Ethyl 3-Hydroxy-2-mercapto-2,3-dimethylnonanoate (5d): Bp 125—128 °C/2 Torr. ^{1}H-NMR (CCl_4); δ=4.10 (q, J=7 Hz, 2H, CH_2), 3.54 (brs, 1H, OH), 2.82 (brs, 0.54H, erythro SH), 2.66 (brs, 0.46H, threo SH), 1.10—1.60 (m, 19H, $5CH_2$ and $3CH_3$), 0.74—0.94 (m, 3H, CH_3). IR (neat); 3500 (OH), 2560 (SH), 1710 cm^{-1} (COO). Found: C, 59.47; H, 10.05%. Calcd for $C_{13}H_{26}O_3S$: C, 59.50; H, 9.99%.

Ethyl 3-Hydroxy-2-mercapto-3-methyldecanoate (5e): Bp 111.5—118 °C/1Torr. ^{1}H-NMR (CCl_4); δ=4.14 (q, J=7 Hz, 2H, CH_2), 3.18 (s, 0.45H, erythro CH), 3.02 (s, 0.55H, threo CH), 2.95 (brs, 1H, OH), 2.28 and 2.12 (each d, J=6 and 5 Hz, total 1H, SH), 1.14—1.60 (m, 18H, $6CH_2$ and $2CH_3$), 0.82—1.00 (m, 3H, CH_3). IR (neat); 3500 (OH), 2560 (SH), 1720 cm^{-1} (COO). Found: C, 59.38; H, 10.11%. Calcd for $C_{13}H_{26}O_3S$: C, 59.50; H, 9.99%.

Ethyl 3-Hydroxy-2-mercapto-3-phenylbutanoate (5f): Bp 123.0—126.5 °C/1 Torr. ^{1}H-NMR (CCl_4); δ=7.16—7.48 (m, 5H, aromatic), 4.18 (q, J=7 Hz, 2H, CH_2), 3.48—3.96 (m, 2H, CH and OH), 2.54 (d, J=2 Hz, 0.56H, erythro SH), 2.44 (d, J=3 Hz, 0.44H, threo SH), 1.40—1.70 (m, 3H, CH_3), 0.76—1.34 (m, 3H, CH_3). IR (neat); 3840 (OH), 2550 (SH), 1700 cm^{-1} (COO). Found: C, 59.92; H, 6.85%. Calcd for $C_{12}H_{16}O_3S$: C, 59.98; H, 6.71%.

Ethyl 3-Hydroxy-2-mercaptohexanoate (5g): Bp 83—86 °C/3 Torr. ^{1}H-NMR (CCl_4); δ=4.15 (q, J=7 Hz, 2H, CH_2), 3.50—3.88 (m, 1H, CH-OH), 3.00—3.30 (m, 2H, CH-SH and OH), 2.18 (d, J=4 Hz, 0.62H, erythro SH), 2.07 (d, 5 Hz, 0.38H, threo SH), 1.16—1.60 (m, 7H, $2CH_2$ and CH_3), 0.80—1.00 (m, 3H, CH_3). IR (neat): 3490 (OH), 2560 (SH), 1720 cm^{-1} (COO). Found: C, 49.72; H, 8.45%. Calcd for $C_9H_{18}O_3S$: C, 49.97; H, 8.39%.

Ethyl 3-Hydroxy-2-mercaptoheptanoate (5h): Bp 93.5—97 °C/2 Torr ^{1}H-NMR (CCl_4); δ=4.18 (q, J=7 Hz, 2H, CH_2), 3.52—3.84 (m, 1H, CH-OH), 3.04—3.30 (m, 2H, CH-SH and OH), 2.22 (d, J=4 Hz, 0.58H, erythro SH), 2.10 (d, J=5 Hz, 0.42H, threo SH), 1.20—1.60 (m, 9H, $3CH_2$ and CH_3), 0.80—1.00 (m, 3H, CH_3). IR (neat); 3500 (OH), 2560 (SH), 1710 cm^{-1} (COO). Found: C, 52.28; H,8.85%. Calcd for $C_9H_{18}O_3S$: C, 52.40; H, 8.79%.

Ethyl 3-Hydroxy-2-mercaptononanoate (5i): Bp 110—114.5 °C/2 Torr. ^{1}H-NMR (CCl_4); δ=4.14 (q, J=7 Hz, 2H, CH_2), 3.50—3.90 (m, 1H, CH-OH), 2.86—3.24 (m, 2H, CH-SH and OH), 2.18 (d, J=4 Hz, 0.60H, erythro SH), 2.08 (d, J=5 Hz, 0.40H, threo SH), 1.18—1.62 (m, 13H, $5CH_2$ and CH_3), 0.78—0.96 (m, 3H, CH_3). IR (neat); 3500 (OH), 2560 (SH), 1710 cm^{-1} (COO). Found: C, 56.31; H, 9.60%. Calcd for $C_{11}H_{22}O_3S$: C, 56.38; H, 9.46%.

Ethyl 3-Hydroxy-2-mercaptodecanoate (5j): Bp 114—118 °C/1 Torr. ^{1}H-NMR (CCl_4); δ=4.16 (q, J=7 Hz, 2H, CH_2), 3.54—3.90 (m, 2H, CH-OH and OH), 3.02—3.28 (m, 1H, CH-SH), 2.20 (d, J=4 Hz, 0.58H, erythro SH), 2.09 (d, J=5 Hz, 0.42H, threo SH), 1.18—1.70 (m, 15H, $6CH_2$ and CH_3), 0.76—1.00 (m, 3H, CH_3). IR (neat); 3500 (OH), 2560 (SH), 1700 cm^{-1} (COO). Found: C, 58.01; H, 9.79%. Calcd for $C_{12}H_{24}O_3S$: C, 58.03; H, 9.74%.

Ethyl 3-Hydroxy-2-mercapto-3-phenylpropionate (5k): Bp 128-131 °C/2 Torr. ^{1}H-NMR (CCl_4); δ=7.20 (s, 5H, aromatic), 4.82 (d, J=6 Hz, 0.40H, erythro CH-OH), 4.70 (d, J=8 Hz, 0.60H, threo CH-OH), 4.04 (q, J=7 Hz, 2H, CH_2), 3.72—3.84 (m, 1H, OH), 3.30—3.60 (m, 1H, CH-SH), 2.10 (d, J=9 Hz, 0.40H, erythro SH), 1.95 (d, J=10 Hz, 0.60H, threo SH), 1.00—1.30 (m, 3H, CH_3). IR (neat); 3490 (OH), 2560 (SH), 1730 cm^{-1} (COO). Found: C, 58.25; H, 6.39%. Calcd for $C_{11}H_{14}O_3S$: C, 58.39; H, 6.24%.

Ethyl 3-Hydroxy-2-mercaptooctanoate (5l): Bp 96.5—100 °C/2 Torr. ^{1}H-NMR (CCl_4); δ=4.16 (q, J=7 Hz, 2H, CH_2), 3.52—3.86 (m, 1H, CH-OH), 3.00—3.26 (m, 2H, CH-SH and OH), 2.20 (d, J=4 Hz, 0.60H, erythro SH), 2.08 (d, J=5 Hz, 0.40H, threo SH), 1.20—1.60 (m, 11H, $4CH_2$ and CH_3), 0.80—1.00 (m, 3H, CH_3). IR (neat): 3500 (OH), 2560 (SH), 1710 cm^{-1} (COO). Found: C, 54.35; H, 9.20%. Calcd for $C_{10}H_{20}O_3S$: C, 54.51; H, 9.15%.

Cross-over Experiment. Preparation of Ethyl 3-Hydroxy-3-methyl-2-(methylthio)nonanoate (6): Into a solution of 20 mmol of the dianion (**2a**) in 40 ml of THF, was added at −78°C a solution of 22 mmol of 2-octanone in 3 ml of THF. After being stirred for 1 h, a solution of 22 mmol of acetophenone in 3 ml of THF was added and the reaction mixture was stirred at −78 °C for 1 h. A solution of 22 mmol of methyl iodide in 3 ml of THF was then added with a syringe over a 3 min period. The resulting solution was stirred at −78 °C for 1 h before quenching with saturated aqueous solution of ammonium chloride (10 ml). The work-up similar to the preparation of **5** and silica-gel chromatography(benzene) gave 2.27 g of acetophenone and 3.36 g (64%) of **6**. ^{1}H-NMR (CCl_4); δ=4.28 (q, J=7 Hz, 2H, CH_2), 3.08 (s, 1H, CH), 3.07 (brs, 1H, OH), 2.20 (s, 3H, SCH_3), 1.20—1.72 (m, 16H, $5CH_2$ and $2CH_3$), 0.86—1.20 (m, 3H, CH_3). IR (neat); 3500 (OH), 1720 cm^{-1}(COO). Found: C, 59.39; H, 9.98%. Calcd for $C_{13}H_{26}O_3S$: C, 59.50; H, 9.99%.

General Procedure. Reaction of Dianion (2a) with Carbonyl Compounds: Into a solution of 20 mmol of the dianion (**2a**) in 40 ml of THF, was added at −78 °C a solution of 22 mmol of a carbonyl compound in 5 ml of THF. After being stirred for 2 h, ethyl chloroformate (20 mmol) in 3 ml of THF was added and the mixture was stirred at −78 °C for 30 min and at 30—35 °C or 15 °C for 1 h before it was quenched with saturated aqueous solution of ammonium chloride solution (10 ml). The reaction mixture was poured into dilute hydrochloric acid and extracted with ether (50× 4 ml). The combined organic layer was washed twice with brine, dried on anhydrous sodium sulfate, and concentrated under reduced pressure. Product isolation and purification by chromatography on silica-gel column (benzene) gave **3** and **7**. The dianion (**2a**) was treated with aldehydes in the presence of triethyl phosphite in a similar manner as described above to give **3** in high yields.

Reaction of Monoanions (2b, 2c) with Carbonyl Compounds: A solution of 20 mmol of *O*-ethyl *S*-ethoxycarbonylmethyl thiocarbonate (**1b**) or *S*-ethoxycarbonylmethyl diethyl phosphorothioate (**1c**) in 3 ml of THF was added to a stirred solution of 22 mmol of LDA in 40 ml of THF at −78 °C. The resulting solution was treating with 24 mmol of aldehydes in a similar manner as described above.

Ethyl (E)-2-Mercapto-2-octenoate (7a): ^{1}H-NMR (CCl_4); δ=6.72 (t, J=7 Hz, 1H, CH=C), 4.18 (q, J=7 Hz, 2H, CH_2), 3.94 (s, 1H, SH), 2.18 (q, J=7 Hz, 2H, CH_2), 1.10—1.60 (m, 9H, $3CH_2$ and CH_3), 0.86 (m, 3H, CH_3). IR (neat); 2560 (SH), 1710 (COO), 1610 cm^{-1} (C=C). Found: C, 59.31; H, 9.13%. Calcd for $C_{10}H_{18}O_2S$: C, 59.37; H, 8.97%.

Ethyl (E)-2-Mercapto-2-decenoate (7b): ^{1}H-NMR (CCl_4); δ=6.59 (t, J=7 Hz, 1H, CH=C), 4.06 (q, J=7 Hz, 2H, CH_2), 3.87 (s, 1H, SH), 2.14 (q, J=7 Hz, 2H, CH_2), 1.10—1.80 (m, 13H, $5CH_2$ and CH_3), 0.85 (m, 3H, CH_3). IR (neat); 2560 (SH), 1720 (COO), 1610 cm^{-1} (C=C). MS (20 eV); m/z 230 (M^+). Found: C, 62.60; H, 9.66%. Calcd for $C_{12}H_{22}O_2S$: C, 62.57; H, 9.63%.

Ethyl (E)-2-Mercapto-2-dodecenoate (7c): ^{1}H-NMR (CCl_4); δ=6.80 (t, J=7 Hz, 1H, CH=C), 4.24 (q, J=7 Hz, 2H, CH_2), 3.99 (s, 1H, SH), 2.20 (q, J=7 Hz, 2H, CH_2), 1.10—1.90 (m, 17H, $7CH_2$ and CH_3), 0.86 (m, 3H, CH_3). IR (neat); 2560 (SH), 1720 (COO), 1605 cm^{-1} (C=C). Found: C, 64.81; H, 10.22%. Calcd for $C_{14}H_{20}O_2S$: C, 65.07; H, 10.14%.

Ethyl (E)-3-Cyclohexyl-2-mercapto-2-propenoate (7d): ^{1}H-NMR (CCl_4); δ=6.40 (d, J=9 Hz, 1H, CH=C), 4.08 (q, J=7 Hz, 2H, CH_2), 3.87 (s, 1H, SH), 2.00—2.32 (m, 1H, CH), 0.80—1.80 (m, 13H, $5CH_2$ and CH_3). IR (neat); 2560 (SH), 1710 (COO), 1610 cm^{-1} (C=C). Found: C, 61.57; H, 8.35%. Calcd for $C_{11}H_{18}O_2S$: C, 61.65; H, 8.46%.

Ethyl (E)-2-Mercapto-2-nonenoate (7e): ^{1}H-NMR (CCl_4); δ=6.60 (t, J=7 Hz, 1H, CH=C), 4.08 (q, J=7 Hz, 2H, CH_2), 3.88 (s, 1H, SH), 2.14 (q, J=7 Hz, 2H, CH_2), 1.10—1.80 (m, 11H, $4CH_2$ and CH_3), 0.90 (m, 3H, CH_3). IR (neat); 2560 (SH), 1710 (COO), 1610 cm^{-1} (C=C). Found:C, 61.05; H, 9.41%. Calcd for $C_{10}H_{20}O_2S$: C, 61.07; H, 9.32%.

Ethyl (E)-2-Octenoate (3a): Bp 64—65 °C/2 Torr. ^{1}H-NMR (CCl_4); δ=6.82 (dt, J=7 Hz, 16 Hz, 1H, CH=C), 5.70 (d, J=16 Hz, 1H, CH=C), 4.08 (q, J=7 Hz, 2H, CH_2), 2.16 (m, 2H, CH_2), 1.47 (m, 9H, $3CH_2$ and CH_3), 0.90 (m, 3H, CH_3). IR (neat); 1640 cm^{-1} (C=C). Found: C, 70.38; H, 10.75%. Calcd for $C_{10}H_{18}O_2$:C, 70.55; H, 10.66%.

Ethyl 2-Decenoate (3b): Bp 87—88.5 °C/2 Torr. The *(E)*- and *(Z)*-isomers of **3b** were separated by silica-gel chromatography using benzene as eluent. *(E)*-isomer: ^{1}H-NMR (CCl_4); δ=6.76 (dt, J=7 Hz, 16 Hz, 1H, CH=C), 5.72 (d, J=16 Hz, 1H, CH=C), 4.12 (q, J=7 Hz, 2H, CH_2), 2.00—2.20 (m, 2H, CH_2), 1.10—1.80 (m, 13H, $5CH_2$ and CH_3), 0.90 (m, 3H, CH_3). IR (neat); 1645 cm^{-1} (C=C). Found: C, 72.51; H, 10.87%. Calcd for $C_{12}H_{22}O_2$: C, 72.67; H, 11.18%. *(Z)*-isomer: ^{1}H-NMR (CCl_4); δ=6.10 (dt, J=7 Hz, 16 Hz, 1H, CH=C), 5.72 (d, J=16 Hz, 1H, CH=C), 4.10 (q, J=7 Hz, 2H, CH_2), 1.98—2.00 (m, 2H, CH_2), 1.00—1.70 (m, 13H, $5CH_2$ and CH_3), 0.88 (m, 3H, CH_3).

Ethyl (E)-*2-Dodecenoate (3c)*: Bp 93—95 °C/2 Torr. ^{1}H-NMR (CCl_4); δ=6.88 (dt, J=7 Hz, 16 Hz, 1H, CH=C), 5.74 (d, J=16 Hz, 1H, CH=C), 4.12 (q, J=7 Hz, 2H, CH_2), 2.14 (m, 2H, CH_2), 1.45 (m, 17H, $7CH_2$ and CH_3), 0.90 (m, 3H, CH_3). IR (neat); 1650 cm^{-1} (C=C). Found: C, 74.03; H, 11.93%. Calcd for $C_{14}H_{26}O_2$: C, 74.29; H, 11.58%.

Ethyl (E)-*3-Cyclohexyl-2-propenoate (3d)*: Bp 57—58 °C/2 Torr. ^{1}H-NMR (CCl_4); δ=6.83 (dd, J=7 Hz, 16 Hz, 1H, CH=C), 5.70 (d, 16 Hz, 1H, CH=C), 4.13 (q, J=7 Hz, 2H, CH_2), 2.09 (m, 1H, CH), 1.75 (m, 4H, $2CH_2$), 0.90 (m, 9H, $3CH_2$ and CH_3). IR (neat); 1640 cm^{-1} (C=C). Found: C, 72.47; H, 9.95%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.95%.

Ethyl (E)-*2-Nonenoate (3e)*: Bp 71.5—73.5 °C/2 Torr. ^{1}H-NMR (CCl_4); δ=6.84 (dt, J=7 Hz, 16 Hz, 1H, CH=C), 5.70 (d, J=16 Hz, 1H, CH=C), 4.10 (q, J=7 Hz, 2H, CH_2), 2.17 (m, 2H, CH_2), 1.49 (m, 11H, $4CH_2$ and CH_3), 0.90 (m, 3H, CH_3). IR (neat); 1645 cm^{-1} (C=C). Found: C, 71.50; H, 11.02%. Calcd for $C_{11}H_{20}O_2$: C, 71.70; H, 10.94%.

Ethyl (E)-*3-Phenyl-2-propenoate (3f)*: Bp 99—100 °C/2 Torr. ^{1}H-NMR (CCl_4); δ=7.62 (d, J=16 Hz, 1H, CH=C), 7.40 (m, 5H, aromatic), 6.34 (d, J=16 Hz, 1H, CH=C), 4.18 (q, J=7 Hz, 2H, CH_2), 1.31 (t, J=7 Hz, 3H, CH_3). IR (neat); 1630 cm^{-1}(C=C). Found: C, 74.88; H, 6.87%. Calcd for $C_{11}H_{12}O_2$: C, 74.98; H, 6.86%.

Ethyl 3-Methyl-2-hexenoate (3g): Bp 51—55 °C/5 Torr. ^{1}H-NMR (CCl_4); δ=5.55 (brs, 1H, CH=C), 4.05 (q, J=7 Hz, 2H, CH_2), 2.56 (t, J=8 Hz, 1.22H, CH_2 for *(Z)*-isomer), 1.96—2.25 (m, 1.95H, CH_2 and CH_3 for *(E)*-isomer), 1.84 (m, 1.83H, CH_3 for *(Z)*-isomer), 1.30—1.72 (m, 2H, CH_2), 1.24 (t, J=7 Hz, 3H, CH_3), 0.94 (m, 3H, CH_3). IR (neat); 1640 cm^{-1} (C=C). Found: C, 69.07; H, 10.55%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%.

Ethyl 3-Methyl-2-nonenoate (3h): Bp 90—93.5 °C/6 Torr. ^{1}H-NMR (CCl_4); δ=5.60 (brs, 1H, CH=C), 4.06 (q, J=7 Hz, 2H, CH_2), 2.56 (m, 1.14H, CH_2 for *(Z)*-isomer), 1.92—2.32 (m, 2.15H, CH_2 and CH_3 for *(E)*-isomer), 1.86 (m, 1.71H, CH_3 for *(Z)*-isomer), 1.20—1.84 (m, 11H, $4CH_2$ and CH_3), 0.90 (m, 3H, CH_3). IR (neat); 1640 cm^{-1} (C=C). Found: C, 72.56; H, 11.25%. Calcd for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18%.

Ethyl (E)-*3-Phenyl-2-butenoate (3i)*: Bp 115—116 °C/5 Torr. ^{1}H-NMR (CCl_4); δ=7.24 (m, 5H, aromatic), 6.05 (m, 1H CH=C), 4.10 (q, J=7 Hz, 2H, CH_2), 2.50 (s, 3H, CH_3), 1.24 (t, J=7 Hz, 3H, CH_3). IR (neat); 1625 cm^{-1} (C=C). Found: C, 75.65; H, 7.55%. Calcd for $C_{12}H_{14}O_2S$: C, 75.76; H, 7.42%. This product was judged as *(E)*-isomer by NMR spectra which is consistent with that of ethyl *(E)*-3-phenyl-2-butenoate reported previously.[4]

Ethyl (E)-*3-Phenyl-2-pentenoate (3j)*: Bp 91—94.5 °C/1 Torr. ^{1}H-NMR (CCl_4); δ=7.20—7.50 (m, 5H, aromatic), 5.96 (s, 1H, CH=C), 4.12 (q, J=7 Hz, 2H, CH_2), 3.08 (q, J=7 Hz, 2H, CH_2), 1.26 (t, J=7 Hz, 3H, CH_3), 1.04 (t, J=7 Hz, 3H, CH_3). IR (neat); 1620 cm^{-1} (C=C). Found: C, 76.38; H, 8.01%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.89%.

Ethyl (E)-*2-Hexenoate (3k)*: Bp 64—65 °C/10 Torr. ^{1}H-NMR (CCl_4); δ=6.80 (dt, J=7 Hz, 16 Hz, 1H, CH=C), 5.70 (d, J=16 Hz, 1H, CH=C), 4.08 (q, J=7 Hz, 2H, CH_2), 1.30—1.90 (m, 5H, CH_2 and CH_3), 0.97 (t, J=7 Hz, 3H, CH_3). IR (neat); 1650 cm^{-1} (C=C). Found: C, 67.51; H, 9.97%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.92%.

Ethyl (E)-*2-Heptenoate (3l)*: Bp 59—60 °C/5 Torr. ^{1}H-NMR (CCl_4); δ=6.82 (dt, J=7 Hz, 16 Hz, CH=C), 5.70 (d, J=16 Hz, 1H, CH=C), 4.08 (q, J=7 Hz, 2H, CH_2), 2.20 (m, 2H, CH_2), 1.50 (m, 7H, $2CH_2$ and CH_3), 0.90 (m, 3H, CH_3). IR (neat); 1640 cm^{-1} (C=C). Found: C, 69.03; H, 10.37%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%.

Preparation of S-[1-(Ethoxycarbonyl)ethyl] Diethyl Phosphorothioate (14):[12] To a stirred solution of 50.0g (0.36 mol) of diethyl phosphite in 250 ml of benzene was added 8.5 g (0.37 mol) of sodium metal under a nitrogen atmosphere. After the mixture has been stirred at room temperature for 2 h, 11.6 g (0.36 mol) of sulfur was added. Stirring was continued at room temperature for overnight and a solution of 65.2 g (0.36 mol) of ethyl 2-bromopropionate in 50 ml of benzene was added over a 20 min period. The reaction mixture was then refluxed for 3 h and the resulting precipitate was filtered. Evaporation and distillation under reduced pressure of the filtrate gave 35.3 g (36%) of **14**. Bp 126.5—127.5 °C/1.2—1.3 Torr. ^{1}H-NMR (CCl_4); δ=3.60—4.30 (m, 7H, $3CH_3\underline{CH_2}$ and CH), 1.00—1.70 (m, 12H, $4CH_3$). IR (neat); 1735 (C=O), 1015 cm^{-1} (P-O). MS (20 eV) m/z 270 (M^+).

Decomposition of S-[1-(Ethoxycarbonyl)ethyl] Diethyl Phosphorothioate Carbanion (15): The carbanion (**15**) was generated by treatment of 5.41g (20 mmol) of **14** with 22 mmol of LDA in 40 ml of THF at −78 °C. After being stirred for 30 min, the reaction mixture was allowed to warm from −78 °C to room temperature before it was quenched with saturated aqueous solution of ammonium chloride (10 ml). The usual work-up and distillation gave 4.1 g (88%) of ethyl 2-(diethoxyphosphinyl)propionate (**16**), bp 101—103 °C/1 Torr. The product was identified by comparison of ^{1}H-NMR and mass spectrum with the corresponding data for independently synthesized material.[7]

Generation of S-*(Ethoxycarbonylmethyl-1-*d*) Diethyl Phosphorothioate (19)*: To a solution of 9.5 mmol of LDA in 40 ml of THF was added a solution of 8.6 mmol of *S*-(ethoxycarbonylmethyl) diethyl phosphorothioate in 5 ml of THF at −78 °C. After stirring for 30 min, the cooling bath was removed, and a mixture of 30 mmol of acetic acid-*d* and 10 ml of deuterium oxide was added. The reaction mixture was then stirred for 15 min before it was quenched with saturated aqueous solution of ammonium chloride (20 ml), and extracted with ether (50×4 ml). The combined organic layer was washed with brine, dried on anhydrous sodium sulfate, and concentrated under reduced pressure. Distillation of the resulting oil gave 4.6 g (89%) of **19**, bp 129—131 °C/1.3 Torr. The degree of deuteration determined by means of ^{1}H-NMR was 87%.

Synthesis of Ethyl 2-Cyclohexilidenepropionate (20): To a solution of LDA (22 mmol) in 40 ml of THF was added dropwise a solution of 5.41 g (20 mmol) of **14** in 5 ml of THF at −78 °C. After being stirred for 30 min, a solution of 2.45 g (25 mmol) of cyclohexanone in 5 ml of THF was added dropwise over a 5 min period and stirred at −78 °C for 1 h and at room temperature for 1 h. The usual work-up and distillation gave 3.27 g (90%) of **20**. Bp 71—72 °C/1 Torr. ^{1}H-NMR (CCl_4); δ=4.06 (q, 2H, CH_2), 2.22—2.43 (m, 4H, $2CH_2$), 1.82 (s, 3H, $C{=}CCH_3$), 1.59 (m, 6H, $3CH_2$), 1.28 (t, J=7 Hz, 3H, $OCH_2\underline{CH_3}$). IR (neat); 1710 (C=O), 1635 cm^{-1} (C=C). MS (20 eV) m/z 182 (M^+). Found: C, 72.56; H, 10.00%. Calcd for $C_{11}H_{18}O_2$: C, 72.46; H, 9.95%.

Preparation of Ethyl 10-(2-Tetrahydropyranyloxy)-2-decenoate (22): 8-(2-Tetrahydropyranyloxy)octanal (**21**) was prepared from 8-(2-tetrahydropyranyloxy)-1-octanol by using chromium trioxide-pyridine complex by the reported procedure.[13] To a mixture of LDA (44 mmol) and TMEDA (44 mmol) in 40 ml of THF was added a solution of 2.4 g (20 mmol) of ethyl mercaptoacetate (**1a**) in 5 ml of THF at −78 °C. After being stirred for 1 h, a solution of 5.02 g (22 mmol) of **21** in 5 ml of THF was added and the reaction mixture was stirred in the presence of triethyl phosphite (30 mmol) at −78 °C for 2 h. Ethyl chloroformate (20 mmol) in 5 ml of THF was then added to the above solution with stirring and the mixture was kept at −78 °C for 30 min and at 30—35 °C for 1 h before it was quenched with saturated aqueous solution of ammonium chloride (10 ml). The usual work-up and silica-gel chromatography (benzene) gave **22** in 63% (3.75 g) isolated yield (*E*/*Z* =94/6). The (*E*)- and (*Z*)-isomers of **22** were separated by silica-gel chromatography using benzene as eluent.

Preparation of Ethyl (E)*-10-Hydroxy-2-decenoate (23)*: A solution of 3.50 g (16 mmol) of **22** and 0.35 g of *p*-toluensulfonic acid in 100 ml of ethanol was refluxed for 1 h, concentrated to half volume, diluted with water, and extracted with ether (50×4 ml). The combined organic layer was dried on anhydrous sodium sulfate and concentrated under reduced pressure. Silica-gel chromatography (ethyl acetate: chloroform=1 : 1) gave **23** as a viscous oil in 79% (2.70 g) isolated yield. ^{1}H-NMR (CCl_4); δ=6.65 (dt, J=7 Hz, 16 Hz, 1H, CH=C), 5.52 (d, 16 Hz, 1H, CH=C), 3.96 (q, J=7 Hz, 2H, CH_2), 3.40 (t, J=6 Hz, 2H, CH_2), 3.02 (brs, 1H, OH), 1.96—2.22 (m, 2H, CH_2), 1.08—1.62 (m, 13H, $5CH_2$ and CH_3).

Preparation of (E)*-10-Hydroxy-2-decenoic Acid (24)*: A solution of 2.57 g (12 mmol) of **23** and 1.40 g of potassium hydroxide in 16 ml of ethanol was refluxed for 1.5 h under a nitrogen atmosphere, concentrated to half volume, diluted with water, and acidified to pH 4.0 with 2.5 M sulfuric acid (1 M=1 mol dm^{-3}). The reaction solution was then extracted with ether (50×4 ml), dried on anhydrous sodium sulfate, and concentrated under reduced pressure. Silica-gel chromatography (ethyl acetate and chloroform) and recrystallization from ether gave pure **24** in 73% (1.63 g) isolated yield. Mp 62.5—63.5 °C. ^{1}H-NMR (CCl_4); δ=6.80 (dt, J=7 Hz, 16 Hz, 1H, CH=C), 6.07 (brs, 2H, OH and COOH), 5.58 (d, J=16 Hz, 1H, CH=C), 3.47 (t, J=6 Hz, 2H, CH_2), 2.05—2.24 (m, 2H, CH_2), 0.92—1.16 (m, 10H, $5CH_2$). IR (disk); 3420 (OH), 1685 (COOH), 1640 cm^{-1} (C=C). Found: C, 64.08; H, 9.51%. Calcd for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74%.

The author would like to thank Drs. Aritsune Kaji and Kazuhiko Tanaka, Department of Chemistry, Faculty of Science, Kyoto University, for their helpful discussion during this work.

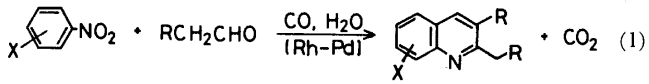
The Ruthenium Catalyzed Synthesis of Quinoline Derivatives from Nitroarenes and Aliphatic Alcohols

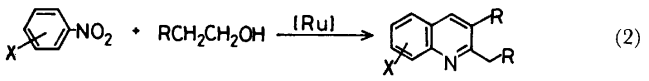
Yoshihisa WATANABE,* Yasushi TSUJI, and Jun SHIDA
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received June 3, 1983)

Nitroarenes are reductively converted into quinoline derivatives with aliphatic alcohols in the presence of a catalytic amount of ruthenium compound at 180 °C. Ruthenium(III) chloride is the most effective catalyst. The reaction of nitrobenzene with 1-propanol and 1-butanol gave 2-ethyl-3-methylquinoline and 3-ethyl-2-propylquinoline in 65 and 70% yields respectively. *p*-Methoxynitrobenzene gave 3-ethyl-6-methoxy-2-propylquinoline in 70% yield with 1-butanol. The reaction appears to include the redox reaction between the nitroarenes and the alcohols, that is, a catalytic hydrogen transfer reaction which generates the aminoarenes and aldehydes. Thus, the alcohol plays roles as both a reductant and an aldehyde precursor.

The Skraup synthesis is well known as the method for the preparation of quinoline derivatives.[1] This method, however, requires a large amount of strong acid and a high reaction temperature. Recently, transition metal-catalyzed synthesis of quinoline derivatives under non-acid conditions have been developed.[2,3] In the previous paper, we have reported. that several transiation metal catalysts are effective for the preparation of quinoline derivatives from aminoarenes. Aminoarenes react with aliphatic aldehydes to give quinoline derivatives in the presence of a rhodium complex such as di-μ-chlorobis(norbornadiene)-dirhodium ($[RhCl(NBD)]_2$),[4] or a rutheinum complex such as dichlorotris(triphenylphosphine)ruthenium ($[RuCl_2(PPh_3)_3]$).[5,6] Employing $[RuCl_2(PPh_3)_3]$ as the catalyst, the quinoline derivatives are also obtained from aminoarenes and allylic alcohols.[6]



(1)



(2)

Although nitroarenes are also important as starting materials for preparations of *N*-heterocycles, few studies have been reported on the synthesis of quinoline derivatives from nitroarenes.[7] We have recently reported that nitroarenes were reductively converted into quinoline derivatives with aliphatic aldehydes in the presence of a rhodium–palladium binary catalyst system (Eq. 1).[8] In that reaction, conditions of water gas shift reaction (carbon monoxide pressure and presence of water) were effective. This reaction made a new entry in quinoline synthesis from nitroarenes.

For the preparation of the quinoline derivatives, we recently offered a new method. Aliphatic alcohols effectively reduced nitroarenes in the presence of a catalytic amount of ruthenium compound and the resulting aldehydes react with the corresponding aminoarenes to give quinoline derivatives (Eq. 2). The preliminary results have been reported with $[RuCl_2(PPh_3)_3]$ as catalyst.[9] Recently, Mares and Boyle published a similar quinoline synthesis from nitroarene and aliphatic alcohols using a binary catalyst, $[Rh(CO)_2Cl]_2$ and $MoCl_5$.[10] This method, however, required a much larger amount of each catalyst (10 mol% each).

In this work, we describe a new finding about a more effective catalyst and give full details of the results.

Results and Discussion

Nitrobenene reacted with aliphatic alcohols in the presence of ruthenium catalyst at 180 °C. Activities of various ruthenium catalysts for this reaction were

a) Nitrobenzene (40 mmol), 1-butanol (20 ml) for 4 h. b) $RuCl_3 \cdot xH_2O$ based on nitrobenzene used. c) Based on nitrobenzene used (GLC analysis): **1b**, 3-ethyl-2-propylquinoline; 2, aniline; **3b**, *N*-butylaniline; **4b**, *N,N*-dibutylaniline. d) Ethanol was used as the alcohol. e) 2-Methylquinoline. f) *N*-Ethylaniline. g) *N,N*-Diethylaniline. h) 1-Propanol was used as the alcohol. i) 2-Ethyl-3-methylquinoline. j) *N*-Propylaniline. k) *N,N*-Dipropylaniline.

examined with 1-propanol as the alcohol. The results are summarized in Table 1. The yield of the product, 2-ethyl-3-methylquinoline (**1a**), strongly depends on the catalyst. Among the ruthenium catalysts examined, the highest catalytic activity is attained with ruthenium(III) chloride ($RuCl_3 \cdot xH_2O$). The addition of a phosphrous ligand on $RuCl_3 \cdot xH_2O$ suppressed the formation of the quinoline derivative (Runs 2—4). Dichlorotris(triphenylphosphine)ruthenium had some activity. With other ruthenium complexes, however, the yield of the quinoline was reduced considerably (Runs 6—10). Aniline (**2**), *N*-propylaniline (**3a**), and *N,N*-dipropylaniline (**4a**) were confirmed as the by-products.

Effects of reaction conditions were examined. The results are shown in Table 2. In Runs 12—17, 1-butanol was used as the alcohol. The yield of product, 3-ethyl-2-propylquinoline (**1b**), depends on the amounts of the catalyst. As the amount of catalyst increased from 1 mol% to 5 mol%, based on the amount of nitrobenzene used, the formation of the alkylquinoline was favored. Employing 5 mol% of $RuCl_3 \cdot xH_2O$ as the catalyst, the alkylquinoline was obtained in 70% yield (Run 14). The yield, however, decreased considerably with 10 mol% of the catalyst owing to side reactions. These results indicate that the optimum catalyst concentration is 5 mol%. 2-Ethyl-3-methylquinoline was obtained in 65% yield with 1-propanol with 5 mol% of catalyst concentration (Run 18).

As for the reaction temperature, the best result was realized at 180 °C. By lowering the reaction temperature to 150 °C, the conversion of nitrobenzene and the yield of the quinoline derivative were drastically reduced. The yield of the product was not improved by elevating the reaction temperature to 200 °C.

This procedure is applicable to a variety of nitroarenes. The results obtained with nitrobenzenes with methyl, methoxyl, and chloro substituents at para or ortho positions are listed in Table 3. *p*-Methoxynitrobenzene and *p*-methylnitrobenzene reacted with 1-butanol to give the corresponding 2,3,6-trisubstituted quinoline derivatives in 78 and 58% yield respectively. The chloro substituent reduced the reactivity of the substrate. On the other hand, *o*-substituted nitrobenzenes gave the quinoline derivatives in much lower yields, probably owing to the steric effect (Runs 22 and 23).

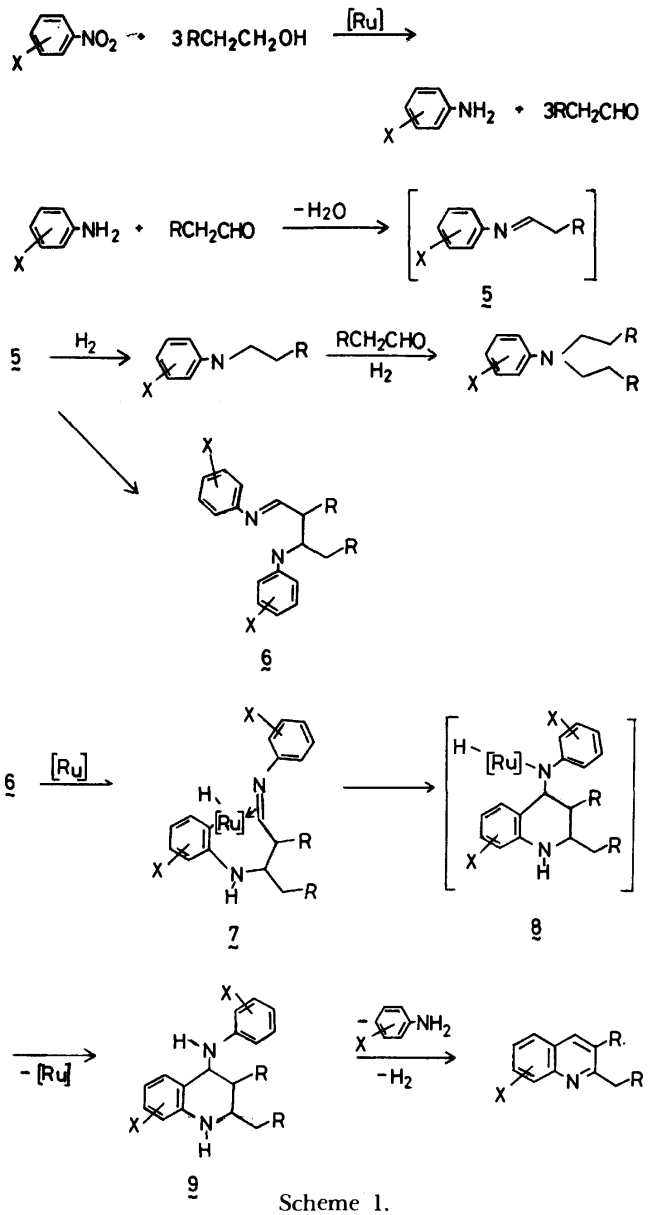
The group VIII metal complexes such as palladium,[11] rhodium,[12] and ruthenium[13] complexes catalyze the hydrogen transfer reaction from alcohols to various hydrogen acceptors. Several novel metal salts such as $RuCl_3 \cdot 3H_2O$, $RhCl_3 \cdot 3H_2O$, $PdBr_2$, and $PdCl_2$



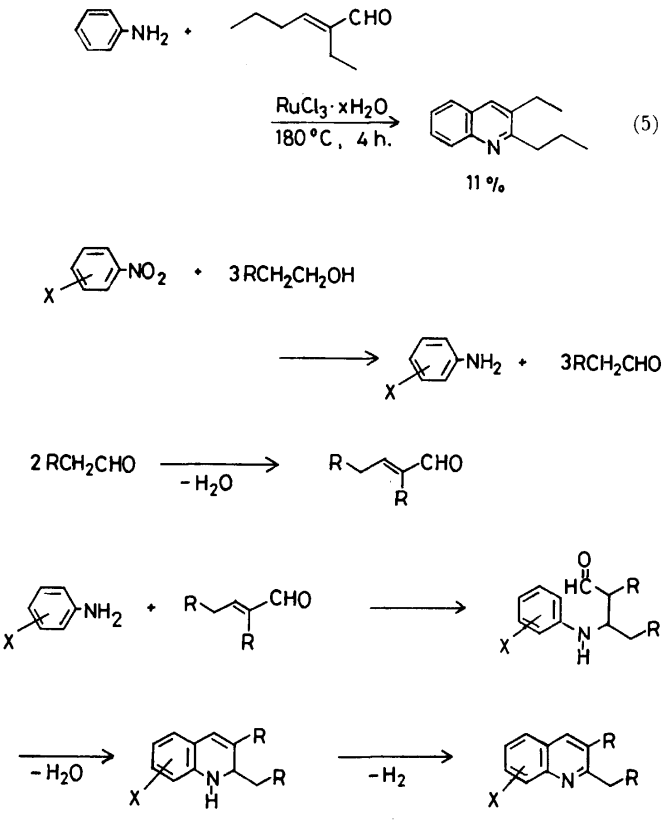
Scheme 1.

catalyze the hydrogen transfer from cyclic amines to nitrobenzenes to give corresponding aniline derivatives.[14]

In this study, the reaction appears to include reduction of nitroarenes with the alcohols by the catalytic hydrogen transfer from the alcohols, generating aminoarenes and aldehydes *in situ* (see the first equation in Scheme 1). Thus the alcohols play roles as both the reductants and aldehyde precursors in these reactions. The alkylquinolines would be formed by the ruthenium catalyzed reaction of the aminoarenes with the aldehydes. Actually, aminoarenes react with aliphatic aldehydes to the corresponding quinoline derivatives in the presence of ruthenium catalysts, as previously reported.[5,6]

It is well known that aminoarene reacts with aliphatic aldehyede to give a Schiff-base dimer on simply mixing at room temperature (Eq. 3).[15,16] In the previous paper,[6] we have suggested that the *N*-heterocyclization to the quinoline derivatives proceeds *via* these Schiff-base dimers (**6**). In a separate reaction, 3-ethyl-2-propylquinoline is obtained in 59% yield in the presence of $RuCl_3 \cdot xH_2O$ from the corresponding Schiff-base dimer (**6a** R=Et, X=H)(Eq. 4). Therefore, we consider that the present reaction also proceeds *via* a Schiff-base dimer (**6**). (Alkylamino)- and (dialkylamino)arenes were also obtained as by-products (Tables 1 and 2). These products could be formed *via* a Schiff-base monomer (**5**).[5] Such a Schiff-base monomer is liable to dimerize. The Schiff-base monomer could not be obtained and only the Schiff-base dimer (**6**) was isolated.[15,16] The Schiff-base dimer (**6**) may be activated at an elevated temperature by so called orthometallation (**7**)[17-23] as suggested in the previous paper,[6] and transformed into the corresponding quinoline derivative. The catalyst appears to be operative in the cyclization step (**7**→**8**), since (**6**) was obtained without catalyst and even at room temperature.

3-Ethyl-2-propylquinoline was also obtained in much lower yield from aniline and 2-ethyl-2-hexenal, an aldol condensate of butanal, in the presence of $RuCl_3 \cdot xH_2O$ (Eq. 5). Therefore the path *via* aldol condensation followed by Michael addition of aniline may be an alternative acceptable path in the present reaction (Scheme 2). Mares *et al.* suggested the path described in Scheme 2 as the most likely route, without positive evidence.[10]



Scheme 2.

Thus, $RuCl_3 \cdot xH_2O$ is the effective catalyst for converting nitroarenes into quinoline derivatives with alcohols. In the reaction, the alcohol plays roles as both a reductant and an aldehyde precursor.

Experimental

Materials. The alcohols, the nitroarenes, and the phosphorus ligands were commercial materials and were purified by distillation or recrystallization before use. Ruthenium(III) chloride ($RuCl_3 \cdot xH_2O$, mainly $x=3$) was purchased from Wako Chemical and used without further purification. $[RuCl_2(PPh_3)_3]$,[24] $[RuHCl(PPh_3)_3]$,[25] $[RuHCl(CO)(PPh_3)_3]$,[26] $[RuH_2(PPh_3)_4]$,[27] $[Ru(CO)_3(PPh_3)_2]$,[26] and $[Ru_3(CO)_{12}]$[28] were prepared by published methods. 2-Ethyl-2-hexenal was prepared from butanal.[29] The Schiff-base dimer (**6a**) was synthesized with aniline and butanol by the method in the literature.[16]

Analytical Procedure. The ^{1}H-NMR spectra were obtained at 100 MHz with a JEOL JNM FX-100 or at 220 MHz with a Varian HR-220 spectrometer. The ^{13}C-NMR spectra were recorded at 25.05 MHz with a JEOL JNM FX-100 spectrometer, with tetramethylsilane as an internal standard. IR spectra were measured on a Hitachi model 215 grating spectrometer. Elemental analysis was performed at the Microanalytical Center of Kyoto University. The mass spectra were recorded on a JMS OISG mass spectrometer. The GLC analysis was performed on a Shimadzu-GC-3BT.

Reaction Procedure. An autoclave (100 ml; SUS 316) equipped with a magnetically driven stirrer was used in the reaction. A typical reaction with 1-butanol and nitrobenzene is described here to exemplify the general procedure adopted. A mixture of nitrobenzene (4.9 g, 40 mmol), 1-butanol (20 ml), and $RuCl_3 \cdot xH_2O$ (487 mg, 2.0 mmol, 5 mol% based on nitrobenzene used) was stirred under an argon atmosphere. The autoclave was heated in 20 min to 180 °C and held at this temperature for 4 h. After cooling, the autoclave was discharged and the reaction mixture was subjected to the GLC analysis with Apiezon Grease L supported on Neopak 1A 60—80 mesh (0.3 cmϕ×3 m). The products were isolated by vacuum fractional distillations. If the products were contaminated with other products, further purification was performed by means of medium pressure column chromatography (absorbent; Silica Gel 60, 0.040—0.063 mm, 230—400 mesh, Merck No. 9385: eluent; a mixture of hexane and ethyl acetate). The products were identified by means of ^{1}H-NMR, ^{13}C-NMR, IR, mass spectra, and elemental analysis. The identifications are confirmed by comparing the analytical date with those published elsewhere.[4-6] The conversion of the substrate and the yield of the product were determined by the internal standard method accordng to the calibration curve obtained for each sample. Biphenyl or triphenylmethane was employed as the internal standard.

Synthesis of 3-Ethyl-2-propylquinoline from Schiff-base Dimer (6a) A solution of **6a** (3.979 g, 13.5 mmol) in benzene (20 ml) was stirred under an argon atmosphere in the presence of nitrobenzene (1.546 g, 12.6 mmol) and $RuCl_3 \cdot xH_2O$ (299 mg, 1.23 mmol, 5 mol% based on nitrogen atom) at 180 °C for 4 h. The GLC analysis of the reaction mixture showed that 8.0 mmol (59% based on **6a**) of 3-ethyl-2-propylquinoline was formed.

Reaction of Aniline with 2-Ethyl-2-hexenal. A mixture of aniline (2.150 g, 23.1 mmol), 2-ethyl-2-hexenal (2.926 g, 23.2 mmol), benzene (10 ml), $RuCl_3 \cdot xH_2O$ (1.11 mmol, 4.8 mol% based on aniline), and nitrobenzene (2.625 g, 21.3 mmol) was stirred at 180 °C for 4 h. By the GLC analysis of the reaction products, 2.6 mmol (11% based on aniline) of 3-ethyl-2-propylquinoline was detected.

Synthesis of *N*-Tripeptidyl-D-glucosamine by the Stepwise Reaction of *N*-Carboxy α-Amino Acid Anhydride[1]

Masanao OYA* and Toshiyuki NEGISHI

Department of Industrial Chemistry, College of Technology, Gunma University, Tenjin-chō, Kiryu, Gunma 376

(Recieved June 14, 1983)

N-Peptidyl-D-glucosamines were synthesized by the stepwise reaction of *N*-carboxy α-amino acid anhydrides (4-alkyl-2,5-oxazolidinediones) with D-glucosamine hydrochloride in the presence of equimolar sodium methoxide in a mixture of acetonitrile and methanol, or in methanol, at a low temperature. Polymerization reaction of *N*-carboxy α-amino acid anhydrides (NCAs) did not occur at −50 °C. The mechanism of the reaction was then studied.

Proteins and peptides containing sugar residues, glycoproteins and glycopeptides, are widely distributed in nature, and have many bioactive properties.[2] Therefore, the syntnesis of models of glycoproteins and glycopeptides are important. In the carbohydrate-peptide linkage, the covalent linkage between the amino sugar-amino acid bonds, have been considered to be of two types. One is a peptide linkage which is formed between the amino residue of glucosamine and the carboxyl residue of amino acid. This bond is generally synthesized by the coupling reaction of an amino group of glucosamine with a carboxyl residue of an amino acid, the amino residue of which is protected, and following removal of protection.[3-8] However, many glycopeptides are unstable to acids or bases. They are decomposed with changing color by both acids or bases. It is therefore important to avoid the deprotecting reaction in strong acidic or basic media.

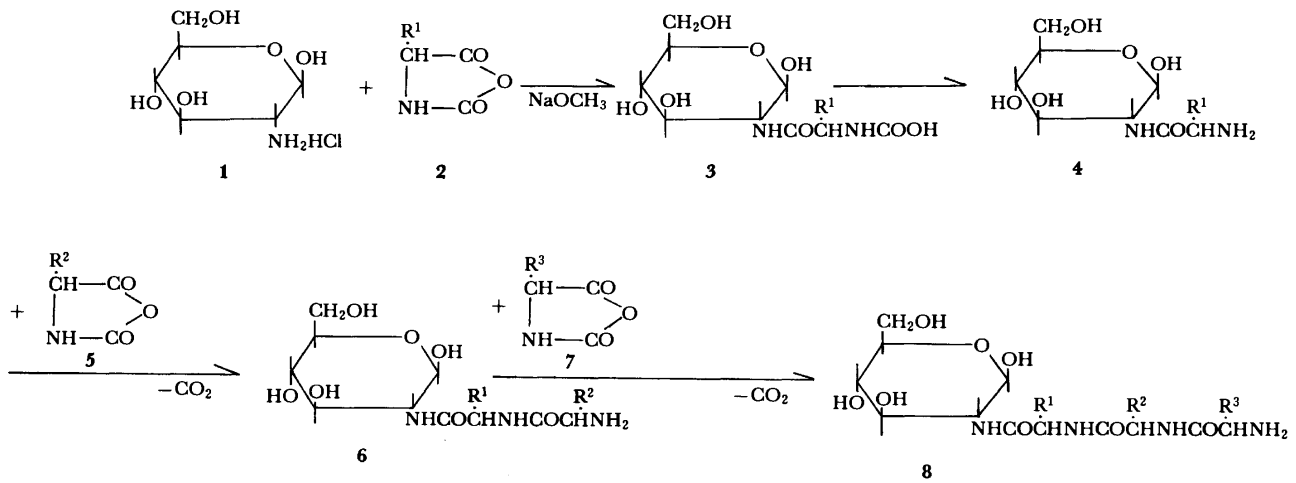
We attempted the synthesis of several *N*-peptidyl-D-glucosamines by the stepwise reaction of *N*-carboxy α-amino acid anhydrides (NCAs) with D-glucosamine having free hydroxyl groups in the mixed solvent of acetonitrile and methanol, or in methanol.

The mechanism of polymerization of NCAs have been studied extensively.[9] In comparison, there is little information on the stepwise reaction of an α-amino or hydroxyl residue with NCA. Bailey reports the synthesis of dipeptides by the stepwise reaction of NCAs with an amino acid ethyl ester in chloroform at −40 °C.[10] This reaction does not occur for any amino acid ester except glycine ethyl ester in chloroform because the polymerization reaction of NCAs occur.[11]

In a previous paper, we reported that the stepwise synthesis of oligopeptides with regular sequence by the method of controlled reaction of NCAs in an acetonitrile water heterogeneous system.[12,13] In another previous study, we reported the steric hindrance of the stepwise reaction of NCAs with the α-amino acid esters.[14] These stepwise syntheses of oligopeptides involves no, or limited removal of protecting groups. Further, these reactions did not lead to racemization.[15]

These studies suggest that NCAs can be utilized for the amino acylation of amino residues of many organic compounds.

When L-alanine was used in the reaction with D-glucosamine, polymerization of the NCA proceeded at −40 °C, but did not proceeded at −50 °C. However the stepwise reaction of L-alanine NCA (**2**; $R^1=CH_3$) with D-glucosamine (**1**) did proceed at −55 °C. It was considered that the steric hindrance of the side chains of both NCA and the compound having α-amino residue determine whether polymerization of NCA or the stepwise reaction proceeds at −20 °C.[11] As the polymerization of L-alanine NCA proceeded at −40 °C, the side chain of D-glucosamine must be more bulky than that of L-alanine NCA. The fact that the stepwise reaction of L-alanine NCA with D-glucosamine proceeded indicate that the steric hindrance of the side chains of both L-alanine NCA and the α-amino residue of the compound do not affect the reaction at −55 °C. The decarboxylation of the carbamic acid (**3**→**4**) must not occur below −54 °C., since carbamic acids are stable at a low temperature. NCAs are



initiated with alcohols to produce dipeptides, polypeptides, and small amounts of amino acid esters.[9] However, the stepwise reaction of NCA with D-glucosamine does proceed in methanol at −55 °C. This indicates that the rate of reaction of NCA with the amino residue of D-glucosamine is faster than that of NCA with the hydroxyl group of methanol.

N-Dipeptidyl-D-glucosamine (**6**) was synthesized by addition of an acetonitrile solution of NCA (**5**) to the solution obtained by filtration of the reaction mixture of *N*-aminoacyl-D-glucosamine (**4**), followed by the same procedure as described above (**4**+**5**→**6**). *N*-Tripeptidyl-D-glucosamine (**8**) was synthesized by addition of the third NCA (**7**) with *N*-dipeptidyl-D-glucosamine (**6**) by the same synthetic procedure of *N*-dipeptidyl-D-glucosamine (**6**+**7**→**8**).

Experimental

D-Glucosamine hydrochloride and amino acids used were commercial products. NCAs were prepared as reported previously.[16]

NMR spectra were obtained on a Brucker WH-270 spectrometer, the chemical shifts are given in δ values (ppm) from sodium 2,2-dimethyl-2-silapentane-5-sulfonate.

N-L-*Alanyl*-D-*glucosamine* (*4*; $R^1=CH_3$). D-Glucosamine hydrochloride (1.5 g, 23.3 mmol) was dissolved in methanol solution (92 cm³) of sodium methoxide (1.3 g, 24 mmol). The solution of L-alanine NCA (2; $R^1=CH_3$, 2.7 g, 23 mmol) in acetonitrile (92 cm³) was then added, and stirred at −50 °C for 120 h. After the reaction, the mixture was raised to room temperature and filtered to remove a small amount of precipitate, and distilled *in vacuo* to remove the solvent. The residual product was dissolved in ethanol and water (90 : 10 v/v). The solution was filtered, and dried *in vacuo* to obtain pure *N*-L-alanyl-D-glucosamine: yield 6.2 g (80%); $[\alpha]_D^{22}$ −8.3° (*c* 0.012 CH_3OH); NMR[17] (0.04 g/ml D_2O) δ=1.36 (t Ala C<u>H</u>$_3$), 3.29 and 3.73 (m glucosamine OH), 4.4 (Ala CH), 7.23 (m CON<u>H</u> and N<u>H</u>$_2$). Found: C, 43.30; H, 6.88; N, 10.55%. Calcd for $C_9H_{18}O_6N_2$: C, 43.20; H, 6.88; N, 11.20%.

N-(L-*Alanyl*-L-*valyl*)-D-*glucosamine* (*6*; $R^1=(CH_3)_2CH$, $R^2=CH_3$). D-Glucosamine hydrochloride (**1**, 5 g, 23.3 mmol) was dissolved in a methanol solution (92 cm³) of sodium methoxide (1.3 g, 24 mmol). The solution of L-valine NCA (**2**; $R^1=(CH_3)_2CH$, 3.4 g, 24 mmol) in acetonitrile solution (92 cm³) was then added, and stirred for 120 h at −50 °C. After the reaction, the mixture was raised to room temperature and filtered to remove a small amount of precipitate. The filtrate was cooled to −50 °C, the solution of L-alanine NCA (2.6 g, 23 mmol) in acetonitrile (52 cm³) and methanol (52 cm³) was then added, and allowed to react as described above. The reaction mixture was raised to room temperature, filtered, and distilled *in vacuo* to obtain the crude product. The product was dissolved in the minimum amount of methanol, filtered, diluted with a half volume of diethyl ether, and filtered again. The solution part was distilled *in vacuo* to obtain crude *N*-(L-alanyl-L-valyl)-D-glucosamine. The crude product thus obtained was purified by columm chromatography, (Sephadex G-10, 2.5×45 cm). Elution with ethanol and water (1 : 1 v/v) separated contaminent, sodium chloride, and pure *N*-(L-alanyl-L-valyl)-D-glucosamine: yield 2.0 g (26%); $[\alpha]_D^{22}$ −22.7° (*c* 0.016 CH_3OH); NMR (2 mg/cm³ DMSO-d_6) δ=0.88 (q Val (C<u>H</u>$_3$)$_2$), 1.28 (t Ala C<u>H</u>$_3$), 1.59 (Val βC<u>H</u>), 3.38, 3.63, and 3.86 (glucosamine OH), 4.23 (Ala and Val αC<u>H</u>), 7.94, 8.02, 8.12, and 8.95 (N<u>H</u>CO and N<u>H</u>$_2$). Found: C, 48.89; H, 8.12; N, 12.12%. Calcd for $C_{14}H_{27}O_7H_3$: C, 48.14; H, 7.74; N, 12.02%.

N-(*γ-Methyl*-L-*α-glutamyl*-L-*phenylalanyl*-L-*alanyl*)-D-*glucosamine* (*8*; $R^1=CH_3$, $R^2=CH_2C_6H_5$, $R^3=CH_2CH_2COOCH_3$). D-Glucosamine hydrochloride (4.3 g, 20 mmol) was dissolved in a methanol solution (86 cm³) of sodium methoxide (1.1 g, 20 mmol). The solution was cooled to −50 °C. The solution of L-alanine NCA (2.5 g, 21 mmol) in acetonitrile (50 cm³) previously cooled to −50 °C was added to the solution of glucosamine, and allowed to react for 70 h at −50 °C, and subsequently for 70 h at −20 °C. After the reaction the resulting mixture was warmed to room temperature, and filtered to remove the precipitate. The filtrate was cooled to −20 °C. Crystals of L-phenylalanine NCA (3.1 g, 16.2 mmol) were added, and allowed to react for 70 h at −20 °C. After the reaction the system was warmed and filtered to separate the precipitate. The clear solution was cooled again to −20 °C, added to the solution of γ-methyl-L-glutamate NCA (3.3 g, 17.6 mmol) in acetonitrile (35 cm³), and allowed to react as above. After the reaction the resulting mixture was warmed, filtered, and distilled *in vacuo* to obtain the crude product (7.5 g, 71% yield). The crude product was purified as *N*-(L-valyl-L-alanyl)-D-glucosamine. Pure product: $[\alpha]_D^{22}$ −12.7° (*c* 0.0063 CH_3OH); NMR (2 mg/cm³ DMSO-d_6) δ=1.29 (Ala C<u>H</u>$_3$), 1.86 (Glu C<u>H</u>$_2$), 3.03 (Phe C<u>H</u>$_2$), 3.39 and 3.61 (glucosamine OH), 3.62 (Glu COOC<u>H</u>$_3$), 3.64 (glucosamine O<u>H</u>), 4.30 (Ala and Glu αCH), 7.25 (Phe C_6H_5), 7.75 and 8.59 (m CON<u>H</u> and N<u>H</u>$_2$). Found: C, 53.75; H, 5.96; N, 9.84%. Calcd for $C_{24}H_{36}O_{10}N_4$: C, 53.33; H, 6.67; N, 10.37%.

The other *N*-tripeptidyl-D-glucosamines were synthesized by the reactions of D-glucosamine (**1**) with the first NCA (**2**), following the second NCA (**5**), and the third NCA (**7**) under almost similar conditions to the tripeptidyl-D-glucosamine described above (Eq. 1).

N-(L-*Alanyl*-L-*leucyl*-L-*alanyl*)-D-*glucosamine* (*8*; $R^1=CH_3$, $R^2=(CH_3)_2CHCH_2$, $R^3=CH_3$). The pure product was obtained in a 40% yield: $[\alpha]_D^{22}$ −33.1° (*c* 0.0136 CH_3OH); NMR (DMSO-d_6 2 mg/cm³) δ=0.85, 0.87, and 0.90 (Leu (C<u>H</u>$_3$)$_2$), 1.22 (Ala C<u>H</u>$_3$), 1.47 and 1.59 (Leu βC<u>H</u>$_2$ and γC<u>H</u>), 3.38 and 3.63 (glucosamine O<u>H</u>), 4.29 (Ala αC<u>H</u>), 4.39 (Leu αC<u>H</u>), 7.93, 8.12, 8.22, and 8.29 (CON<u>H</u> and N<u>H</u>$_2$). Found: C, 48.78; H, 7.95; N, 12.21%. Calcd for $C_{18}H_{34}O_8N_4$: C, 49.76; H, 7.80; N, 12.12%.

N-(L-*Leucyl*-L-*leucyl*-L-*phenylalanyl*)-D-*glucosamine* (*8*; $R^1=CH_2C_6H_5$, $R^2=(CH_3)_2CHCH_2$, $R^3=(CH_3)_2CHCH_2$). This pure product was obtained in a 35% yield: $[\alpha]_D^{22}$ −22.5° (*c* 0.0142 CH_3OH): NMR (DMSO-d_6 2 mg/cm³) δ=0.92 (t Leu (C<u>H</u>$_3$)$_2$), 1.44 and 1.59 (Leu βCH$_2$ and γC<u>H</u>), 2.98 (Phe βCH$_2$), 3.24, 3.30, 3.36, and 3.39 (glucosamine O<u>H</u>), 4.39 (Leu αC<u>H</u>), 4.51 (Phe αC<u>H</u>), 7.24 (Phe C_6<u>H</u>$_5$), 7.81, 8.08, 8.22, and 8.33 (CON<u>H</u> and N<u>H</u>$_2$). Found: C, 59.83; H, 8.00; N, 10.11%. Calcd for $C_{27}H_{44}O_8N_4$: C, 58.70; H, 7.94; N, 10.37%.

N-(L-*Leucyl*-L-*phenylalanyl*-L-*leucyl*)-D-*glucosamine* (*8*; $R^1=(CH_3)_2CHCH_2$, $R^2=CH_2C_6H_5$, $R^3=(CH_3)_2CHCH_2$). The pure product was obtained in a 43% yield. NMR peaks were similar to those of *N*-(L-leucyl-L-leucyl-L-phenylalanyl)-D-glucosamine. $[\alpha]_D^{22}$ −21.6° (*c* 0.0176 CH_3OH). Found: C, 58.70; H, 7.72; N, 10.19%. Calcd for $C_{27}H_{44}O_8N_4$: C, 58.70; H, 7.94; N, 10.37%.

N-(*β-Benzyl*-L-*α-aspartyl*-*β-benzyl*-L-*α-aspartyl*-*β-benzyl*-L-*α-aspartyl*)-D-*glucosamine* (*8*; $R^1=R^2=R^3=CH_2COOCH_2C_6H_5$). Elution of the chromatograph (Sephadex G-10, 2.5×45 cm) was carried out with methanol and water (1 : 1 v/v). The pure product was obtained in a 36% yield. NMR (DMSO-d_6 2 mg/cm³) δ=2.66 and 2.77 (Asp βC<u>H</u>$_2$), 3.22 and 3.59 (glucosamine O<u>H</u>), 4.35 (Asp αC<u>H</u>), 5.13 (Asp Bz C<u>H</u>$_2$), 7.39 (Asp Bz C_6<u>H</u>$_5$), 8.19 (CON<u>H</u> and N<u>H</u>$_2$). Found: C, 57.99; H, 5.49; N, 7.05%. Calcd for $C_{39}H_{46}O_{10}N_4$: C, 58.94; H, 5.70; N, 7.05%. $[\alpha]_D^{22}$ −7.35° (*c* 0.0136 CH_3OH)

We wish to thank Dr. Tatsuo Miyazawa, Professor of The University of Tokyo, and Dr, Toshiya Endo of Gunma University, for helpful advice and measurement of the NMR spectra.

Acylations of 2,2-Dimethyl-2*H*-chromenes

Seiji YAMAGUCHI, Satoru YAMAMOTO, Shoichi ABE, and Yoshiyuki KAWASE*
Department of Chemistry, Faculty of Science, Toyama University, Gofuku 3,190, Toyama 930
(Received June 22, 1983)

Orientation in acylation reactions of 2,2-dimethyl-2*H*-chromenes was studied. Five acetylchromenes were obtained with two methods and six formylchromenes were obtained with a third method. Demethylation of four acyl-methoxy-substituted chromenes gave the corresponding acylchromenols. 2,2-Dimethyl-2*H*-chromene-6-carboxylic acid (anofinic acid) was also obtained by oxidation of 6-formylchromene.

Many naturally occurring 2,2-dimethyl-2*H*-chromenes have an acetyl group in position 6 or 8.[1] But, the introduction of acetyl groups into 2,2-dimethyl-2*H*-chromenes has not been reported, because they were easily resinified with strong acids as acylating agents. We described a new preparative method of 2,2-dimethyl-2*H*-chromenes.[2] Now, we will report the acylation reactions of 2,2-dimethyl-2*H*-chromenes by using weak acids and their orientation. Acetylations were run in two methods; Method A: with acetic anhydride–zinc chloride in benzene at room temp for 3 h, at 80 °C for 20 min in a case of recovery, or at room temp for 1 h in a case that starting chromene was much resinified; Method B: with acetic acid–trifluoroacetic anhydride at room temp for 6 h. Formylations were run in a third method; Method C: with *N*-methylformanilide–phosphoryl chloride at 90 °C for 1 h. Their acylation yields are summarized in Table 1. In these reactions, both acetylations and formylations, similar orientations were observed (Chart 1). In all 2,2-dimethyl-2*H*-chromenes, except in 5-methoxy and 6-methoxy derivatives, the position 6 was the most reactive and the position 3, expected to be a styrene system, was not so reactive. 5-Methoxy derivative (**2**) afforded 8-formyl compound (para to methoxyl group) (**7b**), 6-methoxy derivative (**3**) afforded 7-acyl compounds (ortho to methoxyl group) (**8a, b**), and 8-methoxy derivative (**5**) gave a mixture of 5-acyl compounds (para to methoxyl group) (**10a, b**) and 6-acyl compounds (the most reactive position) (**11a, b**).

The structure of the acyl compounds were chiefly determined by the coupling constants of aromatic hydrogens in their ^{1}H-NMR spectra; other evidences are described below. 6-Acyl-2,2-dimethyl-2*H*-chro-

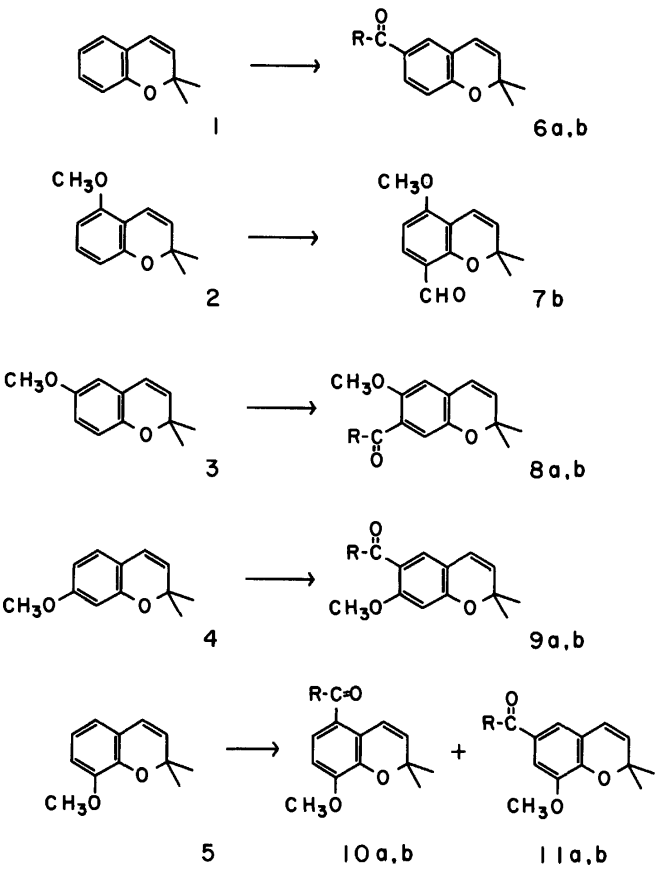

Chart 1.

Table 1. Acylations of 2,2-dimethyl-2*H*-chromenes

2,2-Dimethyl-2*H*-chromene	Acylated position	Yield/% Acetylation Method A	Acetylation Method B	Formylation Method C
1	6	64.3	64.4	39.6
2	8	0[a]	—	45.4
3	7	0[b] / 14.8[c]	35.5	51.9
4	6	8.5 / 25.4[d]	0[a]	55.3
5	5	9.7	8.2	38.2
	6	29.1	19.7	31.0

a) Only resin was obtained. b) Starting chromene was recovered. c) Acetylation was run at higher temp, 80 °C, for 20 min. d) Acetylation was run at room temp for a shorter period, 1 h.

menes (**6a ,b**) showed ortho and meta coupling in their ^{1}H-NMR spectra. There was no E.T. band due to a mesomery between C=O and C=C double bonds, such as 7-acylchromenes may show (Fig. 1). N. M. Venkama and R. G. S. Krishna reported the DDQ oxidation of 2,2,6-trimethyl-2*H*-chromene and 6-ethyl-2,2-dimethyl-2*H*-chromene to 6-formyl- and 6-acetyl-2,2-dimethyl-2*H*-chromene (**6a, b**).[3] Our compounds (**6a, b**) from 2,2-dimethyl-2*H*-chromene were identical with theirs which were obtained from the DDQ oxidation in their spectra. The structure of 8-formyl-5-methoxy-2,2-dimethyl-2*H*-chromene (**7b**) was assured by another synthetic method; dehydrogenetic cyclization of 2-hydroxy-4-methoxy-3-(3-methyl-2-butenyl)-benzaldehyde (**13**) to **7b**(Chart 2). The ^{1}H-NMR spectra of 5-acyl compounds(**10a, b**) showed two doublets with 9—10 Hz ortho coupling and deshielding by 5-acyl groups at 4-H proton.

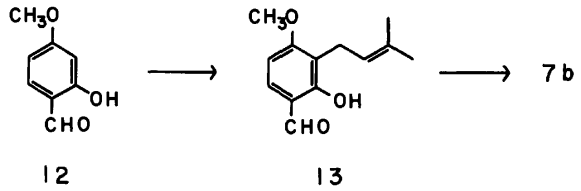

Chart 2.

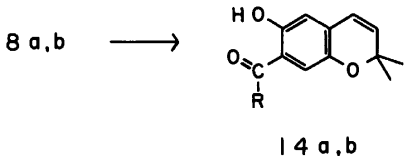

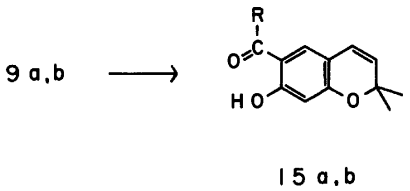

Chart 3.

Phosphoryl chloride is a weaker acid than zinc chloride or trifluoroacetic acid (derived from trifluoroacetic anhydride). Therefore, formylations could be run at higher temperatures than acetylations, and

Chemical shifts: δ, in CCl_4 (Coupling constants: J/Hz).

formylations gave better yields than acetylations in all methoxy-substituted 2,2-dimethyl-2*H*-chromenes. Acetylations of 5-methoxy-2,2-dimethyl-2*H*-chromene (**2**) and 7-methoxy-2,2-dimethyl-2*H*-chromene (**4**) gave mainly resin. This result shows that the methoxyl group in 5- or 7-position enhanced the electron density in the C=C double bond and labilized 2*H*-chromenes against acids. The acetylations of 5,7-dimethoxy-2,2-dimethyl-2*H*-chromene to 6-acetyl-5,7-dimethoxy-2,2-dimethyl-2*H*-chromene (methylevodionol) or 8-acetyl-5,7-dimethoxy-2,2-dimethyl-2*H*-chromene (methylalloevodionol), as we would suppose, gave only resin.

The spectral data of **9a** and **11a** agreed with the reported data of natural methyleupariochromene[4] (encecalin[5]) and acetovanillochromene.[6] Demethylation reactions of **8a, b** and **9a, b** with anhydrous magnesium iodide gave the corresponding chromenols (**14a, b** and **15a, b**) (Chart 3); the spectral data of **15a** agreed with the reported data of natural eupariochromene.[4] Oxidation of **6b** with silver oxide gave 2,2-dimethyl-2*H*-chromene-6-carboxylic acid (**16**) (Chart 4), and its spectral data agreed with the reported data of natural anofinic acid.[7]

Experimental

The boiling points and melting points were uncorrected (in boiling points: 1 mmHg ≈133.322 Pa). The IR, UV, and ^{1}H-NMR spectra were measured on a Hitachi EPI-S2 spectrophotometer, a Hitachi 124 spectrophotometer, and a JEOL JNM-MH-60 spectrometer, respectively.

*Acetylations of 2,2-Dimethyl-2*H*-chromenes. Method A*: To a mixture of 2,2-dimethyl-2*H*-chromenes (10 mmol), zinc chloride (3.4 g, 25 mmol), and dry benzene (5 mL) was added acetic anhydride (1.0 g, 10 mmol) over a 20 min period. The mixture was stirred at room temp for 3 h, at 80 °C for 20 min, or at room temp for 1 h. After the reaction, the mixture was treated with 10% hydrochloric acid and then extracted with ether. The combined ether extracts was washed with 5% sodium hydroxide solution, and dried over anhydrous sodium sulfate. After the removal of the ether, the resulting oil was distilled to give acetylchromenes.

Method B: Under cooling in an ice-water bath, trifluoroacetic anhydride (4.2 g, 20 mmol) was added to a solution of 2,2-dimethyl-2*H*-chromenes (10 mmol) in acetic acid (1.2 g, 20 mmol). The mixture was then allowed to stand for 6 h at room temp. After the reaction, the mixture was treated with ice water, and alkalified with aqueous sodium hydrogencarbonate solution, and then extracted with ether. The ether extracts were dried over anhydrous sodium sulfate. After the removal of the ether, the resulting oil was distilled to give acetylchromenes.

*Formylations of 2,2-Dimethyl-2*H*-chromenes. Method C*: To a mixture of *N*-methylformanilide (30 g, 20 mmol) and phosphoryl chloride (4.4 g, 10 mmol), 2,2-dimethyl-2*H*-chromenes (10 mmol) were added. The mixture was then heated at 90 °C for 1 h with stirring. After cooling, the mixture was boiled with an aqueous sodium hydroxide solution (1.5 g, in 15 mL) for 1 min and then extracted with ether. The ethereal layer was washed with 10% hydrochloric acid and 5% sodium hydroxide solution, and then dried over anhydrous sodium sulfate. After the removal of the ether, the resulting oil was distilled to give formyl 2,2-dimethyl-2*H*-chromenes.

In case of the acylations of **5**, mixtures were obtained. These were separated into components, 5-acyl compounds (**10a, b**) and 6-acyl compounds (**11a, b**) by silica-gel chromatography. The yields and ^{1}H-NMR data of acyl chromenes are summarized in Tables 1 and 2, and some UV data are shown in Figs. 1a and 1b. Some other physical data are listed below.

Another Preparative Method of 7b. To a solution of 2-hydroxy-5-methoxybenzaldehyde (**12**) (2.5 g, 16.4 mmol) in dry benzene (20 mL) was added sodium hydride (53% dispersed in mineral oil; 1.5 g) and 4-bromo-2-methyl-2-butene (2.5 g, 16.8 mmol). The mixture was refluxed overnight. After the reaction, the mixture was poured into 10% hydrochloric acid, and the separated benzene layer was dried over anhydrous sodium sulfate. Removal of the benzene gave an oily residue, which was chromatographed on a silica-gel column. The benzene eluted fractions gave 2-hydroxy-4-methoxy-3-(3-methyl-2-butenyl)benzaldehyde (**13**) (217 mg, 5.8%); IR (neat): 1645 cm^{-1}; ^{1}H-NMR (CCl_4): δ=1.6 (3H, broad s), 1.7 (3H, broad s), 3.3 (2H, d, *J*=7 Hz), 3.9 (3H, S), 5.1 (1H, broad t, *J*=7 Hz), 6.5 (1H, d, *J*=9 Hz), 7.3 (1H, d, *J*=9 Hz), 9.7 (1H, s), 11.4 (1H, s). To a solution of **13** (150 mg, 0.681 mmol) in dry benzene (70 mL),DDQ (170 mg, 0.749 mmol) was added. This mixture was then refluxed for 1 h. After cooling, the mixture was filtered. The filtrate was washed with 5% sodium hydroxide solution and saturated sodium chloride aqueous solution and dried over anhydrous sodium sulfate. After removal of the benzene, the resulting oil was chromatographed on a silica-gel column. The benzene eluted fractions gave **7b** (26 mg, 17.5%). The IR and ^{1}H-NMR spectra were identical with those of **7b** from **2**.

Demethylations of 8a, b and 9a, b. In dry benzene (5 mL) and anhydrous ether (2 mL), magnesium metal (0.2 g, 8.2 mmol) was treated with iodine (1.1 g, 8.7 mmol). The mixture was slightly heated while stirring until the color disappeared. To this mixture was then added a solution of **8a, b** or **9a, b** (5 mmol) in dry benzene (10 mL). and the mixture was refluxed for 3 h with stirring. After cooling, the mixture was treated with 10% hydrochloric acid and then extracted with benzene. The benzene layer was washed with water and dried over anhydrous sodium sulfate. After removal of the benzene, the resulting oil was chromatographed on a silica-gel column . The benzene eluted fractions gave corresponding chromenols (**14a, b** or **15a, b**). **14a**, Yield:

22.1%; mp 66—68 °C (recrystallized from hexane); IR (KBr disk): 1645 cm^{-1}; UV (EtOH): 238 (log ε 4.26), 294 (4.14), 388 nm (3.68); ^{1}H-NMR (CCl_4): δ=1.4 (6H, s), 2.5(3H, s), 5.8(1H, d, J=10 Hz), 6.2 (1H, d, J=10 Hz), 6.6 (1H, s), 7.1 (1H, s), 11.8 (1H, s); Found: C, 71.63; H, 6.57%. Calcd: C, 71.54: H, 5.47%. **14b**, Yield: 20.4%; mp 97—99 °C (recrystallized from hexane); IR (KBr disk): 1645 cm^{-1}; UV (EtOH): 239 (log ε 4.23), 294 (4.16), 391 nm (3.76); ^{1}H-NMR (CCl_4): δ=1.5 (6H, s), 5.9 (1H, d, J=10 Hz), 6.4 (1H, d, J=10 Hz), 6.6 (1H, s), 7.0 (1H, s), 10.0 (1H, s), 10.8 (1H, s); Found: C, 70.68; H, 5.91%. Calcd: C, 70.57; H, 5.92%. **15a**, Yield: 43.9%; mp 72—73.5 °C (recrystallized from hexane); IR (KBr disk): 1655 cm^{-1}; UV (EtOH): 227 sh (log ε 4.16), 234 (4.27), 257 (4.54), 291 sh (3.81), 347 nm (3.79); ^{1}H-NMR (CCl_4); δ=1.5 (6H, s), 2.6 (3H, s), 5.7 (1H, d, J=10 Hz), 6.5 (1H, d, J=10 Hz), 6.5 (1H, s), 7.5 (1H, s), 13.2 (1H, s); Found: C, 71.32; H, 6.39%. Calcd: C, 71.54; H, 6.47%. **15b**, Yield: 54.2%; mp 97—99 °C (recrystallized from cyclohexane); IR (KBr disk): 1635 cm^{-1}; UV (EtOH): 228 sh (log ε 4.16), 235 (4.24), 259 (4.48), 282 sh (3.87), 293 sh (3.82), 349 nm (3.74); ^{1}H-NMR (CCl_4); δ=1.4 (6H, s), 5.5 (1H, d, J=10 Hz), 6.2 (1H, d, J=10 Hz), 6.2 (1H, s), 7.0 (1H, s), 9.6 (1H, s), 12.9 (1H, s); Found: C, 70.49; H, 5.87%. Calcd: C, 70.57; H, 5.92%.

*Oxidation of **6b** to Anofinic Acid.* To a solution of silver nitrate (2.3 g, 14.0 mmol) in water (20 mL), sodium hydroxide (1.0 g) was added. To this silver oxide suspension, a solution of **6b** (1.2 g, 6.38 mmol) in ethanol (20 mL) was added. The mixture was then refluxed for 2 h. After the reaction, the mixture was filtered. The filtrate was washed with ether and then acidified with 10% hydrochloric acid. The crystals thus obtained were collected and recrystallized from benzene-hexane (1 : 9) to give **16** (770 mg, 59.4%); mp 158.5—160 °C; IR (KBr disk): 1675 cm^{-1}; UV (EtOH): 239.5 (log ε 4.68), 280.5 (3.88), 306 (3.78), 318 nm (3.67); ^{1}H-NMR (CCl_4): δ=1.5 (6H, s), 5.8 (1H, d, J=10 Hz), 6.5 (1H, d, J=10 Hz), 7.0 (1H, d, J=9 Hz), 7.9 (1H, d, J=2 Hz), 8.1 (1H, dd, J=9+2 Hz), 10.3 (1H,s); Found: C, 70.75; H, 5.85%. Calcd: C, 70.57; H, 5.92%.

Aliphatic Claisen Rearrangement Promoted by Organoaluminium Reagents

Kazuhiko TAKAI, Ichiro MORI, Koichiro OSHIMA,* and Hitosi NOZAKI
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received July 13, 1983)

Organoaluminium compounds, R_3Al, promote the Claisen rearrangement of allyl vinyl ether derivatives at room temperature under transfer of R or H as a nucleophile to the aldehydic carbon. Treatment of 1-butyl-2-propenyl vinyl ether with a hexane solution of Me_3Al (1.0 M†, 2.2 equiv) in CH_2ClCH_2Cl at 25 °C afforded 5-decen-2-ol (91% yield, E/Z=47/53), which was produced by the [3,3] sigmatropic rearrangement and successive methylation. The rearrangements with alkynylation, alkenylation, and hydrogenation are also achieved. The regular Claisen rearrangement products, or γ,δ-unsaturated aldehydes (ketones), are obtained at 25 °C in good to excellent yields with Et_2AlSPh (2.5 equiv) or the combination of Et_2AlCl (2.0 equiv) and PPh_3 (2.2 equiv).

Although aliphatic Claisen rearrangement[1] provides a means of introducing a carbon-carbon bond in a stereo- and regiospecific manner, higher temperature and longer reaction time limit the synthetic use of this reaction. Some modifications, such as amide-acetal,[2] orthoester,[3] and ester enolate method,[4] have been reported to overcome this difficulty. We report here that the treatment of simple allyl vinyl ether substrates with organoaluminium amphoteric reagents results in the [3,3] sigmatropic rearrangements under mild conditions.[5]

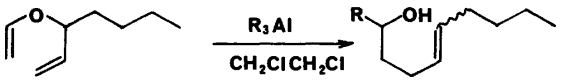
Addition of Lewis acid has been recently well documented as accelerating Diels-Alder reaction,[6] ene reaction,[7] and aromatic Claisen rearrangement.[8] The attempted aliphatic Claisen rearrangement in the presence of common Lewis acid, however, failed. For example, treatment of 1-butyl-2-propenyl vinyl ether (**1**) with $BF_3 \cdot OEt_2$, $TiCl_4$,[9] $SnCl_4$, or $ZnBr_2$ resulted in formation of complex mixtures containing 1-hepten-3-ol but none of the desired rearrangement products. In contrast, organoaluminium reagent, R_3Al or R_2AlSPh, proved to bring about the rearrangement at room temperature under transfer of R, H, or SPh[10] as a nucleophile to the aldehydic carbon.

Treatment of 1-butyl-2-propenyl vinyl ether (**1**) with 2.2 equiv of trimethylaluminium in 1,2-dichloroethane at 25 °C under an argon atmosphere gave 5-decen-2-ol (**2a**) in 91% yield (E/Z=47/53), this was apparently produced by the rearrangement and successive methylation. The use of triethylaluminium resulted in formation of a mixture of the corresponding ethylated alcohol **2b** (75% yield, E/Z=42/58) as well as a hydrogenated one **2c** (19% yield, E/Z=42/58). Meanwhile, the hydrogenated product was obtained exclusively with triisobutylaluminium or diisobutylaluminium hydride. The reactions between triisobutylaluminium and allyl vinyl ether substrates are shown in Table 1.

The E/Z ratios of newly developed double bonds were close to 1/1 and not affected by such solvents as hexane, benzene, dichloromethane, and 1,2-dichloroethane. In ethereal solvents like ether and THF, the reaction did not take place.

Neither methyllithium nor diethylzinc was effective for the transformation. Methylmagnesium iodide was marginal; for example, the reaction of **1** with 3 equiv of MeMgI took 2 h to be completed, affording **2a** in 78% yield (E/Z=52/48).

Because allyl vinyl ether substrates **3** and **4** gave the corresponding [3,3] sigmatropic products respectively



1

2a: R = CH_3
2b: R = CH_2CH_3
2c: R = H(*i*-Bu_3Al)

Scheme 1.

TABLE 1. REACTIONS BETWEEN Bu_3Al AND ALLYL VINYL ETHER SUBSTRATES[a]

Run	Ether[b] R^1	Ether[b] R^2	Conditions Temp/°C	Conditions Time/h	Yield[c] %	E/Z[d]
1	*n*-Bu	H	25	0.25	82	38/62
2	*n*-Bu	Me	25	0.25	89	45/55
3	Ph	H (**3**)	25	0.25	93	*E* only
4	H	Ph (**4**)	25	0.25	91	—
5			25	0.25	90	—
6			60	2	95	—
7			60	2	97	—
8			25	0.25	78	trans/cis 23/77

a) The substrates (2.0 mmol) dissolved in 1,2-dichloroethane (10 ml) were treated with a hexane solution of *i*-Bu_3Al (1.0 M, 4.4 mmol). b) Prepared by the mercury(II) acetate-catalyzed transetherification with ethyl vinyl ether (Runs 1—5). See Ref. 3b. c) Isolated yields. d) the crude prodcts were transformed into trimethylsilyl ethers whose isomeric ratios were determined by GLPC.

†1 M=1 mol dm^{-3}.

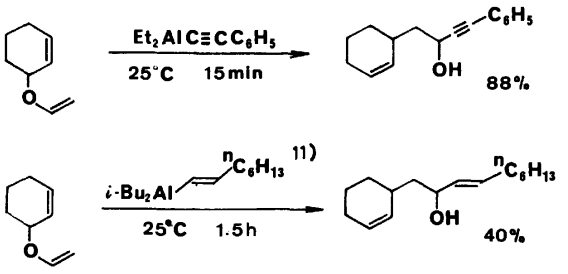
(Runs 3 and 4), the possibility of the following sequence of reactions was rejected: (1) A Lewis acid promoting C-O bond fission to give the ion pair of allylic cation and enolate ion, (2) recombination of the ion pair to afford the aldehyde, and (3) reduction of the aldehyde by i-Bu_3Al.[10]

Table 2 summarizes the reaction between trimethylaluminium and allyl vinyl ether derivatives.

Alkynyl and alkenyl groups were introduced in preference to an alkyl group, as shown in Scheme 2.

The reagent Et_2AlSPh[12] (method A) or a combination of Et_2AlCl and PPh_3 (method B) turned out to be effective for the rearrangement giving regular Claisen products, or γ,δ-unsaturated aldehydes (ketones), as shown in Table 3. The rearrangement did not occur in the presence of Et_2AlSEt, Et_2AlS^tBu, or $^iBu_2AlOPh$. Triphenylphosphine plays an important role in method B, since the reaction of **1** with diethylaluminium chloride alone afforded the same mixture of **2b** (56%, E/Z=46/54) and **2c** (12%, E/Z=48/52) as that with triethylaluminium. A similar combination of Et_2AlI and Et_3N was effective, but the yields were not so good as the yield of Et_2AlCl and PPh_3.

Almost the same yields and selectivities were obtained with Et_2AlSPh and Et_2AlCl-PPh_3 reagents.



Scheme 2.

10			A[e]	0.5	76	—

a) Reactions were carried out in 1,2-dichloroethane at 25 °C. b) The substrates (2.0 mmol) were treated with Et_2AlSPh (5.0 mmol). c) The crude products were reduced with $LiAlH_4$ and transformed into trimethylsilyl ethers. The E/Z ratios of trimethylsilyl ethers were determined by GLPC. d) The substrates (2.0 mmol) were treated with a mixture of Et_2AlCl (4.0 mmol) and PPh_3 (4.4 mmol). e) Dichloromethane was used as a solvent.

It is worth noting that the rearrangement of 2-vinyl-3,4-dihydro-2*H*-pyran derivatives took place under extremely mild conditions (Runs 8 and 9) as compared with the pyrolysis (410—425 °C) without the catalyst described in the literature.[13]

Experimental

The IR spectra were determined on a Shimadzu IR-27-G spectrometer; the mass spectra, on a Hitachi M-80 machine; and the NMR spectra, on a Varian EM-360 spectrometer. The chemical shifts are given in δ, with TMS as the internal standard. The microanalyses were carried out at the Elemental Analyses Center of Kyoto University. 1,2-Dichloroethane and dichloromethane were dried over P_2O_5 and distilled. All the experiments were carried out under an argon atmosphere. Purification of products was performed by preparative thin-layer chromatography (TLC) or column chromatography on silica gel (Merck Kieselgel 60). Analytical GLPC was performed with a Yanagimoto GCG-550-F or Shimadzu GC-4CPT. Preparative GLPC was performed with a JEOL-JGC-20K apparatus.

Preparation of Allylic Vinyl Ethers by Transetherification.[3b] Mercury(II) acetate and ethyl vinyl ether were purified according to the literature.[14] Allylic alcohol (30 mmol), mercury(II) acetate (6.4 g, 20 mmol), and freshly distilled ethyl vinyl ether (150 ml) were boiled under reflux for 20—30 h under an argon atmosphere. The mixture was poured into 5% potassium hydroxide solution (30 ml) and extracted

with hexane. After being dried over anhydrous potassium carbonate, the solvent was evaporated. In order to remove the mercury compounds and the unreacted starting alcohol, the remaining liquid was purified by column chromatography on alumina (Merck Aluminiumoxid 90 aktiv neutral (Aktivitätsstufe III)) using hexane as an eluent.

1-Butyl-2-propenyl Vinyl Ether (1): Bp 52 °C (bath temp, 2 Torr, 1 Torr≈133.322 Pa); IR (neat): 2975, 2945, 1635, 1615, 1320, 1195, 1180, 1045, 990, 923, 825 cm^{-1}; NMR (CCl_4): δ=0.73—1.06 (m, 3H), 1.10—1.75 (m, 6H), 3.83 (d, J=6 Hz, 1H), 3.85—4.18 (m, 1H), 4.13 (d, J=15 Hz, 1H), 5.06 (d, J=11 Hz, 1H), 5.10 (d, J=15 Hz, 1H), 5.68 (ddd, J=15, 11, 6 Hz, 1H), 6.15 (dd, J=15, 6 Hz, 1H); MS m/z (%): 140 (M^+, 1), 97 (12), 96 (15), 81 (9), 55 (100), 54 (13); Found: C, 77.17; H, 11.72%. Calcd for $C_9H_{16}O$: C, 77.09; H, 11.50%.

(E)-*1-Butyl-2-butenyl Vinyl Ether*: Bp 53 °C (bath temp, 4 Torr); IR (neat): 2940, 2860, 1634, 1455, 1320, 1180, 1033, 960, 818 cm^{-1}; NMR (CCl_4): δ=0.92 (bt, J=6 Hz, 3H), 1.10—1.63 (m, 6H), 1.72 (d, J=5 Hz, 3H), 3.80 (d, J=6 Hz, 1H), 3.75—4.08 (m, 1H), 4.09 (d, J=15 Hz, 1H), 5.25 (dd, J=6, 15 Hz, 1H), 5.55 (dq, J=15, 5 Hz, 1H), 6.13 (dd, J=6, 15 Hz, 1H); MS m/z (%): 154 (M^+, trace), 111 (41), 69 (96), 55 (100); Found: C, 77.74; H, 11.94%. Calcd for $C_{10}H_{18}O$: C, 77.87; H, 11.76%.

1-Phenyl-2-propenyl Vinyl Ether (3): Bp 75 °C (bath temp, 2 Torr); IR (neat): 1645, 1620, 1500, 1462, 1320, 1188, 1172, 990, 930, 700 cm^{-1}; NMR (CCl_4): δ=3.90 (dd, J=2, 7 Hz, 1H), 4.17 (dd, J=2, 14 Hz, 1H), 5.00—5.30 (m, 3H), 5.87 (ddd, J=6, 10, 15 Hz, 1H), 6.23 (dd, J=6, 14 Hz, 1H), 7.15—7.30 (m, 5H); MS m/z (%): 160 (M^+, 7), 117 (100), 115 (24), 104 (17), 91 (40); Found: C, 82.60; H, 7.72%. Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.54%.

(E)-*3-Phenyl-2-propenyl Vinyl Ether (4)*: Bp 77 °C (bath temp, 1 Torr); IR (neat): 3040, 2870, 1640, 1620, 1500, 1457, 1320, 1194, 964, 820, 742, 692 cm^{-1}; NMR (CCl_4): δ=3.92 (dd, J=2, 6 Hz, 1H), 4.12 (dd, J=2, 15 Hz, 1H), 4.29 (d, J=5 Hz, 2H), 6.15 (dt, J=15, 5 Hz, 1H), 6.36 (dd, J=10, 15 Hz, 1H), 6.53 (d, J=15 Hz, 1H), 7.06—7.40 (m, 5H); MS m/z (%): 160 (M^+, 3), 117 (100), 115 (29), 91 (19); Found: C, 82.60; H, 7.67%. Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.55%.

2-Cyclohexenyl Vinyl Ether:[14] Bp 53 °C (bath temp, 18 Torr); IR (neat): 2940, 1635, 1612, 1190, 1065, 1012, 810 cm^{-1}; NMR (CCl_4): δ=1.00—2.23 (m, 6H), 3.97 (dd, J=1, 6 Hz, 1H), 4.22 (dd, J=1, 17 Hz, 1H), 4.20—4.47 (m, 1H), 5.70—5.98 (m, 2H), 6.36 (dd, J=6, 17 Hz, 1H); MS m/z (%): 124 (M^+, 6), 82 (13), 81 (100), 80 (37), 79 (43), 53 (23).

2-Vinyl-3,4-dihydro-2H-pyran:[13] Dry DMSO (50 ml) was added at 25 °C by a syringe to the washed sodium hydride (4.0 g of a 60% mineral oil dispersion, 0.10 mol). The mixture was heated at 75 °C and stirred until the hydrogen evolution ceased (*ca.* 1 h). Then, a solution of methyltriphenylphosphonium bromide (35.7 g, 0.10 mol) in warm DMSO (100 ml) was added to the methylsulfinylmethanide ion solution at 0 °C. The resulting greenish red solution was stirred at 25 °C for 15 min before freshly distilled acrylaldehyde dimer (11.2 g, 0.10 mol) was added at 25 °C. An immediate color change was observed. After stirring at 25 °C for 1 h, the reaction mixture was diluted with cold water (300 ml). The solids were removed by filtration and washed with pentane (3×100 ml). The concentrated crude product was distilled to afford the title compound (3.7 g, 34%) as a colorless liquid: Bp 57 °C (20 Torr); IR (neat): 3060, 2920, 2850, 1650, 1428, 1235, 1060, 985, 918, 900, 722 cm^{-1}; NMR (CCl_4): δ=1.47—2.13 (m, 4H), 4.09—4.32 (m, 1H), 4.45—4.63 (m, 1H), 5.03 (ddd, J=11, 10 Hz, 1H), 5.17 (ddd, J=1, 1, 15 Hz, 1H), 5.79 (ddd, J=4, 10, 15 Hz, 1H), 6.23 (d, J=6 Hz, 1H); MS m/z (%): 110 (M^+, 75), 95 (21), 92 (20), 81 (41), 79 (50), 54 (100).

2-Isopropenyl-6-methyl-3,4-dihydro-2H-pyran:[13] This material was prepared from methacrylaldehyde dimer as described for 2-vinyl-3,4-dihydro-2*H*-pyran in 63% yield as a colorless liquid: Bp 74 °C (28 Torr); IR (neat): 3080, 2960, 1722, 1684, 1655, 1462, 1440, 1380, 1238, 1045, 890, 800 cm^{-1}; NMR (CCl_4): δ=1.20—2.20 (m, 4H), 1.69 (s, 3H), 1.74 (s, 3H), 4.10 (dd, J=3, 8 Hz, 1H), 4.27—4.40 (bt, J=3 Hz, 1H), 4.78 (s, 1H), 4.89 (s, 1H); MS m/z (%): 138 (M^+, 12), 98 (20), 95 (90), 71 (49), 68 (100).

Allyl 1-Cyclohexenyl Ether:[15] To a stirred solution of Et_2AlI (1.2 M of a toluene solution, 4.2 ml, 5.0 mmol) and triethylamine (1.0 g, 10 mmol) in dichloromethane (20 ml) was added at 0 °C a dichloromethane solution of cyclohexanone diallyl acetal (0.98 g, 5.0 mmol). After stirring at 25 °C for 5 h, the resulting mixture was poured into 6 M sodium hydroxide solution (20 ml) and extracted with ether. The ethereal layer was washed with sat. sodium hydrogencarbonate (20 ml), dried over potassium carbonate, and concentrated. The crude product was purified by column chromatography on alumina (hexane-ether, 10 : 1) to give the ether (0.40 g, 58%) as a colorless liquid: Bp 72 °C (bath temp, 9 Torr); IR (neat): 2970, 1685, 1382, 1338, 1270, 1084, 910, 778 cm^{-1}; NMR (CCl_4): δ=1.33—1.80 (m, 4H), 1.80—2.14 (m, 4H), 4.05 (d, J=5 Hz, 2H), 4.44 (bt, J=4 Hz, 1H), 5.05 (d, J=10 Hz, 1H), 5.20 (d, J=15 Hz, 1H), 5.86 (ddt, J=10, 15, 5 Hz, 1H); MS m/z (%): 138 (M^+, 21), 109 (19), 105 (38), 95 (20), 94 (35), 79 (26), 55 (35), 41 (100).

Reactions between Triisobutylaluminium and Allyl Vinyl Ether Derivatives. A hexane solution of triisobutylaluminium (1.0 M, 5.0 ml, 5.0 mmol) was added to a solution of an allyl vinyl ether (2.0 mmol) in 1,2-dichloroethane (15 ml) at 25 °C under an argon atmosphere and the whole was stirred at 25 °C (60 °C) for 15 min (2 h). The mixture was diluted with ether (15 ml) and poured into 1 M hydrochloric acid (20 ml). The separated organic layer was washed with brine (2×20 ml), dried over anhydrous sodium sulfate, and concentrated. The crude product was purified by silica-gel column chromatography (hexane-ethyl acetate).

(E)- *and* (Z)-*4-Nonen-1-ol (2c)*: The crude product generated from 1-butyl-2-propenyl vinyl ether (**1**) and triisobutylaluminium was transformed into trimethylsilyl ether with *N*-(trimethylsilyl)imidazole (1.2 equiv) in dichloromethane. GLPC (5% PEG 20M, 2 m, 65 °C) indicated two peaks, T_r=16.0 min ((*Z*)-isomer, 62%) and T_r=17.5 min ((*E*)-isomer, 38%). The analytically pure samples of both isomers were prepared by preparative GLPC (20% PEG 20 M). These samples were identical to the authentic samples.[16] (*E*)-Alcohol: Bp 76 °C (bath temp, 5 Torr); IR (neat): 3350, 2940, 1470, 1380, 1055, 965 cm^{-1}; NMR (CCl_4); δ=0.90 (bt, J=6 Hz, 3H), 1.16—1.70 (m, 7H), 1.80—2.18 (m, 4H), 3.53 (t, J=7 Hz, 2H), 5.23—5.42 (m, 2H); MS m/z (%): 124 (M^+-H_2O, 17), 96 (27), 95 (42), 82 (51), 81 (100), 69 (32), 68 (97), 67 (65), 55 (69). (*Z*)-Alcohol: Bp 80 °C (bath temp, 5 Torr); IR (neat): 3350, 2950, 1475, 1380, 1060 cm^{-1}; NMR (CCl_4); δ=0.90 (bt, J=6 Hz, 3H), 1.04—1.78 (m, 7H), 1.80—2.23 (m, 4H), 3.52 (t, J=7 Hz, 2H), 5.05—5.48 (m, 2H); MS m/z (%): 124 (M^+-H_2O, 11), 96 (26), 95 (40), 82 (45), 81 (90), 68 (87), 67 (78), 55 (95), 41 (100).

(E)- *and* (Z)-*3-Methyl-4-nonen-1-ol*: GLPC analysis (10% PEG 20 M, 2 m, 100 °C) of the corresponding trimethylsilyl ethers indicated two peaks, T_r=20.0 min ((*E*)-isomer, 45%), T_r=17.9 min ((*Z*)-isomer, 55%). (*E*)-Alcohol: Bp 78 °C (bath temp, 1 Torr); IR (neat): 3350, 2990, 2950, 1460, 1376, 1050, 970 cm^{-1}; NMR (CCl_4): δ=0.88 (bt, 3H), 0.98 (d, J=6 Hz, 3H), 1.23—1.65 (m, 7H), 1.90—2.10 (m, 2H), 2.12—2.35 (m, 1H), 3.50 (t, J=7 Hz, 2H), 5.10—5.40 (m, 2H); MS m/z (%): 156 (M^+, 2), 138 (4), 109 (30), 95 (38), 81 (100), 69 (89); Found: C, 76.69; H, 13.20%. Calcd for $C_{10}H_{20}O$: C, 76.86; H, 12.90%. (*Z*)-Alcohol: Bp 75 °C (bath temp, 2 Torr); IR (neat): 3360, 2980, 2940, 1462, 1052, 1000, 968 cm^{-1}; NMR (CCl_4):

Calcd for $C_9H_{16}O$: M, 140.1202.

cis-*and* trans-*2-Allyl-1-cyclohexene*: TLC analysis (hexane-ethyl acetate, 5 : 1) of the product derived from the reaction of allyl 1-cyclohexenyl ether and triisobutylaluminium showed two spots, R_f=0.42 (cis-isomer, 77%) and R_f=0.33 (trans-isomer, 23%). Analytically pure samples of both isomers were prepared by preparative TLC (hexane-ethyl acetate, 5 : 1). *cis*-Isomer:[19] Bp 90 °C (bath temp, 12 Torr); IR (neat): 3400, 3100, 2940, 1647, 1452, 1260, 975, 906, 785 cm^{-1}; NMR (CCl_4): δ=1.03—1.87 (m, 10H), 1.87—2.20 (m, 2H), 3.72—3.87 (bm, 1H), 4.90 (d, J=10 Hz, 1H), 4.93 (d, J=16 Hz, 1H), 5.71 (ddt, J=10, 16, 6 Hz, 1H); MS m/z (%): 140 (M^+, trace), 122 (54), 107 (35), 98 (79), 93 (45), 81 (100). *trans*-Isomer:[19] Bp 94 °C (bath temp, 12 Torr); IR (neat): 3350, 3075, 2940, 1640, 1450, 1055, 1030, 990, 902 cm^{-1}; NMR (CCl_4): δ=0.90—2.10 (m, 11H), 2.25—2.60 (m, 1H), 2.97—3.32 (m, 1H), 5.90 (d, J=10 Hz, 1H), 5.93 (d, J=16 Hz, 1H), 5.95 (ddt, J=10, 16, 6 Hz, 1H); MS m/z (%): 140 (M^+, trace), 122 (41), 107 (17), 98 (55), 93 (43), 81 (100), 67 (43).

Reactions between Trimethylaluminium and Allyl Vinyl Ether Derivatives. A solution of an allyl vinyl ether substrate (2.0 mmol) in 1,2-dichloroethane (15 ml) was treated with a hexane solution of trimethylaluminium (1.0 M, 4.4 ml, 4.4 mmol) at 25 °C (60 °C) for 15 min (2 h). The resulting mixture was diluted with ether (15 ml), and poured into 1 M hydrochloric acid (20 ml). The ethereal extracts were washed with brine (2×20 ml), dried over anhydrous sodium sulfate, and concentrated. The crude product was purified by silica-gel column chromatography (hexane-ethyl acetate).

(E)- *and* (Z)-*5-Decen-2-ol* (**2a**): The product was converted into trimethylsilyl ether, whose E/Z ratio was determined by GLPC (5% PEG 20 M, 2 m, 75 °C). GLPC showed a peak at 11.2 min, corresponding to (*Z*)-1-methyl-3-nonenyl trimethylsilyl ether (53%) and a peak at 12.3 min, corresponding to the (*E*)-isomer (47%). The authentic samples of both isomers were prepared by methylation of (*E*)- and (*Z*)-4-nonenal with MeMgI in THF. (*E*)-Alcohol: Bp 83 °C (bath temp, 5 Torr); IR (neat): 3350, 2940, 1470, 1460, 1375, 1120, 1080, 966 cm^{-1}; NMR (CCl_4); δ=0.89 (bt, J=5 Hz, 3H), 1.13 (d, J=6 Hz, 3H), 1.10—1.60 (m, 7H), 1.80—2.18 (m, 4H), 3.66 (tq, J=6, 6 Hz, 1H), 5.23—5.42 (m, 2H); MS m/z (%): 156 (M^+, 12), 138 (19), 109 (26), 95 (88), 82 (82), 81 (72), 71 (54), 68 (57), 67 (100); Found: C, 76.81; H, 13.09%. Calcd for $C_{10}H_{20}O$: C, 76.86; H, 12.90%. (*Z*)-Alcohol: Bp 59 °C (bath temp, 1 Torr); IR (neat): 3370, 2950, 1465, 1378, 1124, 1078, 955 cm^{-1}; NMR (CCl_4): δ=0.90 (bt, J=5 Hz, 3H), 1.13 (t, J=6 Hz, 3H), 1.10—1.53 (m, 7H), 1.80—2.20 (m, 4H), 3.68 (tq, J=6, 6 Hz, 1H), 5.07—5.47 (m, 2H); MS m/z (%): 156 (M^+, 9), 138 (11), 109 (17), 95 (58), 82 (58), 81 (56), 67 (90), 55 (79), 45 (100); Found: C, 76.74; H, 13.07%. Calcd for $C_{10}H_{20}O$: C, 76.86; H, 12.90%.

(E)-*6-Phenyl-5-hexen-2-ol*:[20] Bp 118 °C (bath temp, 1 Torr); IR (neat): 3375, 2950, 1602, 1498, 1452, 1125, 1068, 960, 740, 690 cm^{-1}; NMR (CCl_4): δ=1.13 (d, J=6 Hz, 3H), 1.40—1.70 (m, 2H), 1.80 (s, 1H), 2.15—2.43 (m, 2H), 3.74 (tq, J=6, 6 Hz, 1H), 6.05 (dt, J=15, 6 Hz, 1H), 6.30 (d, J=15 Hz, 1H), 7.00—7.30 (m, 5H); MS m/z (%): 176 (M^+, 30), 158 (13), 143 (32), 129 (100), 118 (31), 117 (45).

4-Phenyl-5-hexen-2-ol: Bp 86 °C (bath temp, 1 Torr); IR (neat): 3350, 3150, 3050, 1602, 1496, 1125, 910, 705 cm^{-1}; NMR (CCl_4): δ=1.08, 1.14 (d, J=6 Hz, total 3H diastereomeric mixture), 1.20 (bs, 1H), 1.73 (t, J=7 Hz, 2H), 3.16—3.90 (m, 2H), 4.80—5.20 (m, 2H), 5.60—6.25 (m, 1H), 6.88—7.30 (m, 5H); MS m/z (%): 176 (M^+, 1), 158 (13), 143 (50), 132 (53), 129 (23), 118 (26), 117 (100), 91 (16); Found: C, 81.88; H, 9.21%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

1-(2-Cyclohexenyl)-2-propanol: Bp 78 °C (bath temp, 1 Torr); IR (neat): 3350, 2940, 1650, 1450, 1372, 1126, 1014, 716, 672 cm^{-1}; NMR (CCl_4): δ=1.18 (d, J=6 Hz, 3H), 1.08-2.43 (m, 10H), 3.70—4.00 (m, 1H), 5.38—5.70 (m, 2H); MS m/z (%): 140 (M^+, 1), 122 (86), 107 (91), 93 (52), 81 (100), 79 (74); Found: C, 76.90; H, 11.79%. Calcd for $C_9H_{16}O$: C, 77.09; H, 11.50%.

4-(1-Hydroxyethyl)-1-cyclohexanol: Bp 70 °C (bath temp, 1 Torr); IR (neat): 3360, 3040, 2910, 1658, 1440, 1370, 1136, 1060, 942, 854, 650 cm^{-1}; NMR (CCl_4): δ=1.15 (d, J=6 Hz, 3H), 1.10—2.30 (m, 8H), 3.50 (q, J=6 Hz, 1H), 5.57 (s, 2H); MS m/z (%): 126 (M^+, trace), 108 (27), 93 (32), 79 (100), 78 (20), 67 (28); Found: C, 75.94; H, 11.44%. Calcd for $C_8H_{14}O$: C, 76.14; H, 11.18%.

4-(1-Hydroxy-1-methylethyl)-2-methyl-1-cyclohexanol: Bp 97 °C (bath temp, 2 Torr); IR (neat): 3390, 2980, 2925, 1440, 1378, 1150, 940, 910, 785 cm^{-1}; NMR (CCl_4): δ=1.13 (s, 6H), 1.10—2.27 (m, 8H), 1.60 (s, 3H), 5.30 (s, 1H); MS m/z (%): 154 (M^+, trace), 136 (16), 121 (21), 93 (86), 92 (36), 81 (32), 59 (100); Found: m/z 154.1352. Calcd for $C_{10}H_{18}O$: M, 154.1358.

(E)- *and* (Z)-*6-Undecen-3-ol* (**2b**): The reaction was carried out with triethylaluminium as described for trimethylaluminium to give the mixture of (*E*)- and (*Z*)-4-nonen-1-ol (**2c**) and the ethylated alcohols **2b**. The crude product was separated by preparative TLC (hexane-ether, 5 : 1). The isomeric alcohols **2b** were transformed into trimethylsilyl ethers. GLPC analysis (5% PEG 20 M, 2 m, 75 °C) of the trimethylsilyl ethers showed two peaks, T_r=19.8 min ((*E*)-isomer, 42%) and T_r=18.2 min ((*Z*)-isomer, 58%). The authentic samples of both isomers were prepared by ethylation of (*E*)- and (*Z*)-4-nonenal with EtMgBr in THF. (*E*)-Alcohol: Bp 79 °C (bath temp, 3 Torr); IR (neat): 3360, 2960, 1470, 970 cm^{-1}; NMR (CCl_4); δ=0.91 (t, J=7 Hz, 6H), 1.15—1.58 (m,

8H), 1.68 (s, 1H), 1.80—2.23 (m, 4H), 3.39 (tt, J=6, 6 Hz, 1H), 5.23—5.43 (m, 2H); MS m/z (%): 170 (M^+, 2), 152 (11), 123 (14), 109 (25), 96 (42), 81 (74), 67 (100); Found: C, 77.49; H, 13.24%. Calcd for $C_{11}H_{22}O$: C, 77.58; H, 13.02%. (*Z*)-Alcohol: Bp 68 °C (bath temp, 1 Torr); IR (neat): 3350, 2940, 1460, 1114, 964 cm^{-1}; NMR (CCl_4): δ=0.93 (t, J=7 Hz, 6H), 1.06—1.62 (m, 9H), 1.83—2.24 (m, 4H), 3.44 (tt, J=6, 6 Hz, 1H), 5.10—5.46 (m, 2H); MS m/z (%): 170 (M^+, 1), 123 (10), 109 (18), 96 (33), 81 (61), 67 (100); Found: C, 77.36; H, 13.30%. Calcd for $C_{11}H_{22}O$: C, 77.58; H, 13.02%.

1-(2-Cyclohexenyl)-4-phenyl-3-butyn-2-ol: To a stirred hexane solution of PhC≡CLi prepared from phenylacetylene (0.51 g, 5.0 mmol) and butyllithium (1.5 M of a hexane solution, 3.3 ml, 5.0 mmol) was added at 0 °C a hexane solution of diethylaluminium chloride (1.0 M, 5.0 ml, 5.0 mmol) and the whole was stirred at 25 °C for 20 min. After addition of 1,2-dichloroethane (15 ml), a solution of 2-cyclohexenyl vinyl ether (0.25 g, 2.0 mmol) in 1,2-dichloroethane (4 ml) was added to the aluminium reagent at 25 °C and the mixture was stirred for 15 min. After the usual workup, the crude product was purified by preparative TLC (hexane-ether, 5 : 1) to give the desired adduct in 88% yield (0.40 g) as a pale yellow liquid: Bp 130 °C (bath temp, 0.1 Torr); IR (neat): 3320, 2920, 2350, 1650, 1600, 1490, 1442, 1012, 750, 686 cm^{-1}; NMR (CCl_4): δ=1.05—2.62 (m, 10H), 4.16 (t, J=7 Hz, 1H), 5.46—5.74 (m, 2H), 7.13—7.50 (m, 5H); MS m/z (%): 226 (M^+, 1), 225 (12), 183 (19), 167 (19), 131 (100), 103 (25), 95 (35); Found: C, 84.87; H, 8.01%. Calcd for $C_{16}H_{18}O$: C, 84.91; H, 8.02%.

1-(2-Cyclohexenyl)-3-decen-1-ol: A solution of 2-cyclohexenyl vinyl ether (0.25 g, 2.0 mmol) in 1,2-dichloroethane (15 ml) was treated at 25 °C for 1.5 h with a hexane solution of (*E*)-1-octenyldiisobutylaluminium prepared from 1-octyne (0.60 g, 5.5 mmol) and diisobutylaluminim hydride (3.2 ml of a 1.7 M toluene solution, 5.5 mmol). After the usual workup and purification by silica-gel column chromatography gave the title alcohol in 40% yield (0.19 g) as a colorless liquid: Bp 95 °C (bath temp, 0.05 Torr); IR (neat): 3350, 2925, 1450, 960, 715 cm^{-1}; NMR (CCl_4); δ=0.89 (bt, J=6 Hz, 3H), 1.06—2.35 (m, 20H), 4.06 (dt, J=6, 6 Hz, 1H), 5.33—5.70 (m, 4H); MS m/z (%): 236 (M^+, 14), 218 (33), 151 (66), 134 (46), 109 (41), 95 (87), 94 (69), 81 (100); Found: C, 81.21; H, 12.05%. Calcd for $C_{16}H_{28}O$: C, 81.29; H, 11.94%.

Claisen Rearrangement of Allyl Vinyl Ether Derivatives Promoted by Et_2AlSPh (Method A). A solution of thiophenol (0.55 g, 5.0 mmol) in hexane (3 ml) was added at 25 °C to a hexane solution of triethylaluminium (1.0 M, 5.0 ml, 5.0 mmol) and the mixture was stirred at the same temperature for 20 min. After an addition of 1,2-dichloroethane (5 ml), a solution of allyl vinyl ether substrate (2.0 mmol) in 1,2-dichloroethane (3 ml) was added to the aluminium reagent at 25 °C and the whole was stirred for an appropriate time, as listed in Table 3. The reaction mixture was diluted with ether (20 ml) and poured into 1 M hydrochloric acid. The organic layer was separated, combined with three additional extracts of the aqueous layer, and washed with brine (2×20 ml). The ethereal layer was dried over anhydrous sodium sulfate and concentrated. The crude product was purified by column chromatography or preparative TLC (hexane-ethyl acetate).

Claisen Rearrangement of Allyl Vinyl Ether Derivatives Promoted by Et_2AlCl-PPh_3 System (Method B). A mixture of Et_2AlCl (1.0 M of hexane solution, 4.0 ml, 4.0 mmol) and triphenylphosphine (1.2 g, 4.4 mmol) was dissolved in 1,2-dichloroethane (5 ml) at 25 °C and stirred for 10 min. A solution of allyl vinyl ether substrate (2.0 mmol) in 1,2-dichloroethane (10 ml) was added to the reagent at 25 °C and the whole was stirred at the same temperature for an appropriate time, as listed in Table 3. The resulting mixture was diluted with ether (20 ml) and poured into 1 M hydrochloric acid (20 ml). The separated organic layer was washed with brine (2×20 ml), dried over anhydrous sodium sulfate, and concentrated. The crude product was purified by column chromatography or preparative TLC (hexane-ethyl acetate).

A small aliquot was treated with diisobutylaluminium hydride to yield the alcohols. The *E*/*Z* ratios of these aldehydes were calculated from GLPC peak area of the corresponding trimethylsilyl ethers of the alcohols.

(E)-*4-Nonenal*:[16] Bp 80 °C (bath temp, 2 Torr); IR (neat): 2940, 2725, 1730, 1470, 968 cm^{-1}; NMR (CCl_4); δ=0.91 (t, J=6 Hz, 3H), 1.06—1.50 (m, 4H), 1.76—2.13 (m, 2H), 2.13—2.53 (m, 4H), 5.20—5.43 (m, 2H), 9.66 (s, 1H); MS m/z (%): 140 (M^+, trace), 122 (8), 98 (20), 96 (35), 84 (100), 83 (49), 67 (43).

(Z)-*4-Nonenal*:[16] Bp 76 °C (bath temp, 2 Torr); IR (neat): 2970, 2940, 2720, 1730, 1470, 1415, 1055 cm^{-1}; NMR (CCl_4): δ=0.93 (t, J=6 Hz, 3H), 1.10—1.50 (m, 4H), 1.80—2.16 (m, 2H), 2.16—2.52 (m, 4H), 5.15—5.45 (m, 2H), 9.69 (s, 1H); MS m/z (%): 140 (M^+, trace), 122 (5), 98 (12), 96 (19), 84 (49), 67 (33), 55 (64), 41 (100).

(E)-*3-Methyl-4-nonenal*: Bp 72 °C (bath temp, 2 Torr); IR (neat): 3010, 2960, 2750, 1740, 1466, 1385, 976 cm^{-1}; NMR (CCl_4): δ=0.75—1.05 (m, 3H), 1.03 (d, J=6 Hz, 3H), 1.05—1.40 (m, 4H), 1.83—2.00 (m, 2H), 2.17—2.33 (m, 2H), 2.40—2.87 (m, 1H), 5.20—5.40 (m, 2H), 9.60 (t, J=2 Hz, 1H); MS m/z (%): 154 (M^+, 4), 111 (22), 110 (20), 98 (74), 97 (99), 69 (89), 55 (100); Found: C, 77.97; H, 11.86%. Calcd for $C_{10}H_{18}O$: C, 77.87, H, 11.76%.

(Z)-*3-Methyl-4-nonenal*: Bp 70 °C (bath temp, 2 Torr); IR (neat): 2960, 2700, 1728, 1455, 1255, 725 cm^{-1}; NMR (CCl_4): δ=0.76—1.08 (m, 3H), 1.04 (d, J=6 Hz, 3H), 1.13—1.60 (m, 4H), 1.90—2.07 (m, 2H), 2.30 (dd, J=2, 7 Hz, 2H), 2.75—3.18 (m, 1H), 5.08—5.45 (m, 2H), 9.57 (t, J=2 Hz, 1H); MS m/z (%): 154 (M^+, 2), 139 (10), 111 (20), 110 (20), 98 (67), 97 (83), 69 (85), 55 (100); Found: C, 77.94; H, 11.98%. Calcd or $C_{10}H_{18}O$: C, 77.87; H, 11.76%.

(E)-*5-Pheyl-4-pentenal*: Bp 118 °C (bath temp, 2 Torr); IR (neat): 3050, 2920, 2840, 2740, 1725, 1602, 1498, 1452, 962, 742, 690 cm^{-1}; NMR (CCl_4): δ=2.40—2.60 (m, 4H), 6.03 (m, 1H), 6.34 (d, J=15 Hz, 1H), 7.00—7.30 (m, 5H), 9.70 (s, 1H); MS m/z (%): 160 (M^+, 38), 132 (11), 129 (11), 117 (37), 104 (100), 91 (39). The compound was identical with the authentic sample.[21]

3-Phenyl-4-pentenal: Bp 86 °C (bath temp, 3 Torr); IR (neat): 3050, 2840, 2740, 1730, 1498, 1460, 915, 758, 700 cm^{-1}; NMR (CCl_4): δ=2.69 (dd, J=2, 6 Hz, 2H), 3.85 (dq, J=6, 6 Hz, 1H), 4.93 (d, J=16 Hz, 1H), 4.98 (d, J=10 Hz, 1H), 5.90 (ddd, J=6, 10, 16 Hz, 1H), 6.97—7.30 (m, 5H), 9.57 (s, 1H); MS m/z (%): 160 (M^+, 24), 142 (32), 132 (24), 131 (27), 117 (100), 115 (36), 91 (43); Found: C, 82.62; H, 7.59%. Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.55%.

3-Cyclohexene-1-carbaldehyde:[13] Bp 97 °C (bath temp, 20 Torr); IR (neat): 2940, 2710, 1732, 1662, 1442, 1372, 1240, 1044 cm^{-1}; NMR (CCl_4): δ=1.00—2.53 (m, 6H), 5.57 (s, 1H), 9.55 (s, 1H); MS m/z (%): 110 (M^+, 72), 95 (28), 92 (37), 81 (78), 79 (100), 67 (41), 54 (51), 53 (52).

4-Acetyl-2-methyl-1-cyclohexene:[13] Bp 88 °C (bath temp, 25 Torr); IR (neat): 2940, 1718, 1445, 1358, 1168, 775 cm^{-1}; NMR (CCl_4): δ=1.10—2.60 (m, 7H), 1.63 (s, 3H), 2.06 (s, 3H), 5.28 (s, 1H); MS m/z (%): 138 (M^+, 10), 95 (100), 79 (16), 67 (28), 43 (65).

2-Cyclohexene-1-acetaldehyde:[18] Bp 75 °C (bath temp, 20 Torr); IR (neat): 3040, 2950, 2740, 1730, 1445, 720 cm^{-1}; NMR (CCl_4): δ=1.03—2.10 (m, 6H), 2.30 (dt, J=1, 6 Hz, 1H), 2.38 (d, J=1 Hz, 1H), 2.43—2.83 (m, 1H), 5.25—5.80 (m, 2H), 9.70 (d, J=1 Hz, 1H); MS m/z (%): 124 (M^+, 21), 96 (19), 95 (40), 81 (56), 80 (100), 79 (51), 67 (71).

10) We are tempted to assume the following mechanism (Scheme 3): (1) The oxygen atom of an allyl vinyl ether coordinates to an organoaluminium compound, and (2) [3,3] sigmatropic rearrangement occurs and a nucleophilic moiety R or H on the aluminium atom adds to the aldehydic carbon concomitantly.

Mass-spectral Isotope Effects in the Metastable Transition of Benzene and Perdeuterio Benzene. Model Calculation

Ryuichi ARAKAWA and Yozaburo YOSHIKAWA*
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560
(Received April 7 1983)

The abundances of $C_6H_5^+$, $C_6H_4^{+\cdot}$, $C_4X_4^{+\cdot}$, and $C_3X_3^+$ (X=H, D) fragments occurring in the metastable transition of benzene and perdeuterio benzene have been measured by means of electron-impact ionization. The isotope effects on the relative intensities were reproduced by the simple model calculation on the basis of the RRKM theory. The vibrational frequencies of the transition states for the deuteriated and the nondeuteriated were obtained by a vibrational analysis for the assumed geometries and force fields. The transition states for the $C_6H_5^+$ and $C_6H_4^{+\cdot}$ channels preferred a benzene structure while those for the $C_4H_4^{+\cdot}$ and $C_3H_3^+$ has a propargyl-cyclopropene structure. The calculated decay rates for the $C_6H_5^+$, $C_4H_4^{+\cdot}$, and $C_3H_3^+$ fragmentation were compared with those of the photoion photoelectron coincidence (PIPECO) results.

In the study of the metastable transitions of partly deuteriated ions, the isotope effect has been a tool in the structural assignment of both transition and reactant states. The application of the mass-spectral ion abundances of isotopically substituted molecules has been reviewed by Holmes.[1] The relative intensities of fragmentation from complex molecules have been readily explained by the statistical calculation without any serious discrepancy.[2,3] Systematic studies of the transition states have been done in the unimolecular reaction of the methyl radical and the hydrogen-atom loss from 1,3-butadiene and in that of its perdeuterio analog.[4] The model calculation of kinetic isotope effects showed the most plausible transition state for the methyl-elimination reaction to be a 2-methylcyclopropenium ion.

In the metastable transitions of benzene ions, the molecular ions lose $H^\cdot$, H_2, C_2H_2, and $C_3H_3^\cdot$ to yield fragments of $C_6H_5^+$, $C_6H_4^{+\cdot}$, $C_4H_4^{+\cdot}$, and $C_3H_3^+$ respectively. Mass spectral results on ^{13}C- and ^2H-labeled benzene have shown that there was a significant scrambling of carbon and hydrogen atoms prior to dissociation.[5] The first measurement concerning the dissociation rates for the benzene ion as a function of the internal energy was carried out by Andlauer and Ottinger using the charge-transfer reactions with ions of various ionization potentials.[6] Their results triggered arguments for the exsistence of two isolated $C_6H_6^{+\cdot}$ states, one producing $C_6H_5^+$ and $C_6H_4^{+\cdot}$, and the other giving $C_4H_4^{+\cdot}$ and $C_3H_3^+$.[7] Rosenstock *et al.*, by interpreting the photoionization mass spectrum,[8] suggested that the precursor ion for the $C_3H_3^+$ fragment was not the ground state of the benzene ion. Finally, Baer *et al.* measure the absolute fragmentation rates for internal-energy- selected $C_6H_6^{+\cdot}$ ions of several isomers, such as 2, 4- and 1, 5- hexadiyne, obtained by photoion photoelectron coincidence (PIPECO).[9] Their experimental and RRKM calculated rates indicate that benzene and these isomers rearrange to a common precursor and fragment to all product channels by competing pathways and that the existence of isolated states or noncommunicating isomeric structures is highly unlikely.

In the present communication, the mass-spectral isotope effects from metastable transitions were investigated in order to understand better the unimolecular process of benzene ions. The rates of unimolecular decomposition were calculated on the basis of the RRKM theory. The reaction paths were simulated by changing the structures of the transition state (TS) models, including a variety of reaction coordinates. The TS models were determined by changing the bond orders and the angles of the bonds involved in the reaction so as to reproduce the experimental isotope effects. The absolute rate constants of the $C_6H_5^+$, $C_4H_4^{+\cdot}$, and $C_3H_3^+$ fragments obtained from the PIPECO results[9] were helpful in constraining the assumed TS models.

Experimental

A home-built tandem mass spectrometer[10] was used to measure fragment ions. The temperature of the ion source was 150 °C. The electron-ionization energy was 30—50 eV, the electron current was 3 μA, and the ion-accelerating voltage was 1.2 kV. The pressure in the field-free region was always less than 1×10^{-6} Torr (1 Torr=133.32 N m^{-2}).

Fragment ions from metastable transitions occurring in the field-free region between two magnets were detected and their intensities integrated by mean of a multiscan system. For the measurement of the mass spectra, about one hundred scans over several hours were needed to accumulate 10^6 counts for molecular ions. The sample of benzene-d_6 (99% atom D; MERCK) was a commercially available one.

Results and Discussion

The peak-intensity ratios, P_X, of fragment ions for the metastable transitions of $C_6X_6^{+\cdot}$ (X=H,D) are summarized in Table 1. The error given shows the

Table 1. Relativa peak intensities of the fragment ions for the metastable transition of $C_6X_6^{+\cdot}$ (X=H,D)

X	E/eV	$C_6X_5^+$	$C_6X_4^{+\cdot}$	$C_4X_4^{+\cdot}$	$C_3X_3^+$
P_H	50	100	16±2	3.8±0.1	1.1±0.1
	40	100	18	4.2	1.2
	30	100	19	4.5	1.1
P_D	50	100	20±1	10±0.3	2.4±0.1
	40	100	20	11	2.5
	30	100	25	12	3.8

standard deviation after several runs. It is considered impossible to include the systematic error. There was no pressure effect on the measured peak ratios of the parent and metastable product ions. The main process is the hydrogen-atom elimination. The peak ratios did not change above the electron energy of 30 eV. The internal energy distribution, $P(E)$, of the molecular ions formed by electron impact is almost constant in this energy region of ionizing electrons.

The peak intensity of an i-th fragment ion in the mass spectra which does not undergo further decomposition is given by:

$$I_i = c\int_0^\infty P(E)k_i(E)T(E)/\sum k_j(E)\mathrm{d}E.$$

Here, c is a constant, E is the internal excitation energy of the molecular ion, $k_i(E)$ is the rate constant for decay into the i-th fragment, and $T(E)$ is the time factor, $T(E)=\exp(-t_1\sum k_j(E))-\exp(-t_2\sum k_j(E))$, where t_1 and t_2 are the entrance and exit times of the molecular ion in the field free region relative to the time of ion formation(t_1=3.6 and t_2=8.5 μs for $C_6H_6^{+\cdot}$).

The specific rate constant for unimolecular decomposition is given by

$$k(E)=L^*(I^*_{ABC}/I_{ABC})^{1/2}\sum P(E^*)/(hN(E_0+E^*)),$$

where h is Planck's constant, E_0 is the activation energy, $\sum P(E^*)$ is the total number of vibrational-rotational states of the activated complex at energy E^*, $N(E_0+E^*)$ is the level density of the reactant molecule at energy $E=E_0+E^*$, the I^* and I values are the products of the principal moments of inertia for the activated complex and reactant, and L^* is a statistical factor. An algorithm of Stein and Rabinovitch[11] was used for directly computing harmonic oscillator eigenstate sums and densities.

The internal energy of molecular ions consists of the internal thermal energy plus the energy transferred into the ion by the ionization process. Several methods of approximating the expression of $P(E)$ have been examined and these shortcomings analyzed.[12] In the present calculation, the energy-transfer probability was estimated by folding the photoionization cross-section[13] into the HeI photoelectron spectrum[14] under the optical approximation proposed by Miesels *et al.*[12]

The activation energies for the unimolecular decomposition of the benzene ion resulting in the loss of H$^\cdot$, C_2H_2, and $C_3H_3^\cdot$ are 3.60, 4.22, and 4.37 eV respectively, while the ionization energy of benzene is 9.24 eV.[9] That of the H_2 loss was estimated to be 3.86 eV.[15] The activation energies of the deuteriated species are estimated from applying the zero-point energy correction to the values for the nondeuteriated molecules. These corrections were all less than 0.05 eV.

The vibrational frequencies of the deuteriated and the non-deuteriated molecules for the reactant and the TS are obtained by a vibrational analysis for the assumed geometries and force fields.[16] The reactant and the TS models for the competing reactions are represented by the same internal coordinates. The relative rate constants yielding the relative intensities are thought to be independent of the influence of the approximate frequencies resulting from the approximate simple valence force field(diagonal force constant matrix), but one thought to be related to the TS structures. For the TS model, the reacting bond length r modified from the empirical length r_0 is described along the reaction coordinate and adjusted on the basis of Pauling's expression; $r=r_0-0.3\ln(n)$ where n is the bond order. The geometry of each model was most conveniently specified in terms of the bond orders and bond angles. The bond lengths of benzene are summarized in Table 2. The stretching force constants F_r° of the initial state for the reacting bond are modified for the TS model according to $F_r=nF_r^\circ$. The angle bending force constants are also given by $F_a=g(\theta)n_in_jF_a^\circ$, where n_i and n_j are the bond orders in the bending mode and F_a° is the initial bending force constant. The value of $g(\theta)$ refers to the hybridization factor, $g(\theta)=1.39+1.17\cos(\theta)$, where θ is the bond angle. Torsional and out-of-plane bending force constants are retained at the values of the reactant force constants for all the modes. The force constants employed in the frequency calculation are shown in Table 2. In the reaction coordinate, the decomposition frequency is imaginary when the curvature is negative at the barrier. For the reaction proceeding through a simple bond cleavage in the TS model, the force constant for the stretching mode of the reacting bond will be negative.

The reactant configuration of the $C_6X_6^{+\cdot}$ ion formed from benzene by ionization is taken to be identical with that of the neutral molecule. The TS models

Table 2. Bond lengths and force constants to be employed in the frequency calculation

Type of bond	r_0/Å	F_r/mdyn Å^{-1} [a]

a) Stretching force constants are given for bonds with an order of unity. b) Bending force constants correspond to angles of 109.47°, subtended by bonds with an order of unity.

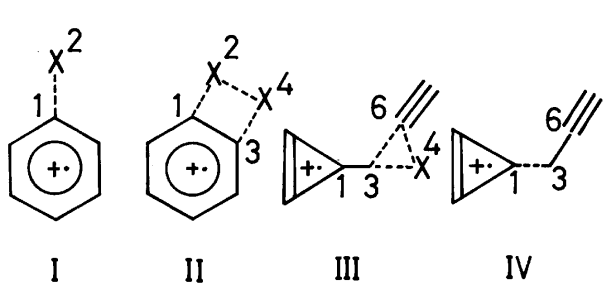

Fig. 1. Assumed geometries of the $C_6X_6^{+\cdot}$ ion for TS models of X$^\cdot$(I), X_2(II), C_2X_2(III), and $C_3X_3^\cdot$(IV) loss(X=H, D).

Table 3. Calculated isotope effect on peak intensities assuming various TS models

Models	Parameters	Fragment	Peak intensities	
			P_H	P_D
I	$n_{12}=0.1$[a] $F_S=-2.0$[b]	$C_6X_5^+$	100(100)[d]	100(100)
II	$n_{12}=0.1$ $n_{34}=0.5$ $F_S=-2.0$	$C_6X_4^{+\cdot}$	15(16)	20(20)
III	$n_{36}=0.2$ $n_{46}=1.0$ $F_S=-2.0$ $N_{rot}=3$[c]	$C_4X_4^{+\cdot}$	4.1(3.8)	7.1(10)
IV	$n_{13}=0.2$ $F_S=-2.0$ $N_{rot}=3$	$C_3X_3^+$	1.2(1.1)	2.6(2.4)

a) n_{ij} is the bond order of the i and j-th atoms: in Fig. 1. b) F_S means the force constant for the corresponding stretching mode of the reacting bond. c) Number of internal free rotations. d) Values in parentheses are experimental.

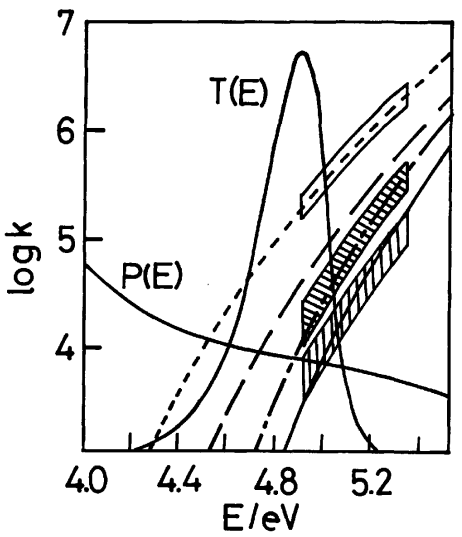

Fig. 2. Relationship among $P(E)$, $T(E)$ and decay rates for unimolecular decomposition of the $C_6H_6^{+\cdot}$ ion. Values of $P(E)$ and $T(E)$ are plotted on a linear scale versus the internal energy E. The decay curves show rate constants of $H^{\cdot}$(----), H_2(——), C_2H_2 (—·—), and $C_3H_3^{\cdot}$(——) loss. Wide lines are absolute rates obtained from PIPECO results of Baer *et al.* without the rate of H_2 loss.[9]

proceeding to the $C_6X_5^+$, $C_6X_4^{+\cdot}$, $C_4X_4^{+\cdot}$, and $C_3X_3^+$ products were assumed to be structures I—IV, they are shown in Fig. 1. The models of TS(I) and TS(II) are of a benzene molecule, and the others of a propargyl-1-cycloprop-2-ene structure similar to that chosen by Baer *et al.* The dissociations giving $C_6X_5^+$ and $C_3X_3^+$ are described as a simple-bond cleavage reactions of C_1–X_2 and C_1–C_3 as is shown in the TS(I) and TS(IV) models. In TS(II) and TS(III) models, a hydrogen-atom transition should occur. The relative motions of the migrating hydrogen atom and the loosing bond are defined by using an appropriate combination of interaction force constants(off-diagonal elements in F-matrix) for the coupling of the stretching modes of the reacting bonds. It requires a constant total bonding for the migrating atom, satisfying $n_{34}+n_{24}=1$ and $n_{34}+n_{46}=1$ for TS(II) and TS(III), respectively. For the sake of simplicity, however, the simple bond cleavage for the stretching modes of C_1–X_2, TS(II) and C_3–C_6, TS(III) are employed as the reaction coordinates. The interaction force constants were not considered. Structural parameters used here are shown in Table 3. The stretching force constants for the reacting bond are fixed at $F_S=-2.0$; the torsional modes of vibration are reduced to free internal rotations.

The calculated isotope effects on the peak intensities are shown in Table 3. The results agree well with the experimental isotope effects. The rate curves and P_X varied with the bond-order parameters, but the P_H/P_D ratio did not change greatly within the limit of the given TS model. The application of a linear structure such as a 1,5-hexadiyne ion to the $C_4H_4^{+\cdot}$ and $C_3H_3^+$ TS models gave insufficient results on isotope effects. The rate constants decaying to $C_6H_5^+$, $C_4H_4^{+\cdot}$, and $C_3H_3^+$ are compared with the results of Baer *et al.* in Fig. 2. Their rates were determined from the total decay rates and the branching ratios if the dissociation channels were in competition. The rate for the H_2 loss channel has not been presented. The vibrational frequencies for the TS(III) and TS(IV) models, obtained from the vibrational analysis, are not very different from those of Baer *et al.* used in the RRKM calculations for the $C_4H_4^{+\cdot}$ and $C_3H_3^+$ channels. The values of the peak intensities are derived from rate curves lying in a metastable window $T(E)$, 4.4—5.2 eV. There is always uncertainty on the $P(E)$ function followed by electron-impact ionization. The relative values of the $P(E)$ function, defined within narrow limits, are necessary to calculate the isotope effects. Therefore, it is improbable that the $P(E)$ curve estimated above causes a large error in the isotope effects. An increase of a few percent in the relative intensities, P_H and P_D can be calculated if the $P(E)$ function is constant. The intensity of $C_6X_5^+$ fragment is relatively reduced because of the smaller values of the $P(E)$ function in the lower-energy region of the window $T(E)$. Such a variation in $P(E)$ does not influence the isotope effects to any large extent. The decay rate for the $D^{\cdot}$ loss is slower by one order of magnitude than that for the $H^{\cdot}$ loss. The metastable window for the C_6D_6 dissociation shifts to a higher energy, 4.7—5.8 eV.

The mass spectral isotope effects support the conclusion that the dissociation of the benzene ion proceeds competitively to all products. The reactant model equivalent to the common precusor from the C_6H_6 isomers is of a benzene molecule, and the TS models are the product-like structures. The measured peak intensities can not directly reflect the absolute rate, but rather the relative TS density yielding the relative rate constant. This analysis requires the absolute decay rates in order to fix the TS model.

The authors wish to thank Mr. Masana Arimura for his helpful discussions.

Palladium(II) Complexes Containing Both the Chelating β-Diketonato and σ-Pyridyl Ligands. Catalyzed Coordination-site Exchange Reactions

Hiroshi TANAKA, Kiyoshi ISOBE, Shinichi KAWAGUCHI,* and Seichi OKEYA†
Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558
†*Faculty of Education, Wakayama University, Fukiage, Wakayama 640*
(Received September 8, 1983)

A novel type of palladium(II) complexes, [Pd(β-dik)(pyridyl)(PPh_3)] and [Pd(β-dik)(pyridyl)]$_2$ containing a chelating acetylacetonate, trifluoroacetylacetonate, or hexafluoroacetylacetonate anion and 2-, 3-, or 4-pyridyl radical as the coexisting ligands were prepared and characterized by elemental analysis and molecular weight determination as well as ^1H and ^{13}C NMR spectroscopy. [Pd(acac)(C_5H_3(6-Cl)N-C^2)(PPh_3)] is stereochemically rigid in solution but undergoes the coordination-site exchange reaction catalyzed by nitrogen and phosphorus bases and donor solvents. Similar reaction of [Pd(acac)(C_5H_4N-C^2)(PPh_3)] is catalyzed by triphenylphosphine liberated by the dinuclear-complex formation reaction (autocatalysis). Intact molecules of [Pd(acac)(C_5H_4N-C^3 and -C^4) (PPh_3)] catalyze mutually their own coordination-site exchange (self-catalysis).

A stable dinuclear complex [PdBr(C_5H_4N-C^2)(PPh_3)]$_2$ (**3a**) was prepared by the reaction of [Pd(PPh_3)$_4$] (**1**) with 2-bromopyridine in toluene at 90°C[1,2] and was disclosed by X-ray analysis to have a novel structure in which two pyridyl ligands are bridging palladium atoms through the C^2 and N atoms.[2,3] A similar reaction of **1** with 2,6-dichloropyridine gave a mononuclear complex *trans*-[PdCl(C_5H_3(6-Cl)N-C^2)(PPh_3)$_2$] (**2d**), which coexists in equilibrium with a minute amount of the dinuclear complex [PdCl(C_5H_3(6-Cl)N-C^2)(PPh_3)]$_2$ in solution and is completely converted into the latter by oxidation of freed triphenylphosphine with hydrogen peroxide.[1,2] On the other hand, the reactions of **1** with 3- and 4-bromopyridines in toluene at 90°C afforded *trans*-[PdBr(C_5H_4N-C^3)(PPh_3)$_2$] (**2b**) and *trans*-[PdBr(C_5H_4N-C^4)(PPh_3)$_2$] (**2c**), respectively, and the corresponding dinuclear complexes have never been obtained.[4] Treatment of complexes **3a**, **2b**, and **2c** with triethylphosphine in diethyl ether at room temperature gave rise to a set of linkage isomers *trans*-[PdBr(C_5H_4N-C^2, -C^3, and -C^4)(PEt_3)$_2$], of which properties and molecular structures were compared with each other.[4]

In the present investigation, a new type of palladium(II) complexes [Pd(β-dik)(pyridyl)(PPh_3)] containing an *O,O'*-chelated β-diketonate anion and a carbon-bonded pyridyl ligand have been derived from complexes **3a**, **2b**, **2c**, and **2d**. This paper reports the properties of these mixed-ligand complexes, laying emphasis on their dynamic behaviors in solution catalyzed by Lewis bases including donor solvents.[5]

Experimental

Preparation of Complexes. [PdBr(C_5H_4N-C^2)(PPh_3)]$_2$ (**3a**), *trans*-[PdBr(C_5H_4N-C^3)(PPh_3)$_2$] (**2b**), *trans*-[PdBr(C_5H_4N-C^4)(PPh_3)$_2$] (**2c**), and *trans*-[PdCl(C_5H_3(6-Cl)N-C^2)(PPh_3)$_2$] (**2d**) were prepared by the methods reported previously.[2,4]

*[PdBr(C_5H_4N-C^3)(PPh_3)]$_n$ (**3b**)*: To a suspension of complex **2b** (6.35 g, 8.05 mmol) in acetone (50 cm^3) was added 12 cm^3 of 30% hydrogen peroxide solution (106 mmol) and the mixture was stirred at room temperature for 24 h. A white precipitate was filtered, washed with acetone and dietyl ether successively, and dried *in vacuo*. The yield was 4.15 g (97.9%).

*[PdBr(C_5H_4N-C^4)(PPh_3)]$_n$ (**3c**)*: White complex **3c** was obtained almost quantitatively (4.50 g, 98.8%) in a similar fashion by the reaction between **2c** (6.82 g, 8.64 mmol) and aqueous hydrogen peroxide (13 cm^3, 115 mmol).

*[PdCl(C_5H_3(6-Cl)N-C^2)(PPh_3)]$_2$ (**3d**)*: Yellow product **3d** from the reaction between **2d** (6.09 g, 7.82 mmol) and aqueous hydrogen peroxide (9 cm^3, 79.4 mmol) was purified by dissolution in dichloromethane and reprecipitation on addition of diethyl ether. The yield was 3.98 g (98.5%).

*[PdClO$_4$(C_5H_4N-C^2)(PPh_3)]$_2$ (**4a**)*: A solution of silver perchlorate (2.00 g, 9.65 mmol) in methanol (10 cm^3) was added to a dichloromethane (100 cm^3) solution of **3a** (3.00 g, 2.85 mmol) and the mixture was stirred at room temperature for 2 h. A precipitate of silver bromide was filtered off and the filtrate was treated three times with deionized water (50 cm^3 each) to extract residual silver perchlorate. The dichloromethane solution was passed through a column of anhydrous sodium sulfate and then concentrated to about 10 cm^3 under reduced pressure. On addition of diethyl ether to the concentrate, a yellow precipitate appeared, which was filtered, washed with the ether, dried *in vacuo*, and purified by reprecipitation from dichloromethane–diethyl ether. The yield was 2.56 g (82.0%).

*{[Pd(C_5H_4N-C^3)(PPh_3)(H_2O)]ClO$_4$}$_n$ (**4b**)*: *Method A*; A solution of silver perchlorate (1.02 g, 4.93 mmol) in methanol (10 cm^3) was added to a suspension of **3b** (2.03 g, 3.76 mmol when n=1) in dichloromethane (10 cm^3) and the mixture was stirred at room temperature for 50 min. After filtration of silver chloride, the filtrate was concentrated to about 2 cm^3. On scratching the wall of vessel with a glass rod after addition of methanol (20 cm^3) to the concentrate, a white precipitate appeared, which was filtered, washed with diethyl ether, and dried *in vacuo*. The yield was 1.84 g (86.7%).

Method B; After the reaction of **2b** (0.653 g, 0.838 mmol) with silver perchlorate (0.209 g, 1.01 mmol) in a mixture of dichloromethane (5 cm^3) and methanol (2 cm^3) at room temperature for 1 h, work up similar to method A gave a white precipitate. The yield was 0.215 g (45.5%) after reprecipitation from dichloromethane–ethanol.

*{[Pd(C_5H_4N-C^4)(PPh_3)(H_2O)]ClO$_4$}$_n$ (**4c**)*: Two preparative methods starting from **3c** and **2c** gave a light yellow powder of **4c** in 100 and 90.8% yields, respectively. The dichloromethane–benzene system was used for reprecipitation.

*[PdClO$_4$(C_5H_3(6-Cl)N-C^2)(PPh_3)]$_2$ (**4d**)*: Yellow complex **4d** was derived analogously from **3d** and **2d** in 89.0 and 81.6%

yields, respectively. Reprecipitation was performed from dichloromethane–diethyl ether.

Thus two methods were used for preparation of type-**4** complexes and method A was found better since products from method B were contaminated with a small amount of free triphenylphosphine. Analogously, the following type-**5** complexes were prepared by each of three methods: (method A) reactions of type-**2** complexes with thallium(I) β-diketonates, (method B) reactions of type-**3** complexes with thallium(I) β-diketonates, and (method C) reactions of type-**4** complexes with potassium β-diketonates. For brevity only the preferable methods are described here for each complex.

*[Pd(acac)(C$_5$H$_4$N-C^2)(PPh$_3$)] (**5a1**)*: *Method B*; Thallium(I) acetylacetonate, Tl(acac) (0.625 g, 2.06 mmol) was added to a solution of **3a** (0.986 g, 0.936 mmol) in dichloromethane (20 cm^3) and the mixture was stirred at room temperature for 30 min. After separation of thallium(I) bromide, the filtrate was concentrated to about 3 cm^3 under reduced pressure. A small amount of diethyl ether was added to the concentrate and crystallization was induced by scratching the flask. The product was filtered, washed with the ether, and recrystallized from dichloromethane–diethyl ether. The yield was 0.925 g (90.5%).

Method C; To a solution of **4a** (0.943 g, 0.863 mmol) in dichloromethane (30 cm^3) was added a methanol (10 cm^3) solution of potassium acetylacetonate (0.729 g, 5.28 mmol) and the mixture was stirred at room temperature for 20 min. After separation of potassium perchlorate by filtration, the solvent was evaporated to dryness under reduced pressure. Dichloromethane (30 cm^3) was added to the residue and insoluble material was filtered off. The filtrate was concentrated to about 2 cm^3 under reduced pressure. Crystallization was induced by scratching the flask after addition of diethyl ether (10 cm^3) to the concentrate. The product was filtered, washed with diethyl ether, and recrystallized from dichloromethane–diethyl ether. The yield was 0.802 g (85.2%).

*[Pd(tfac)(C$_5$H$_4$N-C^2)(PPh$_3$)] (**5a2**)*: The reaction of **3a** with thallium(I) trifluoroacetylacetonate, Tl(tfac) (method B) and that of **4a** with K(tfac) (method C) gave complex **5a2** in 68.7 and 46.9% yields, respectively. Petroleum ether (bp<60 °C) was used instead of diethyl ether for recrystallization.

*[Pd(hfac)(C$_5$H$_4$N-C^2)(PPh$_3$)] (**5a3**)*: Method B using **3a** and thallium(I) hexafluoroacetylacetonate, Tl(hfac), and method C using **4a** and K(hfac) afforded **5a3** in 51.9 and 44.3% yields, respectively.

*[Pd(acac)(C$_5$H$_4$N-C^3)(PPh$_3$)] (**5b1**), [Pd(tfac)(C$_5$H$_4$N-C^3)(PPh$_3$)] (**5b2**), and [Pd(hfac)(C$_5$H$_4$N-C^3)(PPh$_3$)] (**5b5**)*: These 3-pyridyl complexes were prepared by methods C,B, and B in 82.8, 78.6, and 53.2% yields, respectively.

*[Pd(acac)(C$_5$H$_4$N-C^4)(PPh$_3$)] (**5c1**), [Pd(tfac)(C$_5$H$_4$N-C^4)(PPh$_3$)] (**5c2**), and [Pd(hfac)(C$_5$H$_4$N-C^4)(PPh$_3$)] (**5c3**)*: The 4-pyridyl complexes were obtained in 63.9, 63.0, and 63.3% yields by methods C, B, and B, respectively.

*[Pd(acac)(C$_5$H$_3$(6-Cl)N-C^2)(PPh$_3$)] (**5d1**), [Pd(tfac)(C$_5$H$_3$(6-Cl)N-C^2)(PPh$_3$)] (**5d2**), [Pd(hfac)(C$_5$H$_3$(6-Cl)N-C^2)(PPh$_3$)] (**5d3**)*: Methods C, C, and B were used to prepare these complexes in 84.0, 78.4, and 65.8% yields, respectively.

*[Pd(acac)(C$_5$H$_4$ N-C^2)]$_2$ (**6a1**), [Pd(tfac)(C$_5$H$_4$N-C^2)]$_2$ (**6a2**)*, and *[Pd(acac)(C$_5$H$_3$(6-Cl)N-C^2)]$_2$ (**6d1**)*: To a suspension of complex **5a1** (0.356 g, 0.652 mmol) in acetone (10 cm^3) was added 2 cm^3 of aqueous hydrogen peroxide solution (10%, 5.8 mmol) and the mixture was stirred at room temperature for 2 h. A yellow precipitate of **6a1** was filtered, washed with diethyl ether and dried *in vacuo*. The yield was 0.147 g (76.2%). Complexes **6a2** and **6d1** were similarly prepared from **5a2** and **5d1** in 43.6% (0.103 g) and 28.1% (0.120 g) yields, respectively.

*[Pd(acac)(C$_5$H$_3$(6-Cl)N-C^2)(PEt$_3$)] (**7d1**)*: Triethylphosphine (0.115 cm^3, 0.788 mmol) was added to a suspension of **6d1** (0.249 g, 0.392 mmol) in dichloromethane (5 cm^3) and the mixture was stirred at room temperature for 1 h. After evaporation of the solvent, the oily residue was treated with diethyl ether and the extract was concentrated to dryness. The yield was 0.198 g (57.9%).

Measurements. Infrared spectra were recorded in Nujol mull on a JASCO DS 701G spectrophotometer. The NMR spectra were taken with JEOL JNM-MH100 (for ^{1}H) and FX 60Q (for ^{13}C) spectrometers. The molecular weight was determined by vapor pressure osmometry with an instrument manufactured by Knauer in West Berlin, West Germany.

The ^{1}H NMR line shape simulation was carried out with a FACOM 230-60 computer according to the Nakagawa's equation.[6]

Results and Discussion

Synthesis. The 2-, 3-, and 4-pyridyl complexes [PdBr(C$_5$H$_4$N-*C*^{2})(PPh$_3$)]$_2$ (**3a**), [PdBr(C$_5$H$_4$N-*C*^{3})(PPh$_3$)$_2$] (**2b**), [PdBr(C$_5$H$_4$(N-*C*^{4})(PPh$_3$)$_2$] (**2c**), and [PdBr(C$_5$H$_3$(6-Cl)N-*C*^{2})(PPh$_3$)$_2$] (**2d**) were used as the starting materials for the present synthetic work, and the reaction sequences from **2b** and **2c** and also from **2d** are illustrated in Figs. 1 and 2, respectively. Hydrogen peroxide treatment of the mononuclear complexes **2b**, **2c**, and **2d** eliminated one of the two PPh$_3$ ligands in each complex to result in [PdBr(C$_5$H$_4$N-*C*^{3})(PPh$_3$)]$_n$ (**3b**), [PdBr(C$_5$H$_4$N-*C*^{4})(PPh$_3$)]$_n$ (**3c**), and [PdCl(C$_5$H$_3$(6-Cl)N-*C*^{2})(PPh$_3$)]$_2$ (**3d**), respectively. The analytical and molecular weight data of **3d** indicate that the yellow complex is dinuclear. It may have the pyridyl-bridged dinuclear structure similar to that of **3a**.[2,3] Complexes **3b** and **3c** are white and insoluble in usual organic solvents, suggesting that they may have polynuclear structures.

The halide ligands in dinuclear complexes **3a** and **3d** were substituted by the perchlorate ion to result in **4a**

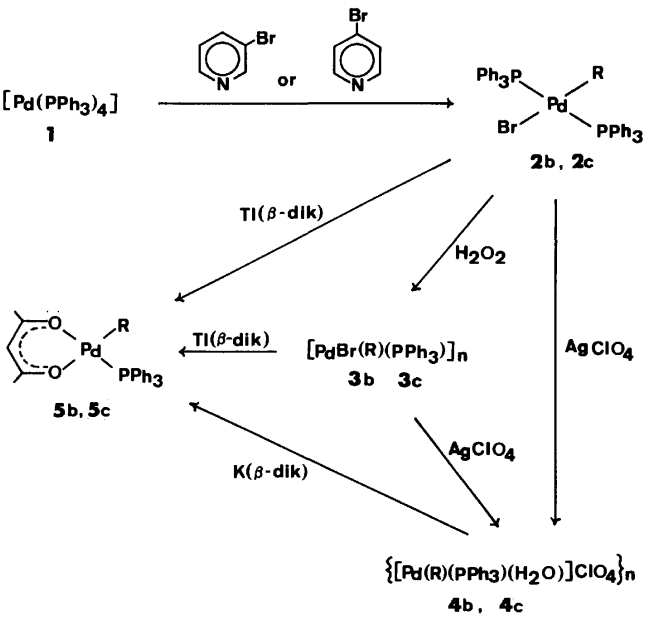

Fig. 1. Reaction sequence for the 3- and 4-pyridyl complexes. R=C$_5$H$_4$N-*C*^{3} and C$_5$H$_4$N-*C*^{4} for complexes b and c, respectively.

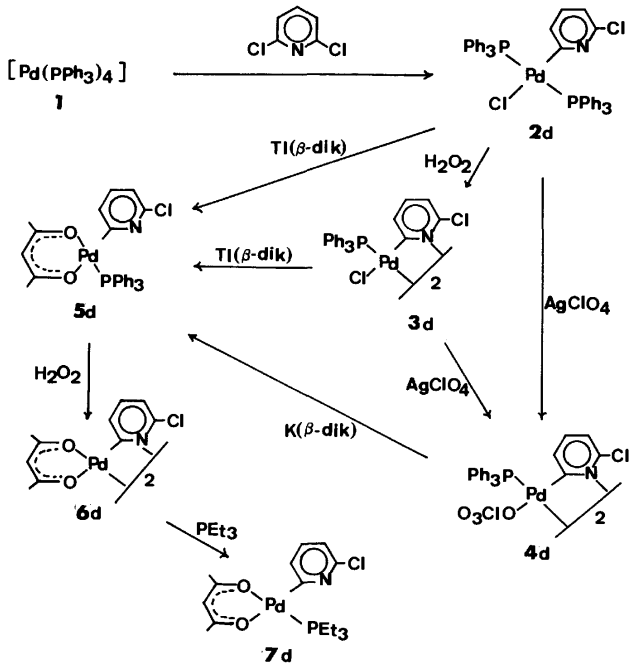

Fig. 2. Reaction sequence for the 6-chloro-2-pyridyl complexes.

and **4d**, respectively, which are yellow and retain the dinuclear structures as evidenced by the analytical and molecular weight data. Although silver perchlorate was again effective in displacing the bromide ligand from **3b** and **3c**, the perchlorate anion was not bound to the metal in these cases, but remained in the outer sphere and instead a water molecule contained in the organic solvents was accepted as a ligand. Silver perchlorate also reacted with mononuclear complexes **2b**, **2c**, and **2d** to remove not only the halide ion but also one phosphine molecule in either case and give rise to **4b**, **4c**, and **4d**, respectively. The molecular weights of **4b** and **4c** determined in dichloromethane at 27°C are 2090 and 1500, respectively, and are much larger than the formula weight (548.2) calculated for the tight ion pair $[Pd(C_5H_4N)(PPh_3)(H_2O)]ClO_4$, indicating that **4b** and **4c** are polynuclear.

The tendency of the σ-carbon-bonded pyridyl ligands to bridge two metal atoms stems from the enhanced basicity of pyridine bound to palladium at either the C^2, C^3, or C^4 position.[4] It seems reasonable on the steric consideration that the 3- and 4-pyridyl ligands favor the polynuclear structure, while the 2-pyridyl ligand stabilizes the dinuclear form. However, it can not be readily rationalized why the perchlorate ion serves as a ligand in the dinuclear 2-pyridyl complexs but not in the polynuclear 3- and 4-pyridyl complexes. It is worth noting that **4a** and **4d** reacted with pyridine to give mononuclear complexes as exemplified by Eq. 1.

$$\underset{\textbf{4a}}{[PdClO_4(C_5H_4N\text{-}C^2)(PPh_3)]_2} + 2py \longrightarrow 2[PdClO_4(C_5H_4N\text{-}C^2)(PPh_3)(py)] \quad (1)$$

Pyridine did not replace the perchlorate ligand, but cleaved the 2-pyridyl bridge. On the other hand, pyridine and even much more basic 4-dimethylaminopyridine in large excess did not split the polynuclear chain in **4b** and **4c**, but merely replaced the aqua ligand (Eq. 2).

$$\underset{\textbf{4b}\quad\textbf{4c}}{\{[Pd(C_5H_4N\text{-}C^3 \text{ or } \text{-}C^4)(PPh_3)(H_2O)]ClO_4\}_n} + n\text{L(py or 4-Me}_2\text{N-py)} \longrightarrow \{[Pd(C_5H_4N\text{-}C^3 \text{ or } \text{-}C^4)(PPh_3)L]ClO_4\}_n + nH_2O \quad (2)$$

However, bidentate β-diketonate anions readily cleaved not only the dinuclear bridge in **4a** and **4d**, but also the polynuclear bridge in **4b** and **4c** to afford the mononuclear type-**5** complexes [Pd(β-dik)(pyridyl)-(PPh_3)], of which the analytical and molecular weight data are listed in Table 1 together with those for complexes **3** and **4**. The type-**5** complexes were also derived by the reactions with thallium(I) β-diketonates from the halogeno complexes **2b**, **2c**, **2d**, **3a**, **3b**, **3c**, and **3d** irrespective of their nuclearity (Figs.1 and 2).

Of the type-**5** complexes, **5a1**, **5a2**, and **5d1** gave the dinuclear complexes **6a1**, **6a2**, and **6d1**, respectively, on

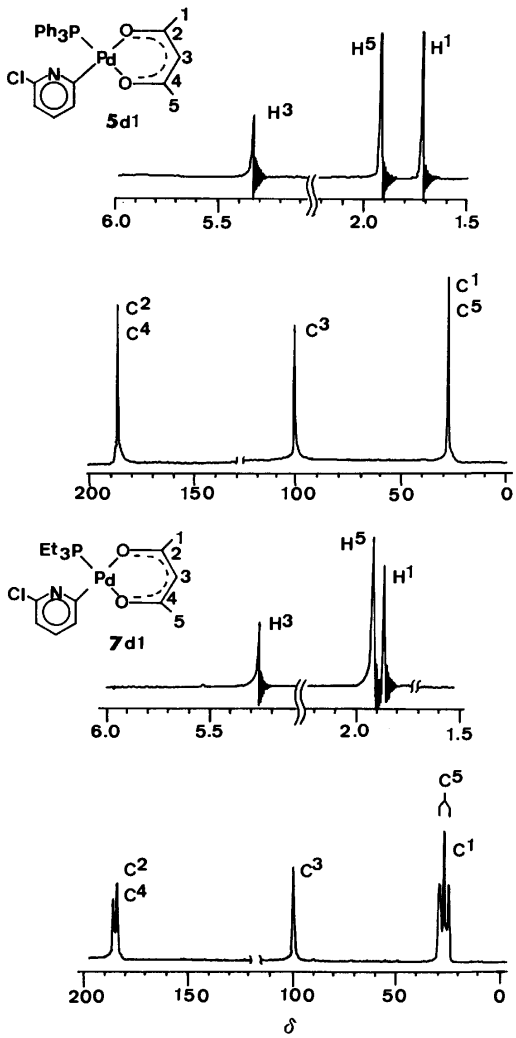

Fig. 3. ^1H and $^{13}C\{^1H\}$ NMR signals from the acetylacetonate ligand in $[Pd(acac)(C_5H_3(6\text{-Cl})N\text{-}C^2)(PPh_3)]$ (**5d1**) and $[Pd(acac)(C_5H_3(6\text{-Cl})N\text{-}C^2)(PEt_3)]$ (**7d1**) in $CDCl_3$ at room temperature. Chemical shifts are shown in ppm from internal Me_4Si.

being treated with hydrogen peroxide. Isolation of similar products from the other 2-pyridyl complexes **5a3**, **5d2**, and **5d3** was unsuccessful. The reactions of type-**5** complexes containing the 3- and 4-pyridyl ligands with hydrogen peroxide resulted in decomposition of complexes. Complexes **6** may return to **5** by virtue of the bridge-splitting reactions with triphenylphosphine, and will also react with other Lewis bases to afford similar mononuclear complexes. Table 1 includes the analytical data for one of these complexes $[Pd(acac)(C_5H_3(6\text{-Cl})N\text{-}C^2)(PEt_3)]$ (**7d1**) following those for type-**6** complexes.

NMR Spectra. The ^1H NMR signals from the β-diketonate ligands in the $[Pd(\beta\text{-dik})(pyridyl)(PPh_3)]$ (**5**) and $[Pd(\beta\text{-dik})(pyridyl)]_2$ (**6**) complexes as well as $[Pd(acac)(C_5H_3(6\text{-Cl})N\text{-}C^2)(PEt_3)]$ (**7d1**) are collected in Table 2, and the ^{13}C NMR data for complexes **5d1**, **5d2**, **5d3**, and **7d1** are listed in Table 3. Figure 3 also compares the ^1H and $^{13}C\{^1H\}$ NMR signals from the acac ligand in **5d1** and **7d1**. Complex **5d1** exhibits two methyl proton signals at δ 1.72 and 1.92 reflecting unequal environments of the two methyl groups. The higher-field signal is assigned to the methyl group which is positioned cis to triphenylphosphine and experiences the anisotropic shielding effect of the phenyl ring.[7] In the case of complex **7d1** two methyl signals lie close to each other, of which the lower-field one (δ 1.91) coincides with that from **5d1** and is assigned to the methyl group trans to the phosphine. Methyl protons situated cis to PEt_3 resonate in much lower field than those cis to PPh_3 in **5d1**.

Complex **5d1** shows only three ^{13}C signals at δ 27.7, 99.6, and 186.7 which are assigned to the CH_3, CH, and CO carbons of the acac ligand, respectively, indicating similarity in the magnetic influences of the 6-chloro-2-pyridyl and PPh_3 ligands on both halves of acac. On the other hand, the pyridyl and PEt_3 ligands in **7d1** exert slightly different influences on the carbonyl carbons, exhibiting two signals at δ 186.7 and 186.9 which can not be separately assigned. Both of the methyl carbons in **7d1** resonate at δ 28.0, one as a singlet and the other as a doublet (J(P-C)=6 Hz). The latter is attributed to C^5 positioned trans to PEt_3.

As is seen in Fig. 4, methyl protons of the tfac ligand

a) β-dik=acac, tfac, and hfac for complexes **1**, **2**, and **3**, respectively. Chemical shifts are given in ppm from internal Me_4Si. Figures in parentheses and brackets give J(C-P) and J(C-F) in Hz.

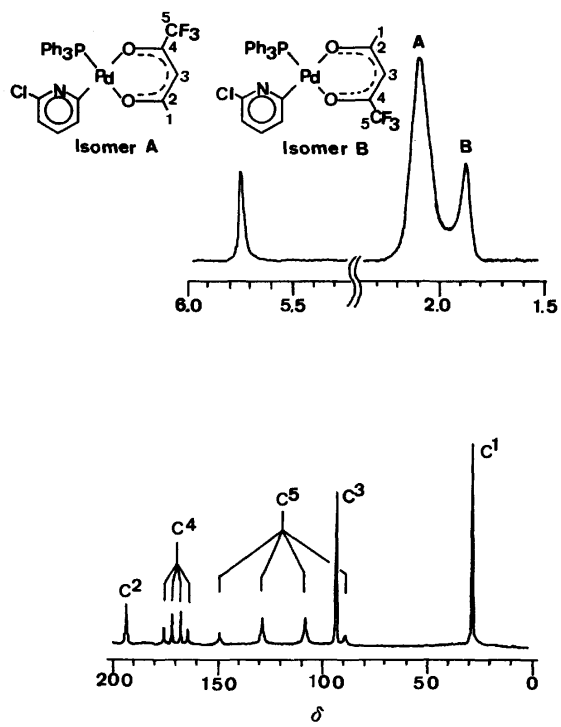

Fig. 4. ^1H and $^{13}C\{^1H\}$ NMR signals from the trifluoroacetylacetonate ligand in [Pd(tfac)(C_5H_3(6-Cl)N-C^2)(PPh_3)] (**5d2**) in $CDCl_3$ at room temperature. Chemical shifts are shown in ppm from internal Me_4Si.

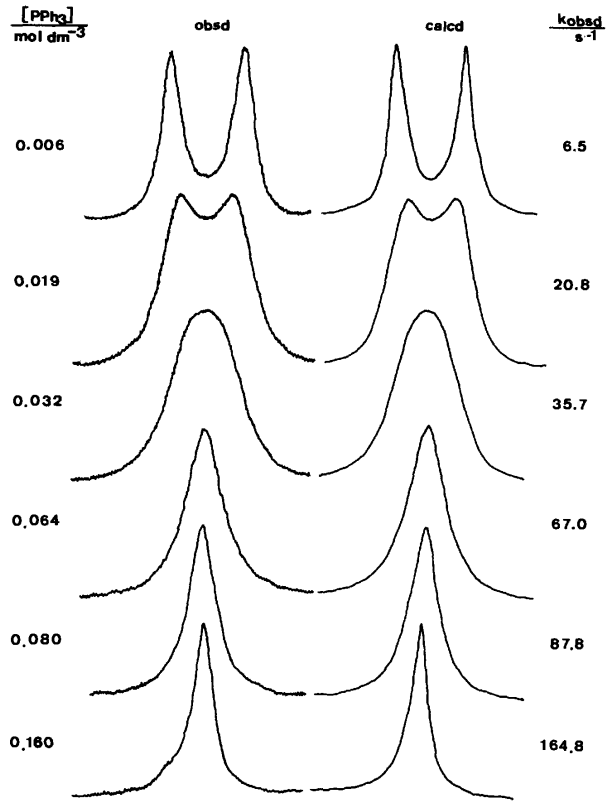

Fig. 5. Methyl proton signals from [Pd(acac)(C_5H_3(6-Cl)N-C^2)(PPh_3)] (**5dl**) in the presence of various concentrations of triphenylphosphine in dichloromethane at −80 °C. [Complex]=0.1 mol dm^{-3}.

in **5d2** exhibit two very broad signals at δ 1.87 and 2.07 with the area ratio of 1:3. There seems to exist two geometrical isomers in solution (Eq. 3) and the minor higher-field signal is assigned to the isomer **B**, in which the methyl group lies at the position cis to PPh_3, and the major one to the other isomer **A**. Similarly to the case of complex **5dl** (Fig. 3), the ^{13}C NMR spectrum of **5d2** involves only one set of signals attributable to the tfac carbons, indicating again that the 6-chloro-2-pyridyl and PPh_3 ligands exert similar trans influences. The hfac ligand in complex **5d3** also shows one set of ^{13}C signals (Table 3).

Coordination-site Exchange Reaction of [Pd(acac)(C_5H_3(6-Cl)N-C^2)(PPh_3)] (5dl) Catalyzed by Lewis Bases. As mentioned already, the acac ligand in complex **5dl** exhibits two sharp methyl signals at δ 1.70 and 1.92 in $CDCl_3$ at room temperature. When an increasing amount of Lewis base such as triphenylphosphine, tri-*o*-tolylphosphine, pyridine, and 2,6-lutidine is added to the solution, these signals become progressively broader to merge into a sharp singlet at δ 1.82. On decreasing temperature of the

solution in dichloromethane, the signal again becomes broader and broader to split into two signals. During these events ^1H signals other than those from the acac-methyls remain unaltered except appearance of peaks due to the added base. These results indicate that **5dl** is stereochemically rigid in noncoordinating solvents but undergoes the coordination-site exchange as shown by Eq. 3 (X=Cl) catalyzed by Lewis bases (L)

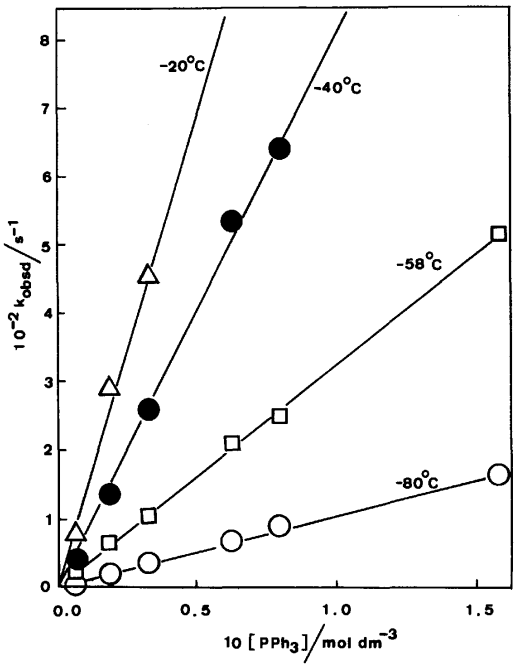

Fig. 6. Pseudo first order rate constant for the coordination-site exchange reaction of complex **5dl** in $CDCl_3$ as a function of triphenylphosphine concentration.

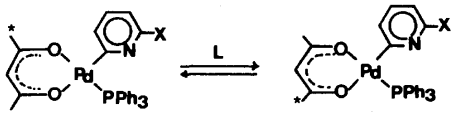
and that the fluxional motion is depressed at lower temperatures.



(3)

Pyridine or triphenylphosphine was added in various amounts to a solution (0.1 mol dm^{-3}) of **5dl** in dichloromethane and the rate of coordination-site exchange was determined at 0°C and lower temperatures by means of the line-shape simulation method. Figure 5 exemplifies the change of methyl signals with the concentration of added triphenylphosphine at −80°C. The values of cal-

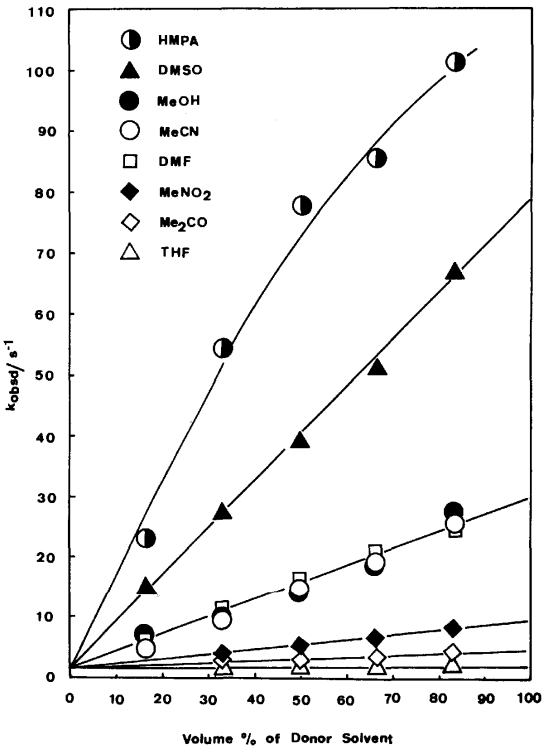

Fig. 8 Pseudo first order rate constant for the coordination-site exchange reaction of complex **5dl** in a mixture of $CDCl_3$ and a donor solvent at 50°C.

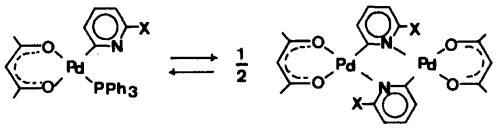
culated pseudo first order rate constant k_{obsd} are also included. As is seen in Fig. 6, the plots of k_{obsd} obtained at several temperatures against the concentration of triphenylphosphine afford straight lines passing through the origin. Similar plots in Fig. 7 show the results obtained with pyridine as a catalyst. Slopes of these straight lines gave the second order rate constants which are listed in Table 4. The activation parameters calculated from the Eyring plots are also included in the table. The catalyzed coordination-site exchange reaction has a rather small $\Delta H^{\neq}$ and a large negative $\Delta S^{\neq}$ in either case, suggesting the associative nature of reaction mechanism as is the case for the ligand substitution reactions of square planer complexes.[8] Triphenylphosphine is much more effective as a catalyst than pyridine, the second order rate constants differing by two orders of magnitude.

Various coordinating solvents were also found to stimulate the coordination-site exchange of **5d1** although their catalytic activities are much weaker than those of pyridine and triphenylphosphine. The following eight solvents were examined: hexamethylphosphoric triamide (HMPA), dimethyl sulfoxide (DMSO), methanol, acetonitrile, *N,N*-dimethylformamide (DMF), nitromethane, acetone, and tetrahydrofuran (THF). The pseudo first order rate constant was determined at 50°C by the same way in a mixture of $CDCl_3$ and a perdeuterated donor solvent containing **5d1** at a constant concentration (0.06 mol dm^{-3}). Complex **5d1** is hardly soluble in these solvents and k_{obsd}'s determined in mixed solvents were plotted against the volume percent of donor solvent (Fig. 8). Fortunately all data except those for HMPA lie on straight lines, giving a common intercept at $k_0=2.0\,s^{-1}$. Extrapolation of these lines to 100% gives rates (k_1) in neat donor solvents which can not be determined directly. Tetrahydrofuran is practically ineffective and the rate value 2.0 s^{-1} given by the intercept corresponds to an intrinsic reaction which is not assisted by donor solvents. It is not certain whether the reaction proceeds truly noncatalytically or is promoted by a trace of triphenylphosphine liberated by reaction 4 (X=Cl). It should be noted that straight lines in Figs. 6 and 7



(4)

which show the catalytic effects of pyridine and triphenylphosphine, respectively, do not give intercepts, but go through the origin. Reaction 4 might be endothermic and liberate a trace amount of the phosphine at 50°C (*vide infra*), although the possibility may not be excluded that some other unimolecular mechanism (*e.g.* transformation *via* a tetrahedral transition state), which is not effective below 0°C, makes the observed minor contribution at 50 °C.

The k_1 values (s^{-1}) decreases in the sequence, HMPA (109.5)>DMSO (78.0)>MeOH (30.3)≈MeCN (29.8)≈DMF (29.1)>$MeNO_2$ (8.8)>Me_2CO (4.9). The tendency may be related to the coordination ability of the solvent. In fact the plot of log k_1 against the donor number[9] of solvent gave a straight line although a few data lie far from this line (Fig. 9).

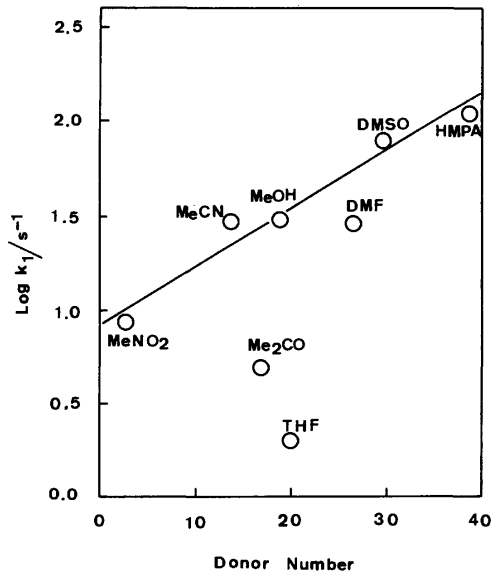


Fig. 9. Relation between the estimated pseudo first order rate constants for the coordination-site exchange reaction of complex **5d1** and donor number of solvents.

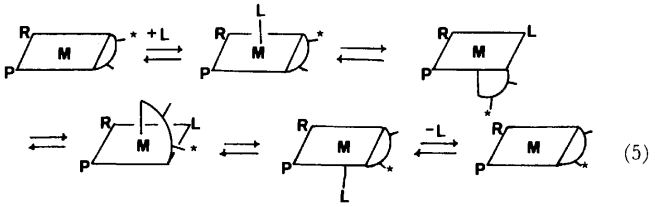
Geometrical isomerization of square-planar complexes has been the subject of extensive investigations.[10] Although some complexes such as *cis*-[PtCl(aryl)$(PEt_3)_2$] isomerize spontaneously in polar solvents,[11] most of the isomerization reactions proceed in the presence of neutral or ionic free ligands as catalysts,[12] and two mechanisms, consecutive displacement and intramolecular rearrangement of five-coordinate intermediates, are well documented.[10] Although the catalytic role of a solvent molecule coordinated to a complex as the fifth ligand has been suggested in some cases,[13] no conclusive evidence for solvent catalysis has yet been reported.

The consecutive displacement mechanism is not applicable to the present reaction, since a readily removable unidentate ligand such as halide is not contained in **5d1** and dissociation of the acetylacetonate ligand to give rise to [Pd(pyridyl)$(PPh_3)L_2$](acac) is not conceivable. By the analogy with the case of five-coordinate square-pyramidal complexes [M$(hfac)_2(PR_3)$] ($M=Pd^{II}$ and Pt^{II}, R=*o*-tolyl and cyclohexyl),[14] the intramolecular rearrangement such as illustrated by Eq. 5 is proposed, where R and P denote the pyridyl and phosphine ligands, respectively, and the trigonal-bipyramidal transition state involved in each step is omitted for the sake of brevity.



(5)

If the addition reaction to form the five-coordinate

intermediate, **5d1**+L$\overset{K}{\rightleftharpoons}$[Pd(acac)(R)($PPh_3$)L], attains equilibrium rapidly and the following intramolecular transformation is the rate-determining step (k_{tr}), the observed first order rate constant should be expressed by Eq. 6.

$$k_{obsd} = \frac{k_{tr}K[L]}{1+K[L]} \quad (6)$$

The linear dependence of k_{obsd} on the fraction of a donor solvent other than HMPA (Fig. 8) indicates that the equilibrium constants are very small for these solvent molecules even in the neat state. The second order rate law also holds for the reaction catalyzed by pyridine and triphenylphosphine, indicating that K[L] in the denominator of Eq. 6 is much smaller than one even for these strong ligands in the concentration regions examined, [py]<5.0 mol dm^{-3} and [PPh_3]<0.15 mol dm^{-3} against [**5d1**]=0.1 mol dm^{-3}. Although K and k_{tr} cannot be estimated separately at the present stage of investigation, the nature of L may influence not only on K but also on k_{tr}, since k_{obsd} spans over many orders of magnitude.

Coordination-site Exchange Reactions of Acetylacetonate Complexes Containing the 2-, 3-, or 4-Pyridyl Ligand. Methyl protons of the acetylacetonate ligand in the 2-pyridyl complex **5a1** show a singlet at δ 1.82 accompanied by two minor signals at δ 2.02 and 2.05. The chemical shifts of the latter signals exactly coincide with those from the dinuclear complex **6a1**, suggesting attainment of the equilibrium shown by Eq. 4 (X=H). Liberated triphenylphosphine may serve as a catalyst for the coordination-site exchange of **5a1** as expressed by Eq. 3 (X=H), exhibiting a single methyl-proton resonance at δ 1.82. This effect may be called autocatalysis, since the catalyzing species is produced by the reacting species. The δ 1.82 signal becomes broader with decreasing temperature, collapses at −20 °C and gives rise to two signals at −60 °C.

The equilibrium constant of Eq. 4 (X=H) was determined to be 0.01 mol dm^{-3} at 37 °C based on the relative intensities of signals from **5a1** and **6a1**. Oxidation of liberated triphenylphosphine with hydrogen peroxide shifts the equilibrium completely to right and the δ 1.82 signal disappears. On the other hand, the ^1H NMR spectrum of **5d1** shows no sign of coexistence of **6d1**, indicating that the dinuclear bridging is less favorable for the 6-chloro-2-pyridyl ligand than for the 2-pyridyl group. However, treatment of **5d1** with hydrogen peroxide yields **6d1** under the preparative condition, supporting existence of the equilibrium, Eq.4 (X=Cl). It is worth noting that 2,6-dichloropyridine does not catalyze the coordination-site exchange of **5d1** (Eq. 3) although 2,6-dimethylpyridine is effective as a catalyst. The steric requirements of the chloro and methyl substituents are quite similar, and their electronic effects may be responsible for the difference in basicities. Similarly the weaker basicity of the 6-chloro-2-pyridyl ligand than that of the 2-pyridyl ligand seems to make the dinuclear structue in **6d1** less favorable than that in **6a1**.

Each of complexes **5b1** and **5c1** containing the 3- and 4-pyridyl ligands, respectively, shows a broad methyl singlet at δ 1.82 in $CDCl_3$ at room temperature. The signal becomes broader with decreasing concentration and temperature, and is converted into two broad signals at δ 1.74 and 1.92 at −60 °C. Thus the singlet at room temperature seems to be caused by the rapid coordination-site exchange catalyzed by some species. No spectroscopic evidence is observed which suggests liberation of triphenylphosphine to form the dinuclear species from **5b1** and **5c1**. Treatment of these complexes with hydrogen peroxide do not afford type-**6** complexes.

These observations allow the presumption that when two molecules of the reacting species encounter with each other, one is coordinated with the metal atom of the other *via* the nitrogen atom of the pyridyl ligand, forming a five-coordinate intermediate which undergoes the coordination-site exchange. Such a catalysis has no precedent and may be termed "self-catalysis" or "mutual catalysis", since molecules of the reacting species mutually serve as the catalyst. Complexes **5b1** and **5c1** are also effective as catalysts for the coordination-site exchange reaction of **5d1**. The carbon-bonded pyridyl ligand shows higher basicity than free pyridine[4] and tends to interact with another metal atom, stabilizing the dinuclear structure of the 2-pyridyl complexes and the polynuclear linkage in the 3- and 4-pyridyl complexes. The enhanced basicity of the pyridyl ligand is origin of the self-catalysis.

We wish to thank Professor Toshio Tanaka (Osaka University) for his helpful advices on the program of ^1H NMR line shape simulation, and also Mr. Junichi Gohda for elemental analyses.

A Study of Inorganic Ion-exchangers. VIII.[1] The Synthesis of the Crystalline $Zr(RNH)_xH_{2-x}(PO_4)_2 \cdot yH_2O$ and Their Characteristics ($R=(C_nH_{2n+1})_3$ and C_5H_5, $n=1—6$)

Etsuro KOBAYASHI* and Shigemitsu SHIN
National Chemical Laboratory for Industry, Yatabemachi, Tsukuba-gun, Ibaraki 305
(Received May 2, 1983)

The synthesis of microcrystalline compounds with the formula of $Zr(RNH)_xH_{2-x}(PO_4)_2 \cdot yH_2O$ ($R=(C_nH_{2n+1})_3$, C_5H_5, $n=1—6$, $x=0.1—0.6$, $y=1—3$) and their characteristics have been investigated. The compounds were formed by means of a hydrothermal reaction between $RNH \cdot H_2PO_4$ and $ZrOCl_2$ in the mole ratio of 4:1 at 130—180 °C. The layer-spacings of the trimethyl-, triethyl-, tripropyl-, tributyl-, tripentyl-, trihexylamine, and pyridine phosphates were 9.9, 13.0, 13.6, 17.0, 16.5, 18.4, and 10.9 Å respectively. In the thermal decomposition of each phosphate, the water of crystallization was eliminated at 105—130 °C. The organic base group in the alkylamine phosphates was burned in the presence of air at 330—360 °C, but this combustion was imperfect in the case of pyridine phosphate. The phosphates condensed at 400—450 °C. $Zr(RNH)_xH_{2-x}(PO_4)_2 \cdot yH_2O$ was also obtained by means of an ion-exchange reaction between γ-$Zr(HPO_4)_2 \cdot 2H_2O$ and the corresponding tertiary amine. In these products, the layer-spacings of the trimethyl-, triethyl-, tripropyl-, tributyl-, tripentyl-, and trihexylamine phosphates were 17.6, 16.4, 16.7, 21.0, 21.5, and 23.2 Å respectively, while those of pyridine and piperidine phosphates were 12.4 and 18.4 Å respectively. The layer-spacings of the products increased roughly with the size of the guest molecules. When $Zr(RNH)_xH_{2-x}(PO_4)_2 \cdot yH_2O$ was treated with HCl, the products from the hydrothermal reaction changed to α-$Zr(HPO_4)_2 \cdot H_2O$, while the products from the ion-exchange reaction returned to γ-$Zr(HPO_4)_2 \cdot 2H_2O$ the raw material.

Recently, inorganic layer structure compounds have been considered to be materials with specific functions. Titanium and zirconium phosphates are useful compounds for ion-exchange, though a compound with a large layer-spacing can not be obtained as a result of the use of hydrogen and exchanged metal ions which are small in radius. The large layer-spacing compounds performing a chemical embellishment are promising as materials with specific functions as catalysers. Zirconium phosphates containing an organic radical have been obtained by means of ion-exchange reactions between α-,β-zirconium(IV) bis(hydrogenorthophosphate) and pyridine,[2] or butylamine.[3] The organo-derivatives of zirconium phosphate with a P-O-P ester bond were obtained by the reactions of γ-$Zr(HPO_4)_2 \cdot 2H_2O$ with ethylene oxide[4] or propylene oxide.[5] By another method, microcrystalline compounds with the $Zr(HOCH_2PO_3)_2 \cdot H_2O$, $Zr(C_6H_5PO_3)_2$, and $Zr(C_2H_5OPO_3)_2$ formulae were formed by slowly decomposing the fluorozirconium complex in the presence of $HOCH_2PO(OH)_2$, $C_6H_5PO(OH)_2$, and $PO(OC_2H_5)_2$.[6]

To develop an inorganic ion-exchanger, we synthesized γ-zirconium phosphate by means of a hydrothermal reaction between $ZrOCl_2$ and MH_2PO_4 (M=Na, K, NH_4).[1] For the present studies, $RNH \cdot H_2PO_4$ ($R=(C_nH_{2n+1})_3$, C_5H_5, $n=1—6$) was prepared by the reaction of phosphoric acid with tertiary amine, while $Zr(RNH)_xH_{2-x}(PO_4)_2$, with a larger layer-spacing than γ-$Zr(HPO_4)_2 \cdot H_2O$, was formed by a hydrothermal reaction between $RNH \cdot H_2PO_4$ and $ZrOCl_2$ in an autoclave. The synthesis conditions were determined, and the characteristics of the product were investigated and compared with those of a product obtained by the ion-exchange between γ-$Zr(HPO_4)_2 \cdot 2H_2O$ and the corresponding tertiary amine.

Experimental

Direct Method Synthesizing $Zr(RNH)_xH_{2-x}(PO_4)_2$. By refluxing between 1 mol of reagent-grade tertiary amine, 1 mol of 85% phosphoric acid, and a little water, an oily tertiary amine phosphate, $RNH \cdot H_2PO_4$ ($R=(C_nH_{2n+1})_3$, C_5H_5, $n=1—6$), was prepared beforehand for the following purpose.

In a 20 cm^3-hard glass tube, 1.61 g of $ZrOCl_2 \cdot 8H_2O$, 2—12 g of $RNH \cdot H_2PO_4$, and 5 cm^3 of water were taken. The contents were then thoroughly mixed, and the tube was sealed. 1—4 sealed tubes thus prepared under varying conditions were placed in a 200-cm^3 stainless steel autoclave with 80 cm^3 of water to prevent the rupture of the glass tubes. The autoclave was then heated at 120—180 °C. The products in the tube were separated from the mother liquors, washed with water, and then dried at 20 °C in a relative humidity (R.H.) of 75%. In direct synthesis by means of a 300-cm^3 autoclave lined with Hastelloy-B, 5—20 times as much of the raw materials were used, and the products were obtained with the above methods.

Formation of $Zr(RNH)_xH_{2-x}(PO_4)_2$ by Means of the Ion-exchange Method. In a 200-cm^3 Erlenmeyer flask, one gram of γ-$Zr(HPO_4)_2 \cdot 2H_2O$ 0.91—8.07 g of tertiary amine and 100 dm^3 of water were mixed and stirred for 24 h at 50 °C; the product thus obtained was separated, washed by means of a centrifugal separator, and finally dried.

Analysis. The P_2O_5 and ZrO_2 as components of the reaction product were determined according to the previously reported methods.[1] H_2O was obtained by deducting the weight of the Tertiary amine from the weight loss of the sample heated at 800 °C. Tertiary amine was obtained by the ammonia-distillation method.

The X-ray diffraction was performed with a Shimadzu Seisakusho diffractometor, using Ni filtered Cu $K\alpha$ radiation at 30 KVP and 20 mA. A Rigaku Denki micro-thermal analyzer with 100 μV of DTA sensibility and 20 mg of TG sensibility was used for the thermal analysis.

Results and Discussion

Reactions of $ZrOCl_2$ with $RNH \cdot H_2PO_4$ (Direct-synthesizing Method). The conditions for the synthesis of $Zr(RNH)_xH_{2-x}(PO_4)_2$ and the analytical data of the products are shown in Table 1.

The influence of the $RNH \cdot H_2PO_4/Zr$ mole ratios on the hydrothermal reaction between $(C_2H_5)_3NH \cdot H_2PO_4$

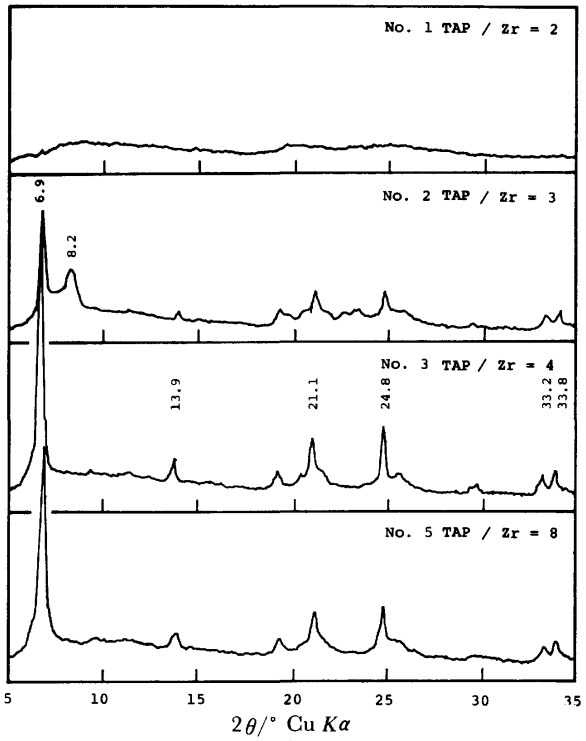

Fig. 1. X-Ray diffraction patterns of $Zr[(C_2H_5)_3NH]_xH_{2-x}(PO_4)_2$. (Influence of mole ratios of $(C_2H_5)_3NH \cdot H_2PO_4$/$ZrOCl_2$).
Numerals on the peaks indicate 2θ/°

and $ZrOCl_2$ were examined in Nos. 1—5 of Table 1; the X-ray diffraction patterns of the reaction products are shown in Fig. 1.

In the $RNH \cdot H_2PO_4$/Zr mole ratio of 2 (No. 1), an amorphous product was formed, though in the X-ray diffraction pattern of the product in the $RNH \cdot H_2PO_4$/Zr mole ratio of 3, the peaks appeared at 6.9 and 8.2°. In the products of the $RNH \cdot H_2PO_4$/Zr mole ratios of 4 (No. 3) and 8 (No. 5), the peak intensity of 6.9° increased and the peak of 8.2° disappeared completely. In Nos. 3, 4, and 5, crystalline products with roughly regular components were obtained. It is considered, therefore, that $RNH \cdot H_2PO_4$/Zr mole ratios of 4 or more are suitable for the synthesis of $Zr(RNH)_xH_{2-x}(PO_4)_2$, which can be written as follows;

$$ZrOCl_2 + 2RNH\,H_2PO_4 \longrightarrow Zr(RNH)_xH_{2-x}(PO_4)_2 + 2\text{-}x\,RNHCl + x\,HCl + H_2O.$$

In the hydrothermal synthesis of γ-$ZrNH_4H(PO_4)_2$,[1] the pH values of the reaction solution were in the range of 2.15—3.56; we are also shown as 2—3 in the formation of $Zr(RNH)_xH_{2-x}(PO_4)_2$.

Influence of Reaction Temperatures: An amorphous product was formed in the mother liquor at temperatures lower than 100 °C. The product crystallized above 120 °C, and the crystallinity was augmented with the elevation of the reaction temperature. The product was red-browned by the thermal decomposition of tertiary amine at 180 °C or higher. In an X-ray diffraction pattern of the reaction product at 250 °C, the diffraction peak-characterized product decreased in intensity; however, the X-ray diffraction peaks of the α-$Zr(HPO_4)_2 \cdot H_2O$ formed as a result of the decomposition of the product appeared anew. It may be concluded, therefore, that heating at 130—180 °C is suitable for the synthesis of $Zr(RNH)_xH_{2-x}(PO_4)_2$.

Composition of Reaction Products: Examples of various reaction conditions are shown in Nos. 6—24 of Table 1.

From the analytical data, the chemical formulae of the products dried in R.H. 75% can be written as follows: $Zr[(CH_3)_3NH]_{0.5}H_{1.5}(PO_4)_2 \cdot 2H_2O$, $Zr[(C_2H_5)_3NH]_{0.5}H_{1.5}(PO_4)_2 \cdot 1.5$—$2.0H_2O$ (No. 19 Product dried in R.H. 0%; 0.5 hydrate), $Zr[(C_3H_7)_3NH]_{0.1-0.2}H_{1.9-1.8}(PO_4)_2 \cdot 1.5$—$2.0H_2O$, (No. 20 Product dried in R.H.

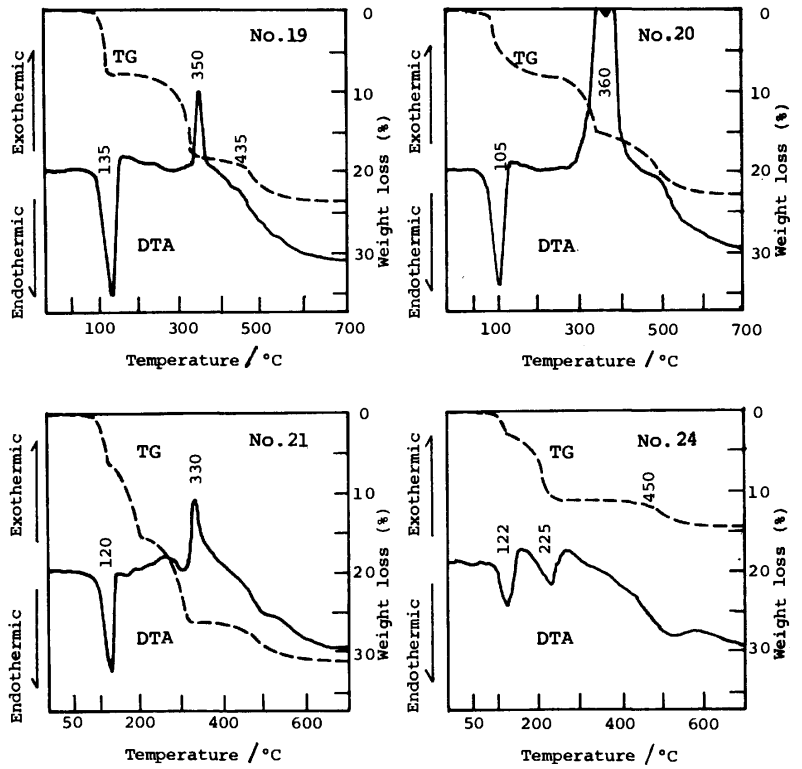

Fig. 2. DTA and TG curves of $ZrRNH_xH_{2-x}(PO_4)_2$ (R= $(C_2H_5)_3$, $(C_3H_7)_3$, $(C_4H_9)_3$, C_5H_5).
No. 19: $Zr[(C_2H_5)_3NH]_{0.5}H_{1.5}(PO_4)_2 \cdot 0.5H_2O$, No. 20: $Zr[(C_3H_7)_3 \cdot NH]_{0.2}H_{1.8}(PO_4)_2 \cdot 1.6H_2O$, No. 21: $Zr[(C_4H_9)_3NH]_{0.5}H_{1.5}(PO_4)_2 \cdot 0.7H_2O$, No. 24: $Zr(C_5H_5NH)_{0.2}H_{1.8}(PO_4)_2 \cdot 0.6H_2O$

Table 2. Formation and analysis of reaction products between γ-$Zr(HPO_4)_2 \cdot 2H_2O$ and tertiary amine

0%; 0.7 hydrate), $Zr[(C_4H_9)_3NH]_{0.3-0.5} \cdot H_{1.7-1.5}(PO_4)_2 \cdot 1.5$—$2.0H_2O$ (No. 21 Product dried R.H. 0%; 0.7 hydrate). $Zr(C_5H_5NH)_{0.2-0.25}H_{1.8-1.75}(PO_4)_2 \cdot 2.5$—$3.0H_2O$ (No. 24 Product dried R.H. 0%; 0.6 hydrate). The mole ratios of tertiary amine/P_2O_5 in the product showed the following order: methylamine=ethylamine > butylamine > pyridine > propylamine phosphates. It is considered that the order is influence by the basicity, size, and structure of the tertiary amines.

Behavior of Thermal Decomposition: The DTA and TG curves of $Zr(RNH)_xH_{2-x}(PO_4)_2 \cdot yH_2O$ are shown in Fig. 2.

The products released the water of crystallization at 105—135 °C, and an endothermic peak appeared on the TG curve. In the trialkylamine phosphates of Nos. 19—21, an exothermic peak owing to the combustion of the amine radical appeared at 330—360 °C, but the exothermic peak could not be recognized because of the incomplete combustion of the aromatic radical in the pyridine phosphate of No. 24.

The formation of pyrophosphate attributable to the condensation of orthophosphate occured at 400—450 °C. This temperature was higher than that of γ-$Zr(HPO_4)_2 \cdot 2H_2O$. Therefore, the $Zr(RNH)_xH_{2-x}(PO_4)_2$, which preserved its layer structure until 400 °C, can be considered to be a catalytic functional material.

Ion-exchange between γ-$Zr(HPO_4)_2 \cdot 2H_2O$ and Tertiary Amines. The conditions for the formation of $Zr(RNH)_xH_{2-x}(PO_4)_2$ and the analytical data of the products are shown in Table 2.

We are afraid that, as $(CH_3)_3N$ and $(C_2H_5)_3N$ have a stronger basicity than the other tertiary amines, γ-

$Zr(HPO_4)_2 \cdot 2H_2O$ as a acid salt was dissolved in the solution of the excess amine. Consequently, the amounts of $(CH_3)_3N$ and $(C_2H_5)_3N$ used were 1/3 equivalents as compared with those of the other tertiary amines. The P_2O_5 contents were about the same as those in the corresponding products obtained by the direct synthesizing method, while the tertiary-amine contents in the trimethylamine, tripropylamine, and pyridine phosphates were larger than in the products of the direct-synthesizing method. The tertiary-amine contents in the tripropylamine phosphates obtained by both methods were less than in the other phosphates. All the products dried in 75 % R.H. at 20 °C have 1—2 mol of the water of crystallization. It can be expected that one molecular layer of water is held between the upper and lower phosphate layers.

Layer-spacing and Orientation of Tertiary Amines. The layer-spacing was determined from a first d value (002) of the X-ray diffraction pattern. The layer-spacings of the trimethylamine, triethylamine, tripropylamine, tributylamine, tripentylamine, trihexylamine, and pyridine phosphates obtained by the direct-synthesizing method were 9.9, 13.0, 13.6, 17.0, 16.5, 18.4, and 10.9 Å, (Å=10^{-10} m) respectively. On the other hand, the layer-spacings of trimethylamine, triethylamine, tripropylamine, tributylamine, pyridine, and piperidine phosphates were 17.66, 16.4, 16.7, 21.0, 21.5, 23.2 12.4, and 18.4 Å respectively.

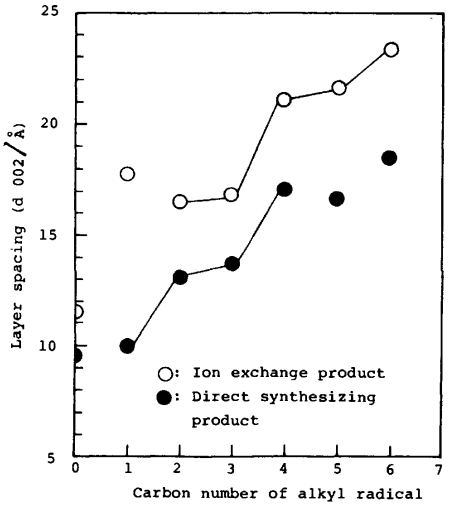

Fig. 3. Relation between layer spacing of product and carbon number of alkyl radical.
○: Ion exchange product of ZrP with NH_4OH. ●: Hydrothermal reaction product of $ZrOCl_2$ with $NH_4H_2PO_4$.

The relation between the layer-spacing of the product and the carbon number of the alkyl group is plotted in Fig 3. In this diagram, the two points at carbon number=0 indicate the layer-spacing of the ion-exchange product between γ-$Zr(HPO_4)_2 \cdot 2H_2O$ with aqueous ammonia and that of the hydrothermal reaction product of $ZrOCl_2$ with $NH_4H_2PO_4$ respectively. The layer-spacing increased with an increase in the carbon numbers of the alkyl group, with the exceptions of the trimethylamine phosphate produced by the ion-exchange and the tripentylamine phosphate produced by the direct method. However, the values of layer-spacing in the cases of n=odd number approximated to that in the cases of $n-1$. The upper and the lower phosphate layers were each connected with the tertiary amines which were sandwiched in the layers. Moreover the C_nH_{2n+1} molecules are considered to be oriented in a step-by-step manner, as is in Fig. 4.

The analytical data in Table 1 show tertiary amine/ZrO_2=0.5 in the products of $n \leqslant 2$ and tertiary amine/ZrO_2=0.1—0.5 in the products of $n \geqslant 3$. If the

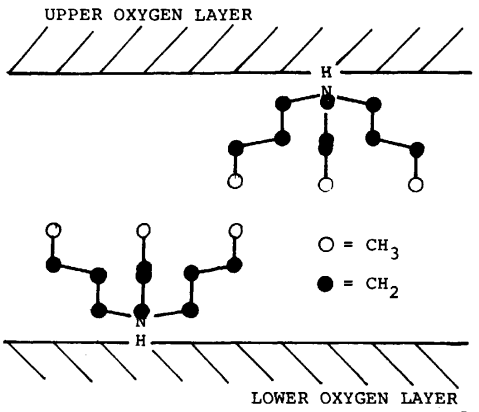

Fig. 4. Interlayer model of $Zr(C_3H_7)_3NH_xH_{2-x}(PO_4)_2$.

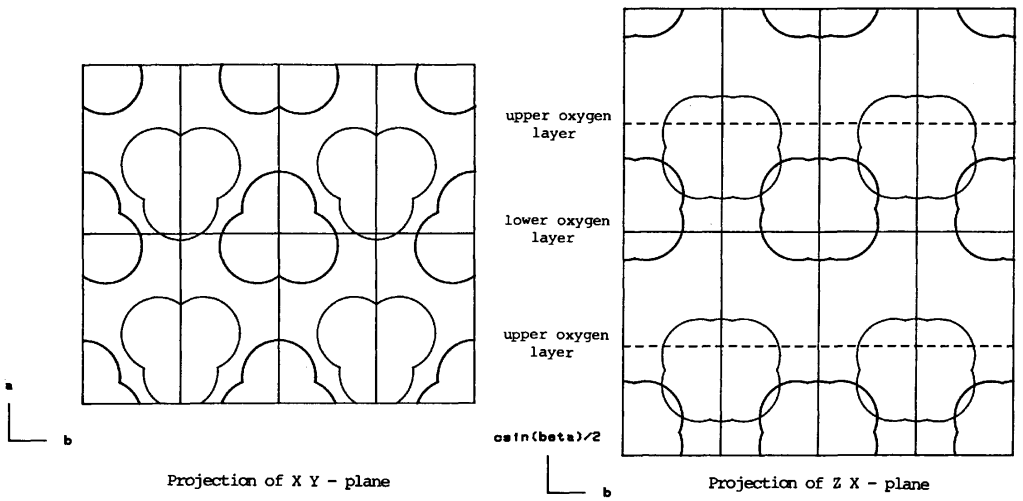

Fig. 5. Configuration of $(C_2H_5)_3N$ in layer spacing of α-$Zr(HPO_4)_2 \cdot H_2O$.

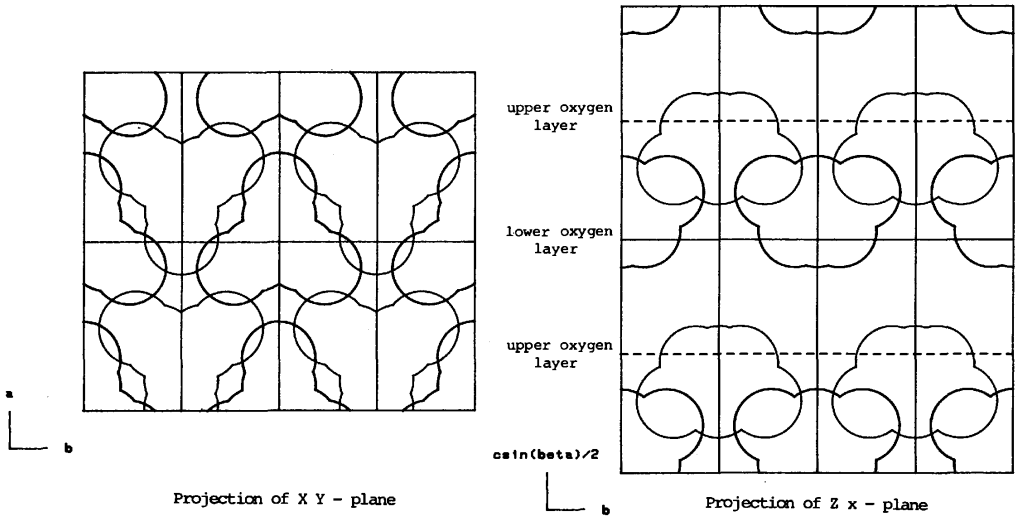

Fig 6. Configuration of $(C_3H_7)_3N$ in layer spacing of α-$Zr(HPO_4)_2$.

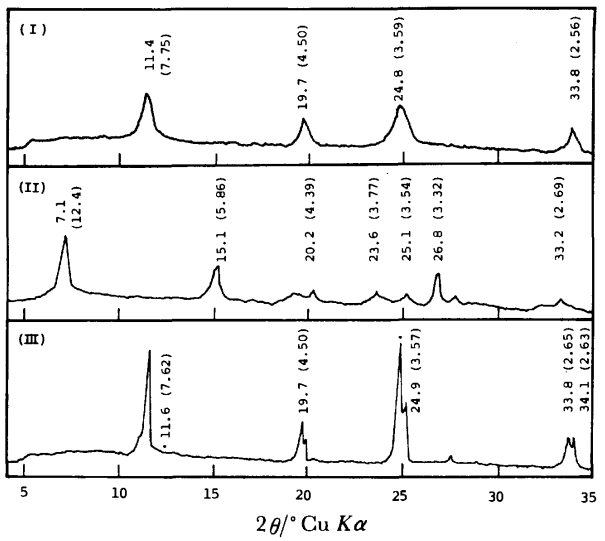

Fig. 7. X-Ray diffraction patterns of zirconium(VI)-bis(hydrogenphosphate).
I: Reaction product between $Zr[(C_4H_9)_3NH]_{0.5}H_{1.5}(PO_4)_2 \cdot 0.7H_2O$ (No. 21) and HCl. II: Reaction product between $Zr[(C_4H_9)_3NH]_{0.5}H_{1.5}(PO_4)_2 \cdot 1.5H_2O$ (Table 2, No. 3) and HCl. III: α-$Zr(HPO_4)_2 \cdot H_2O$. Numerals on the peaks indicate $2\theta/°$ and lattice distances.

value of tertiary amine/ZrO_2 is 0.5, and if the van der Waals radii of CH_2 and CH_3 in the alkyl group are 2 Å, then the arrangement of alkyl groups between the layers of α-$Zr(HPO_4)_2 \cdot H_2O$ may be as projected in Fig. 5 (triethylamine phosphate) and in Fig. 6 (tripropylamine phosphate). If $n \leqslant 2$, the amine molecules between layers of α-$Zr(HPO_4)_2 \cdot H_2O$ are not adjacent to each other and are arranged in a packed state. However ,if $n \geqslant 3$, the products actually have the tertiary amine/ZrO_2 values are 0.1—0.5; consequently, the amine molecules are oriented so as to avoid contact with each other.

Acid Salts of $Zr(RNH)_xH_{2-x}(PO_4)_2$. The X-ray diffraction patterns of the acid salts which are obtained by a hydrochloric acid treatment of the direct-synthesizing and ion-exchange products, and that of α-$Zr(HPO_4)_2 \cdot H_2O$ are shown in Fig. 7.

The direct-synthesizing method is similar to the preparation of $ZrNH_4H(PO_4)_2$[1] as a raw material of γ-$Zr(HPO_4)_2 \cdot 2H_2O$ and the layer-spacing of tributylamine phosphate obtained by the direct-synthesizing method shows a large 17 Å value. It can be simply expected, therefore, that the tributylamine phosphate has the γ-form. Howevere, the X-ray diffraction pattern (I) of the acid-treatment salt of the tributylamine phosphate agreed with that (III) of α-$Zr(HPO_4)_2 \cdot H_2O$. This fact was observed in the acid-treatment salts of the triethylamine, tripropylamine and pyridine phosphates, while the X-ray diffraction pattern (II) of the acid-treatment salt of the tributylamine phosphate obtained by the ion-exchange agreed with that of γ-$Zr(HPO_4)_2 \cdot 2H_2O$ the raw material. A similar phenomenon was also observed in the acid-treatment salts of other $Zr(RNH)_xH_{2-x}(PO_4)_2$ (R=Et, Pr, C_5H_5).

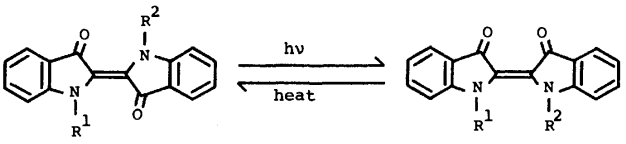
Synthesis and Stereoisomerization of Intra- and Intermolecularly Bridged Indigo

Yoshimori OMOTE,* Atsushi TOMOTAKE, Hiromu AOYAMA, Takehiko NISHIO, and Choji KASHIMA
Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305
(Received August 1, 1983)

The intramolecularly bridged *N,N'*-azelaoylindigo (**3**) and *N,N'*-sebacoylindigo (**4**) have been synthesized from indigo and the corresponding dichloride. The intermolecularly bridged *N',N''*-sebacoylbis(*N*-acetylindigo) (**5**) has been synthesized from *N*-acetylindigo and sebacoyl dichloride. The relative rates of the cis-to-trans thermal isomerization of **3**, **4**, and **5**, compared with that of *N,N'*-diacetylindigo (**1c**), were as follows: **3**, 0.77; **4**, 3.9; **5**, 1.4; **1c**, 1.0.

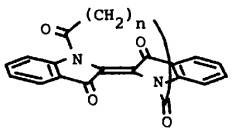
Trichochromes, which were isolated from the red feathers of New Hampshire chickens[1] and human red hair,[2] are low molecular melanin pigments, and are unique in exhibiting photochromism. During the course of an investigation of melanins, we have been interested in indigoid pigments as model compounds of trichochromes.

Indigo (**1a**), an indigoid pigment, exists in trans-form and cannot be isomerized into the corresponding cis-isomer even by irradiation,[3] owing to their photostability caused by a hydrogen-bonding[4] and/or a fast proton transfer in the excited state.[5] Therefore, *N,N'*-dimethyl-(**1b**)[6,7] and *N,N'*-diacetylindigo (**1c**)[3,8] show phototropic behavior, and the stereoisomerization of some *N,N'*-diacylindigo was described in our preceeding report.[9]

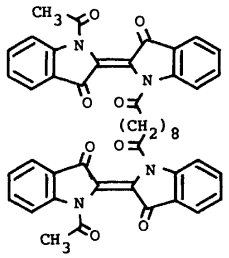


1a : $R^1 = R^2 = H$
1b : $R^1 = R^2 = CH_3$
1c : $R^1 = R^2 = COCH_3$

2 : $R^1 = R^2 = COCO$



3 : n = 7
4 : n = 8



5

On the other hand, *N,N'*-oxalylindigo (**2**), which is an intramolecularly bridged indigo, exists only in the cis-form because of its conformational restriction.[8] Insertion of methylene groups between the two carbonyl carbons of the oxalyl group was expected to cause a relaxation of the restriction. Hence, the synthesis of *N,N'*-azelaoylindigo (**3**), *N,N'*-sebacoylindigo (**4**), and *N',N''*-sebacoylbis(*N*-acetylindigo) (**5**) were carried out, and the cis-to-trans thermal isomerization of these intra- and intermolecularly bridged indigos was investigated.

Results and Discussion

Synthesis of Intra- and Intermolecularly Bridged Indigo. By the reported method,[8] *N,N'*-oxalylindigo (**2**) was synthesized from indigo and oxalyl dichloride in nitrobenzene under mild conditions. Attempted synthesis of compound **3** or **4** by this method failed. These compounds were synthesized by the improved method of Posner.[10]

The structure of *N,N'*-azelaoylindigo (**3**) was confirmed by the IR spectrum which showed two characteristic carbonyl bands at 1670 and 1700 cm^{-1}, by the NMR spectrum which showed the peaks of the methylenic protons at δ=1.3—3.7 and peaks of the aromatic protons at δ=7.4—8.5 and by the elemental analysis. The visible spectrum showed that the absorption maximum of **3** was very similar to that of *N,N'*-diacetylindigo (**1c**) which existed in the trans-form rather than that of *N,N'*-oxalylindigo (**2**) which existed in the cis-form. Therefore the configuration of **3** was assumed to be the trans-form. Similarly the structure and configuration of *N,N'*-sebacoylindigo (**4**) was confirmed by its physical properties in Table 1.

The intermolecularly bridged *N'*, *N''*-sebacoylbis-(*N*-acetylindigo) (**5**) was synthesized from *N*-acetyl

TABLE 1. PHYSICAL PROPERTIES OF INTRA- AND INTERMOLECULARLY BRIDGED INDIGO

a) Measured in xylene at 81.8 °C. b) Compared with **1c**.

indigo[11] and sebacoyl dichloride.

Thermal cis-to-trans Isomerization of Intra- or Intermolecularly Bridged Indigo. The intramolecularly bridged indigo, **3** or **4**, and the intermolecularly bridged indigo, **5**, were dissolved in xylene and irradiated by a mercury lamp using a filter solution which cuts off the wavelength shorter than 550 nm. The color of the solution changed from red to yellow, accompanied by disappearance of the peak of the trans-form near 570 nm, and appearance of the peak of the cis-form near 440 nm. The change of the visible spectrum was measured as shown in Fig. 1, where the solution was heated, and the thermal cis-to-trans isomerization rates were measured at several wavelengths characteristic to the trans-isomer. The rate constants and the relative rates were calculated and are shown in Table 2.

From Fig. 1 and Table 2, the following facts can be pointed out: i) In the case of intramolecularly bridged indigo, the azelaoyl group neither accelerates nor decelerates the isomerization so much, compared with the acetyl group; ii) The sebacoyl group accelerates the isomerization extremely; iii) In the case of intermolecularly bridged indigo, the bridged sebacoyl substituent neither accelerates nor decelerates the isomerization.

It is of interest that a great difference between the isomerization rate of the two intramolecularly bridged indigo, **3** and **4**, was observed. This can be explained by the instability of **4** in the cis-form because of the strain caused by the highly populated methylene chain.

Also, in the intermolecularly bridged indigo **5**, the bridged substituent did not change the stability because there is no steric restriction.

Experimental

Melting points were measured by Micro Melting Point Apparatus (Yanagimoto Seisakusho) and uncorrected. The IR spectra were recorded on JASCO IRA-1 IR Spectrophotometer. The ^{1}H-NMR spectra were determined with Hitachi R-24 NMR Spectrometer. The visible spectra were recorded on a Shimadzu UV-365 UV-VIS-NIR Recording Spectrophotometer.

N,N′-*Diacetylindigo (1c).* Prepared by the method of Blanc and Ross.[12]

N,N′-*Oxalylindigo (2).* Prepared by the method of Wyman and Zenhäusern.[8]

N,N′-*Azelaoylindigo (3).* Indigo (262 mg) and azelaoyl dichloride (0.6 ml) were dissolved in an anhydrous pyridine (100 ml) and the mixture was heated in a sealed tube at 200 °C for 1 h. The reaction mixture was poured into hydrochloric acid (100 ml and water 300 ml) and extracted with dichloromethane. The organic layer was evaporated and purified first with benzene–ethyl acetate (10:1) on silica-gel column chromatography, and then with hexane–dichloro-

methane–acetonitrile (7:2:1) on silica gel (20×20 cm). The product was recrystallized from benzene–hexane to give purple plates. Yield 10%. Mp 228—230 °C. Found: C, 72.74; H, 5.61; N, 6.40%. Calcd for $C_{25}H_{22}N_2O_4$: C, 72.44; H, 5.35; N, 6.75%.

N,N′-*Sebacoylindigo (4).* Prepared from indigo (262 mg) and sebacoyl dichloride (0.8 ml). Yield 19%. Mp 262—264 °C. Found: C, 72.56; H, 5.68; N, 6.41%. Calcd for $C_{26}H_{24}N_2O_4$: C, 72.88; H, 5.64; N, 6.53%.

N-*Acetylindigo.* Prepared by the method previously reported.[11]

N′,N″-*Sebacoylbis(N-acetylindigo) (5).* A solution of *N*-acetylindigo (246 mg) was heated under reflux with stirring in an anhydrous pyridine (15 ml) and sebacoyl dichloride (193 mg) for 10 min. The reaction mixture was treated in the same manner in **3**. Yield 3%. Mp 120—121 °C. Found: C, 72.05; H, 5.10; N, 6.58%. Calcd for $C_{46}H_{38}N_4O_8$: C, 71.30; H, 4.94; N, 7.23%. It was difficult to remove the solvent from the specimen; calculation was taken into account of the solvent for $C_{46}H_{38}N_4O_8 \cdot 0.5\ C_6H_6$: C, 72.31; H, 5.08; N, 6.88%.

Thermal cis-to-trans Isomerization. The compound, **3**, **4**, **5**, or **1c** was dissolved in distilled xylene, the concentration being in the order of 10^{-4} mol/l. The solution was sealed in several ampoules, and was irradiated by a mercury lamp using a filter solution which cuts off the wavelength shorter than 550 nm until the solution reached a photostationary state, and kept in the dark at 81.8 °C. After 1.5 and 5 min., the solution was quenched in a dry ice–methanol mixture at −78 °C. The change of the visible spectrum in thermal cis-to-trans isomerization was recorded between 350 and 650 nm, by JASCO UVIDEC-1 UV and VIS Absorption Spectrometer. Furthermore, the increase of absorption at 560, 570, and 580 nm was recorded by the improved spectrophotometer (JASCO UVIDEC-100 III) and the rate constants were calculated.

The Substituent Effects in Thiophene Compounds. III.[1] ^{1}H NMR and IR Studies in Methyl [*trans*-β-(Substituted 2-thienyl)acrylate]s

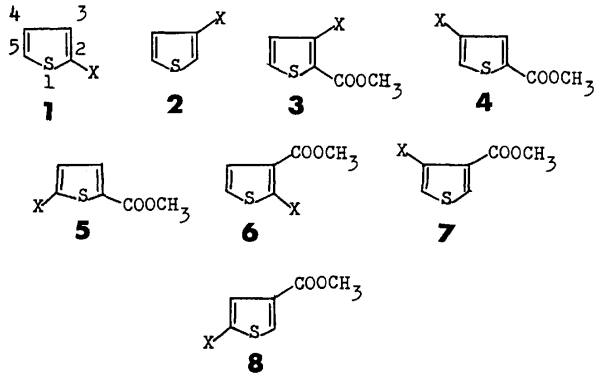
Hajime SATONAKA

Industrial Research Institute of Kanagawa Prefecture, 3173, Showa-machi, Kanazawa-ku, Yokohama 236

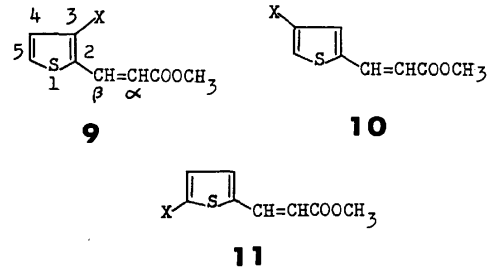
(Received August 2, 1983)

The ^{1}H NMR spectra and IR C=O stretching frequencies of methyl [*trans*-β-(3-, 4-, and 5-substituted 2-thienyl)acrylate]s are reported. The chemical shifts of the ring protons in methyl [*trans*-β-(4- and 5-substituted 2-thienyl)acrylate]s are correlated linearly with those of the corresponding protons in substituted thiophenes and methyl (substituted 2-thiophenecarboxylate)s. The substituent effects on the chemical shifts of α-protons in methyl [*trans*-β-(3- and 5-substituted 2-thienyl)acrylate]s have been interpreted by the mesomeric effect of the substituentes. The plots of the coupling constants in methyl [*trans*-β-(substituted 2-thienyl)acrylate]s against those in substituted thiophenes and methyl (substituted 2-thiophenecarboxylate)s gave good linear correlations. The IR C=O stretching wave numbers showed a narrow range of variation. The coupling constants in methyl [*trans*-β-(substituted 2-thienyl)acrylate]s were found to vary linearly with the electronegativity of the substituents.

In previous investigations,[1,2] the ^{1}H NMR spectra of 2- and 3-substituted thiophenes (**1** and **2**), and methyl (3-, 4-, and 5-substituted 2-thiophenecarboxylate)s (**3**—**5**), and methyl (2-, 4-, and 5-substituted 3-thiophenecarboxylate)s (**6**—**8**) were measured, and the effects of the substituents were discussed.



The investigation has been extended to the substituent effects in methyl [*trans*-β-(3-, 4-, and 5-substituted 2-thienyl)acrylate]s (**9**—**11**). The characteris-



tics of the ^{1}H NMR spectra of methyl [*trans*-β-(substituted 2-thienyl)acrylate]s, and the correlations of the chemical shifts and of the coupling constants between these compounds and substituted thiophenes and methyl (substituted 2-thiophenecarboxylate)s have been discussed in this paper. The coupling constants of methyl [*trans*-β-(substituted 2-thienyl)acrylate]s are correlated with the electronegativities of the substituents. The IR C=O stretching frequencies of methyl [*trans*-β-(substituted 2-thienyl)acrylate]s were measured and compared with those of methyl (substituted 2-thiophenecarboxylate)s.

Results and Discussion

The ^{1}H NMR spectra of methyl [*trans*-β-(3-, 4-, and 5-substituted 2-thienyl)acrylate]s were measured in deuteriochloroform at 25 °C. For convenience, the author used the notations H(2), H(3), H(4), H(5), H(α), and H(β) for the 2-, 3-, 4-, 5-, α-, and β-protons of methyl [*trans*-β-(substituted 2-thienyl)acrylate]s, and *cc*, *p*, *i*, and *s* for the correlation coefficient, slope, intercept, and standard deviation in the least-squares analysis. The ^{1}H NMR spectrum of methyl *trans*-β-(3-chloro-2-thienyl)acrylate (**9**, X=Cl) showed signals of (*ortho*-coupling) ring protons at δ 6.96 and 7.33, of (*trans*-coupling) olefinic protons at δ 7.86 and 6.27, and of methyl protons at δ 3.80. From the detailed analysis of the spectrum, the long-range couplings have been observed between H(5) and H(β) or H(α). It is noteworthy that the long-range coupling is observed between H(5) and H(α), because the interacting

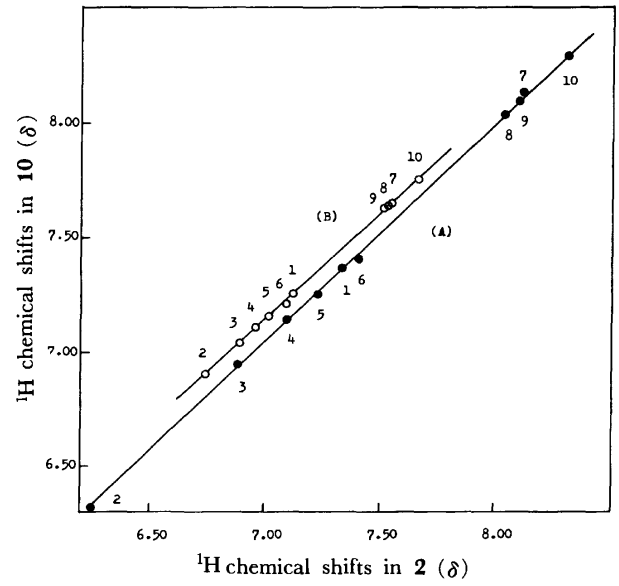


Fig. 1. Correlation between ^{1}H chemical shifts in **10** and **2**; numbering as in Table 2. A, δ_5(**10**) *vs.* δ_2(**2**). B, δ_3(**10**) *vs.* δ_4(**2**).

hydrogen nuclei in this compound are more separated than those in Zig-Zag[3-6] and W-letter couplings.[7,8] The spectra of other methyl [*trans*-β-(substituted 2-thienyl)acrylate]s are similar to this spectrum. In the series of compounds **10** and **11**, the long-range couplings were also found between hydrogens in thiophene ring and those in the side chain. In the series of **10**, both H(3) and H(5) couple with H(α) and H(β), but in the series of **11**, only H(3) with H(α) and H(β). It is found that H(4) in **9** does not couple with any hydrogen in the side chain, whereas H(4) in **11** couples with H(β) in methoxycarbonyl and nitro derivatives (J=0.20 Hz, in both cases). The spectra were assigned on the basis of chemical shifts and characteristic ring and long-range coupling constants. The refined chemical shifts and coupling constants were obtained

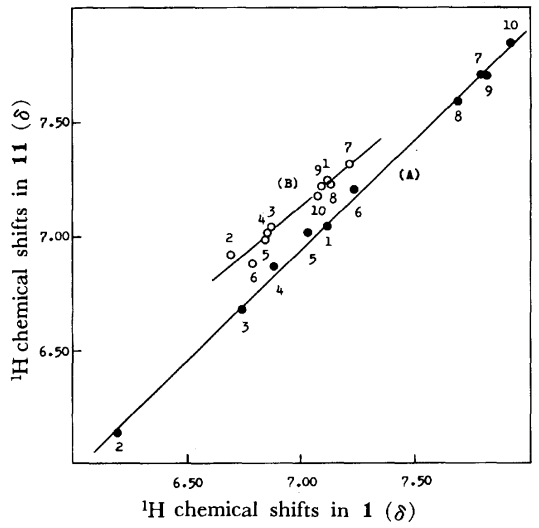

Fig. 2. Correlation between ^{1}H chemical shifts in **11** and **1**; numbering as in Table 3. A, δ_4(**11**) *vs.* δ_3(**1**). B, δ_3(**11**) *vs.* δ_4(**1**).

iteratively using LAOCN 3.[9] The results are given in Tables 1-3. The δ_5 (**10**)[10] *vs.* δ_2 (**2**), and δ_3 (**10**) *vs.* δ_4 (**2**) plots gave excellent correlations, as shown in Fig. 1 (A and B, respectively). Furthermore, the chemical shifts of ring protons in the series of compounds **10** were compared with those in the series of compounds **4**, and good correlations were observed between δ_5(**10**) and δ_5(**4**), and between δ_3(**10**) and δ_3(**4**). These data show that the ^{1}H chemical shifts of 5- and 3-positions in the thiophene ring have the same sensitivity for the substituent effects in both **10** and **4**, and suggest the possibility to estimate empirically with accuracy the ^{1}H chemical shifts of thiophene ring in other 2,4-disubstituted thiophene series. The chemical shifts of H(β) and H(α) in the series of compounds **10** show a narrow range of variation, as expected from those of H(5) in **2**. The effect of a substituent on the 4-position is considered to be transmitted mainly by the inductive effect to δ_β(**10**) and δ_α(**10**). The correlation between δ_α(**10**) and δ_5(**2**) gives a larger *cc* and a steeper *p* than that between δ_β(**10**) and δ_5(**2**).

As shown in Fig. 2, good correlations were obtained between δ_4(**11**) and δ_3(**1**) (A), and between δ_3(**11**) and δ_4(**1**) (B). The chemical shifts of **11** were compared with those of **5**, and better correlations were obtained between δ_4(**11**) and δ_4(**5**), and between δ_3(**11**) and δ_3(**5**). These results also suggest the possibility to estimate the ^{1}H chemical shifts of the thiophene ring in other 2,5-disubstituted thiophene series as in 2,4-disubstituted thiophene series. Quite similarly to the series of compounds **10**, the chemical shifts of H(β) is scarcely affected by the substituent at the 5-position, while that of H(α) considerably by the same substituent. The correlation between δ_α(**11**) and δ_5(**1**) also gives a larger correlation coefficient and a steeper slope than that between δ_β(**11**) and δ_5(**1**). The effect of the substituent on the 5-position is transmitted more strongly to H(α) than H(β) by a factor of about 5. This reason may be ascribed to the resonance effects as shown below. The shift of H(α) is presumed to be caused by a sizable contribution of the resonance structure **c**, which gives the charge delocalization on the α-carbon.

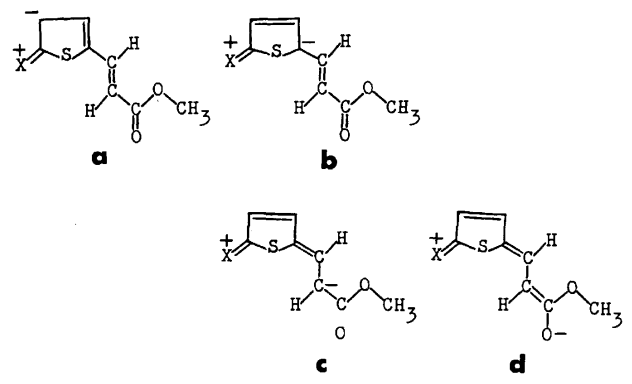

Figure 3 shows a close correlation between the effects of substituents on δ_4(**9**) and δ_4(**2**)(A), and a loose correlation between those on δ_5(**9**) and δ_5(**2**)(B). The chemical shifts of **9** were compared with those of **3**, and a good correlation was obtained between δ_4(**9**) and δ_4(**3**), and a fairly good correlation between δ_5(**9**) and δ_5(**3**). As shown in Table 1, formyl acetyl, and methoxycarbonyl groups cause significantly low field shifts of H(β) signal. These results may be interpreted by the preferred conformation **e**, in which the carbonyl group located very close to H(β) may form an intramolecular

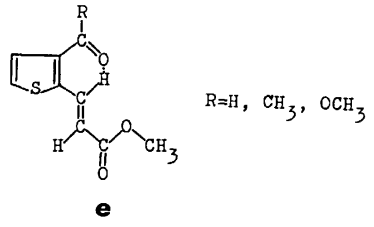
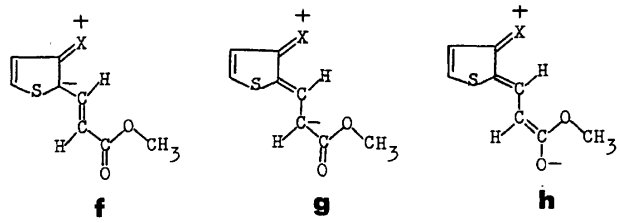


hydrogen bonding. This conformation may rationalize the facts that the chemical shift of the formyl proton in methyl *trans*-β-(3-formyl-2-thienyl)acrylate is shifted considerably towards a lower field than that of the 4-formyl derivative, and also that the former shows the carbonyl band at 1687 cm^{-1}, but the latter at 1701 and 1697 cm^{-1}. The large standard deviation of δ_β(**9**) *vs.* δ_2(**2**) plot may be caused by the complex influence due to neighboring anisotropy, intramolecular hydrogen bonding, inductive, mesomeric, and steric hindrance effects. The resonance contribution (**f**, **g**, **h**) similar to the case of 5-substituted derivatives is again expected with methyl [*trans*-β-(3-substituted 2-thienyl)acrylate]s.



The δ_α(**9**) value is considered to show a narrower range of variation than that of δ_α(**11**) due to the restricted contribution of mesomeric effect by steric hindrance of the 2-substituent. The correlation between δ_α(**9**) and δ_2(**2**) gives a larger *cc* and a lesser *p*. For this reason the substituent effect on the chemical shift of H(α) by the 5-position is more sensitive than that by the 3-position by a factor of about 1.5.

Methyl proton chemical shifts of methyl [*trans*-β-(substituted-2-thienyl)acrylate]s are much less affected by the substituents on the ring, and the substituent effects on these chemical shifts are attenuated to approximately half of those of methyl (substituted 2-thiophenecarboxylate)s. Contrary to the correlation between δ_α(**9**) and δ_α(**11**), the δ_{COOCH_3}(**9**) *vs.* δ_{COOCH_3}(**11**) plot shows that the substituents on the 3-position affect the chemical shift of $COOCH_3$ more remarkably than those on the 5-position. The results of these comparisons are shown in Table 4.

The chemical shifts of the ring protons of methyl

5	**11**	0.905	5.45	698.2	86.5	9[g]

a), d), and e) as in Table 4. f) CHO, $COCH_3$, $COOCH_3$, and NO_2 are excluded. g) $COOCH_3$ is excluded.

[*trans*-β-(substituted 2-thienyl)acrylate]s were calculated by making use of those of 2- and 3-substituted thiophenes. Excluding the chemical shift of H(4) of methyl *trans*-β-(3-methoxy-2-thienyl)acrylate, the observed chemical shifts agree with the calculated values within 0.1 ppm in three cases. These results seem to suggest that the additivity rule which is based on substituted thiophenes, is also applicable to the chemical shifts of the ring protons in methyl [*trans*-β-(substituted 2-thienyl)acrylate]s. It is noteworthy that the chemical shifts of the ring protons in the carbonyl derivatives of **9** are in good agreement with the calculated values, although those of **3** differ from the calculated values, which have been stated in the preceding paper.[2] Since the predominant conformations of carbonyl groups are thought to be the *syn* form in **2**, and the *anti* form in **9**, the chemical shifts of the ring protons in the latter are expected to disagree with the calculated values. Nevertheless, the observed values are in good agreement with the calculated. The unexpected agreement is probably due to the accidental compensation caused by the additional effect of the carbonyl group interacting with the CH group in its proximity.

The wave numbers of the C=O stretching vibrations of the series of methyl [*trans*-β-(substituted 2-thienyl)-acrylate]s were measured in CCl_4. The results are given in Table 5. Although two separated C=O stretching bands of the ester group have been observed in some of methyl (substituted 2-thiophenecarboxylate)s,[2] a peak with a shoulder is usually observed in the series of compounds **9**, **10**, and **11**. The main peak at the higher frequency is assignable to the *syn-s-trans* form, and the shoulder to the *anti-s-trans* form. The C=O stretching wave numbers of *syn-s-trans* form show narrow ranges of variation, being 8 cm^{-1} for **9**, 4 cm^{-1} for **10**, and 10 cm^{-1} for **11**. These ranges are about half as wide as those for methyl (substituted 2-thiophenecarboxylate)s. The correlations between the C=O streching frequencies of methyl [*trans*-β-(substituted 2-thienyl)acrylate]s and those of methyl (substituted 2-thiophenecarboxylate)s are shown in Table 6. A good correlation was observed between $\nu_{C=O}$(**11**)[11] and $\nu_{C=O}$(**5**), and fair correlations between $\nu_{C=O}$(**9**) and $\nu_{C=O}$(**3**), and between $\nu_{C=O}$(**10**) and $\nu_{C=O}$(**4**). The substituent effects to the C=O band by positions 5, 3, and 4 of methyl [*trans*-β-(substituted 2-thienyl)acrylate]s and of methyl (substituted 2-thiophenecarboxylate)s show a considerably similar trend. It is interesting that the substituent effect in **4** is transmitted strongly to the C=O stretching frequency of methoxycarbonyl group, but the effect in **10** very weakly.

Plots of the proton-proton coupling constants in methyl [*trans*-β-(substituted 2-thienyl)acrylate]s against the corresponding coupling constants in substituted thio-

phenes gave good correlations as shown in Fig. 4. Moreover, good linear correlations were observed between the coupling constants for methyl [*trans*-β-(substituted 2-thienyl)acrylate]s and methyl (substituted 2-thiophenecarboxylate)s.

For methyl [*trans*-β-(substituted 2-thienyl)acrylate]s as well as for methyl (substituted 2-thiophenecarboxylate)s,[2] relationships were examined between the coupling constants and the sum of the electronegativities of substituents including 2-(methoxycarbonyl)vinyl group. Good correlations were found for J_{35}(**10**)[12] and J_{45}(**9**), but not for other coupling constants.

Experimental

The ^{1}H NMR spectra of the compounds were obtained at 100 MHz on a JEOL PS-100 spectrometer. The chemical shifts were determined with an accuracy of ±0.005 ppm relative to TMS as an internal standard, and the coupling constants were determined with an accuracy of ±0.02 Hz. The concentrations of the substrates were adjusted approximately to 0.3 mol dm^{-3}. The IR spectra were recorded on a Perkin-Elmer 257 spectrometer.

Methyl *trans*-β-(2-thienyl)acrylate and methyl [*trans*-β-(5-bromo-, 5-formyl-, and 5-nitro-2-thienyl)acrylate]s were prepared according to the reported procedures.[13-16]

Methyl trans-β-*(4-Nitro-2-thienyl)acrylate.* This material was prepared by esterification of the corresponding acid,[17] mp 142°C. Found: C, 45.27; H, 3.20; N, 6.70; S, 15.00%. Calcd for $C_8H_7NO_4S$: C, 45.07; H, 3.31; N, 6.57; S, 15.04%. IR(KBr, cm^{-1}): 3100(=C-H); 1718(C=O); 1634(C=C); 967(*trans* CH=CH); 1535, 1433, 723(thiophene ring).

The following esters were prepared by the condensation of methyl acetate with the corresponding aldehydes[18-31] according to the procedure by Gilman and coworkers.[32]

Methyl trans-β-*(3-Methoxy-2-thienyl)acrylate.* Mp 52°C. Found: C, 54.72; H, 4.95; S, 15.98%. Calcd for $C_9H_{10}O_3S$: C, 54.53; H, 5.08; S, 16.17%. IR (KBr, cm^{-1}): 3090 (=C-H); 1706 (C=O); 1618 (C=C); 970 (*trans* CH=CH); 1537, 1428, 727 (thiophene ring).

Methyl trans-β-*(3-Methyl-2-thienyl)acrylate.* Bp 113—113.5°C/2 mmHg (1 mmHg≈133.322 Pa). Found: C, 59.20; H, 5.66; S, 17.49%. Calcd for $C_9H_{10}O_2S$: C, 59.32; H, 5.53; S, 17.59%. IR (neat, cm^{-1}): 3100 (=C-H); 1715 (C=O); 1622 (C=C); 968 (*trans* CH=CH); 1532, 1438, 713 (thiophene ring).

Methyl trans-β-*(3-Chloro-2-thienyl)acrylate.* Mp 69°C. Found: C, 47.55; H, 3.40; Cl, 17.31; S, 15.63%. Calcd for $C_8H_7ClO_2S$: C, 47.41; H, 3.48; Cl, 17.49; S, 15.82%. IR (KBr, cm^{-1}): 3130 (=C-H); 1721 (C=O); 1630 (C=C); 962 (*trans* CH=CH); 1508, 1422, 708 (thiophene ring).

Methyl trans-β-*(3-Bromo-2-thienyl)acrylate.* Mp 76°C. Found: C, 38.75; H, 2.95; Br, 32.50; S, 13.11%. Calcd for $C_8H_7BrO_2S$: C, 38.88; H, 2.86; Br, 32.33; S, 12.98%. IR (KBr, cm^{-1}): 3130 (=C-H); 1720 (C=O); 1628 (C=C); 962 (*trans* CH=CH); 1503, 1422, 707 (thiophene ring).

Methyl trans-β-*(3-Iodo-2-thienyl)acrylate.* Mp 78°C. Found: C, 32.58; H, 2.60; I, 43.07; S, 10.78%. Calcd for $C_8H_7IO_2S$: C, 32.67; H, 2.40; I, 43.15; S, 10.90%. IR (KBr, cm^{-1}): 3090 (=C-H); 1695 (C=O); 1622 (C=C); 960 (*trans* CH=CH); 1488, 1419, 709 (thiophene ring).

Methyl trans-β-*(3-Formyl-2-thienyl)acrylate.* Mp 112°C. Found: C, 55.17; H, 4.00; S, 16.56%. Calcd for $C_8H_8O_3S$: C, 55.09; H, 4.11; S, 16.34%. IR (KBr, cm^{-1}): 3110, 3090 (=C-H); 1719, 1673 (C=O); 1633 (C=C); 961 (*trans* CH=CH); 1520, 1437, 718 (thiophene ring).

Methyl trans-β-*(3-Acetyl-2-thienyl)acrylate.* Mp 82°C. Found: C, 57.15; H, 4.88; S, 15.38%. Calcd for $C_{10}H_{10}O_3S$: C, 57.13; H, 4.79; S, 15.25%. IR (KBr, cm^{-1}): 3120, 3080 (=C-H); 1698, 1678 (C=O); 1615 (C=C); 978 (*trans* CH=CH); 1503, 1438, 1423, 722 (thiophene ring).

Methyl trans-β-*(4-Methoxy-2-thienyl)acrylate.* Mp 73°C. Found: C, 54.70; H, 5.02; S, 16.29%. Calcd for $C_9H_{10}O_3S$: C, 54.53; H, 5.08; S, 16.17%. IR (KBr, cm^{-1}): 3090 (=C-H); 1706 (C=O); 1629 (C=C); 967 (*trans* CH=CH); 1551, 1430, 720 (thiophene ring).

Methyl trans-β-*(4-Methyl-2-thienyl)acrylate.* Bp 122—124°C/3 mmHg. Found: C, 59.55; H, 5.80; S, 17.65%. Calcd for $C_9H_{10}O_2S$: C, 59.32; H, 5.53; S, 17.59%. IR (neat, cm^{-1}): 3100 (=C-H); 1717 (C=O); 1616 (C=C); 967 (*trans* CH=CH); 1542, 1438, 1427, 721 (thiophene ring).

Methyl trans-β-*(4-Chloro-2-thienyl)acrylate.* Mp 80°C. Found: C, 47.64; H, 3.52; Cl, 17.33; S, 15.65%. Calcd for $C_8H_7ClO_2S$: C, 47.41; H, 3.48; Cl, 17.49; S, 15.82%. IR (KBr, cm^{-1}): 3110 (=C-H); 1710 (C=O); 1633 (C=C); 959 (*trans* CH=CH); 1519, 1438, 1421, 719 (thiophene ring).

Methyl trans-β-*(4-Bromo-2-thienyl)acrylate.* Mp 75°C. Found: C, 38.92; H, 2.80; Br, 32.58; S, 12.91%. Calcd for $C_8H_7BrO_2S$: C, 38.89; H, 2.86; Br, 32.33; S, 12.98%. IR (KBr, cm^{-1}): 3110 (=C-H); 1710 (C=O); 1633 (C=C); 959 (*trans* CH=CH); 1511, 1434, 1418, 718 (thiophene ring).

Methyl trans-β-*(4-Iodo-2-thienyl)acrylate.* Mp 44°C. Found: C, 32.44; H, 2.35; I, 43.36, S, 11.02%. Calcd for $C_8H_7IO_2S$: C, 32.67; H, 2.40; I, 43.15; S, 10.90%. IR (KBr, cm^{-1}): 3080 (=C-H); 1703 (C=O); 1627 (C=C); 964 (*trans* CH=CH); 1500, 1438, 718 (thiophene ring).

Methyl trans-β-*(4-Formyl-2-thienyl)acrylate.* Mp 96°C. Found: C, 54.98; H, 4.15; S, 16.18%. Calcd for $C_9H_8O_3S$: C, 55.09; H, 4.11; S, 16.34%. IR (KBr, cm^{-1}): 3080 (=C-H); 1709, 1672 (C=O); 1633(C=C); 978 (*trans* CH=CH); 1528, 1435, 721 (thiophene ring).

Methyl trans-β-*(4-Acetyl-2-thienyl)acrylate.* Mp 86°C. Found: C, 57.08; H, 4.83; S, 15.09%. Calcd for $C_{10}H_{10}O_3S$: C, 57.13; H, 4.79; S, 15.25%. IR (KBr, cm^{-1}): 3080 (=C-H); 1708, 1668 (C=O); 1631 (C=C); 988 (*trans* CH=CH); 1527, 1408, 728 (thiophene ring).

Methyl trans-β-*(5-Methoxy-2-thienyl)acrylate.* Mp 56°C. Found: C, 54.68; H, 4.82; S, 16.38%. Calcd for $C_9H_{10}O_3S$: C, 54.53; H, 5.08; S, 16.17%. IR (KBr, cm^{-1}): 3090 (=C-H); 1707 (C=O); 1616 (C=C); 973 (*trans* CH=CH); 1538, 1423, 703 (thiophene ring).

Methyl trans-β-*(5-Methyl-2-thienyl)acrylate.* Mp 55°C. Found: C, 59.48; H, 5.31; S, 17.75%. Calcd for $C_9H_{10}O_2S$: C, 59.32; H, 5.53; S, 17.59%. IR (KBr, cm^{-1}): 3080 (=C-H); 1708 (C=O); 1620 (C=C); 992 (*trans* CH=CH); 1536, 1435, 720 (thiophene ring).

Methyl trans-β-*(5-Chloro-2-thienyl)acrylate.* Mp 53°C. Found: C, 47.62; H, 3.42; Cl, 17.23; S, 15.80%. Calcd for $C_8H_7ClO_2S$: C, 47.41; H, 3.48; Cl, 17.49; S, 15.82%. IR (KBr, cm^{-1}): 3060 (=C-H); 1719 (C=O); 1626 (C=C); 969 (*trans* CH=CH); 1524, 1422, 721 (thiophene ring).

Methyl trans-β-*(5-Iodo-2-thienyl)acrylate.* Mp 88°C. Found: C, 32.81; H, 2.55; I, 43.02; S, 11.12%. Calcd for $C_8H_7IO_2S$: C, 32.67; H, 2.40; I, 43.15; S, 10.90%. IR (KBr, cm^{-1}): 3050 (=C-H); 1708 (C=O); 1623 (C=C); 9.71 (*trans* CH=CH); 1519, 1417, 717 (thiophene ring).

Methyl trans-β-*(5-Acetyl-2-thienyl)acrylate.* Mp 147°C. Found: C, 57.48; H, 4.58; S, 15.23%. Calcd for $C_{10}H_{10}O_3S$: C, 57.13; H, 4.79; S, 15.25%. IR (KBr, cm^{-1}): 3080 (=C-H); 1711, 1657 (C=O); 1627 (C=C); 987 (*trans* CH=CH); 1519, 1449, 731 (thiophene ring).

Methyl [*trans*-β-(3-, 4-, and 5-methoxycarbonyl-2-thienyl)-acrylate]s were prepared by the oxidation of the corresponding methyl [*trans*-β-(formyl-2-thienyl)acrylate]s followed by the esterification.

Methyl trans-β-*(3-Methoxycarbonyl-2-thienyl)acrylate.* Mp 82°C. Found: C, 52.95; H, 4.58; S, 14.28%. Calcd for

$C_{10}H_{10}O_4S$: C, 53.09; H, 4.46; S, 14.17%. IR (KBr, cm^{-1}): 3110, 3080 (=C-H); 1719, 1708 (C=O); 1621 (C=C); 978 (*trans* CH=CH); 1518, 1438, 1429, 719 (thiophene ring).

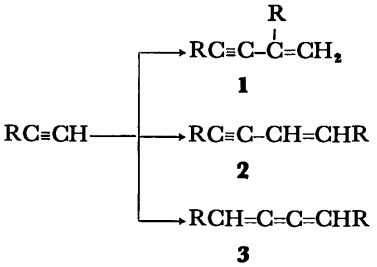
Regioselective Homo- and Codimerization of 1-Alkynes Leading to 2,4-Disubstituted 1-Buten-3-ynes by Catalysis of a $(\eta^5\text{-}C_5Me_5)_2TiCl_2$/RMgX System

Munetaka AKITA, Hajime YASUDA, and Akira NAKAMURA*
Department of Macromolecular Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received August 3, 1983)

A series of 1-alkynes (RC≡CH where R=Et, *n*-Pr, *n*-Bu, *n*-C_6H_{13}, cyclohexyl, Ph, Me_3Si, Me_3SiCH_2, and Me_3SiOCH_2) was found to dimerize regioselectively (>99%) to 2,4-disubstituted 1-buten-3-ynes in 92—99% yields by catalysis of $(\eta^5\text{-}C_5Me_5)_2TiCl_2$/*i*-PrMgBr at 30 °C in 1—3 h. The catalyst system is also effective for the regioselective codimerization of various 1-alkynes with 1-ethynylcyclohexene or ethynylbenzene.

Linear- and cyclo-oligomerizations of 1-alkynes have been extensively studied with a variety of transition metal catalysts. Organometallic complexes of Ni,[1a] Co,[1b] Pd,[1c] and Ti[1d] are known as efficient catalysts for cyclooligomerization of alkynes converting them to substituted or unsubstituted benzenes, cyclooctatetraenes, *etc.* For linear dimerization of 1-alkynes, three different modes are possible as illustrated in Eq. 1.



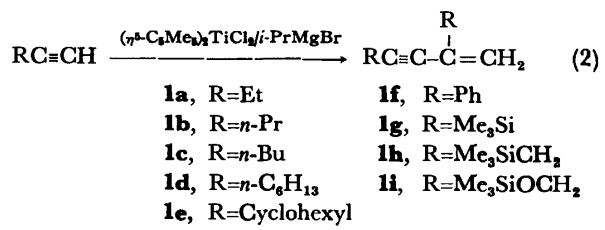
(1)

Only a few catalyst systems have been known for this type of dimerization. $[Cr(O\text{-}n\text{-}Bu)_4]/ZnEt_2$[2] and $[RhCl(PPh_3)_3]$[3] are representative catalysts for the head-to-tail dimerization of 1-alkynes to convert them to 2,4-disubstituted 1-buten-3-ynes (**1**), and some copper salts are known to be catalytically active for the head-to-head dimerization leading to 1,4-disubstituted 1-buten-3-ynes (**2**).[4] $[RuH_2(CO)(PPh_3)_3]$ is the unique catalyst to convert 1-alkynes to cumulene derivatives **3**.[5]

We wish to report herein a novel catalyst system, $(\eta^5\text{-}C_5Me_5)_2TiCl_2$/*i*-PrMgBr, which shows exceedingly high catalytic activities for the linear dimerization of various 1-alkynes to give the head-to-tail bound dimers **1** regioselectively. The present catalyst system is superior to the known catalysts with respect to regioselectivity, yield, reproducibility and broad applicability. Even more important is the experimental simplicity and the mild reaction conditions of our new process. It should be noted here that the formation of higher oligomers are negligible in the present system. This ambient catalyst system is also effective for the regioselective codimerization of two different 1-alkynes, which provides a variety of novel 2,4-disubstituted 1-buten-3-ynes.

Results and Discussion

Regioselective Dimerization of 1-Alkynes. In the preceding paper, we have reported the exceptionally high catalytic activity of $(\eta^5\text{-}C_5Me_5)_2TiCl_2$/RMgX or $(\eta^5\text{-}C_5Me_5)_2TiCl_2/NaC_{10}H_8$ toward the selective isomerization of 1-alkenes to (*E*)-2-alkenes.[6] In our continuing investigations on titanocene species, we have found that "$(\eta^5\text{-}C_5Me_5)_2TiH$" species generated by reduction of $(\eta^5\text{-}C_5Me_5)_2TiCl_2$ with two equivalents of *i*-PrMgBr behaves as an efficient catalyst for the regioselective dimerization of 1-alkynes to lead to **1**. When a mixture of $(\eta^5\text{-}C_5Me_5)_2TiCl_2$/*i*-PrMgBr (2 mol % of $(\eta^5\text{-}C_5Me_5)_2TiCl_2$ based on 1-alkyne was used) and 1-butyne, 1-pentyne, 1-hexyne, or 1-octyne was stirred for 1—3 h at 30 °C in diethyl ether, the highly regioselective dimerization (>99%) occurred to give the corresponding dimers **1a—d** in 92—97% yields. The



(2)

results are given in Table 1. The maximum turnover number for 1-hexyne was 2.0 (mol/mol min) in diethyl ether and 4.5 (mol/mol min) in THF. The corresponding reactions were examined with $(\eta^5\text{-}C_5Me_5)_2TiCl_2/NaC_{10}H_8$ to find a significantly lower activity (turnover number was 0.24 mol/mol min in THF). Though normal and secondary alkyl-substituted acetylenes readily dimerize at ambient temperature, *t*-butylacetylene (3,3-dimethyl-1-butyne) was completely inert to both catalysts even at 60 °C and was recovered quantitatively. The present catalyst system is active also for 1-alkynes containing Me_3Si group, a leaving group useful for organic synthesis, but inactive for 1-alkynes substituted with an electron donating group such as EtO, EtS, or Et_2N. The greater reactivity of $Me_3SiC{\equiv}CH$ compared to *t*-BuC≡CH may be ascribed to the smaller cone angle and higher acidity of the former. The use of bulky $\eta^5\text{-}C_5Me_5$ ligand is essential to perform the present type dimerization. The $(\eta^5\text{-}C_5H_5)_2TiCl_2$/*i*-PrMgBr catalyst system with a less bulky ligand has practically no catalysis and preferred the oligomerization of 1-alkynes.

Regioselective Codimerization of 1-Alkynes. The successful regioselective dimerization of 1-alkynes prompted us to examine the codimerization between

Table 1. Homodimerization of 1-alkynes (RC≡CH) to 2,4-disubstituted 1-buten-3-ynes with $(C_5Me_5)_2TiCi_2/i$-PrMgBr(1:2) catalyst system[a)]

a) Reactions were carried out at 30 °C in diethyl ether with 2 mol% of catalyst. b) Total yield is expressed by (sum of conversion for RC≡CH and R′C≡CH)/2.

ary or tertiary alkylacetylenes (R'C≡CH), the codimers were obtained with moderate regioselectivity (entries 2 and 3). The formation of **4** exceeded over that of the codimer **5** and homodimers **1** and **1'**. Similar trend was observed also in the reaction of ethynylcyclohexane with *t*-butylacetylene (entry 5) or in the reaction shown in entries 4, 6, and 7.

Thus, the more bulky alkyl groups are always introduced to the terminal position (C_4-carbon) of the 1-buten-3-ynes in preference to the internal position (C_2-carbon). In some favorable cases (entries 3, 4, 5, and 7), the formation of the dimers of the type **5** was completely suppressed. These results are reasonably interpreted by the steric effect of alkyl groups. Especially noteworthy is that the present catalyst system showed no catalysis toward the homo-dimerization of *t*-BuC≡CH while it showed exceedingly high activity toward the codimerization of *t*-BuC≡CH with normal or secondary alkyl-substituted acetylenes. Rather exceptional is the behavior of 3-trimethylsiloxy-1-propyne. Though the bulkiness of Me_3SiOCH_2 is nearly equal to that of *n*-Bu group and the acidity of $Me_3SiOCH_2C{\equiv}CH$ is a little higher than that of 1-hexyne as described later, the formation of **5** was completely suppressed. Since oxygen atom has a good affinity toward Ti atom, the observed enhanced regioselectivity is supposed to be the result of the interaction between the oxygen atom of $Me_3SiOCH_2C{\equiv}CH$ and the metal center.

To evaluate the electronic effect of substituent, the codimerization of ethynylcyclohexane with 1-ethynylcyclohexene or ethynylbenzene was tried (entries 15 and 22 in Table 3). Though the bulkiness of these three substituents is nearly the same, the regioisomers, 4-(1-cyclohexenyl)-2-cyclohexyl-1-buten-3-yne (**4n**) and 2-cyclohexyl-4-phenyl-1-buten-3-yne (**4s**), were formed with an extremely high selectivity. This result may be interpreted primarily by electronic effect or acidity of 1-alkynes. The R'C≡C unit of the product is generally derived from the 1-alkynes of higher acidity and the $-C(R){=}CH_2$ unit is from less acidic 1-alkyne. The relative acidity strength of the 1-alkynes was estimated from the ^{1}H-NMR chemical shift values (Table 4) of the CH proton of 1-alkynes as PhC≡CH>1-ethynylcyclohexene >$Me_3SiC{\equiv}CH{\simeq}Me_3SiOCH_2C{\equiv}CH$>*t*-BuC≡CH≃ethynylcyclohexane≃*n*-BuC≡CH>$Me_3SiCH_2C{\equiv}CH$. The CH signal appeared at lower field with increasing the acidity of 1-alkynes.[7] The ^{13}C-NMR chemical shift values also showed the similar relationship. The C≡C and CH frequencies in their IR spectra are useless to estimate the relative acidity strength because the difference is too small. The reactions of 1-hexyne, 3-trimethylsiloxy-1-propyne or 3-trimethylsilyl-1-propyne with 1-ethynylcyclohexene or ethynylbenzene (entries 11—13, 18—20) also showed the highly regioselective formation of **4**. The good selectivity observed in the reaction of $Me_3SiC{\equiv}CH$ with *n*-BuC≡CH or $Me_3SiCH_2C{\equiv}CH$ (entries 4 and 7 in Table 2) also may be interpreted by the relatively high acidity of $Me_3SiC{\equiv}CH$. However, in the reaction of 3,3-dimethyl-1-butyne with 1-ethynylcyclohexene or with ethynylbenzene, no reaction occurred. This is presumably due to the steric reasons as described later in the discussion. The structures of the resulting dimers and codimers were analyzed by the ^{1}H-NMR (see Experimental section) and ^{13}C-NMR (Table 5) with reference to the chemical shift values of starting 1-alkynes and related 1-alkenes.[8] In cases of $CH_2{=}C(CH_2OSiMe_3)C{\equiv}C$-*n*-Bu and $CH_2{=}C(n\text{-Bu})C{\equiv}CPh$, the structures were identified after hydrogenation to $CH_3CH(CH_2OH)C_6H_{13}$ and $CH_3CH(n\text{-Bu})CH_2CH_2Ph$, respectively, by comparison with authentic samples. Thus, the present catalyst provides 1-buten-3-ynes bearing two different substituents on the C-2 and C-4 atom, most of which are not yet synthesized even in combination of conventional organic reactions.[9]

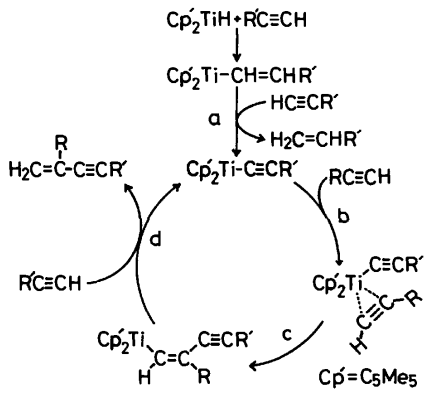
4t(R = Ph)

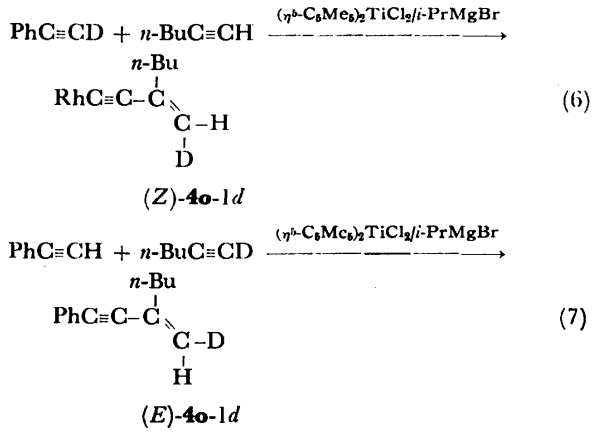
Me_3SiO group, the Me_3SiO group was transformed to *i*-Pr group by reaction with *i*-PrMgBr (Eq. 5). Similar exchange of the Me_3SiO group with an alkyl group is already known for the Ni- or Pd-catalyzed reaction of 3-trialkylsiloxy-1-butenes with PhMgX.[10] The present sequence of reactions provides a useful route to introduce various kinds of alkyl groups into the C-2 atom of the 1-buten-3-ynes.

Reaction Pathway for the Codimerization of 1-Alkynes. A possible mechanism for the selective codimerization of 1-alkynes catalyzed by (η^5-$C_5Me_5)_2$-$TiCl_2$/*i*-PrMgBr is shown in Scheme 1. Reduction of (η^5-$C_5Me_5)_2TiCl_2$ with *i*-PrMgBr will generate low-valent (η^5-$C_5Me_5)_2TiH$ species. The generation of similar species, (η^5-$C_5H_5)_2TiH$, has been suggested by Martin and Sato in the hydrotitanation of conjugated dienes with (η^5-$C_5H_5)_2TiCl_2$/RMgX[11] and in the titanium-assisted hydromagnesiation of disubstituted acetylenes[12] and carbonyl compounds.[13] Hydrotitanation of alkenes with (η^5-$C_5H_5)_2TiH$[14] and hydrozirconation of alkenes or alkynes with (η^5-$C_5H_5)_2$-$ZrHCl$[15] are already known. Formation of the low-valent (η^5-$C_5Me_5)_2Ti$ species may be ruled out because such species generally gives catalytically inactive titana-2,4-cyclopentadienes when it was reacted with 1-alkynes.[16] The reactive species, (η^5-$C_5Me_5)_2TiH$, will readily react with 1-alkynes to give (η^5-$C_5Me_5)_2$-$TiCH{=}CHR'$. Since (η^5-$C_5H_5)_2ZrMe_2$ is known to be cleaved with 1-alkynes (RC≡CH) to give CH_4 and (η^5-$C_5H_5)_2Zr(C{\equiv}CR)_2$,[17] it seems most likely that (η^5-$C_5Me_5)_2TiCH{=}CHR'$ reacts with R'C≡CH to produce (η^5-$C_5Me_5)_2TiC{\equiv}CR'$ (step a). When two different 1-alkynes are present in the system, the more acidic 1-alkyne (R'C≡CH) will cleave the Ti-C bond in preference to the attack of a less acidic alkyne (RC≡CH) to result in the formation of (η^5-$C_5Me_5)_2$-$TiC{\equiv}CR'$. Isolation of (η^5-$C_5Me_5)_2TiC{\equiv}CR$ or (η^5-$C_5H_5)_2TiC{\equiv}CR$ has not been achieved because of its thermal instability. In the case of (η^5-$C_5H_4Me)_2TiC{\equiv}$CPh, spontaneous dimerization to catalytically inactive (η^5-$C_5H_4Me)_4Ti_2$[μ-(1-3-η^2-, 2-4-η^2-1,4-diphenylbutadiene)] occurs when free PhC≡CH is absent in the reaction system.[18] However, we found that when (η^5-$C_5Me_5)_2TiC{\equiv}CPh$ was prepared *in situ* by reaction of (η^5-$C_5Me_5)_2TiCl$ with LiC≡CPh in the presence of excess ethynylbenzene and 1-hexyne (1 : 1 mixture), the catalytic codimerization occurred successfully. The turnover number for this catalyst system (1.8 mol/mol min) is nearly equal to 2.0 mol/mol min for the (η^5-$C_5Me_5)_2TiCl_2$/*i*-PrMgBr system. This finding supports the above reaction pathway through (η^5-$C_5Me_5)_2TiC{\equiv}CR'$ species. Thus, the acidic 1-alkyne forms the (η^5-$C_5Me_5)_2TiC{\equiv}CR'$ at first and then insertion of less acidic 1-alkyne follows (step c) *via* an intermediate coordinated with RC≡CH (step b). The subsequent Ti-C bond fission of the resulting (η^5-$C_5Me_5)_2TiCH{=}C(R)C{\equiv}CR'$ may be done with the



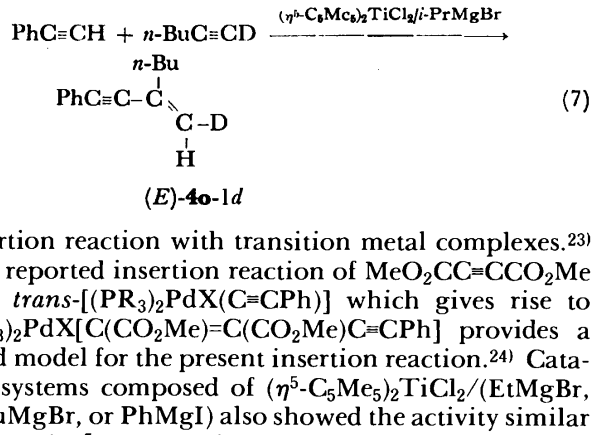
Scheme 1.

acidic R'C≡CH to release CH_2=C(R)C≡CR' and to regenerate (η^5-$C_5Me_5)_2$TiC≡CR' to complete the catalytic cycle. The direction of the alkynyl transfer is assumed to be controlled in the step b by steric repulsion between η^5-C_5Me_5 ligand and alkyl group of 1-alkynes. Coordination of RC≡CH in the opposite direction is sterically improbable. Insertion of RC≡CH to TiC≡CR' bond will occur in the cis-fashion on a plane containing the Ti-C≡CR' bond as predicted by the EH-MO calculation.[19] To verify this postulation, codimerization using PhC≡CD or *n*-BuC≡CD was examined. The 1 : 1 reaction of PhC≡CD with *n*-BuC≡CH in the presence of the catalyst gave (*Z*)-**4o**-1*d* in 98% selectivity (Eq. 6) while 1 : 1 mixture of PhC≡CH and *n*-BuC≡CD gave (*E*)-**4o**-1*d* in 97% selectivity (Eq. 7). The assignment of the structure was made with reference to the ^{1}H-NMR data for butadiene,[20] 1,3-pentadiene,[21] and ethenylbenzene[22] together with the NOE measurement (5—8%) in $CDCl_3$ and C_6D_6. Thus the cis-addition of less acidic 1-alkyne was verified in support of the above mechanism. Similar cis-addition of 1-alkynes is widely observed in the



(6)

(*Z*)-**4o**-1*d*



(7)

(*E*)-**4o**-1*d*

insertion reaction with transition metal complexes.[23] The reported insertion reaction of MeO_2CC≡CCO_2Me into *trans*-[$(PR_3)_2$PdX(C≡CPh)] which gives rise to $(PR_3)_2$PdX[C(CO_2Me)=C(CO_2Me)C≡CPh] provides a good model for the present insertion reaction.[24] Catalyst systems composed of (η^5-$C_5Me_5)_2TiCl_2$/(EtMgBr, *n*-BuMgBr, or PhMgI) also showed the activity similar to that of (η^5-$C_5Me_5)_2TiCl_2$/*i*-PrMgBr for the codimerization of PhC≡CH and *n*-BuC≡CH, suggesting that the resulted Ti-R(R=Et, *n*-Bu, Ph) bond is cleaved by RC≡CH to generate the catalytically active (η^5-$C_5Me_5)_2$TiC≡CR species. The isolation of (η^5-$C_5Me_5)_2$-TiC≡CR (R=*t*-Bu, 1-cyclohexenyl) and its stoichiometric reaction with various 1-alkynes are now in progress to get more evidence to verify the proposed mechanism.

Experimental

General Procedure. All operations were conducted with Schlenk technique under an argon atmosphere. 1-Butyne, 1-pentyne, 1-hexyne, 1-octyne, ethynylbenzene, and 3-oxa-1-pentyne were obtained commercially (Tokyo Kasei Co.), and 3,3-dimethyl-1-butyne,[25] ethynylcyclohexane,[26] 1-ethynylcyclohexene,[27] 3-trimethylsilyl-1-propyne,[28] *N*,*N*-diethylethynylamine,[29] and 3-thia-1-pentyne[30] were prepared by the reported methods. 3-Trimethylsiloxy-1-propyne was prepared from 2-propyn-1-ol and chlorotrimethylsilane. Ethynyltrimethylsilane was prepared from chlorotrimethylsilane and sodium ethynide (suspended in xylene) in DMF. All the ethynyl compounds were purified by distillation after drying over calcium hydride. (η^5-$C_5H_5)_2TiCl_2$[31] and (η^5-$C_5Me_5)_2TiCl_2$[32] were prepared referring to literatures. The GLC analyses were carried out with a Yanagimoto Model G-80 gas chromatograph using a column packed with Celite-Silicone DC-550, and the separation of products were done with a Varian-Aerograph Model 700 gas chromatograph using a column packed with DEGS. ^{1}H- and ^{13}C-NMR spectra were recorded on a Varian XL-100 and a JEOL 90Q instruments, respectively. IR spectra were obtained on a Hitachi EPI-2 spectrometer. Mass spectra were recorded on a JEOL JMS-OISG-2 spectrometer.

Dimerization of 1-Alkynes. To a stirred suspension of dichlorobis(η^5-pentamethylcyclopentadienyl)titanum (39 mg, 0.1 mmol) in diethyl ether (1 cm^3) was added a diethyl ether solution of isopropylmagnesium bromide (*f*=0.97, 0.21 cm^3, 0.2 mmol). The color of the solution immediately turned into deep blue. After stirring the mixture for 10 min at 0 °C, 1-alkyne (5.0 mmol) was added to the resulting catalyst system over a 1 min period. The mixture was allowed to warm to 30 °C, magnetically stirred for 1—3 h, and then quenched with a small portion of 1 mol dm^{-3} aq HCl. The product was distilled and separated into the individual isomers on a preparative gas chromatograph when the separation was necessitated. Characterization of the product was made in terms of the ^{1}H-NMR (100 MHz), mass, IR spectra, and elemental analysis together with the ^{13}C-NMR (22.5 MHz) spectrum (Table 5).

2-Ethyl-1-hexen-3-yne (1a): ^{1}H NMR($CDCl_3$) δ=1.10 (3H, t, *J*=8.0 Hz, $C\underline{H}_3CH_2C$≡C), 1.17 (3H, t, *J*=8.0 Hz, $C\underline{H}_3CH_2C$≡C), 2.16 (2H, q, *J*=8.0 Hz, CH_2C≡C), 2.32 (2H, q, *J*=8.0 Hz, CH_2C≡C), 5.13, 5.18 (2H, m, C=CH_2). 2-Butyl-1-octen-3-yne (1c): ^{1}H NMR ($CDCl_3$) δ=0.91, 0.92 (6H, t, *J*=7.0 Hz, CH_3), 1.1—1.7 (8H, m, CH_2CH_2), 2.14 (2H, t, *J*=7.0 Hz, CH_2C=C), 2.32 (2H, t, *J*=7.0 Hz, CH_2C≡C), 5.12, 5.19 (2H, m, C=CH_2). IR (neat) 3100, 2960, 2935, 2880, 2870, 2740, 1612, 1467, 1382, 1331, 1107, 892 cm^{-1}. MS (70 eV) *m*/*z* (rel intensity), 164 (M^+, 1), 122 (5.8), 107 (6.1). Found: C, 87.53; H, 12.30%. Calcd for $C_{12}H_{20}$: C, 87.73; H, 12.27%.

2-Hexyl-1-decen-3-yne (1d): ^{1}H NMR ($CDCl_3$) δ=0.90 (6H, t, *J*=6.0 Hz, CH_3), 1.1—1.7 (16H, m, $(CH_2)_4$), 2.13 (2H, t, *J*=7.0 Hz, CH_2C=C), 2.30 (2H, t, *J*=7.0 Hz, CH_2C≡C), 5.11, 5.19 (2H, m, C=CH_2). IR (neat) 3090, 2960, 2930, 2860, 2730, 1612, 1466, 892 cm^{-1}. MS (70 eV) *m*/*z* (rel intensity) 220 (M^+, 1), 205 (0.5), 191 (0.9). Found: C, 87.13, H, 12.86%. Calcd for $C_{16}H_{28}$: C, 87.20; H, 12.80%.

2,4-Dicyclohexyl-1-buten-3-yne (1e): ^{1}H NMR ($CDCl_3$) δ=1.0—2.1 (20H, m, cyclohexyl), 1.9—2.2 (1H, m, $(CH_2)_5C\underline{H}C$=C), 2.3—2.7 (1H, m, $(CH_2)_5C\underline{H}C$≡C), 5.11, 5.17 (2H, m, C=CH_2). IR (neat) 3090, 2930, 2860, 2220, 1607, 1450, 888 cm^{-1}. MS (70 eV) *m*/*z* (rel intensity), 216 (M^+, 1), 201 (0.2), 187 (0.3), 173 (0.5). Found: C, 88.49; H, 11.31%. Calcd for $C_{16}H_{24}$: C, 88.82; H, 11.18%.

2,4-Diphenyl-1-buten-3-yne (1f): ^{1}H NMR ($CDCl_3$) δ=5.74, 5.95 (2H, d, J=8.0 Hz, C=CH_2), 7.10—7.80 (10H, m, Ph). IR (neat) 3060, 3035, 2210, 1589, 1572, 1492, 1445, 1338, 1071, 1027, 897, 776, 760, 695 cm^{-1}. MS (70 eV) m/z (rel intensity), 204 (M^+, 1), 203 (0.7), 202 (0.6). Found: C, 93.60; H, 5.96%. Calcd for $C_{16}H_{12}$: C, 94.08; H, 5.92%.

2,4-Bis(trimethylsilyl)-1-buten-3-yne (1g): ^{1}H NMR ($CDCl_3$) δ=0.15 (9H, s, Me_3SiC=C), 0.19 (9H, s, Me_3SiC≡C), 5.68 (1H, d, J=3.0 Hz, C=CH), 6.10 (1H, d, J=3.0 Hz, C=CH). IR (neat) 3075, 2965, 2905, 2135, 1245, 973, 926, 840, 760, 698 cm^{-1}. MS (70 eV) m/z (rel intensity), 196 (M^+, 1), 181 (2.1), 155 (2.5). Found: C, 61.06; H, 10.25%. Calcd for $C_{10}H_{20}Si_2$: C, 61.14; H, 10.26%.

5-Trimethylsilyl-2-trimethylsilylmethyl-1-penten-3-yne (1h): ^{1}H NMR ($CDCl_3$) δ=0.03 (9H, s, $\underline{Me_3}SiCH_2C$=C), 0.10 (9H, s, $\underline{Me_3}SiCH_2C$≡C), 1.57 (2H, s, CH_2C≡C), 1.73 (2H, m, CH_2C=C), 4.86, 5.03 (2H, m, C=CH_2). IR (neat) 3100, 2960, 2900, 2230, 1595, 1292, 1245, 1158, 932, 850, 765, 698 cm^{-1}. MS (70 eV) m/z (rel intensity), 224 (M^+, 1), 209 (0.7), 136 (2.0). Found: C, 64.12; H, 10.75%. Calcd for $C_{12}H_{24}Si_2$: C, 64.20; H, 10.78%.

2-Trimethylsiloxymethyl-4-trimethylsiloxy-1-penten-3-yne (1i): ^{1}H NMR ($CDCl_3$) δ=0.14 (9H, s, $\underline{Me_3}SiOCH_2C$=C), 0.19 (9H, s, $\underline{Me_3}SiOCH_2C$≡C), 4.11 (2H, t, J=2.0 Hz, OCH_2C=C), 4.41 (2H, s, OCH_2C≡C), 5.45, 5.55 (2H, m, C=CH_2). IR (neat) 2960, 2860, 1621, 1372, 1248, 1119, 1097, 1037, 872, 844, 756cm^{-1}. MS (70 eV) m/z (rel intensity), 256 (M^+, 1), 255 (1.1), 241 (1.9), 177 (2.4), 147 (5.6). Found: C, 56.42; H, 9.42%. Calcd for $C_{12}H_{24}O_2Si_2$: C, 56.19; H, 9.43%.

Codimerization of RC≡CH with R'C≡CH. The procedure is essentially the same as that described for the homodimerization of 1-alkynes. For a typical example, a mixture of 1-hexyne (205 mg, 2.5 mmol) and ethynylbenzene (255 mg, 2.5 mmol) was added to the catalyst system, (η^5-$C_5Me_5)_2TiCl_2$/i-PrMgBr (0.1 mmol/0.2 mmol), in diethyl ether (0.3 cm^3) at 0 °C and the mixture was stirred for a fixed time (1—3 h) at 30 °C. After the addition of 1 mol dm^{-3} aq HCl (0.3 cm^3), the organic layer was distilled to give 2-butyl-4-phenyl-1-buten-3-yne (**4o**) in 98% GC yield (90% isolated yield). This procedure was applied for the codimerization of other 1-alkynes and the separation of the isomers was made on a preparative gas chromatograph. The ^{1}H NMR, mass, and IR spectral data for the major products were given below. Elemental analysis agreed well with the calculated values.

2-Ethyl-1-octen-3-yne (4a): ^{1}H NMR ($CDCl_3$) δ=0.92 (3H, t, J=8.0 Hz, CH_3), 1.08 (3H, t, J=8.0 Hz, CH_3), 1.20—1.70 (4H, m, CH_2CH_2), 2.16 (2H, q, J=8.0 Hz, CH_2C=C), 2.31 (2H, t, J=7.2 Hz, CH_2C≡C), 5.12, 5.19 (2H, m, C=CH_2). IR (neat) 3100, 2240, 1615, 893 cm^{-1}. MS (70 eV) m/z (rel intensity) 136 (1), 121 (0.9), 107 (1.9).

2-Butyl-1-hexen-3-yne (5a): ^{1}H NMR ($CDCl_3$) δ=0.91 (3H, t, J=8.0 Hz, CH_3), 1.16 (3H, t, J=8.0 Hz, CH_3), 1.2—1.7 (4H, m, CH_2CH_2), 2.12 (2H, t, J=7.0 Hz, CH_2C=C), 2.31 (2H, q, J=8.0 Hz, CH_2C≡C), 5.12, 5.19 (2H, m, C=CH_2). IR (neat) 3100, 2240, 1615, 890 cm^{-1}. MS, m/z (rel intensity), 136, 121.

2-Butyl-4-cyclohexyl-1-buten-3-yne (4b): ^{1}H NMR ($CDCl_3$) δ=0.90 (3H, t, J=7.2 Hz, CH_3), 1.1—2.0 (14H, m, CH_2CH_2 and C_6H_{11}), 2.13 (2H, t, J=7.0 Hz, CH_2C=C), 2.30—2.70 (1H, m, CH in C_6H_{11}), 5.12, 5.20 (2H, m, C=CH_2). IR (neat) 3090, 2225, 1610, 889 cm^{-1}. MS, m/z (rel intensity), 190 (1), 175 (0.2), 161 (1.3), 148 (1.8).

2-Butyl-5,5-dimethyl-1-hexen-3-yne (4c): ^{1}H NMR($CDCl_3$) δ=0.92 (3H, t, J=7.1 Hz, CH_3), 1.25 (9H, s, $C(CH_3)_3$), 1.25—1.66 (4H, m, CH_2), 2.30 (2H, t, J=7.0 Hz, CH_2C=C), 5.10, 5.19 (2H, m, C=CH_2). IR (neat) 3100, 2225, 1612, 892 cm^{-1}. MS, m/z (rel intensity), 164 (1), 149 (1.2), 122 (3.1), 107 (18).

2-Butyl-4-trimethylsilyl-1-buten-3-yne (4d): ^{1}H NMR ($CDCl_3$) δ=0.18 (9H, s, Me_3Si), 0.91 (3H, t, J=7.0 Hz, CH_3), 1.12—1.72 (4H, m, CH_2), 2.14 (2H, t, J=7.0 Hz, CH_2C=C), 5.21, 5.33 (2H, m, C=CH_2). IR (neat) 3100, 2155, 1605 cm^{-1}. MS, m/z (rel intensity), 180 (1), 165 (4.8), 138 (2.9).

2-Cyclohexyl-5,5-dimethyl-1-hexen-3-yne (4e): ^{1}H NMR ($CDCl_3$) δ=1.0—1.5 (6H, m, CH_2), 1.26 (9H, s, $C(CH_3)_3$), 1.5—1.9 (4H, m, CH_2), 1.9—2.2 (1H, m, CH in C_6H_{11}), 5.08, 5.15 (2H, m, C=CH_2). IR (neat) 3090, 2215, 1607 cm^{-1}. MS, m/z (rel intensity), 190 (1), 175 (0.8), 161 (0.5), 147 (0.6).

2-Hexyl-5-trimethylsilyl-1-penten-3-yne (4f): ^{1}H NMR ($CDCl_3$) δ=0.12 (9H, s, Me_3Si), 0.89 (3H, t, J=6.3 Hz, CH_3), 1.20—1.58 (8H, m, CH_2) 1.60 (2H, s, CH_2C≡C), 2.12 (2H, t, J=7.0 Hz, CH_2C=C), 5.07, 5.14 (2H, m, C=CH_2). IR (neat) 3095, 2230, 1612 cm^{-1}. MS, m/z (rel intensity), 222 (1), 207 (1.0), 193 (0.7), 179 (1.0).

4-Trimethylsilyl-2-trimethylsilylmethyl-1-buten-3-yne (4g): ^{1}H NMR ($CDCl_3$) δ=0.05 (9H, s, $\underline{Me_3}SiCH_2$), 0.15 (9H, s, Me_3SiC≡C), 1.65 (2H, m, $SiCH_2C$=C), 5.01, 5.21 (2H, m, C=CH_2). IR (neat) 3100, 2150, 1595 cm^{-1}. MS, m/z (rel intensity), 210 (1), 195 (0.7), 155 (1.3).

2-Trimethylsiloxymethyl-1-octen-3-yne (4h): ^{1}H NMR ($CDCl_3$) δ=0.14 (9H, s, Me_3Si), 0.93 (3H, t, J=7.1 Hz, CH_3), 2.22—2.72 (4H, m, CH_2), 2.31 (2H, t, J=7.0 Hz, CH_2C≡C), 4.09 (2H, t, J=2.0 Hz, OCH_2C=C), 5.34, 5.46 (2H, m, C=CH_2). IR (neat) 2235, 1620 cm^{-1}. MS, m/z (rel intensity), 210 (1), 195 (1.8), 137 (12).

5,5-Dimethyl-2-trimethylsiloxymethyl-1-hexen-3-yne (4i): ^{1}H NMR ($CDCl_3$) δ=0.12 (9H, s, Me_3Si), 1.23 (9H, s, $(CH_3)_3C$), 4.06 (2H, t, J=2.0 Hz, OCH_2C=C), 5.31, 5.43 (2H, m, C=CH_2). IR (neat) 2225, 1620, 878 cm^{-1}. MS, m/z (rel intensity), 210 (1), 195 (1.4), 153 (0.3).

2-Butyl-4-(1-cyclohexenyl)-1-buten-3-yne (4j): ^{1}H NMR ($CDCl_3$) δ=0.91 (3H, t, J=7.2 Hz, CH_3), 1.14—1.85 (8H, m, CH_2), 1.94—2.35 (6H, m, CH_2C=C), 5.16, 5.25 (2H, m, C=CH_2), 6.0—6.2 (1H, m, CH=C). IR (neat) 3100, 2205, 1605 cm^{-1}. MS, m/z (rel intensity), 188 (1), 173 (0.1), 159 (0.1), 146 (2.4).

4-(1-Cyclohexenyl)-2-trimethylsilylmethyl-1-buten-3-yne (4k): ^{1}H NMR ($CDCl_3$) δ=0.08 (9H, s, Me_3Si), 1.45—1.85 (4H, m, CH_2), 1.69 (2H, m, $SiCH_2C$=C), 1.90—2.32 (4H, m, CH_2C=C), 4.97, 5.14 (2H, m, C=CH_2), 6.00—6.18 (1H, m, CH=C). IR (neat) 3095, 2200, 1592 cm^{-1}. MS, m/z (rel intensity), 218 (1), 203 (0.5), 190 (0.2), 175 (0.3).

4-(1-Cyclohexenyl)-2-trimethylsiloxymethyl-1-buten-3-yne (4l): ^{1}H NMR ($CDCl_3$) δ=0.8 (9H, s, Me_3Si), 1.40—1.72 (4H, m, CH_2), 4.06 (2H, m, OCH_2C=C), 1.86—2.24 (4H, m, CH_2C=C), 5.33, 5.44 (2H, m, C=CH_2), 6.00 —6.18 (1H, m, CH=C). IR (neat) 3095, 2205, 1610 cm^{-1}. MS, m/z (rel intensity), 234 (1), 219 (0.8), 206 (0.2).

4-(1-Cyclohexenyl)-2-trimethylsilyl-1-buten-3-yne (4m): ^{1}H NMR ($CDCl_3$) δ=0.15 (9H, s, Me_3Si), 1.44—1.80 (4H, m, CH_2), 1.96—2.38 (4H, m, CH_2C=C), 5.64 (1H, d, J=3.0 Hz, CH=C), 6.00 (1H, d, J=3.0 Hz, CH=C), 6.03—6.15 (1H, m, CH=C in C_6H_9). IR (neat) 3065, 2180 cm^{-1}. MS, m/z (rel intensity), 204 (1), 189 (0.3), 176 (0.1), 163 (0.7).

4-(1-Cyclohexenyl)-2-cyclohexyl-1-buten-3-yne (4n): ^{1}H NMR ($CDCl_3$) δ=1.0—1.95 (14H, CH_2), 1.95—2.30 (5H, m, CH in C_6H_{11} and CH_2C=C), 5.15, 5.20 (2H, m, C=CH_2), 5.98—6.18 (1H, m, CH=C). IR (neat) 3090, 2200, 1600, 888 cm^{-1}. MS, m/z (rel intensity), 214 (1), 199 (0.3), 185 (0.5), 171 (0.4).

2-Butyl-4-phenyl-1-buten-3-yne (4o): ^{1}H NMR ($CDCl_3$) δ=0.95 (3H, t, J=7.0 Hz, CH_3), 1.20—1.75 (4H, m, CH_2), 2.27 (2H, t, J=7.5 Hz, CH_2C=C), 5.28, 5.41 (2H, m, C=CH_2), 7.16—7.56 (5H, m, Ph). IR (neat) 2960, 2935, 2880, 1609, 1490, 1443, 897 cm^{-1}. MS, m/z (rel intensity), 184 (1), 142 (7.6), 141 (5.4), 127 (2.5).

4-Phenyl-2-trimethylsilylmethyl-1-buten-3-yne (4p): ^{1}H NMR ($CDCl_3$) δ=0.11 (9H, s, Me_3Si), 1.77 (2H, m, $SiCH_2C$=C), 5.08, 5.28 (2H, m, C=CH_2), 7.16—7.50 (5H, m, Ph). IR (neat) 2220, 1600, 870 cm^{-1}. MS, m/z (rel intensity), 214 (1), 199

(0.5), 159 (3.1).

4-Phenyl-2-trimethylsiloxymethyl-1-buten-3-yne (4q): ^{1}H NMR ($CDCl_3$) δ=0.19 (9H, s, Me_3Si), 4.24 (2H, t, J=2.0 Hz, $OCH_2C{\equiv}C$), 5.48, 5.54 (2H, m, $C{=}CH_2$), 7.18—7.56 (5H, m, Ph). IR (neat) 3080, 2218, 1613 cm^{-1}. MS, m/z (rel intensity), 230 (1), 215 (1.1), 159 (0.5), 141 (1.2).

4-Phenyl-2-trimethylsilyl-1-buten-3-yne (4r): ^{1}H NMR ($CDCl_3$) δ=0.21 (9H, s, Me_3Si), 5.74 (1H, d, J=3.5 Hz, C=CH), 6.16 (1H, d, J=3.5 Hz, C=CH), 7.20—7.52(5H, m, Ph). IR (neat) 3080, 2190, 1596, 840 cm^{-1}. MS, m/z (rel intensity), 200 (1), 185 (0.6), 159 (1.0).

2-Cyclohexyl-4-phenyl-1-buten-3-yne(4s): ^{1}H NMR ($CDCl_3$) δ=1.1—1.9 (10H, m, CH_2), 2.1—2.3 (1H, m, CH in C_6H_{11}), 5.27, 5.38 (2H, m, $C{=}CH_2$), 7.12—7.56 (5H, m, Ph). IR (neat) 1607, 892 cm^{-1}. MS, m/z (rel intensity), 210 (1), 195 (0.3), 181 (0.7), 167 (0.6).

Identification of 2-Butyl-4-phenyl-1-buten-3-yne (4o): The structure of the sample was identified with authentic samples after converting it to (3-methylheptyl)benzene by hydrogenation on Pd-charcoal. The authentic sample was prepared from the reaction of phenethylmagnesium bromide with 2-hexanone followed by hydrolysis, dehydration with *p*-toluenesulfonic acid and hydrogenation on Pd-charcoal.

(3-Methylheptyl)benzene: ^{1}H NMR ($CDCl_3$) δ=0.76—1.05 (6H, m, CH_3), 1.07—1.80 (9H, m, CH_2), 2.36—2.80 (2H, m, $C\underline{H}_2Ph$), 7.00—7.42 (5H, m, Ph). IR (neat) 3025, 2940, 2925, 2880, 2860, 1604, 1455, 747, 700 cm^{-1}

Identification of 2-Trimethylsiloxymethyl-1-octen-3-yne (4h). A pure sample of the dimer (700 mg, 3.3 mmol) was treated with 0.1 mol dm^{-3} aq NaOH (1 cm^3) in 5 cm^3 methanol to give 2-hydroxymethyl-1-octen-3-yne in 83% yield which was then converted to a 1:1 mixture of 2-methyl-1-octanol and 2-methyloctanal by hydrogenation on Pd-C. The structure of these two products was identified with authentic samples in terms of the ^{1}H NMR and IR spectra, and gas chromatographic analysis. 2-Methyl-1-octanol was prepared by the literature procedure[33] and was converted to 2-methyloctanal by reaction with pyridinium chlorochromate[34] in CH_2Cl_2.

Analysis of Codimers Obtained from Monodeuterio-1-alkynes. PhC≡CD and *n*-BuC≡CD were prepared by deuteration of PhC≡CMgBr or *n*-BuC≡CMgBr with D_2O (99.5% purity) and were reacted with *n*-BuC≡CH and PhC≡CH, respectively, under the same reaction conditions as described above.

(E)-*2-Butyl-4-phenyl-1-buten-3-yne-1*d ((E)-*4o-1*d): ^{1}H NMR ($CDCl_3$) δ=0.95 (3H, t, CH_3), 1.21—1.74 (4H, m, CH_2), 2.28 (2H, t, $CH_2C{\equiv}C$), 5.41 (1H, m, C=CHD) 7.2—7.5 (5H, m, Ph). IR (neat) 2960, 2940, 2880, 2860, 2260, 2220, 1598, 1580, 1490, 1445, 849 cm^{-1}. MS (70 eV) m/z (rel intensity), 185 (M^+).

(Z)-*2-Butyl-4-phenyl-1-buten-3-yne-1*d ((Z)-*4o-1*d): ^{1}H NMR ($CDCl_3$) δ= 0.95 (3H, t, CH_3), 1.21—1.74 (4H, m, CH_2), 2.28 (2H, t, $CH_2C{\equiv}C$), 5.28 (1H, m, C=CHD) 7.1—7.4 (5H, m, Ph). IR (neat) 2960, 2940, 2880, 2860, 2280, 2240, 1598, 1583, 1490, 1445, 842 cm^{-1}. MS (70 eV) m/z (rel intensity), 185 (M^+).

Preparation of 2-(2-methylpropyl)-4-phenyl-1-buten-3-yne (4t). After treating (η^5-$C_5Me_5)_2TiCl_2$ (39 mg, 0.1 mmol) with isopropylmagnesium bromide (f=0.97, 3.1 cm^3, 3.0 mmol) in diethyl ether (1 cm^3), an equimolar mixture of ethynylbenzene (2.5 mmol) and 3-trimethylsiloxy-1-propyne (2.5 mmol) was added to the resulting solution. The mixture was stirred at 30 °C for 3 h and then quenched with aq HCl. Fractional distillation gave **4t** in 83% yield. ^{1}H NMR ($CDCl_3$) δ=0.97 (6H, d, J=6.0 Hz, $(C\underline{H}_3)_2CH$), 1.80—2.20 (3H, m, $(CH_3)_2C\underline{H}C\underline{H}_2$), 5.27, 5.45 (2H, m, $C{=}CH_2$), 7.20—7.56 (5H, m, Ph). IR (neat) 2960, 2930, 2880, 2220, 1609, 1466, 1443, 1386, 1370, 1315, 901, 758, 695 cm^{-1}. MS, m/z (rel intensity), 184 (1), 169 (1.0), 142 (2.0), 141 (1.4).

We thank Shin-etsu Chemical Industrial Co., Ltd. for supplying sodium ethynide.

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 3, 1983)

Cyclopentadiene was hydrogenated to cyclopentene selectively by using colloidal palladium supported on chelate resin with iminodiacetic acid moieties as a catalyst. The catalyst, containing metal particles of 1—6 nm in diameter, was prepared by reduction of the palladium(II)-chelate resin complex with methanol. Cyclopentene was produced in 97.1% yield at 100% conversion of cyclopentadiene at 30 °C under 1 atm of hydrogen. This value in yield was also achieved on repeated uses of the catalyst. The hydrogenation rate was correlated to the polarity parameter, $E_T(30)$ values, of the solvents used in the reaction, except in the case of dimethyl sulfoxide. The hydrogenation rates of cyclopentadiene (R_D) and cyclopentene (R_E) were expressed as $R_D=k_D[H_2][\text{catalyst}]$ and $R_E=k_E[H_2][\text{cyclopentene}][\text{catalyst}]$, respectively, where k_D and k_E are the rate constants. The equilibrium constant for complex formation between cyclopentadiene and the catalyst, K_D, was estimated to be over 400 times larger than that between cyclopentene and the catalyst, K_E. A mechanism, including the coordination of olefins to the catalyst and the subsequent hydrogenation of the coordinated complexes, was proposed.

Much attention has been paid for heterogenized transition-metal complex catalysts, since recovering and reusing of catalysts are indispensable in practical use of expensive noble metals.[1-4] The heterogenized homogeneous catalysts on organic or inorganic supports often have efficient catalytic properties of homogeneous analogs. Furthermore, the heterogenized catalysts sometimes have advantages in catalyst stability and reaction selectivity. Metal complexes in the heterogenized catalysts have various structures, *e.g.*, chelated structures, dimeric structures, and metal cluster structures, according to the preparative conditions.

We have already shown that finely dispersed colloidal transition metals were obtained by reduction of metal salts with alcohols in the presence of vinyl polymer with polar groups.[5-7] The particle sizes of these colloidal metals were below several nm in diameter, and were distributed in narrow ranges. Some of them exhibited specific selectivities as hydrogenation catalysts for olefins.[8,9] Chini[10] has pointed out that large metal carbonyl clusters could be applied to the chemistry of small metal particles (0.5—3 nm). Finely dispersed colloidal metals supported on polymers could be regarded as macromolecular complexes of metal clusters. Recently, we have reported on the preparation and the characterization of colloidal palladium catalysts supported on chelate resins with iminodiacetic acid moieties.[11] The chelate resin-supported catalysts were composed of small palladium metal particles and palladium complexes with iminodiacetic acid moieties. The sizes of metal particles were distributed from 1 to 6 nm and mainly from 1 to 2 nm. The metal particles in the resin-supported catalyst had catalytic activities for selective hydrogenation of diene to monoenes. The selective hydrogenation of cyclopentadiene is a significant process for utilization of the C_5 fraction of naphtha cracking products.[12,13] Furthermore, cyclopentadiene is one of the simplest dienes as a substrate for partial hydrogenation, since cyclopentadiene and cyclopentene have no isomers, respectively.

In the present paper the selective hydrogenation of cyclopentadiene to cyclopentene using the resin-supported colloidal palladium will be reported in detail with attention to the swelling effect of the polymer matrix on the catalytic properties.

Experimental

Materials. A chelate resin with iminodiacetic acid moieties attached to a styrene-divinylbenzene copolymer matrix, Diaion CR10 (Mitsubishi Chemical Ind. Co. Ltd., the size of the resin bead ranged from 0.3 to 1.2 mm in diameter in the swelled state) was used as a supporting polymer. The resin-supported colloidal palladium was prepared as follows: Palladium(II) chloride (Kojima Chemical Co. Ltd.) and the chelate resin were kept under stirring in water (pH 3) at room temperature for 1 h to form the palladium complex of the chelate resin, and the resulting complex was kept under refluxing in methanol-water (1:1)(pH 11) for 6 h as described previously.[11] The catalyst was preserved in methanol. One cubic centimeter of the resin-supported Pd catalyst swelled in methanol contained 18.5 μg-atom of palladium. The charged molar ratio of iminodiacetic acid moiety to palladium atom was 75.

Cyclopentadiene was obtained by pyrolysis of dicyclopentadiene (Yoneyama Chemical Co. Ltd.), and was purified by distillation under argon before use. Cyclopentene and cyclopentane were obtained from Tokyo Chemical Ind. Co. Ltd. and were distilled under argon.

Commercial guaranteed reagent grade methanol was used after distillation under argon. Ethanol, benzene, hexane, ethyl methyl ketone, ethyl acetate, *N*,*N*-dimethylformamide, and dimethyl sulfoxide at guaranteed reagent grade were used after removal of oxygen. *N*-Benzyliminodiacetic acid was obtained from Aldrich Chemical Co. Inc. Five percent Pd on charcoal was obtained from Nippon Engelhard Ltd.

Commercial pure grade hydrogen (Nippon Oxygen Ltd., 99.99999% of purity) was passed through a Deoxo column (Nippon Engelhard Ltd.) before use to remove trace amounts of oxygen.

Hydrogenation in Methanol. The measured volume (0—2.69 cm^3) of resin-supported Pd catalyst in methanol was put in a 100 cm^3 flask which was attached to the shaker with thermostat (Tokyo Rikakikai Co. Ltd.). After the atmosphere in the flask was replaced with hydrogen, methanol [$(20-x-y)$ cm^3] was added into the flask and the flask was shaken for 1 h. A methanol solution (x cm^3) of cyclopentadiene or cyclopentene (2 mol/dm^3 each) and a methanol solution (y cm^3) of cyclopentane (2 mol/dm^3) were added into the flask, and the flask was shaken vigorously to start the reaction keeping the total pressure in the flask at 1 atm.

The rates of the hydrogenations were determined by the initial rates of the hydrogen uptake.

For the discussion on kinetics, the initial rates with the fresh catalysts were used. The dependence of the rate on hydrogen partial pressure was measured by using the mixed gases of hydrogen and nitrogen. The mixed gases were prepared by adding each gas into a high pressure vessel of stainless steel in different fixed ratios.

Hydrogenation in Other Solvents. Resin-supported Pd catalyst (2.69 cm^3) separated from methanol was washed with a solvent which should be used for the hydrogenation reaction, and kept in the solvent for more than 1 h. After removal of the solvent, the flask containing the catalyst was mounted in the thermostated shaker. The atmosphere in the flask was replaced with hydrogen, and the solvent (19.7 cm^3) was added. After the flask was shaken for 1 h, cyclopentadiene (0.33 cm^3, 4 mmol) was added into the flask, which was shaken vigorously to start the reaction keeping the total pressure at 1 atm.

Analysis of the Products. The products were analyzed with GLPC by using a glass capillary column of Silicone OV-101 (0.28 mmϕ×30 m) at 20 °C with a flame ionization detector. In the present paper, the selectivity (S%) is defined by the yield of cyclopentene at the point of complete disappearance of cyclopentadiene in the reaction mixtures.

Reaction in Gas-phase Using a Closed Circulation System. Resin-supported Pd catalyst (2.69 cm^3) separated from methanol was supported with glass wool in a reactor. Hydrogen, cyclopentadiene, and methanol were introduced into a circulation system from respective vessels by means of the pressure difference. All parts of the reactor system were composed of either Pyrex glass or Teflon, and the volume of the reaction circuit was 940 cm^3. The reaction was started by connecting the circulation system with the reactor. Gaseous mixtures in the reactor were analyzed periodically with GLPC.

Results

Hydrogenation of Cyclopentadiene in Methanol. Selective hydrogneation of cyclopentadiene to cyclopentene took place by using resin-supported Pd catalyst in methanol at 30 °C under an atmospheric pressure of hydrogen. The volume of hydrogen taken up increased proportionally to the reaction time up to the amount equimolar with cyclopentadiene as indicated in Fig. 1 (No. 1). As shown in the preceding paper,[11] the active species of resin-supported Pd catalyst is metallic palladium. The amount of the metallic palladium is 5% of the charged amount of palladium, *i.e.*, 0.93 μg-atom Pd per 1 cm^3 of the resin catalyst. Hydrogenation rates were represented as rates of hydrogen uptake divided by the amount of metallic palladium in the catalyst. The hydrogenation rate decreases to about one-fifth of the initial rate after the conversion of cyclopentadiene reaches 100% as shown in Fig. 1. This decrease of the rate facilitates the isolation of cyclopentene in a high yield because of the minimum subsequent hydrogenation of cyclopentene. The composition of the products was followed by gas chromatographic analyses. The results are presented by circles in Fig. 2. Cyclopentene was obtained in 97.1% yield at complete conversion of cyclopentadiene by using the fresh resin-supported Pd catalyst.

The catalyst can be separated from the reaction mixtures and can be used again as a catalyst. The initial rate of hydrogen uptake and the selectivity for cyclopentene by using fresh and recovered resin-supported Pd catalysts are summarized in Table 1 as well as those with reference catalysts. When palladium on charcoal is used as a catalyst, cyclopentene is obtained in 88.4% yield. The addition of 75-fold molar amount of *N*-benzyliminodiacetic acid disodium salt to the palladium on charcoal results in 93.2% yield of cyclopen-

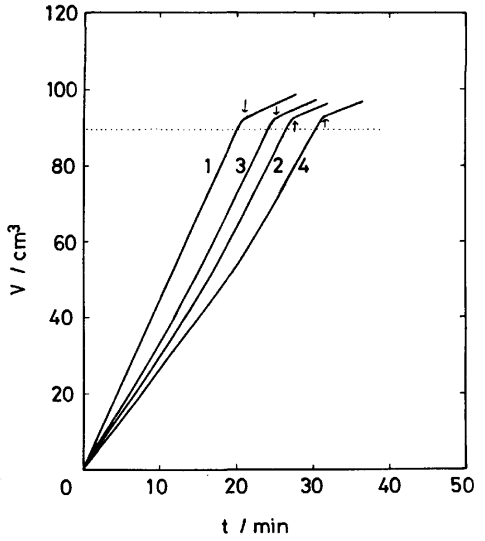

Fig. 1. Hydrogen uptakes (V) against reaction time in the hydrogenation of cyclopentadiene with the fresh (1), reused (2, 3), and pretreated (4) resin-supported Pd catalyst at 30 °C under an atmospheric hydrogen pressure. The dotted line shows the amount equimolar with cyclopentadiene. The arrows represent the points at which 100% conversion of cyclopentadiene was achieved.

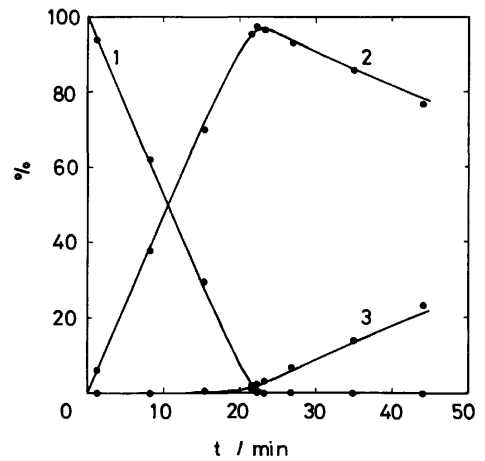

Fig. 2. Experimental and calculated composition (%) of the substrate and products in the hydrogenation of cyclopentadiene. Circles show the experimental values of composition of cyclopentadiene, cyclopentene, and cyclopentane under the conditions [metallic Pd]=0.125 (mol/dm^3), initial concentration of cyclopentadiene=0.2 (mol/dm^3), and $[H_2]$=0.003 (mol/dm^3). The curves are calculated for cyclopentadiene (1), cyclopentene (2), and cyclopentane (3) by assuming k_2=440 (dm^3/mol s), k_4=1000 (dm^3/mol s), m=200 (dm^3/mol) and n=0.5 (dm^3/mol).

Table 1. Hydrogenation of cyclopentadiene[a)]

Run	Catalyst	$r/10^{-1}\,s^{-1}$[b)]	S (%)[c)]
1	Fresh resin-supported Pd	13.4	97.1
2	Recovered resin-supported Pd from run 1	8.2	97.3
3	Recovered resin-supported Pd from run 2	9.4	96.7
4	Resin-supported Pd pretreated with cyclopentane[d)]	7.2	96.6
5	Resin-supported Pd stored in methanol[e)]	13.4	96.7
6	Resin-supported Pd stored in water[e)]	13.6	97.0
7	Commercial Pd on charcoal (5%)	36.0	88.4
8	Pd on charcoal with NBIDA[f)]	37.1	93.2
9	Recovered Pd on charcoal from Run 8[g)]	—	88.9

a) Conditions: 30 °C; H_2, 580 Torr; solvent, methanol; [cyclopentadiene]=0.20 mol/dm^3. b) The initial rate of hydrogen uptake (mol/s) per one g-atom of metallic Pd in the catalyst. c) The selectivity; the yield of cyclopentene at 100% conversion of cyclopentadiene. d) Resin-supported Pd pretreated with methanol containing cyclopentane (0.2 mol/dm^3) for 1 h. e) Under air for 30 d. f) Five percent palladium on charcoal (2.13 mg containing 1 μg-atom of Pd) was used in the presence of *N*-benzyliminodiacetic acid disodium salt (NBIDA) (75 μmol) in methanol (20 cm^3). g) Palladium on charcoal recovered from the reaction mixture in run 8 by decantation was used. Since some of the catalyst was lost in the decantation procedure, the catalytic activity per Pd g-atom was not known exactly.

Table 2. Hydrogenation of cyclopentadiene in various solvents[a)]

Solvent	$r/10^{-1}\,s^{-1}$[b)]	S (%)[c)]	$E_T(30)$/kcal$_{th}$ mol^{-1}[d)]
Methanol	13.4	97.1	55.5
Ethanol	8.0	94.8	51.9
Dimethyl sulfoxide	0.06	—	45.0
N,*N*-Dimethylformamide	7.4	95.6	43.8

Benzene	4.4	94.7	34.5
Hexane	0.62	—	30.9

a) Conditions: 30 °C; H_2 pressure=760 Torr—(vapor pressure of solvent media); catalyst, resin-supported Pd catalyst (2.69 cm^3); solvent, 20 cm^3; [cyclopentadiene]=0.2 mol/dm^3. b) The initial rate of hydrogen uptake (mol/s) per one g-atom of metallic Pd in the catalyst. c) The yield of cyclopentene at 100% conversion of cyclopentadiene. d) From Ref. 22.

tene (run 8). This value is slightly inferior to that with resin-supported Pd, but the yield is reduced to 88.9% by a repeated use of the catalyst (run 9).

After the reaction, the catalyst was separated from the reaction mixture, washed with methanol several times, kept in fresh methanol for 1 h, and then reused. The initial rate (run 2 in Table 1) with the reused resin-supported Pd catalyst is two-thirds of that with the fresh catalyst. But the rate gradually increased with reaction time and recovered to the original value near the hydrogen-uptake equimolar with the charged cyclopentadiene (run 2 in Fig. 1). The yield of cyclopentene at complete conversion of cyclopentadiene is the same as that with the fresh catalyst. When the reused resin-supported Pd catalyst is used again (run 3), the catalytic behavior is similar to that of run 2. To compare with this result, the fresh resin-supported Pd catalyst was kept in methanol containing cyclopentane (0.2 mol/dm^3) for 1 h, washed with methanol and then used as a catalyst. The results were similar to those of the catalyst in the repeated use, as shown at run 4 in Table 1 and Fig. 1.

When resin-supported Pd catalyst was stored in methanol or water under air for 30 d, no difference in the catalytic behavior was observed as shown at runs 5 and 6 in Table 1.

Hydrogenation of Cyclopentadiene in Various Solvents. Hydrogenations of cyclopentadiene in the presence of the resin-supported Pd catalyst were carried out in various solvents at 30 °C under an atmospheric pressure of hydrogen. The results are shown in Table 2 and Fig. 3. The highest activity and selectivity are achieved in methanol among the solvents examined. The hydrogen uptake curves in Fig. 3 are almost linear up to the point where the hydrogen-uptake is equimolar with the charged cyclopentadiene, and the slopes decrease gradually after the equimolar points. The decreasing extents of the rates near the equimolar points are different from each other. When methanol was used as a solvent, the decreasing extent is largest.

Kinetics for Hydrogenation of Cyclopentadiene in Methanol. The dependences of the initial rate on the concentration of cyclopentadiene, the amount of the catalyst, and the pressure of hydrogen were investigated.

Dependence upon Concentration of Cyclopentadiene: The rates of hydrogen uptake are plotted against the concentration (below 0.4 mol/dm^3) of cyclopentadiene in methanol with open circles in Fig. 4. The rate somewhat decreases with increase of the cyclopentadiene concentration. The initial rates were also measured under the condition that the sum of the respective concentrations of cyclopentadiene and cyclopentane was a constant value, 0.4 mol/dm^3, by adding

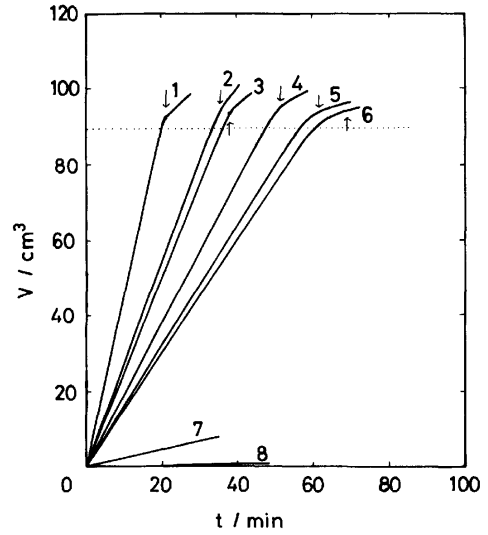

Fig. 3. Hydrogen uptakes (V) against reaction time in the hydrogenation of cyclopentadiene with the resin-supported Pd catalyst at 30 °C under an atmospheric hydrogen pressure in methanol (1), ethanol (2), *N*,*N*-dimethylformamide (3), ethyl acetate (4), ethyl methyl ketone (5), benzene (6), hexane (7), and dimethyl sulfoxide (8). The dotted line shows the amount equimolar with cyclopentadiene. The arrows represent the points at which 100% conversion of cyclopentadiene was achieved.

the appropriate amount of cyclopentane simultaneously at the addition of cyclopentadiene. The results are shown with closed circles in Fig. 4. The dependence of the rates upon the concentration of cyclopentadiene was essentially zero order.

Dependence upon Pressure of Hydrogen: The initial rates of hydrogenation of cyclopentadiene in methanol were measured under partial pressure of hydrogen below 580 Torr (1 Torr≈133.322 Pa). Dependence of the rate upon hydrogen pressure was the first order.

Dependence upon Amount of Catalyst: From the results with various amounts of the catalyst below 1.61 cm^3 in 20 cm^3 of methanol, dependence of the rate upon the amount of the catalyst was the first order.

Kinetic Expression: The kinetic experiments indicate that the rate of hydrogenation of cyclopentadiene, R_D, can be represented by the following Eq. 1, where k_D is a rate constant.

$$R_D=k_D[H_2][\text{catalyst}] \quad (1)$$

The constant k_D was determined at different temperature. The relationship of k_D with temperature is indicated in the Arrhenius plot in Fig. 5. The activation energy is calculated to be 8.0 $kcal_{th}$/mol (1 cal_{th}≈4.184 J) for the hydrogenation of cyclopentadiene.

Kinetics for the Hydrogenation of Cyclopentene in Methanol. Initial rates of the hydrogenation of cyclopentene catalyzed by resin-supported Pd were measured in methanol. Dependence of the rate upon the concentration of cyclopentene, the amount of the catalyst, and the partial pressure of hydrogen were determined.

Results under various cyclopentene concentrations below 0.4 mol/dm^3 are shown with open circles in Fig.

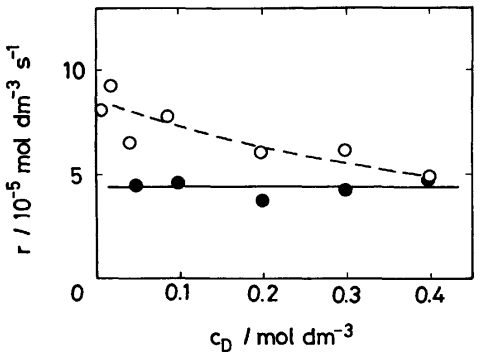

Fig. 4. Dependence of hydrogen uptake rate (r) on cyclopentadiene concentration (c_D) in methanol (20 cm^3) at 30 °C under 580 Torr of hydrogen with the resin-supported Pd catalyst (metallic Pd, 1 μg-atom) without (○) and with addition (●) of cyclopentane ([cyclopentadiene]+[cyclopentane]=0.4 mol/dm^3).

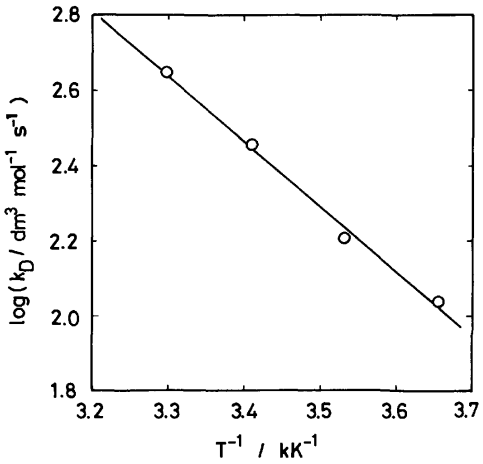

Fig. 5. Arrhenius plot for the rate constant in hydrogenation of cyclopentadiene in methanol.

6. The initial rates of hydrogenation were also measured under the condition that the sum of the respective concentrations of cyclopentene and cyclopentane was a constant value, 0.4 mol/dm^3, by adding the appropriate amount of cyclopentane simultaneously at the addition of cyclopentene. These results are shown with closed circles in Fig. 6, indicating that the dependence upon the cyclopentene concentration is the first order. The hydrogenation rates were measured under various hydrogen pressures below 580 Torr, and the dependence upon the hydrogen pressure was the first order. The rates with various amounts of the catalyst below 1.61 cm^3 in 20 cm^3 of methanol were measured, and the dependence of the rate upon the amount of the catalyst was the first order.

These kinetic experiments indicate that the rate of hydrogenation of cyclopentene, R_E, can be represented by Eq. 2, where k_E is a rate constant.

$$R_E=k_E[H_2][\text{cyclopentene}][\text{catalyst}] \quad (2)$$

Hydrogenation in Gas-phase. Hydrogenations of cyclopentadiene in gas-phase were carried out using a closed circulation system. When the methanol-swelled resin-supported Pd catalyst containing 2.5 μg-atom of metallic palladium was used, the hydrogena-

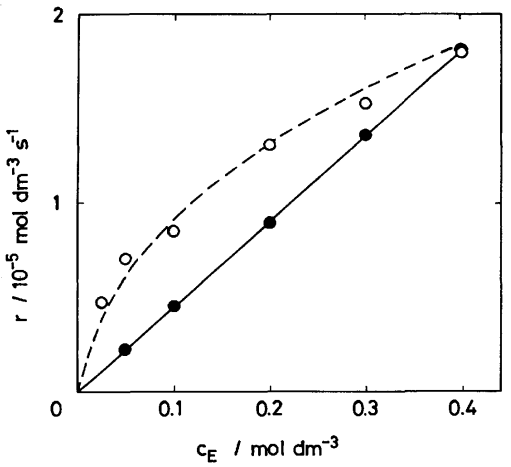

Fig. 6. Dependence of hydrogen uptake rate (r) on cyclopentene concentration (c_E) in methanol (20 cm³) at 30 °C under 580 Torr of hydrogen with the resin-supported Pd catalyst (metallic Pd, 1 μg-atom) without (○) and with addition (●) of cyclopentane ([cyclopentene]+[cyclopentane]=0.4 mol/dm³).

tion proceeded at 25 °C under 280, 70, and 70 Torr of initial partial pressures of hydrogen, cyclopentadiene, and methanol, respectively. After 104 min, the conversion of cyclopentadiene was 14% and the selectivity to cyclopentene was 96%. When the reaction was carried out at 50 °C, the hydrogenation was faster than that at 25 °C by the factor of 9 and the selectivity to cyclopentene at 14% conversion of cyclopentadiene was 90%. When the same gaseous mixture was circulated over the non-swelled resin-supported Pd catalyst (dried at 50 °C for 5 min under vacuum), no hydrogenation products were detected even after 100 min at 50 °C.

Discussion

Kinetics of Hydrogenation of Cyclopentadiene and Cyclopentene. When cyclopentadiene and cyclopentene are hydrogenated independently over the resin-supported Pd catalyst, Eqs. 1 and 2 represent the initial rates of each reaction. For example, the initial rate for cyclopentene is about one tenth of that for cyclopentadiene at 0.1 mol/dm³ of the substrates. When cyclopentadiene is present, however, cyclopentene is not hydrogenated so fast. Thus, cyclopentadiene reacts predominantly and the highly selective hydrogenation of cyclopentadiene to cyclopentene takes place as shown in Table 1 and Fig. 2. In this case, the rate for cyclopentadiene does not change with the reaction time, but the hydrogenation of cyclopentene is suppressed to a very low rate. Indeed, at the reaction time of 10 min in Fig. 2 the hydrogenation rate of cyclopentadiene is almost the same as the initial rate, but that of cyclopentene is nearly equal to zero, although each concentration of cyclopentadiene and cyclopentene is about 0.1 mol/dm³ at this point. This fact suggests that the coordination process of the substrate to the active species of the catalyst is important for the hydrogenation of cyclopentadiene and cyclopentene. Therefore, Eqs. 3—6 are proposed as a scheme, which includes the coordination processes, *i.e.*, the substrate forms an intermediate with the catalyst at first by coordination and then the intermediate reacts with hydrogen to give the product.

$$\text{cyclopentadiene} + \text{catalyst} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{cyclopentadiene - catalyst} \quad (3)$$

$$\text{cyclopentadiene - catalyst} + H_2 \xrightarrow{k_2} \text{cyclopentene} + \text{catalyst} \quad (4)$$

$$\text{cyclopentene} + \text{catalyst} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \text{cyclopentene - catalyst} \quad (5)$$

$$\text{cyclopentene - catalyst} + H_2 \xrightarrow{k_4} \text{cyclopentane} + \text{catalyst} \quad (6)$$

Similar schemes have been proposed for the hydrogenations of alkynes and alkenes using palladium metal catalysts on vitreous supports.[14] Since the active species, the small Pd metal particle, is fixed to the cross-linked polymer matrix, it is assumed that the active species do not affect each other.[15] So the amount of metallic Pd per unit volume of solvent can be used as the catalyst concentration in kinetic studies. The total concentrations of the catalyst, C, cyclopentadiene, D, and cyclopentene, E, are defined in the following equations, respectively:

$$[C] = [\text{catalyst}] + [\text{cyclopentadiene - catalyst}] + [\text{cyclopentene - catalyst}], \quad (7)$$

$$[D] = [\text{cyclopentadiene}] + [\text{cyclopentadiene - catalyst}], \quad (8)$$

$$[E] = [\text{cyclopentene}] + [\text{cyclopentene - catalyst}]. \quad (9)$$

Assuming the steady state (d[cyclopentadiene—catalyst]/dt=0, d[cyclopentene—catalyst]/dt=0) and the negligibly small concentration of the catalyst compared with substrates, Eqs. 10—12 are derived from Eqs. 3—9:

$$-\frac{d[D]}{dt} = [C][H_2]\frac{\dfrac{k_1k_2[D]}{k_{-1}+k_2[H_2]}}{1+\dfrac{k_1[D]}{k_{-1}+k_2[H_2]}+\dfrac{k_3[E]}{k_{-3}+k_4[H_2]}}, \quad (10)$$

$$\frac{d[E]}{dt} = [C][H_2]\frac{\dfrac{k_1k_2[D]}{k_{-1}+k_2[H_2]}-\dfrac{k_3k_4[E]}{k_{-3}+k_4[H_2]}}{1+\dfrac{k_1[D]}{k_{-1}+k_2[H_2]}+\dfrac{k_3[E]}{k_{-3}+k_4[H_2]}}, \quad (11)$$

$$\frac{d[A]}{dt} = [C][H_2]\frac{\dfrac{k_3k_4[E]}{k_{-3}+k_4[H_2]}}{1+\dfrac{k_1[D]}{k_{-1}+k_2[H_2]}+\dfrac{k_3[E]}{k_{-3}+k_4[H_2]}}, \quad (12)$$

where [A] is the concentration of cyclopentane.

When [E] equals to zero in Eq. 10,

$$-\frac{d[D]}{dt} = \frac{k_1k_2[D][C][H_2]}{k_1[D]+k_{-1}+k_2[H_2]}. \quad (13)$$

And when [D] equals to zero in Eq. 11,

$$\frac{d[E]}{dt} = \frac{-k_3k_4[E][C][H_2]}{k_3[E]+k_{-3}+k_4[H_2]}. \quad (14)$$

The initial rate for the hydrogenation of cyclopentadiene alone is expressed by Eq. 13. Since cyclopentadiene has large coordinating ability owing to its con-

jugated double bond,[16] it can be postulated for Eq. 13 that $k_1[D]$ is much larger than $(k_{-1}+k_2[H_2])$. Then Eq. 13 is simplified to Eq. 15:

$$-\frac{d[D]}{dt} = k_2[C][H_2]. \quad (15)$$

Eq. 15 agrees with the experimental result represented by Eq. 1. The rate constant k_2 $(=k_D)$ is calculated to be 440 (dm^3/mol s) from the experimental results. The activation energy (8.0 $kcal_{th}$/mol) obtained from the Arrhenius plot for k_D in the present reaction is comparable with that in the hydrogenation of 1,3-cyclooctadiene with polymer-bound palladium(II) complex catalyst.[17]

The initial rate for the hydrogenation of cyclopentene alone is expressed by Eq. 14 in the above scheme. It is necessary that k_{-3} is large enough comparing with $(k_3[E]+k_4[H_2])$ for Eq. 14 to be simplified to the experimental expression, Eq. 2. This will be discussed in the next section.

Selectivity in the Hydrogenation of Cyclopentadiene to Cyclopentene. The amounts of cyclopentadiene and cyclopentene at a certain reaction time in the hydrogenation of cyclopentadiene can be calculated by integrating Eqs. 10 and 11 numerically. Equations 10 and 11 can be rewritten by using factors m and n as following expressions:

$$-\frac{d[D]}{dt} = [C][H_2]\frac{k_2m[D]}{1+m[D]+n[E]}, \quad (16)$$

$$\frac{d[E]}{dt} = [C][H_2]\frac{k_2m[D]-k_4n[E]}{1+m[D]+n[E]}, \quad (17)$$

where

$$m = \frac{k_1}{k_{-1}+k_2[H_2]}, \quad n = \frac{k_3}{k_{-3}+k_4[H_2]}. \quad (18)$$

The simultaneous differential Eqs. 16 and 17 were solved numerically with a Runge-Kutta method[18] by substituting various values into the factors m, n, and k_4, respectively. When m=200 (dm^3/mol), $n \leq 0.5$ (dm^3/mol), and $k_4 \geq 1000$ (dm^3/mol s) were assumed, the best agreement of the calculated result with the experimental one was obtained. The compositions of each product were calculated by assuming m=200 (dm^3/mol), k_2=440 (dm^3/mol s), n=0.5 (dm^3/mol), and k_4=1000 (dm^3/mol s), and are drawn as curves in Fig. 2. The experimental data are plotted with circles in Fig. 2. K_D and K_E are defined as equilibrium constants of Eqs. 3 and 5, respectively, *i.e.*, $k_1/k_{-1}=K_D$, and $k_3/k_{-3}=K_E$. Since m=200 (dm^3/mol) and $1/m=(1/K_D)+(k_2[H_2]/k_1)$ (from definition), we have obtained $K_D \geq 200$ (dm^3/mol).

In order to make the theoretical expression (Eq. 14) in good agreement with the experimental expression (Eq. 2) within experimental errors, it is necessary that k_{-3} is at least 5 times larger than the sum of $k_3[E]$ and $k_4[H_2]$. From the experimental conditions, the concentration of cyclopentene [E] is less than 0.4 (mol/dm^3) and that of hydrogen [H_2] equals to 0.003 (mol/dm^3) from the solubility of hydrogen in methanol.[19] These experimental data and the value of k_4 ($\geq$1000 dm^3/mol s) lead the conclusion that $K_E \leq 0.5$ (dm^3/mol) and $k_{-3} \geq 15$ (s^{-1}). Thus, since $K_D \geq 200$, K_D is at least 400 times larger than K_E. On the other hand, k_2 is less than a half of k_4 since k_2=440 and $k_4 \geq 1000$. Therefore, the large K_D/K_E ratio is considered to cause the high selectivity for the hydrogenation of cyclopentadiene to cyclopentene.

Since particle size of palladium metal is very small in the present Pd catalyst,[11] the state of active species is supposed to have some properties of metal complexes or metal clusters.[10,20] This would result in the large K_D/K_E ratio for cyclopentadiene and cyclopentene. Since the selectivity with palladium on charcoal increases with the addition of *N*-benzyliminodiacetic acid disodium salt, the iminodiacetic acid moiety in the resin-supported Pd catalyst possibly causes the increase of the selectivity. The increase of selectivity in the successive catalytic reaction by the presence of foreign substances is known, *e.g.*, in the case of Lindlar catalyst modified by quinoline.[21] The iminodiacetic acid moiety in the resin is not lost in repeated uses of the resin-supported Pd catalyst, though *N*-benzyliminodiacetic acid disodium salt is gradually removed in repeated uses of the palladium-on-charcoal catalyst modified with *N*-benzyliminodiacetic acid disodium salt. So the effect of iminodiacetic acid moiety can be emphasized in the repeated uses of the resin-supported catalyst.

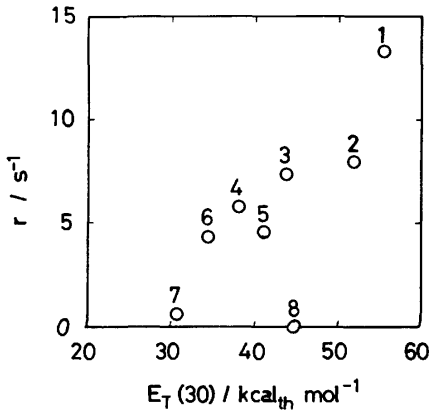

Fig. 7. Correlation of the hydrogenation rate (r) with $E_T(30)$ value of the solvent: 1, methanol; 2, ethanol; 3, *N*,*N*-dimethylformamide; 4, ethyl acetate; 5, ethyl methyl ketone; 6, benzene; 7, hexane; 8, dimethyl sulfoxide. r is the rate of molar hydrogen uptake in a second per molar metallic Pd as catalyst.

Behavior of the Catalyst in Various Reaction Conditions. The hydrogenation rates of cyclopentadiene in various solvents are plotted against the E_T (30) value[22] in Fig. 7. A considerable correlation between the E_T (30) value and the hydrogenation rate is observed, suggesting that the polarity of the solvent affects the rate of hydrogenation. This solvent effect on the rate is supposed to be based on the swelling degree of the resin and on the so-called polar effect which is generally observed in the catalytic hydrogenation of olefins.[23] When dimethyl sulfoxide was used as a solvent, a very low rate was observed compared with that expected from the E_T (30) value. This inhibitory effect of dimethyl sulfoxide on the catalytic activity may be caused by strong coordinating ability of the solvent to the

active species, as the similar effect has been reported in the hydrogenation reaction of dienes by a polymer-bound palladium(II) complex catalyst.[17] In the kinetic measurement the rate in methanol somewhat decreased with the increasing concentration of cyclopentane which was added to make the sum of the concentrations of the substrate and cyclopentane constant. This result may be ascribed to the polarity change of the reaction field by adding cyclopentane, since a very low rate was observed in hexane in contrast with a high rate in methanol. To eliminate the effect of solvent polarity change from kinetic results, the rates were measured in the presence of appropriate amount of cyclopentane as mentioned in the rate dependence on the concentration of cyclopentadiene (Fig. 4).

When the resin-supported Pd catalyst was reused after recovering by filtration from the reaction mixture, the lower initial rate was observed than that with a fresh catalyst. This is probably due to the contact of the catalyst with hydrophobic compounds such as cyclopentane before the start of the reaction, since a similar behavior was observed in the reaction by the catalyst pretreated with methanol containing cyclopentane for 1 h. From the elemental analyses of carbon and nitrogen in the supporting resin, about two-thirds of benzene rings in the resin are considered to have iminodiacetic acid moieties. So the resin consists of the hydrophobic parts like styrene residues and the hydrophilic parts like iminodiacetic acid moieties. The hydrophobicity of the cyclic C_5 compound increases in the order: cyclopentadiene<cyclopentene<cyclopentane.[24] Therefore, when more hydrophobic compound like cyclopentane contacts with the resin-supported Pd catalyst, some cyclopentane would interact with the hydrophobic parts and would remain in the region even after washing with methanol. The hydrophobic parts may surround the active site of the catalyst. Thus in the repeated use, cyclopentadiene might be prevented to approach to the active species of the catalyst by cyclopentene and cyclopentane fixed in the matrix. But, in the steady state of the hydrogenation of cyclopentadiene, the active species is also surrounded by the appropriate amount of cyclopentadiene corresponding to its concentration in the solution. Therefore, it should take a time for the environmental conditions of the active species to achieve the steady state.

The results using a closed circulation reactor indicate that the swelling of the resin with methanol is necessary for resin-supported Pd catalyst to function effectively. In the dry state the resin is shrunk to prevent the substrate from approaching to the active species. When the catalyst was used in the swelled state under the existence of methanol vapor in the gas-phase, the selective hydrogenation of cyclopentadiene was observed to proceed by using a closed circulation reactor.

The authors would like to express their acknowledgment to Mr. Kazuo Seino at the Research Institute for Catalysis, Hokkaido University for his provision of a gas circulating pump for the closed circulation system. The present work was partially supported by a Grant-in-Aid for Developmental Scientific Research No. 485220 from the Ministry of Education, Science, and Culture.

N-Hydroxy Amides. I. Synthesis of *N*-Benzyloxy and *N*-Hydroxy Peptides *via* Polymerization of *N*-Benzyloxy DL-α-Amino Acid *N*-Carboxy Anhydrides

Kazuyuki SHIMIZU, Masayoshi HASEGAWA, and Masayasu AKIYAMA*
Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received August 11, 1983)

Polymerization of *N*-benzyloxy DL-α-amino acid *N*-carboxy anhydrides (*N*-benzyloxy-NCAs) has been carried out in benzene for 30 d with cyclohexylamine as initiator. The N-benzyloxy-NCAs of glycine, alanine, 2-aminobutyric acid, and leucine give the corresponding polymers in good yields, while the starting material is recovered from those of valine and phenylalanine. The different behavior in the polymerization is discussed in terms of steric crowding. Catalytic hydrogenation of the *N*-benzyloxy polymers produces poly(*N*-hydroxy peptide)s. Complex formation of these polymers with iron(III) has been examined. Among the polymers, poly(*N*-hydroxyalanine) is further converted into poly(*N*-acetoxyalanine), which acts as an acyl active polymer. Treatment of poly(*N*-benzyloxyalanine) with $B(CF_3CO_2)_3$ gives 1,4-dihydroxy-3,6-dimethyl-2,5-piperazinedione.

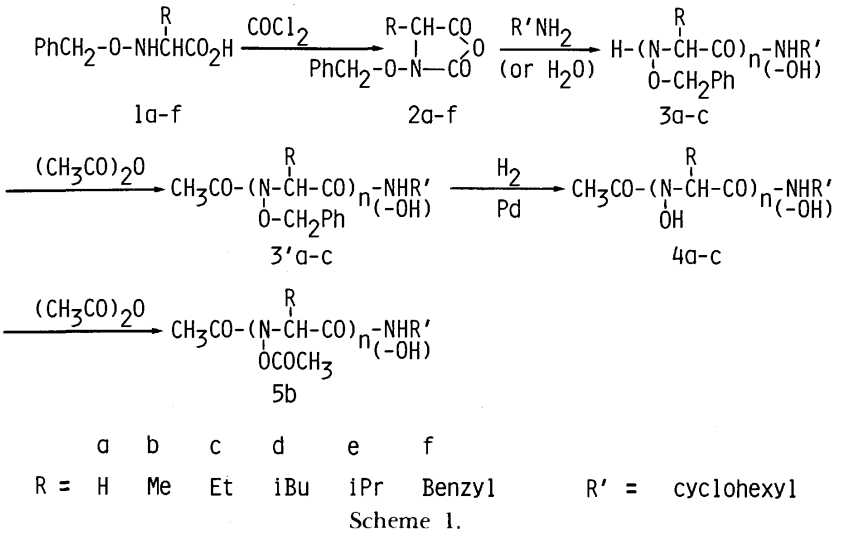
A number of hydroxamic acid derivatives have been found in nature. These natural hydroxamic acids show unique biological activities, including microbial iron transport (siderophore).[1-3] It is worthwhile to synthesize *N*-hydroxy peptides which have hydroxamic acid functions in their peptide backbone. Several simple *N*-hydroxy peptides have already been prepared by a few procedures,[4-7] and studies in this field have become increasingly active.[8-11] In a preliminary letter, we have shown a stepwise synthesis of an alternating *N*-hydroxy peptide by use of *N*-benzyloxy DL-α-amino acid *N*-carboxy anhydrides (*N*-benzyloxy-NCAs).[8] The synthesis was successful because of the slowness of the NCA polymerization. In an attempt to obtain homodetic poly(*N*-hydroxy peptide)s, a prototype of *N*-hydroxy peptides, we felt it necessary to examine polymerization of these new NCAs. This paper describes polymerization of these NCAs and subsequent removal of the benzyl group in the polymers, which will lead to hitherto unknown poly(*N*-hydroxy peptide)s.

Results and Discussion

Scheme 1 depicts the outline of the reactions. *N*-Benzyloxy DL-α-amino acids (**1a—f**) were obtained by reaction of α-bromoalkanoic acids with *O*-benzylhydroxylamine.[12] Their amino group has a low pK_a due to the inductive effect of the oxygen. Phosgenation of **1a—f** in benzene–THF gave *N*-benzyloxy-NCAs (**2a—f**) in good yields.

It is known that NCAs having bulky substituents seldom polymerize, and successful examples are limited to certain polymers, polyproline, poly(*N*-methylalanine), and a few poly(*N*-substituted glycines).[13-16] Preliminary experiments did show, however, that some of the present NCAs can be polymerized into peptide derivatives under well-chosen conditions. The first-order plots of the reactions show a small upward break, familiar in the usual NCA (Fig. 1). They indicate a slow reaction.

Accordingly, polymerization of **2a—f** was performed in benzene at 40 °C for 30 d using cyclohexylamine as an initiator. Water also proved to be an efficient initiator. Typical polymerization results are summarized in Table 1. **2a—d** afforded polymerization products (**3a—d**), although **3d** was a glassy solid and showed a slight deviation in elemental analysis. The starting material was recovered from **2e** and **2f**, and even more forcing conditions failed to give a polymer from **2e**. The degree of polymerization (DP) for polymers obtained is smaller than the value expected from the ratio of NCA



Scheme 1.

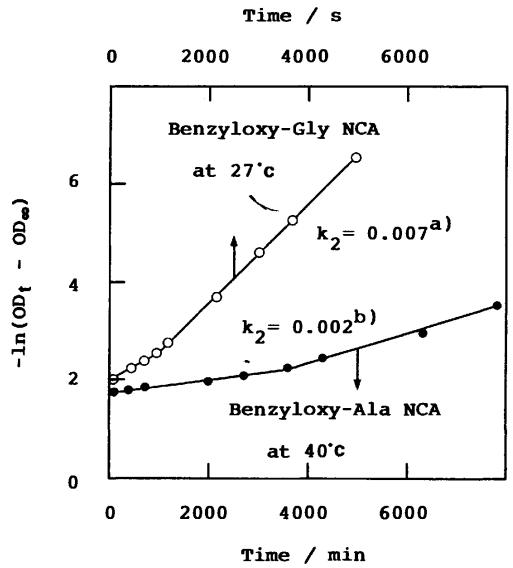


Fig. 1. Pseudo-first-order plots for cyclohexylamine initiated polymerization of *N*-benzyloxy-NCAs of glycine and alanine, as followed by the optical density difference, (OD_t—OD_∞), of the anhydride carbonyl group at 1860 cm^{-1}. [NCA]/[amine]=10. The corresponding second-order rate constants (k_2) appear along with linear portions of the plots: a) 1 $mol^{-1}s^{-1}$: b) 1 $mol^{-1}min^{-1}$.

TABLE 1. POLYMERIZATION OF *N*-BENZYLOXY-NCAs[a]

NCA	R	Yield %	Product	Mol wt (DP)[b]
2a	H	99	**3a**	2350 (14)
2b	Me	99	**3b**	2300 (13)

2e	*i*-Pr		No polymer[d]	
2f	Benzyl		No polymer[d]	

a) Carried out in benzene at 40 °C for 30 d in the presence of cyclohexylamine with a ratio of [NCA]/[amine]=25. b) Degree of polymerization. c) [NCA]/[cyclohexylamine]=50. d) Most of the NCA was recovered unchanged.

to initiator, and a decrease in DP with increasing bulkiness of α-substituents, is also noted. These results indicate that there is a boundary line between α-substituents, *i*-Bu and *i*-Pr, as to polymerizability of these NCAs. The fact that DP is low while the yield is high suggests a concurrent initiation other than that caused by the initiator amine.[17] Initiation by water is most plausible for the present system.

A key factor for the polymerization seems to be steric bulk rather than basicity, since the *N*-benzyloxyamino group has much weaker basicity than the *N*-alkylamino group. Compare, for example, *N*-benzyloxyalanine with *N*-benzylalanine. The NCA of the latter does not polymerize.[15] The former has a less hindered environment around the nitrogen than the latter; there are only two unshared electron pairs and one methylene group on the oxygen adjacent to the nitrogen in the former, while two hydrogens and one phenyl group exist on the adjacent carbon atom in the latter. The failure of **2e** and **2f** in the polymerization is ascribed to a combined steric hindrance of *N*- and C^α-substituents.[18]

In the IR spectra poly(*N*-benzyloxy peptide)s show an amide I band at slightly higher wave number (1670 cm^{-1}) than those of *N*-alkyl substituted polypeptides[15] (1635—1639 cm^{-1}). ^{1}HNMR peaks correspond to protons of the expected structures for the polymers; common peaks observed are around δ=5.0 for $PhCH_2O$-, 5.4 for α-CH, and 7—7.5 for C_6H_5. A molecular formula for each polymer is provided by adequately adding fractions of a water molecule on the basis of observed DP and the initiator used. The detailed data for polymer characterization are presented in the experimental section.

For conversion of poly(*N*-benzyloxy peptide)s into poly(*N*-hydroxy peptide)s several debenzylation procedures were attempted. Treatment of poly(*N*-benzyloxyalanine) (**3b**) with $B(CF_3CO_2)_3$[7] in CF_3CO_2H gave the cyclic dimer of *N*-hydroxy-DL-alanine in 68% yield. The product was identified on the basis of IR, NMR and mass spectral data. The preferential cyclodimerization seemed to occur through fragmentation from a formed *N*-hydroxy peptide *N*-terminus, since no decrease in DP was observed when **3b** was dissolved in CF_3CO_2H for the same period. Hydrogenolysis with Pd catalysts gave partially debenzylated products, or extensively hydrolyzed products when subjected to a prolonged reaction. Hydrolysis in this case is considered to take place on the catalyst surface by the action of water which is generated from occluded oxygen.[19]

Hydrogenolysis was accomplished by reducing *N*-terminal-acetylated polymers (**3′**) with $Pd(AcO)_2$, giving the desired poly(*N*-hydroxy peptide)s (**4**). The catalyst was effective because $Pd(AcO)_2$ is soluble and can penetrate into the polymer entanglement at the outset of the reaction. Typical results are summarized in Table 2. Times required for the reaction apparently depend on the size of the α-substituents. Decrease in DP during the hydrogenolysis was inevitable with **4a**. Polymers (**4a—c**) show ^{1}HNMR signals which correspond to the expected structure; common signals are at δ=2.0 for CH_3CO, 5.3 for α-CH, and 9.2 for HO-N. IR spectra show a broad and strong band in the carbonyl region (1650 cm^{-1}) and new peaks at 3200 and 1180 cm^{-1} due to the *N*-OH moiety.

Hydroxamic acid polymers **4a—c** when mixed with $FeCl_3$ gave an intense violet color characteristic of the complex with $FeCl_3$. The absorbancy of the complex with increasing amounts of iron (III) is shown for poly(*N*-hydroxyalanine) as a representative example (Fig. 2). For comparison, the complex formation

TABLE 2. DEBENZYLATION OF POLYMERS (**3**) BY HYDROGENOLYSIS[a]

Polymer used	(mg)	(DP)	Solvent	Temp °C	Time h		Yield mg	(DP)

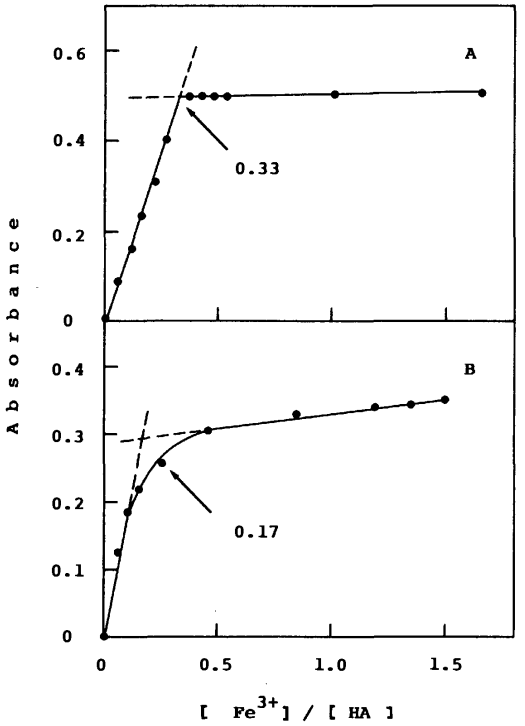

Fig. 2. Plot of absorbance *vs.* the ratio of iron(III) to the hydroxamic acid units; A: DFO and B: poly(*N*-hydroxyalanine) as a representative of these poly(*N*-hydroxy peptide)s. Absorbance at 430—450 nm in A and 450—470 nm in B, in 50% aqueous DMF, pH=3, ionic strength=0.1 (KNO_3).

of a typical trihydroxamic acid, desferrioxamine B (DFO),[20] was measured under similar conditions. An intersection of the dashed lines corresponds to an average molar ratio between Fe^{3+} and the hydroxamic acid groups. DFO gives a sharp inflection, while the polymer reveals considerable curvature. Compared with the ratio of DFO (0.33), values of the ratio for polymers decreased gradually from **4a** to **4c**; 0.26 for **4a**, 0.17 for **4b**, and 0.15 for **4c**. The absorbance of the complex is larger for DFO than that for the polymers under these conditions. These differences clearly indicate that for effective iron binding, considerable chain spacing is necessary between hydroxamic acid groups, while bulky α-substituents in the polymers are unfavorable for formation of stable iron complexes.

By acylation with acetic anhydride, polymer **4b** gave poly(*N*-acetoxyalanine) (**5b**). Strong carbonyl absorptions are observed for **5b** at 1800 (N-O-$COCH_3$) and 1670 (N-CO-) cm^{-1}, the latter amide band being shifted again close to that of the poly(*N*-benzyloxy peptide)s. As expected from the structure, **5b** was able to acetylate cyclohexylamine readily at room temperature.

Experimental

All melting points are uncorrected. IR spectra were taken with a JASCO model DS 403G infrared spectrophotometer. ^{1}HNMR spectra were recorded on a JEOL FX 200 spectrometer with Me_4Si as internal standard. Visible spectra were obtained on a Hitachi 320 spectrophotometer. Elemental analyses was performed by the analytical section, Institute of Physical and Chemical Research, Saitama. *N*-Benzyloxy α-amino-acids were prepared by the reported procedure with slight modifications.[12] Methanesulfonate salt of desferrioxamine B (Desferal) was obtained through Ciba-Geigy, Japan.

N-Benzyloxy α-Amino Acid N-Carboxy Anhydrides (2). *N*-Benzyloxy α-amino acid (0.10 mol) was suspended in a benzene-THF mixture (70 ml, 1:1 v/v). Phosgene from trichloromethyl chloroformate (24 ml, 0.20 mol) was bubbled to the suspension at 40 °C for 1 h, the clear solution which resulted was concentrated before the addition of THF (30 ml). The THF solution was treated with triethylamine (5 g, 0.05 mol) with stirring at −5—−10 °C for 1 h. After filtration of triethylammonium chloride and evaporation of the solvent, the residue was dissolved in diethyl ether and hexane was added. The mixture was kept at −20 °C until crystallization was completed. The crystals were collected and dried in a desiccator over P_2O_5. *N-Benzyloxyglycine NCA (2a)*: Mp 70—71 °C (lit,[8] 63—64 °C) (Found: C, 58.28; H, 4.39; N, 6.86%. Calcd for $C_{13}H_{17}NO_2$: C, 63.86; H, 6.51; N, 5.32%). *N-Benzyloxy-DL-valine NCA (2e)*: Mp 51—52°C (lit,[8] 50—51 °C) (Found: C, 62.71; H. 6.03; H, 5.38%. Calcd for $C_{13}H_{15}NO_4$: C, 62.64; H, 6.07; N, 5.62%). *N-Benzyloxy-DL-phenylalanine NCA (2f)*: Mp 147—148°C (lit,[8] 147—148°C) (Found: C, 68.45; H, 5.12; N, 4.68%. Calcd for $C_{17}H_{15}NO_4$ C, 68.67; H, 5.08; N, 4.71%). These NCAs were stable for several months in the refrigerator. For polymerization they were recrystallized (or reprecipitated) twice from diethyl ether–hexane.

Kinetics by IR. Polymerization of NCAs (**2a** and **2b**) in benzene was initiated with [NCA]/[cyclohexylamine]=10. For **2a**, a portion of the mixture was transferred to the IR cell and spectra of the mixture were taken at appropriate time intervals through a range of 1900—1600 cm^{-1}. The temperature of the cell was 27±1°C. For **2b**, aliquots were transferred at intervals from a polymerization solution maintained at 40± 0.1°C to the IR cell, and the spectra were taken as above.

Polymerizaion. To a solution of the NCA (**2**) (2—3 g, 9.45 mmol) in benzene (19 ml) was added 3.0 ml solution of cyclohexylamine (0.312 g, 3.15 mmol) in benzene (25 ml). The mixture was cooled, degassed, and sealed off under vacuum; it was kept at 40°C for one month. After the tube was opened and the solvent was evaporated, the residue was washed with diethyl ether on a glass filter. The product was dissolved in benzene (**3a** in dioxane) and precipitated into hexane.

Poly(N-benzyloxyglycine) (3a): Mp 164—167°C; IR 1665 cm^{-1} (C=O); ^{1}HNMR ($C_4D_8O_2$) δ=0.8—1.3 (weak m, cyclohexyl), 4.4—4.7 (2H, m, NCH_2), 4.83 (2H, br s, OCH_2), and 7.1—7.6 (5H, m, phenyl). Found: C, 66.23; H, 5.95; N, 8.51%. Calcd for $(C_9H_9NO_2)_{14}\cdot C_6H_{13}N\cdot(11/14)H_2O$: C, 66.18; H, 5.76; N, 8.68%.

Poly(N-benzyloxy-DL-alanine) (3b): Mp 119—121°C; IR 1665 cm^{-1} (C=O); ^{1}H NMR ($C_4D_8O_2$) δ=1.2—1.5 (3H, m, Me), 4.9—5.1 (2H, m, OCH_2), 5.4 (1H, br s, α-H), and 7.1—7.5 (5H, br s, phenyl). Found: C, 67.77; H, 6.57; N, 8.11%. Calcd for $(C_{10}H_{11}NO_2)_{13}\cdot C_6H_{13}N\cdot(12/13)H_2O$: C, 67.62; H, 6.42; N, 8.01%.

Poly(N-benzyloxy-DL-α-aminobutyric acid) (3c): Mp 106—109°C; IR 1655 cm^{-1} (C=O); ^{1}H NMR ($C_4D_8O_2$) δ=0.5—0.9 (3H, m, Me), 1.8—2.2 (2H, br d, C-CH_2), 4.9—5.5 (3H, m, OCH_2 and α-H), and 7.1—7.5 (5H, m, phenyl). Found: C, 68.70; H, 7.10; N, 7.70%. Calcd for $(C_{11}H_{13}NO_2)_7\cdot C_6H_{13}N\cdot(18/7)H_2O$: C, 68.59; H, 7.05; 7.44%.

Poly(N-benzyloxy-DL-leucine) (3d): A glassy solid, IR 1655 cm^{-1} (C=O); ^{1}H NMR ($C_4D_8O_2$) δ=0.4—1.1 (6H, m, 2Me), 1.1—2.2 (3H, m, CH-CH_2), 4.7—5.8 (3H, m, OCH_2 and α-H), and 7.1—7.6 (5H, m, phenyl). Found: C, 70.19; H, 7.94; N, 7.03%. Calcd for $(C_{13}H_{17}NO_2)_6\cdot C_6H_{13}N\cdot H_2O$: C, 70.46; H, 8.23; N, 6.89%.

None of the following solvents gave better polymerization results than benzene; acetonitrile, dichloromethane, dioxane, THF, and toluene.

Debenzylation. *(a) With $B(CF_3CO_2)_3$*: To a solution of the *N*-benzyloxyalanine polymer (**3b**) (400 mg, 2.2 mmol) in trifluoroacetic acid (5 ml) was added $B(CF_3CO_2)_3$ (7.9 g, 22.5 mmol) and stirred for 48 h at room temperauture. The acid was evaporated and methanol was added to the residue. Evaporation and addition of methanol were repeated three times. After filtration of the orthoboric acid derivative and concentration to 3 ml, the solution was introduced into an LH-20 Sephadex column and eluted with methanol. Evaporation of the main fraction gave a crystalline compound (132 mg): yield 68%; mp 212°C (decomp); R_f 0.66 (*n*-BuOH:AcOH:H_2O 4:1:1); IR 1670 cm^{-1} (C=O); ^{1}H NMR (D_2O) δ=1.46 (6H, d, Me), 4.30 (2H, q, α-H). Found: C, 41.33; H, 5.82; N, 15.70%; M^+, 174. Calcd for $C_6H_{10}N_2O_4$: C, 41.60; H, 5.85; N, 15.66%; M^+, 174.

(b) Hydrogenolysis: Before hydrogenolysis, *N*-terminal acetylation was performed by heating the polymers (**3a—c**) (800 mg) with Ac_2O (10 ml) in dioxane (10 ml) at 80°C for 1 h, to give acetylated polymers (**3a′—c′**) (778 mg). A solution of **3a′** (350 mg) and $Pd(AcO)_2$ (500 mg) in trifluoroacetic acid (20 ml), or **3b′** or **3c′** (350 mg) in DMF (20 ml), was reduced with H_2 under atmospheric pressure until Pd metal separated from the solution. After removal of the Pd catalyst and evaporation of the solvent, the residues were washed with Et_2O and dried under vacuum to give white powders (**4a—c**) (Table 2).

Poly(N-hydroxyglycine) (4a): Mp 169—173°C (decomp); ^{1}H NMR (Me_2SO-d_6 at 80°C) δ=1.5 (br, C_6H_{11}-), 2.0 (s, CH_3CO-), 4.5 (2H, CH_2), and 9.5 (1H, HO-N). Found: C, 34.37; H, 4.64; N, 16.98%. Calcd for $(8/14)CH_3CO(6/14)H\text{-}(C_2H_3NO_2)_8\cdot(8/25)C_6H_{12}N\cdot(17/25)OH+H_2O$: C, 34.15; H, 4.87; N, 17.39%.

Poly(N-hydroxy-DL-alanine) (4b): Mp 139—142°C; ^{1}H NMR (Me_2SO-d_6 at 80°C) δ=1.35 (3H, CH_3), 1.7 (br, C_6H_{13}), 2.0 (CH_3CO), 5.3(1H, α-H), and 9.2 (1H, HO-N). Found: C, 42.48; H, 6.33; N, 15.33%. Calcd for $CH_3CO(C_3H_5NO_2)_{30}\cdot(30/50)C_6H_{12}N\cdot(20/50)OH$: C, 42.18; H, 5.98; N, 15.75%.

Poly(N-hydroxy-DL-α-aminobutyric acid) (4c): Mp 161—163 °C; ^{1}H NMR (Me_2SO-d_6 at 80°C) δ=0.85 (3H, CH_3), 1.85 (2H, -CH_2), 2.1 (CH_3CO), 5.3 (1H, α-H), and 9.1 (1H, HO-N). Found: C, 46.81; H, 7.09; N, 13.25%. Calcd for $CH_3CO(C_4H_7NO_2)_7\cdot(7/25)C_6H_{12}N\cdot(18/25)OH+H_2O$: C, 47.07; H, 7.19; N, 12.62%.

Poly(N-acetoxy-DL-alanine) (5b) and Its Use as an Acyl Active Polymer. *(a) Acetylation*: To a suspension of **4b** (135 mg) in THF (10 ml) was added acetic anhydride (5 ml) in THF (10 ml); the mixture was heated at 50°C for 1 h. The resulting solution was concentrated under vacuum and the residue was washed with Et_2O to give a white product. The product was precipitated from THF into Et_2O and dried under vacuum to give **5b** (161 mg, 80%). Mp 154—157°C, IR 1800 (N-O-$COCH_3$) and 1670 (N-CO-) cm^{-1}. Found: C, 46.22; H, 5.59; N, 10.64%. Calcd for $CH_3CO(C_5H_7NO_3)_{30}\cdot(30/50)C_6H_{12}N\cdot(20/50)OH$: C, 46.93; H, 5.54; N, 10.79%.

(b) Acylation with 5b: To a solution of **5b** (95 mg, 0.74 mmol) in THF (10 ml) was added cyclohexylamine (65.6 mg, 0.66 mmol) in THF (10 ml). After the mixture was kept at 25°C for 30 h, the solution was concentrated to dryness and the residue was extracted with Et_2O. Evaporation of the combined ethereal solution gave a crude product (86 mg, 92%) of mp 99—101°C (*N*-cyclohexylacetamide, mp 104°C).

Molecular Weight Determination. The degree of polymerization (DP) was determined by measuring the number average molecular weight of the products (**3a—c** and **4a—c**) with a Hitachi vapour pressure osmometer, model 117. A calibration line was made with benzil as a reference compound. Measurement was performed using dioxane for **3a** at 35°C, benzene for **3b—c** at 40°C, and DMF for **4a—c** at 55°C, respectively. The values are accurate within±5% errors.

Molar Ratio Determination for Iron(III) Complexes. DMF stock solutions of samples were prepared at concentrations of 0.002 hydroxamic acid equiv/l. Aqueous ferric nitrate solutions of approximately 0.003 mol/l were prepared and standardized with EDTA (bismuth method). Aliquots (1 ml) of the sample solution were placed in each of a series of 10 ml volumetric flasks, and varying amounts of iron solution were added. The resulting solutions were diluted to 10 ml, so as to become aqueous 50% DMF solution of ionic strength of 0.1 (KNO_3). The pH of the solutions was made 3.0 with diluted nitric acid. The absorbance of each solution was measured at λ_{max} (450—470 nm).

We thank Messrs. Hiroshi Shimizu, Haruyuki Takeuchi, and Koji Morisada, and Miss Chika

Tsuchiya for performing some of the experiments.

Influence of Boric Acid on the Hydrolysis Rate of a Hydroxy Schiff Base

Hiroshi MATSUDA, Hiroaki NAGAMATSU, Tadashi OKUYAMA,* and Takayuki FUENO
Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received August 13, 1983)

Effects of boric acid on the rate of hydrolysis of a Schiff base derived from α-hydroxyisobutyrophenone and 2-methoxyethylamine were examined in the pH range 4.2—10.4 at 30 °C. The rate increased above pH 7 but decreased below pH 7 with increasing borate concentration following a saturation curve. This is consistent with a reaction sequence involving a preequilibrium formation of a borate-substrate complex followed by its rate-determining decay to the hydrolysis products. The formation constant of the complex showed a bell-shaped change with pH but the rate constant for the complex decay was constant above pH 7, a small change being observed at lower pH. A mechanism involving an intramolecular transfer of the boron-coordinated hydroxide ion to the imine carbon within the complex is presented. Hydrazone formation from the hydroxy ketone was also examined in the presence of boric acid.

Hydrolyses of some hydroxy esters[1,2] and imines[3,4] have been found to be accelerated remarkably by boric acid in aqueous solutions. The reactions undoubtedly proceed through a borate-substrate complex similar to the one formed from diol and boric acid.[5,6] Although detailed mechanisms of the catalytic actions of boric acid are yet to be solved, they are of great interest in view of their similarity to the enzyme catalysis.[2,7]

We previously studied the borate-catalyzed hydrolysis of a hydroxy thiocarboxylic *S*-ester[2] and demonstrated that the catalysis occurs through a mechanism involving an intramolecular transfer of a boron-coordinated hydroxide ion within a borate-substrate complex. In the present investigation are examined effects of added boric acid on the rate of hydrolysis of a Schiff base derived from α-hydroxyisobutyrophenone **1**. It has been found that the hydrolysis is accelerated above pH 7 but the reaction is contrastingly decelerated below pH 7 by boric acid. A mechanism of the borate action on the hydrolysis is proposed.

1

Results

Hydrolysis of the hydroxy Schiff base **1** was studied in aqueous solutions of ionic strength of 0.5 (KCl) at 30 °C. The reaction was monitored by following spectrophotometrically the formation of the product ketone at 245 nm. The rates were first measured without any added boric acid in usual buffer solutions of carboxylates, phosphate, tertiary and secondary amines, carbonate, and 2,2,2-trifluoroethanol as well as in HCl solutions in the pH range 0—12. Buffer effects were observed below pH 9.3 but not examined in detail here. The logarithms of the observed rate constants k_0 extrapolated to zero buffer concentration are plotted against pH in Fig. 1.

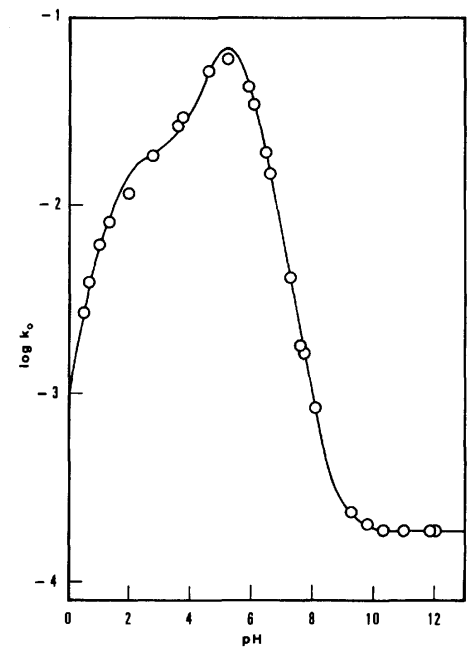

Fig. 1. pH-rate profile for the hydrolysis of the Schiff base **1** at 30 °C. The curve was calculated according to Scheme 1 and parameters given in Table 1.

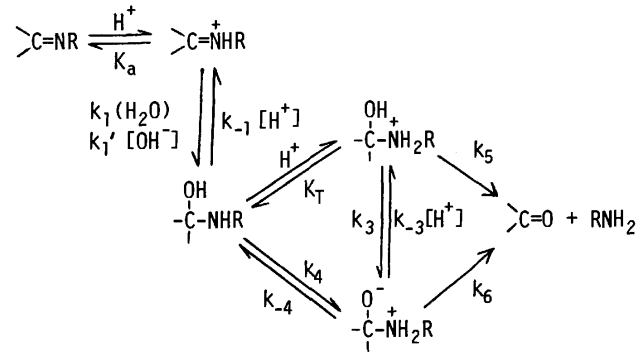

Scheme 1.

The pH rate profile is quite similar to that observed for a benzophenone Schiff base[8a] and may be interpreted in the same way (Scheme 1). This mechanism is analogous to that proposed by Kayser and Pollack;[8b] it involves changes in the rate-determining step of the decay of a carbinolamine (α-amino alcohol) intermediate in a low pH region in addition to the changeover of the slow step from the formation (pH>6) to the decay of the carbinolamine (pH<6). Kinetic parameters (defined in Scheme 1) are summarized in Table 1. The value of pK_a for the protonated Schiff base $\mathbf{1H^+}$ was estimated also from the bell-shaped correlation of pH

Table 1. Kinetic parameters for the hydrolysis of the Schiff base 1[a]

pK_a	5.75
k_1/s^{-1}	1.22×10^{-1}
$k_1'/M^{-1}\ s^{-1}$	2.30×10^{4}
$(K_1k_3/K_T)/s^{-1}$	2.2×10^{-2}
$K_1k_4/M^{-1}\ s^{-1}$	2×10^{-6}
$K_1K_4k_6/M^{-1}\ s^{-1}$	9.0×10^{-4}
K_c/M^{-1}	4.35×10^{2}
$(k_7/K_3)/M^{-1}\ s^{-1}$	$\approx10^{3}$
k_8/s^{-1}	9.9×10^{-3}
$k_8'/M^{-1}\ s^{-1}$	$<10^{2}$

a) 30 °C, μ=0.50 (KCl).

with the equilibrium constant K_{app} for the borate complexation (see below). A solid curve of Fig. 1 is a theoretical one based on the parameters given in Table 1.

When a small amount of boric acid was added to the reaction mixture, the hydrolysis was markedly accelerated at high pH but inhibited at low pH. The spectra of the product solutions were the same as those found in the absence of boric acid. Induction periods were not observed in any kinetic runs.

The dependence of hydrolysis rate on boric acid concentrations was examined at constant pH maintained with a second buffer. The rate increased at pH>7 while it decreased at pH<7 with increasing total borate concentration $[B]_t$, following the saturation curve expressed by Eq. 1 (Fig. 2).

$$k_{obsd} = (k_{obsd}^{0} + k_{\infty}K_{app}[B]_t)/(1+K_{app}[B]_t) \quad (1)$$

where k_{obsd}^{0} is the rate constant observed in the absence of boric acid. Borate is known to associate by itself at higher concentrations especially in the pH range 8—9;[5,9] this may diminish the activity of boric acid. To avoid this effect borate concentrations were kept low

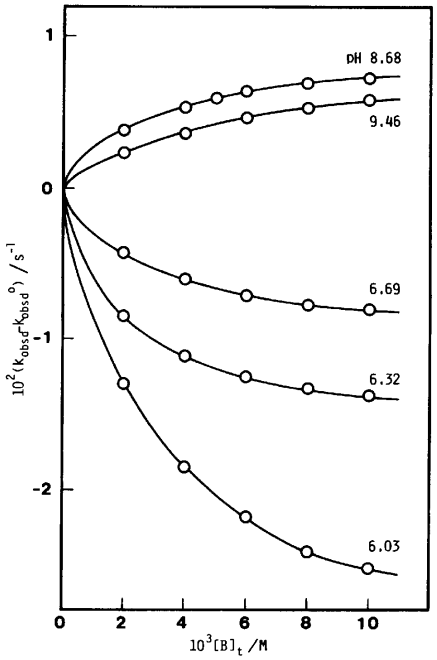

Fig. 2. Dependence of the hydrolysis rate of 1 on the borate concentration at pH indicated (30 °C, μ=0.50).

Table 2. Kinetic parameters for the hydrolysis of the Schiff base 1 in the presence of boric acid[a]

a) 30 °C, μ=0.50 (KCl). b) Deviations are greater than ±0.02 unless stated otherwise. c) ±0.05.

enough ($[B]_t$ <0.01 M (mol dm^{-3}) at pH 6.5—9.5 and <0.2 M at other pH); so the observed curvatures are not affected by the association.

The curved rate dependence of Eq. 1 is consistent with the reaction sequence involving an equilibrium formation of a borate-substrate complex followed by its breakdown to give the hydrolysis products (Eq. 2), where K_{app} and k_∞ stand for the equilibrium constant for the complexation and the rate constant for the decay of the complex, respectively. Constants K_{app} and k_∞ were calculated by a least-squares treatment of the data according to Eq. 4 which is derived from Eq. 1.

$$\mathbf{1} + \text{borate} \overset{K_{app}}{\rightleftharpoons} \text{complex} \overset{k_\infty}{\longrightarrow} \text{products} \quad (2)$$

$$K_{app} = [\text{complex}]/[\mathbf{1}][B]_t \quad (3)$$

$$(k_{obsd} - k_{obsd}^0)/[B]_t = K_{app}k_\infty - K_{app}k_{obsd} \quad (4)$$

Since the substrate concentration ($[\mathbf{1}] \simeq 10^{-4}$ M) is significantly smaller than $[B]_t$ ($>10^{-3}$ M), initial borate concentrations were used for $[B]_t$. The constants K_{app} and k_∞ in various buffer solutions are summarized in Table 2 and plotted against pH in Fig. 3.

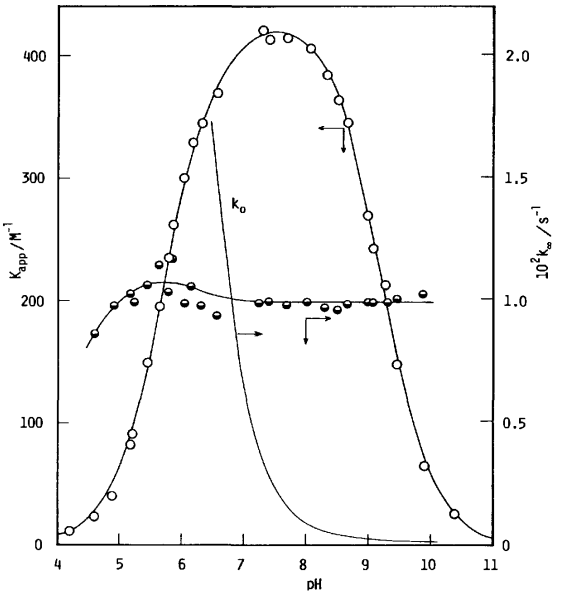

Fig. 3. Correlations of K_{app} (○) and k_∞ (●) with pH. The curves are theoretical (Eq. 8 and 10). Hydrolysis rate k_0 is partly shown.

Possible buffer effects have to be taken into account in two ways. Although borate definitely exerts specific effects on the hydrolysis rate of **1**, potential general base catalytic acceleration must be subtracted, if any, from the observed effects of borate in order to evaluate quantitatively its specific effects. The catalytic constant for such catalysis by borate can be estimated to be $k_B \simeq 5$ $M^{-1}s^{-1}$ from k_1 (for H_2O) and approximate k_B values for phosphate and *N*-methylmorpholine (1 and 1.5 $M^{-1}s^{-1}$, respectively). The apparent catalytic constant k_{Bt}, referring to total borate concentration, is proportional to both conjugate base fraction of borate and acid fraction of the substrate $\mathbf{1}H^+$ (Eq. 5), and the k_{Bt} value is at its maximum at pH≃7.5, where $k_{Bt} \simeq 1.8 \times 10^{-3}$ M^{-1} s^{-1}.

$$k_{Bt} = k_B\left(\frac{[H^+]}{K_a + [H^+]}\right)\left(\frac{K_{BH}}{K_{BH} + [H^+]}\right) \quad (5)$$

a) Calculated from k_{obsd} extrapolated to zero buffer concentration.

From these evaluations, a general-base catalytic contribution is less than 1/10^3 of the observed effects of borate over the whole pH range examined.

Secondly, the borate reaction which is responsible for the specific effects may be subject to the general catalysis by a second buffer added to keep pH constant. Buffer effects were, however, not detected in morpholine (pH 8.1) nor in carbonate buffers (pH 9.3) at borate concentration of 0.01 M. Detailed analyses according to Eq.1 were carried out at varying concentrations of 3 typical buffers and the results are given in Table 3. Both K_{app} and k_∞ are independent of buffer concentrations of acetate (pH 5.24) and *N*-methylmorpholine (pH 7.4) within experimental uncertainties, but k_∞ slightly increases with buffer concentration in phosphate buffer solutions of pH 6.0.

A kinetic investigation of hydrazinolysis of the Schiff base **1** was also attempted to know if boric acid influences the rate, but the attempts were unsuccessful because of a very small spectral change due to the reaction.

The effects of added boric acid on the hydrazone formation from α-hydroxyisobutyrophenone (**2**) were examined briefly as a reverse reaction of the Schiff base hydrolysis. Reactions were carried out in hydrazine buffers (pH 8—9) with or without added boric acid. For runs at pH 7.1 and above pH 9.3, low concentrations of phosphate and carbonate buffers were used to maintain constant pH. A possible initial drop of ketone absorption due to carbinolamine formation was not observed in the absence nor in the presence of boric acid. Observed pseudo-first-order rate constants k_{obsd}' were obtained from the decrease in the ketone absorption (245 nm) and divided by concentrations of neutral hydrazine [Hy] to give rate constants for the hydrazone formation.[10] The rate was linearly increased with

$$k_{obsd}' = k_{Hy}[Hy] \quad (6)$$

$$k_{Hy} = k_{Hy}^0 + k_{Hy}^B[B]_t \quad (7)$$

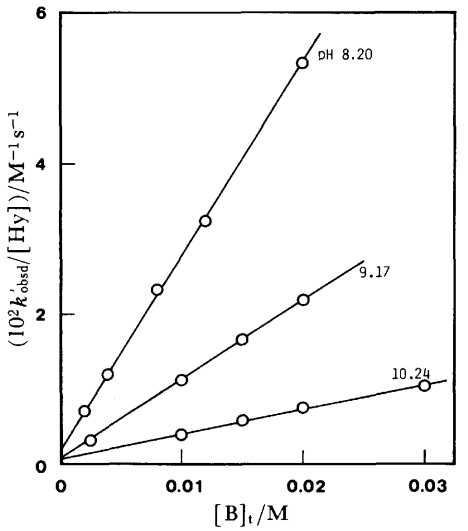

Fig. 4. Dependence of rate for the hydrazone formation from **2** on the borate concentration at pH indicated (30 °C, μ=0.50).

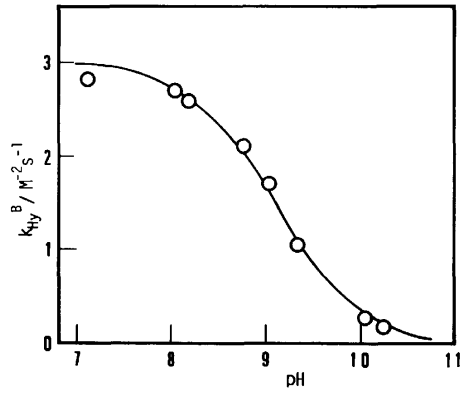

Fig. 5. Plot of k_{Hy}^{B} against pH.

increasing concentration of boric acid $[B]_t$ as shown in Fig. 4. The slopes k_{Hy}^{B} are much greater than those expected for the general catalysis.[11] General catalysis by hydrazine (second-order terms) and borate may be small enough to be neglected under the reaction conditions employed ($[Hy]_t \leq 0.125$ M, $[B]_t \leq 0.03$ M). Plots of the catalytic constants k_{Hy}^{B} *vs.* pH fit a sigmoid curve with $pK_a = 9.2$ (Fig. 5). Boric acid involved in the catalysis is its acid form, a limiting value of the catalytic constant k_{Hy}^{B} at lower pH being 2.9 M^{-2} s^{-1}.

Discussion

Hydrolysis of the Schiff base **1** derived from the α-hydroxy ketone **2** takes place in a usual way in well-behaved buffer solutions, exhibiting a pH-rate profile typical of the hydrolysis (Fig. 1).[8] On the other hand, borate buffer has never shown any unusual effects on the hydrolysis of Schiff bases except for those derived from *o*-hydroxybenzaldehyde.[3,4]

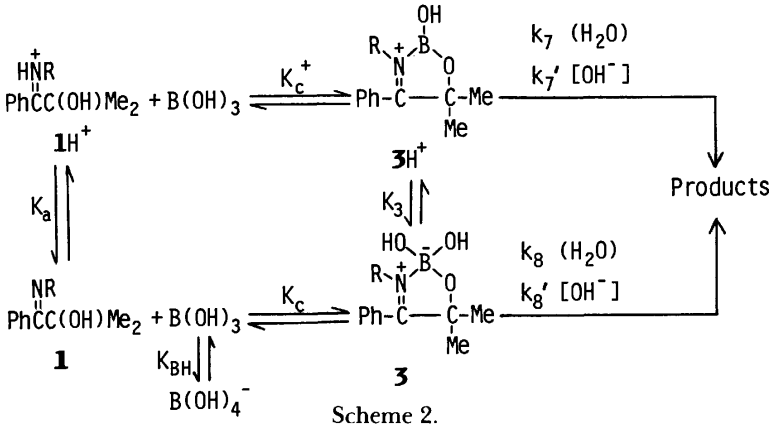
The specific effects of boric acid observed here must arise from the interaction of the hydroxyl group of **1** with boric acid and the associated borate function may facilitate the hydrolysis. In fact the observed rate constants change with borate concentration according to Eq. 1 which is based on the mechanism involving equilibrium formation of a borate-substrate complex. The complex formation must be very rapid as compared with its decay because no induction period was observed in spite of a large extent of complexation during the borate reaction.

The apparent equilibrium constants K_{app} for the complexation show a bell-shaped change with pH as seen in Fig. 3. The bell-shaped pH-K_{app} curve fits well Eq. 8, where $K_c = 435$ M^{-1}, $pK_a = 5.75$, and $pK_{BH} = 9.2$.

$$K_{app} = K_c\left(\frac{K_a}{K_a+[H^+]}\right)\left(\frac{[H^+]}{K_{BH}+[H^+]}\right) \quad (8)$$

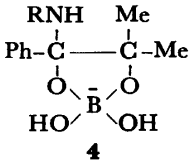
$$K_c = [\mathbf{3}]/[\mathbf{1}][B(OH)_3] \quad (9)$$

The parameters are defined in Scheme 2 which presents possible reaction sequences. A main form of the complex present must consist of the neutral form of the substrate **1** and boric acid (acid form), and the formation constant K_c is as great as 435 M^{-1}; a probable structure **3** is presented in Scheme 2. In this complex **3** a borate group associated with the α-hydroxyl group coordinates on the imine nitrogen in a Lewis acid-base fashion forming a five-membered ring. Salicylaldehyde oxime was reported to form a stable complex with boric acid, the formation constant being about 300 M^{-1} (pH 9.2).[12] Salicylamide was also found to form a borate complex of six-membered ring involving nitrogen.[5] On the other hand, well-known complexations between boric acid and 1,2-diols usually give formation constants of 1—10 M^{-1}.[6] The formation constant K_c observed here is too large to be ascribed to a diol complex, carbinolamine-borate complex like **4**.



Scheme 2.

Furthermore, formation of the carbinolamine intermediate is not always rapid enough. The complex **4** is unlikely and the structure **3** is most probable. The complex **3** may equilibrate with a cationic form $3H^+$ at low pH but its contribution to the kinetics is small even at pH 4; the acid dissociation constant of $3H^+$ is thus estimated to be greater than 10^{-4} ($pK_3<4$).



4

The limiting rate constant k_∞ extrapolated to the infinite concentration of borate refers to the breakdown of the complex to give the hydrolysis products. The k_∞ value does not change greatly over the pH range 5—10, showing only a slight increase at pH about 6 and a tendency to decrease below pH 5. The Schiff base hydrolysis takes place through a nucleophilic reaction of water with the protonated substrate. The borate complexes with Lewis acid-type boron coordination at the imine nitrogen (**3** and $3H^+$) are structurally similar to the protonated Schiff base and may be subject to the nucleophilic attack by water and hydroxide ion.

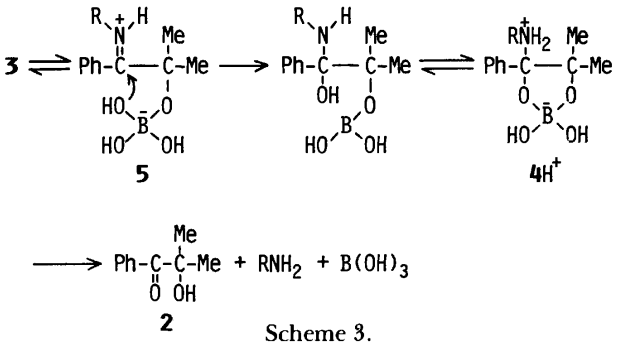
In analogy to the usual mechanism of the Schiff base hydrolysis (Scheme 1), the decrease in k_∞ at low pH (<5) must be due to the changeover of the rate-determining step from the formation to the breakdown of the (complexed) carbinolamine intermediate.

Above pH 5 nucleophilic attacks by water and hydroxide ion on the complexes **3** and $3H^+$ to form carbinolamine species would be rate determining and k_∞ is described by Eq. 10 using rate constants given in Scheme 2.

$$k_\infty = (k_7/K_3)[H^+] + k_7'K_w/K_3 + k_8 + k_8'[OH^-] \quad (10)$$

Since the k_∞ value is constant over pH 7—10, the hydroxide-ion catalysis is negligible ($k_8'<10^2\ M^{-1}\ s^{-1}$). The uncatalyzed term consists of two terms due to the hydroxide ion reaction of $3H^+$ and the water reaction of **3** ($k_7'K_w/K_3+k_8=9.9\times10^{-3}\ s^{-1}$). If the former term mainly contributed to k_∞, $k_7'>10^8\ M^{-1}\ s^{-1}$: This value is too large as compared to the rate constant for the hydroxide reaction of $1H^+$ ($k_1'=2.30\times10^4\ M^{-1}\ s^{-1}$). Thus the main reaction here must be the water reaction of **3**: $k_8=9.9\times10^{-3}\ s^{-1}$, which is about 1/10 of k_1 for $1H^+$. If the water reaction of **3** were mechanistically similar to that of $1H^+$, *i. e.* a simple nucleophilic reaction, the reactivity difference between **3** and $1H^+$ would allow to estimate the rate constant for the hydroxide reaction k_8' from k_1'. Since the reactivity difference is usually smaller toward hydroxide ion than toward water,[8] k_8' must be greater than $10^3\ M^{-1}\ s^{-1}$. This is too large as compared with the observed value ($<10^2\ M^{-1}\ s^{-1}$). That is, a simple water reaction of **3** is unlikely. Observed lack of general base catalysis of the k_∞ reaction in this pH region is also incompatible with the rate-determining water attack on **3**.

An alternative mechanism kinetically equivalent to this process may involve the rearrangement of **3** to an



Scheme 3.

open-type complex like **5** followed by an intramolecular transfer of a hydroxide ion coordinated to the boron atom (Scheme 3). This process does not require any general catalysis and may be more effective than the hydroxide reaction k_8' up to pH 10. Furthermore, this mechanism closely resembles that proposed for the borate catalysis of hydrolysis of a hydroxy thiocarboxylic *S*-ester.[2]

In the pH region near **6**, scattering of plots of k_∞ is rather large because of experimental limitations due to a small rate change caused by boric acid but a small increase in k_∞ seems to be real. This may be attributed to the water reaction of $3H^+$; $k_7/k_3\simeq10^3\ M^{-1}\ s^{-1}$ and $k_7>10^{-1}\ s^{-1}$. The k_7 value is near or greater than k_1, which may not be unreasonable. In accord with the mechanism, general catalysis of the k_∞ process was observed at pH 6.0.

The apparent effect of added boric acid was acceleration of the hydrolysis up to 50-fold at high pH while the deceleration below pH 7. This arises from the smaller reactivity of the complexed substrate **3** than the protonated Schiff base $1H^+$ and the large formation constant K_c of the complex **3**. At higher pH equilibrium concentration of **3** is much greater than that of $1H^+$, which results in acceleration. At lower pH, where the concentration of $1H^+$ is large enough for the hydrolysis to be rapid, added boric acid converts $1H^+$ into less reactive complex **3** to inhibit the hydrolysis. Similar effects of boric acid on the Schiff base hydrolysis were previously examined with *N*-salicylideneaniline.[3] It was noted that the hydrolysis rate increased linearly with boric acid concentration, suggesting that the formation constant of the complex is small in this case. Deceleration has never been observed. The proposed mechanism involving a reaction of a cationic complex (similar to $3H^+$) with hydroxide ion[3] is however very unlikely in view of the present observations.

Hydrazone formation from the hydroxy ketone **2**, a reverse of the hydrolysis, was found to be accelerated by boric acid in the pH range 7—10. The rate increased linearly with borate concentration. A mechanism for the borate catalysis in this pH region is considered, as a microscopic reverse of the hydrolysis, to involve rate-determining formation of a stable borate-hydrazone complex from a borate-carbinolamine adduct. The formation constant for the borate-carbinolamine adduct (similar to **4**) must be small to allow linear dependence of the rate on borate concentration as observed. The key step of the reaction may be an intramolecular hydroxide transfer from the carbon to

the boron atom in accord with the mechanism of the borate-assisted hydrolysis.

Experimental

Materials. α-Hydroxyisobutyrophenone **2** was prepared from α-bromoisobutyrophenone[13] according to the literature.[14] The Schiff base **1** was prepared from **2** and 2-methoxyethylamine in a usual way[15] and recrystallized from ligroine, mp 53.8—54.4 °C. Found: C, 70.26; H, 8.59; N, 6.37%. Calcd for $C_{13}H_{19}NO_2$: C, 70.56; H, 8.65; N, 6.33%.

Other chemicals were obtained as before.[2,7] Glass-distilled water was used throughout.

Kinetic Measurements. All the aqueous solution containing appropriate amounts of boric acid, hydrazine, and other buffers were prepared in a volumetric flask at room temperature and adjusted to ionic strength of 0.5 with KCl. Stock solutions of the substrates were obtained as an acetonitrile solution of about 10^{-2} M. Reactions were started by adding 0.03 cm^3 of the substrate stock solution from a microsyringe into a 3-cm^3 buffer solution equilibrated at 30.0±0.1 °C in a stoppered quartz cuvette inserted in a water-jacketed cell holder. The reaction was followed by the increase (hydrolysis) or the decrease (hydrazone formation) in the absorption of the ketone **2** at 245 nm on a Shimadzu UV 200 or UV 140 spectrophotometer. Pseudo-first-order rate constants were calculated by a modified Guggenheim method.[16] Infinity absorbances calculated coinside well with those observed. pH of buffer and reaction solutions were measured by a Hitachi-Horiba F7 pH meter.

NAD(P)$^+$-NAD(P)H Model. 47. Mechanism of the Formation of 1,4-Dihydronicotinamide in the Reaction of Pyridinium Salt and Amine

Atsuyoshi OHNO,* Satoshi USHIDA, and Shinzaburo OKA
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received August 17, 1983)

An amine reduces 1-benzyl-3-carbamoylpyridinium ion (BNA$^+$) into 1-benzyl-1,4-dihydronicotinamide (BNAH) in aqueous solution. The mechanism of reduction has been elucidated. The covalently bound adduct of the amine and BNA$^+$ at the 6-position is found to be the true reductant. The reduction with formate proceeds through the direct "hydride-transfer" mechanism. Selectivity of nucleophilic attack on the 4- and 6-positions of BNA$^+$ is discussed in terms of hard-soft-acid-base (HSAB) principle.

The biological reduction of NAD$^+$ coupled with oxidation of substrates such as alcohols and amines takes place smoothly. On the other hand, only a few results on the non-enzymic reduction of pyridinium salts, model compounds for NAD$^+$, by organic substrates have been accumulated. As a model for an alcohol dehydrogenase, Ohnishi and Kitami reported the reduction of pyridinium salts by alkoxides.[1] However, the mechanism of the reaction seems to be different from that of the dehydrogenase, because, in their investigation, a direct hydrogen-transfer from an alkoxide to pyridinium salt was not observed. Recently we reported that 1-benzyl-1,4-dihydronicotinamide (BNAH) is produced[2] by the reaction of 1-benzyl-3-carbamoylpyridinium ion (BNA$^+$) with α-ketols such as glyceraldehyde and glycolaldehyde and that the mechanism is different from that suggested for the reaction catalyzed by glyceraldehyde 3-phosphate dehydrogenase.[3] In the reduction of BNA$^+$ with glycolaldehyde, addition of glycolaldehyde to the 4-positon of BNA$^+$ takes place initially, and the adduct acts as the real reductant for another molecule of BNA$^+$.[3]

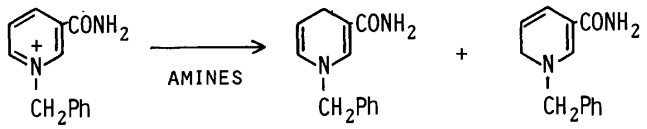
By using a variety of amines and ammonia, Ohnishi reported the formation of BNAH from BNA$^+$.[4] The mechanism of the reduction, however, has remained unclear. In enzymic systems, the reduction of NAD$^+$ by amine is found in the reaction catalyzed by glutamate dehydrogenase,[5] where, according to the suggested mechanism, glutamate is oxidized to 2-iminoglutarate with simultaneous formation of NADH.[6]

$$\mathrm{NAD^+ + HOOCCH_2CH_2\underset{\displaystyle NH_2}{\underset{|}{C}}HCOOH \longrightarrow NADH + HOOCCH_2CH_2\overset{\displaystyle NH}{\overset{\|}{C}}COOH} \quad (1)$$

It is interesting to compare the mechanism of non-enzymic formation of 1,4-dihydropyridine by amines with that of enzymic process, not only from the view point of a simple comparison of the two systems but also from that for understanding biochemical reactions as well as to extend biomimetic reactions. We now report a mechanism of the formation of BNAH in the reaction of BNA$^+$ with amines.

Results and Discussion

According to a literature reported by Ohnishi,[4]



BNA$^+$ BNAH (2)

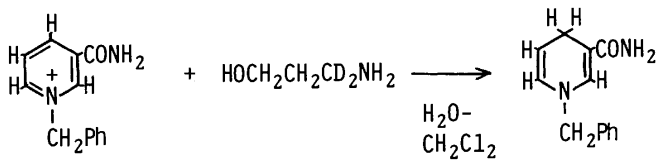
Table 1. Reaction of BNA$^+$ and amines[a]

BNA$^+$/M	Amine/M	Solvent	Reaction time/h	Yield of BNAH/%[g]
0.50[b]	1.60 (AE[d])	H_2O[f]	12	10
0.22[b]	1.88 (DA[e])	H_2O-MeOH	22	8
0.22[b]	1.88 (AE)	H_2O-MeOH	22	9
0.22[c]	1.88 (DA)	CH_3CN	50	18

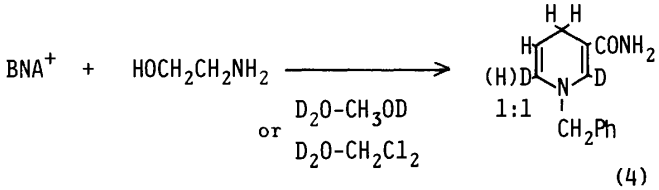
a) At room temperature in the dark. b) Counter anion is Cl^-. c) Counter anion is ClO_4^-. d) 2-Aminoethanol. e) Diethylamine. f) In the presence of CH_2Cl_2 (bi-phase system). g) Yields based on BNA$^+$ were determined on NMR using *p*-nitrotoluene as an internal standard.

BNAH is formed in the reaction of BNA$^+$ and excess of amine in a yield of 18% in acetonitrile and 5% in water, respectively. We re-examined the reaction under similar conditions and obtained the results listed in Table 1. The reduction products were confirmed with an NMR spectrum to be almost consisted of the 1,4-dihydro isomer (more than 90%) with contamination of small amount of the 1,6-dihydro derivative.

Among informations to elucidate the mechanism, the most important one is that which clarifies the

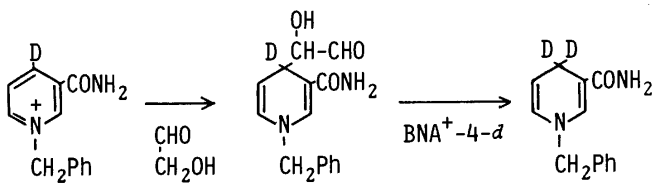


BNA$^+$ (3)



(4)

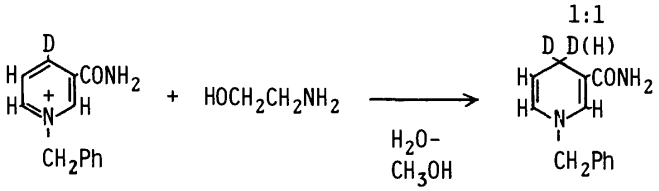
origin of hydrogen at the 4-position of BNAH produced. First of all, the reactions with 3-amino-1-propanol-3,3-d_2 and 2-aminoethanol in D_2O–CH_3OD (50/50 v/v) were carried out.[7] As shown in Eqs. 3 and 4, both hydrogens at the 4-position of the BNAH were "H", which indicates that the hydrogen comes neither from the substrate nor from the solvent. The latter reaction yields BNAH-2,6-d_2. The contamination of deuteriums in BNAH is due to H–D exchange in BNA$^+$.[8] The H–D exchanges at the 2- and 6-positions of BNA$^+$ was confirmed by the observation of disappearance of NMR signals from the protons at 2- and 6-positions of BNA$^+$ in an alkaline buffer solution. Roberts and his co-workers have claimed, in a recent papaer,[9] partial incorporation of deuterium at the 2-position of BNAH in the reduction by sodium dithionite in D_2O suggesting bimolecular isomerization and reisomerization between BNA$^+$ and BNAH. However, it should be noted that BNAH-2-*d* is formed without isomerization.



BNA$^+$-4-*d* BNAH-4,4-d_2

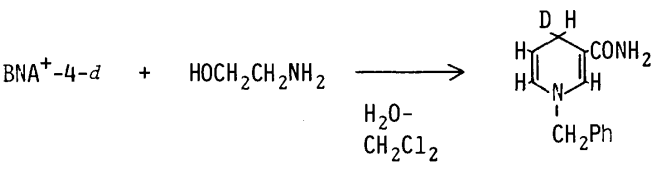
(5)

It is well known that nucleophiles attack easily the pyridinium salt to afford adducts that have dihydropyridine structure.[10] Such adducts sometimes have abilities to reduce pyridinium salt. For example, the adduct of BNA$^+$ and glycolaldehyde reduces BNA$^+$ to form BNAH.[3] The mechanism of this reaction was confirmed by the finding that BNAH-4,4-d_2 was formed from BNA$^+$-4-*d* with glycolaldehyde in protic solvents. The reaction with amine may undergo with the same mechanism and we examined the possibility. When BNA$^+$-4-*d* was reacted with 2-aminoethanol in H_2O–CH_3OH the obtained dihydropyridine was an about 1:1 mixture of BNAH-4-*d* and BNAH-4,4-d_2



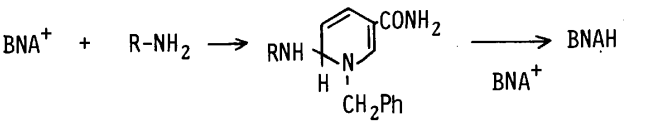
BNA$^+$-4-*d*

(6)



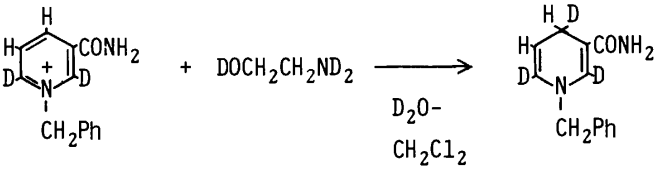
BNAH-4-*d*

(7)



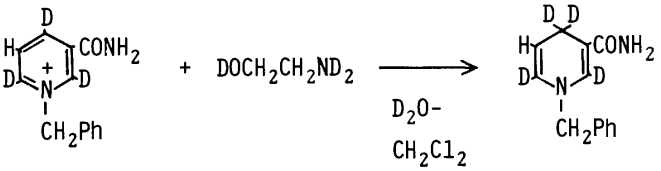
1

(8)



BNA$^+$-2,6-d_2

(9)



BNA$^+$-2,4,6-d_3

(10)

(Eq. 6). On the other hand, when the reaction was carried out in H_2O in the presence of CH_2Cl_2 (bi-phase reaction), the product obtained from the organic layer was BNAH-4-*d* (Eq. 7). If the reductant were the adduct at the 4-position of BNA$^+$, the product should be BNAH-4,4-d_2. Therefore, the above result is inconsistent with the mechanism for the reduction with glycolaldehyde. Because a large amount of absorption at around 350 nm due to the dihydropyridine structure was observed during the reaction, we assumed that the hydrogen transfered from the 6-position of BNA$^+$ through an adduct (**1**) (Eq. 8). Similar idea has appeared in a literature.[11] In order to ascertain the hypothesis, BNA$^+$-2,6-d_2 and BNA$^+$-2,4,6-d_3 were reacted with $DOCH_2CH_2ND_2$ in D_2O in the presence of CH_2Cl_2 (Eqs. 9 and 10). In both cases, incorporated hydrogens at the 4-position were deuterium. Since it has been confirmed that these hydrogens do not come from the solvent, the result clearly indicates that the origin of the hydrogen at the 4-position of BNAH is the 2- or 6-position of BNA$^+$. Whereas the hydrogen at the 2-position of BNA$^+$ can easily be exchanged by deuterium in D_2O under the basic conditions, the exchange at the 6-position is rather slow.[8] On the basis of the result from the reaction in D_2O (Eq. 4) that no deuterium incorporation took place within the limitation of NMR spectroscopy, the possibility of the transfer from the 2-position is excluded or is estimated to be a very minor path, if any. That is, only from the 6-position, the hydrogen-transfer is expected.

In spite that the hydrogen at the 6-position of BNA$^+$ exchanges with a proton from solvent, no deuterium incorporation onto the 4-position was observed in the reaction shown in Eq. 4. This result stems from the fact that the proton exchange and the reaction of **1** with BNA$^+$ proceeds comparably in rate so that the

amount of **1**-6-*d* is not so large. Even though the **1**-6-*d* is produced in certain amount, kinetic isotope effect[11] prefers the "H"-transfer from **1** than "D"-transfer from **1**-6-*d*.

In the reaction described in Eq. 6, the product was a mixture of BNAH-4-*d* and BNAH-4,4-d_2. The result is accounted for by transhydrogenation between initially produced BNAH-4-*d* and BNA^+-4-*d*. The isotope effect of 6[12] suggests that hydrogen dissociates six times as selectively as deuterium does from the 4-positions of BNAH-4-*d* and BNAH-4,4-d_2 accumulating BNAH-4,4-d_2 after repetition of bimolecular isomerization. The easiness of transhydrogenation was ascertained by an experiment; when BNAH-4-*d* was reacted with about tenfold excess of BNA^+-4-*d* for 16 h, the recovered dihydropyridine was found to be solely composed of BNAH-4,4-d_2.

Therefore, it is concluded that the adduct of amine at the 6-position of BNA^+ (**1**) reduces another molecule of BNA^+ to afford BNAH as shown in Eq. 8. The conclusion shows an interesting contrast between the reactions of α-ketols and those of amines. The result also discards the possibility of direct hydrogen-transfer from amines.

Adduct formation from pyridinium salts with many kinds of nucleophiles such as cyanide,[13] thiols,[14] and enolates[15] have been reported.[10] The attack by these nucleophiles is generally thought to occur at the 4-position.[10,16] In contrast, the additions by amine and hydroxide ion[17] take place at the 6-position. Similar reaction centers[18] are, thus, selectively discriminated by nucleophiles depending on their own property. The selectivity can be interpreted in terms of the hard-soft-acid-base (HSAB) principle.[19] Because of adjcent cationic center, the 6-position is harder center than the 4-position for the nucleophilic attack.

In the present system the product had mainly (more than 90%) 1,4-dihydro structure. It is reported[20] that a small amount of pyridinium salt catalyzes the equilibrium between 1,4- and 1,6-isomers with large predominance of the 1,4-isomer. Therefore, it is reasonable that the reaction in an aqueous medium produces an equilibrium mixture containing a large excess of the 1,4-isomer. However, even when the reaction proceeded in a bi-phase system, where the dihydropyridine produced was extracted immediately into organic phase, the predominant product was the 1,4-isomer (more than 97%). Moreover, in the reaction of BNA^+-4-*d* in the bi-phase system, in which there takes place no equilibration between BNA^+ and BNAH, the extracted dihydropyridine was BNAH-4-*d* with 1,4-selectivity. These results indicate that the selectivity for the 1,4-isomer is not due to thermodynamic control but to the kinetic preference of transhydrogenation from **1** to the 4-position of BNA^+. Thus, based on the HSAB principle discussed above, the transferring "hydride" might be a soft species.

Most substrates that reduce NAD^+ in enzymic systems are nucleophiles. As mentioned above, such nucleophiles attack the pyridinium ion to form covalently bound adducts in organic reaction systems. The formation of these adducts seems to be one of the major reasons for the difficulty to achieve the biomimetic reduction of pyridinium ion by a direct hydrogen-transfer from organic substrates.

Although the formation of 1,4-dihydropyridine derivative was observed in the reactions of α-ketols and amines, it has been elucidated that the mechanism is different from that proposed for enzymic reactions. Only one example for direct hydrogen-transfer from a substrate to NAD^+-models was observed in the reduction with formate. Gizzi and Joullie reported a direct deuterium-transfer to 1-(*p*-fluorobenzyl)-3-carbamoylquinolinium chloride in the reduction with DCOOH.[21] We also confirmed the deuterium-transfer in the reduction of BNA^+ with DCOOK[22] under the conditions reported by Ohnishi and Tanimoto.[23]

In the active site of enzymes, the formation of covalently bound adduct between NAD^+ and a substrate is prohibited because of proper orientation of two reactants. Even though the adduct is formed, it cannot be a reductant for another molecule of NAD^+ because of the interference of the enzyme wall. Therefore, in the model system for the reduction of pyridinium salt, the reactants should be designed to suppress the adduct formation as well as the transhydrogenation from the adduct. Facile reductions coupled with oxidation of alcohols or amines have been performed in the case of pyrido[2,3-*d*:6,5-*d'*]dipyrimidine,[24] hydroxyacridinium salt,[25] and deazaflavines.[26] The reason for the facility is thought to be based on the ring structure that have an ability to accept a "hydride" compared to the attack by a nucleophile. In fact, in a certain case,[27] the desired reaction is suppressed by adduct formation, which shows the importance of proper design for model molecules. Unfortunately, these compounds are not direct models for NAD^+ where pyridinium ion participates. Further investigations for the simulation of reduction of NAD^+ by the use of pyridinium salts are desired.

Experimental

Instruments. UV and NMR spectra were obtained on a Union Giken SM-401 and a JEOL JNMFX-100, respectively.

Materials. 3-Amino-1-propanol-3,3-d_2 was prepared from 3-hydroxypropionitrile by the reduction with lithium aluminum deuteride in tetrahydrofuran. ^1H NMR ($CDCl_3$; δ from TMS): 1.70 (t, 2H), 2.70 (bs, 3H), and 3.77 (t, 2H).

BNA^+-4-*d* was prepared from BNA^+ by repetition of reduction by sodium dithionite in D_2O and oxidation by Malachite Green[28] for three times. Deuterium content at the 4-position was more than 97%. BNA^+-2,6-d_2 and BNA^+-2,4,6-d_3 were prepared as follows: The solution of 100 mg of BNA^+ (or BNA^+-4-*d*) and 100 mg of anhydrous sodium tetraborate in 1 cm^3 of D_2O was placed at 60 °C until the NMR signals from the protons at the 2- and 6-positions disappeared. It took about an hour for the disappearance of the proton at the 2-position and about several hours for the one at the 6-position. Water was removed by evaporation and obtained solid was washed with dichloromethane for three times. BNA^+-2,6-d_2 (or BNA^+-2,4,6-d_2) was extracted with methanol from the solid and used without further purification.

Reaction of BNA^+ and Amine. A Typical Procedure: To the solution of BNA^+ (41.5 mg) in a 1:1 (v/v) mixture of H_2O–CH_3OH (0.75 cm^3) 87×10^{-6} cm^3 of 2-

aminoethanol was added. Methanol was added to keep the solution homogeneous. The solution was stirred for 20 h at room temperature in the dark. Reduced products were extracted by 10 cm^3 of ether for three times and collected by removing the solvent. The NMR signals from the product were identical with those from the authentic sample of BNAH. The yield of BNAH was measured on an NMR spectrometer using *p*-nitrotoluene as an internal standard. NMR signals from the products obtained under various conditions are listed in Table 2. Oxidized **1** or decomposed products from BNA$^+$ could not be isolated because of complication.

Table 2. Type of coupling and amount of protons attached to the dihydropyridine ring in ^{1}H NMR spectra of the products

No. of Eq.	Position of the proton[a)]			
	4- (3.16)	5- (4.75)	6- (5.75)	2- (7.16)
3	m (2H)	dt (1H)	d (1H)	s (1H)
4	dd (2H)	m (1H)	m (0.5H)	—
7	d (1H)	dd (1H)	d (1H)	s (1H)
9	d (1H)	d (1H)	—	—
10	—	s (1H)	—	—

a) Chemical shifts (δ from TMS in $CDCl_3$) of each position are represented in parentheses. Each product shows other signals at δ=4.25 (s, 2H), 5.3—5.6 (bs, 2H), and 7.28 (s, 5H). dd: double doublet, dt: double triplet.

For the reaction in bi-phase system, dichloromethane as a solvent for extraction was added to an aqueous solution of BNA$^+$ and the amine.

(Received August 19, 1983)

The ^{13}C NMR chemical shifts of 3*H*-phenothiazin-3-one (**1**) and eleven of its methyl derivatives are reported. The effect of including sulfur 3d orbitals is discussed in relation to the ^{13}C chemical shifts. The chemical shifts of **1** can be explained in terms of both the successive polarization of the long π-conjugated framework promoted by the carbonyl group and the contribution of the sulfur d-orbitals. The ^{13}C chemical shifts gave a better correlation with the CNDO/2 π- and total electron densities calculated by means of the *sp*-basis set than by means of the *spd*-basis set, but an improved correlation was obtained by reducing the extent of d-orbital participation on sulfur. From the correlation of the ^{13}C chemical shifts with the CNDO/2 *sp* π- and the total electron densities of all the carbons of **1** and monomethyl derivatives, the proportionality constants of −300 and −180 ppm/e respectively were obtained.

There have been extensive studies of phenothiazines in connection with medical chemistry, with particular reference to the correlation of the psychopharmacological activities with the molecular structures such as the electronic and steric properties of substituents and the conformational change in the parent molecule.[1] It is well known that phenothiazines can be used as neuroleptics and that they depress the vital function of the dopamine receptor in the central nervous system.[2] Although phenothiazine itself is not an effective neuroleptic, its pharmacological activity is increased by the introduction of both electron-withdrawing group such as Cl or CF_3 at the 2-position and the *N*-side chain such as *N*-[3-(dimethylamino)propyl], *N*-[3-(4-methyl-1-piperazinyl)propyl], or *N*-[3-[4-(2-hydroxyethyl)-1-piperazinyl]propyl] group (for example, trifluoperazine, chlorpromazine, fluphenazine, and perphenazine).[1a,c]

From X-ray analysis[3–9] and the determination of the dipole moment and the molar Kerr constant,[10] phenothiazines are known to have a folded structure about the N–S axis and a quasi-equatorial substituent on the nitrogen. The dihedral angles between the two planes of the benzenoid rings of phenothiazines in a solid vary from 134.4° for thioridazine to 158.5° for orthorhombic phenothiazine.[3] In a solution, however, *N*- and ring inversions take place with butterflylike flapping motion, and the population of the *N*-quasi-axial substituent seems to increase with an increase in the bulkiness of the *N*-substituent.[11]

Although phenothiazin-3-ones have been used as enzyme inhibitors, anthelmintics, stabilizers, antioxidants, dyestuffs, and indicators,[12–22] their relative difficulty of preparation has limited the number of compounds examined. 3*H*-Phenothiazin-3-one (**1**) inhibits the activities of succinoxidase, cytochrome oxidase, and glyoxalase as well as phenothiazine.[13] On the other hand, 3*H*-phenoxazin-3-one is well known to be the chromophore part of actinomycin D, which binds to double-helical DNA and specifically inhibits RNA synthesis.[23]

Whereas many papers have been devoted to the study of the electronic and conformational properties of phenothiazines by means of the ^{13}C NMR[11] and ^{1}H NMR[24–28] chemical shifts, the dipole moments,[10] the molar Kerr constants,[10] the EPR and polarographic oxidation potentials,[29] X-ray crystal analyses,[3–9] and molecular orbital calculations,[11,29] there have been few corresponding data on **1** and its derivatives.

This paper will deal with the ^{13}C NMR spectra of **1** and eleven of its methyl derivatives in order to elucidate how the presence of *p*-benzoquinone monoimine type and the methyl group influences the electronic properties of phenothiazines. The ^{13}C chemical shifts of 3*H*-phenothiazin-3-ones give an index of the electronic densities of their carbons for the ground state and would seem to be useful for any future discussion of their pharmacological properties and reactivities.

Experimental

Materials. **1** was synthesized by the cyclization of *o*-aminothiophenol with *p*-benzoquinone according to the method of Bodea and Raileanu;[30] mp 162—163 °C (lit, 161—162 °C). The monomethyl-3*H*-phenothiazin-3-ones were prepared by the method of Terdic:[31] 1-methyl-(**2**), mp 146—148 °C (lit, 145—147 °C); 2-methyl- (**3**), mp 182—183 °C (lit, 181—183 °C); 4-methyl- (**4**), mp 142—143 °C (lit, 141—143 °C); 6-methyl- (**5**), mp 192—193 °C (lit, 190—192 °C); 7-methyl- (**6**), mp 210—211 °C (lit, 208 °C); 8-methyl- (**7**), mp 181—182 °C (lit, 180—182 °C); 9-methyl- (**8**), mp 179—180 °C (lit, 171—173 °C). Dimethyl- and trimethyl-3*H*-phenothiazin-3-ones were synthesized from *o*-aminothiophenol and the corresponding methyl derivatives of *p*-benzoquinone; 1,2-dimethyl- (**9**), mp 191—192 °C; 1,4-dimethyl- (**10**), mp 146—148 °C; 2,4-dimethyl- (**11**), mp 164—165 °C; 1,2,4-trimethyl- (**12**), mp 160—161 °C. Found for **10**: C, 69.33; H, 4.54; N, 5.97%. Calcd for $C_{14}H_{11}NOS$: C, 69.68; H, 4.59; N, 5.80%. Found for **11**: C, 69.50; H, 4.32; N, 5.65%. Found for **12**: C, 70.43; H, 5.08; N, 5.42%. Calcd for $C_{15}H_{13}NOS$: C, 70.56; H, 5.13; N, 5.49%. All the compounds were purified by TLC and column chromatography and checked by means of their IR and ^{1}H NMR spectra. The *N*-chloro-*p*-benzoquinone monoimine was commercially obtained (guaranteed reagent) and used without further purification.

Procedures. The ^{13}C NMR spectra were recorded on a JEOL FX-100 Fourier-transform spectrometer at room temperature at 25.00 MHz, using a deuterium lock. Samples were prepared in the 9:1 $CDCl_3$–CD_3OD solvent system, with tetramethylsilane as an internal reference, in 5-mm spinning tubes because these compounds were not soluble enough in $CDCl_3$. The melting points were determined on a

Yanagimoto micromelting apparatus and are uncorrected.

Theoretical

The quantum chemical calculations were carried out by the CNDO/2 method[32] and using parametrizations without further modification. The convergence was judged from the electron-density criterion of 10^{-4} in the density matrix. The CNDO/2 program suppled by QCPE[33] Program No. 141 was modified to accommodate atomic orbital matrices greater than seventy. The dihedral angles associated with the inner thiazine ring of **1** in the butterfly structure were calculated by using QCPE[33] Program No. 397. Computations were carried out on a HITAC M-200H computer at the Computer Center of the Institute for Molecular Science.

For Runs 2, 4—13, and 19 in the CNDO calculations of **1** shown in Table 3, the X-ray data for the bond lengths and bond angles of the benzenoid ring and the *p*-benzoquinone imine portion of the actinomycin D obtained from light-atom analysis were used to those for the corresponding bond lengths and bond angles of **1**, except that the bond length of C-6—C-7 was 1.41 Å; for the other runs, their bond angles were assumed to be 120°. For the hydrogen bonding of the carbonyl group of **1** with methanol, the atomic distance between the carbonyl oxygen and the alcoholic hydrogen was presumed to be 1.61 Å, and the hydroxyl group was arranged on the extension line of the carbonyl bond. The geometry of **1** has been transferred to the monomethyl derivatives. The atomic coordinates of the methyl group and methanol were determined from the following bond distances and bond angles: C–C (methyl), 1.51 Å; C–O, 1.43 Å; olefinic (or aromatic) C–H, 1.08 Å; methyl C–H, 1.09 Å; O–H, 1.02 Å; ∠COH, 110°; ∠OCH=∠CCH=109.5°. The bond lengths and angles of planar *N*-chloro-*p*-benzoquinone monoimine were: C=O, 1.23 Å; C=N, 1.33 Å; C=C, 1.32 Å; C–C, 1.49 Å, N–Cl, 1.75 Å; C–H, 1.08 Å; ∠C–C–C, 116°; ∠C=C–C, 122°; ∠C=N–Cl= ∠C=C–H =120°.

Results and Discussion

^{13}C Chemical Shifts of 3H-Phenothiazin-3-one. A reasonably self-consistent set of assignments for the chemical shifts of the 3*H*-phenothiazin-3-ones and the substituent-induced chemical shifts (SCS) of the methyl group are summarized in Tables 1 and 2 respectively. The carbon resonances of **1** can be assigned not directly, but on the basis of the off-resonance decoupling technique and the methyl-substituent effects on benzenes[34] and olefins.[35]

The signal for the carbonyl nuclei in **1** appeared at 183 ppm; it is shifted to a magnetic field higher by 4 ppm relative to those (187.0 and 186.5 ppm, respectively) in *p*-benzoquinone[36] and *N*-chloro-*p*-benzoquinone monoimine.[37] The chemical shifts of carbonyl carbons increase in the order of: **1**

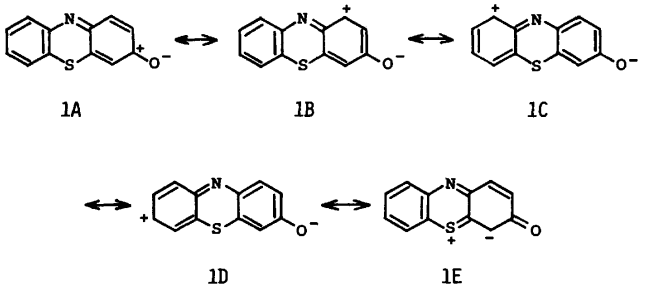
a) Relative to parent. b) Methyl group. c) Substituted carbons indicated by square brackets.

(182.6)<1,4-naphthoquinone (184.7)[38]<*p*-benzoquinone (187.0)[36] <cyclohexenone (198.9)[39]<cyclohexanone (208.8).[40] This order suggests that the upfield shift is closely associated with the delocalization of the partial possitive charge of the carbonyl carbon so long as the steric perturbation is negligible.

The chemical shifts of C-1 and C-2 in **1** move 3—4 ppm to a lower field than those of the corresponding carbons of *N*-chloro-*p*-benzoquinone monoimine. In the *p*-benzoquinone imine framework of **1**, the fact that the signal for the C-4a is more shielded than that for the C-1, in spite of the replacement of sulfur atom more electronegative than hydrogen, may be explained in terms of the normal character of phenyl vinyl sulfides and/or the contribution of the d-orbitals of the sulfur atom. The chemical shifts of the C-4 and C-4a in **1** moved downfield by 4—5 ppm in comparison with those of the corresponding vinyl group of phenyl vinyl sulfide.[41] This deshielding effect may be due to the change in the vinyl group to the olefinic double bond of a cyclic compound because the difference in chemical shifts between ethylene and the olefinic carbons of cyclohexene[42] was observed to be 5 ppm. As will be shown below, the CNDO/2 calculation of **1** suggests that the participation of sulfur d-orbitals results in the enhancement and lowering of the total electron densities of the odd-numbered carbons except for the C-9a and the even-numbered carbons except for the C-4a respectively; especially, the increased total electron densities of C-4a and C-5a adjacent to the sulfur atom are mainly based on the remarkably increased $2p_x$ orbital densities of their carbons.

The biggest differences between the benzenoid carbon shieldings of **1** and phenothiazine are the chemical shifts of C-7 and C-9. The C-7 and C-9 nuclei in the former are more deshielded than those for the corresponding carbon nuclei in the latter by 10 and 20 ppm respectively. As the C-7 and C-9 carbons are meta-carbons relative to the sulfur atom, their chemical shifts are strongly affected not by the sulfur atom, but the polar and electron-withdrawing characteristics of the imino group, promoted by the powerful polarizing carbonyl group, even if the internal olefinic double bond attenuates the transmission effect. The deshielding of C-7 and C-9 reflects the relative importance of the polar canonical forms, 1C and 1D, which have the partial positive charge on the 7 and 9 positions of the aromatic ring attributable to the electron-withdrawing carbonyl group. As a result, the signals for the C-7 and C-9 shifted to a lower field because of their positions para and ortho respectively relative to the imino group.



1A 1B 1C

1D 1E

The nitrogen atom of phenothiazine forms the apex of a flattened pyramid, with the two ipso carbons of the benzenoid moiety and hydrogen as the base. According to the classical resonance theory, a hybrid orbital containing the lone-pair electrons of the nitrogen atom has a perpendicular orientation on the base plane of the pyramid; this orientation is convenient for overlapping the $2p_\pi$ orbitals of the aromatic ring because their orbitals are relatively parallel. Therefore, a part of the lone-pair electrons flows the ortho- and para-carbons of the benzenoid ring through the π-conjugation. In the case of **1**, however, the sp^2 hybrid orbital of the lone-pair electrons is almost perpendicular to the $2p_\pi$ orbitals of the benzenoid ring. Therefore, the delocalization of lone-pair electrons is very poor. The electron-attracting nature of the imino group is facilitated by a fair overlapping between the $2p_\pi$ orbitals of nitrogen and benzenoid carbons, since the C–N bond length of the 3*H*-phenoxazin-3-one skeleton of actinomycin D has been found to be 1.36 Å; this value is smaller than that (1.399 Å) of phenothiazine.[3] The relatively high shielding of C-5a, the bridgehead quaternary carbon linking to the sulfur atom, may be due to the d-orbital contribution of the sulfur atom.

Methyl-subsituent Effect. The methyl substitution on the aromatic ring caused a shift of the ipso carbon downfield by 9—12 ppm and a shift of the para benzenoid carbon upfield by 1—3 ppm. The ortho carbon farther from the thiazine ring shifted downfield by 0.9—1.5 ppm, and another ortho carbon, upfield by 0.0—1.7 ppm. The introduction of the methyl group resulted in an upfield shift of the meta carbon, making it remoter from the thiazine ring, by 0.1—0.7 ppm, but the nearer meta carbon was only slightly affected in the range of −0.1—0.2 ppm. The upfield shift of para carbon induced by methyl substitution was enhanced as the para position approached the sulfur atom.

When a methyl group is introduced on any of the aromatic moiety except for the C-6, the signals for the 2, 4, and 10a carbons, *i.e.*, the even-numbered carbons, in the quinone imine ring shift to a field higher by 0.1—1.7 ppm, while the shielding of the other carbons, *i.e.*, the odd-numbered carbons and the C-4a, in the quinonoid ring is either unaffected or moved only slightly downfield; the substituent effect is transmitted mainly through its π-conjugated framework by means of alternation.

The replacement of the hydrogen of quinone imine by a methyl group caused a deshielding of α-carbon by 8—9 ppm and a shielding of olefinic β-carbon by 2—4.5 ppm, but the chemical shift of β-carbonyl carbon was almost unaffected. The carbonyl carbons of **1** and eleven of its methyl derivatives absorb over a fairly narrow range, *ca.* 2 ppm, or from δ_C=181 to 183. This remarkable insensitivity of carbonyl carbons to substituents has also been observed in methyl-*p*-benzoquinones[36] and 3-substituted and 2-cyclohexenones.[39] The magnitude of the β-effect of methyl group bonded to the 4-position carbon was larger than that of the other monomethyl-3*H*-phenothiazin-3-ones. The magnitude for the β-effect of the 2-methyl group is similar to that of 2-methyl-*p*-benzoquinone.[36]

The chemical shift of methyl carbon increased in the following sequence: 4-methyl=2-methyl< 9-methyl<1-methyl<6-methyl<8-methyl<7-methyl. This order suggests that the shielding of methyl carbon increases when the methyl carbon is spatially near to the more electronegative heteroatom. The electrostatic interaction between the heteroatom and the nearest hydrogen of the methyl group enhances the polarization of the methyl $C^{\delta-}$–$H^{\delta+}$ bond and the resulting higher shielding of methyl carbon. As the methyl group can be treated as a pseudo-π-electron system, the polarization of the C–H bond of the methyl group affects the chemical shifts of α- or ipso carbon as an inductive effect through the σ-bond and those of β- or ortho and para carbons as a resonance effect through the π-bond. The magnitudes of the C_α- and C_{ipso}-SCS of the methyl group decrease with an increase in the shielding of the methyl carbon, except for the methyl C_α-SCS greater than that expected at the C-2; this trend suggests that the α-effect of the methyl group is attenuated by the dispersion of the partially negative charge on the methyl carbon through the C–C σ bond. The deviation of the methyl C_α-SCS on the C-2 may be due to the more important contribution of the π-electron delocalization.

The chemical shifts of dimethyl- and trimethyl-3*H*-phenothiazin-3-ones agreed roughly with the values estimated from the data of monomethyl derivatives by using the additivity relationship, except that those of the C-1 and the C-2 in 1,2-dimethyl- and 1,2,4-trimethyl-3*H*-phenothiazin-3-ones appeared at a field higher by 2 ppm than the estimated values. The magnitude of the difference is responsible for the steric compression effects, which have been found in the chemical shifts of spatially crowded carbons, such as *o*-xylene[34,43] and 1,2- and 2,3-dimethylindoles.[44] Similarly, the chemical shift of methyl carbons is upfield in the sterically more compressed form.

a) More detailed information on molecular geometries are described in the Theoretical section. b) Bond angles of N, C-10a, C-4a, and C-9a. c) Bond angles of N, C-10a, C-5a, and C-9a. d) The bond angles of N, C-4a, C-10a, and C-9a, except for C-5a instead of C-4a for Runs 7 and 9, are equal to the corresponding data for Run 4. ψ_1 represents the dihedral angle between the N—C-10a and the C-4a—S bonds; ψ_2, that between the C-9a—N and the C-10a—C-4a bonds, and ψ_3, that between the N—C-10a and the C-9a—C-5a bonds. e) Sulfur coplanar to the benzenoid ring. f) Sulfur coplanar to the quinonoid ring. g) The bond angles and the approximate dihedral angles of atoms varying from N to C-9a in a clockwise direction on the inner thiazine ring. The angles are defined as shown in Fig. 1 of Ref. 50.

CNDO/2 Calculation of 3H-Phenothiazin-3-ones. None of the crystal structures of **1** have been reported in spite of a detailed clarification of the medicinally more important phenothiazine and its derivatives. On the other hand, in the case of 3*H*-phenoxazin-3-one, the molecular geometry can be presumed from that of actinomycin D, about which detailed stereochemical information with the DNA helix served to clarify the cancer-inhibiting mechanism.[23] X-ray crystal analysis showed the quinonoid portion of the 3*H*-phenoxazin-3-one ring system to be slightly twisted in a propeller-like fashion with respect to the aromatic portion of the chromophore.

In general, the C–S bond is longer than the C–O bond, whereas the interior angle of C–S–C is smaller than that of C–O–C.[45] If the inside thiazine ring of **1** is a planar structure in order to enhance the resonance stabilization between the benzene and the quinone rings, the bond lengths and/or bond angles among C, N, and S atoms must, at least in part, lie outside normal ranges.

There are various possible conformations of **1**, for example; (i) a planar structure, (ii) a twisted quinone fashion, and (iii) a butterfly structure such as phenothiazine. Therefore, CNDO/2 calculations of the above possible molecular structures were carried out in order to obtain information on the conformation with the lowest total energy, the correlation of the ^{13}C chemical shifts with CNDO/2 charge densities, and the magnitude of the sulfur-d-orbital contribution.

Table 3 lists the CNDO/2 total energies and dipole moments of various molecular geometries of **1**. In the *spd* approximation, the total electronic energies of **1** for the (i), (ii), and (iii) structures varied from −552.7 to −566.3 a.u., whereas the total energy for those structures changed only slightly between −131.3 and −131.4 a.u. The inclusion of d-orbitals on the sulfur atom in **1** resulted in a lowering of the total energy of 0.3—0.4 a.u. and of the dipole moment of 0.5—1.6 debye in comparison with the case of the exclusion of d-orbitals. The sulfur 3d orbitals reduce the dipole moment by introducing a *pd* polarization in the opposite sense to the *sp* polarization. The *sp* and *spd* calculations for **1** suggest that Runs 1 and 7 have the lowest total energies, −131.1133 and −131.4210 a.u. respectively; generally, (i) and (ii) are more stable than (iii) unless the repulsion of the cores increases abnormally because of the shorter bond length. The molecular geometry for Run 1 is the ideal geometry considered to maintain the planarity of the inner thiazine ring having the C–S bond length of 1.76 Å observed in phenothiazine[3] under the normal geometries of benzene and *p*-benzoquinone[46] frameworks. Run 7 is responsible for the slightly twisted, semiactual but ideal structure between the benzene and the *p*-quinone imine rings, whose bond lengths and angles are referred to the corresponding data of the 3*H*-phenoxazin-3-one geometry of actinomycin D.

Table 4 shows the CNDO/2 π and total electron densities of **1** and its methyl derivatives for the planar and twisted structures. The ^{13}C chemical shifts gave a better correlation with the π- or total ($\sigma+\pi$) electron densities calculated by the *sp*-basis set rather than the *spd*-basis set except for the α-carbons of the sulfur atom. As Table 4 shows, the *spd* approximation underestimated the total density on the C-4 and results

a) Calculated by *sp* approximation. b) Molecular geometry referred to Run 1. c) *Spd* calculation. d) Hydrogen bonding of the carbonyl group to methanol. e) Geometry associated with Run 8. f) Molecular structure in connection with Run 6.

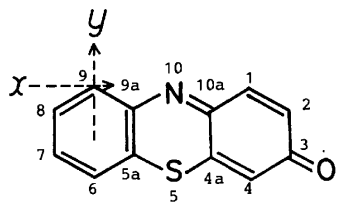

Fig 1. Numbering and coordinate systems for **1**. The *z* axis is perpendicular to this paper.

generally in a lowering of the total electron densities on the β- and δ-carbons numbered from the sulfur atom, and the enhancement of those on the α- and the γ-carbons; the former is mainly attributable to the decreased π-electron density, and the latter, to increases in the σ-electron density and the π-electron density. As has been described above, in the ^{13}C NMR spectrum of **1**, the signal of the C-4 appeared in the highest magnetic field; this trend is in agreement with the theoretical data calculated by means of the *sp* approximation; in the *spd* calculation, the most electron-rich carbon is not the C-4, but the C-2.

The values of the correlation coefficient, *r*, between the ^{13}C chemical shifts of all the carbons in **1** and their total electron densities, calculated in Runs 1, 5, 6, 8, and 10 by means of *sp*- and *spd*-basis sets, are 0.88 and 0.85—0.86 respectively. If it is reasonable that the linear relationship holds between the electron densities calculated by means of the *sp*- and *spd*-basis sets, the value of *r* is enhanced up to 0.89 by evaluating the degree of sulfur-d-orbital participation as 28—36%. From the linear correlation of the ^{13}C chemical shifts with the π-electron densities of the over-all carbons of interest, the best value of *r* is 0.94 for Run 1 when the *spd* contributions are somewhere between 43 and 44%, and a proportionality constant of -350.8 ± 39.6 ppm/e was obtained for the π-electron system composed of *sp* 56% and *spd* 44%.

In the *sp* calculation of **1** in a twisted form, it is the most stable structure that the quinonoid portion is twisted at a torsional angle of 15° with respect to the aromatic ring, where the X-ray-diffraction data of actinomycin D were adopted for the bond lengths and bond angles of these rings. In this case, the value of *r* for their total electron densities is equal to 0.884, enhanced to 0.887 when the carbonyl group is weakly bonded to the solvent by means of hydrogen bonding.

From the linear relationship between the ^{13}C chemical shifts of all the carbons of **1** and its monomethyl derivatives, except for methyl carbons and their CNDO/2 *sp* electron densities in the case of a planar structure carried out in Run 1, the proportionality constants of -297.6 ± 13.8 ppm/e ($r=0.912$) and -179.5 ± 10.2 ppm/e ($r=0.875$) were obtained for the π- and the total electron systems respectively. Improved correlations could be obtained for only quinonoid carbons: -300.7 ± 15.5 ppm/e ($r=0.944$) for the π-system and -181.5 ± 9.6 ppm/e ($r=0.941$) for the total electron system. Similar *sp* calculations on the twisted structure with the torsional angle of 15° gave a

Table 5. Charge distribution in the atomic orbitals of 3*H*-phenothiazin-3-one[a)]

a) *z* axis is perpendicular to the benzenoid plane.

slightly less good correlation of -170.8 ± 9.9 ppm/e ($r=0.931$) for the total electron system.

In the case of phenothiazine, the fair linear relationship between the ^{13}C chemical shifts and the CNDO/2 total electron densities gave a proportionality constant of -127.7 ± 7.1 ppm/e ($r=0.985$).[47] A slope of -171.1 ± 25.0 ppm/e ($r=0.908$) was obtained for the π-electron system;[47] this value is approximately equal to the generally accepted value of -160 ppm/e for the π-electron of aromatics.[48,49] The correlation of the ^{13}C chemical shifts of the *N*-chloro-*p*-benzoquinone monoimine used as a reference compound for the quinone portion of **1** with their charge densities was also examined. An excellent correlation with the experimental results was obtained; the proportionality constants for the π- and total electrons were -458.2 ± 36.1 ppm/e ($r=0.988$) and -224.8 ± 5.3 ppm/e ($r=0.999$) respectively. These results indicate that the proportionality constants of **1** are close to the arithmetic mean values between those of *N*-chloro-*p*-benzoquinone monoimine and phenothiazine in the cases of both π- and total electrons.

Table 5 shows the distribution of charges among the atomic orbitals from the C-4 to the C-6 of **1** in the planar and twisted fashions. The sulfur total electron densities of **1** were evaluated to be 6.05—6.08 and 6.09—6.11 by means of the *sp* and *spd* approximations respectively. The summation of the electron densities of the five d-orbitals calculated varies from 0.46 to 0.53 and decreases as the distance of the C–S bond becomes longer and/or the conformation of **1** approaches the planar structure. The participation of the 3d orbital in bonding brings about a remarkable decrease in the electron density of sulfur $3p_\sigma$ orbitals, chiefly the $3p_x$ orbital; the reverse was found for the $3p_x$ orbitals of C-4a and C-5a adjacent to the sulfur atom. The perturbation of the charge densities of even-numbered carbons non-adjacent to the sulfur by the d-orbitals occurs through the $2p_\pi$ orbitals, as can be clear in Tables 4 and 5. In particular, the $2p_\pi$ electron density on the non-nearest-neighbor carbon, C-4, is strikingly decreased. As has been described above, however, the electron densities calculated by the *spd*-basis set did not fit the observed values of the ^{13}C chemical shifts well. A significantly improved correlation was obtained by reducing the extent of sulfur d-orbital participation to less than 50%.

Thanks are due to the Computer Center of the Institute for Molecular Science for its assistance in the CNDO/2 calculations.

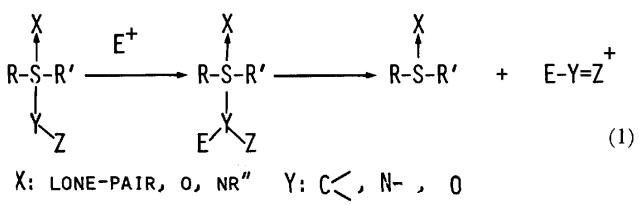
Preparation of *S,S*-Diphenylsulfilimines, -sulfoximines, and -*N*-(*p*-tolylsulfonyl)sulfonediimines *N*-Substituted with Sulfur Groups of Different Oxidation States

Kunihiko Akutagawa, Naomichi Furukawa,* and Shigeru Oae*,†
Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305
(Received September 9, 1983)

S,S-Diphenyl-*N*-(*p*-tolylthio)-, -*N*-(*p*-tolylsulfinyl)-, -*N*-(*p*-toluenesulfinimidoyl)-, -*N*-(*p*-tolylsulfonyl)-, and -*N*-(*p*-toluenesulfonimidoyl)sulfoximines have been synthesized either by sulfenylation, sulfinylation, sulfinimidoylation, sulfonylation, and sulfonimidoylation or by oxidation of the *N*-substituted sulfoximines with sulfur groups of lower oxidation states, *i.e.*, the *N*-sulfenylated sulfoximine. Similar attempts have been made on similarly substituted sulfonediimines. Sulfenylation and sulfonylation of *N*-unsubstituted *N*-(*p*-tolylsulfonyl)sulfonediimine were unsuccessful but its sulfinylation underwent nicely. An attempt to disulfonylation of the *N,N'*-unsubstituted sulfonediimine ended up in the monosulfonylation. *N,N'*-bis(*p*-Tolylsulfonyl)sulfonediimine was successfully prepared by oxidation of the *N*-(*p*-tolylsulfinyl)-*N'*-(*p*-tolylsulfonyl)sulfonediimine with *m*-chloroperbenzoic acid.

Numerous *N*-substituted sulfilimines,[1] sulfoximines,[2] and *N'*-*p*-tolylsulfonylsulfonediimines,[3] such as *N*-alkyl, *N*-aryl-, *N*-sulfonyl, *N*-acyl-, *N*-silyl, and *N*-phosphoryl derivatives, have been prepared. In general, these compounds are fairly stable. Whereas, only a few *N*-substituted derivatives having a heteroatom with lone-pair electrons directly attached to the imino nitrogen atom of sulfilimine have been known. Furthermore, very little of the chemistry of these compounds has been explored. The compounds actually isolated are *N*-chloro-,[4] *N*-bromo-,[4] *N*-iodo-,[4] *N*-sulfenyl-,[5] *N,N*-phthaloyl-,[6] *N*-aryl-[7] derivatives which are in general thermally unstable as compared to other *N*-substituted derivatives having an atom with no electron pair in the *N*-substituent directly combined to the imino nitrogen atom. These sulfilimines bearing *N*-substituents of heteroatoms possessing lone-pair electrons, are generally quite reactive and readily decompose *via* the initial S–N bond fission. These reactive derivatives, upon activation by addition of a suitable electrophile such as sulfenyl chloride, undergo facile cleavage of the S–N linkage. For example, the *N*-chlorosulfilimine readily decomposes even at room temperature to afford the corresponding sulfide and the sulfonium salt ($Ph_2S{=}\overset{+}{N}{=}SPh_2\ Cl^-$) and the decomposition is accelerated further by addition of Brönsted acids. The structures of these activated derivatives formed by addition of an electrophile are considered to be analogous to that of the persulfoxide,[8] or that of the intermediates formed in the treatment of dimethyl sulfoxide with primary or secondary alcohols to afford aldehydes or ketones,[9] or those of the reactions of sulfoxides,[10] sulfilimines,[11] sulfonium ylides,[12] and sulfoximines[13] with carbenes or nitrenes, to afford eventually the reduction products (Eq. 1).



(1)

The repulsive interaction between lone-pair electrons of the imino nitrogen and the adjacent heteroatom is considered to weaken the S–N linkage for facile cleavage. Meanwhile, the sulfilimines having either *N*-aryl, or *N*-phthalimido-substituent attached to the imino nitrogen are relatively stable thermally because the repulsive interactions of lone-pair electrons between the nitrogen atom and the adjacent sulfur atom is relieved considerably in these compounds. Similarly, the *N*-chlororsulfoximine, in which the repulsive interaction between two adjacent heteroatoms is reduced, undergoes degradation to afford the corresponding sulfoxide only at an elevated temperature, *e.g.*, 200 °C.

In order to explore the rough correlation between the nature of the S–N linkage and the stability of the sulfilimine derivatives, various *S,S*-diaryl-*N*-substituted sulfilimines (**1**), -*N*-substituted sulfoximines (**2**), and *N'*-substituted-*N*-(*p*-tolylsulfonyl)sulfonediimines (**3**) containing an S–N group, *e.g.*, *N*-(*p*-tolylthio)-, *N*-(*p*-tolylsulfinyl)-, *N*-(*p*-toluenesulfinimidoyl)-, and *N*-(diphenylsulfonio)sulfonium derivatives have been synthesized and their chemical properties have been examined.

Definition of Abbreviation for the Compounds. The following numbering and abbreviation for the *S,S*-diphenyl sulfur compounds are used through this paper.

Ph–S(NR)–Ph: *N*-*R*-Substituted-*S,S*-diphenylsulfilimines (**1**),
Ph–S(O)(NR)–Ph: *N*-*R*-Substituted-*S,S*-diphenylsulfoximines (**2**),
Ph–S(NR)(NR')–Ph: *N,N'*-*R,R'*-Disubstituted-*S,S*-diphenylsulfonediimines (**3**),
R or R' groups:
R (or R'); H, *N*-unsubstituted- (**a**),
; –STol(*p*-), *N*-(*p*-tolylthio)- (**b**),
; –S(O)Tol(*p*-), *N*-(*p*-tolylsulfinyl)- (**c**),

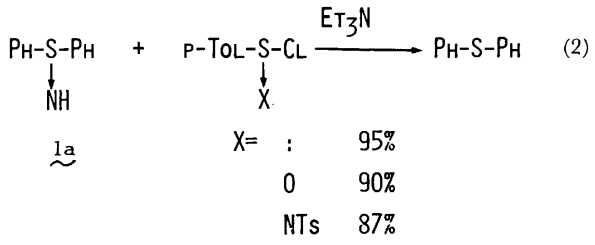
† Present address; Okayama University of Science, Ridai-cho 1-1, Okayama 700.

; $-S(NTs)Tol(p-)$, *N*-(*p*-toluenesulfinimidoyl)- (**d**),
; $-S(O)_2Tol(p-)$, *N*-(*p*-tolylsulfonyl)- (**e**),
; $-S(O)(p\text{-}TolN)Ph$, *N*-(*p*-toluenesulfonimidoyl)- (**f**),
; $-S(Ph)_2$, *N*-(diphenylsulfo)- (**g**).

other derivatives are shown by their *N*-substituent and numbering of the compounds *e.g.*, *N*-chloro-(**1**). Therefore, for expample, **1b** and **3ab** indicate *N*-(*p*-tolylthio)-*S,S*-diphenylsulfilimine and *N'*-unsubstituted *N*-(*p*-tolylthio)-*S,S*-diphenylsulfonediimine respectively.

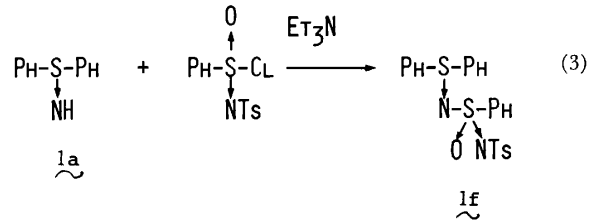
Results and Discussion

N-Substituted S,S-Diphenylsulfilimines (1). Treatment of *N*-unsubstituted sulfilimines with *p*-toluenesulfonyl chloride gave the corresponding thermally extremely stable compounds, *N*-(*p*-toylsulfonyl)-sulfilimines. However, *N*-(*p*-tolylthio)-(**1b**), *N*-(*p*-toylsulfinyl)-(**1c**), *N*-(*p*-toluenesulfinimidoyl)-(**1d**), or *N*-(*p*-toluenesulfonimidoyl)sulfilimines (**1f**) have not been reported in the literature. Preparations of **1b—d** have been attempted, by treating *N*-unsubstituted sulfilimine (**1a**) with *p*-toluenesulfenyl chloride, *p*-toluenesulfinyl chloride, or *p*-toluenesulfinimidoyl chloride in the presence of triethylamine, however only the corresponding reduction product, the sulfide, was obtained (Eq. 2).



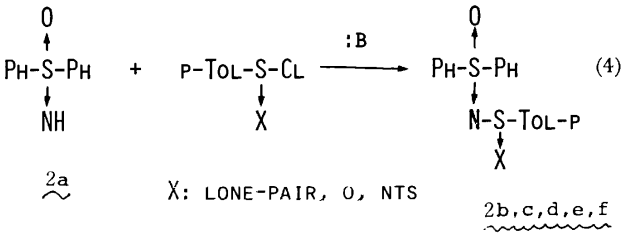
(2)

Finally, diphenyl *N*-(benzenesulfonimidoyl)sulfilimine (**1f**) was prepared by treating **1a** with *N*-benzenesulfonimidoyl chloride in the presence of triethylamine in 89% yield.



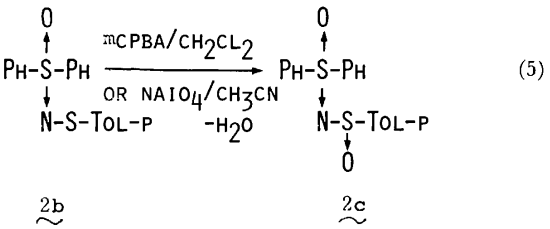
(3)

N-Substituted S,S-Diphenylsulfoximines (2). Conversion of *N*-unsubstituted sulfoximines into the corresponding *N*-(*p*-tolylsufonyl)sulfoximines and the desulfonylation of the latter compound are well known. Thus, *N*-unsubstituted *S,S*-diphenylsulfoximine (**2a**) was shown to react with *p*-toluenesulfonyl chloride in pyridine affording quantitatively the corresponding **2e**, which can reproduce **2a** by treating with concentrated sulfuric acid[14] or sodium in liquid ammonia.[15] However, nothing is known about *N*-substituted sulfoximines (**2b**, **2c**, **2d**, and **2f**). In the course of our systematic study of sulfilimines and their derivatives, especially the bonding nature of the semipolar S–N linkage in sulfilimines, sulfoximines and sulfondiimines, these compounds have been prepared in order to compare the characteristic properties of these bonds with those of known *N*-unsubstituted sulfoximines or *N*-(*p*-toylsulfonyl)sulfoximines. **2b** was prepared by treating *N*-sodium salt of the sulfoximine with *p*-toluenesulfenyl chloride or by treatment of two equivalents of **2a** with *p*-toluenesulfenyl chloride. Other bases such as pyridine or triethylamine gave no good result. The sulfoximines, **2c**, **2d**, and **2f** were prepared by treating the *N*-sodium salt of the sulfoximine with *p*-toluenesulfinyl chloride, *p*-toluenesulfinimidoyl chloride, and *p*-toluenesulfonimidoyl chloride, respectively, in good yields. These compounds were able to be prepared using other bases such as pyridine or triethylamine in good yields.



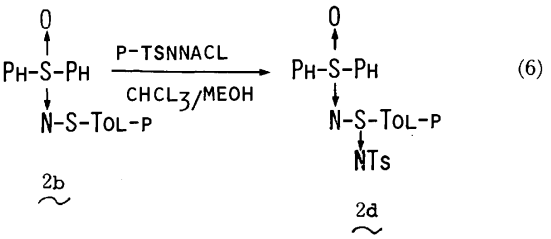
(4)

Another route to prepare **2c**, **2d**, and **2f** has been examined, using **2b** as the key starting material, which was converted to other *N*-substituted **2** by oxidation with such oxidizing reagents, as *m*-chloroperbenzoic acid (**mCPBA**) and sodium salt of *N*-chloro-*p*-toluenesulfonamide (chloramine-*T*). **2b** was oxidized readily with one equivalent of sodium periodate in aqueous acetonitrile or **mCPBA** in dichloromethane to **2c** (Eq. 5).



(5)

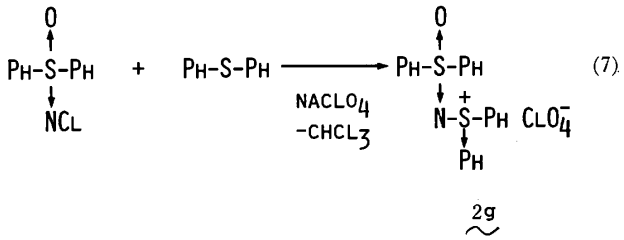
Meanwhile, **2b** reacts with chloramine-*T* to afford **2d** in a good yield in chloroform–methanol solution (Eq. 6).



(6)

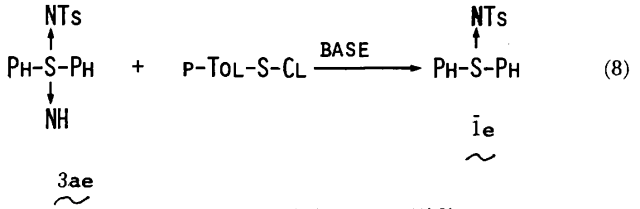
The use of two-fold excess of **mCPBA** in dichloromethane converted **2a** to **2e**, while the use of one equivalent of **mCPBA** oxidized **2c** to **2e**. Thus, these oxidation reactions of **2b** or **2c** should be another convenient way to prepare **2e**. In the same way, **2d** was nicely converted to **2f** by treating with **mCPBA** in dichloromethane in a good yield. Thus, **2b** is a good starting material for preparation of various other *N*-substituted sulfoximine derivatives. **2g** was also prepared by the

reaction of the *N*-chloro-**2** with the sulfide, according to the method reported earlier[16] (Eq. 7).



Thus, one can prepare all kinds of *N*-substituted sulfoximines, **2b—g**. The results are summarized in Scheme 1 and Tables 1 and 2.

Preparation of N'-*Substituted* S,S-*Diphenyl*-N-*(*p-*tolylsulfonyl)sulfonediimines (3).* Treatment of *N'*-unsubstituted *S,S*-diphenyl-*N*-(*p*-tolylsulfonyl)sulfonediimines (**3ae**) with *p*-toluenesulfenyl chloride at −20 °C in the presence of bases, *e.g.*, pyridine, triethylamine or **3ae**, did not afford the corresponding **3be** at all, but the reduction product, **1e** was obtained in a high yield (Eq. 8).



Base: NaH, Et_3N, pyridine, γ-collidine, **3ae**.

Table 1. Preparation of *N*-substituted-sulfoximines

Ph-S(O)-Ph, N-X, X	Condition	Yield/%[a]
S-Tol-*p*	*p*-TolSCl, NaH/PhH	92
(**b**)	*p*-TolSCl, Ph-S(O)-Ph/Et_2O, NH	81

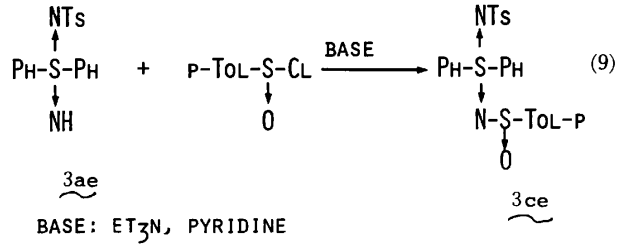
	*m*CPBA/CH_2Cl_2, Ph-S(O)-Ph, N-S-Tol-*p*	85

a) Isolated yield.

However, the reaction of **3ae** with *p*-toluenesulfinyl chloride at −20 °C in the presence of bases, *e.g.*, pyridine or triethylamine proceeded nicely (Eq. 9)



Furthermore, treatment of **3aa** with an equimolar amount of *p*-toluenesulfonyl chloride gave only **3ae**, monosulfonylated product. Disulfonylation of **3aa** was attempted by treating **3ae** with *p*-toluenesulfonyl chloride under various conditions and failed, recovering only **3ae** quantitatively. However, interestingly, **3ee**, *N,N'*-bis(*p*-tolylsulfonyl)sulfonediimine, was obtained in a quantitative yield when **3ce** was oxidized with 1 equiv of **mCPBA** (Eq. 10).

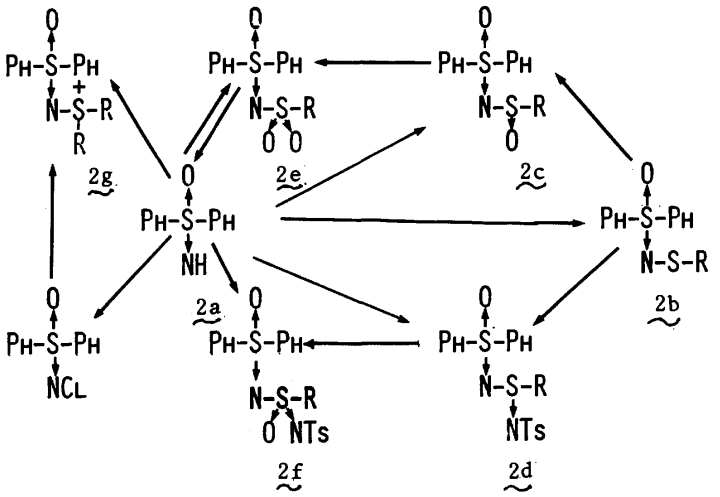
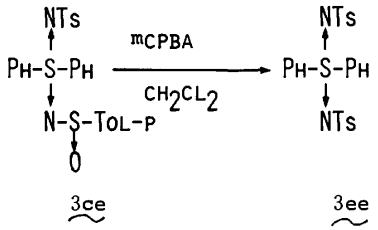


Scheme 1. Diagram of *N*-substituted sulfoximine starting from unsubstituted sulfoximine.



(10)

The lack of reactivity of **3ae** toward the sulfonyl chloride and the facile reaction of **3ce** with **mCPBA** may be reasonably rationalized in the following manner.

Namely, in the former reaction, the nucleophilicity of the imino nitrogen of **3ae** is considerably diminished while the sterically bulky sulfonyl group attached to the imino group would hinder the second sulfonylation of the imino nitrogen; whereas in the latter reaction, no matter whether the oxidation is caused by electrophilic attack of **mCPBA** or nucleophilic attack of the perbenzoate anion, the approach of the oxygen atom of **mCPBA** toward the sulfinyl sulfur atom should not be hindered both sterically and electronically.

These new derivatives of sulfonediimines thus obtained were identified by both spectroscopic and elemental analyses. This is the first and perhaps the best method to prepare *S,S*-diaryl-*N,N'*-bis(*p*-tolylsulfonyl)sulfonediimine. These results are listed in Table 3.

Table 3. Preparation of *N*-substituted-*N'*-*p*-toluenesulfonylsulfonediimines (**3**)

a) Isolated yield.

Experimental

General. Melting points of the products were measured by Yanaco instrument and were uncorrected. IR spectra were obtained using a Hitachi 215 spectrophotometer. ^1H NMR spectra of the all compounds were obtained with a Hitachi Perkin-Elmer R-20 spectrometer in 20% solutions in deuteriochloroform using tetramethylsilane as an internal standard. Mass spectra were recorded on a Hitachi RMU-6MG mass spectrometer with a direct inlet system. Liquid chromatographs were obtained by Yanaco L-1030 instrument using methanol as an eluent. Thin-layer chromatographies were carried out with Merck DC-Plastikofolien Kieselgel 60 F 254 Art 5735 with fluorescent indicator using various solvents and mixed solvents. Development was followed by UV light or by coloring with iodine. Silica gel used for column chromatography was either of Wako or of Merck chromatographic grade. Elemental analyses were carried out at the Chemical Analysis Center of this University. Oxidizing agents, **mCPBA**, sodium periodate and chloramine-*T* were obtained from Wako Pure Chemicals. Anhydrous dichloromethane and ether were obtained by the usual procedures.[17] Other chemicals were of reagent grade.

p-Toluenesulfenyl Chloride. *p*-Toluenesulfenyl chloride was prepared by treating the corresponding disulfide with gaseous chlorine in dichloromethane at 5 °C, accord-

ing to the known method,[18,19] and purified by distillation under reduced pressure. Bp 76.0—78.0 °C/2.5 mmHg (1 mmHg≈133.322 Pa),[18] (77.5—78.2 °C/2.5 mmHg).

o-Nitrobenenesulfenyl Chloride. Mp 74.0—75.0 °C (from tetrachloromethane), (lit, 75 °C[19]).

p-Toluenesulfinyl Chloride. *p*-Toluenesulfinyl chloride was obtained by treatment of *p*-toluenethiol with gaseous chlorine in anhydrous acetic anhydride at 10 °C, in the usual manner.[20] Bp 107.0—109.5 °C/2.5 mmHg, (lit, 92—102 °C/0.5 mmHg).[20]

p-Toluenesulfinimidoyl Chloride. *p*-Toluenesulfinimidoyl chloride was prepared by the reaction of *p*-toluenesulfenyl chloride with anhydrous chloramine-*T* in benzene, according to the previously reported method.[21] Mp 141.5—142.5 °C, (lit, 141.5—142.5 °C).[21]

N-(p-Tolylulfonyl)-p-toluenesulfonimidoyl Chloride. *p*-Toluenesulfonimidoyl chloride was prepared by the reaction of *p*-toluenesulfinyl chloride with commercially available chloramine-*T* in benzene, according to the method reported earlier.[22] Mp 76.5—77.5 °C, (lit, 76—78 °C).[22]

Preparation of 1a, 2a, 3ae. **1a**,[23] **2a**,[24] and **3ae**[25] were prepared by the method reported earlier.

Preparation of 1a, 2a, 3ae. **1a**,[23] **2a**,[24] and **3ae**[25] were prepared by the method reported earlier.

Preparation of N-Chlorosulfoximine. **3a** (2.0 g, 9.2 mmol) was dissolved in 10 mL of acetonitrile. This solution was added to a stirred solution of 15 mL of cold sodium hypochlorite solution. The reaction mixture was stirred for 15 min before the starting sulfoximine disappeared upon checking the TLC or HPLC. The solution was extracted with chloroform, which was dried, filtrated and evaporated. The purification was performed on recrystallization from benzene. Yield was 1.85 g (80%), colorless crystals, mp 150.0—151.0 °C.

Preparation of 1f. To a mixture of **1a** (200 mg, 0.91 mmol) and triethylamine (138 mg) in chloroform, a chloroform solution of *N*-(*p*-tolylsulfonyl)benzenesulfonimidoyl chloride (300 mg, 0.91 mmol) was added. After stirring the reaction mixture for 30 min at 25 °C, solid precipitates were washed with dilute aqueous hydrochloric acid solution, water, and dried over magnesium sulfate. After the solvent was removed, the crude product was purified by column chromatography. The crystals were recrystallized from ethanol. Yield was 401 mg (89%), mp 139.5 °C; IR(KBr) 1315(SO_2), 1305(SO_2), 1240(O=S=N-), 1150(SO_2), 1100(O=S=N-), 1060(O=S=N-), 1035, 1021, and 995 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.32 (3H, s, -$SO_2C_6H_4CH_3$-*p*), 7.00—7.90 (19H, m, aromatic protons); MS (20 eV) *m/z* (rel intensity) (M^+; 0.3), 292(7), 248(36), 186([PhSPh]$^+$; 100), 171(84), 170(81), 155(5), 125(11), 109(13), 90(23), and 77(18). Found: C, 60.70; H, 4.27; N, 5.50%. Calcd for $C_{25}H_{22}N_2O_3S_3$: C, 60.70; H, 4.48; N, 5.66%.

Preparation of 2b. To the ethereal solution of **2a** (10 g, 46 mmol) was added *p*-toluenesulfenyl chloride (3.5 g, 22 mmol) in ether solution under cooling with a Dry Ice-acetone bath with stirring. The reaction mixture was kept at −70 °C for 10 min and the cooling bath was removed and the heterogeneous reaction mixture was stirred until the solution reached at room temperature. The precipitates formed were filtered off after stirring the solution at 25 °C for 20 min. The solvent was evaporated. The crude product was purified through column chromatography and crystals thus obtained were recrystallized from dichloromethane-pentane. Yield was 6.1 g, 81%, mp 110 °C. Sodium salt of *S,S*-diphenylsulfoximine, which was prepared from **2a** and sodium hydride in benzene, also afforded **2b** by the reaction with *p*-toluenesulfenyl chloride in 92% yield. Colorless crystals; mp 110 °C; IR(KBr) 1220(O=S=N-), 1085(O=S=N-), and 980(O=S=N-); ^1H NMR ($CDCl_3$) δ=2.26 (3H, s, -$C_6H_4CH_3$-*p*), 6.96—8.09 (14H, m, aromatic protons); MS (20 eV) *m/z* (rel intensity) 339(M^+; 7), 246(50), 202([PhS(O)Ph]$^+$; 100), 186(75), 174(22), 154(77), 136(22), 123(61), 97(31), 90(31), and 77(17). Found: C, 67.11; H, 4.86; N, 4.15%. Calcd for $C_{19}H_{17}NOS_2$: C, 67.22; H, 5.04; N, 4.12%.

Preparation of S,S-Diphenyl-N-(o-nitrophenylthio)sulfoximine. Yield was 95—98%; colorless crystals; mp 161.0—162.0 °C; IR (KBr) 1210 (O=S=N-), 1090 (O=S=N-), 1005, and 985 (-S=N-); ^1H NMR ($CDCl_3$) δ=6.87—8.17 (14H, m, aromatic protons); Found: C, 58.29; H, 3.81; N, 7.45%. Calcd for $C_{18}H_{14}N_2O_3S_2$: C, 58.36; H, 3.80; N, 7.56%.

Preparation of 2c. This compound was prepared by either one of the following two processes.

Method A: **2a** (3.0 g, 13.8 mmol) and triethylamine (1.7 g, 16.6 mmol) were dissolved in ether. Under stirring and cooling with a Dry Ice-acetone bath, and ethereal solution of *p*-toluenesulfinyl chloride (2.5 g, 14.3 mmol) was added dropwise. After warming at 25 °C for 20 min the precipitates were separated by filtration. Ether was removed, the crude crystals thus obtained were recrystallized from dichloromethane-pentane. Yield was 4.5 g, 92%; mp 192.5—193.0 °C; colorless crystals.

Method B: **2b** (300 mg, 0.88 mmol) was oxidized with **mCPBA** (152 mg) at 25 °C for 15 min. The usual work-up process afforded **2c**. Yield was 267 mg, 85%; IR(KBr) 1235(O=S=N-), 1105(O=S=N-), 1090(O=S=N-), 1075(-S=O), 1040, 1020, and 995(-S-N=); ^1H NMR ($CDCl_3$) δ=2.35 (3H, s, -$C_6H_4CH_3$-*p*), 7.22—8.23 (14H, m, aromatic protons); MS (20 eV) *m/z* (rel intensity) 355(M^+; 9), 264(56), 202([PhSPh]$^+$; 100), 186(14), 174(10), 154(36), 138(11), 124(8), and 109(22). Found: C, 64.55; H, 4.76; N, 3.98%. Calcd for $C_{19}H_{17}NO_2S_2$: C, 64.19; H, 4.82; N, 3.98%.

Preparation of 2d. **2b** (600 mg, 1.77 mmol) was dissolved in chloroform. To this solution was added chloramine-*T* (75 mg) in methanol. After stirring the mixture for 30 min at 25 °C, the solvent was removed *in vacuo*, the crude product was separated through column chromatography using chloroform as eluent. The yield was 782 mg, 87% (recrystallized from ethanol). This sulfoximine was also prepared by the reaction of sodium salt of *S,S*-diphenylsulfoximine with *N*-(*p*-tolylsulfonyl)-*p*-toluenesulfinimidoyl chloride in benzene. Yield was 75% (colorless crystals). Mp 118.0—118.5 C; IR(KBr) 1290(O=S=O), 1280 (O=S=O), 1230(O=S=N-), 1140(O=S=O), 1095(O=S=N-), 1085 (O=S=N-), 1035 and 955 (S(IV)-N); ^1H NMR ($CDCl_3$) δ= 2.34 (3H, s, -$C_6H_4CH_3$-*p*), 2.34 (3H, s, -$SO_2C_6H_4CH_3$-*p*), 7.10—8.12 (18H, m, aromatic protons); MS (20 eV) *m/z* (rel intensity) 508 (M^+; 2), 369 ([PhS(O) (NS(N)$C_6H_4CH_3$-*p*)]$^+$; 100), 339(8), 202(60), 186(28), 169(12), 155(17), 137(40), 125(39), 124(28), 123(28), 109(18), 91(77), 90(62), and 77(16). Found: C, 61.23; H, 4.66; N, 5.41%. Calcd for $C_{26}H_{24}N_2O_3S_3$: C, 61.39; H, 4.75; N, 5.50%.

Preparation of 2g. *S,S*-Diphenyl-*N*-chlorosulfoximine which was prepared by the reaction of **2a** with sodium hypochlorite in aqueous acetonitrile, was dissolved into chloroform at 25 °C. To this solution was added diphenyl sulfide in chloroform with stirring at 25 °C for 30 min. The mixture was washed with an aqueous solution of sodium perchlorate, with water and dried over magnesium sulfate. Chloroform was removed *in vacuo* and the product was separated by column chromatography using chloroform-methanol (9 : 1) as an eluent. Recrystallization of this product was performed from ethanol. Yield was 80%; colorless crystals; mp 155.5—156.0 °C. IR(KBr) 1235(O=S=N-), 1100(O=S=N-), 1090($OClO_3$), 1030, and 985(-S-N=); ^1H NMR ($CDCl_3$) δ=7.23—7.97 (20H, m, aromatic protons). Found: C, 57.49; H, 4.02; N, 2.84%. Calcd for $C_{24}H_{20}NO_5S_2Cl$: C, 57.42; H, 4.01; N, 2.79%.

Preparation of 2e. The sulfonylation of **2a** was

reported earlier.[14] **2c** (300 mg, 0.85 mmol) was dissolved in dichloromethane. To this solution was added a solution of **mCPBA** (220 mg) in dichloromethane. After 2 h of stirring the usual work-up gave the crude product upon column chromatography using chloroform as an eluent. Further purification was carried out by recrystallization from ethanol. Yield was 297 mg, 95%; colorless crystals; mp 137.5 °C.

This sulfoximine was also obtained from the corresponding **2b** by oxidation with 2 equiv of **mCPBA** in dichloromethane. Yield was 99%; IR(KBr) 1295(O=S=O), 1240 (O=S=N-), 1150(O=S=O), 1100(O=S=N-), 1065, 1020, and 995(O=S=N-); ^{1}H NMR ($CDCl_3$) $\delta=2.38$ (3H, s, -$C_6H_4CH_3$-*p*), 7.13—8.06 (14H, m, aromatic protons); MS (20 eV) *m/z* (rel intensity) 371(M^+; 12), 294(2), 278(29), 139([PhS(O)N]$^+$; 100), and 125(45).

Preparation of 2f. To a dichloromethane solution of **2d** (200 mg, 0.39 mmol) was added a dichloromethane solution of **mCPBA** (9 mg). After 8 h, the reaction mixture was washed with water, aqueous sodium carbonate solution and then washed with water. Dichloromethane solution was dried over magnesium sulfate and the solvent was removed under reduced pressure. The solid obtained was purified through column chromatography using chloroform as an eluent. Further purification was accomplished by recrystallization from ethanol. Yield was 163 mg, 79%; colorless crystals; mp 198.0—198.5 °C; IR(KBr) 1300(O=S=O), 1250(O=S=N-), 1235(O=S=N-), 1140(O=S=N-), 1100(O=S=N-), 1060, 1035, 1005, and 990 (-S=N-); ^{1}H NMR ($CDCl_3$) $\delta=2.33$ (3H, s, -$C_6H_4CH_3$-*p*), 2.33 (3H, s, -$SO_2C_6H_4CH_3$-*p*), 7.05—7.95 (18H, m, aromatic protons; MS (20 eV) *m/z* (rel intensity) 524(M^+; 0.9), 447(0.9), 417(1), 385(8), 308(l), 278(11), 264([Ph_2S(O)NSO]$^+$; 100), 246(8), 202(6), 200(13), 139(89), 125(27), and 109(2). Found: C, 59.28; H, 4.41; N, 5.20%. Calcd for $C_{26}H_{24}N_2O_4S_3$: C, 59.52; H, 4.61; N, 5.33(%).

Reaction of 3ae with p-Toluenesulfenyl Chloride. **3ae** (700 mg, 1.9 mmol) and triethylamine (230 mg, 2.3 mmol) were dissolved into dichloromethane (20 mL). To this solution was added dropwise *p*-toluenesulfenyl chloride (300 mg, 1.9 mmol) in dichloromethane (10 mL) at −20 °C under stirring. After the solution was kept for 10 min at −20 °C, the cooling bath was removed and heterogeneous reaction mixture was stirred until the solution was reached at room temperature. After the usual work-up, **1e** (578 mg) was obtained in 86% yield. **3be** was not obtianed.

Preparation of 3ce. **3ae** (3.0 g, 8.1 mmol) was dissolved in 30 mL of dichloromethane. To this solution was added dropwise *p*-toluenesulfinyl chloride (1.5 g) and triethylamine (1.1 g) with stirring at −70 °C under cooling with Dry Ice-acetone bath. After stirring for 20 min at 25 °C, the precipitates were filtrated off. The organic solution was washed with water and dried over magnesium sulfate. The crude product thus obtained was recrystallized from dichloromethane-pentane. Yield was 3.5 g (85%); colorless crystals; mp 143.0—144.0 °C; IR(KBr) 1320 (O=SO), 1305(O=S=O), 1185(O=S=O), 1160(-N=S=N-), 1105(-N=S=N-), 1060(-N=S=N-), and 985(-S-N=); ^{1}H NMR ($CDCl_3$) $\delta=2.34$ (3H, s, -S(O)$C_6H_4CH_3$-*p*), 2.44 (3H, s, -$SO_2C_6H_4C_6H_4CH_3$-*p*), and 7.05—8.27 (18H, m, aromatic protons); MS (20 eV) *m/z* (rel intensity) 354(1), 278(1), 214(1), 200([Ph_2S-N]$^+$; 100), 186(10), 139(1), and 123(6). Found: C, 61.56; H, 4.65; N, 5.47%. Calcd for $C_{26}H_{24}N_2O_3S_3$: C, 61.39; H, 4.75; N, 5.50%.

Preparation of 3ee. Sulfonylation of **3ae** with *p*-toluenesulfonyl chloride in the presence of various bases, such as triethylamine or 2,2,6-trimethylpyridine was not successful, and the original sulfonediimine was recovered nearly quantitatively. However, **3ee** was obtained by another way. To a dichloromethane solution of **3ce** (500 mg, 0.98 mmol) was added a dichloromethane solution of **mCPBA** (2-fold excess) under cooling at 0 °C with an ice-water bath with stirring. After removing the precipitated *m*-chlorobenzoic acid, the solution was washed with aqueous sodium carbonate, water and dried over magnesium sulfate. The solvent was removed by evaporation, the crude crystals were obtained. Purification was achieved by recrystallization from ethanol. Yield was 485 mg, 94%; colorless crystals, mp 213.5 °C; IR(KBr) 1330(O=S=O), 1165(-N=S=N-), 1080 (-N=S=N-), 1050(-N=S=N-), and 995(-S-N=); ^{1}H NMR ($CDCl_3$) $\delta=2.40$ (3H, s, -$NSO_2C_6H_4CH_3$-*p*), 2.40 (3H, s, -$NSO_2C_6H_4CH_3$-*p*), and 7.11—8.02 (18H, m, aromatic protons). MS (20 eV) *m/z* (rel intensity) 370(5), 306(12), 279(42), 265(47), 215(10), 201(66), 186(78), 171(6), 155(23), 139(15), 119(73), and 91([Tol]$^+$; 100). Found: C, 59.97; H, 4.54; N, 5.20%. Calcd for $C_{26}H_{24}N_2O_4S_3$: C, 59.52; H, 4.61; N, 5.33%.

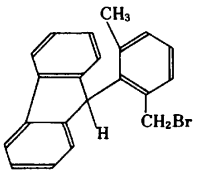
Reactivities of Stable Rotamers. XII. Reactions of 9-(2-Bromomethyl-6-methylphenyl)fluorene Rotamers with Nucleophiles[1,2]

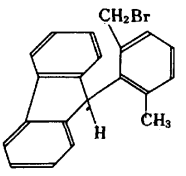
Shigeru MURATA, Seiichiro KANNO, Yo TANABE, Mikio NAKAMURA, and Michinori ŌKI*
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received September 19, 1983)

Rates of some substitution reactions of 9-(2-bromomethyl-6-methylphenyl)fluorene rotamers with nucleophiles are compared. Methanolysis of the rotamers proceeded smoothly in the *sp* form but was sluggish in the *ap*. Reactions of the *sp* form with sodium methoxide afforded 6-methylspiro[benzocyclobutene-1(2*H*), 9'-[9*H*]fluorene] and *sp*-9-(2-methoxymethyl-6-methylphenyl)fluorene, the former being a minor product. In addition to these, isomerization to the *ap* was detected. In contrast, the *ap* form afforded the spiro compound as a major product and the *ap* form of the methoxy compound as a minor product. Menschutkin reactions with pyridine bases were much faster in the *sp* form than in the *ap*. These results are attributed to the steric effect in the transition states of the reactions: the *sp* form reacts much faster than the *ap* because of the presence of the fluorene moiety in proximity of the reaction site in the latter.

Understanding of reactivities of rotational isomers is essential, if we wish to improve the selectivity of a reaction which is carried out at a low temperature, where conformations are frozen. To achieve this end, we have been studying the reactivities of stable rotamers since the success in isolating atropisomers at room temperature.[3,4] In a previous paper,[5] we gave a full account of the research on ionization reactions of 9-(2-bromomethyl-6-methylphenyl)fluorene (**1**) rotamers and a general conclusion is that, if the transition state for a reaction is space-demanding, the reaction is very slow in the *ap* form relative to that in the *sp* form. Similar conclusions were reached in related compounds.[1,6]



sp-1



ap-1

This paper reports the results of investigations on the reactivities of *sp*-**1** and *ap*-**1** with some nucleophiles. Since S_N2 type reactions are space-demanding in their transition states, the relative reactivities (k_{sp}/k_{ap}) are expected to be large in these reactions and the expectation is proved to be true.

Results and Discussion

Main reactions investigated in this work are summarized in the following chart, together with a related reaction.

Methanolysis of alkyl halides is known to be autocatalytic. Therefore, only the initial reaction rates are valid, if we wish to discuss the results quantitatively.[7] Alternatively, a base which shows proton affinity but no affinity to other acids may be added to obtain reliable data. Furthermore, it was pointed out that benzyl halides react in both S_N1 and S_N2 fashions in solvolytic reactions.[8]

Heating a rotamer of **1** in methanol containing *ca.* 2 (v/v)% of chloroform, which was necessary for facile

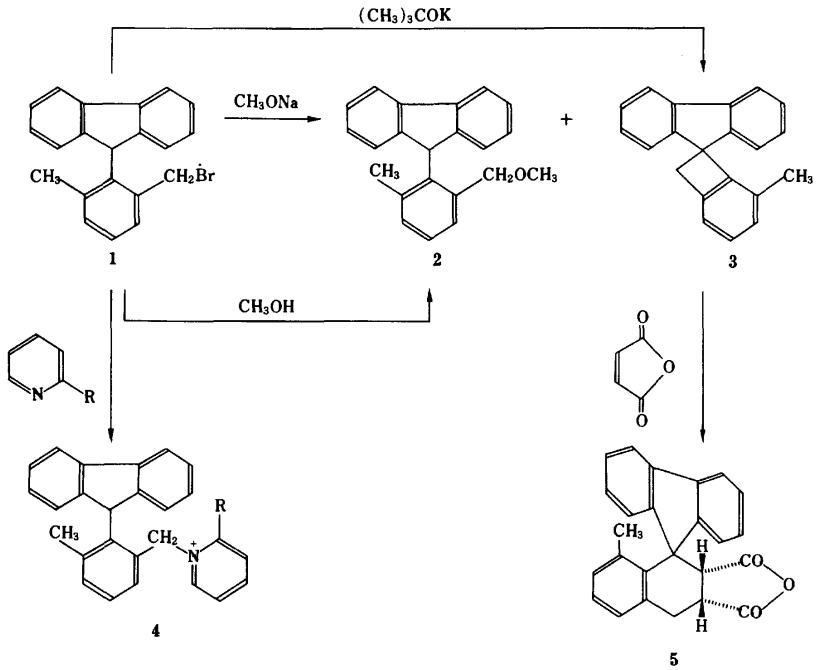


Table 1. Conditions and products of reactions of 1 with sodium methoxide in methanol

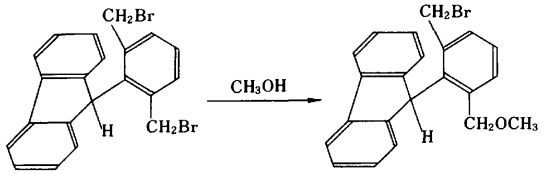
a) Normalized to 100%.

dissolution, at 52 °C afforded methanolysis products, *sp*- and *ap*-9-(2-methoxymethyl-6-methylphenyl)fluorene (**2**). The reaction obeyed the pseudo-first order rate law until 20—30% completion. The rate constants were obtained as follows: $k_{sp}=5.5\times10^{-3}\,min^{-1}$, $k_{ap}=1.9\times10^{-4}\,min^{-1}$. *Under competitive conditions,* k_{sp}/k_{ap} was *ca.* 29 which is in good agreement with the data of the individual constants.[9]

The data allured us to investigate the methanolysis of 9-[2,6-bis(bromomethyl)phenyl]fluorene (**6**).[5] This compound possesses a diastereotopic pair of bromomethyl groups but thier reactivities should be different to a great extent. Indeed, methanolysis of **6** afforded *ap*-9-(2-bromomethyl-6-methoxymethylphenyl)-fluorene (**7**) as a sole product.



6 7

Using a strong base as a nucleophile should erase the effect of proton which is produced by the reaction but may cause deprotonation at the 9-position of fluorene. We have experiences of base-catalyzed isomerization of rotamers of 9-arylfluorenes.[6] Thus the use of a strong base should materialize the competitive reactions between deprotonation from the 9-position of fluorene and nucleophilic substitution at the CH_2Br group in **1**. As such a base, we examined the case of methoxide. This reaction afforded a mixture of 9-(2-methoxymethyl-6-methylphenyl)fluorene (**2**) and a spiro compound, 6-methylspiro[benzocyclobutene-1(2*H*),9′-[9*H*]fluorene] (**3**), which was also prepared by treating either *sp*-**1** or *ap*-**1** with sodium hydride. The reaction conditions and product distributions are summarized in Table 1.

Isomerization of *sp*-**1** to the *ap* form and the reverse are observed at 25 °C to a small extent. Since the formation of **3** must proceed *via* deprotonation at the 9-position followed by an intramolecular S_N2 reaction, the observation of the isomerization suggests that the intramolecular S_N2 reaction is slower than the deprotonation. Nonexistence of the isomerization of **1** in the reactions at 50 °C may mean that the rate of the cyclization is comparable with that of the deprotonation at this temperature. The mechanism of the formation of the isomerized methoxycompound (**2**) is not clear, since **2** can be formed either by isomerization of **1** or that of **2**. Probably the both mechanisms are involved. The most interesting point here is that, in *sp*-**1**, the substitution to produce *sp*-**2** is a main reaction, whereas, in *ap*-**1**, the deprotonation is main. Apparently the S_N2 type substitution is faster than the deprotonation in *sp*-**1**, but the S_N2 type reaction is so slow in the *ap* that the deprotonation becomes the main reaction.

According to the idea discussed above, the reaction of **1** with *t*-butoxide should produce **3** as a sole product, since S_N2 reactions of *t*-butoxide is known to be unimportant.[10] Indeed, treatment of either *sp*-**1** or *ap*-**1** with potassium *t*-butoxide in *t*-butyl alcohol produced the spiro compound (**3**) as a sole product. The relative reactivity (k_{sp}/k_{ap}) was 1.4. The cause for this difference in the reactivities of the rotamers is probably ligation between the cation and the bromine atom in the 2-substituent, which is close to the reaction site in the *sp* form. Since potassium *t*-butoxide exists most probably as ion pairs in *t*-butyl alcohol which has a low dielectric constant,[11] ligation of the bromine to potassium ion should reduce the effective size of the alkoxide to some extent. Such an example of assistance in deprotonation has been reported.[12]

The facile formation of the spiro compound (**3**) was a surprise for us because it contained a benzocyclobutene moiety; benzocyclobutenes are usually prepared by special techniques. In order to confirm the structure, we have carried out a reaction. Benzocyclobutenes are known to be pyrolyzed to produce *o*-quinone dimethides which can be trapped by a dienophile.[13] This reaction is used even for syntheses of natural products.[14] Heating a solution of **3** in toluene with maleic anhydride at 135 °C, we were able to isolate an adduct (**5**). Thus the structure of **3** is supported by a chemical means.

Pyridine bases are known to undergo pure S_N2 reactions with benzyl chloride.[15] Since their basicities are not high, their activity for deprotonation may not be very high as well. Thus it is hopeful that we examine pure S_N2 reactions of **1** without isomerization and formation of **3**, if we use a pyridine base. The results are summarized in Table 2. Compound *sp*-**1** reacts 35 times faster with 2-methylpyridine and 22 times faster with pyridine than *ap*-**1**.

Under the same conditions utilized for the reaction of **1** with 2-methylpyridine, benzyl bromide reacted with the

Table 2. Rates of menschutkin reactions of 1 with pyridine bases

		Pyridine	2-Methylpyridine
Temp/°C		35	34
k_2/L mol^{-1} s^{-1}	*sp*-1	8.5×10^{-4}	2.3×10^{-4}
	ap-1	3.9×10^{-5}	6.7×10^{-6}
k_{sp}/k_{ap}		22	35

base with a rate constant of 3.8×10^{-5} L mol^{-1} s^{-1}. The rate constant is in good agreement with that reported.[16] Thus benzyl bromide is about 6 times more reactive than *ap*-**1** but is less reactive than *sp*-**1** by a factor of *ca.* 6. The tendency of enhancement of the reaction rate by substitution of the ortho position of benzyl halides is known.[17] The explanation of the enhancement by the van der Waals interaction[18] may be valid in this case as well.

If we summarize the results presented above, the S_N2 type reactions are, without exception, slow in *ap*-**1** relative to *sp*-**1**. This is reasonable, from the experiences we have had before,[1,6] since S_N2 type reactions take space-demanding transition states which require high energy state in the *ap* because of the steric effect. The decrease in the difference in reactivities of the rotamers by going from 2-methylpyridine to pyridine is a reflection of the steric effect. It is also interesting to note that the relative reactivity of the bromomethyl group in the rotamers is not dependent on the nucleophilicity[19] of the nucleophiles: steric effects are the controlling factor in determining the relative reactivity because 2-methylpyridine which is rather a strong nucleophile exhibited the highest selectivity.

Experimental

9-(2-Methoxymethyl-6-methylphenyl)fluorene (2). A solution of 29 mg of *sp*-**1** in 3 mL of chloroform and 20 mL of methanol was heated at 50—60 °C for 24 h and then was poured into water. The mixture was extracted with ether and the extract was dried over magnesium sulfate. After evaporation of the solvent, the residue was submitted to silica-gel TLC (1:2 hexane–benzene) to afford *ca.* 95% *sp*-**2**, oil, which gave identical ^{1}H NMR spectrum with an authentic sample.[5]

Similar treatment of *ap*-**1** in methanol showed the presence of the starting material (35%) as well as *ap*-**2** (55%), of which ^{1}H NMR spectrum was identical with that of an authentic sample,[5] after 70 h heating.

ap-*9-(2-Bromomethyl-6-methoxymethylphenyl)fluorene (7).* A solution of 46 mg of **6**[5] in 0.5 mL of chloroform and 30 mL of methanol was heated at 50—60 °C for 7 h and the solvent was evaporaed. The residue was submitted to silica-gel TLC (3:1 hexane–benzene) to give 6 mg of the recovered material and 25 mg (58%) of the desired product. Recrystallization from hexane gave a pure sample, mp 91—92 °C Found: C, 69.43; H, 4.99; Br, 21.34%. Calcd for $C_{22}H_{19}BrO$: C, 69.67; H, 5.05; Br, 21.07%. ^{1}H NMR ($CDCl_3$, δ): 3.38 (2H, s), 3.44 (3H, s), 4.73 (2H, s), 5.57 (1H, s), 7.1—8.0 (11H, m).

6-Methylspiro[benzocyclobutene-1(2H),9′-[9H] fluorene] (3). A solution of 140 mg (0.40 mmol) of a *ca.* 1:1 mixture of *sp*-**1** and *ap*-**1** in 3.5 mL of tetrahydrofuran was mixed with a suspension of 60 mg (2.5 mmol) of sodium hydride in 3.5 mL of tetrahydrofuran. To the mixture was added 0.7 mL of *N,N*-dimethylformamide and the whole was stirred for 3 h at 55—60 °C under a nitrogen atmosphere. After being cooled, the mixture was treated with 7 mL of ether containing 1.4 mL of methanol. Water was added and the organic layer was separated. The organic layer and ether extracts of the aqueous layer were combined, and washed successively with dilute hydrochloric acid and aqueous sodium hydrogencarbonate. The combined solution was dried and evaporated. The residue was purified by TLC (4:1 hexane–benzene) to give 80 mg (75%) of the desired product. Recrystallization of the product from ethanol–pentane gave a pure sample, mp 93 °C. Found: C, 94.28; H, 5.83%. Calcd for $C_{21}H_{16}$: C, 93.99; H, 6.01%. MS showed an M^+ peak at *m/z* 268 while the calculated value is 268. ^{1}H NMR ($CDCl_3$, δ): 1.49 (3H, s), 3.65 (2H, s), 6.9—7.9 (11H, m).

8′-Methyl-3′,4′-dihydrospiro[9H-fluorene-9,1′(2′H)-naphthalene]-cis-2′,3′-dicarboxylic Anhydride (5). A solution of 85 mg (0.32 mmol) of **3** and 40 mg (0.41 mmol) of maleic anhydride in 0.5 mL of toluene was sealed in a tube under a nitrogen atmosphre and heated in a boiling xylene bath for 2 d. The reaction mixture was cooled and the precipitate was collected. Washing the crystals with benzene afforded 45 mg of the desired product whereas the mother liquor afforded 25 mg of the starting material after evaporation followed by TLC on silica gel (3:1 hexane–benzene). The yield was 55%. A pure sample of **5**, mp 235—236 °C, was obtained by recrystallization of the crude product from benzene. Found: C, 82.04; H, 4.69%. Calcd for $C_{25}H_{18}O_3$: C, 81.95; H, 4.95%. MS (M^+): 366. ^{1}H NMR (DMSO-d_6, δ): 1.02 (3H, s), 3.4—4.4 (4H, m), 6.9—8.1 (11H, m). IR (KBr disk): 1860, 1780 cm^{-1}.

1-[2-(9-Fluorenyl)-3-methylbenzyl]-2-methylpyridinium Bromide (4: R=CH$_3$). A solution of 20 mg (57 μmol) of *sp*-**1** in 0.3 mL of acetone containing 50 μL (510 μmol) of 2-methylpyridine. The mixture was stirred for 2 h at 35 °C. The precipitate was collected and was washed with acetone to give 12 mg (48%) of the desired compound. Recrystallization of the product from methanol–ethanol–hexane afforded a pure sample, mp 227 °C (decomp). Found:, 73.30; H, 5.18; N, 3.33; Br, 18.21%. Calcd for $C_{27}H_{24}NBr$: C, 73.30; H, 5.47, N, 3.18; Br, 18.06%. ^{1}H NMR (DMSO-d_6, δ): 1.12 (3H, s), 2.96 (3H, s), 5.50 (1H, s), 6.39 (2H, s), 6.7—9.2 (15H, m).

Similar reaction of *ap*-**1** carried out for 3 d under a nitrogen atmosphere afforded colorless crystals, mp 210 °C (decomp), after recrystallization from acetone–hexane. Found: C, 71.59; H, 5.42; N, 3.11; Br, 17.87%. Calcd for $C_{27}H_{24}NBr\cdot 1/2H_2O$: C, 71.84; H, 5.58; N, 3.10; Br, 17.70%. ^{1}H NMR (DMSO-d_6, δ): 1.81 (3H, s), 2.83 (3H, s), 4.40 (2H, s), 5.77 (1H, s), 6.6—8.5 (15H, m). ^{1}H NMR ($CDCl_3$, δ): 2.04 (3H, s), 2.79 (3H, s), 4.75 (2H, s), 5.62 (1H, s), 7.1—8.3 (15H, m). The *ap*-**4** (R=CH$_3$) was much more soluble in various solvents than *sp*-**4** (R=CH$_3$).

1-[2-(9-Fluorenyl)-3-methylbenzyl]pyridinium Bromide (4: R=H). The reaction of **1** with pyridine was carried out similarly as described for the reaction of 2-methylpyridine.

sp-**4** (R=H), mp 216 °C (decomp). Found: C, 73.40; H, 5.25; N, 3.32; Br, 18.90%. Calcd for $C_{26}H_{22}NBr$: C, 72.90; H, 5.18; N, 3.27; Br, 18.65%. ^{1}H NMR (DMSO-d_6, δ): 1.04 (3H, s), 5.46 (1H, s), 6.38 (2H, s), 6.7—9.2 (16H, m).

ap-**4** (R=H), mp 189 °C (decomp). Found: C, 71.02; H, 4.92; N, 3.14; Br, 18.22%. Calcd for $C_{26}H_{22}NBr\cdot 1/2H_2O$: C, 71.40; H, 5.30; N, 3.20; Br, 18.27%. ^{1}H NMR ($CDCl_3$, δ): 2.79 (3H s) 5.05 (2H, s), 5.60 (1H, s), 7.0—8.2 (16H, m).

Reaction of 1 with Sodium Methoxide. To a solution of 20 mg (57 μmol) of *sp*-**1** or *ap*-**1** and 15 mg of 2-methylnaphthalene, which served as an internal reference in the subsequent analysis, in 0.4 mL of chloroform and 28.6 mL of methanol, was added 1 mL of a methanolic solution of sodium methoxide, which was prepared by adding 0.13 g of sodium to 10.0 mL of methanol. After the solution was heated at appropriate temperatures for given times, the conversion ratio was checked by means of HPLC (a Waters M-6000 instrument) with a UV detecter. The reaction mixture was cooled and diluted with chilled water. The mixture was acidified with dilute hydrochloric acid and was extracted with dichloromethane. The organic layer was washed, dried, and evaporated. The residue in chloroform-*d* showed the presence of the spiro compound (**3**) and the methoxy compound (**2**) in addition to others. The results are summarized in Table 1.

Reaction of 1 with Potassium t-Butoxide. To a solution of 5 mg (14 μmol) each of *sp*-**1** and *ap*-**1** in 14 mL of *t*-butyl alcohol containing 3 mg of 2-methylnaphthalene, was added 1 mL of a solution of potassium *t*-butoxide (280 μmol) in

t-butyl alcohol, of which concentration was determined by titration. After 30 min, the reaction mixture was treated in a usual manner and the products were checked with ^{1}H NMR, HPLC, and/or TLC. No products other than the spiro compound (**3**) were detected.

Determinaion of Rates of Reactions. Methanolysis: A solution of 6.0 mg (17 μmol) each of *sp*-**1** and *ap*-**1** and 2.9 mg of fluorene in 0.4 mL of chloroform and 20 mL of methanol was heated at 52 °C. The aliquot was syringed out at appropriate intervals and the materials were analyzed with the use of HPLC, using the fluorene as an internal standard. The data satisfied the pseudo-first order rate law until 20—30% completion.

Menshutkin Reactions. To a solution of 12.5 mg (36 μmol) of *sp*-**1** or *ap*-**1** in 0.18 mL of dry acetone containing a small amount of dichloromethane or 1,2-dichloroethane in an NMR tube, was added 0.18 mL of a solution (0.190 mol/L) of pyridine and the tube was placed in an NMR probe at 35 °C. The decrease in the amount of the halide (**1**) was measured by taking the signal intensity of the added dichloromethane or 1,2-dichloroethane as an internal standard. The reaction obeyed the second-order rate law until 15—20% completion.

The reaction of **1** with 2-methylpyridine was monitored similarly except that the excess of an acetone solution (1.0 mol/L) of the base was used. Pseudo-first order rate constants thus obtained gave the second-order rate constants.

Competitive Reactions. Methanolysis was carried out as described in the section of rates of methanolysis except that 6.0 mg each of *sp*-**1** and *ap*-**1** were dissolved at the beginning. The relative reactivity was calculated by the following equation, where subscript 0 denotes the initial state.

$$k_{sp}/k_{ap} = \log \frac{[sp]}{[sp]_0} \Big/ \log \frac{[ap]}{[ap]_0}$$

Reaction with potassium *t*-butoxide was carried out similarly using 2-methylnaphthalene as an internal standard.

(Received September 24, 1983)

Apramycin and saccharocin (KA-5685) have been synthesized from previously synthesized neamine (**3**). Addition of allylmagnesium chloride to 4-*O*-[3′,4′-*O*-cyclohexylidene-2′-deoxy-2′-(tosylamino)-α-D-*gluco*-hexodialdo-1′,5′-pyranosyl]-5,6-*O*-cyclohexylidene-1,3-di-*N*-tosyl-2-deoxystreptamine which was derived from **3** through the 6′-*N*-oxide, gave 4-*O*-[3′,4′-*O*-cyclohexylidene-2′,7′,8′,9′-tetradeoxy-2′-(tosylamino)-L-*glycero*- and D-*glycero*-α-D-*gluco*-non-8′-enopyranosyl]-5,6-*O*-cyclohexylidene-1,3-di-*N*-tosyl-2-deoxystreptamines which were in turn converted into 4-*O*-[(8′*S*)-7′-*N*,6′-*O*-carbonyl-2′,3′,7′-trideoxy-8′-*O*-methyl-7′-(methylamino)-2′-(tosylamino)-D-*glycero*-α-D-*allo*-octodialdo-1′,5′:8′,4′-dipyranos-1′-yl]-5,6-*O*-cyclohexylidene-1,3-di-*N*-tosyl-2-deoxystreptamine (**25**), *via* azidonitration of 1-*N*-acetyl-4-*O*-[3′,6′-di-*O*-acetyl-4′,8′-anhydro-2′,7′-dideoxy-2′-(tosylamino)-L-*glycero*-α-D-*gluco*-oct-7′-enopyranos-1′-yl]-5,6-*O*-cyclohexylidene-1,3-di-*N*-tosyl-2-deoxystreptamine and epimerization of the 6′-hydroxyl group. Successive deprotection of **25** afforded aprosamine, from which 1,2′,3,7′-tetrakis(*N*-benzyloxycarbonyl)aprosamine (**28**) was prepared, and glycosidation of **28** with 4-azido-2,3,6-tri-*O*-benzyl-4-deoxy-β-D-glucopyranosyl fluoride or 2,3,4,6-tetra-*O*-benzyl-β-D-glucopyranosyl fluoride, followed by hydrogenolysis, completed the total synthesis.

Apramycin[1] (**1**) and saccharocin[2a] (**2**: antibiotic KA-5685 [2b]) are aminoglycoside antibiotics active against Gram-positive and Gram-negative bacteria including resistant strains of other aminoglycoside antibiotics. Apramycin (**1**) was isolated in 1967 as nebramycin component 2 from fermentation broths of *Streptomyces tenebrarius*,[1a] and saccharocin and KA-5685 (**2**), which were found to be identical with each other later on, were independently reported in 1983 as metabolites of *Saccharopolyspora sp.* by two Japanese groups.[2] Structural studies have revealed that antibiotics **1**[1b] and **2**[2] contain the unusual bicyclic aminooctodialdose and 2-deoxystreptamine units as common structures, and, in addition, 4-amino-4-deoxy-D-glucose and D-glucose units respectively. The unique structural features as well as the opportunity to develop synthetic strategy for the construction of more diverse analogs of these interesting antibiotics have prompted substantial recent synthesis efforts.[3,4] Very recently, the first total synthesis of **1** was disclosed in our laboratories.[5]

Herein we describe in detail, the first total synthesis of apramycin (**1**) and saccharocin (**2**: KA-5685).

Our point of departure is the known aminoglycoside antibiotic, neamine (**3**), which has already been synthesized by one of us[6] and Umezawa.[7] Neamine (**3**) was successively converted into 6′-*N*-(benzyloxycarbonyl)-3′,4′:5,6-di-*O*-cyclohexylidene-1,2′,3-tri-*N*-tosylneamine (**4**) by preferential *N*-benzyloxycarbonylation,[8] *N*-tosylation and *O*-cyclohexylidenation[9] in a 79% overall yield. Saponification of **4** with potassium *t*-butoxide followed by treatment of the resulting 6′-amino compound with 30% aqueous formaldehyde and $NaBH_3CN$[10] afforded the 6′-dimethylamino compound, which after oxidation with *m*-chloroperbenzoic acid gave the *N*-oxide **5** in an 83% overall yield. Treatment of **5** with benzoyl chloride and *N*,*N*-diisopropylethylamine produced the aldehyde, 4-*O*-[3′,4′-*O*-cyclohexylidene-2′-deoxy-2′-(tosylamino)-α-D-*gluco*-hexodialdo-1′,5′-pyranosyl]-5,6-*O*-cyclohexylidene-1,3-di-*N*-tosyl-2-deoxystreptamine (**6**) in a 75% yield, suggesting that the procedure would be useful for the preparation of the aldehydes from the primary amines.[11] Other couples of reagents (acetic anhydride, α-toluenesulfonyl chloride, trifluoroacetic anhydride, mesyl chloride, methanesulfonic anhydride, and tosyl chloride) and bases (*N*,*N*-diisopropylethylamine, 4-dimethylaminopyridine, *N*-methylmorpholine, and pyridine, *etc.*) were investigated, but gave **6** in lower yields.

Addition of allylmagnesium chloride to **6** gave a mixture of the (6′*S*)- and (6′*R*)-alcohols,[3a,12] 4-*O*-[3′,4′-*O*-cyclohexylidene-2′,7′,8′,9′-tetradeoxy-2′-(tosylamino)-L-*glycero*- and D-*glycero*-α-D-*gluco*-non-8′-enopyranosyl]-5,6-*O*-cyclohexylidene-1,3-di-*N*-tosyl-2-deoxystreptamines (**7** and **8**) in 37 and 41% yields, respectively. Reaction with allyltributyltin[13] also gave the similar ratio of the products with that by the Grignard reagent, but allyllithium[13] did not. The stereochemistry

Chart 2.

at C-6′ in **7** and **8** was reasonably clarified by ^{1}H-NMR of the derivatives **10a, b** and **11** as follows. Oxidative cleavage of the olefin group of **7** with osmium tetraoxide and then sodium periodate to give the aldehyde, followed by selective removal of the cyclohexylidene group by aqueous acetic acid, afforded the octodialdose[3a] derivative **9** in a 60% yield. Acetylation of **9** with acetic anhydride and pyridine at 40 °C gave a mixture of the 1-*N*-acetyl-α- and β-acetates, 1-*N*-acetyl-4-*O*-[(8′*S*)- and (8′*R*)-3′,6′,8′-tri-*O*-acetyl-2′,7′-dideoxy-2′-(tosylamino)-L-*glycero*-α-D-*gluco*-octodialdo-1′,5′:8′,4′-dipyranos-1′-yl]-5,6-*O*-cyclohexylidene-1,3-di-*N*-tosyl-2-deoxystreptamines (**10a** and **10b**) in 34 and 37% yields. Similarly, **8** was transformed into a single β-acetate **11**. Their ^{1}H-NMR decoupling revealed the H-6′ methine protons in **10** and **11** to be axial ($J_{5',6'}$=10 Hz) and equatorial ($J_{5',6'}$=2.5 Hz), respectively, assigning the stereochemistry of **7** and **8**. Also, the 1-*N*-acetyl structures of **10** and **11** were deduced by the ^{1}H-NMR spectrum of the 1-*N*-acetyl-3′,5,6,6′,8′-penta-*O*-acetyl derivative **12**, which was formed by removal of the cyclic acetal of **10b** followed by acetylation. All methine protons of the 2-deoxystreptamine moiety were completely assigned in **12**, and the significant downfield shift was observed for the H-1 signal (δ 4.34) in comparison with the H-3 signal (δ 3.40).

The aforesaid intermediate **9** was converted by our method[14] using tosyl chloride and triethylamine, and acetylation into the acetyl glycal, 1-*N*-acetyl-4-*O*-[3′,6′-di-*O*-acetyl-4′,8′-anhydro-2′,7′-dideoxy-2′-(tosylamino)-L-*glycero*-α-D-*gluco*-oct-7′-enopyranos-1′-yl]-5,6-*O*-cyclohexylidene-1,3-di-*N*-tosyl-2-deoxystreptamine (**13**) in a 52% overall yield. The glycal **13** was treated with 0.5 M† hydrochloric acid, followed by acetylation to give **12** as one of the anomeric acetates, supporting the 1-*N*-acetyl structure. Though **13** possessed an acetoxyl group at C-6′ having the (*S*)-configuration which was incompatible with the natural stereochemistry, it was clear that **13** could be a useful intermediate provided that a cis cyclic carbamate formation could be achieved with the appropriate S_N2 inversion at the later stage (for an example: **24**→**25**). On the other hand, the glycal **14**, which was similarly derived from the other alcohol **8**, possessed the natural (*R*)-configuration at C-6′, but, on azidonitration[15] with sodium azide and ammonium ceric nitrate, gave a single (7′*R*,8′*R*)-product **15** with the undesired axial azido group owing to the sizeable steric interactions of the C-6′ axial acetoxyl group. Then, **8** was efficiently transformed into the glycal **13** through the inversion of the 6′-hydroxyl group. Mesylation of **8** followed by displacement reaction with potassium acetate gave the corresponding acetate **16** in an 85% yield, which was identical with the acetate of **7**. As described above, oxidative cleavage of the olefin group and selective hydrolysis of **16** afforded the octodialdose derivative **17**, which was in turn led to the key glycal **13** in a 55% yield.

19 : $R^1=H$, $R^2=ONO_2$

Chart 3.

Azidonitration[15] of **13** gave two major azidoglycosyl nitrates **18** and **19** having the (7′*S*,8′*S*)- and (7′*S*,8′*R*)-configurations in 63 and 14% yields. The stereochemistry was defined by their ^{1}H-NMR spectra. Remarkably, the addition was effectively stereoselective, generating only one of the two possible configurations at C-7′. Treatment of either **18** or **19** with barium hydroxide in methanol afforded the corresponding deacetylated methyl β-glycoside, 4-*O*-[(8′*S*)-7′-azido-2′,7′-dideoxy-8′-*O*-methyl-2′-(tosylamino)-D-*thereo*-α-D-*gluco*-octodialdo-1′,5′:8′,4′-dipyranos-1′-yl]-5,6-*O*-cyclohexylidene-1,3-di-*N*-tosyl-2-deoxystreptamine (**20**) in 71% or 40% yield, along with less than 7% yield of the α-glycoside. In a straightforward fashion **20** was transformed in a 61% overall yield into the 7′-[*N*-(benzyloxycarbonyl)-methylamino] derivative **22** through **21** *via* a four-step process: catalytic reduction, *N*-benzyloxycarbonylation, hydride reduction and again *N*-benzyloxycarbonylation.

Mesylation of **22** afforded quantitatively the labile dimesylate **23**, the C-3′ position of which was selectively chlorinated to form the 3′-chloro compound, by analogy with the results obtained by Umezawa and co-workers.[16] Dechlorination of the intermediate with tributylstannane gave the 3′-deoxy compound, 4-*O*-{(8′*S*)-7′-[*N*-(benzyloxycarbonyl)methylamino]-2′,3′,7′-trideoxy-6′-*O*-mesyl-8′-*O*-methyl-2′-(tosylamino)-D-*glycero*-β-L-*talo*-octodialdo-1′,5′:8′,4′-dipyranos-1′-yl}-5,6-

Chart 4.

O-cyclohexylidene-1,3-di-*N*-tosyl-2-deoxystreptamine (**24**) in an 81% yield from **23**. All attempts[17] to form a cis cyclic carbamate failed, except for epimerization[18] of the 6′-hydroxyl group by heating **24** with sodium acetate trihydrate in 2-methoxyethanol, which yielded only 4-*O*-[(8′*S*)-7′-*N*,6′-*O*-carbonyl-2′,3′,7′-trideoxy-8′-*O*-methyl-7′-(methylamino)-2′-(tosylamino)-D-*glycero*-α-D-*allo*-octodialdo-1′,5′:8′,4′-dipyranos-1′-yl]-5,6-*O*-cyclohexylidene-1,3-di-*N*-tosyl-2-deoxystreptamine (**25**) needed for the apramycin skeleton. The stereochemistry was also confirmed by the ^{1}H-NMR and IR spectra.[17,18]

De-*N*-tosylation of **25** with sodium metal in liquid ammonia followed by alkaline hydrolysis to remove the *N*,*O*-carbonyl group and subsequent acidic hydrolysis to remove the cyclohexlidene group afforded the aminooctodialdose derivative, methyl β-aprosaminide[1b] (**26**) in a 65% overall yield, which was further hydrolyzed with 4M hydrochloric acid to give aprosamine[1b,4] (**27**). Both **26** and **27** were identical in all respects with the naturally derived products, thus setting the stage for introduction of the 4-amino-4-deoxy-D-glucose or D-glucose unit.

Chart 5.

N-Benzyloxycarbonylation of **27** generated the key intermediate for the following glycosidation, 1,2′,3,7′-tetrakis(*N*-benzyloxycarbonyl)aprosamine[4] (**28**) in a 77% yield.

Methanolysis of **28** with a methanolic hydrogen chloride solution or methylation with methyl iodide and silver oxide, to give the corresponding methyl glycoside, followed by catalytic reduction gave the aforesaid methyl β-aprosaminide (**26**) in a fairly good yield (81% or 70%). The findings suggested that the 1,3-diaxial interaction between C-6′- and C-8′- substituents would then lead to the less sterically encumbered transition state and thus to the exclusive formation of the β-glycoside even under acidic conditions, where the anomeric effect could be predominant.[19] Further, reaction of *O*-benzylglycosyl halides with alcohols are known to yield exclusively the corresponding α-glycosides owing to the anomeric effect as commonly seen in carbohydrates.[19-22] Consequently, it was expected that reaction of the appropriate *O*-benzylglycosyl halides with **28** would produce the desired α-glycosyl-β-aprosaminides in reasonable yields. In the glycosidation studies on **28**, a large number of variables including catalyst and temperature were assayed.[20-22] The best result was realized under modified Mukaiyama conditions[20] by using 4-azido-2,3,6-tri-*O*-benzyl-4-deoxy-β-D-glucopyranosyl fluoride (**29**), which was prepared from the corresponding α-D-glycosyl chloride,[22] to give two major products having R_f 0.48 and 0.44 on thin-layer chromatography. The R_f 0.44-substance, which was found to be the desired glycoside **30** by the following chemical and physical evidence, could be isolated by silica-gel column chromatography in a modest yield (40% yield based on unrecovered alcohol **28**). It should be noted, however, that the glycosidation was achieved without protection of the C-5, 6, and 6′ hydroxyl groups. Hydrogenolysis of **30** furnished apramycin (**1**) in a 74% yield, which was identical with the natural antibiotic in all respects including antibacterial activity, but the R_f 0.48-substance did not give **1**.

Similarly, glycosidation of the key alcohol **28** employing 2,3,4,6-tetra-*O*-benzyl-β-D-glucopyranosyl fluoride[20] provided the expected glycoside **31** in a 24% yield (42% yield based on unrecovered **28**) after column chromatography. Hydrogenolysis of **31** completed the synthesis, giving saccharocin (**2**: KA-5685) identical with the natural antibiotic in all respects.

The antibacterial activities of **1**, **2**, **26**, and **27**, which are shown in Table 1, were identical with those of the natural products and their derivatives.

The application of this synthetic strategy for the construction of other related antibiotics as well as some of their potentially therapeutically interesting analogs is an exciting prospect.

Experimental

Melting points were determined on a micro hot-stage Yanaco MP-S3 and were uncorrected. IR and Mass spectra were recorded on Hitachi Perkin-Elmer 225 and Hitachi M-80H (SIMS) spectromters, respectively, and ^{1}H-NMR spectra with TMS as internal standard on a Varian EM-390 (90 MHz) or a Bruker WM 250 spectromter (250 MHz). Optical rotations were measured on a Carl Zeiss photoelectric polar-

imeter. Silica-gel TLC and column chromatography were performed on Merck TLC 60F-254 and Wakogel C-200 or Kieselgel 60. In general, organic solvents were purified and dried by the appropriate procedures, and evaporation and concentration were carried out under reduced pressure below 30 °C.

6′-N-(Benzyloxycarbonyl)-3′,4′:5,6-di-O-cyclohexylidene-1,2′,3-tri-N-tosylneamine (4). To a solution of neamine (**3**: 50 g) in 50% aqueous methanol (500 ml) containing triethylamine (23.8 ml) was added *N*-(benzyloxycarbonyloxy)-5-norbornene-2,3-dicarboximide[8] (53.4 g), and the solution was stirred at room temperature for 5 h. After addition of 28% aqueous ammonia (110 ml), the solution was evaporated to a residue of the 6′-*N*-benzyloxycarbonyl derivative. A solution of the residue in 70% aqueous 1,4-dioxane (1 l) was stirred with tosyl chloride (106.4 g) and Na_2CO_3 (61.1 g) at room temperature for 5 h. After filtration, the filtrate was concentrated to give gummy precipitates, which were washed with water and then dried to give a solid of the tri-*N*-tosyl derivative (166 g). To a solution of the solid in DMF (1.66 *l*) were added 1,1-dimethoxycyclohexane (187 ml) and anhydrous TsOH (2.67 g), and the solution was stirred at 50 °C for 1 d under reduced pressure (≃25 Torr††). After further addition of 1,1-dimethoxycyclohexane (187 ml), the reaction was continued at the same conditions for another 2 d. After addition of triethylamine (2.16 ml) and $NaHCO_3$ (6.51 g), the mixture was evaporated to a residue, which was chromatographed on silica gel (2 kg) with 2:1 toluene-ethyl acetate to give a solid of **4** (132.2 g, 79% from **3**): R_f 0.64 (20:1 $CHCl_3$-MeOH); mp 139—142 °C; $[\alpha]_D^{23}$ −38° (*c* 1.0, $CHCl_3$); IR (KBr): 1700 (NH-CO), and 1160 cm^{-1} (SO_2); ^{1}H-NMR (acetone-d_6): δ=2.39, 2.40, and 2.43 (each 3H, s, Ts), 5.06 (2H, s, CH_2 of Z), and 5.30 (1H, d, H-1′, $J_{1',2'}$=3.5 Hz).

3′,4′:5,6-Di-O-cyclohexylidene-6′,6′-di-N-methyl-1,2′,3-tri-N-tosylneamine 6′-N-oxide (5). A solution of **4** (60.8 g) in *t*-butyl alcohol (1830 ml) containing water (3.10 ml) and potassium *t*-butoxide (63.2 g) was stirred at 70 °C for 1 h. The reaction solution diluted with ethyl acetate (1000 ml) was neutralized with 0.1 M HCl (2100 ml), and the organic layer was washed with a saturated aqueous NaCl solution, dried, and then evaporated to give a solid of the 6′-amino compound (56 g).

To a stirred and ice-cooled solution of the solid in acetonitrile (1030 ml) were added 30% aqueous formaldehyde (52.0 ml), $NaBH_3CN$ (10.6 g), and acetic acid (32.0 ml), and stirring was continued at room temperature for 1 h. The reaction mixture neutralized with a saturated aqueous $NaHCO_3$ solution was extracted with ethyl acetate (400 ml×3). The combined extracts were washed with a saturated aqueous NaCl solution, dried, and evaporated to a residue of the dimethylamino compound (60 g): R_f 0.47 (10:1 $CHCl_3$-MeOH).

A solution of the residue in chloroform (1120 ml) was stirred with *m*-chloroperbenzoic acid (9.80 g) at room temperature for 1 h. The solution diluted with chloroform (500 ml) was washed successively with saturated aqueous $NaHCO_3$ and NaCl solutions, dried, and then evaporated to a residue, which was chromatographed on silica gel (500 g) with 10:1→8:1 chloroform-methanol to give a solid of the monohydrate of **5** (47.1 g, 83% from **4**): R_f 0.36 (10:1 $CHCl_3$-MeOH); mp 175—179 °C; $[\alpha]_D^{23}$ −23° (*c* 1.0, $CHCl_3$); ^{1}H-NMR ($CDCl_3$): δ=2.42 (9H, s, Ts), 3.24 and 3.31 (each 3H, s, NMe_2), and 5.45 (1H, d, H-1′, $J_{1',2'}$=3.0 Hz).

*A) From **10b***: A solution of **10b** (23 mg) in a 2:1:1 mixture (0.5ml) of acetic acid, 1,4-dioxane and water was warmed at 50°C for 1d. The resulting solution diluted with ethyl acetate was washed with a saturated aqueous $NaHCO_3$ solution, dried, and evaporated to give a residue: R_f 0.28 (1:1 benzene-ethyl acetate).

A solution of the decyclohexylidenated product in pyridine (0.5ml) was stirred with acetic anhydride (0.3ml) at 40°C overnight. After addition of a few drops of ethanol, the solution was evaporated to a residue, which was partitioned between ethyl acetate and a saturated aqueous $NaHCO_3$ solution. The organic layer was dried and evaporated to a residue, which was chromatographed on silica gel (2g) with 5:2 benzene-ethyl acetate to give a solid of **12** (13mg, 56% from **10b**): R_f 0.50 (1:1 benzene-ethyl acetate); mp 161—164°C; $[\alpha]_D^{23}$ +58° (*c* 1.0, $CHCl_3$); IR (KBr): 1750 (ester), and 1160 cm^{-1} (SO_2); ^{1}H-NMR ($CDCl_3+D_2O$): δ=1.34, 1.80, 2.06, 2.11, 2.15, and 2.25 (each 3H, s, Ac), 2.40, 2.41, and 2.47 (each 3H, s, Ts), 3.19 (1H, t, H-4', $J_{3',4'}=J_{4',5'}$=9.8 Hz), 3.40 (1H, m, H-3), 3.46 (1H, dd, H-2', $J_{1',2'}$=3.8 Hz, $J_{2',3'}$=10.8 Hz), 3.80 (1H, t, H-4, $J_{3,4}=J_{4,5}$= 9.5 Hz), 4.13 (1H, t, H-5', $J_{5',6'}\approx$9.5 Hz), 4.34 (1H, m, H-1), 4.80 (1H, dd, H-3'), 4.94 (1H, dt, H-6', $J_{6',7'ax}$=9.5 Hz, $J_{6',7'eq}$=5.5 Hz), 5.18 (1H, d, H-1'), 5.22 (1H, t, H-5, $J_{5,6}$=9.5 Hz), 5.56 (1H, dd, H-8', $J_{7'ax,8'}$=10.5 Hz, $J_{7'eq,8'}$=2.5 Hz), and 5.65 (1H, dull t, H-6, $J_{1,6}$=10 Hz).

Found: C, 52.21; H, 5.40; N, 3.88; S, 8.65%. Calcd for $C_{47}H_{57}N_3O_{20}S_3$: C, 52.26; H, 5.32; N, 3.89; S, 8.90%.

*B) From **13***: A solution of **13** (7.7mg) in a 1:1 mixture (0.15ml) of 0.5M HCl and 1,4-dioxane was warmed at 50°C for 2d, and then evaporated to a residue of the octodialdose derivative. The residue was acetylated with acetic anhydride (0.2ml) in pyridine (0.4ml) at 40°C for 13h, and worked up as described above to give two products having R_f-values of 0.50 and 0.45 (1:1 benzene-ethyl acetate). The R_f 0.50-substance (2.5mg, 31%) was identical with **12** in all respects. The R_f 0.45-substance (2.8mg) seemed to be the corresponding (8'*S*)-isomer, but was not further investigated.

1-N-Acetyl-4-O-[3',6'-di-O-acetyl-4',8'-anhydro-2',7'-dideoxy-2'-(tosylamino)-L-glycero-α-D-gluco-*oct-7'-enopyranos-1'-yl]-5,6-O-cyclohexylidene-1,3-di-N-tosyl-2-deoxystreptamine (**13**).*

A)[14] *From **9***: To a stirred and ice-cooled solution of **9** (1.27g) in acetonitrile (25.4ml) were added triethylamine (1.17ml) and tosyl chloride (0.8g), and stirring was continued at room temperature for 12h. After addition of ethanol (0.16ml) and a saturated aqueous $NaHCO_3$ solution (0.3ml), the mixture was evaporated to a residue. The residue was partitioned between chloroform and a saturated aqueous $NaHCO_3$ solution, and the combined organic layers were evaporated to give a solid of the glycal (1.4g): R_f 0.39 (15:1 $CHCl_3$-MeOH).

A solution of the solid in pyridine (28ml) was stirred with acetic anhydride (14ml) at 40°C for 19h. After addition of ethanol (8.6 ml), the resulting solution was neutralized with a saturated aqueous $NaHCO_3$ solution and extracted with

ethyl acetate. The combined extracts were washed with a saturated aqueous NaCl solution, dried, and evaporated to a residue, which was chromatographed on silica gel (60g) with 2:1→3:2 hexane-ethyl acetate to give a solid of **13** (0.73g, 53%): R_f 0.86 (1:1 benzene-EtOAc); R_f 0.40 (3:1 benzene-EtOAc); mp 161—164°C;$[\alpha]_D^{23}$ +98° (*c* 1.0, $CHCl_3$); IR (KBr): 1745 cm^{-1} (ester), ^{1}H-NMR ($CDCl_3$): δ=1.58, 2.20, and 2.23 (each 3H, s, Ac), 3.59 (1H, dd, H-4′, $J_{3',4'}$=9.0 Hz, $J_{4',5'}$=10.5 Hz), 3.91 (1H, dd, H-5′ $J_{5',6'}$=8.0 Hz), 4.74 (1H, dd, H-3′, $J_{2',3'}$=10.5 Hz), 4.84 (1H, dd, H-7′, $J_{6',7'}$=2.3 Hz, $J_{7',8'}$=6.0 Hz), 5.20 (1H, d, H-1′, $J_{1',2'}$=4.0 Hz), 5.32 (1H, m, H-6′), and 6.29 (1H, dd, H-8′, $J_{6',8'}$=1.5 Hz).

Methyl β-Aprosaminide (26). *A) From 25*: To a solution of **25** (19.8 mg) in liquid ammonia (≃6 ml) at −35 °C was added sodium metal (25 mg×3) with stirring, and the resulting deep-blue solution was kept at −35 °C for 15 min. After evaporation of ammonia at room temperature, methanol (0.2 ml) and water (1.8 ml) were added, and the

resulting solution of the detosylated intermediate was heated at 100 °C for 5 h to hydrolyze the cyclic carbamate. To the solution was added Dowex 50WX2 resin (H form, 200—400 mesh, 6.0 ml), and the mixture was allowed to stand overnight at room temperature in order to remove the cyclohexylidene group. The resin was packed in a column, washed with water, and then treated with 1 M aqueous ammonia. The ninhydrin-positive fractions were collected and evaporated to give a solid, which was purified by chromatography over CG-50 resin (NH_4 form, 0→0.2 M aqueous ammonia) to yield a solid of the monohydrate of **26** (5.3 mg, 65%): R_f 0.62 (1 : 3 : 2 $CHCl_3$–MeOH–17% aqueous NH_3); mp 141—143 °C; $[\alpha]_D^{23}$ +108° (*c* 0.6, water)[lit,[1b] $[\alpha]_D^{27}$ +104° (*c* 1.1, water)]; MS (SIMS): *m/z* 393 (M^++1); ^{1}H-NMR (5% ND_3 in D_2O): δ=1.20 (1H, q, H-2ax, *J*=13 Hz), 1.65 (1H, q, H-3′ax, *J*=12 Hz), 1.97 (1H, dt, H-2eq, $J_{1,2eq}=J_{2eq,3}$=3.5 HZ, J_{gem}=13 Hz), 2.12 (1H, m, H-3′eq), 2.35 (3H, s, NMe), 2.46 (1H, dd, H-7′, $J_{6',7'}$=3.0 Hz, $J_{7',8'}$=8.5 Hz), 2.70 and 2.86 (each 1H, m, H-1 and H-3, *vice versa*), 3.01 (1H, dt, H-2′, $J_{1',2'}=J_{2',3'eq}$= 3.5 Hz, $J_{2',3'ax}$=12.5 Hz), 3.14, 3.30, and 3.49 (each 1H, t, H-4, H-5, or H-6, *J*≃9.5 Hz), 3.64 (1H, dd, H-5′, $J_{4',5'}$=10 Hz, $J_{5',6'}$=2.5 Hz), 3.78 (1H, m, H-4′), 4.26 (1H, t, H-6′, *J*≃3 Hz), 4.52 (1H, d, H-8′), 5.14 (1H, d, H-1′). This spectrum was superimposable on that of the naturally derived **26** and the reported spectrum.[1b]

Found: C, 46.59; H, 8.10; N, 13.47%. Calcd for $C_{16}H_{32}N_4O_7\cdot H_2O$: C, 46.82; H, 8.35; N, 13.65%.

B) From 28 by Methanolysis: A solution of **28** (5.0 mg) in 1.2% methanolic hydrogen chloride solution (0.33 ml) was heated in a sealed tube at 73 °C for 5 h, and evaporated to a residue, which was chromatographed on silica gel (1.5 g) with 3 : 2 chloroform–acetone to give a solid of the methyl glycoside (4.5 mg): R_f 0.44 (12 : 1 $CHCl_3$–MeOH); ^{1}H-NMR (50 °C, $CDCl_3$): δ=2.98 (3H, s, NMe), 3.46 (3H, s, OMe).

A solution of the solid in 67% aqueous 1,4-dioxane (0.35 ml) was shaken with palladium black and 3-atm hydrogen at room temperature for 4.5 h, filtered and evaporated to a residue. The residue was purified by chromatography over CG-50 resin (NH_4 form, 0→0.2 M aqueous ammonia) to give a solid of the monohydrate of **26** (1.8 mg, 81% from **28**).

C) From 28 by Methylation: To a stirred solution of **28** (4.5 mg) in acetonitrile (0.011 ml) were added methyl iodide (0.045 ml) and Ag_2O (9.0 mg), and stirring was continued at room temperature for 1 h. After filtration, the filtrate was evaporated to give a solid of the methyl glycoside. The solid was hydrogenated as described above to give a solid of the monohydrate of **26** (1.4 mg, 70% from **28**).

Aprosamine (27). *A) From 26*: A solution of the monohydrate of **26** (20.5 mg) in 4 M HCl (1.3 ml) was heated in a sealed tube at 95 °C for 3 d. The brown solution was evaporated and co-evaporated with toluene to give a residue which was purified by chromatography over CG-50 resin (NH_4 form, 0→0.2 M aqueous ammonia) to give a solid of the free base of **27**. The solid was dissolved in 0.5 M HCl and evaporated to a residue, which was reprecipitated from water–acetone to give a solid of the tetrahydrochloride trihydrate of **27** (20 mg, 70%): R_f 0.46 (1 : 3 : 2 $CHCl_3$–MeOH–17% aqueous NH_3); mp 176—180 °C (decomp); $[\alpha]_D^{25}$ +44° (*c* 1.0, water) [lit, $[\alpha]_D^{25}$ +21.6° (*c* 1.27, water);[1b] $[\alpha]_D^{22}$ +53° (*c* 1.075, water)[4]]; MS (SIMS): *m/z* 379 (M^++1); ^{1}H-NMR (D_2O): δ=1.92 (1H, q, H-2ax, *J*=12.5 Hz), 2.04 (1H, m, H-3′ax), 2.35 (1H, m, H-2eq), 2.55 (1H, dt, H-3′eq, J_{gem}=12.5 Hz, $J_{2',3'eq}=J_{3'eq,4'}$=4 Hz,), 2.81 and 2.82 (3H in total, each s, NMe), 4.51 and 4.58 (1H in total, each t, H-6′, *J*≃3), 5.20 and 5.47 (1H in total, each d, $J_{7',8'ax}$=9.0 Hz, $J_{7',8'eq}$=4.0 Hz, H-8′ax and H-8′eq respectively), 5.75 and 5.77 (1H in total, each d, H-1′, $J_{1',2'}$=3.0 Hz and 3.5 Hz, respectively). This ^{1}H-NMR spectrum was found to be superimposable on that of the naturally derived aprosamine and the reported spectrum.[1b]

Found: C, 30.92; H, 6.87; N, 9.47%. Calcd for $C_{15}H_{30}N_4O_7\cdot 4HCl\cdot 3H_2O$: C, 31.15; H, 6.97; N, 9.69%.

B) From Natural Apramycin (1): A solution of apramycin (**1** : 9.9 mg) in 4 M HCl (0.1 ml) was heated at 95 °C for 7 h. The solution was evaporated and co-evaporated with toluene to a residue, which was purified as described above to give a solid of the tetrahydrochloride trihydrate of **27** (8.6 mg, 81%). The solid was identical with the aforeside synthetic aprosamine in all respects.

*1,2′,3,7′-Tetrakis(*N*-benzyloxycarbonyl) aprosamine (28).* To a stirred and ice-cooled solution of the free base of **27** (12.8 mg) in 80% aqueous acetone (0.48 ml) were added Na_2CO_3 (18 mg), 1 M NaOH (0.04 ml) and benzyl chloroformate (0.023 ml), and stirring was continued at room temperature for 2 h. After filtration, the filtrate was agitated with CG-50 resin (H-form) and again filtrated. The filtrate was neutralized with triethylamine (0.023 ml) and then evaporated to a residue, which was chromatographed on silica gel (1 g) with 15 : 1 chloroform–methanol to give a solid: mp 196—198 °C (decomp). Reprecipitation from ethanol–ether yielded the monohydrate of **28** (24 mg, 77%): R_f 0.38 (15 : 1 $CHCl_3$–MeOH); mp 188—190 °C (decomp); $[\alpha]_D^{23}$ +43° (*c* 1.0, MeOH) [lit,[4] prisms of **28**: mp 233—234.5 °C; $[\alpha]_D^{22}$ +48.8° (*c* 1.005, DMF)]; IR (KBr): 1710—1670 (NH-CO); ^{1}H-NMR (CD_3CN+D_2O): δ=3.00 (3H, s, NMe), and 4.21 (1H, broad s, H-6′).

Found: C, 60.44; H, 5.95; N, 5.94%. Calcd for $C_{47}H_{54}N_4O_{15}\cdot H_2O$: C, 60.51; H, 6.05; N, 6.01%.

*4-Azido-2,3,6-tri-*O*-benzyl-4-deoxy-β-*D*-glucopyranosyl Fluoride (29).* To a stirred solution of 4-azido-2,3,6-tri-*O*-benzyl-4-deoxy-α-D-glucopyranosyl chloride[22] (130 mg) in acetonitrile (0.65 ml) was added AgF (130 mg), and stirring was continued at room temperature for 22 h under protection from light. The reaction mixture was filtered and a saturated aqueous NaCl solution was added to precipitate any silver ions from solution. The mixture was again filtered and evaporated to a residue, which was partitioned between chloroform and water. The organic layer was dried and evaporated to a residue, which was chromatographed on silica gel (4 g) with 4 : 1 benzene–ethyl acetate to give a syrup of **29** (122 mg, 97%): R_f 0.41 (benzene); $[\alpha]_D^{23}$ +108° (*c* 1.0, $CHCl_3$); IR ($CHCl_3$): 2120 cm^{-1} (azide); ^{1}H-NMR ($CDCl_3$): δ=5.19 (1H, dd, H-1, $J_{1,2}$=6.4 Hz, $J_{1,F}$=52 Hz, apparently two doublets at δ=5.06 and 5.32).

Found: C, 67.69; H, 5.98; N, 8.87%. Calcd for $C_{27}H_{28}N_3O_4F$: C, 67.91; H, 5.91; N, 8.80%.

*4-O-[(8′*R*)-2′-Amino-8′-O-(4″-azido-2″,3″,6″-tri-O-benzyl-4″-deoxy-α-D-glucopyranosyl)-2′,7′-bis(*N*-benzyloxycarbonyl)-2′,3′,7′-trideoxy-7′-(methylamino)-D-glycero-α-D-allo-octodialdo-1′,5′ : 8′,4′-dipyranos-1′-yl]-1,3-bis(*N*-benzyloxycarbonyl)-2-deoxystreptamine (30).* Before coupling, **28** was dried overnight at 50 °C under reduced pressure. To a mixture of **28** (12.6 mg, 0.0137 mmol), **29** (7.9 mg, 0.0165 mmol), $SnCl_2$ (5.5 mg, 0.029 mmol), $AgClO_4$ (5.7 mg, 0.027 mmol), and Molecular Sieves 4A (12.6 mg) was added a 4 : 1 mixture (0.189 ml) of 1,4-dioxane–benzene at 0 °C, and the mixture was stirred at this temperature for 24 h. After further addition of the same amounts of **29**, $SnCl_2$, $AgClO_4$ and Molecular Sieves 4A as described above, stirring was continued at 0 °C for another 24 h. The reaction mixture was filtered and the filtrate evaporated to give a residue. The residue was chromatographed on silica gel (1.5 g) with 20 : 1 chloroform–methanol to give two products having R_f-values of 0.44 and 0.48 (15 : 1 chloroform–methanol) with recovery of the unreacted **28** (5.4 mg) having R_f 0.38. The R_f 0.44-substance was the desired glycoside **30** as described below.

30 (R_f 0.44-substance): 4.3 mg (23% from **28**; 40% yield based on the unrecovered **28**); mp 89—92 °C; $[\alpha]_D^{23}$ +63° (*c* 0.5, $CHCl_3$); ^{1}H-NMR (50 °C, CD_3CN+D_2O): δ=3.00

(3H, s, NMe), 3.73 (1H, dt, H-2′, $J_{1',2'}=J_{2',3'eq}=4.0$ Hz, $J_{2',3'ax}=13$ Hz), 4.13 (1H, m, H-7′), 4.27 (1H, dull t, H-6′), 5.24 (1H, d, H-1′), 5.27 (1H, d, H-8′, $J_{7',8'}=9.5$ Hz), and 5.41 (1H, d, H-1″, $J_{1'',2''}=3.0$ Hz).

Found: C, 64.57; H, 6.19; N, 6.96%. Calcd for $C_{74}H_{81}N_7O_{19}$: C, 64.76; H, 5.95; N, 7.14%.

R_f 0.48-substance: 2.1 mg; mp 89—92 °C ; $[\alpha]_D^{28}$ +62° (*c* 0.85, $CHCl_3$); IR ($CHCl_3$): 2115 cm^{-1} (azide); ^{1}H-NMR (50 °C, $CDCl_3+D_2O$): $\delta=2.98$ and 3.02 (3H in total, each s, NMe), and 7.1—7.4 (35H, m, Ph×7).

By catalytic reduction, the R_f 0.44-substance (**30**) yielded apramycin (**1**) as described below, while the R_f 0.48-substance did not give apramycin but gave another product (R_f 0.43 on TLC with 1 : 3 : 2 $CHCl_3$-MeOH-17% aqueous NH_3; apramycin:R_f 0.35). Therefore, the R_f 0.48-substance was not further investigated.

Apramycin (1). A solution of **30** (10 mg) in a 3 : 1 : 1 mixture (0.5 ml) of 1,4-dioxane, acetic acid and water was shaken with palladium black and 3-atm hydrogen at room temperature for 2 h, filtered and evaporated to give a residue. The residue was purified by chromatography over CG-50 resin (NH_4 form, 0→0.1 M aqueous ammonia) to give a solid of the monocarbonate monohydrate of **1** (3.4 mg, 74%): R_f 0.35 (1 : 3 : 2 $CHCl_3$-MeOH-17% aqueous NH_3); mp 237—240 °C (decomp); $[\alpha]_D^{23}$ +162° (*c* 0.94, water) [lit,[1] monohydrate: mp 245—247 °C; $[\alpha]_D^{25}$ +162.5° (water)]; MS (SIMS): *m/z* 540 (M^++1); ^{1}H-NMR (5% ND_3 in D_2O): $\delta=1.18$ (1H, m, H-2ax), 1.68 (1H, q, H-3′ax, $J=12$ Hz), 2.03 (1H, m, H-2eq), 2.14 (1H, m, H-3′eq), 2.39 (3H, s, NMe), 2.69 (1H,dd, H-7′, $J_{6',7'}=2.5$ Hz, $J_{7',8'}=8.5$ Hz), 3.03 (1H, dull dt, H-2′, $J_{2',3'ax}=12.5$ Hz), 4.29 (1H, broad s, H-6′), 4.92 (1H, d, H-8′), 5.15 (1H, d, H-1′, $J_{1',2'}=3.5$ Hz), and 5.37 (1H,d, H-1″, $J_{1'',2''}=3.5$ Hz). This spectrum was superimposable on that of the authentic sample of apramycin and the reported spctrum.[1b]

Found: C, 42.57; H, 7.29; N, 11.45%. Calcd for $C_{21}H_{41}N_5O_{11}\cdot H_2CO_3\cdot H_2O$: C, 42.65; H, 7.32; N, 11.30%.

*4-O-[(8′*R*)-2′-Amino-8′-O-(2″,3″,4″,6″-tetra-O-benzyl-α-*D*-glucopyranosyl)-2′,7′-bis(*N*-benzyloxycarbonyl)-2′,3′,7′-trideoxy-7′-(methylamino)-*D*-glycero-α-*D*-allo-octodialdo-1′,5′ : 8′,4′-dipyranos-1′-yl]-1,3-bis(*N*-benzyloxycarbonyl)-2-deoxystreptamine (31).* Following the procedure described for **30**, a sample of **28** (12.6 mg) was treated with 2,3,4,6-tetra-*O*-benzyl-β-D-glucopyranosyl fluoride[20] (9.0 mg×2), $SnCl_2$ (5.5 mg×2), $AgClO_4$ (5.7 mg×2), and Molecular Sieves 4A (12.6 mg×2) in a 4 : 1 mixture (0.189 ml) of 1,4-dioxane and benzene, and then worked up. Column chromatography on silica gel (1.5 g) with 20 : 1 chloroform–methanol gave two products (4.7 mg and 1.7 mg) having R_f-values of 0.43 and 0.48 (15 : 1 chloroform–methanol) with recovery of the unreacted **28** (5.5 mg). The R_f 0.43-substance was the desired glycoside **31** as described below.

31 (R_f 0.43-substance): 4.7 mg (24% from **28**; 42% yield based on the unrecovered **28**); mp 94—97 °C; $[\alpha]_D^{23}$ +48° (*c* 0.80, $CHCl_3$); ^{1}H-NMR (50 °C, $CDCl_3+D_2O$): $\delta=2.97$ (3H, s, NMe), 3.52 (1H, dd, H-2″, $J_{1'',2''}=4.0$ Hz, $J_{2'',3''}=9.5$ Hz), and 5.28 (1H, d, H-1″).

Found: C, 67.44; H, 6.40; N, 3.81%. Calcd for $C_{81}H_{88}N_4O_{20}$: C, 67.67; H, 6.17; N, 3.90%.

R_f 0.48-substance: 1.7 mg; mp 97—101 °C ; $[\alpha]_D^{23}$ +57° (*c* 0.41, $CHCl_3$): IR ($CHCl_3$): 2110 cm^{-1} (azide); ^{1}H-NMR (50 °C, $CDCl_3+D_2O$): $\delta=3.02$ and 3.05 (3H in total, each broad s, NMe), and 7.1—7.4 (40H, m, Ph×8).

By catalytic reduction, the R_f 0.43-substance (**31**) yielded saccharocin (**2**) as described below, while the R_f 0.48-substance gave another product (R_f 0.46 on TLC with 1 : 3 : 2 $CHCl_3$-MeOH-17% aqueous NH_3; saccharocin: R_f 0.38). Therefore, the R_f 0.48-substance was not further investigated.

Saccharocin (2: KA-5685). A sample of **31** (8 mg) was hydrogenated and then purified as described for apramycin (**1**) to give a solid of the monocarbonate monohydrate of **2** (2.7 mg, 78%): R_f 0.38 (1 : 3 : 2 $CHCl_3$-MeOH-17% aqueous NH_3); mp 187—190 °C (decomp); $[\alpha]_D^{23}$ +175° (*c* 0.5, water) [lit, dihydrate:[2a] mp 188—190 °C; $[\alpha]_D^{24}$ +163.5° (*c* 1.0, water); KA-5685:[2b] $[\alpha]_D^{25}$ +124° (*c* 0.5, H_2O)]; MS (SIMS): *m/z* 541 (M^++1); ^{1}H-NMR (5% ND_3 in D_2O): $\delta=1.21$ (1H, q, H-2ax, $J=12.5$ Hz), 1.67 (1H, q, H-3′ax, $J=11.5$ Hz), 1.98 (1H, dt, H-2eq, $J_{1,2eq}=J_{2eq,3}=4.0$ Hz, $J_{gem}=13$ Hz), 2.12 (1H, dt, H-3′eq, $J_{2',3'eq}=J_{3'eq,4'}=4.0$ Hz, $J_{gem}=11.5$ Hz), 2.39 (3H, s, NMe), 2.68 (1H, dd, H-7′, $J_{6',7'}=2.5$ Hz, $J_{7',8'}=8.5$ Hz), 2.70 and 2.87 (each 1H, m, H-1 and H-3, *vice versa*), 3.01 (1H, m, H-2′), 3.61 (1H, dd, H-2″, $J_{1'',2''}\simeq 4$ Hz, $J_{2'',3''}=10$ Hz), 4.29 (1H, t, H-6′), 4.93 (1H, d, H-8′), 5.15 (1H, d, H-1′, $J_{1',2'}=3.5$ Hz), and 5.35 (1H, d, H-1″). This spectrum was superimposable on that of the authentic antibiotic **2** and the reported spectra.[2]

N-(Phenylsulfonyl)- and *N*-Methyl-*N*-(phenylsulfonyl)benzohydrazonoyl Azides. Thermally Induced Cyclization to Tetrazoles and Decomposition to Benzonitriles[1)]

Suketaka Ito,* Yumo Tanaka, and Akikazu Kakehi
Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380
(Received September 24, 1983)

N-(Phenylsulfonyl)- and *N*-methyl-*N*-(phenylsulfonyl)benzohydrazonoyl azides, prepared from the corresponding hydrazonoyl chlorides and sodium azide, undergo the cyclization to 5-phenyl-1-(phenylsulfonylamino)-1*H*-tetrazoles together with the competitive decomposition to benzonitriles and the Curtius-type rearrangement leading to semicarbazides when heated in benzene under reflux. The tetrazole formation of hydrazonoyl azides may be characteristic of such hydrazonoyl azides as those carrying an *N*-sulfonyl substituent, the strong electron-withdrawing nature of which probably promotes the cyclization.

Imidoyl azides are well known, in general, to cyclize to tetrazoles which are more stable than the azides themselves in many cases.[2)] However, according to Hergarty *et al.*,[3)] *N*-arylbenzohydrazonoyl azides, a class of imidoyl azides, do not undergo this type of cyclization under a variety of conditions in spite of the fact that the corresponding tetrazoles have been obtained from hydrazidines on treatment with nitrous acid:[4)] the hydrazonoyl azides give only semicarbazides *via* an acid-induced Curtius-type rearrangement.

In the course of our investigation of arylsulfonylhydrazine derivatives, we found that the title hydrazonoyl azides undergo the cyclization to 1,5-disubstituted tetrazoles along with the competitive decomposition to benzonitriles. In the present paper, these characteristic behavior of *N*-(phenylsulfonyl)- (**1**) and *N*-methyl-*N*-(phenylsulfonyl)benzohydrazonoyl azides (**2**) are described.

Results and Discussion

Preparation of N-*Methyl*-N-*(phenylsulfonyl)benzohydrazonoyl Chlorides.* *N*-Methyl-*N*-(phenylsulfonyl)benzohydrazonoyl chlorides (**3b—f**), the starting materials for preparing hydrazonoyl azides **2**, were obtained by the *N*-methylation of *N*-(phenylsulfonyl)benzohydrazonoyl chlorides (**4**)[5)] with diazomethane according to the method previously reported for **3a**.[6)] The yields and physical data of **3b—f** are listed in Table 1.

Preparation of N-*(Phenylsulfonyl)- (1) and* N-*Methyl*-N-*(phenylsulfonyl)benzohydrazonoyl Azides (2).* Hydrazonoyl azides **1** and **2** were prepared by the reaction of the corresponding hydrazonoyl chlorides (**4** and **3**) with sodium azide. Azides **1** could be obtained in good yields by using aqueous dioxane as the solvent. The use of DMF or DMSO as the solvent caused the formation of considerable amounts of benzonitriles together with evolution of nitrogen even under cooling. On the other hand, azides **2** could be obtained in satisfactory yields when the reaction was carried out in DMSO at room temperature; and on treatment in aqueous dioxane, no formation of **2** was observed. The results are summarized in Scheme 1 and Table 2.

In the IR spectra of **2a—f**, the azide ν_{as} band (near 2100 cm^{-1}) was observed to split into three peaks. 13-C NMR studies showed that compounds **2** exist in a single geometric isomer; thus, the ternary splits of azide

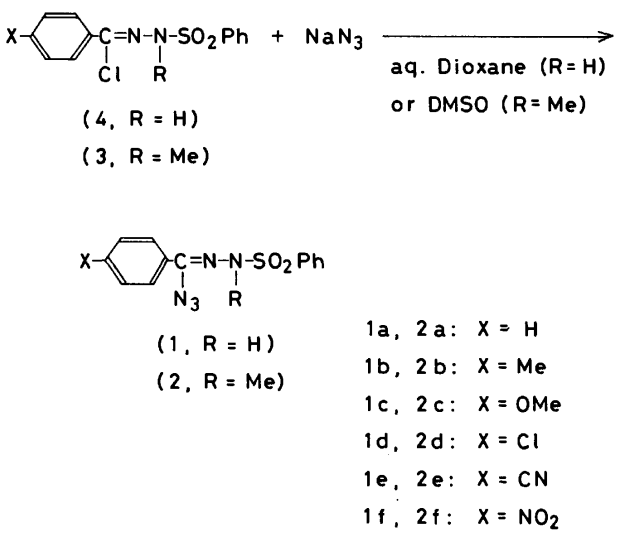
a) Minor peakes due to Fermi resonance are shown in parentheses. b) Signal patterns are as follows: N-H, broad siglet; N-CH_3, singlet; aromatic H, multiplet. c) Other signals are as follows: **1b**, 2.40, s, *p*-CH_3; **1c**, 3.86, s, *p*-OCH_3 ; **2b**, 2.40, s, *p*-CH_3 ; **2c**, 3.87, s, *p*-OCH_3.



Scheme 1.

ν_{as} band should be attributed to Fermi resonance. This type of Fermi resonance has been reported as regards some organic azides.[7]

Azides **2** and azides **1** carrying an electron-donating group in the *C*-aryl group such as **1b** and **1c** are somewhat thermolabile, and **1e** and **1f** are comparatively stable.

Thermolyses of Hydrazonoyl Azides 1 and 2. Hydrazonoyl azide **1a** was heated for 10 h in dry benzene under reflux. Work-up gave 5-phenyl-1-(phenylsulfonylamino)-1*H*-tetrazole (**5a**, 14%), 4-phenyl-1-(phenylsulfonyl)semicarbazide (**6a**, 36%), and benzonitrile (**7a**, 28%). In Tables 3, 4, and 5, the results are summarized along with those obtained from **1b—f** which were treated under the same reaction conditions. In these reactions, small amounts of diphenyl disulfide and *S*-phenyl benzenethiosulfonate were also obtained.

Table 3. Thermolyses of hydrazonoyl azides (**1** and **2**)

Azide	Products[a] and yields/%[b,c) **5** (**8**)	**6** (**9**)	**7**
1a (**2a**)	14 (12)	36 (16)	28 (45)
1b (**2b**)	6 (6)	24 (23)	47 (48)
1c (**2c**)	— (—)	15 (15)	35 (31)
1d (**2d**)	13 (14)	29 (13)	56 (48)
1e (**2e**)	15 (16)	30 (10)	30 (64)
1f (**2f**)	13 (15)	34 (20)	23 (64)

a) The *p*-substituent of 5-aryl group of **5** (**8**), 4-aryl group of **6** (**9**), or compound **7** corresponds to that of *C*-aryl group of the respective reactant, **1a** (**2a**) to **1f** (**2f**). b) Data in parentheses are those of thermolyses of **2**. c) Isolated Yield except those of **7a** and **7b** which were detected by GLC.

On a similar treatment, hydrazonoyl azides **2** underwent the same type of reaction as those of **1** (Tables 3, 4, and 5). Methyl benzenesulfinate and benzenesulfonate were also detected besides *S*-phenyl benzenethiosulfonate in these cases.

The structure assignment of the tetrazoles and semicarbazides obtained was done on the basis of their analytical and spectral data, and the confirmation of the known compounds was made also by direct comparison with authentic specimens.

The present reactions can be explained by the following routes (Scheme 2).

S-Phenyl benzenethiosulfonate would be generated from benzensulfinic acid *via* its disproportionation:[8] benzenesulfinic acid and methyl benzenesulfinate may be formed from the possible *N*-nitrene[9] or azo sulfone[10] intermediate (Scheme 2).

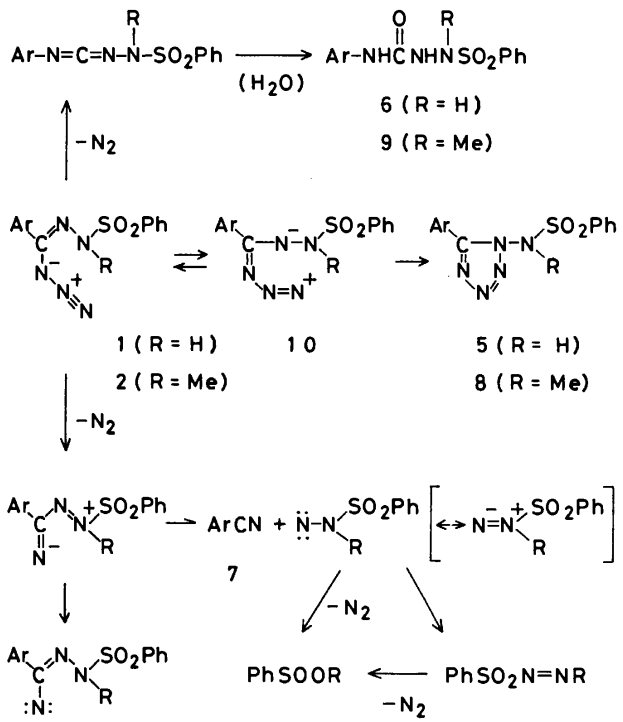
a) NMR signals ($CDCl_3/\delta$) of N-CH_3 in **8a**, **8b**, **8d**, and **8e** are 3.44, 3.41, 3.44, and 3.47 (singlet), respectively. Compound **8f** is almost insoluble in $CDCl_3$. Signals of N-H in compounds **5a—f** are comsealed by those of aromatic protons.

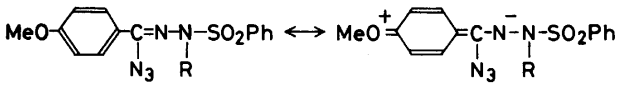


Scheme 2.

Since the disproportionation of benzenesulfinic acid gives also benzenesulfonic acid, the reaction medium should be acidic to a certain extent. Thus, the Curtius-type rearrangement of **1** and **2** leading to **6** and **9** may be acid-induced. Indeed, when **1a** was heated in benzene in the presence of pyridine, **6a** was obtained in a diminished yield (3%) and an increase in the yield of **5a** was observed (14→40%). Methyl benzenesulfonate detected in the reaction of **2** may result from the ester interchange between methyl benzenesulfinate and benzenesulfonic acid.

The tetrazole formation is one of the 1,5-dipolar cyclization. The present reaction is the first example of this type of cyclization of hydrazonoyl azides. The strong electron-withdrawing nature of benzenesulfonyl group probably accelerates the cyclization; that is, the 1,5-dipole structure, **10**, may be stabilized owing to the reduced electron density at the amino nitrogn. This type of contribution can not be expected for *N*-arylbenzohydrazonoyl azides which do not undergo tetrazole formation.

As shown in Table 3, hydrazonoyl azides **1c** and **2c** gave no tetrazoles, which can be explained on the basis of the electron-donating effect of *p*-methoxyl group attached to the *C*-aryl group. That is to say, the electron-donating group may prevent the transformation of azide forms (**1** and **2**) to the 1,5-dipole structure (**10**).



The lower yields of **5b** and **8b** may be also due to the electron-donating effect of *p*-methyl group.

Experimental

Melting points were determined with a Yanagimoto MP-S3 micromelting point apparatus, and are uncorrected. The microanalysis was performed on a Perkin-Elmer 240 elemental analyzer. The IR and NMR spectra were recorded with a Hitachi 260-10 and a Varian EM-360A spectrometer, respectively.

Preparation of N-*Methyl*-N-*(phenylsulfonyl)benzohydrazonoyl Chlorides (3). General Procedure*: To a solution of *N*-(phenylsulfonyl)benzohydrazonoyl chloride[5] (**4**, 10 mmol) in THF (30 ml), slightly excess amounts of an ethereal solution of diazomethane was added by portions. The reaction completed almost immediately with evolution of nitrogen. The removal of solvent gave practically pure **3** (yield: nearly quantitative), which was recrystallized from an appropriate solvent. The results are summarized in Table 1.

Preparation of N-*(Phenylsulfonyl)benzohydrazonoyl Azides (1). General Procedure*: To a homogeneous aqueous dioxane solution of hydrazonoyl chloride **4**, prepared by adding water (10 ml) to a solution of **4** (10 mmol) in dioxane (40 ml), a solution of sodium azide (11 mmol) in water (5 ml) was added at room temperature. The mixture turned pale yellow immediately. After standing for a few minutes, 300 ml of ice water was added to the reaction mixture; and then, the mixture was ice-cooled for 10—15 min. The product separated was purified by crystallization from acetone–hexane. The results are summarized in Table 2.

Preparation of N-*Methyl*-N-*(phenylsulfonyl)benzohydrazonoyl Azides (2). General Procedure*: A mixture of hydrazonoyl chloride **3** (10 mmol), sodium azide (12 mmol), and DMSO (60 ml) was stirred for 10—15 h at room temperature. To the reaction mixture, ice water was added by portions, and the resulting precipitates of hydrazonoyl azide were filtered, dried, and then crystallized from acetone–methanol. The results are summarized in Table 2.

Thermolyses of Hydrazonoyl Azides 1. Typical Procedure: A solution of **1a** (1.505 g, 5 mmol) in dry benzene (30 ml) was refluxed for 10 h. The progress of reaction was checked by means of TLC. The reaction mixture was cooled and filtered to give 4-phenyl-1-(phenylsulfonyl)semicarbazide (**6a**; 498 mg, 34%) as a benzene-insoluble substance, which was purified by crystallization from ethanol. The filtrate was concentrated to about 5 ml by fractional distillation, and then chromatographed on a silica-gel column (20 cm-d, 15 cm-h; eluents: hexane, benzene, benzene–diethyl ether, and benzene–ethanol) to give a benzonitrile fraction, diphenyl disulfide (22 mg, 2%), *S*-phenyl benzenethiosulfonate (203 mg, 16%), 5-phenyl-1-(phenylsulfonylamino)-1*H*-tetrazole (**5a**; 210 mg, 14%; purified by crystallization from ethanol–hexane), **6a** (29 mg, 2%), and an undeterminable mixture (202 mg). From the benzonitrile fraction, **7a** (144 mg, 28%) was detected by GLC (Silicone grease DC-550/celite 545, 2 m; 130 °C). The results are summarized in Tables 3, 4, and 5.

Thermolysis of Ia in the Presence of Pyridine: A solution of **1a** (1.505 g, 5 mmol) and pyridine (0.4 g, 5 mmol) in dry benzene (30 ml) was refluxed for 10 h. A similar work-up of the reaction mixture gave **5a** (596 mg, 40%), **6a** (48 mg, 3%), and **7a** (171 mg, 33%) together with *S*-phenyl benzenethiosulfonate (132 mg, 11%) and trace amounts of diphenyl disulfide.

Thermolyses of Hydrazonoyl Azides **2**. *Typical Procedure*: A solution of **2a** (1.575 g, 5 mmol) in dry benzene (30 ml) was refluxed for 3 h. The reaction mixture was treated in a manner similar to those mentioned above to afford **7a** (232 mg, 45%), **8a** (189 mg, 12%), and **9a** (245 mg, 16%) along with *S*-phenyl benzenethiosulfonate (62 mg), methyl benzenesulfinate (197 mg), methyl benzenesulfonate (141 mg), and an undeterminable mixture (73 mg). The results are summarized in Tables 3, 4, and 5.

Base-induced Dehydrosulfinatocyclization of *N*-Alkyl-*N*-phenylsulfonyl-*N*″-arylbenzamidrazones to 3,4-Diaryl-4*H*-1,2,4-triazoles

Suketaka Ito,* Yumo Tanaka, and Akikazu Kakehi
Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380
(Received October 3, 1983)

3,4-Diaryl-4*H*-1,2,4-triazoles were obtained in good to comparable yields by the reaction of *N*-alkyl-*N*-phenylsulfonyl-*N*″-arylbenzamidrazones with sodium hydride. The reaction probably proceeds *via* the elimination of benzenesulfinic acid and the oxidative cyclization of *N*-alkylidene-*N*″-arylbenzamidrazones generated by the base-catalyzed isomerization of azo intermediates.

As the McFadyen-Stevens[1] and the Bamford-Stevens reactions,[2] such reactions of arylsulfonylhydrazine derivatives involving the elimination of arenesulfonyl group as arenesulfinate anion may be attractive from synthetic aspects.

In a previous paper,[3] we reported a preparative method of 3-aryl-1,2,4-benzotriazines by the mercury(II) oxide-oxidation of *N*-phenylsulfonyl-*N*″-arylbenzamidrazones (**1**). This reaction has been postulated to proceed *via* diazonium benzenesulfinates generaed from intermediate azo sulfones (**2**), the oxidizing producs of the benzamidrazones.

Ar–C(=N–Ar′)–N=N–Z

2 (Z=PhSO$_2$)

3 (Z=Alkyl)

N,*N*-Disubstituted amidrazones such as the title amidrazones (**4**) cannot undergo this type of oxidation leading to the formation of **2**, as a matter of course. However, as has been seen in some reactions of arylsulfonylhydrazines (carrying a free hydrogen at the 2-position) with a base,[4] the base-induced 1,2- (or 1,4-) elimintion of arenesulfinic acid can be expected for the title amidrazones, which would result in the formation of 1,2,4-triazabutadiene intermediates (**3**). The present paper deals with the formation of 3,4-diaryl-4*H*-1,2,4-triazoles (**5**) from *N*-alkyl-*N*-phenylsulfonyl-*N*″-arylbenzamidrazones (**4**) *via* the elimination of benzenesulfinic acid by the action of sodium hydride.

Results and Discussion

Preparation of N-*Alkyl*-N-*phenylsulfonyl*-N″-*arylbenzamidrazones (4).* Amidrazones **4** were prepared by the reaction of anilines with *N*-alkyl-*N*-(phenylsulfonyl)benzohydrazonoyl chlorides (**6**), readily obtainable from *N*-(phenylsulfonyl)benzohydrazonoyl chlorides or *N*-alkyl-*N*-(phenylsulfonyl)benzohydrazides[5] (Scheme 1).

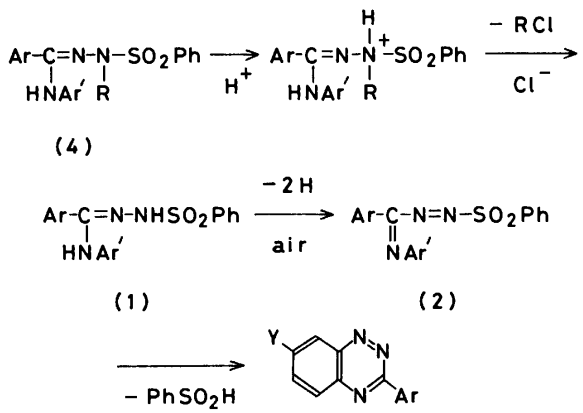
a) Abbreviations are as follows: m, medium; s, strong; w, weak; sh, shoulder. b) Abbreviations are as follows: brs, broad singlet; s, singlet; q, quartet; t, triplet. c) Other signals are as follows: **4b**, 2.24s, *p*-CH_3 (Y); **4c**, 3.71s, *p*-OCH_3 (Y); **4e**, 2.31s, *p*-CH_3 (X), **4f**, 2.31s, *p*-CH_3 (X) and 2.25s, *p*-CH_3 (Y); **4g**, 2.33s, *p*-CH_3 (X); **4i**, 2.27s, *p*-CH_3 (Y).

On heating in refluxing dioxane, hydrazonoyl chlorides **6** and anilines afforded amidrazones **4** only in poor yields (for example, *N*-methyl-*N*-(phenylsulfonyl)-benzohydrazonoyl chloride and aniline gave the corresponding amidrazone in an 18% yield after refluxing for 24 h). However, when chlorides **6** were fused with anilines at 105—110 °C for 3—4 h under an atmosphere of nitrogen, compounds **4** were obtained in good yields. Small amounts of *N*-methyl-*N*-(phenylsulfonyl)benzohydrazide, hydrolyzed products of **6**, were also obtained. The results are summarized in Tables 1 and 2.

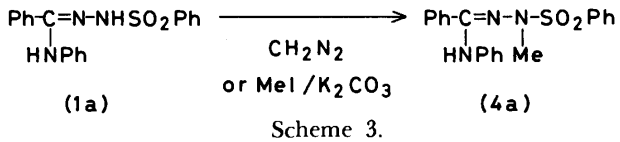
Interestingly, when a fusion of compounds **6** with anilines was conducted at higher temperature, the yields of amidrazones decreased remarkably and the formation of 3-aryl-1,2,4-benzotriazines was observed. For example, *N*-methyl-*N*-(phenylsulfony)-*p*-methylbenzohydrazonoyl chloride gave **4g** in a 19% yield and 7-chloro-3-*p*-tolyl-1,2,4-benzotriazine in a 17% yield on heating with *p*-chloroaniline at 120 °C for 1.5 h, and 7-chloro-3-phenyl-1,2,4-benzotriazine (21%) was obtained by the fusion of *N*-methyl-*N*-(phenylsulfonyl)benzohydrazonoyl chloride with *p*-chloroaniline at 150 °C for 1.5 h. In the latter case, no amidrazone could be detected.

For these benzotriazine formations, the *N*-alkyl group of **4** must be eliminated. Since hydrogen chloride exists in the reaction medium, the reaction may proceed *via* a route which involves the protonation of initially formed amidrazones and the subsequent nucleophilic attack of chloride ion. The resulting *N*-dealkylated amidrazones (**1**) probably undergo air oxidation leading to the formation of benzotriazines *via* **2** (Scheme 2).



Scheme 2.

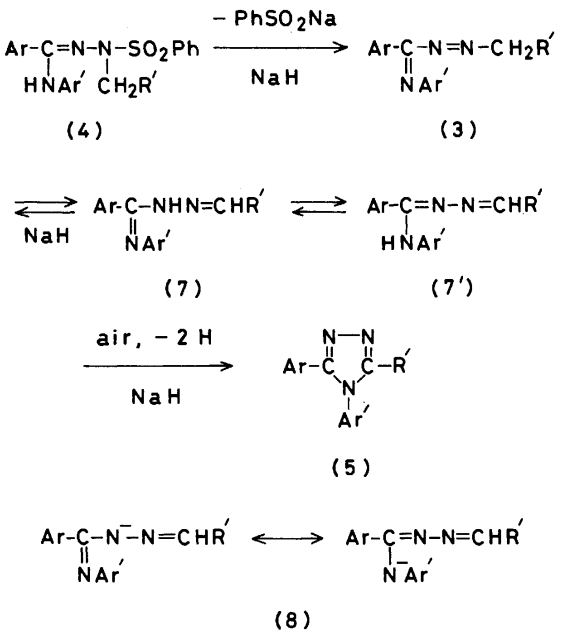
N-Alkylaion of *N*-phenylsulfonyl-*N''*-arylbenzamidrazone (**1**) with diazoalkane or alkyl iodide may be available for preparing **4**. For example, **4a** was obtained in a good yield by these methods (Scheme 3).



Scheme 3.

For the amidrazones, two tautomeric structures, **4**(A) and **4**(B), are possible. The IR spectra of **4** are far simple in the N-H absorption region (>3000 cm^{-1}) as compared with those of *N*-phenylsulfonyl-*N*″-arylbenzamidrazones. According to Walter and Weiss,[6] *N*,*N*-disubstituted *N*″-arylbenzamidrazones prefer to an amide hydrazone form which is stabilized by intramolecular hydrogen bonding. Thus, amidrazones **4** also may take the amide hydrazone structure, **4**(A). The duality of as. ν_{SO_2} and sym. ν_{SO_2} absorptions may be due to Fermi resonance.

Reactions of Amidrazones 4 with Sodium Hydride. Amidrazones **4** were allowed to react with small excess amounts of sodium hydride dispersion in dioxane under reflux.[7] With the progress of reaction, precipitation of sodium benzenesulfinate was observed. The reaction went essentially to completion after about 20 h of refluxing. After removal of the precipitated sodium benzenesulfinate, the reaction mixtures were chromatographed to give 3,4-diaryl-4*H*-1,2,4-triazoles in good to comparable yields along with small amounts of undeterminable oils. The results are summarized in Tables 3 and 4.



Scheme 4.

5h	1584	1073	1007	8.36s				7.00—7.60m
5i	1599	1082	1003	8.32s		2.46	(Y=Me)	7.00—7.60m
5j	1595	1080	1004	8.33s				7.00—7.60m
5k	1596	1073	1012		2.34s			7.00—7.70m
5l	1597	1075	1010		2.37s			7.00—7.70m

The triazoles obtained were confirmed by their analytical and spectral data, and the idetification of known compounds was made by direct comparison with authentic specimens. The absorptions at near 1600, 1080, and 1010 cm^{-1} in the IR spectra can be attributed to the 1,2,4-triazole ring vibrations.[8]

The present triazole formation can be explained by the following route, which involves the 1,4-elimination of benzenesulfinic acid[9] and the base-catalyzed tautomerization[10] of **3** to *N*-alkylidene-*N*''-arylbenzamidrazones (**7** or **7**') followed by oxidative cyclization to 1,2,4-triazoles (Scheme 4).

In view of the acidity of the amino hydrogen of **4**, **4** should generae initially **3**, from which **7** or **7**' may be formed. The cyclization of *N*-arylmethylene-*N*''-arylbenzamidrazones to 3,4,5-trisubstituted 4-*H*-triazoles by mercury(II) oxide-oxidation has been reported by Spassov *et al.*[11] For the oxidative cyclization step, **7** or **7**' to **5**, the anionic 6π-electrocyclic process or intramolecular nucleophilic process of **8** and the subsequent aromatization to **5** may be conceivable.

Experimental

Melting points were determined with a Yanagimoto MP-S3 micromelting point apparatus, and are uncorrected. The microanalysis was performed on a Perkin-Elmer 240 elemen tal analyzer. The IR and NMR spectra were recorded with a Hitachi 260-10 and a Varian EM-360A spectrometers, respectively. *N*-Methyl-*N*-(phenylsulfonyl)benzohydrazonoyl chlorides were prepared by the method previously reported.[5]

Preparation of N-*Ethyl*-N-*(phenylsulfonyl)benzohydrazonoyl Chloride.* To a solution of 1-benzoyl-2-phenylsulfonylhydrazine (5.52 g, 20 mmol) in DMF (50 ml), a 0.58 g-portion (net 24 mmol) of sodium hydride dispersion (70% in liquid paraffin) was added under external cooling. After the cease of gas evolution (a few minutes), ethyl iodide (3.43 g, 22 mmol) was added to the mixture. After stirring for 1 h at room temperature, the DMF solution was poured into water to separate 1-benzoyl-2-ethyl-2-phenylsulfonylhydrazine, which was purified by crystallization from ethanol (yield: 4.95 g, 82%). Mp 162—164 °C; IR(KBr, cm^{-1}): 3210 (NH), 1673 (C=O), 1353, and 1163, (SO_2); NMR ($CDCl_3$), δ=3.73 (2H q, N-$C\underline{H}_2CH_3$, J=7.2 Hz), 1.25 (3H t, N-$CH_2C\underline{H}_3$, J=7.2 Hz), and 7.20—8.20 (11H m, 2Ph and NH). Found: C, 59.35; H, 5.46; N, 9.18%. Calcd for $C_{15}H_{16}N_2O_3S$: C, 59.19; H, 5.30; N, 9.20%.

A mixture of 2-ethylated hydrazine thus obtained (4.53 g, 15 mmol) and 30 ml of thionyl chloride was refluxed for 3 h. After removal of excess thionyl chloride *in vacuo*, the oily residue was chromatographed on a silica-gel column (2.5 cm-d, 15 cm-h; eluent: benzene) to give *N*-ethyl-*N*-(phenylsulfonyl)benzohydrazonoyl chloride (3.49 g, 72%), which was crystallized from benzene-hexane. Mp 63—65 °C; IR (KBr, cm^{-1}): 1591 (C=O), 1350, and 1168 (SO_2); NMR ($CDCl_3$), δ=3.41 (2H q, N-$C\underline{H}_2CH_3$, J=7.0 Hz), 1.07 (3H t, N-$CH_2C\underline{H}_3$, J=7.0 Hz), and 7.30—8.20 (10H m, 2Ph). Found: C, 55.76; H, 4.71; N, 8.70%. Calcd for $C_{15}H_{15}N_2O_2SCl$: C, 55.81; H, 4.68; N, 8.68%.

Preparaton of Amidrazones **4**. *General Procedure*: A mixture of **6** (10 mmol) and aniline (22 mmol) was heated in an oil bath at 105—110 °C for 3—4 h under nitrogen atmosphere. After being cooled, the reaction mixture was extracted with water and chloroform. The chloroform layer was washed and dried, and then concentrated. The chloroform extract was chromatographed on a silica-gel column (2.5 cm-d, 10 cm-h; eluent: benzene–ethanol) to give **4**, which was recrystallized from benzene. The results were summarized in Tables 1 and 2.

Fusion of **6** *with Anilines at a Higher Temperature. A Typical Example*: A mixture of *N*-methyl-*N*-(phenylsulfonyl)-*p*-methylbenzohydrazonoyl chloride (2.582 g, 8 mmol) and *p*-chloroaniline (2.245 g, 17.6 mmol) was heated at 120 °C for 1.5 h in a similar manner. Chloroform extraction followed by chromatography gave amidrazone **4g** (0.569 g, 19%) and 7-chloro-3-*p*-toly-1,2,4-benztoriazine[3] (mp 175—177 °C, 0.342 g, 17%) from the reaction mixture.

N-*Methyltion of* N-*Phenylsulfonyl*-N''-*phenylbenzamidrazone (***1a***). *With Methyl Iodide and Potassium Carbonate*: A mixture of **1a** (703 mg, 2 mmol) and methyl iodide (430 mg, 3 mmol) in THF (30 ml) was stirred with potassium carbonate (420 mg, 3 mmol) for 18 h at room temperature. The reaction mixture was poured into water (150 ml) to give precipitates, which were purified by column chromatography to give **4a** (557 mg, 76%).

With diazomethane: To a solution of **1a** (352 mg, 1 mmol) in THF (15 ml), slightly excess amounts of an ethereal solution of diazomethane was added by portions. After removal of solvent, the residue was chromatographed to give **4a** (313 mg, 89%).

The Reaction of Amidrazones **4** *with Sodium Hydride. General Procedure*: A mixture of **4** (1 mmol) and sodium hydride dispersion (net 1.5 mmol) in dry dioxane (30 ml) was refluxed for 20 h under nitrogen atmosphere. After removal of separated sodium benzenesulfinate by filtration, the reaction mixture was concentrated and chromatographed on a silica-gel column (2.0 cm-d, 10 cm-h; eluent: benzene–ethanol) to give **5**, which was recrystallized from benzene–hexane. The results were summarized in Tables 3 and 4.

The sodium benzenesulfinate above obtained (crude yield: nearly quantitative) was allowed to react with benzyl chloride in ethanol to give phenyl benzyl sulfone, mp 147—148 °C (ethanol), the IR spectrum of which was spectroscopically identical with that of an authentic sample.

Preparation of New Nitrogen-bridged Heterocycles. 8.[1] Syntheses of Some Fused Indolizine Derivatives *via* the Acid-catalyzed Cyclizations of Functionalized 1- and 3-Vinylindolizines

Akikazu KAKEHI,* Suketaka ITO, Shinji MURAKAMI, and Hiroaki SANO
Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380
(Received October 1, 1983)

Pyrano[3,2-*a*] and pyrano[2,3-*b*]indolizin-2-one derivatives were prepared in 12—86% yields by the acid-catalyzed deacetylation-cyclization of 2-acetoxy-1- and 3-[2-(ethoxycarbonyl)vinyl]indolizines with concentrated sulfuric acid at room temperature. On the other hand, similar reactions of 2-acetoxy-3-[1,2-bis(methoxycarbonyl)vinyl]indolizines did not give the initially expected pyrano[2,3-*b*]indolizinones at all, but, instead of them, afforded 3-(methoxycarbonylmethylene)furo[2,3-*b*]indolizin-2-one derivatives in fair yields. Formation mechanisms and some physical properties are also discussed.

In our pevious paper, we reported the direct formation of ethyl 2-oxo-2*H*-pyrano[2,3-*b*]indolizine-3-carboxylates by the reactions of 1-(ethoxycarbonylmethyl)-2-methylpyridinium bromides with diethyl (ethoxymethylene)malonate, in which we proposed the presence of 3-[2,2-bis(ethoxycarbonyl)vinyl]-2-indolizinols as the key intermeiates.[2] More recently, it was found that these 2-indolizinol intermediates could be trapped smoothly with various acylating and alkylating agents to give the corresponding esters and ethers,[3] and that an acetate, 2-acetoxy-[2,2-bis(ethoxycarbonyl)vinyl]-5-methylindolizine, in these compounds was converted slowly to the corresponding pyranoindolizinone in various solvents. These findings focused our attention to the syntheses of fused indolizines starting from readily available 2-acetoxy-3-vinylindolizine derivatives. In this paper, we wish to report the preparations of some 2*H*-pyrano[3,2-*a*] and [2,3-*b*]indolizin-2-one and 3-methylene-2*H*-furo[2,3-*b*]indolizin-2-one derivatives from the reactions of functionalized 2-acetoxy-1- or 3-vinylindolizines with concentrated sulfuric acid.

Results and Discussion

Preparations of 2H-Pyrano[2,3-b]indolizin-2-one Derivatives. Since the spontaneous deacetylation-cyclization of these 2-acetoxy-3-vinylindolizine derivatives could not be actually observed in various solvents except only one example described above, we examined the possibility of this process under various acidic and basic conditions[4] and found a method in which concentrated sulfuric acid was employed as a catalyst. Treatment of 2-acetoxy-3-[2,2-bis(ethoxycarbonyl)vinyl]indolizines (**1**—**4**) with a small amount of concentrated sulfuric acid (1 ml per 1 mmol indolizine) at room temperature gave the expected ethyl 2-oxo-2*H*-pyrano[2,3-*b*]indolizine-3-carboxylates (**5**—**8**) in 41—86% yields as strongly fluorescent orange crystals. Similar treatment of 3-[2-acetyl-2-(ethoxycarbonyl)vinyl]indolizines (**9**—**12**) (cis-trans mixtures) afforded the corresponding 3-acetyl derivatives (**13**—**16**), but the yields were lower (12—54%) than those of **5**—**8**. On the other hand, the reactions of 3-[2-cyano-2-(ethoxycarbonyl)vinyl]indolizines (**17** and **19**) with sulfuric acid at room temperature afforded only undeterminable insoluble substances but those of **17**—**20** at 80—95 °C gave 3-unsubstituted 2*H*-pyranoindolizinones (**21**—**24**) in variable yields (0—50%) (Scheme 2). Several attempts to prepare **23** from indolizine (**19**) and ethyl 2-oxo-2*H*-pyranoindolizine-3-carboxylate (**7**) under various conditions were unsuccessful.

Scheme 2.

The structures of pyranoindolizinones (**5**—**8**, **13**—**16**, **21**, **22**, and **24**) were determined by their NMR spectral inspection and partly by the comparisons of **5**, **7**, and **8** with authentic samples prepared previously by us.[2] In particular, the structures of 3-unsubstituted pyranoindolizinones (**21**, **22**, and **24**) were determined by the presence of a AB type proton signals at near δ 5.9 and 8.0 with the coupling constant of 9.5 Hz together with other signals due to the indolizine moiety in their NMR spectra (see Table 1).

TABLE 1. SOME DATA OF FUNCTIONALIZED 1- AND 3-VINYLINDOLIZINES

Compd No.	Yield %	Mp θ_m/°C	$\nu_{C=O}^{KBr}$/cm^{-1}			δ (vinyl proton)	Formula	Calcd(%)			Found(%)		
								C	H	N	C	H	N

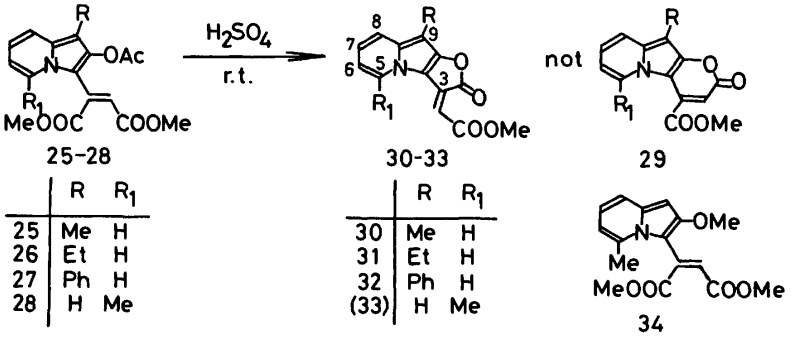
a) This compound is a cis-trans mixture, but its ratio could not be calculated because of the absence of definitely separated signals in the NMR spectrim. b) The peak of major isomer. c) Both vinyl proton signals of cis and trans isomers were overlapped.

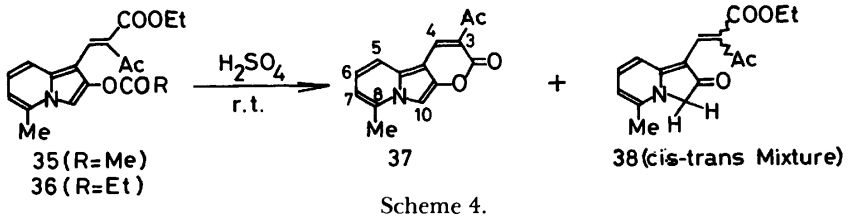
Preparations of 3-Methylene-2H-furo[2,3-b]indolizines. When the acidic treatment of 2-acetoxy-3-[1,2-bis(methoxycarbonyl)vinyl]indolizines (**25—27**) at room temperature were carried out, the initially expected 2-oxo-2*H*-pyranoindolizine-4-carboxylates such as **29** could not be obtained at all, but, instead of them, reddish crystalline substances **30—32** were obtained in 51—68% yields (Scheme 3). Although various reaction conditions such as the quantity and the concentration of sulfuric acid, the reaction time, and the reaction temperature, were tested in the case of 5-methylindolizine (**28**), no furoindolizine (**33**) could be isolated and only a small amount of 2-methoxy-3-vinylindolizine (**34**) could be always obtained.

The structural assignment of 3-methylenefuroindolizinones (**30—32**) was accomplished mainly by their physical and spectral means. The facts that these compounds have not any strong fluorescence characteristics of pyranoindolizinone as seen in **5—8**, **13—16**, **21**, **22**, and **24** and that their NMR spectra were very similar to those of the starting materials **25—27** except the loss of an acetoxyl and a methoxyl proton signals supported clearly these structures fused with a nonaromatic furan ring. The cis configuration of the exo-methylene group in **30—32** was decided by the similarity of the chemical shifts (δ 6.2—6.4) due to the olefinic proton with those (δ 6.1—6.3) of **25—27**. On the other hand, an abnormal product **34** from the reaction of 5-methyl-3-vinylindolizine (**28**) was concluded to be 3-[1,2-bis(methoxycarbonyl)vinyl]-2-methoxy-5-methylindolizine by its NMR inspecion and an unequivocal synthesis (see Experimental section).

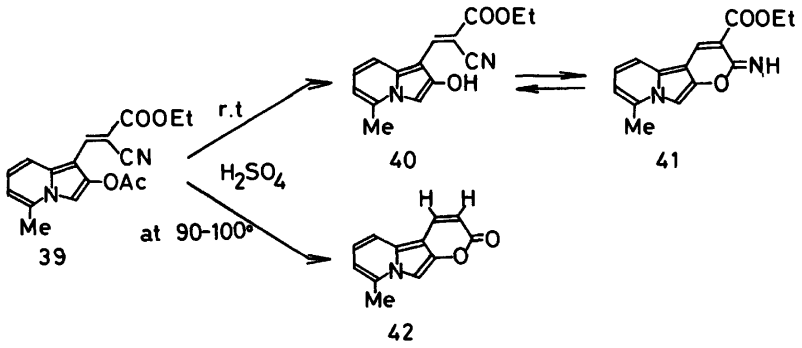
Preparations of 2H-Pyrano[3,2-a]indolizines. Similar reaction of 2-acetoxy-1-[2-acetyl-2-(ethoxycarbonyl)vinyl]-5-methylindolizine (**35**) at room temperature gave the corresponding 3-acetyl-8-methyl-2*H*-pyrano[3,2-*a*]indolizin-2-one (**37**) and an unexpected 1-vinyl-2(3*H*)-indolizinone (**38**) in 12 and 87% yields. The major product **38** was obtained also from the reaction using 2-propionyloxyindolizine deriva-



Scheme 3.



Scheme 4.

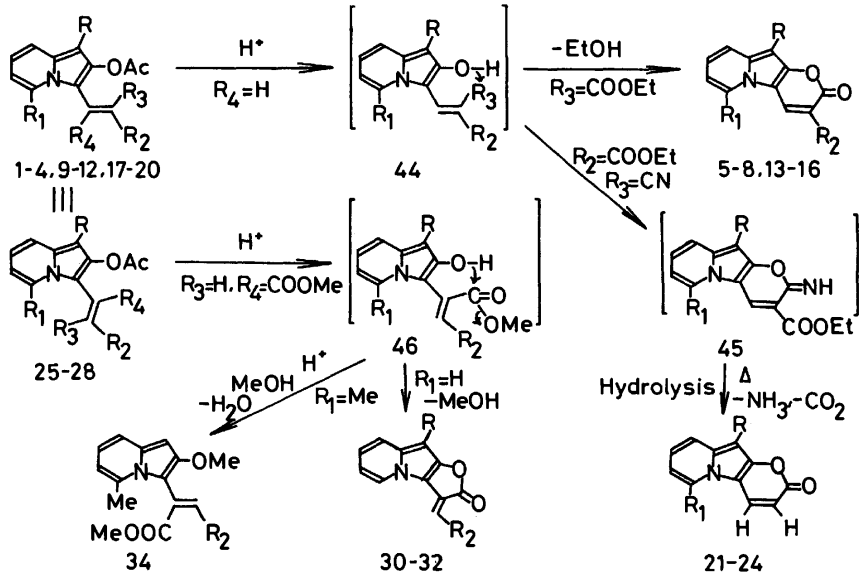


Scheme 5.

tive (**36**) in 89% yield (Scheme 4). Similar reaction of 1-[2-cyano-2-(ethoxycarbonyl)vinyl] derivative (**39**) gave 1-vinyl-2-indolizinol (**40**) and/or pyranoindolizin-2-imine (**41**) in 95% yield. On the other hand, the reaction of **39** under heating conditions afforded the corresponding 3-unsubstituted 8-methyl-2*H*-pyrano[3,2-*a*]indolizin-2-one (**42**) in 41% yield (Scheme 5).

The structures of pyrano[3,2-*a*]indolizinones (**37** and **42**) were determined by the comparisons of their physical and spectral data with those of pyrano[2,3-*b*]indolizinone derivatives. On the other hand, the structure of 1-vinyl-2(3*H*)-indolizinone (**38**) was decided by its NMR inspection and its chemical conversion to acetate 43. Since this compound **38** was a cis-trans mixture (cis:trans=3:4),[5] the NMR spectrum showed multiple complex signals due to the two sets of protons, but a two proton singlet attributable to the 3-methylene group was appeared clearly at δ 4.30. Furthermore, the fact that this group is an active methylene was also indicated by the disappearance of the proton signal with deuterium oxide as seen in known 2(3*H*)-indolizinones.[2] The acetate **43** obtained from **38** was same with compound **35** in the IR spectra, but an another set of proton signals were also appeared in the NMR spectrum of **43** and the melting point (102—104°C) was lower than that (mp 105—106°C) of **35**. Thus, we concluded compound **43** to be a cis-trans mixture[6] of 2-acetoxy-1-[2-acetyl-2-(ethoxycarbonyl) vinyl]-5-methylindolizin (**35**). The structure of product from the reaction of **39** at room temperature was tentatively assigned to be an equilibrium mixture of 1-vinyl-2-indolizinol (**40**) and pyranoindolizin-2-imine (**41**), because this compound has a very strong fluoresence similar to that of tricyclic pyranoindolizinones and extremely low solubility in contract with bicyclic vinylindolizines and vinylindolizinone, and its IR spectrum exhibited a weak cyano absorption band at 2198 cm^{-1}.[7] On the other hand, an alternative possibility of the presence of its 3-cyanopyranoindolizinone derivative was neglected clearly by its elementary analysis, by which the composition of the product was completely in accord with the structure possessing an ethoxycarbonyl group.[8]

Reaction Mechanisms. The formation reaction of 2*H*-pyrano[2,3-*b*]indolizin-2-ones (**5**—**8** and **13**—**16**) and 3-methylenefuro[2,3-*b*]indolizin-2-ones (**30**—**32**) can be explain reasonably by considering the intermediacy of 3-vinyl-2-indolizinol intermediate **44** or **46** from the acetates (**1**—**4**, **9**—**12**, and **25**—**28**) and subsequent intramolecular nucleophilic reactions between the hydroxyl and the ester carbonyl group in the



Scheme 6.

six- or five-membered transition states. Similarly, 3-unsubstituted pyrano[2,3-*b*]indolizin-2-ones (**21**—**24**) must be formed *via* the nucleophilic attack of the hydroxyl group onto the cyano group in **44** followed by the acid hydrolysis and then decarboxylation of the resulting 2*H*-pyrano[2,3-*b*]indolizin-2-imine (**45**). Furthermore, the acid-catalyzed dehydration from indolizinol (**46**) and a methanol generated by the hydro lysis of the methoxycarbonyl group may afford 2-methoxyindolizine (**34**). These mechanisms are summarized in Scheme 6. The fact that no 2-oxopyranoindolizine-4-carboxylate such as **29** could be obtained in the reactions of indolizines (**25**—**28**) may suggest the cis character of the two ester groups in **25**—**28** and the difficulty of the cis-trans isomerization of the vinyl group under reaction conditions employed here. We described previously the cis configuration of this group in **25** and **27**[3] and, here, observed the cis character of the exocyclic 3-methylene group in **30**—**32** and the more diminished yields of 3-acetylpyranoindolizinones (**13**—**16**) compared with those of 2-oxopyranoindolizine-3-carboxylate (**5**—**8**). In the reaction of 5-methylindolizine (**28**), the fact that no tricyclic product such as **29** and **32** was obtained seems to indicate the loss of requisite of planarity for the transition states in such cyclizations owing to the steric repulsion between the 5-methyl and the 3-[1-(methoxycarbonyl)] group, and, thus, to lead to the formation of an ethereal product (**34**) from 2-indolizinol (**46**).

The formation mechanisms of 2*H*-pyrano[3,2-*a*]-indolizinone derivatives (**37**, **41** (or **40**), and **42**) can be also considered by similar manners described above in the cases of 2-acetoxy-3-vinylindolizines, while 1-vinyl-2(3*H*)-indolizinone (**38**) is simply a keto-isomer of 1-vinyl-2-indolizinol intermediate.

Experimental

Melting points were measured with a Yanagimoto micro-melting point apparatus and are uncorrected. Microanalyses were carried out on a Perkin-Elmer 240 Elemental Analyzer. The NMR spectra were determined with a Varian EM360A Spectrometer in deuteriochloroform with tetramethylsilane as an internal standard. .The chemical shifts are expressed in δ values. The IR spectra were taken with a Hitachi 260-10 Infrared Spectrophotometer.

Preparations of 1- and 3-Vinylindolizine Derivatives. These functionalized 2-acetoxy-3-vinylindolizines (**1**—**4**), (**9**—**12**), (**17**—**20**), and (**25**—**28**) and 2-methoxy-5-methyl-3-vinylindolizine (**34**) were obtained as red prisms by the 2(3*H*)-indolizinone route[3] and 2-acetoxy-1-vinylindolizine derivatives (**35**, **36**, and **39**) were given as orange needles by the 2-allylidene-1,2-dihydropyridine route appeared in our previous papers.[9,10] These results and some physical data of new 1- and 3-vinylindolizine derivatives (**2**, **4**, **9**—**12**, **26**, **28**, and **34**—**36**) are summarized in Table 1.

Reactions of 1- and 3-Vinylindolizines with Sulfuric Acid. *Method A*: To 1 mmol of 2-acetoxy-1- or 3-vinylindolizine derivative 1 ml of concentrated sulfuric acid was added and the resulting mixture was kept overnight at room temperature. The reaction solution was poured slowly into a 20 ml of ice-water, neutralized carefully with aqueous potassium carbonate under stirring, and extracted twice with 50 ml portions of chloroform. After the combined extract was filtered through a phase-separating filter paper, the filtrate was concentrated at reduced pressure and the residue was separated by column chromatography (alumina) using ether and then chloroform as eluents. Recrystallization of the crude products from chloroform or ethanol gave the corresponding pyranoindolizinones (**5**—**8** and **13**—**16**) as yellow to orange needles and methylenefuroindolizinones (**30**—**32**) as red prisms.

Method B: The similar mixture of vinylindolizine and concentrated sulfuric acid was heated in a sealed tube at 90—100°C for 1—2 h. The usual work-ups of the resulting solutions gave the corresponding 3-unsubstituted pyranoindolizinones (**21**, **22**, **24**, and **42**) as yellow needles.

a) Known compound, see Ref. 2. b) The preparation of the analytical sample was unsuccessful because of its low yield. c) Cyano band.

The reactions of vinylindolizine (**19**) and ethyl 2-oxo-2*H*-pyranoindolizine-3-carboxylate (**7**) with sulfuric acid were examined in detail under various conditions, but the synthesis of the corresponding 10-phenylpyranoindolizinone (**23**) was not unsuccessful. In the similar reaction (Method A) of **28**, the initially expected pyranoindolizinone such as **29** and methylenefuroindolizinone (**33**) were not obtained at all, but 2-methoxy-3-vinylindolizine (**34**) was isolated in only 7% yield. This compound (**34**) was completely in accord with authentic sample prepared above in all respects. These results and some properties of products are listed in Tables 2—4.

Acetylation of 1-Vinyl-2(3H)-indolizinone (38). A mixture of indolizinone **38** (144 mg, 0.5 mmol), acetic anhydride (1 ml), and pyridine (3 ml) was heated at 70—80 °C in a water bath for 2 h. The unreacted anhydride and pyridine was then removed at reduced pressure and the residual oil was separated by column chromatography (alumina) using hexane and then ether as eluents. The ether layer was collected and concentrated at reduced pressure. Recrystallization from ethanol gave pure 2-acetoxy-1-vinylindolizine (**43**), 118 mg, 72%, orange needles, mp 102—104 °C, ν (KBr) 1751, 1709, and 1673 cm^{-1} (CO), δ ($CDCl_3$)[11] 1.19 (3H, t, J=7.0 Hz, $CH_2\underline{CH_3}$), 2.33, 2.42 (each 3H, s, 2Ac), 2.53 (3H, s, 5-Me), 4.25 (2H, q, J=7.0 Hz, $O\underline{CH_2}CH_3$), 6.61 (1H, br d, J=7.0 Hz, 6-H), 7.03 (1H, q, J=9.0 and 7.0 Hz, 7-H), 7.49 (1H, br d, J=9.0 Hz, 8-H), 7.53 (1H, s, 3-H), and 8.05 (1H, s, vinyl-H). Found: C, 65.89; H, 5.83; N, 4.26%. Calcd for $C_{18}H_{19}NO_5$: C, 65.64; H, 5.82; N, 4.25%.

The NMR signals due to the main isomer in **43** were completely in accord with those of **35**.

3) A. Kakehi, S. Ito, B. Wada, K. Watanabe, K. Nishimura, and A. Kumagai, *Bull. Chem. Soc. Jpn.*, **55**, 3590 (1982).

4) The reaction conditions in which acidic and basic media such as hydrochloric acid, sulfuric acid, sodium ethoxide, potassium t-butoxide, sodium hydroxide, and po tassium carbonate were employed in various solvents were examined.

5) Or cis:trans=4:3. The NMR spectrum of **38** is as follows: Major isomer, δ ($CDCl_3$) 1.37 (3H, t, J=7.0 Hz, $OCH_2\underline{CH_3}$) 2.36 (3H, s, Ac), 2.48 (3H, s, 5-Me), 4.30 (2H, s, methylene, disappeared with deuterium oxide), 4.43 (2H, q, J=7.0 Hz, $O\underline{CH_2}CH_3$), 6.60 (1H, br d, J=7.0 Hz, 6-H), 7.42 (1H, s, vinyl-H), and 6.9—7.9 (2H, m, 7- and 8-H). Minor isomer, δ ($CDCl_3$) 1.34 (3H, t, J=7.0 Hz, $OCH_2\underline{CH_3}$), and 7.37 (1H, s, vinyl-H). The other proton signals due to the minor product were overlapped with those of major isomer.

6) The cis-trans ratio could not be calculated because of the absence of definitely separated signals in its NMR spectrum, but isomer **35** was major.

7) The presence of a strong interaction between these groups in a similar system was reported. See K. Kurita, H. Awaya, Y. Tominaga, Y. Matsuda, and G. Kobayashi, *Yakugaku Zasshi*, **101**, 980 (1981).

8) Because of its extremely low solubility, our attempts to obtain further structural information were unsuccessful.

9) A. Kakehi, S. Ito, T. Maeda, R. Takeda, M. Nishimura, M. Tamashima, and T. Yamaguchi, *J. Org. chem.*, **43**, 4837 (1978).

10) The trans configuration of the 1-vinyl group in **35** and **36** was assigned tentatively from the reasons that the vinyl proton of the trans isomer may appear in lower magnetic field than that of the cis one and that the corresponding pyrano[3,2-*a*]indolizinone (**37**) was formed only in very low yield.

11) This is major compound (**35**). The NMR data of minor compound are as follows: δ ($CDCl_3$) 1.32 (3H, t, J=7.0 Hz, $OCH_2\underline{CH_3}$), 2.33 and 2.38 (each 3H, s, 2Ac), 2.53 (3H, s, 5-Me), and 8.03 (1H, s, vinyl-H). The other signals were overlapped with those of major isomer (**35**).

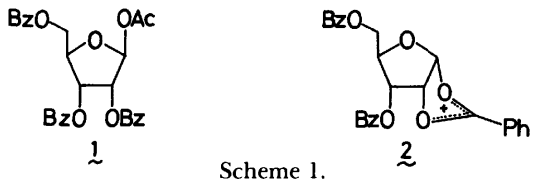
Reactions of 2,3,5-Tri-*O*-benzoyl-D-ribofuranosyl Acetate with Enol Silyl Ethers Catalyzed by Tin(IV) Chloride. Regiochemical Features[1)]

Yayoi S. YOKOYAMA, Tan INOUE, and Isao KUWAJIMA*
Department of Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152
(Received October 5, 1983)

In condensation reactions of 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl acetate with various kinds of enol silyl ethers in the presence of tin(IV) chloride, the acetate behaves as an ambident electrophile to give two types of products arising from nucleophilic attack of the enol ether on C-1 carbon of the ribose derivative and on carbonyl carbon of 2-benzoyloxyl group, depending remarkably on the enol silyl ethers.

Much attention has recently been attracted on *C*-glycosyl nucleosides because of their important antibiotic properties and potent anticancer and antiviral activities.[2)] It is quite important and valuable to prepare them and their structural analogues easily, from the viewpoint to research for higher bioactive compounds. Some of synthetic studies have already been described on formycin,[3)] showdomycin,[4)] pyrazomycin,[5)] and their analogues.[6)] Although they had few synthetic relation to each other, most of these syntheses have a common strategy which involves an introduction of a cyano, aryl, or other nucleophilic moieties to C-1 position of 1-halo- or 1-acetoxy-β-D-ribofuranose derivatives to construct appropriate heterocycles. From this viewpoint, a key reaction is to make the new carbon-carbon bond between C-1 carbon of ribose and various nucleophilic reagents. It has been well documented that 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl acetate (**1**), an easily accessible material, generates an electrophilic species, 1,2-*O*-benzylidene oxonium ion (**2**), by the aid of either appropriate bases or acids through neighboring participation of C-2 benzoyloxyl group. The resulting electrophile **2** has two reaction sites for nucleophiles; C-1 carbon and carbonyl carbon of 2-benzoyloxyl group. Under basic conditions C–C bond formation between **2** and nucleophiles takes place at C-1 and/or 2-benzoyloxyl carbonyl,[6c,7)] whereas reactions with olefins including 1-trimethylsiloxycyclohexene have been reported to proceed selectively on C-1 position in the presence of Lewis acid.[8)]

Based on such feature, we previously examined the use of a enol silyl ether for such purpose and reported synthesis of showdomycin which includes the C–C bond formation between **1** and 1,2-bis(trimethylsiloxy)-cyclobutene as a key step.[4a)] However, it has not been systematically studied what kind of enol silyl ethers react to form desired carbon-carbon linkages. In this paper we describe regiochemical features of the reaction between 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl acetate (**1**) and various kinds of enol silyl ethers, which disclose the scope and limitations to use enol silyl ethers for synthesis of *C*-nucleosides and their analogues.



1 **2**

Scheme 1.

Enol silyl ethers **3a—g** have been chosen as typical nucleophiles and their reactions with **1** have been studied under the influence of 1 equiv of tin(IV) chloride in dichloromethane at room temperature. On contrary to our expectation, the condensation reaction at C-1 position of **1** is not a general phenomenum even on using enol silyl ethers; some of them (**3e—g**) give the desired C-1 condensation products **4e—g**, whereas others (**3a—d**) are found to yield the products **5a—d** selectively arising from their nucleophilic attack on carbonyl carbon of 2-benzoyloxyl group[9)] under same reaction conditions.

As shown in the table, regiochemical results of the reaction are definitely determined by the kind of enol silyl ethers used and no regio-isomer could be detected in every case. According to these results, enol silyl

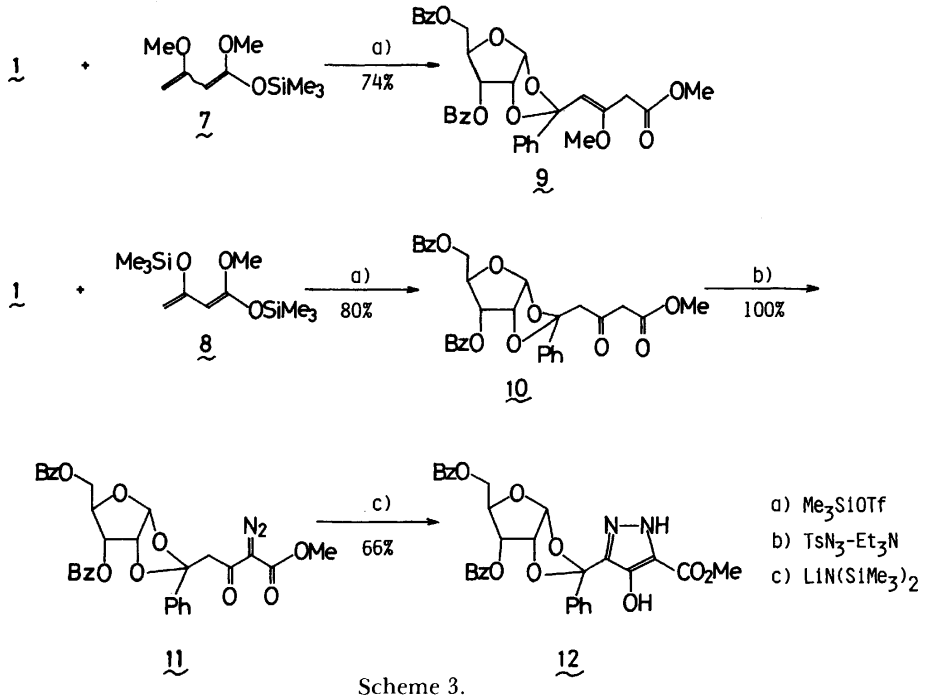
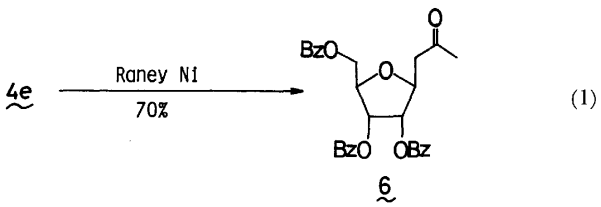


Scheme 3.

ethers seem to be classified into the following two categories. Those of usual acyclic ketones (**3a** and **3b**) and of esters (**3c** and **3d**) generally react on carbonyl carbon of 2-benzoyloxyl group to give the products of type **5**. On the other hand, in the case of enol ethers of ketones having α-hetero substituents (**3e**, **3f**, and **3g**), the reaction takes place selectively on C-1 site of **1** to afford the desired products **4e—g**. Thus, a site-determining influence of α-hetero substituent has now become very important from synthetic viewpoints of *C*-nucleosides. Enol silyl ethers of ketones bearing α-phenylthio group are quite useful for the introduction of 2-oxoalkyl group on C-1 position of **1** because the phenylthio group is easily removable by reduction. For example, α-phenylthio ketone (**4e**) gave the desulfurization product **6** in 70% yield on treatment with Raney nickel in boiling ethanol.



(1)

These regiochemical features have aroused a question whether there are any differences in actual nucleophilic species between these two types of enol silyl ethers. As reported already, tin(IV) chloride readily reacts with usual enol silyl ethers to afford the corresponding α-trichlorostannyl ketones,[10] which might act as real nucleophilic species in this case. In order to clarify such possibility, tin(IV) chloride was treated with **3a** in deuterochloroform at room temperature, and an immediate formation of the corresponding α-trichlorostannyl ketone was confirmed by ^1H NMR analysis of the reaction mixture. Further, treatment of the resulting solution with **1** led to the formation of **5a**.

In the cases of enol silyl ethers (**3e—g**), on the other hand, α-subsituents seem to prevent silyl/stannyl exchange, and the silyl ethers remain unchanged on exposure to tin(IV) chloride.

On the basis of these results, we wish to suggest the following points on the different behaviors observed here. On treatment with **1** in the presence of tin(IV) chloride, enol silyl ethers of usual acyclic ketones and of esters, *e.g.* **3a—d**, undergo silyl/stannyl exchange with tin(IV) chloride initially to yield α-stannyl ketones. Then, the resulting α-stannyl ketones act as nucleophiles to **1** to afford the corresponding **5a—d**. On the other hand, **3e—g** react as olefinic[8] or aromatic nucleophiles[11] in a usual Friedel-Crafts like manner to yield the desired C-1 condensation products **4e—g**.

However, other uncertain site-determining factors might also be involved in this type of reaction, considering an anomolous behavior of 1-trimethylsiloxycyclohexene which affords the condensation product of type **4**[8] irrespective of its facile silyl/stannyl exchange reaction with tin(IV) chloride.

Finally, in order to explore a simple synthetic route to pyrazomycin, we also examined the introduction of an acetoacetic ester moiety on C-1 position by using dienal ethers **7** or **8**. In the presence of trimethylsilyl triflate,[12,13] however, they react on C-2 benzoyloxyl group exclusively to yield **9** or **10**, although construction of requisite pyrazole ring can be efficiently performed through its diazo compound as shown in Scheme 3.

Experimental

General Procedures. IR spectra were taken on a Hitachi 260-10 spectrometer; absorptions are given in reciprocal centimeters. ^1H NMR spectra were recorded on a Hitachi R-24B (60 MHz) or a Varian EM-390 (90 MHz) spectrometer; chemical shifts (δ) are expressed in parts per million down-

field from internal tetramethylilane.

Column chromatography was performed on Wakogel C-200 or Florisil (mesh 100—200). All the reactions were carried out in an glass sealed tube with magnetic stirring bar under dry nitrogen.

Materials. Tetrahydrofuran (THF) was distilled from sodium-benzophenone ketyl in a recycling still immediately before use. Chlorotrimethylsilane, triethylamine, and hexamethylphosphoric triamide (HMPA) were distilled from calcium hydride. Acetonitrile and dichloromethane were distilled successively from phosphorus pentaoxide and potassium carbonate under nitrogen. 3-Trimetylsiloxy-2-pentene (**3a**), 3,3-dimethyl-2-trimethylsiloxy-1-butene (**3b**), 1-phenylthio-2-trimethylsiloxy-1-propene (**3e**), and 3,3-dimethyl-1-phenylthio-2-trimethylsiloxy-1-butene (**3f**) were prepared by the method of House.[14] 1-Ethoxy-1-(*t*-butyldimethylsiloxy)ethylene (**3c**)[15] and 1,3-bis(trimethylsiloxy)-1-methoxy-1,3-butadiene **8**[16] were prepared according to the reported procedure. 1-Ethoxy 2-phenylthio-1-trimethylsiloxyethylene (**3d**) and 1,3-dimethoxy-1-trimethylsiloxy-1,3-butadiene (**7**) were prepared by using THF instead of DME as a solvent in the method of House.[14]

Condensation of 2,3,5-Tri-O-benzoyl-D-ribofuranosyl Acetate (1) with Enol Silyl Ethers (3). 3-Trimethylsiloxy-2-pentene (3a): A mixture of the acetate **1** (75.1 mg, 0.15 mmol) and tin(IV) chloride (0.18 mmol) in dichloromethane (2 ml) was stirred for 5 min at room temperature, and the enol silyl ether **3a** (0.18 mmol) was added to the resulting solution. After stirring for 1.5 h, aq K_2CO_3 solution was added to the reaction mixture and was extracted with ether repeatedly. Organic layer was washed with satd. aq NaCl, dried over anhyd. Na_2SO_4, and concentrated to give an oil, which was separated by silica-gel column chromatography to give **5a** (95.3 mg, 88%) as an oil. Calcd for $C_{31}H_{30}O_8$: C, 70.18; H, 5.70%. Found: C, 69.72; H, 5.70%. **5a** could be separated into diastereomers **5a**$_1$ and **5a**$_2$ by column chromatography **5a**$_1$: IR (neat) 1730, 1715 cm^{-1}; NMR (60 MHz) (CCl_4) δ=0.87 (t, J=7 Hz, 3H), 0.99 (d, J=7 Hz, 3H), 2.21 (q, J=7 Hz, 2H), 2.93 (q, J=7 Hz, 1H), 3.40 (m, 1H), 4.17 (m, 2H), 4.76 (dd, J=9 and 5 Hz, 1H), 5.10 (dd, J=5 and 4 Hz, 1H), 5.90 (d, J=4 Hz, 1H), 7.30 (m, 11H), 7.84 (m, 4H). **5a**$_2$: IR(neat) 1730, 1715 cm^{-1}; NMR (60 MHz) (CCl_4) δ=0.94 (d, J=7 Hz, 3H), 0.97 (t, J=7 Hz, 3H), 2.36 (q, J=7 Hz, 2H), 2.90 (q, J=7 Hz, 1H), 3.45 (m, 1H), 4.18 (m, 2H), 4.70 (m, 2H), 6.05 (d, J=4 Hz, 1H), 7.30 (m, 11H), 7.78 (m, 4H).

In a similar manner, 3,3-dimethyl-2-trimethylsiloxy-1-butene (**3b**), 1-ethoxy-1-(*t*-butyldimethylsiloxy)ethylene (**3c**), and 1-ethoxy-2-phenylthio-1-trimethylsiloxyethylene (**3d**) gave the corresponding condensation products **5b—d**, and 1-phenylthio-2-trimethylsiloxy-1-propen (**3e**) and 3,3-dimethyl-1-phenylthio-2-trimethylsiloxy-1-butene (**3f**) gave **4e** and **4f**, respectively. **5b**: An amorphous oil; IR (Nujol) 1730, 1720 cm^{-1}; NMR(60 MHz) (CCl_4) δ=1.06 (s-like, 9H), 2.86 (s-like, 2H), 6.05 (d, J=4 Hz, 1H), 7.32 (m, 11H), 7.85 (m, 4H); Calcd for $C_{32}H_{32}O_8$: C, 70.58; H, 5.92%. Found: C, 70.74; H, 6.17%. **5c**: An amorphous oil: IR (Nujol) 1720 cm^{-1}; NMR (60 MHz) (CCl_4) δ=1.24 (t, J=7 Hz, 3H), 2.74 (s-like, 2H), 3.56 (m, 1H), 4.04 (q, J=7 Hz, 2H), 4.22 (m, 2H), 4.78 (dd, J=9 and 5 Hz, 1H), 5.20 (dd, J=5 and 4 Hz, 1H), 6.10 (d, J=4 Hz, 1H), 7.30 (m, 11H), 7.85 (m, 4H). **5d**: An amorphous oil: IR (Nujol) 1730, 1720 cm^{-1}; NMR (60 MHz) (CCl_4) δ=1.03 (t, J=7 Hz, 3×1/2H), 1.07 (t, J=7 Hz, 3×1/2H), 3.90 (q, J=7 Hz, 2×1/2H), 3.96 (q, J=7 Hz, 2×1/2H), 4.23 (m, 2H), 4.67 (s, 1×1/2H), 4.78 (s, 1×1/2H), 5.00 (m, 2H), 6.10 (d, J=4 Hz, 1×1/2H), 6.19 (d, J=4 Hz, 1×1/2H), 7.25 (m, 16H), 7.80 (m, 4H); Calcd for $C_{36}H_{32}O_9S$: C, 67.49; H, 5.03; S, 5.00%. Found: C, 67.40; H, 5.05; S, 4.91%. **4e**: An amorphous oil: IR (Nujol) 1730, 1715 cm^{-1}; NMR (60 MHz) (CCl_4) δ=2.17 (s, 3×5/9H), 2.27 (s, 3×4/9H), 3.75 (d, J=8 Hz, 1×4/9H), 3.92 (d, J=4 Hz, 1×5/9H), 4.50 (m, 4H), 5.68 (m, 2H), 7.25 (m, 14H), 7.85 (m, 6H); Calcd for $C_{35}H_{30}O_8S$: C, 68.84; H, 4.95; S, 5.25%. Found: C, 68.89; H, 5.15; S, 5.51%. **4f**: An amorphous oil: IR (Nujol) 1730, 1720 cm^{-1}; NMR (60 MHz) (CCl_4) δ=1.10 (m, 9H), 3.55 (m, 1H), 4.50 (m, 4H), 5.65 (m, 2H). 7.30; (m, 14H), 7.85 (m, 6H); Calcd for $C_{38}H_{36}O_8S$: C, 69.92; H, 5.56; S, 4.91%. Found: C, 70.03; H, 5.16; S, 5.15%.

Desulfuriztion of 4e. Raney nickel (W-2; 1.5 g) was added to a solution of **4e** (105.5 mg, 0.17 mmol) in ethanol (10 ml) and it was heated to reflux for 1 h. Filtration of the reaction mixture through Celite followed by removal of the solvent gave an oil, which was purified by column chromatography on silica gel to afford the desulfurization product **6** (61.6 mg, 70%). IR (Nujol) 1720 cm^{-1}; NMR (60 MHz) (CCl_4) δ=2.10 (s, 3H), 2.79 (d, J=7 Hz, 2H), 4.50 (m, 4H), 5.52 (m, 2H), 7.37 (m, 9H), 7.93 (m, 6H).

The Reaction of 1 with 1,3-Bis(trimethylsiloxy)-1-methoxy-1,3-butadiene (8). The acetate **1** (320.1 mg, 0.63 mmol) was dissoled in dichloromethane (2 ml) and trimethylsilyl triflate (0.80 mmol) was added to this solution at room temperature. After stirring for 5 min, the enol silyl ether **8** (1.0 mmol) was added. The mixture was stirred for 1.5 h at room temperature. The reaction mixture was quenched with satd. aq K_2CO_3 and was extracted several times with ether. The combined organic extracts were washed with satd. aq NaCl and dried over anhyd. Na_2SO_4. Removal of the solvent followed by column chromatography on silica-gel afforded **10** (282.1 mg, 80%) as an oil. IR (neat) 1730 cm^{-1}; NMR(90 MHz) ($CDCl_3$) δ=3.06 (s-like, 2H), 3.41 (s-like, 2H), 3.61 (m, 1H), 3.64 (s, 3H), 4.22 (dd, J=12 and 5 Hz, 1H), 4.45 (dd, J=12 and 4 Hz, 1H), 4.92 (dd, J=9 and 5 Hz, 1H), 5.26 (dd, J=5 and 4.5 Hz, 1H), 6.18 (d, J=4.5 Hz, 1H), 7.38 (m, 11H), 7.93 (m, 4H); Calcd for $C_{31}H_{28}O_{10}$: C, 66.42; H, 5.03%. Found: C, 66.31; H, 5.32%.

In a similar manner, 1,3-dimethoxy-1-trimethylsiloxy-1,3-butadiene (**7**)[17] gave the corresponding **9** as an oil in 74% yield. IR (neat) 1730 cm^{-1}; NMR (60 MHz) (CCl_4) δ=3.32 (s-like, 2H), 3.36 (s, 3H), 3.52 (s, 3H), 3.70 (m, 1H), 4.24 (m, 2H), 4.70 (dd, J=9 and 5 Hz, 1H), 4.86 (s, 1H), 5.02 (dd, J=7 and 6 Hz, 1H), 5.93 (d, J=4 Hz, 1H), 7.27 (m, 11H), 7.83 (m, 4H); Calcd for $C_{32}H_{30}O_{10}$: C, 66.89; H, 5.26%. Found: C, 66.95; H, 5.50%.

Diazo Compound 11 from Diketone 10. To a solution of diketone **10** (923.9 mg, 1.65 mmol) in acetonitrile (5 ml) was added triethylamine (0.3 ml, 2.14 mmol) and *p*-toluenesulfonyl azide (345.2 mg, 1.75 mmol) at room temperature. The mixture was stirred for 1.5 h at that temperature, and the solvent was removed under reduced pressure. The residue was dissolved in ether, washed successively with dil. aq NaOH and satd. aq NaCl, and dried over anhyd. Na_2SO_4. Removal of the solvent followed by column chromatography on Florisil afforded the diazo compound **11** (966.8 mg, 100%). IR (neat) 2150, 1730 cm^{-1}; NMR (90 MHz) ($CDCl_3$) δ=3.45 (s-like, 2H), 3.74 (s, 3H), 3.67 (m, 1H), 4.18 (dd, J=12 and 5 Hz, 1H), 4.42 (dd, J=12 and 4 Hz, 1H), 4.88 (dd, J=9 and 5 Hz, 1H), 5.22 (dd, J=5 and 5 Hz, 1H), 6.15 (d, J=5 Hz, 1H), 7.45 (m, 11H), 7.95 (m, 4H); Calcd for $C_{31}H_{26}O_{10}N_2$: C, 63.48; H, 4.47; N, 4.78%. Found: C, 63.78; H, 4.66; N, 4.66%.

Cyclizatio of Diazo Compound 11. Lithium hexamethyldisilazanide (1.6 ml of 0.58 M THF solution, 0.92 mmol) was added to the diazo compound **11** (253 mg, 0.43 mmol) in a mixture of THF (0.5 ml) and HMPA (0.25 ml) at −78 °C. Then it was warmed up to −20 °C and stirred for 1 h at that temperature. The reaction mixture was poured into buffered solution and extracted several times with ether. The organic layer was washed with satd. aq NaCl and dried over anhyd. Na_2SO_4. Removal of the solvent followed by column chromatography on Florisil afforded the pyrazole **12** (188.5 mg,

66%). IR (neat) 1730cm^{-1}; NMR (90MHz) ($CDCl_3$) δ= 3.83 (s, 3H), 4.14 (quint, J=4.5 Hz, 1H), 4.32 (dd, J=12 and 5 Hz, 1H), 4.56 (dd, J=12 and 4 Hz, 1H), 5.02 (dd, J=9 and 5 Hz, 1H), 5.27 (dd, J=5 and 5 Hz, 1H), 6.29 (d, J=5 Hz, 1H), 6.75 (br s, 1H), 7.43 (m, 11H), 7.95 (m, 4H); Calcd for $C_{31}H_{26}O_{10}N_2$: C, 63.48; H, 4.47; N, 4.78%. Found: C, 63.19; H, 4.60; N, 4.68%.

Studies on Salt Hydrates for Latent Heat Storage. V. Preheating Effect on Crystallization of Sodium Acetate Trihydrate from Aqueous Solution with a Small Amount of Sodium Pyrophosphate Decahydrate

Takahiro WADA,* Koji MATSUNAGA, and Yoshihiro MATSUO
Central Research Laboratory, Matsushita Electric Industrial Co., Ltd., 1006 Kadoma, Osaka 571
(Received June 6, 1983)

Influences of preheating temperature and time were studied on the crystallization of $CH_3CO_2Na \cdot 3H_2O$ from three kinds of CH_3CO_2Na aqueous solutions, whose concentrations were 58.0, 60.3, and 62.8 wt% and which contained a small amount of crystal nucleation catalyst, $Na_4P_2O_7 \cdot 10H_2O$. In 60.3 wt% aqueous solution ($CH_3CO_2Na \cdot 3H_2O$), the nucleation catalyst begins to get deactivated by preheating at about 81 °C, higher by 23 °C than the melting point of $CH_3CO_2Na \cdot 3H_2O$. The temperature at which the catalyst begins to get deactivated is raised with increasing CH_3CO_2Na concentration of the solution; thus, in 62.8 wt% CH_3CO_2Na aqueous solution, the catalyst begins to get deactivated at 85 °C. One hundred samples, each consisting of 8 g of 60.3 wt% CH_3CO_2Na aqueous solution and 0.16 g of $Na_4P_2O_7 \cdot 10H_2O$, all crystallized on cooling to 40 °C, even after they had been preheated at 80 °C for 39 h. These results are explained on the basis of the crystalline adsorption model proposed by Richards.

Sodium Acetate Trihydrate ($CH_3CO_2Na \cdot 3H_2O$) has recently attracted attention as a useful heat storage material because of its large latent heat of fusion (264 J/g).[1,2] $CH_3CO_2Na \cdot 3H_2O$ melt tends to supercool even if cooled considerably below its melting point (58.4 °C).[3,4] Its practical application has been impaired by this supercooling phenomenon.[5] Wada and Yamamoto,[6] in search for a crystal nucleation catalyst, have found that addition of $Na_4P_2O_7 \cdot 10H_2O$ is very effective for preventing the supercooling.

A phase diagram of binary system CH_3CO_2Na–H_2O, based on data from Seidell's compilation,[7] is shown in Fig. 1. The dashed line is the liquidus line for metastable CH_3GO_2Na. It is clear that $CH_3CO_2Na \cdot 3H_2O$ melts incongruently to a 58.0 wt% CH_3CO_2Na aqueous solution in equilibrium with the residual solid, anhydrous CH_3CO_2Na, and that anhydrous CH_3CO_2Na dissolves entirely in its water of crystallization at about 78 °C.

Ternary system CH_3CO_2Na–$Na_4P_2O_7$–H_2O has been investigated between 38 and 85 °C.[9] No double salt formation occurs in this temperature range. Saturation concentrations of $Na_4P_2O_7$ in saturated CH_3CO_2Na solutions are 0.08 wt% at 38 °C, 0.06 wt% at 50 °C, 0.02 wt% at 62 °C, 0.02 wt% at 75 °C, and 0.02 wt% at 85 °C. The lowest formation temperature of anhydrous $Na_4P_2O_7$ is about 47 °C.

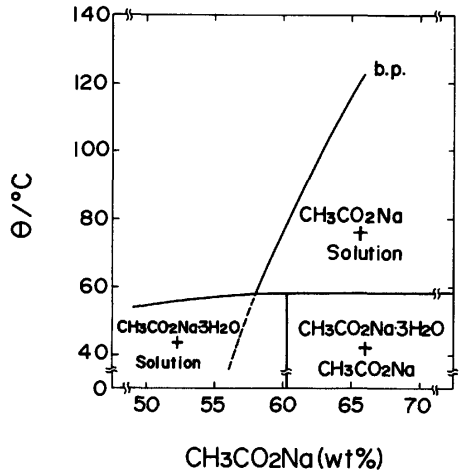

Fig. 1. Phase diagram of the binary system CH_3CO_2Na–H_2O.[8]

The crystallization tendency of the liquid is diminished with increasing preheating temperature.[10,11] Richards[12] studied the preheating effect on crystallization of $CH_3CO_2Na \cdot 3H_2O$ from aqueous solution. He used 20 sealed tubes each containing 3 g of 12 M (1 M= 1 mol dm^{-3}), about 50 wt%, CH_3CO_2Na aqueous solution and kept them at room temperature during intervals between preheating treatments. He reported that $CH_3CO_2Na \cdot 3H_2O$, when preheated at a temperature 2, 3.5, or 7 °C above its melting point, was allowed to crystallize in 100, 35, or 5% of the sample tubes, respectively.

A number of explanations are applicable to the above behavior. Richards[12] proposed the crystalline adsorption model that a crystal form may persist above its melting point if some adsorbent present in a sample binds the crystalline adsorbate more strongly than the liquid adsorbate, that is, if the heat of adsorption of the crystalline adsorbate onto the adsorbent is higher than that of the liquid adsorbate. This crystalline adsorption model is illustrated in Fig. 6. This model is characteristically capable of explaining the fact that reactivation of a deactivated nucleation catalyst can be effected by forced crystallization of the liquid containing that catalyst.

This paper reports influences of preheating temperature and time on crystallization of $CH_3CO_2Na \cdot 3H_2O$ from three kinds of CH_3CO_2Na aqueous solutions, whose concentrations are 58.0, 60.3, and 62.8 wt% and which have a small amount of $Na_4P_2O_7 \cdot 10H_2O$ added. For the system to be useful as a latent heat storage material, the temperature at which the crystal nucleation catalyst begins to get deactivated is very important. Results obtained are explained on the basis of the crystalline adsorption model.

Experimental

$CH_3CO_2Na \cdot 3H_2O$, CH_3CO_2Na, and $Na_4P_2O_7 \cdot 10H_2O$ were guaranteed grade reagents from Wako Pure Chemical Industries, Ltd. Eight grams of CH_3CO_2Na aqueous solu-

tion and 0.16 g of $Na_4P_2O_7 \cdot 10H_2O$ were placed in a tube, which was afterwards sealed. The concentration of the CH_3CO_2Na aqueous solution prepared was 58.0 wt% (peritectic composition), 60.3 wt% ($CH_3CO_2Na \cdot 3H_2O$), or 62.8 wt%. The sealed tubes were put into a water bath equipped with a gently-vibrating rack. Before subsequent steps, all aqueous solutions with a smal amount of $Na_4P_2O_7 \cdot 10H_2O$ added were heated at 70 °C for 1 h and then cooled to room temperature in order to force $CH_3CO_2Na \cdot 3H_2O$ to crystallize, with shaking if necessary.

Experiment 1. One hundred sealed tubes each containing a 60.3 wt% CH_3CO_2Na aqueous solution were heated to a predetermined temperature above the melting point of $CH_3CO_2Na \cdot 3H_2O$, kept there for 3 h, and then cooled to 40 °C at a rate of 5 °C/h. This process was repeated with the preheating temperature raised stepwise. In some of the 100 tubes preheated at a certain temperature, $CH_3CO_2Na \cdot 3H_2O$ failed to crystallize on cooling to 40 °C. Such tubes were excluded because the nucleation catalyst in the tube must have heen deactivatd. This deactivation possibility was supported by the observation that $CH_3CO_2Na \cdot 3H_2O$ scarcely crystallized in the excluded tubes during similar heating and cooling tests as mentioned above. The other two aqueous solutions were examined in the same manner as above. Thus, the influence of preheating temperature on the crystallization of $CH_3CO_2Na \cdot 3H_2O$ from aqueous solution was studied. The percentage of the tubes in which the nucleation catalyst was deactivated was plotted against the temperature difference between the preheating temperature and the melting point to get Fig. 2.

Experiment 2. Experimental procedures were similar to those in *Experiment 1* except that the preheating temperature was kept constant. One hundred tubes were heated to a preheating temperature, kept there for 3 h, and then cooled to 40 °C at a rate of 5 °C/h. In some of the 100 tubes preheated for a certain time, $CH_3CO_2Na \cdot 3H_2O$ failed to crystallize on cooling to 40 °C. Such tubes were excluded for the same reason as in *Experiment 1*. Similar experiments were conducted with a variation of preheating temperature. The influence of preheating time on the crystallization of $CH_3CO_2Na \cdot 3H_2O$ from 60.3 and 58.0 wt% CH_3CO_2Na aqueous solutions was studied by finally plotting the percentage of the tubes in which the catalyst was deactivated against the preheating time to get Figs. 3 and 4, respectively.

Experiment 3. Experimental procedures were similar to those adopted in *Experiment 2* except that, when in some tubes $CH_3CO_2Na \cdot 3H_2O$ failed to crystallize on cooling to 40 °C, these tubes were cooled to room temperature to force $CH_3CO_2Na \cdot 3H_2O$ to crystallize, with shaking if necessary, and returned to subsequent steps. This experiment was conducted on the 58.0 wt% CH_3CO_2Na aqueous solution. The percentage of the tubes in which the catalyst was deactivated was plotted against the preheating time to get Fig. 5.

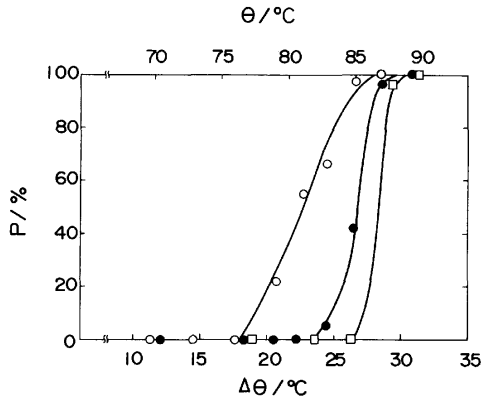

Fig. 2. The influence of preheating temperature on the crystallizaion of $CH_3CO_2Na \cdot 3H_2O$ from the three kinds of aqueous solution with a small amount of $Na_4P_2O_7 \cdot 10H_2O$.
○: 58.0 wt% CH_3CO_2Na aqueous solution, ●: 60.3 wt% CH_3CO_2Na squeous solution, □: 62.8 wt% CH_3CO_2Na aqueous solution.

Results

It is clear from Fig. 2 that under the conditions of *Experiment 1*, the nucleation catalysts in the 60.3 wt% CH_3CO_2Na aqueous solutions begin to get deactivated at 81 °C, higher by 23 °C than the melting point of $CH_3CO_2Na \cdot 3H_2O$ until all of them were deactivated at about 89 °C and that those in the 58.0 and 62.8 wt% solutions begin to get deactivated at 77 and 85 °C until all were deactivated at 85 and 89 °C, respectively. In the 100 tubes each containing 8 g of 60.3 wt% CH_3CO_2Na aqueous solution with no nucleation catalyst added, the cooling to 40 °C preceded by the preheating at 60 °C for 3 h caused no $CH_3CO_2Na \cdot 3H_2O$ to crystallize at all. The present CH_3CO_2Na aqueous solutions with no nucleation catalyst begin to get deactivated at a temperature lower than in the Richards experiment. This may be caused not only by differences in the CH_3CO_2Na concentration and experimental conditions but also by the difference in purity of reagents used. It is evident that the addition of $Na_4P_2O_7 \cdot 10H_2O$ to the CH_3CO_2Na aqueous solution is very effective for preserving the crystal nucleation ability above the melting point of $CH_3CO_2Na \cdot 3H_2O$.

It is understood from Fig. 2 that the temperature at which the catalyst begins to get deactivated is raised with increasing CH_3CO_2Na concentration of the solution containing that catalyst. The amount of the $Na_4P_2O_7 \cdot 10H_2O$ added is so small and the solubility of $Na_4P_2O_7$ in the $CH_3CO_2Na \cdot 3H_2O$ melt is so low[9] that the liquidus lines for $CH_3CO_2Na \cdot 3H_2O$ and CH_3CO_2Na may be considered to be scarcely influenced by the addition of $Na_4P_2O_7 \cdot 10H_2O$ to the CH_3CO_2Na aqueous solution. Figure indicates that the anhydrous CH_3CO_2Na in the 58 wt% aqueous solution is unstable above 58.4 °C, the one in the 60.3 wt% solution is unstable above 78 °C, and that the one in the 62.8 wt% solution is unstable above 97 °C. The deactivation of the nucleation catalyst depends on the CH_3CO_2Na concentration of the solution containing that catalyst, but is not directly related to the existence of anhydrous CH_3CO_2Na in the solution, although Kimura[13] has pointed out that the existence of anhydrous CH_3CO_2Na plays an important role in the crystallization of $CH_3CO_2Na \cdot 3H_2O$ from the solution.

It can be seen from Fig. 3 that in the 100 tubes each containing 8 g of 60.3 wt% CH_3CO_2Na aqueous solution with 0.16 g $Na_4P_2O_7 \cdot 10H_2O$ added, the nucleation catalysts were all caused to deactivate by preheating at 85 °C for 10 h, at 86 °C for 8 h or at 87 °C for 4 h. The preheating time that results in deactivation of all the catalysts is shortened with incressing preheating temperature. As is also seen from Fig. 3, even the preheating of the solutions at 80 °C for 39 h leads in any cases to crystallization on cooling to

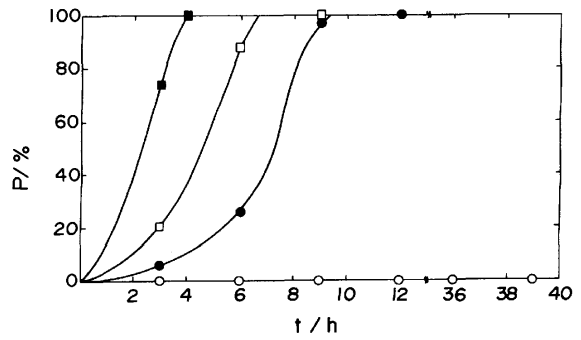

Fig. 3. The influence of preheating time on the crystallization of $CH_3CO_2Na \cdot 3H_2O$ from the 60.3 wt% CH_3CO_2Na aqueous solution.
○: Preheated at 80 °C, ●: preheated at 85 °C, □: preheated at 86 °C, ■: preheated at 87 °C.

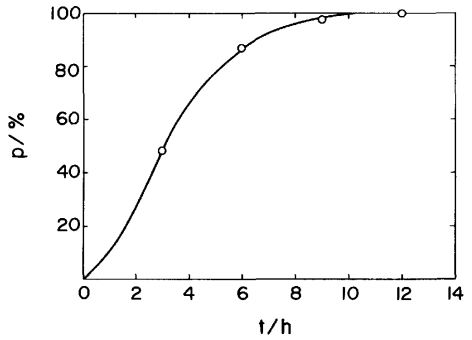

Fig. 4. The influence of preheating time on the crystallization of $CH_3CO_2Na \cdot 3H_2O$ from the 58.0 wt% CH_3CO_2Na aqueous solution preheated at 83 °C.

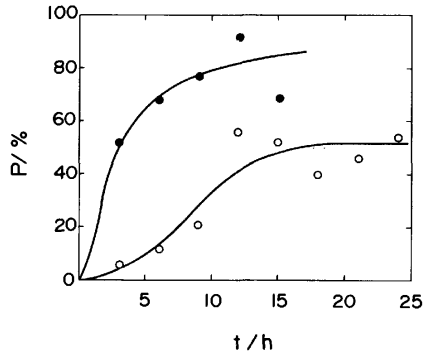

Fig. 5. The influence of preheating time on the crystallization of $CH_3CO_2Na \cdot 3H_2O$ from the 58.0 wt% CH_3CO_2Na aqueous solution under the *Experiment 3* conditions.
○: Preheated at 80 °C, ●: preheated at 83 °C.

40 °C. Thus it is deduced that the nucleation catalysts will not be caused to deactivate at all, no matter how long the solutions containing them are preheated below 80 °C. This is a very important finding from the standpoint of practical application.

It is seen from Fig. 4 that in the 100 tubes each containing a 58.0 wt% CH_3CO_2Na aqueous solution with the catalyst added, the catalysts were all deactivated when preheated at 83 °C for 10 h. The curve in Fig. 4 is similar to those in Fig. 3, so that the preheating time at which the catalysts were all caused to deactivate is supposed to be shorter than 10 h when the preheating temperature is above 83 °C.

In Fig. 5, the percentage of the tubes containing deactivated catalysts seems to approach a constant value, not 100%, with increasing preheating time. When 58.0 wt% CH_3CO_2Na aqueous solutions are preheated at 80 °C under the conditions of *Experiment 3*, the constant value is about 50%, and when they are preheated at 83 °C, it is about 90%. Compared with Fig. 3, it is evident that deactivated catalysts may be reactivated by forced crystallization of $CH_3CO_2Na \cdot 3H_2O$ from solutions containing them.

In 20 tubes each containing 8g of 58 wt% CH_3CO_2Na aqueous solution with 0.0001, 0.0005, or 0.001 g $Na_4P_2O_7 \cdot 10H_2O$ added, $CH_3CO_2Na \cdot 3H_2O$ hardly crystallized on cooling to 40 °C after the $Na_4P_2O_7 \cdot 10H_2O$ had been dissolved entirely in the CH_3CO_2Na solution by preheating at 70 °C. It is understood from this experiment and the phase equilibria of ternary system CH_3CO_2Na–$Na_4P_2O_7$–H_2O that anhydrous $Na_4P_2O_7$ solid is required for the crystallization of $CH_3CO_2Na \cdot 3H_2O$ to occur from the solution near the transition temperature.

Discussion

The results obtained from the present experiments will be discussed on the basis of the crystalline adsorption model proposed by Richards, which is illustrated in Fig. 6. According to this model, the $Na_4P_2O_7 \cdot 10H_2O$ added to a CH_3CO_2Na aqueous solution offers an adsorbent for which the heat of adsorption of crystalline $CH_3CO_2Na \cdot 3H_2O$ is higher than that of liquid adsorbate. The adsorbent is considered to be anhydrous $Na_4P_2O_7$ from the phase equilibria of ternary system CH_3CO_2Na–$Na_4P_2O_7$–H_2O,[9] although Wada and Yamamoto[6] discussed the crystal nucleation catalytic effect from the similarity of crystallographic data between $CH_3CO_2Na \cdot 3H_2O$ and $Na_4P_2O_7 \cdot 10H_2O$. The crystalline $CH_3CO_2Na \cdot 3H_2O$ adsorbed on the adsorbent is not allowed to fuse at its ordinary melting

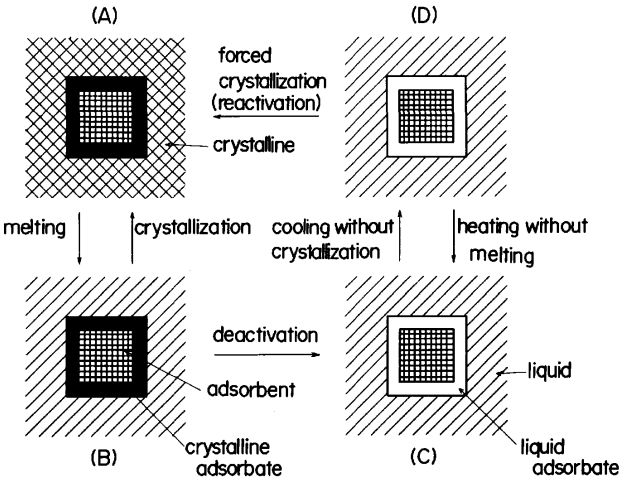

Fig. 6. The crystalline adsorption model proposed by Richards.[11]
(A): Crystalline state, (B): melting state with crystalline adsorbate, (C): melting state with liquid adsorbate, (D): supercooled state.

point but preserves its crystal nucleation ability above its melting point. This condition is shown in Figs. 6(A) snd (B). When the crystalline $CH_3CO_2Na \cdot 3H_2O$ adsorbate is fused entirely at an elevated temperature, $CH_3CO_2Na \cdot 3H_2O$ hardly crystallizes from the solution. This is also shown in Figs. 6(C) and (D). However, even if the crystalline adsorbate has been fused entirely, it is again formed by a forced crystallization of $CH_3CO_2Na \cdot 3H_2O$ from the solution containing the adsorbent. This is shown in Figs. 6(D) and (A). This expectation is compatible with the result obtained from *Experiment 3.*

It is understood on the basis of the concept of adsorption that the melting temperature of crystalline $CH_3CO_2Na \cdot 3H_2O$ adsorbed on the adsorbent depends not only on the difference in the heat of adsorption for the adsorbent between the crystalline $CH_3CO_2Na \cdot 3H_2O$ and the CH_3CO_2Na aqueous solution but also on the CH_3CO_2Na concentration of the solution. The temperatre is lowered with decreasing CH_3CO_2Na concentration of the slution. This is compatible with the result obtained from *Experiment 1.*

It is also plausible that the crystalline $CH_3CO_2Na \cdot 3H_2O$ adsorbate melts faster at higher temperatures. Therefore, the preheating time which results in complete catalyst deactivaion is expected to be shortened with increasing preheatig temperature. This expectation is also compatible with the result obtained in *Experiment 2.*

It is also found that when a small amount of glycine ($H_2NCH_2CO_2H$) or calcium tartrate tetrahydrate ($C_4H_4O_6Ca \cdot 4H_2O$) is added to a CH_3CO_2Na aqueous solution containing with a small amount of $Na_4P_2O_7 \cdot 10H_2O$ the crystal nucleation catalyst is caused to deactivate by heating and cooling cycles, even if the heating is conducted at 75 °C. That is to say, $H_2NCH_2CO_2H$ or $C_4H_4O_6Ca \cdot 4H_2O$ acts as a catalytic poison for the nucleation catalyst $Na_4P_2O_7 \cdot 10H_2O$. This fact is also explained satisfactorily on the basis of the crystalline adsorption model. If these compounds adsorb on the surface of adsorbent more strongly than the crystalline $CH_3CO_2Na \cdot 3H_2O$ adsorbate, that is, the heats of adsorption of these compounds for the adsorbent are higher than that of the crystalline adsorbate, these compounds will adsorb on the surface of adsorbent through displacement of the crystalline $CH_3CO_2Na \cdot 3H_2O$ adsorbate during heating and cooling cycles. Therefore, the crystal nucleation catalysts are caused to deactivate by the thermal cycling.

Thus, the results obtained have all been explained satisfactorily on the basis of the crystalline adsorption model. However, these explanations are qualitative and the existence of crystalline adsorbate above its ordinary melting point has not yet been confirmed. Therefore, quantitative explanations of these behavior are future problems.

The authors wish to express their thanks to Dr. Ryoichi Kiriyama for his helpful discussions and to Drs. Tsuneharu Nitta, Eiichi Hirota, and Masanari Mikoda for their continuous encouragements. They are also grateful to Dr. Ryoichi Yamamoto for his discussion throughout this work.

Studies on Salt Hydrates for Latent Heat Storge. VI. Preheating Effect on Crystallization of Sodium Acetate Trihydrate from Aqueous Solution with a Small Amount of Disodium Hydrogenphosphate

Takahiro WADA* and Yoshihiro MATSUO

Central Research Laboratory, Matsushita Electric Industrial Co., Ltd., 1006 Kadoma, Osaka 571

(Received July 14, 1983)

With particular reference to the use of Na_2HPO_4 as nucleation catalyst for crystallization of $CH_3CO_2Na \cdot 3H_2O$, influences of preheating temperature and time were studied on the crystallization of $CH_3CO_2Na \cdot 3H_2O$ from three kinds of CH_3CO_2Na aqueous solutions, whose concentrations were 58.0, 60.3, and 62.8 wt%. In 60.3 wt% aqueous solution ($CH_3CO_2Na \cdot 3H_2O$), the nucleation catalyst begins to get deactivated by preheating at 81 °C. The temperature at which the catalyst begins to get deactivated is slightly raised with increasing CH_3CO_2Na concentration of the solution. The results obtained are compared with those previously reported on the use of $Na_4P_2O_7 \cdot 10H_2O$ as nucleation catalyst, and are discussed on the basis of the crystalline adsorption model.

Sodium Acetate Trihydrate ($CH_3CO_2Na \cdot 3H_2O$) has recently attracted attention as a useful heat storage material because of its large latent heat of fusion (264 J/g).[1,2] Pure $CH_3CO_2Na \cdot 3H_2O$ melt supercools at condiserably lower temperatures than its melting point (58.4 °C).[3,4] Its practical application has been impaired by this supercooling phenomenon.[5] Wada and Yamamoto[6] found that addition of $Na_4P_2O_7 \cdot 10H_2O$ is very effective for preventing the supercooling. Afterward, Kimura[7] found that addition of a mixture of Na_2HPO_4 and anhydrous CH_3CO_2Na is also effective for the prevention.

Ternary system CH_3CO_2Na–Na_2HPO_4–H_2O has been investigated between 38 and 75 °C.[8] No double salt formation occurs in this temperature range. The saturation concentrations of Na_2HPO_4 in saturated CH_3CO_2Na solutions are 1.5 wt% at 50 °C, 0.7 wt% at 62 °C, and 0.6 wt% at 75 °C. The lowest formation temperature of anhydrous Na_2HPO_4 is about 57 °C.

Recently, Wada *et al.*[9] studied the influence of preheating on the crystallization of $CH_3CO_2Na \cdot 3H_2O$ from aqueous solutions containing $Na_4P_2O_7 \cdot 10H_2O$ as nucleation catalyst and obtained results that the nucleation catalyst $Na_4P_2O_7 \cdot 10H_2O$ begins to get degraded in its nucleation ability by preheating at about 81 °C and that the temperature (T_c) at which the catalyst begins to get degraded in its nucleation ability is raised with increasing CH_3CO_2Na concentration of the solution. Such results have been explained in detail on the basis of the crystaline adsorption model[9] proposed by Richards.[10] This model is illustrated in Fig. 1.

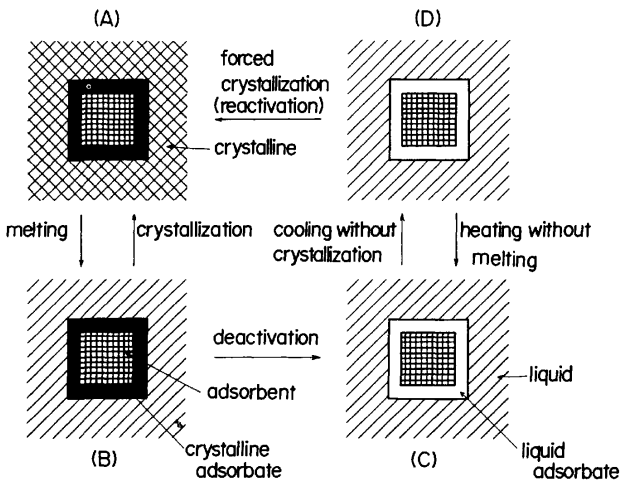

Fig. 1. The crystalline adsorption model for crystal nucleation.
(A): Crystalline state, (B): melting state with crystalline adsorbate, (C): melting state with liquid adsorbate, (D): supercooled state.

It can be seen from Fig. 1 that the crystalline $CH_3CO_2Na \cdot 3H_2O$ adsorbed on the adsorbent ($Na_4P_2O_7$) is not allowed to fuse at its ordinary melting point, preserving its crystal nucleation ability even above its melting point. The heat of adsorption of crystalline $CH_3CO_2Na \cdot 3H_2O$ onto the adsorbet is higher than that of liquid adsorbate. When crystalline $CH_3CO_2Na \cdot 3H_2O$ adsorbate has been fused entirely at an elevated temperature, $CH_3CO_2Na \cdot 3H_2O$ hardly crystallizes from the solution. However, even if the crystalline adsorbate has entirely been fused, it will again be formed during the cooling process becsuse of forced crystallization of $CH_3CO_2Na \cdot 3H_2O$ from the solution containing the nucleation catalyst.

This paper reports influences of preheating temperature and time on the crystal nucleation of $CH_3CO_2Na \cdot 3H_2O$ from sodium acetate solutions containing a small amount of Na_2HPO_4 added. Results obtained are compared with those in the case of solutions containing $Na_4P_2O_7 \cdot 10H_2O$ as nucleation catalyst and subjected to a discussion on the basis of the crystalline adsorpton model.

Experimental

$CH_3CO_2Na \cdot 3H_2O$, CH_3CO_2Na, and Na_2HPO_4 were guaranteed grade reagents from Wako Pure Chemical Industries, Ltd. Experimental procedures are similar to those reported in the preceding paper.[9] Eight grams of CH_3CO_2Na aqueous solution and 0.16 g of Na_2HPO_4 were placed in a tube, which was afterwards sealed. The sealed tubes were put into a water bath equipped with a gently-vibrating rack. Before subsequent steps, all aqueous solutions with a small amount of Na_2HPO_4 added were heated at 70 °C for 1 h and then cooled to room temperature in order to force $CH_3CO_2Na \cdot$

$3H_2O$ to crystallize. Then, the tubes were shaked if necessary.

Experiment 1. One hundred sealed tubes, each containing a CH_3CO_2Na aqueous solution at a concentration of 58.0, 60.3, or 62.8 wt% and a small amount of nucleation catalyst added, were heated to a predetermined temperature, kept there for 3 h and then cooled to 40 °C at a rate of 5 °C/h. This process was repeated with the preheating temperature raised stepwise. In some of the 100 tubes preheated at a certain temperature, $CH_3CO_2Na \cdot 3H_2O$ failed to crystallize on cooling to 40 °C. Such tubes were excluded because the nucleation catalyst in the tube must have been deactivated or degraded in its nucleation ability. This deactivation possibility was supported by the observation that $CH_3CO_2Na \cdot 3H_2O$ scarcely crystallized in the excluded tubes during similar heating and cooling tests as mentioned above. The percentage of the tubes having deactivated nucleation catalysts over the total tubes was plotted against the temperature difference between the preheating temperature and the melting point (58.4 °C) to get Fig. 2.

Experiment 2. One hundred tubes, each containing a 58 wt% aqueous solution and a small amount of nucleation catalyst added, were heated to a constant preheating temperature, kept there for 3 h, and then cooled to 40 °C at a rate of 5 °C/h. This procedure was applied to several preheating temperatures. In some of the 100 tubes preheated for a certain time, $CH_3CO_2Na \cdot 3H_2O$ failed to crystallize on cooling to 40 °C. Such tubes were excluded for the same reason as in *Experiment 1.* The percentage of the tubes in which the nucleation catalyst was deactivated over the total tubes was plotted against the preheating time to get Fig. 3.

Experiment 3. Experimental procedures were similar to those in *Experiment 2* except that those tubes in which $CH_3CO_2Na \cdot 3H_2O$ had failed to crystallize on cooling to 40 °C were not excluded but cooled to room temperature to force $CH_3CO_2Na \cdot 3H_2O$ to crystallize; they were then subjected to sequentially succeeding heating and cooling tests. The percentage of the tubes in which the nucleation catalyst was deactivated over the total tubes was plotted against the preheatng time to get Fig. 4.

Results and Discussion

It is clear from Fig. 2 that, under the conditions of *Experiment 1,* the nucleation catalysts in the 60.3 wt% CH_3CO_2Na aqueous solutions begin to get deactivated at 81 °C, higher by 23 °C than the melting point of $CH_3CO_2Na \cdot 3H_2O$ until all of them were deactivated at about 88 °C. These temperatures are in good agreement with the data obtained when $Na_4P_2O_7 \cdot 10H_2O$ was used as nucleation catalyst. In 58.0 and 62.8 wt% solutios, the nucleation catalysts begin to get deactivated at 81 and 82 °C, until all were deactivated at 88 and 89 °C, respectively. In 100 tubes each containing 8 g of 60.3 wt% aqueous solution with no nucleation catalyst, the cooling to 40 °C preceded by preheating at 60 °C for 3 h caused no $CH_3CO_2Na \cdot 3H_2O$ to crystallize. It is evident that the addition of Na_2HPO_4 is very effective for preserving the crystal nucleation ability above the melting point of $CH_3CO_2Na \cdot 3H_2O$. It is understood from Fig. 2 that T_c is slightly raised with increasing CH_3CO_2Na concentration of the solution. Such a phenomenon is qualitatively similar to one observed in the case of solutions with $Na_4P_2O_7 \cdot 10H_2O$ added as nucleation catalyst; the degree of concentration dependence of T_c is appreciably lower than in the previous case.

It can be seen from Fig. 3 that under the conditions of *Experiment 2,* in the 100 tubes each containing 8 g of 58.0 wt% CH_3CO_2Na aqueous solution and 0.16 g of

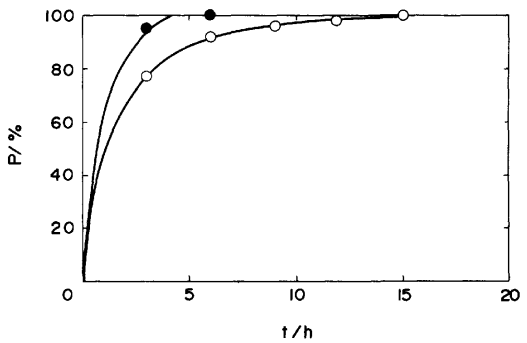

Fig. 3. The influence of preheating time on the crystallization of $CH_3CO_2Na \cdot 3H_2O$ from the 58.0 wt% aqueous solution in use of Na_2HPO_4 as a nucleation catalyst under the conditions of *Experiment 2.*
○: Preheated at 84 °C, ●: preheated at 85 °C.

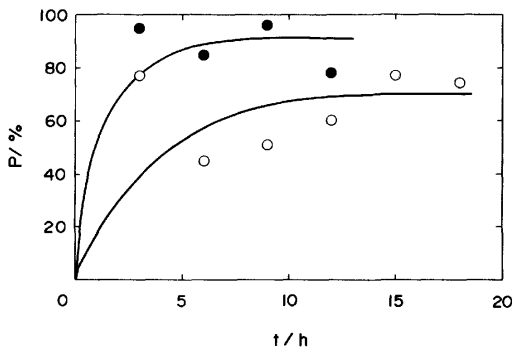

Fig. 4. The influence of preheating time on the crystallization of $CH_3CO_2Na \cdot 3H_2O$ from the 58.0 wt% aqueous solution in use of Na_2HPO_4 as a nucleation catalyst under the conditions of *Experiment 3.*
○: Preheated at 84 °C, ●: preheated at 85 °C.

Na_2HPO_4, $CH_3CO_2Na \cdot 3H_2O$ did not crystallize at all after the tubes had been preheated at 84 °C for 15 h and at 85 °C for 6 h. The preheating time that results in deactivation of all the catalysts is shortened with increasing preheating temperature. This result is similar to the case of $Na_4P_2O_7 \cdot 10H_2O$.

It is seen from Fig. 4 that under the conditions of *Experiment 3,* in some of the 100 pieces of tubes each containing 8 g of 58.0 wt% CH_3CO_2Na aqueous solution and 0.16 g of Na_2HPO_4, $CH_3CO_2Na \cdot 3H_2O$ crystallized even after they had been preheated at 84 °C for 15 h and at 85 °C for 6 h. The percentages of the tubes with deactivated nucleation catalysts seem to approach constant values with increasing preheating time, though with a wide variation; the preheating at 84 or 85 °C corresponds to about 70 or 90%, respectively. Compared with Fig. 3, it is evident that deactivated nucleation catalysts may be reactivated by forced crystallization of $CH_3CO_2Na \cdot 3H_2O$ from solutions containing the crystal nucleation catalyst. The same phenomenon was observed in the case of CH_3CO_2Na aqueous solution with $Na_4P_2O_7 \cdot 10H_2O$ added.

In 20 pieces of tubes each containing 8 g of 58 wt% CH_3CO_2Na aqueous solution with 0.001, 0.01 or 0.04 g Na_2HPO_4 added, $CH_3CO_2Na \cdot 3H_2O$ hardly crystallized on cooling after the Na_2HPO_4 had been dissolved entirely in the CH_3CO_2Na solution by the preheating at 70 °C. It is understood from this experiment and the phase equilibria of ternary system CH_3CO_2Na–Na_2HPO_4–H_2O that the anhydrous Na_2HPO_4 solid in the solution is required for the crystallization of $CH_3CO_2Na \cdot 3H_2O$ to occur from the solution near the transition temperature. A similar conclusion was drawn in our preceding investigation using $Na_4P_2O_7 \cdot 10H_2O$ as crystal nucleation catalyst.

The results obtained from the present experiments will be discussed on the basis of the crystalline adsorption model proposed by Richards, which is illustrated in Fig. 1. According to this model, the Na_2HPO_4 added to a CH_3CO_2Na aqueous solution offers an adsorbent for which the heat of adsorption of crystalline $CH_3CO_2Na \cdot 3H_2O$ is higher than that of liquid adsorbate. From the phase equilibria of ternary system CH_3CO_2Na–Na_2HPO_4–H_2O the adsorbent is considered to be anhydrous Na_2HPO_4.

It is understood on the basis of the concept of adsorption that the melting temperature of crystalline $CH_3CO_2Na \cdot 3H_2O$ adsorbed on the adsorbent is raised with increasing CH_3CO_2Na concentration of the solution. Therefore, T_c is expected to be raised with increasing CH_3CO_2Na concentration. This expectation is compatible with the result shown in Fig. 2.

It is also plausible that the crystalline $CH_3CO_2Na \cdot 3H_2O$ adsorbate melts faster at higher temperatures than T_c. Therefore, the preheating time which results in complete catalyst deactivation is expected to be shortened with increasing preheating temperature. This expectation is also compatible with the result shown in Fig. 3.

According to the crystalline adsorption model a satisfactory, though qualitative, explanation has been given the reactivation of a deactivated nucleation catalyst which is effected by forced crystallization of $CH_3CO_2Na \cdot 3H_2O$ from the solution containing that nucleation catalyst; some quantitative explanation of these crystal nucleation catalytic actions remains to be given.

The authors wish to express their thanks to Dr. Ryoichi Kiriyama for his useful discussions and to Drs. Tsuneharu Nitta, Eiichi Hirota, and Masanari Mikoda for their continuous encouragements. They are also grateful to Dr. Ryoichi Yamanoto for his discussions throughout this work.

Kinetics of Ligand Substitution Reaction between Cyanide Ion and NiL_2 (L=4-(2-Pyridylazo)resorcinol, Diethylenetriamine, and Ethylenediamine)

Hari Chand BAJAJ, Madhu PHULL, and Prem Chandra NIGAM*

Department of Chemistry, Indian Institute of Technology, Kanpur-208016, U.P., India

(Received February 4, 1983)

The kinetics of substitution reaction of cyanide ion with some bis complexes $[NiL_2]^{2-2n}$, where L^{n-} is 4-(2-pyridylazo)resorcinolate, diethylenetriamine, or ethylenediamine, to form the square planar complex $[Ni(CN)_4]^{2-}$ has been studied spectrophotometrically in aqueous solutions. The rate expression has the form: rate $=\{k_d^{NiL_2}+k'[CN^-]\}[NiL_2^{2-2n}]$, where k' is a composite rate constant in case of par and dien and is equal to $k_{CN}^{NiL_2}$ in case of en. These results indicate that these bis complexes are not directly converted into $[Ni(CN)_4]^{2-}$ but first lose one ligand molecule and cyanide assists this loss. The backward reaction between $[Ni(CN)_4]^{2-}$ and L is first order in each reactant and inverse first order in cyanide. Though the mechanism for the reactions appears to be same, there are kinetic differences in the behaviour of en and the other two chelates. The rate determining step for the three reactions have been identified. The activation parameters for the forward reaction have been evaluated to support the proposed mechanism. The temperature dependence of backward reaction has also been given.

The mechanism of formation and dissociation reactions of some complexes of polyamines with nickel(II) has been investigated previously.[1-5] Ligand exchange reactions involving complexes of polyamines and nickel (II) with amine-*N*-acetic acids,[6] 2,2′-bipyridyl, 1,10-phenanthroline, and 2,2″,6′,2″-terpyridyl[7] have been studied extensively. A considerable work has been reported on the formation of $[Ni(CN)_4]^{2-}$ from nickel complexes of amine-*N*-acetic acids,[8] polyamines,[9] 1, 10-phenanthroline,[10] and from $Ni^{2+}_{(aq)}$.[11,12] Crouse and Margerum[13] have studied the reactions of $[Ni(CN)_4]^{2-}$ with various ligands in the presence and the absence of iodine as a scavanger for cyanide ion.

Previously we reported the formation of $[Ni(CN)_4]^{2-}$ from binuclear complexes Ni_2L, where L is ttha[14,15] and dtpa.[15] In the present paper, the kinetics of reactions of NiL_2^{2-2n} with CN^- is reported (Eq. 1).

$$NiL_2^{2-2n} + 4CN^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} [Ni(CN)_4]^{2-} + 2L^{n-} \quad (1)$$

where L^{n-} indicates 4-(2-pyridylazo)resorcinolate (par), diethylenetriamine (dien), or ethylenediamine (en), and k_f and k_b are the overall rate constants for forward and backward reactions.

Experimental

Diethylenetriamine, obtained from Eastman Kodak Co., (U.S.A.) and ethylenediamine (BDH) were purified by distillation at 45 °C under reduced pressure and stored in amber coloured bottles. The monosodium salt of par was obtained from Riedel (Germany) and was used after recrystallization. Sodium perchlorate (AR) was used to maintain ionic strength (I). All other chemicals used were of AR grade. Complex species $[Ni(dien)_2]^{2+}$, $[Ni(en)_2]^{2+}$, $[Ni(par)_2]^{2-2n}$, and $[Ni(CN)_4]^{2-}$ were prepared by mixing stoichiometric amounts of aqueous nickel(II) ion and ligand at appropriate pH. Sodium cyanide and nickel(II) perchlorate solutions were standardized as reported earlier.[8] A borate buffer was used wherever mentioned, otherwise sodium hydroxide and perchloric acid were used to maintain pH.

A stopped-flow spectrophotometer model SF-3A from Hitech, England and an ECIL storage oscilloscope model OS-7865 equipped with a Polaroid camera were used for measuring rates of rapid reactions. Details of apparatus used for the study of slow reactions and pH measurements were reported previously.[8]

Kinetic Measurements

The ligand exchange reactions of $[Ni(dien)_2]^{2+}$ and $[Ni(en)_2]^{2+}$ with cyanide ion were followed at 267 nm (λ_{max} of $[Ni(CN)_4]^{2-}$, $\varepsilon=1.16\times10^4$ dm^3 mol^{-1} cm^{-1}) or 285 nm ($\varepsilon=4.63\times10^3$ dm^3 mol^{-1} cm^{-1}) where the absorbances of the other species were negligible under the present conditions. The forward reactions were run in excess cyanide. The results gave pseudo first order plots, and the rate expression is given by

$$\frac{d[Ni(CN)_4]^{2-}}{dt} = k_{obsd}[NiL_m]_T,$$

where $[NiL_m]_T$ indicates the total concentration of nickel(II) complexes with L^{n-}, which contains mixed cyanide complexes of the type $NiL(CN)_x$. The forward and backward reactions in case of $Ni(par)_2$ were followed at 494 nm (λ_{max} of NiL_2, $\varepsilon=8.2\times10^4$ dm^3 mol^{-1} cm^{-1}) by monitoring disappearance or appearance of $Ni(par)_2$.

The absorbances of par and $[Ni(par)_2]$ remained constant for a pH range of 8—9.5. Considering the protonation constants $\log K_{H_2L}^{H_2L}=2.6$, $\log K_{H_2L}^{HL}=5.5$ and $\log K_{HL}^{H}=12.5$,[16] at higher pH the dominant species of par is the monoprotonated one. The absorption of par increases above pH 9.5 and hence all the reactions were studied at a pH of 9.0±0.1. The reaction of NiL complex with cyanide was also studied at 494 nm ($\varepsilon_{NiL}=3.63\times10^4$ dm^3 mol^{-1} cm^{-1}) by monitoring its disappearance. At the working pH, percentage of NiL was calculated[17] to be 80%.

For the study of reaction of $[Ni(CN)_4]^{2-}$ with par, solutions of par higher than 1.0×10^{-4} mol dm^{-3} could not be used because they do not obey Lambert-Beer law above this concentration. The reaction could not be followed at 267 or 285 nm (absorption maxima of $[Ni(CN)_4)^{2-}]$ because NiL_2 and par also absorb appreciably at these wave lengths ($\varepsilon_{NiL_2}=1.15\times10^4$ dm^3 mol^{-1} cm^{-1}, $\varepsilon_{par}=2.75\times10^3$ dm^3 mol^{-1} cm^{-1} at 267 nm).

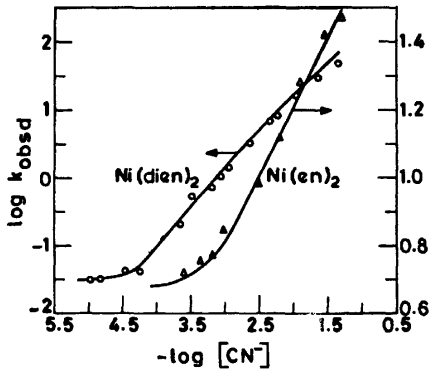

Fig. 1. Cyanide dependence of the observed forward rate constants in the reaction of $[Ni(dien)_2]^{2+}$ and $[Ni(en)_2]^{2+}$ with cyanide ion. pH 11.0, 25 °C and $I=0.1$ mol dm^{-3}.

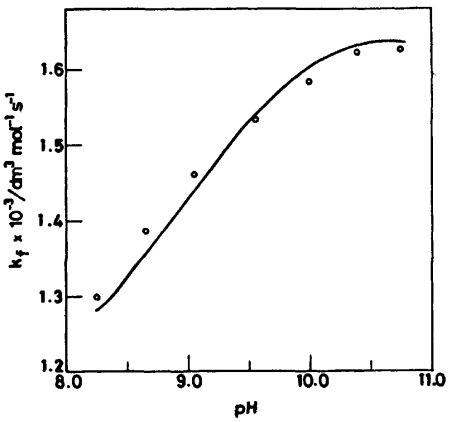

Fig. 2. Effect of pH on the reaction of $[Ni(dien)_2]^{2+}$ with cyanide at 25 °C and $I=0.1$ mol dm^{-3}.

Results

I. Reaction of $Ni(dien)_2$ with Cyanide. The rate of formation of $[Ni(CN)_4]^{2-}$ is first order each in $[Ni(dien)_2]^{2+}$ and CN^- at pH 11.0 where cyanide is present in large excess. The effect of cyanide can be seen in Fig. 1 where the slope of log k_{obsd} *vs.* log [CN$^-$] plot gives the order of reaction in cyanide. The order in cyanide varies from zero at low cyanide concentration to one at higher cyanide concentration. A similar observation was also reported by Coombs and Margerum[18] while studying the reaction of cyanide ion with bis complexes of nickel(II) with imino-*N*-diacetate (ida) and methylimino-*N*-diacetate (mida). The observed zero order dependence in cyanide indicates a slow dissociation step according to Eq. 3 followed by further reaction of NiL with cyanide to give $[Ni(CN)_4]^{2-}$

$$NiL_2 \xrightarrow{k_d^{NiL_2}} NiL + L. \qquad (3)$$

Thus k_{obsd} can be expressed by Eq. 4

$$k_{obsd} = k_d^{NiL_2} + k_3[CN^-]_T. \qquad (4)$$

The values of $k_d^{NiL_2}=3.85\times10^{-2}$ s^{-1} and $k_3=1.34\times10^3$ dm^3 mol^{-1} s^{-1} at 25 °C and $I=0.1$ mol dm^{-3} ($NaClO_4$).

Dependence of k_f on pH: The pH was varied from 8.2 to 11.0 and it was found that the reaction rate increases with an increase of pH and then levels at pH higher than 9.5 (Fig. 2). The difference in reactivities of CN^- and HCN can be resolved using Eq. 5.

$$k_f\frac{[CN]_T}{[CN^-]} = k_{CN} + k_{HCN}K_{HCN}[H^+], \qquad (5)$$

where

$$\frac{[CN]_T}{[CN^-]} = 1 + K_{HCN}[H^+],$$

and K_{HCN} is the protonation constant of cyanide ion (log $K_{HCN}=9.0$ at 25 °C and $I=0.1$). Thus a plot of left hand side of Eq. 5 *vs.* $[H^+]$ gives a straight line (Fig. 3). The values of k_{HCN} and k_{CN} are 1.25×10^3 and 1.65×10^3 dm^3 mol^{-1} s^{-1}, respectively.

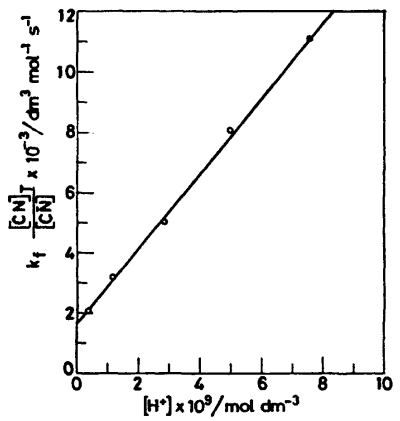

Fig. 3. Resolution of rate constants for the reaction of $[Ni(dien)_2]^{2+}$ with cyanide ion.

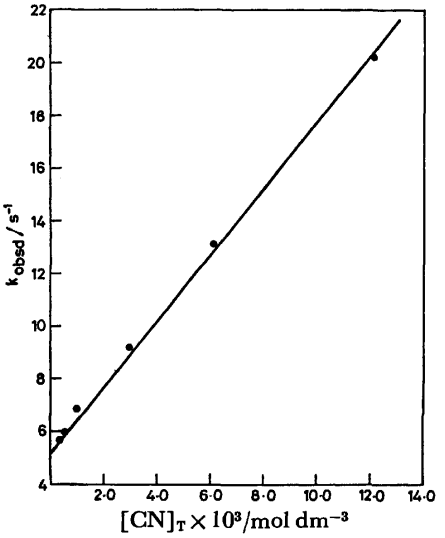

Fig. 4. Plot of k_{obsd} *vs.* $[CN]_T$ for the reaction of $[Ni(en)_2]^{2+}$ with cyanide ion.

II. Reaction of $[Ni(en)_2]^{2+}$ with Cyanide Ion. The rate of reaction of $[Ni(en)_2]^{2+}$ with cyanide is first order in $[Ni(en)_2]^{2+}$ and the rate increases with an increase in cyanide ion concentration (Fig. 1). The nature of dependence on cyanide concentration shows that the bis complex dissociates and the mono-complex formed reacts rapidly with CN^- through the formation of mixed ligand complexes finally giving

TABLE 1. KINETICS OF THE DECOMPOSITION OF $Ni(CN)_4^{2-}$ IN ITS REACTION WITH dien, en, AND par

A. dien: $[Ni(CN)_4^{2-}]_i = 2.6\times10^{-5}$ mol dm^{-3}, pH 11.0, I=0.1 mol dm^{-3}, 25 °C.

$[dien]_T$/mol dm^{-3}	$10^9\times k'_{obsd}$/mol dm^{-3} s^{-1}	$10^6\times k_b$/s^{-1}
1.45×10^{-3}	6.90	4.76
1.09×10^{-3}	5.28	4.84
0.73×10^{-3}	3.61	4.95

B. en: $[Ni(CN)_4^{2-}]_i = 1.65\times10^{-5}$ mol dm^{-3}, pH 10.5, I=0.5 mol dm^{-3}, 25 °C.

$[en]_T$/mol dm^{-3}	$10^5\times k'_{obsd}$/mol dm^{-3} s^{-1}	$10^4\times k_b$/s^{-1}
0.18	5.8	3.2
0.20	7.4	3.7
0.25	8.5	3.4
0.30	9.6	3.2

C. par: $[Ni(CN)_4^{2-}]_i = 4.0\times10^{-6}$ mol dm^{-3}, pH 9.0, I=0.15, 30 °C.

$[par]_T$/mol dm^{-3}	$10^{10}\times k'_{obsd}$/mol dm^{-3} s^{-1}	$10^6\times k_b$/s^{-1}
4.0×10^{-5}	3.45	8.62
6.0×10^{-5}	4.75	7.92
8.0×10^{-5}	6.48	8.10
10.0×10^{-5}	8.24	8.24

$[Ni(CN)_4]^{2-}$. In this case, if first order dependence in cyanide is assumed,

$$k_{obsd} = k_d^{NiL_2} + k'[CN^-]. \quad (6)$$

So a plot of k_{obsd} *vs.* $[CN^-]$ should be a straight line, which is found to be the case for $[CN^-]>10^{-3}$ mol dm^{-3} (Fig. 4). The values of $k_d^{NiL_2}$ and k' obtained from Fig. 4 are 5.1 s^{-1} and 1.3×10^3 dm^3 mol^{-1} s^{-1}, respectively. The value of $k_d^{NiL_2}$ for ethylenediamine is much larger than that for dien. This accounts for the slope being different from the expected value of one (Fig. 1).

Kinetics of Reactions of $[Ni(CN)_4]^{2-}$ with dien and en: The dissociation of $[Ni(CN)_4]^{2-}$ is greatly accelerated by the presence of polyamines in comparison to the much slower reaction of $[Ni(CN)_4]^{2-}$ with amine-*N*-acetic acids[8] or perchloric acid. The reaction is first order each in $[Ni(CN)_4]^{2-}$ and polyamine. A notable feature of these backward reactions is an inverse first order dependence in cyanide and the integrated rate expression has the form

$$(A_i - A_t) + A_i \ln\frac{A_t}{A_i} = -\frac{\varepsilon l}{4}k'_{obsd}t. \quad (7)$$

The terms used in Eq. 7 have their usual meaning as described earlier.[8] The values of $k'_{obsd}$and k_b are given in Table 1.

III. Reaction of $Ni(par)_2$ and $Ni(par)$ with Cyanide. The stability constant of $Ni(par)_2$ is fairly large (log β_2=22.2)[19] and a slow exchange reaction was observed for this system. As in the case of $[Ni(dien)_2]^{2+}$ and $[Ni(en)_2]^{2+}$, a cyanide free path was also observed at $[CN^-]$ less than 10^{-3} mol dm^{-3} (Fig. 5) which indicates the dissociation of bis complex in addition to the cyanide assisted dissociation of $Ni(par)_2$ and

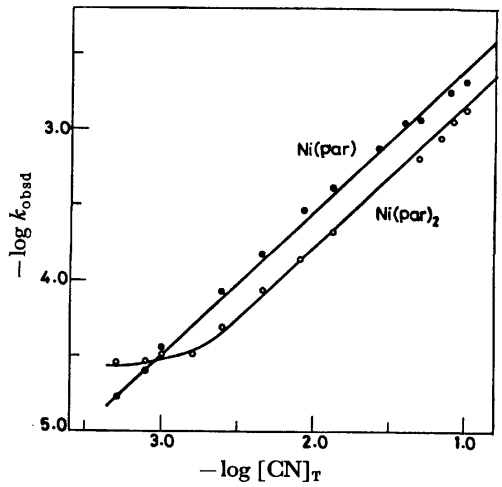

Fig. 5. Effect of cyanide ion concentration on the reaction of $[Ni(par)_2]^{2-}$ and [Ni(par)]. pH 9.0, 30 °C and I=0.15 mol dm^{-3}.

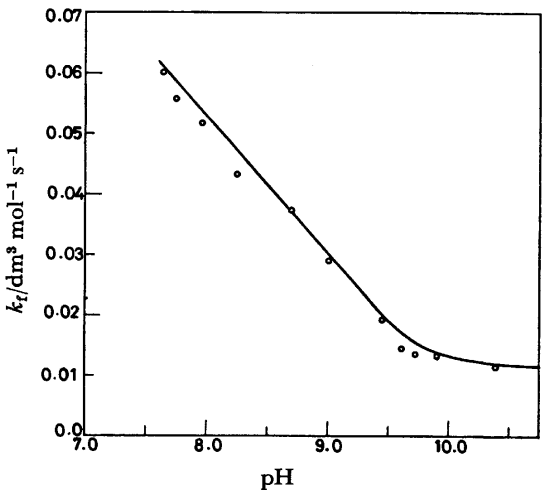

Fig. 6. Effect of hydrogen ion concentration on the reaction of [Ni(par)] with cyanide ion at 30 °C, and I=0.1 mol dm^{-3}.

formation of mixed ligand complexes of type Ni(par)$(CN)_x$ and finally $[Ni(CN)_4]^{2-}$.

The rate of the substitution reaction of monocomplex, [Ni(par)] was found to be first order with respect to cyanide over a wide range of cyanide concentration (Fig. 5). The rate constants are comparable with those of substitution reaction of the biscomplex (Fig. 5). This leads to a conclusion that the rate-determining step is the same in both reactions of Ni(par) and $(Ni(par)_2$ with cyanide ion.

Effect of pH on k_f: The rate of the forward reaction decreased with increase of pH (Fig. 6). This observation can be explained on the basis of labilities and structures[19] of the protonated forms of $Ni(par)_2$. It is also observed that reactions of Ni(par) and $Ni(par)_2$ with cyanide give similar rate constants on variation of pH.

A rate expression consistent with these observations is written below (Eq. 8).

$$k_{obsd} = k_f[CN]_T = \{k_{CN} + k_{HCN}K_{HCN}[H^+] + k'_{CN}K_{NiHL}^{NiL}[H^+] + k'_{HCN}K_{HCN}K_{NiHL}^{NiL}[H^+]^2\}[CN^-], \quad (8)$$

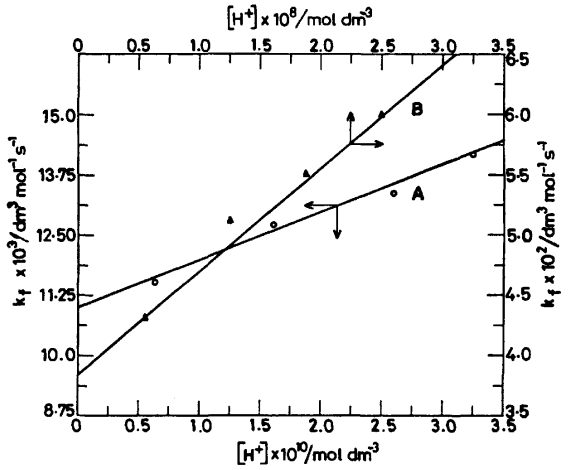

Fig. 7. Resolution of rate constants for the forward reaction of [Ni(par)] with cyanide ion.

where k_{CN} and k_{HCN} are the rate constants for the reaction of Ni(par) with CN^- and HCN while k'_{CN} and k'_{HCN} are rate constants for the reaction of Ni (Hpar) with CN^- and HCN respectively. K^{NiL}_{NiHL} is the protonation constant of Ni(par).

In high pH range, the terms containing protonated form of the complex can be neglected ($K^{NiHPar}_{NiPar}=10^{7.7}$ [20]) in 50% dioxane, the value in aqueous solution is not known). Considering $1 \gg K_{HCN}[H^+]$ at pH>9.5, Eq. 8 under assumption of $[CN]_T \approx [CN^-]$ is transformed to

$$k_f = k_{CN} + k_{HCN}K_{HCN}[H^+]. \quad (9)$$

The value of k_{CN} and k_{HCN} can be evaluated by plotting k_f *vs.* $[H^+]$ (Fig. 7), and are 1.11×10^{-2} and 1.01×10^{-2} $dm^3\ mol^{-1}\ s^{-1}$ respectively.

On the other hand, in lower pH range, the rate expression can be rearranged, assuming that $K_{HCN}[H^+] \gg 1$ and $[CN]_T \approx [HCN]$, to

$$k_f = k'_{CN}\frac{K^{NiL}_{NiHL}}{K_{HCN}[H^+]} + k'_{HCN}K^{NiL}_{NiHL}[H^+]. \quad (10)$$

A plot of k_f *vs.* $[H^+]$ gave a straight line (Fig. 7). The slope and intercept of this line give the values of product of k'_{HCN} and k'_{CN} with K^{NiL}_{NiHL}, and these are 8.36×10^5 and 3.90×10^7 $dm^3\ mol^{-1}\ s^{-1}$ respectively. The solid line in Fig. 6 shows the curve calculated from the various resolved rate constants.

IV. Kinetics of Reaction of $[Ni(CN)_4]^{2-}$ with par. The stability constant of tetracyanonickelate(II) is much greater than those of Ni(par) and $Ni(par)_2$ ($\log\beta_4=30.5$[12], $\log K_{Ni(par)}=17.8$, and $\log\beta_2=22.2$).[19] By using very dilute solution of $[Ni(CN)_4]^{2-}$ ($\approx10^{-6}$ mol dm^{-3}) and a moderately high concentration of par ($\approx10^{-4}$ mol dm^{-3}), it is possible to force the backward reaction. An excellent fit to the data was obtained by assuming a first order dependence in $[Ni(CN)_4]^{2-}$ and par and an inverse first order dependence in cyanide. The rate equation is formulated as given in Eq. 11, assuming that the change in absorbance of par during the course of reaction is negligible due to its high concentration compared to $[Ni(CN)_4]^{2-}$.

$$(A_t-A_0) + (A_\infty-A_0)\ln\frac{A_\infty-A_t}{A_\infty-A_0} = -\frac{\varepsilon l}{4}k'_{obsd}t, \quad (11)$$

where A_0 is the initial absorbance due to par, (A_t and A_∞ are the absorbances at time t and after completion of reaction, ε is the molar absorption coefficient of $Ni(par)_2$ and l is the light path length. Plots of left hand side of Eq. 11 *vs.* t, were linear (Fig. 8). From the plots, k'_{obsd} can be calculated and hence k_b ($k_b=k'_{obsd}/[par]_T$). The values are given in Table 1.

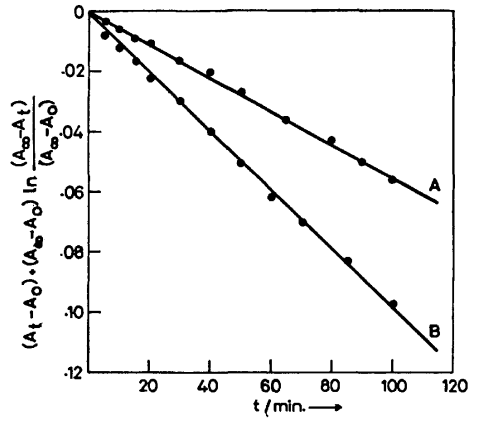

Fig. 8. Inverse first order plots for reaction of $[Ni(CN)_4]^{2-}$ with par at 30 °C, pH 9.0 and $I=0.15$ mol dm^{-3}, using Eq. 11. $[Ni(CN)_4]^{2-}=4\times10^{-6}$ mol dm^{-3}; (A) $[par]=6\times10^{-5}$ mol dm^{-3}, (B) $[par]=1\times10^{-4}$ mol dm^{-3}.

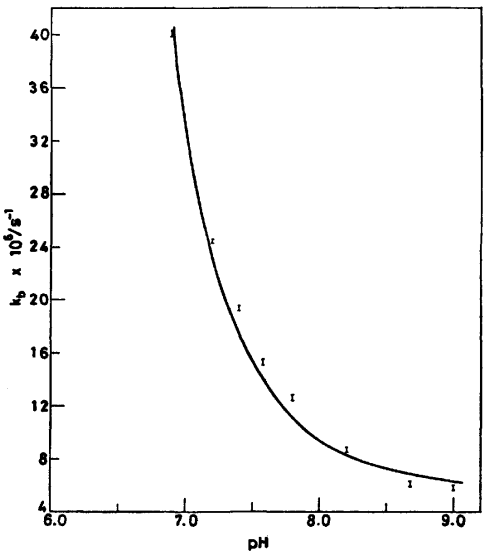

Fig. 9. Effect of pH on the backward reaction between $[Ni(CN)_4]^{2-}$ and par at 30 °C and $I=0.15$ mol dm^{-3}.

Effect of pH on the Reaction of $[Ni(CN)_4]^{2-}$ with par: The reaction was studied in the pH range 6.5—9.5 and the rate increased with decrease of pH (Fig. 9). $[Ni(CN)_4]^{2-}$ is known to be protonated only at pH below 5.0.[12] Therefore, the above behaviour can be explained on the basis of reactivities of the protonated forms of par *viz.* H_2par and Hpar. A rate law expressing the behaviour over the whole pH range investigated can be written as Eq. 12,

$$k_b\frac{[par]_T}{[par^{2-}]}\cdot\frac{1}{[H^+]} = k_{Hpar}K_{Hpar} + k_{H_2par}K_{H_2par}K_{Hpar}[H^+], \quad (12)$$

where

$$\frac{[par]_T}{[par]^{2-}} = 1 + K_{Hpar}[H^+] + K_{H_2par}K_{Hpar}[H^+]^2 + K_{H_3par}K_{H_2par}K_{Hpar}[H^+]^3.$$

From plots of left-hand side of Eq. 12 *vs.* [H$^+$], k_{HL} and k_{H_2L} were calculated to be 6.35×10^{-10} s^{-1} and 3.98×10^{-8} s^{-1}, respectively. Using these values, k_b was calculated for the whole range of pH. A good agreement between the calculated curve and the experimental points (Fig. 9) justifies the assumptions made in deriving the above rate equation.

V. Effect of Temperature on All Three Reactions. The forward reactions were studied in temperature range 25—45 °C at two different cyanide concentrations *i.e.* where order with respect to cyanide is zero and one respectively. The rate constants obeyed the Arrhenius equation. The activation parameters were calculated and are given in Table 2. The high energy of activation at low [CN$^-$] (cyanide independent path) indicates rupture of metal–ligand bond accompanied by a less negative entropy change as compared to cyanide dependent path of high [CN$^-$]. The backward reaction rates ($k_b=K_4^{-1}k_{-3}$) for all the three reactions in this temperature range are given in Table 3. Although these are composite rate constants, they also obeyed the Arrhenius equation.

Discussion

A detailed study of forward and backward reaction (Eq. 1) reveals that the substitution of polydentate ligands in octahedral bis complexes of Ni(II) proceeds by an associative mechanism. A mechanism consistent with experimental observation can now be written (Eqs. 13—17).

$$NiL_2 \xrightarrow{k_d^{NiL_2}} NiL + L, \qquad (13)$$

$$NiL_2 + CN^- \underset{k_{-1}'}{\overset{k_1'}{\rightleftharpoons}} NiL(CN) + L \quad \text{fast}, \qquad (14)$$

$$NiL(CN) + CN^- \underset{}{\overset{K_2}{\rightleftharpoons}} NiL(CN)_2 \quad \text{fast}, \qquad (15)$$

$$NiL(CN)_2 + CN^- \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} NiL(CN)_3 \quad \text{rds}, \qquad (16)$$

$$NiL(CN)_3 + CN^- \underset{}{\overset{K_4}{\rightleftharpoons}} Ni(CN)_4^{2-} + L \quad \text{fast}. \qquad (17)$$

The bis complexes do not convert directly to $[Ni(CN)_4]^{2-}$ but lose one of the ligands before the rate determining step (Eqs. 13 and 14), and mixed ligand complexes of type $NiL(CN)_x$ ($x=1$ or 2) are formed rapidly. Addition of third cyanide (Eq. 16) is rate determining.

The observed first order dependence in cyanide leads to a conclusion that either $k_{CN}^{NiL_2}$ or k_3 may be the slowest step. The average value of $k_{CN}^{NiL_2}$ ($=6.8\times10^4$ dm^3 mol^{-1} s^{-1}) obtained under the condition $[Ni(dien)_2^{2+}]>[CN^-]$ is higher than the observed value of k_3 ($=1.34\times10^3$ dm^3 mol^{-1} s^{-1}) at higher cyanide concentration (Tables 4 and 6) indicating that $k_{CN}^{NiL_2}$ is not the rate determing step for $[Ni(dien)_2]^{2+}$–CN$^-$ reaction system.

However, mono and bis complexes of nickel(II)

and par react with cyanide at similar rates (Fig. 6) under similar conditions. This fact suggests that the rate determining step may be same for both reactions. Based on our earlier studies on reactions of mono complexes[8] of nickel(II) with amine-*N*-acetic acids, this would in all probability be the addition of third cyanide. The observed inverse first order dependence in cyanide for the backward reaction further supports the supposition that the step shown in Eq. 16 is rate determining.

For quantitative conversion to $NiL(CN)_2$ which is the reactive species for forward reaction in presence of moderate or high concentration of cyanide, the stability of the same must be quite high. Values of K_1K_2 (or β_2) can be calculated from an expression derived by us earlier and given in Eq. 18.

$$K_1K_2=\frac{K_4^{-1}k_{-3}\beta_4}{k_3K_{NiL}}, \qquad (18)$$

where the symbols used have their usual meanings.[8] These values, given in Table 6, suggest that rapid conversion of NiL_2 to $NiL(CN)_2$ can be expected. For $[Ni(en)_2]^{2+}$ reaction with cyanide, the value of K_1K_2 ($=1.6\times10^{16}$) is many orders of magnitude higher than the maximum possible value ($=3\times10^{11}$)[12] estimated for $Ni(CN)_2\cdot4H_2O$.[12] The magnitude of stability constant of the ternary complex will be equal to or less than that of $Ni(en)_2\cdot4H_2O$.[12] The large difference in stabilities calculated for $Ni(en)(CN)_2$ shows that Eq. 18, which has been derived on the supposition that addition of third cyanide is rate determining, is not applicable in the case of ethylenediamine complex though it is applicable to $[Ni(dien)_2]^{2+}$ and $[Ni(par)_2]^{2-}$ reaction. It seems that $k_{CN}^{NiL_2}$ for $[Ni(en)_2]^{2+}$ system is smaller than k_3 and the addition of first cyanide is slower than the addition of third cyanide. The observation of a negative salt effect (Table 5) further supports this proposition. A similar conclusion was made earlier by Coombs and Margerum[18] for reactions of $[Ni(ida)_2]$ and $[Ni(mida)_2]$ with cyanide.

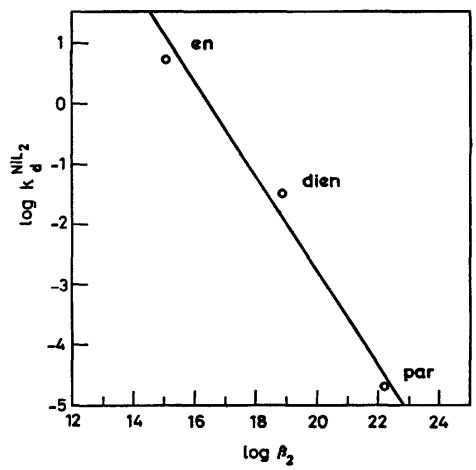

Fig. 10. A Linear Free Energy Relationship (LFER); a plot of $\log k_d^{NiL_2}$ *vs.* $\log\beta_2$.

The different kinetic behaviour of $[Ni(en)_2]^{2+}$ may be due to bidentate nature of ethylenediamine and presence of water molecules in cis positions.[21] Water molecules in cis position are known to be less labile than the ones in trans location.[22] The substitution of cis water by first cyanide is expected to be slower than the substitution, possibly of trans water, during the addition of third cyanide. In case of $[Ni(dien)_2]$ and $[Ni(par)_2]$, on the other hand, no water molecules are present due to tridentate ligands. The order of reactivity of bis complexes is reverse of the order of their stabilities. The dissociation rate constants $k_{CN}^{NiL_2}$ are also directly related to their overall stability constants β_2's. This free energy relationship is shown in

Table 6. Summary of the rate and equilibrium constants obtained at 25 °C and $I=0.1$ mol dm^{-3} ($NaClO_4$)

The Catalytic Isomerization of Butenes over a Graphite Oxide

Susumu TSUCHIYA,* Masahiro MIKAMI, and Hayao IMAMURA
Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Ube, Yamaguchi 755
(Received June 10, 1983)

Synopsis. The relative rate constants and the activation energies of the isomerization of butenes over a graphite oxide have been measured, The reactivity of butenes and the selectivity ratios are in agreement with the characteristics of acid catalysts. The reaction profile shown on the triangular graph is of the rake-type.

Much attention has been paid to the characteristic properties of graphite oxide since Brodie first synthesized the compound.[1,2] Scarecely no study of its catalytic properties has, however, been reported so far. In this study, the isomerization of butenes, employed as a model reaction, has been investigated in order to explore its catalytic characteristics.

Experimental

Materials. The graphite oxide samples used as catalysts were prepared in a manner similar to that decribed previously.[3] The X-ray-diffraction data and the IR spectroscopic data of the sample formed agreed quite well with those reported by Alexanian.[4] The sample was dark brown.

The 1-butene, *cis*-, and *trans*-2-butene used as the reactans were obtained from the Tokyo Kasei Kogyo Co., Ltd.; their purity was confirmed by gas chromatography to be more than 99%. The nitrogen (99.99%) was obtained from the Seitetsu Kagaku Co., Ltd.

Procedure. A usual flow-type system with a by-pass at atmospheric pressure was employed to follow the reaction, nitrogen being used as the diluent. The graphite oxide, the catalyst, the BET surface area of which was 36 m^2/g, had been prepared beforehand; it was fixed in the system. The nitrogen stream with one of the butene isomers as a reactant was flowing only through the by-pass in the meantime; then it was diverted to flow through the reactor. The flowing rate of the nitrogen was *ca.* 15 cm^3/min, the amount of catalyst used being 0.39 g for each run. The [a butene isomer]/[nitrogen] ratio was 1/49. The reaction mixtures were analyzed by means of gas chromatography, with a column packing of 2,4-dimethylsulfolane on Uniport C. Before each run, the catalyst was evacuated at 353 K for 14 h. The experimental results were well reproducible.

Results and Discussion

The double-bond migration and the cis-trans isomerization of butenes took place over graphite oxide. The skeletal isomerization could not be observed. No gaseous hydrocarbon other than the butenes could be detected in the reaction mixtures under the present experimental conditions. The graphite does not show any catalytic activity for a reaction under the same experimental conditions. In the initial stage the activity of a fresh catalyst was very high (the per-pass conversion was 85% at 323 K), but it decreased with time on stream. After about 200 min, the conversion became steady-state (with a per-pass conversion of *ca.* 8% at 323 K). Since the steady state continued a rather long time, all the kinetic studies were carried out in this state.

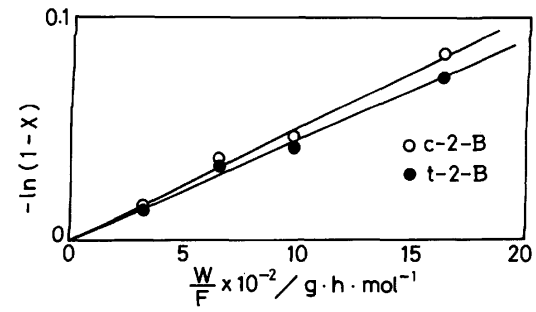

Fig. 1. First-order plots of isomerization of 1-butene over graphite oxide at 328 K.

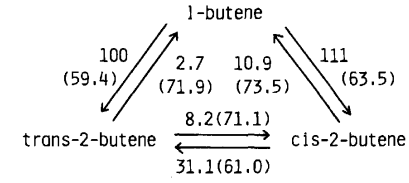

Fig. 2. Relative rate constants at 328 K and activation energies (kJ/mol) bracketed.

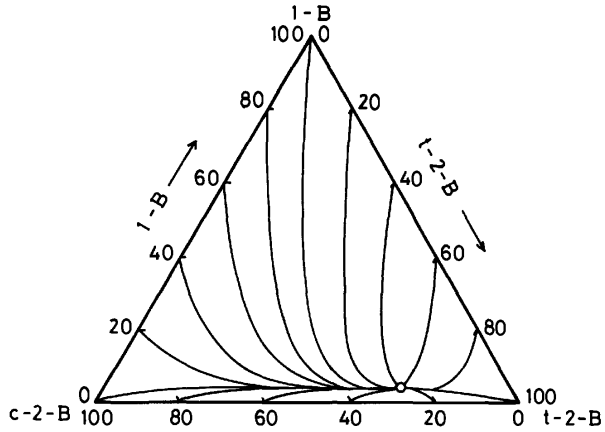

Fig. 3. Reaction profile of isomerization of butenes over graphite oxide at 328 K.

Figure 1 shows the first-order plots of the isomerization of 1-butene. From the rates of reaction and the selectivity ratios at different temperatures, all six of the relative rate constants and the activation energies of the reaction were determined in a manner similar to that described previously.[5] The results are shown in Fig. 2.

When the isomerization of butenes proceeds, the composition of the butenes in the gas phase may vary with the reaction time. The mol% of 1-butene, *cis*-, and *trans*-2-butene corresponding to the reaction time can be calculated from the relative rate constants, k_{ij}.[5-7] Figure 3 shows the reaction paths calculated at 328 K. The triangular graph thus represents one of the catalytic characteristics of graphite oxide for the isomerization of butenes. The time variable, t, is eliminated in

the graph. When the reactants initially contain much more 1-butene than *cis*- or *trans*-2-butene, the curves corresponding to the reaction paths go downwards in an almost straight manner. This profile may be named the "rake-type," which is entirely different from that obtained in the isomerization over KC_8.[5]

Graphite oxide is often called graphitic acid because of its acid character.[10] The acid properties are caused by the acid-hydroxyl groups between the graphite layers, which can be observed by IR spectroscopy. The active sites of graphite oxide for the isomerization of butenes may therefore, have acid properties.

The following mechanisms for the isomerization of butenes have been proposed for different catalytic systems:[6] (1) a hydride-addition mechanism for metals, (2) a carbenium-ion mechanism for acid catalysts, and (3) an allylic mechanism for basic catalysts. When the isomerization takes place with a carbenium-ion mechanism, (1) the order of the relative rate constants of the isomerization is 1-butene>*cis*-2-butene>*trans*-2-butene, and (2) the selectivity ratio, *cis*/*trans*, is about unity, while 1/*cis*-2- and 1/*trans*-2- are less than 3.0, usually less than 1.0.[8-9] The reactivity of butenes as well as the selectivity ratios obtained in the present study are in agreement with a carbenium-ion mechanism for acid catalysts.

A large pulse of 1-butene (50 ml) was introduced into the flow system, where only carrier gas was flowing. The effluent stream was monitored by means of gas chromatography. The graphite-oxide catalyst (0.45 g) employed was at the steady state, as has been mentioned above. The flowing rate of the carrier gas was 8.6 cm^3/min. A large peak with tailing was observed, as is shown in the upper part in Fig. 4; the abscissa is the effluent time. The tailing continued more than 1 h. Since the active sites of graphite oxide may be the hydroxyl groups between the graphite layers, the reactant molecules must get into the space between the graphite layers and chemisorb on the sites for isomerization. The product admolecules then desorb from the sites and crawl out of the layer space. The tailing may correspond to the crawling-out-process.

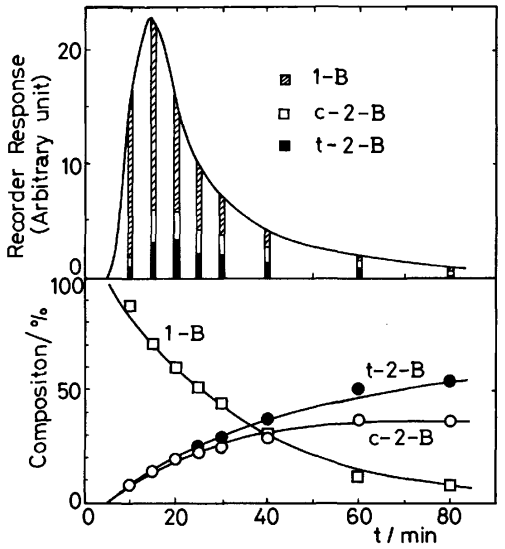

Fig. 4. Effluent peak and composition.
1-Butene (50 ml) was introduced over graphite oxide (0.45 g) at 298 K. Flowing rate of carrier gas was 8.6 cm^3/min.

The composition of the effluent gas was analyzed by means of gas chromatography. The analytical samples were taken out from the effluent at suitable time intervals. The results are shown in Fig. 4; the amounts of the individual butene isomers are shown in the upper part, while the compositions are shown in the lower part. In this case, the reaction time, the contact time, may correspond to the effluent time. The solid lines in the lower part represent the curves calculated from the relative first-order rate constants and the activation energies, the reaction time being assumed to be the effluent time. The points which represent the compositions experimentally obtained fall on the solid lines quite well. These results also support the idea that the isomerization reaction takes place between the graphite layers and proceeds by means of first-order kinetics.

It is, accordingly, concluded that the graphite oxide is a solid-acid catalyst and that it shows the rake-type profile for the isometization of butenes, which takes place between the graphite layers.

Linear Dependence of ODMR Transition Frequency on $T_1 \rightarrow S_0$ Transition Energy. *p*-Dichlorobenzene in Various Matrices

Noriko IWASAKI and Minoru KINOSHITA*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received June 29, 1983)

Synopsis. The linear dependence of ODMR transition frequency on the $T_1 \rightarrow S_0$ transition energy of *p*-dichlorobenzene in various matrices was interpreted with the spin-orbit couplings of the lowest triplet state with the triplet and singlet manifold, by assuming that the matrix dependent shifts in the triplet and singlet state energy are correlated with each other.

Lemaistre and Zewail have explained the origin of the difference in the linewidth between ODMR (optically detected magnetic resonance) and optical transitions, by considering selective spin-orbit coupling (SOC) between singlet and triplet states.[1-3] Their theory has also provided an explanation for the linear dependence of the ODMR transition frequency on the optical transition energy in a system where the ODMR and optical transitions show inhomogeneous broadening.[4] On the other hand, Egmond *et al.* have explained the linear relation of these two transitions by the interaction between triplet states.[5]

Recently we have found a linear correlation between the ODMR transition and the $T_1 \rightarrow S_0$ transition energy of *p*-dichlorobenzene (*p*-DCB) in various matrices,[6] but the origin for the correlation has not yet been clarified. In this note, we apply their methods to the systems of *p*-DCB in various matrices, and show that the SOC with a higher triplet and a singlet state can provide a possible explanation for the correlation between the ODMR transition frequency and the $T_1 \rightarrow S_0$ transition energy rather than the vibronic coupling between triplet states.

At first we apply Zewail's method to a compound which has different electronic energies in various matrices. We assume that the contribution of the solvent to the spin-orbit matrix element is very small, and only the difference of the electronic energies between a perturbing state and the T_1 state has an influence on the ODMR transition energy. We neglect the inhomogeneous broadening in a matrix. The full widths at half maxima (fwhm) of the 0,0 bands of the phosphorescence spectra of *p*-DCB in the matrices are 3—4 cm^{-1} except for fwhm of 20 cm^{-1} in benzene. Therefore, the inhomogeneous broadening effect in the $T_1 \rightarrow S_0$ and ODMR transitions discussed by them is rather small in the case of *p*-DCB and may be neglected compared to the variation of the transition energies with matrix. We thus consider, instead of inhomogeneous broadening, the matrix dependence of the electronic and ODMR transition energies in terms of their method. The electronic energy shifts of the singlet and triplet excited states in various matrices may be written as

$$E^r = E_0^r + \delta_M^r, \tag{1}$$

where r denotes the singlet (S) or the triplel (T) state, E_0^r is the electronic energy of the molecule in a certain standard matrix (M_0) and δ_M^r denotes the energy shift of the molecule in a matrix (M) from E_0^r. We assume that only one magnetic sublevel (say T_y) of its lowest triplet state effectively couples with a particular singlet state through SOC (mechanism 1). According to their method,[2] the total energy for each sublevel is given by

$$E_z^T = E_0^T + Z + \delta_M^T, \tag{2-a}$$

$$E_y^T = E_0^T + Y + \delta_M^T - |\tau^y|^2/[(E_0^S + \delta_M^S) - (E_T^0 + \delta_M^T + Y)], \tag{2-b}$$

$$E_x^T = E_0^T + X + \delta_M^T, \tag{2-c}$$

where X, Y, and Z denote the zero-order energies of the sublevels of the triplet state in zero-magnetic field and τ^y is the SOC matrix element between the perturbing singlet state and the T_y sublevel. The sublevel order of *p*-DCB is $T_y > T_z > T_x$ in energy. The shift of the ODMR transition frequency between the spin-orbitally active magnetic sublevel (T_y) and the inactive sublevel (T_x) is

$$\Delta\hbar\omega_{yx} = -|\tau^y|^2/(\Delta_{ST} - Y + \delta_M^S - \delta_M^T), \tag{3}$$

where $\Delta_{ST} = E_0^S - E_0^T$ is the singlet and triplet energy separation of the molecule in the standard matrix (M_0). Since $\Delta_{ST} \gg Y$, $(\Delta_{ST} - Y) \sim \Delta_{ST}$. In the case of *p*-DCB, the magnitude of Δ_{ST} is larger at least by a factor of about 10^2 than δ_M^T. Although we have not measured δ_M^S, δ_M^S is expected to be comparable with δ_M^T. Therefore, we may expand the denominator in Eq. 3 as

$$\Delta\hbar\omega_{yx} = |\tau^y|^2(\delta_M^S - \delta_M^T)/(\Delta_{ST})^2, \tag{4}$$

where we have omitted the term $-|\tau^y|^2/\Delta_{ST}$ which does not depend on matrices. Assuming that the energy shifts of the singlet and triplet states are correlated as $\delta_M^S = \alpha\delta_M^T$, we obtain

$$\Delta\hbar\omega_{yx} = |\tau^y|^2(\alpha - 1)\delta_M^T/(\Delta_{ST})^2. \tag{5}$$

Equation 5 shows that the ODMR microwave transition frequency depends linearly on the energy shift of the 0,0 band in the phosphorescence spectrum except for the case of $\alpha = 1$. In the case of $\alpha > 1$, *i.e.*, the shift of the singlet energy being larger than that of triplet one, the slope of a plot of $\Delta\hbar\omega_{yx}$ *vs.* δ_M^T becomes positive.

Next we consider the SOC between triplet states (mechanism 2). We assume the two magnetic sublevels (say T_z and T_x) effectively couple with each other. The shifts of the ODMR microwave transitions are given by

$$\Delta\hbar\omega_{zx} = 2|\tau_{j1}^{xz}|^2\varepsilon(\alpha - 1)\delta_M^1/(\Delta_{j1})^3, \tag{6}$$

$$\Delta\hbar\omega_{yx} = -|\tau_{j1}^{xz}|^2(\alpha - 1)\delta_M^1/(\Delta_{j1})^2, \tag{7}$$

where $\varepsilon = (Z_j - X_j) + (Z_1 - X_1)$ is the sum of the $T_z - T_x$ transition energies of the interacting triplet states, and $\alpha\delta_M^1 = \delta_M^1$. Note the negative sign of Eq. 7, which is opposite to Eq. 5.

Finally, we consider an interaction with a higher triplet state, T_j. If V is the operator for the perturbation which does not include spin, for example, one for the vibronic coupling or one for the solvent field perturbation (mechanism 3),[5] the perturbation matrix elemenls are given by

$$<T_i\tau_r|V|T_j\tau_s> = V_{ij}\delta_{rs}. \quad (8)$$

The shift of the energy of the T_{1x} state becomes

$$\Delta E_{1x} = -|V_{j1}|^2/(E_0^j + X_j - E_0^1 - X_1), \quad (9)$$

where the super- or subscripts 1 and j denote the lowest and j-th triplet states, respectively. The shift of the ODMR microwave transition frequency between two sublevels (say, T_z and T_x) is

$$\Delta\hbar\omega_{zx} = -|V_{j1}|^2\varepsilon'/(\Delta_{j1})^2, \quad (10)$$

where $\Delta_{j1}=E_0^j-E_0^1$ is the energy separation of two triplet states, and $\varepsilon'=(Z_j-X_j)-(Z_1-X_1)$ is the energy difference between the $T_z - T_x$ transitions in the lowest and j-th triplet states. We have used the relation $\Delta_{j1} \gg Z_1$, X_1, Z_j, and X_j. Using the equation for the shift of the phosphorescence S,

$$S = -|V_{j1}|^2/\Delta_{j1}, \quad (11)$$

we obtain

$$\Delta\hbar\omega_{zx} = \varepsilon' S/\Delta_{j1}. \quad (12)$$

It may be noted in this case that the perturbation which shifts the phosphorescence origin is the same as that on the ZFS parameters.

The ODMR transition energies are plotted against the $T_1 \rightarrow S_0$ transition energies in various matrices[6,7] in Fig. 1. Only the $T_1 \rightarrow S_0$ transition energy in p-xylene is deviated far apart from that in the other matrices. The ODMR transitions related to the T_y sublevel show the wavelength dependence, while the $T_z - T_x$ transition does not. The slopes of the lines for the $T_y - T_x$ and $T_y - T_z$ transitions are found to be 2.7×10^{-5}, and 3.1×10^{-5}, respectively.

Mechanism 3 can provide an explanation for the linear dependence of the $T_y - T_x$ and $T_y - T_z$ transitions, but is not to give the explanation for the $T_z - T_x$ transition. Independence of the microwave transition from the $T_1 \rightarrow S_0$ transition energy means $\varepsilon'=0$. This may not be acceptable, since we can not expect the same microwave transition energy in different electronic states.

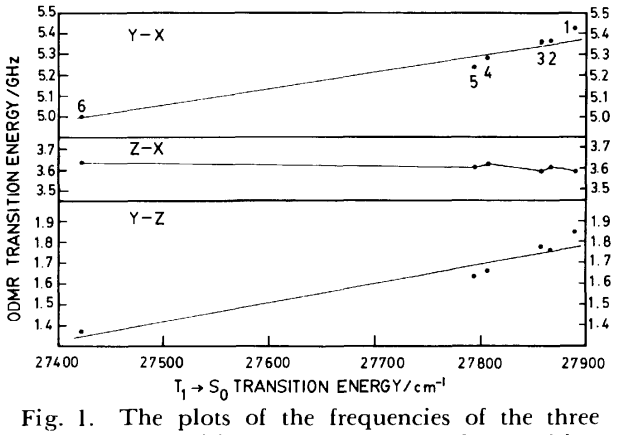

Fig. 1. The plots of the frequencies of the three sublevel transitions *versus* the $T_1 \rightarrow S_0$ transition energy of p-dichlorobenzene in various matrices: 1; in p-dichlorobenzene-d_4, 2; trap 1 in the neat crystal, 3; in p-dibromobenzene, 4; trap 2 in the neat crystal, 5; in benzene, 6; in p-xylene.

We apply mechanism 1 to the system of p-DCB. The triplet state ($^3B_{1u}$) of p-DCB directly couples with the singlet state ($^1B_{3u}$) through the top sublevel, T_y by SOC. This mechanism expects the linear dependence of the $T_y - T_x$ and $T_y - T_z$ transition energies on the $T_1 \rightarrow S_0$ transition energy, and independence of the $T_z - T_x$ transition. This is just the case we have observed in p-DCB. If we assume $\alpha - 1 \sim 1$ and $\tau^y = 63\,cm^{-1}$ for p-DCB, the latter being the value for 1,2,4,5-tetrachlorobenzene,[8] we get $\Delta_{ST} \approx 10^4\,cm^{-1}$. This value seems to be plausible.

The T_z and T_x sublevels of the lowest triplet state of p-DCB couple with the $^3B_{3u}$ by SOC, and mechanism 2 would also explain the experimental results. The shift of the $T_x - T_z$ transition is smaller by a factor of $\varepsilon/\Delta_{j1} \approx 10^{-5} - 10^{-6}$ than that of the other two transitions, as shown in Eqs. 6 and 7. The slope is opposite to the case of mechanism 1.

The magnitude of τ, α, and Δ determines which mechanism, 1 or 2, is dominant. As both α and τ are expected to be comparable for the triplet and singlet B_{3u} states and may be used commonly, the shift of the microwave transition may be written as

$$\Delta\hbar\omega_{yx} = |\tau|^2(\alpha-1)\delta\left(\frac{1}{(\Delta_{ST})^2} - \frac{1}{(\Delta_{j1})^2}\right). \quad (13)$$

Since Δ_{j1} is smaller than Δ_{ST}, the second term in Eq. 13 surpasses the first term. The slopes of microwave transitions are found to be positive, and we expect $\alpha < 1$ in p-DCB. We have neglected completely the spin-distribution change in the triplet state with varying matrices. Especially, the values in p-xylene are very far away from those in the other systems. Therefore, we might have to consider the spin-distribution change of p-DCB in p-xylene. However, the linear dependence of the ODMR microwave transition energy on the $T_1 \rightarrow S_0$ transition energy is well explained by the mechanisms 1 and 2, namely by the SOC's with the triplet and singlet manifolds, with an assumption that the matrix dependent shifts in the triplet and singlet energy are correlated with each other.

Since Δ_{j1} is smaller than Δ_{ST}, the second term in Eq. 13

We are greatly thankful for the referee's important suggestion.

(Received July 4, 1983)

Synopsis. A relaxation obviously different from that due to the triiodide complex formation was observed by the temperature-jump experiments in the iodine-iodide solution. On the basis of the dependences of the relaxation time on the concentration of iodine and iodide and on the temperature, the relaxation was assigned to the complex formation of I_6^{2-}. The rate constants of the reaction were estimated to be 2.2×10^5 M^{-1} ††s^{-1} and 5.3×10^5 s^{-1} for forward and backward processes, respectively.

The iodine-iodide system has been subjected to extensive studies[1-4] in connection with not only the electron-transfer reaction but also the well known "blue starch-iodine" reaction. However the reactions proceeding in this system are complicated depending on the conditions of solution and their mechanisms are still obscure. In the course of our temperature-jump experiments in the cyclodextrin, iodine, and iodide system as a model system of the amylose-iodine solution, we observed a relaxation at micro second region in the iodine-iodide solution. The behavior of the relaxation phenomenon was obviously different from those reported for the hydrolysis of iodine[5] and the triiodide formation reaction.[6] This fact motivated us to clarify the origin of the observed relaxation in the iodine-iodide solution prior to the kinetic investigations on the cyclodextrin-iodide interaction.

In this paper, the observed relaxation will be discussed on the basis of the complex formation reactions proposed for the iodine-iodide system by the spectrophotometric experiments.

Experimental

The kinetic measurements were performed with a Joule heating temperature-jump apparatus equipped with a coaxial cable as a capacitor. Temperature jumps of about 2 °C was attained within 0.7 μs by matching the impedance of sample cell to that of coaxial cable. The temperature of sample solution in the cell was controlled to ±0.5 °C by circulating water from an external thermostat. In order to prevent cavitation by the intense electric current, the sample cell was maintained at constant pressure of 7 atm with nitrogen gas. The details of the apparatus has been described elsewhere.[7] To obtain a rectangular current pulse the ionic strength of solution was adjusted to be 0.023 M by an addition of KI for almost all experiments and of KCl in the case of the experiments changing the iodide concentration. The standardized thiosulfate was used for the determination of the iodine concentration. All chemicals were of reagent grade and used as be received.

Results and Discussion

A typical relaxation curve observed at 500 nm which corresponds to the absorption band of iodine is shown in Fig. 1. The relaxation curve could be analyzed as two relaxations; one has a much faster relaxation time than the resolution time (0.7 μs) of the present apparatus (fast relaxation), and the other has a relaxation time around 2 μs (slow relaxation). The directions of the both relaxation signals indicate the decrease of transmittance. Meanwhile, the relaxation curve observed at 350 nm which is absorption band of triiodide also consists of two relaxations in accordance

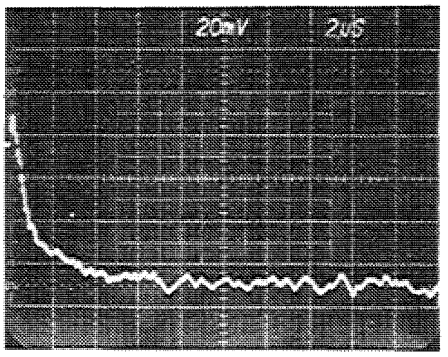

Fig. 1. Typical relaxation curve for the solution of 2.3×10^{-2}M potassium iodide and 5.0×10^{-2}M iodine at 25 °C; sweep=2 μs/division, and λ=500 nm.

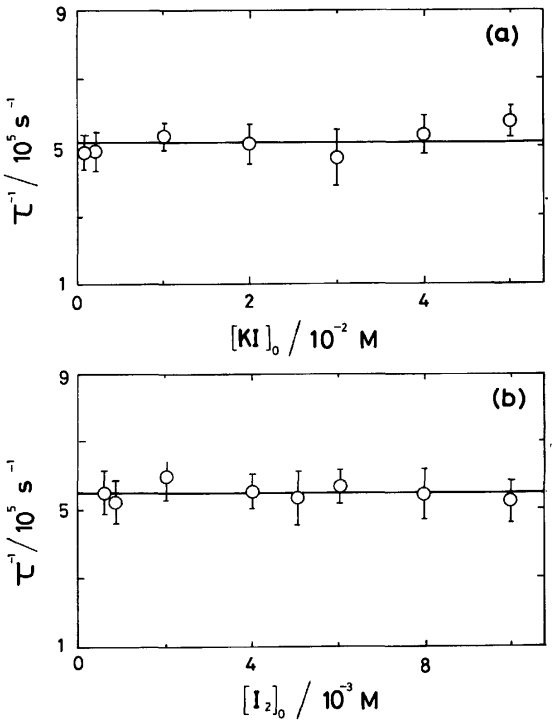

Fig. 2. Dependence of the reciprocal relaxation time on the iodide concentration at constant $[I_2]$ of 5.0×10^{-3}M (a) and on the iodine concentration at constant [KI] of 2.3×10^{-2}M (b) at 25 °C.

†† $1\ M^{-1}=1\ dm^3\ mol^{-1}$.

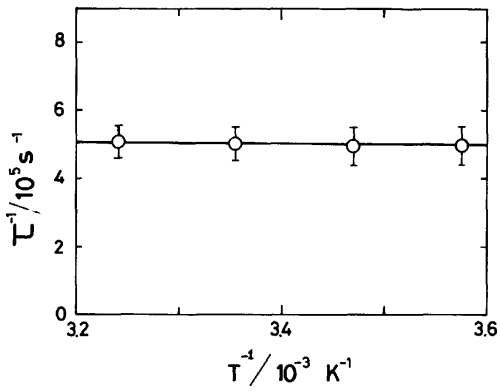

Fig. 3. Dependence of the reciprocal relaxation time on the temperature in the solution of 2.3×10^{-2}M potassium iodide and 4.0×10^{-3}M iodine.

with those observed at 500 nm; the relaxation time as well as the direction of the relaxation signal of the slow process is the same as that obtained from the experiments at 500 nm but the direction of the fast relaxation signal is opposite to that observed at 500 nm. The slow relaxation was examined quantitatively in the present study. The concentration dependence of the reciprocal relaxation time is shown in Fig. 2. The relaxation time is obviously independent of both iodine and iodide concentrations. Further, the relaxation time is insensitive to temperature as can be seen in Fig. 3.

In the system of iodine and iodide, following complex formation have been proposed from the spectrophotometric experiments.[1-6]

$$I^- + I_2 \rightleftharpoons I_3^- \quad (1)$$

$$I^- + I_3^- \rightleftharpoons I_4^{2-} \quad (2)$$

$$I_2 + I_3^- \rightleftharpoons I_5^- \quad (3)$$

$$2\,I_3^- \rightleftharpoons I_6^{2-} \quad (4)$$

Among these four reactions, the triiodide complex formation of Reaction 1 is most well known, and has been studied kinetically by several kinds of methods.[2,4,6] According to these studies, the relaxation due to this reaction is much faster than the resolution time of the present apparatus. In practice, the rapid increase of iodine and decrease of triiodie within 0.7 μs were observed at 550 and 350 nm, respectively, which indicates Reaction 1 is responsible for the fast process. Reaction 2 occurs predominantly at considerably high ionic strength of 2.0 M,[4] and then can be discared in the present system of low ionic strength (I=0.023 M). Reaction 3 is also eliminated from the possible origin of the relaxation because of the positive value of the enthalpy change reported for Reaction 3[3] ($\Delta H_3 \simeq 12$ kcal/mol) resulting in the decrease of iodine concentration with the temperature rise. Finally, Reaction 4 is remained as a plausible mechanism. The relaxation time for the Reaction 4 which is coupled with the fast reaction of triiodide complex formation, can be written as

$$\tau^{-1} = k_{-4}\left\{1+\frac{4K_1K_4(I_2+I^-)I_3^-}{1+K_1(I_2+I^-)}\right\}. \quad (5)$$

In this equation, the second term which can be calculated by using the values of K_1=732 M^{-1} [3] and K_4= 0.42 M^{-1} [1] is far smaller than unity. Thus, Eq. (5) can be transformed to

$$\tau^{-1} = k_{-4}. \quad (6)$$

Firstly, this equation implies that the relaxation time is independent of the concentration of any reaction species, satisfying the present experimental results in Fig. 2. Secondly, the insensitive temperature dependence of the relaxation time in Fig. 3 is consistent with the small and negative value of the enthalpy change (ΔH_4 = −0.77 kcal/mol)[1] for Reaction 4.[8] Thirdly, the increase of both iodine and triiodide concentrations during the relaxation is also consistent with the negative value of ΔH_4. These facts finally enable us to assign the observed relaxation to Reaction 4, and an application of Eq. (6) to the present data gives the values of k_4 and k_{-4} to be 2.2×10^5 M^{-1} s^{-1} and 5.3×10^5 s^{-1} respectively. The obviously small value of binding rate constant k_4 compared with that of the diffusion controlled process suggests the existence of further elementary steps in Reaction 4, but the detailed discussion on the elementary process can not be advanced at the moment.

In conclusion, the relaxation phenomenon observed in the iodine-iodide solutions was assigned to the polyiodide complex formation of I_6^{2-} among the several kinds of complex formations proposed from the spectrophotometric studies. The kinetic studies of the interaction between cyclodextrin and iodide will be reported in a subsequent paper by taking into consideration the polyiodide complex formation.

8) In the case of negative value of ΔH_4, the activation enthalpy of backward $\Delta H^{\ddagger}_{-4}$ should be greater than $|\Delta H_4|$. Accordingly, the enthalpy change ΔH_4 less than −2.0 kcal/mol gives rise to the temperature dependence of relaxation time beyond the experimental errors of about 10%.

Behavior of Amine in Rhodium Complex-Tertiary Amine Catalyst System Active for Hydrogenation of Aldehyde under Oxo Reaction Conditions

Tsutomu MIZOROKI, Mamoru KIOKA, Masayasu SUZUKI, Shiro SAKATANI, Atsushi OKUMURA, and Ken-ichi MARUYA*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received July 11, 1983)

Synopsis. The title reaction was investigated to elucidate the reported disagreements on the kinetics. The concentration and the coordination stability of amine were found to affect the optimum pressure of carbon monoxide and the kinetics, and were suggested to control the reaction mechanism.

Rhodium complex is very active for the hydroformylation of olefin,[1-3] but not so effective for the hydrogenation of aldehyde under the hydroformylation conditions.[3,4] The addition of tertiary amine to the rhodium catalyst, however, markedly facilitates the hydrogenation to make possible one step synthesis of oxo alcohol.[5] With the system of rhodium complex and tertiary amine, the hydroformylation of olefin,[5-7] the hydrogenation of aldehyde,[6,7] and the selective hydrogenation of α,β-unsaturated aldehyde to alcohol[8,9] have been studied, but different optimum pressures of carbon monoxide,[5,9] and linear[6,7] and nonlinear[5,9] dependences on the pressure have been reported. It is accepted that anionic clusters of rhodium are formed in the presence of amine,[7] but the interaction of amine with the rhodium complex is not clear. In this paper we wish to clarify the behavior of amine in the system of rhodium complex and tertiary amine, and to describe a cause of disagreement on the effect of carbon monoxide.

Experimental

$[Rh_2Cl_2(CO)_4]$[10] and $[Rh(acac)(CO)_2]$[11] were prepared according to the procedures in the literatures. Amines were, on occasion, distilled from CaH_2, but typically used without further purification. Aminated polystyrene (Found: H; 9.0, C; 84.4, N; 5.5, Cl; 0.0%) was prepared as described in a previous paper.[9] Other reagents of guaranteed grade were used without further purification. The reactions of hydrogention and hydroformylation, and the reaction of $[Rh_2Cl_2(CO)_4]$ with aminated polystyrene were carried out as described in a previous paper.[9]

Results and Discussion

Figure 1 shows the dependence of the yield of heptanol in the hydroformylation on the content of 1-hexene. The obvious inhibition by olefin is seen on the hydrogenation, but not the hydroformylation. The similar inhibition by carbon monoxide is seen in Fig. 2. Since the yield of alcohol is independent of the concentration of aldehyde in spite of the high pressure of carbon monoxide as shown in Fig. 3, these inhibitions seem to indicate the competitive coordination of olefin and carbon monoxide with amine rather than aldehyde. The optimum pressure of carbon monoxide, P_{CO}(Max), where the highest yield of alcohol is

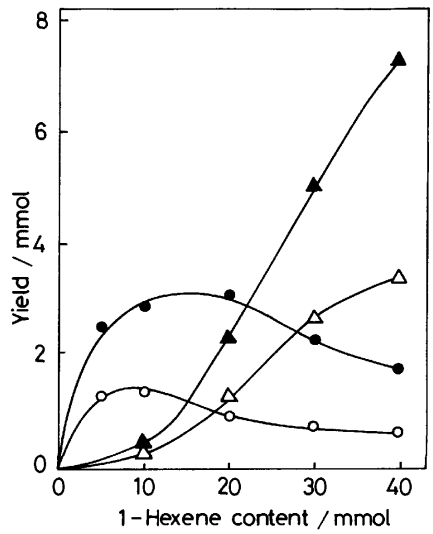

Fig. 1. Dependence of alcohol yields on 1-hexene content in hydroformylation of 1-hexene with $Rh_2Cl_2(CO)_4$ (0.05 mmol) and *N*-methylpyrrolidine (20 mmol) in benzene (20 ml) at 60 kg/cm^2 (P_{H_2}/P_{CO}=1) and 80 °C for 20 min.

N-Methylpyrrolidine; ●: 2.5 mmol, ◑: 5 mmol, ○: 10 mmol.

obtained, seems to increase with an increase in the concentrtion of amine (Fig. 2). Figure 4 shows a good correlation between P_{CO}(Max) and the concentration of amine, including reported P_{CO}(Max)s.[5,9] This indicates that the coordination of amine on the rhodium complex is competitive with carbon monoxide, although Jurewicz *et al.*[7] proposed an equilibrum

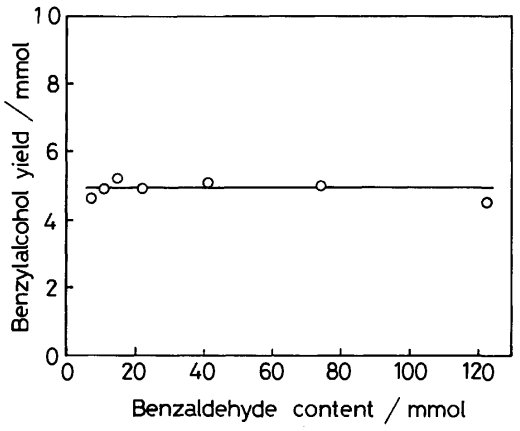

Fig. 3. Dependence of benzyl alcohol yield on content of benzaldehyde in hydrogenation of benzaldehyde with $Rh(acac)(CO)_2$ (0.05 mmol) and *N*-methylpyrrolidine (10 mmol) in benzene (20 ml) at 40 kg/cm^2 (P_{CO}) and 30 kg/cm^2 (P_{H_2}) and 60 °C for 30 min.

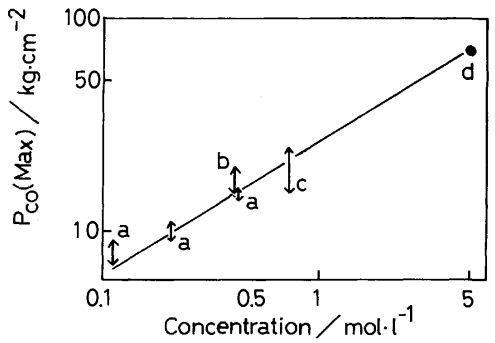

Fig. 4. Dependence of P_{CO}(Max) on concentration of *N*-methylpyrrolidine.
a) Hydrogenation of benzaldehyde at 30 kg/cm^2 (P_{H_2}) and 80 °C. b) Hydrogenation of benzaldehyde at 30 kg/cm^2 (P_{H_2}) and 60 °C. c) Hydrogenation of cinnamaldehyde at 40 kg/cm^2 (P_{H_2}) and 80 °C (Ref. 8). d) Hydroformylation of 1-hexene at 75 kg/cm^2 (P_{H_2}) and 90 °C (Ref. 5).

between $[HRh_x(CO)_y(NR_3)]$ and $[HNR_3^{\ddagger}\cdot Rh_x(CO)_y^{-}]$. Thus, it is concluded that the reported difference of P_{CO}(Max)s[5,9] is because of the different concentrations of amine. In the presence of carbon monoxide and amine, rhodium carbonyl complexes easily transform into anionic clusters,[7,13,14] suggesting that the interacton of amine with rhodium complex may be written as Eq. 1,

$$Rh_x(CO)_{y+1}^{n-} \underset{CO}{\overset{NR_3}{\rightleftharpoons}} Rh_x(NR_3)(CO)_y^{n-} \underset{NR_3}{\overset{olefin}{\rightleftharpoons}} Rh_x(olefin)(CO)_y^{n-}, \quad (1)$$

where $[Rh_x(NR_3)(CO)_y^{n-}]$ and $[Rh_x(olefin)(CO)_y^{n-}]$ may be active for the hydrogenation of aldehyde and the hydroformylation of olefin, respectively.

The results with the catalyst system of polymer amine are different from that of monomer amine. The hydroformylation of 1-hexene (10 mmol) in benzene (20 ml) at 80 °C and 60 kg/cm^2 ($P_{CO}/P_{H_2}=1$) for 60 min with $[Rh_2Cl_2(CO)_4]$ (0.05 mmol) and aminated polystyrene (0.75 matom-N) gave 1.0 mmol of heptanal, 0.9 mmol of 2-methylhexanal, 3.0 mmol of 1-heptanol, and 1.7 mmol of 2-methyl-1-hexanol. Further addition of the polymer (5 matom-N) resulted in no further increase in the yields. These results contrast with the cases of monomer amine where large amounts of amine are used.[5,7-9] It is known that $[Rh_2Cl_2(CO)_4]$ firmly interacts with aminated polystyrne.[6,7,9] $[Rh_2Cl_2(CO)_4]$ (0.05 mmol) was treated with aminated polystyrene (0.5 matom-N) in toluene (20 ml) to give colorless solution and brown polymer while evolving carbon monoxide. In N/Rh>10 the polymer-anchored rhodium complex showed no absorption band in ν(CO) region, while in N/Rh<5 three bands at 2060 (w), 1985 (s), and *ca.* 1800 cm^{-1} (w, broad) due to ν(CO)[9] were observed. These results indicate that polymer amine strongly interacts with rhodium complex to exclude carbon monoxide ligand, leading to a first order dependence on carbon monoxide.[6,7] Thus, it can be concluded that the kinetic disagreement of polymer amine system with monomer one comes from the difference of their coordination stability, though Jurewicz *et al.*[7] attributed the disagreement to the difference of reaction conditions.

The difference between polymer and monomer amines seems to bring about the different dependence on the concentration of aldehyde, *i.e.*, zero order with monomer amine system (Fig. 3) and first order with polymer one.[6] These kinetic difference might suggest different reaction mechanisms. Taking into account the first order dependence on the pressure of hydrogen,[5,6,9] the formation of rhodium hydride with monomer amine system may be a slow step followed by a fast reaction of the hydride with aldehyde, while the coordination of aldehyde or the reaction of a hydride with aldehyde on polymer-anchored rhodium complex may be slow.

A Study of the Thermal Decomposition of Ruthenium Ammine Zeolites

Takashi TATSUMI,* Wataru MAEKAWA, and Hiro-o TOMINAGA
Departmet of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received July 16, 1983)

Synopsis. Treatment of Ru(II) ammine-NaY under nitrogen at 100 and 300 °C leads to formation of $[Ru(NH_3)_5N_2]^{2+}$-NaY and metallic Ru-N_2, respectively. The effect of atmosphere and the type of Ru ammine complexes and zeolites on the decomposition behavior is discussed.

Metal ions can be introduced into zeolites by cation exchange. This ion exchange procedure is expected to give metal catalysts with a highly dispersed metal phase with superior properties to catalysts prepared by impregnation with simple metal halide salts.[1] Recently much attention is being devoted to the catalytic activity of zeolite-supported Ru,[2-5] since Ru has been shown to be one of the best catalysts for the hydrogenation of CO.[10] The preparation of Ru-containing zeolites *via* ammine complexes has been successful and shows promise as an advantageous route to industrially important catalysts.[4-9] Ruthenium is also known to be a highly effective metal for the activation of nitrogen and adsorbs a significant amount of nitrogen during ammonia synthesis, when K is added. Adsorbed or coordinated nitrogen is infrared active in the $\approx 2000\,cm^{-1}$ region of the spectrum.[11] In this paper we describe the IR results of zeolite-supported Ru ammine complexes during heating processes under a nitrogen atmosphere.

Experimental

$[Ru(NH_3)_6]Cl_2$ was prepared by the method of Allen and Senoff.[12] $[Ru(NH_3)_6]Cl_3$ was purchased from Strem Chemicals. The $[Ru(NH_3)_6]^{2+}$ cation was exchanged into the zeolite NaY (Ru content *ca.* 4 wt%) in deoxygenated water under a nitrogen atmosphere. The pH of the exchanged solution was adjusted to 4.5 by the addition of hydrochloric acid. $[Ru(NH_3)_6]^{3+}$ cation was exchanged into the NaY or HY zeolite (Ru *ca.* 4 wt%). In this case no attempt was made to control the pH of the solution. The zeolites were filtered, washed with water and then with ethanol, and dried under vacuum at room temperature for 2 d. Samples for IR investigations were prepared in the form of wafers having a diameter of 20 mm and weights between 25 and 35 mg. IR spectra were recorded on a Nihon Bunko IRA-2 grating spectrophotometer. The wafers were heated to desired temperature in a stream of nitrogen or helium, maintained at that temperature for 30 min, and then subjected to IR analysis at room temperature.

Results and Discussion

The ammine complex $[Ru(NH_3)_6]^{2+}$ was exchanged into the Na-Y zeolite and the zeolite obtained was degassed for 2 d at room temperature. The IR spectrum of the fresh zeolite sample (Fig. 1a) showed three significant bands assigned as follows: $1640\,cm^{-1}$ (very strong, $\delta_d(NH_3)$ in conjunction with adsorbed water), $1450\,cm^{-1}$ (weak, $\delta_d(NH_4)$) and $1320\,cm^{-1}$ (strong, $\delta_s(NH_3)$). The $\delta_s(NH_3)$ band at $1220\,cm^{-1}$ which is characteristic of the original $[Ru(NH_3)_6]Cl_2$ complex,[12] has been shifted by $100\,cm^{-1}$ to higher wavenumber upon exchange into the zeolite. When the pale yellow $[Ru(NH_3)_6]^{2+}$-NaY zeolite sample was kept for a few days under an inert atmosphere, the zeolite turned purple and the band at $1450\,cm^{-1}$ increased in intensity, while the band at $1320\,cm^{-1}$ was shifted to $1340\,cm^{-1}$ and weakened (Fig. 1b). This finding indicates a part of Ru(II) ions has undergone the hydrolysis as follows:

$$[Ru^{II}(NH_3)_6]^{2+}\text{-NaY} + H_2O \longrightarrow [Ru^{III}(NH_3)_5OH]^{2+}\text{-NaY} + NH_4^+.$$

This reaction is closely similar to that proposed by Laing *et al.* to account for the color change of $[Ru(NH_3)_5N_2]^{2+}$-NaY upon storage.[8] This purple zeolite designated as RuNaY was used for the subsequent experiment.

As shown in Fig. 2a, the IR spectrum of the freshly prepared $[Ru(NH_3)_6]^{3+}$-HY sample displayed two intense bands at $1640\,cm^{-1}$ ($\delta_d(NH_3)$ plus $\delta_d(H_2O)$) and $1440\,cm^{-1}$ ($\delta_d(NH_4)$). The band around $1350\,cm^{-1}$ which is typical of deformation band of coordinated NH_3 of $[Ru(NH_3)_6]^{3+}$ was not observed.[12] This fact suggess that the NH_3 ligands which had been present in the coordination sphere of Ru migrated to Brønsted acid site of the zeolite. This is contrasted with the results obtained with the fresh $[Ru(NH_3)_6]^{3+}$-NaY zeolite, which showed an intense band at $1340\,cm^{-1}$ ($\delta_s(NH_3)$) and a very weak NH_4 deformation band.[9]

Figure 1c shows the IR spectrum of RuNaY when

heated under N_2 at 100 °C. The band at 1340 cm^{-1} was attenuated and the strong band developed at 2135 cm^{-1}. The latter may be assigned to the stretching frequency of a coordinated nitrogen molecule and suggested the formation of $[Ru(NH_3)_5N_2]^{2+}$–NaY which was first prepared by Laing *et al.* by the addition of hydrazine to $[Ru(NH_3)_5NO]^{3+}$–NaY.[8] Atmospheric nitrogen seems to have substituted one NH_3 ligand from the residual $[Ru(NH_3)_6]^{2+}$ ion in RuNaY, although this type of simple displacement reaction in solution has not been reported. A similar treatment of RuNaY under helium at 100 °C resulting in the spectrum lacking the band around 2135 cm^{-1}. Recently Aika *et al.* found that N_2 is adsorbed on a support with K[13] or a basic support such as CaO and MgO_2.[14] Thus the band at 2135 cm^{-1} might be due to a N_2 species adsorbed on the NaY support. No band corresponding to the adsorbed N_2 species was found over NaY. It is well known that transition metals which bind nitrogen molecules are in low oxidation states;[15,16] no nitrogen complex of Ru(III) has been reported. As we would expect, treatment of $[Ru(NH_3)_6]^{3+}$–NaY or HY with N_2 at 100 °C afforded a spectrum with no N–N band. From these results we assumed that N_2 is coordinated to a Ru(II) species encaged in NaY.

When RuNaY was subsequently heated at 200 °C, the band at 2135 cm^{-1} was weakened and the band at 1340 cm^{-1} was shifted to 1295 cm^{-1} (Fig. 1d). Subsequent heating at 300 °C resulted in a new band at 2000 cm^{-1} (Fig. 1e). Since its frequency is too low to regard as that arising from ionic Ru species,[15,16] the band is attributable to ν(NN) of a nitrogen molecule chemisorbed to Ru(0) (presumably metallic ruthenium in view of the absence of the band at 1295 cm^{-1}). An almost identical spectrum resulted from the treatment of $[Ru(NH_3)_6]^{3+}$–NaY with N_2 at 300 °C. Heating the samples at 350 °C resulted in the removal of the bands at 2000 and 1450 cm^{-1}, as shown in Fig. 1f. It should be noted that Laing *et al.* have observed a band at 2000 cm^{-1} on the reaction of $[Ru(NH_3)_x(NO)]Y$ with NH_3 at 150 °C.[8] Treatment of RuNaY under helium at 300 °C resulted in only a weak band at 2000 cm^{-1}; the presence of N_2 greatly enhanced the intensity of the ν(NN) band. The nitrogen molecule observed in the case of the treatment under a helium flow is ascribed to the decompsition of the NH_3 ligands. Verdonck *et al.* have shown that on degassing $[Ru(NH_3)_6]^{3+}$–NaY the complex is reduced to the metallic state accompanied by the liberation of N_2.[6]

Treatment of $[Ru(NH_3)_6]^{3+}$–HY with N_2 at 300 °C yielded a band at 2025 cm^{-1}, as shown in Fig. 2d. The difference in wavenumber between the ν(NN) bands in the two zeolites should be accounted for in terms of electron defficiency in the metal on HY. The electron-acceptor strength of the zeolite is expected to increase in the direction NaY<HY. The electron concentration in the metal would decrease accordingly, thus decreasing electron donation to N_2. The bands might be due to N_2 species adsorbed on the zeolite supports but they were observed for neither NaY nor HY without Ru. The acidic property of the HY zeolite is also responsible for the persistence of the $\delta_d(NH_4)$ band during the heating process (Fig. 2d). After the treatment at 300 °C, the $\delta_d(NH_4)$ band was scarcely observed with the RuNaY zeolite, while the $[Ru(NH_3)_6]^{3+}$–HY sample still retained 40—50% of its NH_4^+ (as estimated from the intensity of $\delta_d(NH_4)$).

Determination of the Vapor Pressures of Cesium Fluoride and Cesium Chloride by Means of Surface Ionization

Hiroyuki KAWANO,* Tsutomu KENPŌ, and Yoshiaki HIDAKA
Department of Chemistry, Faculty of Science, Ehime University, 2-5, Bunkyō-chō, Matsuyama 790
(Received August 3, 1983)

Synopsis. A molecular beam of CsF or CsCl effusing from a Knudsen cell was detected with a heated rhenium filament, and the vapor pressure P (in atm) of each halide at a temperature T (in K) was found to be expressed by $\log_{10} P(\mathrm{CsF})=(7.239\pm0.072)-(9883\pm72)/T$ for 630—830 K, $\log_{10} P(\mathrm{CsCl})=(7.269\pm0.064)-(10054\pm66)/T$ for 640—820 K.

When a beam intensity of molecules (MX) effusing from a Knudsen cell at a given temperature is evaluated thermodynamically, it is necessary to know the accurate value of the vapor pressure (P(MX)) at the temperature. Literature values of P(MX), however, are generally in poor agreement with each other. For example, P(CsF) changes from literature to literature by up to ≈6 times. This fact suggests that further investigations should be made with many samples in order to obtain reliable data on the pressure.

From the viewpoint mentioned above, the present authors have tried to measure accurately the pressures of CsF and CsCl using a positive surface ionization technique developed in their laboratory and also to determine the entropy and enthalpy changes due to molecular sublimation. The results thus obtained are summarized together with literature values, thereby indicating that the present method is quite useful for pressure measurements.

Experimental

Sectional views of the present instrument are shown in Fig. 1, where F is the ionizing filament (0.013 cm in diameter) made of rhenium; B the stainless steel box; R the rotatable shutter; P the shield plate; K the Knudsen cell made of stainless steel; H the molybdenum wire heater; W the pipe for cooling water; A_1 and A_2 the calibrated alumel-chromel thermocouples; and C the Faraday cup. A molecular beam of cesium halide (CsX) effusing from the exit slit S_1 (0.12 cm in diameter) impinged upon F after passing through the inlet slit S_2 (0.17 cm in diameter). The ion-extraction voltage applied to F was usually 50 V. A part of the positive ions (Cs^+) emitted from F was collected with C, and the ion current ($i^+(Cs^+)$) was measured with a vibrating reed electrometer. The collection efficiency of the ions was 1.45 ± 0.03%, which was determined in a separate experiment by simultaneous measurement of the ion currents collected by B and C. Accordingly, the total ion current ($I^+(Cs^+)$) is equal to $i^+(Cs^+)/0.0145$. The residual gas pressure inside the vacuum vessel containing the above system was usually $\approx2\times10^{-7}$ Torr (1 Torr≈133.322 Pa). The temperatures (T and T_F) of the cell and the filament were determined with A_1 and an optical pyrometer, respectively. The temperature measured with A_1 was always higher by up to ≈3K than that with A_2. The samples (CsF and CsCl) of optical grade were obtained from Aldrich Chem. Co., Inc., and Wako Pure Chem. Ind., Ltd., respectively.

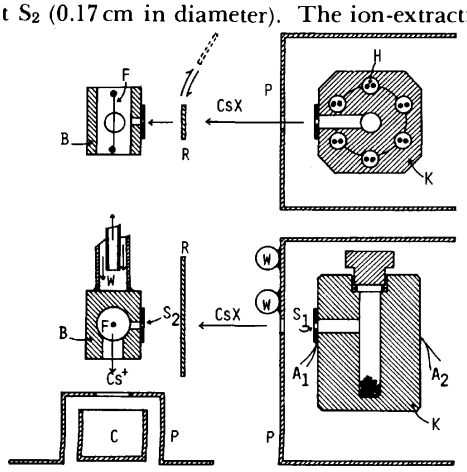

Fig. 1. Horizontal and vertical sectional views of the instrument employed in this work.

Results and Discussion

When the cell containing CsF was heated to 824 K, for example, $I^+(Cs^+)$ was constant at $(4.50\pm0.21)\times10^{-8}$ A without depending upon the filament temperature so long as T_F was higher than ≈1300 K. In this range, therefore, the ionization efficiency of the molecules incident upon F may be concluded to be essentially 100%. A similar result was obtained with CsCl, too. These results may be natural because the first ionization energy (≈3.9 eV) of Cs is much smaller than the effective work function (≈5.4 eV) of Re for positive ion production.[1]

Consideration of the present experimental method and of gas kinetics[2] leads to the following equations:

$$P(\mathrm{CsX}) = \frac{\pi L^2[2\pi M(\mathrm{CsX})RT]^{1/2}}{1.013\times10^6 N_A S_C} N(\mathrm{CsX}), \quad (1)$$

$$N(\mathrm{CsX}) = \frac{I^+(Cs^+)}{e S_F}. \quad (2)$$

Here, P(CsX) is the vapor pressure (in atm) in the cell; L the distance (6.5 cm) between the cell orifice and the ionizing filament; M(CsX) the molecular weight of CsX; R the gas constant; N_A the Avogadro's number; S_C the effusing slit area (1.13×10^{-2} cm^2) of the cell; N(CsX) the flux of sample molecules (in cm^{-2} s^{-1}) at L; e the elementary electric charge; and S_F the sectional area (2.16×10^{-3} cm^2) of the filament intercepting the molecular beam. Consequently, we obtain the relation:

$$P(\mathrm{CsX}) = 1.27[M(\mathrm{CsX})T]^{1/2} I^+(Cs^+), \quad (3)$$

where $I^+(Cs^+)$ is expressed in ampere.

A typical result obtained by the present authors is shown, together with results by other workers,[3-5] in Fig. 2, which leads to a general expression as follows:

$$\log_{10} P(\mathrm{CsX}) = A - B/T. \quad (4)$$

The values of both A and B determined in this work and also cited from literatures[3-8] are summarized in Table 1, where the pressures at three selected tempera-

a) 1 cal=4.184 J.

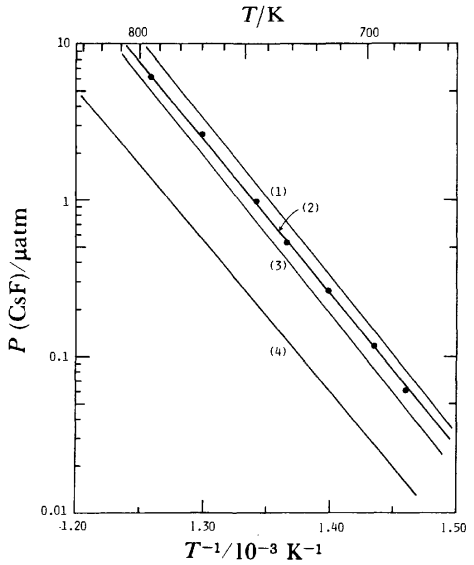

Fig. 2. Temperature dependence of the vapor pressure observed with CsF. (1): Ref. 3, (2): this work at T_F=1600 K, (3): Ref. 4, (4): Ref. 5.

tures are evaluated by substituting the respective values of A and B in Eq. 4. The entropy change due to sublimation ($\Delta S(\bar{T})$) and the heat of sublimation ($\Delta H(\bar{T})$) at the mean temperature ($\bar{T}$) in the range (T_R) covered in each measurement are evaluated from Eqs. 5 and 6, respectively, where 1 cal is equal to 4.184 J.

$$\Delta S(\bar{T}) = (\ln 10)\, R\, A \equiv 4.575\, A \quad \text{cal mol}^{-1}\,\text{K}^{-1}. \tag{5}$$

$$\Delta H(\bar{T}) = (\ln 10)\, R\, B \equiv 4.575 \times 10^{-3}\, B \quad \text{kcal mol}^{-1}. \tag{6}$$

The heat of sublimation at 300 K is given by

$$\Delta H(300) = \Delta H(\bar{T}) + \int_{300}^{\bar{T}} [C_P(\text{c}) - C_P(\text{g})]\,dT, \tag{7}$$

$$\simeq \Delta H(\bar{T}) + a\, R\, (\bar{T} - 300). \tag{8}$$

Here, C_P(c) and C_P(g) are the specific heats of CsX at crystalline and gaseous states, respectively. According to data compiled in Ref. 9, Eq. 7 may be approximated by Eq. 8, where the values of a in the range 300—800 K are taken as 2.34 and 2.47 for CsF and CsCl, respectively.

The temperatures of the ionizing filament in the cases (a)—(e) indicated in the last column in Table 1 were 1910, 1600, 1450, 2108, and 2215 K, respectively. The data (A) and (B) are the mean values of those (a)—(c) and those (d)—(e), respectively. In the case of CsF, the values in Refs. 3 and 4 and Ref. 5 are close to and apart from those in this work, respectively, as may be seen in Fig. 2 and Table 1. Our data on CsCl fall between those in Ref. 3 and those in Ref. 7, and most deviate from those in Ref. 6. Consequently, the data in Refs. 5 and 6 seem to be less accurate probably because of a systematic error.

Conclusion

The positive surface ionization method is quite useful for determining the vapor pressure of cesium halide without citing any thermochemical value from literatures, and hence for checking the accuracy of published data on the pressure. Since the effective work function of an oxygenated tungsten wire for positive ion production is ≈6.7 eV,[1] the ionization efficiency of element having the ionization energy less than ≈6 eV is generally expected to be essentially unity when the wire at a suitable temperature is employed as a beam detector. Therefore, the present method may also be applicable to those salts which include a readily ionized element[1] such as alkali metal, alkaline earth, actinoid, or lanthanoid.

On the Reduction Products of Carbon Dioxide at a p-Type Gallium Phosphide Photocathode in Aqueous Electrolytes

Kaname Ito,* Shoichiro Ikeda, Makoto Yoshida, Soji Ohta, and Takaya Iida
Department of Synthetic Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received August 22, 1983)

Synopsis. Formic acid, formaldehyde, and methanol, previously reported as photoelectrochemical reduction products of CO_2, were observed to be obtained also by photolysis of cell materials such as electrolytes and epoxy resin. The reduction product of CO_2 at a p-GaP photocathode in aqueous electrolytes was experimentally confirmed to be mainly formic acid.

Halmann[1] observed formic acid, formaldehyde, and methanol as reduction products of CO_2 at a p-type gallium phosphide (p-GaP) photocathode in aqueous lithium carbonate electrolyte. Tamura *et al.*[2] reported that their yield increased with addition of crown ether to the electrolyte. In our similar experiments[3] oxalic acid, glycolic acid, ethanol, and acetaldehyde were also observed.

Here, similar organic compounds will be shown to be produced also by photolysis of cell materials such as electrolytes and epoxy resin. When experimental conditions were improved so as to produce no organic compound as a photolytic product, the products obtained by photoelectrochemical reduction of CO_2 in aqueous electrolytes were mainly formic acid.

Experimental

The photoelectrochemical cell with a quartz window was made of Teflon. The structure was designed to separate the cathode chamber from the anode chamber by an ion-exchange membrane, Nafion-315, and to allow operation with a small volume of catholyte of *ca.* 5 ml for easy determination of the products.

The photocathode was prepared by molding p-GaP wafer of *ca.* 1 cm^2 with epoxy resin; it was etched in aqua regia for 1 min before use. The photocathode set in the cell was illuminated through the quartz window and aqueous electrolytes by a 300 W Xenon lamp (Varian). The platinum plate served as an anode and the silver–silver chloride electrode as a reference electrode.

The electrolytes used were 0.1 mol dm^{-3} aqueous solutions of Li_2CO_3, $(C_2H_5)_4NClO_4$ (TEAP), $(C_2H_5)_4NBr$ (TEABr), $(n\text{-}C_4H_9)_4NBr$ (TBABr), and Li_2CO_3 plus 15-crown-5.

The products were detected and determined by high performance liquid chromatography on a column of Shodex HC-125S for carboxylic acids and by steam chromatography on a column of Chromosorb 101 for alcohols and aldehydes.

Results and Discussion

Photoelectolysis as a blank test of the present experiment was performed by bubbling N_2 gas instead of CO_2 to Li_2CO_3 or TEAP solution in the above mentioned cell and by illuminating the p-GaP photocathode with the Xenon lamp. The results are shown in Table 1, in which the results previously reported as photoelectrochemical reduction products of CO_2 are also listed for comparison. The products in N_2 and in CO_2 atmospheres are quite similar, so that they are assumed to be produced by photolysis of cell materials such as electrolytes and epoxy resin.

In order to determine the photolytic products from various electrolytes, they were individually illuminated in quartz test tubes by a 300 W Xenon lamp alone or with the UV-37 filter, Toshiba, to cut off light of wavelength shorter than 370 nm. The results, as summarized in Table 2, show that the photolysis of the electrolytes by illumination of the Xenon lamp alone produces acetaldehyde from TEABr and TEAP, acetaldehyde and ethanol from TBABr, and many kinds of products from 15-crown-5, and also that the photolysis of them by the Xenon lamp with the filter does not produce any organic compounds from TEABr, TEAP, and TBABr, but a large amount of formic acid and a small amount of oxalic acid from 15-crown-5.

The comparison of the results shown in Tables 1 and 2 suggests that formic, oxalic and glycolic acids are produced by photolysis of epoxy resin used for mount-

Table 1. Photoelectrolytic products under N_2 and CO_2 atmospheres in the cell with various electrolytes and a p-GaP photocathode molded by epoxy resin

Photoelectrolysis was performed up to 10 C at −1.2 V *vs.* Ag/AgCl electrode by illuminationg with a 300 W Xenon lamp alone.

ing of a p-GaP electrode. This was experimentally confirmed, although the results are not shown in the present paper.

However, the photolysis of the electrolytes and epoxy resin as cell materials could be prevented, as shown in Tables 3, when the epoxy resin region of a p-GaP electrode was shielded by a platinum foil, the UV-37 filter was set in front of the Xenon lamp to cut off ultraviolet rays, and TEABr, TEAP, or TBABr (except 15-crown-5) was used as an electrolyte.

Under such improved experimental conditions, the photoeletrochemical reduction of CO_2 was carried out up to 100 C at −1.5 V *vs.* Ag/AgCl electrode. The products, as shown in Table 4, were mainly formic acid and sometimes a trace amount of formaldehyde plus methanol.

Accordingly, it may be concluded that the photoelectrochemical reduction products of CO_2 at a p-GaP electrode in aqueous electrolytes are mainly formic acid and the many kinds of products involving large part of formic acid in the previous papers[1-3] are due to photolysis of cell materials. This conclusion coincides with the previously reported fact that only formic acid is mainly produced by electrochemical reduction of CO_2 in aqueous electrolytes.[4,5]

The Sensitization Effect in the Laser-induced Infrared Fluorescence Spectroscopy by Addition of a Second Component. III

Seiichiro HIGUCHI,* Yasuhiro KAGAWA, and Shigeyuki TANAKA

Departmet of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 25, 1983)

Synopsis. The sensitization effect in the infrared fluorescence spectra for diethyl ether–alkene systems has been examined in terms of the quantity and the kind of alkenes added as sensitizers. The sensitivity seems to be determined by the molar ratios between diethyl ether and alkenes, and the sensitization degree lowers in an orderly fashion as the alkene molecules become larger.

In the previous papers,[1,2] we examined the sensitization effect in the laser-induced infrared fluorescence (IR-F) spectroscopy, which was realized when some alkene compounds were added as second components. The degree of sensitization was examined quantitatively in terms of the concentrations of diethyl ether as an objective sample. In the present investigation, we have examined this sensitization effect for the same sample in view of the influence of the quantity and the kind of alkene compounds as the sensitizer.

Experimental

The experimental arrangement for the measurement of IR-F spectra is the same as that described in the previous papers.[1,2] The samples are vibrationally excited with the irradiation of the 10.6 μm lines from a CO_2 laser (output power: 3 W), and the emitted light from samples is spectrally measured. Diethyl ether was used as a sample, and the alkenes such as ethylene, propylene, 1-butene, 1-pentene, and 1-hexene were added as the sensitizing agents. The 8.7 μm band (C–O–C stretching vibration band) of diethyl ether was used as a key band. The measurements were all made for samples in the gaseous state.

Results and Discussion

The Relation between the Degree of Sensitization and the Quantity of a Sensitizing Agent. It was reported in the previous paper[2] that the degree of sensitization increases to a great extent as the concentrations of diethyl ether become lower. It will be reasonable to consider that the sensitivity depends also on the quantity of sensitizing agents. Thus, we have examined the influence of the partial pressure of added alkenes on the sensitized IR-F intensities of the 8.7 μm band of diethyl ether. In Fig.1 are plotted the values of $H_{8.7}/P_E$ ($H_{8.7}$: the peak intensity of the 8.7 μm band of diethyl ether, P_E: the partial pressure of diethyl ether) against the partial pressure of propylene, P_P. $H_{8.7}/P_E$ can be regarded as the intensity per unit concentration of diethyl ether, and therefore, this variable is considered to be a measure of the spectral sensitivity. It is seen that the sensitivity clearly depends on P_P, though the changes of $H_{8.7}/P_E$ with P_P are more gentle than the dependence of $H_{8.7}/P_E$ on P_E.[2] It appears that there is an optimum range of P_P to give the maximum degree of sensitization.

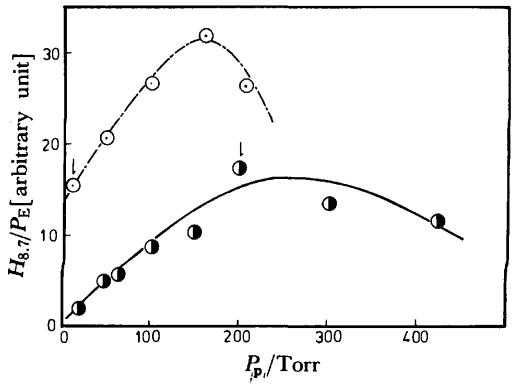

Fig. 1. Plots of values of $H_{8.7}/P_E$ *vs.* P_P on diethyl ether–propylene mixed sample.
$H_{8.7}$: Peak height of 8.7 μm band of diethyl ether, P_E: partial pressure of diethyl ether, P_P: partial pressure of propylene. ◑: P_E=20 Torr, ⊙: P_E=1 Torr. The data marked with arrows correspond to molar ratio of 1:1 (diethyl ether:propylene).

We examined the fashion of the curves in Fig. 1 in view of the kinetics of the energy transfers relating to the infrared emissions in question. We assume that five vibrationally excited energy levels are involved in the kinetics of the energy transfers. One of them is a level of propylene which is responsible for the absorption of the exciting laser light, and the others are those of diethyl ether. Three of the latter four levels yield the infrared emission bands, and the remaining one is representative of all other levels. Moreover, we assume that the sample system is in the stationary state. Under these conditions, the following expression is derived for the population of the emitting energy levels, *i.e.*,

$$X_i = \frac{A_iP_S^5+B_iP_S^4+C_iP_S^3+D_iP_S^2+E_iP_S+F_i}{P_S^5+G_iP_S^4+H_iP_S^3+I_iP_S^2+J_iP_S+K_i}, \quad (1)$$

where X_i is the population of the i-th energy level of the objective sample molecule, resulting from the energy transfers, P_S is the partial pressure of the sensitizer (in this case, P_P), and A_i, B_i, *etc.*, are the constants related to the rate constants for various energy transfers. Formula (1) predicts that when P_S becomes greater, the fashion of the change of X_i (consequently, the fashion of the intensity change of the i-th emission band) becomes gradually flat, converging ultimately to a constant, A_i. This partly explains the fashion of the curves in Fig.1.

Concerning the reason why the sensitivity lowers when P_P becomes greater than a certain magnitude, the following considerations may be possible. The first is the lowering of the effective absorption coefficient of propylene at 10.6μm because of the pressure broadening of rotational lines responsible for the absorption. The second is the weakening of the intensity of the exciting laser light due to the absorption of the added component. The third is that when the number of propylene molecules becomes much larger than that of diethyl ether, the energy first absorbed by propylene molecules may be transferred mainly to the same molecules rather than to diethyl ether. Of course, these are only speculations, and it is highly probable that some other factors play essential roles in the experimental results in question. The problem is related to the mechanism of the

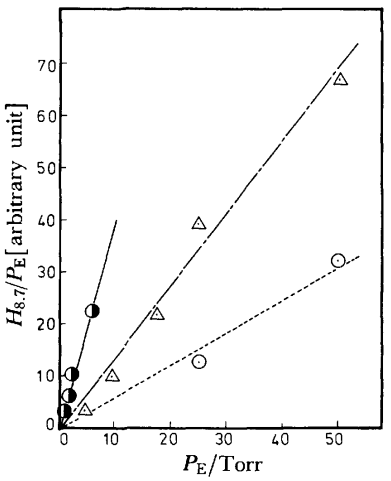

Fig. 2. Effect of molar ratios of diethyl ether to ethylene on the relations between IR-F intensities of 8.7 μm band of diethyl ether and P_E.
◑: 1:100 (diethyl ether:ethylene), △: 1:5, ⊙: 1:1. The points in the case of the molar ratio of 1:1 are only a part of the data up to P_E=100 Torr, which fit well to the straight line shown in the figure.

sensitization effect, and we are not in a position to make further mention of it in the present note.

It is noteworthy that the optimum range of P_p in the case of both P_E=20 Torr (1 Torr≈133.322 Pa.) and P_E=1 Torr seems to be not so different. This fact can be favourably utilized when the effect in question is made use of in analytical applications. Furthermore, it is also noticeable that the values of $H_{8.7}/P_E$ corresponding to the equal molar ratio between diethyl ether and propylene appear to be constant.

Therefore, we have examined the IR-F intensities in terms of the molar ratios between diethyl ether and a sensitizing agent. Figure 2 shows the result for diethyl ether–ethylene system. In this figure are shown the relations between $H_{8.7}$ and P_E for the individual constant molar ratios. From these results, it was proved that the slopes of the straight lines, *i.e.*, $H_{8.7}/P_E$, are kept constant for each of the molar ratios, and that the sensitivity of IR-F becomes rapidly greater when the quantities of ethylene increase relative to those of diethyl ether. The latter result is consistent with the phenomena that $H_{8.7}/P_E$ increases rapidly with lowering P_E under the constant partial pressure of ethylene. To sum up, the IR-F sensitivity changes not only with the quantity of diethyl ether but also with that of sensitizing agents, and the sensitivity is not influenced independently by the two quantities but by the relative magnitudes of them.

The Influence of the Kind of Alkenes on the Degree of Sensitization. We have examined the difference in degree of sensitization due to the kind of alkenes. In Fig. 3 are shown the IR-F spectra for the mixed samples which consist of 50 Torr of diethyl ether and 50 Torr of various alkenes. It is clear that the IR-F intensities of the 8.7 μm band of diethyl ether are markedly different according to the kind of alkenes. Figure 4 shows graphically the dependence of the intensities of the 8.7 and 7.1 μm band of diethyl ether on the kind of sensitizing compounds. It is seen that as the alkene molecules become larger, the sensitized IR-F intensities lower in an orderly fashion. Although any definite interpretation for this result can not be given at present, it can be supposed that the factors which may be related to the phenomenon are the

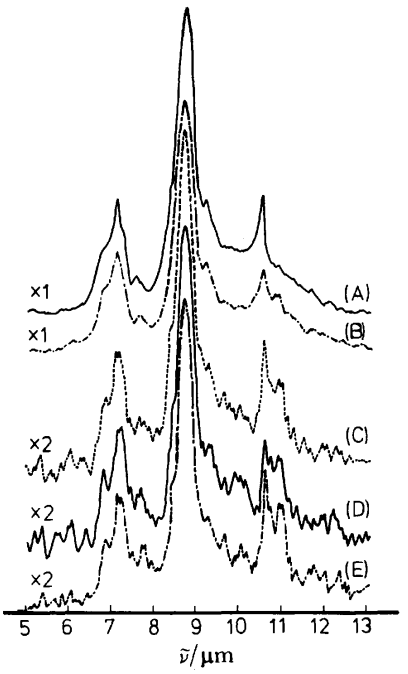

Fig. 3. Effect of the kind of alkenes on IR-F spectra of diethyl ether–alkene mixed samples. (A) ethylene, (B) propylene, (C) 1-butene, (D) 1-pentene, (E) 1-hexene. The instrumental sensitivity for the spectra (C), (D) and (E) is set twice higher than that for (A) and (B).

following, *i.e.*, the characteristics and the number of vibrational levels of the alkenes involved, the intensities of the absorption at 10.6 μm and the agreement of the wavelengths of excitation laser lines with the rotational absorption lines of the alkenes, *etc.*

It can be concluded that though there remain many problems unsolved, the present experimental results give useful guide for the analytical and structural applications of the IR-F spectra sensitized by addition of the alkenes.

Immunoassay Using a Metal-complex Compound as a Chemiluminescent Catalyst. III. Flow-through Analysis of a Labeled Antigen Bound by Immune Reaction

Tadashi HARA,* Motohiro TORIYAMA, and Kazuhiko TSUKAGOSHI
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
(Received May 26, 1983)

Synopsis. By measuring the chemiluminescence intensity by the flow-through method rather than the conventional batchwise method, the sensitivity and precision of immunoassay and the time required for the measurement of the chemiluminescence intensity were improved as follows: 20 ng—50 μg of human albumin per tube, 5.8—7.2% (n=9) coefficient of variation, and 4 min measuring time.

Studies on automatic and continuous immunoassay have been made for non-labeled immunoassays such as laser nephelometry[1-3] and latex-photometric immunoassay,[4] but few such attempts have been made for a labeled immunoassay like enzyme immunoassay (EIA), because the enzyme as a labeling reagent is more unstable than an ordinary chemical reagent and requires some reaction time.

Chemiluminescence complex catalyst immunoassay(CLCCIA), in which a synthesized metal-complex compound acting as a labeling reagent, was reported by the authors for the determination of human serum albumin(HSA) as a model compound for the protein.[5] CLCCIA was also shown to provide the sensitivity necessary for practical immunoassay.[6] Moreover, CLCCIA has the following advantages in comparison with EIA: 1) The labeling reagent, that is, the metal-complex compound is more stable. 2) The analysis utilizing chemiluminescence reaction is more rapid. Judging from these advantages, CLCCIA is suitable for automatic and continuous immunoassay. As the first step for determining such a procedure, a flow-through apparatus by which the chemiluminescence intensity(CL intensity) could be continuously measured was set up and its performance was investigated.

The present method was superior to the previous batchwise method in the following points: 1) The time necessary for the measurement of the CL intensity was reduced to about one-tenth. 2) The limit of detection was also reduced to about one-half. And 3) the coefficient of variation for the measurement was smaller.

Experimental

The following procedures were done as explained in the previous paper:[6] synthesis of iron(III) 4,11,18,25-tetrakis-(chlorocarbonyl)phthalocyanine (TCCP-Fe(III)) as a labeling reagent, labeling of TCCP-Fe(III) to the HSA chosen as an analyte model, preparation of glass beads immobilized with antibodies(Ab-bead), and the competitive immune reaction between labeled HSA and HSA.

A schematic flow diagram of the apparatus used for the measurement of the CL intensity is shown in Fig. 1. Each bottle was filled with (a) a 1.0×10^{-3} mol/dm^3 5-amino-2,3-dihydro-1,4-phthalazinedione (luminol) solution (pH 11.4, a 0.014 mol/dm^3 disodium tetraborate–0.03 mol/dm^3 sodium hydroxide buffer solution (BS-I)), (b) BS-I as a liberating solution, (c) a washing solution (pH 7.2, a 0.0072 mol/dm^3 disodium hydrogenphosphate buffer solution (BS-II)), and (d) a 7.5×10^{-3} mol/dm^3 hydrogen peroxide (H_2O_2) solution.

Each solution was fed at the flow rate of 2.5 cm^3/min by means of pump (e) (ATTO, Perista Mini-pump SJ1211). The CL intensity at the flow-cell (i), which was obtained by winding spirally a 40 cm×0.8 mm diam. transparent poly(vinyl chloride) tube, was measured by means of a photon counter(k)(high voltage=−900 V, gate time=0.1 s, discriminator=330 mV) (Hamamatsu TV, C1230) equipped with a photomultiplier(j) (Hamamatsu TV, R464). The output was recorded with a recorder(l) (Matsushita Communication Industrial, VP6521A).

The CL intensity was measured as follows: 1) The Ab-bead (g) which had been washed with BS-II after the immune reaction was put into a sampler (f) and washed with a washing solution (c) for 2 min. 2) A liberating solution was sent onto an Ab-bead in a sampler from (b) by operating a six-way cock (h) and some labeled antigen was liberated from an immune complex. The liberated HSA and labeled HSA were both introduced into a flow-cell (i), and the chemiluminescence of luminol, which was based on the catalytic action of TCCP-Fe(III) on a labeled HSA, was measured. The maximum CL intensity was obtained in about 30 s after operating a six-way cock, and a standard curve of HSA was obtained from the maximum CL intensity. 3) The inside of the sampler was washed for 1 min with a washing solution by operating again a six-way cock 1 min after its first operation. The Ab-bead in the sampler was replaced by a new Ab-bead and the same procedure was repeated.

Results and Discussion

An immune complex dissociates in a strongly acidic or basic solution as well as a high concentration of salt solution. In order to examine the liberation of antigen from an immune complex, each Ab-bead after immune reaction was washed for 3 min with each pH of solution and the CL intensity due to the labeled HSA on an

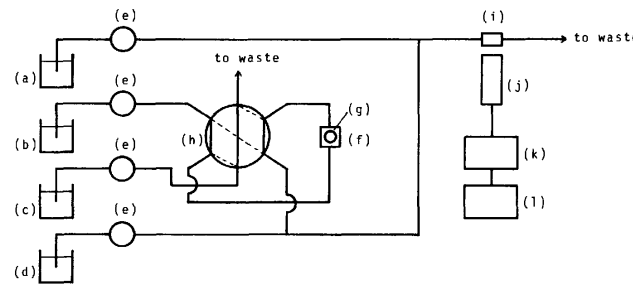

Fig. 1. Schematic flow diagram.

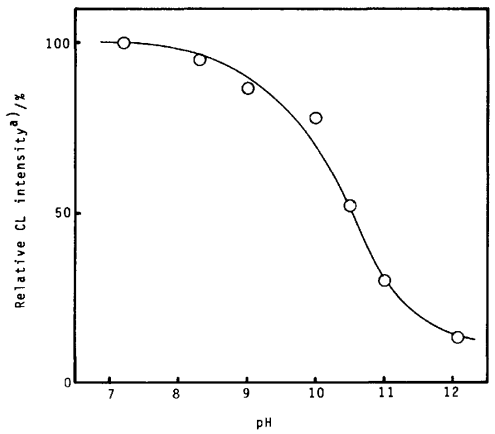

Fig. 2. Effect of pH of a washing solution on the CL intensity.
a) CL intensity at pH 7.2 of a washing solution was normalized to 100%.

Ab-bead was measured by the previous batchwise method (Fig. 2).

As shown in Fig. 2, the CL intensity decreased with an increasing pH value and this decrease corresponded to the amount of labeled HSA which was lost during washing. Most of the immune complex was found to dissociated only by putting an Ab-bead into a washing solution having pH value over 11. On the basis of this result, we achieved a rapid and accurate immunoassay, in which an antigen was liberated from an Ab-bead after the immune reaction and in which the catalytic effect of TCCP-Fe(III) in a liberated antigen solution on the chemiluminescence between luminol and H_2O_2 was measured.

A flow-through apparatus was set up to measure the CL intensity (Fig. 1). Both a luminol solution(a) and a liberating solution(b), shown in Fig. 1, were held at the same pH value and their pH values were changed simultaneously. This change was followed by measuring the CL intensity (Fig. 3). As can be seen from Fig. 3, the CL intensity increased with an increasing pH value of a luminol solution and a liberating solution, and gave a constant value in the vicinity of pH 12. By taking the large background of chemiluminescence at high pH into account, pH 11.4 was chosen as both the luminol solution and the liberating solution in the following experiments.

The relationship between the CL intensity and washing time of an Ab-bead with washing solution(c) shown in Fig. 1 was examined. No change in the CL intensity was observed in 1 to 10 min of washing time; so 2 min washing was recommended.

A standard curve of HSA was obtained under the above-mentioned optimum conditions (Fig. 4). According to the present method, up to 50 μg/tube HSA can be estimated with a limit of detection of 20 ng/tube

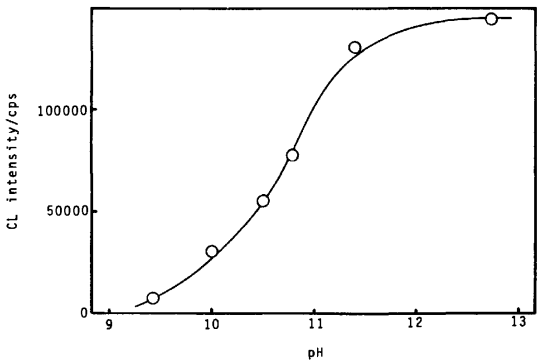

Fig. 3. Effect of pH of a luminol solution and a liberating solution on the CL intensity.

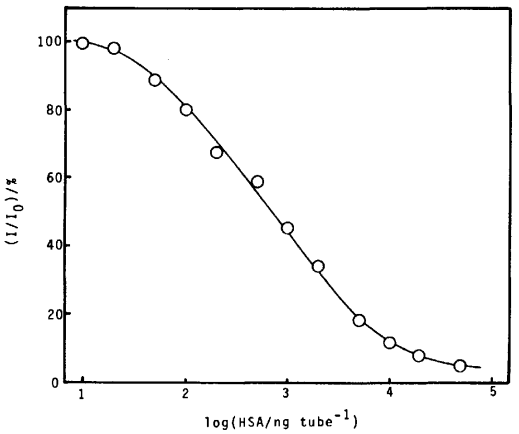

Fig. 4. Standard curve for HSA.
I, I_0: The CL intensity of the sample in the presence or absence of HSA.

and with coefficient of variation 5.8—7.2% for 9 analyses. The present method was superior to the previous batchwise method (limit of detection 50 ng/tube HSA and coefficient of variation 6—16%). The time necessary for analysis of a sample after immune reaction could be reduced to 4 min from 35 min in the previous batchwise method.

Polarographic Minimum Wave of Tetraiodocadmate(II) Complex in Acetonitrile

Yukio NAGAOSA* and Isao TANAKA
Faculty of Engineering, Fukui University, 3-chome Bunkyo, Fukui 910
(Received June 13, 1983)

Synopsis. Tetraiodocadmate(II) anion gives a polarographic minimum wave at potentials above −1.1 V *vs.* Ag/AgCl, when tetrabutylammonium iodide is used as a supporting electrolyte. The experimental results show that the minimum wave appears as a result of electrostatic repulsion between the cadmate(II) anion and the negatively charged mercury surface.

It is well-known that a normal polarographic wave is produced for metal complexes in acetonitrile of an inert aprotic solvent.[1-3] A polarographic minimum wave was observed for tetraiodocadmate(II) anion over the potential range from −1.1 to −1.5 V, when it was extracted into an acetonitrile phase containing 0.1 mol dm^{-3} tetrabutylammonium iodide as the supporting electrolyte and as the extracting agent. An electrochemical interpretation is attempted on the minimum wave in the presence of quaternary ammonium salts, based on the experimental evidence of the electrocapillary curves, the current-time (*i–t*) curves and the effect of different surfactants or inorganic salts. Until now, there has been little reported on the minimum wave in acetonitrile in contrast with the aqueous solutions.[4,5] Further, we should pay attention to the choice of supporting electrolytes in the anodic stripping analysis,[6] because the pre-electrodeposition efficiency is decreased at the potential range inducing such a minimum wave.

Experimental

Cadmium(II) in aqueous solution (20.0 cm^3) is quantitatively extracted into the aqueous phase (10.0 cm^3) containing 0.1 mol dm^{-3} quaternary ammonium iodide, when 10.0 g of ammonium sulfate and a small amount of ascorbic acid were added. A Yanako P-8 polarograph was used for all polarographic work. The electrochemical cell was equipped with a silver-silver chloride reference electrode, a platinum wire counter electrode and the dropping mercury electrode which had the capillary characteristics: m= 0.932 mg s^{-1} and t=6.01 s at an open circuit in acetonitrile. A Watanabe Sokki WTR-2C oscillograph linear corder was used for measuring *i–t* curves, in which a 1 kΩ resistor was inserted into the platinum counter electrode in a series. The chemicals used were available from Wako Junyaku Co., Ltd. The other experimental procedures were similar to that described earlier.[7]

Results and Discussion

Figure 1 shows d.c. polarograms for the teraiodocadmate(II) ion which was extracted into acetonitrile phases containing different kinds of quaternary ammonium iodide (0.1 mol dm^{-3}). Normal well-defined waves were obtained with tetraethylammonium iodide (TEAI) and tetrapropylammonium iodide (TPrAI) at $E_{1/2}$=−0.77 V *vs.* Ag/AgCl, while polarographic minimum waves appeared from about −1.1 V with tetrabutylammonium iodide (TBAI) and tetrapentylammonium iodide (TPeAI). The limiting current on the four polarographic waves were all diffusion-controlled. To clarify the difference in the polarographic wave, we investigated the electrode reaction between the cadmate(II) ion and the mercury electrode by means of the conventional polarographic analysis.[8] The plots of log $i/(i_d-i)$ *vs.* E for the d.c. waves yield straight lines with reciprocal slopes of 30.9 and 34.1 mV for TEAI and TBAI at 25 °C, respectively. It is obvious that the reversibility of the electrode reaction is lowered for TBAI. The electrocapillary and *i–t* curves were examined to ascertain whether the cadmate(II) ion was adsorbed onto the mercury electrode on electrolysis or not. From the electrocapillary curves

(1): 0.1 mol dm^{-3} TEAI at potentials from −1.0 to −1.5 V; (2): 0.1 mol dm^{-3} TBAI at −1.0 V; (3): −1.1 V; (4): −1.2 V; (5): −1.3 V; (6): −1.4 V.

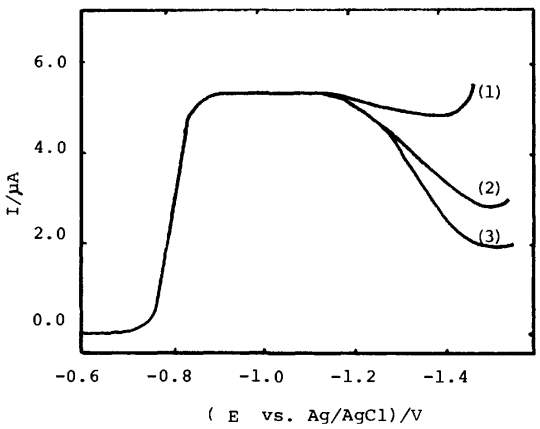

Fig. 3. Effect of inorganic salts on d.c. polarogram of 8.8×10^{-4} mol dm^{-3} tetraiodocamate(II) complex in acetonitrile containing 0.1 mol dm^{-3} TBAI. (1): 0.08 mol dm^{-3} $Al(ClO_4)_3$, (2): 0.07 mol dm^{-3} $LiClO_4$, (3): 0.04 mol dm^{-3} $LiClO_4$.

obtained, it was found that the drop-time was gradually decreased at the potential range from −0.8 to −1.5 V, and that no sharp decrease of drop-time was observed in both cases of TEAI and TBAI. The *i–t* curves shown as in Fig. 2 indicate that the current is almost proportional to $t^{1/6}$ at all potentials investigated, even above −1.1 V for TBAI. These results reveal that no adsorption of the ionic species onto the mercury electrode occurs. There seems to be other reasons for the appearance of the polarographic minimum wave in acetonitrile containing 0.1 mol dm^{-3} TBAI.

The effect of various surfactants and inorganic salts on the minimum wave was investigated for TBAI. It was observed that the addition of triton X-100 and hexadecyltrimethylammonium chloride to the acetonitrile solution recovered the diminution of the reduction current for the cadmate(II) ion at potentials above −1.1 V, but that of sodium dodecylbenzenesulfonate does not. It is interesting to note from Fig. 3 that more positive effect of recovering the minimum wave was obtained with the addition of cations of higher valency ($Al^{3+}>Li^+$). It is also noted that the degree of depression on the minimum wave was decreased as the concentration of salts added was increased.

Y. Umezawa *et al.* have discussed the polarographic behavior of minimum waves for inorganic anions in aqueous medium, based on the quantum mechanical effect and the electrostatic one.[9] In the present study, the appearance of the minimum wave can merely be explained in terms of the electrostatic model:[10] the minimum wave takes place with the electrostatic repulsion between the cadmate(II) anion and the negatively charged mercury surface. This is because the presence of cationic substances gives rise to normal reduction waves. When the large TBA^+ ion was exchanged with a small cation near the mercury electrode, the cadmate(II) ion is possible to approach to the electrode where as a result the electron transfer occurs to a more greater extent. We also consider that the large TBA^+ ion interfere sterically with the approach of the cadmate(II) ion to the electrode. It seems that a slightly negative shift of $E_{1/2}$ by addition of Li^+ or Al^{3+} is attributed to the ion-pair formation with the cadmate(II) ion, or to the salt effect due to increasing supporting electrolyte.[11]

Sodium Dibutyldiselenocarbamate. Analytical Application to the Extraction Spectrophotometry of Heavy Metals

Takaharu HONJO

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received June 13, 1983)

Synopsis. Sodium dibutyldiselenocarbamate is soluble in water, and the form of its dibutyldiselenocarbamic acid is extractable by methylene dichloride; more than 99% of the reagent exists in the methylene dichloride phase in the pH region of 4—10. The reagent readily forms extractable chelates with Au^{III}, Co^{II}, Cu^{II}, Hg^{II}, Ni^{II}, Pd^{II}, and Zn^{II} while it gives considerable white precipitates with Ag^{I} and Hg^{II} in the pH region of 1—7. Each chelate in methylene dichloride absorbs at wavelengths lower than 400 nm. The peak of the copper(II) chelate with the molar absorbtivity of 1.50×10^4 at 442 nm is not affected by the spectra of the reagent and other metal chelates, and it can be used for the selective spectrophotometric determination of copper(II) up to 0—10 μg/cm³.

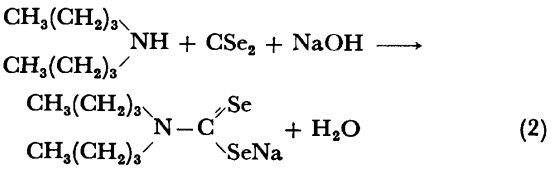
It is well known that heavy-transition metals form more stable complexes with chelating ligands which have π-acceptor donor atoms with unfilled pπ or dπ orbitals, like sulfur and selenium elements. However, scarcely no information on the solvent-extraction reagents with a selenium donor atom has been reported.[1,2] In a previous paper, the present author reported the synthesis of new monoseleno analogs of β-diketone, 1,1,1-trifluoro-4-(2-thienyl)-4-hydroseleno-3-buten-2-one and its analytical utility as an extraction-spectrohotometric reagent for heavy metals.[3] Now that author has investigated a selenium containing a chelating reagent of dithiocarbamate, sodium dibutyldiselenocarbamate, in the anticipation of enhanced stability and selectivity in reactions with heavy-transition metals; the investigation has been undertaken with analytical applications in view

Experimental

Apparatus. A model 323 Hitachi Recording Spectrophotometer; a model 239 Hitachi Digital Spectrophotometer; a Hitachi-Horiba glass electrode pH meter ,model M-5; an Iwaki shaking machine, model KM; a Kubota centrifuge machine, and a Yanagimoto Micro Melting-point Apparatus, Model MP-J2, were used.

Preparation of Metal Solution. The solution of the copper(II) ion was prepared by dissolving $CuSO_4 \cdot 5H_2O$ of a guaranteed-grade reagent in a slightly acidic hydrochloric acid solution to make a 10^{-1} M† aqueous solution. The concentration of the copper(II) ion was standardized complexometrically, and the solution was diluted as required with distilled water. The other guaranteed-grade metal salts of Ag^{I}, Au^{III}, Bi^{III}, Cd^{II}, Co^{II}, Cu^{II}, $Fe^{II,III}$, Hg^{II}, In^{III}, Ir^{III}, Mn^{II}, Ni^{II}, Pb^{II}, Pd^{II}, Pt^{II}, Rh^{III}, Sn^{II}, Tl^{I}, UO_2^{II}, VO_2^{I}, and Zn^{II} were also dissolved in distilled water or in an acidic hydrochloric or nitric acid solution to make a 10^{-1} M aqueous stock solution of each metal ion.

Synthesis of Sodium Dibutyldiselenocarbamate. Carbon diselenide was synthesized by the similar method of Barnard and Woodbridge.[4] It turns from a clear lemon-yellow color to orange within a couple of weeks and finally to black as solid-carbon diselenide polymers form; it is used as soon as possible for the synthesis of sodium dibutyldiselenocarbamate. Sodium dibutyldiselenocarbamate was synthesized by a slight modification of the method of Barnard and Woodbridge.[4]



(2)

Carbon diselenide (2.11 g, 0.0124 M) in dioxane (20 cm³) was added to a solution of sodium hydroxide (0.5 g, 0.0124 M) and dibutylamine (1.6 g, 0.0124 M) in water (20 cm³) at −10 °C for 30 min while being stirred in an atmosphere of nitrogen. In order to avoid possible insoluble impurities coming from the polymerization of carbon diselenide, the solution was filtered once, and the sodium salt of dibutyldiselenocarbamate thus prepared was separated by extraction with methylene dichloride. The methylene dichloride solution was dried over anhydrous sodium sulfate, and the product was recovered by the evaporation of the excess solvent under low pressure. The sodium dibutyldiselenocarbamate thus obtained was an orange-red oily substance, which showed a melting point of 50—60 °C. The reagent was sealed in a brown-colored bottle in a nitrogen atmosphere and stored in a refrigerator kept at 5 °C.

Extraction Procedure. To an aqueous solution containing 10^{-6}—10^{-2} M metal ions we added 10^{-2} M acetic acid (in the pH region of 0—7) or 10^{-2} M boric acid (in the pH region of 7—13); its pH was adjusted to the desired value by means of a 0.1—1 M sodium hydroxide or hydrochloric acid solution. Ten cm³ of this solution and 10 cm³ of 3×10^{-5} M sodium dibutyldiselenocarbamate in methylene dichloride were then introduced into a 50-cm³ glass-stoppered centrifuge tube; the mixture was equilibrated for 1—30 min, after which the phases were separated by centrifugation. Metal complexes of dibutyldiselenocarbamate are also readily extractable in such organic solvents as chloroform, benzene, carbon tetrachloride, and isobutyl methyl ketone. In general, halogen-substituted hydrocarbons with large dielectric constants are superior for the extraction of metal complexes.

Results and Discussion

Sodium dibutyldiselenocarbamate is soluble in water to give a pH of 11.30 and is extractable with methylene dichloride; it is, in fact, remarkably stable in this solvent. However, sodium dibutyldiselenocarbamate is unstable in an acid medium, and the decomposition of the reagent gradually proceeds below pH 4. From the experimental results on the variation of the percentage of the extraction of sodium dibutyldiselenocarbamate (2×10^{-5} M) from an aqueous solution into methylene dichloride as a function of the pH, it was found that more than 99% of the reagent was in the

† 1 M = 1 mol dm⁻³.

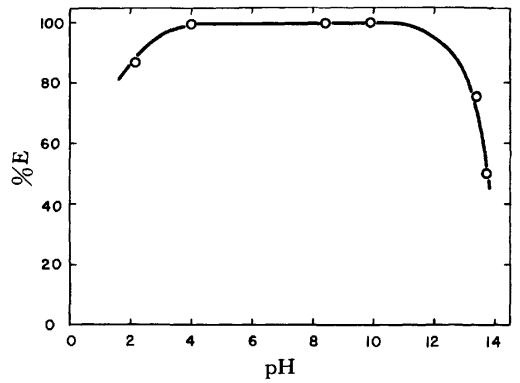


Fig. 1. Variation in the percentage extraction of 2×10^{-5} M dibutyldiselenocarbamic acid from an aqueous solution into methylene dichloride as a function of pH.

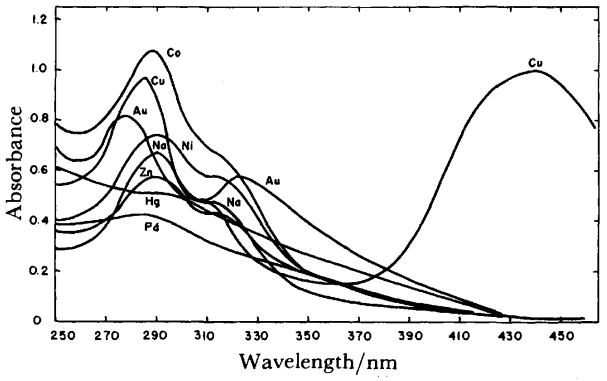

Fig. 2. Absorption spectra of 3×10^{-5} M sodium dibutyldiselenocarbamate and of 1.5×10^{-5} M its metal chelates in methylene dichloride.

methylene dichloride phase in the pH region of 4—10 within 5 min (Fig. 1). The pH value of an aqueous phase corresponding to a 50% extraction of the ligand was 13.7. The sodium dibutyldiselenocarbamate (10^{-3} M) readily forms extractable chelates into methylene dichloride with many metals (trace—10^{-2} M), such as Au^{III}, Co^{II}, Cu^{II}, Hg^{II}, Ni^{II}, Pd^{II}, and Zn^{II}, in the pH region of 1—7 within 30 min. Each metal chelate in methylene dichloride absorbs at wavelengths lower than 400 nm (Fig. 2), shows its own specific color, and has absorption maxima (λ_{max}/nm), as is shown in Table 1, together with the results for dibutyldithiocarbamate. The electronic spectra of metal complexes of dibutyldiselenocarbamate closely resemble those of the corresponding dibutyldithiocarbamate in intensity and position, except for a general red shift, that is, a slight shift to longer wavelengths. Ag^{I} and Hg^{II} give white precipitates. The reaction of the sodium dibutyldiselenocarbamate with Bi^{III}, Cd^{II}, $Fe^{II,III}$, In^{III}, Ir^{III}, Mn^{II}, Pb^{II}, Pt^{II}, Rh^{III}, Sn^{II}, UO_2^{II}, VO_2^{I}, and Tl^{I} is not observed distinctly. The molar absorptivity at the λ_{max} of sodium dibutyldiselenocarbamate and its copper(II) chelate, expressed in cm^2 l mol^{-1}, is 2.37×10^4 (288.5 nm) and 1.69×10^4 (311 nm) for the ligand and 6.66×10^4 (283.2 nm), 3.00×10^4 (308 nm), and 1.50×10^4 (440 nm) for the complex respectively. The peak of the copper chelate at 442 nm is not affected by the spectra of the ligand and other metal chelates, is stable at least for several hours, and can be used for the selective-extraction spectrophotometric determination of copper(II) up to 0—10 μg/cm^3 without such treatment as masking the foreign cations. The results reveal that dibutyldiselenocarbamate has analytical potentiality as diethyldithiocarbamate, one of the most useful agents.[2,7]

(Received June 16, 1983)

Synopsis. Detailed geometries of the sulfite ions and of the oxygen-coordinations around the calcium ions in calcium sulfite tetrahydrate were determined based on the results of the X-ray analysis. It was revealed that the structure consists of two alternating layers, one consisting of calcium ions and water molecules, and the other consisting of sulfite ions and water molecules.

In a previous paper[1] we reported the preparation, the solution and refinement of the crystal structure and the mode of disorder of a sulfite ion of calcium sulfite tetrahydrate. The interatomic distances and angles of the hydrates and anhydride of calcium sulfate were reported in detail.[2-7] But no study has been reported on geometries of the sulfite ions and of the oxygen neighbors of the calcium ions in calcium sulfites. This note reports the interatomic distances and angles and the characteristic layer structure of calcium sulfite tetrahydrate.†††

The atomic coordinates used for the present calculations are the same as in the previous paper.[1]

Results and Discussion

A projection of a part of the structure along the c axis and numbering of the atoms are shown in Fig. 1. The $S(2)O_3^{2-}$ ion is in a disordered state.[1] It can be presumed that the low thermostability of the tetrahydrate is caused by the $S(2)O_3^{2-}$ ion in the disordered state.

The interatomic distances and angles are given in Tables 1 and 2. The S–O and O–O interatomic distances and O–S–O bond angles in the $S(1)O_3^{2-}$ ion are 1.52(2)—1.53(3) Å, 2.37(1)—2.39(1) Å, and 102.2(3)—102.9(4)°, respectively. The corresponding distances and angles in the $S(2)O_3^{2-}$ ion are 1.43(3)—1.44(5) Å, 2.19(4)—2.45(5) Å, and 98.9(14)—117.2(10)°, respectively. These values show that the degree of symmetry of the $S(2)O_3^{2-}$ ion is lower than that of the $S(1)O_3^{2-}$ ion. The average S(2)–O bond distance of 1.44 Å is approximately the same as the S–O bond distances in SO_4^{2-} ions (calcium sulfate dihydrate 1.459 Å,[2-4] calcium sulfate anhydride 1.44 Å[5-7]), but is considerably short-

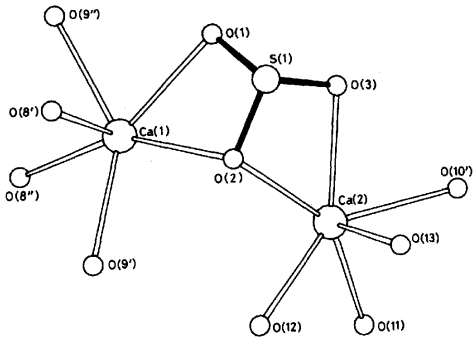

Fig. 2. Environment of the calcium ions.

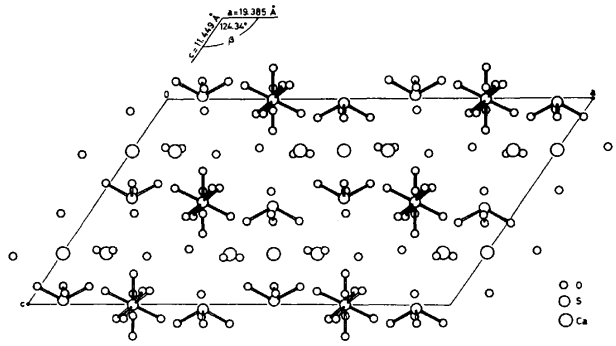

Fig. 3. Projection of the structure along the b axis.

er than 1.53 Å in the $S(1)O_3^{2-}$ ion. One of the reasons for the difference of the S–O bond distances between $S(1)O_3^{2-}$ and $S(2)O_3^{2-}$ may be that only the O atoms of the $S(1)O_3^{2-}$ ion coordinate to the Ca^{2+} ions (*cf.* Fig. 2). Another reason may be that, in many cases, the interatomic distances and angles calculated from the coordinates of the atoms which are in a disordered state give rise to apparent deviations from the usual values.

The coordinations of the O atoms around the Ca^{2+} ions are shown in Fig. 2. Both Ca(1) and Ca(2) are coordinated by six O atoms in distorted octahedral arrangements: two O atoms originate from the $S(1)O_3^{2-}$ ion, and the other four from water molecules. The Ca(1)–O(1) distance is almost the same as the Ca(1)–O(2) distance. The Ca(1)–O(9′) and Ca(1)–O(9″), and the Ca(1)–O(8′) and Ca(1)–O(8″) distances are the same, respectively. The Ca(2)–O distances are similar to the Ca(1)–O distances; the average values are both 2.45 Å. These Ca–O distances are close to those (2.378—2.544 Å) in calcium sulfate dihydrate.[2-4] The O–Ca(2)–O bond angles are also similar to the corresponding O–Ca(1)–O angles. Thus, the geometries of the Ca(1)–O and Ca(2)–O coordinations resemble each other very closely.

The crystal structure viewed along the b axis is shown in Fig. 3. It is observed that two layers, one consisting of the Ca^{2+} ions and water molecules, and the other consisting of the SO_3^{2-} ions and water molecules, arrange alternately parallel to the (001) plane.

Preparation and Characterization of (L-Histidinato)-(L-methioninato)cobalt(III) Bromide

Ken-ichi OKAMOTO,* Hiroko MAKI, and Jinsai HIDAKA
Department of Chemistry, University of Tsukuba, Sakura, Ibaraki 305
(Received, June 24, 1983)

Synopsis. The (L-histidinato)(L-methioninato)cobalt(III) complex was prepared and separated into three geometrical isomers by ion-exchange chromatography. The isomers were characterized from their absorption, ^{1}H NMR, and CD spectra.

Some cobalt(III) complexes with terdentate amino carboxylates, such as L-methioninate, L-histidinate, and L-2,4-diaminobutyrate, have been investigated.[1-8] However, the stereochemical property of the thioether type sulfur atom of the L-met has not been clarified yet.[1,7] The coordinated L-met has a flexible conformation for the six-membered N–S chelate ring, while the L-his takes a rigid conformation for the six-membered N–N chelate ring. This rigidity of the L-his chelate ring is favorable for the investigation of the stereochemical property of the coordinated L-met. This note presents the preparation and separation of (L-histidinato)(L-methioninato)cobalt(III). The isomers obtained are characterized from their absorption, ^{1}H NMR and CD spectra and by comparison with those of $[Co(L\text{-met})_2]^+$[1] and $[Co(L\text{-his})_2]^+$.[2,3]

Experimental

[Co(L-his)(L-met)]Br. A solution of 2.4 g of $CoCl_2 \cdot 6H_2O$ in 5 cm^3 of water was added to a solution containing 1.5 g of L-Hhis and 1.5 g of L-Hmet in 25 cm^3 of water. To the solution 0.75 g of activated charcoal and 3 g of PbO_2 were gradually added and the mixture was then stirred at 60 °C for 40 min. The reaction mixture was filtered in order to remove the excess of PbO_2 and activated charcoal after cooling to room temperature. The filtrate was poured onto a column of Dowex 50W-X8 (Na^+ form, 4 cm×70 cm). After the column had been swept with water, the adsorbed band was eluted with 0.1 mol dm^{-3} aqueous solution of ammonium bromide. Nine colored bands, F1—F9, were eluted in succession. The F3 and F4 eluates or the F6 and F7 ones partially overlapped. Their absorption and CD spectral measurements showed that the F1, F6, and F8 eluates contained the isomers of $[Co(L\text{-his})_2]^+$[2,3] and the F2, F3, and F5 ones were the isomers of $[Co(L\text{-met})_2]^+$.[1] The F4 (violet), F7 (dark violet), and F9 (brown red) eluates, of which the formation ratio was *ca.* F4:F7:F9=2:2:1, were separately concentrated to about 10 cm^3 with a rotary evaporator below 30 °C. The deposited NH_4Br was filtered off and the filtrate was treated with a gel filtration chromatography (Sephadex G-10 resin). The resulting aqueous solution was concentrated with a rotary evaporator again. The crystals of each isomer were obtained by adding ethanol and then ether to the concentrated solution. Found for F4: C, 30.85; H, 4.30; N, 12.57%. Calcd for $[Co(L\text{-his})(L\text{-met})]Br=CoC_{11}H_{18}N_4O_4SBr$: C, 29.94; H, 4.11; N, 12.96%. Found for F7: C, 27.31; H, 4.29; N, 13.41%. Calcd for $[Co(L\text{-his})(L\text{-met})]Br \cdot 0.5NH_4Br$: C, 26.95; H, 4.11; N, 12.85%. Found for F9: C, 14.28; H, 4.11; N, 13.30%. Calcd for $[Co(L\text{-his})(L\text{-met})]Br \cdot 5NH_4Br$: C, 14.19; H, 4.11; N, 13.54%.

Measurements. Electronic absorption spectra were recorded with a JASCO UVIDEC-1 spectrophotometer and CD spectra with a JASCO J-20 spectropolarimeter. ^{1}H NMR spectra were recorded on a JEOL JNM-MH-100 NMR spectrometer in D_2O. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal reference. All the measurements were carried out at room temperature.

Results and Discussion

Three geometrical isomers were isolated for $[Co(L\text{-his})(L\text{-met})]^+$ (Fig. 1), and their absorption and CD spectra are shown in Fig. 2. Splitting pattern of the first absorption band is expected to reflect the geometry of each of the three isomers, as in the case of $[Co(L\text{-met})_2]^+$[1] and $[Co(L\text{-his})_2]^+$.[2,3] Namely, F4, F7, and F9 are assigned to *trans*(N_iS), *trans*(N_iO), and *trans*(N_iN), respectively, where N_i denotes an imidazole nitrogen atom in the L-his, in accordance with the expected

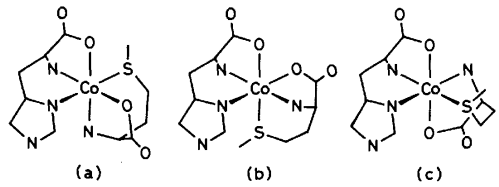

Fig. 1. Three possible isomers of $[Co(L\text{-his})(L\text{-met})]^+$; (a) *trans*($N_iS$), (b) *trans*($N_iO$), and (c) *trans*($N_iN$).

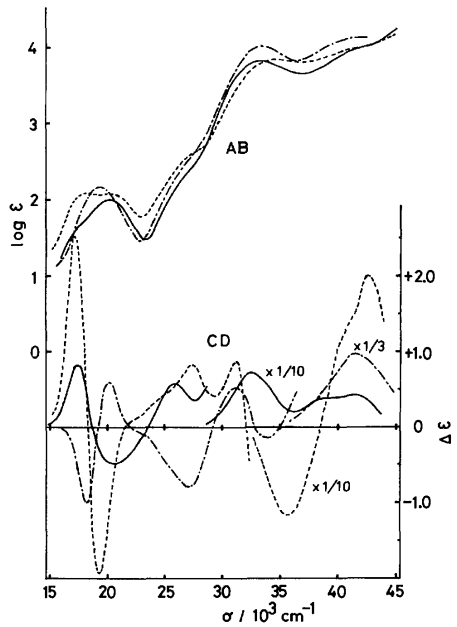

Fig. 2. Absorption and CD spectra of $[Co(L\text{-his})(L\text{-met})]^+$; *trans*($N_iS$) (-·-·-), *trans*($N_iO$) (——), and *trans*($N_iN$) (----).

	S-CH_3	H(C_2)[b]	H(C_5)[b]
trans (N_iS)	2.03[a]	7.78	7.24
trans (N_iO)	1.86	7.88	7.18
	2.12	8.22	7.26
trans (N_iN)	2.29	8.40	7.30

a) Ppm from DSS. b) H(C_2) and H(C_5) denote the 2-proton and 5-proton of imidazole, respectively.

splittigs which were estimated semiempirically.[1-7] As is shown in Table 1, the *S*-methyl proton signals of the *trans*(N_iS) and *trans*(N_iN) isomers appear in lower field than those of the *trans*(N_iO) one. This is in line with the ^{1}H NMR spectral behavior of the cobalt(III) complexes with D- or L-aspartate and L-methioninate;[7,8] namely, this result suggests that the imidazole and amino nitrogen atoms occupy the trans position to the sulfur atoms of the *trans*(N_iS) and *trans*(N_iN) isomers and the oxygen atom occupies the trans position to the sulfur atom of the *trans*(N_iO) one.[9,10] The information from the ^{1}H NMR spectra of the three isomers supports the assignment based on the absorption spectra. When the sulfur, oxygen or nitrogen atom occupies the trans position to the imidazole nitrogen atom, the resonance line of the C_2 proton (near 8 ppm) on the imidazole moiety shifts to the higher field in the order of *S*, *O*, and *N*.

The *R*(*S*) or *S*(*S*) configuration is expected for the coordinated sulfur atom of each isomer. The *trans*-(N_iO) isomer shows two signals due to the *S*-methyl protons and two sets of signals for each of the C_2 and C_5 protons of the imidazole moiety of the L-his (Table 1).[3,5,6] These facts indicate that the *trans*(N_iO) isomer is a mixture of *R*(*S*) and *S*(*S*) configurations. On the other hand, only one signal of the *S*-methyl protons and one set of signals due to the imidazole moiety are observed for the *trans*(N_iS) and *trans*(N_iN) isomers (Table 1). These suggest that the *trans*(N_iS) and *trans*-(N_iN) isomers selectively take the *R*(*S*) or *S*(*S*) configuration. Model construction reveals that the *S*(*S*) configuration is more probable for the *trans*(N_iS) isomer. The *trans*(N_iN) isomer has the *R*(*S*) configuration because the *S*(*S*) configuration is rejected by the striking repulsion between the *S*-methyl group and imidazole ring. The chromatographic separation was repeated for the F7 eluate which contained the *trans*-(N_iO) isomer, but all of its fractionated eluates showed quite similar CD spectra.

The *trans*(N_iS)- and *trans*(N_iN)-[Co(L-his)(L-met)]$^+$ isomers are quasi-antipodal in framework and show almost enantiomeric CD spectra in the first and second absorption band region (Fig. 2). In the region of (30—45)$\times 10^3$ cm^{-1}, however, the *trans*(N_iS) and *trans*(N_iN) isomers show similar CD patterns. The CD spectral behavior in the region of (30—45)$\times 10^3$ cm^{-1} depends mainly on the absolute configuration of the coordinated L-met and/or L-his, as in the case of the cobalt(III) complexes with *S*-methyl-L-cysteinate and *S*-methyl-L-penicillaminate.[11,12] In the first absorption band region, the *trans*(N_iN)-[Co(L-his)(L-met)]$^+$ isomer whose coordinated sulfur atom is regulated to the *R*(*S*) configuration shows a similar CD pattern and a similar intensity to those of the *trans*(*O*)-[Co(L-met)$_2$]$^+$[1] and *trans*(*O*)-[Co(L-his)$_2$]$^+$[2,3] whose frameworks are similar to that of the mixed complex. Some differences are observed for the other isomers of [Co(L-his)-(L-met)]$^+$, [Co(L-met)$_2$]$^+$, and [Co(L-his)$_2$]$^+$.[1-3] In the first absorption band region, the *trans*(N_iO)-[Co(L-his)(L-met)]$^+$ isomer shows two CD bands weaker than those of the *trans*(*N*)-[Co(L-met)$_2$]$^+$ and *trans*(*N*)-[Co(L-his)$_2$]$^+$ isomers, though the CD components in the higher energy side of the three isomers align at *ca.* 20×10^3 cm^{-1}.[1-3] A similar trend is observed for the *trans*(N_iS)-[Co(L-his)(L-met)]$^+$, *trans*(*S*)-[Co(L-met)$_2$]$^+$, and *trans*(N_i)-[Co(L-his)$_2$]$^+$, namely, the negative CD bands at *ca.* 18×10^3 cm^{-1} weaken gradually and shift to the lower energy in the order of the *trans*(N_i), *trans*-(N_iS) and *trans*(*S*) isomers.[1-3] These results suggest that the CD bands in the first absorption band region are contributed from the flexibility of the conformation of the six-membered N-S chelate ring in the L-methioninate.

Synopsis. The third cathodic waves corresponding to the reduction processes from the four-electron to the six-electron reduction products of both 12-molybdophosphate and 12-molybdosilicate are catalytic in nature in the presence of chlorate ions. The six-electron reduction product of 12-molybdophosphate is oxidized by chlorate ions more rapidly than that of 12-molybdosilicate.

It is well known that the reduction products of 12-heteropoly molybdates show a deep blue color, which are often called heteropoly molybdenum blue compounds, and that many workers applied the formation of heteropoly molybdenum blue compounds to the determination of traces of P^{V}, As^{V}, or Si^{IV} without the clarification of the properties of the heteropoly molybdenum blue compounds in detail.

The physicochemical properties of the heteropoly molybdenum blue compounds have been recently clarified by several workers by using various techniques.[1-4] On the other hand, the informations about the chemical reactivities of the heteropoly molybdenum blue compounds are still in scarcity, although such informations seem to be important to the application of the compounds as catalysis.

The authors, therefore, studied recently the electrochemical behaviors of 12-molybdophosphate and 12-molybdosilicate in water–dioxane mixed solutions, and found that the six-electron reduction product of the 12-molybdophosphate is more reactive for a homogeneous electron transfer reaction than that of 12-molybdosilicate.[5,6]

In the present paper are presented the results of a study of the effects of some inorganic anions on the electrode reaction processes of 12-molybdophosphate and 12-molybdosilicate at a thin-layer electrode cell.

Experimental

Materials. Sodium salts of 12-molybdosilicate and 12-molybdophosphate were obtained from Climax Molybdenum Co. and Wako Pure Chemical Ind., respectively. Other chemicals used were of analytical reagent grade. All solutions were prepared with twice-distilled water and deaerated with high-purity nitrogen.

Measurement. Voltammetric experiments were performed with a potentiostat (Hokuto Denko Co., HA 501) in connection with a function generator (Hokuto Denko Co., HB 104).

The thin-layer electrode was constructed by sandwiching a gold-minigrid (500 mesh; Buckbee-Mears Co.) between two glass slides. The electrochemical cell volume was 41.4 μl.

Standard procedures were used for a thin-layer voltammetric experiment.[7]

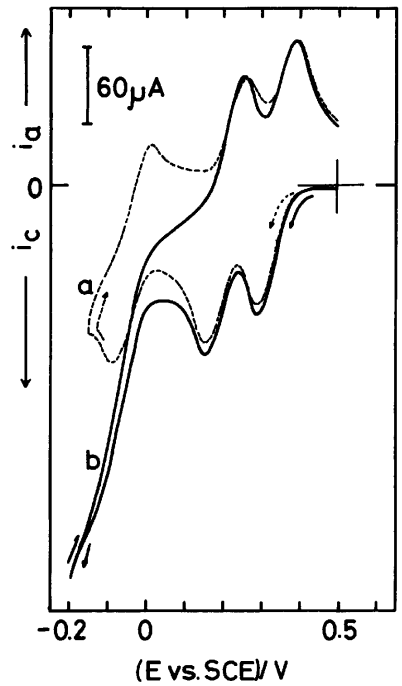

Fig. 1. Thin-layer cyclic voltammograms of 1.0×10^{-3} M 12-molybdophosphate in 50%(v/v) dioxane–water solutions containing 0.5 M H_2SO_4 at 22°C. [$NaClO_3$]: (a) 0, (b) 0.05 M. Scan rate 2 mV s^{-1}; initial potential +0.500 V *vs.* SCE.

Results and Discussion

Typical thin-layer cyclic voltammograms of 12-molybdophosphate are given in Fig. 1. In the absence of chlorate ions, 12-molybdophosphate in 50% (v/v) dioxane–water solutions containing sulfuric acid exhibits three consecutive two-electron reversible waves in agreement with the results of the voltammetric studies at a platinum electrode.[8]

Most of the previous electrochemical investigations of heteropoly molybdates were carried out with sulfuric acid or hydrochloric acid as a supporting electrolyte. Nitrate and perchlorate were little used as a supporting electrolyte. This might be resulted from the consideration of the fact that nitrate and perchlorate oxidized the reduction products of some molybdenum(VI) complexes.[9,10] However, this study has shown that neither nitrate nor perchlorate ions do exhibit a catalytic effect on the electrode reaction processes of 12-molybdophosphate; the cathodic waves of 12-molybdophosphate was found to be little affected by the addition of nitrate or perchlorate ions.

On the other hand, chlorate ions gave a remarkable

influence on the third cathodic wave, although the first two cathodic waves remained almost unchanged upon the addition of chlorate ions. In the presence of chlorate ions, the third cathodic wave exhibited a plateau rather than a peak and increased in height with an increase of chlorate ion concentrations. Moreover, the third anodic peak corresponding to the reoxidation of the six-electron reduction product disappears completely. These indicate that the third reduction wave of 12-molybdophosphate is catalytic in nature in the presence of chlorate ions.

The mechanism of this catalytic wave involves apparently regeneration of the four-electron reduction product of 12-molybdophosphate, which is supported by the disappearance of the third anodic peak. The controlled potential electrolysis was performed at the potential at which the catalytic current was observed in the presence of chlorate ions. The solution subjected to the electrolysis reacted with silver nitrate to yield the precipitates of silver chloride. This indicates that chlorate ions are reduced to chloride ions by the six-electron reduction product of 12-molybdophosphate.

According to these results, this catalytic wave can be explained by the sequence of the following reactions:

$$PMo^{V}_{4}Mo^{VI}_{8}O_{40}^{7-} + 2e^{-} \underset{\text{fast}}{\rightleftharpoons} PMo^{V}_{6}Mo^{VI}_{6}O_{40}^{9-} \quad (1)$$

$$3PMo^{V}_{6}Mo^{VI}_{6}O_{40}^{9-} + ClO_{3}^{-} + 6H^{+} \longrightarrow 3PMo^{V}_{4}Mo^{VI}_{8}O_{40}^{7-} + Cl^{-} + 3H_{2}O \quad (2)$$

The cyclic regeneration of the electroactive four-electron reduction product of 12-molybdophosphate accounts for the enchancement of the reduction current.

The third cathodic wave of the cyclic voltammogram of 12-molybdophosphate in the presence of chlorate ions at a glassy carbon electrode was found also catalytic in nature. At scan rates larger than 20 mV s^{-1}, however, the third cathodic wave depended on the scan rate and the anodic wave corresponding to the third cathodic wave appears on the anodic scan. This indicates that the chemical reaction (Eq. 2) is relatively slow.

The same set of experiments was performed for 12-molybdosilicate. Typical cyclic voltammograms of 12-molybdosilicate are shown in Fig. 2. In the absence of chlorate ions, 12-molybdosilicate in 50% (v/v) dioxane–water solutions containing sulfuric acid also gave three two-electron reversible waves. Neither nitrate nor perchlorate ions exhibited a catalytic activity for the electroreduced 12-molybdosilicate.

In the presence of chlorate ions, the third reduction wave of 12-molybdosilicate, as shown by curve b in Fig. 2, was found to be catalytic in nature. However, it still exhibits a peak rather than a plateau. This appearance of peak may be due to a slow chemical reaction of the six-electron reduction product of 12-molybdosilicate and chlorate ions; chlorate ions can oxidize the six-electron reduction product of 12-molybdosilicate, but more slowly than that of 12-molybdophosphate.

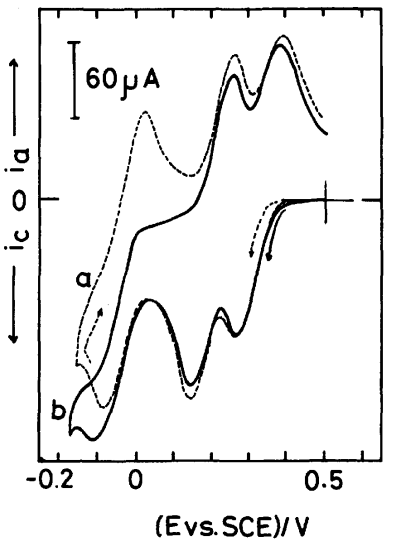

Fig. 2. Thin-layer cyclic voltammograms of 1.0×10^{-3} M 12-molybdosilicate in 50%(v/v) dioxane–water solutions containing 0.5 M H_2SO_4 at 22 °C. [$NaClO_3$]: (a) 0, (b) 0.05 M. Scan rate 2 mV s^{-1}; initial potential +0.500 V *vs.* SCE.

It is interesting to note that the reaction rate of the six-electron reduction product of 12-molybdosilicate for chlorate ions is slower than that of 12-molybdophosphate for chlorate ions. This could support the fact that the six-electron reduction product of 12-molybdophosphate is more reactive for a homogeneous electron transfer reaction than that of 12-molybdosilicate.[6]

This study was supported in part by Science Research Grants nos. 56104001, 56540334, and 57540343, for which the authors thank the Ministry of Education, Science and Culture.

The Incorporation of Dicarboxylates into Octacalcium Bis(hydrogenphosphate) Tetrakis(phosphate) Pentahydrate

Hideki MONMA

National Institute for Research in Inorganic Materials, 1-1 Namiki, Sakura-mura, Niihari-gun, Ibaraki 305

(Received July 28, 1983)

Synopsis. Octacalcium bis(hydrogenphosphate) tetrakis(phosphate) pentahydrate (OCP) has been found to complex with saturated aliphatic dicarboxylate ions, $C_nH_{2n}C_2O_4^{2-}$; n=1—6. These organic substances were incorporated, instead of HPO_4^{2-}, into the "B-layer" of the OCP structure. The incorporation caused expansion in the basal spacing (d_{100}) of OCP from 18.7 Å to 19.6—26.1 Å. A possible structural model is proposed for the incorporation.

Octacalcium bis(hydrogenphosphate) tetrakis(phosphate) pentahydrate ($Ca_8(HPO_4)_2(PO_4)_4\cdot 5H_2O$; OCP), which has a structural similarity to hydroxyapatite, has become of biological and bio-material interest. The structure of OCP, as shown in Fig. 1, is composed of alternative stackings of "apatitic layers" (A-layers) similar to the apatite structure and "hydrated layers" (B-layers) corresponding to the composition of brushite ($CaHPO_4\cdot 2H_2O$).[1-3] In the preceding paper,[4] it was pointed out as a feature of the OCP structure that the B-layers contained +Ca-HPO_4-Ca+ pillars. It was claimed that succinate ions ($C_2H_4C_2O_4^{2-}$) were able to replace the HPO_4^{2-} in the pillar, which resulted in an expansion of the basal spacing (d_{100}) of OCP. In the present work, a series of saturated aliphatic dicarboxylate ions were investigated to determined whether the ions were able to be incorporated into OCP or not.

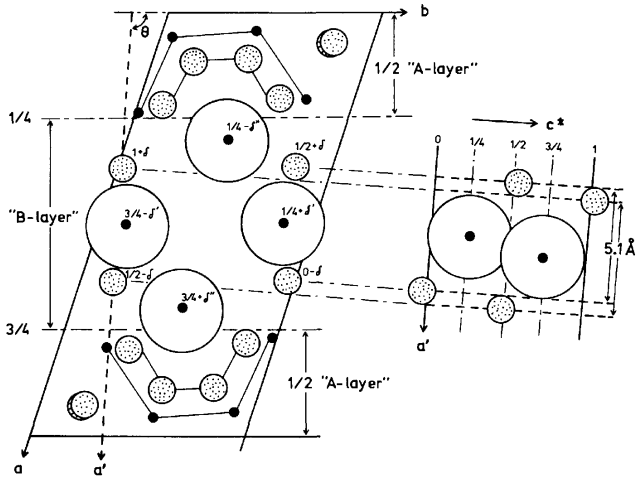

Fig. 1. Simplified OCP structure projected on the a-b plane and +Ca-HPO_4-Ca+ pillars projeted on the a'-c* plane, where ●: P, ⊙: HPO_4, ◎: Ca, c*: vertical to the a-b plane, δ: 0.0313, δ': 0.0168, δ'': 0.0045, θ: 94.1°, the corners of the larger and smaller half hexagons: P and Ca sites in hydroxyapatite, respectively. The illustration was based on the Ref. 1).

Experimental

Powdery α-tricalcium bis(phosphate) (α-$Ca_3(PO_4)_2$) synthesized by solid state reaction[4] was heated in aqueous solutions containing dicarboxylate ions ($C_nH_{2n}C_2O_4^{2-}$; n=0—6) at 40 °C for 3 h. All reactant solutions were prepared at a concentration of 0.25 mol dm^{-3} from chemical reagents of dicarboxylic acids and distilled water. Initial pH's were adjusted to 6.4 ± 0.1 for malonic acid (n=1) and 6.0 ± 0.1 for the other acids (n=0,2—6) with ammonia water. The resulting solid products were examined with respect to product phase and interplanar spacings of OCP by X-ray diffraction, and Ca/P ratio by chemical analyses. The chemical composition of OCP phase was estimated by distributing the residual amount on quantitative analyses of Ca and PO_4 among the other components (H, $C_nH_{2n}C_2O_4$, and H_2O), using the Ca/P ratio of products (OCP+ unreacted α-$Ca_3(PO_4)_2$), conversion of α-$Ca_3(PO_4)_2$ into OCP, and a general formula of dicarboxylate-complexed OCP determined in this work.[4]

Results and Discussion

In the case of the oxalate solution (n=0), α-$Ca_3(PO_4)_2$ was converted completely into calcium oxalate without formation of OCP. OCP was formed from the other reactant solutions (n=1—6). Table 1 lists interplanar spacings and chemical compositions of OCP, Ca/P ratios of products and some reference data. It was clear that the organic substances caused expansions of the basal spacing (d_{100}) of OCP and increases in the Ca/P ratio. Here, adopting the same structural consideration introduced in the preceding paper, dicarboxylate ions incorporated as +Ca-$C_nH_{2n}C_2O_4$-Ca+ instead of +Ca-HPO_4-Ca+ can be illustrated as shown in Fig. 2. The structures of the dicarboxylate ions were taken from those of corresponding acids,[5] and the arrangements and numerals were determined graphically using the radii of $r_{Ca^{2+}}$= 0.99 Å, r_C=0.77 Å, and r_O≈1 Å. The r_O of carboxyl oxygen was estimated from bond lengths of C-O and O-Ca in calcium carboxylate crystals, *e.g.*, calcium

a) Pure OCP.[4] b) $C_nH_{2n}C_2O_4^{2-}$. The case of n=0 (oxalate) formed calcium oxalate. c) $Ca_8(HPO_4)_{2-z}(PO_4)_4(C_nH_{2n}C_2O_4)_z \cdot mH_2O$. d) Mole ratio of OCP+unreacted α-$Ca_3(PO_4)_2$. e) Conversion of α-$Ca_3(PO_4)_2$ into OCP.

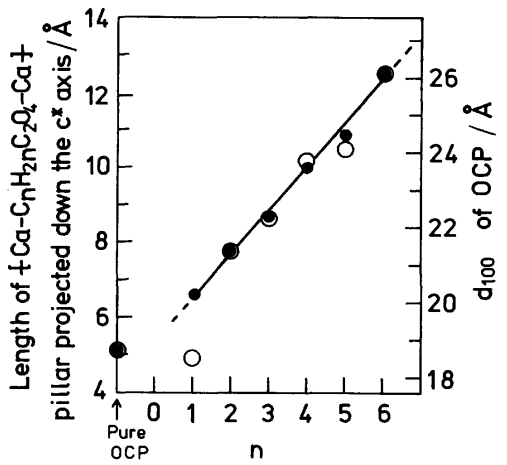

Fig. 3. Pillar lengths and basal spacings of dicarboxylate-complexed OCP.
●: Experimentally obtained, ○: graphically obtained.

formate and calcium oxalate.[5] In addition, we assumed there were no changes in the b and c* directions on the basis of the very small changes in d_{010} and d_{002}, *i.e.*, the b and c directions. Figure 3 shows plots of the lengths of +Ca-$C_nH_2C_{2n}O_4$-Ca+ pillars and d_{100} values *vs.* n, where $[d_{100}(\text{graphic})] \approx [d_{100}(\text{experimental}) - \text{pillar length down the c*}]_{\text{pure OCP}} + [\text{pillar length down the c*}]_{\text{dicarboxylate-complexed OCP}}$, because $\sin\theta \approx 1$ (refer to Fig. 1). The experimental data showed a good linearity, and supported the graphic data approximately. However, departures of graphic data for n=1 and n=5 from the line left an uncertainty about the structural model. The data given in Fig. 3 were considered to confirm the previous claim about succinate-complexed OCP.[4] A general formula would be apparently $Ca_8(HPO_4)_{2-z}(PO_4)_4(C_nH_{2n}C_2O_4)_z \cdot mH_2O$; $0 \leq z \leq 1$, $m \gtrsim 5$, n=1—6 in analogy with that of the succinate-complexed OCP.

Acid Catalysis of the Denitrosation of *N*-Methyl-*N'*-cyclohexyl-*N*-nitrosothiourea

Masayoshi ISOBE

Department of Chemistry, Saitama Medical School, Moroyama, Saitama 350-04

(Received February 2, 1983)

Synopsis. The kinetics of denitrosation of *N*-methyl-*N'*-cyclohexyl-*N*-nitrosothiourea has been studied in the range of pH 3.45—3.73 using four organic acids; acetic acid, formic acid, chloroacetic acid, and cyanoacetic acid. Analyses of the kinetic data including the Brönsted plots have shown that the reaction is subject to a general acid catalysis.

It has been observed that many aliphatic nitroso compounds can act as nitrosating agents of naturally existing amines under conditions analogous to those found in the rat or human stomach (pH 1.7—3.6 with thiocyanate or other nucleophiles as catalyst).[1] Certain aromatic *N*-nitroso compounds have also long been known to be good transnitrosating agents.[2] In addition to above substances, *N*-methyl-*N'*-cyclohexyl-*N*-nitrosothiourea(**1**) was found to undergo denitrosation under nearly neutral conditions (pH 6.7). To investigate acid catalysis of the denitrosation of **1**, the buffer dilution study was performed in the range of pH 3.45—3.73.

Results and Discussion

Pseudo first-order rate constants were measured in a series of buffer solutions of four carboxylic acids at different buffer concentration. The results are summarized in Table 1. The plots of k_{obsd} *vs.* $[buffer]_T$ (total concentration of buffer) are shown in Fig. 1. Since the denitrosation of **1** is catalyzed by buffer and H_3O^+, the k_{obsd} is given by Eq. 1,

$$k_{obsd} = k_H{}^+[H_3O^+] + k_{HA}'[HA] \quad (1)$$

where k_{HA}' and k_{H^+} are second-order rate constants for the buffer catalysis and the hydronium-ion catalysis, respectively. Therefore, the slope and the intercept in Fig. 1 correspond to k_{HA}' and $k_H{}^+[H_3O^+]$, respectively. The slopes and the intercepts were calculated by least squares computation. The k_{H^+} values were obtained from the intercepts. Since the true buffer catalysis is associated with the concentration of acid form of buffer, true second-order rate constants for the general acid catalysis (k_{HA}) are equal to $k_{HA}'/1-\alpha'$ (α'; dissociated fraction of acid). The k_{H^+} and k_{HA} determined are summarized in Table 2. From the data of Table 2, the average k_{H^+} value of **1** for all buffers determined at pH 3.45—3.73 was calculated to be 4.85 ± 0.93. The lowest k_{H^+} value for cyanoacetic acid buffer among those for other acids may be caused by somewhat hindered approach of hydronium ion to the amino nitrogen atom of **1** due to the interaction between hydronium ion and the resonance-stabilized anion partly formed by the abstraction of the α-hydrogen of the parent acid. This anion must be analogous to that formed from mandelonitrile by the attack of base. This average k_{H^+} value was 45 times greater than k_{HA} value for cyanoacetic acid and about 260 times greater than that for acetic acid, respectively. The former value was almost the same with that of acid catalysis in ether hydrolysis (*ca.* 40)[3] and the latter was about 1.7 times greater than that of acid catalysis in hydrolysis of 1,1-dimethoxy-2-phenylethene (*ca.* 160).[4]

The Brönsted plots of pK_a *vs.* log k_{HA} provided the linear relationship (r=0.998, slope($-\alpha$)=−0.38) presented by Eq. 2, as shown in Fig. 2.

$$\log k_{HA} = 0.006 - 0.38\,pK_a \quad (2)$$

This indicates that the denitrosation of **1** is a general acid catalysis. The higher general acid catalysis by the acids possessing electron-withdrawing substituent at the α position suggests that the acid-catalyzed denitrosation of **1** would occur through rate-determining protonation (Scheme 1). The rate of denitrosation at 36.9 °C was measured in CH_3COOD/D_2O to evaluate the solvent deuterium isotope effect. The results at the same buffer concentration (0.05 M, $[HA(DA)]/[A^-]$=0.42, μ=0.2) also showed that denitrosation of **1** involves rate-determining protonation ($k(CH_3COOH/H_2O)/k(CH_3COOD/D_2O)$=1.36, $k(CH_3COOH/$

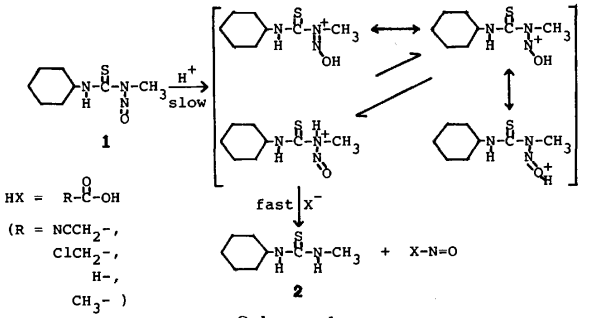

Scheme 1.

H_2O)=1.38×10^{-3} s^{-1}, $k(CH_3COOD/D_2O)$=1.01×10^{-3} s^{-1}). The analogous general acid-catalyzed denitrosation has also been observed in decomposition of *N*-*n*-butyl-*N*-nitrosoacetamide[5] or *N*-nitroso-2-pyrrolidone.[6] The latter showed the Brönsted relationship with a slope(α) of 0.64. Since the rate of protonation of **1** is influenced by the reduced basicity of the amino nitrogen atom due to electron-withdrawing property of the nitroso-substituent, which may also be true for the protonation of *N*-nitroso-2-pyrrolidone, the difference in α between **1** (α=0.38) and *N*-nitroso-2-pyrrolidone (α=0.64) must be caused by the basicity difference of the amino nitrogen atom which is affected by the thiocarbonyl group in **1** or the carbonyl group in the latter. These results suggest that **1** would also be subject to general acid catalysis by carboxylic acid residue of an enzyme under acidic conditions.

Experimental

N-Methyl-N'-cyclohexyl-N-nitrosothiourea (1). *N*-Methyl-*N'*-cyclohexylthiourea (**2**) (0.6 g, 3.48 mmol), which was obtained from the reaction of cyclohexylamine and methyl isothiocyanate in acetone at room temperature (18 h), was treated with sodium nitrite (0.36 g, 5.23 mmol) in acetic acid (5 ml)-acetic anhydride (20 ml) at 0 °C (1 h). The reaction mixture was poured in ice-water and extracted with ether (80 ml) three times. The ethereal solution was washed with 5% Na_2CO_3 solution (4 times), 5% $NaHCO_3$ solution (3 times), saturated NaCl solution, dried ($MgSO_4$), and evaporated to give an orange liquid, which upon trituration with pentane gave yellow crystals of **1** (0.39 g, 56%). **1**: Mp 44.5—45.5 °C (lit,[7] mp 35—36 °C); IR (KBr) 3310 (NH), 2930, 2860, 1515, 1495, 1407, 1175, 1000, 965, 910, and 790 cm^{-1}; NMR (CCl_4) δ 8.36 (1H, br, NH), 4.34 (1H, m, methine), 3.43 (3H, s, $-CH_3$), 2.40—1.00 (10H, m, $-CH_2-$). Found: C, 47.63; H, 7.46; N, 21.20; S, 15.90%. Calcd for $C_8H_{15}ON_3S$: C, 47.73; H, 7.51; N, 20.88; S, 15.93%. **2**: Mp 163—164 °C (lit,[7] mp 165—166 °C).

Product Analysis. A solution of *N*-methyl-*N'*-cyclohexyl-*N*-nitrosothiourea(**1**)(150 mg, 0.745 mmol in 5 ml of methanol was added to 150 ml of Tris buffer solution (pH 6.70, 0.05 M, μ=0.2 with NaCl) and stirred for 5 h at 37 °C. After cooling, the contents were saturated with NaCl and extracted with ether (80 ml×3) and the combined extracts were washed with saturated NaCl solution, dried ($MgSO_4$), and evaporated to give a solid and yellow liquid. The product was separated with pentane to **2** (white solid, 53 mg, 41%) insoluble in pentane and cyclohexyl isothiocyanate (**3**, yellow liquid, 45 mg, 43%) soluble in pentane. **3**: IR(neat) 2950, 2870, 2110(N=C=S), 1450, 1360, and 1307 cm^{-1}; NMR (CCl_4) δ 3.85—3.45 (1H, m, methine), 2.25—1.20 (10H, m, $-CH_2-$).

Kinetic Measurements. The kinetic measurements of the denitrosation of **1** were carried out at 36.9±0.3 °C in a thermostated UV cell. The appropriate buffer solution (3 ml) was transferred into each cell with a pipet, and after standing for thermal equilibration, the reaction was initiated by adding 20 μl of the substrate solution (1 mg/0.4 ml-MeOH) with the aid of a microsyringe. The progress of the reaction was monitored spectrophotometrically by following the disappearance of the absorption maximum at 270 nm. The reaction followed pseudo first-order kinetics; infinity readings were obtained after 8—10 half lives.

Ozonation of Xanthene

Masaki MATSUI,* Yoshihiko MIYAMOTO, Katsuyoshi SHIBATA, and Yoshimi TAKASE
Department of Industrial Chemistry, Faculty of Engineering, Gifu University, Yanagido, Gifu 501-11
(Received April 5, 1983)

Synopsis. The ozonation of xanthene was studied using an oxygen stream. Ozone attacks the methylene group of xanthene *via* a 1,3-dipolar insertion reaction to give the hydrotrioxide intermediate, followed by a loss of singlet oxygen to form xanthydrol. The ozonation of xanthydrol gave singlet oxygen, water and xanthone accompanied by autoxidation.

Methylene group ozonation gives the corresponding carbonyl group. In 1949, Cavill *et al.* reported that xanthene ozonation gave xanthyldrol and xanthone.[1] However, a detailed study of this mechanism has not been reported. In this paper, the authors discuss the ozonation mechanism of xanthene which may possibly produce intermediates capable of giving off singlet oxygen.

Experimental

General. Liquid chromatography was performed with a Jasco Twincle liquid chromatography. Mass spectra were obtained with a Hitachi M-52 spectrometer. Gas chromatography was performed with a Shimadzu 4C-PF gas chromatograph. Melting points were measured with a Yanagimoto micro melting point apparatus and are uncorrected. Ozone was generated by a Nihon Ozon 0-1-2 type ozonizer.

Materials. Xanthene (Nakarai Kagaku Yakuhin Co.) was recrystallized from ethanol. Mp 100.4 °C (lit, 100.5 °C);[2] NMR (CCl_4) δ=4.02 (2H, s) and 6.8—7.3 (8H, m); MS (70 eV) *m/e* (rel intensity) 182(56), 181(100), 152(44), and 76(23). Xanthydrol was synthesized according to the literature.[3] Mp 121.1 °C (lit, 121—123 °C); NMR ($CDCl_3$) δ=2.24 (1H, s), 5.75 (1H, s) and 6.9—7.6 (8H, m); MS (70 eV) *m/e* (rel intensity) 198(16), 197(25), 181(100), and 153(89); IR (KBr disk) 3300 cm^{-1} (OH). Xanthone (Nakarai Kagaku Yakuhin Co.) was recrystallized from ethanol. Mp 175.1 °C (lit, 173.5 °C);[4] MS (70 eV) *m/e* (rel intensity) 196(100), 168(52), and 139(21); IR (KBr disk) 1655 cm^{-1} (C=O).

Ozonation Reaction. Ozonations in all cases were carried out with ozone-oxygen mixtures (ozone: 9.4 mg/min, oxygen: 200 ml/min) on 0.27 mmol of xanthene and xanthydrol in 20 ml of solvent. Products determination was made immediately by liquid chromatography and xanthone was isolated by liquid chromatography. The mass spectra, IR spectra, and mp of xanthone were compared with those of an authentic sample. Though xanthydrol could not be isolated, the NMR and LC analysis of the ozonated solution showed the formation of xanthydrol. Yields were determined by comparison with standard solution of known compounds. The conditions in the liquid chromatography were as follows: column: SS-10, mobile phase: chloroform: hexane= 5:1, detector 254 nm. And the conditions in the gas chromatography for the identification of *o*-dibenzoylbenzene and (*Z*)-α,β-dibenzoylstilbene were as follows: column: 3ϕ×1 m, 2% OV-1, on Gas Chrom Q, injection temp: 280 °C, detector temp: 280 °C, column temp: 130—240 °C, 10 °C/min, detector: FID.

Results and Discussion

Xanthene reacts with ozone to give water, xanthydrol and xanthone. The results of the reactions are shown in Table 1. It was found that 1.2—1.4 molar equivalents of ozone were consumed in reacting with xanthene, indicating that oxidation of xanthene to xanthone does not proceed only with ozone. The greater the polarity of the solvent, the greater is the conversion of xanthene, suggesting a 1,3-dipolar insertion of ozone to the methylene group. The carbonium ion character of the intermediate should be stabilized by the resonance effect from oxygen at the 10-position. In the case of xanthydrol ozonation, from the facts that (1) only 0.2—0.3 molar equivalent of ozone was consumed in reacting with xanthydrol, (2) the rate of the reaction did not depend on the solvent as in the case of xanthene, and (3) when the xanthydrol solution was allowed to stand, xanthone was formed by autoxidation, it is considered that the role of ozone in the ozonation of xanthydrol to xanthone is not particularly significant compared with that of ozone to oxidize xanthene to xanthydrol. On the other hand, it is of interest to identify molecular oxygen by decomposition of the hydrotrioxides. Stary and Kovač reported that the decomposition of aldehyde- and acetal-hydrotrioxides gave singlet oxygen.[5,6] The ozonation of

TABLE 1. OZONATION OF XANTHENE AND XANTHYDROL[a]

Run	Substrate	Solvent	Conversion %	Ozone (10^{-4} mol)	Ozone/Substrate reacting ratio[b]	Yield[c]/% Xanthydrol	Yield[c]/% Xanthone

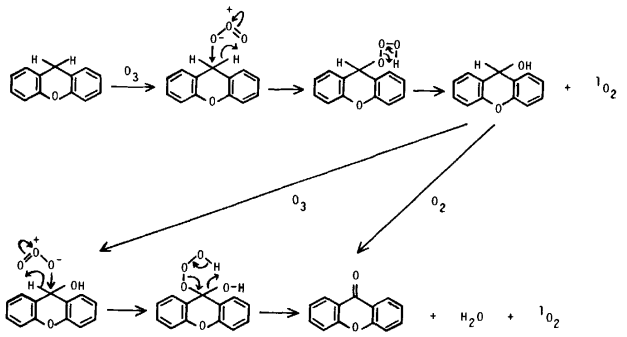
4	Xanthydrol	Tetraphenylcyclopentadienone	87	—	75	—	2

a) The substrates (2.7 mmol) were ozonized in dichloromethane (20 ml) at −78 °C. Singlet oxygen acceptor (0.37 mmol) was then added to the ozonized solutions and allowed to warm to −20 °C. b) Yields were based on the substrates reacting.

TABLE 3. THE DISTRIBUTION OF SINGLET OXYGEN PRODUCTS IN THE OXIDATION OF 1,2-DIMETHYLCYCLOHEXENE

Method	Product distributions/%	
	1-Methyl-2-methylenecyclohexanol	1,2-Dimethylcyclohex-2-en-1-ol
Xanthene-hydrotrioxide decomposition[a)]	93	7
Photooxidation[b)]	89	11
Hydrochlorite-hydrogen peroxide method[b)]	91	9

a) Xanthene (1.1 mmol) was ozonized in dichloromethane (20 ml) at −78 °C. 1, 2-Dimethylcyclohexene (1.9 mmol) was then added to the ozonized solution and allowed to warm to −20 °C. The hydrotrioxide products were reduced to the corresponding alcohols by sodium borohydride and analyzed by GLC. b) Ref. 7.



Scheme 1.

xanthene and xanthydrol was carried out at −78°C and then the excess ozone was removed. 1,3-Diphenylisobenzofuran and tetraphenylcyclopentadienone, singlet oxygen acceptors, were added to the ozonated solution which was then allowed to warm to −20°C. As expected, *o*-dibenzoylbenzene and (*Z*)-α,β-dibenzoylstilbene were detected. The results are shown in Table 2. The product yields were low because of the instability of the hydrotrioxides. In order to obtain further evidence that decomposition of xanthene-hydrotrioxide gives singlet oxygen, the technique of Foote *et al.* was also used.[7] The result is shown in Table 3. The products distribution by decomposition of xanthene-hydrotrioxide was the same as that by the sensitized photooxidation and hydrochlorite-hydrogen peroxide method. The probable reaction mechanism of xanthene ozonation is shown in Scheme 1.

The authors thank Prof. Teijiro Kitao of University of Osaka Prefecture for a useful discussion.

The Reaction of 3,5-Diphenyl-1,2,4-dithiazol-1-ium Perchlorate with Active Methylene Compounds

Isao SHIBUYA
National Chemical Laboratory for Industry, Yatabe, Ibaraki 305
(Received June 1, 1983)

Synopsis. The reaction of 3,5-diphenyl-1,2,4-dithiazol-1-ium perchlorate with several kinds of active methylenes gives a number of heterocycles, such as 4-hydroxy and 4-mercaptopyrimidine, pyrimidinone, and thiazole derivatives. On treatment with hydroxylamine-*O*-sulfonic acid, the 4-mercaptopyrimidines lead to the aminothio compounds or the isothiazolo[5,4-*d*]pyrimidine.

Some heteroaromatic cationic species have high reactivity against nucleophiles, such as amino compounds and various kinds of carbanions.[1] The reactivities of heteroaromatic cations are essentially similar, but, strictly speaking, they react with a nucleophile in slightly different fashions to lead to various types of derivatives.[2] 3,5-Diphenyl-1,2-dithiol-1-ium cation was found to react with active methylenes to produce a number of derivatives.[3] It can therefore be assumed that 3,5-diphenyl-1,2,4-dithiazol-1-ium cation, the *N*-analog of the corresponding dithiolium cation, would afford several derivatives by treatment with active methylenes. In the present study, the reaction of 3,5-diphenyl-1,2,4-dithiazol-1-ium perchlorate (**1**) with several active methylene compounds was carried out in order to survey its reactivity.

The starting material, **1**, was obtained by treating thiobenzamide with thiobenzanilide *S*-oxide in acetic anhydride–perchloric acid.[4]

When cyanoacetamide, benzoylacetamide, and benzoylacetoanilide were heated to reflux with **1** in MeO-Na–MeOH, **2**, **3**, and **4** were afforded in 92, 38, and 44% yields respectively. These were same compounds given by the reaction of 2,4,6-triphenyl-1,3,5-thiadiazin-1-ium salt with these reagents,[5] so that **2**, **3**, and **4** were identified to be 5-cyano- and 5-benzoyl-4-hydroxy-2,6-diphenylpyrimidine, and 5-benzoyl-2,3,6-triphenyl-4(3*H*)-pyrimidinone. 3,5-Diphenyl-1,2-dithiol-1-ium salt similarly reacted with these reagents to afford the corresponding pyridines and pyridinone,[3] and consequently the behavior of **1** and the corresponding dithiolium salt toward these reagents was assumed to be the same.

Malononitrile, ethyl cyanoacetate, and diethylcarbamoylacetonitrile were heated to reflux with **1** in presence of sodium hydride, and then treated with hydrochloric acid to afford yellow powders of **5**, **6**, and **7** in 92, 42, and 47% yields respectively. Compounds **5** and **6** were confirmed to be 5-cyno- and 5-ethoxycarbonyl-4-mercapto-2,6-diphenylpyrimidine which are given by the reaction of 2,4,6-triphenyl-1,3,5-thiadiazin-1-ium salt with the two reagents.[5] The UV and IR spectra of **7** were similar to those of **5** and **6**. Its MS data and analytical results supported the conclusion that **7** is 5-diethylcarbamoyl-4-mercapto-2,6-diphenylpyrimidine.

On the other hand, benzoylacetonitrile and phenylsulfonylacetonitrile gave a common product, **8**, in 42 and 53% yields, respectively, when treated with **1** in the presence of sodium hydride. Its IR spectrum had an absorption assignable to a cyano group, but neither a benzoyl nor a phenylsulfonyl group. The molecular weight of **8** was determined by its MS data to be 262. These spectral data and the analytical results supported the assignment that **8** is 5-cyano-2,4-diphenylthiazole.

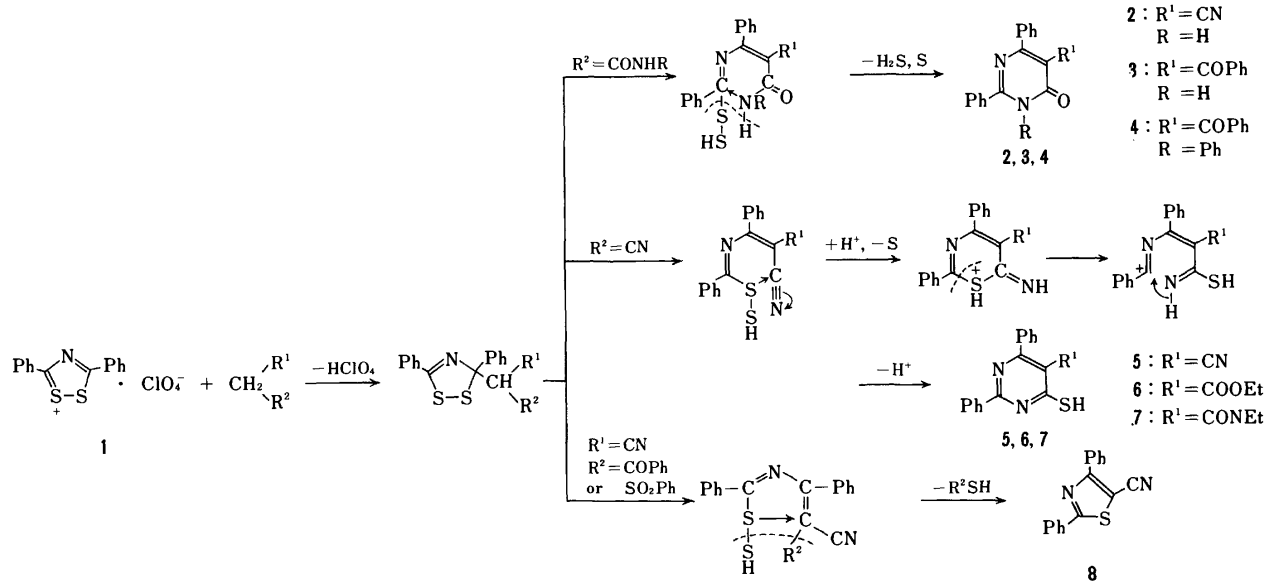
The reaction of the corresponding dithiolium salt with active methylene possessing ester groups gives a number of 2*H*-thiopyran-2-ones,[3] while the reaction of **1** with diethyl malonate and ethyl benzoylacetate did not give 6*H*-1,3-thiazin-6-ones. This fact suggested that **1** has no reaction mode in which an ester group of these reagents participates.

The results of forming **2**—**8** are summarized in Scheme 1.

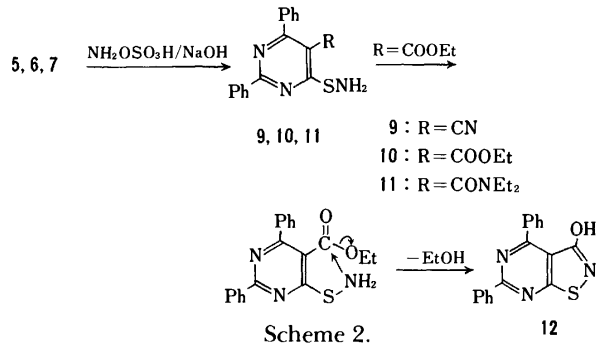
When treated with hydroxylamine-*O*-sulfonic acid in the presence of sodium hydroxide, **5** and **7** gave white powders of **9** and **11** in good yields. Their IR spectra have two absorptions assignable to the N–H stretching in the range of 3376—3244 cm^{-1} and an absorption of a pyrimidine ring at around 1525 cm^{-1}. Their molecular weights were determined by their MS data to be 304 and 378. These spectral data suggested that **9** and **11** are 4-(aminthio)-5-cyano- and 4-(aminothio)-5-diethylcarbamoyl-2,6-diphenylpyrimidines respectively. Their analytical results also supported the structure assignments. On treatment with hydroxyamine-*O*-sulfonic acid under the same conditions as the above, however, **6** did not give the corresponding aminothiopyrimidine, **10**, but another product, **12**, was obtained. The spectrum of **12** had no absorption assignable to an ester group (*ca.* 1750 cm^{-1}). The molecular weight was determined to be 305. The structure of **12** was thus confirmed by these spectral and the analytical data to be 3-hydroxy-4,6-diphenylisothiazolo[5,4-*d*]pyrimidine. The reaction could be assumed to proceed as follows: **6** leads to **10** in the same fashion as do the other two mercaptopyrimidines (**5** and **7**); however, **6** further cyclizes to form **12** together with the elimination of ethanol (Scheme 2). This process could be regarded as analogous to that forming 3-amino-4,6-dimethylisothiazolo[5,4-*b*]-pyridine.[6]

Experimental

Reactions of 1 with Cyanoacetamide, Benzoylacetamide, and Benzoylacetanilide. Into a solution of cyanoacetamide, benzoylacetamide, or benzoylacetanilide (1.5 mmol) in 1 mol dm^{-3} MeONa–MeOH (3 ml), **1** (0.36 g, 1.0 mmol) was added with stirring in small portions, and then heated to reflux for 1 h. The reaction mixture was poured into dilute hydrochloric acid. The resulting precipitate was filtered off and recrystallized from acetonitrile to afford 5-cyano- or 5-benzoyl-4-hydroxy-2,6-diphenylpyrimidine (**2**, **3**), or 5-benzoyl-2,3,6-triphenyl-4(3*H*)-pyrimidinone (**4**) in 92, 38, 44% yield. Their IR spectra could be completely superimposed on those of the authentic samples.[5]



Scheme 1.



Scheme 2.

Reaction of 1 with Malononitrile, Ethyl Cyanoacetate, and Diethylcarbamoylacetonitrile. Into a solution of malononitrile ethyl cyanoacetate, or diethylcarbamoylacetonitrile (1.5 mmol) and sodium hydride (0.10 g, 4.2 mmol) in THF (3 ml), **1** (0.36 g, 1.0 mmol) was added with stirring in small portions, and heated to reflux for 1 h. The reaction mixture was poured into dilute hydrochloric acid. The precipitate was separated by decantation, and dissolved again in 2 mol dm^{-3} HCl–EtOH (3 ml); the resulting mixture was allowed to stand overnight. The solution was poured into an excess amount of water. The resulting precipitate was recrystallized from acetonitrile (**5**, **6**) or ethanol (**7**) to give 5-cyano-, 5-ethoxycarbonyl-, or 5-diethylcarbamoyl-4-mercapto-2,6-diphenylpyrimidine (**5**, **6**, or **7**) in 92, 42, or 47% yield. The IR spectra and the melting points of **5** and **6** agreed with those of their authentic samples.[5] The data of 7 are presented below.

Mp, 266 °C; IR (KBr), 3058—2872, 1609, 1552, 1496, and 1235 cm^{-1}. UV_{max} (EtOH), 256 (ε 25400), 314 (12600), and 381 nm (4100); MS *m/e*, (rel intensity) 364 (M^+, 11.5), 330 (M^+-SH, 20.5), 291 (M^+-NEt_2, 20.5), 264 (13.1), 104 (72.3), and 72 (Et_2N^+, 100). Found: C, 69.14; H, 5.80; N, 11.57; S, 8.53%. Calcd for $C_{21}H_{21}N_3SO$: C, 69.39; H, 5.82; N, 11.56; S, 8.82%.

5-Cyano-2,4-diphenylthiazole (8). Into a solution of benzoylacetonitrile (0.22 g, 1.5 mmol) and sodium hydride (0.10 g, 4.2 mmol) in THF (3 ml), **1** (0.36 g, 1.0 mmol) was added with stirring in small portions, heated to reflux for 1 h. The reaction mixture was poured into dilute hydrochloric acid, and the precipitate was recrystallized from cyclohexane to give 0.11 g (42%) or 0.14 g (53%) of **8**; m, 132 °C. MS *m/e*, (rel intensity) 262 (M^+, 50.7), 159 (M^+-PhCN, 100), 115 (Ph_2N^+, 23.6). UV_{max} (EtOH), 266 (ε 31000) and 318 nm (12100). Found: C, 73.50; H, 3.67; N, 10.60; S, 12.56%. Calcd for $C_{16}H_{10}N_2S$: C, 73.26; H, 3.84; N, 10.68; S, 12.72%.

4-(Aminothio)-5-cyano- and 4-(Aminothio)-5-diethylcarbamoyl-2,6-dipenylpyrimidine (9 and 11). Into a solution of hydroxylamine-*O*-sulfonic acid (0.50 g, 4.4 mmol) in 2 M NaOH (10 ml), **5** (0.29 g, 1.0 mmol) or **7** (0.37 g, 1.0 mmol) was added with stirring in small portions at 0—5 °C, and then allowed to stand at room temperature overnight. The resulting white powders were filtered off and recrystallized from ethanol to give **9** (0.22 g, 72%) or **11** (0.24 g, 63%).

9: Mp, 147 °C; IR (KBr), 3376, 3288, 2216, 1525, 1491, 1442, and 1379 cm^{-1}. Catalytic Conversion of Allylic Esters to Corresponding Allylic Silanes with Hexamethyldisilane and Palladium(0) or Rhodium(I) Complexes

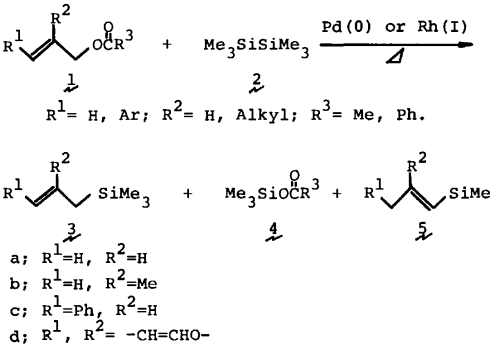
Hisao URATA, Hiroharu SUZUKI,* Yoshihiko MORO-OKA,* and Tsuneo IKAWA
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta-cho, Midori-ku, Yokohama 227
(Received June 20, 1983)

Synopsis. Treatment of allylic esters ($R^1CH=CR^2CH_2OCOR^3$: R^1=H, Ar; R^2=H, alkyl; and R^3=Me, Ph) with hexamethyldisilane in the presence of catalytic amounts of PdL_4 (L=PPh_3 or $P(OPh)_3$) or $RhCl(PPh_3)_3$ gives the corresponding allylic silanes in the excellent yield.

Synthetic utility of disilanes ($Cl_nMe_{6-n}Si_2$: n=0—6) have recently been developed. Monosilylation[1] and disilylaion ("double silylation")[2] of many classes of organic substrates have been achieved *via* the cleavage of Si-Si bond catalyzed by transition metal complexes. Disilane can also be used in the Pd(0)-catalyzed reductive dehalogenation of α-halogenated carbonyl and cyano compounds.[3] We report herein a simple preparative method of allylic silances, **3**, from allylic esters, **1**, and hexamethyldisilane, **2**, by using PdL_4 (L=PPh_3 or $P(OPh)_3$) or $RhCl(PPh_3)_3$ as catalyst.

Results and Discussion

Treatment of allylic acetates or benzoates, **1**, with hexamethyldisilane, **2**, in the presence of catalytic amounts of Pd(0) or Rh(I) complex at 140—160°C in sealed tube gave the corresponding allylic silanes, **3** (Eq. 1). Trimethylsilyl acetate[4] or benzoate,[5] **4**, was also formed in this reaction. The products were separated by column chromatography on silica gel and were identified and quantified by means of ^{1}H-NMR and GLC. Gaseous by-products were also identified and quantified by use of GLC. The results of the Pd(0) and Rh(I)-catalyzed conversion of allylic esters to allylic



(1)

silanes are summarized in Table 1.

As shown in Table 1, β-methallyl acetate, β-methallyl benzoate, cinnamyl acetate, and furfuryl acetate were efficiently converted to the corresponding allylic silanes. Trimethylsilyl group was regioselectively introduced into the α-position of cinnamyl group to give (*E*)-cinnamyltrimethylsilane,[6] **3c** (entries 12 and 13).

Tetrakis(triphenylphosphite)palladium(0) effectively catalyzed the reaction of allyl acetate or benzoate with hexamethyldisilane to give allyltrimethylsilane,[6] **3a**, in an excellent yield whereas tetrakis(triphenylphosphine)palladium(0) and chlorotris(triphenylphosphine)rhodium(I) caused side reaction to afford propylene and (*E*)-1-propenyltrimethylsilane,[7] **5**, the double bond migration product of **3a**. The isomerization of allyltrimethylsilane, **3a**, to (*E*)-1-propenyltrimethylsilane, **5**, was examined under the various

1) A: $Pd(PPh_3)_4$, B: $Pd[P(OPh)_3]_4$, C: $RhCl(PPh_3)_3$. 2) Propylene was detected as a by-product. 3) Ref. 11. 4) 2,5-Dimethyl-1,5-hexadiene was obtained in a 17% yield. 5) β-Methylstyrene was obtained in a 40% yield. 6) Furfuryltrimethylsilane was obtained. Ref. 12.

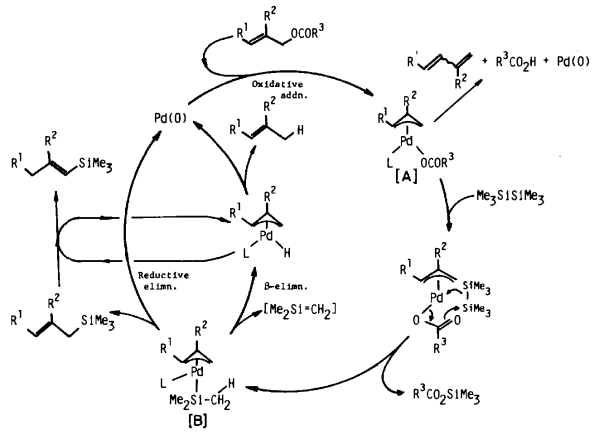
Conditions
A) 150 °C-2 h (no reaction)
B) $Pd(PPh_3)_4$—150 °C-2 h (no reaction) (2)
C) $Pd(PPh_3)_4$-AcOH—160 °C-2 h (20%)

conditions (Eq. 2).

Allyltrimethylsilane, **3a**, was isomerized to (*E*)-1-propenyltrimethylsilane, **5**, in a 20% conversion under the conditions C where palladium hydride was an actual active species.[8] This suggests the double bond migration of **3a** to **5** occurs by way of the addition-elimination of Pd–H formed by β-elimination from intermediary Pd–$SiMe_3$ species.

The applicability of the present method is however limited to the allylic esters having no *primary* or *secondary* alkyl group at the γ-position of allylic moiety. When R^1 was *primary* or *secondary* alkyl group, treatment of **1** with Pd(0) or Rh(I) complex gave the conjugated diene even in the presence of excess amounts of hexamethyldisilane. These results well agreed with those reported by Tsuji *et al.*[9]

From the results mentioned above, the following mechanism would be proposed for the conversion of allylic esters to the allylic silanes catalyzed by Pd(0) complex (Scheme 1).



Scheme 1.

Allylic ester oxidatively adds to palladium(0) complex to give a π-allylpalladium carboxylate complex [**A**][10] followed by a nucleophilic attack of disilane to form a trimethylsilyl-π-allylpalladium species [**B**] and trimethylsilyl ester. The reductive elimination from [**B**] affords allylic silane and Pd(0) complex. The Pd–H species formed *via* the β-elimination from [**B**] promotes the double bond migration of the allylic silane to the vinylic one and ultimately turns to Pd(0) with formation of the alkene such as propylene or β-methylstyrene.

Experimental

All reactions were conducted in Pyrex sealed tubes under nitrogen atmosphere.

Synthesis of (E)-*Cinnamyltrimethylsilane (entry 12).* Tetrakis(triphenylphosphine)palladium (62.8 mg, 0.054 mmol) was placed in a Pyrex tube equipped with a three-way stopcock. After the atmosphere was replaced with nitrogen, hexamethyldisilane (0.70 g, 4.78 mmol) and cinnamyl acetate (0.87 g, 4.94 mmol) were added. Then the tube was sealed and heated at 160 °C for 10 h. Bulb to bulb distillation of the resultant mixture gave trimethylsilyl acetate[4] (0.60 g, 95%), ^{1}H-NMR (CCl_4) δ=0.20 (9H, s), 1.97 (3H, s). Purification of the residue by column chromatography (silica gel, benzene) afforded (*E*)-cinnamyltrimethylsilane[6] (0.72 g, 79%), bp 234 °C; IR (CCl_4) 960 cm^{-1} (*trans* CH=CH); ^{1}H-NMR (CCl_4) δ=0.05 (9H, s), 1.63 (2H, m), 6.10 (2H, m), 7.11 (5H, bs).

Synthesis of Allyltrimethylsilane and (E)-*1-Propenyltrimethylsilane (entry 1).* $Pd(PPh_3)_4$ (57.6 mg, 0.05 mmol), hexamethyldisilane (1.44 g, 10.05 mmol), and allyl acetate (1.02 g, 10.22 mmol) were placed in a Pyrex tube under N_2. After the tube was sealed and heated at 180 °C for 2 h, bulb to bulb distillation of the resultant mixture gave a mixture (2.40 g) of trimethylsilyl acetate[4] (100%), allyltrimethylsilane[6] (48%), and (*E*)-1-propenyltrimethylsilane[7] (48%), IR (CCl_4) 982 cm^{-1} (*trans* CH=CH); ^{1}H-NMR (CCl_4) δ=0.02 (9H, s), 1.80 (3H, d, *J*=5 Hz), 5.44 (1H, d, *J*=19 Hz), 6.06 (1H, dq, *J*=19 and 5 Hz). Propylene was also detected from gas phase by GLC analysis in a 2% yield.

Isomerization of Allyltrimethylsilane to (E)-*1-Propenyltrimethylsilane.* To a benzene solution (1 ml) of $Pd(PPh_3)_4$ (66.2 mg, 0.057 mmol) and acetic acid (3 μl) was added allyltrimethylsilane (0.77 g, 6.75 mmol). After the mixture was heated at 160 °C for 2 h in a Pyrex sealed tube, ^{1}H-NMR measurement of the reaction mixture showed a 20% conversion of (*E*)-1-propenyltrimethylsilane.

The authors are grateful to the Toshiba Silicon Co. Ltd. for a generous gift of disilane residue in the direct synthesis.

A Convenient Synthesis of 3-Aminotropolone and Its Reactions with Orthoesters. Formation of 8*H*-Cyclohept[*d*]oxazol-8-ones

Kimiaki IMAFUKU,* Miki FURUYA,† and Zhong-Tian JIN††
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860
††*Department of Chemistry, Yanbian University, Yanji, Jilin Province, People's Republic of China*
(Received June 21, 1983)

Synopsis. Schmidt reaction of 3-acetyltropolone gave 3-acetamidotropolone, which was hydrolyzed to afford 3-aminotropolone (**3**). The compound **3** reacted with orthoformate, orthoacetate, orthopropionate, and orthobenzoate to give the corresponding 2-substituted 8*H*-cyclohept[*d*]oxazole-8-one derivatives.

Recently, we found and reviewed that 3-acetyltropolone is very useful as starting material for the synthesis of heterocycle-condensed troponoid compounds.[1] In this series, we reported that 3-acetyltropolone and its methyl ethers reacted with hydroxylamine to afford 8*H*-cyclohept[*d*]isoxazol-8-one and 8*H*-cyclohept[*c*]isoxazol-8-one as a major and minor product, respectively.[2] It is also known that 3-aminotropolone reacted with formamide, acetic anhydride, or *p*-nitrobenzaldehyde to give 8*H*-cyclohept[*d*]oxazol-8-ones,[3,4] while 2-amino-3-hydroxytropone reacted with acetic anhydride to give 4*H*-cyclohept[*d*]oxazol-4-one.[5,6] The 1,3-dipolar addition of arenecarbonitrile oxide to tropone gave 4*H*-cyclohept[*d*]isoxazol-4-one derivatives.[7]

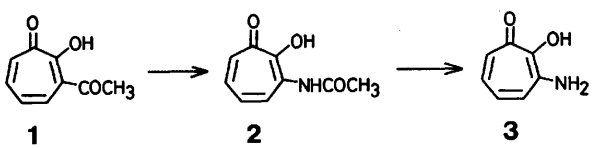
Previously, 3-aminotropolone was prepared from 3-nitrotropolone[8] or 3-bromotropolone.[9] On the other hand, it was reported that Schmidt reaction of 4-acetyltropolone afforded 4-aminotropolone.[10]

In a series of 3-acetyltropolone chemistry, we wish to report the convenient synthesis of 3-aminotropolone by Schmidt reaction of 3-acetyltropolone and its conversion to 8*H*-cyclohept[*d*]oxazole-8-ones by reactions with orthoesters.

Results and Discussion

When we applied the Schmidt reaction to 3-acetyltropolone(**1**),[11] 3-acetamidotropolone(**2**)[3] was isolated. The compound **2** was readily hydrolyzed to give 3-aminotropolone(**3**), whose averall yield based on **1** was 56%.

A mixture of 3-aminotropolone (**3**) and triethyl orthoformate or triethyl orthoacetate was heated under reflux to afford respectively 8*H*-cyclohept[*d*]oxazole-8-one (**4a**)[4] (44%) and its 2-methyl derivative (**4b**)[3] (73%). In the NMR spectrum of the compound **4a**, the H-2 proton in the oxazole ring is observed at lower magnetic field (δ=8.21) than the H-2 proton in oxazole ring (δ=7.95).[12] In a similar manner, the reaction with triethyl orthopropionate and trimethy orthobenzoate gave 2-ethyl- and 2-phenyl-8*H*-cyclohept[*d*]oxazol-8-ones (**4c** and **4d**) in 80 and 10% yields, respectively.



1 2 3

Scheme 1.

Experimental

Measurements. The melting points were determined with a Yanagimoto MP-S2 melting point-measuring apparatus and are uncorrected. The IR spectra were taken on a JASCO IRA-1 spectrophotometer, and the UV spectra on a Hitachi EPS-3T spectrophotometer. The NMR spectra were recorded with a Hitachi R-24 spectrometer (60 MHz).

3-Acetamidotropolone (2). Sodium azide (2.60 g, 40 mmol) was added to a solution of 3-acetyltropolone (**1**) (3.28 g, 20 mmol) in chloroform (40 ml). Concentrated sulfuric acid (10 ml) was carefully dropped into the mixture in an ice-cooled bath under stirring. After stirring for 2 h at room temperature, the chloroform was removed by decantation. After cold water (80 ml) was added to the residue, a precipitate was collected and recrystallized from methanol to give 2.3 g (66%) of 3-acetamidotropolone (**2**) as colorless needles: mp 119—120 °C (lit,[3] 107—108 °C); IR ($CHCl_3$) 3315 (NH), 1702 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.30 (3H, s, CH_3), 7.0—7.6 (3H, m), 9.1—9.4 (1H, m, NH).

3-Aminotropolone (3). 3-Acetamidotropolone (**2**) (2.0 g) in 50% sulfuric acid (22 ml) was heated on a water bath for 1 h. The mixture was neutralized with sodium hydrogencarbonate solution, acidified slightly with 30% acetic acid, and extracted with chloroform. The evaporation residue from the extract was recrystallized from benzene–petroleum ether to give 1.3 g (85%) of 3-aminotropolone (**3**) as yellow needles: mp 86 °C (lit,[8] 86 °C); NMR ($CDCl_3$) δ=5.6—6.7 (2H, br, NH_2), 6.6—7.5 (m, 4H).

Reaction of 3-Aminotropolone (3) with Triethyl Orthoformate. A mixture of 3-aminotropolone (**3**) (137 mg, 1.0 mmol) and triethyl orthoformate (2 ml) was refluxed for 2 h. After cooling, the precipitate was collected and recrystallized from benzene–hexane to give 65 mg (44%) of 8*H*-cyclohept[*d*]oxazol-8-one (**4a**) as pale yellow needles: mp 149—150 °C (lit,[4] 150—151 °C); IR ($CHCl_3$) 1625 cm^{-1} (C=O); UV (CH_3OH) 237 (log ε 4.56), 310 nm (3.94); NMR ($CDCl_3$) δ=6.8—8.0 (4H, m), 8.21 (1H, s, H-2).

Reaction of 3 with Triethyl Orthoacetate. A mixture of **3** (274 mg, 2.0 mmol) and triethyl orthoacetate (2 ml) was refluxed for 2 h. The reaction mixture was dissolved in chloroform and twice washed with water. After removal of the solvent, the residue was recrystallized from benzene–hex-

ane to give 234 mg (73%) of 2-methyl-8*H*-cyclohept[*d*]oxazol-8-one (**4b**) as pale yellow needles: mp 150—151 °C (lit,[3] 144—145 °C); IR ($CHCl_3$) 1640 cm^{-1} (C=O); UV (CH_3OH) 243 (log ε 4.44), 312 nm (3.68); NMR ($CDCl_3$) δ=2.67 (3H, s, CH_3), 6.9—7.8 (4H, m).

Reaction of 3 with Triethyl Orthopropionate. A mixture of **3** (274 mg, 2.0 mmol) and triethyl orthopropionate (2 ml) was refluxed for 2 h and worked up, as mentioned above, to afford 280 mg (80%) of 2-ethyl-8*H*-cyclohept[*d*]oxazol-8-one (**4c**) as pale yellow needles: mp 92—93 °C (from benzene–hexane); IR ($CHCl_3$) 1640 cm^{-1} (C=O); UV (CH_3OH) 245 (log ε 4.49), 312 nm (3.83); NMR ($CDCl_3$) δ=1.50 (3H, t, J=7 Hz, CH_3), 3.03 (2H, q, J=7 Hz, CH_2), 6.9—7.8 (4H, m). Found: C, 68.51; H, 5.21; N, 7.92%. Calcd for $C_{10}H_9NO_2$: C, 68.56; H, 5.18; N, 8.00%.

Reaction of 3 with Trimethyl Orthobenzoate. A solution of **3** (137 mg, 1.0 mmol) and trimethyl orthobenzoate (182 mg, 1.0 mmol) in chloroform (2 ml) was refluxed for 2 h. After removal of the solvent, the residue was chromatographed on a Wakogel B-10 plate (30×30 cm^2) with ethyl acetate to give 23 mg (10%) of 2-phenyl-8*H*-cyclohept-[*d*]oxazol-8-one (**4d**) as pale yellow needles: mp 149—150 °C (from benzene–hexane); IR ($CHCl_3$) 1640 cm^{-1} (C=O); UV (CH_3OH) 275 (log ε 4.42), 349 (sh, 3.84), 365 nm (sh, 3.63); NMR ($CDCl_3$) δ=7.0—7.8 (7H, m,), 8.1—8.5 (2H, m, H-2′, 6′). Found: C, 75.32; H, 4.06; N, 6.28%. Calcd for $C_{14}H_9NO_2$: C, 75.50; H, 3.96; N, 6.26%.

(Received June 25, 1983)

Synopsis. Several aromatic and aliphatic α,β-unsaturated ketones were converted to the corresponding γ-keto acids by the electrochemical reduction in acetonitrile in the presence of CO_2. The yields of the keto acid were 73—82% when the enones have at least one aromatic substituent. In the case of aliphatic enones, the yields of the carboxylation reaction were 67% for 2-cyclohexen-1-one and 44% for 3-buten-2-one.

γ-Keto acids or γ-keto esters are useful intermediates for γ-lactones, cyclopentenones, butenolides, 1,3-cyclopentanediones and heterocyclic compounds. Available synthetic methods of γ-keto acid or γ-keto esters usually need multi-stage reactions.[1a-g] In recent years, electrochemical carboxylation of various unsaturated compounds has received considerable attention from synthetic and mechanistic point of views. Among these, reductive carboxylation of α,β-unsaturated ketones has been reported,[2-4] where γ-keto acids were produced. However, the yields were not satisfactory in the earlier works because of the formation of dimeric and polymeric products.

We would like to report the effective transformation of aromatic and aliphatic α,β-unsaturated ketones into γ-keto acid by electrochemical carboxylation with CO_2 in acetonitrile under the controlled potential conditions.

Results and Discussion

The α,β-unsaturated ketones, 4-phenyl-3-buten-2-one (**1**), 1,3-diphenyl-2-propen-1-one (**2**), 1,3,3-triphenyl-2-propen-1-one (**3**), 2-cyclohexen-1-one (**4**), 3-methyl-2-cyclohexen-1-one (**5**), and 3-buten-2-one (**6**) were used for starting materials. The polarographic half-wave potential in each case is summarized in Table 1. The aromatic enones **1**—**3** showed two one-electron reduction waves, while the aliphatic enones **4**—**6** exhibited only a single one-electron wave. For all of the compounds studied, the half-wave potentials of both the first and second waves are more positive than that of carbon dioxide (*ca.* −2.5 V).

When carbon dioxide was introduced into the solution of the aromatic enone **2**, the first wave grew as CO_2 concentration increased and the final height of it became approximately two times of that of the original first wave. A similar phenomenon was observed for the aliphatic enone **4**. These facts suggest that at the first wave potential the ECE reaction of an anion radical with CO_2 proposed by Wawzonek[2] may operate to afford the carboxylated product.

When preparative electrolysis of the aromatic enone **2** was carried out at the potential of the first wave, at which the anion radical species is formed, the carboxylated product was obtained less selectively (35%), and considerable amounts of dimeric and polymeric materials were formed, in accordance with the results shown by Wawzonek. When the electrolysis of the enone **2** was made at the potential of the second wave, 2,4-diphenyl-4-oxobutanoic acid was produced in 77% yield (run 2 in Table 1). In this case, by-products were a minor amount of a dihydro compound, 1,3-diphenyl-1-propanone, and traces amounts of dimeric and polymeric materials. Similar results were also obtained with the aromatic enones **1** and **3** (runs 1 and 3). Here, it is worth noting that an introduction of bulky phenyl groups into the enone moiety does not hinder the efficiency of the carboxylation reaction. This is the marked difference from the cases of aliphatic enones. The fact that more selective transformation of the enone **2** into the γ-keto acid was achieved at the second wave potential, at which dianion species is formed, suggests that a pathway arising from the reaction of the dianion with CO_2 is more effective to the carboxylation reaction.

On the other hand, the second reduction waves were not observed for the aliphatic enones **4**—**6**. When the electrolysis of **4** was carried out at −2.40 V, the yield of the keto acid was 43% and considerable amounts of dimeric products of cyclohexenone were formed (50%, run 4). When a methyl group was attached to the 3-position of cyclohexenone ring, the yield of γ-keto acid decreased to 10% (run 10). With the enone **5**, the carboxylation reaction became rather a minor path and a large amount of a mixture of dimeric compounds was obtained in 80% yields. In order to examine the effect of the anion radical concentration on the electrode surface on the competitive pathways of carboxylation and dimerization, we carried out a series of controlled current experiments with 2-cyclohexen-1-one (**4**) (runs 5—9). When the current density, which should relate to the radical concentration on the electrode surface, was chosen to be 20 A dm^{-2}, the yield of the keto acid was only 18% (run 9). By lowering the current density, the yields were definitely improved up to 67% (run 6). With 2-buten-1-one (**6**), the carboxylation also occurred in moderate yield (run 12), but a detailed study has not been done in this case.

Table 1. Electrolyses of α,β-unsaturated ketones with CO_2 in acetonitrile

Run	Starting materials (mmol)	Half wave potential / V	Conditions[a] / V or A dm^{-2}	Conversion / %	Yield of the products[b]/% γ-Keto acid	Saturated ketone	Dimeric products	Current[c] efficiency / %

a) Electricity was 2.0 F mol^{-1} for runs 1—11, and 4.0 F mol^{-1} for run 12. b) Based on reacted ketones. c) Current efficiency of carboxylation.

Experimental

General. Guaranteed grade enones were purified by distillation or recrystallization before use. Acetonitrile was purified in the usual way.[5] The base solution used for polarographic measurements and preparative electrolyses was always acetonitrile containig 0.1 mol dm^{-3} tetraethylammonium perchlorate. All the potential values cited are referred to a saturated calomel electrode using acetonitrile as the solvent.[6] Preparative electrolyses were carried out in a divided cell with a mercury pool cathode at 5—10°C under the controlled potential conditions. A solution of a enone (10 mmol dm^{-3}) was placed into the cathode compartment and saturated with bubbling CO_2. In some experiments, the electrolyses were made under the controlled current. The electrolyzed solution was evaporated to remove the solvent and the residue was taken into a small amount of water, acidified, and extracted with ether throughly. The condensed extract was subjected to product analyses. The γ-keto acids were isolated by silica-gel column chromatography or preparative GLC after esterifications. Reaction conditions and results are summarized in Table 1. All the spectroscopic data, melting points, and elemental analyses agreed with those of the authentic samples.

A Simple and Convenient Method for the Synthesis of Sulfones Using Polyethylene Glycols or Their Dialkyl Ethers as Solvents or Catalysts

Kazuaki SUKATA
Nihon Tokushu Kagaku Kogyo Co., Ltd., 3-36, Tohda-cho, Moriguchi, Osaka 570
(Received June 2, 1983)

Synopsis. Various alkyl *p*-tolyl sulfones were prepared in good yields under mild conditions in the presence of polyethyene glycols or their dialkyl ethers as solvents or catalysts.

It has been reported[1] that the alkylation of sodium *p*-toluenesulfinate in methanol (MeOH) or *N*, *N*-dimethylformamide gives both the *p*-toluenesulfinic ester and the sulfone, and alkylation with hard alkylating agents gives predominantly the ester, whereas a soft alkylating agent gives predominantly the sulfone. This alkylation usually gives the sulfone only in moderate yields.[1]

$$R-SO_2^- + R'X \longrightarrow R-\overset{\overset{O}{\uparrow}}{\underset{\underset{O}{\downarrow}}{S}}-R' + S-\overset{\overset{O}{\uparrow}}{S}-OR' + X^-$$

Recently, Veenstra and Zwanenburg[2] have reported the reaction of tetrabutylammonium *p*-toluenesulfinate with alkyl halides as an improved method for the synthesis of sulfones. More recently, Manescalchi *et al.*[3] have reported a similar method using Amberlyst A-26, a macroreticular anion-exchange resin. In these methods, however, the tedious preparation of tetrabutylammonium *p*-toluenesulfinate or the sulfinate form of Amberlyst A-26 is required before reaction with the alkyl halide.

In this paper, a simpler and more convenient method for the synthesis of sulfones using polyethylene glycols (PEG) or their diethyl ethers is reported.

The reactions were carried out with sodium *p*-toluensulfinate monohydrate and various alkyl halides in PEG having an average molecular weight of 400 (PEG-400), PEG-400 diethyl ether (PEG-400-Et_2), or MeOH containing PEG-1000 or PEG-1000-Et_2 as a catalyst. Table 1 shows the results. In all cases, the sulfones were obtained in good to excellent yields. When PEG-400 was employed as a solvent, GLC showed that the product was almost entirely the sulfone because of the rapid hydrolysis of the ester. In the case of PEG-400-Et_2 or MeOH with a catalytic amount of PEG-1000 or PEG-1000-Et_2, however, GLC showed that a small amount of the ester remained under the experimental conditions used. These facts indicate that PEG is a good solvent for the alkylation of sulfinate anion to yield sulfones.

Table 1. Reaction of $C_7H_7SO_2Na \cdot H_2O$ with alkyl halides[a]

Alkyl halide	Solvent	Catalyst[b]	Time / h	Temp / °C	Yield[c] / %	Mp θ_m or Bp θ_b/°C (mmHg)	Lit Mp θ_m or Bp θ_b/°C (mmHg)

a) All reactions were carried out with $C_7H_7SO_2Na \cdot H_2O$ (0.05 mol) and alkyl halide (0.075 mol) in a solvent (20 ml) with or without a catalyst (0.005 mol). b) A: PEG-1000-Et_2, B: PEG-1000. c) Isolated yields. Unless otherwise noted, purities were >99% by GLC. d) Purities were 98% by GLC. e) Purities were 97% by GLC. f) See Experimental section. g) Forty milliliters of solvent were used.

Experimental

Materials. Methanol and PEG-400 (reagent grade, Kishida Kagaku Co., Ltd.) were dried with molecular sieves 4A. PEG-1000 (reagent grade, Kishida Kagaku Co., Ltd.) was used without further purification. PEG-400-Et_2 and PEG-1000-Et_2 were prepared according to the method previously reported.[4] Sodium *p*-toluenesulfinate ($C_7H_7SO_2Na$ nH_2O, $n\approx1$) (reagent grade, Tokyo Kasei Kogyo Co., Ltd.) was used as obtained. The physical properties (bp or mp) of ethyl *p*-tolyl sulfone,[5] butyl *p*-tolyl sulfone,[6] allyl *p*-tolyl sulfone,[2,7] benzyl *p*-tolyl sulfone,[8] cyanomethyl *p*-tolyl sulfone,[2,10] and bromometyl *p*-tolyl sulfone[2,9] were in good agreement with those reported in the literature (Table 1) and satisfactory IR spectra for these compounds were obtained.

Typical Procedure for the Reaction of Sodium p-*Toluenesulfinate Monohydrate with Alkyl Halides. Bromomethyl* p-*Tolyl Sulfone*: A mixture of powdered sodium *p*-toluenesulfinate monohydrate (9.8 g, 0.05 mol) and dibromomethane (13.0 g, 0.075 mol) was stirred at 80 °C for 4 h in PEG-400 (20 ml). After removal of the excess dibromomethane, the reaction mixture was poured into water (300 ml). The precipitated white solid was collected and recrystallized from ethanol–water, giving 11.1 g (89%) of bromomethyl *p*-tolyl sulfone, mp 87—88 °C (lit,[9] mp 90—92 °C).

Butyl p-*Tolyl Sulfone*: A mixture of powdered sodium *p*-toluenesulfinate monohydrate (9.8 g, 0.05 mol), butyl bromide (10.3 g, 0.075 mol), MeOH (20 ml), and PEG-1000-Et_2 (5.3 g, 0.005 mol) was stirred at 60 °C for 7 h. The reaction mixture was diluted with water (200 ml) and extracted with benzene (20 ml×3). The benzene layers were combined, washed with water, and dried. After removal of the benzene, the residual oil was distilled under reduced pressure, giving 8.8 g (83%) of butyl *p*-tolyl sulfone, bp 137—142 °C/1 mmHg (1 mmHg=133.322 Pa) (lit,[6] bp 175—177 °C/4 mmHg). The purity was 98% by GLC.

Octyl p-*Tolyl Sulfone*: A mixture of powdered sodium *p*-toluenesulfinate monohydrate (9.8 g, 0.05 mol), octyl bromide (14.5 g, 0.075 mol), and PEG-400 (20 ml) was stirred at 60 °C for 3 h. After the reaction mixture had been treated according to the method for butyl *p*-tolyl sulfone, the residual oil was distilled under reduced pressure, giving 12.6 g (94%) of octyl *p*-tolyl sulfone (>99% pure), bp 175—178 °C/0.5 mmHg. Redistillation of the product gave pure octyl *p*-tolyl sulfone having bp 150—151 °C/0.12 mmHg, mp 40.0—40.5 °C; IR (neat) 1310, 1140 cm^{-1} ($-SO_2-$). Found: C, 66.90; H, 9.07; S, 11.93%. Calcd for $C_{15}H_{24}O_2S$: C, 67.12; H, 9.01; S, 11.94%.

The author thanks Nihon Tokushu Kagaku Kogyo Co., Ltd. for permission to publish this article, and also Dr. Nobuaki Wada for useful suggestions during this work.

Generation and Reactions of 5,6-Dimethylene-2-cyclohexene-1,4-diones. A New Synthesis of Polycyclic 1,4-Benzoquinones

Yoshinori KANAO† and Masaji ODA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
†*Department of Chemistry, Faculty of Science, Tohoku University, Aobayama, Sendai 980*

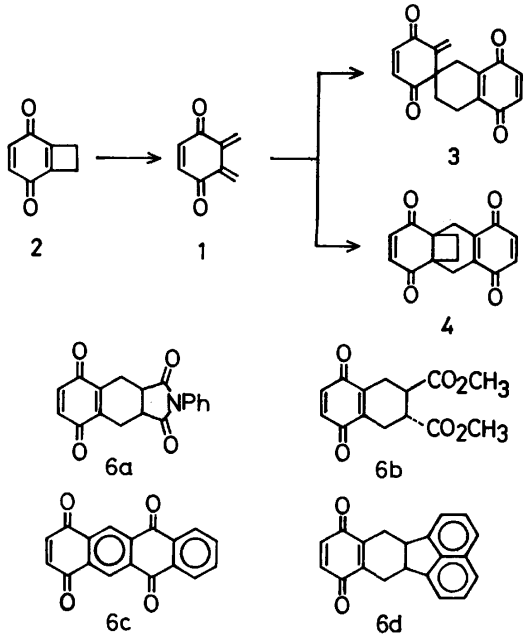
(Received July 4, 1983)

Synopsis. 1,2,3,6-Tetrahydrobenzocyclobutene-3,6-dione underwent thermal ring opening of the four-membered ring at 140°C to generate 5,6-dimethylene-2-cyclohexene-1,4-dione. This is a highly reactive substance and was trapped as dimers or Diels-Alder adducts giving polycyclic 1,4-benzoquinones. Intramolecular rearrangements preferably took place in some derivatves.

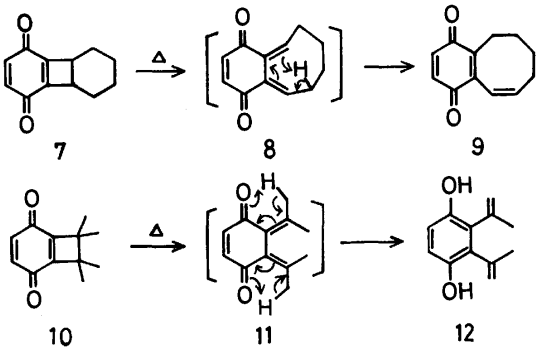
5,6-Dimethylene-1,3-cyclohexadienes (*o*-quinodimethanes) have proved to be useful intermediates in organic syntheses by virtue of their high reactivity in cycloaddition reactions.[1] Accordingly, 5,6-dimethylene-2-cyclohexene-1,4-dione (**1**) is an interesting compound, since its Diels-Alder reactions with dienophiles would afford polycyclic 1,4-benzoquinones in a single step. Although the intermediary formation and some reactions of 2,3-dimethyl and benzo derivative of **1** have been reported,[2,3] the parent compound **1** remains unknown. We have recently reported the synthesis of 1,2,3,6-tetrahydrobenzocyclobutene-3,6-dione (**2**) which is considered to be a promising precursor for **1**.[4] This paper describes the results of thermolysis of **2** and some derivatives in the absence or presence of trapping agents.

Thermal electrocyclic ring opening of the cyclobutene of **2** readily took place at about 140°C. This temperature is considerably lower than that required for the ring opening of 1,2-dihydrobenzocyclobutene, which ring-opens at about 200°C,[1a] probably because there is no loss of aromatic stabilization in the ring opening of **2**. In a typical experiment, heating of a 0.05 M solution of **2** in xylene under reflux for 2 h gave dimers **3** and **4** in 11% and 39% yield, respectively. The ^{1}H NMR spectrum of **3** shows the presence of six olefinic protons including two exocyclic methylene protons and the absence of symmetry, whereas that of **4** shows the presence of four olefinic protons and a mirror plane, supporting the assigned structures. Dimer **3** is thus a Diels-Alder adduct of two molecules of **1**, and dimer **4** is that of **1** and **2**. The predominant formation of **4** is in accord with the high dienophilicity of the strained internal double bond of **2** as previously observed in its Diels-Alder reactions.[5] As might be expected, **2** gave only **3** under conditions of flash vacuum thermolysis at 350°C where **2** would rapidly open to **1**.

In the presence of excess of dienophiles (5 equiv.) such as *N*-phenylmaleimide (**5a**), dimethyl fumarate (**5b**), 1,4-naphthoquinone (**5c**), and acenaphthylene (**5d**) **1** could form adduct **6a** (29%), **6b** (47%), **6c** (11%), and **6d** (28%), respectively. The yields were, however, poor to moderate due to the competition of the dimerization forming **4**. In the case of **5c**, the primary Diels-Alder adduct was apparently further oxidized to **6c** under the reaction conditions. Although hydrocarbon **5d** could form adduct **6d**, other simple olefins such as indene and cyclooctene failed to form adducts giving only the dimers.



When alkyl groups are present on the four-membered ring, intramolecular rearrangements become feasible in the ring-opened form and were actually observed to take place. Thermolysis of 1,4,4b,5,6,7,8,8a-octahydrobiphenylene-1,4-dione (**7**) at 140°C gave 1,4,7,8,9,10-hexahydrobenzocyclooctene-1,4-dione (**9**) in 72% yield. The rearrangement can be accounted for in terms of conrotatory ring opening to a (*E,Z*)-cyclooctadiene **8** followed by [1,5] sigmatropic hydrogen shift. A molecular model of **8** suggests the favorable spatial location of a methylene proton for the hydrogen shift. On the other hand, 1,1,2,2-tetramethyl derivative **10** gave 2,3-diisopropenylhydroquinone (**12**) in 51% yield. The formation of **12** can be rationalized by a double [1,5] sigmatropic hydrogen shift involving the carbonyl groups in the ring-opened form **11**.



Experimental

All the melting points were determined on either a Yamato MP-21 or a Mettler FP-2 apparatus and are uncorrected. Infrared spectra were recorded with a Hitachi 215 grating spectrophotometer, and electronic absorption spectra with a Hitachi 323 spectrophotometer. ^{1}H NMR spectra were obtained with either a JNM-PMX 60 or a JNM-FX90Q spectrometer using $(CH_3)_4Si$ as an internal standard. Mass spectra were measured with a Hitachi M-52 mass spectrometer. Merck Kieselgel 60 was used for column chromatography.

Thermolysis of 1,2,3,6-Tetrahydrobenzocyclobutene-3,6-dione (2) in the Absence of Trapping Agent. A solution of **2** (268 mg, 2 mmol) in xylene (10 ml) was heated under reflux under a nitrogen atmosphere for 2 h. After evaporation of the solvent, the residue was chromatographed on silica gel (50 g) and eluted with benzene–ethyl acetate (95:5). The first yellow band gave **3** (31 mg, 11.5%) and the second yellow band **4** (150 mg, 39%). **3**: Yellow crystals from dichloromethane–hexane, mp 147—149 °C. MS *m/z* (rel intensity) 268 (M^+; 100), 240 (61); IR (KBr)1684, 1670, 1640, 1598 cm^{-1}; UV (EtOH) λ_{max} 240 (log ε 4.32), 338 nm (2.97); ^{1}H NMR ($CDCl_3$) δ 1.95 (2H, dd, J=6, 7 Hz), 2.47 (2H, m), 2.86 (1H, m), 3.20 (1H, m), 5.29 (1H, s), 6.18 (1H, s), 6.78 (2H, s), 6.79 (1H, d, J=10.4 Hz), 6.97 (1H, d, J=10.4 Hz); Found: C, 71.25; H, 4.52%. Calcd for $C_{16}H_{12}O_4$: C, 71,63; H, 4.51%. **4**: Yellow crystals from dichloromethane–hexane, mp 204—205 °C; MS *m/z* 268 (M^+, 13), 240 (100); IR (KBr) 1662, 1648, 1600, 1292, 824 cm^{-1}; UV (EtOH) λ_{max}=225 (log ε 4.22), 240 (4.19), 248 (4.19), 340 nm (2.88); ^{1}H NMR ($CDCl_3$) δ=2.13 (4H, m), 2.36 (2H, d, J=16.4 Hz), 3.37 (2H, d, J=16.4 Hz), 6.87 (2H, s), 6.91 (2H, s); Found: C, 71.57; H, 4.46%. Calcd for $C_{16}H_{12}O_4$: C, 71.63; H, 4.51%.

Flash Vacuum Thermolysis of 2. Sublimatively vapourized **2** (51 mg) was passed through a preheated quartz column (15×200 mm) packed with Pyrex glass chips at 350 °C at 0.5 mmHg. The pyrolysate was led into a receiver cooled at 0 °C, but yellow solids condensed on the inside of the wall of the column just out the electronic furnace. After cooling to room temperature the condensate was washed out with dichloromethane into the receiver. The solvent was evaporated and the residue chromatographed on silica gel to give **3** (14 mg, 27%).

General Procedure for the Trapping Experiments with Dienophiles. Solutions of **2** (134 mg, 1 mmol) and a dienophile (5 mmol) in xylene (10 ml) were heated under reflux under a nitrogen atmosphere for 2 h. After evaporation of the solvent the residue was chromatographed on silica gel and eluted with benzene–ethyl acetate.

(a) With N-Phenylmaleimide: Unreacted *N*-phenylmaleimide (742 mg), dimer **4** (32 mg, 24%), and adduct **6a** (90 mg, 29%) were obtained. **6a**: Yellow crystals from benzene–dichloromethane, mp 243—244 °C; IR (KBr) 1700, 1644, 1590, 1386, 1180 cm^{-1}; ^{1}H NMR ($CDCl_3$–CD_3SOCD_3) δ=2.7—3.2 (4H, m), 3.3—3.6 (2H, m), 6.87 (2H, s), 7.1—7.6 (5H, m); Found: C, 70.16; H, 4.12; N, 4.49%. Calcd for $C_{18}H_{13}NO_4$: C, 70.35; H, 4.26; N, 4.56%.

(b) With Dimethyl Fumarate: Unreacted dimethyl fumarate (580 mg), adduct **6b** (130 mg, 47%), and dimer **4** (30 mg, 22%) were obtained. **6b**: Yellow crystals from dichloromethane–hexane, mp 91—92 °C; IR (KBr) 1730, 1655, 1600, 1305, 1232 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.6—3.3 (6H, m), 3.77 (6H, s), 6.78 (2H, s); Found: C, 60.37; H, 5.13%. Calcd for $C_{14}H_{14}O_6$: C, 60.43; H, 5.07%.

(c) With 1,4-Naphthoquinone: Unreacted naphthoquinone (686 mg) and adduct **6c** (30.5 mg, 11%) were obtained. **6c**: Deep yellow crystals from benzene–dichloromethane, mp 261—262 °C (lit.[6] 262 °C).

(d) With Acenaphthylene: Unreacted acenaphthylene, adduct **6d** (79 mg, 28%), and dimer **4** (15 mg, 11%) were obtained. **6d**: Yellow crystals from dichloromethane, mp 176—177 °C; IR (KBr) 1645, 1590, 1325, 1290, 783 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.6—3.4 (4H, m), 4.10 (2H, m), 6.61 (2H, s), 7.2—7.8 (6H, m); Found: C, 83.88; H, 4.77%. Calcd for $C_{20}H_{14}O_2$: C, 83.90; H, 4.93%.

Thermal Rearrangement of 1,4,4b,5,6,7,8,8a-Octahydrobiphenylene-1,4-dione (7): A solution of **7** (90 mg) in xylene (10 ml) was heated under reflux under a nitrogen atmosphere for 5 h. After evaporation of the solvent, the residue was chromatographed on silica gel (3 g) and eluted with hexane–ethyl acetate (9:1) to give **9** (65 mg, 72%); yellow crystals from dichloromethane–hexane, mp 59—60 °C; IR (KBr) 1650 1590, 1300, 855 cm^{-1}; UV (cyclohexane) λ_{max}=249 (log ε 4.20), 368 (3.25), 439 sh (2.34), 460 sh (2.09), 492 sh nm (1.64); ^{1}H NMR ($CDCl_3$) δ=1.60 (4H, m), 2.21 (2H, m), 2.63 (2H, m), 6.02 (1H, dd, J=12.0, 5.4 Hz), 6.26 (1H, d, J=12.0 Hz), 6.71 (2H, s); Found: C, 76.72; H, 6.51%. Calcd for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43%.

Thermal Rearrangement of 1,1,2,2-Tetramethyl-1,2,3,6-tetrahydrobenzocyclobutene-3,6-dione (10): A solution of **10** (150 mg) in xylene (10 ml) was heated under reflux under a nitrogen atmosphere for 1 h. After evaporation of the solvent the residue was chromatographed on silica gel (15 g) and eluted with hexane–ethyl acetate (92:8) to give **12** (112 mg, 74.5%); colorless crystals from hexane–ethyl acetate, mp 119—121 °C; IR (KBr) 3240, 1640, 1610, 1340, 1290, 878, 809 cm^{-1}; ^{1}H NMR ($CDCl_3$–CD_3OD) δ=2.04 (6H, s), 4.97 (2H, br. s), 5.35 (2H, br. s), 6.70 (2H, s); Found: C, 75.49; H, 7.52%. Calcd for $C_{12}H_{14}O_2$: C, 75.76: H, 7.42%.

(Received July 11, 1983)

Synopsis. Methoxy-substituted 2-isopropenyl-2,3-dihydrobenzofurans were prepared from methoxy-substituted phenols and 1,4-dibromo-2-methyl-2-butene in one-step reactions. Their acylations with acetic acid-trifluoroacetic anhydride or *N*-methylformanilide-phosphoryl chloride were studied.

In our previous paper, we reported a new preparative method of 2-isopropenyl-2,3-dihydrobenzofuran (**1**) from phenol and 1,4-dibromo-2-methyl-2-butene and its acylations with acetic acid-trifluoroacetic anhydride (acetylation) or with *N*-methylformanilide-phosphoryl chloride (formylation).[1] Some naturally occurring hydroxy or methoxy-substituted 2-isopropenyl-2,3-dihydrobenzofuran derivatives having an acetyl group in 5 or 7 position have been reported.[2-8] Now, we report the preparation of methoxy-substituted 2-isopropenyl-2,3-dihydrobenzofurans and their acylations.

By the method used before, 2-isopropenyl-5-methoxy-2,3-dihydrobenzofuran (**3**) was obtained from *p*-methoxyphenol and 1,4-dibromo-2-methyl-2-butene. From *m*-methoxyphenol, a mixture of 4-methoxy **2** and 6-methoxy derivative **4** was obtained. But 7-methoxy derivative **5** was not obtained by this method, it was prepared by dehydration of 2-(1-hydroxy-1-methylethyl)-7-methoxy-2,3-dihydrobenzofuran with phenyl isocyanate.

Acetylations were run with acetic acid-trifluoroacetic anhydride at room temp for 3 h and formylations were run with *N*-methylformanilide-phosphoryl chloride at 90 °C for 1 h. Thier yields are summarized in Table 1. Phosphoryl chloride which used in formylations is a weaker acid than trifluoroacetic acid which derived from trifluoroacetic anhydride in the acetylations. Therefore, formylations can run at higher temp than acetylations, and the former showed better yields than the latter. In all 2-isopropenyl-2,3-dihydrobenzofurans, the position 5 was the most reactive. In 5-methoxy derivative **3**, formylation at 90 °C afforded 6-formyl compound **9b**, but acetylation at room temp could not afford any acetylated compound.

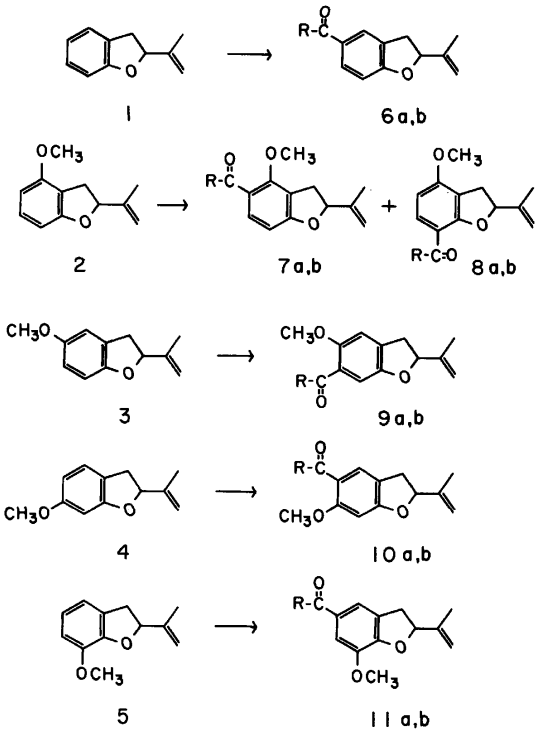
TABLE 1. ACYLATIONS OF 2-ISOPROPENYL-2,3-DIHYDROBENZOFURANS

2-Isopropenyl-2,3-dihydrobenzofuran	Acylated position	Yield/%	
		Acetylation[a]	Formylation[b]
1	5	45.9[c]	20.9[c]
2	5	14.5[d]	27.9[d]
	7	21.7[d]	55.7[d]
3	6	0	24.8
4	5	32.0	46.7
5	5	12.8	64.1

a) With acetic acid-trifluoroacetic anhydride at room temp for 6 h (**1**) or 3 h (**2**—**5**). b) With *N*-methylformanilide-phosphoryl chloride at 90 °C for 1 h. c) Reported in our previous paper.[1] d) Calcd by the methoxy signal ratio in the ^{1}H-NMR spectra.

The structure of the acyl compounds were determined by the coupling constants among aromatic hydrogens in their ^{1}H-NMR spectra. The yields of **7a, b** and **8a, b** were calculated by methoxy signal ratio in their ^{1}H-NMR spectra. By addition of europium tris-dipivaloylmethanate, the methoxy signal of 5-acyl compound **7a, b** shifted to a low field than that of 7-acyl compound **8a, b**, perhaps because they have different chelating structures.

The spectral data of **11a** agreed with the data of the natural compound reported by Bohlmann *et al.*[3]



Experimental

The boiling points and melting points were uncorrected (in boiling points: 1 mmHg=133.322 Pa); the IR spectra were measured on a Hitachi EPI-S2 spectrophotometer, and the ^{1}H-NMR spectra, on a JEOL JNM-MH-60 spectrometer.

Preparation of Methoxy-substituted Dihydrobenzofurans (2—8). By the method described in our previous paper,[1] **3** was obtained from *p*-methoxyphenol and a mixture of **2** and **4** was obtained from *m*-methoxyphenol. The mixture was separated on silica gel with cyclohexane. **2**. Yield: 2.4%; ^{1}H-NMR (CCl_4): δ=1.8 (3H, s), 2.8 (1H, dd, J=16+9 Hz), 3.2 (1H, dd, J=16+9 Hz), 3.8 (3H,s), 4.8 (1H, broad s), 5.0 (1H, broad s), 5.1 (1H, t, J=9 Hz), 6.2 (1H, d, J=9 Hz), 6.3 (1H, d, J=9 Hz), 6.9 (1H, t, J=9 Hz); Found: C, 75.96; H, 7.19%. Calcd for $C_{12}H_{14}O_2$: C, 75.76;H, 7.42%. **3**. Yield: 59.3%; bp 110—117 °C (2 mmHg); ^{1}H-NMR (CCl_4): δ=1.8

(3H, s), 3.0 (1H, dd, J=16+9 Hz), 3.3 (1H, dd, J=16+9 Hz), 3.8 (3H, s), 4.9 (1H, broad s), 5.1 (1H, broad s), 5.1 (1H, t, J=9 Hz), 6.6— 6.8 (3H,m); Found: C, 75.76; H, 7.69%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%. **4**. Yield: 13.8%; ^{1}H-NMR (CCl_4) : δ=1.8 (3H, s), 2.9 (1H, dd, J=16+9 Hz), 3.2 (1H, dd, J=16+9 Hz), 3.7 (3H, s), 4.8 (1H, broad s), 5.0 (1H, broad s), 5.1 (1H,t,J=9 Hz), 6.2 (1H, d, J=2 Hz), 6.2 (1H, dd, J=9+2 Hz), 6.9 (1H, d, J=9 Hz); Found: C, 75.65; H, 7.33%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

Dehydrative Preparation of 5. By the method similar to that described in our previous paper,[1] 7-methoxy-2,3-dihydrobenzofuran-2-carboxylic acid[9] gave methyl 7-methoxy-2,3-dihydrobenzofuran-2-carboxylate: yield, 86.6%; bp 172—173.5 °C (17 mmHg); IR (neat): 1760 cm^{-1}; ^{1}H-NMR (CCl_4): δ=3.3 (1H, dd, J=16+8 Hz), 3.4 (1H, dd, J=16+9 Hz), 3.7 (3H, s), 3.8 (3H, s), 5.1 (1H, dd, J=9+8 Hz), 6.6 (3H, s); Found: C, 63.50; H, 5.91%. Calcd for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%. The product was converted to 2-(1-hydroxy-1-methylethyl)-7-methoxy-2,3-dihydrobenzofuran: yield, 53.0%; IR (neat) 3400 cm^{-1}; ^{1}H-NMR (CCl_4): δ=1.2 (3H, s), 1.3 (3H,s), 2.2 (1H, broad s), 3.1 (1H, dd, J=16+9 Hz), 3.2(1H, dd, J=16+8 Hz), 3.8 (3H, s), 4.6 (1H, dd, J=9+8 Hz), 6.7 (3H, s); Found: C, 68.99; H, 7.90%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%. A mixture of 2-(1-hydroxy-1-methylethyl)-7-methoxy-2,3-dihydrobenzofuran (1.02 g, 4.90 mmol) and phenyl isocyanate (5.85 g, 4.90 mmol) was refluxed for 10 h.[10] After the reaction, the mixture was distilled. The fraction boiling at 118—136 °C (2 mmHg) (0.679 g, 72.9%) showed two peaks (5:1) in GLC. The mixture was separated into components by silica gel chromatography. The fractions eluted with 1:4 benzene–hexane gave 2-isopropyl-7-methoxybenzofuran (101 mg, 10.8%); ^{1}H-NMR (CCl_4): δ=1.4 (6H, d, J=7 Hz), 3.1 (1H, m, J=7 Hz), 3.9 (3H, s), 6.2 (1H, s), 6.6 (1H, t, J=5 Hz), 6.9 (2H, d, J=5 Hz); Found: C, 75.47;H, 7.14%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%. The fractions eluted with 2:3 benzene–hexane gave 2-isopropenyl-7-methoxy-2,3-dihydrobenzofuran (**5**) (258 mg, 27.7%); ^{1}H-NMR (CCl_4): δ=1.8 (3H, s), 3.0 (1H, dd, J=15+9 Hz), 3.2 (1H, dd, J=15+9 Hz), 3.8 (3H, s), 4.8 (1H, broad s), 5.1 (1H, broad s), 5.1 (1H, t, J=9 Hz), 6.6 (3H, s); Found: C, 75.74; H, 7.12%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

Acylations of Methoxy-substituted Dihydrobenzofurans 2—5. By a method similar to that described in our previous paper,[1] dihydrobenzofuran **2—5** was acetylated with acetic acid and trifluoroacetic anhydride for 3 h at room temp, and was formylated with *N*-methylformanilide and phosphoryl chloride for 1 h at 90 °C. In case of the acylations of **2**, mixtures were obtained; the spectrum of the acetylated compounds showed two methoxy signals at 3.85 (**8a**) and 3.88 ppm (**7a**) (relative intensity 3:2), which shifted to 3.87 and 4.03 ppm by the addition of europium trisdipivaloylmethanate, and the spectrum of the formylated compounds showed signals at 3.84 (**8b**) and 3.93 ppm(**7b**) (relative intensity 2:1), which shifted to 3.90 and 4.06 ppm by similar treatment. Their yields were calculated by the methoxy signal ratio in their ^{1}H-NMR spectra.

The yields of acyl dihydrobenzofurans **7a**, **b**—**11a**,**b** are summarized in Table 1. And their physical data are listed below.

Mixture of **7a** and **8a**; bp 225—240 °C (14.5 mmHg) (bath temp); IR (neat): 1670 cm^{-1}; ^{1}H-NMR (CCl_4): δ=1.8 (s, **7a** and **8a**), 2.45 (s, **7a**), 2.48 (s, **8a**), 3.0 (dd, J=16+10 Hz, **7a** and **8a**), 3.4 (dd, J=16+10 Hz, **7a** and **8a**), 3.85 (s, **8a**) 3.88 (s, **7a**), 4.95 (broad s, **7a** and **8a**), 5.1 (broad s, **7a** and **8a**), 5.3 (t, J=10 Hz, **7a** and **8a**), 6.43 (d, J=10 Hz, **8a**), 6.55 (d, J=10 Hz, **7a**), 7.65 (d, J=10 Hz, **7a**), 7.75 (d, J=10 Hz, **8a**); Found: C, 72.22; H, 6.99%. Calcd for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94%. **10a**; mp 111— 112 °C (recrystallized from cyclohexane); IR (KBr disk): 1650 cm^{-1}; ^{1}H-NMR (CCl_4): δ=1.8 (3H, s), 2.6 (3H, s), 3.0 (1H, dd, J=16+9 Hz), 3.2 (1H, dd, J=16+9 Hz), 3.8 (3H, s), 4.9 (1H, broad s), 5.1 (1H, broad s), 5.2 (1H, t, J=9 Hz), 6.4 (1H, s), 7.7 (1H, s); Found: C, 72.23; H, 7.08%. Calcd for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94%. **11a**: bp 230—255 °C (15 mmHg); IR (neat): 1670 cm^{-1}; ^{1}H-NMR (CCl_4): δ=1.8 (3H, s), 2.4 (3H, s), 3.0 (1H, dd, J=16+9 Hz), 3.3 (1H, dd, J=16+9 Hz), 3.9 (3H, s), 4.9 (1H, broad s), 5.1(1H, broad s), 5.2 (1H, t, J=9 Hz), 7.3 (2H, s); Found: C, 72.23; H, 7.08%. Calcd for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94%. Mixture of **7b** and **8b**; bp 220—265 °C (14.5 mmHg); IR (neat): 1635 cm^{-1}; ^{1}H-NMR (CCl_4): δ=1.8 (s, **7b** and **8b**), 3.0 (dd, J=16+8 Hz, **7b** and **8b**), 3.3 (dd, J= 16+8 Hz, **7b** and **8b**), 3.84 (s, **8b**), 3.93 (s, **7b**), 4.9 (s, **7b** and **8b**), 6.39 (d, J=9 Hz, **8b**), 6.51 (d, J=9 Hz, **7b**), 7.53 (d, J=9 Hz, **8b**), 7.63 (d, J=9 Hz, **7b**), 10.08 (s, **8b**), 10.14 (s,**7b**); Found: C, 71.15; H,6.50%. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%. **9b**; mp 64—66 °C (recrystallized from cyclohexane); IR (KBr disk): 1670 cm^{-1}; ^{1}H-NMR (CCl_4): δ=1.7 (3H, s), 3.0 (1H, dd, J=16+8 Hz), 3.3 (1H, dd, J=16+8 Hz), 3.7 (3H, s), 4.8 (1H, broad s), 5.0(1H, broad s), 5.1 (1H, t, J=8 Hz), 6.7 (1H, s), 6.9 (1H, s), 10.2 (1H, s); Found: C, 71.62; H, 6.70%. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%. **10b**; mp 97—99 °C (recrystallized from cyclohexane); IR (KBr disk): 1680 cm^{-1}; ^{1}H-NMR (CCl_4): δ=1.7 (3H, s), 3.0 (1H, dd, J=16+9 Hz), 3.2 (1H, dd, J=16+9 Hz), 3.9 (3H, s), 4.9 (1H, broad s), 5.0 (1H, broad s), 5.2 (1H, t, J=9 Hz), 6.3 (1H, s), 7.5 (1H, s), 10.1 (1H, s); Found: C, 71.32; H, 6.35%. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%. **11b**;Benzene eluted oil; IR (neat): 1690 cm^{-1}; ^{1}H-NMR (CCl_4): δ=1.8 (3H, s), 3.1 (1H, dd, J=16+9 Hz), 3.3 (1H, dd, J=16+9 Hz), 3.8 (3H, s), 4.9 (1H, broad s), 5.1 (1H, broad s), 5.2 (1H, t, J=9 Hz), 7.1 (2H, s), 9.7 (1H, s); Found: C, 71.30; H, 6.43%. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%.

10) Refluxing for 5 h gave a mixture of 7-methoxy-2-isopropenyl-2,3-dihydrobenzofuran (21.9%) and 7-methoxy-2-isopropylbenzofuran (9.3%); longer refluxing caused an isomerization of the dihydrobenzofuran **5** to the benzofuran.

Synthetic Photochemistry. XXVII.[1] An Efficient Synthesis of Deoxytrisporone by Photocycloaddition

Hitoshi TAKESHITA,* Seiji HATTA, and Toshihide HATSUI
Research Institute of Industrial Science, 86, Kyushu University, Sakamoto, Kasuga, Fukuoka 816
(Received July 11, 1983)

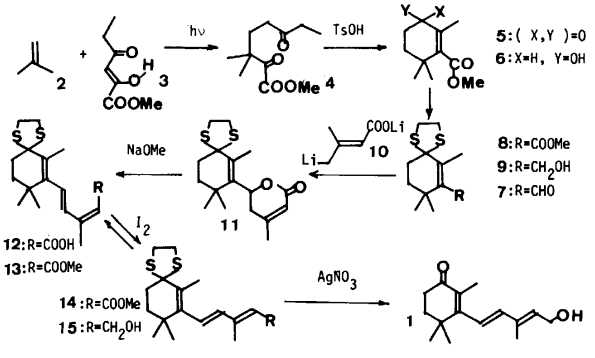
Synopsis. Deoxytrisporone was synthesized from isobutene and methyl 2,4-dioxohexanoate to show the utility of the regioselective photocycloaddition of β-diketone for construction of polysubstituted cyclohexenones.

Deoxytrisporone (**1**)[2,3] is a fundamental trimethylcyclohexene derivative. We have accomplished its facile total synthesis by photocycloaddition of 2-methylpropene (**2**) with methyl 2,4-dioxohexanoate (**3**)[4] followed by a series of chemical conversions which will be described herein.

Photocycloaddition of **2** with **3** gave a single 1:1-adduct (**4**) in 56% yield. The structure of **4** was shown to be methyl 3,3-dimethyl-2,6-dioxooctanoate, on the basis of its NMR spectroscopic analysis[5] as well as its chemical conversion: Treatment of **4** with *p*-toluenesulfonic acid (TsOH) gave an α,β-unsaturated ketone, methyl 3-oxo-β-cyclogeranate (2,6,6-trimethyl-3-oxo-1-cyclohexene-1-carboxylate, **5**), which upon borohydride reduction yielded a dihydro derivative (**6**).[6]

The keto ester (**5**) was converted to the 3,3-ethylenedithio derivative (**7**) of β-cyclocitral *via* corresponding derivatives (**8**, **9**) of methyl β-cyclogeranate and β-cyclogeraniol by consecutive reactions with 1,2-ethanedithiol and boron trifluoride, lithium aluminum hydride (LAH), and the Collins reagent. The dianionic species[7] generated from 3-methyl-2-butenoic acid (**10**) and lithium diisopropylamide (LDA) was treated at −30°C with **7** to give 1:1-condensates from which, a crystalline δ-lactone (**11**) has been isolated in 74% yield. A mild sodium methoxide treatment of **11** quantitatively gave the (2*Z*,4*E*)-trienic acid (**12**) whose methyl ester (**13**) can be equilibrated to a 2:3-mixture with the (2*E*,4*E*)-ester (**14**) iodine in benzene.[8] Isolation of **14**, a colorless oil, from the mixture was accomplished by high-pressure liquid chromatography (HPLC).

The LAH-reduction of **14** quantitatively gave the colorless oily alcohol (**15**) which was immediately treated with silver nitrate[9] to form a colorless oil whose identity with **1** was confirmed by comparison of the H-NMR spectrum taken in a carbon tetrachloride solution.[2]



Consequently, the alternative synthesis of **1** has been completed.

Experimental

Photocycloaddition of 2 with 3. Formation of 4: In ethyl acetate (30 cm³), **2** (*ca.* 20 cm³), and **3** (10.0 g) were internally irradiated by means of a 100-W high-pressure mercury lamp at −50 to −60°C under N_2 atmosphere for 37 h. Silica-gel chromatography of the mixture from hexane-ethyl acetate (9:1) eluted a colorless oil, 6.7 g (56%) [Found: C, 61.76; H, 8.59%. Calcd for $C_{11}H_{18}O_4$: C, 61.66; H, 8.47%. δ=1.02 (3H, t, *J*=8 Hz), 1.21 (6H, s), 1.92 (2H, m), 2.36 (2H, m), 2.42 (2H, q, *J*=8 Hz), and 3.83 (3H, s). δ(C)=7.9, 23.5 (2C), 32.5, 35.9, 37.5, 45.5, 52.3, 164.0, 201.1, and 210.0. ν: 1715, 1740 cm⁻¹].

Dehydration of 4 to 5. A mixture of **4** (4.00 g) and TsOH (30 mg) was refluxed in benzene (20 cm³) for 17 h. Subsequent silica-gel chromatography gave, from hexane-ethyl acetate (4:1), a colorless liquid (**5**), 3.3 g (90%) [Found: C, 66.93; H, 8.28%. M. W., 196.1119. Calcd for $C_{11}H_{16}O_3$: C, 67.32; H, 8.22%; M. W., 196.1099. δ=1.24 (6H, s), 1.70 (3H, s), 1.90 (2H, m), 2.52 (2H, m), and 3.80 (3H, s). δ(C)=13.0, 26.8 (2C), 34.1, 34.2, 37.5, 51.6, 130.9, 154.7, 168.5, 198.3. ν: 1715, 1665 cm⁻¹].

$NaBH_4$-reduction of 5. In methanol (4.5 cm³), **5** (1.00 g) was reduced with $NaBH_4$ (300 mg) for 1 h at 15—20°C to give a colorless liquid (**6**), 920 mg (91%) [δ=1.06 (3H, s), 1.09 (3H, s), 1.2—2.0 (4H, m), 1.73 (3H, s), 2.73 (1H, br), 3.72 (3H, s), and 3.94 (1H, t, *J*=5 Hz)].

The Reaction of 5 with 1,2-Ethanedithiol. In anhydrous CH_2Cl_2 (5 cm³), **5** (500 mg) and BF_3-etherate (1 cm³) were kept at 15—20°C for 35 h. The mixture was washed with 5% NaOH and then with water, and the solvent was removed to leave colorless needles (**8**), mp 89—91°C, 700 mg (≈100%) [Found: M. W., 272.0878. Calcd for $C_{13}H_{20}O_2S_2$: 272.0904. δ=1.05 (6H, s), 1.65 (3H, m), 1.88 (3H, s), 2.28 (2H, m), 3.28 (4H, s), and 3.71 (3H, s). δ(C)=17.4, 28.0 (2C), 33.1, 38.0, 40.0, 40.6 (2C), 51.2, 69.6, 133.4, 139.3, 170.1. ν: 2900, 1725 cm⁻¹].

The LAH-reduction of 8. In anhydrous ether (50 cm³), **8** (700 mg) was reduced with LAH (400 mg) at 15—20°C for 3 h to give colorless needles (**9**), mp 88—89°C, 625 mg (≈100%) [Found, M. W., 244.0951. Calcd for $C_{12}H_{20}OS_2$: 244.0952. δ=1.04 (6H, s), 1.37 (1H, br. s), 1.65 (2H, m), 2.04 (3H, s), 2.22 (2H, m), 3.31 (4H, s), and 4.08 (2H, s). δ(C)=16.0, 27.9 (2C), 34.0, 38.4, 40.1, 40.4 (2C), 59.1, 71.5, 133.9, 142.2. ν: 3300 cm⁻¹].

Oxidation of 9. A mixture of **9** (600 mg) with Collins reagent (3 g, 5 equiv.) in CH_2Cl_2 (5 cm³) was kept at 15—20°C for 3.5 h with stirring. Then, the mixture was chromatographed on a silica-gel column to give a colorless oil (**7**), 430 mg (72%) [Found: M. W., 242.0808. Calcd for $C_{12}H_{18}OS_2$: 242.0798. δ=1.18 (6H, s), 1.62 (2H, m), 2.24 (2H, m), 2.32 (3H, s), 3.37 (4H, s), and 10.06 (1H, s). δ(C)=16.1, 27.6 (2C), 33.1, 39.5, 39.6, 41.1 (2C), 71.9, 142.3, 152.5, and 193.9. ν: 1675 cm⁻¹].

Reaction of 7 with 10 and LDA. To tetrahydrofuran (THF, 1 cm³) containing diisopropylamine (12 mg), commercially available *n*-BuLi (1.8 cm³ of 1 M solution) was added at −45°C, and kept stirring for 1 h, while the temperature

was gradually raised to 18°C. After cooling the mixture to −40°C, **10** (120 mg) was added to the mixture in a 1-h period, and maintained at 15—20°C for 1 h. To the mixture, **7** (120 mg) was introduced at −30°C and was kept under stirring for 9 h, then the temperature was gradually raised to 15°C. The mixture was treated with 10% HCl, and extracted with ether. The ethereal extract was washed with aqueous $NaHCO_3$, and chromatographed on a silica-gel column to give colorless needles (**11**), mp 153—154.5°C, 119 mg (74%) [Found: M. W., 324.1220. Calcd for $C_{17}H_{24}O_2S_2$: 324.1218. δ=1.00 (3H, s), 1.12 (3H, s), 1.67 (2H, m), 1.98 (3H, br. s), 2.05 (3H, s), 2.22 (2H, m), 3.30 (4H, s), 4.96 (1H, dd, *J*=13, 5 Hz), and 5.79 (1H, br. s). δ(C)=17.6, 22.9, 27.3, 28.3, 34.4, 34.6, 38.6, 39.8, 40.4, 40.7, 72.2, 75.6, 116.3, 136.0, 139.0, 157.3, and 165.2. ν: 2925, 1705 cm^{-1}].

NaOMe-treatment of 11. In methanol (1 cm^3), **11** (40 mg) and NaOMe (8 mg) were kept at 15—20°C for 6.5 h. After acidification with 10% HCl, the mixture was extracted with ether; removal of the organic layer left the carboxylic acid (**12**), which was immediately esterified with diazomethane, and chromatgraphed on a silica-gel column to give a colorless oil (**13**), 38 mg (91%) [Found: M. W., 338.1376. Calcd for $C_{18}H_{26}O_2S_2$: 338.1373. δ=1.05 (6H, s), 1.65 (2H, m), 1.98 (3H, d, *J*=1 Hz), 2.04 (3H, d, *J*=1 Hz), 2.25 (2H, m), 3.32 (4H, s), 3.68 (3H, s), 5.66 (1H, br. s), 6.48 (1H, d, *J*=18 Hz), and 7.58 (1H, d, *J*=18 Hz). δ(C)=18.4, 20.8, 28.6 (2C), 34.4, 38.9, 40.1, 40.7 (2C), 50.9, 71.9, 116.9, 131.4, 131.9, 134.8, 142.1, 151.1, and 166.7. ν: 2900, 1715, 1620, 1450, 1435 cm^{-1}].

Treatment of 13 with Iodine. In anhydrous benzene-ether (1:1, 1 cm^3), and **13** (10 mg) and I_2 (2 mg) were kept at 15—20°C for 72 h. After washings with $Na_2S_2O_3$, the mixture was separated by HPLC on μ-Polasil with hexane–ethyl acetate (80:1); less polar fractions yielded colorless needles, mp 115—116°C (**14**), 4.8 mg (48%) [Found: C, 63.96; H, 7.76%. M. W., 338.1378. Calcd for $C_{18}H_{26}O_2S_2$: C, 63.86; H, 7.76%. M. W., 338.1373. δ=1.00 (6H, s), 1.68 (2H, m), 1.91 (3H, d, *J*=1 Hz), 2.26 (2H, m), 2.31 (3H, d, *J*=1 Hz), 3.31 (4H, s), 3.70 (3H, s), 5.75 (1H, br. s), 6.08 (1H, d, *J*=16, and 6.48 (1H, d, *J*=16 Hz). δ(C)=13.5, 18.2, 28.5 (2C), 34.4, 38.4, 40.0, 40.5 (2C), 50.9, 71.6, 118.6, 131.0, 133.5, 137.4, 142.0, 152.1, and 167.2. ν: 1715, 1420, 1230, 1150, 980, 875, 840 cm^{-1}]. The more polar fractions yielded recovered **13**, 3.2 mg (32%).

LAH-reduction and Hydrolysis of 14 (as a Mixture with 13) to 1. To the above mixture of **13** and **14** (10 mg) in anhydrous ether (5 cm^3), LAH (3 mg) was added and kept at 15—20°C for 1 h; the mixture was then extracted with benzene and water, and chromatographed on a silica-gel column to give a colorless liquid, **15**, 5.1 mg (54%) [Found: *m/e*, 310 (M^+). δ=1.00 (6H, s), 1.6—1.75 (2H, m), 1.89 (3H, s), 1.94 (3H, s), 2.2—2.3 (2H, m), 3.32 (4H, s), 4.28 (2H, d, *J*=8 Hz), 5.55 (1H, t, *J*=8 Hz), 6.12 (1H, d, *J*=16 Hz), and 6.34 (1H, d, *J*=16 Hz) together with 1.82 (3H, s), 5.62 (1H, t, *J*=8 Hz), and 6.04 (1H, s) of the contaminated *Z,E*-isomer]. This was dissolved in ether (1.5 cm^3), and hydrolyzed with aqueous $AgNO_3$ (5 mg) at −5°C for 2 h. The mixture was then washed with aqueous NH_4Cl, and chromatographed on a silica-gel column; the eluant from ethyl acetate–hexane (1:9) gave a colorless liquid, 3.7 mg (98%), whose NMR figures [δ^{CCl_4}=1.17 (6H, s), 1.76 (3H, s). 1.85 (3H, s), 2.40 (2H, m), 4.22 (2H, d, *J*=7 Hz), 5.75 (1H, br. t, *J*=7 Hz), and 6.15 (1H, s). ν: 1665 cm^{-1}] were in accord to those reported of **1**.[9]

The 2*H*-Cyclohepta[*b*]furan-2-one Formation from 2,4-Dichloro-5-methoxytropone with Dimethyl Malonate and Methyl Acetoacetate

Hitoshi TAKESHITA,* Akira MORI, and Tomoyoshi MINAMI
Research Institute of Industrial Science, 86, Kyushu University, Sakamoto, Kasuga, Fukuoka 816
(Received August 3, 1983)

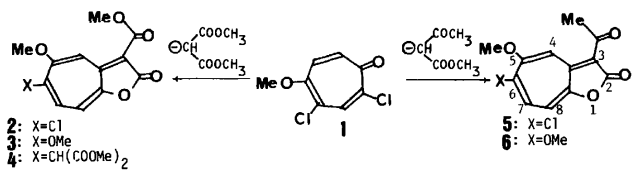
Synopsis. 2,4-Dichloro-5-methoxytropone afforded 3,5,6-trisubstituted 2*H*-cyclohepta[*b*]furan-2-one derivatives by condensation with dimethyl malonate and methyl acetoacetate in an exclusive *ciné*-condensation mode in various solvents.

Recently, we have reported[1] a solvent effect on the condensation of 2,5-disubstituted tropones with dimethyl malonate (DM); a concomitant formation of *ciné*- and normal condensates in the 2*H*-cyclohepta[*b*]furan-2-one (oxazulanone) formation from 5-chloro-2-methoxytropone (**A**) was a characteristic feature. In connection to our recent synthesis of the 1*H*-cyclohepta[1,2-*d*;3,4-*d'*]- and 1*H*-cyclohepta[1,2-*d*;4,5-*d'*]diimidazoles,[2] same ring systems to unique metabolites from marine organisms, paragracine[3] and zoanthoxanthins,[4] from 2,4-dichloro-5-methoxytropone (**1**), we thought it would be worthwhile to examine the further cyclohepta[*b*]furanone formation by condensation of **1**[5] with active methylene derivatives.[6] Since the intermediates possess the two leaving groups in the conjugated positions, two different products could be formed by the *ciné*-condensation reaction. In this paper, we wish to describe the results.

When **1** was allowed to react with DM in methanol, a rapid reaction occurred at 15 °C to give two products, **2** and **3**, both yellow crystals, in sum of *ca.* 50 to 60% yields. The major product, **3**, was shown to be a secondary product derived from **2** and sodium methylate. The NMR of **2** showed a small but characteristic long-range coupling between the methoxyl signal at δ[7]= 4.13 and an aromatic proton signal at δ=8.55, but other than this, no spin-spin interaction was detectable for this signal. Since these cycloheptafuranones exhibited a clear meta-coupling between H_4–H_6 in the 5-substituted derivatives,[1] the chlorine must be located on C-6. The J_{vic} value of the other two aromatic protons, 10.5 Hz, is compatible to that of H_7–H_8 in view of the bond alternation in this conjugated system. Therefore, **2** is 6-chloro-5-methoxy-3-methoxycarbonyl-2*H*-cyclohepta[*b*]furan-2-one, and not the alternative, **2a**, 7-chloro-6-methoxy-3-methoxycarbonyl derivative.[1] On the other hand, the NMR spectrum of **3** showed a close resemblance to that of **2**. Both methoxyl signals revealed a long-range spin-spin splitting with the protons on the seven-membered ring. The condensation of **1** with DM for a prolonged time afforded another product, **4**, which was independently prepared by further reactions of **2** or **3** with DM. The malonyl group of **4** was deduced to be at C-6; the NMR signal of C-4 proton at δ=8.48 resembled those at 8.55 and 8.58 of **2** and **3**, while the *AB*-doublets were moved to δ=7.16 and 7.46 (J=10 Hz) from 6.79 and 7.20 (J=10.5Hz) in **3**. As expected, **3** was undetectable in the reaction of **1** in benzene. The yields of **2** were most satisfactory in dimethyl sulfoxide (DMSO).

Similarly, **1** was treated with methyl acetoacetate (MA) in methanol at 15 °C; the products were again the *ciné*-products, 6-chloro-5-methoxy derivative (**5**) and 5,6-dimethoxy derivative (**6**). According to the NMR analysis, the position of the methoxy group of **5** was at C-5, because the same long-range splitting behavior was found. A further treatment of **5** under the reaction conditions gave **6**. The reaction features in the different solvents of **1** with MA was parallel to those of **1** with DM.

It has been noted that, in the cyclohepta[*d*]imidazole formation,[2] the introduction of substituents, such as halogens or methoxy group, on the seven-membered ring caused a diminishment of the reactivity toward nucleophilic attack; the present results however disagree for **1** gave the condensates in good yields.



Scheme 1.

Experimental

The Condensation of 1 and Dimethyl Malonate with NaOMe. a): To an anhydrous MeOH solution (8 cm³) of DM (160 mg) containing NaOMe (55 mg), **1** (60 mg) was added in dropwise at 10—15 °C. Instantly, dark yellow color developed in the solution. After 2 h, the mixture was poured into ice-water, acidified with dil HCl, and extracted with $CHCl_3$. The major product, **2**, obtained by silica gel column chromatography (hexane:ethyl acetate, 9:1) was further purified by fractional recrystallizations from benzene to give yellow needles, mp 249—250 °C (decomp), 29 mg (55%) [Found: C, 53.64; H, 3.37%. Calcd for $C_{12}H_9O_5Cl$: C, 53.65; H, 3.38%. δ=3.92 (3H, s), 4.13 (3H, br. s), 7.04 (1H, d, J=10.5 Hz), 7.72 (1H, d, J=10.5 Hz), and 8.55 (1H, br. s). ν: 1755, 1683, 1580, 1520, 1242, 895, 790, 760 cm^{-1}. λ_{max}^{MeOH}: 294 nm (ε=25000), 306 (25000), 402 (19000)], together with a trace amount of **3**, yellow needles, mp 259—260 °C (from benzene) [Found: C, 58.85; H, 4.47%. Calcd for $C_{13}H_{12}O_6$: C, 59.09; H, 4.58%. δ=3.92 (3H, s), 3.98 (3H, s), 4.12 (3H, br. s), 6.79 (1H, d, J=10.5 Hz), 7.20 (1H, d, J=10.5 Hz), and 8.58 (1H, br. s). ν: 1743, 1675, 1583, 1538, 1470, 1240, 695 cm^{-1}. λ_{max}^{MeOH}: 278 nm (ε=23000), 294 (21000), 402 (18000)]. The recovered **1**, 14 mg (24%), was obtained from the fractions eluted by hexane: ethyl acetate (1:1).

b): Similarly, **1** (30 mg) was allowed to react with DM (80 mg) and NaOMe (25 mg) in methanol (4 cm³) for 22 h. Similar work-up yielded **2**, 22%, and **3**, 28%, together with some of the recovered **1**.

c): To an anhydrous benzene dispersion (10 cm³) of DM (130 mg) and NaOMe (45 mg), **1** (50 mg) was added under stirring for 20 min at 10—15 °C. The mixture was then diluted with water, acidified with dil HCl, and was $CHCl_3$ extracted. Purification by silica gel column chromatography

of the extracts yielded **2**, 32.5 mg (61.5%), and the recovered **1**, 4.3 mg (8.6%).

d): Similarly, **1** (50 mg) was treated with DM (130 mg) and NaOMe (45 mg) in benzene (10 cm^3) at 10—15 °C for 20 min. The products were isolated by silica-gel column chromatography to give **2**, 36.7 mg (61.3%).

e): Similarly, a mixture of **1** (50 mg), DM (130 mg), and NaOMe (40 mg) in benzene (10 cm^3) was kept at 10—15 °C for 2 d. The mixture was chromatographed on a silica-gel column; the yield of **2** has dropped to 2 mg (3%) and another product, **4**, pale yellow needles, mp 209.5—210 °C (from benzene) [Found: C, 55.82; H, 4.38%. Calcd for $C_{17}H_{16}O_9$: C, 56.04; H, 4.43%. δ=3.77 (6H, s), 3.92 (3H, s), 4.05 (3H, s), 5.09 (1H, s), 7.16 (1H, d, J=10 Hz), 7.46 (1H, d, J=10 Hz), and 8.48 (1H, s). ν: 1758, 1680, 1590, 1518, 1470, 1405, 1250, 890, 765 cm^{-1}. λ_{max}^{MeOH}: 283 nm (ε=25000), 294 (25000), 393 (19000)] was obtained, 16 mg (18%).

f): To anhydrous DMSO solution (10 cm^3) of DM (1.05 g) and NaOMe (400 mg), **1** (220 mg) was added. After 40 min, the mixture was diluted with water, and extracted by $CHCl_3$. Silica-gel chromatography gave yellow crystals, **2**, 231 mg (92%), together with the recovered **1** (25 mg, 12%).

The Reaction of 2 with Dimethyl Malonate. To an anhydrous MeOH solution (4 cm^3) of DM (100 mg) and NaOMe (20 mg), **2** (20 mg) was added at 15 °C and kept 12 h. The mixture was diluted with ice-water, extracted with $CHCl_3$, and purified on a silica-gel column to give **4**, 20 mg (74%).

The Reaction of 3 with Dimethyl Malonate. Similarly, **3** (20 mg) was mixed with DM (100 mg) and NaOMe (15 mg) in a MeOH (4 cm^3) solution at 15 °C. A similar work-up after 12 h yielded **4**, 15 mg (54%).

The NaOMe-catalyzed Reaction of 1 with Methyl Acetoacetate. *a)*: To an anhydrous MeOH solution (8 cm^3) of MA (160 mg) and NaOMe (55 mg), **1** (60 mg) was added under stirring at 10—15 °C. After 5 min, the separated crystals were collected by filtration. After fractional recrystallizations from benzene, **5**, yellow needles, mp 235—236 °C, 45 mg (74%) [Found: C, 56.96; H, 3.60%. Calcd for $C_{13}H_9O_4$: C, 57.05; H, 3.59%. δ=2.61 (3H, s), 4.14 (3H, br. s), 7.11 (1H, d, J=11.5 Hz), 7.78 (1H, d, J=11.5 Hz), and 9.00 (1H, br. s). ν: 1743, 1638, 1515, 1450, 1240 cm^{-1}. λ_{max}^{MeOH}: 239 nm (ε=22000), 305 (23000), 410 (20000)], was obtained together with the recovered **1**, 3 mg (5%).

b): Anhydrous benzene dispersion (10 cm^3) of MA (160 mg) and NaOMe (55 mg) was mixed with **1** (60 mg) and kept at 10—15 °C for 2 h. Then the mixture was diluted with water and extracted with $CHCl_3$. Silica gel chromatography of the product gave **5**, 54 mg (84%).

c): To an anhydrous DMSO solution (3 cm^3) of MA (160 mg) and NaOMe (55 mg), **1** (60 mg) was added, the mixture was kept at 10—15 °C After 5 min, it was chromatographed on a silica-gel column to give **5**, 64 mg (quantitative yield).

The Conversion of 5 to 6. **5** (27 mg) was dissolved in a mixture of MeOH (1 cm^3) and benzene (7 cm^3) containing NaOMe (10 mg) at 15—20 °C for 2 d. Then the mixture was poured into water, and extracted with $CHCl_3$. Silica-gel chromatography of the extracts gave yellow needles, mp 244—245 °C (from benzene), **6**, 22 mg (80%) [Found: C, 63.50; H, 4.94%. Calcd for $C_{13}H_{12}O_5$: C, 62.90; H, 4.87%. δ=2.60 (3H, s), 3.98 (3H, s), 4.12 (3H, s), 6.85 (1H, d, J=11 Hz), 7.26 (1H, d, J=11 Hz), and 9.00 (1H, br. s). ν: 1722, 1640, 1623, 1588, 1460, 1243 cm^{-1}. λ_{max}^{MeOH}: 285 nm (ε=19000), 301 (20000), 414 (19000)].

Reactions of 3-Acetyltropolone Methyl Ethers with 1,2-Cyclohexanediamine

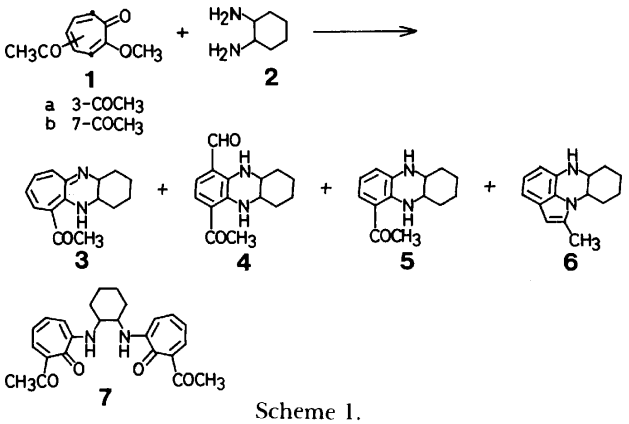
Yasunori SUDOH† and Kimiaki IMAFUKU*

Department of Chemistry, Faculty of Science, Kumamoto Universuty, Kurokami, Kumamoto 860

(Received July 25, 1983)

Synopsis. 3-Acetyl-2-methoxytropone reacted with 1,2-cyclohexanediamine (**2**) (a mixture of *cis* 60% and *trans* 40%) to give four *cis-trans* pairs of 6-acetyl-5*H*-1,2,3,4,4a,11a-hexahydrocyclohepta[*b*]quinoxaline (**3**), 6-acetyl-9-formyl-1,2,3,4,4a,5,10,10a-octahydrophenazine (**4**), 6-acetyl-1,2,3,4,-4a,5,10,10a-octahydrophenazine (**5**), and 1-methyl-6*H*-6a,7,8,-9,10,10a-hexahydropyrrolo[3,2,1-*de*]phenazine (**6**). The reaction of 2-acetyl-7-methoxytropone with **2** gave *cis*- and *trans*-*N,N'*-bis(6-acetyl-7-oxo-1,3,5-cycloheptatrienyl)-1,2-cyclohexanediamine, besides the above products. The *cis*- and *trans*-isomers of **4**, **5**, and **6** were secondary products from the *cis*- and *trans*-isomers of **3**, respectively.

Recently, we found and reviewed that 3-acetyltropolone and its methyl ethers reacted with a variety of nucleophilic reagents having two functional groups to give heterocycle-fused troponoid compounds.[1] On the extension of this series, we carried out the reactions with 1,2-alkanediamines in order to obtain diazaheptalene derivatives.[2] However, the desired compounds were not isolated, but 1*H*-2,3-dihydrocyclohepta[*b*]pyrazine derivatives and some rearrangement products were obtained.[2] In this paper, we describe the reactions of 3-acetyltropolone methyl ethers with 1,2-cyclohexanediamine.



Scheme 1.

A solution of 3-acetyl-2-methoxytropone (**1a**) and an equimolar amount of 1,2-cyclohexanediamine (**2**) (a mixture of *cis* 60% and *trans* 40%) in methanol was refluxed for 2 h to afford *cis*- and *trans*-6-acetyl-5*H*-1,2,3,4,4a,11a-hexahydrocyclohepta[*b*]quinoxaline [**3a** (44%) and **3b** (27%)], *cis*- and *trans*-6-acetyl-9-formyl-1,2,3,4,4a,5,10,10a-octahydrophenazine [**4a** and **4b** (mix. 1%)], *cis*- and *trans*-6-acetyl-1,2,3,4,4a,5,10,10a-octahydrophenazine [**5a** and **5b** (mix. 1%)], and *cis*- and *trans*-1-methyl-6*H*-6a,7,8,9,10,10a-hexahydropyrrolo[3,2,1-*de*]phenazine [**6a** (5%) and **6b** (3%)]. The structures were determined by their elemental analyses and spectral data, which were analogous with those of previously reported compounds.[2]

Refluxing of **1a** with five molar amounts of the diamine (**2**) caused remarkable decreases of the yields of **3a** (19%) and **3b** (3%). Instead, the yields of the by-products increased [**4a** (8%), **4b** (5%), **5a** (3%), **5b** (2%), **6a** (12%), and **6b** (7%)]. This result suggested that the compounds (**4a**, **4b**, **5a**, **5b**, **6a**, and **6b**) were secondary products from the compounds (**3a** and **3b**).

A solution of **3a** in methanol was refluxed for 21 h in the presence of the diamine (**2**) gave **4a** (26%), **5a** (7%), and **6a** (36%). The same treatment of **3b** with the diamine (**2**) also gave **4b** (16%), **5b** (10%), and **6b** (24%).

When a mixture of 2-acetyl-7-methoxytropone (**1b**) and an equimolar amount of **2** was refluxed for 2 h, dimeric products—*cis*- and *trans*-*N,N'*-bis(6-acetyl-7-oxo-1,3,5-cycloheptatrienyl)-1,2-cyclohexanediamine (**7a** and **7b**) were obtained in 10 and 7% yields, respectively, besides **3a** (13%) and **3b** (10%). Furtheremore, the prolonged reaction (24 h) gave five pairs of *cis*- and *trans*-isomers [**3a** (55%), **3b** (15%), **4a** and **4b** (mix. 2%), **5a** and **5b** (mix. trace), **6a** (1%), and **6b** (0.5%)].

Experimental

Measurements. The melting points were determined with a Yanagimoto MP-S2 apparatus and are uncorrected. The HPLC separations were performed on an Altex 330/110A/153 apparatus with a HY-ODS column. The IR and UV spectra were taken on a JASCO IRA-1 and a Hitachi EPS-3T spectrophotometer, respectively. The ^{1}H NMR spectra were recorded with a Hitachi-Perkin-Elmer R-24 spectrometer (60 MHz). The high-resolution mass spectra were obtained with a JEOL JMS-DX-300 apparatus.

Material. 1,2-Cyclohexanediamine (purchased from Tokyo Kasei Co., Ltd.) is a mixture of approximately 60% of *cis*- and 40% of *trans*-isomer.

Reaction of 3-Acetyl-2-methoxytropone (1a) with 1,2-Cyclohexanediamine (2). A mixture of 3-acetyl-2-methoxytropone (**1a**) (178 mg, 1.0 mmol) and 1,2-cyclohexanediamine (**2**) (0.1 ml, 1.0 mmol) in methanol (10 ml) was refluxed for 2 h. After removal of the solvent, the residue was four times chromatographed on a Wakogel B-10 plate (30×30 cm^2) with benzene. The first fraction was collected and recrystallized from hexane to give 12 mg (5%) of *cis*-1-methyl-6*H*-6a,7,8,9,10,10a-hexahydropyrrolo[3,2,4-*de*]-phenazine (**6a**) as colorless plates; mp 149—150°C; IR ($CHCl_3$) 3380 cm^{-1} (NH); UV (CH_3OH) 226 (log ε 4.47), 283 (3.94), 295 nm (sh, 3.91); NMR ($CDCl_3$) δ=1.1—2.2 (8H, m, $CH_2\times4$), 2.37 (3H, s, CH_3), 3.20 (1H, br, NH), 3.5—3.8 (1H, m, CH), 3.8—4.4 (1H, m, CH), 6.02 (1H, s, H-2), 6.18 (1H, dd, J=6, 3 Hz, H-5), 6.78 (1H, dd, J=8, 6 Hz, H-4), 6.84 (1H, dd, J=8, 3 Hz, H-3). Found: *m/e* 226.1446 (M$^+$). Calcd for $C_{15}H_{18}N_2$: M, 226.1470. The third fraction was recrystallized from hexane to give 8 mg (3%) of *trans*-1-methyl-6*H*-6a,7,8,9,10,10a-hexahydropyrrolo[3,2,1-*de*]phenazine (**6b**) as colorless prisms; mp 195—196°C; IR ($CHCl_3$) 3370 cm^{-1} (NH); UV (CH_3OH) 227 (log ε 4.41), 280 nm (3.91); NMR ($CDCl_3$) δ=1.1—2.2 (8H, m, $CH_2\times4$), 2.43 (3H, s, CH_3), 2.6—3.4 (1H, m, CH), 3.45 (1H, br, NH), 3.4—4.1 (1H, m, CH), 6.07 (1H, s, H-2), 6.23 (1H, dd, J=5, 3 Hz, H-5), 6.82 (1H, dd, J=8.5, 5 Hz, H-4), 6.87 (1H, dd, J=8.5, 3 Hz, H-3). Found: *m/e* 226.1458 (M$^+$). Calcd for $C_{15}H_{18}N_2$: M,

The Preparation of 1-Carbamoyl-3-cyanoguanidine and 1-Cyanobiuret from Cyanourea[1)]

Kokoro Iio

Industrial Products Research Institute, Yatabe-machi Higashi, Tsukuba-gun, Ibaraki 305

(Received September 7, 1983)

Synopsis. Cyanourea in an aqueous or organic solution which was allowed to stand at room temperature gave 1-carbamoyl-3-cyanoguanidine and 1-cyanobiuret. The reaction was promoted by a mixture of cyanourea and its alkali salt. 1-Cyanobiuret was also obtained quantitatively by the reaction of cyanourea with alkali cyanate.

It has previously been reported[2,3)] that 1-carbamoyl-3-cyanoguanidine (**1**) was obtained by the reaction of 2-methyl-1-carbamoylisourea with cyanamide, while 1-cyanobiuret (**2**) was obtained by the reaction of *S*-methyl 1-thioallophanate with cyanamide.

In this paper, the author will describe convenient methods of synthesizing **1** and **2** from cyanourea (**3**).

When **3** in a crystalline state had been kept for a long time in the atmosphere, the IR spectrum of **3** showed new absorptions at 2200 and 740 cm^{-1}. This fact was explained by the formation of **1**. Potassium, sodium, or copper(II) salt of **3** in the crystalline state, however, could be kept under the same conditions without any transformation. On the other hand, the formation of **1** was found in an aqueous solution of **3** or its alkali salt. The yield of **1** was enhanced by mixing **3** with its alkali salt; especially when their molar ratio was 3/1, **1** and alkali salt of **2** were obtained in 80 and 1% yields respectively when the solution was kept at 35 °C for a week. A similar reaction was also observed in organic solutions. Even if **3** and its alkali salt were slightly soluble in ethanol, dioxane and acetonitrile, **1** and the alkali salt of **2** were obtained in low yields. The yield of the alkali salt of **2** was enhanced by using DMF or sulfolane as a solvent. Only **3** in sulfolane, however, gave **1** and ammelide, which was the cyclic compound of **2**, in 11 and 14% yields respectively. This fact suggests that the free state of **2** was unstable and cyclized to ammelide, while the alkali salt of **2** was stable. **1**, the alkali salt of **2**, and ammelide were confirmed by comparing their IR spectrum and melting points with those of an authentic sample.[2,3)] These results are summarized in Table 1.

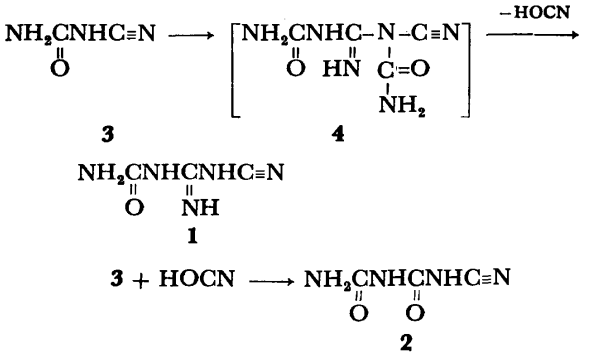
TABLE 1. PREPARATION OF 1 AND 2 FROM 3

3		Solvent	Products (Yield/%[b)])	
Free[a)]	K salt[a)]		1	2[c)]
1	0	H_2O	6	0
0	1	H_2O	11	0
1	1	H_2O	68	1
3	1	H_2O	80	1
1	1	EtOH	9	1
1	1	Dioxane	24	3
1	1	CH_3CN	22	4
1	1	DMF	28	30
1	1	Sulfolane	22	38
3	1	Sulfolane	31	27
1	0	Sulfolane	11	14[d)]

a) Molar ratio. b) Yield based on 2 **3**→**1**+**2**. c) Yield of K salt of **2**. d) Yield of ammelide.

Though **1** could be constituted by the addition of cyanamide to **3**, cyanamide was not detected in any case and did not react with **3**. On the other hand, **2** was obtained quantitatively by the reaction of **3** with alkali cyanate in water, DMF, and sulfolane at room temperature. Ammonia was detected in the aqueous solution, but was not detected in organic solutions. It may be suggested that the decomposition of cyanic acid to ammonia and carbon dioxide caused the low yield of **2** in the aqueous solution.

These results suggest that **3** was dimerized to the labile intermediate (**4**), that **1** was formed by the elimination of cyanic acid from **4**, and that then cyanic acid reacted with the remaining **3** to form **2**.



Experimental

The melting points are uncorrected. The IR spectra were taken with a Hitachi EPI-2 spectrometer.

Materials. The **3** was prepared by the alkali hydrolysis of cyanoguanidine.[4)] The other reagents were commercially available and were used after purification if necessary.

Reaction of 3 in an Aqueous Solution. A mixture of **3** (1.70 g) and its potassium salt (2.46g) in water (10ml) was allowed to stand for a week at 35 °C. The precipitate was then filtered off and washed with a small amount of water to give 1.72 g (68%) of **1**;[2)] mp>360 °C. IR (KBr) 2200, 2100, 1700, 1650, 1595, 770, and 740 cm^{-1}. After the pH had been made 3.5—4.0 with 6 mol dm^{-3} of nitric acid, the filtrate was evaporated and extracted with DMF. The residue was dissolved in water, and copper(II) chloride was added to form copper(II) salt of **2** (0.1 g, 1%);[3)] mp>360 °C. Found: N, 28.41%. Calcd for $C_6H_6N_8O_4Cu \cdot 4H_2O$: N, 28.75%.

In the cases of ethanol, dioxane, and acetonitrile solutions, the method was similar to that described above.

Reaction of 3 in DMF Solution. A mixture of **3** (1.70 g) and its potassium salt (2.46 g) in DMF (10 ml) was allowed to stand for a week at 35 °C. The precipitate, potassium salt of **2**, was then filtered off and washed with methanol. The yield was 1.98 g (30%). The filtrate was evaporated under reduced pressure. The residue was dissolved in water, and the insoluble crystals, **1**, were filtered off. The yield was 0.70 g (28%).

In the case of the sulfolane solution, the method was similar to that described above.

Reaction of 3 with Potassium Cyanate. **3** (2.55g) and potassium cyanate (3.05g, as the purity was 80%) were dissolved in water (10ml). The reaction mixture was then kept at room temperature for 24 h. Potassium salt of **2** was subsequently deposited by the addition of 2-propanol. The yield was 4.46g (90%).

In the case of DMF and sulfolane, potassium salt of **2** was deposited quantitatively from the solution.

The author is indebted to Dr. Eiichi Ichikawa of the Tokyo Institute of Technology for his kind suggestions.

††*Institute for Molecular Science, Okazaki 444*

(Received May 12, 1983)

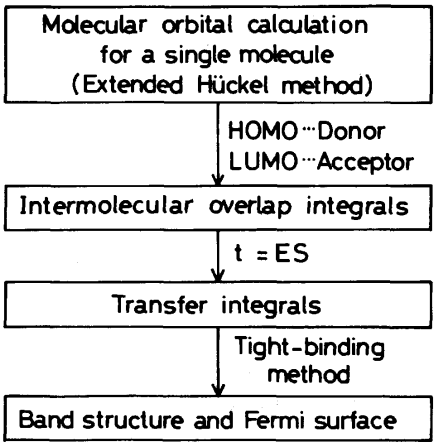
Based on the extended Hückel molecular orbital calculations, the relation between the anisotropy of the band structure and the arrangement of the organic molecules is investigated for two organic donors, tetrathiafulvalene (TTF) and bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF). The intermolecular overlaps of their HOMO are calculated while the intermolecular arrangements are varied. The maps of the overlaps thus obtained are then used to estimate the band-structure parameters of $(TMTTF)_2X$ and $(BEDT\text{-}TTF)_2ClO_4(C_2H_3Cl_3)_{0.5}$. The Fermi surface of $(TMTTF)_2X$ is quasi-one-dimensional and not closed. On the contrary, $(BEDT\text{-}TTF)_2ClO_4(C_2H_3Cl_3)_{0.5}$ is regarded as a two-dimensional semimetal.

It has been widely believed that a face-to-face stacking of planar molecules is an indispensable requirement of organic metals and that most of organic metals are quasi-one-dimensional conductors. In these compounds, the intermolecular π-π interaction is responsible for their one-dimensional energy band. However, charge- and spin-density-wave instabilities inherent in one-dimensional metals tend to destroy the metallic states. In the organic superconductors $(TMTSF)_2X$ (TMTSF; tetramethyltetraselenafulvalene, X=PF_6, AsF_6, SbF_6, ClO_4, *etc.*), however, it has been pointed out that the metallic states are stabilized by the relatively large transverse interaction.[1,2] Molecular orbital calculations using seiempirical parameters (extended Hückel method) have been performed by different authors for the $(TMTSF)_2X$ series compounds. Whangbo *et al.*,[3] Grant,[4] and the present authors[5] obtained a quasi-one-dimensional Fermi surface, at least when selenium 4 d orbitals were not included in the calculation. In these calculations, the ratio of the transverse and the longitudinal transfer integrals t_b/t_a was about 0.1. Including selenium 4d orbitals, Whangbo *et al.* noticed a large enhancement of the transverse dispersion leading to a closed Fermi surface on the a* b* plane. However, we found that the change in t_b/t_a was too small to close the Fermi surface. Minot and Louie obtained a complicated semimetallic band structure, with closed Fermi surfaces, by using 'swelled' selenium 4p orbitals, but no 4d orbital.[6] We obtained a similar result when the ionization potential of selenium 4d atomic orbitals was chosen close to the energy level of the highest occupied molecular orbital (HOMO).

On the other hand, increasing interest has been taken in the cation radical salts of BEDT-TTF (4,5-4',5'-bis(ethylenedithio)tetrathiafulvalene). Saito *et al.* reported that the conductivity of $(BEDT\text{-}TTF)_2ClO_4(C_2H_3Cl_3)_{0.5}$ is metallic down to 16 K; below this temperature it decreases slightly, but remains high ($670\ \Omega^{-1}\ cm^{-1}$) even at 1.4 K.[7] The X-ray structure analysis showed that this compound does not have the column structure characteristic of one-dimensional organic conductors.[8] We have calculated the intermolecular overlap integrals of this compound and showed the importance of the transverse interactions.[9] Recently it has also been observed that, in β-$(BEDT\text{-}TTF)_2PF_6$, which shows metal-insulator transition at 297 K, the most conducting axis is parallel to the molecular plane.[10] These results suggest that, in BEDT-TTF compounds, the transverse interaction is more important than, or at least is similar in importance to, the longitudinal interaction.

The present investigation is intended to clarify the relation between the anisotropy (dimensionality) of the band structure and the mode of the intermolecular arrangement of organic molecules. In the calculation, the methyl groups of TMTSF can be replaced by hydrogens (TSF; tetraselenafulvalene) without any significant change in the molecular orbitals. However, if its selenium atoms are replaced by sulfur (TTF; tetrathiafulvalene), the subsequent significant contraction of the atomic orbitals influences the molecular orbitals. In the present investigation, the calculation is performed for two organic donors, TTF and BEDT-TTF.

In order to discuss the physical properties on the basis of quantum-chemical calculations, it is necessary to



Scheme

carry out an energy-band calculation which takes the three-dimensional periodicity of the crystal into consideration. However, it is not easy to calculate the energy-band structure considering all electrons because of the large size of the organic molecules and because of the complicated crystal structures. Since the anisotropy of the physical properties mainly reflects the shape of the Fermi surface, we may neglect the levels other than the conduction level. Our procedure of the approximate band-structure calculation is thus (Scheme);

(1) Since the size of the organic molecules is very large, the molecular orbitals of a single molecule are calculated by means of the extended Hückel method.

(2) In the case of donor molecules, the intermolecular overlap S of the HOMO is calculated.

(3) Transfer integrals t are estimated using the relation $t=ES$, where E is a constant of the order of energy of the HOMO. This relation is the same as that generally used in the extended Hückel method to obtain resonance integrals.

(4) Using the standard tight-binding approximation, the band structure of the conduction band and the shape of the Fermi surface are obtained.

Alternatively, the transfer integrals can be obtained by calculating the molecular orbitals of a dimer. Unlike this method, our approximation completely neglects the polarization of the molecular orbitals caused by the interaction with other molecules. However, the simplicity of the calculation is more efficient in comparing a number of different intermolecular arrangements. In the present investigation, the intermolecular overlaps of the HOMO are calculated while the molecular arrangements are varied. Using the maps of the intermolecular overlaps thus obtained, the band-structure parameters of $(TMTTF)_2X$ and $(BEDT\text{-}TTF)_2ClO_4(C_2H_3Cl_3)_{0.5}$ are estimated, and the shape of their Firmi surface is discussed. In addition, the characteristic side-by-side arrangement of BEDT-TTF molecules in $(BEDT\text{-}TTF)_2ClO_4(C_2H_3Cl_3)_{0.5}$ is interpreted in view of the electronic stabilization due to the maximum overlap of the conduction orbitals.

Molecular Orbital Calculation

The molecular structures of TTF and BEDT-TTF were idealized so as to have a D_{2h} symmetry, based on the crystal structures of TTF-TCNQ and $(BEDT\text{-}TTF)_2ClO_4(C_2H_3Cl_3)_{0.5}$ (Fig. 1).[8,11] All the atoms except the hydrogens in BEDT-TTF were put on the xy-plane, and the x-axis was placed so as to correspond with the long axis of the molecule. The C-H bond lengths were assumed to be 1 Å.

Since the large size of the molecules prevented us from adopting *ab initio* calculations, the simple extended Hückel method was used. The parameters (Table 1) were taken from Ref. 12.

The coefficients of the HOMO are shown in Table 2. The HOMO of BEDT-TTF as well as that of TTF has a π-character with B_{1u} symmetry (in the D_{2h} point group) and has nodes on all the C-S bonds. The electron density is largest on the inner sulfur atom, S_1. The fact that the charge density on the outer sulfur atom, S_2, of BEDT-TTF is larger than the charge on the C_2 of TTF, shows the considerable expansion of the HOMO of BEDT-TTF in comparison with TTF.

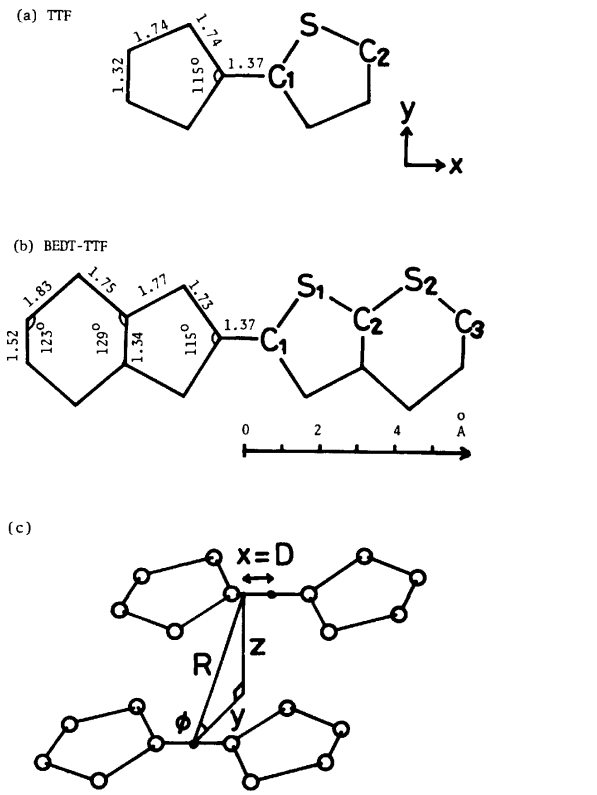


Fig. 1. Molecular structures of (a) TTF and (b) BEDT-TTF. Bond lengths in Å. (c) Relative orientation of a molecular dimer. D represents the molecular slipping along the long axis, R stands for the distance between the long axes of the two molecules, and ϕ is changed from 0° (the side-by-side arrangement) to 90° (the face-to-face stacking).

Intermolecular Overlaps

Since, both in the $(TMTTF)_2X$ analogs and in many BEDT-TTF salts, molecules are arranged so as to keep their long axes and their molecular planes parallel to each other, we did not consider the relative rotation of the molecules. The relative arrangement of two molecules is represented by a set of cylindrical coordinates

(D, R, ϕ), as is shown in Fig. 1 (c).

The molecular orbital calculation of a dimer when ϕ=90° has been repeatedly carried out for TCNQ and TTF as a function of D, in which attention has been paid to the most favored slipping D of the stacked molecules.[13] The total energy of a dimer may be divided into the core repulsion and the electronic bonding energy. In the case of TCNQ, the core repulsion is a flat function of D over a wide range of D, and the maximum of the overlap of the lowest unoccupied molecular orbitals (LUMO) corresponds with the minimum of the total energy and also agrees with the slipping in the actual crystals.[13,14] On the contrary, in the case of TTF, the actual slipping corresponds with the minimum of the core repulsion, and the overlap of the HOMO has a *minimum* near this slipping. The applica-

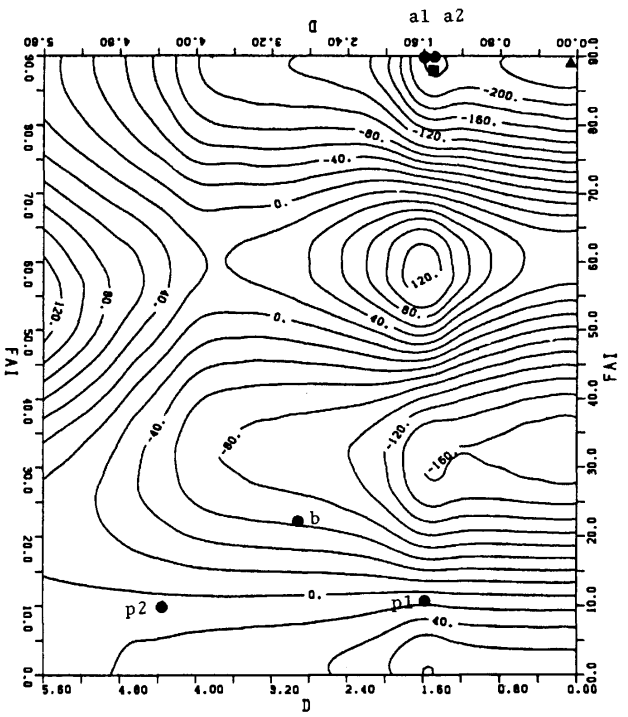

Fig. 2. Overlap integral ($\times 10^{-4}$) of the HOMO between two TTF molecules as a function of the slipping D and the relative angle ϕ (FAI) (see Fig. 1(c)). The triangle designates the stacking mode in TTF-$I_{0.72}$ or TTF-$SCN_{0.58}$. The aquare shows the slipping in the TTF-TCNQ analogs. The other symbols correspond to the interactions in $(TMTTF)_2X$ shown in Fig. 5.

The symbols a1, a2, *etc.* correspond to the interactions in $(BEDT\text{-}TTF)_2ClO_4$ $(C_2H_3Cl_3)_{0.5}$ shown in Fig. 6.

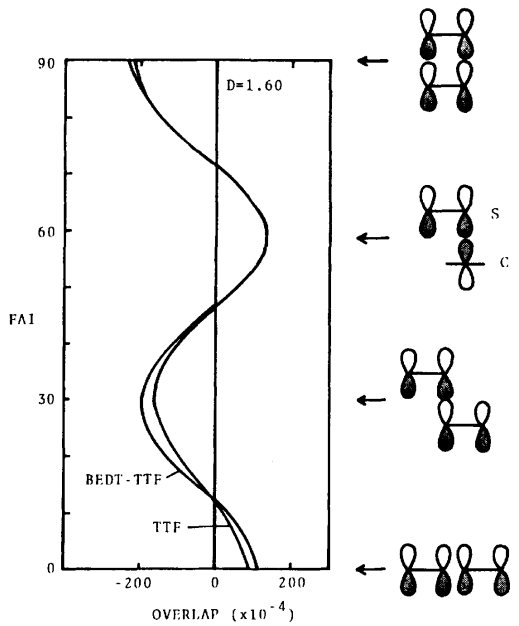

Fig. 4. Cross section of Figs. 2 and 3 at $D=1.60$ Å. In the right hand, the HOMO viewed along the long axes of the molecules are shown.

tion of the local-density-functional theory also suggests the importance of the core repulsion.[15] These results are not surprising, for the van der Waals radius of sulfur is considerably larger than those of carbon and nitrogen. In order to eliminate the effect of this core repulsion, we restricted our calculation to the plane of a crumpled cylinder where the shortest sulfur-to-sulfur distance was arbitrarily fixed as 3.80 Å. The effect of changing the sulfur-to-sulfur distance will be discussed later. By this 'rigid-body approximation,' the coordinate R is given as a function of the other two coordinates, D and ϕ.

In Figs. 2 and 3, the intermolecular overlap integrals are shown as a function of D and ϕ. Figure 4 shows the cross-section of Figs. 2 and 3 at $D=1.60$ Å. The largest overlap at $\phi=90°$ corresponds to the normal face-to-face stacking. The interaction at $\phi=0°$ is the π-like interaction of the p_z (and d) orbitals. The peak around $\phi=30°$ corresponds to the σ-like interaction. In these contexts, σ-like and π-like represent the overlaps which mainly come from the components of the p_z orbitals projected parallel to and perpendicular to the bonding direction respectively. The peak at $\phi=60°$, $D=1.60$ Å, mainly comes from the overlap between the central carbon, C_1, and the sulfur.

The interactions of the TMTTF molecules in $(TMTTF)_2Br$ are shown in Fig. 2 by five symbols, a_1, a_2, p_1, p_2, and b, which correspond to the interactions designated in Fig. 5.[16] Other $(TMTTF)_2X$ type compounds are isostructural to $(TMTTF)_2Br$, regardless of X. The longitudinal interactions, a_1 and a_2, are the same as that of TTF in TTF-TCNQ (the square in Fig. 2). Though the shortest sulfur-to-sulfur distance is found in p_1 and p_2, these interactions ($\phi=10°$) are located nearly midway between the σ-like and the π-like overlaps of the p_z orbitals. As a consequence, these interactions are

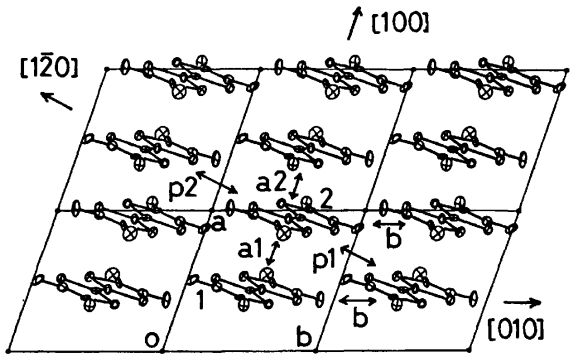

Fig. 5. Intermolecular interactions in $(TMTTF)_2X$.

smaller than the oblique interaction, b, which is close to the peak of the σ-like interaction. Near the region where the overlap crosses zero, the magnitude of the overlap is sensitive to a small variation in the crystal structures. This is also valid for $(TMTSF)_2X$, which is isostructural to $(TMTTF)_2X$. This is the reason why Grant found that the magnitudes of p_1 and p_2 were very sensitive to the kinds of anions, but that other interactions were hardly changed by the anions.[4] The large aniotropy which all the $(TMTSF)_2X$ series compounds show, comes from the large longitudinal interactions, a_1 and a_2, which are scarcely changed by the anions. On the contrary, the difference in the anions, X, causes a small structural variation, which gives rise to the sensitive change of p_1 and p_2, and influences the distortion of the Fermi surface. Therefore, it is possible that the onset of spin-density waves and other instabilities are influenced by the small variation in the crystal structure produced by the anions.

The map of BEDT-TTF in Fig. 3 resembles that of TTF. Figure 4 shows that, in BEDT-TTF, the transverse interactions at $\phi=0°$ and 30° are somewhat enhanced in comparison with those in TTF. The three symbols, a, p, and q, stand for the interactions along [100], [$\bar{1}$02], and [102] respectively in $(BEDT\text{-}TTF)_2ClO_4(C_2H_3Cl_3)_{0.5}$ (Fig. 6). It is worth noting that the overlap along the $\phi=90°$ direction, which exists universally in TTF salts, is not observed in this crystal. As is shown in Fig. 3, p and a are close to the peaks at $\phi=30°$ and $\phi=0°$ respectively. However, q_1, q_2, and q_3 are apart from the peak at $\phi=60°$, $D=1.60$ Å, and are smaller than the other interactions, a and p.

Models of the Energy-band Structures

In actual crystals, the sulfur-to-sulfur distances, $R_{S\text{-}S}$ are not always $R_0=3.80$ Å. However, as is shown in Fig. 7, the overlap integrals change similarly in all the directions as a function of the sufur-to-sulfur distance. Therefore one can estimate the intermolecular overlaps in the actual crystals by using Fig. 7 together with Figs. 2 and 3. The transfer integrals, t, can then be obtained from the relation; $t=E\,S$. Though the best choice of the E value depends on the parameters used for the molecular orbital calculation, we ordinarily use $E=-10$ eV, because it has given realistic values of the transfer integrals for a number of com-

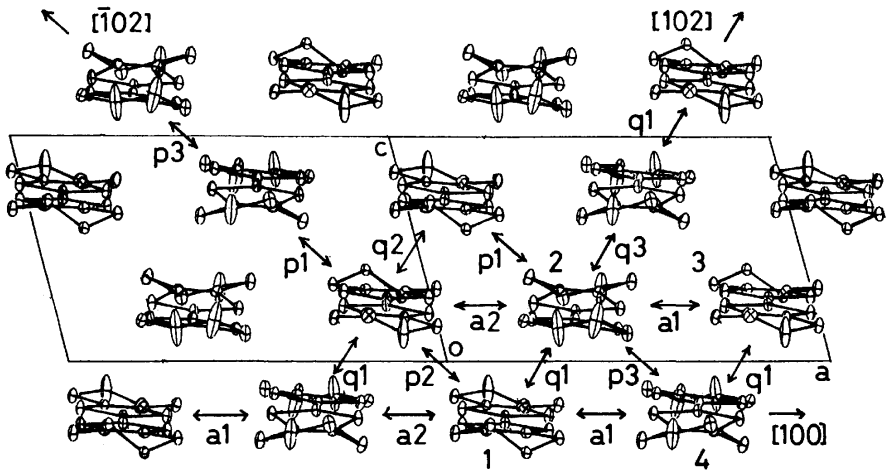

Fig. 6. Intermolecular interactions in $(BEDT\text{-}TTF)_2ClO_4(C_2H_3Cl_3)_{0.5}$.

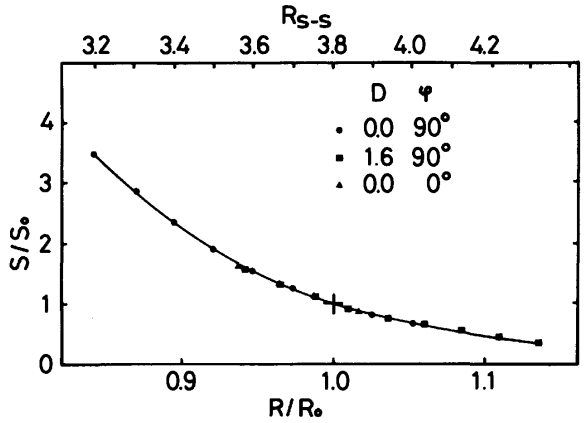

Fig. 7. Relative change of the overlap S as a function of the intermolecular sulfur-to-sulfur distance R, compared with the overlap S_0 at R_0=3.80 Å.

pounds.[9,14,17] When the transfer integrals are estimated, it is easy to obtain the conduction-band structure by the use of the standard tight-binding theory.

From Figs. 2 and 7, the transfer integrals of $(TMTTF)_2X$ were estimated (Table 3(a)). From the standard tight-binding approximation, the matrix elements of the secular equation were;[18]

$$H_{11} = H_{12} = 2t_b \cos kb,$$

$$H_{12} = H_{21}^* = t_{a1} + t_{a2}e^{-ika} + t_{p1}e^{-ikb} + t_{p2}e^{i(kb-ka)}.$$

Solving the resulting quadratic equation, the following dispersion relation was obtained;

$$\varepsilon = 2t_b \cos kb + \Delta^{1/2},$$

$$\Delta = [(t_{a1}+t_{a2})\cos(ka/2) + (t_{p1}+t_{p2})\cos(ka/2-kb)]^2 + [(t_{a1}-t_{a2})\sin(ka/2) + (t_{p1}-t_{p2})\sin(ka/2-kb)]^2.$$

Using this relation, the energy-band structure and the Fermi surface were numerically calculated (Fig. 8). From the stoichiometry, the upper band is exactly half-filled, and the Fermi surface is a plane located around $k_F=\pi/2a$. The deviation from the averaged k_F is about 0.15 π/a. Since, in such a half-filled band, a closed orbit

arises only at t_a/t_b=1.0,[19] one may safely conclude that the Fermi surface is a plane.

Table 3(b) shows the band parameters of $(BEDT\text{-}TTF)_2ClO_4(C_2H_3Cl_3)_{0.5}$ estimated similarly from Figs. 3 and 7. The matrix elements of the secular equation were obtained by reference to Fig. 6;

$$H_{11} = H_{22} = H_{33} = H_{44} = 0,$$

$$H_{12} = H_{21}^* = H_{34}^* = H_{43} = t_{q1} + t_{p1}e^{-ikc},$$

$$H_{13} = H_{31}^* = t_{p2}e^{-ika} + t_{q2}e^{-i(ka+kc)},$$

$$H_{14} = H_{41}^* = H_{23} = H_{32}^* = t_{a1} + t_{a2}e^{-ika},$$

$$H_{24} = H_{42}^* = t_{p3} + t_{q3}e^{ikc}.$$

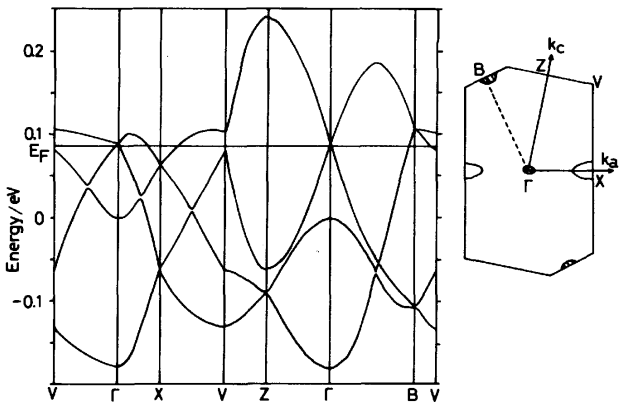

Fig. 9. Band strure and Fermi surface of (BEDT-TTF)$_2$ClO$_4$(C$_2$H$_3$Cl$_3$)$_{0.5}$ calculated by using the transfer integrals in Table 3(b). The shaded region indicates hole-like part.

By solving the secular equation, the band structure and the Fermi surface were found to be as is shown in Fig. 9. From the stoichiometry of the complex, the conduction band is three-quarters filled. Since the unit cell contains four molecules, the conduction level splits into four bands. Because the alignments along p and q have a fourfold periodicity, if the difference of the overlaps belonging to the same direction, p and q, is very large, the energy gap which is opened between the third and the fourth levels makes the compounds semiconductive. However, since the small difference in the calculated overlaps was not regarded as meaningful because of the qualitative nature of the calculation, the interactions belonging to the same direction were averaged in the model in Table 3(b). Consequently, the resulting band structure is two-dimensional and semimetallic. These results agree with the obwervation of the conductivity and the Drude-like optical reflectance along the two directions.[7,23]

Discussion

The organic superconductors (TMTSF)$_2X$ are isostructural to (TMTTF)$_2$Br. In the present investigation, we did not deal with the calculation of selenium analogs. However, as has already been reported,[10] the band structure of (TMTSF)$_2X$ is qualitatively similar to that of (TMTTF)$_2X$. One of the central points of interest with regard to the band structure of (TMTSF)$_2X$ is whether or not there exists a closed Fermi surface. The only experimental evidence of the closed orbit so far is the observation of the Shubnikov-de Haas resistance.[20] However, as was discussed by Horovitz *et al.*,[21] this observation can be interpreted in terms of the semimetallic electronic states under the spin-density-wave states. Since the large calculated anisotropy agreed with the anisotropy of the conductivity (σ_a/σ_b=300)[22] and the analysis of the optical reflectance (t_b=0.14 eV),[24] we conclude that the Fermi surface at high temperatures is a distorted plane, as is shown in Fig. 8.

Another open question is by what mechanism organic molecules are made to be aligned in the transverse directions, as is found in the actual crystals. Considering a chain of organic donors, the bottom of the conduction band corresponds to the bonding alignment of the element orbitals (HOMO), while the top has an antibonding nature. If this band is partially filled, the wider the band splits (or the stronger the interaction is), the more stable the system becomes by means of the intermolecular bonding, compared with the independent molecules. If the core repulsion is not as dominant as this electrical bonding energy, the orientation giving the maximum of the overlap of the HOMO can be expected to correspond with the most stable molecular alignment. In (BEDT-TTF)$_2$ClO$_4$-(C$_2$H$_3$Cl$_3$)$_{0.5}$, the interactions, a and p, are close to the peaks of the overlap in Fig. 3. Therefore, the alignment of the molecules along these directions is favorable because of the intermolecular bonding interaction of the HOMO. The absence of the ϕ=90° interaction is probably due to the large core repulsion of the out-of-plane ethylene groups.

The authors wish to thank Dr. Imoto for a part of the program and to Mr. Tajima for his valuable discussions on the band structures. The computations are carried out partly on the HITAC M-200H computer system at the Institute for Molecular Science and partly on the HITAC M-280H computer system at the Computer Center of the University of Tokyo.

Plastic Phase of Formylferrocene Studied by X-Ray Diffraction and Mössbauer Spectroscopy

Kumiko SATO,* Makoto IWAI, Hirotoshi SANO, and Michiko KONNO†
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
†*The Institute for Solid State Physics, The University of Tokyo, Roppongi-7, Minato-ku, Tokyo 106*
(Received June 7, 1983)

The structures of both the crystal and the plastic phases of formylferrocene have been determined to be orthorhombic by single-crystal X-ray diffraction. The structural change proposes a mechanism of the transition that postulates the translational molecular motion along the a-axis. Mössbauer spectra observed in the plastic phase show little fluctuation of the electric field gradient ascribed to the orientational disorder between x, y, and z axes of the molecule.

It is known that organometallic compounds, such as ferrocene derivatives, exhibit various kinds of mesophase transitions. Malthete and Billard have reported that ferrocene derivatives of *N*-(*p*-benzoyloxybenzylidene)aniline exhibit mesomeric properties.[1] The plastic crystal (PC) phases of formyl- and polychloroferrocenes were studied and the former especially has been widely investigated by Daniel *et al.*[2-4] Although the structure of the ordered low-temperature phase of formylferrocene was determined to be orthorhombic (space group $P2_12_12_1$; Z=4, a=7.635, b=10.520, c=11.281 Å) by using a single crystal, the structure of the PC phase was assinged to a simple face-centered cubic (f.c.c.) lattice with a unit-cell parameter a=9.99 Å accompanied by orientational disorder based on a Debye-Scherrer pattern.

In the present paper the plastic phase transition in formylferrocene has been studied by means of single crystal X-ray diffraction and Mössbauer spectroscopy. Although the present X-ray diffraction data determined at room temperature agreed essentially with those reported by Daniel *et al.*, the results obtained for the PC phase determined by oscillation and Weissenberg photographs were found to be orthorhombic, with a'=11.9, b'=16.4, c'=7.0 Å at 50 °C. The temperature dependence of the Mössbauer spectra was determined in order to confirm dynamic molecular motion.

Experimental

Formylferrocene was synthesized by acylation of ferrocene with *N*,*N*-dimethylformamide. The products were separated by column chromatography on an alumina and purified by recrystallization and sublimation. The purity was checked by melting point and elemental analysis. The thermal properties of formylferrocene were determined by a Rigaku Thermoflex Differential Scanning Calorimeter (DSC). The thermal parameters at transition and melting points were found to be ΔH=12.09±0.04 and 2.184±0.008 kJ mol^{-1} and ΔS=38.37±0.12 and 5.82±0.04 J mol^{-1} deg^{-1}, respectively, which agreed with the values reported in the previous paper.[2]

Mössbauer spectra were determined by using an Austin Science Associated Mössbauer spectrometer. Velocity calibration was carried out based on the room-temperature spectra of metallic iron. By fitting the resonance line with a Lorentzian function, the Mössbauer parameters were extracted. A high-temperature apparatus was constructed with a heater in a vacuum furnace. The sample was sealed to suppress sublimation. Temperature was checked by using a CA thermocouple with a precision of about ±0.05°.

Because our results on the structural analysis of the PC phase of formylferrocene contradicted those reported by Daniel *et al.*, the crystal structure of this compound at room temperature was determined in order to confirm that the compound used here has the same crystal structure in the crystal phase as the one used by them.

Single crystals suitable for X-ray study were obtained by a slow sublimation method. A crystal specimen with approximate dimensions of 0.28×0.25×0.23 mm was used, kept in a Lindemann-glass capillary filled with nitrogen gas. Intensity data were collected on a four-circle diffractometer with Mo $K\alpha$ radiation monochromated by a graphite plate.

The crystals are orthorhombic with space group $P2_12_12_1$, a=10.525(9), b=11.294(10), c=7.639(5) Å, V=908.1(13) Å^3 and Z=4 at room temperature. The details of the basic crystal data have been omitted in the present paper as the results obtained at room temperature agree essentially with those reported by Daniel *et al.* in 1981.[3] There are, however, some comments in connection with the crystal structure. The positions of hydrogen atoms could be determined and are shown in Table 1. In refinement, incorporating the model with two-fold disorder, the cyclopentadienyl rings are found to be twisted approximately by 36° around the molecular axis with respect to one another, as shown by the solid circles in Fig. 1. The disordered model involves two alternative ring orientations in a ratio of occupancy of 0.85:0.15. A composite structure, which attempts to model the disorder, gives R=3.72% over 1001 independent reflections with $|F_o|>3\sigma(|F_o|)$ up to 2θ=60°.†† The disordered structure at room temperature provides a useful clue to understanding the molecular motion of this compound at the transition point as described later.

Results and Discussion

Crystal Structure. Formylferrocene exists approximately on the a and c plane and a prominent feature of the molecular structure is the layer structure along b axis. There exist the 020 reflections with a significant intensity characteristic of a layer structure.

The molecules occupying in the ratio of 0.85 exhibit an appreciable interaction between neigh-

†† The complete F_o—F_c data are deposited as Document No. 8401 at the Office of the Editor of the Bulletin of the Chemical Society of Japan.

bouring molecules along the b axis. The nearest distance between O(1) and H(5) is estimated to be 2.53 Å and the C(5)-H(5)···O′(1) bond angle 128°. The H(11)-O′(1) distance is estimated to be 2.84 Å, the O(1)-H(11)···O′(1) bond angle 148° and the H(2)-O′(1) distance 2.81 Å the C(2)-H(2)···O′(1) bond angle 132°. There is a network of intermolecular interaction along c axis as shown by broken lines in Fig. 2.

The molecules occupying in the ratio of 0.15 are twisted approximately by 36° around the molecular axis and too far separated to form an intermolecular bonding network. At room temperature the probability of molecules sitting in the disordered positions is about 15% and the possibility may increase with increasing temperature.

Plastic Crystalline Structure. The crystal specimen was heated by electrically heated air, controlled with a precision of about ±0.25°. In the PC phase, oscillation and Weissenberg photographs were taken at temperatures from 45 to 70 °C. After the transition at 43.5 °C, there remained only five independent reflections with significant intensity, 111, 210, 030, 121, and 220. Oscillation and Weissenberg photographs indicate that the PC phase is orthorhombic, $a'=11.9$, $b'=16.4$ ($b'=3/2b$, where b stands for the lattice

constant at room temperature), $c'=7.0$ Å at 50 °C. The lattice constant exhibits no serious change up to 70 °C.

These results contradict the f.c.c. structure with the lattice constant 9.99 Å concluded by Daniel *et al.*,[3] since the observed reflections cannot be interpreted by the f.c.c. structure. The X-ray powder pattern at 50 °C exhibits two characteristic reflections with very strong intensity. Although these reflections seem to correspond to 111 and 200 in f.c.c. lattice, they consist of five overlapped reflections, *i.e.*, 111, 210, 030, 121, and 220 in the orthorhombic lattice. The results indicate that the PC phase of formylferrocene is explained not by f.c.c. but by an orthorhombic structure, although there are few reports suggesting any orthorhombic PC phase.

Phase Transition Model. The PC phase yeilds only a few diffracted X-ray reflections at low Bragg angles, as a consequence of the very high Debye-Waller factors owing to orientationally disordered molecules, but a detailed comparison of the structural data of the crystal phase with those of the PC phase permit a hypothetical structure for the PC phase.

A structural model of the PC phase may be proposed based on the structure determined at room temperature having six molecules in a unit-cell as shown in Fig. 3. The iron atoms lie in the mirror planes at $Z'=0$ and 1/2 as illustrated with open and solid circles, respectively. There exist four crystallographically independent molecules, I, II, III, and IV, in the unit cell. Furthermore, molecules III and IV are located in the mirror planes both at $y'=1/2$ and there is a two fold axis along a′. Although the space group could not be unequivocally determined, the PC phase exhibits an increase in symmetry compared to the crystal phase.

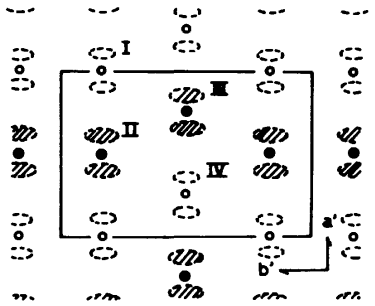

Fig. 3. A proposed structure of the PC phase projected along c' axis. Open circles refer to iron atoms in each molecule lying on the mirror plane at $z=0$. Solid circles refer to iron atoms in each molecule lying on the mirror plane at $z=1/2$.

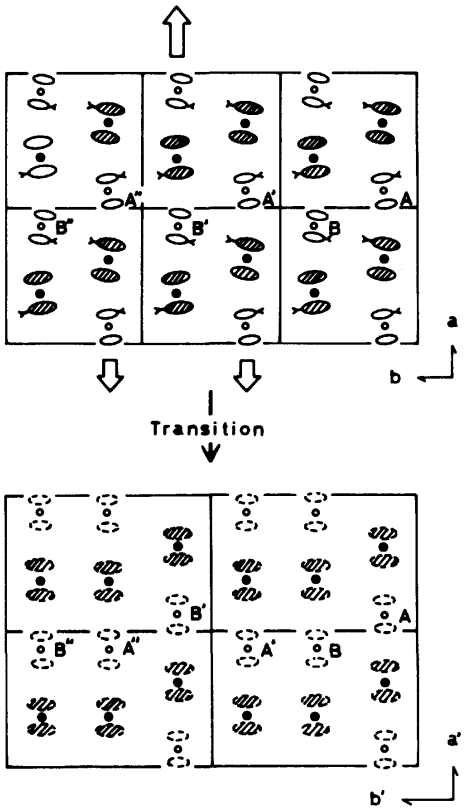

Fig. 4. The upper part shows schematically the crystal structure at room temperature and the lower part the proposed PC phase structure (a triad structure).

The structure proposed for the PC phase dose not give rise to any essential deviations of molecular positions from the crystal structure in the crystal state at room temperature.

The projections of the structures of modifications viewed along the c axis of the crystal phase and the c' axis of the PC phase are given in the upper and lower parts of Fig. 4, respectively. Bragg reflections observed in the PC phase have little contribution from carbon and oxygen atoms, because of the large Debye-Waller factors ascribed to the large thermal motion of cyclopentadienyl rings and the formyl groups which make their scattering factors much

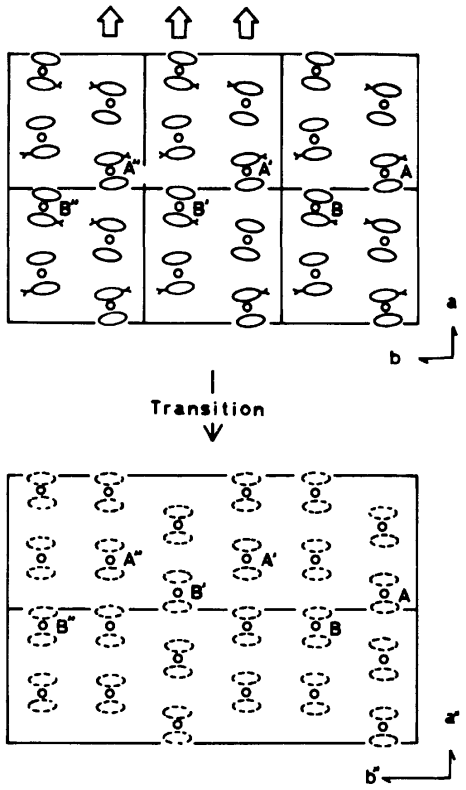

Fig. 5. The upper part shows schematically the crystal structure at room temperature and the lower part the proposed PC phase structure (a hexa-periodical structure).

weaker compared with that of iron atoms.

The 030 reflections with significant intensities indicate a triad structure for the PC phase. The lattice constant of the b' axis in the PC phase *vs.* that of b axis in the crystal phase gives a ratio of 3:2. The structural change which accounts for the different lattice suggests a cooperative slide of the layer consisting of molecules on the a and c planes along the a axis. As shown in Fig. 4, in the crystal phase, the molecules A, A', and A'' are equivalent in each cell separated by translating molecules to the nearest molecular position along the b axis. In the PC phase, the molecule B' will probably be equivalent with the molecule A because of the reason described above. The molecules A, A', A'', B, B', and B'' in the crystal phase correspond to those in the PC phase, respectively. There is an indication that the iron atoms cooperatively slide along the a axis at the phase transition point. The schematic features of the phase transition are indicated by downward and upward arrows in Fig. 4, although the model described above seems to overestimate the sliding motion up and down along the a axis.

An alternative model is shown in Fig. 5, where the PC phase is considered to have a hexa-periodical structure. The 030 reflections with significant intensities are regarded as the 060 reflections. As shown in Fig. 5, in the PC phase the molecule A can be described as equivalent to the molecule A in the adjacent unit-cell repeatedly appearing along the b' axis. This model requires that all the molecules slide upward along the a axis as

shown by the arrows in Fig. 5. In this case, the positional deviation from the original molecular position in the crystal phase is also considered to occur in the direction of the c axis, causing the change of molecular positions undetectable by X-ray analysis.

Although it remains undetermined whether a triad or a hexa-periodical structure is to be prefered for the PC phase, it is concluded that formylferrocene acquires a considerable degree of translational freedom in the direction of the a axis above the transition point.

When the plastic crystalline molecules are almost spherical, the entropy of melting is expected to be close to the value of $3R/2$ which is expected for molecules possessing freedom in three dimensional translation based on the classic theory. Because each molecule can rotate without significant translational motion of the centers of gravity in the crystal phase, the molecule may have as much rotational entropy in the plastic crystal as in the liquid phase. On the other hand, formylferrocene with the first-order transition has an entropy of melting of 1.39 entropy units which is less than $3R/2$. Molecules that have anisotropic structures may need translation of the center of gravity, such as the translational motion to the adjacent position, so that they can start rotating and a kind of cooperative motion, making the transition first order at the transition point from crystal to PC phase. Since a part of the translational entropy has already been consumed below the melting point, the entropy of melting is interpreted to be less than $3R/2$.

There exists no significant change of the lattice constant between 50 °C and room temperature, except that the b axis in the PC phase *vs.* the b′ axis in the crystal phase is in the ratio of 3:2, and the PC phase remains orthorhombic. This is one of strong pieces of evidence supporting the anisotropic molecular rotation in the PC phase. The a axis in the PC phase lengthens by *ca.* 13%, while the c and b axes become shortened by *ca.* 8 and 3% of each axis in the crystal phase at room temperature. It has generally been known that the lattice constant in the PC phase is larger than that in the crystal phase. The present data, which indicate an anisotropic expansion, also suggest an anisotropic orientation such as a partial rotation around the molecular axis. The results of the crystal structure in the crystal phase, involving occupancy of two alternative ring orientations in the ratio of 0.85:0.15 provide us with additional evidence supporting rotational motion around the molecular axis. The orientational disorder in the PC phase may have the effect of deteriorating a weak intermolecular bonding network found along the b and c axes in the crystal phase at room temperature. This model provides a possible explanation for the contraction of the b and c axes, although further investigations should be carried out for more detailed discussions.

Mössbauer Spectra. The values of the isomer shift and quadrupole splitting are 0.43 and 2.23 mm s^{-1} at room temperature, respectively, and the electronic state of the iron atom is found to be divalent with a low-spin state. The characteristically large quadrupole splitting is attributed to the large electric field gradient: that is, a larger population of electrons in the x, y directions than in the z direction for iron atoms.

In the Mössbauer spectra there exists no serious difference between the crystal and the plastic crystal phase, as shown in Fig. 6. If there is any fluctuation of the electric field gradient owing the orientational disorder between x, y, and z axes, one can expect a change in the spectral line shape. In the case of acetylferrocene, an orientational phase transition was observed at a temperature a few degrees below the melting point in X-ray diffraction. The temperature dependence of the recoil-free fraction in the Mössbauer spectra of acetylferrocene was ascribed to the quadrupole relaxation effect caused by the orientational disorder.[5] In the PC phase of formylferrocene, the unchanged line-width indicates either that there may be little orientational disorder around x or y axes of the molecule or that the quadrupole relaxation time may be very long.

Mössbauer spectra cannot be detected above 85 °C

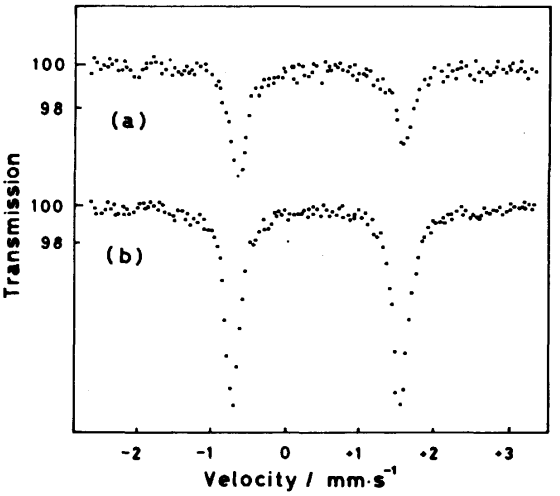

Fig. 6. (a) Mössbauer spectrum of the PC phase at 75 °C, which indicates an asymmetric quadrupole split line. (b) Mössbauer spectrum of the crystal phase at room temperature.

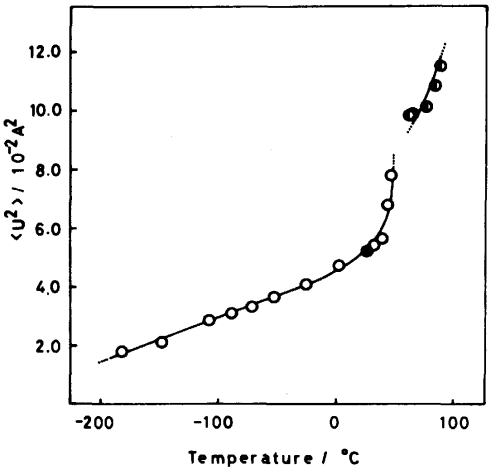

Fig. 7. The temperature dependence of the mean-square amplitude. The solid circle shows the value estimated from the thermal factor based on the X-ray study.

because of a rapid decrease of the recoil-free fraction in the higher temperature phase. The areal intensity of the Mössbauer spectrum abruptly decreases at the transition point, as shown in Fig. 7, and is related to the mean-square amplitude of Mössbauer atoms $<U^2>$ as follows:

$$A \propto f = \exp\left[-\frac{4\pi^2}{\lambda_\gamma^2}\langle U^2\rangle\right],$$

where λ_γ is the wavelength of the Mössbauer γ-ray and f is the recoil-free fraction. In the high-temperature approximation, $<U^2>$ can be estimated from the areal intensity. The solid circle in Fig. 7 is the value of the isotropic mean-square amplitude estimated from the thermal factor determined by the X-ray analysis for the crystal phase at room temperature, which agrees with the value obtained by the Mössbauer spectrum.

The mean-square amplitude shows a linear temperature dependence in the temperature range from about -200 °C to 0 °C, indicating an harmonic lattice vibration, but a significant deviation is found near the transition temperature, *e.g.*, an abruptly increased value, 0.07 $Å^{-2}$, is given before the transition. This indicates a substantial modification in the lattice characteristics of the solid. Although a thin sample, 32.8 mg cm^{-2}, shows no detectable spectra after the transition, because of the decreasing spectral intensity, definite spectra are successfully obtained with a thick sample, 97.5 mg cm^{-2}. The percent effects of the spectrum cannot precisely be normalized with those obtained for the thin sample because of a saturation effect. Therefore, the mean-square amplitude in the PC phase shown in Fig. 7 may be underestimated.

The PC phase of formylferrocene is characterized by the abnormally large translation similar to that expected in the liquid phase. The ratio, δ, between the mean square-root amplitude and the mean intermolecular distance has been used as an estimation of lattice vibrations in metallic solids and crystals of metal halides.[6] The value of δ is estimated at approximately 5% for formylferrocene at temperatures from 50 °C to 85 °C below the melting point, 123.5 °C, while other ferrocene derivatives, mono- and diacetylferrocene and ferrocenemono- and dicarboxylic acid, reveal the values of 2 to 3% even near the melting points. The anomalous value of δ for formylferrocene in the PC phase below the melting point suggests an unusual lattice vibration in the crystal phase. There may exist an anisotropic translation of molecules in the PC phase as was proposed for the transition in the previous section.

The authors wish to thank Prof. Yoshihiko Saito for his helpful discussions concerning the crystallographic aspects of this work.

Nonisothermal Kinetics of Crystal Growth from Preexisting Nuclei

Takeo Ozawa
Electrotechnical Laboratory, Sakura-mura, Niihari-gun, Ibaraki 305
(Received June 22, 1983)

Fundamental kinetic equations for nonisothermal crystal growth from preexisting nuclei are derived, by introducing a concept of reduced time. A method of kinetic analysis of thermoanalytical data of these processes is proposed, and all kinetic parameters can be estimated by the method, so that the process proceeding under various temperature changes can also be predicted.

It is well known that crystalline nuclei form first in supercooled liquids and amorphous solids, and then they grow to crystallites. Some solid reactions also proceed in a similar way to this nucleation-and-growth process. When they occur isothermally, these processes follow Avrami's equation;

$$-\ln(1-C) = Zt^n, \quad (1)$$

where C, Z, t, and n are respectively the conversion, a constant, the time, and an integer dependent on the mechanism of the process.[1-3] Evans[4] derived this equation in an ingenious way, in which the nuclei are compared to rain-drops falling down on a pond and the fronts of the crystal growth are compared to the traversing wave fronts caused by the rain drops. He calculated expectancy of the number of the wave fronts passing over a particular point, and the unconverted fraction can be calculated by using the expectancy thus calculated and Poisson's distribution.

In 1971 the present author set forth theoretical considerations of nonisothermal kinetics of the processes by extending Evans' way to nonisothermal conditions. A method for kinetic analysis of thermoanalytical data of the processes proceeding at a linear rate of heating or cooling was also derived, and the method was applied to crystallization of poly(ethylene terephthalate) observed at linear cooling rates by differential scanning calorimetry (DSC).[5]

Recently various amorphous materials, such as amorphous magnetic materials and amorphous silicon for solar photovoltaic cells, are under extensive research and development, and to evaluate their thermal stability, crystallization behaviors of these materials are investigated by differential thermal analysis and DSC. To estimate the kinetic parameters for predicting the crystallization behavior is also important in research of latent heat thermal energy storage materials, especially of the materials containing nucleating agent. The kinetic analysis is also useful for inorganic glasses. For analyzing thermoanalytical data of crystallization of inorganic glasses and amorphous materials, mainly Kissinger plot[6] proposed for usual chemical reactions has been applied to the data. Therefore, it is erroneous to apply the plot to the crystallization processes for estimating the activation energy, as was already pointed out by Matusita and Sakka,[7] though the plot is rigorously applicable to first order reactions and approximately applicable to reactions of the other orders.[8]

Matusita and Sakka[7] derived a theory and an analytical method of the processes, in which the random nucleation occurs in lower temperature range and prior to the growth, which proceeds separately after the nucleation. They applied their method to crystallization of inorganic oxide glasses. However, they derived the theory roughly, neglecting the rigorous theoretical derivations of nonisothermal relations for crystallization[5] and chemical reactions,[8] so that "modified Ozawa plot" proposed by them should be corrected by rigorous theoretical considerations. To derive rigorous nonisothermal equations, isothermal equations for each unit process should be expanded separately to nonisothermal equations, because the expansion of isothermal kinetic equations as a whole may lead to erronous results.[5]

Moreover, their method does not have any means to check the applicability of the method in itself. In other words, there is no means to confirm certain applicability of the method by observing consistency between the observed process and the model on which the theory and method are based. Therefore, we can not deny possibility that the method may be applied outside of its applicability. A method to estimate the kinetic parameter, n, is also not included in their method, so that n may be determined inaccurately. By the method, the activation energy can only be estimated, and the other kinetic parameters can not be obtained. Therefore, the crystallization behavior of the materials under various conditions can not be predicted for assessing thermal stability of the materials, though Matusita and Sakka clearly and exactly criticized the arbitrary and unsupported application of the Kissinger plot.

The present author's theory and the method for kinetic analysis of the thermoanalytical data cover more general cases, in which the random nucleation and the growth occur either concurrently or separately.[5] However, the applicability of these theory and method is limited in the cases of linear heating or cooling. For the cases, in which the nucleation occurs separately in the lower temperature range prior to the growth, a simple, but rigorous, theory and method can be derived, and they are applicable to more general cases of temperature change. One can overcome the above-mentioned drawbacks by the present author's method for kinetic analysis based on this rigorous theory, and one can also predict the process proceeding under various types of temperature changes using the kinetic parameters thus obtained. In this paper, the theory and the method are reported.

Models

There are two models for the case of crystal growth

from preexisting nuclei with negligible concurrent random nucleation. The first model is the crystal growth from impurity or nucleating agent, as is the case for latent heat thermal energy storage materials containing nucleating agent, and the number of the nuclei is independent on the thermal history of the materials. The second case is that the temperature range for random nucleation is much lower than that for the crystal growth, and the two temperature ranges are separated clearly, so that the number of the nuclei existing in the beginning of the growth is constant during the growth but dependent on the thermal history in the nucleation temperature range. For the crystal growth there are three cases, *i.e.*, one-dimensional growth, two-dimensional growth and three-dimensional growth.

Method for Deriving the Kinetic Equation

As mentioned before, the excellent and elegant way of Evans[4] is adopted and extended in this paper. First, let us consider the case in which many stones fall on the pond at the same time t_1. The stones are compared to the nuclei, and the wave fronts caused by the stones are compared to the front of the crystal growth. The expectancy, E, of the number of the wave fronts passing over a particular point until the time t_2 is equal to the number of the stones falling in a circle, the radius of which is the distance the wave fronts traversed from t_1 to t_2. It is given as follows:

$$E = \pi NR^2, \tag{2}$$

where N and R are the number of stones falling in a unit area and the distance which the wave fronts traversed from t_1 to t_2, respectively, and R is given below.

$$R = \int_{t_1}^{t_2} v\mathrm{d}t, \tag{3}$$

where v is the linear velocity of the wave fronts.

Because the fronts of crystal growth pass over a particular point only once in contrast with the wave fronts on the pond, the part of the pond, over which the wave fronts have not yet passed, has real physical meaning in crystallization, and it is the fraction of unconverted portion. The conversion of the crystallization can thus be expressed by applying Poisson's distribution as follows:

$$1 - C = \exp(-E), \tag{4}$$

or

$$-\ln(1-C) = E. \tag{5}$$

By applying this derivation to the nonisothermal conditions, we can obtain the fundamental equation for nonisothermal crystallization from preexisting nuclei.

Fundamental Equation for Nonisothermal Crystallization from Preexisting Nuclei

The number of preexisting nuclei per unit volume is dependent on the above-mentioned models. For the first model, the number of the nuclei, N, is a constant.

$$N = \text{constant} \tag{6}$$

On the other hand, N is given below for random nucleation for the second model as follows:

$$N = \int_0^{t_1} \nu(T)\mathrm{d}t, \tag{7}$$

where $\nu(T)$ is a nucleation rate per unit volume as a function of the temperature, T, and as is assumed in the model, the nucleation does not occur after the time t_1.

The expectancy, E, can be derived, taking into accounts of the dimension of the growth. For the one-dimensional growth,

$$E = dNR, \tag{8}$$

where d is the cross section of the needle-like crystallites. For the two-dimensional growth,

$$E = \pi dNR^2, \tag{9}$$

where d is the thickness of the disk-like crystallites. For the three-dimensional growth,

$$E = \frac{4\pi}{3} NR^3. \tag{10}$$

Taking account of the temperature dependence of the linear growth velocity, *i.e.*,

$$v(T) = v_0 f(T), \tag{11}$$

let us introduce a concept, reduced time, θ, namely[8,9]

$$\theta = \int f(T)\mathrm{d}t, \tag{12}$$

and

$$R = v_0\theta. \tag{13}$$

Thus, the fundamental equation is given as follows:

$$-\ln(1-C) = Z_0\theta^m, \tag{14}$$

where Z_0 equals to gNv_0^m and g and m are a constant and the number of the growth dimension, respectively. The constant, g, is equal to d, πd and $4\pi/3$ respectively for the one-dimensional growth, the two-dimensional growth and the three-dimensional growth. The integer, n, in Eq. 1 is equal to the number of growth dimension, m, for the isothermal crystallization from the preexisting nuclei without the concurrent random nucleation, while n is equal to $(m+1)$ for the isothermal crystallization with the concurrent random nucleation. The constant, Z, in Eq. 1 is equal to $gN\{v(T)\}^m$. We also get the next equation for the crystallization rate per unit reduced time,

$$\frac{\mathrm{d}C}{\mathrm{d}\theta} = mZ_0(1-C)\theta^{m-1}, \tag{15}$$

and the crystallization rate per unit real time is given below:

$$\frac{\mathrm{d}C}{\mathrm{d}t} = \frac{\mathrm{d}C}{\mathrm{d}\theta}\frac{\mathrm{d}\theta}{\mathrm{d}t} = mZ_1(1-C)\theta^{m-1}, \tag{16}$$

where Z_1 is $gNv_0^{m-1}v(T)$.

Equations for Linear Heating and Cooling

First, we will consider N for the second model. When the melt is cooled at a linear rate, ϕ_1, to the temperature

where the nucleation does not occur and heated again at a linear rate, ϕ_2, to the temperature at which the crystal growth begins, N is given according to Eq. 7 as follows:

$$N = \left\{\frac{1}{\phi_1}+\frac{1}{\phi_2}\right\}\int_{T_1}^{T_2} v(T)\mathrm{d}T, \tag{17}$$

where T_1 and T_2 are the minimum and maximum temperatures of the nucleation, and the integral in Eq. 17 is a constant. Expressing this constant to be N_0 we get

$$N = N_0\left\{\frac{1}{\phi_1}+\frac{1}{\phi_2}\right\}. \tag{18}$$

When the materials are, then, heated up at a linear heating rate, ϕ_3, in the temperature range of the crystal growth, R is given as follows:

$$R(T) = \frac{1}{\phi_3}\int_{T_3}^{T} v(T)\mathrm{d}T, \tag{19}$$

where T_3 is the minimum temperature for the crystal growth.

Combining these relations, we get the equation for the first model:

$$-\ln(1-C) = \frac{Z_0}{\phi_3{}^m}\{F(T)\}^m, \tag{20}$$

where

$$F(T) = \int_{T_3}^{T} f(T)\mathrm{d}T. \tag{21}$$

For the second model, we get

$$-\ln(1-C) = \frac{Z_0{}'}{\phi_3{}^m}\{F(T)\}^m\left\{\frac{1}{\phi_1}+\frac{1}{\phi_2}\right\}, \tag{22}$$

where Z_0' is $gN_0v_0{}^m$.

For the crstallization rate per unit real time, we get following two equations for the first and second models:

$$\frac{\mathrm{d}C}{\mathrm{d}t} = \frac{mZ_1}{\phi_3{}^{m-1}}(1-C)\{F(T)\}^{m-1}, \tag{23}$$

$$\frac{\mathrm{d}C}{\mathrm{d}t} = \frac{mZ_1{}'}{\phi_3{}^{m-1}}(1-C)\{F(T)\}^{m-1}\left\{\frac{1}{\phi_1}+\frac{1}{\phi_2}\right\}, \tag{24}$$

where Z_1' is $gN_0v_0{}^{m-1}v(T)$.

If the temperature dependence of the linear crystal growth rate follows Arrhenius law, namely

$$f(T) = \exp\left(-\frac{\Delta E}{\mathbf{R}T}\right), \tag{25}$$

where ΔE and $\mathbf{R}$ are the activation energy and the gas constant, respectively, we obtain the next equation for the reduced time:

$$\theta = \frac{\Delta E}{\phi_3\mathbf{R}}\mathrm{p}\left(\frac{\Delta E}{\mathbf{R}T}\right), \tag{26}$$

where p is the p function proposed by Doyle[10] and $v(T)$ is assumed to be negligibly small at T_3. The p function is given as follows:

$$\mathrm{p}(y) = \frac{\exp(-y)}{y} - \mathrm{Ei}(-y), \tag{27}$$

where Ei is the exponential integral function. Therefore,

$$E(T) = \frac{\Delta E}{\mathbf{R}}\mathrm{p}\left(\frac{\Delta E}{\mathbf{R}T}\right). \tag{28}$$

Thus, we get the fundamental equations for the first and second models:

$$-\ln(1-C) = \frac{Z_0\Delta E^m}{\phi_3{}^m\mathbf{R}^m}\left\{\mathrm{p}\left(\frac{\Delta E}{\mathbf{R}T}\right)\right\}^m, \tag{29}$$

$$-\ln(1-C) = \frac{Z_0{}'\Delta E^m}{\phi_3{}^m\mathbf{R}^m}\left\{\mathrm{p}\left(\frac{\Delta E}{\mathbf{R}T}\right)\right\}^m\left\{\frac{1}{\phi_1}+\frac{1}{\phi_2}\right\}, \tag{30}$$

and the crystallization rate is given as follows:

$$\frac{\mathrm{d}C}{\mathrm{d}t} = \frac{mZ_1\Delta E^{m-1}}{\phi_3{}^{m-1}\mathbf{R}^{m-1}}(1-C)\left\{\mathrm{p}\left(\frac{\Delta E}{\mathbf{R}T}\right)\right\}^{m-1}, \tag{31}$$

$$\frac{\mathrm{d}C}{\mathrm{d}t} = \frac{mZ_1{}'\Delta E^{m-1}}{\phi_3{}^{m-1}\mathbf{R}^{m-1}}(1-C)\left\{\mathrm{p}\left(\frac{\Delta E}{\mathbf{R}T}\right)\right\}^{m-1}\left\{\frac{1}{\phi_1}+\frac{1}{\phi_2}\right\}. \tag{32}$$

At the maximum rate of crystallization,

$$\frac{\mathrm{d}^2C}{\mathrm{d}t^2} = 0. \tag{33}$$

On the other hand, we have the next two relations;

$$\frac{\mathrm{d}C}{\mathrm{d}t} = \frac{\mathrm{d}C}{\mathrm{d}\theta}\frac{\mathrm{d}\theta}{\mathrm{d}t} = \exp\left(-\frac{\Delta E}{\mathbf{R}T}\right)\frac{\mathrm{d}C}{\mathrm{d}\theta}, \tag{34}$$

and

$$\frac{\mathrm{d}^2C}{\mathrm{d}t^2} = \exp\left(-\frac{2\Delta E}{\mathbf{R}T}\right)\frac{\mathrm{d}^2C}{\mathrm{d}\theta^2} + \frac{\phi_3\Delta E}{\mathbf{R}T^2}\exp\left(-\frac{\Delta E}{\mathbf{R}T}\right)\frac{\mathrm{d}C}{\mathrm{d}\theta}. \tag{35}$$

The above-mentioned p function can also be approximated as follows:

$$\mathrm{p}(y) \approx \frac{\exp(-y)}{y^2} \qquad (20\leqq y\leqq 50). \tag{36}$$

By applying this approximation and combining Eqs. 33 and 35, we get

$$\frac{\mathrm{d}C}{\mathrm{d}\theta} + \theta\frac{\mathrm{d}^2C}{\mathrm{d}\theta^2} = 0. \tag{37}$$

The same relation was also found previously for the usual chemical reactions.[8,9] By applying Eq. 5, the right hand side of Eq. 14 is found to be unity, so that the conversion at the maximum rate, C_m, is given as follows;

$$-\ln(1-C_m) = 1, \tag{38}$$

then

$$C_m = 1 - \frac{1}{\mathrm{e}}. \tag{39}$$

Namely, the conversion at the maximum rate is about 63.2%, which is equal to that for the first order reaction.[11]

For nonisothermal crystallization in cooling mode, we drive the same equations as Eqs. 14, 16, 20 and 23, in which the lower limits of the integrals of $R(T)$, $F(T)$ and θ are the melting temperature or its time.

Methods for Kinetic Analysis of Thermoanalytical Data

First of all, we should ascertain whether the process under measurement is the first model or the second one. It is useful for this purpose to observe the effect of the

thermal history in the nucleation temperature range, for instance by changing ϕ_1 and/or ϕ_2 in wide range. Then, the value of m can be determined by using Eqs. 20 and 22, namely for the first model,

$$\log(-\ln(1-C)) = \log[Z_0\{F(T)\}^m] - m\log\phi_3, \quad (40)$$

and for the second model cooled and heated at the same rate ($\phi_1=\phi_2=\phi_3$),

$$\log(-\ln(1-C)) = \log[2Z_0'\{F(T)\}^m] - (m+1)\log\phi_3. \quad (41)$$

When we observe the process at different rates of heating and cooling and plot $\log(-\ln(1-C))$ against $\log\phi_3$ at the same temperature, we get linear plots, and the slopes of the plots are equal to $-m$ or $-(m+1)$, because the first term in the right hand side of the above equations is constant at the same temperature. When we use the specimens of the second model obtained by quenching and observed the crystal growth at different heating rates ($\phi_1 \gg \phi_2=\phi_3$), the slopes of the plots are also equal to $-(m+1)$, because $1/\phi_1$ is negligibly small and

$$\log\{-\ln(1-C)\} = \log[Z_0\{F(T)\}^m] - (m+1)\log\phi_3. \quad (42)$$

From the intercept of these plots, we get the first terms in Eqs. 40, 41, and 42, and they are the temperature integral of Z or $gN_0\{v(T)\}^m$. These plots are essentially the same as those proposed for more general cases by the present author previously.[5] As pointed out previously, we can predict the crystallization behavior at linear rates by using the kinetic parameters thus obtained.

For the case that m equals to unity, *i.e.*, the one-dimensional growth, a simple relation can be applied to the data. From Eqs. 23 and 24, we get for the first model

$$\frac{dC}{dt} = Z(1-C), \quad (43)$$

where Z is $gNv(T)$.
and for the second model

$$\frac{dC}{dt} = Z'(1-C)\left\{\frac{1}{\phi_1}+\frac{1}{\phi_2}\right\}, \quad (44)$$

where Z' is $gN_0v(T)$. When both the conversion and the rate of conversion are obtained, we can directly estimate Z or Z' as a function of the temperature by using the above relation. The temperature dependence of the linear growth rate can also be obtained by comparing the rate of conversion observed at different heating rates at a given conversion, as is seen in Eqs. 23 and 24. However, the obtained values are somewhat complicated for the case that m is not equal to unity.

If the temperature dependence of the crystal growth rate follows the Arrhenius law, further kinetic analysis can be done by using the data obtained at different heating rates, because the p function can be approximated as follows, and this is much better approximation than Eq. 36;[10]

$$\log p(y) \approx 2.315 - 0.4567y \quad (20 \leqq y \leqq 60). \quad (45)$$

We get the next equations at a given conversion from Eqs. 29, 30, and 45; for the first model,

$$\log\phi_3 + 0.4567\frac{\Delta E}{RT} = \text{constant}, \quad (46)$$

and for the second model ($\phi_1=\phi_2=\phi_3$, or common ϕ_1 but different $\phi_2=\phi_3$),

$$\log\phi_3 + 0.4567\frac{m\Delta E}{(m+1)RT} = \text{constant}. \quad (47)$$

Thus, when we plot the logarithm of the heating rate against the reciprocal absolute temperature at a given conversion, we obtain linear plots and we can estimate the activation energy from the slope as is described in Eqs. 46 and 47. This relation is also applicable to the maximum rates, such as the peaks in DSC curves, because the conversions at the maximum rates are equal to each other, as is shown in Eq. 39. The above procedure to estimate the activation energy is similar to, but somewhat different in its coefficient from, so-called "modified Ozawa plot" proposed by Matusita and Sakka,[7] and it is essentially the same as the procedure for usual chemical reactions.[8]

By applying rougher approximation, *i.e.*, Eq. 36, we get the next equations at a given conversion and also at the maximum rate; for the first model

$$\frac{\Delta E^m}{\phi_3{}^m R^m}\left\{\exp\left(-\frac{\Delta E}{RT}\right)\Big/\frac{\Delta E^2}{R^2T^2}\right\}^m = \text{constant}, \quad (48)$$

and for the second model

$$\frac{\Delta E^m}{\phi_3{}^{m+1}R^m}\left\{\exp\left(-\frac{\Delta E}{RT}\right)\Big/\frac{\Delta E^2}{R^2T^2}\right\}^m = \text{constant}. \quad (49)$$

Therefore, for the first model

$$\ln\frac{\phi_2}{T^2} + \frac{\Delta E}{RT} = \text{constant}, \quad (50)$$

and for the second model

$$\ln\frac{\phi_3{}^{m+1}}{T^{2m}} + \frac{\Delta E}{RT} = \text{constant}. \quad (51)$$

The activation energy can also be estimated by the similar plots of $\ln\phi_3/T^2$ or $\ln\phi_3{}^{m+1}/T^{2m}$ against the reciprocal absolute temperature. Kissinger plot mentioned in the introduction is the same plot as Eq. 50 applied to the maximum rate, but modification such as shown in Eq. 51 should be made. Moreover, these plots are applicable to a given conversion. Matusita and Sakka[7] derived an equation similar to, but different in its exponent from, Eq. 51. These plots are not preferable to the plots by Eqs. 46 and 47, because they are based on the rough approximation of Eq. 36 and the terms are complicated, so that much error may be involved in actual applications. Recently, it was pointed out from experimental evaluation for usual chemical reactions that Kissinger plot has no practical advantages over Ozawa plot and that the conversion at the peak of heat-flux DSC curve is not practically a constant due to instrumental effect and heat transfer within the sample, while uniform temperature within the sample is implicitly assumed in all theoretical considerations.[12]

When the linear plots obtained at different conversions are not parallel to each other and the activation energies estimated vary along the conversion, the observed process is inconsistent with

the model from which the theory and the method are derived, and we should abandon the kinetic analysis. When we get the constant activation energy, we can calculate the reduced time at different conversions by using the activation energy and Eq. 26, so that we can draw the curve of the conversion versus the reduced time, which is the experimental master curve. Because the reduced time is proportional to the real time in isothermal cases and also equal to the real time at infinite temperature, the methods for analyzing isothermal data can be applied to this experimental master curve. For example, when we plot $\log(-\ln(1-C))$ against $\log\theta$, we get a linear line with the slope of m and, when we plot $-\ln(1-C)$ against θ^m, we get also a linear line. In both plots for the second model, both ϕ_1 and ϕ_2 should be constant and common, otherwise they should be reduced taking into account of their effect in Eqs. 14 and 30.

The linearity of these master lines can be used to ascertain the consistency between the observed process and the model on which the theory and the method are based. We can also calculate the reduced time for various temperature changes by using the activation energy, and, thus, we can predict the crystallization behavior for the various types of temperature changes.

Concluding Remarks

The nonisothermal kinetic models in this paper are those of the special cases dealt with in the previous paper.[5] However, because the random nucleation does not occur concurrently with the crystal growth in the present cases, the more generally applicable equations are derived here than in the previous paper. The relations described previously for the general model[5] are limited for the case of the linear cooling and heating. On the other hand, the relations applicable to various types of temperature changes are presented in the present paper.

The concept of the reduced time can be introduced in the more complicated process than the usual chemical reactions[8] and diffusions,[9] and it is also clearly shown that the concept of the reduced time is very useful and effective in nonisothermal kinetics. As is seen in Eqs. 14 and 15, the real time, t, in the isothermal kinetic equations can be replaced by the generalized time, *i.e.*, the reduced time, and this generalized nonisothermal kinetic equations are applicable both to nonisothermal cases and to isothermal cases, where θ is equal to $tf(T)$ and Z is replaced by Z_0.

The conversion at the maximum rate for the linearly heated process in which Arrhenius law holds is revealed to be constant even in the complicated processes such as the crystal growth, and it is interesting to note that this constancy is also found in the usual chemical reactions and diffusion in which Arrhenius law holds,[11] so that it seems to be generally true that the conversion at the maximum rate for the linear heating is constant for the process in which only a single unit process proceeds and Arrhenius law holds for the rate constant.

The Structure of Liquid Alcohols by Neutron Diffraction. I. Molecular Structure of Methyl Alcohol

Yukio TANAKA,† Norio OHTOMO,† and Kiyoshi ARAKAWA*
Research Institute of Applied Electricity, Hokkaido University, Sapporo 060
†Faculty of Engineering, Hokkaido University, Sapporo 060
(Received June 25, 1983)

The structure factor $S_m(Q)$ for liquid methyl alcohol (CD_3OD) at room temperature was obtained by means of the LINAC-TOF neutron diffraction method. An analysis of the diffraction data was carried out, and the molecular structure of CD_3OD in liquid phase was determined as: the O-D, C-O, and C-D bond lengths are 0.990±0.010, 1.435±0.005, and 1.085±0.005 Å, respectively. The O-D and C-D lengths were found to be longer than those values determined in gaseous phase.

The usefulness of the LINAC-TOF neutron diffraction method for the structure analysis of liquid systems has recently become progressively evident. Its merit in comparison with usual X-ray analysis is especially clear for the structure analysis of liquids composed of molecules including hydrogen atoms. In the preceding papers,[1,2] the structure of liquid water (D_2O) was determined to contain hydrogen-bonded tetrahedral pentamers as a main constituent. Here we extend our study of liquid structures to the next example of hydrogen-bonded liquids, *i.e.*, liquid methyl alcohol. Then, the present study aims first to determine the structure of methyl alcohol molecules in liquid phase.

By using microwave[3-5] and electron diffraction techniques,[6] several authors have performed studies of gaseous methyl alcohol and its molecular geometry in gaseous phase has been elucidated. However, studies of the molecular structure in its liquid phase are very few. From a great deal of spectroscopic data, the hydroxyl groups in liquid methyl alcohol are known to be concerned with hydrogen bonding.[7,8] The molecules are supposed to make up an aggregate by hydrogen bonding in the liquid. It is expected, for example, that, as well as in the case of water, the O–H bond length of methyl alcohol molecules is strongly influenced by the existence of hydrogen bonding in the liquid phase. Thus, the determination of the molecular geometry of liquid methyl alcohol is required as the starting point of a detailed investigation of its properties, and also the variation in the molecular structure from gaseous to liquid phases is very interesting.

Recently, Montague *et al.*[9] performed a neutron diffraction study of liquid CD_3OD by means of the reactor conventional method. However, as described in later sections, their results are considered to contain important implausible aspects, showing the restriction in the conventional method. Then, we have carried out a LINAC-TOF neutron diffraction measurement on methyl alcohol and have made an analysis of the data to determine its molecular structure.

Experimental

The experiment was performed by means of the TOF neutron diffraction method, using pulsed neutrons produced by electron LINAC at Hokkaido University. As the sample, deuterated methyl alcohol CD_3OD (purity of deuteration 99.5%, Commisariat à l'Energie Atomique (CEA), France) was used. Measurements were carried out at room temperature at five different scattering angles: 2θ=32.0°, 42.0°, 66.5°, and 90.5° at 10.0±0.5 °C, and, 2θ=140.7° at 16.5±0.5°C.

Corrections for background, absorption, multiple scattering, inelastic scattering, and incoherent scattering were performed in the usual manner.[2,10,11] Absolute normalization of data was carried out by using the scattering data from a polycrystalline vanadium rod as an isotropic and incoherent scatterer. The structure factors $S_m(Q)$ thus determined after all corrections and calibrations of Q-scale are shown in Fig. 1 for five scattering angles. The coincidence of the values from different angles in each overlapping region of Q is quite well as seen in Fig. 1, and, combining these data sets, we obtained the final $S_m(Q)$ values of wide Q range as given in Table 1. The statistical error for values of the $S_m(Q)$ is smaller than 1.0%, and the resolving power $\Delta Q/Q$ less than a few % in the whole range of Q.[11]

Procedures of Analysis

The structure factor $S_m(Q)$ for molecular liquids consists of an intramolecular structure factor $f_1(Q)$ and

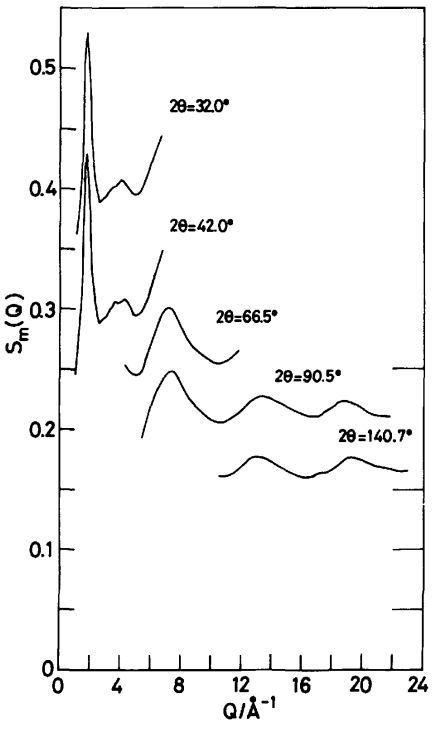

Fig. 1. Observed neutron structure factors $S_m(Q)$ for deuterated methyl alcohol at various scattering angles.

intermolecular one. The $S_m(Q)$ for a higher Q region is characteristic of the intramolecular structure ($S_m(Q) \rightarrow f_1(Q)$ for high Q). The $f_1(Q)$ is written as

$$f_1(Q) = (\sum_i b_i)^{-2} \sum_{ij} b_i b_j j_0(Q r_{ij}) \exp(-\gamma_{ij} Q^2), \quad (1)$$

where b_i is the coherent scattering length of i-th nucleus in the molecule, r_{ij} the distance between i-th and j-th nucleus, $2\gamma_{ij}$ the mean square variation to the distance r_{ij} and $j_0(x)=\sin x/x$ a zeroth order spherical Bessel function. $\sum$ is over all the nuclei in the molecule. With respect to γ_{ij}, we assume that $\gamma_{ij}=1/2D_{ij}^2 r_{ij}$, where D_{ij} is estimated to be 0.06 Å$^{1/2}$ per Å for all distances in the same molecule.[1,2,6,12]

In the observed $S_m(Q)$ curves marked features are found as follows: the height of the first peak at *ca.* Q=1.8 Å^{-1}, a doublet of the hump at *ca.* 4 Å^{-1}, a shape of the second peak at *ca.* 7 Å^{-1}, and the peaks at *ca.* 13 and 19 Å^{-1}. With reference to the higher Q region ($Q \gtrsim 6$ Å^{-1} in the present study), being compared with the case of water,[1,2] the intensity of the second peak ($Q \simeq 7$ Å^{-1}) and the bent of the curve at *ca.* Q=8 Å^{-1} are distinctive. Then, for determining the intramolecular structure, reproduction of those features of $Q \gtrsim 6$ Å^{-1} is required in our calculation of $f_1(Q)$.

The structure of methyl alcohol molecule CD_3OD is shown schematically in Fig. 2. With respect to the intramolecular parameters, it is assumed that deute-

$$\varepsilon = (\sum_i^N \{S_m(Q)_{obsd} - f_1(Q)_{calcd}\}^2)^{1/2} / \sum_i^N S_m(Q)_{obsd},$$

where N is the number of data points in the fitting range of Q, 6—18 Å^{-1}. Variation of ε with distances r_{OD} and r_{CD} is shown in the insets.

rium atoms in the methyl group rotate about the methyl axis (defined as C-X axis in Fig. 2), and that the three C-D bonds in the methyl group are equivalent as well as the three DCD angles. Then, we characterize the molecular structure by seven structural parameters, *i.e.* the bond lengths r_{OD}, r_{CO}, r_{CD}, the DCD angle in the methyl group, the hydroxyl angle COD, the tilt angle and the methyl rotation angle τ (Fig. 2). In order to determine the molecular parameters, $f_1(Q)$ were calculated for more than 12000 models by using Eq. 1 and the curves obtained were compared with the observed $S_m(Q)$ data in the higher Q region ($Q \gtrsim 6$ Å^{-1}). The magnitudes of the parameters were varied in reference to the values given in Table 2.

Results and Discussion

Determination of Intramolecular Parameters for Liquid Methyl Alcohol. By making the calculated $f_1(Q)$ curves fit with the observed $S_m(Q)$ data, we have determined the best structural model for liquid methyl alcohol as follows: $r_{OD}=0.990\pm0.010$ Å, $r_{CO}=1.435\pm0.005$ Å, $r_{CD}=1.085\pm0.005$ Å, DCD=109.5±0.5°, COD=112.0±3.0° and tilt=0.0±3.0°.

Concerning the best structural model, slight arbitrariness still remains in its detailed structure. The methyl rotation angle τ was not decided uniquely in the present study, and the following two models remains undiscriminated as the best ones (Fig. 3): the one is that with $\tau=15.0\pm3.0°$ and the other that with free rotation of methyl group (Table 3). Taking account of the symmetry of the arrangement of deuterium atoms in the methyl group, the two models are regarded as effectively identical with each other. As seen in Table 3, the molecular parameters of the two best models are essentially in good agreement on the whole, though slight discrepancy is observed for the COD angle (and, of course, for the methyl rotation angle τ). The best fit $f_1(Q)$ curves with the experimental data are shown in Fig. 3, including the curve calculated by using Lees and Baker's parameters for gaseous molecules[3] for comparison. Variations of ε with the C-D and O-D bond lengths for the model of fixed methyl group ($\tau=15.0°$) are also shown in Fig. 3.

The best structural parameters determined are tabulated in Table 4, together with those by Montague *et al.*[9] and by Magini *et al.*,[12] where the values also determined in gaseous and crystalline states are shown.

Variation of the Structure of Molecules in Liquid State from that in Gaseous State. The $f_1(Q)$ curve calculated by using the molecular parameters given by Lees and Baker[3] (microwave spectroscopy) is shown in

Fig. 3, together with the present $S_m(Q)$ data in liquid phase. In the range of $Q \gtrsim 6$ Å^{-1}, a significant disagreement is seen between the present $S_m(Q)$ curve and Lees and Baker's one. This is ascribed to the variation of the intramolecular structure of molecules within liquids in comparison with that in gaseous state, as seen in Table 4.

The most remarkable change of intramolecular parameters from liquid to gaseous state is that in the O–D distance. As seen in Table 4, the O–D distance determined in the present study is 0.990±0.010 Å, and a stretching of the bond length compared with that in gaseous phase, 0.945—0.960 Å,[3-6] is obvious. The magnitude of this stretch is found to be similar to the case in water: from 0.96 Å in gaseous state to 0.98 Å in liquid state.[1,2] With respect to the nearest intermolecular O···O distance, Magini *et al.*[12] reported recently the value of about 2.8 Å from the result by their X-ray diffraction experiment on liquid methyl alcohol. The value is nearly identical with the nearest O···O distance in liquid water.[1,2] These all results support an idea that, concerning the distances, r_{OD} and $r_{O\cdots O}$, the situations in hydrogen bonded state are quite similar between the two liquids, methyl alcohol and water.

With respect to other molecular parameters (C–O distance, C–D distance, DCD angle and tilt angle), the following features are pointed out. The present value of C–O distance is 1.435±0.005 Å. This is in good agreement with the value given by Magini *et al.* (1.437 Å) in liquid phase,[12] and is longer than that in gaseous systems, 1.425—1.428 Å.[3-6] Concerning the methyl group, a slight shortening of the C–D distance and a slight increase of the DCD angles are observed in comparison with those in gaseous state. As described in the preceding item, it is found that the tilt angle becomes zero in liquid state. On the other hand, the angle is observed to be 3°09′—3°30′ in gaseous phase.[3-5]

In a recent neutron diffraction study on liquid CD_3OD by means of the reactor conventional method, Montague *et al.*[9] have reported a result on the structure analysis of the liquid, and the molecular parameters determined are listed up together in Table 4 for comparison. Noticeable discrepancies between the present results and theirs are found, especially with respect to the O–D distance. The O–D distance assigned by Montague *et al.*, 1.03 Å, is fairly longer than that for heavy water, 0.98 Å, and still longer than that in heavy ice-I (1.01 Å).[13] This is clearly unreasonable.

Concluding Remarks

A neutron diffraction study of liquid methyl alcohol (CD_3OD) by means of the LINAC-TOF method was performed, and the geometry of molecules within the liquids was determined. The present study has made it clear that the LINAC-TOF neutron diffraction method is useful in determining the molecular structure in liquid state. And then, due to a series of recent successful results on D_2O,[1,2] CD_3COCl,[10] and CD_3OD *etc.* by our group, the present LINAC-TOF neutron diffraction method may be said to have been established as a means for the structure analysis of molecular fluids.

Effect of Temperature on the Polarographic Catalytic Current Produced by Proteins in the Presence of Cobalt Salts

Kenji KANO,† Ichiro TOKIMITSU,†† Tokuji IKEDA, and Mitsugi SENDA*

(Received July 5, 1983)

The effect of temperature on the polarographic catalytic hydrogen evolution current (Brdička current) produced by ribonuclease-A in an ammoniacal buffer containing cobalt salt has been studied using the theoretical equation of Brdička current. With increasing temperature, the Brdička current at −1.3 V increased between 10 and 30 °C then fell off above 30 °C, whereas the currents at −1.4 and −1.5 V decreased continuously. Analysis showed that the initial increase of the Brdička current at −1.3 V was only apparent and that the Brdička current constant, k_B, which represents the catalytic activity of the protein, always decreased with increasing temperature in the potential range of −1.3 to −1.5 V. Further analysis has revealed that the intrinsic catalytic activity of the protein–cobalt(0) complex, which is transiently formed on the electrode surface and which catalyzes the hydrogen evolution, increases with increasing temperature whereas the life time of the complex decreases and the latter decrease cancels the former increase, resulting in the decrease of the k_B value with increasing temperature.

The Brdička current, or polarographic catalytic hydrogen evolution current produced by proteins containing so-called Brdička-active groups, such as SH- and/or SS-groups[1] and others,[2,3] in the presence of cobalt salt, has found a variety of applications in structure analysis as well as trace analysis of proteins (see Ref. 4—6 for review). The effect of temperature on the Brdička current has been studied by many investigators,[5—11] but these studies have remained qualitative or at most semiquantitative. This is probably due to the lack of a suitable theoretical equation to predict the Brdička current in a quantitative way. In previous papers,[6,12] we have presented a theoretical equation for the Brdička current, in which it is expressed as a function of the surface concentration of protein, the bulk concentration of cobalt ion and two parameters representing the properties of the protein–cobalt(0) complex which catalyzes the hydrogen evolution. In this study, the effect of temperature on the Brdička current has been analyzed by the theoretical equation presented in the previous papers.

Experimental

Bovine pancreas ribonuclease-A (Type-A, Sigma Chemical Co., lot No. 58C-0116) was obtained commercially and used as received. All other chemicals were of reagent grade quality. The apparatus for the electrochemical measurements has been described in a previous paper.[12] Potentials were measured against a saturated calomel electrode (SCE). All measurements were made in a thermostat which was controlled within ±0.5 °C.

Results and Discussion

Figure 1 shows d.c. polarograms of ribonuclease-A (RNase) at 10, 25, and 40 °C in a base solution (0.1 mol dm^{-3} ammonia, 0.1 mol dm^{-3} ammonium chloride, and 0.1 mol dm^{-3} potassium chloride, pH 9.5 at 25 °C) containing 2×10^{-4} mol dm^{-3} hexaamine cobalt(III) chloride, Co(III). The Brdička current of RNase showed a typtical double-step wave with two maxima. With increasing temperature, the height of the first wave at −1.35 V (so-called Brdička first wave) increased, whereas that of the second wave at −1.55 V (so-called Brdička second wave) decreased, and the second maximum disappeared at increased temperature. The reduction waves of cobalt(II) to cobalt(0) shifted to less negative potential with increasing temperature both in the presence and in the absence of RNase. The limiting diffusion current of cobalt ion also increased with increasing temperature.

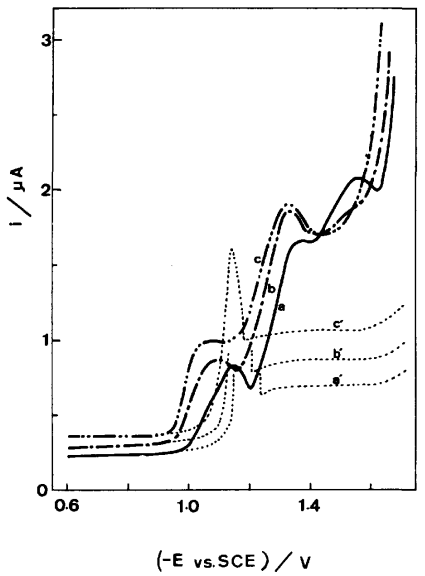

Fig. 1. D.c. polarograms of 4 μg cm^{-3} RNase at a) 10, b) 25, and c) 40 °C in the base solution containing 2×10^{-4} mol dm^{-3} Co(III). The broken lines represent d.c. polarograms in the absence of RNase at a') 10, b') 25, and c') 40 °C.

Many previous authors[7—11] have measured the maximum heights of the first and second waves of Brdička current to study the effect of temperature on the Brdička current. However, as the temperature and other experimental conditions change, the maxima are not always

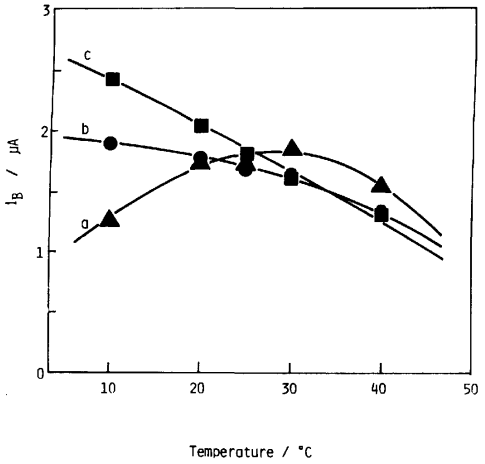

Fig. 2. Temperature dependence of the Brdička currents of 4 μg cm^{-3} RNase at a) −1.3, b) −1.4, and c) −1.5 V in the base solution containing 2×10^{-4} mol dm^{-3} Co(III).

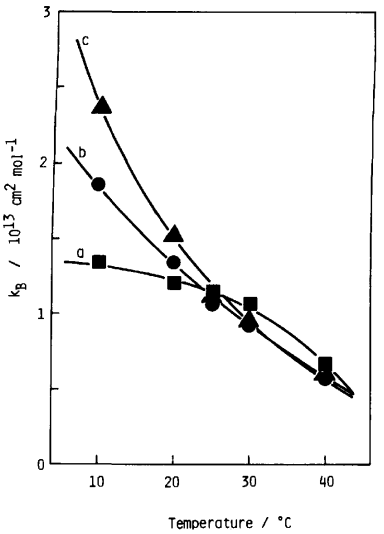

Fig. 3. Temperature dependence of the k_B values of RNase at a) −1.3, b) −1.4, and c) −1.5 V in the base solution.

well-defined and the potential of the maxima also shifts as shown in Fig. 1. Accordingly we have measured the heights of the Brdička current at three fixed potentials, *i.e.* −1.3, −1.4, and −1.5 V, as a function of temperature. In measuring the current with a dropping mercury elecrode (DME), the current intensity at the maximum growth of each mercury drop was taken and the net Brdička current, i_B, was obtained by correcting for the diffusion current of cobalt ion, i_{Co}. Figure 2 shows i_B at −1.3, −1.4, and −1.5 V plotted against temperature. With increasing temperature, i_B at −1.3 V increased initially from 10 °C to 30 °C, then decreased, whereas at −1.4 and −1.5 V, i_B decreased continuously.

It has been shown[6,12] that the Brdička current observed in the presence of Co(III) at low concentration, usually less than 2×10^{-4} mol dm^{-3}, can be expressed by

$$i_B = FAk_B\Gamma f_{Co}, \quad (1)$$

where F is Faraday, A the surface area of mercury electrode, k_B the Brdička current constant representing the catalytic activity of the protein, Γ the surface concentration of the protein adsorbed on the electrode surface, and f_{Co} the flux of cobalt ion at the electrode surface. In Eq. 1, f_{Co} and Γ as well as k_B depend on temperature. f_{Co} at a given temperature can be estimated from i_{Co} (broken lines in Fig. 1) according to the Ilkovič equation; $f_{Co}=i_{Co}/nFA=(7D_{Co}/3\pi t)^{1/2}C_{Co}$ at DME, where n is the number of electrons involved (here $n=3$), D_{Co} the diffusion coefficient of the cobalt ion, C_{Co} the bulk concentration of the cobalt ion and t the drop time. It has been shown[6,12] that Γ is given by the Koryta equation,[13] $\Gamma=(12D_pt/7\pi)^{1/2}C_p$ at DME in good approximation, for the Brdička current of RNase at the potential $E\geqq-1.5$ V and $C_p\leqq4$ μg ml^{-1} under the usual DME conditions, where D_p and C_p are the diffusion coefficient and the bulk concentration of the protein, respectively. The values of D_p at different temperatures were estimated by $D_p=(\text{const.})T/\eta$,[14] where $D_p=13.1\times10^{-7}$ cm^2 s^{-1} at 20 °C,[15] T; the absolute temperature, and η; the viscosity of water at each temperature,[16] respectively. Thus f_{Co} and Γ for a given temperature were calculated and k_B's at three different potentials were determined by Eq. 1. The results are plotted against temperature in Fig. 3. Note that k_B decreased continuously with increasing temperature at all potentials.

The negative temperature coefficient of the Brdička current has been pointed out by many previous authors,[7-11] who have interpreted this phenomenon by the decreased adsorption of protein on the electrode surface at increased temperature. The present result clearly indicates that the negative temperature coefficient of the Brdička current is due to the negative temperature coefficient of k_B, and is not attributable to the decreased adsorption of protein. Also it is clear that the initial increase of i_B at −1.3 V (the Brdička first wave, curve a in Fig. 2) is due to the increase in Γ and f_{Co}, and does not indicate any increase in the catalytic activity itself of the protein with increasing temperature, as Březina and Gultajaj[7] have suggested.

The mechanism of the Brdička current is not yet fully understood, but it is now generally accepted[5,6,17] that zero-valent cobalt, Co(0), which is liganded to a Brdička active group of protein to form a protein-Co(0) complex on the electrode surface, may catalyze the hydrogen evolution before the complex is decomposed into Co(0)-amalgam. The proposed mechanism has led to a theoretical equation for the Brdička current,[6,12]

$$i_B = H_1C_{Co}/[H_2+C_{Co}], \quad (2)$$

with

$$H_1 = FAn_ck_c\Gamma, \quad (3)$$

$$H_2 = (k_d/k_f)C_{Co}/f_{Co}, \quad (4)$$

where k_c is the constant representing the intrinsic cata-

lytic activity of the protein-Co(0) complex, n_c the number of sites where the protein-Co(0) complex can be formed per protein molecule, and k_f and k_d the rate constants of formation and decomposition of the protein-Co(0) complex, *i.e.* k_f/k_d represents the stability or life time of the complex. Equation 2 also predicts that $n_c k_c(k_f/k_d)=k_B$ in Eq. 1, which is valid for $f_{Co}(k_f/k_d)\ll 1$ or at sufficiently low value of C_{Co}, usually[12] less than 2×10^{-4} mol dm^{-3}. Thus, the dependence of i_B on C_{Co} was analyzed using Eqs. 2—4 in the C_{Co} range between 5×10^{-5} and 2×10^{-3} mol dm^{-3} at different temperatures to give the $n_c k_c$ and k_f/k_d values as functions of temperature. The results are shown in Figs. 4 and 5.

As seen in Fig. 4, $n_c k_c$ increases with increasing temperature at all potentials, except at -1.5 V where $n_c k_c$ tends to decrease slightly. The decreasing tendency of $n_c k_c$ at -1.5 V is probably due to overestimation of Γ at such a negative potential. The adsorption of protein is usually weaker,[18] so that the Koryta equation is not valid, but gives an overestimated value of Γ, *i.e.* $\Gamma<(12D_p t/7\pi)^{1/2}C_p$, and the weaker the adsorption, the lower is Γ. On the other hand, k_f/k_d always decreases with temperature (Fig. 5). Thus the decrease in the stability or life time of the protein-Co(0) complex cancels the increase in the intrinsic catalytic activity of the complex, resulting in the decrease in the over-all catalytic activity of the protein, *i.e.* the k_B value, with increasing temperature. In the above discussion, the change of the pH with temperature is not taken into account; this is calculated to be from 9.95 to 9.05 for the temperature change from 10 to 40 °C in ammoniacal buffer.[19] It has been shown[20] that both $n_c k_c$ and k_f/k_d decrease with decreasing pH. This implies that the "true" temperature coefficient should be larger for $n_c k_c$ and smaller for k_f/k_d. However this correction for pH change can be shown to be not sufficiently significant to modify the above conclusion.

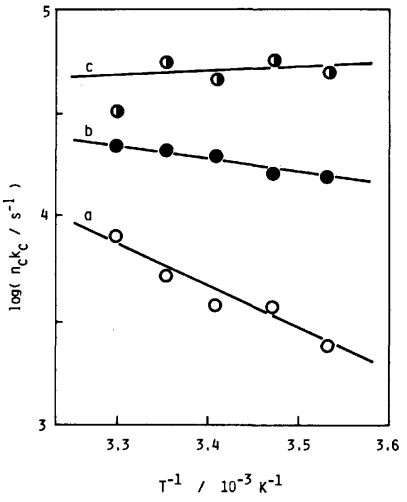

Fig. 4. Temperature dependence of the $n_c k_c$ values of RNase at a) -1.3, b) -1.4, and c) -1.5 V in the base solution.

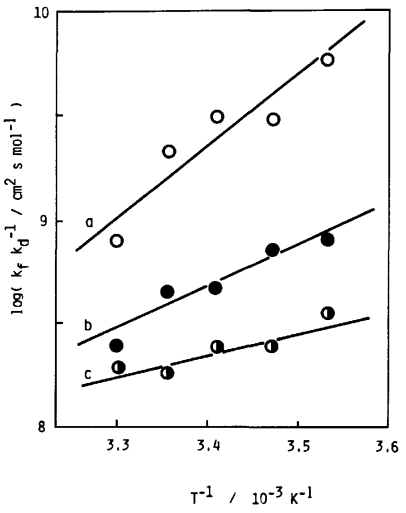

Fig. 5. Temperature dependence of the $k_f k_d$ values of RNase at a) -1.3, b) -1.4, and c) -1.5 V in the base solution.

The slopes of the linear plots in Fig. 4 give the apparent activation energy of the catalytic hydrogen evolution on the electrode surface, which was calculated to be 37 kJ mol^{-1} at -1.3 V, 17 kJ mol^{-1} at -1.4 V (and -1 kJ mol^{-1} at -1.5 V). Also, the plots in Fig. 5 give the difference between the apparent activation energies of the formation and the decomposition of the protein-Co(0) complex, which was calculated to be -64 kJ mol^{-1} at -1.3 V, -36 kJ mol^{-1} at -1.4 V and -20 kJ mol^{-1} at -1.5 V. The potential dependence of these energy values may be associated with the conformational change of the protein absorbed on the electrode surface.

Electrical Relaxations in Mixtures of Lithium Chloride and Glycerol[1)]

F. Scott HOWELL,* Cornelius T. MOYNIHAN,† and Pedro B. MACEDO††
Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioicho 7-1, Chiyoda-ku, Tokyo 102
††*Vitreous State Laboratory, Department of Chemical Engineering and Materials Science, The Catholic University of America, Washington, D.C. 20064, U.S.A.*
(Received July 22, 1983)

The dielectric constant ε' and the electrical conductivity σ were measured as a function of frequency (0.1—2 MHz) and temperature for an electrolyte-polar solvent system: lithium chloride in glycerol. Mole fractions of LiCl were 0, 1, 2, 5, 10, 20, and 33.3%. Data were analysed in terms of an inverse complex permittivity (electrical modulus). At lower mole fractions, two separate modulus relaxations were observed, one due to the ionic diffusion and the other to the dipole reorientation. These two relaxation processes converged with increasing LiCl mole fraction and were not distinguishable at 20%. The moduli isotherms at 33.3% were characteristic of a fused salt. Average relaxation times and distributions for both processes were determined by computer fits to a Gaussian distribution in the logarithms of these times. Their temperature and mole fraction dependences are discussed. The conductivity relaxations became slightly broader than single at 10%; this shows the influence of the charge concentration on the structural relaxation process.

Numerous studies have been conducted on dielectric relaxation in solutions of electrolytes in polar solvents. Some of these have been limited because the frequency, temperature, and/or concentration ranges studied were narrow. We report here a study of electrical relaxations in mixtures of LiCl in glycerol[2)] covering the 0—33.3 mol% LiCl range, i.e., from the dilute solution to the solvated melt where the number of solvent molecules is sufficient to fill more than the first solvation sphere of the ions.[3)] These solutions are highly viscous and supercool readily, so a wide range of temperature can be investigated over a wide frequency range in which accurate complex permittivity measurements can be made by conventional audio bridge techniques. The purpose of this work was to determine as a function of composition the relative contributions of ionic transport and reorientation of polar solvent molecules to the electric field relaxation in the mixture.

Experimental

Materials. A stock solution of lithium chloride in glycerol, containing nominally 33.3 mol% LiCl, was prepared by weight from Fisher Certified Reagent grade LiCl and Fisher Reagent grade glycerol. The salt was placed in a flask and dried to constant weight in an oven at 160 °C before the glycerol was added. The mixture, in a tightly-capped flask, was then heated and stirred on a hot-plate magnetic stirrer to bring the salt into solution. This 33.3% solution was too viscous to flow readily at room temperature and could be poured only when hot. The lower mole fraction mixtures (approximately 20, 10, 5, 2, and 1%) were formed by dilution of the 33.3 mol% mixture with glycerol. The pure glycerol and all mixtures were stored in tightly-capped flasks in a dessicator.

All the solutions were analyzed by titration of chlorine ions with a silver nitrate solution using the absorption indicator method. The density measurements for glycerol agreed with Bosart and Snoddy's results.[4)] The kinematic viscosity of the pure glycerol, measured at (20.0±0.1) °C with a factory-calibrated Cannon-Fenske capillary viscometer, was 0.0014 $m^2 s^{-1}$ (14 St), which corresponds to a glycerol–water solution of 0.998 mass fraction.[5)]

Apparatus and Procedures. Glass transition temperatures for glycerol and the mixtures were measured on a Perkin-Elmer differential scanning calorimeter (DSC-1B) at a heating rate of twenty degrees per minute. T_g was taken as the extrapolated point at which the heat capacity curve begins to rise rapidly.[6)]

The cell was described previously.[7,8)] Its vacuum capacitance was measured before each sample was poured in. This C_0 value changed slightly whenever the cell was disassembled for cleaning and then reassembled; it ranged from 0.81 to 0.90 pF.

Measurements of the equivalent parallel capacitance C and the conductance G were carried out over the frequency range 0.1 Hz to 2 MHz. We used a modified Cole-Berberian[9)] bridge (0.1 Hz to 500 Hz), a General Radio 1615A bridge (500 Hz to 100 kHz), and a Wayne-Kerr B601 bridge (15 kHz to 2 MHz). Electronic frequency counters (Hewlett-Packard 522B or 3734-A) were used to assure frequency accuracy wthin 0.2%.

The LiCl–glycerol mixtures were thermostated in a Tenney Jr. Environmental Chamber. The temperature range from −85 to −20 °C was sufficient to cover the relaxations studied. Chamber temperatures were determined with an accuracy of 0.1 °C by calibrated copper-constantin thermocouples located at the cell.

Densities of three of the mixtures were measured at 0 °C and at room temperature with a dilatometer.

Results and Discussion

Solution Properties. Table 1 compares the result of the composition analysis with the mixture compositions calculated from the reagent masses used. The densities and the glass transition temperatures are also listed.

The T_g measured for glycerol (192.8 K) does not agree with the value reported by Matheson *et al.* ((186.0 ±2) K).[10)] They used a DTA technique with a scanning rate of two degrees per minute. The discrepancy may be resolved by the difference in scanning rates (20 *vs.* 2 K min^{-1}), by uncertainties in our DSC temperature scale, or by differences in the water content of the glycerol samples studied.

TABLE 1. LiCl IN GLYCEROL: ANALYTICAL RESULTS

Nominal[a] content LiCl/mol%	Nominal content LiCl/wt%	Analysed content LiCl/wt%	Density[b] g cm^{-3}	T_g[c] K
Glycerol	0		1.275	192.8
1	0.462	0.474		191.9
2	0.931	0.926		
5	2.364	2.378		195.6
10	4.87	4.86	1.299	200.1
20	10.32	10.29	1.323	208.6
33.3	18.71	18.68		229.5

a) Calculated by assuming that the glycerol was 100% pure. b) At 0 °C; the changes in density per degree were -6.0×10^{-4} g cm^{-3} K^{-1}. c) Uncertainty: ±2 K.

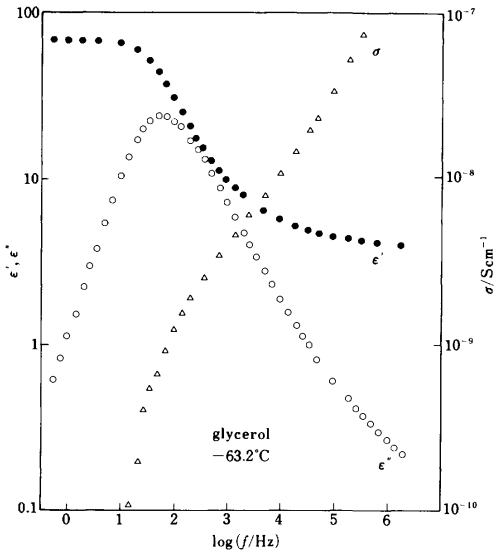

Fig. 1. Frequency dependence of conductivity △ and complex permittivity, ε': ● and ε'' :○, for glycerol at −63.2 °C. Left-side scale for permittivity, right-side scale for conductivity.

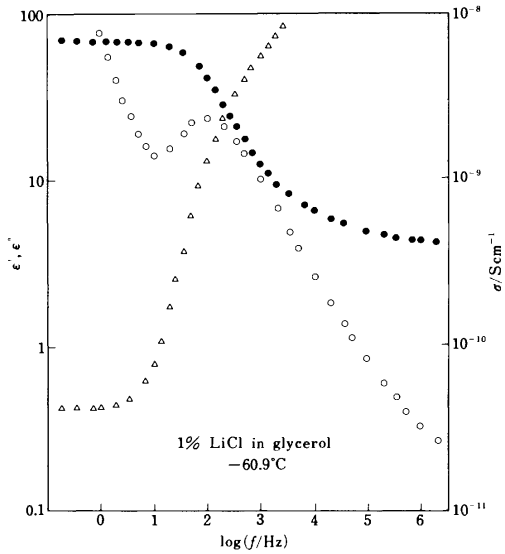

Fig. 2. Frequency dependence of conductivity and complex permittivity for 1 mol% LiCl in glycerol at −60.9 °C. Symbols and scales in Fig. 1.

Conductivities σ and dielectric constants (real parts of the complex relative permittivities) ε' were calculated from the experimental parallel G and C values *via* these equations:

$$\sigma = \varepsilon_0 G/C_0, \quad \varepsilon' = C/C_0, \tag{1}$$

where ε_0 is the permittivity of free space. Complete tables of σ and ε' values as functions of temperature and frequency are available.[1] In Figs. 1—4, experimental values of σ, ε', and $\varepsilon''=G/2\pi fC_0$ are plotted as a function of the logarithm of the measurement frequency f for glycerol and three mole fractions of LiCl in glycerol. At the temperatures selected, the complete relaxation could be seen within the experimentally available frequency range.

At low frequencies, the conductivity of the salt-glycerol mixtures becomes frequency-independent at the value σ_0. For glycerol this value is apparently much lower than the values available in these experiments.

The real part of the complex permittivity exhibits a frequency-independent shoulder (typically one decade wide) at low frequencies. This value is designated as ε_g

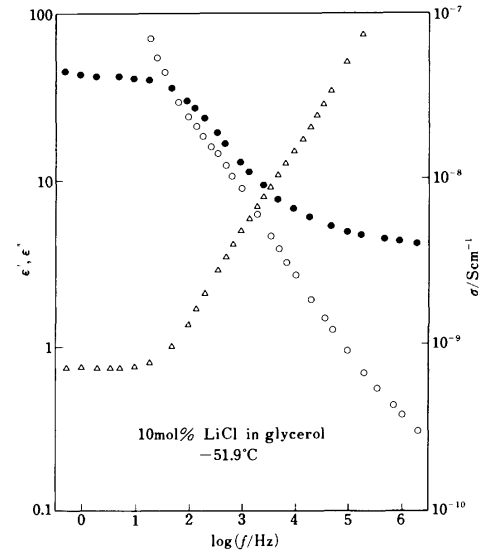

Fig. 3. Frequency dependence of conductivity and complex permittivity for 10 mol% LiCl in glycerol at −51.9 °C. Symbols and scales in Fig. 1.

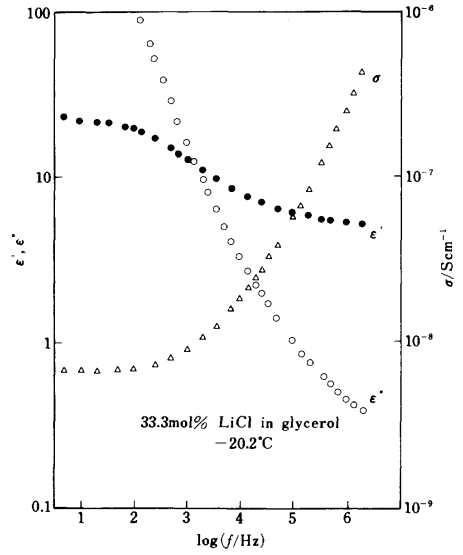

Fig. 4. Frequency dependence of conductivity and complex permittivity for 33.3 mol% LiCl in glycerol at −20.2 °C. Symbols and scales in Fig. 1.

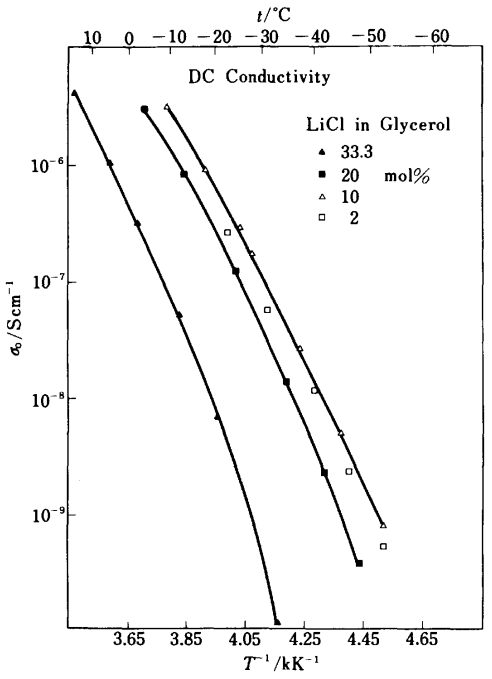

Fig. 5. Arrhenius plots of d.c. conductivity: 2, 10, 20, and 33.3 mol% LiCl in glycerol.

for glycerol and as ε_{LCg} for the salt-glycerol mixtures. The very rapid rise in ε' at still lower frequencies (beginning, for example, in Fig. 3 below 1 Hz and in Fig. 4 below 10 Hz) is due to electrode polarization and related sample-electrode interface effects which have been dealt with extensively in earlier papers.[7,11,12] These demonstrate that the frequency dependences of σ and ε' at frequencies higher than the frequency at which electrode-related effects are seen can be associated with the Li^+ ionic conductivity mechanism and with the glycerol dipole dielectric relaxation.

Figure 5 shows Arrhenius plots of the d.c. conductivity for the 2, 10, 20, and 33.3 mol% mixtures of LiCl. The 1% data fell slightly below the 2% points. The 5% data almost overlapped the line connecting the 10% points; the latter show a slightly higher activation energy. At a given temperature, the magnitudes of the d.c. conductivities occur in the following order: 33.3%≪20%≅1%<2%<5%≅10%.

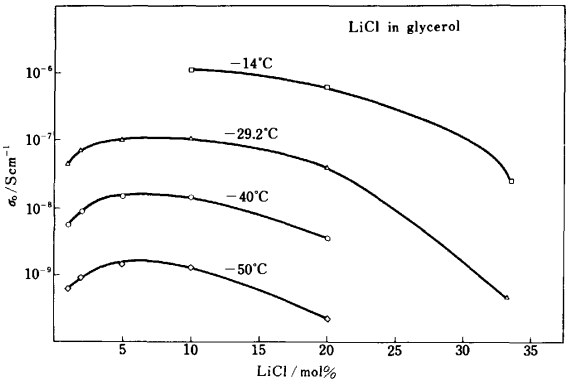

Fig. 6. Mole fraction dependence of d.c. conductivity for mixtures of LiCl in glycerol at various temperatures.

Figure 6 shows the d.c. conductivity as a function of mole fraction for various temperatures. A maximum in isothermal conductivity is seen between 5% and 10% mole fraction of LiCl. A similar maximum was reported by Bressel[13] for aqueous LiCl solutions and by Kartzmark *et al.*[14] for aqueous $LiNO_3$ solutions. The values of the molar conductivity, $\Lambda = \sigma_0/c$, where c is the amount-of-substance concentration, decrease monotonically with increasing mole fraction of LiCl and do not exhibit a minimum.

This maximum found in σ_0 can be explained by the mole fraction dependences of the different components of the conductivity. The value of the conductivity is given by $\sigma_0 = \sum N_i z_i \mu_i$, where N_i is the number of i-type ions per unit volume, z_i is the charge number of the ith ion, and μ_i is the electric mobility of the ith ion. N_i increases with increasing mole fractions of salt ions, but these additional ions introduce stronger electrical forces into the mixture and increase the viscosity and internal pressure. The total ionic diffusion mobility μ_i is inversely proportional to the average dielectric relaxation time, which is approximately the time for the mixture's local structure to break up. The ions will move as soon as the solvent structure opens to allow diffusive motion. This average dielectric relaxation time, in turn, is proportional to viscosity, by Debye's relation and McDuffie's results.[15] Thus the maximum found in σ_0 is due to the fact that the ionic electrical mobilities decrease much faster with increasing mole fraction of salt than the number of ions per unit volume increases.

Bartoli *et al.*[2] suggested that ion-pairing, which would decrease the N_i contribution to σ_0 at higher mole fractions, was responsible for the leveling out of σ_0 as a function of mole fraction. But this proposal neglects the mole fraction dependence of the ionic mobilities and does not easily explain the sharp decrease in σ_0 beyond 10 mol%. Nor is other evidence for ion-

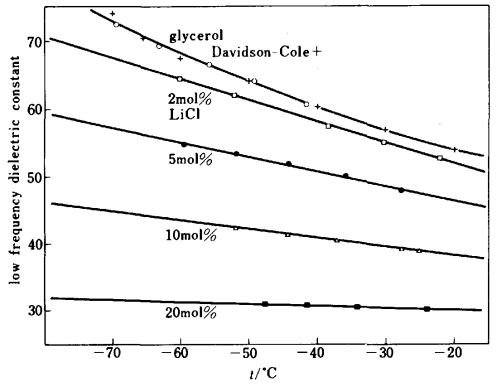

Fig. 7. Temperaure dependence of the low frequency dielectric constant for mixtures of LiCl in glycerol and for glycerol.

pairing available.

Figure 7 shows the low frequency limit of the real part of the complex permittivity as a function of temperature for glycerol and four mole fractions of salt in glycerol. The glycerol data of Davidson and Cole are included in the figure; the agreement is excellent.[16]

Within experimental error, the ε_{LCg} values for the 1% mole fraction were the same or slightly higher than the ε_g values and so have been omitted from Fig. 7.

The decrease of ε_g and ε_{LCg} with increasing temperature is due to the increasing thermal energy in the liquid mixture; this increased energy opposes the forces due to the external field, which tend to align the glycerol dipoles. Pottel has reported a similar temperature dependence for 1 mol dm^{-3} aqueous solutions of divalent sulfate salts.[17]

Modulus Data. Figures 8 and 9 show the low frequency dependences of the real and imaginary parts of the inverse complex relative permittivity, or complex electrical modulus, for each mole fraction of LiCl in glycerol at a selected temperature. The temperatures were chosen so that the entire electrical relaxation fell with the frequency ranges of the modified Cole-Berberian and General Radio bridges. In these figures, some data sets at higher mole fractions were shifted along the horizontal frequency axis by the number of decades indicated in the legend. At the lowest frequencies both M' and M'' decrease to zero. The zero lines are stepped up by the vertical scale shifts indicated in the legends. The 2% data for M'' at frequencies above 100 Hz overlap the 1% data and are omitted from the figure for convenience. Higher mole fraction data sets of M'' also have high frequency points which would appear on the figure beyond the peak; these have also been omitted.

Figure 10 shows the real and imaginary parts of the complex modulus for pure glycerol at −63.2 °C. Notice that the low frequency value of M' levels out at a non-zero value.

The complex modulus M^* is a function of angular frequency:

$$M^* = M' + iM'' = (\varepsilon^*)^{-1} = \varepsilon'/(\varepsilon'^2+\varepsilon''^2) + i\varepsilon''/(\varepsilon'^2+\varepsilon''^2). \quad (2)$$

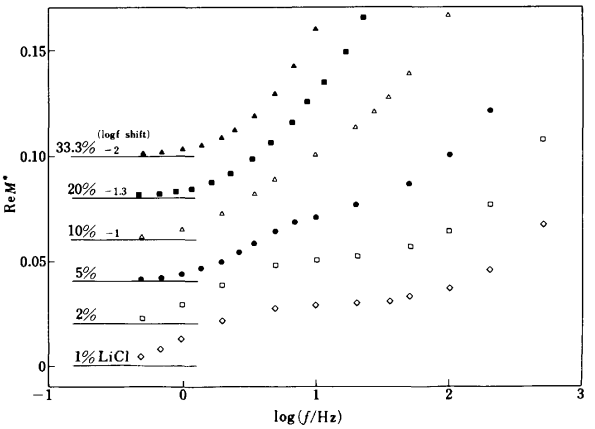

Fig. 8. Low frequency dependence of the real part of the complex modulus (M') of various mole fractions of LiCl in glycerol at typical temperatures. Vertical scale is labeled for 1 mol% data and should be stepped by 0.02 for each higher mole fraction. Horizontal scale is correct for 1, 2, and 5 mol% data; higher mole fraction data are shifted left as noted to avoid data overlap. Temperatures: 1 mol%, −60.9 °C; 2 mol%, −60.1 °C; 5 mol%, −51.8 °C; 10 mol%, −51.9 °C, frequency shifted by one decade; 20 mol%, −41.6 °C, frequency shifted by 1.3 decades; 33.3 mol%, −20.2 °C, frequency shifted by 2 decades.

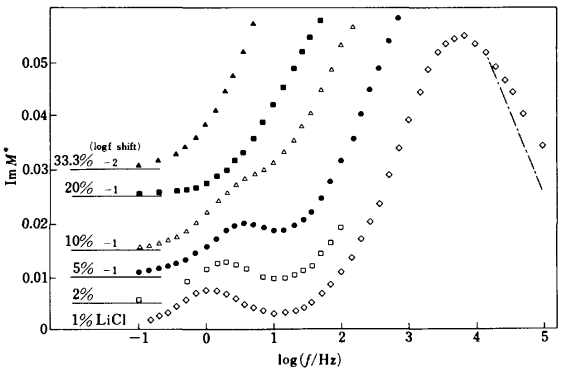

Fig. 9. Low frequency dependence of the imaginary part of the complex modulus (M'') of various mole fractions of LiCl in glycerol at typical temperatures, as listed in caption for Fig. 8. Vertical scale is labeled for 1 mol% data and should be stepped by 0.005 each for 2, 5, and 10 mol% data, by 0.01 for 20 mol% data, and again by 0.005 for 33.3 mol% data. Horizontal scale is correct for 1 and 2 mol% data; it should be shifted left by one decade for 5, 10, and 20 mol% data and by two decades for the 33.3 mol% data.

This formalism was first suggested in 1967 by McCrum *et al.*[18] and has been employed to describe electrical relaxations by analogy with the well-known compressional and shear moduli for viscoelastic flow.[11] The complex electrical modulus has been helpfully explained in terms of the more usual admittance, impedance, and permittivity formalisms by Hodge *et al.*[19] The mathematics of this M^* formalism has been developed in several reports.[7,8,12,19-21] The present case, in which a conducting dielectric

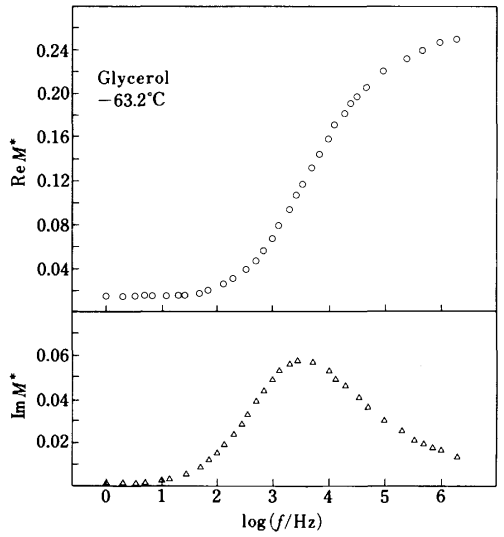

Fig. 10. Frequency dependence of the real (M') and imaginary (M'') parts of the complex modulus of glycerol at −63.2 °C.

undergoes a relaxation involving molecular mechanisms which do not contribute to the long-range conduction process, has been discussed in detail (see Eq. 15 in Refs. 7 and 21).

The complex modulus can be decomposed into two additive terms, which represent the conductivity relaxation (at lower frequencies) and the dielectric relaxation (at higher ones). If both these relaxations occurred at single relaxation times, the complex modulus equation would be

$$M^*(\omega) = M_s i\omega\tau_\sigma/(1+i\omega\tau_\sigma) + (M_\infty - M_s)i\omega\tau_D/(1+i\omega\tau_D). \quad (3)$$

Here M_s is the reciprocal of ε_s, the frequency-independent value of the dielectric constant at low frequency; M_∞ is the reciprocal of the high frequency value, ε_∞. τ_σ is the conductivity relaxation time. τ_D is the dielectric relaxation time at constant displacement vector and is related to the conventional dielectric relaxation time for constant electric field, τ_E, by $\tau_D=(M_s/M_\infty)\tau_E$.

One or both of the terms in Eq. 3 may need to be modified to allow for a distribution of relaxation times. In this work a log gaussian distribution of times[22-23] was used to generate best-fit curves to the M^* data at each temperature and concentration.

$$M^* = M_s\int_{-\infty}^{\infty} g_\sigma\left(\ln\frac{\tau_\sigma}{\tau'_\sigma}\right)\left[\frac{(\omega\tau_\sigma)^2+i\omega\tau_\sigma}{1+(\omega\tau_\sigma)^2}\right] d\ln\frac{\tau_\sigma}{\tau'_\sigma} + (M_\infty - M_s)\int_{-\infty}^{\infty} g_D\left(\ln\frac{\tau_D}{\tau'_D}\right)\left[\frac{(\omega\tau_D)^2+i\omega\tau_D}{1+(\omega\tau_D)^2}\right] \times d\ln\frac{\tau_D}{\tau'_D}. \quad (4)$$

The log gaussian distribution functions are the subscripted g's:

$$g_\sigma(\ln\tau_\sigma/\tau'_\sigma) = b_\sigma(\pi)^{-1/2}\exp(-b_\sigma^2\ln^2(\tau_\sigma/\tau'_\sigma)),$$
$$g_D(\ln\tau_D/\tau'_D) = b_D(\pi)^{-1/2}\exp(-b_D^2\ln^2(\tau_D/\tau'_D)). \quad (5)$$

The primed *tau*'s are the most probable relaxation times for the respective distribution functions; the b values are inversely proportional to the widths of the distributions. A b value greater than 2.5 is considered equivalent to a delta function distribution, *i.e.* a single relaxation time. Fit parameters obtained at each temperature and concentration are given in Tables 2—5.

The M' data sets for glycerol level out at the expected non-zero $M_s=1/\varepsilon_s$ values at low frequencies. The fits shown in Table 2 were performed for data up to the peak in the M'' values.

For the dilute and moderately concentrated mixtures (1, 2, 5, 10 mol%), each conductivity and dielectric wave (in M') and peak (in M'') was fit separately to a log gaussian distribution. If sufficient data were available to show both peaks, a six-parameter function, the sum of two log gaussian distributions, was fit to the entire spectrum up to the top of the dielectric peak; this procedure reproduces Eq. 4. The 20 mol% data fits are discussed below. The 33.3 mol% data were fit to one broad log gaussian distribution; Table 5 shows the results.

For all cases, the data at frequencies beyond the maximum value of M'' were excluded when the least-squares fit was performed. No attempt was made to introduce a low, broad function centered a decade or so higher in frequency than the M'' maximum, a procedure which would probably have reproduced the high frequency shape of the data more adequately than the one we used. The high-frequency asymmetry in the M^* data which other authors[24] and ourselves[8,21] have reported was thus ignored. The generated fits fall inside the data points for frequencies beyond the dielectric M'' peak, as the dotted line for the 1 mol% data in Fig. 9 shows. All fits have an overall accuracy of about 3%; as might be expected, the fit is usually worst in the M'' valley between the conductivity peak and the dielectric peak.

The fit reported in Table 4 for the 20 mol% data was not acceptable. We believe that the conduction and the dipole reorientation processes contribute almost equally to the observed spectra. Extrapolation of the ratios of the average times (see below) as a function of concentration to the 20 mol% case indicated that the two peaks would be within a factor of ten in center frequencies. The six-parameter sum of two log gaussian distributions, however, was unable to separate the two presumed processes: the central

times could not be well-specified. Thus the fits shown in Table 4 are from a log gaussian distribution using three parameters which fortunately converged. This fit was in error by 100% for the data in the lowest decade of frequency, but it did match the data near the M'' maximum sufficiently closely for the fit program to converge.

Average Times. The average relaxation times

for each process can be calculated from the fit parameters. For a logarithmic gaussian distribution:[23]

$$\langle\tau\rangle = \tau' \exp(-1/4b^2). \quad (6)$$

The τ' and b are to be subscripted for either conductivity relaxation or dielectric relaxation at constant displacement vector (σ or D).

For the 20% data, the average time which this procedure generates is a compromise between $\langle\tau_\sigma\rangle$ and $\langle\tau_D\rangle$. A rough extrapolation of the ratios of the average times as a function of mole fraction indicated that the two times were within a factor of ten of each other when the LiCl mole fraction was about 20%.

The procedure of omitting from the fit the M^* data at frequencies beyond the dielectric M'' maximum had no significant effect on either of the average times calculated from the fit parameters.

Dielectric Times: Figure 11 shows the Arrhenius plots of the logarithms of the average dielectric relaxation times (at constant displacement vector) for glycerol and for the 1, 2, 5, and 10% LiCl mixtures with glycerol. At a given temperature, the increase in the magnitude of the logarithm of $\langle\tau_D\rangle$ from one to ten per cent was found to be linear with the mole fraction.

A wide distribution of dielectric relaxation times is observed. The cooperative aspects of the structural break-up are thus reflected in the dielectric behavior. The dielectric width parameter b_D decreases slightly with increasing concentration. Harris and O'Konski report a similar broadening for aqueous 1:1 electrolyte solutions.[25] They suggest that two processes are responsible for increasing the relaxation times of the polar solvent molecules. First, because more of the solvent molecules are bound in complexes with the cations at higher concentrations, there are fewer available to reorient freely with the applied electric field. Secondly, more of these free solvent molecules are in the second coordination shells of the solvated ions and are thus somewhat hindered in following the electric field.

At each concentration the dielectric width parameter b_D tends to increase with increasing temperature. This corresponds to a narrowing of the peak; Bartoli *et al.* found a similar narrowing in NaCl-glycerol mixtures.[2] As the temperature is increased, the amount of bonding in the liquid is lowered as the liquid structure becomes more randomized by the increased thermal energy of the individual molecules or complexes. The environmental relaxation model[26] had predicted such a temperature behavior of the width parameter associated with the structural rearrangement.

Conduction Times: Figure 12 shows the Arrhenius plots of the logarithms of the average conductivity relaxation times for all six mole fractions of LiCl in glycerol. $\langle\tau_\sigma\rangle$ decreases with increasing mole fraction for 1, 2, and 5 mol% LiCl. As the salt concentration in the sample increases, the conductivity increases; consequently, the electric field decays with a shorter time constant.

The 5 and 10 mol% values of $\langle\tau_\sigma\rangle$ are indistinguishable; the same line is used for both sets of data. These time values reflect the reversal in the concentration dependence of the d.c. conductivity in Fig. 6.

Distribution of Conduction Times: The dilute salt-glycerol mixtures show a single relaxation time for the conductivity relaxation at those temperatures at which sufficient data are available for a six-parameter sum of two log gaussian functions to be fit. When

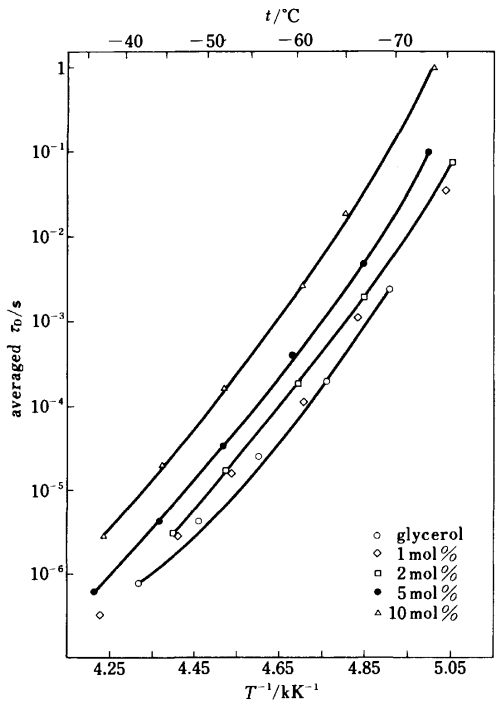

Fig. 11. Arrhenius plots of the average dielectric relaxation times at constant displacement vector for glycerol and for mixtures of 1, 2, 5, and 10 mol% LiCl in glycerol.

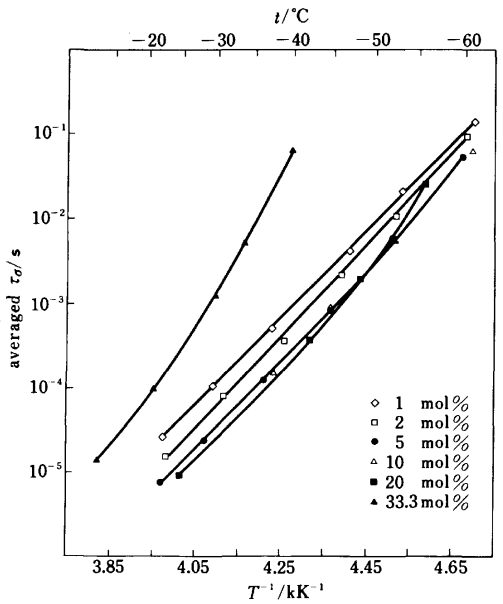

Fig. 12. Arrhenius plots of the average conductivity relaxation times for mixtures of 1, 2, 5, 10, 20, and 33.3 mol% LiCl in glycerol.

a 'single' relaxation is reported in the tables, b converged to a value greater than 2.5. Thus $\tau_\sigma' = \langle \tau_\sigma \rangle$. This result was confirmed by calculating the average relaxation times from the d.c. conductivity and the low-frequency frequency-independent value of ε', using $\langle \tau_\sigma \rangle = \varepsilon_0 \varepsilon_s / \sigma_0$.[11] These independent calculations gave times which agreed with the fit values.

At the higher temperatures studied for these dilute salt-glycerol mixtures, only enough data was available to characterize the conductivity relaxation. Values of b_σ slightly lower than 2.5 were obtained, but these are an artifact of the fit procedure for the log gaussian function; this procedure included some of the data points beyond the M'' conductivity peak and thus some contribution from the beginnings of the dielectric relaxation. Single relaxation times were always achieved when both peaks were available for fitting.

Some structural considerations which could explain these results are given below. Besides these, the low concentration of charge carriers would give rise to long-range ionic conduction with little or no dispersion in ε' and σ at frequencies near the M'' conduction peak. This has been found to be the case in vitreous ionic conductors, specifically Phasil glass[27] and GeO_2,[28] as well as in ionically conducting single crystals which contain only a small concentration of charge carriers, such as NaCl crystals doped with divalent chlorides.[29]

The 10 mol% LiCl mixture shows a distribution of conduction relaxation times which is slightly broader than single. The average b_σ value is 2.17. At this moderate mole fraction, the number of charge carriers and the structural details of the glycerol reorientations are beginning to influence the conduction process. Part of the measured dispersion in ε' is thus due to the conductivity relaxation: this conclusion was impossible to draw using the complex permittivity data representation.[2]

Structural Consideration: This distribution of relaxation times which appears in the conduction modulus with increasing mole fraction of salt can be explained in terms of the interaction of the structural break-up process and the ionic diffusion process and by the increasingly cooperative character of the ionic conduction as the mole fraction of salt increases. We assume with Litovitz and McDuffie that the rate of an electrical relaxation is determined by the time in which a cooperative break-up occurs in the local structure of the liquid. Such a structural time would ordinarily be determined by an ultrasonic measurement, but it is reasonable to use the average dielectric relaxation time for constant displacement vector in place of the structural relaxation time for glycerol, since the ratio of the structural time and the usual dielectric relaxation time τ_E is only 1.5.[15,30]

If the characteristic time for structural relaxations is comparable to an electrical relaxation time, a distribution of electrical times is observed: this is the case for the dielectric relaxations reported here at all mole fractions. If, however, this structural time is much shorter than an electrical time, then the process will show a single electrical relaxation time, as is the case for the conductivity relaxations here at very low mole fractions.

When the mole fraction of ions is very low, the few ions present have to execute a large number of jumps in order to relax the electric field. If the ionic jump time is denoted as t_j, then we have $\tau_\sigma \gg t_j$ for the dilute cases. This also means that the field-biased ionic jumps are uncorrelated: the occurrence of a jump by a given ion does not bias the probability or direction of subsequent jumps by that ion or by other ions in its vicinity. At low concentrations, the details of the structural process are averaged out before the electric field decays, and thus the decay is seen as occurring with a single relaxation time.

When the mole fraction is increased to 10 mol%, however, it takes a much shorter time, that is, fewer jumps by a larger number of ions, before the field decays to zero. τ_σ becomes more comparable to t_j in this case. As the ionic concentration becomes higher, the average distance of ionic separation becomes smaller; thus the interionic coulombic interaction begins to become significant. The movement of an ion from one site to another will perturb the electrical potential in its vicinity; at a moderate mole fraction, other ions will be in the region of perturbed potential and their future motions will be biased. This cooperative motion of the ions will lead to a non-exponential decay function[24] and to dispersions in ε' and σ associated with long-range ionic migration.

Earlier reports[11,12] on alkali silicate glasses have followed Stevels,[31] Taylor,[32] and Isard[33] in suggesting that the dispersion in the complex permittivity would be accounted for by the lack of translational invariance of the free energy barriers impeding ionic diffusion in a vitreous quasi-lattice. These reports postulated that materials with a long-range lattice structure, such as ionic crystals, would have free energy barriers against ionic diffusion which would be regularly spaced and of equal height. For such equivalent lattice sites it was asserted that, on the average, the ions would spend the same duration of time at each site during the conduction process and that the long-range diffusion process would thus exhibit a single relaxation time. But recent experimental results for single crystals which contain a high concentration of charge carriers, $LiGaO_2$[34] and beta-alumina,[35] have shown a distribution of conductivity relaxation times when analysed in the complex modulus representation. These results underline the need in future theoretical work to pay more attention to the concentration of charge carriers. Not only a distribution of microscopic conductivities but also a moderate mole fraction of charge carriers, as in our 10 mol% LiCl mixture, can give rise to a distribution of conductivity relaxation times.

Jonscher[36] has advanced a model based on relaxation of screening charge about an ion following a jump, to account for the high frequency dispersion of the conductivity of dielectric materials. He had in mind producing an explanation only for the very high frequency losses due to localized motions, which are observed in all types of amorphous systems (insulators, ionic conductors, and electronic conductors), but his

model involves cooperative motion *via* interionic interactions and seems capable of expansion to the present system.

Higher Concentration Times: The 33.3 mol% average conduction times shown in Fig. 12 are much longer than the times for any of the other concentrations. This reflects the increase in viscosity and the sharp rise in the glass transition temperature for this concentration.

The 20 mol% average times are also displayed in Fig. 12 as if they were average conduction times, although we think that these apparent fit times are some compromise values between the dielectric reorientation time and the ionic conductivity time. The curvature in the Arrhenius plot is much different from that seen for the lower concentration data, especially at the lowest temperatures. The curve for the 20 mol% average times bends away from the slopes of the lower concentrations and towards the slope of the 33.3 mol% average conductivity times.

Distributions at Higher Concentrations: The 33.3 mol% data exhibit a wide conductivity relaxation. The magnitude of b_σ decreases by about 10% as the temperature increases. The modulus wave and peak broaden with increasing temperature in a way similar to the highly viscous liquid behavior of the glass-forming nitrate mixture studied earlier.[8] This similarity is another indication that the 33.3 mol% LiCl glycerol mixture should be considered a quasi-fused-salt.

The 20 mol% data show a wide distribution of relaxation times similar to that for the 33.3 mol% results. Over a temperature increase of about 40 K, the width parameter broadens from 0.466 to 0.290. This temperature dependence of the width parameter at least suggests the onset of fused salt behavior, even when it is remembered that the fit is only apparent (since the two times have moved so close together that the fit functions cannot separate them).

Ratios of Average Electrical Times: The ratio of the average conductivity relaxation time to the average dielectric relaxation time at constant displacement vector is given in Table 3, for those temperatures at which both relaxations could be adequately fit by the six-parameter sum of two gaussian functions. This ratio is a strong function of concentration, dropping from an average value of 1400 at 1 mol% LiCl to 580 at 2 mol%, 170 at 5 mol%, and about 40 at 10 mol%. This decrease in the $\langle\tau_\sigma\rangle/\langle\tau_D\rangle$ ratio with increasing concentration is due to the facts that $\langle\tau_\sigma\rangle$ decreases with concentration, remaining constant between 5 and 10 mol%, while $\langle\tau_D\rangle$ increases with concentration. The extrapolation of this dependence to 20 mol% LiCl yields a ratio of about six, while further extension to the 33.3 mol% case yields a value of less than one.

At a given concentration, an increase in temperature increases the magnitude of the ratio of electrical times. Over the temperature range −61 °C to −37 °C, the ratio increases by more than 15% for the 1 mol% mixture, while for the 10 mol% mixture the ratio more than doubles. Only when the ratio is less than 100 does the conductivity relaxation show a distribution of relaxation times.

The authors are grateful to M. Samanta and Dr. Regan Howard for their assistance with the chemical analyses and the DSC measurements. They are especially grateful to Dr. William Stamm for measuring the 2 mol% data. This research was partially supported by the United States Office of Naval Research. One of us (FSH) acknowledges with gratitude the Traineeship provided by the United States National Aeronautics and Space Administration.

Volume and Adiabatic Compressibility of Amino Acids in Urea-Water Mixtures

Toshio Ogawa,* Motoo Yasuda, and Kiyoshi Mizutani
Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464
(Received August 2, 1983)

Apparent molal volumes (ϕ_V) and apparent molal adiabatic compressibilities (ϕ_{KS}) at 25 °C have been obtained for the following amino acids in water and in urea-water mixtures (up to 8 mol kg^{-1} urea for ϕ_V and at 3 mol kg^{-1} for ϕ_{KS}) from measurements of density and ultrasonic velocity: glycine, L-alanine, β-alanine, α-aminoisobutyric acid, L-valine, L-serine, and L-threonine. The limiting values ϕ_V° and ϕ_{KS}° were calculated by a linear extrapolation using the least-squares method. These data were used to derive the volumes of transfer and the adiabatic compressibilities of transfer of the amino acids from water to aqueous urea solutions. Both of these transfer functions were positive. The results were interpreted in terms of structure-breaking interaction of urea upon water.

In recent years, mixed aqueous solvents are used extensively in chemistry and other fields to control factors, *e.g.*, solubility, reactivity, and stability of systems. Due to the high solubility of urea in water and its protein-denaturing ability in aqueous solutions urea-water mixtures have been employed as the solvents for extensive experimental investigations. The theoretical treatment of the mixtures also has been carried out by Frank and Franks.[1] It is generally accepted that urea does not appreciably interact with either hydrophobic or hydrophilic molecules or groups, and acts mainly to disrupt hydrogen bonding among water molecules in aqueous medium. Thus, as noted by Mathieson and Conway, thermodynamic and transport properties of aqueous urea solutions with added electrolytes or nonelectrolytes have been interpreted in terms of nonspecific interaction of urea with the solute.[2] The values of the thermodynamic functions are consistent with the hypothesis that urea solutions are similar to water but with less structure.

For a better understanding of an increased interest in the states of water in the living cells it will be necessary to carry out systematic investigations of model systems under various conditions. In the present work densities and ultrasonic velocities were measured at 25 °C for aqueous amino acid solutions and for amino acid-urea-water ternary systems at various concentrations. Apparent molal volumes and apparent molal adiabatic compressibilities and their limiting values were calculated from these data.

Experimental

The amino acids and urea used in this study were guaranteed reagents from Wako Chemical Industries, Ltd., and were used without further purification. As seen later, their limiting apparent molal volumes in aqueous solutions measured here were all in good agreement with the values reported recently by other workers, except α-aminoisobutyric acid, for which there is no previous value reported. The densities of the amino acids solutions were measured in water and in 1, 3, 5, and 8 mol kg^{-1} aqueous urea solutions and the ultrasonic velocities in water and in 3 mol kg^{-1} urea solution.

All solutions were prepared by weight in the concentration range 0.2—1 mol kg^{-1} (the number of moles of amino acid per kg of mixed solvent whenever the mixed solvent was used); the highest concentration depends on the solubility of the amino acids. The experimental errors were greatly reduced by employing the rather high amino acid concentration range.[3-5] Fresh stock solutions of urea were prepared for each series of measurements; the densities and ultrasonic velocities were determined for each stock solution.

The densities were measured to $\pm 2\times10^{-6}$ g cm^{-3} with an Anton Paar DMA 02D Densimeter. The system was calibrated with dry air and distilled water; their densities were taken from the literatures.[6,7]

The ultrasonic velocities were measured at 5 MHz to a precision of ±0.1 m s^{-1} using an improved ultrasonic interferometer designed by Nomura and Kawaizumi,[8] and the principle of the system is identical with the one used by Nomura *et al.*[5] Since there is an error due to the temperature variation, a relative error is estimated to be $\delta u/u = \pm 1.0\times10^{-4}$. The temperature control of the thermostated bath systems regulating the densimeter and ultrasonic interferometer was better than ±0.005 °C.

Results

The densities and ultrasonic velocities were determined at 25 °C for the following amino acids; glycine (Gly), L-alanine (Ala); β-alanine (β-Ala), α-aminoisobutyric acid (Me-ala), L-valine (Val), L-serine (Ser), and L-threonine (Thr). The apparent molal volumes were calculated from the relation:

$$\phi_V = \frac{M}{d} + \frac{1000(d_0 - d)}{m d_0 d}, \quad (1)$$

where d_0 and d are the densities of a solvent and a solution respectively and m is the molal concentration; M, the molecular weight of the amino acid. The adiabatic compressibilities β_S and the apparent molal adiabatic compressibilities ϕ_{KS} were calculated using Eqs. 2 and 3 respectively, where β_S is expressed in bar^{-1}.

$$\beta_S = \frac{100}{du^2}, \quad (2)$$

$$\phi_{KS} = \frac{\beta_S M}{d} + \frac{1000(\beta_S d_0 - \beta_S^\circ d)}{m d_0 d}, \quad (3)$$

where u is the velocity of sound (m s^{-1}) and β_S° is the adiabatic compressibility of the solvent. The limiting values ϕ_V° and ϕ_{KS}° were obtained by linear extrapolation using the least-squares fit to the equations:

Table 1. Limiting apparent molal volumes of amino acids in water

Amino acid	ϕ_V° / cm^3 mol^{-1}	S_V / cm^3 mol^{-2} kg	σ[a] / cm^3 mol^{-1}	ϕ_V° / cm^3 mol^{-1}
Glycine	43.23	0.82	0.01	43.19[b]
L-Alanine	60.50	0.59	0.02	60.47[b]
β-Alanine	58.25	0.95	0.02	58.28[c]
α-Aminoisobutyric acid	77.54	0.21	0.01	—
L-Valine	90.78	0.16	0.01	90.78[b]
L-Serine	60.72	1.14	0.02	60.62[d]
L-Threonine	76.94	0.89	0.01	76.83[e]

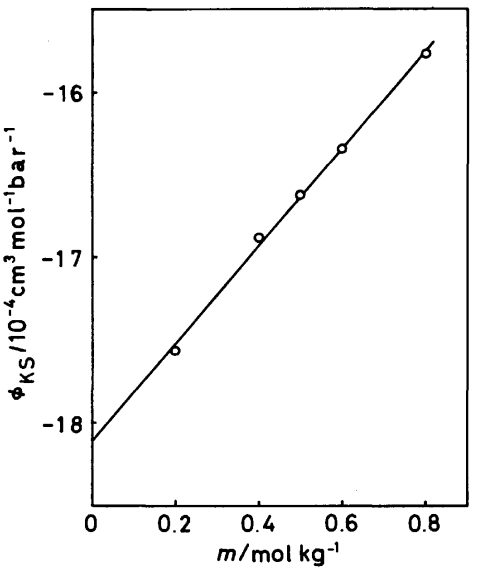

Fig. 2. Plot of ϕ_{KS} *vs.* m for glycine in 3 mol kg^{-1} urea solution.

$$\phi_V = \phi_V^\circ + S_V m, \tag{4}$$

and

$$\phi_{KS} = \phi_{KS}^\circ + S_K m, \tag{5}$$

where $\phi_V^\circ = \overline{V}^\circ$ and $\phi_{KS}^\circ = \overline{K}^\circ$ are the infinite dilution partial molal volume and partial molal adiabatic compressibility, respectively, and S_V and S_K are the experimental slopes. The ϕ_V and ϕ_{KS} of glycine in 3 mol kg^{-1} aqueous urea solutions are plotted against the amino acid molality in Figs. 1 and 2 respectively. The values of ϕ_V°, S_V, and standard deviations, σ, obtained in water are listed in Table 1 along with literature values reported recently. The apparent molal volumes at infinite dilution in 1, 3, 5, and 8 mol kg^{-1} aqueous urea solutions are given in Table 2, and the apparent molal adiabatic compressibilities at infinite dilution and standard deviations, σ, in water and in 3 mol kg^{-1} aqueous urea solutions are given in Table 3.

As seen from Table 1, our results are in good agreement with the literature values. As with the apparent molal adiabatic compressibilities our results are in good agreement with the values reported by Millero *et al.*,[9] but Cabani *et al.* obtained rather larger (less negative) values.[10] For example, the $10^4 \times \phi_{KS}^\circ$ value of glycine is reported as −27.00 by Millero *et al.* and as −25.0 by Cabani *et al.* The main reason for the discrepancy is probably due to the difference in the extrapolation procedure, thus Cabani *et al.* fitted to the equation

$$\phi_{KS} = \phi_{KS}^\circ + Bm + Cm^2. \tag{6}$$

Table 2. Limiting apparent molal volumes of amino acids in urea-water mixtures

Amino acid	ϕ_V° / cm^3 mol^{-1}			
	1[a]	3[a]	5[a]	8[a]
Glycine	43.92	44.78	45.39	46.08

Table 3. Limiting apparent molal adiabatic compressibilities

Amino acid	Water		Urea-Water[a)]	
	ϕ_{KS}° / 10^{-4} cm^3 mol^{-1} bar^{-1}	σ / 10^{-4} cm^3 mol^{-1} bar^{-1}	ϕ_{KS}° / 10^{-4} cm^3 mol^{-1} bar^{-1}	σ / 10^{-4} cm^3 mol^{-1} bar^{-1}
Gly	−27.16	0.36	−18.11	0.05
Ala	−24.74	0.18	−15.30	0.14
β-Ala	−26.36	0.11	−16.67	0.09
Mc-ala	−23.46	0.27	−12.55	0.10
Val	−30.43	0.10	−15.91	0.45
Ser	−29.88	0.10	−19.49	0.16
Thr	−31.23	0.10	−19.01	0.18

a) Urea concentration is 3 mol kg^{-1}.

In our experiment no systematic deviations at higher concentrations from the straight line expressed by Eq. 5 were observed up to the highest concentration studied, and so our data were extrapolated using Eq. 5 following Millero *et al.*[9)]

Discussion

The volume and compressibility behaviour of solutes in solution can provide information concerning solute-solvent and solute-solute interactions. The infinite dilution partial molal volumes and adiabatic compressibilities are, by definition, independent of solute-solute interactions and thus determined only by the respective intrinsic value and the solute-solvent interactions. Accordingly, they can be used to examine solute-solvent interactions. The slopes, S_V and S_K, can be assumed to be an indication of solute-solute interactions. The volumes of transfer, $\Delta\overline{V}_{tr}^{\circ}=\overline{V}^{\circ}$(urea)$-\overline{V}^{\circ}$(water), for some amino acids studied are plotted *versus* the urea concentration (Fig. 3). The magnitudes of the transfer functions increase continuously with the urea concentration. The same trend was observed by Enea *et al.*[14)] for the transfer functions of the heat capacities and volumes of three amino acids (Gly, Ala, and Ser) and several oligopeptides in urea-water systems. Detailed results are, however, presented only for 7 mol dm^{-3} urea concentration, and we cannot compare our volume data with their data directly, though the sequence of increment of $\Delta\overline{V}_{tr}^{\circ}$ for these three amino acids are identical with ours. Desrosiers *et al.*[15)] also observed the same trend for the transfer functions of the volume, expansibility, compressibility and heat capacity of alkali halides in urea-water mixtures. The transfer functions of volume for Ala and β-Ala are very similar up to 8 mol kg^{-1} urea concentration, though their $\overline{V}^{\circ}$ values differ by *ca.* 2 cm^3 mol^{-1} in urea-water mixtures as well as in water. This fact indicates the more effective hydration of β-Ala in aqueous urea solutions in comparison with Ala to almost the same amount as in water. In Fig. 4 $\overline{V}^{\circ}$'s are plotted *versus* V_W; V_W is the van der Waals volume, which was calculated using the data reported by Bondi[16)] and by Edward.[17)] As seen from Fig. 4, the amino acids having no OH group lie almost on a straight line both in water and in 8 mol kg^{-1} urea. Positions of

○: in water, ●: in 8 mol kg^{-1} urea.

serine and threonine which have OH groups are below the straight line in urea solution as in water. This fact shows that even in 8 mol kg^{-1} urea solution there is a rather large volume decrease brought about by hydrogen bonding of the OH group with water.

Millero *et al.*[9] estimated the intrinsic partial molal volume $\overline{V}°$(int) of amino acids from the crystal volume and also from the partial molal volume of uncharged isomers. The intrinsic volume is made up of two terms, the van der Waals volume and the volume due to packing effects. They obtained the electrostriction partial molal volume, $\overline{V}°$(elect), due to the hydration of amino acid from the experimentaly measured $\overline{V}°$ and the reasonably estimated $\overline{V}°$(int):

$$\overline{V}°(\text{elect}) = \overline{V}° - \overline{V}°(\text{int}). \quad (7)$$

Using the corresponding equation for the adiabatic compressibility

$$\overline{K}°(\text{elect}) = \overline{K}° - \overline{K}°(\text{int}), \quad (8)$$

they also estimated the electrostriction partial molal compressibilities of the amino acids. From both $\overline{V}°$(elect) and $\overline{K}°$(elect) they estimated the number of water molecules hydrated to the amino acids as 4.1±0.4. Recently, Shahidi and Farrell[13] also calculated the electrostriction volumes and the number of hydrated water for the amino acids from a somewhat different standpoint using Eq. 9 and consideration of the branching effects

$$\overline{V}° = 4\pi(r_w + 0.57)^3 N_A/3 - \sum_{i=1}^{m} n_i\sigma_i - E, \quad (9)$$

where r_W is the van der Waals radius of the amino acid, n_i is the number of interacting groups of type i in the solute, which contains m different interacting groups with the solvent; σ_i is the volume decrease due to the specific group-solvent interaction (*e.g.*, hydrogen-bonding),[18] and N_A is the Avogadro constant. The van der Waals radius is calculated from the van der Waals volume V_W assuming the amino acid to be spherical *i.e.*, $r_W=(3V_W/4\pi)^{1/3}$. The value 0.57 in Eq. 9 is added to the van der Waals radius because there is an empty volume between the solute and the solvent, which is assumed to be a spherical shell of constant thickness of 0.57 Å. An average of 13.0±1.2 cm^3 mol^{-1} was obtained for the electrostriction E for the α-amino acids. Since the volume of water is decreased by 3 cm^3 per mole when taken from the bulk phase to the region near the amino acid,[9] the number of water molecules involved in hydration of the α-amino acid is calculated as to be 4.33±0.39.

As noted by Millero *et al.*,[9] $\overline{K}°$(int) is small and as a first approximation one can assume $\overline{K}°$(int)=0. This makes $\overline{K}°=\overline{K}°$(elect). Thus the adiabatic compressibilities are the better measure for the hydration of the solute. The partial molal adiabatic compressibilities of the seven amino acids studied increase (*i.e.*, less negative) in the following order in water:

Thr<Val<Ser<Gly<β-Ala<Ala<Me-ala,

and in the following order in 3 mol kg^{-1} urea solution:

Ser<Thr<Gly<β-Ala<Val<Ala<Me-ala.

From these two series it is seen that the most hydrophobic solute studied, valine, is most affected by the transfer from water to 3 mol kg^{-1} urea solution. Of the solutes having an OH group threonine is more hydrophobic than serine and has a larger value of $\Delta\overline{K}_{tr}°$. The sequence Gly<β-Ala<Ala<Me-ala is the same both in water and in urea solution. By the introduction of the methyl group in glycine, *i.e.*, Gly→Ala and Ala→Me-ala, cospheres of the hydrophilic COO^- and NH_3^+ groups overlap with that of the hydrophobic group, thus decreasing their hydration ability in that order both in water and in aqueous urea solution. The decrease in hydration is reflected in the increase in compressibility. Concerning alanines, β-alanine with a larger charge separation has a larger negative value of adiabatic compressibility, indicating that β-alanine has a larger number of hydrated water molecules. According to Millero *et al.*[9] the number of water molecules hydrated to the amino acid, n_H, is given by

$$n_H = -\overline{K}°(\text{elect})/\beta_B°\overline{V}_B°, \quad (10)$$

where $\beta_B°$ is the compressibility of bulk water and $\overline{V}_B°$ is the molar volume of bulk water. As shown by Desrosiers *et al.*,[15] $\beta_B°$ and $\overline{V}_B°$ values in 3 mol kg^{-1} urea solution differ only slightly from those in pure water. Thus the ratio $\overline{K}°$(urea)/$\overline{K}°$(water) represents the ratio of hydration number of the solute in aqueous urea solution to that in water. The ratios for valine and α-aminoisobutyric acid are 0.52 and 0.53 respectively and those for the other amino acids studied are 0.61—0.67. The results show that more hydrophobic amino acids undergo more dehydration effect of urea.

As noted by Enea and Jolicoeur,[14] urea-water mixtures exhibit a dielectric constant similar to water (8% higher at 3 mol dm^{-3} urea), so the electrostatic hydration effects of amino acids should be comparable in both solvents; further, it may be improbable that the pK values of amino acids in urea-water mixtures differ appreciably from those in pure water. The pH values of 0.3 mol kg^{-1} amino acid aqueous solutions studied here, *e.g.*, glycine; 6.0, β-alanine: 6.8, were very close to the isoelectric point of the respective amino acid. Those of the corresponding aqueous urea solutions were only *ca.* 0.4 pH unit higher than those in water, *e.g.*, glycine: 6.4, β-alanine: 7.2. Accordingly, all amino acid molecules can be considered to exist virtually as zwitter ions in both solvents; hence, association or dissociation effects of ionic groups to $\phi_V°$ or $\phi_{KS}°$ must be trivial for water→aqueous urea transfer.

As noted above, the amino acids have *ca.* 4 molecules of hydrated water on an average, then how many water molecules hydrate the amino acids in 3 mol kg^{-1} urea-water mixtures? Since, for example, the value of $\overline{K}°$(urea)/$\overline{K}°$(water) for alanine is 0.6, it is estimated that it has 2.4 hydrated water molecules in the solvent. On the other hand, the value of $\Delta\overline{V}_{tr}°$ of alanine from water to the solvent was 1.25 cm^3 mol^{-1}; if it is supposed that this increment of volume is entirely due to the decrease in hydration in the solvent, the decrease in hydrated water molecules is 1.25/3=0.42, thus the alanine molecule has 3.6 water molecules in the solvent. Accordingly, the compressibility data gave the smaller hydration number than that derived from the vol-

ume data. Of these two values, 2.4 and 3.6, we consider that the former may be more correct, because the compressibility data are more directly related to hydration; the same relationship as for alanine was seen for the other amino acids studied. Thus, using the compressibility data as a measure of hydration, we tried to estimate the thickness of the empty volume between the amino acid and the solvent in 3 mol kg^{-1} urea solution, which is 0.57 Å in aqueous solution, from Eq. 9. The decrease in the thickness brings about the decrease in $\Delta\overline{V}_{tr}^{\circ}$, so seemingly the increase in hydration number in the solvent. The electrostriction E in Eq. 9 was modified by a factor $\overline{K}^{\circ}$(urea)/$\overline{K}^{\circ}$(water) of respective amino acid; the resulting electrostriction E' was used, together with σ_i and $\overline{V}^{\circ}$(urea), to calculate the thickness for each amino acid in the mixed solvent. As with σ_i values, the hydrogen-bonding effect of OH group of serine and threonine is still apparent in even 8 mol kg^{-1} urea solution as seen from Fig. 4, so the values in water were used. The results show that the thickness is 0.54±0.02 Å instead of 0.57 Å in water. Though more experimental studies must be necessary to draw a firm conclusion, the decrease in thickness by 0.03 Å on the average might be due to the lower structure in the mixed solvent broken by the presence of urea. In order to clarify the thermodynamics of amino acid solutions, similar studies in other mixed solvent media are in progress.

The authors wish to express their thanks to Professor Hiroyasu Nomura and Dr. Fumio Kawaizumi of Nagoya University for their helpful suggestion on making the improved ultrasonic interferometer.

Kinetic and Mechanistic Studies on the Kölbel-Engelhardt Reaction over an Iron Oxide Catalyst

Yasushi MIYATA, Masamichi AKIMOTO,* Nobukazu OOBA, and Etsuro ECHIGOYA
Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received August 2, 1983)

The yield and selectivity to hydrocarbons in the Kölbel-Engelhardt (KE) reaction over a Fe_2O_3 catalyst at 548—593 K under atmospheric pressure were as low as 0.6—2.2% and 2.0—3.8%, respectively, but the observed four characteristic features of the reaction, *i.e.*, the distribution of produced hydrocarbons following the Schulz-Flory plot, the decrease in propagation probability with increasing reaction temperature, nearly the same value of propagation probability irrespective of a great change in contact time of the reaction, and the remarkable decrease in the yield ratio of olefins to paraffins with increasing contact time of the reaction agreed with the common features of the synthesis of hydrocarbons by the Fischer-Tropsch reaction. The catalyst was composed of Fe_3O_4 with a low concentration of χ-type carbide (Fe_5C_2) during the KE reaction, and the results of the effect of contact time on the reaction revealed that formation of hydrocarbons took place following the water-gas shift (WGS) reaction. Furthermore, both the rates of formation of hydrocarbons in the reactions of carbided iron catalyst (Fe_5C_2) with H_2O and with H_2 at 573 K were smaller by a factor of >5 than the rate of formation of hydrocarbons in the KE reaction at a steady state at 573 K. Thus, it is concluded that a much greater portion of hydrocarbons produced in the KE reaction was *via* a sequential reaction pathway involving the WGS reaction followed by the Fischer-Tropsch reaction, not *via* the decomposition of carbided iron catalyst with H_2O and its reduction with H_2. Based on the observed increase in the catalytic activity of Fe_2O_3 upon addition of a small amount of such metal oxides as Cu, Pt, Co, Ni, and Rh oxides, the mechanical mixture of a WGS reaction catalyst and a Fischer-Tropsch reaction catalyst is proposed to be an effective catalyst for the production of hydrocarbons and one illustration of this view is presented.

The catalytic reaction of CO with H_2O to produce hydrocarbons and CO_2 is known as the Kölbel-Engelhardt (KE) reaction.[1] Recently, the KE reaction has received a great deal of attention as a process for the production of hydrocarbons from CO-rich synthesis gas, and the catalytic activity of Fe and Fe-based catalysts,[2-4] a RuY-zeolite catalyst[5] and supported Rh catalysts[6] has been investigated. However, the mechanism of the KE reaction has not been firmly established. There are two possible pathways by which the reaction may proceed. The first pathway involves the coupling of a WGS reaction and a Fischer-Tropsch reaction. The second possibility involves a reaction of H_2O with metal carbide or surface carbons to form hydrocarbons. Gustafson and Lunsford[5] indicated that the KE reaction over a RuY-zeolite catalyst by which only CH_4, CO_2, and H_2 were produced proceeds *via* a sequential reaction pathway involving the WGS reaction followed by the methanation reaction. While the first pathway is thus generally acceptable there are reports[7,8] which suggest that H_2O may react with metal carbide to form hydrocarbons in the KE reaction over Fe-based catalysts.

In the present work, we have mechanistically investigated the KE reaction over a Fe_2O_3 catalyst and have then discussed the promotional effects of Cu, Pt, Co, Ni, Cr, Rh, Ru, and Pd oxides on the catalytic activity of Fe_2O_3 in relation to the mechanism of the KE reaction.

Experimental

Reaction and Analysis The catalytic reaction of CO with H_2O was carried out at 548—593 K with a conventional flow fixed-bed reactor at atmospheric pressure. The reactor system comprised a 18-mm-i.d. Pyrex tube, 350 mm long, and a concentric thermowell. The reactor was heated with a cylindrical electric furnace. The catalyst was of powder-type, and Rasching rings (3×3 mm) were added above and below the catalyst bed. Research grade CO–Ar mixed gas (CO 90.2 vol%, Japan Oxygen Company, Ltd.) was used. It was fed into the reactor after bubbling through a H_2O-saturator held at a controlled temperature. The standard feed rate of the CO–Ar gas was 20 NTP cm^3 min^{-1} and the feed molar ratio of CO to H_2O was always 3. Purchased He and H_2 of greater than 99.99% purity were used without further purification. All reaction products were analyzed by gas chromatography. Two columns in series, 2.0 m of Porapak Q(383 K) and 1.5 m of Molecular sieve 5A(308 K), and hydrogen as the carrier gas were used for the analysis of CO, CO_2, Ar, and H_2O. Hydrogen, CH_4, and CO were analyzed by means of 2.0 m of Molecular Sieve 5A (323 K) with Ar as the carrier gas, and hydrocarbons were analyzed with a temperature-programmed FID system (Shimadzu GC-MINI 2, 333→473 K, Chromosorb 102 3.0 m).

Catalyst. A Fe_2O_3 catalyst was prepared following the method reported[9]: the $Fe(OH)_3$ cake obtained was dried at *ca.* 380 K in an electric oven for 24 h and was then calcined at 673 K in air for 6 h. X-Ray powder diffraction analysis revealed that Fe_2O_3 thus prepared was of α-type (hematite).[10] Its surface area determined by the conventional B.E.T. method was 28 m^2 g^{-1}. We also prepared metal oxide-promoted Fe_2O_3 catalysts and SiO_2-and Al_2O_3-supported metal oxide catalysts using an impregnation method. Metal oxide-promoted Fe_2O_3 catalysts were prepared by use of the Fe_2O_3 catalyst prepared above. Al_2O_3 employed as a carrier was JRC-ALO-4(60—80 mesh, 166—174 m^2g^{-1}), one of the referenced Al_2O_3 catalysts in the Catalysis Society of Japan.[11] SiO_2(32—60 mesh) as a carrier had a B. E. T. surface area of 200 m^2 g^{-1}. Metal nitrates were used as a catalyst resource for Cu, Co, Ni, and Cr oxides whereas metal chlorides were used similarly for Ru, Rh, and Pd oxides. These impregnated catalysts were then calcined at 673 K in air for 3 h. Supported Pt oxide catalysts were similarly prepared by use of $H_2PtCl_6 \cdot 6H_2O$. A CuO-ZnO catalyst (24 m^2 g^{-1}), a commercial catalyst for the WGS reaction, was prepared following the

method reported.[12]

Results

KE Reaction over Fe_2O_3. The characteristic feature of the KE reaction over Fe_2O_3 was first investigated. Non-pretreated Fe_2O_3 catalyst (15.0 g) was packed in the reactor and was heated to the reaction temperature after complete purging of air from the reactor with He at room temperature. Table 1 summarizes the steady-state catalytic activities of Fe_2O_3 in the KE reaction at 548, 573, and 593 K. These catalytic activities were obtained after a preliminary period of 4—5 h and the conversion of H_2O was always nearly 100% at these three reaction temperatures. The main products in the reaction were CO_2 and H_2, as reported previously.[2-4] The conversion of CO and the yield of hydrocarbons were 30.5 and 0.6% at 548 K, and the conversion increased to 45.2 and 67.5% with increasing reaction temperature from 548 K to 573 and 593 K but the yield of hydrocarbons still remained to be as low as 1.7% (selectivity=3.8%) and 2.2% (3.2%) at 573 and 593 K, respectively (Table 1). The equilibrium conversion of CO due to the WGS reaction calculated on the basis of thermodynamic data[13] is 32.7% at a (CO/H_2O) feed molar ratio of 3 at 600 K. Hence, the relatively great values of the conversion of CO, 45.2 and 67.5%, found at 573 and 593 K (Table 1) are probably caused by the occurrence of the Boudouard reaction($2CO \rightarrow CO_2+C$). On the other hand, the distribution of hydrocarbons produced by the KE reaction at these three reaction temperatures followed the Schulz-Flory plot† (Fig. 1, at 573 K). The values of propagation probability obtained are also summarized in Table 1. The propagation probability decreased with increasing reaction temperature (Table 1).

Table 1. Summary of the steady-state catalytic activity of Fe_2O_3 for the KE reaction[a]

Reaction temp/K	548	573	593
Conversion of CO/%	30.5	45.2	67.5

Propagation probability/—	0.66	0.48	0.38

a) Catalyst: Fe_2O_3 15.0 g, non-pretreated. Contact time: 311 g-catalyst·h·mol CO^{-1}. CO/H_2O feed molar ratio: 3. b) Hydrocarbons. C_2'=ethylene, C_2=ethane, C_3'=propylene, C_3=propane, C_n($n \geq 4$)=hydrocarbons having n carbon atoms in a molecule. c) Hydrocarbons having eight and more than eight carbon atoms in a molecule.

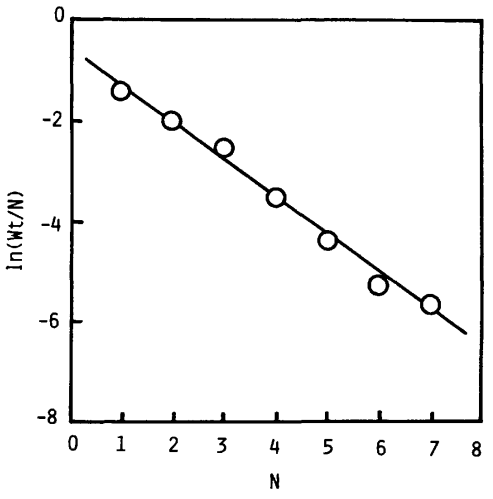

Fig. 1. Schulz-Flory plot for the hydrocarbons obtained at a steady state in the KE reaction at 573 K. Catalyst: Fe_2O_3 15.0 g, non-pretreated. Contact time: 311 g-catalyst·h·mol CO^{-1}. CO/H_2O feed molar ratio: 3.

The steady state of Fe_2O_3 during the KE reaction at a (CO/H_2O) feed molar ratio of 3 at 573 K was quenched by flushing the reactor with He. The result of X-ray powder diffraction analysis revealed that the quenched catalyst was composed of Fe_3O_4 (magnetite)[14] and Fe_5C_2 (χ-type carbide)[15] with a ratio of the strongest diffraction peak of 100:5.

Effect of Contact Time. Figure 2 shows the effect of contact time on the KE reaction over Fe_2O_3 at 573 K. At a contact time of 18.7 g-catalyst·h·mol CO^{-1} the yield of hydrocarbons was negligible although the conversion of CO was as high as 18.0%: both the yields of CO_2 and H_2 were nearly the same as the conversion of CO. However, formation of hydrocarbons was seen at 29.4 g-catalyst·h·mol CO^{-1} and the yield of hydrocarbons then increased with increasing contact time of the reaction to reach 2.8% at 562 g-catalyst·h·mol CO^{-1} (Fig. 2). The propagation probability calculated on the basis of the Schulz-Flory plot remained nearly constant at 0.47—0.49 at 573 K although the contact time changed greatly between 29.4 and 562 g-catalyst·h·mol CO^{-1}. In contrast, the ratio of the combined yield of $C_2H_4+C_3H_6$ to that of $C_2H_6+C_3H_8$ was 25.9, 9.4, and 0.5 at 29.4, 141, and 562 g-catalyst·h·mol CO^{-1}, respectively. Thus the ratio of the yield of olefins to that of paraffins decreased markedly with increasing contact time of the reaction.

Reaction of H_2O with Carbided Iron Catalyst. The reaction of H_2O with Fe_5C_2 was studied at 573 K. The

† Schulz-Flory plot

$$\ln \frac{W_t}{N} = N \ln P + \ln \frac{(1-P)^2}{P},$$

where N, P, and W_t are number of carbon atom in hydrocarbon molecule produced, propagation probability, and distribution (carbon weight fraction) of hydrocarbon molecule having N carbon atoms, respectively.

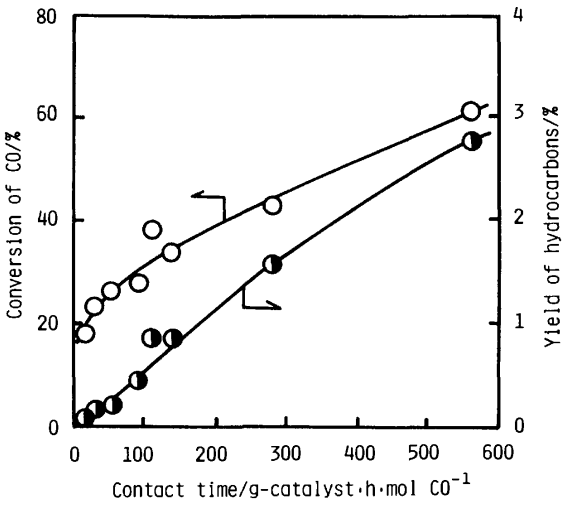

Fig. 2. Effect of contact time on the KE reaction at 573 K.
Catalyst: Fe_2O_3, non-pretreated. CO/H_2O feed molar ratio: 3.
○: Conversion of CO, ◑: Yield of hydrocarbons.

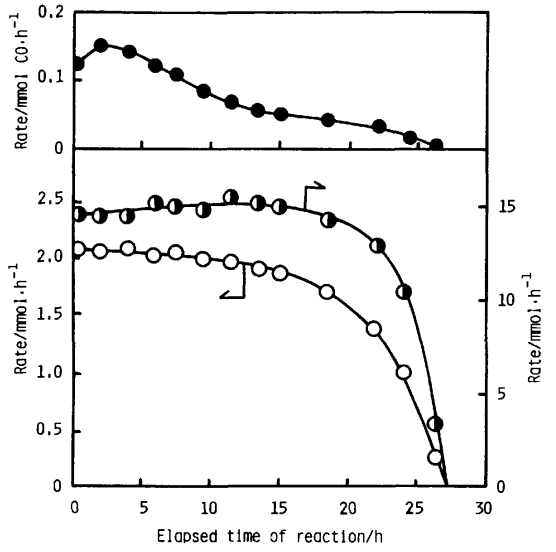

Fig. 3. Variation in the rates of H_2, CO_2, and hydrocarbon formations during the reaction of H_2O with carbided iron catalyst at 573 K.
Catalyst pretreatment: Fe_2O_3 (15.0 g) was carbided in a stream of CO-Ar(CO 90.2 vol%, 60 NTP cm^3 min^{-1}) at 573 K for 22 h.
Reaction with H_2O: Ar/H_2O feed molar ratio=3, Ar 20 NTP cm^3 min^{-1}.
○: Rate of CO_2 formation, ◑: rate of H_2 formation, ●: rate of hydrocarbon formation.

Fe_2O_3 catalyst (15.0 g) had been carbided in a stream of CO-Ar (CO 90.2 vol%, 60 NTP cm^3 min^{-1}) at 573 K for 22 h. The result of X-ray powder diffraction analysis revealed that the Fe_2O_3 catalyst was completely carbided to Fe_5C_2[15] by the above pretreatment. Figure 3 shows variation in the rates of formation of H_2, CO_2, and hydrocarbons with time during the reaction of H_2O with the carbided iron catalyst at 573 K. The rate of formation of hydrocarbons showed the maximum value (0.15 mmol $CO \cdot h^{-1}$) at 45 min, but it then decreased with time and reached negligible values within 27 h. The rates of formation of CO_2 and H_2 also showed a similar behavior (Fig. 3). Thus, the decomposition of Fe_5C_2 with H_2O at 573 K was completed within 27 h. It should be noted that the maximum rate of formation of hydrocarbons obtained in the reaction of H_2O with the carbided iron catalyst at 573 K was smaller by a factor of five than the rate of formation of hydrocarbons at a steady state in the KE reaction at 573 K (0.816 mmol $CO \cdot h^{-1}$, Table 1). The hydrocarbons formed in the reaction had the distributions similar to those of hydrocarbons produced in the KE reaction (Table 1) although the distribution of CH_4 in the former reaction was fairly greater than that in the latter reaction and although the yield of higher hydrocarbons was negligible in the former reaction (*i.e.*, C_1 47 wt%, C_2' 12 wt%, C_2 9 wt%, C_3' 16 wt%, C_3 7 w%, and C_4 9 wt% at 18 h). The result of X-ray powder diffraction analysis revealed that the carbided iron catalyst completely changed to Fe_2O_3 after the reaction with H_2O at 573 K for 27 h.

Table 2. Material balance for the reaction of H_2O with carbided iron catalyst at 573 K for 27 h[a]

Reactants and products	Amount/mol
H_2O fed	0.42
H_2O reacted	0.38
H_2 evolved	0.37
CO_2 evolved	0.061
Hydrocarbons formed	0.002[b]
Carbon in carbided iron catalyst	0.075[c]

a) Reaction conditions: see Fig. 3. b) Carbon atoms converted to hydrocarbons. c) Calculated as Fe_5C_2 in atom unit.

The material balance for the reaction of H_2O with the carbided iron catalyst at 573 K for 27 h (Fig. 3) is presented in Table 2. The amount of oxygen caught by the carbided iron catalyst was 0.38—0.061×2=0.26 atoms, which is nearly equal to the amount of oxygen contained in 15.0 g of Fe_2O_3 (0.28 atoms). Similarly, the amount of CO_2 evolved (0.061 mol) was nearly equal to that of carbon previously existed in the Fe_5C_2 (0.075 atoms), and the ratio of the amount of H_2 evolved to that of CO_2 evolved was 0.37/0.061=6.0. The total yield of hydrocarbons was as low as (0.002/0.075)×100 =3% (Table 2).

Reduction of Carbided Iron Catalyst with H_2. The Fe_2O_3 catalyst (15.0 g) had similarly been carbided in a stream of CO-Ar at 573 K for 22 h, and the carbided iron catalyst obtained was then reduced at 573 K in a stream of H_2-Ar (H_2 33.3 vol%, 30 NTP cm^3 min^{-1}). The main product in the reaction was CH_4. Although formation of C_2H_4, C_2H_6, and C_3H_6 was seen at the initial stages of the reaction, the yield of these hydrocarbons was as low as 0.05, 0.5, and 0.6%, respectively, of the yield of CH_4. The rate of formation of hydrocarbons in the reduction experiment at 573 K was 0.22,

0.19, and 0.12 mmol $CO \cdot h^{-1}$ at 10, 30, and 60 min, respectively. These three values were much smaller than the rate of formation of hydrocarbons observed in the KE reaction at a steady state at 573 K (0.816 mmol $CO \cdot h^{-1}$, Table 1).

Effect of Pretreatment of Catalyst. The effect of pretreatment of Fe_2O_3 on its catalytic activity for the KE reaction was studied. When the catalyst had been reduced at 573 K in a stream of CO–Ar (CO 90.2 vol%, 60 NTP $cm^3\ min^{-1}$) for 23 h, the conversion of CO, the yield and selectivity to hydrocarbons were 64.4, 3.1, and 4.8%, respectively, at 30 min (Table 3). These values are clearly greater than those observed at a steady state in the KE reaction over the non-pretreated Fe_2O_3 catalyst (Table 1). The decrease in catalytic activity of the prereduced Fe_2O_3 with time (Table 3) was probably caused by the reoxidation of the catalyst with H_2O. Similarly, the catalytic activity of Fe_2O_3 was much more greatly enhanced by the pretreatment with CO and H_2 (Table 3). The X-ray diffraction pattern of the catalyst prereduced with CO and H_2 could not be measured because the reoxidation took place in atmosphere.

Promotional Effect of Metal Oxides. The activity of metal oxide-promoted Fe_2O_3 catalysts for the KE reaction was monitored at 573 K (Table 4). When the Fe_2O_3 catalyst had been promoted by oxides of Cu, Pt, Co, and Ni, the conversion of CO, the yield and selectivity to hydrocarbons fairly increased although the distribution of hydrocarbons formed remained nearly unchanged. In contrast, the catalytic activity of Fe_2O_3 rather decreased when it had been promoted by oxides of Cr, Rh, Ru, and Pd. Unlike Cr, Ru, and Pd oxides, however, Rh oxide was able to enhance the yield and selectivity to hydrocarbons markedly (Table 4). Since the Fe_2O_3 catalyst impregnated with HCl (0.7 wt%) showed a negligible activity for the KE reaction at 573 K (conversion of CO=1.6%, yield of hydrocarbons =0%), the extremely low catalytic activity of the Fe_2O_3 promoted by oxides of Rh, Ru, and Pd (Table 4) can be attributed to the presence of Cl^- in these catalysts (See preparation of catalyst).

The catalytic activity of SiO_2-supported Cu, Pt, Co, Ni, Cr, Rh, Ru, and Pd oxides for the KE reaction was similarly monitored at 573 K (Table 5). The catalysts had been reduced at 573 K in a stream of H_2 (20 NTP $cm^3\ min^{-1}$) for 3 h because the metal oxide-promoted Fe_2O_3 catalysts were exposed to H_2 at 573 K formed via the WGS reaction during the KE reaction. The main products in the reaction were CO_2 and H_2, and with the exception of the catalytic results for the supported Co and Ni oxides both the yields of CO_2 and H_2 were nearly equal to the conversion of CO. Thus, only the supported Co and Ni oxide catalysts were able to produce hydrocarbons whereas the other supported metal oxide catalysts promoted

Table 3. Effect of various pretreatments on the catalytic activity of Fe_2O_3 in the KE reaction at 573 K[a]

Pretreatment	CO[b]		CO and H_2[c]

a) Catalyst: M_xO_y-SiO_2 15.0 g, previously reduced in a stream of H_2 (20 NTP cm^3 min^{-1}) at 573 K for 3 h. Contact time: 311 g-catalyst·h·mol CO^{-1}. CO/H_2O feed molar ratio: 3. The catalytic activity was determined after a preliminary period of 20 min. b) Hydrocarbons. The other products were CO_2 and H_2.

only the WGS reaction (Table 5). The observation of the relatively great catalytic activities of the supported Pt and Cu oxide catalysts for the WGS reaction agrees with the previous results reported.[16] Hence, one could say that Pt and Cu oxides have a relatively great ability to catalyze the WGS reaction whereas Co and Ni oxides are able to catalyze both the WGS and the KE reactions. No formation of hydrocarbons over the SiO_2-supported Rh oxide catalyst is attributable to its fairly low catalytic activity for the WGS reaction as seen in the extremely low conversion of CO (Table 5).

Discussion

We first discuss the mechanism of the KE reaction over iron-based catalysts. Although the yield and selectivity to hydrocarbons in the KE reaction at 548—593 K were as low as 0.6—2.2% and 2.0—3.8%, respectively (Table 1), the observed four characteristic features of the reaction, *i.e.*, the distribution of produced hydrocarbons following the Schulz-Flory plot, the decrease in propagation probability with increasing reaction temperature, nearly the same value of propagation probability irrespective of the great change in contact time of the reaction, and the remarkable decrease in the yield ratio of olefins to paraffins with increasing contact time of the reaction (Table 1, Figs. 1 and 2) well agree with the common features of the synthesis of hydrocarbons by the Fischer-Tropsch reaction reported. The findings that only the WGS reaction took place at sufficiently small contact times of the KE reaction and that formation of hydrocarbons became to be observable at a relatively great contact time of the reaction (Fig. 2) suggest that the KE reaction over Fe_2O_3 proceeds *via* a sequential reaction pathway involving the WGS reaction followed by the hydrogenation of CO to hydrocarbons.

Formation of hydrocarbons by the reaction of carbided iron catalysts with H_2O was already found.[7,8] Based on this finding the mechanism of the KE reaction over iron oxide catalysts was proposed in which hydrocarbons are formed via a direct reaction of H_2O with iron carbide.[7] However, the two findings made in the present work, *i.e.*, the low rate of formation of hydrocarbons in the reaction of H_2O with carbided iron catalyst at 573 K as compared with the rate of formation of hydrocarbons in the KE reaction over Fe_2O_3 at a steady state at 573 K (Fig. 3) and the very low concentration of Fe_5C_2 in the catalyst during the KE reaction at 573 K (See Results section) do not support the mechanism of the KE reaction reported.[7] Since the ratio of the total yield of H_2 to that of CO_2 in the reaction of the carbided iron catalyst with H_2O at 573 K was 6.0 and since the total yield of hydrocarbons in the reaction was as low as 3% of the amount of carbon existed in the carbided iron catalyst (Table 2), we believe that the reaction of the carbided iron catalyst (Fe_5C_2) with H_2O proceeds preferentially in the following reaction scheme:

$$2Fe_5C_2 + 23H_2O \longrightarrow 5Fe_2O_3 + 23H_2 + 4CO_2. \quad (1)$$

On the other hand, both the selective formation of CH_4 in the reduction of the carbided iron catalyst with H_2 at 573 K and the low rate of CH_4 formation as compared with the rate of formation of hydrocarbons observed in the KE reaction at a steady state at 573 K (See Results section) do not support the view that the C_2 and higher hydrocarbons obtained in the KE reaction were produced *via* a reduction of the carbided iron catalyst with H_2 formed by the WGS reaction. Although a very little portion of hydrocarbons produced in the KE reaction was caused by the decomposition of Fe_5C_2 by H_2O and by the hydrogenation of Fe_5C_2 and/or carbons[6,17] deposited on the catalyst surface, we may conclude that a much greater portion of hydrocarbons produced in the KE reaction was via a sequential reaction pathway involving the WGS reaction followed by the Fischer-Tropsch reaction. This mechanism of the KE reaction over Fe_2O_3 agrees with that reported for a RuY-zeolite catalyst.[5] The observed increase in the yield of hydrocarbons with increasing the degree of reduction of Fe_2O_3 (Table 3) suggests the role as the active sites played by the zerovalent iron atoms and/or metallic irons for the catalytic hydrogenation of CO to hydrocarbons. Based on these findings made in the present work, we propose the following catalytic cycle during the course of the KE reaction over Fe_2O_3.

$$Fe_3O_4 + 4CO \longrightarrow 3Fe + 4CO_2 \quad (2)$$

$$3Fe + 4H_2O \longrightarrow Fe_3O_4 + 4H_2 \quad (3)$$

$$5Fe + 4CO \longrightarrow Fe_5C_2 + 2CO_2 \quad (4)$$

$$3F_5C_2 + 32H_2O \longrightarrow 5Fe_3O_4 + 6CO_2 + 32H_2 \quad (5)$$

$$n\mathrm{CO} + 2n\mathrm{H_2} \xrightarrow{\mathrm{Fe}} -(\mathrm{CH_2})_n- + n\mathrm{H_2O} \quad (6)$$

We now discuss the promotional effect of metal oxides on the catalytic activity of Fe_2O_3 in the KE reaction. The observed increase in the yield and selectivity to hydrocarbons upon addition of Cu and Pt oxides to Fe_2O_3 which were able to catalyze the WGS reaction (Tables 4 and 5) supports the mechanism of the KE reaction over Fe_2O_3 proposed in the present work. Since the cat-

alytic activity and selectivity of Fe_2O_3 for the KE reaction were also enhanced by the addition of Co, Ni, and Rh oxides which were able to catalyze the hydrogenation of CO to hydrocarbons (Tables 4 and 5), one could say that the mechanical mixture of two catalysts one of which has an ability to promote the WGS reaction and the another has an ability to promote the hydrogenation of CO to hydrocarbons is an effective catalyst for the production of hydrocarbons by the KE reaction. One illustration of this view is presented in Table 6. Here, CuO-ZnO was used as a catalyst for the WGS reaction whereas Al_2O_3-supported Ni (5 wt%) and SiO_2-supported Co (5 wt%) were used as catalysts for the hydrogenation of CO to hydrocarbons. In the case of CuO-ZnO+Ni-Al_2O_3 catalyst, the yield and selectivity to hydrocarbons at 573 K, 13.8 and 24.1%, are much greater than those observed over Fe_2O_3 at 573 K (Table 1) although the distribution of CH_4 in the hydrocarbons produced was as high as 77 wt% and that of C_2H_4 was only 0.2 wt%. A similar increase in the yield and selectivity to hydrocarbons was also seen in the case of CuO-ZnO+Co-SiO_2 catalyst (Table 6).

ENDOR Study of Benzothiazolone Azine Cation Radicals by Means of a TM_{110} Mode Cavity

Javier LOPEZ,† Jun YAMAUCHI,* Keiichi OKADA, and Yasuo DEGUCHI
College of Liberal Arts and Sciences, Kyoto University, Sakyo-ku, Kyoto 606
(Received August 3, 1983)

The electron nuclear double resonance (ENDOR) spectra of benzothiazolone azine cation radicals were observed by means of an ENDOR spectrometer equipped with a TM_{110} mode cavity. Highly diluted solutions of the radicals and a high radiofrequency power of 300 W facilitated the ENDOR observation. The obtained ENDOR values are different from the previously published results determined only from the ESR data, especially for the substituted alkyl groups. The assignment of the hyperfine coupling constants was made on the basis of the molecular orbital calculations as well as the re-examination of the ESR spectrum simulation. Good agreement between the calculated and the measured spectra is obtained if one assumes that the hyperfine coupling constants of the two different sets of nitrogen nuclei are equal as has been pointed out earlier.

Benzothiazolone azine and similar systems are well-known as two-step redox systems.[1] One can see easily from Fig. 1 that the intermediate compound B is a radical species. Hünig *et al.*[2] tried to observe ESR spectra of the benzothiazolone azine cation radicals, but no well-resolved ESR spectra could be obtained. As far as we know, no further ESR experiments have been performed to obtain more knowledge about spin density distributions in these systems. Recently well-resolved ESR spectra were obtained by means of a cylindrical TE_{011} mode cavity and spectral simulations were carried out.[3] No ENDOR spectra, however, could be observed successfully with the same type of ENDOR cavity. The nitrogen nucleus causes a short relaxation time due to the quadrupole moment. It is, therefore, very difficult to saturate the ESR transition of the radical containing the nitrogen nucleus although this is needed for performing ENDOR spectroscopy.

Möbius *et al.*[4] developed a TM_{110} mode cavity several years ago. The TM_{110} mode cavity allows one to apply higher radiofrequency power than the TE_{011} mode cavity does. In addition, the direction of the magnetic field of the radiofrequency is the same as that of the sample tube. The TM_{110} mode cavity, therefore, is more appropriate for the application of the ENDOR spectroscopy to systems which become saturated only with difficulty, like benzothiazolone azine cation radicals. This advantage was utilized for ^{14}N ENDOR observation of di-*t*-butyl nitroxide, which is not saturated easily, presumably because of a quadrupole moment and high freedom of molecular motions.[5]

The assignment and analysis of the coupling constants and ESR spectra in the work published previously[3] were mainly performed by means of MO calculations: Hückel and McLachlan method.[6,7] As is mentioned in that work, the obtained results are not necessarily final and conclusive ones. Successful application of ENDOR spectroscopy can help to confirm the calculated data and the conclusions in the published work.

Experimental

The synthesis of 2(3-alkyl)-benzothiazolone azine is described elsewhere.[1,3] The cation radicals of $\mathbf{1}^{+}$, $\mathbf{2}^{+}$, and $\mathbf{3}^{+}$ (Fig. 2) can be obtained by oxidation of the neutral compound with lead tetraacetate in various kinds of solvents. In our case, the oxidation of the neutral precursor was performed in an evacuated sealed sample tube using dichloromethane as a solvent. The previously published ESR spectra were observed in acetone at 295 K. Acetone was found to be inappropriate for ENDOR observation since it has a higher polarity than dichloromethane. Polar solvents can be disadvantageous for the ENDOR spectroscopy, since they cause lower *Q*-values for the cavity.

The ESR spectra of $\mathbf{1}^{+}$, $\mathbf{2}^{+}$, and $\mathbf{3}^{+}$ were recorded with a JEOL ES-EDX2, FE 3X spectrometer equipped with a cylindrical TE_{011} mode cavity. The observed ESR spectra show an observable temperature dependence, which is probably caused by the molecular motions of the benzothiazolone groups with respect to the inter-nitrogen bond as well as those of methyl and ethyl groups attached to the nitrogen atoms. The anisotropic effects of the nitrogen and the sulfur atoms may also be responsible. The ESR spectrum of $\mathbf{1}^{+}$ is not perfectly symmetric around the center. This is also attributed to the molecular motions and the anisotropic effects. The displayed ESR spectra in Figs. 3—5 were observed in an extremely diluted acetone solution

of the corresponding cation radicals, which had been isolated and purified several times. The ESR spectra when ENDOR was observed were rather less resolved because the oxidation reaction was performed in the sample tube under high vacuum and because ESR observation was made

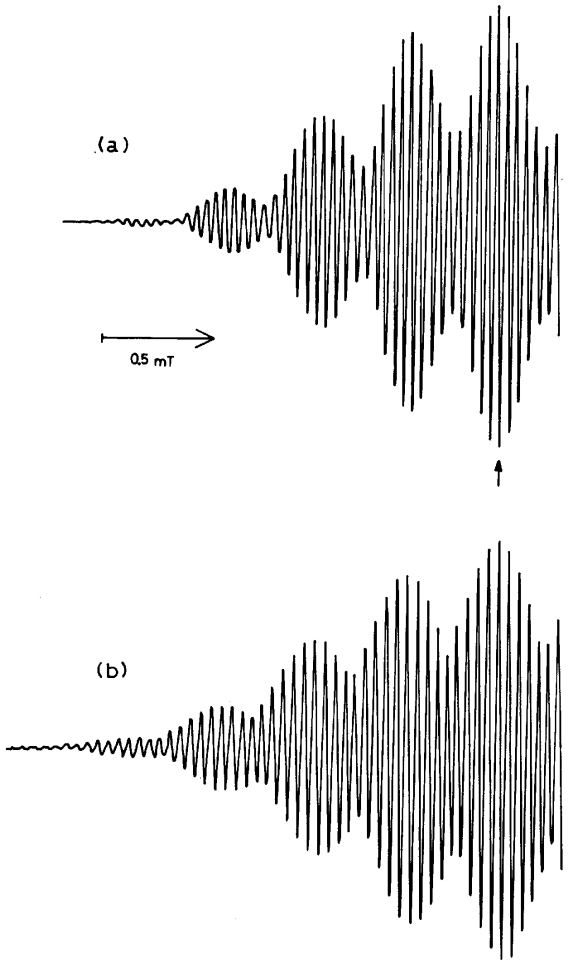

Fig. 4. The ESR and the simulated spectra of $\mathbf{2}^{+}$. The ESR spectrum (a) is recorded in acetone at 295 K.

with an 80 Hz field modulation in a cylindrical TM_{110} mode cavity. Good agreement of the calculated and the original spectra were obtained for $\mathbf{1}^{+}$, $\mathbf{2}^{+}$, and $\mathbf{3}^{+}$ on the basis of the MO data and the hyperfine coupling constans determined from the ENDOR, as is shown in Figs. 3—5. The hyperfine coupling constants were calibrated by using an alkaline solution of a nitrosyl bis(sulfate) ion. The original ESR spectra were recorded with a 100 kHz field modulation in acetone at 295 K, whereas in ENDOR an 80 Hz field modulation was employed.

The ENDOR spectra (Fig. 6) were observed by means of the TM_{110} mode cavity under the following conditions: microwave power 50 mW, radiofrequency power 300 W (ENI-type A300 power amplifier), field modulation 80 Hz, modulation amplitude 0.1 mT, and FM modulation of radiofrequency 2.5 kHz. For the ENDOR spectroscopy, a more diluted (nearly colorless) solution than that for the ESR spectroscopy had to be used. No ENDOR spectra could be obtained in the same concentration which produced the best ESR. The best ENDOR spectra were observed at 223 K. In Table 1 the hyperfine coupling constants of $\mathbf{1}^{+}$,$\mathbf{2}^{+}$, and $\mathbf{3}^{+}$ are listed.

Discussion

One can see from the ENDOR values in Table 1 that the hyperfine coupling constants of $\mathbf{1}^{+}$, $\mathbf{2}^{+}$, and $\mathbf{3}^{+}$

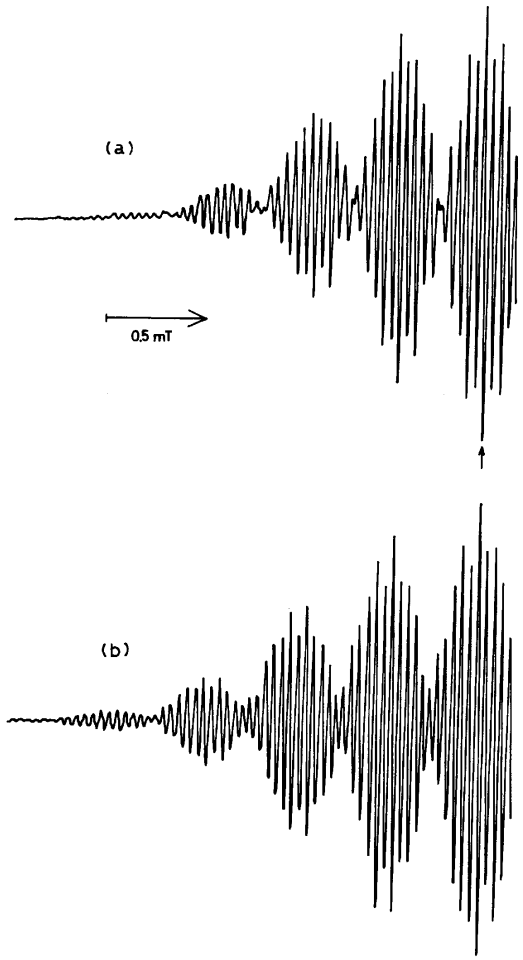

Fig. 5. The ESR and the simulated spectra of $\mathbf{3}^{\dagger}$. The ESR spectrum (a) is recorded in acetone at 295 K.

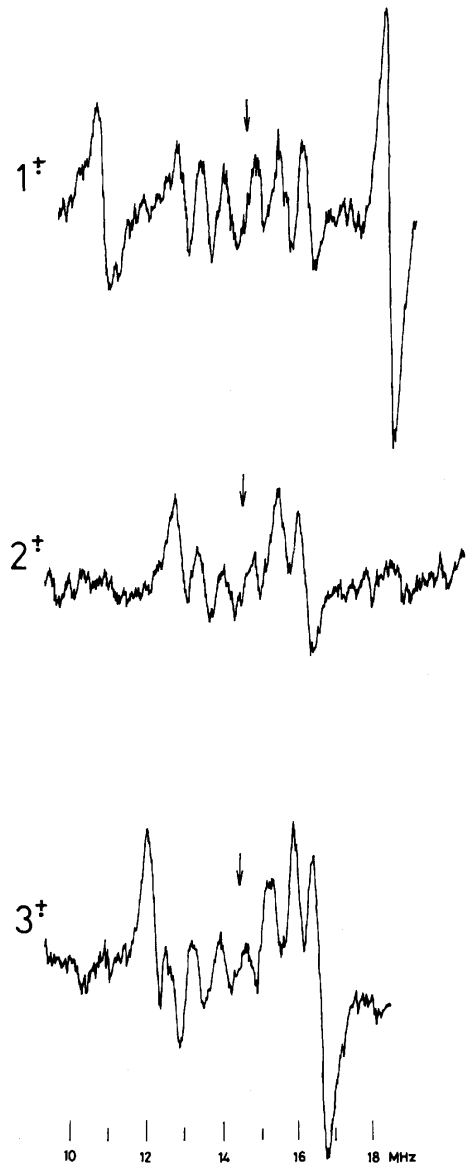

Fig. 6. The ENDOR spectra obtained in dichloromethane at 223 K. The arrow indicates the free proton frequency.

are very similar, except for the biggest value due to the protons of the alkyl substituent. This means that these coupling constants are very weakly influenced by the different alkyl substituents. The following procedure was chosen for the assignment of the coupling constants. The hyperfine coupling constants of the methyl protons in $\mathbf{1}^{\dagger}$ can be easily assigned, since the ENDOR signals in the spectrum of $\mathbf{1}^{\dagger}$ at 10.63 and 18.18 MHz disappear in the spectrum of $\mathbf{2}^{\dagger}$. These signals also do not appear in the spectrum of $\mathbf{3}^{\dagger}$ in which another pair of absorption lines appears instead. Thus, the biggest proton coupling constants 0.268 and 0.154 mT can be assigned to the methyl protons and the methylene protons of the ethyl groups, respectively. Then, the remanining coupling constants must be assigned to the ring protons of the two benzo moieties. There are four different sets of the ring protons, but the recorded ENDOR spectra for all systems show only three different values for the ring protons. One can, therefore, conclude either that the missing coupling constant must be less than the line width (*ca.* 0.015 mT) or that two coupling constants have similar values so that their absorption lines are not resolved. The best calculated spectra are obtained if one assumes that the missing coupling constant is almost the same as the smallest of the three. Hückel and McLachlan methods for the calculation of spin density, as is discussed later, predict the same conclusion. This is also compatible with the ESR simulation. Thus, the smallest coupling may be assigned to two kinds of equivalent protons, so that one has three different sets of the ring protons out of four equivalent proton groups.

The assignment of the coupling constants to the ring protons was made on the basis of the MO data obtained from the Hückel and McLachlan methods. The π-electron MO calculation of benzothiazolone azine framework was discussed in detail in the previous paper.[3] We employed the same MO parameters and no further modification was made. The results are shown in Table 1, where the proton hyperfine coupling constants are also estimated using the

McConnell equation[8] with a proportionality constant $|Q|=2.1$ mT. By comparing the ENDOR results with those arrived at previously from the ESR study,[3] the following conspicuous facts are revealed: 1) the alkyl protons have much larger coupling constants (almost two times bigger) than those from the ESR data[3]; 2) ENDOR shows slightly bigger coupling constants of the ortho protons ($H_{3,3'}$) of the two benzo moieties and slightly smaller ones of the two meta protons ($H_{4,4'}$ and $H_{6,6'}$), while in the para protons ($H_{5,5'}$) the constants have almost the same value; 3) in conjunction with fact 1), one has to take into account the deuteron hyperfine coupling constant, which was neglected in the previous work.[3] After we consider the reliability of proton ENDOR, we re-examined the spectral simulation of the ESR on the basis of the coupling constants determined from the ENDOR. First, the big nitrogen hyperfine coupling constants are again confirmed: these constitute the fundamental group pattern of the ESR spectra, as is discussed in the literature.[3] Next, by changing the proton coupling constants little by little from the ENDOR values, as well as changing the deuteron coupling constant starting from 0.041 mT predicted from $A_D/A_H=1/6.51437$[9] where $A_H=0.268$ mT of the methyl protons, an acceptable set of the hyperfine coupling constants for each compound is obtained; these are shown in Table 1. Figures 3—5 are comparisons between the experimental and the simulated spectra. The newly determined values do not deviate from the ENDOR values as much as 0.03 mT. Such agreement is rather satisfactory, considering the fact that the ESR spectra were recorded under different conditions (*e.g.* different temperature and solvent) for the best resolution.

The ESR simulations in this paper are more reliable than the previous ones, because the ENDOR results are taken into account this time. Again, the equivalent hyperfine coupling constants could be assigned to the thiazolone and the bridged nitrogen atoms. This may support the validity of the choice of the MO parameters in the previous paper.[3] Agreement between the experimental and the theoretical proton hyperfine coupling constants at the ring positions are also excellent, except for the para positions ($H_{5,5'}$). The McLachlan calculation predicts a quite small difference between the ortho ($H_{3,3'}$) and para ($H_{5,5'}$) protons. The deuteron coupling constants is taken into consideration this time and found to be 0.0435 mT, giving $A_D/A_H=1/6.8$. From the methyl coupling constant 0.298 mT, 0.0456 mT is expected theoretically.[9]

Next, we comment about the R-substitution effect. The alkyl substitution never has a severe effect on the unpaired electron distribution, as was said in the first section of this discussion. However, the spectrum itself is influenced dramatically because of the big spin density at the nitrogen atoms to which the alkyl groups are attached. There are a lot of data for the nitrogen and the methyl or ethyl proton hyperfine coupling constants where the alkyl groups are attached directly to the nitrogen atom.[10-12] For the nitrogen and methyl protons, the same order of magnitude of the couplings are commonly observed.[12] In this work, however, the methyl hyperfine coupling constant is reduced to 75%, as compared to the nitrogen value. This may be caused by the deformed bond angle around the nitrogen atom in the thiazolone ring. On the other hand, the relation in magnitude between the methyl and the ethyl coupling constants is as usual, *i.e.* the methylene protons of the ethyl have sometimes *ca.* 50% of the methyl coupling constants.[12]

Two similar systems (**4** and **5** in Fig. 2) were investigated some years ago.[2] They do not contain sulfur but non-π part, $>C(CH_3)_2$, is introduced in the sulfur position of the compounds **1**—**3**. Therefore, the π-system does not extend over the five-membered rings, as in **1**—**3**. The ESR spectrum of 5^+ could not be analyzed, since it showed a poor resolution. A comparison of the calculations for 1^+-3^+ and 4^+-5^+ shows a similar behavior. The large spin densities are greatly delocalized in the ortho and para, and less delocalized in the meta positions, both for 1^+, 2^+, 3^+, and for 4^+, 5^+. The Hückel and McLachlan methods give inequivalent spin densities for the two different sets of nitrogen nuclei in 5^+, $A_{N1}/A_{N10}=1.4$.[3] This is also the case for 1^+, 2^+, and 3^+ when the proposed set of the MO parameters is used. In 4^+ the nitro-

gen and the vinyl protons have the same coupling constant. This, however, does not mean that the same spin densities are located on these nuclei. The nitrogen coupling constant in $\mathbf{4}^{\dagger}$ differs only by 0.021 mT from that in $\mathbf{1}^{\dagger}$, $\mathbf{2}^{\dagger}$, $\mathbf{3}^{\dagger}$. Nevertheless, the coupling constants of the methyl protons do not have similar values. These inconsistencies certainly suggest the necessity of the ENDOR experiments in the two above-mentioned systems. A common feature of all systems ($\mathbf{1}^{\dagger}$ through $\mathbf{5}^{\dagger}$) is that about 70% of the spin density is located on the atom sequence >N-C=N-N=C-N< and only a small amount is located on the two benzo moieties.

Some concluding remarks should be made about the TM_{110} mode cavity. The application of this cavity has not yet been widely extended after its development.[4] The collected experience with this cavity shows that it offers a better resolution in the ENDOR spectroscopy than the TE_{011} mode cavity and it also allows one to observe much more easily nitrogen ENDOR.[5] However, we did not succeed till now in detecting the nitrogen ENDOR for the present series of compounds. This may be due to the properties of the bobbin with which the radiofrequency signal is transmitted to the cavity.

Kinetic Studies of the Complex Formation in the System of Cyclodextrin, Iodine, and Iodide

Takayuki SANO, Masako YAMAMOTO,† Hiroka HORI, and Tatsuya YASUNAGA*
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
†Department of Home Economics, Hiroshima Women's University, Hiroshima 734
(Received August 4, 1983)

Kinetic studies of complex formation in the system consisting of cyclodextrin, iodine, and iodide have been made by the temperature-jump method. By addition of α-cyclodextrin to the iodine–iodide solution, a new relaxation in addition to that due to I_6^{2-}, formation was observed, but not in the case of addition of β-cyclodextrin. The reciprocal relaxation time is independent of the iodine concentration, but increases with increase of both iodide and α-cyclodextrin concentration, with a tendency to reach a constant value at their high concentrations. From these concentration dependences of the relaxation time, the observed relaxation was assigned to the conformational change of the complex between α-cyclodextrin and iodide ion, and the rate constants were estimated to be 5.9×10^5 and 1.2×10^5 s^{-1} for the forward and backward processes, respectively. A rationalization for the difference between α-cyclodextrin and β-cyclodextrin in this complex formation is proposed in terms of the molecular structure of cyclodextrin.

The cyclodextrins are well known for their ability to form inclusion complexes with a variety of guests,[1–3] and the main driving forces of the complex formation have been attributed to hydrogen bonding,[4] hydrophobic interaction,[5] and van der Waals forces[6] depending on the nature of the guest molecules. Kinetic studies[7–9] of the inclusion complex formation of cyclodextrin have revealed the importance of the conformational change of cyclodextrin and the breakdown of the water structure around guest substances. However, the details of the reaction mechanism are still obscure especially with respect to the effect of the structure of cyclodextrin.

Meanwhile, Noltmeyer and Saenger[10] have reported that the α-cyclodextrin–iodine complex has the same structure as the amylose–iodine complex. This fact motivated us to start some kinetic studies of the complex formation of the cyclodextrin with iodine in connection with our previous studies on the amylose–iodine complex formation.[11] In the preliminary temperature-jump experiment, an addition of α-cyclodextrin to the iodine–iodide solution gives rise to new relaxation besides that which was observable without cyclodextrin.[12] The present work was undertaken to clarify the mechanism of the new relaxation with use of both α- and β-cyclodextrins.

Experimental

Materials. The α- and β-cyclodextrins were purchased from Nakarai Co., and used as received. Iodine and potassium iodide were of reagent grade and used without further purification.

Measurements. Kinetic measurements were carried out by a temperature-jump method[13] with detection of transmittance at 500 nm which corresponds to the absorption band of iodine. The ionic strength of the solution was kept at 0.023 M†† to attain a rapid temperature rise within 0.75 μs. Spectrophotometric measurements were made on a Union Giken SM-401 spectrophotometer. All the experiments were carried out at 25 °C.

†† 1 M=1 mol dm^{-3}.

Results and Discussion

A typical relaxation curve observed in a solution containing α-cyclodextrin, iodine, and iodide is shown in Fig. 1. This relaxation becomes predominant with increase of α-cyclodextrin concentration, and is obviously different from that observed in the iodine–iodide solution in both the relaxation time and the direction of the relaxation signal.[12] The present relaxation spectra show a decrease of iodine concentration and was characterized by a single relaxation. In order to simplify the analysis, the kinetic experiments were undertaken by changing the concentration of one species while keeping those of the other two constant. The plots of the reciprocal relaxation time, τ^{-1} against the total concentration of α-cyclodextrin, iodine, and iodide are shown in Figs. 2, 3, and 4. As shown in these figures, the value of τ^{-1} increases with concentration of α-cyclodextrin and iodine, showing a trend to level off at high concentration, but it is independent of that of iodine. In contrast to the α-cyclodextrin, the addition of β-cyclodextrin to the iodine–iodide solution did not give rise to any new re-

laxation, which is indicative of the specificity of the present relaxation to α-cyclodextrin.

In the solution containing the α-cyclodextrin, iodine, and iodide, according to the investigations reported so far,[7,13-15] the following reactions are at least expected to proceed,

$$I^- + I_2 \rightleftharpoons I_3^- \qquad K_I, \qquad (I)$$

$$2I_3^- \rightleftharpoons I_6^{2-} \qquad K_{II}, \qquad (II)$$

$$CD + I^- \rightleftharpoons CDI \qquad K_{III}, \qquad (III)$$

where CD and CDI denote the free α-cyclodextrin and the complex of α-cyclodextrin and iodide, respectively. Among these three reactions, the relaxations due to the reactions I and II, which are much faster than the present relaxation, have been already investigated kinetically by the temperature-jump method.[13,14] As for the reaction III, the kinetic studies have not been performed successfully because of the existence of relaxation due to the conformational change of α-cyclodextrin.[7] Accordingly, we first examined reaction III, and also the complex formations of α-cyclodextrin with I_2, I_3^-, or I_6^{2-} as origin of the present relaxation, but failed to explain all the concentration dependences of the relaxation time in Figs. 2, 3, and 4. By reference to the concentration dependence of relaxation time in Figs. 2 and 3 specific to the intramolecular process following the fast binding pro-

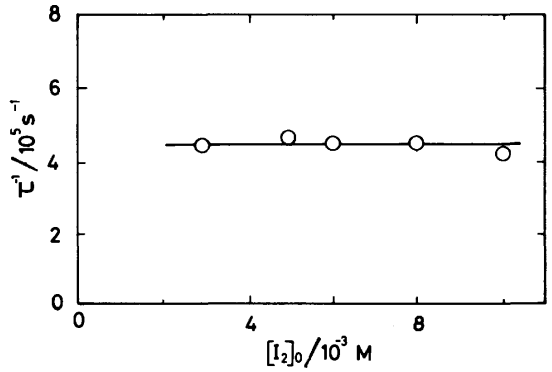

Fig. 4. Dependence of the reciprocal relaxation time on the iodine concentration at constant $[KI]=2.3\times10^{-2}$ M and $[\alpha\text{-CD}]=4.0\times10^{-3}$ M at 25 °C.

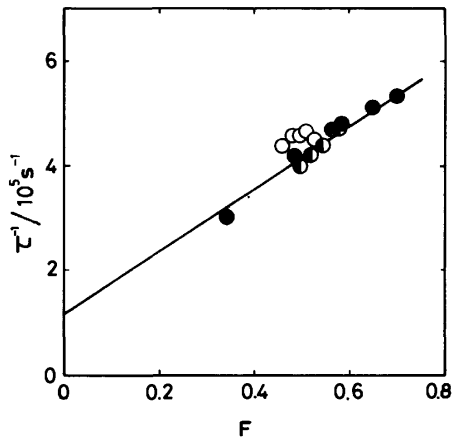

Fig. 5. Plots of τ^{-1} *vs.* the concentration term F in the Eq. (1). The circles correspond to those in Figs. 2, 3, and 4.

cess, we analyzed the kinetic data with the reaction scheme as follows:

$$CD + I^- \overset{K_1}{\rightleftharpoons} CDI' \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} CDI''. \qquad (IV)$$

This reaction is a modification of reaction III and the binding process of iodide ion to α-cyclodextrin is followed by the intramolecular process of the complex. If the reactions I and II and the first step of reaction IV are faster than the second step, the relaxation time for the second step can be finally represented by

$$\tau^{-1} = k_2F + k_{-2}, \qquad (1)$$

with

$$F = \frac{K_1[CD + I^-(1 + K_1(I^- + I_2 + CD))]}{K_1[CD + I^-(1 + K_1(I^- + I_2 + CD))] + 1}. \qquad (2)$$

The derivation of this equation will be described in the appendix section. The value of K_1, 2.1±0.3 M^{-1}, was determined so as to obtain a best linear relationship between the observed τ^{-1} and the concentration term F, in the Eq. 1. The final results are shown in Fig. 5. The values of k_2, $(5.9\pm0.5)\times10^5$ s^{-1}, and k_{-2}, $(1.2\pm0.5)\times10^5$ s^{-1}, were obtained from the slope and intercept of the straight line, respectively. Using

these values of K_1 and $K_2=k_2/k_{-2}$, the overall binding constant of reaction IV, $K_{IV}=K_1(1+K_2)$, was found to be 13±2 M^{-1}. The good agreement of this value with the binding constant obtained statically by the conductometric method (12.4 M^{-1})[15] gives proof of the validity of an assignment of the present relaxation to reaction IV. Furthermore, it was recognized from the spectrophotometric experiments that the addition of α-cyclodextrin to the iodine–iodide solution results in the increase in I_2 concentration and the decrease in I_3^- concentration in solution. This spectrophotometric result implies the complex formation of α-cyclodextrin with I^- rather than I_2, I_3^-, and I_6^{2-}, supporting the present assignment of the kinetic data.

The apparent difference in the kinetic behavior observed in the present studies for the α-cyclodextrin and β-cyclodextrin can be discussed from the viewpoint of the molecular structure of cyclodextrin. For α-cyclodextrin, a conformational change in the inclusion complex formation was proposed by X-ray crystallographic studies,[16] while there is no evidence of such conformational change for the β-cyclodextrin. Accordingly, at the present stage, the second process of reaction IV can be ascribed to a conformational change resulting from the "strained"[16] structure of α-cyclodextrin.

In conclusion, the present work clarifies that, in contrast to the polyiodide chain structure proposed by Noltemeyer and Saenger[10] for the α-cyclodextrin–iodine complex in the solid state, α-cyclodextrin binds predominantly with I^- rather than I_2, I_3^-, or I_6^{2-} in solution. Furthermore, the difference observed in the present kinetic experiments on the α- and β-cyclodextrins was ascribed to the "strained" conformation of α-cyclodextrin.

Appendix

If reactions I, II, and the first step in IV in the text are much faster than the second step of reaction IV, the following relationships can be derived from the mass balance and the mass conservation laws;

$$K_1(I^-\Delta I_2+I_2\Delta I^-) = \Delta I_3^-, \tag{A1}$$

$$2K_{II}I_3^-\Delta I_3^- = \Delta I_6^{2-}, \tag{A2}$$

$$K_1(I^-\Delta CD+CD\Delta I^-) = \Delta CDI', \tag{A3}$$

$$\Delta I^- + \Delta I_3^- + 2\Delta I_6^{2-} + \Delta CDI' + \Delta CDI'' = 0, \tag{A4}$$

$$\Delta I_2 + \Delta I_3^- + 2\Delta I_6^{2-} = 0, \tag{A5}$$

$$\Delta CD + \Delta CDI' + \Delta CDI'' = 0. \tag{A6}$$

The rate equation for the second step of reaction IV is

$$\frac{d\Delta CDI''}{dt} = k_2\Delta CDI' - k_{-2}\Delta CDI'', \tag{A7}$$

Combining the Eqs. A1—A6, the Eq. A7 is converted into the next equation

$$\frac{d\Delta CDI''}{dt} = -(k_2F+k_{-2})\Delta CDI'', \tag{A8}$$

with

$$F = \frac{K_1(I^-+CD)+(1+4K_{II}I_3^-)K_IK_1I^-(I^-+I_2+CD)}{1+K_1(I^-+CD)+K_IK_1I^-(I^-+I_2+CD)(1+4K_{II}I_3^-)}. \tag{A9}$$

Accordingly, the relaxation time can be represented by

$$\tau^{-1} = k_2F + k_{-2}.$$

Under the present experimental conditions, Eq. A10 can be rewritten in good approximation as

$$\tau^{-1} = k_2\frac{K_1\{CD+I^-(1+K_I(I^-+I_2+CD))\}}{1+K_1\{CD+I^-(1+K_I(I^-+I_2+CD))\}} + k_{-2}. \tag{A11}$$

Competition between Hydrogen Fluoride and Hydrogen Chloride Molecular Elimination Channels in the Infrared Multiple-photon Decomposition of 1,2-Dichloro-1,1-difluoroethane

Yo-ichi ISHIKAWA* and Shigeyoshi ARAI
The Institute of Physical and Chemical Research, Wako, Saitama 351
(Received August 25, 1983)

Time-resolved infrared emission spectra have been measured in the infrared multiple-photon decomposition of $CClF_2CH_2Cl$. The spectra were composed of emissions attributable to vibrationally excited HF* and HCl*. The emission yield of HF* increased rapidly with an increase in the fluence, while the yield of HCl* showed a maximum at 20 J cm^{-2}. These results suggest that the HF and HCl molecular elimination channels compete with each other in the unimolecular decomposition of highly vibrationally excited parent molecules. The stochastic trajectory calculations provided a satisfactory description of the fluence dependences of the HF and HCl yields observed here for $CClF_2CH_2Cl$ and previously for CHClFCHClF.

The infrared multiple-photon decomposition (IRMPD) of large molecules frequently shows more than one reaction channel, leading to a variety of products.[1] For the occurrence of a particular reaction channel, the parent molecules must be excited to levels above the threshold energy of the corresponding channel in the multiple-photon excitation process. The branching ratio among the channels can be interpreted in terms of the distribution of excited molecules with respect to the internal energy and the kinetic parameters of excited molecules as a function of the internal energy. Although there are several quantitative methods of determining product yields in the IRMPD of large molecules, the energy distribution and kinetic parameters have been studied to only a limited extent.

The effects of the laser fluence (J cm^{-2}) and the intensity (W cm^{-2}) on the IRMPD of large molecules have been reported extensively in recent publications.[1,2] It is generally accepted that an increase in the fluence significantly increases product yields, while, in contrast, a change in the intensity slightly affects the IRMPD. However, the laser intensity is directly proportional to the rates of optical absorption and stimulated emission for molecules in an intense laser field. The energy distribution should depend on the rates of these optical processes as well as on the rates of the decomposition of excited molecules.

West *et al.* have investigated the fluence dependences of HF and HCl molecular elimination channels in the IRMPD of $CClF_2CH_3$ using an infrared emission spectroscopic technique.[3] Krajnovich *et al.* have studied the fluence dependences of Cl atomic elimination and C-C bond rupture in the IRMPD of C_2F_5Cl by the use of a molecular-beam technique.[4] These experiments have, in principle, two advantages. One is that there is no complication caused by the subsequent reactions of initial intermediate products; another is that the fluence variation within the reaction zone is relatively small. Since IRMPD usually requires high fluences, the laser beam is tightly focussed in a reaction cell. Therefore, the resulting inhomogeneity of the fluence must be considered carefully in the analysis of the data. In infrared-emission and molecular-beam experiments, it is possible to detect emitting species and fragment species produced in a small reaction zone, where the fluence variation is somewhat limited.

In this study we have examined the IRMPD of $CClF_2CH_2Cl$ using a time-resolved infrared-emission spectroscopic technique. The experimental results show that HF and HCl molecular-elimination reactions occur competitively in the decomposition of highly vibrationally excited parent molecules. In addition, the fluence dependences of the channels are quite different from each other. These findings are similar to those obtained with the IRMPD of CHClFCHClF in a previous study.[5] The stochastic trajectory calculations can satisfactorily explain the observed fluence dependences in both studies on a reasonable assumption of kinetic parameters.

Experimental

The experimental apparatus used here is essentially the same as in a previous study.[6] The details have been described elsewhere.[7] The pulsed beam from a Lumonics TEA 103 CO_2 laser was truncated by an iris with a diameter of 9.9 mm and focussed in an irradiation cell by means of a BaF_2 lens with a focal length of 20 cm. The pulse profile was a spike of 80-ns fwhm without any tail. The laser was tuned to the R(20) line of the 9.6-μm CO_2 band at 1078.59 cm^{-1} and operated at a repetition rate of 0.7 Hz. The intensity distribution across the laser beam after passing through the iris was nearly flat; the deviation from the mean value was less than 15%. The beam area at focus was estimated to be 5×10^{-3} cm^2 from the beam divergence of 2 mrad. The laser fluence at focus was calculated from the beam area and the laser energy. The length of the reaction zone inside the cell was 2 cm along the laser beam, and the focal point was in the middle. The fluence at each end was estimated to be 60% of that at focus. In addition, the optical system was arranged so that the emission at focus could be monitored most efficiently during the observation. An InSb detector was set behind the exit slit of a Ritsu Kogaku MC-20L monochromator. Raw signals from the detector were first amplified by means of a PAR model 115 preamplifier. Then, the amplified signals were treated with a PAR model 162 boxcar averager and PAR model 155 gated integrator for the spectrum measurements, and with a Biomation 8100 transient digitizer and Keisoku Giken model 8100 signal averager for the time-resolved intensity measurements. The aperture duration, τ_g, and the aperture delay, τ_d, used for the boxcar averager were 10 and 3 μs respectively. The laser pulse picked up with a photon-drag detector (Hamamatsu TV, model B749) was used as a trigger signal of the detection system. The overall rise time was about 2 μs.

The flow rate of a reactant gas in the cell was 10 Torr

$cm^3\,min^{-1}$ (1 Torr≈133.3 Pa),[8] and the pressure was measured with a MKS Baratron model 220 BH manometer (10 Torr pressure range). The reactant gas, $CClF_2CH_2Cl$, was purchased from PCR Research Chemicals and was purified by trap-to-trap distillation before use.

Results and Discussion

First of all, the final products in the IRMPD of $CClF_2CH_2Cl$ were examined using infrared-absorption spectroscopic analysis. A special cell with a KBr window at each end (10 cm in length and 1.5 cm in inner diameter) was filled with 5-Torr $CClF_2CH_2Cl$. The laser beam was tightly focussed by means of a 7.5-cm focal length BaF_2 lens. The pulse energy and the focus fluence were 0.20 J and 280 J cm^{-2} respectively. The infrared-absorption spectrum was measured after irradiation using a JASCO type A-102 infrared spectrometer. The products assigned in the infrared spectrum are HCl (ν_1=2900 cm^{-1}), SiF_4 (ν=1030 cm^{-1}),[9] CF_2CHCl (ν_1=3130 cm^{-1}; ν_2=1740 cm^{-1}; ν_3=1330 cm^{-1}; ν_4=1200 cm^{-1}; ν_5=970 cm^{-1}),[10] and CClFCHCl (ν_3 for cis- and/or trans-form=1650 cm^{-1}; ν_6 for trans-form=850 cm^{-1}).[11] The formation of SiF_4 is explained by the secondary reaction of the primary product, HF, with the glass wall. These products suggest that the α,β-molecular elimination of HF and HCl occurs in the IRMPD of $CClF_2CH_2Cl$:

$$CClF_2CH_2Cl + mh\nu \rightarrow CF_2CHCl + HCl, \quad (1)$$

and:

$$CClF_2CH_2Cl + nh\nu \rightarrow CClFCHCl + HF. \quad (2)$$

Figure 1 presents the fluence effects on the infrared emission spectra for 1-Torr $CClF_2CH_2Cl$ irradiated at 1078.59 cm^{-1} in a flow system. The fluences at focus are indicated in the same figure. The slit function, with 0.056 μm fwhm, is also illustrated at the top of the figure. The emission with two peaks in the wavelength region from 3.1 to 4.2 μm is due to highly vibrationally excited HCl*, while the emission in the region from 2.2 to 3.1 μm is due to HF*. The spectral simulation based on the spectroscopic constants of HCl and HF supports the above assignments.[5,6] We could not detect any meaningful emission in the same wavelength region when the empty cell was irradiated at a fluence of 53 J cm^{-2}, as is shown in Fig. 1f. Since all the spectra have been measured under the same conditions except for the fluence, the intensities of the HF* and HCl* emissions can be said to be proportional to the yields of HF* and HCl* respectively among the spectra. As the fluence is increased, the intensity of HF*(I_{HF^*}) grows much more rapidly than the intensity of HCl*(I_{HCl^*}). The ratio of I_{HF^*} to I_{HCl^*} changes from 0.4 at 11 J cm^{-2} to 2.5 at 43 J cm^{-2}, where HF* and HCl* emission intensities are monitored at the wavelengths of about 2.8 and 3.8 μm respectively.

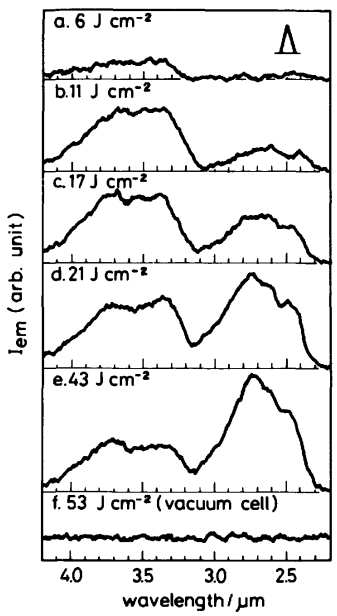

Fig. 1. Infrared fluorescence spectra observed for 1-Torr $CClF_2$-CH_2Cl irradiated with CO_2 TEA laser. Laser wavenumber, 1078.59 cm^{-1}.

Setser and his co-workers have examined the HF(DF) and HCl(DCl) elimination reactions of highly vibrationally excited haloethanes prepared in radical combination reactions.[12,13] They estimated that α,α-elimination contributes approximately 10% to the total molecular elimination in CHF_2CH_3. We have measured the fluorescence spectrum in the IRMPD of $CHCl_2CF_3$, where the α,α- and α,β-elimination channels were expected to give HCl* and HF* respectively. There appears to be no contribution of HCl* emission to the observed spectrum in Fig. 2. These facts suggest that α,α-elimination is a minor process in the decomposition of vibrationallly excited haloethanes.

Figure 3 presents the time dependences of the emission intensities observed at 2.4, 2.8, 3.0, 3.4, and 3.8 μm for 1-Torr $CClF_2CH_2Cl$. The fluence was 29 J cm^{-2}. The spectrum simulation suggests that the emission at 2.4 μm mainly corresponds to the R-branch of the HF* (v'=1)→HF(v''=0) transition, and those at 2.8 and 3.0 μm, to several transitions (Δv=1) originating from HF* at various vibrational levels. Similarly, the emissions at 3.4 and 3.8 μm are due to several transitions (Δv=1) of vibrationally excited HCl*. The emission profiles show a rapid initial rise and then a rapid

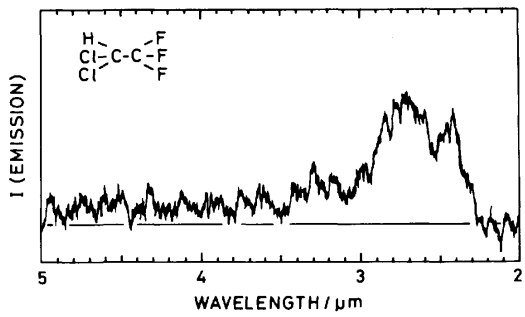

Fig. 2. Infrared fluorescence spectra observed for 5-Torr $CHCl_2CF_3$ irradiated with CO_2 TEA laser. Laser wavenumber, 1078.59 cm^{-1}; fluence, 40 J cm^{-2}; wavelength resolution, 0.068 μm fwhm.

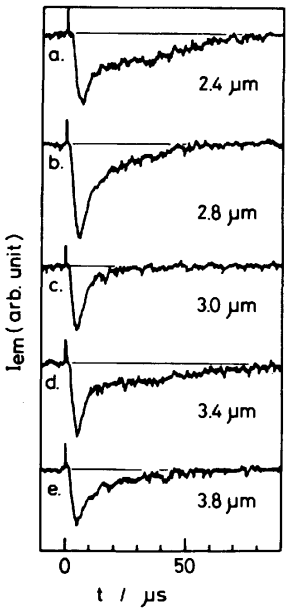

Fig. 3. Typical HF* and HCl* fluoresence signals observed for 1.0-Torr $CClF_2CH_2Cl$. Laser fluence, 29 J cm^{-2}; emission measurement wavelength, 3.8 and 3.4 μm for HCl* and 3.0, 2.8, and 2.4 μm for HF*; wavelength resolution, 0.056 μm fwhm; laser wavenumber, 1078.59 cm^{-1}.

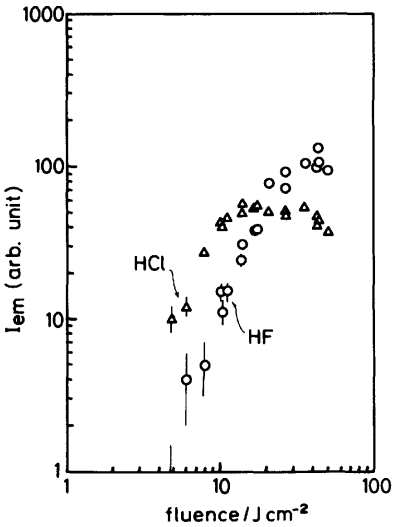

Fig. 4. Peak emission intensities of HCl* (triangles, at 3.8 μm) and HF* (circles, at 2.8 μm) *vs.* laser fluence observed for IRMPD of $CClF_2CH_2Cl$. Laser wavenumber, 1078.59 cm^{-1}.

decay, followed by a slower decay. Although the slow-decay component is relatively small in the emission at 3.0 μm, there is no essential difference in dynamic behavior between the two emitting species, HF* and HCl*. Both may be produced by a similar process, *i.e.*, molecular elimination from highly vibrationally excited $CClF_2CH_2Cl$*. The considerably different fluence dependences observed for HF* and HCl* seem to exclude the possibility that the initial molecular elimination to form HCl* and $CHClCF_2$ is followed by the subsequent elimination of HF* from $CHClCF_2$.

The rate constants for the quenching of vibrationally excited HF* and HCl* by some simple molecules have been determined in laser-induced infrared fluorescence experiments.[14,15] On the assumption that the quenching-rate constants of HF* and HCl* by $CClF_2CH_2Cl$ are approximately the same as those by CH_4, the lifetimes of HF* and HCl* are estimated to be a few microseconds in 1-Torr $CClF_2CH_2Cl$. Since these lifetimes are much shorter than the spontaneous fluorescence lifetimes of HF* and HCl*,[16] these excited molecules can be said to be mainly deactivated in collisions. We propose that large fractions of HF* and HCl* are produced during the laser pulse by means of Reactions 1 and 2. These fractions are responsible for the initial emission spikes in Fig. 3. The rise time of the spike corresponds to the response time of the detection system, while the rapid decay is due to the collisional deactivation of HF* and HCl*. On the other hand, HF* and HCl* are also produced in the collision-induced excitation of $CClF_2CH_2Cl$, followed by immediate decomposition:

$$CClF_2CH_2Cl'' + CClF_2CH_2Cl'' \rightarrow CClF_2CH_2Cl^{\dagger} + CClF_2CH_2Cl', \quad (3)$$

and:

$$CClF_2CH_2Cl^{\dagger} \rightarrow CF_2CHCl + HCl^* \rightarrow CClFCHCl + HF^*, \quad (4)$$

where $CClF_2CH_2Cl^{\dagger}$ represents a reactant molecule excited to a level beyond the decomposition threshold. $CClF_2CH_2Cl''$ is excited below or just above the threshold. Its lifetime is as long as several dozen microseconds. $CClF_2CH_2Cl'$ is a deactivated molecule. The collision-induced processes cause a delayed fluorescences of HF* and HCl* lasting for about 80 μs.

The emission intensities of HF* and HCl* are plotted against the laser fluence in Fig. 4, where I_{HF^*} and I_{HCl^*} are measured at 2.8 and 3.8 μm respectively. The Einstein coefficient of HF* is about five times larger than that of HCl*.[17] Therefore, I_{HF^*} divided by a factor of five and I_{HCl^*} are proportional to the yields of HF* and HCl* on the same scale, if the quenching rate of HF* is equal to that of HCl*. West *et al.* have measured the fluence dependences of the HF* and HCl* emission intensities in the IRMPD of $CClF_2CH_3$.[3] In their measurements, both intensities were found to increase almost linearly with an increase in the fluence. They reported that the calculated RRKM curves for k(HF) and k(HCl) *vs.* the internal energy are virtually parallel over a wide range. This result leads to the constant HF*/HCl* ratio in the corresponding range. In our study of $CClF_2CH_2Cl$, however, the HF*/HCl* ratio clearly depends on the laser fluence. The emission due to HCl* is much stronger than that due to HF* at lower fluences, while I_{HF^*}/I_{HCl^*} is about three at 50 J cm^{-2}. This fact suggests that highly vibrationally excited $CClF_2CH_2Cl$ decomposes competitively *via* HF and HCl molecular-elimination channels and that the branching ratio changes depending on the internal energy of the excited parent molecule. We also observed similar fluence dependences of I_{HF^*} and I_{HCl^*} for a mixture of 0.2-Torr $CClF_2CH_2Cl$ and 4-Torr Ar when

it was irradiated in the fluence region from 30 to 43 J cm^{-2}. Krajnovich *et al.* have examined the IRMPD of C_2F_5Cl in a molecular beam. Cl atomic elimination was dominant at lower fluences. As the fluence was increased, however, the atomic elimination approached saturation, and the C-C bond scission became more eminent.[4] The fluence dependences seem to be consistent with the present study.

The infrared fluorescence experiment can not provide any information concerning the production of HF and HCl in a ground vibrational state. In comparing the observed results with the calculated ones, we assume that the emission intensities of HF* and HCl* are proportional to the total yields of HF and HCl respectively. We simply use the peak emission intensities monitored at 2.8 and 3.8 μm in place of the integrated emission intensities, because a change in fluence does not appreciably affect the shapes of the fluorescence spectra due to HF* and HCl*. It is extremely difficult to separate the HF* and HCl* produced directly in the IRMPD from those produced in collision-induced processes. Therefore, I_{HF^*} and I_{HCl^*} probably correspond to the emissions of HF* and HCl* arising from the IRMPD, not only within the laser pulse, but also after the pulse.

Barker proposed an exact stochastic method based on an energy-grained master equation for the theoretical interpretation of IRMPD.[18] The method has been further applied to consecutive and competitive IRMPD.[19] The details will not be given here. Although there has been no kinetic or thermodynamic study of the two elimination channels of $CClF_2CH_2Cl$ itself, the Arrhenius parameters of HF and HCl elimination reactions have been reported on a number of halogenated hydrocarbons: log A=13—14 and E_0=55—70 kcal mol^{-1} (1 cal=4.184 J) for HF elimination; log A=11—14 and E_0=50—60 kcal mol^{-1} for HCl elimination.[20] The numerical values and assumptions employed for the present calculations are as follows: (a) σ_0 (infrared absorption cross-section of $CClF_2CH_2Cl$ in a ground vibrational state)=1.3×10^{-19} cm^2; (b) the fundamental vibrational frequencies of the $-CH_2Cl$ group in the CH_3CH_2Cl and the $-CClF_2$ group in CF_3CClF_2[21] were used for those of the $-CH_2Cl$ and $-CClF_2$ groups in $CClF_2CH_2Cl$; (c) the laser pulse was assumed to have a 80-ns duration and a constant intensity; (d) parent molecules excited to levels higher than threshold energies were assumed to undergo competitively three processes: collisional deactivation (k_d=1×10^6 s^{-1}), HF elimination, and HCl elimination. The cross-section was determined from the absorption measurement at 1078.59 cm^{-1}. The fundamental vibration frequencies are tabulated in Table 1. The weights of the three reaction processes depend on their rates. The number of trajectories is 1000 in the present calculation.

The simulation of the fluence dependences shown in Fig. 4 was performed for various Arrhenius parameters of the two reaction channels. The absorption cross-section was assumed to have the following form with respect to a given energy level n: $\sigma_n=\sigma_0/(n+1)^\alpha$, where α can be regarded as a parameter. The following set of numerical values gave the best-fitting simulation: log A=12 and E_0=50 kcal mol^{-1} for HCl elimination; log A=14 and E_0=68 kcal mol^{-1} for HF elimination; α=0.2. Table 2 shows the calculated results of the IRMPD of $CClF_2CH_2Cl$ at various fluences using the above-mentioned parameters. The decomposition within the laser pulse becomes more important with an increase in the fluence. In the intermediate fluence region of 10—20 J cm^{-2}, however, the decomposition after the end of the pulse contributes significantly to the total production of HCl,[23] where HCl elimination has a lower threshold energy. The typical energy distributions $P(n)$, *i.e.*, the fraction of molecules at a given energy level n, are illustrated in Fig. 5, where $CClF_2CH_2Cl$ is supposed to be irradiated at six different fluences. The cross-hatched and filled areas correspond to the fractions of the HCl (F_{total}(HCl)) and HF(F_{total}(HF)) elimination channels respectively in the figure. As the degree of vibration freedom s is as large as 18 in $CClF_2CH_2Cl$, the unimolecular decomposition rates calculated for molecules at levels a little higher than the threshold energies, *i.e.*, n=17—23 for HCl elimination and n=23—27 for HF elimination, are smaller than the assumed quenching rate. The k_{HCl} (n) and k_{HF} (n) are about equal to the quenching rate k_d at n=24 and 28 respectively. The two rate constants are roughly equal to each other at n=35; the value is 2.0×10^8 s^{-1}. When the laser fluence is 20 J cm^{-2}, the absorption rate for the molecule at n=50 is five times less than k_{HCl} and 30 times less than k_{HF}. Therefore, it is hard to excite molecules to such high energy levels.

The calculated fluence dependences of the HCl elimination and HF elimination are shown in Fig. 6, where the decomposition after the end of the pulse

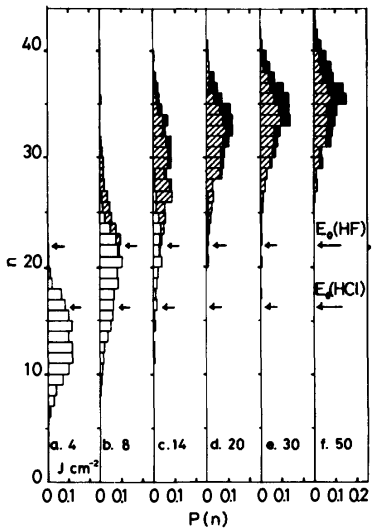

Fig. 5. Typical vibrational population distributions for $CClF_2CH_2Cl$ irradiated at various fluences. Cross-hatched and filled areas indicate the extents of HCl and HF elimination reactions, respectively. $\sigma_n = \sigma_0/(n+1)^{0.2}$ cm^2. The postirradiation decomposition was taken into consideration.

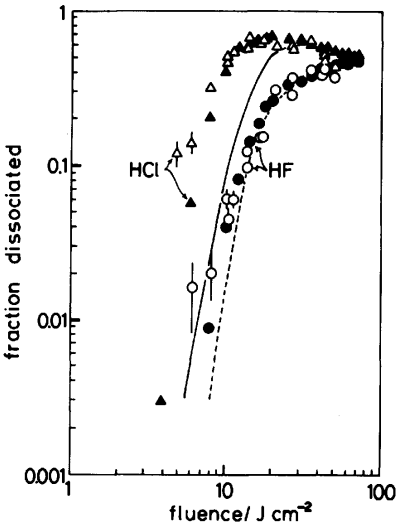

Fig. 6. Comparison of calculated yields of HCl and HF to observed ones in IRMPD of 1-Torr $CClF_2CH_2Cl$ at various fluences. Filled triangles, calculated yields of HCl; triangles, observed yields of HCl; filled circles, calculated yields of HF; circles, observed yields of HF. Solid and dotted curves show the calculated fractions of HF and HCl produced within the pulse.

has been taken into consideration. The filled triangles and filled circles present F_{total}(HCl) and F_{total}(HF) respectively. The same figure also shows the fluence dependences of the observed I_{HCl^*} (open triangles) and I_{HF^*} (open circles) values, where the scales have been chosen arbitrarily so that the experimental data fit the calculated ones. The I_{HF^*}/F_{total} (HF) ratio was found to be approximately three times larger than the I_{HCl^*}/F_{total} (HCl) ratio. From the emission efficiencies of HCl* and HF*, the factor can be expected to be five if these molecules are in the $v'=1$ state.[17] The solid and dotted curves in Fig. 6 present the fractions of HCl and HF respectively which are produced within the pulse.

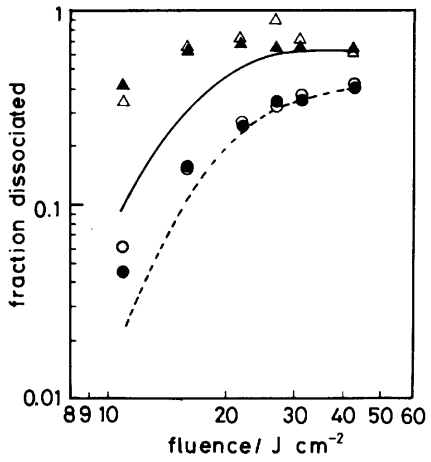

Fig. 7. Comparison of calculated yields of HCl and HF to observed ones in IRMPD of 2-Torr CHClFCHClF at various fluences. Filled triangles, calculated yields of HCl; triangles, observed yields of HCl; filled circles, calculated yields of HF; circles, observed yields of HF. Solid and dotted curves show the calculated fractions of HF and HCl produced within the pulse.

Our previous paper has reported the fluence dependences of I_{HF^*} and I_{HCl^*} in the IRMPD of CHClFCHClF using the same experimental technique.[5] By applying the stochastic trajectory calculation to the compound, we obtained the results in Fig. 7. The fundamental vibration frequencies are also tabulated in Table 1. The kinetic parameters for the HF and HCl elimination reactions are the same as $CClF_2CH_2Cl$. The α parameter is changed into 0.3, which seems to give a better fit. I_{HF^*}/F_{total} (HF) is four times larger than I_{HCl^*}/F_{total} (HCl).

At present, the calculations seems to have a somewhat unavoidable uncertainty because of the lack of the kinetic parameters of $CClF_2CH_2Cl$ and CHClFCHClF, together with incomplete understanding of the multiple-photon absorption process. However, the calculated results satisfactorily describe the fluence dependences of I_{HF^*} and I_{HCl^*} for the IRMPD of $CClF_2CH_2Cl$ and CHClFCHClF. It is interesting that the IRMPD is able to induce the reaction channel with a higher threshold energy, rather than the channel with the lowest threshold energy, under some selected experimental conditions.

The authors wish to express their thanks to Miss Kyoko Sugita for the computer calculations. They also wish to express their thanks to Dr. Takashi Igarashi for the assignments of the fundamental vibration frequencies of haloethanes.

Sodium Sulfate Doped with Sodium Vanadate and Rare Earth Sulfate as a Solid Electrolyte for a Sulfur Dioxide Gas Detector

Nobuhito IMANAKA, Gin-ya ADACHI,* and Jiro SHIOKAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565
(Received August 31, 1983)

Sodium sulfate doped with $NaVO_3$ and $Ln_2(SO_4)_3$ (Ln=Eu, Pr, and Y) show higher electrical conductivity for Na^+ ions and maintains a high temperature phase, Na_2SO_4-I, without showing phase transformation. The electromotive force (EMF) using solid solutions, Na_2SO_4-$NaVO_3$-$Ln_2(SO_4)_3$ (Ln=Pr and Y), as solid electrolytes exhibits good agreement with the calculated value, the temperature as low as 673 K which is approximately 300 K lower than pure sodium sulfate can be.

Influence of sulfur dioxide exhausted from coal power plants and automobiles to the environment has been taking place and becoming a serious problem. Especially, acid rain resulting from the absorption of sulfur dioxide and nitrogen dioxide by water is considerably affecting the surroundings in North America and some other countries.

Recently, some attempts have been made to utilize sodium sulfate as a solid electrolyte for a SO_2 gas sensor.[1-4] However, in practical use, a phase transformation from Na_2SO_4-III (a low temperature phase) to Na_2SO_4-I (a high temperature phase)[5-21] is a serious obstacle. In addition, other disadvantages in using sodium sulfate alone as an electrolyte are its lower electrical conductivity and the difficulty in obtaining a SO_2-SO_3 equilibrium on the surface of the electrolyte. Mono-, di-, and trivalent cations have been doped in order to improve their electrical and thermodynamic properties.[22-26] In our previous study,[27] sodium sulfate doped with $NaVO_3$ and $Ln_2(SO_4)_3$ (Ln=Eu and Pr) has been found to show no phase transformation, to maintain a Na_2SO_4-I-similar phase, and to increase the electrical conductivity.

In the present study, effects of doping with rare earth sulfates and sodium vanadate into sodium sulfate on the electrical conductivity and on the phase transformation of the solid solutions are examined, and also EMF measurements by applying Na_2SO_4-$NaVO_3$-$Ln_2(SO_4)_3$ (Ln=Pr and Y) as an electrolyte for a SO_2 gas concentration cell are to be discussed.

Experimental

Materials. Rare earth sulfate was prepared by adding concentrated H_2SO_4 into rare earth oxide. Sodium vanadate was synthesized by heating the mixture of Na_2CO_3 and NH_4VO_3 (by molar ratio 1:2) at 823 K for 5 h in air. A mixture of appropriate amount of Na_2SO_4 and $Ln_2(SO_4)_3$ (Ln=Eu, Pr, and Y) were pelletatized and heated at 1073 K for 3 h in air. In Na_2SO_4-$NaVO_3$-$Ln_2(SO_4)_3$ (Ln=Eu, Pr, and Y) systems, the heated pellets were ground, remade into pellets and sintered 3 h at 1073 K in air.

Measurements. Phases and thermal properties were measured with X-ray diffraction method and thermal analysis. Electrical conductivity measurements were carried out by a complex impedance method[28] using a Hewlett Packard vector impedance meter 4800 A. The apparatus for the electrical conductivity measurements is shown in Fig. 1. EMF measurements were performed by constructing a SO_2 gas concentration cell which is depicted in Fig. 2. The inner quartz tube compartment was separated by spring loading the electrolyte with a quartz rod. A gold O-ring was used in order to separate the test and the reference SO_2 gas completely. The SO_2 gas concentration was regulated by changing SO_2 and O_2 gas flow rate. A Pt net was applied as an electrode so that the electrolyte could maintain good contact with the SO_2 gas. EMF measurements were performed with a Takeda Riken Digital Multimeter TR-6855. The response time, which is here defined as the time required from the test gas arrival at the electrolyte to the attainment of about 96% of the calculated EMF, was also measured.

Results and Discussion

Electrical Conductivity, Phases, and Thermal Properties. The Na_2SO_4-$Ln_2(SO_4)_3$ (Ln=Eu, Pr, and Y): Sodium sulfate doped with $Ln_2(SO_4)_3$ (Ln=Eu, Pr, and Y) ex-

Table 1. The phases and thermal properties of Na_2SO_4-$Pr_2(SO_4)_3$

Sample No.	Na_2SO_4 (mol%)	$Pr_2(SO_4)_3$ (mol%)	Phases	DTA peaks T/K
1	99.1	0.9	α+Na_2SO_4-V	573

3	95.2	4.8	γ	573
4	90.7	9.3	γ	853

α phase is similar to phase Na_2SO_4-III.[18,19] γ phase is different from any Na_2SO_4 phase.

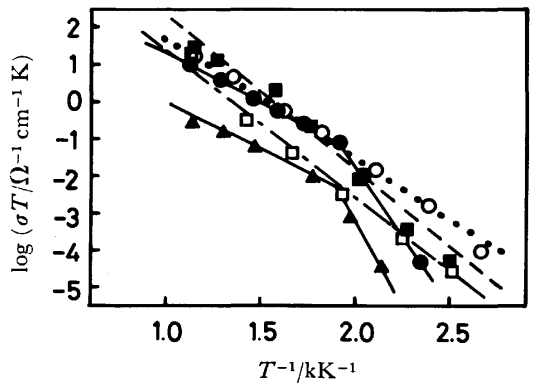

Fig. 3. Temperature dependences of electrical conductivities for the Na_2SO_4-$Pr_2(SO_4)_3$.
—□— Na_2SO_4 : $Pr_2(SO_4)_3$=90.7 : 9.3, —■— Na_2SO_4 : $Pr_2(SO_4)_3$=95.2 : 4.8, ···○··· Na_2SO_4 : $Pr_2(SO_4)_3$=98.4 : 1.6, —●— Na_2SO_4 : $Pr_2(SO_4)_3$= 99.1 : 0.9, —▲— Na_2SO_4.

hibits almost the same electrical conductivity, phases, and thermal properties with one another.

The representative results of Na_2SO_4-$Pr_2(SO_4)_3$ are listed in Table 1. Sodium sulfate doped with 0.9 mol% or 1.6 mol% $Pr_2(SO_4)_3$ exhibits phase α which is similar to the Na_2SO_4-III phase [18,19] including a starting material (Na_2SO_4-V phase). The other two samples show phase γ which is different from any Na_2SO_4 phase. All samples exhibit an endothermal peak in DTA curves, indicating that the phase transformation still exists.

Electrical conductivity measurements in the systems of Na_2SO_4-$Pr_2(SO_4)_3$ are shown in Fig. 3. Doping $Pr_2(SO_4)_3$ into Na_2SO_4 increases the concentration of cation vacancies of the sulfate, and then the electrical conductivity enhances. A break or bend in $\log(\sigma T)$ *vs.* $1/T$ curves is due to the phase transformation in the sulfate. The solid solution of sodium sulfate doped with 1.6 mol% $Pr_2(SO_4)_3$ did not exhibit any break. The III-I phase transformation appeared to be fairly suppressed. However, the phase transformation was found to still remain on DTA measurement. The sulfate doped with 4.8 mol% $Pr_2(SO_4)_3$ gives the highest electrical conductivity (from 571 K to 873 K) in the Na_2SO_4-$Pr_2(SO_4)_3$ systems.

This fact means that the number of cation vacancies which is effective for cation conduction becomes a maximum with the doping. By doping $Pr_2(SO_4)_3$ more than 4.8 mol%, cation vacancies appear to make clusters and then the electrical conductivity in Na_2SO_4-$Pr_2(SO_4)_3$ systems rather decreases.

Table 2. The phases and thermal properties of Na_2SO_4-$NaVO_3$-$Y_2(SO_4)_3$

Sample No.	Na_2SO_4 (mol%)	$NaVO_3$ (mol%)	$Y_2(SO_4)_3$ (mol%)	Phases	DTA peaks T/K
1	98.3	0.7	1.0	α	485
2	96.9	1.1	2.0	α	408, 463
3	95.7	1.3	3.0	β	—
4	93.6	2.4	4.0	β	—
5	91.4	3.6	5.0	β	573 (very small)

α phase is similar to phase Na_2SO_4-III.[18,19] β phase is similar to phase Na_2SO_4-I.[18,19]

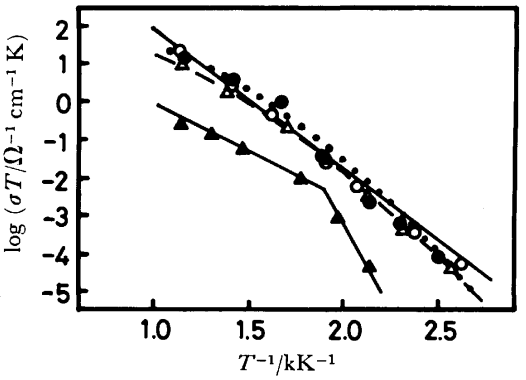

Fig. 4. Temperature dependences of electrical conductivities for the Na_2SO_4-$NaVO_3$-$Y_2(SO_4)_3$ which exhibit β phase.
—○— Na_2SO_4 : $NaVO_3$: $Y_2(SO_4)_3$ = 91.4 : 3.6 : 5.0, ···●··· Na_2SO_4 : $NaVO_3$: $Y_2(SO_4)_3$ = 93.6 : 2.4 : 4.0, —△— Na_2SO_4 : $NaVO_3$: $Y_2(SO_4)_3$ = 95.7 : 1.3 : 3.0, —▲— Na_2SO_4.

Although the electrical conductivities of the sulfates increase with the $Ln_2(SO_4)_3$ (Ln=Eu, Pr, and Y) doping, the phase transformation still remains. Therefore, the bicomponent solid solutions do not seem to be appropriate as solid electrolytes for a SO_2 gas detector.

The Na_2SO_4-$NaVO_3$-$Ln_2(SO_4)_3$(Ln=Eu, Pr, and Y) Systems: The phases and thermal properties of sodium sulfate doped with $NaVO_3$ and $Ln_2(SO_4)_3$ (Ln=Eu, Pr, and Y) are all similar.

A typical behavior (Na_2SO_4-$NaVO_3$-$Y_2(SO_4)_3$) is presented in Table 2. Samples No. 1 and 2 show phase α which is similar to the phase Na_2SO_4-III.[18,19] On the other hand, samples No. 3, 4, and 5 show phase β which resembles the phase Na_2SO_4-I.[18,19] From DTA measurements, the samples which show phase α exhibit endothermal peaks, that is, a phase transformation still remains. The samples which exhibit phase β show no endothermal peak, indicating that no phase transformation occurs.

The plots of $\log(\sigma T)$ *vs.* $1/T$ for sodium sulfate doped with $NaVO_3$ and $Y_2(SO_4)_3$(phase β) are given in Fig. 4. The slope of the Na_2SO_4-$NaVO_3$-$Y_2(SO_4)_3$ curves closely approaches that of Na_2SO_4-I (a high

temperature phase). The electrical conductivity of Na_2SO_4-$NaVO_3$-$Y_2(SO_4)_3$ systems is increased with doping $Y_2(SO_4)_3$ because of the increase in cation vacancies. In addition, the Na_2SO_4-$NaVO_3$-$Y_2(SO_4)_3$ systems maintain a Na_2SO_4-I-like phase (phase β) which is excellent in Na^+ ion conduction.

As mentioned above, the conductivity of Na_2SO_4-I is considerably high and the three component systems also support the similar structure with the Na_2SO_4-I phase. Therefore, the conductivity of the solid solution is also high. The Na_2SO_4-$NaVO_3$-$Y_2(SO_4)_3$ systems are considered to be very good ionic conductors. In this system, sodium sulfate doped with 3.6 mol% $NaVO_3$ and 5.0 mol% $Y_2(SO_4)_3$ shows the best linearity in the three $\log(\sigma T)-1/T$ curves. The three component systems, including rare earth sulfates other than $Y_2(SO_4)_3$ also give the similar optimum composition of 91:4:5.

EMF Measurements. The EMF measurements were performed with Na_2SO_4-$NaVO_3$-$Ln_2(SO_4)_3$ (Ln=Eu, Pr, and Y) (91:4:5) as solid electrolytes. Temperature dependences of measured EMF/calculated EMF ratio with a fixed SO_2 gas concentration are shown in Fig. 5.

The measured EMF for pure Na_2SO_4 and Na_2SO_4-$Ln_2(SO_4)_3$ (Ln=Eu, Pr, and Y) solid solutions were less than half of calculated EMF. The measured value for sodium sulfate doped with 4.0 mol% $NaVO_3$ and 5.0 mol% $Eu_2(SO_4)_3$ is consistent with that calculated at 623 K and appears to be an appropriate electrolyte. However, the measured value of the EMF has exceeded that calculated at 673 K. This appears to have resulted because Eu^{3+} ions in the systems are easily reduced to a divalent state with SO_2 gas and change in free energies for the reduction might have been added to the calculated EMF value. Thus, the solid solution of Na_2SO_4-$NaVO_3$-$Eu_2(SO_4)_3$ is not appropriate for the electrolyte.

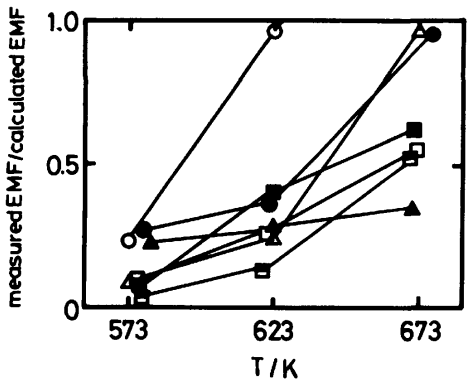

Fig. 5. The ratio of measured EMF/calculated EMF for Na_2SO_4, Na_2SO_4-$Ln_2(SO_4)_3$, Na_2SO_4-$NaVO_3$-$Ln_2(SO_4)_3$ (Ln=Eu, Pr, and Y) with initial SO_2 gas composition, approximately 24 and 8 vol%.
—○— Na_2SO_4 : $NaVO_3$: $Eu_2(SO_4)_3$=91.0 : 4.0 : 5.0, —●— Na_2SO_4 : $NaVO_3$: $Pr_2(SO_4)_3$=91.1 : 3.9 : 5.0, —△— Na_2SO_4 : $NaVO_3$: $Y_2(SO_4)_3$ = 91.4 : 3.6 : 5.0, —□— Na_2SO_4 : $Eu_2(SO_4)_3$=95.9 : 4.1, —■— Na_2SO_4 : $Pr_2(SO_4)_3$=95.2 : 4.8, —▬— Na_2SO_4 : $Y_2(SO_4)_3$ =95.0 : 5.0, —▲— Na_2SO_4.

The systems of Na_2SO_4-$NaVO_3$-$Ln_2(SO_4)_3$ (Ln= Pr and Y) give almost the same EMF as calculated one at 673 K. In the temperature range higher than 673 K, the electrolytes became soft because of $NaVO_3$. The EMF measurements in variation of the test SO_2 gas concentration were conducted with the Na_2SO_4-$NaVO_3$-$Ln_2(SO_4)_3$ (Ln=Pr and Y) systems as solid electrolytes at 673 K.

Results of the EMF measurements with the Na_2SO_4-$NaVO_3$-$Pr_2(SO_4)_3$ electrolyte are presented in Fig. 6. The calculated EMF is cited from theoretical one of Jacob and Rao.[2] The measured EMF shows good

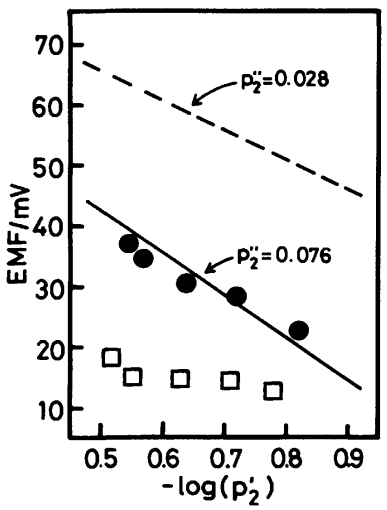

Fig. 6. Variation of the EMF for the concentration cell; $Pt|O_2(p_1'), SO_2(p_2')|Na_2SO_4$ (3.9 mol% $NaVO_3$, 5.0 mol% $Pr_2(SO_4)_3)|O_2(p_1''), SO_2(p_2'')|Pt$, with p_1''= 0.924, p_2''=0.076 (●) and p_1''=0.972, p_2''=0.028 (□) at 673 K.
—— and —— are calculated EMF,[2] respectively.

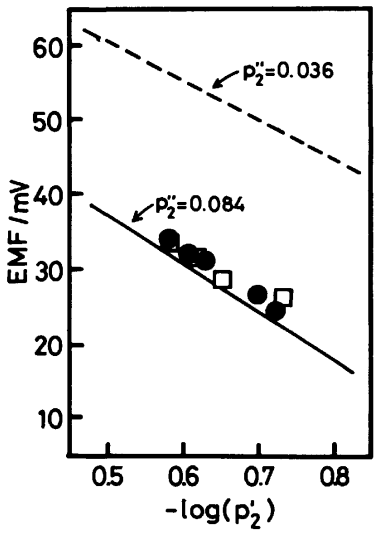

Fig. 7. Variation of the EMF for the concentration cell; $Pt|O_2(p_1'), SO_2(p_2')|Na_2SO_4$ (3.6 mol% $NaVO_3$, 5.0 mol% $Y_2(SO_4)_3)|O_2(p_1''), SO_2(p_2'')|Pt$, with p_1''= 0.916, p_2''=0.084 (●) and p_1''=0.964, p_2''=0.036 (□) at 673 K.
—— and —— are calculated EMF,[2] respectively.

accordance with the calculation in which the initial reference SO_2 gas concentration is 7.6 vol%. Sodium sulfate doped with $NaVO_3$ and $Pr_2(SO_4)_3$ is able to use for a solid electrolyte, a temperature as low as 673 K which is approximately 300 K lower than pure sodium sulfate can be operative. In the case that the initial reference SO_2 gas concentration is 2.8 vol%, the measured EMF is appreciably smaller than the calculated EMF. The EMF results for the Na_2SO_4-$NaVO_3$-$Y_2(SO_4)_3$ electrolyte are also presented in Fig. 7. The measured EMF also shows good agreement with the calculated EMF if the initial reference SO_2 gas concentration is 8.4 vol%. The difference between the measured and the calculated EMF also becomes larger when the initial reference SO_2 gas concentration is 3.6 vol%.

Dependence of the initial reference SO_2 gas concentration on the measured EMF/calculated EMF ratios at 673 K for the Na_2SO_4-$NaVO_3$-$Ln_2(SO_4)_3$ (Ln= Pr and Y) electrolytes are shown in Fig. 8. The measured EMF/calculated EMF ratio abruptly decreases

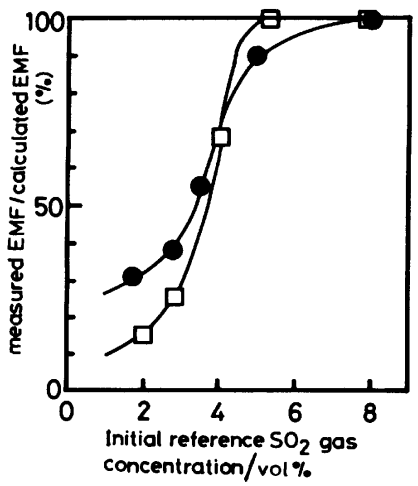

Fig. 8. Dependences of initial SO_2 gas concentration for reference on measured EMF/calculated EMF at 673 K.

● Na_2SO_4 : $NaVO_3$: $Y_2(SO_4)_3$=91.4 : 3.6 : 5.0.

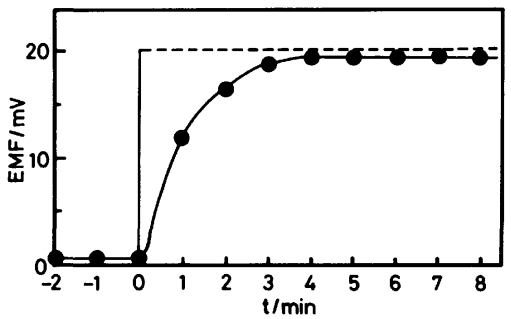

Fig. 9. A typical EMF response for the Na_2SO_4-$NaVO_3$-$Y_2(SO_4)_3$(91.4 : 3.6 : 5.0) electrolyte at 673 K.
The test and the reference SO_2 gas concentration are 20.5 and 9.7 vol%, respectively.
—— is calculated EMF.[2]

when the initial reference SO_2 gas concentration becomes less than 5 vol%. The electrolyte can not detect SO_2 gas accurately because the SO_2 gas concentration on the surface for the reference electrode is smaller than 5 vol% and the electrical conductivity of the electrolyte is appreciably low because the operating temperature is as low as 673 K.

A typical EMF response for the Na_2SO_4-$NaVO_3$-$Y_2(SO_4)_3$ electrolyte at 673 K is presented in Fig. 9. The EMF increases immediately when the test SO_2 gas reaches the surface of the electrolyte. However, about 4 min are necessary for the EMF to attain 96% of the calculated EMF. Jacob and Rao[2] have described that approximately 4 min are required to attain 98% of the calculated EMF when pure sodium sulfate is used as a solid electrolyte at 973 K. The response time in our measurement coincides with their results. However, operating temperature of ours is approximately 300 K lower than theirs.

In conclusion, sodium sulfate doped with $NaVO_3$ and $Ln_2(SO_4)_3$ (Ln=Pr and Y) has suitable properties for the solid electrolyte because the solid solution shows considerably high electrical conductivity. The sulfate can be utilized as the solid electrolyte for a SO_2 gas sensor even at 673 K which is approximately 300 K lower than pure sodium sulfate can be used. The doping of sodium vanadate as well as rare earth sulfates makes considerable progress in the improvement of the electrolyte.

Kinetics of the Conformational Change and Subunit Dissociation of Aldolase

Yoko OHGA, Mamoru NAKANISHI, and Masamichi TSUBOI*
Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received September 8, 1983)

The kinetics of acid denaturation of muscle aldolase were examined by stopped-flow fluorescence and stopped-flow light scattering measurements. The denaturation reaction was found to consist of three distinguishable steps—step I with fluorescence increase only, step II with both fluorescence increase and light scattering decrease, and step III with fluorescence decrease alone. Circular dichroism and sedimentation equilibrium measurements were also made at different pH's in the course of the acid denaturation. It was concluded that in the acid denaturation of this enzyme a rearrangement of the secondary or tertiary structures takes place rapidly (4 s^{-1} at 21.5 °C and at pH 3.4), and then the subunit dissociation occurs more slowly (0.04 s^{-1} at 21.5 °C and at pH 3.4), with further conformational change. The subunit dissociation was found to be caused by two H^+ per tetramer.

We have recently proposed a new method of characterizing the subunit-structure of a macromolecule.[1] The method consists of the use of a stopped-flow light scattering measurement in combination with a stopped-flow fluorescence measurement. By this combination, one can establish a sequence of *cause and effect* between an inter-subunit dissociation reaction and an intra-subunit conformation change in the macromolecule in question. The method was once applied to the subunit structure of concanavalin A and *Limulus* haemocyanin.[1] Practically the same method was followed by Tashiro *et al.*[2] with bovine liver glutamate dehydrogenase. In this paper, we examine the applicability of this method with a slightly more complex example, namely aldolase.

Rabbit muscle aldolase is an enzyme which splits fructose 1,6-diphosphate to yield glyceraldehyde 3-phosphate and dihydroxyacetone phosphate in the second stage of glycolysis.[3] The enzyme is tetramer with each subunit having a molecular weight of 40 000.[4] Kawahara and Tanford showed that the four-subunit structure of the enzyme is dissociated into monomers by guanidine hydrochloride.[5] The enzyme is also dissociated by urea or acid.[6,7] The subunit reassociation and reactivation of denatured aldolase were found to be slow processes (3 h at 0 °C), and the kinetics of these processes were once examined by Teipel.[8] The kinetics of unfolding and subunit dissociation of the enzyme, however, have not been examined so far.

Experimental

Aldolase. Rabbit muscle aldolase was purchased from Sigma as a crystalline suspension in 3.2 M† ammonium sulfate. After centrifugation of the suspension the enzyme solution was obtained by dialyzing it against 0.01 M sodium citrate buffer (pH 5.4) for a few days at 4 °C. Protein concentrations were determined spectrophotometrically using the value of $E^{1\%}_{1\,cm}$=9.1 at 280 nm.[9] Buffer systems used are: citric acid+sodium citrate buffer (in the pH 6—3 range) and sodium citrate+HCl buffer (in the pH 2—2.7 range). The enzyme solution was filtered everytime before the light scattering measurement through a 0.45 μm Millipore type HA filter.

Fluorescence Measurements. Fluorescence spectra were observed by a Hitachi Fluorescence Spectrophotometer model 650-10S with circulating water to maintain the temperature of the cell at 25 °C.

Circular Dichroism Measurements. Circular dichroism spectra were measured by a JASCO CD Spectrometer J 20 at room temperature. All the measurements were made with a 1 mm path length quartz cell.

Stopped-flow Measurements. The rate of fluorescence and light scattering changes (in intesity) were examined with a Union Giken stopped-flow spectrophotometer RA-401 in combinaton with a microcomputer RA-450 system.[10] We used a Hoya UV 33 cut filter (which allows the emitted light of wavelength longer than 330 nm to come into the detector) in the fluorescence measurements. For the light scattering measurements a 4 mW He-Ne laser was used. For introducing the laser beam into the cell window, an optical fiber was used. This makes it easier to guide the beam and to adjust the position and direction of the light path than a convensional mirror system. All scattering measurements were made at the angle of 90° to the incident beam, since the dimension of the protein molecule was small relative to the wavelength of the light.

Results

Fluorescence Spectra. We first observed the fluorescence spectra of rabbit muscle aldolase at several pH values and the results are shown in Fig. 1. As is seen in the figure, the emission maximum is shifted towards longer wavelength on going from pH 4.4 to pH 3.4. The pH dependence of the wavelength (λ_{max}) of the emission maximum and the intensity are shown in Fig. 2. From this figure it is suggested that the enzyme is denatured in acidic pH and the denaturation point is around pH 3.7. This value is in agreement with the previously proposed denaturation point.[6]

Circular Dichroism. The observed molecular ellipticity [θ] of this enzyme at 225 nm was plotted against pH as shown in Fig. 2 (c). In the acid denaturation a loss of gross secondary or tertiary structure is seen from the figure.

Sedimentation Equilibrium. Dissociation of aldolase into dimer and monomer has next been examined at acidic pH. According to the results of sedimen-

† 1M=1 mol dm^{-3}.

tation equilibrium measurements (see Table 1) aldolase is considered to be tetramer at pH 5.4, a mixture of dimer and monomer at pH 3.5, and monomer at pH 2.7.

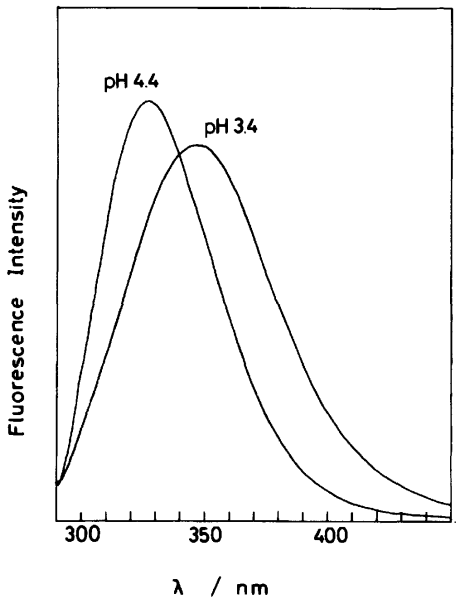

Fig. 1. Fluorescence spectra of aldolase (0.13 mg ml^{-1}), excited at 280 nm. Solvents, 0.1 M citrate buffer. Temperature, 25 °C.

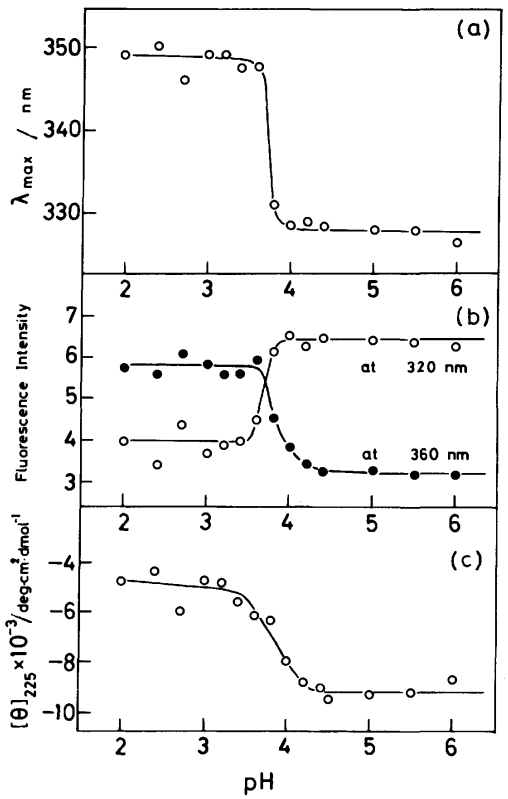

Fig. 2. Effects of pH on (a) the fluorescence peak position, (b) fluorescence intensities, (c) circular dichroism of aldolase. For the fluorescence measurements, the protein concentration was 0.13 mg ml^{-1}, and for the circular dichroism measurements 1.3 mg ml^{-1}. For both measurements, the solvents were 0.1 M citrate buffer. Temperature, 25 °C.

This conclusion is consistent with the previous results.[4]

Kinetic Measurements. After a rapid change of pH from 5.4 to 3.4 of aldolase solution, time-dependent fluorescence and light scattering measurements were made. As may be seen in Fig. 3 (a) and (b), the fluorescence increase (excited at 280 nm and observed all the

Table 1. Apparent molecular weights of aldolase determined by sedimentation equilibrium measurements[a] at different pH's

pH 5.4	174 000± 3 600
pH 3.5	59 800—87 200[b]
pH 2.7	50 300± 400

a) All the experiments were made with aldolase solutions of 0.44 mg ml^{-1} in 0.1 M sodium citrate buffer. b) At pH 3.5, log c *versus* r^2 relation (where c is the concentration and r the distance from the axis of rotation) was not found to be linear, showing that the molecules are not homogeneous.

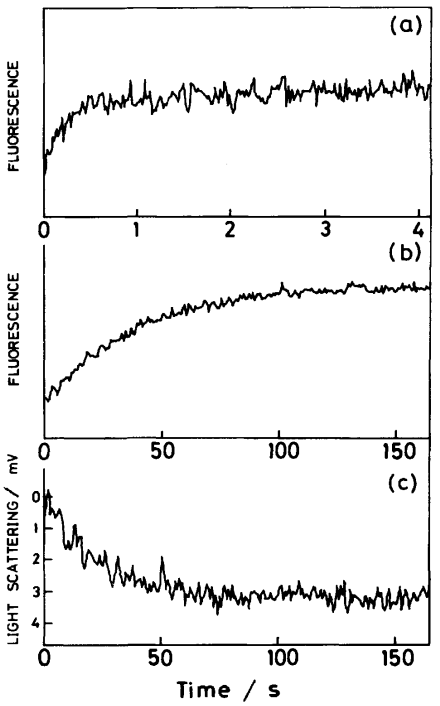

Fig. 3. The time dependence of the increase in the fluorescence intensity (a) and (b) and of decrease in the light scattering intensity (c), of aldolase solution on pH=5.4→3.4 jump. In each experiment, aldolase solution of 3.2 mg ml^{-1} in 0.01 M citrate buffer (pH 5.4) was rapidly mixed with an equal volume of 0.2 M citrate buffer (pH 3.4) at time zero with a stopped-flow device. The final pH was found to be 3.4 and the final concentration of aldolase was 1.6 mg ml^{-1}. Temperature, 21.5 °C. The fluorescence was excited at 280 nm and observed with a cut-filter of 330 nm. The light scattering was observed at 632.8 nm. The ordinate scale (read in mV) is arbitrary but should be taken as equal to that of Fig. 4(c), because all the experimental conditions were the same for these two recordings.

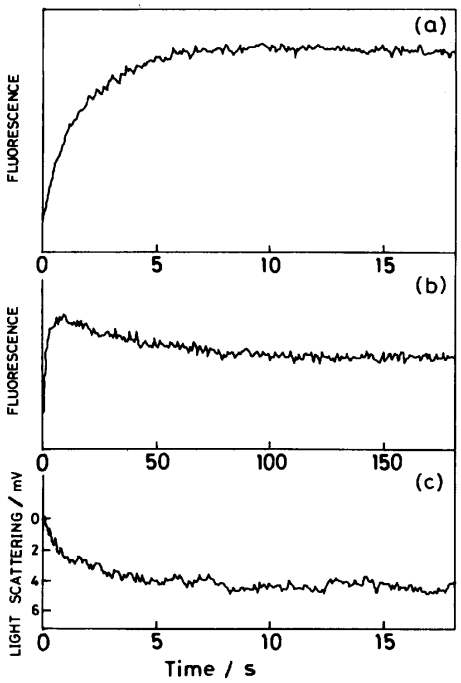

Fig. 4. The time dependent changes in fluorescence intensity ((a) and (b)) and in the light scattering intensity (c) of aldolase solution on pH=5.4→2.7 jump. In each experiment, aldolase solution of 3.2 mg ml^{-1} in 0.01 M citrate buffer (pH 5.4) was rapidly mixed with an equal volume of 0.2 M citrate buffer (pH 2.7) at time zero with the stopped-flow device. The final pH was found to be 2.7 and the final concentration of aldolase was 1.6 mg ml^{-1}. Temperature, 21.5 °C. The fluorescence was excited at 280 nm and observed with a cut-filter of 330 nm. The light scattering was observed at 632.8 nm. The ordinate scale (read in mV) is arbitrary but should be taken as equal to that of Fig. 3(c), because all the experimental conditions were the same for these two recordings.

emitted light of wavelength longer than 330 nm) takes place in two steps. In both steps the fluorescence intensity was found to increase as nearly first-order process with rate constants of 4.0 and 0.03 s^{-1} at 21.5 °C. In the course of these processes, however, the light scattering intensity (at 632.8 nm) was found to decrease in only one step. Its rate constant is nearly equal to that of the second step of the fluorescence increase (step II). Similar experiments were made with different final pH's (to which pH jumps were made from pH 5.4). An example (pH=5.4→2.7 jump) is shown in Fig. 4. The rate constants of the light scattering and fluorescence change were both found to be dependent on the final pH of the solution. As may be seen in Fig. 5, the rate constant of the second-step reaction (step II) is nearly proportional to square of the H^+ concentration, $[H^+]^2$. The rate constant of the first-step (step I) would probably be also proportional to $[H^+]^2$, but it could not be confirmed because the reaction was found too fast to be observed for pH≦3.2 (see Fig. 5). At pH lower than 3.2, on the other hand, even slower reaction (let us call it step III) came out, which could be monitored by a very slow fluorescence decrease. This is seen in Fig. 4 (b). Its rate

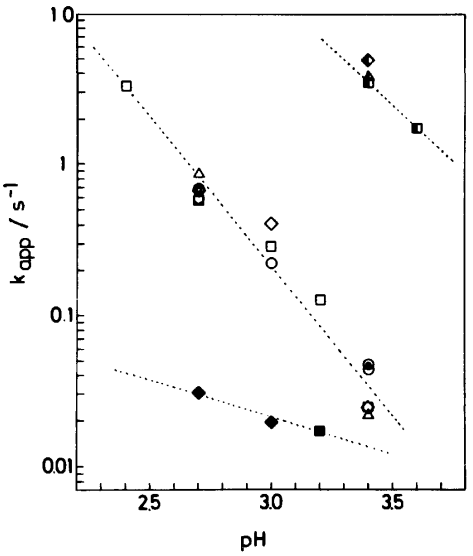

Fig. 5. Observed rate constants of the fluorescence and light scattering changes plotted against the pH values to which the pH jumps (from pH=5.4) were made at 21.5 °C.
◭ △ Fluorescence changes observed with aldolase concentration 6.2 mg/ml. ◐ ◇ ◆ Fluorescence changes, at 1.6 mg ml^{-1}. ◧ □ ■ Fluorescence changes, at 0.67 mg ml^{-1}. ◎ Light scattering changes, at 6.2 mg ml^{-1}. ○ Light scattering changes, at 1.6 mg ml^{-1}.

constants are plotted in Fig. 5 with black squares. The kinetic measurements were also done at different aldolase concentrations, 0.67—6.2 mg/ml. The rate constants of both fluorescence and light scattering changes, however, were found to be independent of the protein concentration (see Fig. 5).

Discussion

Present experimental results indicate that the acid denaturation of rabbit muscle aldolase consists of three distinguishable steps. Step I is a fast reaction in which fluorescence increases but no change in the light scattering takes place. Step II is a slow reaction in which a fluorescence increase and a light scattering lowering take place simultaneously. Step III is a further slower reaction in which fluorescence decreases and no light scattering change occurs. An interpretation of this set of steps is schematically represented in Fig. 6.

Apparently, the subunit dissociation takes place in step II. The rate constant of this dissociation reaction is about 0.04 s^{-1} at pH 3.4 but 0.6 s^{-1} at pH 2.7. The amplitude of the light scattering change is greater at pH 2.7 than that at pH 3.4 (see Figs. 3(c) and 4(c)). These facts may be interpreted by taking into account the finding (by sedimentation equilibrium measurements) that at pH 3.4 aldolase tetramer dissociates only into dimer-monomer mixture, whereas at pH 2.7 completely into monomer (Table 1). The rate of light scattering decrease was found to be independent of the protein concentration. This fact is explained if we assume (i) that tetramer←dimer back reaction is very slow (≈10^{-3} s^{-1}),[8] and (ii) that dimer⇄monomer equilibrium takes place very fast (>1 s^{-1}). In order to explain

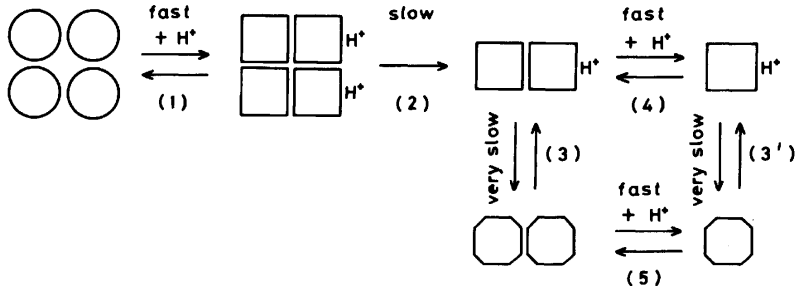

Fig. 6. Schematic representation of the proposed mechanism of acid denaturation of aldolase. We speculate that the observed step I corresponds to the process (1), the observed step II to the processes (2)+(4), and the observed step III to the processes (3)+(3') or (3)+(3')+(5).

the fact that this rate is proportional to $[H^+]^2$ we have to assume, in addition, (iii) that every tetramer has two sites of H^+ binding, which are essential to cause the tetramer→dimer dissociation. Because the step II fluorescence increase takes place simultaneously with the molecular weight change, it is likely (iv) that this fluorescence change is caused merely by a new exposure of some tyrosine or tryptophan groups located on the dimer surface, rather than an intra-dimer or intra-monomer conformation change.

The fluorescence change of step I (fast) must be attributed to an intra-tetramer, intra-dimer, or intra-monomer conformational change, because it is not accompanied by any molecular weight change. This fast conformational change seems to prepare for a two-site H^+ binding to cause the subunit dissociation. The fluorescence change of step III must be ascribed to an intra-monomer (intra-subunit) conformational change. This seems to be a final adjustment to reach a stable conformation of the monomer (or dimer) in acidic pH.

We thank Dr. A. Ikai and Dr. M. Kikuchi for the sedimentation equilibrium measurement. We also thank Dr. K. Watanabe for the circular dichroism measurement and Dr. A. Y. Hirakawa and Dr. H. Todoriki for the use of an optical fiber. This work was supported in part by a grant from Ministry of Education, Science and Culture.

Note added in proof. It is speculated that the two sites of proton binding, which are essential to cause the tetramer →dimer dissociation, are Asp 358 of the two β-subunits. In the α-subunits, this is replaced by Asn358 (This is the only difference in the amino acid sequences of α and β subunits; C. Y. Lai, *Arch. Biochem. Biophys.*, **166**, 358 (1975)), and cannot be protonated. Therefore, it is understandable that the effective protonation sites are only two, instead of four, per tetramer.

Induction of the β-Form of Poly(*S*-carboxymethyl-L-cysteine) and Poly[*S*-(2-carboxyethyl)-L-cysteine] by Chromium(III), Iron(III), and Lanthanum(III) Chlorides

Kazuki OKA, Hiroshi MAEDA,* and Shoichi IKEDA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received October 7, 1983)

The β-form was induced by the addition of $CrCl_3$, $FeCl_3$, and $LaCl_3$ to the salt-free solutions of fully ionized poly(*S*-carboxymethyl-L-cysteine) (poly[Cys(CH_2COOH)]) and poly[*S*-(2-carboxyethyl)-L-cysteine] (poly[Cys(CH_2CH_2COOH)]). The induction occurred below the equivalent point in both polypeptides. The inducing powers of the three trivalent cations were rather similar. They were weaker than Cu^{2+} ions in the case of poly[Cys(CH_2COOH)], while they were comparable with Cd^{2+} ions in the case of poly[Cys(C_2H_4COOH)]. Cu^{2+} and Cd^{2+} ions were the most effective species among divalent cations in the induction of the β-form of poly[Cys(CH_2COOH)] and Poly[Cys(C_2H_4COOH)], respectively.

Recently, the effects of various divalent metal ions on the conformation of poly[Cys(CH_2COOH)][1] and poly[Cys(C_2H_4COOH)][2] were studied. Transition metal ions, such as Cu^{2+}, Cd^{2+}, Zn^{2+}, and Ni^{2+}, effectively induced the β-form of these two polypeptides, while alkaline earth ions (Mg^{2+}, Ca^{2+}, and Ba^{2+}) were not effective inducers. Based on these results, it is likely that the β-form of these polypeptides is induced *in solution* only when their negative charges are annihilated by the redistribution of charges between the side chains and bound cations. In the present study, the effects of three kinds of trivalent metal chlorides, $CrCl_3$, $FeCl_3$, and $LaCl_3$, on the conformation of both polypeptides are examined in the fully ionized state.

Experimental

Poly[Cys(CH_2COOH)] (Lot No. KO125W; M_W=12 000, Dp=75) and poly[Cys(CH_2CH_2COOH)] (Lot No. H920WR; M_W=16 000, Dp=92) were the same samples as used in the previous studies.[1,2] Here M_W and Dp represent the molecular weight and the degree of polymerization, respectively. Reagent grade $CrCl_3 \cdot 6H_2O$, $FeCl_3 \cdot 6H_2O$, and $LaCl_3 \cdot 7H_2O$ were purchased from Nakarai Chemicals Ltd. (Kyoto) and used without further purification. Doubly distilled water was used to prepare the solutions.

Circular dichroism (CD) spectra were taken on a JASCO J-40 A circular dichrograph using a cell of 1 mm path length. Measurements of pH were carried out on a Hitachi-Horiba F-7 ss pH meter. These measurements were carried out at 25±2 °C. The polymer concentration C_p is expressed in the residue molarity, mol dm^{-3} (M), which is kept constant at 1.0×10^{-3} M in the present study. Metal concentration C_M is expressed in molarity (M), mol dm^{-3}. To compare the effects of trivalent ions with those of divalent ions, the metal concentrations are also expressed in normality (equiv dm^{-3}) and designated as C_s. Stock solutions of metal chlorides were used within half an hour after their preparation. After metal solutions were added to the polypeptide solutions, the mixtures were incubated for at least 24 h before the measurements, unless otherwise stated.

Results

In Figs. 1(a) and (b), the CD spectra of poly[Cys(CH_2COOH)] (a) and poly[Cys(C_2H_4COOH)] (b) are shown when various amounts of $CrCl_3$ are added. When $CrCl_3$ is not added, the CD spectra indicate the random coil state of respective polypeptides.[3] The CD spectra change with the addition of $CrCl_3$; the residue ellipticity around 200 nm, $[\theta]_{200}$, changes from negative to positive and reaches as large as about 4×10^4 and 2×10^4 in the case of poly[Cys(CH_2COOH)] and poly[Cys(C_2H_4COOH)], respectively. The CD spectra at large values of C_M/C_p resemble those of the β-form in the case of poly[Cys(C_2H_4COOH)].[3] In the case of poly[Cys(CH_2COOH)], however, the negative band around 225 nm shifts to 230 nm as C_M/C_p increases from 0.202 to 0.253. This shift of band position as well as a large residue ellipticity at 200 nm suggest a possible contribution from some electronic transition involving Cr^{3+} ions.

A charge transfer from a sulfur to Cr atom has been reported to exist around 240—260 nm.[4-6] Peerce *et al.* reported an absorption band around 195 nm for a complex of Cr(III) with a ligand containing sulfur and nitrogen atoms.[6] When a sulfur atom was substituted by a methylene group, this absorption was not found any more.[6] It is likely that an electronic transition involving a thioether and Cr is present in this wavelength region. All these results suggest that the CD spectra of both polypeptides should be carefully interpreted when Cr^{3+} ions are bound to them.

Contrary to the case of $CrCl_3$, normal CD pattern is obtained for the β-forms induced by $FeCl_3$ or $LaCl_3$. The CD spectra in the presence of $FeCl_3$ are shown in Figs. 2(a) and (b).

In Figs. 3 and 4, the residue ellipticities at 200 nm are plotted against the mixing ratio for poly[Cys(CH_2COOH)] and poly[Cys(C_2H_4COOH)], respectively. As a comparison, the results obtained on Cu^{2+} ions in the case of poly[Cys(CH_2COOH)] and Cd^{2+} ions in the case of poly[Cys(C_2H_4COOH)] are also shown in these figures. These ions are the most effective species among divalent metal cations in the induction of the β-form of each polypeptide. To facilitate the comparison, the abscissa is expressed as C_s/C_p instead of C_M/C_p, where C_s represents the normality of various metal ions. The equivalent point is thus located at C_s/C_p=1, irrespective of the valences of ions. In the case of poly[Cys(CH_2COOH)], both Fe^{3+} and La^{3+} ions are less effective to induce the β-form than Cu^{2+}

ions. In the case of poly[Cys(C_2H_4COOH)] both Fe^{3+} and La^{3+} ions have a comparable power to or even stronger power than Cd^{2+} ions.

In Figs. 5(a) and (b), the state of poly[Cys(CH_2-COOH)] solutions at various values of C_M/C_p is diagramatically shown, at 1 h (a) and 48 h (b) after the addition of metal chlorides. In Figs. 6(a) and (b), corresponding results on poly[Cys(C_2H_4COOH)] are given. Slow precipitation occurs for $CrCl_3$ and $LaCl_3$ in the case of poly[Cys(CH_2COOH)], while it occurs only for $CrCl_3$ in the case of poly[Cys(C_2H_4COOH)]. Among three metal chlorides, the least solubility is found in $LaCl_3$ solutions for both polypeptides. In $CrCl_3$ and $LaCl_3$ solutions, poly[Cys(C_2H_4COOH)] is more soluble than poly[Cys(CH_2COOH)]. As discussed previ-

the present study on $CrCl_3$ and $LaCl_3$ is interesting but puzzling.

Values of pH of the solutions of both polypeptides in the presence of the metal chlorides are shown in Fig. 7. The changes of pH are rather similar among three metal chlorides. This is in contrast to the result shown in Figs. 3 and 4, where a marked increase of $[\theta]_{200}$ is observed only for $CrCl_3$. The observed pH change supports the suggested interpretation that some contribution other than the conformational change is involved in the CD spectra of the solutions containing $CrCl_3$.

In Fig. 7, changes of pH take place at higher metal concentrations C_M in the case of poly[Cys(C_2H_4-COOH)] as compared with the case of poly[Cys(CH_2-COOH)]. This result implies that the binding of cations is stronger in poly[Cys(CH_2COOH)] than in poly[Cys(C_2H_4COOH)].

In Fig. 7, values of pH of the solutions of poly-[Cys(C_2H_4COOH)] are higher by approximately one

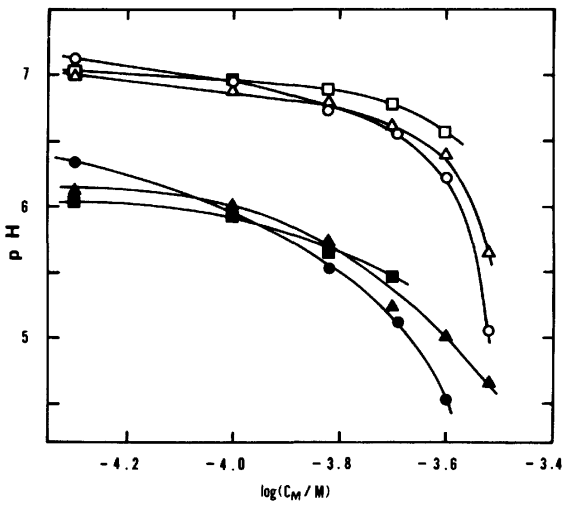

Fig. 7. Variation of pH with the logarithm of metal concentration C_M.

pH unit than those of poly[Cys(CH_2COOH)]. This simply stems from different intrinsic dissociation constants K_0 of the carboxyl groups of the two polypeptides; pK_0=3.25 for poly[Cys(CH_2COOH)][7] and pK_0=4.00 for poly[Cys(C_2H_4COOH)].[8]

Time courses of $[\theta]_{200}$ after the addition of metal chlorides are shown in Figs. 8(a) and (d) for poly[Cys(CH_2COOH)] and poly[Cys(C_2H_4COOH)], respectively. As shown in these figures, stationary values are reached within 5—6 h. Based on these results, all the data presented in the preceding sections were taken at 24 h (or longer) after the addition of metal chlorides, to confirm the equilibrium values.

Discussion

Comparison of the Extents of the β-Form Induction between the Two Polypeptides. The total change of $[\theta]_{200}$ associated with the complete conversion is undoubtedly larger for poly[Cys(CH_2COOH)] than for poly[Cys(C_2H_4COOH)].[3,9] However, the magnitude of the total change has been definitely evaluated for none of these two polypeptides. This is one of the problems of comparing the extent of the β-form induction between these two polypeptides, which was discussed previously.[2] In the present study, however some conclusion can be derived on the effect of trivalent cations. Comparison of Fig. 3 with Fig. 4 shows that the values of $[\theta]_{200}$ of the two polypeptides are very similar at the same mixing ratio C_s/C_p for $FeCl_3$ and $LaCl_3$. The result suggests that the induction of the β-form occurs more extensively for poly[Cys(C_2H_4COOH)] than for poly[Cys(CH_2COOH)] at the same value of C_s/C_p. On the other hand, the binding of counterions is suggested to occur more strongly for poly[Cys(CH_2COOH)] than for poly[(Cys(C_2H_4COOH)] from the pH changes. When these two results are combined, it is likely that the β-form is induced more effectively in the case of poly[Cys(C_2H_4COOH)] than poly[Cys(CH_2COOH)], if compared at the same bound fraction of counterions. This situation is the same as that found for proton binding.[7]

Comparison of the Effect of the Trivalent Ions with That of the Divalent Ions. In the present study, all three kinds of trivalent ions induce the β-form of poly[Cys(CH_2COOH)] and poly[Cys(C_2H_4COOH)] to approximately comparable extents with those found in the case of effective divalent cations. Counterion condensation of trivalent ions occurs more predominantly over divalent ions.[10] However, this cannot explain the effectiveness of the trivalent ions in the induction of the β-form. As described in the introduction part, the induction of the β-form occurs as a result of the annihilation of negative charges on the polypeptides by bound cations. However, the situation at the equivalent point is not uniquely determined but depends on the valency of bound counterions. A complete cancellation of charges takes place in the case of monovalent and diva-

lent cations such as protons or Cu^{2+} ions. In contrast to these cases, complete cancellation between opposite charges cannot be expected in the case of trivalent ions, since a bound trivalent ion interacts most likely with two (or perhaps four) side chains, leaving a positive (or negative) charge. Under this situation, there would be a distribution of positive and negative charges on the pleated sheets, their sum being zero at the equivalent point. This supposed unique situation of trivalent ions would provide additional stability which is lacking in the case of monovalent and divalent counterions. Effective but rather nonspecific induction of the β-form found in the present study may be ascribed to this unique stabilization factor of trivalent ions.

The specificity of counterion species is expected to originate from the specificity involved in the interaction of carboxyl group with bound counterions. The precipitation of poly(acrylic acid) by various metal cations provides an interesting example. The effect of $LaCl_3$ on the precipitation of poly(acrylic acid) was similar to that of $MgCl_2$, $CaCl_2$, and $BaCl_2$ (designated as type L precipitation).[11] This behavior of $LaCl_3$ is in marked contrast with the present result. In the present study, $LaCl_3$ behaves like $CrCl_3$ and $FeCl_3$, quite differently from alkaline earth divalent cations, in the induction of the β-form of the polypeptides carrying carboxyl groups.

Preparation of Graphite Fluoride by Vertical Vibrating Reactor

Nobuatsu WATANABE,* Saburo KATOH, and Tsuyoshi NAKAJIMA
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received July 20, 1983)

A study was made of the yield and crystallinity of graphite fluoride using a vertical vibrating reactor, which made it possible to prepare much graphite fluoride. The yield of graphite fluoride decreased beyond 500 °C for natural graphite and petroleum coke heat-treated at 2800 °C, and beyond 300 °C for calcined petroleum coke. The crystallinity of graphite fluoride was improved through the decomposition and refluorination process in these temperature ranges where the yield decreased. It was found that a sublimative solid by-product was formed together with gaseous fluorocarbons. It was a white solid fluorocarbon with 5—9 cyclohexane rings.

There are two kinds of stable graphite fluorides, $(CF)_n$ and $(C_2F)_n$, prepared by a high temperature reaction between a carbon material and fluorine gas. Their formation and yield depend on the crystallinity of the starting carbon material, on reaction temperature, and on fluorine pressure. When natural graphite is used as a raw material, $(CF)_n$ and $(C_2F)_n$ are formed at *ca.* 600 °C and 350—400 °C, respectively.[1] Between these temperatures, a mixture of $(CF)_n$ and $(C_2F)_n$ is obtained.

As the rotary reactor[1] previously reported produces only 1—2 g of graphite fluoride, it is not suitable for the evaluation of the yield of the graphite fluoride. In this study, the yield and crystallinity of graphite fluoride were investigated using a vertical vibrating reactor which made it possible to prepare 5—40 g of graphite fluoride. It has been said that the decrease in the yield of graphite fluoride is due to the formation of gaseous fluorocarbons such as CF_4 and C_2F_6. However, it was found in the present study that solid fluorocarbons with molecular weights of 798—2016 were formed together with the gaseous compounds. The structure of these solid fluorocarbons was also studied.

Experimental

Samples. Starting carbon materials were natural graphite (290—833 and 61—74 μm) and petroleum coke (original and heat-treated at 2800 °C). Fluorine gas of purity, 99.4—99.7% was used for the fluorination of carbon materials. Most of the impurity contained in fluorine gas was nitrogen.

Vertical Vibrating Reactor. Figure 1-a is the schematic diagram of the vertical vibrating reactor for the production of 5—40 g of graphite fluoride. This vibration system was adopted to achieve the continuous mixing of a carbon material. When the mixing of carbon is insufficient, the explosive decomposition of formed graphite fluoride sometimes occurs due to the lack of supply of fluorine gas. The mixing of

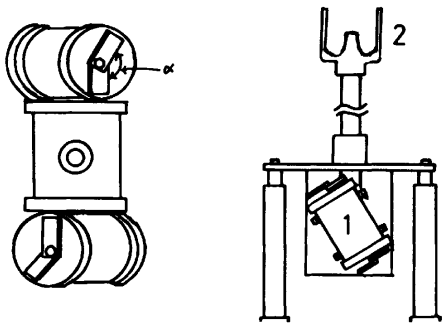

Fig. 1-b. Uras vibrator.
1: Uras vibrator, 2: reaction vessel.

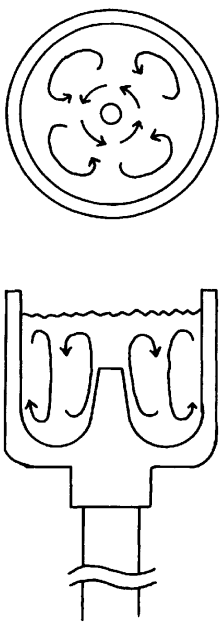

Fig. 1-c. Aspect of movement of carbon material by vibration.

carbon is therefore very important for the fluorination of large amounts of carbon. Vibration caused by a Uras vibrator (Fig. 1-b) installed at the bottom of the nickel reactor is transmitted through a nickel rod to a reaction vessel. The adjustment of vibration is made by changing the angle (α) between two unbalanced weights attached to the Uras vibrator. The aspect of movement of a carbon material in the reactor is schematically shown in Fig. 1-c.

Fluorination Reaction and Analyses of the Product. After pumping at room temperature, the reactor containing the starting carbon material was heated to a temperature between 300 and 600 °C; this was followed by further pumping for several hours. The reactor was then filled by argon gas at 1 atm, and a mixture of argon and fluorine gases was supplied to the reaction system (gas flow rate, F_2: 80 ml/min for natural graphite or 60 ml/min for petroleum coke, Ar: 70 ml/min). Unreacted fluorine gas was made to react with soda lime. After fluorination, the graphite fluoride prepared was analyzed by X-ray diffractometry (by Cu $K\alpha$) and elemental analysis. In addition to these analytical methods, the structure of the solid by-product was investigated by IR, ^{19}F-NMR, ESCA, and mass spectroscopies.

Results and Discussion

Yield of Graphite Fluoride. Figure 2 shows the yield of $(CF)_n$ and the time required for the completion of fluorination reaction as a function of the amount of each carbon material. The yield was decreased with increasing amounts of natural graphite, because it took a much longer time for fluorination with any increase in raw material and the decomposition of graphite fluoride to gaseous fluorocarbons occurred at the same time.

Figure 3 is the change of yield for the fluorination of a fixed amount of natural graphite as a function of reaction time and temperature. No unreacted graphite was detected under any condition. As seen in the figure, the yield decreased with increasing time and temperature. The decrease in yield started at *ca.* 500 °C for natural graphite and at *ca.* 300 °C for the original petroleum coke. The remarkable decrease in yield was observed especially in the latter case.

Composition and Crystallinity of Graphite Fluoride Prepared from Natural Graphite. Figure 4 is the composition and crystallinity of $(CF)_n$ prepared from natural graphite at 600 °C. The interlayer spacing and half width of the (001) diffraction line (d_{001}, β_{001}) decreased with increasing time, which means the improvement of crystallinity of graphite fluoride, while the chemical composition, F/C was almost unchanged. The improvement of crystallinity would be attained by eliminating the disordered parts among crystallites of graphite or $(CF)_n$. The disordered parts are easily attacked by fluorine gas to give gaseous fluorocarbons such as CF_4 and C_2F_6.[1,2]

The change in composition and cystallinity of graphite fluoride prepared from the flaky natural graphite

F/C: ○; from elemental analysis, ●; from weight increase.

is shown in Fig. 5 as a function of temperature. $(CF)_n$ was prepared at around 600 °C with d_{001} of 585—590 pm and F/C of 1. An F/C value of more than unity is attributable to CF_2 and CF_3 groups at the edge of the crystallite. As $(C_2F)_n$ was mainly formed at 450—500 °C, the d_{001} and F/C approached 900 pm and 0.5, respectively, with decreasing temperature. As shown in the lower part of Fig. 5, the F/C calculated from the weight increase of a carbon material started to deviate from that obtained by elemental analysis at around 500 °C, and their difference was caused by the decomposition of graphite fluoride to gaseous fluorocarbons. No decomposition of graphite fluoride occurred in the temperature regions where $(C_2F)_n$ was preferentially formed.

Composition and Crystallinity of Graphite Fluoride Prepared from Petroleum Coke. When graphite fluoride was prepared from the original petroleum coke, the d_{001} and β_{001} decreased remarkably in a temperature range higher than 350 °C, while the F/C was between 1.1 and 1.2 at 350—500 °C (Fig. 6). Graphite fluoride prepared at 300—500 °C had larger d_{001} and β_{001} values than $(CF)_n$ prepared from the natural graphite. This is not because of the simultaneous formation of $(C_2F)_n$ but is attributed to the formation of $(CF)_n$ with low crystallinity. It is known that only $(CF)_n$ is formed from a carbon material with low crystallinity under any condition and F/C is much greater than unity because of CF_2 and CF_3 groups on the surface.[2] The crystallinity of graphite fluoride has also a close relation with that of a raw material. With increasing temperature, the crystallinity of $(CF)_n$ was remarkably improved by the decomposition of amorphous parts to gaseous fluorocarbons, the d_{001} and β_{001} approaching those of $(CF)_n$ prepared from natural graphite. The F/C obtained from weight increase decreased monotonously with increasing temperature, corresponding to the decrease in the yield.

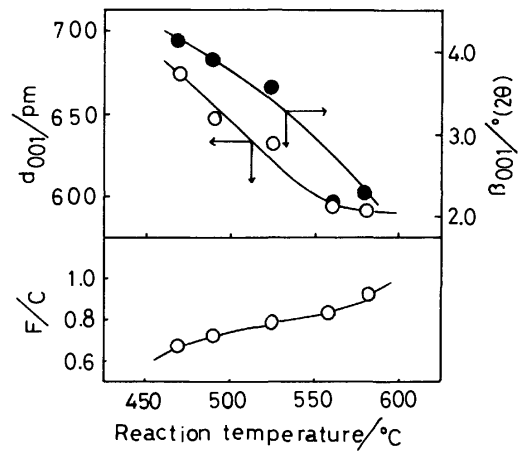

Fig. 7. Dependence of crystallinity and composition of graphite fluoride on reaction temperature.
Carbon material: petroleum coke heat-treated at 2800 °C.

The temperature dependences of the composition and crystallinity of graphite fluoride prepared from the petroleum coke heat-treated at 2800 °C were similar to those from the natural graphite (Fig. 7). The yield started to decrease at 500 °C as in the case of the natural graphite, but, the rate of decrease was larger than that in the natural graphite. The F/C value was much smaller than unity since $(C_2F)_n$ was formed from the graphitized carbon. The d_{001} and β_{001} approached those of $(CF)_n$ with increasing temperature, and only $(CF)_n$ was prepared at 580 °C.

Structure of Solid By-product. It was found that a white solid by-product was formed in the upper part of the reactor when the fluorination of a carbon material was made at a temperature where the yield of graphite fluoride largely decreased. In addition to gaseous

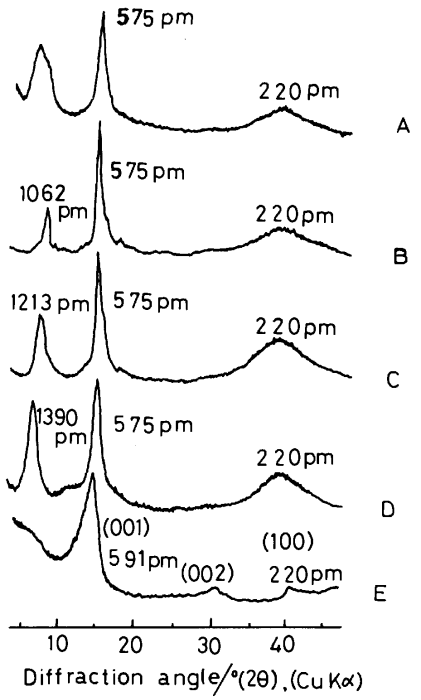

Fig. 8. X-Ray diffraction patterns of by product.

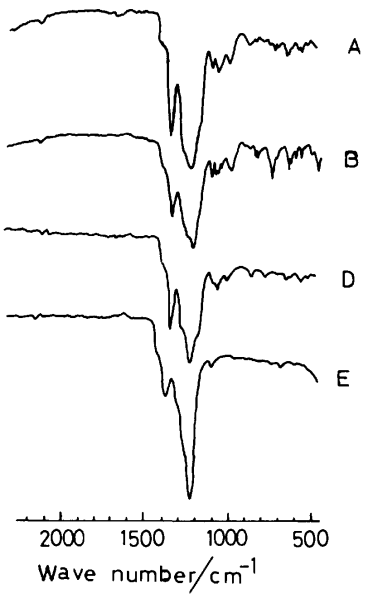

Fig. 9. IR spectra of by-product.
A: Original by-product, B: sublimated at 150 °C, D: residue on sublimation at 300 °C, E: graphite fluoride, $(CF)_n$.

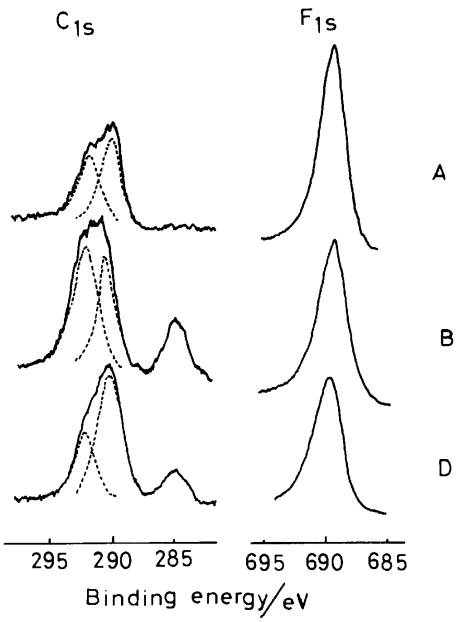

Fig. 10. ESCA spectra of by-product.
A: Original by-product, B: sublimated at 150 °C, D: residue on sublimation at 300 °C.

fluorocarbons, this solid by-product would also cause the decrease in the yield. In this section, the structure of solid by-product was described.

a) X-Ray Diffraction Patterns: Figure 8 is the X-ray diffraction patterns of the by-product. The by-product obtained gave the pattern A, which has nearly the same peaks as (001) and (100) diffraction lines of $(CF)_n$ except for a broad one at 6—9° in 2θ (Cu $K\alpha$). By sublimation at several temperatures, this by-product was separated into three groups, giving the pattern B (sublimated at 150 °C), C (sublimated at 200—250 °C), and D (residue on sublimation at 300 °C). As seen in B, C, and D, the broad diffraction line at 6—9° was separated into three different peaks. With increasing the sublimation temperature, the separated peak was shifted to a lower angle, corresponding to a larger d spacing.

b) ^{19}F-NMR Spectra: The 2nd moment obtained from the absorption derivative of the by-product was 10.1 G^2; this value is very near that of $(CF)_n$, 10.6 G^2.[1] Poly(tetrafluoroethylene) (Teflon) had the value, 5.0 G^2, which is different from the by-product value. This suggests that the unit structure in the by-product is the same as that for $(CF)_n$.

c) IR Spectra: Figure 9 is the IR spectra measured by the KBr method. The spectra of the by-product was very similar to that of $(CF)_n$. The absorption at 1215 cm^{-1} was ascribed to the CF stretching vibration and those at 1380 and 1110 cm^{-1} were due to the symmetric and asymmetric stretching vibrations of CF_2 bonds, respectively.[3] The latter two absorptions were larger in the by-product than in $(CF)_n$, which indicates that the by-product contains more CF_2 groups than $(CF)_n$ does. It is known from the spectra of Teflon that the absorptions due to the bending vibration of CF_2 appear between 500 and 900 cm^{-1},[4] where many small absorptions were also observed in the by-product.

d) ESCA Spectra: In the C_{1s} spectra of the by-products, two peaks corresponding to CF and CF_2 covalent bonds were observed at 290.5 and 292.4 eV, respectively.[1] These two chemical bonds between carbon and fluorine are the same as those of $(CF)_n$. In $(CF)_n$ powder, a small peak due to CF_3 group is observed at 294 eV in addition to the above two peaks. However, the by-products had only two peaks corresponding to CF

Table 1. Elemental analysis of by-product

Sample	F(wt%)	C(wt%)
A	67.66	31.66
B	66.60	31.25
C	70.75	29.88
D	66.86	33.92

Table 2. Composition and molecular weight of by-product by mass spectra

Sample	Composition	Molecular weight	Number of cyclohexane ring
B	$C_{19}F_{30}$-$C_{25}F_{38}$	798—1022	5—7
C	$C_{24}F_{36}$-$C_{40}F_{56}$	972—1544	7—13
D	$C_{43}F_{60}$-$C_{54}F_{72}$	1656—2016	14—19

and CF_2 groups and the ratio of CF_2/CF for the by-product was much larger than that of $(CF)_n$. This tendency was more distinctive in the by-products sublimated at a lower temperature.

e) Chemical Analysis and Mass Spectra: The results of chemical analysis are shown in Table 1. Though the fluorine content in a single crystal of $(CF)_n$ is 61.3 wt%, analyzed values are often larger than 61.3 wt% owing to the CF_2 and CF_3 groups on the surface. The highest value hitherto found is 65 wt%. However, the fluorine content in the by-product was 66—70 wt%, much higher than in $(CF)_n$. This is consistent with the presence of more CF_2 groups on the surface of the by-product than there were CF groups in the bulk. Mass spectra revealed that samples B, C, and D separated by sublimation were not a single compound but a mixture of those with different compositions. From the analytical results obtained in the previous sections, the by-product would have a structure in which some cyclohexane rings to which fluorines are bonded are linked with each other. Based on this model, the molecular weight and number of cyclohexane ring were calculated from the result of mass spectra. As shown in Table 2, the raw by-product would be a mixture of fluorocarbons consisting of 5—19 cyclohexane rings with molecular weight of 798—2016. The molecular weight increased in the order of B, C, and D, which is consistent with the fact that the sublimation temperature and *d* spacing obtained from X-ray diffraction pattern increased in the same order.

The analytical results are summarized as follows.

(1) All the by-products separated by sublimation had the same two peaks as (001) and (100) diffraction lines of ideal $(CF)_n$ crystal. The diffraction line at 6—9° in 2θ gave a larger *d* spacing for the sample separated at a higher temperature.

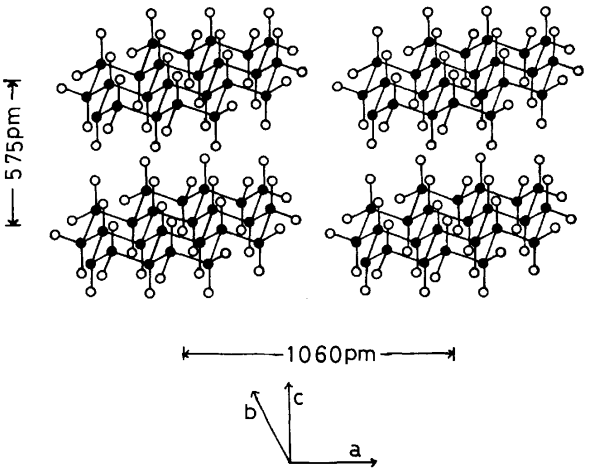

Fig. 11. Crystal structure of $C_{24}F_{36}$.
○: F, ●: C.

(2) IR and ESCA spectra showed that the by-product had the same CF and CF_2 groups as $(CF)_n$ and the ratio of CF_2/CF was much larger in the by-product than in $(CF)_n$.

(3) ^{19}F-NMR spectrum indicated that the unit structure of the by-product was the same as that of $(CF)_n$.

(4) Molecular weight was between 798 and 2016, corresponding to fluorocarbon compounds with 5—19 cyclohexane rings.

From these results, the by-product is regarded as a mixture of low molecular weight fluorocarbons having the same structural unit as that of $(CF)_n$. As an example, the crystal structure of $C_{24}F_{36}$ molecule with 7 cyclohexane rings is shown in Fig. 11, where each molecule is arranged in cubic system. The *d* spacing along the c-axis is 575 pm and the lattice parameter along the a and b-axis is almost the same as that of the diameter of a circular molecule.

Response Time Curves of Neutral Carrier Membrane Electrode of Tubular Shape

Hisao DEGAWA,* Noriko SHINOZUKA, and Shigeo HAYANO
Institute of Industrial Science, The University of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received July 22, 1983)

A tubular flow-through electrode system for measuring the response time curves under the step change of concentration using an ammonium ion-selective poly(vinyl chloride) membrane electrode was described. The response time data are analyzed by the curve fitting method using two theoretical equations, which are an exponential type equation based on an assumption of the film diffusion and a square root type one based on that of the diffusion within the membrane, and a semiempirical equation of hyperbolic type. A method of curve fitting in which the equilibrium potential is regarded as an unknown parameter was described in detail. The initial part of the response time curves, where the potential change is large, was fitted by the exponential type equation, while the following part close to the equilibrium potential was fitted by the square root type one. The semiempirical equation could also be fitted to the wide range of the curves. The dependence of the time constant of the exponential type equation upon the flow rate of sample solution is examined; the results firmly supports both the film diffusion as a determining process for the initial part of the curve and the reliability of the present experimental system.

The discovery of the electrically neutral carrier antibiotics which show the selective complexation behavior toward alkali cations, and the synthesis of the macrocyclic polyethers which show the same behavior as the antibiotics have yielded a large number of ion-selective membrane electrodes of practical use. Among the performance characteristics of these electrodes, the dynamic response behavior is not satisfactorily characterized compared with the selectivity behavior. This is mainly due to the difficulties in obtaining the reproducible data of response times under the step change of concentration. Response time curves (potential *vs.* time curves), particularly of the order of a few tenths of milliseconds to some seconds, are greatly dependent on the flowing conditions of the bathing solution and are subject to electrical noise. The precise characterization of the response time of ion-selective electrodes is prerequisite for the monitorings in continuous flow-through systems and for the measurements during chemical reactions. Moreover, it is supposed that the investigation of the rate determining processes in the dynamic response of ion-selective electrodes can contribute to the understanding of the electrode response mechanism. Usually the investigation can be done by the curve fitting method using the theoretical equations which predict the response time curves.

In general, to precisely measure response time curves of ion-selective electrodes, it is necessary to control the thickness of the stagnant (adhering) film of the conditioning solution. This is achieved by using simple electrode configurations where the thickness of the stagnant film is straightforward function of the flow rate of the bathing solution. To satisfy this requirement, three geometric types are considered; these are the rotating disk electrode, the so-called wall-jet electrode, and the tubular electrode. Oosterhuis *et al.*[1] applied a rotating disk electrode system to an amperometric flow cell detector for HPLC and continuous flow analysis because the system provided a high sensitivity by controlling the rotation speed. However, to the best of our experience, an application of the rotating disk electrode to the concentration step was unsuccessful, since the sufficiently fast step change was not attained and the measured potential was distorted by electrical noise. Lindner and coworkers[2–5] studied the dynamic chracteristics of precipitate-based electrodes and neutral carrier electrodes using an elaborate apparatus mounted with the solution jets perpendicular to the electrode surface; their apparatus corresponds to the wall-jet electrode system. Akiyama *et al.*[6] also examined the factors affecting the transient response properties of the valinomycin based potassium ion-selective electrode using a wall-jet system, and concluded that the diffusion through a stagnant solution layer was rate controlling. Quite recently, we reported a tubular flow-through electrode system for measuring the response time curves of an ammonium selective poly(vinyl chloride) (PVC) membrane electrode.[7] In the report, we attempted curve fittings using two theoretical equations described by Morf *et al.*[8] The theoretical equations are an exponential type one that based on the assumption of the adhering film diffusion and a square root type one based on that of the diffusion within the membrane. According to Morf *et al.*,[8] the square root type equation essentially explains the dynamic response of carrier membranes. The study by Akiyama *et al.*[6] and our preliminary results,[7] however, suggest that the square root type equation do not always cover the dynamic response behavior of the eletrodes.

The present paper gives a more detailed report dealing with examinations of the curve fitting method and with discussion on the rate determining processes of the dynamic response of the electrode.

Experimental

Chemicals and Membrane Electrode. Macrotetrolide actin mixture (tetranactin 65%, trinactin 30%, dinactin 5%) was kindly supplied by Research Laboratories, Chugai Pharmaceutical Co., Ltd. and was used as ion-selective ligand.[9] The electrode membrane consisted of ligand (5%), dibutyl sebacate (70%, Tokyo Kasei Kogyo Co., Ltd.), and PVC (25%, HS-589, Toyo Soda Manufacturing Co., Ltd.). The tubular

flow-through electrode unit was prepared in the manner mainly after Fraticelli and Meyerhoff.[10] Tygon tubing of internal diameter 0.8 mm was employed as a main part of the tubular electrode. The mixture containing membrane components was cast into a cut opening (*ca.* 2 mm diameter) of the side of the tubing, within which a syringe needle was inserted as a mandrel. Thus the membrane having a smooth cylindrical surface inside the tube was formed.

Apparatus and Procedure. Figure 1 schematically illustrates an experimental set-up for the response time measurement. The tubular membrane electrode (12 in Fig. 1) was attached to the flow system. A silver wire coated with silver chloride (10) was immersed in inner reference solution (11). A conventional silver-silver chloride electrode was placed in the reference electrode compartment (13) containing the waste solution. To eliminate electrical noise, particularly arising from the source of 50 Hz line, a stainless steel pipe (9) was inserted in the upper stream of the tubular electrode, and was connected to the ground terminal of a home made differential impedance converter (5); the terminal was also connected to a shield box made of aluminum chassis which covered the tubular electrode and the reference electrode compartments. A digital storage device (1 on the right in Fig. 1, Auto Digitizer Model 210, Autnics Co., Ltd) provides the resolution of 12-bit, the maximum sampling speed of 1 μs/word, and the storage capacity of 4 Kword. For the acquisition and processing of data, a microcomputer (PC-8801, CPU: μPD780C-1 (Z-80A compatible), 4 MHz, Nippon Electric Co., Ltd.) was used with programmable interfaces μPD8255AC-5 (NEC).

A Liquid drive syringe unit was constructed by attaching a commercial glass syringe (10 ml) to Union Giken Sample Mixing Device MX-7 and connecting Gas Drive Unit-A; a total distance of displacement of the syringe plunger was 40 mm. A linear potentiometer (2 in Fig. 1, Model LP-100F, Midori Precisions Co., Ltd.) was attached to the syringe unit to measure the flow rate of the bathing solution. Another digital storage device with an 8-bit resolution (1 on the left in Fig. 1, Wave Memory Model WM-841, NF Circuit Design Block Co., Ltd.) linked the linear potentiometer to the microcomputer. To interchange the bathing solution, a T-joint for use in HPLC (8) was set as shown in Fig. 1.

In all measurements, 0.1 mol dm^{-3} lithium chloride was used as supporting electrolyte of the bathing solution to eliminate streaming potential between the tubular electrode and the reference electrode compartment. The reason for the use of lithium chloride is that the selectivity coefficient of lithium ion is sufficiently low. Step changes in solution concentrations were attained by closing a cock (6), opening a cook (7), and triggering the gas drive unit to inject new solution into the tubular electrode which had already been exposed to conditioning solution. All measurements were made at room temperature (*ca.* 20 °C).

Results and Discussion

As mentioned above, to investigate the rate determining processes in the dynamic response of the ammonium ion-selective electrodes, two theoretical models[8] containing the intrinsic parameters were used for the curve fitting. Additionally, to sufficiently describe the experimental curves, a semiempirical equation was also applied to the curve fitting. The semiempirical equation will be introduced in the following context.

Theoretical Equations. An exponential type equation which is based on the assumption that the diffusion of fresh electrolyte into the static layer controls the response time is as follows:

$$E(t) = E(\infty) + s\log\left[1-\left(1-\frac{a_i^\circ}{a_i}\right)\exp\left(-\frac{t}{\tau'}\right)\right], \quad (1)$$

$$\tau' \approx \frac{\delta^2}{2D'}, \quad (2)$$

where $E(t)$ is the potential measured at the time t, $E(\infty)$ is the final potential after the activity step, s is the slope of the calibration graph, a_i° is the activity of the conditioning solution, a_i is the activity of the newly injected solution, δ is the thickness of the aqueous adhering layer, and D' is the diffusion coefficient of ion within the adhering layer. Another is a square root type equation derived from the assumption that the diffusion process within the membrane is regarded as rate controlling:[8]

$$E(t) = E(\infty) = s\log\left[1-\left(1-\frac{a_i^\circ}{a_i}\right)\frac{1}{(t/\tau)^{1/2}+1}\right], \quad (3)$$

$$\tau = \frac{DK^2\delta^2}{\pi D'^2}, \quad (4)$$

where D is the mean diffusion coefficient of electrolyte within the membrane and K is the salt distribution constant.

Curve Fitting Procedure. This paragraph describes a procedure of curve fitting using the exponential type equation; the same procedure can also be applied to the other equations. Our treatment of the least-squares estimate is on the basis of Wentworth's Papers[11,12] and Deming's book[13] dealing with the method of curve fitting applicable to some nonlinear equations. For curve fitting, we rewrite Eq. 1:

$$E(t) = E(\infty) + s\log\left[1-\left(1-\frac{a_i^\circ}{a_i}\right)\exp\left(-\frac{t-\theta}{\tau'}\right)\right], \quad (5)$$

where θ is an time adjustable parameter additionally introduced in order to allow the situation that the theoretical curve do not necessarily pass through the origin of E *vs.* t relationship. In this equation, the unknown parameter to be determined are $E(\infty)$, τ', and θ (but in our previous paper,[7] $E(\infty)$ was regarded as an

experimentally measurable quantity).

The least-squares problem is to determine the three parameters so as to obtain a minimization of the sum of the squares of the residuals:

$$\Sigma[\{E_i(t) - \bar{E}_i(t)\}^2] = \text{minimum}, \tag{6}$$

under the restriction that the condition equations

$$F_i(\bar{t}_i,\ \bar{E}_i(t),\ E(\infty),\ \tau',\ \theta) = \bar{E}_i(t) - E(\infty) - s\log\left[1-\left(1-\frac{a_i^\circ}{a_i}\right)\exp\left(-\frac{\bar{t}_i-\theta}{\tau'}\right)\right] = 0, \tag{7}$$

$$(i = 1,\ 2,\ \cdots\ n)$$

be satisfied. The symbol n is the number of the observed points, $E_i(t)$ is the observed value of the potential, and $\bar{E}_i(t)$ is the adjusted or calculated value of the potential. The weighting factor is treated as equal for all the points. It is assumed that the condition equations are linear with respect to t_i, $E_i(t)$, $E(\infty)$, τ', θ; Eq. 7 are expanded to the first order terms in a Taylor's Series about the point $(t_i, E_i(t), E^\circ(\infty), \tau'^\circ, \theta^\circ)$, where $E^\circ(\infty)$, τ'°, θ° are values of the first approximations. The Taylar's Series expansion and Eq. 6 yield normal equations:

$$\left.\begin{aligned}
&\Sigma\frac{\partial F_i}{\partial E(\infty)}\frac{\partial F_i}{\partial E(\infty)}\Delta E(\infty) + \Sigma\frac{\partial F_i}{\partial E(\infty)}\frac{\partial F_i}{\partial \tau'}\Delta\tau' + \Sigma\frac{\partial F_i}{\partial E(\infty)}\frac{\partial F_i}{\partial \theta}\Delta\theta = \Sigma\frac{\partial F_i}{\partial E(\infty)}F_i^\circ\\
&\Sigma\frac{\partial F_i}{\partial \tau'}\frac{\partial F_i}{\partial E(\infty)}\Delta E(\infty) + \Sigma\frac{\partial F_i}{\partial \tau'}\frac{\partial F_i}{\partial \tau'}\Delta\tau' + \Sigma\frac{\partial F_i}{\partial \tau'}\frac{\partial F_i}{\partial \theta}\Delta\theta = \Sigma\frac{\partial F_i}{\partial \tau'}F_i^\circ\\
&\Sigma\frac{\partial F_i}{\partial \theta}\frac{\partial F_i}{\partial E(\infty)}\Delta E(\infty) + \Sigma\frac{\partial F_i}{\partial \theta}\frac{\partial F_i}{\partial \tau'}\Delta\tau' + \Sigma\frac{\partial F_i}{\partial \theta}\frac{\partial F_i}{\partial \theta}\Delta\theta = \Sigma\frac{\partial F_i}{\partial \theta}F_i^\circ
\end{aligned}\right\} \tag{8}$$

where assuming $\partial F_i/\partial t_i=0$ and $\Delta E(\infty)=E^\circ(\infty)-E(\infty)$, $\Delta\tau'=\tau'^\circ-\tau'$, $\Delta\theta=\theta^\circ-\theta$. This equations can be solved for $\Delta E(\infty)$, $\Delta\tau'$, $\Delta\theta$; the least-square estimates of the parameters $E(\infty)$, τ', θ are calculated. It is usual to repeat the computations using the new $E(\infty)$, τ', θ as the first approximations; setting $E^\circ(\infty)=E(\infty)$, $\tau'^\circ=\tau'$, $\theta^\circ=\theta$, the normal equations 8 are iteratively solved. As a measure of fit, the variance σ^2 is employed:

$$\sigma^2 = \frac{\Sigma\{E_i(t)-\bar{E}_i(t)\}^2}{n-m}, \tag{9}$$

where m is the number of the unknown parameters. Using the new parameters, the variance or the standard error can be calculated. If the iterative procedure results in a satisfactory convergence of the variance, the three parameters are finally determined. Practically, the iterative computations are continued untill the change in σ^2 for successive iterations, $\Delta\sigma^2$, becomes less than a criterion which is previously evaluated by the estimated error in the experiments or some other convenience.

To determine the first approximate values $E^\circ(\infty)$, τ'°, θ°, the following procedure was carried out. The potential at the nearly equilibrium part (*i.e.* at 5 s) on E-t curve was employed as the $E^\circ(\infty)$, with which the plot of the left hand function *vs.* t of the linearized equation (from Ep. 5)

$$\ln\frac{1-a_i^\circ/a_i}{1-10^{\{E(t)-E^\circ(\infty)\}/s}} = \frac{1}{\tau'^\circ}t - \frac{\theta^\circ}{\tau'^\circ}, \tag{10}$$

yields the parameters τ'° and θ°.

Results of Curve Fitting. A typical response time curve of the ammonium ion-selective electrode for the concentration change from 1×10^{-4} to 1×10^{-3} mol dm^{-3} ammonium chloride is shown in Fig. 2. The linearized plot of Eq. 10 using 56.1 mV as $E^\circ(\infty)$ is illustrated in Fig. 3. In this example, a straight line is fitted in a range of 60 to 460 ms; the range corresponds to the potential level of 25.9% to 96.8% of the $E^\circ(\infty)$. The correlation coefficient is 0.997.. The lower limit of the range was determined at a flection point of the response time curve; the occurrence of the flection point may due to the unavoidable marginal zone between the conditioning solution and the injection solution. Beyond the range, a deviation notably occurs. The reciprocal slope and the intercept of the fitted straight line determined the values τ'°=158 ms and θ°=40 ms. A result of the iterative procedure with these values is shown in Table 1. As a criterion of $\Delta\sigma^2$, 0.25 (mV)^2 was employed. The $E(\infty)$ gradually approaches the potential of Nernstian response as the successive iteration is continued. Correspondently it is observed that τ' and θ slightly change. The facts that the $E(\infty)$ becomes a reasonable value and that the standard error is sufficiently small (σ=0.8 mV) indicate that this procedure of curve fitting is appropriate for the estimation of the parameters $E(\infty)$, τ', θ. The resultant value τ' will be tried to confirm by examining the flow rate dependence of τ' in the following

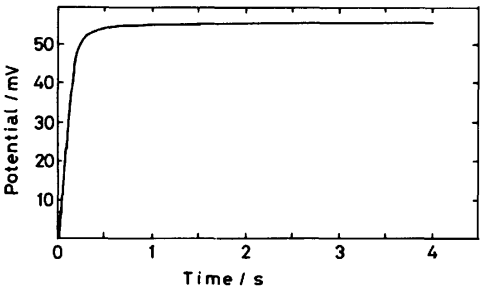

Fig. 2. Typical response time curve for 1×10^{-4} to 1×10^{-3} mol dm^{-3} NH_4Cl. Flow rate is 1.2 m s^{-1}.

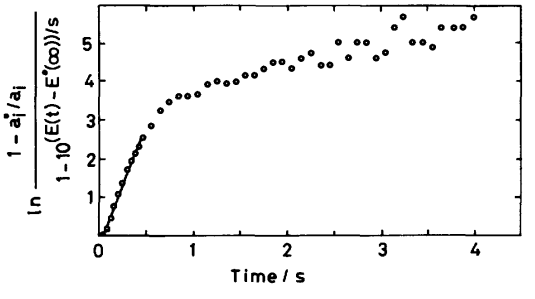

Fig. 3. Linearized plot of the Eq. 10 using the data of Fig. 2. Straight line is fitted in a range of time from 60 to 460 ms.

paragraph. The value θ can be regarded as a time lag due to the marginal zone of the flowing solution.

On the other hand, the linearized plot derived from the square root type equation 3 is shown in Fig. 4. In pratice, we determined the range of regression so that the range should be as wide as possible under the restriction that the correlation coefficient is more than 0.97 for example. The plot is fitted in a range of time from 480 to 1450 ms; the range corresponds to the potential level of 97.3% to 99.3% of the $E°(\infty)$. The correlation coefficient is 0.970. From this linearized plot, $\tau°$ and $\theta°$ were estimated at 0.33 ms and 457 ms respectively ($E°(\infty)$=56.1 mV). In this case, the iterative computation was carried out only once because the variance immediately converged. As the result, the three parameters were obtained: $E(\infty)$=56.1 mV, τ=0.38 ms, θ=448 ms. The standard error was 0.1 mV. The fact that the lower limit of the fitted range of Eq. 3 is close to the upper limit of the range of the exponential type equation means that the square root time dependence specific to the neutral carrier membrane becomes apparent after the outside equilibration is attained. In this case, the ratio of $\tau'/\tau(\approx D'/(DK^2))$ was about 400. For useful electrode systems, K must be sufficiently less than 1. Accordingly, it seems that the yielded ratio $\tau'/\tau(\approx 400)$ is a reasonable value. If we knew the numerical values D and K in this experimental system, the confirmation of the meaning of τ would be attained. At the present speaking, however, this cannot be done. In the literature,[8] concerning the potassium ion-selective membrane electrode in a fast stirring condition (so-called immersion technique), τ is reported to be 2 ms. Additionally, it is also described that for silcone rubber

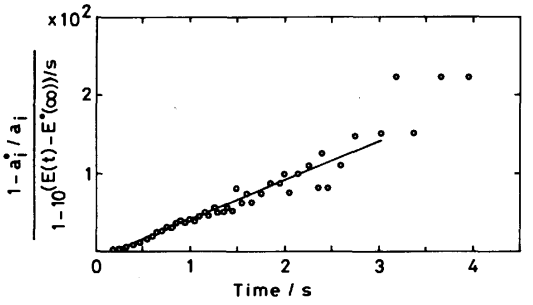

Fig. 5. Linearized plot of the semi-empirical equation using the data of Fig. 2. Straight line is fitted in a range of time from 200 to 3050 ms.

membrane in a rapid flow-through system, τ of down to 1 ms is observed. Under the circumstances, our result of τ=0.38 ms may not be unreasonable. The result of θ=448 ms and upper limit 460 ms of the range of Eq. 1 slightly overlap. In authers' opinion, as mentioned above, the diffusion process within the membrane equivalently begins at the time θ=448 ms. Practically, best fitting by Eq. 1 up to 97% potential completion means the response rate of the electrode is considerably fast. The more precise measurements with this electrode, however, is rather difficult for the diffusion within the membrane.

A Semi-empirical Equation. It seems that a parabola can be fitted to the plot in Fig. 4. This means that instead of Eq. 3 the following equation can be applied to the curve fitting.

$$E(t) = E(\infty) + s\log\left[1-\left(1-\frac{a_i^\circ}{a_i}\right)\frac{1}{t/\tau+1}\right], \qquad (11)$$

Accordingly a plotting shown in Fig. 5 was attempted. A straight line can be fitted to the plot in a range of time from 200 to 3050 ms; the range corresponds to the potential level of 83.8% to 99.7% of the $E°(\infty)$. The correlation coefficient is 0.947. The iterative computation yielded the following values: $E(\infty)$=56.2 mV, τ=27.3 ms, θ=165 ms, σ=0.4 ms. As a matter of fact, Eq. 11 can also be derived from the principle of second-order kinetics described by Morf[14] or Buffle and Parthasarathy.[15] According to Morf,[14] the time constant τ of Eq. 11 is equal to $1/(|a_i-a_i^\circ|k)$, where k is the rate constant of an kinetic equation of ion transfer reaction

$$\frac{d}{dt}\Delta a_i(t) = -k[\Delta a_i(t)]^2, \qquad (12)$$

$$(\Delta a_i(t) = |a_i'(t)-a_i|).$$

When the potential change is sufficiently small, the logarithmic function in Eq. 11 can be linearized:

$$E(t) = E(\infty) - \frac{1}{At+B}, \qquad (13)$$

where A and B are constants. This hyperbolic type expression is equivalent to Müller's equation.[16,17] However, Eq. 11 or 13 is rationalized not for neutral carrier membrane electrodes but for solid-state membrane electrodes (*e.g.* chloride electrode). Therefore the measured time constant τ=27.3 ms is not necessarily to be interpreted by the second-order kinetics mentioned

above.

We cannot theoretically explain why Eq. 11 is more fitted to the data than Eq. 3 is. Qualitatively, the exponential type curve is fast to approach the equilibrium potential, while the square root type curve is slow to do; the hyperbolic type curve has a medium property between the other two equations. In authors' opinion, the setting of $E°(\infty)$ is just appropriate to the curve fitting with Eq. 11. In our treatment, the potential at 5 s was employed as $E°(\infty)$ and the range of observation was restricted up to 4 s. If the Eq. 3 is forced to be fitted to the potential at about 4 s, the equilibrium potential should be higher than the potential at 5 s. At present, we can only say that the semi-empirical equation (Eq. 11) is apparently fitted to the data if the potential at several seconds is taken as equilibrium potential.

Effect of Flow Rate. A remarkable character of our apparatus is that the thickness of the adhering layer can be controlled by varying the flow rate. The flow rate was varied from 1.1 to 2.6 m s^{-1}. This corresponds to the Reynolds number from 860 to 2040. The flow of fluid in a smooth pipe at Reynolds numbers up to about 2000 is always laminar. If the wall of our tubular electrodes, however, have rough surface, the turbulent flow may occurs. Therefore we must examine both the cases of the laminar flow and the turbulent flow. For the turbulent flow in a smooth pipe, the thickness of adhering layer δ is expressed as a function of the flow rate of sample solution:[18]

$$\delta = (\text{const})v^{-7/8}, \tag{14}$$

where v is the linear flow rate and (const) is a lumped constant. By eliminating δ from Eqs. 2 and 14, a theoretical relationship between τ' and v is derived:

$$\tau' = (\text{const})'v^{-7/4}, \tag{15}$$

where (const)' is a lumped constant. On the other hand, assuming the laminar flow, $\tau' \propto v^{-2/3}$. Figure 6 shows a log-log plot of τ' against v using the data for concentration change from 1×10^{-4} to 1×10^{-3} mol dm^{-3} NH_4Cl. In this case, every upper limit of the range of regression is fixed on 97% of completion of potential response. The slope of the straight line drawn through the experimental points is -1.3; the correlation coefficient is 0.973. A series of the experimental data is located between the turbulent domain and the laminar domain, but is rather close to the turbulent one. In this paragraph, the flow rate dependence of the time constants are discussed; but the absolute values of the time constants are not confirmed yet. The facts that the initial part of the response time data was best fitted by Eq. 1 and that the flow rate dependence of the time constants was approximately agree with the expectation assuming the turbulent flow, however, support the assumption that the initial part of the response time data is due to the film diffusion.

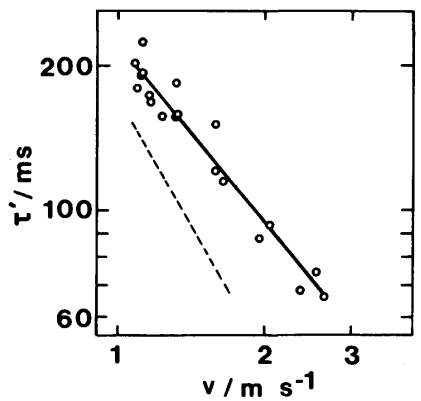

Fig. 6. Log-log plot of the time constant τ'(in Eq. 15) against the linear flow rate v using the data for concn change from 1×10^{-4} to 1×10^{-3} mol dm^{-3} NH_4Cl. The full line is drawn through the points; the slope is -1.3. The broken line represents a theoretical slope (-1.75). Every upper limit of the range of regression is 97% of completion of potential response.

Theoretically the dependence of the square root type equation (Eq. 3) upon the flow rate is the same with that of the exponential type one (refer to Eqs. 2 and 4). Actually, the slope of log-log plot of τ in Eq. 3 against v using the same data that was described above was also close to the theoretical one. The range of regression was from 97% to 99%. But the correlation coefficient was considerably less than that of Fig. 6. This is due to the fact that the effect of experimental error becomes relatively large because of the slightly variation in potential.

Conclusion

An application of tubular flow-through electrode to the measurement of the response time curve yields reproducible data which could be analyzed by the curve fitting method. For the curve fitting, two theoretical equations and a semi-empirical equation were used. A method of curve fitting in which the equilibrium potential was regarded as an unknown parameter provided reasonable results concerning the time constant, the equilibrium potential, and the adjustable parameter of time. On the response time curves, the first part where the potential change is large was fitted by the theoretical equation based on the film diffusion, while the next part close to the equilibrium potential was fitted by that based on the diffusion process within membrane. On the other hand, a semi-empirical equation of hyperbolic type could also be fitted to the wide range of the response time curves.

The fact that the dependence of the time constant of the exponential type equation upon the flow rate was fairly consistent with the theoretical expectation supports both the explanation of the first part of the response time curves by means of the film diffusion and the reliablity of the present experimental system.

The Sodium Isotopic Exchange Rate between High-temperature Phases of Disodium Zirconium(IV) Bis(orthophosphate) and Aqueous Solutions

Yasushi INOUE* and Yoshimune YAMADA
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki-aza-Aoba, Sendai 980
(Received July 25, 1983)

A monohydrate (Phase II) and three anhydrous phases prepared by the thermal treatment (at 250, 700, and 900 °C respectively for Phases III, IV, and V) of disodium zirconium(IV) bis(orthophosphate) trihydrate were studied from the sodium isotopic exchange rate between them and aqueous solutions. In Phases III and IV, which had been sufficiently adapted in water in advance, the rate was found to be controlled by the diffusion of sodium ions along the direction perpendicular to the layers consisting of zirconium atoms and the diffusion constants, and their activation energies (for Phases III and IV, 57 and 52 kJ/mol) were evaluated. When these phases were used as dried, the rate was governed by the irreversible dissociation of sodium in the solid phases. In Phase II, used as dried, and in Phase V, used as dried and wetted, the rate was controlled by neither particle diffusion, film diffusion, nor chemical reaction alone. This behavior was attributed to the complex behavior of phase transformation as the isotopic exchange proceeded.

The dehydration of the disodium zirconium(IV) bis(orthophosphate) trihydrate (hereafter this material will be referred to as Phase I) obtained from the zirconium(IV) bis(hydrogenphosphate) monohydrate prepared by the direct precipitation method[1] was found to give a monohydrate and three anhydrous phases, depending on the temperature of thermal treatment and on the surrounding humidity. The most suitable conditions for the preparation and for the storage of these five phases, including Phase I, were also established in addition to the examination of phase transformation brought about by immersing them in aqueous solutions.[2]

As Phase I is the most stable of them at room temperatures, it was at first used for the study of the sodium isotopic-exchange rate to provide fundamental data which would be useful for elucidating ion-exchange kinetics. It was concluded that the rate was controlled by the particle diffusion along the direction perpendicular to the layers of crystals; the diffusion constants and their activation energies were obtained as has previously been described.[3]

Since this type of material, known as "crystalline zirconium phosphate", can be used as an ion exchanger at high temperatures, the study of ion-exchange kinetics for its high-temperature phases is interesting. The rate for them acquires additional interest from the facts that their structures differ in different phases and that the capillary water introduced by placing them in contact with aqueous solutions plays an important role in the rate of the exchange.

This paper will deal with the radiochemical experiments performed to measure the isotopic-exchange rate of sodium ions between $Na_2Zr(PO_4)_2 \cdot nH_2O$($n$=0, 1) and concentrated sodium nitrate solutions and will discuss the results with reference to their phase stability in aqueous solutions.[2]

Experimental

Preparation of the Materials Spiked with ^{22}Na. Phase I labeled with ^{22}Na at about 40 μCi/g(1 Ci=3.7×10^{10} Bq), with uniform crystal sizes, was prepared by the procedure reported previously.[3] Its average size is given in Table 1. The radiochemical purity of ^{22}Na was confirmed by gamma-ray spectrometry. The monohydrate (Phase II) was obtained by drying Phase I over P_2O_5 for three weeks, while the anhydrous phases, phases III, IV, and V, were formed by heating Phase I at 250, 700, and 900 °C respectively for 4 d.[2] They were stored *in vacuo* over P_2O_5 and used for the rate measurement (as a dried system). In addition, parts of them were immersed in water for a definite period of time (Phases III and IV, 1 d; Phase V, one week) to adapt them to aqueous solutions and then also used for the experiments (wet system).

TABLE 1. PARTICLE SIZE OF THE SAMPLES

No.	Mean crystal size/μm		
	Length	Width	Thickness
1	286±44	238±32	16±3
2	190±24	159±15	16±2

The Measurement of the Isotopic-exchange Rate. All the experiments were performed in a nitrogen atmosphere. The rate was measured by using the same apparatus as before.[3] A 400-mg portion of the sample was placed in the cage and immersed in 200 cm^3 of a 5-mol dm^{-3} sodium nitrate solution, whose pH was adjusted to 11 by sodium hydroxide, while the cage was rotated at a rate of 1200 min^{-1}. The solution had been adjusted in advance to a constant temperature within ±0.1 °C. Aliquots of the solution (about 0.2 cm^3) were taken out at appropriate time intervals in order to measure the radioactivity with a well-type NaI(Tl) scintillation counter. The time of contact of the solution with the exchanger was taken as the time which elapsed between the immersion of the cage and the withdrawal of an aliquot of the solution.

The fractional attainment of equilibrium, $F=C_t/C_\infty$, was calculated from these results; here, C_t is the total radioactivity of the solution at time t and C_∞ at $t=\infty$. C_∞ was calculated by means of this equation; $C_\infty=CM/(M+m)$, where C is the initial total radioactivity of the exchanger and where m and M are the total amounts of Na^+ ions in the exchanger and in the solution respectively. After the experiments were finished, it was confirmed microscopically that the particles did not break down at all during this series of procedures.

The other materials, apparatus, and experimental proce-

dures were the same as had been described previously,[3] except as otherwise noted.

Results and Discussion

The sodium isotopic-exchange rate was measured with two types of samples: (a) dried and (b) wet. The results for each type of experiment will be described separately for convenience.

Wet System. The fractional attainment of equilibrium, F, against the square root of the time needed for Phase III is shown in Fig. 1. For Phase IV, curves similar to Fig. 1 were also obtained, though the rate was slower for Phase IV than for III. This figure clearly indicates that a linear relation held between F and $\sqrt{t}$ in the F range smaller than about 0.4 except for the initial portion of these plots. The curves also reveal that the rate was independent of the particle size. In this manner, the dependence of the rate on various experimental factors for Phases III and IV is similar to that for Phase I; hence, we can analyze the data by applying the same assumptions made for Phase I, that is, the rapid attainment of exchange equilibrium on the surface of the crystals, followed by a slow diffusion into the bulk of them, a diffusion along the direction perpendicular to the layers consisting of zirconium atoms. The diffusion constant, D, can, therefore, be obtained from F by means of this equation;

$$F = \frac{2}{\pi^{1/2}}\sqrt{\beta t}.$$

where $\beta = D/l$, and l is the half-thickness of the crystals.[3] For calculating D, a revised value of l was used in place of that presented in Table 1. When Phase I is transformed to Phase III, the interlayer distance decreases from 0.983 to 0.839 nm.[2] This inevitably shortens the thickness of the crystals to 0.839/0.983×16=13.7 nm. When log D was plotted against $1/T$, a good linearity was obtained, as is shown in Fig. 2. From the Arrhenius equation, $D = D_0\exp(E_a/RT)$, the activation energy and the constant, D_0, were evaluated. The values of D_0 for Phases III and IV respectively were 1.1×10^{-3} and 9.5×10^{-5} m^2/s, while those of E_a were 57±3 and 52±5 kJ/mol. It is not strange that the diffusion constants and their activation energies for these phases are about the same, for Phase IV is transformed to Phase III immediately after being immersed in water.[2] The slightly higher activation energy for Phase III than for IV can be explained in terms of the lower diffusion barrier in the latter, since the latter has more crystal defects than the former.[2] The exchange rate is much faster for Phases III and IV than for Phase I, and the activation energy of particle diffusion in these anhydrous phases has values about half that in Phase I (101 kJ/mol).[3] These differences cannot be attributed to the difference in the size of the openings, which interconnect the layers and which have a diameter of 0.24 nm at the largest, large enough to allow sodium ions to diffuse across the layers. Phase I contains three molecules of water of crystallization per formula, while the anhydrous phase has only a small amount of capillary water. Phase I, therefore, requires sodium ions to travel as large hydrated ions instead of free sodium ions, the species participating in the diffusion in the anhydrous phases. The difference between the trihydrate and anhydrous phases, therefore, results from the difference in the size of the ions traveling through the layers.

The F *vs.* $\sqrt{t}$ plots for Phase V are shown in Fig. 3, which indicates that no linearity held and that the rate slowed down abruptly after 60 min. This relation cannot be explained by the diffusion mechanism alone, but it might be due to the slow transformation of the crystals as the exchange proceeds.

Dried System. Contrary to the rate for the wet system, Phases III and IV when dried did not show a linear relation between F *vs.* $\sqrt{t}$, but they did show one between $-\log(1-F)$ and t, as is shown in Figs. 4 and 5. This means that the exchange rate is not controlled by the particle diffusion, but by either film diffusion or a chemical reaction. The film diffusion, however, does not appear to control the rate under the conditions adopted in the present experiments, *i.e.*, a high sodium-

ion concentration and a high stirring speed in the range where it does not affect the exchange rate. Moreover, if the rate is controlled by the film diffusion, it must be faster for a dried than for a wet system. The experimental data, however, do not support this assumption. From these considerations, it can reasonably be assumed that the rates for the dried Phases III and IV are governed by a chemical reaction. The sodium in completely dried samples is considered to be strongly bonded with phosphate groups and not to be dissociated. As an ion-exchange reaction occurs between dissociated ions in the crystals and those present in the solution, sodium must be dissociated before the ion-exchange reaction commences.

If sodium is dissociated irreversibly with the rate constant, k, and if the sodium ions thus formed participate in the isotopic exchange reaction, that is,

$$\overline{RA} \xrightarrow{k} \overline{R} + \overline{A^+}$$

$$\overline{A^+} + B^+ \underset{}{\overset{K}{\rightleftarrows}} A^+ + \overline{B^+}$$

$$K = \frac{m_B C_A}{m_A C_B}.$$

From the material balance,

$$m_{RA} + m_R = E,$$

$$m_R = m_A + m_B,$$

where R^- is the matrix of the exchanger; K, the equilibrium constant of the exchange reaction; m, the amount of designated species in the exchanger; E, the specific ion-exchange capacity, and C, the concentration of designated species in the solution, and where a bar refers to the solid phase.

From the experimental conditions, C_A/C_B is always unity. Thus,

$$m_{RA} = E - m_A - m_B = E - \frac{1+K}{K} m_B.$$

The rate of increase of m_B can be written by;

$$\frac{dm_B}{dt} = K\frac{dm_A}{dt} Kkm_{RA} = KkE - k(1+K)m_B. \quad (1)$$

By integrating Eq. 1, we obtain:

$$m_B = \frac{1}{k(1+K)} [KkE - \exp\{-k(1+K)t+g\}], \quad (2)$$

where g is the integration constant.

By applying the initial conditions, $t=0$, and $m_B=0$, Eq. 2 becomes;

$$Q = m_B = \frac{KkE}{k(1+K)}[1-\exp\{-k(1+K)t\}], \quad (3)$$

$$Q_\infty = \frac{KkE}{k(1+K)}.$$

When we set $Q/Q_\infty=F$, we obtain:

$$\log(1-F) = -\frac{k}{2.303}(1+K)t.$$

In the isotopic exchange, $K=1$; therefore,

$$\log(1-F) = -\frac{2k}{2.303}t. \quad (4)$$

Equation 4 agrees with the results of the experiments.

Even when the dissociation reaction proceeds reversibly, Eq. 4 is valid. If we consider that the dissociation

reaction is reversible, the same relation must hold for a wet system. However, as the isotopic-exchange reaction for a wet system is much faster than this and is controlled by the particle diffusion, the reversible dissociation cannot be rate controlling. Accordingly, when the completely dried Phases III and IV are in contact with the solution without having been wet in advance, the rate of exchange reaction is controlled by the irreversible dissociation of sodium in the exchanger, which is much slower than the particle diffusion.

The reaction rate constants, k, were obtained from the slopes of the straight lines in Figs. 4 and 5; they are plotted against $1/T$ in Fig. 6. The activation energies of

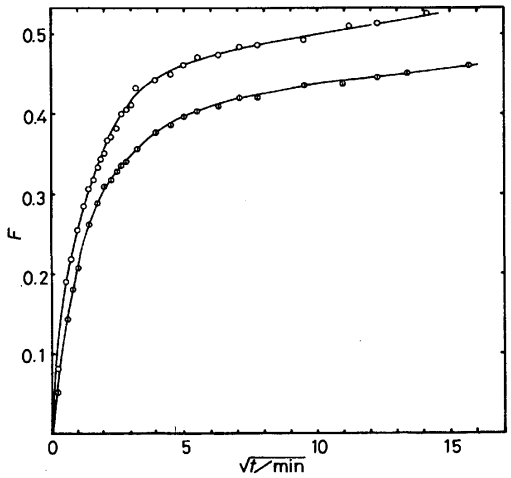

Fig. 8. Isotopic exchange rate for Phase V (dried system).

○: 18.4 °C, ⓘ: 5.4 °C.

the dissociation reaction for Phases III and IV were 63±2 and 56±2 kJ/mol respectively, while the frequency factors of the Arrhenius equation, k_0, are 1.2×10^8 and 2.6×10^6 s^{-1}. The faster reaction rate for Phase III than for IV can be ascribed to the lower temperature of the thermal treatment of the former.

The plots of F against $\sqrt{t}$ for Phases II and V are shown in Figs. 7 and 8. Contrary to Phases III and IV, neither these plots nor the plots of $-\log(1-F)$ *vs.* t are straight lines; hence, the rate is governed by neither film diffusion, particle diffusion, nor a chemical reaction alone.

In the case of Phase II, the rate slowed down markedly with the progress of the exchange. The rate will be controlled at first by the faster diffusion in Phase II, followed by the slower diffusion in Phase I, which is formed as the exchange reaction proceeds.[2] In other words, the curves may result from a complicated combination of the transformation rate of the crystals and the diffusion of ions in them.

Figure 8 indicates that the isotopic-exchange rate for Phase V behaved similarly to that for Phase II and was slower than that for a wet system. The reason for this rather complicated behavior is not clear, but it may be due to the complex behavior of the transformation of this phase.[2]

Further investigations must be undertaken before the kinetics of the sodium isotopic-exchange reaction for Phases II and V can be unambiguously determined.

Stability Constants of Scandium Complexes. I. Monocarboxylate Complexes Species

Hisako Itoh, Naomi Itoh, and Yasuo Suzuki*
Department of Industrial Chemistry, Faculty of Engineering, Meiji University, Higashi-mita, Tama-ku, Kawasaki 214
(Received August 26, 1983)

The stability constants of scandium complexes with some carboxylate ligands were determined potentiometrically at 25.0 and 40.0 °C and at an ionic strength of 0.10 with potassium nitrate as supporting electrolyte. The constants of the scandium complexes were appreciably greater than those of the corresponding lanthanoid complexes, as expected. The changes in free energy, enthalpy, and entropy for the formation of the scandium complexes were calculated from the stability constants at two temperatures.

Since scandium has a similar outer electron shell configuration to the trivalent lanthanoids, the chemical properties of scandium are close to those of the trivalent lanthanoids. The stability constants of various lanthanoid complexes have been determined by many investigators,[1] however, only a few investigations of scandium complexes have been reported so far. Trivalent scandium, which is the only oxidation state for scandium in solution, has a smaller ionic radius than any of the lanthanoids but is larger than that of aluminium.[2] Thus scandium(III) should form more stable complexes with both anionic and neutral ligands than the lanthanoids,[3] although it undergoes extensive hydrolysis in aqueous solution. In the present study, the stability constants of scandium complexes with some monobasic carboxylic acids were determined and compared with those of the corresponding lanthanoid complexes.

The method employed for determining constants was based on conventional potentiometry as developed by Bjerrum,[4] Sonesson,[5] and others, and has been used in the previous work[6,7] by one of the authours.

Experimental

Reagents. Scandium nitrate stock solution was prepared by dissolving scandium oxide of 99.9% purity in nitric acid and diluting to a definite volume with water. The concentration of excess nitric acid was as high as 0.035 mol dm^{-3} to prevent hydrolysis. The potasium nitrate stock solution was prepared from the purified salt. The buffer solution of each ligand acid was prepared by half neutralization of the acid solution with an appropriate amount of carbonate-free standard sodium hydroxide.

Apparatus. The pH of the sample solution was measured with an Orion model 701A digital pH/mV meter equipped with Orion Ross 810100 pH and 800500 double-junction reference electrodes. The instrument is capable of measuring pH of a solution with an accuracy of 0.001 unit.

Procedures. An aliquot portion of scandium nitrate solution was added to a volumetric flask together with a carboxylate buffer solution and potassium nitrate to bring the final solution to an ionic strength of 0.10. The flask was brought to the mark with water then suspended in a constant temperature bath set at 25.0 °C for 24 h. The sample solutions used in measuring acid dissociation constants were prepared in the same way as the sample solutions described above, but without scandium nitrate.

Results and Discussion

There have been no previous reports on the stability constants of scandium complexes with the ligand acids used in the present study, except for acetylacetone,[8] acetic acid,[9] and D-gluconic acid.[10] The stability constants of the scandium complexes obtained are shown in Table 1, along with the values from the previous work. The stability constants obtained are in good agreement with those of the previous work.

The relation between basicity of ligands and the stability constants of complexes has been extensively discussed.[11–16] The ligands of stronger basicity produce more stable complexes, in other words, ligands which strongly combine with protons form stable complexes with metal ions. The linear correlations between the basicity of a series of ligands and the stability constants of complexes have been reported.[11–16] The relation

Table 1. Logarithms of stability constants and thermodynamic data of scandium complexes at 25.0 °C and at I=0.10 (KNO_3)

Ligand acid	This work	Previous work	$-\Delta G$ / kJ mol^{-1}	$-\Delta H$ / kJ mol^{-1}	$T\Delta S$ / kJ mol^{-1}
α-Hydroxyisobutyric acid	4.84	—	27.6	115	−87.0
Isobutyric acid	4.47	—	25.5	90.1	−64.6
Glycolic acid	4.40	—	25.5	121	−96.2
Acetic acid	3.48	3.16[8]	19.6	1.25	18.8
Propionic acid	3.77	—	21.3	8.78	12.5
Mandelic acid	2.91	—	16.7	−5.43	22.1
D-Gluconic acid	4.21	3.92[9]	23.8	−52.3	76.5
Acetylacetone	7.77	8.88[7]	44.3	388	−344

between the stability constants of the scandium complexes and the basicity of the ligand acids used here is shown in Fig. 1. Isobutyric, acetic, and propionic acids do not have an alcoholic OH group, whereas α-hydroxyisobutyric, glycolic, mandelic, and D-gluconic acids have OH. In the latter acids, the OH group apparently contributes to form five-membered rings, consequently the stability constants are greater than those of the former.

In considering the ionic radius, it is expected that the greater the charge and smaller the ionic radius, the greater will be the stability of the complexes, since the energy of an ionic bond corresponds to the electrostatic work to bring metal ions close to ligands. The relationship to the stability constants of α-hydroxyisobutyrato, glycolato, gluconato, and mandelato complexes against ionic radius is shown in Fig. 2. The stability constants of scandium complexes are on the extrapolated lines of those of the lanthanoid complexes. In the case of the mandelato complexes, the gradient of the line is smaller than the others, possibly due to steric hindrance. The relations between the stability constants of isobutyrato, acetato, and propionato complexes and ionic radius are shown in Fig. 3. The scandium complexes are on the extrapolated lines of the lighter rare earth complexes rather than the heavier rare earth complexes. The previous investigations[17-21] indicated that the relation between the stability constants and ionic radii was remarkably different for each of the ligands studied, and that the trends in the stability of the rare earth complexes were dependent on the changes in the coordinating characteristics of the ligands as well as on the changes in the degree of cationic hydration. Therefore, the scandium complexes are thought to be similar to the lighter rare earth complexes with regard to the coordinating characteristics and the degree of cationic hydration.

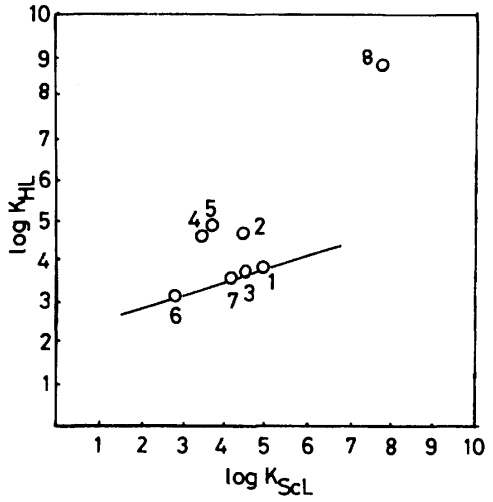

Fig. 1. Relation between stability constants of scandium complexes and basicity of ligands.

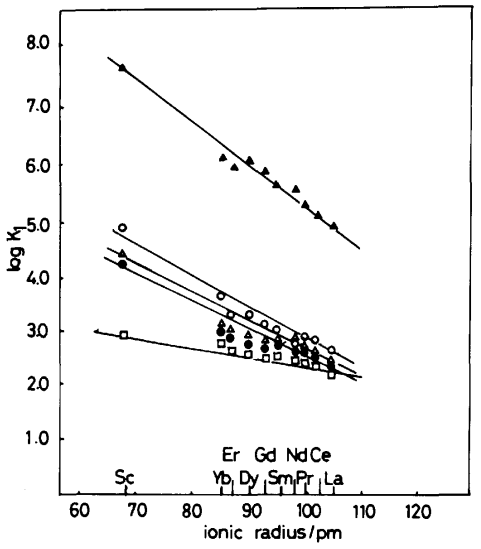

Fig. 2. Logarithms of stability constants of rare earth complexes. I.
○: α-Hydroxyisobutyrate, ●: D-gluconate, △: glycolate, ▲: acetylacetonate, □: mandelate.

The relation betweeen the stability constants of α-hydroxyisobutyrates and glycolates and ionization enthalpies of the rare earth elements are shown in Fig. 4. A straight line through yttrium, lanthanum, lutetium, and scandium, which have no d- and f-electrons, was obtained. Since electronegativity or ionization enthalpy is a measure of attracting electrons from the donor atoms of ligands, the linear relationships between the stability constants and the ionization enthalpy is reasonable. However, such lines were not obtained for isobutyrato, acetato, propionato, mandelato, gluconato, and acetylacetonato complexes.

The calculated values of the change in free energy, enthalpy, and entropy for the formation of the scandium complexes are shown in Table 1. Thermody-

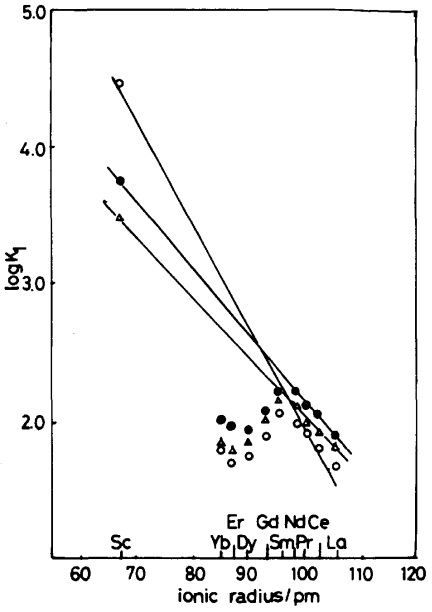

Fig. 3. Logarithms of stability constants of rare earth complexes. II.

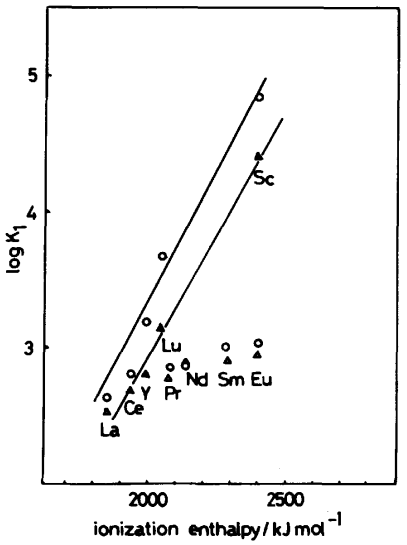

Fig. 4. Logarithms of stability constants of α-hydroxyisobutyrate and glycolate complex species *versus* ionization enthalpy.
○: α-Hydroxyisobutyrate, △: glycolate.

namic data on the scandium complexes indicate that $-\Delta H$ values are larger than $T\Delta S$ values for the α-hydroxyisobutyrate, isobutyrate, glycolate, and acetylacetonate systems. However, the entropy terms are larger than the enthalpy terms for acetato, propionato, mandelato, and gluconato complexes. The formation reactions of mandelato, and gluconato complexes are endothermic and the existence of the complexes is due to favorable entropy change. The increase in ΔS would be due to the increase in steric hindrance, thereby loosening the bond and increasing the configurational entropy of ligands such as mandelic and D-gluconic acids.

Synthesis of [3](1,1′)[3](3,3′)- and [4](1,1′)[4](3,3′)Ruthenocenophanes

Shin-ichi KAMIYAMA* and Akira KASAHARA†
Government Industrial Research Institute, Tohoku, 115-10 Ishiyose, Minaminome, Haranomachi, Sendai 983
†*Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992*
(Received March 22, 1983)

[3](1,1′)[3](3,3′)- and [4](1,1′)[4](3,3′)Ruthenocenophanes were synthesized *via* cyclization of the propionic acid derivatives of [3](1,1′)- and [4](1,1′)ruthenocenophanes with polyphosphoric acid or trifluoroacetic anhydride, respectively. The ^{1}H NMR, IR, and electronic spectra of these dibridged ruthenocenes were measured and compared with those of monobridged ruthenocenes.

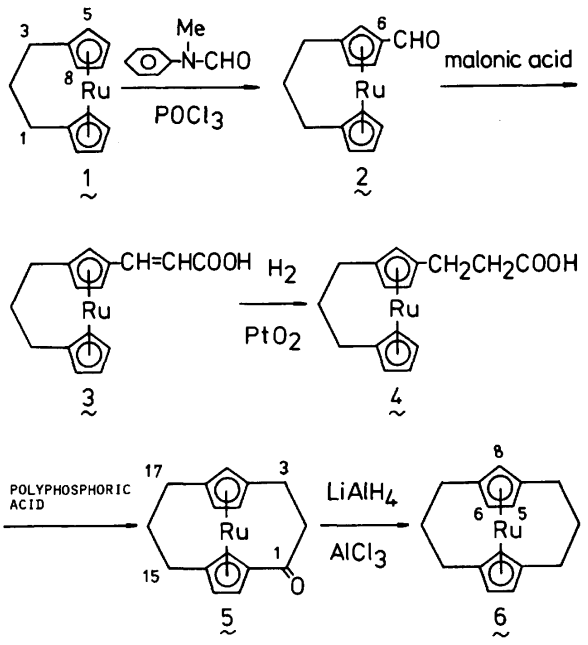
There have been a large number of studies[1–19] on heteroannularly multibridged ferrocenes including tri-, tetra-, and pentamethylene chains, because their unusual chemical and physical properties can be compared with those of cyclophanes.[20] However, no synthetic work on multibridged ruthenocenes has been found in the literature. Studies on the bridged ruthenocenes include our previous description of the synthesis and properties of [3](1,1′)- and [4](1,1′)ruthenocenophanes.[21] The synthesis of [5](1,1′)ruthenocenophanes[22] with substituents in their chains has been reported by Nesmeyanov *et al.* The precise structures of [3](1,1′)- and [4](1,1′)ruthenocenophanes have been uncovered by X-ray crystal analysis.[23] Since the distance between two cyclopentadienyl (Cp) rings in ruthenocene[24] is longer than that in ferrocene,[25] the steric strain in ruthenocenophanes can be expected to be larger than that in the corresponding ferrocenophanes. In this paper, we wish to describe the synthesis and spectral properties of [3](1,1′)[3](3,3′)- and [4](1,1′)[4](3,3′)ruthenocenophanes[26] and compare these results with those of the corresponding monobridged ruthenocenes.

Results and Discussion

[3][3]- and [4][4]Ferrocenophanes can be prepared *via* a stepwise cyclization and/or bridge enlargement in more advantageous yields than a one-step process.[2,7] Accordingly, we synthesized [3](1,1′)[3](3,3′)- and [4](1,1′)[4](3,3′)ruthenocenophanes (**6** and **15**) from the corresponding monobridged compounds.

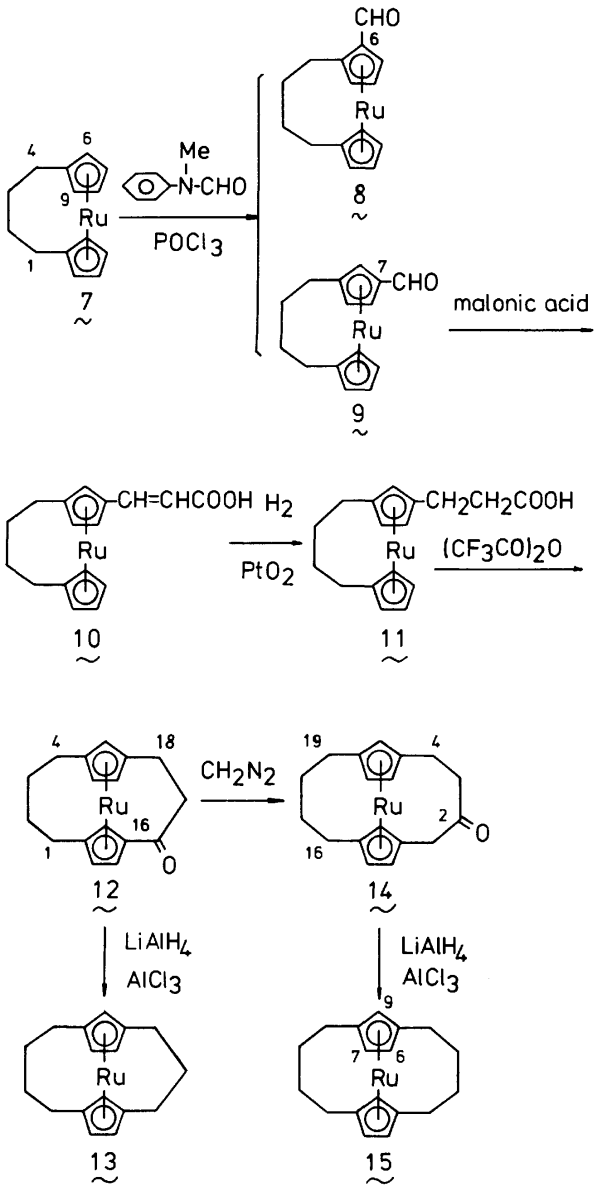
Synthesis of [3][3]Ruthenocenophanes. 6-Formyl[3](1,1′)ruthenocenophane (**2**) was synthesized in 52% yield by formylation of [3](1,1′)ruthenocenophane (**1**) with *N*-methylformanilide and $POCl_3$ without any solvent.[21] A small amount of the isomer, 5-formyl[3](1,1′)ruthenocenophane, which was not isolated in pure state, was also produced. Condensation of **2** with malonic acid in the presence of piperidine gave 6-(2-carboxyvinyl)[3](1,1′)ruthenocenophane (**3**) in good yield, and the subsequent hydrogenation of **3** over PtO_2 afforded 6-(2-carboxyethyl)[3](1,1′)ruthenocenophane (**4**). Cyclization of **4** with polyphosphoric acid gave [3](1,1′)[3](3,3′)ruthenocenophan-1-one (**5**) in 54% yield, while the reaction of **4** with trifluoroacetic anhydride did not produce **5**. [3](1,1′)[3](3,3′)Ruthenocenophane (**6**) was obtained by reduction of **5** with lithium aluminum hydride–aluminum trichloride in the usual manner (Scheme 1).

Synthesis of [4][3]- and [4][4]Ruthenocenophanes. Formylation of [4](1,1′)ruthenocenophane (**7**) with *N*-methylformanilide and $POCl_3$ without any solvent afforded 6-formyl- and 7-formyl[4](1,1′)ruthenocenophanes (**8** and **9**) in 12 and 79% yields, respectively. 7-(2-Carboxyethyl)[4](1,1′)ruthenocenophane (**11**) was prepared from **9** in good yield, in a manner similar to the one utilized in the preparation of **4**. Cyclization of **11** with trifluoroacetic anhydride in refluxing cyclohexane for 2 weeks[21] gave [4](1,1′)[3](3,3′)ruthenocenophan-16-one (**12**) in 80% yield. Bridge enlargement of **12** with diazomethane led to formation of [4](1,1′)-[4](3,3′)ruthenocenophan-2-one (**14**) in 83% yield, accompanied by a small amount of the isomer, [4](1,1′)-[4](3,3′)ruthenocenophan-1-one, which was not isolated in pure state. Reduction of **12** and **14** with lithium aluminum hydride–aluminum trichloride in the usual manner gave good yields of [4](1,1′)[3](3,3′)- and [4](1,1′)[4](3,3′)ruthenocenophanes (**13** and **15**), respectively (Scheme 2).



Scheme 1. Synthesis of [3][3]ruthenocenophanes.

^1H NMR Spectra. The chemical shifts of Cp ring protons in [*m*](1,1′)- and [*m*](1,1′)[*n*](3,3′)ruthenocenophanes (*m*, *n*=3, 4), together with those of the corresponding ferrocenophanes, are listed in Table 1. The signals observed in the ^1H NMR spectra of these ruthenocenophanes are assigned on the basis of the analogy to those of the corresponding ferrocenophanes and tri- and tetrabridged ferrocenes. The Cp ring protons of dibridged ruthenocenes **6** and **15** shift to lower fields than those of the corresponding ferrocenophanes **6′** and **15′**. These results are in accordance with those of ruthenocene and ferrocene.[27]



Scheme 2. Synthesis of [4][3]- and [4][4]Ruthenocenophanes.

The inductive effects of the methyl and ethyl groups have been reported to influence the chemical shifts of Cp ring protons only to a small extent in the ^1H NMR spectra of alkylferrocenes.[28] The differences in the chemical shifts of dimethyl and diethyl 1,1′-ruthenocenes are 0.05[29] and 0.04 ppm, respectively (Table 2). Accordingly, the nonequivalence of the Cp ring protons in ruthenocenophanes and ferrocenophanes cannot be due to the inductive effects of methylene bridges.

The difference in chemical shifts of Cp ring protons of monobridged ruthenocenes **1** and **7** are 0.23 and 0.14 ppm, respectively. We have previously discussed these chemical shifts and splittings of Cp ring protons in **1** and **7**, and have proposed that the nonequivalent shielding of Cp rings from their original parallel geometry.[21] Such a shift difference seems to be closely related to the dihedral angles of two Cp rings in **1** and **7**; these dihedral angles are found to be *ca.* 15° and 2°, respectively.[23]

On the other hand, the difference in the chemical shifts of the Cp ring protons of [3](1,1′)ferrocenophane (**1′**) and of [4](1,1′)ferrocenophane (**7′**) is 0.04 ppm; the corresponding difference for [3](1,1′)[3](3,3′)ferrocenophane (**6′**) is 0.05 and for [4](1,1′)[4](3,3′)ferrocenophane (**15′**) is 0.08 ppm. Hisatome *et al.* have not given clear-cut explanations of these results.[15] Simple molecular models for **1′** and **7′** suggest that the dihedral angles for the two Cp rings in **1′** and **7′** are *ca.* 0°. It has been reported that the dihedral angle of two Cp rings in **6′** is 9°.[30] Again, a simple molecular model for **15′** suggests that the dihedral angle in **15′** is *ca.* 0°.

Such a correlation between shift difference in Cp ring protons and the dihedral angle of two Cp rings in the monobridged systems is not found in the dibridged systems. In ruthenocenophane system, the difference in the chemical shifts of Cp ring protons of **6** is 0.12 and that of **15** is 0.21 ppm. The distance between two Cp rings in ruthenocene[24] is longer than

that in ferrocene[25] by 0.36 Å. Accordingly, the dihedral angle in **6** may be more than 9°, which may be larger than that in **15**. On the basis of molecular model examinations, the considerable strain in **6** and **15** might result in the deviations of two Cp rings from their original sp^2 planes. This might affect the chemical shifts and splittings of the Cp ring protons in **6** and **15**. Such an assumption would be confirmed by X-ray crystal analysis.

The chemical shifts of methylene protons of bridges in [*m*](1,1′)- and [*m*](1,1′)[*n*](3,3′)ruthenocenophanes (*m*, *n*=3, 4), together with those of the corresponding ferrocenophanes, are summarized in Table 3. The methylene protons of **7** and **15** with one and two tetramethylene bridges show two multiplets. However, methylene protons of **1** with one trimethylene bridge show one broad singlet, while those of **6** with two trimethylene bridges show two broad singlets. This seems to suggest that **6** has a more rigid structure than **1**, in contrast to the systems of **7** and **15**. On the other hand, **6′** shows one multiplet, in contrast to **6**. Although **15′** shows two multiplets, similar to **15**, the widths of the multiplets in **15′** are larger than those in **15**. These results suggest that the ruthenocenophanes **6** and **15** have more rigid structures than those of the corresponding ferrocenophanes **6′** and **15′**, and that **6** has the most rigid structure among these phane compounds.

IR Spectra. The frequencies of carbonyl-stretching absorptions in [*m*](1,1′)- and [*m*](1,1′)[*n*](3,3′)-ruthenocenophanones (*m*, *n*=3, 4), together with those of the corresponding ferrocenophanones, are listed in Table 4. In our previous paper,[21] the carbonyl-stretching vibrations have suggested that the π-orbitals of the carbonyl group effectively conjugate with the π-systems of the adjacent Cp ring in [3](1,1′)-ruthenocenophan-1-one (1656 cm^{-1}), as in acetylruthenocene (1658 cm^{-1}). The dihedral angle between the plane of the carbonyl group and the plane of the adjacent Cp ring has been considered to become smaller when two Cp rings are tilted to a greater extent. We have confirmed this assumption from the ^{13}C NMR measurements of several ruthenocenophanones and ferrocene homologs.[31] The carbonyl group in the ruthenocenophanone **5** with two trimethylene bridges is located at higher frequency (1686 cm^{-1}) than that in [3](1,1′)ruthenocenophan-1-one with one trimethylene bridge. A similar trend is observed in ferrocene homologs; [3](1,1′)ferrocenophan-1-one (1658 cm^{-1}) and [3](1,1′)[3](3,3′)ferrocenophan-1-one (1665 cm^{-1}). Owing to an additional trimethylene bridge, therefore, the dihedral angles between the carbonyl group and the adjacent Cp ring in **5** and the corresponding ferrocenophanone might be larger than those in [3](1,1′)ruthenocenophan-1-one and the corresponding ferrocenophanone.

Electronic Spectra. The spectra of trimethylene bridged ruthenocenes **6** and **1** and tetramethylene bridged ruthenocenes **15** and **7** are shown in Figs. 1 and 2, respectively. The intensities of the charge transfer band in the 230—260 nm region and the spin-allowed d-d band in 310—340 nm region of the dibridged ruthenocene **6** increase as compared with those of the monobridged ruthenocene **1** (Fig. 1). In the spectrum of the dibridged ruthenocene **15**, again, the intensity of the charge transfer band increases, while the intensity of spin-allowed d-d band decreases relative to that for the monobridged ruthenocene **7** (Fig. 2). We have previously reported that the ring-tilting would increase the intensity of the spin-allowed d-d band in the electronic spectra of **1** and **7**.[21] Recently, the dihedral angles of two Cp rings in **1** and **7** have been found to be *ca.* 15° and 2°, respectively.[23] These results suggest that the intensity of the spin-allowed d-d band might be affected by the steric strain at the Ru atom, and that **6** might be the most compressed among [*m*](1,1′)- and [*m*](1,1′)[*n*](3,3′)ruthenocenophanes (*m*, *n*=3, 4).

Experimental

Measurements. All the melting points are uncorrected. The ^1H NMR spectra were obtained in $CDCl_3$ with a JEOL JNM-FX 100 spectrometer (100 MHz) at room temperature. All the chemical shifts are expressed in δ (ppm; downfield from internal Me_4Si). The IR spectra were measured in KBr pellets with a Hitachi Model 285 infrared spectrometer. All IR spectral data are expressed in cm^{-1}. The electronic spectra were recorded in abs EtOH with a Hitachi Model 100—60 double beam spectrophotometer at room temperature. All absorption frequencies are given in λ (nm). The mass spectra were obtained with a JEOL JMS-DX 300 mass spectrometer using a direct insertion probe at 70 eV ionizing energy.

Materials. [3](1,1′)- and [4](1,1′)Ruthenocenophanes (**1** and **7**) were prepared according to the method in the literature.[21] Column chromatographic separations were carried out with Merck Kieselgel 60 (70—230 mesh), Wakogel C-200 (200 mesh), Mallinckrodt silicic acid (100 mesh) or Kanto Kagaku silica gel (100 mesh). All the synthetic reactions were performed under a N_2 atmosphere.

6-Formyl[3](1,1′)ruthenocenophane (2). A mixture of [3](1,1′)ruthenocenophane (**1**) (3.0 g, 11 mmol), *N*-methylformanilide (1.7 g, 13 mmol) and $POCl_3$ (3.7 g, 24 mmol) was vigorously stirred at 70 °C for 4 h. After the addition of sodium acetate trihydrate (16.5 g) in water (100 ml), the solution was stirred at 70 °C for 2 h, and then extracted with ether. The residue was chromatographed over silica gel with benzene–ethyl acetate as eluent. The first band eluted with benzene yielded a small amount of 5-formyl[3](1,1′)-ruthenocenophane, which was not isolated in pure state.

The second band eluted with benzene–ethyl acetate (40:1) yielded **2** (1.7 g, 52%), pale orange prisms, mp 90—91 °C (hexane–ethyl acetate). ^1H NMR: δ=1.76 (4H, bs, bridged $-CH_2-$), 1.84(2H, bs, bridged $-CH_2-$), 4.39 (1H, dd, J=1.3 and 3.1 Hz, Cp), 4.57 (1H, dd, J=1.5 and 2.9 Hz, Cp), 4.75 (3H, m, Cp), 4.95 (1H, t, J=1.2 Hz, Cp), 5.05 (1H, dd, J=1.2 and 2.4 Hz, Cp) and 9.65 (1H, s, −CHO). IR: 1650 (C=O). Electronic spectrum ($\lambda_{max}(\varepsilon)$): 253 (10500) and 345 (2960). MS (*m/z*): 299 (M^+, 71) and 270 ([M−CHO]$^+$, 100). Found: C, 55.93; H, 4.62%. Calcd for $C_{14}H_{14}ORu$: C, 56.18; H, 4.71%.

6-(2-Carboxyvinyl)[3](1,1′)ruthenocenophane (3). A solution of **2** (1.0 g, 3.3 mmol), malonic acid (0.69 g, 6.6 mmol) and piperidine (0.24 g) in dry pyridine (15 ml) was stirred at 100 °C for 3 h. The cooled solution was diluted with water and extracted with chloroform. The extract was washed with dil HCl and water, and then extracted with a 2 M NaOH solution (1 M=1 mol dm^{-3}). The aqueous layer

was acidified with dil HCl, and placed in a refrigerator overnight. The precipitates were found to be **3** (0.95 g, 84%), orange plates, mp 205—206 °C (EtOH). ^{1}H NMR: δ=1.74 (4H, bs, bridged -CH_2-), 1.89 (2H, bs, bridged -CH_2-), 4.34 (1H, m, Cp), 4.56 (3H, m, Cp), 4.74 (2H, m, Cp), 4.89 (1H, m, Cp), 5.90 and 7.53 (2H, an AX system, J=15.5 Hz, *trans* olefinic protons). IR: 1665 (C=O) and 1605 (C=C). $\lambda_{max}(\varepsilon)$: 275 (17600) and 365 (714). MS: 341 (M^+, 100), 296([M−CO_2-H]$^+$, 87) and 270 ([M−CH=CHCO_2H]$^+$, 11). Found: C, 56.43; H, 5.16%. Calcd for $C_{16}H_{16}O_2Ru$: C, 56.30; H, 4.72%.

6-(2-Carboxyethyl)[3](1,1′)ruthenocenophane (4). A solution of **3** (4.0 g, 12 mmol) in ethanol (500 ml) was hydrogenated over PtO_2 (50 mg) at room temperature for 20 h under H_2 1 atm to give **4** (4.0 g, 99%), yellow needles, mp 131—132 °C (EtOH). ^{1}H NMR: δ=1.73 (6H, bs, bridged -CH_2-), 2.50 (4H, s, -CH_2- of -$CH_2CH_2CO_2H$), 4.32 (1H, m, Cp), 4.36 (2H, m, Cp), 4.44 (1H, m, Cp), 4.54 (2H, m, Cp), and 4.63 (1H, m, Cp). IR: 1686 (C=O). $\lambda_{max}(\varepsilon)$: 270^{sh} (646) and 324 (898). MS: 343 (M^+, 75) and 284 ([M−CH_2CO_2-H]$^+$, 100). Found: C, 56.01; H, 5.24%. Calcd for $C_{16}H_{18}$-O_2Ru: C, 55.97; H, 5.28%.

[3](1,1′)[3](3,3′)Ruthenocenophan-1-one (5). A suspension of **4** (0.80 g, 2.3 mmol) and polyphosphoric acid (400 g) was vigorously stirred at 100 °C for 24 h. The cooled solution was poured into ice-cold water, and extracted with chloroform. The residue was chromatographed over silica gel with benzene-ethyl acetate (5:1) to give **5** (0.40 g, 54%), deep yellow needles, mp 150—151 °C (hexane-ethyl acetate). ^{1}H NMR: δ=1.69 (4H, bs, bridged -CH_2-), 1.78 (2H, bs, bridged -CH_2-), 2.4—3.2 (4H, m, H(2) and H(3) of bridged -CH_2-), 4.4—4.5 (2H, m, Cp), 4.5—4.6 (1H, m, Cp), 4.6—4.7 (1H, m, Cp), 4.78 (1H, s, Cp), and 4.82 (1H, s, Cp). $\lambda_{max}(\varepsilon)$: 254 (5830), 340^{sh} (1160), and 372 (1320). MS: 325 (M^+, 100), 297 ([M−CO]$^+$, 70), 283 ([M−CH_2CO]$^+$, 11), and 269 ([M−CH_2CH_2CO]$^+$,9). Found: C, 59.23; H, 5.11%. Calcd for $C_{16}H_{16}ORu$: C, 59.06; H, 4.96%.

[3](1,1′)[3](3,3′)Ruthenocenophane (6). A solution of **5** (0.40 g, 1.2 mmol) in dry ether (50 ml) was added dropwise to a suspension of $LiAlH_4$ (0.60 g, 16 mmol) and $AlCl_3$ (3.2 g, 24 mmol) in dry ether (50 ml). After refluxing for 4 h, the reaction mixtures were extracted with ether. The residue was chromatographed over silica gel with benzene to yield **6** (0.30 g, 78%), pale yellow needles, mp 114—115 °C (ethyl acetate). $\lambda_{max}(\varepsilon)$: 272^{sh} (481) and 322 (778). MS: 311 (M^+, 100), 297([M−CH_2]$^+$, 16), and 283([M-CH_2CH_2]$^+$, 7). Found: C, 62.01; H, 5.40%. Calcd for $C_{16}H_{18}Ru$: C, 61.72; H, 5.83%.

6-Formyl- and 7-formyl[4](1,1′)ruthenocenophanes (8 and 9). [4](1,1′)Ruthenocenophane (**7**) (1.5 g, 5.3 mmol), *N*-methylformanilide (0.78 g, 5.8 mmol), and $POCl_3$ (0.89 g, 5.8 mmol) were stirred at 70 °C for 4 h. After the addition of sodium acetate trihydrate (7.2 g) in water (50 ml), the solution was stirred at 70 °C for 2 h. The residue was separated into two bands by chromatography over silica gel with hexane-ethyl acetate as eluent. The first band eluted with hexane-ethyl acetate (20:1) yielded **8** (0.20 g, 12%), deep yellow prisms, mp 144—145 °C (hexane-ethyl acetate). ^{1}H NMR: δ=1.5—1.7 (4H, m, H(2) and H(3) of bridged -CH_2-), 2.2—2.5 (4H, m, H(1) and H(4) of bridged -CH_2-), 4.45 (1H, m, Cp), 4.58 (2H, t, J=2.2 Hz, Cp), and 4.66 (1H, m, Cp), 4.74(1H, d, J=2.9 Hz, Cp), 4.92 (2H, m, Cp), and 9.97 (1H, s, -CHO). IR: 1669 (C=O). $\lambda_{max}(\varepsilon)$: 248 (10400) and 351 (1090). MS: 313 (M^+, 57), 284 ([M−CHO]$^+$, 100), 270 ([M−CH_2CHO]$^+$, 22), and 256 ([M−CH_2CH_2CHO]$^+$, 33). Found: C, 57.13; H, 5.10%. Calcd for $C_{15}H_{16}ORu$: C, 57.49; H, 5.15%.

The second band eluted with hexane-ethyl acetate (5:1) yielded **9** (1.3 g, 79%), deep yellow needles, mp 90—91 °C (hexane-ethyl acetate). ^{1}H NMR: δ=1.5—1.7 (4H, m, H(2) and H(3) of bridged -CH_2-), 2,2—2.5 (4H, m, H(1) and H(4) of bridged -CH_2-), 4.59 (3H, m, Cp), 4.74(1H, m, Cp), 4.90, (1H, m, Cp), 4.96 (1H, m, Cp), 5.14 (1H, s, Cp), and 9.63 (1H, s, -CHO). IR: 1669 (C=O). $\lambda_{max}(\varepsilon)$: 257 (13300) and 359 (2060). MS: (M^+, 91), 284 ([M−CHO]$^+$, 100), 270 ([M−CH_2CHO]$^+$, 16), and 256 ([M−CH_2CH_2CHO]$^+$, 31). Found: C, 57.75; H, 5.20%. Calcd for $C_{15}H_{16}ORu$: C, 57.49; H, 5.15%.

7-(2-Carboxyvinyl)[4](1,1′)ruthenocenophane (10). The aldehyde **9** (1.9 g, 6.1 mmol) was treated with malonic acid (1.3 g, 12 mmol) and piperidine (0.27 g) in dry pyridine (30 ml) at 100 °C for 3 h. The cooled solution was extracted with chloroform. The extract was washed with dil HCl and water, and then extracted with a 2 M NaOH solution. Acidification of the aqueous layer with dil HCl gave the precipitate of **10** (1.9 g, 88%), pale orange prisms, mp 189—190 °C (EtOH). ^{1}H NMR: δ=1.4—1.7 (4H, m, H(2) and H(3) of bridged -CH_2-), 2.2—2.4 (4H, m, H(1) and H(4) of bridged -CH_2-), 4.29 (1H, m, Cp), 4.56 (2H, m, Cp), 4.71 (1H, m, Cp), 4.76 (2H, d, J=1.0 Hz, Cp), 4.93 (1H, s, Cp), 5.90 and 7.50 (2H, an AX system, J=15.6 Hz, *trans* olefinic protons). IR: 1666 (C=O) and 1611 (C=C). $\lambda_{max}(\varepsilon)$: 287 (18800) and 354 (4800). MS: 355 (M^+, 100), 310 ([M−CO_2-H]$^+$, 45), and 284 ([M−CH=CHCO_2H]$^+$, 39). Found: C, 57.37; H, 5.59%. Calcd for $C_{17}H_{18}O_2Ru$: C, 57.45; H, 5.10%.

7-(2-Carboxyethyl)[4](1,1′)ruthenocenophane (11). Hydrogenation of **10** (4.0 g, 11 mmol) over PtO_2 (50 mg) in ethanol (500 ml) gave **11** (4.0 g, 99%), pale yellow prisms, mp 128—129 °C (EtOH). ^{1}H NMR: δ=1.4—1.6 (4H, m, H(2) and H(3) of bridged -CH_2-), 2.2—2.4 (4H, m, H(1) and H(4) of bridged -CH_2-), 2.49(4H, s, -CH_2- of -CH_2CH_2-CO_2H), 4.31 (1H, m, Cp), 4.42 (1H, m, Cp), 4.5—4.6 (4H, m, Cp), and 4.63 (1H, m, Cp). IR: 1701 (C=O). $\lambda_{max}(\varepsilon)$: 313 (312). MS: 357 ($M^+$, 14), 312([M−$CO_2H$]$^+$, 41), 298 ([M−$CH_2CO_2H$]$^+$, 83), and 284 ([M−$CH_2CH_2CO_2H$]$^+$, 100). Found: C, 56.80; H, 5.67%. Calcd for $C_{17}H_{20}O_2Ru$: C, 57.13; H, 5.64%.

[4](1,1′)[3](3,3′)Ruthenocenophan-16-one (12). A mixture of **11** (5.0 g, 14 mmol) and $(CF_3CO)_2O$ (15 g, 0.70 mol) in dry cyclohexane (500 ml) was refluxed for 2 weeks. The cooled mixture was poured into saturated aq $NaHCO_3$ and extracted with ether. The residue was chromatographed over silica gel with benzene-ethyl acetate(1:1) to give **12** (3.8 g, 80%), yellow prisms, mp 139—140 °C (hexane-ethyl acetate). ^{1}H NMR: δ=1.4—1.6 (4H, m, H(2) and H(3) of bridged -CH_2-), 2.1—2.4 (4H, m, H(1) and H(4) of bridged -CH_2-), 2.87 (4H, bs, H(17) and H(18) of bridged -CH_2-), 4.57 (1H, dd, J=1.2 and 2.0 Hz, Cp), 4.82 (1H, dd, J=1.2 and 2.1 Hz, Cp), 4.93 (1H, dd, J=2.4 and 4.9 Hz, Cp), 4.94 (1H, dd, J=2.4 and 4.8 Hz, Cp), 5.20 (1H, t, J=1.0 Hz, Cp), and 5.28 (1H, t, J=1.1 Hz, Cp). $\lambda_{max}(\varepsilon)$: 259 (4840) and 333^{sh} (787). MS: 339 (M^+, 100), 311 ([M−CO]$^+$, 100), 297 ([M−CH_2-CO]$^+$, 48), and 283 ([M−CH_2CH_2CO]$^+$, 69). Found: C, 60.00; H, 5.24%. Calcd for $C_{17}H_{18}ORu$: C, 60.16; H, 5.35%.

[4](1,1′)[3](3,3′)Ruthenocenophane (13). A suspension of **12** (0.50 g, 1.5 mmol), $LiAlH_4$ (0.17 g, 4.4 mmol), and $AlCl_3$ (0.88 g, 6.64 mmol) in dry THF (50 ml) was refluxed for 3 h. After the excess reagent was decomposed with moist THF and water, the products were extracted with ether. The residue was chromatographed over silica gel with benzene to yield **13** (0.35 g, 72%), pale yellow needles, mp 40—41 °C (benzene). ^{1}H NMR: δ=1.3—1.7 (10H, m, bridged -CH_2-), 1.8—2.3 (4H, m, bridged -CH_2-), 4.33 (2H, dd, J=1.2 and 2.0 Hz, Cp), 4.52 (2H, s, H(9) and H(15) of Cp), and 4.68 (2H, dd, J=1.2 and 2.1 Hz, Cp). $\lambda_{max}(\varepsilon)$: 266^{sh} (645) and 319 (606). MS: 325 (M^+, 100) and 297 ([M−CH_2CH_2]$^+$, 87). Found: C, 62.43; H, 6.16%. Calcd for $C_{17}H_{20}Ru$: C, 62.75; H, 6.19%.

[4](1,1′)[4](3,3′)Ruthenocenophan-2-one (14). To a solution of **12** (2.5 g, 7.4 mmol) in methanol (100 ml) and ether (150 ml), CH_2N_2 (0.37 mol) in ether (500 ml) was

added. The resulting solution was stirred at 0 °C for 10 h in the dark, and then evaporated. The residue was chromatographed over silica gel with benzene-ethyl acetate as eluent. The first band eluted with benzene-ethyl acetate (10:1) yielded **14** (2.2 g, 83%), pale orange prisms, mp 118—119 °C (hexane-ethyl acetate). ^{1}H NMR: δ=1.4—1.6 (4H, m, H(17) and H(18) of bridged -CH_2-), 2.1—2.3 (4H, m, H(16) and H(19) of bridged -CH_2-), 2.5—2.6 (2H, m, H(4) of bridged -CH_2-), 2.7—2.9 (2H, m, H(3) of bridged -CH_2-), 3.16 (2H, s, H(1) of bridged -CH_2-), 4.50 (2H, dd, J=1.2 and 2.3 Hz, Cp), 4.58 (2H, dd, J=1.2 and 2.3 Hz, Cp), and 4.78 (2H, s, H(9) and H(15) of Cp). IR: 1686 (C=O). $\lambda_{max}(\varepsilon)$: 280^{sh} (1490). MS: 353 (M^+, 98), 325 ([M−CO]$^+$, 100), 311 [M−CH_2CO]$^+$, 47), and 297 ([M−CH_2CH_2CO]$^+$, 85). Found: C, 61.43; H, 5.79%. Calcd for $C_{18}H_{20}ORu$: C, 61.17; H, 5.70%.

The second band eluted with benzene-ethyl acetate (1:20) yielded a small amount of [4](1,1′)[4](3,3′)ruthenocenophan-1-one, which was not isolated in the pure state.

[4](1,1′)[4](3,3′)Ruthenocenophane (15). A mixture of **14** (1.0 g, 2.8 mmol), $LiAlH_4$ (0.32 g, 8.4 mmol), and $AlCl_3$ (1.7 g, 13 mmol) in dry THF (100 ml) was refluxed for 5 h, and then extracted with ether. The residue was chromatographed over silica gel with benzene-ethyl acetate (20:1) to yield **15** (0.72 g, 75%), pale yellow needles, mp 94—95 °C (petroleum ether). $\lambda_{max}(\varepsilon)$: 280^{sh} (292) and 309 (260). MS: 339 (M^+, 100) and 311 ([M−CH_2CH_2]$^+$, 66). Found: C, 63.76; H, 6.58%. Calcd for $C_{18}H_{22}Ru$: C, 63.69; H, 6.53%.

Catalytic Reduction of 4*H*-Cyclopenta[*def*]phenanthrene under Mild Conditions

Masahiro MINABE,* Yōji YAMAMOTO,† Masaaki YOSHIDA, Katsuko NAKADA, and Kazuo SUZUKI**

Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishiicho, Utsunomiya 321

†*Department of Agricultural Chemistry, Faculty of Agriculture, The University of Tokyo, Bunkyo-ku, Tokyo 113*

(Received April 22, 1983)

The catalytic hydrogenation of 4*H*-cyclopenta[*def*]phenanthrene over Raney nickel afforded 8,9-dihydro-4*H*-cyclopenta[*def*]phenanthrene and 1,2,3,3a-tetrahydro derivative. Under these conditions, di- and tetrahydro compounds were reduced into two diastereomers, *cis*-3a-*cis*-9a- and *trans*-3a-*cis*-9a-1,2,3,3a,8,9,9a,9b-octahydro-4*H*-cyclopenta[*def*]phenanthrene. The reduction over palladium gave a dihydro compound and a platinum catalyst provided products analogous with those obtained over Raney nickel.

One of polynuclear aromatic hydrocarbons, 4*H*-cyclopenta[*def*]phenanthrene (**1**), is made up of one five-membered and three six-membered rings, and is of interest for its the carcinogenic property.[1] The reactivity of **1** with electrophiles has been found to differ from those of phenanthrene, fluorene, and pyrene.[2] The C_8–C_9 bond of **1** shows the double bond character. For example, **1** was converted into the stable C_8–C_9 ozonide[3] and into the 8,9-diketone.[4,5]

Catalytic hydrogenation of **1** has been reported to give only 8,9-dihydro-4*H*-cyclopenta[*def*]phenanthrene (**2**) when it is carried out using copper chromite at 160 °C[6] or over palladium-on-charcoal at room temperature.[7] The reactivity of C_8–C_9 bond of **1** would seem to be preferable to that of C_9–C_{10} bond of phenanthrene, and may be ascribed to the distorted phenanthrene moiety of **1** by the central methylene bridge.

Our present interest is whether the hydrogenation of **1** proceeds regiospecifically. For example, reduction of benz[*a*]anthracene using a Pd/C catalyst took place at the K-region to give 5,6-dihydro compound in a predominant yield, while an analogous reaction in the presence of a Pt catalyst occurred regiospecifically to afford 8,9,10,11-tetrahydro compound.[8]

The present paper deals with the detailed investigation on the catalytic reduction of **1** in order to clarify the reactivity of **1** and the related derivatives. This may give information on the hydrogenation of other aromatic hydrocarbons.

Results and Discussion

The catalytic hydrogenation of **1** was carried out at room temperature under an atmospheric pressure of

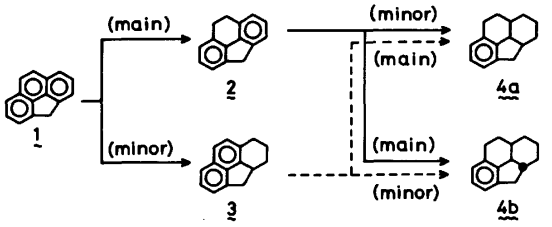


Scheme 1. Diagram of hydrogenation of **1**.

hydrogen, as is summarized in Table 1. These conditions are controllable and practical for preparation of hydroarenes.

Figure 1 shows a typical process of the reaction of **1** using a Raney nickel catalyst (W-7). The hydrocarbon **1** was easily converted into **2** (max. yield 75%) and 1,2,3,3a-tetrahydro-4*H*-cyclopenta[*def*]phenanthrene (**3**)[9] (max. yield 5%) in an earlier stage. Dihydro compound **2** was gradually hydrogenated under these conditions to afford two diastereomeric 1,2,3,3a,8,9,9a,9b-octahydro-4*H*-cyclopenta[*def*]phenanthrenes having melting points of 53—55 °C (**4a**) and of 63—65 °C (**4b**). On the other hand, tetrahydro compound **3** was smoothly reduced into **4a** and **4b**. Further hydrogenations of **4a** and **4b** to perhydro derivatives (**5**)[10] did not proceed under the same conditions. The amount of catalyst affected only the progress of hydrogenation, but not the proportion of the products in the range of 0.2 g to 2.0 g of catalyst per 1 mmol of **1**.

The hydrogenation of **1** over a neutral nickel catalyst (W-4) afforded, **2**, **3**, **4a**, and **4b**, similar to the case of W-7. Minor but significant differences due to the catalytic species could be detected: one of these is that the reaction was accelerated by W-4 catalyst. Second, about 13% of **5** was formed after 21 h, different from the instance of W-7.

Hydrogenation of **1** over a palladium-on-charcoal (5%) was substantially slow and furnished predominantly **2**. Reduction of **2** was scarcely possible, since more than 88% of **2** remained intact after a period of 48 h.

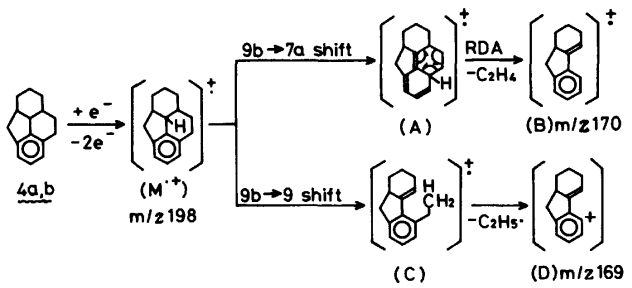
Figure 2 shows a typical pattern of the hydrogenation of **1** in the presence of a platinum oxide catalyst. Arene **1** was reduced to **2** and **3**, as was the case over Raney nickel, but those di- and tetrahydroarenes were again converted into **4a** and **4b**. Hydrogenation of **4a** was faster than that of **4b** under these conditions.

Four kinds of diastereomers in 1,2,3,3a,8,9,9a,9b-octahydro derivatives of **1** may exist, namely (i) *cis*-3a-*cis*-9a, (ii) *trans*-3a-*cis*-9a, (iii) *trans*-3a-*trans*-9a, and (iv) *cis*-3a-*trans*-9a. However, the former two structures are possible and the latter two are impossible, judging from the consideration that the catalytic hydrogenation would proceed *via* cis-addition and that **3** gave both **4a** and **4b**. The first suggestion on the assignment is ascribed to the findings that the non-planar **3** afforded **4a** more predominantly than **4b** over a nickel catalyst, due to the catalytic hindrance. One of the diastereomers, **4a** may be assigned to be *cis*-3a-*cis*-9a. Isomeric **4b** (*trans*-3a-*cis*-9a), whose protons at both 9a- and 9b-positions are located *trans* with respect to 3a-hydrogen, would thermodynamically be more stable than **4a**. The boiling point of **4a** seems to be higher than that of **4b**, based on the GLPC using a nonpolar liquid phase.

The yield of **4b** is more than that of **4a** in reduction of the planar molecule **2**. This would seem to disagree with the general finding that the hydrogenation of aromatics is controlled kinetically to afford all-*cis* compound under the conditions of relatively low temperature using nickel or platinum catalyst. The internal strain of **4a** may be significant due to the *cis-cis* configuration of the *peri*-condensed skeleton, differing from the case of hydrogenated phenanthrene. Consequently, the hydrogenation of **2** could be controlled thermodynamically.

In an earlier stage of the reduction of **3** using a platinum oxide, the ratio of **4a**/(**4a**+**4b**) is larger than the case over a nickel catalyst; this accords with the von Auwers-Skita rule. The decrease of the ratio, **4a**/(**4a**+**4b**), with the extension of the reaction time would be ascribed to the fact that unstable **4a** rather than stable **4b** is easily reduced to perhydro compound 5.

The relative intensity of the molecular ion to the total ion intensity of **4b** is greater than the case of **4a**. This is consistent with the assignment of **4a** and **4b**, since $M^{\cdot+}$ of *trans*- or *exo*-form isomer is generally more intense than that of *cis*- or *endo*-isomer.[11] The fragmentations of **4a** and **4b** show remarkable differences. The relative intensities at *m/z* 170 and *m/z* 169 are 62 and 80% for **4a** and 88 and 8% for **4b** to each



Scheme 2. Speculation on fragmentation pathways of **4a** and **4b**.

molecular ion intensity.

The ion (B) at *m/z* 170 is speculated to form through the 1,3-hydrogen shift of H_{9b} of $M^{\cdot+}$ to C_{7a} to give ion (A), followed by retro-Diels-Alder reaction (RDA) with *cis*-elimination of ethylene under the electron-impact conditions, as is shown in Scheme 2. The generation of ion (D) at *m/z* 169 is considered to be mainly due to the 1,3-hydrogen shift of H_{9b} to C_9 to yield ion (C) and the elimination of ethyl radical from (C). Ions (B) plus (D) from **4a** (1.4 times of $M^{\cdot+}$) are more intense than those from **4b**; this would be due to the stabilities of **4a** and **4b** under the conditions used.[11,12] Isomer **4a** may be less stable thermodynamically than **4b** due to the distorted configuration, and readily undergoes dissociation to ions (A) and (C).

The migration of hydrogen during the hydrogenation is interesting. 9,10-Dihydrophenanthrene has been found to be converted to phenanthrene and tetrahydrophenanthrene under vigorous conditions (100—140 atom, 250 °C).[13] The conversion of **2** to **3** is neglected because that no **3** was detected in the reduction of **2** in all cases examined here. This suggests that **2** and **3** are independently formed by different attacks on the 8,9-positions and on the 1,2,3,3a-positions, respectively. Preferential formation of **2** may be due to the high double bond character at the C_8–C_9 bond.

In the catalytic reduction of **1** under mild conditions, the palladium catalyst seems useful for the preparation of **2**: this accords with the suggestion by Fu, Lee, and Harvey.[8] Raney nickel is available for the synthesis of octahydro compounds **4a** and **4b**, and a platinum catalyst affords further hydrogenated arenes such as **5**. The order of reactivity agrees only with that of the activity of catalyst (Pt>Ni>Pd) used as evaporated metallic films on deuteration of benzene.[14]

Experimental

All the melting points are uncorrected. The ^{1}H NMR, ^{13}C NMR, IR, and UV data were recorded on a JNM-C-60HL (JEOL, 60 MHz, using Me_4Si in $CDCl_3$), a JNM-FX-100 (JEOL, 25 MHz, from Me_4Si in $CDCl_3$), an IR-G (JASCO, as KBr-disk), and a UV-180 (Shimadzu, in cyclohexane) spectrometers, respectively. The mass spectra were measured (direct inlet) at 70 eV on an M-80 GC-MS apparatus (Hitachi) with an M-003 computer data system. An equimolar mixture of **4a** and **4b** was submitted to GC-MS (column: Silicone OV-1, 10%, 1 m, 160 °C) at 20 eV to compare the relative intensities of $M^{\cdot+}$; 32.1% of $\sum_{18}$ in **4a** and 35.7% of $\sum_{18}$ in **4b** were observed.

The GLPC data were obtained with a JGC-1100FP gaschromatograph (JEOL) equipped with a column (3 mmϕ, 0.2 m) containing PEGA (10%) on Diasolid (80—100 mesh) at 145 °C under 0.59 kg cm^{-2} of nitrogen, by means of comparison of each peak area using a TR-2217 automatic integrator (Takeda Riken).

The Raney nickel catalysts (W-4 and W-7) were prepared by standard procedure using nickel-aluminium alloy (48% of nickel): the quantity of catalyst was indicated as weight of the alloy. The palladium-on-charcoal (5%) was also prepared by a known method. The Adams platinum oxide was purchased from Kawaken Fine Chemical Co.

In Table 1, the amount of catalyst means the weight based on 1 mmol of reactant in HOEt (50 ml) over nickel catalyst or in EtOAc (50 ml) over Pd-C or PtO_2. Docosane was added as an internal reference for quantitative treatment.

Hydrogenation of 1 over R-Ni (W-7). To a mixture of **1** (190 mg, 1 mmol) in HOEt (30 ml) placed in the Paal-type hydrogenation flask (so-called "Magen"), R-Ni catalyst was added to HOEt (20 ml) (time, 0 h). Upon substitution of air with hydrogen (4 times), the flask was shaken at room temperature under an atmosphere of hydrogen. In order to follow the sequence of reduction, a small amount of reaction mixture (*ca.* 0.2 ml) was taken out *via* Teflon septum by an injector, filtered and submitted to GLPC after each 1/6, 1/3, 1/2, 3/4, 1, 3/2, 2 h and additionally every 1 h.

Hydrogenation of 1 over Adams PtO_2. Platinum oxide (25.4 mg) was added with 10 ml of EtOAc into a solution of **1** (95.1 mg, 0.5 mmol) in EtOAc (15 ml) placed in a stainless steel autoclave. After 4 purges with hydrogen, the mixture was stirred at room temperature under a hydrogen pressure of 5.0 kg cm^{-2}. After each prescribed time, the proportion of mixture was measured by GLPC.

Hydrogenation of 3 over R-Ni (W-7). Tetrahydro compound **3** (97.1 mg, 0.5 mmol) was treated with R-Ni (W-7, 0.5 g) in HOEt (25 ml) for 2 h. The reaction mixture was filtered and the residue was extracted with HOEt (100 ml). The filtrate and extract were combined and evaporated to dryness. The residue was extracted with cyclohexane (10 ml), and the solution was chromatographed on a column (17 mmϕ; 85 cm) of silica gel with petroleum ether (bp 50—65 °C) as eluent. The rate of effusion was *ca.* 0.65 ml/min. The eluate, which ranged from 287 ml to 333 ml, gave 39.2 mg (40%) of **4b**, mp 63—65 °C, by recrystallization from petroleum ether: retention time, 12.8 min (on a GLPC with a column containing Silicone SE-30, 120 °C). IR: 3050, 2970, 2880, 1604, 1482, 1443, 1329, 1152, 1083, 944, 842, 807, and 762 cm^{-1}. UV_{max}: 220 (log ε 3.91), 268 (2.86), and 276 nm (2.86). ^{1}H NMR: δ=0.73—3.14 (m, 15H) and 6.80—7.05 (m, 3H). ^{13}C NMR: δ=22.8, 24.6, 25.1, 27.3, 28.6, 32.4, 38.9, 41.0, 44.2, 122.4, 124.8, 126.2, 133.9, 141.3, and 142.9. MS *m/z* ($\sum_1$): 199 (4.2), 198 (25.9, $M^{\cdot+}$), 197 (7.6, $M^{\cdot+}-1$), 171 (3.3), 170 (22.9, $C_{13}H_{14}$), 169 (2.1, $C_{13}H_{13}$), 156 (1.4, $C_{12}H_{12}$), 155 (3.6, $C_{12}H_{11}$), 142 (5.0, $C_{11}H_{10}$), 129 (3.5, $C_{10}H_9$), 128 (1.2, $C_{10}H_8$), and 28 (0.5, C_2H_4). Found: C, 90.67; H, 9.08%. Calcd for $C_{15}H_{18}$: C, 90.85; H, 9.15%.

The fraction from 333 ml to 352 ml was a mixture (17.6 mg) of **4a** and **4b**.

In addition, 36.4 mg (37%) of **4a**, mp 53—55 °C (from hexane), was afforded from the eluate, which ranged from 352 ml to 404 ml: retention time, 16.8 min (SE-30, 120 °C). IR: 3050, 2970, 2870, 1603, 1492, 1450, 1332, 843, and 787 cm^{-1}. UV_{max}: 212 (log ε 4.14) and 266 nm (2.69). ^{1}H NMR: δ=0.77—3.05 (m, 15H) and 6.82 (3H, s). ^{13}C NMR: δ=24.0, 26.1, 29.2, 41.4, 44.4, 125.9, 131.1, and 144.3. MS *m/z* ($\sum_1$): 199 (4.2), 198 (25.1, $M^{\cdot+}$), 197 (2.1, $M^{\cdot+}-1$), 171 (2.1), 170 (15.6, $C_{13}H_{14}$), 169 (20.0, $C_{13}H_{13}$), 156 (7.8, $C_{12}H_{12}$), 155 (4.9, $C_{12}H_{11}$), 142 (3.7, $C_{11}H_{10}$), 129 (1.0, $C_{10}H_9$), 128 (0.6, $C_{10}H_8$), and 28 (0.5, C_2H_4). Found: C, 90.92; H, 9.32%. Calcd

for $C_{15}H_{18}$: C, 90.85; H, 9.15%.

Conversion of 2-Sulfinylated 2-Alkenoate Esters to (2*E*,4*E*)-2,4-Alkadienoate Esters by Pyrolysis

Rikuhei TANIKAGA,* Yoshihito NOZAKI, Masaharu NISHIDA, and Aritsune KAJI
Department of Chemistry, Faculty of Science, Kyoto University Sakyo-ku, Kyoto 606
(Received July 1, 1983)

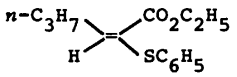
Thermal reaction of ethyl (2*E*)-2-phenylsulfinyl-2-alkenoates (*E*-**2**) prepared from aldehydes and ethyl 2-phenylsulfinylacetate have been investigated. Refluxing of *E*-**2** or their *Z*-isomers in xylene resulted in the formation of ethyl (2*E*,4*E*)-2,4-alkadienoates accompanied by ethyl (2*E*)-4-hydroxy-2-alkenoates. Ethyl 2-cycloalkylidene-2-phenylsulfinylacetates were found to be more susceptible to pyrolysis. The enoate esters (**2**) undergo migration of their carbon-carbon double bond and then [2,3]sigmatropic rearrangement to benzenesulfenate esters, followed by thermolytic extrusion of a benzenesulfenic acid probably *via* ethyl (2*E*)-4-phenylsulfinyl-2-alkenoates to afford ethyl (2*E*,4*E*)-2,4-alkadienoates.

(2*E*,4*E*)-2,4-Alkadienoate esters (**1**) are versatile synthetic intermediates for naturally occurring compounds.[1-3] A number of syntheses of (2*E*,4*E*)-*N*-isobutyl-2,4-decadienamide (pellitorine) have been accomplished by the pathway *via* decadienoic acid or its esters,[1,4,5] which in turn were prepared by a number of routes.[6-11] We previously reported that pyrolysis of 2-phenylsulfinyl-2-alkenoate esters (**2**) led to the formation of **1**.[7]

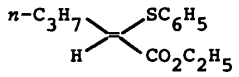
Saturatd sulfoxides with one or more β-hydrogen atoms are known to undergo readily syn elimination on pyrolysis to form olefins by way of a concerted five-membered cyclic pathway.[12,13] This reaction is of great value for making carbon-carbon double bonds and introducing unsaturation at the α-position of esters, ketones and aldehydes,[14] but the corresponding thermal reaction of α,β- and β,γ-unsaturated sulfoxides had scarecely been investigated.[15] Cookson and Parsons reported the formation of 2-methyl-1,3-nonadien-5-one from 2-methyl-4-phenylsulfinyl-2-nonen-5-one, but no explanation of this observation was given.[16] Recently Nokami *et al.* prepared butyl 2,4-decadienoate by pyrolysis of butyl 2-phenylsulfinyl-2-decenoate and proposed an attractive mechanism involving a flexible seven-membered cyclic transition state.[9] It seems interesting to clarify whether this mechanism is operative or not. The present report aims at elucidating the mechanism of this novel conversion of **2** to **1**.

Results and Discussion

Ethyl (2*E*)-2-phenylsulfinyl-2-alkenoates (*E*-**2**) were easily prepared by treatment of aldehydes with ethyl 2-phenylsulfinylacetate and a catalytic amount of piperidine.[17] Their configurations were assigned by the comparison of δ values for olefinic protons (-CH=) in ^{1}H-NMR spectra of the corresponding sulfides (**3**). For example, the olefinic proton of ethyl (2*E*)-2-phenylthio-2-hexenoate (*E*-**3a**) appeared at δ 6.41, whereas that of its *Z*-isomer (*Z*-**3a**) at δ 7.36. It seems reasonable to conclude that the chemical shift of the proton cis to the carbonyl group must show up at a lower field than that cis to the sulfenyl group.



E-3a



Z-3a

When ethyl (2*E*)-2-phenylsulfinyl-2-hexenoate (*E*-**2a**) was refluxed for 4 h in xylene containing anhydrous potassium carbonate ethyl (2*E*,4*E*)-2,4-hexadienoate (**1a**) and ethyl (2*E*)-4-hydroxy-2-hexenoate (**4a**) were formed, but (2*E*,4*Z*)-, (2*Z*,4*E*)-, and (2*Z*,4*Z*)-2,4-hexadienoate esters were scarecely found (GLPC).

The results obtained in the thermolysis of *E*-**2a**—**g** are summarized in Table 1.

The carbon-carbon double bonds of α,β-unsaturated sulfoxides and sulfilimines are known to migrate under basic conditions.[18,19] O'Connor established that base-catalyzed equilibriation between α,β- and β,γ-unsaturated sulfoxides greatly favored the latter ones.[18] Therefore, **2** may at first undergo migration of their double bonds to yield ethyl 2-phenylsulfinyl-3-alkenoates (**5**), which may produce **1** and **4** with loss of the sulfenic acid group. This assumption appears to be consistent with the findings that both *E*-**2a** and *Z*-**2a** gave **1a** and **4a** in the same ratio.

In order to study the validity of the seven-membered transition state for the diene formation (Ei mechanism; Fig. 1),[9] pyrolysis of ethyl 2-cyclopentylidene-2-

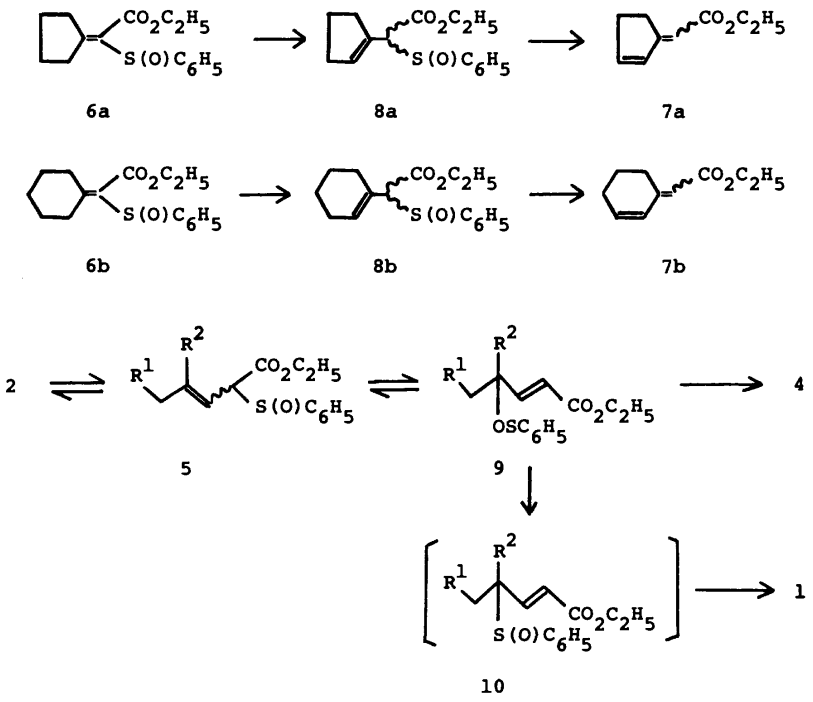

Scheme 1.

phenylsulfinylacetate (**6a**) and ethyl 2-cyclohexylidene-2-phenylsulfinylacetate (**6b**) was then investigated. Refluxing of **6a** and **6b** in xylene afforded ethyl 2-(2-cyclopentenylidene)acetate (**7a**) and ethyl 2-(2-cyclohexenylidene)acetate (**7b**) in 59 and 51% yields, respectively. The yields were moderate because **7** were somewhat unstable at high temperature. The α,β-unsaturated sulfoxides **6a**, **6b**, and **2a** were found to be labile to pyrolysis in that order. If the seven-membered transition state were operative, neither **6a** nor **6b** might show high reactivities because the hydrogen atom at δ position is located too far (3.5—4.0 Å) from the sulfinyl oxygen atom in the intermediary β,γ-unsaturated sulfoxides **8a** and **8b**.[20]

On the basis of these findings, the mechanism shown in Scheme 1 seems to be more reasonable than the Ei mechanism.

In the present transformation, it is assumed that the [2,3]sigmatropic rearrangement of **5** would take place in the first step to yield the sulfenate esters **9**, which produce **1** probably *via* the sulfoxides **10**. The rapid [2,3]sigmatropic rearrangement of **5** may be supported by the observations that the treatment of **2** with an equimolar amount of piperidine in acetonitrile resulted in the formation of **4**, the hydrolysis products of **9**, in high yields,[21] and in the attempted preparation of **8a** the oxidation of the corresponding sulfide, ethyl 2-(1-cyclopentenyl)-2-(phenylthio)acetate, with *m*-chloroperbenzoic acid at 0 °C gave ethyl (2*E*)-2-(2-hydroxycyclopentylidene)acetate, but did not allow the isolation of **8a**. Since it is known that the introduction of an electron-withdrawing group at the phenyl group of sulfoxides brings about the acceleration of thermolysis,[22] the *p*-chloro derivatives, **2b** and **2e**, were examined. The yields of **1** were rather low, however, probably owing to the ready hydrolysis of **9**.

Although the thermal rearrangement of sulfenates to sulfoxides is known to occur in benzylic derivatives,[23] we could not rigorously prove, at the present time, that the thermal reaction of **2** proceeds through ethyl (2*E*)-4-

phenylsulfinyl-2-alkenoates (**10**). However, it shoud be pointed out that **10a**, prepared from the corresponding sulfide by oxidation, produced **1a** upon heating in xylene.[24] In addition it was observed that the attempted isolation of **9a** from the reaction mixture of benzenesulfenyl chloride with sodium salt of **4a** was unsuccessful, but **1a** was detected in the pyrolysis product of that mixture. The predominant formation of the (2*E*,4*E*)-isomers of **1** might also be in accordance with the mechanism shown in Scheme 1.

Experimental

NMR spectra were recorded with a JEOL JNM-PS-100 or a Hitachi R-24B spectrometer in $CDCl_3$ using TMS as an internal standard. IR spectra were taken on a Hitachi 215 spectrometer. Mass spectra were determined with a Hitachi M-52 spectrometer. GLPC analysis was performed with a Varian 920 using a glass column (1 m×6 mm) packed with 20% silicone DC-550 or a Shimadzu GC-6AM using a SS-4 glass capillary column (30 m×0.3 mm). Column chromatography was performed using Wakogel 200 silica gel.

Materials. All aldehydes were commercially available and purified by distillation before use. Commercial acetonitrile and piperidine were used without purification. Xylene and tetrahydrofuran (THF) were distilled over CaH_2 prior to use.

*Ethyl 2-(Phenylthio)acetate (**11a**).* To a solution of sodium ethoxide prepared by dissolving Na (11.5 g, 0.5 mol) in ethanol (300 ml), benzenethiol (55.1 g, 0.5 mol) was added at room temperature. To the stirred solution was added dropwise a solution of ethyl bromoacetate (83.5 g, 0.5 mol) in ethanol (50 ml) at 0 °C. The reaction mixture was refluxed for 1 h, diluted with water (500 ml), and extracted with chloroform (300 ml). The chloroform solution was washed with water and dried over anhydrous Na_2SO_4. After removal of chloroform **11a** was obtained as a colorless liquid by distillation *in vacuo*: yield 88.0 g (90%); bp 101—104 °C/0.4 mmHg (1 mmHg≈133.322 Pa).[25]

Ethyl 2-(*p*-chlorophenylthio)acetate (**11b**) was obtained as a colorless liquid by the similar method: yield 85%; bp 130—133 °C/1.8 mmHg.[26]

*Ethyl 2-Phenylsulfinylacetate (**12a**).* A solution of **11a** (88.0 g, 0.45 mol) and $NaIO_4$ (115 g, 0.54 mol) in water (400 ml) and methanol (100 ml) was kept stirring at room temperature for 1 d, and filtered. The filtrate was extracted with chloroform (300 ml). The chloroform layer was washed with water, dried over anhydrous Na_2SO_4, and concentrated to afford **12a** as a colorless liquid: yield 94.2 g (99%); NMR ($CDCl_3$) δ=1.19 (3H, t), 3.62 (1H, d), 3.82 (1H, d), 4.09 (2H, q), and 7.4—7.8 (5H, m).[27]

Ethyl 2-(*p*-chlorophenylsulfinyl)acetate (**12b**) was similarly prepared by oxidation of **11b**: yield 96%; colorless solid; mp 43 °C; NMR ($CDCl_3$) δ=1.20 (3H t, J=7 Hz), 3.64 (1H, d, J=12 Hz), 3.82 (1H, d, J=12 Hz), 4.10 (2H, q, J=7 Hz), 7.44 (2H, d, J=8 Hz), and 7.60 (2H, d, J=8 Hz); IR (Nujol) 1725, 1270, and 1050 cm^{-1}. Found: C, 48.70; H, 4.55%. Calcd for $C_{10}H_{11}ClO_3S$: C, 48.67; H, 4.50%.

*Ethyl (2E)-2-Phenylsulfinyl-2-hexenoate (E-**2a**).* A solution of **12a** (2.12 g, 10 mmol), butanal (1.08 g, 15 mmol), and piperidine (0.08 g, 1 mmol) in acetonitrile (30 ml) was allowed to stand at 0 °C for 2 d. After removal of acetonitrile the residue was chromatographed on a silica-gel column with a chloroform eluent to give *E*-**2a** (1.46 g, 55%) and **12a** (0.7 g, recovery 33%). *E*-**2a**: viscous colorless oil; NMR ($CDCl_3$) δ=0.98 (3H, t, J=7 Hz), 1.14 (3H, t,J=7 Hz), 1.4—1.8 (2H, m), 2.73 (2H, q, J=7 Hz), 4.06 (2H, q, J=7 Hz), 7.12 (1H, t, J=7 Hz), and 7.3—7.7 (5H, m); IR (neat) 1720, 1200, and 1050 cm^{-1}; MS m/z 266 (M^+). Found: C, 63.34; H, 6.91%. Calcd for $C_{14}H_{18}O_3S$: C, 63.13; H, 6.81%.

Other ethyl (2*E*)-2-phenylsulfinyl-2-alkenoates (*E*-**2b—g**) were obtained by similar treatment of **12a** or **12b** (10 mmol) with aldehydes (15 mmol) and piperidine (1 mmol).

*Ethyl (2E)-2-(p-Chlorophenylsulfinyl)-2-hexenoate (E-**2b**)*: Viscous colorless oil; yield 68%, NMR ($CDCl_3$) δ=0.96 (3H, t, J=7 Hz), 1.14 (3H, t, J=7 Hz), 1.4—1.8 (2H, m), 2.70 (2H, q, J=7 Hz), 4.06 (2H, q, J=7 Hz), 7.11 (1H, t, J=7 Hz), 7.34 (2H, d, J=8 Hz), and 7.53 (2H, d, J=8 Hz); IR (neat) 1725, 1210, and 1055 cm^{-1}; MS m/z 301 (M^+). Found: C, 56.10; H, 5.89%. Calcd for $C_{14}H_{17}ClO_3S$: C, 55.89; H, 5.70%.

*Ethyl (2E)-2-Phenylsulfinyl-2-octenoate (E-**2c**)*: Viscous colorless oil; yield 51%; NMR ($CDCl_3$) δ=0.90 (3H, t, J=7 Hz), 1.15 (3H, t, J=7 Hz), 1.0—1.8 (8H, br), 4.06(2H, q, J=7 Hz), 7.13 (1H, t, J=7 Hz), and 7.3—7.7 (5H, m); IR (neat) 1720, 1210, and 1050 cm^{-1}: MS m/z 294 (M^+). Found: C, 65.50: H, 7.59%. Calcd for $C_{16}H_{22}O_3S$: C, 65.27; H, 7.53%.

*Ethyl (2E)-2-Phenylsulfinyl-2-decenoate (E-**2d**)*: Viscous colorless oil; yield 50%; NMR ($CDCl_3$) δ=0.87 (3H, t, J=7 Hz), 1.14 (3H, t, J=7 Hz), 1.0—1.8 (12H, br), 4.06 (2H, q, J=7 Hz), 7.14 (1H, t, J=7 Hz), and 7.3—7.7 (5H, m); IR (neat) 1720, 1210, and 1050 cm^{-1}; MS m/z 322 (M^+). Found: C, 67.31; H, 8.02%. Calcd for $C_{18}H_{26}O_3S$: C, 67.04; H, 8.13%.

*Ethyl (2E)-2-(p-Chlorophenylsulfinyl)-2-decenoate (E-**2e**)*: Viscous colorless oil; yield 77%; NMR ($CDCl_3$) δ=0.87 (3H, t, J=7 Hz), 1.14 (3H, t, J=7 Hz), 1.0—1.8 (12H, br), 4.06 (2H, q, J=7 Hz), 7.10 (1H, t, J=7 Hz), 7.34 (2H, d, J=8 Hz), and 7.54 (2H, d, J=8 Hz); IR (neat) 1725, 1210, and 1055 cm^{-1}; MS m/z 357 (M^+). Found: C, 60.62; H, 7.34%. Calcd for $C_{18}H_{25}ClO_3S$: C, 60.62: H, 7.06%.

*Ethyl (2E)-2-Phenylsulfinyl-2-dodecenoate (E-**2f**)*: Viscous colorless oil; yield 53%; NMR ($CDCl_3$) δ=0.87 (3H, t, J=7 Hz), 1.14 (3H, t, J=7 Hz), 1.0—1.8 (16H, br), 4.06 (2H, q, J=7 Hz), 7.13 (1H, t, J=7 Hz), and 7.3—7.7 (5H, m); IR (neat) 1720, 1210, and 1050 cm^{-1}; MS m/z 350 (M^+). Found; C, 68.50; H, 8.75%. Calcd for $C_{20}H_{30}O_3S$: C, 68.53; H, 8.63%.

*Ethyl (2E)-2-Phenylsulfinyl-3-cyclohexyl-2-propenoate (E-**2g**)*: Viscous colorless oil; yield 71%; NMR ($CDCl_3$) δ=1.14 (3H, t, J=7 Hz), 1.0—1.9 (10H, br), 3.0—3.4 (1H, m), 4.06 (2H, q, J=7 Hz), 6.98 (1H, d, J=9 Hz), and 7.3—7.7 (5H, m); IR (neat) 1720, 1210, and 1050 cm^{-1}; MS m/z 306 (M^+). Found: C, 66.91; H, 7.41%. Calcd for $C_{17}H_{22}O_3S$: C, 66.63; H, 7.24%.

*Ethyl (2E)-2-Phenylthio-2-hexenoate (E-**3a**).* Trifluoroacetic anhydride (0.63 g, 3 mmol) was added to a stirred solution of *E*-**2a** (0.53 g, 2 mmol) and NaI (0.75 g, 5 mmol) in acetone (30 ml) at 0 °C.[28] The mixture was stirred for 2 min, diluted with benzene (100 ml), and washed with water, aq $NaHCO_3$, aq $Na_2S_2O_3$, and then water. After drying over anhydrous Na_2SO_4 the solvent was evaporated to give *E*-**3a** in a quantitative yield; yellowish liquid; NMR ($CDCl_3$) δ=0.96 (3H, t, J=7 Hz), 1.09 (3H, t, J=7 Hz), 1.4—1.7 (2H, m), 2.53 (2H, q, J=7 Hz), 4.11 (2H, q, J=7 Hz), 6.41 (1H, t, J=7 Hz), and 7.2—7.5 (5H, m); IR (neat) 1720 cm^{-1}; MS m/z 250 (M^+). Found: C, 67.06; H, 7.23%. Calcd for $C_{14}H_{18}O_2S$: C, 67.16; H, 7.25%.

*Ethyl (2Z)-2-Phenylthio-2-hexenoate (Z-**3a**).* Similar reduction of ethyl (2*Z*)-2-phenylsulfinyl-2-hexenoate (*Z*-**2a**)[7] gave *Z*-**3a** in a quantitative yield; yellowish liquid; NMR ($CDCl_3$) δ=0.98 (3H, t, J=7 Hz), 1.09 (3H, t,J=7 Hz), 1.4—1.7 (2H, m), 2.54 (2H, q, J=7 Hz), 4.11 (2H, q, J=7 Hz), 7.36 (1H, t, J=7 Hz), and 7.2—7.5 (5H, m); IR (neat) 1720 cm^{-1}; MS m/z 250 (M^+). Found: C, 67.03; H, 7.21%. Calcd for $C_{14}H_{18}O_3S$: C, 67.16; H, 7.25%.

*Ethyl 2-(1-Hydroxycyclopentyl)-2-phenylsulfinylacetate (**13a**).* A solution of ethyl 2-phenylsulfinylacetate (7.29 g, 44 mmol) in anhydrous THF (15 ml) was added under argon

atomosphere at −78 °C to a stirred solution of lithium diisopropylamide (44 mmol) prepared from diisopropylamine (6.16 ml) and butyllithium (29.0 ml, 1.55 M solution in hexane) in anhydrous THF (30 ml), and stirring was continued for 1 h at −60 °C. A solution of cyclopentanone (3.80 ml, 43 mmol) in anhydrous THF (10 ml) was added dropwise. The resultant solution was stirred for 1.5 h at −60 °C, quenched with aq NH_4Cl, and diluted with ether (300 ml). The ethereal solution was washed with 10% HCl and aq saturated NaCl, dried over anhydrous Na_2SO_4, and evaporated. The residue was chromatographed on silica gel with a benzene eluent to give **13a** (8.75 g, 78%) as a yellowish liquid; NMR (CCl_4) δ=1.22 (3H, t, J=7 Hz), 0.9-2.3 (10H, m) 3.00 (1H, s), 3.52 (1H, s), 4.01 (2H, q, J=7 Hz), and 7.0—7.4 (5H, m).[29]

Ethyl 2-Cyclopentylidene-2-(phenylthio)acetate (14a). A solution of **13a** (3.65 g, 13 mmol) in acetic anhydride (10 ml) was refluxed for 3 h, cooled to room temperature, neutralized with 30% aq NaOH, and diluted with ether (200 ml). The ethereal solution was washed with water, dried over anhydrous Na_2SO_4 and evaporated. The residue was dissolved in anhydrous THF (5 ml), and the resultant solution was added to a solution of lithium diisopropylamide (14.4 mmol) in anhydrous THF (30 ml) at −10 °C. The mixture was stirred at room temperature for 2 h, quenched with aq NH_4Cl, and extracted with ether (200 ml). The ethereal extract was washed with 10% HCl and aq saturated NaCl, dried over anhydrous Na_2SO_4, and evaporated. The product **14a** was separated by chromatography on a silica-gel column using a hexane–benzene mixture (v/v=1/1); yellowish liquid; yield 1.17 g (50%); NMR (CCl_4) δ=1.00 (3H, t, J=7 Hz), 1.5—2.0 (4H, m), 2.4—2.9 (4H, m), 3.95 (2H, q, J=7 Hz), and 6.9—7.4 (5H, m); IR (neat) 1705 cm^{-1}; MS m/z 262 (M^+).[29]

Ethyl 2-Cyclopentylidene-2-phenylsulfinylacetate (6a). To a solution of **14a** (4.07 g, 15.5 mmol) in dichloromethane (100 ml) was added a solution of *m*-chloroperbenzoic acid (3.68 g, 17 mmol) in dichloromethane (50 ml) at 0 °C. The reaction mixture was stirred at 0 °C for 1 h and neutralized with aq $NaHCO_3$. The organic layer was washed with aq saturated NaCl, dried over anhydrous Na_2SO_4, and evaporated. The residual crude **6a** was purified by chromatography on silica gel using chloroform; colorless liquid; yield 2.74 g (64%); NMR ($CDCl_3$) δ=1.03 (3H, t, J=7 Hz), 1.7—2.0 (4H, m), 2.8—3.1 (4H, m), 3.98 (2H, q, J=7 Hz), and 7.3—7.7 (5H, m); IR (neat) 1710 and 1045 cm^{-1}; MS m/z 278 (M^+). Found: C, 64.92; H, 6.61%. Calcd for $C_{15}H_{18}O_3S$: C, 64.72; H, 6.52%.

Ethyl 2-Cyclohexylidene-2-phenylsulfinylacetate (6b). Similar treatment of cyclohexanone with lithium enolate of **12a**, followed by elimination and oxidation procedures as described above, yielded **6b** as a colorless liquid; overall yield 27%; NMR ($CDCl_3$) δ=1.02 (3H, t, J=7 Hz), 1.5—2.0 (6H, m), 2.3—2.9 (4H, m), 3.92 (2H, q, J=7 Hz), and 7.3—7.7 (5H, m); IR (neat) 1720 and 1047 cm^{-1}; MS m/z 292 (M^+). Found: C, 65.93; H, 6.91%. Calcd for $C_{16}H_{20}O_3S$: C, 65.72; H, 6.89%.

General Pyrolysis of Ethyl 2-Phenylsulfinyl-2-alkenoates (2). A mixture of **2** (10 mmol) and anhydrous K_2CO_3 (12 mmol) in xylene was refluxed while the reaction was monitored by TLC and GLPC. The reaction completed after 4 h in the cases of *E*-**2a**—**f** and *Z*-**2a**, but *E*-**2g** remained unreacted after 15 h. After cooling K_2CO_3 and xylene were removed by filtration and evaporation. The residue was separated through silica-gel column chromatography with a hexane–benzene mixture (v/v=1/1) and then chloroform to afforded **1** and **4**.[21] The ratio of (2*E*,4*E*)/(2*E*,4*Z*)+(2*Z*,4*E*)+(2*Z*,4*Z*) was determined by GLPC analysis using a capillary column. The configuration of **1** was determined by comparison of NMR spectra of authentic **1a** (=**1b**), **1c**[30], and **1d** (=**1e**).[31,32] Physical data of **1e** and **1g** are as follows.

Ethyl (2E,4E)-2,4-Dodecadienoate (1f): Colorless liquid; NMR(CCl_4) δ=0.88 (3H, t, J=7 Hz), 1.25 (3H, t, J=7 Hz), 1.0—1.7 (10H, m) 2.0—2.4 (2H, m), 4.07 (2H, q, J=7 Hz), 5.64 (1H, d, J=15 Hz), 5.8—6.3 (2H, m), and 7.0—7.4 (1H, m); IR (neat) 1720, 1640, and 1620 cm^{-1}; MS m/z 224 (M^+). Found: C, 74.90; H, 10.71%; Calcd for $C_{14}H_{24}O_2$: C, 74.95; H, 10.78%.

Ethyl (2E)-3-(1-Cyclohexenyl)-2-propenoate (1g): Colorless liquid; NMR (CCl_4) δ=1.25 (3H, t, J=7 Hz), 1.4—2.4 (8H, br), 4.07 (2H, q, J=7 Hz), 5.58 (1H, d, J=15 Hz), 5.23 (1H, m), and 7.1—7.6 (1H, m); IR (neat) 1720 and 1630 cm^{-1}; MS m/z 180 (M^+). Found: C, 73.35; H, 9.03%. Calcd for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%.

Pyrolysis of Ethyl 2-Cyclopentylidene-2-phenylsulfinylacetate (6a). A mixture of **6a** (1.39 g, 5 mmol) and anhydrous K_2CO_3 (0.83 g, 6 mmol) in xylene (6 ml) was refluxed monitoring with TLC and GLPC. The reaction was completed within 20 min. After removal of K_2CO_3 and xylene chromatograpy on silica gel with hexane–benzene (v/v=1/1) as an eluent gave ethyl 2-(2-cyclopentenylidene)acetate (**7a**) as a colorless liquid; yield 0.45 g (59%); *E*/*Z*=54/46; NMR ($CDCl_3$) δ=1.27 (3H, t, J=7 Hz), 2.4—3.1 (4H, m), 4.13 (2H, t, J=7 Hz), 5.56 (s, =CHCO, *Z*-isomer), 5.70 (s, =CHCO, *E*-isomer), and 6.1—6.7 (2H, m); IR (neat) 1700 cm^{-1}; MS m/z 152 (M^+). Found: C, 71.23; H, 7.92%. Calcd for $C_9H_{12}O_2$: C, 71.02; H, 7.95%.

Pyrolysis of Ethyl 2-Cyclohexylidene-2-phenylsulfinylacetate (6b). A mixture of **6b** and anhydrous K_2CO_3 was similarly refluxed for 1 h. Chromatography on silica gel with hexane–benzene as an eluent afforded ethyl 2-(2-cyclohexenylidene)acetate (**7b**) as a colorless liquid; yield 51%; *E*/*Z*=51/49; NMR ($CDCl_3$) δ=1.24 (3H, t, J=7 Hz), 1.5—1.9 (2H, m), 2.1—2.5 (3H, m), 2.8—3.0 (1H, m), 4.11 (2H, q, J=7 Hz), 5.41 (s, =CHCO, *Z*-isomer), 5.50 (s, =CHCO, *E*-isomer), and 5.9—6.3 (2H, m); IR (neat) 1705 cm^{-1}; MS m/z 166 (M^+). Found: C, 72.45; H, 8.51%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%.

Oxidation of Ethyl 2-(1-Cyclopentenyl)-2-(phenylthio)acetate (15a). To a stirred solution of **15a**[20] (2.62 g, 10 mmol) in dichloromethane (100 ml) was added dropwise a solution of *m*-chloroperbenzoic acid (2.37 g, 11 mmol) in dichloromethane (50 ml) at 0 °C, and the resultant mixture was stirred for 30 min at 0 °C. During the oxidation ethyl (2*E*)-2-(2-hydroxycyclopentylidene)acetate (**16a**) and diphenyldisulfide were gradually formed (TLC and GLPC). The reaction mixture was neutralized with aq $NaHCO_3$, washed with aq saturated NaCl, and dried over anhydrous Na_2SO_4. After evaporation of the solvent the residue was chromatographed on a silica-gel column successively using hexane–benzene (v/v=2/1), benzene and chloroform to give diphenyldisulfide (0.32 g), *S*-phenyl benzenethiosulfonate (*ca.* 0.1 g), **15a** (1.23 g, 47% recovery), **16a** (0.76 g, 45%), and some unidentified compounds. **16a**: colorless liquid; NMR ($CDCl_3$) δ=1.1—2.2 (4H, m), 1.24 (3H, t), 2.6—3.0 (2H, m), 3.8 (1H, s), 4.10 (2H, q), 4.51 (1H, m), and 5.93 (1H, q, J=2 Hz).[20]

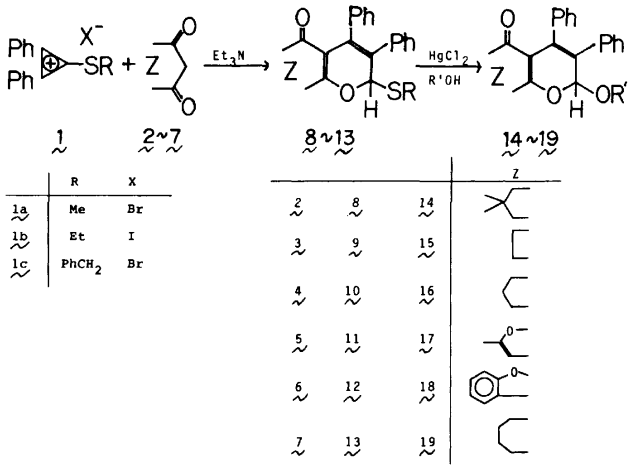
(Received August 29, 1983)

This study treats the reactions of methylthio-, ethylthio-, or benzylthiodiphenylcyclopropenium ion (**1**) with 5-, 6-, and 7-membered cyclic 1,3-diketones, giving either 2-alkylthio-2*H*-pyrans or dienone derivarives. Treatment of **1** with 1,3-cyclopentanedione, 1,3-cyclohexanedione, 5,5-dimethyl-1,3-cyclohexanedione, 4-hydroxy-6-methyl-2-pyrone, 4-hydroxycoumarin, and 1,3-cycloheptanedione in the presence of triethylamine afforded 2-alkylthio-2*H*-pyrans. The structure of the products was elucidated on the basis of their elemental analyses, IR, ^{1}H-NMR, ^{13}C-NMR, and mass spectroscopic data, as well as chemical transformations. 2-Alkylthio-2*H*-pyrans with mercury(II) chloride in an alcohol underwent conversion to the corresponding 2-alkoxy-2*H*-pyrans. The ^{1}H- and ^{13}C-NMR data of these compounds clearly show that the equilibrium lies completely on the side of the 2*H*-pyran. In contrast, the reaction of **1** with 1,3-indandione yielded the ring-opened dienone derivative as a mixture of *E* and *Z* isomers.

2*H*-Pyrans are apparently not well known.[1] Electrocyclic ring openings of 2*H*-pyrans and ring closures of dienones have been of considerable interest in view of the yet unresolved questions of how the presence of heteroatoms in a conjugated chain exerts influence on the electrocyclic process.[2] Although some synthetic routes to the stable 2*H*-pyrans like halogen-substituted 2*H*-pyrans have been developed,[2] neither physical nor chemical properties of sulfur-containing 2*H*-pyrans have been reported. Quite recently, we have communicated[3] the reaction of alkylthiodiphenylcyclopropenium salts **1** which acyclic 1,3-diketones to give the cyclopentadienol derivatives. Here we describe a novel cyclization reaction of **1** with cyclic 1,3-diketones to produce 2-alkylthio-substituted 2*H*-pyrans.

Methylthio-, ethylthio-, and benzylthiodiphenylcyclopropenium salts **1a—c** were prepared by the previously reported method.[3] A mixture of **1**, cyclic 1,3-diketone, and triethylamine in a molar ratio of 1:1:2 was stirred in dry benzene at room temperature for 15 min. The product was then purified by recrystallization or by column chromatography. Cyclic 1,3-diketones such as 5,5-dimethyl-1,3-cyclohexanedione (**2**), 1,3-cyclopentanedione (**3**), 1,3-cyclohexanedione (**4**), 4-hydroxy-6-methyl-2-pyrone(**5**), 4-hydroxycoumarin (**6**) and 1,3-cycloheptanedione (**7**) gave the corresponding 2-alkylthio-2*H*-pyrans **8—13** in good yield as shown in Table 1. Treatment of the compounds with mercury (II) chloride in an alcohol yielded the corresponding desulfurization products: 2-alkoxy-2*H*-pyrans **14—19**.



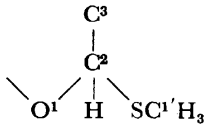
Scheme 1.

The 2-alkylthio- and 2-alkoxy-2*H*-pyran structures of the products **8—19** were elucidated on the basis of elemental analyses, MS, ^{1}H- and ^{13}C-NMR spectroscopic studies. For example, the ^{1}H- and ^{13}C-NMR spectrum of **8a** showed a singlet at δ=6.03 for one hydrogen and an sp^3 carbon bonded to one hydrogen at δ=88.3.

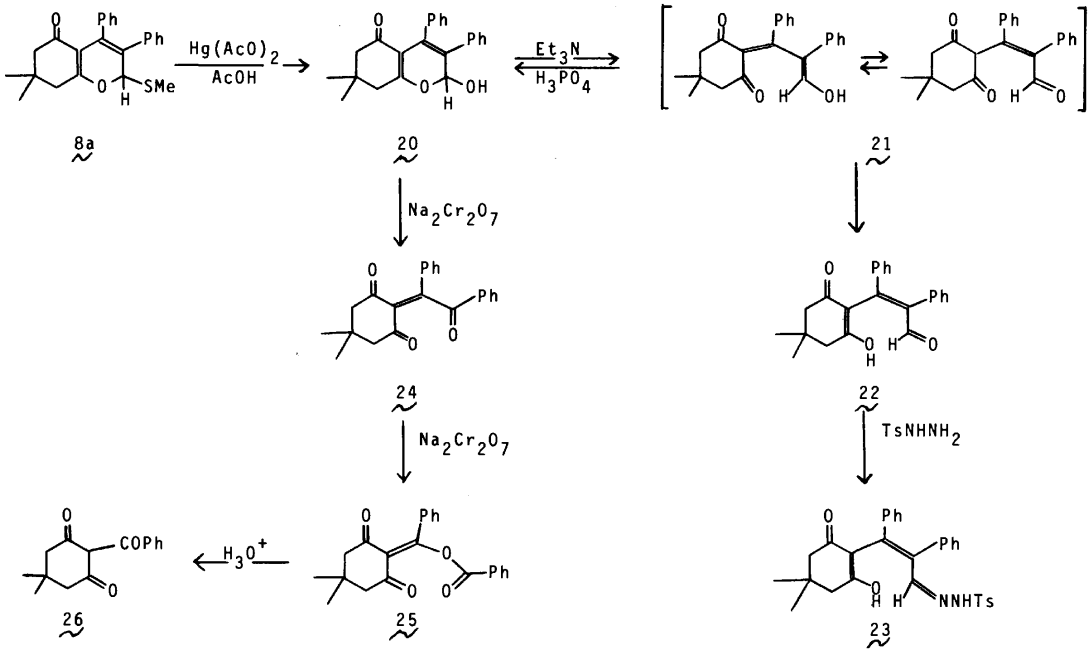
TABLE 1. ALKYLTHIO- AND ALKOXY-2*H*-PYRAN DERIVATIVES

Reactant		Product	Yield/%
1a	**2**	**8a**(R=Me)	84
1b	**2**	**8b**(R=Et)	58
1c	**2**	**8c**(R=PhCH$_2$)	67
1a	**3**	**9**(R=Me)	89
1a	**4**	**10**(R=Me)	74
1a	**5**	**11**(R=Me)	90
1a	**6**	**12**(R=Me)	84
1a	**7**	**13**(R=Me)	63
8a	MeOH	**14a**(R′=Me)	93
8a	EtOH	**14b**(R′=Et)	78
8a	*i*-PrOH	**14c**(R′=*i*-Pr)	80
8b	MeOH	**14a**(R′=Me)	83
9	MeOH	**15a**(R′=Me)	87
9	EtOH	**15b**(R′=Et)	81
10	MeOH	**16**(R′=Me)	74
11	EtOH	**17**(R′=Et)	89
12	EtOH	**18**(R′=Et)	65
13	EtOH	**19**(R′=Et)	61

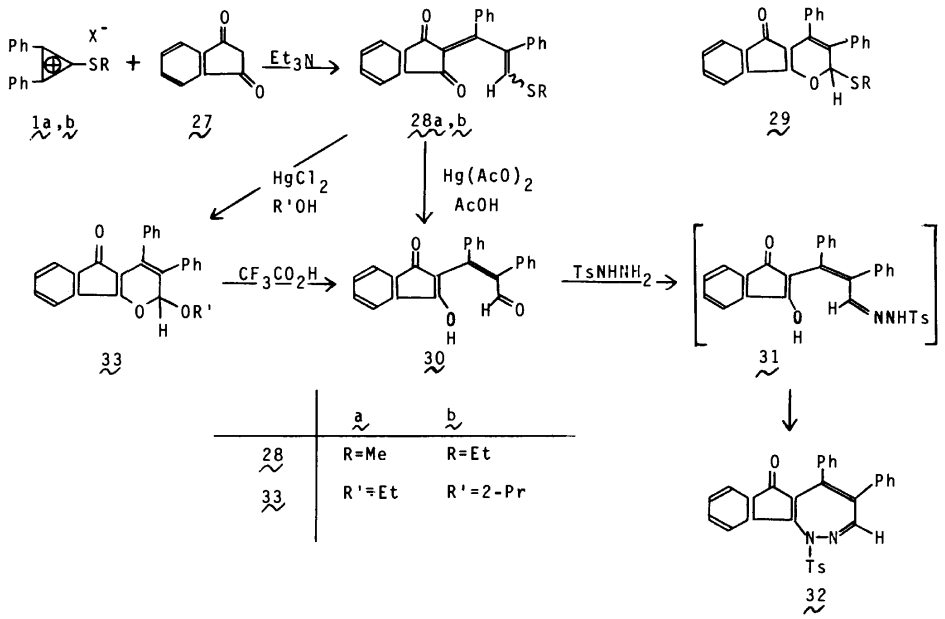
Coupling constants were $^{1}J_{C^3H}$=170 Hz and $^{3}J_{C^3SC^1'H}$=$^{3}J_{HC^3SC^1'}$=3 Hz, thus indicating the framework:



On treatment with mercury(II) acetate in acetic acid 2-alkylthio-2*H*-pyrans **8a** and **8b** gave 2-hydroxy-2*H*-pyran (**20**). The ^{1}H-NMR spectroscopic studies of **20** were interesting. A chloroform-*d* solution of **20** which showed a singlet at δ=5.76 due to the C-2 hydrogen, gave two new singlets at 9.22 (D_2O exchangeable, OH) and 9.80 (HC=O) on addition of a small amount of triethylamine to the solution. Attempt at isolation of the expected α,β-unsaturated aldehyde **22** failed, and **20** was recovered from the solution. However, treatment of a solution with *p*-toluenesulfonohydrazide in ethanol containing 10% of triethylamine yielded the corresponding *p*-tolylsulfonyl hydrazone **23** in 38% yield. The unsaturated aldehyde **22** must be stabilized as enolate anion, since **20** was soluble in aqueous sodium hydroxide and acidification of the solution with phosphoric acid yielded **20**. These results indicate that 2-hydroxy-2*H*-pyran **20** is not stable in a basic solvent, but under acidic or neutral conditions the equilibrium lies completely on the side of 2*H*-



Scheme 2.



Scheme 3.

pyran **20**. The aldehyde **22** may be formed *via* either isomerization of **20** or electrocyclic ring opening of **20** to give **21**, followed by keto-enol isomerization.

Oxidation of **20** with sodium dichromate in acetic acid yielded the benzoylphenylmethylene derivative **24** as an initial oxidation product in 45% yield; further oxidation under the same reaction conditions gave **25** in 24% yield. The latter product **25** produced the known 2-benzoyl-5,5-dimethyl-1,3-cyclohexanedione (**26**)[4] on hydrolysis in an acidic medium (Scheme 2).

A spontaneous reaction took place between **1a** (or **1b**) and 1,3-indandione (**27**) in the presence of triethylamine. In contrast to the reactions of 1,3-diketones **2**—**7**, the product isolated by column chromatography showed no peak corresponding to the 2*H*-pyran structure **29** in ^{1}H- and ^{13}C-NMR spectra. The product is most likely to be an *E,Z*-isomer mixture of the dienone **28**, since the ^{1}H-NMR spectrum gave olefinic protons at δ=6.60 and 6.71 in a 1:2 ratio.

Treatment of **28** with mercury(II) acetate in acetic acid yielded a resinous crystalline mass, the structure of which was establised to be the ring-opened vinyl aldehyde **30**. The ^{1}H-NMR spectrum of **30** showed two singlets at δ=4.44 (OH) and 9.59 (HC=O). The aldehyde **30** was converted by *p*-toluenesulfonohydrazide to the diazepine **32**[5] *via* the *p*-tolylsulfonylhydrazone **31** intermediate. In contrast, the reaction of **28a** with mercury(II) chloride in an alcohol afforded 2-alkoxy-2*H*-pyran **33** (the C-2 hydrogen as a singlet at around δ=6.0). Addition of a small amount of trifluoroacetic acid to a solution of **33** in $CDCl_3$ yielded a ^{1}H-NMR spectrum in agreement with the structure **30**.

The reaction mechanism shown in Scheme 4 is proposed. The initial step involves a nucleophilic attack of the carbanion generated from 1,3-diketone on the cyclopropene ring of **1**. Subsequent elimination of the acidic methine hydrogen and ring opening gives either a conjugated betaine or a dienone intermediate, followed by intramolecular cyclization leading to the 2-alkylthio-2*H*-pyran. A cyclic 1,3-diketone like 1,3-indandione (**27**), which has little flexibility, gave no cyclization product, while 5-, 6-, and 7-membered flexible 1,3-diketones **2**—**7** yielded only 2-alkylthio-2*H*-pyran derivatives.

Experimental

General. Melting points are uncorrected. The ^{13}C FT NMR spectra were recorded on a JEOL JNM FX-60 spectrometer (15.04 MHz), and ^{1}H-NMR spectra, on a Hitachi-Perkin-Elmer R-24 (60 MHz). The IR spectra were recorded on a JASCO A-3 spectrometer, and mass spectra on a Hitachi RMU-7M mass spectrometer.

Alkylthiodiphenylcyclopropenium Ions ***1a—c.*** Methylthio-, ethylthio-, and benzylthiodiphenylcyclopropenium ions **1a**—**c** were prepared as previously described.[3]

The Reaction of Alkylthiodiphenylcyclopropenium Salts ***1a—c*** *with Cyclic 1,3-Diketones* ***2—7.*** *(a) The Reaction of* ***1a*** *with* ***2***: A mixture of **1a** (1 mmol), **2** (1 mmol), and triethylamine (2 mmol) in dry benzene (15 cm^3) was stirred for 20 min at room temperature. After the separation of the precipitate, the benzene solution was condensed and chromatographed over silica gel (chloroform) to give colorless crystals of 7,7-dimethyl-3,4-diphenyl-2-methylthio-5,6,7,8-tetrahydro-2*H*-1-benzopyran-5-one (**8a**) in 84% yield. **8a**: mp 190—192 °C: IR (KBr) 1670 and 1630 cm^{-1}: ^{1}H-NMR ($CDCl_3$) δ=1.16 (3H, s, Me), 1.21 (3H, s, Me), 2.30 (5H, s, MeS and CH_2), 2.48(2H, s, CH_2), 6.03(1H, s, CH), and 6.9—7.2 (10H, m, 2Ph); ^{13}C-NMR ($CDCl_3$) δ=13.9 (q, MeS), 27.3 and 29.4 (q, 2Me), 31.8 (s), 42.9 (t), 51.7 (t), 88.3 (d), 116.5 (s), 123.4 (s), 126.6 (d), 127.0 (d), 127.4 (d), 127.8 (d), 129.2 (d), 132.4 (s), 136.9 (s), 137.8 (s), 168.5 (s), and 193.5 (s): MS (*m/z*) 376 (M^+). Found: C, 76.33; H, 6.44%. Calcd for $C_{24}H_{24}O_2S$: C, 76.56; H, 6.42%. *(b) The Reaction of* ***1b*** *with* ***2***: A similar reaction of **1b** with **2** yielded 7,7-dimethyl-3,4-diphenyl-2-ethylthio-5,6,7,8-tetrahydro-2*H*-1-benzopyran-5-one (**8b**) in 58%. **8b**: mp 152—154 °C; IR (KBr) 1650 and 1620 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.17 (3H, s, Me), 1.22 (3H, s, Me), 1.37 (3H, t, *J*=7.5 Hz, MeCH_2), 2.28 (2H, s, CH_2CO), 2.48 (2H, s, CH_2C=C), 2.77 (2H, q, CH_2S), 6.16 (1H, s, CH), and 6.8—7.4 (10H, m, 2Ph); MS (*m/z*) 390 (M^+). Found: C, 77.02; H, 6.79%. Calcd for $C_{25}H_{26}O_2S$: C, 76.89; H. 6.71%. *(c) The Reaction of* ***1c*** *with* ***2***: Similar reaction of **1c** with **2** yielded 2-benzylthio-7,7-dimethyl-3,4-diphenyl-5,6,7,8-tetrahydro-2*H*-1-benzopyran-5-one (**8c**) in 67% yield. **8c**: mp 157—159 °C; IR (KBr) 1665, 1650, and 1620 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.11 (3H, s, Me), 1.18 (3H, s, Me), 2.25 (2H, s, CH_2C=C), 2.29 (2H, CH_2CO), 3.94 (2H, dd, *J*=2.5 and 14.5 Hz, PhCH_2S), 6.06 (1H, s, CH), and 6.8—7.4 (15H, m, 3Ph); MS (*m/z*) 452 (M^+). *Oxidation of **20** with Sodium Dichromate. (a)*: A mixture of **20** in acetic acid (1 mmol in 5 cm^3) and sodium dichromate in water (1 mmol in 2 cm^3) was stirred for 10 min. The resulting solution was diluted with water and extracted with chloroform. The chloroform extract was condensed and chromatographed over silica gel (chloroform, petroleum ether, and ethyl acetate in 4:4:1, v/v). 2-(Benzoylphenylmethylene)-5,5-dimethyl-1,3-cyclohexanedione (**24**) was obtained in 45% yield. **24**: mp 156—157 °C; IR (KBr) 1710 and 1670 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.12 (6H, s, Me_2), 2.57 (2H, s, CH_2), 2.63 (2H, s, CH_2), and 7.0—7.9 (10H, m, 2Ph); ^{13}C-NMR ($CDCl_3$) δ=28.5 (q), 29.9 (s), 53.1 (t), 54.5 (t), 128.2 (d), 128.3 (d), 128.7 (d), 129.0 (d), 129.8 (d), 133.2 (d), 133.3 (s), 133.6 (s), 134.8 (s), 161.9 (s), 194.7 (s), 196.6 (s), and 197.6 (s); MS (*m/z*) 332 (M^+). Found: C, 79.28; H, 6.07. Calcd for $C_{22}H_{20}O_3$: C, 79.50; H, 6.06. *(b)*: Further oxidation of **24** was carried out as follows. A mixture of **24** (1 mmol) and sodium dichromate (2 mmol) in acetic acid (20 cm^3) was stirred at room temperature for 5 h. The resulting solution was treated as above to yield 2-[α-(benzoyloxy)benzylidene]-5,5-dimethyl-1,3-cyclohexanedione (**25**) in 24% yield. **25**: mp 146—148 °C; IR(KBr) 1730, 1680, and 1660 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.25 (6H, s, Me_2), 2.46 (2H, s, CH_2), 2.78 (2H, s, CH_2), and 6.9—8.1 (10H, m, 2Ph); ^{13}C-NMR ($CDCl_3$) δ=28.2 (q), 33.1 (s), 42.2 (t), 51.0 (t), 127.7 (s), 128.3 (s), 128.5 (d), 128.9 (d) 130.0 (d), 133.6 (d), 134.1 (d), 136.6 (s), 162.8 (s), 166.3 (s), 192.1 (s), and 196.4 (s); MS (*m/z*) 348 (M^+). Found: C, 75.82; H, 5.66%. Calcd for $C_{22}H_{20}O_4$: C, 75.84; H, 5.79%.

*Hydrolysis of **25**.* In a mixture of concd HCl (1 cm^3) and 20% aqueous ethanol (20 cm^3), some **25** (0.3 mmol) was kept for 2 d. The resulting solution was quenched in water and extracted with chloroform. The chloroform extract was condensed under reduced pressure and then dissolved in 30 cm^3 of ether. The solution was shaken with an aqueous saturated solution of copper(II) acetate (0.3 mmol) and the resulting precipitate was separated. The precipitate was treated with 3 M hydrochloric acid (1 M=1 mol dm^{-3}) to give colorless crystals. The crystals were collected and recrystallized from petroleum ether to yield the known 2-benzoyl-5,5-dimethyl-1,3-cyclohexanedione **26** in 36% yield. **26**: mp 120—121 °C (lit,[4] mp 120—122 °C); ^{1}H-NMR ($CDCl_3$) δ=1.08 (6H, s, Me_2), 2.24 (2H, s, CH_2), 2.49 (2H, s, CH_2), and 7.1—7.5 (5H, br s, Ph); MS (*m/z*) 244(M^+).

*The Reaction of **1a** or **1b** with 1,3-Indandione **27**.* The reaction was carried out as was described in the reaction of **1a** with **2**. The salt **1a** gave **28a** in 41% yield. **28a**: mp 190—191 °C; IR (KBr) 1690 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.18 (3H, s, MeS), 6.60 and 6.71 (1H, s, 1:2, C=CH), and 6.8—8.1 (14H, m, Arom); MS(*m/z*) 381 (M^+−1). Found:C, 78.22; H, 4.66%. Calcd for $C_{25}H_{18}O_2S$: C, 78.50; H, 4.74%. The salt **1b** yielded **28b** in 37% yield. **28b**: mp 134—136 °C; IR (KBr) 1650 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.11 (3H, t, *J*=7 Hz, CH_3), 2.54 (2H, q, CH_2), 6.49 and 6.58 (1H, s, 1:2, C=CH), and 6.8—8.0 (14H, m, Arom); MS (*m/z*) 396 (M^+). Found: C, 78.43; H, 4.96%. Calcd for $C_{26}H_{20}O_2S$: C, 78.76; H, 5.08%.

*The Reaction of **28a** with Mercury(II) Acetate in Acetic Acid.* The compound **28a** was treated in a way similar to that described in the reaction of **8a** with mercury(II) acetate in acetic acid; **30** was obtained in 50% yield. **30**: resinous; IR (KBr) 3400, 1700, and 1680 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ= 4.44 (1H, s, exchangeable with D_2O, OH), 6.4—8.3 (14H, m, Arom), and 9.59 (1H, s, CHO); MS (*m/z*) 352 (M^+). Found: C, 81.66; H, 4.67%. Calcd for $C_{24}H_{16}O_3$:C, 81.80; H, 4.57%.

The reaction of 30 with *p*-toluenesulfonohydrazide in ethanol at room temperature for 2 d yielded the corresponding diazepine **32** in 44% yield. **32**: mp 280—281 °C; IR (KBr) 1730 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.30 (3H, s, CH_3), 6.5—9.1 (18H, m, Arom), and 8.38 (1H, s, N=CH); MS (*m/z*) 502 (M^+). Found: C, 74.06; H, 4.50; N, 5.70%. Calcd for **31**, $C_{31}H_{24}N_2O_4S$:C, 71.52; H, 4.65; N, 5.38% and for **32**, $C_{31}H_{22}N_2O_3S$: C, 74.08; H, 4.41; N, 5.57%.

*The Reaction of **28a** with Alcohol in the Presence of Mercury(II) Chloride.* The compound **28a** was treated as described in the reaction of **8a**. The reaction of **28a** in ethanol yielded **33a** in 84%. **33a**: mp 133—134 °C; IR (KBr) 1690 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.23 (3H, t, *J*=7 Hz, CH_3), 3.82 (2H, q, CH_2), 5.93 (1H, s, CH), and 6.6—7.7 (14H, m, Arom); MS (*m/z*) 380 (M^+). Found: C, 82.01; H, 5.27%. Calcd for $C_{26}H_{20}O_3$: C, 82.08; H, 5.29%.

The reaction of **28a** in 2-propanol gave **33b** in 63% yield. **33b**: mp 135—136 °C; IR (KBr) 1700 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.26 (6H, d, *J*=7Hz, Me_2), 4.24 (1H, sept, $O\underline{CH}Me_2$), 6.13 (1H, s, CH), and 6.9—7.4 (14H, m, Arom); ^{13}C-NMR ($CDCl_3$) δ=23.2 (q), 73.2 (d, $CHMe_2$), 106.1 (d, CH), 118.3 (d), 121.7 (d), 122.4 (s), 126.9 (d), 127.4 (s and d), 127.6 (s), 127.8 (d), 129.5 (d), 130.2 (d), 130.3 (d), 131.0 (d), 132.6 (d), 134.5 (s), 135.0 (s), 137.0 (s), 188.8 (s); MS (*m/z*) 394 (M^+). Found: C, 82.34; H, 5.55%. Calcd for $C_{27}H_{22}O_3$: C, 82.21; H, 5.62%.

(Received September 5, 1983)

New chiral diphosphinites were prepared starting from (+)-diethyl tartrate. The asymmetric hydrogenation of dehydroamino acids, itaconic acid and dehydrodipeptides was studied using Rh(I)–diphosphinite catalysts. In the hydrogenation of dehydroamino acid derivatives, an introducion of ω-(dimethylamino)alkyl group in the ligands did not raise the optical yield. By the use of Rh(I)–diphosphinite having 3-(dimethylamino)propyl group, the inversion of the preferred product was observed. Itaconic acid can be hydrogenated in a good optical yield (76% e.e.) by use of the diphosphinite having 2-(dimethylamino)ethyl group. The diphosphinites having ω-dimethylamino group gave high optical yields in the case of dehydrodipeptides with a chiral center. Especially Rh(I)-catalysts coordinated by diphosphinites with 4-methyl or 4-methoxyl group on the phenyl ring of the ligand gave excellent stereoselectivities (more than 98% d.e.) in the case of Ac-ΔPhe-(*S*)-Phe-OH. The effect of these new chiral diphosphinites on the asymmetric hydrogenation of dehydroamino acids, itaconic acid and dehydrodipeptides was discussed in terms of the stereocontrol induced by electrostatic interaction between the dimethylamino group of the ligand and the substrate and by the steric interaction between the ligand and the substrate.

Recently, asymmetric hydrogenation of prochiral olefins has been studied very actively using many chiral ligands. In the hydrogenation of dehydroamino acid derivatives, several ligands could give high enough optical yields to be practically applied for amino acid production.[1]

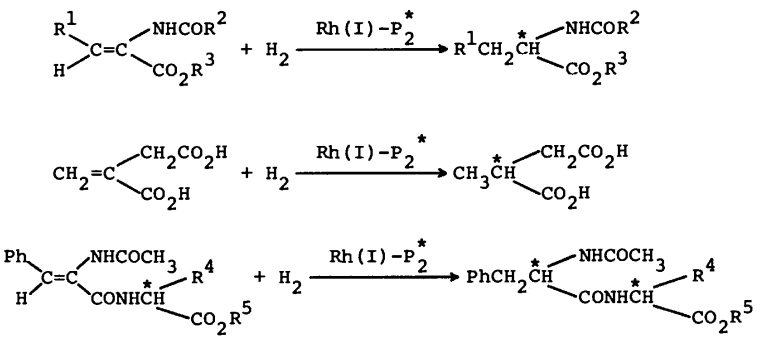
Since most of these ligands were designed to control the asymmetric induction only by the steric interaction between the substrate and phenyl groups on phosphorus atoms of the ligand,[2] the efficiency of these ligands seems to depend strongly on the structure of olefins.[3]

We intended to introduce both electrostatic and steric effects into the asymmetric hydrogenation of olefinic compounds. The electrostatic interaction between ligand and olefin will serve more significantly to discriminate the prochiral face of the substrate. So we prepared new chiral diphosphinites with pyrrolidine moiety, some of them having ω-(dimethylamino)alkyl substituent on the pyrrolidine ring. The dimethylamino group is expected to interact with a carboxyl group of prochiral olefins. These diphosphinites were used for asymmetric hydrogenation of dehydroamino acid derivatives, itaconic acid and dehydrodipeptides.[4] The result of itaconic acid and dehydrodipeptides strongly suggested that an electrostatic effect contributed to the stereoselection (Scheme 1).

Result and Discussion

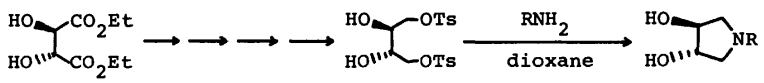
The preparative route to the diphosphinites (**1**—**5**) is shown in Scheme 2. 1,4-Di-*O*-tosyl-L-threitol was induced from (+)-diethyl tartrate by conventional method.[5] *N*-Substituted (*S,S*)-3,4-pyrrolidinediols were obtained by the reaction of the corresponding amine and 1,4-di-*O*-tosyl-L-threitol. These diols were easily converted to the diphosphinites (**1**—**5**) by the reaction with chlorodiarylphosphine in the presence of triethylamine.[6] Diphosphinite (**1**) is a carbon analog of **2** and is expected to show a similar steric effect to that of **2**.

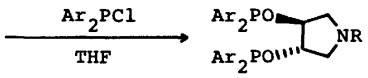
The result of asymmetric hydrogenation of dehydroamino acid derivatives with Rh(I)–diphosphinite (**1**—**3**) catalysts are summarized in Table 1. Rh(I)–diphosphinite (**1**—**3**) catalysts gave low optical yields. In



Scheme 1.

the hydrogenation of α-acetamidocinnamic acid, diphosphinite (**1**) without dimethylamino group, gave (*S*)-product in a higher optical yield than that with **2** (29% e.e. and 16% e.e., respectively). In the case of other *N*-acyl dehydroamino acids, diphosphinite (**1**) also gave (*S*)-product in higher optical yields than those with diphosphinite (**2**). It is noted that diphosphinite (**3**), which has a longer aminoalkyl group than **2**, gave (*R*)-product although the absolute configrations of the diphosphinites (**1**—**3**) are the same. The inversion of





diphosphinite	Ar	R

a) Hydrogenations were performed in ethanol-benzene (2/1) under atmospheric hydrogen pressure at 20 °C. b) Substrate/Rh=100. c) Diphosphinite/Rh=1.5. d) Optical yields (% e.e.) were calculated from the specific rotation of the product and that of optically pure substance: *N*-acetyl-(*S*)-phenylalanine, $[\alpha]_D^{26}$ +46.0° (*c* 1.0, EtOH);[1a] *N*-acetyl-(*S*)-phenylalanine methyl ester, $[\alpha]_D^{25}$ +15.9° (*c* 2.0, MeOH);[13] *N*-acetyl-(*S*)-phenylalanine isopropyl ester, $[\alpha]_D^{25}$ +76.1° (*c* 1.0, $CHCl_3$);[13] *N*-benzoyl-(*S*)-phenylalanine, $[\alpha]_D^{27}$ −40.3° (*c* 1.0, MeOH);[1a] *N*-benzoyl-(*S*)-phenylalanine methyl ester, $[\alpha]_D^{25}$ −45.3° (*c* 1.3, 95% EtOH);[18] *N*-acetyl-(*R*)-alanine, $[\alpha]_D^{26}$ +66.3° (*c* 2.0, H_2O).[1a] e) Addition of triethylamine (NEt_3/Rh=10).

the preferred product using diphosphinite (**3**) was also observed in the reaction of esters. This inversion in the system of **3** is considered to arise mainly from the change of the conformation of phenyl group on phosphorus atoms by the steric repulsion between the dimethylamino group and the phenyl groups. The results obtained indicate that the diphosphinite with a longer aminoalkyl group lowered the (*S*)-selectivity in the reaction of dehydroamino acid derivatives.

The rate of the hydrogenation with Rh(I)-diphosphinite (**2** or **3**) catalyst was much slower than that with Rh(I)-diphosphinite (**1**) catalyst, especially for dehydroamino acid esters. The suppression of the hydrogenation of esters would be ascribed to the coordination of the dimethylamino group onto rhodium and the weaker coordination ability of esters onto rhodium than that of carboxylic acids. The reaction was also suppressed by the presence of bulky alkyl substituent in the dehydroamino acid ester. The results of the hydrogenation of dehydroamino acids make it unlikely that any electrostatic interaction exists between carboxyl group of the substrate and the dimethylamino group of the ligand in the rhodium complex.

The low stereoselectivity by Rh(I)-diphosphinite (**1**—**3**) catalysts can be explained by the presence of several kinds of Rh(I) species in the reaction systems. ^{31}P NMR spectra of Rh(I)-diphosphinite (**2** or **3**)-α-acetamidocinnamic acid systems showed the presence of several Rh(I) species in the solution (Fig. 1). The different ^{31}P NMR patterns of the two systems (**2** and **3**), as well as CD spectra (*vide infra*), suggest the presence of different rhodium species in each system which has a different stereoselectivity.

Triethylamine addition into rhodium-chiral diphosphine systems increased the optical yields of hydrogenation of *N*-acyl dehydroamino acids.[7] It is thought that triethylamine deprotonates a carboxyl group of the substrate on rhodium. In our diphosphinite (**1**—**3**) systems, however, the addition of triethylamine lowered the optical yield of the hydrogenation of α-acetamidocinnamic acid (Table 1). Amine addition increased the intensity of the absorptions corresponding to d-d transition and CT transition of the rhodium complex for both systems (**2** and **3**). The intensity of the CD spectrum was reduced by the amine addition in the system of Rh(I)-(**2**)-α-acetamidocinnamic acid while the intensity was increased by the additive amine in the system of **3** (Fig. 2). The different effect of the additive amine on the CD spectra of the two systems would indicate that the main Rh(I) species have different coordination manners for these two diphosphinite systems.

We applied the diphosphinite (**1**—**3**) catalysts to itaconic acid (α-methylenesuccinic acid) which has a structure similar to α-acetamidoacrylic acid. Itaconic acid is considered to be more suitable to examine the effect of electrostatic interaction because of the presence of two carboxyl groups in the molecule. The dimethylamino group of **2** and **3** may interact electrostatically with β-carboxyl group of itaconic acid to enable the three points' recognition of the prochiral face of itaconic acid. As shown in Table 2, Rh(I)-diphosphinite (**2** and **3**) catalysts gave much higher optical yields for itaconic acid than those of α-acetamidoacrylic acid. It is noted that diphosphinite (**2**) gave the highest optical yield (66% e. e.) among the ligands examined; the optical yield increased to 76% e.e. by lowering the reaction temperature (−20 °C).[8] Since the catalyst of **1**, sterically similar to **2**, gave a lower optical yield (42% e. e.) than the catalyst of **2**, the above results would indicate the enhancement of the stereoselectivity by the dimethylamino group of **2** in the reaction of itaconic acid. The

(b): (a) + NEt_3.

catalyst of **3** gave lower optical yield (45% e. e.). This decrease in the (*S*)-selectivity is in accord with the results of the hydrogenation of dehydroamino acid derivatives in the system of **3**.

In the reaction of itaconic acid, addition of triethylamine (NEt_3/Rh=10) lowered drastically the optical yield. The ^{31}P NMR spectrum of Rh(I)-diphosphinite (**2**)-itaconic acid system showed the presence of several Rh(I) species in the solution, but the addition of amine simplified the spectrum and no P-P coupling was observed (Fig. 3). These are explained by the competitive coordination between the diphosphinite and amine onto rhodium. Amine addition increased the intensity of absorption spectra in the systems of **1** and **2**, and the intensity of CD spectra also increased in both systems (Fig. 4). These would correspond to the competitive coordination between the diphosphinite and amine. Thus the addition of triethylamine weakened the stereocontrol by the diphosphinite to result in the decrease of the optical yield. On the other hand, it is also possible that triethylamine deprotonates the carboxyl

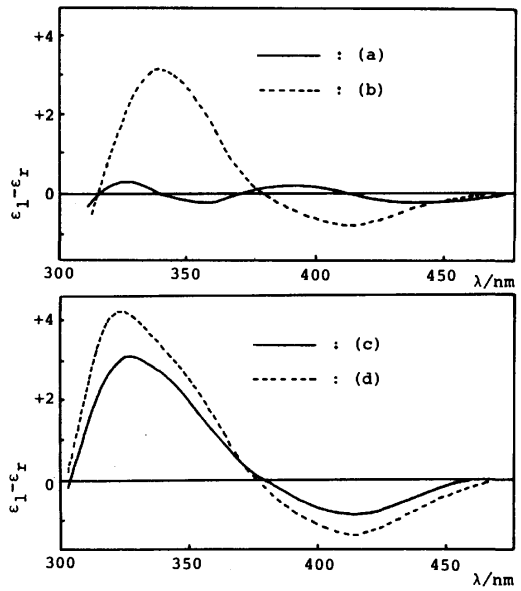

Fig. 4. CD spectra of Rh(I)-diphosphinite (**1**)- or (**2**)-itaconic acid systems in methanol solution.
(a): $[Rh(CH_2{=}C(CH_2CO_2H)CO_2H)(\mathbf{1})]^+BF_4^-$,
(b): (a) + NEt_3,
(c): $[Rh(CH_2{=}C(CH_2CO_2H)CO_2H)(\mathbf{2})]^+BF_4^-$,
(d): (c) + NEt_3.

group of itaconic acid, as is supposed in the hydrogenation of dehydroamino acid.[7] The reaction of monosodium salt of itaconic acid gave lower optical yield in methanol than the reaction of itaconic acid in the absence of amine in methanol (25% e. e. and 51% e. e., respectively). Therefore, the presence of itaconate anion does not serve to raise the optical yield unless the interaction exists between itaconate anion and the ligand.

As mentioned previously, several Rh(I) species are present in the solution to lower the optical yield. In order to decrease the number of Rh(I) species in the solution, the following diphosphinites (**4** and **5**) were examined. They have an electron-donating group (4-methyl or 4-methoxyl group) on the phenyl group on phosphorus atom and are expected to coordinate more strongly onto rhodium. As shown in Table 3, the reaction rate increased strikingly in the case of α-acetamidocinnamic acid by the introduction of the electron-donating substituent on the phenyl group, though the optical yield did not change so much. On the other hand, the reaction rate in the hydrogenation of itaconic acid was almost unchanged, but the optical yield slightly decreased as the coordination of diphosphinites onto rhodium became stronger. This different behavior seems to indicate that the coordination mode of the substrates was different between itaconic acid[9] and dehydroamino acid.

The electrostatic interaction between diphosphinite (**2**) and itaconic acid was expected, but considered to be not strong enough to allow the precise discrimination of the prochiral face of itaconic acid. In the case of dehydrodipeptides,[10] the carboxyl group of the sub-

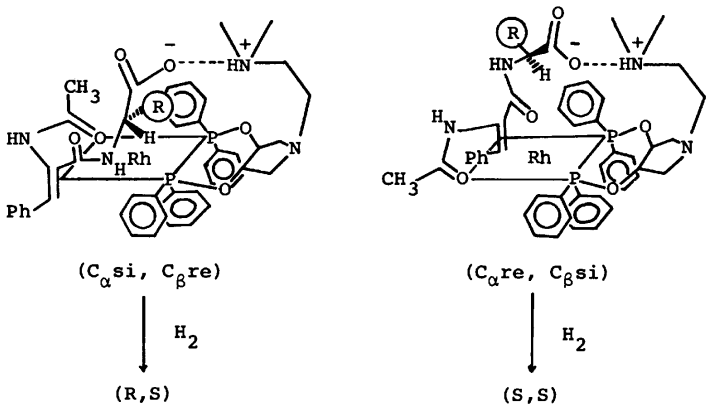
a) Hydrogenations were performed in ethanol under atmospheric hydrogen pressure. b) Dehydrodipeptide/Rh = 50. c) Diphosphinite/Rh = 1.5.

strate is expected to interact more easily with the dimethylamino group of the ligands. Accordingly, our diphosphinite catalysts were applied to the asymmetric hydrogenation of dehydrodipeptides (Table 4). The reaction of Ac-⊿Phe-Gly-OH, using diphosphinite (**2** and **3**) catalysts, having the dimethylamino group, proceeded as rapidly as the reaction with diphosphinite (**1**). These results present an interesting contrast with the reaction of dehydroamino acid derivatives using diphosphinites with the dimethylamino group. Diphosphinites (**2** and **3**) gave (*S*,*S*)-products with high stereoselectivity in the reaction of Ac-⊿Phe-(*S*)-Phe-OH (90% d.e. and 86% d.e., respectively), while diphosphinite (**1**) gave the product with much lower stereoselectivity (58% d.e.). These results indicate the effect of the dimethylamino group on the asymmetric induction. Introduction of the electron-donating substituent on the phenyl group of the diphosphinite (**2**) increased the reactivity and gave an extremely high stereoselectivity (more than 98% d. e. with both **4** and **5**). The presence of the dimethylamino group in the ligand induced also high stereoselectivity (96% d. e. with **5**) in the reaction of Ac-⊿Phe-(*S*)-Ala-OH, while diphosphinite (**1**) gave only low stereoselectivity (36% d. e.). In the case of Ac-⊿Phe-(*S*)-Phe-OMe, the reactivity was extremely low using diphosphinites (**2** and **5**) with the dimethylamino group, as was observed in the reaction of dehydroamino acid esters. Hydrogenation took place smoothly using diphosphinite (**1**) without dimethylamino group, but the stereoselectivity was very low. This striking difference between the reaction of Ac-⊿Phe-(*S*)-Phe-OH and that of Ac-⊿Phe-(*S*)-Phe-OMe will further support the electrostatic interaction between the carboxyl group of the dipeptide and the dimethylamino group of the ligand.

These results indicate the importance of the chiral center in the substrate, as well as the dimethylamino group of the ligand for asymmetric induction (Scheme 3). The electrostatic interaction between the dimethylamino group of the ligand and the carboxyl group of the dipeptide will play a role to fix the substrate onto rhodium. In the case of dehydrodipeptide with a chiral center, coordination of the substrate onto rhodium by the ($C_\alpha$si, $C_\beta$re) face of the double bond is unfavorable because of the steric repulsion between the substituent on the chiral carbon of the substrate and the phenyl



Scheme 3.

group of the ligand. So the coordination by the (Cαre, Cβsi) face becomes favorable, resulting in the predominant (*S*, *S*)-product formation. That is to say, the electrostatic interaction emphasized the steric effect of the chiral center of the dipeptide, resulting in the high stereoselective induction.

For dehydrodipeptides with (*R*)-chiral center, (*R*, *R*)-product was formed in a high stereoselectivity instead of (*S*, *R*)-isomer.[11]

In the case of dehydroamino acids, the dimethylamino group in the ligand and the carboxyl group of the substrate are too distant to interact strongly enough to increase the optical yield. On the other hand, in the case of itaconic acid, the carboxyl group of the substrate would interact with the dimethylamino group of the ligand to give high optical yield. Furthermore, in the case of dehydrodipeptides with a chiral center, the electrostatic interaction fixed the substrate onto rhodium to induce excellent stereoselectivity by emphasizing the steric effect. The detailed study of the asymmetric hydrogenations of dehydrodipeptides and dehydrooligopeptides is in progress using diphosphinite systems. Our ligand with the dimethylamino group will be applied for more complex substrates with many functional groups.

Experimental

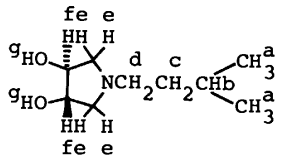
^{1}H NMR spectra were recorded on Hitachi R-24 High Resolution NMR spectrometer (60 MHz) with tetramethylsilane as internal standard. ^{31}P NMR spectra were recorded on a JEOL JNM-FX60Q spectrometer with triphenylphosphine as external standard (6.2 ppm). CD spectra were recorded on a JASCO J-40A spectropolarimeter. Optical rotations were measured with a UNION PM101 automatic digital polarimeter.

Materials. α-Acetamidocinnamic acid, α-acetamidoacrylic acid, and itaconic acid were purchased as commercial products. α-Benzoylaminocinnamic acid,[12] methyl α-acetamidocinnamate,[13] isopropyl α-acetamidocinnamate,[13] methyl α-benzoylaminocinnamate,[13] *N*-acetyl dehydrophenylalanylglycine,[14] *N*-acetyl dehydrophenylalanyl-(*S*)-phenylalanine,[14] *N*-acetyl dehydrophenylalanyl-(*S*)-alanine,[14] and *N*-acetyl dehydrophenylalanyl-(*S*)-phenylalanine methyl ester[10c] were prepared by the conventional methods. All substrates except α-acetamidoacrylic acid and itaconic acid were purified by repeated recrystallization.

Ethanol and methanol were dried and distilled over magnesium and stored under nitrogen. Tetrahydrofuran, diethyl ether, dioxane, triethylamine, and benzene were dried and distilled over sodium and stored under nitrogen. 1,4-Di-*O*-tosyl-L-threitol was prepared through four steps from (+)-diethyl tartrate.[5] Chlorodi-*p*-tolylphosphine and chlorobis(4-methoxyphenyl)phosphine were prepared by the reaction of corresponding Grignard reagent and sodium diethyl phosphite followed by hydrolysis and chlorination with phosphorus trichloride.[15]

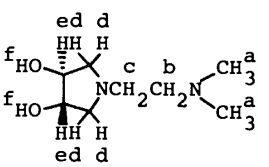
$[Rh(cod)_2]^+BF_4^-$(cod: 1,5-cyclooctadiene) was prepared by a conventional method and stored under nitrogen.[16]

Preparation of Diphosphinites. (3S,4S)-N-Isopentyl-3,4-pyrrolidinediol (6): Isopentylamine (4 cm^3, 3.4×10^{-2} mol) and 1,4-di-*O*-tosyl-L-threitol (4.8 g, 1.1×10^{-2} mol) were reacted in dioxane (6 cm^3) under reflux with stirring for 20 h under nitrogen. The reaction mixture was evaporated under reduced pressure, and the residual solid was extracted with THF in an ice-water bath. The extract was evaporated to dryness under reduced pressure. Recrystallization of the residue from diethyl ether with hexane gave 650 mg of pale yellow crystals containing a small amount of ammonium salt and unchanged amine. (85 mol% purity, 34% yield) This diol was used for the preparation of diphosphinite (**1**) without further purification. ^{1}H NMR ($CDCl_3$) δ=0.87 (6H, d, H^a), 1.38 (3H, br m, H^b, H^c), 2.33—3.11 (6H, m, H^d, H^e), 4.11 (2H, br t, H^f), 4.87 (2H, s, H^g).



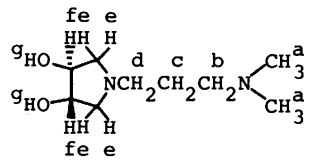
6

(3S,4S)-N-[2(Dimethylamino)ethyl]-3,4-pyrrolidinediol (7): *N*,*N*-Dimethylethylenediamine (18.2 g, 2.1×10^{-1} mol) and 1,4-di-*O*-tosyl-L-threitol (30 g, 6.9×10^{-2} mol) were reacted in dioxane and the product was treated in the manner described above. The crude diol was purified by short column chromatography of neutral alumina (ethanol eluent) and recrystallization from THF. In this way, the diol was obtained as white crystals. (2.4 g, 20% yield) $[\alpha]_D^{25}$ +2.9° (*c* 0.90, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ=2.22 (6H, s, H^a), 2.43—3.10 (8H, m, H^b, H^c, H^d), 4.02 (2H, br t, H^e), 4.87 (2H, s, H^f).



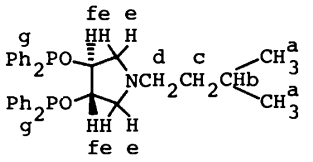
7

(3S,4S)-N-[3-(Dimethylamino)propyl]-3,4-pyrrolidinediol (8): *N,N*-Dimethyl-1,3-propanediamine (4.2 cm³, 3.3×10⁻² mol) and 1,4-di-*O*-tosyl-L-threitol (4.8 g, 1.1×10⁻² mol) were reacted in dioxane and the product was treated in the manner described previously. The crude diol was obtained as oily material containing a small amount of ammonium salt and unchanged amine (530 mg, 93 mol% purity, 25% yield); this diol was used without further purification in the preparation of the diphosphinite (**3**). ^{1}H NMR ($CDCl_3$) δ= 1.66 (2H, br m, H^c), 2.20 (6H, s, H^a), 2.20—3.08 (8H, m, H^b, H^d, H^e), 4.07 (2H, br t, H^f), 4.97 (2H, s, H^g).



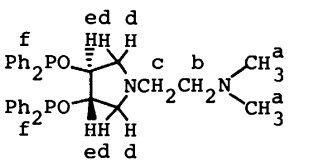
8

(3S,4S)-N-Isopentyl-3,4-bis(diphenylphosphinooxy)pyrrolidine (1): The phosphinitation of the diol (**6**) was performed in 2 steps because of the contamination by impurities (ammonium salt and amine). To the solution of the diol (**6**) (490 mg, 2.82×10⁻³ mol) and triethylamine (1.3 cm³, 9.3×10⁻³ mol) in THF (30 cm³), chlorodiphenylphosphine (0.6 cm³, 3.3×10⁻³ mol) in THF (5 cm³) was added dropwise in 3 h with stirring in an ice-water bath. After the addition, the mixture was stirred for 1.5 h at 0 °C. The white precipitate was filtered off and the filtrate was evaporated to dryness under reduced pressure. ^{1}H NMR of the oily residue indicated the formation of monophosphinite and diphosphinite (**1**). This oily product was further phosphinitated and treated as before. The resulting oily product was extracted with ether, and the ether extract was concentrated. Addition of hexane to the ether solution gave white precipitate of diphosphinite (**1**) at −50 °C. Repeated recrystallization from ether-hexane gave pure diphosphinite (**1**) as white crystals. (1.05 g, 68% yield) mp 54.5—57.2 °C (corr); $[\alpha]_D^{25}$ +59.8° (*c* 0.48, C_6H_6); ^{1}H NMR ($CDCl_3$) δ=0.86 (6H, d, H^a), 1.34 (3H, br m, H^b, H^c), 2.31—3.13 (6H, m, H^d, H^e), 4.65 (2H, br m, H^f), 7.40 (20H, m, H^g). Found: C, 72.66; H, 6.86; N, 2.62; P, 11.61. Calcd for $C_{33}H_{38}NP_2O_2$: C, 73.18; H, 6.88; N, 2.58; P, 11.43.



1

(3S,4S)-N-[2-(Dimethylamino)ethyl]-3,4-bis(diphenylphosphinooxy)pyrrolidine (2): Chlorodiphenylphosphine (0.65 cm³, 3.6×10⁻³ mol) in THF (3 cm³) was added dropwise to the solution of the diol (**7**) (310 mg, 1.7×10⁻³ mol) and triethylamine (0.5 cm³, 3.6×10⁻³ mol) in THF (20 cm³) in 30 min with stirring in an ice-water bath. After the addition, the mixture was stirred for 3 h at 0 °C. The white precipitate was filtered off and the filtrate was evaporated to dryness under reduced pressure. The oily residue was purified by recrystallization from ether-hexane, and the pure diphosphinite was obtained as white crystals having a melting point near the r.t. (610 mg, 63% yield) $[\alpha]_D^{25}$ +55.4° (*c* 0.97, C_6H_6); ^{1}H NMR ($CDCl_3$) δ=2.22 (6H, s, H^a), 2.41—3.17 (8H, m, H^b, H^c, H^d), 4.64 (2H, br m, H^e), 7.41 (20H, m, H^f).

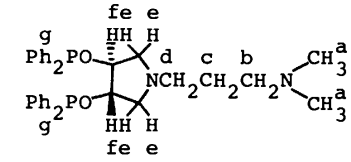


2

Found: C, 70.70; H, 6.94; N, 5.25; P, 11.59. Calcd for $C_{32}H_{36}N_2P_2O_2$: C, 70.83; H, 6.68; N, 5.16; P, 11.41.

(3S,4S)-N-[3-(Dimethylamino)propyl]-3,4-bis(diphenylphosphinooxy)pyrrolidine (3): The phosphinitation of the diol (**8**) was performed in 2 steps. To the solution of the diol (**8**) (530 mg, 2.8×10⁻³ mol) and triethylamine (1.2 cm³, 8.6×10⁻³ mol) in THF (30 cm³), chlorodiphenylphosphine (0.5 cm³, 2.8×10⁻³ mol) in THF (5 cm³) was added dropwise in 30 min with stirring in an ice-water bath. The resulting mixture was further stirred for 30 min at 0 °C. Filtration of the reaction mixture followed by evaporation of the filtrate gave oily monophosphinite. The monophosphinite was further phosphinitated with 0.5 cm³ of chlorodiphenylphosphine and 1.2 cm³ of triethylamine, and treated as before. The oily product was purified by recrystallization from ether-hexane and pure diphosphinite (**3**) was obtained as a colorless oil. (800 mg, 57% yield) $[\alpha]_D^{25}$ +56.0° (*c* 0.31, C_6H_6); ^{1}H NMR ($CDCl_3$) δ=1.61 (2H, m, H^c), 2.17 (6H, s, H^a), 2.17—3.13 (8H, m, H^b, H^d, H^e), 4.64 (2H, br, m, H^f), 7.44 (20H, m, H^g).

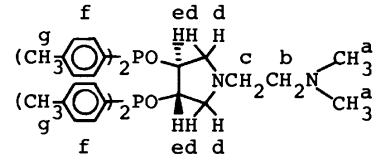
Found: C, 71.20; H, 6.98; N, 4.91; P, 11.08. Calcd for $C_{33}H_{38}N_2P_2O_2$: C, 71.20; H, 6.88; N, 5.30; P, 11.12.



3

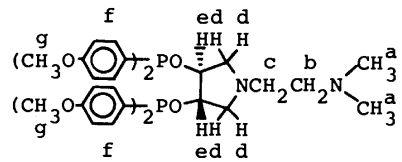
(3S,4S)-N-[2-(Dimethylamino)ethyl]-3,4-bis(di-p-tolylphosphinooxy)pyrrolidine (4): To the solution of the diol (**7**) (500 mg, 2.9×10⁻³ mol) and triethylamine (2.8 cm³, 20×10⁻³ mol) in THF (50 cm³), chlorodi-*p*-tolylphosphine (1.9 g, 7.6×10⁻³ mol) in THF (15 cm³) was added dropwise in 2 h with stirring at −30 °C. The mixture was further stirred for 2 h at 0 °C. Similar treatment of the reaction mixture to the case of (**2**) and recrystallization of the product from ether-hexane gave pure diphosphinite (**4**) as white needles. (780 mg, 45% yield) mp 74.5—76.5 °C (corr); $[\alpha]_D^{25}$ +60.4° (*c* 0.51, C_6H_6); ^{1}H NMR ($CDCl_3$) δ=2.18—3.09 (26H, m, H^a, H^b, H^c, H^d), 4.52 (2H, br m, H^e), 6.96—7.44 (16H, m, H^f).

Found: C, 72.48; H, 7.59; N, 4.57; P, 10.16. Calcd for $C_{36}H_{44}N_2P_2O_2$: C, 72.22, H, 7.40; N, 4.67; P, 10.34.



4

(3S,4S)-N-[2-(Dimethylamino)ethyl]-3,4-bis[bis(4-methoxyphenyl)phosphinooxy]pyrrolidine (5): To the solution of the diol (**7**) (600 mg, 3.4×10⁻³ mol) and triethylamine (5.5 cm³, 40×10⁻³ mol) in THF (50 cm³), chlorobis(4-methoxyphenyl)phosphine (2.2 g, 7.8×10⁻³ mol) in THF (15 cm³) was added dropwise in 2 h with stirring at −30 °C. The mixture was further stirred for 30 min at 0 °C. Similar treatment of the reaction mixture to the case of **2** and recrystallization of the product from ether-hexane gave pure diphosphinite (**5**) as white crystals. (1.67 g, 47% yield) mp 62.8—65.7 °C (corr); $[\alpha]_D^{25}$ +58.9° (*c* 0.95, C_6H_6); ^{1}H NMR ($CDCl_3$) δ=2.17 (6H, s, H^a) 2.33—3.06 (8H, M, H^b, H^c, H^d), 3.72 (12H, s, H^g), 4.43



5

(2H, br, m, H^e), 6.57—7.48 (16H, m, H^f).

Found: C, 65.27; H, 6.77; N, 4.03; P, 9.16. Calcd for $C_{36}H_{44}N_2P_2O_6$: C, 65.24; H, 6.96; N, 4.22; P, 9.36.

Hydrogenation Procedure. Dehydroamino Acid Derivatives and Itaconic Acid: Typically, $[Rh(cod)_2]^+BF_4^-$ (4.1 mg, 1.0×10^{-5} mol) and a diphosphinite (1.5×10^{-5} mol) were dissolved in a solvent (3 cm^3) under nitrogen and the solution was stirred at r.t. for 5 min. This catalyst solution was transferred into the hydrogenation flask containing the substrate (1.0×10^{-3} mol) and a solvent (7 cm^3) by a narrow stainless steel tube under nitrogen. After the solution was stirred for 1 h at r. t. under nitrogen, degassing under reduced pressure and filling the flask with hydrogen were repeated several times, quickly. The resultant solution was stirred vigorously until the required amount of hydrogen had been absorbed. The reaction mixture was worked up by the conventional method[17] and the optical yield was determined polarimetrically. In the case of itaconic acid, hydrogen was introduced after stirring of the mixture for 5 min under nitrogen.

Dehydrodipeptides: $[Rh(cod)_2]^+BF_4^-$ (4.1 mg, 1.0×10^{-5} mol) and a diphosphinite (1.5×10^{-5} mol) were dissolved in ethanol (2 cm^3) under nitrogen and the solution was stirred at r. t. for 5 min. This catalyst solution was transferred into the hydrogenation flask containing a dehydrodipeptide (5.0×10^{-4} mol) and ethanol (3 cm^3) by a narrow stainless steel tube under nitrogen, and the hydrogenation procedure described above was carried out. The reaction mixture was worked up by the conventional method[10] and the optical yield was determined by ^1H NMR usig a shift reagent ($Eu(tfc)_3$).

^{31}P NMR Spectra. The Typical Procedure for Preparation of the Sample: The solution of $[Rh(cod)_2]^+BF_4^-$ (37 mg, 9.1×10^{-5} mol) and a diphosphinite (9.1×10^{-5} mol) in methanol (1 cm^3) containing 10% of an internal lock (CD_3OD or C_6D_6) in a Schlenk tube was degassed by a freeze and thaw cycle. Hydrogen was introduced and the solution was stirred at r. t. for the time necessary for removing the coordinated cod. Then the solution was evacuated by three freeze and thaw cycles and transferred into a Schlenk tube containing a substrate (1.8×10^{-3} mol) with a narrow stainless steel tube under nitrogen, further degassed by the above procedure, and stirred at r. t. for 30 min. Finally, the solution was transferred into a NMR tube and the tube was sealed under nitrogen.

CD Spectra. The Typical Procedure for Preparation of the Sample: The stock solution of $[Rh(cod)_2]^+BF_4^-$ (8.1 mg, 2.0×10^{-5} mol) and a diphosphinite (2.4×10^{-5} mol) in methanol (20 cm^3) was evacuated by two freeze and thaw cycles. The solution (2.5 cm^3) was treated as described above and transferred into a Schlenk tube containing the methanol solution of a substrate (2.5×10^{-5} mol, 2.5cm^3), further degassed, and stirred at r. t. for 30 min. The resultant solution was transferred into a 10 mm cell under nitrogen.

The authors express their gratitude to Professor A. Yamamoto and Dr. F. Ozawa, Tokyo Institute of Technology, for ^{31}P NMR spectroscopy, and to Professor M. Kobayashi, Tokyo Metropolitan University, for CD spectroscopy.

The Synthesis of Coleon B Tri-*O*-methyl Ether

Takashi MATSUMOTO,* Sachihiko IMAI, Katsumi NISHIZAKI, Fumio KURIHARA, and Fumitaka GOTO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received September 12, 1983)

Methyl (+)-12-benzoyloxy-11,14-dioxo-8,12-abietadien-18-oate was converted into methyl 11,12,14-trimethoxy-8,11,13-abietatrien-18-oate (**8**). The Grignard reaction of **8** with phenylmagnesium bromide, followed by oxidation with lead tetraacetate, afforded 11,12,14-trimethoxy-19-norabieta-4(18),8,11,13-tetraene. This was then converted into 3α-bromo-11,12,14-trimethoxy-18-norabieta-8,11,13-trien-2-one (**15**) by a series of reactions: selenium dioxide oxidation, catalytic hydrogenation, dehydration, hydroxybromination, and Jones oxidation. Acetalization of **15** with 1,2-ethanediol, followed by oxidation with Jones reagent and then with oxygen in the presence of potassium *t*-butoxide, afforded 3-bromo-2,2-ethylenedioxy-6-hydroxy-11,12,14-trimethoxy-18-norabieta-5,8,11,13-tetraen-7-one, which was converted into (−)-coleon B tri-*O*-methyl ether (**4**) by hydrolysis and dehydrobromination. Another conversion of **15** into **4** was also achieved by a series of reactions: debromination, acetalization, Collins oxidation, oxygen oxidation, hydrolysis, and dehydrogenation.

Coleon B (**1**), a highly oxygenated tricyclic norditerpene phenol, has been isolated from the leaves of *Coleus igniarius* Schweinf. (Labiatae) by Eugster *et al.*[1] Recently, the synthesis of coleon B tetra-*O*-methyl ether (**2**) was reported by Burnell *et al.*[2] In the previous paper,[3] we also reported the synthesis of an A and B ring analog of coleon B, (−)-6-hydroxy-19-norabieta-3,5,8,11,13-pentaene-2,7-dione (**3**). As an extension of the previous work,[3] we here describe the successful synthesis of (−)-coleon B tri-*O*-methyl ether (**4**), starting from methyl (+)-12-benzoyloxy-11,14-dioxo-8,12-abietadien-18-oate (**5**)[4] which was prepared from (+)-dehydroabietic acid (**6**).

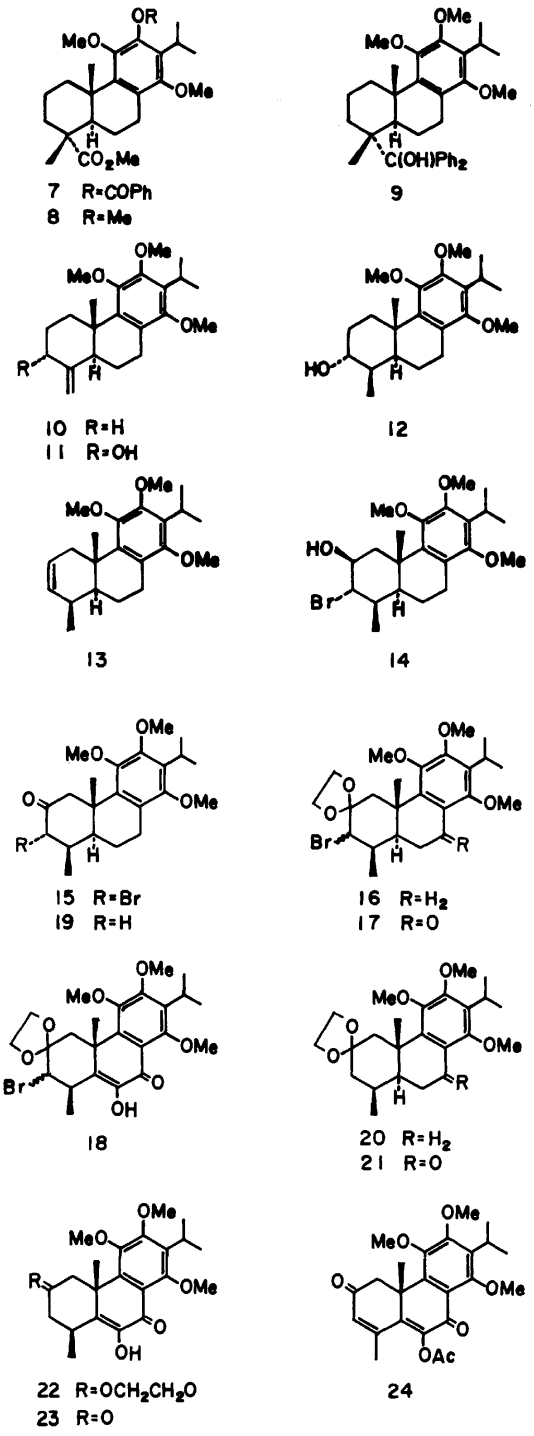
6

The 11,14-dioxo compound **5** was reduced with sodium dithionite in aqueous acetic acid at 80—95 °C or with zinc powder and dilute hydrochloric acid in benzene at 55—60 °C. The resulting phenol was methylated with methyl iodide in the presence of anhydrous potassium carbonate in refluxing ethyl methyl ketone to afford methyl 12-benzoyloxy-11,14-dimethoxy-8,11,13-abietatrien-18-oate (**7**) in 87.1% or 78.0% yield. The dimethoxy compound **7** was then converted into methyl 11,12,14-trimethoxy-8,11,13-abietatrien-18-oate (**8**: 82.4%) by alkaline hydrolysis and subsequent methylation. The Grignard reaction of **8** with phenylmagnesium bromide at 95—105 °C afforded a diphenylmethanol derivative (**9**: 71.3%). This was treated with lead tetraacetate and calcium carbonate in refluxing benzene to give 11,12,14-trimethoxy-19-norabieta-4(18),8,11,13-tetraene (**10**: 57.5%). The presence of an *exo*-methylene group at C-4 in **10** was supported by its ^{1}H NMR spectrum, which showed two broad singlet signals at δ 4.53 and 4.78 due to two olefinic protons. The tetraene **10** was oxidized with selenium dioxide in refluxing aqueous ethanol to yield 11,12,14-trimethoxy-19-norabieta-4(18),8,11,13-tetraen-3α-ol (**11**: 56.6%). The stereochemistry of the hydroxyl group at C-3 in **11** was assigned to be α-configuration from its ^{1}H NMR spectrum, which showed a broad signal due to the C-3 proton at δ 4.21 with half-height width of 5.4 Hz, suggesting the presence of an equatorial β proton. Catalytic hydrogenation of **11** in ethyl acetate over PtO_2 at room temperature afforded 11,12,14-trimethoxy-18-norabieta-8,11,13-trien-3α-ol[5] (**12**: 97.4%) which was dehydrated with phosphoryl chloride in refluxing pyridine to give 11,12,14-trimethoxy-18-norabieta-2,8,11,13-tetraene (**13**) in quantitative yield. The ^{1}H NMR spectrum of **13** showed doublet signals at δ 1.06 due to the C-4 methyl group and at δ 5.59 due to two olefinic protons. The tetraene **13** was treated with *N*-bromosuccinimide[6] in dimethyl sulfoxide containing a small quantity of water at room temperature under a stream of nitrogen to give a bromohydrin (**14**), which was used without purification in the next reaction. In the ^{1}H NMR spectrum of **14**, the down field shift of the signal (δ 1.38) due to the methyl group at C-10 relative to the corresponding signals for **12** (δ 1.28) and **13** (δ 1.26) suggested a 1,3-diaxial-*cis*-relationship between the methyl group and the new hydroxyl group. From the above spectral data and a well-documented mechanistic pathway (*trans*-diaxial addition),[7] the structure of **14** was assigned to be 3α-bromo-11,12,14-trimethoxy-18-norabieta-8,11,13-trien-2β-ol. Oxidation of the crude **14** in acetone with Jones reagent afforded 3α-bromo-11,12,14-trimethoxy-18-norabieta-8,11,13-trien-2-one (**15**) in 62.4% yield from **13**. To protect the carbonyl group as ethylene acetal, the

ketone **15** was refluxed with 1,2-ethanediol and *p*-toluenesulfonic acid in benzene to give a mixture of the C-3 epimeric acetals (**16**: 88.2%). Oxidation of the mixture (**16**) in acetone with Jones reagent afforded a mixture of the corresponding 7-oxo compounds (**17**: 81.8%[8]). This was then treated with oxygen in *t*-butyl alcohol in the presence of potassium *t*-butoxide to give a diosphenol derivative (**18**: 27.7%). The stereochemistry of the bromine atom at C-3 remains unsettled. Hydrolysis of **18** with dilute hydrochloric acid in refluxing acetic acid afforded a bromo ketone, which was immediately refluxed with pyridine to give the desired (−)-6-hydroxy-11,12,14-trimethoxy-19-norabieta-3,5,8,11,13-pentaene-2,7-dione (coleon B tri-*O*-methyl ether) (**4**) in 36.2% yield.



Subsequently, another conversion of **15** into **4** was also carried out as follows. Debromination of **15** with sodium iodide and chlorotrimethylsilane in refluxing acetonitrile[9] afforded 11,12,14-trimethoxy-18-norabieta-8,11,13-trien-2-one (**19**: 90.0%). The ketone **19** was treated with 1,2-ethanediol and *p*-toluenesulfonic acid in refluxing benzene to give an acetal (**20**: 93.0%). Oxidation of **20** with Collins reagent[10] in dichloromethane at room temperature afforded the corresponding 7-oxo compound (**21**: 41.4%). This was further oxidized with oxygen in *t*-butyl alcohol in the presence of potassium *t*-butoxide to give a diosphenol derivative (**22**: 86.9%). Hydrolysis of **22** with dilute hydrochloric acid at room temperature afforded 6-hydroxy-11,12,14-trimethoxy-18-norabieta-5,8,11,13-tetraene-2,7-dione (**23**: 96.7%). Dehydrogenation of **23** with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone and acetic acid in refluxing benzene under a stream of nitrogen produced **4** (*ca.* 59%).[8]

In the present study, the latter route for the synthesis of **4** from **15** was superior to the former one.

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform, and the ^{1}H NMR spectra in carbon tetrachloride at 60 MHz, with tetramethylsilane as an internal standard, unless otherwise stated; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, m: multiplet. The column chromatography was performed using Merck silica gel (0.063 mm).

Methyl 12-Benzoyloxy-11,14-dimethoxy-8,11,13-abietatrien-18-oate (7). *a)*: A solution of sodium dithionite (11 g) in water (30 ml) was added dropwise at 80—95 °C to a stirred solution of methyl (+)-12-benzoyloxy-11,14-dioxo-8,12-abietadien-18-oate (**5**)[4] (550 mg) in acetic acid (30 ml). The mixture was stirred at this temperature for 15 min, cooled, and extracted with ether. The ether extract was washed successively with water, aqueous sodium hydrogencarbonate, and water. The solution was dried over sodium sulfate and evaporated *in vacuo* to give a crude phenol.

A stirred solution of the above crude phenol in ethyl methyl ketone (25 ml) was refluxed for 13 h with methyl iodide (3.0 ml) and anhydrous potassium carbonate (5.0 g). The mixture was cooled, diluted with water, and extracted with ether. The ether extract was washed successively with water, aqueous sodium thiosulfate, and water. The dried solution was evaporated *in vacuo*. The residue was recrystallized from methanol containing a small amount of acetone to give **7** (430 mg: 73.4%), mp 192.5—196 °C, $[\alpha]_D$+70.9°(*c* 1.27); IR: 1730, 1720 cm^{-1}; ^{1}H NMR: δ=3.53 and 3.60 (3H, each s, $-OCH_3$),[11] 3.66 (3H, s) and 3.73 (3H, s) ($-CO_2CH_3$ and $-OCH_3$), 7.43—7.7 (3H, m) and 8.08—8.3 (2H, m) ($-C_6H_5$). Found: C, 72.63; H, 7.85%. Calcd for $C_{30}H_{38}O_6$: C, 72.85; H, 7.74%. The mother liquor of recrystallization was evaporated *in vacuo*. The residue was chromatographed on silica gel (30 g), using ether–benzene (1:99) as the eluent, to give some additional **7** (80 mg after recrystallization: 13.7%).

b): A solution of **5** (5.080 g) in benzene (50 ml) was stirred at 55—60 °C for 30 min with a mixture of zinc powder (12 g) and dilute hydrochloric acid (10%:120 ml). After cooling, the benzene solution was separated. This was washed with water, dried over sodium sulfate, and evaporated *in vacuo* to give a

crude phenol. The crude phenol was immediately methylated for 14 h with methyl iodide (7.0 ml) and anhydrous potassium carbonate (25 g) in refluxing ethyl methyl ketone (70 ml). After the work-up as described in *a*), the crude product was purified by recrystallization and column chromatography to give **7** (4.174 g: 78.0%).

Methyl 11,12,14-Trimethoxy-8,11,13-abietatrien-18-oate (8). A mixture of **7** (14.482 g) and aqueous sodium hydroxide (10%: 72 ml) in ethanol (600 ml) was refluxed for 4 h. The mixture was concentrated *in vacuo*, acidified with dilute hydrochloric acid, and extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo* to give a crude phenol.

A stirred solution of the above crude phenol in ethyl methyl ketone (150 ml) was refluxed for 16 h with methyl iodide (35 ml) and anhydrous potassium carbonate (50 g). The mixture was cooled, diluted with water, and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (800 g: 70—230 mesh), using ether—benzene (1:99) as the eluent, to give **8** (9.763 g: 82.4%). This was recrystallized from methanol, mp 96—97 °C, $[\alpha]_D$+97.4°(*c* 2.84), IR:1715 cm^{-1}; ^1H NMR:δ=1.25 (3H, s, C_4-CH_3), 1.30 (3H, s, C_{10}-CH_3), 1.30 (6H, d, J=7 Hz, -CH($C\underline{H}_3$)$_2$), 3.58, 3.62, 3.70, and 3.73 (each 3H and s, -CO_2CH_3 and 3-OCH_3). Found: C, 71.00; H, 9.06%. Calcd for $C_{24}H_{36}O_5$· $\frac{1}{2}$, 71.25; H, 8.97%.

Grignard Reaction of 8 with Phenylmagnesium Bromide. A solution of **8** (2.908 g) in dry ether (13 ml) was added to a refluxing ether solution of phenylmagnesium bromide prepared from magnesium turnings (0.699 g) and bromobenzene (3.0 ml) in dry ether (10 ml). The mixture was refluxed for 1 h and the ether was removed. The viscous residue was heated at 95—105 °C for 8 h. After cooling, the mass was carefully hydrolyzed with a mixture of dilute hydrochloric acid and ice, and then extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (200 g: 70—230 mesh), using benzene as the eluent, to give a diphenylmethanol derivative **9** (2.710 g: 71.3%), $[\alpha]_D$ +89.8°(*c* 2.25), IR: 3587 cm^{-1}; ^1H NMR: δ=1.34 (6H, s, C_4-CH_3 and C_{10}-CH_3), 2.43 (1H, bs, -OH), 3.30 (3H, s) and 3.72 (6H, s) (3-OCH_3), 7.03—8.0 (10H, m, 2-C_6H_5). Found: C, 79.65; H, 8.57%. Calcd for $C_{35}H_{44}O_4$: C, 79.51; H, 8.39%.

11,12,14-Trimethoxy-19-norabieta-4(18),8,11,13-tetraene (10). A solution of **9** (166.3 mg) in dry benzene (2.0 ml) was added to a stirred suspension of lead tetraacetate (87%: 167.4 mg) and calcium carbonate (188.7 mg) in dry benzene (1.0 ml). The mixture was refluxed for 5 h, cooled, and then filtered. The filtrate was diluted with ether and the solution was washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated *in vacuo*. The residue was chromatographed on silica gel (15 g), using hexane-benzene (7:3) as the eluent, to give **10** (62.3 mg: 57.5%), $[\alpha]_D$ +176°(*c* 3.15), IR: 1644 cm^{-1}; ^1H NMR: δ=1.10 (3H, s, C_{10}-CH_3), 1.30 (6H, d, J=7 Hz, -CH($C\underline{H}_3$)$_2$), 3.60 (3H, s) and 3.76 (6H, s) (3-OCH_3), 4.53 and 4.78 (each 1H and bs, -$\underline{C}$=CH_2). Found: C, 76.60; H, 9.64%. Calcd for $C_{22}H_{32}O_3$; C, 76.70; H, 9.36%.

11,12,14-Trimethoxy-19-norabieta-4(18),8,11,13-tetraen-3α-ol (11). Selenium dioxide (96%: 0.505 g) was added to a stirred solution of **10** (3.011 g) in ethanol (56.0 ml) and water (3.2 ml). The mixture was refluxed for 4 h, cooled, and then filtered. The filtrate was evaporated *in vacuo*. The residue was chromatographed on aluminium oxide (Merck activ. II—III: 180 g), using ether-benzene (2:8 and then 4:6) as the eluent, to give **11** (1.785 g: 56.6%). This was recrystallized from hexane, mp 141.5—142.5 °C, $[\alpha]_D$ +153° (*c* 1.91); IR: 3605, 3450 cm^{-1}; ^1H NMR: δ=1.05 (3H, s, C_{10}-CH_3), 1.30 (6H, d, J=7 Hz, -CH($C\underline{H}_3$)$_2$), 1.63 (1H, s, -OH), 3.61 (3H, s) and 3.76 (6H, s) (3-OCH_3), 4.21 (1H, bs, $W_{1/2}$=5.4 Hz, $C_{3\beta}$-H), 4.62 and 4.97 (each 1H and bs, -$\underline{C}$=CH_2). Found: C, 73.26; H, 9.22%. Calcd for $C_{22}H_{32}O_4$: C, 73.30; H, 8.95%.

11,12,14-Trimethoxy-18-norabieta-8,11,13-trien-3α-ol (12). A solution of **11** (285 mg) in ethyl acetate (10.0 ml) was hydrogenated at room temperature for 3 h in an atmosphere of hydrogen using PtO_2 (60 mg). After the usual work-up, the crude product was chromatographed on silica gel (20 g), using ether-benzene (3:97) as the eluent, to give **12** (279 mg: 97.4%). This was recrystallized from acetone-hexane, mp 176—177 °C, $[\alpha]_D$ +103° (*c* 1.55); IR: 3613, 3462 cm^{-1}; ^1H NMR ($CDCl_3$): δ=1.01 (3H, d, J=7 Hz, C_4-CH_3), 1.28 (3H, s, C_{10}-CH_3), 1.33 (6H, d, J=7 Hz, -CH($C\underline{H}_3$)$_2$), 1.61 (1H, s, -OH), 3.65 (3H, s) and 3.80 (6H, s) (3-OCH_3). Found: C, 72.95; H, 9.71%. Calcd for $C_{22}H_{34}O_4$: C, 72.89; H, 9.45%.

11,12,14-Trimethoxy-18-norabieta-2,8,11,13-tetraene (13). A mixture of **12** (2.210 g), phosphoryl chloride (2.96 ml), and pyridine (28.0 ml) was refluxed for 1 h, cooled, and then poured into ice-dilute hydrochloric acid. The mixture was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (110 g), using hexane-benzene (7:3) as the eluent, to give **13** (2.100 g: 100%), $[\alpha]_D$+292° (*c* 1.74), IR: 1646 cm^{-1}; ^1H NMR: δ=1.06 (3H, d, J=7.5 Hz, C_4-CH_3), 1.26 (3H, s, C_{10}-CH_3), 1.31 (6H, d, J=7 Hz, -CH($C\underline{H}_3$)$_2$), 3.59, 3.76, and 3.79 (each 3H and s, 3-OCH_3), 5.59 (2H, bd, J=3 Hz, C_2-H and C_3-H). Found: C, 76.96; H, 9.64%. Calcd for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36%.

3α-Bromo-11,12,14-trimethoxy-18-norabieta-8,11,13-trien-2-one (15). A solution of **13** (1.076 g) in dimethyl sulfoxide (12.0 ml) containing a small quantity of water (0.17 ml) was stirred with *N*-bromosuccinimide (1.668 g) at room temperature for 2 h under a stream of nitrogen. The stirred mixture was cooled in an ice-water bath and aqueous sodium hydrogencarbonate was added. The mixture was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give the crude 3α-bromo-11,12,14-trimethoxy-18-norabieta-8,11,13-trien-2β-ol (**14**); IR: 3560, 3440 cm^{-1}; ^1H NMR: δ=1.31 (9H, d, J=7 Hz, C_4-CH_3 and -CH($C\underline{H}_3$)$_2$), 1.38 (3H, s, C_{10}-CH_3), 3.58, 3.74, and 3.83 (each 3H and s, 3-OCH_3).

The above crude bromohydrin (**14**) in acetone (12.0 ml) was oxidized with Jones reagent [2.5 M (1 M=1 mol dm^{-3}): 3.50 ml] at 0—5 °C for 5 min. The mixture was diluted with water and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (80 g), using benzene as the eluent, to give **15** (856 mg: 62.4%), $[\alpha]_D$ +153° (*c* 1.57), IR: 1706 cm^{-1}; ^1H NMR: δ=1.06 (3H, d, J=7 Hz, C_4-CH_3), 1.26 (3H, s, C_{10}-CH_3), 1.31 (6H, d, J=7 Hz, -CH($C\underline{H}_3$)$_2$), 3.62, 3.74, and 3.82 (each 3H and s, 3-OCH_3), 4.06 (1H, bs, $C_{3\beta}$-H); MS (*m/z*): 440 (M^++2), 438 (M^+).

3-Bromo-2,2-ethylenedioxy-11,12,14-trimethoxy-18-norabieta-8,11,13-triene (16). A mixture of **15** (405 mg), 1,2-ethanediol (1.14 ml), *p*-toluenesulfonic acid (200 mg), and dry benzene (20.0 ml) was refluxed for 8 h with a water separator containing 4 Å Molecular Sieves. The mixture was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (20 g), using hexane-benzene (2:8) as the eluent, to give a mixture of the C-3 epimers (**16**) (394 mg: 88.2%). MS (*m/z*): 484

(M⁺+2), 482 (M⁺).

3-Bromo-2,2-ethylenedioxy-11,12,14-trimethoxy-18-norabieta-8,11,13-trien-7-one (17). A solution of **16** (109.0 mg) in acetone (3.0 ml) was oxidized with Jones reagent (2.5 M: 0.32 ml) at 0—10 °C for 35 min and then at room temperature for 1.5 h. The mixture was diluted with water and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using hexane–benzene (1:9) as the eluent, to give the starting **16** (45.5 mg: 41.7%). Further elution with ether–benzene (5:95) gave **17** (53.5 mg: 47.7%, 81.8%[a]), IR: 1673 cm⁻¹; MS (*m/z*): 498 (M⁺+2), 496 (M⁺).

3-Bromo-2,2-ethylenedioxy-6-hydroxy-11,12,14-trimethoxy-18-norabieta-5,8,11,13-tetraen-7-one (18). A stream of oxygen was bubbled in a stirred solution of **17** (171.5 mg) and potassium *t*-butoxide (433.2 mg) in *t*-butyl alcohol (8.0 ml) at 35 °C for 35 min. The mixture was diluted with water and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using ether–benzene (1:99) as the eluent, to give **18** (48.9 mg: 27.7%). This was recrystallized from acetone–hexane, mp 173—174 °C, $[\alpha]_D$ +67.2° (*c* 0.625); IR: 3394, 1686, 1627 cm⁻¹; ¹H NMR (90 MHz): δ=1.33 (6H, d, *J*=7 Hz, -CH(C<u>H</u>₃)₂), 1.49 (3H, d, *J*=7 Hz, C_4-CH_3), 1.63 (3H, s, C_{10}-CH_3), 2.10 (1H, d, *J*=14 Hz) and 2.80 (1H, d, *J*=14 Hz) (C_1-H_2), 3.73, 3.84, and 3.88 (each 3H and s, 3-OCH_3), 3.89—4.2 (4H, m, -OCH_2-CH_2O-), 4.33 (1H, d, *J*=11 Hz, C_3-H), 6.93 (1H, s, -OH). Found: C, 56.31; H, 6.18%. Calcd for $C_{24}H_{31}O_7Br$: C, 56.36; H, 6.11%.

6-Hydroxy-11,12,14-trimethoxy-19-norabieta-3,5,8,11,13-pentaene-2,7-dione (Coleon B Tri-O-methyl Ether) (4). A solution of **18** (13.9 mg) and dilute hydrochloric acid (10%: 0.1 ml) in acetic acid (2.0 ml) was refluxed for 1 h. The solution was concentrated *in vacuo*, diluted with water, and extracted with ether. The ether extract was successively washed with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo* to give a crude bromo ketone (11.0 mg), which was used without purification in the next reaction.

A solution of the above crude bromo ketone (11.0 mg) in pyridine (2.0 ml) was refluxed for 3 h. The solution was cooled, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (5.0 g), using ether–benzene (1:99) as the eluent, to give **4** (3.8 mg: 36.2%), $[\alpha]_D$ −52.8° (*c* 0.625); IR: 3325, 1651, 1626 cm⁻¹; ¹H NMR (90 MHz): δ=1.35 (6H, d, *J*=6.5 Hz, -CH(C<u>H</u>₃)₂), 1.63 (3H, s, C_{10}-CH_3), 2.47 (3H, d, *J*=2 Hz, C_4-CH_3), 2.23 (1H, d, *J*=16 Hz) and 3.62 (1H, d, *J*=16 Hz) (C_1-H_2), 3.74, 3.89, and 3.93 (each 3H and s, 3-OCH_3), 5.98 (1H, bs, C_3-H), 7.89 (1H, s, -OH); MS (*m/z*): 386 (M⁺).

11,12,14-Trimethoxy-18-norabieta-8,11,13-trien-2-one (19). A mixture of **15** (308.6 mg) and sodium iodide (316.0 mg) in acetonitrile (5.0 ml) was stirred at room temperature for 5 min. A solution of chlorotrimethylsilane (98%: 0.27 ml) in acetonitrile (5.0 ml) was then added to the above mixture, and this was refluxed for 2 h. The mixture was cooled, diluted with water, and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate,and evaporated *in vacuo*. The residue was chromatographed on silica gel (20 g), using ether–benzene (3:97) as the eluent, to give **19** (228.7 mg: 90.0%). This was recrystallized from hexane, mp 111.5—112.5 °C, $[\alpha]_D$ +111° (*c* 0.820) (lit,[b] mp 111.5—113°C, $[\alpha]_D$ +98°), IR: 1697 cm⁻¹; ¹H NMR: δ=1.07 (3H, d, *J*=7 Hz, C_4-CH_3), 1.29 (3H, s, C_{10}-CH_3), 1.30 (6H, d, *J*=7 Hz, -CH(C<u>H</u>₃)₂), 3.60, 3.74, and 3.81 (each 3H and s, 3-OCH_3). Found: C, 73.05; H, 8.94%. Calcd for $C_{22}H_{32}O_4$: C, 73.30; H, 8.95%.

2,2-Ethylenedioxy-11,12,14-trimethoxy-18-norabieta-8,11,13-triene (20). A mixture of **19** (55.2 mg), 1,2-ethanediol (0.2 ml), and *p*-toluenesulfonic acid (60 mg) in dry benzene (10.0 ml) was refluxed for 16 h with a water separator containing 4 Å Molecular Sieves. After the work-up as described for the preparation of **16**, the crude product was chromatographed on silica gel (10 g), using ether–benzene (1:99) as the eluent, to give **20** (57.6 mg: 93.0%). This was recrystallized from hexane, mp 123—125.5 °C, $[\alpha]_D$ +70.6° (*c* 1.105); ¹H NMR: δ=1.11 (3H, d, *J*=7 Hz, C_4-CH_3), 1.30 (6H, d, *J*=7 Hz, -CH(C<u>H</u>₃)₂), 1.37 (3H, s, C_{10}-CH_3), 3.58, 3.75, and 3.78 (each 3H and s, 3-OCH_3), 3.75—4.0 (4H, m, overlap,-OCH_2-CH_2O-). Found: C, 71.05; H, 8.78%. Calcd for $C_{24}H_{36}O_5$: C, 71.25; H, 8.97%.

2,2-Ethylenedioxy-11,12-14-trimethoxy-18-norabieta-8,11,13-trien-7-one (21). Chromium trioxide (700 mg) was added to a stirred solution of **20** (122.5 mg) and pyridine (1.13 ml) in dichloromethane (7.0 ml). The mixture was stirred at room temperature for 23 h, diluted with water, and extracted with ether. The ether extract was washed successively with aqueous sodium hydroxide, water, dilute hydrochloric acid, and brine. The dried solution was evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using ether–benzene (5:95) as the eluent, to give **21** (52.5 mg: 41.4%). This was recrystallized from acetone–hexane, mp 151.5—152.5 °C, $[\alpha]_D$ +145° (*c* 0.415), IR: 1670 cm⁻¹; ¹H NMR: δ=1.28 (6H, d, *J*=7 Hz, -CH(C<u>H</u>₃)₂), 1.44 (3H, s, C_{10}-CH_3), 3.66 (3H, s),and 3.80 (6H, s) (3-OCH_3). Found: C, 68.57; H, 8.43%. Calcd for $C_{24}H_{34}O_6$: C, 68.87; H, 8.19%.

2,2-Ethylenedioxy-6-hydroxy-11,12,14-trimethoxy-18-norabieta-5,8,11,13-tetraen-7-one (22). A stream of oxygen was bubbled in a stirred solution of **21** (22.2 mg) and potassium *t*-butoxide (66.6 mg) in *t*-butyl alcohol (3.5 ml) at 35—40 °C for 100 min. After the work-up as described for the preparation of **18**, the crude product was chromatographed on silica gel (10 g), using ether–benzene (5:95) as the eluent, to give **22** (18.4 mg: 86.9%). This was recrystallized from acetone–hexane, mp 216—217 °C, $[\alpha]_D$ +40.0°(*c* 0.475); IR: 3394, 1684, 1625 cm⁻¹; ¹H NMR (90 MHz): δ=1.32, 1.34, and 1.36 (each 3H, d, and *J*=7 Hz, C_4-CH_3 and -CH(C<u>H</u>₃)₂), 1.65 (3H, s, C_{10}-CH_3), 1.81 (1H, d, *J*=14 Hz) and 2.90 (1H, d, *J*=14 Hz) (C_1-H_2), 3.72, 3.86, and 3.88 (each 3H and s, 3-OCH_3), 6.92 (1H, s, -OH); MS (*m/z*): 432 (M⁺).

6-Hydroxy-11,12,14-trimethoxy-18-norabieta-5,8,11,13-tetraene-2,7-dione (23). A solution of **22** (33.5 mg) and dilute hydrochloric acid (10%: 0.75 ml) in tetrahydrofuran (3.0 ml) was stirred at room temperature for 20 h. The solution was diluted with ether. The ether solution was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using ether–benzene (5:95) as the eluent, to give **23** (29.1 mg: 96.7%). This was recrystallized from acetone–hexane, mp 169—170 °C, $[\alpha]_D$ +61.5° (*c* 0.390); IR: 3397, 1705, 1628 cm⁻¹; ¹H NMR (90 MHz): δ=1.34 (6H, d, *J*=7 Hz, -CH(C<u>H</u>₃)₂), 1.44 (3H, d, *J*=7 Hz, C_4-CH_3), 1.72 (3H, s, C_{10}-CH_3), 2.20 (1H, d, *J*=16 Hz) and 3.57 (1H, d, *J*=16 Hz) (C_1-H_2), 3.72, 3.86, and 3.90 (each 3H and s, 3-OCH_3), 7.06 (1H, s, -OH); MS (*m/z*): 388 (M⁺).

Dehydrogenation of 23. A stirred mixture of **23** (10.0 mg), 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (98%: 6.5 mg), and acetic acid (0.15 ml) in dry benzene (3.0 ml) was refluxed for 37 h under a stream of nitrogen. The mixture was cooled and then filtered. The filtrate was washed successively with sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue

was chromatographed on silica gel (10 g), using ether–benzene (5:95) as the eluent, to give the starting **23** (2.2 mg: 22%). Further elution gave a mixture (5.3 mg) of **4** and **23**. The ^{1}H NMR spectrum of the mixture indicated that it was composed of approximately 3.5 mg (35%, 59%[8]) of **4** and 1.8 mg (18%) of **23**.

The above mixture of **4** and **23** was acetylated at 80—85 °C for 1 h with acetic anhydride (0.2 ml) in pyridine (0.4 ml). After the usual work-up, the crude product was chromatographed on silica gel (10 g), using ether–benzene (1:9) as the eluent, to give 6-acetoxy-11,12,14-trimethoxy-19-norabieta-3,5,8,11,13-pentaene-2,7-dione (**24**) (3.3 mg). IR: 1765, 1655 cm^{-1}; ^{1}H NMR (90 MHz): δ=1.32 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 1.68 (3H, s, C_{10}–CH_3), 2.31 (3H, d, J=1.8 Hz, C_4–CH_3), 2.32 (3H, s, $-OCOCH_3$), 3.68, 3.84, and 3.92 (each 3H and s, 3-OCH_3), 6.06 (1H, bs, C_3-H); MS (m/z): 428 (M^+).

Hydrolysis of **24** with dilute hydrochloric acid in refluxing ethanol afforded **4**.

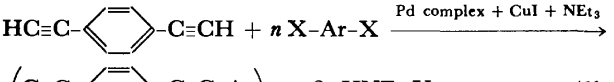
Palladium Catalyzed C-C Coupling for Synthesis of π-Conjugated Polymers Composed of Arylene and Ethynylene Units

Kenichi SANECHIKA, Takakazu YAMAMOTO,* and Akio YAMAMOTO
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227
(Received October 11, 1983)

Palladium compounds such as $Pd(PPh_3)_4$ and $Pd(OAc)_2$ catalyze polycondensation between dihalo aromatic compounds, X-Ar-X (Ar=*p*-phenylene, 2,5-thiophenediyl, 9,10-anthracenediyl, 2,6-pyridinediyl, *p*-benzenedicarbonyl, *p*-xylene-α,α′-diyl), and acetylenic compounds (*p*-$C_6H_4(C{\equiv}CH)_2$ or *p*-$C_6H_4(C{\equiv}CMgBr)_2$). The polymers obtained have high thermal stabilities and most of them show fluorescence. One of the polymers is converted into semiconductors by doping with electron acceptors.

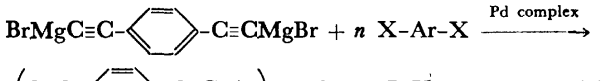
Preparation of π-conjugated polymers and studying their electric conducting properties are the subject of recent interest.[1-5] We have reported preparation of several π-conjugated, thermostable polymers such as poly(thienylene),[6] poly(phenylene),[7] and poly(1,1′-ferrocenediyl),[8] which are converted into semiconductors on doping with electron acceptors. We now report two new methods for preparation of π-conjugated polymers composed of arylene and ethynylene units.

Method I.



$$n\,HC{\equiv}C\text{-}Ar\text{-}C{\equiv}CH + n\,X\text{-}Ar\text{-}X \xrightarrow{\text{Pd complex + CuI + NEt}_3} \{C{\equiv}C\text{-}Ar\text{-}C{\equiv}C\text{-}Ar\}_n + 2n\,HNEt_3X \quad (1)$$

Method II.



$$n\,BrMgC{\equiv}C\text{-}Ar\text{-}C{\equiv}CMgBr + n\,X\text{-}Ar\text{-}X \xrightarrow{\text{Pd complex}} \{C{\equiv}C\text{-}Ar\text{-}C{\equiv}C\text{-}Ar\}_n + 2n\,MgBrX \quad (2)$$

Both the methods utilize Pd-catalyzed C-C coupling reactions. The basic reaction for Method I,

$$RC{\equiv}CH + R'X + Et_2NH \xrightarrow{\text{Pd complex}} RC{\equiv}CR' + Et_2NH_2X \quad (3)$$

was developed by Hagihara and his coworkers.[9] They utilized a similar reaction to synthesize Pt-, Pd-, or Ni-containing polyynes.[10] The basic reaction for Method II,

$$RhC{\equiv}CMgBr + PhI \xrightarrow{\text{Pd complex}} PhC{\equiv}CPh + MgBrI \quad (4)$$

was developed by Sekiya and Ishikawa.[11] Polymers containing C≡C bonds in their main chains have been recently prepared by several research groups.[10,12,13] A part of results given in this paper was reported elsewhere.[14]

Results and Discussion

We first examined applicability of the Pd-catalyzed coupling reactions (3) and (4), which have been mainly developed for monohaloaromatic compounds, to condensation of two acetylene units with dihaloaromatic compounds (Eqs. 5 and 6).

$$X\text{-}Ar\text{-}X + 2PhC{\equiv}CH \xrightarrow{\text{Pd}} PhC{\equiv}C\text{-}Ar\text{-}C{\equiv}CPh \quad (5)$$

$$X\text{-}Ar\text{-}X + 2PhC{\equiv}CMgBr \xrightarrow{\text{Pd}} PhC{\equiv}C\text{-}Ar\text{-}C{\equiv}CPh \quad (6)$$

As shown in Table 1, $Pd(PPh_3)_4$ and $Pd(OAc)_2$ serve as good catalysts for the coupling reactions between dihaloaromatic compounds and the acetylenic compounds when used with an appropriate co-catalyst and/or base, whereas $PdCl_2$, $FeCl_2$, $FeCl_3$, $NiCl_2$, and $NiCl_2$(bpy) were not effective for the C-C coupling reaction. Use of pyridine, instead of NEt_3, did not give the product, either. The products were characterized by elemental analysis and IR spectroscopy. The products, except for 1,4-bis(phenylethynylcarbonyl)benzene obtained in Nos. 2 and 3, fluoresce by visible light strongly when irradiated by UV light. Fluorescence of 9,10-bis(phenylethynyl)anthracene (product in No. 1) pre-

a) Excess NEt_3 was added. In toluene under reflux. Amount of Pd catalyst = 0.01 mol per mol of X-Ar-X. b) $C_5H_3NBr_2$ = 2,6-Dibromopyridine. $C_6H_4(CH_2Cl)_2$ = p-Bis(chloromethyl)benzene. c) Yield based on the weight of carbon in the polymer (calculated from the weight and carbon content of polymer). Yield after removing toluene extractable fraction (see Experimental). d) In THF under reflux. Amount of Pd catalyst = 0.01 per mol of X-Ar-X.

pared through an independent reaction route have been extensively studied.[15] Recently Marvel and his coworkers reported preparation of 1,4-bis(phenylethynyl)benzene by a similar Pd-catalyzed coupling reaction.[16] 1,4-Bis(phenylethynylcarbonyl)-benzene and 2,5-bis(phenylethynyl)thiophene prepared in Nos. 2 (or 3) and 8, respectively, are new compounds.

Based on the results shown in Table 1, we have carried out the polycondensation expressed by Eqs. 1 and 2. Table 2 shows the results. The repeating units of the new polymers thus obtained are shown below.

	Color	Fluorescence
 (1)	Yellow	Bluish purple
 (2)	Yellow	Bluish purple
 (3)	Red	Green
 (4)	Light yellow	Purple
 (5)	White	None
 (6)	Yellow	Purple

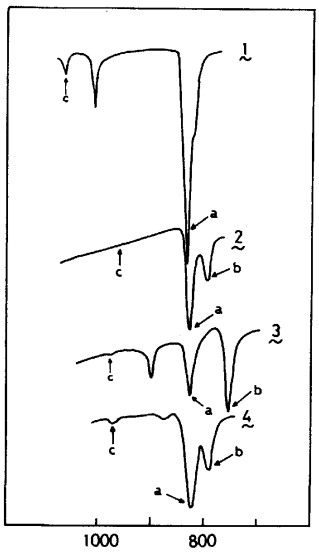

Fig. 1. IR spectra (in the range of 1100—700 cm^{-1}) of **1**—**4** obtained in Runs 1, 3, 4, and 5 (Table 2). Arrows a, b, and c show δ(C-H) of p-phenylene unit, δ(C-H) of other arylene unit, and position of ν(C-Br) of the terminal -Ar-Br group, respectively.

As shown in Table 2, yields of polymers attained by using Method I and Method II are comparable. Since Method II requires precaution to remove water from the reaction system, we consider that Method I is suprior to Method II in preparing the polymers.

The polymers, except for **5**, show strong fluorescence when irradiated by UV light. The polymers have low solubility in solvents. TGA curves of **1**, **2**, and **3** indicate that these polymers have high thermal stabilities. Degradation of these polymers starts at about 380 °C under N_2, and the TGA curves show residual weight of 70—85% at 800 °C. IR spectra of **1**—**6** are consistent with the structures described above, showing ν(C≡C) bands at about 2200 cm^{-1}, δ(C-H) of the phenylene unit at 830—835 cm^{-1}, and δ (C-H) of other arylene units, Ar, (*e.g.*, *cf.* Fig. 1). The IR spectrum of **5** shows a strong ν(C=O) band at 1630 cm^{-1}. IR spectra of **1**, **4**, and **6** show weak ν(C-halogen) bands of terminal groups of the polymers but ν(C-H) of terminal -C≡CH group is not observable in the IR spectra.[17] Since the ν(C-H) absorption band of -C≡CH generally has an absorption coefficient comparable to that of the ν(C-halogen) absorption band, the IR data indicate that most of terminal groups of the polymers are consisted of the halogenated group, -Ar-X. The low solubility of the polymers prevented measuring molecular weights of

the polymers by usual methods. However, if we assume that the both polymer ends have halogen, the molecular weights of the polymers are calculated from their halogen contents. The molecular weights of **1**, **2**, **3**, and **4** prepared by Method I thus calculated are 1400(Run 1)—1690(Run 2), 4000, 1760, 1550, respectively. Polymers **1** and **2** prepared by Method II have comparable molecular weights to those of **1** and **2** prepared by Method I. Deposition of the polymers from the polymerization solvent seems to prevent further elongation of the polymer chain by the polycondensation. The molecular weight of some polymers can be roughly estimated also by comparing the strength of ν(C–halogen) absorption band with that of δ(C–H) of the phenylene and arylene unit in IR spectra of the polymers. The molecular weights thus estimated roughly agree with the molecular weights calculated from the halogen content. Powder X-ray diffraction patterns of the polymers show sharp diffraction bands, indicating high crystallinity of the polymers.

Polymers **1**—**6** are insulators having electric conductivity (σ) of below 10^{-12} S cm^{-1}. Polymers **1**, **2**, and **4** showed no apparent interaction with I_2, whereas **3** and **5** showed interaction with I_2 (gas). Polymer **3** showed electric conductivity of $\sigma=4\times10^{-5}$ S cm^{-1} after exposure to vapor of I_2 for 18 h at room temperature, but the iodine adduct of **5** (iodine: 24 wt% per **5**) remained as an insulator. Polymer **3** showed certain electric conductivity ($\sigma=6.6\times10^{-8}$ S cm^{-1} at 247 K) after exposure to vapor of AsF_5, whereas it did not interact with tetracyanoethylene and tetracyanoquinodimethane as proved by no change in IR spectrum after dipping **3** in solutions of these electron acceptors.

Experimental

Materials, Analysis, and Manipulation. $Pd(PPh_3)_4$ was prepared according to literature.[18] $Pd(OAc)_2$, CuI, PPh_3, NEt_3, and crystalline dihaloaromatic compounds were used as purchased from Tokyo Kasei Kogyo Co., Ltd. or Kanto Chemical Co., Inc. 2,5-Dibromothiophene was recrystallized from hexane at 78 °C. PhC≡CMgBr was prepared *in situ* by a reaction of PhC≡CH with EtMgBr in a 1:1 ratio. 1,4-Diethynylbenzene was prepared according to literature,[19] and purified by sublimation: mp 96 °C (lit, 96.5 °C). Solvents were dried over CaH_2 or Na, distilled under N_2, and stored under N_2. Microanalysis of C, H, and N was performed with a Yanagimoto CHN Autocorder MT-2, and that of halogen with a Yazawa halogen analyzer. IR spectra were recorded on a Hitachi 295 spectrometer. Thermogravimetric analysis was performed with a Shimadzu thermoanalyzer DT-30. Powder X-ray diffraction patterns were obtained with Phillips PW-1051. Electric conductivity was measured wth a Takeda Riken TR-8651 electrometer. The powdery polymer–electron acceptor adduct was molded into a pellet (diameter=1.3 cm) by pressing it at 600 kg/cm^2. From the pellet a bar was obtained by cutting off other parts of the pellet and the electric conductivity was measured with the bar using the four-point method. Reactions listed in Tables 1 and 2 were carried out under nitrogen or argon by using Schlenk type tubes.

Coupling Reactions between X-R-X and PhC≡CH or PhC≡CMgBr (cf. Table 1).

No. 1: $Pd(PPh_3)_4$ (36 mg, 0.031 mmol) and CuI (12 mg, 0.062 mmol) were added to a mixture of 9,10-dibromoanthracene (1.06 g, 3.15 mmol), PhC≡CH (0.645 g, 6.32 mmol), and NEt_3 (1.6 cm^3, 15 mmol). The reaction mixture was stirred for 3 h under reflux. Then, it was poured into an excess amount of methanol after cooling to room temperature. The light precipitate was collected by filtration and recrystallized to yield 0.72 g (1.9 mmol) of known 9,10-bis(phenylethynyl)anthracene.[15] Condensation of the methanol solution gave another crop (9.59 g, 1.3 mmol) of 9,10-bis(phenylethynyl)anthracene. Found: C, 95.4; H, 4.6%. Calcd for $C_{30}H_{18}$: C, 95.2; H, 4.8%.

Nos. 2—4 were carried out analogously. *p*-$(PhC{\equiv}CCO)_2C_6H_4$ was characterized by IR and elemental analysis. Found: C, 86.2; H, 4.2%. Calcd for $C_{24}H_{14}O_2$: C, 86.2; H, 4.2; mp 185 °C. IR(KBr): 2200s, 1640s, 1320m, 1205m, 1030m, 750s, 695m, 680m. 1,4-bis(phenylethynyl)benzene was characterized by IR and mp, 182 °C (lit,[19] 180—183 °C).

No. 5: A THF (11 cm^3) solution of C_2H_5MgBr (13.6 mmol) was added to a THF solution of PhC≡CH (1.39 g, 13.6 mmol) at room temperature, and the mixture was stirred for 2 h. To this mixture were added 0.80 g (3.4 mmol) of *p*-dibromobenzene, 10 mg of $Pd(OAc)_2$ and 34 mg of PPh_3. After the reaction mixture was stirred for 2 h under reflux, it was cooled to room temperature. Excess of dil. aqueous HCl solution was added to the reaction mixture. Extraction of the product with benzene, drying the benzene solution with $MgSO_4$, purification by column chromatography (Al_2O_3, benzene), and evaporation of benzene gave crystals of 1,4-bis(phenylethynyl)benzene: yield=0.87 g (92%), after recrystallization from toluene. Reactions shown by Nos. 6 and 7 were carried out analogously.

No. 8: A THF (14 cm^3) solution of C_2H_5MgBr (24.2 mmol) was added to 2.48 g (24.2 mmol) of phenylacetylene. After stirring for 1.5 h at room temperature, 2,5-dibromothiophene (2.93 g, 12 mmol), $Pd(OAc)_2$ (39 mg, 0.12 mmol), and PPh_3 (100 mg, 0.24 mmol) were added to the reaction mixture. After stirring the reaction mixture for 2 h under reflux, it was cooled to room temperature. An excess amount of dil aqueous HCl solution was added to the reaction mixture. Extraction of the product with benzene, drying the benzene solution with $MgSO_4$, purification by the column chromatography, and recrystallization from methanol gave 2.61 g (76%) of brown 2,5-bis(phenylethynyl)thiophene, which was characterized by IR and elemental analysis; mp 85 °C. Found, 83.8; H, 4.3; S, 10.7%. Calcd. for $C_{20}H_{12}S$: C, 84.5; H, 4.3; S, 11.3%. IR(KBr disk): 1590m, 1480m, 1440m, 800s, 750s, and 680s.

Polycondensation (cf. Table 2). Run 1: $Pd(PPh_3)_4$ (27 mg, 0.023 mmol) and CuI (8 mg, 0.04 mmol) were added to a mixture of *p*-diethynylbenzene (300 mg, 2.38 mmol), *p*-dibromobenzene (562 mg, 2.38 mmol), and NEt_3 (2 cm^3) in toluene (39 cm^3). After stirring for 2 h under reflux, the reaction mixture was poured into excess methyl alcohol. The precipitate obtained was separated by filtration, washed repeatedly with methyl alcohol, and dried under vacuum to obtain 510 mg of **1**. After removing a toluene-soluble fraction of **1** by extraction with hot toluene using a Soxhlet extractor, the yellow solid was dried under vacuum to yield 0.43 g of **1**. Found: C, 83.5; H, 3.7; Br, 11.4%. From the toluene extract we obtained 80 mg of low molecular weight **1**. Polymerization in Run 2 was carried out analogously.

Run 3: $Pd(PPh_3)_4$ (45 mg, 0.039 mmol) and CuI (15 mg, 0.080 mmol) were added to a mixture of *p*-diethynylbenzene (514 mg, 4.07 mmol), 2,5-dibromothiophene (985 mg, 4.07 mmol), and NEt_3 (3 cm^3) in toluene (50 cm^3). After stirring for 2 h under reflux, the polymer obtained was treated as in the case of Run 1 to obtain 810 mg of crude **2**, from which 710 mg of toluene-unextractable **2** was obtained. Found: C, 80.2; H, 2.9; Br, 4.0%.

Runs 4—6 were carried out analogously. Analytical data of **3**, **4**, and **5** are as follows. **3**: Found: C, 87.3; H, 3.8; Br, 9.1%. **4**: C, 80.7; H, 3.2; N, 6.1; Br, 10.3%. **5**:C, 77.4; H, 3.7; Br, 4.4%.

Run 7: When a THF (9.2 cm^3) solution of C_2H_5MgBr

(15.6 mmol) was added into a Schlenk tube containing 986 mg (7.82 mmol) of 1,4-diethynylbenzene at room temperature, vigorous evolution of ethane was observed. After addition of 7 cm^3 of THF and stirring the reaction mixture for 5 h at room temperature, 2.58 g (7.82 mmol) of *p*-diiodobenzene in 5 cm^3 of THF, 18 mg (0.080 mmol) of $Pd(OAc)_2$, and 42 mg (9.16 mmol) of PPh_3 were added. This reaction mixture was stirred for 2 h under reflux. After cooling to room temperature, the reaction mixture was poured into an HCl–methyl alcohol mixture (150 cm^3). This light yellow precipitate was collected by filtration, washed with methyl alcohol, and dried under vacuum to obtain 920 mg of crude **1**. Removing a toluene-soluble fraction (by Soxhlet technique) gave 800 mg of **1**. Found: C, 80.4; H, 3.0; I, 15.7%.

Runs 8 and 9 were carried out analogously. **6**: C, 90.9; H, 4.7; Br, 1.2%.

ESR in Mercury(II) Iodide Thiocyanate

Kunio TAKEI,* Kazuo SUGIHARA, Hitoshi HAGIWARA, and Seisuke NAKAMURA
Department of Industrial Chemistry, Faculty of Engineering, Miyazaki University, Kirishima, Miyazaki 880
(Received August 2, 1982)

Powder of mercury(II) iodide thiocyanate (HgISCN) gives a weak electron spin resonance (ESR) signal at $g=2.003$ in the dark. When the powder is irradiated, the ESR-signal intensity increases during the exposure. When the light is turned off, the intensity decreases. The ESR-signal may be due to electrons trapped by lattice defects.

Mercury(II) iodide thiocyanate (HgISCN), was prepared for the first time by Rao and Watson[1] in order to study the photochromism of this compound, but its crystal structure was not investigated. In recent years,[2,3] though, the photochromic process of HgISCN has been studied in our laboratory by the use of the radioisotopic tracer technique. When powder of labeled HgISCN with radioactive tracers is exposed to sunlight, it immediately turns from orange yellow to black, and ^{203}Hg, ^{35}S and ^{131}I atoms diffuse toward the crystal surface and escape into atmosphere. On the other hand, the ^{14}C atom does not move. The black color of this powder is somewhat bleached by keeping it in the dark at room temperature for several months. These results suggest that the electrons belonging to $(SCN)^-$ or I^- may be optically excited to the conduction band and may be trapped by the lattice defects or impurity levels. These trapped electrons must show an ESR-signal. It was found that HgISCN is, optically, a very sensitive compound, showing the ESR-signal during irradiation with light, and thermally it is an unstable compound, decomposing at 165 °C. HgISCN seems to be a molecular compound between mercury(II) iodide and mercury(II) thiocyanate. The present paper will present the results of our ESR experiments.

Experimental

Materials. The powder of mercury(II) iodide thiocyanate was prepared as reported in a previous paper.[2,3] The chemical analysis with an atomic-absorption apparatus exhibited this Hg content for HgISCN: calcd 52.02%, obsd 53%, while the chemical analysis by a fused method[4] exhibited this S content for HgISCN: calcd 8.32%, obsd 8.0%. This powder shows photochromic behavior.

ESR. ESR measurements were made in the dark by the use of ESR equipment [JEOL, X-band] at a field of 3250 ± 250 G (1 G=10^{-4} T). Then, the HgISCN powder was irradiated at room temperature with a tungsten lamp of 150 W through the window of the cavity of the ESR equipment for the appropriate length of times. The ESR-signal intensity of the powder rapidly grew and then gradually approached saturation after 30 min irradiation. When the light was switched off after saturation has been reached, the ESR-signal decayed rapidly. The excitation intensity in front of the window of the cavity was measured as 7000 lx with a Toshiba luxmeter. The rise-and-decay ESR experiments were repeated at various temperatures (*cf.* Fig. 2). The temperature was controlled at about 60, 25, −10, and −50 °C by flowing through nitrogen gas, warmed with a heater or cooled with liquid nitrogen, into the cavity: it was measured by means of a copper-constantan thermocouple.

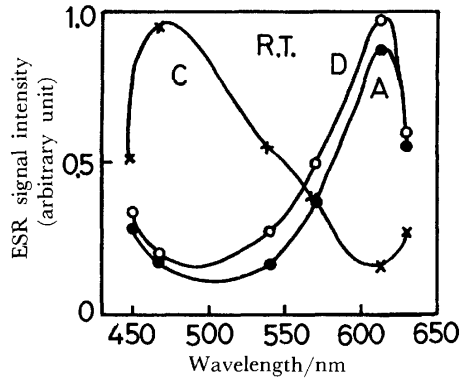

Fig. 1. Excitation spectra of the ESR signal intensity for A, C, and D. A: powder of HgISCN, C: one of the thermal decomposition products of $Hg(SCN)_2$, D: powder of $Hg(SCN)_2$ which was heated up to 155—158 °C.

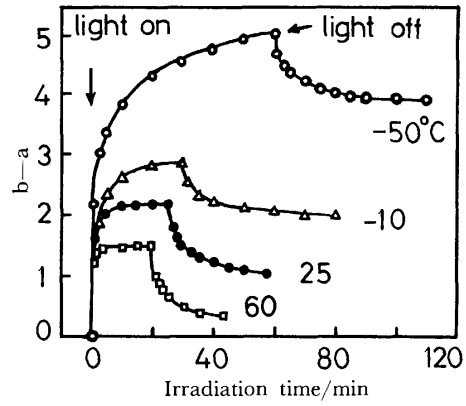

Fig. 2. The relationship between b—a and irradiation time at various temperatures. a is the ESR signal intensity of a nonirradiated HgISCN powder normalized to that of MnO. b is the ESR signal intensity of an irradiated HgISCN powder normalized to that of MnO.

Excitation Spectra of ESR-signal. Monochromatic light was obtained by the use of six filters made by the Shimadzu Co. The radiation from the tungsten lamp was selected with filters and was focussed on a capillary glass tube containing HgISCN powder (*cf.* Fig. 1).

Results and Discussion

ESR-signal of Nonirradiated Powder of HgISCN. A weak signal for the nonirradiated orange yellow powder of HgISCN, which is conveniently denoted by A, was observed at $g=2.003$. The observed ESR-signal

of A is ascribed not to an impurity, but to a defect in A. This can be explained as follows. A was formed when a mixture of mercury(II) iodide and mercury(II) thiocyanate was heated at 162°C. The mixture heated only to 150°C gave no ESR-signal at all. When heated up to 155—158°C, though, the mixture begins to show the ESR-signal (g=2.003). This signal may be due to mercury(II) thiocyanate, because mercury(II) thiocyanate heated to 155—158°C, denoted by D, gives a weak ESR-signal at g=2.003, while mercury(II) iodide heated to the same temperature shows no ESR-signal. Mercury(II) thiocyanate decomposes at 165°C into a black powder, denoted by B, and into a yellow powder, denoted by C. B and C gave weak signals at g=2.003. The signal intensity of B was not sensitive to light, but that of C was sensitive to light. B was removed from A by washing with concentrated hydrochloric acid containing pottasium chlorate. The X-ray diffraction pattern of A was different from those of B, C, and D. The patterns of B and D were similar to those of cubic mercury(II) sulfide and of mercury(I) thiocyanate respectively, while the pattern of C showed that C is a nearly amorphous material. In order to make clear the origin of the ESR-signal of A, the excitation spectra of the ESR-signal was measured. The spectra of A and D were similar to each other, while the spectrum of C was entirely different from that of A or D (*cf.* Fig. 1). Consequently, when the mixture is heated to 155—158°C, the mixture may begin to form a structure of A, although its fraction may be small. In order to form A, the mixture must be heated to 162°C. It is not clear, however, whether the observed ESR-signal of A is attributed to the lattice defects which are formed in A in the 155—162°C range or to the signal of D, which exists in A as an impurity. This problem was solved by the following experiment. If A contains a small quantity of D as an impurity, the ESR-signal intensity of a mixture of A and D must become stronger than that of A when a small quantity of D is added to A. Various quantities of D were added to A, and the ESR-signals of these mixtures were measured at room temperature. Quantities of mixtures in the quartz-glass capillary tube were kept constant in order to keep the quality factor in the cavity constant. The experimental results show that the ESR-signal intensities of A containing D at 4.17, 8.30, or 12.5 wt% of D are smaller than the intensity of alone A and that they gradually decrease according to the increase in the content of D (*cf.* Fig. 3). This fact shows that the signal of A is attributed not to the signal of D in A as an impurity, but to the lattice defects in A.

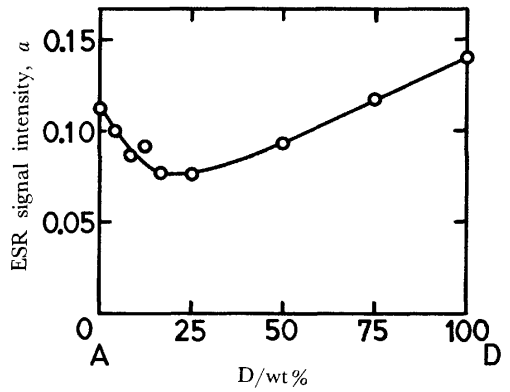

Fig. 3. The relationship between the ESR signal intensity in the dark of A containing D at various weight percents and the weight percent of D. The ESR signal intensities are normalized to that of MnO.

ESR-signal of Irradiated HgISCN. A quartz-glass capillary tube containing MnO powder was put into the cavity. The ESR of MnO was then measured as a standard of the ESR-signal at the same time as the ESR of A put into another quartz-glass capillary tube was measured. When A was irradiated with a tungsten lamp, MnO powder was irradiated at the same time. The ESR-signal intensity of MnO during the exposure did not change from that of MnO in the dark. When a is the signal intensity of A in the dark normalized to that of MnO, and b is the signal intensity of an irradiated A normalized to that of MnO, b—a means the increase in the signal intensity during exposure to the light. Figure 2 shows the b—a relationships and the irradiation times at various temperatures. The rising curves of the ESR-signal intensity during the irradiation show the speed at which the traps are filled with excited electrons. The saturation value of b—a was reached after about 10 min under the irradiation at 60°C, but the saturation was not reached even after 60 min under the irradiation at −50°C. The decay curves of the ESR-signal intensity show the detrapping speed of electrons from the traps. When the light was switched off at the saturation of b—a at 60°C, the value of b—a decreased rapidly; it approached a zero value after 20 min. When the light was switched off after saturation had been reached at −50°C, the value of b—a decreased slowly, but it was still somewhat big even after 60 min. It takes a long time at −50°C before the value of b—a reaches zero.

Under constant excitation with light, the rising-and-decay curves of the ESR-signal intensity may be discussed by the use of a simple electron-trapping model in terms of a simple first-order reaction equation. If F is the number of photons absorbed per unit of volume per unit of time, the number of optically excited electrons may be proportional to F. It is assumed that the θ fraction of mF, where m is the proportional constant, is trapped by trap and that the $(1-\theta)$ fraction of mF is consumed by recombination or fluorescence. If p is the probability of an electron escaping from a trap with a depth of E and a cross-section for the capture of an electron, S, at a certain temperature T, the filling speed of an electron into a trap may be given by $dn/dt=\theta mF-np$, where n is number of trapped electrons and $p=Nv S\cdot\exp(-E/kT)$.[5] N is the effective density of states in the conduction band, v is the thermal velocity of an electron, and k is the Boltzmann constant. At saturation with a value of b—a, $dn/dt=0$ and $\theta mF=n_0 p$, where n_0 is the value of n at the saturation. Then, $dn/dt=p(n_0-n)$. The solution of this equation is:

$$n = n_0(1-e^{-pt}). \quad (1)$$

The rate of change of the number of trapped electrons during the decay is $-dn/dt=np$. The solution of this equation is:

$$n = n_0 e^{-pt}. \quad (2)$$

The rising-and-decay curves of the ESR-signal intensity are shown by Eqs. 1 and 2 respectively. These equations contain the term of $1/e^{E/kT}$. At some time t, a value of $1/e^{pt}$ at a higher temperature may become smaller than those at a lower temperature if N, v, S, and E are independent of the temperature in the range of 60—−50°C. Therefore, it is expected that, at 60°C, n may rapidly increase and n_0 may be reached rapidly after irradiation. At −50°C, n may slowly increase, and n_0 may be reached slowly after irradiation. Similarly, the decay rate may be effected to be big at 60°C and small at −50°C. The value of n_0 at −50°C in Fig.2 is bigger than that at 60°C. This comes from the fact that the lower the temperature, the greater the number of the trapped electrons. The results in Fig.2 nearly satisfy these expectations. The actual filling and detrapping speeds may be a mean of the individual speeds for the individual traps with a given depth E, because there are a number of traps with various depths.

Excitation Spectra of ESR-signal. The excitation spectra of the ESR-signal of HgISCN at room temperature are shown in Fig. 1. The most sensitive wavelength of the ESR-signal is located at about 620 nm.

The authors wish to thank Dr. S. Fujiwara for his many helpful discussions and suggestions during this work.

An Electrochemical Study on Anion Doping-Undoping Process of Polyacetylene by Means of FFT Impedance Measurement

Tetsuya OSAKA* and Takashi KITAI

Department of Applied Chemistry, School of Science and Engineering, Waseda University, Okubo, Shinjuku-ku, Tokyo 160

(Received June 27, 1983)

An electrochemical anion doping-undoping process of *cis*-polyacetylene, $(CH)_x$, was investigated in 1 mol dm^{-3} $LiClO_4$ or $LiBF_4$ in propylene carbonate by the FFT impedance measurement. This could be applied to the system with time-variation because of its high speed measuring duration. The doping-undoping process of the anion was represented by the Randles-type equivalent circuit, considering the corrective term concerned with surface roughness. The impedance behavior of the doping-undoping process was pursued by the variation of resistive component, *Rr*. The value of *Rr* was mainly reflected by the dopant concentration at the surface. The variation of *Rr* indicated that rapid or strong-drive doping produces non-uniformity of dopant distribution in the film and high dopant concentration at the surface.

A conduction polymer has recently been developed as a new electrode material for high-density batteries. Polyacetylene, $(CH)_x$, is very suitable as a new electrode material, since its conductivity can be varied over twelve orders of magnitude depending on the dopant concentration[1] and it can be easily synthesized. Polyacetylene can be electrochemically doped as either n-type or p-type to induce semiconducting and ultimately metallic conditions with a variety of species.[2,3] Accordingly, some attempts have been made to use polyacetylene as an electrode material in lightweight rechargeable storage batteries.[4,5] Studies of the electrochemical characteristics of polyacetylene, however, are recent and so far there have been only a few reports on the analysis of the electrochemical doping or undoping process of polyacetylene.[6] In this paper, we report the electrochemical doping-undoping process of polyacetylene as a cathode by means of electrochemical measurements, especially the FFT impedance method.[7] The FFT impedance method has an advantage of rapid measurement for the frequency-dispersion within a very short time-duration. Phenomena with time-variation such as the doping-undoping process may be analyzed easily by this method.

Experimental

The *cis*-polyacetylene films with 0.3 mm thickness were prepared by the Shirakawa method.[8] The working electrode consisted of a single circular film of 8 mmϕ of the *cis*-$(CH)_x$ (weight density 0.44 g cm^{-3}), attached to a platinum plate as a current collector. A circular platinum or lithium mounted on platinum counter electrode was placed opposite to the *cis*-$(CH)_x$ working electrode in a Teflon or glass cell. A Li/Li^+, reference electrode was set at the mid point between the working and counter electrodes, and the potential was referred to the Li/Li^+ in the same solution. The electrolyte solution was 1.0 mol dm^{-3} $LiClO_4$ or 1.0 mol dm^{-3} $LiBF_4$ in propylene carbonate (PC). The solvent and electrolyte were purified and handled in the usual method.[4,9] Electrochemical measurements were performed by voltammetry and the FFT impedance method with frequency range between 0.01 and 2.5 kHz. The system and method for the FFT impedance measurements were the same as described in the previous paper.[7] All experiments were carried out in a dry and inert Ar gas atmosphere.

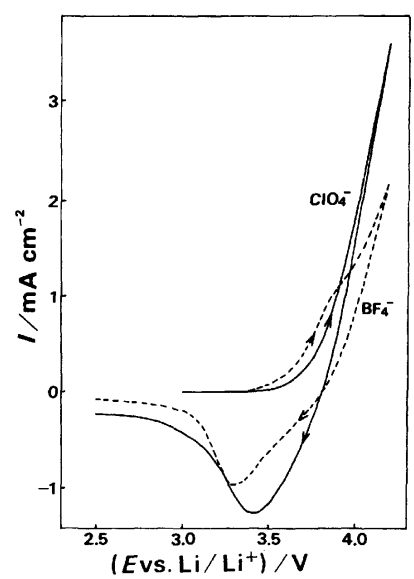

Fig. 1. Current *vs.* potential curves of $(CH)_x$ electrode at anion doping-undoping process in various solutions at 1 mV s^{-1} at Ar atmosphere.
——: 1 mol dm^{-3} $LiClO_4$/PC, ----: 1 mol dm^{-3} $LiBF_4$/PC.

Results and Discussion

Current vs. *Potential Curves of $(CH)_x$ Electrode.* Figure 1 shows the typical current *vs.* potential curves of the $(CH)_x$ electrode at the third time scan for the anion doping-undoping process in 1 mol dm^{-3} $LiClO_4$/PC and 1 mol dm^{-3} $LiBF_4$/PC using a scan rate of 1 mV s^{-1}, since the behavior of current *vs.* potential curves with 1 mV s^{-1} becomes steady-state from the third time scan. The first time scan showed the greatest difference from the steady-state of the current *vs.* potential curve, *i.e.*, the doping at the first time scan was small. In Fig. 1, the anodic current indicates anion doping into $(CH)_x$ and the cathodic current indicates anion undoping from doped $(CH)_x$, respectively. The electrochemical doping reaction involves the partial oxidation of $(CH)_x$ as shown in Eq. 1.[3,5]

$$(CH)_x + xyClO_4^- \longrightarrow [(CH^{+y})(ClO_4)_y^-]_x + xye. \quad (1)$$

The $(CH)_x$ film is doped readily to the composition of $[CH(ClO_4)_y]_x$ or $[CH(BF_4)_y]_x$ from approximately the

same potential around 3.4 V in each electrolyte solution. The anodic doping current increases more rapidly for ClO_4^- doping than for BF_4^- doping, though at the initial doping potential the increase for BF_4^- anion is greater than that for ClO_4^- anion. In Fig. 1, the charging ratio from anodic scan until the anodic current becoming zero at cathodic scan was 1.47% for ClO_4^- and 0.72% for BF_4^-, respectively.† At the cathodic scan, the cathodic currents for the undoping process show a peak at 3.4 V for ClO_4^- undoping and at 3.3 V for BF_4^- undoping. It is assumed from the behavior of the current-potential curves that ClO_4^- anion doping-undoping occurs easier than BF_4^- anion doping-undoping. The doping process as seen in Eq. 1 shows that the doped polymer is utilized as a cathode material, and the characteristics of doping-undoping process for ClO_4^- may be superior to that for BF_4^-, thus the polyacetylene doped ClO_4^- anion might be a superior cathode for a high power density battery of $(CH)_x$.

Impedance Measurements of the $(CH)_x$ Electrode. Figures 2(a) and 2(b) show the impedance of the $(CH)_x$ electrode at various potentials in 1 mol dm^{-3} $LiBF_4$/PC during anodic and cathodic scans, respectively, at 1 mV s^{-1}. At the anodic scan in Fig. 2(a), the impedance plots are semi-circles, and their diameters decrease with the doping process. The behavior of the cathodic scan for the undoping process is also similar to that of the anodic scan as seen in Fig. 2(b), and the diameters increase with the undoping process. Figure 3 shows the impedance representation of $(CH)_x$ in 1 mol dm^{-3} $LiClO_4$/PC at various doping levels using

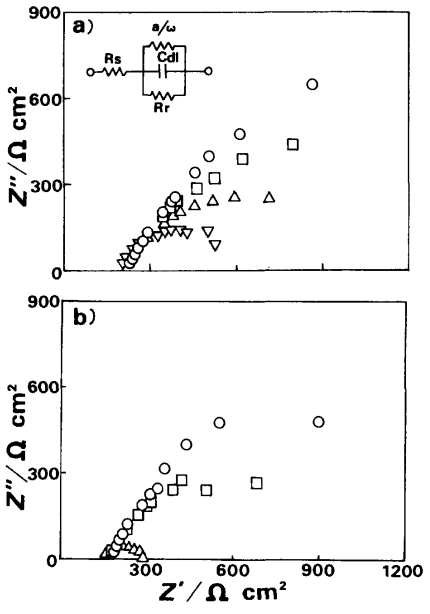

Fig. 2. Impedance representations of $(CH)_x$ electrode at anion doping-undoping process with using potential-sweep at 1 mV s^{-1} in 1 mol dm^{-3} $LiBF_4$/PC at Ar atmosphere.

† Here, 1% doping corresponds to 278 mC.

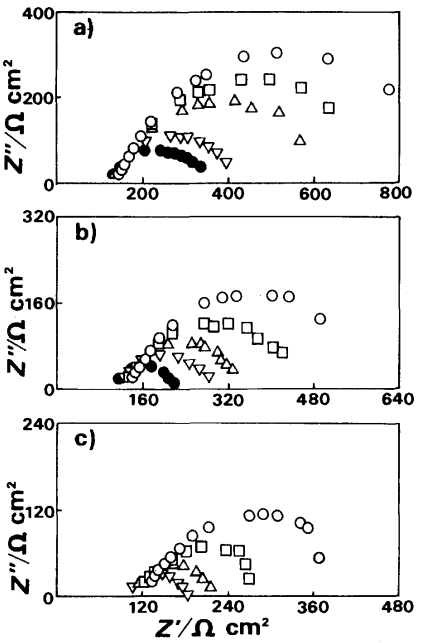

Fig. 3. Impedance representations of $(CH)_x$ electrode at anion doping process with using potential-step in 1 mol dm^{-3} $LiBF_4$/PC at Ar atmosphere.
a) Doping at constant potential of 3.6 V at various charges; ○: 0.2 mC, □: 3.4 mC, △: 10.4 mC, ▽: 44.0 mC, ●: 70.0 mC. b) Doping at constant potential of 3.8 V at various charges; ○: 0.4 mC, □: 11.0 mC, △: 30.0 mC, ▽: 50.0 mC, ●: 90.0 mC. c) Doping at constant potential of 4.0 V at various charges; ○: 1.2 mC, □: 19.6 mC, △: 56.6 mC, ▽: 96.0 mC.

potential-step doping. The doping potentials for *p*-$(CH)_x$ are 3.6, 3.8, and 4.0 V for Figs. 3(a)—(c), respectively. The behavior shown in Fig. 3 is similar to that in Fig. 2(a) for the potential-scaning doping process. However, the greater the anodic potential of the doping level becomes, the earlier the diameter of semi-circle becomes small, namely, the diameter of semi-circle is shorter even at the same charging value when the doping is performed at the more anodic potential. This behavior is shown more clearly in Fig. 5. The impedance representation of $(CH)_x$ for ClO_4^- anion doping-undoping process is similar to that for BF_4^-.

The theoretical equivalent circuit for the analysis and the interpretation of the experimental data shown in Fig. 2 are described as follows. The doping-undoping results are interpreted by the Randles-type equivalent circuit shown in Fig. 2(a), which displays a semi-circle in the impedance representation. The components of *Rs*, *Rr*, *Cdl*, and $a\,\omega^{-1}$, (ω: angular frequency) are the solution resistance, the resistive component due to the electrode reaction, the double-layer capacitance, and the corrective term concerned with surface roughness.[10] The surface of polyacetylene film may be porous because of it being composed of a fibril unit, thus the term concerned with the roughness, $a\,\omega^{-1}$, should be added into the circuit. If porous states are assumed, the double-layer capacitance, *Cdl*, means the total value of each pore's double-layer capacitance. The resistive component, *Rr*, arises

mainly from two factors of the partial oxidation or reduction (*i.e.*, doping-undoping) reaction and of the film resistivity itself. The diffusion of the anion into the film (or diffusion of anion from exterior to interior of fibrils) is not directly detected between these frequency regions as seen in Fig. 2. The double-layer capacitance, *Cdl*, of $(CH)_x$ shows the same value of *ca.* 8.0 μF cm^{-2} as that of the platinum electrode and also the value of *Cdl* is scarcely changed by the doping-undoping process. The value of the term '*a*' is very large and it is scarcely changed by the doping-undoping process. This means that the semi-circle is hardly inclined from the real component axis as is seen in Fig. 2. Accordingly, the information from the values of *Cdl* and '*a*' suggests that the surface porosity scarcely influences the impedance behavior of the polyacetylene film. This conclusion may be due to the very fine porosity of the $(CH)_x$ film (of the order of ten nm) formed by the fibril unit. A slight variation of *Rs* was observed in Figs. 2 and 3; this can be caused by the swelling of the $(CH)_x$ film on doping, which causes a decrease of the distance between the electrodes.[††] The value of *Rr*, which corresponds to the diameter of the semi-circle, changes greatly during the doping-undoping process. The value of *Rr* decreases with doping, while it increases with undoping. Consequently, the values of *Rs*, *Cdl*, and '*a*' are scarcely changed by the doping-undoping process but the opposite is true for *Rr*. Accordingly, there is a high possibility that the doping-undoping process of $(CH)_x$ is associated with the variation of *Rr*.

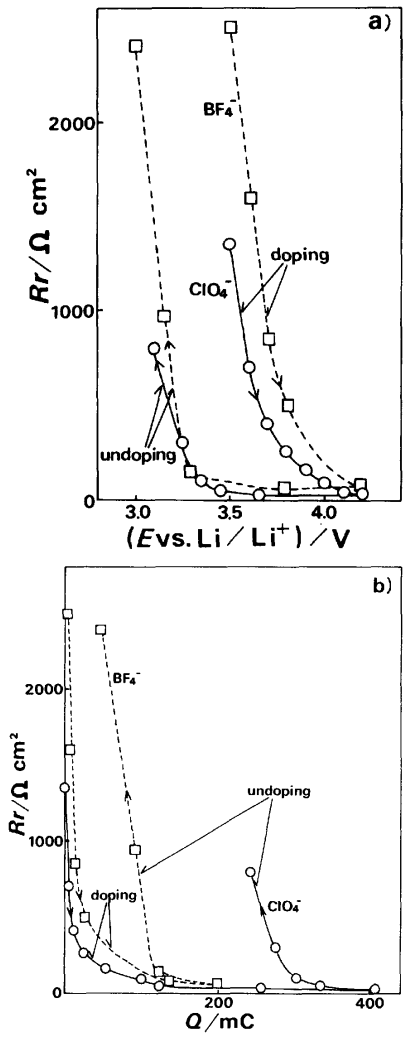

Fig. 4. Variation of resistive component, *Rr*, in equivalent circuit as a function of potential, *E*, (Fig. 4(a)) or amount of charge, *Q*, (Fig. 4(b)) of $(CH)_x$ electrode at anion doping-undoping process with using scaning at 1 mV s^{-1} in various solutions.
○: 1 mol dm^{-3} $LiClO_4$/PC, □: 1 mol dm^{-3} $LiBF_4$/PC.

Variation of Rr Value of $(CH)_x$ at Doping-Undoping Process. Figure 4(a) shows the variation of the *Rr* value of the $(CH)_x$ electrode as a function of the potential during the potential-sweep doping-undoping process with 1 mV s^{-1} in the two kinds of solution. In both solutions of $LiClO_4$ and $LiBF_4$ in propylene carbonate, the value of *Rr* greatly decreases at the initial doping potential and finally reaches a small constant value. During the undoping scan, the value of *Rr* increases with the undoping process. The decrease of *Rr* for ClO_4^- ion is larger than that for BF_4^- ion at the same doping potential. At the beginning of the cathodic scan, an anodic current is observed until 3.8 V in the current *vs.* potential curves in Fig. 1. From the potential of 3.8 V during cathodic scan, anion undoping starts to occur and the values of *Rr* begins to increase abruptly at *ca.* 3.3 V after sufficient undoping process. A similar variation of *Rr* is observed in both scans and in both solutions, but during the anion doping process, the value of *Rr* for ClO_4^- doping is always smaller than that of BF_4^- doping at the same potential. This indicates that a greater amount of ClO_4^- anion is doped at the same potential and that the ClO_4^- anion can be doped more easily than the BF_4^- anion.** Since the measured impedance reflects the value not at the whole impedance of polyacetylene film electrode but at the interface between film electrode and solution, the variation of *Rr* is assumed to correspond to that at the surface region of $(CH)_x$ and the electrode reaction at the interface. The value of *Rr* is considered to contain two factors (i) the reaction resistance for the doping-undoping process at the interface as shown in Eq. 1 and (ii) the film resistivity of the $(CH)_x$ film itself at the actual surface region. The main factor related to the abrupt variation of *Rr* is more probably the latter than the former, because the former is usually not more than one hundred ohms. The variation of *Rr* can also be represented as a function of the amount of charge doped as seen in Fig. 4(b). In Fig. 4(b), the value of *Rr* decreases abruptly with the increase in the amount of charge, *Q*, especially at the beginning of the doping process, and it becomes constant after 100 mC.

[††] The cell used has the volume of 0.283 cm^3 for electrolyte solution and the distance between working and reference electrodes is 0.58 cm. The swelling of $(CH)_x$ film is observed *ca.* 0.2 cm at the most, which may cause the decrease of *Rs ca.* 30%.

** The Stokes' radii of ClO_4^- and BF_4^- ions in PC were reported as 0.31 and 0.28 nm, respectively.[11] Thus, the above results cannot simply be explained by the radii of ions. The ease of doping in the $(CH)_x$ film might be discussed by considering the interaction between the dopant ions and $(CH)_x$ or other factors.

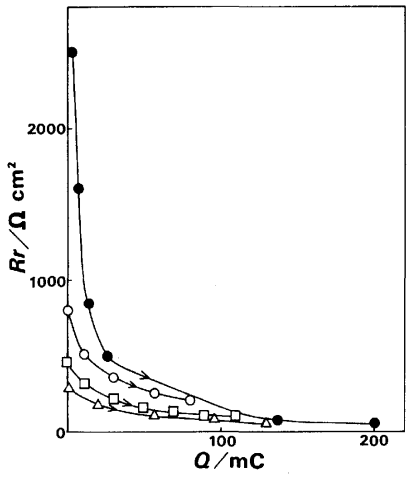

Fig. 5. Variation of resistive component, *Rr*, in equivalent circuit as a function of amount of charge of $(CH)_x$ electrode at anion doping-undoping process with using potential-step at various potentials in 1 mol dm^{-3} $LiClO_4$/PC.
○: 3.6V, □: 3.8V, △: 4.0V, ●: potential-sweep doping at 1 mV s^{-1}.

On the other hand, the value of *Rr* increases with the decrease in *Q*, and the abrupt increase starts from a different point of the fairly doped amount of charge. This can be explained by the fact that the dopant anions entered deeply into the fibrils from the film surface but can not get out of them so easily. These results also strongly indicate that the variation of *Rr* does not reflect the total dopant concentration but only the dopant concentration at the surface of the $(CH)_x$ film. The hysteresis in the potential *vs.* charge relation similar to that in Fig. 4(b) has already been noted and discussed.[5,12,13] The hysteresis can be explained more readily by the variation of *Rr* as seen in Fig. 4(b).

Figure 5 shows the relationship between *Rr* and *Q* for the anion doping process by various doping methods in 1 mol dm^{-3} $LiBF_4$/PC In Fig. 5, the value of *Rr* at the potential-sweep doping with 1 mV s^{-1} is always larger than that at the potential-step doping. During the potential-step doping the value of *Rr* is decreased to less values by the very small charge of several mC's at the initial doping stage as compared with that during the potential-sweep doping. Moreover, the decrease of *Rr* occurs earlier at more anodic potential doping even for the same amount of charge doped. In the case of the potential-sweep doping with 1 mV s^{-1}, the doping rate is slower as compared with that of the potential-step doping. Then, the anion dopant diffuses more readily into the interior of the polyacetylene film. It is expected that the dopant concentration at the surface of the film is higher for the faster or stronger doping process. This assumption can readily explain the different variation of *Rr* by the different doping method. A similar behavior was observed also in 1 mol dm^{-3} $LiClO_4$/PC.

In conclusion, the resistive component, *Rr*, in the equivalent circuit reflects the dopant concentration at the surface of the film and the doped conditions can be detected by the variation of *Rr*. Rapid doping produces non-uniform dopant conditions of the surface concentration of dopant being very high. These non-uniformed states of the dopant cause the decrease of *Rr* and they tend to make the film potential more anodic.

The authors are indebted to Mr. Yoshimitsu Sawada, Showa Denko Co. Ltd., for providing polyacetylene samples and for helpful discussion.

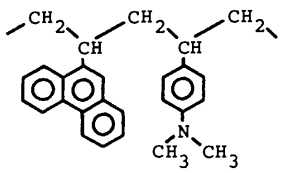
(Received August 11, 1983)

In the electron-transfer reaction from the fluorescent intramolecular exciplexes of a copolymer containing phenanthrene and *N,N*-dimethylaniline moieties, and of a model compound to electron acceptors, the reactivity of the exciplexes was studied kinetically in polar and nonpolar media. The copolymer was poly(9-vinylphenanthrene-co-*p*-dimethylaminostyrene) and the model compound was *N,N*-dimethyl-4-[3-(9-phenanthryl)propyl]aniline. The oxidation potential of the exciplex was evaluated by the relation of the exciplex-quenching rate constants to the reduction potentials of electron-accepting quenchers according to the equations of Rehm and Weller. It was found that the electron-donating ability of these intramolecular exciplexes resembled with each other and was larger than that of excited phenanthrene. In polar media the donating ability was very close to that of the phenanthrene anion radical.

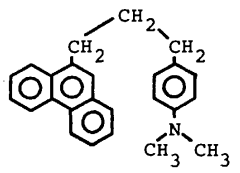
Much attention has been given to exciplexes as reaction intermediates in photoinduced electron-transfer and photochemical reactions. In the field of polymer chemistry, several papers have been published dealing with exciplex-forming polymers in recent years.[1-4] In a previous paper[2] we reported the intramolecular exciplex formation in 9-vinylphenanthrene–*p*-dimethylaminostyrene copolymers, P(VPh–co-DMAS), and photoinduced electron transfer from the copolymer to *p*-dicyanobenzene. The *p*-dicyanobenzene anion radical was concluded to be generated by both the electron-transfer process *via* exciplex and the direct electron-transfer process from the excited phenanthrene unit in the copolymer.

We now want to estimate the reactivity of the exciplex in the electron-transfer reaction between an exciplex and other molecules. The electron-donating ability of an exciplex can be estimated from the relation between exciplex-quenching rate constants by electron acceptors and reduction potentials of the acceptors applying the equations of Rehm and Weller.[5,6] Such a reaction between an exciplex and other molecules has been studied recently and a few papers on exciplex-quenching reactions have appeared in the field of low-molecular-weight compound.[7-11]

In this paper the reactivity of the fluorescent exciplex formed on P(VPh–co-DMAS) is estimated kinetically in polar and nonpolar media, and compared with that of the model compound *N,N*-dimethyl-4-[3-(9-phenanthryl)propyl]aniline, Ph$\{CH_2\}_3$DMA.



P(VPh-co-DMAS)



Ph$\{CH_2\}_3$DMA

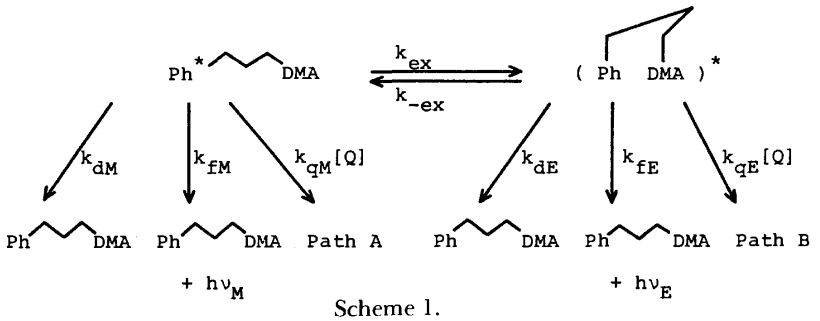
Experimental

Materials. P(VPh–co-DMAS), which has 59 mol% of the VPh unit, was described in the literature.[2] Ph$\{CH_2\}_3$DMA[12] was synthesized according to the method of Thomas and coworkers who prepared *N,N*-dimethyl-4-[3-(1-pyrenyl)-propyl]aniline.[13] Phenanthrene used for measurements was zone-refined reagent (Tokyo Chemical Ind. Co.). *N,N*-dimethylformamide (DMF) was obtained by removing water as benzene azeotrope, followed by fractional distillation after drying over CaH_2. CH_3CN was Dotite Spectrosol Grade and was used without further purification. 1,4-Dioxane was refluxed over sodium and then distilled through a Vigreux column. *p*-Dicyanobenzene was sublimed under reduced pressure and recrystallized from acetone. Benzonitrile was purified by fractional distillation after drying over P_2O_5. Pyridine, acrylonitrile, and cinnamonitrile were purified by fractional distillation. Biphenyl and naphthalene were recrystallized from methanol and tetrahydrofuran, respectively. Fumaronitrile (Tokyo Chemical Ind. Co.) was used without purification. Another electron-accepting quenchers (Guaranteed Reagent, Nakarai Chemicals, LTD) were used without further purification.

Measurements. Fluorescence spectra were recorded by a Shimadzu RF-502A spectrofluorometer at 25 °C. Solution samples were made free from oxygen by freeze-pump-thaw cycles on a vacuum line. Fluorescence lifetime was measured by the pulse method with a small Blumlein-type nitrogen gas laser as described in the literature.[2] A sample solution was sealed in a 3 mm Pyrex glass capillary tube after degassed by four freeze-pump-thaw cycles on a vacuum line. Fluorescence was detected through appropriate cutoff filters and a monochrometer (Union FS-401) by a photomultiplier (Hamamatsu TV 1P28) and an oscilloscope (Tektronix 485). The exciplex fluorescence was monitored at 440 nm in dioxane and at 460 nm in CH_3CN and in DMF. Phenanthrene fluorescence was monitored at 370 nm both in dioxane and CH_3CN.

Results and Discussion

In Fig. 1 are shown the fluorescence spectra of P(VPh–co-DMAS) containing 59 mol % of the VPh unit and Ph$\{CH_2\}_3$DMA in dioxane. They are found to exhibit an intense and broad intramolecular exciplex fluorescence at *ca.* 440 nm. These exciplex fluorescence are observed in a longer wavelength region in a polar solvent DMF also as shown in Fig. 1. We have determined the quenching rate constants of these two kinds of (Ph–DMA) intramolecular exciplexes with a number of electron acceptors. In general, a fluorescence-quenching rate constant can be determined by either a fluorescence intensity measurement or a fluorescence



Scheme 1.

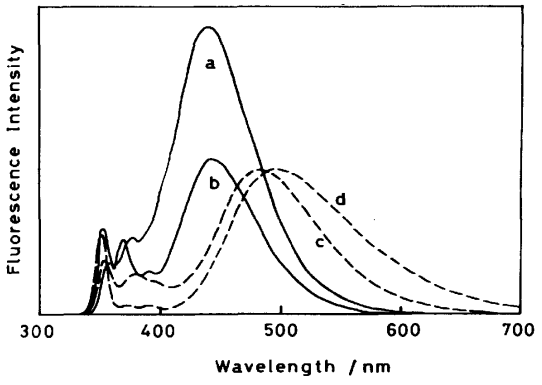


Fig. 1. Fluorescence spectra of P(VPh-co-DMAS) and Ph{CH_2}$_3$DMA: P(VPh-co-DMAS) in (a) dioxane and in (c) DMF, [VPh unit]=3×10^{-4} mol dm^{-3}, excitation at 352 nm; Ph{CH_2}$_3$DMA in (b) dioxane and in (d) DMF, [Ph{CH_2}$_3$DMA]= 2×10^{-4} mol dm^{-3}, excitation at 350 nm. Fluorescence intensities were normalized at Ph monomer fluorescence part [(a) and (b)] or at exciplex fluorescence part [(c) and (d)].

lifetime measurement. In this paper the exciplex-quenching rate constant, k_{qE}, was obtained from exciplex fluorescence lifetime data but not from exciplex fluorescence intensity quenching data by the following reasons. As shown in Scheme 1 some electron acceptors, Q, can quench an excited phenanthrene portion, Ph*, (Path A) as well as the exciplex (Path B). In such a case, the quantum yields of the exciplex and Ph* monomer fluorescence under stationary conditions are presented by the following equations 1—4.

$$\Phi_E^\circ = \frac{k_{ex}k_{fE}}{(k_{fM}+k_{dM}+k_{ex})(k_{fE}+k_{dE}+k_{-ex})-k_{ex}k_{-ex}}, \quad (1)$$

$$\Phi_E = \frac{k_{ex}k_{fE}}{(k_{fM}+k_{dM}+k_{ex}+k_{qM}[Q])(k_{fE}+k_{dE}+k_{-ex}+k_{qE}[Q])-k_{ex}k_{-ex}}, \quad (2)$$

$$\Phi_M^\circ = \frac{k_{fM}(k_{fE}+k_{dE}+k_{-ex})}{(k_{fM}+k_{dM}+k_{ex})(k_{fE}+k_{dE}+k_{-ex})-k_{ex}k_{-ex}}, \quad (3)$$

$$\Phi_M = \frac{k_{fM}(k_{fE}+k_{dE}+k_{-ex}+k_{qE}[Q])}{(k_{fM}+k_{dM}+k_{ex}+k_{qM}[Q])(k_{fE}+k_{dE}+k_{-ex}+k_{qE}[Q])-k_{ex}k_{-ex}}, \quad (4)$$

where Φ_E° and Φ_E are the exciplex fluorescence quantum yields in the absence and presence of Q, Φ_M° and Φ_M are the Ph* monomer fluorescence quantum yields in the absence and presence of Q, respectively, k_{ex} and k_{-ex} are the rate constants of the exciplex formation and dissociation processes, respectively, k_{dM}, k_{fM}, and k_{qM} are the rate constants of radiationless deactivation, fluorescence and quenching of the excited phenanthrene part, respectively, and k_{dE}, k_{fE}, and k_{qE}, are the corresponding rate constants of the exciplex. The value of I_E°/I_E ratio can be expressed by Eq. 5,

$$I_E^\circ/I_E = \Phi_E^\circ/\Phi_E = \frac{\Phi_M^\circ}{\Phi_M}\times\left(\frac{k_{qE}[Q]}{k_{fE}+k_{dE}+k_{-ex}}+1\right) = \frac{I_M^\circ}{I_M}\times(1+k_{qE}\tau_E^\circ[Q]), \quad (5)$$

where I_E° and I_E are the exciplex fluorescence intensity in the absence and presence of Q, I_M° and I_M are the Ph* monomer fluorescence intensity in the absence and presence of Q, and τ_E° is lifetime of the exciplex fluorescence in the absence of Q, respectively. Therefore k_{qE} cannot be determined from the measurement of exciplex fluorescence intensity only. On the other hand, as the exciplex fluorescence lifetime depends only on its decay processes, the value of τ_E°/τ_E can be expressed by Stern-Volmer equation 6. Typical examples of exciplex

$$\tau_E^\circ/\tau_E = 1 + k_{qE}\tau_E^\circ[Q], \quad (6)$$

fluorescence lifetime measurements for P(VPh-co-DMAS) - and Ph{CH_2}$_3$DMA - acceptor systems are shown in Figs. 2 and 3, respectively. It has been reported that in such intramolecular excited complex systems, especially in polymer systems, the accurate fluorescence decay seemed to be multicomponent decay.[14] However, the observed exciplex fluorescence decay curves could be analyzed by a single exponential kinetics as shown in Figs. 2 and 3.

The phenanthrene fluorescence-quenching rate constant, k_{qPh}, for phenanthrene-acceptor systems and k_{qE} for (Ph-DMA) intramolecular exciplexes-acceptor systems by Eq. 6 are listed in Table 1 together with the reduction half-wave potentials[15] of electron-accepting quenchers, $E_{1/2}$. Phenanthrene has a unique redox potential in the sense that the electron-donating ability of the phenanthrene anion radical [$E_{1/2}(Ph/Ph^-)$= -2.5 V[16]] is larger than that of excited phenanthrene [$E_{1/2}(Ph^+/Ph^*)=-2.1$ V[15]] (Scheme 2). In this respect the quenchers are classified into three groups in Table 1. As shown in Scheme 2, Q_c is a strong electron acceptor which can accept an electron from both the phenanthrene anion radical and excited phenanthrene, Q_b is a moderate one which can accept only from the phenanthrene anion radical, and Q_a is a weak one which cannot accept from either.

TABLE 1. EXCIPLEX AND PHENANTHRENE FLUORESCENCE QUENCHING RATE CONSTANTS MEASURED IN POLAR SOLVENTS

Quencher	$E_{1/2}$[b]/V		k_q[a]/mol^{-1} dm^3 s^{-1}		
			Phenanthrene	Ph{CH$_2$}$_3$DMA	P(VPh-co-DMAS)
Biphenyl	−2.70[e]	Q_a			9.8×10^6
Naphthalene	−2.63[d]			1.5×10^8	3.0×10^7
Pyridine	−2.62[d]		*6.8×10^5		
Benzonitrile	−2.44[c]	Q_b	*1.2×10^6	5.0×10^9	2.0×10^9
Methyl benzoate	−2.32[c]			4.2×10^9	2.3×10^9
Acrylonitrile	−2.17[c]			3.8×10^9	2.0×10^9
Ethyl benzoate	−2.14[e]			4.8×10^9	1.8×10^9
Cinnamonitrile	−1.99[c]	Q_c	*3.0×10^9	6.3×10^9	4.2×10^9
p-Dicyanobenzene	−1.67[c]		*9.3×10^9	7.3×10^9	4.7×10^9
Fumaronitrile	−1.36[c]		*1.2×10^{10}	7.1×10^9	5.7×10^9
Maleic anhydride	−0.85[d]		*1.6×10^{10}	7.3×10^9	5.6×10^9

a) Fluorescence-quenching rate constants k_q were determined in DMF and CH_3CN(*). b) $E_{1/2}$ (V *vs.* SCE). c) In DMF. d) In CH_3CN. e) In 75% aqueous dioxane.

In simple fluorescer-quencher systems, fluorescence-quenching rate constants k_q are correlated to the free energy change for the reaction ΔG and the free energy change of activation ΔG^* by Eq. 7,[5,6]

$$k_q = \frac{2.0 \times 10^{10}}{1 + 0.25\left[\exp\left(\frac{\Delta G^*}{RT}\right) + \exp\left(\frac{\Delta G}{RT}\right)\right]}, \quad (7)$$

$$\Delta G = 23.06\,[E_{1/2}(D^+/D) - E_{1/2}(A/A^-) - e_0^2/\varepsilon a] - \Delta E_{0,0},$$

$$\Delta G^* = \left[\left(\frac{\Delta G}{2}\right)^2 + (\Delta G^*(0))^2\right]^{1/2} + \frac{\Delta G}{2},$$

where $\Delta G^*(0)$ is ΔG^* at $\Delta G=0$, and is assumed to be 2.4 kcal mol^{-1},[6] $\Delta E_{0,0}$ is the 0-0 excitation energy of fluorophore, and the term $e_0^2/\varepsilon a$ is the Coulomb attraction energy and is *ca.* 0.06 V in CH_3CN solution (calculated with the values of dielectric constant ε=37.5

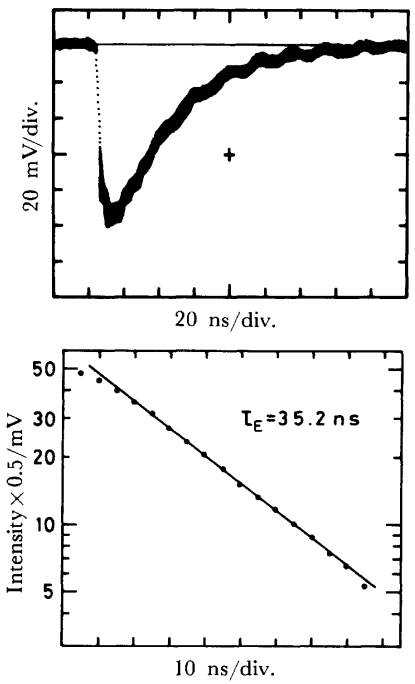

Fig. 2. Typical exciplex fluorescence decay curve and its semilogarithmic plot of P(VPh-co-DMAS)-maleic anhydride system in dioxane: [VPh unit]= 1.4×10^{-3} mol dm^{-3}, [maleic anhydride]=2.23×10^{-3} mol dm^{-3}. Monitored at 440 nm.

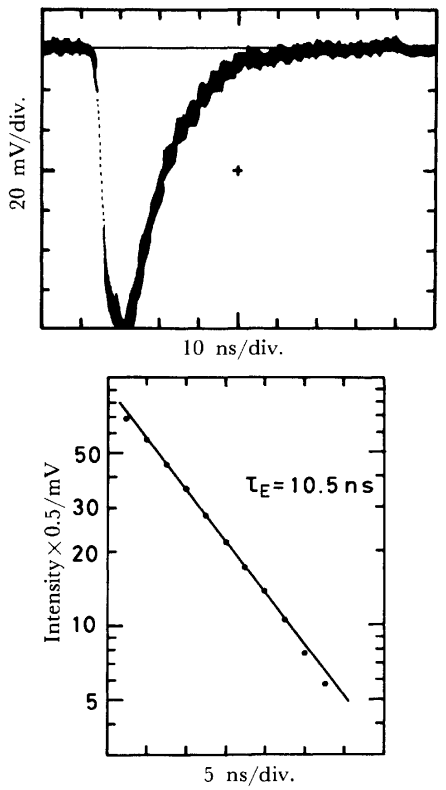

Fig. 3. Typical exciplex fluorescence decay curve and its semilogarithmic plot of Ph{CH$_2$}$_3$DMA-maleic anhydride system in CH_3CN:[Ph{CH$_2$}$_3$DMA]= 1.4×10^{-3} mol dm^{-3}, [maleic anhydride]=3.34×10^{-3} mol dm^{-3}. Monitored at 460 nm.

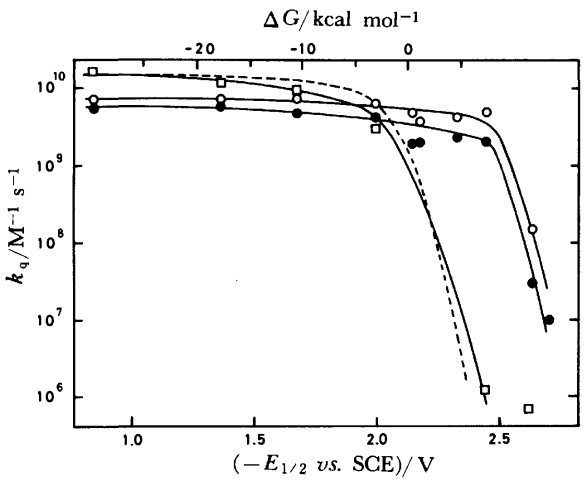

Fig. 4. Quenching of (Ph-DMA) intramolecular exciplexes by electron acceptors in polar solvents. Plots of log k_q *vs.* $E_{1/2}$ of the quenchers: (●) P(VPh-co-DMAS) in DMF, (○) Ph{CH_2}$_3$DMA in DMF, (□) phenanthrene in CH_3CN, the dotted line was calculated from the Eq. 7 for the phenanthrene-acceptor system.

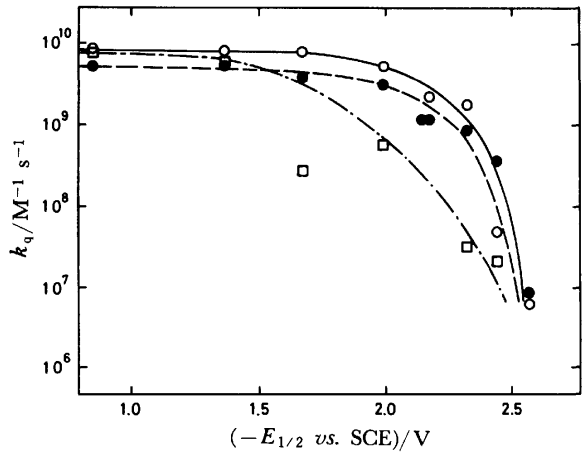

Fig. 5. Quenching of (Ph-DMA) intramolecular exciplexes by electron acceptors in nonpolar solvent(dioxane). Plots of log k_q *vs.* $E_{1/2}$ of the quenchers: (●) P(VPh-co-DMAS), (○) Ph{CH_2}$_3$DMA, (□) phenanthrene.

and distance between ion radicals a=7 Å). Figure 4 illustrates the plots of log k_{qPh} *vs.* ΔG for the excited phenanthrene-acceptor system in CH_3CN. The experimental values of k_{qPh} are in fair agreement with the calculated dotted line by equation 7. Similar relation can be expected for two (Ph-DMA) intramolecular exciplexes-acceptor systems in DMF. The determined k_{qE} values are plotted for $E_{1/2}$ values also in Fig. 4. The tendency of k_{qE} for two intramolecular exciplex systems is similar to each other. In the phenanthrene system, k_{qPh} has diffusion-controlled values only for strong quenchers Q_c and decreases with decreasing reduction potentials of quenchers, whereas in these intramolecular exciplex systems the quenching reactions for Q_c and moderate quenchers Q_b are found to proceed at nearly diffusion-controlled rates and for weak quenchers Q_a smaller values of k_{qE} are obtained. Therefore the electron-donating ability of these intramolecular exciplexes resembles with each other and can be larger than that of excited phenanthrene. That is, the oxidation potentials of the exciplexes can be located in between the two observed points —2.44 V of benzonitrile and —2.63 V of naphthalene, where a large decrease in the quenching rate constant k_{qE} was observed. Although the experimental data points at low $E_{1/2}$ region were not sufficient, we estimated the oxidation potentials of the exciplexes. From Eq. 7 it can be seen that a plot of log k_q *vs.* ΔG (or $E_{1/2}$) should approach a constant limiting value at large negative ΔG (or higher $E_{1/2}$), be linear at large positive ΔG (or low $E_{1/2}$) with a slope of $-(1/2.303\,RT)$, and have an intermediate region (centered at ΔG=0[17]). For very small values of $\Delta G^*(0)$ the intermediate region is very small and the connection between the limiting value and the limiting slope takes place in a very narrow ΔG range. These two lines intersect at *ca.* ΔG=0[18] ultimately. The constant limiting value at higher $E_{1/2}$ and the limiting slope at low $E_{1/2}$ intersect at the oxidation potentials of exciplexes, yielding $E_{1/2}$ values of *ca.* —2.5 V[19] for two kinds of intramolecular exciplexes. This value —2.5 V happens to be very close to the reduction potential of phenanthrene.

One can conclude from the results in polar media that the electron-donating ability of the intramolecular exciplex on P(VPh-co-DMAS) is similar to that of Ph{CH_2}$_3$DMA, is larger than that of excited phenanthrene, and is very close to that of the phenanthrene anion radical.

In nonpolar solvent dioxane k_{qE} and k_{qPh} are also similarly determined and plotted for $E_{1/2}$ in Fig. 5. The estimation of electron-donating ability of (Ph-DMA) intramolcular exciplexes was not feasible because $E_{1/2}$ measured in polar media was used instead of one in dioxane. It can be seen, nevertheless, that the behavior of k_{qE} of two exciplex systems was similar to each other and the exciplexes were better donors than excited phenanthrene.

As a photosensitizer excited phenanthrene cannot donate an electron to moderate electron acceptors, Q_b, but the (Ph-DMA) intramolecular exciplexes can. P(VPh-co-DMAS) may act as a photosensitizer in the case of the electron-transfer reactions to moderate electron acceptors because in this copolymer the efficient energy migration can take place from an excited phenanthrene unit to an exciplex-forming site on the polymer chain.[2]

Initial Process of Photo-oxidation of Ethanol by Uranyl Ions in the Rigid Matrix at 77 K

Toshie HARAZONO, Shin SATO, and Hiroshi FUKUTOMI*

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received September 2, 1983)

ESR spectra of radicals produced in the uranyl ion-photosensitized decomposition of ethanol have been measured in the rigid matrix at 77 K. At high concentrations of uranyl ions (>1 mol dm^{-3}), methyl radicals were observed. With decreasing concentrations of uranyl ions, $CH_3\dot{C}HOH$ radicals became important, as expected from the previous studies. This result suggests that the charge transfer mechanism is important in the ethanol rigid matrix, although the hydrogen atom abstraction mechanism is accepted as the main initial process.

The photochemistry of uranyl ions has been extensively investigated during the last fifty years.[1] In aqueous solutions, the quenching processes of the luminescence from excited uranyl ions by a variety of substrates were studied and several mechanisms have been proposed. In the case of alcohols, the quenching process is believed to occur through the intermolecular abstraction of a hydrogen atom by excited uranyl ions from a C–H bond of the hydroxylated carbon atom of alcohols.[2]

Liquid phase ESR studies using the spin-trapping method supported this mechanism.[3] All normal alcohol (RCH_2OH) used as substrates gave the alcohol radicals ($R\dot{C}HOH$) spin-trapped. In the case of secondary alcohols, the radicals produced by the loss of a hydrogen atom from the weakest C–H bond were observed; *i.e.*, $(CH_3)_2CHCH_2OH$ gave $(CH_3)_2\dot{C}CH_2OH$ and 2-propanol gave $(CH_3)_2\dot{C}OH$.

One exception was found with methanol. In this case, the principal radical spin-trapped was $CH_3O\cdot$ but not $\dot{C}H_2OH$. This reaction was classified as an exception due to an atypical behavior of methanol to uranyl ions.[1]

In the rigid matrix at low temperatures, a C–C bond cleavage was observed with secondary and tertiary alcohols.[4] For example, the photolysis of uranyl ions in a *t*-butyl alcohol glass gave the ESR spectrum of methyl radicals. This reaction was tentatively explained in terms of the charge transfer mechanism followed by the C–C bond cleavage:

$$(CH_3)_3COH + (UO_2^{2+})^* \rightarrow (CH_3)_3CO\cdot + UO_2^+ + H^+$$
$$(CH_3)_3CO\cdot \rightarrow (CH_3)_2CO + \cdot CH_3.$$

A similar observation was made with 1-propanol, for which ethyl radicals were found to be formed:

$$CH_3CH_2CH_2OH + (UO_2^{2+})^* \rightarrow CH_3CH_2CH_2O\cdot + UO_2^+ + H^+$$
$$CH_3CH_2CH_2O\cdot \rightarrow CH_2O + CH_3CH_2\cdot.$$

On the other hand, in the ethanol rigid matrix at 77K, the observed radicals were reported to be only $CH_3\dot{C}HOH$, suggesting that the abstraction of a hydrogen atom by excited uranyl ions from a C–H bond is the main process even in the matrix of ethanol as was found in the liquid phase.

Obviously there is some controversy in the mechanism of the photo-oxidation of alcohols by uranyl ions in the rigid matrix. We, therefore, have studied this reaction in some detail.

Experimental

The yellow crystalline powder of uranyl perchlorate, $UO_2(ClO_4)_2\cdot 7H_2O$, was prepared by the recrystallization from the perchloric acid solution of uranium trioxide, which was obtained by heating analytical grade $UO_2(NO_3)_2\cdot 6H_2O$ at 400 °C. Water, which was distilled after having been passed through an ion exchange resin column, was further refluxed with potassium permanganate and distilled twice. Ethanol (Wako Co.) was of guaranteed grade and used without further purification.

The observation of ESR spectra was made by means of a JEOL JES-FX3 spectrometer. A sample used for the ESR measurement was prepared by dissolving the $UO_2(ClO_4)_2\cdot 7H_2O$ powder in the known amount of ethanol or the mixture of the alcohol and water,and degassed under vacuum at the liquid nitrogen temperature. The yellow rigid glass thus obtained was irradiated with the light from a high-pressure mercury lamp (Ushio Electric Co.) through a filter (Corning 052) which cut off the wavelengths shorter than 365 nm. The ESR measurement was carried out during the light irradiation.

Results

When a 0.1 M (M=mol dm^{-3}) ethanol solution of $UO_2(ClO_4)_2\cdot 7H_2O$ was irradiated, the ESR spectrum, which appeared initially, was that of No. 5 spectrum shown in Fig. 1, and after a long irradiation, the spectrum changed to that of No. 6, together with an increase in the total intensity. This spectral change suggests that there are two kinds of radicals produced initially and their stabilities are not equal. Therefore, we measured the ESR spectra initially observed with the samples of various concentrations of $UO_2(ClO_4)_2\cdot 7H_2O$.

Figure 1 shows the results, where the numbers from 1 to 6 indicate the difference of the concentration of uranyl ions. All the spectra were obtained at 10 min from the start of light irradiation. No spectral change except the total intensity could be recognized during the first 10 min. The No. 1 spectrum clearly shows the presence of methyl radicals, while the No. 6 spectrum may be assigned to that of ethanol radicals ($CH_3\dot{C}HOH$).[5]

In order to investigate the stabilities of these radicals, the signal intensities were measured by turning off the lamp after a 30 min-irradiation. The intensity of the spectrum due to methyl radicals decayed to half in about 14 min, while the spectrum of $CH_3\dot{C}HOH$ radicals did not decay at all. This decay process

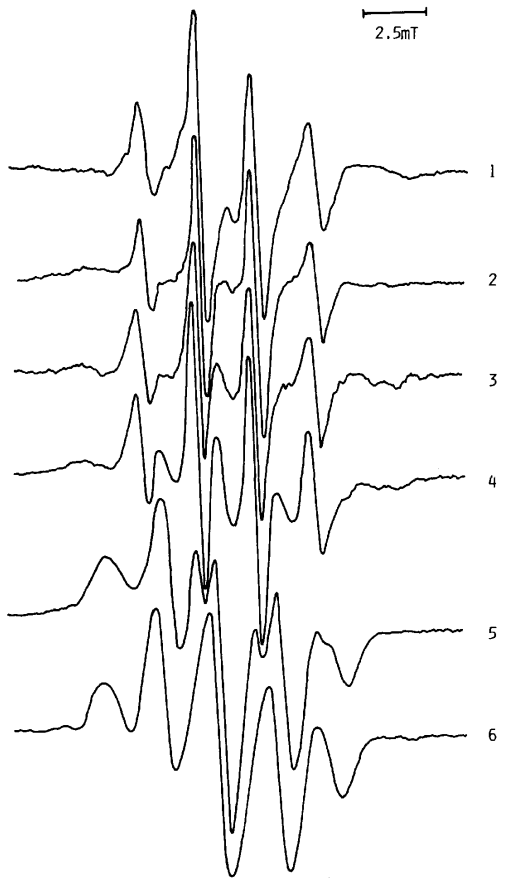

Fig. 1. ESR spectra of radicals initially produced in the uranyl ion-photosensitized decomposition of ethanol in the rigid matrix at 77 K. The numbers indicate the concentration of $UO_2(ClO_4)_2 \cdot 7H_2O$ in the matrix: 1, 2.5 M; 2, 1.8 M; 3, 1.0 M; 4, 0.5 M; 5, 0.1 M; 6, 0.04 M. Relative ESR intensities are arbitrarily adjusted.

was independent of both of the concentration of uranyl ions and the irradiation time.

Figure 2 shows the effect of the addition of water to the ethanol solution, where the concentration of uranyl ions was kept constant at 0.1 M (1 M=1 mol dm^{-3}). With the increase of water content, the ESR spectrum due to methyl radicals became more prominent than that due to $CH_3\dot{C}HOH$ radicals.

Discussion

According to the previous measurement on the ESR spectrum of the photolysis of uranyl ions in an ethanol rigid matrix, only $CH_3\dot{C}HOH$ radicals were observed,[4] but this measurement was carried out at low concentrations of uranyl ions (0.05—0.1 M); therefore, it is possible to overlook the spectrum due to methyl radicals initially produced. The present experiments clearly showed that methyl radicals are produced at the beginning of light irradiation.

The formation of methyl radicals may be explained in terms of the charge transfer mechanism followed by the C–C bond cleavage:

$$CH_3CH_2OH + (UO_2^{2+})^* \rightarrow CH_3CH_2O\cdot + UO_2^+ + H^+, \quad (1)$$

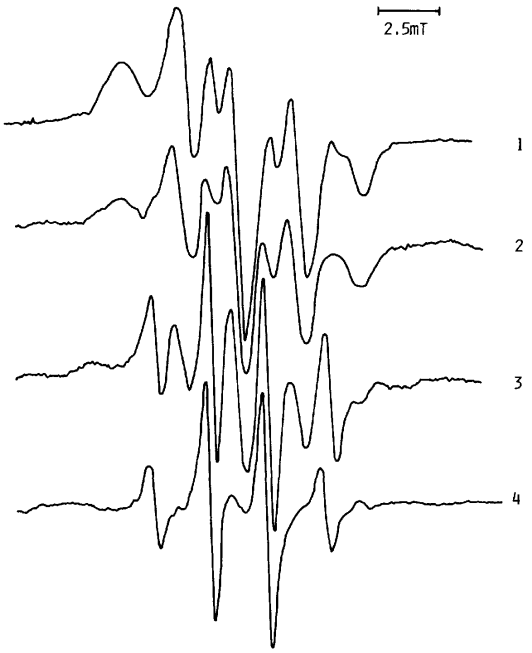

Fig. 2. ESR spectra of radicals produced in the uranyl ion-photosensitized decomposition of ethanol in the rigid matrix at 77 K. The numbers indicate the content of water: 1, no water added; 2, 20 volume % of water; 3, 50%; 4, 95%. The concentration of uranyl ions is kept constant at 0.1 M.

$$CH_3CH_2O\cdot \rightarrow \cdot CH_3 + CH_2O. \quad (2)$$

This is consistent with the mechanism proposed for the photosensitized decomposition of 1-propanol and secondary and tertiary alcohols in the rigid matrix at 77K.

For the formation of ethanol radicals ($CH_3\dot{C}HOH$) at lower concentrations of uranyl ions, we can consider three mechanisms: 1) the abstraction of a hydrogen atom by excited uranyl ions, 2) the abstraction of a hydrogen atom by ethoxyl radicals produced in Reaction 1 from the surrounding ethanol, and 3) the hydrogen atom abstraction by methyl radicals produced in Reaction 2.

The first mechanism may be discarded because, if this mechanism is operative, the formation of $CH_3\dot{C}HOH$ radicals should have been observed even at higher concentrations of uranyl ions. The third mechanism may also be disregarded since, if this is the case, the increase of $CH_3\dot{C}HOH$ radicals should have been observed with the decay of methyl radicals after the light irradiation was turned off.

It is well known that alkoxyl radicals are so reactive that the ESR spectra cannot easily be observed in the rigid matrix at 77 K;[6,7] therefore, if ethoxyl radicals are surrounded by ethanol, the abstraction of a hydrogen atom, Reaction 3, will occur immediately after the formation of ethoxyl radicals.

$$CH_5CH_2O\cdot + CH_3CH_2OH \rightarrow CH_3CH_2OH + CH_3\dot{C}HOH. \quad (3)$$

With the increase of uranyl ions, the concentration of free ethanol molecules from which the hydrogen atom is abstracted by ethoxyl radicals is concomitantly re-

duced, and Reaction 2 becomes more prominent than Reaction 3.

The decay of methyl radicals observed in the present experiments is probably due to the back reaction of UO_2^+ ions:

$$\cdot CH_3 + H^+ + UO_2^+ \rightarrow CH_4 + UO_2^+.$$

The Difference in Quenching Mechanism between Rigid Matrix and Liquid Phase. As has been discussed above, in the rigid matrices of alcohols at 77 K, the charge transfer mechanism seems to be the main process for the quenching of excited uranyl ions. On the other hand, the hydrogen atom abstraction mechanism is believed to be operative in the liquid phase photochemistry of uranyl ions.[1,8]

In the liquid phase, ethanol molecules surround an uranyl ion as shown in Fig. 3, and because of the

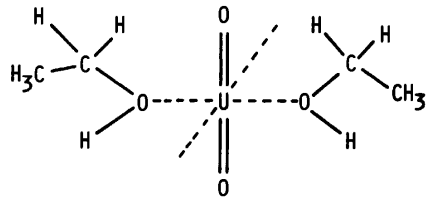

Fig. 3. The configuration of ethanol molecules around a uranyl ion in the liquid phase.

thermal vibration, an oxygen atom of the uranyl ion and a hydrogen atom of the C–H bond may occasionally approach each other very closely; therefore, when the excitation of uranyl ions occurs, the abstraction of a hydrogen atom may easily take place. On the other hand, in the rigid matrix at low temperatures, the ligand molecules will be mainly water, if $UO_2(ClO_4)_2 \cdot 7H_2O$ is used as the source of uranyl ions, since the heat of coordination is larger for water than for ethanol.[9] Consequently, the quenching of excited uranyl ions probably occurs through the hydrogen bond attached to an oxygen atom of the uranyl ion (Fig. 4). This process may be one detail of the charge transfer mechanism. A different approach is obviously necessary to establish these detailed mechanisms.

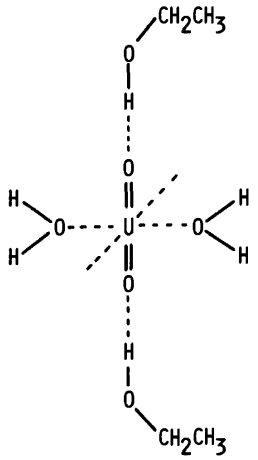

Fig. 4. The configuration of ethanol and water molecules around a uranyl ion in the rigid matrix at low temperatures.

The Laser-flash Photolysis of Propanone, Butanone, and 2-Pentanone. Study of Triplet Decay Processes in Aliphatic Carbonyl Compounds

Ikuo NAITO* and Wolfram SCHNABEL†

Department of Photography, Kyushu Sangyo University, Matsugadai, Higashi-ku, Fukuoka 813
†*Hahn-Meitner Institute für Kernforschung Berlin, Bereich Strahlenchemie, Glienicker Str. 100, D-1000 Berlin 39, Fed. Rep. of Germany*

(Received February 7, 1983)

The laser-flash photolysis of propanone, butanone, and 2-pentanone were carried out in dichloromethane (265 nm, 15 ns flash duration). The emission spectra (fluorescence, phosphorescence, and P-type delayed fluorescence) and the transient absorption spectra (triplet state and acetyl radical) were recorded. From the decays of the emission and the absorption, the unimolecular (triplet decay) and bimolecular (T-T annihilation and self quenching) reaction-rate constants were determined. Oxygen quenched the triplet states with a diffusion-controlled rate constant (k_{O_2}=*ca.* $3\times10\,dm^3\,mol^{-1}\,s^{-1}$).

Photochemical processes induced by stationary irradiation of aliphatic carbonyl compounds have been studied before in the absence and presence of quenchers.

Recently, the triplet state of propanone was investigated in detail by the use of tetramethyl-1,2-dioxetane (Chemiluminescence technique).[1]

In the flash photolysis studies of propanone, triplet-triplet absorption and phosphorescence spectra were recorded at wavelengths longer than λ=300 nm by Porter *et al.*[2] In these studies the ketyl radical formed from the triplet propanone was also detected.[3]

In the laser-flash photolysis of 2-hexanone, 5-methyl-2-hexanone, and poly(3-buten-2-one), triplet 1,4-biradical intermediates produced by a Norrish Type II reaction were detected recently.[4] In the photolysis of 3,3-dimethyl-2-butanone, poly(4,4-dimethyl-1-penten-3-one), and poly(3-methyl-3-buten-2-one), on the other hand, only radicals produced by α-cleavage in a Type I reaction were detected.[4] The triplet lifetimes of propanone, butanone, and 2-pentanone were reported to be relatively long [τ_T=47 μs,[4] 0.94 μs,[5] (propanone), 13 μs, (butanone in gas phase),[6] 77 ns,[7] and 240 ns (in the gas phase)[8] (2-pentanone)].

This paper reports on studies concerning the 265 nm laser-flash photolysis of propanone, butanone, and 2-pentanone carried out in dichloromethane solution in order to elucidate the physical and chemical deactivation processes of the triplet aliphatic carbonyl compounds.

Experimental

Materials. The propanone, butanone, and 2-pentanone were dried on sodium sulfate and distilled twice using a split-tube column.

The dichloromethane (for fluorescence spectroscopy) was washed five times with a 5% sodium carbonate solution and five times with distilled water. After drying on anhydrous calcium chloride, the dichloromethane was distilled twice using the split-tube column.

The acetonitrile (for spectroscopy) was refluxed five times on diphosphorus pentaoxide and distilled twice using the split-tube column.

The hexane (for fluorescence spectroscopy) was washed five times with sulfuric acid and five times with distilled water. After drying on anhydrous calcium chloride and calcium hydride, the solvent was distilled twice using the split-tube column.

The methanol (for spectroscopy) was refluxed with magnesium methoxide for eight hours and distilled twice using the split-tube column.

Apparatus. The flash photolysis system consisting of a Nd-laser has been described before (265 nm, 15 ns flash length).[9] The output of the laser and the intensity of the incident laser light were determined by means of the cycloreversion reaction of *r*-1,*t*-2,*t*-3,*c*-4-tetraphenylcyclobutane in 1-chlorobutane (ϕ=0.34).[10] The transient absorptions were measured using a pulsed Xenon lamp (Osram XBO 450 W). For the emission measurements a gating system was used.[11] This system protected the highly sensitive photomultiplier (RCA 78-35) from the strong emission during and immediately after the flash. The gating times of 1—2 μs (propanone) and 100—200 ns (butanone and pentanone) were applied. At the wavelengths longer than λ=400 nm, filters (Schott, BG 23, GG 455, *etc.*) were used. By choosing an appropriate concentration of the solute (3×10^{-2} mol dm^{-3}), the absorbance at λ=265 nm was kept at 0.5. After the solutions were filled in rectangular cells (optical length: 1.0×10^{-2} m) they were saturated with purified argon and, then, the laser-flash photolyis was carried out. The O_2 impurity of the argon gas was estimated to be less than 1×10^{-1}%. The emission and the absorption spectra were normalized with respect to an incident intensity of 2.0×10^{-8} einstein per flash.

Results and Discussion

1. Emission Spectra. During and immediately after the flash, a strong emission was detected in the wavelength range of 300—500 nm. The spectrum exhibited an emission maximum at λ=400 nm which agrees with the reported maximum of the fluorescence spectrum.[12]

Figure 1 shows time-resolved emission spectra monitored several microseconds after the flash by using the gating system [monitored at 6, 8, and 10 μs (propanone), 1.0, 1.5, 2.0, and 2.5 μs (butanone), 0.8, 1.0, 1.2, and 1.6 μs (2-pentanone)]. The emission spectrum, first-recorded, possesed the maximum in the wavelenth range of 410—430 nm. The maximum shifted to longer wavelengths with the lapse of the time after the flash. The spectra of butanone recorded at 2.0 μs and of 2-pentanone recorded at 1.2 μs at after the flash had two maxima, at λ=410 and 445 nm. Since the excited singlet lifetimes of these compounds have been reported to be much shorter than the time range investi-

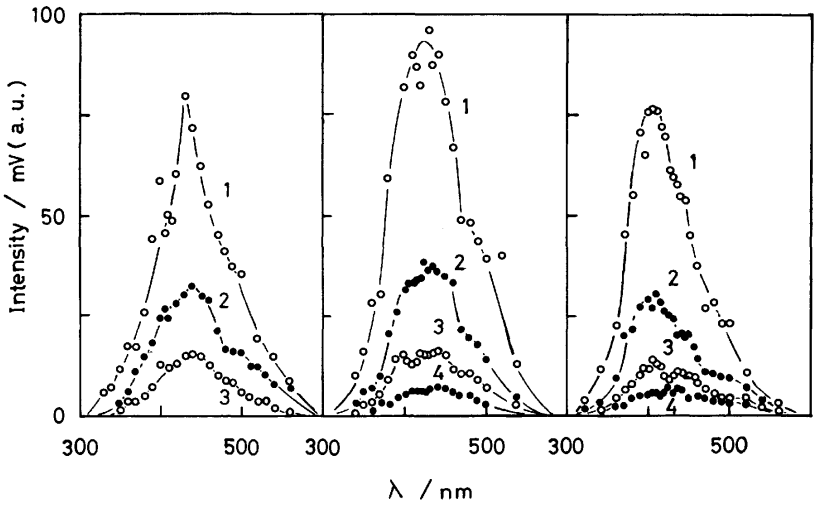

Fig. 1. Time-resolved emission spectra of propanone, butanone, and 2-pentanone in dichloromethane (3.0×10^{-2} mol dm^{-3}) recorded with the aid of a gating system. Time of recording: a) (propanone) 6 (1), 8 (2), and 10 (3) μs; b) (butanone) 1.0 (1), 1.5 (2), 2.0 (3), and 2.5 (4) μs; c) (2-pentanone) 0.8 (1), 1.0 (2), 1.2 (3), and 1.6 μs after the flash. The spectra were normalized with respect to an incident intensity of 2×10^{-8} einstein per flash.

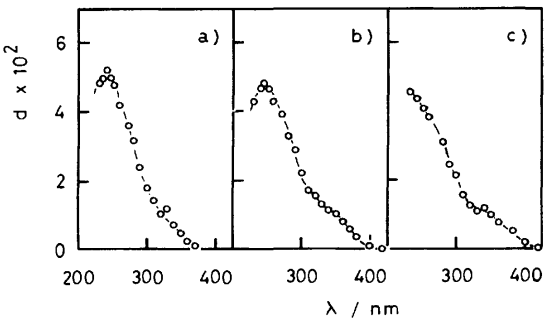

Fig. 2. Transient absorption spectra of propanone, butanone, and 2-pentanone monitored immediately after the flash in dichloromethane solution (3.2×10^{-2} mol dm^{-3}). a: propanone; b: butanone; c: 2-pentanone. The spectra were normalize with respect to an incident intensity of 2×10^{-8} einstein per flash.

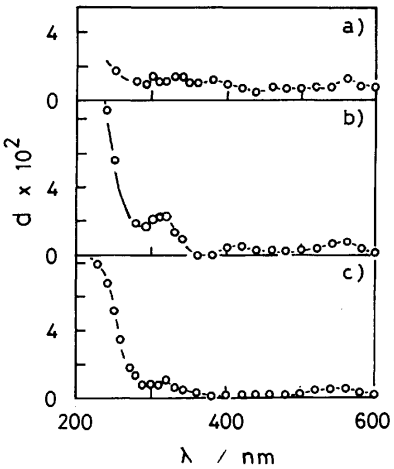

Fig. 3. Transient absorption spectra of the long-lived species of propanone (a), butanone (b), and 2-pentanone (c) in dichloromethane solution (3.2×10^{-2} mol dm^{-3}) recorded at 14(a), 7(b), and 2(c) μs after the flash. The spectra were normalized with respect to an incident intensity of 2×10^{-8} einstein per flash.

gated here,[13] it seems that the observed emission is due to the P-type delayed fluorescence and the phosphorescence. On this basis, the spectra recorded latest are attributed to the phosphorescence. Indeed, they agree with the phosphorescence spectra reported in the literature.[14]

2. Absorption Spectra of the Transient Species. The absorption spectra of transient species monitored immediately after the flash are shown in Fig. 2. The spectra exhibit an absorption maximum at λ=240 nm (propanone), at λ=245 nm (butanone), and at a wavelength shorter than 240 nm (2-pentanone). These transient absorption spectra are assigned to triplet-triplet absorption on the basis of the decay rate, which corresponds to the rate of the decay of the long-lived emission (*vide ante*).

Figure 3 presents absorption spectra of long-lived species, recorded at 14 μs (propanone), 7 μs (butanone), and 2 μs (2-pentanone). The spectra which have maxima around 320 nm and at λ=560 nm resemble strongly the spectrum of the acetyl radical reported by Noda *et al.*[15] Therefore, they are assigned to acetyl radicals. The generation of acetyl radical is feasible, in the present case, in terms of the generally accepted mechanism that the α-cleavage reaction is an important route in the deactivation of the triplet states of the carbonyl compounds.

3. Decay of the Transient Absorption and Emission. Figure 4 presents oscilloscope traces depicting the decay. The decays of both the absorption and the emission obeyed first-order kinetics. Whereas the decay rate ($k_{meas.}$) of the transient absorption was constant at all wavelengths monitored, the $k_{meas.}$ value of the emission depended on the wavelength. Figure 5 shows the effect of the laser light intensity on the $k_{meas.}$ value, obtained by means of the decay of the absorption at λ=250 nm and those of the emissions at λ=360 and

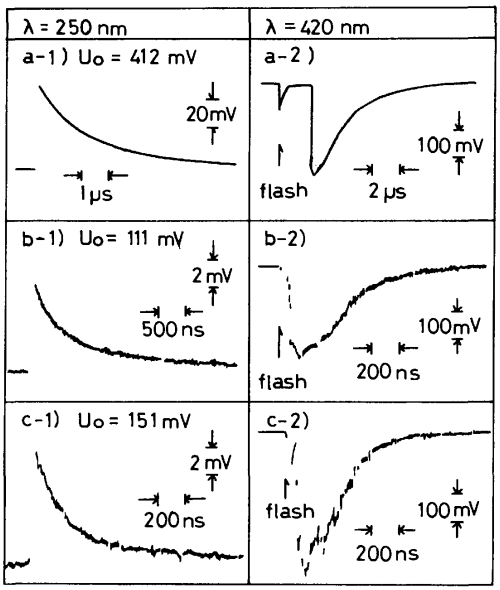

Fig. 4. Typical oscilloscope traces illustrating changes of the absorption (1) and the emission (2) of propanone (a), butanone (b), and 2-pentanone (c) in dichloromethane solution (3.0×10^{-2} mol dm^{-3}). Monitored at wavelength: λ=250 nm (absorption) and 420 nm (emission), flashed photons (10^{-8} einstein per flash): 2.0 (a-1), 2.2 (a-2), 1.0 (b-1), 1.4 (b-2), 0.8 (c-1), and 1.0 (c-2).

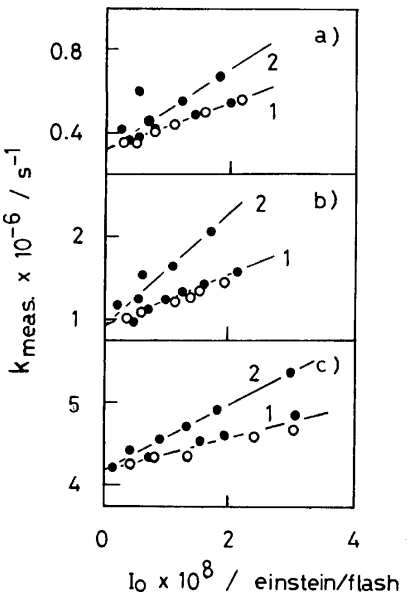

Fig. 5. The plot of the $k_{meas.}$ values as a function of the flashed photons. a: propanone; b: butanone; c: 2-pentanone in dichloromethane solution (3×10^{-2} mol dm^{-3}). Curve 1: absorption at λ= 250 nm and emission at λ=500 nm. Curve 2: emission at λ=360 nm.

500 nm. The two emission wavelengths were chosen with the intention to discriminate, possibly, delayed fluorescence from phosphorescence. It can be seen from Fig. 5, $k_{meas.}$ value increased linearly with the incident intensity, I_0, which is proportional to the quantity of the absorbed photons. This behavior is indicative for triplet-triplet annihilation. Actually, the same linear relationship between the $k_{meas.}$ value an I_0 was found for the decay of the absorption at all wavelengths and the decay of the emission at λ=500 nm (straight line 1, in Fig. 5). On the other hand, a slope about twice that of straight line 1 was found for straight line 2, obtained by monitoring the decay of the delayed fluorescence at λ=360 nm. As a matter of fact, the decay rate constant of the P-type delayed fluorescence should be twice as large as the triplet decay rate constant. These results confirm the assumed attribution of the transient absorption spectrum recorded immediately at the end of the flash to the triplet states.

4. Dependence of the Triplet Decay Rate on the Absorbed Photons. In a simplified way, the triplet decay can be considered being due to two Reactions, 1 and 2;

$$T_1 \xrightarrow{\Sigma k'} S_0, \quad (1)$$

$$T_1 + T_1 \xrightarrow{k'_{T-T}} 2\,S_0, \quad (2)$$

where $\Sigma k'$, and k'_{T-T} are the apparent rate constants of all first order (including self-quenching) and second-order (T-T annihilation) processes respectively. The rate of the triplet decay is given by Eq. 3:

$$-\frac{d[T]}{dt} = \Sigma k'[T] + k'_{T-T}[T]^2, \quad (3)$$

By dividing both sides of Eq. 3 by [T], the triplet concentration, Eq. 4 is obtained:

$$-\frac{d[T]}{[T]dt} = \Sigma k' + k'_{T-T}[T]. \quad (4)$$

The left side of Eq. 4 can be transformed into $[-d(\ln[T])/dt\ (\equiv k_{meas.})]$. Figure 5 shows that the $k_{meas.}$ values is directly proportional to I_0. The initial triplet concentration, $[T]_0$, is obtained from I_0 using a quantum yield of the intersystem crossing, $\phi_{ic}=1.0$ (propanone[5] and butanone[6]) and 0.63 (2-pentanone).[7]

The experimental decay rate constant, $k_{meas.}$ is expressed by Eq. 5:

$$k_{meas.} = \Sigma k' + k'_{T-T}[T]_0. \quad (5)$$

Figure 6 shows the plots of the $k_{meas.}$ values, determined by the absorption measurements at various initial concentrations of the carbonyl compounds ($[S_0]$), *vs.* $I_{abs.}$, which is proportional to $[T]_0$. For all initial concentrations of the carbonyl compound, the plots yielded straight lines being parallel to each other.

As far as the T-T annihilation is concerned, it has to be taken into account that two pathes are possible as is shown below;

$$T_1 + T_1 \xrightarrow{\alpha} S_1^* + S_0, \quad (6a)$$

$$T_1 + T_1 \xrightarrow{(1-\alpha)} 2\,S_0. \quad (6b)$$

Here, α denotes the portion of the triplet states reacting accordig to Reaction 6a which regenerates the triplet state *via* the intersystem crossing ($S_1^* \rightarrow T_1$). This process occurs rather rapidly, *i.e.* the singlet lifetime (∠10 ns[13]) is much shorter than the triplet lifetime. Consequently, the apparent rate constant, k'_{T-T}, is related to the rate constant of the T-T annihilation, k_{T-T}, according to Eq. 7:

Table 1. Triplet decay rate constants $\sum k_T$, and rate constants of triplet-triplet annihilation. k_{T-T}, and self-quenching $k_{self.}$

Compound	$\sum k_T \times 10^{-6}$	$k'_{T-T} \times 10^{-9}$	$k_{self.} \times 10^{-6}$
	s^{-1}	$dm^3\ mol^{-1}$	s^{-1}
Propanone	0.16	3	3
Butanone	0.73	7	6
2-Pentanone	3.8	6	6

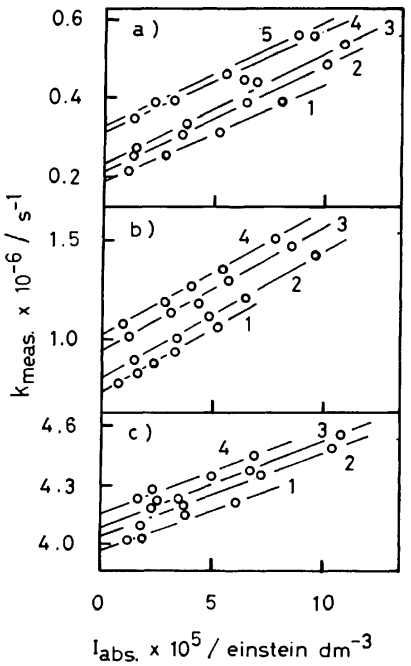

Fig. 6. The triplet decay rate, $k_{meas.}$, as a function of the absorbed photons per flash observed with the ketone solutions of various concentration in dichloromethane. a: [propanone]=1.3 (1) 2.0 (2), 2.6 (3), 5.2 (4), and 6.5 (6)$\times 10^{-2}$ mol dm^{-3}; b: [butanone]= 0.7 (1), 2.1 (2), 4.2 (3), and 5.6 (4)$\times 10^{-2}$ mol dm^{-3}; c: [2-pentanone]=0.7 (1), 1.4 (2), 2.0 (3), and 3.4 (4)$\times 10^{-2}$ mol dm^{-3}.

$$k'_{T-T} = (1-\alpha\,\phi_{ic}/2)\,k_{T-T}. \quad (7)$$

The values of k'_{T-T}, obtained from the slope of the straight lines in Fig. 6, are listed in Table 1. Because α is not known, the values of k_{T-T}, could not be calculated.

5. Self-quenching. The intercept of the straight lines in Fig. 6 corresponds to the values of $\sum k'$, in Eq. 5. The plots of $\sum k'$, obtained with the three carbonyl compounds, *vs.* the carbonyl concentration are shown in Fig. 7. The straight lines observed reflect the dependence of $\sum k'$, on the carbonyl concentration according to Eq. 8;

$$\sum k' = \sum k_T + k_{self.}[S_0], \quad (8)$$

where $k_{self.}$ is the rate constant of the self-quenching reaction: $S_0 + T_1 \rightarrow S_0 + S_0$ and $\sum k_T$ is the sum of all the first-order rate constants. The values of $\sum k_T$ and $k_{self.}$ obtained from the intercept and the slope of the straight lines in Fig. 7 are given in Table 1. The $\sum k_T$ values found with propanone and butanone are

Concentrations of carbonyl compounds: 3.0×10^{-2} mol dm^{-3}. Flashed photons: 2.0×10^{-8} einstein per flash, a) pseudo first order rate constants (error limit: ±20%), b) Ref. 17, c) Ref. 18, d) Ref. 19.

greater than the values previously reported [$\sum k_T = 2.1 \times 10^4$ s^{-1} (propanone in acetonitrile)[2] and 7.7×10^4 s^{-1} (butanone in the gas phase)[6]]. The $k_{self.}$ value is in the order of 10^6 dm^3 mol^{-1} s^{-1}.

6. Reaction of Triplets with Molecular Oxygen. Oxygen was found to quench the triplet states very effectively. Rate constants, k_{O_2}, were determined by measuring the triplet decay rate in O_2-saturated solution ($k_{meas.O_2}$) by using Eq. 9:

$$k_{meas.O_2} = k_{meas.} + k_{O_2}[O_2]. \quad (9)$$

As can be seen from Table 2, $k_{O_2} = (3.0 \pm 1.5) \times 10^{10}$ dm^3 mol^{-1} s^{-1} was found, *i.e.* the reaction of O_2 with the triplet states of the carbonyl compounds under investigation is encounter-controlled.

7. Solvent Effects. Three additional solvents were used in this work besides dichloromethane; acetonitrile, methanol, and hexane. As can be seen from Table 2, $k_{meas.}$ value is the same within the error limit, except for hexane. The hydrogen abstraction reaction, presumable, becomes important in hexane and thus leads to faster triplet decay rates.

Conclusion

Propanone, butanone, and 2-pentanone were irradiated in dilute solution at room temperature with 15 ns flashes of 265 nm light. The absorption and emission measurements were carried out. The T–T absorption, prompt and the P-type delayed fluorescence, and the phosphorescence were observed. The rate constants of the T–T annihilation and the self-quenching were measured. The k'_{T-T} (*ca.* 5×10^9 dm^3 mol^{-1} s^{-1}) was found to be about four times lower than in the case of benzophenone.[20] This difference might be indicative for the fact that a significant portion of the T–T annihilation reactions regenerate the triplet states *via* $T_1 + T_1 \rightarrow S_1^* + S_0$, following by $S_1^* \rightarrow S_0$. The self-quenching rate constans are much higher than the value reported for propanone (10^3 dm^3 mol^{-1} s^{-1}).[21] Actually, the present values lie in the range of 10^5 to 10^7 dm^3 mol^{-1} s^{-1} pertaining to aromatic carbonyl compounds such as acetophenone and benzophenone.[20]

It appears, that in the case of propanone and butanone the α-cleavage reaction is the most important chemical deactivation process for the triplet states. The same holds for 2-pentanone, despite the fact that the α-hydrogen abstraction leading to the triplet 1,4-biradicals is feasible in this case.

The authors wish to thank Professor Setsuo Takamuku of Osaka University and Assistant Professor Kazuyuki Horie of the University of Tokyo for their useful discussions, and Dr. G. Beck of Hahn-Meitner-Institut für Kernforschung Berlin for his assistance in running the laser flash photolysis apparatus.

Oxygen- and Carbon Monoxide-binding Affinity of the Liposomal Heme under Semiphysiological Conditions

Eishun TSUCHIDA,* Hiroyuki NISHIDE, Makoto YUASA, and Mikiya SEKINE
Department of Polymer Chemistry, Waseda University, Shinjuku-ku, Tokyo 160
(Received June 9, 1983)

Oxygen- and carbon monoxide-binding affinity ($P_{1/2}$) of the [α,α,α,α-*meso*-tetrakis(*o*-pivalamidophenyl)-porphinato]iron(II)-mono(1-dodecyl-2-methylimidazole) complex incorporated in liposome of phosphatidylcholine (abbreviated as liposomal heme) were measured in pH 7.0 aqueous solution at 15—37 °C. The $P_{1/2}(O_2)$ and $P_{1/2}(CO)$ values at 37 °C were 49 and 0.02 mmHg,† respectively. Enthalpy and entropy changes for the reversible bindings were similar to those of hemoglobin. The relationship between temperature and $P_{1/2}$ for the dimyristoylphosphatidylcholine-liposomal heme had a breaking point at *ca.* 24 °C, which agreed with the phase transition temperature of the liposomal heme.

Much effort has been made to mimic natural oxygen carriers like hemoglobin by using modified synthetic iron-porphyrin derivatives.[1-6] Success was reported in oxygen-binding in aprotic and organic solvents but not in aqueous media.

The authors have recently found that the [α,α,α,α-*meso*-tetrakis(*o*-pivalamidophenyl)porphinato]iron(II) (abbreviated as heme) complex of mono(1-dodecyl-2-methylimidazole) incorporated in liposome of phosphatidylcholine (abbreviated as "liposomal heme") binds molecular oxygen reversibly under semiphysiological conditions (in pH 7.0 aqueous media at 37 °C).[7] It was considered that the iron porphyrin complex was embedded in a bilayer of liposome and that the hydrophobic environment of the inner region of liposome protected the oxygen adduct from its proton-driven oxidation.[8] The oxygen-binding and -dissociation proceeded very rapid, and their kinetic constants were comparable to those of hemoglobin (Hb).[9] Oxygen-binding affinity ($P_{1/2}(O_2)$: oxygen pressure at half oxygen-binding) was also preliminarily reported to be similar to that of Hb in blood.[10]

The present paper describes the oxygen- and carbon monoxide-binding affinity ($P_{1/2}(O_2)$ and $P_{1/2}(CO)$) for the liposomal heme composed of dimyristoylphosphatidylcholine (DMPC), dipalmitoylphosphatidylcholine (DPPC), and egg yolk lecithin (EYL) in pH 7.0 phosphate buffer solution at 15—37 °C. The binding-affinity was discussed in connection with the phase state of phospholipid, which was estimated by differential scanning calorimetry (DSC) and the fluorescence polarization method.

Experimental

Preparation of Liposomal Hemes. [α,α,α,α-*meso*-Tetrakis(*o*-pivalamidophenyl)porphinato]iron(III) bromide was prepared as reported.[11,12] 1-Dodecyl-2-methylimidazole (DMI) was prepared by the reaction of dodecyl bromide with 2-methylimidazole at 200 °C: bp 150 °C/1.5 mmHg; Found: C, 76.1; H, 12.9; N, 11.0%; C/N, 6.91, Calcd for $C_{16}H_{30}N_2$: C, 76.8; H, 12.0; N, 11.2%; C/N, 6.86; NMR ($CDCl_3$) δ=0.95 (3H, dodecyl-CH_3), 1.30—1.85 (20H, dodecyl-$(CH_2)_{10}$-), 2.30 (s, 3H, imidazole 2-CH_3), 3.90 (t, 2H, Im-CH_2-), 6.90 (d, 1H, imidazole 4 or 5-CH), 6.95 (d, 1H, imidazole 4 or 5-CH) ppm.

Dimyristoylphosphatidylcholine (DMPC) and dipalmitoylphosphatidylcholine (DPPC) were purchased from Sigma Co. (special grade). Egg yolk lecithin (EYL) was obtained and purified by the reported method.[13]

The iron porphyrin (1 μmol), 1-dodecyl-2-methylimidazole (50 μmol) and phosphatidylcholine (200 μmol) were mixed in dichloromethane. By evaporating the solution under reduced pressure, a thin film was prepared on the glass wall of a round flask. Oxygen-free pH 7.0 M/15 phosphate buffer solution (20 cm^3) was added, and the mixture was ultrasonicated and homogenized in an ice-water bath. Then a small excess of L-ascorbic acid (20-fold mol of the iron(III)) was added to the solution under nitrogen atmosphere, and the mixture was incubated at room temperature for 2 h. The red transparent solution showed the ultraviolet (UV) and visible absorption spectrum with maxima at 438, 535, and 562 nm, which agreed with the pentacoordinate deoxy complex of the liposomal heme.[7]

Oxygen-binding Equilibrium Curve. An oxygen adduct (λ_{max}=422 and 546 nm) of the liposomal heme was formed by bubbling oxygen gas through the solution. The spectral change in visible region was measured with a spectrophotometer (Hitachi Co., UV-320) and the oxygen concentration in the solution was monitored with an oxygen probe (Yellow Springs Instrument Co., YSI 5331) at the same time, after equilibrium was reached. Equilibrium between the deoxy heme and the oxygen adduct was shown in Fig. 1 (a); the visible absorption spectrum changes through isosbestic points at 520, 536, 552, and 589 nm by bubbling oxygen and nitrogen gas. The percentage of oxygen-binding was calculated from the differential absorbance at 562 nm.

For reference, the red blood cell suspension was prepared by the method of Imai.[14] The oxygen-binding equilibrium curve of the red blood cell suspension was measured with the above-mentioned apparatus; it was consistent with the curve reported.[14,15] This result supports the validity of the measurements in the present experiment.

Carbon Monoxide-binding Equilibrium Curve. The carbon monoxide adduct (λ_{max}=423 and 540 nm) was formed by bubbling the mixture gas of carbon monoxide and nitrogen; the carbon monoxide concentration was determined by infrared spectroscopy. Equilibrium between the deoxy heme and the carbon monoxide adduct was shown in Fig. 1(b); the UV (Soret band) absorption spectrum was changed through isosbestic points at 403, 431, and 464 nm. The percentage of carbon monoxide-binding was calculated from the differential absorbance at 438 nm after equilibrium was reached.

Differential Scanning Calorimetry (DSC) Measurement. The liposome solution of DMPC(2.5 mmol dm^{-3}) and the DMPC-liposomal heme solution were prepared in the same manner as above. The DSC thermogram of these samples were measured with a differential scanning calorimeter (Seiko Co., SSC-560U).

† 1 mmHg≈133.3 Pa.

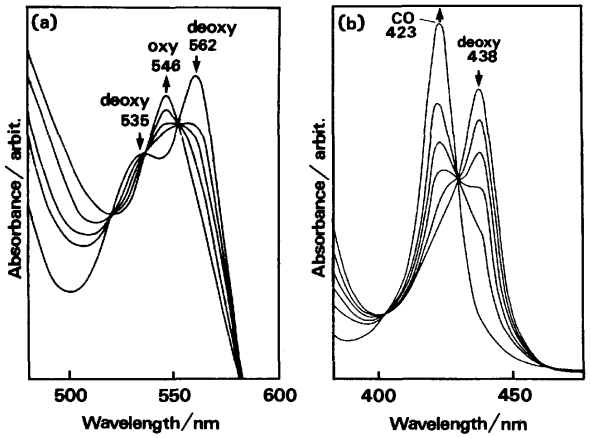

Fig. 1. Visible spectra of the DMPC-liposomal deoxy-heme and its oxygen adduct (a) and ultraviolet spectra of the DMPC-liposomal deoxy-heme and its carbon monoxide adduct (b) in pH 7.0 phosphate buffer solution at 37°C.
[heme]=0.05 mmol dm^{-3}. After bubbling oxygen: $P(O_2)$=0, 25, 50, 100, 760 mmHg (a); after bubbling carbon monoxide: $P(CO)$=0, 0.0034, 0.0071, 0.014, 0.034, 760 mmHg (b).

Fluorescence Measurement. Fluorescent compounds, 1,6-diphenyl-1,3,5-hexatriene (DPH) and 8-anilino-1-naphthalenesulfonic acid (ANS), were used as probes for monitoring fluidity in the liposome lipid layers. A thin film composed of heme (0.075 μmol), DMI (3.76 μmol), and DMPC (15 μmol) was prepared according to the above mentioned method. For labelling, DPH (0.05 μmol) or ANS (0.5 μmol) and phosphate buffer solution (5 cm^3) were added and the mixture was ultrasonicated and homogenized in an ice-water bath. In a similar manner, the fluorescent probe-labelled liposome of DMPC was prepared. Fluorescence intensity was measured by fluorescence polarimeter (Japan Spectroscopic Co., JASCO FP-550). The lights at 360 and 366 nm were used for excitation of liposome-incorporated DPH and ANS , respectively. Fluorescence intensities (I) were measured at 433 nm for DPH and 480 nm for ANS, respectively. Fluorescence polarization (P) was calculated by the equation: $P=(I_{\parallel}-I_{\perp})/(I_{\parallel}+I_{\perp})$, where $I_{\parallel}$ and $I_{\perp}$ are the fluorescence intensities polarized parallel and perpendicular to the direction of polarization of the excitation beam, respectively, and simultaneously measured.

Results and Discussion

The oxygen-binding equilibrium curve of the DMPC-liposomal heme was shown in Fig. 2. Deviation of the oxygen-dissociation curve from this oxygen-binding curve was within 5%; the former was obtained by measuring the oxygen-binding % from the oxygen adduct to the deoxy state by bubbling nitrogen gas and the latter from the deoxy state to the oxygen adduct by bubbling oxygen gas. Figure 2 shows that oxygen-binding equilibrium curve is hyperbolic like that of myoglobin (Mb). ($P_{1/2}(O_2)$) of the DMPC liposomal heme is 49 and 22 mmHg at 37 and 25°C, respectively. The ($P_{1/2}(O_2)$) value at 25°C is comparable with the previously reported ($P_{1/2}(O_2)$) value (=38 mmHg at 25°C) of the heme complex with 1,2-dimethylimidazole in toluene.[16,17] Figure 2 also means that the ($P_{1/2}(O_2)$) value of the liposomal heme in aqueous medium is close to $P_{1/2}$ (*ca.* 27 mmHg at 37°C) of Hb in blood[18] but is fairly far from that (0.9 mmHg at 37°C) of Mb.[19] This suggests that the liposomal heme has a potential to act as an oxygen carrier, under physiological conditions, which transports oxygen from the lung ($P(O_2)$=*ca.* 110 mmHg) to Mb in muscle tissue as Hb does.

The carbon monoxide-binding equilibrium curve (Fig. 3) of the DMPC-liposomal heme is also hyperbolic like that of Mb. The $P_{1/2}$ (CO) value is 0.020 and 0.0075 mmHg at 37 and 25°C, respectively. The latter value agrees with the $P_{1/2}$ (0.0089 mmHg at

[heme]=0.01 mmol dm^{-3}.

25 °C) of the corresponding heme complex in toluene.[20] These gaseous molecule-binding affinities of the liposomal heme suggest that the heme complex behaves as in toluene, although it is solubilized in the aqueous medium.

The oxygen-binding and -dissociation behaviors of the DPPC- and EYL-liposomal hemes were the same as that of the DMPC-liposomal heme except for the $P_{1/2}$ (O_2) of the DPPC-liposomal heme at 37 °C.

Temperature (T)-dependence of $P_{1/2}(O_2)$ and $P_{1/2}$(CO), *i.e. van't Hoff plots*; *ln* $(760/P_{1/2})$ vs. $1/T$, were shown in Figs. 4 and 5. The van't Hoff plots for the oxygen binding of the DPPC- and EYL-liposomal heme give linear relationships. On the other hand, the temperature dependences of oxygen- and carbon monoxide-binding for the DMPC-liposomal heme have breaking points at *ca.* 24 °C. Enthalpy change (ΔH) and entropy change (ΔS) for the oxygen- and carbon monoxide-binding equilibrium were determined and were given in Table 1. $\Delta H(O_2)$ and $\Delta S(O_2)$ for the oxygen-binding of the EYL-liposomal heme and the DMPC-liposomal heme (above 24 °C) were estimated to be *ca.* −15 kcal mol^{-1} and *ca.* −45 eu†, respectively. These values are comparable to those of the corresponding heme complex in toluene[17] and those of Hb[19,21] and Mb.[19,22] They are also comparable to those of iron(II) protoporphyrin *IX* N-[3-(1-imidazoryl)propyl]amide, which was previously evaluated with kinetic methods in aqueous medium.[23] This result indicates that the oxygen- and carbon monoxide-binding by the EYL-liposomal heme and DMPC-liposomal heme (above 24 °C) proceed in the same way as do the bindings by Hb, Mb and iron porphyrin complexes.

On the contrary, both $\Delta H(O_2)$ and $\Delta S(O_2)$ values for the DPPC-liposomal heme and the DMPC-liposomal heme (below 24 °C) are much larger than those of the others (Table 1). The phospholipid environment gives a large effect on the oxygen-binding affinity of the heme through its enthalpy contribution. ΔH(CO) and ΔS(CO) for the DMPC-liposomal heme (below 24 °C) are also much larger than those above 24 °C. One can say that the gaseous molecule-binding affinity is relatively decreased for the DPPC-liposomal heme and the DMPC-liposomal heme (below 24 °C) because the enthalpy gain in the binding equilibrium is much reduced (*ca.* 10 kcal mol^{-1}).

The liposome of DPPC has its transition temperature (T_c) between gel and liquid crystal phase of phospholipid at 41 °C, and the liposome of EYL has it at −15—−7 °C.[24] It is reasonable to assume that the DPPC-liposomal heme is situated below its T_c and the EYL-liposomal heme is above its T_c under these experimental conditions. The liposome of DMPC has its T_c at 23 °C[24]; T_c of the DMPC-liposomal heme was measured as described below.

DSC thermograms are shown in Fig. 6. The DMPC-liposome gives T_c at 24 °C, which agrees with the literature datum.[24] For the DMPC-liposomal

† 1 eu=1 cal mol^{-1} K^{-1}.

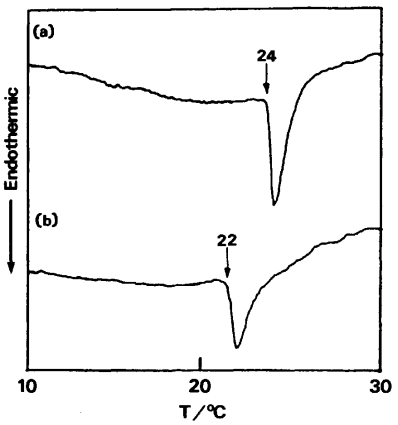

Fig. 6. DSC thermograms of the DMPC-liposome (a) and the DMPC-liposomal heme (b). [DMPC]=2.5 mmol dm^{-3}.

heme, the endothermic peak is brodened and shifted to the lower temperature at 22 °C. This means that incorporation of the heme complex into the phospholipid bilayer causes partial disorder in the alkyl chain orientation of phospholipid molecules.

Fluorescence measurement on the liposomal heme was carried out to monitor fluidity in the liposome lipid layers by using DPH and ANS. DPH is known as the probe embedded in the hydrophobic region of the liposome,[25] and ANS is the probe in the hydrophilic region.[26] The reciprocal of the degree of fluorescence polarization ($1/P$) is a parameter to represent the fluidity in the liposome lipid layers; values are given in Fig. 7. Figure 7(a) shows T_c obserbed at 24 °C for the DMPC-liposome and the DMPC-liposomal heme, and Fig. 7(b) shows values at 24 °C for the former and at 21 °C for the latter. From these data, one can say at least that the DMPC-liposomal heme has its T_c at *ca.* 24 °C.

Thus T_c of the DMPC-liposomal heme agrees with the breaking point of the temperature dependence of oxygen- and carbon monoxide-binding by the DMPC-liposomal heme. The oxygen- and carbon

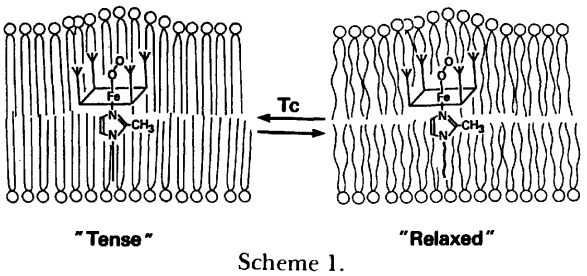

Scheme 1.

monoxide-binding affinity of the liposomal heme is dependent on the phase state of the phospholipid.

The solubility of oxygen in a DPPC-liposome has been previously reported;[27] it was slightly affected by the phase state of the phospholipid. Thus the dependence of gaseous molecule-binding affinity on T_c can not be explained only by the solubility of oxygen in the liposome phospholipid layer.

The gaseous molecule-binding affinity of the liposomal heme may be explained by using Scheme 1 as follows. Above T_c, phospholipid molecules are in the liquid crystal state, which provides an environment just like organic solvents such as toluene around heme; the heme complex is in a "*relaxed*" state, and the gaseous molecule-binding affinity and the ΔH values are comparable with those of the corresponding heme complex in toluene and with those of Hb and Mb. On the other hand, below T_c, phospholipid molecules are in the crystal state which causes an orientation of the DMI ligand; this is supported by the existence of the phase transition for the liposomal heme as well as the liposome without the heme complex (see the results by the DSC and fluorescence measurements). The orientation of the DMI ligand probably causes a structural distortion of the heme complex, because the bulky heme molecule is embedded in the phospholipid-DMI bilayer in the crystal state. The heme complex is in a "*tense*" state, and this may be one of the reasons for the low oxygen-binding affinity of the DMPC-liposomal heme (below T_c) and the DPPC-liposomal heme. The "*tense*" and "*relaxed*" states of the heme complex for the liposomal heme are not the same ones as the tense(T)- and relaxed(R)-states for Hb; The latter are caused by globin protein. But the gaseous molecule-binding phenomenon of the liposomal heme resembles that of Hb.

This work was partially supported by a Grant-in-Aid for Special Project Research (Design of Multiphase Biomedical Materials, No. 57219016) from the Ministry of Education, Science and Culture.

A New and Effective Synthetic Method for the Preparation of the Esters, Peptides, and Lactones Using 3-(5-Nitro-2-oxo-1,2-dihydro-1-pyridyl)-1,2-benzisothiazole 1,1-Dioxide. Synthesis of (±)-(*E*)-8-Dodecen-11-olide, Recifeiolide

(Received July 8, 1983)

3-(5-Nitro-2-oxo-1,2-dihydro-1-pyridyl)-1,2-benzisothiazole 1,1-dioxide (BID-NPy), readily prepared from 3-chloro-1,2-benzisothiazole 1,1-dioxide and 5-nitro-2-pyridone, proved to be a very useful condensing reagent. A variety of esters, dipeptides, and lactones were obtained in excellent yields. Furthermore, BID-NPy was successfully employed for the lactonization step in a new synthesis of a naturally occurring (±)-(*E*)-8-dodecen-11-olide, recifeiolide.

Saccharin is a commercially available industrial product. Its derivative, 3-chloro-1,2-benzisothiazole 1,1-dioxide (BID-Cl) was found to have reactivities as a condensing reagent and has been utilized in the preparation of some peptides.[1] However, the yields were not so good and BID-Cl was found to be very unstable to moisture and could not be stored for a long time. Therefore, we tried to prepare various saccharin derivatives, which are generally stable crystalline compounds,[2] and found that 3-(5-nitro-2-oxo-1,2-dihydro-1-pyridyl)-1,2-benzisothiazole 1,1-dioxide (BID-NPy) (**1**) was a new condensing reagent for the preparation of esters, peptides, and lactones.

BID-NPy was easily prepared by the reaction of BID-Cl and 5-nitropyridone in dry CH_3CN in the presence of triethylamine (TEA). The structure of **1** was confirmed by elemental analysis. The IR spectrum cleanly showed the presence of the carbonyl group at 1670 cm^{-1}. This compound was quite stable on storage.

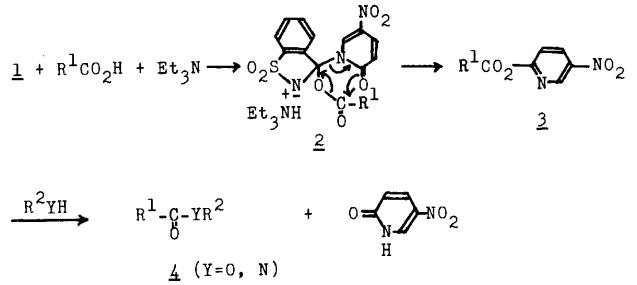
a) This means *N*-protected amino acids (Y=Z or Boc).

First, **1** was allowed to react with a carboxylic acid in order to check its reactivity. A suspension of equimolar amount of phenylacetic acid, benzyl alcohol, and **1** in dichloromethane was treated with 1 equiv of TEA at −10°C to room temperature under N_2 to give the expected benzyl phenylacetate in 95% yield. In a similar manner, a variety of esters were obtained in excellent yields, as shown in Table 1. BID-NPy also proved to be an excellent reagent for synthesizing various protected dipeptide esters. The results are shown in Table 2.

The probable course of the reactions of **1** with acids is illustrated in Scheme 1. Formation of the activated ester (**3**, R′= CH_2Ph) could be actually isolated.



Scheme 1.

The preliminary results of ester and amide bond formation with BID-NPy encouraged us to use it to make macrolide. Initially, when TEA was added to a suspension of ω-hydroxy carboxylic acid and **1** (equimolar amount) in dichloromethane at room temperature under N_2 and the reaction mixture was stirred overnight, the yields of the corresponding lactones were not satisfactory. Many attempts to improve the yields under various conditions were unsuccessful. However, when a catalytic amount of *p*-toluenesulfonic acid (TsOH) was added to the reaction mixture, the yield of lactone was increased. Thus, the active ester prepared by the addition of equimolar amount of TEA to a suspension of carboxylic acids **5a—g** and **1** in 1,2-dichloroethane was added dropwise to a refluxing 1,2-dichloroethane containing 2 equiv of TsOH in a period of 6 h using a mechanically driven syringe. The usual work-up of the reaction mixture gave monolides in quite high yields with a small amount of diolides. Such an effect of the acid catalyst seems to be due to the activation of the intermediary active ester, as shown in 7. The results are listed in Table 3.

TABLE 3 LACTONIZATION OF ω-HYDROXY CARBOXYLIC ACIDS

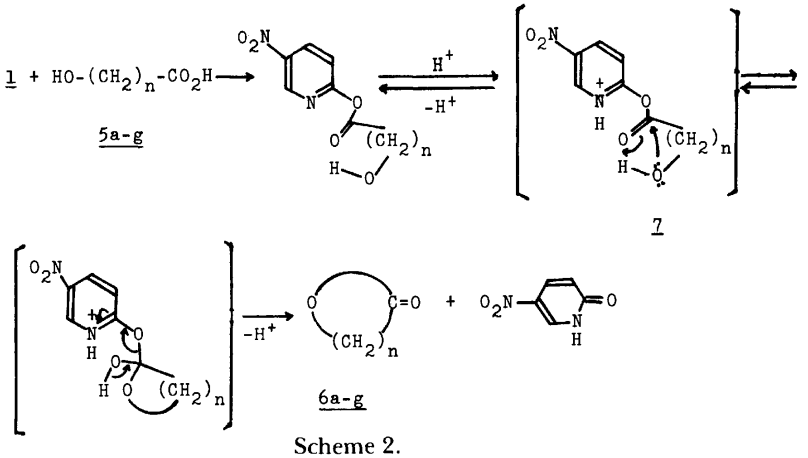
	Hydroxy acids	Lactones(**6a—g**) Ring size	Yield/%
5a	$HO(CH_2)_{10}CO_2H$	12	72
5b	$HO(CH_2)_{11}CO_2H$	13	71
5c	$HO(CH_2)_{12}CO_2H$	14	86
5d	$HO(CH_2)_{14}CO_2H$	16	88
5e	$HO(CH_2)_{15}CO_2H$	17	81
5f	$CH_3(CH_2)_5CH(OH)(CH_2)_{10}CO_2H$	13	86
5g	$CH_3(CH_2)_5CH(OH)CH_2$-Z-$CH{=}CH(CH_2)_7CO_2H$	13	68

The yields of the monolides from ω-hydroxy carboxylic acids (**5a—g**) are comparable to those obtained by any existing methods.[3]

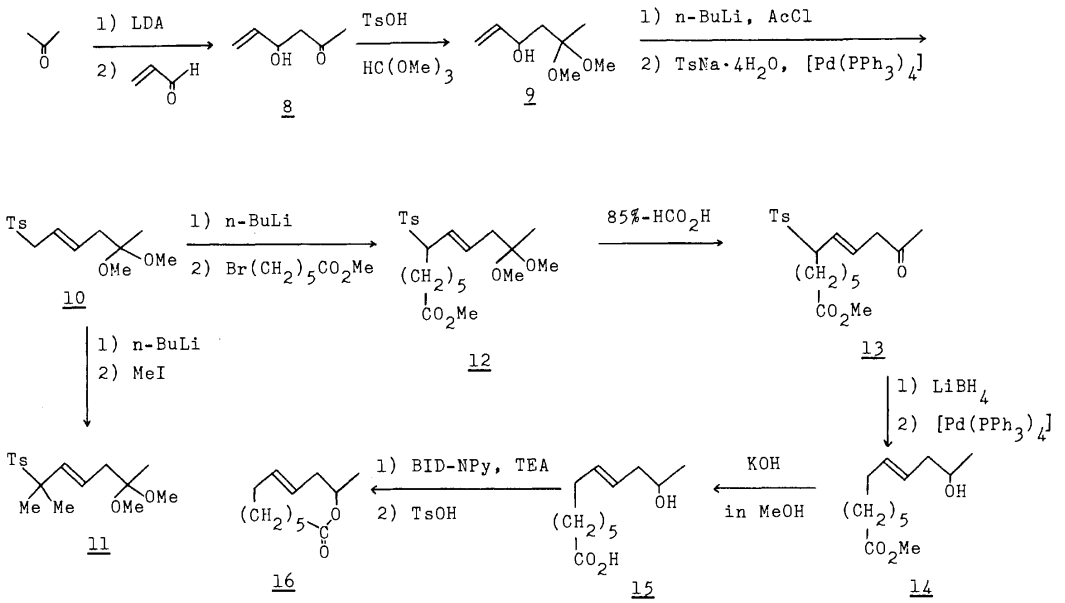
The starting materials (**5a**, **5c**, and **5d**) have been effectively made by modified Baeyer-Villiger oxidation[4] of the corresponding ketones. It was found that the addition of boron trifluoride etherate was quite effective for the oxidation of the ketones with *m*-chloroperbenzoic acid (MCPBA) in chloroform. The resulting lactones were directly saponified to give the corresponding ω-hydroxy carboxylic acids **5a**, **5c**, and **5d**, in 69, 78, and 82% yields, respectively.

Based on these results, we examined how to apply **1** to the synthesis of a naturally occurring macrolide, (±)-recifeiolide (**16**) isolated from *fungus Cephalosponim recifei*,[5] by the cyclization of (±)-11-hydroxy-(*E*)-8-dodecenoic acid (**15**).[6]

In the synthesis of **15**, one of the important points is the creation of the carbon-carbon double bond at C-8 of the chain with *E*-stereochemistry. In this regard, recently a convenient method for the preparation of allylic sulfones from the corresponding allylic acetate has been invented in our laboratory.[7] The stereochemistry of the double bond in the resulting allylic sulfones was completely *E*-form. Based on this finding, the synthesis of **16** was carried out according to



Scheme 2.



Scheme 3.

Scheme 3.

The reaction of acrylaldehyde with lithiated acetone in THF at −78°C gave the hydroxy ketone (**8**) in 89% yield. Acetalization of the carbonyl group of **8** by the use of 3 equiv of methyl orthoformate gave the compound (**9**) in 82% yield. The hydroxyl group of **9** was acetylated with *n*-BuLi and acetyl chloride. The crude acetate was converted to the corresponding sulfone (**10**) using a catalytic amount of $[Pd(PPh_3)_4]$ (5 mol%) and sodium *p*-toluenesulfinate in THF–MeOH in 78% yield from **9**. Stereochemistry[7,8] of the double bond in **10** was confirmed to be *E*-form by NMR spectrum of its dimethyl product (**11**), that is, the coupling constant between the two olefinic protons was 15.2 Hz. Treatment of the compound (**10**) with *n*-BuLi in the presence of HMPA, followed by the addition of 1.1 equiv of methyl 6-bromohexanoate, gave the alkylated product (**12**) in 90% yield. Deprotection of the acetal group of **12** by the treatment with 85% formic acid for 1 min at room temperature gave the keto ester (**13**) in 95% yield. Reduction of the carbonyl group to the alcohol and the subsequent detosylation[9] were accomplished in one-pot as follows: A solution of **13** in THF was treated with $LiBH_4$ at −10°C for 5 min and then $[Pd(PPh_3)_4]$ (6 mol%) was added. The mixture was allowed to stand for 1.5 h at room temperature to yield the hydroxy ester (**14**) in 72% yield. Its NMR and IR spectra were completely in accordance with the reported ones.[6] Hydrolysis of **14** with 40%-methanolic KOH solution gave the hydroxy acid (**15**) as a precursor of recifeiolide in 97% yield. It was lactonized using BID–NPy by high dilution method. The active ester derived from the reaction of **15** with **1** in 1,2-dichloroethane at −5°C was added slowly to a refluxing 1,2-dichloroethane containing 2 equiv of TsOH in a period of 15 h under N_2. The desired product (**16**) was separated in 81% yield with a preparative TLC.

As mentioned above, BID–NPy was found to be a versatile condensing reagent for the preparation of esters, peptides, and macrolides.

Experimental

All the melting points were determined with a micro melting apparatus (Yanagimoto-Seisakusho) and were uncorrected. The ^{1}H-NMR and IR spectra were recorded on JEOL JNM-PMX-60 and JASCO IRA-1 diffraction grating infrared spectrometer, respectively. The chemical shifts are recorded in the δ scale relative to TMS as an internal standard. For the reactions requiring slow addition, a Natume syringe pump, model KN-202, was used.

Materials. All the solvents were distilled and stored over a drying agent. Thin-layer chromatography (TLC) was performed on Merck's silica gel 60 PF_{254} (Art. 7749).

Preparation of BID-Cl. A mixture of $SOCl_2$ (10.62 g, 90 mmol) and saccharin (5.50 g, 30 mmol) was refluxed for 15 h in dioxane (100 ml) in the presence of active charcoal (0.8 g) and a catalytic amount of DMF (0.19 g, 2.6 mmol). The hot reaction mixture was filtered through celite to remove the charcoal. After evaporation of the solvent *in vacuo*, the resulting product was recrystallized from dry benzene. Yield, 4.60 g, 76%. Mp 145—147°C (lit, 143—145°C).[10] This BID-Cl was found to be unstable to moisture and thus was kept under vaccum.

Preparation of BID-NPy (1). To a suspension of BID-Cl (2.02 g, 10 mmol) and 5-nitro-2-pyridone (1.12 g, 8 mmol) in dry CH_3CN (25 ml) was added TEA (0.81 g, 8 mmol) at 0°C. A yellowish white crystalline precipitate started to separate almost immediately. After the suspension was stirred for 2 h at room temperature, the precipitate was filtered, washed with chloroform to remove triethylammonium chloride and recrystallized from CH_3CN to give pure BID-NPy (**1**) in 77% yield. 1.89 g, mp 239—241°C; IR (KBr) 3100, 1670, 1605, 1560, 1350, 1180 cm^{-1}; Found: C, 47.24; H, 2.18; N, 13.54%. Calcd for $C_{12}H_7N_3O_5S$: C, 47.22; H, 2.31; N, 13.77%.

Preparation of Esters from Carboxylic Acids and Alcohols. To a mixed suspension of **1** (152 mg, 0.5 mmol), phenylacetic acid (68 mg, 0.5 mmol), and benzyl alcohol (54 mg, 0.5 mmol) in CH_2Cl_2 (3 ml) was added a solution of TEA (51 mg, 0.5 mmol) in CH_2Cl_2 (2 ml) at −10°C under N_2. The suspension became clear after a few minutes as the slightly soluble **1** was consumed in the progress of the reaction. The reaction mixture was gradually raised to room temperature.

After stirring overnight, the solvent was evaporated *in vacuo* and the resulting residue was taken up in AcOEt (30 ml). This was then washed successively with a saturated solution of $NaHCO_3$, with 1 mol dm^{-3} HCl, and with brine. The resulting residue was then subjected to preparative TLC (solvent; benzene: AcOEt=5:1, v/v) to afford 112 mg of benzyl phenylacetate, (95% yield). An oil.[17] IR (neat) 1735 cm^{-1}; NMR ($CDCl_3$) δ=3.50 (s, 2H), 4.98 (s, 2H), 7.13 (s, 5H), 7.15 (s, 5H).

The other esters shown in Table 1 were prepared in a similar manner.

Benzyl Cinnamate: IR (neat) 1710,1630, 1160 cm^{-1}; NMR ($CDCl_3$) δ=5.09 (s, 2H), 6.29 (d, J=17 Hz, 1H), 7.22 (m, 10H). p-*Nitrophenyl Phenylacetate*: Mp 61—63 °C (lit, 62—63 °C).[18] 2,2,2-*Trichloroethyl Benzoate*: IR (neat) 1735, 1235, 1138 cm^{-1}; NMR ($CDCl_3$) δ=4.92 (s, 2H), 7.42—7.62 (m, 3H), 8.0—8.13 (m, 2H).[19] *Pentachlorophenyl Benzoate*: Mp 159—161 °C (lit, 159—160 °C).[19] p-*Nitrophenyl Benzoate*: Mp 142—144 °C (lit, 142 °C).[19] N-*(Benzoyloxy) Succinimide*: Mp 137—139 °C (lit, 139—140 °C).[17]

Preparation of Benzyloxycarbonyl Dipeptide Esters. Z--Cys(Bzl)-Gly-OEt: To a mixed suspension of **1** (152 mg, 0.5 mmol) and Z-Cys(Bzl)-OH (173 mg, 0.5 mmol) in CH_2Cl_2 (3 ml) was added a solution of TEA (51 mg, 0.5 mmol) in CH_2Cl_2 (2 ml) dropwise at −10 °C under N_2. After stirring for 2 h at −10 °C, H-Gly-OEt·HCl (70 mg, 0.5 mmol) and a solution of TEA (51 mg, 0.5 mmol) in CH_2Cl_2 (2 ml) were successively added to the reaction mixture. The solution was stirred at 0 °C for 2 h and stirring was continued overnight at room temperature. The solvent was evaporated *in vacuo* and the resulting residue was taken up in AcOEt (30 ml). This was then successively washed with a saturated solution of $NaHCO_3$, with 1 mol dm^{-3} HCl, and with brine, dried over Na_2SO_4, and evaporated to dryness *in vacuo*. The resulting residue was subjected to preparative TLC (solvent; benzene: AcOEt=1:1, v/v) to separate the desired product. Recrystallization from benzene-hexane gave the product, Z-Cys(Bzl)-Gly-OEt, in quantitative yield (208 mg).

In a similar manner, various benzyloxycarbonyl dipeptide esters were prepared, as shown in Table 2.

*Lactonization of ω-Hydroxy Carboxylic Acids. 12-Dodecanolide (**6b**)*: To a suspension of **5b** (43 mg, 0.2 mmol) and **1** (61 mg, 0.2 mmol) in 1,2-dichloroethane (95 ml) was added a solution of TEA (21 mg, 0.2 mmol) in 1,2-dichloroethane (5 ml) dropwise at −0 °C in a period of 10 min under N_2. After about 30 min the initial suspension became a clear yellowish solution. Stirring was continued for about 1 h to complete the formation of the active ester. The resulting reaction mixture containing the active ester was added slowly to a refluxing dry 1,2-dichloroethane (50 ml) containing anhydrous TsOH (76 mg, 0.4 mmol) with a mechanically driven syringe in a period of 6 h. After the addition, it was further refluxed for 2 h. The solvent was evaporated *in vacuo* and the resulting residue was partitioned between water and AcOEt. The AcOEt layer was successively washed with 10% $NaHCO_3$, 1 mol dm^{-3} HCl, and brine. The solution was dried over Na_2SO_4 and was evaporated *in vacuo*. The resulting residue was subjected to preparative TLC (solvent; hexane:ether=10:1, v/v). Two fractions were obtained. From the first fraction (R_f=0.64), monolide was obtained as an oil (28 mg, 71%). Its spectral data (IR, NMR), behavior on TLC, and GLC were identical with the authentic sample. MS m/z 198 (M^+); IR (neat) 1735, 1245 cm^{-1}; NMR ($CDCl_3$) δ=1.1—2.0 (m, 18H), 2.35 (t, J=6 Hz, 2H), 4.15 (t, J=6 Hz, 2H). The crystalline substance obtained from the second fraction (R_f=0.52) was found to be the dimeric lactone by comparison with the authentic sample. 7 mg, 18%; mp 102—103 °C (lit, 103—104 °C).[3b]

Other ω-hydroxy carboxylic acids (**5a**, **5c—g**) were cyclized in a similar manner.

6a: An oil, MS m/z 184 (M^+); IR (neat) 2930, 2870, 1738, 1465, 1440, 1350, 1245, 1170, 1140, 1090 cm^{-1}; NMR ($CDCl_3$) δ=1.15—1.84 (m, 16H), 2.31 (t, J=6 Hz, 2H), 4.01 (t, J=6 Hz, 2H).

6c: An oil, MS m/z 212 (M^+); IR (neat) 2930, 2845, 1730, 1460, 1370, 1285, 1258, 1225, 1170, 1100 cm^{-1}; NMR ($CDCl_3$) δ=1.06—1.83 (m, 20H), 2.30 (t, J=6 Hz, 2H), 4.13 (t, J=6 Hz, 2H).

6d: Mp 35—36 °C (lit, 34 °C).

6e: After the addtion of the active ester, the reaction mixture was further refluxed for 10 h. MS m/z 254 (M^+); IR (neat) 2940, 2845, 1730, 1460, 1380, 1350, 1250, 1160 cm^{-1}; NMR ($CDCl_3$) δ=1.16—1.83 (m, 26H), 2.30 (t, J=6 Hz, 2H), 4.15 (t, J=6 Hz, 2H).

6f: An oil, MS m/z 282(M^+); IR (neat) 2920, 2860, 1725, 1470, 1370, 1320, 1245, 1170, 1138 cm^{-1}; NMR ($CDCl_3$) δ= 0.93 (t, J=7 Hz, 3H), 1.03—1.86 (m, 28), 2.35 (t, J=6 Hz, 2H), 4.70—5.00 (m, 1H).

6g: An oil, MS m/z 280 (M^+); IR (neat) 2920, 2850, 1720, 1640, 1440, 1360, 1230, 1170 cm^{-1}; NMR ($CDCl_3$) δ=0.93—1.01 (t, J=7 Hz, 3H), 1.02—1.93 (bm, 24H), 2.10—2.46 (bt, 2H), 3.50—4.01 (bm, 1H), 5.35—5.56 (m, 2H).

*Preparation of ω-Hydroxy Carboxylic Acids (**5a**, **5c**, and **5d**). 13-Hydroxytridecanoic Acid (**5c**)*: A solution of cyclotridecanone (0.98 g, 5 mmol) in CH_2Cl_2 (30 ml) was treated with freshly distilled boron trifluoride etherate (0.85 g, 6 mmol) for 15 min. To the reaction mixture was added MCPBA (purity 70%, 2.59 g, 15 mmol) in a period of about 20 min and the reaction mixture was stirred for 15 h at 40 °C. The mixture was cooled and water was added to it. The excess peroxy acid was destroyed by the dropwise addition of 10% solution of Na_2SO_3 and then the layers were separated. The aqueous portion was extracted with CH_2Cl_2 three times. The combined organic extracts were washed with water, dried over Na_2SO_4, and evaporated to dryness *in vacuo*. The crude lactone thus obtained was directly subjected to alkaline hydrolysis with 1 mol dm^{-3} NaOH in methanol and water (4:1). The solution was heated at 60 °C for 1 h. After cooling, the mixture was concentrated to half the volume, diluted with water, and washed with chloroform. The aqueous layer was acidified with 1 mol dm^{-3} HCl (pH=3) at 0 °C to give a crystalline substance. After standing for about 1 h, the precipitate was filtered and recrystallized from 1,2-dichloroethane to give **15c** (0.90 g, 78%). Mp 78—79 °C (lit, 79 °C).[20]

In a similar manner, other carboxylic acids were prepared from the corresponding cycloalkanones.

*11-Hydroxyundecanoic Acid (**5a**)*: 69%, mp 65—67 °C (lit, 66 °C).[21]

*15-Hydroxypentadecanoic Acid(**5d**)*: 82%, mp 80 °C (lit, 82—84 °C).[19]

Preparation of Methyl 6-Bromohexanoate: 6-Bromohexanoic acid prepared by the reported method[19] was treated with diazomethane in ether. Distillation of the crude product gave pure oily product: Bp 72—78 °C/1 Torr: IR (neat) 2950, 1730, 1432, 1251, 1200,1168 cm^{-1}; NMR ($CDCl_3$) δ=1.30—2.13 (m, 6H), 2.30 (t, J=6 Hz, 2H), 3.37 (t, J=6 Hz, 2H), 3.63 (s, 3H).

*4-Hydroxy-5-hexen-2-one (**8**)*. To a solution of diisopropylamine (1.11 g, 11 mmol) in THF (15 ml) was slowly added a solution of *n*-BuLi (*ca.* 15% in hexane, 6.68 ml, 10 mmol) dropwise at −50 °C under N_2. After stirring for about 1 h at −50 °C to −30 °C, the reaction mixture was cooled to −78 °C and a solution of acetone (5.80 g, 10 mmol) in THF (5 ml) was slowly added to the reaction mixture during 1 h. The reaction mixture was stirred for about 30 min at −78 °C to −30 °C and again the temperature was cooled to −78 °C. A solution of acrylaldehyde

(6.72 g, 12 mmol) in THF (2 ml) was added all at once. After 5 min, the reaction mixture was quenched with CH_3OH–HCl. The solution was evaporated to dryness and the residue was partitioned between ether and water. The resulting mixture of products was separated by column chromatography (silica gel, solvent; benzene: AcOEt=3:1 v/v). The desired product was obtained in 89% yield (1.02 g). IR (neat) 3400, 2980, 2930, 1700, 1640, 1420, 1365, 1160, 1120, 1060, 990, 925 cm^{-1}; NMR ($CDCl_3$) δ=2.20 (s, 3H), 2.63 (d, J=6 Hz, 2H), 3.50 (s, 1H), 4.33—4.70 (bm, 1H), 4.94—6.21 (bm, 3H).

5,5-Dimethoxy-1-hexen-3-ol (9). To a solution of **8** (342 mg, 3 mmol) in MeOH (15 ml) in the presence of Molecular Sieves (4A, 1/16, 3 g) was added trimethyl orthoformate (1.32 ml, 12 mmol) at room temperature under N_2. A catalytic amount of TsOH (68 mg, 12 mol%) was added to the reaction mixture and, after stirring for 3 h, it was made slightly basic (pH=8) by adding a saturated solution of Na_2CO_3. The MeOH was removed *in vacuo* and the resulting residue was taken up in chloroform (40 ml). The organic layer was washed with water three times, dried over Na_2SO_4, and evaporated. The resulting residue was subjected to preparative TLC (solvent; benzene: AcOEt=2:1, v/v) to give 393 mg of the desired product (82%). IR (neat) 3460, 3080, 2960, 2840, 1640, 1450, 1420, 1370, 1265, 1220, 1140, 1040, 985, 920 cm^{-1}; NMR ($CDCl_3$) δ=1.26 (s, 3H), 1.80 (bm, 2H), 3.01 (s, 6H), 3.63 (s,1H), 4.13—4.53 (bm, 1H), 4.90—6.20 (bm, 3H).

5,5-Dimethoxy-1-tosyl-2-hexene (10). n-BuLi (3 mmol) was added dropwise to a solution of **9** (480 mg, 3 mmol) in THF (6 ml) at −78 °C under N_2. The mixture was stirred for about 30 min. To the reaction mixture was added a solution of acetyl chloride (273 mg, 3.5 mmol) at −78 °C. After 10 min, the reaction was found to be complete and the mixture was quenched with a buffer solution of K_2HPO_4–NaOH (pH=7). The solvent was evaporated and the residue was taken up in chloroform. The chloroform solution was washed with a small amount of water, dried, and evaporated. The crude product was obtained in quantitative yield and used in the subsequent reaction. IR (neat) 2940, 2840, 1738, 1640, 1420, 1370, 1240, 1040, 925, 845, 800 cm^{-1}; NMR ($CDCl_3$) δ=1.33 (s, 3H), 2.08 (s, 3H) 1.95—2.35 (bm, 2H), 3.20 (s, 6H), 4.95—6.10 (bm, 5H).

Sodium p-Toluenesulfinate Tetrahydrate (0.8 g, 3.2 mmol) was dissolved in MeOH (2 ml) and THF (4 ml) at room temperature under N_2. The crude acetylated compound obtained above (*ca.* 3 mmol) in THF (2 ml) was added to it. A solution of $[Pd(PPh_3)_4]$ (174 mg, 0.15 mmol) in THF (2 ml) was added to the reaction mixture. After 30 min, the clear brownish solution changed to light yellow, accompanied by precipitation, and gradually it turned lemon yellow. After stirring overnight, KCN (36 mg) dissolved in a minimum amount of water was added to the reaction mixture. The solution became colorless. The solvent was evaporated *in vacuo* and the resulting residue was dissolved in CH_2Cl_2 (40 ml) and the insoluble materials were filtered. The filtrate was dried over Na_2SO_4. After removal of the solvent, the residual oil was subjected to preparative TLC (solvent; hexane: AcOEt=2:1, v/v) to give the desired product (**10**) (698 mg, 78%) from **9**. MS m/z 267 (M^+—OMe); IR (neat) 2960, 1735, 1595, 1380, 1360, 1310, 1295, 1280, 1230, 1138, 1080, 1030, 960, 805, 725 cm^{-1}; NMR ($CDCl_3$) δ=1.06 (s, 3H), 2.20—2.40 (bm, 2H), 2.46 (s, 3H), 3.10 (s, 6H), 3.76 (d, J=6 Hz, 2H), 5.30—5.67 (bm, 2H), 7.20 (d, J=8 Hz, 2H), 7.60 (d, J=8 Hz, 2H).

6,6-Dimethoxy-2-methyl-2-tosyl-3-heptene (11). To a solution of **10** (100 mg, 0.34 mmol) in THF (4 ml) was added one equiv of n-BuLi (0.34 mmol) dropwise at −78 °C under N_2. After 10 min, hexamethylphosphoric triamide (HMPA) (0.4 ml) was added and then after 1 h, a solution of CH_3I (53 mg, 0.37 mmol) in THF (1.5 ml) was dropwise added. The reaction mixture was stirred for 2 h at −78 °C, warmed to room temperature, and then cooled down at −78 °C again. This alkylation procedure was repeated once again. The crude material was purified by preparative TLC (solvent; hexane:AcOEt=2:1, v/v) to afford **11** in 53% yield. MS m/z 295(M^+—OMe); IR (neat) 2940, 1590, 1292, 1170, 1150, 1120, 972, 810 cm^{-1}; NMR ($CDCl_3$) δ=1.13 (s, 3H), 1.43 (s, 6H), 2.35 (d, J=7 Hz, 2H), 2.42 (s, 3H), 3.14 (s, 6H), 5.27 (dd, J=7, 15.2 Hz, 1H), 5.60 (d, J=15.2 Hz, 1H), 7.23 (d, J=8 Hz, 2H), 7.57 (d, J=8 Hz, 2H).

Methyl (E)-11,11-Dimethoxy-7-tosyl-8-dodecenoate (12). To a solution of **10** (570 mg, 1.91 mmol) in THF (10 ml) was added 1.1 equiv of n-BuLi at −78 °C under N_2, followed by the addition of HMPA (2 ml) after 20 min. After 1 h, a solution of methyl 6-bromohexanoate (439 mg, 2.10 mmol) in THF (5 ml) was dropwise added in a period of 20 min at −78 °C. The reaction mixture was allowed to stand overnight at room temperature. The usual work-up gave an oily crude product which was purified by preparative TLC (solvent; hexane:AcOEt=2:1, v/v). Yield was 90% (an oil, 737 mg). MS m/z 395 (M^+—OMe); IR (neat) 2950, 1729, 1590, 1295, 1140, 1080, 1045, 968, 805, 750 cm^{-1}; NMR ($CDCl_3$) δ=1.10 (s, 3H), 1.13—2.50 (m, 12H), 2.40 (s, 3H), 3.10 (s, 6H), 3.20—3.53 (m, 1H), 3.60 (s, 3H), 5.17—5.47 (m, 2H), 7.27 (d, J=8 Hz, 2H), 7.56 (d, J=8 Hz, 2H).

Methyl (E)-11-Hydroxy-8-dodecenoate (14). The compound(**12**) (616 mg, 1.45 mmol) was dissolved in 85% formic acid (4.5 ml). The formic acid was immediately removed *in vacuo* to give a residue which was taken up in AcOEt. The organic solution was washed with 10% $NaHCO_3$, brine, and dried over $MgSO_4$. Removal of the solvent gave an oily keto ester (**13**) in 95% yield, which was used in the subsequent reaction without further purification. IR (neat) 2930, 1722, 1710, 1595, 1295, 1135, 1080, 965, 810 cm^{-1}; NMR ($CDCl_3$) δ=1.03—2.37 (m, 12H), 2.03 (s, 3H), 2.43 (s, 3H), 3.08 (d, J=6 Hz, 2H), 3.23—3.57 (m, 1H), 3.63 (s, 3H), 5.27—5.60 (m, 2H), 7.34 (d, J=8 Hz, 2H), 7.59 (d, J=8 Hz, 2H).

To a solution of **13** (86 mg, 0.23 mmol) in THF (2 ml) was added $LiBH_4$ (910 mg, 0.5 mmol) in one portion at −10 °C under N_2. After 5 min, 6 mol% of $[Pd(PPh_3)_4]$ (16 mg) dissolved in THF (2 ml) was added to the reaction mixture at −10 °C. The reaction mixture was stirred for 1.5 h at room temperature. The color of the solution gradually changed into dark brown. The reaction mixture was quenched with water. The THF was removed *in vacuo* to give a residue which was taken up in AcOEt. The AcOEt solution was washed with brine and dried over $MgSO_4$. The solvent was removed under reduced pressure. The residue was subjected to preparative TLC (solvent; hexane:AcOEt=4:1, v/v) to give the desired product (**14**) in 72% yield (37 mg) from **13**. Its IR and NMR data were in accord with the reported ones.[6b] CI-MS m/z 229 (M^++1); IR (neat) 1730, 962 cm^{-1}; NMR ($CDCl_3$) δ=1.07—1.77 (d, J=6 Hz, 3H), 1.17 (d, J=6 Hz, 3H), 1.77—2.47 (m, 6H), 3.43—4.02 (m, 1H), 3.60 (s, 3H), 5.13—5.47 (m, 2H).

(±)-(E)-11-Hydroxy-8-dodecanoic Acid (15). To **14** (424 mg, 1.86 mmol) was added 6 mol dm^{-3} methanolic KOH solution (3.8 ml) at room temperature. Water (2 ml) was added to the solution and the reaction mixture was stirred for 1 h at room temperature and extracted with ether three times. The aqueous layer was acidified with 6 mol dm^{-3} HCl. The separated oil was extracted with chloroform. The organic solution was washed with brine and dried over $MgSO_4$. Removal of the solvent afforded **15** in 97% yield (386 mg). IR and NMR data of **15** thus obtained were in good agreement with the reported ones.[6a] IR (neat) 1700, 965 cm^{-1}; NMR ($CDCl_3$) δ=1.00—1.80 (m, 8H), 1.17 (d, J=6 Hz, 3H), 1.80—

2.53 (m, 6H), 3.50—4.10 (m, 1H), 5.20—5.43 (m, 2H), 6.93 (bs, 2H).

(±)-(E)-8-Dodecen-11-olide, Recifeiolide (16). To a suspension of **15** (50 mg, 0.23 mmol) and **1** (78 mg, 0.25 mmol) in 1,2-dichloroethane (180 ml) was added a solution of TEA (24 mg, 0.23 mmol) in 1,2-dichloroethane (5 ml) dropwise at −5 °C. After about half an hour, the initial suspension became a clear yellowish solution. It was diluted with 1,2-dichloroethane (60 ml). The reaction mixture was added slowly to a refluxing 1,2-dichloroethane containing anhydrous TsOH (88 mg, 0.46 mmol) with a mechanically driven syringe under N_2. After completion of the addition, it was further refluxed for 2 h. The solvent was evaporated and the resulting residue was partitioned between AcOEt and water. The AcOEt portion was washed successively with 10% $NaHCO_3$ and brine. After drying, the resulting residue was subjected to preparative TLC (solvent; hexane: AcOEt=8:1, v/v) to give the desired product (**16**) (37 mg, 81%). Its spectral data were completely in accordance with the reported values.[6] An oil; CI-MS *m/z* 197(M^++1); IR (neat) 1720, 1245, 965 cm^{-1}; NMR ($CDCl_3$) δ=1.23 (d, J=6 Hz, 3H), 1.10—1.90 (m, 8H), 1.90—2.77 (m, 6H), 4.60—5.00 (m, 1H), 5.00—5.50 (m, 2H).

The Reaction of *N*-Aryl-*C*-ethoxycarbonylnitrilimine with Olefins[1]

Tomio SHIMIZU,* Yoshiyuki HAYASHI, Toshiyuki NISHIO, and Kazuhiro TERAMURA
Department of Color Chemistry and Technology, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606
(Received August 1, 1983)

C-Ethoxycarbonylnitrilimines treated with monosubstituted olefins predominantly gave 5-substituted 3-ethoxycarbonyl-2-pyrazolines. From the analysis of the relative rate and regioselectivity of a variety of monosubstituted olefins for the cycloaddition, the nitrilimine is shown to have reactivity and regioselectivity similar to the throughly studied diphenylnitrilimine. The cycloaddition regioselectivity is discussed in terms of frontier orbital energies and coefficients.

Nitrilimines have been widely investigated and are one of the most versatile 1,3-dipoles for cycloaddition. *C*-Ethoxycarbonylnitrilimines especially have led to the synthesis of functional heterocyclic compounds. The reactivity of 1,3-dipolar cycloaddition reactions has been explained by frontier molecular orbital (FMO) theory,[2] but only a qualitative prediction has been made for the reactivity of nitrilimines. Recently, diphenylnitrilimine was identified at 85 K.[3] But the structural data of the nitrilimine can not be applied to the prediction of reactivity of the nitrilimine at ambient temperature. Some 1,3-dipoles react with monosubstituted electron-rich olefins to form products predicted by dipole-LUMO control. However for conjugated and electron-deficient dipolarophiles the regiochemistry of the reaction depends on which frontier orbital interaction (dipole-HOMO/dipolarophile-LUMO or dipole-LUMO/dipolarophile-HOMO) is dominant.[2] The reaction of diphenylnitrilimine with monosubstituted olefins gives predominantly 5-substituted 2-pyrazolines[4] and the orientation phenomena can be explained more or less satisfactorily by electronic effects alone. Dipole-LUMO/dipolarophile-HOMO interaction only controls the reaction of *N*-phenylsulfonylnitrilimine.[5] While the preparation and reaction of *C*-ethoxycarbonylnitrilimines have been the subject of intensive study,[6,7] a systematic investigation of the reactivity has not been carried out. Recently, 4-substituted 2-pyrazolines were claimed to be the exclusive products of the reaction of *C*-ethoxycarbonyl-*N*-arylnitrilimines with acrylic acid derivatives,[7] although the structure was assigned tentatively on the

basis of FMO theory only. We have investigated the reactivity and regioselectivity of *C*-ethoxycarbonyl-*N*-arylnitrilimines toward olefins.

Results and Discussion

Cycloadducts (**2**) were obtained when the reaction of olefins with ethyl chloroglyoxylate arylhydrazones (**1**) was carried out in the presence of triethylamine (Table 1). NMR analysis of the reaction mixture showed that the cycloadducts were formed quantitatively but an attempt to isolate pure material from liquid product (**2i**) by distillation failed because of decomposition to 3-ethoxycarbonyl-1-phenylpyrazole (**4**), which was also obtained in high yield by distillation of the reaction mixture of **1** with vinyl acetate. The structure of the cycloadducts was identified on the basis of elemental analysis and of their characteristic IR and NMR spectra. Both electron-rich and electron-deficient monosubstituted olefins gave exclusively one of two possible isomers, 5-substituted 2-pyrazolines. A distinction between the two isomers was made on the basis of the chemical shift of the methylene and methine hydrogens on the pyrazoline ring in the NMR spectra (Table 2). The three hydrogens show ABX or A_2X patterns depending on the substituent. Methylene chemical shifts at both 4- and 5-positions would be expected to be approximately same and in our cases the appearance of the methylene protones at δ 2.6—3.7 is compatible with both assignment. The methine chemical shift at the 5-position would be expected to appear at lower field than that at the 4-position,[8] although the chemical shift data for CH are much less abundant and less reliable than those for $-CH_2-$. The methine chemical shift at δ 4.0—5.8 was too low to be assigned to CH at the 4-position. Several attempts to prepare an authentic 4-substituted 2-pyrazoline failed, and therefore, we compared the chemical shifts with those of the thoroughly studied diphnylnitrilimine cycloadducts(**3**)[9a] (Table 2). Both substituents, phenyl and ethoxycarbonyl at 3-position, would have roughly the same effects on the chemical shift of methylene protones at the 4-position. Between the cycloadducts (**2** and **3**) having the same substituent at the 5-position each of methine and metylene protons shows comparable chemical shifts. Tewari *et al.*[7a] and Padwa *et al.*[7b] assigned 4-substituted 2-pyrazoline structures to the reaction products from *C*-ethoxycarbonyl-*N*-arylnitrilimines and acrylamide or methyl acrylate, respectively, on the basis of orbital interaction as discussed later. We confirmed these reactions but the chemical shifts of the products showed comparable δ values to ours. Thus, it seems reasonable to assume that all *C*-ethocycarbonylnitrilimines prepared so far give 5-substituted 2-pyrazolines almost exclusively, when reacted with monosubstituted olefins.

a) **2d** was dissolved in DMSO-d_6, the others were dissolved in $CDCl_3$. b) Data were cited from Ref. 9a and 11.

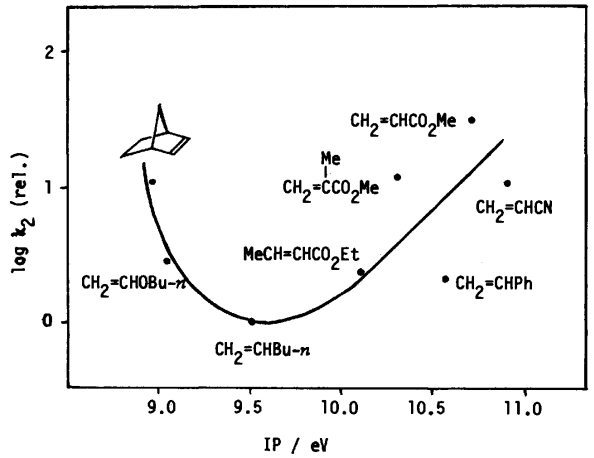

Fig. 1. The relative reaction rates and the ionic potentials of the dipolarophiles.

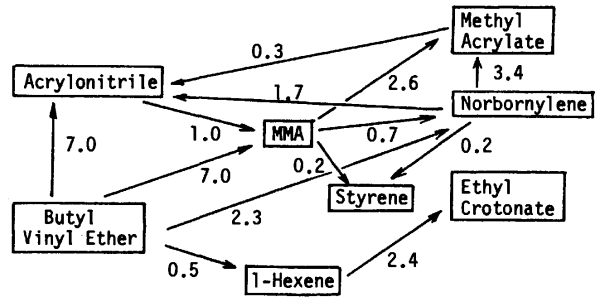

Fig. 2. The relative reaction rates of the diporaro-philes.
The numbers show relative reaction rates, x, where $x=k_B/k_A$ in the presence of both dipolarophiles, A and B. (B is shown after the arrow.)

In order to obtain additional criteria for the reactivity of the nitrilimine, competitive reactions of **1** were carried out between a variety of pairs of dipolarophiles (Fig. 2.). Relative rates in reference to 1-hexene are shown in Fig 1. These results clearly indicate that *C*-ethoxycarbonylnitrilimine is similar in reactivity to diphenylnitrilimine[9b] except for a lower reactivity toward electron-poor dipolaropiles.

The interpretation of the reactivity and regioselectivity of cycloadditions of the nitrilimine with electron-rich or conjugated olefins is fully in agreement with the prediction[2] that dipole-LUMO/dipolarophile-HOMO interaction is important and 5-substituted 2-pyrazolines are favored. On the other hand, it should be expected that the reaction of electron-deficient dipolarophiles and nitrilimines having relatively high HOMO energy is controlled by dipole-HOMO/dipolarophile-LUMO interaction. It is erroneously accepted that the coefficient of the nitrogen atom in HOMO of diphenylnitrilimine is much larger than that of the carbon atom. Consequently, the 4-substituted 2-pyrazolines are favored or the predominant formation of 5-substituted 2-pyrazolines with electron-deficent dipolarophiles can be only explained by an energetically unfavorable dipole-LUMO/dipolarophile-HOMO interaction [see interaction (a) in Fig. 3] based on the erroneous assumption.[2a] Recently, Houk and Caramella on the basis of *ab initio* molecular orbital calculations argued that in the non-planar most stable conformation of H-C≡$\overset{+}{N}$-$\overset{-}{N}$-H the biggest HOMO coefficient is to be found on the carbon atom[10] and this is also the case in diphenylnitrilimine.[11] Therefore the formation of 5-substituted 2-pyrazolines can be explained satisfactorily on the basis of dipole-HOMO control [see interaction (c) in Fig. 3] by assuming that the coefficient of carbon atom in HOMO of diphenyl- or *C*-ethoxycarbonyl-*N*-phenylnitrilimine is much larger than that of nitrogen atom.

Experimintal

Measurements. All the melting and boiling points are uncorrected. The IR spectra were determined on a Hitachi 215 Infrared Spectrophotometer. The ^{1}H NMR spectra were measured on a Varian T-60A instrument with TMS as an internal standard.

Materials. Ethyl chloroglyoxalate phenylhydrazone (**1**)[12] was prepared according to the method described in the literature. All the olefins are commercially available and

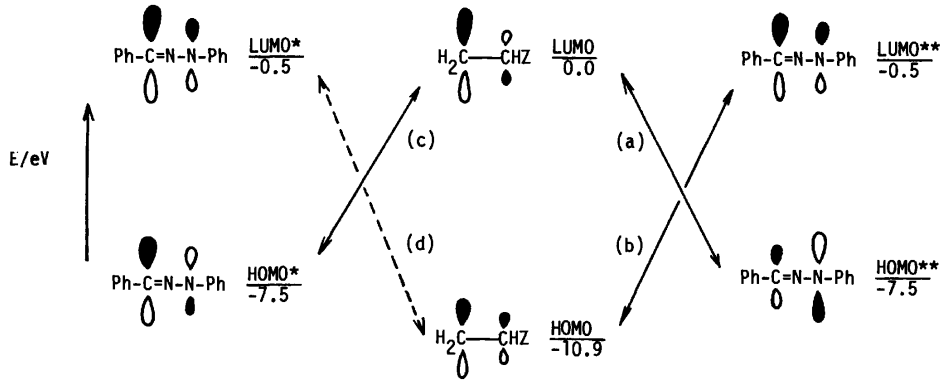

Fig. 3. Frontier orbital interactions (a—d) of diphenylnitrilimine and electron-deficient olefins.
* Magnitude of the coefficients is estimated from the calculation based on *ab initio* molecular orbital method.[10,11]
** Magnitude of the coefficients is estimated from the calculation based on CNDO/2 molecular orbital method.[2a]

were used after fractional distillation under nitrogen.

Reaction of 1 with Olefins. General Method: To a stirred chloroform (100 ml) solution of triethylamine (2.7 g, 26.4 mmol) and olefin (40 ml), was added a chloroform (20 ml) solution of ethyl chloroglyoxalate phenylhydrazone (3.0 g, 13.2 mml) at room temperature. After refluxing the chloroform solution for 2 h, the reaction mixture was cooled, washed with water several times. The chloroform solution was dried over sodium sulfate and the solvent and an excess amount of olefin were evaporated in a rotary evaporator at up to 60 °C *in vacuo*, giving crystals (**2a—d**, **2h—j**, **2m**, and **2n**), which were recrystallized from ethanol. Analysis of the residue by NMR after the evaporation gave aproximate yields of the other oily products as shown in Table 1. Distillation of the reaction mixture of **1** and butyl vinyl ether *in vacuo* gave 3-ethoxycarbonyl-1-phenylpyrazole (**4**) quantitatively; bp 180—185 °C/2 mmHg (1 mmHg≈133.322 Pa). NMR ($CDCl_3$) δ=1.33 (t, 3H, J=7 Hz), 4.37 (q, 2H, J=7 Hz), 6.95 (d, 1H, J=2 Hz), 7.0—7.85 (m, 5H), and 8.0 (d, 1H, J=2Hz).

Relative Reaction Rate of Dipolarophiles in Cycloaddition of C-Ethoxycarbonyl-N-phenylnitrilimine. This measurement was carried out according to the method described in the literature.[9b] To a refluxing chloroform solution (100 ml) of ten molar equivalents (0.13 mol) of two kind of dipolarophile and triethylamine (0.13 mol), was added dropwise a chloroform solution (20 ml) of ethyl chloroglyoxalate phenylhydrazone (3.0 g, 13 mmol) over a period of 1 h. After cooled to room temperature, the mixture was washed with water several times, dried (Na_2SO_4) and the solvent and the excess of the dipolarophiles was evaporated *in vacuo* at up to 60 °C. The residue was analysed by NMR in deuteriochloroform and the ratio of the competitive reaction products between dipolarophiles were estimated from the integration of each characteristic peaks. The results of the measurements are shown in Fig. 2.

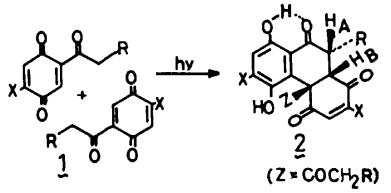
(Received August 15, 1983)

Upon irradiation a regio- and stereoselective cycloaddition occurred intramolecularly between two acyl-1,4-benzoquinone moieties connected by a polymethylene bridge. The regio- and stereoselectivities are different from those of the corresponding intermolecular cycloaddition; this was interpreted in terms of the Diels-Alder reaction between an acyl-1,4-benzoquinone moiety and a photochemically produced dienol.

In 1979 we reported[1] that 2-alkanoyl-1,4-benzoquinones (**1**) underwent a regio- and stereoselective dimerization on photolysis to give racemic 4aα-acyl-10β-alkyl-5,8-dihydroxy-4aα,10aα-dihydro-1,4,9(10*H*)-phenanthrenetriones (**2**).[2] We are interested



in whether a similar cycloaddition can occur intramolecularly between two acylquinone moieties. If such reactions could proceed, we might obtain, by a simple procedure, a group of compounds which have characteristic structures and properties. Actually the substrates, 2,2′-(α,ω-dioxo-α,ω-alkanediyl)bis(1,4-benzoquinone)s (**5a—d**)[3] prepared by the processs given in Scheme underwent the expected cycloaddition. When a degassed solution of **5** in acetonitrile[4] (0.05 mol dm^{-3}) was irradiated through Pyrex filter by a high pressure mercury-arc lamp, an intramolecular addition product of the substrate was obtained as the sole product in the yield of 25—30%. The yield of the product raised to 54% when the lower initial concentration of **5c** (0.002 mol dm^{-3}) was used.[5] Without light, a degassed solution of **5** had remained unchanged on standing at room temperature over a week.

7Ba-d

The ^{1}H NMR data of the products (Table 1) were similar to those of **2**, suggesting a compound either of the structures **7A—D**.[6] While the signals of **2** at about δ 4.1 due to H_B were doublets ($J\simeq4$ Hz), the corresponding signals of the products derived from **5a**,[7] **5b**, and **5d** were singlets and that of the product from **5c** was a double doublet (J=1—2 Hz). The double resonance technique revealed that the atoms coupling with the atom giving the double doublet were an olefinic and an aromatic protons,[8] but not the proton corresponding to H_A of **2**. This fact exclude the possibilities of **7A** and **7C**, which should show a doublet due to the atom corresponding to H_B of **2**. The structure of the product derived from **5d** was unequivocally established as (4a*RS*,-8a*SR*,13b*SR*)-10,13-dihydroxy-2,12-dimethyl-6,7,8,8a-tetrahydro-1,4,5,9(13b*H*)-benz[*e*]anthracenetetrone (**7Bd**) by the X-ray structural analysis. The perspective view of a molecule of **7Bd** is given in Fig. 1.

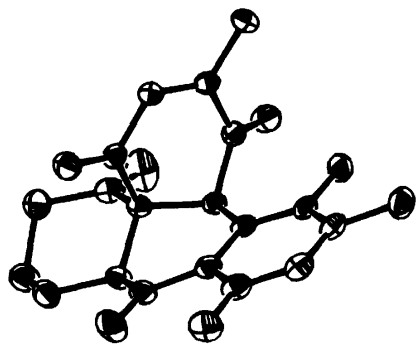

Fig. 1. Perspective view of (4a*R*,8a*S*,13b*S*)-10,13-dihydroxy-2,12-dimethyl-6,7,8,8a-tetrahydro-1,4,5,9-(13b*H*)benz[*e*]anthracenetetraone (**7Bd**).

The above finding indicates that the regio- and stereoselectivities of the intramolecular addition are different from those of the intermolecular one. The stereochemistry of the reactions is explicable in terms of the Diels-Alder reaction between an acylquinone moiety and a photochemically produced dienol moiety. For the intramolecular addition reaction, four orientations, **8A-D** corresponding to **7A-D**, may be possible. In **8C** and **8D** the access of two molecular planes is sterically hindered by the polymethylene chain existing inside the *cis*-dienol form. Such hindrance may not be exerted either in **8A** nor in **8B**. Though **8B** may be less favorable than **8A** because of steric hindrance caused by folding the polymethylene chain of **8B**, the chain (n=3 and 4) is not long enough to construct **8A**. Consequently the reaction to give **7B** may proceed preferentially. Second, for the intermolecular addition of **1** with the dienol **9**, orientations **10A—D** can be drawn. In **10C, D** the access of the molecular planes are hindered by a process similar to that explained for **8C, D**. **10B** is sterically hindered by the overlapping of the alkyl and acyl groups. Because of the least steric hindrance of **10A**, the selective formation of **2** is feasible.

To examine the above steric effect towards the access of the molecular planes, we investigated the photolysis of 2-isobutyryl-1,4-benzoquinone (**11**). The cycloaddition through the corresponding orientation, **12**, may be unfavorable because a methyl group locates inside the *s-cis* dienol form. On irradiation, **11** did not afford the corresponding dimer **13**, but gave 2,2-dimethyl-5-hydroxy-3(2*H*)-benzofuranone (**14**), an intramolecularly cyclized product in 20% yield.

If the above cycloadditions proceed through the dienols, **6** and **9**,[9] they should be trapped with another dienophile present in the reaction solution. As stated previously,[1] however, no such adducts were obtained and **2** was still the only isolable product when the photolysis of **1** was effected in the presence of maleic anhydride, *N*-phenylmaleimide, or dimethyl acetylenedicarboxylate. A similar result was obtained for the intramolecular reaction. When a solution of **5c** in acetonitrile (0.002 mol dm^{-3}) was irradiated in the presence of maleic anhydride (0.2 mol dm^{-3}), no adducts between them were obtained and **7Bc** was isolated in a yield of 57%, a comparable yield with the reaction in the absence of maleic anhydride (*vide supra*).

Experimental

All new compounds gave satisfactory results in mass spectrometry. ^{1}H NMR spectra were measured by a JEOL JNM FX-100 and FX-90Q spectrometers.

α,ω-Bis(2,5-dihydroxyphenyl)-α,ω-alkanediones (4).[10] Glutaryl or adipoyl dichloride (0.05 mol) was added dropwise to a suspension of $AlCl_3$ (0.1 mol) in a solution of *p*-dimethoxybenzene or 2,5-dimethoxytoluene (0.1 mol) in 1,2-dichloroethane (100 cm^3) with stirring. After further stirring under refluxing for 8 h and subsequent addition of ice water and concentrated hydrochloric acid (10 cm^3), the reaction mixture was extracted with diethyl ether. The concentrated residue of the extract gave, after recrystallization from ethanol, a yellow solid of α,ω-bis(2-hydroxy-5-methoxyphenyl)-α,ω-alkanedione (**3**), which contained a small amount of α,ω-bis(2,5-dimethoxyphenyl)-α,ω-alkanedione. This crude product was treated with BBr_3 in dichloromethane in the usual manner to give a yellow solid of α,ω-bis(2,5-dihydroxyphenyl)-α,ω-alkanedione (**4**), which was recrystallized from ethanol.

1,5-Bis(2,5-dihydroxyphenyl)-1,5-pentanedione (4a). Yield 80%. Mp 211—213 °C. Found: C, 64.31; H, 5.10%. Calcd for $C_{17}H_{16}O_6$: C, 64.55; H, 5.10%.

1,5-Bis(2,5-dihydroxy-4-methylphenyl)-1,5-pentanedione (4b). Yield 80%. Mp 202—203 °C. Found: C, 66.49; H, 5.90%. Calcd for $C_{19}H_{20}O_6$: C, 66.27 H, 5.85%.

1,6-Bis(2,5-dihydroxyphenyl)-1,6-hexanedione (4c). Yield 85%. Mp 236—238 °C. Found: C, 65.25; H, 5.55%. Calcd for $C_{18}H_{18}O_6$: C, 65.44; H, 5.49%.

1,6-Bis(2,5-dihydroxy-4-methylphenyl)-1,6-hexanedione (4d). Yield 85%. Mp 137—139 °C (recrystallized from EtOH–THF (1:1)). Found: C, 67.08; H, 6.19%. Calcd for $C_{20}H_{22}O_6$: C, 67.02; H, 6.19%.

The ^{1}H NMR and IR data of **4** are presented for **4d**; δ (acetone-d_6)=1.81 (4H, m, $(-COCH_2\underline{CH_2})_2$, 2.23 (6H, broad s, 2ArMe), 3.05 (4H, m, $(-COC\underline{H_2}CH_2)_2$), 6.72 (2H, broad s, 2ArH), 7.31 (2H, s, 2ArH), 7.97 (2H, s, 2OH), 11.85 (2H, s, 2 chelated OH); ν (KBr) 3480 (broad and strong), 3080, 2980, 2920, 2880, 1660, 1610, 1600 cm^{-1}.

2,2'-(1,5-Dioxo-1,5-pentanediyl)bis(1,4-benzoquinone) (5a) and 2,2'-(1,5-Dioxo-1,5-pentanediyl)bis(5-methyl-1,4-benzoquinone) (5b). A solution of DDQ (4 mmol) in dry acetone (5 cm^3) was added to a solution of **4a** or **4b** (2 mmol) in dry acetone (30 cm^3) under a dry atmosphere. After about 0.5 h the solvent was evaporated under 10^{-4} mmHg (1 mmHg=133.322 Pa). The solid residue was extracted with hot benzene. The crystals which deposited on cooling were recrystallized from benzene.

5a: Mp 108—110 °C, Yield 80%. Found: C, 65.28; H, 3.81%. Calcd for $C_{17}H_{12}O_6$: C, 65.38; H, 3.87%. ^{1}H NMR ($CDCl_3$): δ=2.04 (2H, quintet, *J*=7.0 Hz, $(-COCH_2)_2C\underline{H_2}$), 2.96 (4H, t, *J*=7.0 Hz, $(-COC\underline{H_2})_2CH_2$), 6.8—7.0 (6H, m, ArH). Calcd for $C_{19}H_{16}O_6$: C, 67.05; H, 4.75%. ^{1}H NMR ($CDCl_3$): δ= 1.98 (2H, quint, *J*=7.0 Hz, $(-COCH_2)_2C\underline{H_2}$), 2.07 (6H, t, *J*= 1.0 Hz, 2ArMe), 2.93 (4H, t, *J*=7.0 Hz, $(-COC\underline{H_2})_2CH_2$), 6.57 (2H, q, *J*=1.0 Hz, 2ArH), 6.88 (2H, s, 2ArH). IR (KBr): ν 3060, 2980, 2910, 2890, 1710, 1660, 1605 cm^{-1}. UV (MeCN): λ_{max} (ε) 250 (3.50×10^4), 314 (1.30×10^3) (sh), 450 (100) nm.

2,2'-(1,6-Dioxo-1,6-hexanediyl)bis(1,4-benzoquinone) (5c) and 2,2'-(1,6-Dioxo-1,6-hexanediyl)bis(5-methyl-1,4-benzoquinone) (5d). A solution of **4c** or **4d** and DDQ was prepared as above. On standing for about 0.5 h a yellow solid crystallized out; this was recrystallized from dry acetone, with care taken to avoid contact with moisture.

5c: Mp 146—151 °C, Yield 70%. Found: C, 66.34; H, 4.36%.

Calcd for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%. ^{1}H NMR ($CDCl_3$): δ=1.71 (4H, m, (-$COCH_2\underline{CH_2}$-)$_2$), 2.90 (4H, m, (-$COCH_2$-$\underline{CH_2}$-)$_2$), 6.8—6.9 (6H, m, ArH). IR (KBr): ν 3060, 2960, 2920, 2880, 1700, 1650, 1610 cm^{-1}. UV (MeCN): 246 (3.29×10^4), 300 (960) (sh), 445 (67) nm.

5d: Mp 145—149 °C, Yield 75%. Found: C, 67.75; H, 5.05%. Calcd for $C_{20}H_{18}O_6$: C, 67.79; H, 5.12%. ^{1}H NMR ($CDCl_3$): δ=1.62 (4H, m, (-$COCH_2\underline{CH_2}$-)$_2$, 2.08 (6H, d, J=1.5 Hz, 2ArMe), 2.90 (4H, m, (-$COCH_2\underline{CH_2}$-)$_2$), 6.61 (2H, q, J=1.5 Hz, 2ArH), 6.93 (2H, s, 2ArH). IR (KBr): ν 3050, 2960, 2910, 2880, 1710, 1660, 1610 cm^{-1}. UV (MeCN): λ_{max} (ε) 250 (3.55×10^4), 315 (1.24×10^3) (sh), 435 (75) nm.

Photolysis of 5. A Pyrex glass tube containing a dry acetonitrile solution of **5** (0.05 or 0.002 mol dm^{-3}) was sealed after having been degassed by the thaw-freeze-pump method and irradiated by a 300 W high pressure mercury-arc lamp for 5 h (the yield of **7B** was not increased by prolonged irradiation). Because **7B** was decomposed by silica gel, its isolation and purification could not be performed by column chromatography, but were effected as described in the following to give **7B** in the yield of 25—30%. The yields did not seem to vary much with **5** but did depend on the isolation, because it was decomposed with a trace amount of water contained in solution and sometimes even with moisture in the isolation procedure. No other products except tar were found. Remaining **5** could not be recovered (it was also decomposed by silica gel and water).

The concentrated residue of the irradiated solution of **5a** was washed with ethyl acetate and dissolved in hot dry acetone. Yellow crystals of **7Ba** were obtained by allowing the solution to stand after addition of petroleum ether.

The concentrated residue of the irradiated solution of **5c** was repeatedly extracted with hot benzene. The concentrated residue of the combined extract was recrystallized from dry acetone to give yellow needles of **7Bc**, which contained acetone as crystal-solvent. These were dried at about 60 °C under 10^{-4} mmHg.

The concentrated residue of the irradiated solutions of **5b** and **5d** were repeatedly extracted with hot benzene. The concentrated residues of the extract were dissolved in a small amount of hot benzene. Yellow crystals of **7Bb** and **7Bd** were obtained by allowing the solutions to stand after an addition of petroleum ether. The crystals of **7Bd** containing benzene as crystal-solvent were dried at about 60 °C under 10^{-4} mmHg.

Isobutyryl-1,4-benzoquinone (11). A mixture of *p*-dimethoxybenzene (5 g), isobutyric acid (5 g), and polyphosphoric acid (70 g) was stirred for 5 h at 60 °C. The reaction mixture was diluted with excess water and extracted with diethyl ether. The concentrated residue of the washed and dried extract was distilled under reduced pressure to give 2′, 5′-dimethoxyisobutyrophenone in the yield of 55%. Bp 120—121 °C/2 mmHg. Found: C, 69.08; H, 7.61%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%. ^{1}H NMR ($CDCl_3$): δ=1.10 (6H, d, J=6.7 Hz, CH$\underline{Me}_2$), 3.40 (1H, hept, J=6.7 Hz, C$\underline{H}$Me$_2$), 3.67 (3H, s, OMe), 3.72 (3H, s, OMe), 6.7—6.9 (3H, m, ArH).

The treatment of 2′,5′-dimethoxyisobutyrophenone with BBr_3 in the usual manner gave a yellow liquid of isobutyryl hydroquinone in the yield of 80%. Bp 137—138 °C/2 mmHg. Found: C, 66.81; H, 6.84%. Calcd for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71%. ^{1}H NMR (acetone-d_6): δ=1.15 (6H, d, J=6.5 Hz, CH$\underline{Me}_2$), 3.37 (1H, hept, J=6.5 Hz, C$\underline{H}$Me$_2$), 6.7—7.1 (3H, m, ArH), 8.90 (1H, s, OH), 11.85 (1H, s, chelate OH). A solution of isobutyrylhydroquinone in benzene was stirred with an excess of Ag_2O and $MgSO_4$ for 0.5 h.[10] The concentrated residue of the filtered solution was sublimed *in vacuo* to give a yellow solid of isobutyryl-1,4-benzoquinone (**11**) in the yield of 70%. Mp 27—28 °C. Found: C, 67.21; H, 5.72%. Calcd for $C_{10}H_{10}O_3$: C, 67.40; H, 5.66%. ^{1}H NMR ($CDCl_3$): δ=1.10 (6H, d, J=6.8 Hz, CH$\underline{Me}_2$), 3.11 (1H, hept, J=6.8 Hz, C$\underline{H}$Me$_2$), 6.67 (3H, s, ArH). IR (KBr): ν 3060, 3000, 2960, 2920, 2880, 1700, 1670, 1600 cm^{-1}. UV (MeCN): λ_{max} (ε) 246 (1.90×10^4), 300 (461) (sh), 450 (30) nm.

Photolysis of 11. A solution of **11** in actonitrile (0.1 mol dm^{-3}) was irradiated in degassed condition by a 300 W high pressure mercury-arc lamp for 10 h. The concentrated residue of the solution was submitted to column chromatography on silica gel with an eluent of petroleum ether–diethyl ether (2 : 1) to give 2,2-dimethyl-5-hydroxy-3(2*H*)-benzofuranone (**14**) in the yield of 20%. No other products except tar were found and no unreacted **11** was recovered. **14**: Mp 158—159 °C (recrystallized from benzene). Found: C, 67.24; H, 5.72%. Calcd for $C_{10}H_{10}O_3$: C, 67.40; H, 5.66%. ^{1}H NMR ($CDCl_3$): δ=1.45 (6H, s, 2Me), 6.20 (1H, s, OH), 6.9—7.3 (3H, m, ArH). IR (KBr): ν 3280 (broad and strong), 3020, 2980, 2920, 1710, 1630 cm^{-1}. UV (EtOH): λ_{max} (ε) 253 (7.67×10^3), 370 (4.48×10^3) nm.

X-Ray Structural Analysis. The compound of **7Bd** was crystallized from toluene to give crystals containing solvent molecules. A single crystal of an approximate size, $0.1\times0.5\times0.8$ mm, was used for the intensity measurement. The crystal data were: monoclinic, $P2_1/a$, a=17.537(1), b=10.358(1), c=10.588(1) Å, β=91.942(7)°, V=1922.2(2) Å^3, Z=4, D_m=1.378 g cm^{-3} (by floatation method with petroleum ether–carbon tetrachloride solution), D_c=1.382 as $C_{20}H_{18}O_6\cdot1/2(C_6H_5CH_3)$. The unit-cell dimensions were obtained by means of the least-squares technique with the values of 35 reflections. The intensities of 2543 independent reflections were collected in the range of $\sin\theta/\lambda\leqq0.65$ by a θ—2θ scan mode (2°/min) on a Rigaku four-circle diffractometer with Ni-filtered Mo $K\alpha$ radiation. The crystal structure was solved by MULTAN. Refinement was effected by the constraint full matrix least-squares method[11] because of the disorder of solvent molecule. The difference Fourier synthesis after the anisotropic refinement of the nonhydrogen atoms revealed all the hydrogen atoms except the methyl and hydroxyl hydrogen atoms. The final refinement, including the contribution of hydrogen atoms, reduced the R factor to 0.088 without $|F_{obsd}|$=0. The final atomic parameters[12] are given in Table 2. The bond distances and bond angles are shown in Figs. 2 and 3 respectively.

We wish to thank Dr. Yoshitaka Itatani, Faculty of Pharmacutical Sciences, Kanazawa University, for the NMR measurements and for his valuable discussion. The calculations of the X-ray structural analysis were done on an ACOS 700S computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University.

Conformational Studies of Neopentyl- and Trimethylsilylmethyl-substituted Germyl Radicals by Electron Spin Resonance

Kunio MOCHIDA

Department of Chemistry, Faculty of Sciences, Gakushuin University, 1-5-1 Mejiro, Toshima-ku, Tokyo 171

(Received August 30, 1983)

Conformational analyses of a series of neopentyl- and trimethylsilylmethyl-substituted germyl radicals by electron spin resonance (ESR) were investigated on the basis of the modified $\cos^2\theta$ rule. Dimethylneopentylgermyl radical has the conformations with the neopentyl group rotating freely. On the other hand, dimethyl(trimethylsilylmethyl)germyl radical has the preferred conformations with trimethylsilylmethyl group eclipsing with the singly occupied orbital on a germanium atom. The ESR spectra of dineopentylmethylgermyl and bis(trimethylsilylmethyl)methylgermyl radicals showed the existence of two kinds of methylene protons due to the nonplanar geometries and the slow inversion of these germyl radicals. Conformations of trineopentylgermyl and tris(trimethylsilylmethyl)germyl radicals are also discussed.

In connection with stabilization of the radicals and stereoselectivity in homolytic reactions, the structures and conformations of alkyl radicals have been widely studied by ESR.[1] Substituents located in the β position of group 4B-centered radicals also stabilize the radicals and exert stereochemical effects in group 4B-centered radical reactions.[2] However, there are few reports on the structures and conformations of β-substituted 4B-centered radicals by ESR.[3-6]

We have previously reported on the ESR spectra of benzyl-substituted germyl radicals.[5,6] Benzyl-substituted germyl radicals have nonplanar configurations and the preferred conformations of these germyl radicals are those with the phenyl ring of the benzyl group eclipsing the singly occupied orbital on a germanium atom on the basis of the values of the hyperfine splitting constants (hfsc) of the benzylic protons and the marked temperature dependence. Such preferred conformations of benzyl-substituted germyl radicals are due to the interaction between a singly occupied orbital on a germanium atom and the phenyl π orbitals.

In this paper, the ESR spectra of neopentyl- and trimethylsilylmethyl-substituted germyl radicals are reported. Neopentyl and trimethylsilylmethyl groups are more hindered sterically and interacted less electronically with a singly occupied orbital on a germanium atom than a benzyl group. Therefore, the conformations of neopentyl- and trimethylsilylmethyl-substituted germyl radicals are expected to be different from those of benzyl-substituted germyl radicals.

Results and Discussion

Neopentyl- and trimethylsilylmethyl-substituted germyl radicals were generated by abstraction of hydrogen from the corresponding hydrogermanes using photochemically generated *t*-butoxyl radicals.[7,8]

$$(CH_3)_3CO\text{-}OC(CH_3)_3 \xrightarrow{h\nu} 2(CH_3)_3CO\cdot \quad (1)$$

$$R = CH_2C(CH_3)_3,\ CH_2Si(CH_3)_3$$

$$n = 1-3$$

The *g* factors and hfsc's of a series of neopentyl- and trimethylsilylmethyl-substituted germyl radicals at various temperatures are summarized in Table 1.

ESR Spectra of Neopentyl-substituted Germyl Radicals. Figure 1 shows the ESR spectrum of dimethylneopentylgermyl radical at −100°C. It consists of a nonet arising from the circumstance that the magnitude of the coupling constant of the methyl protons is the same as that of the methylene protons. The line intensities of this germyl radical are satisfactorily reproduced by computer simulation. The outermost lines of the

nonet are lost in the noise. The spectrum of dimethylneopentylgermyl radical was measured over a temperature range between −70 and −135°C. As shown in Table 1, the methylene and methyl protons hfsc's are equivalent and there is no temperature dependence with experimental error over the investigated temperature range.

Figure 2 shows the ESR spectrum of dineopentylmethylgermyl radical at −60°C. It consists of a quartet due to 3 methyl protons further split into two sets of triplets (6.68 and 3.67 G, 1 G=10^{-4} T), indicative of the existence of two kinds of methylene protons. The hfsc's of the two sets of triplets showed small temperature dependence, while the methyl proton hfsc was almost constant. The experimental spectra of dineopentylmethylgermyl radical were reproduced by computer simulation with the listed hfsc's.

Figure 3 shows the ESR spectrum of trineopentylgermyl radical at −60°C which consists of a septet due to 6 equiv methylene protons. The methylene protons hfsc's showed small negative temperature dependence.

ESR Spectra of Trimethylsilylmethyl-substituted Germyl Radicals. Figure 4 shows the ESR spectrum of dimethyl(trimethylsilylmethyl)germyl radical at −120°C which consists of a septet due to 6 methyl protons split further into a triplet due to 2 methylene protons. As shown in Table 1, the methylene proton hfsc's were temperature dependent while the methyl proton hfsc's were almost constant over the investigated temperature range. The methylene proton hfsc's decreased without selective line broadening as the temperature was lowered.

Figure 5 shows the ESR spectrum of bis(trimethylsilylmethyl)methylgermyl radical at −40°C which consists of a quartet due to 3 methyl protons further split into two sets of triplets (5.98 and 3.63 G), indicative of the existence of two kinds of methylene protons. The hfsc's of two sets of triplets showed small temperature dependence, while the methyl proton hfsc was almost constant. The experimental spectra of this germyl rad-

ical were well reproduced by computer simulation with the listed hfsc's.

Figure 6 shows the ESR spectrum of tris(trimethylsilylmethyl)germyl radical at −60 °C which consists of a septet due to 6 equiv methylene protons. The ^{29}Si species (^{29}Si natural abundance=4.7%) attributed to the principal radical was observed as shown in Fig. 6. The methylene proton hfsc's showed no temperature dependence.

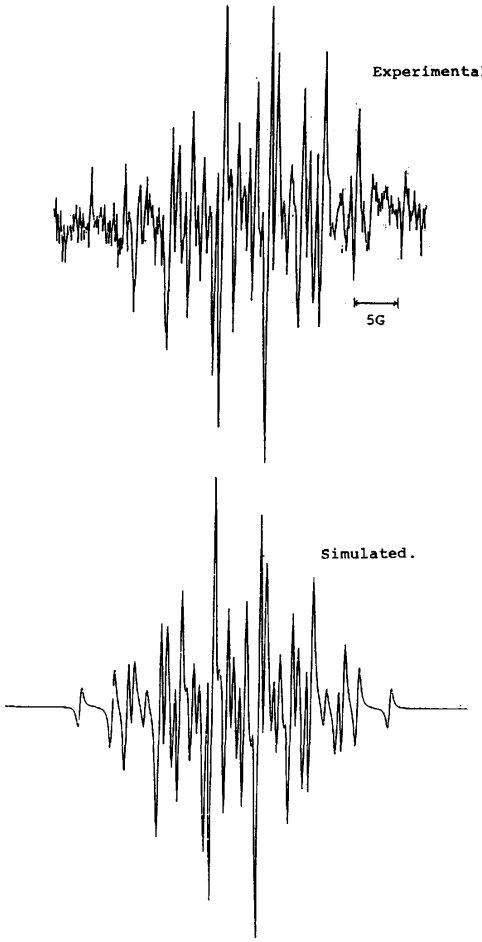

Fig. 5. ESR spectrum of bis(trimethylsilylmethyl)-methylgermyl radical at −40 °C.

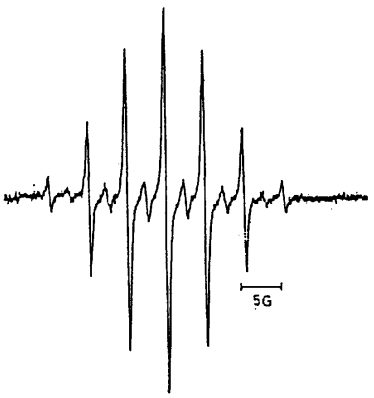

Fig. 6. ESR spectrum of tris(trimethylsilylmethyl)-germyl radical at −60 °C.

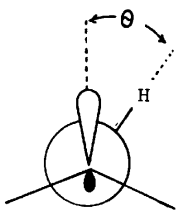
Conformations of Neopentyl- and Trimethylsilylmethyl-substituted Germyl Radicals. Organogermyl radicals are inferred to have nonplanar configurations on the basis of the ESR parameters,[9] the IR data,[10] and the stereochemistry of a chlorine-abstraction from carbon tetrachloride with a chiral germyl radical.[11] Therefore, it is reasonable to discuss the conformations of neopentyl- and trimethylsilylmethyl-substituted germyl radicals by the modified $\cos^2\theta$ rule by Eqs. 3 and 4, where θ is the dihedral angle between the β carbon–hydrogen bond and the p orbital at the radical center.[6b,12]

$$a(\beta\text{-H}) = B\cos^2\theta \quad (0°<\theta<90°) \tag{3}$$

$$a(\beta\text{-H}) = B'\cos^2\theta \quad (90°<\theta<180°) \tag{4}$$



Constants B and B', depend on whether or not the β-proton is placed on the same side of the larger lobe of the singly occupied orbital. Since freely rotating methyl protons ($<\cos^2\theta>=1/2$) showed hfsc's around 5.4 G for organogermyl radicals studied here, $(B+B')/2$ may be estimated roughly as 10.8 G. Constants B and B' may depend highly on the extent of the pyramidality of the radical center. Constants B and B' are taken roughly as 5 and 15 G, respectively, when the pyramidality of the germyl radicals may be supposed to be similar to that of 1,1-difluoroalkyl radicals where B/B' is estimated to be *ca.* 0.31 by INDO calculation.[12a]

Conformations of Dimethylneopentylgermyl and Dimethyl(trimethylsilylmethyl)germyl Radicals. Equilibrium conformations, **1**—**12**, for the methylene protons in the germyl radicals and the corresponding phases for angular dependence are illustrated as Fig. 7. Values of the methylene protons hfsc's are calculated in Table 2.

Taking into consideration that the freely rotating methylene proton hfsc's for equilibrium conformations as shown in Fig. 7 are estimated as around 5.4 G, for radicals with conformations, **1**, **6**, **7**, or **8** (R^1=R^2=Me), the methylene proton hfsc is expected to decrease as the temperature is lowered. On the other hand, for radicals with conformations, **3**, **4**, **10**, or **11** (R^1=R^2=Me), the methylene proton hfsc is expected to increase as the temperature is lowered.

The temperature dependences of the methylene proton hfsc's of dimethylneopentylgermyl and dimethyl(trimethylsilylmethyl)germyl radicals are shown graphically in Fig. 8. It is seen that the magnitude of

Table 2. Values of the methylene protons Hfsc's for conformations, **1**—**12**

	1	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**11**	**12**

$a(\beta\text{-H}^2)$	3.75	0	1.25	3.75	5	3.75	1.25	0	3.75	11.25	15	11.25

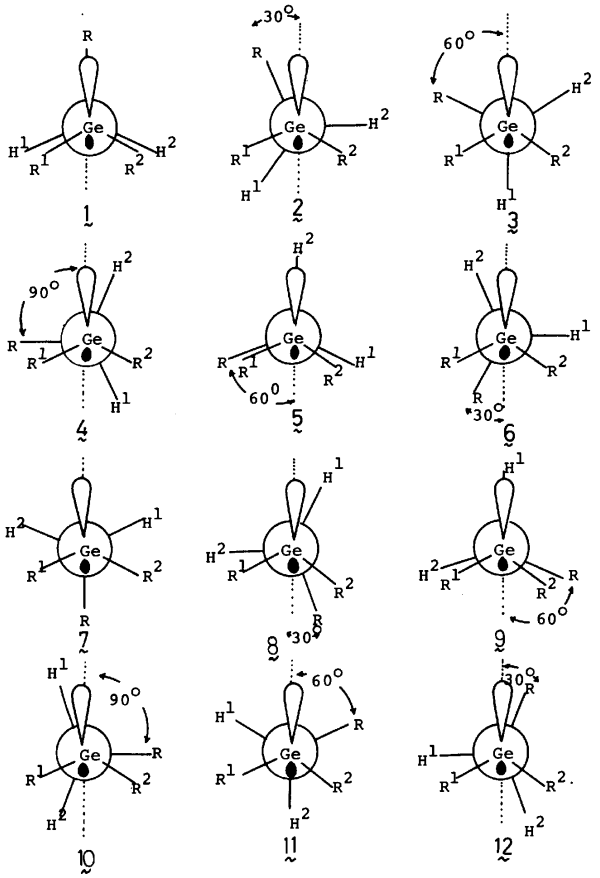

Fig. 7. Equilibrium conformations for the methylene protons in the germyl radicals and the corresponding phases for angular dependence.

the methylene proton hfsc's of dimethylneopentylgermyl radical is almost the same as that of the methyl proton hfsc's and the methylene proton hfsc's showed no temperature dependence with experimental errors. Therefore, the dimethylneopentylgermyl radical has the conformation with the neopentyl group rotating freely in the investigated temperature range.

On the other hand, the methylene protons hfsc's of dimethyl(trimethylsilylmethyl)germyl radical decreased as the temperature was lowered. Therefore, this germyl radical has the preferred conformations, **1**, **6**, **7**, or **8**; the trimethylsilylmethyl group eclipsing or nearly so with the singly occupied orbital on a germanium atom. For favoring such conformations, the odd electron is delocalized onto the carbon-silicon bond hyperconjugatively as well as onto d orbitals of the silicon atom (*p—d*) homoconjugatively.[13]

Conformations of Dineopentylmethylgermyl and Bis(trimethylsilylmethyl)methylgermyl Radicals. The ESR spectra of dineopentylmethylgermyl and bis(trimethylsilylmethyl)methylgermyl radicals showed the existence of two kinds of the methylene proton hfsc's without significant temperature dependence.

Recently, the activation barrier for inversion of a pyramidal germyl radical is estimated to be about 7.0 kcal mol^{-1} (1cal=4.184 J).[14] On the other hand, the barrier for rotation about the Ge-C bond is smaller than that about the C-C bond due to the longer Ge-C bond length (2.00 Å) compared to the C-C bond length

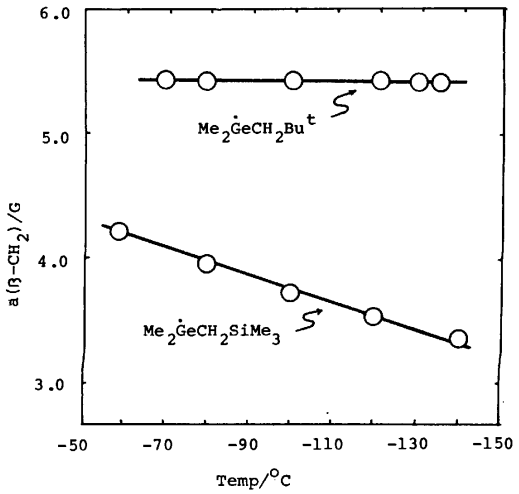

Fig. 8. Temperature dependence of a(β-CH_2) of $Me_2\dot{G}eCH_2Bu^t$ and $Me_2\dot{G}eCH_2SiMe_3$.

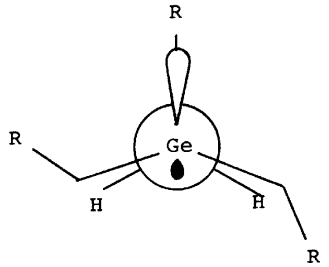
(1.54 Å). Therefore, the existence of two kinds of methylene proton hfsc's of dineopentylmethylgermyl and bis(trimethylsilylmethyl)methylgermyl radicals can be explained reasonably by assuming that the configurations of these germyl radicals are fixed to nonplanar geometry and the inversion rates of these germyl radicals are much smaller than those of rotation of substituents about the Ge-C bond.

Typical equilibrium conformations of dineopentylmethylgermyl and bis(trimethylsilylmethyl)methylgermyl radicals are shown in Fig. 7 (R^1=Me, R^2=CH_2R, R=Bu^t or $SiMe_3$). Conformations, **8**, **9**, **10**, and **11** may be eliminated due to steric repulsion between R-substituted methyl groups (R=Bu^t or $SiMe_3$) on a Ge atom and R groups on $a\beta$-C atom. The potential energies in the various conformations as shown in Fig. 7 are not taken into consideration. However, $a(\beta$-$H^1)$ and $a(\beta$-$H^2)$ in conformations, **1**—**12** except for **8**, **9**, **10**, and **11**, average roughly 5.8 and 3.3 G, respectively, with listed hfsc's in Table 2. These values reproduce experimental data of two kinds of methylene proton hfsc's of dineopentylmethylgermyl and bis(trimethylsilylmethyl)methylgermyl radicals.

Conformations of Trineopentylgermyl and Tris(trimethylsilylmethyl)germyl Radicals. Taking into consideration the steric hindrance of *t*-butyl or trimethylsilyl groups, the conformation **1**, **2**, or **12** as shown in Fig. 7 (R^1, R^2=CH_2R, R=Bu^t or $SiMe_3$) may be selected as a candidate for the preferred conformation of trineopentylgermyl or tris(trimethylsilylmethyl)germyl radical. For example, the conformation **1** for these germyl radicals are shown in the following to minimize the steric repulsion of the substituents.



Fast rotational interconversion among three individual conformations, **1**, **2**, and **12** as shown in Fig. 7 (R^1, R^2=CH_2R, R=Bu^t or $SiMe_3$), of equal probability 1/3 will make the 6 methylene protons epuivalent. Such a correlated interconversion for tris(trimethylsilylmethyl)aminium ion radical has been reported.[15]

Experimental

ESR Measurements. The Varian X band spectrometer, light sources, and sample tubes are as described previously.[16]

The field sweep of the spectrometer was calibrated with an aqueous solution of Fremy's salt (a_N=13.07 G). The *g* factors were determined by reference to that of the anthracene cation radical (*g*=2.002565) with a dual cavity.

All samples were throughly degassed using a freeze-pump-thaw cycle.

Materials. Di-*t*-butyl peroxide (DTBP) was distilled prior to use. Dimethyldichlorogermane, bp 121—122 °C,[17] dimethylphenylchlorogermane, bp 113 °C/17 mmHg (1 mmHg≈133.322 Pa),[18] methylphenyldibromogermane, bp 139—140 °C/15 mmHg,[19] and (chloromethyl)trimethylsilane, bp 98 °C[20] were prepared as described literatures.

Preparation of Dimethylneopentylchlorogermane. Neopentylmagnesium chloride was prepared (5.3 g, 0.22 mol) in THF (100 ml). The Grignard reagent was added to dimethyldichlorogermane (30.0 g, 0.17 mol) in ether (400 ml). After the mixture was stirred under gentle reflux for 2 h, the resulting salt was filtered off and the solvent was removed. Fractional distillation gave dimethylneopentylchlorogermane (6.5 g, 0.03 mol, 17.6%), bp 70.0—72.5 °C/16 mmHg.

Preparation of Dimethylneopentylgermane. A mixture of dimethylneopentylchlorogermane (6.5 g, 0.03 mol) and lithium aluminum hydride (1.4 g, 36.4 mmol) in ether (200 ml) was stirred with reflux for 2 h. After hydrolysis with water, the organic layer was dried over calcium chloride. The solvent was removed and then fractional distillation gave dimethylneopentylgermane (4.5 g, 25.8 mmol, 82.8%), bp 122.0—122.5 °C. n^{20} 1.4302; IR (cm^{-1}, neat) 2020 (Ge-H), 1240 (Ge-Me); NMR ($CDCl_3$) δ=0.21 (d, *J*=4.0 Hz, 6H), 0.92 (d, *J*=4.0 Hz, 2H) 0.97 (s, 9H), 3.89 (*m*, 1H). Found: C, 47.91; H, 10.46%, Calcd for $C_7H_{18}Ge$: C, 48.10; H, 10.38%.

Preparation of Dineopentylmethylphenylgermane. Neopentylmagnesium chloride was prepared from neopentyl chloride (46.0 g, 0.43 mol) and magnesium (10.5 g, 0.43 mol) in THF (300 ml). To this Grignard reagent, methylphenyldibromogermane (19.0 g, 0.06 mol) was added. The mixture was stirred with reflux for 10 h. After hydrolysis with water, the organic layer was extracted and dried over sodium sulfate. The solvent was removed and then fractional distillation gave dineopentylmethylphenylgermane (14.0 g, 0.05 mol, 84.6%), bp 92.5—93.0 °C/0.15 mmHg. NMR ($CDCl_3$) δ=0.63 (s, 3H), 0.91 (s, 18H), 1.14 (s, 4H), 7.37 (m, 5H); IR (cm^{-1}, neat) 1240 (Ge-Me).

Preparation of Dineopentylmethylchlorogermane. Iodine monochloide (7.4 g, 45.6 mmol) in dichloromethane (10 ml) was added to dineopentylmethylphenylgermane (13.5 g, 44.0 mmol) in dichloromethane (50 ml). The mixture was stirred at room temperatre for 5 h. After the solvent was removed, fractional distillation gave dineopentylmethylchlorogermane (8.1 g, 30.5 mmol, 69.3%), bp 102—103 °C/9 mmHg. NMR ($CDCl_3$) δ=0.87 (s, 3H), 1.04 (s, 18H), 1.34 (s, 4H).

Preparation of Dineopentylmethylgermane. A mixture of dineopentylmethylchlorogermane (7.3 g, 27.5 mmol) and lithium aluminum hydride (1.2 g, 30.4 mmol) in ether (200 ml) was stirred with reflux for 2 h. After hydrolysis with water, the organic layer was dried over calcium chloride. The solvent was removed and then fractional distillation gave dineopentylmethylgermane (6.0 g, 26.0 mmol, 94.5%), bp 83.0—84.0 °C/19 mmHg. n^{20}1.4420; IR (cm^{-1}, neat) 2040 (Ge-H), 1240 (Ge-Me); NMR ($CDCl_3$) δ=0.25 (d, *J*=4.0 Hz, 3H), 0.94 (d, *J*=4.0 Hz, 4H), 0.97 (s, 18H), 4.02 (m, 1H). Found: C, 56.92; H, 11.52%. Calcd for $C_{11}H_{26}Ge$: C, 57.22; H, 11.35%.

Preparation of Trineopentylgermane. Neopentylmagnesium bromide was prepared from neopentyl bromide (24.2 g, 0.16 mol) and magnesium (4.0 g, 0.16 mol) in THF (200 ml). To this Grignard reagent, tetrachlorogermane (10.0 g, 0.05 mol) in ether (50 ml) was added. The mixture was stirred with reflux for 10 h. The resulting salt was filtered off and the solvent was removed. The crude trineopentylchlorogermane was added to lithium aluminum hydride (4.0 g, 0.10 mol) in ether (200 ml) and then stirred with reflux for 5 h. After hydrolysis with water, the organic layer was dried over sodium sulfate. The solvent was removed and then fractional distillation gave trineopentylgermane, bp 140 °C/16 mmHg. IR (cm^{-1}, neat) 2040 (Ge-H); NMR ($CDCl_3$) δ=0.94 (d, *J*=4.0 Hz, 6H), 0.97 (s, 27H), 4.03 (m, 1H). For ESR measurements, the sample was purified by preparative GLC (SE30 20% 2 m).

Preparation of Dimethylphenyl(trimethylsilylmethyl)germane. (Lithiomethyl)trimethylsilane was prepared from (chloromethyl)trimethylsilane (12.3 g, 0.10 mol) and dispersed lithium (2.8 g, 0.4 mol) in ether (200 ml) at −10 °C. To this ether solution, dimethylphenylchlorogermane (8.0 g, 0.04 mol) in ether (50 ml) was added over a period of 30 min while the temperature was maintained below 10 °C. After addition was completed, the mixture was stirred with reflux for 5 h. Methanol was added to this solution and then the mixture was hydrolyzed with water. The solution was extracted with ether and the ether solution was dried over calcium chloride. Fractional distillation gave dimethylphenyl(trimethylsilylmethyl)germane (6.8 g, 25 mmol, 63.7%), bp 115 °C/15 mmHg.

Preparation of Dimethyl(trimethylsilylmethyl)germane. Iodine monochloride (3.2 g, 0.02 mol) in dichloromethane (10 ml) was added to dimethylphenyl(trimethylsilylmethyl)-germane (5.0 g, 0.02 mol) in dichloromethane (50 ml). The mixture was stirred at room temperature for 5 h. After the solvent was removed, the crude dimethyl(trimethylsilylmethyl)chlorogermane was added to lithium aluminum hydride (1.0 g, 25 mmol) in ether (100 ml). The mixture was stirred with reflux for 5 h. After hydrolysis with water, the organic layer was extracted with ether and the ether solution was dried over calcium chloride. The solvent was removed and then fractional distillation gave dimethyl(trimethylsilylmethyl)germane, bp 121 °C. n^{20} 1.4440; IR (cm^{-1}, neat) 2020 (Ge-H), 1225 (Ge-Me); NMR ($CDCl_3$) δ=−0.18 (d, *J*=4.0 Hz, 2H), 0 (s, 9H), 0.19 (d, *J*=4.0 Hz, 6H), 3.82 (m, 1H). Found: C, 37.16; H, 9.39%. Calcd for $C_6H_{18}SiGe$: C, 37.75; H, 9.51%.

Preparation of Bis(trimethylsilylmethyl)methylphenylgermane. (Lithiomethyl)trimethylsilane was prepared from (chloromethyl)trimethylsilane (12.3 g, 0.10 mol) and dispersed lithium (2.8 g, 0.40 mol) in ether (200 ml) at −10 °C. To this ether solution, methylphenyldibromogermane (6.0 g, 0.02 mol) in ether (50 ml) was added over a period of 30 min while the temperature was maintained below 10 °C. After addition was completed, the mixture was stirred with reflux for 5 h. Methanol was added to this solution and then the mixture was hydrolyzed with water. The solution was extracted with ether and the ether solution was dried over calcium chloride. Fractional distillation gave bis(trimethylsilylmethyl)methylphenylgermane, bp 105 °C/4.0 mmHg.

Preparation of Bis(trimethylsilylmethyl)methylchlorogermane. Iodine monochloride (1.6 g, 0.01 mol) in dichloromethane (20 ml) was added to bis(trimethylsilylmethyl)methylphenylgermane (30 g, 8.8 mmol) in dichloromethane (10 ml). The mixture was stirred at room temperature for 5 h. After the solvent was removed, fractional distillation gave bis(trimethylsilylmethyl)methylchlorogermane, bp 98—103 °C/12 mmHg.

Preparation of Bis(trimethylsilylmethyl)methylgermane. A mixture of bis(trimethylsilylmethyl)methylchlorogermane (2.0 g, 6.7 mmol) and lithium aluminum hydride (1.0 g, 25.0 mmol) in ether (200 ml) was stirred with reflux for 2 h. After hydrolysis with water, the organic layer was extracted with ether. The ether solution was dried over calcium chloride. The solvent was removed and then fractional distillation gave bis(trimethylsilylmethyl)methylgermane (1.2 g, 4.6 mmol, 68.7%), bp 89 °C/30 mmHg. n^{25} 1.4627; IR (cm^{-1}, neat) 2020 (Ge-H), 1250 (Ge-Me,Si-Me); NMR ($CDCl_3$) δ=—0.16 (d, J=4.0 Hz, 4H), 0 (s, 18H), 0.22 (d, J=4.0 Hz, 3H), 3.91 (m, 1H). Found: C, 41.19; H, 9.70%. Calcd for $C_9H_{26}Si_2Ge$: C, 41.09; H 9.96%.

Preparation of Tetrakis(trimethylsilylmethyl)germane. (Lithiomethyl)trimethylsilane was prepared from (chloromethyl)trimethylsilane (61.3 g, 0.5 mol) and dispersed lithium (13.9 g, 2.0 mol) in ether (300 ml) at —10 °C. To this ether solution, tetrachlorogermane (21.4 g, 0.10 mol) in ether (50 ml) was added over a period of 30 min while the temperature was maintained below 10 °C. After the addition was completed, the mixture was stirred with reflux for 10 h. Methanol was added to this solution and the mixture was hydrolyzed with water. The solution was extracted with ether and the ether solution was dried over calcium chloride. Fractional distillation gave tetrakis(trimethylsilylmethyl)germane (14.0 g, 33 mmol, 33.0%), bp 127—130 °C/5 mmHg. n^{16} 1.4725; IR (cm^{-1}, neat) 1240 (Si-Me); NMR ($CDCl_3$) δ=—0.13_5 (s, 2H), —0.04 (s, 9H). Found: C, 45.17; H, 10.03%. Calcd for $C_{16}H_{44}Si_4Ge$: C, 45.60; H, 10.52%.

Preparation of Tris(trimethylsilylmethyl)bromogermane. Tris(trimethylsilylmethyl)bromogermane was prepared by bromination of tetrakis(trimethylsilylmethyl)germane (10.0 g, 23 mmol) with an equivalent amount of bromine (4.0 g, 24 mmol) in 50 ml of refuxing 1,2-dibromoethane for 30 min. The solvent was removed under reduced pressure, leaving about 10 ml of residue. Fractional distillation gave crude tris(triethylsilylmethyl)bromogermane (7.5 g, 18 mmol, 78.7%), bp 125—126 °C/5 mmHg. NMR (CCl_4) δ=—0.02_3 (s, 2H), 0.05 (s, 9H).

Preparation of Tris(trimethylsilylmethyl)germane. A mixture of tris(trimethylsilylmethyl)bromogermane (7.5 g, 18 mmol) and lithium aluminum hydride (3.0 g, 79.2 mmol) in ether (200 ml) was stirred with reflux for 3 h. After hydrolysis with water, the organic layer was dried over calcium chloride. The solvent was removed and then fractional distillation gave tris(triethylsilylmethyl)germane (4.3 g, 13 mmol, 71.3%), bp 117—118 °C/18 mmHg. n^{16}1.4620; IR (cm^{-1}, neat) 1985 (Ge-H), 1235 (Si-Me); NMR (CCl_4) δ=—0.19 (d, J=3.8 Hz, 6H), —0.05 (s, 27H), 4.00 (sept., J=3.8 Hz, 1H). Found: C, 43.03; H, 10.09%. Calcd for $C_{12}H_{34}Si_3Ge$: C, 42.99; H, 10.22%.

The author is grateful to Professor Hideki Sakurai and Dr. Mitsuo Kira of Tohoku University for their interests, encouragements, and computer simulation of ESR spectra. I also thank Professor Tadashi Suehiro of Gakushuin University for accomodation of a Varian E-9 ESR spectrometer and Mr. Isoo Miyagawa for preparation of dimethylneopentylgermane and dineopentylmethylgermane.

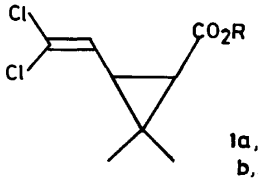
A Convenient Synthesis of 4-(2,2-Dichloroethenyl)-5,5-dimethyltetrahydro-2-furanone Derivatives, a Key Intermediate of Permethrinic Acid[1)]

Sadao Tsuboi, Eiichiro Amano, and Akira Takeda*
Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700
(Received September 5, 1983)

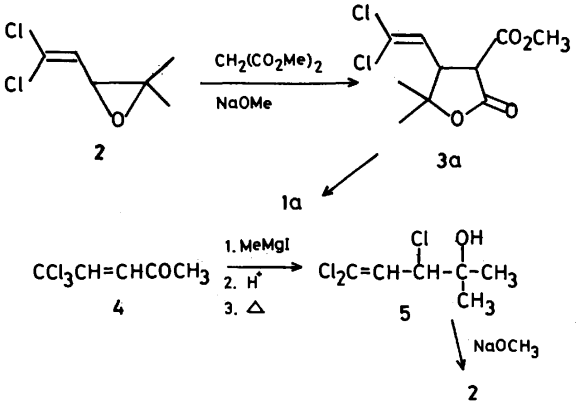
A key intermediate of 2-(2,2-dichloroethenyl)-3,3-dimethylcyclopropanecarboxylic acid, 3-alkoxycarbonyl-(or acyl)-4-(2,2-dichloroethenyl)-5,5-dimethyltetrahydro-2-furanone was prepared by the base-catalyzed condensation of 2-methyl-3,5,5-trichloro-4-penten-2-ol with acetate derivatives such as malonic esters, acetoacetic esters, and benzoylacetate. The reactivity of 3-acetyl-4-(2,2-dichloroethenyl)-5,5-dimethyltetrahydro-2-furanone to an excess amount of thionyl chloride in ethanol was also examined. An analog, 5-butyl-4-(2,2-dichloroethenyl)-3-ethoxycarbonyl-5-methyltetrahydro-2-furanone was also prepared in 31% yield.

A large number of synthetic methods of permethrinic acid [2-(2,2-dichloroethenyl)-3,3-dimethylcyclopropanecarboxylic acid] (**1a**, R=H), the acid moiety of the insecticide Permethrin (NRDC 143)[2b)], have been reported since the first synthesis by Farkas *et al.*[2,3)] Klemmensen *et al.*[4)] have reported a convenient synthesis of ethyl ester **1b** (R=Et) of permethrinic acid



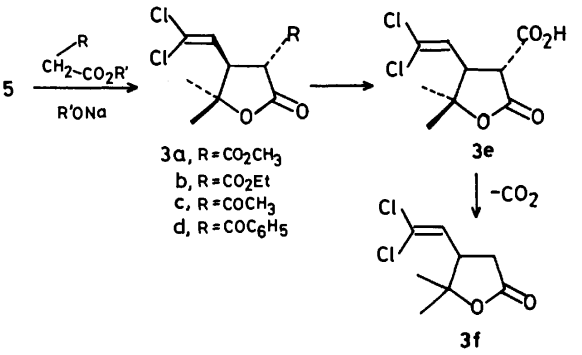
1a, R = H
b, R = Et

from 4-(2,2-dichloroethenyl)-3-methoxycarbonyl-5,5-dimethyltetrahydro-2-furanone (**3a**), which was derived from the reaction of 1,1-dichloro-3,4-epoxy-4-methyl-1-pentene (**2**)[5)] with dimethyl malonate in the presence of base. We had reported a facile synthesis of **2** by dehydrochlorination of 3,5,5-trichloro-2-methyl-4-penten-2-ol (**5**),[5)] which was readily prepared by the Grignard reaction of 5,5,5-trichloro-3-penten-2-one (**4**)[6)] with methylmagnesium iodide.



Recently we found that the chlorohydrin **5** reacts with methyl sodiomalonate to give the lactone **3a**. As an extension of the previous work[5,6)] and to establish the generality of this reaction we investigated in detail the base-catalyzed condensation of **5** with acetate derivatives such as malonic esters and acetoacetic esters. This paper will describe and discuss the results of these reactions.

Chlorohydrin **5** reacted with sodiomalonic esters at room temperature to give the lactones **3a** and **3b** in 30%



(52%)[7)] and 41% (49%)[7)] yields, respectively. Hydrolyses of **3a** and **3b** gave the corresponding lactone acid **3e**, which released carbon dioxide to yield **3f**[4)] when heated. Reaction of methyl acetoacetate with **5** in the presence of sodium methoxide gave 3-acetyl-4-(2,2-dichloroethenyl)-5,5-dimethyltetrahydro-2-furanone (**3c**) in 50% yield. However, the reaction of ethyl benzoylacetate with **5** in the presence of sodium ethoxide afforded only the poor yield (7%, 24%[7)]) of 3-benzoyl-4-(2,2-dichloroethenyl)-5,5-dimethyltetrahydro-2-furanone (**3d**) along with a mixture of unidentified products and the starting materials. The lactones **3c** and **3d** can be easily converted to **3f** by the deacylation with sodium ethoxide or aqueous sodium hydroxide.[8,9)]

Lactones **3** obtained in the present reactions were characterized by analytical and spectroscopic data, and by comparison with literature data[4)] in the case of the known lactones (**3a** and **3f**). The physical properties and analyses of lactones **3** are listed in Table 1. IR spectra of **3** showed characteristic strong peaks at around 1770 cm^{-1} due to the carbonyl groups of lactone rings. When the olefinic proton of **3a** at the ^1H NMR measurement was irradiated, the coupling constant between C_3–H and C_4–H was observed to be 12.1 Hz. This suggests that the configuration between R and dichloroethenyl group is *trans*.[10)] The best evidence that the lactones **3** have no isomers comes from the clear ^{13}C-NMR spectra which were summarized in Table 2. The signals due to lactone carbonyls exhibit upfieid-shifts of *ca.* 8 ppm from that of unsubstituted γ-butyrolactone.[11)]

Conversion of lactone **3c** to chloroester **6** was attempted by means of the procedure used for the ring opening of pyrocin (**7**).[8)] Treatment of **3c** with a ten-

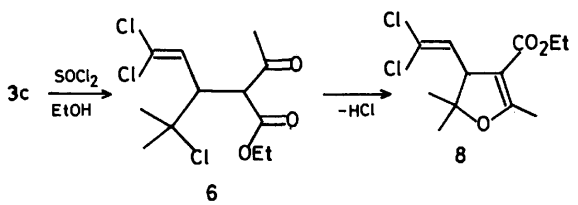
a) Measured in $CDCl_3$. Assignments are consistent with the multiplicities observed in off-resonance decoupled spectra unless otherwise indicated. b) Signals in parenthesis seem to be those of an enol isomer (22%). * Assignment may be interchangeable.

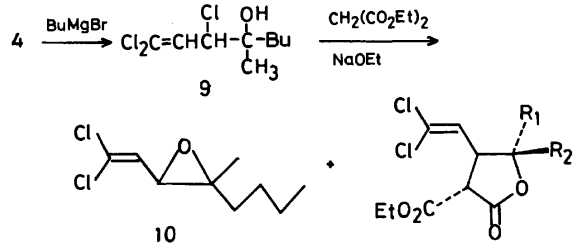
fold excess of thionyl chloride in ethanol resulted in the formation of 4-(2,2-dichloroethenyl)-3-ethoxycarbonyl-2,5,5-trimethyl-4,5-dihydrofuran (**8**) in 79% yield. Dihydrofuran **8** is thought to have been derived from **6** by the spontaneous dehydrochlorination.



6 **8**

An analog of the lactone **3** was prepared by the adaptation of the method described above. Reaction of **4** with butylmagnesium bromide gave 1,1,3-trichloro-4-methyl-1-octen-4-ol (**9**) in 64% yield. ^{1}H NMR analysis showed that the alcohol **9** exists in two diastereomeric forms, *dl-erythro* and *dl-threo* (3 : 2). Condensation of **9** with diethyl sodiomalonate afforded the dehydrochlorination product of **9**, 1,1-dichloro-3,4-epoxy-4-methyl-1-octene (**10**) (30% yield) and a 3 : 2 diastereomeric mixture of 5-butyl-4-(2,2-dichloroethenyl)-3-ethoxycarbonyl-5-methyltetrahydro-2-furanones (**11a, b**) [31% (45%)[12)] yield]. The epoxide **10**, which was identified by the independent synthesis from **9**, was a mixture of *cis* and *trans* isomers (2 : 3). It has been shown in the previous paper that the *erythro* alcohol is cyclized to the *trans* epoxide and the *threo* alcohol to the *cis* epoxide, respectively.[5)] The stereochemistry of **11a** and **11b** was determined by a detailed study of their proton and ^{13}C NMR spectra. The chemical shift of

methyl carbon of C_5 in **11b** was considerably upfieid from that of methyl carbon of C_5 in **11a**.[13] In addition, the chemical shift of C_1 of butyl group in **11a** was upfield from that of C_1 of butyl group in **11b**. This showed that the methyl group of C_5 and dichloroethenyl group in **11b** was *cis*.[13] This was further confirmed by the observation of 18% NOE between the olefin proton and the methyl protons of C_5 in **11b**.



11a, $R_1=CH_3$; $R_2=Bu$
b, $R_1=Bu$; $R_2=CH_3$

The reaction mechanism on the present reaction is discussed as follows. In the reaction of chlorohydrin **5** with malonic ester and acylacetate under the basic conditions, one can imagine that the initially formed product would be most likely epoxide **2**, which is subsequently attacked by the carbanion of esters to afford the corresponding lactones **3**. This prospect seemed to be valid because both reactions of sodiomalonate with chlorohydrin **5** and with epoxide **2**[4,14] yielded the lactones **3**. However, attempted reactions of acetoacetic esters with **2** resulted in the recovery of the starting materials, while the reactions of acetoacetic esters with **5** gave lactones **3** in reasonable yields, as described above. A number of experiments between acetoacetic esters and **2** were conducted under various conditions, using alcohols, tetrahydrofuran (THF), and *N,N*-dimethylformamide (DMF) as a solvent, in the presence of equimolar or excess amount of base (NaOR and NaH), but the desired product **3** could not be isolated. This result strongly suggests that the present reaction between **5** and acetate derivatives proceeds *via* not the epoxide **2** but an S_N2 substitution product **12** as an intermediate.

Experimental

The melting points and boiling points are uncorrected. Elemental analyses were carrried out by Mr. Eiichiro Amano. Analytical determinations by GLPC were performed on a Hitachi Model K-53 gas chromatograph filled with 10% Apiezon Grease L on Chromosorb W (3 mm o.d. × 1 m). High-performance liquid chromatography (HPLC) was performed with Yanagimoto components consisting of a PN-101 pump and R-203 differential refractometer. Infrared spectra were determined with a JASCO A-102 diffraction grating infrared spectrophotometer. ^1H NMR spectra (60 MHz) were recorded with a Hitachi Model R-24 apparatus. ^{13}C NMR spectra were obtained with a JEOL LTD, JNM-FX100 apparatus. Chemical shifts were measured using TMS as an internal standard and are given in terms of δ (ppm).

The synthesis of *2-methyl-3,5,5-trichloro-4-penten-2-ol (5)* was described in the previous paper.[5]

4-(2,2-Dichloroethenyl)-3-methoxycarbonyl-5,5-dimethyltetrahydro-2-furanone (3a). Sodium (0.2 g, 8.8 mmol) was dissolved in 50 ml of dry methanol. To the solution was added 1.16g (8.8mmol) of dimethyl malonate. After the mixture was stirred at room temperature for 1 h, **5** (1.62 g, 8 mmol) was added. The mixture was stirred for 1 d, and then condensed *in vacuo*. The residual oil was poured into water, acidified with 10% HCl, and the organic material was extracted with ether. The ethereal layer was washed with water and dried over $MgSO_4$. Removal of the solvent gave a mixture of an oil and crystals. The filtration afforded 0.638 g (30%, 52%[7]) of **3a**: mp 102—103 °C (lit,[4] mp 100—102 °C). IR and ^1H NMR data were identical with those of the authentic sample.[4] The filtrate (1.09 g) was a mixture of **5** and dimethyl malonate (1:1 1.09g by ^1H NMR).

4-(2,2-Dichloroethenyl)-5,5-dimethyl-3-ethoxycarbonyltetrahydro-2-furanone (3b) was prepared in 41% (49%)[8] yield from 0.813 g (4 mmol) of **5** and 0.705 g (4.4 mmol) of diethyl malonate, as described above. The physical properties and analytical data are shown in Table 1.

4-(2,2-Dichloroethenyl)-5,5-dimethyl-2-oxotetrahydro-3-furancarboxylic Acid (3e). The mixed solution of 0.5 g (1.87 mmol) of **3a** and 40 ml of 2 M NaOH (1 M=1 mol dm^{-3}) was stirred at room temperature for 16 h. The mixture was extracted with ether. The organic layer, after being dried over $MgSO_4$, was condensed to leave 0.421 g (89%) of **3e**: mp 128—129 °C (from benzene). The physical data and analyses are shown in Table 1.

3-Acetyl-4-(2,2-dichloroethenyl)-5,5-dimethyltetrahydro-2-furanone (3c). Sodium (0.247 g, 10.7 mmol) was dissolved in 20 ml of dry methanol. Methyl acetoacetate (1.24 g, 10.7 mmol) was added, and the mixture was stirred at 50 °C for 1 h. To the solution was added slowly 2.14 g (10.7 mmol) of **5** under reflux. The mixture was stirred at the reflux temperature for 24 h. After being cooled, the mixture was condensed *in vacuo*, and neutralized with 50% CH_3CO_2H. The organic layer was extracted with ether, and dried over $MgSO_4$. After removal of the solvent, the residual oil was distilled *in vacuo*. The first fraction (1.2 g) was distilled at 110 °C/24 Torr (1 Torr≈ 133.322 Pa). GLPC analysis showed it consists of a 1:1 mixture of the starting materials. The second fraction was collected at 112 °C/0.07 Torr to give 1.33 g (50%, 76%[7]) of **3c**: on TLC analysis (silica gel, 3:1 hexane:acetone), one spot at R_f 0.35. Spectral data and analysis are shown in Table 1.

3-Benzoyl-4-(2,2-dichloroethenyl)-5,5-dimethyltetrahydro-2-furanone (3d). From a mixture of **5** (2.03 g, 10 mmol), ethyl benzoylacetate (1.92 g, 10 mmol), sodium (0.23 g, 10 mmol), and dry ethanol (20 ml), 3.2 g of an oil was obtained by the same treatment as described in the preparation of **3c**. The distillation gave 1.95 g of the first fraction at bp 125 °C/15 Torr, consisting of a 71:29 mixture of ethyl benzoylacetate and **5**, and 0.377 g of the second fraction distilling at bp 180—210 °C/0.1 Torr. TLC analysis (silica gel, 3:1 hexane: acetone) of the second fraction gave two spots at R_f 0.45 and 0.33. The component at R_f 0.33 was collected by preparative TLC to give 0.206 g (7%, 24%[7]) of **3d**. Physical properties and analyses are shown in Tables 1 and 2.

4-(2,2-Dichloroethenyl)-3-ethoxycarbonyl-2,5,5-trimethyl-4,5-dihydrofuran (8). To a solution of **3c** (0.502 g, 2 mmol) in 20 ml of dry ethanol was slowly added 1.4 ml (20 mmol) of thionyl chloride. The solution was heated at 70 °C for 6 h. After being cooled, the mixture was condensed *in vacuo* to give 0.56 g (79%) of **8**: one spot at R_f 0.79 on TLC analysis (silica gel, 3:1 hexane: acetone); IR (neat) 1705 (ester C=O), 1645, 1625 cm^{-1} (C=C); NMR ($CDCl_3$) δ=1.08 (t, 3H,

OCH_2CH_3), 1.12 (s, 3H, C_5-CH_3), 1.22 (s, 3H, C_5-CH_3), 1.98 (s, 3H, =C-CH_3), 3.57 (d, 1H, J=10 Hz, C_4-H), 3.92 (q, 2H, OCH_2CH_3), 5.49 (d, 1H, J=10 Hz, =CH). Found: C, 51.77; H, 5.85%. Calcd for $C_{12}H_{16}Cl_2O_3$: C, 51.63; H, 5.78%.

Reaction of **2** *with Acetoacetic Esters in the Presence of Base.* Reactions of **2** with sodioacetoacetic esters prepared by dissolving acetoacetic esters in the solvents in the presence of NaOR or NaH were carried out under following conditions: (a) **2** (0.5 g, 2.9 mmol), methyl acetoacetate (0.349 g, 2.9 mmol), $NaOCH_3$ (5.0 mmol), MeOH (4.5 ml), at room temperature for 2.5 h and at reflux temperature for 1 h; (b) **2** (1.0 g, 5.9 mmol), ethyl acetoacetate (0.858 g, 6.6 mmol), EtOH (7 ml), at room temperature for 12 h, and at reflux temperature for 6 h; (c) **2** (1.0 g, 5.9 mmol), methyl acetoacetate (0.767 g, 6.6 mmol), NaH (7.2 mmol), THF (10 ml), at room temperature for 22 h and at reflux temperature for 20 min; (d) **2** (1.0 g, 5.9 mmol), methyl acetoacetate (1.56 g, 12 mmol), NaH (18 mmol), THF (5 ml), at reflux temperature for 16 h; (e) **2** (1.0 g, 5.9 mmol), ethyl acetoacetate (0.858 g, 6.6 mmol), NaH (7.9 mmol), DMF (6 ml), at 70—75 °C for 10 h. After the usual work-up, the starting materials were recovered for all procedures.

The Epimeric Mixture (3:2 erythro: threo*) of 1,1,3-Trichloro-4-methyl-1-octen-4-ol (9).* An ethereal solution of *n*-BuMgBr (0.10 mol) in dry ether (50 ml) was added dropwise to a solution of **4** (15 g, 0.08 mol) in 50 ml of dry ether at −30 °C during a period of 2 h. After being stirred at −20 — −10 °C for an additional 4 h, the mixture was acidified with 10% HCl. The usual work-up gave an oil, which was distilled to give 12.5 g of **9**, yield 64%: bp 95—102 °C (2 mm); IR (neat) 3350 (OH), 1620 (C=C), 872, 746 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (broad t, 3H, $CH_3(CH_2)_3$), 1.21—1.71 (m, 9H, $CH_3(CH_2)_3C$-CH_3), 3.74 (broad s, 1H, OH), 4.67 (d, 1H, J=10 Hz, $\rangle$CHCl), 6.16 (d, 0.6H, J=10 Hz, *erythro* =CH-), 6.18 (d, 0.4H, J=10 Hz, *threo* =CH-). Found: C, 43.83; H, 5.92%. Calcd for $C_9H_{15}Cl_3O$: C, 44.02; H, 6.16%.

The Epimeric Mixture (2:3 cis: trans*) of 1,1-Dichloro-3,4-epoxy-4-methyloctene (10).* To a stirred solution of **9** (4.9 g, 0.02 mol) in 40 ml of dry ether was added sodium methoxide (2.38 g, 44 mmol) in several portions at −5 °C. The mixture was stirred at room temperature for 6 h, and then acidified with 10% HCl with cooling. The organic layer was extracted with ether, and the ethereal extract was dried over $MgSO_4$. After removal of the solvent, the residual oil was distilled to give 2.5 g of **10**, yield 60%: bp 124—129 °C (20 mm); IR (neat) 1614 (C=C), 930, 895, 860 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.9 (broad t, 3H, $CH_3(CH_2)_3$), 1.28 (s, 1.8H, *trans* O-C-CH_3), 1.34 (s, 1.2 H, *cis* O-C-CH_3), 1.1—1.7 (m, 6H, $CH_3(CH_2)_3$), 3.44 (d, 1H, J=8 Hz, $\rangle$CH-CH=), 5.75 (d, 1H, J=8 Hz, =CH-). Found: C, 51.46; H, 6.48%. Calcd for $C_9H_{14}Cl_2O$: C, 51.69; H, 6.75%.

Reaction of **9** *with Diethyl Malonate in the Presence of Sodium Ethoxide.* A mixture of chlorohydrin **9** (2.76 g, 11.2 mmol) and diethyl sodiomalonate prepared from sodium (0.284 g, 12.3 mg-atom) and diethyl malonate (1.97 g, 12.3 mmol) in dry ethanol (10 ml) was heated at reflux temperature for 24 h. After removal of the solvent, the residue was poured into water. The mixture was acidified with dilute acetic acid and the organic layer was extracted with ether. The ethereal layer was washed with water, and dried over $MgSO_4$. After removal of the solvent, the residual oil was distilled *in vacuo*. The first fraction at bp 140 °C/2 Torr. gave 1.4 g of **10** (28% yield) and diethyl malonate (47:53 by ^1H NMR). Column chromatography (silica gel, 3:1 hexane: acetone) of the residual oil (1.74 g) gave 42 mg (2%) of **10**, 0.168 g of diethyl malonate, and 1.12 g (31%, 45%[12]) of a diastereomeric mixture of *5-butyl-4-(2,2-dichloroethenyl)-3-ethoxycarbonyl-5-methyltetrahydro-2-furanone (11)* as an oil. HPLC analysis (Yanapak SA-I, 6×250 mm; 10:1 hexane: ethyl acetate, 1.7 ml/min) showed two peaks at retention times (integrated percentages) of 10.8 (60%) and 15.2 min (40%). Each component was isolated by preparative HPLC. The first fraction yielded t-*5-butyl*-t-*4-(2,2-dichloroethenyl)*-r-*3-ethoxycarbonyl*-c-*5-methyltetrahydro-2-furanone (11a)*: an oil; IR (neat) 1790 (lactone C=O), 1742 (ester C=O), 1626 (C=C); ^1H NMR ($CDCl_3$) δ=0.92 (broad t, 3H, $CH_3(CH_2)_3$-), 1.32 (t, J=7.5 Hz, 3H, $CO_2CH_2CH_3$), 1.52 (s, 3H, C_5-CH_3), 1.1—1.6 (m, 6H, $CH_3(CH_2)_3$-), 3.56 (d, J=12 Hz, 1H, C_3-H), 3.87 (q, J=10 and 12Hz, 1H, C_4-H), 4.30 (q, J=7 Hz, 2H, $CO_2CH_2CH_3$), 5.85 (d, J=10 Hz, 1H, -CH=): ^{13}C NMR ($CDCl_3$) δ=13.9 (q, $CH_3(CH_2)_3$-), 14.0 (q, $CO_2CH_2CH_3$), 23.0 (t, $CH_3CH_2CH_2CH_2$), 25.0 (q, C_5-CH_3), 25.4 (t, $CH_3CH_2CH_2CH_2$-), 36.3 (t, $CH_3CH_2CH_2CH_2CH_2$-), 50.8 (d, C_4), 52.3 (d, C_3), 62.4 (t, $CO_2CH_2CH_3$), 87.4 (s, C_5), 124.0 (d, -CH=), 125.9 (s, Cl_2C=), 166.5 (s, CO_2Et), 169.3 (s, lactone C=O). Found: C, 52.19; H, 6.33%. Calcd for $C_{14}H_{20}Cl_2O_4$: C, 52.02; H, 6.24%. The second fraction gave c-*5-butyl*-t-*4-(2,2-dichloroethenyl)*-r-*3-ethoxycarbonyl*-t-*5-methyltetrahydro-2-furanone (11b)*: an oil; IR (neat) 1788 (lactone C=O), 1740 (ester C=O), 1625 (C=C); ^1H NMR ($CDCl_3$) δ=0.94 (broad t, 3H, $CH_3(CH_2)_3$-), 1.32 (s, 3H, C_5-CH_3), 1.34 (t, J=7 Hz, 3H, $CO_2CH_2CH_3$), 1.1—1.6 (m, 6H, $CH_3(CH_2)_3$-), 3.56 (d, J=12 Hz, 1H, C_3-H), 3.91 (q, J=10 and 12 Hz, 1H, C_4-H), 4.31 (q, J=7 Hz, 2H, $CO_2CH_2CH_3$), 5.85 (d, J=10 Hz, 1H, -CH=); ^{13}C NMR ($CDCl_3$) δ=13.8 (q, $CH_3(CH_2)_3$-), 14.0 (q, $CO_2CH_2CH_3$), 21.6 (q, C_5-CH_3), 22.7 (t, $CH_3CH_2CH_2CH_2$-), 25.3 (t, $CH_3CH_2CH_2CH_2$-), 39.8 (t, $CH_3CH_2CH_2CH_2$-), 48.3 (d, C_4), 52.1 (d, C_3), 62.4 (t, $CO_2CH_2CH_3$), 87.2 (s, C_5), 124.4 (d, -CH=), 125.8 (s, Cl_2C=), 166.4 (s, CO_2Et), 169.1 (s, lactone C=O). Found: C, 52.24; H, 6.27%. Calcd for $C_{14}H_{20}Cl_2O_4$: C, 52 .02; H, 6.24%.

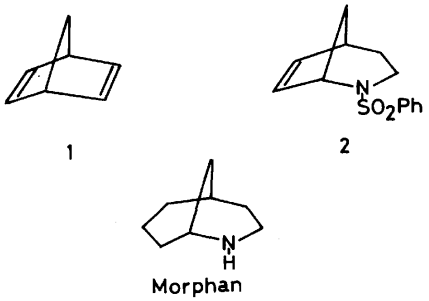
A Synthetic Route to the Morphan Ring System by Skeletal Transformation of Norbornadiene[1)]

Hiroo INOUE,* Toshiki ORIGUCHI, and Katsumi UMANO
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591
(Received September 8, 1983)

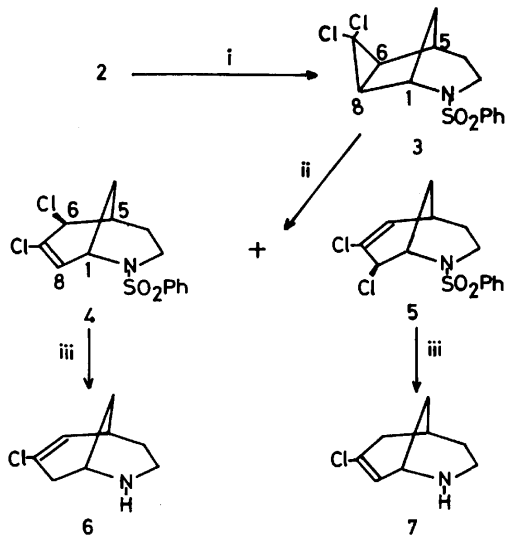
The morphan skeleton was prepared from 2-phenylsulfonyl-2-azabicyclo[3.2.1]oct-6-ene (**2**), derived from norbornadiene, through the addition of dichlorocarbene to the monoene **2** and the subsequent thermal isomerization of the adduct obtained. The isomerization products, 2-phenylsulfonyl-6,7-dichloro-2-azabicyclo-[3.3.1]non-7-ene and 2-phenylsulfonyl-7,8-dichloro-2-azabicyclo[3.3.1]non-6-ene, which are mutually convertible in the presence of lithium chloride, were converted into various morphans by reductive dechlorination and alkylation. Furthermore, the 6,7-pyridazino-annelated morphan was synthesized by the cycloaddition of dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate to 2-phenylsulfonyl-2-azabicyclo[3.3.1]non-6-ene.

In the course of our studies on the reactivity of the methano-bridged azabicyclic molecules,[2)] we took an interest in the morphan ring system having pharmacological activity.[3)] The morphan ring system has been synthesized by using mostly intramolecular cyclization reactions starting from an appropriate material.[3,4)] We planned to construct the morphan skeleton by an alternative route, utilizing skeletal transformation of available bicyclic molecule such as norbornadiene (**1**). The transformation of the diene **1** to 2-phenylsulfonyl-2-azabicyclo[3.2.1]oct-6-ene (**2**) through ring expansion has already been reported.[5,6)] We examined to transform the monoene **2** to the morphan ring system and now wish to report a novel synthetic route to various morphans starting from the diene **1**.



Results and Discussion

Ring Expansion of the Monoene 2 to the Morphan Ring System. On the basis of the fact that the dichlorocarbene adduct to norbornene readily undergoes ring expansion,[7)] the ring expansion of the monoene **2** was carried out using the dichlorocarbene adduct to the monoene **2**. The cheletropic addition of dichlorocarbene to the monoene **2**, using hexadecyltrimethylammonium bromide as the phase-transfer catalyst, gave 2-phenylsulfonyl-7,7-dichloro-2-azatricyclo-[3.2.1.0.^{6,8exo}]nonane (**3**) in 56% yield (Scheme 1). During this reaction, no rearrangement occurred. The exo configuration of the adduct **3** was determined by the absence of the coupling between 1-H and 8-H. The thermal isomerization of the adduct **3** was achieved successfully by heating the adduct **3** at 130—135 °C in the absence or presence of the solvent, thus giving rise to 2-phenylsulfonyl-6,7-dichloro-2-azabicyclo[3.3.1]-



Scheme 1. i) $|CCl_2$, r.t., 48 h; ii) 130—135 ℃, 1.5 h; iii) $LiAlH_4$, THF, r.t., 30 h.

non-7-ene (**4**) and its positional isomer (**5**) which can be separated readily by silica-gel chromatography (Scheme 1). The position of the double bond of **4** and **5** was determined by the fact that the doublet absorptions of vinyl protons at δ=5.37 (**4**) and 5.94 (**5**) collapse to singlet by double irradiation of 1-H of **4** and 5-H of **5** respectively. The absence of the coupling between 5-H and 6-H for **4** and between 1-H and 8-H for **5** indicated the configuration of endo 6-H for **4** and endo 8-H for **5**. The yields of **4** and **5** are shown in Table 1. The polar solvent was favorable for isomerization, although no significant solvent effect on the isomer ratio was observed. Furthermore, we found that the treatment of **4** or **5** with lithium chloride in *N*, *N*-dimethylformamide (DMF) at 50 °C for 7 h results in the migration of the double bond to give the equilibrium mixture of **4** and **5** in the ratio of 65:35, although no allylic rearrangement occurs in the absence of lithium chloride under similar conditions (Table 2). The reaction is considered to proceed through the intermediate A to give **4** and **5**.

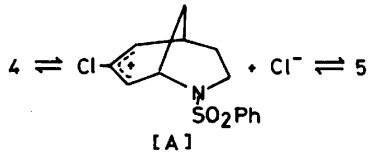


Table 1. The yields of **4** and **5** in the thermal isomerization of **3**[a)]

Solvent	Time/h	Yield/%		Recov./%
		4	**5**	**3**
None	1.5	54	43	0
m-Xylene	3.0	18	9	72
Chlorobenzene	1.5	65	33	0
DMF	1.5	56	41	0

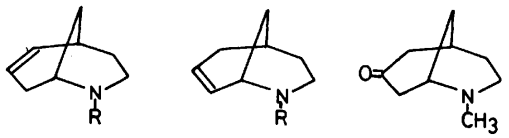
a) Temperature: 130—135 °C.

Table 2. The allylic rearrangement of **4** and **5** in the presence of lithium chloride[a)]

Substrate	Temp/°C	Time/h	Yield/%	
			4	**5**
4	50	1	84	16
4	50	3	68	32
4	50	7	65	35
4	80	15	64	35
5	50	3	58	42
5	50	7	63	37

a) Solvent: DMF.

Reductive Dechlorination of Compounds 4 and 5. The reductive cleavage of the C_6–Cl bond of **4** with lithium aluminium hydride in tetrahydrofuran (THF) at room temperature for 30 h proceeded by the S_N2' process, accompanied by the cleavage of the N–S bond, to give 7-chloro-2-azabicyclo[3.3.1]non-6-ene (**6**) in 80% yield (Scheme 1). Next, compound **6** was treated with sodium in liquid ammonia for 40 min to give 2-azabicyclo[3.3.1]non-6-ene (**8a**) in 78% yield. Attempts to undergo one-step dechlorination of **4** with sodium in liquid ammonia failed because of the destruction of the morphan skeleton. Compound **8a** was alkylated with methyl iodide and benzyl bromide to give **8b** and **8c** in 52 and 77% yields respectively.



8 9 10

(a; R=H, b; R=CH_3, c; R=$PhCH_2$)

Compound **5** also was converted into **9a—c** by the steps shown in the case of **4**. The yields in the conversion of **5** into **7**, **7** into **9a**, and **9a** into **9b**, **c** were 76, 52, 36, and 70% respectively. The structure of **8b** and **9b** was established by the fact that the melting points and NMR spectra of picrates of **8b** and **9b** prepared here are identical to those of two isomers (**8b** and **9b**) prepared by an alternative route[8)] starting from 2-methyl-2-azabicyclo[3.3.1]nonan-7-one (**10**) [**8b** picrate: δ 5.84 (single multiplet, 2H, 6- and 7-H); **9b** picrate: δ 6.45 (a doublet of triplets, 1H, 7-H) and δ 5.82 (poorly resolved triplet, 1H, 8-H)].[8)] Thus, it was established that the morphan derivatives having a double bond at 6- or 7-position are synthesized from the diene **1** by skeletal transformation.

Annelation of Pyridazine Ring onto the Morphan Ring. We attempted to annelate a heterocyclic ring instead of the benzene ring of 6,7-benzomorphans. Previously it has been reported that 1,2,4,5-tetrazines undergo cycloaddition to various dienophiles to form pyridazines.[9)] To annelate a pyridazine ring onto the 6,7-position of the morphan ring, we carried out the cycloaddition of dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate (**12**) to 2-phenylsulfonyl-2-azabicyclo-[3.3.1]non-6-ene (**11**). When a solution of a 1:2 mixture of **11** and **12** in chloroform was stirred at 50 °C for 15 h, the reaction proceeded with the evolution of nitrogen gas to give 2-phenylsulfonyl-3′,6′-bis(methoxycarbonyl)-6,7-(4′,5′-pyridazino)-2-azabicyclo[3.3.1]non-6-ene (**14**) in a quantitative yield, together with dimethyl 1H,4H-1,2,4,5-tetrazine-3,6-dicarboxylate (**15**) in nearly equimolar amounts with those of **14**. In equimolar solution of **11** and **12** in chloroform, the reaction gave **14** and **15** in 31 and 36% yields respectively. These facts indicate that the reaction proceeds by the cycloaddition of **12** to **11** to give the intermediate dihydropyridazine adduct (**13**) by release of nitrogen, followed by the dehydrogenation of **13** with **12** to give **14**, as shown in Scheme 2.

Next, we carried out the cycloaddition of **12** to 2-phenylsulfonyl-7-chloro-2-azabicyclo[3.3.1]non-6-ene (**16**) under conditions similar to those described above. The reaction proceeded through the evolution of nitrogen gas and then the dehydrochlorination of the intermediate adduct to give **14** in 37% yield. Thus, it was established that the pyridazine ring is annelated onto the morphan ring.

The above results provide a new route for the preparation of the morphan ring system from readily available diene **1**.

Experimental

The ^1H NMR spectra were determined on a Hitachi R-24A NMR spectrometer at room temperature with $CDCl_3$ as a solvent, using tetramethylsilane as the internal standard. The ^{13}C NMR and IR spectra were measured with a JEOL FX 90Q

Fourier transformation NMR spectrometer and a Hitachi 215 grating infrared spectrometer, respectively. All melting points were uncorrected. Compound **1** was obtained commercially and compound **2** was synthesized by the modification of the methods described in the literature.[5,6]

2-Phenylsulfonyl-7,7-dichloro-2-azatricyclo[3.2.1.0.^{6,8exo}]nonane (**3**). A 50% aqueous sodium hydroxide solution(73 g) was stirred, drop by drop, into a solution of **2** (6.6 g, 27 mmol) in chloroform (115 g) with hexadecyltrimethylammonium bromide (0.98 g) for 1 h at room temperature. After stirring for 2 d, the reaction mixture was extracted with chloroform. The chloroform solution was washed with water and dried over anhydrous magnesium sulfate. After removal of the chloroform *in vacuo*, the residue was chromatographed with a silica-gel column [chloroform–hexane (10:1) as an eluant] to give **3** (5 g, 56%), which was recrystallized from ethanol: mp 113—115 °C; IR (KBr) 1350 and 1170 cm^{-1} (SO_2); ^{1}H NMR δ=1.15—2.32 (m, 6H, 4-CH_2, 6-H, 8-H, and 9-CH_2), 2.51 (m, 1H, 5-H), 2.72—3.87 (m, 2H, 3-CH_2), 4.50 (d, 1H, J=4.7 Hz, 1-H), and 7.20—8.05 (m, 5H, aromatic). Found: C, 50.80; H, 4.62; N, 4.46%. Calcd for $C_{14}H_{15}NO_2SCl_2$: C, 50.60; H, 4.56; N, 4.22%.

Ring Expansion of **3**. In the Absence of Solvent. Compound **3** (3 g, 9 mmol) was placed in a test tube and heated at 130—135 °C for 1.5 h. The mixture was cooled and chromatographed with a silica-gel column (benzene as an eluant) to give 1.62 g (54%) of **4** and 1.29 g (43%) of **5**. Compounds **4** and **5** were recrystallized from ethanol. **4**: mp 136.5—138.5 °C; IR (KBr) 1350 and 1165 cm^{-1} (SO_2); ^{1}H NMR δ=1.40—2.30 (m, 4H, 4-CH_2 and 9-CH_2), 2.45 (m, 1H, 5-H), 2.82 (m, 1H, 3-$H_{exo\ or\ endo}$), 3.60 (m, 1H, 3-$H_{exo\ or\ endo}$), 4.18 (s, 1H, 6-H), 4.48 (m, 1H, 1-H), 5.37 (d, 1H, J=6.3 Hz, 8-H), and 7.18—8.02 (m, 5H, aromatic). Found: C, 50.61; H, 4.61; N, 4.27%. Calcd for $C_{14}H_{15}NO_2SCl_2$; C, 50.60; H, 4.56; N, 4.22%. **5**: mp 108—109 °C; IR (KBr) 1340 and 1165 cm^{-1} (SO_2); ^{1}H NMR δ=1.10—2.42 (m, 4H, 4-CH_2 and 9-CH_2), 2.60 (m, 1H, 5-H), 3.00 (m, 1H, 3-$H_{exo\ or\ endo}$), 3.70 (m, 1H, 3-$H_{exo\ or\ endo}$), 3.97 (s, 1H, 8-H), 4.42 (m, 1H, 1-H), 5.94 (d, 1H, J=6.3 Hz, 6-H), and 7.25—8.00 (m, 5-H, aromatic). Found: C, 50.58; H, 4.72; N, 4.31%. Calcd for $C_{14}H_{15}NO_2SCl_2$: C, 50.60; H, 4.56; N, 4.22%.

In the Presence of Solvent. A solution of **3** (3 g, 9 mmol) in *m*-xylene, chlorobenzene, or DMF (10 cm^3) was refluxed for 1.5 h. After the removal of the solvent, the mixture was worked up as described above.

Conversion of **5** *into* **4**. A solution of a mixture of **5** (1 g, 3 mmol) and lithium chloride (0.63 g, 15 mmol) in DMF (40 cm^3) was stirred at 50 °C for 7 h. After the removal of DMF *in vacuo*, water (20 cm^3) was added and the mixture was extracted with chloroform. The chloroform solution was washed with water, dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo*. The residue was chromatographed with a silica-gel column (benzene as an eluant) to give **4** (0.63 g, 63%) with recovery of **5** (0.37 g, 37%).

7-Chloro-2-azabicyclo[3.3.1]non-6-ene (**6**). A solution of **4** (1.25 g, 3.8 mmol) in THF (17 cm^3) was added, drop by drop, to a suspension of lithium aluminium hydride (0.6 g, 16 mmol) in THF (43 cm^3) at room temperature. The mixture was stirred for 30 h at room temperature and water was added. After filtration of the mixture, the filtrate was extracted with chloroform. The chloroform solution was washed with water and dried over anhydrous magnesium sulfate. The removal of the solvent *in vacuo* gave **6** (0.48 g, 80%): IR (KBr) 3250 cm^{-1} (NH) and 1645 cm^{-1} (C=C); ^{1}H NMR δ=1.10—1.85 (m, 4H, 4-CH_2 and 9-CH_2), 1.90 (s, 1H, NH), 2.20—3.11 (m, 4H, 3-CH_2 and 8-CH_2), 2.55 (m, 1H, 5-H), 3.25 (m, 1H, 1-H), and 5.78 (d, 1H, J=6.7 Hz, 6-H). The treatment of **6** with hydrogen chloride in ether gave HCl salt of **6** which was recrystallized from acetonitrile: mp 216—218 °C; Found: C, 49.50; H, 6.68; N, 7.37%. Calcd for $C_8H_{13}NCl_2$: C, 49.50; H, 6.76; N, 7.22%.

7-Chloro-2-azabicyclo[3.3.1]non-7-ene (**7**) was prepared from **5** in 76% yield by procedures similar to those in the case of **6**. **7**: IR (KBr) 3250 cm^{-1} (NH) and 1645 cm^{-1} (C=C): ^{1}H NMR δ=1.10—2.10 (m, 4H, 4-CH_2 and 9-CH_2), 2.20 (s, 1H, NH), 2.20—3.20 (m, 5H, 3-CH_2, 5-H, and 6-CH_2), 3.45 (m, 1H, 1-H), and 5.66 (d, 1H, J=6.7 Hz, 8-H). HCl salt of **7**: mp 216.5—218 °C; Found: C, 49.54; H, 7.00; N, 7.21%. Calcd for $C_8H_{13}NCl_2$: C, 49.50; H, 6.76; N, 7.22%.

2-Azabicyclo[3.3.1]non-6-ene (**8a**). A piece of sodium was added under stirring to a solution of **6** (0.6 g, 3.8 mmol) in ether (10 cm^3) and liquid ammonia (25 cm^3) at −78 °C until the solution kept the dark blue color for about 5 min. After stirring for 40 min, ammonia was removed, methanol was added, and the resulting solution extracted with ether. The ether solution was washed with water and dried over anhydrous sodium sulfate. The removal of ether gave **8a** (0.36 g, 78%): IR (KBr) 3270 cm^{-1} (NH) and 1645 cm^{-1} (C=C); ^{1}H NMR δ=1.00—3.00 (m, 9H, 3-CH_2, 4-CH_2, 5-H, 8-CH_2, and 9-CH_2), 2.10 (s, 1H, NH), 3.10 (m, 1H, 1-H), and 5.77 (m, 2H, 6-H and 7-H). HCl salt of **8a** was recrystallized from acetonitrile: mp 278—279 °C; Found: C, 60.26; H, 9.15; N, 8.80%. Calcd for $C_8H_{14}NCl$: C, 60.17; H, 8.86; N, 8.77%.

2-Azabicyco[3.3.1]non-7-ene (**9a**) was prepared from **7** in 52% yield by the procedures being similar to those in the case of **8a**. **9a**: IR (KBr) 3260 cm^{-1} (NH) and 1615 cm^{-1} (C=C); ^{1}H NMR δ=1.20—3.10 (m, 9H, 3-CH_2, 4-CH_2, 5-H, 6-CH_2, and 9-CH_2), 2.07 (s, 1H, NH), 3.32 (m, 1H, 1-H), 5.50 (dd, 1H, J=9.7, 6.0 Hz, 8—H),and 5.97 (dt, 1H, J=9.7, 4.0 Hz, 7-H). $(COOH)_2$ salt of **9a**: mp 210.5—212 °C; Found: C, 64.26; H, 8.59; N, 8.41%. Calcd for $C_{18}H_{28}N_2O_4$: C, 64.25; H, 8.33; N, 8.33%.

Alkylation of **8a** *and* **9a**. *With Methyl Iodide*: Sodium hydride (0.16 g, 3.2 mmol) was added to a solution of **8a** or **9a** (0.2 g, 1.6 mmol) in dimethyl sulfoxide (10 cm^3) and the mixture was stirred at 45 °C for 20 min. A solution of methyl iodide (0.71 g, 5 mmol) in dimethyl sulfoxide (5 cm^3) was added to the resulting solution. After stirring for 10 min, the mixture was poured into water (80 cm^3) and extracted with ether. The ether solution was washed with water and dried over anhydrous sodium sulfate. The removal of ether gave **8b** and **9b** in 52 and 36% yields, respectively. The melting points and NMR spectra of picrates of **8b** and **9b** were identical to those described in the literature.[9]

With Benzyl Bromide: A mixture of **8a** (0.28 g, 2.3 mmol), benzyl bromide (0.39 g, 2.3 mmol), sodium hydrogencarbonate (0.33 g, 3.9 mmol), and DMF (30 cm^3) was refluxed for 4 h. After filtration of the reaction mixture, the filtrate was evaporated and the residue was extracted with ether. The ether solution was washed with water and dried over anhydrous sodium sulfate. The removal of ether gave **8c** (0.38 g, 77%): ^{1}H NMR δ=1.50—2.05 (m, 4H, 4-CH_2 and 9-CH_2), 2.17 (m, 1H, 5-H), 2.25—2.67 (m, 4H, 3-CH_2 and 8-CH_2), 2.92 (m, 1H, 1-H), 3.49 (s, 2H, -C$\underline{H}_2$Ph), 5.72 (m, 2H, 6-H and 7-H), and 7.16 (s, 5H, aromatic). $(COOH)_2$ salt of **8c**: mp 177.5—180 °C; Found: C, 67.27; H, 7.12; N, 4.79%. Calcd for $C_{17}H_{21}NO_4$: C, 67.33; H, 6.93; N, 4.62%. Compound **9c** was prepared by the procedures being similar to those in the case of **8c**. **9c** (70% yield): ^{1}H NMR δ=1.15—2.80 (m, 9H, 3-CH_2, 4-CH_2, 5-H, 6-CH_2, and 9-CH_2), 3.12 (m, 1H, 1-H), 3.49 (s, 2H, -C$\underline{H}_2$Ph), 5.55 (m, 1H, 8-H), 6.03 (m, 1H, 7-H), and 7.18 (s, 5H, aromatic). $(COOH)_2$ salt of **9c**: mp 183—184.5 °C; Found: C, 67.18; H, 6.96; N, 4.55%. Calcd for $C_{17}H_{21}NO_4$: C, 67.33; H, 6.93; N, 4.62%.

2-Phenylsulfonyl-2-azabicyclo[3.3.1]non-6-ene (**11**). Benzenesulfonyl chloride (0.28 g, 1.6 mmol) was added gradually to a solution of **8a** (0.16 g, 1.3 mmol) in 2 M† sodium hydroxide (11 cm^3) and the mixture was stirred at room temperature for 5 h. The resulting solution was extracted

† 1 M=1 mol dm^{-3}.

with chloroform, and the chloroform solution was washed with water and dried over anhydrous sodium sulfate. After the removal of chloroform *in vacuo*, the residue was chromatographed on a silica-gel column using benzene as the eluant to give 0.32 g (91%) of **11**, which was recrystallized from ethanol: mp 108.5—110.5 °C; IR (KBr) 1310 and 1155 cm^{-1}(SO_2); ^1H NMR δ=1.31—1.76 (m, 4H, 4-CH_2 and 9-CH_2), 1.76—2.56 (m, 3H, 5-H and 8-CH_2), 3.06 (m, 1H, 3-$H_{exo\ or\ endo}$), 3.66 (m, 1H, 3-$H_{exo\ or\ endo}$), 4.21 (m, 1H, 1-H), 5.58 (m, 2H, 6-H and 7-H), and 7.26—7.86 (m, 5H, aromatic). Found: C, 63.77; H, 6.80; N, 5.29%. Calcd for $C_{14}H_{17}NO_2S$: C, 63.84; H, 6.52; N, 5.32%.

2-Phenylsulfonyl-7-chloro-2-azabicyclo[3.3.1]non-6-ene (16) was prepared from **6** by procedures similar to those used in the case of **11**. **16**: mp 124—126 °C; IR (KBr) 1350 and 1170 cm^{-1} (SO_2); ^1H NMR δ=1.40—2.05 (m, 4H, 4-CH_2 and 9-CH_2), 2.05—2.95 (m, 3H, 5-H and 8-CH_2), 3.03 (m, 1H, 3-$H_{exo\ or\ endo}$), 3.72 (m, 1H, 3-$H_{exo\ or\ endo}$), 4.33 (m, 1H, 1-H), 5.76 (d, 1H, J= 6.0 Hz, 6-H), and 7.30—7.95 (m, 5H, aromatic). Found: C, 56.22; H, 5.40; N, 4.79%. Calcd for $C_{14}H_{16}NO_2ClS$: C, 56.46; H, 5.43; N, 4.70%.

2-Phenylsulfonyl-3',6'-bis(methoxycarbonyl)-6,7-(4',5'-pyridazino)-2-azabicyclo[3.3.1]non-6-ene (14). A solution of a mixture of **11** (0.1 g, 0.38 mmol) and **12** (0.15 g, 0.76 mmol) in chloroform (10 cm^3) was stirred at 50 °C for 15 h. After the removal of chloroform *in vacuo*, the residue was chromatographed on a silica-gel column using chloroform as the eluant to give **14** (0.18 g, 91%) and **15** (0.11 g, 57%). Compound **14** was recrystallized from chloroform–benzene and **15** from chloroform–hexane. **14**: mp 197—199 °C; IR (KBr) 1735 cm^{-1} (CO); ^1H NMR δ=1.50—3.70 (m, 9H, 3-CH_2, 4-CH_2, 5-H, 8-CH_2, and 9-CH_2), 3.86 (s, 3H, -CO_2Me), 3.92 (s, 3H, -CO_2Me), 4.52 (m, 1H, 1-H), and 7.30—7.85 (m, 5H, aromatic); ^{13}C NMR δ=27.1, 29, 29.8, and 30.3 (4-, 5-, 8-, and 9-C), 37.7 (t, 3-C), 45.7 (d, 1-C), 53.1 and 53.3 (OMe), 127, 129.3, and 132.7 (aromatic), 137.6 and 140 (s, 6- and 7-C), 151.2 and 152 (s, 3'- and 6'-C), and 164.5 and 164.7 (s, CO). Found: C, 55.38; H, 4.77; N, 9.70%. Calcd for $C_{20}H_{21}N_3O_6S$: C, 55.67; H, 4.92; N, 9.74%. **15**: mp 174.5—175.5 °C; IR (KBr) 1728 cm^{-1} (CO); ^1H NMR 3.83 (s, 6H, -CO_2Me), and 7.42 (brs, 2H, NH). Found: C, 35.99; H, 4.04; N, 27.99%. Calcd for $C_6H_8N_4O_4$: C, 36.08; H, 4.00; N, 27.75%.

Reaction of 16 with 12. A solution of a mixture of **16** (0.1 g, 0.34 mmol) and **12** (0.13 g, 0.68 mmol) in chloroform (5 cm^3) was stirred at 50 °C for 15 h. The reaction mixture was worked up as described in the case of **11**.

Syntheses of Aryl Glyoxylate. I. The Reaction of Alkyl Dichloro(alkoxy)acetates with Aromatics in the Presence of Lewis Acid

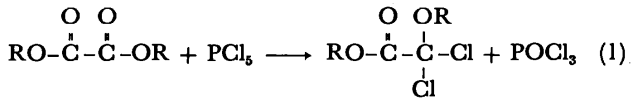
Osamu ITOH,* Takayoshi NAGATA, Isamu NOMURA, Tetsuya TAKANAGA, Toshio SUGITA, and Katsuhiko ICHIKAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received September 19, 1983)

Ethyl dichloro(ethoxy)acetate (**1**) and methyl dichloro(methoxy)acetate (**2**) were characterized. The reaction of **1** and **2** with aromatics in the presence of $AlCl_3$ gave a considerable yield of aromatic α-keto ester. The aromatics included mono- and polymethylbenzene and anisol. The reaction was studied under various conditions and the results were compared with the acylation by ethoxalyl or methoxalyl chloride. The reaction mechanism was also discussed.

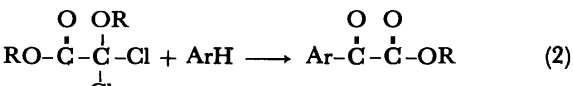
The chemical properties of ethyl dichloro(ethoxy)-acetate (**1**) and methyl dichloro(methoxy)acetate (**2**) which are prepared by the reactions of dialkyl oxalate and phosphorus pentachloride[1] appear to have not been fully studied, in spite of their potential wide usability in organic synthesis.



(1)

1: R=Et, **2**: R=Me

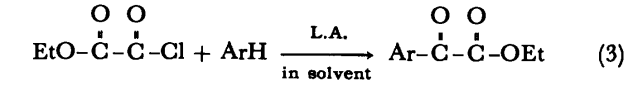
In this paper we wish to report the syntheses of aromatic α-keto esters by the reactions of **1** and **2** with aromatics in the presence of Lewis acids.



(2)

3: R=Et, **4**: R=Me

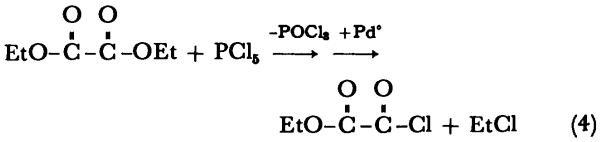
Needless to say, aromatic α-keto esters can be prepared by the Friedel-Crafts acylation of aromatics with ethoxalyl chloride.[2]



(3)

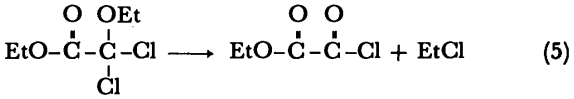
3

Ethoxalyl chloride is usualy prepared by two-step reactions of diethyl oxalate with phosphorus pentachloride.[3]



(4)

However the reaction intermediate should be one of the titled compounds. The reaction mixture of Eq. 1 or Eq. 4 (for 4 d at 95—100 °C) was subjected to a fractional distillation and the higher boiling fractions were found to be a mixture of **1** and diethyl oxalate. One more careful fractional distillation gave the fraction which consisted of 80% of **1** and 20% of diethyl oxalate. It was very difficult to obtain a fraction of more than 95% in purity. This fraction was heated at 180—200 °C for 6 h and then pure ethoxalyl chloride was obtained in 58% (corr. value; 70%). The conversion of **1** to ethoxalyl chloride was followed by GLC and ^{13}C NMR spectra. The evolved gas was partially trapped by Dry Ice–methanol and was identified to be ethyl chloride by ^1H NMR (CH_3: 3.55, CH_2: 1.50 in $CDCl_3$ *cf.* CH_3: 3.57. CH_2: 1.48 in CCl_4).



(5)

1 could not be purified to 100%, but the analogue, methyl dichloro(methoxy)acetate (**2**) was purified by two fractional distillations. The elemental analysis of the most purified fraction coincided with the calculated value for $C_4H_6O_3Cl_2$.

Syntheses of Aromatic α-Keto Esters. Compounds **1** and **2** in $CHCl_3$ reacted with the aromatics (ArH) in the precence of $AlCl_3$, $FeCl_3$, and $TiCl_4$ to form aromatic α-keto esters. To the $CHCl_3$ solution of an equivalent mole of **1** and ArH, powdered $AlCl_3$ (2 equiv mol) was added in parts with constant stirring, keeping the temperature under 5 °C (Method A). After 2 h, the reaction mixture was poured into ice water. The products were distilled out and analyzed by GLC, ^1H and ^{13}C NMR. Once **1** and **2** were treated with $AlCl_3$ or $FeCl_3$, **1** and **2** could not be recovered, and then the end point of the reaction could not precisely be detected. Although these reactions were very rapid, 2 h were too short to complete the reaction. However the isolated yields under such reaction conditions were fairly good; they are shown in the first column of Table 1.

The numbers of the yields could indicate a relative rate of the reaction, from the point of view as mentioned above, though the reaction mixture was heterogeneous. The numbers within parentheses were corrected values based on the purity of **1**, and the contaminated diethyl oxalate had no effect on the reaction.

In the reaction of **1** with benzene at bp of $CHCl_3$, ethyl phenylglyoxylate (20%) and a little (3.6%) ethyl *p*-ethylphenylglyoxylate were obtained. The latter was obtained through a fast ethylation of benzene with ethyl chloride and $AlCl_3$, followed by acylation of ethylbenzene. When **1** was treated with $AlCl_3$ or $FeCl_3$ at bp of CH_2Cl_2 or $CHCl_3$, it rapidly decomposed to eliminate ethyl chloride gas. So **1** reacted in two ways: the acylation of ArH and the decomposition, depending upon the reaction conditions. At a lower temperature, the rate of the decomposition might be much slower than that of the acylation. These reactions were

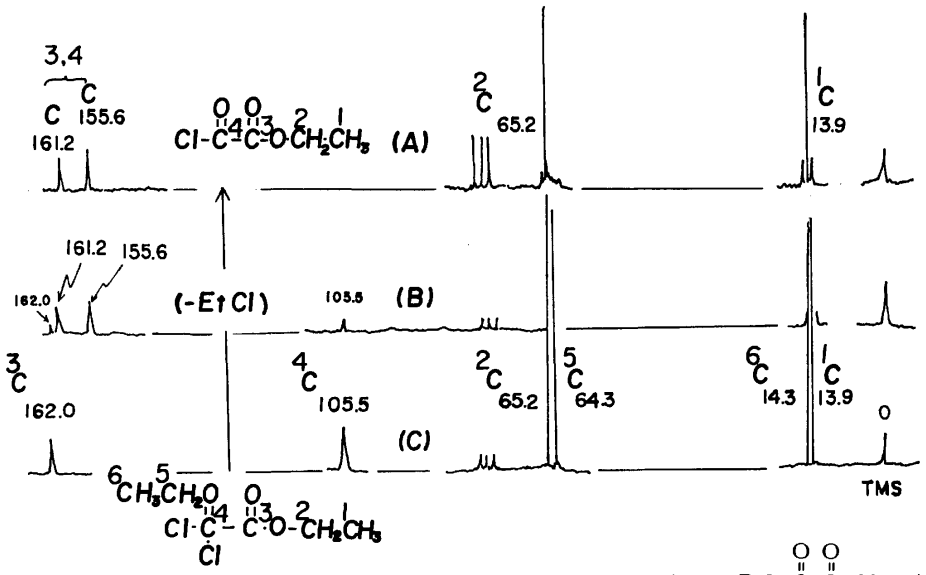


Fig. 1. C-13 NMR spectral change in the decomposition of **2** to EtO-C(=O)-C(=O)-Cl. (A) After 2 h at 200 °C, spectrum of EtO-C(=O)-C(=O)-Cl. (B) Spectrum of mixtures. (C) Spectrum of **2**; before heating.

Table 1. Yields of substituted phenylglyoxylates[a)]

Starting materials	3	Column No. Products Substituents	1 **1** (%) (Corr. value)	2 **1** or **11** (%) Max. value	3 Ethoxalyl chloride (%)	4 (%)

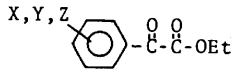
Benzene	**3g**	H	—	20[e)]+3.6[f)]	13.6	50[h)]

a) All compounds recorded in this table gave satisfactory analysis. Isolated yields in all cases. Method A: ArH (0.05 mol) and **1** (0.05 mol) were dissolved in 100 ml of $CHCl_3$ at 0—5 °C. Powdered $AlCl_3$ (0.1 mol) was added into the well-stirring reaction mixture for 20—40 min. The reaction time is 80—120 min. b) CH_2Cl_2 solvent; mesitylene (0.50 mol), $AlCl_3$ (0.10 mol), **2** (0.05 mol). c) Reaction time is 1 day at r.t. d) **1** was added to the CH_2Cl_2 solution. e) Benzene (0.24 mol), $AlCl_3$ (0.2 mol), **1** (0.1 mol). f) Another compound=ethyl *p*-ethylphenylglyoxylate. g)Ref. 2; solvent is $C_6H_5NO_2$. h) Ref. 2; solvent is C_6H_6. In our case (Table 2), the yields is 47%.

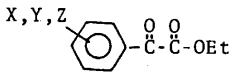
dependent on the following three factors: the solvents, the catalysts, and the reagent ratio. 1) The best solvent is CH_2Cl_2. Other usable solvents are $CHCl_3$ and CH_3NO_2, but CS_2, Et_2O, and $C_6H_5NO_2$ are not good solvents. 2) The best catalysts are $AlCl_3$, $TiCl_4$, and $SnCl_4$. When $TiCl_4$ was used, the reaction worked well in a homogeneous state. This reaction will be reported in future. 3) The reagent ratio of ArH, $AlCl_3$, and **1** or **2** must be the most suitable value in response to the reactivity of ArH; the ratios of 1:2:1 and 10:2:1 were generally used.

In the cases of mesitylene, toluene, benzene, and anisol, the reactions under the optimum conditions were tried; the maximum yields are shown in the second column of Table 1.

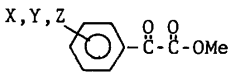
The configuration of the Aromatic α-Keto Esters. The aromatic α-keto esters (**3e—g**) were identified with the authentic samples obtained by the known methods as mentioned above Eq. 3 and in Ref. 3 (*cf.* footnote of Table 1). By using ^1H and ^{13}C NMR spectra of each compound, we were able to assign their configurations.



3a; 2,4,6-Me_3
3b; 3,4-Me_2
3c; 2,4-Me_2
3d; 2,5-Me_2
3e; 2-or 4-Me
3f; 2-or 4-MeO



3g; unsubstituted



4

There were many other compounds (**3a—d**) which could not be found in the literature, but these configurations were determined by ^{13}C NMR spectra. The observed chemical shifts were compared with the calculated values; the values almost coincided.

In the case of toluene, the product was a mixture whose composition were variable with the reaction conditions; it always included two compounds. The C, H analysis of the mixture coincided with the calculated values for $C_{11}H_{12}O_3$. The isolation of one of the mixtures was very difficult. From the reaction of toluene with methoxalyl chloride (*cf*; Table 2), an almost pure compound (95%), one of the two compounds, was obtained; its configuration was determined to be methyl *p*-methylphenylglyoxylate. The other compound, therefore, was deduced to be methyl *o*-methylphenylglyoxylate.

In the case of anisole, the same method was applied.

Table 2. Yields of substituted phenylglyoxylates[a)]

Starting materials		Column 1 Reagent **2**	Column 2 Reagent MeO-C(=O)-C(=O)-Cl
Mesitylene	**4a**	15	18
Toluene	**4e**	0[b)]	50 (*o*/*p*=0.05)
Anisole	**4f**	0[c)]	50 (*o*-: trace)
Benzene	**4g**	38 and 47[d)]	62

a) Method B: mole ratio of ArH: $AlCl_3$: **2** or MeO-C(=O)-C(=O)-Cl was about 30:2:1. An acylating reagent was added at the end. b) No distillable product was obtained. c) Some other product was obtained. d) To the cooled mixture of ArH and an acylating reagent, $AlCl_3$ was added.

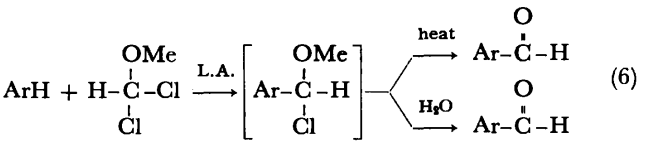
The Reaction of Ethoxalyl Chloride with ArH in $CHCl_3$. The yields of classical Friedel-Crafts reaction using ethoxalyl chloride as an acylating reagent are shown in column 4. These values were very large, in comparison with our data, although the reaction conditions were very severe, at higher temperature for longer reaction time in CH_2Cl_2 or in nitrobenzene. We also reexamined this reaction under our reaction conditions (0 °C, 80 min, in $CHCl_3$); the available data are tabulated in the column 3.

These values in the columns 1 and 3 show only small differences. However, under the reaction without solvents, great diffrences were observed between the reaction of **2** with ArH and that of methoxalyl chloride with ArH (Columns 1 and 2 in Table 2).

*The Reaction of **2** and Methoxalyl Chloride with ArH without a Solvent.* Compounds **2** was a little more stable under these reaction conditions than **1** was, although **2** decomposed to eliminate methyl chloride under more severe conditions (*e.g.*, at bp of CH_2Cl_2). The reaction of **2** with ArH at 0 °C was studied in detail. To an aromatic hydrocarbon containing 2 equivs of $AlCl_3$, 1 equiv of **2** was added with good stirring and cooling with ice. The results with respect to mesitylene, toluene, anisole, and benzene are shown in the first column of Table 2. In the second column, the yields of aromatic α-keto esters obtained by the reaction of methoxalyl chloride with ArH without solvent are shown. The yield of the reaction of **2** with mesitylene decreased from 53% (in the case of **1**) to 15%. In the case of anisole, an aromatic α-keto ester was not obtained, but some other compound[4)] was obtained. In the case of toluene, none of the product could be distilled out. Only when $AlCl_3$ was added to the toluene solution of **2**, a little amount of α-keto ester and some other product happened to be obtained. We can not yet explain why the reaction in toluene did not work well.

In contrast to this reaction, the reaction of methoxyalyl chloride with ArH was a normal reaction and the yields increased except only the case of mesitylene.

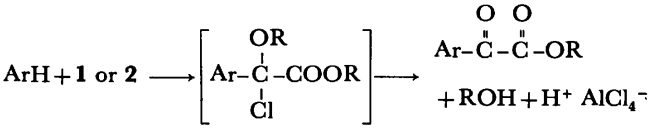
The Reaction Mechnism. An analogous reaction to this was reported earlier by Riech and Gross:[5)] the formylation of ArH by dichloro(methoxy)methane in the presence of $AlCl_3$, $TiCl_4$, and $SnCl_4$ (Eq. 6). They explained the reaction route through the parenthesized intermediate.



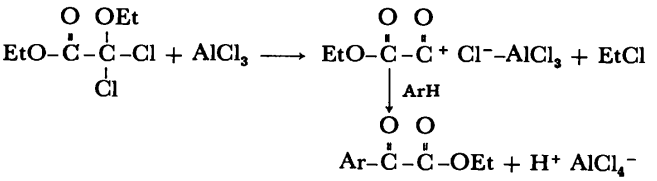
(6)

The parenthesized compound was not the final product, but the reaction product, which was labile to heat or to work-up condition.

The same mechanism was most probable for the aromatic α-keto ester reaction.



In the case of **1**, another mechanism could be as follows:



When ArH was added after the treatment of **1** or **2** with $AlCl_3$ in a solvent, the yield of the product greatly decreased or reduced to zero. Thus, the latter mechanism is not probable. The parenthesized compound of this reaction Ar-C(OR)(Cl)-C(=O)-OR, is more stable than Ar-C(OMe)(Cl)-H, that of the formylation reaction. The parenthesized compound was the reaction product, and then it changed to aromatic α-keto esters under work-up.

Aromatic α-keto esters were generally synthesized through the oxidation of mandelic acid derivatives,[6)] but the yield of oxidation was generally low. Recently a new synthesis of α-keto esters and acids was reported by Mosher and *et al.*[7)] The acylating reagents was

 , which was prepared by the reaction between ethoxalyl chloride and imidazole. This method is the best method on laboratory scale. In comparison to these methods, **1** and **2** are easily prepared in large scale and the cost to prepare **1** and **2** is most inexpensive. In addition, **1** and **2** have other usabilities in organic synthesis. The other kinds of aromatic α-keto esters could be synthesized using **1**, **2**, ethoxalyl and methoxalyl chloride. The application of this reaction to halobenzenes, biphenyl, and naphthalene will be reported in future.

Experimental

Measuremets. Melting and boiling points were uncorrected. ^{1}H NMR spectra were measured on a JEOL-60 (60 MHz) spectrometer with tetramethylsilane as an internal standard, and IR spectra on a Hitachi EPI-G_2 infrared spectrometer.^{13}C NMR spectra were measured on a JEOL-PFT-100 spectrometer.

Materials. The following materials were synthesized according to the reported method[1] and an improved one.

1. An equivalent mole of diethyl oxalate (2mol) and PCl_5 (2mol) were mixed and then heated at 105—115 °C for 6—10 h. The reaction mixture was distilled through a Vigrew column by a water pump. The amounts of the third, fourth and fifth fraction (bp of them, 80—92 °C/18 mmHg, 92—98 °C/18mmHg and 99 °C/18mmHg—104 °C/24mmHg) were 79, 44, and 194 g; their purities were 76, 88, and 95%. These fractions was further subjected to efficient fractional distillation. The total yield amounted to 67% (1.35 mol), as found by GLC analyses.

2. Dimethyl oxalate (236 g, 2.0 mol) and PCl_5 (417 g, 2.0 mol) were mixed in a solid state and heated at 110 ± 5 °C for 10—15 h. An aliquot was analyzed by GLC. After dimethyl oxalate of more than 80% converted to **2**, oxyphosphoryl chloride and then **2** were distilled off from the reaction mixture. The first fraction (bp 35 °C/49 mmHg) and the second fraction (bp 44 °C/36 mmHg—50 °C/36 mmHg) were composed of oxyphosphoryl chloride and a little dimethyl oxalate. The third fraction (bp 77 °C/34 mmHg—87 °C/32 mmHg) was composed of 60% of **2** and 40% of dimethyl oxalate. The GLC analysis gave the total yield as 190 g, 55%. The third and fourth fractions were combined and this was subjected to efficient distillation. The fraction of constant bp, 80 °C/22 mmHg (98 g, 28%) was analyzed as shown below. Calcd for $C_4H_6O_3Cl_2$: C, 27.77; H, 3.49; Cl, 40.98%. Found: C, 27.96; H, 3.42; Cl, 40.83%. ^{1}H NMR δ=3.82 (s, 3H) 3.93 (s, 3H). IR: $\nu_{C=O}$ 1770 cm^{-1}: $\delta_{C=O\ or\ C=O}$ 1285, 1200, and 1150 cm^{-1}: ν_{C-Cl} 660 cm^{-1}.

Reaction of Substituted Benzene with 1 or 2 in $CHCl_3$. The substituted benzene (0.05 mol) and **1** or **2** (0.05 mol) were dissolved in 100 ml of $CHCl_3$ and kept at 0—5 °C on the ice bath. Powdered $AlCl_3$ (0.1 mol) was added into the well-stirred reaction mixture for 20—40 min. Then it was kept at 0—5 °C for 80 min. The reaction mixture was

poured into ice water and then $CHCl_3$ was added; this mixture was extracted two times and the $CHCl_3$ solution was washed with a 10% solution of sodium hydrogencarbonate and then with water and dried with $MgSO_4$. After distilling off $CHCl_3$, the residue was distilled by an oil pump. The distillates were analyzed by GLC, IR, and NMR. The chemical shift of ^{13}C NMR was compared with the calculated value. The elemental analyses of all of the products showed that the structures were right (see Table 3).

The Reaction of Ethoxalyl Chloride with Aromatics in $CHCl_3$. These reactions were carried out in the same way as above.

The Reaction of **2** *or Methoxalyl Chloride with ArH without Solvents.* Powdered $AlCl_3$ (0.05 mol) was suspended in the cooled aromatics (1.5 mol). Compound **2** or methoxalyl chloride (0.025 mol) was added to the cooled mixture for about 10—25 min. After 2 h the organic layer was washed with 10% sodium hydrogen-carbonate solution and water, and was dried with $MgSO_4$. After distilling off $CHCl_3$, the residue was distilled by an oil pump. All products gave satisfactory analyses of C and H.

^{13}C NMR Spectra of **3** *and* **4**. The chemical shifts of a series of **3** and **4** in $CDCl_3$ solution using TMS as a standard, are summarized in Table 4. The assignments were made with the help of off-resonance decoupling, the comparison of the signal intensity, and the use of the long range coupling constants. Furthermore, the observed chemical shifts were compared with the calculated values. Each signal were reasonably assigned to be due to the corresponding carbon, on the basis of the signals of ethyl phenylglyoxylate and methyl phenylglyoxylate.

Studies of Bitter Peptides from Casein Hydrolyzate. IX.[1] Syntheses and Bitter Taste of Bitter Peptide BPIa Dimer, (Arg-Gly-Pro-Pro-Phe-Ile-Val)$_2$, and Gly-Gly BPIa Derivatives[2]

Ichizo MIYAKE, Katsushige KOUGE, Hidenori KANEHISA, and Hideo OKAI*
Department of Fermentation Technology, Faculty of Engineering, Hiroshima University, Shitami, Saijo-cho, Higashihiroshima 724
(Received October 1, 1983)

In order to elucidate the relationship between taste exhibition and chemical structure of bitter peptide BPIa, di-BPIa, Gly-Gly-BPIa, BPIa-Gly-Gly, and Gly-Gly-BPIa-Gly-Gly were synthesized. All of the peptides possessed a strong bitter taste of the same level as that of BPIa. In addition, the CD curves of the peptides were similar to that of BPIa. The results suggested that their spatial structures are essentially similar and that the whole molecular shape of BPIa contributes to its bitterness.

Minamiura *et al.* isolated a bitter heptapeptide named BPIa from cow milk casein hydrolyzate by bacterial proteinase and determined its amino acid sequence to be H-Arg-Gly-Pro-Pro-Phe-Ile-Val-OH.[3] We synthesized it and confirmed that synthetic BPIa was identical to Minamiura's natural one.[4] Synthetic BPIa possessed an extremely bitter taste, with a threshold value of 0.05 mM (1 M=1 mol dm^{-3}). To elucidate the relationship between chemical structure and bitterness of BPIa, various fragments and analogs which possessed several characteristic features of BPIa have been prepared in our laboratory. N-Terminal hexapeptide (des-Val^7-BPIa) exhibited the same bitterness as BPIa, whereas the bitterness of des-Arg^1-BPIa and of N-terminal pentapeptide fragment were much weaker than that of BPIa.[5] These results indicated that both arginine residue in the N-terminal position and hydrophobic amino acids in the C-terminal moiety are necessary for the intense bitter taste of BPIa. This finding was favored by the bitterness exhibited by both Arg^1- and C-terminal tripeptide-substituted analogs of BPIa.[6,7] On the other hand, the analogs in which prolylproline resiude was substituted for glycylglycine or D-prolyl-D-proline residues exhibited a weaker bitterness than BPIa, and their CD curves measured in water were different from that of BPIa.[8] The results suggested that the spatial structure of BPIa molecule attributed to prolylproline in the center also contributes to its bitter taste. In addition, retro-BPIa, which has the reverse sequence of BPIa, exhibited a strong bitter taste of the same level as that of BPIa. This indicated that it is possible for the N-terminal basic amino acid residue and C-terminal hydrophobic amino acids moiety in BPIa to change places with each other.[9] In the previous paper,[1] we reported that *cyclo*-BPIa, in which N-terminal arginine and C-terminal valine residues were combined, possessed the same bitternss as BPIa and that its CD curve measured in water was similar to that of BPIa. The findings of *cyclo*-BPIa suggested that the two bitter functional groups of both terminals of BPIa are situated close together in the molecule and that the bitterness of BPIa is caused by its characteristic spatial structure which is analogous to that of *cyclo*-BPIa.

The next subject in the investigations of BPIa is to examine the relationship of molecular size to bitter taste. We prepared a dimerized BPIa (di-BPIa, **1**) and ascertained whether or not the synergistic effect by molecular size for bitter taste was produced.

The synthesis of di-BPIa was carried out according to Fig. 1. Boc-Arg(NO_2)-Gly-OH was coupled with H-Pro-Pro-Phe-Ile-Val-OBzl·HCl, which was an intermediate in the synthesis of BPIa,[4] by the mixed anhydride method to yield the protected BPIa derivative (**12**). It was converted to the corresponding heptapeptide ester hydrochloride (**13**) by the action of hydrogen chloride in formic acid. Then **13** was coupled with the acid (**14**) derived from another intermediate in the synthesis of BPIa, Z-Arg(NO_2)-Gly-Pro-Pro-Phe-Ile-Val-OBzl, by the dicyclohexylcarbodiimide-1-hydroxybenzotriazole (DCC-HOBt) method to yield acyltetradecapeptide ester (**15**). The catalytic hydrogenation of **15** gave di-BPIa (**1**). The purity of final product and its intermediates was confirmed by thin-layer chromatography on two solvent systems and by elemental analyses.

Taste of peptides was organoleptically determined by panel evaluation employing five people. Di-BPIa

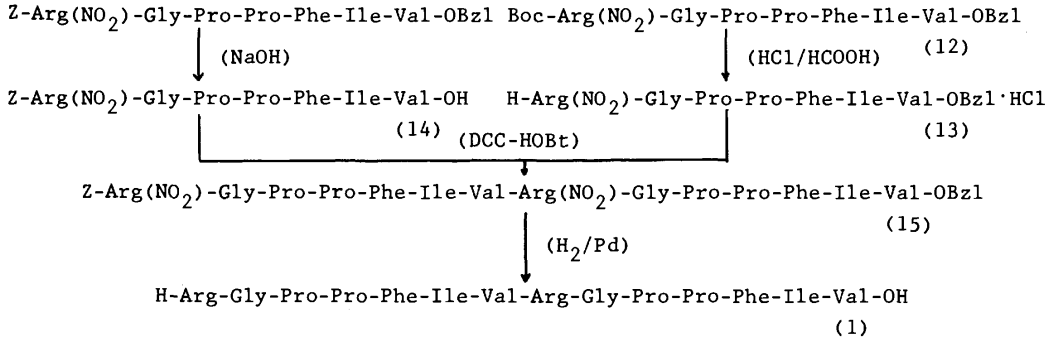

Fig. 1. Synthesis of di-BPIa.

TABLE 1. THE THRESHOLD VALUE FOR BITTER TASTE OF BPIa AND ITS DERIVATIVES

Compound	Threshold value for bitter taste/mM
BPIa	0.05
di-BPIa (**1**)	0.04
Gly-Gly-BPIa (**2**)	0.08
BPIa-Gly-Gly (**3**)	0.05
Gly-Gly-BPIa-Gly-Gly (**4**)	0.04

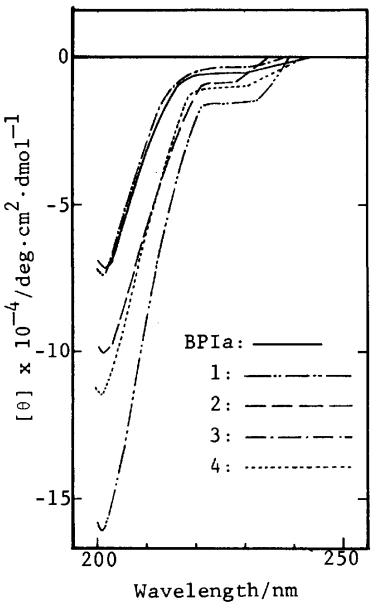

Fig. 2. CD curves of BPIa and its derivatives in water.

exhibited a strong bitter taste. Although we at first expected that di-BPIa would exhibit much stronger bitterness than BPIa, actually its threshold value was nearly equal to that of BPIa, as shown in the Table. This suggested that the bitterness of di-BPIa is caused by one of a pair of BPIa molecules and that the size of BPIa molecule is fit for a receptor of bitter taste in a taste bud. CD curves of di-BPIa and BPIa measured in water are presented in Fig. 2. The pattern of di-BPIa is similar to that of BPIa. It seems that the spatial structure of BPIa, which is important for showing the strong bitter taste, is kept in di-BPIa.

To further ascertain the relationship of the molecular shape of BPIa to its bitter taste, we prepared Gly-Gly-BPIa (**2**), BPIa-Gly-Gly (**3**), and Gly-Gly-BPIa-Gly-Gly (**4**), in which a tasteless glycylglycine was coupled to either the N-terminal or the C-terminal or both terminals of BPIa and examined whether both the strong bitter taste and CD pattern of BPIa were maintained in those BPIa derivatives in spite of the introduction of glycylglycine residue.

The sequence of reactions employed for the synthesis of Gly-Gly-BPIa is shown in Fig. 3. Condensation of Z-Gly-Gly-OH with H-Arg(NO_2)-Gly-OBzl·HCl by the 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) method gave Z-Gly-Gly-Arg(NO_2)-Gly-OBzl (**5**). Saponification of **5** gave the corresponding acid (**6**). Then **6** was coupled with H-Pro-Pro-Phe-Ile-Val-OBzl·HCl by DCC-HOBt method to yield acylnonapeptide ester (**7**). It was hydrogenated in the

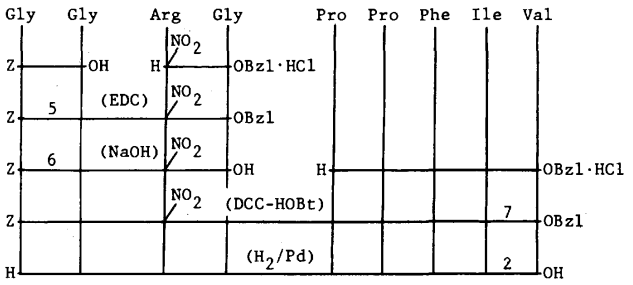

Fig. 3. Synthesis of Gly-Gly-BPIa.

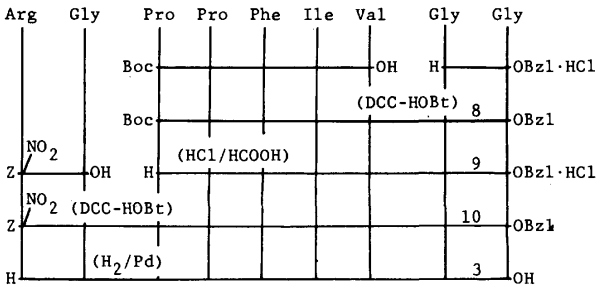

Fig. 4. Synthesis of BPIa-Gly-Gly.

presence of palladium black to yield Gly-Gly-BPIa (**2**).

The synthetic route for BPIa-Gly-Gly is shown in Fig. 4. Boc-Pro-Pro-Phe-Ile-Val-OH, which was an intermediate in the synthesis of *cyclo*-BPIa,[1] was coupled with H-Gly-Gly-OBzl·HCl by DCC-HOBt method to yield the protected heptapeptide (**8**). It was converted to the corresponding heptapeptide ester hydrochoride (**9**) by the action of hydrogen chloride in formic acid. Condensation of Z-Arg(NO_2)-Gly-OH with **9** by DCC-HOBt method afforded the fully protected BPIa-Gly-Gly (**10**). The catalytic hydrogenation of **10** yielded BPIa-Gly-Gly (**3**). Gly-Gly-BPIa-Gly-Gly (**4**) was yielded by hydrogenation of Z-Gly-Gly-Arg(NO_2)-Gly-Pro-Pro-Phe-Ile-Val-Gly-Gly-OBzl (**11**) derived from **6** and **9** by DCC-HOBt method.

The results of sensory tests are listed in the Table. All the Gly-Gly introduced BPIa derivatives possessed a strong bitter taste of the same level as BPIa. The results indicated that glycylglycine residue coupled not only to the N-termial but also to the C-terminal of BPIa did not affect the bitterness of BPIa. The CD curves of these peptides in water are shown in Fig. 2. These indicated similarly shaped curves with nagative troughs at 202 nm to that of BPIa. The results of CD measurements indicated that the spatial structure of BPIa is kept in those BPIa derivatives and that the structure causes the bitterness of BPIa.

Experimental

All the melting points are uncorrected. Thin-layer chromatography was carried out on Merck silica gel G with the solvent systems: R_f^1, 1-butanol-acetic acid-pyridine-water (4:1:1:2, v/v); R_f^2, chloroform-methanol (5:1, v/v). Spots of materials possessing a free amino group on a thin layer plate were detected by spraying ninhydrin, and those of amino group blocked materials by spraying 25% hydrogen bromide in acetic acid and then ninhydrin. The optical

rotations were measured on a Union PM-101 polarimeter. Amino acid analyses in acid hydrolyzate with 6 M hydrochloric acid at 110°C for 72 h were performed with a Hitachi amino acid analyzer, KLA-5 type. Prior to analyses, the compounds were dried over phosphorus pentaoxide at 66°C and 2 mmHg (1 mmHg≈133.332 Pa) for 2 h.

Z-Gly-Gly-Arg(NO_2)-Gly-OBzl (5). To a solution of Z-Gly-Gly-OH[10] (2.66 g, 10 mmol), H-Arg(NO_2)-Gly-OBzl·HCl[1] (4.0 g, 10 mmol), and NMM (1.1 ml, 10 mmol) in DMF (20 ml), EDC (2.12 ml, 15 mmol) was added at 0°C with stirring. The reaction mixture was stirred for 3 h at 0°C, then at room temperature overnight. A large amount of water was poured into the mixture. The obtained precipitate was filtered, and washed with 4% sodium hydrogencarbonate, 0.5 M hydrochloric acid, and water successively. It was recrystallized from hot methanol: yield 4.68 g (76%); mp 101—103°C; $[\alpha]_D^{20}$ −8° (*c* 2, DMF); R_f^1 0.86 and R_f^2 0.57.

Found: C, 51.00; H, 5.54; N, 17.85%. Calcd for $C_{27}H_{34}O_9N_8 \cdot H_2O$: C, 51.25; H, 5.74; N, 17.71%.

Z-Gly-Gly-Arg(NO_2)-Gly-OH (6). Compound **5** (1.83 g, 3 mmol) was saponified with 1 M sodium hydroxide (3.6 ml, 3.6 mmol) in methanol (15 ml) for 1.5 h at room temperature. After evaporation, the aqueous solution was acidified to pH 3 with 1 M hydrochloric acid, and extracted with 1-butanol. The extract was washed with water and dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo* and the residue was crystallized with ether. It was recrystallized from methanol-ether: yield 0.94 g (60%); mp 139°C; $[\alpha]_D^{20}$ −15° (*c* 1, DMF); R_f^1 0.62 and R_f^2 0.07.

Found: C, 45.70; H, 5.35; N, 21.59%. Calcd for $C_{20}H_{28}O_9N_8$: C, 45.80; H, 5.38; N, 21.37%.

Z-Gly-Gly-Arg(NO_2)-Gly-Pro-Pro-Phe-Ile-Val-OBzl (7). To a solution of **6** (0.53 g, 1 mmol) and H-Pro-Pro-Phe-Ile-Val-OBzl·HCl[4] (0.70 g, 1 mmol) and NMM (0.11 ml, 1 mmol) in DMF (8 ml), HOBt (0.15 g, 1.1 mmol), and DCC (0.25 g, 1.2 mmol) were added at 0°C with stirring. The reaction mixture was stirred for 3 h at 0°C and then at room temperature overnight. DCUrea was filtered off and the filtrate was dissolved in 1-butanol. The solution was washed with 4% sodium hydrogencarbonate, 0.5 M hydrochloric acid, and water successively, then dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo* and the residue was crystallized with ether. It was recrystllized from methanol-ether: yield 0.78 g (67%); mp 125°C (decomp); $[\alpha]_D^{20}$ −51° (*c* 1, DMF); R_f^1 0.81 and R_f^2 0.70.

Found: C, 56.98; H, 6.79; N, 15.17%. Calcd for $C_{57}H_{77}O_{14}N_{13} \cdot 2H_2O$: C, 56.86; H, 6.78; N, 15.12%.

H-Gly-Gly-Arg-Gly-Pro-Pro-Phe-Ile-Val-OH·AcOH (2). Compound **7** (0.47 g, 0.4 mmol) was dissolved in a mixture of methanol (5 ml) and acetic acid (5 ml), and hydrogenated in the presence of palladium black for 24 h at room temperature. The filtrate from catalyst was evaporated *in vacuo* and the residual oil was solidified by the aid of acetone. It was recrystallized from methanol-ether: yield 0.31 g (80%); $[\alpha]_D^{20}$ −122° (*c* 0.5, H_2O); R_f^1 0.65 and R_f^2 0.00. Amino acid ratios in acid hydrolyzate: Arg 0.90, Gly 2.65, Pro 2.03, Phe 1.07, Ile 1.00, Val 1.00.

Found: C, 53.42; H, 7.42; N, 16.54%. Calcd for $C_{42}H_{66}O_{10}N_{12} \cdot CH_3COOH \cdot 2H_2O$: C, 53.10; H, 7.50; N, 16.89%.

Boc-Pro-Pro-Phe-Ile-Val-Gly-Gly-OBzl (8). To a solution of Boc-Pro-Pro-Phe-Ile-Val-OH[1] (2.02 g, 3 mmol), H-Gly-Gly-OBzl·HCl[11] (1.16 g, 4.5 mmol) and NMM (0.50 ml, 4.5 mmol) in DMF (10 ml), HOBt (0.61 g, 4.5 mmol) and DCC (0.93 g, 4.5 mmol) were added at 0°C with stirring. The reaction mixture was stirred for 3 h at 0°C and kept in a refrigerator overnight. DCUrea was filtered off and the filtrate was dissolved in 1-butanol. The solution was washed with 4% sodium hydrogencarbonate, 4% citric acid, and water successively, then dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo* and the residue was crystallized with ether: yield 2.45 g (93%); mp 193—196°C; $[\alpha]_D^{20}$ −36° (*c* 1, DMF); R_f^1 0.86 and R_f^2 0.76.

Found: C, 62.87; H, 7.86; N, 11.28%. Calcd for $C_{46}H_{65}O_{10}N_7$: C, 63.06; H, 7.50; N, 11.19%.

H-Pro-Pro-Phe-Ile-Val-Gly-Gly-OBzl·HCl (9). Compond **8** (1.75 g, 2 mmol) was dissolved in 98% formic acid (5 ml) and 3.5 M hydrogen chloride in dioxane (10 ml) at 0°C. After 30 min, the solvent was removed by evaporation and the oily residue was solidified by the aid of ether: yield 1.60 g (98%); mp 160—162°C; $[\alpha]_D^{20}$ −39° (*c* ,1 DMF); R_f^2 0.77 and R_f^2 0.44.

Found: C, 58.12; H, 7.17; N, 11.69%. Calcd for $C_{41}H_{57}O_8N_7 \cdot 2H_2O$: C, 58.04; H, 7.37; N, 11.56%.

Z-Arg(NO_2)-Gly-Pro-Pro-Phe-Ile-Val-Gly-Gly-OBzl (10). This compound was prepared from Z-Arg(NO_2)-Gly-OH[4] (0.50 g, 1 mmol) and **9** (0.81 g, 1 mmol) as described for the preparation of **7**: yield 0.97 g (83%); mp 145°C (decomp); $[\alpha]_D^{20}$ −41° (*c* 1, DMF); R_f^1 0.84 and R_f^2 0.70.

Found: C, 58.80; H, 6.70; N, 15.35%. Calcd for $C_{57}H_{77}O_{14}N_{13}$: C, 58.60; H, 6.64; N, 15.59%.

H-Arg-Gly-Pro-Pro-Phe-Ile-Val-Gly-Gly-OH·AcOH (3). Compound **10** (0.47 g, 0.4 mmol) was treated with hydrogen as described for the preparation of **2**: yield 0.32 g (83%); $[\alpha]_D^{20}$ −90° (*c* 0.5, H_2O); R_f^1 0.62 and R_f^2 0.00. Amino acid ratios in acid hydrolyzate: Arg 0.95, Gly 3.38, Pro 1.84, Phe 1.04, Ile 1.00, Val 0.94.

Found: C, 52.78; H, 7.36; N, 16.83%. Calcd for $C_{42}H_{66}O_{10}N_{12} \cdot CH_3COOH \cdot 2H_2O$: C, 53.10; H, 7.50; N, 16.89%.

Z-Gly-Gly-Arg(NO_2)-Gly-Pro-Pro-Phe-Ile-Val-Gly-Gly-OBzl (11). This compound was prepared from **6** (0.53 g, 1 mmol) and **9** (0.81 g, 1 mmol) as described for the preparation of **7**: yield 0.96 g (75%); mp 149°C (decomp); $[\alpha]_D^{20}$ −41° (*c* 1, DMF); R_f^1 0.85 and R_f^2 0.59.

Found: C, 57.18; H, 6.64; N, 16.54%. Calcd for $C_{61}H_{83}O_{16}N_{15}$: C, 57.13; H, 6.52; N, 16.38%.

H-Gly-Gly-Arg-Gly-Pro-Pro-Phe-Ile-Val-Gly-Gly-OH·AcOH (4). Compound **11** (0.39 g, 0.3 mmol) was hydrogenated as described for the preparation of **2**: yield 0.23 g (71%); $[\alpha]_D^{20}$ −100° (*c* 0.5, H_2O); R_f^1 0.59 and R_f^2 0.00. Amino acid ratios in acid hydrolyzate: Arg 1.15, Gly 5.28, Pro 2.02, Phe 1.02, Ile 1.00, Val 0.95.

Found: C, 53.16; H, 7.42; N, 17.84%. Calcd for $C_{46}H_{72}O_{12}N_{14} \cdot CH_3COOH \cdot H_2O$: C, 52.83; H, 7.12; N, 17.97%.

Boc-Arg(NO_2)-Gly-Pro-Pro-Phe-Ile-Val-OBzl (12). Boc-Arg(NO_2)-Gly-OBzl[1] (1.41 g, 3 mmol) was saponified with 1 M sodium hydroxide (3.6 ml, 3.6 mmol), as described for the preparation of **6**, except for acidification. Aqueous 10% citric acid solution was used instead of 1 M hydrochloric acid: yield of hygroscopic Boc-Arg(NO_2)-Gly-OH, 0.74 g (67%); R_f^1 0.69 and R_f^2 0.08. Then this compound was coupled with H-Pro-Pro-Phe-Ile-Val-OBzl·HCl[4] to yield **12**. To a solution of Boc-Arg(NO_2)-Gly-OH (0.74 g, 2 mmol) and NMM (0.22 ml, 2 mmol) in DMF (6 ml), ethyl chloroformate (0.2 ml, 2 mmol) was added at −5°C with stirring. After 10 min, a precooled solution of H-Pro-Pro-Phe-Ile-Val-OBzl·HCl[4] (1.40 g, 2 mmol) and NMM (0.22 ml, 2 mmol) in chloroform (4 ml) was added to it. The reaction mixture was stored in an ice bath for 1 h, then at room temperature overnight. The mixture was evaporated *in vacuo* and the residue was dissolved in ethyl acetate. The solution was washed with 4% sodium hydrogencarbonate, 4% citric acid, and water successively, then dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo* and the residual oil was crystallized with ether; yield 1.45 g (71%); mp 130°C (decomp); $[\alpha]_D^{20}$ −49° (*c* 1, DMF); R_f^1 0.86 and R_f^2 0.69.

Found: C, 58.66; H, 7.27; N, 15.25%. Calcd for $C_{50}H_{73}O_{12}N_{11}$: C, 58.86; H, 7.21; N, 15.10%.

H-Arg(NO_2)-Gly-Pro-Pro-Phe-Ile-Val-OBzl·HCl (13). Compound **12** (1.02 g, 1 mmol) was treated with hydrogen

chlorid as described for the preparation of **9**: yield 0.84 g (88%); mp 157—160°C; $[\alpha]_D^{20}$ −47° (*c* 1, DMF); R_f^1 0.78 and R_f^2 0.31.

Found: C, 55.32; H, 6.89; N, 15.60%. Calcd for $C_{45}H_{66}O_{10}N_{11}Cl \cdot H_2O$: C, 55.46; H, 7.03; N, 15.81%.

Z-Arg(NO$_2$)-Gly-Pro-Pro-Phe-Ile-Val-OH (14). To a solution of Z-Arg(NO$_2$)-Gly-Pro-Pro-Phe-Ile-Val-OBzl[4] (1.05 g, 1 mmol) in methanol (5 ml), 1 M sodium hydroxide (2 ml, 2 mmol) was added. After 6 h at room temperature, the mixture was evaporated *in vacuo* and diluted with water. The solution was extracted with ethyl acetate. The aqueous layer was acidified to pH 3 with 1 M hydrochloric acid and extracted with 1-butanol. The extract was washed with water and dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo* and the product was crystallized with ether. It was recrystllized from methanol-ether: yield 0.81 g (84%); mp 185°C (decomp); $[\alpha]_D^{20}$ −43° (*c* 1, DMF); R_f^1 0.69 and R_f^2 0.18.

Found: C, 56.98; H, 6.61; N, 16.04%. Calcd for $C_{46}H_{65}O_{12}N_{11}$: C, 57.30; H, 6.80; N, 15.98%.

Z-Arg(NO$_2$)-Gly-Pro-Pro-Phe-Ile-Val-Arg(NO$_2$)-Gly-Pro-Pro-Phe-Ile-Val-OBzl (15). This compound was prepared from **13** (0.57 g, 0.6 mmol) and **14** (0.58 g, 0.6 mmol) as described for the preparation of **7**: yield 0.84 g (75%); mp 158°C (decomp); $[\alpha]_D^{20}$ −59° (*c* 1, DMF); R_f^1 0.82 and R_f^2 0.58.

Found: C, 61.88; H, 6.99; N, 16.49%. Calcd for $C_{98}H_{134}O_{21}N_{22} \cdot H_2O$: C, 61.88; H, 7.31; N, 16.20%.

H-Arg-Gly-Pro-Pro-Phe-Ile-Val-Arg-Gly-Pro-Pro-Phe-Ile Val-OH·2AcOH (1). Compound **15** (0.37 g, 0.2 mmol) was treated with hydrogen for 48 h as described for the preparation of **2**: yield 0.30 g (90%); $[\alpha]_D^{20}$ −84° (*c* 1, methanol); R_f^1 0.44 and R_f^2 0.00. Amino acid ratios in acid hydrolyzate: Arg 1.67, Gly 2.00, Pro 3.97, Phe 2.32, Ile 2.19, Val 2.07.

Found: C, 54.62; H, 7.40; N, 16.06%. Calcd for $C_{76}H_{118}O_{15}N_{20} \cdot 2CH_3COOH \cdot 5H_2O$: C, 54.53; H, 7.78; N, 15.90%.

The air-dried product lost 4.9% of its weight after drying or 2 h at 110°C and 2 mmHg. Calcd for $5H_2O$: 5.1%.

CD Measurement. This was performed with a JASCO J-20A. A cell of path length 0.2 mm was used and runs were made at ambient temperature. Patterns in water are presented in Fig. 2.

Sensory Test. Taste of the peptides was organoleptically determined by panel evaluation employing four people. A series of solutions of decreasing concentration, each half as strong as the preceding one, were prepared. Before tasting the sample, the mouth was thoroughly rinsed with deionized water. The sample solution was held in the mouth for *ca.* 10 s and then spit out, and the threshold value was determined. The results are listed in the Table.

The authors wish to express their thanks to Associate Professor Michio Kondo of Saga University for the CD measurements. Thanks are also due to Dr. Shinji Okumura of Ajinomoto Co. Inc., for supplying some amino acids.

(Received October 1, 1983)

In order to ascertain the validity of the structure of bitter peptide BPIa (H-Arg-Gly-Pro-Pro-Phe-Ile-Val-OH) isolated from casein hydrolyzate by Minamiura *et al.*, the C-terminal octapeptide of β-casein (H-Arg-Gly-Pro-Phe-Pro-Ile-Ile-Val-OH) determined by Ribadeau Dumas *et al.*, which is assumed to correspond to BPIa, was synthesized and compared with the synthetic BPIa which was confirmed to be identical with the natural one. The two synthesized peptides, however, did not match on thin-layer chromatography. The result indicates that the structure of BPIa need not be converted to Ribadeau Dumas' formula. The octapeptide possessed an extremely bitter taste, with a threshold value of 0.004 mM (1 M=1 mol dm^{-3}). It is the most bitter peptide.

Many bitter peptides have been found in the proteolytic hydrolyzates of casein. Minamiura *et al.* isolated a bitter heptapeptide named BPIa from cow milk casein hydrolyzate by alkaline proteinase of *Bacillus subtilis*, and determined its amino acid sequence to be H-Arg-Gly-Pro-Pro-Phe-Ile-Val-OH.[3] In this series of studies of bitter peptides, we previously described the synthetic identification of BPIa.[4] Synthetic BPIa was indistinguishable from Minamiura's natural one when thin-layer chromatography, paper electrophoresis, and carboxymethylcellulose column chromatography were used. We also found that the synthetic BPIa possessed an extremely bitter taste, whose threshold value was 0.05 mM. Ribadeau Dumas *et al.* determined the whole primary structure of bovine β-casein which contains the partial sequence of -Arg^{202}-Gly-Pro-Phe-Pro-Ile-Ile-Val^{209}-OH in the C-terminal portion.[5] Although the sequence of BPIa can not be found in the structure of Ribadeau Dumas' formula, it is similar to the C-terminal of the formula. Aoyagi and Izumiya synthesized a hexapeptide, H-Arg-Gly-Pro-Phe-Pro-Ile-OH (**1**), corresponding to the C-terminal portion (202—207) of β-casein and suggested that BPIa is to be changed so as to correspond to the C-terminal portion of Ribadeau Dumas' formula from the result that the synthetic hexapeptide possessed a bitter taste, with its threshold value of 0.13—0.25 mM.[6] They also synthesized a heptapeptide, H-Gly-Pro-Phe-Pro-Ile-Ile-Val-OH (**2**), corresponding to the C-terminal portion (203—209) and compared it with the natural peptide isolated from tryptic hydrolyzate of casein.[7] They reported that the two peptides matched each other closely and that the treshold value of bitter taste of the two peptides was 0.17—0.34 mM, and supported Ribadeau Dumas' formula.

In order to ascertain the validity of the structure of BPIa, it becomes necessary to compare BPIa with the C-terminal octapeptide (202—209) of Ribadeau Dumas' formula. In the present paper, we describe the synthesis of the octapeptide, H-Arg-Gly-Pro-Phe-Pro-Ile-Ile-Val-OH (**3**), the measurement of its threshold value of bitter taste, and the comparison between sythetic BPIa and **3**. Further, this paper deals with the synthesis of a heptapeptide, H-Arg-Gly-Pro-Phe-Pro-Ile-Val-OH (**4**), in which an isoleucine residue of **3** is missing.

The sequence of reactions employed for the synthesis of **3** is shown in Fig. 1. The syntheses of the intermediates (**5**, **6**, **15**, and **16**) had been performed and was described in the previou paper.[4] Compound **6** was coupled with Boc-Ile-OH by the mixed anhydride (MA) method to yield Boc-Ile-Ile-Val-OBzl (**7**). Removal of Boc group from **7** with hydrogen chloride in dioxane afforded the corresponding tripeptide ester hydrochloride (**8**). Compound **8** was coupled with Boc-Pro-OH by MA method to yield Boc-Pro-Ile-Ile-Val-OBzl (**9**). This was converted to the corresponding tetrapeptide ester hydrochloride (**10**) by the action of hydrogen chloride in dioxane. Compound **10** was coupled with Boc-Phe-OH by MA method to form Boc-Phe-Pro-Ile-Ile-Val-OBzl (**11**). After the treatment of **11** with hydrogen chloride in dioxane, the resulting pentapeptide ester hydrochloride (**12**) was coupled with Boc-Pro-OH by MA method to yield Boc-Pro-Phe-Pro-Ile-Ile-Val-OBzl (**13**). It was converted to the corresponding hexapeptide ester hydrochloride (**14**) by the action of hydrogen chloride in dioxane. Then compound **14** was coupled with Z-Arg(NO_2)-Gly-OH (**16**) by the dicyclohexylcarbodiimide (DCC) method to yield the protected octapepide (**17**). Catalytic hydrogenation of **17** gave the desired product (**3**).

The synthetic route for heptapeptide **4** is shown in Fig. 2. MA and DCC methods were used for the coupling reactions. The removal of Boc groups of the intermediates was performed by the action of hydrogen chloride in dioxane. The protected heptapetide (**24**) derived from Z-Arg(NO_2)-Gly-OH (**16**) and H-Pro-Phe-Pro-Ile-Val-OBzl·HCl (**23**) was hydrogenated in the presence of palladium black to yield the heptapeptide **4**. The homogeneity of final products was confirmed by thin-layer chromatgraphy, paper electrophoresis, amino acid analysis, and elemental analysis.

The taste of **3** and **4** was organoleptically determined by a panel evaluation employing four persons. The

TABLE 1. THE THRESHOLD VALUES FOR BITTER TASTE OF SYNTHESIZED PEPTIDES AND TYPICAL BITTER SUBSTANCES

Compound	Threshold value for bitter taste/mM
Arg-Gly-Pro-Phe-Pro-Ile (**1**)	0.13—0.25
Gly-Pro-Phe-Pro-Ile-Ile-Val (**2**)	0.17—0.34
Arg-Gly-Pro-Phe-Pro-Ile-Ile-Val (**3**)	0.004
Arg-Gly-Pro-Phe-Pro-Ile-Val (**4**)	0.11
Arg-Gly-Pro-Pro-Phe-Ile-Val (BPIa)	0.05
Caffeine	1.0
Strychnine	0.003
Brucine	0.0008

results are listed in Table 1. The synthesized peptides possessed a strong bitter taste. The threshold value of **3** was 0.004 mM; this is the most bitter among the peptides as far as we know. By comparison with some alkaloids known to have strong bitterness, the potency of **3** corresponds to 250 times that of caffeine and is nearly equal to that of strychnine. In this connection, the threshold value of brucine, which is an alkaloid and the most bitter substance known, is 0.0008 mM. The cause of the strong bitterness of this peptide can be shown by comparing the bitterness of **3** with that of **1** and **4**. It is obvious that **3** became the most bitter one due to the increase of the number of hydrophobic amino acids in the C-terminal moiety. Further, the difference in potency between **2** and **3** indicates that N-terminal arginine residue is indispensable for the extremely bitter taste observed in **3**. These findings agree with those obtained in our previous investigations of bitterness in BPIa.

The CD curves of **3**, **4**, and BPIa are presented in Fig. 3. These peptides showed similarly shaped curves. It seems that the whole molecular shape is also important for showing the strong bitter taste in peptides which are related to BPIa, in addition to the presence of both basic and hydrophobic amino acids.

In addition, electrophoretic tests of the octapeptide **3**, the heptapeptide **4**, and the synthetic BPIa, which was confirmed to be identical with the natural one,[4] were carried out. The mobilities of both **3** and **4** were indistinguishable from that of BPIa on paper electrophoresis. However, on thin-layer chromatography, by using the solvent system, 1-butanol–acetic acid–pyidine–water (4:1:1:2, v/v), the R_f value of BPIa was not identical with that of **3**, but nearly equal to that of **4**. These results indicate that BPIa does not correspond to the C-termial portion of β-casein

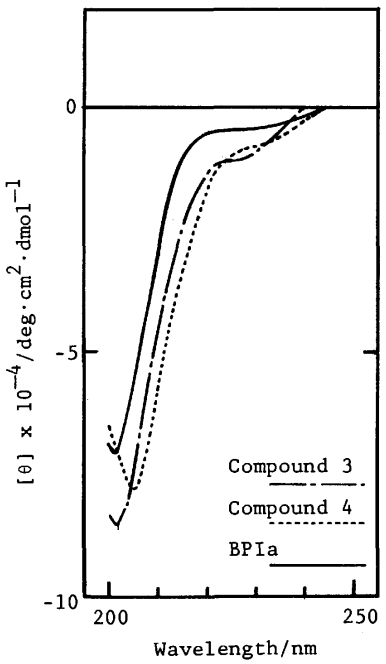

Fig. 3. CD curves of **3**, **4**, and BPIa.

determined by Ribadeau Dumas *et al.* One possible explanation for our finding is that there are other kinds of variants in β-casein, perhaps due to differeces between the cattle species throughout the world, a possibility of gene mutation among the same species, and other factors besides those known at the present.

Experimental

All the melting points are uncorrected. Thin-layer chromatography was carried out on Merck silica gel G with the solvent systems: R_f^1, 1-butanol-acetic acid-pyridine-water (4:1:1:2, v/v); R_f^2, chloroform-methanol (5:1, v/v). Spots of materials possessing a free amino group on a thin layer plate were detected by spraying ninhydrin, and those of amino group blocked materials by spraying 25% hydrogen bromide in acetic acid and then ninhydrin. The optical rotations were measured on a Union PM-101 polarimeter. Amino acid analyses in acid hydrolyzate with 6 M hydrochloric acid at 110 °C for 72 h were performed with a Hitachi amino acid analyzer, KLA-5 type. Prior to analyses, the compounds were dried over phosphorus pentaoxide at 66 °C and 2 mmHg (1 mmHg≈133.332 Pa) for 2 h, except in the case of compound **22**.

Boc-Ile-Ile-Val-OBzl (7). Boc-Ile-OH·DCHA (9.08 g, 22 mmol) was dissolved in ethyl acetate (150 ml), and 1 M sulfuric acid (50 ml) was added to the mixture with stirring. The organic layer was washed with water and dried over anhydrous sodium sulfate. The solution was concentrated to dryness *in vacuo*, and the oily residue was dissolved in THF (40 ml) and NMM (2.2 ml, 20 mmol). ECF (2.0 ml, 20 mmol) was added to the mixture at −5 °C with stirring. After 10 min, a precooled solution of H-Ile-Val-OBzl·HCl[4] (7.14 g, 20 mmol) and NMM (2.2 ml, 20 mmol) in chloroform (40 ml) was added to it. The reaction mixture was stored in an ice bath for 1 h and then at room temperature overnight. The mixture was evaporated *in vacuo* and the oily residue was dissolved in ethyl acetate. The solution was washed successively with 4% sodium hydrogencarbonate, 4% citric acid, and water, and then dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo* and the oily residue was crystallized with ether-petroleum ether: yield 8.86 g (83%); mp 173—175 °C (lit,[7] 173—174 °C): $[\alpha]_D^{20}$ −75° (*c* 1, ethanol) (lit,[7] −77° (*c* 2.2, ethanol)); R_f^1 0.98 and R_f^2 0.72.

Found: C, 65.30; H, 8.98; N, 7.75%. Calcd for $C_{29}H_{47}O_6N_3$: C, 65.26; H, 8.88; N, 7.87%.

H-Ile-Ile-Val-OBzl·HCl (8). Compound **7** (5.34 g, 10 mmol) was dissolved in 4.1 M hydrogen chloride in dioxane (50 ml). The solution was allowed to stand for 2 h at room temperature and then evaporated *in vacuo*. The oily residue was solidified by the aid of ether: yield 4.52 g (96%); mp 240 °C; $[\alpha]_D^{20}$ −39° (*c* 1, methanol); R_f^1 0.92 and R_f^2 0.64.

Found: C, 61.13; H, 8.67; N, 9.05%. Calcd for $C_{24}H_{40}O_4N_3Cl$: C, 61.32; H, 8.58; N, 8.94%.

Boc-Pro-Ile-Ile-Val-OBzl (9). To a chilled solution of Boc-Pro-OH (1.05 g, 5 mmol) and NMM (0.55 ml, 5 mmol) in THF (10 ml), ECF (0.5 ml, 5 mmol) was added at −5 °C with stirring. After 10 min, a precooled solution of **8** (2.35 g, 5 mmol) and NMM (0.55 ml, 5 mmol) in DMF (10 ml) was added to it. The reaction mixture was stored in an ice bath for 1 h and then at room temperature overnight. The mixture was diluted with ethyl acetate and the solution was washed successively with 4% sodium hydrogencarbonate, 4% citric acid, and water, and then dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo* and the residue was crystallized with ether-petroleum ether: yield 2.74 g (87%); mp 192—194 °C (lit,[7] 191—193 °C); $[\alpha]_D^{20}$ −100° (*c* 1, ethanol) (lit,[7] −82° (*c* 1.1, ethanol)); R_f^1 0.98 and R_f^2 0.78.

Found: C, 64.55; H, 8.80; N, 8.88%. Calcd for $C_{34}H_{54}O_7N_4$: C, 64.73; H, 8.63; N, 8.88%.

H-Pro-Ile-Ile-Val-OBzl·HCl (10). Compound **5** (3.15 g, 5 mmol) was treated with hydrogen chloride as described for the preparation of **8**: yield 2.69 g (95%); mp 240 °C<; $[\alpha]_D^{20}$ −91° (*c* 1, methanol); R_f^1 0.90 and R_f^2 0.55.

Found: C, 61.13; H, 8.34; N, 10.03%. Calcd for $C_{29}H_{47}O_5N_4Cl$: C, 61.41; H, 8.35; N, 9.88%.

Boc-Phe-Pro-Ile-Ile-Val-OBzl (11). This was prepared from Boc-Phe-OH·DCHA (1.56 g, 3.5 mmol) and **10** (1.70 g, 3 mmol) in the same way as described for the preparation of **7**: yield 2.06 g (88%); mp 163—165 °C (lit,[7] 165—166 °C); $[\alpha]_D^{20}$ −84° (*c* 1, ethanol) (lit,[7] −81° (*c* 2.0, ethanol)); R_f^1 0.98 and R_f^2 0.71.

Found: C, 66.54; H, 8.02; N, 8.89%. Calcd for $C_{43}H_{63}O_8N_5$: C, 66.38; H, 8.16: N, 9.00%.

H-Phe-Pro-Ile-Ile-Val-OBzl·HCl (12). Compound **11** (2.34 g, 3 mmol) was treated with hydrogen chloride, as described for the preparation of **8**: yield 2.09 g (97%); mp 160—162 °C; $[\alpha]_D^{20}$ −80° (*c* 1, methanol); R_f^1 0.90 and R_f^2 0.64.

Found: C, 63.25; H, 7.77; N, 9.81%. Calcd for $C_{38}H_{56}O_6N_5 \cdot 1/2H_2O$: C, 63.10; H, 7.94; N, 9.68%.

Boc-Pro-Phe-Pro-Ile-Ile-Val-OBzl (13). This was prepare from Boc-Pro-OH (0.65 g, 3 mmol) and **12** (2.14 g, 3 mmol), as described for the preparation of **9**: yield 2.33 g (89%); mp 131—134 °C; $[\alpha]_D^{20}$ −114° (*c* 1, methanol); R_f^1 0.97 and R_f^2 0.80.

Found: C, 65.59; H, 8.36; N, 9.50%. Calcd for $C_{48}H_{70}O_9N_6$: C, 65.88; H, 8.06; N, 9.60%.

H-Pro-Phe-Pro-Ile-Ile-Val-OBzl·HCl (14). Compound **13** (1.65 g, 2 mmol) was treated with hydrogen chloride, as describd for the preparation of **8**: yield 1.49 g (92%); mp 157—159 °C; $[\alpha]_D^{20}$ −95° (*c* 1, methanol); R_f^1 0.87 and R_f^2 0.60.

Found: C, 63.44; H, 7.91; N, 10.79%. Calcd for $C_{43}H_{63}O_7N_6Cl$: C, 63.64; H, 7.83; N, 10.36%.

Z-Arg(NO$_2$)-Gly-Pro-Phe-Pro-Ile-Ile-Val-OBzl (17). To a solution of Z-Arg(NO$_2$)-Gly-OH[4] (0.68 g, 1.65 mmol) in DMF (3 ml), DCC (0.34 g, 1.65 mmol) was added at 0 °C with stirring. After 20 min, a precooled solution of **14** (1.22 g, 1.5 mmol) and NMM (0.17 ml, 1.5 mmol) in chloroform (3 ml) was added to it. The reaction mixture was stirred for 3 h at 0 °C and then at room temperature overnight. DCUrea was filtered off and the filtrate was diluted with ethyl acetate.

The solution was washed successively with 4% sodium hydrogencarbonate, 0.5 M hydrochloric acid, and water, and then dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo* and the residue was collected by the aid of ether. It was recrystallized from methanol-ether: yield 1.36 g (78%); mp 129—132 °C; $[\alpha]_D^{20}$ −103° (*c* 1, methanol); R_f^1 0.95 and R_f^2 0.59.

Found: C, 60.22; H, 7.33; N, 13.90%. Calcd for $C_{59}H_{82}O_{13}N_{12}\cdot 1/2H_2O$: C, 60.23; H, 7.11; N, 14.29%.

H-Arg-Gly-Pro-Phe-Pro-Ile-Ile-Val-OH·HCl (3). Compound **17** (0.47 g, 0.4 mmol) was dissolved in a mixture of methanol (3 ml) and acetic acid (3 ml) and hydrogenated in the presence of palladium black for 23 h at room temperature. The filtrate from catalyst was evaporated *in vacuo* and the residual oil was solidified by the aid of ether to give 0.31 g (81%) of **3** as a hygroscopic acetate form. It was dissolved in methanol (3 ml) and 4.1 M hydrogen chloride in dioxane (1 ml) was added to it. The solution was evaporated *in vacuo* and the residue was crystallized from acetone and ether: yield 0.29 g (76%); $[\alpha]_D^{20}$ −108° (*c* 0.5, H_2O); R_f^1 0.65 and R_f^2 0.00. Amino acid ratios in acid hydrolyzate: Arg 0.88, Gly 1.02, Pro 1.97, Phe 1.01, Ile 1.89, Val 1.00.

Found: C, 52.62; H, 7.80; N, 14.92%. Calcd for $C_{44}H_{72}O_9N_{11}Cl\cdot 4H_2O$: C, 52.50; H, 8.01; N, 15.31%.

Boc-Pro-Ile-Val-OBzl (18). This was prepared from Boc-Pro-OH (2.15 g, 10 mmol) and H-Ile-Val-OBzl·HCl[4] (3.57 g, 10 mmol), as described for the preparation of **9**: yield 4.47 g (86%); mp 102—103 °C; $[\alpha]_D^{20}$ −94° (*c* 1, methanol); R_f^1 0.94 and R_f^2 0.69.

Found: C, 64.78; H, 8.50; N, 8.23%. Calcd for $C_{28}H_{43}O_6N_3$: C, 64.96; H, 8.37; N, 8.12%.

H-Pro-Ile-Val-OBzl·HCl (19). Compound **18** (1.04 g, 2 mmol) was dissolved in 4.1 M hydrogen chloride in dioxane (10 ml). The solution was allowed to stand for 1 h at room temperature and then evaporated *in vacuo*. The residual syrup was washed three times with ether by decantation, and dried in a vacuum desiccater: yield 0.91 g (100%); R_f^1 0.82 and R_f^2 0.48.

BoC-Phe-Pro-Ile-Val-OBzl (20). This was prepared from Boc-Phe-OH·DCHA (0.98 g, 2.2 mmol) and **19** (0.91 g, 2 mmol), as described for the preparation of **7**. The product was obtained as an oly form: yield 1.12 g (84%); R_f^1 0.98 and R_f^2 0.70.

H-Phe-Pro-Ile-Val-OBzl·HCl (21). Compound **20** (1.12 g, 1.68 mmol) was treated with hydrogen chloride, as described for the preparation of **8**. The product was obtained as a hygroscopic solid: yield 0.93 g (92%); R_f^1 0.87 and R_f^2 0.63.

Boc-Pro-Phe-Pro-Ile-Val-OBzl (22). This was prepared from Boc-Pro-OH (0.33 g, 1.55 mmol) and **21** (0.93 g, 1.55 mmol), as described for the preparation of **9**: yield 0.84 g (71%); mp 61—63 °C; $[\alpha]_D^{20}$ −113° (*c* 1, methanol); R_f^1 0.93 and R_f^2 0.69.

Found: C, 65.84; H, 7.90; N, 8.93%. Calcd for $C_{42}H_{59}O_8N_5$: C, 66.20; H, 7.81; N, 9.19%.

H-Pro-Phe-Pro-Ile-Val-OBzl·HCl (23). This was prepared from **22** (0.76 g, 1 mmol), as described for the preparation of **8**. The product was obtained as a hygroscopic solid: yield 0.57 g (81%); R_f^1 0.79 and R_f^2 0.55.

Z-Arg(NO₂)-Gly-Pro-Phe-Pro-Ile-Val-OBzl (24). To a solution of Z-Arg(NO_2)-Gly-OH[4] (0.41 g, 1 mmol) and **23** (0.59 g, 0.81 mmol) and NMM (0.09 ml, 0.81 mmol) in DMF (4 ml), DCC (0.21 g, 1 mmol) was added at 0 °C with stirring. The reaction mixture was stirred for 3 h at 0 °C and then at room temperature overnight. DCUrea was filtered off and the filtrate was diluted with ethyl acetate. The solution was washed successively with 4% sodium hydrogencarbonate, 0.5 M hydrochoric acid, and water, and then dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo* and the residue was solidified with ether. It was recrystallized from methanol-ether: yield 0.67 g (79%); mp 93—94 °C; $[\alpha]_D^{20}$ −90° (*c* 1, mthanol); R_f^1 0.83 and R_f^2 0.66.

Found: C, 59.48; H, 6.98; N, 14.46%. Calcd for $C_{53}H_{71}O_{12}N_{11}\cdot H_2O$: C, 59.37; H, 6.86; N, 14.37%.

H-Arg-Gly-Pro-Phe-Pro-Ile-Val-OH·AcOH (4). A solution of **24** (0.32 g, 0.3 mmol) in methanol-acetic acid (1:1, 6 ml) was hydrogenated in the presence of palladium black for 23 h at room temperature. The catalyst was removed by filtration and the filtrate was evaporated *in vacuo*. The residue was crystallized by the aid of acetone. It was recrystallized from methanol-ether: yield 0.17 g (67%); $[\alpha]_D^{20}$ −110° (*c* 0.5, H_2O); R_f^1 0.57 and R_f^2 0.00. Amino acid ratios in acid hydrolyate: Arg 0.91, Gly 1.01, Pro 1.88, Phe 1.09, Ile 1.00, Val, 0.98.

Found: C, 56.05; H, 7.84; N, 16.30%. Calcd for $C_{38}H_{60}O_8N_{10}\cdot CH_3COOH\cdot 1/2H_2O$: C, 56.35; H, 7.75; N, 16.40%.

Paper Electrophoresis. This was carried out under the following conditions: paper, Toyo Roshi No. 51A chromatography paper; solvent, pyridine-acetic acid-water (10:0.4:90, v/v) (pH 6.4): voltage gradient, 15 V/cm; charge period, 2.5 h. Electrophoretic mobilities were recorded as R_{Arg}, the ratio of the distance the compounds moved to that which a standard arginine spot moved on the same electrophoreogram. The compounds (**3** and **4**) and BPIa migrated toward the cathode and revealed a single spot after being sprayed with Sakaguchi reagent; ninhydrin gave the same result. The R_{Arg} value of both **3** and **4** was 0.72; BPIa gave the same R_{Arg} value.

CD Measurement. This was performed with a JASCO J-20A. A cell of path length 0.2 mm was used and runs were made at ambient temperature. Patterns in water are shown in Fig. 3.

Sensory Test. Taste of the synthesized peptides was organoleptically determined by panel evaluation employing four persons. A series of solutions of decreasing concentration, each half as strong as the preceding one, were prepared. Before tasting the sample, the mouth was thoroughly rinsed with deionized water. The sample solution was held in the mouth for *ca.* 10 s and then spit out, and then the threshold value was determined. The results are listed in the Table.

The authors wish to express their thanks to Associate Professor Michio Kondo of Saga University for the CD measurements. Thanks are also due to Dr. Shinji Okumura of Ajinomoto Co., Inc., for supplying some amino acids.

Asymmetric Hydrogenation of Dehydrodipeptides with Rhodium(I)-Chiral Diphosphinites. Selective (*S,S*)- and (*R,R*)-Product Formation by Double Asymmetric Induction

Masanobu YATAGAI, Takamichi YAMAGISHI,* and Mitsuhiko HIDA
Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received October 6, 1983)

In the hydrogenation of dehydrodipeptides, the effect of chiral center of the substrate ((*S*) or (*R*)) on the asymmetric induction was examined using the catalysts of Rh(I)-chiral diphosphinite containing pyrrolidine moiety (POP). The catalysts with POP's having the ω-(dimethylamino)alkyl group indicated an extremely large double asymmetric induction to give (*S,S*)- or (*R,R*)-product in high stereoselectivities, depending on the chiral center of the substrates. This result was ascribed to the electrostatic interaction between the ligand and substrate. POP's without ω-(dimethylamino)alkyl group gave (*R,R*)-product for (*R*)-substrate in a high stereoselectivity by the steric effect between the ligand and substrate, while for (*S*)-substrate, (*S,S*)-product was obtained in a low stereoselectivity.

In the catalytic asymmetric hydrogenation with Rh(I) catalysts, asymmetric induction is generally caused by the steric interaction between the ligand and the substrate on the rhodium species.[1] If the electrostatic interaction between the ligand and the substrate intensifies the stereocontrol, the chiral catalyst will be more widely applied to the asymmetric reactions.

The authors prepared new chiral diphosphinites with pyrrolidine moiety (POP's) from (+)-diethyl tartrate, which are listed in Table 1. Some of them have ω-(dimethylamino)alkyl substituent, which is expected to interact electrostatically with a carboxyl group of the substrate. They were applied to the asymmetric hydrogenation of olefinic compounds with a carboxyl group and proved to be very effective for the hydrogenation of dehydrodipeptides with (*S*)-chiral center.[2,3] In the reaction of dehydrodipeptides, the carboxyl group can approach the dimethylamino group of the ligand on rhodium species, causing a strong electrostatic interaction. In the reaction of Ac-ΔPhe-Gly-OH without a chiral center, however, only moderate optical yields were obtained.[2,3] This would indicate that the steric effect by the chiral center of the dehydrodipeptides and the electrostatic interaction between the ligand and substrate lead to the high stereoselectivity in the Rh(I)–POP-catalyzed hydrogenation.

In this paper, we will describe how the chiral center ((*S*) and (*R*)) of dehydrodipeptides affects the stereoselectivity, leading to an extremely large double asymmetric induction in the Rh(I)–POP-catalyzed hydrogenation.

TABLE 1. CHIRAL DIPHOSHINITES (POP's)

Diphosphinite[a] 	Ar	R
POP-AE	Ph	$CH_2CH_2N(CH_3)_2$
p-Me-POP-AE	CH_3-	$CH_2CH_2N(CH_3)_2$
p-MeO-POP-AE	CH_3O-	$CH_2CH_2N(CH_3)_2$
POP-AP	Ph	$CH_2CH_2CH_2N(CH_3)_2$
POP-IP	Ph	$CH_2CH_2CH(CH_3)_2$
p-MeO-POP-IP	CH_3O-	$CH_2CH_2CH(CH_3)_2$
POP-BZ	Ph	CH_2Ph

a) AE, AP, IP, and BZ represent alkyl group(R) of POP and denote dimethylaminoethyl, dimethylaminopropyl, isopentyl, and benzyl, respectively.

Results and Discussion

The catalysts of the diphosphinites (POP's) were examined for the asymmetric hydrogenation of dehydrodipeptides. POP-AE and POP-AP have ω-(dimethylamino)alkyl groups, which facilitate electrostatic interaction between the ligand and substrate. POP-IP is a carbon analogue of POP-AE, and the isopentyl group will have a similar steric factor to that of the 2-(dimethylamino)ethyl group of POP-AE. For *p*-Me-POP-AE, *p*-MeO-POP-AE, and *p*-MeO-POP-IP, the increasing in the electron density on the phosphorus atoms of the ligands will cause the stronger coordination of them onto rhodium. The results of asymmetric hydrogenations of dehydrodipeptides using Rh(I)–POP catalysts are summarized in Table 2. For the substrates with (*S*)-chiral center, POP's with ω-(dimethylamino)alkyl group showed good to excellent stereoselectivities. For Ac-ΔPhe-(*S*)-Phe-OH, the stereoselectivity with *p*-Me-POP-AE and *p*-MeO-POP-AE was near 100% d.e. POP's without dimethylamino group gave low or moderate optical yields. These results clearly indicated the contribution of the dimethylamino group of POP in the asymmetric induction.

From the hydrogenation of Ac-ΔPhe-Gly-OH and dehydrodipeptides with (*S*)-chiral center, the present POP's were considered to have (*S*)-selectivity.[2,3] Surprisingly, the hydrogenation of dehydrodipeptides with (*R*)-chiral center using POP's with dimethylamino group gave (*R,R*)-product with high optical yields (86—96% d.e.) instead of (*S,R*)-isomer. The reaction of Ac-ΔPhe-(*R*)-Phe-OH was much slower than that of Ac-ΔPhe-(*S*)-Phe-OH. Achiral 1,2-bis-

[bis(4-methoxyphenyl)phosphinooxy]ethane catalyst gave (*S,S*)- or (*R,R*)-product with low optical yields (20% d.e.) for Ac-⊿Phe-(*S*)-Ala-OH and Ac-⊿Phe-(*R*)-Ala-OH, respectively. These results indicate that the POP catalysts caused an excellent double asymmetric induction, leading to high stereoselectivity for both (*S*)- and (*R*)-substrate. This makes a striking contrast to the results reported with chiral diphosphines.[4]

It is further noted that POP's without dimethylamino group gave (*R,R*)-product in fairly high stereoselectivities (68—90% d.e.), though they gave low optical yields for (*S,S*)-isomer from (*S*)-substrates.

[Rh(*p*-MeO-POP-AE)(cod)]$^+BF_4^-$ was treated with an equimolar amount of perchloric acid in ethanol-methanol solution; this resulted in an orange-yellow precipitate. ^1H NMR spectra of this orange-yellow complex (A) in CD_3OD showed that the protonation occurred mainly at the ω-dimethylamino group of *p*-MeO-POP-AE. The hydrogenation with the complex (A) afforded much lower stereoselectivities for Ac-⊿Phe-(*S*)-Ala-OH and Ac-⊿Phe-(*R*)-Ala-OH (62% and 66% d.e., respectively) (Table 3). From these results, it is concluded that the dimethylamino group of POP plays an important role in the asymmetric induction by electrostatic interaction with a carboxyl group of the substrate. The result of the hydrogenation of Ac-⊿Phe-(*S*)-Ala-OMe with POP-AP supports the above conclusion: In the reaction of Ac-⊿Phe-(*S*)-Ala-OMe, Rh(I)-(POP-AP) catalyst gave a very low optical yield ((*S,S*)/(*R,S*)=46/54, 8% d.e.), while the same catalyst afforded a high diastereomeric excess ((*S,S*)/(*R,S*)=91/9, 82% d.e.) in the reaction of Ac-⊿Phe-(*S*)-Ala-OH.

(*R*)-Selectivity observed in the case of Ac-⊿Phe-(*S*)-Ala-OMe by POP-AP was in accord with the reactions of dehydroamino acids using POP-AP where electrostatic interaction is not likely to function.[3]

Tertiary amine moiety of *p*-MeO-POP-IP was also converted to the ammonium type by treating [Rh(*p*-MeO-POP-IP)(cod)]$^+BF_4^-$ with $HClO_4$. The resulting complex (B) gave similar stereoselectivities for both (*S*)- and (*R*)-substrates to that for *p*-MeO-POP-IP complex (Table 3). Therefore, it is unlikely that nitrogen of the pyrrolidine ring contributed to the asymmetric induction. In the case of dehydrodipeptide esters, electrostatic interaction between the substrate and the ligand will be impossible. However, the double asymmetric induction with POP-IP was also observed for the esters with (*R*)-chiral center (Table 4). Therefore, it would be the steric effect of the POP's without dimethylamino group that produced a fairly large double asymmetric induction for (*R,R*)-products from (*R*)-substrates. In the reaction of the substrate with (*R*)-chiral center, methoxyl group on the ligand slightly lowered the (*R,R*)-selectivity, contrary to the results of the (*S*)-substrate (Tables 2 and 4), since strong coordination of the ligand onto rhodium increased (*S*)-selectivity inherent to the ligand.

As shown in Fig. 1, the system of Rh(I)-(*p*-MeO-POP-IP) containing Ac-⊿Phe-Ala-OH gave the same CD spectra irrespective of the chirality in the substrate. On the other hand, CD spectra of the system of Rh(I)-(*p*-MeO-POP-AE) containing Ac-⊿Phe-Ala-OH depended on the chirality of the substrate. This indicates that the substrate with (*S*)-chiral center coordinates onto rhodium in a different mode from that for the substrate with (*R*)-chiral center in the *p*-MeO-POP-AE system. That is to say, the dimethyl-

amino group of the ligand could affect the step of prochiral face selection of the substrate by means of the electrostatic interaction with the carboxyl group of the substrate to emphasize the steric effect of the chiral center in the substrate.

In the reaction of Ac-⊿Phe-(*S*)-Ala-OH in ethanol, *p*-MeO-POP-AE afforded much higher optical yield than *p*-MeO-POP-IP, while similar optical yields were obtained by the above two diphosphinites in the reaction of Ac-⊿Phe-(*R*)-Ala-OH in ethanol. The hydrogenation of Ac-⊿Phe-(*R*)-Ala-OH in 2-propanol using *p*-MeO-POP-AE gave higher optical yield than that by *p*-MeO-POP-IP (86% and 78% d.e., respectively). This is because a decrease in the polarity of solvent can emphasize the electrostatic interaction between the ligand and substrate. But the difference in the optical yields between the two diphosphinites in 2-propanol was not large. So it is considered that the contribution of the electrostatic interaction for (*R,R*)-product formation would be smaller than that for (*S,S*)-product formation.

As described so far, the present POP's with the dimethylamino group showed an excellent stereoselectivity in the hydrogenation of dehydrodipeptides with (*S*)- or (*R*)- chiral center by the extremely large double asymmetric induction. These phenomena will be ascribed mainly to the contribution of the electrostatic interaction to emphasize the stereocontrol for asymmetric induction. The steric interaction between the substituent on the chiral center of the substrate and the phenyl group on the phosphorus atom of the ligand evoked by the electrostatic interaction will affect the selection of the prochiral face of the substrate in coordination onto rhodium.[3] On the other hand, POP's without dimethylamino group indicated high (*R*)-selectivity in the reaction of the (*R*)-substrate due to the steric effect of the ligand, though the details of the stereocontrol are not clear in the present stage.

p-MeO-POP-AE and *p*-MeO-POP-IP were applied to the hydrogenation of Ac-⊿Phe-Asp-OH with two carboxyl groups capable of interaction with the ligand. *p*-MeO-POP-AE showed a double asymmetric induction in the case of both Ac-⊿Phe-(*S*)-Asp-OH and Ac-⊿Phe-(*R*)-Asp-OH, while with *p*-MeO-POP-IP the chirality newly formed was the same for both substrates. This would suggest the possibility of selecting the newly formed chirality of the product by utilizing the steric factor and/or electrostatic factor of the present POP catalysts. Furthermore, it will be fruitful to apply the present POP catalysts to other substrates, for example, dehydrodipeptides of Y-AA-⊿AA-OH type, or dehydrooligopeptides.

Experimental

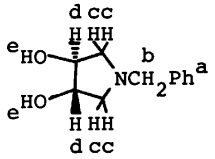
^{1}H NMR spectra were recorded on a HITACHI R-24 High Resolution NMR spectrometer (60 MHz) with tetramethylsilane as internal standard. CD spectra were recorded on a JASCO J-40A spectropolarimeter. Optical rotations were measured with a UNION PM 101 automatic digital polarimeter.

Rh(I) catalysts were prepared *in situ* from $[Rh(cod)_2]^+BF_4^-$ and a diphosphinite (POP). The procedure of asymmetric hydrogenations and determination of the optical yields were the same as described previously.[3] CD spectra were measured by the method described previously.[3]

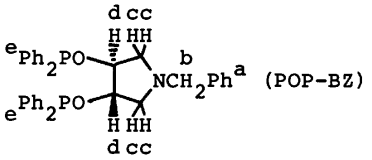
Materials. All *N*-acetyl dehydrodipeptides were prepared by Bergmann's method.[5] Esterification of *N*-acetyl

dehydrodipeptides was performed by a conventional method.[4c] All solvents were dried, distilled, and stored under nitrogen. $[Rh(cod)_2]^+BF_4^-$ was prepared by a conventional method and stored under nitrogen.[6]

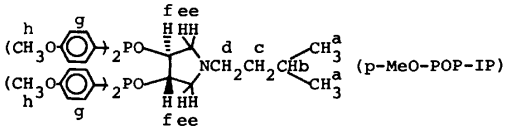
Preparation of Chiral Diphosphinites (POP-BZ and p-MeO-POP-IP). *(3S, 4S)-N-Benzyl-3,4-pyrrolidinediol*: Benzylamine (30 cm³, 27.5×10^{-2} mol) and 1,4-di-*O*-tosyl-L-threitol (24.2 g, 5.6×10^{-2} mol) were reacted in dioxane under nitrogen; the product was treated in the manner described previously.[3] (7.0 g, 64% yield) $[\alpha]_D+8.5°$ (*c* 2.07, $CHCl_3$); ^1H NMR δ=2.45—2.89 (4H, m, H^c), 3.55 (2H, s, H^b), 4.01 (2H, br t, H^d), 4.30 (2H, s, H^e), 7.18(5H, s, H^a).



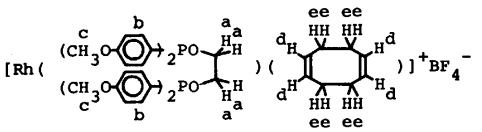
(3S,4S)-N-Benzyl-3,4-bis(diphenylphosphinooxy)pyrrolidine (POP-BZ): The diol (870 mg, 4.5×10^{-3} mol) and chlorodiphenylphosphine (2.2 g, 1.0×10^{-2} mol) were reacted in the presence of triethylamine (1.0 g, 1.0×10^{-2} mol); white crystals of POP-BZ were obtained by the work up described previously.[3] (1.8 g, 90% yield) $[\alpha]_D+50.4°$ (c 1.02, C_6H_6); ^1H NMR ($CDCl_3$) δ=2.53—3.11 (4H, m, H^c), 3.56 (2H, br s, H^b), 4.55 (2H, br m, H^d), 7.20 (25H, s, m, H^a, H^e).



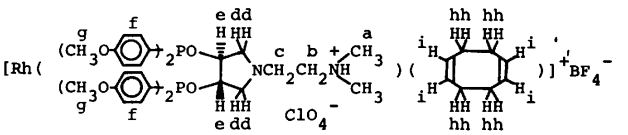
(3S,4S)-N-Isopentyl-3,4-bis[bis(4-methoxyphenyl)phosphinooxy]-pyrrolidine (p-MeO-POP-IP): (3S,4S)-*N*-Isopentyl-3,4-pyrrolidinediol (200 mg, 1.2×10^{-3}mol) and chlorobis(4-methoxyphenyl)phosphine (670 mg, 2.4×10^{-3} mol) were reacted in the presence of triethylamine (720 mg, 7.1×10^{-3} mol); white crystals of *p*-MeO-POP-IP were obtained by the procedure described previously.[3] (310 mg, 40% yield) $[\alpha]_D^{20}$ +53.3° (c 0.27, C_6H_6); ^1H NMR ($CDCl_3$) δ=0.85 (6H, d, H^a), 1.31 (3H, br m, H^b, H^c), 2.24—3.00 (6H, m, H^d, H^e), 3.72 (12H, s, H^h), 4.46 (2H, br m, H^f), 6.75—7.48 (16H, m, H^g).



[Rh(1,2-bis{bis(4-methoxyphenyl)phosphinooxy}ethane) (cod)]$^+$ BF_4^-: To the solution of ethylene glycol (250 mg, 4.0×10^{-3} mol) and pyridine (700 mg, 8.8×10^{-3} mol) in THF (10 cm³), chlorobis(4-methoxyphenyl)phosphine (2.4 g, 8.5×10^{-3} mol) was added dropwise in 1.5 h with stirring in an ice-water bath. The resulting mixture was stirred overnight at r.t. Filtration of the reaction mixture, followed by evaporation of the filtrate, gave an oily product containing monophosphinite. This oily product was phosphinitated with 520 mg of chlorobis(4-methoxyphenyl)phosphine and 600 mg of pyridine, and the same work up as above gave an oily product. This oil was purified from diethyl ether–hexane, and crude diphosphinite was obtained. (100 mg, 70 mol% purity) This diphosphinite and $[Rh(cod)_2]^+BF_4^-$ (54 mg, 1.3×10^{-4} mol) are dissolved in CH_2Cl_2 (5 cm³) and the solution was stirred at r.t. for 1 h. Addition of ether (10 cm³) to this solution gave a yellow precipitate, and yellow needles were obtained by recrystallization of this precipitate from CH_2Cl_2–THF–diethyl ether (73 mg, 64% yield). ^1H NMR ($CDCl_3$) δ=3.74 (20H, s, m, H^c, H^e), 4.27 (4H, br, H^a), 6.54—7.70 (20H, br m, H^b, H^d).

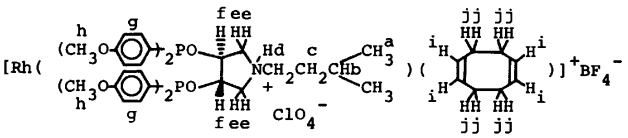


Rh Complex A: To the solution of the *p*-MeO-POP-AE (83 mg, 1.25×10^{-4} mol) and $[Rh(cod)_2]^+BF_4^-$ (47 mg, 1.15×10^{-4} mol) in ethanol (20 cm³) and methanol (5 cm³), $HClO_4$ (1.21×10^{-4} mol) was added as an ethanol solution. This solution was stirred for 15 min at r.t.; orange-yellow crystals precipitated from the solution. This mixture was concentrated by evaporation and filtrated under nitrogen. Yellow-orange crystals of complex **A** were dried under reduced pressure. (56 mg, 48% yield) ^1H NMR (CD_3OD): δ=2.76—3.58 (14H, s, br m, H^a, H^b, H^c, H^d), 3.84 (20H, br m, H^g, H^h), 5.05 (2H, br, H^e), 6.63—7.78 (20H, br m, H^f, H^i).



A

Rh Complex B: To the solution of *p*-MeO-POP-IP (70 mg, 1.05×10^{-4} mol) and $[Rh(cod)_2]^+BF_4^-$ (40 mg, 1.0×10^{-4} mol) in ethanol (10 cm³), $HClO_4$ (1.05×10^{-4} mol) was added as an ethanol solution. This solution was stirred for 5 min at 0°C; yellow crystals separated from it. The remaining mixture was cooled to −20°C and filtrated under nitrogen. Crystals of complex **B** were dried under reduced pressure. (73 mg, 69% yield) ^1H NMR (CD_2Cl_2) δ=0.91 (6H, br d, H^a), 1.66 (3H, br, H^b, H^c), 3.74 (26H, br m, H^d, H^e, H^h, H^i, H^j), 4.79 (2H, br, H^f), 6.36—7.70 (20H, br m, H^g, H^i).



B

The authors express their gratitude to Professor M. Kobayashi and Dr. N. Kamigata, Tokyo Metropolitan University, for CD spectroscopy.

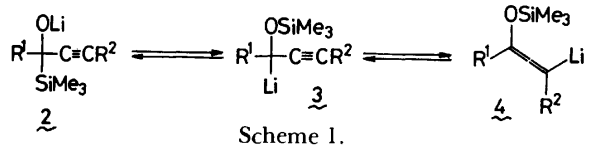
Specific Generation of Lithiated 3-Trimethylsiloxy-1,2-propadiene Derivatives from 1-(Trimethylsilyl)propargyl Alcohols

Masahiro KATO and Isao KUWAJIMA*
Department of Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152
(Received October 19, 1983)

1-(Trimethylsilyl)propargyl alcohols have been prepared by treating acyltrimethylsilanes with magnesium acetylides, and their base-induced reactions involving rearrangement of silyl group have been examined. Treatment of the alcohol with an equimolar amount of butyllithium in hexane followed by addition of tetrahydrofuran has allowed to generate the lithiated 3-trimethylsiloxy-1,2-propadiene, which reacts with an alkyl iodide to afford the alkylated 1-trimethylsiloxy-1,2-propadiene in high yield. Further, a catalytic amount of butyllithium also effects an efficient conversion of the alcohol to the corresponding 1-siloxy-1,2-propadiene through a similar rearrangement process.

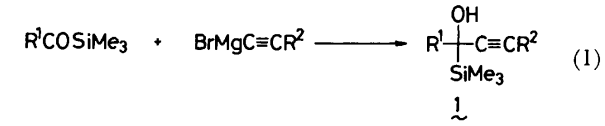
Strong affinity of silicon atom to oxide anion has sometimes allowed a facile transfer of trialkylsilyl group from carbon to oxygen. Under basic conditions, 1-(trialkylsilyl)alkanols undergo rearrangement to yield the corresponding alkyl silyl ethers, which is well documented as Brook rearrangement.[1,2] Similar migration of silyl group has also been proposed for Peterson type olefination reaction[2] of 2-(trialkylsilyl)-alkanols under basic conditions.[3] In these rearrangement processes, formation of the corresponding carbanionic species during equilibration with the alkoxides has been assumed or proved in certain cases, but it has been quite difficult to make use such kinds of nucleophilic species for carbon chain homologation because of their high lability under reaction conditions. To control a generation of such carbanionic species effectively through this rearrangement, an additional anion-stabilizing substituent such as phenyl or olefinic group seems to be required, and we have recently reported several synthetic applications of such anionic species generated from 1-(trimethylsilyl)-allylic alcohols[4] and 3-trimethylsilyl-4-penten-1-ol derivative[5] for synthesis of enol silyl ethers and 1,5-heptadien-3-ol, an oxy-Cope rearrangement precursor.

Based on a similar background, 1-(trimethylsilyl)-propargyl alcohols (**1**) have also been expected to undergo silyl group migration to generate anionic species of propargyl silyl ether **3** or 1-trimethylsiloxy-1,2-propadiene derivatives **4** under basic conditions. Different from the precedent cases, an internal coordination of siloxy group to metal which has brought about a thermodynamic stability may be ruled out from these anionic species **3** and **4**, but allenic species **4** is expected to be much more common than **3** judging from literatures dealing with metallated allene derivatives.[6] Resulting nucleophiles **4** seem to be especially useful on synthetic standpoints that selective introduction of various organic substituents may be feasible on both α- and β-carbons of α,β-unsaturated carbonyl compounds (Scheme 1). In this paper we describe full details on the rearragement reactions of the propargyl alcohol **1** to afford siloxy allenes **5** and **6**.[7,8]



Scheme 1.

The starting materials, 1-(trimethylsilyl)propargyl alcohols (**1**) were easily prepared by treating the corresponding acyltrimethylsilanes[9] with appropriate bromomagnesium acetylides (Eq. 1). A straight-chained acyltrimethylsilane undergoes addition of acetylides quite efficiently in ether to give the corresponding **1** as a sole product, whereas a small amount of rearrangement prouct, propargyl silyl ether, is also formed from the addition reaction of an α-branched acyltrimethylsilane when ether or tetrahydrofuran (THF) is employed as the solvent. In the latter case, use of hexane as the reaction solvent excludes the formation of side-product, and the desired **1** could be obtained in high yield.



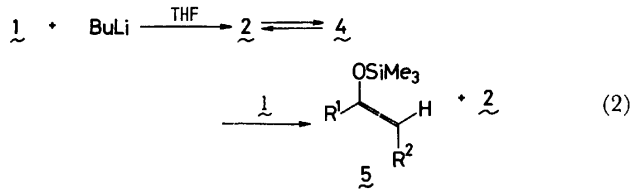
(1)

TABLE 1. PREPARATION OF 1-(TRIMETHYLSILYL)-PROPARGYL ALCOHOLS (**1**)

	R^1	R^2	Yield/% of **1**
a)	C_3H_7	C_6H_5	96
b)	$C_6H_5CH_2CH_2$	C_4H_9	95
c)	$C_6H_5CH_2CH_2$	C_6H_5	99
d)	$C_6H_5CH_2CH_2$	$SiMe_3$	96
e)	$C_6H_5CH_2CH_2$	CH_2OCH_3	94

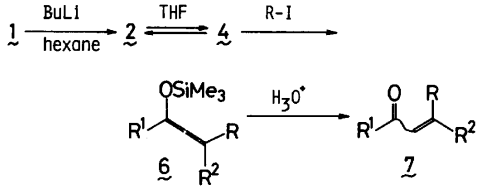
On lithiation of this alcohol **1** with butyllithium, we have experienced similar difficulties encountered with 1-(trimethylsilyl)allylic alcohols:[4] complete conversion of the alcohol **1** to the lithium alkoxide **2** is quite difficult when tetrahydrofuran is used as the solvent. Formation of complex mixture has usually been observed on treatment of the resulting solution with various electrophiles. This curious result may be explained by assuming that an extremely rapid equilibrium between the lithium alkoxide **2** and the lithiated allenic species **4** has been attained through rearrangement of silyl group from carbon to oxygen before complete formation of **2**. The resulting carbanionic species **4** may be protonated by the remaining alcohol **1**, which leads to fomation of a mixture of siloxyallene **5** and its lithiated one **4** together with the alkoxide **2** and butyllithium (Eq. 2).

However, use of a nonpolar solvent such as hexane has excluded the equilibration between **2** and **4**, and the alcohol **1** can be converted to the corresponding lithium alkoxide **3** almost completely. Further, addition of



(2)

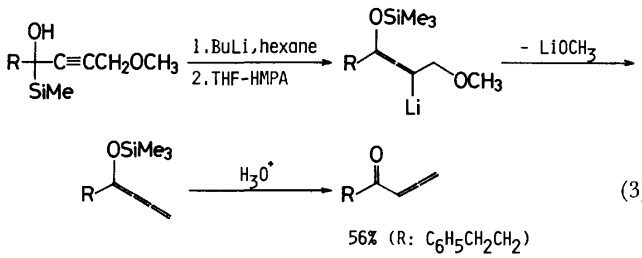
THF to the resulting hexane solution induces the equilibration to generate **4**. Carbon chain homologation can be achieved efficiently by the *in situ* reaction of this species with appropriate alkyl halides. Although two types of alkylation products may be conceivable during this procedure, the reaction takes place selectively on allenic carbon as expectedly,[6] and the corresponding α,β-unsaturated ketone **7** is obtained in high yield after aqueous work-up of the reaction mixture (see Scheme 2 and Table 2). Only exceptional case is that bearing a leaving group on an appropriate position, which undergoes a facile elimination as shown in the following example.



Scheme 2.

TABLE 2. ALKYLATION OF LITHIATED ALLENES **4**

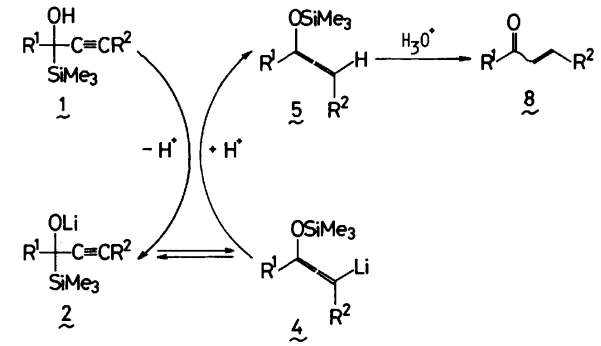
	R^1	R^2	R-I	Yield/% of **7**
a)	C_3H_7	C_6H_5	CH_3-I	92
b)	$C_6H_5CH_2CH_2$	C_4H_9	CH_3-I	94
c)	$C_6H_5CH_2CH_2$	C_6H_5	CH_3-I	92
d)	$C_6H_5CH_2CH_2$	C_6H_5	C_4H_9-I	86
e)	$C_6H_5CH_2CH_2$	$SiMe_3$	CH_3-I	87
f)	$C_6H_5CH_2CH_2$	$(C_2H_4O_2)$-$CHCH_2CH_2$	CH_3-I	82



(3)

56% (R: $C_6H_5CH_2CH_2$)

Further, in a similar manner with 1-(trimethylsilyl)-allylic alcohols,[4] the alcohols **1** undergo a specific conversion to the corresponding 1-trimethylsiloxy-1,2-propadienes in excellent yield under the influence of a catalytic amount of butyllithium in THF through the following four steps: (1) formation of the alkoxide **2**, (2) generation of lithiated allenic species **4** *via* equilibration, (3) protonation of **4** with the remaining alcohol, and (4) regeneration of the alkoxide **2**. This transformation has been effected by treating the alcohol **1** with *ca.* 5 mol% of butyllithium in THF at −78 °C followed by warming up to 0 °C.



Scheme 3.

In most cases, protonation takes place selectively on terminal allenic carbon to yield **5**, but the alcohol prepared from silylacetylene afforded a mixture of the corresponding **5** (63%) and the propargyl silyl ether (29%).

Unfortunately, on an attempt for purification, the resulting siloxyallenes **5** and **6** are very labile on column chromatography and sometimes on heating for a distillation. Accordingly, the yields of the products were determined on the basis of α,β-unsaturated ketones **8** obtained by aqueous work-up of the reaction mixture. The results are shown in Table 3.

TABLE 3. CATALYTIC CONVERSION OF ALCOHOLS **1** TO **8** *via* **5**

	R^1	R^2	Yield/% of **8**
a)	C_3H_7	C_6H_5	96
b)	$C_6H_5CH_2CH_2$	C_4H_9	97
c)	$C_6H_5CH_2CH_2$	C_6H_5	89
d)	$C_6H_5CH_2CH_2$	$SiMe_3$	63[a]
e)	$C_6H_5CH_2CH_2$	CH_2OCH_3	80

a) The propargyl silyl ether was also formed in 29% yield.

However, the crude products **5** are usually pure enough for further synthetic elaboration without purification. By using the crude 5, several organic substituents can be introduced on the central carbon of the allenic linkages very efficiently under the influence of Lewis acid as shown below. For example, the crude **5** (R^1=C_3H_7, R^2=C_6H_5) obtained from the corresponding alcohol **1** gave the condensation product in 81% overall yield on treating with a benzaldehyde acetal. Thus, starting from the alcohol **1**, this procedure has allowed to effect two types of carbon chain homologation on each α- and β-carbon, respectively, by way of lithiated allenic species **4**.

81%

Experimental

General Methods. Boiling points are uncorrected. Infrared (IR) spectra were recorded on a Hitachi EPI-G3 spectrometer; absorptions are reported in reciprocal centimeters. Proton nuclear magnetic resonance spectra (^{1}H NMR) were obtained on a Hitachi R-24B spectrometer; chemical Shifts (δ) are expressed in part per million downfield from tetramethylsilane. Analytical gas-liquid chromatography (GLC) was performed on a Hitachi 163 instrument with a flame-ionization detector and nitrogen carrier gas (1.0—1.3 kg/cm^2) using a OV-101 fused silica 20 m capillary column (Hitachi Chemi-Column). Microanalysis were performed with a Perkin-Elmer 240 at the Microanalytical Laboratory, Tokyo Institute of Technology.

Reactions involving air- or moisture-sensitive compounds were carried out in appropriate round-bottomed flasks with stirring bars under nitrogen or argon. Bulb-to-bulb distillation was performed with a Buchi Kugelrohr apparatus.

Preparative thin-layer chromatography (TLC) was carried out on glass plates (20×20 cm) coated with Merck silica gel PF 254 (1 mm thick).

Hexane was distilled from sodium. Ether and tetrahydrofuran (THF) were distilled from sodium/benzophenone ketyl immediately before use.

Materials. Acyltrimethylsilanes were prepared from the corresponding enol trimethylsilyl ethers of benzene- or methane-thiol esters according to the procedure developed in our laboratory.[9]

Preparation of 1-(Trimethylsilyl)propargyl Alcohols (1). *General Procedure*: To ethylmagnesium bromide (32 mL of 0.71 M THF solution, 22.5 mmol) diluted with ether (50 mL) was added an ethereal solution (25 mL) of a substituted acetylene (25 mmol) at 0 °C and it kept stirring for 30 min at room temperature. Then, an acyltrimethylsilane (15 mmol) in ether (25 mL) was added to the resulting solution and was stirred further 10 min at 0 °C. The reaction mixture was quenched with satd aq NH_4Cl and was extracted three times with 50 mL portions of ether. The extracts were washed with satd aq NaCl and were dried over anhyd $MgSO_4$. Removal of the solvent from the filtrate followed by distillaion gave the corresponding 1-(trimethylsilyl)propargyl alcohol (**1**).

*1-Phenyl-3-trimethylsilyl-1-hexyn-3-ol (**1a**)*: Bp 101—102 °C/0.05 mmHg;[10] IR (neat) 3400, 2200, 1245, 840 cm^{-1}; NMR (CCl_4) δ=0.16 (s, 9H), 0.80—1.20 (m, 3H), 1.43—1.87 (m, 5H including a singlet of OH at 1.73), 7.03—7.43 (m, 5H); Calcd for $C_{15}H_{22}OSi$: C, 73.10; H, 9.02%. Found: C, 73.21; H, 8.94%.

*1-Phenyl-3-trimethylsilyl-4-nonyn-3-ol (**1b**)*: Bp 118—119 °C/0.025 mmHg; IR (neat) 3430, 1600, 1250, 845 cm^{-1}; NMR (CCl_4) δ=0.12 (s, 9H), 0.73—2.03 (m, 10H including a singlet of OH at 1.55), 2.06—2.47 (m, 2H), 2.67—3.05 (m, 2H), 7.13 (s, 5H); Calcd for $C_{18}H_{28}OSi$: C, 74.94; H, 9.78%. Found: C, 74.81; H, 9.79%.

*1,5-Diphenyl-3-trimethylsilyl-1-pentyn-3-ol (**1c**)*: Bp 146—147 °C/0.037 mmHg; IR (neat) 3410, 1600, 1250, 850 cm^{-1}; NMR (CCl_4) δ=0.18 (s, 9H), 1.76—2.16 (m, 3H including a singlet of OH at 1.91), 2.75—3.16 (m, 2H), 7.00—7.50 (m, 10H).

*5-Phenyl-1,3-bis(trimethylsilyl)-1-pentyn-3-ol (**1d**)*: Bp 104—105 °C/0.025 mmHg; IR (neat) 3400, 2135, 1248, 845 cm^{-1}; NMR (CCl_4) δ=0.12 (s, 9H), 0.19 (s, 9H), 1.62—2.03 (m, 3H including a singlet of OH at 1.67), 2.68—3.03 (m, 2H), 7.16 (s, 5H); Calcd for $C_{17}H_{28}OSi_2$: C, 67.04; H, 9.27%. Found: C, 67.32; H, 9.22%.

*6-Methoxy-1-phenyl-3-trimethylsilyl-4-hexyn-3-ol (**1e**)*: Bp 110—112 °C/0.027 mmHg; IR (neat) 3370, 2200, 1246, 840 cm^{-1}; NMR (CCl_4) δ=0.15 (s, 9H), 1.65—2.08 (m, 2H), 2.37 (s, 1H), 2.68—3.10 (m, 2H), 3.31 (s, 3H), 4.12 (s, 2H), 7.13 (s, 5H); Calcd for $C_{16}H_{24}OSi$: C, 69.52; H, 8.75%. Found: C, 69.20; H, 8.60%.

*Alkylation of a Lithiated Allene **4** Generated from **2**.* *General Procedure*: To a hexane (1 mL) solution of 1-(trimethylsilyl)propargyl alcohol (**1**) (1 mmol) was added butyllithium (0.55 mL of 2.0 M hexane solution, 1.1 mmol) at 0 °C and it was stirred for 30 min. After cooling to −78 °C, THF (5 mL) was added and it was stirred for 10 min at that temperature. Then, an appropriate alkyl iodide (1.2 mmol) in THF (1 mL) was added and the reaction mixture was stirred for 1.5 hr at −40 °C. Hexane (20 mL) precooled to −78 °C was added to the reaction mixture and was poured into a buffer (KH_2PO_4–NaOH) solution. The aqueous layer was extracted twice with 20 mL portions of ether, and the combined extracts were dried over anhyd $MgSO_4$. After removal of the solvent, the crude 1-(trimethylsiloxy)allene (**6**) was dissolved in THF (10 mL) and 3—5 drops of 1M HCl was added. After stirring for 20 min at room temperature, the reaction mixture was treated with aq $NaHCO_3$ and was extracted twice with 20 mL portions of ether. The combined extracts were washed with satd aq NaCl and dried over anhyd $MgSO_4$. Removal of the solvent followed by separation with TLC gave a mixture of the corresponding (*E*)- and (*Z*)-α,β-unsaturated ketone.

*5-Methyl-1-phenyl-3-trimethylsiloxy-3,4-nonadiene (**6a**)*: IR (neat) 1950, 1600, 1250, 850 cm^{-1}; NMR (CCl_4) δ=0.12 (s, 9H), 0.70—2.93 (m, 16H), 7.10 (s, 5H).

*2,6-Diphenyl-4-trimethylsiloxy-2,3-hexadiene (**6c**)*: IR (neat) 1934, 1600, 1250, 845 cm^{-1}; NMR (CCl_4) δ=0.10 (s, 9H), 2.00 (s, 3H), 2.30—3.00 (m, 4H), 7.12 (s, 10H).

(E)-*2-Phenyl-2-hepten-4-one (**7a-(E)**)*: 16%; IR (neat) 1675, 1595 cm^{-1}; NMR (CCl_4) δ=0.95 (t, J=7 Hz, 3H), 1.33—1.93 (m, 2H), 2.43 (t, J=7 Hz, 2H), 2.50 (s, 3H), 6.36 (s, 1H), 7.03—7.63 (m, 5H).

(Z)-*2-Phenyl-2-hepten-4-one (**7a-(Z)**)*: 76%; IR (neat) 1685, 1655, 1610 cm^{-1}; NMR (CCl_4) δ=0.70 (t, J=6 Hz, 3H), 1.03—1.70 (m, 2H), 1.98 (t, J=6 Hz, 2H), 2.11 (s, 3H), 5.99 (s, 1H), 7.00—7.40 (m, 5H).

(E)-*5-Methyl-1-phenyl-4-nonen-3-one (**7b-(E)**)*: 45%; IR (neat) 1676, 1609 cm^{-1}; NMR (CCl_4) δ=0.66—1.67 (m, 7H), 1.76—2.30 (m, 2H), 2.04 (d, J=1 Hz, 3H), 2.40—3.02 (m, 4H), 5.87 (q, J=1 Hz, 1H), 7.04 (s, 5H).

(Z)-*5-Methyl-1-phenyl-4-nonen-3-one (**7b-(Z)**)*: 49%; IR (neat) 1679, 1606 cm^{-1}; NMR (CCl_4) δ=0.68—1.57 (m, 7H), 1.78 (d, J=1 Hz, 3H), 2.34—3.01 (m, 6H), 5.85 (q, J=1 Hz, 1H), 7.01 (s, 5H).

(E)-*1,5-Diphenyl-4-hexen-3-one (**7c-(E)**)*: 28%; IR (neat) 1680, 1600 cm^{-1}; NMR (CCl_4) δ=2.48 (d, J=1.6 Hz, 3H), 2.60—3.06 (m, 4H), 6.32 (q, J=1.6 Hz, 1H), 6.97—7.45 (m, 10H).

(Z)-*1,5-Diphenyl-4-hexen-3-one (**7c-(Z)**)*: 64%; IR (neat) 1685, 1655, 1610 cm^{-1}; NMR (CCl_4) δ=2.13 (d, J=1.4 Hz, 3H), 2.13—2.87 (m, 4H), 5.96 (q, J=1.4 Hz, 1H), 6.65—7.47 (m, 10H).

(E)-*1,5-Diphenyl-4-nonen-3-one (**7d-(E)**)*: 17%; IR (neat) 1668, 1585 cm^{-1}; NMR (CCl_4) δ=0.73—1.57 (m, 7H), 2.67—3.17 (m, 6H), 6.22 (s, 1H), 7.10 (s, 5H).

(Z)-*1,5-Diphenyl-4-nonen-3-one (**7d-(Z)**)*: 69%; IR (neat) 1680, 1650, 1605 cm^{-1}; NMR (CCl_4) δ=0.70—1.57 (m, 7H), 2.07—2.87 (m, 6H), 5.95 (s, 1H), 6.70—7.37 (m, 10H).

(E)-*1-Phenyl-5-trimethylsilyl-4-hexen-3-one (**7e-(E)**)*: 39%; IR (neat) 1675, 1578, 1250, 850 cm^{-1}; NMR (CCl_4) δ=0.11 (s, 9H), 2.12 (d, J=2 Hz, 3H), 2.60—2.98 (m, 4H), 6.25 (q, J=2 Hz, 1H), 7.09 (s, 5H).

(Z)-*1-Phenyl-5-trimethylsilyl-4-hexen-3-one (**7e-(Z)**)*: 48%; IR (neat) 1675, 1570, 1242, 850 cm^{-1}; NMR (CCl_4) δ=0.13 (s, 9H), 1.93 (d, J=1.8 Hz, 3H), 2.60—2.94 (m, 4H), 6.56 (q, J=1.8 Hz, 1H), 7.10 (s, 5H).

(E)- *and* (Z)-*4-Methyl-6-oxo-8-phenyl-4-octenal Ethylene Acetal (7f)*: 82%; IR (neat) 1678, 1610 cm^{-1}; NMR (CCl_4) δ=1.47—3.03 (m, 11H), 3.60—3.91 (m, 4H), 4.71 and 4.78 (t, J=4 Hz, 1H), 5.94 (q, J=1 Hz, 1H), 7.08 (s, 5H).

1-Phenyl-4,5-hexadien-3-one. To a THF (6 mL) solution of 6-methoxy-1-phenyl-3-trimethylsilyl-4-hexyn-3-ol (276 mg, 1.0 mmol) was added butyllithium (0.67 mL of 1.5 M hexane solution, 1.0 mmol) and hexamethylphosphoric triamide (HMPA) successively at −78°C, and it was stirred for 2 h at −40°C. Then, the reaction mixture was worked up in a similar manner as described above to afford the title compound (96 mg, 56%). Bp 90—92°C/0.08 mmHg; IR (neat) 1940, 1915, 1665, 855 cm^{-1}; NMR (CCl_4) δ=2.80 (s, 4H), 5.70 (d, J=6 Hz, 2H), 5.65 (dd, J=6 and 6 Hz, 1H), 7.08 (s, 5H); Calcd for $C_{12}H_{12}O$: C, 83.69; H, 7.02. Found: C, 83.89; H, 7.10%.

Conversion of 1-(Trimethylsilyl)propargyl Alcohol (1) to the 1-Trimethylsiloxy-1,2-propadiene (5) Catalyzed by Butyllithium. General Procedure: Buytllithium (0.04 mL of 1.5 M hexane solution, 0.06 mmol) was added to a THF (5 mL) solution of a 1-(trimethylsilyl)propargyl alcohol (**1**) (1 mmol) at −78°C, and the reaction mixture was warmed up to 0°C during 1 h. After stirring for 20 min at that temperature, the reaction mixture was worked up in a similar manner as described above to give the corresponding **8**.

1-Phenyl-3-trimethylsiloxy-1,2-hexadiene (5a): Bp 88—89°C/0.035 mmHg; IR (neat) 1925, 1250, 850 cm^{-1}; NMR (CCl_4) δ=0.13 (s, 9H), 0.94 (t, J=7 Hz, 3H), 1.71—1.81 (m, 2H), 2.17 (dt, J=7 and 2 Hz, 2H), 6.38 (t, J=2 Hz, 1H), 7.16 (s, 5H).

1,5-Diphenyl-3-trimethylsiloxy-1,2-pentadiene (5c): IR (neat) 1930, 1250, 850 cm^{-1}; NMR (CCl_4) δ=0.14 (s, 9H), 2.40—3.00 (m, 4H), 6.37 (t, J=2 Hz, 1H), 6.90—7.37 (m, 10H).

(E)-*1-Phenyl-1-hexen-3-one (8a-(E))*: 24%; IR (neat) 1675, 1650, 1600 cm^{-1}; NMR (CCl_4) δ=0.95 (t, J=7 Hz, 3H), 1.68 (tq, J=7 and 7 Hz, 2H), 2.55 (t, J=7 Hz, 2H), 6.58 (d, J=16 Hz, 1H), 7.41 (d, J=16 Hz, 1H), 7.15—7.55 (m, 5H).

(Z)-*1-Phenyl-1-hexen-3-one (8a-(Z))*: 72%; IR (neat) 1675, 1590 cm^{-1}; NMR (CCl_4) δ=0.85 (t, J=7 Hz, 3H), 1.56 (tq, J=7 and 7 Hz, 2H), 2.31 (t, J=7 Hz, 2H), 6.01 (d, J=12 Hz, 1H), 6.65 (d, J=12 Hz, 1H), 7.08—7.65 (m, 5H).

(E)-*1-Phenyl-4-nonen-3-one (8b-(E))*: 75%; IR (neat) 1685, 1665, 1620 cm^{-1}; NMR (CCl_4) δ=0.71—1.62 (m, 7H), 1.88—2.38 (m, 2H), 2.63—2.95 (m, 4H), 5.95 (dq, J=16 and 1 Hz, 1H), 6.68 (dt, J=16 and 6 Hz, 1H), 7.09 (s, 5H).

(Z)-*1-Phenyl-4-nonen-3-one (8b-(Z))*: 22%; IR (neat) 1682, 1610 cm^{-1}; NMR (CCl_4) δ=0.68—1.61 (m, 7H), 2.42—3.05 (m, 6H), 5.83—6.12 (m, 2H), 7.10 (s, 5H).

(E)-*1,5-Diphenyl-1-penten-3-one (8c-(E))*: 43%; IR (neat) 1680, 1650, 1600 cm^{-1}; NMR (CCl_4) δ=2.89 (s, 4H), 6.56 (d, J=16 Hz, 1H), 7.41 (d, J=16 Hz, 1H), 6.97—7.50 (m, 10H).

(Z)-*1,5-Diphenyl-1-penten-3-one (8c-(Z))*: 46%; IR (neat) 1678, 1595; NMR (CCl_4) δ=2.40—2.97 (m, 4H), 5.97 (d, J=12 Hz, 1H), 6.63 (d, J=12 Hz, 1H), 6.87—7.60 (m, 10H).

(E)-*5-Phenyl-1-trimethylsilyl-1-penten-3-one (8d-(E))*: 52%; IR (neat) 1670, 1249, 842 cm^{-1}; NMR (CCl_4) δ=0.10 (s, 9H), 2.79 (s, 4H), 6.29 (d, J=19 Hz, 1H), 6.91 (d, J=19 Hz, 1H), 7.05 (s, 5H).

(Z)-*5-Phenyl-1-trimethylsilyl-1-penten-3-one (8d-(Z))*: 11%; IR (neat) 1680, 1240, 845 cm^{-1}; NMR (CCl_4) δ=0.11 (s, 9H), 2.67—2.93 (m, 4H), 6.17 (d, J=14 Hz, 1H), 6.70 (d, J=14 Hz, 1H), 7.02 (s, 5H).

(E)-*6-Methoxy-1-phenyl-4-hexen-3-one (8e-(E))*: 53%; IR (neat) 1680, 1660, 1625 cm^{-1}; NMR (CCl_4) δ=2.79 (s, 4H), 3.27 (s, 3H), 3.93 (dd, J=4 and 1.8 Hz, 1H), 6.16 (dt, J=16 and 1.8 Hz, 1H), 6.67 (dt, J=16 and 4 Hz, 1H). 7.11 (s, 5H).

(Z)-*6-Methoxy-1-phenyl-4-hexen-3-one (8e-(Z))*: 27%; IR (neat) 1680, 1610 cm^{-1}; NMR (CCl_4) δ=2.63—2.90 (m, 4H), 3.28 (s, 3H), 4.35 (d, J=2 Hz, 2H), 6.00—6.18 (m, 2H), 7.10 (s, 5H).

The Reaction of 1-Phenyl-3-trimethylsiloxy-1,2-hexadiene with Benzaldehyde Dimethyl Acetal. 1-Phenyl-3-trimethylsiloxy-1,2-hexadiene was prepared from 1-phenyl-3-trimethylsilyl-1-hexyn-3-ol (246 mg, 1.0 mmol) by procedures described above. The crude diene was dissolved in dichloromethane (4 mL) and was added to a mixture of benzaldehyde dimethyl acetal (152 mg, 1.0 mmol) and titanium tetrachloride (0.11 mL, 1.0 mmol) in dichloromethane (8 mL) at −78°C. After stirring for 1 h at that temperature, the reaction mixture was poured into 0.4 M aq $NaHCO_3$ (20 mL) and was filtered through Celite. The aqueous layer was extracted twice with 20 mL portions of dichloromethane, and the combined extracts were dried over anhyd $MgSO_4$. Removal of the solvent from the filtrate followed by separation with TLC afforded 2-(α-methoxybenzyl)-1-phenyl-1-hexen-3-one (237 mg, 81% based on 1-phenyl-3-trimethylsilyl-1-hexyn-3-ol). Bp 118—119°C/0.024 mmHg; IR (neat) 1680 cm^{-1}; NMR (CCl_4) δ=0.61 (t, J=8 Hz, 3H), 0.91—2.35 (m, 4H), 5.00 (s, 1H), 6.43 and 6.45 (s, 1H), 7.07 (s, 5H), 7.21 (s, 5H); Calcd for $C_{20}H_{22}O_2$: C, 81.60; H, 7.53%. Found: C, 81.84; H, 7.58%.

(Received July 1, 1983)

The interactions between 4 anionic surfactants and 3 azo oil dyes have been studied by a spectrophotometer. The spectrographic behavior of these solutions was dependent on the kinds of hydrophilic groups in each surfactant and the kind of auxochrome in the azo oil dyes. In particular, a sulfate and two sulfonates including strongly hydrophilic groups interacted strongly with the oil dyes (4-NH_2) which have an amino group at 4-position of naphthalene. At lower concentrations, an isosbestic point was recognized; this occurred because of the formation of the hydrophobic dye-surfactant complex (1:1). In the neighborhood of the cmc region, the spectrum with a peak at 520 nm changed with temperature into another one with a 440 nm band; this is the so-called thermochromism. This may be attributed to the fact that, in the presence of surfactant micelles, the 4-NH_2 exhibits an azo form at higher temperature, but a resonance stabilized azonium form is found at lower temperature.

A number of investigations have been made on the interactions between surfactants and dyes in order to clarify the formation of dye–surfactant complexes.[1-3] In recent years, Nemoto[4] and Kuroiwa[5] have published reviews on interactions between surfactants and dyes. For example, Kuroiwa[6] studied a complex of dispersing dye and anionic surfactant; Nemoto[7] studied that of acid–nonionic surfactant. But few studies have been made on the interactions between oil dyes and surfactants.

The changes of complementary color of the dye solutions include solvatochromism,[8] halochromism,[9] and thermochromism.[10] However, these have not been measured in the presence of surfactant micelles.

We have reported the solubilization of some oil dyes by sodium dodecyl sulfate.[11] We found that the surfactant anion interacted strongly with the oil dye including amino group at 4-position of naphthalene; moreover, the spectrum with a peak at 520 nm changed with temperature into another one with a 440 nm band.

In this paper, we report the interaction between 4 anionic surfactants, which have different hydrophilic groups, and 3 azo oil dyes, which have different functional groups in aqueous solutions by the spectrographic method. We discuss the effect of surfactant micelle structure on the protonation equilibrium of azo oil dyes.

Experimental

Materials. *Anionic Surfactants*: Sodium dodecyl sulfate (SDS) was supplied by Nihon Surfactant Industries, Co., Ltd, Tokyo, Japan; sodium 1-dodecanesulfonate (DSS), sodium dodecylbenzenesulfonate (SDBS), and sodium laurate (SL) were purchased from Tokyo Kasei Kogyo Co., Ltd, Tokyo. They are more than 99.5% pure. All surfactants were extracted with ether and crystallized from ethanol; their purities were ascertained by surface tension measurements and differential thermal analysis. Oil dyes: The details of 4-phenylazo-1-naphthylamine (4-NH_2), 4-phenylazo-1-naphthol (4-OH), and Naphthalene-1-azobenzene (NA) were described in our previous paper.[11]

Methods. *Preparation of Surfactant Solution Including Oil Dye*: Into several 100 ml glass-stoppered Erlenmeyer flasks, 50 ml portions of a given concentration of a surfactant solution were placed; a measured amount of oil dye was added to each. The mixtures were stirred with ultrasonic waves for 5 min, then they were stirred by a shaker (model SS-82 D type of Tokyo Rikakikai Co., Ltd, Tokyo) for 24 h and allowed to stand for 24 h in a thermostat at 30 °C in order to establish a solubilization equilibrium.

Determinaton of Maximal Absorption (λ_{max}) and Optical Density of the Solution Owing to Temperature Change. After equilibrium had been established, these mixtures were centrifuged. Then the supernatant liquids of these solutions were collected. The temperature dependence of each maximal absorption and the optical density of each solution were measured by a double beam spectrophotometer (model UVIDEC 505 of Nihon Bunko Ltd, Tokyo) with a quartz cell (1.0, 10.0, or 20.0 mm in length).

Determinaton of cmc of Surfactant by Dye-solubilization Method. The cmc of surfactants determined by the dye-solubilization method were the same as reported previously.[11]

Determination of cmc of Surfactant Alone. The cmc of surfactants alone were determined by the surface tension method.[12] The surface tensions of the surfactant alone were measured at 30 °C with a Wilhelmy tensiometer (model CBVP-A3 of Kyowa Kagaku Co., Ltd, Tokyo) equipped with a platinum plate.

Determinaton of Binding Molar Ratio of Dye-surfactant Complex. The binding molar ratio of dye-surfactant complex was investigated with the continuous variation in optical density method by Kuroiwa and Ogasawara[13] at 30 and 70 °C.

Results

The cmc Given by Dye-solubilization Method and by Surface Tension Method. The cmc given by dye (4-NH_2) solubilization method (I), and that of the surfactant alone given by surface tension method (II) are shown in Table 1. The spectrographic measurements have been made at the following concentrations: A region (below I), B region (between I and II), and C region (above II).

Thermochromism. Oil dyes used in this study were almost insoluble in water at room temperature, but they dissolved slightly in hot water: the complementary color of the solution was yellowish. The complementary color of 4-NH_2 in SDS, DSS, and

Table 1. Cmc by dye solubilization method (I) and surface tension method (II)

Surfactant	cmc/mol dm^{-3}	
	I	II
SDS	2.1×10^{-3}	8.0×10^{-3}
DSS	2.5×10^{-3}	9.8×10^{-3}
SDBS	1.4×10^{-2}	2.0×10^{-2}
SL	1.8×10^{-2}	3.0×10^{-2}

SDBS micellar solutions changed (reddish→yellowish) with increasing temperature; thus the so-called thermochromism occurred. However, the complementary color of 4-NH_2 in SL micellar solution (yellowish) did not change with increasing temperature. Moreover, in the case of NA, and 4-OH, no thermochromism occurred in any surfactant micellar solution.

The Shift of Maximal Absorption with Increase of Temperature. (1) For SDS-4-NH_2 Systems: (a) Concentration of SDS; (i) A Region. Optical densities for the SDS solutions of 3.2×10^{-4} mol dm^{-3} including 4-NH_2 of 1.6×10^{-4} mol dm^{-3} in the temperature range 30°C to 70°C are plotted against the measuring wavelength in Fig. 1. As can be seen from Fig. 1, the maximal absorption was about 440 nm; this was not dependent on temperature. But the optical density at maximal absorption increased with increasing temperature: the so-called transition of chemical species. An isosbestic point was recognized at higher wavelength (about 520 nm) than that at the maximal absorption (440 nm).

(ii) B Region. Optical densities for the SDS solutions of 5.0×10^{-3} mol dm^{-3} including 4-NH_2 of 1.6×10^{-4} mol dm^{-3} in the temperature range 30°C to 72°C are plotted against the measuring wavelength in Fig. 2. The maximal absorption shifted from longer wavelengths (520 nm) to shorter wavelengths (440 nm) with increase in temperature: the so-called hypsochromic shift.

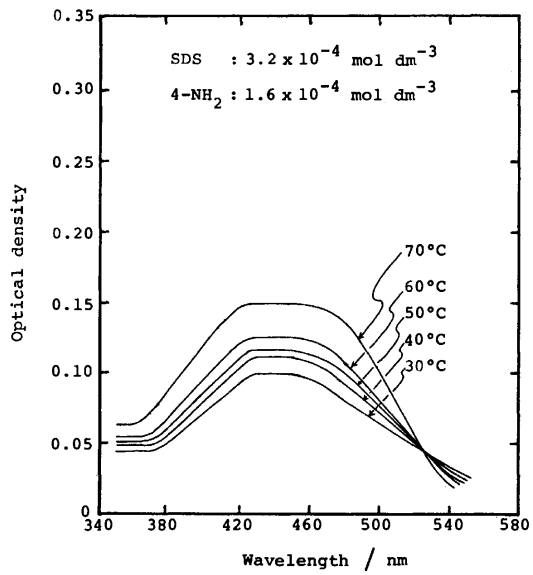

Fig. 1. Effect of temperature on absorption spectra for SDS solution which have dissolved 4-NH_2. (below I: A region)

(iii) C Region. Optical densities for the SDS solutions of 1.6×10^{-2} mol dm^{-3} including 4-NH_2 of 1.6×10^{-4} mol dm^{-3} in the temperature range 30°C to 70°C are plotted against the measuring wavelength in Fig. 3. The maximal absorption was not dependent on temperature; its wavelength was about 520 nm, which was about 80 nm higher than that below the cmc. The optical density at maximal absorption increased with increase in temperature. The maximal absorption caused by the increase of temperature changed considerably in the SDS concentration range 2.2×10^{-3} mol dm^{-3} to 1.0×10^{-2} mol dm^{-3}. The shifting temperature, at which the maximal absorption moved from 520 nm to 440 nm, increased with increasing concentration of SDS at the above-mentioned cmc region (58°C to 70°C).

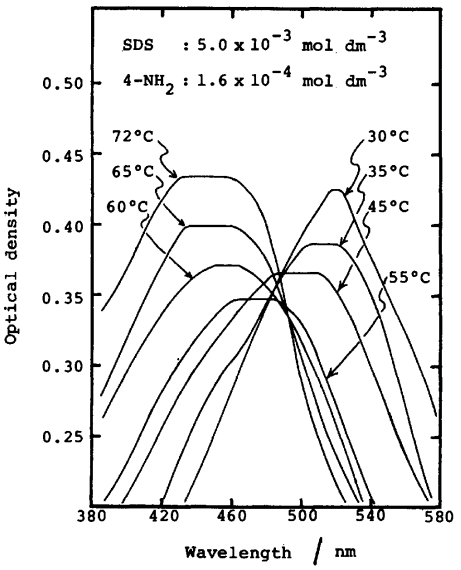

Fig. 2. Effect of temperature on absorption spectra for SDS solution which have dissolved 4-NH_2. (between I and II: B region)

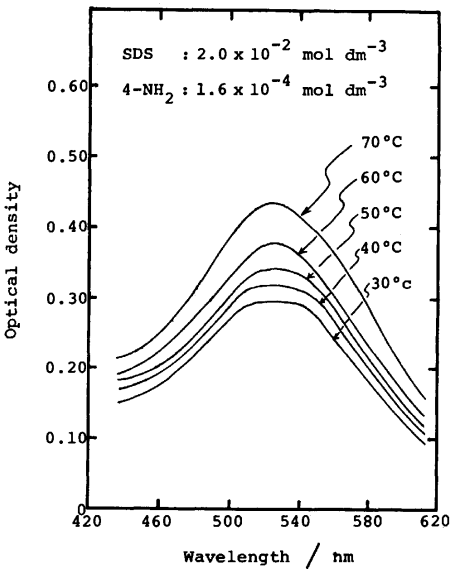

Fig. 3. Effect of temperature on absorption spectra for SDS solution which have dissolved 4-NH_2. (above II: C region)

(b) Concentration of 4-NH_2: As the amounts of 4-NH_2 in each concentration of SDS were considerably higher than the limits of solubilization, thermochromism was not observed. The optimum amount of 4-NH_2 for the observation of thermochromism was just lower than the limit of solubilization.

(2) For SDBS-4-NH_2 Systems: The maximal absorptions of the solutions below the cmc and above the cmc were the same as those of SDS. The change of maximal absorption (520 nm to 440 nm) with increase in temperature was also recognized in the SDBS solutions of 3.0×10^{-2} mol dm^{-3}. Thermochromism also occurred in the SDBS concentration of the cmc range (I, II in Table 1), and for the dye amount just lower than the limit of solubilization as in the case in SDS solutions.

(3) For DSS-4-NH_2 Systems: The maximal absorption of the solutions below the cmc and above the cmc were the same as those of SDS. The change of maximal absorption (520 nm→440 nm) with increase in temperature was also recognized in the DSS solutions of 1.0×10^{-2}mol dm^{-3}. Optical densities for the DSS solutions of 1.0×10^{-2} mol dm^{-3} (at C region) including 4-NH_2 of 1.6×10^{-4} mol dm^{-3} in the temperature range 20°C to 75°C are plotted against the measuring wavelength in Fig.4. In the case of SDS and SDBS, the optical density at about 520 nm decreased with increase in temperature, but in the case of DSS, it increased with increasing temperature until 35°C, and then it decreased for higher temperatures. 4-NH_2 in the DSS solutions was found to undergo both hyperchromic effect and transition of chemical species. Thermochromism also occurred in the SDS concentration of the cmc range (I, II in Table 1) and for the dye amount just lower than the limit of solubilization, as in the case in SDS solutions.

(4) For SL-4-NH_2 Systems: Optical densities for the SL solutions of 5.0×10^{-2} mol dm^{-3} (at B region), including 4-NH_2 of 1.6×10^{-4} mol dm^{-3} in temperature range 30°C to 70°C are plotted against the measuring

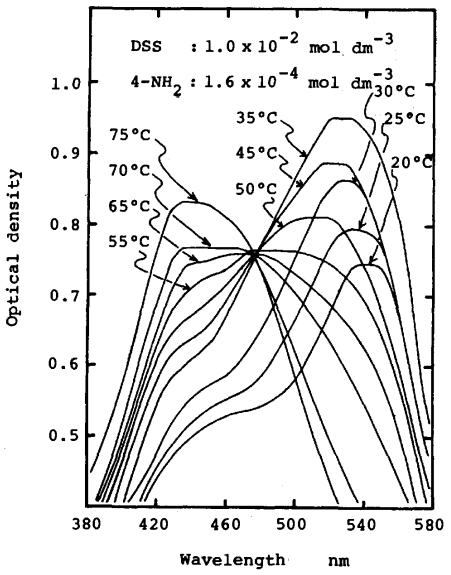

Fig. 4. Effect of temperature on absorption spectra for DSS solution which have dissolved 4-NH_2. (between I and II: B region)

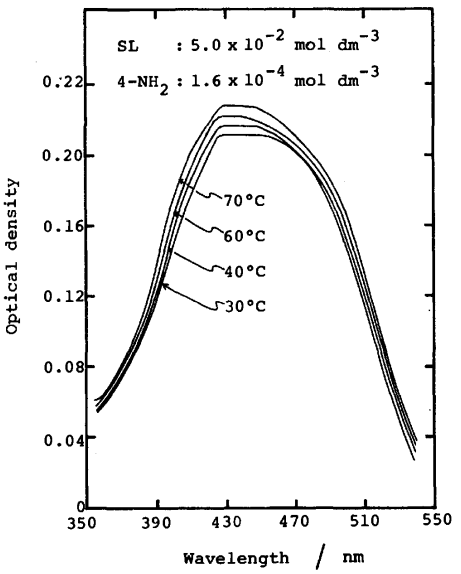

Fig. 5. Effect of temperature on absorption spectra for LS solution which have dissolved 4-NH_2. (regardless of the concentration of LS)

wavelength in Fig. 5. Figure 5 shows that the maximal absorption of SL solutions was independent of temperature. Thus, we found that the concentration of SL is not significant.

(5) For 4-OH and NA: All of the maximal absorptions of the solutions were unchanged with increase in temperature; the values were 480 nm (4-OH) and 380 nm (NA) for all kinds and concentrations of surfactants.

Discussion

The Isosbestic Point at A Region. In the case of 4-NH_2 and anionic surfactants except SL of lower concentration, the isosbestic point was recognized at a 520 nm band, as shown in Fig. 1. Kuroiwa[14] describes how the isosbestic point like this is recognized in SDS (and/or SDBS)-1,4,5,8-tetraaminoanthraquinone system because of the formation of a dye-surfactant complex.

Nemoto *et al.*[15,16] report that the distinction between hydrophilic and hydrophobic complexes can be made by measuring the surface tension of the solution and by extracting the solution from chloroform. In the same manner, we previously confirmed the hydrophobic complex.[11] Except for SL, the formation of hydrophobic complex in the cases of SDBS and DSS was thus established. We adopted the continuous variation method[13] in order to determine the binding molar ratio of these complexes. The results are shown in Table 2. Except for SL, surfactants including strongly polar groups and 4-NH_2 seem to form a hydrophobic complex of 1:1.

TABLE 2. MOLAR RATIO OF COMPOUND FORMED FROM DYE (4-NH_2) AND VARIOUS SURFACTANTS BY CONTINUOUS VARIATION METHOD (λ_{max}=440 nm)

Surfactant	Ratio (S:D)
SDS	1 : 1
DSS	1 : 1
SDBS	1 : 1
SL	—

The Thermochromism at B Region. As can be seen from Figs. 1 and 3, the maximal absorption of 4-NH_2 at A region is at the 440 nm band, while that at C region is at the 520 nm band regardless of temperature: it seems that the maximal absorption at 440 nm band arises from the dispersing state of 4-NH_2 in monomer phase, while that at 520 nm band arises from that solubilized into micellar phase. The maximal absorption at B region, in other words, that at the neighborhood of the cmc, is dependent on temperature. The results can be interpreted as follows. The cmc of anionic surfactants are shifted from lower concentration to higher concentration with increasing temperature.[17] Moreover, it is well known that the amount of solubilization is dependent on the concentration of anionic surfactant.[18,19] Thus, with increasing temperature, the values of the cmc shifted from lower concentration to higher concentration and the number of surfactant micelles decreased; as a result, the 4-NH_2 solubilized in surfactant micelle is released into a monomer phase. Therefore, the complementary color of the solution at B region changed with temperature; the so-called thermochromism occurred.

In the C region, there are many micelles in the solution, so that the increase of the value of cmc is slight and the 4-NH_2 solubilized in micelle does not release into the monomer phase with increasing temperature. Therefore, thermochromism does not occur. In general, a dye including amino group in organic solvent takes the azo form.[20] The spectrum in dodecane provides an absorption band at 440 nm, which is attributed to the azo form. Accordingly, the tautomer of 4-NH_2 at both A region and B region under higher temperature seems to be azo form.

Secondly, we consider the structure of 4-NH_2 in surfactant micellar solutions other than SL. For the location of 4-NH_2 in surfactant micelle, we[21] found that, because the functional group of the dye is fairly strong and dissociates slightly, it thrusts the functional group out of the SDS micelles and its hydrophobic parts penetrate into the palisade layers of SDS micelles. Moreover, because the pH of the SDS solution to which 4-NH_2 was added is larger than that of SDS alone (6.8—7.9), 4-NH_2 is thought to act as a base.

Klotz *et al.*[22] describe the protonation process as follows: the first proton goes to the amino group and then a second proton goes to the azo group with an increase in the hydrogen ion concentration. On the contrary, Tanizaki *et al.*[9] point out that a proton addition to amino group must shift the color band to a shorter wavelength, because the electronic theory insists that the protonated amino group cannot be conjugated with the ring system because of the number of the π-type electrons is too few: the protonation to the β-azo-nitrogen atom of the dye shifts the color band to a longer wavelength than that of azo form. The halochromism of 4-NH_2 is shown in Fig. 6. As can be seen from Fig. 6, the spectrum with a peak at a 440 nm band in an alkaline solution changed into another one (520 nm) with an increase in the hydrogen ion concentration. According to Tanizaki *et al.*,[9] the spectrum with a peak at 520 nm seems to be the protonation to β-azo-nitrogen atom of the dye (in

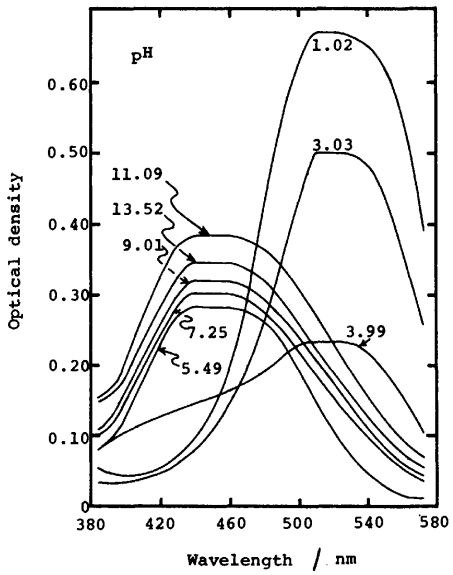

Fig. 6. Effect of pH on absorption spectra for 4-NH_2 aqueous solutions.

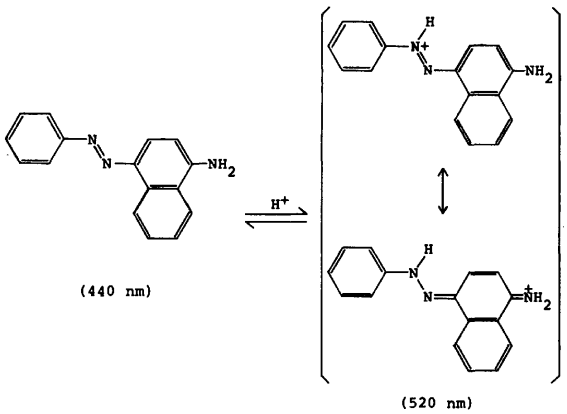

Fig. 7. Relationship between protonation process of dye and λ_{max}.

Fig. 7). However, this study was not made in a higher acid solution but in a neutral solution. From the study of synthesis of oil dye reported previously,[21] we found that the replacement reaction occurred not at the position of azo group, but at the position of amino group. Furthermore, Matsuoka *et al.*[23] suggest that, when the proton goes to β-azo-nitrogen atom, electric charge transfer occurs; as a result a nitrogen atom of amino group becomes positively charged. The 4-NH_2, described previously, was solubilized into SDS micelle as the functional group (amino group) out of the micelle,[21] and then it becomes a counterion for the surface negative charge of the micelle. And so this micelle was stable at room temperature. Therefore, the quinoidal form of 4-NH_2 was stabilized in the SDS micelle at room temperature.

For SL Solutions. As can be seen from Fig. 5, regardless of the concentration of SL and temperature, the maximal absorption was still a peak at 440 nm. SL is mild alkaline, so that the pH value of solution is shifted to basic 8.5, to prevent protonation. In general, an aliphatic soap like SL is partly hydrolyzed in water.[24] It seems that, because the aliphatic acid

produced is preferentially solubilized into SL micelles, the 4-NH_2 is adsorbed on the surface (hydrophilic parts) of the solubilized micelles, as mentioned by Kondo and Meguro.[25] Therefore, 4-NH_2 is always placed in the bulk phase, and the maximal absorption is 440 nm. However, an aliphatic soap like SL does not form a spherical micelle like SDS, but a hexagonal packing of cylindrical micelles,[26] where the insoluble hydrocarbon chains are turned inward, in a neutral particle of soap, and the heavily hydrated carboxylate group is presented to the surrounding water.[27] It seems that the 4-NH_2 exists in the surrounding water, even when the concentration of SL is somewhat above the cmc.

In any event, because the polar nature of SL is weaker than that of SDS, the proton in water is not in contact with the dye; so the protonation to the 4-NH_2 did not occur.

A Consideration on the Structure of the Nascent Fibril Produced by *Acetobacter xylinum*

Akira KAI

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received July 11, 1983)

The structure of the nascent fibril produced by *Acetobacter xylinum* was examined by electron microscopy and resistance to alkali. It was found that the inner part of the fibril after production is stained uniformly with sodium tungstophosphate. This suggests that the nascent fibril is in an amorphous state. Moreover, the fact that in the amorphous fibril microscopic fibrils with closely similar widths always appear in the course of time and that the X-ray diffraction diagram of the never-air-dried fibril treated with 11 wt% aqueous NaOH solution show cellulose I not cellulose II diffraction patterns, indicate that the arrangement of cellulose chains in its cross section can transform easily to that of chains in ellulose I crystalline. For such an arrangement, it must be presumed that in the nascent fibril cellulose chains are in the form of sheets of monomolecular layers corresponding to the $(1\bar{1}0)$ plane of cellulose I crystalline.

The structure of the fibril after production by *Acetobacter xylinum (A. xylinum)* is still unknown. Brown *et al.* suggested initially that a fibril (a microfibril) crystallized simultaneously when it is extruded from a synthesizing site in the envelope of a bacterial cell.[1] But lately, they suggested that a nascent microfibril is composed of bundles of chains in the tactoidal state since the inner part of the fibril from an incubated medium with fluorescent brightener was dyed by the brightener.[2,3] Zaar reported that fibril formation from *A. xylinum* is similar to that described by Brown *et al.* He presumed that the crystallization of a fibril (a microfibril) occurred after extrusion from the synthesizing site.[4,5] Colvin *et al.*, from observation of the freeze-etching of incubated suspension of *A. xylinum* reported that a nascent fibril has a dense core surrounded by a sheath of amorphous gel.[6–8] We suggested, from the negative staining behavior of the nascent fibrils, that they are in a homogeneous amorphous state.[9]

It was found that in the course of time microscopic fibrils with almost the same width of 40—50 Å develop in the amorphous fibril.[10,11] Since the same transformation of the amorphous fibril always occurred, we have presumed that it is composed not of random chains but of chains which retain a specific correlation with each other.

In this paper the structure of the fibril produced by *A. xylinum* was examined with respect to its staining behavior toward sodium tungstophosphate and its resistance to alkali.

Experimental

Culture of Cells and Preparations of the Samples for Electron Microscopy. The methods described previously were followed.[10] Two series of samples were prepared for electron microscopy; one of the series is the fibrils from the glucose medium with sodium tungstophosphate and the other is the fibrils, stained by an aqueous solution of sodium tungstophosphate before drying, from the glucose medium without the staining agent.

Ten ml of *A. xylinum*-preserved culture medium (IFO 13693) was added to 100 ml of complex medium (distilled water: 100 ml, D-glucose: 1 g, peptone: 1 g, yeast extract: 0.3 g, sodium chloride: 0.2 g, disodium hydrogenphosphate (anhydrous): 0.14 g, citric acid: 0.035 g, pH adjusted to 6.8 with 1 M† HCl or NaOH aq) and incubated at 28 °C for 72 h. After being thus cultured, 10 ml of the liquid phase of the starter culture was added to 100 ml of the fresh complex medium, and was incubated at 28 °C for 48 h. Separating the cellulose produced in the incubated medium requried filtration through a membrane filter of 5 μm pore size while cooling the filtrate with ice water. The filtrate was immediately filtered through a membrane filter of 0.45 μm pore size, allowing the cells to collect on the membrane filter. Cells were washed with a buffer solution (pH 6.8, disodium hydrogenphosphate: 0.14 wt%, citric acid: 0.035 wt%, 0 °C) to remove the medium components. They were then suspended in 60 ml of the fresh buffer solution. A 4 ml quantity of 0.2 wt% glucose medium (pH 6.8) with 2 wt% sodium tungstophosphate was added to 36 ml of cellulose-free cell suspension. The final concentrations of glucose and sodium tungstohosphate in the medium were 0.02 and 0.2 wt% respectively. These values were determined for the concentrations easily observable by electron microscopy without washing the fibrils produced. A drop of the culture medium was immediately placed on a sheet mesh covered with a collodion membrane and incubated in a 100%RH atmosphere at 28 °C for a given time. After the fibrils so produced had been allowed to settle on the sheet mesh by removing the medium, they were dried over P_2O_5 at room temperature for more than 24 h, and observed through an electron microscope. Preparations of the sample for the fibrils from 0.02 wt% glucose medium without staining agent are the same as described above except for staining with addition of a drop of 0.5 wt% aqueous sodium tungstophosphate solution for 15 min before drying. In the above incubation procedure, the complex medium was sterilized by autoclaving while the glucose medium was sterilized by filtration.

For electron microscopy, all preparations were examined with a JEOL JEM-100U electron microscope operating at 80 kV.

Measurement of the Linear Growth Rate of a Cellulose Fibril.

The linear growth rate of a cellulose fibril at a given temperature was obtained from the relation between the time of incubation and the mean length of ten fibrils after glucose incubation for a given time at a given temperature. The linear growth rate was constant within the range of the measurable length of a fibril.

Resistance of the Never-air-dried Fibrils to Alkali. Samples: 40 ml of 3 wt% glucose medium (pH 6.8) was added to 200 ml

† 1 M=1 mol dm^{-3}.

of cellulose-free cell suspension and incubated at 28 °C for a given time. Cellulose gels in the incubated mediums were the samples for alkali-treatment.

Alkali-treatment of the Never-air-dried Cellulose Gels: To the incubated medium an equal volume of aqueous NaOH was added dropwise at twice the given concentration. It was kept at 20 °C for 1 h and then 30 vol% aqueous acetic acid solution was added to neutralize. The solution was dialyzed through Cellulose Dialyzer Tubing (Nakarai Chemicals Ltd make, through M.W. cut-off: 8000, diameter: 90 mm, thickness: 0.09 mm) until sodium acetic acid free, and then boiled to collect cellulose. The cellulose collected, before drying, was again boiled in 1 wt% aqueous NaOH solution for 10 h under a nitrogen atmosphere, then neutralized and washed. The wet cellulose was compressed to a disk with the diameter of 1.5 mm and a thickness of about 1 mm for X-ray diffraction photography.

The X-ray diffraction diagram of the cellulose was taken with a flat-film camera with Ni filtered Cu $K\alpha$ radiation (35 kV, 15 mA, time of exposure: about 35 min) at specimen film distance of 50 mm. A Rigaku Denki make, Rota-Unit RU-3v X-ray camera was used.

Results and Discussion

The structure of the cellulose fibril after production by *A. xylinum* may be mainly determined by the mechanism of biogenesis of the fibril. However, it is supposed that if the structure of a fibril after extrusion from a cell is in an amorphous state, it may also be affected by the physicochemical environment, that is, temperature, the elapsed time of an amorphous fibril, the pH of medium and medium components *etc.* Therefore, first, the relation between the linear growth rate of a fibril produced by *A. xylinum* empolyed in this study and the temperature of incubation was examined.

The linear growth rate of a microfibril was maximum at about 28 °C as is evident from Fig. 1. As shown in Fig. 2a, the fibril, with its inner part stained uniformly, was obtained from a medium incubated with sodium tungstophosphate for 30 min at the most suitable temperature, 28 °C for the biogenesis of fibril. Moreover, it was found that the inner part of the fibril obtained from the incubated medium without staining agent at 28 °C for 5 min was uniformly stainable,

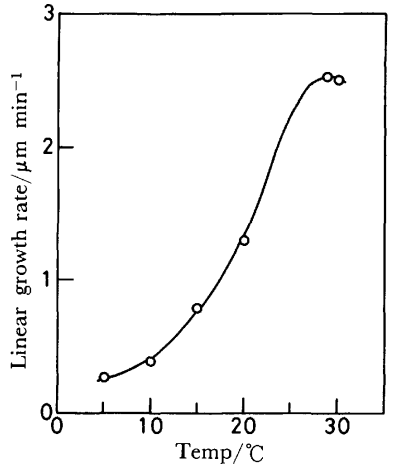

Fig. 1. Influence of temperature on the growth rate of the microfibril in glucose incubation.
Concentration of glucose: 1 wt%, pH of culture medium: 6.8.

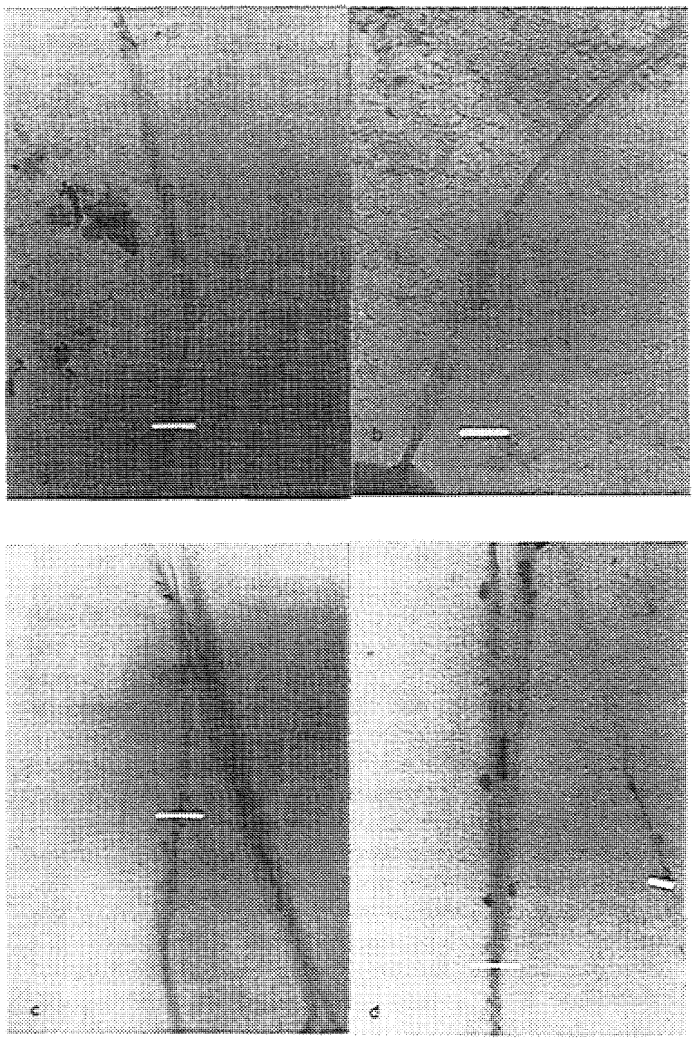

Fig. 2. Electron micrographs of the fibril obtained from 0.02 wt% glucose incubation included 0.2 wt% sodium tungstophosphate (pH 6.8) (a, c, and d) and the fibril obtained from 0.02 wt% glucose incubation (pH 6.8) (b) for a given time at 28 °C. The fibril obtained from the medium without staining agent before drying, was stained with 0.25 wt% aqueous sodium tungstophosphate solution for 15 min at room temperature. Time of incubation; a: 30 min, b: 5 min, c: 1 h, d: 5 h.
Scale bars=0.1 μm.

similar to the fibril obtained from the incubated medium with staining agent (Fig. 2b). The higher electron opacity of the twisted, thickened portions of these fibrils seemed to be the cause of the uniform staining of their inner part. In these fibrils the dense core, as reported by Colvin *et al.*, could not be found. According to the staining behavior of a nascent fibril toward sodium tungstophosphate, the fibril after production seemed to retain an amorphous state for about 30 min. Subsequently unevenness occurred perpendicular to the long axis of the fibril (some striations occurred parallel to the fibril axis) (Fig. 2c). Later microscopic fibrils with similar widths of 40—50 Å appeared simultaneously within the amorphous fibril about 5 h after production (Fig. 2d). Since the same transformation of the amorphous fibril as shown

in Fig. 2 always occurred, we suggested that a nascent fibril is composed not of random chains but of chains keeping specific correlation with each other.

The microscopic fibrils found in this study correspond to the elementary fibril formerly regarded as the fundamental structure of bacterial cellulose.[12-14] Recently, Brown *et al.*[1,2] and Zaar[4,5] pointed out that the synthesizing sites exist in the envelope of the cell and microfibrils (which correspond to the microscopic fibrils named in our paper) with the width of 30 Å are extruded from the synthesizing sites. Their illustrations allow us to understand the reproducibility of the microscopic fibrils in the amorphous fibril. Furthermore, the so-called "microfibril" of the earlier workers are assemblies of microscopic fibrils as shown in Fig. 2d. However, it is not always clear whether the crystallization of microscopic fibrils occurs before assembly or after.

It is considered that the staining agent, sodium tungstophophate does not have affinity towards polysaccharides. If this is true, it is to be assumed that sodium tungstophosphate does not change the structure of the nascent fibril, but is absorbed in it when it is extruded from the cell and is rejected from the stained fibril in the course of crystallization. Indeed, the reproducibility of the width of a microscopic fibril seems to support this process. On the other hand, according to Brown *et al.*[2,3] the cellulose material obtained from the incubated medium with a fluorescent brightener having a vital stain[15] is also in a non-crystalline state because the inner parts of fibril are stained. They also reported that this amorphous cellulose stained by brightener became cellulose I crystalline after drying. Although the microscopic fibrils could not be found in the cellulose material; its crystallinity was reduced, and the width of a crystallite changed from 30 to 28 Å. However, it is noteworthy that the influence of both sodium tungstophosphate and the brightener on the width of a crystallite after drying seems to be little different, although the influences of both on the morphology of the product are different because of their different affinity. This fact suggested that the fibril after production is not a mere bundle of chains but is restorable to the original width of the crystallite even if the product has absorbed the staining agent. For such a structure to be restorable, it must be assumed that in the nascent fibril cellulose chains are in the form of sheets of a monomolecular layer corresponding to the $(1\bar{1}0)$ plane of cellulose I. If the fibril after production has such a structure, the results observed both by Brown *et al.* and in this study can be satisfactorily explained.

It was found that the stainable state of the inner part of a fibril obtained from the incubation at 5 °C was retained for about 3 h (At this temperature the linear growth rate of a fibril is equivalent to about 1/10 of its value at 28 °C. See Fig. 1) as shown in Fig. 3. Although the influence of temperature on the crystallization of the amorphous fibril is unknown, it is apparent that the inner part of a fibril after production is in a stainable state even if the linear growth rate is different, and moreover, the microscopic fibrils after assembly are in an amorphous state.

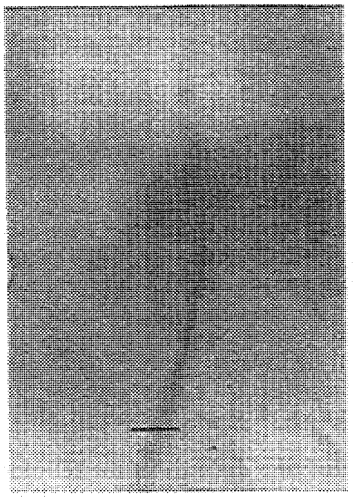

Fig. 3. Electron micrograph of the fibril obtained from 0.02 wt% glucose incubation included 0.2 wt% sodium tungstophosphate (pH 6.8) for 3 h at 5 °C. Scale bar=0.1 μm.

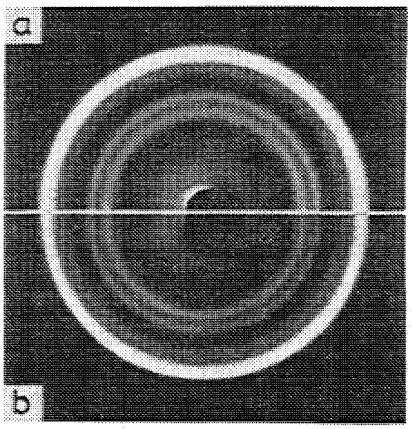

Fig. 4. X-Ray diffraction photograph of the 11 wt% alkali-treated cellulose from the glucose medium incubated for 5 h at 28 °C.
a: Purified and dried cellulose. b: Never-air-dried cellulose was treated in 11 wt% aqueous NaOH solution, then purified and dried.

It is very difficult to determine directly the structure of a fibril after production because the quantities required for usual analytical measurements are not easily obtainable, and even if they can be obtained, the structure of the nascent fibril is very changeable. However, it is supposed that the examination of the resistance of the never-air-dried fibrils to alkali allows us to assume the structure of a fibril after production. From the relation between the yield of cellulose as a function of the incubation time and the progress of the transformation of an amorphous fibril, it is assumed that the never-air-dried cellulose material from the incubated glucose medium at 28 °C for 5 h is composed of 11 wt% of the fibril having the stainable inner part, 60 wt% of the fibrils with staining-unevenness, and 29 wt% of microscopic fibrils.[16] The X-ray diffraction diagram of the never-air-dried cellulose treated with 11 wt% aqueous NaOH solution showed apparently cellulose I as shown in Fig. 4. The diffraction patterns of cellulose II could not be found in the diagram. This result

suggest that not only the microscopic fibrils but also the fibrils with staining unevenness already have the lattice of cellulose I crystalline or a structure able be transform easily to cellulose I crystalline. In spite of the never-air-dried cellulose material containing the amorphous fibrils, the non-occurrence of the diffraction pattern of cellulose II may be due to reject amorphous material by alkali-treatment. But, the weights of the sample treated with 11 wt% alkali and the untreated sample were almost the same. This result shows that the non-occurrence of the diffraction pattern of cellulose II is not because of rejecting the low order region. Accordingly, it is reasonable that the non-occurrence of cellulose II is due to the structure of an amorphous fibril. If an amorphous fibril is composed of some sheets of monomolecular layers corresponding to the $(1\bar{1}0)$ plane of cellulose I as described above, it is supposed that the nascent fibrils may have resistance to 11 wt% alkali, and furthermore, the dehydration of the water contained among the cellulose sheets or the shrinkage of some part of the fibril with alkali-treatment allow the cellulose sheets to bind easily. The structure of the nascent fibril proposed in this paper may also be supported by papers reporting that the swelling of cellulose I with alkali-treatment takes place along the $(1\bar{1}0)$ plane in the first place.[17,18]

Structural Characterization of Soluble Products from a Series of Reductively Butylated Coals Prepared in Refluxing Tetrahydrofuran

Mikio MIYAKE,* Masayuki SUKIGARA, Masakatsu NOMURA, and Shōichi KIKKAWA†
Department of Applied Chemistry, Faculty of Engineering, Osaka University, 2-1, Yamada-oka, Suita, Osaka 565
(Received July 15, 1983)

A series of butylated Yūbari coals were prepared by an improved reductive alkylation method, and detailed structural parameters of respective solution products in pentane (PS) and benzene (BS) were estimated; this experimental procedure is likely to offer more insight into chemical structures of products and important factors effective for solubilization than any analyses on a single product. The PS and BS have average molecular weights of 700—800 and 1500—2050 and are composed of about two and more than five structural units, respectively. These values suggest that the BS molecule is quite large compared with the corresponding products obtained by other methods such as hydrocracking. On the other hand, the ring sizes of one structural unit of the respective products are roughly the same (about three rings). The BS materials are coal macromolecules with stackings loosened by introduction of alkyl groups, while the PS materials are products through cleavage of bonds connecting the structural units and through addition of so many alkyl groups as to increase the affinity for the solvent. In addition, an absence of intermolecular hydrogen bonds mainly due to OH groups contributes to quite a high solubility of the alkylated coals. Increase in BS yield accompanies an increase in aliphatic carbon ratio and polymerization degree and a decrease in size of aromatic ring systems. These results may be ascribed to the heterogeneity of coal constituents.

For the purpose of structural analysis of coals, many methods to transform coals to soluble derivatives have been reported. Among them, reductive alkylation proposed by Sternberg *et al.*[1] is accepted to be one of the most promising methods.[2—13] Soluble materials in reductively alkylated coals were analyzed by applying various techniques.[3,5,6,8,11—13] Compounds contained in alkylated coals were identified by gas chromatography–mass spectrometry preceded by mild oxidation.[14] Some information about the reaction mechanism has been obtained by conducting reactions using model compounds[5,15] and various alkyl halides.[10,12] However, effects of change of a series of reaction conditions, such as reaction time, on the structure of soluble products have hardly been reported, since Sternberg's procedure requires a reaction time as long as 2—14 d.[1—13]

In our previous papers[16,17] we have proposed an improved method which has solved the problems of Sternberg's procedure, such as long reaction time[1—13] and contamination of an electron transfer agent, naphthalene.[18,19] It has been demonstrated that almost all carbonaceous matters in Yūbari coal (more than 90 wt%) can be solubilized in hot benzene by only 6 h reaction.[16,17] However, no detailed structural characterization has yet been reported.

The present study aims at a structural characterization of a series of soluble materials from butylated Yūbari coals obtained by varying the reaction conditions of the improved method. Analysis of these products is likely to offer more insight into the chemical structure of reductively alkylated coals than analysis of a single product. Furthermore, information will be obtained about key factors leading to highest solubility and the solubilization mechanism.

Experimental

Reaction Procedures. Yūbari coal (86.0% C) was used as a coal sample, whose proximate and ultimate analyses were described elsewhere.[16,17] Dry pulverized coal (10 g) was allowed to react in a flask with stirring with molten potassium metal (4—12 g) (mp 63 °C) in refluxing tetrahydrofuran, THF, (150 cm³) (bp 66 °C) for 2—12 h. After this anion formation reaction, the flask was cooled to −50 °C and 1 mol of butyl iodide was added dropwise. The stirring was continued at room temperature overnight to alkylate the coal anions and to destroy the excess potassium. The solid product was washed with aqueous ethanol solutions repeatedly until no iodide ion had become detected in the filtrate, and dried under vacuum at 90 °C for 12 h. The alkylated coal samples were extracted with pentane or benzene by using Soxhlet thimbles; a dried extract thus obtained will be termed PS or BS (BS contains the PS fraction), respectively. Detailed procedures were previously described.[16,17]

To investigate the effect of OH groups on the solubilization, methylated or hydrogenated coals also was prepared by adding 1 mol of methyl iodide or ethanol, respectively, to a coal anion suspension which had been prepared by 6 h reaction with 8 g of molten potassium. They were each extracted with benzene to give BS and BI (benzene insoluble). The BS material from the methylated coal was further hydrogenated in a similar manner as described just above.

Analysis of Products. Analytical data of the alkylated coals were reported elsewhere.[16,17] The PS and BS materials were subjected to an ultimate analysis, a ^{1}H NMR spectroscopy, and an average-molecular-weight measurement, as previously conducted.[16,17] The hydrogens in NMR spectra are classified as follows: the hydrogen attached to an aromatic carbon, H'_{ar}; the hydrogen attached to an α carbon to an aromatic ring, H'_{α}; the hydrogen contained in a methylene group at other than α positions, H'_{β}; the hydrogen contained in a methyl group, H'_{γ}.

The amount of OH groups was determined by the acetylation method using pyridine.[20] IR spectra of BS were obtained with hexachlorobutadiene solutions on a Hitachi 260-10 infrared spectrophotometer.

†Present adress: Department of Applied Chemistry, Osaka Institute of Technology, 5-16-1, Ohmiya, Asahi-ku, Osaka 535.

Structural parameters were estimated according to the equations by Ouchi *et al.*[21,22] with a slight modification as follows: The contribution of sulfur atoms and inert oxygen atoms was neglected because the original Yūbari coal contained few sulfur atoms (0.3 wt%) and a relatively small amount of inert ether bonds (less than 40% of the total oxygen atoms) for the present reaction. The latter was determined from the amounts of OH groups before and after the reductive hydrogenation. Tsukashima *et al.*[3] also neglected the effect of sulfur and inert oxygen atoms with regard to structural parameters for reductively methylated Yūbari coals. Therefore, in the present study, all oxygen atoms in soluble products are assumed to be present as group $-O-(CH_2)_3CH_3$ at positions peripheral to aromatic rings. The structural parameters concerned are as follows: The carbon aromaticity, $f_a=(C'-H'_\alpha/2-H'_\beta/2-H'_\gamma/3)/C'$; the degree of aromatic ring condensation, $H'_{au}/C'_a=(H'_{ar}+H'_\alpha/2+O'+2N')/(C'-H'_\alpha/2-H'_\beta/2-H'_\gamma/3)$; the degree of substitution of aromatic nuclei, $\sigma=(H'_\alpha/2+O'+2N')/(H'_{ar}+H'_\alpha/2+O'+2N')$; the degree of aliphatic chain substitution of aromatic nuclei, $\sigma_{al}=(H'_\alpha/2)/(H'_{ar}+H'_\alpha/2+O'+2N')$; the number of aromatic carbons per molecule, $C'_{ar}=C'\cdot f_a$; the number of aliphatic carbons per molecule, $C'_{al}=C'-C'_{ar}$; the number of aromatic carbons per structural unit, $C'_{ar(u.s.)}=3/(H'_{au}/C'_a-1/2)$; the number of structural units per molecule, $n=C'_{ar}/C'_{ar(u.s.)}$; the number of aromatic rings per structural unit, $R_{a(u.s.)}=C'_{ar(u.s.)}(1-H'_{au}/C'_a)/2+1$; the number of aromatic rings per molecule, $R_a=n\cdot R_{a(u.s.)}$; the number of total rings per molecule, $R_t=C'-H'/2+1-C'_{ar}/2$; the number of naphthenic rings per molecule, $R_N=R_t-R_a$; the average number of carbon atoms in side chains, $C'_{side}=C'_{al}-3\cdot R_N$, where C', H', *etc.* denote the numbers of carbon atoms, hydrogen atoms, *etc.* in PS and BS molecules, respectively. Division of each of the above values per molecule by n gives the corresponding value per structural unit.

Results and Discussion

Structural Character of PS and BS. Basic data obtained for PS and BS materials are summarized in Table 1, which contains the items: yields of butylated coals and soluble materials, ultimate analyses, hydrogen distributions, and average molecular weights. The yields of the soluble materials, PS and BS, from raw Yūbari coal are trace and 2 wt%, respectively. The treatment of the coal gave PS and BS in 18—39 and 74—93 wt% yields, respectively. The average molecular weights obtained for the PS and BS are 700—800 and 1520—2050, respectively; the molecular weight of the PS is less than half that of the BS. The average molecular weights, corrected for introduced butyl groups, also are given in Table 1.

In Table 2 are given the number of butyl groups introduced per 100 carbon atoms and the values of f_a, H'_{au}/C'_a, σ σ_{al}, and n for PS and BS materials. The number of introduced butyl groups was estimated in a similar manner as reported conventionally for soluble products;[5,9] that is, it was estimated on the assumption that the change in H/C atomic ratio of products relative to raw coal is due exclusively to the introduction of alkyl groups. The numbers obtained are 9.3—17.7 and 6.1—12.1 for the PS and BS, respectively. It should be noted that the estimated values become uncertain when the soluble products themselves are different in H/C value from the original coal. The high values of σ (0.55—0.64) and σ_{al} (0.39—0.45) for both the PS and BS idicate that the aromatic nuclei have many substituents, especially alkyl side-chains. The PS material show lower f_a and slightly higher σ and σ_{al} values than the BS, suggesting themselves to be abundant in aliphatic carbons and alkyl side-chains. The number of structural units, n, in the BS molecule is more than 5.0, whereas that in the PS is less than 2.6.

The numbers of individual rings and carbons per molecule and per structural unit for the PS and BS materials are shown in Tables 3 and 4, respectively. The BS molecules have high values of R_t, R_a, C'_{ar}, and

BS	93	12.1	0.50	0.88	0.58	0.39	7.1

C'_{al}, at least higher than twice those for the PS molecules. On the other hand, the ring sizes per structural unit are roughly the same as seen from $R_{t(u.s.)}$, $R_{a(u.s.)}$, and $C'_{ar(u.s.)}$. The number of each of the rings per BS molecule decreases with an increase in the BS yield. The increase in C'_{side} and C'_{al}/C'_{ar} of both the PS and BS molecules is dependent on the increase in the number of butyl groups introduced. It should be noted that, in high yield regions of PS, the number of carbons in side chains exceeds that in aromatic rings, which has resulted from an introduction of many bulky butyl groups.

Factors Governing the Production of PS and BS. For the conventional reductive alkylation, it has been reported[1,5,15] that coals are solubilized by introduction of alkyl groups to their condensed aromatic nuclei to loosen their stacking and by cleavage of ether and some carbon-carbon linkages connecting ring systems.

Two important reaction factors to produce PS from coal or BS are considered: the first is a depolymerization, that is, cleavage of bonds connecting structural units to produce small molecules (molecular weights, 700—800 as observed; 450—560 on butyl-free basis) with about two structural units; the second is an addition of many alkyl groups, as seen from the values of C'_{al}/C'_{ar} and $C'_{side(u.s.)}$, which results in increasing the affinity for the solvent, pentane.

On the other hand, the BS materials are macromolecules (observed molecular weights, 1520—2050; n, 5.0—7.1) with a loosened stacking by introduction of alkyl groups. In addition, the absence of intermolecular hydrogen bonds due to alkylation of polar groups, such as OH group, may contribute to the attainment of quite high BS yields. Effect of this factor is to be discussed in detail in the next section.

With an increase in the BS yield, the values of H'_{au}/C'_a, C'_{side}, and C'_{al}/C'_{ar} increase and those of f_a and total and aromatic rings per molecule and per structural unit decrease. This result may be ascribed to the addition of many butyl groups caused under the severe reaction conditions. However, the value of n increases with an increase in the BS yield, which should have decreased by cleavage of ether and some carbon-carbon bonds when severe reaction conditions were applied. A possible interpretation for these results is that the constituents in coal are heterogeneous, that lowly polymerized materials, which are composed of more developed aromatic ring systems relatively easy to get anionized because of their high electron affinity, will preferentially be converted to BS at an early stage, and that highly polymerized materials with less condensed aromatic ring systems and higher aliphatic carbon ratios will resist the reaction so as to get converted later. This view is in accord with an observation that a BS produced at an early stage has slightly higher σ_{al} and $C'_{side(u.s.)}$ values (*i.e.*, it contains more alkyl groups) than a BS produced later, and also with a report[2,9,23] that the solubility of low rank coals, which may be considered to be composed of similar materials as contained in the BS produced later, is considerably low for the conventional reductive alkylation (or hydrogenation) method.

Effects of OH Groups on Coal Solubilization. Table 5 summarizes the yields of the BS and BI from methylated and hydrogenated coals and from further

TABLE 5. PROPERTIES OF METHYLATED AND HYDROGENATED COALS

Coal	Yield of fraction/wt%		No. of OH's per 100 C's		OH per O/%	
	BS	BI	BS	BI	BS	BI
Me-coal[a)]	84	16	0.4	3.1	7	58
Hy-coal[b)]	18	82	2.6	3.7	47	67
Hy-Me-BS[c)]	50	50[d)]	2.1	3.9	38	48

a) Methylated coal. b) Hydrogenated coal. c) BS from Me-coal was further hydrogenated. d) Starting material contained no BI fraction.

hydrogenated BS of the methylated coal, the amount of OH groups per 100 carbon atoms, and the ratio of OH groups to the total oxygen atoms contained. The number of OH groups per 100 carbon atoms in the original Yūbari coal is estimated to be 3.0.

The yield of BS from the hydrogenated coal is only 18 wt%, extremely low compared with the value of 84 wt% for the methylated coal. The fractions from the hydrogenated coal contain more OH groups than those from the methylated one, since the ether bonds and OH groups in the original coal are converted to $-O-CH_3$ and -OH groups by the methylation and hydrogenation, respectively.[1,3)] The decrease in OH groups caused by the methylation has also been suggested with the conventional procedures.[3)] In all the cases, the OH groups are caused to accumulate in the BI fractions. This suggests that the presence of OH groups in large quantity will hinder the solution probably through formation of hydrogen bonds. When the BS from the methylated coal which has already been released from the stacking is further hydrogenated, the amount of OH groups is increased by a demethylation on $-O-CH_3$ groups[1)] and a large amount of BI (50 wt%) is newly formed, into which the OH groups are also made to accumulate.

IR spectra of various BS's are shown in Fig. 1. The BS materials from the hydrogenated coal and from the further hydrogenaed BS of the methylated coal show absorption bands assignable to intermolecular hydrogen bonds at about 3100—3600 cm^{-1}, whereas the corresponding absorption is hardly observed for the BS from the methylated coal. Hence, it has been demonstrated that the extremely high BS yield from the reductively alkylated coals is due at least to the absence of intermolecular hydrogen bonds.

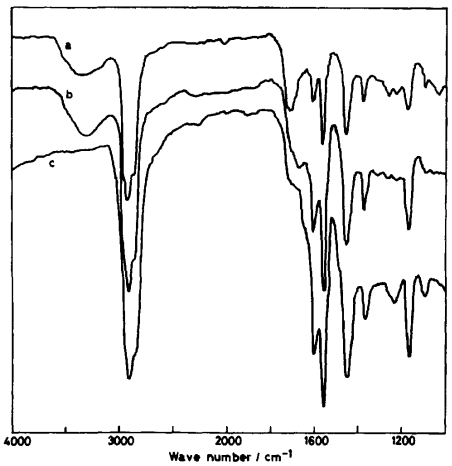

Fig. 1. IR spectra of BS fractions from (a) hydrogenated coal, (b) further hydrogenated BS of methylated coal, and (c) methylated coal.
