12, 1983)

The bromochlorinations of 1-phenylpropenes with tetrabutylammonium dichlorobromate(1−) in aprotic solvents (dielectric constants 5—36) were found to be completely *anti* stereospecific and nonregiospecific, although Markownikoff adduct was mainly formed. In marked contrast, addition of molecular bromine chloride to the same alkenes was found to give nonstereospecific and regiospecific adducts. These results suggest that the addition of bromine chloride in the form of $(n\text{-}C_4H_9)_4NBrCl_2$ involves a rate- and product-determining attack of a chloride ion to a three-center bound π complex.

The stereochemistry of bromine addition to aryl-substituted alkenes has been shown to be markedly dependent both on the brominating agents and on the solvents employed.[2] The *anti* stereospecific additions were observed for the reaction with a tribromide ion[3,4] or with pyridine–bromine complex[4] as brominating agents. However, only a few systematic studies have been carried out on reaction with a dichlorobromate-(1−) ion as a bromochlorinating agent. It has been reported that 1-phenylpropenes give bromochlorinated adducts by reaction with $(CH_3)_4NBr_2Cl$ and pyridine–bromine chloride in a completely *trans* manner, while addition of molecular bromine chloride gives significant amounts of *cis*-adduct.[4] We have reported that tetrabutylammonium dichlorobromate(1−) reacted with stilbenes and 2-butenes to give the corresponding bromo chloro adducts in almost quantitative yields, and that the additions were in a completely *anti*-stereospecific manner.[1] In an attempt to gather more detailed information on bromochlorination with a dichlorobromate(1−) ion, we have investigated the regio- and stereochemistry of the addition to 1-phenylpropenes in solvents with widely different polarities. The reactions of 1-phenylpropenes with molecular bromine chloride were also carried out for comparison with the reactions of a dichlorobromate(1−) ion. This paper will describe reaction features of bromochlorination of 1-phenylpropenes with a dichlorobromate(1−) ion.

Results and Discussion

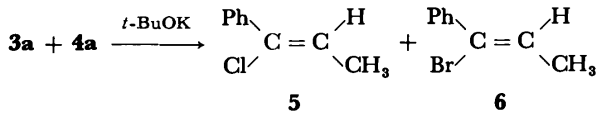
The reaction of tetrabutylammonium dichlorobromate(1−) [$(n\text{-}C_4H_9)_4NBrCl_2$, **1**] with *cis*-1-phenylpropene (**2a**) in chloroform gave a mixture of *threo*-2-bromo-1-chloro-1-phenylpropane (**3a**) and *threo*-1-bromo-2-chloro-1-phenylpropane (**4a**) in almost quantitative yield. *trans*-1-Phenylpropene (**2b**) was reacted with **1** to give a mixture of *erythro*-2-bromo-1-chloro and *erythro*-1-bromo-2-chloro adducts (**3b** and **4b**, respectively).

$$PhCH=CHCH_3 + \mathbf{1} \longrightarrow PhCHClCHBrCH_3 + PhCHBrCHClCH_3$$

2a	**3a**, 76%	**4a**, 24%
2b	**3b**, 95%	**4b**, 5%

Fig. 1.

Structural assignments of the bromo chloro compounds **3a** and **4a** were deduced by dehydrohalogenation to haloalkenes (Fig. 2). When a mixture of **3a** and **4a** was treated with 0.78 equivalent of potassium *t*-butoxide in *t*-butyl alcohol, the alkene (**5**) with recovery of the unreacted bromo chloro compound (**4a**) was obtained in good yield.



5 **6**

Fig. 2.

^{1}H-NMR analysis of the reaction mixture revealed that one isomer (**3a**), which gives **5**, was consumed faster than the other (**4a**); this other isomer (**4a**), which gives **6**, disappeared slowly. Thus, the more facile elimination of **3a** (than that of **4a**) would be due to either differences in eclipsing effect of the bulky substituents or in the ability of the leaving groups. The relative reactivities of **3a** and **4a** are in accordance with the usual reactivities of hydrogen halide eliminations.[5]

The structures of the major and minor products from **2a** and **2b** were also determined by comparisons of their ^{13}C- and ^{1}H-NMR spectra with those of the corresponding dibromo and dichloro adducts. Selected ^{1}C- and ^{1}H-NMR spectra of *threo*- and *erythro*-1,2-dihalo-1-phenylpropanes are listed in Tables 1 and 2, respectively. NMR analysis of the mixture of two regioisomers could be used to determine the amounts of each isomer.

The present addition reaction appeared to be stereospecific but not regiospecific. The lack of regiospecificity cannot be ascribed to the subsequent isomerization of the bromochloroalkanes, since prolonged reaction time did not cause a change of the isomer ratio of the products. Interconversions between two regioisomers (pure **3a** or the mixed isomers; **3a**:**4a**=60:40) were examined. However, no isomerization was observed in chloroform at room temperature for 3 h by using either 2 equivalents of **1** or of tetrabutylammonium chloride. Another possibility for the formation of *anti*-Markownikoff adduct (**4a** or **4b**) from dichloro adduct of alkenes can also be excluded, since no dichloroalkane was found in the reaction product.

When the reaction was carried out in the presence of a free radical inhibitor, 2,6-di-*t*-butyl-4-methylphenol, the product composition did not change within experimental error. Moreover, the same product ratio was obtained under either an oxygen or nitrogen atmosphere. These results indicate that the reaction proceeds in an electrophilic process rather than in a free radical one.

The regio- and stereochemistry of the reactions of **2a** and **2b** were investigated in solvents with widely different polarities in order to determine the mechanism of the reaction. Table 3 presents data for the effect of solvents on the regiochemistry of the addition to **2a** and **2b**. The reactions were completely *anti* stereospecific and nonregiospecific in all the aprotic solvents employed. No solvent effects on the regiochemistry have been observed (Table 3). A similar stereochemical result has been previously observed for the reaction of *cis*-stilbene with **1**.[1]

In contrast to the present results, Heasley *et al.*[4] have reported that the reactions of **2a** and **2b** with molecular bromine chloride (BrCl) in dichloromethane and carbon tetrachloride occurred in a nonstereospecific manner, although *anti* additions were favored. We have reinvestigated the reaction of the same alkenes with BrCl in various solvents to compare the results with that of **1**. Although the bromo chloro adducts were the major products in all cases, as expected, substantial amounts of dichloro and dibromo adducts were also found in the product. None of the *anti*-Markownikoff adducts were detected by ^1H- and ^{13}C-NMR analyses of the product mixtures in any of the solvents employed. The results are shown in Table 4.

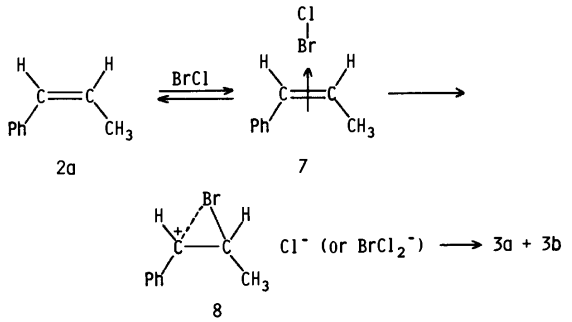
CH_3NO_2	35.87	49.8	50.2	9.1	90.9

a) Based on the amount of bromo chloro compounds, as determined by GLC analysis. Values were not corrected for FID response factors. Percentages are normalized to 100%. Yields of bromo chloro compounds were determined by GLC and found to be more than 70% in all runs. Other products were 5—10% of the dichloride and 12—20% of the dibromide. b) See footnote a in Table 3. c) At 20 °C. d) Data from Ref. 4.

These results show that the stereochemistry of the addition to *cis*-alkene (**2a**) is dependent on the polarity of the solvent. The addition in acetic anhydride or in nitromethane was nonstereospecific. The results of *trans*-alkene (**2b**) showed a much smaller dependency on the nature of the solvent. All the additions to **2b** were found to be *anti* stereoselective. A similar stereochemistry has been observed for the addition of bromine to these alkenes.[2] Since it is quite reasonable to consider that the process is the same for both bromine and bromine chloride additions,[4,6] a mechanism such as that illustrated in Fig. 3, similar to bromine addition, would be involved in the addition with bromine chloride.



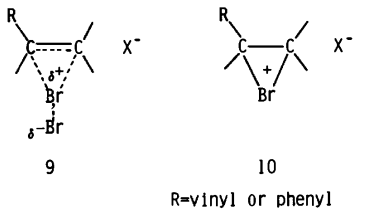
2a 7 8

Fig. 3.

The solvent dependency of the stereochemistry and the regiospecific addition observed for the reaction with these alkenes are fully in accordance with the mechanism involving a very weakly bridged benzylic carbonium ion intermediate (**8**) prior to the product-determining step.[2] The fact that the stereochemistry of the addition to **2a** is more sensitive to solvent polarity than that of the addition to **2b** gives strong evidence for the presence of the intermediate (**8**). The intermediate (**8**) for the reaction of **2a** tends to take a more energetically favored conformation due to the eclipsing effect of the adjacent methyl and phenyl groups. Furthermore, the peculiarity of stereochemistry observed in dioxane is easily explained in terms of specific solvation for the carbonium ion intermediate.[2]

As has been described above, the additions to alkenes appeared to be strikingly different in reactions with **1** and with BrCl in all aprotic solvents employed. These marked differences in the reactions of **1** and BrCl suggest that these two reactions are quite different in their mechanisms. The formation of completely *anti* stereospecific and *anti*-Markownikoff adducts in reaction with **1** rules out a weakly bridged benzylic-like ion intermediate (**8**), such as is shown in Fig. 3. If an intermediate such as **8** was involved, the complete formation of Markownikoff adduct would be expected.

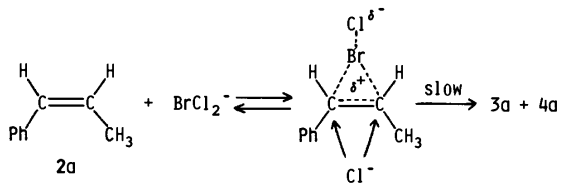
The large differences of product distribution obtained by the reaction with **1** are consistent with the previous proposal that this reagent is an independent electrophile rather than a precursor of BrCl.[1] The reactions of $BrCl_2^-$ presently studied and Br_2Cl^- (or Br_3^-) reported by Heasley *et al.*[4] seem to involve similar mechanisms. Two possible mechanisms have been proposed by them, involving attack of a halide ion on a three-center bound π complex (**9**)[7] or on the bromonium ion intermediate (**10**).



9 10

R=vinyl or phenyl

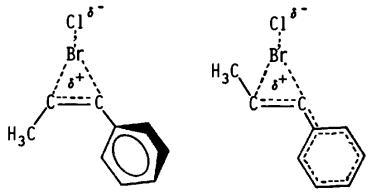
The bromonium ion intermediate (**10**), however, is hardly acceptable for the reaction of $BrCl_2^-$ since the present reaction gave nonregiospecific products. Thus, the $AdEC_2$ process involving an intermediate like **9** at the product-determining step would be applicable to the reaction of $BrCl_2^-$, as depicted in Fig. 4.



2a 11

Fig. 4.

The regiochemistry of the reaction of **1** would be dependent on the electronic effect of the phenyl ring which stabilizes the developing cationic character on the carbon in the complex (**11**). The *cis*- and *trans*-alkenes gave somewhat different regiochemical results. Markownikoff adducts were obtained mainly from both *cis*- and *trans*-alkenes (**2a** and **2b**) as given in Table 3. The *cis*-alkene gave less regioselectivity than the *trans*-alkene. The differences may be ascribed to the ability of stabilization of a cationic center by phenyl groups. The phenyl ring of the intermediate (**12**) formed from the *cis*-alkene would be skewed by the eclipsing effect.



12 13

The intermediate (**13**) formed from the *trans*-alkene would be free from such an eclipsing effect and the developing cationic character would be delocalized over the phenyl ring. This type of stabilization may develop the cationic character on the carbon adjacent to the phenyl ring. Thus, attack of a chloride ion to the benzylic carbon atom would be more favored in the intermediate from *trans*-alkene than in that from *cis*-alkene. In fact, the *trans*-alkene (**2b**) was found to react faster than the *cis*-alkene (**2a**).[8]

Experimental

NMR spectra were recorded on a JEOL JNM FX-60Q and a JEOL C-60HL spectrometer using TMS as an internal standard. Mass spectra were recorded on a JMS-D-300 Mass

spectrometer. The GLC analyses were performed on a Yanako G-180 Gas Chromatograph. Tetrabutylammonium dichlorobromate(1-) (**1**) was prepared by the literature procedure.[9] All the organic starting materials, including the solvents, were distilled before use. Bromine chloride was prepared by adding an equimolar amount of bromine to a chlorine-carbon tetrachloride solution.

Reaction of cis-*1-Phenylpropene (**2a**) with 1.* Details of the reaction have been reported previously.[1] The mixture of **2a** (5.90 g, 50 mmol) and **1** (19.7 g, 50 mmol) in 100 ml of chloroform was stirred at 0 °C for 10 min. After the usual work-up procedure, distillation afforded 9.3 g (80%) of a mixture of two isomeric bromochloroalkanes (**3a** and **4a**): bp 90—91 °C/1 mmHg (1 mmHg≈133.322 Pa); MS M^+ at m/z= 232, 234, 236 (100:128:32); Found: m/z 231.9649. Calcd for $C_9H_{10}BrCl$: M, 231.9655. Although attempts to separate **3a** and **4a** by GLC were unsuccessful, ^{1}H-NMR analysis by integration of methyl protons revealed the product composition to be 76% of **3a** and 24% of **4a**. The major product was characterized as **3a** on the basis of the ^{1}H- and ^{13}C-NMR spectra of an authentic sample.[4]

Reaction of trans-*1-Phenylpropene (**2b**) with 1.* The reaction was carried out similarly to that of **2a**. Distillation afforded 9.6 g (82%) of mixed bromochloroalkanes (**3b** and **4b**): bp 91—92 °C/1 mmHg; MS M^+ at m/z=232, 234, 236 (100:128:32); Found: m/z 231.9648. Calcd for $C_9H_{10}BrCl$: M, 231.9655. ^{1}H-NMR analysis established the product composition as 96% of **3b** and 4% of **4b**. The major product was also characterized as **3b** on the basis of the ^{1}H- and ^{13}C-NMR spectra of an authentic sample.[4]

*Dehydrohalogenation of Regioisomers (**3a** and **4a**).* To 2.34 g (10 mmol) of the mixture composed of **3a** (76%) and **4a** (24%) in *t*-butyl alcohol (50 ml) was added 6 ml (2.23 mmol) of potassium *t*-butoxide in *t*-butyl alcohol (0.372 mol dm^{-3}); the mixture was stirred at 20 °C. After 30 min, 1 ml of the solution was taken up, shaken with water, and extracted with pentane. The pentane layer was washed with dilute acid and dried over $MgSO_4$. Evaporation of the pentane and analysis of the residue by ^{1}H NMR showed the composition to be: **3a**, 53.3%; **4a**, 25%; **5**, 21.7%; and **6**, 0%. The reaction was carried out further by the addition of 15 ml (5.58 mmol) of potassium *t*-butoxide solution (0.372 mol dm^{-3}); this mixture was stirred for 1 h. The reaction mixture was then worked up in a fashion similar to that described above. Evaporation of the pentane gave 1.58 g of the crude product. ^{1}H NMR showed the composition to be: **3a**, 0.5%; **4a**, 23%; **5**, 76.5%; and **6**, 0%. Column chromatography of this residue on silica gel with hexane as the eluent gave almost pure **4a** (150 mg) and **5** (711 mg). The data for **4a** are as follows: ^{1}H NMR ($CDCl_3$) δ=1.46 (3H, d, J=6.6 Hz, CH_3), 4.45 (1H, approx. quintet, CHCl), 5.06 (1H, d, J=6.6 Hz, CHBr), and 7.32 (5H, m, C_6H_5); MS M^+ at m/z=232, 234, 236 (100:127:32); Found: m/z 231.9649. Calcd for $C_9H_{10}BrCl$: M, 231.9655. The data for **5** are as follows: ^{1}H NMR (CCl_4) δ=1.90 (3H, d, J=6.7 Hz, CH_3), 6.31 (1H, d, J=6.7 Hz, CHCl), and 7.28—7.62 (5H, m, C_6H_5); MS M^+ at m/z=152, 154 (100:32); Found: m/z 152.0388. Calcd for C_9H_9Cl: M, 152.0393. The ^{1}H-NMR spectrum for **5** corresponds well with that reported in the literature.[10]

*Dehydrochlorination of Pure Regioisomer (**4a**).* To 120 mg (0.51 mmol) of **4a** in *t*-butyl alcohol (5 ml) was added 2 ml (0.74 mmol) of potassium *t*-butoxide solution (0.372 mol dm^{-3}); this mixture was stirred at 20 °C. After 30 min, the reaction mixture was worked up as described above. Evaporation of pentane gave 75 mg of crude product **6** as a colorless oil: ^{1}H NMR (CCl_4) δ=2.00 (3H, d, J=7.5 Hz, CH_3), 6.40 (1H, d, J=7.5 Hz, CHBr), and 7.35—7.80 (5H, m, C_6H_5); MS M^+ at m/z=196, 198 (100:97); Found: m/z 195.9898. Calcd for C_9H_9Br: M, 195.9888. The spectral patterns of this product were identical with those of a sample prepared by dehydromination of *threo*-1,2-dibromo-1-phenylpropane.

*Reaction of 1 with **2a** or **2b** in Various Solvents.* To 2 mmol of the alkene in 20 ml of the solvent was added 2 mmol of **1** at 0 °C over 5 min with stirring. After the yellow color disappeared, the mixture was washed with water and dried over Na_2SO_4. The product of the reaction in acetic anhydride was isolated by pouring the reaction mixture into water, followed by extraction with ether and washing with aq $NaHCO_3$ then water. After the solvent was removed under reduced pressure, the residues were analyzed by ^{1}H NMR and ^{13}C NMR in some cases. The relative amounts of products were determined from the ratio of the peak areas of the methyl protons of the bromo chloro compounds (**3a** and **4a** or **3b** and **4b**), and also from the ratio of peak heights of aliphatic carbons (^{13}C NMR). The results are given in Table 3.

*Reaction of Bromine Chloride with **2a** or **2b** in Various Solvents.* To 2.1 mmol of the solvent, was added 1.7 ml of BrCl solution in CCl_4(1.2 mol dm^{-3}) at 0 °C with stirring. Products of the reactions in acetic anhydride and dioxane were isolated by extraction with ether as described above. Products of the reactions in carbon tetrachloride, chloroform, dichloromethane, and nitromethane were obtained by direct evaporation of the solvent. GLC analysis of the residue gave six peaks with retention times of 12.3, 13.7, 18.9, 21.1, 27.6, and 32.8 min. These were assigned to be *erythro*-1,2-dichloro-, *threo*-1,2-dichloro-, *erythro*-2-bromo-1-chloro-, *threo*-2-bromo-1-chloro-, *erythro*-1,2-dibromo-, and *threo*-1,2-dibromo-1-phenylpropanes, except for unreacted alkene, respectively. GLC analyses were performed on a High vacuum silicon grease (25%)-Celite 545 (2 m) column at 120 °C with helium as a carrier gas (35 ml/min). The results are given in Table 4.

*The Reaction of 1 with **2a** in the Presence of a Radical Inhibitor.* When **2a** was treated with **1** in chloroform as described above, O_2 was bubbled during the reaction. The product ratio of 76.5:23.5 was obtained by ^{1}H-NMR analysis for **3a** and **4a**, respectively. The reaction was carried out with 1.18 g (10 mmol) of **2a**, 3.93 g (10 mmol) of **1**, and 0.70 g (0.3 mmol) of 2.6-di-*t*-butyl-4-methylphenol in chloroform (30 ml). After the usual work-up, the product ratio of 77.8: 22.2 was obtained by ^{1}H-NMR analysis for **3a** and **4a**, respectively. ^{13}C-NMR analysis also showed a 76.5:23.5 mixture of **3a** and **4a**, respectively.

Stability of the Bromo Chloro Compounds under the Reaction Conditions. To 1 mmol of the two regioisomers (**3a** and **4a**) in chloroform (10 ml) was added 2 mmol of **1** and allowed to stand for 3 h at room temperature with stirring. The mixture was shaken with aq sodium sulfite. The chloroform layer was separated, washed with water, and dried over $MgSO_4$. After the solvent was removed, the residue was analyzed by ^{1}H-NMR spectrum. No interconversion was observed. Namely, the same isomer compositions were observed within experimental error: Starting from a 60:40 mixture of **3a** and **4a** recovered a 59:41 mixture of **3a** and **4a**, and only **3a** was recovered from **3a** without contamination with **4a**.

The authors wish to thank Dr. Seizi Kozuka of Osaka City University for helpful discussions.

The Changes in Conformation and Complexability of 6,6′-Diamino-2,2′-bipyridine by Protonation

Noriyuki KISHII, Koji ARAKI, and Shinsaku SHIRAISHI*
Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
(Received November 30, 1983)

The reaction of 6,6′-dibromo-2,2′-bipyridine with ammonia in an autoclave gave 6,6′-diamino-2,2′-bipyridine (DABP) in more than 80% yields. DABP behaved as a diacidic base in the pH range of 0 to 10 with the conformational changes. DABP formed complexes with Cu(II), Ni(II), Co(II), and Zn(II). The amino groups at 6 and 6′ positions play a role as strong electron-donationg groups and not as coordination sites. p*K*a values and complex formation constants were estimated.

2,2′-Bipyridine (bpy) is well known as a typical ligand that forms stable complexes[1] with various transition metal ions in a wide pH range. Particularly, in last 15 years, tris(bpy) ruthenium complex has been extensively studied because of its potential applicability to photolysis of water in coupling with an electron acceptor such as methylviologen.[2] Various kinds of bpy derivatives have been synthesized and examined as to the effects of substituents on the complexing properties and on the physical properties of the complexes.[3,4] Among these derivatives, 6,6′-dimethyl-2,2′-bipyridine (Mbpy) exhibits an unique behavior in the complex formation due to the steric hindrance of the substituents at 6- and 6′- positions.[5] Mbpy forms almost exclusively mono or bis complex with various metals, while many other bpy derivatives usually form stable tris-bpy complexes. In a few tris complexes of Mbpy exceptionally known, the methyl substituents were reported to affect on the wavelength and/or life time of luminescence of ruthenium(II) complexes.[6] The recent interest in this field seems to be focussed on the examination of the effect of the substituents on bpy or analougus complexes with various metal ions.[7,8] 6,6′-Diamino-2,2′-bipyridine (DABP) is expected to exhibit interesting properties as a metal ligand. There was, however, no paper reported as to the properties of DABP and its complexing ability with metal ions except only two reports on the synthesis of DABP.[9,10] In this paper, we wish to report an improved synthesis and some physical properties of DABP along with complex formation. The influence of the amino group at 6,6′-positions on the ability of complex formation with some transition metal ions will be discussed.

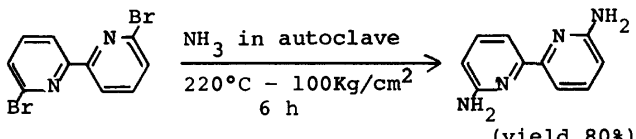
Results

Preparation of 6,6′-Diamino-2,2′-bipyridine. 2,2′-Bipyridine (bpy) is rarely susceptible to either electrophilic or nucleophilic substitution reactions.[11] The usual Chichibabin reaction using sodium amide gave only a trace amount of amino derivatives.[10] Burstall reported that 6,6′-dibromo-2,2′-bipyridine (DBBP) was easily converted to DABP by the reaction with aqueous ammonia in a sealed tube for 14h,[9] but attempted preparation according to the report resulted in unsatisfactory results. An improved amination method was explored.

An unsealed glass ampoule containing DBBP was placed in an autoclave, into which liquid ammonia was added. DBBP was allowed to react with ammonia at 220 °C under a pressure of 100 kgf cm^{-2} (kgf= 9.80665N) for 6 h. After the reaction, the solid in the ampoule was dissolved in dilute aqueous HCl and filtered. Basification of the filtrate with aqueous ammonia gave crude DABP as a precipitate. Purification was effected by sublimation and the total yield was 80%. In these reaction conditions, there was no recovery of DBBP nor char formation and DBBP was considered to be fully converted into DABP. The remainder of DABP might be left unprecipitated in the bacified solution though its limited solubility. The reaction conditions described above were fairly optimized one. Three hours' reaction was not enough fully to convert DBBP into DABP, and longer reaction time more than 10 h also reduced the yield of DABP by noticeable char formation. The presence of metals diminished the yield of DABP, which is the reason why DBBP was placed in a glass ampoule. Imperfect purification of DBBP, especially residual copper, deteriorated the DABP formation and resulted in char formation. This may be due to the catalytic degradation of DBBP or DABP with copper or other metals.

Acid-base Properties of DABP. 2,2′-Bipyridine (bpy) and 1,10-phenanthrorine (phen) have been thought to be monoacidic base though they have two sites for potonation.[12] The second protonation occurs, however, only in a strong acid such as concentrated sulfuric acide.[13,14] The acid-base properties of DABP, which has four potentially basic nitrogen atoms in the molecule, were examined and it was found to act as a diacidic base in the pH range from 0 to 10.

The absorption spectra of DABP changed with pH (Fig. 1). Stepwise protonation is suggested. Figure 1-A shows the spectral change of DABP with isosbestic points due to the first protonation step, where DABP changed from free form to monoprotonated form with isosbestic points. Figure 1-B shows the spectral change of DABP with different isosbestic points from monoprotonated form to diprotonated form. The pattern of the spectral change in the first step is very similar to that of bpy, suggesting that this is due to monoprotonation step. This was confirmed by acid-base titration. The second step is diprotonation process. This



Scheme 1.

is not experimentally confirmed but plausibly considered to be so by the exsistence of isosbestic points in the spectral change. As shown in Fig. 1, DABP showed two stages of equilibrium substantially separated from each other, suggesting that the proton dissociation constants for mono and diprotonated forms of DABP were greatly different from each other. The pKa_4 for the first protonation stage and pKa_3 for the second protonation stage of DABP were determined to be 6.72 and 2.2 respectively by plotting the absorbances at 360 nm for the first stage protonation, and at 350 and 250 nm for the second stage protonation against pH (Fig. 2). The values are larger than those of bpy (4.5 and −0.5).[15,13] The pKa_4 was very close to 6.86 of 2-aminopyridine (Ampy),[16] where the amino group effects to strengthen the basicity of pyridine ring by its strong electron donating property.

The chemical shifts of ^{1}H-NMR spectra of DABP and related compounds in various media are listed in Table 1. The assignment was according to the literature.[17,18] The chemical shifts of DABP in DMSO were nearly close to those of Ampy except 3-H, and were shifted to upper field comparing with those of bpy. This indicates that the electron distribution on pyridine ring of DABP is similar to that of Ampy and their electron density are higher than that of bpy, being consistent with the pKa data described above.

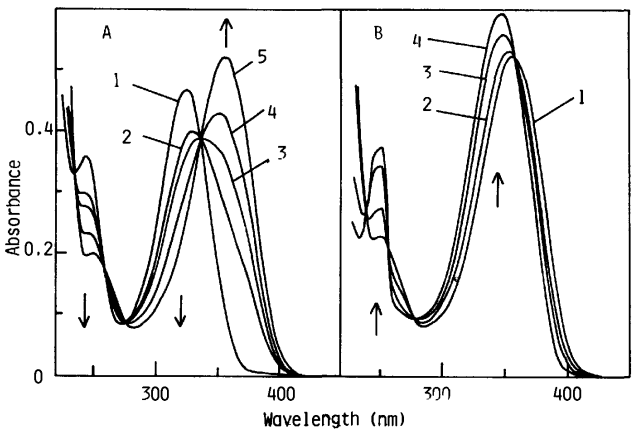


Fig. 1. The spectral Change of DABP (3.33×10^{-5} mol dm^{-3}).
A:Change from free to monoprotonated form 1) pH 10.00, 2) pH 7.00, 3) pH 6.57, 4) pH 6.00, 5) pH 4.90.
B: Change from mono to diprotonated form 1) pH 3.63, 2) pH 2.35, 3) pH 1.46, 5) pH 0.60.

Complex Formation. DABP showed the spectral change by complexation with metal ions. Figure 3 shows the spectral change of DABP as a function of Cu(II) concentration.

Continuous variation method was applied to the DABP-metal systems in a buffer solution of pH 9.3. The total concentration of metal and ligand employed was 2.00×10^{-5} mol dm^{-3}. The result confirmed the 1:1 stoichiometry of the DABP-metal systems except with Zn(II) (Fig. 4). There was nothing observed to indicate the formation of DABP tris complexes. In this respect, DABP resembles Mbpy in the pattern of the complex formation,[5] suggesting that the amino groups at 6 or 6′-positions act like methyl groups of Mbpy. The formation constants of 1:1 complexes ($\log K_1$) were obtained at pH 4.0 and 9.3 by the Rose-Drago method (Table 2). Typical examples are shown in Fig. 5. The constant for Zn(II) at pH 9.3 was not obtained, because Zn(II) forms only 2:1 complex (DABP:Metal) at the

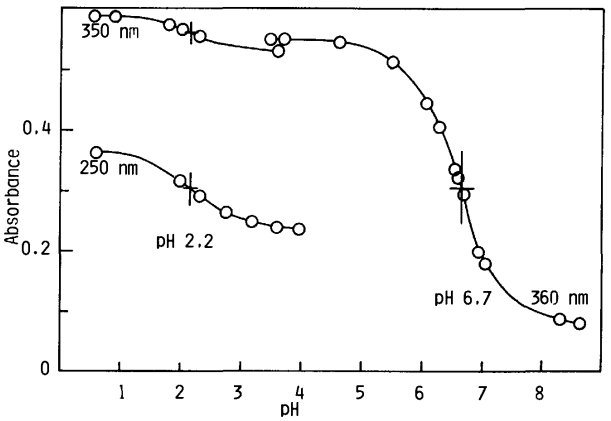

Fig. 2. The Absorbance of DABP (3.33×10^{-5} mol dm^{-3}) as a Function of pH.

TABLE 2. THE COMPLEX FORMATION CONSTANTS ($\log K_1$)

pH. At pH 1.0, the spectral changes of DABP was too small to estimate the complex formation constants. Cu(II) had the highest complexability at pH 9.0 among the metal ions employed and the order of abilities of complexation were Cu(II)>Cu(I)>Ni(II)>Co(II). This order was the same as for bpy.[19] The log K_1 values of DABP were smaller than those of bpy but larger than those of Mbpy.[20] The complex formation constants observed at pH 4.0 were smaller than those at pH 9.3. The order of the ability of complexation of metals with DABP at pH 4.0 was the same as that at pH 9.3 and also the same as that of bpy except Zn(II).

Discussion

The Protonation Site and the Conformation of Protonated DABP. ^{1}H NMR spectrum of DABP in DMSO showed nearly the same chemical shifts as that of Ampy except the signal due to the ring proton at 3 position. The proton at 3 position of bpy in either protic or aprotic solvent is known to show an anomalous chemical shift comparing to the proton at 5 position due to the effect of diamagnetic anisotropy of neighbouring pyridine ring, and the conformation of bpy in solution is predicted by the relative chemical shift of the proton at 3 position to that at 5 postion $\delta_{H\text{-}3}-\delta_{H\text{-}5}$).[18] The relative chemical shifts of DABP in DMSO were 0.98, which is almost the same as that (0.91) of bpy. Bpy in solution is known to have transoidal conformation,[15,18] suggesting that the free form of DABP has transoidal conformation in the solution.

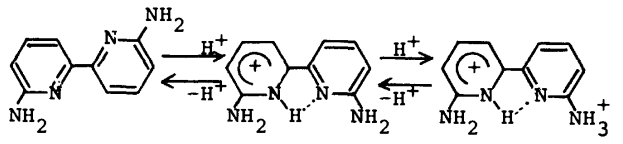
The UV absorption spectrum also supports transoidal conformation of free DABP. Figure 6 shows the absorption spectra of DABP in buffer solutions of pH 9.3, pH 4.0, and pH 1.0 corresponding to free, monoprotonated, and diprotonated form of DABP. Bpy has two bands at 232 nm and 279 nm in basic

solution.[15] Free form of DABP also has two bands at 244 and 325 nm. The spectral shapes of bpy and DABP resembles each other except that the two peaks of DABP are at longer wave lengths than those of bpy.

Monoprotonated DABP seems to have a cisoidal conformation, and the site for protonation seems to be on the ring nitrogen and not on the amino groups. Two bands of monoprotonated DABP appeared at 251 nm and 357 nm, being red-shifted in comparison with those of the free form. The monoprotonation of bpy is known to cause the red-shift comparing with free form.[15] The relative chemical shift ($\delta_{H\text{-}3}-\delta_{H\text{-}5}$) of monoprotonated DABP is 0.30 ppm and is near to 0.40 ppm of monoprotonated bpy. This also suggests that the monoprotonated DABP has the same conformation as that of monoprotonated bpy, which is known to have cisoidal conformation.[15] Thus monoprotonated DABP is concluded to have the cisoidal conformation to form chelation ring and the bacisity of the pyridine ring is increased as 100 times large as that of bpy by introduction of amino groups at 6- and 6'- positions.

The second protonation seems to be different from that of bpy. Two bands still appeared at 252 nm and 348 nm in the absorption spectrum of diprotonated DABP, whereas the second protonation on bpy leads to loss of one of the two peaks to exhibit only one absorption at 290 nm.[13] The second protonation on bpy at the other pyridine ring causes repulsive interaction between the two protonated sites and makes two pyridine rings twisted.[15] The disappearance of one of the two peaks observed in bpy seems to be due to the destruction of the coplanarity of the linked aromatic rings and is not observed in the case of 1,10-phenanthrorine,[13] nor in the dication of bpy formed by *N*-alkylation with 1,2-dichloroethane.[18] The second protonation on DABP is suggested not to destroy the conjugation so much as in the case of bpy. ^{1}H-NMR spectra also suport the consideration. The relative chemical shift of proton at 3 position to that at 5 position was 0.25 ppm, and being close to 0.3 ppm of monoprotonated DABP. Thus the secondly protonated DABP has still cisoidal conformation, and therefore, the second protonation is plausively considered to occur at amino group.

In a strong acid, however, the destruction of cisoidal conformation seems to be caused by the third and fourth protonation.[21] The relative chemical shifts of 3 position to that of 5 position in D_2SO_4 were 0.12, 0.08, and 0.05 ppm respectively for bpy, DABP, and Ampy. The value of DABP is intermediate between those of bpy and Ampy. In these conditions, bpy has twisted conformation and the proton at 3 position is not affected so much by the neighbouring aromatic rings. Thus the first and second stage protonation of DABP were suggested to occur as shown in scheme 2. It may be plausible from the electrostatic point of view too.



Scheme 2.

This may be the reason that the *K*a for the second protonation of DABP became larger about 1000 times than that of bpy.

Exchange of Proton with Metal Ion and the Effects of the Amino Group. Absorption spectra of Ni(II) complex with DABP in buffer solutions of pH 9.3 and 4.0 are shown in Fig. 7 along with that of monoprotonated DABP. Spectra of Ni(II) complex at pH 9.3 and pH 4.0 were almost the same as each other and very close to that of monoprotonated DABP, suggesting that complexing site for metal ions is the site where protonation occurs, and that proton and metal ion compete with each other in coordination. Supposing an equilibrium of ternary system among L, LH, and LM (Scheme 3), the equilibrium constants of the exchange between proton and metal ions (K_{ex}) can be estimated either by using the values of log K_1 at pH 9.3 and p*K*a or by using log K_1 at pH 4.0 for any of the metal ions forming 1 : 1 complex with DABP. The two independently obtained values of K_{ex} were nearly the same for Ni(II) and Co(II). Therefore, there is considered to exsit the ternary equilibrium among L, LH, and LM in moderate pH region and the metal decomplexation at lower pH region is also considered to be

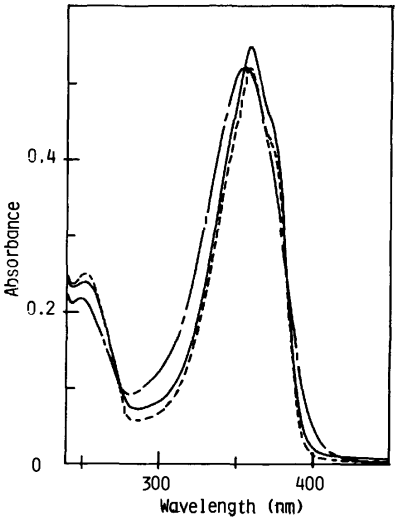


Fig. 7. Comparison of the Spectra of DABP (3.33×10^{-5} mol dm^{-3}) and DABP-Ni Systems in Different Buffer Solutions.
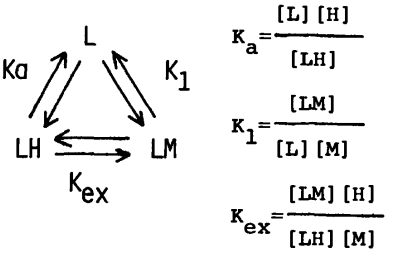
------ with excess amounts of Ni(II) in pH 9.3, —— with excess amounts of Ni(II) in pH 4.0, —·— in pH 4.0 without metal ion.



Scheme 3.

due to the exchange of metal ion with proton.

As discussed above, the sites for protonation and metal complexation of DABP are the ring nitrogen atoms. Electron donation by amino groups increases the basicity of ring nitrogen atoms of DABP and influences the complex formation properties. However, basicity is not directly related to complex formation ability. The ability of complex formation of DABP was less than that of bpy, although DABP has higher basicity than bpy. Mbpy which has higher bacicity than bpy is known to have less complexability than bpy. The substituents at 6- and 6′- positions decrease the complexability. For the compounds having similar steric effects, however, the basicity of the complexing site determines the complexability. The complex formation constants of DABP (log K_1=6.7 for Cu(II)) is larger than that of Mbpy (4.23) according to the higher basicity of DABP (pKa=6.7) than that of Mbpy (4.88). The differences in log K_1 and pKa are found to be almost parallel.

DABP forms only 1:1 complex with metal ions such as Cu(II), Ni(II), and Co(II) and no bis nor tris complexes due to the steric hindrance of the amino groups. Therefore, the complexes of DABP are more pH-sensitive than tris complexes of other bipyridine derivatives. Although pKa of 2,2′-bipyrazine is 0.5, tris-(bipyrazine)ruthenium is stable in concentrated sulfuric acid.[7] And tris(bipyridine) complex with Fe(II) is stable in the pH region of 1.0—9.0, though pKa of bipyridine is 4.5.[22] Whereas, the stability constant of DABP drastically changes between pH 4.0 and pH 9.3 about 100 times. This pH-sensitive properties of DABP for complex formation can be used as a pH- swich for selective uptake and release of metal ions.[24]

Experimental

6,6′-Dibromo-2,2′-bipyridine (DBBP). To a suspension of 2,6-dibromopyridine(50 g, 0.21 mol) in diethyl ether (350 cm^3), which was cooled under −60 °C in liquid nitrogen-hexane bath, butyllithium (2.2 mol dm^{-3} in hexane, 130 cm^3, 0.29 mol) was added slowly. Then the reaction mixture was cooled to −90 °C and a fine powder of anhydrous copper(II) (14.2 g, 1.04 mol) was added. The mixture was allowed to warm to −70 °C with efficient stirring. After 30 min, oxygen was bubbled slowly through the solution at −50 °C for 30 min. The reaction mixture was poured into aqueous HCl (6N, 500 cm^3) with stirring. The solid part was collected by filtration, washed with water and dried under vacuum. The dried solid was extracted with hot benzene. The benzene extract was evaporated. The residue was recrystallized from benzene to give colorless needles of DBBP in pure form, 20.2 g (61%). Mp 225—226 °C (lit.[23] 226—227 °C).

6,6′-Diamino-2,2′-bipyridine (DABP). DBBP (3.0 g, 9.6 mmol) was placed in a glass ampoule. Liquid ammonia (30 g) was also placed in another ampoule. The unsealed ampoules were placed in an 500 cm^3 autoclave, and heated up to 220 °C. The inner pressure rised up to 100 kgf cm^{-2}. Heating was continued for 6 h. After the reaction, the solid in the glass ampoule was dissolved in dilute aqueous HCl (50 cm^3) and filtered in order to remove insoluble matters, and unreacted starting material. Aqueous ammonia was added into the filtrate to precipitate a solid , which was collected by filtration, washed with aqueous ammonia and water, and dried under vacuum. The crude products were sublimated under vacuum (2 mmHg (270 Pa)-150—200 °C) to give 1.42 g (80%) of purified DABP, mp 185—186 °C (lit,[9] 186 °C). Found C, 64.67; H, 5.19; N, 30.21%. Calcd for $C_{10}H_{10}N_4$ C, 64.50; H, 5.41; N, 30.09%. The reaction for 3 h gave unreacted starting material (0.81 g, 27%) and DABP (0.93 g, 52%).

Spectral Measurements. The absorption spectra were recorded with a JASCO UVIDEC-505 spectrophotometer at 20 °C. The buffer solutions used were as follows: pH 1.0, HCl-KCl buffer; pH 4.0, 0.2 mol dm^{-3} acetic acid-sodium acetate buffer; pH 9.3, 0.2 mol dm^{-3} potassium borate buffer. The ionic strength was not adjusted. ^{1}H-NMR spectra were recorded with JEOL JMN-MH 100 spectrometer. The chemical shifts were determined by 10 mmol of substance in 0.4 cm^3 DMSO-d_6 with tetramethylsilane (TMS) as internal standard or in 0.4 cm^3 D_2O with TMS as external standard, and reported in ppm from TMS.

Determination of Complex Formation Constants. Metal salts used were, Cu(II)$Cl_2\cdot 2H_2O$, Ni(II)$Cl_2\cdot 6H_2O$, Co(II)$Cl_2\cdot 6H_2O$, Zn(II)$(CH_3COO)_2\cdot 2H_2O$, and Cu(I)Cl of Special grade quality (Wako Pure Chemical Co). Typical procedure is as follows: 0.01 cm^3 of metal solution (0.01—1.0 mol dm^{-3}) was added to 3 cm^3 of buffer solution containing 1.00×10^{-7} mol of DABP. The changes of absorbance and composition of the solution were plotted according to Rose-Dorago Method. Wavelengths used for the determination were as follows. Cu(II), 367 nm; Ni(II), 360 nm; Co(II), 360 nm; Zn(II), 365 nm; Cu(I), 360 nm.

Continuous variation method. The total concentration of metal ions and DABP was 2.00×10^{-5} mol dm^{-3}. The differences in absorbance were plotted against the composition of the solutions (metal ion/DABP). The wavelengths used for the measurement were the same ones used in the experiment described above.

The Reaction of Butadienylphosphonates with a Oxosulfonium Ylide, Phosphonium Ylides, and Ketone Enolates

Toru MINAMI,* Takenobu YAMANOUCHI, Shigehumi TOKUMASU, and Ichiro HIRAO
Department of Industrial Chemistry, Kyushu Institute of Technology, Sensuicho, Tobata, Kitakyushu 804
(Received December 23, 1983)

The condensation of diethyl (ethoxycarbonylmethyl)phosphonate (**1a**) with cinnamaldehyde in the presence of piperidine gave a 1:1 mixture of diethyl (1*E*,3*E*)- (**2a**) and (1*Z*,3*E*)-(1-ethoxycarbonyl-4-phenyl-1,3-butadienyl)phosphonates (**2b**) in 82% yield, while a similar reaction using diethyl [cyanomethyl- (**1b**) and methylsulfonylmethyl]phosphonates (**1c**) exclusively gave diethyl (1*E*,3*E*)-[1-cyano- (**3**) and 1-methyl-sulfonyl-4-phenyl-1,3-butadienyl]phosphonates (**4**) in 78% and 93% yields, respectively. The reaction of the butadienylphosphonates **2**—**4** with dimethyloxosulfonium methylide (**5**) gave mixtures of (*E*)- and (*Z*)-(1-substituted 2-styrylcyclopropyl)phosphonates **7**—**9** in good yields. Similar treatment of the butadienylphosphonate **2** with phosphonium ylides **16a**—**c** led to (3-substituted 1-ethoxycarbonyl-2-styrylcyclopropyl)phosphonates **17a**—**c** in moderate yields. Reduction and oxidation of **7** were studied. The reaction of the phosphonates, **2** and **4**, with ketone enolates and ketones resulted in the formation of unexpected olefins **22**—**24** and dienes **20a, b**. The reaction mechanism is discussed.

In recent years, vinylphosphonates containing electronegative substituents on the α-carbon atom as well as vinylphosphonium salts have been extensively used as versatile reagents for the synthesis of a variety of heterocyclic and carbocyclic compounds, functionalized unsaturated systems such as olefins, dienes and their analogues, and benzene derivatives.[1] As a continuation of the studies on vinylphosphonates, we have previously reported the synthesis of diethyl 4-phenyl-1,3-butadienylphosphonates bearing electronegative substituents and their reactions with oxosulfonium and phosphonium ylides.[2] Since we incorrectly assigned the structures of the reaction products in an earlier communication, we wish to revise the structures and to report further details of the results in this paper. Some studies on the reaction of the phosphonates with nucleophiles such as ketone enolates are also described.

Results and Discussion

The Reaction with Dimethyloxosulfonium Methylide and Phosphonium Ylides. As described in previous communication,[2] the condensation of diethyl (ethoxycarbonylmethyl)phosphonate (**1a**) with cinnamaldehyde in the presence of piperidine gave a 1:1 mixture of diethyl (1*E*,3*E*)-(**2a**) and (1*Z*,3*E*)-(1-ethoxycarbonyl-4-phenyl-1,3-butadienyl)phosphonates (**2b**) in 82% yield, while the reaction using diethyl [cyanomethyl-(**1b**) and methylsulfonylmethyl]phosphonates (**1c**) afforded exclusively diethyl (1*E*,3*E*)-[1-cyano-(**3**) and 1-methylsulfonyl-4-phenyl-1,3-butadienyl]phosphonates (**4**) in 78% and 93% yields, respectively.

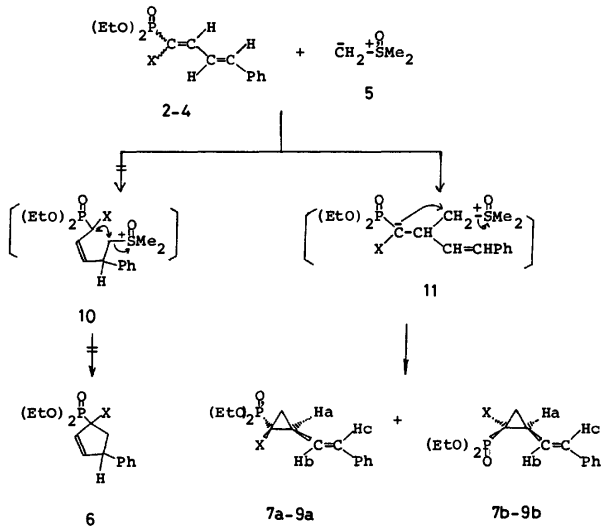
TABLE 1. THE REACTION OF DIETHYL (1-SUBSTITUTED 4-PHENYL-1,3-BUTADIENYL) PHOSPHONATES **2-4** WITH DIMETHYLOXOSULFONIUM METHYLIDE (**5**)

Butadienyl-phosphonates	Products (Product ratio)	Yields/%
2[a]	**7a**+**7b** (1:1)	91
3	**8a**+**8b** (9:1)	87
4	**9a**+**9b** (1:4)	41

a) A 1:1 mixture of **2a** and **2b**.

The reaction of these butadienylphosphonates with dimethyloxosulfonium methylide (**5**) gave mixtures of two isomeric products **7**—**9**, regardless of the stereochemistry of the starting butadienylphosphonates (Table 1). However, this reaction can be said to proceed nearly stereospecifically, since the reaction using single starting butadienylphosphonates **3** and **4** preferentially yielded **8a** and **9b**.



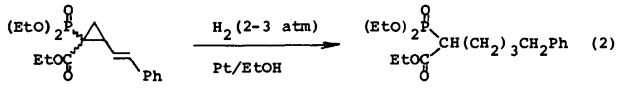
2, 7a, 7b: X = CO_2Et
3, 8a, 8b: X = CN
4, 9a, 9b: X = SO_2Me

Scheme 1.

Although we previously assigned the structures of the products to be diethyl (1-substituted 4-phenyl-2-cyclopentenyl)phosphonates **6**[2], we wish to revise them

here into structures **7**—**9**, since further study of the products indicated that our previous structural assignment was incorrect. The products are composed of mixtures of two stereoisomers, (*E*)- and (*Z*)-(1-substituted 2-styrylcyclopropyl)phosphonates **7**—**9**, whose structural assignment rests upon the following spectroscopic and chemical evidence.

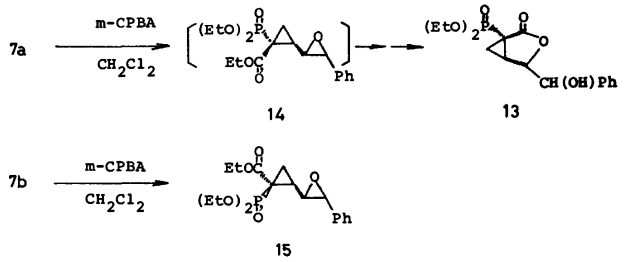
The ^{1}H-NMR spectrum ($CDCl_3$) of **7a** shows methine Ha (m, 1H) at δ 2.15—3.0 and styryl Hb (dd, J=8.61, 15.93 Hz, 1H) and Hc (d, J=15.93 Hz, 1H) at δ 5.70—6.20 and at δ 6.68, while that of **7b** exhibits the corresponding peaks at δ 2.15—2.70 (m, Ha), 6.10—6.65 (dd, J=6.78, 15.93 Hz, Hb), and 6.71 (d, J=15.93 Hz, Hc). On the other hand, the ^{13}C-NMR spectra of **7a** and **7b** reveal a styryl β-carbon at δ 124.7 ppm (s) and at δ 126.7 ppm (d, $^3J_{P\text{-}C}$=4.3 Hz), respectively. Similarly, the styryl β-carbon of **8a** and **9a** resonates at δ 123.3 ppm (s) and at δ 123.1 ppm (s), whereas the corresponding carbon of **8b** and **9b** is found at δ 124.0 ppm (d, $^3J_{P\text{-}C}$=3.4 Hz) and at δ 124.3 ppm (d, $^3J_{P\text{-}C}$=3.4 Hz). Comparing the styryl β ^{13}C chemical shifts in **7a**—**9a** and **7b**—**9b**, it is observed that those in the latter are at 0.7 to 2.0 ppm lower fields from those in the former. It is also found that the compounds **7b**—**9b** have a coupling between phosphorus and the styryl β-carbon of 3.4 to 4.3 Hz, while the compounds **7a**—**9a** show none of the corresponding coupling. On the basis of these results, it can be said that the stereochemistry of **7a** and **7b** is correlated to that of the compounds **8a** and **9a**, and of their isomers **8b** and **9b**, respectively. Since treatment of the butadienylphosphonates **3** and **4** with the ylide **5** predominantly led to **8a** and **9b** as mentioned above, it would be reasonable to assign their structures as diethyl (*E*)-(1-cyano-2-styrylcyclopropyl)- and (*E*)-(1-methylsulfonyl-2-styrylcyclopropyl)-phosphonates rather than as the corresponding (*Z*)-isomers, due to more sterically favorable structures. Accordingly, the stereochemistry of **7a** and **7b** was assigned as (*E*)- and (*Z*)-form, respectively. Furthermore, that the products **7a** and **7b** are stereoisomeric with each other and contain the cyclopropyl moiety in the molecules was evident from the fact that catalytic hydrogenation of the mixture in ethanol over platinum catalyst at low hydrogen pressure gave only diethyl (1-ethoxycarbonyl-5-phenylpentyl)phosphate (**12**) in good yield. For it is well known that the cyclopropyl ring easily undergoes the ring opening in a catalytic hydrogenation.[3]



(2)

7 **12**

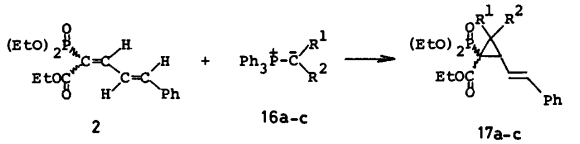
In addition, the structures of **7a** and **7b** were clearly established by their oxidations. Oxidation of **7a** with *m*-chloroperbenzoic acid converted into a lactone **13** in 91% yield, which would be formed *via* a cyclopropyloxirane **14**, while similar treatment of **7b** led to a cyclopropyloxirane **15** in 81% yield (Scheme 2). This result is obviously consistent with the above assigned structures **7a** and 7b, since only the *E*-isomer **7a** in which the ethoxycarbonyl and the styryl groups are located *cis* to each other can lead to **13**.



Scheme 2.

As shown in Scheme 1, these results imply that the ylide carbanion dose not attack on the δ-carbon of the butadienylphosphonates **2**—**4**, but on the β-carbon to give the intermediate **11**, followed by the elimination of dimethyl sulfoxide to lead to the cyclopropylphosphonates **7**—**9**.

The reaction of **2** with various phosphonium ylides **16a**—**c** similarly produced diethyl (3-substituted 1-ethoxycarbonyl-2-styrylcyclopropyl)phosphonates **17a**—**c** in rather low yields (45%—58%) along with comparable yields of triphenylphosphine.



16a, 17a: $R^1 = R^2$ = Me

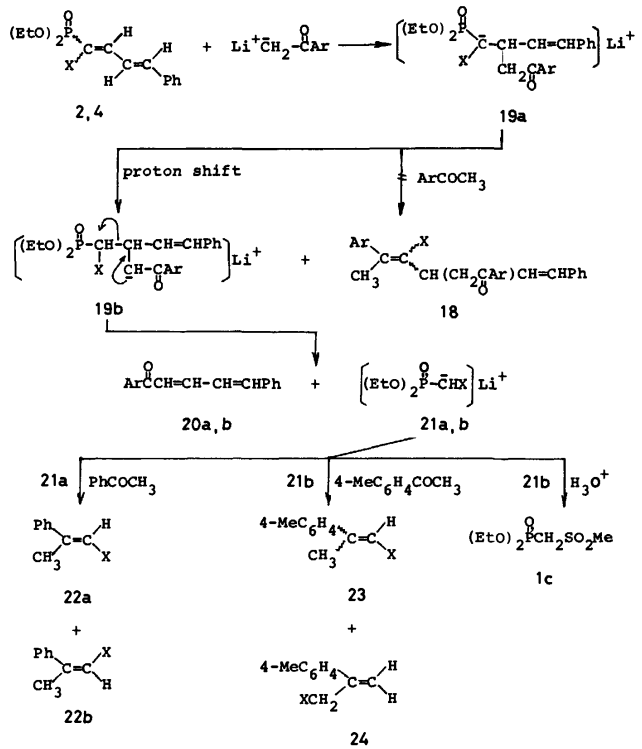
16c, 17c: R^1 = *n*-C_5H_{11}, R^2 = H

+ Ph_3P (3)

The Reaction with Ketone Enolates. Darling and co-workers[4] reported that diethyl butadienylphosphonate containing no substituent undergoes the Michael addition of ketone enolate anions at the δ-position to give keto phosphonate carbanions (1,4-Michael adducts), but no Wittig-Horner reaction product was observed. On the other hand, Martin and Garrison[5] have recently reported that the reaction of [1-(methylthio)butadienyl]phosphonate with nucleophiles such as the enolate anion of formylcyclohexane and lithium dialkylcuprate(I)s similarly gives 1,4-Michael adducts, which subsequently undergo the Wittig-Horner reaction with ketones to yield dienes. Accordingly, it is of interest to examine the reactivity of the (4-phenylbutadienyl)phosphonates **2**—**4** bearing electronegative substituents toward ketone enolate anions, whether the phosphonates undergo 1,4-addition as previously reported or 1,2-addition as in the above-mentioned reaction with ylides. The reaction of **4** with equimolar amounts of the enolate anion of 4-methylacetophenone in the presence of excess 4-methylacetophenone unexpectedly gave 1-(4-methylphenyl)-5-phenyl-2,4-pentadien-1-one (**20b**), 1-methylsulfonyl-2-(4-methylphenyl)-1-propene (**23**), and 2-(4-methylphenyl)-3-methylsulfonyl-1-propene (**24**) in 41, 22, and 36% yields, respectively. Similar treatment of **2** with the enolate anion of acetophenone in the presence of acetophenone likewise led to 1,5-diphenyl-2,4-pentadien-1-one (**20a**), (*E*)- and (*Z*)-1-ethoxycarbonyl-2-phenyl-1-propene (**22a**) and (**22b**) in 51, 37, and 21% yields, respectively. On the other hand, the reaction of **4** with equimolar amounts of the enolate anion of 4-methylacetophenone resulted in the for-



20a: Ar = Ph
20b: Ar = 4-MeC_6H_4
2, 21a, 22a, 22b: X = CO_2Et
4, 21b, 23, 24: X = SO_2Me

Scheme 3.

mation of **20b** (37%) and diethyl (methylsulfonylmethyl)phosphonate (**1c**) (26%). On the basis of these results, the reaction of the butadienylphosphonates **2**, **4** with ketone enolates in the presence of excess ketones can be accounted for by a sequence of a nucleophilic attack of the enolate anions on the β-carbon of the butadienylphosphonates, the proton shift from methylene adjacent to the aroyl group to phosphoryl-stabilized carbanions in **19a** and decomposition of the resultant **19b** to butadienes **20** and the phosphonate carbanions **21**, which react with excess ketones to afford the olefins **22—24** (Scheme 3).

Thus, in contrast to the results reported by Darling *et. al.*[4] and Martin *et. al.*[5] the above results show that butadienylphosphonates containing the phenyl group at the δ position undergo a Michael addition of nucleophiles to the β-carbon but not to the δ-carbon, primarily due to a large steric hindrance.

Studies on the effects of δ substituents on reactivities of butadienylphosphonates and their synthetic applications are in progress.

Experimental

General. ^{1}H-NMR and ^{13}C-NMR spectra were taken in $CDCl_3$ solution on a JEOL JNM-FX-60 operating at 60 and 15.04 MHz with Me_4Si as an internal standard. IR spectra were recorded with a Shimadzu IR-408 instrument. Mass spectra were taken with a JEOL DX-300 spectrometer. Melting points were measured in open capillary tubes and are uncorrected. Distillations of products were carried out with a Kugelrohr apparatus, and bath temperatures are reported.

General Procedure for the Preparation of Diethyl (1-Substituted 4-phenyl-1,3-butadienyl)phosphonates **2—4**. A solution of a phosphonate **1** (0.05 mol) and cinnamaldehyde (6.61 g, 0.05 mol) in 100 ml of dry ethanol containing catalytic amounts of piperidine was refluxed for *ca.* 30 h until disappearance of the carbonyl absorption at 1675 cm^{-1} in the IR spectrum. After removal of solvent ethanol, the residue was dissolved in 100 ml of dry benzene containing catalytic amounts of *p*-toluenesulfonic acid and the solution was refluxed for 3 h. After the usual work-up, bulb-to-bulb distillation of the residue gave a butadienylphosphonate.

*Diethyl (1E,3E)-(**2a**) and (1Z,3E)-(1-Ethoxycarbonyl-4-phenyl-1,3-butadienyl)phosphonate (**2b**).* The reaction was carried out as described above by using diethyl (ethoxycarbonylmethyl)phosphonate (**1a**) (11.21 g, 0.05 mol) to give 13.87 g (82%) yield of a 1:1 mixture of **2a** and **2b** [bp 178 °C/1 mmHg (1 mmHg≈133.322 Pa)]. Pure samples of each were obtained by preparative TLC. The product **2a** had the following properties: IR (neat): 1710, 1610, 1580, 1560, 1235, 1020 cm^{-1}; ^{1}H NMR δ=1.34 (6H, t, J=6.96 Hz, $POCH_2\underline{CH_3}$), 1.36 (3H, t, J=6.96 Hz, $OCH_2\underline{CH_3}$), 3.80—4.52 (6H, m, $PO\underline{CH_2}CH_3$ and $O\underline{CH_2}CH_3$), 6.80—8.10 (8H, m, olefinic and phenyl H); ^{13}C NMR δ=14.0, 16.1 (d, $^3J_{p\text{-}c}$=6.9 Hz), 60.8, 62.2 (d, $^2J_{p\text{-}c}$=6.0 Hz), 119.9 (d, $^1J_{p\text{-}c}$=186.5 Hz), 124.1 (d, $^3J_{p\text{-}c}$=19.8 Hz), 127.7, 128.6, 129.7, 135.3, 145.9, 154.6 (d, $^2J_{p\text{-}c}$=7.7 Hz), 164.4 (d, $^2J_{p\text{-}c}$=13.8 Hz); MS m/z 338 (M^+). The product **2b** had the following properties: IR (neat): 1710, 1610, 1580, 1560, 1235, 1020 cm^{-1}; ^{1}H NMR δ=1.34 (9H, t, J=6.96 Hz, $POCH_2\underline{CH_3}$ and $OCH_2\underline{CH_3}$), 3.80—4.50 (6H, m, $PO\underline{CH_2}CH_3$, and $O\underline{CH_2}CH_3$), 6.80—8.50 (8H, m, olefinic and phenyl H); ^{13}C NMR δ=14.2, 16.3 (d, $^3J_{p\text{-}c}$=6.9 Hz), 61.1, 62.2 (d, $^2J_{p\text{-}c}$=5.2 Hz), 119.4 (d, $^1J_{p\text{-}c}$=185.7 Hz), 124.9 (d, $^3J_{p\text{-}c}$=6.0 Hz), 128.1, 128.7, 129.9, 135.6, 146.7, 156.6 (d, $^2J_{p\text{-}c}$=7.7 Hz), 165.8 (d, $^2J_{p\text{-}c}$=13.8 Hz); MS m/z 338 (M^+).

Found (for a mixture of **2a** and **2b**): C, 60.05; H, 6.90. Calcd for $C_{17}H_{23}O_5P$: C, 60.35; H, 6.85%.

*Diethyl (1E,3E)-(1-Cyano-4-phenyl-1,3-butadienyl)phosphonate (**3**).* The reaction was carried out as described above by using diethyl cyanomethylphosphonate (**1b**) (8.86 g, 0.05 mol) to afford 11.36 g (78%) yield of **3** as a single product. Its structural assignment was made on the basis of the close similarity of its ^{1}H- and ^{13}C-NMR spectra to those of **2a**, as shown below. The product **3** had the following properties: bp 168 °C/2 mmHg; IR (neat): 2160, 1605, 1205 cm^{-1}; ^{1}H-NMR δ=1.39 (6H, dt, J=0.55 Hz, 6.96 Hz, $OCH_2\underline{CH_3}$), 3.80—4.45 (4H, m, $O\underline{CH_2}CH_3$), 7.0—8.05 (8H, m, olefinic and phenyl H); ^{13}C NMR δ=16.2 (d, $^3J_{p\text{-}c}$=6.0 Hz), 63.4 (d, $^2J_{p\text{-}c}$=6.0 Hz), 101.1 (d, $^1J_{p\text{-}c}$=202.0 Hz), 114.5 (d, $^2J_{p\text{-}c}$=12.0 Hz), 123.5 (d, $^3J_{p\text{-}c}$=18.1 Hz), 128.3, 129.0, 130.9, 134.5, 147.5, 159.4 (d, $^2J_{p\text{-}c}$=6.9 Hz); MS m/z 291 (M^+).

Found: C, 61.81; H, 6.20; N, 4.92. Calcd for $C_{15}H_{18}O_3NP$: C, 61.85; H, 6.23; N, 4.81%.

*Diethyl (1E,3E)-(1-Methylsulfonyl-4-phenyl-1,3-butadienyl)-phosphonate (**4**).* The reaction was carried out as described above by using diethyl (methylsulfonylmethyl)phosphonate (**1c**) (11.51 g, 0.05 mol) to produce 10.70 g (93%) yield of **4** as a sole product, whose structural assignment was similarly made by comparison of its ^{1}H- and ^{13}C-NMR spectra with those of **2b**. The compound **4** had the following properties: Mp 113—114 °C; IR (KBr) 1610, 1575, 1550, 1300, 1240, 1120 cm^{-1}; ^{1}H NMR δ=1.31 (6H, t, J=7.05 Hz, $OCH_2\underline{CH_3}$), 3.13 (3H, s, $SO_2\underline{Me}$), 3.80—4.50 (4H, quint., $O\underline{CH_2}CH_3$), 6.75—8.40 (8H, m, olefinic and phenyl H); ^{13}C NMR δ=16.0 (d, $^3J_{p\text{-}c}$=6.9 Hz), 42.9, 62.8 (d, $^2J_{p\text{-}c}$=5.2 Hz), 122.3 (d, $^3J_{p\text{-}c}$=6.0 Hz), 128.0, 128.7, 128.8 (d, $^1J_{p\text{-}c}$=179.7 Hz), 130.4, 134.7, 149.1, 154.5 (d, $^2J_{p\text{-}c}$=6.0 Hz) MS Found: m/z 344.0821. Calcd for $C_{15}H_{21}O_5SP$: 344.0846 (M^+).

General Procedure for the Synthesis of (1-Substituted 2-styrylcyclopropyl)phosphonates **7—9**. To a solution of dimethyloxosulfonium methylide (**5**) (5 mmol) in 15 ml of dry DMSO was added a butadienylphosphonate (5 mmol) in 5 ml of dry DMSO. The reaction mixture was then stirred at 50 °C for 5 h. After conventional work-up, distillation of the residue produced a mixture of two stereoisomers. Pure samples of each were obtained by preparative TLC.

Diethyl (E)-(1-ethoxycarbonyl-2-styrylcyclopropyl)phosphonate (7a): Yield 0.81 g (2.30 mmol, 46%); bp 190 °C/1 mmHg; IR (neat) 1705, 1580, 1240 cm^{-1}; ^1H NMR δ=0.90—2.10 (11H, m, CH_3 and cyclopropyl methylene H), 2.15—3.0 (1H, m, Ha), 3.60—4.50 (6H, m, $\underline{CH_2}CH_3$), 5.70—6.20 (1H, dd, J=8.61 Hz, 15.93 Hz, Hb), 6.68 (1H, d, J=15.93 Hz, Hc), 7.0—7.60 (5H, phenyl H); ^{13}C NMR δ=14.3, 16.5 (d, $^3J_{p\text{-}c}$=6.0 Hz), 19.4, 27.9 (d, $^1J_{p\text{-}c}$=187.4 Hz), 30.3, 61.7, 62.7 (d, $^2J_{p\text{-}c}$=5.2 Hz), 124.7, 126.1, 127.6, 128.6, 134.0, 136.8, 167.5; MS m/z 352 (M^+).

Diethyl (Z)-(1-ethoxycarbonyl-2-styrylcyclopropyl)phosphonate (7b): Yield 0.79 g (2.24 mmol, 45%); bp 190 °C/1 mmHg; IR (neat): 1705, 1580, 1240 cm^{-1}; ^1H NMR δ=0.90—1.50 (9H, m, Me), 1.50—2.15 (2H, m, cyclopropyl methylene H), 2.15—2.70 (1H, m, Ha), 3.75—4.50 (6H, m, $\underline{CH_2}CH_3$), 6.10—6.65 (1H, dd, J=6.78 Hz, 15.93 Hz, Hb), 6.71 (1H, d, J=15.93 Hz, Hc), 6.90—7.50 (5H, m, phenyl H); ^{13}C NMR δ=14.1, 16.4 (d, $^3J_{p\text{-}c}$=6.0 Hz), 21.2, 27.9 (d, $^1J_{p\text{-}c}$=187.4 Hz), 33.7 (d, $^2J_{p\text{-}c}$=2.6 Hz), 61.7, 62.4 (d, $^2J_{p\text{-}c}$=6.0 Hz), 126.1, 126.7 (d, $^3J_{p\text{-}c}$=4.3 Hz), 127.4, 128.5, 133.5, 136.9, 169.6; MS m/z 352 (M^+).

Found (for a mixture of **7a** and **7b**): C, 60.96; H, 7.39%. Calcd for $C_{15}H_{25}O_5P$: C, 61.36; H, 7.15%.

Diethyl (E)-(1-Cyano-2-styrylcyclopropyl)phosphonate (8a): Yield 1.19 g (3.9 mmol, 78.3%); bp 175 °C/2 mmHg; IR (neat): 2215, 1250 cm^{-1}; ^1H NMR δ=1.38 (6H, t, J=7.05 Hz, $CH_2\underline{CH_3}$), 1.55—2.20 (2H, m, cyclopropyl methylene H), 2.20—3.0 (1H, m, Ha), 3.90—4.50 (4H, m, $\underline{CH_2}CH_3$), 5.65—6.15 (1H, dd, J=8.61 Hz, 15.75 Hz, Hb), 6.76 (1H, d, J=15.75 Hz, Hc), 7.31 (5H, s, phenyl H); ^{13}C NMR δ=12.4 (d, $^1J_{p\text{-}c}$=196.0 Hz); 16.2 (d, $^3J_{p\text{-}c}$=6.0 Hz), 20.1, 28.5, 63.7 (d, $^2J_{p\text{-}c}$=6.9 Hz), 116.8 (d, $^2J_{p\text{-}c}$=3.4 Hz), 123.3, 126.1, 127.9, 128.4, 135.2, 135.7; MS m/z 305 (M^+).

Diethyl (Z)-(1-Cyano-2-styrylcyclopropyl)phosphonate (8b): Yield 0.133 g (0.44 mmol, 8.7%); bp 175 °C/2 mmHg; IR (neat): 2215, 1250 cm^{-1}; ^1H NMR δ=1.0—1.56 (6H, m, $CH_2\underline{CH_3}$), 1.56—2.20 (2H, m, cyclopropyl methylene H), 2.25—3.0 (1H, m, Ha), 3.70—4.55 (4H, m, $\underline{CH_2}CH_3$), 6.0—6.50 (1H, dd, J=8.70 Hz, 15.94 Hz, Hb), 6.78 (1H, d, J=15.94 Hz, Hc), 7.30 (5H, br.s, phenyl H); ^{13}C NMR δ=12.3 (d, $^1J_{p\text{-}c}$=197.7 Hz), 16.3 (d, $^3J_{p\text{-}c}$=6.0 Hz), 21.2, 32.3, 63.6 (d, $^2J_{p\text{-}c}$=6.0 Hz), 119.0 (d, $^2J_{p\text{-}c}$=4.3 Hz), 124.0 (d, $^3J_{p\text{-}c}$=3.4 Hz), 126.3, 128.3, 128.7, 135.1, 136.3; MS m/z 305 (M^+).

Found (for a mixture of **8a** and **8b**): C, 62.55; H, 6.68; N, 4.54%. Calcd for $C_{16}H_{20}O_3NP$: C, 62.94; H, 6.60; N, 4.59%.

Diethyl (Z)-(1-Methylsulfonyl-2-styrylcyclopropyl)phosphonate (9a): Yield 0.146 g (0.41 mmol, 8.2%); Oil; IR (neat): 1310, 1230, 1130 cm^{-1}; ^1H NMR δ=1.38 (6H, t, J=7.14 Hz, $CH_2\underline{CH_3}$), 1.55—2.40 (2H, m, cyclopropyl methylene H), 2.40—3.20 (1H, m, Ha), 3.08 (3H, s, $SO_2\underline{Me}$), 3.90—4.60 (4H, m, $\underline{CH_2}$-CH_3), 5.95—6.70 (1H, dd, J=8.79 Hz, 15.93 Hz, Hb), 6.81 (1H, d, J=15.93 Hz, Hc), 7.31 (5H, s, phenyl H); ^{13}C NMR δ=16.4 (d, $^3J_{p\text{-}c}$=6.0 Hz), 17.2, 30.0, 42.4, 42.5 (d, $^1J_{p\text{-}c}$=176.6 Hz), 63.5 (d, $^2J_{p\text{-}c}$=6.0 Hz), 64.2 (d, $^2J_{p\text{-}c}$=6.9 Hz), 123.1, 126.3, 128.1, 128.7, 136.0, 136.3; MS Found: m/z 358.1005. Calcd for $C_{16}H_{23}O_5SP$: 358.1004 (M^+).

Diethyl (E)-(1-Methylsulfonyl-2-styrylcyclopropyl)phosphonate (9b): Yield 0.582 g (1.62 mmol, 32.8%); mp 77 °C; IR (KBr) 1300, 1230, 1130 cm^{-1}; ^1H NMR δ=1.0—1.60 (6H, m, $CH_2\underline{CH_3}$), 1.60—2.30 (2H, m, cyclopropyl methylene H), 2.60—3.30 (1H, m, Ha), 3.15 (3H, s, $SO_2\underline{Me}$), 6.0—6.50 (1H, dd, J=8.42 Hz, 15.75 Hz, Hb), 6.75 (1H, d, J=15.75 Hz, Hc), 7.30 (5H, s, phenyl H); ^{13}C NMR δ=16.3 (d, $^3J_{p\text{-}c}$=6.0 Hz), 19.2, 28.8 (d, $^2J_{p\text{-}c}$=2.5 Hz), 41.3, 42.3 (d, $^1J_{p\text{-}c}$=183.2 Hz), 63.3 (d, $^2J_{p\text{-}c}$=6.9 Hz), 63.7 (d, $^2J_{p\text{-}c}$=6.1 Hz), 124.3 (d, $^3J_{p\text{-}c}$=3.4 Hz), 126.1, 127.7, 128.6, 134.6, 136.5; MS Found: m/z 358.0985. Calcd for $C_{16}H_{23}O_5SP$: 358.1004 (M^+).

Diethyl (1-Ethoxycarbonyl-3,3-dimethyl-2-styrylcyclopropyl)-phosphonate (17a). To a solution of isopropylidenetriphenylphosphorane (**16a**) (5 mmol), *in situ* generated from isopropyltriphenylphosphonium bromide (1.97 g, 5 mmol) and butyllithium (5.5 mmol), in 15 ml of THF was added **2** dissolved in 10 ml of THF at room temperature. The solution was then refluxed for 6 h. After conventional work-up, the residue was chromatographed on silica gel using benzene and chloroform as eluent. The first fraction gave 0.80 g (61%) yield of triphenylphosphine. Distillation of the oily product obtained from the second fraction gave **17a** (1.11 g, 58%), which is composed of two stereoisomers. The separation of the two isomers was not attempted. The compound **17a** had the following properties: bp 170 °C/1 mmHg; IR (neat): 1720, 1600, 1260 cm^{-1}, ^1H NMR δ=1.0—1.60 (15H, m, Me), 2.39—2.96 (1H, m, CH-), 3.85—4.55 (6H, m, OCH_2), 6.25—6.75 (1H, dd, J=8.42 Hz, 15.80 Hz, olefinic H), 6.75—7.0 (1H, 2xd, olefinic H), 7.20—7.55 (5H, m, phenyl H); MS Found: m/z 380.1773. Calcd for $C_{20}H_{29}O_5P$: 380.1771 (M^+).

Diethyl [1-Ethoxycarbonyl-3-(4-methoxyphenyl)-2-styrylcyclopropyl]phosphonate (17b). The reaction was carried out as described above using **2** (0.66 g, 2 mmol) and 4-methoxybenzylidenetriphenylphosphorane (**16b**) (2 mmol). After the usual work-up, the residue was similarly chromatographed on silica gel to give 0.26 g (50%) of triphenylphosphine and 0.41 g (45%) of **17b**: Oil; IR (neat): 1720, 1260 cm^{-1}; ^1H NMR δ=1.27 (9H, t, J=7.1 Hz, $CH_2\underline{CH_3}$), 1.1—2.45 (2H, m, CH-), 3.71 (3H, s, OCH_3), 3.75—4.40 (6H, m, $\underline{CH_2}CH_3$), 5.75—6.25 (1H, dd, olefinic H), 6.55—6.90 (1H, 2xd, olefinic H), 7.0—7.55 (9H, m, aromatic H); MS Found: m/z 458.1904. Calcd for $C_{25}H_{31}O_6P$: 458.1858 (M^+).

Diethyl (1-Ethoxycarbonyl-3-pentyl-2-styrylcyclopropyl)phosphonate (17c). The reaction was carried out as described above using **2** (0.66 g, 2 mmol) and *n*-hexylidenetriphenylphosphorane (**16c**). After the usual work-up, the residue was similarly chromatographed on silica gel to give 0.43 g (51%) of **17c**: Oil; IR (neat): 1710, 1610, 1250 cm^{-1}; ^1H NMR δ=0.85—2.20 (22H, m, CH_3, CH_2, CH-), 3.85—4.45 (6H, m, OCH_2), 6.05—6.40 (1H, m, olefinic H), 6.50—6.85 (1H, m, olefinic H), 7.27 (5H, s, phenyl H); MS Found: m/z 422.2269. Calcd for $C_{23}H_{35}O_5P$: 422.2222 (M^+).

Hydrogenation of **7**. The hydrogenation of **7** (1:1 mixture of **7a** and **7b**) (0.35 g, 1 mmol) was accomplished in 10 h in ethanol over Pt (PtO_2, 20 mg) to afford **12** (0.28 g, 79%) as a colorless oil: IR (neat): 1720, 1260 cm^{-1}; ^1H NMR δ=1.13—2.25 (15H, m, CH_3 and CH_2), 2.61 (2H, t, J=8.06 Hz, $CH_2\underline{CH_2}Ph$), 2.80—3.25 (1H, m, CH-), 3.85—4.40 (6H, quint. OCH_2), 7.19 (5H, s, phenyl H); MS Found: m/z 356.1717. Calcd for $C_{18}H_{29}O_5P$; 356.1751.

Oxidation of **7a**. A solution of a mixture of **7a** (0.16 g, 0.45 mmol) and *m*-chloroperbenzoic acid (70%, 0.19 g, 1.67 equiv) in 5 ml of CH_2Cl_2 was refluxed for 10 h. After the usual work-up, the residue was chromatographed on preparative TLC with ether as eluent to give 0.14 g (91%) of *1-diethoxyphosphinyl-4-(α-hydroxybenzyl)-3-oxabicyclo[3.1.0]-hexan-2-one* (**13**): Oil; IR (neat): 3300, 1770, 1260 cm^{-1}; ^1H NMR δ=1.35 (6H, t, J=6.96 Hz, CH_3), 1.02—2.18 (2H, m, cyclopropyl CH_2), 2.30—2.85 (1H, cyclopropyl CH-), 3.40—3.75 (1H, br., OH, D_2O exchangeable), 3.90—4.60 (5H, m, OCH_2 and lactone CH-), 4.85—5.10 (1H, br., -$\underline{CH}$ (OH)Ph), 7.37 (5H, s, phenyl H); ^{13}C NMR δ=16.2, 16.4 (d, $^3J_{p\text{-}c}$=6.9 Hz), 23.3 (d, $^1J_{p\text{-}c}$=200.3 Hz), 24.7, 63.2 (d, $^2J_{p\text{-}c}$=6.0 Hz), 63.6 (d, $^2J_{p\text{-}c}$=5.2 Hz), 73.5, 82.5, (d, $^3J_{p\text{-}c}$=2.6 Hz), 126.3, 128.0, 128.6, 138.7, 171.6 (d, $^2J_{p\text{-}c}$=10.3 Hz); MS Found: m/z 341.1175. Calcd for $C_{16}H_{22}O_6P$: 341.1154 (M^++1).

Oxidation of **7b**. A solution of **7b** (0.20 g, 0.568 mmol) and *m*-chloroperbenzoic acid (70%, 0.21 g, 1.50 equiv.) was treated under the same condition as **7a**. After a similar work-up, the residue was chromatographed on preparative TLC with ether as eluent to give 0.170 g (81%) of *(E)-2-[(Z)-1-ethoxycarbonyl-1-diethoxyphosphinylcyclopropyl]-3-phenyloxirane (15)*: Oil; IR (neat): 1720, 1260, 1020 cm^{-1}; ^1H NMR δ=0.80—2.10 (12H, m, CH_3, cyclopropyl CH_2 and CH-), 3.20—3.50 (1H, m, -CH(O)-CHPh), 3.50—4.50 (7H, m, OCH_2 and -CH(O)-CHPh), 7.28 (5H, s, phenyl H); ^{13}C NMR δ=13.9, 16.1 (d, $^3J_{p-c}$=5.2 Hz), 19.3, 24.6 (d, $^1J_{p-c}$=194.3 Hz), 30.4 (d, $^2J_{p-c}$=2.6 Hz), 58.6, 60.0 (d, $^3J_{p-c}$=3.4 Hz), 61.7, 62.4 (d, $^2J_{p-c}$=6.0 Hz), 125.6, 128.1, 136.5, 169.0 (d, $^2J_{p-c}$=7.7 Hz); MS Found: *m/z* 368.1359. Calcd for $C_{18}H_{27}O_7P$: 368.1362 (M^+).

Reaction of **4** *with 4-Methylacetophenone in the Presence of Lithium Diisopropylamide (LDA). A. The Reaction Using Excess Amounts of 4-Methylacetophenone*: To a cooled solution of LDA (1.1 mmol) in THF (15 ml) at −75 °C was added 4-methylacetophenone (0.30 g, 2.24 mmol). The solution was stirred for 1 h at this temperature. Then the butadienylphosphonate **4** (0.33 g, 0.96 mmol) was added to the solution and the mixture was stirred at −75 °C for 0.5 h and at refluxing temperature for 10 h. After a conventional work-up, the residue was chromatographed on preparative TLC with $CHCl_3$ as eluent to give **20b** (97 mg, 41%), **23** (44 mg, 22%) and **24** (73 mg, 36%), respectively.

1-(4-Methylphenyl)-5-phenyl-2,4-pentadien-1-one (20b): Mp 84—85 °C; IR (KBr): 1640 cm^{-1}; ^1H NMR δ=2.36 (3H, s, Me), 6.60—7.60 (11H, m, aromatic and olefinic H), 7.88 (2H, d, *J*=8.10 Hz, the other aromatic H); MS Found: *m/z* 248.1216. Calcd for $C_{18}H_{16}O$: 248.1201 (M^+).

1-Methylsulfonyl-2-(4-methylphenyl)-1-propene (23): Oil; IR (neat): 1300, 1120 cm^{-1}; ^1H NMR δ=2.38 (3H, s, Me), 2.56 (3H, d, *J*=1.17 Hz, Me(H)C=C(H)), 3.04 (3H, s, SO_2Me), 6.38—6.60 (1H, q, *J*=1.17 Hz, olefinic H), 6.80—7.50 (4H, m, aromatic H); MS Found: *m/z* 210.0746. Calcd for $C_{11}H_{14}O_2S$: 210.0715 (M^+). This compound was consistent with an authentic sample independently prepared from **1c** and 4-methylacetophenone.

2-(4-Methylphenyl)-3-methylsulfonyl-1-propene (24): Mp 56—57 °C; IR (KBr): 1300, 1120 cm^{-1}; ^1H NMR δ=2.35 (3H, s, Me), 2.71 (3H, s, SO_2Me), 4.17 (2H, s, CH_2SO_2Me), 5.50 (1H, s, olefinic H), 5.72 (1H, s, olefinic H), 6.90—7.50 (4H, m, phenyl H); MS Found: *m/z* 210.0738. Calcd for $C_{11}H_{14}O_2S$: 210.0715 (M^+). This compound was consistent with an authentic sample prepared from **1c** and 4-methylacetophenone.

B. The Reaction Using an Equimolar Amount of 4-Methylacetophenone. The reaction was similarly carried out at −75 °C for 1 h and at room temperature for 10 h using the procedure described above with **4** (0.34 g, 0.99 mmol), 4-methylacetophenone (0.15 g, 1.12 mmol) and LDA (1.1 mmol) in dry THF (20 ml). After the usual work-up, similar treatment of the residue gave **20b** (90 mg, 37%) and **1c** (60 mg, 26%).

Reaction of **2** *with Acetophenone in the Presence of LDA.* The reaction was carried out as described above using **2** (0.34 g, 1 mmol), acetophenone (0.24 g, 2 mmol) and LDA (1 mmol). After similar treatment, **20a**, **22a**, and **22b** were obtained in 0.12 g (51%), 0.07 g (37%), and 0.04 g (21%) yields, respectively.

1,5-Diphenyl-2,4-pentadien-1-one (20a): Oil; IR (neat): 1650 cm^{-1}; ^1H NMR δ=6.70—8.10 (14H, m, aromatic and olefinic H); MS Found: *m/z* 234.1035. Calcd for $C_{17}H_{14}O$: 234.1044 (M^+).

(E)-1-Ethoxycarbonyl-2-phenyl-1-propene (22a): Oil; IR (neat): 1720 cm^{-1}; ^1H NMR δ=1.07 (3H, t, *J*=7.14 Hz, CH_2CH_3), 2.17 (3H, d, *J*=1.47 Hz, CH_3(H)C=C(H)), 3.99 (2H, q, *J*=7.14 Hz, OCH_2CH_3), 5.90 (1H, q, *J*=1.47 Hz, CH_3(H)C=C(H)), 6.90—7.50 (5H, m, phenyl H); MS Found: *m/z* 190.1013. Calcd for $C_{12}H_{14}O_2$: 190.0994 (M^+). This compound was consistent with an authentic sample prepared from **1a** and acetophenone.

(Z)-1-Ethoxycarbonyl-2-phenyl-1-propene (22b): Oil; IR (neat): 1710 cm^{-1}; ^1H NMR δ=1.30 (3H, t, *J*=7.18 Hz, CH_2CH_3), 2.57 (3H, d, *J*=1.17 Hz, CH_3(H)C=C(H)), 4.42 (2H, q, *J*=7.18 Hz, OCH_2CH_3), 6.13 (1H, q, *J*=1.17 Hz, CH_3(H)C=C(H)), 7.10—7.60 (5H, m, phenyl H); MS *m/z* 190 (M^+). This compound was consistent with an authentic sample prepared from **1a** and acetophenone.

We are grateful for support of this work by a Grant-in-Aid for Scientific Research (No 58550548) from the Ministry of Education, Science and Culture.

Carbon-13 NMR Spectra of 5-(4-Substituted Benzylidene)-2,3,4,5-tetrahydropyridines

Yoshito TAKEUCHI,* Takashi BANDO, Shuji TOMODA, and Yujiro NOMURA
Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received December 26, 1983)

Carbon-13 chemical shifts for a series of 5-(4-substituted benzylidene)-2,3,4,5-tetrahydropyridines were determined. The substituent chemical shifts (SCS) were correlated with σ_I and σ_R° values by means of DSP and DSP-NLR analysis. It was found that as a substituent the C=C-C=N moiety is as mild as C=C and that the former can be approximated as a vinylogue of the C=N moiety. C-13 lanthanoid-induced shifts (LIS) of the parent compound were also discussed.

Numerous attempts have been made to correlate electronic substituent constants with C-13 chemical shifts of substituted aromatic systems.[1] Extention of these correlation to the aromatic systems with additional π-bonded side chains continue to interest several group of investigaters[2] in connection with the elucidation of the mechanism of transmission of the electronic substituent effect through the conjugated system.

Recently we prepared a series of 5-(4-substituted benzylidene)-2,3,4,5-tetrahydropyridine (**1a—1g**) by the reaction of 2,3,4,5-tetrahydropyridine trimer and appropriately substituted benzaldehydes.[3] These compounds are interesting in that the side chain C=C double bond is further conjugated with C=N double bond, and that the two double bonds are fixed in the *s-trans* conformation. In this study we compare C-13 substituent chemical shifts (SCS) of **1** with those of 4-substituted styrenes (**2**)[4] and 4-substituted phenylacetylenes (**3**),[5] in order to estimate the effect of additional conjugation by C=N bond upon the electronic property of styrene framework.

Comparison will also be made with SCS of *N*-(4-substituted benzylidene)-methylamines (**4**),[6] *N*-(4-substituted benzylidene)-*t*-butylamines (**5**)[6] and *N*-(4-substituted benzylidene)anilines (**6**),[7] and *N*-benzylidene(4-substituted aniline)s (**7**)[7] where C=N bond is directly bonded to the benzene ring.

Experimental

The preparation of benzylidenetetrahydropyridines **1a—1g** were already reported.[3]

The solutions for NMR measurements were prepared by dissolving *ca.* 50 mg of the **1a—1g** into $CDCl_3$ (1.0 ml) containing 1% tetramethylsilane (TMS) which acts as the internal standard. For LIS (lanthanoid-induced shift) study, 54 mg (0.316 mmol) of 5-(4-substituted benzylidene)-2,3,4,5-tetrahydropyridine was dissolved in $CDCl_3$ (1.0 ml), and a weighed amount of Eu(fod)$_3$ was added. The molar ratio of shift reagent/solute varied from 0.023 to 0.297.

The instrument employed was JEOL FX-90Q spectrometer operating at 22.5 MHz with a 10 mm $^1H/^{13}C$ dual probe. The spectra were obtained with proton noise decoupling for 5KHz spectral width, collection of 8K data points in the FID, and 13 μs pulse width (45°). Usually 100 scans were accumlated with a 3.5s pulse interval after each pulse. C-13 NMR chemical shifts of **1a—1g** were listed in Table 1. Assignment of C-13 NMR signals of **1a** was already reported.[8] Assignments of signals for **1b—1g** were made by comparison with the data for corresponding styrenes (**2a—2g**).[4]

Results and Discussion

The Nature of C=C-C=N Moiety. Compounds **1** may be regarded as one of aromatic systems of the general type *p*-X-C_6H_4-Y which has been extensively investigated in view of the electronic interaction between the two substituents as manifested by C-13 SCS.[9] A comparison of SCS of **1** with those of **2** is expected to depend on the difference of the interactions, one between X (variable substituents) and C=C-C=N and the other between X and C=C moiety. If the additional C=N bond does not affect the interaction to any significant extent, the correlation of SCS of **1a—1g** with those of **2a—2g** for the equivalent positions should provide a linear correlation with a slope of unity. The result of correlations is listed in Table 2.

TABLE 2. CORRELATION BETWEEN SCS FOR 1 AND 2[a]

Carbon	a	b	r
C5(Cβ)	0.759	−0.443	0.993
Cα	1.932	0.885	0.975
Cl′	1.104	0.250	>0.999
C3′	1.040	0.266	0.998
C4′	1.024	−0.559	0.999

a) SCS(**1**)=a·SCS(**2**)+b; r, correlation coefficient.

Except for C2′ (meta to the substituent), a reasonable correlation (r>0.975) is always obtained. The slope of the correlation at Cl′ is larger than unity by 0.1, suggesting that the interaction of C=C-C=N moiety with X is a little larger than that of C=C moiety. The deviation of the slope from unity is much more enhanced at side-chain carbons (Cα and Cβ). This is consistent with the contribution of such a zwitterionic canonical structure as

$$>C=C-C=N- \cdots\cdots >C^{+}-C=C-N^{-}- \quad (1)$$
$$\alpha\ \beta\ 6 \qquad\qquad \alpha\ \beta\ 6$$

DSP and DSP-NLR Analysis. In order to clarify the nature of the interaction shown in Table 2, a DSP (dual substituent parameter) or a DSP-NLR (nonlinear resonance effect)[9,10] of **1** and **2** together with a variety of related systems **3**—**7** were attempted. DSP or DSP-NLR analyses were made on an identical sets of substituents, *i.e.*, NMe_2, OMe, Me, Cl, CN, and NO_2, wherever possible. In certain cases SCS data for one or two substituents were not available but from previous experiences, this will not likely to cause a serious error. According to Taft *et al.*[9] C-13 SCS of appropriate carbons of substituted aromatic system of the general type X-C_6H_4-Y where X and Y are variable and fixed substituent, respectively, can be correlated with the DSP and DSP-NLR based on the equation

$$\text{C-13 SCS} = \rho_I\sigma_I + \rho_R\sigma_R^{\circ}/(1-\varepsilon\sigma_R^{\circ}), \quad (2)$$

where σ_I and σ_R° are inductive and resonance substituent constants, respectively, and ρ_I and ρ_R are transmission coefficients determined by the least-square method. ε is null in DSP analysis by definition, while a constant for each fixed substituent Y in DSP-NLR analysis and characterizes the electron demand exerted by Y.

The results of the ayalyses for Cl′, Cα, and C5(Cβ), are summerized in Table 3. In this Table cases where f, the goodness of fit parameter, is above 0.06, the critical value for an acceptable fit, are also included for the sake of comparison. At Cl′, both ρ_I and ρ_R of **1** are larger than those of **2**, which corresponds to the slope (1.1) of the correlation given in Table 2. The ε value is small, comparable with that for **2**, to indicate that the C=C-C=N moiety is "mild" in the sense that there is no additional interaction with X through the π-frame. It is in sharp contrast with much larger ε values for **3**, **5**—**7**.

It is reported[9] that ε values in DSP-NLR analyses largely depend on the nature of terminal atoms with which Y is bonded to the benzene ring. In **1**—**6**, although the terminal atoms are all carbons, the termini can be subdivided into three types, *i.e.*, C=C, C≡C, or C=N. Our data indicate that a C=C terminal is milder than C≡C, C=N (**5**, **6**) or N=C (**7**) termini regardless of the presence of further conjugation.

A large deviation of the solpe from unity found in the correlation for Cα and Cβ given in Table 2 clearly shows that a considerable perturbation was invoked in the electronic properties of C=C bond in **1**. The slope for Cα is three times as large as that for Cβ probably because of the contribution of dipolar structure as shown in Eq. (1).

The DSP analyses of SCS for these side-chain carbons show that at Cα both ρ_I and ρ_R for **1** are larger than those for **2**. The increase is more significant for ρ_R. At Cβ, the contrary is the case. Thus, both ρ_I and ρ_R of **1** are smaller than those for **2**, and the decrease is larger for ρ_I. In view of the rather small difference between **1** and **2** of ρ_I and ρ_R at Cl′, it may be concluded that the side-chain carbon nuclei rather than the aromatic carbon atoms are much more affected by the elongation of conjugated system.

There remains one small problem. May **1** be ragarded as a vinylogue of **4**—**6**? ρ_I and ρ_R of **1** at C6 are −1.38 and −1.17, respectively, with f=0.16. The resonance effect of X is transmitted to C6 of **1** even more effectively than to Cα of **4**—**6**. Hence, **1** may be regarded as a vinylogue of such imines as **4**—**6** at least in a qualitative manner. The smaller ρ_I of **1** at C6 corresponds to the greater number of intervening bond or greater distance be-

a) Values in parentheses. In certain DSP-NLR analyses ε values did not converge on reasonables values.
b) For definition of parameters, see Eq(1).

tween X and C-6 while larger ρ_R of **1** indicates more effective transmission of resonance effect to C-6 through π-frame as compared with that between X and Cα.

Lanthanoid-induced Shifts. Lathanoid-induced shifts of C-13 nuclei are due to the combination of contact and pseudo contact shifts. The contact term, which is much more important in conjugated systems than in saturated systems, causes in certain cases an alternating sign along the carbon chain.[11]

The contact shift arises from the delocalization of the unpaired electron of the shift reagent to the substrate atoms. It occurred to us that there might be parallelism between the extent of spin delocalization and the transmission of substituent effect through the π-frame. Thus the sign of ρ values of **1** at C6 (both negative) clearly establishes the alternating nature of the ρ signs along the π-chain Cl'-Cα-Cβ-C6. This alternation has been pointed out[5] for side-chain C-13 shifts for **2** and chalcones (two carbon unit). Our system is, to the best of our knowledge, the longest π-chain with alternating ρ signs.

With this in mind, we measured LIS of **1a** by Eu(fod)$_3$. The result is summarized in Fig. 1, where the observed LIS are plotted against the molar ratio [Eu(fod)$_3$]/[solute]. Clearly, the sign of LIS does alternate along Cl'-Cα-Cβ-C6 chain. Negative LIS for Cβ and Cl' are associated with positive ρ values, and positive LIS for Cα and C6 with negative ρ values. This parallelism is another piece of evidence to the through conjugation in Ph-C=C-C=N moiety.

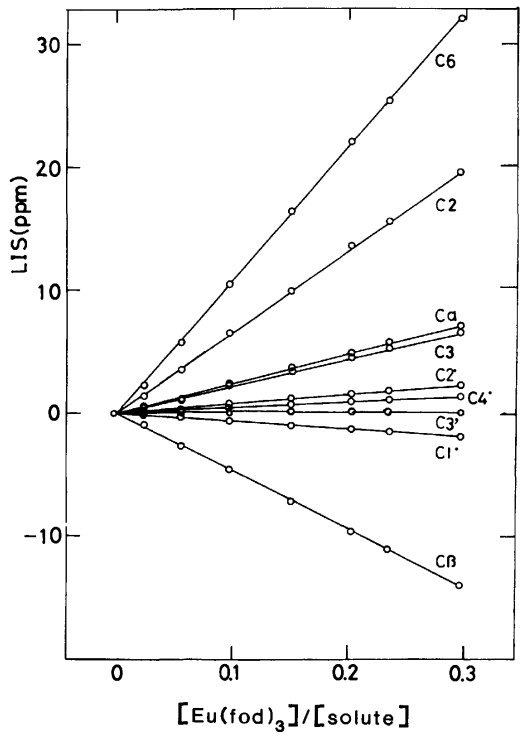

Fig. 1. Lanthanoid-induced shifts (LIS) in 5-benzylidene-2,3,4,5-tetrahydropyridine (**1a**).

Conclusion

The nature of C=C-C=N moiety in **1** as a substituent is mild and very close to the C=C moiety in respect to the magnitude of interaction with the variable substituent X attached to the same aromatic ring. The transmission of substituent effect of X to the side chain of **1** is somewhat different from that of compounds with -C=N or -N=C side-chains. The general behavior of **1** may, however, be regarded as a vinylogue of benzylideneamines. In **1**, the alternation of signs of ρ values in DSP analyses are parallel with that of LIS along Cl'-Cα-Cβ-C6 linkage. This phenomenon might be useful for theoretical treatment of the substituent effect in aromatic system.

The present work was partially suppoted by a Grant-in-Aid for Scientific Research No. 443007 from the Ministry of Education, Science and Culture.

Base-induced Cyclization of *N*-[Bis(ethoxycarbonyl)methyl]-2-bromo-3-hydroxybutyramide Derivatives

Masao Shiozaki,* Noboru Ishida, Tetsuo Hiraoka, and Hiroshi Maruyama
Chemical Research Laboratories of Sankyo Company Limited, Hiromachi 1-2-58, Shinagawa-ku, Tokyo 140
(Received December 24, 1983)

Treatment of (2*R*,3*R*)-*N*-(2,4-dimethoxybenzyl)-*N*-[bis(ethoxycarbonyl)methyl]-2-bromo-3-hydroxybutyramide (**5**) with DBU yielded the bicyclic β-lactam **13** by a direct cyclization, and its diastereoisomer **14** and the γ-lactam **15** *via* the *trans*-epoxide **6**. The same treatment of (2*S*,3*R*)-isomer (**11**) gave the direct cyclization product **14** in 93% yield. On the other hand, reaction of **5** and **11** with sodium hydride afforded the 2-azetidinone derivatives (mainly **14** (23%) from **5**, and **19** (75%) from **11**, respectively) *via* the corresponding epoxides **6** and **12**.

The first report on the discovery of thienamycin (isolation, structure, and biological activity) by the groups of Merck Sharp and Dohme Research Laboratories in 1976 produced a broad impact on organic chemists as well as medicinal chemists. This was because of the unique structure of thienamycin, different from that of traditional β-lactam antibiotics, and because of its powerful biological activity. Since its discovery, many congeners of thienamycin have been isolated as natural products and, at the same time, many attempts at syntheses of these carbapenems have been carried out by many groups. As one of such groups, we have reported on the stereocontrolled syntheses of monocyclic intermediates to carbapenems possessing a (1-hydroxy)ethyl side chain at the C-3 position.[1] Ahead of the cyclization of *N*-(2,4-dimethoxybenzyl)-*N*-(*t*-butoxycarbonylmethyl)-2-bromo-3-hydroxybutyramide[1b] obtained from L-threonine, the cyclization of 2-bromo-3-hydroxybutyramide derivatives (**5** and **11**) by means of bases was investigated in order to use the results in carbapenem synthesis.[2] As a result, it was confirmed that whether passing through the 2,3-epoxy derivatives (**6** or **12**) or not, base-induced intramolecular S_N2 cyclization occurred to give β-lactam derivatives as main products, together with the starting threonines (L-, L-*allo*, D-, and D-*allo*-). Thus we might be able to obtain the desired stereoisomer at the C-3 position and a hydroxyethyl side chain of β-lactam congeners.

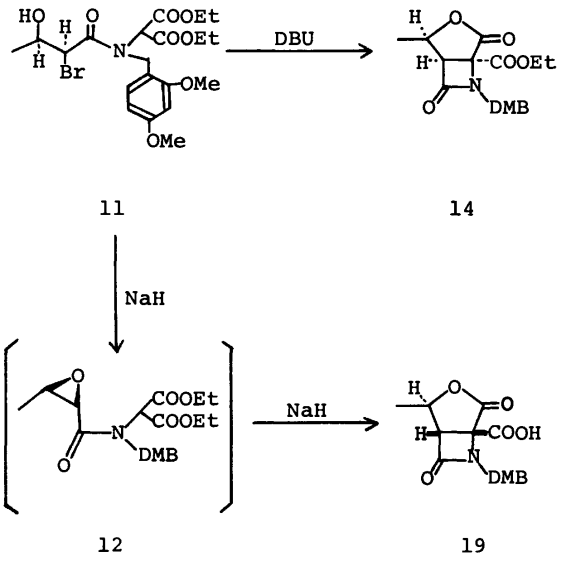
Scheme 2.

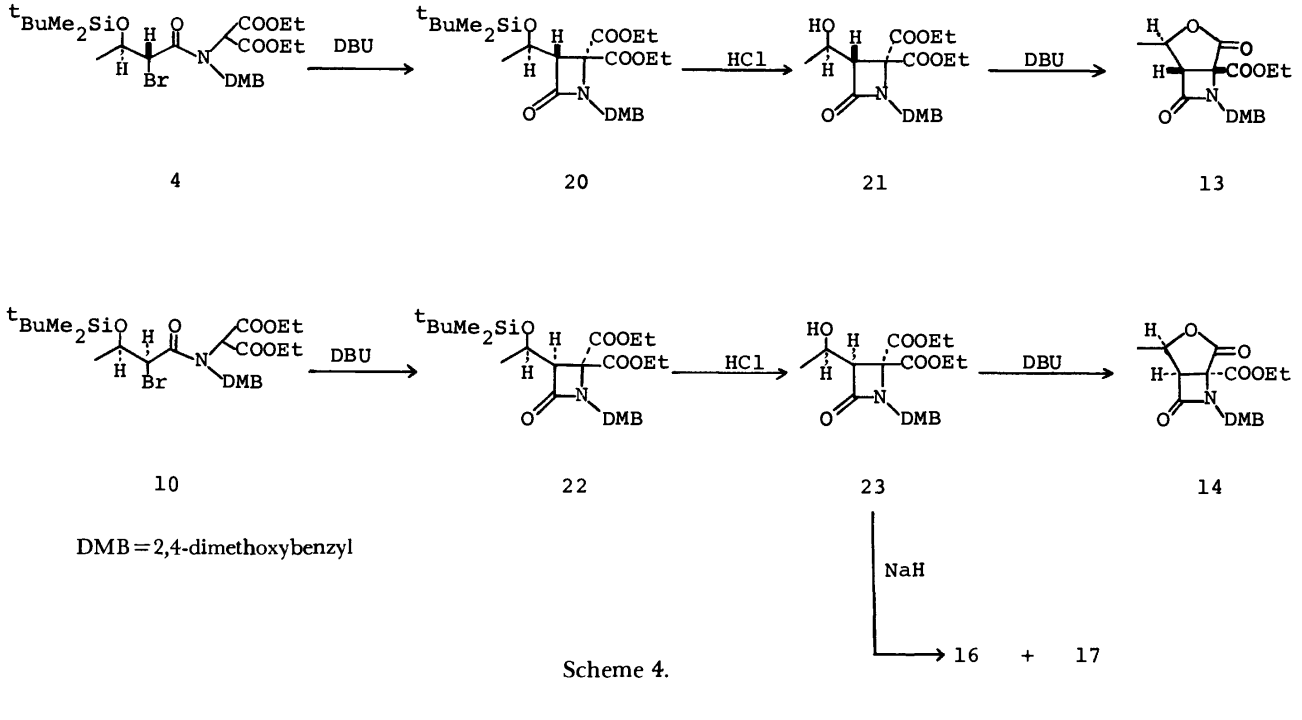
We wish here to report the results.

The starting **5** and **11** were synthesized as follows (Scheme 1). (2*R*,3*R*)-2-Bromo-3-hydroxybutyric acid (**1**) obtained from (2*R*,3*R*)-threonine (D-*allo*-threonine) was converted to the corresponding *t*-butyldimethylsilyl ether **2**, which was further treated with oxalyl dichloride in tetrahydrofuran (THF) at 20 °C for 3—16 h to give the acid chloride **3**. Treatment of **3** with diethyl (2,4-dimethoxybenzylamino)malonate in THF in the presence of Et_3N gave the *t*-butyldimethylsilyl ether **4**: Mp 90—91 °C: $[\alpha]_D^{25}$ −18.5° (*c*=2.00, $CHCl_3$). Desilylation of **4** with EtOH–H_2O–conc. HCl (9:2:1) gave **5**: Mp 74.5—75.5 °C: $[\alpha]_D^{24}$ −18.0° (*c*=2.00, $CHCl_3$). In addition, (2*S*,3*R*)-2-bromo-3-hydroxybutyric acid (**7**) obtained from (2*S*,3*R*)-threonine (L-threonine) was converted to **11** *via* **8**, **9**, and **10** according to the procedures described above. In the proton NMR of these *N*,*N*-disubstituted amides which contain a chiral part on the molecule, each of the methylene protons neighboring the nitrogen becomes non-equivalent. As a result, the methylene protons often show an AB-type coupling, and each part of the malonyl esters occasionally shows a different chemical shift.

Treatment of **5** with 2 equivalents of NaH in THF at 0 °C for 30 min gave the *trans*-epoxide **6** in 86% yield (Scheme 2). However, treatment of **5** with 1 equivalent of NaH resulted only in the recovery of the starting **5**. On the other hand, treatment of **5** with 2 equivalents of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in THF at 25 °C for 4 h gave mainly three products, a 6:1 mixture of bicyclic lactone azetidinones (**13** and **14**) in 75% yield (both were inseparable chromatographically and the ratio of **13** and **14** (6:1) was estimated by comparison with the authentic ^{1}H-NMR data of **13** and **14** obtained from **21** and **23**, respectively), and the hydroxy γ-lactam **15** in 7% yield. This result reveals that treatment of **5** with DBU incurs both direct 2-azetidinone formation to give **13** and epoxidation to give the intermediate **6**, and then successive ring closure of **6** branches off two pathways to give a normal ring closure product with a 4-membered ring and a 5-membered ring product, which results in a violation of Baldwin's ring closure rules.[3] As a matter of course, treatment of the epoxide **6** with DBU yielded two products, **14** and **15**, in 60% and 30% yields, respectively. On the other hand, treatment of **6** with 1.2 equivalents of NaH at 25 °C for 2 h gave **14** (23%) as a major product, and **15** (7.5%), **16** (6%), **17** (2%), and an unknown product (**18**) (mp 148—153 °C) as minor products. In this experiment, **14** was obtained *via* lactonization of the corresponding hydroxy carboxylic acid. The absolute configuration and the rate of racemization of **16** and **17** were not clear; however, the value of $[\alpha]_D^{25}$ of **16** was −2.7° in EtOH. The tendency for ring closure of the epoxide **6** by treatment with DBU or NaH was a little different, that is, the yields of **14** and **15** were 60% and 30% for use of DBU,



Scheme 3.



Scheme 4.

but 23% and 7% for use of NaH. In addition, it was obvious that the common intermediate to form **14**, **16**, and **17** was the compound **23**, as mentioned later.

We tried the cyclization of **11** with DBU and NaH (Scheme 3). Treatment of **11** with 2 equivalents of DBU in THF at 25 °C for 3 h gave **14** (93%), *via* a corresponding hydroxy carboxylic acid and by direct cyclization without passing through the epoxide **12**, as a single product. However, treatment of **11** with 3.7 equivalents of NaH in THF at 15 °C for 16 h gave a carboxylic acid **21** (76%) as a crystalline solid: Mp 180—184 °C; $[\alpha]_D^{25}$ −77.9° (*c*=2.00, THF), *via* the *cis*-epoxide **12**.

Alternatively, the compounds **13**, **14**, **15**, and **17** were synthesized from the O-protected compounds, **4** and **10** (Scheme 4). Treatment of **4** with DBU gave **20** (93%) as an oil: $[\alpha]_D^{25}$+28.5° (*c*=2.55, $CHCl_3$). Desilylation of **20** with EtOH–H_2O conc. HCl (9:2:1) at 20 °C for 16 h gave **21** (92%). Lactonization of **21** with DBU gave **13** (89%). In the same way, cyclization of **10** with DBU gave **22** (86%). Desilylation of **22** with EtOH–H_2O-conc. HCl (9:2:1) at 25 °C for 3 h gave **23** (60%) as a crystyalline solid: Mp 91—92 °C; $[\alpha]_D^{24}$ −75.6° (*c*=0.44, $CHCl_3$). Lactonization of **23** with DBU gave **14** in good yield. On the other hand, treatment of **23** with 1.56 equiv of NaH at 15 °C for 16 h gave **16** (13.9%), whose $[\alpha]_D^{24}$ value was −2.8° (*c*=0.47, EtOH), and **17** (7.5%).

Thus, we can obtain the required stereoisomers by use of the reaction of the O-protected or nonprotected 2-bromo-3-hydroxybutyramide derivatives or their corresponding epoxides[4] with alkaline metal or amine base.

Experimental

Melting points were determined on a Yanagimoto micromelting point apparatus and were uncorrected. Optical rotations were obtained by the use of a Perkin-Elmer 241 polarimeter. ^{1}H-NMR spectra were recorded at 60 MHz with a Varian T-60 spectrometer using tetramethylsilane as an internal standard. The IR absorption spectra were determined on a Jasco IR A-2 spectrophotometer. Mass spectra were obtained on a JMS-OlSG mass spectrometer. Preparative TLC was performed on silica gel plates (Merck 60 PF_{245}), and column chromatography was carried out on columns packed with Merck silica gel 60 using slightly increased pressure (1.5 atm) for elution. Elemental analyses were performed by the Analytical Centre of Analytical and Metabolic Research Laboratories, Sankyo Company, Limited.

(2R,3R)-2-Bromo-3-(t-butyldimethylsilyloxy)butyric Acid (2). To a solution of (2*R*,3*R*)-2-Bromo-3-hydroxybutyric acid[1c] (**1**, 18.3 g, 0.10 mol) in DMF (50 ml) was added *t*-butyldimethylsilyl chloride (45 g, 0.30 mol), Et_3N (30 g) and 4-dimethylaminopyridine (1.0 g). The mixture was stirred for 16 h at room temperature, then poured into water (300 ml), adjusted to pH 2 with dil HCl and then pH 8 with powdery $NaHCO_3$, and washed twice with Et_2O (each 200 ml). The aqueous layer was saturated with NaCl, and reacidified to pH 2 with dil HCl, and extracted with Et_2O (200 ml×3). The extract was washed with brine, dried over $MgSO_4$, and concentrated *in vacuo* to give 6.4 g (21.5%) of **2**, which was employed for the next reaction without further purificaiton. ^{1}H NMR ($CDCl_3$) δ=0.12 (6H, s), 0.90 (9H, s), 1.38 (3H, d, *J*=6 Hz), 4.01 (1H, d, *J*=8 Hz), 4.20 (1H, qd, *J*=6, 8 Hz), 9.62 (1H, bs, COOH). IR ν_{max} (film) 3600—2400, 1720 cm^{-1}. MS *m/z* 241 (M^+–Bu^t, ^{81}Br), 239.

(2S,3R)-2-Bromo-3-(t-butyldimethylsilyloxy)butyric Acid (8). (2*S*,3*R*)-2-Bromo-3-hydroxybutyric acid (**7**) was treated as described above to give **8** (30%) as an oil. IR ν_{max} (film) 3600—2400, 1723 cm^{-1}. NMR ($CDCl_3$) δ=0.12 (6H, s), 0.93 (9H, s), 1.21 (3H, d, *J*=6 Hz), 4.0—4.4 (2H, m), 9.51 (1H, bs, COOH). MS *m/z* 241 (M^+–Bu^t, ^{81}Br), 239.

(2R,3R)-2-Bromo-3-(t-butyldimethylsilyloxy)butyryl Chloride (3). To a solution of **2** (6.0 g, 20.2 mmol) in THF (30 ml) was added oxalyl dichloride (5.0 ml, 59 mmol) at 25 °C. After 3 h stirring, the reaction mixture was concentrated *in vacuo* to give 6.3 g (99%) of **3** as an oil, which was employed for the next reaction without purification. NMR ($CDCl_3$) δ=0.10 (6H, s), 0.88 (9H, s), 1.40 (3H, d, *J*=6 Hz), 4.1—4.5 (2H, m). IR ν_{max} (film) 1810 cm^{-1}.

(2S,3R)-2-Bromo-3-(t-butyldimethylsilyloxy)butyryl Chloride (9). The acid **8** was treated as described above to give an acid chloride **9** (quantitative), which was employed for the next reaction without purification. IR ν_{max} (film) 1815 cm^{-1}.

(2R,3R)-N-(2,4-Dimethoxybenzyl)-N-[bis(ethoxycarbonyl)methyl]-2-bromo-3-(t-butyldimethylsilyloxy)butyramide (4). To a solution of **3** (5.25 g, 16.6 mmol) and diethyl (2,4-dimethoxybenzylamino)malonate[1b] (5.40 g, 16.6 mmol) in THF (50 ml) was added a solution of Et_3N (1.70 g, 16.6 mmol) in THF (20 ml) at 5 °C with stirring over a period of 10 min. After the stirring was continued for 30 min at room temperature, the reaction mixture was extracted with EtOAc. The organic layer was washed with dil HCl, sat $NaHCO_3$ and brine, dried over $MgSO_4$, and concentrated *in vacuo* to give an oily residue which was chromatographed on a silica-gel (200 g) column. Elution with cyclohexane–EtOAc (4:1) gave 0.25 g of an unknown material at lower R_f value and 5.32 g (54%) of **4** as a crystalline solid: Mp 90—91 °C (from hexane). $[\alpha]_D^{25}$ −18.5° (*c*=2.0, $CHCl_3$). IR ν_{max} ($CHCl_3$) 1750 (shoulder), 1740, 1665, 1613, 1590 cm^{-1}. NMR ($CDCl_3$) δ=0.12 (6H, s), 0.90 9H, s), 1.05 3H, t, *J*=7 Hz), 1.26 (3H, t, *J*=7 Hz), 1.31 3H, d, *J*=6 Hz), 3.4—4.6 [12H, m, (containing 3H singlet at δ= 3.80 and 3H singlet at δ=3.83)], 4.70 (2H, s), 5.58 (1H, s), 6.28—6.48 (2H, m), 7.22 (1H, d, *J*=9 Hz).

Found: C, 51.97; H, 7.11; N, 2.27; Br, 13.17%. Calcd for $C_{26}H_{42}NO_8SiBr$: C, 51.60; H, 6.95; N, 2.32; Br, 13.21%.

(2S,3R)-N-(2,4-Dimethoxybenzyl)-N-[bis(ethoxycarbonyl)methyl]-2-bromo-3-(t-butyldimethylsilyloxy)butyramide (10). The acid chloride (**9**, 3.25 g) was treated as described above to give 1.62 g (26%) of **10**, 2.18 g of unknown material and 0.88 g of *N*-(2, 4-dimethoxybenzyl)-*N*-[bis(ethoxycarbonyl)methyl]-2-bromocrotonamide, which was due to the contamination of the corresponding acid chloride in the starting **9**. MS *m/z* 548 (M^+–Bu^t, ^{81}Br), 546. IR ν_{max} (film) 1750, 1662, 1612, 1588 cm^{-1}. NMR ($CDCl_3$) δ= 0.10 (3H, s), 0.14 (3H, S), 0.90 (9H, s), 1.20 (3H, t, *J*=7 Hz), 1.22 (3H, t, *J*=7 Hz), 1.25 (3H, d, *J*=6 Hz), 3.78 (3H, s), 3.80 (3H, s), 3.9—4.9 (9H, m), 6.40 (1H, d, *J*= 2 Hz), 6.40 (1H, dd, *J*=2, 9 Hz), 7.16 (1H, d, *J*=9 Hz).

Found: C, 51.83; H, 7.20; N, 2.30; Br, 13.14%. Calcd for $C_{26}H_{42}O_8NBrSi$: C, 51.60; H, 6.95; N, 2.32; Br, 13.21%.

(2R,3R)-N-(2,4-Dimethoxybenzyl)-N-[bis(ethoxycarbonyl)methyl]-2-bromo-3-hydroxybutyramide (5). A solution of **4** (4.26 g, 7.0 mmol) in EtOH (180 ml) and dil HCl (H_2O/conc. HCl=2/1, 60 ml) was stirred for 8 h at 20 °C, concentrated to a volume of 100 ml, and extracted with EtOAc (300 ml). The organic layer was washed with sat $NaHCO_3$ and brine, dried over $MgSO_4$ and concentrated to give an oily residue which was chromatographed on a silica-gel (100 g) column. Elution with cyclohexane–EtOAc (1:1) gave 3.45 g (quantitative) of **5** as a crystalline solid: Mp 74.5—75.5 °C (from EtOH). $[\alpha]_D^{24}$ −18.0° (*c*=2.00, $CHCl_3$). IR ν_{max} ($CHCl_3$) 3560, 1760—1740, 1650, 1613, 1590 cm^{-1}. NMR ($CDCl_3$) δ=1.17 (3H, t, *J*=7 Hz), 1.22 (3H, t, *J*=7 Hz), 1.40 (3H, d, *J*=6 Hz), 3.52 (1H, d, *J*= 4 Hz, OH), 3.78 (3H, s), 3.81 (3H, s), 4.08 (2H, q, *J*=7 Hz), 4.11 (2H, q, *J*=7 Hz), 4.40 (1H, d, *J*=3.5 Hz, C_2–H), 4.48, 4.85 (2H,

AB-q, J=16 Hz), 4.63 (1H, s), 6.28—6.47 (2H, m, olefinic), 7.02—7.17 (1H, m, olefinic).

(2S,3R)-N-(2,4-Dimethoxybenzyl)-N-[bis(ethoxycarbonyl)methyl]-2-bromo-3-hydroxybutyramide (11). The silyl ether **10** was treated with EtOH-H_2O-conc. HCl (9:2:1) for 1 h at 20 °C as described above to give **11** (81.5%) as a viscous oil. IR ν_{max} (film) 3475, 1750, 1739, 1655, 1610, 1587 cm^{-1}. NMR ($CDCl_3$) δ=1.20 (3H, t, J=7 Hz), 1.22 (3H, t, J=7 Hz), 1.26 (3H, d, J=7 Hz), 3.84 (6H, s), 3.97—5.05 (10H, m), 6.48 (1H, d, J=2 Hz), 6.48 (1H, dd, J=2, 9 Hz), 7.15 (1H, J=9 Hz).

Found: C, 48.76; H, 5.80; N, 2.81; Br, 16.17%. Calcd for $C_{20}H_{28}O_8NBr$: C, 48.95; H, 5.71; N, 2.85; Br, 16.30%.

(2S,3R)-N-(2,4-Dimethoxybenzyl)-N-[bis(ethoxycarbonyl)methyl]-2,3-epoxybutyramide (6). To a solution of **5** (490.3 mg, 1.0 mmol) in THF (4 ml) was added NaH (55% dispersion in mineral oil, 83 mg, 2.0 mmol) at 0 °C. After 30 min stirring, the starting **5** had disappeared completely. The reaction mixture was diluted with EtOAc, washed with 5% HCl, sat $NaHCO_3$ and brine, dried over $MgSO_4$, and concentrated *in vacuo* to give an oily residue which was chromatographed on preparative silica-gel TLC plates. Development with cyclohexane-EtOAc (1:1) gave 352 mg (86%) of **6** as a viscous oil. NMR ($CDCl_3$) δ=1.20 (6H, t, J=7 Hz), 1.22 (3H, d, J=5 Hz), 3.65 (1H, dq, J=2, 5 Hz), 3.38 (1H, d, J=2 Hz), 3.80 (3H, s), 3.81 (3H, s), 4.10 (2H, q, J=7 Hz), 4.13 (2H, q, J=7 Hz), 4.71 (2H, s), 5.29 (1H, s), 6.43 (2H, m), 7.17 (1H, d, J=9 Hz). IR ν_{max} (film) 1750—1730, 1672, 1612, 1590 cm^{-1}.

Found: C, 58.30; H, 6.51; N, 3.29%. Calcd for $C_{20}H_{27}O_8N$: C, 58.67; H, 6.65; N, 3.42%.

Reaciton of 5 with DBU. To a solution of **5** (245 mg, 0.5 mmol) in THF (4 ml) was added DBU (152 mg, 1 mmol) at 25 °C with stirring. After 4 h, the reaction mixture was diluted with EtOAc, then washed with 10% HCl, sat $NaHCO_3$ and brine, dried over $MgSO_4$, and concentrated *in vacuo* to give an oily mixture. The mixture was chromatographed on preparative silica-gel TLC plates. Development with EtOAc-cyclohexane (1:1) gave 136 mg (75%) of a 6:1 mixture of **13** and **14** which could not be separated because the R_f values of 0.40 were almost the same (The ratio of **13**:**14** was estimated by comparison with authentic ^{1}H-NMR data of **13** and **14** obtained from **21** and **22**, respectively.), and 14 mg (7%) of **15** (R_f=0.25). MS m/z 409 (M^+), 223, 167, 151. IR ν_{max} (film) 3360, 1750 (shoulder), 1730, 1695, 1612, 1590 cm^{-1}. NMR ($CDCl_3$) δ=1.07 (3H, t, J=7 Hz), 1.19 (3H, t, J=7 Hz), 1.25 (3H, d, J=7 Hz), 2.55—3.12 (1H, m), 3.6—4.3 [12H, m, (containing 6H singlet at δ=3.77)], 4.49, 4.78 (2H, AB-q, J=16 Hz), 6.35 (1H, d, J=2 Hz), 6.35 (1H, dd, J=2, 9 Hz), 6.90 (1H, d, J=9 Hz).

Found: C, 58.22; H, 6.99; N, 3.37%. Calcd for $C_{20}H_{27}O_8N$: C, 58.67; H, 6.65; N, 3.42%.

Reaction of 6 with DBU. A soluiton of 6 (205 mg, 0.5 mmol) and DBU (80 mg, 0.53 mmol) in THF (5 ml) was stirred for 6 h at 25 °C and concentrated *in vacuo* to give an oily mixture, which was chromatographed on preparative silica-gel TLC plates. Development with cyclohexane-EtOAc (1:1) gave 61 mg (29.8%) of **15** on R_f=0.25 as a viscous oil, and an acidic product on R_f=0, which was eluted off from the silica gel with MeOH. The MeOH solution was concentrated *in vacuo* to give an oily residue which was diluted with EtOAc. The EtOAc solution was washed with 5% HCl, H_2O and brine, dried over $MgSO_4$, and concentrated *in vacuo* to give 108 mg (59.5%) of the lactonized product **14** as a viscous oil. MS m/z 363 (M^+). IR ν_{max} (film) 1770, 1750 (shoulder), 1735 (shoulder), 1613, 1590 cm^{-1}. NMR ($CDCl_3$) δ=1.26 (3H, t, J=7 Hz), 1.55 (3H, d, J=6 Hz), 3.90 (1H, d, J=7 Hz, C_1-H), 4.22 (2H, q, J=7 Hz), 4.38, 4.63 (2H, AB-q, J=15 Hz), 4.76 (1H, quintaplet, J=7 Hz, C_2-H), 6.2—6.5 (2H, m), 7.12 (1H, d, J=9 Hz).

Found: C, 59.47; H, 5.86; N, 3.73%. Calcd for $C_{18}H_{21}O_7N$: C, 59.49; H, 5.83; N, 3.86%.

Raction of 6 with NaH. To a solution of **6** (150 mg, 0.367 mmol) in THF (2 ml) was added NaH (55% dispersion in mineral oil, 20 mg, 0.458 mmol) at 25 °C with strirring. After 2 h, the reaction mixture was diluted with EtOAc, washed with 5% HCl, H_2O, brine, dried over $MgSO_4$, and concentrated *in vacuo* to give an oily residue which was chromatographed on a preparative silica-gel TLC plate. Development with cyclohexane-EtOAc (1:1) gave 7 mg (6%) of **16** (R_f=0.683); $[\alpha]_D^{25}$ −2.7 ° (c=0.77, EtOH), 15 mg of a mixture of **17** and unknown **18** (R_f=0.583, Fractional crystallization of this mixture from *i*-Pr_2O gave 11 mg of **18** as a crystalline solid; mp 148—153 °C. The remaining mother liquor contained 4 mg of a 1:1 mixture of **17** and **18**. This was estimated by the comparison with the ^{1}H NMR of each authentic sample of **17**, obtained from **23**, and **18**.), 17 mg (7.5%) of **15** (R_f=0.283), and an acidic product (R_f=0) which was eluted off from the silica-gel with MeOH, and concentrated *in vacuo* to give an oily residue which was diluted with EtOAc (50 ml). The solution was washed with 10% HCl, H_2O and brine, dried over $MgSO_4$, and concentrated *in vacuo* to give 31 mg (23.3%) of **14**.

Reaction of 11 with DBU. A solution of **11** (120 mg, 0.245 mmol) and DBU (76 mg, 0.500 mmol) in THF (2 ml) was stirred for 1 h at 25 °C. The precipitated DBU-HBr salt was filtrated, and the filtrate was concentrated *in vacuo* to give an oily residue which was chromatographed on a preparative silica gel TLC plate. Development with cyclohexane-EtOAc (1:1) gave an acidic material of R_f=0. The silica gel layer of this part was eluted with MeOH which was concentrated *in vacuo* to give a residue. The residue was diluted with EtOAc which was washed with 10% HCl, H_2O and brine, and dried over $MgSO_4$, and then concentrated *in vacuo* to give 83 mg (93.4%) of **14** as a viscous oil.

Reaction of 11 with NaH. To a solution of **11** (120 mg, 0.245 mmol) in THF (2 ml) was added NaH (55% dispersion in mineral oil, 40 mg, 0.917 mmol) under cooling with ice bath.

The mixture was kept for 16 h at 15 °C, then diluted with EtOAc, washed with 10% HCl, H_2O and brine, dried over $MgSO_4$, and concentrated *in vacuo* to give a crude crystalline acid. The acid was suspended in a small amount of EtOAc, triturated in large excess of hexane, and then collected by suction filtration to give 62 mg (75.6%) of **19** as a crystalline solid: Mp 180—184 °C (from EtOAc). $[\alpha]_D^{23}$ −77.9 °C (c=2.00, THF). IR ν_{max} (Nujol) 3500—2400, 1780, 1740, 1730 (shoulder), 1613, 1588 cm^{-1}. NMR (DMF-d_7) δ=1.40 (3H, d, J=6 Hz), 3.78 (6H, s), 4.10 (1H, d, J=1 Hz), 4.47 (2H, s), 4.93 (1H, dq, J=1, 6 Hz), 6.55 (1H, dd, J=2, 9 Hz), 6.58 (1H, d, J=2 Hz), 7.18 (1H, d, J=9 Hz), 10.50 (1H, bs, COOH).

Found: C, 57.49; H, 5.22; N, 4.18%. Calcd for $C_{16}H_{17}O_7N$: C, 57.31; H, 5.11; 4.18%.

(3S)-1-(2,4-Dimethoxybenzyl)-3-[(R)-1-(t-butyldimethylsilyloxy)ethyl]-4,4-bis(ethoxycarbonyl)-2-azetidinone (20). To a solution of **4** (1.0 g, 1.65 mmol) in THF (20 ml) was added DBU (300 mg, 1.97 mmol) at 20 °C. After 16 h stirring at 20 °C, the reaction mixture was diluted with EtOAc, washed with a cold 5% HCl aqueous solution, sat $NaHCO_3$ and brine, dried over $MgSO_4$, and concentrated *in vacuo* to give 0.79 g (92.8%) of **20** as an oil. $[\alpha]_D^{25}$ +28.5 ° (c=2.55, $CHCl_3$). NMR ($CDCl_3$) δ=0.08 (6H, s), 0.88 (9H, s), 1.04 (3H, t, J=7 Hz), 1.26 (3H, t, J=7 Hz), 1.33 (3H, d, J=6 Hz), 3.6—4.5 [12H, m, (containing 6H singlet at δ=3.79)], 4.50, 4.79 (2H, AB-q, J=15 Hz), 6.39 (1H, d, J=2 Hz), 6.39 (1H, dd, J=2, 9 Hz), 7.09 (1H, d, J=9 Hz). IR ν_{max} (film) 1770, 1742, 1613, 1590 cm^{-1}. MS m/z 466 (M^+−C_4H_9).

Found: C, 58.84; H, 7.45; N, 2.58%. Calcd for $C_{26}H_{41}O_8NSi$: C, 59.58; H, 7.83; N, 2.67%.

(3S)-1-(2,4-Dimethoxybenzyl)-3-[(R)-1-(hydroxy)ethyl]-4,4-bis(ethoxycarbonyl)-2-azetidinone (21). A solution of **20** (523.7 mg, 1.0 mmol) in EtOH–H_2O–conc HCl (9:2:1, 24 ml) was allowed to stand for 16 h at 20 °C. The reaction mixture was diluted with EtOAc, washed with water, sat $NaHCO_3$ and brine, dried over $MgSO_4$, and concentrated *in vacuo* to give a crude mixture which was chromatographed on preparative silica-gel TLC plates. Development with cyclohexane–EtOAc (1:1) gave 376 mg (91.8%) of **21** (R_f=0.52) as a viscous oil. IR ν_{max} (film) 3475, 1765-1730, 1610, 1588 cm^{-1}. NMR ($CDCl_3$) δ=1.10 (3H, t, J=7 Hz), 1.28 (3H, t, J=7 Hz), 1.38 (3H, d, J=6 Hz), 3.18 (1H, bs, OH), 3.66 (1H, d, J=9 Hz), 3.78 (6H, s), 3.88 (2H, q, J=7 Hz), 4.27 (2H, q, J=7 Hz), 4.38, 4.72 (2H, AB-q, J=15 Hz), 4.0—4.5 (1H, m), 6.38 (1H, d, J=2 Hz), 6.38 (1H, dd, J=2, 9 Hz), 7.05 (1H, d, J=9 Hz). MS m/z 409 (M^+), 364.

Found: C, 59.27; H, 5.94; N, 3.80%. Calcd for $C_{18}H_{21}O_7N$: C, 59.49; H, 5.83; N, 3.86%.

(3R)-1-(2,4-Dimethoxybenzyl)-3-[(R)-1-(t-butyldimethylsilyloxy)ethyl]-4,4-bis(ethoxycarbonyl)-2-azetidinone (22). A solution of **10** (485 mg, 0.80 mmol) in THF (5 ml) containing DBU (122 mg, 0.802 mmol) was refluxed for 30 min. After cooling, the reaction mixture was diluted with EtOAc, washed with 1% HCl, sat $NaHCO_3$ and brine, dried over $MgSO_4$, and concentrated *in vacuo* to give a crude oil which was chromatographed on silica-gel preparative TLC plates. Development with cyclohexane–EtOAc (3:1) gave 363 mg (86%) of **22** (the same R_f value as that of the starting **10**). NMR ($CDCl_3$) δ=0.05 (3H, s), 0.08 (3H, s), 0.88 (9H, s), 1.05 (3H, t, J=7 Hz), 1.24 (3H, t, J=7 Hz), 1.35 (3H, d, J=6 Hz), 3.62 (1H, d, J=3.5 Hz), 3.78 (6H, s), 3.78 (2H, q, J=7 Hz), 4.20 (2H, q, J=7 Hz), 4.33 (1H, dq, J=3.5, 6 Hz), 4.43, 4.72 (2H, AB-q, J=15 Hz), 6.36 (1H, d, J=2 Hz), 6.36 (1H, dd, J=2, 9 Hz), 7.16 (1H, d, J=9 Hz). IR ν_{max} (film) 1770, 1740, 1613, 1590 cm^{-1}. MS m/z 466 (M^+–Bu^t).

Found: C, 58.86; H, 7.44; N, 2.70%. Calcd for $C_{26}H_{41}O_8NSi$: C, 59.58; H, 7.83; N, 2.67%.

(3R)-1-(2,4-Dimethoxybenzyl)-3-[(R)-1-(hydroxy)ethyl]-4,4-bis(ethoxycarbonyl)-2-azetidinone (23). A solution of **22** (350 mg, 0.668 mmol) in EtOH–H_2O–conc HCl (9:2:1, 8 ml) was allowed to stand for 3 h at 25 °C. The reaction mixture was diluted with EtOAc, washed with water, sat $NaHCO_3$ and brine, dried over $MgSO_4$, and concentrated *in vacuo* to give a crude oily mixture which was chromatographed on silica-gel preparative TLC plates. Development with cyclohexane–EtOAc (1:1) gave 164 mg (60%) of **23** (R_f=0.367) as a crystalline solid: Mp 91—92 °C (from EtOAc-hexane). $[\alpha]_D^{24}$ −75.6 (c=0.44, $CHCl_3$). NMR ($CDCl_3$) δ= 1.08 (3H, t, J=7 Hz), 1.28 (3H, t, J=7 Hz), 1.43 (3H, d, J=6 Hz), 1.95 (1H, d, J=6 Hz, OH), 3.6—4.2 [8H, m, (containing 6H singlet at δ=3.81)], 4.25 (4H, q, J=7 Hz), 4.48, 4.81 (2H, AB-q, J=15 Hz), 6.39 (1H, d, J=2 Hz), 6.39 (1H, dd, J=2, 9 Hz), 7.13 (1H, d, J=9 Hz). IR ν_{max} (Nujol) 3390, 1760—1730, 1610, 1585 cm^{-1}.

Found: C, 58.70; 6.63; N, 3.44%. Calcd for $C_{20}H_{27}O_8N$: C, 58.67; H, 6.65; N, 3.42%.

(1R,2R,5R)-6-(2,4-Dimethoxybenzyl)-5-ethoxycarbonyl-2-methyl-4,7-dioxo-3-oxa-6-azabicyclo[3.2.0]heptane (14). Treatment of **23** with one equivalent of DBU as described above in the formation of **14** from **11** by DBU gave **14** in 72% yield.

(Z)- and (E)-1-(2,4-Dimethoxybenzyl)-3-ethylidene-4-ethoxycarbonyl-2-azetidinone (16) and (17). To a solution of **23** (120 mg, 0.293 mmol) in THF (2 ml) was added NaH (55% dispersion in mineral oil, 20 mg). The mixture was stirred for 16 h at 15 °C, and diluted with EtOAc. The solution was washed with H_2O and brine, dried over $MgSO_4$, and concentrated *in vacuo* to give an oily residue which was chromatographed on a silica-gel preparative TLC plate. Development with cyclohexane–EtOAc (4:1) gave 13 mg (13.9%) of **16** (R_f=0.17) and 7 mg (7.5%) of **17** (R_f=0.070). **16**: $[\alpha]_D^{25}$ −2.8° (c=0.47, EtOH). NMR ($CDCl_3$) δ=1.26 (3H, t, J=7 Hz), 2.00 (3H, d, J=7 Hz), 3.78 (3H, s), 3.81 (3H, s), 4.20 (2H, q, J=7 Hz), 4.21 (1H, d, J=1 Hz), 4.27, 4.72 (2H, AB-q, J=14.5 Hz), 5.66 (1H, dq, J=1, 7 Hz), 6.40 (2H, m), 7.10 (1H, d, J=9 Hz). IR ν_{max} (film) 1750, 1720 (shoulder, w), 1613,1590 cm^{-1}. MS m/z 319 (M^+), 290, 246, 218, 166, 151.

Found: C, 63.39; H, 6.54; N, 4.26%. Calcd for $C_{17}H_{21}O_5N$: C, 63.88; H, 6.57; N, 4.38%. **17**: NMR ($CDCl_3$) δ=1.27 (3H, t, J=7 Hz), 1.76 (3H, d, J=6.5 Hz), 3.80 (3H, s), 3.82 (3H, s), 4.22 (2H, q, J=7 Hz), 4.25, 4.70 (2H, AB-q, J=14 Hz), 4.38 (1H, d, J=1 Hz), 6.15 (1H, dq, J=1, 6.5 Hz), 6.41 (1H, dd, J=2, 9 Hz), 6.41 (1H, d, J=2 Hz), 7.12 (1H, d, J=9 Hz). IR ν_{max} (film) 1760—1740, 1612, 1590 cm^{-1}. MS m/z 319 (M^+), 290, 246, 218, 166, 151, 126, 121.

Found: C, 63.34; H, 6.49; N, 4.27%. Calcd. for $C_{17}H_{21}O_5N$: C, 63.88; H, 6.57; N, 4.38%.

(Received December 28, 1983)

Irradiation of 1,4-dibromo-2,5-piperazinedione (**1**) with olefins in acetonitrile gave mixtures of addition products (1:1-adducts and 1:2-adducts). Addition of 1,2-epoxybutane (a hydrogen bromide scavenger) resulted in enhanced yields of the adducts. Structures of the adducts were elucidated and a reaction mechanism is discussed.

The allylic bromination of olefins by *N*-bromosuccinimide (NBS) was believed to involve the bromide atom chain (the Goldfinger mechanism). However, Skell and his co-workers[1,2] showed that the reaction of NBS with cyclohexene in dichloromethane gave 3- and 4-bromocyclohexenes and 1-bromo-2-succinimidocyclohexane. Thus the substitution and the addition are competitive processes (substitution/addition= 0.17). Chow and his co-workers[3] similarly exemplified that in the photolysis of an acetonitrile solution of NBS in the presence of cyclohexene the succinimido radical preferentially added to the olefin double bond to give the same adduct. These findings suggest the intervention of the succinimido radical as the chain carrier where the concentration of NBS is kept high by using good NBS dissolving solvents and the concentration of the bromine molecule is kept low by added olefins. The addition reaction of acylaminyl radicals to olefins, however, has not been so thoroughly examined. Thouchard and Lessard[4] reported that the photochemical reaction of *N*-haloacetamides with olefins gave addition products in good yields, but *N*-halo-*N*-methylacetamides failed to add to simple olefins.[5] In a previous paper,[6] we described that irradiation of 1,4-dibromo-2,5-piperazinedione (**1**) with cyclohexene resulted in the radical addition of **1** to cyclohexene to give 1-(2-bromocyclohexyl)-2,5-piperazinediones (1:1-adducts) and 1,4-bis(2-bromocyclohexyl)-2,5-piperazinediones (1:2-adducts) in acetonitrile, dichloromethane, or chloroform, which are characterized as good solvents for **1**. This paper concerns the product distribution in photoaddition of **1** to 1-alkene isomers in acetonitrile. The structures of adducts and the reaction mechanism are also discussed.

Results and Discussion

The photoreaction of 1,4-dibromo-2,5-pipera-

a) A mixture of **1** (2 mmol) and an olefin (20 mmol) in 10 cm^3 of acetonitrile was irradiated at ambient temperature for 5 h. Isolated yields are given based on **1** employed. b) 1,2-Epoxybutane (4 mmol) was added. c) A mixture of two stereoisomers. d) Unchanged **1** was recovered in 60% yield.

zinedione (**1**, 2 mmol) with isomeric 1-alkenes (**2**—**5**, 20 mmol) was carried out in acetonitrile using a high pressure mercury lamp at ambient temperature. The reaction gave mixtures of 1 : 1-adducts (**2′**—**5′**; characterized by ′) and 1 : 2-adducts (**2″**—**5″**; characterized by ″) in addition to allylic brominated products and dibromides. The adduct mixtures were separated by silica-gel column chromatography, and the structures were determined by elemental and spectroscopic analyses. The results are summarized in Scheme 1 and Table 1.
