Studies on the Electronic Absorption Spectra of Some Selected Furan Derivatives. Molecular Orbital Calculations

Rafie Hassan ABU-EITTAH*,† and Maher Mohamed HAMMED
Department of Chemistry, Faculty of Science, University of Cairo, Giza, Egypt

(Received April 5, 1982)

The electronic absorption spectra of three groups of furan derivatives: 2-formyl, 2-acetylfuran, and 2-furoic acid, *N*-(2-furylmethylene)amines and phenylfurans were investigated. The predominant conformation as well as the polarity of the molecule could be predicted from its spectrum. The investigated molecules were proved to be "all planar" configuration which led to substantial interaction between the electronic states of the subsystems. The preferred conformations of *N*-(2-furylemthylene)methylamine and *N*-(2-furylemthylene)aniline were predicted with the aid of molecular orbital calculations.

The electronic absorption spectra of furan derivatives are rarely found in the literature. Horvath and Kiss[1] attributed the long wavelength absorption of extremely low intensity in the spectrum of furan to a singlet-triplet transition and the main absorption band in the UV region to a singlet $\pi\rightarrow\pi^*$ transition. The triplet states of furan, thiophene, and pyrrole were detected by variable-angle electron impact spectroscopy.[2] In furan, the singlet-triplet transition occurs with maximum intensity at 3.99 and 5.22 eV.

The absorption spectra of numerous furfural acetals[3] and 2-arylfuran[4] have been reported. The conformation of 2-furylphenyl ketone has been investigated by means of spectroscopic methods.[5] It was suggested that furyl conjugation with the carbonyl group is superior to phenyl conjugation with the same group.[5] The absorption spectra of some furylcarbonyl derivatives have been measured, and the band maxima were correlated to the reactivity of the carbonyl group of the compounds.[5] Head and Jones[6] investigated the electronic absorption spectra of some *N*-(2-furylmethylene)arylamines in ethanol. The dipole moments of some furfural derivatives in benzene, dioxane, and CCl_4 were determined from dielectric data.[7,8]

In this work the electronic absorption spectra of three groups of furan derivatives: acylfurans and 2-furoic acid, *N*-(2-furylmethylene)amines, and phenylfurans, have been investigated. The results give much information on the nature of the spectra of furan derivatives as well as on the conformation of the composite furan derivatives. Molecular orbital calculations were performed on representative examples of the compounds studied. The SCF-Cl and the MIM methods were used and proved to be useful for conformational analysis.

Experimental

Methanol, ethanol, and cyclohexane were BDH reagent grade chemicals and were purified by the conventional methods reported.[9]

2-Acetylfuran and furfural (Koch light reagent grade) were used after purification by vacuum distillation. 2-Furoic acid (BDH reagent grade) was purified by crystalization. 2-Phenylfuran was prepared by suspending stabilized benzene diazonium salt (0.1 mol) in furan (150 ml) and vigorously stirring throughout the preparation while adding sodium hydroxide and sodium acetate.[4] After 24 h of stirring, the product was steam distilled. The product was extracted with ether and then vacuum distilled (bp 94 °C/10 mmHg, 1 mmHg≈133.322 Pa). In a similar way 2-(*p*-chlorophenyl)furan was prepared. 2,4-Diphenylfuran was prepared by oxidizing 1,3-diphenyl-2-buten-1-one (0.1 mol) with selenium dioxide (0.05 mol) in dioxane. The product was distilled in a vacuum (200 °C/3 mmHg) and solidified in the side arm. The compound was purified by recrystallization from ethanol (mp 109—110 °C).[11] 2,5-diphenylfuran was prepared by heating 1,4-diphenyl-1,4-butanedione, which was prepared from phenacyl bromide,[12] with concentrated HCl (one part of 1,4-diphenyl-1,4-butanedione to two parts of HCl) at 130—150 °C. The product was precipitated from ice cold water and purified by crystallization from ethanol (mp 91 °C).[13]

N-(2-Furylmethylene) amines were prepared by mixing the stoichiometric amounts of furfural and an appropriate amine in benzene.[6] The temperature of the mixture was kept near 5 °C for 1 h. The benzene solution was dried over magnesium sulfate and evaporated to give the imines that were purified by vacuum distillation or recrystallization. The compounds thus prepared were *N*-(2-furylmethylene)-methylamine, *N*-(2-furylmethylene)aniline, *N*-(2-furylmethylene)-*o*-toluidine, *N*-(2-furylmethylene)-*p*-toluidine, *N*-(2-furylmethylene)-*o*-chloroaniline, *N*-(2-furylmethylene)-*o*-methoxyaniline, *N*-(2-furylmethylene)-*p*-methoxyaniline, *N*-(2-furylmethylene)-*p*-nitroaniline, and *N*-(2-furylmethylene)-2-pyridinamine. Melting points and boiling points agreed with the values reported in the literature.[14—16]

The absorption spectra were measured with a Beckman DK-1 spectrophotometer using 1.0 cm fused silica cells.

Results and Discussion

A. Electronic Absorption Spectra. (I) Carbonyl and Carboxy Derivatives of Furan: Figure 1a shows the electronic absorption spectra of furan, furfural, 2-acetylfuran, and 2-furoic acid in a nonpolar solvent. The spectrum of furan has been investigated.[1,2] Substitution, in the furan nucleus, by a formyl, acetyl or carboxyl group reduced the symmetry from C_{2v} to C_s and perturbed significantly the electronic spectrum of furan (Fig. 1a). At least two $\pi\rightarrow\pi^*$ transitions (280—210 nm) appear in the spectra of substituted compounds in addition to an $n\rightarrow\pi^*$ (≈330 nm) transition. The spectra of the formyl and acetyl derivatives show much similarities but differ basically from that of 2-furoic acid. Such differences are mainly due to the dimerization of the acid, specially in nonpolar solvent. A large increas in intensity of the

† Present address: Chemistry Department, Faculty of Science, King Abdulaziz University, Jeddah, Saudi Arabia.

longest wavelength transition of the acid, in nonpolar solvent, suggests that such a transition is not n→π^* but π→π^* of the dimer. The n→π^* band is probably somewhere in the 280 nm region. The spectrum of

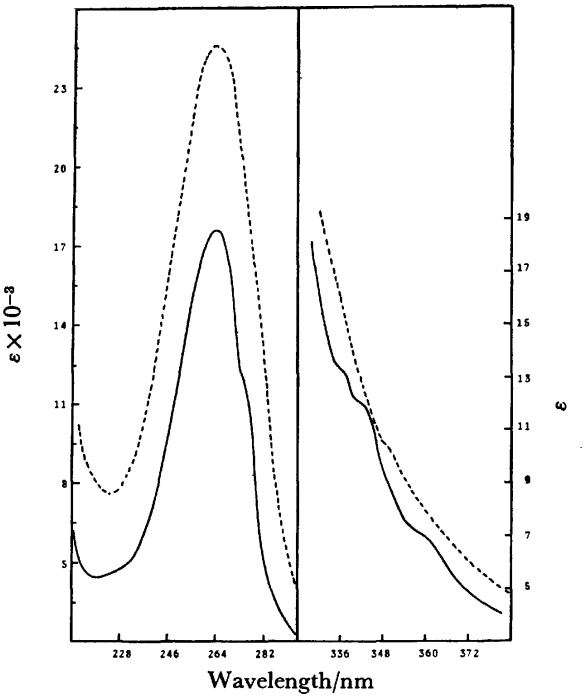

Fig. 2a. Electronic absorption spectra of *N*-(2-furylmethylene)methylamine.
—— In cyclohexane, ---- in ethanol.

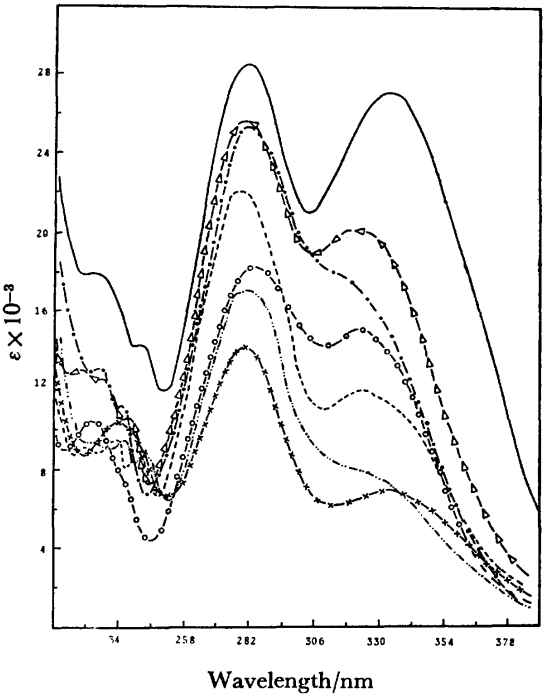

Fig. 2b. Electronic absorption spectra (in cyclohexane) of:
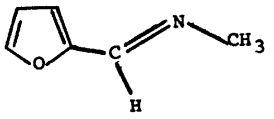
—·—·— *N*-(2-furylmethylene)aniline, ---- *N*-(2-furylmethylene)-*o*-toluidine, —··—··— *N*-(2-furylmethylene)-*o*-chloroaniline, —×—×— *N*-(2-furylmethylene)-*o*-methoxyaniline, ---- *N*-(2-furylmethylene)-*p*-toluidine, —○—○— *N*-(2-furylmethylene)-*p*-chloroaniline, —— *N*-(2-furylmethylene)-*p*-methoxyaniline.

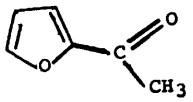
2-furoic acid in methanol is that of a mixture of the monomer and dimer, and the 310 nm band partially comprises an n→π* transition. On dilution, the longest wavelength band disappears and the spectrum obtained is only that of the monomer (Fig. 1b). Table 1 shows the values of band maxima and band intensities of furfural, 2-acetylfuran, and 2-furoic acid.

(II) Furylmethylenes: In a previous study[17] the electronic absorption spectra of *N*-(2-thenylidene) amines were investigated. In this work the spectra of a variety of *N*-(2-furylmethylene) amines were studied (Figs. 2a and 2b). Although *N*-(2-furylmethylene)-methylamine (**a**) and 2-acetylfuran (**b**) are π-isoelectronic and of the same symmetry and their π→π* transitions are of nearly the same energy, the n_N→π* transition being of much lower energy and having lower intensity than the n_O→π* transition (Tables 1 and 2). The spectrum of *N*-(2-furylmethylene)aniline



(**a**)

differs basically from that of the methylamine derivative. Figure 2b suggests that the interaction between the subsystems of *N*-(2-furylmethylene)methylamine and benzene is pronounced as will be discussed below. The spectreum of *N*-(2-furylmethylene)aniline provides



(**b**)

some important information about the conformation of the molecule. If the molecule is a "free rotator"

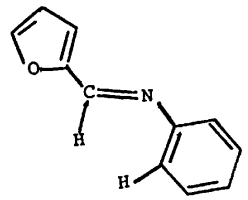
around the single bond (C–C) or (N–C), its spectrum may become superposition of the spectra of its subsystems. On the other and, if the steric factor owing to the H–H repulsion is pronounced, the molecular



structure would be distorted and the spectrum of the composite molecule would resemble either of the sepectra of its constituents. From the spectrum of the molecule (Fig. 2b), one can predict that the molecule is not a "free rotator" and the molecular structure is not apparently distorted. This will be theoretically confirmed below. The position of the band maxima did not vary on scanning the spectrum in polar solvent. Therefore, it can be said that the molecule has no strong dipole. The feature of the overlap of the transitions is very significant in the spectra of *N*-(2-furylmethylene) amines as in the spectra of the related compounds, *N*-benzylidene-anilines and azobenzenes.

To confirm the relation between the spectra of *N*-(2-furylmethylene) amines and the conformations of these compounds, the spectra of a series of *N*-(2-furylmethylene)anilin derivatives have been investigated (Fig. 2b). An important result is that the feature of the spectra of all derivatives (except the nitro derivatives) is very much similar to that of the parent compound *N*-(2-furylmethylene)aniline. The spectra show three $\pi \rightarrow \pi^*$ electronic transitions with a degree of overlap and intensity depended on the substituents, whose band maxima are not so different from each other. This indicates that planarity of the molecule is pronounced. It is true that, generally, transitions in *N*-(-*o*)-substituted(2-furylmethylene)anilines have lower intensity than those in *p*-substituted furyl isomers.

The spectra of the nitro derivatives (Fig. 3), differ significantly from those of *N*-(2-furylmethylene) amines as a result of the perturbation of a nitro group. From the spectra one can tell that the nitro derivatives have nearly the "all-planar" configuration. If planarity of the molecule is apparently distorted, the spectrum of the composite molecule should be similar to those of the subsystems as stated above. Such behavior is not encountered in the spectra of the compounds studied.

The absorption spectra of *N*-(2-furylmethylene)-2-pyridinamine in cyclohexane and methanol are shown in Fig. 3. The internal rotation of either the furan or the pyridine nucleus seems to be restricted, since the spectrum observed differs significantly from those of the subsystems. The molecule will aquire a quasi-rigid configuration, and the electronic interaction between the two subsystems (pyridine and 2-furylmethylene) is significant. All transitions observed are $\pi \rightarrow \pi^*$, which shift to red in polar media. This suggests that the excited state has a polar structure. Table 2 gives the values of band maxima and intensities of *N*-(2-furylmethylene) amines.

(III) 2-Phenylfurans: An objective of this work is to investigate the extent of mixing of the electronic states of furan with those of other subsystems when

the two chromophores are joined through a single bond. The above section has shown that such interaction is significant when furan nucleus is attached to either a carbonyl group or a benzylimino group. A theoretical treatment of the extent of "state mixing" in phenylfurans and bifurans has been reported.[18] The spectrum of 2-phenylfuran (Fig. 4) consistis of two intense structured band systems (I and II), which are blurred with no shift in band maxima as the solvent is changed from cyclohexane to methanol. The numberical values of band maxima indicate that the bands do not correspond to localized transitions in either the "benzene" or "furan" nucleus. Substitution of a chlorine atom into furan such as 2-(*p*-chlorophenyl) furan did not affect the spectrum significantly. The vibrational components of an electronic transition in a sterically hindered molecule are blurred. This is not to be the case in a non-hindered molecule (compare the spectra of *cis*- and *trans*-stilbenes). Figure 4 indicates clearly the well resolved vibrational components of bands I and II, suggesting that the conformation of 2-phenylfuran is planar or nearly planar. Molecular orbital calculations show that as the angle of twist increases the lowest transition energy increases (reaching to a maximum value when the subsystems are perpendicular).[18] This result is also confirmed when one considers the spectrum of biphenyl.[19]

A comparison of the electronic spectra of 2-phenylfuran with biphenyl is worthwhile. The lowest $\pi \rightarrow \pi^*$ transition (276 nm) for 2-phenylfuran is at longer wavelength than that of biphenyl (247 nm) although one expected the reverse. It was expected that the higher symmetry and larger delocalization energy of biphenyl might give rise to a lower transition energy for biphenyl than that for 2-phenylfuran. However, the release of steric hindrance in 2-phenyl furan results in the transition energy lower than that of biphenyl.

Figure 5a shows the absorption spectra of 2,4-diphenylfuran. The results indicate that planarity of the 2,4-diphenyl derivative is more distorted than that of the monophenyl derivative. The shoulder shown in the spectrum of 2,4-diphenylfuran ($\lambda \approx 300$ nm, $\varepsilon \approx 400$) was not observed in the spectra of the furan derivatives studied. This suggests that the band designated as I corresponds to two overlapping transitions. A confirmation of this suggesstion was obtained from molecular orbital calculation.[18] 2-Phenylfuran had two electronic transitions at 4.33 and 4.92 eV whereas the 3-phenyl derivative had transition energies at 4.58 and 4.98 eV.

The spectra of 2,5-diphenylfuran in cyclohexane and methanol are given in Fig. 5b. The pronounced red shift and intensification of the band corresponding to the lowest energy transition, compared to that of 2,4-diphenylfuran, are evidence of a nearly "all planar" conformation for the 2,5-diphenyl derivative. This result indicates the dependence of the electronic absorption spectrum on the conformation of the molecule. Table 3 shows the values of band maxima and intensities of the studied phenylfurans.

B. Molecular Orbital Calculations. The method of molecule-in-molecule[20] has been very nicely adopted to MO calculations on composite systems such as

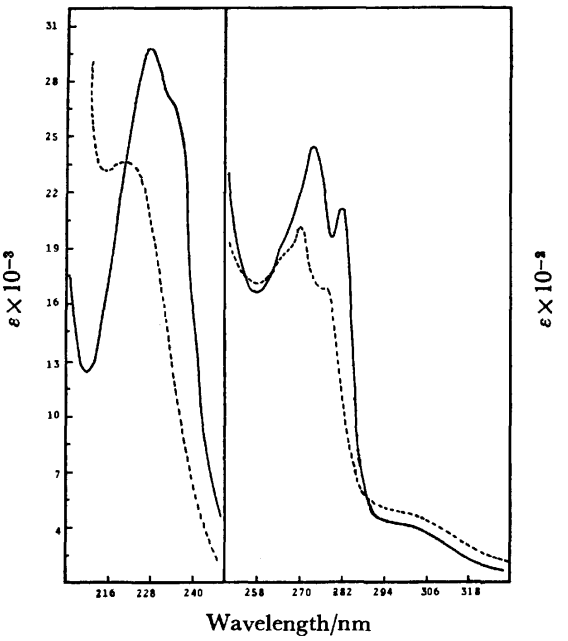


Fig. 5a. Electronic absorption spectra of 2,4-diphenylfuran.
—— In cyclohexane, ---- in methanol.

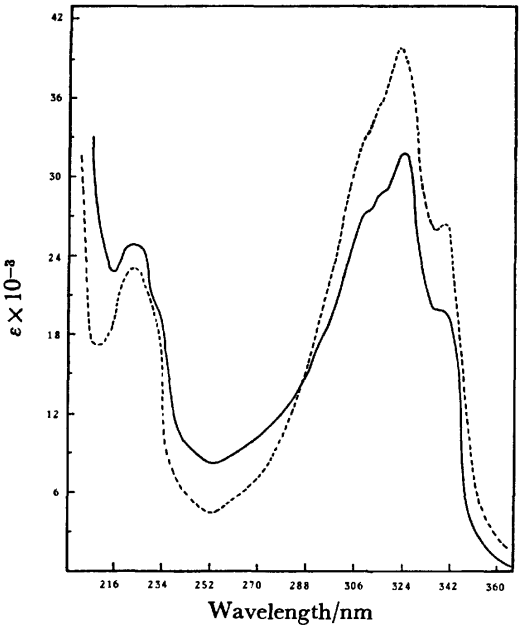

Fig. 5b. Electronic absorption spectra of 2,5-diphenylfuran.
—— In cyclohexane, ---- in ethanol.

phenylthiophenes,[21] bithienyls,[22] and phenylfurans.[18] The results encouraged us to adopt this method for calculations on *N*-(2-furylmethylene)aniline.

The two subsystems of the composite molecule, *N*-(2-furylmethylene)aniline, are 2-furylmethyleneamine (A) and benzene (B). The core of the molecule-in-molecule method is to calculate the interaction between the electronic states of subsystems (A) and (B). The PPP[23] version of the SCF method was applied to the two conformers, Ia and Ib, and the SCF MO's were computed. The CI state functions and the corresponding energies were then calculated. The results

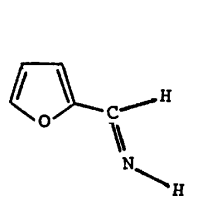
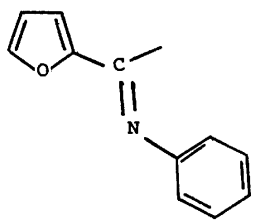
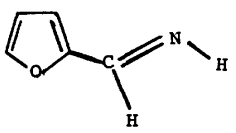
are given in Table 4. The electronic states of the planar conformers, IIa and IIb, of *N*-(2-furylmethylene)aniline were calculated by considering the following interactions between (i) the CI state function of subsystems (A) and (B); (ii) the CI state functions of the subsystems and charge transfer configurations



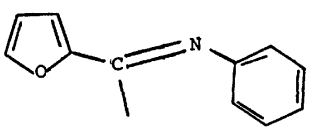
(Ia)



(IIa)



(Ib)



(IIb)

where an electron transfers from (A) to (b) or from (B) to (A); (iii) the ground state and the charge transfer configurations. The results are listed in Table 5.

The oscillator strength was calculated from the equation

$$f = 2.085 \times 10^{-5} M^2 \bar{\nu},$$

where M is the electric dipole transition moment and $\bar{\nu}$(cm^{-1}) is the wave number of the electronic transition. The moment, $\vec{M}$, was calculated from the equation

$$\vec{M} = \langle \psi_0 | \hat{M} | \psi_E \rangle,$$

where ψ_0 and ψ_E are the ground and excited state wave functions respectively. In the molecule-in-molecule procedure the wave functions have the forms:

$$\psi_0 = {}_a\Gamma + \sum_n b_n T_n,$$

$$\psi_E = \sum_n C_n \Lambda_n + \sum_{n'} d_{n'} T_{n'} + e\Gamma,$$

Table 6. Calculated and observed transition energies and oscillator strengths

Compound	Transition energy/eV		Oscillator strength

a) The conformer Ia. b) The conformer Ib. c) The conformer IIa. d) The conformer IIb.

where Λ_n is the nth excited state function of the subsystem and T is the charge transfer state function. In the ZDO approximation

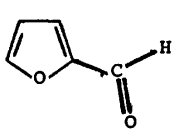
$$\langle\psi_0|\hat{M}|\psi_E\rangle = a\sum_n\langle\Gamma|\hat{M}|\Lambda\rangle+\sum_n\sum_{n'}b_nd_{n'}\langle T_n|\hat{M}|T_{n'}\rangle.$$

The first term was calculated by the usual procedure and the second term was zero unless $n=n'$.

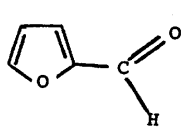
(IV) Comparison with Experimental Results: Table 6 shows comparison of theoretical results with the experimental data. For *N*-(2-furylmethylene)methylamine the correspondence between the theoretical computation using conformer Ia and the experimental results is quite satisfactory. The computed transition energies of 3.36, 4.94, and 5.97 eV favour conformer IIb for *N*-(2-furylmethylene)aniline. Computations on conformer IIa predict the presence of two overlapping transitions in the region of 5.0 eV (at 4.90 and 5.09) and two overlapping transitions in the region of 6.0 eV (at 6.0 and 6.02). Experimentally three transitions were observed at 3.90, 4.40, and 5.44 eV.

Discussion and Conclusion

Many studies have been reported on the electronic structure of the rotational isomers of furfural but none has been reported on *N*-(2-furylmethylene)methylamine. Infrared spectra[24] show the presence of two carbonyl absorption bands corresponding to two conformers. On the other hand dipole moment measurements[8] indicate that at room temperature the mixture of the two conformers contains mainly conformer IIIa. The low temperature NMR spectra[25] indicate that conformer IIIb is energetically favored. The IR spectrum of furfural has been interpreted on the basis that at room temperature conformer IIIa is predominant in carbon tetrachloride.[24] Calculations by the PPP-CI and DelRe method[26] of the dipole moments have provided no reason to conclude, as shown previously,[15,26] that conformer IIIa of furfural is predominant at room temperature.



(IIIa)



(IIIb)

Molecular orbital calculations performed in this work were not *ab initio*, yet some important results were obtained. It was proved that *N*-(2-furylmethylene)-methylamine exists mainly as conformer Ia (oxygen and nitrogen atoms are in the same side).

Molecular orbital calculations on *N*-(2-furylmethylene)aniline were not yet reported. The calculated spectrum for conformer IIb agrees with the experimental data, rather than that for conformer IIa. Although the molecule is rather large, yet the adopted method was shown to be useful for conformational analysis. Figure 2b shows the electronic absorption spectra of the studied *N*-(2-furylmethylene)arylamines. Table 2 gives the numerical values of band maxima. It can be seen that solvent polarity slightly affects the band maxima indicating that the contribution of charge transfer configuration to the state functions is slight (Table 5). Conformer IIa may have a stronger dipole than IIb. Hence an electronic transition from one subsystem to the other would result in a significant change in dipole moment and consequently an apparent shift in the band maxima with solvent polarity. Such a spectral shift was not observed experimentally. It may be interesting to compare the wave functions of the excited states of conformers IIa and IIb of *N*-(2-furylmethylene)aniline (Table 5). For conformer IIa the form of the wave functions indicates extensive mixing between the states of the subsystems (θ's and Y's) to produce the electronic states of the composite molecule. On the other hand the extent of mixing of the states of the subsystems is slight for conformer IIb. Such situation leads to 'localized' transitions of either of the subsystems of the composite molecule. The interaction between the excited states of the subsystems and the charge transfer configurations lowers the transition energies in the composite molecule relative to those in the isolated subsystems. The results of this work indicate that conformer IIb is predominant for *N*-(2-furylmethylene)aniline.

Studies of Molecular Complexes of Some π Donors with Iodine by Constant Activity Method

Vinay P. SHEDBALKAR and Subray N. BHAT*

Department of Chemistry, North-Eastern Hill University Shillong 793 003, Meghalaya, India

(Received August 27, 1982)

The iodine complexes of benzene, toluene, *o*-, *m*-, *p*-xylene and mesitylenes in cyclohexane are studied by using constant activity method. The association constants and the other thermodynamic parameters of the complexes are determined and the results are compared with those obtained by using conventional spectral methods. The blue shifted iodine band maxima are determined directly.

Although extensive spectrophotometric studies have been made on molecular complexes of iodine with various electron donors, reliable informations are still lacking on thermodynamic and spectral constants, particularly for weak donor–iodine complexes.[1–4] The constant activity method proposed by Childs *et al.*,[5] allows precise determination of the position as well as molar extinction coefficient of the blue-shifted iodine band, ε_{BS}, directly. So recently we have begun the investigations of a number of electron donor–acceptor complexes of iodine by the constant activity method, some of which were studied by the earlier investigators by spectral methods, but whose importance as typical examples is so great that extra efforts to obtain accurate data are justified.[6–7] In the present paper, the studies of iodine complexes of weak donors, namely benzene, toluene, xylenes, and mesitylene by constant activity method, have been reported.

Materials and Method

Solid tetramethylammonium pentaiodide ($TMAI_5$) was prepared as described by Chattaway and Hoyle.[8] All the donors namely benzene, toluene, xylenes, and mesitylene and acceptor, iodine, were purified by the standard procedures. Purified cyclohexane was used as solvent.

The procedure used to obtain the equilibrium constant, K_c, is based on using a mixture of tetramethylammonium polyoidides to maintain a constant activity of iodine, *e.g.*,

$$(CH_3)_4NI_5(s) \rightleftharpoons (CH_3)_4NI_3(s) + I_2.$$

The concentration of iodine is controlled by the temperature of the experiment. Addition of a donor to this system establishes a second equilibrium between donor and iodine,

$$D + I_2 \rightleftharpoons DI_2.$$

The latter equilibrium can be analyzed directly from the increase in absorbance at the isosbestic point of iodine in visible region and the procedure used to obtain the equilibrium constant, K_c, has been described in detail elsewhere.[6,7]

For obtaining isosbestic point, as well as the molar extinction coefficient at the isosbestic point, ε_{isos}, the spectra of pure iodine and complexed iodine in cyclohexane were recorded by keeping the iodine concentration constant (≈0.4 mM†) and varying the donor concentration (1—5 M). Pure $TMAI_5$ was equilibrated with cyclohexane (≈48 h) at constant temperature (in a thermostat) and the spectrum of iodine in the equilibrium solution was recorded. Then a series of several solutions of donors in cyclohexane were similarly equilibrated with $TMAI_5$ (≈150 mg) and spectra were recorded for all those solutions at all constant temperatures.

The spectra were recorded in UV and visible region by Beckmann 26 recording spectrophotometer fitted with a temperature control accessories with a four position manual sample changer. The spectra were recorded at 25, 30, 35, and 40 °C and the temperature of the solution could be controlled within ±0.1 °C. However, for the sake of brievity, the data at only one temperature have been reported.

For locating the blue-shifted iodine band of the donor–iodine complex, the spectrum of the complex was recorded with the donor and the constant activity source of iodine in the sample cell and only the constant activity source of iodine in the reference cell, at constant temperature.

Results and Discussion

Benzene–Iodine System. Figure 1 shows the iso-

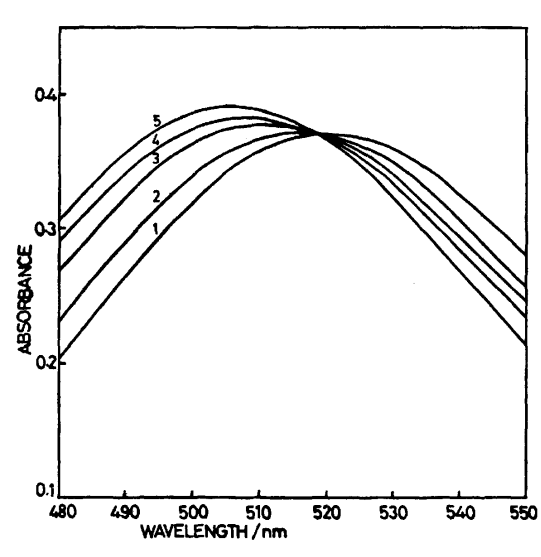

Fig. 1. Isosbestic point of the benzene-iodine complex in cyclohexane at 25 °C, cell path = 1.00 cm.
(1) Iodine alone (4.0×10^{-4} M); (2) I_2 + 1 M benzene; (3) I_2 + 2 M benzene; (4) I_2 + 3 M benzene; (5) I_2 + 4 M benzene.

† 1 M = 1 mol dm^{-3}.

sbestic point of benzene–iodine complex (at 518 nm). The molar extinction coefficient of iodine in cyclohexane at 518 nm is 962 $dm^3\ mol^{-1}\ cm^{-1}$ (Table 1). The isosbestic point does not vary with the concentration of the donor (in the experimental range of concentration of 1 M to 5 M) and the increase in absorbance at the isosbestic point is attributed solely to the formation of the complex. The charge-transfer band appears at 298 nm (Table 2). The equilibrium constants were determined at 25, 30, 35, and 40 °C, but K_c value at only one temperature, *i.e.*, 25 °C has been listed for the sake of brievity (Table 3). Our data agree with those of Plucknett[9] as well as of Childs *et al.*,[5] but differ from those of Keefer[10]. The K_c values obtained by constant activity method *i.e.* K_c^* are generally higher than those obtained by conventional spectral method using Benesi-Hildebrand[11] procedure. The discrepancy is more in weak complexes. In the case of strong complexes like pyridine–iodine, the contribution due to nonspecific interaction between the donor and iodine is around zero and under such circumstances K_c^* will be equal to K^{th} (*i.e.*, corrected equilibrium constant[4,12]). Moreover, the activity coefficient, γ, varies throughout the range of donor concentration and the values of association constant corrected for γ_{I_2} estimated from solubility parameters are comparable to those reported, obtained by B-H method[12]. Trotter and Hanna[13] had suggested a simple model. According to them a molecule of D replaces one of the molecules in the solvent shell surrounding A, and the equilibrium constant is given by

$$K_{exp} = K^* - [S]_0^{-1},$$

where $[S]_0^{-1}$ is the molar volume of the pure solvent and K^* is the true association constant (corresponding to the equilibrium $AS_n + DS_m \rightleftharpoons \overline{AD}SP + qS$). Applying the correction due to this, the corrected values are given in Table 3. Here it must be worth mentioning that the literature data correspond to heptane (as solvent) and our data correspond to cyclohexane. If one carefully goes through the literature data, one finds that $K_{heptane} > K_{cyclohexane}$.

The concentrations of benzene used for obtaining equilibrium constants are from 0.25 M to 1.5 M. We observed ΔA_{CT} (the change in A_{CT}—Absorbence at the charge-transfer band corrected for free iodine band and donor) varies reasonably linearly with ΔA_{isos}, and the linear regression line forced through the origin is used to calculate the limiting slope of the plot. The molar absorptivity of the charge-transfer band is 9450

±100 $dm^3\ mol^{-1}\ cm^{-1}$ which is higher than the reported value. (As the intensity of a CT transition is best measured by its oscillator strength, *f*, or its transition dipole moment, μ_{VN}, the results for alkyl benzenes –iodine complexes are summarised in Table 2) As we do not have any informations regarding the experimental conditions of Childs *et al.*[5] we are unable to comment on this. However, it is worth mentioning that Orgel and Mulliken[14] are of the opinion that approximately, one fourth of the CT band intensity for benzene–iodine interaction in CCl_4 is due to absorption by complex and the remaining results from "donor–acceptor contacts" due to which the molar absorptivity is high. Lane *et al.*,[12] have rightly pointed out in the case of weak molecular complexes (when the donor concentration is high), the value of ε determined using different concentration scales can differ widely (due to $d\gamma_A^*/dC_D \neq 0$). The molar absorptivity of the complex appears to decrease with the increase in temperature which may be due to band broadening.[2,4] The enthalpy, $-\Delta H°$ (6.65 $kJ\ mol^{-1}$), agrees well with the literature value. The heats of complexation must be considered as representing a composite results for benzene–iodine of different aggregation.

The visible spectrum of iodine–benzene system in cyclohexane obtained by the constant activity method has been shown in Fig. 2. The blue-shifted iodine band maximum (λ_{BS}) is at 503±2.0 nm (Table 2). An examination of the spectra at different concentrations of benzene (0.1 M to 1.5 M) shows that the blue-shifted iodine band position slightly shifts to lower wavelengths with the increase in concentration of donor. However, the shift is within the experimental error. Similar observations were made recently for benzene–iodine system from supersonic beam method.[15] Voigt[16] has reported that iodine absorbs at 502 nm in benzene. This change in λ_{BS} (with concentration), may be due to specific and non-specific interaction of iodine with the medium. The so called dielectric theory may successfully correlate the solvent shift of the absorption band to the dielectric media. As the dielectric constant is increased, (concentration of benzene is increased), the absorbance energy increases, *i.e.*, there is a blue shift in the absorption medium.

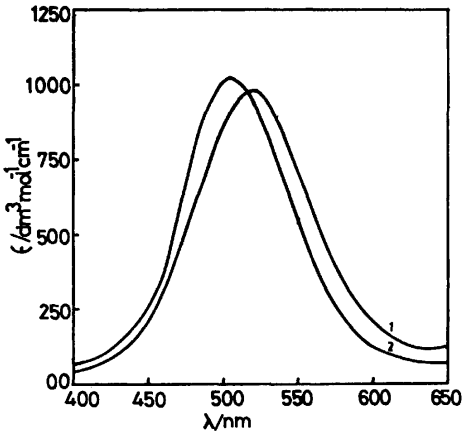

Fig. 2. Visible spectra of benzene–iodine complex in cyclohexane by constant activity method at 25 °C. 1. Free iodine; 2. complexed iodine.

The "blue-shift" of iodine band in polar media is due to perturbation of I_2 by its complexing partner.[1] The B←X electronic transition in I_2 shifts an electron from a π_g to a σ_u antibonding orbital which is spacially larger. So the magnitude of the iodine blue shift should correlate well with the electron donor ability of the bonding solvent molecules. The molar absorptivity of the blue shifted iodine band maximum, ε_{BS}, is 1023±50 $dm^3\ M^{-1}\ cm^{-1}$. The characteristic intensification of the shifted iodine band is explained by increased mixing of the $^3\pi_{o+u}$ state (520 nm band) with either CT the state or with the other excited states (like $^1\Sigma_u^+$ state). The shift and mixing should be greater the stronger the complex, leading to a greater borrowing intensity and therefore a more intense band.[1] The oscillator strength and the transition dipole moments for the blue shifted iodine band are reported in Table 2.

Toluene–Iodine System. The isosbestic point, charge-transfer band, blue-shifted iodine band and the molar extinction coefficients of toluene–iodine system are given in Tables 1—3. It can be seen from the data that the average equilibrium constant at 25 °C is 0.409 $dm^3\ mol^{-1}$ and it is slightly lower than the literature value of 0.500 $dm^3\ mol^{-1}$. The enthalpy is higher than that of benzene–iodine complex which is expected. The molar extinction coefficient of toluene–

iodine complex at CT band (310 nm) is slightly lower than that of benzene–iodine which is not expected (provided the structures are the same). Such discrepancy was reported earlier also. Murakami[17] is of the opinion that since "the degree" of overlapping between orbital functuons which are essential to CT interactions is considerably different for different models, it is reasonable to assume that each configuration has its own molar extinction coefficient. The oscillator strength and transition dipole moments of toluene–iodine are higher compared to those of benzene–iodine complex, which is expected. The blue-shifted iodine band maximum which is slightly concentration dependent of the donor for toluene–iodine appears at 500 nm ($\varepsilon_{BS}=1039$ dm^3 mol^{-1} cm^{-1}). This observation of λ_{BS}, ε_{BS}, f and μ_{VN} data (Table 2) indicate that toluene–iodine is definitely a stronger complex compared to benzene–iodine.

Xylenes–Iodine System. The isosbestic points, charge-transfer bands, blue-shifted iodine bands and their molar extinction coefficients of *o*-, *m*-, and *p*-xylene–iodine complexes are summarised in Tables 1—3. The molar extinction coefficients of the charge-transfer bands are higher than those compiled by Tamres.[18] (In the absence of detailed information in the literature we are not in a position to comment on this) The oscillator strengths and transition dipole moments of CT band indicate that *p*-xylene–iodine complex seems to be stronger compared to the others. These go in parallel with the ionization potentials of the donors. The molar extinction coeffecients, the oscillator strengths and transition dipole moments of visible bands are nearly the same (Table 2). So it is not possible to compare the strength of xylene–iodine complexes from visible absorption band data.

Mesitylene–Iodine System. The spectral and thermodynamic parameters of mesitylene–iodine complexes are reported in Table 1—3. Judging from the position of blue-shifted band and equilibrium constant and other thermodynamic parameters, it is clear that mesitylene–iodine complex is stronger compared to benzene–iodine or xylenes–iodine complexes.

Thus, as shown earlier, our present observations confirm our earlier suggestive evidences that the constant activity method (sometimes known as polyiodide solubility method or simply solubility method) is a convenient alternative to purely spectral methods for determining K_c and ε_{CT} especially for weak molecular complexes of iodine. Secondly the blue shifted iodine band maximum can be obtained precisely and directly. In addition to this, the heat of complexation can be determined by temperature dependence study of the absorbance of the complex using only a single solution of donor with excess of polyiodide.

One of the authors (V.P.S.) is thankful to CSIR, India, for the award of JRF. The authors are thankful to Prof. T.S.B. Narasaraju, Head, Chemistry Department for providing research facilities.

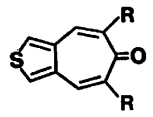
(Received January 24, 1983)

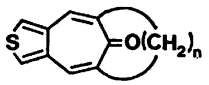
Using a helium discharge lamp with an energy of 21.21 eV ($He(I)_\alpha$ line) the photoelectron (PE) spectra of the heterotropones **1**—**7** have been investigated and compared with the PE spectra of benzologue tropones and with the PE data of thiophene, furan and pyrrole. The first five ionization events in the PE spectra of **1** to **7** could be assigned to electron ejections from $2a_2(\pi)$, $4b_1(\pi)$, $9b_2(n)$, $3b_1(\pi)$, and $1a_2(\pi)$ orbitals. This assignment has been deduced by means of experimental correlation techniques and using ZDO calculations of the LCBO and HMO type as well as semiempirical SCF versions (MINDO/3 and PPP).

The photoelectron (PE) spectra of tropone, benzotropone, naphthotropone and related alkylderivatives have been investigated by several groups[1-3] using an open helium discharge lamp with an energy of 21.21 eV ($He(I)_\alpha$ line). Although the variations due to alkyl substitution and due to hydrocarbon annelation have been studied in great detail,[1] informations concerning the effect of hetero atoms are sparse.

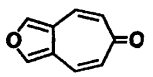
Therefore we felt it of interest to investigate the PE spectra of tropone derivatives with variable hetero fragments. The investigated systems are collected below:



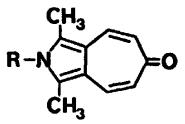
1 R=H
2 R=CH_3



3 n=5
4 n=6



5



6 R=H
7 R=CH_3

The measured vertical ionization potentials are compared with results of semiempirical MO calculations.

The PE Spectra of Thiophene-fused Propones 1 to 4

The He(I) PE spectra of 6*H*-cyclohepta[*c*]thiophen-6-one (**1**), 5,7-pentamethylene-6*H*-cyclohepta[*c*]thiophen-6-one (**3**), 5,7-hexamethylene-6*H*-cyclohepta[*c*]-thiophen-6-one (**4**), 6*H*-cyclohepta[*c*]furan-6-one (**5**), 1,3-dimethyl-2*H*,6*H*-cyclohepta[*c*]pyrrol-6-one (**6**), and 1,2,3-trimethyl-6*H*-cyclohepta[*c*]pyrrol-6-one (**7**) are shown in Fig. 1 and the measured vertical ionization potentials, $I_{v,j}$, of the first PE bands of **1** to **4** collected in Tables 1 and 2. For the assignment of these data we assume the validity of Koopmans' theorem.[4]

$$I_{v,j} = -\varepsilon_j \quad (1)$$

This approximation relates the vertical ionization potentials to the one-electron energies of canonical molecular orbitals derived for the electronic ground state.

The PE spectrum of **1** shows below 12 eV two band systems with strongly overlapping ionization events. The first peak with approximate maxima at 8.62, 8.77, and 9.09 eV is assigned to three ionization events (bands 1 to 3) while the two maxima at 10.68 and 10.84 eV should correspond to two transitions. This assignment is supported by the comparison with the PE spectra of the alkyl derivatives **2**, **3**, and **4**. In the case of **2** and **3** the alkyl groups yield a definite separation of the first peak into three separated bands. The two latter molecules additionally provide evidence that the second peak between 10 and 11 eV is the result of two transitions (bands 4 and 5) as the small

5	10.84	$1a_2(\pi)$	−11.29	−11.02	−11.33	−11.76

a) The orbital numbering corresponds to the valence electrons; the core orbitals are neglected. b) Some σ orbitals between the π levels have been omitted.

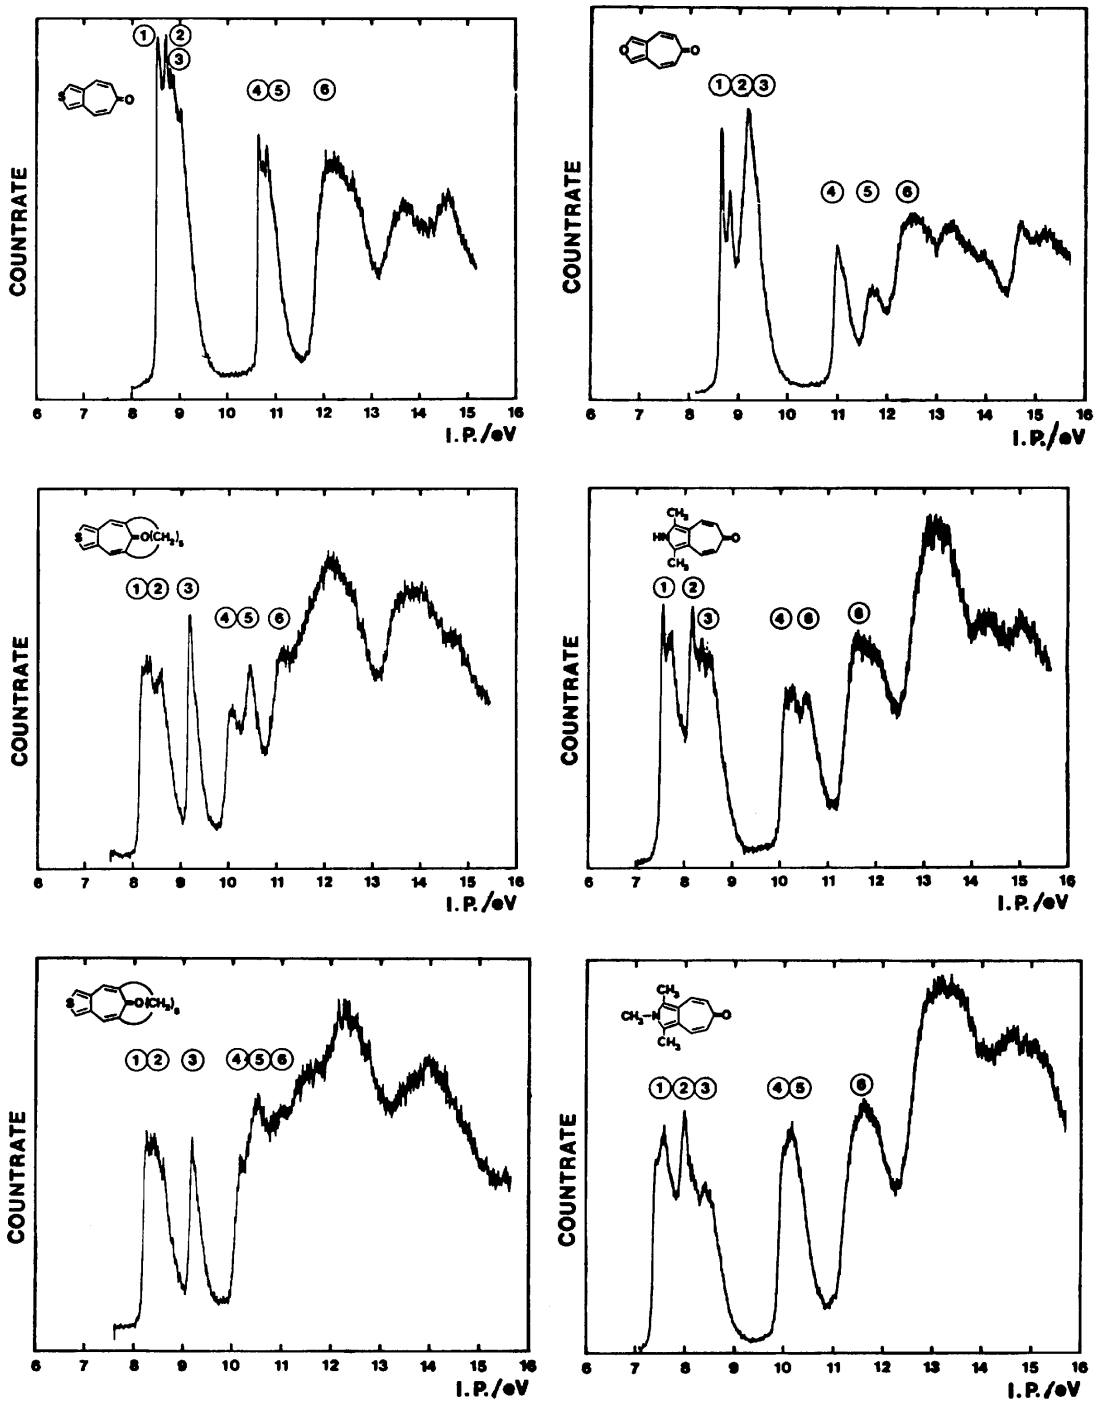

Fig. 1. He(I) PE spectra of **1**, and **3**—**7**.

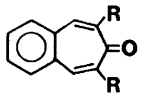
Table 2. Vertical ionization potentials in the thiophene series **1**, **2**, **3**, and **4** for the first five ionization events. The irreducible representations correspond to the unsubstituted molecule **1**. All values in eV

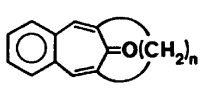
Peak	Assignment	1	2	3	4
1	$2a_2(\pi)$	8.62	8.40	8.25	8.22
2	$4b_1(\pi)$	8.77	8.59	8.57	8.38
3	$9b_2(n)$	9.07	9.09	9.15	9.14
4	$3b_1(\pi)$	10.68	10.48	10.01	10.11
5	$1a_2(\pi)$	10.84	10.61	10.43	10.48

gap of 0.16 eV in **1** is increased to 0.38 and 0.37 eV in **3** and **4**.

The PE spectra of the four thiopheno-tropones are similar to the PE data obtained for benzotropones with the corresponding substituents (**8** to **11**) as counterparts of **1** to **4**.[1)]



8 R=H
9 R=CH_3



10 n=5
11 n=6

This close resemblence, at least for the first band system is not surprising since the first ionization events in **8** to **11** correspond to MO's predominantly localized in the seven-membered ring. The replacement of one double bond by a sulfur will not cause large variations in the IP's as the electronegativities of carbon and sulfur are of comparable size.[5] The difference between the two types of tropones is caused by the inclusion of a 3p-orbital on the sulfur center only. As a result of this restriction all coefficients in the a_2 orbitals are set to 0 in the hetero position as shown below.

The pairwise analogy between **1/8**, **2/9**, **3/10**, and **4/11** suggests that two bands of the first peak are the result of ionization events out of π orbitals (b_1 and a_2) while the third one is due to the lone pair of the carbonyl group.[1-3] The correspondence between the second band system with two strongly overlapping maxima leads to the assumption that the π-orbitals of b_1 and a_2 symmetry lead to these peaks. To assign the ionization events in the sulfur derivatives explicitly we discuss the sequence of the π-orbitals in the unsubstituted molecule **1** in some detail.

a) ZDO Models: To derive the orbital energies of the π MO's of **1** we make use of the linear combination of bonding orbitals (LCBO)[6] successfully applied in the benzologue tropone series by Heilbronner *et al.*[1] Two alternatives for the construction of the molecular orbitals of **1** are displayed below:

A **B**

In the case of **A** the MO's are constructed from bonding orbitals of C=C and C=O double bond fragments and from the sulfur 3p AO. In the alternative model we couple the orbitals of the thiophene moiety to the remaining bonding fragments. To calculate the orbital energies in the zero differential overlap (ZDO) model we have to estimate the energies of the basis orbitals in **A** and **B**.

For the complete fragmentation scheme **A** one has to know the diagonal elements $A_a=A_e$, $A_b=A_d$, A_f and A_c as well as the interaction parameters $B_{ab}=B_{ed}$, $B_{ef}=B_{af}$, $B_{bc}=B_{dc}$, and B_{bd} respectively. For the fragments of the tropone unit we use the parameters derived by Heilbronner *et al.*:[1]

$$A_a = A_e = -10.64\,\text{eV},$$
$$A_f = -13.70\,\text{eV},$$
$$B_{af} = B_{ef} = -0.9\,\text{eV}.$$

For the double bonds b and d of the thiophene moiety we neglect the inductive effect of the carbonyl group, an approximation which should be allowed due to the remarkable separation between b and d and the carbonyl chromophore. As the electronegativity of C and S are of comparable magnitude we neglect this influence too. These simplifications lead to a basis orbital energy of $A_b=A_d=-10.22$ eV.[1] From our previous experience with thiophene derivatives we choose the following S dependent parameters:[7] $A_c=-9.4$ eV and $B_{bc}=B_{dc}=-1.8$ eV. The interaction integrals that couple the thiophene moiety to the triene fragment once again were taken from Ref. 1 $B_{ab}=B_{ed}=-1.215$ eV. The same value also has been used in the case of B_{bd}.

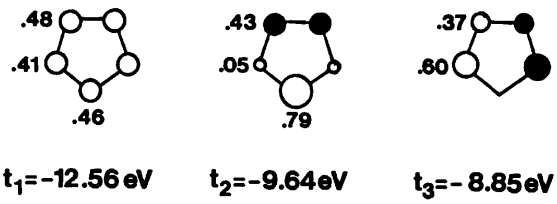


Fig. 2. HMO levels for thiophene.

In the case of **B** one has to determine the LCAO coefficients and the orbital energies of the thiophene fragment, t, which are then coupled to the basis orbital energies and resonance integrals of a, b, and c, the values of which already have been explained. The basis energies for thiophene are taken from experiment:[8] $A_s=-9.4$ eV, $A_c=-7.0$ eV, $B_{cc}=-3.0$ eV, and $B_{cs}=-1.8$ eV. The MO wave functions obtained by the Hückel (HMO) model[9] are displayed in Fig. 2. With these LCAO coefficients it is possible to calculate the B parameters of the second LCBO alternative. The new interaction integrals for the LCBO approach **B** are listed below:

$$B_{at_1} = B_{ct_1} = -0.8188\,\text{eV},$$
$$B_{at_2} = B_{ct_2} = -0.7374\,\text{eV},$$
$$B_{at_3} = -0.6388\,\text{eV}, \qquad B_{ct_3} = +0.6388\,\text{eV}.$$

Solving the secular determinants for the two LCBO models **A** and **B** described above yields the eigenvalues for the π orbital energies given in Table 1. It is seen that both sets are in line with the measured ionization energies. A closer look into the corresponding columns, however, demonstrated that model **B** leads to the better agreement in comparison with the experiment. Thus a more realistic description of the orbitals of **1** is obtained if the thiophene orbitals are coupled to the remaining bonding fragments.

b) Semiempirical MO Calculations on 1: To support the assignment based on the LCBO model we also performed semiempirical calculations using the MINDO/3 method[10] and the PPP-Hamiltonian.[12,13] The results of both approaches are included in Table 1. In the case of the PPP model the canonical orbital energies were corrected according to Eq. 2:[14]

$$\varepsilon_j = 0.168\,\text{eV} + 0.932 \times \varepsilon_j^{PPP} \qquad (2)$$

Thi ₃linear dependence has been obtained earlier and is based on a regression analysis on several thiophene derivatives. The agreement between the measured IP's and the semiempirical calculations is as good as can reasonably be expected. Both types confirm the assignment derived within the LCBO framework and experimentally deduced from the benzologue tropone.

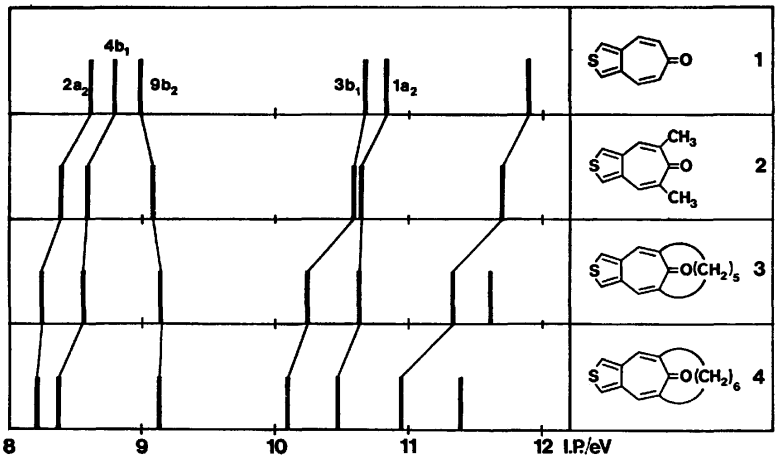

Fig. 3. Correlation between the first bands in the PE spectra of **1**, **2**, **3**, and **4**.

Table 3. Comparison between measured ionization potentials, $I_{v,j}$, and calculated orbital energies of **5**, **6**, and **7**. All values in eV

Compd	Peak	$I_{v,j}$	Assignment[a]	LCBO **B**	HMO	MINDO/3[b]	PPP
5	1	8.65	$2a_2(\pi)$	−8.68	−8.78	−8.50	−9.86
	2	9.17	$4b_1(\pi)$	−8.82	−8.96	−9.26	−9.18
	3		$9b_2(n)$			−9.60	
	4	10.98	$1a_2(\pi)$	−11.03	−10.68	−11.23	−11.99
	5	11.70	$3b_1(\pi)$	−11.50	−11.74	−11.86	−12.20
6 [c]	1	7.55	$2a_2(\pi)$	−7.07	−7.75[d]	−8.14	−9.04[d]
	2	8.16	$4b_1(\pi)$	−7.87	−8.65	−8.57	−8.98
	3	8.50	$9b_2(n)$			−9.33	
	4	10.21	$3b_1(\pi)$	−10.73	−10.75	−10.93	−11.68
	5	10.56	$1a_2(\pi)$	−10.85	−10.38	−10.90	−11.66
7 [c]	1	7.59	$2a_2(\pi)$		−7.75[d]	−8.11	−8.82
	2	8.01	$4b_1(\pi)$		−8.55	−8.43	−8.91
	3	8.44	$9b_2(n)$			−9.30	
	4	10.14	$3b_1(\pi)$		−10.32	−10.66	−11.45
	5		$1a_2(\pi)$		−10.38	−10.87	−11.60

a) The orbital numbering corresponds to the valence electron configuration; the core orbitals are neglected. b) Some σ orbitals between the π levels have been omitted. c) The MO's of the methyl substituents have been neglected in the numbering of the irreducible representations. d) Results obtained by simple perturbation theory (formula 3).

In Table 2 and Fig. 3 we have correlated the different ionization potentials in the thiophene series **1** to **4**.

In analogy to the benzotropones **9** and **10** a remarkable separation between $4b_1$ and $9b_2$ is found for $n=5$ and 6. This observation has been rationalized by the fact that for $n=5/6$ the carbonyl group is strongly bent out of the molecular plane and behaves as a predominantly unconjugated fragment.[1] This PE spectroscopic finding is in line with the results of various physicochemical investigations.[1]

The PE Spectra of 5, 6, and 7

The He(I) PE spectra of the furan derivative **5** and the two pyrrole descendents **6** and **7** are also shown in Fig. 1. The measured vertical ionization potentials are collected in Table 3 together with the results of the already discussed computational procedures. As the LCBO approach **B** gave better results only this model has been used in the case of **5**, **6**, and **7**. Additionally simple HMO results[9] are added in Table 3.

To rationalize the variation of the IP's in **5**, **6**, and **7** in comparison to **1** it is constructive to discuss the shift of the two highest occupied MO's in the series furan, pyrrole and thiophene.[8,15] A schematical representation is given in Fig. 4. A detailed explanation for the observed variations and the unexpected changes in pyrrole have been discussed elsewhere.[8] If we rely on the validity of Koopmans' theorem in the case of the tropone derivatives, we expect for the first two bands of **1** ($2a_2$, $4b_1$) a similar shift by replacing the sulfur atom by oxygen or NR as for the first two bands in the series thiophene, furane and pyrrole. According to Fig. 4 the $2a_2$ MO of the heterotropones should be constant if **1** and **5** are considered and shifted to higher energies if $2a_2$ of **1** is correlated with $2a_2$ of

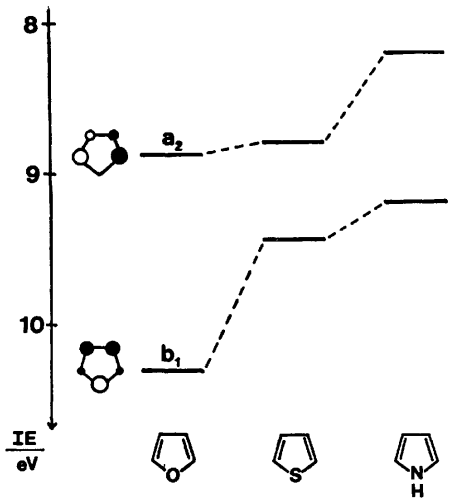

Fig. 4. Correlation of the two lowest ionization energies of furan, thiophene and pyrrole.

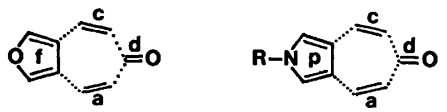
the pyrrole derivatives **6** and **7**. For the $4b_1$ MO one expects a stabilization going from **1** to the furane molecule **5** and a lowering if **1** is compared with **6** and **7**. These expectations are fulfilled as displayed in the correlation diagram of Fig. 5. For the comparison of the measured IP's of **5**, **6**, and **7** we follow the lines of the foregoing paragraph.

a) ZDO Models: For **5** and **6** we performed LCBO calculations of the type **B**. HMO data of the furane



B

moiety were chosen to fit the experimental IP's of furan.[16] With the following parameters ($A_o=-11.0$ eV, $A_c=-7.3$ eV, $A_{c'}=-7.0$ eV, all interaction integrals -3 eV) an almost perfect agreement between HMO energies and measured data is observed:

	$I_{v,j}$	ε_j^{HMO}/eV
$1a_2$	8.88	9.07
$2b_1$	10.31	10.31
$1b_1$	14.40	14.48

The MO coefficients obtained with this approximation are collected in Fig. 6a. The calculation of the unknown interaction integrals in **5** then is straightforward and not explicitly performed in this context. Inspection of the LCBO results in Table 3 demonstrates that the measured ionization energies are reproduced with high accuracy. Also the HMO results on the right hand of the LCBO calculations lead to a satisfactorical description of the ionization energies. The HMO parameters were taken from the literature.[17]

The pyrrole basis orbital energies were calculated with HMO parameters close to Eland's values:[17] $A_{NH}=-9.61$ eV, $A_c=-6.64$ eV, $A_{c'}=-6.37$ eV, all interaction integrals are set to -2.70 eV. The HMO energies are compared below with the measured ionization potentials of pyrrole:[18]

	$I_{v,j}$	ε_j^{HMO}/eV
$1a_2$	8.21	8.24
$2b_1$	9.20	9.24
$1b_1$	13.0	12.93

The HMO wave functions for the LCBO model are given in Fig. 6b. The calculated orbital energies for **6** confirm the qualitative assignment. Furthermore it is seen that also the HMO calculations with the parameters of Ref. 7 are in good agreement with the measured ionization energies. The inductive effect of the methyl groups in **6** and **7** has been taken into account by the simple first order perturbation theory:[9]

$$\delta\varepsilon_j = \sum_\mu c_{j\mu}^2 \delta\alpha_\mu + \sum_\omega c_{j\omega}^2 \delta\alpha_\mu/3. \qquad (3)$$

For the perturbation parameter $\delta\alpha_\mu$ a value of 1.16 eV has been used. The indices ω refer to the position ortho to μ.

*b) Semiempirical MO Calculations on **5**, **6**, and **7***: The results of the semiempirical calculations of the MINDO/3 and PPP type in Table 3 suggest for all three heterotropones **5**, **6**, and **7** the same orbital sequence as in the thiophene derivative **1**. The variation of $2a_2$ and $4b_1$ upon changes of the hetero fragment have already been commended on. It is seen that MINDO/3 leads to the better agreement with the measured data while the PPP model fails to reproduce the sequence $2a_2$ on top of $4b_1$ in the case of **5** and **6**.

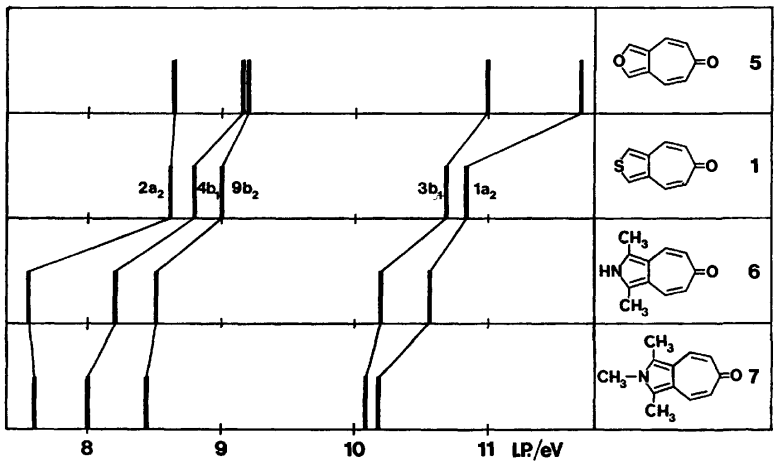


Fig. 5. Correlation between the first bands in the PE spectra of **1**, **5**, **6**, and **7**.

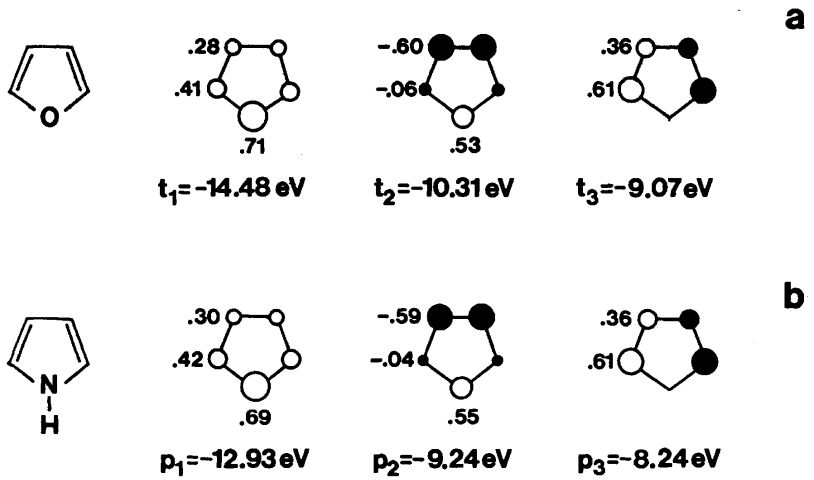

Fig. 6. HMO levels for furan (**a**) and pyrrole (**b**).

Conclusions

In the present publication we have investigated the He(I) PE spectra of seven heterotropones containing sulfur, oxygen and nitrogen as hetero fragment. The sequence of the ionization potentials has been derived by experimental correlation techniques and by simple LCBO considerations based on the validity of Koopmans' theorem. Although it has been demonstrated that ionization events in heterocycles are accompanied by significant reorganization effects of the electrons[19,20] that can be taken into account by sophisticated many-body procedures, our approach is as successful as the LCBO calculation of Heilbronner *et al.*[1] in the benzologue tropones. The comparison between the PE spectra of **1**/**2** with thiophene, of **5** with furane and **6**/**7** with pyrrole lead to an unambigous assignment of the ionization potentials of the tropone derivatives. It has been demonstrated that the variation of the hetero group leads to significant changes in the magnitude of the IP's but the sequence is constant in all investigated compounds.

The investigation of the PE spectra of the tropones **1** to **7** allowed a rationalization of the changes in the electronic structure of these molecules upon variation of the hetero fragment. However, it should be noted that no direct conclusions regarding the "aromaticity" or "reactivity" of these compounds should be drawn from these results.

Experimental

The heterotropones **1** to **5** were prepared according to methods described in the literature.[21] The PE spectra were recorded on a PS 18 spectrometer of Perkin-Elmer Ltd. (Beaconsfield, England) and calibrated with Ar. A resolution of about 20 meV of the Ar line was obtained.

The work in Heidelberg has been supported by the Fonds der Chemischen Industrie and the BASF Aktiengesellschaft in Ludwigshafen. H. Y. is grateful to the Humboldt-Stiftung for a fellowship. We thank Professor R. Kreher for samples of **6** and **7**.

Ion Exchange Equilibria between Alkali Metals and Hydrogen Ions on Iron(III) Antimonate, an Inorganic Ion Exchanger

Jagdish Prasad RAWAT* and Balbir SINGH
Department of Chemistry, Aligarh Muslim University, Aligarh-202001 India

(Received July 19, 1982)

Ion exchange equilibria of alkali metal ions (Li^+, Na^+, K^+ and Rb^+)/H^+ systems have been studied at 30, 40, 50, and 60 °C on iron(III) antimonate as a cation exchanger. The exchange isotherms have been measured for both forward and backward reactions with solutions of ionic strength 0.1 by the batch technique. The isotherms showed S-shaped curves for each exchange system except Li^+/H^+. Selectivity coefficients vary with the equivalent fraction ($\bar{X}_M$) of the alkali metal ions in the exchanger and give linear functions against $\bar{X}_M$ in the range from 0—0.40. The selectivity sequence shows $Na^+ < Li^+ < K^+ < Rb^+$. The overall thermodynamic data are evaluated.

Synthetic inorganic ion exchangers have been developed in recent years. The primary aim of most of the studies done in this field has been to achieve the separations. Besides the preparation of new materials and their applications to the separations interest has also been developed towards the study of ion exchange equilibria on these materials. Because of their thermal stability, their rigid structure and consequently negligible swelling, the ion exchange equilibrium studies at different temperatures on these materials will be simpler than on organic ion exchange resins which swell quite appreciably and are prone to thermal instability. The contributions of Larsen Vissers,[1] Ruvarac,[2] Amphlett,[3] Alberti,[4] Nancollas & Dyer[5] are noteworthy in this field. Recently Abe and Sudoh[6,7] described the ion exchange equilibrium studies on antimonic acid for the systems of transition metal ions/H^+ and from these results the appropriate thermodynamic data were derived.

The influence of temperature on the equilibrium between alkaline earth metal ions and hydrogen ion on tantalum arsenate has been described in our earlier paper.[8] Similar studies on the equilibria between alkaline earth metal ions and sodium ion on iron(III) antimonate have also been described.[9] The ion exchange characteristics of iron(III) antimonate are of considerable interest since it behaves as a cation exchanger with different selectivities for cations.[10]

Limiting our attention to series of ions belonging to the same group of the periodic table, that is having the same valency and similar electronic structure, we can study the effects of ion size and hydration upon equilibria eliminating the problem of the influence of eletronic and valency differences. Alkali metal ions can be taken as models for metal ions since they have univalent positive charge. Furthermore, they form inoic bonds and the effect of complex formation can be avoided.

Experimental

The iron(III) antimonate was prepared as described previously.

Determination of Maximum Uptake of Alkali Metal Ions on Iron(III) Antimonate. A 0.1 mol dm^{-3} solution of alkali metal chloride was passed continuously through the iron(III) antimonate column in H^+ form until the change in concentration of the alkali metal ion was negligible between the influent and effluent. The equivalent fraction of H^+ and M^+ in iron(III) antimonate was calculated on the basis of total exchange capacity.

Ion Exchange Equilibria. In the forward reactions the iron(III) antimonate (0.5 g) in H^+ form was immersed in 20 cm^3 of a mixed solution of varying ratio of alkali metal chloride/hydrochloric acid in the conical flasks with intermittent shaking at 30±1, 40±1, 50±1 and 60±1 °C. The ionic strength in the mixed solution was adjusted to 0.1 with hydrochloric acid.

In the reverse reactions the ion exchanger iron(III) antimonate in the respective alkali metal forms corresponding in weight (0.5 g in the hydrogen form) was immersed in the 20 cm^3 of the mixed solution of alkali metal chloride/hydrochloric acid at an ionic strength of 0.1.

Theoretical Aspects. The ion exchange reactions of the univalent alkali metal ions/H^+ exchange systems on iron(III) antimonate can be represented by the following expression:

$$\bar{H}^+ + M^+ \rightleftharpoons \bar{M}^+ + H^+, \quad (1)$$

where the bar refers to iron(III) antimonate phase and M^+ is the alkali metal ion.

The corrected selectivity coefficient of the above reaction can be defined as:

$$K_c = \frac{\bar{X}_M \cdot X_H}{\bar{X}_H \cdot X_M} \frac{\gamma_H}{\gamma_M}, \quad (2)$$

where K_c is the corrected selectivity coefficient, $\bar{X}_M$ and $\bar{X}_H$ are the equivalent fractions of the metal and H^+ in the exchanger phase, respectively. X_H and X_M are the equivalent fractions of exchanging H^+ and M^+ in the solution phase, respectively. γ_H and γ_M the activity coefficients of hydrogen and the metal in solution respectively. For dilute concentrations the contribution of the activity coefficient ratio (γ_H/γ_M) may be taken as unity.

The thermodynamic equilibrium constant K_a can be calculated using the simplified form of the expression given by Gains and Thomas (11):

$$\ln K_a = \int_0^1 \ln K_c d\bar{X}_M. \quad (3)$$

The change in the free energy of the ion exchange reaction, ΔG° was calculated from the thermodynamic equilibrium constant K_a using the expression:

$$\Delta G^\circ = -RT \ln K_a. \quad (4)$$

The standard enthalpy change, ΔH° has been calculated from the plot of $\log K_a$ against $1/T$.

The standard entropy change, ΔS° is then calculated by the relation:

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ. \quad (5)$$

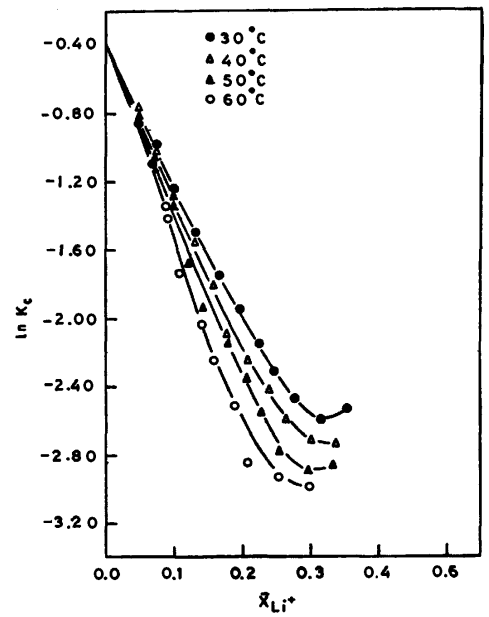

Fig. 5. Logarithms of selectively coefficient *vs.* ionic fractions of Li^+ in exchanger phase.

Results and Discussion

The equilibrium was attained for the forward and backward ion exchange reactions within 6 h shaking. The ion exchange isotherms for the systems Li^+/H^+, Na^+/H^+, K^+/H^+, and Rb^+/H^+ in a temperature range of 30—60 °C are shown in Figs. 1 to 4. Ion exchange isotherms have been used to represent graphically experimental data pertinent to ion competition (at different concentration ratios).

For Li^+/H^+ and Na^+/H^+, the isotherms showed that the exchange does not go to completion although entering cation is initially preferred and the degree of exchange gives a value lower than unity. For K^+/H^+ and Rb^+/H^+ the entering cations show a selectivity reversal with increasing equivalent fraction in the exchanger. The isotherms for the reverse exchange are performed only at 30±1 °C and can be plotted

TABLE 1. THERMODYNAMIC PARAMETERS ON IRON(III) ANTIMONATE AT AN IONIC STRENGTH OF 0.1 AND VARIOUS TEMPERATURES

Alkali metal ion	K_a				$\Delta G°$/kJ equiv^{-1}				$\Delta H°$/kJ equiv^{-1} 30—60 °C	$\Delta S°$/J equiv^{-1} deg^{-1}
	30 °C	40 °C	50 °C	60 °C	30 °C	40 °C	50 °C	60 °C		
Li^+	0.08	0.06	0.05	0.04	6.50	7.20	8.10	8.78	17.06	77.60±0.17
Na^+	0.05	0.04	0.03	0.02	7.69	8.74	9.61	10.66	22.17	98.40±0.35
K^+	0.37	0.30	0.27	0.22	2.56	3.15	3.55	4.18	13.85	54.14±0.18
Rb^+	0.60	0.51	0.45	0.40	1.31	1.74	2.17	2.56	11.09	40.98±0.23

TABLE 2. HYPOTHETICAL THERMODYNAMIC DATA ON "ZERO LOADING" OF THE ION EXCHANGE REACTION AT 30 °C

	Li^+	Na^+	K^+	Rb^+
$\ln K_{c\,\bar{x}_M \to 0}$	−0.35	−1.50	−2.00	−1.25
$\frac{\Delta G°_{\bar{x}_M \to 0}}{\text{kJ equiv}^{-1}}$	0.88	3.79	5.06	3.16
$\Delta H°_{\bar{x}_M \to 0}$	0.00	0.00	0.00	0.00
$\frac{\Delta S°_{\bar{x}_M \to 0}}{\text{J equiv}^{-1}}$	−2.9	−12.5	−16.7	−10.4

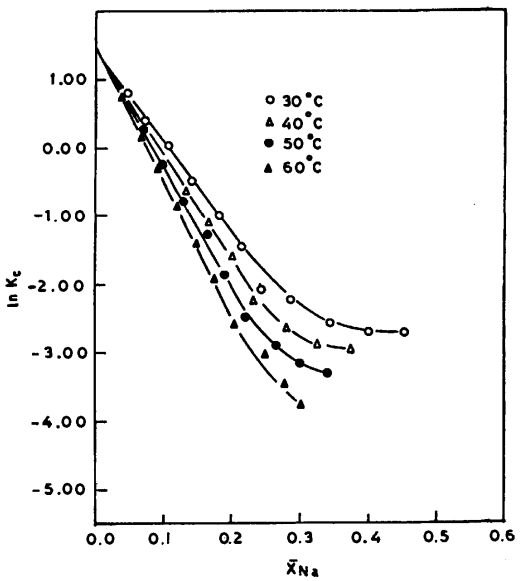

Fig. 6. Logarithms of selectivity coefficient *vs.* ionic fractions Na^+ in exchanger phase.

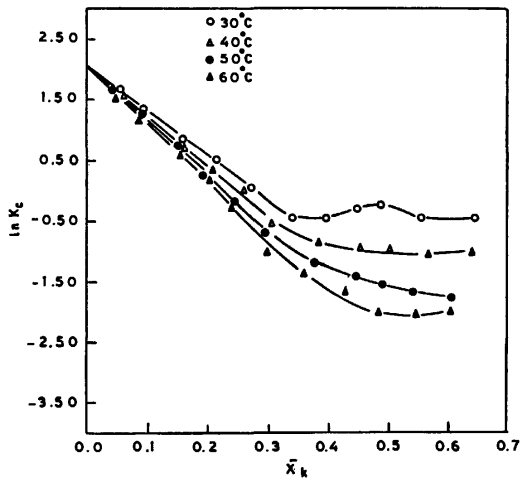

Fig. 7. Logarithms of selectivity coefficients *vs.* ionic fractions of K^+ ions in the exchanger phase.

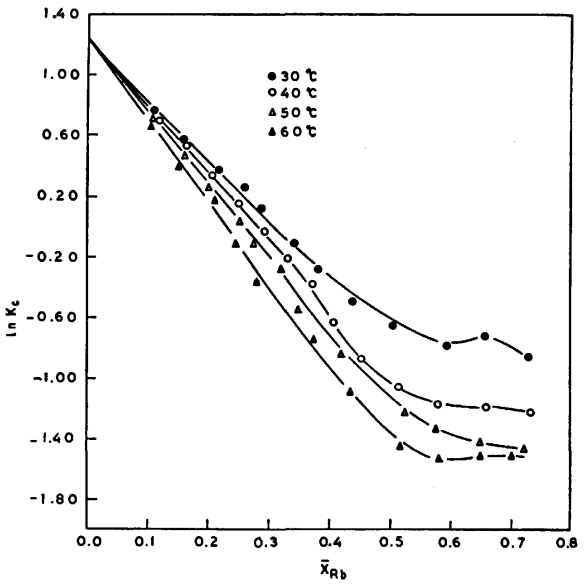

Fig. 8. Logarithms of selectivity coefficients *vs.* ionic fractions of Rb in exchanger ohase.

on the curves of the isotherms for the forwared exchange (Fig. 1 to 4). Thus the ion exchange reactions are reversible throughout the entire range of the compositions studied.

The selectivity of the exchanger can be measured in terms of K_c, which is the quantitative measure of the prefernce of the exchanger for one ion over another in solution with it. The ln K_c *vs.* $\bar{X}_M$ which is referred to as Kielland plot gave fairly straight line for all systems at lower values of $\bar{X}_M$ (Figs. 5 to 8). The linear Kielland plot was also observed for the alkali metal ions/H^+ systems on crystalline antimonic acid.

The thermodynamic equilibrium constant K_a was evaluated from Eg. 3 by assuming that the relation between ln K_c *vs.* $\bar{X}_M$ remains unity over entire range 0 to 1 of X_M. The $\Delta H°$ and $\Delta S°$ showed a corresponding change in their values with the change in temperature since the plots of log K_a *vs.* $1/T$ showed fairly good linearity over the entire range of temperatures studied. The thermodynamic selectivity series was found to be:

$$Na^+ < Li^+ < K^+ < Rb^+.$$

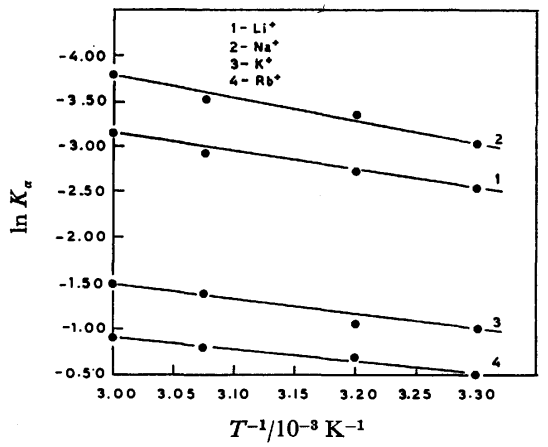

Fig. 9. Temperature dependence of thermodynamic equilibrium constant.

Interpretation of the Selectivity in the Infinitesimal Concentration of the Alkali Metals. The hypothetical thermodynamic data in infinitesimal concentration were calculated for interpretation of the selectivity of the alkali metal in the trace amounts on iron(III) antimonate and for comparison with those data obtained with other exchangers. The values of $(\ln K_c)\overline{X}_M \rightarrow 0$ were obtained by extrapolating to "zero loading" (7) of the alkali metals on Fig. 5—8. From these values the hypothetical thermodynamic data were calculated by the similar treatment as for the overall equilibrium constants. The accuracy of these values may be higher than those of the latter. The calculated $(\Delta H^\circ)\overline{X}_M \rightarrow 0$ values indicate that there is no enthalpy change in the reaction when metal ion concentration in the solid phase approaches to zero over the entire range of temperatures. While the $(\Delta S^\circ)\overline{X}_M \rightarrow 0$ increases with increasing ionic radii of alkali metals except for Rb^+.

The Authors are thankful to Prof. W.Rahman, Head, Department of Chemistry, Aligarh Muslim University, Aligarh. One of the authors (B.S.) is thankful to C.S.I.R., New Delhi for financial assistance.

Extraction and Spectrophotometric Determination of Iron(III) with N^1-Hydroxy-N^1,N^2-diphenylbenzamidine in Presence of Azide

Ghirma Moges, Demirew Assefa, and Bhagwan Singh Chandravanshi*
Department of Chemistry, Addis Ababa University, P.O. Box 1176, Addis Ababa, Ethiopia
(Received April 11, 1983)

N^1-Hydroxy-N^1,N^2-diphenylbenzamidine (HDPBA) reacts with iron(III) in the presence of azide to give a violet-coloured complex insoluble in water. The mixed ligand complex having a composition of 1:2:2 (Fe: HDPBA:N_3^-) is quantitatively extracted into chloroform at pH 2—5. The violet-coloured complex has an absorption maximum at 530 nm with a molar absorptivity of 4900 l mol^{-1} cm^{-1}. On the basis of this sensitive colour reaction, a highly selective method has been developed for the extraction and spectrophotometric determination of microgram quantities of iron(III). The effect of foreign ions and several experimental variables have been studied. The method is simple, rapid, precise, and free from the regid control of experimental parameters.

N^1-Hydroxy-N^1,N^2-diphenylbenzamidine (HDPBA) and its analogues are typical monobasic and bidentate chelating agents for metal ions.[1—18] These reagents have been used for the spectrophotometric determination of iron(III) in ethanol.[19,20] However, the method is neither sensitive nor selective and suffers from the serious interferences due to many common metal ions. Recently N^1-Hydroxy-N^1,N^2-diarylbenzamidines have been reported[21] as reagents for the extraction and spectrophotometric determination of iron(III) in the presence of azide. This method, though quite selective is relatively less sensitive. Beside these, the method requires a large excess of the reagent for the complete extraction of iron(III) and benzene is used as a solvent which is lighter than water, and in which the reagent is relatively less soluble. Hence, in the present investigation, detailed studies have been made for the extraction of iron(III) with HDPBA and azide in different experimental conditions to overcome these problems. These studies have resulted in the development of simple, rapid, sensitive, and highly selective method for the extraction and photometric determination of iron(III).

The present investigation deals with the extraction and spectrophotometric determination of microgram quantities of iron(III) as a mixed ligand complex with HDPBA and azide. The present method is more sensitive and highly selective than the parent HDPBA method[19] and other methods[21] using HDPBA analogues as reagents. The present paper also describes a new extraction-photometric method for the determination of iron(III) as simple chelate complex with HDPBA in chloroform. However this method is not selective and is relatively less sensitive.

Experimental

Apparatus. A Beckman(R) model 24 UV-VIS spectrophotometer equipped with 1-cm quartz cells was used for absorbance measurements. A Beckman CHEM MATE pH meter was used for the measurements of pH. A Pye Unicam model SP 191 atomic absorption spectrophotometer equipped with a hallow cathode lamp and air-acetylene flame was used for the determination of iron in the aqueous phase.

Standard Iron(III) Solution. A stock solution of iron(III) was prepared by dissolving 4.0402 g of hydrated iron(III) nitrate (BDH, Analar) in 100 ml of 1:5 (v/v) nitric acid and diluted to 1 litre with distilled water. This solution was standardized gravimetrically.[22] A working solution of iron(III) was prepared by diluting a suitable aliquot of stock solution with distilled water to give 0.1 mg of iron(III) per millilitre.

A 1 M (M=mol dm^{-3}) solution of azide was prepared by dissolving sodium azide (BDH, AnalaR) in distilled water. All the other chemicals used were of analytical reagent grade.

Reagent Solutions. The reagent, HDPBA, was prepared by the condensation of *N*-phenylbenzimidoyl chloride with *N*-phenylhydroxylamine in diethyl ether medium at low temperature, mp 163 °C; reported[1,19] 163 °C.

A 0.25% (w/v) solution of the reagent in acetone was used for the formation of simple iron(III)–HDPBA complex and its subsequent extraction into chloroform. A 0.1% (w/v) solution of the reagent in chloroform was used for the extraction of mixed ligand complex.

Procedure for Extraction of Iron(III) as Mixed Ligand Complex. Transfer an aliquot of iron(III) solution containing 30—300 μg of the metal in a 50-ml beaker. To this, add 10 ml of 1 M sodium azide solution and adjust the pH to 2—5 with 2 M hydrochloric acid. Transfer the solution into a 100-ml separatory funnel, wash the beaker with few ml of water, and add the washings to the funnel. Adjust the volume of the aqueous phase to 25 ml and add 10 ml of 0.1% (w/v) solution of reagent in chloroform. Shake the mixture for two min and allow the two phases to separate. Collect the organic phase into a 50-ml beaker containing about 2 g of anhydrous sodium sulfate. Wash the aqueous phase twice with 5 ml of chloroform and add the washing to the main extract. Transfer the coloured extract into a 25-ml volumetric flask and dilute to volume with chloroform. Measure the absorbance at 530 nm against chloroform as a reference.

Procedure for Extraction of Iron(III) as Simple Complex. Transfer an aliquot of iron(III) solution containing 0.05—0.40 mg of the metal in a 50-ml beaker. To this, add 5 ml of 0.25% (w/v) solution of the reagent in acetone and dilute the solution to about 20 ml with water. Adjust the pH of the solution to 8—10 using 1 M ammonia or 1 M hydrochloric acid. Transfer the solution into a 100-ml separatory funnel and wash the beaker with few ml of water and then with chloroform and add the washings to the funnel. Adjust the volumes of aqueous and organic phases to 25 and 10 ml respectively and then proceed as for extraction of mixed ligand complex. Measure the absorbance at 520 nm against chloroform as a reference.

Results and Discussion

Absorption Spectra. The absorption spectra of the reagent (HDPBA), iron(III)–HDPBA complex, and

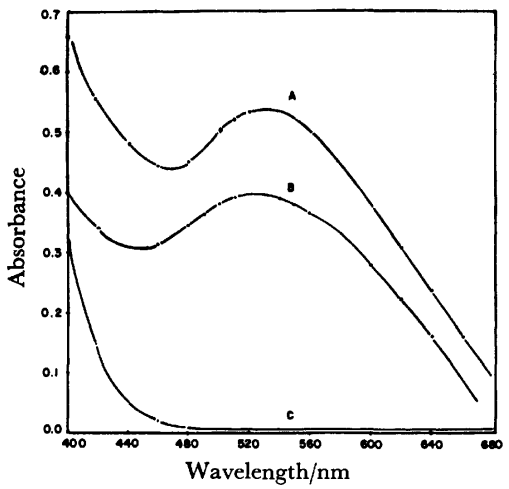

Fig. 1. Absorption spectra of iron(III) complex and reagent.
A: 1.09×10^{-4} M Fe(III) + 1.8×10^{-3} M HDPBA + 0.4 M azide, B: 1.09×10^{-4} M Fe(III) + 1.8×10^{-3} M HDPBA, C: 1.8×10^{-3} M HDPBA in chloroform.

iron(III)–HDPBA–azide complex in chloroform are shown in Fig. 1. The iron(III)–HDPBA–azide complex shows maximum absorption around 530 nm while iron(III)–HDPBA complex shows maximum absorption at 520 nm. Thus, there is a shift in the absorption maximum due to the formation of mixed ligand complex. As the reagent shows negligible absorption in the region of 450—700 nm, the reagent blank can be replaced by chloroform.

Choice of Solvent. Several organic solvents such as benzene, toluene, *o*-xylene, chlorobenzene, *o*-dichlorobenzene, diethyl ether, chloroform, and carbon tetrachloride were found to extract both the simple and the mixed ligand complexes quantitaively. The spectra of both the complexes were found to be similar in all nonpolar organic solvents. However, slight variations in the absorbance values were noticed. Chloroform was found to be the best solvent because the extraction of iron(III)–HDPBA and iron(III)–azide–HDPBA complexes are readily accomplished in it. It was also preferred because of its higher density than water allowing easy separation from the separatory funnel, its low cost, easy to recover and higher solubility of HDPBA in it than in other solvents.

It has also been found that iron(III) as a mixed ligand complex is quantitatively extracted by the chloroform solution of reagent. However, iron(III) as a simple complex can not be quantitatively extracted by the chloroform solution of reagent. Hence, the reagent was introduced in acetone solution to precipitate iron(III) as iron(III)–HDPBA complex and then the complex was quantitatively extracted by chloroform. However, care must be exercised about the amount of acetone in the aqueous phase that it should not exceed more than 50% (v/v). Increasing amount of acetone in the aqueous phase decreases the percent extraction of iron(III) as well as separation of the two phases becomes difficult.

Effect of pH. The optimum pH range for the complete extraction of iron(III)–HDPBA complex was found to be 8—11 while in the presence of azide, the optimum pH range for the complete extraction of iron(III)–HDPBA–azide complex was found to be 2—5. Thus, the pH range for complete extraction of iron(III) has been shifted from basic to the acidic medium due to formation of the mixed ligand complex. It has also been found that there is no formation of mixed ligand complex in the strongly acidic medium as reported by earlier workers.[21]

Effect of Amount of Reagents. A 1:8 molar ratio of iron to HDPBA was found to be adequate for the complete extraction of iron(III)–HDPBA complex while a 1:5 molar ratio of iron to HDPBA was necessary for the complete extraction of azide–iron(III)–HDPBA complex. A large excess of the reagent upto 50-fold had no adverse effect. Thus, the present method has a distinct advantage over the reported method.[21] in which a large excess of reagent (30-fold) is required for the complete extraction.

The optimum concentration range of azide in the aqueous phase for the complete extraction of iron(III) as a mixed ligand complex was found to be 0.25 to 0.50 M. Higher concentration of azide upto 1.0 M did not have any effect on the extraction. It was also found that the extraction of iron(III)–HDPBA–azide complex is dependent on the concentration of azide in the aqueous phase and not simply on the molar ratio of iron(III) to azide as reported in literature.[21]

Effect of Other Variables. Both the simple and mixed ligand complexes were completely extracted into chloroform within 2 min. The chloroform extracts of both the complexes were stable for at least 48 h at 27±2 °C. The volume of the aqueous and organic phases can vary from 1:1 to 5:1 without any adverse effect on the absorbance values or the extraction efficiency of both systems. Variation in temperature of the aqueous phase between 20 and 35 °C did not affect absorbance value of both the systems.

Beer's Law, Optimum Concentration Range, Molar Absorptivity, Sensitivity, and Precision. Beer's law obeys in the concentration ranges 1.8—16 ppm for simple system and 1.2—11.2 ppm of iron(III) for mixed ligand complex system. The optimum concentration ranges for the determination of iron as evaluated from the Ringbom's plot[23] are 3.0—14 ppm and 2.4—10 ppm for simple and mixed ligand complex systems respectively. The molar absorptivities of the Fe(III)–HDPBA and Fe(III)–HDPBA–azide complexes are 3.6×10^{3} and 4.9×10^{3} l mol^{-1} cm^{-1} respectively. The photometric sensitivities[24] of the colour reactions are 0.0155 and 0.0114 μg cm^{-2} of iron(III) for simple and mixed ligand complexes respectively. Thus, the present method is found to be more sensitive than the literature method[21] with similar reagents.

The relative standard deviations for the determination of iron(III) as simple and mixed ligand complexes were found to be ±0.50 and ±0.70% respectively.

Effect of Foreign Ions. The influence of foreign ions was studied by adding known quantities of an ion in question to an aliquot of standard iron(III) solution and determining the iron content according to the procedures described earlier. The tolerence limits of foreign ions (ppm) which causes an error less than

±2% are shown in parentheses.

Mixed Ligand Complex System (pH=3.0, 6 ppm Iron). Chloride, nitrate, sulfate (2000); arsenate, phosphate, borate (400); citrate or tartrate (100); cyanide or thiocyanate (40); ammonium (2000); alkali and alkaline earth metals (1000); Zn^{2+} or Cd^{2+} (800); Cr^{3+} or Mn^{2+} (600); Ti^{4+} or Zr^{4+} (800); Al^{3+} or La^{3+} (400); Ni^{2+} or Co^{2+} (400); Cu^{2+} (200); Hg^{2+} (200); Mo^{6+} (50); U^{6+} (50).

Vanadium(V) interferes with the determination. However, its interference was eliminated by its prior extraction at pH 0.5 and then iron(III) was extracted after raising the pH to 3.0

Simple Complex System (pH=9, 8 ppm Iron). Chloride, nitrate, sulfate (2000); phosphate, arsenate, borate (400); citrate, tartrate (200); alkali and alkaline earth metals (1000); ammonium (1000); Zn^{2+}, Cd^{2+}, Hg^{2+} (200); Al^{3+}, La^{3+} (200); Cr^{3+} (200); Th^{4+} (200); Ti^{4+}, Zr^{4+} (100); W^{6+} (50). Cu^{2+}, Ni^{2+}, Co^{2+}, Mn^{2+}, V^{5+}, Mo^{6+}, and U^{6+} interfere with the determination of iron(III) with HDPBA and the method is not selective.

Thus, there is a great improvement in the selectivity of the method for the determination of iron(III) with HDPBA due to formation of mixed ligand complex in the presence of azide. Furthermore, the sensitivity of the method is also increased considerably.

Composition of Complexes. The composition of both complexes were determined by different methods.[25] The ratio of iron(III) to HDPBA in Fe(III) HDPBA complex was determined by continuous variations[26] and mole ratio[27] methods. The result obtained by both methods indicates the formation of 1:3 (Fe:HDPBA) complex. The ratio of iron(III) to HDPBA in the mixed ligand complex was also determined by continuous variations and mole ratio methods. The concentration of azide was kept constant excess for these experiments. To determine the ratio of iron(III) to azide, the concentration of iron(III) was kept constant and HDPBA was taken in constant excess, and then the concentration of azide was varied. Iron(III) was extracted as a mixed ligand complex into chloroform and determined according to the procedure described earlier. The remaining iron(III) in the aqueous phase was determined by atomic absorption spectroscopy and the distribution ratio, D, of iron(III) was calculated at different concentrations of azide in the aqueous phase. Log D was plotted aqainst log $[N_3^-]$. The slope of the curve gave the number of azide ions in the ternary complex. These results indicated the formation of 1:2:2 (Fe:HDPBA:N_3^-) mixed ligand complex. It may be suggested from the composition and extractability as a neutral complex into chloroform that only one HDPBA molecule is deprotonated in the complex formation. However, the structure of the mixed Ligand complex has not been confirmed.

It can be noted that the earlier workers[21] have reported the composition of the mixed ligand complex as 1:1:2 (Fe:HDPBA:N_3^-). In contrast to that, it has been found to be 1:2:2 (Fe:HDPBA:N_3^-) in the present investigation.

Silent Electric Discharge in the Equimolar Dihydrogen-Carbon Monoxide Mixture

Sintaro HATA, Koji HIRAMOTO, Katsuaki KATOH and Kazuo SASAKI*

Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Saijo-cho, Higashi-Hiroshima 724

(Received April 11, 1983)

Synopsis. The purpose of this paper is focused on seeking the possibility of utilizing electric discharge in H_2–CO mixtures as a mean of industrial processes. Along this line, the silent discharge in the equimolar mixture of CO and H_2 has been studied as a function of both the flow rate of reacting gas mixture and the length of the discharge tube. The yield of formaldehyde, the main product, increased with increasing flow rate of gas. At a given flow rate, however, the yield increased with increasing tube length indicating that the selectivity of formaldehyde can be increased steadily by increasing the rate of gas flow. The best value of the formaldehyde selectivity was 34% at the shortest residence time (0.25 s). Improvement of this value seems to be promising.

Although recent development of plasma chemistry[1,2] is attracting a growing attention in several special fields, the application of it for the mass production industry seems very limited. However, it is also a fact that the glow discharge has been utilized in ozone production and also in acetylene industry.[3] This shows that there still remain possibilities of utilizing the discharge reaction in some organic raw material industries. We thus attempted to study the reaction occuring in an equimolar mixture of H_2 and CO. There are several papers[4–7] which deal with the same gas system with use of various modes of discharge. Among these, Blaustein and Fu[6] showed that in a microwave discharge in static gas (H_2/CO=5) gave conversion of CO to CH_4 an C_2H_2 of approximately 17 and 22%. No yield of HCHO was reported. Quite recently, the system has been studied by Bauer[7] using several modes of glow discharge (dc, pulsed dc and rf). Reaction products seem a complex mixture and only a few compounds were analyzed quantitatively.

Experimental

An equimolar mixture of H_2–CO was used as the reactant. A 135 VA transformer provided high voltage upto 15 kV. Four discharge tubes having the same dimensions of tube diameters (o.d.=12, i.d.=10 mm) but different in tube length (2, 6, 12, and 24 cm) were used. The reactor circuit was composed of a small diaphragm pump, a rotameter and two-stage gas trap which were placed in series with the discharge tube. A gas burette, which served as the gas reservoir, was connected to the gas circuit. Of the two gas traps, one contained 150 ml of water to trap water soluble products and the other was cooled by Dry Ice–methanol mixture. Total volume of the gas circuit except the gas burette was *ca.* 840 ml. Discharge voltage was fixed at 12 kV throughout the experiments.

The product analyses were carried out separately for the gaseous products and the liquid products. Formaldehyde which was trapped in water was analyzed spectrophotometrically with use of acetylacetone and ammonium acetate. Sampling was made periodically in every 2 h. For the gaseous products, 1 ml of gas was taken with an injection syringe while for formaldehyde 10 ml of trap water was withdrawn for each time. After each time of sampling, 10 ml of fresh water was supplied to the water trap to keep the amount of trapping water constant (150 ml).

Results and Discussion

Experiments were conducted by circulating the reacting gas mixture. The gas flowing out of the discharge tube was first led to the water trap to remove the water soluble products and then to the cold trap to condense components of high boiling point. Actually, however, no detectable amount of condensate was obtained in the cold trap other than water which came from the water trap. A small amount of oily material accumulated gradually on the surface of the discharge tube.

Result of gas phase analysis is listed in Table 1. It is seen that CH_4, CO_2, and C_2H_6 are the major products in the gas phase. It is a marked contrast that no acetylene was detected in our system, while it is dominant in the discharge reaction in low pressure gases.[6,7]

The amount of HCHO trapped in water was analyzed separately. No effort was made for methanol and other alcohols which might be existed in the water trap.

General features of HCHO production can be summarized as follows.

1. In every measurement, regardless of both the tube length and flow rate, the accumulation of HCHO in water trap exhibits a downward convex curve against the reaction time, *i.e.*, the rate is rather dull at the initial stage of reaction but becomes increasingly fast with the elongation of the reaction time. This is a marked contrast to the accumulation of CH_4 in gas phase, where the amount of CH_4 increases almost linearly with the increase of reaction time.

TABLE 1. COMPOSITION OF GAS PHASE PRODUCTS

Compound	Concn/mol%
H_2	49.706
CO	39.551
Air	2.386
CO_2	3.580
CH_4	4.676
C_2H_4	0.094
C_2H_8	0.006
C_4	Trace
C_5	Trace

Tube length: 6 cm. Flow rate: 42 ml min^{-1} Discharge time: 12 h.

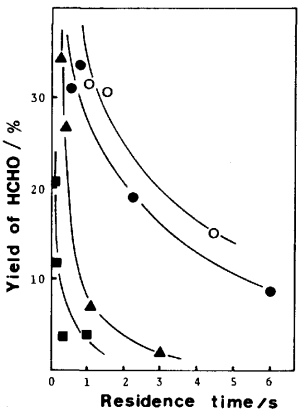

Fig. 1. Percentage yield (selectivity) of formaldehyde after 12 h of reaction as a function of the residence time. Discharge voltage: 12 kV. Curve parameter is the length of tube. ○: 24 cm, ●: 12 cm, ▲: 6 cm, ■: 2 cm.

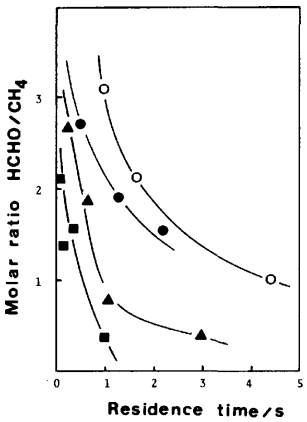

Fig. 2. Molar ratio of formaldehyde to methane against the residence time. Symbols are same as in Fig. 1.

2. The yield of HCHO increases with the increasing flow rate when the tube length is fixed. This effect is, however, only significant at the lower flow rate (*ca.* 300 ml min^{-1}) and becomes insignificant at higher rates. The effect of flow rate on the CH_4 formation seems, on the other hand, to be opposite and the lower flow rate seems to favour the production of CH_4.

3. When the flow rate is fixed, the HCHO yield increases almost linearly with increasing tube length. This applies also to the formation of CH_4.

The downward convex shape observed in the accumulation curve of HCHO seems to suggest that some sort of intermediate(s) is converted gradually to HCHO to enhance the reaction rate. On the other hand, the accumulation of CH_4, being the most dominant gaseous product, increases almost linearly with the reaction time. It is thus more likely that the accumulation of some compounds, which is rather inert against the discharge reaction than H_2 or CO themselves, will act as the energy carrier (sensitizer) as rare gas atoms do. Methane may be a candidate if this is the case.

The percentage yield of HCHO after 12 h. of the discharge reaction is plotted in Fig. 1 against the residence time (τ) of flowing gas molecule in the discharge tube. In this figure, values of percentage yield were calculated on the base of total gas volume decreased and no correction was applied for the volume occupied by gaseous products. Similarly, the molar ratio of $HCHO/CH_4$ in the reaction products is shown in Fig. 2. In these figures, lines were drawn to connect points of the same tube length. Figure 1 indicates clearly that the shorter the residence time the better the yield of HCHO, and that the increase in the tube length favours the formation of HCHO.

As has been described above, the effect of flow rate on the yield of HCHO is insensitive at higher flow rate. This indicates, at least apparently, that the use of an execessive flow rate is meaningless for increasing the yield of HCHO. However, the increase in flow rate results in the diminution of CH_4 yield reflecting upon the steep rise of the selectivity of HCHO as is seen in Figs. 1 and 2.

The rather contradicting findings with respect to the tube length and the residence time tell us that, at a given tube length, the decrease in the residence time improves the product selectivity. Note that the integrated residence time ($N\tau$, N being the number of circulation over the whole reaction time) is unchanged by the change of flow rate when the tube length is fixed. It should be also noted that, when a comparison is made at a fixed residence time, the integrated residence time increases with increasing tube length. This must increase the product yield.

Concluding Remarks

Results obtained can be summarized as follows. The main product of silent discharge reaction occuring in equimolar H_2–CO mixture at atmospheric pressure is formaldehyde, which has never been noticed in the recent works using glow discharge[7] and microwave discharge[6] conducted in low pressure gas mixtures. Although methane is found to be the second dominant product in agreement with these authors, it is contrasting that no acetylene is detectable in our experiment.

Experiments has been conducted (along the line) to increase the selective formation of formaldehyde over many by-products particularly methane. (In order to accomplish this purpose.) It was found essential to shorten the one pass-residence time. For instance, with a Siemens tube of 6 cm length the selectivity of formaldehyde increased steeply from 2.0 to 34.3% by decreasing residence time from 3.0 to 0.25 s, respectively. Corresponding to these figures, molar ratio $HCHO/CH_4$ increased from 0.22 to 2.6.

The linear velocity of flowing gas which employed in the present experiments was in the order of 24 cm s^{-1} at the highest. A hundred times greater velocity can easily be attained. If the length of discharge tube could be elongated to such a degree without purturbing the reaction conditions employed here, a very high selectivity of HCHO production is expected.

The authors are indeed grateful to the reviewer who kindly gave us notice of Bauer's work.[7]

XPS Studies of the Platinum Species Photodeposited on Titania from Aqueous Chloroplatinic Acid

Choi Sungbom,† Maki Kawai,†† and Kazunori Tanaka*
The Institute of Physical and Chemical Research (Riken), Wako, Saitama 351
(Received July 1, 1983)

Synopsis. Several Pt/TiO_2 catalysts were prepared by photodeposition from aqueous H_2PtCl_6 in the presence or absence of a CH_3COOH-CH_3COONa buffer. The examination of these catalysts by X-ray photoelectron spectroscopy (XPS) revealed that the higher the buffer concentration, the more highly reduced the deposited platinum became.

Platinum-loaded titania (Pt/TiO_2) is known as the most active catalyst in a number of photocatalytic processes. As a means of platinum loading, the photodeposition method of Kraeutler and Bard[1] has been widely used. In this method, the platinizing solution contains acetate, which is considered to act as the reducing agent. Although these authors claimed that the platinum deposit is really metallic, Koudelka *et al.*[2] found no perceptible quantities of metallic platinum on their Pt/TiO_2 samples, which had been prepared by a similar method. Lehn *et al.*,[3] on the other hand, photodeposited platinum from aqueous K_2PtCl_4 on $SrTiO_3$ without adding any organic material.

It thus seemed expedient to prepare a series of Pt/TiO_2 catalysts from aqueous H_2PtCl_6 solutions containing different concentrations of a CH_3COOH-CH_3COONa (AH-ANa) buffer and to examine the oxidation state of the platinum deposit. It would also be interesting to see how the platinum oxidation state of these catalysts varies after their use in typical photosynthetic or photocatalytic reactions. Methanol decomposition and benzene oxidation have been chosen for this purpose.

Experimental

Apparatus. The platinum oxidation state of Pt/TiO_2 catalysts was examined by means of a Hewlett-Packard 5950A X-ray photoelectron spectrometer with monochromatized Al $K\alpha$ X-rays (1486.6 eV). Spectra were recorded at 250 K with a flood gun. The binding energies E_b are referred to the $4f_{7/2}$ peak (84.0 eV) of the Au evaporated onto the sample.

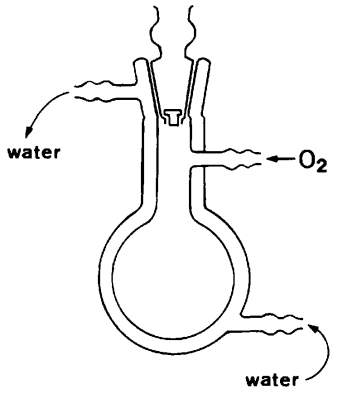

Fig. 1. Reaction vessel II (Water-mantled Pyrex-made).

The lamp-housing quartz reaction vessel (I) used for the platinum photodeposition and methanol decomposition has been described previously.[4] The water-mantled Pyrex reaction vessel (II) used for benzene oxidation is illustrated in Fig. 1. It has a capacity of *ca.* 50 cm^3. The reaction products of the benzene oxidation were analyzed by means of gas chromatography using a 2 m×3 mm i.d. column of 30% PEG 20M on 30—60 mesh chromosorb WAW.

Materials. The rutile-free anatase, with a BET surface area of 11.5 m^2/g, was taken from the same bottle as had been used previously.[4] All the chemicals except for Adams platinum were commercially available and were used as received. The Adams platinum, whose main constituent had been verified to be α-PtO_2 by X-ray powder diffraction, was generously supplied by Professor Takagi of Nihon University.

Catalyst Preparation. The procedure for preparing Pt/TiO_2 catalysts (2.5 wt% Pt) has been presented before.[4] In brief, they were prepared by the photodeposition of platinum on TiO_2 from aqueous TiO_2 suspensions containing H_2PtCl_6 and an AH-ANa buffer (pH 4.07). The buffer concentration was varied from catalyst to catalyst, while the H_2PtCl_6 concentration was fixed so as to give 2.5 wt% of Pt for all catalysts.

Kinetic Procedure. The methanol decomposition was run in reaction vessel I. It was charged with the Pt/TiO_2 catalyst (50 mg), methanol (100 cm^3), and distilled water (100 cm^3). After 30-min N_2 bubbling with magnetic stirring, this reaction mixture was irradiated with a 100-W high-pressure Hg lamp for 1 h at 40 °C, with continued magnetic stirring.

The benzene oxidation was run in reaction vessel II. It was charged with water (10 cm^3), benzene (1 cm^3), and the Pt/TiO_2 catalyst (50 mg), set on a shaker, and connected to an atmospheric O_2 bulb. The reaction mixture was irradiated at 20 °C for 3 h with vigorous shaking with a 500-W Xe lamp, using two filters, UV-33 and IRA-25S, in series. After the reaction, acetic acid (15 cm^3) was added to make the reaction mixture homogeneous, and aliquots were analyzed for phenol.

Results

Oxidation State of the Photodeposited Pt. All of the catalyst samples prepared were examined by means of XPS. The XPS spectra are shown in Fig. 2A. The molar ratios (AH+ANa)/H_2PtCl_6 pertaining to each catalyst preparation are given in Table 1. A comparison of the XPS spectra with these molar ratios reveals that the lower the ratio, the more oxidized state the deposited platinum remains in.

Figure 2B shows the Pt 4f spectra taken with a Pt plate and PtO_2 powders, together with the standard E_b values ($4f_{5/2}$ and $4f_{7/2}$) for Pt^0 and Pt^{IV} determined from these spectra. The corresponding values for Pt^{II} obtained with PtO are 76.6 and 73.4 eV, according to Kim *et al.*[5] Turning back to Fig. 2A, we see that the triplet character (peaks at 73.5, 76.0, and 78.8 eV) of Sample 5 prepared from a buffer-free suspension is

5	0	II+IV	0.10

a) The molar ratio of acetic acid (AH) plus sodium acetate (ANa) to hexachloroplatinic acid (H_2PtCl_6). AH/ANa=4.56, giving rise to a pH of 4.07. b) The main oxidation states of the deposited platinum, judged from the XPS spectra of Fig. 2. c) Percentage conversion of benzene to phenol. d) Hydrogen-treated sample 1 (*cf.* Fig. 2).

attributable to the partial overlap of the two doublets of the Pt^{II} and Pt^{IV} species; the Pt^{II} $4f_{5/2}$ and Pt^{IV} $4f_{7/2}$ components are superimposed on each other. Upon the addition of an acetate buffer (Sample 3 or 4), the left-wing peak of the triplet became smaller, while the right one was intensified, suggesting the enrichment of the Pt^{II} components. Upon going to a higher buffer concentration (Sample 2), only the Pt^{II} species became predominant. A still further increase in the buffer concentration (Sample 1) resulted in an ill-defined spectrum, which, however, suggests the appearance of Pt^0. The main platinum oxidation states thus estimated from Fig. 2A for each catalyst are listed in Table 1.

The Cl/Pt molar ratio of the photodeposited species was less than 0.7, judging from the area under the Cl 2s peak. This is a much smaller amount of chlorides than would be expected from the $PtCl_6^{2-}$ or $PtCl_4^{2-}$ adsorption; it is in qualitative agreement with the results of Koudelka *et al.*[2], who found a Cl/Pt ratio<1.

Photodeposition Process. From the above results, it may be concluded that the photodeposition from aqueous H_2PtCl_6 on TiO_2 does not yield Pt^0 unless acetate is present in a large excess relative to the platinum complex. Even in a large excess of it, the deposited platinum species tend to remain partially in oxidative states, Pt^{II} and Pt^{IV}. In view of the above-mentioned dearth of chloride, these oxidative species must exist as oxides, hydroxides, or chloride oxides rather than as the tetra- or hexachloroplatinate.

On the basis of these findings, one may speculate that these steps occur in photodeposition: (i) the adsorption of $PtCl_6^{2-}$ and $PtCl_4^{2-}$ ions, (ii) the rapid conversion of these chlorides to the oxides or hydroxides, and (iii) their photo-assisted reduction to Pt^0. The mechanism of each step is not yet clear, however.

Pt Oxidation State after Reactions. Figure 2C shows how the Pt 4f spectra of the Pt/TiO_2 catalysts vary after their use or after hydrogen treatment. A comparison of Fig. 2A with Fig. 2C (Samples 1 and 3) reveals that the oxidized platinum is easily reduced to Pt^0 by either mild hydrogen treatment (1 atm, 1.5 h, 20 °C in water) or subjection to methanol decomposition. The reduction due to methanol decomposition seems reasonable in view of the expected occurrence of hydrogen recombination on the platinum surface:

$$2H^+ + 2e^- \rightarrow H_2. \quad (1)$$

In contrast, the subjection of Catalyst 5 to benzene oxidation did not cause any appreciable change in the XPS spectrum. This intactness might result from a subtle balance between the reductive trend due to the H_2 produced by Reaction 1 and the oxidative trend due to the O_2 or H_2O_2 involved in this reaction:

$$O_2 + 2e^- + 2H^+ \rightarrow H_2O_2. \quad (2)$$

The last column of Table 1 compares the catalytic activities of three different catalyst samples for benzene oxidation. The H_2-treated sample (1-HT) bearing only Pt^0 is prominent, exhibiting an activity which is several times that of the other two. This rather unexpected effect of Pt^0 remains to be elucidated.

We wish to thank Dr. Shousuke Teratani of Riken and Dr. Yuzuru Takagi of Nihon University for their valuable suggestions. It is also a pleasure to acknowledge numerous discussions on the XPS data with Dr. Masayuki Uda of Riken. This work was supported by a grant from the Science and Technology Agency towards the Solar Energy Research Project.

Effect of Urea on Hydrophobic Side Chain Interactions in Polypeptides at the Air-Water Interface

Akira SHIBATA,* Shinsuke YAMASHITA, and Takuya YAMASHITA
Faculty of Pharmaceutical Sciencs, Tokushima University, Shomachi, Tokushima 770
(Received October 6, 1983)

Synopsis The surface activity of urea at the polypeptide monolayer-water interface was investigated by the surface pressure analysis. The expansion of the monolayer is attributed to the penetration of polypeptide monolayer by urea in the subsolution. The hydrophobic side chain interactions in polypeptides are weakened by the action of urea. The surface activity of urea depends on the difference in the chemical composition and the geometrical arrangement of side chains between benzyloxycarbonyl derivatives of basic poly(α-amino acid) and benzyl esters of acidic poly(α-amino acid).

In view of the intense current interest concerning the mode of action of denaturants on biological macromolecules, it seems desirable to advance our understanding of this phenomenon by appropriate experimental studies. Considerable evidence exists from model compound studies to the effect that urea (1) interacts strongly with peptide backbone groups, thus weakening interpeptide hydrogen bonds,[1,2] and (2) enhances the solubility of nonpolar groups, thus reducing hydrophobic interactions.[3] It is difficult to assess the relative significance of such effects in studies with natural biopolymers. Thus far synthetic polypeptides as protein analogs have been provided useful informations concerning protein structure and function.

The purpose of this work is to clarify the effect of urea on the hydrophobic side chain interactions in synthetic polypeptides at the air-water interface.

Experimental

Synthetic polypeptides used here were poly(N^{δ}-benzyloxycarbonyl-L-ornithine) (PLO(Z)), poly(N^{ε}-benzyloxycarbonyl-L-lysine) (PLL(Z)), poly(β-benzyl L-aspartate) (PBLA), and poly(γ-benzyl L-glutamate) (PBLG). The samples and spreading solvents were the same as those used in the preceding work.[4] Urea solutions were treated with activated charcoal in order to remove surface active contaminants. A 10 to 1 compression of the surface of the urea subsolutions, after being left to stand for 20 min, produced less than 0.1 mN m^{-1} film pressure. The surface pressure was measured by the Wilhelmy method at 25±0.5 °C. The films were compressed at a rate of 0.01 nm^2 residue^{-1} min^{-1}.

Results and Discussion

Figure 1 shows the π-A curves for PLO(Z) spread on distilled water, and on 1.0, 2.0, 3.0, and 4.0 M (1 M=1 mol dm^{-3}) urea subsolutions. Plateaux are seen in the curves. The plateau which is characteristic of a number of synthetic polypeptide monolayers is associated with the collapse or transition of the monolayer in the α-helical conformation from a two-dimensional oriented state to a three-dimensional disoriented state.[4,5] The surface tension of water increases with an increase in urea concentration.[6] This is due to the desorption of urea from the subsolution surface. Increasing the concentration of urea in the subsolution progressively expanded the condensed regions of PLO(Z) monolayer (Fig. 1). By measuring the change in surface pressure ($\Delta\pi$) due to the change in mole fraction of urea(Δx) in subsolution, the surface concentration of urea was calculated from:[6,7]

$$(1/RT)(\Delta\pi)/(\Delta x)\,|_A = \Gamma_2/x - \Gamma_1/(x-1) = I/x(1-x), \quad (1)$$

where x is the mole fraction of urea, R is 8.3×10^7 ergs per mole, T is the absolute temperature, Γ_1 is the surface concentration of water, Γ_2 is the surface concentration of urea, A is the area per residue of PLO(Z). I is defined by the expression

$$I = (1-x)\Gamma_2 - x\Gamma_1. \quad (2)$$

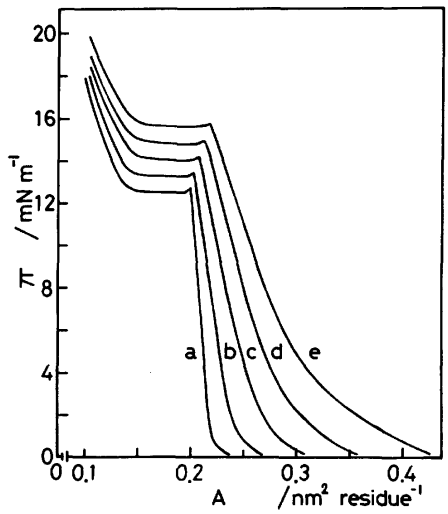

Fig. 1. Surface pressure-area curves for PLO(Z) monolayers on urea subsolutions.

0.23	0.018	1.37
0.23	0.035	2.85
0.23	0.051	3.85
0.23	0.067	4.81
0.25	0.035	2.85
0.25	0.051	3.73
0.25	0.067	4.97
0.27	0.051	3.60
0.27	0.067	4.89

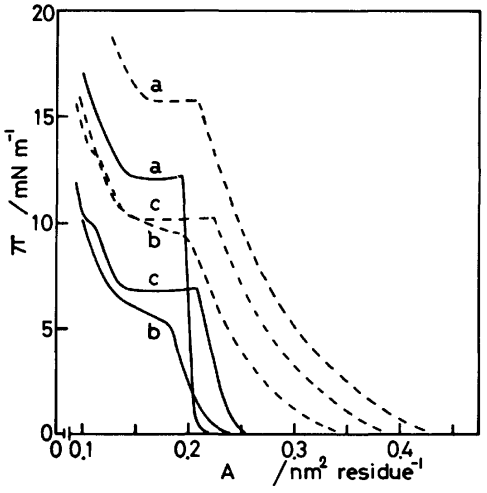

Fig. 2. Surface pressure-area curves for PBLA(a), PBLG(b), and PLL(Z)(c) monolayers on distilled water(——) and 4.0 M urea subsolution(----).

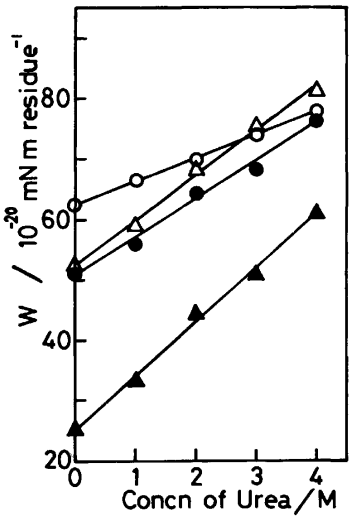

Fig. 3. Work of collapse for PLO(Z)(○), PLL(Z)(●), PBLA(△), and PBLG(▲) monolayers as a function of urea mole fraction.

At the mole fractions of urea used here ($x \leq 0.067$) I is approximately the surface concentration of urea. The results are given in Table 1. When we take the order of magnitude of the effective thickness of the interfacial region to be 10^{-7} cm, for 1, 2, 3, and 4 M bulk concentrations, the concentration of urea in a bulk volume 1 cm×1 cm×10^{-7} cm would be 1×10^{-10}, 2×10^{-10}, 3×10^{-10}, and 4×10^{-10} ml/l, respectively. Therefore, the results indicate that the surface concentration of urea required to provide energy for the observed expansions of the PLO(Z) monolayers is of the same order of magnitude as the bulk concentration of urea (Table 1). There was no surface excess concentration of urea. The film expansion with increase in the concentration of urea can be attributed to the penetration of PLO(Z) monolayer by urea in the subsolution.

Figure 2 shows the π-A curves for PBLA, PBLG, and PLL(Z) spread on distilled water and 4.0 M urea subsolution. The presence of urea brings about the film expansion and the increase in transition pressure for all polymers. The transition pressures were 12.5 mN m^{-1} for PLO(Z), 6.5 mN m^{-1} for PLL(Z), 12.1 mN m^{-1} for PBLA, and 5.3 mN m^{-1} for PBLG, respectively. The addition of one $-CH_2-$ group to the β-C is the direct cause of the lowering of the plateau by 6—7 mN m^{-1}. The lowering of the plateau may arise from the reduction of the adhesion of the polymer to the subsolution by direct hydrophobic interaction with the water, because the methylene side group is close to the backbone.[8]

The work required for collapse of monolayers provides an information concerning the effect of urea on the hydrophobic side chain interactions in polypeptides. The work required for collapse of monolayer, W, is given by

$$W = \pi_{tr} \cdot \Delta A, \tag{3}$$

where π_{tr} is the transition pressure, and ΔA is the difference between initial and final areas of collapse. Figure 3 shows the work of collapse for the monolayers of PLO(Z), PLL(Z), PBLA, and PBLG as a function of urea concentration. The work of collapse for these polymers increases linearly with an increase in concentration of urea, C. The values of dW/dC($\times10^{-20}$ mN m residue^{-1} M^{-1}) were 3.9 for PLO(Z) 6.0 for PLL(Z), 7.6 for PBLA, and 9.0 for PBLG respectively. The addition of one $-CH_2-$ group to the β-C increases the value of dW/dC. This suggests that the hydrophobic side chain interactions in polypeptides are weakened by the action of urea. The obtained values are also larger for benzyl esters of acidic poly(α-amino acid) than for benzyloxycarbonyl derivatives of basic poly(α-amino acid). The surface activity of urea depends on the difference in the chemical composition and geometrical arrangement of side chains between the benzyl esters of acidic poly(α-amino acid) and the benzyloxycarbonyl derivatives of basic poly(α-amino acid).

Synopsis. Single crystals of three new sulfides were prepared in evacuated silica tubes heated in the temperature range 890—1200 °C. Nd_3SbS_6 is a red transparent crystal. Is is tetragonal, space group $I4_1/acd$ with lattice parameters a=15.54(1) and c=19.52(2) Å. $Ce_6Sb_8S_{21}$ and $Ce_3Sb_3S_{10}$ are isostructural with $La_6Sb_8S_{21}$, and $La_3Sb_3S_{10}$, respectively.

Lanthanoid sulfides have been the subject of intensive investigation for their interesting physical properties such as super-conducting property.[2] However, most of these investigations involved binary sulfides of lanthanoid. There has been little effort to prepare ternary sulfides containing antimony.[3,4] We have started this study to clarify the crystal chemistry of the ternary sulfides.

Recently, we studied a La–Sb–S system and obtained the three new compounds, $LaSbO_2S_2$, $La_6Sb_8S_{21}$, and $La_3Sb_3S_{10}$.[5] In the present work, we have extended our experiment to Ce–Sb–S and Nd–Sb–S systems, and found three more new compounds. This paper reports the synthetic conditions and crystal data of these compounds.

Experimental

The syntheses were made by applying the double silica tube method described in the previous paper.[5] The starting materials were cerium and neodymium metal chips (99.9%), sulfur powder (99.99%), and antimony trisulfide (99.99%). They were mixed in various molar ratios, sealed into an evacuated silica tube, and heated in an electric furnace. Temperature and heating period were decided by a trial and error method.

Reaction products were examined by X-ray powder diffraction patterns using a 114.6 mm Gandolfi camera with Ni-filtered Cu $K\alpha$ radiation. X-Ray single crystal measurements were performed on precession and Weissenberg cameras. The least-squares computer program of Appleman and Evans[6] was used to calculate the lattice parameters. Some of the products were chemically analyzed with an electron microprobe analyzer using an operating voltage of 20 kV, and a probe current of 0.02 μA. The standards used were analyzed monazite (Ce), synthetic $Nd_3Ge_5O_{12}$, (Nd) and Sb_2S_3 (Sb and S).

Results and Discussion

The powder diffraction patterns of the products showed the presence of three unknown compounds: two among the products in the Ce–Sb–S system, and one among those in the Nd–Sb–S system. The former two compounds were proved to be $Ce_6Sb_8S_{21}$ and $Ce_3Sb_3S_{10}$ because they exhibited isostructural powder diffraction patterns with those of $La_6Sb_8S_{21}$ and $La_3Sb_3S_{10}$, respectively.[5] On the other hand, the latter compound gave a powder pattern which has never been reported before. The subsequent electron microprobe analysis has revealed it to be Nd_3SbS_6, which is a new type of compounds in the Ln (lanthanoids)–Sb–S system. Table 1 gives the results of chemical analysis for $Ce_6Sb_8S_{21}$, and Nd_3SbS_6. The powder diffraction patterns for the three new sulfides are listed in Table 2.

Table 1. Electron microprobe chemical analysis of $Ce_6Sb_8S_{21}$ and Nd_3SbS_6

	$Ce_6Sb_8S_{21}$			Nd_3SbS_6	
	wt%	Atomic ratio		wt%	Atomic ratio
Ce	35.59	6.35	Nd	57.86	3.33
Sb	38.97	8	Sb	14.66	1
S	27.03	21.08	S	24.60	6.37
Total	101.59		Total	97.12	

$Ce_6Sb_8S_{21}$. The product is obtained as blackish-red crystals having metallic luster. It is isostructural with $La_6Sb_8S_{21}$:[5] orthorhombic, space group P222. The lattice parameters obtained from the powder data are a=14.27(1), b=15.23(1), and c=8.645(9) Å. These values are slightly smaller than those reported for $La_6Sb_8S_{21}$, a=14.317(2), b=15.239(4), and c=8.685(1) Å. This result is consistent with the lanthanoid contraction. The crystal has plate-like habits with well-developed (010) faces, and elongated along the c axis.

The best crystals were obtained in the following procedures. A mixture of Ce, S, and Sb_2S_3 in a molar ratio 6:9:4, was heated at the reaction temperature of 1000 °C for 1 h and kept at the growth temperature of 900 °C for 1 week. The maximum synthesized crystal is 0.5×0.2×0.1 mm^3 in size.

$Ce_3Sb_3S_{10}$. The crystal is bright red and transparent having the same appearance as $La_3Sb_3S_{10}$.[5] The X-ray single crystal photographs have indicated that $Ce_3Sb_3S_{10}$ and $La_3Sb_3S_{10}$ are isomorphous. It belongs to the monoclinic system. However, as reported for $La_3Sb_3S_{10}$,[5] the presence of very weak superstructure reflections and very diffuse nature of the diffraction spots precluded the determination of the true cell and space group. The lattice parameters of the average lattice were calculated as a=13.15(1), b=14.20(2), c=5.568(6) Å, and β=95.17(8)°, which are slightly smaller than those of $La_3Sb_3S_{10}$: a=13.209(6), b=14.229(6), c=5.583(1) Å, and β=94.54(3)°.[5]

Thin plate crystals of 0.25×0.1×0.02 mm^3 in maximum size were synthesized by heating the mixture of Ce, Sb, and Sb_2S_3 in a molar ratio, 6:9:4. The suitable

a) Intensities were visually estimated: vs(very strong) > s > m(medium) > w(weak) > vw.

reaction and growth temperatures were 1200 °C and 1000 °C, respectively. Both $Ce_6Sb_8S_{21}$ and $Ce_3Sb_3S_{10}$ were able to be synthesized from the starting materials of the same composition. It was found that the appearance of each phase largely depends upon the growth temperature.

Nd_3SbS_6. The crystal is red and transparent. It has short prismatic shape with the maximum size of 0.15×0.05×0.05 mm³. The X-ray single crystal photographs have indicated that it belongs to the tetragonal system. The space group was determined as $I4_1/acd$ by the extinction rule. The elongation axis of the crystal is *c*. The indexing of the X-ray powder pattern was made with the aid of the single crystal photographs. As shown in Table 2, they are successfully indexed on the basis of the tetragonal cell. The lattice parameters were calculated as a=15.54(1) and c=19.52(2) Å from the powder data.

The optimum synthetic condition for the preparation of single crystal is as follows. A mixture of Nd, S, and Sb_2S_3 in a molar ratio, 6:9:4, was heated at 1100 °C for 2 h, and the temperature was dropped to 1040 °C. Then, it was slowly lowered to 890 °C at a rate of 6.25 °C/h. The temperature was raised again to 1040 °C, kept for 1 h, and slowly lowered in the same manner. This process was repeated four times in all. The run was terminated by turning off the furnace power to allow natural cooling. Attempts to synthesize at a fixed temperature, *i.e.* 1000 °C, did not yield any good crystals.

The authors wish to thank Mr. Ritsuro Miyawaki of the University of Tsukuba for his kind assistance in the chemical analysis.

(Received August 25, 1983)

Synopsis. The title compound has been prepared and the crystal structure determined by the X-ray diffraction method. The complex ion is the *trans(P, N)* isomer, where one of the N atoms of (2-aminoethyl)dimethylphosphine (edmp) occupies the position trans to the P atom of the other edmp ligand.

In the course of our preparative studies[1,2] of the series-complexes $[Co(en)_x(edmp)_y(dmpe)_z]^{3+}(x+y+z=3)$, where en, edmp, and dmpe denote ethylenediamine, (2-aminoethyl)dimethylphosphine, and 1,2-bis(dimethylphosphino)ethane, respectively, we have obtained $[Co(edmp)_2(dmpe)]Br_3\cdot 2H_2O$ by the reaction of *trans*-$[CoCl_2(edmp)_2]ClO_4$ with dmpe. There are three possible geometrical isomers of the complex ion (Fig. 1). In order to determine the geometrical configuration, crystals of the complex have been subjected to X-ray structure analysis.

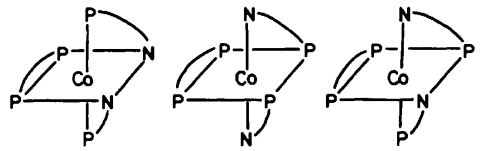

Fig. 1. Three geometrical isomers of $[Co(dmpe)(edmp)_2]^{3+}$.

Experimental

Preparation of the Complex. To an oxygen-free methanol solution (50 cm^3) of *trans*-$[CoCl_2(edmp)_2]ClO_4$[3] (205 mg, 0.467 mmol) was added dropwise an oxygen-free methanol solution (50 cm^3) of dmpe[2] (70 mg, 0.467 mmol) with stirring under an atmosphere of nitrogen at room temperature. After 12 h the resulting yellow solution was filtered to remove yellow precipitate of *fac*-$[Co(edmp)_3]X_3$ ($X=Cl^-$ or ClO_4^-).[1] The filtrate was diluted with water (1 dm^3) and poured on a column (ϕ 3×120 cm) of SP-Sephadex C-25. The adsorbed product was eluted with 0.2 mol dm^{-3} NaCl, giving two main yellow bands with several minor ones. The complex of the second main band was *fac*-$[Co(edmp)_3]^{3+}$. The eluate of the first main band was evaporated to dryness under reduced pressure, and the complex was extracted with a small amount of methanol. The extract was diluted several times with water and rechromatographed in a similar manner using a small column (ϕ 1×10 cm) and 1 mol dm^{-3} NaBr. The yellow eluate was concentrated to a small volume in a desiccator over P_4O_{10} to yield orange yellow crystals. Yield: 13 mg (4%). Most of the reaction product was *fac*-$[Co(edmp)_3]^{3+}$. Found: C, 24.32; H, 6.11, N, 4.07%. Calcd for $C_{14}H_{44}N_2Br_3CoOP_2$=$[Co(edmp)_2(dmpe)]Br_3\cdot 2H_2O$: C, 24.19; H, 6.38; N, 4.03%. The complex is soluble in water and alcohols, but insoluble in nonpolar solvents such as chloroform.

Crystal Structure Determination. Crystals are prismatic b. Crystal data are; monoclinic, $P2_1/a$, a=16.380(5), b=19.845(6), c=9.538(3) Å, β=122.34(2)°, V=2619.4(14) Å^3, Z=4, D_x=1.76, D_m=1.76(2) Mg m^{-3}, MW=695.1, λ(Mo $K\alpha$)=0.70926 Å, μ=5.44 mm^{-1}. The intensity measurements were performed to 2θ=60° ($+h$, $-k$, $\pm l$ set) on a Rigaku AFC-5 four-circle diffractometer with Mo Kα radiation monochromated by a graphite plate and with a crystal of 0.2×0.2×0.2 mm^3 in dimensions. 6613 reflections were measured and 3299 unique ones were obtained. Lorentz, polarization and absorption corrections were applied.[4] The structure was solved by direct methods with MULTAN78.[5] Starting with the positions of the Co and three Br atoms those of the other non-H atoms were determined from electron-density maps and refined by block-diagonal least squares with anisotropic thermal parameters using UNICS III computation program system.[6] The psitions of all the H atoms were calculated except those of water molecules and not refined. Final R was 0.071, wR=0.071, S=2.2 for 3299 unique reflections. Complex neutral-atom scattering factors were taken from International Tables for X-Ray Crystallography.[7]

Results and Discussion

Final atomic parameters of non-H atoms are presented in Table 1 and a perspective drawing of the complex cation in Fig. 2.[8] This is the *trans(P, N)* isomer. Bond lengths and bond angles are listed in Table 2.

Co	-P(1)	-C(8)	118.8(4)	P(1)	-C(1)	-C(2)	108.4(8)
C(1)	-P(1)	-C(7)	105.2(6)	N(1)	-C(2)	-C(1)	109.2(11)
C(1)	-P(1)	-C(8)	103.6(5)	P(2)	-C(3)	-C(4)	111.8(11)
C(7)	-P(1)	-C(8)	100.8(6)	N(2)	-C(4)	-C(3)	112.0(14)
Co	-P(2)	-C(3)	101.6(5)	P(3)	-C(5)	-C(6)	110.3(8)
Co	-P(2)	-C(9)	120.8(5)	P(4)	-C(6)	-C(5)	105.3(7)
Co	-P(2)	-C(10)	123.1(4)				

Bond length of Co–P(1) is longer than Co–P(2) by 0.049(4) Å, indicating trans influence of the ligating P atoms. A difference of 0.022(4) Å is also found in the bond distances between Co and P atoms of the dmpe ligand, which may be less meaningful since two Co–P bond lengths in $[Co(en)_2(dmpe)]^{3+}$ differ by 0.016(3) Å.[10] The five-membered chelate ring formed by the dmpe ligand takes an envelope conformation as shown in Fig. 3. Conformation of the same ligand in $[Co(en)_2(dmpe)]^{3+}$ is a twisted (gauche) one. The asymmetry of the ring conformation may be caused to release the steric repulsion between two methyl groups, C(9) and C(12) [3.49(2) Å]. The methyl C(13) atom is in close contact with the N(1) atom [3.07(1) Å].

In the *trans(P, P)* isomer, in which the positions of P(1) and N(1) atoms are interchanged, the steric interactions between methyl groups C(9) and C(12) and between C(13) and C(7′) will render the complex unstable. The *trans(N, N)* isomer will also be unstable since it has two pairs of mutually trans P donating atoms as

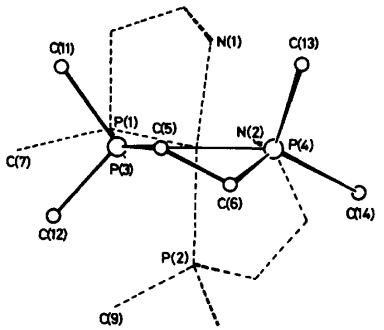

Fig. 3. The dmpe ligand viewed along the line through the Co atom and the midpoint of P(3)–P(4) axis.

exemplified by the elongation of the Co–P(1) bond. This the *trans(P, N)* isomer will be the most stable among the isomers from both steric and electronic factors.

The complex in aqueous solution shows an absorption spectrum very similar to that of $[Co(en)(dmpe)_2]^{3+}$,[2] giving the d-d bands at 24150 cm^{-1} (log ε=2.79) and *ca.* 29000 cm^{-1}(log ε=2.7, shoulder), and the Co–P charge transfer band at 36900 cm^{-1}(log ε=4.42). The thermal stability is also similar to that of $[Co(en)(dmpe)_2]^{3+}$; the complex in water or other solvents is stable at room temperature, but decomposes slowly on heating. The complex in water in the presence of excess NaCl changes to *trans*-$[CoCl_2(edmp$ or $dmpe)_2]^+$ and a small amount of Co(II) species by heating at 60—70 °C for several hours.

Pressure and Temperature Effects on Octahedral-Tetrahedral Equilibria in Pyridine Solutions of Some Cobalt(II) Halides. II

Kazuo KOJIMA,* Takeru MIYASHITA, and Jiro MATSUDA
Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603
(Received September 2, 1983)

Synopsis. Temperature and pressure effects on the configuration equilibrium of cobalt(II) iodide in pyridine solution have been studied spectrophotometrically. High temperature favors the tetrahedral species but high pressure favors the octahedral species, the heat and volume changes being 65.3 kJ mol^{-1} and -6 cm^3 mol^{-1}, respectively. Comparisons among three kinds of halide are also made.

We have reported[1] the ΔH and the ΔV values determined in terms of the shift of the equilibrium $[CoX_2(py)_2]$ (tetrahedral)$+2py \rightleftharpoons [CoX_2(py)_4]$ (octahedral), where X is Cl or Br. This note deals with the case of X= I and discusses the relation among the chloride, the bromide and the iodide complexes.

The experimental details (except that the commercial chemical pure reagent $CoI_2 \cdot 4H_2O$ was used after dehydration in the present study) and the method of determining the values of ΔH and ΔV were the same as previously described.[1]

Results and Discussion

Figure 1 shows the absorption spectra of CoI_2 in pyridine at various temperatures. There found two bands, the one is the T-band due to the tetrahedral species $[CoI_2(py)_2]$ and the other the O-band due to the octahedral species $[CoI_2(py)_4]$. The T-band intensity increases steeply with increasing temperature; two peaks at 658, 685 nm and a shoulder near 626 nm are well-resolved at 74.6 °C. This trend suggests that the equilibrium mentioned above shifts to the tetrahedral-species side with increasing temperature, although the variation of the O-band spectrum with the temperature changes is not found to be clear because of the low molar absorption coefficient of $[CoI_2(py)_4]$.

A plot of the logarithm of A'_{685} *vs.* T^{-1} in Fig. 2 gives a straight line, from the slope of which the ΔH value of 65.3 kJ mol^{-1} is obtained, being comparable with the value of 69.4 kJ mol^{-1}.[2]

The ΔH values increase in the order $Cl^- < Br^- < I^-$, which is consistent with the result of King *et al.*[2] They proposed that this order is ascribed to the degree of contribution of the dative π-bonding to the Co–py bond and that this π-bonding is related to the polarizability of halide ion. By plotting the ΔH values *vs.* the electronic polarizability of halide ions in crystals[3] in Fig. 3, we can find the linear relation between them. Furthermore, we are concerned in the relation between the ΔH values and the electronegativity of halide ions.

Because CoI_2 is less soluble in pyridine (its solubility is the order of one-hundredth of those of the other halides), the intensities of the O- and T-band are weak at room temperature and 1 atm, so that the changes in the absorption spectra with the variation of pressure are not very clear (not shown). However, from the plot of the logarithm of the ratio of the integrated-intensities

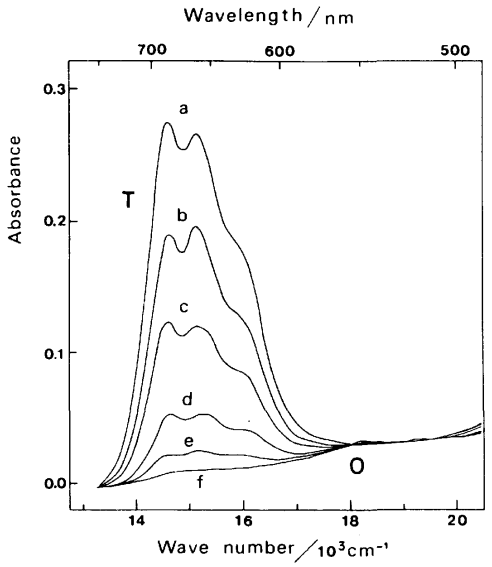

Fig. 1. Absorption spectra of CoI_2 in pyridine at various temperatures (1 atm), uncorrected for the thermal expansion of the solution. Concn: 5.320×10^{-4} mol dm^{-3} (25 °C), optical path length: 0.98 cm.
a: 74.6 °C, b: 62.6 °C, c: 55.0 °C, d: 43.2 °C, e: 34.6 °C, f: 24.4 °C.

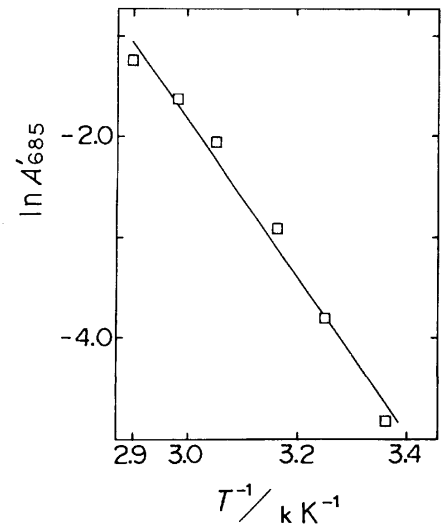

Fig. 2. Logarithm of the corrected absorbance for CoI_2 *vs.* reciprocal of the absolute temperature.
A'_{685} denotes the absorbance at 685 nm corrected by the approximate thermal expansion coefficient of pyridine as in Ref. 1. The line is the least-square fit to the data.

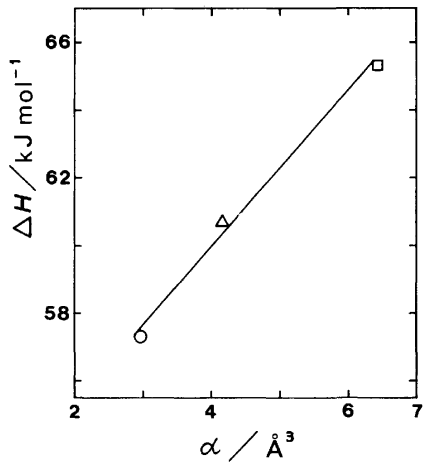

Fig. 3. ΔH *vs.* electronic polarizability of halide ions. ○: Cl^-, △: Br^-, □: I^-. ΔH values for the chloride and bromide are taken from Ref. 1.

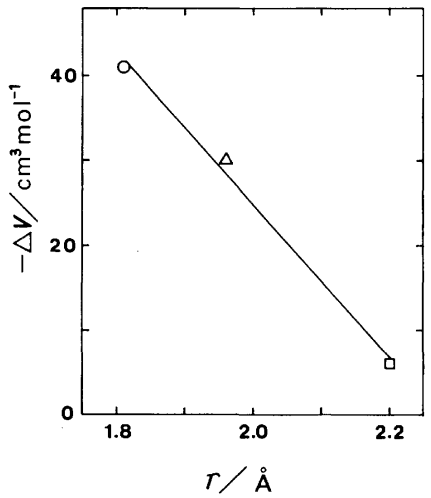

Fig. 4. ΔV at 1 atm *vs.* ionic radii of halide ions. ○: Cl^-, △: Br^-, □: I^-. ΔV values for the chloride and bromide are taken from Ref. 1.

of the O-band to those of the T-band against pressure, we obtain the ΔV value of $-6\ cm^3\ mol^{-1}$ over the pressure range 1 bar to 3 kbar.

The values of ΔV at 1 atm show a linear variation with the ionic radii of the halide ions, as exhibited in Fig. 4. This implies that the larger the ionic radius, the smaller the volume difference between $[CoX_2(py)_4]$ and $[CoX_2(py)_2]$ solvated with two pyridine molecules.

Another effect of pressure on the relation between ΔV and pressure has been described previously.[1] In the present study, the relation for the iodide is found to be the most linear.

Efficient Synthesis and Structure of Bis[acetonitrile(11,13-dimethyl-1,4,7,10-tetraaza-10,13-cyclotridecadien-12-ylidene)nickel(II)] Perchlorate

Katsura Mochizuki,* Koshiro Toriumi,† and Tasuku Ito†
Department of Chemistry, Yokohama City University, Yokohama 236

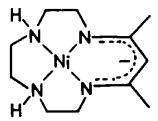
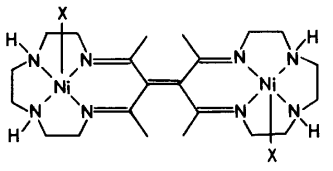
(Received September 20, 1983)

Synopsis. The titled binuclear nickel(II) complex has been synthesized by the oxidation of 11,13-dimethyl-1,4,7,10-tetraaza-10,13-cyclotridecadienatonickel(II) perchlorate with iron(III) perchlorate in deoxygenated CH_3CN in *ca.* 70% yield and its structure has been determined.

Cunninghum *et al.* reported a synthesis of [NiI(Me$_2$[13]dienN$_4$ylidene)]$_2$I$_2$ (**2b**), a dimer of [Ni(Me$_2$[13]dienatoN$_4$)]$^+$ (**1**),[1] though the yield was as low as less than a few percent.[2] In the formation of such a dimer, the combination of radicals formed at the γ-position of the six-membered diiminato chelate ring, *i.e.*, one electron oxidation of the coordinated ligand and the further oxidation of the bridging C–C bond to a C=C double bond should take place.[3] The low yield of the preparation of **2b** by Cunninghum's method is caused by the occurrence of side reactions such as ligand dehydrogenation and ligand oxygenation. Such reactions have been known to take place in the oxidation of **1** with Br_2[4] and in the oxidation of [Co(Me$_2$[14]dieneN$_4$)]$^{2+}$.[5]



1



2a: X=CH_3CN Y=ClO_4^- n=4
2b: X=Y=I^- n=2
2c: X=Y=NCS^- n=2

In the present study, the titled nickel(II) complex has been efficiently synthesized by the oxidation of [Ni(Me$_2$[13]dienatoN$_4$)](ClO$_4$) (**1**) in deoxygenated CH_3CN with ion(III) perchlorate, selected as an appropriate and noncoordinating oxydizing agent.[6] In this reaction, the side reactions were suppressed substantially. The dimeric structure of the oxidation product has been confirmed by X-ray analysis as well as a measurement of FD-mass spectra.

To confirm the formation of a radical at the γ-position by the oxidation with ion(III) ions, cyclic voltammograms of [M(Me$_2$[X]dienatoN$_4$)](ClO$_4$) (M=Ni, Cu; X=13, 14) in CH_3CN were measured. Irrespective of kinds of the metal ions, these complexes showed similar irreversible waves with strong anodic peaks (E_{pa}) but did not give corresponding cathodic peaks (i_{pc}=0). Heights and positions of the anodic peaks were scan rate dependent. The electrochemical data were:[7] E_{pa}(M=Ni, X=13)=+0.64 V, E_{pa}(M=Ni, X=14)=+0.64 V, E_{pa}(M=Cu, X=13)=+0.50 V, E_{pa}(M=Cu, X=14)=+0.56 V. These E_{pa} values are in the narrow range of +0.5—+0.7 V and are definitely more negative than $E_{1/2}$ values of Ni^{II}/Ni^{III} couples reported for other macrocyclic nickel(II) complexes (see below).[3,8] A number of tetraaza macrocyclic nickel(II) complexes, which do not have a delocalized six-membered chelate ring, have been known to show quasi-reversible waves ($i_{pc}/i_{pa}\simeq1$) in cyclic voltammograms at $E_{1/2}$=+0.7—+1.3 V in CH_3CN. The waves correspond to Ni^{II}/Ni^{III} couples.[3,8] Furthermore, the constant electrolysis of [Ni(Me$_4$[14]tetraenatoN$_4$)]$^{2+}$, which has the delocalized six-membered rings, at +0.65 V in CH_3CN give the dimeric complex.[9] These facts suggest strongly that the observed waves are attributed to radical formations at the γ-positions. On the basis and from the observed E_{pa} values, we chose Fe(ClO$_4$)$_3$·6H$_2$O ($E_{1/2}$(II)/(III)=+1.1 V *vs.* SCE in CH_3CN[10]) as the oxidizing agent in the preparation of the titled complex.

Figure 1 shows the structure of **2a** and Table 1 lists bond lengths and angles of interest. The complex has an inversion center at midpoint of the C(12)–(12′) bond. The bridge head carbons, C(12) and C(12′), are connected by a double bond to produce a binuclear complex. In the present complex an acetonitrile molecule is coordinated to each nickel(II) ion in five-coordinate fashion. Perchlorates are not involved in coordination. In view of bond lengths and angles, C(12)–C(12′), N(1)–C(13), and N(10)–C(11) are double bonds. Four methyl groups produce large strain to C(12)–C(12′) double bond,[2] so that the double bonds are almost completely localized and the entire complex adopts a chair-like structure as in dodecachloroheptafluvalene.[11] The skeletal structure in **2a** is very similar to that reported for the iodo complex **2b**.[2]

a) Estimated standard deviations are in parentheses.

dienN$_4$ylidene)]$_2$(ClO$_4$)$_4$ in Nujol mull shows a broad band around 500 nm, characteristic of five-coordinate species.

Data of absorption spectra and molar conductivities of **2b** suggest the presence of five-coordinate species in acetonitrile and aqueous solutions.[12]

By using the present synthetic procedures, a relatively large amount of **2a** can be obtained. Iodo and thiocyanato derivatives, **2b** and **2c** were prepared successfully from **2a** and characterized (see Experimental).

Experimental

Materials. [Ni(Me$_2$[13]dienatoN$_4$)](ClO$_4$) (**1**) was synthesized according to the literature.[13]

[Ni(CH$_3$CN)(Me$_2$[13]dienN$_4$ylidene)]$_2$(ClO$_4$)$_4$ (**2a**): Through an acetonitrile solution (50 cm^3) containing 2.0 g of **1** was bubbled a stream of N$_2$ gas for 30 min to remove dissolved oxygen. To the solution was added gradually 2.5 g of Fe(ClO$_4$)$_3$·6H$_2$O dissolved in a small amount of acetonitrile. N$_2$ bubbling was continued for further 30 min. After standing the solution in an open beaker overnight, red brown prismatic crystals formed were filtered and washed with minimum amount of acetonitrile (yield, *ca.* 70%). Found: C, 30.63; H, 4.74; N, 13.63%. Calcd for Ni$_2$C$_{26}$H$_{46}$N$_{10}$O$_{16}$Cl$_4$: C, 30.80; H, 4.57; N, 13.99%. IR (Nujol mull, cm^{-1}) 1651 (C=N); MS (FD), *m/e*, 833 ([Ni(Me$_2$[13]dienN$_4$ylidene)]$_2$(ClO$_4$)$_3^+$). The complex easily releases acetonitriles and absorbs water in the air to produce [Ni(Me$_2$[13]dienN$_4$ylidene)]$_2$(ClO$_4$)$_4$·2H$_2$O. This complex was also prepared in the same manner as described above by use of water (pH=*ca.* 2 with HClO$_4$) in place of acetonitrile. Found: C, 27.32; H, 4.20; N, 11.59%. Calcd for Ni$_2$C$_{22}$H$_{44}$N$_8$O$_{18}$Cl$_4$: C, 27.30; H, 4.58; N, 11.58%. UV$_{max}$(CH$_3$CN) 362 nm (ε 3510) 420 nm (shoulder); Molar conductivity (Ω^{-1} cm^2 mol^{-1}) Λ (H$_2$O, 2.50×10^{-4} mol dm^{-3}, pH 4.7, 25 °C) 476.

[NiX(Me$_2$[13]dienN$_4$ylidene)]$_2$X$_2$ (X=I$^-$(**2b**), NCS$^-$(**2c**)) were prepared by use of anion exchange resin (Amberlite IRA-410) at pH<3. **2b**: Found: C, 25.19; H, 3.97; N, 10.58%. Calcd for Ni$_2$C$_{22}$H$_{40}$N$_8$I$_4$: C, 25.37; H, 3.87; N, 10.76%. IR (Nujol mull, cm^{-1}) 1632 (C=N); UV$_{max}$(CH$_3$CN) 550 nm (broad); Λ (H$_2$O, 2.50×10^{-4} mol dm^{-3}, pH 5.4, 25 °C) 368. **2c**: Found: C, 40.26; H, 5.24; N, 21.58%. Calcd for Ni$_2$C$_{26}$H$_{40}$N$_{12}$S$_4$: C, 40.75; H, 5.26; N, 21.93%. IR (Nujol mull, cm^{-1}) 1651 (C=N), 2075 (N=C=S); Λ (H$_2$O, 2.41×10^{-4} mol dm^{-3}, pH 5.4, 25 °C) 353.

Other materials used were reagent grade.

X-Ray Analysis. The procedures used for data collection (a Rigaku AFC-5 diffractometer, Mo $K\alpha$) as well as the method used in the solution and refinement of the structure were standard and have been described previously.[14] Crystal data: Monoclinic, P2$_1$/n, a=13.533(2), b=11.471(1), c=93.76(1)°, V=2060.2(6) Å^3, z=2, D_x=1.64 g cm^{-3}, R=0.087 for 2857 independent reflections with $F_o > 3\sigma(F_o)$ ($2\theta < 60°$). Table 2 lists atomic coordinates.[15] Hydrogen atoms are not included in the calculation.

Measurements. Absorption spectra were measured with a Hitachi 340 spectrophotometer. A conductometer E518 (Metrohm Herisau) was used. Cyclic voltammograms were recorded with a Yanagimoto Polarographic Analyzer P-1100. Half wave potentials at 25 °C measured with three-electrode system were refered to SCE.

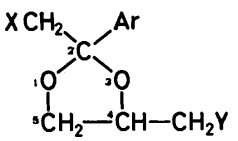
(Received July 29, 1983)

Synopsis. The ^{13}C-NMR spectra of the title compounds were assigned and the substituent effect was discussed briefly. ^{13}C-NMR of 2-aryl-4-benzoyloxymethyl-2-bromomethyl-1,3-dioxolanes provides the way to discriminate the cis and the trans isomers.

4-(Substituted aryl)-2-(1-imidazolyl)-1,3-dioxolanes have been shown to have antifungal activities towards *Microporum canis, Ctenomyces menlagrophytes, Trichophyton rubrum,* and other fungi.[1] These compounds are also active to some gram-negative and gram-positive bacilli. The antifungal and bactericidal activities are known to be sensitive to the stereochemistry of these compounds.

In our recent investigations on a series of the title compounds carrying 1-pyrazolyl, 1-imidazolyl, 1,2,4-triazol-1-yl, and 1-tetrazolyl groups as azolyl group (X in formula I), a number of their derivatives which are analogous to the azolyldioxolanes were synthesized from the corresponding 2-bromomethyl-1,3-dioxolanes.[2] Since the 2- and 4-carbon atoms of the dioxolane ring are asymmetric, two pairs of enantiomers mutually diasteromeric to each other are possible.



Formula I.

The pharmaceutical activities are strongly dependent on the stereochemistry. *r*-2-(1-Azolylmethyl)-2-(2,4-dichlorophenyl)-*c*-4-hydroxymethyl-1,3-dioxolanes and their derivatives are usually far more active than the other diastereomers, *t*-4-hydroxymethyl compounds.[3]

In this paper, ^{13}C-NMR spectral data of these dioxolanes are reported and their possobility to use for assigning the diastereomers.

Experimental

Preparation of the materials was reported elsehwere.[2,4] NMR spectra were recorded on a JEOL JNM FX-90Q spectrometer usually in chloroform-*d* solutions. The assignment of ^{13}C-NMR spectra were carried out by use of off-resonance technique. Aromatic carbon resonances were estimated by the additivity values[5] and by mutual comparison of the spectra. In some cases, selective decoupling technique was also employed.

Results and Discussion

^{13}C-Chemical shifts of 2-(1-azolylmethyl)-2-(2,4-dichlorophenyl)-4-hydroxymethyl-1,3-dioxolanes, their methanesulfonates, benzoates, and some of their ethers are given in Table 1. The dioxolanes are mostly cis isomers, which are pharmaceutically more active than the corresponding trans isomers. ^{13}C-Chemical shifts of the cis and the trans isomers of 2-aryl-2-bromomethyl-4-benzoloxymethyl-1,3-dioxolanes are also

given in Table 2. These bromides are the intermediates for the syntheses of the compounds in Table 1, and their stereochemistry is very important in the pharmaceutical purpose.

The assignment of the dioxolane spectra in Tables 1 and 2 was carried out according to the method cited in the literatures on simple dioxolanes.[5,6] Quite naturally, the chemical shifts of methylene carbon atom on 4-carbon atom (4-CH_2) are affected predominantly by the oxygen containing substituent (Y) on it and that on 2-carbon atom (2-CH_2) by the nature of the azole moiety. The effect by the substituent Y on 4-CH_2 group is transmitted to the ring carbon atoms in an alternate way. The 4-CH_2 carbon atom attached directly to the substituent Y resonates at the lower field as the substituent becomes more electronegative *i.e.*, in the increasing δ-values in the order of $OH<OCOC_6H_5<OSO_2CH_3$. The sequence of chemical shifts is similar as to the second neighbor carbon atom(C-5), but reversed as to the neighbor carbon atom(C-4). The effect is rather long range, the order of chemical shifts being preserved even on C(2) when compared among the derivatives carrying similar heteroaromatic moiety.

The 2-CH_2 chemical shift is linearly correlated with the N-CH_3 carbon chemical shift of the corresponding *N*-methylazole reported by Roberts and co-workers.[7] The 2-CH_2 chemical shift decreases in the increasing order of acidity.[8]

Signals of azole moiety were assigned without difficulty by comparing with the spectra of the corresponding *N*-methylazoles.[7] Chemical shifts of the carbon atoms in azolyl(X) or 2-aryl group, as well as those of benzoyl or methanesulfonyl group(Y), remain constant irrespective of the substituents in other part of the molecule.

It is important to establish the method to differentiate the cis and the trans isomers of the precursor bromides **30—39**. For this purpose. ^{13}C-NMR spectra of these bromides (in Table 2) were carefully examined. The difference in chemical shifts between the cis and the trans isomers ($\Delta\delta$) is given in Table 3. Without exception, the $\Delta\delta$ value is negative for the 4-CH_2 and positive for 4-carbon atom of the dioxolane ring. The high field shift of the 4-CH_2 chemical shift in the trans isomer is very probably due to the anisotropy effect of the 2-aryl group located just opposite to this methylene group. Another very remarkable difference in $\Delta\delta$ is observed with the 2-CH_2 group of the 4-benzoyloxyl derivatives **30—37**. Since the effect is obscured with the 4-ethyl derivatives (**38** and **39**), the high field shift is supposed to be originated from the anisotropy effect by the benzoyl group. In conclusion, the $\Delta\delta$ values are not large but very consistent in sign, hence usable to discriminate the each diastereoisomer.

Photoreductive Dehalogenation of Organic Halides in the Presence of Lithium Aluminum Hydride

Nobujiro SHIMIZU,* Kenji WATANABE, and Yuho TSUNO
Department of Chemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812
(Received August 11, 1983)

Synopsis Lithium aluminum hydride markedly accelerates photoreductive dehalogenation of cyclopropyl, aromatic, and olefinic halides carried out in ether.

UV irradiation of organic halides in a hydrogen donating solvent often leads reductive dehalogenation.[1] Cyclopropyl bromides are thus obtainable by irradiating the corresponding *gem*-dibromides in ether, although in moderate to low yields.[2] We here report that irradiation in the presence of lithium aluminum hydride (LAH) results in significant improvement in the efficiency and yield of the photoreduction of halides including cyclopropylidene dihalides. Most of the experimental results are summarized in Table 1.

Figure 1 illustrates the photoreduction of 7,7-dibromonorcarane (**1a**) in the presence or absence of LAH carried out at 0 °C under nitrogen with a 100 W mercury lamp using *ca.* 0.02 M (1 M=1 mol dm^{-3}) ethereal solutions. Obviously, LAH exerts a marked rate accelerating effect which increases in keeping with the amount of LAH added. For example, **1a** disappeared practically in 15 min on irradiation in the presence of 2 molar amounts of LAH affording 7-bromonorcarane (**2a**, cis/trans=3.2) as the principal product (75%), whereas in the absence of the hydride, an incomplete photolysis resulted even after prolonged irradiation up to 4 h. LAH also facilitates the

β-Bromostyrene	2	0.5		55 (styrene)

a) Each halide was irradiated in ether (*ca.* 0.02 M) with a 100 W medium pressure mercury lamp at 0 °C under nitrogen. b) Determined by GLC. c) Isomer ratio (cis/trans) was given in parentheses. d) Dark reaction. e) Recovery of the starting material.

photoreduction of the bromide **2a**; so prolonged irradiation leads to the formation of the fully reduced hydrocarbon **3a** in substantial quantity, especially so when large amounts of LAH are used.[3] LAH itself is capable of reducing most organic halides[4] but the contribution of this thermal process was negligibly small under the present photolysis conditions.

Other halides **1b—j**— they were thermally almost inert toward LAH under the photolysis conditions given in the table for each halide — also underwent rapid reduction on irradiation in the presence of LAH. The reduction proceeded more rapidly for bromides than for chlorides and a selective dehalogenation was feasible for a mixed halide **1i**. For preparative purpose, concentrated solutions could be used as well. For example, **2a** was prepared in 70% isolated yield by irradiating a 0.2 M ethereal solution of **1a** in the presence of 2 molar amounts of LAH (0 °C, 1.5 h).[5]

Two additional observations are worth stating. First, 2,3-diethoxybutane (**4**) was formed in substantial quantity in all LAH-assisted photoreductions. Second, the photolysis of **1a** using lithium aluminum deuteride led no D-incorporation in the products **2a** and **3a**. These results suggest that LAH does not act as a hydrogen donor toward an alkyl (or aryl) radical in contrast to sodium borohydride.[6] Presumably, LAH would

$$\text{R-X} \overset{h\nu}{\rightleftharpoons} \text{R}\cdot + \cdot\text{X} \overset{\text{LAH}}{\longrightarrow} \text{R}\cdot + \text{HX} + \text{LiAlH}_3^{-}\cdot$$

$$\text{R-X} + \text{LiAlH}_3^{-}\cdot \longrightarrow \text{R}\cdot + \text{LiX} + \text{AlH}_3$$

$$\text{R}\cdot + \text{ether} \longrightarrow \text{R-H} + \mathbf{4}$$

depress the recombination between an alkyl and a halogen radicals *vis* efficient capture of the latter. Moreover, aluminum hydride anion radical which would result may induce homolysis of another molecule of a halide. Besides, LAH suppressed the formation of a polymeric material, especially in the photolyses of cyclopropylidene dibromides, and this would also be partly responsible for the observed rate acceleration.

Experimental

Lithium aluminum hydride (Wako Pure Chemical) was used directly as slurries in ethereal solutions. Photolyses were carried out with a 100 W medium pressure mercury lamp (Eikosha Halos PIH-100) at 0 °C under nitrogen. All products **2—4** were characterized by comparison of their spectral data with those reported or those of authentic samples prepared separately. The following photolysis was representative.

Photolysis of 7,7-Dibromonorcarane (1a) in the Presence of LAH. To a cold stirred solution of LAH (965 mg) in ether (500 ml) was added a mixture of **1a** (3.23 g, 12.7 mmol) and tridecane (0.20 ml as an internal standard). The mixture was irradiated with stirring for 30 min at 0 °C and quenched with cold hydrochloric acid. GLC analysis of the crude oil obtained after workup indicated the formation of 7-bromonorcarane (**2a**, cis/trans=3.2) and norcarane (**3a**) in 62 and 24% yields, respectively. The oil was fractionated under reduced pressure to give **2a** (cis/trans=3.35, 1.17 g, 53%), bp 83—85 °C/20 Torr (1 Torr=133.3 Pa) [lit,[7] bp 84—86 °C/23 Torr], together with a low-boiling fraction (760 mg) which was shown to be a mixture of **3a** and 2,3-diethoxybutane (1:1 mixture of two diastereoisomers) in the ratio 1:3.

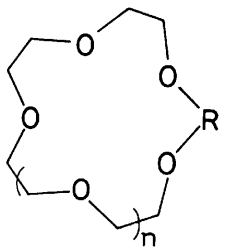
Ring-contracted Crown Ethers: 14-Crown-5, 17-Crown-6, and Their Sila-analogues. Drastic Decrease in Cation-binding Ability

Mikio Ouchi, Yoshihisa Inoue,* Takashi Kanzaki, and Tadao Hakushi*
Department of Applied Chemistry, Himeji Institute of Technology, 2167 Shosha, Himeji, Hyogo 671-22
(Received August 22, 1983)

Synopsis. As compared with symmetrical 3*m*-crown-*m*, the ring-contracted(3*m*−1)-crown-*m* showed drastic decrease in cation-binding ability, which is attributable not to the diminished cavity size but to the disordered conformation induced by ring contraction.

The control of complexation phenomena has been the major subject of the crown ether chemistry. Recent investigations from this laboratory[1] have shown that the introduction of an extra methylene group into a symmetrical 3*m*-crown-*m* (*m*=4—6) affects remarkably its cation-binding ability toward alkali metal ions; *e.g.* 16-crown-5 derivatives possess much higher Na^+/K^+ selectivity than the parent 15-crown-5. Our subsequent interest in this field is directed toward ring-contracted (3*m*−1)-crown-*m* (*m*=5, 6). Pedersen first reported the effect of ring-contraction upon complex formation,[2] however, no clear-cut discussion was made. In the present study, we report the cation-binding ability of 14-crown-5 (**2**), 17-crown-6 (**5**), and their sila-analogues (**3**, **6**), and the results are discussed in view of the size-fit concept and conformational difference.

In order to evaluate the cation-binding ability, extrations of aqueous alkali metal picrates (Na^+, K^+, Rb^+, and Cs^+) were carried out at 25 °C with dichloromethane solutions of **2**, **3**, **5**, and **6**, and the results were compared with those for the parent 15-crown-5 (**1**) and 18-crown-6 (**4**) and also with those for acyclic analogues, tetraglyme (**8**) and pentaglyme (**9**).



1, *n*=1; R=CH_2CH_2 **5**, *n*=2; R=CH_2
2, *n*=1; R=CH_2 **6**, *n*=2; R=$Si(CH_3)_2$
3, *n*=1; R=$Si(CH_3)_2$ **7**, *n*=1; R=$(CH_2)_4$
4, *n*=2; R=CH_2CH_2

As can be seen from Table 1, the ring-contracted crown ethers **2**, **3**, **5**, and **6** showed extremely low extractabilities as is the case with the open-chain analogues **8** and **9** under the conditions employed,[3] where 15-crown-5 and 18-crown-6 gave moderate extractabilities. It should be noted that, in spite of the longer O-Si-O bond (3.3 Å) than the O–C–O bond (2.8 Å) of **2** and **5**, the sila-crown ethers **3** and **6** show practically the same extractabilities as the corresponding carbon analogues **2** and **5**. This result is very significant in ascertaining the origin of the extremely low extractability for the ring-contracted crown ethers, and may suggest that the reduced cavity size is not the most important factor which is responsible for the low extractability.

Table 1. Extraction of alkali metal picrates[a]

Ligand	Extractability/%[b]			
	Na^+	K^+	Rb^+	Cs^+
15-Crown-5 (**1**)	13.2	14.3	9.6	3.3
14-Crown-5 (**2**)	0.1	0.2	0.2	0.2
Sila-14-crown-5 (**3**)	0.1	0.4	0.5	0.5
Tetraglyme (**8**)	0.1	0.1	0.1	0.1
18-Crown-6 (**4**)	6.3	69.3	57.6	36.7
17-Crown-6 (**5**)	0.8	1.7	1.0	0.7
Sila-17-crown-6 (**6**)	0.3	1.8	1.1	0.7
17-Crown-5 (**7**)	1.8	1.9	0.9	0.7
Pentaglyme (**9**)	0.2	0.7	0.6	0.5

a) Temperature 25.0±0.1 °C; aqueous phase(10 mL): [picrate]=3×10^{-3} M; organic phase(CH_2Cl_2, 10 mL): [ligand]=3×10^{-3} M. b) % Picrate extracted into organic phase.

The drastic decrease in cation-binding ability of **2**, **3**, **5**, and **6** may rather be accounted for in terms of the disordered conformation of crown ether ring. Examinations with CPK molecular model revealed that one of the five or six donor oxygen atoms of **2**, **3**, **5**, and **6** can not be accomodated in the plane which is composed of the rest of the oxygen atoms, while the cavity sizes of the crown ethers do not differ significantly; *ca.* 1.7 Å for **1-3** and 2.5—2.6 Å for **4-6**.

17-Crown-5 (**7**) was synthesized in order to obtain additional support for the above explanation. It was synthesized in 16% yield by the reaction of 1,4-butanediol with tetraethylene glycol ditosylate in tetrahydrofuran in the presence of NaOH as a base.

Definitive evidence arises from the comparison of extractabilities of 17-crown-5 and 17-crown-6. In spite of the reduced number of donor oxygen atoms from six to five, 17-crown-5 still gave comparable extractabilities for all cations. This clearly indicates that one of the formal donor oxygen atoms of 17-crown-6 and probably of 14-crown-5 and their sila-analogues **3** and **6** no longer acts as an effective donor atom due to the conformational disorder of the ring-contracted crown ethers.

Experimental

General. Infrared spectra were obtained on a JASCO A-100 grating spectrophotometer. Mass spectra were measured at 20 eV using Hitachi RM-50GC instrument. ^1H and

^{13}C NMR spectra were obtained in chloroform-*d* solution containing 1% tetramethylsilane as an internal standard, using JEOL PMX-60 and FX-60 spectrometers. UV-VIS spectra were recorded on a Shimiadzu UV-300 spectrophotometer.

Synthesis. 14-Crown-5(**2**) and 17-crown-6 (**5**) were synthesized according to the procedure described in the literature.[4]

1,4,7,10,13-Pentaoxacycloheptadecane (17-Crown-5, 7). 1,4-Butanediol (5.4 g, 0.06 mol) in tetrahydrofuran(THF) (100 mL) was added to a stirred suspension of sodium hydroxide (6.0 g, 0.15 mol) in THF (300 mL) at 66 °C, and the stirring was continued for 1 h at 66 °C. To the mixture was added tetraethylene glycol ditosylate[5] (25.1 g, 0.05 mol) in THF (150 mL) dropwise over 2 h and stirring was continued for 24 h at 66 °C under a nitrogen atmosphere. The solvent was evaporated and the residue was extracted with chloroform. The chloroform extract was dried over magnesium sulfate and the solvent was evaporated. Distillation of the product under a reduced pressure gave 2.0 g (16%) of **7**: bp 105—107 °C/0.13 Torr(1 Torr=133.322 Pa); MS, *m/z* 248 (M^+); ^1H NMR δ=3.63—3.83 (20H, m) and 1.60—1.80 (4H, m); ^{13}C NMR δ=71.8(t), 71.1(t), and 27.5(t, $OCH_2\underline{C}H_2\underline{C}H_2CH_2O$); IR(neat) 2850, 1450, 1350, 1290, 1250, and 1100 cm^{-1}. The ^1H NMR spectrum was in agreement with published data.[6]

2,5,8,11,14,17-Hexaoxaoctadecane (Pentaglyme, 9) was prepared from ethylene glycol monomethyl ether (5.3 g, 0.07 mol) and triethylene glycol ditosylate[5] (13.8 g, 0.03 mol) in the presence of sodium hydroxide in THF according to the procedure described above. Distillation of the product gave 3.7 g (46%) of **9**: bp 100—108 °C/0.27 Torr; MS, *m/z* 266 (M^+); ^1H NMR δ=3.55—3.78 (20H, m) and 3.38 (6H, s); ^{13}C NMR δ=73.0 (t), 71.6 (t), and 59.3 (q, CH_3O); IR (neat) 2800, 1450, 1350, 1290, 1240, and 1110 cm^{-1}; Found: C, 54.19; H, 10.11; Calcd for $C_{12}H_{26}O_6$: C, 54.12; H, 9.84.

Extraction. Sodium, potassium, rubidium, and cesium picrates were prepared according to Wong's method.[7,8] Commercially available 15-crown-5 (Nisso Co.), 18-crown-6 (Nisso Co.), tetraglyme (Nakarai Chemical Co.), and sila crown ethers **3** and **6** (Petrarch Systems Inc.) were used without further purification. The extraction procedures were similar to those reported by Kimura *et al.*[9] Equal volumes (10 mL) of a dichloromethane solution of a ligand (3×10^{-3} M) and of an aqueous alkali metal picrate (3×10^{-3} M) were introduced into an Erlenmeyer flask, which was then stoppered and shaken for 10 min at 25.0±0.1 °C using a TAIYO M100L incubator. The mixture was then allowed to stand for at least 2 h at that temperature in order to complete the phase separation. After the phase separation 2 mL of the dichloromethane phase was withdrawn, to which 2 mL of acetonitrile was added. After further dilution, if necessary, with a 1:1 mixture of dichloromethane and acetonitrile, the picrate concentration in the organic phase was determined from its absorption at 375 nm. The molar extinction coefficients at 375 nm for sodium, potassium, rubidium, and cesium picrates are 18600, 19000, 18800, and 18500 M^{-1} cm^{-1}, respectively.

This work was partially supported by a grant from the Hyogo Foundation for the Promotion of Science and Technology, which is gratefully acknowledged. We thank Prof. T. Shono and Mr. S. Kitazawa of Osaka University for the stimulating discussion on the CPK model.

(Received August 25, 1983)

Synopsis On treating a ball-milled mixture of L-leucine and such diluents as silicone dioxide in hydrochloric acid, a part of L-leucine was transformed into D-leucine.

Racemization of optically active amino acids is of great interest with regard to the origin of optical activity. Mechanochemical racemization has not been reported yet, though several studies have been reported concerning racemization on γ-irradiation,[1] and acid-catalyzed[2,3] or base-catalyzed racemization of α-amino acids[4] under drastic conditions. It is known that little racemization occurs on treating a 6 M hydrochloric acid solution (1M=1 mol dm^{-3}) of α-amino acids at about 100 °C for 20 h.[3] In this paper, racemization of L-leucine on mechanochemical treatment was investigated.

A 10-g portion of a sample was inserted in a stainless-steel mill (in diameter of 10 cm and in capacity of 900 cm^3) containing ten stainless-steel balls (with a density of 8.2 g/cm^3 and in diameter of 2.5 cm) and thirty balls in diameter of 1.9 cm. The mill was rotated at a velocity of 120 min^{-1}. This procedure is called "ball-milling" hereafter. The ball-milled samples were L-leucine, silicone dioxide, talc, alminium oxide, titanium dioxide, microcrystalline cellulose (MCC), ethyl cellulose (EC), and a mixture of L-leucine and one of the other powders (diluents).

After a suspension of various samples containing L-leucine in a 6 M hydrochloric acid solution had been set aside for 30 min at room temperature, the suspension was centrifuged. The degree of optical rotation, $[\alpha]_D$, of the supernatant was measured with a Yanaco automatic polarimeter (Model OR-50).

N-(trifluoroacetyl)leucine isopropyl esters were derived as follows. Approximately 100 mg of leucine obtained by evaporating the supernatant was dissolved in 6.9 cm^3 of a saturated solution of hydrogen chloride in isopropyl alcohol and the solution was heated under reflux for 3 h. The solvent was removed under vacuum with a rotary evaporator. After washed by adding 5 cm^3 of dichloromethane and vacuum evaporating twice, the residue was dissolved in 2 cm^3 of dichloromethane and treated with 3 cm^3 of trifluoroacetic anhydride. The solution was heated under reflux for 15—30 min, and then the solvent was removed under vacuum. The residue was washed twice as before.[5] A dichloromethane solution of these derivatives was analysed by gas chromatography using a 30 m×0.24 mm fused-silica capillary column coated with OA-201 (optically active liquid of Shimadzu Seisakusho) as a stationary phase. This analysis was carried out at 110 °C with an inlet nitrogen pressure of 1 kg/cm^2. The IR spectra were measured by the use of Nujol method with a JASCO diffraction granting infrared spectrophotometer (Model IRA-2).

Results and Discussion

L-Leucine was ball-milled with diluents and treated in hydrochloric acid. The $[\alpha]_D$ value of the supernatant decreased by ball-milling with diluents, though the values for L-leucine ball-milled for 60 h without any diluent (b-L-leucine) or a mixture of b-L-leucine and a diluent ball-milled without leucine (b-diluent) were nearly identical with the value for original L-leucine.

N-(Trifluoroacetyl)leucine isopropyl esters, derived from leucine[5] obtained by evaporating the supernatant, were analyzed by gas chromatography. Hatano *et al.* found that keto acids and ammonia were formed on γ-ray irradiation in aqueous solutions of amino acids or oxidation of them in alkaline solutions.[6] On the other hand, Arakawa *et al.* showed that, on oxidation of amino acids in acidic or neutral solutions, both deamiation and decarboxylation occurred with subsequent formation of the coresponding aldehydes.[7] A large amount of bubbles were generated on treating the mixtures of L-leucine and diluents in hydrochloric acid; from this fact, decarboxylation is suggested to occur. These facts suggest that the peak "P" in Fig. 1 is due to 3-methylbutanal formed by deamination and decarboxylation of leucine. A peak of D-leucine was observed for the ball-milled mixture with talc, silicone dioxide, alminium oxide or titanium dioxide. In contrast, no peak of D-leucine was observed for b-L-leucine, a mixture of b-L-leucine and a b-diluent, or a ball-milled mixture with MCC or EC. Racemization percentage shown in Fig. 2 is twice the percentage of D-leucine in all the leucine, obtained from the peak areas of D- and L-leucine in the chromatogram. After keeping the mixture for some days in a stoppered bottle at room temperature after the end of ball-milling, the racemization percentage was determined. As is shown in Fig. 2, racemization percentage decreased gradually with the lapse of the time after the end of ball-milling. These results show that racemization of L-leucine takes place while the surface of the diluent in the mixture is active.

Figure 3 shows the effect of ball-milling with talc on IR spectra of L-leucine. The spectra of the mixtures of L-leucine and talc were nearly identical with those of

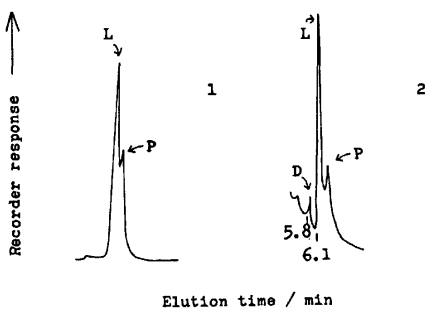

Fig. 1. Gas chromatogram of leucine derivatives. Sample 1: L-leucine, 2: a mixture with silicone dioxide ball-milled together for 18 h. (content of L-leucine; 10 w/w %). P; A peak of a degradation product.

the mixtures of b-L-leucine and b-talc. It is considered from this fact that the changes in the range of 1600—1640 cm^{-1} and 3000—3400 cm^{-1} regions are not due to the adsorption of water. In this case the effect was as follows; (1) the absorbance at 3000—3400 cm^{-1} region (assigned to the NH_2 stretching vibration) increased, (2) the absorbance at 1600—1640 cm^{-1} region (assigned to the COO^- asymmetric stretching vibration) increased, and (3) the band at 1410 cm^{-1} (assigned to the COO^- symmetric stretching vibration) and the band at 1510 cm^{-1} (assigned to the NH_3^+ symmetric stretching vibration) disappeared. The similar effect was also observed upon ball-milling with silicone dioxide, MCC, or EC. Jackovitz and Walter reported an analogous change in the IR spectra of leucine on complexation with such metals as palladium. They considered that leucine in the metal complex was in the state of $NH_2CH(R)COO^-$ ($R=(CH_3)_2CHCH_2-$) where N and O binded with metals,[8] though leucine is in the state of $NH_3^+CH(R)COO^-$ in crystal powders.[9] These facts suggest that leucine in the ball-milled mixture with talc or silicone dioxide is also in the state of $NH_2CH(R)COO^-$ where N and O interact with these diluents. According to Jackovitz and Walter, the band in the range of 1550—1600 cm^{-1} due to the NH_2 scissors vibration is at a higher frequency, when the N-metal bond is stronger. The band in the range of 1570—1640 cm^{-1} due to the COO^- asymmetric stretching vibration is also at a higher frequency, when the O-metal bond is stronger.[8] The IR spectra suggested that the interaction force of L-leucine with talc in the ball-milled mixture was stronger than the force with silicone dioxide. A remarkable change was not observed in the spectra of the mixture with titanium dioxide or alminium oxide. This result shows that leucine in the ball-milled mixture with these diluents is in the state of $NH_3^+CH(R)COO^-$.

Bonner *et al.* found an approximately linear relationship between the extent of racemization and that of degradation upon γ-irradiation for the aqueous sodium salts of leucine.[1] The $[\alpha]_D$ values for the samples within 25 d from the end of ball-milling were nearly identical, and it is not considered from this fact that the degradation percentage for the mixture with talc or silicone dioxide is larger than the percentages for the other mixtures. The racemization percentages within 25 d from the end of ball-milling shown in Fig. 2 are large when leucine is in the state of $NH_2CH(R)COO^-$. It is also shown that racemization of L-leucine takes place more easily when the interaction force with a diluent is stronger. Bonner *et al.* irradiated γ-ray on aqueous solutions of sodium salts or hydrochloride salts of amino acids and found that $NH_2CH(R)COO^-$ suffered 5—11% of racemization and that $NH_3^+CH(R)COOH$ racemized little.[1]

(Received September 2, 1983)

Synopsis. Kinetic measurements of rotamer isomerization of the title compounds show that the rotational barriers in these compounds are considerably higher than those in the *peri*-unsubstituted and the *peri*-chloro or *peri*-methyl compounds, affording a support to our earlier finding that the rotational barrier increases and then decreases as the *peri*-substituent becomes bulkier in 9-*t*-alkyltriptycenes.

We have shown that introduction of a chloro or a methyl group into a *peri*-position of 9-(1-cyano or methoxycarbonyl-1-methylethyl)triptycene (**1** and **2**) causes a decrease of the energy barrier to rotation about the bridgehead-to-substituent bond relative to the *peri*-unsubstituted compound.[2] A more extensive study on the effect of the *peri*-substituent on the rotational barrier in 9-(1,1-dimethyl-2-phenylethyl)triptycenes (**3**) revealed that a relatively small *peri*-substituent such

d	Cl	Cl
e	CH_3	H

as fluoro and methoxyl raises the barrier relative to the *peri*-unsubstituted compound **3a**, while a *peri*-group bulkier than chloro decreases the barrier.[3] Molecular deformation in this highly congested system might partly explain these phenomena.[3] These findings urged us to examine whether a fluoro or a methoxyl group at a *peri*-position raises the rotational barrier in compounds **1** and **2** as well. The results are presented in this note.

Results and Discussion

Reactions of 9-(1-cyano-1-methylethyl)anthracene with tetrafluoro- and 3,6-dimethoxybenzynes gave stereoselectively the ±*sc* atropisomers of **1b** and **1c**, respectively. Kinetic measurements of isomerization were carried out in 1-chloronaphthalene at three to four points of temperature. The equilibrium and rate constants obtained are compiled in Table 1 and the kinetic parameters therefrom are given in Table 2. The rotational barriers in these compounds are actually higher not only than that in the *peri*-unsubstituted derivative **1a** but also than those in the *peri*-chloro (**1d**) and the *peri*-methyl (**1e**) compounds. As shown in Fig. 1, the dependence of the energy barrier upon the *peri*-substituent in compounds **1** is very similar to that found in compounds **3**. This clearly shows that the appearance of the maximal barrier at a relatively small

peri-substituent is a general phenomenon in 9-*t*-alkyltriptycenes.

The equilibrium constant at 200 °C, K_{473}(±*sc*/*ap*), becomes larger as the *peri*-substituent becomes bulkier with an exception of **1b**:**1a**, 2.3; **1b**, 1.9; **1c**, 4.4; **1d**, 6.8; **1e**, 15. This trend is reasonable from the standpoint of steric effects because methyl is bulkier than cyano. Deviation from the trend by **1b**, where K_{473} is smaller than the statistical value of 2.0, may be ascribed to the electrostatic repulsion between the fluoro and cyano groups overweighing the steric effect.

9-(1-Methoxycarbonyl-1-methylethyl)anthracene failed to react with tetrafluorobenzyne to give **2b**, but reacted with 3,6-dimethoxybenzyne to afford stereoselectively the ±*sc* rotamer of **2c**. Heating a sample of ±*sc*-**2c** in 1-chloronaphthalene for *ca.* 5 h at 189 °C caused the complete equilibration of the rotamers but the equilibrium population of *ap*-**2c** was *ca.* 2-3%, which made the kinetic measurement of isomerization impossible. The overwhelming abundance of the ±*sc* rotamer may be due to the attractive interaction[4] between the methoxycarbonyl and the *peri*-methoxyl groups in ±*sc*-**2c** together with the steric effect also favoring the ±*sc* rotamer.

Experimental

Melting points are not corrected. ^{1}H NMR spectra were recorded on a Varian EM-390 spectrometer at 90 MHz at ambient temperature of *ca.* 35 °C. Experimental procedures of the kinetic measurements were described before.[2,3]

9-(1-Cyano-1-methylethyl)-1,2,3,4-tetrafluorotriptycene (1b). Reaction of 9-(1-cyano-1-methylethyl)anthracene[2] with pentafluorophenyllithium according to the procedure described in the literature[5] followed by column chromatography on silica gel with hexane–benzene as the eluent gave ±*sc*-**1b** in 41% yield, mp 239—240 °C (from tetrahydrofuran–hexane). Found: C, 73.23; H, 3.78; N, 3.66%. Calcd for $C_{24}H_{15}F_4N$: C, 73.28; H, 3.78; N, 3.56%. ^{1}H NMR ($CDCl_3$, δ): 2.39 (3H, d, *J*=7.0 Hz), 2.43 (3H, s), 5.73 (1H, br d, *J*=1.8 Hz), 7.0—7.2 (4H, m), 7.3—7.7 (3H, m), 8.0—8.2 (1H, m). The *ap* rotamer of **1b** was purely isolated from the equilibrated mixture of rotamers by column chromatography on silica gel, mp 231—232 °C (from tetrahydrofuran–hexane). Found: C, 73.11; H, 3.77; N, 3.56%. ^{1}H NMR ($CDCl_3$, δ): 2.41 (6H, d, *J*=6.3 Hz), 5.77 (1H, br d, *J*=1.8 Hz), 7.0—7.2 (4H, m), 7.3—7.6 (2H, m), 7.8—8.1 (2H, m).

9-(1-Cyano-1-methylethyl)-1,4-dimethoxytriptycene (1c). Reaction of 9-(1-cyano-1-methylethyl)anthracene[2] with 3,6-dimethoxyanthranilic acid[6] according to the general procedure described before[3] gave ±*sc*-**1c** in 50% yield, mp 293—296 °C (from tetrahydrofuran–ethanol). Found: C, 81.81; H, 5.83; N, 3.63%. Calcd for $C_{26}H_{23}NO_2$: C, 81.86; H, 6.08; N, 3.67%. ^{1}H NMR ($CDCl_3$, δ): 2.40 (3H, s), 2.42 (3H, s), 3.81 (3H, s), 3.82 (3H, s), 5.85 (1H, s), 6.58 (2H, s), 6.9—7.1 (4H, m), 7.3—7.7 (3H, m) 8.1—8.3 (1H, m). Column chromatography of the equilibrated rotamer mixture on alumina gave *ap*-**1c**, mp 297—298.5 °C (from ethanol). Found: C, 81.64; H,5.92; N, 3.64%. ^{1}NMR ($CDCl_3$, δ): 2.43 (6H, s), 3.72 (3H, s), 3.82 (3H, s), 5.90 (1H, s), 6.58 and 6.67 (2H, AB-q, *J*=9 Hz), 6.9—7.1 (4H, m), 7.3—7.5 (2H, m), 7.9—8.1 (2H, m).

±sc-*1,4-Dimethoxy-9-(1-methoxycarbonyl-1-methylethyl)triptycene (*±sc-*2c),* mp 222—224 °C, was synthesized similarly as ±*sc*-**1c** from 9-(1-methoxycarbonyl-1-methylethyl)anthracene[2] and 3,6-dimethoxyanthranilic acid[6] in 6% yield. Found: C, 78.28; H, 6.38%. Calcd for $C_{27}H_{26}O_4$: C, 78.24; H, 6.32%. ^{1}H NMR ($CDCl_3$, δ): 2.18 (6H, s),[7] 3.59 (3H, s), 3.65 (3H, br s), 3.80 (3H, s), 5.84 (1H, s), 6.48 and 6.59 (2H, AB-q, *J*=9 Hz), 6.7—7.1 (4H, m), 7.2—7.9 (4H, m).

Preparation of New Nitrogen-bridged Heterocycles. 7.[1] Reactions of 3-[Bis(methylthio)methylene]-2(3*H*)-indolizinones with Some Pyridinium *N*-Aminides

Akikazu KAKEHI,* Suketaka ITO, and Bunzo WADA
Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380
(Received September 8, 1983)

Synopsis. The reactions of 3-[bis(methylthio)methylene]-2(3*H*)-indolizinones with pyridinium, quinolinium, and isoquinolinium *N*-aminides gave unstable 1,3-dipolar spiro-adducts with the elimination of a methanethiol, and some of these adducts isomerized thermally to afford the corresponding *N*-ylide derivatives.

Ketene dithioacetals are now widely recoginized as versatile intermediates in the syntheses of a variety of organic compounds. In particular, the members conjugated with a vinyl or a keto group serve as carbonyl umpolung reagents,[2] Diels-Alder dienes,[3] and reagents for the preparation of various heterocycles.[4] Recently, we reported the preparation of dihydroaromatic ketene dithioacetals, 3-[bis(methylthio)methylene]-2(3*H*)-indolizinone derivatives, and their transformation into 2*H*-pyrano[2,3-*b*]indolizinones by the reactions with various activated acetates in the presence of alkali.[5] The reaction with actates is the first case in which the high electrophilicity of these α-oxo ketene dithioacetals serves for the syntheses of fused heterocycles. In this note, we wish to report the reactivity of 3-[bis(methylthio)methylene]-2(3*H*)-indolizinones as a dipolarophile and thermal behavior of the resulting 1,3-dipolar spiro-adducts.

When an equimolar mixture of 3-[bis(methylthio)-methylene]-1-methyl-2(3*H*)-indolizinone **1** and 1-aminopyridinium iodide **3** was treated with potassium carbonate in THF at room temperature and then separated carefully by column chromatography, red spiro-adduct **4** was obtained in a quantitative yield. A similar treatment of 1-phenyl derivative **2** and *N*-aminide **3** gave the corresponding compound **5** in a 66% yield. In these reactions, methanethiol was detected by its unpleasant odor. These compounds **4** and **5**, however, were extremely unstable and converted rapidly to intractable tarry materials even at room temperature. So, we next examined the reactions of the stabilized bicyclic *N*-aminides instead of monocyclic one. As might be expected, the reactions of **1** and **2** with 1-aminoquinolinium iodide **6** and 2-aminoisoquinolinium iodide **9** in the presence of alkali afforded relatively stable crystalline spiro-adducts **7**, **8**, **10**, and **11** in 69—100% yields.

Interestingly, compounds **7**, **10**, and **11** isomerized smoothly into the corresponding quinolinium *N*-ylide **12**, and isoquinolinium *N*-ylides **14** and **15** on standing at room temperature or on heating in boiling xylene, while no *N*-ylide **13** could be obtained from the thermolysis of **8** under the same conditions. On the other hand, the reactions of acyclic ketene dithioacetals **16** and **17** with **3** in the presence of alkali afford-

a) NMR data of ylidic compounds in $CDCl_3$ as follows: **12**, δ 1.89 (3H, s, 1'-Me), 2.68 (3H, s, SMe), and 7.00—8.80 (11H, m, other protons). **14**, δ 1.93 (3H, s, 1'-Me), 2.70 (3H, s, SMe), and 7.00—8.80 (11H, m, other protons). **15**, δ 2.55 (3H, s, SMe) and 6.80—8.70 (16H, m, other protons). **18**, δ 2.47 (3H, s, SMe), 3.51 (3H, s, OMe), and 7.70—8.80 (5H, m, pyridine protons). **19**, δ 1.12 (3H, t, J=7.0 Hz, $CH_2\underline{CH_3}$), 2.47 (3H, s, SMe), 3.98 (2H, q, J=7.0 Hz, $O\underline{CH_2}CH_3$), and 7.70—8.80 (5H, m, pyridine protons). b) The analysis could not be performed because of its thermal instability. c) The cyano absorption band appeared at 2162 cm^{-1}. d) The cyano absorption band appeared at 2178 cm^{-1}.

ed only stable pyridinium *N*-ylides **18** and **19** in good yields, respectively, but did not cycloadducts at all.

Structural elucidation of these spiro-adducts **4**, **5**, **7**, **8**, **10**, and **11** was mainly accomplished by their NMR and IR spectral inspection and partly by their elemental analyses. In particular, their NMR spectra (See Table 1) supported clearly the presences of 2(3*H*)-indolizinone[5] and 3,3a-dihydropyrazolo[1,5-*a*]pyridine moieties.[6] The IR spectra exhibited also the presence of a carbonyl band (near 1600 cm^{-1}) characteristic of 2(3*H*)-indolizinone derivative.[5] Similarly, the structures of *N*-ylides **12**, **14**, **15**, **18**, and **19** were determined by their elemental analyses and by comparison of their spectral data with those of known pyridinium *N*-ylides.[6,7]

The formation of the spiro-adducts **4**, **5**, **7**, **8**, **10**, and **11** may be considered by 1,3-dipolar cycloaddition between ketene dithioacetals **1** and **2** and *N*-amimides **3**, **6**, and **9** followed by the elimination of one molecule of methanethiol from the resulting primary spiro-adducts. Since facile transformations from these spiro-adducts **7**, **10**, and **11** to the corresponding *N*-ylides **12**, **14**, and **15** were observed but the reverse reaction was not, an alternative path *via* 1,5-dipolar cyclization of the *N*-ylides such as **12**—**15** which were formed initially by the nucleophilic substitutions of *N*-aminides onto dithioacetals may be discarded.

Experimental

Melting points were measured with a Yanagimoto micro melting point apparatus and are uncorrected. Microanalyses were carried out on a Perkin-Elmer 240 Elemental Analyzer. The NMR spectra were determined with a Varian EM360A Spectrometer in deuteriochloroform with tetramethylsilane as an internal standard. The chemical shifts are expressed in δ values. The IR spectra were taken with a Hitachi 260-10 Infrared Spectrophotometer.

Reactions of Ketene Dithioacetals with N-*Aminides. General Procedure*: A solution of acetal (*1* or **2**, 1 mmol) and pyridinium salt (1 mmol) in THF (30 mol) was treated with anhydrous potassium carbonate (5 g) under stirring at room temperature for 30 min. Insoluble inorganic substances were filtered and the filtrate was immediately concentrated *in vacuo* at below 10 °C. The residue was separated by column chromatography (alumina) using ether and then chloroform as eluents and the chloroform layer was concentrated carefully by centrifugal freezing dryer (Yamato, RC-11). Recrystallizations from chloroform–hexane at below 5 °C gave pure adducts **7**, **8**, **10**, and **11**, but those of **4** and **5** were unsuccessful because of their thermal instability. On the other hand, only pyridinium *N*-ylides **18** and **19** were formed from the reactions of acyclic acetals **16** and **17** with **3**. The results and data are shown in Tables 1 and 2.

Isomerization of Spiro-adducts to N-*Ylides.* Spiro-adducts **7** and **10** smoothly isomerized to the corresponding *N*-ylides **12** and **14** on standing at room temperature for 3—4 d, but the conversion of **11** to **15** was accomplished by heating for 30 min in boiling xylene. On the other hand, adduct **8** decomposed under above conditions and no ylide could be obtained. The results and data are summarized in Table 2.

(Received September 16, 1983)

Synopsis. 2-(4-Cyanobutyl)-4,5,6,7-tetrahydrobenzimidazole was obtained by treating 2-aminocyclohexanone oxime with ethyl acetimidate hydrochloride in acetic acid at below 50 °C, though only 2-methyl-4,5,6,7-tetrahydrobenzimidazole was produced by the reaction of 2-aminocyclohexanone oxime and free ethyl acetimidate in neutral solvents. A novel Beckmann fission reaction of dimeric 2-aminocyclohexanone oxime is presumed to participate in the formation of 2-(4-cyanobutyl)-4,5,6,7-tetrahydrobenzimidazole.

2-Aminocyclohexanone oxime (**1**) reveals an electrophilic property at the nitrogen atom of its amino group and a nucleophilic one at the carbon atom bearing hydroxyimino group and thus reacts readily with reagents having reactive functional groups to give various kinds of heterocyclic compounds, such as 2-mercaptoimidazoles,[1] phenazines,[2] and 2-amino-ε-caprolactam.[3] In this study we describe the reactions of **1** with ethyl acetimidate and its hydrochloride, and we continue the structure elucidation.

Results and Discussion

We have obtained **2** as a sole product in 89.2% yield by heating a mixture of **1** and ethyl acetimidate in methanol and/or chloroform under reflux. When we used ethyl acetimidate hydrochloride in chloroform, methanol or a mixture of chloroform and pyridine, only a small amount of 1,2,3,4,6,7,8,9-octahydro phenazine (**4**) was obtained with virtual recovery of the starting materials. When ethyl acetimidate hydrochloride was used in acetic acid at above 80 °C, **4** was obtained as a major product.[2] However, **3** was mainly obtained at below 50 °C.[4] The structure of this new compound **3** has been studied by various means. This material has a molecular formula $C_{12}H_{17}N_3$ and must be formed by the condensation of two molecules of **1** with the elimination of 1 mol of ammonia and 2 mol of water. In the ^{1}H-NMR spectrum, two kinds of 8H multiplets were observed at δ 1.6—2.1 and δ 2.2—2.9, and a 1H doublet, which was replaced by deuterium. oxide, was observed at δ 7.3—8.1. The 1H doublet at low field was assumed to be an imino proton adjacent to olefin or electron-withdrawing groups. The UV spectrum showed an absorption maximum at 226 nm. The MS spectrum showed the parent peak at *m/z* 203 and fragment peaks at 175, 163, 150, 137, 108, 95, and 77, but these peaks are not highly informative. Since constructive structural data were not obtained merely from these data, an X-ray

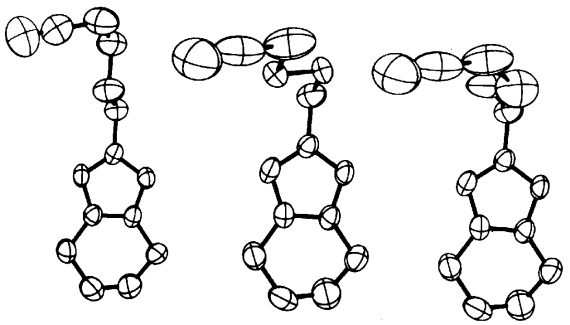

Fig. 1. ORTEP drawings of the molecule **3** determined by X-ray structure analysis.[5] Three conformers of the side chain exist in a monoclinic crystal. The ellipsoids are drawn to enclose 50% probability.

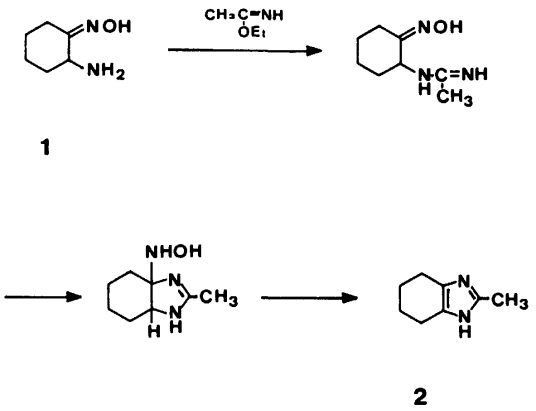
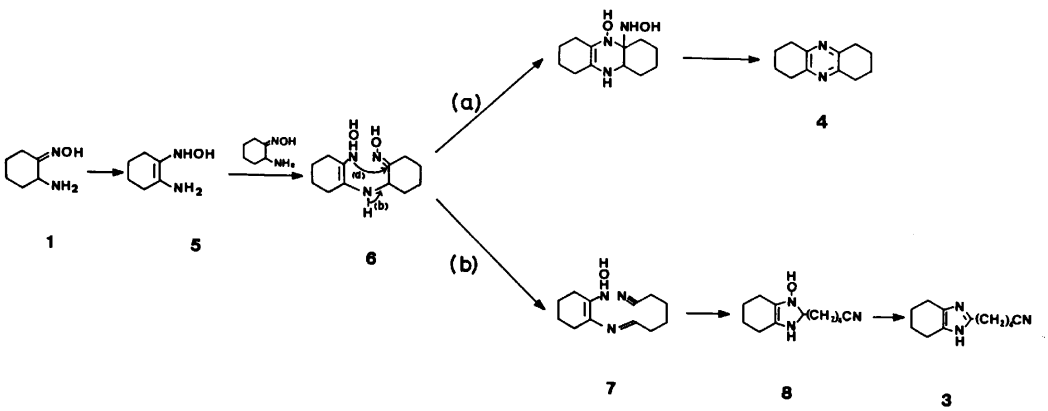


Scheme 1.



Scheme 2.

crystal structure analysis was then carried out with a single crystal grown from a ethyl acetate solution and the structure was established as **3** (Fig. 1).

The formation of 2-(4-cyanobutyl)-4,5,6,7-tetrahydro benzimidazole from 2 mol of 2-aminocyclohexanone oxime is quite unexpected and unusual. A plausible mechanism to account for its formation is depicted in Schemes 1 an 2.

By treating **1** with ethyl acetimidate in usual solvents such as chloroform and/or methanol, **2** was obtained as the expected product. When ethyl acetimidate hydrochloride was used in acetic acid, the reaction rate became slower and **1** was isomerized to 1-amino-2-(hydroxyamino)cyclohexene (**5**), and **5** reacted with another **1** to give 1-[2-(hydroxyimino)cyclohexylamino]-2-(hydroxyamino)cyclohexene (**6**). At above 80 °C, the carbon atom bearing hydroxyimino group was attacked by the nitrogen of hydroxyamino group to give **4** (path *a* in Scheme 2). When the reaction conditions were milder (at below 50 °C), on the contrary, a Beckmann fission reaction of **6** proceeded to give 1-(6-nitrilohexylideneamino)-2-(hydroxyamino)cyclohexene (**7**), which was converted to **8** by ring closure and finaly to **3** by dehydration (path *b* in Scheme 2).

Although the details of the role of ehtyl acetimidate hydrochloride in this reaction remain to be clarified, no such Beckmann fission reaction has ever been reported to the best of our knowledge.

Experimental

Measurements. The IR, UV, and mass spectra were recorded on Shimadzu IR-40, Shimadzu UV-220, and Hitachi RMU-7M spectrometers respectively. The ^{1}H-NMR spectra were recorded on Hitachi R-24B (60 MHz) spectrometer, using TMS as the internal standard. The X-ray diffraction data were obtained on a Rigaku automated four-circle diffractometer. The details of the crystal structure was reported by a separate cover.[5]

Preparations. 2-Aminocyclohexanone oxime (**1**) was prepared by the method described in the patent.[6]

2-Methyl-4,5,6,7-tetrahydrobenzimidazole (2): To a solution of 2-aminocyclohexanone oxime 64 g (0.5 mol) in methanol (500 ml) was added dropwise an ethyl acetimidate 43.5 g (0.5 mol) in the solution of methanol (50 ml) under reflux during 1 h, and the reaction mixture was heated under reflux for additional 6 h. After the reaction, the solvent was evaporated out, and the crude product was purified by recrystallization from ethyl acetate to give 60.7 g (89.2%) of **2** as a white solid; mp 225—226 °C. ^{1}H-NMR ($CDCl_3$), δ=1.6—2.1 (m, 4H), 2.33 (s, 3H), 2.1—2.8 (m, 4H), 8.7—9.3 (m, 1H); IR (KBr) 3190, 3100, 3000, 2940, 2850, 2760, 1630, 1540, 1460, 1440, 1420, 1240, 1040, 940 cm^{-1}. Found: C, 70.63; H, 8.79; N, 20.50%. Calcd for $C_8H_{12}N_2$: C, 70.55; H, 8.88; N, 20.57%.

2-(4-Cyanobutyl)-4,5,6,7-tetrahydrobenzimidazole (3): A mixture of 2-aminocyclohexanone oxime 12.8 g (0.1 mol), ethyl acetimidate hydrochloride 12.4 g (0.1 mol) and acetic acid 100 ml was heated at 40 °C. After 3 h, acetic acid was removed under reduced pressure, water (30 ml) was added to the residue, and the solution was extracted with benzene (50 ml). The water layer was adjusted to pH 10 with 2 M (1 M=1 mol dm^{-3}) sodium hydroxide solution and the solution was extracted with three 100 ml portions of benzene and then dried over anhydrous magnesium sulfate. After removal of the benzene, the residue was purified by recrystallization from ethyl acetate to give 8.6 g (84.6%) of **3** as a white solid; mp 177—178 °C. ^{1}H-NMR ($CDCl_3$) δ=1.5—2.1 (m, 8H), 2.2—2.8 (m, 8H), 7.3—8.2 (m, 1H); IR (KBr) 3180, 3100, 3020, 2950, 2860, 2770, 2260, 1630, 1440, 1240, 1040 cm^{-1}. Found: C, 70.88; H, 8.49; N, 20.63%. Calcd for $C_{12}H_{17}N_3$: C, 70.90; H, 8.43; N, 20.67%.

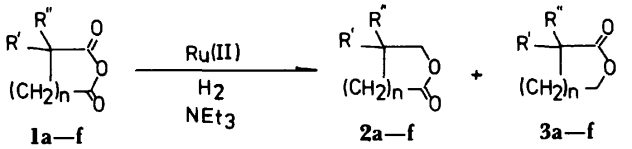
(Received September 19, 1983)

Synopsis. Regioselective hydrogenation of unsymmetrically substituted cyclic anhydrides catalyzed by ruthenium complexes with mono-, di-, or triphosphine ligands produced the corresponding two isomeric lactones, where the regioselectivity was influenced by the bulkiness of the substituent(s) on the anhydrides and of the phosphine ligands of catalyst.

We have previously reported that a ruthenium complex having the diop ((−)-2,3-*O*-isopropylidene-1,4-bis(diphenylphosphino)-2,3-butanediol ligand catalyzed stereoselective hydrogenation of prochiral and *meso*-cyclic anhydrides to the corresponding optically active lactones.[1] Such an enantiotopes differentiating reaction is rarely found in the asymmetric reactions catalyzed by transition metal complexes.[2] However, still ambiguous is how the ruthenium complex distinguishes between pro-*R* and pro-*S* groups in a prochiral molecule. In order to obtain more informations about the steric interaction between the cyclic anhydride and the catalyst, the regioselectivity of the hydrogenation of unsymmetrically substituted cyclic anhydrides, which can potentially produce two isomeric lactones **2** and **3**, (Scheme 1), was examined using ruthenium complexes



Scheme 1.

having mono-, di-, or triphosphine ligands as catlysts. It was briefly reported that $RuCl_2(PPh_3)_3$ catalyzed hydrogenation of 2,2-dimethylsuccinic anhydride gave preferentially 2,2-dimethyl-γ-butyrolactone.[3] More recently we have shown that the stoichiometric reaction of $RuH_2(PPh_3)_4$ with 2-alkylsuccinic anhydrides afforded two isomeric complexes, in which $RuH(OCOCHRCH_2CHO)(PPh_3)_3$ is the major product.[4] These results promoted us to reinvestigate the systematic study on the catalytic hydrogenation of cyclic anhydrides to reveal the factors which govern the stereo- and regioselectivities for the transformation of cyclic anhydrides to lactones.

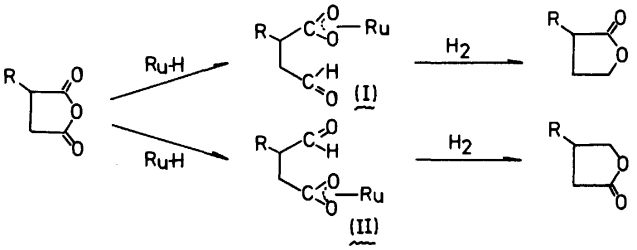
Experimental

Ruthenium complexes, $RuCl_2(PPh_3)_3$, $Ru_2Cl_4(dppb)_3$,[5] $Ru_2Cl_4(diop)_3$,[6] and $RuCl_2(ttp)$,[7] (ttp=bis(3-diphenylphosphino)propyl)phenylphosphine) methods in the literatures.

Hydrogenation of Cyclic Anhydrides. A toluene solution containing cyclic anhydride (5 mmol), $MgSO_4$, and triethylamine (0.1 cm^3) was allowed to react with hydrogen gas (10 atom) in the presence of ruthenium complex (0.1—0.2 mmol) at 120 °C for 10—20 h. After being returned to atmospheric pressure, the insoluble materials were separeted by filtration, and the filtrate was evaporated to remove the solvent. The hydrogenated products were isolated by vaccum distillation and identified by ^1H NMR, mass, and IR spectroscopies. The molar ratio of two isomers in each product was determined by GC using acetophenone or propiophenone as an internal standard. Table 1 summerizes the representative results. Hydrogenation of racemic 2-methylsuccinic anhydride using the chiral complex $Ru_2Cl_4(diop)_3$ was carried out in the similar manner to that described above, and the diastereomeric products were isolated by preparative GC (Carbowax 3 m). The optical purities of lactones were determined by measurement of the optical rotation,[8] **2a**; $[\alpha]_D$=+1.3°. 5.9%e.e., **3a**; $[\alpha]_D$=−2.9°, 11.3%e.e.

Results and Discussion

The hydrogenation of cyclic anhydrides **1a—f** catalyzed by ruthenium complexes produces the corresponding isomeric lactones **2a—f** and **3a—f**, where the reaction preferentially occured at the less hindered carbonyl group to give **2a—f** selectively except phenylsuccinic anhydride (**1d**). This is a marked contrast to that the reduction of cyclic anhydrides with $LiAlH_4$ or $NaBH_4$ tends to take place selectively at the more hindered carbonyl group.[9] The regioselectivity increased in the order of 2-methyl<2-isopropyl<2,2-dimethyl-substituted cyclic anhydride, which is the order of the steric bulkiness of the substituent(s). It is possible that the hydrogenation of cyclic anhydrides proceeded *via* an intermediacy ruthenium formyl carboxylate complex formed by the cleavage of one of two C-O bonds on the anhydride.[4] The initial attack of ruthenium to the carbonyl group and succesive C-O fission of one of the C-O bonds should be controlled by the steric hindrance of substituent to give preferentially the formyl carboxylate complex (**II**) as shown in Scheme 2. Thus the carbonyl group adjacent to substituent(s) becomes less reactive. In the case of phenylsuccinic anhydride (**1d**) the more hindered carbonyl group was reduced selectively to some extent. It is obvious that the electron-withdrawing phenyl group weakens the neighboring C-O bond, resulting in the preferable formation of the intermediate complex (**II**) as shown in Scheme 2.



Scheme 2.

Table 1. Regioselective hydrogenation of cyclic anhydrides

Run	Cyclic anhydride		Catalyst[a]	Temp/°C	Time/h	Yield/%	2/3

21			(A)	120	20	11	3/97
22			(B)	120	20	20	2/98
23			(D)	120	20	17	0/100
24	(**1f**)		(D)	140	20	29	1/99

a) (A) = $RuCl_2(PPh_3)_3$; (B) = $Ru_2Cl_4(dppb)_3$; (C) = $Ru_2Cl_4(diop)_3$; (D) = $RuCl_2(ttp)$.

To clarify further that the steric interaction between the substituent and ligand controls the selectivity, the hydrogenation of racemic 2-methylsuccinic anhydride (**1a**) with the chiral ruthenium complex $Ru_2Cl_4(diop)_3$ was examined. Of interest is that 2-methyl-γ-butyrolactone (**2a**) obtained from the hydrogenation of racemic **1a** using $Ru_2Cl_4(diop)_3$ was found to contain *R*-isomer in excess (5.9%e.e.), while 3-methyl-γ-butyrolactone (**3a**) obtained as the minor component contained the *S*-isomer in excess (11.3%e.e.).[8] The 2-methylsuccinic anhydride recovered from the reaction mixture exhibited negligible optical activity. These results obviously indicate that the optical activity of the above mentioned lactones could be explained in term of difference in the reactivities between *R*- and *S*-enantiomers toward the chiral complex $Ru_2Cl_4(diop)_3$ caused by the distinctive steric interaction of the chiral phosphine ligand with the substituent on *R*- and *S*-enantiomers. This is supported by the fact that the hydrogenation of (*R*)-2-methylsuccinic anhydride[11] catalyzed by $Ru_2Cl_4(diop)_3$ exhibited the apparently higher regioselectivity than that with *S*-enantiomer as shown in Table 1. The similar difference in the reactivity was observed in the hydrogenation of 2-isopropylsuccinic anhydride (**1c**) catalyzed by $Ru_2Cl_4(diop)_3$.

In conclusion the factor which governs primarily the regio- and stereoselectivities of the ruthenium complex-catalyzed hydrogenation of cyclic anhydrides is the steric interaction between substituent(s) on the substrate and the phosphine ligand. In the case of phenylsuccinic anhydride the electronic effect becomes superior to the effect of the steric demand. With the combination of this hydrogenation of cyclic anhydrides and the dehydrogenation of diols catalyzed by the same complex,[10] the selectivity of the latter being in the opposite direction to the former, the synthetic control of lactone formation can be performed employing the dicarboxylic acids as the starting materials.

Synthesis of 1,2-Polymethyleneimidazoles Utilizing Intramolecular Ring Transformation

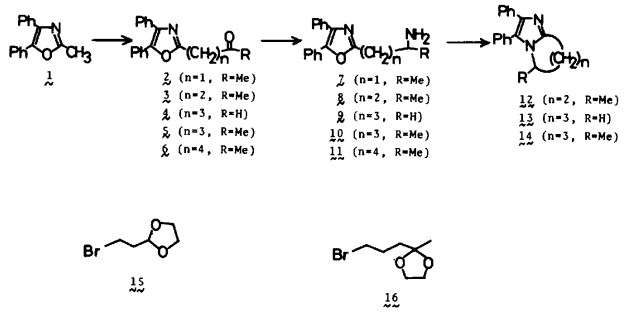
Tadashi SASAKI,* Masatomi OHNO, and Eikoh ITO
Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464
(Received October 8, 1983)

Synopsis. Among the intramolecular cyclodehydration of 2-(β-, δ-, and ε-aminoalkyl)oxazoles, 2-(δ-aminoalkyl)oxazoles afforded the desired 1,2-tetramethyleneimidazoles on pyrolysis, while 2-(β- and ε-aminoalkyl)oxazoles unchanged under the same conditions.

We have recently studied[1] an intramolecular cyclodehydration of 2-(γ-aminoalkyl)oxazole affording 1,2-trimethyleneimidazole (*i.e.*, **3**→**8**→**12**) based on the intramolecular ring transformation strategy.[2-4] To apply this method for the synthesis of other 1,2-polymethyleneimidazoles, it is significant to know the effects induced by the number of bridging atoms between an oxazole and an amino function. For this purpose, 2-(β-, δ-, and ε-aminoalkyl)oxazoles were prepared and their pyrolysis was studied.

2-Methyloxazole **1**[5] was lithiated with *n*-BuLi in THF at −78 °C[6] and acylated with ethyl acetate to give β-oxazolyl ketone **2** in 51% yield. The lithiated **1** afforded δ-oxazolyl aldehyde **4** in 65% yield on treatment with bromo acetal **15**[7] followed by hydrolysis of the coupled acetal. δ-Oxazolyl ketone **5** was prepared in 46% yield by the transformation of **4** *via* Grignard reaction followed by the oxidation of the resulting secondary alcohol with pyridinium chlorochromate (PCC). ε-Oxazolyl ketone **6** was similarly prepared in 45% yield from **1** and bromo acetal **16**[8] The carbonyl function of **2**, **4**, **5**, and **6** was indicated by strong absorptions at 1715, 1725, 1715, and 1715 cm^{-1} respectively and their structures were supported by the spectral and elemental analyses. The prepared ketones **2**, **5**, and **6** were reductively aminated to the corresponding amines **7**, **10**, and **11** respectively on treatment with $NaBH_3CN$ in the presence of ammonium acetate. This conversion was indicated by methyl doublets at δ 1.24 (J=6.8 Hz) for **7**, 1.12 (J=6.8 Hz) for **10**, and 1.05 (J=6.8 Hz) for **11** and D_2O-exchangeable N–H signals at δ 1.80 for **7**, 1.90 for **10**, and 1.70 for **11** in the ^1H NMR spectra. Without further purification, δ-oxazolyl amine **10** was directly heated at 280 °C under reduced pressure (5 mmHg, 1 mmHg≈133.322 Pa) to give cyclodehydrated 1,2-tetramethyleneimidazole **14** in 50% overall yield from **5**. In the same manner as for δ-oxazolyl ketone **5**, δ-oxazolyl aldehyde **4** was successfully transformed to **13** in 29% overall yield. The structure of **13** was definitely confirmed by the spectral comparison with an authentic sample reported in the literature,[9] and with the spectral data for **13** in hand, that of **14** was readily determined; ring closure was verified by disappearance of D_2O-exchangeable N–H signal and the chemical shift of ring protons at δ 1.60—2.30 (4H, m, C-6 and C-7 H), 2.70—3.15 (2H, m, C-8 H), and 3.90—4.50 (1H, m, C-5 H). In contrast to the successful ring transformation of **9** and **10**, any attempted pyrolysis of 2-(β- and ε-aminoalkyl)oxazoles **7** and **11** resulted in the recovery of the starting material.

In summary, cyclodehydration of 2-(aminoalkyl)oxazoles was found to be effective for the synthesis of not only 1,2-trimethylene- but also tetramethyleneimidazole ring system. Further application could make this strategy quite capable of providing a number of different fused ring system of interest.



Experimental

Melting points were measured with a Yanagimoto micro-melting point apparatus and are uncorrected. IR spectra were obtained on a JASCO-IRA-1 spectrometer. ^1H NMR spectra were recorded on a JEOL C-60-HL spectrometer and chemical shifts are reported in ppm (δ) relative to Me_4Si as internal standard. Microanalyses were performed with Perkin-Elmer 240B elemental analyzer. Pyrolysis was carried out with a Sibata Glass Tube Oven GTO-250.

2-(2-Oxopropyl)-4,5-diphenyloxazole (2). To a solution of **1**[5] (2.0 g, 8.5 mmol) in dry THF (30 ml) was added a solution of *n*-BuLi in hexane (1.6 M, 6.3 ml, 10.2 mmol) dropwise over 15 min at −78 °C under the current of N_2. After the resulting deep orange-red suspension was stirred at −78 °C for additional 20 min, ethyl acetate (0.95 ml, 9.7 mmol) was added and the mixture was stirred at −78 °C for 30 min. The resulting mixture was then slowly warmed to room temperature and quenched with 30 ml of phosphate buffer (pH 7). The organic layer was extracted with $CHCl_3$ (3×20 ml). The combined $CHCl_3$ solution was washed 3 times with water, dried over $MgSO_4$, and concentrated to leave a yellow oil, which was chromatographed on a silica gel column (AcOEt/hexane 1:2) to give crude **2**. Further purification by recrystallization from ethanol gave 1.2 g (51%) of **2** as yellow crystals; mp 106—108 °C; IR (KBr) 3090, 2910, 1715, 1600, 1570, and 1510 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.30 (3H, s, CH_3), 3.97 (s, 2H, CH_2), and 7.20—7.80 (10H, m, Ar). Found: C, 77.70; H, 5.72; N, 5.05%. Calcd for $C_{18}H_{15}NO_2$: C, 77.96; H, 5.45; N, 5.05%.

2-(4-Oxobutyl)-4,5-diphenyloxazole (4). To a solution of the lithiated **1** (2.0 g, 8.5 mmol) prepared as above, **15**[7] (1.1 ml, 9.4 mmol) was added and the mixture was stirred at −78 °C for 30 min. The resulting mixture was then slowly warmed to room temperature and quenched with 30 ml of phosphate buffer (pH 7). The organic layer was extracted with $CHCl_3$ (3×30 ml). The combined $CHCl_3$

solution was washed 3 times with water, dried over $MgSO_4$, and concentrated to leave acetal as a yellow oil. A mixture of crude acetal and 0.5 M aqueous HCl (40 ml) was heated under reflux for 1 h. After cooling to room temperature, an orange oil was extracted with $CHCl_3$ (3×30 ml). The combined $CHCl_3$ solution was washed 3 times with water, dried over $MgSO_4$, and concentrated to leave an oil, which was chromatographed on s silica gel column (AcOEt/hexane 1:1) to afford 1.6 g (65%) of **4** as a yellow oil; IR (neat) 3045, 2940, 2810, 2710, 1725, 1600, 1570, and 1500 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.18 (2H, quintet, J=6.8 Hz, CH_2), 2.50—3.10 (4H, m, CH_2×2), 7.20—7.80 (m, 10H, Ar), and 9.78 (1H, t, J=1.2 Hz, CHO). Found: C, 78.24; H, 6.00; N, 4.78%. Calcd for $C_{19}H_{17}NO_2$: C, 78.33; H, 5.88; N, 4.81%.

2-(4-Oxopentyl)-4,5-diphenyloxazole (5). To a solution of methylmagnesium iodide in ether (6 ml) prepared from magnesium (70 mg, 2.9 mmol) and methyl iodide (0.18 ml, 2.9 mmol), was added a solution of **4** (640 mg, 2.2 mmol) in ether (4 ml) at room temperature. After stirring at room temperature for 1.5 h, the reaction mixture was quenched with saturated aqueous ammonium chloride (20 ml) and extracted with ether (3×15 ml). The combined ether solution was dried over $MgSO_4$ and concentrated to leave crude alcohol as a yellow oil, which was dissolved in CH_2Cl_2 (4 ml). This solution was added to a solution of PCC (630 mg, 2.9 mmol) in CH_2Cl_2 (4 ml) and stirred at room temperature for 17 h. After removal of the solvent, the residue was extracted with ether (3×10 ml). Concentration of the combined ether solution and subsequent chromatography on a silica-gel column (Et_2O/hexane 1:1) gave 320 mg (48%) of **5** as a yellow oil; IR (neat) 3050, 2940, 1715, 1600, 1570, 1500, and 1445 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.18 (3H, s, CH_3), 2.45—3.08 (6H, m, 3×CH_2), and 7.20—7.80 (10H, m, Ar). Found: C, 78.56; H, 6.32; N, 4.53%. Calcd for $C_{20}H_{19}NO_2$: C, 78.66; H, 6.27; N, 4.59%.

2-(5-Oxohexyl)-4,5-diphenyloxazole (6). By the similar procedure to the preparation of **4**, ε-oxazolyl ketone **6** was prepared by the reaction of the lithiated **1** with bromoacetal **16**[8] at −78 °C, followed by hydrolysis of the resulting acetal with 0.5 M aqueous HCl. Purification was performed on a silica-gel column (Et_2O/hexane 1:1); yield 45; yellow oil; IR (neat) 3050, 2940, 1715, 1600, 1575, 1500, and 1445 cm^{-1}; ^1H NMR ($CDCL_3$) δ=1.50—3.00 (8H, m, 4×CH_2), 2.14 (3H, s, CH_3), and 7.20—7.80 (10H, m, Ar). Found: C, 78.86; H, 6.60; N, 4.63%. Calcd for $C_{21}H_{21}NO_2$: C, 78.97; H, 6.63; N, 4.39%.

2,3-Diphenyl-5,6,7,8-tetrahydroimidazo[1,2-a]pyrdine (13). A solution of **4** (470 mg, 1.6 mmol), $NaBH_3CN$ (710 mg, 11.3 mmol), and ammonium acetate (1.2 g, 15.6 mmol) in dry methanol (16 ml) was heated under reflux for 3 h. The resulting mixture was acidified with concentrated aqueous HCl (pH 2) and then basified with 20% aqueous NaOH (pH 9). After extraction with $CHCl_3$ (3×15 ml), the combined organic layer was dried over $MgSO_4$. Removal of the solvent yielded crude amine **9** as a yellow oil, which was then heated at 280 °C under 5 mmHg for 20 min in a glass tube oven with a trap bulb heated at 200 °C. Tetrahydroimidazopyridine **13** was trapped as a yellow oil, which immediately solidified on cooling; 130 mg (29%); mp 140—142 °C (from AcOEt) (Lit,[9] 137—138 °C). Its spectral data are in good agreement with those reported in the literature.

5-Methyl-2,3-diphenyl-5,6,7,8-tetrahydroimidazo[1,2-a]pyridine (14). In the same way as above, **14** was obtained in 50% yield by the reductive amination of **5**, followed by pyrolysis of the crude 2-(δ-aminoalkyl)oxazole **10**. An analytical sample was obtained by chromatographic purification; mp 116—119 °C; IR (KBr) 3040, 2830, 1600, 1510, 1440, and 1420 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.98 (3H, d, J=6.8 Hz, CH_3), 1.60—2.30 (4H, m, C-6 and C-7 H), 2.70—3.15 (2H, m, C-8 H), 3.90—4.50 (1H, m, C-5 H), and 7.10—7.60 (10H, m, Ar). Found: C, 83.51; H, 6.81; N, 9.68%. Calcd for $C_{20}H_{20}N_2$: C, 83.30; H, 6.99; N, 9.71%.

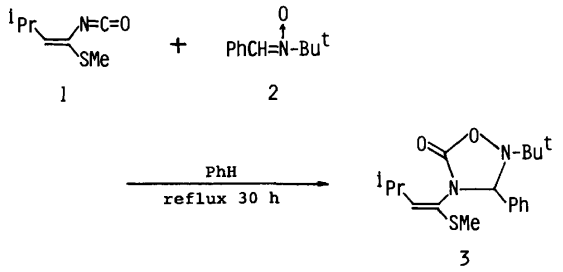
Cycloaddition of Vinyl Isocyanate to 1,3-Dipoles

Yoshiki OHSHIRO,* Mitsuo KOMATSU, Aiichiro OKAMURA, and Toshio AGAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka 2-1, Suita, Osaka 565
(Received October 14, 1983)

Synopsis. 1,2-Cycloadditions of 3-methyl-1-(methylthio)-1-butenyl isocyanate with *N*-*t*-butyl-α-toluenimine *N*-oxide and with *in situ*-generated *N*-*t*-butyl-α-methyl-α-lactam afforded an oxadiazolidinone derivative and a hydantoin derivative in 100 and 46% yields, respectively.

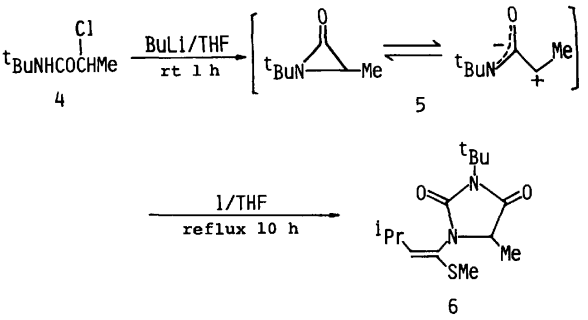
Vinyl isocyanates are known to undergo 1,2- and/or 1,4-cycloaddition reactions with several unsaturated compounds and have been often utilized in heterocyclic synthesis.[1,2] Previously we reported synthesis and 1,4-cycloaddition reactions of α-alkylthio(or arylthio)vinyl isocyanates,[3] which are expected to be reagents equivalent to acyl isocyanates[4] because the (alkylthio)vinyl group is easily converted to a carbonyl group.[5] Here we wish to report 1,2-cycloaddition reactions of 1,3-dipoles to the (alkylthio)vinyl isocyanate leading to heterocycles having the (alkylthio)vinyl substituent.

Reaction of (*E*)-3-methyl-1-(methylthio)-1-butenyl isocyanate (**1**) and *N*-*t*-butyl-α-toluenimine *N*-oxide (**2**) in refluxing benzene for 30 h under a nitrogen atmosphere to give 2-*t*-butyl-4-[3-methyl-1-(methylthio)-1-butenyl]-3-phenyl-1,2,4-oxadiazolidin-5-one (**3**) quantitatively.



The structure of the oxadiazolidone **3** was determined by spectral data and elemental analysis. The IR spectrum of **3** shows a strong carbonyl absorption at 1740 cm^{-1} as well as a weak one at 1625 cm^{-1} due to the olefinic bond. In the NMR spectrum, two methyl doublets were observed at δ 0.17 and 0.93 (relative area 3H, respectively). These are assignable to the isopropyl group whose methyl groups became nonequivalent by the presence of the asymmetric carbon in the oxadiazolidine ring. The unusual higher shift of one of the methyl signals is due to the deshielding effect by the phenyl ring.

As another candidate for a 1,3-dipole, it is known that an α-halo amide generates an α-lactam and/or a 1,3-dipole such as **5** upon treatment with a strong base.[6] Thus the α-chloropropanamide **4** was reacted with the isocyanate **1** after treatment with butyllithium. 1,2-Cycloadditon again occurred to give the hydantoin derivative **6**. The IR spectrum of **6** showed two carbonyl absorptions at 1770 and 1715 cm^{-1} and a weak one at 1630 cm^{-1} due to the C=C bond. In the NMR spectrum, two doublets of the nonequivalent methyl group of the isopropyl function was observed at δ 0.95 and 1.13. The



mass spectrum as well as elemental analysis showed good agreement with the structure of the hydantoin **6**.

Thus the two heterocyclic compounds having a thiovinyl substituent were prepared by 1,2-cycloaddition of the (alkylthio)vinyl isocyanate with the 1,3-dipoles. Higher convertibility of the thiovinyl group, as is already mentioned, will enable further conversion of the compounds into various heterocycles and it will increase utility of the (alkylthio)vinyl isocyanates.

Experimental

A melting point was determined on a Yanagimoto micro melting point apparatus and melting and boiling points were uncorrected. ^{1}H-NMR spectra were obtained with a JOEL JNM PMX-60 spectrometer in $CDCl_3$ using TMS as an internal standard. IR spectra were taken on a JASCO IRA-1 spectrophotometer. Mass spectrometry was performed on a Hitachi RMU-6E spectrometer at an ionizing voltage of 70 eV.

Materials. (*E*)-3-Methyl-1-(methylthio)-1-butenyl isocyanate (**1**: bp 31—34 °C/267 Pa) and *N*-*t*-butyl-α-toluenimine *N*-oxide (**2**) were prepared according to the literatures.[3,7] *N*-*t*-Butyl-2-chloropropanamide (**4**) was prepared from *N*-*t*-butylamine and 2-chloropropionyl chloride by the usual manner. Commercially available butyllithium (15% in hexane) was used.

The Reaction of the Isocyanate 1 with the N*-Oxide 2.* A solution of **1** (1.7 g, 10 mmol) and **2** (1.9 g, 10 mmol) in dry benzene (20 ml) was stirred at reflux for 30 h. The reaction mixture was concentrated and chromatographed on a SiO_2 column to give 3.6 g (100%) of 2-*t*-butyl-4-[3-methyl-1-(methylthio)-1-butenyl]-3-phenyl-1,2,4-oxadiazolidin-5-one (**3**): mp 147—148 °C (colorless needles from benzene-hexane); IR (Nujol) 1740 (C=O) and 1625 cm^{-1} (C=C); ^{1}H-NMR δ=0.17 (3H, d, *J*=6.8 Hz, Me), 0.93 (3H, d, *J*=6.4 Hz, Me), 1.18 (9H, s, *t*Bu), 1.8—2.3 (1H, m, CH), 2.30 (3H, s, SMe), 5.57 (1H, d, *J*=10.2 Hz, =CH), 5.83 (1H, s, CH), 7.2—7.7 (5H, m, Ph); MS *m*/*z* 247 (M^+—BuNO). Found: C, 64.71; H, 7.99; N, 8.29%. Calcd for $C_{18}H_{26}N_2O_2S$: C, 64.85; H, 7.84; N, 8.38%.

The Reaction of the Isocyanate 1 with the 1,3-Dipole 5. To a solution of the amide **4** (1.56 g, 9.6 mmol) in THF (20 ml) was added dropwise a solution of butyllithium in hexane (6.4 ml, 9.6 mmol) and the mixture was stirred for 1 h at room temperature. To this mixture was added a solution of the isocyanate **1** (1.5 g, 9.6 mmol) in THF (10 ml) at 0 °C and was stirred for 10 h at reflux. After removal of THF

and addition of cold water, the reaction mixture was extracted (ether), dried (Na_2SO_4), and chromatographed on a SiO_2 column to give 1.3 g (46%) of 1-*t*-butyl-4-methyl-3-[3-methyl-1-(methylthio)-1-butenyl]-2,5-imidazolidinedione (**6**): bp 60 °C (bath temp)/66 Pa by pot distillation; IR (neat) 1770 (C=O), 1715 (C=O), and 1630 cm^{-1} (C=C); ^{1}H-NMR δ=0.95 (3H, d, J=6.2 Hz, Me), 1.13 (3H, d, J=6.2 Hz, Me), 1.37 (3H, d, J=7.0 Hz, Me), 1.62 (9H, s, *t*Bu), 2.12 (3H, s, SMe), 2.2—2.6 (1H, m, CH), 4.17 (1H, q, J=7.0 Hz, CH), 5.72 (1H, d, J=10.0 Hz, =CH); MS *m/z* 284 (M^+). Found: C, 58.83; H, 8.60; N, 9.57; S, 11.22%. Calcd for $C_{14}H_{24}N_2O_2S$: C, 59.13; H, 8.51; N, 9.85; S, 11.26%.

Laboratoire de Chimie Therapeutique, Universite Paul Sabatier 31077 TOULOUSE Cedex France

† *Laboratoire de Chimie Organique Structurale, Universite Paul Sabatier 31077 TOULOUSE Cedex France*

(Reçu Mars 10, 1983)

Synopsis. La stéréochimie de cinq α-oxo aldoximes R–CO–CH (NOH) (R=Me **1**, Et **2**, *n*-Pr **3**, *i*-Pr **4**, *t*-Bu **5**) a été étudiée : la configuration connue est E dans tous les cas mais les deux conformères *s*-cis et *s*-trans peuvent exister en différentes proportions lorsque varient la taille de R, la température ou le pH.

Les α-oxo aldoximes R–CO–CH(NOH) constituent une classe importante parmi les antidotes des toxiques organophosphores.[1-4] La géométrie du motif –CO–C(NOH)– est susceptible d'influer sur la réactivité biologique. Il est ainsi important de bien connaitre la stéréochimie de ces composés: la configuration *E* est maintenant bien établie[5-10] mais les conformations en solution ont été peu étudiees[11-14] et sont encore mal connues.

Nous étudions ici, comme nous l'avons déjà fait pour des α-hydroxyimino cétones cyclaniques[15] ou aromatiques,[16] les problèmes conformationnels posés dans la série des α-oxo aldoximes aliphatiques.

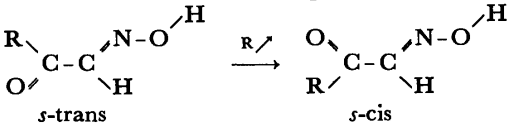
Etude dipolemétrique. (Tableau 1) Les valeurs expérimentales permettent par comparaison des valeurs obtenues et théoriques d'éliminer les conformations *c* et *d* mais ne permettent pas de trancher entre les formes *s*-trans *a* et *s*-cis *b*.

Etude par spectrométrie infrarouge. L'étude en solution met en évidence au niveau du groupe carbonyle des dédoublements de bande ou des dissymétries avec ou sans épaulement (Fig. 1). La bande principale est situé dans tous les cas entre 1680 et 1705 cm^{-1}. Cette bande principale peut:

—s'accompagner d'une bande plus faible située à fréquence plus basse (1675 cm^{-1}) et correspondant à une bande CO liée (cas de **1**). Il s'agit alors d'un phénomène d'association qui disparait par dilution suffisante (Fig. 1) et qui correspond à la formation de liaisons hydrogène intermoléculaires entre le groupe carbonyle et l'hydroxyle du groupe oxime.[7]

—s'accompagner d'une bande plus faible située à fréquence plus élevée (1711 cm^{-1}, cas de **5**); cette bande qui persiste malgré la dilution est sensible aux conditions de solvant (augmentation en passsant du CCl_4 au CH_3CN) et pourrait alors correspondre à une bande de Fermi.[17]

—se dédoubler: elle apparait comme un pic dissymétrique pour **1** ou **2**, ou présentant un épaulement pour **3** et **4**, **5** (Fig. 1). Ces dédoublements peuvent être d'origine conformationnelle: l'évolution de la bande CO quand la taille de R augmente peut être raisonnablement attribuée à une modification de l'équilibre conformationnel au profit de la forme *s*-cis:



s-trans *s*-cis

Le pic de fréquence la plus élevée correspondrait alors à la vibration du carbonyle de la forme *s*-trans.

—l'enregistrement du spectre de **5** en solution dans CCl_4 à 65° puis à 5 °C montre une légère diminution de la bande à 1687 par rapport à celle à 1680 cm^{-1} confirmant ainsi que la première correspond à la forme *s*-trans, moins stable à basse température, et la deuxième à la forme *s*-cis plus stable.

—l'enregistrement des spectres dans des solvants de polarité variable (CCl_4 et CH_3CN) n'entraine pas de modifications notables à ce niveau; ce résultat s'explique car les polarités théoriques (Tableau 1) des deux isomères conformationnels *a* et *b* sont voisines.

—notons enfin la diminution des fréquences de vibration du carbonyle à la fois pour les isomères *s*-cis et *s*-trans lorsque l'encombrement de R augmente.[18]

	α	β	RM_D	$P_{2\infty}$	μ_D
1	17, 23	−0, 14	20, 51	268, 08	3, 48
2	13, 92	−0, 014	25, 15	259, 72	3, 39
3	12, 40	−0, 19	29, 80	261, 08	3, 36
4	12, 96	+0, 01	29, 80	278, 31	3, 49
5	10, 17	+0, 05	34, 45	254, 30	3, 28

Etude par RMN en variation de température. L'étude dans CH_2Cl_2 entre +80 et −40 °C montre que le signal du proton du groupe –CH= est déplacé vers les champs faibles. Cette variation est la plus im-

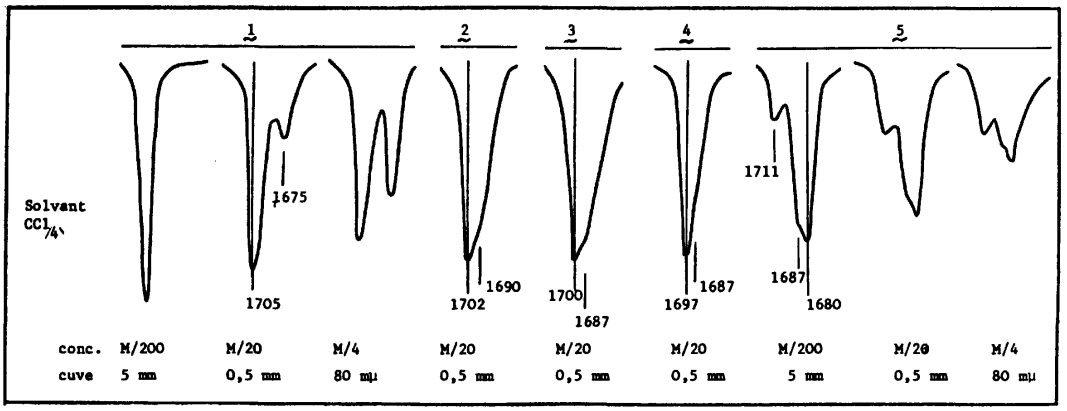


Fig. 1. Etude infra-rouge: bandes d'absorption du groupe carbonyle des α-oxo aldoximes.

TABLEAU 1. DIFFÉRENTES CONFORMATIONS POSSIBLES POUR LES α-OXO ALDOXIMES R-CO-C(NOH)H *E*; VALEURS THÉORIQUES μ_{th} [( )=VALEURS FOURNIES PAR LE 2-MODE DE CALCUL] ET EXPÉRIMENTALES μ_{exp} DES MOMENTS DIPOLAIRES

Conformations					
	s-trans			*s*-cis	
a		$\mu_{th}=2,56$ (2,68)	b		$\mu_{th}=3.04$ (2.79)
c		$\mu_{th}=1.08$ (0.30)	d		$\mu_{th}=5,56$ (5,48)

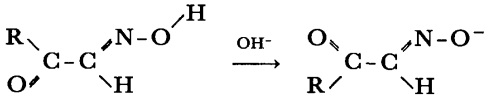
R=	Me	Et	Pr	*i*-Pr	*t*-Bu
μ_{exp}=	3,48	3,39	3,36	3,48	3,28

TABLEAU 2. ETUDE RMN: VARIATIONS DU DÉPLACEMENT CHIMIQUE DE -CH=N- EN FONCTION DE LA TEMPÉRTURE ET DU pH (δ/ppm)

Solvant		1	2	3	4	5
CH_2Cl_2	−40 °C	7,65	7,65	7,63	7,64	8,08
	+35 °C	7,55	7,58	7,57	7,56	7,83
	+80 °C	7,51	7,52	7,50	7,49	7,76
D_2O	pH 1—2	7,59	—	—	—	7,64
	pH 13—14	7,95	—	—	—	8,21

portante pour **5** (0,32 ppm) et est plus réduite pour les autres dérivés (0.13 à 0.15 ppm). L'effet du à l'abaissement de température peut être attribué au déplacement de l'équilibre conformationnel vers la forme *s*-cis qui place le proton -CH= dans le cone de déblindage du groupe carbonyle et entraine son déplacement vers les champs faibles. L'effet dû à l'augmentation du volume de R traduit la croissance de l'interaction stérique de ce groupe avec la paire libre de l'azote conduisant à une relative déstabilisation du conformère *s*-trans. L'effet de température, plus fort sur **5** que sur **1—4**, correspond à un déplacement de l'équilibre vers la forme *s*-cis plus facile.

De plus en milieu alcalin on s'attend à voir le signal -CH=, dans l'anion R-CH=NO^-, déplacé vers les champs forts; cependant, comme l'a remarqué Liepin'sh[10] ce déplacement se fait vers les champs faibles (Tableau 2); ceci correspond à un changement de conformation préférentielle de la forme *s*-trans vers *s*-cis;



Conclusion. De l'ensemble de ces résultats il ressort que les α-oxo aldoximes étudiées peuvent exister en solution sous deux conformations *s*-trans *a* et *s*-cis *b*; la première est majoritaire pour les composés avec R peu encombré (R=Me, Et, Pr, *i*-Pr) et la deuxième pour le composé **5** (R=*t*-Bu).

Partie experimentale

Synthèse. Les produits étudiés ont été préparés selon des méthodes deja décrites.[2,3]

Etude dipolemétrique. Moments calculés(μ_{calc}): Nous avons obtenu les moments par additivité d'incréments de liaison suivant deux modes de calcul:

- avec les angles CCO, ONC, NCC, HON égaux à 120°
- avec CCO=120°, ONC=111°, NCC=126° HON=103°, valeurs déduites des molécules de formaldoxime[19] et de diméthylglyoxime.[20] Les incréments utilisés sont : (C=N) =1,8 D ; (C=O)=3,0 D; (H-O)=1,5 D; (N-O)=0,3 D;

Moments expérimentaux (μ_{exp}): Les moments ont été mesurés dans le dioxanne à 25 °C, avec des fractions massiques comprises entre 0,0005 et 0,010. Les résultats figurent dans le tableau:

	α	β	RM_D	$P_{2\infty}$	μ_D
1	17,23	−0,14	20,51	268,08	3,48
2	13,92	−0,014	25,15	259,72	3,39
3	12,40	−0,19	29,80	261,08	3,36
4	12,96	+0,01	29,80	278,31	3,49
5	10,17	+0,05	34,45	254,30	3,28

Etude par spectrométrie infrarouge. Les spectres ont été enregistrés sur un spectrophotometre Beckman IR 9; la précision des mesures de réquence d'absorption est ±2 cm^{-1}.

Etude par spectrométrie RMN. Les spectres sont enregistrés sur un spectrophotomètre 90 MHz BRUCKER; les concentrations sont de 0.5 M.

The Reaction of 1,1-Dimethyl-1-Phenacylhydrazinium Bromide with Aqueous Sodium Hydroxide

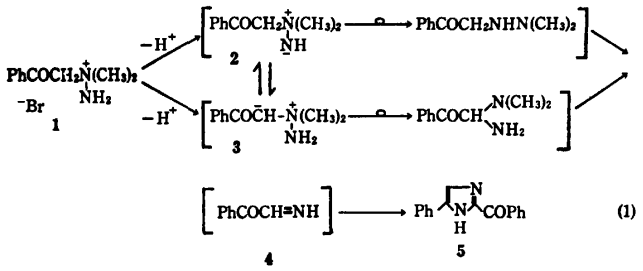
Kunio KANO† and Jean-Pierre ANSELME*

Department of Chemistry, University of Massachusetts at Boston, Harbor Campus, Boston, Massachusetts 02125, U.S.A.

(Received October 26, 1982)

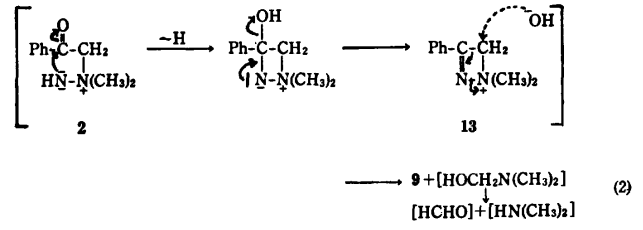
Synopsis. The reaction of 1,1-dimethyl-1-phenacylhydrazinium bromide with 1 M aqueous sodium hydroxide give benzoic acid, 3-phenyl-1-methylpyrazole, 5-benzoyl-3-phenyl-1-methylpyrazole, and benzonitrile as the major components; the expected product, 2-benzoyl-5-phenylimidazole was formed in only small amounts. Mechanisms to rationalize the formation of the major products are discussed.

In contrast to the vigorous conditions usually necessary,[1,2] the Wawzonek rearrangement of 1,1-dimethyl-1-phenacylhydrazinium bromide (**1**) proceeded smoothly upon heating in 1-propanol,[3] to afford 2-benzoyl-5-phenylimidazole (**5**).[4] It thus became of interest to investigate the behavior of **1** in the presence of aqueous alkali.

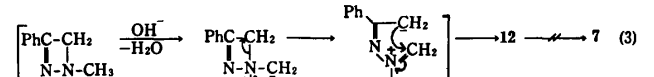


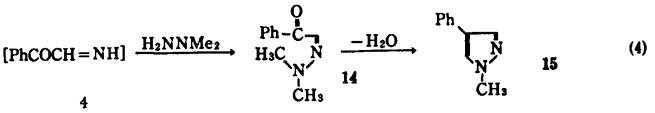
The treatment of 80 mmol of 1,1-dimethyl-1-phenacylhydrazinium bromide (**1**) with 1 M aqueous NaOH gave only trace amounts of 2-benzoyl-5-phenylimidazole (**5**); seven compounds were characterized: benzoic acid (**6**, 24.6 mmol), 3-phenyl-1-methylpyrazole (**7**, 12.2 mmol), 5-benzoyl-3-phenyl-1-methylpyrazole (**8**, 3.3 mmol), benzonitrile (**9**, 2.2 mmol), trace amounts of acetophenone (**10**), acetophenone dimethylhydrazone (**11**) and 3-phenyl-1-methyl-2-pyrazoline (**12**); dimethylamine and trimethylamine were subsequently characterized from the evolved gases.

The formation of benzonitrile can be rationalized *via* an internal nucleophilic attack of the negative nitrogen of the aminimide **2** on the carbonyl group to give the diazetinium ion **13**.[5] Fragmentation of

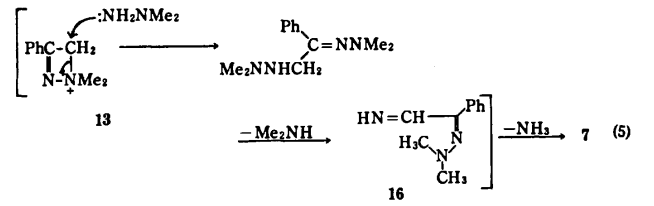


13 or attack of **13** by hydroxide ion (*vide infra*) yields benzonitrile. Support for this mechanism was obtained from the bromination of acetophenone dimethylhydrazone (**11**) with *N*-bromosuccinimide which afforded benzonitrile as one of the products;[6] presumably α-bromination followed by an internal nucleophilic displacement by the sp^3 nitrogen lead to **13**. A Stevens rearrangement of **13** (Eq. 3) can account for the formation of 3-phenyl-1-methyl-2-pyrazoline (**12**). The reaction of **1** with base in the presence of **12** did not result in an increase in the yield of **7** and thus rules **12** out as the source of **7**.[7] An alternate path to **7** involving the condensation of phenylglyoxaldimine (**4**), a probable intermediate in the rearrangement of **1** to **5**,[3] with 1,1-dimethylhydrazine at more reactive *imino* carbon followed by cyclization of the resulting phenylglyoxal dimethylhydrazone (**14**)[6,8] would lead to 4-phenyl-1-methylpyrazole (**15**) and not to **7**. On



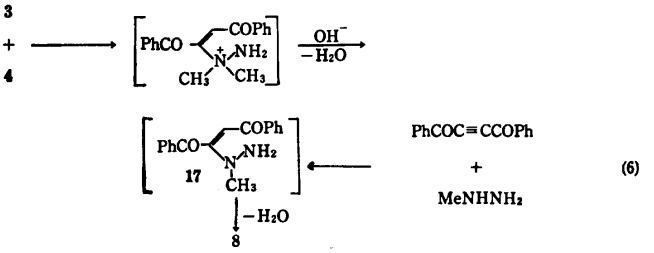


the other hand, attack of 1,1-dimethylhydrazine on **13** (*vide infra*) can lead to an intermediate **16** with the structural features required to undergo cyclization to yield 3-phenyl-1-methylpyrazole (**7**) (Eq. 5). A



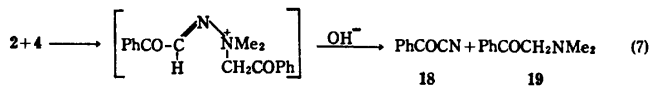
control experiment in which the reaction of **1** with hydroxide ion was carried out in the presence of added 1,1-dimethylhydrazine resulted in a seven-fold increase in the yield of **7** at the expense of benzonitrile.

NMR experiments demonstrated that the CH_2 hydrogens also underwent deuterium exchange and make it likely that ylide **3**, derived from removal of a hydrogen from the CH_2, is also generated.[9] A mechanism proceeding *via* the same intermediate **17** presumably involved in the synthesis of **8** from dibenzoylacetylene and methylhydrazine,[10] explains the formation of **8** (Eq. 6). It is interesting to note that the reaction of **1** with water gave an approximately 1:1 mixture of **2** and **5**.

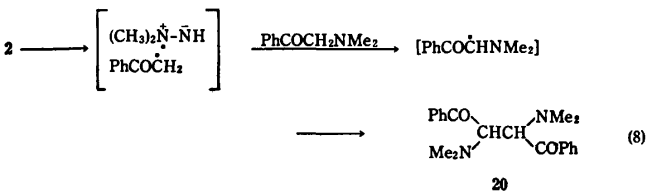


† Taken from the M. S. Thesis of Kunio Kano, University of Massachusetts at Boston, June 1980.

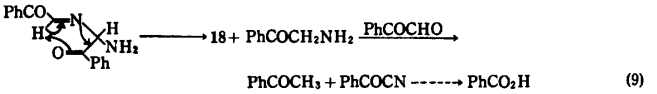
It was initially surmized that *in situ* hydrolysis[11] of benzoyl cyanide (**18**) perhaps generated by air oxidation of phenylglyoxaldimine (**4**), could help account for the formation of benzoic acid. However, the reaction of **1** with hydroxide under *oxygen-free* nitrogen left the yield of benzoic acid unaffected. The hydrazinium salt **1** or more likely the aminimide **2** could act as the oxidizing agent (Eq. 7).[12]



Apparent support for this path came from the reaction of benzaldehyde, *p*-chlorobenzaldehyde and *p*-bromophenylglyoxal with **1** under the same conditions, which gave benzonitrile, *p*-chlorobenzonitrile and *p*-bromobenzoic acid respectively. However, α-dimethylaminoacetophenone (**19**), the expected by-product (Eq. 7) could not be detected by TLC. The reaction of **19** with 1 M sodium hydroxide in the presence of oxygen gave sodium benzoate (60%); the reaction of **1** with hydroxide in the presence of **19** gave 2,3-bis(dimethylamino)-1,4-diphenyl-1,4-butanedione (**20**).[13,14]

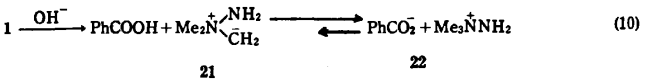


The self-condensation product of **4** which cyclized to **5**,[3] could collapse in an alternate fashion to give benzoyl cyanide and phenacylamine (Eq. 9). Con-



densation of the latter compound with phenylglyoxal hydrate was shown to yield benzoid acid and acetophenone, presumably *via* fragmentation of the intermediate imine, in a fashion analogous to the formation of **18** from phenylglyoxaldoxime with acetyl chloride.[15] Phenacyl alcohol, which might have arisen from attack of hydroxide ion on **1**, was not converted to benzoic acid as expected.[16] Furthermore, the addition of phenacyl alcohol to a reaction of **1** with base resulted in a *decrease* in the yield of benzoic acid.

In view of the failure of these mechanisms, the path involving the direct attack of the hydroxide ion at the carbonyl carbon was reluctantly considered (Eq. 10). Indeed, trimethylhydrazinium iodide under the



conditions of the reaction gave trimethylamine.[17] Nucleophilic displacement on the methyl group of trimethylhydrazinium ion can lead to methanol and 1,1-dimethylhydrazine, necessary to account for the formation of acetophenone dimethylhydrazone and of the pyrazoles.

Experimental

Elemental analysis were carried out at the Microanalysis Laboratories of the University of Massachusetts at Amherst. Mass spectra were taken at Chemical Spectrometry Laboratory of Massachusetts Institute of Technology and obtained on a Varian Mat 44 mass spectrometer. The infrared spectra were recorded on a Perkin-Elmer model 137B Infrared spectrophotometer and the NMR spectra were determined on a Hitachi Perkin-Elmer R-24 (60 MHz) in deuteriochloroform unless otherwise noted, using tetramethylsilane as internal standard. The vapor phase chromatograms were obtained on a Perkin-Elmer Vapor Fractometer 154D (column: silicone grease).

Reaction of 1,1-Dimethyl-1-phenacylhydrazinium Bromide (1) with 1 M Aqueous Sodium Hydroxide. To 80 mmol of **1** was added 120 ml of 1 M aqueous NaOH, previously degassed for 1 h with purified nitrogen. The reaction mixture was stirred for 24 h at ambient temperature and the reaction flask was protected from light. The reaction mixture was extracted with ether and the ethereal layer was washed with water until it was neutral. The ethereal solution was dried over $MgSO_4$ and evaporated *in vacuo*. The aqueous layer was neutralized with conc. hydrochloric acid, the resulting precipitate was collected, and the filtrate was extracted with ether. The ethereal solution was dried over $MgSO_4$ and evaporated *in vacuo*; the residue and the precipitate obtained from neutralization of the aqueous phase were combined and crystallized from water to give 3.0 g (24.6 mmol) of benzoic acid, mp 121—122 °C.

The IR, NMR, and VPC of the residue obtained from the original ethereal phase were determined. VPC showed a 5.1:1 ratio of 3-phenyl-1-methylpyrazole (**7**)[18] to benzonitrile and trace amounts of acetophenone, acetophenone dimethylhydrazone (**11**) and 3-phenyl-1-methyl-2-pyrazoline (**12**).[19] The mixture was then chromatographed on 50 g of neutral aluminum oxide (powder) using benzene as eluent. The first fraction gave 0.73 g (2.7 mmol) of 5-benzoyl-3-phenyl-1-methylpyrazole (**5**), the second fraction gave 1.9 g of a mixture of **8** and **7** in a ratio of 1:12.1, the third fraction gave 0.175 g (1.07 mmol) of **7**. The total yields of **7** and **8** were 12.2 mmol and 3.3 mmol respectively. The purity and identity of each fraction was checked by TLC and NMR.

In a separate experiment, three picric acid–ethanol traps were attached to the outlet of the reaction vessel; 1.2 g of a mixture of the picrates of dimethylamine and trimethylamine was collected, and its NMR indicated it to be composed of 4 mmol of trimethylamine picrate and 0.7 mmol of dimethylamine picrate.

Reaction of 1 with 1 M NaOH in the Presence of 1,1-Dimethylhydrazine. The reaction of **1** (20 mmol) with 30 ml of 1 M NaOH under nitrogen was carried out and analyzed as described previously, except that 20 mmol of 1,1-dimethylhydrazine was added to the reaction mixture. There was a seven-fold increase in the yield of 3-phenyl-1-methylpyrazole (**7**).

Reaction of 1 in Water. A solution of 5.18 g (20 mmol) of **1** in 100 ml of distilled water was stirred for 5 d at ambient temperature. The precipitate was filtered to give 2 g of a mixture of **5**, **7**, **8**, and the filtrate was extracted with ether. The ethereal layer was dried over $MgSO_4$ and the ether was evaporated to give 0.19 g of a mixture of **5**, **7**, **8**, and other minor products. The aqueous layer was acidified with concd hydrochloric acid and then was extracted with ether. The ethereal solution was dried over $MgSO_4$ and the ether was evaporated to yield 0.10 g (8%) of benzoic acid.

5-Benzoyl-3-phenyl-1-methylpyrazole (**8**) (0.8 g, 31%), mp 65.5—67 °C, was obtained as white crystals from the precipitate after three recrystallizations from ether–pet. ether followed by column chromatography (silica gel).

Reaction of ***1*** *with* p-*Bromophenylglyoxal.* To **1** (1.04 g, 4 mmol) and *p*-bromophenylglyoxal monohydrate (0.92 g, 4 mmol) was added 6 ml of previously degassed 1 M aqueous NaOH and stirred for 24 h. The reaction mixture was acidified with concd HCl; the precipitate was filtered and washed with water. Its IR showed it to be a mixture (0.19 g) of benzoic acid and *p*-bromobenzoic acid.

Reaction of Phenylglyoxal with Phenacylamine. To a suspension of phenylglyoxal monohydrate (2.13 g, 14 mmol) and phenacylamine hydrochloride (2.4 g, 14 mmol)[20] in THF (40 ml) was added triethylamine (1.4 g, 14 mmol) in THF (15 ml); the solution was stirred overnight at room temperature. Triethylamine hydrochloride was filtered and THF was evaporated from the filtrate. The residue was dissolved in 50 ml of ether, then the solution was washed with water, dried over anhydrous $MgSO_4$ and the ether was evaporated. A solution of the residue in toluene (100 ml) was heated to reflux overnight. The cooled reaction mixture was washed with aqueous $NaHCO_3$ and water, dried and the toluene was evaporated. To the residue was added 2,4-dinitrophenylhydrazine solution. The R_f value (silica gel, chloroform) and the IR spectrum of the product were identical with that of authentic acetophenone 2,4-dinitrophenylhydrazone. The sodium bicarbonate solution was neutralized with concd hydrochloric acid to give 0.63 g (37%) of benzoic acid, mp 120—121.5 °C.

Reaction of Trimethylhydrazinium Iodide with 1 M Sodium Hydroxide. To 16.2 g (80 mmol) of trimethylhylhydrazinium iodide in 250 ml three-necked round bottom flask equipped with a 250 ml addition funnel, a nitrogen gas inlet and reflux condenser was added 120 ml of 1 M aqueous NaOH; the condenser was connected to a trap containing 50 ml of a saturated ethanolic solution of picric acid. After the addition, nitrogen gas was bubbled through the reaction flask for 3 d at ambient temperature, The solid which precipitated in the trap was collected, dried and shown to be trimethylamine picrate, mp 221—223 °C, by comparison with an authentic sample.

*2,3-Bis(dimethylamino)-1,4-diphenyl-1,4-butanedione (**20**).* A mixture of 2.70 g (12.5 mmol) of α-dimethylaminoacetophenone in 30 ml of 1 M aqueous NaOH was degassed for 30 min, then added to **1** (5.18 g, 20 mmol). The reaction mixture was treated as described previously in the general procedure. The solid present in the viscous residue which had been left standing, was filtered recrystallized from ether–pet. ether to give pale yellow crystals, mp 136—138 °C. Mass spectrum: *m/e* 324, 162, 105, 77; NMR($CDCl_3$): δ 7.80 (ArH, m, 5H), 4.92 (CH, s, 1H), 2.26 (CH_3, s, 6H); IR: 1680 cm^{-1}.

Chemical-state Analysis by Means of Soft X-Ray Spectroscopy. I. $L_{2,3}$-Emission Spectra for Phosphorus, Sulfur, and Chlorine in Various Compounds

Kazuo TANIGUCHI

Department of Solid-State Electronics, Osaka Electro-Communication University, 18-8, Hatsucho, Neyagawa, Osaka 572

(Received May 18, 1983)

The phosphorus-, sulfur-, and chlorine-$L_{2,3}$ emission spectra in various compounds are obtained using secondary excitation. The spectra are discussed from the point of view of chemical-state analysis. It should be noted that the spectra of a highly ionic bond reveal scarcely no influence of the cations. However, the spectra with a covalent character are complex as a result of the molecular orbital generated with the covalent bond. The spectral features are influenced by the chemical condition of the surrounding atoms and are sensitive to oxygen and hydrogen.

X-Ray spectroscopy has long been a basic method for studying the elemental compositions of materials and the electronic structures of atoms. It has been known since the 1920's that the X-ray emission spectrum of an element varies according to the state of its chemical combination. However, the effect of chemical combinations on X-ray spectra has been found to be very slight except in the case of a light element. In an earlier work, Lindh and Lundquist[1] were able to observe the chemical-combination effect of X-ray spectra in their studies of the $K\beta$ emission spectra of phosphorus, sulfur, and chlorine compounds. The problems encountered by earlier investigators in X-ray emission spectroscopy were generated mainly by the highly energetic conditions of the direct-electron bombardment of the sample deposited on the anticathode of the X-ray tube. This type of excitation leads to sample oxidation, reduction, decomposition, and other reactions with the anticathode material, which thereby generate a variety of products which add to the complexity to the observed spectra.

The twenty-year period between 1930 and 1950 there were fluorescence X-ray investigations of the $K\beta$ spectra from the point of view of the chemical-state analysis of sulfur, chlorine, and phosphorus in various compounds. The results of these investigations also showed that the effect of chemical bonding had very little influence on an X-ray spectrum.

As was noted earlier,[2] the $K\beta$ emission spectrum is related to the 3p character in the valence band. However, the $L_{2,3}$ emission spectrum is sensitive to the 3s and 3d character of the valence band. For an isolated phosphorus, sulfur, or chlorine in its ground state, the valence-band electrons tend to remain in the 3s and 3p character. In chemical combination, however, some of these valence-band electrons may be partially involved, to a greater or lesser extent, in the 3d orbital and may thereby enhance the 3d character of the molecular orbital structure. In the $L_{2,3}$ emission spectra, therefore, the chemical effect is more extensitive than in the $K\beta$ emission spectra.

Henke and Smith[3] were able to demonstrate the feasibility of obtaining the $L_{2,3}$ spectra of phosphorus, sulfur, and chlorine in various compounds by applying spectrographic techniques of such efficiency as to minimize the effects of radiation decomposition. The $L_{2,3}$ emission spectra of sulfur and chlorine in several compounds have since been more precisely measured and studied from the point of view of the molecular orbital.[2,4–6] However, no sufficiently systematic investigation of the $L_{2,3}$ emission spectra of phosphorus, sulfur, and chlorine in various compounds has been made.

We attempt to describe a chemical-state analysis by means of soft X-ray spectroscopy in this and in companion papers;[7,8] also, in this paper we will try to make clear the relationship between the character of the chemical state and the $L_{2,3}$ emissiom spectra.

Experimental

The high-efficiency techniques which have been developed by Henke *et al.*[9,10] for the secondary excitation of ultrasoft X-ray spectra have made possible the interpretation of the valence-band X-ray spectra for the light element. Ultrasoft X-ray excitation greatly reduces the radiation damage to samples and provides a considerably improved peak-to-background ratio. The basic spectrographic approach that was used in this laboratory is shown in Fig. 1. The X-ray spectrometer is of a vacuum X-ray type provided with a Soller collimator (0.3 mm spacing, 100 mm length). After reflection from the plane crystal, the beam

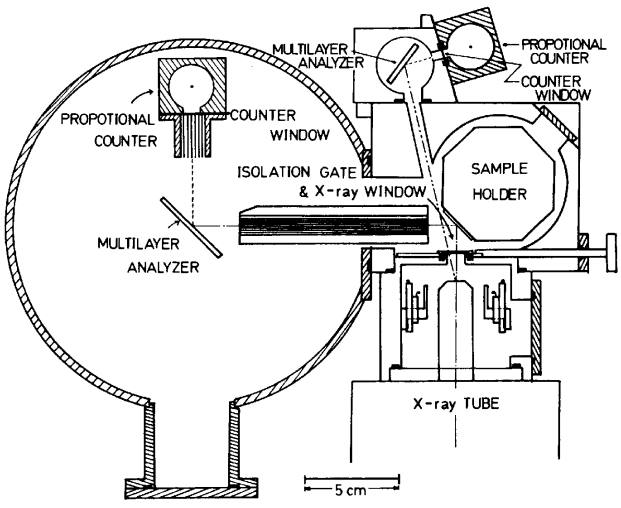

Fig. 1. A single-crystal spectrographic approach for low energy X-ray spectroscopy applying closely coupled demountable X-ray source, the development of large-soap-film crystals, and tuned subatmospheric pressure.

from the fluorescent radiator passes through the Soller collimator (1.0 mm spacing, 20 mm length) before the counter. The most intense and practical line source in the $L_{2,3}$ of phosphorus, sulfur or chlorine is C$K\alpha$ (44.6 Å). It is generated in our demountable source using a copper anode coated with a colloidal graphite. The source is stable for many hours of operation, typically at 8 kV and 150 mA. The X-ray tube window is constructed with a polycarbonate film (Kimfoil) with an aluminum coating a few hundred angstrom thick which has an effective transmission band for the carbon $K\alpha$ (44.6 Å) radiation.

The plane crystal is a specially developed Langmuir-Blodgett-type multilayer[11] analyzer, of lead stearate for chlorine and sulfur compounds or of lead lignocerate for phosphorus compounds, which has $2d$-spacing of 100 Å or 130 Å respectively. Background and impurity lines of a higher order can be reduced by using a gas-flow proportional counter with a pulse-height discriminator. Propane gas at a pressure of 60 mmHg (1 mmHg ≈133.322 Pa) is used as a counting gas and is sealed in the counter with poly(vinyl formal) film (Formver). The solid specimens are prepared by pressing a fine powder into a smooth aluminum ring in order to keep the target sample pure and at a constant pressure. The liquid samples are measured under freezing conditions using the cryostat shown in Fig.2. The spectrum is calibrated by the sharp $M\zeta$ lines of zirconium (81.9 Å) and molybdenum (64.5 Å). A detailed description of these experimental techniques has been reported elsewhere.[10] In order to insure that the radiation decomposition effect upon these measurements would be negligible, the measurement has been done twice for each spectrum with two identical samples. The total counting time is 50 s per point, and the counter is scanned step by step, by 1/10 s or 2/10 degree.

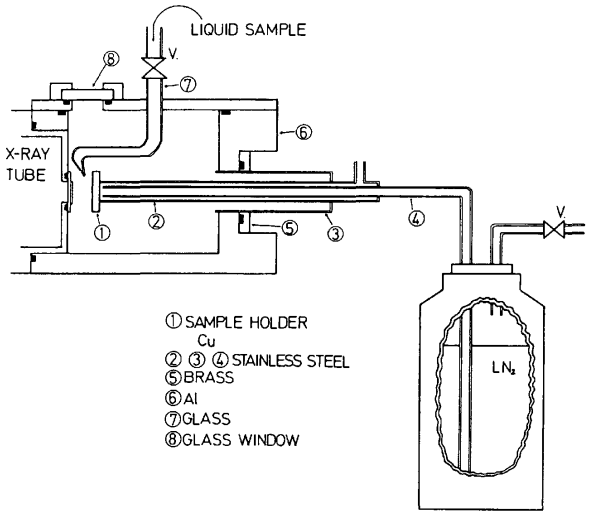

Fig. 2. Sketch of the cryostat for sample holder. The liquid samples were measured at the freezing conditions using the cryostat controlled by liquid nitrogen.

Figure 3 shows schematically a flow- and pressure-regulated system for the counter, and vacuum systems for the sample chamber and the X-ray tube. The optimum pressure in the counter (P.C.) is maintained by the controls with valves (Vl and V2). The gas pressure is indicated by the gauges (P.G.) and the manometer (U.M.M.). The gas is allowed to flow through the flow meter (F.M.) at a rate of 50 cm³/min. The V3 valve is usually closed, but it is opened in order to keep the same pressure in the counter and the spectrometer when the spectrometer is pumped down to a vacuum

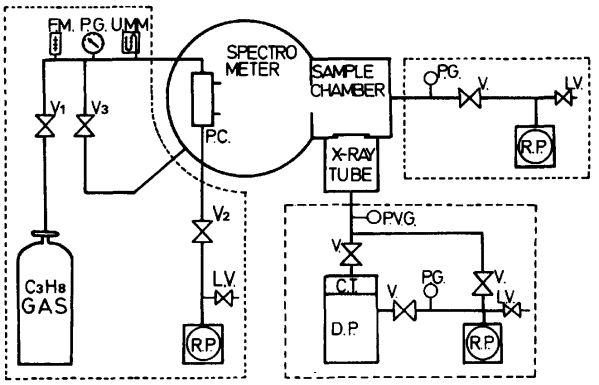

Fig. 3. Schematic diagram of the flow and pressure regulated system for the counter, and vacuum systems for the sample chamber and the X-ray tube.

from the atmosphere. The spectrometer and the sample chamber are pumped to about 10^{-3}'s Torr (1 Torr≈ 33.322 Pa) by means of a rotary pump. The X-ray tube is pumped to about 10^{-6}'s Torr by means of a diffusion pump and rotary pump.

Results and Discussion

In a previous paper,[2] our studies of the sulfur $L_{2,3}$ emission spectra and molecular orbital studies of sulfur compounds were reported. In that paper, the $L_{2,3}$ fluorescence spectra of sulfate ions (SO_4^{2-}) reveal scarcely no influence of the cations of these sulfate compounds. In the case of perchlorate ions (ClO_4^-), the same phenomenon is observed in the $L_{2,3}$ fluorescence spectra. Cl $L_{2,3}$ emission spectra for $LiClO_4$, $NaClO_4$, $KClO_4$, and $AgClO_4$ are shown in Fig. 4. It should be noted that the $L_{2,3}$ fluorescence spectra of perchlorate ions reveal scarcely no influence of the

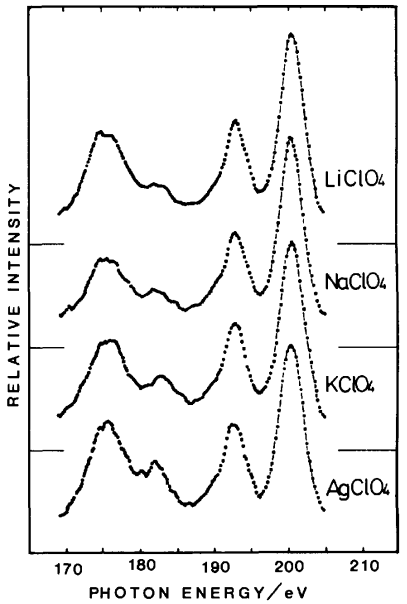

Fig. 4. Chlorine-$L_{2,3}$ emission spectra for $LiClO_4$, $NaClO_4$, $KClO_4$, and $AgClO_4$. Chlorine-$L_{2,3}$ emission spectra have been excited by C$K\alpha$ radiation and analyzed by lead stearate.

cations. This reflects the fact that the covalent interaction between the ions is relatively small, thus accounting for the narrow emission bands, which can be attributed either to the cations or to the anions. With this evidence for strong localization, it seems reasonable to suggest that the crystal effect should be neglected.

In general, there is a similarity in features of the $L_{2,3}$ emission spectra between the molecules with different central atoms, but all with the T_d symmetry, although the energy ranges of the emission spectra are different. A comparison of the features of the $L_{2,3}$ emission spectra for the central atom of the T_d symmetry with Li_3PO_4, Li_2SO_4, and $LiClO_4$ is shown in Fig. 5. There are seven occupied orbitals ($4a_1$, $3t_2$, $5a_1$, $4t_2$, le, $5t_2$, and $1t_1$) in the valence band for these examples of T_d molecular symmetry. Hence, transitions into the 2p-level are allowed only from the a_1, t_1, and e orbitals by the dipole-selection rule. The peaks at lower energy and a middle energy should be assigned to $4a_1$ and $5a_1$ respectively, whose molecular orbitals consist mainly of the 3s population. The main peak at a higher energy has to be assigned to the le and $5t_2$ orbitals with then comparatively high 3d population. The intensity ratios of the peak at a middle energy (from $5a_1$) and at a higher energy (le+$5t_2$) increase with the increase in the atomic number of X for the XO_4^{2-} cluster. It seems reasonable that the 3d population in the valence band increases with a increase in the atomic number of X; therefore, the peak at a higher energy, which is assigned to the le and $5t_2$ orbitals, with then comparatively high 3d population, will increase. In the $LiClO_4$, a small peak appears between $4a_1$ and $5a_1$. This peak should be assigned to $3t_2$, where molecular orbital consists mainly of the 3p and 3d populations of Cl and the 2s population of O. The electron transition involves two excited states, and, as the initial vacancy (core level) has two possible states, $2p_{1/2}$ (L_{II}) and $2p_{3/2}$ (L_{III}), corresponding to the $2p^5$ configuration, the emission component which is due to a transition from a molecular orbital to the 2p levels will result in two emission lines. This spin-orbit separation, however, is about 1.2 eV, and the energy resolution of the spectrometer is about 1 eV for this wavelength region. Therefore, the emission spectra can reflect the structure of the molecular orbital, as the spin-doublet effect need not be so considered.

The phosphorus $L_{2,3}$ fluorescence spectra of Li_3PO_4, K_3PO_4, KH_2PO_4, and H_3PO_4, all of which are composed of the phosphate ion (PO_4^{3-}), are shown in Fig. 6. In this figure, the spectrum of H_3PO_4 differs from that of another phosphate especially in the middle-energy range, though the peak positions on the lower-energy side and the higher-energy side are quite the same. The phosphate anion for strong localization

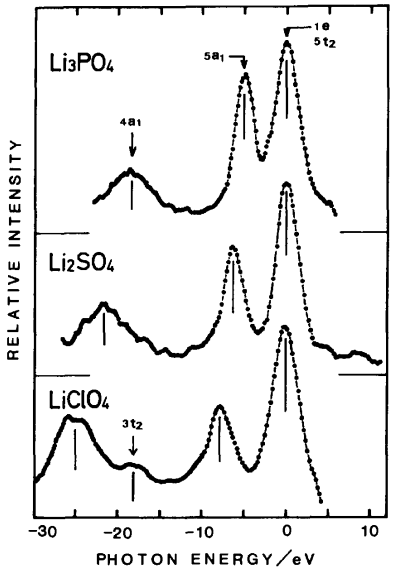

Fig. 5. Comparison of the feature of the $L_{2,3}$ emission spectra of the central atoms of T_d symmetry for Li_3PO_4, Li_2SO_4, and $LiClO_4$. Also shown are the positions of peaks and the molecular orbital assignment for each peak.

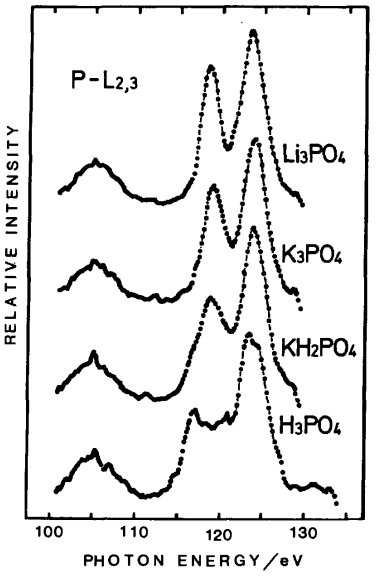

Fig. 6. Comparison of the phosphorus-$L_{2,3}$ emission spectra. Phosphorus-$L_{2,3}$ emission spectra have been excited by $CK\alpha$ radiation and analyzed by lead lignocerate.

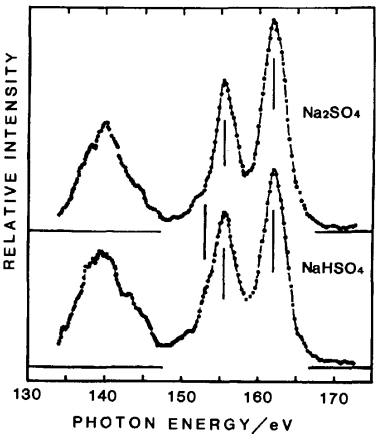

Fig. 7. Sulfur-$L_{2,3}$ emission spectra for Na_2SO_4 and $NaHSO_4$. Sulfur-$L_{2,3}$ emission spectra have been excited by $CK\alpha$ radiation and analyzed by lead stearate.

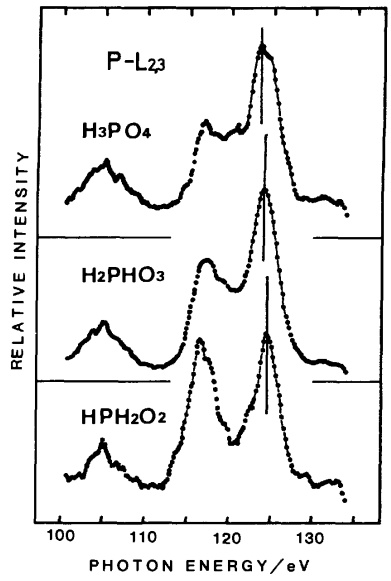

Fig. 8. Comparison of the phosphorus-$L_{2,3}$ emission spectra for phosphoric acid, phosphonic acid, and phosphinic acid. Phosphorus-$L_{2,3}$ emission spectra have been excited by C$K\alpha$ radiation and analyzed by lead lignocerate.

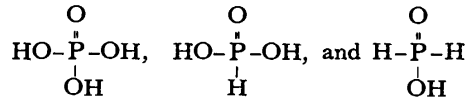
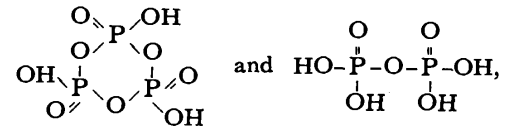
has a tetrahedral symmetry (T_d point group). However, the phosphate anion of H_3PO_4 does not have tetrahedral symmetry because there is not strong localization between PO_4^{3-} and the three H^+. Therefore, in view of the three hydrogens, it seems reasonable that H_3PO_4 has molecular symmetry. If Fig. 6 is looked at carefully, it can be found that the spectral feature of KH_2PO_4 differ just a little from those of other phosphate compounds. The same phenomenon is observed in sulfur compounds. Figure 7 shows a comparison of the sulfur $L_{2,3}$ emission spectra for Na_2SO_4 and $NaHSO_4$. In this case also, there is a hump on the low-energy side of the middle peak in $NaHSO_4$. This may reflect the fact that the structure of the valence band molecular orbital is affected by the H-atom contribution. These facts may suggest that X-ray emission spectra can give information about the chemical bonding of hydrogen; if so, this would be very important.

The P $L_{2,3}$ emission spectra for phosphoric acid (H_3PO_4), phosphonic acid (H_2PHO_3), and phosphinic acid (HPH_2O_2), are compared in Fig. 8. Each spectrum consists of three major peaks, at about 105, 117, and 124 eV. The measured spectra difference depends upon the chemical state. In proportion to the decrease in the number of oxygen atoms, the peak at about 124 eV shifts to the higher-energy side just a little and the peak at about 117 eV increases. The structural formulas for H_3PO_4, H_2PHO_3, and HPH_2O_2 are:



respectively. In the structural formula of H_3PO_4, the central P atom combines with O atoms only. In the H_2PHO_3, the central P atom combines with three O atoms and one H atom. In the HPH_2O_2, however, the central P atom combines with two O atoms and two H atoms. The peak at about 117 eV increases corresponding to the number of direct combinations of the H atom to the P atom. On the other hand, the structural formulas for *cyclo*-triphosphoric acid ($H_3P_3O_9$) and pyrophosphoric acid ($H_4P_2O_7$) are:



respectively; here, the central P atom combines directly with the O atom, like only H_3PO_4. In this case, the spectral features of these compounds have something in common (Fig. 9). It seems reasonable to consider that the spectral features of these compounds are influenced by the surrounding atoms, but not by the bond conditions.

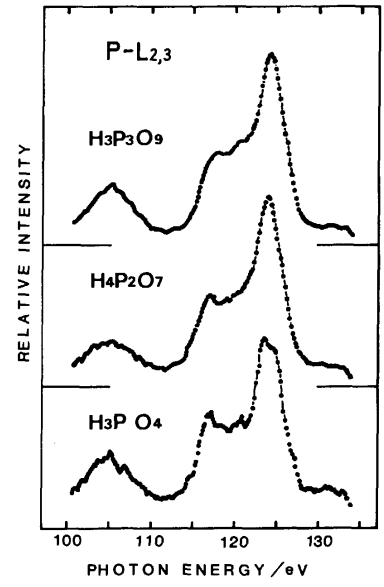


Fig. 9. Comparison of the phosphorus-$L_{2,3}$ emission spectra for phosphoric acid, *cyclo*-triphosphoric acid, and pyrophosphoric acid. Phosphorus-$L_{2,3}$ emission spectra have been excited by C$K\alpha$ radiation and analyzed by lead lignocerate.

The relation between the number of oxygen atoms and the spectral features will be considered. The Cl $L_{2,3}$ emission spectra of NaCl, $NaClO_2$, $NaClO_3$, and $NaClO_4$ are shown in Fig. 10. It is shown that the main peak of the $L_{2,3}$ emission spectra shifts to the higher-energy side and decreases with the increase in the oxidation number. The peak of the higher-energy side appears, and then increases in proportion to the increase in the number of oxygens. It is reasonable to think that the Cl-3d atomic orbital population increases in the valence band according to the increase in the number of oxygens combined to the chlorine atom. Thus, it is found that the 3d atomic orbital plays a very important role in the molecular orbital for the chemical combination of chlorine and oxygens.

Figure 11 shows a comparison of the sulfur $L_{2,3}$ emission spectra for $Na_2S_2O_4$, $Na_2S_2O_5$, $Na_2S_2O_6$, and $Na_2S_2O_7$. These spectra change corresponding to the

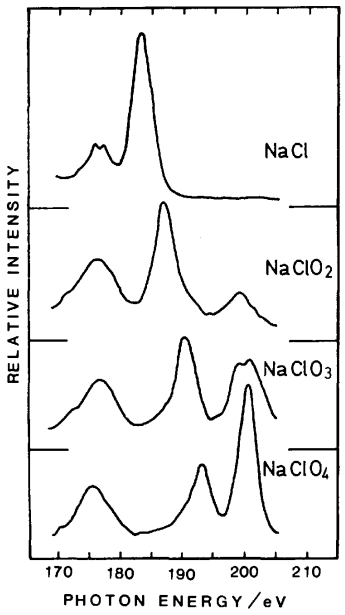

Fig. 10. Chlorine-$L_{2,3}$ emission spectra for NaCl, $NaClO_2$, $NaClO_3$, and $NaClO_4$. Chlorine-$L_{2,3}$ emission spectra have been excited by C$K\alpha$ radiation and analyzed by lead stearate.

chemical-bond state and also with the bonding O atom number. It can thus be thought that the existence of the oxygen atom makes the molecular orbital of the valence band attracted to the O-2p level. In Fig. 11, in proportion to the increase in the quantity of oxygen, the middle peak shifts to the higher-energy side and decreases just a little, while the peak of the higher-energy side increases and shifts just a little to the higher-energy side, but the peak of the lower-energy side does not show any influence of the quantity of oxygen.

Finally, the Cl $L_{2,3}$ emission spectra of LiCl, NaCl, KCl, and AgCl are shown in Fig. 12 in order to make possible a consideration of the relation of the ionic bond and covalent bond to the X-ray spectra. Since these compounds all have highly ionic bonds except for AgCl, the $L_{2,3}$ spectra of these compounds can be expected to be due to the electon transition from the M_1 level to the $L_{2,3}$ levels. However, these spectra have mainly two peak components. Each peak shifts just a little to the higher-energy side according to the order of the increase in the atomic number: Li, Na, and K, but it shifts to the lower-energy side for Ag. The differences in electronegativity between the cation and the anion of the molecule are 2, 2.1, 2.2, and 1.1 for LiCl, NaCl, KCl,and AgCl respectively. Therefore, it seems reasonable that the spectral peaks shift to the higher-energy side with the increase in the ionic character. If these compounds have a highly ionic bond, only the major components in the $L_{2,3}$ spectrum can be expected to fill the $L_{2,3}$ core from the M_1 level. Therefore, it is reasonable to think that the most intense peak is due to the transition from M_1 to $L_{2,3}$.

Cooper and Lavilla[12] interpreted the lower-energy peak in the spectrum of argon as a *'semi-Auger'* process in the $L_{2,3}$ emission, which is a *'shake-up'* process accompanied by the X-ray emission. The final state of

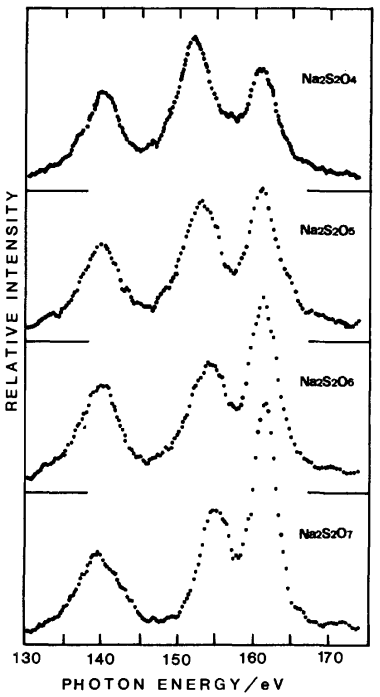

Fig. 11. Sulfur-$L_{2,3}$ emission spectra for $Na_2S_2O_4$, $Na_2S_2O_5$, $Na_2S_2O_6$, and $Na_2S_2O_7$. Sulfur-$L_{2,3}$ emission spectra have been excited by C$K\alpha$ radiation and analyzed by lead stearate.

the X-ray emission can be mixed strongly with states where one of the $M_{2,3}$ electrons is removed and the other is excited, provided that these levels have the same parity. A similar satellite structure is observed in the XPS spectra of argon and alkali halides.[13] A study of the Cl $L_{2,3}$ spectrum clearly indicates that the low-energy tail is due to a series of transitions of this type. The small peak is observed at the higher-energy side in AgCl; this may reflect the fact that this peak is due to a

transition from a molecular orbital in the valence band to the $L_{2,3}$ level, because AgCl has a small ionic character and a strongly covalent character.

Conclusion

In this work, it has been shown that a spectral feature is closely connected with the chemical state and that the $L_{2,3}$ emission spectra are very useful for chemical-state analysis. The following properties have been found:

(1) The $L_{2,3}$ emission spectra of the highly ionic bond scarcely reveals any influence of the cations.

(2) The $L_{2,3}$ emission spectra for the molecular T_d symmetry of different central atoms have similar features.

(3) The peak related to the hydrogen atom is observed on the lower side of the middle peak in the $L_{2,3}$ emission spectra. This is suggests that the X-ray emission spectra give information about the existence of hydrogen in the chemical combination.

(4) In the $L_{2,3}$ emission spectra of the oxyanions, the middle peak shifts to the higher-energy side and its intensity decreases, while the peak of the higher-energy side increases according to the increase in the number of oxidation. It is reasonable to think that the oxygen 2p electron will diffuses into the 3d atomic orbital of the central atom in the valence molecular orbital when the central atom combines with oxygen.

(5) The spectral feature is influenced by the kind of ligand if this atom forms a part of the molecular orbital.

(6) In a highly ionic bond, the spectrum is simple, with two peak components. However, the spectrum is different according to its covalent character.

In this work, we can not interpret the spectra quantitatively as transitions from the molecular orbitals with the help of a molecular orbital calculation. This will remain a subject for future study.

The main program of this work was begun by the author during his stay at the University of Hawaii. The author wishes to express his thanks to Professor B.L.Henke for his kind guidance. We also gratefully acknowledge some very useful discussions with Dr. Sigero Ikeda of Osaka University and Dr. Yōichi Gōshi of Tokyo University, and the invaluable help of the undergraduate students in their laboratories.

Chemical-state Analysis by Means of Soft X-Ray Spectroscopy. II. $K\beta$ Spectra for Phosphorus, Sulfur, and Chlorine in Various Compounds

Kazuo TANIGUCHI

Department of Solid-State Electronics, Osaka Electro-Communication University, 18-8, Hatsucho, Neyagawa, Osaka 572

(Received May 18, 1983)

The phosphorus-, sulfur- and chlorine-$K\beta$ spectra in various compounds are obtained by means of secondary excitation using a simple quasi-two-crystal X-ray spectrometer. The spectra thus obtained change depending upon the chemical state. The spectra are discussed from the point of view of chemical-state analysis. The spectral features are especially influenced by the hydrogen and oxygen of the ligand. The peak on the lower-energy side appears to be related to the oxygen, and the peak grows with an increase in the oxidation number. The spectrum gives information on the structural formula.

In previous paper[1,2] we have studied the $L_{2,3}$ emission spectra of phosphorus, sulfur, and chlorine in various compounds. As was noted earlier, the $K\beta$ emission spectrum is related to the 3p character of the valence band. The $L_{2,3}$ emission spectrum, however, is sensitive to the 3s and 3d character of the valence band. Therefore, it is well known that the emission spectrum originating from electron transitions between the valence band and the inner shell provides a powerful technique for obtaining information about the electronic structure in the valence band or the chemical-bonding state.

The first evidence in a study of the $K\beta$ emission spectra for phosphorus, sulfur, and chlorine compounds that X-ray spectra were influenced by the chemical combination was reported by Lindh and Lundquest,[3] who worked with direct electron bombardment. Following this discovery, very active investigations were begun to ascertain the effects of chemical combination on the X-ray spectra of many elements using a fluorescent-excitation technique. However, the effects of chemical combination on the X-ray spectra were found to be very slight except in the case of the light elements.

Recently, Takahashi *et al.*[4-6] obtained the $K\beta$ spectra of phosphorus, sulfur, and chlorine compounds and discussed the $K\beta$ spectral profile from the standpoint of chemical-state analysis. However, no sufficient discussion of the peak profile has yet been made because the spectrum is obtained with a single crystal spectrometer. A high-resolution spectrometer is necessary to observe fine splitting structures originating from chemical bonding, as the separation in the energy of the valence-band molecular orbitals is less than several electron volts. Gōshi[7] designed and constructed a simple two-crystal spectrometer in order to obtain highly energy resolved $K\beta$ X-ray emission spectra and then applied it to chemical-state analysis. Whitehead[8] obtained the $K\beta$ spectra of sulfur and chlorine compounds using a double-crystal X-ray spectrometer and discussed the spectra in terms of the molecular-orbital theory. Gōshi *et al.*,[9] in the latest date, constructed a wide-range two-crystal vacuum X-ray spectrometer and showed many possibilities in chemical shift measurement and chemical-state analysis.

There have been many experiments and studies of the $K\beta$ spectra for the third-period elements in various compounds. However, no sufficient and systematic investigation of the $K\beta$ spectra for these compounds, and no systematic studies of chemical-state analysis using these spectra, have yet been done. In this paper, a systematic investigation of the P-, S- and Cl $K\beta$ spectra in various phosphorus, sulfur and chlorine compounds, and a discussion from the point of view of chemical-state analysis, will be done using a simple quasi-two-crystal spectrometer in order to obtain the high-resolution spectra. We have attempted to present the results of chemical-state analysis by means of soft X-ray spectroscopy in this and in companion papers;[10,11] also in this paper we will try to make clear the relationship between the character of the chemical state and the $K\beta$ emission spectra.

Experimental

We designed and constructed a new, simple quasi-two-crystal spectrometer using a commercial single-crystal spectrometer. By rotating the detector arm at $3\Delta\theta$ relative to the rotation angle of the first crystal, (1) the analyzer wavelength can be obtained directly according to Bragg's diffraction law, $2d\sin\theta=n\lambda$, and (2) the scanning range satisfying Bragg's diffraction law is extended.

Figure 1 shows a schematic diagram of the quasi-two-crystal spectrometer in which a two-crystal attachement is added to a commercial single-crystal spectrometer. A parallel-foil collimator, A, limits the divergence of the X-

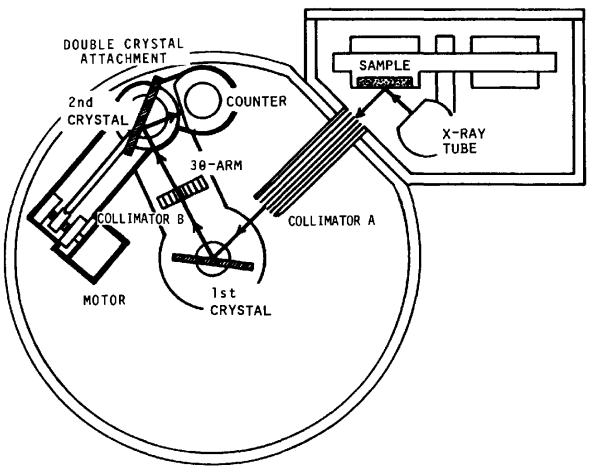

Fig. 1. Schematic diagram of the quasi two-crystal spectrometer.

rays incident on the first crystal, and the collimator, B, between the first- and second-crystals, limits the scattering of the X-rays. An attachment which includes the second crystal and a detector is coupled to the detector arm. The second crystal can be rotated by several degrees for fine adjustment using a bar driven through gears by a small motor. The collimator, A, is 10 cm long with 0.24 mm spacing and with a vertical 1 mm-spacing collimator attached. A flat Ge(110···$2d$=6.532 Å) was used as an analyzer crystal. Background and impurity lines of a higher order can be reduced by using a gas-flow proportional counter with a pulse-height discriminator. P-10 gas is used as the counting gas and is sealed in the counter with a polycarbonate film window (6 μm thick). A Philips PW2188 chromium-target X-ray tube is used and operated at 50 kV and 50 mA. The primary characteristics of this spectrometer are: (1) the intensity and resolution are the same as those of an orthodox two-crystal spectrometer, and (2) it is easy to use and can easily be constructed. A detailed description of this spectrometer has been reported elsewhere.[12]

The solid specimens are prepared by pressing a fine powder into a smooth aluminum ring, thus keeping the target sample pure and at a constant pressure. The liquid samples are measured using a sample holder which is sealed with a polystyrene film window (15 μm thick). The spectrum is calibrated by the sharp Cu$K\beta$ line. In order to insure that the radiation-decomposition effect upon these measurements is negligible, the measurement has been done twice for each spectrum, using two identical samples. The total counting time is 30 s per point, and the counter is scanned, step by step, by 0.01 ° of 3θ.

Results and Discussion

In previous[1] and companion[10] papers, it has been shown that the $L_{2,3}$ fluorescence spectra of sulfate ions (SO_4^{2-}) reveal scarcely no influence of the cations of sulfate compounds. The same phenomenon is expected in the $K\beta$ fluorescence spectra. The S$K\beta$ emission spectra for Na_2SO_4, $CoSO_4$, $NaHSO_4$, $(NH_2)_2H_2SO_4$, and H_2SO_4 are shown in Fig. 2. In the ions of polyatomic compounds, the individual ionic groups, such as SO_4^{2-} in solid Na_2SO_4, K_2SO_4, or $CaSO_4$, are essentially isolated anions, as a whole, and are not signifcantly affected by the cations. In the $K\beta$ spectra from sulfate ions with a T_d symmetry, however, there are two main components. The T_d molecular symmetry has seven occupied orbitals ($4a_1$, $3t_2$, $5a_1$, $4t_2$, $1e$, $5t_2$, and $1t_1$) in the valence band. Hence, transitions into the 1s-level are allowed only from the t_2 orbital by the dipole-selection rule, and it seems that the main peak C, known as $K\beta_{1,3}$, should be a transition from the $4t_2$ orbital, whose molecular orbital consists mainly of the 3p population of sulfur and the 2p population of oxygen. It seems that the position of the main peak C is not influenced by the kind of cation. If the cation of these compounds is replaced by hydrogen, however, the main peak C shifts just a little (≈1 eV). Because X-ray emission involves two levels, the chemical effect is the result of the shift of the core level also and of the structure of the valence band. The effect of the core-level shift is simply to shift the emission spectrum in terms of energy. Therefore, the spectral feature is related to the structure of the valence band. It seems reasonable that the main peak of the $K\beta$ spectra is not shifted by the shift of the core level 1s of sulfur in relation to hydrogen, because the 1s level of hydrogen is separated from the 1s level of sulfur; therefore, the molecular orbital in the valence band is affected in relation to hydrogen. The peak A, known as $K\beta'$ at a lower energy, should be identified as the $3t_2$ orbital, whose molecular orbital consists mainly of the 3p population of sulfur and the 2s population of oxygen. It should be noted that the position of the peak A shows scarcely no influence of the cations; however, the peak A shifts just a little, like peak C, when the cation is replaced by hydrogen. The spectra can be expected to have one more component, as there is the $5t_2$ molecular orbital in the valence band. That is the very small peak D, known as $K\beta''$, because the $5t_2$ orbital consists of the 3d population of sulfur and the 2p population of oxygen. There is a small hump on the lower-energy side of the main peak C. This peak probably originates from the $5a_1$ molecular orbital, whose molecular orbital consists mainly of the 3s population of sulfur and the 2s, 2p population of oxygen. If a symmetry of molecule is distorted and the $5a_1$ molecular orbital contains the 3p population, an electron transition is allowed to the 1s level from $5a_1$, with its 3p population, although transition into the 1s level is not allowed from the a_1 orbital by the dipole-selection rule. It thus seems that the peak B is influenced by the chemical bonding conditions and by the other cations.

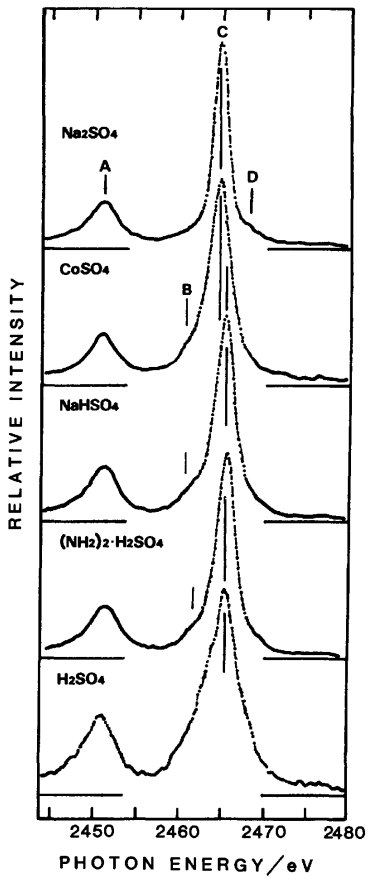

Fig. 2. Comparison of S$K\beta$ spectra of sulfate compounds.

The Cl$K\beta$ spectra for $LiClO_4$, $NaClO_4$, and $KClO_4$ are shown in Fig. 3. It should be noted that the $K\beta$

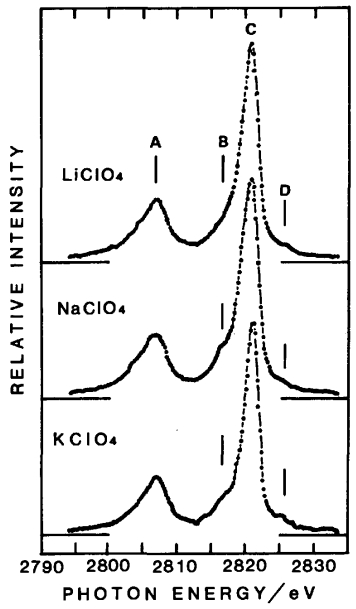

Fig. 3. Comparison of Cl$K\beta$ spectra of perchlorate compounds.

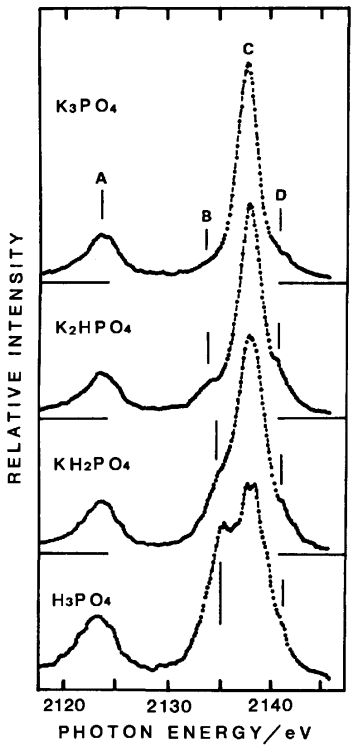

Fig. 4. Comparison of P$K\beta$ spectra of potassium phosphates and phosphoric acid.

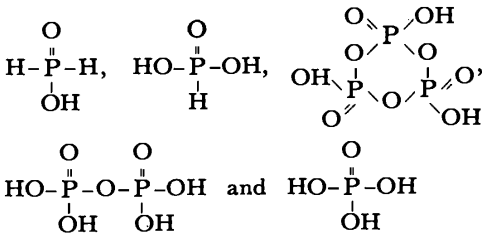
spectral profiles of perchlorate ions reveal scarcely no influence of the cation, except for the hump B. The hump B grows up in proportion to the increase in the atomic number of the cation. It seems that the hump B originates from the electron transition from the $5a_1$ molecular orbital of the distorted T_d symmetry to the 1s level, and that the molecular orbital is affected by the interaction between the anion and the cation. If the covalent interaction between the ions is relatively small, it seems that hump B becomes negligibly small.

The P$K\beta$ spectra for K_3PO_4, K_2HPO_4, KH_2PO_4, and H_3PO_4 in each of which the metallic cation is replaced by hydrogen, are compared in Fig. 4. The covalent interaction between PO_4^{3-} and the cations of these compounds is relatively large except in the case of H_3PO_4. No hump B appears in the spectrum in the case of K_3PO_4, but the hump B appears and grows in the cases of K_2HPO_4 and KH_2PO_4, and the hump B grows into a large peak in the case of H_3PO_4. Moreover, the hump B shifts to the higher-energy side according to the contribution of hydrogen. It seems that hydrogen contributes to the hump B and that the intensity of the hump B increases according to the increase in the covalent interaction between the anion and the cation. The main peak C shifts just a little in relation to the hydrogen atom. There is a small component D on the higher-energy side of the main peak.

For a consideration of the contributions of the hydrogen ion or the hydroxide ion in the $K\beta$ spectrum, the P$K\beta$ spectra for phosphinic acid (HPH_2O_2), phosphonic acid (H_2PHO_3), *cyclo*-triphosphoric acid ($H_3P_3O_9$), and pyrophoshoric acid ($H_4P_2O_7$) are compared in Fig. 5. The measured spectra change depending upon the chemical state. The spectra of HPH_2O_2 and H_2PHO_3 have hump B, while $H_3P_3O_9$, $H_4P_2O_7$, and H_3PO_4 have peak B, which is clearly separated from the main peak C. The structural formulas for HPH_2O_2, H_2PHO_3, $H_3P_3O_9$, $H_4P_2O_7$, and H_3PO_4 are:



respectively. In the structural formula of HPH_2O_2 or H_2PHO_3, the central P atom combines with O, OH, and H. However, in the case of $H_3P_3O_9$, $H_4P_2O_7$, or H_3PO_4, the central P atom combines with O and OH. In these cases, the $K\beta$ spectral features for these compounds have something in common with each other. However, in the case of the O$K\alpha$ spectrum for these compounds, the spectral features change.[11] It seems reasonable to consider that those spectral features are influenced by the conditions of the surrounding atoms for the observed atom, not by the difference in structure formulas. The same conclusion can be observed for the $L_{2,3}$ emission spectra.[2]

In a companion paper,[10] it will be shown that the main peak of the $L_{2,3}$ emission spectra shifts to the higher-energy side with the increase in the oxidation number. The same phenomenon is observed in the $K\beta$ spectra of oxide compounds. Figure 6 compares the Cl$K\beta$ spectra for NaCl, NaClO, $NaClO_2$, $NaClO_3$, and $NaClO_4$. These spectra change corresponding to the chemical-bond state and also with the number of bonding oxygen atoms. These spectra have fine structures depending upon the chemical state. The main peak C and the small peak D on the higher-energy side shift to higher energy side, but the peak A on the lower-energy side only shifts a little, to higher energy side with the increase in the oxidation number. If

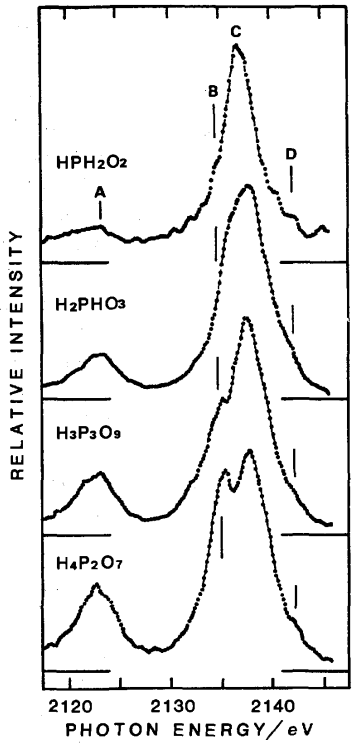


Fig. 5. Comparison of P$K\beta$ spectra of phosphinic acid, phosphonic acid, *cyclo*-triphosphoric acid, and pyrophosphoric acid.

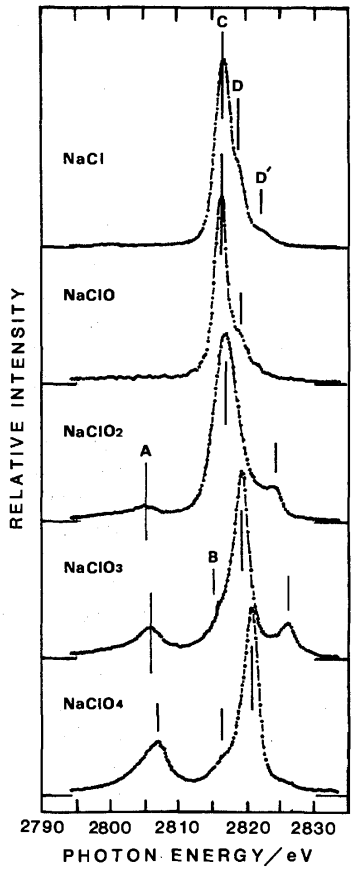

Fig. 6. Comparison of Cl$K\beta$ spectra of NaCl, NaClO, $NaClO_2$, $NaClO_3$, and $NaClO_4$ which are different in the bonding oxygen atom number.

NaCl is of a perfect ionic bond, one can expect that the spectrum will consist of only one component, because there is only the 3p level of the Cl ion which is allowed the transition to the inner ls level. However, the spectrum of NaCl has three components. It seems reasonable to say, therefore, that NaCl involves a partial covalent character. The peak A originates from the transition from the molecular orbitals which consist mainly of the Cl-3p and O-2s populations. Therefore, the peak A grows in proportion to the increase in the number of oxygen. The peak D originates from the transition from the molecular orbitals which consist mainly of the O-2p population, but the molecular orbital involves the Cl-3p or Cl-3d population a little. In the case of ClO_4^-, the peak D is negligibly small, because the ClO_4^- has the oxygen lone pair orbital. However, the peak B on the lower-energy side of the main peak seems to grow with the increase in the oxidation number.

A similar example of the sulfur $K\beta$ spectra for $Na_2S_2O_4$, $Na_2S_2O_5$, $Na_2S_2O_6$, and $Na_2S_2O_7$ is shown in Fig. 7. These spectra consist of five peaks, and they show differences in the chemical-bond state as a function of the number of bonding oxygen atoms. Each peak shifts to the higher-energy side with an increase in the number of oxygen atoms. This fact can be thought to indicate that the initial level (core vacancy) for the electron transition shifts to the higher-energy side according to the increase in the quantity of oxygens combined with the sulfur atom. While the peak A develops with the oxygen atoms, the peak E decays,

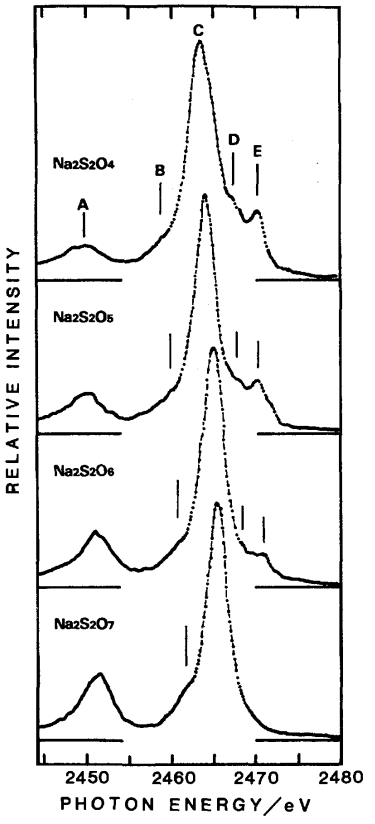

Fig. 7. Comparison of S$K\beta$ spectra of $Na_2S_2O_4$, $Na_2S_2O_5$, $Na_2S_2O_6$, and $Na_2S_2O_7$ which are different in the bonding oxygen atom number.

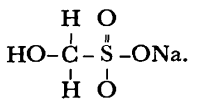
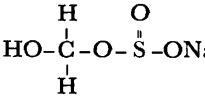
and it is barely seen in the $Na_2S_2O_7$ spectrum. The peak D is clearly observed in either $Na_2S_2O_4$ or $Na_2S_2O_5$, but not in $Na_2S_2O_6$ or $Na_2S_2O_7$, while in the case of the peak B, the opposite behavior is seen.

We should like to demonstrate another case of the relation between the $K\beta$ spectrum and the chemical-bond-state conditions. Figure 8 shows a comparison of the sulfur $K\beta$ spectra for sodium benzenesulfinate ($C_6H_5SO_2Na$), sodium sulfate (Na_2SO_3), sodium hydrogensulfite ($NaHSO_3$), sodium hydroxymethanesulfinate ($HOCH_2SO_2Na$), and sodium hydroxymethanesulfinate ($HOCH_2SO_3Na$). These compounds contain mainly three or four components in the $K\beta$ spectra. It seems that these spectra all show similar features, but differ from the spectrum of sulfate compounds. However, the intensity ratio of the spectral components of these compounds changes with the chemical state. These compounds contain the $-CSO_2-$ or $-SO_3-$ in their structural formulas. It seems that the main peak B reveals scarcely no influence of the chemical state. However, the peaks A and C change with the chemical state, and it seems that the intensity of the peak C decreases and the position of the peak C shifts to the higher-energy side according to the increase in the peak A. In the case of $NaHSO_4$ in Fig. 2, the small peak B which is contributed by the hydrogen atom appears on the lower-energy side of the main peak of the S $K\beta$ spectra. From these considerations, it seems reasonable that the small peak D of $NaHSO_3$, $HOCH_2SO_3Na$ and $HOCH_2SO_2Na$ is related to the hydrogen atom. In Ref. 5, it is supposed, from an X-ray spectral analysis, that the structural formula for $HOCH_2SO_3Na$ is a sulfone-type structure:



If this conclusion is true, the spectrum of $HOCH_2SO_3Na$ should be classified in the sulfate (SO_4^{2-}) group, as the 2p electrons of carbon play the same role in the valence band as the 2p electron of oxygen in combination with sulfur. However, the spectral profile of $HOCH_2SO_3Na$ seems to be classifiable in the sulfite (SO_3^{2-}) group. Our spectrum analysis suggests that the structural formula for $HOCH_2SO_3Na$ should be given as follows:



The lowest-energy peak originates from the electron transition from the molecular orbital which consists mainly of the 3p population of sulfur and the 2s population of oxygen. Therefore, if it is no contributed with oxygen atoms, the peak A should not be in the $K\beta$ spectra. The S $K\beta$ spectra for sulfur compounds which contain thiourea or other such substances, but do not contain the oxygen atom, are shown in Fig. 9. These compounds contain mainly two components. The main peak B reveals scarcely no influence, but the intensity and position of peak A are affected by the chemical state. The structural formula for the com-

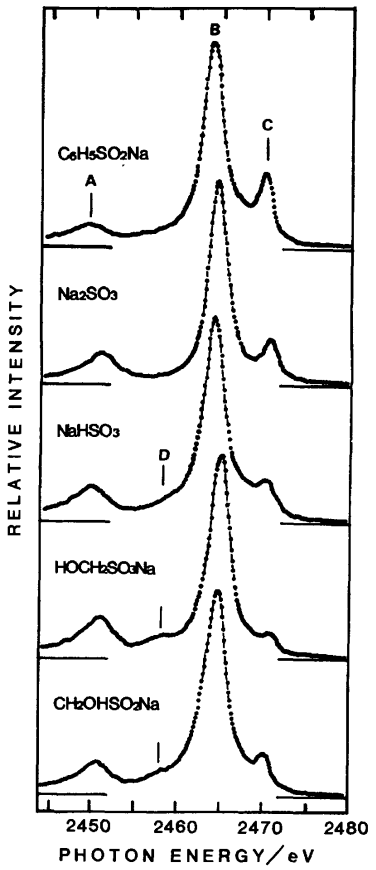


Fig. 8. Comparison of S $K\beta$ spectra of sodium benzenesulfinate, sodium sulfate, sodium hydorgensulfite, sodium hydroxymethanesulfinate, and sodium hydroxymethanesulfonate.

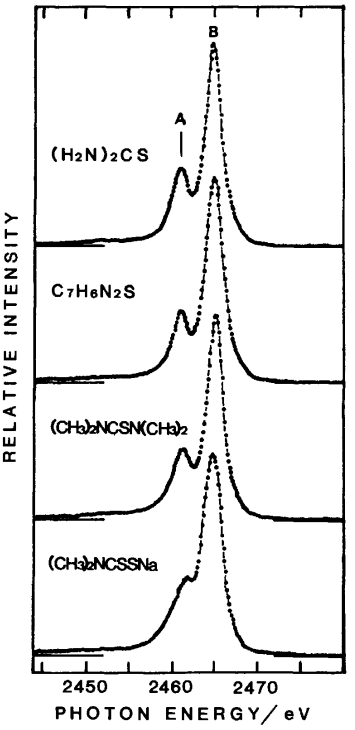

Fig. 9. Comparision of S $K\beta$ spectra of thiourea, 2-mercaptobenzimidazole, tetramethylthiourea, and sodium dimethyldithiocarbamate which do not contain oxygen.

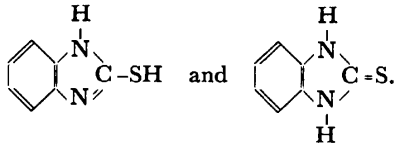
pounds of thiourea has a double bond of carbon and sulfur. The two structural formulas in 2-mercaptobenzimidazole ($C_7H_6N_2S$) may be given as the follows:



I II

However, in comparing the spectra, it seems reasonable to say that the structural formula for ($C_7H_6N_2S$) has a thiocarbonyl form II. This conclusion is the same as that is given in Ref. 5.

Finally, the Cl $K\beta$ emission spectra of HCl, LiCl, NaCl,and KCl are shown in Fig. 10 in order to consider the relation of the ionic bond and the covalent bond with the $K\beta$ X-ray spectra. These spectra have satellite peaks depending upon the chemical state. Therefore, it should be noted that these compounds have a partial covalent character and that the Cl $K\beta$ spectrum is affected by the kind of cation. If these compounds have a highly ionic bond, these spectra can be expected to have only one peak component, originating from the 3p atomic level. However, one can not discuss the ionic and covalent characters of these compounds from their $K\beta$ spectra alone. Although each peak shifts a little to the higher-energy side according to the atomic-number-increase order: Li, Na, and K, in the Cl $L_{2,3}$ emission spectra, the main peak in the case of the $K\beta$ spectra reveals scarcely no influence of the cations.

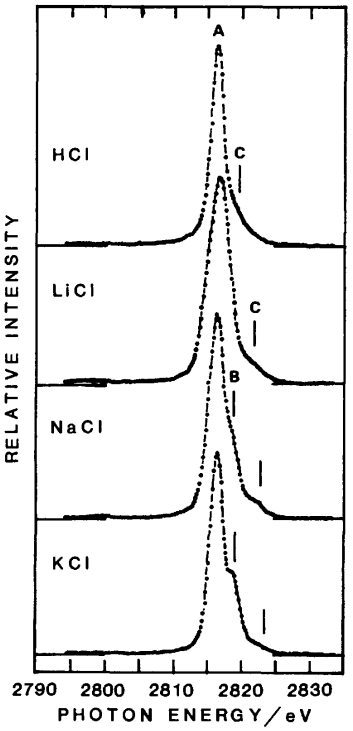


Fig. 10. Comparison of the Cl $K\beta$ spectra of HCl, LiCl, NaCl, and KCl which combine with different cations.

Conclusion

In this paper, we constructed a simple two-crystal spectrometer and showed, using it, that spectra taken with a high resolution spectrometer can give us not only important information for studies of molecular orbitals, but also useful information for application to chemical-state analysis.

We have found the following properties:

(1) Although the $L_{2,3}$ emission spectra of the highly ionic bond reveal scarcely no influence of the cations,[10] the $K\beta$ spectra for phosphorus, sulfur, and chlorine in various compounds are affected by the kind of cation.

(2) The $K\beta$ spectra for the different central atoms of compounds which have T_d molecular symmetry show features similar, as with the $L_{2,3}$ emission spectra.

(3) A peak related to the hydrogen or hydroxyl group is observed on the lower-energy side of the main peak, except in the case of HCl. It seems that the X-ray emission spectra give information about the contribution of hydrogen.

(4) The each peak of the $K\beta$ spectra shifts to the higher-energy side with an increase in the oxidation number.

(5) As the spectral features are sensitive to the chemical condition of the surrounding atoms, one can consider and decide the structural formula from a comparison of the spectra.

In this work, we can not interpret the spectra by the help of a molecular-orbital calculation and can not discuss the spectra quantitatively. This must remain a subject for future study.

We gratefully acknowledge some very useful discussions with Dr. Yōichi Gōshi of Tokyo University and Dr. Sigero Ikeda of Osaka University and invaluable assistance in this work of Mr. Shinji Nagaura of this university.

Chemical-state Analysis by Means of Soft X-Ray Spectroscopy. III. O$K\alpha$ Emission Spectra for Oxyanions in Different Salts

Kazuo TANIGUCHI

Department of Solid-State Electronics, Osaka Electro-Communication University, 18-8, Hatsucho, Neyagawa, Osaka 572

(Received May 24, 1983)

The oxygen $K\alpha$ spectra of the oxyanions in different salts are obtained by secondary excitation. The obtained spectra are affected by the cations, the central atom, and the chemical-bond condition. Generally, there are four components in the spectra, but one small component may originate from the anomalous reflection of an analyzing crystal. The spectra are discussed from the point of view of chemical-state analysis.

Until a few years ago valence-band spectra originating from the electron transition from the valence-band orbitals to the inner-core level were interpreted by studying the complex interactions involving an isolated atomic model or by using solid-state-band models. Because X-ray emission involves two levels, the chemical effect is the result of the shift of the core level and of the structure of the valence-band orbital levels. Therefore, the X-ray-emission spectra can be directly applied, using standard sample systems, for the identification of an unknown valence state and for investigations of the electronic structures of chemical compounds.

In previous papers[1,2] and companion papers,[3,4] we have studied the valence-band spectra, that is the $L_{2,3}$ emission and $K\beta$ spectra for phosphorus, sulfur, and chlorine, in various compounds and discussed the spectral profile from the point of view of chemical-state analysis. It is concluded that the spectral features of the $K\beta$ or $L_{2,3}$ emission spectra are especially influenced by the oxygen of the ligand. In the ground state, two 2s-electrons and four 2p-electrons are present in the valence band, but they will obviously be directly involved in bonding. The O$K\alpha$ spectrum yields information only about the valence orbitals containing the O-2p population, because the spectra reflect the p-like symmetry on account of the dipole-selection rule. In general, the O-2p electron is related to valence-band orbitals when oxygen combines with another atom. Therefore, one can expect to get information about the electronic structure and be able to apply it to the chemical-state analysis from the results of the analysis of the O$K\alpha$ spectra.

The first evidence in studies of the O$K\alpha$ spectra in various oxide compounds that the X-ray spectra were influenced by the chemical combination was reported on the 1940's;[5,6] using the direct electron bombardment. As samples are decomposed under such electron bombardment, however, fluorescence excitation is frequently used in the region of soft X-rays.[7-11] Recently, O$K\alpha$ spectra have been obtained using low-energy-electron-induced X-ray spectroscopy,[12] a high-resolution concave-grating-grazing incidence spectrometer,[13] synchrotron radiation as a light source for the excitation of substances,[14,15] or the ion-induced X-ray excitation method.[16] Andermann *et al.* have measured the O$K\alpha$ spectra for the oxide compounds with a grating spectrogaph and discussed the C–O bond on the basis of the spectra thus obtained[17] by applying spectral techniques of such efficiency as to minimize the effects of radiation decomposition. Kosuch *et al.* have shown that the comparison of the O$K\alpha$ spectrum with the other X-ray spectra is a useful technique for the investigation of the electronic structures of chemical compounds.[14,15]

In this and in companion papers[3,4] we present the results of chemical-state analysis by means of soft X-ray spectroscopy; in this paper we will also try to make clear the relationship between the character of the chemical state and the O$K\alpha$ emission spectra.

Experimental

Measurements of the oxygen $K\alpha$ spectrum were carried out using the single flat-crystal spectroscopic method with a TAP($2d$=25.8 Å) analyzing crystal. The basic spectrographic approach that is used in this laboratory is shown in Fig. 1. The X-ray spectrometer is a vacuum type equipped with a fine Soller collimator 10 cm long and with 0.08 mm spacing. It has a simple close-coupling of a high-intensity, demountable, low-energy X-ray excitation source. The most intense and practical line source in the oxygen K excitation is Cu$L\alpha$ (13.3 Å). It is generated in a demountable Henke-type tube[18] using a copper anode. The source is stable for many hours of operation, typically at 9 kV and 220 mA. The X-ray tube window is constructed of 6 μm polycarbonate film with an aluminum coating a few hundred angstroms thick. Propane gas at a pressure of 65 mmHg (1 mmHg≈133.322 Pa) is used as the proportional counting gas, and the counting gas in the counter is isolated from the vacuum chamber with poly-(vinyl formal). This spectroscopic approach has been described in detail elsewhere.[18,19] As the oxygen $K\alpha$ emission spectra analyzed with a KAP crystal show a strong anoma-

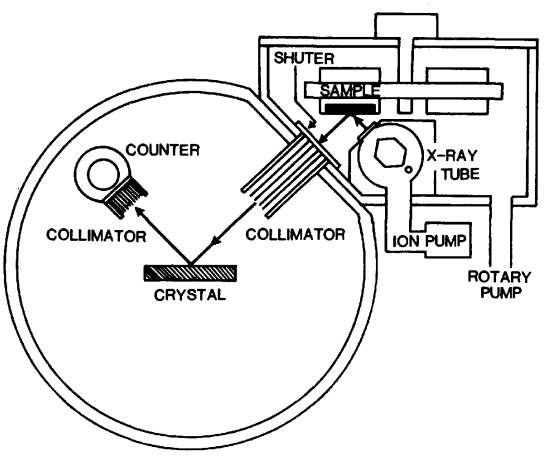

Fig. 1. A single-crystal spectrographic approach for low energy X-ray spectroscopy applying closely coupled demountable X-ray source.

lous peak on the high-energy side of the main peak,[8,20] a flat TAP was used as the analyzer crystal. The solid specimens were prepared by pressing a fine powder into a smooth aluminum ring in order to keep the target sample pure and at a constant pressure. In order to insure that the radiation decomposition effect upon these measurements was negligible, the measurement was done twice for each spectrum with two identical samples. The total counting times were 30 s per point, and the counter was scanned, step by step, by 0.05° of 2θ arm.

Results and Discussion

The spectral features of the O$K\alpha$ spectra for Li_3PO_4, Li_2SO_4, and $LiClO_4$ are compared in Fig. 2. The anions of these compounds all have the T_d molecular symmetry, but with different central atoms. There are mainly four components. These components are probably related to the molecular orbital in the valence band. There are seven occupied orbitals ($4a_1$, $3t_2$, $5a_1$, $4t_2$, 1e, $5t_2$, and $1t_1$) in the valence band for these T_d molecular symmetries. The main peak C originates from the electron transition from the O-2p lone-pair level ($1t_1$) to the O-1s core level. The hump B on the lower-energy side of the main peak probably orignates from the $5t_2$ and 1e molecular orbitals, whose molecular orbitals consist mainly of the oxygen-2p and the central atom-3d population. The peak A on the lower-energy side should be assigned to $4t_2$, with its comparatively high 3p population of the central atom and its relatively poor 2p population of the oxygen. The peak C and the hump B shift to the higher-energy side, and the peak A shifts to the lower-energy side, in proportion to the increase in the atomic number of the central atom with the T_d molecular symmetry. Thus, the domain of the spectra of interest is expanded in proportion to the increase in the atomic number of the central atom.

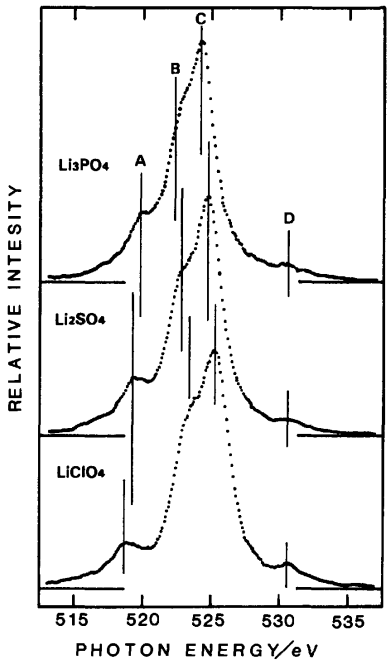

Fig. 2. Comparison of the O$K\alpha$ emission spectra for Li_3PO_4, Li_2SO_4, and $LiClO_4$. O$K\alpha$ spectra have been excited by Cu$L\alpha$ radiation and analyzed by TAP crystal.

In general, there are similar features of the $L_{2,3}$ emission spectra or the $K\beta$ spectra for all anions having the T_d molecular symmetry, though with different central atoms, although the energy ranges of the emission spectra are different,[3,4] and the domain of spectra of interest is expanded in proportion to the increase in the atomic number of the central atom. It should be noted that the peak position of D reveals scarcely no influence of the central atom. It seems reasonable to say that the peak D is due to an enhanced reflectivity of the analyzed crystal with the local continuum background in this energy region.[8]

In companion papers,[3,4] the $L_{2,3}$ emission spectra of the central atom are reported to reveal scarcely no influence of the cations for the phosphate, sulfate, or perchlorate compounds, but the $K\beta$ spectra of the central atom are affected just a little by the cation for these compounds. Kosuch *et al.* conclude that the oxygen $K\alpha$ spectra of oxyanions from different salts do not show any influence of the cation within the limits of accuracy of the measurements.[14] The oxygen $K\alpha$ spectra for lithium sulfate, sodium sulfate, and potassium sulfate are compared in Fig. 3 in order to consider the influences of the cations. Here, the intensity (in arbitrary units) is presented as a function of the 2θ of the Bragg angle θ. Each of the experimental spectra was resolved into its component lines in order to consider

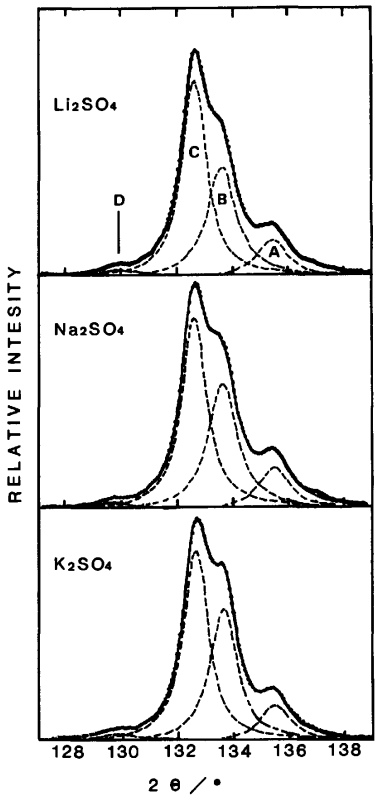

Fig. 3. Comparison of the O$K\alpha$ emission spectra for Li_2SO_4, Na_2SO_4, and K_2SO_4 in order to consider the influences of cations. O$K\alpha$ spectra have been excited by Cu$L\alpha$ radiation and analyzed by TAP crystal. Fit through the experimental points is the sum of convolution function of Lorentzian components with Gaussian function.

it more efficiently. The outmost line is the fitting curve, which is the sum of the emission components, which are also plotted here. Each line component is used as the convolution function, alone the with Lorentzian and Gaussian functions. It can be seen that the peak component B is affected little by the cation. As the main peak C originates from the lone-pair orbital $1t_1$, it seems reasonable to say that the peak C reveals scarcely no influence of the cation. On the other hand, the peak B and the peak A should be affected by the cations, because the oxygen atom is directly related to the cation. It seems that the hump B grows in proportion to the atomic number of the cations. The intensity ratios of the peaks C and B are 0.56, 0.65, and 0.75 for lithium sulfate, sodium sulfate, and potassium sulfate respectively.

The O$K\alpha$ spectra for K_2HPO_4, and KH_2PO_4, in each of which the metallic cation is replaced by hydrogen, are compared with K_3PO_4 in Fig. 4. The spectral features of the O$K\alpha$ spectra for their compounds are especially influenced by hydrogen, as are the $L_{2,3}$ emission spectra (in Ref. 3). The peaks A and B shift to the lower-energy side, and the peak A decreases in proportion to the relation with hydrogen. This phenomenon is very different from the $K\beta$ spectra (in Ref. 4), because the peak on the lower-energy side of the main peak of $K\beta$ shifts to the higher-energy side and increases in proportion to the relation with hydrogen. It can be noted from the $K\beta$ spectra that the molecular level concerning the O–H bond is created on the lower-energy side of the $4t_2$ level, which consists mainly of the 3p population and which is and shifted to near the $4t_2$ level in proportion to the relation with hydrogen. On the other hand, the electron population of oxygen-2p diffuses to lower-energy molecular orbitals with the

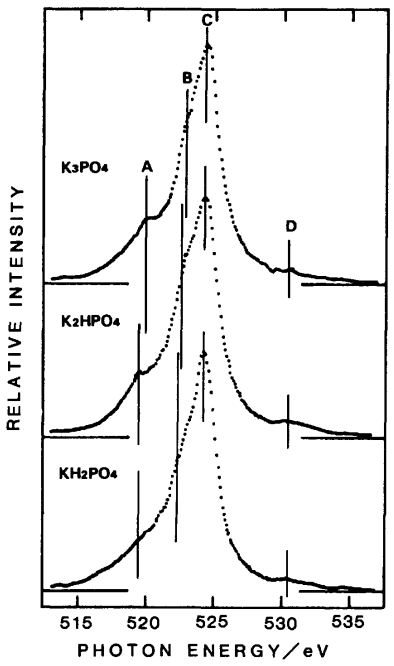

Fig. 4. Comparison of the O$K\alpha$ emission spectra for K_3PO_4, K_2HPO_4, and KH_2PO_4. O$K\alpha$ spectra have been excited by Cu$L\alpha$ radiation and analyzed by TAP crystal.

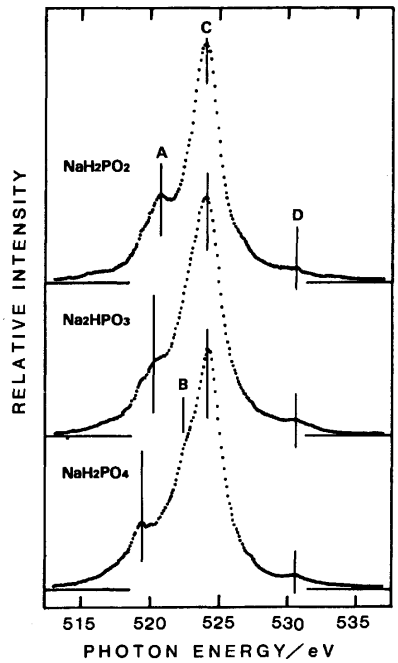

Fig. 5. Comparison of the O$K\alpha$ emission spectra for NaH_2PO_2, Na_2HPO_3, and NaH_2PO_4. O$K\alpha$ spectra have been excited by Cu$L\alpha$ radiation and analyzed by TAP crystal.

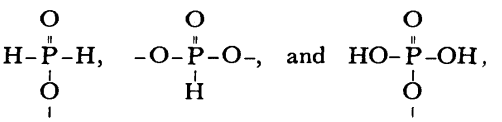
relation with hydrogen. Figure 5 shows the same phenomenon in the O$K\alpha$ spectra for NaH_2PO_2, Na_2HPO_3, and $NaHPO_4$. The O$K\alpha$ spectrum for NaH_2PO_4, consists of three components A, B, and C. However, the O$K\alpha$ spectra for NaH_2PO_2 and Na_2HPO_3 consist of only two components, A and C. Moreover, the peak A of NaH_2PO_2 shifts to the higher-energy side as compared with the cases of NaH_2PO_4 and Na_2HPO_3. The structural formulas for $H_2PO_2^-$, HPO_3^{2-}, and $H_2PO_4^-$ are;



respectively. In the structural formula of $H_2PO_4^-$, the central P atom combines directly with oxygen only, but the partial oxygen atoms combine with hydrogen. In the structural formulas of $H_2PO_2^-$ and HPO_3^{2-}, on the other hand, the central P atom combines directly with oxygen and hydrogen, but the oxygen atom does not combine with hydrogen. In the case of the O$K\alpha$ spectra for NaH_2PO_2, and Na_2HPO_3, the hump B does not appear. Therefore, it seems that the hump B appears when the central atom combines directly with O ions (including OH ions). In the structural formulas of $H_2PO_2^-$ or HPO_3^{2-}, the central P atom combines directly with only two or three oxygen atoms respectively. It may be seen that the peak A is related with the number of the oxygen which is combined with the central atom of the oxyanion, and is shifted to the lower-energy side in proportion to the number of the directly combined oxygen atom with the central atom. Moreover, the peak A for these compounds shifts to the higher-energy side compared with the case of K_3PO_4. It is reasonable that the peak A is related with the

number of oxygen which is combined with the central atom of the oxyanion and is shifted to the lower-energy side in proportion to the number of oxygen.

Figure 6 compares of the $OK\alpha$ spectra for sodium sulfite (Na_2SO_3) and sodium sulfate (Na_2SO_4) with their hydrogensulfite ($NaHSO_3$) and hydrogensulfate ($NaHSO_4$). There are two components in the $OK\alpha$ spectra in the case of SO_3^{2-}, but three components in the case of SO_4^{2-}. The spectral domain of SO_4^{2-} expands compared with that of SO_3^{2-}. The sharpness of the spectra for $NaHSO_3$ or $NaHSO_4$ is inferior to that for Na_2SO_3 or Na_2SO_4 respectively. It seems that the spectral components are broadened a little with the relation to hydrogen.

In Figs. 7 and 8, the relations between the spectral features and the coodination number of oxygen are shown. In both cases, the main peak C shifts to the higher-energy side and the peaks A and B shift to the lower-energy side according to the coodination number of oxygen. However, each peak component shifts to the higher-energy side in the case of the $K\beta$ spectra, and the middle peak only shifts to the higherenergy side, but the higher-energy peak increases in the case of the $L_{2,3}$ emission spectra in proportion to the coordination number of oxygen.

As the chemical effect of the X-ray spectra is the result of the shift of the core level and of the structure of the valence-band orbitals, the variation in the spectral profile will give us information about valence-band orbitals, because the core level is shifted simply with differ chemical states.

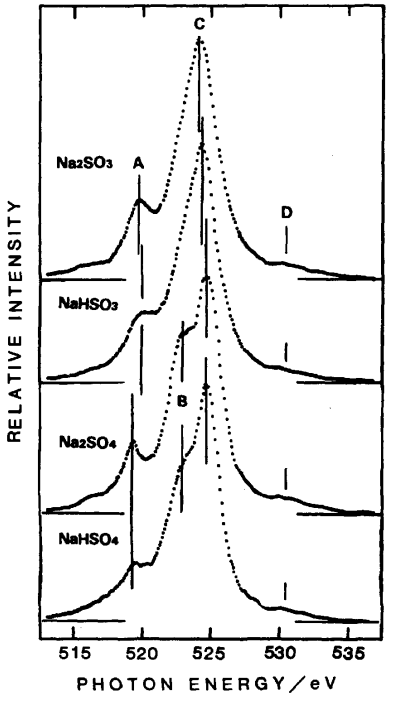


Fig. 6. Comparison of the $OK\alpha$ emission spectra for Na_2SO_3, and Na_2SO_4, with $NaHSO_3$ and $NaHSO_4$. $OK\alpha$ spectra have been excited by Cu$L\alpha$ radiation and analyzed by TAP crystal.

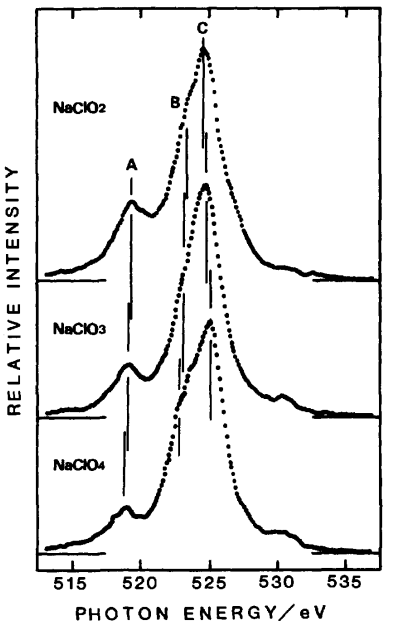

Fig. 7. Comparison of the $OK\alpha$ emission spectra for $NaClO_2$, $NaClO_3$, and $NaClO_4$. $OK\alpha$ spectra have been excited by Cu$L\alpha$ radiation and analyzed by TAP crystal.

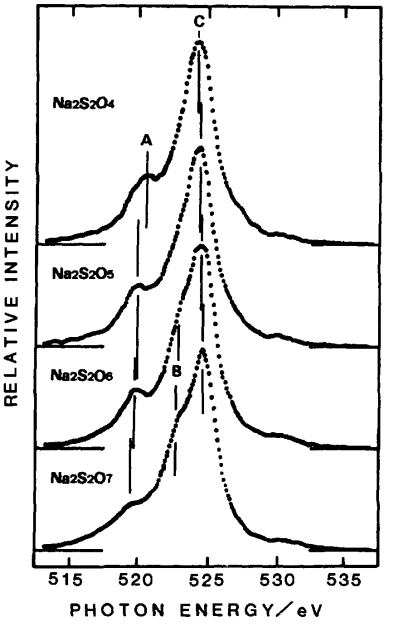

Fig. 8. Comparison of the $OK\alpha$ emission spectra for $Na_2S_2O_4$, $Na_2S_2O_5$, $Na_2S_2O_6$, and $Na_2S_2O_7$. $OK\alpha$ spectra have been excited by Cu$L\alpha$ radiation and analyzed by TAP crystal.

Conclusion

In this work, it has been shown that a spectral feature is closely affected by the chemical state and that the $OK\alpha$ spectra give us not only information for studies of molecular orbitals, but also provide a useful technique for application to chemical-state analysis, because oxygen 2p is related in almost all molecular orbitals of the valence band. The following properties

have been found:

1) The O$K\alpha$ spectra for oxyanions are expanded in proportion to the increase in the atomic mumber of the central atom.

2) The O$K\alpha$ spectra are affected a little by the cations, because oxygen atom is directly related to the cation. This conclusion is very different from that is the case of the $L_{2,3}$ emission spectra for the central atom, and also from the conclusion of Kosuch *et al.* about the O$K\alpha$ spectra.

3) The O$K\alpha$ spectra are especially influenced by hydrogen. It seems that the electron population of oxygen 2p diffuses to the lower-energy molecular orbitals in the relation to the hydrogen.

4) The O$K\alpha$ spectral profile is affected by the quantity of oxygen, the lower-energy peak shifts to the lower-energy side, and the main peak at a higher-energy shifts to the higher-energy side in proportion to the quantity of oxygen, and the hump B appears only when the central atom combines directly with the O (including OH) ions.

In this work, we can not interpret the spectra quantitatively as transitions from the molecular orbital with the help of a molecular orbital calculation. However, it seems that it will be very useful in studying the electronic structure and molecular orbital in chemical compounds in combination with the results of the $L_{2,3}$ emission spectra, the $K\beta$ spectra, and the O$K\alpha$ spectra from various compounds with the help of a molecular orbital calculation. These are subjects for future study in our work.

We gratefully acknowledge some very useful discussions with Dr. Yōichi Gōshi of Tokyo University and Dr. Sigero Ikeda of Osaka University and invaluable assistance in this work of Mr. Masaru Matsuo of this University.

Molecular and Crystal Structures of *endo*- and *exo*-*N*-Methyl-3,7-epoxy-3-methoxy-7-oxo-1,2-benzo-1-cycloheptene-4,5-dicarboximide

Hatsue TAMURA, Toshikazu IBATA, and Kazuhide OGAWA*
College of General Education, Osaka University, Toyonaka, Osaka 560
(Received June 27, 1983)

The crystal structures of *endo*- and *exo*-adducts of 1-methoxy-2-benzopyrylium-4-olate with *N*-methylmaleimide have been determined by means of X-ray analysis. The colorless crystals of the *endo*-adduct are orthorhombic, with the space group $P2_12_12_1$ and with a=14.432(3), b=11.874(2), c=7.762(1) Å, and Z=4. The colorless crystals of the *exo*-adduct are monoclinic, with the space group $P2_1/a$ and with a=13.381(2), b=12.825(1), c=7.4793(4) Å, β=92.13(1)°, and Z=4. The structures were deduced by a direct method and refined by a block-diagonal least-squares technique. The final R values for the *endo*- and *exo*-adducts are 0.047 for 1160 observed reflections and 0.067 for 1986 observed reflections respectively. The configurations of the *endo*- and *exo*-adducts are coincident with those assigned on the basis of the NMR data. The observed values of the ring-current effect on the *N*-methyl chemical shift of the *endo*-adduct and the coupling constants of the vicinal methine protons of both adducts are in good agreement with the ones calculated on the basis of the present X-ray crystal-structure analysis.

The chemistry of carbonyl ylide has received the continuous interest of heterocyclic chemists for the past two decades.[1] One of the present authors (T. I.) has reported the novel formation of carbonyl ylide by the carbene-carbonyl reaction.[2] As an application of this reaction, the $Cu(acac)_2$-catalyzed decomposition of *o*-methoxycarbonyl-α-diazoacetophenone (**1**) was reported to give 1-methoxy-2-benzopyrylium-4-olate (**3**) as a transient species in a high yield *via* an intramolecular carbene-carbonyl reaction of intermediate keto carbene (**2**). The cycloaddition of the pyrylium-4-olate (**3**) to *N*-methylmaleimide gave two adducts: **4a**, mp 210°C; **4b**, 230°C.[3] The reaction procedure is shown in Scheme 1. The two adducts, **4a** and **4b**, were assigned to *endo*- and *exo*-cycloadducts respectively on the basis of their NMR data.[3] In order to confirm the assignment of the structures, an X-ray analysis of the adducts was carried out. Then, using the crystal data thus obtained, the ring-current effect and the coupling constants were calculated according to Farnum-Wilcox's method[4] and Williamson-John's equation[5] respectively.

Experimental

Colorless crystals of the *endo*- and *exo*-adducts were obtained from benzene solutions. The crystal data of the *endo*- and *exo*-adducts, along with the experimental conditions, are listed in Table 1. The X-ray intensity data were measured on a Rigaku four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation. The numbers of non-zero reflections used in the structure determination were 1160 for the *endo*- and 1986 for the *exo*-adduct. The intensities were corrected for Lorentz and polarization effects.

The NMR spectra of the *endo*- and *exo*-adducts were reexamined on a Hitachi NMR spectrometer, model FT-100, in $CDCl_3$, using TMS as the internal standard, to obtain accurate values of the chemical shifts and coupling constants.

Structure Determination. Using 170 reflections with $|E| \geq 1.39$ for the *endo*-adduct and 170 reflections with $|E| \geq 1.80$ for the *exo*-adduct, the crystal structures were determined by the direct method with the MULTAN 78 program.[6] The *E*-maps computed with the phase sets of the highest combined figure of merit (2.996 for the *endo*-adduct and 3.000 for the *exo*-adduct) revealed the positions of all the non-hydrogen atoms. Several cycles of block-diagonal least-squares refinement with isotropic temperature factors brought the R values to 0.096 for the *endo*-adduct and to 0.121 for the *exo*-adduct. The refinement with anisotropic temperature factors then reduced the R values to 0.061 for the *endo*-adduct and to 0.081 for the *exo*-adduct. At this stage, all the hydrogen atoms except those of the methyl groups were located by means of difference syntheses. After several cycles of block-diagonal least-squares refinement, the R values were reduced to 0.047 for the *endo*-adduct and to 0.067 for the *exo*-adduct. The function minimized was $\sum w(F_o - |F_c|)^2$ with the following weighting scheme: $w = 1/(\sigma(F_o)^2 + 0.0823|F_o| + 0.0013|F_o|^2)$ for the *endo*-adduct and $w = 1/(\sigma(F_o)^2 + 0.0783|F_o| + 0.0028|F_o|^2)$ for the *exo*-adduct.

The non-hydrogen atoms were drawn at the 50% probability level and the hydrogen atoms were drawn with an arbitrary diameter.

Results and Discussion

Molecular Structure. The molecular structures of the *endo*- and *exo*-adducts are given in Figs. 2(a) and 2(b)[10] respectively. It was confirmed from these structures that the assignment of the configuration to these compounds deduced from the NMR data[3] was correct. The corresponding bond distances and angles in the *endo*- and *exo*-adducts agree fairly well with each other. As is shown in Fig. 1, the N-C, C-O, and C-C bond lengths in the succinimide ring system of both compounds are comparable to those in the derivatives of succinimide.[11-13] The bond lengths between the bridged oxygen atom(O(1)) and the bridgehead carbon atom (C(4) or C(7)) in both compounds are similar to those found in some oxygen-bridged ring compounds.[14] The difference between the O(1)-C(4) and O(1)-C(7) bond distances in the *endo*- or *exo*-adduct can be regarded as significant. The intramolecular distances between O(1) and Me(15) are shorter than the van der Waals' distance; that is, they are 2.749 Å in the *endo*-adduct and 2.792 Å in the *exo*-adduct.

(b) Dihedral angles(ϕ/°) between the planes:
(A)-(B) 116.1(or 243.9)
(B)-(C) 45.8
(C)-(D) 115.4
(B)-(D) 69.7

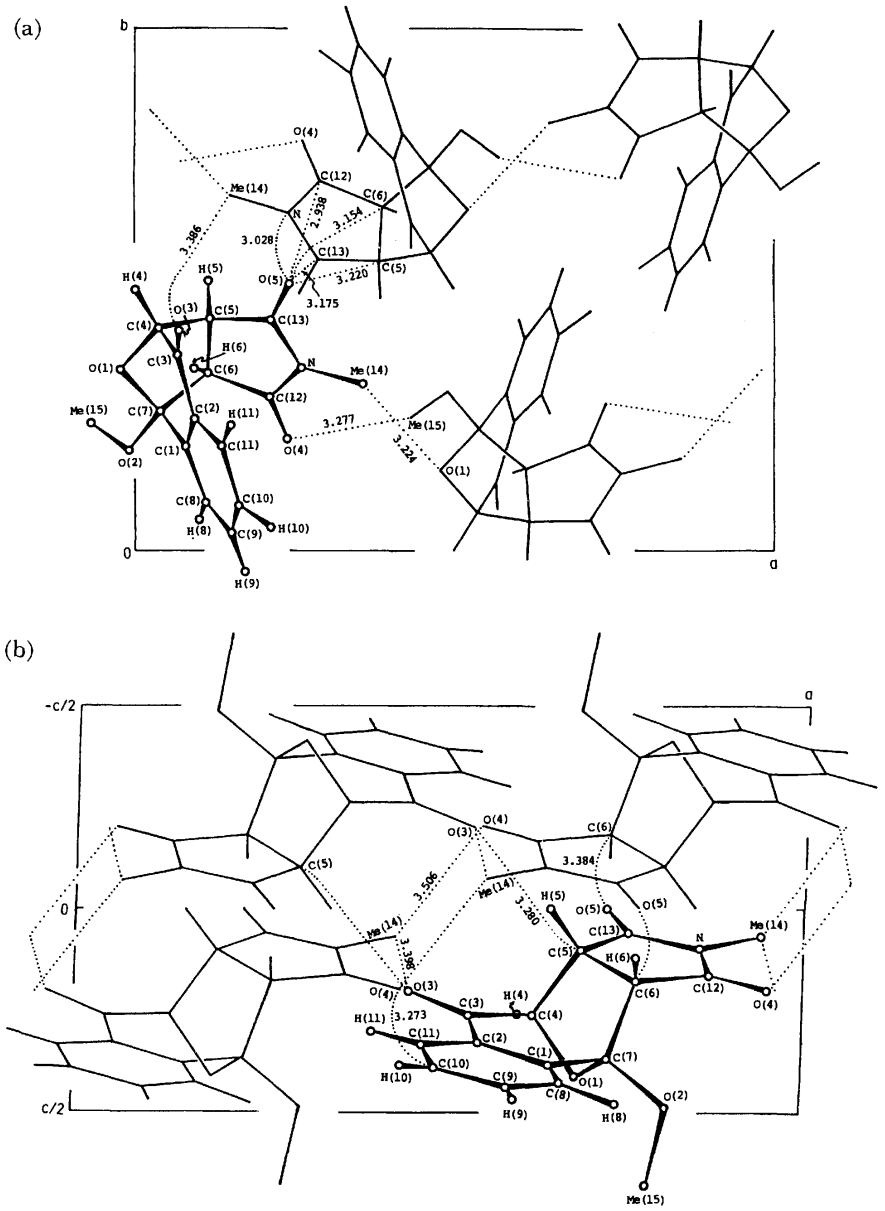

Fig. 3. (a) Crystal structure of the *endo*-adduct projected along the c axis. (b) Crystal structure of the *exo*-adduct projected along the b axis.

them are given in Table 3. The differences between the dihedral angles in the *endo*-adduct and the corresponding ones in the *exo*-adduct are not regarded as significant, but the dihedral angle between the plane (A) and the plane (B) of the *endo*-adduct is opposite to that of the *exo*-adduct in sign, that is, direction. The five-membered ring of the succinimide moiety is planar, with all deviations within ±0.04 Å in the *endo*-adduct and within ±0.02 Å in the *exo*-adduct. The C(3) and O(3) atoms deviate from the plane of the benzene ring by 0.033 Å and by −0.111 Å respectively in the *endo*-adduct, while they deviate by 0.106 and 0.225 Å in the *exo*-adduct.

Crystal Structure. The crystal structure of the *endo*-adduct projected along the c axis is shown in Fig. 3(a) and that of the *exo*-adduct projected along the b axis in Fig. 3(b). Some of the shorter intermolecular contacts are shown by dotted lines.

Ring-current Effect. The ring-current effect on chemical shifts and the values of the coupling constants are usually calculated using the Johnson-Bovey equation[15] and the Karplus equation[16] respectively. However, almost all the present calculations have been based on the values obtained by an inspection of such models as the CPK model or the Dreiding model. In this respect, the molecular model based on the atomic coordinates determined by X-ray analysis is expected to make possible a better interpretation of the NMR data and afford solider grounds for those equations than the above-mentioned models.

The *endo*-adduct showed its *N*-CH_3 signal at 2.37 ppm, and the *exo*-adduct, at 3.08 ppm, which was similar to the value of *N*-methylsuccinimide (2.98 ppm). This high-field shift of the *endo*-adduct by 0.71 ppm was attributed to the ring-current effect by the benzene ring located close to the *N*-CH_3 group. The values of 3.18 as *Z* and 0.50 as *ρ* in Farnum-Wilcox's double-torus model[4] were derived from the molecular structure found in the present X-ray work, as is shown in Fig. 4. The value of the ring-current effect of the *endo*-adduct was estimated from the "isoshielding" lines of the Johnson-Bovey ring-current effect by the use of the values of *Z* and *ρ* obtained above. This calculated value (0.85 ppm) is close to the experimental one (0.71 ppm).

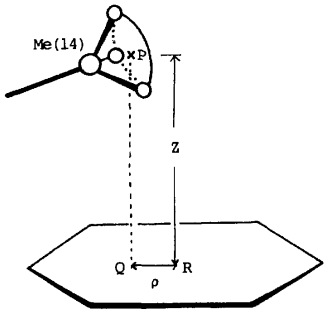

Fig. 4. Configuration of the methyl group (Me(14)) and the benzene ring in the calculation of the ring current effect of the *endo*-adduct.
P: The center of the triangle of the hydrogen atoms, Q: the foot of perpendicular line from P to the plane of the benzene ring, R: the center of the benzene ring. Tetrahedral structure and the C-H bond length of 1.08 Å are assumed for Me(14) radical. The parameters, *Z* and *ρ*, which are used for the estimation of the ring current effect, can be obtained as shown in the figure.

TABLE 4. OBSERVED AND CALCULATED VALUES OF VICINAL COUPLING CONSTANTS

		$J_{5,6}$/Hz	$J_{4,5}$/Hz
endo-Adduct	Obsd	9.5	9.2
	Calcd[a]	9.5	9.1
exo-Adduct	Obsd	7.5	0.0
	Calcd[a]	10.0	0.0

a) Williamson-Johnson's equation:

$$J_{HH} = \begin{cases} 10\cos^2\phi & (0° \leq \phi \leq 90°) \\ 16\cos^2\phi & (90° \leq \phi \leq 180°). \end{cases}$$

Coupling Constant. The observed coupling constants, $J_{5,6}$ and $J_{4,5}$, of both adducts are listed in Table 4. The coupling constants of the vicinal protons depend mainly on the dihedral angle, and they can be calculated by the Karplus method.[16] Of the several modified Karplus equations thus far reported, Williamson-Johnson's equation[5] was found to be most suitable for the ring system in this work. According to the present X-ray crystal-structure analysis, the dihedral angles between the C(5)–C(6)–H(6) plane and the C(6)–C(5)–H(5) plane, and between the C(5)–C(4)–H(4) plane and the C(4)–C(5)–H(5) plane, in the *endo*-adduct were found to be 13° and 17° respectively, while the corresponding dihedral angles in the *exo*-adduct were found to be 1° and 89°. The coupling constants calculated by substituting these dihedral angles (*φ*) in Williamson-Johnson's equation[5] are also shown in Table 4. These calculated values are in good agreement with the observed values obtained on the basis of the NMR spectra.

(Received July 4, 1983)

The ESR spectra of three paramagnetic species trapped in single crystals of chloro(5,10,15,20-tetraphenylporphyrinato)cobalt(III) ($Co^{III}Cl(tpp)$), have been observed at 4.2 K to room temperature. Based on the ESR parameters obtained, the paramagnetic species have been identified as two $Co^{II}(tpp)$ with different axial ligand effects and a previously reported cation radical, $[Co^{III}(tpp)]^{2+\cdot}(Cl^-)_2$. A correlation diagram among *g*, *A*, and axial ligation made from published data of cobalt(II) complexes has been successfully used for identification of the two trapped $Co^{II}(tpp)$ species: one is four-coordinate $Co^{II}(tpp)$ and the other five-coordinate $Co^{II}X(tpp)$ in which X is presumably Cl^-. Their electronic and molecular structures are discussed according to McGarvey's theory. Finally, the formation mechanism of the three paramagnetic species in $Co^{III}Cl(tpp)$ is discussed, based on the results obtained from the single crystalline ESR measurements.

The functional properties of metalloenzymes can often be understood by the study of their prosthetic groups, as has been seen in the famous study of Wang.[1] On the other hand, the study on redox reactions including metalloporphyrin has become increasingly important. In the course of our investigation of chloro(5,10,15,20-tetraphenylporphyrinato)-cobalt(III) ($Co^{III}Cl(tpp)$ (**1**), Fig. 1), we have found by ESR studies[2,3] that in solutions of **1** whose solvents are aromatic or chlorinated hydrocarbons, a π cation radical, $[Co^{III}(tpp)]^{2+\cdot}(Cl^-)_2$, is formed and that the formation of the radical occurs reversibly with small enthalpy change. Subsequent ESR measurements[4] on single crystals of **1** in which the radical is trapped have provided some information about the electronic and molecular structures of the radical and have also shown the existence of two $Co^{II}(tpp)$ species which are influenced by axial ligation. Such co-existence of both oxidation and reduction products in the crystals prepared under ambient conditions and the reversible behavior of the cation radical in the solution are regarded as inherent properties of **1**. These facts can be closely related to the redox reaction of metalloenzyme. We have carried out detailed ESR investigations of the crystals trapping the two $Co^{II}(tpp)$ species. The analysis of the ESR parameters obtained has given useful information for understanding the inherent properties of **1**.

In this paper, we first describe the results obtained from angular dependences of the ESR spectra due to two $Co^{II}(tpp)$ species trapped in the single crystals of **1**.

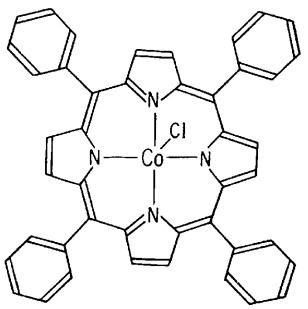

Fig. 1. Chloro(5,10,15,20-tetraphenylporphyrinato)-cobalt(III).

Second, the identification of the two trapped $Co^{II}(tpp)$ species is given using a diagram of correlation among *g*, *A*, and axial ligation made from the published data of many cobalt(II) porphyrins and their related compounds. Third, their electronic and molecular structures are elucidated according to a theoretical treatment reported by McGarvey. Finally, the formation mechanism of the three paramagnetic species in **1** will be presented, based on the results obtained from the single crystalline ESR measurements and those published previously.

Experimental

$Co^{III}Cl(tpp)$ (**1**), was prepared by using a method previously reported.[5] The spontaneous evaporation of the solvent from the solution of **1** gave crystals of various external forms: obelisk, pyramid, prism, and bulky shape. The single crystals doped with 1 mol% of pure $Co^{II}(tpp)$ were also prepared for the comparison with the trapped paramagnetic species. Previously, the X-ray analysis of the obelisk crystals[5] has been reported: **1** is a five-coordinate cobalt(III) complex of tpp which has a square-pyramidal structure with a chlorine atom at the apex. Continuing X-ray analyses[6] for various crystals have shown that the sixth ligand position is completely or partially occupied by water contaminated from the atmosphere. The relationships between the a and b axis and the external forms are illustrated in Fig. 2. The

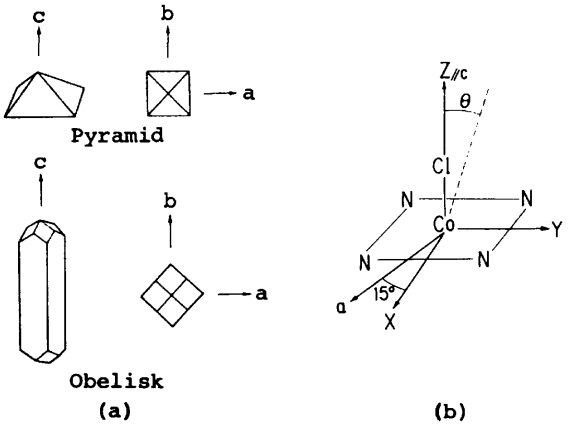

Fig. 2. (a) Crystal axis in pyramid and obelisk type crystals of **1**. (b) Relationship between crystal axes and molecular axes.

Co–Cl bond is parallel to the c axis and the angle between the a axis and one of the Co–N bonds is 15 °. Typical sizes of the obelisk and pyramid crystals used for the measurements were $0.1\times0.1\times0.3$ and $0.2\times0.2\times0.1\,cm^3$, respectively. The ESR spectra were measured at 4.2 K to room temperature with an ESR spectrometer, JEOL FE-3X equipped with 100 kHz magnetic field modulation. The microwave frequency and the magnetic field were directly determined by using a frequency counter, Takeda Riken TR-5211, and a field measurement unit, JEOL ES-FC-4, respectively. ESR parameters were determined by simulation using a JEOL ES-9835 computer system.

Results and Discussion

(1) The ESR Spectra of Paramagnetic Species in the Obelisk and Pyramid Crystals of $Co^{III}Cl(tpp)$. Figure 3 shows the ESR spectra of the paramagnetic species in the pyramid and obelisk type single crystals of **1** with crystal setting of $c\perp H_0$ at 77 K. As can be easily seen from the spectra, three different hyperfine (hf) patterns due to ^{59}Co with $I=7/2$ are clearly distinguished. Hereafter, we call these species α, β, and γ, as is shown in Fig. 3. The saturation behaviors of the three hf patterns were different from one another. The hf pattern due to γ was clearly observed at 4.2 K and

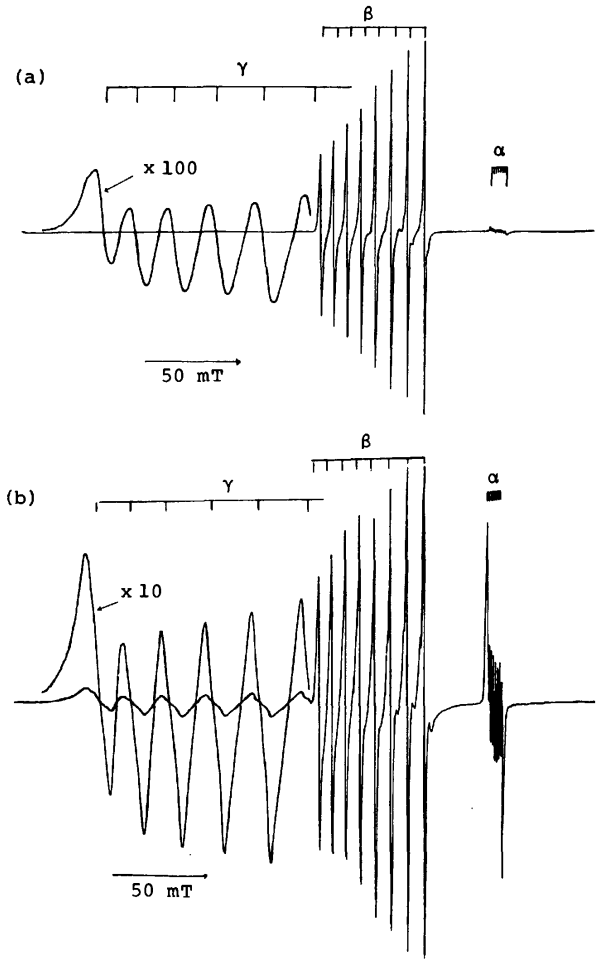

Fig. 3. The ESR spectra of paramagnetic species trapped in (a) obelisk and (b) pyramid type crystals of **1** at 77 K ($c\perp H$). Note that three species, α, β, and γ are clearly distinguished.

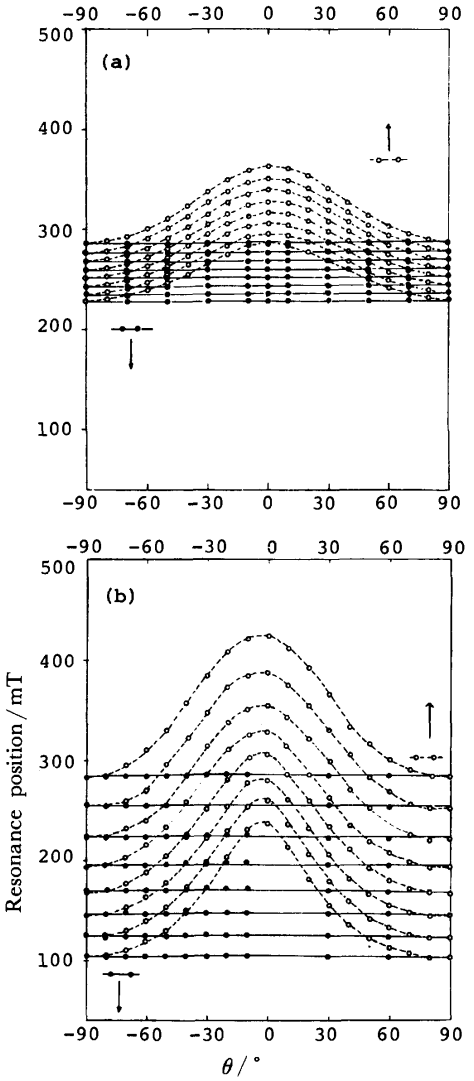

Fig. 4. Angular variations of the ESR positions of (a) β and (b) γ species trapped in **1**.

disappeared at above 120 K, but those due to α and β were observable even at room temperature. That is, the relaxation time of γ is considerably shorter than those of two others. α[2-4] has previously been identified as a π cation radical, $[Co^{III}(tpp)]^{2+\cdot}(Cl^-)_2$. In order to determine the electronic structures of β and γ, the angular variation of the absorption lines due to these species were measured both for the plane including the c axis and for the ab plane, which are shown in Fig. 4. The measurements show clearly that the g values of both β and γ are minimum at $\theta=0°$ ($g_\parallel$), and maximum at $\theta=90°$ ($g_\perp$). Such angular dependences are characteristic of the d_{z^2} orbital with a configuration of the z axis along the Co–Cl bond. The $g_\parallel$ of β is very close to that of free-electron predicted by first-order perturbation theory.[7] This means that the separations of excited states of β from the ground state are large enough to approximate the system with the first-order

perturbation theory. On the other hand, $g_\parallel$ of γ is very small compared with the predicted free-electron value, as will be discussed later.

The concentrations of the paramagnetic species in both pyramid and obelisk crystals were different but their ESR parameters agreed within the experimental errors, which means that the ESR parameters do not depend on the external crystal forms. The ESR parameters of β and γ were estimated by the best fit of the experimental data to an equation derived from the second-order perturbation theory,[8] which are listed in Table 1. The ESR parameters of β and γ are very close to those of two sites of Co^{II}(tpp) diluted in H_2(tpp),[9] respectively.

In order to obtain further information about the electronic environments of β and γ in the crystal of **1**, pure Co^{II}(tpp) (**2**) was doped in **1**. The ESR spectrum of **2** magnetically diluted in **1** is well resolved at 77 K, as is shown in Fig. 5 ($c \perp H_0$). At room temperature, no ESR signal was observed because of a short spin lattice relaxation time just as in the case of γ. It is seen in Fig. 5 that molecules of **2** are properly exchanged with those of **1**. Hereafter this paramagnetic species is called δ. The estimated ESR parameters of the species are also listed in Table 1. The angular dependence of the species also shows the d_{z^2} ground state, but the ESR parameters did not coincide with those of β or γ, nor with those in previous reports.

(2) Correlation Diagram of g, A, *and Axial Ligation.* In order to clarify the electronic and molecular structures of β and γ, correlation among g, A, and axial ligation was examined by using the data of cobalt(II) porphyrins and their related compounds. The data are also listed in Table 1 in order of $g_\perp$ value. A diagram of the correlation is shown in Fig. 6. It is seen from the figure that $g_\perp$ and $g_\parallel$ have linear relationships with $A_\perp$ and $A_\parallel$, respectively. These relationships can be simply expressed as

$$g_\perp = 2.3675 + 20.47A_\perp, \quad (1)$$

$$g_\parallel = 2.1662 - 13.70A_\parallel, \quad (2)$$

with the correlation coefficients 0.82 in Eq. 1 and 0.21 in Eq. 2, respectively. From the diagram the isotropic part of g, g_0, was estimated to be 2.233. The values of $g_\perp$ and $A_\perp$ decrease as the coordination number of Co^{II}(tpp) increases; four-, five-, and six-coordination.

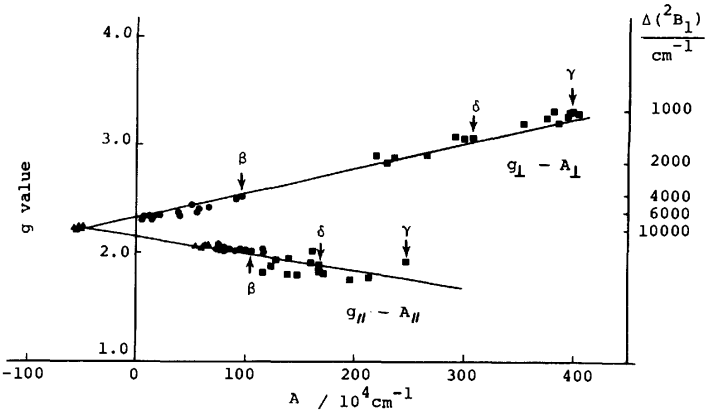

Fig. 6. A correlation diagram among g, A, and axial ligation.
■: Four-coordinate complex, ●: five-coordinate complex, and
▲: six-coordinate complex.

On the other hand, $A_{\parallel}$ decreases with the increase of the coordination number, but $g_{\parallel}$ has a reverse relation. It should be noted here that the sign of $A_{\perp}$ of six-coordinate complexes is minus. This has been already pointed out by Lin.[10] Such a linear relationship between g and A has also been observed in vanadium complexes.[11] In our diagram the relationship between ESR parameters and axial ligation is obvious. That is, the diagram is instructive for assigning the molecular environments of β, γ, and δ. As is shown in Fig. 6, γ resides on the right-end of the four-coordinate complex group and δ is, in the left-hand side of the group. On the other hand, β is on the right-end of five coordinate complex group. This means that β is fundamentally five-coordinate complex and the axial ligand is rather weak, while γ and δ are both four-coordinate complexes. Based on such procedures, γ can be assigned as the square-planar Co^{II}(tpp); on the other hand, β is square-pyramidal Co^{II}(tpp), and also δ is probably tetragonal with a weak axial ligand effect. It is not clear from the results what kind of atom is ligated in the cases of β and δ, but Cl^- in β is most probable as is discussed later.

(3) Theoretical Consideration for the Linear Relationships. The theoretical investigations of cobalt(II) complexes with planar ligands have been carried out by many authors.[12] For the interpretation of the linear relationships, we adopted McGarvey's treatment, which is analytical for the ESR parameters.

McGarvey[13] carried out the third-order perturbation treatment of low spin cobalt complexes with C_2 symmetry including the configurations with excited states $^2B_1$ and $^4B_1$. Dickinson and Chien[14] simplified the treatment and derived the theoretical g values as

$$g_{\perp}=2.0023+2c_3^2-3c_1^2, \quad (3)$$

$$g_{\parallel}=2.0023+2/3c_3^2-6c_1^2+6c_1, \quad (4)$$

where $c_1=\lambda/\Delta(^2B_1)$, $c_3=\lambda/\Delta(^4B_1)$, and λ is the single electron spin-orbit coupling constant, $\Delta(^{2,4}B_1)$ represents energy separation between the ground state $^2A_1$ and the excited state, $^2B_1$ or $^4B_1$. The value of λ for the Co^{2+} ion is 530 cm^{-1},[9] however, as the covalency due to complex formation causes a decrease of 20—40%, we assumed as $\lambda=400\,cm^{-1}$ according to Assour.[9] Energy separations obtained for the cobalt(II) complexes are also given in Table 1. The $\Delta(^2B_1)$ is ranging from 1300 to 13000 cm^{-1}. Introduction of a base along the z axis destabilizes the d_{z^2} orbital relative to the d_{xz} and d_{yz} orbitals, which results in an increase of $\Delta(^2B_1)$. Thus five-coordinate complexes of N_4X type have $\Delta(^2B_1)$ values larger than those of four-coordinate complexes. Those of the N_5 complexes are of the order of 7000 cm^{-1}. Further the separation of the six-coordinate complexes having two bases should be much larger than those of five-coordinate complexes. The relation between $\Delta(^2B_1)$ and $g_{\perp}$ values is also shown in Fig. 6, from which $\Delta(^2B_1)$ can be estimated by substituting the ESR parameters, $g_{\perp}$ or $A_{\perp}$, obtained experimentally.

The principal values of the hyperfine tensor, $A_{\parallel}$ and $A_{\perp}$,[13] are also expressed as functions of c_1 and c_3:

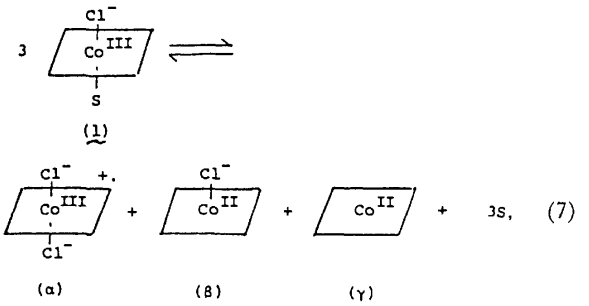
$$A_{//}=K+(P/7)[4-4c_3-6c_1+(2/9)c_3^2+15c_1^2], \quad (5)$$

$$A_{\perp}=K+(P/7)[-2+45c_1+2c_3+(4/3)c_3^2-(57/2)c_1^2], \quad (6)$$

where K is the isotropic Fermi hyperfine interaction parameter, $P=2\beta_e\beta_n\gamma Co(d_{z^2}|r^{-3}|d_{z^2})$ is the dipolar splitting constant, and β_e and β_n are electronic and nuclear magnetons, respectively. The linear relationships of Eqs. 1 and 2 can be derived from Eqs. 3 to 6, if we assume that c_3 is constant and the square terms in Eqs. 3 to 6 are neglected compared with the other terms.[15] The average value of the dipolar splitting constants of cobalt(II) complexes listed in Table 1, P_{av}, is obtained as 0.0219 cm^{-1} which nicely coincides with the value of free Co^{2+} ion ($P=0.0220\,cm^{-1}$);[16] this coincidence means that P_0 should be regarded as a standard value to measure electron density on the $3d_{z^2}$ orbital.

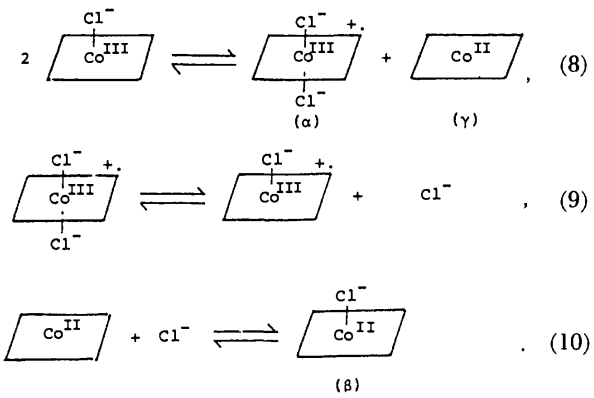
Since P is proportional to the electron density on the $3d_{z^2}$ orbital, the quantity $[(P_0-P)/P_0]$ has often been used as a measure of electron delocalization to the ligands. The value of 0.715 obtained in the case of β is very large compared with those of γ and δ. As can be seen in Table 1, P values of five coordinate complexes are very small compared with those of four- and six-coordinate complexes. This means probably that the spins of five-coordinate complexes including β are delocalized as far as axial ligand. On the other hand, those of γ and δ are not so delocalized.

(4) On the Mechanism of Three Paramagnetic Species Formation in $Co^{III}Cl$(tpp). As described in the previous paper,[2] the π cation radical (α) is formed by thermal activation in chlorinated hydrocarbons. The formation of the species occurs reversibly with small enthalpy change (ΔH). From the ESR measurements described above, it has been found that the crystals grown from the chlorinated solutions trap β and γ in addition to α. The result may indicate an equilibrium between the diamagnetic species **1** and the paramagnetic species (α, β, and γ):



where S means a solvent molecule or a ligand molecule such as water contaminated on crystallization. On the other hand, the crystals doping **2** showed only the formation of δ. This fact excludes the possibility that the formation of β and γ on crystallization originates from free **2**. Therefore, the formation of these species is probably inherent in the solution of **1**.

The detailed examination of Eq. 7 provides several possibilities as the elementary reaction. It was clarified by 400 MHz FT-NMR[17] that **1** in chlorinated hydrocarbons has two axial ligands, one Cl^- and the other water or solvent molecule, at low temperature as low as −60 °C. As the temperature increased, the sixth ligand is removed, which leads to the possibility of a kind of disproportionation expressed by Eq. 8.[2] The temperature dependence of the α concentration shows the appropriateness of this process.



The six-coordinate cation radical formed is also labile for the dissociation into a five-coordinate cation radical and an anion,[3] as is seen in Eq.9. The existence of the five-coordinate $Co^{III}(tpp)$ (β) in the crystal may show the possibility of a recombination reaction of Eq. 10.

In conclusion, **1** is very likely to give the three kinds of paramagnetic species. It should be understood that the observation of these species supports the apparent equilibrium described in Eq. 7 as the results of the several elementary reactions.

Effects of Dispersion in Carbon Monoxide Adsorption and Carbon Monoxide Hydrogenation over Alumina-supported Ruthenium Catalysts

Toshio OKUHARA,* Tomoo KIMURA, Kenji KOBAYASHI,† Makoto MISONO, and Yukio YONEDA
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received July 23, 1983)

Ru/Al_2O_3 catalysts prepared from $[Ru_3(CO)_{12}]$ and from $RuCl_3$ were characterized by chemisorption of H_2 and CO, and by infrared measurement of adsorbed CO. By using these catalysts, the effect of the dispersion on the activity and selectivity in CO hydrogenation was studied. Ru/Al_2O_3 catalysts prepared from $[Ru_3(CO)_{12}]$ showed high dispersions (>80%), and were more active and selective for the production of olefins in the CO hydrogenation than Ru/Al_2O_3 catalysts prepared from $RuCl_3$. However, the distribution of product hydrocarbons was not sensitive to the Ru dispersion. Infrared study of adsorbed CO revealed that twin-type CO ($Ru(CO)_2$) as well as linear-type CO (Ru-CO) was present on each Ru/Al_2O_3. The twin-type CO was more strongly held and was less reactive to hydrogenation. For each series of Ru/Al_2O_3, the turnover frequency increased as the dispersion decreased. This change has been explained by the poisoning effect of the twin-type CO. The higher activity of Ru/Al_2O_3(A) was ascribed to the lower concentration of the twin-type CO on the surface.

In Fisher-Tropsh synthesis, Ru shows high activity and selectivity for the production of long-chain hydrocarbons.[1] The effect of Ru dispersion on the activity of this reaction has been studied by several workers.[2-6] King reported that the turnover frequency (abbreviated as TOF) of both methane formation and CO conversion over supported Ru catalysts declined as the dispersion increased.[2] This is in contrast with the case of Pt or Pd.[7] Kikuchi *et al.* also observed similar changes of TOF with the dispersion over Ru/Al_2O_3 and Ru/V_2O_3. However, TOF over Ru/V_2O_3 was considerably higher than that over Ru/Al_2O_3, indicating that the TOF was dependent not only on the dispersion but also on the nature of the supports.[5] Fujimoto *et al.* reported that the change of TOF with Ru dispersion appeared in a different manner depending on the reaction conditions.[6]

The dispersions of Ru catalysts used in the above studies were limited up to 60%. The authors[8] and Bell *et al.*[4,9] found that Ru/Al_2O_3 prepared from carbonyl complex like $[Ru_3(CO)_{12}]$ or $[Ru_6C(CO)_{17}]$ showed dispersions higher than 60%. As for the highly dispersed Ru/Al_2O_3, Kellner and Bell[4] reported that the TOF decreased as the dispersion increased up to 90%. On the other hand, the authors observed that the TOF for the Ru/Al_2O_3 prepared from $[Ru_3(CO)_{12}]$ was unexpectedly high at high Ru loading levels.[10]

Recently, infrared spectroscopic studies[11-14] have shed light on the surface state of Ru catalysts under reaction conditions. The Ru surface was almost entirely covered by adsorbed CO during the hydrogenation of CO,[11] and the active sites were limited to a small portion of the metal surface.[12] Kellner and Bell,[4,9] and the authors[15] showed that both linear-type CO and twin-type CO (diadsorbed CO) were present on Ru/Al_2O_3. However, there are very few instances in which physical properties and catalysis of highly dispersed Ru catalysts were studied concurrently.

The present study was undertaken to determine the prime factor controlling the change of the TOF with the dispersion of Ru, since, in spite of several efforts, the reason why TOF changes with dispersion has not yet been clarified. The Ru/Al_2O_3 catalysts having a wide range of dispersion were systematically prepared from $RuCl_3$ and $[Ru_3(CO)_{12}]$. By the use of these catalysts, the influences of preparation method and dispersion on the TOF, product distribution and olefin/paraffin ratio were investigated. Moreover, infrared measurement of adsorbed CO was performed to elucidate the strength of adsorption, the reactivity toward hydrogenation and the role of each adsorbed CO in the catalytic reaction.

Experimental

Catalysts. Ru/Al_2O_3 catalysts were prepared using γ-Al_2O_3 (Reference Catalyst of the Catalysis Society of Japan, ALO-4, 170 $m^2\ g^{-1}$) from $[Ru_3(CO)_{12}]$ (Strem Chemical Co.) and $RuCl_3 \cdot 3H_2O$ (Kanto Chemical). $[Ru_3(CO)_{12}]$ was adsorbed from hexane solution at room temperature onto the Al_2O_3 which had been dried in a N_2 flow at 450 °C. Then the solvent was removed in a stream of N_2 at room temperature. The catalysts obtained by the decomposition and reduction with H_2 at 450 °C are designated as Ru/Al_2O_3 (A) hereafter. The second class of Ru/Al_2O_3 catalysts were prepared by incipient wetness impregnation with an aqueous solution of $RuCl_3$ and are designated as Ru/Al_2O_3 (B). The loading amount of Ru metal was altered from 0.9 to 4% for Ru/Al_2O_3 (A) and 0.5 to 5% for Ru/Al_2O_3 (B).

Chemisorption of hydrogen and CO. The pretreatment conditions and procedure have been described in the previous paper.[15] Chemisorption measurement was carried out at room temperature in a conventional static system having a volume of 60 cm^3. Since adsorption of hydrogen to Al_2O_3 alone was negligible, the dispersion of Ru was calculated from the total uptake of hydrogen under an equilibrium pressure of about 60 mmHg. The chemisorption of CO on Ru was calculated from the differences in the uptake of CO between Ru/Al_2O_3 and Al_2O_3 under an equilibrium pressure of about 40 mmHg.

Catalytic Reactions. After the evacuation of the catalyst at 450 °C for 1 h, the catalyst was reduced with H_2 (600 mmHg (1 mmHg≈133.322 Pa)) at 450 °C for 2 h in a closed circulation system having a volume of about 200 cm^3. Then the catalyst was cooled *in vacuo* to 200 °C. Hydrogenation of CO was carried out at 200 °C under the total pressure of about 500 mmHg (H_2/CO=2) in the same system. The reaction was repeated by replacing the reactant gases after a short period of evacuation (≃10 min). The rate and the

†Present address: Nippon Electric Co., Ltd.

distribution of product hydrocarbons were determined at about 10—30% conversion in the second run, in which the reaction proceeded at a steady rate and the selectivity was independent of the conversion in the above conversion range. The product hydrocarbons except for methane were collected in a trap kept at liquid-nitrogen temperature during the reaction to prevent the secondary reactions such as hydrogenation of olefins and hydrogenolysis of products. Actually, when the reaction was carried out without a liquid-nitrogen trap, considerable increases of both methane and paraffin fractions were observed. The column materials used for gas chromatographic analyses consisted of Molecular Sieve 5A (25°C) to separate methane and CO, and Porapak Q (60°C) to separate CO_2, ethylene and ethane. A VZ-7 column (kept at 25°C) was used for C_3 through C_6 hydrocarbons. The formation of methanol and ethanol was checked with Porapak Q (100°C), but was not detected. Hydrogenolysis of ethane was also carried out at 150°C in the same system under the initial pressure of 108 mmHg (H_2/ethane=2) after the same pretreatment as in the case of the hydrogenation of CO.

Infrared Spectroscopy. The procedure has been described in the previous paper.[15] The catalyst was first kept in contact with CO (20 mmHg) at room temperature for 0.5 h. After CO was evacuated at desired temperatures for 1 h, infrared spectra were recorded using a Fourier-transform spectrometer (JEOL JIR 10) at room temperature. The weight of the sample disk was about 60 mg for all catalysts.

Results

Chemisorption of Hydrogen and CO. H/Ru and CO/Ru are summarized in Table 1, where the H/Ru or CO/Ru=number of hydrogen atoms or CO molecules chemisorbed/number of Ru in the catalysts. In the chemisorption of hydrogen, the H/Ru ratio was higher than 0.79 for all Ru/Al_2O_3 (A). The H/Ru for Ru/Al_2O_3 (B) progressively increased as Ru concentration decreased, but they were not more than 0.41. Hereafter, the dispersion of the Ru will be defined as H/Ru×100(%).

The CO/Ru ratio was always greater than the H/Ru. Particularly, in the case of low loading catalysts, *e.g.*, 0.5% Ru/Al_2O_3 (B) and 0.9% Ru/Al_2O_3 (A), high CO/Ru ratios (>1.4) were observed. The CO/H ratio reached 3.6 and 2.7 over 0.5 and 0.9% Ru/Al_2O_3 (B), respectively. The uptakes of H_2 and CO became very small (H/Ru=0.1, CO/Ru=0.1), when 2.5% Ru/Al_2O_3 (A) was pretreated with O_2 (50 mmHg) at 450°C for 4 h followed by reduction with H_2 (600 mmHg) at 450°C for 3 h.

Table 1. Chemisorption of H_2 and CO on ruthenium catalysts

Catalyst	wt%	H/Ru	CO/Ru	CO/H	$\bar{d}$/Å[a]
Ru/Al_2O_3(A)	0.9	0.85	1.41	1.7	(10)
(from[$Ru_3(CO)_{12}$])	2.5	0.82	1.10	1.3	(10)
	4.0	0.79	1.01	1.3	(11)
	2.5[b]	0.10	0.11	1.1	83
Ru/Al_2O_3(B)	0.5	0.41	1.46	3.6	20
(from $RuCl_3$)	0.9	0.38	1.03	2.7	22
	2.5	0.21	0.32	1.5	40
	5.0	0.18	0.26	1.4	46

a) Mean diameter calculated from the adsorption of hydrogen. b) Pre-oxidized sample.

The average particle size was calculated from the hydrogen adsorption as given in Table 1, by assuming that a hydrogen atom is adsorbed on an Ru atom at 1:1 stoichiometry and that the average area of Ru is 8.17 Å^2.[16] The average size of Ru particle on Ru/Al_2O_3 (B) was in the range of 20 to 46 Å, and was less than 10 Å for Ru/Al_2O_3 (A).

Activity and Selectivity. The rates of the CO hydrogenation per gram of Ru are plotted as a function of Ru loading in Fig. 1. The rate for Ru/Al_2O_3 (B) was much less susceptible to the Ru loading levels than that for Ru/Al_2O_3 (A). 4% Ru/Al_2O_3 (A), which was about 30 times more active than 0.9% Ru/Al_2O_3 (A), exhibited the highest activity among the Ru/Al_2O_3 catalysts used.

Figure 2 shows the olefin/paraffin ratio in C_2 through C_4 hydrocarbons as a function of the Ru dispersion. The ratios in these hydrocarbons increased monotonically as the dispersion increased. The selectivity to C_2–C_4 olefins among total hydrocarbons increased from about 40 to 60% in the range of the dispersion from 20 to 85%.

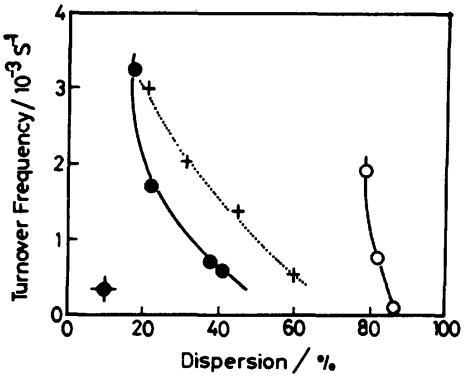

Fig. 4. Change of turnover frequency for the CO hydrogenation as a function of Ru dispersion at 200°C.
○: Ru/Al_2O_3 (A), ●: Ru/Al_2O_3 (B), ◆: Pre-oxidized 2.5% Ru/Al_2O_3 (A), +: King's data.

The influences of the dispersion on the product distribution are shown in Fig. 3. Except for a slight increase in the fraction of C_2 through C_4 hydrocarbons at very high dispersions, the distribution of product hydrocarbons was nearly constant over the wide range of dispersion. The preoxidized 2.5% Ru/Al_2O_3 (A) exhibited an unusual activity and selectivity. The activity for the CO hydrogenation was 1/16 of 2.5% Ru/Al_2O_3 (A) treated ordinarily and methane was the main product (≃70%).

In Fig. 4, the TOF for CO hydrogenation was plotted as a function of the Ru dispersion. King's data for Ru/Al_2O_3,[2] which were adjusted to the present reaction conditions, assuming that the pressure dependence and activation energy were the same as those reported by Vannice,[17] are also shown in Fig. 4. The TOF-dispersion correlation showed two separate lines in Fig. 4. The TOF obtained over Ru/Al_2O_3 (B) is consistent with King's data. On the other hand, with the exception of the dispersion of 85%, the TOF of Ru/Al_2O_3 (A) was appreciably higher than that expected from Ru/Al_2O_3 (B). It is noted that the TOF for the pre-oxidized 2.5% Ru/Al_2O_3 (A) is far below the two lines. In contrast with the CO hydrogenation, the TOF for the hydrogenolysis of ethane was nearly constant, except for 0.9% Ru/Al_2O_3 (A), as shown in Fig. 5.

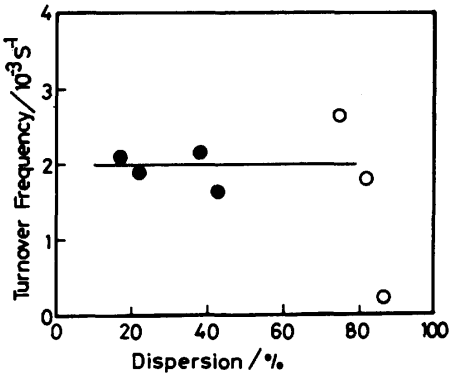

Fig. 5. Change of turnover frequency for the hydrogenolysis of ethane as a function of Ru dispersion at 150°C.

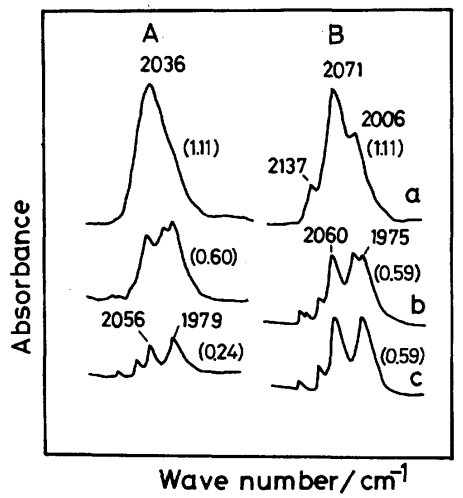

Fig. 7. Changes of infrared spectra of CO adsorbed on Ru/Al_2O_3 (A) by evacuation or hydrogenation: (A) 2.5 wt% (B) 0.9 wt%; (a) after evacuation at 25°C, (b) after evacuation at 200°C, (c) after the reaction with H_2 (100 mmHg) at 200°C, for 1 h.
Figures in parentheses are the integrated intensity of CO(a) per gram of Ru loaded (arbitrary unit).

Infrared Spectra of CO Adsorbed on Ru/Al_2O_3. CO adsorbed is denoted as CO(a) hereafter. Figures 6 and 7 show infrared spectra of CO(a) on Ru/Al_2O_3 (B) and Ru/Al_2O_3 (A), respectively. Spectra a and b in these figures were recorded after evacuation at 25 and 200°C, respectively. Spectra c were taken after the reaction of CO(a) with H_2 (100 mmHg) at 200°C for 1 h. Over Ru/Al_2O_3 (B), three well resolved bands appeared at 2137—2141, 2073—2083, and 2013—2029 cm^{-1} after the evacuation at 25°C (Fig. 6). Both the shape and position of the bands were almost independent of the loading amount of Ru. The evacuation at 200°C caused complete elimination of the highest frequency band and a considerable decrease in the medium frequency band. The remaining CO(a) showed a paired band located at 2075—2087 and 2009—2021 cm^{-1}. As the dispersion increases, the relative intensity of the paired band increases (spectra b in Fig. 6). CO(a) on Ru/Al_2O_3 (A) gave a broad band, as shown in Fig. 7.

Figure 8 shows the relationship between the dispersion and the band intensity of the inactive CO(a). The relative amount of the inactive CO(a) significantly increased as the dispersion increased for each series of Ru/Al_2O_3. Infrared spectra of CO(a) taken under the reaction conditions are shown in Fig. 9. The spectra in the region of CO stretching were essentially unchanged during the reaction for 3 h. Bands attributable to CH_x stretching frequencies observed between 2800 and 3000 cm^{-1} continued to increase with the reaction time, in agreement with the result reported before.[11,13] Over 0.9% Ru/Al_2O_3 (A), two strong bands can be seen at 2056 and 1979 cm^{-1}, while broad bands appeared near 2033 cm^{-1} over 2.5% and 4% Ru/Al_2O_3 (A), and 2.5% Ru/Al_2O_3 (B). The relative amounts of CO(a) per gram of Ru during the reaction, which were estimated from the area of the bands, were fairly consistent with those obtained by chemisorption (CO/Ru in Table 1).

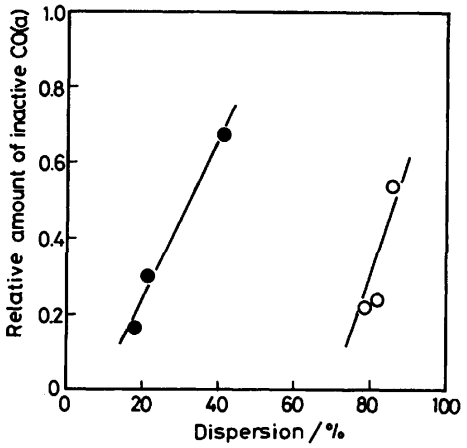

Fig. 8. Relationship between the relative amount of inactive CO(a) and the dispersion:
O: Ru/Al_2O_3 (A), ●: Ru/Al_2O_3 (B).
The ordinate shows the integrated intensity of bands normalized by that of bands obtained after evacuation at 25°C.

(a) 0.9% Ru/Al_2O_3 (A), (b) 2.5% Ru/Al_2O_3 (A), (c) 4% Ru/Al_2O_3 (A), (d) 2.5% Ru/Al_2O_3 (B).
Spectra were taken after 2 h under reaction at 200°C (P_{H_2}=200 mmHg, P_{CO}=60 mmHg).
Figures in parentheses are the integrated intensity of CO(a) per gram of Ru loaded (arbitrary unit).

Discussion

Dispersion and CO Adsorption Data. Chemisorption data in Table 1 demonstrate that the dispersion of Ru/Al_2O_3 (A) is rather high, even at high loading levels, compared with that of Ru/Al_2O_3 (B). Kellner and Bell[4] observed that the dispersion of 1.3% Ru/Al_2O_3, which was prepared from $[Ru_3(CO)_{12}]$, decreased to 60% from 90% during a reaction cycle of CO hydrogenation. They attributed the decrease to the rapid growth of Ru particles, which was accelerated by the temperature rise due to the heat of reaction. However, in the present work the dispersion of 4% Ru/Al_2O_3 (A) decreased from 80% to only 74% after the use for reaction. So, the dispersion of the fresh catalysts may be used as "dispersion" during the reactions carried out in this work.

In chemisorption of CO, the CO/Ru ratio exceeded unity at low loading levels, in agreement with the results of Kobayashi and Shirasaki[18] and Dalla Betta.[19] This suggests that more than two molecules of CO are adsorbed on a single Ru atom, that is, multiple CO adsorption. One hydrogen atom may be considered to be adsorbed on the surface of one Ru atom at 1:1 stoichiometry, since it was reported that the particle size calculated from hydrogen adsorption agreed with that obtained from electron micrographs on Ru/Al_2O_3 and Ru/SiO_2.[16] Accordingly, the ratio in the uptake of CO to hydrogen atom (CO/H) gives the average number of CO molecules attached on each surface Ru atom. The CO/H ratio for Ru/Al_2O_3 (A) was less than 1.65, suggesting that the linear-type CO (Ru–CO) occupied a considerable part of the surface sites. The IR band at about 2036 cm^{-1} for 2.5% Ru/Al_2O_3 (A) (Fig. 7) is assigned to the linear-type CO on the basis of the previous studies.[13,14] As shown in Fig. 7, a considerable amount of linear-type CO is present on 2.5% Ru/Al_2O_3 (A).

The paired IR band observed on these Ru/Al_2O_3 catalysts was quite similar to that of the twin-type CO on Ru/Al_2O_3.[20] It is known that $[Rh_2(CO)_4Cl_2]$ and

$[Ru(CO)_2X_n]$ (X=halogen)[21] shows a paired band associated with the symmetric and assymmetric vibration of the coordinated CO. Accordingly, the paired band observed on Ru/Al_2O_3 can be assigned to the twin-type CO, as reported by Kellner and Bell.[9] In the case of Ru/Al_2O_3 (B), the twin-type CO is the main species on the surface (Fig. 6). However, the CO/H values higher than 3 observed for 0.5% Ru/Al_2O_3 (B) seem to be unusual and the exact structure is not clear. The increase in the CO/H with the Ru dispersion suggests that adsorption sites available for the multiply bonded CO are edge or corner sites of Ru particles. The absence of twin-type CO on a single crystal surface of Ru[22,23] supports the assertion that the twin-type CO is formed on the edge or the corner sites of Ru particles.

Activity, Selectivity vs. *Dispersion.* Although low catalytic activity of low loading Ru/Al_2O_3 (A) is consistent with the result of Kellner and Bell,[4] the high activity of 4% Ru/Al_2O_3 (A) in the CO hydrogenation is a noticeable feature of Ru/Al_2O_3 (A) (Fig. 1). The change of TOF with the dispersion for the CO hydrogenation (Fig. 4) is not so simple as reported by King.[2] One possible reason for the two distinct correlations for Ru/Al_2O_3 (A) and Ru/Al_2O_3 (B) is the effect of the chloride ion remaining on Ru/Al_2O_3 (B) after reduction, but its effect is not known exactly. In any event, Fig. 4 suggests that the TOF for the CO hydrogenation cannot be determined only by the dispersion. Actually, Kikuchi *et al.* showed that the value of the TOF depended on the nature of the supports.[5] Moreover, the pre-oxidized 2.5% Ru/Al_2O_3 (A) showed a rather low TOF in spite of the low dispersion (Fig. 4).

In order to explain the change of the TOF, Kellner and Bell supposed that the electron density was reduced by the interaction with the support as the Ru particle size decreased, and that this led to the weakening of CO adsorption and the reduction of the ability to dissociate CO over highly dispersed catalysts.[4] Contrary to the idea of Kellner and Bell, CO was more strongly adsorbed as the Ru particle size decreases, as shown in Figs. 6 and 7. If the strongly bonded CO dissociates more easily, the TOF would increase with dispersion.

As shown in Figs. 6 and 7, the twin-type CO is more strongly held than the linear-type CO. Comparison of spectra b with c in Figs. 6 and 7 reveals the reactivity of CO(a) toward hydrogenation. Only a small decrease in the band intensity was observed for low loading catalysts after the reaction with H_2 (0.5% Ru/Al_2O_3 (B) and 0.9% Ru/Al_2O_3 (A)), indicating that the twin-type CO was almost inactive for the hydrogenation. It may be emphasized that the relative concentration of inactive twin-type CO increased with the dispersion over each series of Ru/Al_2O_3 (Fig. 8). If one compares these trends with the change of TOF (Fig. 4), it may be stated that the TOF is inversely correlated with the surface concentration of inactive twin-type CO and that the structure-sensitive behavior in the CO hydrogenation is explained by the poisoning effect of the inactive CO. That is, the TOF decreased with the dispersion, since the increasing portion of active sites is occupied by the inactive twin-type CO.

Since the linear-type CO readily reacted with H_2 compared with the twin-type CO (Fig. 7), weakly bonded linear-type CO is probably catalytically active for this reaction. Indeed, only a small amount of linear-type CO is present on the less active 0.9% Ru/Al_2O_3 (A), while other catalysts have a considerable amount of this species under the reaction conditions (Fig. 9). In contrast to the CO hydrogenation, the TOF for the hydrogenolysis of ethane changed little (Fig. 5). This may be explained by the absence of the poisoning materials in this reaction.

Another important feature of Ru/Al_2O_3 (A) is seen in the olefin/paraffin ratio in the product hydrocarbons. As shown in Fig. 2, the ratio in C_2, C_3, and C_4 hydrocarbons increases as the dispersion increases. If the olefin/paraffin ratio is determined by the relative rate of the two processes,[24] *i.e.*, β-elimination of hydrogen from and hydrogen addition to surface alkyl intermediates, the ratio will be controlled by whether the sites adjacent to the alkyl intermediates are empty or occupied by hydrogen atoms. In this case, the olefin/paraffin ratio depends on the ability of hydrogenation under the reaction conditions. It is known that CO(a) acts as a poison for the dissociative adsorption of H_2. Accordingly, the strength of CO(a) would affect the ability of hydrogenation. Since the strength of CO adsorption increased with the Ru dispersion (Figs. 6 and 7), the increase of the olefin/paraffin ratio can be explained in terms of the inhibition of hydrogen-activation by adsorbed CO.

The possibility of the chain growth is essentially independent of the dispersion as shown in Fig. 2, which is consistent with the data of King[2] and Bell *et al.*[4] for supported Ru catalysts. Although a drastic decline in chain growth for higher hydrocarbons was observed in the case of Ru/Y-zeolite,[25] this is probable due to the cage effect of the zeolite and not to the size effect of Ru particles.

Studies of Acylamino Acid Monolayers by π-A curves. I. Acylamino Acids with Alkyl Side Chain

Katashi TAKAHASHI,* Fudeko TANAKA, and Kinsi MOTOMURA†
Faculty of Home Life Science, Fukuoka Women's University, Fukuoka 813
†*Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812*
(Received September 5, 1983)

In order to obtain some information regarding the behavior of amino acids at interfaces, the monolayers of *N*-acyl L-α-amino acids with alkyl side chains on water have been investigated by measuring the surface pressure *vs.* area curves at various temperatures. It has been found that *N*-octadecanoylglycine and *N*-octadecanoylalanine form the condensed monolayers over the whole surface pressure range measured, *N*-octadecanoylvaline forms the expanded monolayer at a lower surface pressure, and *N*-octadecanoylleucine and *N*-octadecanoylisoleucine collapse at high surface pressures. From the experimental results, it has been concluded that the amino acid residue with a long side chain occupies a large area at the air/water interface and interferes with the condensation of acylamino acid monolayer. It has also been found that the methyl esterification of amino acid residue makes the monolayer state unstable although it produces less significant effect than the increase in the alkyl chain length of amino acid residue.

The behavior of amino acid molecules at interfaces is of great interest from the biological and chemical viewpoints. The conformation of protein molecules is clearly related to the orientation of the side chains of amino acids and the interaction between them. It is noted that surfactants synthesized from amino acids are important in connection with their biode-composition.

Several investigations were carried out for the surface activity of amino acids and their derivatives.[1-4] The critical micelle concentration of mixtures of *N*-lauroyl amino acid sodium salts was also measured.[5] On the other hand, the antibacterial ability of amino acid derivatives was reported by several workers.[6,7] Now it is necessary to investigate systematically the behavior of amino acid molecules at interfaces. For this purpose, insoluble monolayers of acylamino acids on water seem to be appropriate.

In the present paper, *N*-acyl L-α-amino acids with alkyl side chains are used and the surface pressure *vs.* area curves are measured as a function of temperature.

Experimental

Materials. Eight *N*-acyl L-α-amino acids and two *N*-acyl L-α-amino acid methyl esters used in this work are listed with their abbreviations in Table 1. They were prepared from fatty acids and L-α-amino acids. The amino acids (Wako Pure Chemical Industries, Special Grade) were used without further purification. The fatty acids were purified by repeated recrystallizations from ethyl alcohol. Amino acid methyl ester hydrochlorides were first synthesized by the thionyl chloride method.[7] Next, acylamino acid methyl esters were synthesized by making them react with fatty acids in the presence of 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride in chloroform.[8] Acylamino acids were obtained by the hydrolysis of acylamino acid methyl esters. The acylamino acid methyl esters were purified by repeated recrystallizations from methyl alcohol. The acylamino acids were recrystallized from ethyl alcohol and acetone. Their purity was checked by the elemental analysis and potential difference titration.

TABLE 1. MATERIALS USED

Compound	Abbreviation
Octadecanoylglycine	OcD-Gly
Octadecanoylalanine	OcD-Ala
Octadecanoylvaline	OcD-Val
Octadecanoylleucine	OcD-Leu
Octadecanoylisoleucine	OcD-Ile
Docosanoylvaline	Doc-Val
Docosanoylleucine	Doc-Leu
Docosanoylisoleucine	Doc-Ile
Octadecanoylvaline methylester	OcD-Val-OMe
Docosanoylvaline methylester	Doc-Val-OMe

Procedure. Benzene was used as the spreading solvent; for OcD-Gly, a small amount of ethyl alcohol was added to facilitate its dissolution. The surface pressure was measured by a Wilhelmy type surface balance. The films were compressed at the constant rate of 0.017 $nm^2\ min^{-1}$. The temperature was held constant within 0.1 K.

Results and Discussion

It is reasonably expected that the difference in the interfacial behavior between amino acids is reflected in the surface pressure *vs.* area curves of acylamino acid monolayers. First, the surface pressure π of OcD-Gly, OcD-Ala, OcD-Val, OcD-Leu, and OcD-Ile monolayers on water were measured as a function of area *A* peroctadecanoylamino acid molecule at 298.2 K. The surface pressure *vs.* area curves of acylamino acids are depicted in Fig. 1. It is seen that they differ remarkably with each other and become expanded with increase in the length of the alkyl side chain of amino acid. The π *vs.* *A* curve of OcD-Gly seems to be quite similar to that of octadecanoic acid. This fact indicates that OcD-Gly forms a condensed film. Therefore, we may say that the glycine residue of OcD-Gly is immersed in the substrate and acts as a part of the hydrophilic portion. The OcD-Ala monolayer also seems to form the condensed film, although its limiting area estimated from the π *vs.* *A* curve is larger than that of OcD-Gly. This may be attributable to a bigger side chain of the alanine residue.

On the other hand, it is seen from Fig. 1 that the π *vs.* *A* curves of OcD-Val, OcD-Leu, and OcD-Ile monolayers are significantly different in shape from those of OcD-Gly and OcD-Ala monolayers. The OcD-Val, OcD-Leu, and OcD-Ile monolayers are clearly ex-

panded films in a lower surface pressure region. In a higher surface pressure region, they seem to transform into other states; however, the transformation of OcD-Val is markedly different from those of OcD-Leu and OcD-Ile. In order to clarify this point, the variation of π *vs.* A curve with temperature was investigated.

The π *vs.* A curves of OcD-Val monolayer at 283.2, 288.2, 293.2, 298.2, 300.7, and 303.2 K are shown in Fig. 2. The surface pressure of the break point on the curve is found to increase greatly with increasing temperature. This temperature dependence resembles that of the film-forming substance which transforms from the expanded to the condensed state.[9-11] Furthermore, it turns out that the OcD-Val monolayer forms a condensed film over the whole surface pressure range measured at 283.2 K since its π *vs.* A curve is similar to that of OcD-Ala monolayer shown in Fig. 1. Thus, we can conclude that the OcD-Val monolayer transforms from the expanded to the condensed film at the break of the π *vs.* A curve. Comparing the π *vs.* A curve of OcD-Val monolayer with that of OcD-Ala monolayer, it is noticed that the bigger side chain of valine residue makes its state expanded up to a fairly high surface pressure at 298.2 K.

Similarly, the π *vs.* A curves of OcD-Leu and OcD-Ile, which have longer side chains than OcD-Val, were measured as a function of temperature; their results are illustrated in Figs. 3 and 4, respectively. It is seen that the surface pressure increases slightly with increasing temperature at a large area while it varies irregularly with temperature at a small area. Furthermore, the shape of the curves at the transition region are abnormal. This fact may indicate that the monolayers collapse and change into three-dimensional

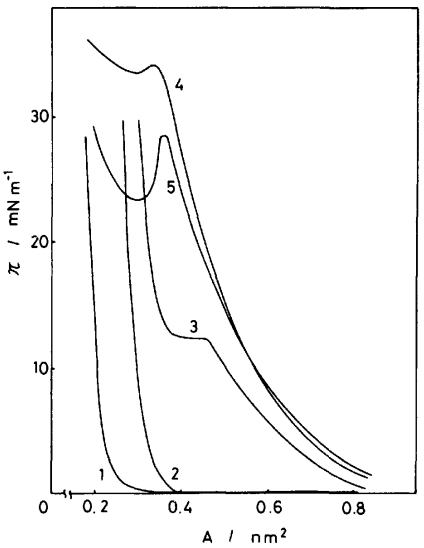

Fig. 1. Surface tension *vs.* area curves of Octadecanoylamino acid monolayers at 298.2 K. 1) OcD-Gly, 2) OcD-Ala, 3) OcD-Val, 4) OcD-Leu, 5) OcD-Ile.

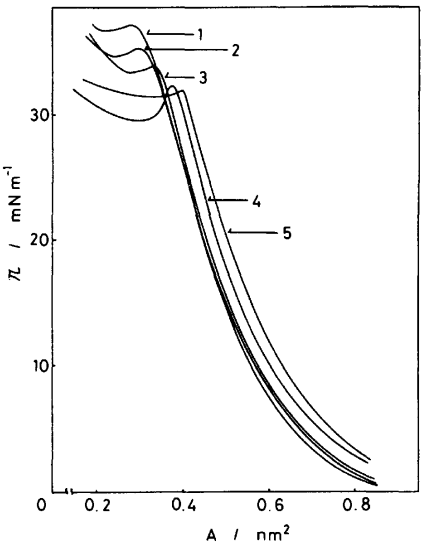

Fig. 3. Surface tension *vs.* area curves of OcD-Leu monolayer. 1) 288.2 K, 2) 293.2 K, 3) 298.2 K, 4) 300.7 K, 5) 303.2 K.

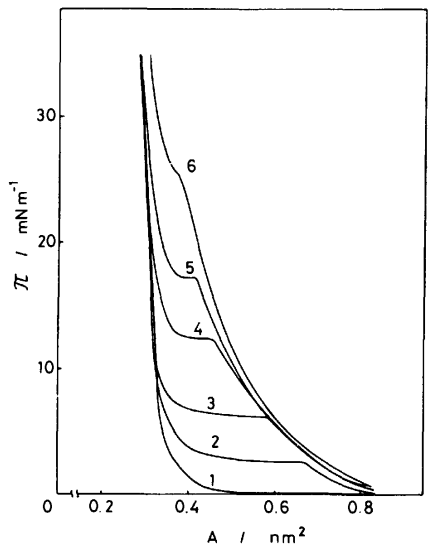

Fig. 2. Surface tension *vs.* area curves of OcD-Val monolayer. 1) 283.2 K, 2) 288.2 K, 3) 293.2 K, 4) 298.2 K, 5) 300.7 K, 6) 303.2 K.

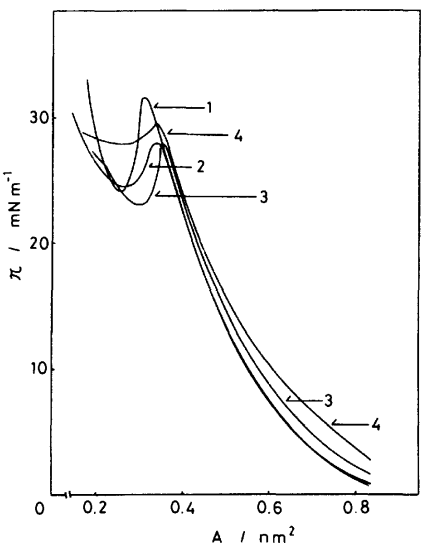

Fig. 4. Surface tension *vs.* area curves of OcD-Ile monolayer. 1) 283.2 K, 2) 293.2 K, 3) 298.2 K, 4) 303.2 K.

bulk phases at high surface pressures. It may be said, therefore, that the intermolecular force between the octadecanoyl groups is not strong enough to make the condensed monolayers of OcD-Leu and OcD-Ile stable. Now measurements seem to be required for acylamino acids having a longer acyl chain.

The π *vs.* A curves of Doc-Leu and Doc-Ile measured at various temperatures are illustrated in Figs. 5 and 6, respectively. It is seen from Fig. 6 that Doc-Ile forms a condensed film of which the limiting area is larger than that of the OcD-Val monolayer at 283.2 K. With an increase in temperature, the Doc-Ile monolayer becomes expanded in a lower surface pressure region. At temperatures above 303.2 K, the curve shows a striking resemblance to that of OcD-Ile given in Fig. 4. In the case of Doc-Leu, the temperature dependence of the π *vs.* A curve is qualitatively similar to that of Doc-Ile, although a typical condensed film is not realized even at the lowest temperature measured. The above results lead us to the conclusion that the amino acid residue with a long side chain occupies a large area at the air/water interface and interferes with the condensation of acylamino acid monolayer. Furthermore, it is noteworthy that the collapse of the expanded films is attended by remarkable super-compression.

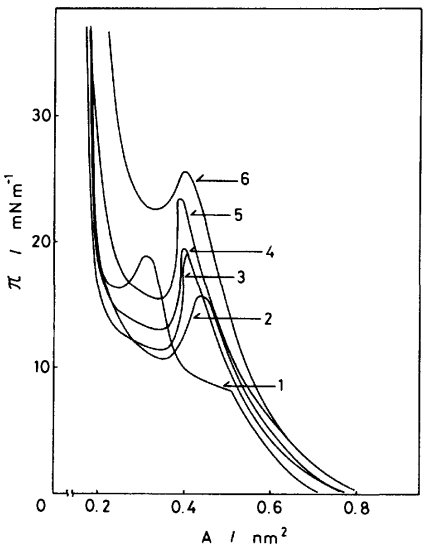

Fig. 5. Surface tension *vs.* area curves of Doc-Leu monolayer. 1) 283.2 K, 2) 288.2 K, 3) 293.2 K, 4) 298.2 K, 5) 303.2 K, 6) 308.2 K.

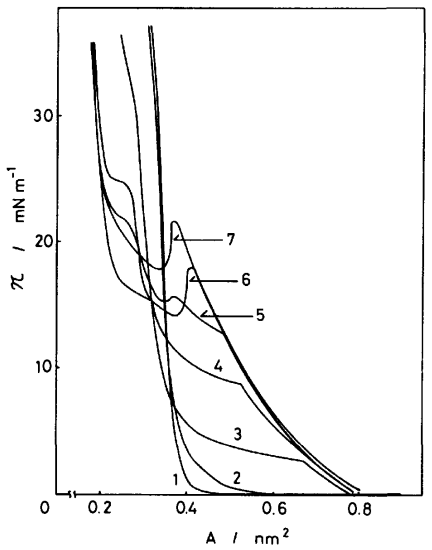

Fig. 6. Surface tension *vs.* area curves of Doc-Ile monolayer. 1) 283.2 K, 2) 288.2 K, 3) 293.2 K, 4) 298.2 K, 5) 300.7 K, 6) 303.2 K, 7) 308.2 K.

It is important to examine the difference between the π *vs.* A curves of *N*-acylleucine and *N*-acylisoleucine which are isomeric with each other. From Figs. 3 and 4, we can see that the OcD-Leu monolayer remains in an expanded state up to a higher surface pressure value than the OcD-Ile monolayer. Comparison between Figs. 5 and 6 tells us that the expanded film of Doc-Leu is hard to transform into the condensed film. Therefore, it can be said that the isobutyl group of *N*-acylleucine forces the monolayer to stay in the expanded state up to a high surface pressure as compared with the s-butyl group of *N*-acylisoleucine.

It is now interesting to investigate the behavior of the monolayer of *N*-acylvaline methyl ester which is an isomer of *N*-acylleucine and *N*-acylisoleucine although different in polar group. In Fig. 7, the π *vs.* A curve of OcD-Val-OMe are drawn at various temperatures. The temperature dependence resembles that of Doc-Leu and Doc-Ile rather than of OcD-Leu and OcD-Ile. It is clear by comparison with Fig. 2 that the methyl esterification makes the monolayer state somewhat unstable. Therefore, Doc-Val-OMe may be expected to form a condensed film at temperatures under consideration by the strong intermolecular interaction between docosanoyl groups. The experimental results for Doc-Val-OMe, which are illustrated in Fig. 8, support the above view. These findings indicate that the increase in the alkyl chain length of the amino acid residue by one carbon atom produces more significant effect on the monolayer behavior than the methyl esterification of the carboxyl group.

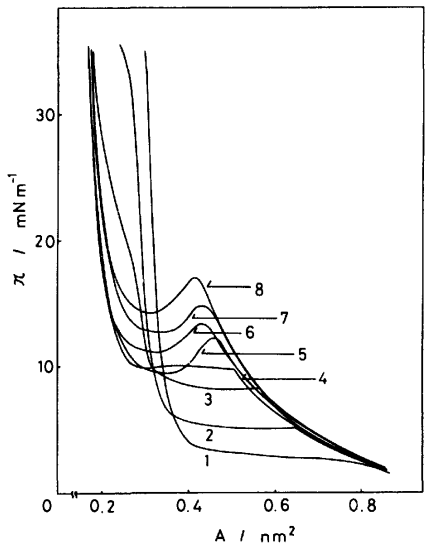

Fig. 7. Surface tension *vs.* area curves of OcD-Val-OMe monolayer. 1) 283.2 K, 2) 288.2 K, 3) 293.2 K, 4) 295.7 K, 5) 298.2 K, 6) 300.7 K, 7) 303.2 K, 8) 308.2 K.

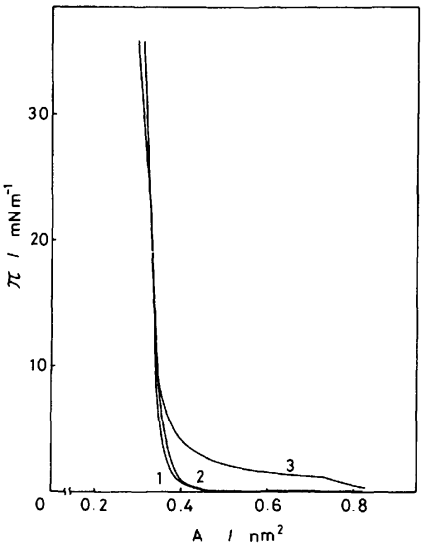

Fig. 8. Surface tension *vs.* area curves of Doc-Val-OMe monolayer. 1) 283.2 K, 2) 303.2 K, 3) 308.2 K.

It has been found from the measurements on the monolayers of acylamino acids that the length and chemical structure of the alkyl side chain of amino acid play a significant role in the monolayer behavior. Further information will be provided by making a similar investigation of amino acids with aromatic or polar side chains.

A Fluorescence Study of the Adsorption of Water, Methanol, and Acetic Acid on an Activated Europium Ion-exchanged Mordenite

Tsuyoshi ARAKAWA,* Midori TAKAKUWA, and Jiro SHIOKAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, 2-1 Yamadaoka, Suita, Osaka 565
(Received September 5, 1983)

The adsorption of water, methanol, and acetic acid on an activated Eu(III) ion-exchanged mordenite(Eu-M) has been studied by the measurement of the fluorescence of the Eu^{2+} ion which was produced by the dehydration at 500 °C. The emission peak of the Eu^{2+} ion sifted to a shorter wavelength on exposure to water and other simple molecules. The magnitude of the shift was correlated to the specific dielectric constant of the adsorbate. The quantum yield for the Eu^{2+} emission band after gas adsorption decreased in all cases. Also, the lifetime in the Eu^{2+}-adsorbate system was shorter than that in an activated Eu-M sample. The rate constants for the radiationless transitions were more sensitive to the nature of the adsorbates, and the order of the quenching power was $H_2O>D_2O>CH_3OH$.

The rare-earth ion-exchanged zeolites are well known as active catalysts for the cracking of fuel oil. The reduction-oxidation of the rare-earth ion in the zeolites, however, has apparently not been studied. We have now studied the fluorescence properties of rare-earth ion-exchanged zeolites in an attempt to clarify the catalytic properties of these compounds. Especially, we have found, from measurements of the fluorescence for europium ions, that Eu(III) is reduced to Eu(II) as Eu(III) ion-exchanged Y type zeolite or mordenite is evacuated at above 300 °C under a pressure of less than 10^{-2} Pa.[1,2]

Physicochemical studies of the synthetic zeolites have been performed by several methods, *i.e.*, X-ray diffraction, electron resonance, infrared spectroscopy, reflectance spectroscopy, Mössbauer spectroscopy, magnetic susceptibility, and X-ray photoelectron spectroscopy, but the interpretation of the results and the establishment of firm conclusions are frequently difficult.[3] Also, there have been a number of studies of the adsorption of various gases on the transition-metal ion-exchanged zeolites. Especially, the formation of a carbonyl, nitrosyl, or ammine complex in the zeolite has been reported on the basis of adsorption measurements and ESR spectroscopy.[4-6] Although fluorescence spectroscopy is by no means a new technique, its application to the study of gas adsorption on rare-earth ion-exchanged zeolites as described here is new. In the case of Eu^{2+}-doped phosphors, it is well known that the emission band for the Eu^{2+} ion changes with the variation in the chemical environment around the Eu^{2+} ion, since the emission for the Eu^{2+} ion is due to a transition between $4f^7$ and $4f^65d$, and so the 5d electron will be most noticeably affected by the crystal field.[7-9] Thus, after gas adsorption on an activated europium ion-exchanged mordenite (Eu-M), the peak position of the emission band for the Eu^{2+} ion can be expected to change with the adsorbates.[10]

In this study, the unique features that have been observed only in an activated Eu-M during the adsorption of water, methanol, and acetic acid are presented.

Experimental

Materials. The Eu-M samples were prepared starting from Na-mordenite, which had been supplied by the Norton Company. The parent mordenite had the following composition; $Na_8(AlO_2)_8\cdot(SiO_2)_{40}\cdot 24H_2O$. This mordenite was ion-exchanged in an excess of a 0.02 M solution containing $EuCl_3$ (pH=4), washed, dried at 100 °C, and calcined in air at 450 °C. The exchanged mordenite was analyzed for europium by means of X-ray fluorometry and for sodium by means of flame photometry. The close correspondence between the decrease in the sodium content and the increase in the europium content indicated that a simple ion-exchange process had occurred. Thus, the exchanged level of the Eu^{3+} ion was 5.8%.

Water, dehydrated methanol, and acetic acid were degassed by the freeze-pump-thaw technique.

Adsorption Measurements. The adsorption experiments were performed on a silica balance, using a sample of 1.0×10^{-4} kg. The sensitivity was 10^{-7} kg. The apparatus of the gravimetric adsorption system, used in connection with a vacuum system, was similar to that described by Boudart *et al.*[11] The pressure was monitored by a digital manometer (Validyne CD-23). The mordenite samples were evacuated for 2 h at room temperature before they were slowly heated at increments of 200 °C/h to 500 °C. The evacuation was then continued at 500 °C for 4 h. The adsorbate was introduced on a dehydrated sample at 25 °C.

Fluorescence and UV Experiments. The emission and excitation spectra were measured using a Shimadzu Recording Absolute Spectrofluorophotometer (RF-502) at room temperature. The UV spectra were taken with a Shimadzu UV-180 apparatus, using MgO as a reference. The particle size of the zeolite was in the 10^{-5}—10^{-4} m range, so that light scattering would be as uniform as possible. The UV spectra in the region from 200 to 400 nm were recorded using a glass filter (UV D-25), since the UV spectra in the region were affected by the fluorescence of a divalent europium ion, as will be described below. Prior to the adsorption, the sample in a quartz cell was dehydrated at 500 °C for 4 h under a pressure of 10^{-5} Torr(1 Torr=133.322 Pa), and then the adsorbate was introduced on dehydrated samples at 25 °C. The inlet adsorbate-gas pressure was the saturated vapor pressure at 25 °C. The quantum yield (Q_0) was decided using the following equation[12];

$$Q_0 = Q_{sample} \times \frac{I_{CaWO_4:Pb}}{I_{sample}}, \quad (1)$$

where Q_{sample} is the photoluminescence outputs (PL) and is comparable to the PL of $CaWO_4$:Pb(NBS 1026), and where I_{sample} and $I_{CaWO_4:Pb}$ are the intensities obtained from the UV spectra.

Lifetime Measurement. The lifetimes were measured using a Nitrogen Laser (337 nm) with a lifetime of less than 5 ns. Also, for the measurement of the lifetimes the monochrometer was used in order to be capable of selecting the

emission wavelength. The lifetimes were determined from the oscilloscope trace as the slope of log I *vs.* t.

Results

Adsorption Measurement. The adsorption of water, methanol, or acetic acid was rapid, and equilibrium was always attained within 1 or 2 h. The adsorption isotherms at 25 °C in Na-M and Eu-M are shown in Fig. 1. The amount of water adsorbed on Eu-M is more than that adsorbed on Na-M. For the adsorption of other species, the difference in the adsorbed amount between Eu-M and Na-M is small. The net amount of adsorption on europium was obtained from the difference between Eu-M and Na-M. In the case of water, this gave a quantity of adsorbed water per europium ion equal to 5.8 when the uptake at 10 Torr was plotted. Since the coordination number of water for the dehydrated europium chloride is 6,[13] the high uptake of water in Eu-M must be mainly due to the formation of the Eu^{2+}-aqua complex. In the case of CH_3OH, the observed CH_3OH/Eu ratio was about unity (1.3). The observed CH_3COOH/Eu ratio was also about unity (1.3). It is considered that, in the system of Eu-CH_3OH or Eu-CH_3COOH, the majority of Eu^{2+} ions exist in a state in which one molecule is coordinated to one Eu^{2+} ion in mordenite.

Fluorescence under Gas Adsorption. The compounds activated with an Eu^{2+} or Eu^{3+} ion generally exhibit fluorescence.[14,15] When Eu-M was degassed at 500 °C, the band emission for the Eu^{2+} ion(peak at 478 nm) and the emission lines for the Eu^{3+} ion, which had peaks at around 570($^5D_0$–$^7F_0$), 590($^5D_0$–$^7F_1$), and 620 nm ($^5D_0$–$^7F_2$), were observed.[2] However, the variation in the fluorescence for the Eu^{3+} ion under gas adsorption is not discussed in this paper, as the relative intensities of the emission lines were much smaller than that of the band emission for Eu^{2+} and the shift of the peak position for the emission band was not observed after the adsorption of gases. On the other hand, the band emission for the Eu^{2+} ion drastically changed after gas adsorption. Some typical excitation and emission spectra for the Eu^{2+} ion in mordenite are shown in Fig. 2. Curve 1 is the band emission for the Eu^{2+} ion which is produced in the course of evacuation at 500 °C. Curve 2 is the emission band when the dehydrated sample is exposed to water. The results of the other adsorbates are summarized in Table 1. The optimum excitation wavelength after gas adsorption was 355 nm in all cases. The emission band thus shifted to a shorter wavelength under gas adsorption.

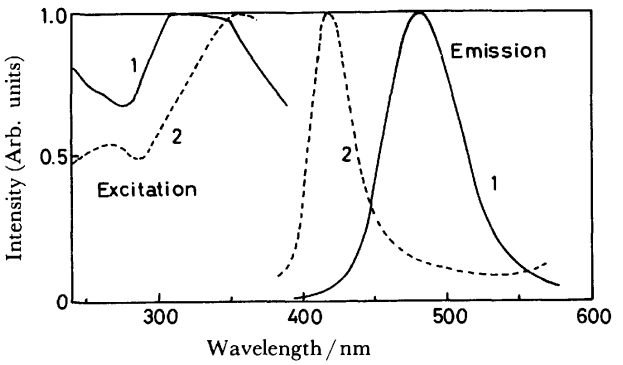

Fig. 2. The emission spectra for Eu^{2+} of Eu-M. (1) Degassed at 500 °C for 4 h and then cooled in vacuum to 25 °C. (2) After the introduction of water to (1).

TABLE 1. THE PEAK POSITION OF THE EMISSION BAND FOR THE Eu^{2+}-ADSORBATE SYSTEM IN MORDENITE

Adsorbate	Peak position (nm)
None	478
H_2O	419
D_2O	419
CH_3OH	418
CH_3COOH	415

UV Spectra. Figure 3 shows some typical absorption spectra before and after the adsorption of water and methanol. Although two bands appear after gas adsorption, the degree of splitting changes almost not at all from Eu-H_2O to Eu-CH_3COOH. On the other hand, the absorption edge of the spectra in the system for all Eu^{2+}-adsorbated molecules, which is the lowest energy edge (or the longest wavelength), almost agreed with the emission peak in Table 1.

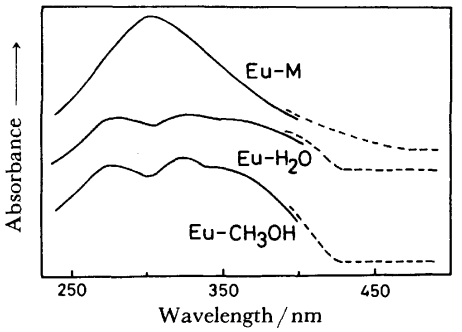

Fig. 3. Absorption spectra of Eu^{2+}-M, Eu^{2+}-H_2O and Eu^{2+}-CH_3OH system. The solid lines are the spectra with a glass filter (UV D-25).

Quantum Yield and Lifetimes. The quantum yield for the Eu^{2+} emission band after gas adsorption under the saturated vapor pressure at 25 °C is summarized in Table 2; it is then compared with the dehydrated sample. The quantum yield after gas adsorption decreases in all cases. That is, H_2O, CH_3OH, and CH_3COOH are quenchers. However, the degree of quenching is dependent on the adsorbates.

Only lifetimes longer than 5 ns could be measured. Thus, the lifetime for the adsorption of CH_3COOH could not be measured. The lifetimes were determined from the oscillograms. Although the oscillogram was composed of two parts (an initial increase in light intensity and then a decay), the results in Table 2 are for only the decreasing part of the picture; the increase was too short to be measured accurately. The decreasing part of the oscillogram represented an exponential decay in the systems of Eu^{2+}–H_2O and Eu^{2+}–D_2O. In an Eu^{2+}–CH_3OH system, although the light intensity decreased exponentially, it was proved that there were two lifetimes from the oscilloscope trace, the slope of log I *vs.* t. In all cases, the lifetime in the Eu^{2+}-adsorbated system is shorter than that in a dehydrated Eu-M. Although the influence of the concentration of an adsorbate on the lifetimes could not be examined as well as in a homogeneous system,[16] the luminescence decay rates in Eu^{2+}–CH_3OH must decrease with the increase in the number of methanol molecules coordinated to the Eu^{2+} ion. Therefore, it would seem that there are two sites where the coordination number of CH_3OH molecules for the Eu^{2+} ion are different from each other. This assumption would be appropriate since the value of CH_3OH/Eu^{2+} is not an integral number as described above.

TABLE 2. LIFETIMES AND QUANTUM YIELDS

Adsorbate	τ/ns	Q_0/%
None	1.1×10^3	0.9
CH_3OH	16,100	0.4
D_2O	7.2	0.2
H_2O	4.8	0.6
CH_3COOH	—	0.08

Discussion

Shift of Emission Peak. The emission for the Eu^{2+} ion is normally associated with the transitions from $4f^65d$ to $4f^7$ where $4f^65d$ is the excited state of Eu^{2+}. Two factors determine the wavelength of the emission band; the splitting of the 5d levels by the crystal field of the surrounding ligand ions and, on the other hand, the energy gap between the 4f ground state and the center of the gravity of 5d excited levels.[7,9] The existence of two peaks in Fig. 3 may be a result of the splitting of the 5d orbitals which increased after gas adsorption. That is, the shift of the emission peak after gas adsorption must be attributed to the fact that the adsorbate molecules are coordinated to an Eu^{2+} ion, as has been described above. Especially, in the Eu^{2+}–H_2O system, it was confirmed that the Eu^{2+}-aqua complex was formed after water adsorption. Moreover, we discussed the shift after gas adsorption. The relationship between the difference in the emission peak before and after gas adsorption and the specific dielectric constant (ε) of adsorbates is shown in Fig. 4. The magnitude of the shift ($\Delta\sigma_F$) is predicted by the approximate equation;[17]

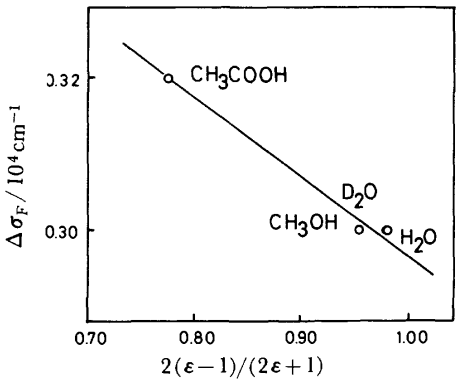

Fig. 4. The relationship between the dielectric constant of adsorbates and the shift of emission peaks for Eu^{2+}-adsorbated molecule in mordenite.

$$\Delta\sigma_F = \frac{2(\varepsilon-1)}{2\varepsilon+1}\alpha, \tag{2}$$

where α is the constant, which is determined by the photoexcited process of the Eu^{2+}-adsorbated molecule. Figure 4 well exhibits the relation of Eq. 2. As can be seen from the finding that the optimum excitation level after the adsorption rarely changed, the variation in the chemical environment around the Eu^{2+} ion under various condition of gas adsorption seems to be relatively unimportant in causing the variation in the excitation process. In Fig. 3, it may be seen that the lowest energy edge (or longest wavelength) almost agrees with the emission peak in Fig. 2. Therefore, it can qualitatively be mentioned that the shifts of the emission peak are dependent on the dielectric constant of the adsorbates, as the adsorbed molecules affect the dipole-dipole interaction Eu^{2+} ion in the dehydrated mordenite.

Rate Constant for Radiative and Radiationless Transitions. The information obtained from the lifetime and quantum-yield measurement enables us to calculate some of the rates of radiationless transitions. The quantum yield may be expressed as;

$$Q_0 = \frac{K_f}{K_f+K_i}, \tag{3}$$

where K_f is the radiative rate constant and K_i is the radiationless rate constant. Also, the observed lifetime, τ, is derived as the following equation;

$$\tau = \frac{1}{K_f+K_i}. \tag{4}$$

From Eqs. 3 and 4, we can calculate K_f and K_i. The results are given in Table 3. The radiationless constant, K_i, increases under the gas adsorption. Comparing the systems of Eu^{2+}–CH_3OH, Eu^{2+}–D_2O, and

TABLE 3. RATE CONSTANTS FOR RADIATIVE (K_f) AND RADIATIONLESS (K_i) TRANSITIONS

Adsorbate	$K_f/10^6\ s^{-1}$	$Q_0/\%$	$K_i/10^6\ s^{-1}$
None	0.09	0.9	0.9
CH_3OH	0.5, ~0	0.4	62, 10
D_2O	0.2	0.2	138
H_2O	1.2	0.6	207

Eu^{2+}–H_2O, the values of K_i are 62, 138, and 207 respectively. That is, the quenching rate constants are more sensitive to the nature of the adsorbates. The order of the quenching power is $H_2O(79)>D_2O(78)>CH_3OH(33)$. The values in parentheses are the dielectric constants. The order associates with the magnitude of the dielectric constant for the adsorbates.

It is considered that the results in this paper lead to a new method for investigating surface characteristics. Further detailed studies to investigate these interesting problems are now in progress.

We are grateful of Prof. H. Mikawa and Dr. Y. Shirota of Osaka University for their support of the measurements of the lifetimes.

Nonisothermal Crystallization of Poly(tetrafluoroethylene)

Takeo OZAWA
Electrotechnical Laboratory, Sakura-mura, Niihari-gun, Ibaraki 305
(Received September 6, 1983)

Crystallization of poly(tetrafluoroethylene) was observed by differential scanning calorimetry at constant cooling rates. A method for kinetic analysis of thermoanalytical data of nonisothermal crystallization was applied to analyze the data, and it was elucidated that poly(tetrafluoroethylene) crystallizes one-dimensionally from preexisting nuclei, which are presumably impurities. These results are in accordance with electron-microscopic observation of the crystalline morphology of poly(tetrafluoroethylene), which consists of band-like or star-like crystallites. The kinetic parameters, especially the temperature dependence of the linear growth rate, were estimated.

Isothermal crystallization of various polymers has been extensively observed mainly by differential scanning calorimetry (DSC). However, for some polymers such as poly(tetrafluoroethylene) (PTFE), the crystallization is so rapid that one can not observe isothermal crystallization, because it crystallizes in the period during which the sample is cooling to a desired constant temperature. To observe these crystallization behavior, we should observe the process in cooling mode. The present author published a method for analyzing thermoanalytical data of crystallization, and the method was applied to nonisothermal crystallization of poly(ethylene terephthalate) proceeding at constant cooling rates.[1] For more simple crystallization mechanism, *i.e.*, crystallization from preexisting nuclei, another method was devised by the author.[2]

On the other hand, in some actual processes such as fabrication and melt spinning of crystalline polymers, crystallization proceeds nonisothermally, so that nonisothermal observation of crystallization has also actual meaning. Moreover, thermoanalytical observation of crystallization behavior was recently extensively investigated especially for amorphous materials such as amorphous magnetic materials by differential thermal analysis and DSC.

PTFE dealt with in this paper has some unusual features, one of which is its crystalline morphology; the spherulite has not been observed. Bunn *et al.*[3] reported striated band-like structures on fractured surfaces of PTFE. On the other hand, Symons observed dendrites and star-like crystals in the solution-grown crystals[4] and he also observed both the plate-like single crystals of clear hexagonal habit and the striated broad needles.[5] Afterword, Rahl *et al.*[6] observed emulsion-grade PTFE and found ribbon-like and rod-like crystallites; they postulated that these crystallites consist of single crystals of extended chain packing. Thus, it is interesting to know the crystallization kinetics of the polymer, especially the mechanism of the crystal growth. The nonisothermal crystallization was observed with a DSC, and the data were analyzed by the above-mentioned methods. These results are reported in this paper, and the applicability of the method for kinetic analysis of nonisothermal crystallization is illustrated in this report.

Experimental

Teflon No. 5 (E. I. du Pont de Nemours & Co. Inc., bulk polymerized PTFE), Teflon No. 6J (Mitsui Fluorochemicals Co., Ltd., emulsion polymerized PTFE), and Polyflon F-101 (Daikin Co., Ltd., emulsion polymerized PTFE) were used as received. Teflon No. 5 gamma-irradiated by 1 Mrad to decrease the molecular weight was also investigated. A DSC made by Rigaku Denki Co., Ltd. was used; the sample of 10—20 mg was heated in the flow of dry nitrogen up to 350—360 °C and then cooled immediately at a programmed cooling rate of 1, 3 or 5 K/min. Because the temperature of the sample is measured in this apparatus with a thermocouple, a junction of which is located on the bottom of the sample holder, the temperature can be measured precisely even in the cooling mode.

Results and Discussion

As is well known, for isothermal crystallization Avrami's equation holds;

$$-\ln(1-C) = Z t^n, \tag{1}$$

where C, t, Z, and n are the crystallized fraction, the time, a constant and an integer related to the nucleation and the growth dimension, respectively. As was elucidated in the previous paper, the following nonisothermal equation was derived instead of the above Avrami's equation.

$$-\ln(1-C) = \chi_c(T)/\phi^n, \tag{2}$$

or

$$\log(-\ln(1-C)) = \log \chi_c(T) - n \log \phi, \tag{3}$$

where T, ϕ, and $\chi_c(T)$ are respectively the temperature, the cooling rate, and the cooling crystallization function, which is the function characteristic of the sample; this function is dependent on the temperature but independent on the cooling rate. Therefore, the straight line should be obtained by plotting $\log(-\ln(1-C))$ against the logarithms of the cooling rates.

In order to observe this relation, the DSC curves of crystallization were converted to integral type curves of C versus t as is shown in Fig. 1, where C is estimated as follows;

$$C = \int_0^t (dH/dt)\, dt \Big/ \int_0^\infty (dH/dt)\, dt, \tag{4}$$

where dH/dt is the rate of heat evolution due to the exothermic crystallization observed by DSC.

Typical plots of $\log(-\ln(1-C))$ against $\log \phi$ are shown in Fig. 2, where the straight lines of the slope of unity are drawn. As is clearly seen, the crystallization follows Eq. 3 with $n=1$. The values of n obtained by

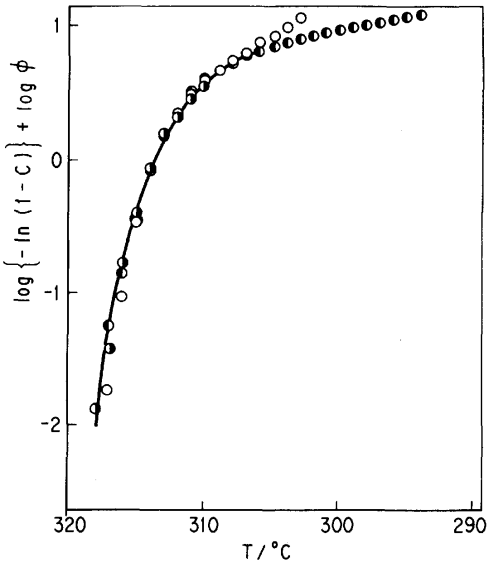

Fig. 3. Experimental master curve reduced to ϕ=1 K/min for Teflon No. 5. The cooling rates are 4.5°C/min (◐), 2.9°C/min (O) and 0.9°C/min (◑).

the similar plots for the other samples are tabulated in Table 1. Although the data are somewhat scattered in a few cases, the values of n are estimated to be approximately unity for all samples by the method of the least square. It can be concluded from these facts that the crystals grow one-dimensionally from preexisting nuclei. However, the origin of the nuclei is not elucidated in this investigation.

This mechanism of one-dimensional growth is in accordance with the above-mentioned report of Bunn *et al.*[3] who observed the fractured surface of the sintered Teflon No. 5 with an electron-microscope and found band-like crystals. The one-dimensional growth is also in accordance with the formation of dendrites and star-shaped crystals in the solution-grown crystallization observed by Symons[4] and with needle-like structure found in sintered deposits by Symons.[5] From the electron-microscopy, the electron-diffraction and the optical observation, Symons proposed a model of a stack of single crystal plate or lamella of hexagonal habit, in which molecular chains are folded and perpendicular to the basal plane.[5] The one-dimensional growth mechanism is also in accordance with the observation of Rahl *et al.*[6] who found ribbon-like and rod-like crystals, and they postulated extended chain structure. According to Symons' models, the value of n obtained in this investigation corresponds to the mechanism of whole process of crystallization and not to the growth of single crystals of hexagonal habit postulated by Symons.[5]

From Eq. 3, another plot can be derived; if one plots $\log(-\ln(1-C))$ against the temperature, the curves of different cooling rates can be superposed on each other by longitudinal shift and an experimental master curve can be obtained. The superposition could not be made, if the slow "secondary" (post-Avrami) crystallization occurs. A typical experimental master curve drawn in this way is shown in Fig. 3. Except the latter part, the curves can be superposed on each other very well, and the discrepancy in the latter part seems to indicate the existence of the secondary crystallization. After the completion of the process, *i.e.*, C=1, the heat of crystallization of the gamma-irradiated sample is measured to be about 50% of the heat of the fusion of the sample by using the peak areas of DSC curves, and that of the Teflon No. 5 is about 30% of the heat of the fusion of the sample. These facts also suggest the

existence of the secondary crystallization, since the crystallinity of the sample sintered ordinarily is higher than those observed in cooling crystallization, and the effect of the secondary crystallization is smaller in the cooling crystallization than in the isothermal run, because the sample is cooled rapidly through the temperature range of the secondary crystallization.

The intercepts of the plots as shown in Fig. 2 give the cooling crystallization function, $\chi_c(T)$. Namely for the crystal growth from preexisting nuclei,[1]

$$\chi_c(T) = gN\int_{T_m}^{T} \{R_c(T) - R_c(\theta)\}^m v(\theta)\, d\theta, \quad (5)$$

where g, N, T_m, θ, $(m+1)$ and $v(\theta)$ are the geometrical factor, the density of the nuclei, the melting temperature, a variable, the growth dimension and the linear growth rate, respectively, and

$$R_c(T) = \int_{T_m}^{T} v(\theta)\, d\theta. \quad (6)$$

For the one-dimensional growth in which m is equal to zero,

$$\chi_c(T) = gN\int_{T_m}^{T} v(\theta)\, d\theta. \quad (7)$$

The values of the function obtained for the samples are plotted in Fig. 4. It is interesting to note that $\chi_c(T)$ for the Teflon No. 5 locates in higher temperature range than the gamma-irradiated Teflon No. 5, though the latter seems to have large tendency to crystallize due to the low molecular weight caused by gamma-irradiation. Since $\chi_c(T)$ represents the nature of crystallization of the sample, it is very interesting to compare $\chi_c(T)$ for Teflon No. 6J with that for polyflon F-101; both samples are polymerized by emulsion-polymerization and used in paste extrusion, and the two curves resemble to each other.

For the one-dimensional growth from the preexisting nuclei, another following simple relation holds from Eq. 2, because $n=1$.

$$\frac{1}{1-C}\frac{dC}{dt} = \frac{d\chi_c(T)}{dT} \quad (8)$$

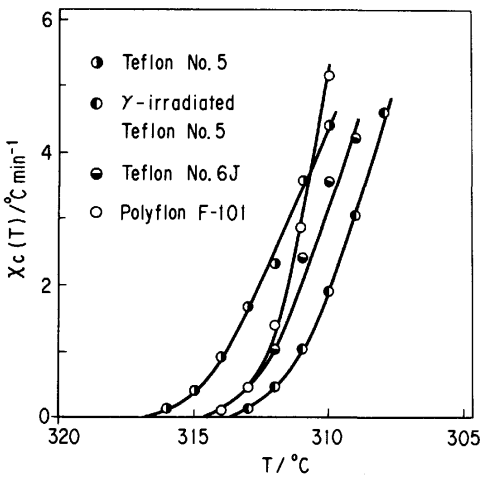

Fig. 4. Cooling crystallization functions for indicated samples.

Because $d\chi_c(T)/dT$ is equal to $gNv(T)$, which is equal to Z in Eq. 1,[2] we can estimate Z directly from the DSC curves by using Eq. 8. The values of Z thus estimated are plotted in Figs. 5 and 6 for Teflon No. 5 and gamma-irradiated Teflon No. 5. As is seen in these figures, the values obtained from the DSC curves at different cooling rates are on the same curve. From these facts the crystallization of Teflon No. 5 and gamma-irradiated Teflon No. 5 is ascertained to follow Avrami's model of the one-dimensional growth from preexisting nuclei. It is interesting that Z of gamma-irradiated Teflon No. 5 is in the lower temperature range, but its maximum is larger than Teflon No. 5. This tendency is in accordance with that of $\chi_c(T)$. On the other hand, the values of Z thus estimated for the other PTFE's are not on the same curve and large scattering of the values is observed. For these

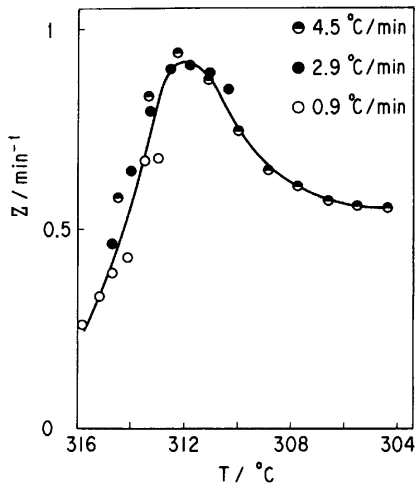

Fig. 5. Temperature dependence of kinetic parameter, Z, for Teflon No. 5. The cooling rates are 4.5°C/min (◓), 2.9°C/min (●), and 0.9°C/min (○).

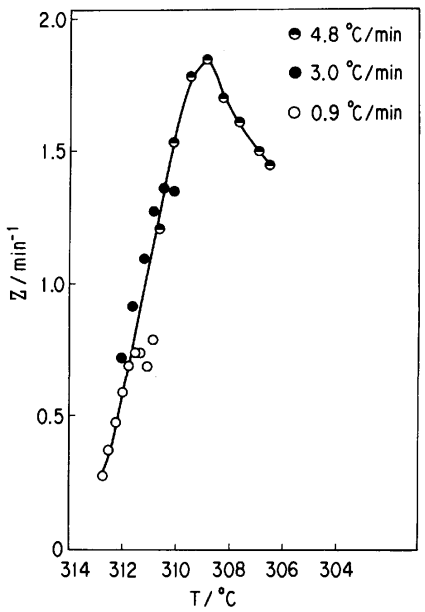

Fig. 6. Temperature dependence of kinetic parameter, Z, for gamma-irradiated Teflon No. 5. The cooling rates are 4.8°C/min (◓), 3.0°C/min (●), and 0.9°C/min (○).

emulsion-polymerized PTFE's, the values of n are also scattered and somewhat different from unity, so that other processes, such as the secondary crystallization, seem to have large effect for these PTFE's.

For poly(vinylidene difluoride), Nakamura *et al.*[7] observed nonisothermal crystallization by DSC and found that $\log(-\ln(1-C))$ is in a linear relation with $\log\phi$ and that the slope is four, which indicates homogeneous random nucleation and three-dimensional growth mechanism. They also observed the crystallization isothermally and elucidated the same mechanism by applying the above-mentioned Avrami's equation. In three examples of nonisothermal crystallization of polymers, *i.e.*, poly(ethylene terephthalate),[1] poly(vinylidene difluoride),[7] and poly(tetrafluoroethylene), the applicability of the present author's theory and method of nonisothermal crystallization is illustrated, and the theory and method are clearly shown to be applicable to other substances, such as amorphous materials and so on.

The author wishes to thank Miss Michiko Osawa for her assistance in the data processing.

Optically Active and Racemic Glycerides. II. Thermodynamic Studies on the Polymorphic Transition of (*R*)- and (*RS*)-1,2-Diglycerides

Makio Iwahashi,* Kazuhide Ashizawa,† Miyuki Ashizawa,
Yoshihide Kaneko,†† and Mitsuo Muramatsu†††
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158.
(Received September 6, 1983)

The polymorphic relationship between optically active (*R*)- and for racemic (*RS*)-forms of 1,2-distearin and 1,2-dipalmitin were studied by X-ray diffraction, infrared spectrum, and the thermal analysis. These glycerides have two crystalline forms, α and β, wherein α is metastable and β is stable under ordinary conditions. The $\alpha \rightarrow \beta$ transformation for the (*RS*)-1,2-distearin crystal was extremely slow as compared with that for the (*R*)-form crystal, implying that the β-form crystal of (*RS*)-1,2-distearin is an eutectic mixture of small (*R*)- and (*S*)-crystals while the α-form crystal of (*RS*)-1,2-distearin is composed of a replacement type solid solution of (*R*)- and (*S*)-1,2-distearin molecules. Almost the same results were obtained with 1,2-dipalmitin, for which the rate of $\alpha \rightarrow \beta$ transformation is higher than that for the 1,2-distarin, probably because of a higher mobility of this compound.

In the preceding paper[1] on stability of (*S*)- and (*RS*)-α-monostearin crystals, it was pointed out that the (*RS*)- form crystal is a racemic compound, and that the interaction between (*R*)- and (*S*)-molecules in the (*RS*)-crystal is stronger than that between (*S*)- and (*S*)-molecules even above the melting point of the (*RS*)-crystal. Such polymorphic stabilities have been discussed frequently with monoglycerides and triglycerides[2,3] but fewly with 1,2-diglycerides. Thus, the present study deals with the polymorphic relationship of optically active (*R*)- and racemic (*RS*)-forms of 1,2-distearin as well as of 1,2-dipalmitin. Attempts have been made to clarify the mechanism of the extremely slow $\alpha \rightarrow \beta$ transition of (*RS*)-1,2-glycerides as compared with that of (*R*)-1,2-diglycerides by means of X-ray diffraction, infrared spectrum and the thermal analysis for these glycerides. A similar mechanism could be applied to 1,3-diglycerides for which rapid $\alpha \rightarrow \beta$ transformation had been reported.[4-6]

Bold and thin lines express the phases of β- and α-forms, respectively, and dotted lines the liquid state. The enthalpy values for the peaks: X=123.1 kJ mol^{-1}, Y=77.2 kJ mol^{-1}, and Z=76.4 kJ mol^{-1}.

Experimental

Materials. Chemically pure (≥99%) samples of (*R*)- and (*RS*)-1,2-dipalmitins and (*R*)- and (*RS*)-1,2-distearins from Fluka AG (Switzerland) were further purified by repeated recrystallization from hexane to give β-form (stable) crystals of these 1,2-diglycerides. The samples of α-form (metastable) were obtained by rapid cooling of molten samples of the stable glycerides. Melting points of these samples (Table 1) were in good agreement with the reference values.[4,8,9]

Apparatus and Procedures. The calorimetric experiments were carried out with a differential scanning calorimeter (Shimadzu Model DSC-30 equipped with Model LTC-30 cooling unit) in a temperature range from 173 to 473 K (accuracy ±2.5 mJ s^{-1}) by the use of a standard sample of KNO_3[10] for thermal calibration. Identification of the polymorphic

crystals was achieved with an X-ray diffraction unit (Rigaku Denki Model 2001), and an IR spectrometer (Hitachi Perkin-Elmer Model 215). For more details, an X-ray small-angle diffraction unit (Rigaku Denki Model 2202E1) was used.

Results and Discussion

In Figs. 1 and 2 which show the DSC performance for (*RS*)- and (*R*)-1,2-distearins, respectively, the first (X) and the second (Z) endothermic peaks are attributable to the fusion of crystals of β- and α-forms, respectively. This was confirmed by the data based on the measurements of X-ray diffraction (Fig. 3), IR spectrum (Fig. 4), melting point and enthalpy of fusion (Table I). The first exothermic peaks (Y), therefore, are attributable to the formation of α-form crystals: The enthalpy amounts calculated from the peaks (Y) were 77.2 and 79.4 kJ mol^{-1} for (*RS*)- and (*R*)-distearins, respectively, in approximate agreement with our observed values (75.8 and 73.3 kJ mol^{-1} for (*RS*)- and (*R*)-forms) for the α-form crystals. This was indeed the case of (*RS*)-distearin for which the DSC performance (Fig. 1) remained unchanged when heating and/or cooling rates were varied.

On the other hand, (*R*)-stearin showed rather peculiar behavior in its performance (Fig. 2); After formation of α-crystal, it was molten (mp of β-form) by re-heating to give an endothermic peak followed by an exothermic one indicative of formation of β-form: The enthalpy value (121.1 kJ mol^{-1}) for the exothermic peak *U*, in good agreement with that (120.0 kJ mol^{-1}) for the endothermic one *V*, agrees well with the enthalpy of fusion (124.0 kJ mol^{-1} from Table 1) for the β-form crystal. It seems that the interval (in temperature scale), *l* in Fig. 2, between the $\alpha \rightarrow$ liquid and liquid $\rightarrow \beta$ transformations is longer for higher

Table 1.

	1,2-Dipalmitin				1, 2-Distearin			
	(*R*)		(*RS*)		(*R*)		(*RS*)	
	α	β	α	β	α	β	α	β
Mp θ_m/K	322.5	341.1	322.1	336.3	333.1	349.1	332.8	344.9
		341.1 ~ 342.1[8]	323.1[4]	336.6[4]		349.1 ~ 350.1[8]	332.6[4]	344.1[4]
		340.1 ~ 340.6[9]				347.6 ~ 348.1[9]		344.6 ~ 345.6[8]
Enthalpy of fusion / kJ mol^{-1}	52.7[a]	97.2	52.0	98.7	73.3	124.0	75.8	123.1
Entropy of fusion / J K mol^{-1}	163.4	284.9	161.2	293.4	220.0	355.1	227.7	356.9

a) Enthalpy of crystallization: Enthalpy of fusion for α-(*R*)-crystal of 1, 2-dipalmitin could not be obtained for overlaping of the endo-thermic peak due to the fusion of α-crystal with the subsequent peak (exothermic) due to rapid formation of β-crystal.

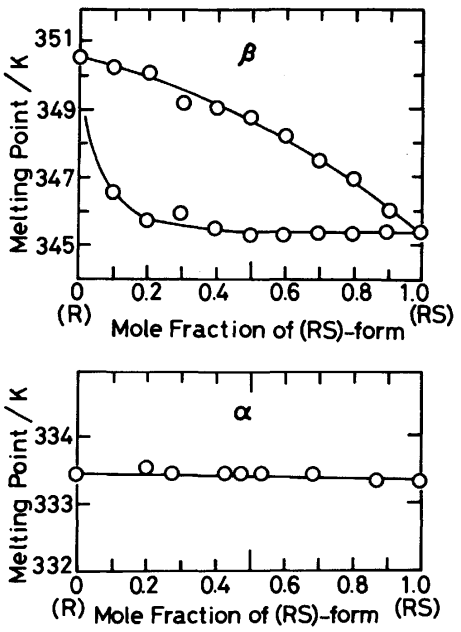

Fig. 5. Melting point-composition diagrams for mixtures of (*R*)- and (*RS*)-1,2-distearins in α-(bottom figure) and β-(upper) forms. Mixture of (*R*)- and (*RS*)-1,2-distearins were prepared by mixing (*R*)- and (*RS*)- forms with hexane and standing overnight *in vacuo* to evaporate the solvent.[1]

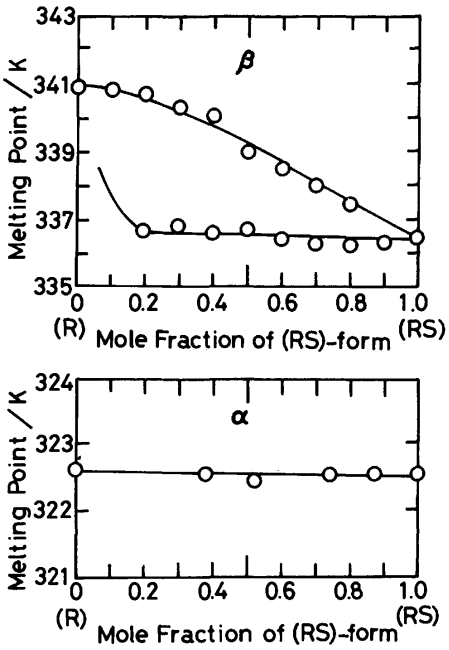

Fig. 6. Melting point-composition diagrams for mixtures of (*R*)- and (*RS*)-1,2-dipalmitins in α-(bottom figure) and β-(upper) forms. the heating rate. Howe and Malkin,[4] and Chapman[11] reported that the formation of the β-form crystal resulted from holding of the α-form crystal of (*RS*)-1,2-distearin for several hours at a temperature slightly below its mp and that both (*R*)- and (*RS*)-1,2-distearins have only two polymorphic forms, α and β, and do not possess a transition temperature between them. Taking account of all these results, we must conclude that the α-form crystal is less stable than the β-form crystal throughout all temperature region; The α- and β-crystals are in monotropic relationship,[12] giving higher stability to the latter. A similar relationship has been observed for the α- and β-crystals of chloramphenicol palmitate.[13]

In order to compare the rate of $\alpha \rightarrow \beta$ transformation between (*R*)- and (*RS*)-1,2-distearins, the DSC scanning for the α-crystals of (*R*)- and (*RS*)-form were carried out, after they had been allowed to stand for three months at room temperature. It was found that the α-(*R*)-crystal was transformed into its β-form, whereas the α-(*RS*)-crystal remained unchanged. Such phenomena could probably suggest that, like the case of (*RS*)-α-monostearin,[1] the (*RS*)-1,2-distearin is composed of a racemic compound. However, both X-ray diffraction patterns (including X-ray small-angle diffraction) and the infrared absorption spectra were almost the same between (*R*)- and (*RS*)-forms irrespective of their crystalline forms (see Figs. 3 and 4). In addition, practically no difference is found in entropy of fusion between (*R*)- and (*RS*)-distearins whatever they are in α- or β-form (see Table 1). Nevertheless, the melting point-composition diagrams (Fig. 5) indicates that the β-(*RS*)-1,2-distearin crystal(upper figure) possesses a minimum melting point at which the crystal seems to be an eutectic mixture of (*R*)- and (*S*)-crystallites in 1:1 molar ratio, whereas the α-crystal (bottom) shows a performance typical to solid solution. There are two types of solid solution, replacement and penetration types.[14] In the former, different kind of molecules freely occupy the lattice points in a crystal, whereas in the latter one kind of molecules can penetrate, with certain limit in its composition, among other kind of molecules occupying their lattice points. The Hume-Rothery rules[14] for the replacement type solid solution can be applicable to the (*R*)- and (*S*)-1,2-distearin molecules which are all the same in their size and attractive force. The $\alpha \rightarrow \beta$ transformation of (*RS*)-1,2-distearins, therefore, must be accompanied by an entropic decrease corresponding to a molecular rearrangement from a solid solution type to an eutectic type, *i.e.*, replacement-type distribution (random) to microcrystallite mixture (microordered).[15] In the case of (*R*)-1,2-distearin, such an entropic decrease is not involved in such transformation. The same is true for 1,3-distearin which has no asymmetric carbon atoms and which is characterized by higher rate of $\alpha \rightarrow \beta$ transformation.[4]

All of the above experimental techniques, DSC scanning, X-ray diffraction, IR spectropy, and the melting point-composition diagrams were applied to α- and β-crystals of (*R*)- and (*RS*)-1,2-dipalmitin, for which essentially the same results were obtained as is summarized in Table 1. A typical example is shown in Fig. 6 which suggests an entropic decrease accompanying the $\alpha \rightarrow \beta$ transformation (random→microordered) of (*RS*)-1,2-dipalmitin. Similarly, the DSC performance was almost the same as that in Fig. 1 from which the enthalpies of fusion for α- and β-forms are tabulated in the 4th and 5th column of Table 1. Only one exception is that the $\alpha \rightarrow \beta$ transformation of (*R*)-

1,2-dipalmitin was so fast that the *l*-value in Fig. 2 was always zero irrespective of the heating rate, *i.e.*, the peaks *Z* and *U* overlap each other. This is evidently attributable to a higher mobility of the C_{16}-compound than that of the C_{18}-glyceride. One, therefore, could not estimate the enthalpy of fusion for α-form but of crystalization (peak *Y*), which is listed in the second column.

The authors wish to express their thanks to Mr. Kazuo Ohbu and Kazuhisa Yoshida of Lion Co. Ltd. (Tokyo) for obtaining the results of the X-ray small angle diffraction.

Furan Ring Formation in OH-initiated Photooxidation of 1,3-Butadiene and *cis*-1,3-Pentadiene

Tomohiro OHTA

Department of Environmental Sciences, Tokyo Metropolitan Research Laboratory of Public Health, Hyakunincho, Shinjuku-ku, Tokyo 160

(Received September 16, 1983)

Reactions of hydroxyl radicals with 1,3-butadiene and *cis*-1,3-pentadiene in the presence of oxygen were studied in the gas phase. Two OH radical sources were employed; photolysis of H_2O_2 at 254 nm and photolysis of methyl nitrite at 360 nm. In the reaction system for 1,3-butadiene, furan was detected besides acrylaldehyde and in the *cis*-1,3-pentadiene system, 2-methylfuran was detected besides acetaldehyde, acrylaldehyde, and crotonaldehyde by gas chromatographic analysis. Approximate yields of furan and 2-methylfuran were 5.3—6.7% and 6.7—8.4%, respectively, which were sensitive to the conditioning of the surface of reactor but insensitive to hydroxyl radical sources, the surface material of reaction vessel or the surface to volume ratio of reactors. The yields of aldehydes were also measured. Isotopic labeling experiment with $^{18}O_2$ by use of mass spectrometry indicated that abstraction of vinyl-hydrogen from 1,3-butadiene and *cis*-1,3-pentadiene occurred about 3% of the time. Photooxidation of 2,5-dihydrofuran initiated with ·OH radicals was also discussed to explain the increase of furan in the dark after the irradiation.

Atmospheric reactions of ·OH radicals with simple monoolefins are understood to be initiated mainly by ·OH radical addition to double-bond and partly by hydrogen abstraction at allylic position.[1] When a general olefin $R_1R_2C{=}CR_3R_4$ is photooxidized in NO_x-polluted atmosphere, major expected products are $R_1R_2C{=}O$ and $R_3R_4C{=}O$. It is interesting to know whether the general rule is applicable to diolefins. Environmental chamber studies[2,3] have shown that the major initial products of NO_x-air photooxidation of 1,3-butadiene were formaldehyde and acrylaldehyde. *cis*-1,3-Pentadiene is expected analogously to produce formaldehyde, acetaldehyde, acrylaldehyde, and crotonaldehyde in the similar photooxidation process. However, in our previous study[4] on the determination of relative rate constants for the reactions of diolefins with ·OH radicals by photolyzing H_2O_2 in the presence of oxygen and pairs of diolefins, it was found that furan was formed in the reaction of ·OH with 1,3-butadiene and that 2-methylfuran was formed in *cis*-1,3-pentadiene system, in addition to the expected aldehydes. In order to determine the yield of furans and to make an assumption on the mechanism for furan ring formation in the photooxidation of the conjugated diolefins, we carried out several experiments on the system and proposed a mechanism involving abstraction of vinyl-hydrogen by ·OH from conjugated diolefins.

Experimental

Two ·OH radical sources were employed separately; photolysis of hydrogen peroxide (H_2O_2, 90 %) at 254 nm and methyl nitrite (CH_3ONO) at 360 nm. Hydrogen peroxide was used for runs to examine the dependence of the product yield on the initial concentrations of reactants and wall effect. First, 1 Torr (1 Torr=133 Pa) of H_2O_2 (90%) was introduced in a quartz cylindrical reaction cell which was 15 cm in length and 4 cm in diameter (surface to volume ratio, S/V,=1.1 cm^{-1}): this cell was named reactor A for later discussion. Then, diluted 1,3-butadiene or *cis*-1,3-pentadiene in O_2 was added by measuring the pressure with MKS Baratron. Oxygen or nitrogen gas was filled into the cell to pressurize the mixture up to 760 Torr. After allowing the mixture to stand for about 10 min, the cell was irradiated with two 15 W germicide lamps (National GL-15, 254 nm). Products and reactants for 1,3-butadiene system were analyzed by gas chromatography with flame ionization detector by using 1-m glass column of Porapak T operated at 145 °C. For the reaction system of *cis*-1,3-pentadiene, 1-m stainless steel column of Porapak Q was employed. Products of several runs were trapped in a tube filled with small glass beads immersed in liquid oxygen and the solidified fraction was vaporized and, then, analyzed by use of a gas chromatograph-mass spectrometer (LKB 9000) with the same kind of column used for each reaction system. Further identification was made with infrared spectrometer for the effluents from thermal conductivity detector (TCD) corresponding to furan and 2-methylfuran collected repeatedly in the trap cooled with liquid nitrogen by monitoring TCD signal. Carrier gas was helium.

The other ·OH radical source, CH_3ONO, was used for the experiments to carry out the reactions of ·OH with the diolefins in the absence of H_2O_2 and in the presence of NO_x, and also to examine wall effect on the reaction. Atkinson *et al.*[5,6] have shown that CH_3ONO is a good source *via* Reactions 1 to 3.

$$CH_3ONO + h\nu(360\,nm) \rightarrow CH_3O + NO \quad (1)$$

$$CH_3O + O_2 \rightarrow HO_2 + CH_2O \quad (2)$$

$$HO_2 + NO \rightarrow HO + NO_2 \quad (3)$$

Methyl nitrite was prepared from the reaction of methanol, sodium nitrite and sulfuric acid, according to Atkinson *et al.*[5,6] Crude CH_3ONO was vacuum distilled in a greaseless high-vacuum system and stored under vacuum at 77 K in the dark. Procedure for preparing the reaction mixture was similar to the method for the H_2O_2 system. The irradiation source was black light blue fluorescence lamps (Toshiba BLB, λ_{max}=360 nm).

Four more reactors were used besides reactor A, in order to check wall effect: reactor B was 2 l-quartz cylindrical cell (S/V=0.55 cm^{-1}); reactor C was 188 ml-Pyrex cylindrical cell (S/V=1.2 cm^{-1}); reactor D was 94 ml-Pyrex long tube cell (S/V=4.0 cm^{-1}); reactor E consisted of 25.2 l-Pyrex photochemical chamber and 7.57 l-stainless steel optical absorption cell of UV-VIS spectrometer.[7]

The reaction of ·OH with 2,5-dihydrofuran in the presence of oxygen was also studied in reactors A and C with similar methods.

Photolysis of the mixture, $H_2O_2/^{18}O_2/N_2$/diolefin, was carried out several times in reactor A and isotopic product analysis was made by means of GC-MS with the same proce-

dure as for mass spectroscopic identification.

1,3-Butadienen was from Takachiho Kagaku. Acetaldehyde, acrylaldehyde, crotonaldehyde, furan, 2-methylfuran, *cis*-1,3-pentadiene, and 2,5-dihydrofuran were purchased from Tokyo Kasei. They were degassed before use by trap to trap distillation. Heavy oxygen ($^{18}O_2$, 98.6%) was obtained from Merck Frosst Canada and the purity was confirmed by means of mass spectrometer and the detected impurity was only $^{16}O^{18}O$. Research grade N_2 and O_2 were from Nippon Sanso.

Results

Typical gas chromatograms for the products in the photooxidation of either 1,3-butadiene or *cis*-1,3-pentadiene with H_2O_2 are shown in Figs. 1 and 2, respectively, together with identified compounds. It is noteworthy that Porapak Q or R could not separate acrylaldehyde and furan produced in the reaction of 1,3-butadiene. Each peak had GLC elution times, mass spectra, and infrared spectra identical with those of the respective commercial samples. The identified products under our experimental conditions were furan (C_4H_4O), and acrylaldehyde (C_2H_3CHO) in the reaction of 1,3-butadiene (C_4H_6) and 2-methylfuran (C_5H_6O), acetaldehyde (CH_3CHO), acrylaldehyde, and crotonaldehyde (C_3H_5CHO) in the reaction of *cis*-1,3-pentadiene (C_5H_8).

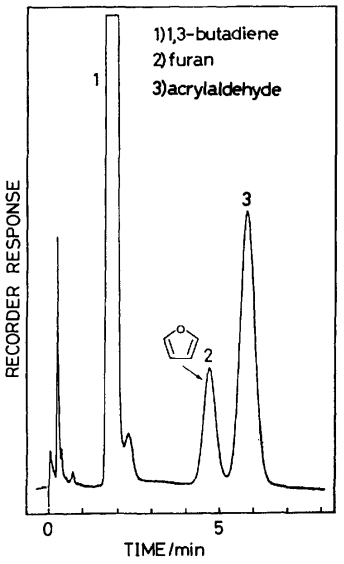

Fig. 1. Typical gas chromatogram of the products in the photolysis of the mixture, H_2O_2[1.0 Torr]/1,3-butadiene[0.4 Torr]/O_2[760 Torr], at 254 nm.

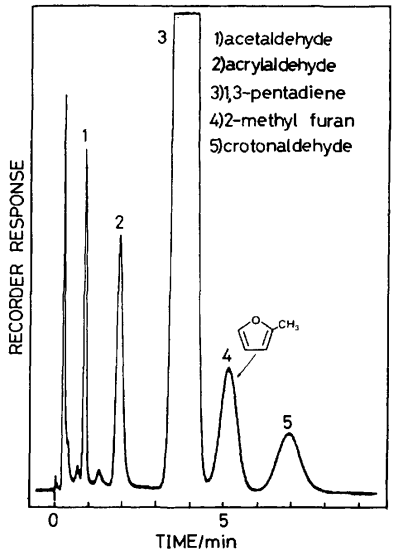

Fig. 2. Typical gas chromatogram of the products in the photolysis of the mixture, H_2O_2[1.0 Torr]/*cis*-1,3-butadiene[0.3 Torr]/O_2[760 Torr], at 254 nm.

For the reaction systems in which H_2O_2 was used as radical source, the reaction cell was kept in the dark after a few minutes irradiation and the concentration of products were measured intermittently. It was observed that furan and 2-methylfuran increased gradually until about 50 min after a few minutes irradiation, while aldehydes remained almost constant (Fig. 3). The yield of furans was determined after the cease of the formation in the dark and the yield of other compounds was determined from the first injection to GC about 30 s after turning off the lamps. For the runs at low pressures, nitrogen was filled upto 760 Torr just after photolysis and gas chromatographic analysis was made. Since it was noticed that furans yield became somewhat larger as the conditioning of the wall surface of reaction cell was improved by repeating the experiments, these series of runs were made after conditioning the surface of the reactor A well. The product yield obtained with various initial conditions is presented in Table 1 for the 1,3-butadiene system and in Table 2 for the *cis*-1,3-pentadiene system. The increase of furan after the photolysis observed for Runs 1 to 6 in Table 1 is shown in Fig. 3. Product yield at 760 Torr total pressure was almost independent of the variation of the initial concentrations of reactants, or of the addition of one of products. But pressure effect was observed: at low total pressure around 2.5 Torr, the yield of furans increased and that of aldehydes decreased (Tables 1 and 2). The difference observed in the pressure effect indicates that some fraction of furan and 2-methylfuran, at least, was not formed *via* initial ·OH addition to the double bonds.

Figure 4 shows the product yield after 1.5 min irradiation of the mixture CH_3ONO [1.0 Torr]/1,3-butadiene [0.27 Torr]/O_2 [760 Torr] in comparison

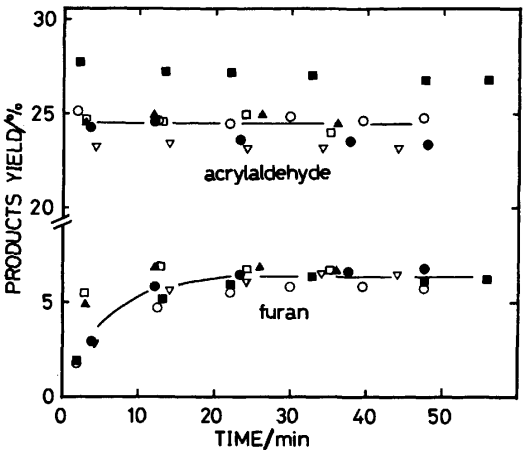

Fig. 3. Dark increase of furan after 1.5—3.0 min irradiation of the mixture H_2O_2/1,3-butadiene/O_2 for Runs 1 to 6 in Table 1.

with the results for the mixture H_2O_2 [1.0 Torr]/1,3-butadiene [0.3 Torr]/O_2 [760 Torr]. It was noticed that the yield of acrylaldehyde was larger and the increase of furan in the dark was faster in the CH_3ONO system than in the H_2O_2 system and that 1,3-butadiene was consumed by NO_2 in the dark. The addition of a proper amount of NO to the CH_3ONO system made the increase of furan in the dark stop and the consumption of 1,3-butadiene in the dark more significant. These facts indicate that some peroxy radicals exist as intermediate compounds to form furan.

In order to examine the wall effect on the reaction, product yield for both ·OH sources in different five reactors were measured and summarized in Tables 3 and 4, for the 1,3-butadiene and for the *cis*-1,3-pentadiene systems, respectively. Irradiation was usually 1 to 2 min for the runs in reactors A to D, and it was 10 to 15 min in reactor E. In the latter case, the yield was corrected by considering the consumption of the diolefins with the dark reactions of NO_2 in CH_3ONO system. The yield of CH_3CHO in CH_3ONO/*cis*-1,3-pentadiene system was lower limit, since the peak of CH_3CHO was on the shoulder of large peak of CH_3ONO in gas chromatogram and the peak height of CH_3CHO was measured from the higher valley rather than ambiguous lower valley. Throughout this series, wall surface was kept rather clean without repeating extra runs. The results showed that the yield of furan and 2-methylfuran was almost independent of the surface material of the reactors or the surface to volume ratio of reactors, or ·OH radical sources, whereas aldehydes yield in the CH_3ONO system was larger than that in the H_2O_2 system. Larger yield of acrylaldehyde in the photolysis of CH_3ONO/1,3-butadiene may be attributed to the faster reaction of NO with peroxy radicals to produce alkoxy radicals which are the precursors of acrylaldehyde than the reactions between some peroxy radicals to lead unspecified products. Since no definite dependence of the yield of furans on S/V of reactors was measured, the discrepancy of the yield in the clean reactor (Tables 3 and 4) and well conditioned reactor (Tables 1 and 2) may be attributed to other reasons: for example, conditioning of the surface would suppress

the wall decay of the intermediate working as reservoir of the precursor radicals of furans.

Results for several isotopic labeling experiments with heavy oxygen are summarized in Tables 5 and 6 for the photolysis of H_2O_2/1,3-butadiene/$^{18}O_2$/N_2 and H_2O_2/*cis*-1,3-pentadiene/$^{18}O_2$/N_2 respectively. Before and after the photolysis, a small fraction of the reaction mixture in the reactor was analyzed by mass spectrometer. Oxygen-16 molecule was not detected in the mixture before the irradiation, and very small amount of $^{16}O_2$ (less than 5%) was detected after the photolysis in some runs. Addition of NO changed the ratio of labeled aldehyde, but the yield for labeled furans was not affected.

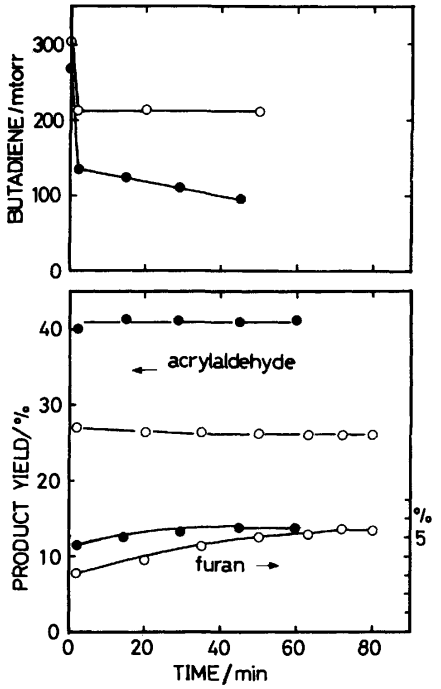

Fig. 4. Difference in the dark reactions after 1.5 min irradiation at 360 nm of the mixture of CH_3ONO[1.0 Torr]/1,3-butadiene[0.27 Torr]/O_2 [760 Torr], (closed circle) and after 1.5 min irradiation at 254 nm of the mixture of H_2O_2[1.0 Torr]/1,3-butadiene[0.30 Torr]/O_2[760 Torr], (open circle).

Discussion

Detection of both ^{18}O-aldehydes and ^{16}O-aldehydes suggests that ·OH addition to nonterminal double-bond carbon atom also occurs as well as to the terminal carbon atom against the assumption of the occurrence of only terminal addition by Maldotti *et al.*[3] In view of the low yield of the detected products, undetected products by our method, such as hydroxy ketones, hydroxy aldehydes and other compounds, might be produced. As an example, possible ·OH addition steps to 1,3-butadiene are shown in Reactions 4 and 5 (O* indicates ^{18}O).

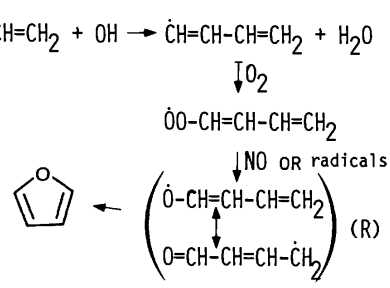
Formation of ^{16}O-furan and ^{18}O-furan in isotopic labeling experiments suggests that two pathways for the formation of furans at least exist. Furan (C_4H_4O) has two less hydrogen atoms than the parent molecule, 1,3-butadiene(C_4H_6), and also *cis*-1,3-pentadiene (C_5H_8) must lose two hydrogen to form 2-methylfuran (C_5H_6O). The fact that the pressure effect on the formation of furans was observed adversely to the pressure effect on the formation of aldehydes indicates that the ways of initial attack to diolefins by ·OH were different for the two processes. Furthermore, the fact that the addition of NO changed the ratios of ^{18}O labeled aldehydes significantly but did not affect those for furans suggests that the precursors for ^{18}O-furan might be consumed by single pathway without competitive reactions to lead other products. Therefore, it is reasonable to assume that one of the terminal vinyl-hydrogen was abstracted by ·OH radicals in the first step and, then, $^{18}O_2$ added to the unpaired elctron on the radicals and that through some radical-radical reactions, an alkoxy radical, ·R in Scheme 1, was formed. The radical was stabilized by resonance as shown in Scheme 1, and a new bond would be formed between the two radical centers to make furan rings.

Some semi-quantitative discussions on the abstraction pathway in diolefins are tried by comparing with the abstraction pathway in ethylene and benzene. Average yield of furan determined from the runs at 760



Scheme 1.

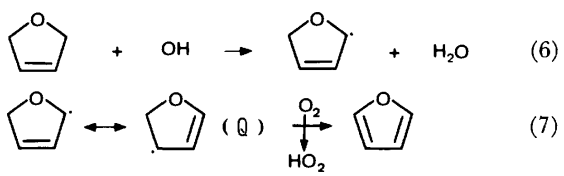
Torr without added gas (Runs 1—6 in Table 1) was 6.7% and that of 2-methylfuran was 8.4% from Runs 1—8 in Table 2. And average mixing ratio of labeled furan was 38% from Table 3 and that of labeled 2-methylfuran was 42% from Table 4. Thus, the abstraction of vinyl-hydrogen in 1,3-butadiene occurred 2.5% (=6.7×0.38) of the time and the abstraction in *cis*-1,3-pentadiene occurred 3.5% of the time. This fairy larger contribution of the abstraction pathway to the overall rate constants was surprising. Overall rate constants for the reaction of ·OH with 1,3-butadiene[8] and *cis*-1,3-pentadiene[4] were 68.5×10^{-12}, 103×10^{-12} cm^3 mol^{-1} s^{-1}, respectively. The assigned rate constants for the abstraction of the vinyl-hydrogen were 1.7×10^{-12} (= $68.5\times10^{-12}\times0.025$) and 3.6×10^{-12} cm^3 mol^{-1} s^{-1}, respectively. The contribution of the abstraction of one vinyl-hydrogen in 1,3-butadiene was 4.3×10^{-13} (=$1.7\times10^{-12}/4$) cm^3 mol^{-1} s^{-1}, which is larger than the contribution of the abstraction of a primary C-H bond in alkane by a factor of 6.6,[1] whose bond dissociation energy (BDE) is 98 kcal mol^{-1} (1 cal=4.18 J) and smaller than BDE of C_4H_5-H. Concerning the abstraction of vinyl-hydrogen in ethylene by ·OH, which is exothermic by 11 kcal mol^{-1},[9] two different views have been proposed: BDE(H-C_2H_3)=108, BDE(H-OH) 119 kcal mol^{-1}. Meagher and Heicklen[10] reported that the hydrogen abstraction reaction contributed 26% of the total reaction pathway under their experimental conditions from the analysis of the formic acid yield. However, Atkinson *et al.*[1] concluded that the contribution of the abstraction was very minor in consideration of the comprehensive product study of the reaction of ·OH with propylene by Cevetanovic[11] and the rate constant study of Howard:[12] Howard has shown from a determination of the absolute rate constant for the reaction of ·OH with ethylene over the total pressure range of 0.7—7 Torr of helium, that abstraction of vinyl-hydrogen at room temperature is implied to be negligible, because the rate constant for

ethylene extrapolates to essentially zero at zero pressure. As for hydrogen abstraction by ·OH radicals in benzene, Perry *et al.*[13] reported that the occurrence of the reaction was 1—8% of the time from the study on the temperature dependence of the rate constant. Carbon–hydrogen bond energy in benzene is 110.5 kcal mol^{-1}.[9] If we assume the bond energy of C–H in 1,3-butadiene similar to that in ethylene and benzene, the observed value in 1,3-butadiene appeared to be larger than that expected from the previous works. However, the detection of labeled furans evidently suggests the occurrence of the abstraction of vinyl-hydrogen by ·OH radicals in 1,3-butadiene and *cis*-1,3-pentadiene. But it is obviously necessary to detect directly the abstracted radicals (C_4H_5· and C_5H_7·) by means of more sophisticated techniques, such as flow system coupled to photoionization mass spectrometer.

The mechanism for the formation of ^{16}O-furanes remains unclear in this work. But it is reasonable to assume that ^{16}O came from ·OH radicals and ·OH–diolefin adducts were precursors for furans, since H_2O_2 did not react with the studied conjugated dienes in the dark.

The increase of furans in the dark after irradiation may be attributed to the decomposition of some complexes formed by reversible recombination reactions of peroxy radicals. Benson described[14] that usual alkyl radicals would irreversibly combine with oxygen molecule to become peroxy radicals followed by some reactions to form oxygen containing compound *via* some complexes of peroxy radicals. He also suggested[14] that unsaturated resonance-stabilized radicals, such as allyl and benzyl radicals, would have much smaller equilibrium constant in the combination reaction with O_2, and that back reaction might become important. In the reaction systems studied here, the unsaturated resonance-stabilized radicals, ·R in Scheme 1, and/or other unknown precursors of ^{16}O-furan would combine to form some metastable compound as reserviors for radicals, and, after turning off the lamps, the metastable complex would decompose to produce the initial radicals or the other precursors.

In order to support this assumption, similar size resonance-stabilized radicals were produced and it was examined whether the increase of the products in the dark was observed or not: the reaction of ·OH with 2,5-dihydrofuran (DHF) in the presence of oxygen was studied. DHF has four labil allylic hydrogens for ·OH attack to form radical ·Q in Reaction 6. The radical ·Q is expected to be stabilized by resonance and to lose another hydrogen by O_2 to ultimately form furan (Reaction 7).



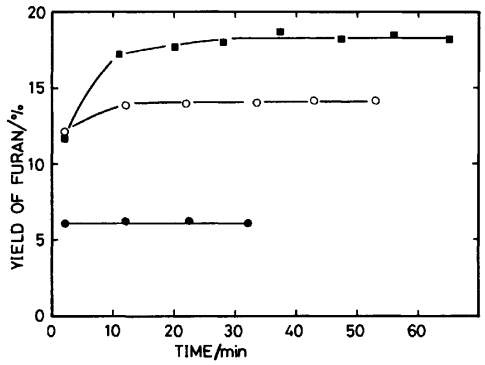


Fig. 5. Dark increase of furan after 1.5 min irradiation of 2,5-dihydrofuran (DHF): initial concentrations (torr): DHF, 0.19; H_2O_2, 1.0; O_2, 760 (closed squares): DHF, 0.32; CH_3ONO, 0.82; O_2, 760 (open circles): DHF, 0.35; CH_3ONO, 0.76; NO, 0.05; O_2, 160; N_2, 600 (closed circle).

By use of a similar procedure used for 1,3-butadiene, the mixture, H_2O_2[1.0 in Torr]/DHF[0.19]/O_2[760], CH_3ONO[0.82]/DHF[0.32]/O_2[760], and NO[0.05]/CH_3ONO[0.76]/DHF[0.35]/O_2[160]/N_2[600], were photolyzed. The detected product under this gas chromatographic condition was only furan. The plots of the yield of furan *vs.* time are shown in Fig. 5. Furan showed increase in the dark after 1.5 min irradiation in the absence of NO, similar to the reactions of the diolefins. However, the addition of NO to the mixture, CH_3ONO/DHF, before the irradiation suppressed the increase of furan in the dark. Thus, the increase of furan in the dark may be explained by the similar assumption that some fraction of ·Q combined with O_2 to form ·QO_2 and that the ·QO_2 radicals were stored as some metastable complexes with fairy large lifetime and, then, the complex decomposed to ·QO_2 and supplied ·Q in the system to form furan even in the dark *via* Reaction 7. Addition of NO to the mixture made ·QO_2 quenched to ·QO to lead other unspecified products. Therefore, it is reasonable to assume that some unsaturated resonance-stabilized radicals consisting of four carbon and an oxygen atom form some metastable compound in the presence of oxygen whose lifetime is in the order of minutes in our reactors. Spectroscopic technique will be able to detect the complexes.

Ring formation from the reaction of 1,3-butadiene with sulfur atoms,[15] and nitrogen atoms[16] were reported. The formation of thiophene was proposed to proceed mainly *via* sulfur atom addition in the 1,2-positions and lose two hydrogens unimoleculary.[15] The formation mechanism of pyrrole was not presented in the paper.[16] Furan was not detected in the reaction of oxygen atoms (^3P) with 1,3-butadiene.[17] There still remain uncertainties in the mechanism for the formation of furan type compound from the reactions of radicals with 1,3-butadiene.

I wish to thank Drs. Hajime Akimoto and Shiro Hatakeyama for very helpful discussions and Dr. Isao Mizoguchi for encouragement.

(Received November 2, 1983)

The surface tension of the aqueous solution of 2-(octylsulfinyl)ethanol and decylammonium chloride mixture has been measured by changing the total molality and composition of surfactants at 298.15 K under atmospheric pressure. It has been observed that the surface tension decreases with increasing the total molality at a constant composition and with decreasing the composition of decylammonium chloride at a constant total molality. Further the surface tension *vs.* total molality curve has been found to have a break point at a relatively low concentration. The thermodynamic equations have been developed so as to be applicable to the adsorption of nonionic-ionic mixture and used to calculate the surface density and the surface composition. It has been shown that the surface density *vs.* molality curve has the discontinuous change caused by the transition from a gaseous to an expanded film. By drawing the two-dimensional phase diagram and comparing it with the diagrams of the ionic-ionic surfactant mixtures, it has been proved that the shape of the phase diagram is affected greatly by the difference in the surface activity between the two surfactants.

The adsorption at water/air interface in a relatively dilute concentration region has been investigated in our laboratory for various types of surfactants[1,2] and cationic–cationic surfactant mixtures such as dodecylammonium chloride (DAC)–decylammonium chloride (DeAC)[3] and dodecyltrimethylammonium chloride (DTAC)–DeAC.[4] It has been observed that the surface tension *vs.* concentration curve has a break point at which a gaseous and an expanded film coexist in equilibrium. As for the ionic surfactant mixtures, we have derived the relation between compositions of the adsorbed film and the bulk phase and shown that the phase diagrams are useful in describing the miscibility of surfactants and phase transition in the mixed adsorbed films. Some studies on cationic–nonionic surfactant mixtures have been carried out from the viewpoints of their mixed micelle formation[5,6] or of their adsorption at water/air interface.[7] In the present study, 2-(octylsulfinyl)ethanol (OSE) is used as the nonionic surfactant for the following reasons; (a) the synthesis and purification of OSE is relatively easy,[8] (b) the adsorption behavior of OSE in the dilute concentration region has been already reported[2] and (c) information about the solution properties of OSE is available.[9,10] By measuring the surface tension of the aqueous solution of OSE–DeAC mixture and applying the thermodynamic equations, which are developed in the present paper, we consider the adsorption of surfactant mixtures from their aqueous solution at the solution/air interface.

Experimental

2-(Octylsulfinyl)ethanol and decylammonium chloride were synthesized and purified by the methods described previously.[1,11] Their purities were checked by the elementary analysis and guaranteed by the absence of minimum near their critical micelle concentration of the surface tension *vs.* concentration curves at 298.15 K. Water was triply distilled from alkaline permanganate solution. The surface tension was measured by the drop volume technique described in our previous paper.[1] The temperature was kept constant at 298.15 K by immersing the measuring cell in a thermostated water bath. The error estimated for the surface tension value was less than 0.05 mN m^{-1}.

Results and Discussion

It has been shown that the total molality of surfactants m and the composition of the second surfactant X_2 in the aqueous solution are the suitable thermodynamic independent variables to describe the adsorption behavior of surfactant mixture at constant temperature T and pressure p.[3,4] Here m and X_2 are defined as

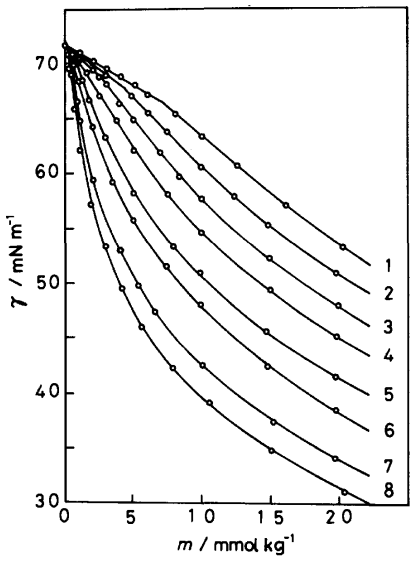
$$m = m_1 + m_2, \tag{1}$$

and

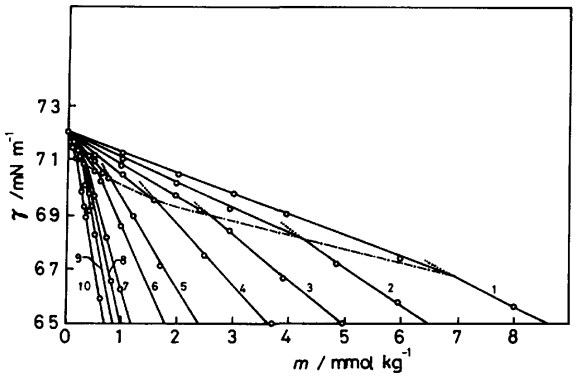
$$X_2 = m_2/(m_1 + m_2), \tag{2}$$

where the subscripts 1 and 2 refer to 2-(octylsulfinyl)ethanol and decylammonium chloride, respectively. The surface tension γ of the aqueous solution of surfactant mixture was measured as a function of m at various X_2 values at 298.15 K under atmospheric pressure.

Figure 1(a) shows the plot of γ against m at constant X_2. It is seen that each curve has a break point at a relatively high surface tension and a relatively low concentration. It is also found that the m value of the break point increases, while the corresponding γ value decreases, as X_2 increases. The detailed features are given in Fig. 1(b), in which the γ *vs.* m curves are magnified around the break points. It has been already verified that the presence of a break point on the γ *vs.* m curve results from the phase transformation between two states in the adsorbed film.[1–4] Accordingly we can say that the phase transition takes place also in the present nonionic–ionic surfactant system. Taking up the γ values at a given m value from Figs. 1(a) and 1(b), the γ *vs.* X_2 curves are obtained as shown in Fig. 2. It is seen that γ increases with increasing X_2 and some curves have the break points connected by the dotted line. It is clear that the regions above and below the dotted line correspond to



(a)



(b)

Fig. 1. (a) Surface tension *vs.* total molality curves at constant bulk composition: (1) X_2=1, (2) 0.979, (3) 0.950, (4) 0.901, (5) 0.801, (6) 0.700, (7) 0.360, (8) 0. (b) Surface tension *vs.* total molality curves at constant bulk composition: (1) X_2=1, (2) 0.979, (3) 0.950, (4) 0.901, (5) 0.801, (6) 0.700, (7) 0.496, (8) 0.360, (9) 0.200, (10) 0.

the different states in the adsorbed films. The surface tension of the phase transition point denoted by γ^{eq} is plotted against X_2 in Fig. 3. The value of γ^{eq} decreases slightly up to about 0.8 and then rapidly with increasing X_2. This behavior is undoubtedly related to the difference in the surface activity between the two surfactants as will be discussed later.

Now let us develop our thermodynamic treatment[3,4,12] so as to be applicable to the nonionic-cationic surfactant mixture. Since decylammonium chloride is a uni-uni valent strong electrolyte and 2-(octylsulfinyl)ethanol is a nonionic surfactant, the surface tension of the aqueous solution is expressed in the differential form as a function of the chemical potential of species at constant temperature and pressure:

$$d\gamma = -\Gamma_1^H d\mu_1 - \Gamma_{2+}^H d\mu_{2+} - \Gamma_{2-}^H d\mu_{2-}, \quad (3)$$

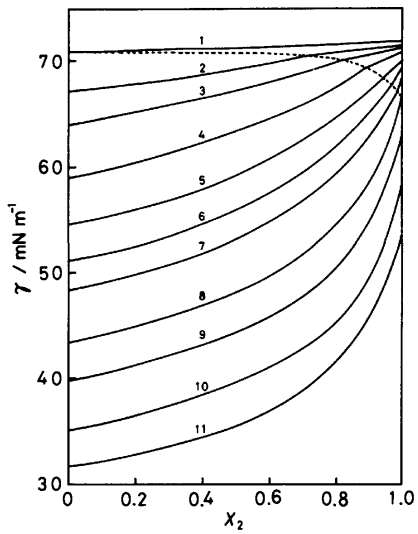


Fig. 2. Surface tension *vs.* bulk composition curves at constant total molality: (1) m=0.2 mmol kg^{-1}, (2) 0.5, (3) 0.8, (4) 1.5, (5) 2.5, (6) 3.5, (7) 4.6, (8) 7.25, (9) 10, (10) 15, (11) 20.

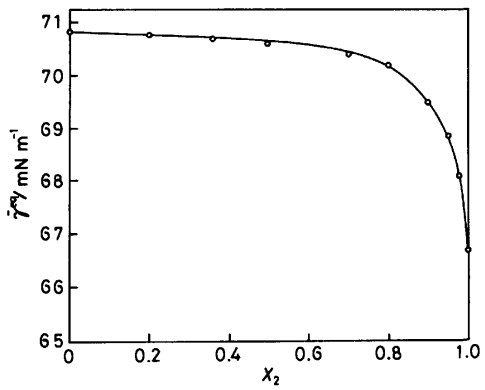

Fig. 3. Equilibrium surface tension *vs.* bulk composition curve.

where Γ_1^H, Γ_{2+}^H, and Γ_{2-}^H are the surface excess numbers of moles per unit surface area of 2-(octylsulfinyl)ethanol, decylammonium ion, and chloride ion, respectively. In Eq. 3, the surface excess quantities are defined with respect to the two dividing planes which make the surface excess numbers of moles of air and water be zero.[1,10] Taking notice that the suitable concentration variables are the total molality m and the composition X_2 defined by Eqs. 1 and 2 and assuming that the solution is ideal, Eq. 3 can be rewritten in the form

$$d\gamma = -RT[(\Gamma_1^H + 2\Gamma_2^H)/m]dm - RT[(2X_1\Gamma_2^H - X_2\Gamma_1^H)/X_1X_2]dX_2, \quad (4)$$

where Γ_2^H is the surface excess number of moles of DeAC defined by

$$\Gamma_2^H = \Gamma_{2+}^H = \Gamma_{2-}^H. \quad (5)$$

By introducing the total surface excess numbers of moles of surfactants defined by

$$\Gamma^{H} = \Gamma_1^{H} + \Gamma_2^{H} \quad (6)$$

and the composition of DeAC in the adsorbed film by

$$X_2^{H} = \Gamma_2^{H}/\Gamma^{H}, \quad (7)$$

Eq. 4 is rearranged to yield

$$d\gamma = -(RT\Gamma^{H}/m)(1+X_2^{H})dm - (RT\Gamma^{H}/X_1X_2)[(2-X_2)X_2^{H} - X_2]dX_2. \quad (8)$$

Thus we can evaluate the surface composition X_2^{H} by applying Eq. 8 to the experimental results:

$$X_2^{H} = [X_2 - (X_1X_2/m)(\partial m/\partial X_2)_{T,p,\tau}]/[(2-X_2) + (X_1X_2/m)(\partial m/\partial X_2)_{T,p,\tau}]. \quad (9)$$

The total surface density Γ^{H}, on the other hand, can be evaluated by

$$\Gamma^{H} = -[m/RT(1+X_2^{H})]/(\partial\gamma/\partial m)_{T,p,X_2}. \quad (10)$$

It should be noted that the value of Γ^{H} cannot be directly calculated from the derivative of γ with respect to m without knowing the values of X_2^{H} given by Eq. 9. This point is essentially different from the adsorption of ionic-ionic surfactant mixtures.

Let us first evaluate the composition of surfactants in the adsorbed film at constant T, p, and γ. Apply ing Eq. 9 to the m *vs.* X_2 curve shown by the full line in Fig. 4, which is obtained from Fig. 1(a), the value of X_2^{H} can be calculated numerically. The resulting m *vs.* X_2^{H} is depicted by the chain line in Fig. 4. Such a diagram gives us the relation between X_2^{H} and X_2 at a given value of γ. It is worth noting that the value of X_2^{H} is always smaller than the corresponding one of X_2. This implies that the difference in the surface activities between surfactants has a great influence on the surface composition. The diagrams 1 and 3, which are the ones for the gaseous and expanded films, respectively, have a shape essentially similar to each other, though the former is a deflated cigar type and the latter a swollen cigar one. When the phase transition takes place in the adsorbed film, the shape becomes more complicated as shown in Fig. 4 (diagram 2); the m *vs.* X_2 curve has a break point indicated by A and correspondingly the m *vs.* X_2^{H} curve changes discontinuously from the value of the gaseous film $X_2^{H,g}$ (point B) to that of the expanded film $X_2^{H,e}$ (point C). It is also seen that $X_2^{H,g}$ has a larger value than $X_2^{H,e}$, which is closely related to the variation of γ^{eq} with X_2 given in Fig. 3.[4] The present results are qualitatively akin to those of our previous ionic-ionic surfactant mixtures, but the diagrams are somewhat swollen compared with those of DAC-DeAC and DTAC-DeAC systems.[3,4] This suggests that OSE is more surface active than DTAC and DAC.

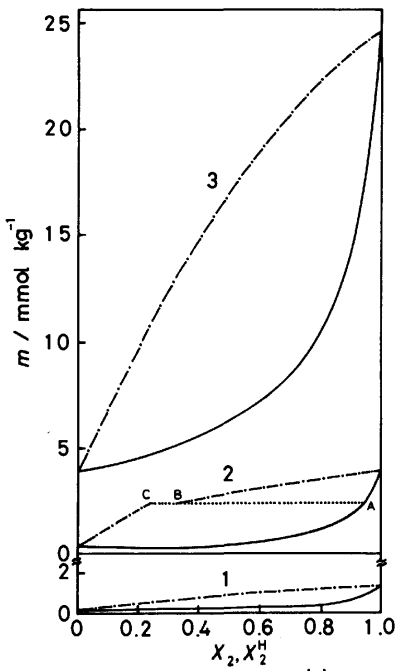

Fig. 4. Total molality *vs.* composition curves at constant surface tension: (1) γ=71 mN m^{-1}, (2) 69, (3) 50; (——) m *vs.* X_2, (-·-) m *vs.* X_2^{H}.

Now the values of Γ^{H} can be evaluated numerically by applying Eq. 10 to the experimental γ *vs.* m curves shown in Fig. 1(a) and using the X_2^{H} values calculated above. In Fig. 5 are drawn the Γ^{H} *vs.* m curves at various X_2 values. As is expected from Fig. 1, the value of Γ^{H} increases monotonously with m and changes discontinuously at the m value corresponding to the break point in Fig. 1. It is seen that the Γ^{H} value of OSE (X_2=0) is fairly large compared with that of DeAC (X_2=1). Taking account of the fact that the hydrocarbon chain length of OSE is shorter than that of DeAC, we can say that the repulsive force among the charged head groups of DeAC considerably diminishes its adsorption. Picking up the values of Γ^{H} at fixed m values in Fig. 5, the Γ^{H} *vs.* X_2 curves are depicted in Fig. 6. It is interesting to note that the variation of Γ^{H} with X_2 is considerably pronounced when X_2 is close to unity. Further, it is seen that the Γ^{H} value is nearly constant up to X_2=*ca.* 0.7 and then decreases suddenly with increase in X_2 at a high total concentration. This fact suggests that the OSE molecules play a predominant role in the adsorption behavior until the value of X_2 becomes considerably large because the surface activity of OSE is fairly high compared with that of DeAC.

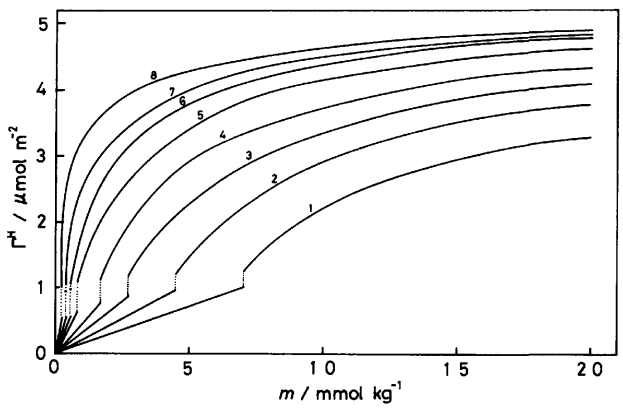

Fig. 5. Total surface density *vs.* total molality curves at constant bulk composition: (1) X_2=1, (2) 0.979, (3) 0.950, (4) 0.901, (5) 0.801, (6) 0.700, (7) 0.496, (8) 0.

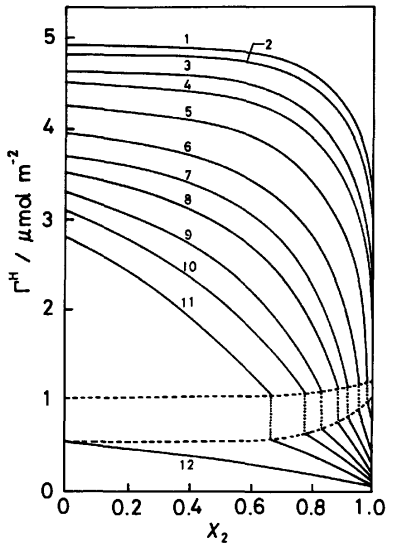

Fig. 6. Total surface density *vs.* bulk composition curves at constant total molality: (1) m=20 mmol kg^{-1}, (2) 15, (3) 10, (4) 8, (5) 5, (6) 3, (7) 2, (8) 1.5, (9) 1, (10) 0.75, (11) 0.5. (12) 0.2.

To make sure that the phase transition of the mixed adsorbed film takes place from a gaseous to an expanded state like those of pure OSE and DeAC films[2] and to get an insight into the film behavior, the surface pressure Π *vs.* the mean area per adsorbed molecule A curves are useful. Π and A are respectively defined by

$$\Pi = \gamma^0 - \gamma, \tag{11}$$

and

$$A = 1/N_A\Gamma^H, \tag{12}$$

where γ^0 is the surface tension of pure water and N_A is the Avogadro's number. By making use of Figs. 1 and 5, the Π *vs.* A curves at constant X_2 in Fig. 7 are obtained. It is seen that the shapes of the curves are similar to each other and vary regularly from the shape of OSE to that of DeAC. This proves that the phase transition of the mixed adsorbed films takes place from the gaseous to the expanded state.

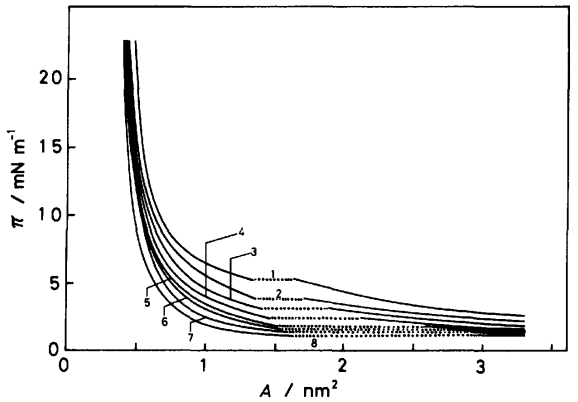

Fig. 7. Surface pressure *vs.* mean area per molecule curves at constant bulk composition: (1) X_2=1, (2) 0.979, (3) 0.950, (4) 0.901, (5) 0.801, (6) 0.700, (7) 0.496, (8) 0.

For mixed insoluble films spread on water, the Π *vs.* A curves are depicted under the condition that the film composition is kept constant. For mixed adsorbed films, the corresponding curves can be drawn; the results are shown in Fig. 8. Comparing Fig. 8 with Fig. 7, we notice that the dependence of the isotherm on the composition is more regular when X_2^H is kept constant. Further it is important to note that the equilibrium transition pressure γ^{eq} between the gaseous and expanded films increases with decreasing A in Fig. 8 while it is constant in Fig. 7.

We have previously shown[3,4] that the phase transition between the gaseous and expanded states of the mixed adsorbed film can be well described by the plots of γ^{eq} against the compositions of the gaseous film $X_2^{H,g}$ and the expanded film $X_2^{H,e}$ corresponding to the two-dimensional phase diagram used commonly in the study of mixed insoluble monolayers.[13] The numerical values of $X_2^{H,g}$ and $X_2^{H,e}$ can be obtained from the diagram 2 in Fig. 4 and the analogous ones at other γ^{eq} values; the phase diagram is illustrated in Fig. 9. The areas above the γ^{eq} *vs.* $X_2^{H,g}$ curve and below the γ^{eq} *vs.* $X_2^{H,e}$ curve correspond to the region of the gaseous and the expanded phase, respectively. It turns out that the value of $X_2^{H,e}$ is smaller than that of $X_2^{H,g}$ over the whole range. This observation is the same as that obtained for the ionic-ionic surfactant

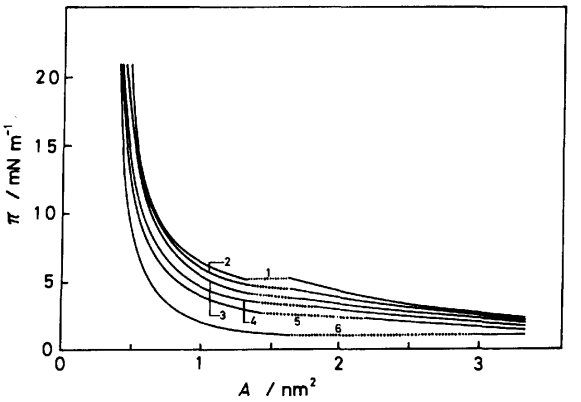

Fig. 8. Surface pressure *vs.* mean area per molecule curves at constant surface composition: (1) X_2^H=1, (2) 0.8, (3) 0.6, (4) 0.4, (5) 0.2, (6) 0.

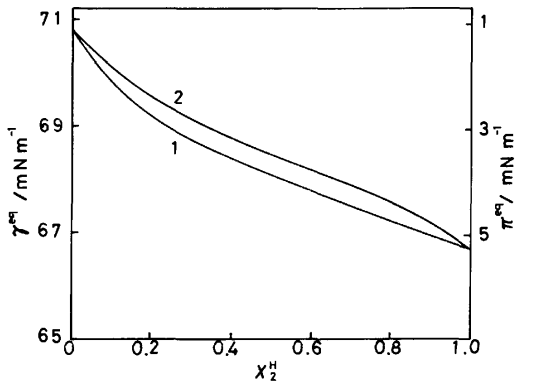

Fig. 9. Equilibrium surface tension (pressure) *vs.* surface composition curves: (1) $\gamma^{eq}(\Pi^{eq})$ *vs.* $X_2^{H,e}$, (2) $\gamma^{eq}(\Pi^{eq})$ *vs.* $X_2^{H,g}$.

mixtures in our previous papers.[3,4] The phase diagrams, however, are different in shape; the present one has a cigar form and the previous ones have crescent shaped forms. This fact indicates that the difference in the surface activity between two surfactants of the present system is larger than DAC–DeAC and DTAC–DeAC systems.

Magnetic Circular Dichroism and Electronic States of Tetrachloroplatinate(II) and Tetrachloropalladate(II) Ions

Kazuhiko NAKAYAMA,* Takashi KOMORITA, and Yoichi SHIMURA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received August 25, 1983)

The magnetic circular dichroism (MCD) spectra of K_2PtCl_4 and K_2PdCl_4 have been carefully remeasured over the visible-near UV region. The examination of the electronic absorption and the MCD spectra together with their Gaussian analyses strongly suggests that the band of K_2PtCl_4 at 30.3×10^3 cm^{-1} contains both $\Gamma_5(^1E_g)$ and $\Gamma_3(^1B_{1g})\leftarrow\Gamma_1(^1A_{1g})$ transitions, and the band of K_2PdCl_4 at 21.1×10^3 cm^{-1} all three spin-allowed d-d transitions. The separation of the $\Gamma_2(^1A_{2g})$ and $\Gamma_5(^1E_g)$ excited states is considerably large with K_2PtCl_4 as compared with K_2PdCl_4. The MCD for the high-intensity absorption bands in K_2PtCl_4 is different from that reported previously. On the basis of new MCD result, the bands at 43.3 and 46.6×10^3 cm^{-1} have been assigned to d-p transitions, $a_{2u}(p_z)\leftarrow a_{1g}(d_{z^2})$ and $e_g(d_{xz,yz})$, respectively.

The solution MCD spectrum of K_2PtCl_4 was obtained firstly by D. S. Martin, Jr. *et al.*[1] for the d-d transition region, and then by McCaffery *et al.*[2] over the visible-near UV spectral region. That of K_2PdCl_4 was measured partly by the latter group. We have reinvestigated the spectra of these two compounds carefully in order to clarify the electronic states of square-planar complexes, providing more reliable spectra over a broader wave number range.

The electronic states of $PtCl_4^{2-}$ and $PdCl_4^{2-}$ have been studied most extensively by solution, single-crystal, and polarized single-crystal absorption spectra, and moreover polarized single-crystal reflection and MCD spectra, as well as ligand field and molecular orbital theories, angular overlap treatments, and so on; then several different spectral assignments have been made (Tables 1 and 2). One of the major problems remaining unsettled is the position of the d_{z^2} metal orbital, and another is the origins of the high-intensity bands of $PtCl_4^{2-}$. This paper intends to throw light on these problems, together with the assignments of the other bands, consistent with many experimental facts given by previous workers.

Experimental

Materials. Potassium tetrachloroplatinate(II) was purchased from Higuchi Chemical Labolatory Ltd., and was recrystallized from an aqueous solution containing hydrochloric acid.

Potassium tetrachloropalladate(II) was prepared from palladium chloride and potassium chloride.

Measurements. Electronic absorption spectra were recorded with a Hitachi 330 spectrophotometer, and MCD spectra with a JASCO MOE-1 spectropolarimeter in a magnetic field of 1.5 T, being remeasured with inversion of magnetic field in order to obtain a greater precision.[30] Spectral measurements of K_2PtCl_4 and K_2PdCl_4 were made in 0.50 M and 2.0 M HCl aqueous solutions, respectively, at room temperature (1 M=1 mol dm^{-3}).

Gaussian Analyses. Gaussian analyses of absorption and MCD curves were performed using a version of program LGNS[31] adapted to the ACOS computer system. In the MCD curve analysis of K_2PtCl_4, the spectrum was divided into two parts (22.0×10^3—26.4×10^3 cm^{-1} and 26.0×10^3—34.2×10^3 cm^{-1}) in order to keep a precision in weak bands. An A term was analyzed as two B terms with opposite signs. All the calculations were carried out at Computation Center, Osaka University.

Results and Discussion

Ligand-field Absorption Bands. In a square-planar d^8 system (D_{4h}) without spin-orbit coupling, the d-d transitions ($d_{x^2-y^2}\leftarrow d_{xy}$, $d_{xz,yz}$, and d_{z^2}) give rise to six excited states: $^{1,3}A_{2g}$, $^{1,3}E_g$, and $^{1,3}B_{1g}$. These states are split and scrambled under spin-orbit coupling into 12 excited states.

$$d_{x^2-y^2}\longleftarrow d_{xy}\quad\begin{cases}^3A_{2g}(\Gamma_1+\Gamma_5)\\ ^1A_{2g}(\Gamma_2)\end{cases},$$

$$d_{x^2-y^2}\longleftarrow d_{xz,yz}\quad\begin{cases}^3E_g(\Gamma_1+\Gamma_2+\Gamma_3+\Gamma_4+\Gamma_5)\\ ^1E_g(\Gamma_5)\end{cases},$$

$$d_{x^2-y^2}\longleftarrow d_{z^2}\quad\begin{cases}^3B_{1g}(\Gamma_4+\Gamma_5)\\ ^1B_{1g}(\Gamma_3)\end{cases}.$$

1) K_2PtCl_4: Absorption and MCD data are given in Fig. 1 and Table 3. The assignment of the band at 25.6×10^3 cm^{-1} has been well established ($\Gamma_2(^1A_{2g})\leftarrow\Gamma_1(^1A_{1g})$) by the polarized absorption spectra.[6-9,28] The band at 30.3×10^3 cm^{-1} has been assigned to $\Gamma_5(^1E_g)\leftarrow\Gamma_1(^1A_{1g})$ by the MCD spectrum[1,2] and the polarization properties[6,9,28] (Table 1). By careful examination of the band shape, it is found to be unsymmetrical (Figs. 1 and 2), which suggests that there is another component in the higher energy side. The MCD spectrum also

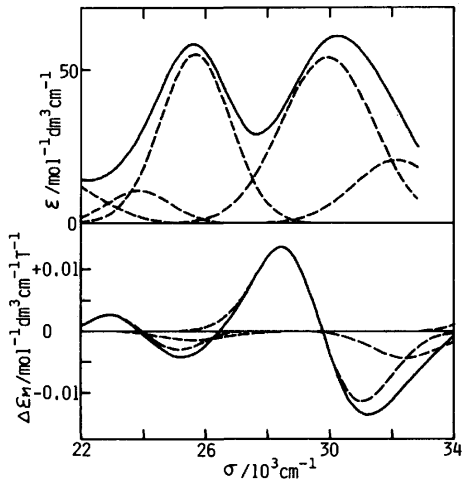

Fig. 2. Gaussian analyses of K_2PtCl_4. ------: Gaussian components and ——: sum of them. The sum fits in very closely with the experimental curve to such an extent that it is impossible to show the difference between them in this figure. An A-term curve is given by a sum of two B terms with opposite signs (See Experimental). Standard deviations are 0.11 $mol^{-1}dm^3cm^{-1}$ for the absorption curve, and 3.4×10^{-5} (in $(22.0—26.4)\times10^3cm^{-1}$) and 1.3×10^{-4} $mol^{-1}dm^3cm^{-1}T^{-1}$ (in $(26.0—34.2)\times10^3$ cm^{-1}) for the MCD one.

suggests the presence of a positive B term for the component. The results of Gaussian analyses for the absorption and MCD curves support this expectation (Fig. 2 and Table 5).[32] It seems reasonable to assign the component to the third spin-allowed d-d transition, $\Gamma_3(^1B_{1g}) \leftarrow \Gamma_1(^1A_{1g})$.

Gaussian analysis of the absorption curve indicates the existence of a minor component under the lower edge of the band at 25.6×10^3 cm^{-1}. This component has been detected in the polarized single-crystal spectra at liquid helium temperature,[8,9,28] and assigned to $\Gamma_5(^3B_{1g}) \leftarrow \Gamma_1(^1A_{1g})$. The MCD exhibits a negative A term in the transition region (Fig. 1), compatible with an assignment to a degenerate excited state; moreover it has the same sign as the A term for the $\Gamma_5(^1E_g)$ state with which the excited state is mixed. This interpretation can explain the MCD band at 22.9×10^3 cm^{-1} near the valley of the absorption spectrum, and leads to the result that the MCD band at 25.2×10^3 cm^{-1} primarily consists of the negative part of the negative A term for $\Gamma_5(^3B_{1g}) \leftarrow \Gamma_1(^1A_{1g})$ rather than the positive B term for $\Gamma_2(^1A_{2g}) \leftarrow \Gamma_1(^1A_{1g})$ as mentioned previously.[2] Thus the latter is considerably smaller than the appearance (Fig. 2 and Table 5). This is consistent with the fact that the MCD under the absorption band at 30.3×10^3 cm^{-1} resembles that in the spin-allowed d-d transition region of K_2PdCl_4, very closely in shape, or the ratio of the positive band to the negative one (*vide infra*, Figs. 1 and 3).

a—c, f—i, k, l) As in Table 1. d) For the bands 7 and 8, in an aqueous solution containing Cl^-. e) π-s: Pd(5s)←Cl(π). j) Not $PdCl_4^{2-}$.

The assignments for the bands at *ca.* 18×10^3 and 21×10^3 cm^{-1} are not straightforward because of many possibilities of spin-triplet excited states, the MCD spectrum also indicating the presence of more than two components in the region. However, it is likely that these bands are tentatively assigned to $\Gamma_1(^3A_{2g}+^3E_g)+\Gamma_2(^3E_g)+\Gamma_5(^3A_{2g}+^3E_g)$ and $\Gamma_3(^3E_g)+\Gamma_5(^3A_{2g}+^3E_g)$ respectively, on the basis of the polarized absorption spectra[9,11] and the available energy calculations.[10,29] (The Γ_4 components arising from $^3B_{1g}$ and ^3E_g are expected to have almost zero intensity since no Γ_4 state is produced from spin- or orbitally-allowed one-electron-transitions with close transition energies).

2) K_2PdCl_4: In general, square-planar palladium(II) complexes have remarkably reduced intensities of the spin-triplet transitions relative to those of the spin-singlet ones, in comparison with the platinum analogs; so, for simplicity we may neglect spin-orbit coupling for palladium(II) complexes in a discussion of the electronic states.

Absorption and MCD data are given in Fig. 3 and Table 4. The shoulder centered at *ca.* 16.9×10^3 cm^{-1} is roughly assigned to the spin-forbidden d-d transitions, $^3A_{2g}$, ^3E_g, and/or $^3B_{1g}\leftarrow{}^1A_{1g}$. Further details of these transitions will not be discussed.

The main band with a peak at 21.1×10^3 cm^{-1} is apparently unsymmetrical, which indicates the presence of transition components more than one. The MCD under the band is very similar to that for the band at 30.3×10^3 cm^{-1} of K_2PtCl_4 as described in the

previous section. From this observation it is reasonable to consider that the band at 21.1×10^3 cm^{-1} includes the same transition components (^1E_g and $^1B_{1g}\leftarrow{}^1A_{1g}$) as the latter band. The cross point (or zero point) of the apparent A term exists at higher energy than the absorption peak; therefore, it can be predicted that there is another absorption component at lower energy than the cross point. Then the component should correspond to the band at 25.6×10^3 cm^{-1} of K_2PtCl_4, being assigned to the $^1A_{2g}\leftarrow{}^1A_{1g}$ transition. This prediction is supported by the polarized absorption spectra.[17,25] The MCD for the transition is expected to be considerably weak from a comparison between two MCD curves of the Pd and Pt compounds in the spin-allowed d-d transition region.

The absorption band at $21.1\times10^3\,cm^{-1}$ consequently contains all three spin-allowed d-d transitions. On the basis of this conclusion, the Gaussian analyses of the absorption and MCD curves were carried out (Fig. 4), the numerical data being given in Table 5 together with the assignments. These are compatible with the polarized absorption spectra.[17,25]

3) Comparison of Two Compounds: The electronic structures of the two compounds are different in two points. Firstly, the separation of the $\Gamma_2(^1A_{2g})$ and $\Gamma_5(^1E_g)\leftarrow\Gamma_1(^1A_{1g})$ transitions is considerably large with K_2PtCl_4 as compared with K_2PdCl_4. This seems to be primarily due to the high π-bonding character of Pt–Cl over Pd–Cl bonds.[29] Secondly, the electronic spectrum of K_2PtCl_4 exhibits a structure in the region of the spin-triplet transitions, for which the MCD is also complicated. This fact can be attributed to the substantial spin-orbit coupling. In K_2PdCl_4 the electronic and MCD spectra are simplified because of a minor spin-orbit coupling as assumed previously.

Considering the above two points, the absorption and MCD spectra of K_2PdCl_4 can be easily correlated with those of K_2PtCl_4 and in fact they correspond to each other very well. That the $\Gamma_3(^1B_{1g})\leftarrow\Gamma_1(^1A_{1g})$

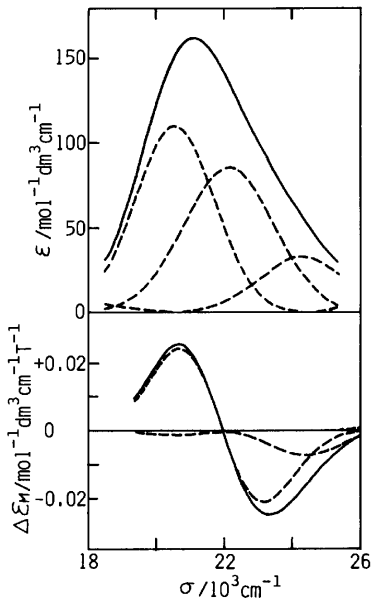

Fig. 4. Gaussian analyses of K_2PdCl_4. See the figure caption of Fig. 2. Standard deviations are 0.27 $mol^{-1}\,dm^3\,cm^{-1}$ and $2.1\times10^{-4}\,mol^{-1}\,dm^3\,cm^{-1}\,T^{-1}$ for the absorption and MCD curves, respectively.

transition has never been evidently identified seems to be ascribed to its low intensity, which is valid for both compounds (Figs. 2 and 4, and Table 5). A combination of this deduction with the data of the polarized single-crystal absorption spectra[9,28] leads to the following result: the low transition-probability with in-plane polarized light is responsible for the low intensity of the $\Gamma_3(^1B_{1g}) \leftarrow \Gamma_1(^1A_{1g})$ transition, at least in K_2PtCl_4. That is to say, the transition does not largely couple with the e_u molecular vibration, but with the b_{2u} one to gain the intensity. This interpretation can also explain the difference in the peak-positions at *ca.* 29—30×10^3 cm^{-1} between the in- and out-of-plane polarized spectra,[8,9,28] which had been a troublesome problem in an assignment of the absorption bands. In brief, the band at 29.2×10^3 cm^{-1} in the in-plane polarized spectrum[9] is composed mainly of the $\Gamma_5(^1E_g) \leftarrow \Gamma_1(^1A_{1g})$ transition, whereas the band at 29.8×10^3 cm^{-1} in the out-of-plane polarized spectrum[9] includes the $\Gamma_3(^1B_{1g}) \leftarrow \Gamma_1(^1A_{1g})$ transition to a considerable extent in addition to the $\Gamma_5(^1E_g) \leftarrow \Gamma_1(^1A_{1g})$ one. As to K_2PdCl_4, a similar discussion cannot be made owing to the smaller splitting between the $^1A_{2g}$ and $^1E_g+{}^1B_{1g} \leftarrow {}^1A_{1g}$ transitions.[17,25]

High-intensity Absorption Bands. *1) K_2PtCl_4*: The MCD above 35×10^3 cm^{-1} is different from that reported by McCaffery *et al.*[2] in two substantial points. First, they had observed a shoulder at *ca.* 44×10^3 cm^{-1}, whereas we have never detected it in spite of careful measurements. Secondly, they had observed a positive B term coinciding with the absorption peak at 46.2×10^3 cm^{-1}; however, we have done a positive A term corresponding to the absorption peak. From the facts that we have measured the MCD spectrum in the same solvent as used by McCaffery *et al.*, and that no difference is found between both absorption spectra; low resolving power of their CD instrument seems to have precluded accurate recordings.

The Gaussian analysis of the absorption curve above 42×10^3 cm^{-1} indicates the presence of absorption components at *ca.* 43.3×10^3 cm^{-1} and 46.5×10^3 cm^{-1} (Table 5). McCaffery *et al.* assigned the 43.3×10^3-cm^{-1} band to $^1A_{2u}+{}^1E_u(\pi) \leftarrow {}^1A_g$ ($b_{1g}(d_{x^2-y^2}) \leftarrow b_{2u}(\pi)+e_u(\pi)$), and the 46.5×$10^3$-cm^{-1} one to $^1A_{2u} \leftarrow {}^1A_{1g}$ ($a_{2u}(p_z) \leftarrow a_{1g}(d_{z^2})$) (Fig. 5). Kroening *et al.*[21] and Elding and Olsson[27] assigned the former band to $^1E_u \leftarrow {}^1A_{1g}$ ($a_{2u}(p_z) \leftarrow e_g(d_{xz,yz})$). Both assignments are based on the MCD result of McCaffery *et al.*; however, these assignments should be reconsidered from the situation described above.

The main band at 46.6×10^3 cm^{-1} shows an A-term MCD, which requires an assignment to a degenerate

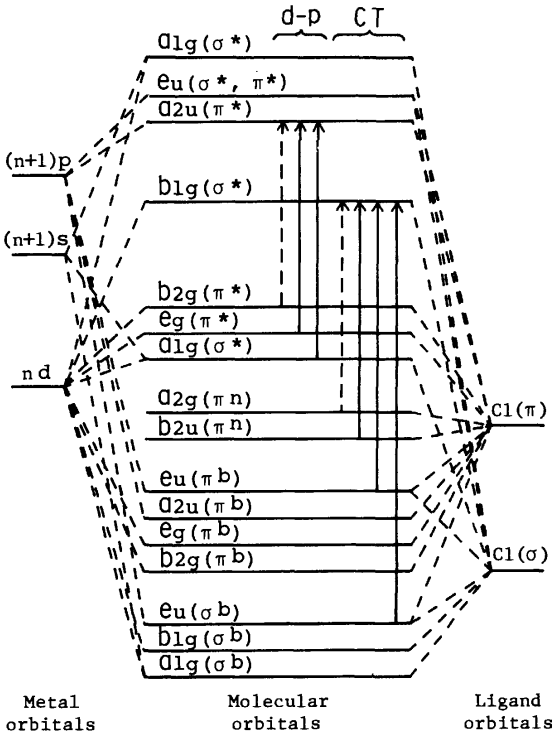

Fig. 5. Relative molecular orbital energy levels for square-planar MCl_4^{2-} complexes (D_{4h}). In a d^8 system, the $b_{2g}(\pi^*)$ and all the orbitals below it are doubly occupied. Transitions to be considered in the assignments of high-intensity bands are shown with full-drawn (for allowed transitions) and dashed (for orbitally-forbidden ones) arrows.

excited state. Considering simply, there are three candidates: $b_{1g}(d_{x^2-y^2}) \leftarrow e_u(\sigma)$, $b_{1g}(d_{x^2-y^2}) \leftarrow e_u(\pi)$, and $a_{2u}(p_z) \leftarrow e_g(d_{xz,yz})$ (Fig. 5). This band is the lowest dipole-allowed transition correlated to a degenerate excited state, and a $b_{1g} \leftarrow e_u(\sigma)$ transition generally occurs in higher energy than the corresponding $b_{1g} \leftarrow e_u(\pi)$ one; therefore the assignment to the former is excluded. In K_2PdCl_4 a negative A term has been observed for the $b_{1g} \leftarrow e_u(\pi)$, transition (*vide infra*). If this is the case with K_2PtCl_4, the assignment to it is also excluded, since the MCD for the band of interest exhibits a positive A term. On the other hand, the band which has been assigned to $a_{2u} \leftarrow e_g$ in $[Pt(NH_3)_4]^{2+}$,[33,34] $[Pt(en)_2]^{2+}$,[34] and $[Pt(tn)_2]^{2+}$,[34] shows a positive A term. Thus, the band at 46.6×10^3 cm^{-1} can be reasonably assigned to the d-p transition, $a_{2u} \leftarrow e_g$ (Fig. 5).

The component at 43.3×10^3 cm^{-1} shows a B-term MCD. Although it is impossible to say definitely that the band exhibits only a B term from the MCD feature alone, the polarized reflection spectra by Anex and Takeuchi[23] indicate the existence of an out-of-plane polarized band with an in-plane polarized one in the region under consideration; therefore, the band should be assigned to a $^1A_{2u} \leftarrow {}^1A_{1g}$ transition. There are two transitions which agree with the excited state: $b_{1g}(d_{x^2-y^2}) \leftarrow b_{2u}(\pi)$ and $a_{2u}(p_z) \leftarrow a_{1g}(d_{z^2})$ (Fig. 5). In K_2PdCl_4 the former transition has a remarkably low intensity as a dipole-allowed transition,[25] as expected for a pure $\sigma^* \leftarrow \pi$ transition by Jørgensen.[35] If this is also the case with K_2PtCl_4, the band at 43.3×10^3 cm^{-1} is too intense to be assigned to $b_{1g} \leftarrow b_{2u}$. The assignment $a_{2u} \leftarrow a_{1g}$, combined with that of the band at $46.6 \times 10^3 cm^{-1}$ seems at a glance to be inconsistent with the corresponding d-d transitions. However, this might be rationalized by the difference in interelectronic repulsion and configuration interaction between the d-d and d-p transitions.[25] Particularly, the $^1A_{2u}(p_z \leftarrow d_{z^2})$ excited state is presumed to be lowered in energy by configuration interaction with the $^1A_{2u}(b_{1g}(d_{x^2-y^2}) \leftarrow b_{2u}(\pi))$ one close to it.[21] Therefore, the band at $43.3 \times 10^3 cm^{-1}$ is also assigned to a d-p transition ($a_{2u} \leftarrow a_{1g}$; Fig. 5).

The above assignments are not in conflict with the experimental results of Anex and Takeuchi,[23] who observed two bands, of which one is out-of-plane and the other is in-plane polarized around 44×10^3 cm^{-1}, the former occurring in lower energy. This order of two components agrees with our assignment. In the previous assignments,[23,27] the 43.3×10^3-cm^{-1} band in solution had been correlated with the higher-energy band (at 44.3×10^3 cm^{-1}) in crystal, and the 46.6×10^3-cm^{-1} band in solution with the lower-energy one (at 43.6×10^3 cm^{-1}) in crystal; then the difference in their relative positions between solution and crystal spectra had been explained by exciton theory.[23] However, our assignment makes the explanation needless.

Finally, the assignment of the shoulder at *ca.* 38×10^3 cm^{-1} remains. Most of the previous workers have assigned it to a d-d transition ($^1B_{1g} \leftarrow {}^1A_{1g}$). On the other hand, Gray and Ballhausen[5] have done it to a spin-forbidden charge-transfer (CT) transition, Ito *et al.*[14] to an orbitally-forbidden d-p one ($a_{2u}(p_z) \leftarrow b_{2g}(d_{xy})$; Fig. 5). In addition to these, there is also a possibility of a spin-forbidden d-p transition. The assignment to a d-d transition is easily excluded on the basis of the discussion made in the previous section. The MCD for the shoulder shows a negative B term, resembling apparently that for the band at *ca.* 29×10^3 cm^{-1} of K_2PdCl_4 (Figs. 1 and 3). However, the shoulder seems to be too remote from a dipole-allowed ligand-to-metal CT band (which is absent below 50×10^3 cm^{-1}) to be assigned to the orbitally-forbidden CT transition ($b_{1g}(d_{x^2-y^2}) \leftarrow a_{2g}(\pi)$) as in K_2PdCl_4 (*vide infra*). A similar difficulty arises for the possible assignment to a spin-forbidden CT transition. The single-crystal polarized spectra by Kroening *et al.*[21] have shown a band at *ca.* $36.5 \times 10^3 cm^{-1}$ in both polarizations. The band has so low intensity that it is not likely to have the same origin as the shoulder at 38×10^3 cm^{-1} in solution. Their data suggest that the neighboring band at higher energy which is presumed to correspond to the shoulder also appears in both polarizations. If the presumption is valid, the assignment to the orbitally-forbidden d-p transition ($a_{2u} \leftarrow b_{2g}$) is unreasonable. It is because that the transition is vibronically allowed by a coupling only with the b_{2g} molecular vibration, being out-of-plane polarized. On the other hand, the assignment to a spin-forbidden d-p transition can be a candidate if spin-orbit coupling is taken into account, although the assignment cannot explain the very simple MCD feature. As has been discussed so far, the assignment of the shoulder at 38×10^3 cm^{-1} is still ambiguous and thus further details will be deferred.

2) K_2PdCl_4: It has been found that both bands at 35.7 and 44.9×10^3 cm^{-1} are in-plane polarized, by the polarized reflection spectra;[23] and that in addition, the former includes a $^1A_{2u}$ component, by the polarized absorption spectra.[17,25] The MCD result is consistent with these facts. Therefore, the lower-energy band can be assigned to $^1A_{2u} + {}^1E_u(\pi) \leftarrow {}^1A_{1g}$ ($b_{1g}(d_{x^2-y^2}) \leftarrow b_{2u}(\pi) + e_u(\pi)$), and the higher-energy one to $^1E_u(\sigma) \leftarrow {}^1A_{1g}$ ($b_{1g} \leftarrow e_u(\sigma)$) (Fig. 5). In view of MCD, the $^1A_{2u}$, $^1E_u(\pi)$, and $^1E_u(\sigma) \leftarrow {}^1A_{1g}$ transitions correspond to a negative B term, a negative A term, and a positive A term, respectively.

The assignments to be considered for the shoulder at *ca.* 29×10^3 cm^{-1} are ones to spin-forbidden and orbitally-forbidden CT transitions.[14,27] In K_2PdBr_4 there is another band, which is assigned to a spin-forbidden CT transition,[25] in addition to the band corresponding to the shoulder of K_2PdCl_4; thus, the former assignment is excluded. The orbitally-forbidden CT transition ($b_{1g} \leftarrow a_{2g}$) is expected to be allowed *via* an e_u vibration, being in-plane polarized. This has been confirmed for the shoulder,[7,17] which supports the latter assignment.

The above all assignments (Tables 4 (footnotes) and 5) have been made on the basis of our MCD data and many experimental ones reported by previous workers. The study on the electronic spectra of square-planar complexes (particularly palladium(II)) with nitrogen and oxygen in addition to chlorine as coordinating atoms will be reported in the near future.

Spectrophotometric Determination of Lead, Zinc, and Cadmium after Extraction of Their Diethyldithiocarbamates into Molten Naphthalene and Replacement by Copper

Abdul WASEY, Raj K. BANSAL, Masatada SATAKE,*,† and Bal K. PURI
Department of Chemistry, Indian Institute of Technology, Hauz Khas, New Delhi-110016, India
†*Faculty of Engineering, Fukui University, Fukui 910*
(Received September 10, 1983)

A method is proposed for the extraction of lead, zinc, and cadmium as their diethyldithiocarbamates into molten naphthalene. These complexes are quantitatively extracted into molten naphthalene. After extraction, the solidified naphthalene containing the colorless complex of each of the above metals is dissolved in chloroform and the metal is replaced by copper(II) to develop a yellow color of copper(II) diethyldithiocarbamate. The absorbance is measured at 440 nm. Beer's law is obeyed in the concentration range of 5.0—130.0 μg for lead, 3.0—60.0 μg for zinc, or 5.0—100.0 μg for cadmium in 10 ml of the final solution. The molar absorptivities ($1\ mol^{-1}\ cm^{-1}$) and Sandell sensitivities ($\mu g/cm^2$) for lead, zinc, and cadmium are calculated to be 1.15×10^4, 0.0098, 1.11×10^4, 0.0059, and 1.15×10^4, 0.0098 respectively. Solutions containing 45.0 μg of lead, 40.0 μg of zinc, and 43.0 μg of cadmium separately gave mean absorbances of 0.250, 0.620, and 0.440 with standard deviations of 0.0027, 0.0059, and 0.0038, respectively. Conditions have been decided for the determination of lead, zinc, and cadmium in some alloys and synthetic mixtures.

Sodium diethyldithiocarbamate is one of the most popular and versatile organic reagents, which react with many metal ions.[1] Studies of this reagent for use in solvent extraction have revealed that even with the proper control of pH, this reagent is not selective in extracting specific metals although many masking agents have been used.[2] Liquid-liquid extraction no doubt is an excellent technique for the separation and concentration of metal ions. But it cannot be applied directly for those metal ions which form complexes with the chelating agents only at high temperature and form complexes having low solubilities at room temperatures.[3] In such cases, the metal complex is first precipitated at high temperature and then it is extracted into a suitable organic solvent at room temperature.[3] Thus the method is time consuming. Fujinaga and coworkers have developed a new method of extraction *i.e.* "Solid-liquid separation after liquid-liquid extraction" in which the above mentioned difficulty is overcome.[4,5] The technique is especially useful for the extraction of those metal ions which form complexes with complexing agents at high temperature.[3] In the present communication, conditions have been decided for the extraction of lead, zinc, and cadmium as their diethyldithiocarbamates into molten naphthalene and subsequent spectrophotometric determination after dissolution of the solid naphthalene containing the metal complex in chloroform and replacing the metal by copper(II) to develop a yellow color. The interference of various ions has been studied and the method is applied to the determination of lead, zinc and cadmium in some alloys.

Sodium diethyldithiocarbamate[6] has also been used for the spectrophotometric determination of copper after extraction into molten naphthalene in the pH range of 2.0—8.0. The molar absorptivity was reported to be $1.20\times10^4\ l\ mol^{-1}\ cm^{-1}$. It was compared with the present method.

Experimental

Reagents. Solutions of lead nitrate, zinc sulfate, and cadmium sulfate were prepared in distilled water from their A. R. grade reagents and standardized by the known methods.[7] A 1×10^{-3} M (1 M=1 mol dm^{-3}) solution of sodium diethyldithiocarbamate (Na ddtc) was prepared in distilled water.

Chloroform and naphthalene were tested for impurities spectrophotometrically before use.

Apparatus. An Elico pH meter and a Pye-Unicam SP-700 recording spectrophotometer were used.

General Procedure. An aliquot of each of the metal solution was taken in a beaker and 1 cm^3 of 1.0×10^{-3} M Na ddtc solution was added to it. The pH of the solutions was adjusted to 7.0 for lead, 4.5 for zinc, and 7.5 for cadmium with the buffer solution, perchloric acid (0.2 M) or sodium hydroxide (0.2 M) (Fig. 2). These solutions were transferred to 100 cm^3 round-bottom flasks and warmed in a water-bath at about 60 °C and then naphthalene (2.0 g) was added to each. The flask was stoppered and heating was continued until naphthalene melted. The mixture was stirred vigorously until the naphthalene solidified forming very fine crystals in all the cases. Once more the naphthalene was melted, shaken vigorously, and allowed to stand at room temperature. The naphthalene containing the colorless complex was separated by filtration, dried in the folds of a filter paper, and dissolved in chloroform. In each case, the solution was made exactly to 10 cm^3 in a volumetric flask. This 10 cm^3 extract in chloroform was treated with aqueous copper sulfate solution (10 cm^3 of 1×10^{-3} M) to develop a yellow color in the chloroform layer which was separated and dried with anhydrous sodium sulfate (2.0 g). A portion of this solution was taken in a 1-cm cell and the absorbance was measured at 440 nm in each case against the reagent blank.

Results and Discussion

Absorption Spectra. It has already been established that copper is extracted quantitatively into molten naphthalene as a diethyldithiocarbamate complex in the pH range of 2—11 and has an absorption maximum at 440 nm. The stability constant of copper(II) diethyldithiocarbamate as indicated in the literature is two times more than those of lead, zinc, and cadmium diethyldithiocarbamates.[8] Obviously these metals can be quantitatively replaced by copper from the chloroform layer into the aqueous layer after

their extraction as diethyldithiocarbamates.

The absorption spectra of sodium diethyldithiocarbamate and lead, zinc, and cadmium complexes in naphthalene and chloroform solution were recorded against water and reagent blank after replacing the metal by copper(II). It was observed that copper complex absorbed strongly at 440 nm, where the reagent blank absorbed negligibly (Fig. 1).

Effect of pH. Extractions were carried out at different pH's keeping other conditions constant. It was found that the extractions were quantitative in the pH range of 6.2—8.3 for lead, 4.8—9.3 for zinc, and 6.6—11.5 for cadmium (Fig. 2).

Effect of Reagent Concentration. At optimum pH, extractions were carried out at varying reagent concentrations. It was observed that the extractions were quantitative for 0.5—4.0 cm^3 of the reagent in all the cases (Fig. 3). So 1.0 cm^3 of the reagent was used throughout the experiments in all the cases.

Effect of Electrolytes. Various electrolytes such as sodium chloride, sodium nitrate, sodium acetate, and sodium perchlorate (0.01—1.0 M) caused no improvement in extraction, indicating no salting-out effect.

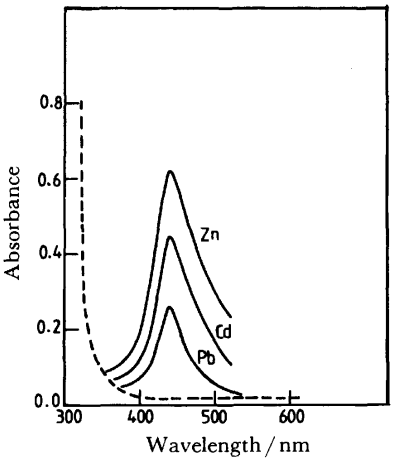

Fig. 1. Absorption spectra of Na ddtc and Cu complex in naphthalene-chloroform solution. Pb: 45.0 mg; Zn: 40.0 mg; Cd: 43.0 mg; Na ddtc (1×10^{-3} M); 2.0 ml in each case; pH: 8.3; naphthalene: 2.0 g. Reference: Water and reagent blank.

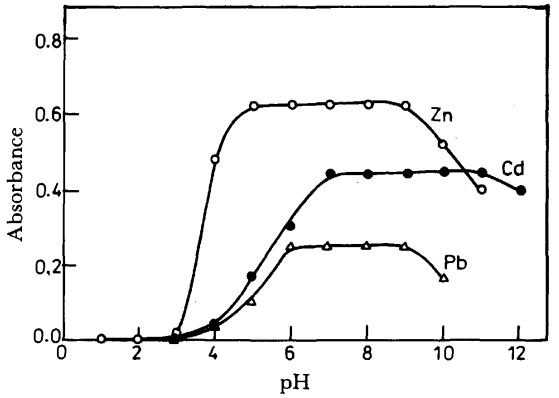

Fig. 2. Effect of pH. Pb: 45.0 mg; Zn: 40.0 mg; Cd: 43.0 mg; Na ddtc (1×10^{-3} M): 2.0 ml in each case; naphthalene: 2.0 g. Wavelength: 440 nm. Reference: Reagent blank.

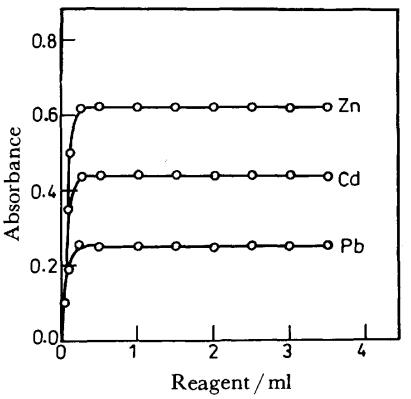

Fig. 3. Effect of reagent concentration. Conditions were same as in Fig. 2. Reference: Reagent blank.

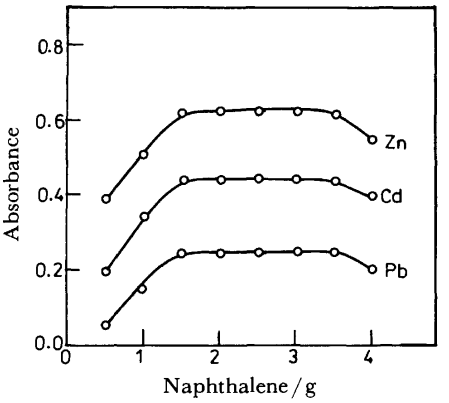

Fig. 4. Effect of amount of naphthalene. Conditions were same as in Fig. 2. Reference: Reagent blank.

Effect of Amount of Naphthalene. The amount of naphthalene was varied from 0.25—4.0 g. The absorbance remained constant when the naphthalene used was in the range of 1.4—3.5 g (Fig. 4).

Effect of Volume of Aqueous Phase. Since the volume of the aqueous phase is very large as compared to that of naphthalene (2.0 g), it was necessary to study the effect of the volume of the aqueous phase on the extraction on these metal ddtc complexes. The volume of the aqueous phase was varied from 10 to 70 cm^3. The extraction was quantitative when the volume of the aqueous phase did not exceed 40 cm^3 for lead and 50 cm^3 for zinc and cadmium. Above these volumes of the aqueous phase the extraction was not quantitative (Fig. 5).

Effect of Digestion and Shaking Times. The complex was digested at high temperature on a boiling water-bath (81 °C) between 1—10 min before extraction into naphthalene. It was observed that the constant absorbance was obtained by digesting between 2—10 min for cadmium, zinc, and lead. Therefore, 5 min of digestion time was selected. The effect of shaking time on the absorbance was also examined. It was observed that the extraction of the complex into molten naphthalene was very fast and no change was seen in the degree of the extraction when shaking time was varied from 1—20 min. Therefore, 2

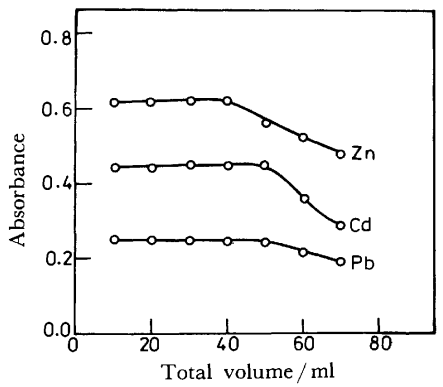

Fig. 5. Effect of volume of aqueous phase. Conditions were same as in Fig. 2. Reference: Reagent blank.

min of shaking time was chosen in all the cases for the further work.

Beer's Law and Sensitivity. Under the optimum conditions described above, calibration curves were constructed at 440 nm in each case. Beer's law held in the concentration range of 5.0—130.0 μg for lead, 3.0—60.0 μg for zinc, and 5.0—100.0 μg for cadmium in 10 cm^3 of the chloroform solution. The molar absorptivities (1 mol^{-1} cm^{-1}) and Sandell sensitivities (μg/cm^2) were calculated to be 1.15×10^4, 0.0098; 1.11×10^4, 0.0059; and 1.15×10^4, 0.0098, respectively (for lead, zinc, and cadmium). Solutions containing 45.0 μg of lead, 40.0 μg of zinc, and 43.0 μg of cadmium gave mean absorbances of 0.250, 0.620, and 0.440 with standard deviations of 0.0027, 0.0059, and 0.0038, respectively. The percentage of the extraction was established in each case by back-extracting the metal from the chloroform layer (before replacing by copper) with 20 cm^3 of 4 M HNO_3 and then determining the metals by atomic absorption spectrophotometry. It was 95.75, 92.40, and 95.80% respectively. These values are consistent with those obtained spectrophotometrically after metal ion exchange with copper(II).

Composition of the Metal Complex. The nature of lead, zinc, and cadmium diethyldithiocarbamates extracted into molten naphthalene was studied by the Job's method of continuous variation and the mole ratio method. A sharp peak at 0.33 mole fraction in Job's curve and a clear break at 1:2 (metal:Na ddtc) ratio in the mole-ratio plot suggested the extraction of $Pb(C_5H_{10}NS_2)_2$, $Zn(C_5H_{10}NS_2)_2$, and $Cd(C_5H_{10}NS_2)_2$ into the molten naphthalene.

Effect of Diverse Ions. The interference of various ions has been studied in detail. Generally, 5.0 mg of the anions and 1.0 mg of the cations were added, individually to the solutions containing 45.0 μg of lead, 40.0 μg of zinc, or 43.0 μg of cadmium before

		Cd: 30.0	29.7, 29.8, 29.6, 29.7, 29.7	29.7	1.10	29.9

extraction. Among the anions examined (Table 1), only iodide and sulfate interfered with the determination of lead, but their relatively low concentration can be tolerated. Citrate and Na_2H_2 edta interfered in all the cases, the extraction being impossible in the presence of Na_2H_2 edta in all the cases obviously due to higher stability constant of metal edta complex than that of the metal ddtc complex.[9] Citrate can be tolerated in a relatively low concentration (Table 1). Among the cations examined (Table 2), Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Pd^{2+} seriously interfered, but Co^{2+} and Ni^{2+} can be tolerated if present in a relatively low concentration. The interference of copper was eliminated by preextraction (chloroform extraction) at pH 2.5 and from the aqueous solution these metal ions (Pb, Zn, and Cd) can be extracted at their respective pH range. To eliminate the effect of palladium the extraction of lead, zinc, and cadmium were carried out at about pH 9 where palladium does not form complexes with Na ddtc. In all the cases Fe^{3+} was masked by adding 10 cm^3 of 5% NaF before extraction. The interference from Cu^{2+}, Co^{2+}, Ni^{2+}, Fe^{3+}, Pd^{2+}, Zn^{2+}, and Cd^{2+} in the determination of lead can also be eliminated by adding 10 cm^2 of 5% NaCN solution before extraction (Table 2).

Determination of Lead, Zinc, and Cadmium in Alloys and Synthetic Mixtures. A Sample of 100 mg of the alloy of known composition was taken in a beaker and 15—20 cm^3 of concentrated nitric acid were added. When the vigorous reaction was over, the solution was evaporated on a hot plate to about 5 cm^3. It was diluted with 50 cm^3 of distilled water, heated again for 20—25 min, filtered through a Whatman No.42 filter paper and the filtrate was collected in a 1 liter volumetric flask. The residue was washed ten times with dilute HNO_3 (1:1000) and the volume was made upto the mark with distilled water. An aliquot of this sample solution was taken and analyzed by the general procedure already stated. Five replicate determinations were made for each sample. The interference of various ions have been eliminated as stated in Table 2.

One of us (A.W.) is grateful to the C.S.I.R., New Delhi, India for financial assistance.

Syntheses of 2Fe-2S Ferredoxin Model Complexes of Cys-Containing Oligopeptides by Reaction with $Fe_2S_2^{2+}$ Ion or by Sulfide Incorporation

Norikazu UEYAMA, Satoru UENO, Michio NAKATA, and Akira NAKAMURA*
Department of Macromolecular Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received September 12, 1983)

The 2Fe-2S ferredoxin model complexes of two peptide ligands, Z-L-Ala-L-Cys-OMe (Z=benzyloxycarbonyl) and Z-L-Cys-L-Ala-L-Ala-L-Cys-OMe, were synthesized from $[NMe_4]_2[Fe_2S_2Cl_4]$ by addition of triethylamine. These were characterized by absorption, CD, and MCD spectra in dimethyl sulfoxide or *N,N*-dimethylformamide. Incorporation of inorganic sulfide to the iron(III) complex, $[Fe(Z\text{-cys-Ala-Ala-cys-OMe})_2]^-$ (rubredoxin models), results in the selective formation of a 2Fe-2S cluster by a controlling ability of the peptides.

The 2Fe-2S type of iron-sulfur proteins plays important roles in biochemical reactions, *e.g.* photosynthesis, and have been the subjects of many biological and physicochemical studies.[1] The structure of the active site in oxidized *Spirulina platensis* ferredoxin which is responsible for photosynthetic electron transfer in blue-green algae was confirmed by an X-ray analysis.[2] Three cysteinyl thiolates in one characteristic Cys-A-B-C-D-Cys-X-Y-Cys sequence bind a $[Fe_2S_2]^{2+}$ core.

Structural analogs of 2-Fe ferredoxins, such as $[Fe_2S_2(S_2\text{-}o\text{-xyl})_2]^{2-}$ (S_2-*o*-xyl=*o*-xylene-α,α'-dithiolate) were synthesized and the structure was confirmed crystallographically by Mayerle *et al.*[3] Such analogs have extremely low redox potentials, for example at −1.50 V (*vs.* SCE) in *N,N*-dimethylformamide (DMF) for $[Fe_2S_2(S_2\text{-}o\text{-xyl})_2]^{2-}$,[4] while spinach ferredoxin exhibits one at −0.42 V (*vs.* NHE).[5] The positive shift of the redox potentials of native 2Fe-2S ferredoxins is apparent. Probably the peptide sequence is responsible for this.

An important problem exists in the incorporation of S^{2-} into $[Fe(SR)_4]^-$ to give a 2Fe-2S type, since 2-Fe ferredoxins are formed from 1-Fe iron proteins in nature. Rydon *et al.* reported that the incorporation of S^{2-} and Fe^{3+} in dimethyl sulfoxide (DMSO) into denatured rubredoxin results in the formation of an Fe_4S_4 complex.[6] They also reported the formation of an Fe_4S_4 type complex from Ac-Gly_2-Cys-$(Gly_2\text{-Cys})_n$Gly-NH_2 (n=0—3), iron(III) chloride, and sodium sulfide in DMSO.[7] However, Sugiura *et al.* observed the formation of an Fe_2S_2 complex by the reaction among HS-$(CH_2)_n$SH, iron(III) chloride, and S^{2-}.[8] The difference in these studies is probably attributable to the structure of thiolate ligands; Cys-containing peptide or alkanedithiolate. The Gly-Gly peptide sequence used by Christou *et al.*[6] does not contribute to the bending of the peptide chains which facilitates chelation by the two cysteinyl thiolates. Therefore, we are interested in the synthesis of an Fe_2S_2 complex of Z-Cys-Ala-Ala-Cys-OMe by the reaction of $[Fe_2S_2Cl_4]^{2-}$ with the peptide. The Ala-Ala sequence, interposed between the two cysteinyl residues, promotes the formation of a hairpin turn conformation and enables to chelate to a tetrahedral iron(III) ion. The formation of the tetrapeptide chelate has already been confirmed for palladium(II) and iron(III) ions.[9] We also examined incorporation of S^{2-} into the oxidized rubredoxin analog of a Cys-X-Y-Cys peptide. Recently, Coucouvanis *et al.*[10] reported the synthesis of $[Fe_2S_2\{Ac\text{-}Gly_2\text{-}(cys\text{-}Gly_2)_2NH_2\}]^{2-}$ by the same procedure as mentioned above, but they have not examined the incorporation of S^{2-} into their complexes.

Experimental

All procedures were carried out under argon atmosphere.

Materials. All solvents were purified by distillation before use. The syntheses of Z-Ala-Cys-OMe and Z-Cys-Ala-Ala-Cys-OMe will be reported elsewhere.[11].

Syntheses of $[NMe_4]_2[Fe_2S_2(Z\text{-cys-Ala-Ala-cys-OMe})_2]$ and $[NMe_4]_2[Fe_2S_2(Z\text{-Ala-cys-OMe})_4]$. $[NMe_4]_2[Fe_2S_2Cl_4]$ was prepared by the reaction of $[NMe_4]_2[Fe_2S_2(S_2\text{-}o\text{-xyl})_2]$ (500 mg, 7.6×10^{-4} mol) with PhCOCl (0.46 cm^3, 4×10^{-3} mol) according to the procedure reported by Wong *et al.*[12] The 2Fe-2S complex of Z-Cys-Ala-Ala-Cys-OMe (**1**) was synthesized by the addition of triethylamine (2×10^{-3} cm^3, 1.43×10^{-5} mol) to a solution of $[NMe_4]_2[Fe_2S_2Cl_4]$ (1.7 mg, 3.7×10^{-6} mol) and Z-Cys-Ala-Ala-Cys-OMe (4.2 mg, 8.2×10^{-6} mol) in 2.0 cm^3 of *N,N*-dimethylformamide (DMF). The solution was concentrated *in vacuo* after 5 h. The crude product was washed with methanol and dried *in vacuo*.

$[NMe_4]_2[Fe_2S_2(Z\text{-Ala-cys-OMe})_4]$ (**2**) was synthesized by the reaction of Z-Ala-Cys-OMe (6.6 mg, 1.94×10^{-5} mol) with $[NMe_4]_2[Fe_2S_2Cl_4]$ (2.0 mg, 4.3×10^{-6} mol), followed by the addition of triethylamine (3×10^{-3} cm^3, 2.1×10^{-5} mol) in 2.0 cm^3 of DMF as mentioned above.

Incorporation of S^{2-} to Iron(III) Complex of the Cys-containing Peptides. A solution of $[Fe(Cys\text{-peptide})_4]^-$ was prepared by the same procedure reported previuosly.[13] Iron(III) chloride (3.7 mg, 2.3×10^{-5} mol) and Z-Ala-Cys-OMe (31.7 mg, 9.3×10^{-5} mol) or Z-Cys-Ala-Ala-Cys-OMe (24.2 mg, 4.7×10^{-5} mol) were dissolved in 2 cm^3 of DMSO. The addition of triethylamine (7×10^{-3} cm^3, 5×10^{-5} mol) to the solution gave a deep red-violet solution. Quick addition of Na_2S (1.8 mg, 2.3×10^{-5} mol) resulted in rapid development of a black color. The solution was characterized by absorption, CD, and EPR spectra. The values of ε for absorption and $\Delta\varepsilon$ for CD and MCD are based upon the molar concentration of $Fe_2S_2^{2+}$ ion.

Physical Measurement. Absorption spectra were measured on a JASCO UVIDEC-5A in visible region. CD and MCD spectra were recorded on a JASCO J-40 spectrometer equipped with electromagnets. The magnetic field was calibrated by using a $K_3[Fe(CN)_6]$ aqueous solution, $\Delta\varepsilon_M$ of 3.0 at 420 nm. EPR spectra were obtained at 77 K on a JEOL JESFE1X with 100 kHz magnetic field modulation. The *g*-value (g=1.981) was standardized by using Mn^{2+}. Cyclic voltammetries were measured with a Yanaco-P8-CV equipped with a function generator Yanaco Model FG-1218. Sample solutions were 10^{-3} mol dm^{-3} in DMF containing 0.05

mol dm^{-3} $[N(n\text{-}Bu)_4][ClO_4]$ as a supporting electrolyte. The voltammograms were recorded at 25°C *vs.* a saturated calomel electrode (SCE) as the reference.

Results and Discussion

Syntheses and Spectral Characterization of $[Fe_2S_2(Z\text{-}Ala\text{-}cys\text{-}OMe)_4]^{2-}$ *and* $[Fe_2S_2(Z\text{-}cys\text{-}Ala\text{-}Ala\text{-}cys\text{-}OMe)_2]^{2-}$. The Cys-containing peptide complexes possessing an Fe_2S_2 core were prepared quantitatively by the addition of triethylamine to a solution containing the corresponding peptides and $[Fe_2S_2Cl_4]^{2-}$. An attempt to isolate these complexes as crystals has been unsucessful due to its instability in air. Only a solid material was obtained.

Figure 1 shows the absorption and CD spectra of $[NMe_4]_2[Fe_2S_2(Z\text{-cys-Ala-Ala-cys-OMe})_2]$ (**1**) and $[NMe_4]_2[Fe_2S_2(Z\text{-Ala-cys-OMe})_4]$ (**2**), and the absorption spectra of $[NMe_4]_2[Fe_2S_2Cl_4]$. **1** exhibits three characteristic absorptions due to the core, $Fe_2S_2^{2+}$, at 325 nm (ε:11 100), 414 nm (ε:8 760), and 445 nm (ε:7 150) similar to those of oxidized native 2Fe-2S ferredoxin, while **2** shows only a broad absorption at 450—400 nm. Both complexes provide a strong absorption at 310 nm with similar intensity. Such three characteristic absorptions were reported for native 2Fe-2S ferredoxins and an alkanedithiolate complex. The 2Fe-2S complex of $Ac\text{-}Gly_2\{Cys\text{-}Gly_2\}_2\text{-}NH_2$ was reported to exhibit absorption maxima at 333, 423, and 458 nm.[10] The oxidized native 2Fe-2S ferredoxin was reported to show three absorption maxima at 323—325 nm (ε:12 000—15 000), 423 nm (ε:9 700), and 466 nm (ε: 8 520) in visible region.[14] Absorption maxima at 294 nm (ε:14 500), 338 nm (ε:16 200), 414 nm (ε:17 000), and 590 nm (ε:4 800) with a shoulder at around 455 nm in DMF were observed in the oxidized 2Fe-2S model complex, $[Fe_2S_2(S_2\text{-}o\text{-xyl})_2]^{2-}$.[3,4]

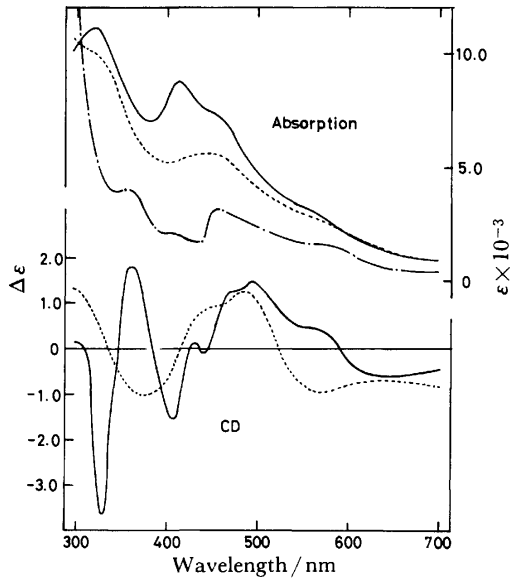

Fig. 1. Absorption and CD spectra of $[Fe_2S_2(Z\text{-Ala-cys-OMe})_4]^{2-}$ ----, $[Fe_2S_2(Z\text{-cys-Ala-Ala-cys-OMe})_2]^{2-}$ ——, $[Fe_2S_2Cl_4]^{2-}$ -·-·- in DMF.

CD spectra of **1** and **2** are quite different from that of the native 2Fe-2S ferredoxin as listed in Table 1. Well-defined troughs at 332, 408, and 660 nm and peaks at 363, 470, and 495 nm were observed in the DMF solution of **1**. The low values of Δε observed for **1** and **2** are distinct from the observed high extrema of native 2Fe-2S ferredoxins with the characteristic peptide sequence. The higher Δε values of **1** at 363 nm (Δε:+1.94) and 332 nm (Δε:−3.61) than those of **2** indicate that chelation by the tetrapeptide leads to the fixation of the peptide conformation where chiral effect of cysteine residues is not averaged.

As listed in Table 2, the MCD spectrum of **1** indicates typical peaks at 486 nm ($\Delta\varepsilon_M$:+0.58) and 526 nm ($\Delta\varepsilon_M$:+0.62) and a broad shoulder at 560 nm ($\Delta\varepsilon_M$:+0.54) of an oxidized 2Fe-2S core reported by Stephens *et al.* for 2Fe-2S ferredoxins of *Spirulina maxima* and putidaredoxin.[14]

Positive MCD transitions at 480 nm ($\Delta\varepsilon_M$:+0.76), and 566 nm ($\Delta\varepsilon_M$:+0.21) in **1** are also observed as well as the oxidized native 2Fe-2S ferredoxin. Unfortunately, assignments of the MCD transitions also in **1** or oxidized native 2Fe-2S ferredoxin were not possible because of the complexity of the energy levels of the Fe_2S_2 core. However, by comparing the native 2Fe-2S ferredoxins with 1Fe or 4Fe-4S ferredoxins, Stephens *et al.* reported that the native 2Fe-2S ferredoxins exhibit a characteristic shape with a positive MCD transition at 486 nm ($\Delta\varepsilon_M$:+0.58).[14] Generally, the MCD spectra of 4Fe-4S ferredoxins have the strongest peak ($\Delta\varepsilon_M$: +1.0—+1.8) at 380—390 nm. However, in the case of the model complex **1**, the MCD peak at 380—385 nm was weak ($\Delta\varepsilon_M$:+0.06) and the strongest MCD peak was observed at 480 nm ($\Delta\varepsilon_M$:+0.76) indicating presence of a 2Fe-2S core.

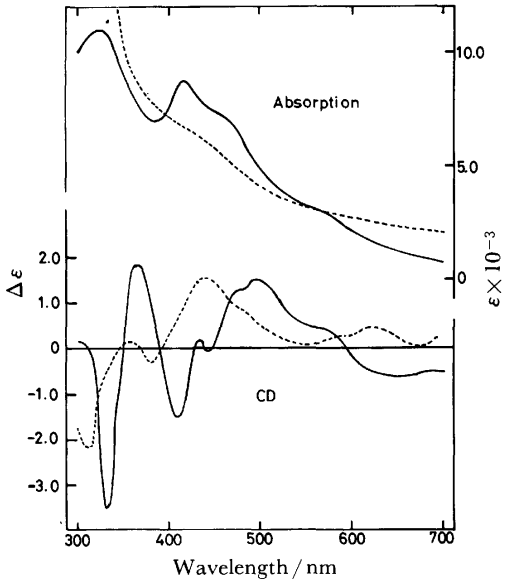

Fig. 3. Absorption and CD spectra of $[Fe_2S_2(Z\text{-cys-Ala-Ala-cys-OMe})_2]^{2-}$ —— and its reduced species with 10 equiv of dithionite complex of 18-crown-6 ---- in DMF.

Electrochemical and Chemical Reduction of $[Fe_2S_2(Z\text{-cys-Ala-Ala-cys-OMe})_2]^{2-}$. Importance of the peptide sequence in the stability of redox couple (2-/3-) was investigated by cyclic voltammetry. Figure 2 shows the cyclic voltammograms of **1** and **2** in DMF at room temperature. Although a reduction peak was observed at −1.22 V(*vs.* SCE) for **1** and −1.25 V(*vs.* SCE) for **2**, no oxidation peak has been recognized. At a low temperature (−12°C), an oxidation peak for **1** was observed ($E_{p,a}$: −1.23 V, $E_{p,c}$: −0.83 V, $i_{p,c}/i_{p,a}$=1/20), while it was undetectable for **2**. The results indicate that both synthetic complexes are readily decomposed by electrochemical reduction and suggest that the chelating peptide such as Z-Cys-Ala-Ala-Cys-OMe has a potential ability to maintain the $[Fe_2S_2]^+$ ion during the redox couple. A stable redox couple of $[Fe_2S_2(S_2\text{-}o\text{-xyl})_2]^{2-}$ in acetonitrile/hexamethylphosphoric triamide(HMPA) (7:3 v/v) was found by Mascharak *et al.*[4] Actually, at the same concentration (10^{-3} mol dm^{-3}) in DMF, a quasi-reversible redox couple ($i_{p,c}/i_{p,a}\simeq 1$) of $[Fe_2S_2(S_2\text{-}o\text{-xyl})_2]^{2-}$ was detected at −1.62 V($E_{p,a}$) and −1.44 V($E_{p,c}$) in fair agreement with their values in the different solvents. **1** or **2** exhibited a positive shift (ΔV=0.37—0.40 V) of the reduction peak in the cyclic voltammogram as compared with the reduction peak of $[Fe_2S_2(S_2\text{-}o\text{-xyl})_2]^{2-}$. Therefore, the reduction of **1** and **2** with $Na_2S_2O_4$ was examined. The reduction of a model complex, $[Fe_2S_2(S_2\text{-}o\text{-xyl})_2]^{2-}$, has been known to require sodium acenaphthylenide in HMPA.[4] Figure 3 shows the visible spectrum of **1** reduced by $Na_2S_2O_4$ complexed with 18-crown-6 in DMF.[15] The spectrum indicates the formation of a $[Fe_4S_4]^{2+}$ core possessing a characteristic absorption maximum at 420 nm (ε: 6 600) in DMF. Also the CD spectrum of the reduced species of **1** exhibits a different pattern from that of **1**. The CD maximum at 440 nm (Δε: +1.57) corresponds to that of $[Fe_4S_4(Z\text{-cys-Gly-Ala-cys-OMe})_2]^{2-}$.[16] The reduction of **2** by $Na_2S_2O_4$ provided the same type of a product having $[Fe_4S_4]^{2+}$ that was detected by an absorption maximum at 420 nm (ε: 4 820). The formation of $[Fe_4S_4X_4]^{2-}$ (X=SR, Cl) by the reduction of $[Fe_2S_2X_4]^{2-}$ was reported by Cambray *et al.*[17] and Wong *et al.*,[12] respectively, except for $[Fe_2S_2(S_2\text{-}o\text{-xyl})_2]^{2-}$. Thus, binuclear-to-tetranuclear conversions have been found to take place by chemical means, which are reflected by the irreversibility of the cyclic voltammograms of **1** and **2** at room temperature. The *o*-xylene-α,α′-dithiolate ligand prevents the $[Fe_2S_2]^+$ core from the reductive conversion to the $[Fe_4S_4]^{2+}$ core. The results suggest that chelation of the

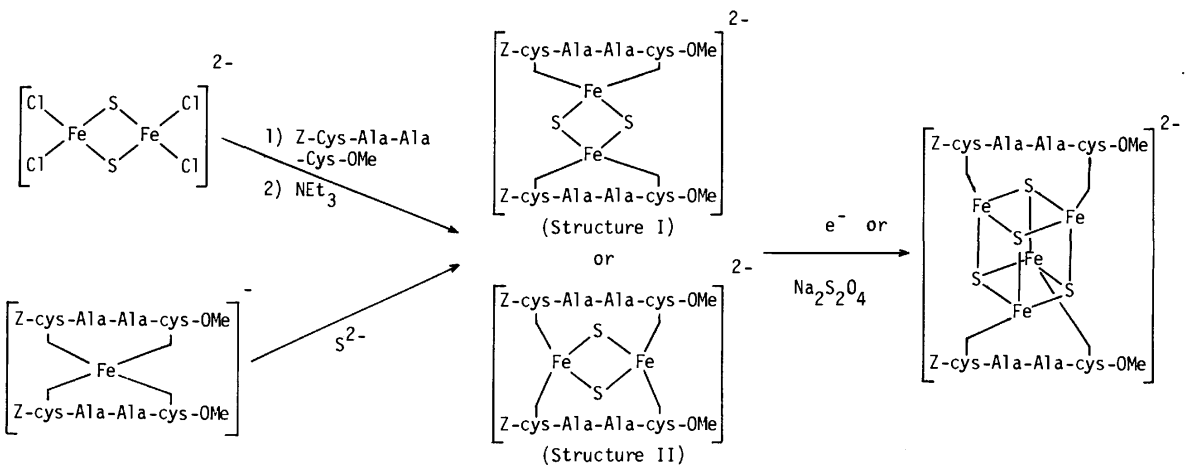

Fig. 4. Syntheses and reactions of the 2Fe-2S complexes of Z-Cys-Ala-Ala-Cys-OMe.

tetrapeptide is involved not for one iron(III) (structure I in Fig. 4) but for two iron(III) ions in a FeS_2Fe system (structure II) and that the alkanedithiolate ligand is more suitable for the chelation to one iron(III) ion. The coordination of Z-Cys-Ala-Ala-Cys-OMe in the structure II corresponds to that of the native Cys-X-Y-Cys sequence as reported with the X-ray analysis.[2] It is plausible that the complex having the structure II easily associates to the 4Fe-4S type by reduction.

Fe^{III}/Cys-containing peptides/S^{2-} Complexes. The formation of iron-sulfur clusters by incorporation of inorganic sulfide(S^{2-}) into Fe^{III}/Cys-containing peptide complexes was studied. On the basis of the investigation on iron-sulfur protein models, Sugiura *et al.*[8] and Cambray *et al.*[17] have found the selective formation of 2Fe-2S complexes from iron(III) complexes of simple thiolate ligands by incorporation of inorganic sulfide. On the other hand, Christou *et al.* reported the formation of a 4Fe-4S complex by the incorporation of inorganic sulfide into iron(III) complexes of Ac-Gly$_2$-(cys-Gly$_2$)$_4$-NH_2.[7] Thus, it is interesting to determine which type of complexes is formed by the incorporation of inorganic sulfide into the present Fe^{III}/peptide complexes. The peptide ligand probably controls the incorporation and the stability of the products.

The addition of an equimolar amount of Na_2S to a solution of Fe^{III}/Cys-containing peptide(1:4) complexes results in the rapid development of black color. We have already established that Fe^{III}/Cys-containing peptide(1:4) complexes provide a Fe(S-Cys)$_4$ core as a model of rubredoxin, especially in the case of macro-ring chelation by Z-Cys-Ala-Ala-Cys-OMe.[18] Tables 1 and 2 list the CD and MCD spectra of the products of the sulfide incorporation, *i.e.* Fe^{III}/Cys-containing peptide/S^{2-} complexes. The absorption spectrum of each of these complexes had maxima at 300 and 415 nm and a weak shoulder around 450 nm, similar to those of **1**. On the other hand, 4Fe-4S ferredoxin model complexes, $[Fe_4S_4(SR)_4]^{2-}$, show two absorption maxima around 300 and 410 nm in DMF or in DMSO/H_2O (8:2 v/v).[19] Sugiura *et al.* reported that the product formed between Fe^{III}/alkanethiolate complexes with inorganic sulfide has absorption maxima at 330, 410, and 450 nm and there is a considerable similarity in spectra between their complexes and the 2Fe-2S ferredoxins.[8] They revealed also that reconstituted adrenodoxins exhibit an absorption maximum at 410 nm with a weak shoulder at 450 nm which is due to a 2Fe-2S cluster.[20] From the comparison of these data with our results, a major component of an iron-sulfur cluster involved in the system, Fe^{III}/peptide complexes/S^{2-}, is suggested to be a 2Fe-2S cluster. The CD (Table 1) and MCD (Table 2) spectra of the Fe^{III}/Cys-containing/S^{2-} system were more highly structured than the corresponding absorption spectra(Table 1) and these are useful for identification of the complexes. In the case of the Fe^{III}/Z-Cys-Ala-Ala-Cys-OMe/S^{2-} system, CD troughs at 331 nm ($\Delta\varepsilon$:−2.71) and 401 nm ($\Delta\varepsilon$:−2.19), and peaks at 366 nm ($\Delta\varepsilon$:+1.14) and 477 nm ($\Delta\varepsilon$:+1.39) were observed, which correspond to those of **1** (Table 1), though the positions of absorption maxima are somewhat ambiguous. In order to compare with the above CD spectrum, $[Fe_4S_4(Z\text{-cys-Ala-Ala-cys-OMe})_2]^{2-}$ was synthesized by a ligand exchange reaction of $[(n\text{-}Bu)_4N]_2[Fe_4S_4(S\text{-}i\text{-}Pr)_4]$ with Z-Cys-Ala-Ala-Cys-OMe in solution.[16] The 4Fe-4S complex in DMF provides two CD troughs at 330 nm ($\Delta\varepsilon$:−0.8) and 400 nm ($\Delta\varepsilon$:−0.7), and two peaks at 360 nm ($\Delta\varepsilon$:+0.2) and 430 nm ($\Delta\varepsilon$:+0.9). The CD spectra of the Fe^{III}/Z-Cys-Ala-Ala-Cys-OMe/Na_2S (1:2:1) system indicate the preferential formation of an 2Fe-2S cluster although being not consistent completely with the CD extrema of **1**. The inconsistency between their CD extrema seems to be caused by the contamination of the 4Fe-4S cluster. The CD spectrum of the Fe^{III}/Z-Ala-Cys-OMe/S^{2-} complex was completely different from that of $[NMe_4]_2[Fe_2S_2(Z\text{-Ala-cys-OMe})_4]$ (Table 1) The low $\Delta\varepsilon$ values suggest that the Fe^{III}/Z-Ala-Cys-OMe/S^{2-} system results in the preferential formation of the 4Fe-4S cluster.

Recently the MCD spectra of ferredoxins of various 2Fe-2S and 4Fe-4S types have been reported in detailed.[11] Those data indicated that the 4Fe-4S ferredoxin in both $Fe_4S_4^{2+}$ and $Fe_4S_4^{+}$ states exhibit only positive MCD bands in all the region from 300 to 2000

nm, whereas the 2Fe–2S ferredoxins show positive and negative bands. The MCD spectra were used to establish whether the structure of the iron-sulfur centers in the peptide complexes is like 2Fe–2S or 4Fe–4S type. The tetrapeptide complex, Fe^{III}/Z-Cys-Ala-Ala-Cys-OMe/S^{2-} (1:2:1), exhibited the strongest peak at 482 nm ($\Delta\varepsilon_M$:+0.23) due to the 2Fe–2S cluster (Table 2). Therefore, the absorption, CD, and MCD results indicate that a 2Fe–2S cluster forms predominantly in the Fe^{III}/tetrapeptide/S^{2-} system and small amounts of other types of clusters are contaminated.

The 2Fe–2S cluster in these peptide complexes was also established by the analysis of the EPR spectra of the Fe^{III}/Cys-containing peptide/S^{2-} system. The EPR signals at g=4.18 of the peptide complexes disappeared completely on the addition of S^{2-} and new signals appeared at g=2.04, 2.00, and 1.98; g_{av}=2.01 for the tetrapeptide complex and at g_{av}=2.06 for the dipeptide complex. Laskowski *et al.* reported that a 4Fe–4S ferredoxin analog, $[Fe_4S_4(SCH_2Ph)_4]^{3-}$, exhibits two EPR signals at g=2.04 and 1.93 in acetonitrile below 15 K.[21] The EPR data of the reduced 2Fe–2S ferredoxin analog are not available at present. From these data and the fact that the EPR signals of the peptide complexes with inorganic sulfide are measurable at 77 K, it is apparent that the tetranuclear cluster are not preferentially formed at least by the simple addition of inorganic sulfide to Fe^{III}/Cys-containing peptide(1:4) complexes.

Thus, a major part of iron-sulfur clusters in the Fe^{III}/Cys-containing peptide/S^{2-} system is the 2Fe–2S type, which is different from the previous study of Rydon *et al.* on iron(III) complexes of sequential oligopeptide, Ac-Gly_2-(Cys-Gly_2)$_n$-NH_2.[7] Probably their peptides, having more than two Cys residues and Gly-Gly residues interposed between the two Cys residues, do not have any controlling power for the selective formation of a 2Fe–2S type ferredoxin core.

We thank Professor Yukio Sugiura for useful discussion on the characterization of 2Fe–2S complexes. The present work was supported by a Grant-in-Aid (No. 56430014) from the Ministry of Education, Science and Culture.

Preparation and Circular Dichroism Spectra of Cobalt(III) Complexes Containing an Optically Active $NH_2CH_2CH(CH_3)X^-$-*N,X* (X=S or Se) Ligand

Kyoko NAKABAYASHI, Kaoru DOI, Masaaki KOJIMA, and Junnosuke FUJITA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received September 24, 1983)

Several cobalt(III) complexes of the $[Co(apS \text{ or } apSe)(N_4)]^{2+}$ type were prepared, where apS and apSe denote chiral 1-amino-2-propanethiolate-*N,S* and 1-amino-2-propaneselenolate-*N,Se* ligands, respectively, and N_4 is (en=ethylenediamine)$_2$, (*R*-chxn=(*R,R*)-1,2-cyclohexanediamine)$_2$, or tren=tris(2-aminoethyl)amine. Their circular dichroism (CD) spectra were compared with one another and with those of complexes containing such ligands as achiral 2-aminoethanethiolate-*N,S*, 2-aminoethaneselenolate-*N,Se*, or chiral 1-amino-2-propanolate-*N,O* (apO). The vicinal CD curves of *S*-apS obtained from CD spectra of the en and *R*-chxn complexes are similar and very large in magnitude in the d-d absorption band region. These curves are very similar to the CD spectrum of $[Co(S\text{-apO})(NH_3)_4]^{2+}$. The vicinal CD curve of *S*-apSe shows a similar pattern, but the magnitude is smaller than those of the *S*-apS and *S*-apO ligands. The vicinal effect of the protonated *S*-apSH ligand is much smaller compared with that of its conjugate base (*S*-apS) ligand. The tren complexes of *S*-apS and *S*-apSe exhibit CD spectra fairly different from the vicinal CD curves of the respective ligands in the d-d absorption band region.

Nishide *et al.*[1] reported that cobalt(III) complexes containing a chiral aminoalkanolate-*N,O* chelate ligand such as *S*-apO (*S*-apOH=(*S*)-1-amino-2-propanol) exhibit exceptionally strong circular dichroism (CD) in the d-d absorption band region, which is attributed to the large vicinal effect of the alcoholate ligand. It is of interest to examine whether the corresponding thiolate-*N,S* and selenolate-*N,Se* chelate ligands give a similar effect. However, complexes with chiral aminoalkanethiolate-*N,S* or the corresponding selenolate-*N,Se* chelate ligands do not seem to be known except for $[Co(R\text{-cys})(en)_2]^+$ and $[Co(S\text{-pen})(en)_2]^+$ (en=ethylenediamine, *R*-cys=(*R*)-cysteinate(2-)-*N,S*, *S*-pen=(*S*)-penicillaminate(2-)-*N,S*).[2,3] The complexes with *R*-cys or *S*-pen will not be suitable for studying the vicinal effect, since the ligands have a carboxylato substituent and the chelate ring formed by *N,S* chelation will be conformationally unstable by forming hydrogen bonds between the carboxylato and other groups. In fact, the *R*-cys chelate ring in *Λ*-$[Co(R\text{-cys})(en)_2]^+$ in crystals forms a *δ* conformer with the axially disposed carboxylato group.[3] It is known that the vicinal effect of a chiral ligand is particularly sensitive to the conformation in a complex.[4]

In the present study, we have prepared complexes of the $[Co(apS \text{ or } apSe)(N_4)]^{2+}$ type, where apS and apSe denote 1-amino-2-propanethiolate-*N,S* and 1-amino-2-propaneselenolate-*N,Se* ligands, respectively, and N_4 is $(en)_2$, (*R*-chxn=(*R,R*)-1,2-cyclohexanediamine)$_2$, or tren=tris(2-aminoethyl)amine, and measured their CD spectra in order to see the vicinal effect of these chiral ligands. To our knowledge, the *S*- or *R*-apSe complexes prepared in this study are the first cobalt(III) complexes containing an optically active selenolate ligand.

Experimental

Ligands. The apSH ligand was prepared by the method of Owen[5] and resolved by the procedure of Piper *et al.*[6] to obtain $(+)_{589}$-apSH·HCl($[\alpha]_{589}$=+34.2° (*c* 1.2, H_2O); lit, $[\alpha]_{589}$=+35.3° (*c* 1.46, H_2O)[6]). The absolute configuration of the $(+)_{589}$-isomer has not been determined yet, but can be assigned to *S* configuration on the basis of the isomer distribution of $[Co(apS)(R\text{-chxn})_2]^{2+}$ and related complexes, and CD spectra of these complexes (*vide infra*). Both *rac*- and $(+)_{589}$-apSH·HCl were oxidized with H_2O_2[7] to give the respective disulfide hydrochlorides $(NH_2CH_2CH(CH_3)S-)_2\cdot 2HCl$ which were used to prepare cobalt(III)–apS complexes.

Racemic 2,2′-diselenodipropylamine dihydrochloride, $(NH_2CH_2CH(CH_3)Se-)_2\cdot 2HCl$ was prepared by the method of Yokoyama *et al.*[8] and used to prepare cobalt(III)–apSe complexes without optical resolution.

Optically active *R*-chxn was obtained by resolving *rac*-chxn (Tokyo Kasei Kogyo Co., Ltd.) according to the method of Treptow,[9] and tren was obtained by separating from crude triethylenetetramine (Tokyo Kasei Co., Ltd.).[10]

Δ(lel$_3$)-[*Co*(R-*apS*)(R-*chxn*)$_2$]*SiF*$_6\cdot 4H_2O$, Δ(oblel$_2$)-[*Co*(S-*apS*)(R-*chxn*)$_2$]*ZnCl*$_4$, Λ(lelob$_2$)-[*Co*(S-*apS*)(R-*chxn*)$_2$]*ZnCl*$_4\cdot H_2O$. An aqueous solution (10 cm^3) containing *R*-chxn·2HCl (3.0 g, 16 mmol) and NaOH (1.28 g, 32 mmol) was deoxygenated by bubbling nitrogen for 15 min, and then was syringed into a deoxygenated, aqueous solution (10 cm^3) of $CoCl_2\cdot 6H_2O$ (1.90 g, 8 mmol) with stirring. The mixture became a pinkish orange suspension. To the mixture was added a deoxygenated aqueous solution (8 cm^3) containing *rac*-$(NH_2CH_2CH(CH_3)S-)_2\cdot 2HCl$ (1.01 g, 4 mmol) and NaOH (0.32 g, 8 mmol). The mixture was stirred under an atmosphere of nitrogen for 3 h at room temperature. The resulting brown solution was filtered to remove a small amount of insoluble material, and the filtrate was passed through a column (ϕ2.7 cm × 5 cm) of SP-Sephadex C-25. The Sephadex charged with the product was placed on the top of a column (ϕ7 cm × 40 cm) of SP-Sephadex C-25, and the product was eluted with 0.1 mol dm^{-3} $Na_2[Sb_2(d\text{-tartrate})_2]$, giving two main brown bands A and B. The first band A contains the *Λ*(*lelob*$_2$), and the second band B a mixture of the *Δ*(*lel*$_3$) and *Δ*(*oblel*$_2$) isomers. The structural assignment for the isomers was made on the basis of the elution order, formation ratio, and CD spectra of the isomers (*vide infra*). No indication of the presence of the *Λ*(*ob*$_3$) isomer was observed in the column chromatography. The eluate of band B was diluted 20 times with water, passed through an SP-Sephadex C-25 column (ϕ2.7 cm × 120 cm), and the complex adsorbed was eluted with 0.15 mol dm^{-3} $(NH_4)_2SO_4$. Bands B-I (*Δ*(*lel*$_3$)) and B-II (*Δ*(*oblel*$_2$)) were eluted separately in this order. Each eluate of bands A, B-I, and B-II was diluted with water and passed again through an SP-Sephadex C-25 column (ϕ1.5 cm × 2 cm). The column charged with A was washed thoroughly with 0.1 mol dm^{-3}

HCl (10 dm^3), and the complex was eluted with 0.8 mol dm^{-3} HCl. The eluate was evaporated to a small volume under reduced pressure. The concentrate was mixed with excess $ZnCl_2$ (0.2 g) in 3 mol dm^{-3} HCl (0.3 cm^3) to precipitate brown tetrachlorozincate of the complex. It was recrystallized from water–ethanol. Found: C, 29.47; H, 6.17; N, 11.52%. Calcd for $C_{15}H_{38}N_5Cl_4CoSZn$: C, 29.89; H, 6.35; N, 11.62%. The complex of B-I was eluted from the column with 0.4 mol dm^{-3} $(NH_4)_2SiF_6$. The eluate was allowed to stand overnight in a refrigerator to give purplish brown needles, which were collected and washed with cold water. Found: C, 30.26; H, 7.66; N, 11.89%. Calcd for $C_{15}H_{44}N_5CoF_6O_4SSi$: C, 30.45; H, 7.50; N, 11.84%. The complex of B-II was isolated as tetrachlorozincate by the same method as that for A. Found: C, 30.82; H, 6.31; N, 11.88%. Calcd for $C_{15}H_{36}N_5Cl_4CoSZn$: C, 30.81; H, 6.21; N, 11.98%. The total yield and the formation ratio, $\Delta(lel_3)$ (B-I): $\Delta(oblel_2)$ (B-II): $\Lambda(lelob_2)$ (A) determined by reference to optical densities of the eluates were *ca.* 80% and 3.6:2.4:1, respectively. The main by-product was Δ-$[Co(R\text{-chxn})_3]^{3+}$.

The same experiment was carried out using the optically active disulfide derived from $(+)_{589}$-apSH·HCl, instead of the racemic one. Two isomers, $\Delta(oblel_2)$ and $\Lambda(lelob_2)$ were formed in the formation ratio of 2.3:1.

Λ- and Δ-[Co(S-apS)(en)$_2$]SiF$_6$·0.5H$_2$O. These complexes were prepared from $Co(ClO_4)_2\cdot 6H_2O$, en, and the optically active disulfide by a method similar to that for $[Co(apS)(R\text{-chxn})_2]^{2+}$. After stirring for 3 h at room temperature, the product was chromatographed by use of an SP-Sephadex C-25 column and an eluent, 0.1 mol dm^{-3} $Na_2[Sb_2(d\text{-tartrate})_2]$. Two brown bands of the Λ- and Δ-isomers were eluted separately, the former being eluted faster. Each eluate was diluted 20 times with water, and passed through a column of SP-Sephadex C-25. The column was washed with 0.02 mol dm^{-3} NH_4Cl (1 dm^3), and the complex was eluted with 0.4 mol dm^{-3} $(NH_4)_2SiF_6$. The eluate was left in a refrigerator to yield brown crystals. Found for the Λ-isomer: C, 19.76; H, 5.87; N, 16.66%. Found for the Δ-isomer: C, 19.94; H, 5.98; N, 16.83%. Calcd for $C_7H_{25}N_5CoF_6O_{0.5}SSi$: C, 20.00; H, 5.99; N, 16.66%. The total yield and the formation ratio, Λ-isomer: Δ-isomer based on optical densities of the eluates were *ca.* 90% and 1.9:1, respectively.

p-[Co(S-apS)(tren)](ClO$_4$)$_2$ and t-[Co(S-apS)(tren)]ZnCl$_4$·0.5ZnCl$_2$.[11] These complexes were prepared from $CoCl_2\cdot 6H_2O$ (8 mmol), tren (8 mmol), and the optically active disulfide (4 mmol), by a method similar to that for $[Co(apS)(R\text{-chxn})_2]^{2+}$. After stirring for 2 d at room temperature, a small portion of the resulting solution was set aside to examine the formation ratio of the isomers, and to the rest was added 4 cm^3 of 60% $HClO_4$. Brown crystals were precipitated, collected, washed with ethanol, and recrystallized from 10^{-3} mol dm^{-3} HCl–60% $HClO_4$. Yield: 2.15 g. The complex was the *p*-isomer as confirmed by column chromatography (Dowex 50W × 2, 2 mol dm^{-3} HCl). Found: C, 21.87; H, 5.37; N, 14.08%. Calcd for $C_9H_{26}N_5Cl_2CoO_8S$: C, 21.87; H, 5.30; N, 14.17%. The filtrate and washings were combined, diluted with water, and passed through a column (ϕ3 cm × 35 cm) of Dowex 50W × 2. By elution with 2 mol dm^{-3} HCl, two bands, T-I (dark brown, *t*-isomer) and T-II (brown, *p*-isomer) appeared separately. The eluate of fast-moving band T-I was collected and evaporated to a small volume under reduced pressure. On addition of $ZnCl_2$ (0.3 g) in 3 mol dm^{-3} HCl (0.4 cm^3) the concentrate gave pink precipitate, which was collected, washed with methanol and acetone, and air-dried. Yield: 0.18 g. Found: C, 18.91; H, 4.53; N, 18.91; Cl, 31.04%. Calcd for $C_9H_{26}Cl_5CoSZn_{1.5}$: C, 18.94; H, 4.60; N, 18.94; Cl, 31.06%. The eluate of band T-II was diluted with water, passed through an SP-Sephadex C-25 column, and the complex was eluted with 0.8 mol dm^{-3} $NaClO_4$. Upon evaporation of the eluate additional 1.3 g of the *p*-isomer perchlorate was obtained. The formation ratio of the *p*- to *t*-isomer contained in the reaction mixture was found to be 15:1 by column chromatography (Dowex 50W × 2, 2 mol dm^{-3} HCl).

[Co(aeS)(en)$_2$]Cl$_2$·H$_2$O and Λ-[Co(aeS)(en)$_2$](ClO$_4$)$_2$ (aeSH=2-aminoethanethiol). The racemic complex was prepared by the method of Lane *et al.*[12] and resolved by column chromatography (SP-Sephadex C-25, 0.1 mol dm^{-3} $Na_2[Sb_2(d\text{-tartrate})_2]$). From the first band the Λ-isomer was isolated as perchlorate. Found: C, 15.87; H, 4.82; N, 15.38%. Calcd for $C_6H_{22}N_5Cl_2CoO_8S$: C, 15.87; H, 4.88; N, 15.42%. The complex has been resolved by fractional crystallization of the diastereomer with $[Sb_2(d\text{-tartrate})_2]^{2-}$.[13]

Δ(lel$_3$)-[Co(R-apSe)(R-chxn)$_2$](ClO$_4$)$_2$·2.5H$_2$O, Δ(oblel$_2$)-[Co(S-apSe)(R-chxn)$_2$](ClO$_4$)$_2$·2.5H$_2$O, and Λ(lelob$_2$)-[Co(S-apSe)(R-chxn)$_2$]$^{2+}$. These complexes were prepared by a method similar to that for the corresponding apS complexes using $CoCl_2\cdot 6H_2O$ (1.19 g, 5 mmol), *R*-chxn·2HCl (1.88 g, 10 mmol), *rac*-$(NH_2CH_2CH(CH_3)Se\text{–})_2\cdot 2HCl$ (0.87 g, 2.5 mmol), and the equivalent amount of NaOH (1.0 g, 15 mol). The mixture was stirred for 3 h at room temperature. The resulting brown solution containing brown precipitate was mixed with water (1 dm^3) and the solution was poured on a column of SP-Sephadex C-25 (ϕ3 cm × 150 cm). By elution with 0.2 mol dm^{-3} Na_2SO_4, the product adsorbed was separated into two brown bands, C and D. The first band C contains the $\Delta(lel_3)$ isomer, and the other D a mixture of the $\Delta(oblel_2)$ and $\Lambda(lelob_2)$ isomers. No band indicative of the $\Lambda(ob_3)$ isomer was observed. The eluate of band D was diluted 20 times with water, poured on a column (ϕ3 cm × 70 cm)of SP-Sephadex C-25, and the complexes adsorbed were eluted with 0.1 mol dm^{-3} $Na_2[Sb_2(d\text{-tartrate})_2]$. Two bands, D-I ($\Lambda(lelob_2)$) and D-II ($\Delta(oblel_2)$) were eluted separately. Each eluate of bands C, D-I, and D-II was diluted with water, poured on a column (ϕ2 cm × 2 cm) of SP-Sephadex C-25, and the complex was eluted with 0.8 mol dm^{-3} $NaClO_4$. The eluate was stored in a refrigerator overnight to yield crystals of the complex perchlorate, which were collected, washed with a small amount of cold water, and air-dried. Yields: $\Delta(lel_3)$-isomer, 530 mg; $\Delta(oblel_2)$-isomer, 65 mg; $\Lambda(lelob_2)$-isomer, 5 mg. The apSe complexes in solution are rather unstable, and decompose during the course of crystallization to decrease the yield extremely. Found for the $\Delta(lel_3)$-isomer: C, 26.98; H, 5.89; N, 10.58%. Found for the $\Delta(oblel_2)$-isomer: C, 27.19; H, 5.94; N, 10.58%. Calcd for $C_{15}H_{41}N_5Cl_2CoO_{10.5}Se$: C, 26.96; H, 6.18; N, 10.48%. The elemental analysis of the $\Lambda(lelob_2)$-isomer was not carried out because of a very low yield, and the complex was assumed to be anhydrous for determining the formation ratio of the isomers by spectrophotometric methods. The formation ratio, $\Delta(lel_3)$ (C): $\Delta(oblel_2)$ (D-II): $\Lambda(lelob_2)$ (D-I), in the reaction mixture was 5.3:3.8:1.

Λ(R)- and Δ(S)-[Co(apSe)(en)$_2$]ZnCl$_4$·H$_2$O and Λ(S)- and Δ(R)-[Co(apSe)(en)$_2$]SiF$_6$·H$_2$O. The racemates of these diastereomers were prepared from $CoCl_2\cdot 6H_2O$ (0.4 g, 1.67 mmol), en (0.2 g, 3.34 mmol), and the diselenide (0.29 g, 0.84 mmol) by a method similar to that for $[Co(apSe)(R\text{-chxn})_2]^{2+}$. The mixture was stirred for 3 h, and then chromatographed by use of an SE-Toyopearl[14] column (ϕ3 cm × 20 cm). By elution with 0.1 mol dm^{-3} Na_2SO_4, two brown bands, E-I and E-II were eluted separately. Bands E-I and E-II contain racemates of the diastereomers, $\Lambda(R)$ and $\Delta(S)$, and $\Lambda(S)$ and $\Delta(R)$, respectively. Each eluate was diluted 20 times with water and passed through an SP-Sephadex C-25 column (ϕ2.7 cm × 120 cm). By elution with 0.1 mol dm^{-3} $Na_2[Sb_2(d\text{-tartrate})_2]$, the band was separated into two. The enantiomers being eluted faster were those of

Λ(R) and *Λ(S)* in E-I and E-II, respectively. The eluate of the *Λ(R)* (or *Λ(S)*) isomer was diluted 20 times with water and poured on an SP-Sephadex C-25 column (φ1.5 cm × 2 cm). The column was washed with 0.01 mol dm^{-3} HCl (8 dm^3), and the complex was eluted with 0.8 mol dm^{-3} HCl. The eluate was evaporated to a small volume under reduced pressure below 35 °C. To the concentrate was added $ZnCl_2$ (0.3 g) in 3 mol dm^{-3} HCl (0.4 cm^3). The solution was mixed with methanol and allowed to cool in a refrigerator overnight to yield brown powder, which was collected, washed with acetone, and air-dried. Found: C, 15.51; H, 4.50; N, 12.91%. Calcd for $C_7H_{26}N_5Cl_4CoSeZn$: C, 15.53; H, 4.84; N, 12.94%. The eluate of the *Λ(S)* (or *Δ(R)*) isomer was diluted 20 times with water and passed through an SP-Sephadex C-25 column (φ1.5 cm × 2 cm). The column was washed thoroughly with 0.01 mol dm^{-3} NH_4Cl (10 dm^3), and the complex was eluted with 0.4 mol dm^{-3} $(NH_4)_2SiF_6$. The eluate was allowed to cool in a refrigerator overnight to yield brown needles, which were collected, washed with cold water, and air-dried. Found: C, 17.75; H, 5.56; N, 14.94%. Calcd for $C_7H_{26}N_5CoF_6OSeSi$: C, 17.65; H, 5.50; N, 14.70%. The formation ratio, *Λ(R)* + *Λ(S)*(E-I):*Λ(S)* + *Δ(R)*(E-II) determined by optical densities of the eluates was 1:4.

(−)$_{589}$-p-[Co(S-apSe)(tren)](ClO$_4$)$_2$ and t-[Co(rac-apSe)(tren)](ClO$_4$)$_2$·H$_2$O. A mixture of racemic *p*- and *t*-[Co(apSe)(tren)]$^{2+}$ was prepared from $CoCl_2 \cdot 6H_2O$ (4 mmol), tren (4 mmol), and the diselenide (2 mmol) by a method similar to that for $[Co(apSe)(R\text{-chxn})_2]^{2+}$. The mixture was stirred for 4 d at room temperature, and then concd HCl was added to make the solution slightly acidic. The solution was chromatographed in a similar manner to that for $[Co(apSe)(R\text{-chxn})_2]^{2+}$. By elution with 0.1 mol dm^{-3} Na_2SO_4 adjusted to pH 2 with HCl, two bands appeared; a fast-moving dark brown band (*p*-isomer) and a slow-moving dark green-brown one (*t*-isomer). The *p*-isomer was isolated as perchlorate by the same method as that for $[Co(apSe)(R\text{-chxn})_2]^{2+}$. Yield: 700 mg. The *t*-isomer was isolated as tetrachlorozincate by the same method as that for *Λ*-$[Co(R\text{-apSe})(en)_2]^{2+}$ and then converted into perchlorate by use of a QAE-Sephadex (ClO_4^- form) column. Yield: 100 mg. Found for the *t*-isomer: C, 19.35; H, 4.58; N, 12.61%. Calcd for $C_9H_{28}N_5Cl_2CoO_9Se$: C, 19.33; H, 5.04; N, 12.52%.

The *p*-isomer was resolved as follows; a mixture of the *p*-isomer perchlorate (0.27 g, 0.5 mmol) and potassium *d*-tartrate hemihydrate (0.117 g, 0.5 mmol) in 10 cm^3 of water was stirred for 30 min. The solution was evaporated to 1.5 cm^3 under reduced pressure below 35 °C and filtered to remove the potassium perchlorate precipitated. The filtrate was mixed with methanol (5 cm^3) and cooled (−10 °C) overnight. Brown granular crystals which formed were collected and recrystallized three times from water–methanol. Yield: 32 mg. No change in the Δε value was observed with further recrystallization. This diastereomer was converted into perchlorate by use of a QAE-Sephadex (ClO_4^- form) column. Found: C, 19.74; H, 4.72; N, 12.93%. Calcd for $C_9H_{26}N_5Cl_2CoO_8Se$: C, 19.97; H, 4.84; N, 12.93%. Attempts to resolve the *t*-isomer by column chromatography and by chemical methods were all unsuccessful.

Λ-[Co(aeSe)(en)$_2$](ClO$_4$)$_2$(aeSeH=2-Aminoethaneselenol). The racemic complex was prepared by the method of Stein *et al.*[15] and resolved by SP-Sephadex C-25 column chromatography using 0.1 mol dm^{-3} $Na_2[Sb_2(d\text{-tartrate})_2]$ as an eluent. The fast-moving *Λ*-isomer was isolated as perchlorate by the same method as that for $[Co(apSe)(R\text{-chxn})_2]^{2+}$. Found: C, 14.23; H, 4.57; N, 13.92%. Calcd for $C_6H_{22}N_5Cl_2CoO_8Se$: C, 14.38; H, 4.43; N, 13.98%. The CD spectrum agreed well with that reported by Konno *et al.*[16] who resolved the complex by fractional crystallization of the diastereomer with $[Sb_2(d\text{-tartrate})_2]^{2-}$.

[Co(S-apOH)(NH$_3$)$_4$]Br$_3$·2.5H$_2$O. This complex was prepared by the method of Nishide *et al.*[1]

Measurements. Absorption and CD spectra were recorded on a Hitachi 323 spectrophotometer and a JASCO J-40 CS spectropolarimeter, respectively. Optical rotations at 589 nm were measured with a JASCO DIP-4 polarimeter.

Results and Discussion

Preparation and Structural Assignment of the Complexes. The present $[Co(apS \text{ or } apSe)(N_4)]^{2+}$-type complexes were prepared by oxidizing Co^{II}-N_4 species with the disulfide or diselenide, $(NH_2CH_2CH(CH_3)X-)_2$ (X=S or Se) according to the method for analogous aminoalkanethiolato-*N,S*[12,17] or selenolato-*N,Se*[15] complexes of cobalt(III). Time required for the oxidation was nearly the same between the apS and apSe complexes, but different between the en and *R*-chxn, and the tren complexes. While the former complexes took a few hours to complete the oxidation, the latter complexes of apS and apSe 2 and 4 d, respectively. Such differences in reactivity seem to be related with reducing strength of Co^{II}-N_4 species toward the disulfide and diselenide. The apS complexes are stable in acidic solution, but slowly decompose in basic solution to give Co^{II} species. The apSe complexes are less stable than the corresponding apS complexes under the same conditions. The *p*-$[Co(apSe)(tren)]^{2+}$ complex in solution is the least stable among the complexes prepared in this study. Thus spectral measurements of the apSe complexes were carried out in 0.01 mol dm^{-3} $HClO_4$ solutions. The lower stability of the apSe complexes might be related to the fact that the complexes exhibit Se-to-Co^{III} charge transfer bands at lower energy (*ca.* 33000 cm^{-1}) than that of the corresponding bands of apS complexes (*ca.* 35000 cm^{-1}); coordinated selenolates are considered to be better reductants than coordinated thiolates.[15]

Except for the pink crystals of *t*-$[Co(apS)(tren)]ZnCl_4 \cdot 0.5ZnCl_2$, all the complexes are brown in the solid state. The pink *t*-$[Co(apS)(tren)]ZnCl_4 \cdot 0.5ZnCl_2$ complex indicates the ligation of the S atom to Zn^{2+} in crystals. Interaction between soft metal ions and thiolato cobalt(III) complexes have been investigated in some detail.[18] For example, a brown solution of $[Co(aeS)(en)_2]^{2+}$ in water turns red upon addition of Ag^+ or $HgCH_3^+$.[18] Since Zn^{2+} is a less soft acid than those ions, it interacts with the S atom of apS only in the solid state of *t*-$[Co(apS)(tren)]ZnCl_4 \cdot 0.5ZnCl_2$. The interaction disappears when the complex is dissolved in water, a brown solution being obtained. The absorption spectrum is identical with that of the corresponding perchlorate which was prepared by use of an anion-exchange resin. Other tetrachlorozincates of the apS and apSe complexes prepared in this study form brown crystals and will involve no interaction between Zn^{2+} and the S or Se atom even in the solid state.

Both chelate rings of *S*(or *R*)-apS and *S*(or *R*)-apSe will be stabilized in the *δ*(or *λ*)-*gauche* conformation with the methyl group disposed equatorially, while the *R*-chxn chelate ring is forced to take the *λ*-*gauche* conformation. Thus there are four possible diaster-

eomers of $[Co(apX)(R\text{-chxn})_2]^{2+}$ (X=S, Se), which can be designated as $lel_3(\Delta(\lambda\lambda\lambda))$, $oblel_2(\Delta(\delta\lambda\lambda))$, $lelob_2(\Lambda(\delta\lambda\lambda))$, and $ob_3(\Lambda(\lambda\lambda\lambda))$. Each of the apS and apSe complexes formed three isomers in the preparation where the *rac*-dicalcogenide was used. The isomers were assigned on the basis of the elution order in column chromatography, the isomer distribution, and the CD spectra. In column chromatography, the lel_3 isomer will be eluted faster by elution with SO_4^{2-}, since its structure is most favorable in forming an ion pair with SO_4^{2-}.[19,20] By elution with $[Sb_2(d\text{-tartrate})_2]^{2-}$, on the other hand, a Λ-isomer is usually eluted faster than a Δ-one.[21] For the isomer distribution, the Δ-isomer will be formed in a larger amount than the Λ-one, since the $lel_2(\Delta(\lambda\lambda))$ structure formed by two *R*-chxn ligands is less crowded than the $ob_2(\Lambda(\lambda\lambda))$ one.[22] For a relation between optical activity and absolute configuration of a complex, it is known that a complex with a positive main CD band in the first absorption band region takes Λ configuration (Figs. 1 and 2).[23] On the basis of these diagnoses, all the isomers of $[Co(apX)(R\text{-chxn})_2]^{2+}$ (X=S, Se) were assigned as given in the experimental section.

In order to assign the absolute configuration of (+)$_{589}$-apSH·HCl, the same bis(*R*-chxn) complex was

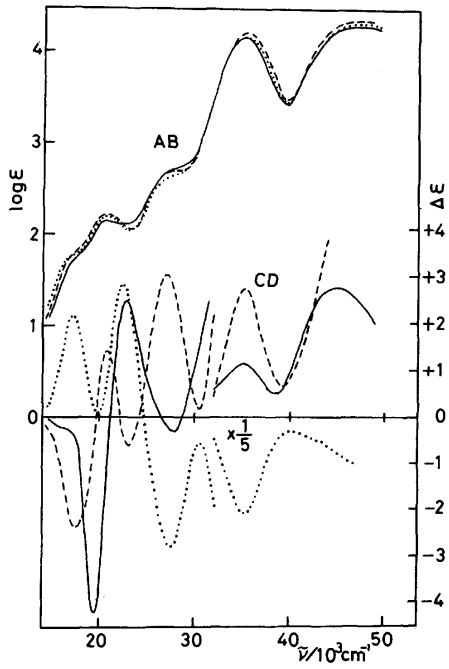

Fig. 1. Absorption and CD spectra of $\Delta(oblel_2)$-$[Co(S\text{-apS})(R\text{-chxn})_2]^{2+}$ (——), $\Delta(lel_3)$-$[Co(R\text{-apS})(R\text{-chxn})_2]^{2+}$ (– – – –), and $\Lambda(lelob_2)$-$[Co(S\text{-apS})(R\text{-chxn})_2]^{2+}$ (·····).

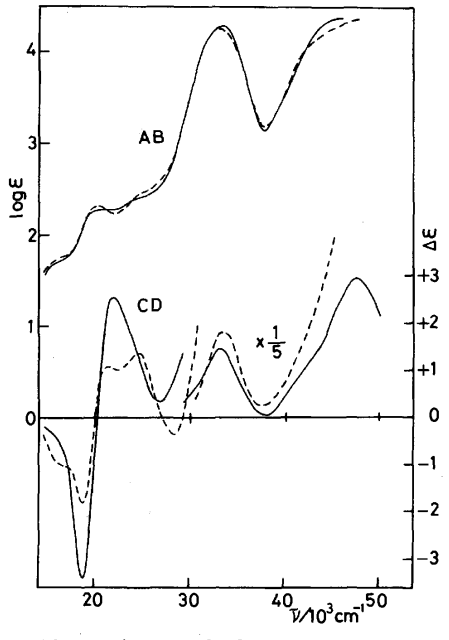

Fig. 2. Absorption and CD spectra of $\Delta(oblel_2)$-$[Co(S\text{-apSe})(R\text{-chxn})_2]^{2+}$ (—) and $\Delta(lel_3)$-$[Co(R\text{-apSe})(R\text{-chxn})_2]^{2+}$ (– – –).

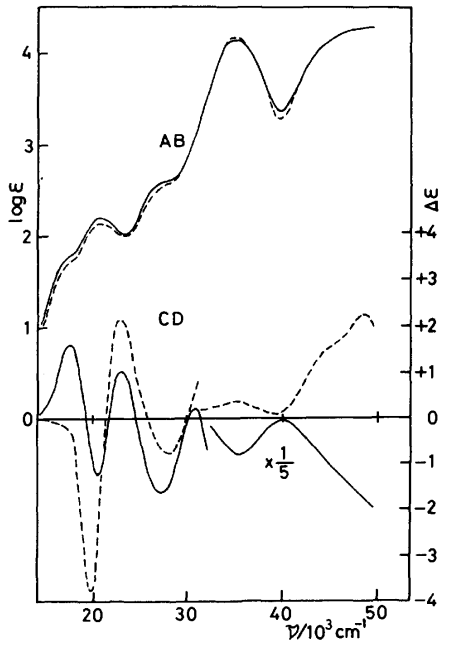

Fig. 3. Absorption and CD spectra of Λ-$[Co(S\text{-apS})(en)_2]^{2+}$ (——) and Δ-$[Co(S\text{-apS})(en)_2]^{2+}$ (– – – –).

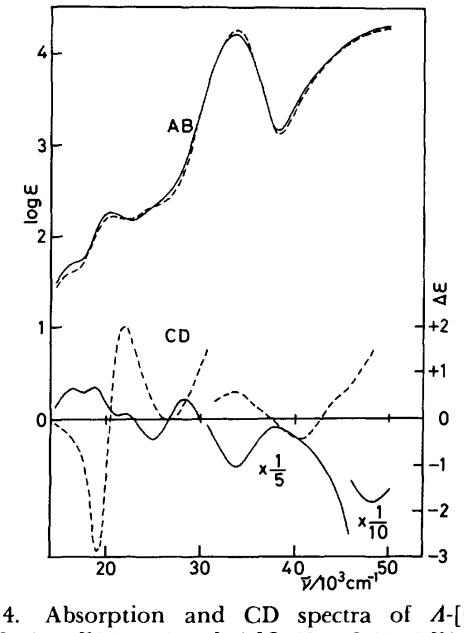

Fig. 4. Absorption and CD spectra of Λ-$[Co(S\text{-apSe})(en)_2]^{2+}$ (——) and Δ-$[Co(S\text{-apSe})(en)_2]^{2+}$ (– – – –).

prepared by use of the optically active disulfide derived from (+)$_{589}$-apSH·HCl. Only two isomers, $\Delta(oblel_2)$($\delta\lambda\lambda$) and $\Lambda(lelob_2)$($\delta\lambda\lambda$) were formed. Thus the absolute configuration of (+)$_{589}$-apSH·HCl can be assigned to *S*, since the *S*-apS chelate ring will be stabilized in the *δ-gauche* conformation as stated previously.

In a similar manner, structures of diastereomeric pairs, Λ- and Δ-[Co(*S*-apS)$(en)_2]^{2+}$, and Λ- and Δ-[Co(*S*-apSe)$(en)_2]^{2+}$ were assigned. The absorption and CD spectra of these complexes are given in Figs. 3 and 4. The [Co(apX)(tren)]$^{2+}$(X=S, Se) complex forms two geometrical isomers, *p* and *t*.[11] The isomers were assigned by comparing the elution order in column chromatography, the formation ratio, and the absorption spectra with those of *p*- and *t*-[Co(aeS)(tren)]$^{2+}$ reported previously.[24] The optically active *p*- and *t*-[Co(*S*-apS)(tren)]$^{2+}$ isomers were prepared by use of the optically active disulfide. The optically active *p*-isomer of apSe was obtained by resolving the racemate with *d*-tartrate ions, but the resolution of the other *t*-isomer was not achieved. The absorption and CD spectra of the tren complexes are given in Figs. 5 and 6. The spectral data of all the complexes are listed in Table 1.

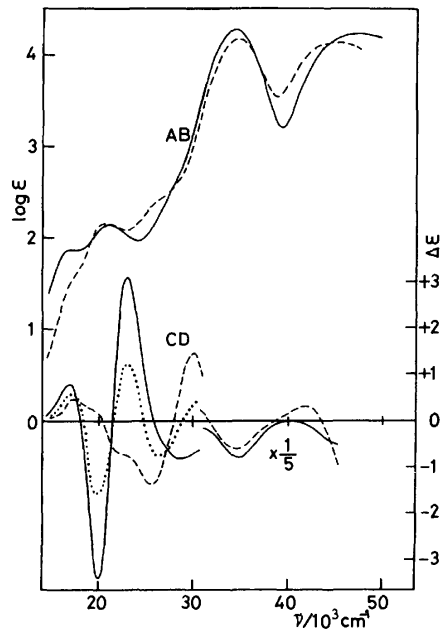

Fig. 5. Absorption and CD spectra of *t*(——) and *p*(----) isomers of [Co(*S*-apS)(tren)]$^{2+}$, and the mean CD curve of the two spectra (·····).

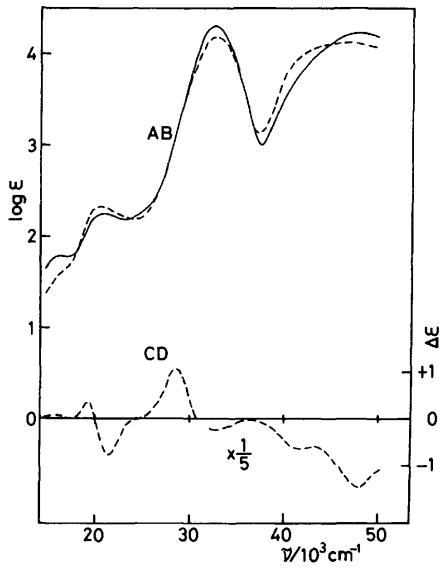

Fig. 6. Absorption spectrum of *t*-[Co(*rac*-apSe)-(tren)]$^{2+}$ (——), and absorption and CD spectra of (−)$_{589}$-*p*-[Co(*S*-apSe)(tren)]$^{2+}$ (----).

Absorption and CD Spectra. All the apS and apSe complexes show absorption spectra similar to one another; the spectra exhibit the split first absorption band, shoulder in the second absorption band region, and the strong X-to-Co^{III} (X=S, Se) and N-to-Co^{III} charge transfer bands in the ultraviolet region. All the bands of apSe complexes shift to the low energy side compared with the corresponding bands of apS complexes. These spectral features are quite similar to those of [Co(aeX)$(en)_2]^{2+}$ (X=S, Se) reported previously.[12,13,15,25] Although spectral differences among the isomers are very small in the *R*-chxn and en complexes of apX (X=S, Se), the spectra of *p*- and *t*-[Co(apX)(tren)]$^{2+}$ (X=S, Se) isomers are fairly different from each other. Some tren complexes with a similar chelate ligand such as aeS[24] or an amino acidate ion[26–28] also show a fairly large difference between the *p*- and *t*-isomers. The *p*- and *t*-isomers are geometrical isomers in which the X atom (X=O, S, Se) occupies the position cis and trans, respectively, to the tertiary amine nitrogen which will exert a weaker ligand field than the primary amine nitrogens. Thus the splitting of the d-d transition components would differ between the geometrical isomers to cause different d-d absorption spectra.[29]

In Fig. 3 are shown CD spectra of Δ- and Λ-[Co(*S*-apS)$(en)_2]^{2+}$. The spectra in the d-d absorption band region are not enantiomeric, but rather similar in pattern. In general, the optical activity of a metal complex is understood as a superposition of the configurational (chiral arrangement of ligands around the metal ion) and the vicinal (chiral ligand) effects. When the optical activity of Δ- and Λ-[Co(*S*-apS)-$(en)_2]^{2+}$ is this case, the spectra suggest that the vicinal effect of *S*-apS is stronger than the configurational effect in these isomers. Figures 7 and 8 show the configurational ($\Delta\varepsilon(\Lambda)=1/2\{\Delta\varepsilon[\Lambda(S)]-\Delta\varepsilon[\Delta(S)]\}$) and vicinal ($\Delta\varepsilon(S)=1/2\{\Delta\varepsilon[\Lambda(S)]+\Delta\varepsilon[\Delta(S)]\}$) effect curves, respectively, obtained from the observed CD spectra. The configurational CD curve for $\Delta\varepsilon(\Lambda)$ is very similar to the observed CD spectrum of Λ-[Co(aeS)-$(en)_2]^{2+}$ indicating that the additivity in CD between the configurational and vicinal effects holds for [Co-(*S*-apS)$(en)_2]^{2+}$. The vicinal CD curve of *S*-apS quite resembles that calculated from the observed CD spectra of $\Delta(\lambda\lambda\lambda)$-[Co(*R*-apS)(*R*-chxn)$_2]^{2+}$ and $\Delta(\delta\lambda\lambda)$-[Co-(*S*-apS)(*R*-chxn)$_2]^{2+}$($1/2\{\Delta\varepsilon[\Delta(\delta\lambda\lambda)]-\Delta\varepsilon[\Delta(\lambda\lambda\lambda)]\}$). Thus it is clear that in the *S*-apS complexes, the vicinal effect is stronger than the configurational effect. The large vicinal effect of *S*-apS corresponds well to those of the structurally similar *S*-apO and related deprotonated aminoalkanolate ligands.[1] In Fig. 8 is given the CD

Table 1. Absorption and CD spectral data of the complexes

Solvent, a): water. b): concd H_2SO_4, c): 0.01 mol dm^{-3} $HClO_4$.

spectrum of [Co(*S*-apO)$(NH_3)_4$]$^{2+}$ for comparison. The spectrum is similar in both pattern and magnitude to the vicinal CD curve of *S*-apS, although the CD bands shift to the high energy side compared with the corresponding bands of *S*-apS. The result also supports the previous assignment that $(+)_{589}$-apSH·HCl has *S* configuration.

In order to observe the vicinal effect of *S*-apS in the [Co(*S*-apS)(N_4)]$^{2+}$-type complex, it is desirable to prepare [Co(*S*-apS)$(NH_3)_4$]$^{2+}$. However, attempts to prepare this complex have been unsuccessful, and instead we have prepared [Co(*S*-apS)(tren)]$^{2+}$, where no configurational chirality is involved. In Fig. 5 are shown the CD spectra of *p*- and *t*-[Co(*S*-apS)(tren)]$^{2+}$. In the d-d absorption band region, the isomers exhibit CD spectra quite different from each other. The CD pattern of the *t*-isomer resembles the calculated vicinal CD curve of *S*-apS (Fig. 8), but the magnitude is *ca.* 1.5 times as large. Similar differences in CD spectra between *p*- and *t*-isomers have been reported for some tren complexes.[1,32] The tren complex is not suitable for observing the vicinal effect of *S*-apS in the [Co(*S*-apS)(N_4)]$^{2+}$-type complexes. It is interesting to note, however, that the mean curve of the CD spectra of *p*- and *t*-[Co(*S*-apS)(tren)]$^{2+}$ resembles more the calculated curve than the individual CD spectra (Fig. 5).

Nishide *et al.*[1] reported that absorption and CD spectra of S-apO and related aminoalkanolato-*N,O* complexes of cobalt(III) change remarkably with changes in pH of solutions. Similar spectral changes were observed for the *S*-apS complexes. The changes are instantaneous and reversible, and attributed to an acid-base equilibrium of the thiol proton.[33] Figure 9 shows the absorption and CD spectra of Δ- and Λ-[Co(*S*-apSH)$(en)_2$]$^{3+}$ in concd H_2SO_4, where the thiolate chelates will be completely protonated.[33] Both isomers show much more simple absorption and CD patterns than those of their conjugate bases (Fig. 3). In the first absorption band region, the protonated Λ-isomer gives a large positive and a small negative CD

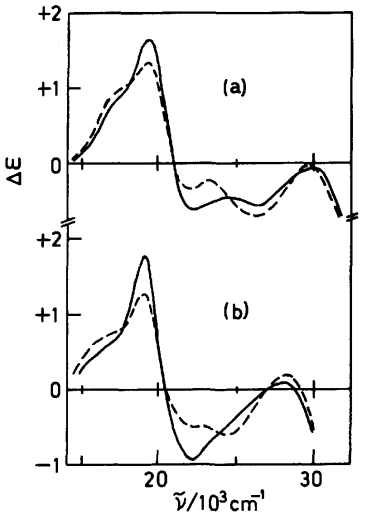

Fig. 7. (a): Configurational effect CD ($\Delta\varepsilon(\Lambda)$) curve of $[Co(S\text{-apS})(en)_2]^{2+}$ (——) and the observed CD spectrum of Λ-$[Co(aeS)(en)_2]^{2+}$ (----). (b): Configurational effect CD ($\Delta\varepsilon)\Lambda$)) curve of $[Co(S\text{-apSe})(en)_2]^{2+}$ (——) and the observed CD spectrum of Λ-$[Co(aeSe)(en)_2]^{2+}$ (----).

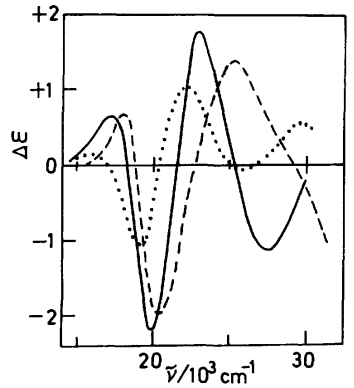

Fig. 8. Vicinal effect CD curves of *S*-apS (——) and *S*-apSe (·····) calculated from Δ- and Λ-$[Co(S\text{-apX})(en)_2]^{2+}$ (X=S, Se), and the observed CD spectrum of $[Co(S\text{-apO})(NH_3)_4]^{2+}$ (----).

band, and the other Δ-isomer only a large negative band. These CD patterns are very similar to those of the corresponding $\Lambda(lel)$- and $\Delta(ob)$-isomers of a bis(en) complex containing a chiral diamine such as (*S*)-1,2-propanediamine.[34] The additivity between the configurational and vicinal effects also holds in the protonated complexes as shown in Fig. 10(a), where the configurational CD curve ($\Delta\varepsilon(\Lambda)$) is compared with the CD spectrum of Λ-$[Co(aeSH)(en)_2]^{3+}$ in concd H_2SO_4. The calculated vicinal CD curve of *S*-apSH shows a single negative band in the first absorption band region, and the magnitude is much smaller than that of the vicinal CD curve of the conjugate base, *S*-apS (Figs. 8 and 10(b)). Very similar CD changes have been observed between the corresponding *S*-apO and *S*-apOH, and between related chiral aminoalkanolato and alcohol complexes. The results together with those described previously lead to the conclusion that aminoalkanethiolato-*N*,*S* cobalt(III) complexes exhibit optical activity very similar to that of the corresponding aminoalkanolato-*N*,*O* complexes in the d-d absorption band region.

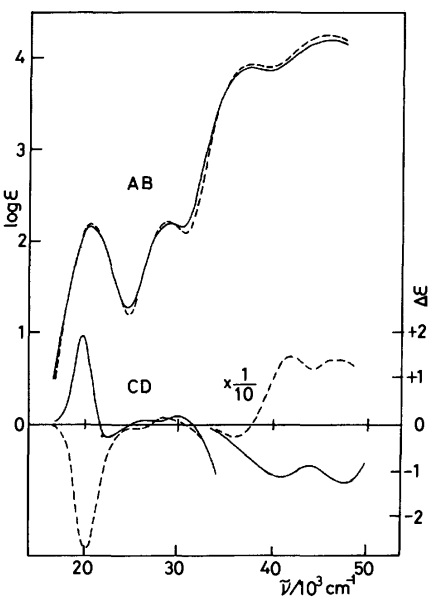

Fig. 9. Absorption and CD spectra of Λ(——) and Δ(----) isomers of $[Co(S\text{-apSH})(en)_2]^{3+}$ in concd H_2SO_4.

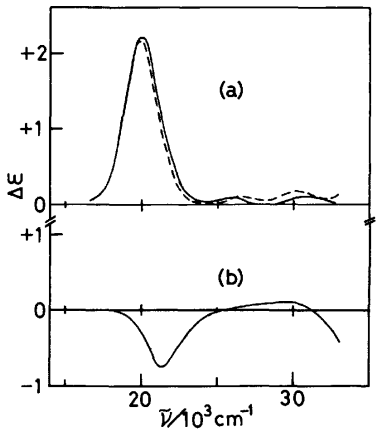

Fig. 10. (a): Configurational effect CD ($\Delta\varepsilon(\Lambda)$) curve of $[Co(S\text{-apSH})(en)_2]^{3+}$(——) and the observed CD spectrum of Λ-$[Co(aeSH)(en)_2]^{3+}$ in concd H_2SO_4 (-----). (b): Vicinal effect CD curve of *S*-apSH (——) calculated from Δ- and Λ-$[Co(S\text{-apSH})(en)_2]^{3+}$.

On the other hand, optical activity of the apSe complexes seems to somewhat differ from that of the apS complexes in the d-d absorption band region. The CD spectra of $\Lambda(lel)$-$[Co(S\text{-apSe})(en)_2]^{2+}$ and $\Delta(lel_3)$-$[Co(R\text{-apSe})(R\text{-chxn})_2]^{2+}$ are fairly different from those of the corresponding isomers of the apS complexes, although other isomers of these en and *R*-chxn complexes show CD patterns similar to those of the corresponding apS complexes (Figs. 1—4). In Figs. 7 and 8 are given the configurational ($\Delta\varepsilon(\Lambda)$) and vicinal ($\Delta\varepsilon(S)$) effect curves, respectively, obtained from the CD spectra of Λ- and Δ-$[Co(S\text{-apSe})(en)_2]^{2+}$. The configurational effect resembles the CD spectrum of Λ-$[Co(aeSe)(en)_2]^{2+}$, and the vicinal effect curve is also similar to that derived from the *R*-chxn complexes. Thus the additivity between the two effects also holds

for the apSe complexes. While the configurational CD curve of [Co(*S*-apSe)(en)$_2$]$^{2+}$ is quite similar to that of the corresponding *S*-apS complex, the vicinal CD curve of *S*-apSe is fairly small in magnitude as compared with those of *S*-apS and *S*-apO, although these curves show a similar pattern, giving (+), (−), and (+) bands from small to large wave numbers in the first absorption band region. Thus it can be concluded that the vicinal effect of the aminoalkaneselenolate-*N*, *Se* chelate ligands is smaller than those of the corresponding thiolate-*N*,*S* and alcoholate-*N*,*O* ligands.

We have shown that the protonated *S*-apSH complexes give absorption and CD spectra quite different from those of the deprotonated ones and similar to those of the corresponding (*S*)-1,2-propanediamine complexes. However, the protonated *S*-apSe complexes were not so stable as to allow the spectral measurements.

Figure 6 shows the CD spectrum of (−)$_{589}$-*p*-[Co(apSe)(tren)]$^{2+}$. The spectrum is quite different from the vicinal CD curve of *S*-apSe obtained from [Co(*S*-apSe)(en)$_2$]$^{2+}$ as has been observed for the corresponding *S*-apS complexes. However, the fact that the CD magnitude is smaller than that of the corresponding *S*-apS complex agrees with the previous result that the vicinal effect of *S*-apSe is smaller than that of *S*-apS. The absolute configuration of apSe in the (−)$_{589}$-isomer may be assigned to *S*, since the CD pattern is rather similar to that of the corresponding *S*-apS complex. All attempts to resolve the *t*-isomer were unsuccessful.

Oxidative Degradation of Monosaccharides by Iron(III) Chlorides with a Near-UV to Visible Light under Aerobic Atmosphere

Koji ARAKI,* Masato SAKUMA, and Shinsaku SHIRAISHI*
Institute of Industrial Science, The University of Tokyo, 7-22-1, Roppongi, Minato-ku, Tokyo 106
(Received October 4, 1983)

Monosaccharides were oxidatively degraded by $FeCl_3$ with irradiation of a near-UV to visible light under aerobic atmosphere. D-Fructose and D-arabinose were degraded to D-erythrose in a yield of more than 80 mol%. D-Glucose and D-mannose were at first degraded to D-arabinose, which was subsequently degraded to D-erythrose. While, D-ribose was directly degraded to D-erythrose and D-glyceraldehyde. The degradation processes were selective, and these reactions were shown to proceed *via* formation of an Fe(III)-monosaccharide complex. The kinetic data and other features of these reactions were also discussed.

Carbohydrate is one of the main components of living organisms bearing variety of functions, and is the most abundant organic resources in nature.[1] Many metal ions are known to form complexes with carbohydrates and other polyhydroxy compounds, and these complexes are the subject of intense studies because of their physiological and clinical importances.[2-8] Among them, an Fe(III)-carbohydrate complex has been studied by several workers in relation to its potential use for the treatment of iron-deficient anemia.[5-8] However, only a little has been known as to the photochemical properties of these complexes.[9]

Photooxidation of organic substrates by an aqueous Fe(III) ion has been studied for long time,[10] and alcohols are known to be oxidized to give the corresponding aldehydes or ketones in high yields.[11,12] The photoreaction was suggested to proceed by radical processes,[13] and, therefore, the reaction was inhibited by the presence of oxygen.[11,12]

In the preceding letter, we reported that photooxidation of D-fructose by $FeCl_3$ gave D-erythrose in a high yield and that the reaction proceeded even under aerobic conditions *via* formation of an Fe(III)-D-fructose complex.[14] Since this finding might imply physiological importance, we further extended this study, and we now wish to report the more detailed studies of the photooxidation of D-fructose and several other monosaccharides by $FeCl_3$ under aerobic conditions.

Experimental

Materials and Photoreactions. D-Erythrose was purchased from Aldrich Chem. Co., and other monosaccharides were obtained from Wako Pure Chem. Ind. Ltd. Other chemicals were also commercial products, and some of them were purified by conventional methods before use.

Sample solutions were prepared freshly with deionized water, and 70 or 500 ml of the solution was irradiated internally under aerobic conditions. For the irradiation under anaerobic conditions, the solution was degassed by three times of freeze-thaw cycles. Light-source was a 100 W high-pressure mercury lamp (Type UM-102, Ushio Electric Inc.) fitted in a Pyrex-made double jacket. The jacket and the reaction vessel were kept at 20 °C by circulating water during irradiation.

For the measurement of quantum yield, a CRM-FA spectroirradiator with a 2 kW Xenon lamp (JASCO) was used. Sample solutions in quartz cells were irradiated by the light of known wavelength and energy at 20 °C.

Analyses. Decrease of pH of a solution during photoirradiation was monitored by a HM-20B pH meter (Toa Electronics Ltd.). The amount of H^+ formed was determined by titration of the irradiated solution with a 0.2 M† NaOH solution. Absorption spectra were recorded by a UVIDEC 505 spectrophotometer (JASCO) at 20 °C, and Fe(III) concentration of a sample solution was determined from the absorbance at 330 nm after 500 times of dilution with a 0.2 M HCl solution.

The irradiated solution was deionized by Amberlite IR-120 (H^+ form) and IRA-410 (HCO_3^- form) (Rohm & Haas Co.), and then water was evaporated to give a colorless syrup. The syrup was analyzed by the following three chromatographic methods; 1) high-performance liquid chromatography (HPLC) (TSK-GEL LS-450NH_2, 300×4 (ID) mm; CH_3CN 85%-H_2O 15%) with a RI-8 refractometer (Toyo Soda Manufacturing Co., Ltd.); 2) gas-liquid chromatography (GLC) after acetylation of the syrup with *N*-methylimidazole-acetic anhydride according to the method of Wachowiak and Connors[15] (Type G-2800 gas chromatograph, Yanaco; Silicone OV-17, 2000×3 (ID) mm); and 3) thin-layer chromatography (TLC) after treating the syrup with 2,4-dinitrophenylhydrazine hydrochloride (DNPH)-1,2-dimethoxyethane (DME) according to the method of Honda *et al.*[16] (Silica Gel 60F_{254}, E. Merck A G.; $CHCl_3$ 80%-CH_3OH 20%). The mass spectrum of the pre-acetylated sample after gas chromatographic separation was recorded by a JMS-DX300 mass spectrometer (JEOL).

Gases evolved from the irradiated solution were analyzed both by gas-solid chromatography (GC-4B gas chromatograph, Shimadzu; Molecular Sieve 5A or Unibeads 1S, 2000×3 (ID) mm) and mass spectrometry (RMU-7M high-resolution mass spectrometer, Hitachi, Ltd.).

Results

Oxidation of D-Fructose. An $FeCl_3$ (0.25 M)-D-fructose (0.5 M) solution (70 ml), pH of which was 1.38, was irradiated for 3 h. The initial brown solution became colorless with considerable pH decrease after irradiation. Absence of Fe(III) and formation of Fe(II) were confirmed by color reactions with potassium thiocyanate and 1,10-phenanthroline, respectively.[17] A colorless syrup obtained from the irradiated solution (yield 95—98 wt% to the initial D-fructose) was subjected to further analyses. HPLC showed the consumption of D-fructose during photoirradiation. Gas chromatogram of the pre-acetylated sample indicated the existence of a single oxidation product, and the retention time of the peak of this product coincided with that of pre-acetylated D-erythrose. Structural information of this product was further derived from

† 1 M=1 mol dm^{-3}.

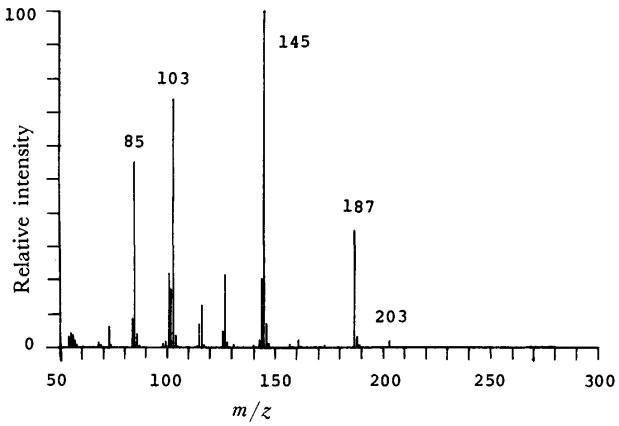

Fig. 1. The mass spectrum of the pre-acetylated oxidation product after gas chromatographic separation (23 eV E. I.).

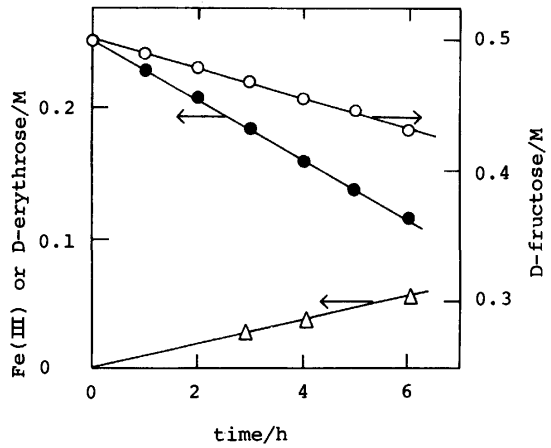

Fig. 2. Photoreaction of the $FeCl_3$ (0.25 M)–D-fructose (0.5 M) solution (500 ml) at 20°C. D-Fructose (○), Fe(III) (●), and D-erythrose (△) concentrations as a function of the irradiation time.

the GC-mass spectrometric analysis. The mass spectrum of the compound shown in Fig. 1 was found to be indistinguishable from that of D-erythrose triacetate (MW 246). Though no molecular ion peak was observed in the spectrum (m/z_{max}=203 at 23 eV E. I.), peracetyl derivatives of monosaccharides have been reported not to exhibit their molecular ion peaks.[18] In addition, the fragmentation pattern of the spectrum could reasonably be interpreted for D-erythrose triacetate based on the fragmentation pattern of other peracetylated monosaccharides.[18,19] Thus, the product was concluded to be D-erythrose. Quantitation of D-erythrose by GLC using dihydroxyacetone and/or caffeine as an internal standard revealed that D-erythrose comprised nearly 90 mol% of D-fructose oxidized, confirming that D-erythrose is the main product of the photooxidation of D-fructose.

Analysis of the syrup after treating with DNPH-DME showed several spots (R_f valuses: 0.39 (major), 0.41 (minor), 0.54 (minor), and 0.81 (minor)) in addition to those corresponding to D-fructose (0.22) and unreacted DNPH (0.62). They were assigned to be due to D-erythrose (0.39 (major) and 0.41 (minor)), D-glyceraldehyde (0.53), and formaldehyde and/or glyoxal (0.80).

A small amount of gas evolution was also observed during photoirradiation. Gases evolved under anaerobic conditions were analyzed only qualitatively by gas chromatography and mass spectrometry, which indicated the formation of CO, CO_2, and H_2.

Based on these results, we concluded that the irradiation of a Pyrex-filtered light to an acidic $FeCl_3$–D-fructose solution induces mainly the oxidative degradation of D-fructose to D-erythrose.

Figure 2 shows the time course of the reaction for a 500 ml of an $FeCl_3$ (0.25 M)–D-fructose (0.5 M) solution irradiated under aerobic atmosphere. The amount of D-fructose and Fe(III) decreased linearly as a function of time with a concomitant linear increase in the formation of D-erythrose. Even when 70 ml of this solution was irradiated under the same conditions, Fe(III) decreased linearly with the same decreasing rate. Therefore, the reaction is dependent on the light intensity under our experimental conditions. No reaction proceeded without irradiation or in the absence of any one of the substrates.

Table 1 summarizes the results of irradiation under different conditions. In all cases, 2 mol of Fe(III) oxidatively degraded 1 mol of D-fructose to give 2 mol of H^+

Table 1. Changes in the solution composition of the Fe(III)-D-fructose solution after irradiation[a]

Initial conditions				Irradiation time/h	Changes after irradiation			
Fructose/M	Fe(III)/M		Atmosphere		Fructose/M	Fe(III)/M	H^+/M	Erythrose/M[b]
0.5	$FeCl_3$	0.25	Anaerobic	2	−0.099	−0.198	+0.196	+0.080 (81%)
0.5	$FeCl_3$	0.25	Aerobic	2	−0.099	−0.199	+0.192	+0.084 (85%)
0.5[c]	$FeCl_3$	0.25	Anaerobic	2.5	−0.112	−0.224	+0.220	+0.092 (82%)
0.5[c]	$FeCl_3$	0.25	Aerobic	2.5	−0.112	−0.226	+0.222	+0.097 (87%)
0.5	$Fe(NO_3)_3$	0.25	Aerobic	2.5	−0.108	−0.222	+0.219	+0.092 (85%)
0.1	$FeCl_3$	0.1	Aerobic	0.5	−0.016	−0.034	+0.034	+0.014 (88%)
0.2	$FeCl_3$	0.1	Aerobic	0.5	−0.019	−0.040	+0.040	+0.016 (84%)
0.2	$FeCl_3$	0.2	Aerobic	0.5	−0.014	−0.030	+0.030	+0.012 (86%)
0.3	$FeCl_3$	0.1	Aerobic	0.5	−0.030	−0.062	+0.062	+0.026 (87%)
0.5	$FeCl_3$	0.1	Aerobic	0.5	−0.038	−0.078	+0.078	+0.033 (87%)
0.5	$FeCl_3$	0.25	Aerobic	0.5	−0.027	−0.055	+0.053	+0.023 (85%)

a) Sample solutions (70 ml) were irradiated internally at 20 °C. b) Conversion based on the D-fructose oxidized (mol%). c) Ref. 14.

according to the Eq. 1, and more than 80 mol% of D-fructose oxidized was converted to D-erythrose. Little

$$\text{D-fructose} + 2\text{Fe(III)} \xrightarrow{h\nu} \text{D-erythrose} + 2\text{Fe(II)} + 2\text{H}^+ \quad (1)$$

difference was observed for the reactions under aerobic and anaerobic atmosphere. These results are in good accordance with the earlier findings.[14] Use of $Fe(NO_3)_3$ instead of $FeCl_3$ did not practically alter the result, excluding the possible participation of counter anions in the reaction. Changes in the initial concentrations of the substrates did not affect the reaction scheme either. However, the reaction rate was sensitive to the initial substrate concentrations, and a higher D-fructose concentration increased the rate, while a higher Fe(III) concentration decreased the rate.

Oxidation of D-Glucose. Addition of D-glucose to an aqueous $FeCl_3$ solution caused the similar changes in color and pH of those observed when D-fructose was added. A brown $FeCl_3$ solution became reddish with a slight decrease in pH, suggesting the formation of an Fe(III)–D-glucose complex. Fig. 3 shows the difference spectrum between before and after addition of D-glucose to the Fe(III) solution, which is thought to represent the absorption due to the complex.

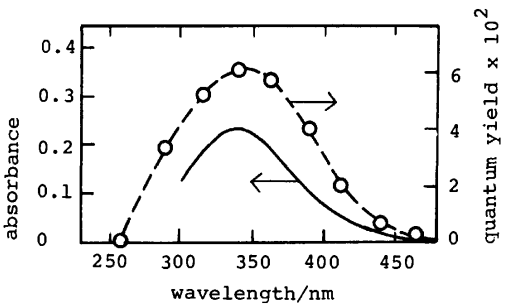

Fig. 3. The difference spectrum between before and after addition of D-glucose (——), and quantum yields of the reduction of Fe(III) (-○-) for the $FeCl_3$ (2×10^{-3} M)–D-glucose (5×10^{-1} M) solution at 20 °C.

Irradiation of a Pyrex-filtered light to an $FeCl_3$–D-glucose solution caused the reduction of Fe(III) with the concomitant consumption of D-glucose under aerobic atmosphere. Quantum yields of the reduction of Fe(III) at different wavelengths were also shown in Fig. 3, and this action spectrum coincided well with the difference spectrum, confirming that the Fe(III)–D-glucose complex is the photoreactive species. These photochemical properties of an $FeCl_3$–D-glucose solution were little different from those of an $FeCl_3$–D-fructose solution.

Colorless syrup was obtained from the irradiated solution (yield 96—100 wt% to the initial D-glucose). Analysis by HPLC and GLC indicated the formation of two products, D-arabinose and D-erythrose, as the main oxidation products. TLC after treating with DNPH also confirmed that these two compounds were the main products (R_f for D-arabinose is 0.30) along with minor spots corresponding to those for D-glyceraldehyde and for formaldehyde and/or glyoxal. Thus, more than 80 mol% of D-glucose oxidized by $FeCl_3$ was found to be degraded to D-arabinose and D-erythrose.

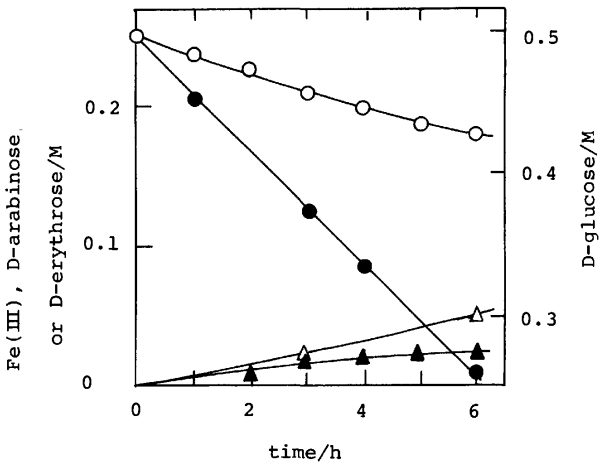

Fig. 4. Photoreaction of the $FeCl_3$ (0.25 M)–D-glucose (0.5 M) solution (500 ml) at 20 °C. D-Glucose (○), Fe(III) (●), D-arabinose (▲), and D-erythrose (△) concentrations as a function of the irradiation time.

The time course of the reaction is shown in Fig. 4, which is somewhat more complex compared to that for the oxidation of D-fructose. Fe(III) concentration decreased linearly as a function of time, indicating that the reaction is light intensity dependent. However, decrease in D-glucose concentration and increase in D-arabinose and D-erythrose concentrations were not linear, suggesting that more than one step may be

Table 2. Changes in the solution composition of D-glucose–$FeCl_3$ solution after irradiation[a]

Initial conditions		Irradiation time/h	Changes after irradiation

a) Monosaccharide (0.5 M)-$FeCl_3$ (0.25 M) solutions (70 ml) were irradiated internally for 3 h at 20 °C.
b) Conversion based on the substrate oxidized was given in parenthesis (mol%).

involved in the reaction. The results of the irradiation under different conditions are summerized in Table 2. The reaction rate was affected by the initial substrate concentrations, and higher concentration of D-glucose increased the rate, while higher concentration of $FeCl_3$ decreased the rate.

Oxidation of D-Arabinose, D-Mannose, and D-Ribose. Photooxidations of D-arabinose, D-mannose, and D-ribose by $FeCl_3$ were also studied under aerobic atmosphere, and the results are shown in Table 3. All of these monosaccharides were susceptible to the photooxidation. The oxidation product from D-arabinose was identified to be D-erythrose with nearly 90 mol% of yield. D-Mannose yielded D-arabinose and D-erythrose, quite similar to D-glucose. In the case of D-ribose, however, formation of a considerable amount of D-glyceraldehyde in addition to D-erythrose was observed by HPLC and GLC.

Discussion

D-Fructose was oxidatively degraded by $FeCl_3$ with a Pyrex-filtered light according to the Eq. 1, and more than 80 mol% of D-fructose oxidized was converted to D-erythrose, demonstrating that the oxidation process has high specificity. The reaction was shown in the preceding letter to proceed *via* formation of the Fe(III)-D-fructose complex.[14] This conclusion was deduced from the results that little difference was observed for the reactions under aerobic and anaerobic conditions and that the action spectrum of the quantum yield for the reduction of Fe(III) coincided with the absorption band of the complex. The formation of D-erythrose can best be explained by the oxidative cleavage of the bond between C-2 and C-3 of D-fructose. Therefore, it is quite probable that both or at least one of hydroxyl groups at C-2 and C-3 are involved in coordination with Fe(III). Though Charley *et al.* presented the possible structure of the Fe(III)-D-fructose complex precipitated from a weakly basic solution, no experimental evidences as to the position of iron chelation were shown,[5] and the structure of the complex in an acidic solution is not yet clear now. It is worth to note that lead tetraacetate also cleaves the bond between C-2 and C-3 of D-fructose to yield 3-*O*-glycoloyl-D-erythrose.[20] This reaction was reported to proceed from β-D-fructofuranose where hydroxyl groups at C-2 and C-3 are in *cis* configuration feasible for metal coordination. In our photoreaction, D-erythrose instead of its glycolic ester was directly formed. As formations of formaldehyde, CO, CO_2, and H_2 were observed, glycolic ester unit may be further degraded into these compounds.

The reaction was linearly dependent on the light intensity. Therefore, higher initial D-fructose concentrations increased the rate because of the increase in the concentration of the complex. However, higher initial Fe(III) concentrations decreased the rate. As the free Fe(III) ion itself has the absorption at the region where the complex shows its absorption band (300—400 nm), the result is explained by assuming that light absorption of the complex was comparatively decreased because of the light absorption by the free Fe(III) ion. To clarify more detailes of the reaction, however, the structure and other properties of the complex have still to be studied.

Photooxidation of D-glucose was also shown to proceed *via* formation of the Fe(III)-D-glucose complex, and photochemical properties of the complex were substantially similar to those of the Fe(III)-D-fructose complex. However, more than two moles of Fe(III) with respect to the D-glucose oxidized was reduced during photoirradiation, and the time course of the reaction was more complex compared to that of D-fructose (Fig. 4). Though Fe(III) decreased almost linearly, consumption of D-glucose became slower as the reaction proceeded, suggesting that the primary oxidation product was further oxidized by Fe(III). As shown in Table 3, D-arabinose was oxidized to D-erythrose in a high yield under similar conditions. Therefore, it is likely that D-glucose is oxidatively degraded to the primary product, D-arabinose, which is subsequently oxidized to D-erythrose according to the Eq. 2. This

$$\begin{aligned} \text{D-glucose} + 2\text{Fe(III)} &\xrightarrow{h\nu} \\ &\text{D-arabinose} + 2\text{Fe(II)} + 2\text{H}^+ \\ \text{D-arabinose} + 2\text{Fe(III)} &\xrightarrow{h\nu} \\ &\text{D-erythrose} + 2\text{Fe(II)} + 2\text{H}^+ \end{aligned} \qquad (2)$$

view is further supported by the following fact. The sum of the amount of D-arabinose and D-erythrose is almost the same as the amount of D-glucose decreased, and the total amount of monosaccharides oxidized by $FeCl_3$ is approximately the half of the Fe(III) reduced if we assume the Eq. 2 (Table 2). Lead tetraacetate is also known to cause the stepwise degradation of α-D-glucose into 3-*O*-formyl-D-arabinose, which is further degraded to 2,3-di-*O*-formyl-D-erythrose.[21]

The first and second steps of the reaction in the Eq. 2 are the oxidative cleavage of the bond between C-1 and C-2 of monosaccharides. Since the photooxidation of D-fructose cleaved the bond between C-2 and C-3, it seems that the photooxidation by Fe(III) causes the

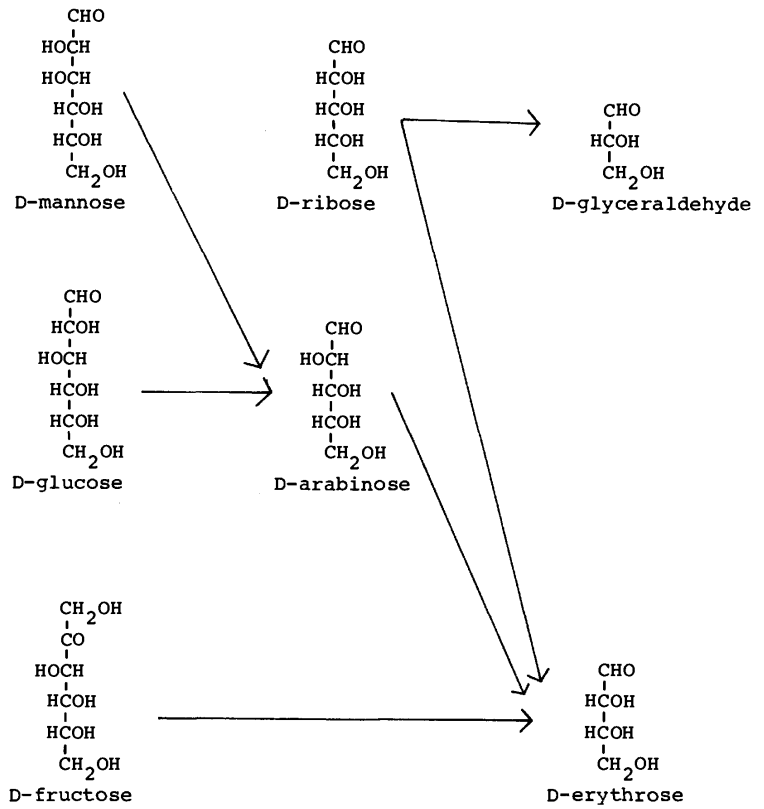

Fig. 5. Oxidative degradation of monosaccharides by $FeCl_3$ with irradiation of a Pyrex-filtered light.

cleavage of the bond between the anomeric and its adjacent carbons. In order to test whether this is the general feature of the oxidation of monosaccharides by $FeCl_3$, we studied the oxidation of D-mannose and D-ribose. Reaction of D-mannose was quite similar to that of D-glucose, suggesting that D-mannose is also oxidized stepwise *via* D-arabinose to D-erythrose. These are also the bond cleavage at the anomeric carbon. While in the case of D-ribose, approximately two moles of Fe(III) with respect to the D-ribose oxidized was reduced, suggesting that both D-erythrose and D-glyceraldehyde are directly formed from D-ribose. Though the formation of D-erythrose is due to the cleavage of the bond between C-1 and C-2, the formation of D-glyceraldehyde may be the result of the cleavage of the bond between C-2 and C-3. The latter process does not involve the anomeric carbon at C-1, and is different from other results observed here. Unlike D-arabinose, hydroxyl groups of D-ribose at C-2 and C-3 are *cis*-diol. This may enable the participation of the C-3 hydroxyl group in coordination with Fe(III), and can be the possible reason for the formation of D-glyceraldehyde. Indeed, Ca^{2+} and La^{3+} are reported to bind preferentially with α-furanose and α-pyranose forms of D-ribose which have three consecutive *cis*-hydroxyl groups from C-1 to C-3.[22]

The results presented in this paper demonstrated that many of monosaccharides are oxidatively degraded by $FeCl_3$ with irradiation of a near-UV to visible light under aerobic conditions. Except for D-ribose, the degradation processes are selective. These degradation pattern of monosaccharides are summarized in Fig. 5.

Syntheses and Properties of Dinuclear Copper(II) Complexes with 2,6-Bis[bis(2-pyridylmethyl)aminomethyl]-4-methylphenol

Masatatsu SUZUKI,*,† Hajime KANATOMI, Youichi DEMURA, and Ichiro MURASE
Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810
(Received October 11, 1983)

The dinucleating ligand, 2,6-bis[bis(2-pyridylmethyl)aminomethyl]-4-methylphenol](Hbpmp), formed two types of dinuclear copper(II) complexes, $[Cu_2(bpmp)X_2]^{n+}$(X=Cl^-, N_3^- py(pyridine), or Him(imidazole), and n=1 or 3), and $[Cu_2(bpmp)X]^{2+}$(X=CH_3COO^- or im^-). On the basis of the dinucleating nature of the ligand (bpmp), the elemental analyses and the conductivity measurements in acetonitrile, it is concluded that the complexes have dimeric unit of $[Cu_2(bpmp)X_2]^{n+}$ or $[Cu_2(bpmp)X]^{2+}$. In $[Cu_2(bpmp)X_2]^{n+}$ type complexes, two copper(II) ions are linked only by a single phenolate bridge. Magnetic susceptibilities of those complexes obey Curie-Weiss law in the temperature range 80—300 K with the Weiss constants ≈ -4 K, indicating that weak antiferromagnetic interactions are present in these complexes. In $[Cu_2[bpmp)X]^{2+}$ type complexes, however, two copper(II) ions are bridged by phenolate and acetate, or phenolate and imidazolate. Cryomagnetic measurements of the acetato and the imidazolato complexes showed antiferromagnetic interactions with the $-2J$ values of 82 and 66 cm^{-1}, respectively. All the complexes exhibited absorption bands at 20000—22000 cm^{-1} except for the azido complex. The origin of those bands are discussed.

Various types of quinquedentate and septidentate dinucleating ligands (L) such as Schiff-bases derived from 2,6-diformyl-4-methylphenol and various amines, 2,6-bis[bis[2-(2-pyridyl)ethyl]aminomethyl]-4-methylphenol (Hbpep), *etc.*, have been designed.[1-6] Dinuclear copper(II) complexes with those ligands are of current interest as models for the active sites of type III coppers such as hemocyanin, tyrosinase, and multicopper oxidases. General formula of those complexes is $[Cu_2(L)X]^{2+}$, in which two copper ions are linked by two bridging groups, *viz.*, phenolate or alkoxide, and additional bridging ligand (X) (X= OH^-, Cl^-, N_3^-, $C_3H_3N_2^-$ (pyrazolate), CH_3COO^-, *etc.*).

In the previous studies,[7-9] however, we found that the dinucleating ligand, 2,6-bis[bis(2-pyridylmethyl)-aminomethyl]-4-methylphenol (Hbpmp) forms new type of five-coordinate dinuclear cobalt(II) complexes, $[Co_2(bpmp)X_2]^+$ (X=Cl^-, Br^-, NCS^-, and N_3^-), in which two cobalt(II) ions are linked only by a single phenolate bridge. In those complexes, two vacant coordination sites (the sixth coordination sites) are positioned in close proximity and some of the complexes react reversibly with molecular oxygen to form μ-peroxo complexes. Such type of dinuclear copper(II) complexes bridged only by a single phenolate group is rare and attractive for studying interactions with various molecules such as hydrogen peroxide, ascorbic acid, *etc.*, with two copper(II) ions. Therefore, we have undertaken to prepare such type of dinuclear copper(II) complexes with bpmp, $[Cu_2(bpmp)X_2]^{n+}$. This paper deals with the preparations, and magnetic and electronic properties of those complexes. $[Cu_2(bpmp)X]^{2+}$ type complexes in which X acts as bridging ligand are also reported, where X represents CH_3COO^- or im^- (imidazolate).

Experimental

Preparation. The dinucleating ligand, Hbpmp, was prepared according to the literature.[7]

$[Cu_2(bpmp)(py)_2](ClO_4)_3 \cdot 2H_2O$. Pyridine (1.5 mmol) was added to a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (1 mmol) and Hbpmp (0.5 mmol) in methanol (50 cm^3) with stirring. The blue crystals deposited were filtered, washed with ethanol, and dried *in vacuo*.

$[Cu_2(bpmp)(Him)_2](ClO_4)_3 \cdot H_2O$. Imidazole (1.5 mmol) was added to a hot methanol solution (50 cm^3) of $Cu(ClO_4)_2 \cdot 6H_2O$ (1 mmol) and Hbpmp (0.5 mmol) with stirring to give blue oil. The resulting oil was dissolved in 50 cm^3 of methanol on heating to give violet solution. On cooling, the blue crystals formed were collected by filtration, washed with ethanol, and air dried *in vacuo*.

$[Cu_2(bpmp)(N_3)_2]ClO_4$. A solution of sodium azide (1.5 mmol) in water was added to a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (1 mmol) and Hbpmp (0.5 mmol) in 50 cm^3 of CH_3CN and CH_3OH mixture (1:1). The resulting brown solution was filtered and the filtrate was allowed to stand overnight to give brown crystals, which were collected by filtration, washed with ethanol and dried *in vacuo*.

$[Cu_2(bpmp)Cl_2]ClO_4 \cdot CH_3OH \cdot H_2O$. A solution of NaCl (1.5 mmol) in water was added to a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (1 mmol) and Hbpmp (0.5 mmol) in 50 cm^3 of aqueous methanol (1:1). The resulting brown solution was allowed to stand overnight to give blue grey crystals, which were collected by filtration, washed with ethanol, and dried *in vacuo*.

$[Cu_2(bpmp)(CH_3COO)](ClO_4)_2$. Sodium acetate (0.05 mmol) was added to a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (1 mmol) and Hbpmp (0.05 mmol) in methanol (30 cm^3). To the resulting brown solution was added 50 cm^3 of ethanol to give brown crystals, which were collected by filtration, washed with ethanol, and dried *in vacuo*.

$[Cu_2(bpmp)im](ClO_4)_2 \cdot 1.5CH_3CN$. A solution of CH_3ONa (1 mmol) in methanol (5 cm^3) was added to a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (1 mmol), Hbpmp (0.5 mmol), and Him (0.5 mmol) in acetonitrile (30 cm^3) to give a dark brown solution. Addition of ethanol to the brown solution gave brown crystals, which were collected by filtration, washed with ethanol, and dried *in vacuo*.

Measurements. The electronic spectra in solution and in solid were obtained with a Hitachi EPS-3T recording spectrophotometer and infrared spectra were recorded with a Hitachi 295 spectrophotometer by means of KBr disk. Magnetic susceptibilities were measured by Faraday method in the temperature range 80—300 K. Diamagnetic correction was made using Pascal's constants.[10] Molar conductivities of the complexes were determined in acetonitrile solution (10^{-3} mol dm^{-3}) at 25°C.

†Present adress: Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920.

Results and Discussion

$[Cu_2(bpmp)X_2]^{n+}$ Type Complexes. As was mentioned before, dinucleating ligands (L) such as bpep have been shown to form $[Cu_2(L)X]^{2+}$ type complexes. However, the addition of NaX to a mixture of Hbpmp and $Cu(ClO_4)_2 \cdot 6H_2O$ gave a new type of dinuclear complexes, $[Cu_2(bpmp)X_2]^+$ (X=Cl$^-$ and N_3^-).

The infrared spectra of $[Cu_2(bpmp)X_2]ClO_4$ complexes indicated the presence of uncoordinated perchlorate ions because no splitting of the ν(Cl-O) bands was observed definitely. The azido complex exhibited a single strong ν_{asymm} (N_3) band at 2038 cm^{-1}, suggesting that each azide ion coordinates to copper(II) ion in a similar way. In addition, the molar conductivities of those complexes indicated the presence of 1:1 electrolytes in acetonitrile (Table 1).[11] Those observations imply that the complexes have dimeric unit of $[Cu_2(bpmp)X_2]^+$ in which each X$^-$ ion coordinates to copper(II) ion and two copper(II) ions are linked only by a single phenolate bridge as was found for the corresponding dinuclear cobalt(II) complexes.[9] A possible structure of $[Cu_2(bpmp)X_2]^+$ type complexes is given in Fig. 1.

The addition of such bases as pyridine or imidazole to a mixture of Hbpmp and $Cu(ClO_4)_2 \cdot 6H_2O$ in methanol also afforded $[Cu_2(bpmp)X_2]^{3+}$ type complexes. The infrared spectra and molar conductivities also suggested that the complexes have dimeric unit of $[Cu_2(bpmp)X_2]^{3+}$ in which two copper(II) ions are bridged only by a single phenolate.

The present dinucleating ligand (bpmp) contains two tripodal parts ($N(CH_2py)_2(CH_2C_6H_5O^-)$). It is known that the tripod ligands which form three five-membered chelate rings tend to enforce trigonal bipyramidal copper(II) complexes with an additional unidentate ligand.[12] In general, trigonal bipyramidal copper(II) complexes show a band with a high energy shoulder in the d-d region.[13] However, $[Cu_2(bpmp)Cl_2]^+$ shows a band at *ca.* 14000 cm^{-1} with a low energy shoulder at $\approx$10000 cm^{-1} both in solid and acetonitrile (Fig. 2 and Table 2). This spectral pattern is indicative of a square pyramidal or a distorted square pyramidal structure about copper(II) ion.[13] An additional band is observed at 20000—22000 cm^{-1} both in solid and in acetonitrile. The complexes containing phenolate group(s) have been shown to display

phenolate (Opπ) to copper(II) ($d_{x^2-y^2}$) charge-transfer (CT) bands in the visible or the near-ultraviolet region.[5,6,14,15] It is unlikely that the band is ascribed to the d-d transitions since such a (distorted) square pyramidal complex with ClN_3O donor set would not exhibit the d-d band at such high energy. It is also unlikey that chloride (pπ) to copper CT transitions occur at such low energy; chloride to copper CT transitions would be expected to occur at about 30000 cm^{-1}.[16] Therefore, we believe that the band at 20000—22000 cm^{-1} is ascribed to phenolate to copper CT transition. A shoulder observed at 30000 cm^{-1} is assigned to chloride to copper CT transitions.

The azido complex exhibits a broad band at 13000 cm^{-1} in the reflectnace spectrum, while in the absorption spectrum, this band is resolved into a single band and a low energy shoulder. This spectral pattern is also indicative of a (distorted) square pyramidal structure. An intense band (ε=2500 mol^{-1}dm^3 cm^{-1}) is observed at 25000 cm^{-1}. This band is assigned to azide to copper CT transitions. Phenolate to copper CT transition may be hidden under this intense band.

The pyridine and the imidazole complexes exhibit the d-d band maxima at 15000—16000 cm^{-1} in the reflectance spectra, which are shifted to blue (1000—2000 cm^{-1}) compared with those of the chloro and the azido complexes. These blue shifts of the d-d band maxima of the former two complexes are attributed to the stronger ligand field strengths of pyridine and imidazole. The pyridine and the imidazole complexes show bands at 20000—21000 cm^{-1}. We tentatively assigned those bands to phenolate to copper CT transitions. If these assignments are correct, the energies of phenolate to copper CT transitions of $[Cu_2(bpmp)X_2]^{n+}$ type complexes are much lower than that of $[Cu_2(bpep)N_3]^{2+}$ (26000 cm^{-1}). This shift of the CT transition energies may be attributed to the geometries of the Cu-O-Cu moieties.[17]

Sakurai *et al.*[18] reported that $[Cu_2(tba)_2pcp]^{3+}$ (tba=tris(2-benzimidazolylmethyl)amine and pcp=4-chlorophenolate) in which two copper(II) ions are bridged only by a single phenolate group shows a reduced magnetic moment (1.7 BM[††]) at room temperature in acetone. However, magnetic property of this complex has not been fully investigated. The magnetic susceptibilities of the present complexes obey Curie-Weiss law in the temperature range 80—300 K with Weiss constants of −4— −5 K (Fig. 3 and Table 3). This implies that, although antiferromagnetic interactions are present between two copper(II) ions, they are very weak. Thus in these complexes, phenolic oxygens are not good mediator for antiferromagnetic superexchange pathway. In order to discuss their magnetisms more fully, precise structure data are necessary.

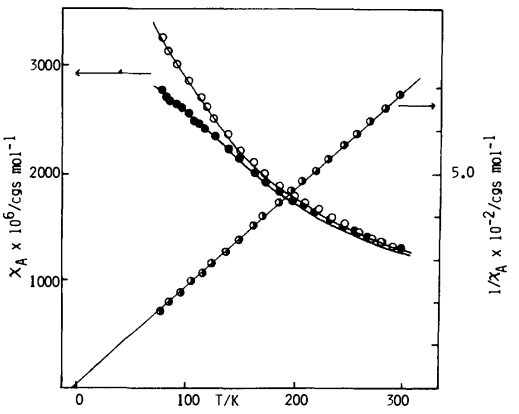

Fig. 3. Temperature dependence of inverse magnetic susceptibilities of $[Cu_2(bpmp)Cl_2]ClO_4\cdot CH_3OH\cdot H_2O$ (◑), and temperature dependence of magnetic susceptibilities of $[Cu_2(bpmp)(CH_3COO)](ClO_4)_2$ (●) and $[Cu_2(bpmp)im](ClO_4)_2\cdot 1.5CH_3CN$ (○). Solid curves for $[Cu_2(bpmp)(CH_3COO)](ClO_4)_2$ and $[Cu_2(bpmp)im](ClO_4)_2\cdot 1.5CH_3CN$ are drawn based on the Eq. 1 using the parameters listed in Table 3.

As was mentioned before, the dinucleating ligand, bpep, forms $[Cu_2(bpep)X]^{2+}$ type complexes [X=Cl$^-$ and N_3^-),[5] whereas bpmp forms $[Cu_2(bpmp)X_2]^+$ type complexes. This suggests that in the bpmp complexes, it is difficult for the binding sites available for linking two copper ions by one atom bridge such as Cl$^-$ to approach in close proximity. Thus the chelate ring size of dinucleating ligand has a significant influence on stereochemistry of dinuclear copper(II) complex. It was attempted to prepare $[Cu_2(bpmp)X]^{2+}$ type complexes containing one atom bridge (X), and $[Cu_2(bpmp)(OH)](ClO_4)_2$ was obtained (*vide infra*).

$[Cu_2(bpmp)X]^{2+}$ Type Complexes. The addition of NaOH to a mixture of Hbpmp and $Cu(ClO_4)_2\cdot 6H_2O$ in aqueous acetonitrile afforded green powder. The elemental analysis of the green powder is in agreement with $[Cu_2(bpmp)(OH)](ClO_4)_2$. Although magnetic susceptibility data over temperature range 80—300 K suggested that antiferromagnetic interaction is present in this complex, the data could not be explained on the basis of the Bleaney-Bowers equation.[19] The preparation of the complex was repeated several times

[††] 1 BM=0.9273$\times 10^{-23}$ JT^{-1}.

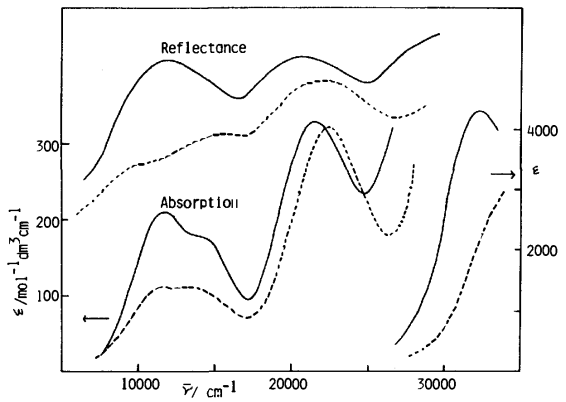

Fig. 4. Reflectance and absorption spectra of $[Cu_2(bpmp)im](ClO_4)_2 \cdot 1.5CH_3CN$ (——) and $[Cu_2(bpmp)(CH_3COO)](ClO_4)_2$ (----).

under various conditions. However, magnetic susceptibilities of those complexes were found to be highly dependent on the preparative conditions. Thus, in this experiment, magnetically pure $[Cu_2(bpmp)(OH)](ClO_4)_2$ could not be obtained.

On the other hand, the acetate-bridged complex, $[Cu_2(bpmp)(CH_3COO)](ClO_4)_2$, was easily obtained by mixing Hbpmp, $Cu(ClO_4)_2 \cdot 6H_2O$, and CH_3COONa in methanol. The infrared spectrum showed that $\Delta\tilde{\nu}(\tilde{\nu}_{asymm}(CO_2^-) - \tilde{\nu}_{symm}(CO_2^-))$ is $\approx 120\,cm^{-1}$, suggesting that the acetate ion acts as bridging ligand in syn-syn configuration.[20] The reflectance spectrum exhibits three bands at 9600, 15300, and 21700 cm^{-1} (Fig. 4). The former two bands are assigned to the d-d bands and this spectral pattern suggests a (distorted) square pyramidal coordination geometry about copper(II). The absorption spectrum is different from the reflectance spectrum, implying that the structural change occurs in acetonitrile. The band at 21700 cm^{-1} can be assigned to phenolate to copper CT transition and/or bridging acetate to copper CT transition, since dimeric copper(II) acetate monohydrate shows carboxylate to copper CT transition in this region.[21]

Such dinuclear copper(II) complexes with acetate bridge in syn-syn configuration and additional bridging ligand are rare.[3,4] Reed *et al.*[4] reported that $[Cu_2(L\text{-}Et)(CH_3COO)](ClO_4)_2$ (L-Et=1,3-bis[bis(1-ethylbenzimidazole-2-ylmethyl)amino]-2-propanolate) is essentially spin free. However, the present complex showed demagnetization by spin-pairing. Magnetic susceptibility data can be explained on the basis of the Bleaney-Bowers equation,

$$\chi_A = Ng^2\beta^2/3KT[1 + 1/3\exp(-2J/KT)]^{-1} + N\alpha, \quad (1)$$

where the symbols have their usual meanings. The $-2J$, g, and $N\alpha$ values were determined by the best fit of the χ_A values to the Bleaney-Bowers equation (1) (Fig. 3 and Table 3). The $-2J$ value thus obtained is 82 cm^{-1}, indicating that antiferromagnetic interaction is present between two copper(II) ions.

In the course of the preparation of $[Cu_2(bpmp)(Him)_2](ClO_4)_3$ (blue crystals) in acetonitrile, very small amount of brown crystals were obtained as a byproduct. The elemental analysis showed that the brown compound has a chemical composition of $[Cu_2(bpmp)(im)](ClO_4)_2 \cdot 1.5CH_3CN$. This brown compound was easily prepared by the method described in the experimental section. Since the complex contains imidazolate and phenolate anions, the imidazolate and phenolate are expected to act as bridging ligands. The conductivity measurement indicated the presence of a 2:1 electrolyte in acetonitrile. This implies that the complex has a dimeric unit, $[Cu_2(bpmp)im]^{2+}$, in acetonitrile.

The complex shows a single band at 11800 cm^{-1} in the reflectance spectrum, whereas in the absorption spectrum this band is resolved into a band and a high energy shoulder. As was mentioned before, trigonal bipyramidal complexes show a band with a high energy shoulder and the energies of the main bands are much lower than those of square pyramidal complexes with the same donor sets. Thus the electronic spectra both in solid and in acetonitrile suggest that the complex adopts a trigonl bipyramidal structure. The complex also exhibits a band at 21500 cm^{-1} both in solid and in acetonitrile. This band is assigned to imidazolate ($p\pi$) to copper(d_{z^2}) or less probably to phenolate to copper(d_{z^2}) CT transition. The magnetic susceptibilities were measured in the temperature range 80—300 K. The experimental data can be well explained on the basis of the Bleaney-Bowers equation (Fig. 3). This supports that the complex has a dinuclear unit with an imidazolate bridge. The $-2J$ value obtained is 66 cm^{-1}, indicating the presence of antiferromagnetic interaction between two copper(II) ions. Since the complex is trigonal bipyramidal, the magnetic d orbital (d_{z^2}) seems to interact mainly with the bridging imidazolate and only weakly with bridging phenolate which is in the equatorial plane. Therefore, it is probable that the bridging imidazolate provides the major superexchange pathway for the antiferromagnetic interaction between copper(II) ions. The magnitude of the antiferromagnetic interaction for the present complex is comparable to those of the imidazolate-bridged dinuclear copper(II) complexes so far reported.[22]

Our thanks are due to Prof. S. Kida, Prof. H. Okawa, Dr. Y. Nishida, and Dr. M. Mikuriya for their helpful disucssions.

Magnetic and Spectral Properties of 3,5-Dichloropyridine Adducts of Dimeric Copper(II) Acetate, Chloroacetate, and Dichloroacetate

Yoneichiro MUTO,* Tadashi TOKII, Kiyohiko CHIJIWA, and Michinobu KATO†
Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

(Received October 19, 1983)

Three complexes with the empirical formula of $Cu(RCOO)_2 \cdot L$, where $R=CH_3$, CH_2Cl, or $CHCl_2$ and L=3,5-dichloropyridine, were prepared and studied. These complexes display the antiferromagnetic behavior typical of dimeric copper(II) carboxylates. The singlet-triplet splitting energy ($-2J$) is 349 cm^{-1} for the acetate, 340 cm^{-1} for the monochloroacetate and 312 cm^{-1} for the dichloroacetate. Comparison of their magnetic and electronic spectral properties with those of the corresponding pyridine adducts indicates that both the $-2J$ and $\tilde{\nu}_{max}$(absorption maximum of Band I) values of the respective 3,5-dichloropyridine adducts are higher than those of the pyridine adducts. The influence of the pyridines on both the magnetic and spectral properties was discussed.

It has already been pointed out that the antiferromagnetic interaction in dimeric copper(II) carboxylate adducts, $[Cu(RCOO)_2 \cdot L]_2$ (*cf.* Fig. 1), tends to increase as either the addend ligand L or the carboxylate substituent R becomes a stronger electron donor.[1] Therefore, the singlet-triplet separation ($-2J$, a measure of the magnitude of the magnetic interaction) is expected to increase as the pK_a of L becomes higher.[2] In the previous study of dimeric copper(II) acetate adducts with thiazoles,[3] however, we have found that, while the pK_a of thiazole (2.44)[4] is lower than that of pyridine (5.32),[5] the $-2J$ value of the thiazole adduct (344 cm^{-1}) is higher than that of the pyridine adduct (325 cm^{-1}).[6]

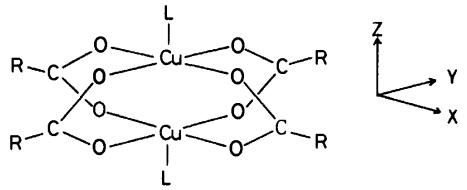

Fig. 1. Molecular structure of $[Cu(RCOO)_2 \cdot L]_2$ with reference axes marked.

In the present study, we have prepared copper(II) acetate, chloroacetate and dichloroacetate complexes with 3,5-dichloropyridine (3,5-Cl_2py) as the addend ligand which is a much weaker base (pK_a=0.67)[7] than pyridine (py). The magnetic and spectral properties of the copper(II) carboxylate complexes with 3,5-dichloropyridine and pyridine were compared with each other and the influence of the addend ligands on the magnetic interaction was discussed. The magnetic susceptibilities of dimeric copper(II) acetate complexes with 4-cyanopyridine (4-CNpy)[8] and caffeine (caf)[9] were also re-examined to contribute to the discussion.

Experimental

Syntheses. $Cu(CH_3COO)_2 \cdot L$ (L=3,5-Cl_2py and 4-CNpy): A solution of L (5 mmol) in ethanol (5 ml) was added to a solution of $Cu(CH_3COO)_2 \cdot H_2O$ (5 mmol) in ethanol (30 ml) with a few drops of glacial acetic acid. After the solution had been allowed to stand overnight at *ca.* 5 °C in a freezer, the separated green crystals were collected, washed with ethanol and dried at *ca.* 60 °C.

$Cu(CH_3COO)_2 \cdot caf$: This complex was prepared according to the method of Melnik.[9]

$Cu(ClCH_2COO)_2 \cdot L$ and $Cu(Cl_2CHCOO)_2 \cdot L$ (L=3,5-Cl_2py and py): A solution of L (5 mmol) in chloroform (20 ml) was added to one of the carboxylates (5 mmol), $Cu(ClCH_2COO)_2$ and $Cu(Cl_2CHCOO)_2$, suspended in chloroform (30 ml). After the resulting solution had been concentrated to one-third of its volume, it was allowed to stand overnight at *ca.* 5 °C in a freezer. The green crystals were collected, washed with benzene and dried at *ca.* 60 °C.

The results of the elemental analyses are given in Table 1.

TABLE 1. ANALYTICAL DATA

Complex	Found (Calcd) (%)			
	C	H	N	Cu
$Cu(CH_3COO)_2$(3,5-Cl_2py)	32.70 (32.79)	2.75 (2.75)	4.05 (4.25)	19.17 (19.28)
$Cu(CH_3COO)_2$(4-CNpy)	41.87 (42.03)	3.62 (3.53)	9.94 (9.80)	22.32 (22.24)
$Cu(CH_3COO)_2$(caf)	38.38 (38.35)	4.31 (4.29)	14.96 (14.91)	16.83 (16.91)
$Cu(ClCH_2COO)_2$(3,5-Cl_2py)	27.06 (27.13)	1.76 (1.77)	3.48 (3.51)	15.90 (15.95)
$Cu(ClCH_2COO)_2$(py)	33.00 (32.79)	2.77 (2.75)	4.13 (4.25)	19.19 (19.28)
$Cu(Cl_2CHCOO)_2$(3,5-Cl_2py)	23.07 (23.13)	1.08 (1.08)	2.93 (3.00)	13.43 (13.60)
$Cu(Cl_2CHCOO)_2$(py)	27.61 (27.13)	1.80 (1.77)	3.43 (3.51)	15.78 (15.95)

Physical Measurement. Magnetic susceptibilities in the temperature range of 80—300 K were determined by the Faraday method. The correction for diamagnetic contribution (χ_{dia}) was made by use of Pascal's constants.[10] The cryomagnetic data were fitted to the Bleaney-Bowers equation (1) allowing for the presence of paramagnetic impurity,[11]

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1}(1-P) + \frac{Ng_i^2\beta^2}{4kT}\cdot P + N\alpha, \quad (1)$$

where P is the mole fraction of the noncoupled copper(II) impurity, g_i is the average g factor for the impurity which was fixed at 2.2 throughout the present study, and the other symbols have their usual meanings. The best-fit parameters, $-2J$, g, $N\alpha$, and P, were obtained by using a nonlinear least-squares program written by T. Nakagawa (The University of Tokyo) and Y. Oyanagi (The University of Tsukuba), SALS (model D), on a FACOM M-200 computer at the Nagoya University Computation Center. As a convenient statistical indicator of the quality of the least-squares fits, the discrepancy index, σ_{dis}, was employed:

$$\sigma_{dis} = \left[\frac{\sum(\chi_{obsd}-\chi_{calcd})^2}{\sum\chi_{obsd}^2}\right]^{1/2} \quad (2)$$

The thermal magnetic data are shown in Figs. 2 and 4 as plots of χ_A *vs.* T. The values of χ_{dia}, g, $N\alpha$, P, $-2J$, and σ_{dis} are summarized in Table 2.

Reflectance spectra were recorded on a Hitachi Recording Spectrophotometer 323.

Results and Discussion

The variable-temperature magnetic susceptibility data of the complexes prepared in the present study are well represented by Eq 1, indicating that the complexes all have a dimeric structure similar to that found for copper(II) acetate monohydrate, $[Cu(CH_3COO)_2\cdot H_2O]_2$.[12] From Table 2, we can see the following trends in the magnetic properties. First, the antiferromagnetic interactions in the respective 3,5-dichloropyridine adducts are stronger than those in the corresponding pyridine adducts. Secondly, the $-2J$ values in both the series of 3,5-dichloropyridine and pyridine adducts decrease as the parent carboxylic acids become stronger.

The reflectance spectra of the complexes resemble with each other in shape and are quite similar to those of $[Cu(CH_3COO)_2(py)]_2$ (*cf.* Fig. 3).[13] The spectra show two bands having maxima at *ca.* 26000 cm^{-1} (Band II)[14] and *ca.* 14000 cm^{-1} (Band I)[14] with a shoulder at *ca.* 8000 cm^{-1}. The wave numbers of the

band maxima ($\tilde{\nu}_{max}$) are listed in Table 3 and their spectral curves are shown in Fig. 3. For comparison, the reflectance spectral curve of $[Cu(CH_3COO)_2(py)]_2$[13] is given in Fig. 3. It is now generally recognized that Bands I and II can be assigned respectively to a ligand field transition involving the positive hole promotion $d_{x^2-y^2} \rightarrow d_{xz}$, d_{yz}[15,16] (*cf.* the coordinate system given in Fig. 1) and to a charge transfer from the carboxylato-oxygen atoms to the metal ion.[17,18] Accordingly, Band I is expected to be sensitive to the nature of both the ligands $RCOO^-$ and L. As can be seen in Table 3 and Fig. 3, the $\tilde{\nu}_{max}$ values of Band I for the 3,5-dichloropyridine adducts are higher than those for the corresponding pyridine adducts. The order of the increase in the $\tilde{\nu}_{max}$ values is the same as that in the $-2J$ values, giving a linear relation between the $\tilde{\nu}_{max}$ and $-2J$ values ; *i.e.*, "higher $\tilde{\nu}_{max}$—higher $-2J$". This linear relation may be explained in terms of the electroneutrality principle[19] as follows. In dimeric copper(II) carboxylate adducts, $[Cu(RCOO)_2 \cdot L]_2$, when the L→Cu donation becomes weaker, the covalent Cu—O bonds in the CuO_4 basal plane will become stronger to maintain the electroneutrality over the whole molecule; *i.e.*, a weaker L→Cu donation will cause a stronger ligand field of the four carboxylato-oxygen atoms around the metal ion. This leads to a larger splitting of the d-d energy levels, resulting in a blue shift of Band I. This assumption is consistent with the observation by Dubicki and Martin[8] that, in a series of dimeric copper(II) acetate adducts with pyridine analogues, Band I shifts to a higher energy as the pK_a of the addend ligand decreases. For the mechanism of the magnetic interaction in dimeric copper(II) carboxylates, experimental evidence[20-23] shows that the spin-coupling between the unpaired electrons of copper(II) ions operates predominantly by superexchange interaction through the bridging carboxylato ligands rather than by direct Cu—Cu interaction. Accordingly, the magnetic interaction will become stronger as the Cu—O bonds become stronger. In the present complexes, the increase in both $-2J$ and $\tilde{\nu}_{max}$ accompanied with the replacement of pyridine with 3,5-dichloropyridine takes place in accord with the expectation based on their pK_a values (py=5.32[6] and 3,5-Cl_2py=0.67[7]) as stated above. The effect of Cu→L π-back-donation on the magnetic interaction in the present adducts may not be entirely negligible. However, the π-back-donation will make the metal more positive and thus will enhance the antiferromagnetic interaction: an effect of the same trend as caused by weak L→Cu σ donation.

From the experimental results and discussion stated above, we can conclude that, contrary to the result by Jotham, Kettle and Marks,[1] the antiferromagnetic interaction in dimeric copper(II) carboxylate adducts should become stronger as the basicity of the addend ligands becomes weaker. The values of $-2J$ for dimeric copper(II) acetate adducts with some pyridine analogues were previously reported to decrease as the pK_a values of the addend ligands decrease: 4-CH_3py (325 cm^{-1})>4-CH_3COpy (311 cm^{-1})>4-CNpy (300 cm^{-1}).[8] However, we have found the reverse order: 4-CH_3py (333 cm^{-1})<4-CNpy (345 cm^{-1}) (*cf.* Table 2 and Fig. 4). We have further found that the $-2J$ of the 4-cyanopyridine adduct of dimeric copper(II) trichloroacetate (229 cm^{-1}) is higher than that of the corresponding pyridine adduct (189 cm^{-1}).[24] The present result can explain the apparent anomalous magnetism of dioxane adducts. Dioxane has no appreciable π-acceptor ability, and it usually appears to be the weakest base (pK_a=−2.92)[25] in a series of adducts for a given copper(II) carboxylate dimer. Thus, dioxane adducts usually give the highest values in both $-2J$ and $\tilde{\nu}_{max}$ (Band I) for dimeric copper(II) carboxylate adducts.[26] For the 3,5-dichloropyridine and pyridine adducts, both $-2J$ and $\tilde{\nu}_{max}$ values decrease as the parent carboxylic acid becomes stronger (*cf.* Tables 2 and 3). This trend can be explained in terms of weakening of the ligand field strength of the four carboxylato-oxgen atoms.[8,27]

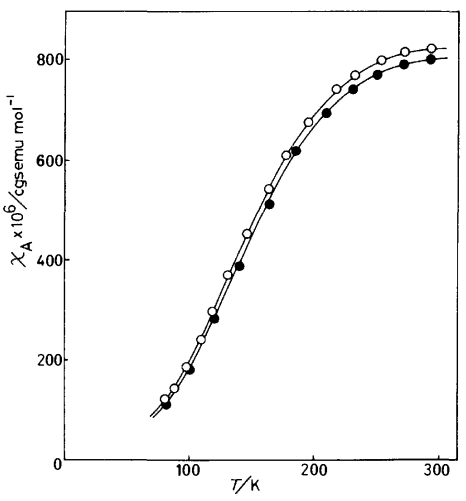

Fig. 4. Variation of magnetic susceptibilities with temperature.
(●) $Cu(CH_3COO)_2$(caf), (○) $Cu(CH_3COO)_2$(4-CNpy). The solid curves were obtained as described in text.

It must be noted here that the extremely high $-2J$ values have been reported for dimeric copper(II) acetate adducts of quinuclidine ($495 \pm 49\,cm^{-1}$)[28] and caffeine ($700\,cm^{-1}$).[9] These high $-2J$ values are unacceptable on referring to our present conclusion. The pK_a value of quinuclidine (11.49)[29] is very large. Actually, Jotham, Kettle, and Marks have re-evaluated the $-2J$ value of the quinuclidine adduct to be $318\,cm^{-1}$ by applying a least-squares fitting procedure to the reported magnetic data.[1] For the caffeine adduct, the reported magnetic susceptibilities do not agree completely with the values calculated by Eq. 1 using the reported parameter values of $-2J=700\,cm^{-1}$, $g=2.20$, $N\alpha=0$, and $P=0$. Accordingly, we repeated the magnetic measurement on the newly prepared caffeine adduct. The least-squares fitting of the cryomagnetic data gave a $-2J$ value of $353\,cm^{-1}$ (*cf.* Table 2 and Fig. 4). These renewed $-2J$ values are not abnormally high and are just comparable to those reported for well-characterized dimeric copper(II) acetate adducts.[20]

The present study was partially supported by a Grant-in-Aid for Scientific Reseach No. 58540395 from the Ministry of Education, Science and Culture.

(Received October 25, 1983)

Reactions of *trans*-chloro(cyanomethyl)bis(triphenylphosphine)palladium(II), *trans*-[PdCl(CH_2CN)(PPh_3)$_2$] (**1**), with an equimolecular amount of Tl(β-dik) (β-dik=etac, acac, tfac, bzac, and dbm) in dichloromethane afforded the *O,O'*-chelated β-dik complexes [Pd(CH_2CN)(β-dik)(PPh_3)] (**3**). Hydrogen peroxide oxidation and chloride abstraction by $AgClO_4$ or $AgBF_4$ of **1** gave the neutral [PdCl(CH_2CN)PPh_3]$_n$ and the cationic [Pd(CH_2CN)(PPh_3)$_2$]$_m$$X_m$ (X=ClO_4 or BF_4), respectively, from either of which complexes **3** were also obtained by the reactions with the β-dik anions. No pure product corresponding to **3** was isolated by a similar treatment of **1** with Tl(hfac). On the other hand, chloro(cyanomethyl){1,2-bis(diphenylphosphino)ethane}palladium(II), [PdCl(CH_2CN)(dppe)] (**2**), reacted only with Tl(hfac) in refluxing acetone to give the cationic [Pd(CH_2CN)(dppe)]$_2$-(hfac)$_2$, which was also derived from **2** *via* [Pd(CH_2CN)(dppe)]$_2$$X_2$ (X=ClO_4 or BF_4).

In recent years many cyanoalkyl complexes of the type [MX(RCN)L_2] (M=Pd^{II}, Pt^{II}; X=halides or other monoanions; R=$(CH_2)_n$ (n=1,2,3), $CH_2C_6H_4$; L_2=2PPh_3, diphosphines) have been prepared[1-7] and their structures and various kinds of reactions have been studied extensively.[5-14] Among the cyanoalkyls examined, the complexes of *o*-cyanobenzyl, [MX(*o*-$CH_2C_6H_4CN$)L_2], underwent the widest range of reactions: (1) displacement of L by bidentate phosphorus ligands, (2) insertion of CO in the σ M-C bond, (3) formation of the cationic *cis*-[M($CH_2C_6H_4CN$)L_2]$_2$-(BF_4)$_2$ by abstraction of X,[6,7] and (4) nucleophilic attack by alcohols, thiols, and other nucleophiles on the coordinated CN group.[6,10-12] Moreover, the thermodynamically unstable *cis*-[PtX($CH_2C_6H_4CN$)-(PPh_3)$_2$] (X=Cl, Br) isomerized to the trans isomers, the reaction being catalyzed by free PPh_3.[6]

Although the cyanomethyl complexes of platinum-(II), [PtX(CH_2CN)L_2], have been also known to undergo the similar reactions to (1) and (3), and cis-trans isomerization,[3,5] only few studies have been performed on reactions of the palladium(II) analogue[2,14] which was found to decompose on irradiation in the solid state or in solution.[9] In this paper, we report the reactions of *trans*-[PdCl(CH_2CN)(PPh_3)$_2$] (**1**) and [PdCl(CH_2CN)-(dppe)] (**2**) with various Tl(β-dik) to know what kind of bonding mode is found for the β-dik ligands in the product complexes since β-dik anions are well-known as versatile ligands to coordinate to metal ions in various kinds of bonding modes.[15]

Results and Discussion

Thallium(I) β-diketonates employed, except 1,1,1,5,5,5-hexafluoro-2,4-pentanedionate, readily react with **1** in dichloromethane at room temperature to yield the *O,O'*-chelated β-dik complexes [Pd(CH_2CN)(β-dik)PPh_3] (**3**). Hydrogen peroxide oxidation of **1** in a dichloromethane-acetone mixture causes precipitation of the rather insoluble neutral species [PdCl(CH_2CN)PPh_3]$_n$ (**4**), from which complexes 3 are also produced by the reactions with Tl(β-dik). Abstraction of chloride from **1** by $AgClO_4$ or $AgBF_4$ in a dichloromethane-methanol mixture gives the less soluble cationic species [Pd(CH_2CN)(PPh_3)$_2$]$_m$$X_m$ (**5**) (X=ClO_4 (**5a**) or BF_4 (**5b**)), which reacts with K(β-dik) in the same solvent mixture to afford **3**. Thus, complexes **3** can be derived from **1** by the three routes.

In the case of the reaction with the hfac anion which is the least basic β-dik ligand employed, the complex of type **3** can not be obtained by any route mentioned above. This is presumably because of incapable displacement of the coordinated PPh_3 by the hfac anion (see Experimental section). Instead, the cationic *trans*-[Pd(CH_2CN)(S)(PPh_3)$_2$](hfac) (**6**) is isolated, after some make-up, from the reaction mixture of **5** and K(hfac). The complex contains an acetone molecule (S) in the coordination sphere.

In the reactions of **2**, which bears the chelating diphosphine ligand, with the more basic β-dik anions, the formation of the complexes containing the centralcarbon-bonded or *O*-unidentate β-dik ligand is expected. Nevertheless, such a product can not be isolated as a pure solid in these reactions. On the contrary, Tl(hfac) reacts with **2** in refluxing acetone to give the cationic [Pd(CH_2CN)(dppe)]$_2$(hfac)$_2$ (**7**) with the *N*-bonded CN groups. When the chloride ion is abstracted from **2** by $AgClO_4$ or $AgBF_4$ to yield [Pd(CH_2CN)(dppe)]$_2$$X_2$ (**8**) (X=ClO_4 (**8a**) or BF_4 (**8b**)) and then **8** is allowed to react with K(hfac), complex **7** is also produced by the anion exchange.

All the reactions are summarized in Scheme 1. The analytical and molecular weight data for the newly prepared complexes are listed in Table 1.

Characterization of the O,O'-Chelated β-dik Complexes 3. As is seen in Table 2, the IR spectra of complexes **3a—3e** exhibit a sharp band at the 2200—2212 cm^{-1} region, which is assigned to the ν(C≡N) vibration of the free CN group.[16] The bands of strong to medium intensities at the 1620—1500 cm^{-1} region are assigned to the ν(C···O) + ν(C···C) vibrations of the *O,O'*-chelated β-dik ligands.[17]

††In this paper β-dik represents a monoanion of ethyl 3-oxobutanoate (etacH) or that of β-diketones such as 2,4-pentanedione (acacH), 1,1,1-trifluoro-2,4-pentanedione (tfacH), 1,1,1,5,5,5-hexafluoro-2,4-pentanedione (hfacH), 1-phenyl-1,3-butanedione (bzacH), and 1,3-diphenyl-1,3-propanedione (dbmH).

Table 3 lists the ^1H NMR data for the *O,O'*-chelated β-dik complexes **3** in $CDCl_3$. The spectrum of **3b** is very simple and exhibits three singlets at 1.63, 1.98, and 5.23 ppm and a doublet at 1.35 ppm with relative intensities of 3:3:1:2 in addition to other signals assignnable to the phenyl protons. The doublet is due to the cyanomethyl protons which couples to cis ^{31}P, the coupling constant being 3.0 Hz appropriate for cis coupling.[2] The 5.23-ppm signal is due to the methine proton of the acac ligand and others due to the methyl protons, of which the higher-field signal at 1.63 ppm is assigned to the methyl cis to P and the lower one at 1.98 ppm to trans to P by reference to the data for the analogous complexes [PdCl(acac)PPh_3], [Pd(acac)(acac-

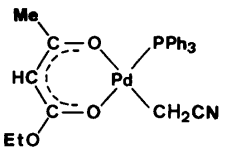
3d	2 / 3	cis	1.80	Ph	5.96	1.44d (3.5)
		trans	Ph	2.16	5.99	1.41d (3.5)
3e			Ph	Ph	6.63	1.55d (3.0)

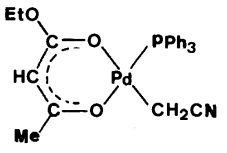
a) Chemical shift (δ) in ppm from internal Me_4Si at 33 °C. Figures in parentheses are $^3J(^{31}P\text{-}H)$ in Hz. d: Doublet. b) Cis and trans abbreviate cis(Me, P) and trans(Me, P), respectively. See text. c) CH_3-CH_2 signals for the ester appear at 1.28 (triplet), 4.20 (quartet) ppm (cis isomer) and at 0.77 (triplet), 3.21 (quartet) ppm (trans isomer), respectively.

C^3)PPh_3],[18] and [Pd(acac)(etac-C^3)PPh_3].[19] Complex **3e** exhibits a methine singlet at 6.63 ppm and a cyanomethyl doublet at 1.55 ppm with ^2J(P-H)=3.0 Hz.

On the other hand, the spectrum of **3a** in $CDCl_3$ is rather complex and shows two methyl signals at 1.62 and 1.97 ppm in the intensity ratio of *ca.* 1:2. Owing to the unsymmetrical nature of etac, two geometrical isomers, cis(Me,P) and trans(Me,P), coexist in the case of **3a**. By reference to the data of **3b**, these two signals at



cis (Me, P)



trans (Me, P)

higher and lower fields are readily attributed to the methyl protons of the cis and trans isomers, respectively. A similar situation is present in either case of **3c** and **3d**, the isomer ratios of cis to trans being *ca.* 1:2 and *ca.* 2:3, respectively. In the case of **3d**, splitting of the cyanomethyl proton signal is observed, discriminating a slightly different magnetic environment based on the different trans ligands.

Table 4. $^{31}P\{^1H\}$ NMR Data for the starting complexes and some products in $CDCl_3$[a]

No.	P (PPh_3) or P^1, P^2 (dppe)	$J(P^1\text{-}P^2)$
1	27.0	
3a-*cis*[b]	64.4	
3a-*trans*[b]	33.5

5a[c]	25.2[d]	
2	44.1d 60.3d	23
7	50.4d, br 62.5d[e]	20
8a[c]	55.2d 65.0d	17

a) Chemical shift (δ) in ppm downfield from external H_3PO_4 and coupling constant (*J*) in Hz. d: Doublet, br: broad. b) The major component in equilibrium was assigned to trans. c) In CD_3CN. d) The half width slightly increased with increasing temperature as follows: 2 (−30 °C), 4 (−10 °C), and 10 (30 °C) Hz. e) Minor signals appear at the higher-field side (52.1 and 68.8 ppm) of each doublet. See Fig. 1.

The $^{31}P\{^1H\}$ NMR data for the starting complexes and some products in $CDCl_3$ or CD_3CN are listed in Table 4. The spectrum of **3b** in $CDCl_3$ exhibits a single signal at 33.3 ppm downfield from external H_3PO_4, while **3a** shows two signals at 33.5 and 64.4 ppm in the same solvent, disclosing the presence of cis and trans isomers in the solution. On the basis of their relative intensities, the more intense higher-field signal is assigned to the PPh_3 ligand of the trans(Me,P) isomer and the lower-field one to that of cis(Me,P) isomer.

The $^{13}C\{^1H\}$ NMR spectra of **3a**, **3b**, and *trans*-[$PdCl(CH_2CN)(PPh_3)_2$] (**1**) were measured in $CDCl_3$ using Me_4Si as internal standard at room temperature. These data are collected in Table 5. As is seen in the Table, the cyanomethyl-CH_2 signal of **1** appears at −5.0 ppm as a triplet indicating the trans configuration of two PPh_3, while that of **3b** is observed at −9.1 ppm as a doublet owing to cis coupling to one phosphorus atom. For the acac ligand in **3b**, either signal of the methyl and carbonyl carbons is splitting indicating

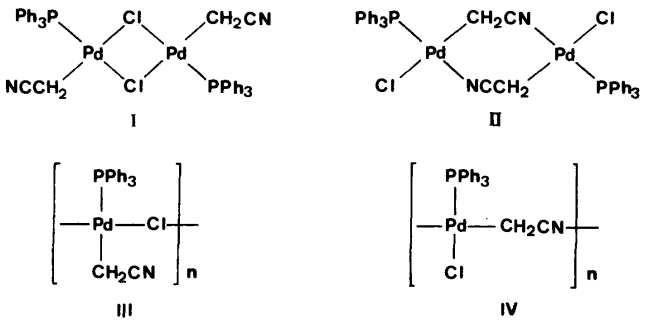
a) Chemical shift (δ) in ppm from internal Me_4Si. Figures in parentheses and double parentheses give $J(^{31}P\text{-}C)$ and $1/2|^nJ(P\text{-}C)+^{n+2}J(P\text{-}C)|$ (n=1—4) in Hz, respectively. d: Doublet, t: triplet, vt: virtual triplet. b) Except for C^5, C^6, and C^8, the major component in equilibrium was assigned to trans. c) No splitting of signals for the cis and trans isomers was observed.

that two acetyl groups have a slightly different magnetic environment. Two singlets appearing at 27.4 and 186.4 ppm are assigned to the methyl (C^5) and carbonyl (C^6) carbons cis to P, respectively, whereas two doublets resonating at 27.6 and 186.4 ppm are attributed to those (C^9, C^8) trans to P. The $^{13}C\{^1H\}$ NMR spectrum of **3a** also discloses the presence of cis(Me,P) and trans(Me,P) isomers in solution. The ethoxycarbonyl carbon (C^8) of the cis isomer and the methyl (C^5) and acetyl carbonyl (C^6) carbons of the trans isomer couple to the trans phosphorus atom, each appearing as a doublet and hence, two sets of these signals are readily assigned as shown in Table 5. The cis and trans isomer ratio based on the ^1H NMR data is referred to assign other signals.

*Neutral Species [PdCl(CH_2CN)PPh_3]$_n$ (**4**).* The yellow precipitate obtained by hydrogen peroxide oxidation of **1** in a dichloromethane-acetone mixture gives satisfactory analysis as [PdCl(CH_2CN)PPh_3]$_n$. Four possible structures are conceivable:



The NMR data for this species are not available because of its insolubility in any solvent appropriate to measurement. As is seen in Table 2, the IR spectrum of **4** shows two ν(Pd-Cl) bands at 315 and 280 cm^{-1}, frequencies of which are comparable to 288 cm^{-1} for **1**, indicating that the chloride-bridging structures I and III are eliminated. In contrast with **3**, species **4** exhibits two $\nu(C\equiv N)$ bands at 2250 and 2260 cm^{-1}, the former one as a strong band and the latter as a shoulder. These frequencies are 40—60 cm^{-1} higher than those for **3a—e**, revealing that the CN group coordinates to another palladium atom.[16,20] Thus, it seems likely that the *N*-bonded CN-bridging structures II and IV coexist in the solid state of **4**. This is not the case of the dimers [PdCl($CH_2C_6H_4Y$)PPh_3]$_2$ (Y=H or CN), in which the chloride-bridging structure of type I was proposed.[7]

Cationic Diphosphine Complexes. All the cationic complexes except **6** have the *N*-bonded CN-bridging structure on the basis of the $\nu(C\equiv N)$ frequencies in their IR spectra (Table 2). The cationic diphosphine complexes **8** derived from **2** are soluble only in coordinating solvents and the cations are dimeric in CH_3CN as is revealed by their molecular weight measurements (Table 1). As described earlier, this type of complex has been prepared by Ros *et al.* for the cyanomethyl complexes with platinum(II)[5] and for the *o*-cyanobenzyl complexes with platinum(II)[6] and palladium(II).[7] Addition reactions of a variety of nucleophiles to the *N*-bonded CN groups of the *o*-cyanobenzyl complexes[10-12] have been also studied. However, the present cyanomethyl complexes of palladium(II) fails to add these nucleophiles so long as we have tried briefly. The X-ray analysis for [Pt(*o*-$CH_2C_6H_4CN$)(dpe)]$_2$(BF_4)$_2$ (dpe=*cis*-1,2-bis(diphenylphosphino)ethylene) established the *N*-bonded CN-bridging structure of the dimeric cation.[21]

As is seen in Table 4, the $^{31}P\{^1H\}$ NMR spectrum of the starting PPh_3 complex **1** in $CDCl_3$ shows a singlet at 27.0 ppm, while that of the diphosphine complex **2** in the same solvent exhibits two doublets at 44.1 and 60.3 ppm with $J(P^1\text{-}P^2)$=23 Hz, reflecting a different magnetic environment of two phosphorus atoms P^1 and P^2. The higher-field signal at 44.1 ppm is assigned to P^1 trans to the CH_2CN ligand, which has the greater trans influence than chloride, while the 60.3-ppm signal is due to P^2 trans to the chloride. The spectrum of the ClO_4 salt **8a** in CD_3CN is similar to that of **2** in $CDCl_3$ and two doublets appear at 55.2 (P^1) and 65.0 (P^2) ppm with $J(P^1\text{-}P^2)$=17 Hz. The downfield shift of the P^1 and P^2 signals for **8a** compared with those of **2** can be generally understood as the coordination effect of the free CN group of **2** to another metal atom and as the replacement effect of chloride by the second CN group, although the solvent effect can not be ignored, too (see data for **7** in $CDCl_3$). The ^1H NMR spectrum of **8a** in CD_3CN shows a cyanomethyl signal at 1.34 ppm as a

a) Chemical shift (δ) in ppm from internal Me_4Si. Figures in parentheses, double parentheses, braces, and brackets give $J(^{31}P^1\text{-}C)$, $J(^{31}P^2\text{-}C)$, $J(^{31}P\text{-}C)$, and $J(^{19}F\text{-}C)$ in Hz, respectively. $J(^{31}P\text{-}C)$ describes $J(^{31}P^1\text{-}C^n)$ and/or $J(^{31}P^2\text{-}C^n)$. b) In $CDCl_3$. c) In CD_3CN. d) Indiscernible because of overlapping with other signals.

doublet of doublets with $^3J(P^1\text{-}H)=9.0$ and $^3J(P^2\text{-}H)=3.0$ Hz in accordance with the diphosphine-chelating structure.

Table 6 lists the $^{13}C\{^1H\}$ NMR data for the diphosphine complexes **2**, **7**, and **8a**. The starting complex **2** shows the cyanomethyl-CH_2 and -CN signals at −0.7 and 125.5 ppm, respectively. The CH_2 signal appears as a doublet of doublets by coupling to trans P^1 and cis P^2 with $^2J(P^1\text{-}C)=105$ and $^2J(P^2\text{-}C)=3$ Hz, respectively. The coupling constant of 105 Hz for $^2J(P^1\text{-}C)$ is surprisingly large, but it is not impossible because the appreciably large trans coupling constants are observed: $^2J(P\text{-}C)=75$ Hz for $[Pt(CH_3)\{P(CH_3)_2(C_6H_5)\}_3]^+$,[22] 72 Hz for $[Pt(tfac(2\text{-})\text{-}C,O)(PPh_3)_2]$,[23] and 70 Hz for $[Pd(tfac(2\text{-})\text{-}C,O)(PPh_3)_2]$[24] and *cis*-$[Pt(acac\text{-}C^1)(py)\{P(p\text{-}ClC_6H_4)_3\}_2]^+$.[25] When the cationic dimer (**8a**) with the *N*-bonded CN group is prepared, it is interesting to see that the cyanomethyl-CN signal observed at 126.2 ppm couples to a phosphorus atom, although three-bond coupling of the CN carbon in **2** to trans P^1 is not appreciated. This fact suggests that the CN carbon signal of **8a** couples to trans P^2 through C-N-Pd-P^2 bond. The large coupling constant of 43 Hz for $^3J(P^2\text{-}C)$ may be allowed when it is compared with 105 Hz for the two-bond trans coupling ($^2J(P^1\text{-}C)$) of the cyanomethyl-CH_2 signal in **2**.

In contrast to **8**, the hfac salt **7** is appreciably soluble even in noncoordinating solvents and the cation is found to be dimeric in dichloromethane by the molecular weight measurement. Figure 1 displays the temperature-dependent $^{31}P\{^1H\}$ NMR spectra of **7** in $CDCl_3$. The spectrum at 32 °C is of the basically AB quartet type, exhibiting two doublets at 50.4 (P^1) and

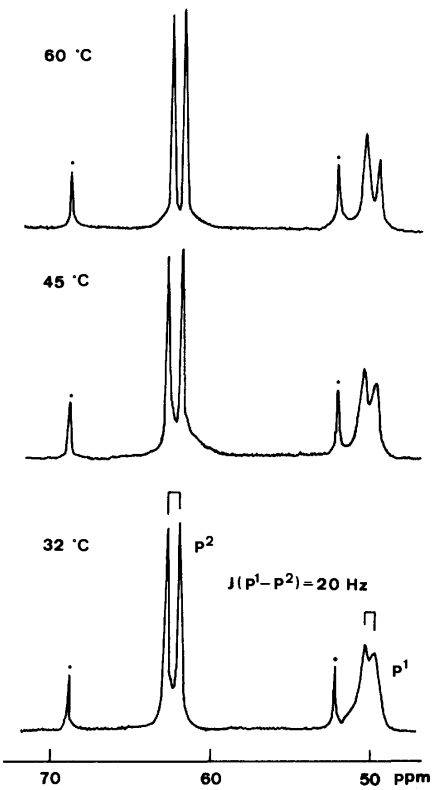

Fig. 1. Temperature-dependent $^{31}P\{^1H\}$ (24.2 MHz) NMR spectra of $[Pd(CH_2CN)(dppe)]_2(hfac)_2$ (**7**) in $CDCl_3$ with external H_3PO_4. Two minor signals denoted by asterisks are due to some decomposed species.

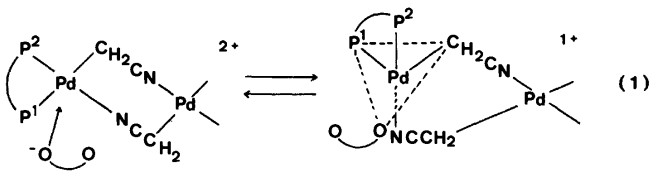
62.5 (P^2) ppm with J(P^1-P^2)=20 Hz, although the broadening is taking place in the higher field signal. In contrast to the ClO_4 anion, the hfac anion in **7** has the potentially coordinating power to form the five-coordinate complex. If the oxygen donor of the anion approaches from the P^1 side to the central palladium atom, the resulting complex **A** should have the trigonal-bipyramidal structure in which only the P^1 atom is appreciably sterically distorted, as exemplified below.



(1)

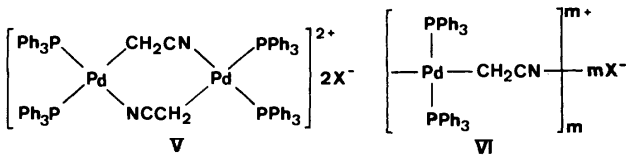
7 **A**

When the addition-elimination rate of the hfac anion in equilibrium (1) is slow on the NMR time scale, the broadening of only the P^1 signal can be observed with retention of the P^1-P^2 coupling. As the rate becomes more rapid, the normal AB quartet pattern will be restored. In fact, the broad P^1 signal sharpen gradually with increasing temperature, giving the well-resolved doublet at 60°C. Minor signals observed at each lower-field side of the two doublets increase in their intensities with time, and hence these signals can be regarded as those of some decomposed species.

In spite of the existence of equilibrium (1) in solution, the cyanomethyl-proton signal of **7** in $CDCl_3$ appears at 1.32 ppm as a doublet of doublets, the coupling constants being the same degree (^3J(P^1-H)=10.5; ^3J(P^2-H)=3.5 Hz) as those for **8a**. The methine proton of the hfac anion in **7** resonates at higher field (5.38 ppm in $CDCl_3$) than that in [Pd(hfac)$_2$] (6.42 ppm in the same solvent). Such a upfield shift is generally recognized as is due to the higher charge density on the noncoordinating anion.[26]

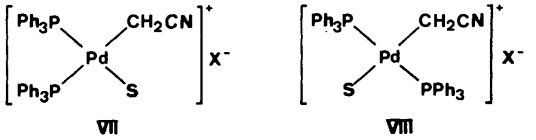
As is seen in Table 6, the $^{13}C\{^1H\}$ NMR spectrum of **7** in $CDCl_3$ shows three signals originated from the hfac anion in addition to the spectrum of **8a**. The CF_3-, CH-, and CO-carbon signals appear at 118.1, 85.2, and 173.5 ppm as a quartet with ^1J(C-F)=291 Hz, a singlet, and a quartet with ^2J(C-F)=31 Hz, respectively. These chemical shifts and coupling constants are very similar to those for the outer-sphere complexes [Pd(PMe$_2$Ph)$_4$](hfac)$_2$ and [Pd(dppe)$_2$](hfac)$_2$ in $CDCl_3$ and CD_3OD, respectively,[26b] indicating that the hfac ligand in **7** is present as a counter anion. The cyanomethyl-CN signal appears at 125.7 ppm as a doublet with ^3J(P^2-C)=40 Hz, also supporting the N-bonded CN-bridging structure of the cation.

Cationic Triphenylphosphine Complexes. The IR spectra of the cationic PPh_3 complexes **5** in the solid state exhibit only one sharp ν(C≡N) band at around 2250 cm^{-1} and either one of two possible structures of the cationic dimer V and polimer VI is conceivable as



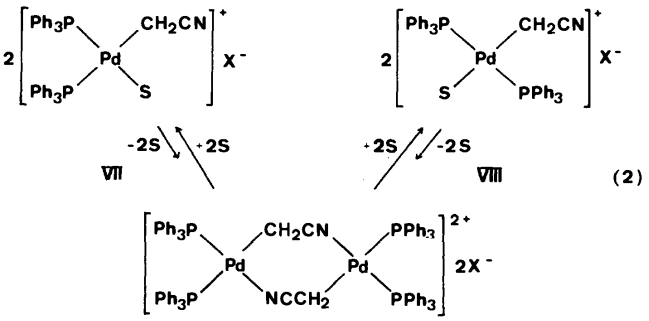
V **VI**

the solid state structure of **5**. Because of the less soluble nature in noncoordinating solvents, the molecular weight and NMR measurements of **5** were performed in CH_3CN and CD_3CN, respectively. As is seen in Table 1, each molecular weight of **5a** and **5b** has a half value of the formula weight in CH_3CN, and hence the Pd-N bonds in structure V or VI are brorken to give the following *cis*- or *trans*-PPh_3 complex in which a solvent molecule S occupies the vacant coordination site. The



VII **VIII**

^1H NMR spectrum of **5a** at 33 °C shows a broad signal assignable to the cyanomethyl proton at 1.26 ppm from internal Me_4Si. However, when the temperature is decreased, the signal further broadens until it begin to split into three peaks at −5°C, and then gives a sharp triplet with ^3J(P-H)=6.8 Hz at −30°C. These results imply that two molecules of PPh_3 have the mutually trans configuration like structure VIII at −30°C, although the complex is stereochemically nonrigid at the higher temperature. For such a spectral change in ^1H NMR, two explanations are possible: (1) dissociation and coordination of a PPh_3 molecule in structure VIII are taking place rapidly on the NMR time scale, (2) cis-trans isomerization (Eq. 2) is taking place between structures VII and VIII *via* the cationic dimer similar to **8**, both at the higher temperatures. In



(2)

the case of (2), the isomerization can be promoted by the coordination of the free CN group in structure VII or VIII to another molecule. The choice of either one of the two mechanisms mentioned above is not possible at the present stage of investigation.

These dynamic behaviors of the species in solution are also consistent with the temperature-dependent $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$ NMR data for **5a** in CD_3CN. The $^{31}P\{^1H\}$ NMR spectrum of **5a** at −30°C shows a single signal at 25.2 ppm with the half width of *ca.* 2 Hz, indicating the existence of the environmentally equivalent two phosphorus atoms at this temperature, although the half width slightly increases with increasing temperature owing to the occurrence of the stereochemical nonrigidity. In the case of the $^{13}C\{^1H\}$ NMR spectrum of **5a**, the signal intensities for the cyanomethyl-CH_2 and -CN carbons are too weak to perceive their temperature-dependent spectral changes, while the phenyl-ring carbon signals of the PPh_3 ligands are useful to examine the structural

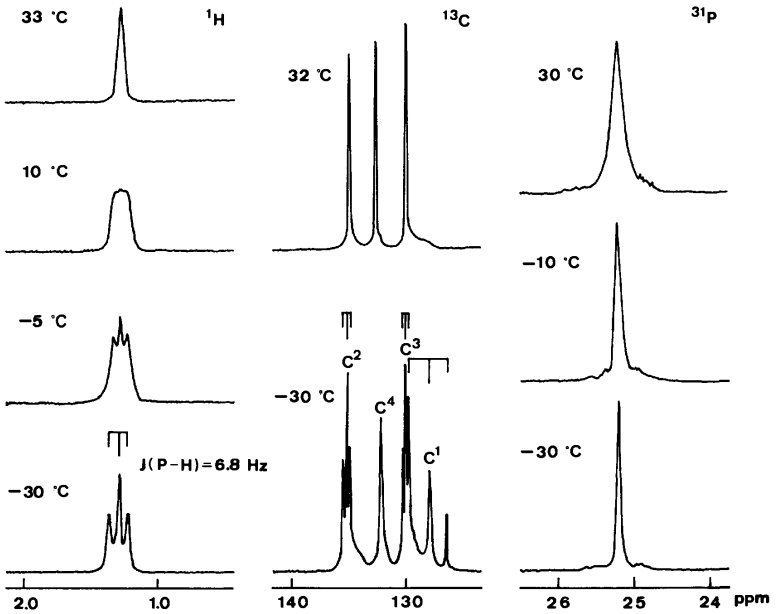


Fig. 2. Temperature-dependent ^{1}H (100 MHz), ^{13}C{^{1}H} (15.0 MHz), and ^{31}P{^{1}H} (24.2 MHz) NMR spectra of $[Pd(CH_2CN)(PPh_3)_2]_m(ClO_4)_m$ (**5a**) in CD_3CN with internal Me_4Si, external Me_4Si, and external H_3PO_4, respectively.

change of the complex in solution. At −30 °C, each signal appears at 127.8 (C^1), 134.8 (C^2), 129.8 (C^3), and 132.4 (C^4) ppm from external Me_4Si (see Table 5 for the numbering system). Except for C^4, which is most distant from P, all other carbon signals resonate as triplets by virtual coupling to the mutually trans 2P atoms, the coupling constants being 24.2 (C^1), 6.5 (C^2), and 5.1 (C^3) Hz. On the other hand, these couplings are lost at 32 °C and each signal appears as a singlet, again indicating the dynamic behavior of **5a** at this temperatures. These spectral change are summarized in Fig. 2.

Although no attempt is made to isolate the cationic species $[Pd(CH_2CN)(CH_3CN)(PPh_3)_2]X$ (X=ClO_4 or BF_4) which is thought to exist in the acetonitrile solution of **5**, a similar complex $[Pd(CH_2CN)(acetone)(PPh_3)_2](hfac)$ (**6**) can be isolated. The IR spectrum of **6** in the solid state shows a strong ν(C≡N) band at 2200 cm^{-1} and three strong to medium bands assignable to the ν(C⋯O) and ν(C⋯C) at 1673, 1548, and 1520 cm^{-1}. These frequencies are consistent with the formulation as $[Pd(CH_2CN)(acetone)(PPh_3)_2](hfac)$. When the complex is dissolved in $CHCl_3$, however, another weak band appears at the higher-frequency side of the strong ν(C≡N) band, suggesting the formation of the cationic species with the *N*-bonded CN group in the solution. The ^{1}H NMR spectrum of **6** in $CDCl_3$ at 33 °C exhibits a sharp signal at 1.43 ppm and a broad one at 5.37 ppm, which are assigned to the cyanomethyl and the hfac-CH protons, respectively. As the temperature is decreased, the CH signal moved gradually to the higher-field side and newly two signal appeared, giving three methine proton signals at 6.34, 5.72, and 4.68 ppm at −45 °C. Although such a complex behavior in the IR and ^{1}H NMR spectra of **6** predicts the formation of the *O,O'*-chelated and *O*-unidentate species of the hfac ligand in solution in addition to the existence of equilibrium (2) (X=hfac), this ambiguity is not pursued further in view of their insufficient data.

Experimental

The starting complexes *trans*-$[PdCl(CH_2CN)(PPh_3)_2]$ (**1**) and $[PdCl(CH_2CN)(dppe)]$ (**2**) were prepared according to the literature.[2]

Preparation of [Pd(CH$_2$CN)(β-dik)(PPh$_3$)] (3) by the Reactions of 1 with Tl(β-dik). General Procedure: Equimolecular amounts of an appropriate Tl(β-dik)[27] were allowed to react with **1** in dichloromethane at room temperature. Thallium(I) chloride began to precipitate immediately and the mixture was stirred for the time noted below before filtration. The filtrate was concentrated under reduced pressure and petroleum ether was added to the concentrate to obtain a crude precipitate. The color and appearance, the reaction time, the solvent of crystallization, and the yield were as follows. **3a**: White needles, 1 h, dichloromethane-petroleum ether, 62%; **3b**: yellow plates, 3 h, acetone, 89%; **3c**: yellow needles, 3 h, dichloromethane-petroleum ether, 63%; **3d**: white needles, 12 h, dichloromethane-petroleum ether, 93%; **3e**: yellow needles, 5 h, dichloromethane-petroleum ether, 98%.

In a similar reaction of **1** with Tl(hfac), only oily substance was obtained, from which a pure solid could not be isolated. The crude substance shows two ν(C≡N) bands at 2210 and 2240 cm^{-1} and their relative intensity varies with repeated preparations. The ν(C⋯O)+ν(C⋯C) bands appear at 1668s, 1638sh, and 1525s cm^{-1}, indicating that the main product contains the hfac ligand as a counter anion.[28] The signal intensity of the ^{1}H NMR spectrum reveals that the molar ratio of PPh_3 to CH_2CN in the specimen is always $1:1 \ll PPh_3:CH_2CN < 2:1$.

Preparation of the Neutral [PdCl(CH$_2$CN)(PPh$_3$)]$_n$ (4) by Hydrogen Peroxide Oxidation of 1. Acetone (20 cm^3) and a 30% aqueous solution (5 cm^3) of H_2O_2 were added successively to a dichloromethane (10 cm^3) solution of **1** (616 mg, 0.814 mmol) and the mixture was stirred for 40 h during which a small amount of white precipitate was formed. The total volume of the mixture was reduced before filtration to obtain **4** in a satisfactory yield. The yield was 326 mg (84%).

Preparation of the Cationic [Pd(CH_2CN)(PPh_3)$_2$]$_m$$X_m$ (X= ClO_4 (5a) or BF_4 (5b)) by Chloride Abstraction of 1. A methanol (10 cm^3) solution of $AgClO_4$ (260 mg, 1.25 mmol) was added to a solution of **1** (935 mg, 1.24 mmol) in dichloromethane (40 cm^3). Silver chloride began to precipitate immediately and the mixture was stirred for 24 h at room temperature before filtration. The filtrate was concentrated under reduced pressure to obtain a pale yellow powder of **5a**. The yield was 840 mg (88%). Similarly, **1** (304 mg, 0.402 mmol) in dichlomethane (20 cm^3) was allowed to react with $AgBF_4$ (78.4 mg, 0.402 mmol) in methanol (10 cm^3) for 22 h. After the same procedure as described above, addition of petroleum ether to the concentrate gave a white precipitate (214 mg) of **5b** in a 70% yield.

Reactions of 4 with Tl(acac) and Tl(tfac). A methanol (10 cm^3) solution of Tl(acac) (74 mg, 0.243 mmol) was added to a suspension of **4** (104 mg, 0.234 mmol for n=1) in acetone (20 cm^3) at room temperature. After being stirred for 10 h, the precipitated TlCl was filtered off and the filtrate was evaporated to dryness under reduced pressure. The residue was redissolved in acetone and the solution was concentrated to separate out yellow plates of **3b**. The yield was 85 mg (71%). Similarly, Tl(tfac) (127 mg, 0.356 mmol) in methanol (10 cm^3) was allowed to react with a acetone (30 cm^3) suspension of **4** (120 mg, 0.271 mmol for n=1) overnight. Filtration, concentration to dryness, and then redissolution of the residue in dichloromethane (5 cm^3) afforded a yellowish green solution, from which **3c** was deposited on addition of petroleum ether. Recrystallization from acetone-petroleum ether gave yellow crystals in a 63% yield (96%).

Reaction of 5a with K(acac). To a solution of **5a** (224 mg, 0.296 mmol for n=1) in dichloromethane (20 cm^3) was added dropwise a methanol (10 cm^3) solution of K(acac) (57 mg, 0.412 mmol). After being stirred for 2 h, the solvent was evaporated to dryness under reduced pressure. Dichloromethane (10 cm^3) was added to the residue and the undissolved $KClO_4$ was filtered off. Addition of petroleum ether to the filtrate gave a yellow plates (126 mg) of **3b** in an 84% yield.

Preparation of the Cationic [Pd(CH_2CN)(acetone)(PPh_3)$_2$](hfac) (6) by the Reaction of 5a with K(hfac). A solution of K(hfac) (70 mg, 0.282 mmol) in methanol (3 cm^3) was added slowly to a dichloromethane (20 cm^3) solution of **5a** (218 mg, 0.282 mmol for m=1). After being stirred for 10 min, the solvent was evaporated to dryness, the residue was redissolved in a small amount of acetone, and then the undissolved $KClO_4$ was filtered off. Petroleum ether was added to the filtrate and the solution was allowed to stand to separate yellow needles of **6** in a 26% yield (65 mg).

Preparation of the Cationic [Pd(CH_2CN)(dppe)]$_2$(hfac)$_2$ (7) by the Reaction of 2 with Tl(hfac). Complex **2** (232 mg, 0.400 mmol) was allowed to react with Tl(hfac) (165 mg, 0.400 mmol) in refluxing acetone over 20 h. After the solvent was evaporated to dryness, dichloromethane was added to the residue, the undissolved TlCl was filtered off, and again the solvent was evaporated to dryness. The residue was redissolved in a small amount of acetone and diethyl ether was added to precipitate acetone solvate of **7**. The product was collected, washed with diethyl ether, and then dried *in vacuo* at 50 °C for 3 h. The yield of a yellow powder of **7** was 109 mg (36%).

Preparation of the Cationic [Pd(CH_2CN)(dppe)]$_2$$X_2$ (X= ClO_4 (8a) or BF_4 (8b)) by Chloride Abstraction of 2. To a solution of **2** (160 mg, 0.275 mmol) in dichloromethane (13 cm^3) was added dropwise a solution of $AgClO_4$ (57 mg, 0.275 mmol) in methanol (15 cm^3). After being stirred for 19 h, the precipitated AgCl was filtered off and the filtrate was concentrated under reduced pressure to deposit a white powder of **8a**, which was gathered and washed with acetone and dried *in vacuo*. The yield was 136 mg (77%). In the case of the reaction of **2** with $AgBF_4$, after removal of the precipitated AgCl, the solvent was evaporated to dryness. The residue was redissolved in dichloromethane and diethyl ether was added to obtain a white precipitate of **8b**. Recrystallization twice from dichloromethane-diethyl ether gave a white powder in a 79% yield.

Reaction of 8a with K(hfac). A solution of K(hfac) (74 mg, 0.300 mmol) in methanol (10 cm^3) was added to a suspension of **8a** (120 mg, 0.132 mmol) in dichloromethane (10 cm^3). After being stirred for 2 h at room temperature, the solvent was evaporated to dryness under reduced pressure to leave **7** and $KClO_4$. The residue was redissolved in methanol and the undissolved $KClO_4$ was removed by filtration. The solvent was again evaporated to dryness and the crude product was recrystallized twice from acetone-diethyl ether to give a white powder of **7**. The yield was 119 mg (56%).

Measurements. Infrared spectra were obtained in Nujol mull or in a chloroform solution with a JASCO DS 701G (4000—200 cm^{-1}) infrared spectrophotometer. NMR spectra in $CDCl_3$ or CD_3CN were recorded on JEOL JNM MH-100 (for ^{1}H), FX-60Q (for ^{13}C and ^{31}P) instruments. Molecular weight was determined in CH_2Cl_2 (at 28 °C) or CH_3CN (at 39 °C) with a vapor pressure osmometer manufactured by Knauer, West Berlin, West Germany.

Kinetics and Equilibrium Studies on the Anation Reactions in Pentakis(dimethyl sulfoxide)dioxouranium(VI) and Tetrakis-(hexamethylphosphoric triamide)dioxouranium(VI) Ions in Nonaqueous Media

Hideo Doine, Yasuhisa Ikeda, Hiroshi Tomiyasu, and Hiroshi Fukutomi*

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received October 26, 1983)

The anation reactions in $[UO_2(dmso)_5]^{2+}$ (dmso=dimethyl sulfoxide) and $[UO_2(hmpa)_4]^{2+}$ (hmpa=hexamethylphosphoric triamide) ions by SCN^- and N_3^- have been studied by the stopped-flow method in DMSO and acetonitrile. For the anation reactions of $[UO_2(dmso)_5]^{2+}$ in DMSO as a medium, the pseudo-first order rate constant(k_{obsd}) is expressed by $k_{obsd}=\{k_{-1}+(k_1+k_{-1})\times K_{os}[X]\}/(1+K_{os}[X])$, where X=$SCN^-$ and $[UO_2(dmso)_5]^{2+}$ for the anation reactions by SCN^- and N_3^-, respectively. The values of k_1, k_{-1}, and K_{os} at 25 °C are 2.06×10^2 s^{-1}, 62 s^{-1}, 35 M^{-1} (M=mol dm^{-3}), and 7.60×10^2 s^{-1}, 0.0 s^{-1}, and 41 M^{-1} for the SCN^- and N_3^- anation reactions in $[UO_2(dmso)_5]^{2+}$, respectively. For the anation reaction in $[UO_2(hmpa)_4]^{2+}$ by SCN^-, the pseudo-first order rate constant was found to be proportional to the concentrations of $[UO_2(hmpa)_4]^{2+}$ and free HMPA: $k_{obsd}=k_f[UO_2(hmpa)_4^{2+}]+k_b[HMPA]_{free}$. The values of k_f and k_b at 25 °C are 9.70×10^3 M^{-1} s^{-1} and 9.05×10^2 M^{-1} s^{-1}, respectively. The equilibrium constants for the titled reactions were also measured at 25 °C: K=85 $M^{-1}$for the anation reaction of $[UO_2(dmso)_5]^{2+}$ by SCN^- in DMSO and K'=42.7 for the SCN^- anation reaction in $[UO_2(hmpa)_4]^{2+}$ in acetonitrile. The kinetic results suggest that the anation reactions in uranyl complexes proceed through an associative or an associative interchange mechanism.

For ligand exchange reactions in the equatorial position of uranyl complexes, it is proposed that most of the reactions proceed through the dissociation (D) or the dissociative interchange (I_d) mechanism.[1-8]

The authors have reported that the ligand substitution reactions in $[UO_2(dmf)_5]^{2+}$ (dmf=*N*,*N*-dimethylformamide) ion proceeded *via* an associative interchange (I_a) mechanism and the anation rate constant depended on the basicity of entering ligands.[9] Few other studies on the anation reactions of uranyl complexes have been reported.

A detailed kinetic and equilibrium study on the anation reactions in $[UO_2(dmso)_5]^{2+}$ and $[UO_2(hmpa)_4]^{2+}$ ions was performed for the following reactions:

$$[UO_2(dmso)_5]^{2+} + SCN^- \rightleftharpoons [UO_2(dmso)_4NCS]^+ + DMSO,$$

$$[UO_2(dmso)_5]^{2+} + N_3^- \rightleftharpoons [UO_2(dmso)_4N_3]^+ + DMSO,$$

$$[UO_2(hmpa)_4]^{2+} + SCN^- \rightleftharpoons [UO_2(hmpa)_3NCS]^+ + HMPA.$$

The reaction mechanism is discussed by comparing the results of kinetic study of these reactions with the previous results for the anation rcactions in $[UO_2(dmf)_5]^{2+}$.

Experimental

Synthesis of Complexes. The $[UO_2(dmso)_5](ClO_4)_2$ and $[UO_2(hmpa)_4](ClO_4)_2$ complexes were prepared under an atmosphere of nitrogen by refluxing hydrated uranyl perchlorate with triethyl orthoformate at 60°C for 1 h, followed by the addition of dimethyl sulfoxide and hexamethylphosphoramide at room temperature, respectively. The resulting light yellow crystals of these complexes were recrystallized from dichloromethane and washed with dried diethyl ether, and freed of the diethyl ether *in vacuo* for 2 d. Calcd for $[UO_2(dmso)_5](ClO_4)_2$: C, 13.97; H, 3.52%. Found: C, 13.45; H, 3.41%. Calcd for $[UO_2(hmpa)_4](ClO_4)_2$: C, 24.3; H, 6.12; N, 14.18%. Found: C, 24.6; H, 6.10; N, 14.50%. Elemental analysis of the complexes was carried out by using a Shimadzu CHN-1A analyzer.

Other Materials. Hexamethylphosphoric triamide (Wako Pure Chemical Ind. Ltd.) was distilled twice under reduced pressure and stored over 4A molecular sieves (Wako). Dimethyl sulfoxide (Wako) was kept in contact with barium oxide for 2 d, distilled twice under reduced pressure and stored over 4A molecular sieves. Acetonitrile (MeCN) (Wako) was dehydrated with calcium oxide and diphosphorus pentaoxide, and distilled. Triethyl orthoformate(Wako) was of guaranteed grade and used without further purification. Sodium thiocyanate (Wako) was dried at 100°C for 2 h and stored *in vacuo*. The concentration of azide ion in DMSO solution was determined by measuring sodium ion concentration with a Varian-Techtron 1100 flame-spectrophotometer. The amount of water contained in DMSO and MeCN solvents was measured by a Mitsubishi CA-02 moisture-meter and the maximum concentration was found to be less than 0.03 M. Anhydrous sodium perchlorate (Wako) was used to adjust the ionic strength of solutions to 0.2 M.

Measurement of NMR Spectra. ^1H NMR spectra were measured at 100 Hz on a JEOL JNM-FX 100 FT-NMR spectrometer equipped with a JNM-VT-3B temperature controller.

Measurement of Equilibrium Constants. The equilibrium constants between uranyl complexes and thiocyanate or azide ions were measured spectrophotometrically by using a Shimadzu UV-210A double-beam spectrophotometer with a cell compartment thermostated at 25°C. The ionic strength of sample solutions was adjusted to 0.2 M by using sodium perchlorate.

Kinetic Measurements. The anation rates were measured by using a specially designed double-beam stopped-flow apparatus with a nitrogen-pressurized flow system. The temperature of the sample solutions was adjusted by a conventional temperature controller. The memorized stopped-flow signals were introduced to a Sord microcomputer (M223 Mk III), accumulated and curve-fitted. At least ten runs were performed for cach measurement.

Results and Discussion

Equilibrium of $[UO_2(dmso)_5]^{2+}$ Ion with SCN^- and N_3^-. The ^1H NMR spectra of solutions

containing $[UO_2(dmso)_5]^{2+}$, DMSO, CD_3CN, and $(CD_3)_2CO$ were observed at −65 °C. It was shown that the structure of $[UO_2(dmso)_5]^{2+}$ was consistent with that reported by Fukutomi *et al.*, *i.e.*, a pentagonal bipyramidal structure.[2] In the case of N_3^- anation, the area of the dmso methyl proton signal varied according to the concentration of added N_3^-. It was suggested that this reaction proceeded stoichiometrically as given by Eq. 1 with a fairly large equilibrium constant. It was impossible, in fact, to determine the equilibrium constant of this reaction by measuring the spectral change. Kinetic measurements also proved that the backward reaction rate constant is zero and the equilibrium constant is fairly large.

$$[UO_2(dmso)_5]^{2+} + N_3^- \rightleftharpoons [UO_2(dmso)_4N_3]^+ + DMSO \quad (1)$$

Figure 1 shows the spectral change of $[UO_2(dmso)_5]^{2+}$ with varying the concentration of $[UO_2(dmso)_5]^{2+}$ from 0.002 to 0.006 M at a constant concentration of SCN^- (2.0×10^{-4} M). Although an isosbestic point is not observed, the most probable reaction corresponding to the spectral change seems to be

$$[UO_2(dmso)_5]^{2+} + SCN^- \overset{K}{\rightleftharpoons} [UO_2(dmso)_4NCS]^+ + DMSO. \quad (2)$$

The equilibrium constant (K) for this process was obtained from the following equation.

$$\frac{[SCN^-]}{Abs - \varepsilon_1[UO_2(dmso)_5^{2+}]} = \frac{1}{K(\varepsilon_2-\varepsilon_1)[UO_2(dmso)_5^{2+}]} + \frac{1}{\varepsilon_2-\varepsilon_1}, \quad (3)$$

where Abs is the observed absorbance, and ε_1 and ε_2 are the molar extinction coefficients of $[UO_2(dmso)_5]^{2+}$ and $[UO_2(dmso)_4NCS]^+$, respectively. The plot of

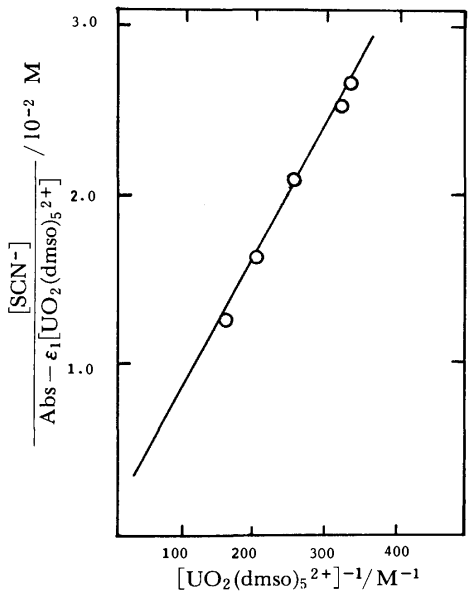

Fig. 2. The plot of $[SCN^-]/(Abs-\varepsilon_1[UO_2(dmso)_5^{2+}])$ *vs.* $1/[UO_2(dmso)_5^{2+}]$ for the anation reaction of $[UO_2(dmso)_5]^{2+}$ by SCN^- at 25 °C, 430 nm, and ionic strength=0.2 M ($NaClO_4$).

Table 1. Equlibrium constants of ligand substitution reactions in uranyl complexes at 25 °C[a]

Reaction	Solvent	K[b] / M^{-1}	K'[c]
$[UO_2(dmf)_5]^{2+}+SCN^-$	DMF	186±28	2400±210
	MeCN		2626±150
			2480±120[d]
$[UO_2(dmso)_5]^{2+}+SCN^-$	DMSO	85±9	1197±120
	MeCN		342±30
$[UO_2(hmpa)_4]^{2+}+SCN^-$	MeCN		42.7±4.0

a) The quoted errors represent the standard deviation. b) $K=[UO_2S_{n-1}L^+]/([UO_2S_n2^+][L^-]$. c) $K'=K\cdot[S]$. d) Measured in MeCN-DMF(50 vol%) mixed solvent.

$[SCN^-]/(Abs-\varepsilon_1[UO_2(dmso)_5^{2+}])$ against $1/[UO_2(dmso)_5^{2+}]$ gave a straight line as shown in Fig. 2, which supports the validity of the reaction given by Eq. 2. From the slope and intercept, the value of K was calculated and listed in Table 1.

Equilibrium of $[UO_2(hmpa)_4]^{2+}$ Ion with SCN^-. The ^1H NMR spcctra of solutions containing $[UO_2(hmpa)_4]^{2+}$, HMPA, CD_3CN, and $(CD_3)_2CO$ were observed at −65 °C. From the area ratio of the methyl proton signals of the coordinated and free HMPA, the structure of $[UO_2(hmpa)_4]^{2+}$ was proved to the same as that reported by Williams *et al.*,[10] *i.e.*, square bipyramidal. In this reaction, the equilibrium constant was measured in MeCN under the conditions of $[UO_2(hmpa)_4^{2+}]>[SCN^-]$. The value of equilibrium constant (K) was calculated by using a similar equation to Eq. 3, and is listed in Table 1.

The equilibrium constants for the reactions of $[UO_2(dmf)_5]^{2+}$ and $[UO_2(dmso)_5]^{2+}$ ions with SCN^- were also measured in MeCN under the conditions of T=25 °C and ionic strength= 0.2 M ($NaClO_4$). The

calculated values of K and K' are listed in Table 1, where K and K', denote the equilibrium constants defined as below.

$$K = \frac{[UO_2S_{n-1}NCS^+]}{[UO_2S_n^{2+}][SCN^-]}, \quad K' = K[S],$$

S = DMF, DMSO, and HMPA

As seen in Table 1, the equilibrium constants for the SCN^- anation reaction towards $[UO_2(dmf)_5]^{2+}$ ion in MeCN and DMF are consistent with each other within experimental errors. Moreover, the equilibrium constant measured in MeCN-DMF mixed solvent (50% in volume) was in good agreement with those measurcd in each solvent. The similar values of solubility parameters[11] and dielectric constants of MeCN and DMF might lead to the consistency of these results. The dielectric constant has an effect on the solvation of ions and the solubility parameter is concerned with the intermolecular forces. Thus, MeCN and DMF can be considered as almost equivalent solvents for the reactions containing relatively large ionic species. The order of K' values for the reactions of different uranyl complexes with thiocyanate ion in MeCN is consistent with the order of the donor property of the coordinated organic ligands, HMPA>TMP[12]>DMSO>DMF. Especially, the logarithmic values of the equilibrium constants showed a good linear relationship to the E_B parameter[13] of each organic ligand rather than the donor number (DN)[14] (Fig. 3).

Kinetic Study on the Reactions of $[UO_2(dmso)_5]^{2+}$ Ion with SCN^- and N_3^-. On the basis of the results of equilibrium constants measured spectrophotometrically, the pseudo-first order rate constant (k_{obsd}) for the anation reactions by SCN^- and N_3^- were measured under the conditions of $[UO_2(dmso)_5^{2+}]<[SCN^-]$ and $[UO_2(dmso)_5^{2+}]>[N_3^-]$, respectively.

Figures 4 and 5 show the plots of k_{obsd} *vs.* $[SCN^-]$ and $[UO_2(dmso)_5^{2+}]$, which do not display a simple linear relationship, and the values of k_{obsd} approach each limiting value at high concentration region of SCN^- and $[UO_2(dmso)_5]^{2+}$, respectively. Attempts were made to examine the effect of water on the anation reactions, in which the concentration of water was changed from 0.03 to 0.1 M. It was found that water made no effect on the present anation reactions in this concentration range.

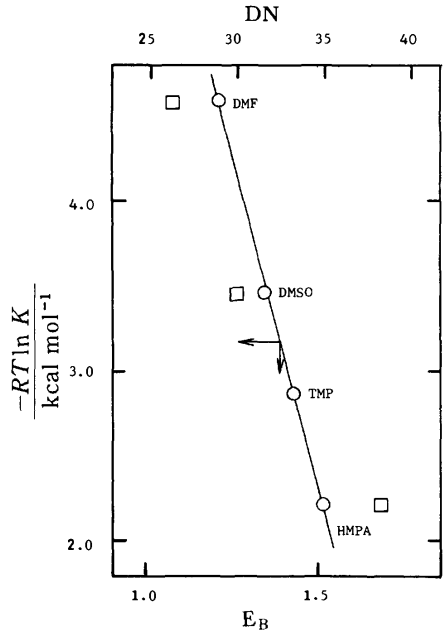

Fig. 3. The plot of $-RT\ln K$ *vs.* E_B and DN of the coordinated molecules: ○; E_B, □; DN.

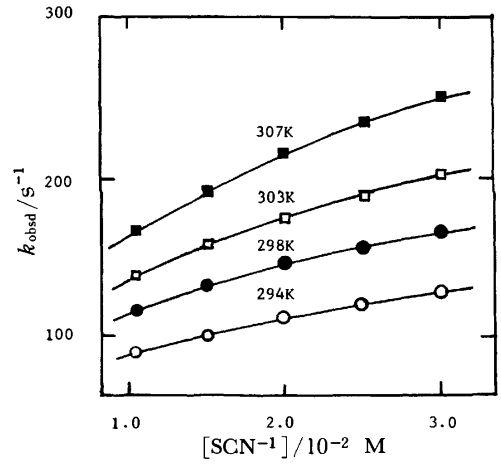

Fig. 4. Plots of k_{obs} *vs.* $[SCN^-]$ for the anation reaction of $[UO_2(dmso)_5]^{2+}$ by SCN^-. The solid lines denote the least-squares best-fit lines.

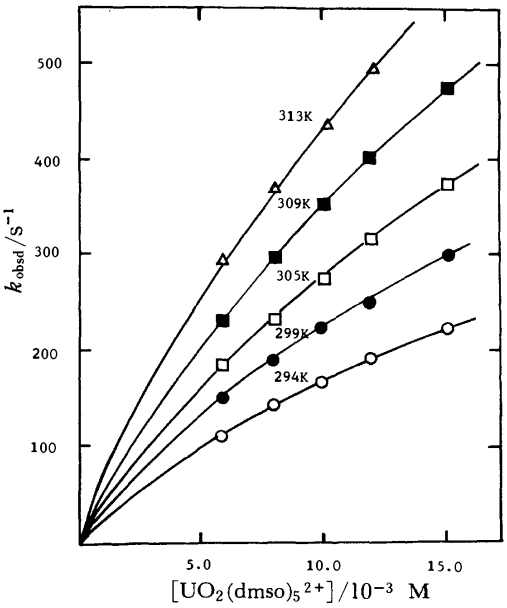

Fig. 5. Plots of k_{obsd} *vs.* $[UO_2(dmso)_5^{2+}]$ for the anation reaction by N_3^-. The solid lines denote the least-squares best-fit lines.

Taking into account the result that the anation reaction in $[UO_2(dmf)_5]^{2+}$ proceeded through the I_a mechanism,[9] the following I mechanism appears to be the most probable mehanism for the present anation reactions.

$$[UO_2(dmso)_5]^{2+} + L^- \overset{K_{os}}{\rightleftharpoons} [UO_2(dmso)_5]^{2+} \cdots L^-,$$

$$[UO_2(dmso)_5]^{2+} \cdots L^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [UO_2(dmso)_4L]^+ + DMSO,$$

were L is SCN^- or N_3^- ion, and K_{os} is the outersphere complex formation constant. According to this mechanism, the observed rate constant, k_{obsd}, is given by Eq. 4.

$$k_{obsd} = \frac{k_{-1}+(k_1+k_{-1})K_{os}[X]}{1+K_{os}[X]}, \quad (4)$$

Table 2. Kinetic parameters of ligand substitution reactions[a)]

$[UO_2(dmso)_5]^{2+}+N_3^-$	DMSO	$k_1=7.5\times10^2$	43.3±0.9	−45.8±5.0	I_a
$[UO_2(hmpa)_4]^{2+}+SCN^-$	MeCN	$k_f=9.7\times10^3/M^{-1}$	62.6±1.5	41.1±5.3	A

a) The quoted errors respresent the standard deviation. Ionic strength=0.2 M($NaClO_4$).

where X is SCN^- and $[UO_2(dmso)_5]^{2+}$ for the anation reactions by SCN^- and N_3^-, respectively, since the measurements were carried out under the conditions of $[UO_2(dmso)_5^{2+}]<[SCN^-]$ and $[UO_2(dmso)_5^{2+}]>[N_3^-]$. When $K_{os}[X]\ll1$, Eq. 4 can be simplified to $k_{obsd}=k_{-1}+(k_1+k_{-1})K_{os}[X]$. This agrees with the dependence of k_{obs} on [X] in the low concentration region. If the values of $K_{os}[X]$ are much larger than unity, Eq. 4 becomes $k_{obsd}=k_1+k_{-1}$, which is consistent with the fact that limiting values of k_{obsd} are obtained at high [X].

The values of k_1, k_{-1}, and K_{os} were calculated by the nonlinear least-squares method and are listed in Table 2. The solid lines in Figs. 4 and 5 obtained from the calculated values agree with the experimental results. The activation parameters for k_1 obtained from the Eyring plot are shown in Table 3.

The outersphere complex formation constants for both reactions are similar as shown in Table 2. This seems to be reasonable since SCN^- and N_3^- ions have the same charge, similar size and structure. Thus the interatomic distance between $[UO_2(dmso)_5]^{2+}$ and SCN^- or N_3^- in the outersphere complexes is assumed to be the same. In this case, the Fuoss equation[15)] gives the same value for the outersphere association constant.

The interchange rate constants of the present reactions depended on the nature of the entering ligands, SCN^- and N_3^-. The difference of the reactivities, *i.e.*, $k_1^{N_3^-}/k_1^{SCN^-}\simeq3.8$ cannot be attributed to the outersphere complex formation, because the value of this ratio is larger than the corresponding value for K_{os}, $K_{os}^{N_3^-}/k_{os}^{SCN^-}\simeq1.2$ at 25 °C. Thus the different reactivity may be due to a difference in nucleophilicity of SCN^- and N_3^-.

Kinetic Study on the Reaction of $[UO_2(hmpa)_4]^{2+}$ Ion with SCN^-. On the basis of the spectrophotometric measurement of the equilibrium constant, the pseudo-first order rate constants, k_{obsd}, for the anation reaction in $[UO_2(hmpa)_4]^{2+}$ with SCN^- were measured under the conditions of $[UO_2(hmpa)_4^{2+}]>[SCN^-]$ in MeCN. The plots of k_{obsd} against the concentration of $[UO_2(hmpa)_4]^{2+}$ in Fig. 6 show a simple linear relationship. The effect of water on the present anation reaction was also examined, where the concentration of water was changed from 0.05 to 0.1 M. It was found that water made no evident effect on this reaction in this concentration range.

The simple relationship shown in Fig. 6 can be explained by an A or an I mechanism. In the A mechanism,

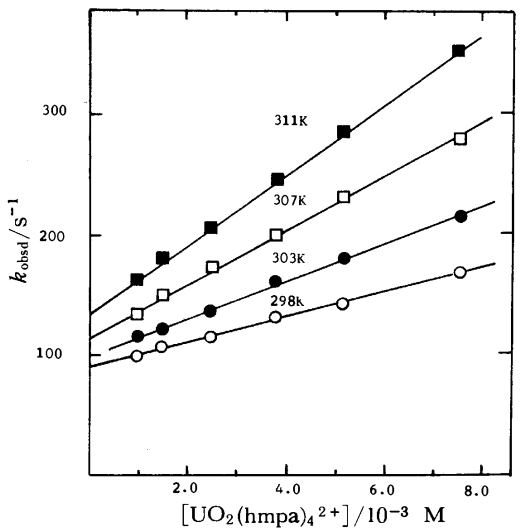

Fig. 6. Plots of k_{obsd} *vs.* $[UO_2(hmpa)_4^{2+}]$ for the anation reaction by SCN^-. The solid lines denote the least-squares best-fit lines.

$$[UO_2(hmpa)_4]^{2+} + SCN^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [UO_2(hmpa)_4NCS]^+,$$

$$[UO_2(hmpa)_4NCS]^+ \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} [UO_2(hmpa)_3NCS]^+ + HMPA,$$

where $k_{obsd}=k_f[UO_2(hmpa)_4^{2+}]+k_b[HMPA]_{free}$ in which k_f and k_b are $k_1k_2/(k_{-1}+k_2)$ and $k_{-1}k_{-2}/(k_{-1}+k_2)$, respectively. In the I mechanism,

$$[UO_2(hmpa)_4]^{2+} + SCN^- \overset{K_{os}}{\rightleftharpoons} [UO_2(hmpa)_4]^{2+}\cdots NCS^-,$$

$$[UO_2(hmpa)_4]^{2+}\cdots NCS^- \underset{k'_{-1}}{\overset{k'_1}{\rightleftharpoons}} [UO_2(hmpa)_3NCS]^+ + HMPA,$$

where $k_{obsd}=k'_1K_{os}[UO_2(hmpa)_4^{2+}]/(1+K_{os}[UO_2(hmpa)_4^{2+}])+k'_{-1}[HMPA]_{free}$. When $K_{os}[UO_2(hmpa)_4^{2+}]$ is much smaller than unity, k_{obsd} can be simplified as follows:

$$k_{obsd} = k'_1K_{os}[UO_2(hmpa)_4^{2+}]+k'_{-1}[HMPA]_{free}.$$

Thus, both the two mechanisms can explain the experimental results shown in Fig. 6. On the other hand, as mentioned in the study on the equilibrium constant, it is shown that DMF and MeCN can be regarded as solvents having similar effect on the solvation of the species in the present study. Therefore, if the reaction proceeded through the I mechanism, the outersphere complex formation constant for this reaction is expected to be of the same order as that for the anation reaction in $[UO_2(dmf)_5]^{2+}$ with SCN^- in DMF. Since the K_{os} value for the latter reaction was $148M^{-1}$ at 25 °C[9] and the concentration range of $[UO_2(hmpa)_4]^{2+}$ is larger than 7.58×10^{-3} M, the product of K_{os} and $[UO_2(hmpa)_4^{2+}]$ has much the same value as unity. Thus it is not likely that this reaction proceeds through the I mechanism. The HMPA concentration dependence of the pseudo-first order rate constants based on the A mechanism is shown in Fig. 7 and the calculated values of k_f and k_b are listed in Table 2.

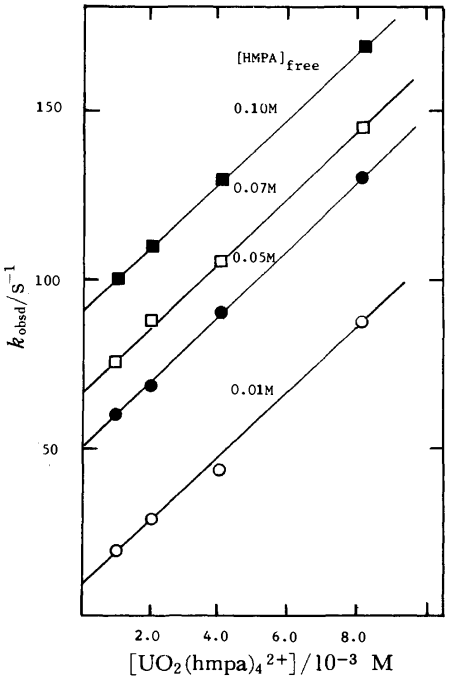

Fig. 7. Plots of k_{obsd} *vs.* $[UO_2(hmpa)_4^{2+}]$ at various concentrations of free HMPA.

It is concluded that the anation reactions in $[UO_2(dmso)_5]^{2+}$ proceeded through the Ia mechanism since the interchange rate constants depended on the nature of entering ligands, SCN^- and N_3^-. The anation reaction in $[UO_2(hmpa)_4]^{2+}$ with SCN^- ion was observed to proceed through the A mechanism, which is consistent with the results obtained by NMR[10] for the ligand exchange reaction in this complex.

It is proposed that the ligand substitution reactions in uranyl complexes with five ligands in the equatorial plane proceed through the associative interchange mechanism, while $[UO_2(hmpa)_4]^{2+}$ with less coordination number than five, reacts *via* the associative mechanism by forming a pentacoordinated intermediate.

The authors wish to express their thanks to Dr. Roderick D. Cannon of the University of East Anglia, U. K., Messrs. Takashi Kojima and Naoshi Fujiwara for their helpful discussions. This work was partly supported by the Grant-in-Aid for Developmental Scientific Research No. 584024 from the Ministry of Education, Science and Culture.

Reaction of Organoboranes with Lead(IV) Acetate Azide. A Synthesis of Azidoalkanes from Alkenes *via* Hydroboration

Yuzuru MASUDA,* Masayuki HOSHI, and Akira ARASE
Department of Applied Chemistry, Kitami Institute of Technology, Kitami, 090
(Received March 12, 1983)

Trialkylboranes prepared from alkenes *via* hydroboration react with lead(IV) acetate azide in dichloromethane at −25 °C to form the corresponding azidoalkanes in a one-pot manner. One or two of the alkyl groups of trialkylboranes are utilized in the reaction. For example, 1-azidohexane is afforded from 1-hexene in 50% yield based on the alkene employed.

For several years, the authors have been studying the combination of alkyl groups of organoboranes[1] with ligands of metal compounds *via* the severance of carbon-boron linkage, by redox reaction of organoboranes with metal compounds.[2]

In the course of study on such oxidative transformations of trialkylboranes by metal compounds, the authors have found that lead(IV) acetate has interesting characteristics for reactions with organoboranes.

For example, it affords alkyl acetates from saturated trialkylboranes (Eq. 1),[3] 1-halo-1,2-dialkylethylenes from (1-halo-1-alkenyl)dialkylboranes (Eq. 2),[4] and (*Z*)-enol acetates from mixtures of trialkylborane and 1-alkyne (Eq. 3):[5]

$$R_3B + 2\,Pb(OCOCH_3)_4 \longrightarrow 2\,ROCOCH_3 + RB(OCOCH_3)_2 + 2\,Pb(OCOCH_3)_2 \quad (1)$$

$$R_2BCX{=}CHR' \xrightarrow{Pb(OCOCH_3)_4} RCX{=}CHR'\ (Z \text{ or } E) \quad (2)$$

$$R_3B + HC{\equiv}CR' \xrightarrow{Pb(OCOCH_3)_4} \begin{matrix} R & & OCOCH_3 \\ & C{=}C & \\ H & & R' \end{matrix} \quad (3)$$

Lead(IV) acetate azide $Pb(OAc)_{4-n}(N_3)_n$, readily prepared by reaction of lead(IV) acetate with azidotrimethylsilane at −40 to −20 °C, transfers its acetoxy and azido groups to alkenes, giving a mixture of disubstituted alkanes consisting of *vic*-diazido and *vic*-acetoxy azido compounds (Eq. 4):[6]

$$RCH{=}CH_2 \xrightarrow{Pb(OAc)_{4-n}(N_3)_n} \underset{N_3}{RCHCH_2{-}N_3} + \underset{OAc}{RCHCH_2{-}N_3} \quad (4)$$

From these results it seemed probable that azidoalkane and/or alkyl acetate would be formed in the reaction of trialkylborane with lead(IV) acetate azide (Scheme 1).

$$\left[Pb(OAc)_4 + n\,(CH_3)_3SiN_3\right] \downarrow$$

$$R_3B \xrightarrow{Pb(OAc)_{4-n}(N_3)_n} R{-}N_3 + R{-}OAc$$

$$\uparrow \quad \left[3\,R'CH{=}CH_2 + BH_3{\cdot}THF\right]$$

Scheme 1.

Results and Discussion

To a dichloromethane solution of 2 mmol of lead(IV) acetate was added 4 mmol of azidotrimethylsilane at −25 °C over 10 min. After 15 min, 2 mmol of trihexylborane was added to this solution at −25 °C and the solution was stirred at this temperature for several hours. The solution was allowed to warm up to room temperature (20 °C). GLPC analysis of the reaction mixture revealed that 1.26 mmol of 1-azidohexane was formed as the major product accompanied by 2-azidohexane and hexyl acetate as the minor products (Scheme 2).

$$Pb(OAc)_4 + 2(CH_3)_3SiN_3 \xrightarrow[-25\ ^\circ C]{CH_2Cl_2} \xrightarrow[-25\ ^\circ C]{(C_6H_{13})_3B} \xrightarrow{\text{room temp.}} n\text{-}C_6H_{13}\text{-}N_3 + \underset{N_3}{n\text{-}C_4H_9CHCH_3} + n\text{-}C_6H_{13}OAc$$

Scheme 2.

In any of blank experiments using pairs of trihexylborane and azidotrimethylsilane, hexyl acetate and azidotrimethylsilane, and hexyl acetate and lead(IV) acetate azide, no azidohexane was obtained. Accordingly, it is apparent that azidohexanes are formed by the reaction of lead(IV) acetate azide with trihexylborane.

The yield of azidoalkanes did not increase after the reaction over 6 h at −25 °C. This fact seems attributable to a decomposition of lead(IV) acetate azide during such a long reaction time.[6] The exchange reaction of the acetoxy group of lead(IV) acetate by the azido group was rapid at −40 to −20 °C,[6] and the reaction of trialkylboranes with lead(IV) acetate was very sluggish at temperatures below 0 °C.[3]

Accordingly, the following procedure, in which lead(IV) acetate azide was produced in the presence of trihexylborane in a one-pot manner, was examined to minimize the possibility of the unfavorable decomposition of lead(IV) acetate azide and to increase the yield of azidohexane. Thus, lead(IV) acetate was added to a solution of 2 mmol of trihexylborane in

$$R_3B + Pb(OAc)_4 \xrightarrow[CH_2Cl_2]{(CH_3)_3SiN_3} R{-}N_3 + R{-}OAc$$

Scheme 3.

dichloromethane, and then 2 mmol of azidotrimethylsilane was slowly added at −25 °C (Scheme 3). The results are shown in Table 1.

In this case, the reaction was fairly rapid and the maximum yield of azidohexanes was obtained after the reaction at −25 °C for 4 h. In Expt 4, a total 1.74 mmol (87%, based on R_3B) of 1-azidohexane and 2-azidohexane is formed, indicating that one of the three hexyl groups of trihexylborane is utilized for the reaction.

Table 2 shows how the yield varies with the amounts of lead(IV) acetate and azidotrimethylsilane. In the course of this experiment, it was recognized that a very slow addition of azidotrimethylsilane increased the yield of azidohexanes appreciably (for example, see the difference between Expts 9 and 10). Thus this step was carried out over a period of 1.5 or 2 h.

In the reactions with 2 mmol of the Pb(IV) compound (Expts 6 and 7), the total amounts of azidohexanes and hexyl acetate formed in each reaction were 1.96 and 1.93 mmol, respectively, suggesting that one equivalent of the Pb(IV) compound is required for the reaction of the first alkyl group in trihexylborane. The reaction of the second alkyl group in trihexylborane was rather sluggish compared with that of the first one. However, in the reaction with two or more equivalents of the lead(IV) compound to R_3B (2 mmol), the total amounts of the products formed in the reaction mixture exceeded 2 mmol and reached about 3.5 mmol in some cases, indicating that the second alkyl group in trihexylborane can also participate in the reaction, but not the third one.

The difference in the ratio of azide to acetate anions in the lead(IV) compound shows a small but evident effect on the product distribution. Thus, in Expts 7, 11, and 12, where the ratio is 2 or 4, the amounts of the azidohexanes are more than those in Expts 6, 10, 13, and 14, where the ratio is 1.

The amounts 12 and 13% of 2-azidohexane in Expts 11 and 12, respectively, indicate that most of the secondary hexyl groups in trihexylborane are converted to 2-azidohexane, whereas the amounts 105 and 104% of 1-azidohexane indicate that a considerable portion of the primary hexyl groups remains unreacted. These facts suggest that in this reaction the secondary alkyl group is more reactive than the primary one when they are on the same boron atom.[7] This characteristic of the reaction is well shown in Expt 29, where dicyclohexylhexylborane was employed (Table 3). However, the preference of the secondary alkyl group to the primary one is not so excellent compared to that observed in the reaction of trialkylboranes with lead(IV) acetate.[3]

In tetrahydrofuran, acetonitrile, benzene, diethyl ether, and hexane, a certain amount of 1-azidohexane could be formed, but the yields could not exceed those obtained in dichloromethane.

Similar reactions were carried out by using several alkenes as substrates in dichloromethane. The results are shown in Table 3.

In these reactions the formation of a small amount of alkyl acetate cannot be avoided. However, azidoalkanes can be isolated easily from the reaction mixture by applying simple column chromatography using silica

Table 1. Reaction[a] of trihexylborane with lead(IV) acetate azide in dichloromethane (1)

Expt No.	Reaction time/h	Yield of product/mmol(%)[b]		
		1-Azidohexane	2-Azidohexane	Hexyl acetate
1	0.5	1.30 (65)	0.10 (5)	0.14 (7)
2	1	1.42 (71)	0.12 (6)	0.12 (6)
3	1.5	1.52 (76)	0.18 (9)	0.10 (5)
4	4	1.60 (80)	0.14 (7)	0.08 (4)
5	6	1.58 (79)	0.16 (8)	0.10 (5)

a) The reactions were carried out in dichloromethane (8 ml) at −25 °C by using 2 mmol of trihexylborane, 2 mmol of lead(IV) acetate, and 4 mmol of azidotrimethylsilane. b) Determined by GLPC, based on trihexylborane.

Table 2. Reaction[a] of trihexylborane with lead(IV) acetate azide in dichloromethane (2)

Expt No.		$Pb(OAc)_4$	$(CH_3)_3SiN_3$	Yield of product/mmol(%)[b]		
		mmol	mmol	1-Azidohexane	2-Azidohexane	Hexyl acetate
6	(n-$C_6H_{13})_3B$	2	2	1.56 (78)	0.16 (8)	0.24 (12)
7	(2 mmol)	2	4	1.62 (81)	0.20 (10)	0.11 (6)
8		2.4	4.8	1.80 (90)	0.18 (9)	0.16 (8)

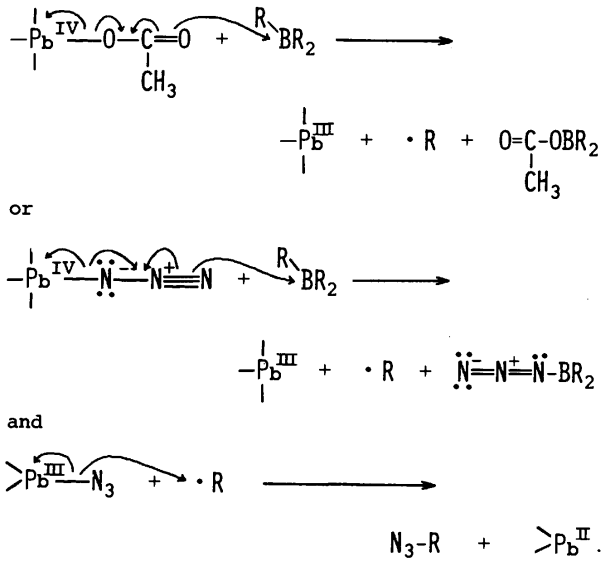
a) Carried out in dichloromethane (8—12 ml, except Expt Nos. marked with c) for 4 h at −25 °C, then with a rise from −25 °C to room temperature over 2 h, and finally 4 h at room temperature. Azidotrimethylsilane was added very slowly (over 1.5—2 h). b) Determined by GLPC (except Expt Nos. marked with c) based on R_3B used and expressed so as to become 300% when all alkyl group of R_3B have reacted completely. c) Preparative experiments. Azidoalkanes were isolated by column chromatography.

gel. Thus, the present reaction can be used as a general synthetic method for azidoalkanes.

The formation of azidoalkanes was moderately depressed when the reaction was carried out in the presence of added garvinoxyl (20 mol% to R_3B), a reagent for trapping radicals. Therefore, the reaction seems to proceed *via* a radical process.

When the reaction of trialkylborane involves a radical mechanism, the secondary alkyl group tends to react more easily than the primary one.[2,3] There is the same tendency in the present reactions as mentioned above.

From these results, the mechanism of the present reaction may be written as follows (Eq. 5):



(5)

Next we offer some characteristic features of the present reaction, in comparison with reactions which have hitherto been reported.

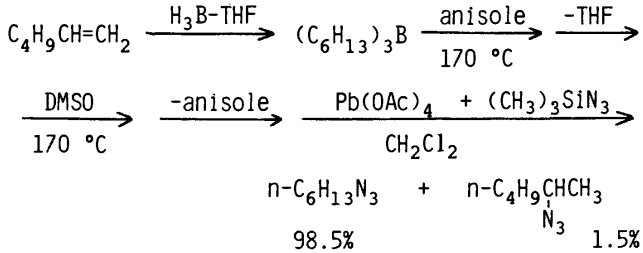
(1) Azidoalkanes are usually prepared by reactions using haloalkanes or diazo compounds as starting materials,[8] while the present reaction makes use of alkene.

(2) Azidoalkanes have also been synthesized by reactions of alkenes with mercury(II) azide[9] where the azido group is introduced in the "Markownikoff" fashion,[10] while the present reaction is in the "anti-Markownikoff" fashion.

(3) A method for synthesis of azidoalkanes using organoboranes, iron(II) azide, and hydrogen peroxide has been reported.[11] Yields of our reaction are mostly higher than those of the above reaction.

(4) As described above (Scheme 1), diazido compounds and acetoxy azido compounds[6] are formed by the reaction of olefin with lead(IV) acetate azide,[12] while in the pesent reaction these compounds are not detected, but mainly azidoalkane is formed.

In the present reaction, contamination of 1-azidoalkane by 2-azidoalkane cannot be avoided when trialkyl-



Scheme 4.

boranes from 1-alkenes are employed.[7] 2-Azidoalkane must come from the secondary alkyl groups which are originally present in trialkylboranes. Thus, to minimize the amount of 2-azidoalkane, most of the secondary alkyl groups in the trialkylborane were converted to primary alkyl groups or removed from trialkylborane by successive treatments of trialkylboranes with anisole and dimethyl sulfoxide before the reaction with lead(IV) acetate azide (Scheme 4).[13]

Although the yield was caused to be lowered a little by using this trialkylborane, the amount of 2-azidoalkane could be markedly reduced and highly isomerically pure 1-azidoalkane was obtained (97—99%).

Experimental

Instruments. GLPC was performed using a NEVA Model 1400. ^{1}H NMR spectra were obtained on a Hitachi R-20A spectrometer (60 MHz). Infrared spectra were recorded on a Hitachi 285 spectrometer. Mass spectra were obtained on a Hitachi M-52 mass spectrometer.

Materials. Commercial 1-hexene, 1-octene, cyclopentene, cyclohexene, cyclooctene, and tetrahydrofuran were dried over lithium aluminium hydride and used after distillation in an argon atmosphere. Commercial 2-norbornene and 1-butene were used without any purification. Dichloromethane was dried over phosphorus pentoxide and used after distillation in an argon atmosphere. Anisole and dimethyl sulfoxide were dried over Molecular Sieve 5A and distilled before use.

The tetrahydrofuran solution of borane,[14] lead(IV) acetate[15] (purity>98%),[16] and azidotrimethylsilane[17] (bp 93—95 °C; lit 95 °C) were prepared by the methods described in the literature.

Reaction of Trialkylboranes with Lead(IV) Acetate Azide. The following procedure is representative. A dry, 100-ml round bottomed flask, equipped with a gas inlet, a magnetic stirring bar, a septum inlet, and a dropping funnel, was flushed with argon. In this flask 3.75 ml (30 mmol) of 1-hexene was hydroborated with 10 mmol of borane in tetrahydrofuran, and then the tetrahydrofuran was removed under reduced pressure at 25 °C. In an argon atmosphere, 13.3 g (30 mmol) of lead(IV) acetate in 40 ml of dichloromethane was added to trihexylborane[14] at −25 °C and 4.20 ml (30 mmol) of azidotrimethylsilane in 10 ml of dichloromethane was added dropwise (for 2 h) through the dropping funnel. The solution was stirred at −25 °C for 4 h, then with a rise from −25 °C to room temperature over 2 h, and finally at room temperature for 4 h. The light brown color of the solution changed into white after the reaction. The reaction mixture was transferred into a separatory funnel together with 100 ml of diethyl ether and 30 ml of water. Then it was saturated with sodium chloride, and the lower aqueous layer was separated and extracted three times with diethyl ether. The combined organic layer and diethyl ether extracts were washed with a saturated aqueous sodium chloride solution, and dried over anhydrous magnesium sulfate. After evaporation of the solvent, the products were separated by column chromatography (silica gel, 150 g). On elution with pentane (200 ml) and then with a mixture of pentane (200 ml) and dichloromethane (200 ml), 1.85 g of a mixture containing 13.6 mmol of 1-azidohexane and 1.01 mmol of 2-azidohexane was obtained. The GLPC retention times, n_D values, and IR, ^{1}H NMR, and mass spectra of these products were consistent with those obtained for authentic samples.[8]

An analytical experiment was carried out by using smaller amounts of reagents, and the reaction mixture was analyzed by GLPC using the internal standard method (FFAP, supported on Diasolid M, was used as the liquid phase).

Reactions using tributylborane[14] and trioctylborane[14] were carried out under the same conditions as described above. From trioctylborane (10 mmol), on elution with hexane (200 ml) and a mixture of hexane (200 ml) and benzene (200 ml), 10.6 mmol of 1-azidooctane with 0.90 mmol of 2-azidooctane was obtained.

A reaction of tricycloalkylborane[14] was carried out under the same conditions as described above by using 10 mmol of tricycloalkylborane, 20 mmol of lead(IV) acetate, and 80 mmol of azidotrimethylsilane. From tricyclopentylborane, on elution with pentane (200 ml) and with a mixture of pentane (200 ml) and dichloromethane (200 ml), 10.4 mmol of azidocyclopentane was obtained. From tricyclohexylborane, tricyclooctylborane, and trinorbornylborane, 16.2 mmol of azidocyclohexane, 8.5 mmol of azidocyclooctane, and 10.3 mmol of *exo*-2-azidonorbornane, respectively, were obtained on elution with hexane (200 ml) and with a mixture of hexane (200 ml) and benzene (200 ml). The GLPC retention times, n_D values, and IR, ^{1}H NMR, and mass spectra of these azidocyclohexane and *exo*-2-azidonorbornane were consistent with those obtained from authentic samples.[8,10]

Reaction of Trihexylborane with Lead(IV) Acetate Azide in the Presence of Garvinoxyl. The reaction was carried out under the same conditions as described above using 2 mmol of trihexylborane, 2 mmol of lead(IV) acetate, 4 mmol of azidotrimethylsilane, and 0.20 g (20 mol%) of garvinoxyl. The total yields of 1- and 2-azidohexane in this reaction and those in the absence of garvinoxyl (in parentheses) are as follows: 30 min, 24% (56%); 45 min, 32% (61%); 2.5 h, 34% (65%); 5 h, 37% (71%).

Reaction of Trialkylborane with Lead(IV) Acetate Azide after Successive Treatments with Anisole and Dimethyl Sulfoxide. In an argon-flushed flask equipped with the same apparatus as described above and a reflux condenser, 30 mmol of 1-hexene was hydroborated with 10 mmol of borane in tetrahydrofuran. After addition of 5 ml of anisole, the tetrahydrofuran was removed under reduced pressure (20 Torr) at 25 °C. The solution was heated at 170 °C for 2 h and allowed to react with 0.5 mmol of dimethyl sulfoxide at 170 °C for 2 h. The anisole was removed under reduced pressure (3 Torr, 1 Torr≈133.322 Pa) at 50 °C. Then the reaction of trihexylborane with 30 mmol of lead(IV) acetate and 30 mmol of azidotrimethylsilane was carried out in the same manner as described above. The products were separated by column chromatography (silica gel, 150 g). On elution with pentane (200 ml) and with a mixture of pentane (200 ml) and dichloromethane (200 ml), 9.55 mmol of 1-azidohexane with 0.18 mmol of 2-azidohexane was obtained.

Similarly, 9.20 mmol of 1-azidooctane with 0.28 mmol of 2-azidooctane was obtained from 30 mmol of 1-octene.

Analytical Data of Products. *1-Azidohexane*: IR (film) ν_{N_3} 2100 cm^{-1} (v.s.); ^{1}H NMR (CCl_4, TMS) δ=0.89 (t, 3H), 1.15—1.75 (m, 8H), and 3.20 (t, 2H); n_D^{20} 1.4320 (lit[8] 1.4318). Found: C, 56.56; H, 10.29; N, 33.15%. Calcd for $C_6H_{13}N_3$: C, 56.66; H, 10.30; N, 33.04%.

1-Azidooctane: IR (film) ν_{N_3} 2100 cm^{-1} (v.s.); ^{1}H NMR (CCl_4, TMS) δ=0.87 (t, 3H), 1.15—1.70 (m, 12H), and 3.19 (t, 2H); n_D^{20} 1.4401 (lit[8] 1.4368).

Azidocyclopentane: IR (film) ν_{N_3} 2100 cm^{-1} (v.s.); ^{1}H NMR (CCl_4, TMS) δ=1.5—1.9 (m, 8H), and 3.7—4.0 (m, 1H); MS *m/z* 111 (M^+); n_D^{20} 1.4660 (lit[8] 1.4616).

Azidocyclohexane: IR (film) ν_{N_3} 2100 cm^{-1} (v.s.); ^{1}H NMR (CCl_4, TMS) δ=1.1—2.1 (m, 10H) and 3.0—3.5 (m, 1H); MS *m/z* 125 (M^+); n_D^{20} 1.4697 (lit[8] 1.4693).

Azidocyclooctane: IR (film) ν_{N_3} 2090 cm^{-1} (v.s.); ^{1}H NMR (CCl_4, TMS) δ=1.1—2.2 (m, 14H) and 3.2—3.7 (m, 1H); n_D^{20} 1.4921.

exo-*2-Azidonorbornane*: IR (film) ν_{N_3} 2100 cm^{-1} (v.s.); ^1H NMR (CCl_4, TMS) δ=0.95—1.7 (m, 8H), 2.2—2.4 (m, 2H), and 3.25—3.55 (m, 1H); MS *m/z* 137 (M^+); n_D^{20} 1.4936 (authentic sample,[10] 1.4893).

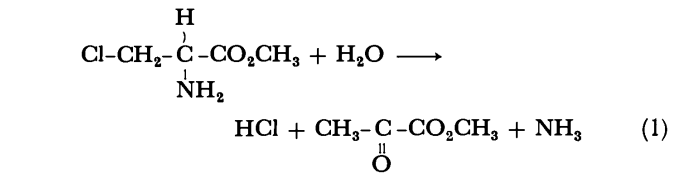
Pyridoxal Methochloride Catalysis of the β-Elimination Reaction of Methyl 3-Chloroalaninate in Water

Hiroki KONDO,* Kanzi MORITA, Tatsuya KITAMIKADO, and Junzo SUNAMOTO
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received April 11, 1983)

The β-elimination reaction of methyl 3-chloroalaninate has been investigated in the absence and presence of pyridoxal methochloride (**2**) or pyridoxal (**3**). Apparently, compound **2** was about twice as effective as **3** in the catalytic reaction that proceeds via a Schiff base of substrate and **2** or **3**. The pH-rate profiles for the catalytic reaction with **2** and **3** were analyzed in terms of ionization of the various Schiff base species present in solution. It was found that the reactivity of the Schiff base decreases as the ionization of the molecule progresses. The reaction mechanism and its relevance to the catalysis of pyridoxal phosphate-dependent enzymes are discussed.

Pyridoxal phosphate (PLP) is a coenzyme involved in the metabolism of amino acids in biological systems. These metabolic reactions include transamination, racemization and decarboxylation. They can be mimicked in model systems mostly in the presence of metal ions and at high temperature.[1] Through these biomimetic studies an insight was gained into the reaction mechanism of pyridoxal catalysis in enzymic systems. Thus, a Schiff base formed between pyridoxal and amino acid is always postulated as a key intermediate in all the reactions mentioned above. Nevertheless, much remains to be elucidated as to the catalytic mechanism of this and related vitamins, *e.g.*, the protonation state of a reactive Schiff base species. This particular problem happens because pyridoxal and the Schiff base derived therefrom can have various ionic forms in aqueous media that differ in number and/or the site of protonation.[2] We have been interested in the pyridoxal catalysis of the β-elimination reaction of amino acids in the absence of a metal ion.[3] 3-Chloroalanine is a substrate suitable for mechanistic studies, as this compound is known to undergo β-elimination spontaneously[4] and in the presence of pyridoxal.[5] In addition, an enzyme which promotes β-elimination of 3-chloro-D-alanine was recently found in *Pseudomonas putida* CR 1—1.[6] In this article, we have attempted a mechanistic study on the pyridoxal methochloride catalysis of the reaction of methyl 3-chloroalaninate (Eq. 1). This particular



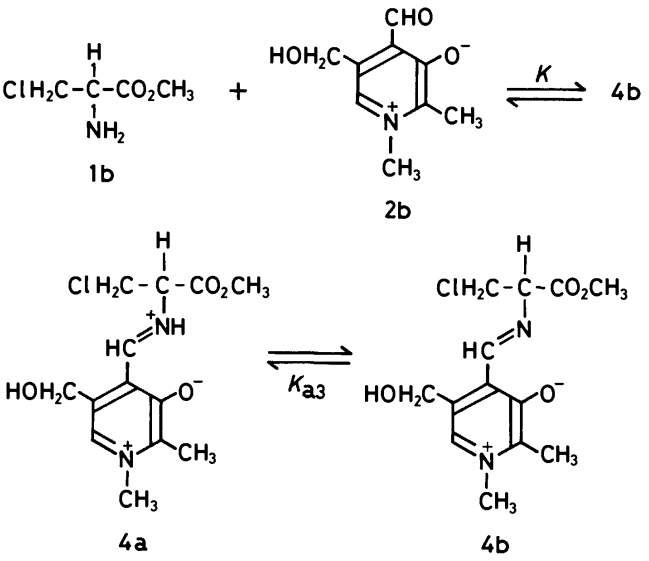
$$\mathrm{Cl\text{-}CH_2\text{-}\underset{\underset{\mathrm{NH_2}}{|}}{\overset{\overset{\mathrm{H}}{|}}{C}}\text{-}CO_2CH_3 + H_2O \longrightarrow HCl + CH_3\text{-}\overset{\overset{\mathrm{O}}{\|}}{C}\text{-}CO_2CH_3 + NH_3} \qquad (1)$$

catalyst was chosen, because there are only two ionic forms of Schiff base for this compound (Scheme 1). This should facilitate the analysis of kinetic data on the catalytic β-elimination of the substrate.

Experimental

Materials. Pyridoxal hydrochloride was obtained from Wako Pure Chemical Ind. Pyridoxal methochloride (**2**) was prepared from pyridoxal (**3**) according to the literature.[7] Methyl L-3-chloroalaninate hydrochloride (**1**) was prepared from dimethyl L-cystinate and chlorine.[8] All other chemicals were obtained from commercial sources. Glass-distilled water was used in all experiments.

Apparatus. Electronic absorption spectra were taken on a Hitachi 124 spectrophotometer. The pH values of aqueous solutions were determined with a Toa pH meter HM-5A connected with a Toa combination electrode GS 195C. Computations were carried out on a Sord microcomputer 223 Mark II with a program written in the Basic.

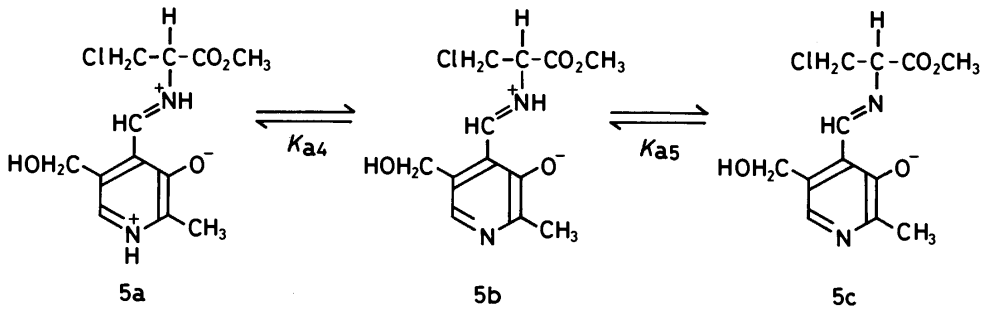


Scheme 1.

Equilibrium Measurements. Since 3-chloroalanine is labile at ambient temperatures, equilibrium studies on the formation of a Schiff base of **2** were carried out with alanine. The pertinent equilibria are depicted in Scheme 1 (but note that the amino acid illustrated is **1** but not alanine). The amino acid, **2** and the Schiff base derived thereof exist over the pH range of 5 to 11 in two ionic forms.[9] The protonated species is designated by the symbol a, while the deprotonated species by b. The acid dissociation constants of amino acid, **2** and the Schiff base are referred to as K_{a1}, K_{a2}, and K_{a3}, respectively. The pK_{a2} for **2** was determined as 4.0 by a spectrophotometric titration. The protonated form of Schiff base (HSB or **4a**) has an absorption maximum at 414 nm and the deprotonated form (SB^- or **4b**) at 374 nm. To determine both the equilibrium constant for the Schiff base formation K, defined by Eq. 2, and pK_{a3} electronic absorption spectra were

$$K = \frac{[\mathbf{4b}]}{[\mathbf{1b}]\,[\mathbf{2b}]} \qquad (2)$$

taken at pH values 6.00, 7.00, 8.00, and 9.00 by varying the concentrations of alanine (0.1, 0.2, 0.4, 0.6, 0.8, and 1.0 M) at 30.0 °C, μ=1.0 (KCl). Equilibrium was reached within a few minutes after mixing. The data were analyzed according



Scheme 2.

basically to the same method as that described previously.[10-12] Other pK_a values used in the calculation were 4.0 and 9.2 for **2** and alanine, respectively. The results are the following: K 5±1 M^{-1}†, pK_{a3} 8.0±0.2. The molar extinction coefficients of HSB and SB^- are 4000±1000 and 6000±1000 at 374 nm, and 8000±2000 and 1200±100 cm^{-1} M^{-1} at 414 nm, respectively. The corresponding equilibrium constant for the Schiff base of **3** and alanine was reported as 9 M^{-1}.[10]

Kinetics. All experiments were carried out at 25.0 °C, unless otherwise specified. The rate of the β-elimination reaction of **1** was determined by following the release of chloride ion by means of Volhard titration. The reaction mixture (10 ml) consisted of 0.010 M **1**, 0—0.020 M **2** or **3** in 0.10 M phosphate (pH 6—8.5) or borate buffer (pH>8.5). An aliquot (1 ml) was withdrawn from the reaction solution at appropriate time intervals, quickly transferred to a quenching solution (6 ml) containing 0.083 M silver nitrate and 1 M nitric acid and kept on ice for later titration. The excess silver ion was back-titrated with 0.1 M potassium thiocyanate in the presence of ferric ammonium sulfate as indicator. The amount of chloride ion at infinite time agreed well with the theoretical value. Data obeyed pseudo-first-order kinetics with usually a correlation coefficient 0.99 or greater.

Another reaction product, methyl pyruvate, was determined by the 2,4-dinitrophenylhydrazone method. The hydrazone was assayed spectrophotometrically at 530 nm (ε 10500),[13] after removing the insoluble hydrazone of **2** or **3** by filtration. The amount of pyruvate at infinite time agreed well with the theoretical value.

Data Processing. The catalytic rate constant k_2 of Eq. 7 was analyzed in terms of a difference in reactivity of the Schiff base species involved. As shown in Schemes 1 and 2, the Schiff bases of **2** and **3** are present in two or three ionic forms over the pH range studied.[9] Thus this idea is formulated as in Eqs. 3 and 4 for **2** and **3**, respectively. By combining Eqs. 2 and 3 one

$$k_2[\mathbf{1}][\mathbf{2}] = k_a[\mathbf{4a}] + k_b[\mathbf{4b}] \quad (3)$$

$$k_2[\mathbf{1}][\mathbf{3}] = k'_a[\mathbf{5a}] + k'_b[\mathbf{5b}] + k'_c[\mathbf{5c}] \quad (4)$$

obtains Eq. 5, where K_{pH} is the operational equilibrium constant defined by Eq. 6. Since the pK_{a2} for **2** is known, four

$$k_2 = \{k_a[H^+] + k_b K_{a3}\} \times \frac{K_{pH}}{[H^+] + K_{a3}} \quad (5)$$

$$K_{pH} = \frac{\left\{1 + \frac{[H^+]}{K_{a3}}\right\} K}{\left\{1 + \frac{[H^+]}{K_{a1}}\right\}\left\{1 + \frac{[H^+]}{K_{a2}}\right\}} \quad (6)$$

unknown parameters, K_{a1}, K_{a3}, k_a, and k_b remain to be determined. They were optimized by essentially the same procedures as those described for the analysis of spectroscopic data. It should be noted here that the Schiff base formation constants K used in the calculation were those for alanine, because we were unable to determine the corresponding values for **1** precisely. Although the equilibrium constants for alanine and **1** may not be exactly identical, it would be reasonable to assume that the relative magnitudes of the constants for **2** and **3** do not differ significantly between alanine and **1**. We have confirmed that as long as this assumption holds, the main conclusions drawn by this data processing do not change appreciably.

† 1 M=1 mol dm^{-3}.

Results

The β-elimination reaction of **1** in buffered aqueous media obeyed a pseudo-first-order rate law with respect to the substrate both in the absence and presence of catalyst **2** or **3**. It was found that the observed first-order rate constants are dependent linearly on the catalyst concentration over a 0—0.02 M range. The k_1 term of Eq. 7 represents the spontaneous reaction of the

$$k_{obsd} = k_1 + k_2[\mathbf{2} \text{ or } \mathbf{3}] \quad (7)$$

substrate. The logarithm of k_1 increases slightly with pH, but the slope of a straight line (0.12) fitted to data points is far from unity (Fig. 1), suggesting that the specific base catalysis is not working over the pH range studied. A similar insensitivity of rates to pH was reported in the β-elimination of *O*-phosphoserine over a pH range of 7 to 14.[14] It should be noted that the linear analysis of kinetic data in Fig. 1 is an approximation, as the rate increase at pH 7—8 could reflect the acid dissociation of **1a** (protonated form) to **1b**. If the data are analyzed by this scheme, **1b** is about twice as reactive as **1a**. The k_2 term refers to the catalytic reaction, proceeding via a Schiff base of the substrate

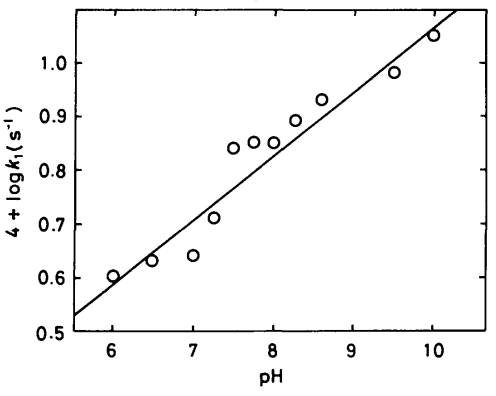


Fig. 1. pH-Dependence of the spontaneous β-elimination rate constants of **1** in water at 25.0 °C.

Table 1. Specific rate constants of individual Schiff base species in the β-elimination of **1** with **2** or **3** in water at 25.0 °C

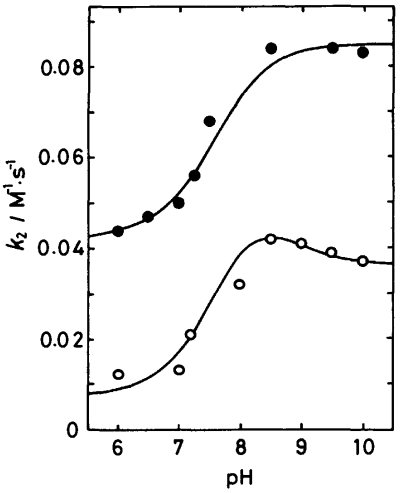

Fig. 2. pH-Rate profiles for the β-elimination of the Schiff base of **1** with **2** (●) and **3** (○) at 25.0°C. The theoretical curves were drawn based on the rate constants given in Table 1 and the following pK_a values: pK_{a1} 7.6; pK_{a2} 4.0; pK_{a3} 6.5; pK_{a4} 5.9; pK_{a5} 8.5; pK_a of **3** 4.23 and 8.70 (V. R. Williams and J. B. Nielands, *Arch. Biochem. Biophys.*,**53**, 56 (1954)).

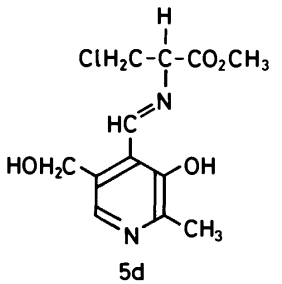
with **2** or **3**. The treatment according to Eq. 7 is warranted, since the Schiff base formation is not extensive under the present conditions. The pH dependence of k_2 is shown in Fig. 2 for both **2** and **3**. Compound **2** is apparently twice as effective as **3** at any pH value studied.

The two pH-rate profiles for the β-elimination of the Schiff base of **1** were interpreted in terms of a difference in reactivity of the various species of Schiff base (see Experimental section). The Schiff base of **2** is present in two ionic forms, **4a** and **4b** (Scheme 1), and the experimental data are explicable by the sigmoidal curve generated with the aid of the parameters listed in Table 1. It is manifest that the protonated species (**4a**) is 6.5 times more reactive than **4b**. There are three ionic species, **5a**, **5b**, and **5c** (Scheme 2), in the Schiff base of **3** in the pH region studied, and the skewed bell-shaped curve created by the parameters listed in Table 1 fits neatly the data points. The analysis clearly reveals that the specific rate constant decreases with the degree of deprotonation on the Schiff base molecule, *i.e.*, **5a**>**5b**>**5c**.

Activation parameters for the spontaneous and **2**-catalyzed β-elimination reaction of **1** were determined at pH 10. The Schiff base of **1** and **2** exists solely in the deprotonated form (**4b**) and the parameters obtained represent those for the SB^- species (Table 2). The reaction is characterized by the large negative entropy of activation and this is compatible with the bimolecular character of β-elimination reactions.[3] The smaller enthalpy of activation for the catalytic reaction may be associated with the labilization of the substrate's α-hydrogen through formation of a Schiff base with **2**.

Discussion

The purpose of the present investigation was two-fold. A mechanistic study of PLP-dependent reactions has often been complicated, because the active Schiff base exists in a variety of ionic forms that differ in reactivity (*e.g.*, see Scheme 2). If one takes into account prototropic equilibrium between, for example, **5b** and **5d**, which could happen in a medium of low dielectric constant,[2] the number of the active Schiff bases further increases. In contrast, the number of Schiff base species derived from an *N*-substituted pyridoxal like **2** is small (Scheme 1). This should ease the analysis of kinetic data in a Schiff base reaction, as has been proven above. Moreover, the presence of a positive charge as a result of the *N*-substitution on the pyridoxal molecule should increase the electron-withdrawing ability of the catalyst, leading to labilization of the α-hydrogen of the Schiff base.[15] This idea has been supported by the finding that **2** is more effective both apparently (Fig. 2) and in terms of specific rate constants than **3** in the elimination reaction of **1** (Table 1).



5d

The results given in Table 1 demonstrate that the Schiff bases of **2** and **3** are more reactive when they have more positive charges on them. These data agree with the above argument and may also be reasonable from a

Table 2. Activation parameters for the spontaneous and **2**-catalyzed β-elimination of **1** in water at pH 10

	Rate constant	Temperature/°C			E_a	$\Delta H^{\ddagger}$ [a]	$\Delta S^{\ddagger}$
		15	25	30	kcal mol^{-1} [b]	kcal mol^{-1} [b]	e.u.
Spontaneous	$k_1 \times 10^3/s^{-1}$	0.84	1.29	1.42	6.3	5.8	−53
Catalytic	$k_2 \times 10/s^{-1}\ M^{-1}$	0.64	0.83	1.01	5.3	4.7	−48

a) Values at 25.0 °C. b) 1 cal=4.184 J.

mechanistic point of view, as PLP serves basically as an electron sink in its catalysis.[16] It may be fair, however, to mention the kinetic equivalence of the reaction, since others dealing with similar data reached a somewhat different conclusion.[5] For example, the reaction of **4b** is equivalent kinetically to the reaction of **4a** with hydroxide ion (Eq. 8), where K_w stands for the

$$k_b[\mathbf{4b}] = k_b'' \frac{K_{a3}}{K_w} [\mathbf{4a}][OH^-] \quad (8)$$

ionization product of water. Although it is not possible to distinguish rigorously between these two mechanisms at present, we favor the k_b pathway for the following reason. It is obvious from the spectroscopic data that the Schiff base of **2** exists in two ionic forms, **4a** and **4b**. If one assumes that the k_b pathway is actually the k_b'' pathway, *i.e.*, the reaction of **4a** with OH^-, one could naturally expect a similar reaction for **4b**. Since the concentration of **4b** is over a thousand times higher than that of **4a** at pH 10, this could have brought about a pH-dependent rate increase in the alkaline region, unless **4a** is over a thousand times more reactive than **4b** in the reaction with OH^-. Hence, the lack of such a tendency at high pH values supports the contention that the k_b pathway is the more likely one.

It is noticeable that the catalytic β-elimination is not subject to the hydroxide ion catalysis. This may be understood, since the spontaneous reaction is little affected by the hydroxide ion concentration and in the catalytic reaction the electron sink labilizes the α-hydrogen so that a strong base such as hydroxide ion may not be needed for its abstraction. We suppose that water is the base responsible for the abstraction of α-hydrogen. This may raise a question about the occurrence of general base catalysis in the Schiff base reaction. An increase in phosphate buffer concentration from 0.10 to 1.0 M at pH 8 and at different catalyst concentraions gave rise to a modest increase (15% at maximum) in the observed rate, indicating that at least the buffer components used in these experiments do not affect the rates significantly. Finally, the relevance of the present data to the enzymatic catalysis is mentioned. A number of PLP-dependent enzymes including 3-chloro-D-alanine chloride-lyase show an absorption maximum at ≈420 nm.[17] Unambiguous assignment of this band is obscured, since **4a**, **5a** and **5b** provide similar spectra.[10] In light of the fact that **4a** and **5a** show the highest reactivity in the present reaction, the enzyme-bound PLP may carry a proton on the pyridine nitrogen.[15] This could explain in part a higher reactivity of the coenzyme in enzymatic systems.

The authors are grateful to Dr. J. Kikuchi for helpful discussions. This work was supported by a Grant-in-Aid for Special Project Research 56109007 from the Ministry of Education, Science and Culture.

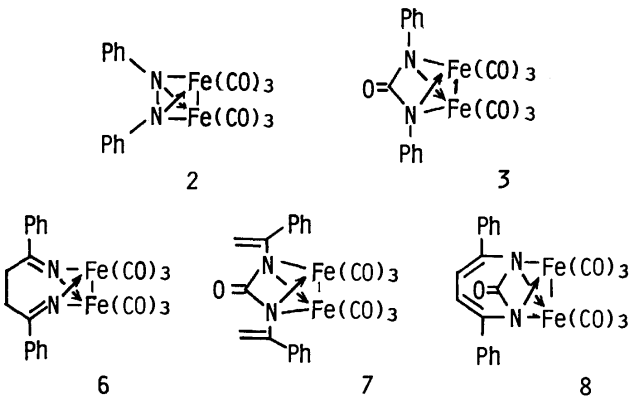
Nonacarbonyldiiron or Pentacarbonyliron Induced Decomposition of Organic Azides and an Azirine. Novel Reduction and Carbonyl Insertion of the Complexed Nitrene Intermediate in Protic Solvents

Makoto NITTA* and Tomoshige KOBAYASHI
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160
(Received June 20, 1983)

The thermal reactions of $[Fe_2(CO)_9]$ or the photochemical reactions of $[Fe(CO)_5]$ with organic azides and an azirine in protic media have been investigated. The thermal reaction of azidobenzene (**1**) with $[Fe_2(CO)_9]$ in methanol under mild conditions gave aniline and methyl phenylcarbamate, along with *N,N'*-diphenylurea, while in the presence of water, **1** afforded aniline and *N,N'*-diphenylurea, in good combined yield. Similarly, the thermal reaction of α-azidostyrene (**4**) with $[Fe_2(CO)_9]$ in methanol gave methyl 1-phenylvinylcarbamate and acetophenone which could be derived from the corresponding enamine, while in the presence of water, **4** gave only acetophenone in good yield. The photoirradiation of $[Fe(CO)_5]$ with **1** or **4** also gave results similar to the $[Fe_2(CO)_9]$-induced reaction. However, the thermal reaction of 3-phenyl-2*H*-azirine (**5**) with $[Fe_2(CO)_9]$ in methanol gave 2,5-diphenylpyrazine in low yield, in addition to acetophenone and methyl 1-phenylvinylcarbemate, although 5 afforded only acetophenone in the presence of water. The reaction pathways for the formation of the products are discussed on the basis of the formation of a complexed nitrene intermediate, reduction of which induces amine or enamine and carbonyl insertion to yield an organic isocyanate in protic media.

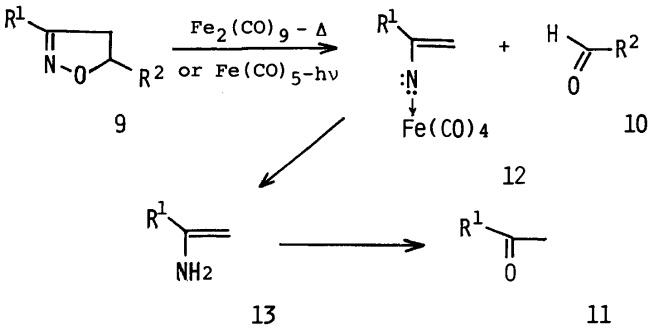
Reaction of azidobenzene (**1**) with $[Fe_2(CO)_9]$ under mild conditions has been shown to give complexes such as bisnitrene complex **2** and urea-based complex **3** in benzene solution.[1,2] In the context of these reactions, the decomposition of **1** in the presence of $[Fe(CO)_5]$ and acetic acid has been studied to give *N,N'*-diphenylurea.[3] The urea-based complex **3**, which could be derived from the complexed phenylnitrene intermediate,[1,4] is proposed as the possible precursor.

In contrast to these studies, transition-metal prompted reactions of the azirine ring system, which can be considered an isomer of vinylnitrene, have been widely studied from both the synthetic and mechanistic point of view.[5,6,7-14] Among these reactions, $[Fe_2(CO)_9]$-induced reaction of 3-phenyl-2*H*-azirine (**5**) in aprotic media has been shown to give complexes such as **6**, **7**, **8**, along with pyrrole and acetophenone albeit in low combined yield.[5] However, the $[Fe_2(CO)_9]$[5] $[Fe(CO)_5]$[6] prompted reaction of α-azidostyrene (**4**) in a similar media gives the complexes **6** and **7**, along with acetophenone or 3,6-diphenylpyridazine. The complexed 1-phenylvinylnitrene is proposed as a key intermediate in the reactions of **4** and **5**. However, the best explanation for the difference of the product composition resulting from the reaction of **4** and **5** could be a further intervention of the complexed azirine in the case of **5**.[5] No reaction of **4** or **5** with $[Fe(CO)_5]$ or $[Fe_2(CO)_9]$ in protic media has been investigated.



Scheme 1.

Previously the reaction of 3,5-disubstituted isoxazolines (**9**) with $[Fe(CO)_5]$ or $[Fe_2(CO)_9]$ in methanol has been shown to undergo the N-O and C_4-C_5 bond cleavage to give two fragments of aldehydes **10** and ketones **11** in good yields.[15] The complexed vinylnitrene species **12**, which could be reduced to the corresponding enamine **13** in protic media, is proposed

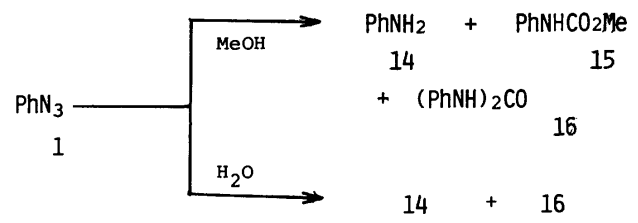


Scheme 2.

as the precursor of the ketones. In connection with the above results, it seemed conceivable that $[Fe(CO)_5]$ or $[Fe_2(CO)_9]$ induced decomposition of organic azides in protic media might provide evidence for the behavior of the complexed nitrene species. This paper describes the reduction and carbonyl insertion of the complexed nitrene species which results from the reaction of azidobenzene (**1**), α-azidostyrene (**4**), and 3-phenyl-2*H*-azirine (**5**) with $[Fe_2(CO)_9]$ or $[Fe(CO)_5]$.

Results and Discussion

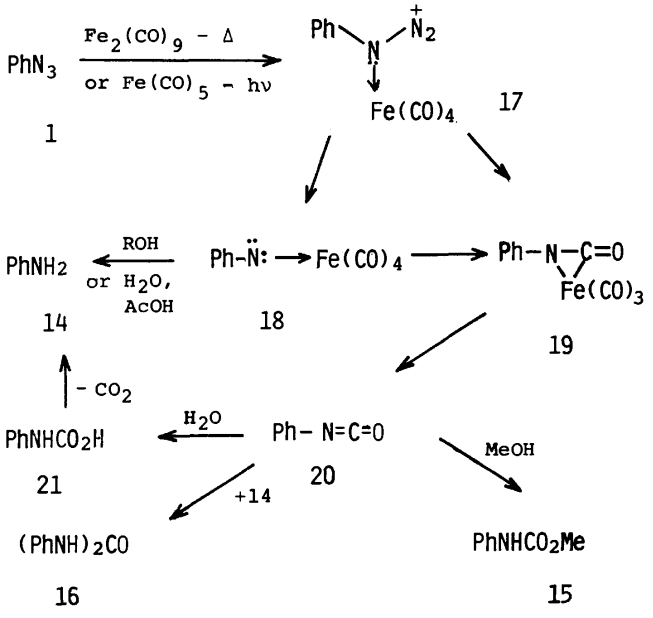
Treatment of azidobenzene (**1**) with $[Fe_2(CO)_9]$ in anhydrous methanol at 50 °C afforded aniline (**14**), methyl phenylcarbamate (**15**), and *N,N'*-diphenylurea (**16**), in 21, 51, and 20% yields respectively (Table 1, entry 1). Use of acetonitrile containing water as the



Scheme 3.

reaction solvent gave **14** and **16** in 67 and 23% yields (entry 2). The combined yield of **14**—**16** for each case is very good; the reaction conditions and the products are summarized in Table 1. The structure of the products was identified by comparison of the spectral properties with those of authentic materials. The irradiation of a solution of **1** and $[Fe(CO)_5]$ in anhydrous methanol or in acetonitrile containing water gave results similar to the $[Fe_2(CO)_9]$-induced reactions (entries 3 and 4). However, the reaction of **1** with $[Fe(CO)_5]$ in anhydrous methanol at the refluxing temperature proceeded very slowly and, gave **15** and **16** in 11 and 3% yields, with the remainder being recovered starting material (entry 5). Thus the $[Fe(CO)_5]$ could not act effectively at the low temperature and phbtochemically genarated $[Fe(CO)_4]$ species[15-17] could be very effective to induce the decomposition of **1**. At high temperature, thermal reaction of **1** with $[Fe(CO)_5]$ in acetic acid also proceeded smoothly (entries 6 and 7).

Possible pathways for the formation of the products, **14**, **15**, and **16** were shown in Scheme 4. The initial step in the present reactions is probably n-donor complexation of **1** to the thermally or photochemically generated $[Fe(CO)_4]$ species to give **17** followed by the elimination of a nitrogen molecule to give the phenylnitrene complex **18**.[1,2,5,6] In aprotic media, complexes such as **2** and **3** could be obtained from **18**.[1,2] However, the protonation and subsequent reduction of the phenylnitrene moiety of **18** by the central metal could occur in protic media such as methanol, acetonitrile containing water, or acetic acid, to give

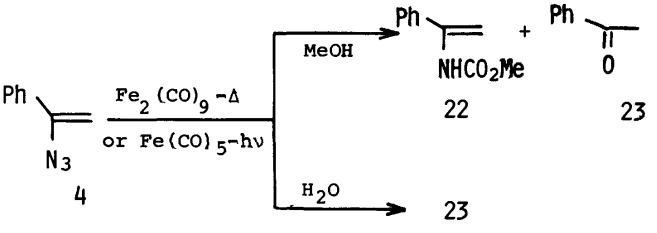


Scheme 4.

aniline **14**. The intramolecular insertion of ligand-carbonyl into metal-nitrogen bond of **18** could give the complex **19**, decomplexation of which could give phenyl isocyanate (**20**). The concerted formation of **19** from **17** may not be ruled out (*vide infra*). In contrast to the present reaction, the carbonylation of azidobenzene to give phenyl isocyanate has been shown to proceed possibly *via* free phenylnitrene under drastic conditions.[18] Phenyl isocyanate **20** is known to be trapped to give **15** in methanol, while in the presence of water, **20** would also give **14** *via* **21**. The formation of **16** can be rationalized on the basis of the reaction of **20** with **14**.[19]

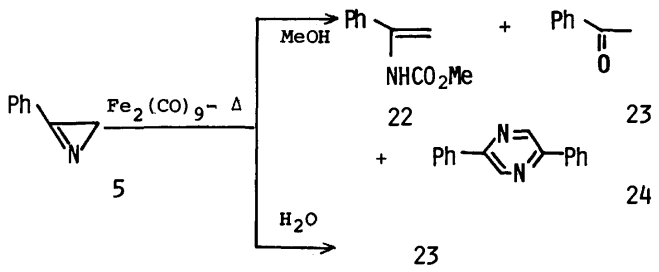
Previously, thermal reaction of aromatic azides with $[Fe(CO)_5]$ in acetic acid has been shown to give *N,N'*-diphenylurea. The urea-based complex, such as **3** in Scheme 1 is proposed as the reasonable intermediate.[3] However attempted thermal reaction of **1** with $[Fe(CO)_5]$ in acetic acid at 100 °C (entry 6) gave **14** and **16** in 33 and 52% yields similarly to the case of entries 2 and 4. On the other hand, the similar reaction of **1** with $[Fe(CO)_5]$ at 100 °C in a tenfold concentrated acetic acid solution gave only **16** in 67% yield (entry 7). Thus the formation of **16** in acetic acid seems dependent on the concentration of aniline **14** which is derived from the reduction of **18** in acetic acid.[20] In a concentrated media of acetic acid, **14** is actually trapped quickly by **20** (see Experimental section), thus only **16** could be obtained in entry 7.

Similarly to the above reactions, $[Fe_2(CO)_9]$ or $[Fe(CO)_5]$ induced reactions of **4** and **5** were studied in protic solvents. The reaction conditions and the products are summarized in Table 2. Treatment of **4** with $[Fe_2(CO)_9]$ in methanol at 50 °C afforded methyl 1-phenylvinylcarbamate (**22**)[21] and acetophenone (**23**) in 44 and 18% yields (Table 2, entry 1). The carbamate **22** is labile and it is hydrolysed by TLC on silica gel to give acetophenone. Accordingly the products, **22** and **23**, in Table 2 were isolated by distillation using a Kugelrohr apparatus. A similar result was also obtained by the photoirradiation of $[Fe(CO)_5]$ and **4** (entry 3). However, the thermal reaction of **4** with $[Fe(CO)_5]$ in methanol at the refluxing temperature proceeded very slowly, and 80% of **4** was recovered (entry 4). Similar to the case of **1**, reaction of **4** with $[Fe_2(CO)_9]$ or $[Fe(CO)_5]$ in acetonitrile containing water afforded only **23** in moderated yield (entries 2 and 5).



Scheme 5.

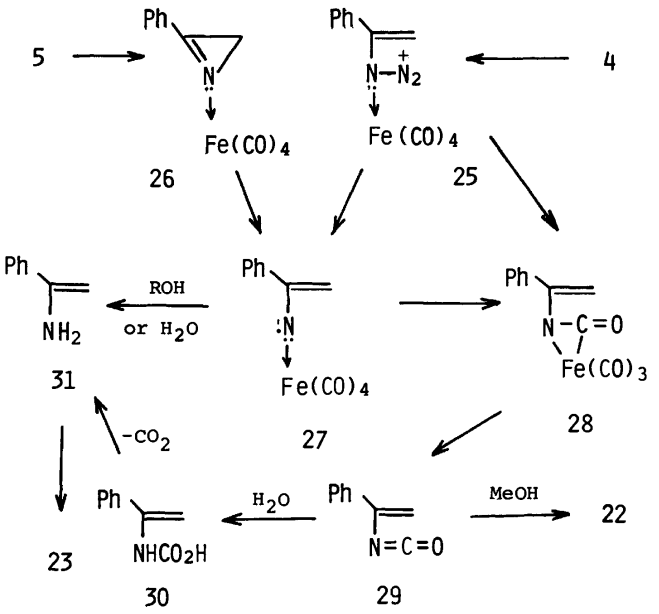
The thermal reaction of **5** with $[Fe_2(CO)_9]$ in methanol at 50 °C, on the other hand, afforded **22** and **23** in 14 and 34% yields, along with 2.2% of 2,5-diphenylpyrazine (**24**) (entry 6). It is notable that the major product from **4** in methanol is carbamate **22**, while that from **5** is acetophenone. Use of acetonitrile



Scheme 6.

containing water as the reaction solvent **5** afforded only acetophenone **23** in 72% yield (entry 7) as in the case of entries 2 and 5 in Table 2. However, irradiation of a solution of **5** with or without [$Fe(CO)_5$] in methanol resulted in the complete disappearance of **5** and afforded **24** in 42 or 35% yield, respectively. Thus the formation of **24** might be explained by the photochemical C-C bond cleavage of the azirine ring to give nitrile ylide.[22]

The reaction pathways for **4** and **5** are very similar to the case of **1**. The carbamate **22** would arise from **4** and **5** *via* methanol-addition of 1-phenylvinyl isocyanate (**29**), which could be derived from carbonyl insertion of the complexed 1-phenylvinylnitrene **27** *via* **25** or **26**.[5,6] The protonation and the subsequent reduction of vinylnitrene moiety of **27** may occur in protic media to give enamine **31**, which may be decomposed by stray water to give **23**. This fact and the lability of **22** to hydrolysis even on TLC plates could explain the previous studies shown in Scheme 2. Another pathway for the formation of **23** would be H_2O-addition of **29** to give **30** followed by decarboxylation to give **31**. Thus in the presence of water, only **23** could be obtained. In the reaction of **4** in methanol (entries 1 and 3) **22** predominates over **23**, while in that of **5**, **23** predominates over **22** (entry 6). This fact may be explained by the direct carbonylation of **25** to give **28**. A minor amount of 2,5-diphenylpyrazine **24** may arise from addition of **27** with **26** or from dimerization of **26**,[9] in the reaction of **5**. However, C-C and/or C=N bond cleavage of the azirine ring can not be ruled out to lead to **24**.[8,9]



Scheme 7.

In conclusion, the decomposition of **1**, **4**, and **5** with iron carbonyl species afford complexed nitrene intermediates under mild conditions. In a protic solvent this intermediate undergoes reduction to give an amine and carbonyl insertion to give an organic isocyanate in good combined yield. No complexes, such as **2**, **3**, **6**, **7**, and **8** were obtained in protic media.

Experimental

General. Solvents were purified and dried by standard methods. All reactions were carried out under a dry nitrogen atmosphere. Photoirradiations were carried out using Rayonet photoreactor (MGR-100) fitted with RPR-350 nm lamps through a Pyrex filter. The thermal reactions were carried out under unlighted conditions. Azidobenze (**1**),[23] α-azidostyrene (**4**),[24] and 3-phenyl-2*H*-azirine (**5**)[24] were synthesized according to the literature-procedures. All of the products are known compounds and were identified by comparison of the spectral data with those of authentic samples.

Thermal Reaction of 1 with [$Fe_2(CO)_9$]. A mixture of **1** (119mg, 1mmol) and [$Fe_2(CO)_9$] (364mg, 1mmol) in 10cm^3 of anhydrous methanol or acetonitrile containing water (1 mmol) was stirred at 50 °C for a period indicated in Table 1. The solution was filtered through Celite and the filtrate was evaporated. The residue was separated by TLC on silica gel using benzene or dichloromethane as the eluent to give the products, which are summarized in Table 1.

Table 1. Reaction of azidobenzene in the presence of [$Fe_2(CO)_9$][a] or [$Fe(CO)_5$][b]

Entry	Metalcarbonyl	Solvent	Reaction conditions	Reaction time/h	Yield of product/%			
					14	**15**	**16**	**1**
1	$Fe_2(CO)_9$	MeOH	50 °C	3	21	51	20	
2	$Fe_2(CO)_9$	MeCN-H_2O[c]	50 °C	3	67	—	23	
3	$Fe(CO)_5$	MeOH	*hν*	4	10	53	20	
4	$Fe(CO)_5$	MeCN-H_2O[c]	*hν*	8	47	—	40	
5	$Fe(CO)_5$	MeOH	Reflux	8	—	11	3	>30[f]
6[d]	$Fe(CO)_5$	AcOH	100 °C	3	33	—	52	
7[e]	$Fe(CO)_5$	AcOH	100 °C	6	—	—	67	

a) An equimolar quantity of [$Fe_2(CO)_9$] was used. b) 1.2 molar equivalent amount of [$Fe(CO)_5$] was used. c) Contained an equivalent amount of water. d) 1 mol of Ph-N_3 and 2 mol of [$Fe(CO)_5$] was dissolved in 5 cm^3 of AcOH. e) 10mmol of Ph-N_3 and 20mmol of [$Fe(CO)_5$] was dissolved in 5cm^3 of AcOH. f) This compound is volatile under the workup conditions and the yield is low.

TABLE 2. REACTION OF α-AZIDOSTYRENE AND 3-PHENYL-2H-AZIRINE IN THE PRESENCE OF $[Fe(CO)_9]$[a] OR $[Fe(CO)_5]$[b]

Entry	Compound	Metalcarbonyl	Solvent	Reaction conditions	Reaction time/h	Yield of product/%		
						22	**23**	Others
1	4	$Fe_2(CO)_9$	MeOH	50 °C	3	44	18	—

7	5	$Fe_2(CO)_9$	MeCN-H_2O[c]	50 °C	24	—	72	—
8	5	None	MeOH	hν	2.5	—	—	42 (**24**)
9	5	$Fe(CO)_5$	MeOH	hν	2.5	—	—	35 (**24**)

a) An equivalent amount of $[Fe_2(CO)_9]$ was used. b) 1.2 molar equivalent amount of $[Fe(CO)_5]$ was used. c) Contained an equivalent amount of water.

Photoirradiation of **1** *with* $[Fe(CO)_5]$. A solution of **1** (119 mg, 1 mmol) and $[Fe(CO)_5]$ (232 mg, 1.2 mmol) in 20 cm^3 of anhydrous methanol or acetonitrile containing water (1 mmol) was irradiated for a period indicated in Table 1. The solution was concentrated and filtered through Celite. The filtrate was evaporated and the residue was separated by TLC on silica gel using benzene or dichloromethane as the eluent to give the products, which are summarized in Table 1.

Thermal Reaction of **1** *with* $[Fe(CO)_5]$ *in Methanol.* A solution of **1** (119 mg, 1 mmol) and $[Fe(CO)_5]$ (232 mg, 1.2 mmol) in 10 cm^3 of anhydrous methanol was refluxed for 8 h. The solution was concentrated and chromatographed on Florisil to give the products, which are listed in Table 1.

Photoirradiation of **15** *with* $[Fe(CO)_5]$. A solution of **15** (151 mg, 1 mmol) and $[Fe(CO)_5]$ (232 mg, 1.2 mmol) in 20 cm^3 of anhydrous methanol was irradiated for 5 h. The photolysate was filtered through Celite and the filtrate was evaporated. The resulting residue was recrystallized to give **15** in 100% yield.

Photoirradiation of **16** *with* $[Fe(CO)_5]$. A solution of **16** (212 mg, 1 mmol) and $[Fe(CO)_5]$ (232 mg, 1.2 mmol) in 20 cm^3 of anhydrous methanol was irradiated for 5 h. The photolysate was filtered through Celite and the filtrate evaporated. The resulting residue was recrystallized to give 100% of **16**.

Thermal Reaction of **1** *with* $[Fe(CO)_5]$ *in AcOH.* A solution of **1** (119 mg, 1 mmol) and $[Fe(CO)_5]$ (392 mg, 2 mmol) in 5 cm^3 of AcOH was heated at 100 °C for 3 h. The solution was diluted with 50 cm^3 of benzene and then neutralized with aqueous sodium hydrogencarbonate solution. The organic layer was separated and dried over sodium sulfate. After evaporation of the solvent, the residue was separated by TLC on silica gel using dichloromethane as the eluent to give **14** (31 mg, 33%) and **16** (55 mg, 52%).

Thermal Reaction of **1** *with* $[Fe(CO)_5]$ *in AcOH (Concentrated Conditions).* A solution of **1** (1.19 g, 10 mmol) and $[Fe(CO)_5]$ (392 mg, 20 mmol) in 5 cm^3 of AcOH was heated at 100 °C for 6 h. After addition of 10 cm^3 of water to this solution, the precipitated colorless crystals were collected to give **16** (782 mg, 67%). The filtrate was neutralized with aqueous sodium hydrogencarbonate solution and extracted with benzene. Evaporation of the solvent gave no other product.

Reaction of **14** *with* **20** *in AcOH.* Phenyl isocyanate **20** (101 mg, 1 mmol) was added dropwise to a stirred solution of **14** (93 mg, 1 mmol) in 5 cm^3 of AcOH. After stirring for 5 min, the solvent was evaporated and the residue was collected to give 210 mg (98%) of **16**.

Thermal Reaction of **4** *with* $[Fe_2(CO)_9]$. A solution of **4** (145 mg, 1 mmol) and $[Fe_2(CO)_9]$ (364 mg, 1 mmol) in 10 cm^3 of anhydrous methanol or acetonitrile containing water (1 mmol) was heated at 50 °C for 7 h. The solution was filtered through Celite and the filtrate was concentrated. The resulting residue was distilled *in vacuo* using a Kugelrohr apparatus to give the products, which are summarized in Table 2.

Photoirradiation of **4** *with* $[Fe(CO)_5]$. A solution of **4** (145 mg, 1 mmol) and $[Fe(CO)_5]$ (236 mg, 1.2 mmol) in 20 cm^3 of anhydrous methanol or acetonitrile containing water (1 mmol) was irradiated. The solution was concentrated and filtered through Celite. The filtrate was evaporated and the residue was distilled as described above to give the products.

Thermal Reaction of **4** *with* $[Fe(CO)_5]$. A solution of **4** (145 mg, 1 mmol) and $[Fe(CO)_5]$ (236 mg, 1.2 mmol) in 10 cm^3 of anhydrous methanol was refluxed for 7 h. The solution was concentrated and chromatographed on Florisil. The fraction eluted with hexane gave 116 mg (80%) of **4**. Then, the first fraction eluted with benzene gave 6 mg (5%) of **22**, and the second fraction gave 24 mg (13%) of **23** (Table 2, entry 4).

Thermal Reaction of **5** *with* $[Fe_2(CO)_9]$. A solution of **5** (117 mg, 1 mmol) and $[Fe_2(CO)_9]$ (364 mg, 1 mmol) in 10 cm^3 of anhydrous methanol or acetonitrile containing water (1 mmol) was heated at 50 °C for a period indicated in Table 2. The solution was filtered through Celite and the filtrate was evaporated. The residue was distilled as described above to give the products, **22** and/or **23**. After the distillation, the residual oil was purified by TLC on silica gel to give **24**: mp 196—197 °C (from EtOH).[8]

Photoirradiation of **5** *without* $[Fe(CO)_5]$. A solution of **5** (117 mg, 1 mmol) in 10 cm^3 of anhydrous methanol was irradiated for 2.5 h. The evaporation of the solvent and the following separation by TLC on silica gel gave **24** (42 mg, 41%).

Photoirradiation of **5** *with* $[Fe(CO)_5]$. A solution of **5** (117 mg, 1 mmol) and $[Fe(CO)_5]$ (232 mg, 1.2 mmol) in 10 cm^3 of anhydrous methanol was irradiated for 2.5 h. The evaporation of the solvent and the following separation by TLC on silica gel gave **24** (41 mg, 35%).

Stereoselective Catalytic Hydrogenation of α-Hydroxy Ketoximes

Kaoru HARADA and Shozo SHIONO*
Department of Chemistry, The University of Tsukuba, Sakura-Mura, Niihari, Ibaraki 305
(Received July 11, 1983)

Two isomers(*E* and *Z*) of benzoin oxime and 2-hydroxy-1-phenyl-1-propanone oxime were catalytically hydrogenated by using palladium on charcoal and erythro amino alcohols were obtained in about 80% diastereomeric excess. The syn-anti isomerization of these oximes in the presence of palladium on charcoal was also studied in connection with the stereoselectivity of the catalytic hydrogenation of the oximes.

The stereochemistry of catalytic hydrogenation of oximes of α-keto amides[1] and Schiff bases prepared from α-keto esters with optically active amines[2] have been studied. The steric course of the catalytic hydrogenation reaction was explained by the chelation mechanism assuming that the substrate forms a five-membered chelated structure with the catalyst and subsequent hydrogenation reaction takes place from the less bulky side of the chelated substrate. This mechanism was supported by various hydrogenolytic catalytic asymmetric transamination[2-4] and also by the infrared absorption spectrum of ethyl 2-hydroxyimino-3-oxo-3-phenylpropionate on palladium metal, which was measured by using the high-sensitivity reflection method.

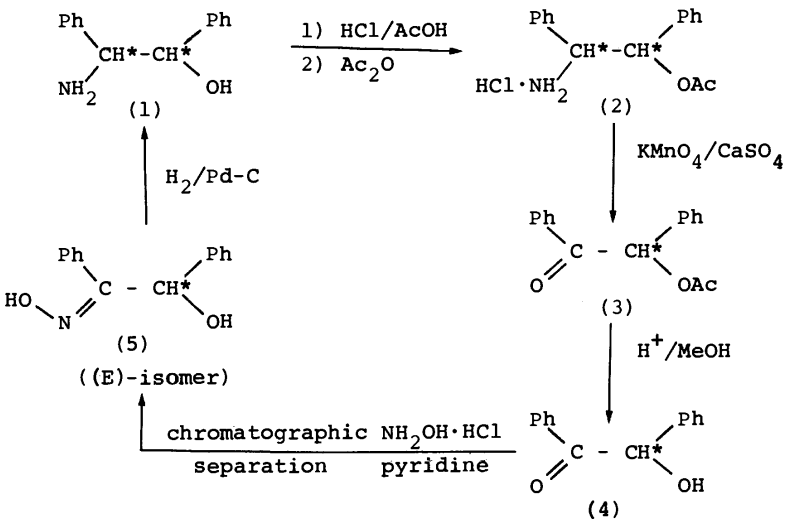
The substrates, which have been used in the previous studies of the chelation mechanism, contain an asymmetric center out of the chelated ring when they form a chelated structure with the catalyst. If the substrate contains an asymmetric center in the five-membered chelated ring, a relatively high asymmetric yield might be obtained by the catalytic hydrogenation. In order to examine the consideration, the catalytic hydrogenation of oximes, whose asymmetric center is in the five-membered chelated ring, was performed.

It was reported that the catalytic hydrogenation of racemic (*E*)-benzoin oxime afforded *erythro*-2-amino-1,2-diphenylethanol (*erythro*-ADE) dominantly.[6] However, the exact ratio of the diastereomer has not been clarified yet. In the present study, a cyclic reaction pathway as shown in Scheme 1 was designed and the catalytic hydrogenation of optically and racemic benzoin oxime was carried out. If the stereoselectivity of the catalytic hydrogenation is sufficiently high, optically active *erythro*-ADE could be synthesized again from optically active *erythro*-ADE used as a starting material. In addition, in order to examine the substituent effect, hydrogenation of (±)-2-hydroxy-1-phenyl-1-propanone oxime (HPPO) was also performed.

Oxime of α-keto amide has (*E*)- and (*Z*)-isomers, and only the (*E*)-isomer could form a five-membered chelated structure with the catalyst. However, the *E*—*Z* isomeric ratio of the substrate used in the catalytic hydrogenation has not been clarified yet, and the steric course of the hydrogenation of (*E*)-oximes might be different from that of (*Z*)-oximes. In order to clarify the stereochemistry of the hydrogenation of oximes, both (*E*)- and (*Z*)-isomers were isolated and each of the oximes was catalytically hydrogenated. The syn-anti isomerization of the oximes in the presence of palladium on charcoal was also studied in connection with the stereoselectivity of the catalytic hydrogenation of the oximes.

Results and Discussion

Hydrogenation of Substrates. Substrates, (*E*)- and (*Z*)-benzoin oxime and (*E*)- and (*Z*)-HPPO, were hydrogenated by using palladium on charcoal in several solvents and at various temperatures. The diastereomeric ratio of amino alcohol was determined by gas chromatographic analysis, which are summarized in Tables 1 and 2.



Scheme 1.

Table 1. Catalytic hydrogenation of (*E*)-oximes of *R*(—)-benzoin and racemic 2-hydroxy-1-phenyl-1-propanone

substrate	Solvent	Temp/°C	Yield/%	Erythro: Threo	O.P./%[a]	Configuration[b]
(*E*)-Benzoin oxime	MeOH	20	79	93 : 7	95	*S*
	EtOH	0	78	96 : 4		*S*
	EtOH	20	71	93 : 7		*S*

a) Optical purity. b) Configuration of newly formed asymmetric moiety. c) Racemic oxime was used.

Table 2. Catalytic hydrogenation of (*Z*)-oximes of racemic benzoin and racemic 2-hydroxy-1-phenyl-1-propanone

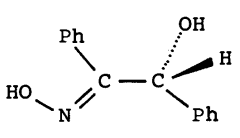
Substrate	Solvent	Temp/°C	Yield[a]/%	Erythro: Threo
(*Z*)-Benzoin oxime	MeOH	20	68	88:12
	EtOH	20	71	89:11
	AcOEt	20	55	86:14
(*Z*)-2-Hydroxy-1-phenyl-1-propanone oxime	MeOH	20	59	91:9
	EtOH	20	64	93:7
	EtOH	40	75	91:9
	EtOH	60	46	85:15
	AcOEt	20	80	93:7

a) Determined by isolation.

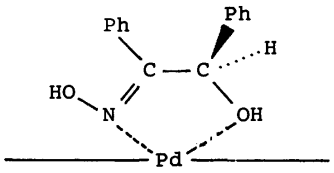
In the hydrogenation of (*E*)-oximes of both benzoin and HPPO, erythro amino alcohols were obtained in about 80% diastereomeric excess in every solvent and at every temperature employed. Similar results were obtained in the hydrogenation of the corresponding (*Z*)-oximes.

In the case of (*E*)-benzoin oxime, the conformation of the substrate in solution could be shown in Structure 1 considering the steric repulsion between the phenyl groups of the molecule. If the hydrogenation of the (*E*)-benzoin oxime proceeds from the less bulky side of the substrate in Structure 1, *threo*-ADE would be produced, which is inconsistent with the experimental results. On the other hand, if the (*E*)-benzoin oxime forms a five-membered chelated structure with the palladium metal first as shown in structure 2, and then hydrogenation proceeds from the less bulky side of the substrate as expected by the chelation mechanism, *erythro*-ADE would be formed dominantly. In the hydrogenation of (*E*)-HPPO, the formation of erythro amino alcohol could also be explained by the chelation mechanism.

The (*E*)-oxime could also form a five-membered intramolecular hydrogen bonding between the nitrogen and the hydroxyl group at α-position. If the hydrogenation reaction proceeds from the less bulky side of the intramolecularly hydrogen bonded substrate, erythro amino alcohol could also be produced. However, examination of the molecular structure by the use of a molecular model indicates that the distance between the nitrogen and the hydroxyl group at the α-position of the (*E*)-benzoin oxime seems to be too long for the formation of rigid intramolecular hydrogen bonding. Therefore, the contribution of the hydrogen bonded steric course for the hydrogenation of (*E*)-oxime would not be so important.



Structure 1.



Structure 2.

According to the chelation mechanism, the stereoselectivity in the hydrogenation of (*E*)-HPPO is assumed to be smaller than that of (*E*)-benzoin oxime. However, the stereoselectivity in the hydrogenation of (*E*)-HPPO was almost the same as that in (*E*)-benzoin oxime. This might be explained by the adsorption of phenyl groups of benzoin oxime on the catalyst, and other conformation of chelated ring structure could be possible other than the prefered conformation.

On the other hand, the (*Z*)-oxime could not form the five-membered chelated structure, but could form a six-membered intramolecular hydrogen bonding. The distance between the hydroxyl group attached to nitrogen and the hydroxyl group at α-position seems to be adequate to form a rigid intramolecular hydrogen bonding by using a molecular model. If the substrate forms the six-membered intramolecular hydrogen bonding first, and then hydrogenation reaction takes place from the less bulky side of the substrate, erythro amino alcohol would be obtained. This consideration

is consistent with the experimental results. The results obtained in the hydrogenation of the (*Z*)-oxime are similar to those of the corresponding (*E*)-oxime. Considering the conformation of the substrate by using molecular model, the steric bulkiness around the diastereomeric face of the (*E*)-oxime forming the five-membered chelated structure with the catalyst is almost the same as that of the corresponding (*Z*)-oxime forming the six-membered intramolecular hydrogen bonding. This observation suggest that both (*E*)- and (*Z*)-oximes could be hydrogenated in chelated form and in intramolecular hydrogen bonded form, respectively.

Effect of Isomerization of Benzoin Oxime on the Hydrogenation. Isomerization of benzoin oxime in the presence of palladium on charcoal was observed and the time-courses of the isomerization were shown in Fig. 1. The isomerization of a few derivatives of benzoin oxime was also examined. Benzoin acetate oxime, in which the hydroxyl group of the benzoin oxime is protected by an acetyl group, isomerized in the presence of palladium on charcoal. However, *N,O*-diacetylbenzoin oxime, in which the hydroxyimino group of benzoin acetate oxime is protected by an acetyl group, did not isomerize under these conditions. These results indicate that the hydrogen atom of the hydroxyimino group of benzoin oxime might play an important role in the isomerization in the presence of palladium on charcoal. Therefore, benzoin oxime might isomerize *via* a nitroso compound and the hydrogenation of the compound to ADE might proceed as shown in Fig. 2. In order to confirm the possible

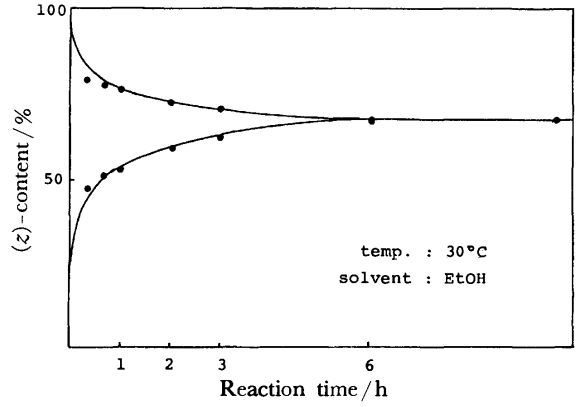


Fig. 1. Isomerization of benzoin oxime in the presence of palladium on charcoal.

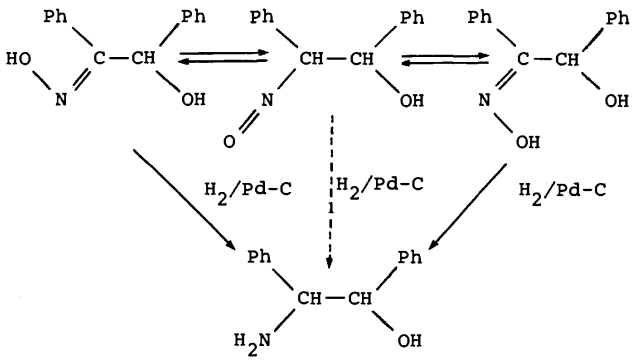

Fig. 2. Mechanism of isomerization of benzoin oxime.

hydrogenation pathway, the hydrogenation of (*E*)-benzoin oxime was carried out in CD_3OD by using palladium on charcoal. If the hydrogenation of (*E*)-benzoin oxime proceeds *via* the nitroso compound, deuterium should be combined to the asymmetric carbon attached to the amino group of ADE. ^1H NMR spectrum of ADE, which was obtained by hydrogenation of (*E*)-benzoin oxime in CD_3OD, indicates that the integrated value of proton on the asymmetric carbon attached to amino group was almost equal to that on the asymmetric carbon attached to hydroxyl group. The mass spectrum of TFA derivative of ADE obtained by hydrogenation of (*E*)-benzoin oxime in CD_3OD was almost equal to that of TFA derivatives of both *erythro*- and *threo*-ADE (Table 3). These results indicate that the hydrogenation reaction does not proceed *via* the nitroso compound but through hydrogenation of the carbon–nitrogen double bond of the substrate oxime.

TABLE 3. FRAGMENT PEAK OF MASS SPECTRA OF *N,O*-BIS (TFA)-ADE AND RELATIVE INTENSITY

N,O-Bis(TFA) derivatives	Fragment peak	Relative intensity/%
erythro-ADE	78	8.8
	107	13.1
	202[a)]	100
	203[b)]	13.3
threo-ADE	78	9.3
	107	14.1
	202[a)]	100
	203[b)]	12.4

	202[a)]	100
	203[b)]	17.6

a) Ph-CH=NH^+-CO-CF_3. b) Ph-CH=O^+-CO-CF_3.

The influence of the syn-anti isomerization of the oximes during the hydrogenaiton was examined. In the hydrogenation of (*E*)-benzoin oxime, if it is assumed that the rate of hydrogenation reaction of the (*Z*)-oxime is much larger than that of the (*E*)-oxime, the (*E*)-oxime would isomerize to the (*Z*)-isomer first, and then the newly formed (*Z*)-isomer would be hydrogenated to form ADE. If this is the case, ADE would be obtained in rather low chemical yield in a short reaction time in the hydrogenation of (*E*)-benzoin oxime, because of the low concentration of the (*Z*)-oxime. In order to estimate the rate of hydrogenation of (*E*)- and (*Z*)-benzoin oxime, the time-courses of the chemical yield of ADE were measured. The results are shown in Fig. 3. The chemical yield of ADE obtained by hydrogenation of the (*E*)-oxime was 15% at the reaction time of 30 min, while the chemical yield of ADE obtained from the (*Z*)-oxime was 18% at the same reaction time. These results suggest that the rate of hydrogenation of the (*E*)-oxime is similar to that of the (*Z*)-oxime.

Considering the overall results, it could be concluded that (*E*)-benzoin oxime is hydrogenated mainly after forming a five-membered chelated structure with the

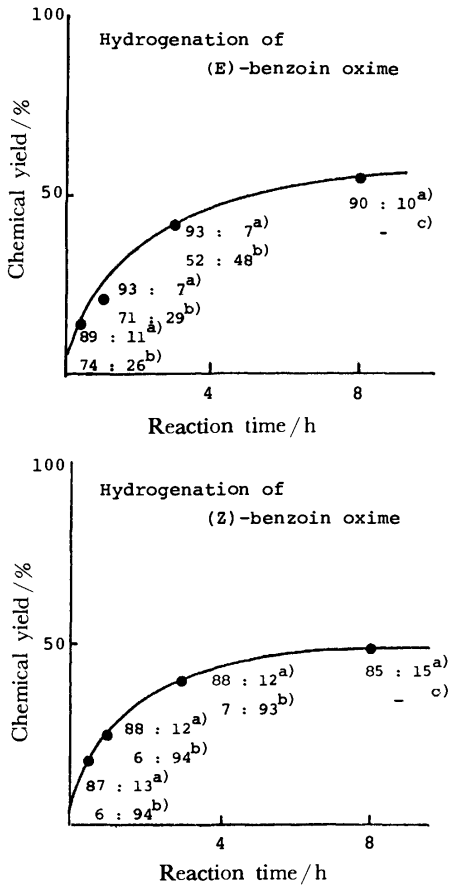

Fig. 3. Time-course of chemical yield of ADE in hydrogenation of benzoin oxime.
a) Diastereomeric ratio, erythro: threo, b) *E*-*Z* isomeric ratio, *E*:*Z*. c) *Syn-anti* isomeric ratio could not be determined.

catalyst (chelation mechanism) and (*Z*)-benzoin oxime is hydrogenated mainly after forming a intramolecular six-membered hydrogen bonding (intramolecular hydrogen bonding mechanism).

Experimental

All the melting point are uncorrected. The specific rotation were measured with a JASCO DIP-181 Digital Polarimeter. NMR spectra were obtained with a Hitachi R-24A spectrometer and the chemical shifts were given in δ values (ppm) from tetramethylsilane (TMS). Mass spectra were obtained with a Hitachi RMU-6M mass spectrometer. All the gas chromatographic analyses were carried out with a Hitachi 163 gas chromatograph. 5% Palladium on charcoal was purchased from Nippon Engelhald.

(−)-erythro-2-Amino-1,2-diphenylethyl Acetate Hydrochloride (2). (−)-*erythro*-ADE (**1**) (5.41 g, 0.025 mol) was suspended in 500 ml of AcOH. Hydrogen chloride gas was bubbled into the suspension for 9 h at 80 °C and the resulting clear solution was cooled to room temperature. Then Ac_2O was added to the mixture under stirring and the mixture was stirred for additional 5 h and concentrated *in vacuo*. The crude product obtained was recrystallized from MeOH-Ether, yield 4.74 g (64%), mp 168—169 °C, $[\alpha]_D^{11}$ −89.8° (*c* 1, MeOH), ^{1}H NMR (DMSO-d_6): δ=2.13 (s, 3H), 4.62 (d, 1H), 6.28 (d, 1H), 7.24 (m, 10H), 9.02 (s, br, 3H). Found: C, 65.92; H, 6.14; N, 4.75%. Calcd for $C_{16}H_{18}NO_2Cl$: C, 65.86; H, 6.21; N, 4.75%.

R(−)-Benzoin Acetate (3). To a suspension of $KMnO_4$ (5.02 g, 0.032 mol) and $CaSO_4 \cdot 2H_2O$ (3.75 g, 0.022 mol) in 50 ml of water and 50 ml of *t*-butyl alcohol was added (−)-*erythro*-2-amino-1,2-diphenylethyl acetate hydrochloride (**2**) (4.87 g, 0.017 mol) and the suspension was heated for 2 h at 60 °C. The reaction mixture was filtered and the residue was washed with ethyl acetate. The combined solution was washed with water and dried over magnesium sulfate and concentrated *in vacuo*. The residue was purified by column chromatography on silica gel using benzene-ethyl acetate (100:1 v/v) as an eluent. The solid obtained was recrystallized from hexane, yield 1.61 g (37.3%), mp 80.5—82 °C, $[\alpha]_D^{18}$ −214.3° (*c* 1, chloroform) (lit,[7] $[\alpha]_D^{14}$ −217.7°), ^{1}H NMR ($CDCl_3$): δ=2.15 (s, 3H), 6.81 (s, 1H), 7.66 (m, 10H). Found: C, 75.86; H, 5.64%. Calcd for $C_{16}H_{14}O_3$: C, 75.57; H, 5.54%.

R(−)-Benzoin (4). A solution of *R*(−)-benzoin acetate (**3**) (800 mg, 3.15×10^{-3} mol) in 30 ml of abs. methanol was refluxed for 2 h in the presence of a catalytic amount of concd. sulfuric acid. To the reaction mixture was added 100 ml of ethyl acetate, and organic layer was washed with saturated $NaHCO_3$ and water and dried over magnesium sulfate, and was concentrated *in vacuo*. The residue was purified by column chromatography on silica gel using benzene-ethyl acetate (20:1 v/v) as an eluent. The solid obtained was recrystallized from ethanol, yield 498 mg (75%), mp 130—131 °C (lit,[8] 132—133 °C), $[\alpha]_D^{22}$ −111.6° (*c* 1, acetone), (lit,[8] $[\alpha]_D^{25}$ −118.3°), ^{1}H NMR ($CDCl_3$): δ=4.51 (d, 1H), 5.92 (d, 1H), 7.66 (m, 10H). Found: C, 79.21; H, 5.68%. Calcd for $C_{14}H_{12}O_2$: C, 79.22; H, 5.69%.

R(−)-(E)-Benzoin Oxime (5). To a solution of *R*(−)-benzoin (**4**) (473 mg, 2.23×10^{-3} mol) in 5 ml of pyridine was added a solution of hydroxylamine hydrochloride (468 mg, 6.73×10^{-3} mol) in 5 ml of pyridine under cooling in an ice bath. The reaction mixture was stirred for 90 min at room temperature and then concentrated *in vacuo*. The residue was extracted with ethyl acetate and the extract was washed with 10% citric acid and water and dried over magnesium sulfate, and was concentrated *in vacuo*. The residue was purified by column chromatography on silica gel using benzene-ethyl acetate (5:1 v/v) as an eluent. The solid obtained was recrystallized from benzene, yield 295 mg (58%), mp 156—158 °C (lit,[7] 163—164 °C), $[\alpha]_D^{20}$ −2.9° (*c* 0.5, chloroform) (lit,[7] $[\alpha]_D^{24}$ −3.2°). Found: C, 73.97; H, 5.75; N, 6.19%. Calcd for $C_{14}H_{13}NO_2$: C, 73.99; H, 5.76; N, 6.16%.

(±)-(Z)-Benzoin Oxime. (±)-(*Z*)-Benzoin oxime was isolated by column chromatography of (±)-benzoin oxime as in the same way as *R*(−)-(*E*)-benzoin oxime. Yield from benzoin was 47%, mp 102.5—103.5 °C (lit,[9] 99 °C). Found: C, 73.88; H, 5.75; N, 6.15%. Calcd for $C_{14}H_{13}NO_2$: C, 73.99; H, 5.76; N, 6.16%.

(±)-2-Hydroxy-1-phenyl-1-propanone. To a solution of PhMgBr, prepared from bromobenzene (10.36 g, 0.066 mol) and magnesium (1.60 g, 0.066 atom), in 40 ml of ether was added a solution of lactonitrile (2.13 g, 0.03 mol) in 10 ml of ether and the mixture was refluxed for 90 min. Then 10 ml of water and 30 ml of 10% sulfuric acid was added to the mixture. The ether layer was washed with saturated $NaHCO_3$ and water and dried over magnesium sulfate, and was concentrated *in vacuo*. The residue was purified by column chromatography on silica gel using benzene-ethyl acetate (25:1 v/v) as an eluent, yield 2.35 g (57%), bp 72 °C/3 mmHg (lit,[10] 125—126 °C/14 mmHg), ^{1}H NMR ($CDCl_3$): δ=1.40 (d, 3H), 3.88 (s, 1H), 5.08 (q, 1H), 7.60 (m, 5H). Found: C, 72.62; H, 6.94%. Calcd for $C_9H_{10}O_2$: C, 71.98; H, 6.71%.

(±)-(E)-2-Hydroxy-1-phenyl-1-propanone Oxime and (±)-(Z)-2-Hydroxy-1-phenyl-1-propanone Oxime. To a solution of (±)-2-hydroxy-1-phenyl-1-propanone (1.967 g, 0.013 mol) in 20 ml of pyridine was added a solution of hydroxylamine hydrochloride (2.711 g, 0.039 mol) in 20 ml of

pyridine under cooling. The reaction mixture was stirred for an additional 2 h at room temperature and concentrated *in vacuo*. The residue was extracted with ethyl acetate and the extract was washed with 10% citric acid and water and dried over magnesium sulfate, and was concentrated *in vacuo*. The oily product obtained was purified by silica-gel column chromatography. Elution was carried out with benzene–ethyl acetate (10:1 v/v) to separate (*E*)-isomer and (*Z*)-isomer. (*E*)-Isomer was purified by thin-layer chromatography using benzene–ethyl acetate (1:1 v/v) as a developing solvent, yield 1058 mg (49.3%), oil, ^{1}H NMR (DMSO-d_6): δ=1.51 (d, 3H), 3.62 (s, 1H), 4.80 (q, 1H), 5.30 (s, 1H), 7.56 (s, 5H). Found: C, 64.60; H, 6.75; N, 8.05%. Calcd for $C_9H_{11}NO_2$: C, 65.43; H, 6.71; N, 8.47%. (*Z*)-Isomer was recrystallized from benzene, yield 441 mg (20.6%), mp 130—131 °C, ^{1}H NMR (DMSO-d_6): δ, 1.32 (d, 3H), 2.50 (s, 1H), 5.00 (s, 1H), 5.28 (q, 1H), 7.92 (m, 5H). Found: C, 65.43; H, 6.71; N, 8.44%. Calcd for $C_9H_{11}NO_2$: C, 65.43; H, 6.71; N, 8.47%.

Assignment of Structure of Two Oximes ((±)-(E)-2-Hydroxy-1-phenyl-1-propanone Oxime and (±)-(Z)-2-Hydroxy-1-phenyl-1-propanone Oxime). Of the two isomers of benzoin oxime, the (*E*)-isomer is known to be colored blue by spraying a 0.5% $CuCl_2$ solution on thin layer chromatography.[9] In the case of 2-hydroxy-1-phenyl-1-propanone oxime, one isomer was colored blue and other isomer was not colored on thin-layer chromatography, therefore the structure of the former isomer was determined as the (*E*)-isomer.

Catalytic Hydrogenation of R(−)-(E)-Benzoin Oxime (5). *R*(−)-(*E*)-Benzoin oxime 5 (20 mg, 8.8×10^{-5} mol) was hydrogenated by using 5% palladium on charcoal (10 mg) in a solvent (2 ml) (methanol, ethanol, 2-propanol and *N,N*-dimethylformamide) at a temperature (0, 20, and 40 °C) at atmospheric pressure. After hydrogenation, the solvent was removed *in vacuo*. The ratio of each diastereomers was determined by gas chromatography of the trifluoroacetyl derivative of the hydrogenated product and the chemical yield was determined by isolation.

Hydrogenations of (±)-(*Z*)-benzoin oxime, (±)-(*E*)-2-hydroxy-1-phenyl-1-propanone oxime and (±)-(*Z*)-2-hydroxy-1-phenyl-1-propanone oxime were carried out in the same way as described above. The results are summarized in Table 1 and 2.

Trifluoroacetylation of Hydrogenated Product. To a suspension of 2 mg of the hydrogenated product in 0.4 ml of ethyl acetate was added 0.2 ml of trifluoroacetic anhydride and the mixture was heated in a screw capped vial for 2 h at 80 °C. The solvent was evaporated *in vacuo* and the residue was extracted with ethyl acetate. The extract was washed with 10% citric acid, saturated $NaHCO_3$ and water and dried over magnesium sulfate, and was concentrated *in vacuo*. The residue was dissolved in ethyl acetate and the solution was injected into a gas chromatograph to determine the ratio of the diastereomers of amino alcohol. A stainless steel column (2 m×3 mm I.D.) filled with Chromosorb W AW DMCS coated with 5% SE-52 was used for determination of diastereomeric ratio of ADE obtained by the hydrogenation of (*E*)- and (*Z*)-benzoin oxime. Column temperature was raised from 100 °C to 180 °C at a rate of 1 °C per minute. The retention times of *erythro*- and *threo*-isomers were 52.6 and 56.2 min, respectively. A glass capillary column (25 m×0.3 mm I.D.) coated with a chiral stationary phase (Chirasil-Val) was used for determination of diastereomeric ratio of 1-amino-1-phenyl-2-propanol obtained by the hydrogenation of (*E*)- and (*Z*)-2-hydroxy-1-phenyl-1-propanone oxime. Column temperature was raised from 100 °C to 180 °C at a rate of 3 °C per minute. The retention times of (1*S*,2*S*)-, (1*R*,2*R*)-, (1*S*,2*R*)- and (1*R*,2*S*)-isomers were 13.12, 13.87, 14.79, and 15.28 min, respectively. The same glass capillary column was used for determination of optical purity of ADE obtained by the hydrogenation of *R*(−)-(*E*)-benzoin oxime. Column temperature was raised from 80 °C to 180 °C at a rate of 0.5 °C per minute. The retention times of (1*S*,2*R*)-, (1*R*,2*S*)-, (1*S*,2*S*)- and (1*R*,2*R*)-isomers were 65.86, 66.16, 66.86 and 67.55 minute, respectively.

Authentic threo and erythro amino alcohols (ADE and 1-amino-1-phenyl-2-propanol) were derivatized with trifluoroacetic anhydride and the products were analyzed by gas chromatography. In each analysis, only original diastereomer was detected. These results indicate that the epimerization during the derivatization would be very small or none.

Isomerization of Benzoin Oxime in the Presence of Palladium on Charcoal. To a solution of (±)-(*E*)-benzoin oxime (30 mg, 1.32×10^{-4} mol) in 3 ml of ethanol was added 5% palladium on charcoal (30 mg). After stirring for a definite time (20, 40, and 60 min and 2, 3, and 6 h) at 30 °C, 0.1 ml of the mixture was collected and filtered. The filtrate was concentrated *in vacuo* and the residue was dissolved in 0.1 ml of pyridine. To the solution was added 0.1 ml of trimethylsilylating reagent [*N,O*-bis(trimethylsilyl)-1-iminoethanol:*N*-trimethylsilylimidazole:trimethylchlorosilane 1:1:1 v/v/v] and the reaction mixture was stirred for 15 min at room temperature and was injected into a gas chromatograph with a stainless steel column (2 m×3 mm I.D.), which was filled with Chromosorb W AW DMCS coated with 5% SE-52, to determine *E–Z* isomeric ratio. Column temperature was 180 °C. The retention times of (*E*)- and (*Z*)-isomers were 14.68 and 17.94 min, respectively. Isomerization of (±)-(*Z*)-benzoin oxime was carried out in the same way as that of (±)-(*E*)-benzoin oxime.

Hydrogenation of (±)-(E)-Benzoin Oxime (Experiment of the Time-course of Reaction Yield). (±)-(*E*)-Benzoin oxime (20 mg, 8.8×10^{-5} mol) was dissolved in 2 ml of ethanol and to the solution was added 10 mg of palladium on charcoal. After stirring for a definite time (30 min, 60 min, 3 h, and 8 h) at 20 °C under hydrogen atmosphere, 0.2 ml of the mixture was collected and filtered. A solution of 1-naphthylamine (internal standard) (2 mg, 1.4×10^{-5} mol) in 0.2 ml of ethanol was added to the filtrate and concentrated *in vacuo*. The residue was trifluoroacetylated in the same way as written above. The ratio of each diastereomers and reaction yield were determined by gas chromatography of the trifluoroacetyl derivative of the hydrogenated product.

Hydrogenation of (±)-(*Z*)-benzoin oxime and analysis of the hydrogenated product were carried out in the same way as those of (±)-(*E*)-benzoin oxime.

Hydrogenation of (±)-(E)-Benzoin Oxime in CD_3OD. (±)-(*E*)-Benzoin oxime (50 mg, 2.3×10^{-4} mol) was dissolved in 5 ml of CD_3OD and the solution was stirred for 1 h at 20 °C. Then to the solution was added 25 mg of 5% palladium on charcoal and the mixture was stirred for 6 h at 20 °C under hydrogen atmosphere. Catalyst was filtered off and the filtrate was concentrated *in vacuo*.

We wish to express our sincere thanks to Dr. Shinya Nomoto for his kind advice and invaluable discussion.

Effects of Surface Fluorination on Catalytic Activities and Surface Compositions of TiO_2-Al_2O_3 and TiO_2-SiO_2-Al_2O_3

Susumu Okazaki,* Akito Kurosaki, and Shinzo Suzaki
Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Nakanarusawa, Hitachi 316
(Received July 30, 1983)

Studies showed that the ternary oxide having the atomic ratio of Ti/Si/Al=47.5/47.5/5 exhibited a high catalytic activity for cumene cracking after a surface fluorination using 1 wt% hydrofluoric acid. The catalytic activity for CH_3OH conversion into olefins was highly dependent on the preparation method. That is, the ternary mixed oxide promoted olefin formation slightly when the mixed oxide was prepared only by coprecipitation. Surface treatment, using gaseous CF_3Cl was effective in enhancing catalytic activity. Although the binary oxide, TiO_2-Al_2O_3, itself, was catalytically inactive for olefin formation, TiO_2-Al_2O_3 prepared by coprecipitation became active after the treatment using CF_3Cl. Such an enhancement was found also for the ternary oxide, TiO_2-SiO_2-Al_2O_3, and is ascribable to increased acid strength, as determined by NH_3 adsorptions at various temperatures. The XPS measurements showed that F atoms introduced into mixed metal oxides by the fluorination using CF_3Cl, selectively combined with Al atoms on the mixed oxides prepared by coprecipitation. The XPS measurements of the mixed oxides before and after fluorination using CF_3Cl showed that the coprecipitation preparation is more preferable than the impregnation method in maintaining surface composition during fluorination.

Recently TiO_2-SiO_2[1] and TiO_2-Al_2O_3[2] have been recognized as fairly strong solid acids, like SiO_2-Al_2O_3. Hence, the formation of relatively strong acid sites in the ternary oxide containing TiO_2, SiO_2, and Al_2O_3 seems promising. Furthermore, since the solid acidities of SiO_2-Al_2O_3[3,4] and TiO_2-SiO_2 are enhanced by a surface fluorination, it may be possible to obtain a stronger solid acid by surface fluorination of TiO_2-Al_2O_3 and TiO_2-SiO_2-Al_2O_3.

Since through mixing of the component oxides is very difficult, especially for the ternary oxide, the preparation method may greatly affect the solid acidity and the catalytic activity. Additionally, the method and conditions of the surface fluorination may also have a considerable effect on them.

In general, surface fluorination has been carried out by using aqueous solutions of HF,[5,6] NH_4F,[7] or NH_4HF_2.[8] Recently, gaseous fluorination using fluorohydrocarbons such as CF_3Cl and CF_2ClCF_2Cl has also been found to be effective to increase solid acidity and catalytic activities for CH_3OH conversion into olefins by Al_2O_3-Cr_2O_3,[9] and for paraffin conversion by Al_2O_3.[10]

In this work, the catalytic activities of TiO_2-Al_2O_3 and TiO_2-SiO_2-Al_2O_3 were studied with an emphasis on the effects of the preparation method and surface fluorination. The surface composition and solid acidity, which are closely related to the catalytic activities, were also examined. For comparison, the effect of surface fluorination on the catalytic activities and the surface compositions of TiO_2, Al_2O_3, SiO_2-Al_2O_3, and SiO_2-TiO_2 were investigated. Cumene cracking was selected because it is a typical reaction catalyzed by solid acids, even relatively weak ones.[11] To elucidate the nature of the strong acid sites, the CH_3OH conversion into olefins was adopted because it has been clearly established that the reaction is promoted only by fairly strong Brönsted acid sites.[12] Finally, the cyclopropane isomerization was carried out to elucidate the acid property of sites on the solid surface.

Experimental

Catalysts. Binary oxides of TiO_2 and Al_2O_3 with various atomic ratios of Ti/Al such as 9/1, 5/5, 1/9 were used as catalysts. For the TiO_2-SiO_2 catalyst, a mixed oxide of an atomic ratio of Ti/Si=1 was used as a representative species, since it has been previously determined that this ratio showed the largest acidity.[5] A typical solid acid catalyst, SiO_2-Al_2O_3 (Nikki Chemical Co. N-631L, Si/Al(atomic ratio)=85/15) was used to evaluate catalytic activities of other oxides by comparison of its catalytic activity. To determine the effect of a small Al component addition to the TiO_2-SiO_2(Ti/Si=1), the catalytic activity of the ternary oxide, TiO_2-SiO_2-Al_2O_3, with the Ti/Si/Al atomic ratio of 47.5/47.5/5 was examined.

For preparations of the single and mixed oxides, titanium tetraisopropoxide, aluminum isopropoxide or nitrate, and ethyl silicate were used as starting materials. The single oxides (TiO_2 and Al_2O_3), and TiO_2-SiO_2 were prepared by addition of aqueous solutions of the respective components to water with vigorous stirring, followed by neutralization with 28% aqueous ammonia. The TiO_2-Al_2O_3(TiO_2-Al_2O_3(Cop)) was prepared by addition of 2-propanol, containing definite amounts of alkoxides of Al and Ti, to dilute nitric acid to prevent the formation of deposits during the addition, and to ensure sufficient mixing of the components. One ternary oxide sample (TiO_2-SiO_2-Al_2O_3(Cop)) was prepared from the solution containing ethyl silicate and alkoxides of Ti and Al using the same procedure as that for the binary oxide, TiO_2-Al_2O_3(Cop).

To examine the effect of the preparation method, the mixed oxides were also prepared by impregnation. For the binary oxide, TiO_2-Al_2O_3(Imp), the impregnation was carried out by addition of TiO_2, which was prepared from alkoxide and heat-treated at 500 °C, to the aqueous solution of aluminum nitrate, followed by evaporation to dryness. For the ternary oxide, TiO_2-SiO_2-Al_2O_3(Imp), the impregnation was done in the same way by addition of TiO_2-SiO_2(Ti/Si=1), prepared by coprecipitation from titanium alkoxide and ethyl silicate, to the solution of aluminum nitrate.

All the single and mixed oxides were dried at 120 °C for 24 h and then heat-treated at 500 °C, unless otherwise noted, for 3 h before their use as a catalyst, or before surface fluorination.

Reagents. The CF_3Cl was supplied by the Mitsui Fluorochemical Co., with purity higher than 99.9%. All other reagents were commercial products of the highest grade, and were used without further purification.

Surface Treatment. The oxide surfaces were treated with hydrofluoric acid of different concentrations(0.05—10 wt%), or gaseous CF_3Cl. The treatment with the acid was

carried out by immersing the oxides (*ca.* 10 g) in a solution (*ca.* 30 ml) at room temperature for 48 h, followed by evaporation to dryness at 120 °C and heat-treatment at 500 °C for 3 h. The treatment with CF_3Cl was carried out in a reactor at 450 °C immediately before use as catalyst.

Reaction Procedure. The cyclopropane isomerization and the CH_3OH conversion into olefins (abbreviated as MTG) were carried out in a pulse reactor using He as a diluent at 150 or 250 °C, and 400 °C, respectively. The pulse size was about 1.0 μl (for CH_3OH) or 1.1 μl (for cyclopropane), and the weight of catalyst was kept constant at 30 mg (MTG) or 50 mg (cyclopropane isomerization).

The product gas of the cyclopropane isomerization was analyzed by gas chromatography using a column packed with Porapack N at 100 °C. For MTG, the pulse reactor was connected with a modified gas-chromatographic analyzer. The product gas of the MTG, including CO and CH_4, was first condensed at about −196 °C in a 3 m column packed with Tenax GC. Then the condensed products were allowed to evaporate by removal of the liquid nitrogen trap, followed by heat-treatment up to 150 °C. The evaporated gas was passed through TCD, and the composition of the product was analyzed.

The cumene cracking was carried out under ordinary pressure using a conventional flow reactor. The products were analyzed by gas chromatography using a column packed with DC 550 supported on Chromosorb (15 wt%).

Determinations of Surface Properties. Surface areas were determined by applying the BET equation for the adsorption isotherm of N_2 at −196 °C. Surface acidities were measured by the amounts of NH_3 adsorbed at different temperatures. The Brönsted and Lewis acidity was examined by observing the infrared absorption spectra of pyridine adsorbed on oxide samples which were fabricated into discs under a pressure of *ca.* 500 kg cm^{-2}.

Determinations of Surface Composition and Bonding. The compositions in the surface layer were determined by XPS, using a Shimadzu ESCA-750 analyzer. In this determination, the spectra were measured with Mg $K\alpha$ radiation; the base pressure of the spectrometer was usually below 10^{-7} Torr (1 Torr≈133.322 Pa) during the experiments. The peak positions, given by their maxima, were measured with respect to the position of C1s, for which the value of the binding energy was taken as 285 ev. The surface compositions were calculated from the area of the respective peaks (*i.e.*, the maxima in the counting rate) on the basis of photoionization cross sections at 1254 ev, in units of the C1s cross section of 22200 barns.[13] The errors inherent in such a determination are generally 10—30% of the observed value.

Results and Discussion

Catalytic Activities for Cumene Cracking before and after Fluorination Using Hydrofluoric Acid. Similar to TiO_2 and Al_2O_3, the mixed oxides with various Ti/Al atomic ratios, which were prepared from Al$(NO_3)_3$ and titanium tetraisopropoxide by coprecipitation, showed little catalytic activity before fluorination. After fluorination using 1 wt% hydrofluoric acid, only TiO_2-Al_2O_3(Ti/Al=9/1) showed a rather high catalytic activity; the concentration of hydrofluoric acid was found to be optimum at 1 wt% for enhancement of the catalytic activity. However, even the catalytic activity of the TiO_2-Al_2O_3 treated with the hydrofluoric acid at this optimum concentration (1 wt%) was less than that of the component oxide, TiO_2, fluorinated with 1 wt% hydrofluoric acid. Furthermore, the catalytic activity of the fluorinated TiO_2-Al_2O_3(Ti/Al=9/1) was far less than that of the fluorinated TiO_2-SiO_2(Ti/Si=1).[5]

Since cumene cracking can be promoted even by relatively weak Brönsted acid sites,[11] the catalytic activity for cumene cracking may be the measure of the total amount of Brönsted acid sites, including weak ones. Thus, the result indicates that the amount of total Brönsted acid sites formed on TiO_2-Al_2O_3 after fluorination may be less than that on the fluorinated TiO_2 or fluorinated TiO_2-SiO_2.

A catalyst which was more active than the fluorinated TiO_2 or fluorinated TiO_2-SiO_2 was obtained by addition of relatively small amounts of Al_2O_3 to TiO_2-SiO_2. Thus, TiO_2-SiO_2-Al_2O_3(Cop) which contained 5 atom% of Al showed higher initial catalytic activity than that of the fluorinated TiO_2 or fluorinated TiO_2-SiO_2 even before fluorination (Fig. 1). The catalytic activity of the ternary oxide was also higher than that of SiO_2-Al_2O_3 as is shown in Fig. 1. Hence, the higher catalytic activity of the ternary oxide(Cop) may be due to the coexistence of the three components(Ti, Si, and Al) itself. With surface fluorination of the ternary oxide (47.5/47.5/5)(Cop) using 1wt% hydrofluoric acid, both the initial catalytic activity and the activity maintenance were considerably increased. On the other hand, initial catalytic activity of the ternary oxide with the same atomic ratio, prepared by impregnation was noticeably lower than that of the ternary oxide(Cop). Furthermore, the activity of the fluorinated ternary oxide(Imp) decreased significantly with process time (Fig. 1); this evidence indicates the large effect of the preparation method on the catalytic activity of the mixed oxide.

Catalytic Activity for CH_3OH Conversion. Table 1 shows the catalytic activity for the MTG by various oxides, before and after fluorination. Before fluorination, ternary oxide(Cop) promoted the formation of a small amount of propene, although ternary oxide (Imp) promoted only the formation of dimethyl ether, which can be activated even by relatively weak acid

a) TiO_2 and Al_2O_3 were heat-treated at 600 °C (and the others at 500 °C) for 3 h before use as catalyst. b) These data were measured for the third pulse. c) Untreated TiO_2-SiO_2-Al_2O_3 showed little catalytic activity for CH_3OH conversion.

sites.[12] After fluorination, all oxides, except TiO_2, exhibited some degree of catalytic activity. In particular, mixed oxides containing Al and prepared by coprecipitation, such as TiO_2-Al_2O_3(Cop) and TiO_2-SiO_2-Al_2O_3(Cop), showed high activity after fluorination using CF_3Cl. The ternary oxide fluorinated with hydrofluoric acid, however, was significantly less active. Since MTG is known to be promoted only by strong acid sites,[12] these facts suggest that fluorination using CF_3Cl may be effective, but that using hydrofluoric acid is almost completely ineffective in the formation of strong acid sites.

Although TiO_2 was markedly active as a catalyst for cumene cracking after fluorination using hydrofluoric acid, it was quite inactive for the MTG after fluorination using the acid or CF_3Cl. This is plausibly ascribable to the low acid strength of the sites formed on TiO_2 by treatment with hydrofluoric acid, even though the number of these relatively weak acid sites might be fairly large.

TiO_2 fluorinated using CF_3Cl could not promote even the formation of dimethyl ether, in contrast the fluorinated Al_2O_3 appreciably increased formation of olefins besides dimethyl ether. Thus, the Al component seems important for the formation of acid sites strong enough to promote the MTG.

Acid Properties of Mixed Oxides. Infrared studies of the adsorption of pyridine were performed on TiO_2-Al_2O_3(9/1) (Cop) and TiO_2-SiO_2-Al_2O_3(47.5/47.5/5) (Cop) or (Imp) to know about the acid properties. After evacuation at 300 °C for 2 h, the sample was left in contact with 5 Torr of pyridine at room temperature for 0.5 h, and then further evacuated at 170 °C for 1 h.

TiO_2-Al_2O_3(9/1): This mixed oxide gave only bands at about 1600, 1580, 1490, and 1440 cm^{-1} which were all attributable to pyridine on Lewis acid sites.[14]

Table 2. Catalytic activities for cyclopropane isomerization

Catalyst	Reaction temperature	Conversion[a]
	°C	%
TiO_2-Al_2O_3 (Ti/Al=9/1)		
Before fluorination	150	1.0
	250	15.5
	150	19.2
Fluorinated with 1 wt% HF acid	250	93.0

a) The conversion was calculated from the result of the first pulse (for 150 °C reaction) or the third pulse (for 250 °C reaction).

Although the band at 1540 cm^{-1} due to pyridinium ion[14] was scarcely observable for the evacuated samples before and after fluorination, it became clearer after sample contact with H_2O vapor(5 Torr) for 1 min. Together with the band at about 1640 cm^{-1}, these bands indicate that Brönsted acid sites were abundantly formed on the fluorinated mixed oxide by interaction of H_2O with the surface.

The catalytic activities of mixed oxides for cyclopropane isomerization (150 and 250 °C), which is promoted not by Lewis, but by Brönsted acid sites,[15] were remarkably increased by surface fluorination, as is shown in Table 2. This fact further verified the formation of Brönsted acid sites after surface fluorination.

TiO_2-SiO_2-Al_2O_3(47.5/47.5/5): Like the spectrum for TiO_2-Al_2O_3 described above, that obtained for the ternary oxide prepared by impregnation showed the presence of only Lewis acid sites. After surface fluorination using hydrofluoric acid, a weak band specific to pyridinium ion appeared at 1540^{-1}.

On the other hand, the spectrum for the ternary oxide prepared by coprecipitation showed the bands at 1550 and 1640^{-1} due to Brönsted acid sites in addition to those due to Lewis acid sites, even before surface fluorination. The formation of the Brönsted acid sites on the unfluorinated ternary oxide may have resulted from sufficient mixing of the component metal atoms (or ions); the Brönsted acid sites may function as active sites not only for the cumene cracking but also for MTG.

NH_3 Adsorption: In order to know the strengths and numbers of acid sites, adsorption of NH_3 on various oxides, including SiO_2-Al_2O_3, was carried out at temperatures from 100 °C to 500 °C.

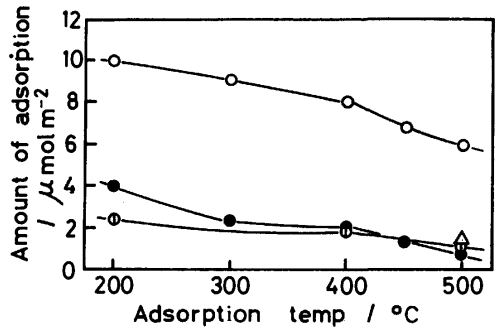

Fig. 2. NH_3 adsorptions at various temperatures.
●: TiO_2-SiO_2-Al_2O_3(47.5/47.5/5)(Cop); before treatment; ○: TiO_2-SiO_2-Al_2O_3(47.5/47.5/5)(Cop) treated with CF_3Cl; △: TiO_2-SiO_2-Al_2O_3(47.5/47.5/5)-(Cop) treated with 1 wt% hydrofluoric acid; ○: SiO_2-Al_2O_3(85/15)(N-631L).

As is shown in Fig. 2, the ternary oxide prepared by coprecipitation showed a notably high adsorptive activity for NH_3 after the surface fluorination using CF_3Cl. In particular, the amount of adsorption on the fluorinated ternary oxide at 500 °C was about 6 times that of the typical strong solid acid catalyst, SiO_2-Al_2O_3, and was higher than Al_2O_3-Cr_2O_3 fluorinated with CF_3Cl, which has been reported to be a strong acid catalyst for MTG.[9] The amount of adsorption at 500 °C on the ternary oxide(Cop), fluorinated using hydrofluoric acid, was only about the same as that on SiO_2-Al_2O_3. These facts support the suggestions that remarkably strong acid sites may be formed on the ternary oxide(Cop) treated with CF_3Cl, and that surface fluorination using CF_3Cl is far more effective in strengthening solid acidity than that using hydrofluoric acid.

Surface Compositions. Table 3 shows the surface compositions which were examined by recording the XPS spectra. As the results show, the surface composition generally differs from the designed one to a considerable extent. In particular, the Al component tends to concentrate in the surface layer, even for mixed oxides prepared by coprecipitation. Such a tendency has also been observed for the binary oxides, TiO_2-Al_2O_3, which is coprecipitated from the solution containing equimolar aluminum nitrate and

a) The numbers in parentheses indidate the atomic ratio of Ti, Si, and Al components.

ethyl silicate.[16] The higher concentration of Al component in the surface layer may possibly be due to a difference in the pH value for the precipitation as hydroxides. That is, for the precipitation of Al^{3+} as $Al(OH)_3$, the solution must be more alkaline than for Ti^{4+} and Si^{4+}; thus Al^{3+} tends to deposit as a hydroxide on the surface of the hydroxides of Ti and Si, which have already formed in the neutralization using aqueous ammonia.

Although the Al content in the surface layer of the fresh ternary oxide(Cop) is less than that in the fresh ternary oxide(Imp), the difference is relatively small. However, for the samples fluorinated with CF_3Cl, the surface composition greatly differs depending on the preparation methods. That is, during fluorination, the Al and Si components in the ternary oxide prepared by impregnation were lost largely from the surface layer, resulting in a remarkable increase of Ti content in the surface layer. On the other hand, the surface composition of the ternary oxide prepared by coprecipitation was scarcely changed by surface fluorination.

Similarly, the surface composition of SiO_2-Al_2O_3 was not appreciably changed by surface fluorination using CF_3Cl; The Si component in TiO_2-SiO_2 was lost mostly during the surface fluorination. Nevertheless, the mixed oxides were prepared by coprecipitation.

These results suggest that Al atoms may firmly combine with F atoms, especially in preference to Si atoms, and thus prevent the formation of volatile SiF_4. However, such Al atom behavior may be displayed only when the Al atoms are sufficiently close to Si atoms, so that the effect of Al component on the retention of Si component was fully exhibited in the mixed oxide prepared by coprecipitation.

Bonding in Surface Layer. Figures 3 and 4 give the detailed F1s and O1s peaks of various oxides.

F1s Peaks: The peaks due to F1s in the spectra for SiO_2-Al_2O_3, TiO_2-Al_2O_3(Cop), and the ternary oxide (Cop) were found only at 687.9, 686.9, and 687.4 eV, respectively, after fluorination using CF_3Cl. Since the peak positions are all close to that for AlF_3(687.3 eV) or Al_2O_3 fluorinated using CF_3Cl(687.4 eV), this indicates that F atoms introduced by the fluorination are selectively bound to the Al atoms in the mixed oxides.

The binding energies of the F1s peaks in the fluorinated ternary oxide(Imp) are found at 684.9 and 688.5 eV. Since the binding energy in TiO_2 fluorinated using CF_3Cl is found at 684.5 eV, the stronger peak at 684.9 eV is assignable to the F atom bound to a Ti atom in the ternary oxide(Imp), Observation of the peak due to Ti-F bonding on the surface of the ternary oxide prepared by impregnation may result from the removal of a larger amount of Al atoms as volatile aluminum chloride.

O1s Peaks: The spectrum for O1s of the fresh ternary oxide(Imp) gave two peaks, their maxima being observed at 530.3 and 532.7—533.0 eV. The former peak at 530.3 eV almost coincided with that due to TiO_2 or TiO_2-Al_2O_3, while the latter peak coincided

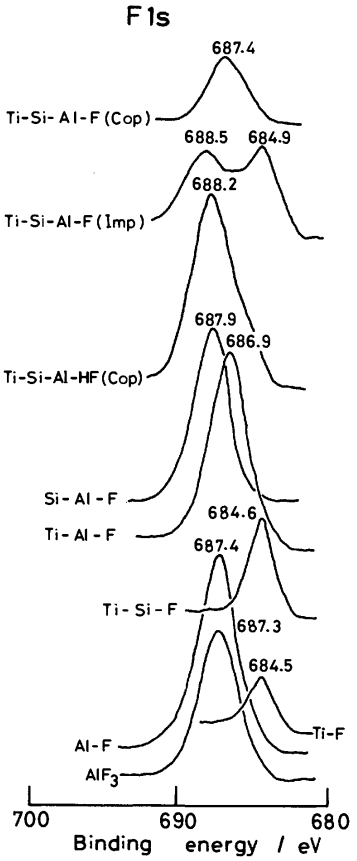

Fig. 3. XPS spectra of F1s.
Ti, Si, and Al indicate the samples of TiO_2, SiO_2 and Al_2O_3, respectively, and "-F" indicates the samples treated with CF_3Cl.

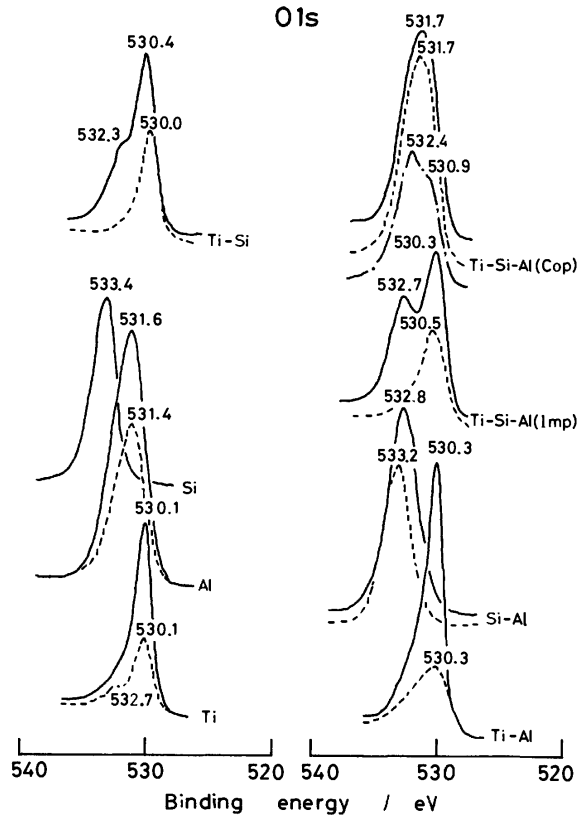

Fig. 4. XPS spectra of O1s.
Full lines and broken lines indicate the spectra for fresh oxides and treated oxides, respectively.

with that due to SiO_2 or SiO_2-Al_2O_3.

After fluorination using CF_3Cl, the ternary oxide(Imp) gave only one peak at 530.5 eV, that position almost coinciding with one obtained for fresh ternary oxide(Imp) at 530.3 eV. Furthermore, this peak position is close to that obtained for fluorinated TiO_2-(530.1 eV). Hence, the peak at 530.0 eV is assignable to the O atom bound to a Ti atom; the absence of other peaks except that 530.5 eV is compatible with the previous assumption that the surface layer of the fluorinated ternary oxide(Imp) is composed mainly of fluorinated titanium oxide.

On the other hand, for the ternary oxide(Cop), only one broad peak was given at around 531.7 eV. The peak position and shape of the peak were not changed by surface fluorination using CF_3Cl. Namely, the concentration of Ti component by the fluorination with CF_3Cl appeared improbable for the mixed oxide prepared by coprecipitation.

Thus, the preparation of the ternary oxide by coprecipitation was essential for maintaining the homogeneity in the surface compositions. The fluorination of the homogeneous surface using, not hydrofluoric acid, but gaseous CF_3Cl was remarkably effective for the formation of strong acid sites on the mixed oxide surface.

The authors wish to express their thanks to the Mitsui Fluorochemical Co., for their financial support of this study.

A DNMR Study of Restricted Methylene Rotation in 2-Pyridylmethyl- and 3-Methyl-2-pyridylmethyllithium

Hideki MATSUI, Akihiro YOSHINO, Tadayoshi YOSHIDA, and Kensuke TAKAHASHI*
Department of Industrial Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received September 2, 1983)

Thermodynamical parameters for the restricted rotation of the title carbanions have been obtained by means of the DNMR techniques. The activation energies and entropies thus obtained are about 93 kJ mol^{-1} and 95 J K^{-1} mol^{-1} for the two carbanions studied; these values are larger than those of the similar rotations observed in arylmethanide ions. The methylene rotation is thus extremely hindered in these carbanions.

Rotational barriers about bonds with partial double-bond character have been studied extensively by means of the DNMR techniques. Especially, a lot of interesting information on rotation about the N-C bonds in amides has been obtained so far.[1] These techniques have also been applied to the hindered rotations in cations and anions with large conjugated π-systems. The barriers and the mechanism of rotation of phenyl groups in the arylmethanide-ion systems have been reported.[2-5] 2-Pyridylmethanide ions discussed in this study are one of the systems similar to the phenylmethanide ion, which is the simplest one among the arylmethanide ions. A hindered rotation about the bond between the methylene group and the pyridine ring has been previously noted.[6] The aim of this study is to obtain temperature-dependent NMR spectra of the two title carbanions (hereafter referred as **1** and **2**, as shown in Fig. 1) and to evaluate the barriers for the rotation about the bond between the pyridine ring and the α-carbon by means of the DNMR techniques.

Experimental

All reagents used were commercially available. Precursors (2-picoline and 2,3-lutidine) were dried with calcium hydride and distilled in a vacuum and then divided to a suitable amount in several Pyrex ampoules with breakable seals. Butyllithium in hexane was also ampouled with the same manner in a vacuum after filtering to remove small suspended solid particles. Precursors were reacted in vacuum with butyllithium in a small reaction vessel with a 5-mm o.d. NMR tube. About two hours after the reaction started, hexane was distilled off and *ca.* 0.35 ml of dried THF-d_8 was introduced into the system. The prepared THF-d_8 solution of the carbanion was transferred into an NMR tube, a small amount of TMS was added, and the tube was sealed off. The concentration of the sample was about 1.3 mol dm^{-3}, on the basis of the precursor used. The ^{1}H NMR spectra were recorded at a sweep time of 200 s and with a sweep width of 120 or 300 Hz, with a Hitachi R-20B spectrometer at 60 MHz equipped with a R-202VTC temperature controller. The temperature was calibrated with temperature-dependent chemical shifts of methanol (low-temperature range) or ethylene glycol (high-temperature range) using the standard equation. Theoretical DNMR spectra were calculated by a modified Quabex program[7] with a Hitachi M-170 computer and plotted with an on-line XY-plotter.

ported.[6] The DNMR analyses were carried out to the spectra of the methylene proton signals. The analyses were performed as an AB system although there is a small coupling between a methylene proton and a ring proton, as stated before.[6] The analyses need a parameter concerned with the line widths. This is determined by visual fittings of the calculated and observed spectra at both the slow- and fast-exchange limits. Two limiting T_2^* values thus determined were the same for **1** but were different for **2**. For the latter case, the T_2^* value was linearly correlated with the temperature studied. The parameters used for the DNMR analyses are given in Table 2. The chemical shift between two methylene protons of **1** was also linearly correlated with the temperature. But the value for **2** was kept constant because of the line-shape-fitting consideration. The kinetic parameters have been determined by visual fittings of the calculated lineshapes with the experimental ones. Several typical DNMR spectra are given in Fig. 3. The rate constants thus determined are given in Table 3. The thermodynamic parameters were obtained by the Eyring and Arrhenius plottings of the rate constants with inverse temperatures, one of which is shown in Fig. 4. The parameters thus determined are given in Table 4.

The hindered rotations of several substituted phenylmethanide ions have rates within the NMR-time scale and have been studied many researchers.[2,3,8-12] As compared with the values previously studied, the values obtained in this study are characteristic from

two view points, as follows. (1) The activation energies of the 2-pyridylmethanide ions observed are larger than those observed in the similar systems. This means that the methylene rotation is extremely hindered in the carbanions studied. (2) The activation entropies are large and positive.

Generally speaking, the barrier of the hindered rotation of the aryl group in various arylmethanide ions is related to both the extent of delocalization of the electronic charge from the α-carbon to the aryl ring and the ionic nature of the carbon-metal bond.

The hindered rotations of the lithium salts have rates within the NMR-time scale for several arylmethanide ions. But for the other salts, such as the potassium and cesium ones, the barriers are too high to be studied by the DNMR techniques.[2,9,11] The reason may be the covalent nature of the carbon-metal bond. The nature of the carbon-metal bond is related to the hybridization of the α-carbon, which is reflected by the one-bond carbon-proton coupling constants. The observed ^{13}C NMR data are given in Table 5. The $^1J(CH)$ values of **1** and **2** are about 150 Hz, which are much larger than that of phenylmethyllithium (133 Hz).[13] The observed $^1J(CH)$ of the α-carbons are almost the same with those of the C_4. This shows that the α-carbons have the high sp^2-hybridized nature which is in favor with the delocalization of the extra-electronic charge from the α-carbon to the ring. And this results in a high barrier in the carbanions. This tendency is also strengthened by the nitrogen atom in the ring, whose electron-attracting nature is profitable for the charge migration from the α-carbon to the ring.

The coalescene temperatures of the two carbanions (**1** and **2**) are about 288 and 303 K. Although they are different for the two, the activation parameters are almost the same. Therefore, the introduction of the methyl group is apparently not effective for the rotation of the methylene group. This is a peculiar and unexpected result. Because some appreciable effects of the alkyl qroups were reported by Fraenkel *et al.* and Bushweller *et al.*,[2,4] it might be expected that the introduction of a methyl group at the 3-position would cause a decrease of the rotation barrier of the bond in both the electronic and steric senses. Our experimental results are thus unexpected. Therefore, it must be noted that the 3-positioned methyl group does not interfere the methylene rotation of the carbanions studied.

The observed activation entropies of the 2-pyridylmethanide ions are large and positive. This large entropy increase would be caused by the different solvations around the lithium atom accompanied with the change of the carbanions from the ground planar structure to an excited twisted one. This explanation needs more knowledge about the solvation change of the counter cation. Therefore, it is not clear at present.

Thermodynamic Study on Solvent Extraction of Alkali Metal Picrates by 15-Crown-5

Yasuyuki TAKEDA,* Tsuyoshi NAMISAKI, and Shizuo FUJIWARA
Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260
(Received September 22, 1983)

In order to obtain enthalpy (ΔH_1°) and entropy changes (ΔS_1°) for overall extraction reactions of 15-crown-5 (15C5) with alkali metal picrates between benzene and water, and those (ΔH_2° and ΔS_2°) for partition of 15C5 itself, overall extraction equilibrium constants of 1:1:1 complexes of 15C5 with the salts and distribution coefficients of 15C5 were determined at 20, 30, 35, and 40 °C. The ΔH_1° and ΔS_1° values of 15C5 for the alkali metals are all negative. Both the ΔH_2° and ΔS_2° values are positive. In general, the ΔH_2° and ΔS_2° values play a major role in determining the magnitude of ΔH_1° and ΔS_1° values, respectively, except the case of entropy change for the potassium system. Enthalpy (ΔH_4°) and entropy changes (ΔS_4°) for ion-pair extractions of 15C5-alkali metal ion complexes by picrate anions were calculated by using the ΔH_1° and ΔS_1° values, and the literature values for complex-formation reactions of 15C5 with alkali metal ions in water. Both ΔH_4° and ΔS_4° values vary with the alkali metal ion held in the 15C5 cavity. The ΔH_4° and ΔS_4° values for Na^+, Rb^+, and Cs^+ are all negative, whereas those for K^+ are all positive.

15-Crown-5 (15C5) constitutes a most fundamental skeleton along with 12-crown-4 and 18-crown-6 among various crown compounds. Benzo-15-crown-5 (B15C5), which is a derivative of 15C5, is used as a pendant of polymers, a moiety of bis(crown ether)s, and a colorimetric reagent. These compounds are important for analytical chemistry as versatile agents in solvent extraction. Thus, a detailed study on the extraction process of metal ions with 15C5 and B15C5 would be in order.

For the benzene/water system, extraction-selectivity tendencies of 15C5 and B15C5 for alkali metal ions are almost similar to each other, which are consistent with size relationship.[1,2] The extractability of 15C5 for the same alkali metal ion is larger than that of B15C5 except for Li^+.[1,2] For further study on the role of B15C5 in the extraction process, enthalpy and entropy changes for the overall extraction reactions of B15C5 with sodium and potassium picrates have been determined.[3] The enthalpy and entropy changes for both systems are large and negative.[3]

In the present work, enthalpy and entropy changes for the overall extraction reactions of 15C5 with alkali metal picrates, and those for partition of 15C5 itself have been determined between benzene and water. Enthalpy and entropy changes for ion-pair extractions of 15C5-alkali metal ion complexes by picrate anions were calculated by using these thermodynamic quantities and the literature values for complex-formation reactions of 15C5 with alkali metal ions in water.

Experimental

15-Crown-5 (Nisso Co., Ltd.) was used without further purification. Benzene, picric acid, NaOH, and KOH were analytical grade reagents. Rubidium and caesium hydroxides were reagent-grade. Benzene was washed three times with distilled water.

The benzene phase of 15C5 (1.3×10^{-4}—5.8×10^{-2} M; 1 M=1 mol dm^{-3}), and the aqueous phase of the alkali metal hydroxide (6.1×10^{-3}—1.2×10^{-2} M) and picric acid ((4.1—9.7)$\times10^{-3}$ M) in a stoppered glass tube (30 ml) were shaken in a thermostated water bath for 45 min and centrifuged. The initial volume of each phase was 10 ml in all the cases. Extractions were carried out at pH 10.0—11.7. The picrate in the benzene phase was back-extracted into 8 ml of 0.01 M NaOH aqueous solution, and the picrate concentration was determined spectrophotometrically (λ_{max}=356 nm, $\varepsilon=1.45\times10^4$ cm^{-1} M^{-1}). In blank experiments, there was no extraction in the absence of 15C5. Extractions were conducted at 20, 30, 35, and 40±0.3 °C.

The Distribution Coefficient of 15C5. A 13 ml benzene solution containing 15C5 (7.7×10^{-5}—6.0×10^{-4} M) and an equal volume of distilled water in a stoppered glass tube were shaken in a thermostated water bath for 40 min and centrifuged. A portion 12 ml of the benzene phase and an equal volume of aqueous solution (pH 10.5—11.0) containing NaOH (1.1×10^{-1}M) and picric acid (1.0×10^{-1} M) were placed in a stoppered glass tube and shaken. After centrifuging, the picrate in the benzene phase was back-extracted into 10 ml of 0.01 M NaOH aqueous solution, and the picrate concentration was determined spectrophotometrically (λ_{max}= 356 nm, $\varepsilon=1.45\times10^4$ cm^{-1} M^{-1}). Experiments were conducted at 20, 30, 35, and 40±0.3 °C.

Results

When an equilibrium is established between an aqueous phase of alkali metal ion (M^+) and picrate ion (A^-), and a benzene phase of crown ether (L), the equilibrium constants is defined as

$$K_{ex}=[MLA]_o/[M^+][L]_o[A^-], \quad (1)$$

$$K_{D,L}=[L]_o/[L], \quad (2)$$

$$K_{ML}=[ML^+]/[M^+][L], \quad (3)$$

$$K_{ex'}=[MLA]_o/[ML^+][A^-], \quad (4)$$

where the subscript "o" and the lack of subscript denote the organic and aqueous phases, respectively. Thus, K_{ex} can be written as

$$K_{ex}=K_{ML}K_{ex'}K_{D,L}^{-1}. \quad (5)$$

The distribution ratio of the alkali metal may be represented by

$$D=[MLA]_o/[M^+]. \quad (6)$$

The substitution of Eq. 1 into Eq. 6 gives

$$D=K_{ex}[L]_o[A^-]. \quad (7)$$

Log ($D/[A^-]$) *vs.* log $[L]_o$ plots show a straight line with a slope of 1 in every case. This indicates that the K_{ex} can be described by Eq. 1. The values of $[L]_o$ and $[A^-]$ in Eq. 7 were calculated by

Table 1. Summary of equilibrium constants

Temp/°C	$K_{D,L}$	log K_{ex}			
		Na^+	K^+	Rb^+	Cs^+
20	0.12_6	4.06	2.68	2.30	2.05
25[1]	0.15_6	3.90	2.58	2.14	1.90
30	0.16_3	3.80	2.53	2.03	1.81
35	0.20_0	3.68	2.41	1.95	1.65
40	0.22_1	3.52	2.37	1.86	1.57

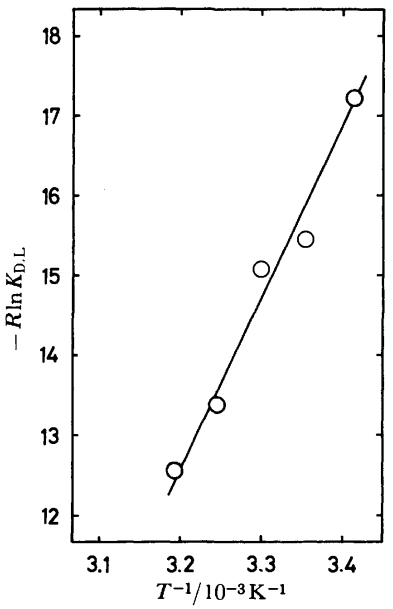

Fig. 1. $-R\ln K_{D,L}$ *vs.* T^{-1} plots for 15C5 between benzene and water.

$$[L]_o=([L]_t-[MLA]_o)/(1+K_{D,L}^{-1}), \quad (8)$$

$$[A^-]=[HA]_t-[MLA]_o, \quad (9)$$

where the subscript "t" denotes the total concentration. The equilibrium constants are listed in Table 1.

It can be seen from Figs. 1 and 2 that the $-R\ln K_{D,L}$ *vs.* T^{-1} and $R\ln K_{ex}$ *vs.* T^{-1} plots show a linear relationship. The enthalpy change (ΔH_n°) and the entropy change (ΔS_n°) for Eqs. 1 and 2 were calculated from these data by means of the following equations: $\Delta G^\circ=-RT\ln K$ and $\Delta G^\circ=\Delta H^\circ-T\Delta S^\circ$, where ΔG° and the subscript "n" designate the free energy change and the number of equation, respectively. The thermodynamic quantities are summarized in Table 2.

Discussion

As can be seen from Table 2, the $T\Delta S_2^\circ$ value is canceled by the ΔH_2° value, resulting in much greater solubility of 15C5 in water than in benzene. The ΔH_2° and $T\Delta S_2^\circ$ (at 25 °C) values of dibenzo-18-crown-6 (DB18C6) between benzene and water are 8.4 and 25 kJ mol^{-1} respectively.[5] 15-Crown-5 and DB18C6 are hydrated in an aqueous phase through hydrogen bonds between ether oxygen atoms of the crown ethers and water molecules. When the crown ethers pass over into the benzene phase from the aqueous phase, the water molecules bound to the crown ethers have to be released. The breaking of the hydrogen bonds and the release of the water molecules would lead ΔH_2° and ΔS_2° of both 15C5 and DB18C6 to positive values. The same tendency has been reported for transfer of 18-crown-6 and cryptand 222 from water to methanol (ΔH_2° and $\Delta S_2^\circ>0$).[6]

Table 2. Thermodynamic quantities

ΔH_2°/kJ mol^{-1}=20.9		$T\Delta S_2^\circ$/kJ mol^{-1} (at 25 °C)=16.1	
	ΔH_n°/kJ mol^{-1}[a]		
	n=1	n=3[4]	n=4
Na^+	-45.3	-6.28	-18.1
K^+	-27.3	-17	10.6
Rb^+	-37.7	-7.95	-8.8
Cs^+	-42.5	-5.4	-16.2
	$T\Delta S_n^\circ$/kJ mol^{-1} (at 25 °C)[b]		
	n=1	n=3[4]	n=4
Na^+	-22.9	-2.2	-4.6
K^+	-12.5	-13.0	17
Rb^+	-25.3	-4.4	-4.8
Cs^+	-31.6	-0.6	-15

a) $\Delta H_1^\circ=-\Delta H_2^\circ+\Delta H_3^\circ+\Delta H_4^\circ$, b) $\Delta S_1^\circ=-\Delta S_2^\circ+\Delta S_3^\circ+\Delta S_4^\circ$

The ΔH_1° and ΔS_1° values of 15C5 for all the alkali metal ions are negative (Table 2). Both ΔH_1° and ΔS_1° values vary somewhat with the alkali metal ion trapped in the 15C5 cavity. Tables 1 and 2 show that the smallest $-\Delta H_1^\circ$value of K^+ is balanced by the smallest $-T\Delta S_1^\circ$ value, resulting in the second largest log K_{ex} value and the second largest $-\Delta H_1^\circ$ value of Cs^+ is canceled by the largest $-T\Delta S_1^\circ$ value, resulting in the smallest log K_{ex} value.

In general, the ΔH_2° and ΔS_2° values play a major role in determining the magnitude of ΔH_1° and ΔS_1° values, respectively, except the case of entropy change for the potassium system, whereas the ΔH_3° and ΔS_3° values play a minor role except for the potassium system.

Both ΔH_4° and ΔS_4° values vary with the alkali metal ion held in the 15C5 cavity (Table 2). This may be attributed to the fact that, since surface charge of alkali metal ions larger than the 15C5 cavity is not effectively shielded by the 15C5 ring, chemical natures of the 15C5 complexes with alkali metal ions (Na^+, K^+, Rb^+, Cs^+) are different from each other. The K_{ex} value (at 25 °C) sequences of 15C5 for the alkali mtal ions are $Na^+ \gg K^+ > Rb^+ > Cs^+$. The highest extractability for Na^+-15C5 complex is due to the largest $-\Delta H_4^\circ$ and the second smallest $-T\Delta S_4^\circ$ values. The second greatest $-\Delta H_4^\circ$ value of 15C5 complex with Cs^+ is canceled to a considerable extent by the largest $-T\Delta S_4^\circ$ value. Thus, the 15C5 complex with Cs^+ shows the lowest extractability. It is very interesting that ΔH_4° and ΔS_4° values for 15C5 complexes with Na^+, Rb^+, and Cs^+ are all negative, whereas those for 15C5 complex with K^+ are all positive. For the reaction corresponding to Eq. 4, the number of chemical species is larger for the reactant system than for the product system. This is presumably the dominant factor in determining the ΔS_4° values of 15C5 complexes with Na^+, Rb^+, and Cs^+ to be negative. The fact that, although the ΔH_4° value of the 15C5 complex with K^+ is by far the most unfavorable-or ion-pair extraction of the K^+ complex, the extraction efficiency of the K^+ complex is the second largest depends totally on much the greatest $T\Delta S_4^\circ$ value (Table 2). The reason why the ΔH_4° and ΔS_4° values of the 15C5 complex with K^+ are positive and large cannot be clearly explained at the present time. However, it is conceivable that the positive ΔS_4° value of the 15C5 complex with K^+ is due to the difference in the hydration state between the 15C5 complex with K^+ in the aqueous phase and the 15C5 complex with potassium picrate in the benzene phase.

Effects of Alkyl Chain Length on Molecular Interactions. I. Solid Complex Formation in the Pyrene-*N*-Alkyl-2,4,6-trinitroaniline Systems

Atsushi TOGASHI and Yoshio MATSUNAGA*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received October 5, 1983)

Phase diagrams were prepared for the fifteen binary systems consisting of pyrene as an electron donor and *N*-alkyl-2,4,6-trinitroanilines as electron acceptors. The thermal stability of the orange 1:1 complex between pyrene and the unsubstituted 2,4,6-trinitroaniline (mp 236 °C) is drastically decreased by *N*-alkylation; *e.g.*, the *N*-pentyl-2,4,6-trinitroaniline complex melts at 97 °C. The systems with the *N*-hexyl and *N*-heptyl derivatives give two peritectics each, while most of the higher homologues produce a single peritectic or a eutectic. Unstable red solids were formed on rapid cooling of the molten pyrene-*N*-hexyl-2,4,6-trinitroaniline mixtures. This red complex becomes relatively more stable with increase of the alkyl chain length, possibly because of the enhanced tendency for chain alignment. In the systems with the *N*-pentadecyl and *N*-heptadecyl derivatives, the stable existence of the red 1:1 complex could be demonstrated.

Many organic compounds that form liquid crystals when heated have elongated molecules. Generally, these molecules have a rigid central part and one or two flexible terminal groups. The effects of the alkyl chain length in the terminal substituents on the liquid crystalline properties have been studied for a large number of homologous series. The lower homologues are commonly purely nematic, whereas the higher homologues are purely smectic. The flexible terminal groups are supposed to bring about partial breakdown of the molecular order produced by the attraction between the rigid central parts. As the nematic phase is less ordered than the smectic phase, one might assume that shorter alkyl chains tend to diminish the thermal stability of the regular molecular arrangement, while longer ones tend to restore it though the arrangement achieved is not the same as the original one. If this is so, analogous effects would be widely observable with ordinary organic solids; however, little attention has been paid to this problem.

In the present series of communications, we record studies on the effects of the alkyl chain length on intermolecular interactions such as charge transfer and proton transfer operating in solid complex formation. Systematic studies may hopefully provide a way to control such interactions. As early as 1910, Sudborough and Beard reported the preparation of 1,3,5,-trinitrobenzene complexes with aminobenzoic acids and their methyl and ethyl esters.[1] The progressive lowering of their melting points in this order appears to be consistent with the above-mentioned trends. To the authors' knowledge, no further work on such solid complexes is available.

Experimental

Materials. The yellow-colored *N*-alkyl-2,4,6-trinitroanilines were obtained by the condensation of appropriate amines with 2,4,6-trinitrochlorobenzene in boiling ethanol.[2] The alkyl groups employed and the melting points of the products were as follows: butyl, 83.5 °C; pentyl, 73.5 °C; hexyl, 70.2 °C; heptyl, 59.5 °C; octyl, 63.5 °C; nonyl, 55.6 °C; decyl, 70.2 °C; undecyl, 68.4 °C; dodecyl, 76.3 °C; tridecyl, 77.0 °C; tetradecyl, 79.0 °C; pentadecyl, 83.5 C; hexadecyl, 88.3 °C; heptadecyl, 89.0 °C; octadecyl, 91.5 °C. The pyrene, Eastman white label, was recrystallized from xylene. Binary mixtures in known proportions were melted in small test tubes, shaken well to insure homogeneity and then rapidly cooled.

Measurements. The calorimetric curves were recorded on a Rigaku Denki Thermoflex differential scanning calorimeter during the process of heating. The heating rate in this work was generally 5 °C min^{-1} but a rate as high as 20 °C min^{-1} was occasionally employed for the determination of melting points of metastable forms. The binary mixture was put into an open aluminum pan so that the color change on heating could be observed through a window. The diffuse reflectance of the solid component compounds and the molecular complexes was measured with a Beckman DK 2A spectroreflectometer. The spectrum was then plotted using the Kubelka-Munk function.

Results and Discussion

Shinomiya has prepared the phase diagram of the pyrene-2,4,6-trinitroaline system.[3] The eutectic on the donor-rich side is located at 139.5 °C and 8 mol% (hereafter, the composition is given by mol% of the acceptor) and the other one at 180.5 °C and 88 mol%. The stable 1:1 complex melts at a temperature as high as 236 °C. When the *N*-butyl and *N*-pentyl derivatives are employed as electron acceptors, the diagrams are essentially of the same type; that is, the orange 1:1 complexes melt congruently (see Fig. 1a). However, the temperatures are lowered to 104.5 and 97 °C respectively.

As is evident from Fig. 1b, the 1:1 complex becomes so unstable for the *N*-hexyl derivative that it undergoes decomposition at 85.5 °C, exhibiting a peritectic point at 55 mol%. Thus, the decrease in the thermal stability of the orange 1:1 complex by the *N*-alkylation is remarkable. In this system, another peritectic is found at 97 °C and 37 mol%, suggesting the formation of a 2:1 complex. The latter is also orange-colored. In addition, red solids crystallize when the molten mixtures around this composition are quenched. The melting point of this metastable phase (68 °C) is measurable by a rapid heating (see the shaded circles in Fig. 1b) though these red solids change monotropically to orange solids on storage at room temperature. The endothermic peak due to the melting is followed by an exothermic peak and the stable orange-colored solid is formed. The pyrene-*N*-heptyl-2,4,6-trinitroaniline system behaves similarly; however, the stabilities of the complexes are further diminished. Namely, the peri-

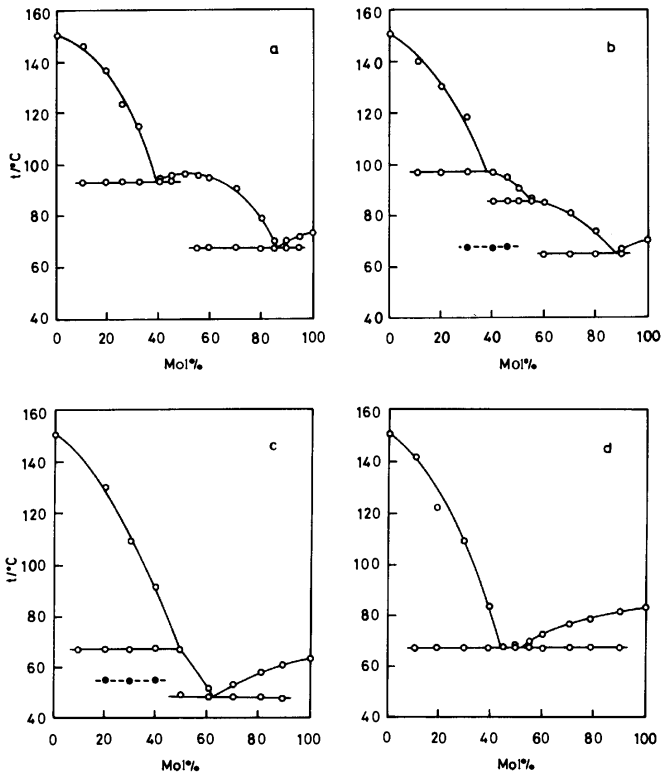

Fig. 1. Phase diagrams of the systems of pyrene with (a) *N*-pentyl-2,4,6-trinitroaniline, (b) the *N*-hexyl analogue, (c) the *N*-octyl analogue, and (d) the *N*-pentadecyl analogue. The shaded circles are the melting points of the metastable phase.

tectic due to the 1:1 complex is at 63 °C and 65 mol% and that due to the 2:1 complex at 85 °C and 38 mol%. In the composition range of the latter complex, a red complex melting at 61 °C is obtainable. The eutectic point of this system is located at 53 °C and 90 mol%.

The combination of pyrene and the *N*-octyl derivative exhibits only one peritectic at 67 °C and 48 mol%, giving no evidence for the formation of the 1:1 complex (see Fig. 1c). Metastable red solids appearing in the range from 20 to 40 mol% melt at 54.5 °C regardless of the composition. The phase diagrams of the same type were afforded by the next five higher homologues. In the case of the *N*-nonyl derivative, the system gives a peritectic at 71.5 °C and 49 mol% and a eutectic at 45.5 °C and 71 mol%. The latter temperature is the lowest among the eutectics observed in the present series. Moreover, it may be added that only in this system the red solids were so unstable that we failed to record the melting point on the calorimetric curve even with the highest rate of heating. With the *N*-decyl derivative, both the peritectic and eutectic raise appreciably; that is, the former lies at 90.5 °C and 42 mol% and the latter at 63 °C and 77 mol%. The melting point of the metastable red solid was determined as 60 °C. The peritectic and eutectic points fall again with the *N*-undecyl derivative. They are found at 76 °C and 46 mol% and at 59 °C and 73 mol%. As a result the red solids melt at 56.5 °C. The peritectic continues to fall with the *N*-dodecyl and *N*-tridecyl derivatives. They lie at 75.5 °C and 44 mol% and at 65 °C and 47 mol% respectively. On the other hand, the eutectic changes rather irregularly; that is, 64 °C and 65 mol% for the former homologue and 62.5 °C and 55 mol% for the latter. The melting point of the metastable red form shows a similar tendency to the eutectic; namely, 61.5 and 58.5 °C were recorded for these systems. Thus, the melting point of the red phase is not much affected by the alkyl chain length up to the *N*-tridecyl derivative; however, a rather large alternation in the thermal stability is demonstrated beyond this member in the series. Such an alternating effect is strongly reminiscent of the well-known alternation of the melting points of long chain compounds, which is attributed to the fact that the alkyl chains in the crystal lattice are in the form of long, straight but zig-zag chains and lie with their axes parallel.[4]

When molten mixtures of pyrene and *N*-tetradecyl-2,4,6-trinitroaniline are slowly cooled, no stable complex is found. The eutectic is located at 59 °C and 50 mol%, whereas the metastable red complex can be formed by rapid cooling in this system also. Its melting point is lower by 10 °C than the eutectic. The yellow solids exothermally produced above this melting point are mixtures of the component compounds. Therefore, the stability of the orange complex is now definitely lower than that of the red one though the latter is still metastable. The systems with the next two even-numbered homologues maintain a similar behavior. Each diagram shows only a eutectic point which is at 67.5 °C and 42 mol% and at 72 °C and 44 mol%. The red complex formed in the former system melts at 55.5 °C and that in the latter at 63.5 °C.

The systems with the *N*-pentadecyl and *N*-heptadecyl derivatives are of particular interest because in them the stable existence of the red complexes could be demonstrated. As is shown in Fig. 1d, the freezing point curve of the hydrocarbon meets a horizontal line at 68 °C and 44 mol% and that of the *N*-pentadecyl derivative at the same temperature and 53 mol%. Although the equilibrium curve involving the congruently-melting red complex is not distinguishable from the eutectic horizontal, the composition range strongly suggests that the ideal mole ratio of this phase is 1:1. In the case of the *N*-heptadecyl derivative, the binary system is somewhat complicated and has a peritectic point at 72.5 °C and 47 mol%, supporting the formation of a 1:1 complex. The eutectic point lies at 71 °C and 40 mol%. Occasionally, we obtained yellow mixtures of the solid component compounds from the melts of this system. Upon heating, this yellow mass melts but immediately solidifies into the red complex. This change is accompanied by evolution of heat.

The thermal stabilities are plotted against chain length in Fig. 2 for the above-mentioned three kinds of molecular complexes. Open circles represent the congruent or incongruent melting points of the orange 1:1 complexes. The stability diminishes rapidly with increase in the alkyl chain length and this complex can be found only in the region I which extends up to the *N*-heptyl derivative. In view of the enhanced flexing of the alkyl chains, the lowering of melting point in this region is reasonable. The metastable red complex

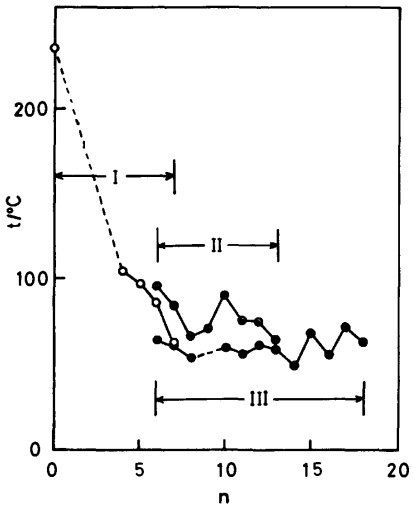

Fig. 2. Congruent or incongruent melting points of the orange-colored 1:1 complex (○), of the orange-colored 2:1 complex (⊙), and of the red-colored 1:1 complex (●) plotted against the *N*-alkyl chain length.

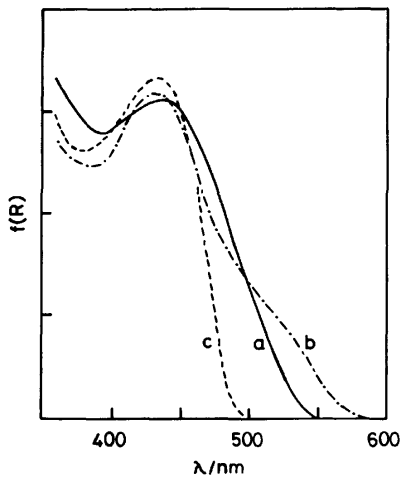

Fig. 3. Diffuse reflection spectra of (a) the orange-colored pyrene-*N*-butyl-2,4,6-trinitroaniline complex, (b) red-colored pyrene-*N*-heptadecyl-2,4,6-trinitroaniline complex, and (c) the latter acceptor compound alone.

is formed first with the *N*-hexyl derivative. The melting point fluctuates around 60°C (see shaded circles) and then tends to raise slowly with marked alternation. If one assumes that the 1:1 composition found in Fig. 1d is applicable to all the complexes in the region III, the melting point under consideration may be congruent except for the cases of the *N*-hexyl, *N*-heptyl, and *N*-octyl derivatives. When the regions I and III are overlapped with each other, the orange and red complexes may be regarded as polymorphs. The primary factor in determining the mode of molecular packing would be the charge-transfer interaction in the former complexes and the compromise between the alkyl chain alignment and the charge-transfer interaction in the latter. As is indicated by the melting point alternation, with increase in the alkyl chain length the alignment becomes relatively more important. The region II, where the orange-colored 2:1 complexes are formed, occupies about two thirds of region III. It may be noted that *N*-alkyl-2,4,6-trinitroanilines themselves also exhibit the fall of the melting point with increase of the alkyl chain length in the lower homologues and rise in the higher homologues.

The visible spectra of the orange 1:1 complex and red 1:1 complex are shown in Fig. 3. The former is represented by the *N*-butyl-2,4,6-trinitroaniline complex and the latter by the *N*-heptadecyl-2,4,6-trinitroaniline complex. For the sake of comparison, the spectrum of the acceptor is also shown. The absorption in the range from 500 to 550 nm arising from the complex formation may account for the orange color. The additional absorption appearing in the red complex is weaker but extends to about 600 nm. A shoulder may be located at about 530 nm. The shift of the absorption band to the longer wavelength-side may be interpreted by the small resonance energies in the red complex, reflecting a mode of molecular packing unfavorable to the intermolecular charge-transfer interaction. Preliminary X-ray diffraction studies on the red complexes gave patterns with a strong peak in the proximity of $2\theta = 3°$ in accordance with the parallel arrangement of the pentadecyl and heptadecyl chains.

In this connection, it may be worthwhile to mention the effects of alkyl chain length on complex formation in solution studied by Foster and Hammick.[5] They have determined the association constants for the interactions of *N*-alkylanilines with 1,3,5-trinitrobenzene and 2,4,6-trinitrotoluene in cyclohexane. According to their study, complexes of greater stability are formed with the higher homologues of both series; *e.g.*, the association constant is 8.2 l mol^{-1} for the *N*-butylaniline-1,3,5-trinitrobenzene complex and 11.6 l mol^{-1} for the corresponding *N*-dodecylaniline complex. The wavelength of the maximum absorption due to the charge-transfer interaction rises with the first few homologues of both these series, thereafter remaining sensibly constant. Because of the three dimensional order, the effects of alkyl chain length on the stability of complexes in the solid state are entirely different from those observed for the complexes in solution.

(Received May 28, 1983)

The kinetics of the racemization and dissociation of $[Fe(phen)_3]^{2+}$ were investigated in the presence of a series of 1-alkanesulfonate ions (n-$C_nH_{2n+1}SO_3^-$, n=2, 4, 6,...,14). The racemization rate increased, while the dissociation rate decreased, gradually as a function of the alkanesulfonate concentration at low concentrations of each alkanesulfonate. With alkanesulfonates of $n \geqq 8$, the second phase of rate changes, *i.e.*, steep increases in both rates, were observed at higher concentrations. The gradual initial changes in the rates were explained in terms of the formation of the 1:1 aggregate of the complex cation with the alkanesulfonate ion caused by hydrophobic interaction. The formation constant ($mol^{-1}\,dm^3$) increased almost exponentially from 4 (n=4) to 770 (n=14) with the increase in the alkyl-chain length, the energy of the hydrophobic interaction of the complex cation and the alkanesulfonate anion being 0.9 kJ mol^{-1} per methylene group of the latter. The second phase of the rate changes were explained in terms of the formation of the 1:m aggregate of the complex cation with the alkanesulfonate ions. The rate behavior of the hydrophobic aggregates is discussed in connection with the reaction mechanisms of the racemization and dissociation of $[Fe(phen)_3]^{2+}$.

A study of hydrophobic interaction is very important not only for understanding the nature of the interaction determining the tertiary and quarternary structures of proteins in biological systems,[1] but also for discerning the nature of the solute-solute interaction in an aqueous solution containing a hydrophobic metal complex.[2-4] However, few investigations have so far been done to clarify the nature of the interaction of a complex with a monomeric surfactant,[5] although much attention has been paid recently to the interaction of metal complexes with micelles.[6-11]

The $[Fe(phen)_3]^{2+}$ (phen=1,10-phenanthroline) ion is known to racemize by means of an intramolecular twist mechanism.[12] The nature of the twist mechanism, however, does not seem to be fully understood.[12] We previously studied the effects of inorganic anions,[13,14] inorganic cations,[15] and organic cations[15] on the rates of the racemization and dissociation of $[Fe(phen)_3]^{2+}$. The changes in the rates in the presence of inorganic anions were reasonably explained in terms of the ion-pair formation of the complex ion with the anions.[13,14] On the other hand, the effects of organic cations such as alkylammonium ions on the racemization and dissociation rates were explained by a consideration of the formation of the 1:1 aggregate of the complex and the alkylammonium cations caused by hydrophobic interaction between them.[15]

The present study is concerned with the effects of 1-alkanesulfonate ions (n-$C_nH_{2n+1}SO_3^-$, n=2, 4, 6,···, 14) on the rates of the racemization and dissociation of $[Fe(phen)_3]^{2+}$. As the hydrophobicity of alkanesulfonate anions varies with the alkyl-chain length, different effects can be expected for alkanesulfonates with different chain lengths. A comparison of the effect of each alkanesulfonate with that of the alkylammonium cation of the same alkyl-chain length will show the roles of the charge and the hydrophobic group in the interaction between the complex and organic ions, and their effects on the racemization and dissociation rates. The results will also give a basis for understanding the nature of the interaction of a metal-complex cation with ionic surfactants.

Experimental

The sodium 1-alkanesulfonates used were guaranteed-grade reagents of the Tokyo Kasei Kogyo Co., Ltd. They were recrystallized three times from an ethanol-methanol (5:1) solution and dried at 70°C *in vacuo* for 5 h. The concentrations of the solutions of these salts were determined by weighing well-dried reagents. The surface tension of the solutions of these surfactants showed no minimum around the cmc (critical micelle concentration).[16] Kinetic data were obtained at 25°C in solutions containing the perchlorate of the complex (5×10^{-5} mol dm^{-3}) and a sodium alkanesulfonate. Racemization was followed by polarimetry, and dissociation, by spectrophotometry. For measuring the dissociation rates, $NiCl_2$ (5×10^{-4} mol dm^{-3}) was added to the sample solution as a scavenger of the liberated phenanthroline. For the systems containing dodecane- and tetradecanesulfonates, the measurements were carried out at a low $NiCl_2$ concentration of 1×10^{-4} mol dm^{-3} to minimize the precipitation of nickel(II) sulfonate. The first-order rate constants for racemization and dissociation were obtained, respectively, from the $\ln [\alpha_0/\alpha_t]$ *vs.* t and $\ln[(D_0-D_t)/(D_0-D_\infty)]$ *vs.* t plots, where α and D, with the subscripts showing the time, represent the optical rotation (546 nm) and the absorbance (510 nm) of the sample solution respectively. A Union SM401 spectrometer was used for the observation of the absorption spectra. The other chemicals and procedures were the same as those described in our previous paper.[13]

Results

Profile of the Rate Changes with the Alkanesulfonate Concentrations. The kinetic results for the racemization and dissociation of $[Fe(phen)_3]^{2+}$ in the presence of various sodium alkanesulfonates (n-$C_nH_{2n+1}SO_3Na$, n=2, 4, ···, 14) are depicted in Figs. 1 ($n \leqq 6$), and 2 ($n \geqq 8$, with the abscissa on a logalithmic scale); a linear scale plot for a part of the latter is drawn in Fig. 3 for ease of comparison with Fig. 1. In solutions of the alkanesulfonates of n=2 and 4 (Fig. 1), the racemization rates increased, and the dissociation rates decreased,

The solid lines in the figure are those calculated by substituting the parameter values (Table 1) into Eq. 5.

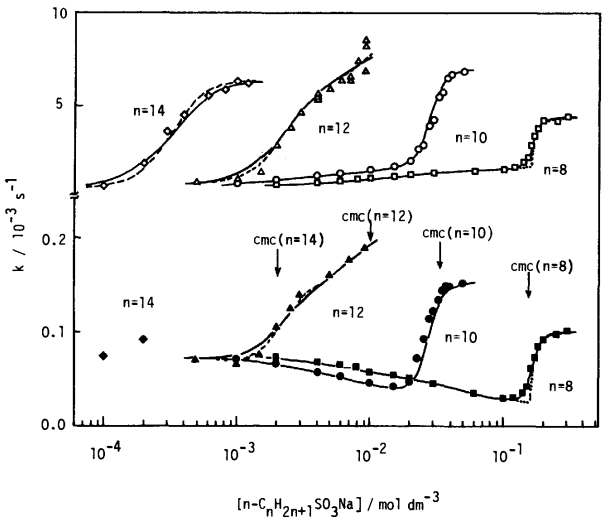

Fig. 2. The racemization (open marks) and dissociation (closed marks) rate constants of $[Fe(phen)_3]^{2+}$ in alkanesulfonate ($n \geqq 8$) solutions at 25.0°C.
○, ●: n-$C_8H_{17}SO_3Na$; □, ■: n-$C_{10}H_{21}SO_3Na$; △, ▲: n-$C_{12}H_{25}SO_3Na$; ◇, ◆: n-$C_{14}H_{29}SO_3Na$.
The solid and dotted lines in the figure are those calculated on the basis of Eqs. 10 and 15, respectyvely. For systems containing dodecane- or tetradecanesulfonate, the solid lines are those calculated by assuming the presence of 1:3 aggregates, and the broken lines, 1:4 aggregates. The parameter values given in Table 2 were used in these calculations.

monotonously with the increase in the alkanesulfonate concentration. Similar changes in the rates were also observed for sulfonates of n=6, 8, 10, 12, and 14 at concentrations lower than 0.5, 0.10, 0.015, 0.001, and 0.0001 mol dm^{-3} respectively (see Figs. 1 and 3). The changes in both the racemization and dissociation rates with the alkanesulfonate concentration were larger for the sulfonate with a longer alkyl chain. At

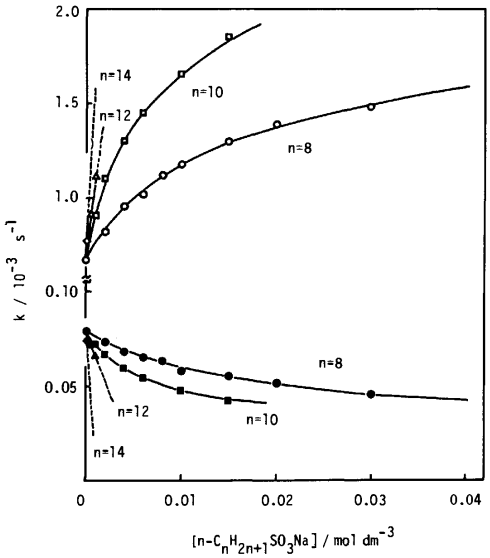

Fig. 3. The racemization (open marks) and dissociation (closed marks) rate constants of $[Fe(phen)_3]^{2+}$ in alkanesulfonate ($n \geqq 8$) solutions of low concentrations at 25.0°C.
○, ●: n-$C_8H_{17}SO_3Na$; □, ■: n-$C_{10}H_{21}SO_3Na$; △, ▲: n-$C_{12}H_{25}SO_3Na$, ◇, ◆: n-$C_{14}H_{29}SO_3Na$.

higher concentrations of the sulfonates than those mentioned above (Fig. 2), the racemization rate increased steeply with the increase in the alkanesulfonate concentration to a rate several times as large as that in water, and then it reached a plateau. The dissociation rates also increased to a rate larger than that in pure water.

Kinetics in Alkanesulfonate Solutions of the Lower Concentrations (Figs. 1 and 3): The changes in rates with the alkanesulfonate concentrations in this region are similar to those observed for $[Fe(phen)_3]^{2+}$–alkyltrimethylammonium systems. Thus, the rate changes can be thought to arise from the formation of the 1:1 aggregate[15] (or ion pair[13]) of complex ion and an alkanesulfonate ion. The following mechanism was considered:

$$[Fe(phen)_3]^{2+} + RSO_3^- \overset{K_1}{\rightleftharpoons} [Fe(phen)_3]^{2+}\cdot RSO_3^-, \quad (1)$$

$$\Delta\text{-}[Fe(phen)_3]^{2+} \xrightarrow{k_{0r}} rac\text{-}[Fe(phen)_3]^{2+}, \quad (2r)$$

$$[Fe(phen)_3]^{2+} \xrightarrow{k_{0d}} [Fe(phen)_2]^{2+} + phen \xrightarrow{fast} Fe^{2+} + 3\,phen, \quad (2d)$$

$$\Delta\text{-}[Fe(phen)_3]^{2+}\cdot RSO_3^- \xrightarrow{k_{1r}} rac\text{-}[Fe(phen)_3]^{2+}\cdot RSO_3^-, \quad (3r)$$

$$[Fe(phen)_3]^{2+}\cdot RSO_3^- \xrightarrow{k_{1d}} [Fe(phen)_2]^{2+}\cdot RSO_3^- + phen \xrightarrow{fast} Fe^{2+} + 3\,phen + RSO_3^-, \quad (3d)$$

$$K_1 = \frac{[Fe(phen)_3^{2+}\cdot RSO_3^-]}{[Fe(phen)_3^{2+}][RSO_3^-]}\frac{f_1}{f_2 f_1}, \quad (4)$$

where k_0 and k_1 are the rate constants of the complex cations not associated with and associated with the alkanesulfonate ion respectively, and where f_z represents the activity coefficient of an ion with a charge of

a) k_{0r}. b) k_{0d}. c) The values obtained from dissociation experiments. d) The value estimated from those obtained for systems containing alkanesulfonate of shorter alkyl-chain lengths.

$\pm z$ and can be calculated with the Debye-Hückel equation.[14] The rate constants for racemization and dissociation are expressed as:

$$k^{obsd} = \frac{k_0 + k_1K_1f_2[RSO_3^-]}{1 + K_1f_2[RSO_3^-]}. \quad (5)$$

Additional subscripts, r and d, may be attached to the symbols for rate constants to distinguish between racemization and dissociation. The kinetic data for $n=4$—10 (Figs. 1 and 3) were analyzed in terms of the least-squares fit to Eq. 5. The K_1 and k_1 values thus obtained are listed in Table 1.

In the cases of $n=12$ and 14 (Fig. 3), where the alkanesulfonate concentrations are very low ($[RSO_3^-] \ll 1/K_1$), Eq. 5 can be reduced to:

$$k^{obsd} = k_0 + (k_1 - k_0)K_1[RSO_3^-]. \quad (6)$$

The k_{1d} value of 0.017×10^{-3} s^{-1} was assumed for $n=12$ and 14 by extrapolation from the k_{1d} values for $n \leqq 10$, which are shown to be independent of the alkyl-chain length of the alkanesulfonate ion (Table 1). The k_{1r} values were obtained from Eq. 6 with the K_1 values obtained from dissociation experiments. The solid lines in Figs. 1 and 3 are those calculated with the parameter values listed in Table 1.

Kinetics in Solutions of Higher Alkanesulfonate Concentrations: The rate behavior of the complex ion at the sulfonate concentrations higher than 0.10, 0.015, 0.001, and 0.0001 mol dm^{-3} for n=8, 10, 12, and 14 respectively may be related to the formation of higher aggregates than 1 : 1 or to the interaction with micelles.

In order to ascertain whether or not the micelles are concerned with the observed changes in rates, the cmc values of the alkanesulfonates were determined in the presence of 5×10^{-5} mol dm^{-3} $[Fe(phen)_3]^{2+}$ by means of the surface-tension and light-scattering methods.[16] The surface tension of the solutions containing sodium alkanesulfonates decreased remarkably in the presence of 5×10^{-5} mol dm^{-3} $[Fe(phen)_3]^{2+}$, and the break-point of the surface tension *vs.* concentration curve appeared at a lower concentration. This appears to be consistent with a previous finding that the cmc value of sodium dodecyl sulfate (SDS) decreased remarkably in the presence of 1×10^{-4} mol dm^{-3} $[Co(phen)_3]^{3+}$.[17] However, light-scattering measurements, which can detect the micelle formation more directly, showed that the cmc values[18] remained almost unchanged in the presence of the complex ions, and that the pre-aggregation of the complex cation with the alkanesulfonate ions took place at a concentration below the cmc. The contradictory results of the surface-tension and light-scattering experiments may have arisen from the fact that the surface-tension measurements are an indirect method of determining the cmc value, or that they cannot distinguish between the formation of micelles and that of premicellar aggregates such as a 1 : m aggregate.

Since a steep rise in the rate was observed before the alkanesulfonate concentration reached the cmc value for the $[Fe(phen)_3]^{2+}$-containing system, the observed rate changes cannot be attributed to the interaction of the complex ion with the alkanesulfonate micelle.

Let us now consider the formation of 1 : m ($m \geqq 2$) aggregates. The following equations must be added to Eqs. 1-4:

$$[Fe(phen)_3]^{2+} + m\,RSO_3^- \overset{\beta'_m}{\rightleftharpoons} [Fe(phen)_3]^{2+} \cdot m\,RSO_3^-, \quad (7)$$

$$\Delta\text{-}[Fe(phen)_3]^{2+} \cdot m\,RSO_3^- \xrightarrow{k_{mr}} rac\text{-}[Fe(phen)_3]^{2+} \cdot m\,RSO_3^-, \quad (8r)$$

$$[Fe(phen)_3]^{2+} \cdot m\,RSO_3^- \xrightarrow{k_{md}} [Fe(phen)_2]^{2+} \cdot m\,RSO_3^- + phen \xrightarrow{fast} Fe^{2+} + 3\,phen + m\,RSO_3^-, \quad (8d)$$

$$\beta'_m = \frac{[Fe(phen)_3{}^{2+} \cdot m\,RSO_3^-]}{[Fe(phen)_3{}^{2+}][RSO_3^-]^m}. \quad (9)$$

Then, the observed reaction rate constant can be expressed as:

$$k^{obsd} = \frac{k_0 + k_1\beta'_1[RSO_3^-] + \sum_{m=2}^{\infty} k_m\beta'_m[RSO_3^-]^m}{1 + \beta'_1[RSO_3^-] + \sum_{m=2}^{\infty} \beta'_m[RSO_3^-]^m}, \quad (10)$$

where k_m represents the rate constant of the complex cation associated with m alkanesulfonate anions, and where $\beta'_1 (=K_1f_2)$ and β'_m are the concentration formation constants of the 1 : 1 and 1 : m aggregates. Because of the difficulty in estimating the activity coefficients of higher aggregates, the concentration equilibrium constants were used in the analysis. Although the ionic strength of the medium was not maintained constant, it can be expected that an analysis in such a way will at least qualitatively give a proper interpretation

TABLE 2. THE m AND $\log\beta'_m$ VALUES OBTAINED FROM THE ANALYSIS OF THE KINETIC RESULTS IN SOLUTIONS OF HIGH ALKANESULFONATE CONCENTRATIONS, AND OTHER PARAMETER VALUES ASSUMED FOR THE ANALYSIS[a)]

Alkanesulfonate	m	$\log\beta'_m$	β'_1[b)]	$k_{md}/10^{-3}$ s^{-1}	$k_{mr}/10^{-3}$ s^{-1}
n-$C_8H_{17}SO_3^-$	14±2	11.8±1.6	34	0.100	4.4

	4	14.4±0.4	710	—	6.3

a) Each of the figures under m and $\log\beta'_m$ is the average of the values obtained from the racemization and dissociation experiments. b) $\beta'_1=K_1f_2$. c) The m values for this system are assumed by analogy with the values for the systems containing decane- and tetradecanesulfonates. d) The value of m which best fits the experimental data is 3.4. Thus, the experimental results were analyzed by assuming an integer m value of 3 or 4.

of the experimental results for two reasons. Firstly, the high charge of the higher aggregate will be reduced by ion association with sodium ions, and therefore the activity coefficient of the higher aggregate will not so greatly depend on the ionic strength of the medium. Secondly, the rate changes at the higher alkanesulfonate concentrations are observed in a narrow range of the sulfonate concentration; accordingly, the activity coefficients of the ions involved in the reaction can be regarded as almost constant in the region where the most remarkable change in rate was observed.

In addition to the free complex ion and the 1:1 aggregate, one higher aggregate species (1:m) was considered for the systems containing octane-, decane-, and tetradecanesulfonate. Under these conditions, the transformation of Eq. 10 leads to:

$$\log\left\{\frac{(k^{obsd}-k_0)+(k^{obsd}-k_1)\beta'_1[RSO_3^-]}{(k_m-k^{obsd})}\right\} = \log\beta'_m + m\log[RSO_3^-]. \quad (11)$$

The values of m and β'_m were obtained by analyzing the kinetic data in the following way. The values of k_0, k_1, and β'_1 have been obtained above from the analysis of the rates at lower sulfonate concentrations. The rate constant of the 1:m aggregate, k_m, was regarded as equal to the rate constant at the plateau (Fig. 2, Table 2). By assuming that $[RSO_3^-]$ equals the total alkanesulfonate concentration, the plot of the left-side term of Eq. 11 *vs.* $\log[RSO_3^-]$ gave approximate values of m and $\log\beta'_m$. Then, these values of m and $\log\beta'_m$ were used to calculate the $[RSO_3^-]$ value, with which the plot as described above was repeated to give better values of m and $\log\beta'_m$. This procedure was repeated until reproducible values of m, β'_m, and $[RSO_3^-]$ were obtained. The values of m and β'_m thus obtained for the systems containing octane-, decane-, and tetradecanesulfonate are listed in Table 2, along with the value of k_m assumed for the analysis. The m and β'_m values given for the octanesulfonate system are the lower limits, since the decrease in $[RSO_3^-]$ upon micelle formation was disregarded. The solid lines in Fig. 2 show the k_r and k_d values calculated with the parameter values listed in Tables 1 and 2. In the case of tetradecanesulfonate-containing systems, the solid and broken curves correspond to the formation of the 1:3 and 1:4 aggregates respectively. The good agreement between the observed and the calculated rate constants suggests that the approximations adopted in the analysis of the experimental results are reasonably good in these cases. Aggregates other than those considered above may be present in each system, but they will not appreciably differ in the aggregation number from those considered or, if they do appreciably differ, they will not be present in appreciable concentrations. Thus, no further analysis has been carried out.

The dodecanesulfonate-containing system shows a feature different from the octanesulfonate-, decanesulfonate-, and tetradecanesulfonate-containing systems; at least two steps of changes are observed in the rate increase occurring in the region of 10^{-3}—10^{-2} mol dm^{-3} (Fig. 2). In this case, analysis was carried out by assuming the presence of the 1:3 and 1:8 aggregates or the 1:4 and 1:8 aggregates. These particular aggregates were chosen by analogy with the systems containing decane- and tetradecanesulfonate. The least-squares fit of the kinetic data to Eq. 10 with m=3 and 8 or m=4 and 8 led to the parameter values listed in Table 2. These parameter values were used to calculate the rate constants at each dodecanesulfonate concentration. The solid and broken lines in Fig. 2 were obtained by assuming the formation of the 1:3 and 1:8 aggregates and of the 1:4 and 1:8 aggregates respectively. Better fits of the calculated lines to the observed rate constants were obtained when the 1:4 aggregate was assumed to exist, although the 1:3 aggregate seems more natural from the shape of the complex.

Kinetics in Micellar Solutions: As has been described above for system containing octanesulfonate, the change in rate observed above the cmc was accounted for by considering the interaction of the complex ion with monomeric sulfonate ions. If we consider the aggregate of the complex ion with the micelle in place of the 1:m aggregate, the following reactions are substituted for Eqs. 7—10:

$$[Fe(phen)_3]^{2+} + \text{micelle} \overset{K_M}{\rightleftharpoons} [Fe(phen)_3]^{2+}\cdot\text{micelle}, \quad (12)$$

$$\Lambda\text{-}[Fe(phen)_3]^{2+}\cdot\text{micelle} \xrightarrow{k_{rM}} rac\text{-}[Fe(phen)_3]^{2+}\cdot\text{micelle}, \quad (13r)$$

$$[Fe(phen)_3]^{2+}\cdot micelle \xrightarrow{k_{dM}} [Fe(phen)_2]^{2+}\cdot micelle + phen \xrightarrow{fast} Fe^{2+} + 3\,phen + micelle, \quad (13d)$$

$$K_M = \frac{[Fe(phen)_3^{2+}\cdot micelle]}{[Fe(phen)_3^{2+}][micelle]}. \quad (14)$$

Then, the observed rate constant is expressed as:

$$k = \frac{k_0 + k_1\beta'_1[RSO_3^-] + k_M K_M[micelle]}{1 + \beta'_1[RSO_3^-] + K_M[micelle]}. \quad (15)$$

When the total concentration of the surfactant (C_S) is much larger than that of the complex, [micelle] can be expressed as:

$$[micelle] = \frac{C_S - cmc}{N}, \quad (16)$$

where N is the aggregation number of the micelle. An analysis of the kinetic data for the systems of octanesulfonate leads to $K_M=(800\pm300)N\,mol^{-1}\,dm^3$, $k_{Mr}=(4.6\pm0.3)\times10^{-3}\,s^{-1}$, and $k_{1d}=(0.105\pm0.004)\times10^{-3}\,s^{-1}$. Calculation with the parameter values gives the dotted curve shown in Fig. 2. The poor agreement between the calculated and observed rates strongly suggests the existence of at least one 1:m ($m\geqq2$) species.

Discussion

The formation of aggregates of $[Fe(phen)_3]^{2+}$ with alkansulfonate ions and the racemization and dissociation of the complex in the aggregates will now be discussed in comparison with the case of the aggregates with alkyltrimethylammonium ions.

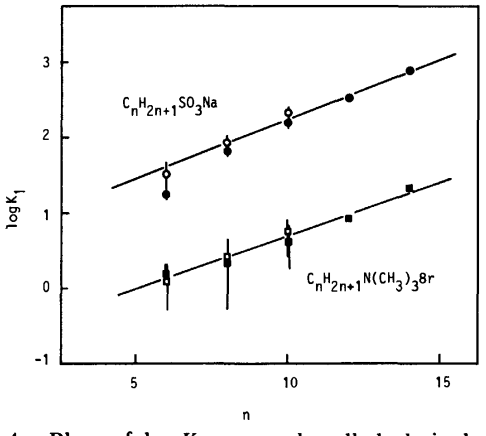

Fig. 4. Plots of $\log K_1$ versus the alkyl chain length (n) of the alkanesulfonate and alkyltrimethylammonium ions. The open marks are the results for racemization and the closed marks are those for dissociation.
○, ●: n-$C_nH_{2n+1}SO_3Na$; □, ■: n-$C_nH_{2n+1}N(CH_3)_3$-Br.

Formation of 1:1 Aggregate: Figure 4 shows the plot of the logarithm of the 1:1-aggregate formation constant ($\log K_1$) against the alkyl-chain length (n) of the sulfonate ion, together with a similar plot previously obtained for the systems containing alkyltrimethylammonium salts. A linear relationship was found between $\log K_1$ and n ($n\geqq8$), suggesting that the formation of the 1:1 aggregate is caused by hydrophobic interaction. The almost identical slopes of the two lines (Fig. 4) suggest that the interactions of the complex cation with alkanesulfonate anions and with alkyltrimethylammonium cations are of the same nature, or that hydrophobic interaction is responsible for the formation of the 1:1 aggregates. This is also supported by the result of our NMR study that the hexanesulfonate ion associates with $[Fe(phen)_3]^{2+}$ in such a way that the alkyl chain of the sulfonate ion lies on the phenanthroline ligand.[19] The energy of hydrophobic interaction between the complex and alkanesulfonate ions was estimated to be (0.9 ± 0.1) kJ mol^{-1} per methylene group from the slope of the line in Fig. 4. This is consistent with the value of (0.8 ± 0.1) kJ mol^{-1} obtained previously for the $[Fe(phen)_3]^{2+}$-alkyltrimethylammonium system.[15] The value of K_1 for each of the alkanesulfonate ions was about 40 times as large as that for the alkyltrimethylammonium ion of the same alkyl-chain length, reflecting the difference in the electrostatic energy between the cation-cation and the cation-anion interaction; this corresponds to a difference of 9.2 kJ mol^{-1} in the free-energy change in the ion-pair formation.

Formation of 1:m Aggregates: Aggregates higher than 1:1 were found to be formed for the $[Fe(phen)_3]^{2+}$-RSO_3^- system, but not for the $[Fe(phen)_3]^{2+}$-alkyltrimethylammonium system. This indicates that electrostatic attraction between the complex cation and sulfonate anions partly compensates for the repulsion between sulfonate anions, thus facilitating the formation of the 1:m aggregate. Since a remarkable increase in the rates of racemization and dissociation of $[Fe(phen)_3]^{2+}$ occurred below the cmc, premicellar aggregates must be responsible for the changes in the rates. Thus, "micellar catalysis" may, in some cases, originate from interaction with surfactant ions rather than from that with micelles.

Racemization-rate Constants of $[Fe(phen)_3]^{2+}$ in the Aggregates: The values of k_{1r} for $[Fe(phen)_3]^{2+}$ in the 1:1 aggregate were two (n=4) to three (n=10) times as large as the value of k_{0r}. This resembles our previous finding that the formation of the 1:1 aggregate with the alkyltrimethylammonium cation (n-$C_nH_{2n+1}N^+$-$(CH_3)_3$, n=6—10) increased the racemization rate of the complex ion by a factor of two to four. The similarity between these two cases shows that the difference in the charge of the organic ions has little effect on the racemization rate. This confirms the previous argument that the effect of the organic ions accelerating the racemization of $[Fe(phen)_3]^{2+}$ is caused by an interaction of the complex ion with the alkyl group of the organic ions, and not by their action as electron donors.[15]

The following mechanism is proposed for this acceleration. In a transition state of the racemization through a twist process, the metal-ligand bonds of the complex ion have to stretch to a considerable extent so as to relax the steric repulsion between the phenanthroline ligands, especially between hydrogen atoms at the 2 and 9 positions of the ligands. As a result, the hydrophobic phenanthroline ligands are exposed to the solvent more extensively in the transition state of the racemization than in the initial state; therefore, the

transition state is more hydrophobic than the initial state[20] and is more strongly stabilized by the hydrophobic interaction. Thus, the association of the complex ion with the alkylammonium or alkanesulfonate ion may lead to the acceleration of the racemization. An alternative explanation of the role of the alkyl group in accelerating the racemization may be that its aggregate formation with the complex cation removes the iceberg structure around the complex cation, thus facilitating the intramolecular twist racemization. Similar mechanisms can account for the larger values of k_{mr} for the complex in $1:m$ aggregates than the values of k_{1r} in 1:1 aggregates (Tables 1 and 2); the hydrophobic stabilization of the transition state is greater for the $1:m$ aggregate than for the 1:1 aggregate, or the iceberg structure is more efficiently removed from the complex in a $1:m$ aggregate than in a 1:1 aggregate.

Dissociation-rate Constants of $[Fe(phen)_3]^{2+}$ in the Aggregates: The values of k_{1d} for $[Fe(phen)_3]^{2+}$ in the 1:1 aggregates were one-fourth of the value of k_{0d}, and were almost independent of the value of n (n=6, 8, and 10; Table 1). The lower rate constant for the 1:1 aggregate can be related to a smaller number of water molecules in direct contact with the complex ion if the dissociation of the complex ion proceeds through a 7-coordinate transition state with a coordinated water molecule.[13] The situation is similar to the case of the hydrophobic aggregate with the alkylammonium cation.[15] However, the complex ions in the present aggregates show small but appreciable values of k_{1d}, in contrast to the very small values for the complex ion in the aggregate with alkyltrimethylammonium cations.[15] This difference indicates that the dissociation-rate constant is affected by the charge of the aggregates. The higher charge (+3) of the aggregate of the complex cation with the alkylammonium cation causes a stronger electrostriction of water around the aggregate. Therefore, the activity of the water should be lowered and the water-molecule-assisted dissociation should be retarded.

The values of k_{md} for $[Fe(phen)_3]^{2+}$ in $1:m$ aggregates were ten times as large as the value of k_{1d} (Tables 1 and 2). This may be because monomeric water molecules exist among the sulfonate ions in the $1:m$ aggregates; such water molecules should have no necessity to break hydrogen bonding with bulk water to react with the complex ion. The large k_{md} values may also result from the greater stabilization of the transition state, which should be more hydrophobic than the initial state because of the expansion of metal-ligand bonds.[20]

This research was partly supported by a Grant-in-Aid for Science Research No. 574234 from the Ministry of Education, Science and Culture. We wish to thank Professor Shoichi Ikeda and Dr. Sumio Ozeki of Nagoya University for their helpful discussions.

(Received May 28, 1983)

The kinetics of the racemization of $[Ni(phen)_3]^{2+}$ were investigated in the presence of 1-alkanesulfonate ions (n-$C_nH_{2n+1}SO_3^-$; n=8, 10, 12, and 14). The racemization rate decreased with the increase in the alkanesulfonate concentrations in the region of low sulfonate concentrations; then, in the region of higher concentrations, it began to increase, but it never exceeded the rate in water. The rate changes at low and high alkanesulfonate concentrations were related to the formation of the 1:1 and 1:m aggregates of the complex ion with alkanesulfonate ions respectively. A comparison of the aggregate formation constants of $[Ni(phen)_3]^{2+}$ with those of $[Fe(phen)_3]^{2+}$ confirmed that hydrophobic interaction is responsible for the aggregate formation. The energy of hydrophobic interaction between $[Ni(phen)_3]^{2+}$ and an alkanesulfonate ion was estimated to be 1.0±0.1 kJ mol^{-1} per methylene group of the latter. The kinetic behavior of the racemization of $[Ni(phen)_3]^{2+}$ in the aggregates was also compared with those of the racemization and dissociation of $[Fe(phen)_3]^{2+}$, and it was discussed in relation to the racemization mechanism of $[Ni(phen)_3]^{2+}$. The reaction rates of the complexes in D_2O solutions were also reported.

Aromatic diimines, such as 1,10-phenanthroline and 2,2′-bipyridine, are among the most important ligands in coordination chemistry. Because of their hydrophobicity, metal complexes of these ligands show unique interactions with hydrophobic solutes in aqueous solutions.[1-3]

We previously measured the effects of alkylammonium cations[4] and 1-alkanesulfonate anions[5,6] on the rates of racemization and dissociation of $[Fe(phen)_3]^{2+}$. The results at low organic-ion concentrations were related satisfactorily to the formation of the 1:1 aggregates of the complex and organic ions caused by hydrophobic interactions. In solutions of higher alkanesulfonate concentrations, the rate behavior of the complex was related to the formation of the 1:m aggregates of the complex and alkanesulfonate ions.

One object of the present work is to confirm the formation of the aggregates of the tris(1,10-phenanthroline)metal ion with alkansulfonate ions and to see whether the aggregate formation occurs entirely by means of electrostatic and hydrophobic interactions or by any other interactions specific for the metal ion of the chelate. Another object is to disclose the effect of RSO_3^- on the racemization rate of $[Ni(phen)_3]^{2+}$. A comparison of the effect with those of RSO_3^- on the racemization and dissociation rates of $[Fe(phen)_3]^{2+}$ previously obtained[6] will give information regarding the racemization mechanism of $[Ni(phen)_3]^{2+}$.[7]

Experimental

The synthesis and optical resolution of $(-)_{589}$-$[Ni(phen)_3](ClO_4)_2 \cdot 3H_2O$ was carried out according to the method of Dwyer and Gyarfas;[8] $[\alpha]_{589} = -1400°$. Deutrium oxide was supplied by the Aldrich Chemical Co. (99.8 atom% D). Racemization rates were obtained at 25.0°C by following the decrease in the optical rotation (405 nm) of the solution, containing 5×10^{-5} mol dm^{-3} of the optically active complex as perchlorate and a proper concentration of 1-alkanesulfonate, on a Union PM101 automatic polarimeter. The reactions were followed for two to four half-lives. They were first order in the concentration of the metal complex in the time range studied. The racemization-rate constant was defined as $k_r = [\ln(\alpha_0/\alpha_t)]/t$, where α_0 and α_t represent the optical rotations at times zero and t respectively, and was calculated by the usual method for the first-order reactions. The racemization and dissociation rates of $[Fe(phen)_3]^{2+}$ in H_2O and D_2O were obtained at 25.0°C with 5×10^{-5} mol dm^{-3} $[Fe(phen)_3](ClO_4)_2$ in a way similar to that described in our previous paper.[6] The other chemicals and procedures were the same as those described previously.[6]

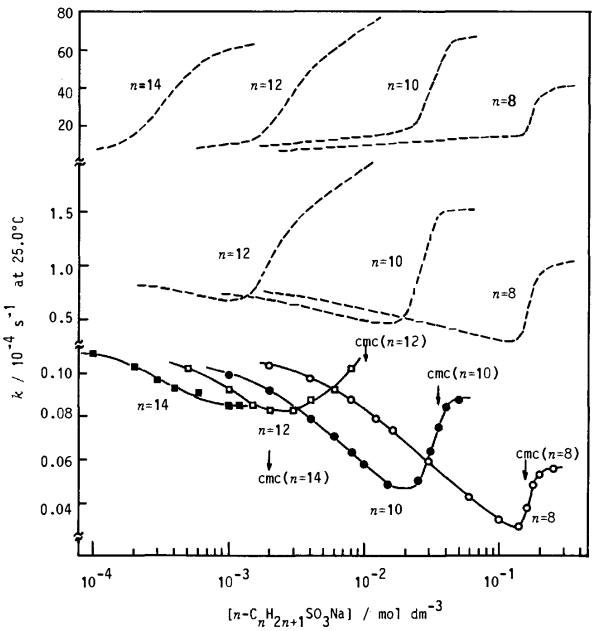

Fig. 1. The racemization rate constants of $[Ni(phen)_3]^{2+}$ (5×10^{-5} mol dm^{-3}) in the presence of sodium alkanesulfonates: ○, n-$C_8H_{17}SO_3Na$; ●, n-$C_{10}H_{21}SO_3Na$; □, n-$C_{12}H_{25}SO_3Na$; ■, n-$C_{14}H_{29}SO_3Na$. The solid curves show the values calculated on the basis of Eq. 8. The arrows indicate the cmc values for each sodium alkanesulfonate. The broken curves give the results previously obtained for the dissociation (middle) and racemization (top) of $[Fe(phen)_3]^{2+}$.

TABLE 1. THE AGGREGATION NUMBER OF ALKANESULFONATE (m) IN THE AGGREGATE WITH $[Ni(phen)_3]^{2+}$ AND THE AGGREGATE FORMATION CONSTANTS OF THE 1 : 1 (K_1) AND 1 : m (β'_m) AGGREGATE OF THE COMPLEX WITH ALKANESULFONATE AT 25.0 °C[a)]

Alkanesulfonate	K_1/mol^{-1} dm^3	m	log(β'_m/mol^{-m} dm^{3m})
n-$C_8H_{17}SO_3^-$	54±4 (70±14)	14±2 (14±2)	11.7±1.6 (11.8±1.6)
n-$C_{10}H_{21}SO_3^-$	164±14 (177±34)	8±1 (8±1)	12.8±1.6 (13.1±1.2)
n-$C_{12}H_{25}SO_3^-$[b)]	280±80 (320±40)	3 (3—4)	8.7±0.4[c)] (8.0—10.8)
		8 (8)	19.5±0.5[c)] (18.0—19.0)
n-$C_{14}H_{29}SO^{3-}$	430±390 (770±120)	3±1 (3—4)	10.5±3.5 (10.8—14.4)

a) The values in parentheses are those for the systems of $[Fe(phen)_3]^{2+}$-alkanesulfonates (from Ref. 6). b) The m values for this system are assumed to be equal to the values for the systems containing decane- and tetradecanesulfonate. c) These values were obtained by assuming k_3 and k_8 to be equal to 0.83 and 1.10 respectively.

Results

In Fig. 1, the measured rate constants of the racemization of $[Ni(phen)_3]^{2+}$ are plotted against the logarithm of the alkanesulfonate-ion concentration. The racemization and dissociation rate constants of $[Fe(phen)_3]^{2+}$ previously obtaind are also shown in the figure. A comparison of the profiles of the rate changes of the two complexes suggests that the rate behavior of $[Ni(phen)_3]^{2+}$ may be explained in a fashion similar to the case of $[Fe(phen)_3]^{2+}$;[5,6] the complex ion forms the 1:1 and 1:m ($m \geqq 2$) aggregates with alkanesulfonate ions in the regions of low and high alkanesulfonate concentrations respectively. Then, the following mechanism can be considered:

$$(-)\text{-}[Ni(phen)_3]^{2+} + RSO_3^- \overset{\beta'_1}{\rightleftharpoons} (-)\text{-}[Ni(phen)_3]^{2+}\cdot RSO_3^-, \quad (1)$$

$$(-)\text{-}[Ni(phen)_3]^{2+} + m\,RSO_3^- \overset{\beta'_m}{\rightleftharpoons} (-)\text{-}[Ni(phen)_3]^{2+}\cdot m\,RSO_3^- \quad (2)$$

$$(-)\text{-}[Ni(phen)_3]^{2+} \xrightarrow{k_0} rac\text{-}[Ni(phen)_3]^{2+}, \quad (3)$$

$$(-)\text{-}[Ni(phen)_3]^{2+}\cdot RSO_3^- \xrightarrow{k_1} rac\text{-}[Ni(phen)_3]^{2+}\cdot RSO_3^-, \quad (4)$$

$$(-)\text{-}[Ni(phen)_3]^{2+}\cdot m\,RSO_3^- \xrightarrow{k_m} rac\text{-}[Ni(phen)_3]^{2+}\cdot m\,RSO_3^- \quad (5)$$

$$\beta'_1 = \frac{[Ni(phen)_3{}^{2+}\cdot RSO_3^-]}{[Ni(phen)_3{}^{2+}][RSO_3^-]} = K_1\frac{f_2 f_1}{f_1}, \quad (6)$$

$$\beta'_m = \frac{[Ni(phen)_3{}^{2+}\cdot m\,RSO_3^-]}{[Ni(phen)_3{}^{2+}][RSO_3^-]^m}, \quad (7)$$

where k_0, k_1, and k_m represent the rate constants of the complex cation associated with zero, one, and m alkanesulfonate ions respectively, and where f_z shows the activity coefficient of an ion as a function of its charge ($\pm z$).[9] Therefore, the racemization rate constant is expressed by:

$$k = \frac{k_0 + k_1\beta'_1[RSO_3^-] + \sum_{m=2}^{\infty} k_m\beta'_m[RSO_3^-]^m}{1 + \beta'_1[RSO_3^-] + \sum_{m=2}^{\infty}\beta'_m[RSO_3^-]^m}. \quad (8)$$

The kinetic results were analyzed on the basis of Eq. 8 in a way similar to that used for the $[Fe(phen)_3]^{2+}$-RSO_3^- system.[6] The k_0, k_1, K_1 ($=\beta'_1/f_2$), m, k_m, and β'_m values thus obtained are listed in Tables 1 and 2. They were substituted into Eq. 8 to calculate the solid curves in Fig. 1.

The rate constants of the racemization of $[Ni(phen)_3]^{2+}$, as well as those of the racemization and dissociation of $[Fe(phen)_3]^{2+}$, as measured in H_2O and D_2O solutions, are listed in Table 3.

TABLE 2. RACEMIZATION RATE CONSTANTS OF $[Ni(phen)_3]^{2+}$ IN THE 1:1 AND 1:m AGGREGATES OF THE COMPLEX ION WITH ALKANESULFONATE IONS[a)]

Alkanesulfonate	k_1	k_m	m
None	(k_0=0.113±0.002)	—	—

$[Fe(phen)_3]^{2+}$ racemization	6.7±0.3	5.50±0.27	0.82±0.08

Discussion

*Formation of the 1:1 and 1:*m *Aggregates.* In octanesulfonate- and decanesulfonate-containing systems, the racemization rate of $[Ni(phen)_3]^{2+}$ changed with the alkanesulfonate concentration in a similar way to that of the dissociation rate of $[Fe(phen)_3]^{2+}$. On the other hand, in dodecanesulfonate- and tetradecanesulfonate-containing systems, the features of the rate change were somewhat different between the two complexes (Fig. 1). The results of the analysis (Table 1) showed, however, that the K_1, m, and β'_m values for the $[Ni(phen)_3]^{2+}$-RSO_3^- systems agreed with

those previously obtained for the $[Fe(phen)_3]^{2+}$-RSO_3^- systems within the limits of experimental uncertainty, even for the latter systems.[6] This confirmed that the rate changes of $[Ni(phen)_3]^{2+}$ in the dodecane- and tetradecanesulfonate solutions were also induced by the formation of the 1:1 and 1:*m* aggregates.

The essential agreements of the values for K_1, *m*, and β'_m between the two complexes (Table 1) also suggests that the formation of aggregates is not specific for the kind of metal ion in the tris(1,10-phenanthroline)metal chelate, but that hydrophobic interaction is responsible for the aggregate formation, as has been proposed previously.[6] The energy of hydrophobic interaction between $[Ni(phen)_3]^{2+}$ and RSO_3^- was estimated from the K_1 values (Table 1) to be 1.0 ± 0.1 kJ mol^{-1} per methylene group of the sulfonate ion, a value consistent with that of 0.9 ± 0.1 kJ mol^{-1} obtained for $[Fe(phen)_3]^{2+}$-RSO_3^- systems.

Rate Constants of $[Ni(phen)_3]^{2+}$ in the 1:1 and 1:m Aggregates. The Mechanism of the Racemization of the Complex: The rate *vs.* concentration curves for the racemization of $[Ni(phen)_3]^{2+}$ are analogous to those for the dissociation, rather than those for the racemization, of $[Fe(phen)_3]^{2+}$ (Fig. 1). The ratios of the rate constants, k_1/k_0 ($\approx$0.1) and k_m/k_1 ($\approx$9), for the racemization of $[Ni(phen)_3]^{2+}$ (Table 2) were of magnitudes comparable to those ($k_1/k_0\approx0.2$ and $k_m/k_1\approx10$) for the dissociation of $[Fe(phen)_3]^{2+}$. These observations may reflect the process of racemization-*via*-dissociation for $[Ni(phen)_3]^{2+}$.

While $[Fe(phen)_3]^{2+}$ was shown to dissociate by the aid of nucleophiles including water,[10] the racemization of $[Ni(phen)_3]^{2+}$ was reported to be unaffected by a strong nucleophile such as hydroxide.[11] In order to see if water is involved in the rate-determining step of the $[Ni(phen)_3]^{2+}$ racemization, studies were made for the D_2O-H_2O isotope effects of this reaction as well as the dissociation and racemization of $[Fe(phen)_3]^{2+}$. Table 3 shows that the rate in D_2O was about 80% of the rate in H_2O in each case studied. This shows that water is involved in the rate-determining step of each reaction;[12] thus, our attempt to use the H-D isotope effect for the differentiation of the reaction mechanisms failed. Considering that an intramolecular mechanism has been confirmed for the racemization of $[Fe(phen)_3]^{2+}$,[7] the participation of water molecules in the rate-determining step of the reaction may indicate that a reorganization of the hydration sphere is necessary even for the intramolecular reaction. The failure in differentiating the mechanism by means of the H-D isotope effect may also be due to the fact that the hydrogen atom of H_2O is not directly concerned with the nucleophilic attack of a water molecule, but is involved in the hydrogen bonding with other water molecules or anions.

Kinetics of the Racemization and Dissociation of Tris(1,10-phenanthroline)-iron(II) and Tris(2,2′-bipyridine)iron(II) in Sodium Dodecyl Sulfate Solutions[1)]

Satoshi TACHIYASHIKI* and Hideo YAMATERA†
Laboratory of Chemistry, Kagawa Nutrition College, Sakado, Saitama 350-02
†*Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya, 464*
(Received August 12, 1983)

The kinetics of the racemization and dissociation of $[Fe(phen)_3]^{2+}$ (phen=1,10-phenanthroline) and $[Fe(bpy)_3]^{2+}$ (bpy=2,2′-bipyridine) was investigated in aqueous sodium dodecyl sulfate (SDS) solutions. The racemization and dissociation rates of the complexes increased with the increase in the SDS concentration to reach limiting values at concentrations above the critical micelle concentration (cmc). The rate changes occurring below the cmc were explained in terms of the formation of at least three kinds of premicellar aggregates of the complex ion with dodecyl sulfate ions. In the region slightly above the cmc, where the concentration of the complex ion is larger than that of the micelle, the rates continued to increase with the increase in the micellar concentration, suggesting that the complex ions interacted with the micelles. A comparison of the kinetic behavior in aqueous micellar solutions with that in organic solvents revealed that the complexes were located inside the micelle-water interface. The mechanisms of the acceleration in the micelle were discussed.

The micellar catalysis of chemical reactions has attracted much attention recently.[2)] Most of the studies reported so far have, however, been concerned with organic reactions. Relatively few are concerned with the reactions involving metal complexes.[2)] They include studies of the Hg^{2+}-induced aquation of $[CoCl(NH_3)_5]^{2+}$,[3)] the formation of Ni^{2+} and Mn^{2+} complexes with hydrophobic ligands,[4-6)] and electron-transfer reactions of hydrophobic metal complexes[7,8)] in sodium dodecyl sulfate (SDS) solutions. In all cases, changes in rate were observed in the regions of the SDS concentration both above and below the cmc. The changes in the rate above the cmc have been discussed as an example of micellar catalysis, but less attention has been paid to the changes in rate occurring below the cmc.

We previously studied the effects of alkyltrimethylammonium bromides[9)] and sodium 1-alkanesulfonates[10,11)] on the rates of the racemization and dissociation of $[Fe(phen)_3]^{2+}$ (phen=1,10-phenanthroline). Each of the cationic and the anionic surfactants affects the rates mainly at concentrations below the cmc. The rate changes were explained by the formation of premicellar aggregates of the complex ion with the surfactant ions. Above the cmc of each system, however, we could not specify whether or not the complex ion interacted with the micelles, since the rates remained almost unchanged above the cmc.

In this paper, we will report on kinetic studies of the racemization and dissociation of $[Fe(phen)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$ (bpy=2,2′-bipyridine) in SDS solutions; investigations were made to elucidate the nature of the interaction of the complex ions with monomeric and micellar dodecyl sulfate ions below and above the cmc, and to clarify the dependence of the racemization and dissociation rates on the SDS concentration.

Experimental

The synthesis and optical resolution of $(+)_{589}$-$[Fe(phen)_3](ClO_4)_2 \cdot 2H_2O$[12)] and $(+)_{589}$-$[Fe(bpy)_3](ClO_4)_2 \cdot 2H_2O$[13)] were carried out according to the method of Dwyer and Gyarfas; $[\alpha]_{589}=1400°$ and $[\alpha]_{589}=4900°$. Sodium dodecyl sulfate from Merck (for tenside test) was recrystallized five times from ethanol and then dried under reduced pressure. Sodium chloride from Merck (Suprapur) and hydrochloric acid from Wako (Super Special Grade) were used without further purification. The kinetic measurements were carried out at 25.0 °C with the perchlorate of each complex ([complex]=5×10^{-5} mol dm^{-3}) in solutions containing SDS[14)] with and without NaCl ([NaCl]=0, 0.02, 0.15, 0.40, and 1.00 mol dm^{-3}). The dissociation rates of the complexes were observed in the presence of 5.0×10^{-4} mol dm^{-3} nickel(II) chloride, except for the systems containing HCl. (Both Ni^{2+} and H^+ are effective scavengers for the ligands released during the reactions.) The racemization rates of $[Fe(phen)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$ were observed by following the optical rotation of the solutions at 546 and 589 nm, and their dissociation rates, by following the absorbance at 510 and 520 nm, respectively. Multiple measurements under the same experimental conditions gave rate constants reproducible within ±5% and ±1% respectively for the racemization and dissociation of the complexes. The other reagents and procedures were described in our previous paper.[15)]

Results and Discussion

Interaction of $[Fe(phen)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$ with Dodecyl Sulfate Ions Below cmc. Rate Behavior of the Complexes in SDS Solutions: Figure 1 shows the observed racemization and dissociation rate constants of $[Fe(phen)_3]^{2+}$ against the SDS concentration in the absence and the presence of NaCl (0, 0.02 and 0.15 mol dm^{-3}). The dissciation rate of the complex slightly decreased, and the racemization rate slightly increased, with the increase at SDS concentrations below 0.3×10^{-3} mol dm^{-3}. In the range of $(0.3—1.0) \times 10^{-3}$ mol dm^{-3}, the rates increased steeply with the increase in the SDS concentration in the presence of NaCl, while the dodecyl sulfate of the complex was precipitated in this range of SDS concentrations in the absence of NaCl. Such a precipitation has also been reported for the $[Ru(bpy)_3]^{2+}$-SDS system[16)]. At SDS concentrations higher than 1×10^{-3} mol dm^{-3}, the increases in the rates became less steep and reached the limiting values within the range of experimental uncertainty at the SDS concentration characteristic of

the system. Similar features are shown by $[Fe(bpy)_3]^{2+}$, as is depicted in Fig. 2. With the rate changes of the complexes in SDS solutions, the absorption spectra of the complexes changed slightly in a fashion similar to that reported for the $[Fe(phen)_2(CN)_2]$-SDS system.[7]

Formation of the Premicellar Aggregates of the Complex Ions with Dodecyl Sulfate Ions: The cmc values of the SDS solutions containing the complex ions[17] are indicated by arrows in Figs. 1 and 2. Since the rate change in each system occurred mainly below the respective cmc, the change may be accounted for by the formation of the premicellar aggregates of the complex ions with dodecyl sulfate ions, and not by the interaction of the complex ions with micelles. The same applies to the spectral changes accompanied by the rate changes. This is in contrast to the previous reports on the $[Fe(phen)_2(CN)_2]$, $[Fe(phen)_2(CN)_2]^+$, and $[Ru(bpy)_3]^{2+}$[16] systems, in which the spectral changes of the complexes in SDS solutions were related to the incorporation of the complexes into SDS micelles.[7,8,16]

Analysis of the Kinetic Results: The racemization and dissociation rates of $[Fe(phen)_3]^{2+}$ changed with the SDS concentration in at least three steps (Fig. 1): changes in the regions of the SDS concentrations below 0.3×10^{-3} mol dm^{-3}, changes between 0.3 and 1.0×10^{-3} mol dm^{-3} and changes higher than 1×10^{-3} mol dm^{-3}. The rate changes of the three steps can be related to the formation of at least three kinds of aggregates of the complex ion with dodecyl sulfate ions.

By analogy with the previous results for the $[Fe(phen)_3]^{2+}$-1-dodecanesulfonate[11] and $[Ni(phen)_3]^{2+}$-1-dodecanesulfonate systems,[18] the first step in the rate change can be attributed to the formation of the 1:1 aggregate of the complex ion and the dodecyl sulfate ion, and the second and third steps, to the formation of 1:3 or 1:4 and 1:8 aggregates. Then, the gross rate constant, k, can be expressed as:

$$k = \frac{k_0 + k_1\beta'_1[DS^-] + k_m\beta'_m[DS^-]^m + k_8\beta'_8[DS^-]^8}{1 + \beta'_1[DS^-] + \beta'_m[DS^-]^m + \beta'_8[DS^-]^8}, \quad (1)$$

where k_0, k_1, k_m, and k_8 represent the rate constants of the complex ion aggregated with zero, one, m (m=3 or 4), and eight dodecyl sulfate ions respectively. The β'_1, β'_m, and β'_8 mean the gross concentration formation constants for the aggregates of the complex ion with one, m, and eight dodecyl sulfate ions respectively, and $[DS^-]$, the concentration of free dodecyl sulfate ions.

In the analysis of the kinetic data for the $[Fe(phen)_3]^{2+}$- SDS system, the values of β'_1, k_{1r} (k_1 for racemization), and k_{1d} (k_1 for dissociation) were assumed to be equal to the corresponding values for the $[Fe(phen)_3]^{2+}$-1-dodecanesulfonate system, *i.e.*, k_{1r}= 2.1×10^{-3} s^{-1}, $k_{1d}=0.026\times10^{-3}$ s^{-1}, and β'_1= 270, 220, and 170 $mol^{-1}dm^3$ for systems without NaCl, with [NaCl]=0.02, and 0.15 mol dm^{-3} respectively.[11] With these parameter values, the kinetic results at low SDS concentrations were analyzed graphically by disregarding the formation of the 1:8 aggregate. The transformation of Eq. 1 disregarding the $[DS^-]^8$ terms leads to this relation:

$$k = k_m - \frac{1}{\beta'_m}\frac{(k-k_0) + (k-k_1)\beta'_1[DS^-]}{[DS^-]^m}. \quad (2)$$

Plots of k *vs.* $\{(k-k_0)+(k-k_1)\beta'_1[DS^-]\}/[DS^-]^m$ should give a straight line with a slope of $-1/\beta'_m$ and an intercept of k_m for m= 3 and 4. The transformation of Eq. 1 (including the $[DS^-]^8$ terms) leads to this relation:

$$k = k_8 - \frac{1}{\beta'_8}\frac{(k-k_0) + (k-k_1)\beta'_1[DS^-] + (k-k_m)\beta'_m[DS^-]^m}{[DS^-]^8} \quad (3)$$

The k_8 and β'_8 values were obtained by plotting the rate constants at high SDS concentrations against the ratio appearing at the extreme right of Eq. 3. Then, the sets of the k_m, β'_m, k_8, and β'_8 values for m=3 and 4 were recalculated by the least-squares fit[19] of Eq. 1 to the kinetic data; they are given in Table 1. These values were

a) The parameter values of k_{0r}=0.65, k_{0d}=0.0794, 0.0757, and 0.0746, of k_{1r}=2.1, k_{1d}=0.026/10^{-3}s^{-1}and of β_1'=270, 220, and 170 for systems of [NaCl]=0, 0.02, and 0.15 mol dm^{-3} respectively, were assumed for the analysis of the results for $[Fe(phen)_3]^{2+}$-SDS systems. The values of k_{0r}=0.61 and 0.59, and of k_{0d}=0.118 and 0.122/10^{-3}s^{-1} for systems of [NaCl]=0 and 0.15 mol dm^{-3} respectively, and β_1'=0 were assumed for $[Fe(bpy)_3]^{2+}$-SDS systems. b) Average values obeained from racemization and dissociation experiments. c) Average values of the rate constants in solutions of the SDS concenration higher than 0.012 mol dm^{-3}. These values were assumed for the analysis.

used to calculate the k_r and k_d values, which are shown as the solid (for m=3) and broken (for m=4) curves in Fig. 1.

The changes in the racemization and dissociation rates of $[Fe(bpy)_3]^{2+}$ (Fig. 2) with the SDS concentration are similar to those for $[Fe(phen)_3]^{2+}$(Fig. 1). This suggests that the mechanisms of the rate changes are similar between the two complexes. Since the k_1 and β_1' values for the $[Fe(bpy)_3]^{2+}$-SDS or similar systems were not available, and since the formation of the 1:1 aggregate showed only a small effect on the measured reaction rates (as may be seen from the rate changes at low concentrations in Fig. 2), the kinetic results for the system were analyzed by disregarding the formation of the 1:1 aggregate. The disregard of the formation of the 1:1 aggregate for the $[Fe(phen)_3]^{2+}$-SDS system has little effect on the k_m, k_8, β_m', and β_8' values, although it enlarged the difference between the observed and the calculated rate constants at low SDS concentrations. For the $[Fe(bpy)_3]^{2+}$-SDS system, the calculated rate constants based on the parameter values obtained by disregarding the formation of the 1:1 aggregate agreed well with the observed values at low SDS concentrations (Fig. 2), showing that the approximation for the analysis was reasonably good. The results of the analysis for this system are listed in Table 1.

Table 1 shows that the aggregate formation constants, β_m' and β_8', are larger for systems with added NaCl than those without NaCl and larger for systems containing $[Fe(phen)_3]^{2+}$ than those containing $[Fe(bpy)_3]^{2+}$. This is natural since hydrophobic interaction is more pronounced in NaCl solutions than in solutions without NaCl, and phen is more hydrophobic than bpy.

Interaction of $[Fe(phen)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$ with SDS Micelles Above cmc. The phenomenon that the rates changed below the cmc, while they remained almost constant above the cmc, suggests that the complex ions

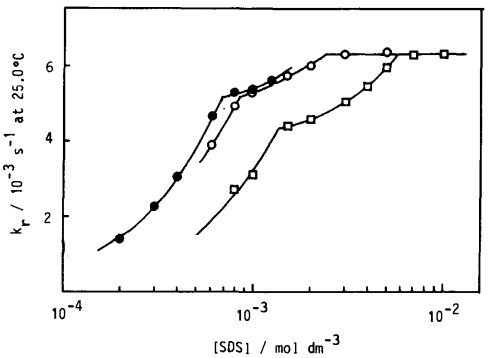

Fig. 3. Plot of the racemization rate constants of $[Fe(phen)_3]^{2+}$ against the logarithm of SDS concentration. ○, [NaCl]=0.4 mol dm^{-3}, $[Fe(phen)_3^{2+}]$=5×10^{-5} mol dm^{-3}; ●, [NaCl]=1.0 mol dm^{-3}, $[Fe(phen)_3^{2+}]$=5×10^{-5} mol dm^{-3}; □, [NaCl]=0.15 mol dm^{-3}, $[Fe(phen)_3^{2+}]$=2.5×10^{-4}mol dm^{-3}.

did not interact with micelles or that the reactivities of the complexes in the micelles were nearly the same as those in the aggregates. In order to clarify whether or not the complex ions interacted with the micelles, we measured the racemization rates of $[Fe(phen)_3]^{2+}$ in NaCl solutions ([NaCl]=0.4 and 1.0 mol dm^{-3} with [complex]=5×10^{-5} mol dm^{-3} and [NaCl]=0.15 mol dm^{-3} with [complex]=25×10^{-5} mol dm^{-3}, Fig. 3). In each case, the rate increased with an increase in the SDS concentration, steeply in the first region and then linearly and less steeply in the second region, until the rate reached a limiting value. Two break points were clearly observed. The SDS concentration at the first break point roughly corresponds to the cmc value,[20,21] suggesting that the micelles participated in the rate increase at the second step. The linear rate increase in the second region and the sharpness of the second break indicate that the association constant of the complex ions with the micelles is large and that the

a) 0.02 mol dm^{-3}. b) The values in parentheses are the standard deviations.

association with the micelles was completed at the second break point. The number of $[Fe(phen)_3]^{2+}$ per micelle was calculated on the basis of the micellar concentration at the second break point and the concentration of the complex to be 6.7 and 4.3 in 0.15 and 0.4 mol dm^{-3} NaCl solutions respectively.[22] A similar number, 4.1, was reported for the $[Ru(bpy)_3]^{2+}$-SDS system.[16]

Location of the Complex Ions in a Micelle: The limiting rate of the racemization and dissociation of $[Fe(phen)_3]^{2+}$ in SDS solutions were, respectively, 10 and 1.7 times the rates in pure water, while those of $[Fe(bpy)_3]^{2+}$ were, respectively, 2.8 and 1.2 times the rates in pure water (Figs. 1 and 2). Similar increases in the reaction rates were also observed when the complex ions were dissolved in organic solvents[23-25] or were in contact with alkyl groups.[9,11] By analogy, the complex ions in the micelle are in contact with the alkyl chains of the dodecyl sulfate ions. Table 2 lists the rate constants at various temperatures for the racemization of the complexes in micellar solutions and in pure water, as well as the activation parameters. Figure 4 shows a plot of the activation enthalpy *vs.* the activation entropy for the racemization of $[Fe(phen)_3]^{2+}$ in aqueous and in alcohol-water solutions.[26] The fact that the activation parameters for the racemization of $[Fe(phen)_3]^{2+}$ in the micellar solution are close to those in pure butanols and in concentrated aqueous ethanol (0.90 mol. fraction) suggests that the complex ions were located inside the micelle-water interface or at the "Stern region"[27,28] of the micelle, and not on the interface. The activation parameters for $[Fe(bpy)_3]^{2+}$ also showed a similar, though less pronounced, tendency.

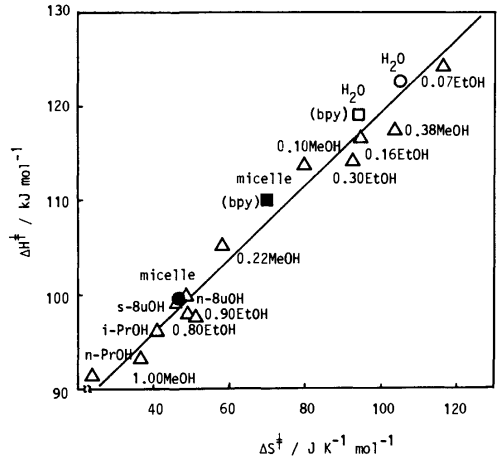

Fig. 4. Plot of activation enthalpy *vs.* activation entropy for the racemization of $[Fe(phen)_3]^{2+}$ (circle) and $[Fe(bpy)_3]^{2+}$ (square) in aqueous and micellar solutions and for the racemization of $[Fe(phen)_3]^{2+}$ in alcohol-water and alcohol solutions. ○, □: No SDS, no NaCl; ●, ■: 2×10^{-2} mol dm^{-3} SDS, no NaCl; △: alcohol-water (mole fraction of the alcohol is shown) and alcohol solutions.

Mechanism of Acceleration of the Reactions in the Micelle: The racemization of the complexes is known to proceed by means of an intramolecular twist mechanism in organic solvents.[25] The same is probably true for the complexes in the micelle. Table 2 shows that the higher rate of the racemization in micelles was brought about by the decrease in the activation enthalpy, though this decrease was partially compensated for by the decrease in the activation entropy. This can be related to the hydrophobic nature of the complex ions. In an aqueous solution, a cage-like "iceberg" structure formed around the complex ions[9] has to be broken for the complex ions to racemize, while no such iceberg structure is formed in the micelles and both $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are expected to be smaller.

The dissociation rates of the complexes increased in the micelle, though the increase was much less pronounced than that of the racemization rates. The higher rate of the dissociation of $[Fe(phen)_3]^{2+}$ in the micelle is related mainly to a smaller activation enthalpy, and that of $[Fe(bpy)_3]^{2+}$, to a larger activation entropy (Table 3). This difference may be due to the difference in the mechanism of the dissociation between the two complexes; in the latter complex, dissociation

probably occurs through a five-coordinate intermediate with an open bipyridine chelate ring.

Kinetics and Mechanism of Dissociation of $[Fe(bpy)_3]^{2+}$ in Acidic Micellar Solutions: The increase in the HCl concentration increased the dissociation rate of $[Fe(bpy)_3]^{2+}$ in solutions with (1×10^{-2} mol dm^{-3}) and without SDS (Fig. 5). The rate changes with the HCl concentration can be described by the mechanism proposed by Basolo *et al.* (Fig. 6).[29] According to this mechanism, the dissociation rate constant, k', is expressed by:

$$k' = \frac{k_1'(k_2' + k_3'[H^+])}{k_{-1}' + k_2' + k_3'[H^+]}, \quad (4)$$

where k_1', k_{-1}', k_2', and k_3' are the rate constants for the reaction steps shown in Fig. 6. When $[H^+]$ is sufficiently low, the value of k' will be approximately equal to the limiting value given by:

$$k_0' = k_1'\left(\frac{k_2'}{k_{-1}' + k_2'}\right). \quad (5)$$

Then Eq. 4 is transformed to:

$$k' = k_1' - \frac{k_{-1}' + k_2'}{k_3'}\frac{k' - k_0'}{[H^+]}. \quad (6)$$

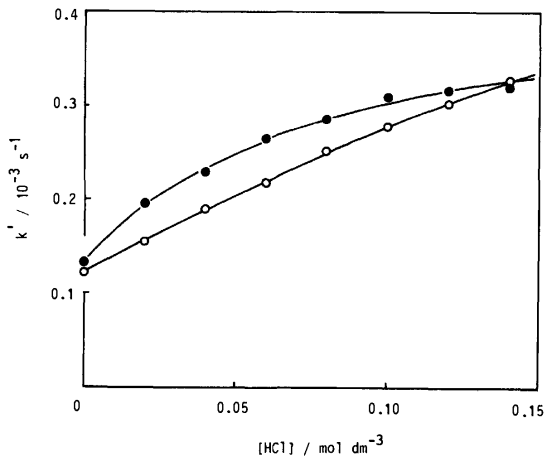

Fig. 5. Acid dependences of the dissociation rate constant of $[Fe(bpy)_3]^{2+}$ in aqueous and micellar solutions (I=0.15, NaCl): ○, No SDS; ●, 1×10^{-2} mol dm^{-3} SDS.

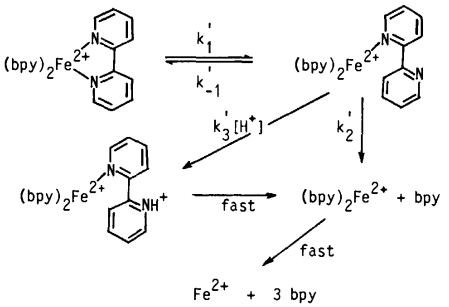

Fig. 6. Reaction scheme of the acid dependent dissociation of $[Fe(bpy)_3]^{2+}$.

TABLE 4. RESULTS OF THE ANALYSIS OF THE ACID DEPENDENCE OF THE DISSOCIATION RATE OF $[Fe(phen)_3]^{2+}$ IN AQUEOUS AND MICELLAR SOLUTIONS

	[SDS]=0	[SDS]=0.01 mol dm^{-3}
k_1' / 10^{-3} s^{-1}	1.3±0.5	0.44±0.03
k_2'/k_{-1}'	0.10±0.05	0.43±0.04
k_3'/k_{-1}' / mol^{-1} dm^3	1.8±1.1	18.1±4.3

The k' values were plotted against $(k'-k_0')/[H^+]$ to give a straight line with a slope of $-(k_{-1}'+k_2')/k_3'$ and an intercept of k_1'. These values, together with the k_0' ($=k_1'k_2'/(k_{-1}'+k_2')$) value, gave the k_2'/k_{-1}' and k_3'/k_{-1}' values listed in Table 4. The table shows that the rate constant of the formation of a five-coordinate intermediate with an open bipyridine chelate ring, k_1', is smaller in the presence of SDS than in its absence. In spite of this lower rate of intermediate formation, the dissociation rate of the complex was higher in the solution containing SDS (Fig. 5, for $[H^+]\leqq0.14$ mol dm^{-3}) because of the larger fraction of the intermediate undergoing dissociation (because of the larger $(k_2'+k_3'[H^+])/(k_{-1}'+k_2'+k_3'[H^+])$ value).

Mössbauer Spectroscopic Studies of the Effects of the $^6Li(n, \alpha)T$ Reaction in Lithium Tris(oxalato)ferrate(III)

Junko AKASHI, Yoshio UCHIDA, Tomoko KOJIMA, Motomi KATADA, and Hirotoshi SANO*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received June 4, 1983)

The chemical effects of the $^6Li(n,\alpha)T$ reaction in lithium tris(oxalato)ferrate(III) crystals were examined by means of Mössbauer spectroscopy. Neutron irradiations were carried out under different conditions in order to clarify the mechanism of the effects. The reduced iron(II) species observed in the spectrum of $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$, subjected to neutron irradiation (8.6×10^{15} n cm^{-2}) at 200 K, shows a larger Q.S. value than that in the spectrum of the sample neutron-irradiated at an ambient temperature (300—320 K) in a reactor, suggesting that the initially produced iron(II) species changes into another iron(II) species during the irradiation at the ambient temperature. A species identical with the initial iron(II) species produced in the neutron irradiation was found to be prepared by the pyrolysis of $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$. A comparison of neutron-irradiated hydrous and anhydrous $Li_3[Fe(C_2O_4)_3]$ suggests that the change in the iron(II) species is influenced by the existence of crystal water.

Mössbauer spectroscopy is one of the most useful tools in studying the chemical states nondestructively in solids. Based on the results of Mössbauer spectroscopic studies, it has been reported that iron(III) oxalate is reduced by γ-ray irradiation and that the results can be interpreted by the formation of iron(II) oxalate,[1] *i.e.*;

$$Fe_2(C_2O_4)_3 \rightarrow 2FeC_2O_4 + 2CO_2$$

Temperley suggested that the γ-ray-radiolysis of ammonium and sodium tris(oxalato)ferrate(III) could be explained by assuming this reaction;[2]

$$2M_3[Fe(C_2O_4)_3] \rightarrow 2FeC_2O_4 + 3M_2C_2O_4 \rightarrow 2CO_2,$$

while the iron(II) species observed in the Mössbauer spectrum of γ-ray-irradiated potassium tris(oxalato)-ferrate(III) was not definitely assigned to an iron(II) oxalate.[2] Bancroft *et al.* proposed this reaction;

$$2(K_3[Fe(C_2O_4)_3]\cdot 3H_2O) \rightarrow 2K_2[Fe(C_2O_4)_2(H_2O)_2] + K_2C_2O_4 + 2CO_2 + 2H_2O,$$

for the reduction induced by the γ-irradiation of the tris(oxalato)ferrate(III).[3]

Studies of the photo-irradiated potassium tris(oxalato)-ferrate(III) by using Mössbauer and infrared absorption spectroscopy have also revealed that several kinds of reduced iron species other than $FeC_2O_4\cdot 2H_2O$ were produced.[4]

Recently, we ourselves reported that a reduced iron(II) species was found in the Mössbauer spectrum taken for the $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ sample subjected to the $^6Li(n,\alpha)T$ reaction,[5] although the mechanism of the formation of iron(II) species had not yet been clarified in detail.

In the present paper, the species produced by the $^6Li(n,\alpha)T$ reaction in lithium tris(oxalato)ferrate(III) were compared with those produced by thermal decomposition in order to clarify the processes caused by the $^6Li(n,\alpha)T$ reaction.

Experimental

$Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ was prepared by a conventional method. The particle size of the sample was adjusted to 200—350 mesh throughout this work. The difference in the effects of the particle size will be shown elsewhere. Thermogravimetry and differential scanning calorimetry were carried out for $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ both in air and under nitrogen. The heating rate was kept at 5 K min^{-1}. Anhydrous $Li_3[Fe(C_2O_4)_3]$ was prepared by allowing the hydrous compound to stand for 10 min in an oven at 450 K in air. The anhydrous compound was kept in a desiccator over P_2O_5 to avoid moisture. The neutron irradiation of each 100-mg portion of the sample heat-sealed in a polyethylene envelope was carried out in a 100-kW Triga Mark II reactor at the Atomic Energy Institute of Rikkyo University. The irradiated samples were kept in liquid nitrogen until IR and Mössbauer measurements has been carried out.

In the thermal decomposition of $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$, a brown powder was obtained by putting the sample in an oven at 525—545 K for 5—10 min, either in air or under nitrogen, while a yellow powder was obtained when the sample was put in an oven at 500—510 K for 5—10 min under nitrogen.

The Mössbauer spectra were determined by using a constant-acceleration-type spectrometer. The isomer-shift values were reported with respect to iron foil. The infrared spctra were taken by the KBr method.

Results and Discussion

Mössbauer spectra of the neutron-irradiated (for 2 h at a fluence rate of 1.2×10^{12} n s^{-1} cm^{-2}) $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ are shown in Fig. 1. The new doublet produced by the $^6Li(n,\alpha)T$ reaction shows a different Q.S. value depending on the temperature during the irradiation. The doublet A in Fig. 1(a), where the neutron irradiation was carried out at 200 K, has a larger Q.S. value (2.63 mm s^{-1}) than that (1.97 mm s^{-1}) of the doublet B shown in Fig. 1(b), where the neutron irradiation was carried out at the ambient temperature in the reactor (roughly estimated to be 300—320 K). The isomer-shift values of these doublets coincide with each other within the limits of experimental error. Figure 1(c) shows the spectrum of the same sample as that shown in Fig. 1(a) after it had been allowed to stand for 5 months at room temperature (295—298 K). The doublet A decreases in intensity, and a doublet appears at the same position as that of the doublet B. The results suggest that an unstable species which has a larger Q.S. value changes into a stable species during the irradiation at the ambient temperature or during storage for a long time at room temperature.

The results of the thermogravimetry and differential

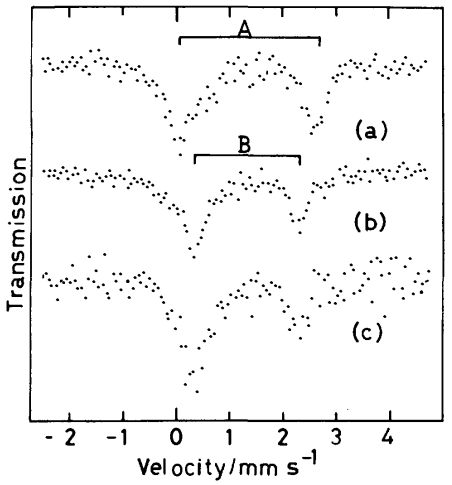

Fig. 1. Mössbauer spectra at 80 K of (a) neutron-irradiated (1.2×10^{12} n s^{-1} cm^{-2}, 2 h, at 200 K) $Li_3[Fe(C_2O_4)_3]\cdot4.5H_2O$, (b) neutron-irradiated (1.2×10^{12} n s^{-1} cm^{-2}, 2 h, at an ambient temperature) $Li_3[Fe(C_2O_4)_3]\cdot4.5H_2O$, and (c) neutron-irradiated (1.2×10^{12} n s^{-1} cm^{-2}, 2 h, at 200 K) $Li_3[Fe(C_2O_4)_3]\cdot4.5H_2O$ after storage for 5 months at room temperature.

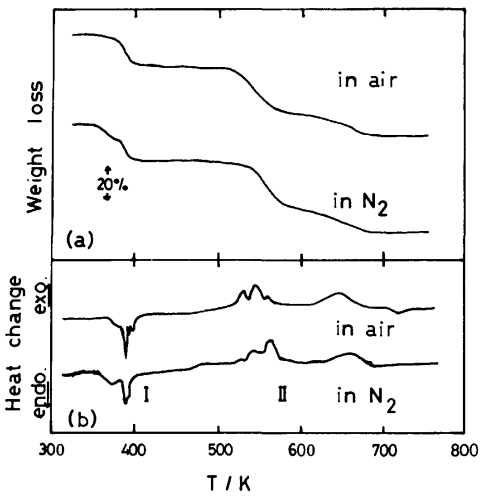

Fig. 2. (a) TG curves for $Li_3[Fe(C_2O_4)_3]\cdot4.5H_2O$ in air and under nitrogen, and (b) DSC curves for $Li_3[Fe(C_2O_4)_3]\cdot4.5H_2O$ in air and under nitrogen.

scanning calorimetry of $Li_3[Fe(C_2O_4)_3]\cdot4.5H_2O$, both in air and under nitrogen, are shown in Fig. 2. As is shown by the TG curves, the hydrous complex evolves 4.5 mol of water endothermically in stage I. The split peak in the DSC curves of dehydration indicates that the water molecules are not held uniformly in the crystal lattice. On the basis of the results, it is concluded that the dehydration ocurrs at a higher temperature in lithium tris(oxalato)ferrate(III) than the temperature reported for the corresponding potassium salt.[6-9]

For $K_3[Fe(C_2O_4)_3]\cdot3H_2O$, a decomposition reaction such as

$$K_3[Fe(C_2O_4)_3]\rightarrow K_2[Fe(C_2O_4)_2]+1/2K_2C_2O_4+CO_2$$

was proposed for the second stage under nitrogen, where one mol of CO_2 was evolved.[6-9] On the contrary, a weight change corresponding to two moles of CO_2 was observed in stage II of the thermal decomposition of $Li_3[Fe(C_2O_4)_3]\cdot4.5H_2O$, either in air or under nitrogen.

A Mössbauer spectrum of thermal-decomposition product in stage II in air is shown in Fig. 3(a). When the decomposition occurs at 525—545 K, a doublet ascribed to a high-spin iron(III) species (I.S.=0.44, Q.S.=0.95 mm s^{-1}) is observed. The same species was also found in the spectrum of the sample decomposed under nitrogen in the same temperature range. As the weight loss of the sample in stage II corresponds to two moles of CO_2, the formation of $Li[Fe(III)(C_2O_4)_2]$ may be suggested for this stage.

A Mössbauer spectrum at 80 K of the sample thermally decomposed at 500—510 K under nitrogen is shown in Fig. 3(b). The Mössbauer parameters of the iron(II) species produced thus coincide with those of

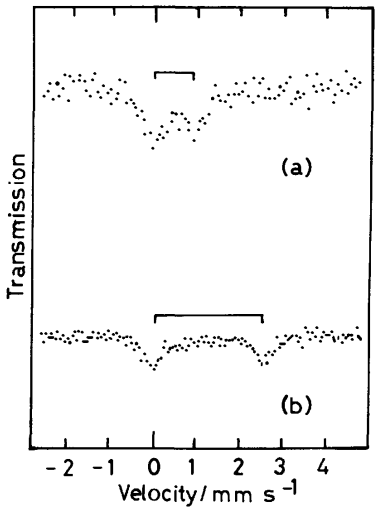

Fig. 3. Mössbauer spectra at 80 K of $Li_3[Fe(C_2O_4)_3]\cdot4.5H_2O$ (a) decomposed at 525—545 K in air, and (b) decomposed at 500—510 K under nitrogen.

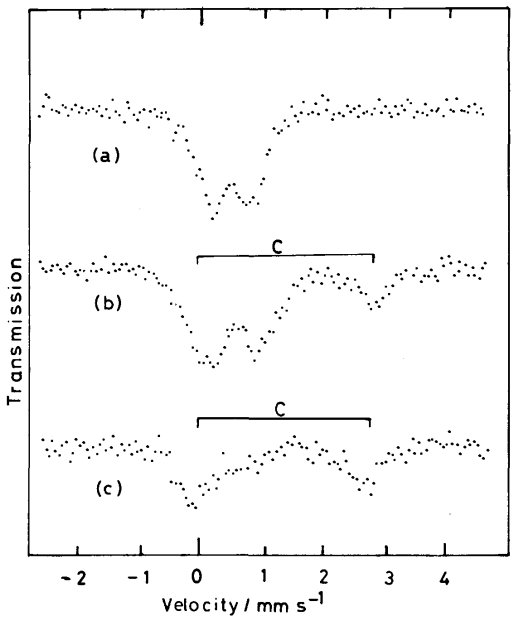

Fig. 4. Mössbauer spectra at 80 K of (a) unirradiated, (b) neutron-irradiated (5×10^{11} n s^{-1} cm^{-2}, 2 h), and (c) neutron-irradiated (1.2×10^{12} n s^{-1} cm^{-2}, 4 h) anhydrous $Li_3[Fe(C_2O_4)_3]$.

the doublet A in Fig. 1. The formation of this yellow product may correspond to a small heat change without any remarkable change in the weight at 465 K under nitrogen. The color change is accompanied by a reduction of iron(III) to iron(II), as is observed in the thermal decomposition of $K_3[Co(C_2O_4)_3]\cdot 3H_2O$ at 393 K.[6]

A Mössbauer spectrum at 80 K of anhydrous $Li_3[Fe(C_2O_4)_3]$ is shown in Fig. 4(a). The dehydration of the sample was confirmed by measuring the weight loss of the sample by heating and IR spectrum of the sample; the weight loss of the compound coincides with the theoretical value within 2%. Although the Mössbauer spectrum of $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ consists of a broad single peak due to magnetic relaxation, the spectrum of the anhydrous compound consists of an asymmetric doublet with a narrower line-width. The difference between the Mössbauer spectra of the hydrous and anhydrous lithium tris(oxalato)ferrate(III) implies that the spin-spin relaxation time decreases in the anhydrous compound compared with the hydrous compound because of the decreased average Fe-Fe distance.

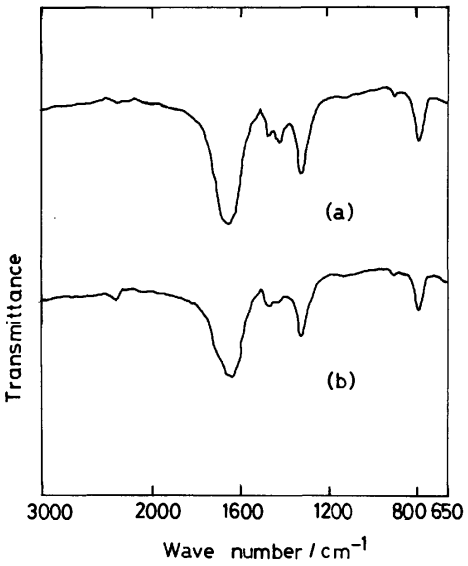

Fig. 5. IR spectra of (a) neutron-irradiated (1.2×10^{12} n s^{-1}cm^{-2}, 4 h) $Li_3[Fe(C_2O_4)_3]$, and (b) thermally decomposed (500—510 K under nitrogen) $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$.

Table 1. Mössbauer parameters of the species A, B, and C shown in Figs. 1 and 4, and of the thermally decomposed $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$

Species	I.S. / mm s^{-1}	Q.S. / mm s^{-1}
A	1.26	2.63
B	1.32	1.97
C	1.32	2.86
Product after heating at 525—545 K in air	0.44	0.95
Product after heating at 500—510 K under nitrogen	1.30	2.60

A Mössbauer spectrum of neutron-irradiated (5×10^{11} n s^{-1}cm^{-2}, 2 h, at the ambient temperature) anhydrous $Li_3[Fe(C_2O_4)_3]$ is shown in Fig. 4(b). The doublet C (I.S.=1.32, Q.S.=2.86 mm s^{-1}) is ascribed to a high-spin iron(II) species produced by neutron irradiation; it is similar in I.S. value to the doublets A and B. When the anhydrous $Li_3[Fe(C_2O_4)_3]$ is irradiated at a higher neutron fluence rate (1.2×10^{12} n s^{-1}cm^{-2}) and for a longer period (4 h) than those in Fig. 4(b), a species which has the same Mössbauer parameters as the doublet C is obtained as the main product, as is shown in Fig. 4(c). The Mössbauer parameters for the species A, B, and C, shown in Figs. 1 and 4, and the thermally decomposed products are summarized in Table 1 for the sake of comparison. As may be seen in Fig. 5, the IR spectrum of the sample shown in Fig. 4(c) is similar to that of the thermally decomposed product at 500—510 K under nitrogen. Thus, the species produced through the neutron irradiation of $Li_3[Fe(C_2O_4)_3]$ is concluded to be produced also by the thermal decomposition. Although the cause of different Q.S. values of the product in the anhydrous compound has not yet been fully elucidated, the different crystal structure of the anhydrous compound may explain the small difference in the Q.S. value of the new species produced in the original host crystal lattice.

The Fe(II) species produced in the neutron-irradiated $Li_3[Fe(C_2O_4)_3]$ and $Li_3[Fe(C_2O_4)_3]\cdot 4.5H_2O$ are ascribed to a precursor of $[Fe(C_2O_4)_2]^{2-}$ and a hydrous or anhydrous $[Fe(C_2O_4)_2]^{2-}$ species respectively. Since the weight decrease corresponding to one mol of the oxalato ligand is not observed in the neutron irradiation of the sample, decomposed fragment species, such as CO_2, produced from the oxalato ligand seem to remain in the crystal lattice of the irradiated sample.

As the spectral component C remains even after a long period of irradiation of the anhydrous compound, the change in the species A to the species B, shown in Fig. 1(a) and in Fig. 1(b) respectively, can be concluded to be related to the existence of crystal water, for instance, in such a way that the presence of water molecules is involved in stabilizing the species A to B, although further investigations are required to identify those iron(II) species.

Preparation of Aluminum Fluoride Film with Graphite Fluoride

Nobuatsu WATANABE,* Hidehiko OHARA, and Tsuyoshi NAKAJIMA
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto, 606
(Received July 25, 1983)

An aluminum fluoride film covered by graphite fluoride on metallic aluminum was prepared by reaction in the ternary system of aluminum, graphite and fluorine gas at 450—550 °C. The film consisted of a large amount of aluminum fluoride covered by thin graphite fluoride layers. The contact angle of a water drop on the film was around 120 °, which decreased to 85—95 ° during 45 d probably due to reaction with moisture and/or water drop. Almost no oxygen was detected in the film. The film formation would be based on the reduction of oxide layer on aluminum by carbon radical produced by thermal decomposition of graphite fluoride.

An aluminum fluoride film covered by graphite fluoride is formed by the reaction of metallic aluminum with graphite fluoride in a fluorine atmosphere at 450—600 °C.[1)]

$$Al + (CF)_n + F_2 \xrightarrow{450-600°C} \text{Aluminum fluoride film with graphite fluoride} \quad (1)$$

This film had a low surface energy with a contact angle for a water drop, *ca.* 120 ° and was an electric insulator. The value of the contact angle is the same as that on the basal plane of graphite fluoride.[2)] The fluoride film is also prepared through another route of the ternary system of aluminum, graphite and fluorine gas,[1)] in which graphite fluoride would be preferentially formed and then react with aluminum.

In this study, the preparation and structure of the aluminum fluoride film with graphite fluoride was investigated in the ternary system of aluminum, natural graphite and fluorine gas.

Experimental

An aluminum plate (18×14×0.8 mm, purity: 99.99%) was used after immersion in 10% NaOH solution for 5 min and in 3 M† HNO_3 for 10 s to remove oily material on the surface. Other starting materials were Madagascar natural graphite (40—47 μm, purity: 99.4%) and high purity fluorine gas (99.4%).

The fluoride film is prepared as follows. A nickel vessel containing the aluminum plate (2 sheets) and graphite powder (1 g) was placed in a nickel reactor, followed by pumping at room temperature. After heating to a reaction temperature, the reactor was filled with fluorine gas of 1 atm. During the reaction, the reactor was rotated at 2 min^{-1} by a motor with a mechanical seal. The fluoride film so prepared was analyzed by contact angle measurements (at 30 °C), X-ray diffractometry (by Cu$K\alpha$), X-ray microanalyzer, IR and ESCA spectroscopies.

Resuts

Contact Angle of a Water Drop on the Fluoride Film. A fluoride film having a high contact angle (Fig. 1) and smooth surface was obtained by the reaction performed at 450—500 °C. It was very difficult to prepare such a film below 400 °C, and aluminum plate was often deformed at higher temperature of 550—600 °C.

Figure 2 is the change of a contact angle on a surface film of aluminum as a function of reaction time. A

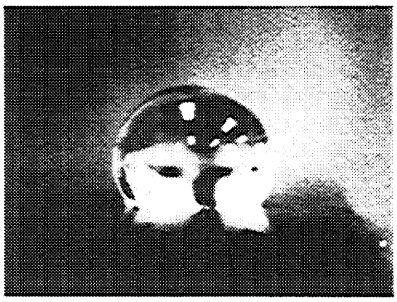

Fig. 1. Contact angle of water drop (θ) on the graphite fluoride film.
θ=125°, Preparation of the film: 500 °C, 24 h.

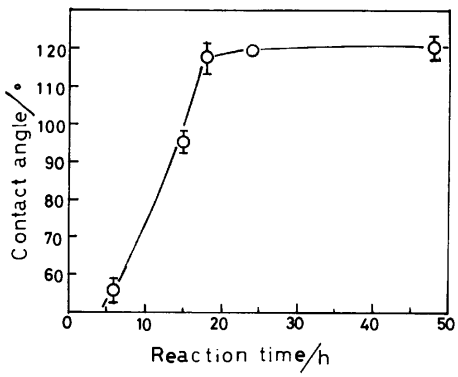

Fig. 2. Contact angle of water drop on surface film of aluminum as a function of reaction time.
Reaction temperature: 500 °C.

fluoride film with a contact angle of 120 ° was prepared by the reaction for 20 h. The change in the surface appearance with reaction time is shown in Fig. 3. At the beginning of a reaction, a white amorpous substance of 50—100 μm in thickness and with a low contact angle was formed on the surface of the aluminum (Fig. 3a). It consisted of aluminum fluoride and fluorinated aluminum carbide, as shown later from X-ray diffraction pattern and ESCA spectra. As the reaction progressed, a black part began to appear as shown in Fig. 3b, being a very thin film (<10 μm) with a higher contact angle. After 20 h, the film formation was completed. The aluminum surface was covered by a thin black film of 3—8 μm with a contact angle of 127.5 ° (Fig. 3c).

Figure 4 shows the change of the contact angles of fluoride films prepared at different temperatures with the holding time in air. The contact angle gradually decreased from 120 ° to 85—95 ° during 45 d. This might be due to reaction with moisture in air or the

†1 M=1 mol dm^{-3}

water drop used in the contact angle measurement. The decrease in the contact angle was larger for a fluoride film wetted by a water drop on the contact angle measurement than for that only left in air.

IR Spectra. Figure 5 shows the IR spectra (ATR) of the fluoride films. Figure 5a was measured several days after preparation of a film having a contact angle of 92—133°. A broad absorption observed around 1220 cm^{-1} is assigned to a CF stretching vibration (1215 cm^{-1}) and CF_2 symmetric and asymmetric vibrations (1380, 1110 cm^{-1}) of graphite fluoride.[3] A strong absorption around 600 cm^{-1} indicates aluminum

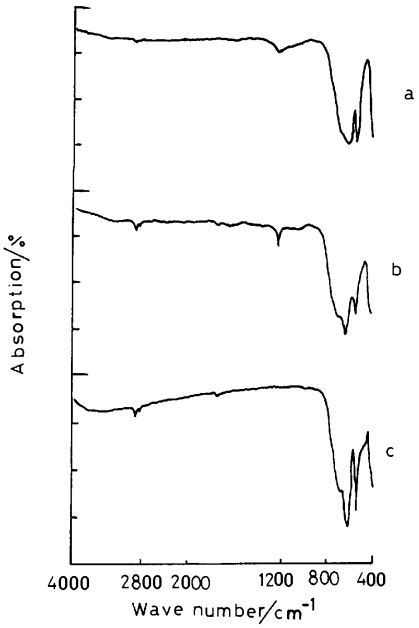

Fig. 5. IR spectra (ATR) of surface film of aluminum.
a: θ=92—133°, reaction: 500 °C, 24 h. b: θ=114→70°, reaction: 450 °C, 48 h. c: θ=Spread, reaction: 550 °C, 72 h.

fluoride. It was found from the intensity of each absorption band that the fluoride film contained a large amount of aluminum fluoride and a small amount of graphite fluoride. Figure 5b was obtained for a sample whose contact angle decreased from 114° to 70° by the reaction with moisture and water drops. In addition to a sharp absorption of the CF stretching vibration, two absorptions for carbonyl groups appeared around 1600 cm^{-1} and 2800—3000 cm^{-1}, respectively. The decrease of contact angle is probably because CF_2 group was removed by the reaction with water and the carbonyl groups were newly formed. Only carbonyl groups were found for a film on which water drop spread (Fig. 5c).

X-Ray Diffraction Pattern. An example of the X-ray diffraction pattern of a fluoride film in given in Fig. 6 where α and γ-AlF_3 and metallic aluminum were observed. No diffraction line of graphite fluoride was detected probably because of the very thin film.

X-Ray Microanalysis. Figure 7 is the elemental analysis of a cross section of a fluoride film. It was

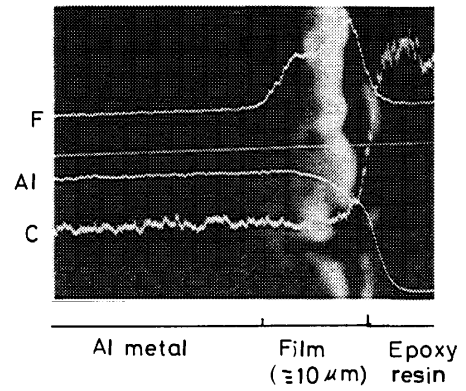

Fig. 7. Elemental analysis by X-ray microanalyser Reaction: 500 °C, 24 h.

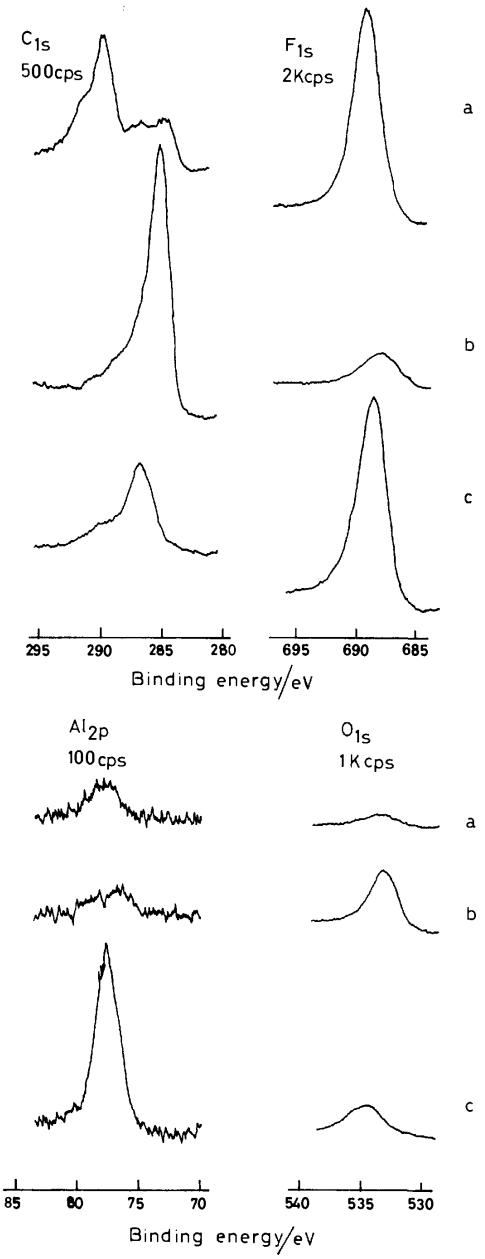

Fig. 8. ESCA spectra of surface film of aluminum. a: θ=106.3°, reaction: 450 °C, 24 h. b: θ= 121.3→83.7°, reaction: 475 °C, 48 h. c: θ=81.0°, reaction: 550 °C, 24 h.

found that the film contained large amounts of fluorine and aluminum, and a small amount of carbon. The amounts of fluorine and carbon increased toward the surface of the film while that of aluminum gradually decreased. It is surprising that no oxygen was detected in the film.

ESCA Spectra. ESCA provides the information on a chemical bond of a solid surface. Figure 8a is the spectra of a film with a high contact angle. C_{1s} spectrum had two peaks at 290.0 and 292.0 eV corresponding to CF and CF_2 groups of graphite fluoride, respectively. The position of the F_{1s} peak is the same as that of graphite fluoride. The peak for Al_{2p} was found at 77.9 eV slightly higher than that of aluminum fluoride. O_{1s} peak was observed although the peak intensity was extremely low compared with that of the F_{1s} peak. Figure 8b was obtained for a film after its contact angle decreased from 121.3° to 83.7°. The C_{1s} and F_{1s} peaks corresponding to CF and CF_2 groups were decreased remarkably by the decomposition of thin graphite fluoride layers. The C_{1s} peak, indicating hydrocarbon compounds, appeared strongly at 285.0 eV, and the F_{1s} peak was shifted to 688.0 eV near that of aluminum fluoride. On the other hand, the intensity of O_{1s} peak increased considerably probably because of the formation of carbonyl groups. Figure 8c shows the spectra of a film with a low contact angle. It seems that this sample was in the course of the formation of graphite fluoride film as shown in Fig. 3a. The C_{1s} spectrum had a strong peak at 286.7 eV which was consistent with that of aluminum carbide, Al_4C_3, fluorinated by fluorine gas at 500 °C. The peak around 290 eV indicating graphite fluoride had a low intensity. Fluorinated aluminum carbide gave an F_{1s} peak at the same position, 688.7 eV, as that of graphite fluoride. This result suggests the formation of an Al-C-F bond. The high intensity of the Al_{2p} formation of an Al-C-F bond. The high intensity of the Al_{2p} peak would be due to fluorinated carbide and aluminum fluoride since the graphite fluoride layer was not formed appreciably. The O_{1s} peak was found at a higher posi-

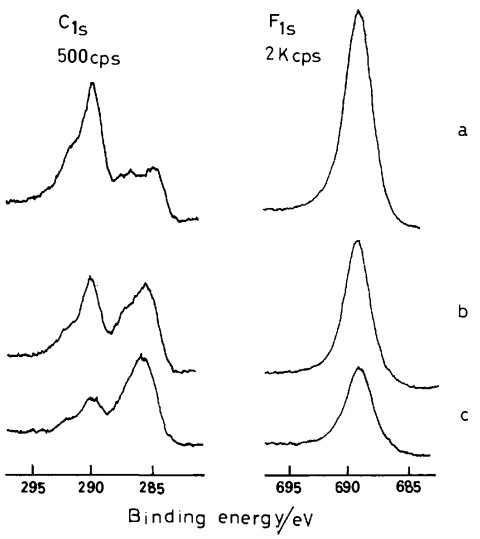

Fig. 9. ESCA spectra of surface film of aluminum. a: Film surface, b, c: polished by an emery paper.

tion than that of aluminum oxide probably because of the formation of fluoride oxide. Figure 9 is the spectra of the inside of a film obtained by polishing with an emery paper. Graphite fluoride decreased toward the inside of the film, while the peak of the fluorinated carbide at 286.7 eV increased. The latter was also decreased by further polishing and the peak for the aluminum substrate appeared.

Discussion

Structure of the Fluoride Film. From the results obtained by X-ray diffractometry, IR and ESCA spectroscopies, it was found that the fluoride film consisted of a large amount of aluminum fluoride and thin graphite fluoride layers around the film surface. The CF group comprised in graphite fluoride and fluorinated aluminum carbide rapidly decreased from the surface of the film into the inside. ESCA spectra suggested that graphite fluoride layers were chemically bonded to aluminum metal through the fluorinated aluminum carbide.

The contact angle of the water drop on the film was around 120°, which was almost equal to that for graphite fluoride prepared from flaky natural graphite.[2] The contact angle gradually decreased from *ca.* 120° to around 90°. This was explained by the IR spectra of the films. As shown by ESCA spectra, graphite fluoride on the surface of the fluoride film would have a chemical bond with the aluminum substrate through the fluorinated aluminum carbide having an ionic nature. Aluminum carbide with an ionic bond is easily decomposed by reaction with water. There would be many CF_2 groups around the edge of the graphite fluoride layer of the film as well as graphite fluoride powder. It is expected that these CF_2 groups are slightly ionic in chemical bond, being different from the CF_2 group with a covalent bond in graphite fluoride itself. For this reason, the CF_2 groups of the fluoride film would be decomposed by the reaction with moisture in air or water drop. As a result, the carbonyl groups were formed on the surface of the film.

No oxygen was detected on elemental analysis by X-ray microanalyzer. In this case, the analyzed depth is about 1 μm and the detection limit of oxygen is 0.1%. The analyzed area was a cross section of a fluoride film (≅10μm) bonded to aluminum substrate as shown in Fig. 7. In the case of ESCA, the analyzed area is the sample surface itself (2×10^{-5} m^2), and the analyzed depth is limited by the mean free path of the photoelectron in the solid; this is only several nanometers. Oxygen adsorbed on a sample surface is therefore easily detected by ESCA measurement. For example, almost the same amount of oxygen is detected for the surface of poly(tetrafluoroethylene) which does not contain oxygen in the structure. Accordingly, it can be said that the fluoride film contains almost no oxygen.

Reaction of Aluminum with Graphite Fluoride and Fluorine. The attempts to prepare a pure aluminum fluoride film on the surface of aluminum were made by electrochemical fluorination in hydrogen fluoride and by reaction with fluorine gas at a high temperature. However, they were unsuccessful because oxygen contained in the surface oxide layer of aluminum could not be removed by such fluorination reactions.[4] Since aluminum oxide is very stable, it is very difficult to reduce aluminum oxide below 600°. The reduction of an oxide film on aluminum would be attained only by chemically active species such as radicals. Graphite fluoride somewhat decomposes at 450—600°C, giving CF_2 radicals[5-7] with life time of the order of second.[8-10]

$$2(CF)_n \longrightarrow n\mathrm{C(amorphous)} + xCF_2 + yC_2F_4 \quad (2)$$

The products obtained by thermal decomposition of $(CF)_n$ are amorphous carbon, unsaturated fluorocarbons (C_2F_4, C_3F_6) and saturated fluorocarbons (CF_4, C_2F_6, C_3F_8).[5-7] It was reported that C_2F_4 does not decompose to CF_4 below 700°C.[11] The saturated fluorocarbons are therefore regarded as 2nd order products of CF_2 radicals. It is then expected that the CF_2 radical decomposes to a carbon radical and CF_4 by the disproportionation reaction.

$$2CF_2 \longrightarrow C^* + CF_4 \quad (3)$$

C*: carbon radical

This carbon radical would reduce the oxide layer of aluminum.

$$Al_2O_3 + 3C^* \longrightarrow 2Al + 3CO \quad (4)$$

$$CO + F_2 \longrightarrow COF_2 \quad (5)$$

Metallic aluminum Al* would immediately react with fluorine gas, CF_2 radical, carbon radical C* and/or graphite fluoride.

$$Al^* + 3/2F_2 \longrightarrow AlF_3 \quad (6)$$

$$Al^* + CF_2 \longrightarrow Al\text{-}CF_2 \quad (7)$$

$$Al^* + C^* \longrightarrow Al\text{-}C \quad (8)$$

$$Al^* + (CF)_n \longrightarrow Al\text{-}(CF)_n \quad (9)$$

The product of reactions (7) and (8) would further react with radical species and/or graphite fluoride to produce the fluoride film with graphite fluoride.

Kinetic Trace Determination of Molybdenum(VI), L-Ascorbic Acid, and Thiosulfate Using Landolt Reaction by the Aid of Fluorometry

Masamitsu KATAOKA,* Hirotoshi HEMMI, and Tomihito KAMBARA†

Department of Chemistry, Faculty of Science, Hokkaido University, Kita 10, Nishi 8, Kita-ku, Sapporo 060

(Received September 19, 1983)

Trace amounts of molybdenum(VI) can be determined by the use of their catalytic effects on the peroxoborate-iodide redox reaction in acidic medium. The indicator reaction is transformed to a Landolt reaction by the addition of ascorbic acid into the reaction mixture, *i.e.*, the iodine produced by the reaction is immediately reduced by ascorbic acid. The end of the induction period of the Landolt process was fluorometrically detected by the aid of disappearence of fluorescence of Rhodamine B. Trace determination of molybdenum(VI) was carried out by employing the linear relationship between the reciprocal of induction period and catalyst concentration. The most suitable concentrations of sodium peroxoborate, potassium iodide, and hydrochloric acid in the reaction mixture were found to be 9 mM, 0.1 M, and 0.1 M, respectively. By this method, molybdenum(VI) can be determined from 80 nM to 10 mM (7.675 ng ml^{-1} to 95.95 mg ml^{-1}). The effect of foreign ions were studied and an equal amount of tungsten(VI), and 10-fold amounts of zirconium(IV), iron(II), iron(III), vanadium(IV), and copper(II) were found to show interference. Ascorbic acid and thiosulfate in micro mol l^{-1} levels were also determined by the present method employing the linear relationship between the induction period and the reductant concentration.

Kinetic methods of analysis by the aid of catalytic reactions are used in many fields of chemical analysis because of their extremely high sensitivity, and are summarized in books[1-4] and reviews[5-14]

The Landolt reaction is frequently applied to the micro-determination of various metal ions[15-23] and some reducing agents.[24] Svehla[14] reviewed the application of Landolt reaction in quantitative catalytic analysis.

The present authors had been reported kinetic micro-determinations of molybdenum(VI),[25] tungsten(VI), and vanadium(V)[26] which catalyse the redox reaction of peroxoborate-iodide system, using iodide ion-selective electrode as the tracer of reaction rate. In the present work, the indicator reaction is transformed to a Landolt reaction by the addition of L-ascorbic acid. The end of the induction period was monitored fluorophotometrically. Micro amounts of molybdenum(VI) can be determined by plotting the reciprocal of the induction period against its concentration. Also, L-ascorbic acid and thiosulfate in micro molar levels were determined by the use of the linear relationship between the induction period and their concentration.

Theory

The indicator reaction on which the present method is based proceeds as follows:

$$BO_3^- + 3\,I^- + 2\,H^+ \longrightarrow BO_2^- + I_3^- + H_2O. \quad (1)$$

In the presence of catalyst, this redox reaction proceeds with a considerable rate, but it proceeds very slowly without catalyst. In the presence of a reducing agent, *e.g.*, ascorbic acid, triiodide ions produced are immediataly reduced so that the iodide ion concentration is kept constant until all the L-ascorbic acid is oxidized.

$$C_6H_8O_6 + I_3^- \longrightarrow C_6H_6O_6 + 3\,I^- + 2\,H^+ \quad (2)$$

When ascorbic acid has been consumed completely, triiodide ions appear in the reaction mixture and the solution turns yellow. The time length necessary to elapse till the appearance of triiodide ions is called the induction period.

Concentration of hydrogen ion does not change during induction period because the oxidation of ascorbic acid releases the same number of hydrogen ions, as shown in Eq. 2. Thus, iodide and hydrogen ion concentrations remain constant so long as ascorbic acid is present. The reaction rate can be expressed as

$$-\frac{d[BO_3^-]}{dt} = (k \cdot C_k + k')[BO_3^-] \quad (3)$$

where k and k' are the products of rate constants of catalyzed and uncatalyzed reaction including the concentrations of hydrogen and iodide ion, and C_k is the catalyst concentration. Integration of Eq. 3 yields

$$\frac{1}{t} = \frac{k \cdot C_k + k'}{\ln \dfrac{[BO_3^-]_0}{[BO_3^-]_0 - [C_6H_8O_6]_0}}$$

where t is the induction period and $[BO_3^-]_0$ and $[C_6H_8O_6]_0$ are the initial concentrations of peroxoborate ion and ascorbic acid, respectively.

Hence plotting the reciprocal of induction period against catalyst concentration gives a linear calibration graph.

The end of the induction period, *i.e.*,the appearance of triiodide ion in the reaction mixture was fluorophotometrically detected by the aid of the following reaction:[27]

$$\underset{\text{(fluorescence)}}{\text{Bhodamine B}} + I_3^- \longrightarrow \underset{\text{(none-fluorescence)}}{\text{Product.}} \quad (5)$$

Here triiodide ion may act as a quenching ion.[28] Some reductants, *i.e.*, ascorbic acid and thiosulfate ion, can also be determined by utilizing the linear relationship between the induction period and their concentration.

† Present address: Hakodate Technical College, Tokura-cho, 226, Hakodate 042.

Experimental

Apparatus. All the fluorescence measurements were carried out with a Shimadzu spectrofluorophotometer, RF-510, connected with a Shimadzu recorder, U-125MU. The temperature of the fluorophotometric cell was kept constant to 25±0.5°C by the use of a Yanagimoto constant temperature bath, P8-PC. A Hitachi pH meter, F-5 was used for pH measurements.

Reagents. Molybdenum(VI) stock solution(0.01 M) was prepared by dissolving 1.7656 g of analytical reagent grade ammonium molybdate tetrahydrate obtained from Kishida Chemicals Co. into 1 dm^3 (dm^3=litre) of water. Concentration of the solution was standardized by an adding excess amount of 0.01 M Na_2H_2 edta and the solution was then back titrated with 0.01 M lead sulfate by the aid of XO metallochromic indicator at pH 5. Sodium peroxoborate solution (0.05 M) was prepared every week by dissolving 3.8465 g of sodium peroxoborate tetrahydrate obtained from Wako Pure Chemicals Co. into 0.5 dm^3 of water. It was stored in a dark bottle in a refrigerator. Potassium iodide solution (1 M) was prepared by dissolving about 166 g of reagent into 1 dm^3 of water. The stock solution was potentiometrically titrated against silver nitrate standard solution and stored in a dark bottle. Rhodamine B was obtained from Wako Pure Chemicals Co. as a chloride salt and 0.01 M stock solution was prepared by dissolving 0.4790 g of reagent into 100 ml of water. A stock solution was potentiometrically standardized with silver nitrate solution. L-Ascorbic acid was obtained from Wako Pure Chemicals Co. and a stock solution was prepared by dissolving 1.7613 g of reagent into 100 ml of water just before use. The chemicals used in this study were all of analytical reagent grade. All the water used was deionized and then twice distilled.

Procedure. The established procedure for the determination of 80 to 200 nM of molybdenum(VI) is as follows. To a 50 ml volumetric flask containing an appropriate amount of molybdenum(VI) sample solution were added 10 ml of 10 μM Rhodamine B solution and 18 ml of 50 mM sodium peroxoborate solution; the flask was filled up to the mark with water (solution A). To another 50-ml flask containing 10 ml of 1 M potassium iodide were added 3 ml of 0.1 M ascorbic acid solution and 10 ml of 1 M hydrochloric acid; this solution was diluted to the needed volume (solution B). Both solutions were thermostated at 25°C, and a 1-ml portion of solution A was transfered fluorometric cell (10×10×45 mm) in the spectrofluorophotometer. An equal amount of solution B was rapidly poured into the cell and the recorder switched on at the same time. The reaction solution in the cell was quickly mixed by using a small stirrer, and the fluorescence intensity was recorded at 555 nm of excitation and 573 nm of emission wave length. The amount of ascorbic acid added to the reaction mixture was changed according to the molybdenum(VI) ion concentration range.

Results and Discussion

Effect of pH. Effect of pH on the rate of the reaction was examined with fixed concentrations of sodium peroxoborate, potassium iodide and ascorbic acid. The pH of the reaction mixture was varied by the use of hydrochloric acid or acetate buffer. Calibration graphs for molybdenum(VI) in the concentration range from 2 to 10 μM with different pH values were obtained; the slopes of these graphs were plotted against pH. As shown in Fig. 1, the slope of the

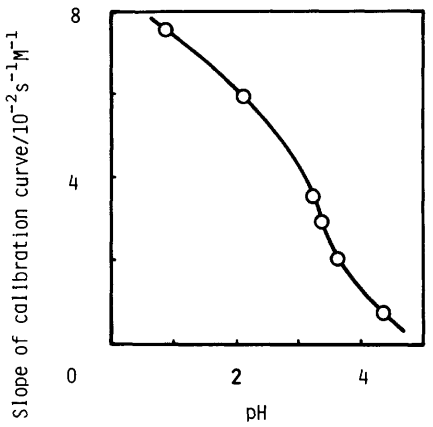

Fig. 1. Effect of pH on the slope of calibration curves. Composition of the reaction mixture: [$NaBO_3$]=2.5 mM, [KI]=1.0 mM, [Rh.B]=1.0 μM, [Asc.]=0.2 mM, temp=25±0.5°C, range of molybdenum(VI): 2 to 10 μM, pH of the reaction mixture was adjusted with HCl or acetate buffer.

Composition of the reaction mixture: [$NaBO_3$]=2.5 mM, [HCl]=0.1 M, [Rh.B]=1.0 μM, [Asc.]=1.0 mM, temp=25±0.5°C, A: [Mo(VI)]=6.0 μM, B: black, C: difference of reciprocal of induction period, (A—B).

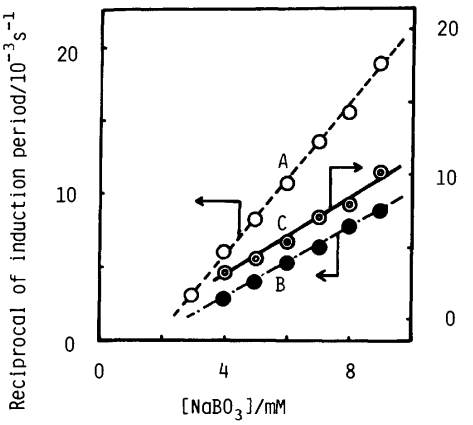

Fig. 3. Effect of potassium iodide concentration on the reciprocal of induction period.
Composition of the reaction mixture: [KI]=0.1 M, [HCl]=0.1 M, [Rh.B]=1.0 μM, [Asc.]=1.5 mM, temp=25±0.5°C, A; [Mo(VI)]=1.0 μM, B; black, C; difference of reciprocal of induction period, (A—B).

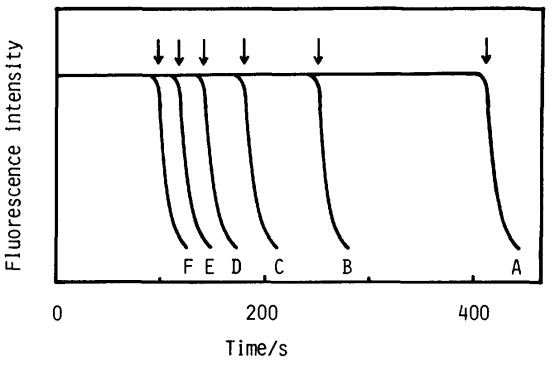

Fig. 4. Fluorescence intensity-time curve.
Composition of the reaction mixture: [KI]=0.1 M, [$NaBO_3$]=9 mM, [HCl]=0.1 M, [Rh.B]=1 μM, [Asc.]=5 mM, temp=25±0.5 °C, [Mo(VI)]: A; 0, B; 2, C; 4, D; 6, E; 8 F; 10 μM.

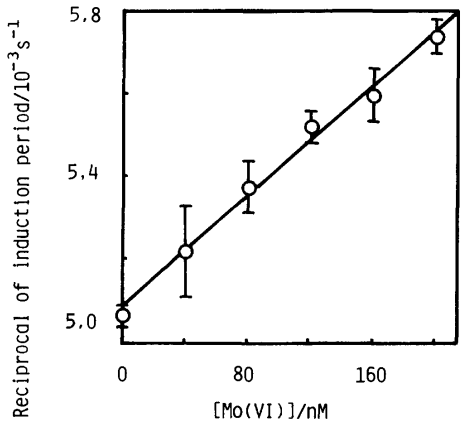

Fig. 5. Calibration curve for molybdenum(VI) (40—200 nM).
Composition of reaction mixture: [$NaBO_3$]=9.0 mM, [KI]=0.1 M, [HCl]=0.1 M, [Rh.B]=1.0 μM, [Asc.]=3 mM, temp=25±0.5 °C.

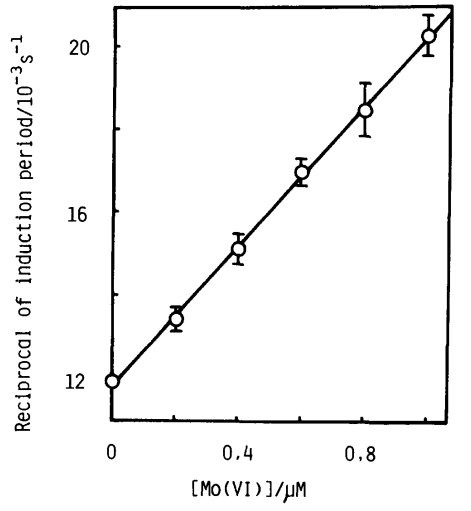

Fig. 6. Calibration curve for molybdenum(VI) (0.2—1.0 μM).
Composition of reaction mixture: [$NaBO_3$]=9 mM, [KI]=0.1 M, [HCl]=0.1 M, [Rh.B]=1.0 μM, [Asc.]=1.5 mM, temp=25±0.5 °C.

calibration curve increased with decreasing pH of the reaction mixture. The most suitable pH was found to be unity, because the rate of the blank reaction suddenly increased at pH values lower than unity.

Effect of Potassium Iodide Concentration. The dependence of iodide ion concentration on the reciprocal of induction period was investigated. The results are shown in Fig. 2. Various amounts of potassium iodide solution were added to the reaction mixture containing 6 μM of molybdenum(VI) (curve A). The blank reaction was also carried out (curve B). The differences of reciprocal of induction period are also shown in the figure (curve C). It was found that the net value (curve C) became almost constant at the iodide ion concentrations higher than 0.1 M. Thus, the concentration of potassium iodide was adjusted to 0.1 M.

Effect of Sodium Peroxoborate Concentration. The effect of peroxoborate ion concentration on the reciprocal of induction period was examined. The results are shown in Fig. 3. The net value of reciprocal of induction period increased with increasing the sodium peroxoborate concentration. However, a high peroxoborate ion concentration is not suitable because it decomposes itself by generating bubbles in the fluorometric cell. Thus, the peroxoborate ion concentration was adjusted to 9 mM.

Effect of Rhodamine B Concentration. Rhodamine B ion concentration lower than 0.1 μM is not suitable because of low fluorescence intensity. Rhodamine B ion concentration more than 0.1 mM is also not suitable because the reaction mixture becomes turbid. A concentration of 1.0 μM was adopted because the sharpness of the change in fluorescence intensity at the end of induction period is increased with decreasing its concentration.

Calibration Graph. The calibration graph for molybdenum(VI) was obtained according to the above procedure. Fluorescence intensity-time curves for various molybdenum(VI) concentrations in the range from 0 to 10 μM are shown in Fig. 4. Arrows in the figure show the end of induction period. As shown in Figs. 5 and 6, the calibration graphs of molybdenum(VI) are linear over the concentration range from 80 to 200 nM and 0.2 to 1.0 μM. The number of measurements at each molybdenum(VI) ion concentration levels are three and the graph is shown in mean and 95% confidence limit. Relative standard deviation at 8×10^{-8} and 2×10^{-7} M molybdenum(VI) concentrations are 0.47 and 0.24%, respectively.

Determination of Ascorbic Acid and Thiosulfate Ion. Since the induction period is linear to reductant concentration, micro-determination of a reducing agent such as ascorbic acid or thiosulfate is feasible. Concentration of potassium iodide, sodium peroxoborate, hydrochloric acid, Rhodamine B, and molybdenum(VI) were kept to 0.5 mM, 7.5 mM, 0.1 M, 1.0 μM, and 1.0 μM, respectively. A good calibration graph was obtained for the ascorbic acid concentration range from 1 to 10 μM. One can easily determine more concentrated ascorbic acid up to 10 mM by increasing the catalyst concentration. Thiosulfate ion in the concentration range from 2 to 10 μM was also determined by using

TABLE 1. EFFECT OF DIVERSE IONS

Diverse ion	Concentration of diverse ion			
	0.5 μM	5.0 μM	50 μM	500 μM
W^{VI}	+7.64	+49.73	—	—
Zr^{IV}	+1.48	+3.88	+113.3	—
Fe^{II}	+0.95	+4.88	+46.41	—
Fe^{III}	−0.31	+4.41	+44.63	—
Cr^{VI}	+2.44	+4.47	+13.28	—
V^{IV}	+3.18	+4.80	+11.63	+144.6
Mn^{II}	+1.27	−0.28	−3.51	−4.13
Zn^{II}	—	—	—	+0.23
Cr^{III}	—	+1.62	−8.39	−5.35
Cu^{II}	+0.58	−15.64	—	—

[$NaBO_3$]=9.0 mM, [KI]=0.1 M, [HCl]=0.1 M, [Rh.B]= 1.0 μM, [Asc.]=1.5 mM, temp=25±0.5 °C, [Mo(VI)]= 0.5 μM, Figures in the table show relative errors in percent.

the same composition of reaction solution. Relative standard deviations of 2μM ascorbic acid and 2μM thiosulfate ion concentration levels are 2.56 and 1.76%, respectively.

Interference. Interference by some diverse ions for the determination of molybdenum(VI) was evaluated; the results are shown in Table 1. The composition of the reaction solution is the same as that used for construction of the calibration graph and molybdenum(VI) concentration was kept to 0.5μM. The concentration of diverse ions were changed to 1 to 1000 times more than that of molybdenum(VI). Triplicate measurements were carried out in the presence and absence of interferent. Plus sign in the table implies acceleation of the rate of indicator reaction. Equal amounts of tungsten(VI), and tenfold amounts of zirconium(IV), iron(II), iron(III), vanadium(IV), copper(II), and chromium(VI) show interference.

Mössbauer Study of Tin(II) Chloride Hydroxide and Tin(II) Hydroxide Oxide

Sumio ICHIBA* and Mitsuru TAKESHITA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received September 19, 1983)

The precipitates obtained by addition of a solution of $NaHCO_3$ to a solution of $SnCl_2$ at various pH were studied by thermal analysis, Mössbauer spectroscopy, and X-ray powder diffraction. The formula of the tin(II) chloride hydroxide precipitate obtained in the range of pH 1.9—2.5 was determined as $2SnO \cdot SnCl_2 \cdot H_2O$, or $Sn_3O(OH)_2Cl_2$, and the formula of the hydroxide oxide obtained in the range of pH 7.0—7.7 was $3SnO \cdot 2H_2O$, or $Sn_3(OH)_4O$. In the intermediate pH range, the chloride ions were gradually replaced by hydroxide ions. The dehydration of hydroxide oxide to produce SnO occurred in two stages and the disproportionation reaction of SnO to SnO_2 and β-tin proceeded *via* Sn_2O_3.

When a solution of an alkali is added to a solution of a tin(II) compound, in the absence of a strong-donor anion, the precipitate is a basic chloride salt at first, but further addition of hydroxide ion results in the gradual replacement of the anion by hydroxide and finally, the precipitate turns into a hydroxide oxide. These tin(II) chloride hydroxide and hydroxide oxide have been studied by many workers and various formulas have been reported.[1-4] Among others, Donaldson *et al.* have reported that the only one preparable as a clearly defined crystalline phase of tin(II) chloride hydroxide from aqueous solution is $Sn_4(OH)_6Cl_2$[2] and that the most probable composition of the tin(II) hydroxide oxide is $5SnO \cdot H_2O$, or $Sn_5O_3(OH)_4$.[3] Howie and Moser obtained single crystals of tin(II) hydroxide oxide, they were able to establish the crystal structure by X-ray diffraction and determined the formula to be $3SnO \cdot H_2O$.[4] Furthermore, Honnick and Zuckerman synthesized tin(II) hydroxide, $Sn(OH)_2$, by an anhydrous, organometallic method.[5]

In this study, the precipitates obtained on addition of a solution of $NaHCO_3$ to a solution of $SnCl_2$ as a function of pH were examined by thermal analysis, X-ray powder diffraction, and Mössbauer spectroscopy. The thermal behavior of the tin(II) chloride hydroxide and hydroxide oxide was also examined by quenching, X-ray powder diffraction, and Mössbauer spectroscopy.

Experimental

Preparation of Tin(II) Chloride Hydroxide and Tin(II) Hydroxide Oxide. Tin(II) chloride dihydrate (2.5 g) was dissolved in 8 mol dm^{-3}-HCl (3 ml). The saturated aqueous solution of $NaHCO_3$ was added to the solution under an atmosphere of nitrogen until the pH of the solution reached the predesignated value, while the solution was stirred by means of ultrasonic waves. The white precipitates filtered off were washed throughly with de-airated water, ethanol, and diethyl ether successively under nitrogen and dried for 2 d in vacuum over potassium hydroxide pellets.

Thermal Decomposition Products of Tin(II) Chloride Hydroxide and Tin(II) Hydroxide Oxide. The samples of the thermal decomposition products for the study of the thermal behavior of the tin(II) chloride hydroxide and hydroxide oxide were prepared by heating the material in a furnace with a nitrogen gas flow up to a temperature where the reaction occurred in the DTA curve and then rapidly cooled to room temperature.

Measurements. TG and DTA heating-curves were recorded simultaneously using a Sinku-riko TGD-5000 RH instrument by heating the sample at a rate of 10 °C min^{-1} in flowing nitrogen gas. About a 10-mg sample was placed in a cell and α-alumina was used as the reference material. The Mössbauer spectra were measured using a constant acceleration type spectrometer and the accuracy was within 0.05 mm s^{-1}. The γ-ray source of calcium stannate was used at room temperature and the sample was cooled to 93 K in a liquid nitrogen cryostat. The velocity scale was calibrated against the spectra of $BaSnO_3$ and β-Sn at room temperature. All isomer shifts are reported relative to $BaSnO_3$. Mössbauer parameters were deduced from Lorentzian curves computer-fitted to the spectra by the least squares method.

Results and Discussion

TG-DTA curves of the precipitate obtained at pH 2.4 are shown in Fig. 1. The weight loss occurs in two stages; the first stage at about 170 °C is dehydration and the second stage over the range 350—550 °C is volatilization of $SnCl_2$. The TG-DTA curves of the precipitates obtained at pH 7.2 and 7.5 are shown in Figs. 2 and 3, respectively. In these cases, the dehydration occurs in two stages. It is to be noted that if the precipitates were obtained with stirring other than

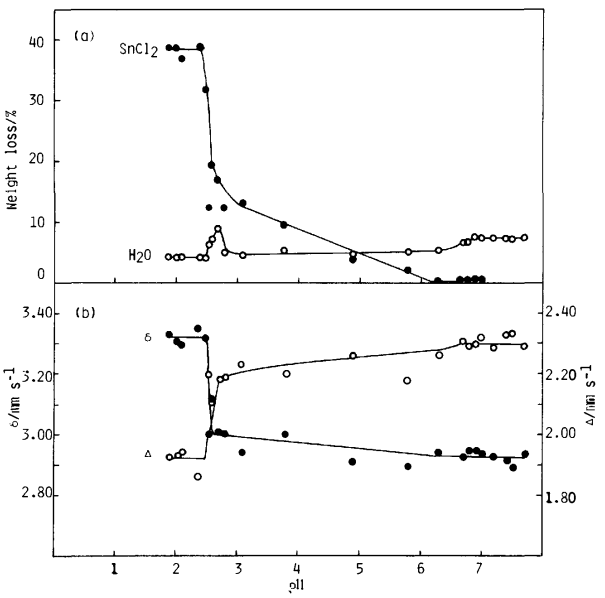

Fig. 4. The plots of the analytical data (a) and Mössbauer parameters (b) against pH.

by means of ultrasonic waves, the reliable weight loss curves could not be recorded. The analytical data, including the residual SnO from the TG curves over the pH range 1.90—7.70, are listed in Table 1, along with the Mössbauer parameters. The variations of the values against pH are schematically shown in Fig. 4.

From the analytical data in Table 1, the precipitates obtained over the pH range 1.90—2.50 are tin(II) chloride hydroxide, the formula of which is $2SnO \cdot SnCl_2 \cdot H_2O$, or $Sn_3O(OH)_2Cl_2$. The formula of the tin(II) hydroxide oxide precipitates obtained over the pH range 7.20—7.70 is $3SnO \cdot 2H_2O$, or $Sn_3(OH)_4O$. In disagreement with these formulas, Donaldson *et al.* have previously reported the formula $3SnO \cdot SnCl_2 \cdot H_2O$, or $Sn_4(OH)_6Cl_2$, for the crystalline basic chloride which was obtained by addition of ammonia solution to the solution of tin(II) chloride over the pH range1.14—4.5.[2] They have also reported the formula $5SnO \cdot 2H_2O$, or $Sn_5O_3(OH)_4$, for the tin(II) hydroxide oxide which was prepared by addition of an oxygen free solution of alkali or alkali carbonate to oxygen free solutions of tin(II) sulfate, under nitrogen, until the pH of the solution was between 10 and 12.[3] Accordingly, the Mössbauer parameters in Table 1 and the X-ray diffraction diagrams shown in Figs. 6(a), 8(a), and 10(a) are not in agreement with the data of Donaldson *et al.*[2,3,6] Another formula $3SnO \cdot H_2O$ has been reported by Howie and Moser for the single crystals of hydroxide oxide obtained from stannous perchlorate solution by prolonged passage of oxygen-free nitrogen containing a very low concentration of ammonia.[4]

Tin(II) ions complex with Cl^- in solution containing hydrochloric acid; Haight *et al.* reported the relative population of various $SnCl_n^{2-n}$ complexes at ion strength 4.0 and varying chloride ion concentration.[7] On the other hand, bivalent tin ion can hydrolyze water and Tobias found that the main product of hydrolysis is the cyclic polynuclear ion $Sn_3(OH)_4^{2+}$.[8] By neutralizing the solution of $SnCl_2$ in hydrochloric acid with $NaHCO_3$, tin(II) ions complexed with Cl^- hydrolyze water and culminate in the precipitation of the tin(II) chloride hydroxide at pH 1.9—2.5. With increasing OH^- concentration, the chloride ions are replaced by hydroxide ions, the fraction of the $Sn_3(OH)_4^{2+}$ ions increase, and finally, the single phase of $Sn_3(OH)_4O$ precipitates in the pH range above 7.0 according to the reaction:

$$Sn_3(OH)_4^{2+} + 2(OH)^- \rightarrow Sn_3(OH)_4O + H_2O.$$

The Mössbauer parameters, both the isomer shift and quadrupole splitting, of the precipitates obtained over the pH range 2.55—4.90 changed with pH from the values of the chloride hydroxide to the hydroxide oxide. Accordingly the materials are not a mixture of the chloride hydroxide and hydroxide oxide. The Cl^- ligands of Sn^{II} are gradually replaced by OH^- as the pH rises. The X-ray diagrams of those materials gave weak patterns similar to those of $Sn_3(OH)_4O$.

The Mössbauer spectra and X-ray powder diagrams of tin(II) chloride hydroxide obtained at pH 2.4 and the thermal decomposition products obtained by heating to higher temperatures are shown in Figs.5 and 6, respectively. The Mössbauer parameters deduced from the spectra and existing phases are shown in Table 2.

The dehydrated product heated up to 200 °C changes to contain two species of Sn^{II}, which are equivalent in the initial compound. The product with smaller isomer shift is coordinated with more oxygen ligands; the other product with larger shift is coordinated with more chlorine ligands. The endothermic peak at 390 °C in the DTA curve in Fig. 1 is a melting reaction because the samples heated up to 370 and 420 °C gave similar Mössbauer parameters and X-ray diagrams, as is shown

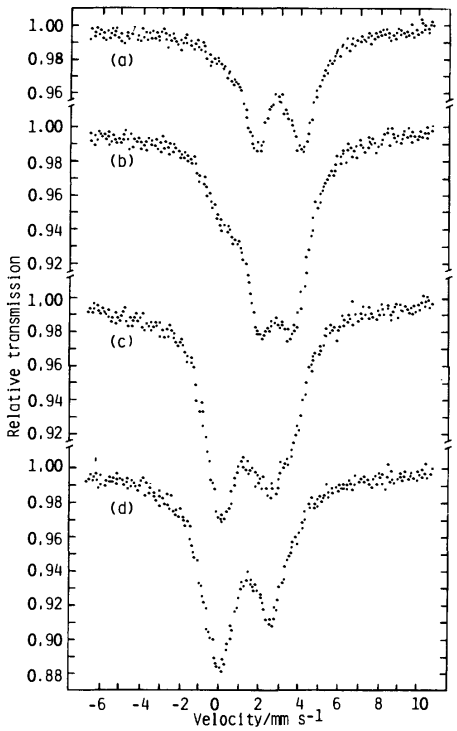

Fig. 7. Mössbauer spectra of tin(II) hydroxide oxide precipitated at pH 7.2 (a), and the thermal decomposition products by heating up to, (b) 260 °C; (c) 600 °C; (d) 700 °C.

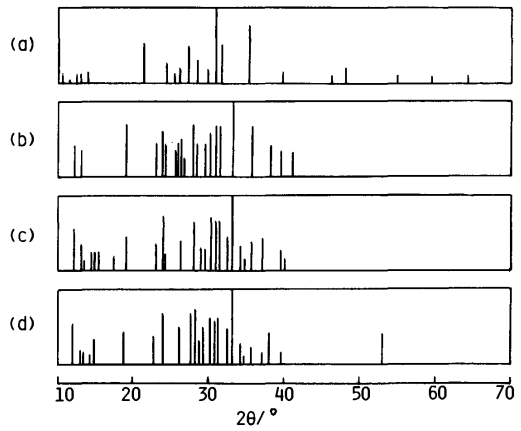

Fig. 6. X-Ray powder diagrams of tin(II) chloride hydroxide precipitated at pH 2.4 (a), and the thermal decomposition products by heating up to, (b) 200 °C; (c) 370 °C; (d) 420 °C.

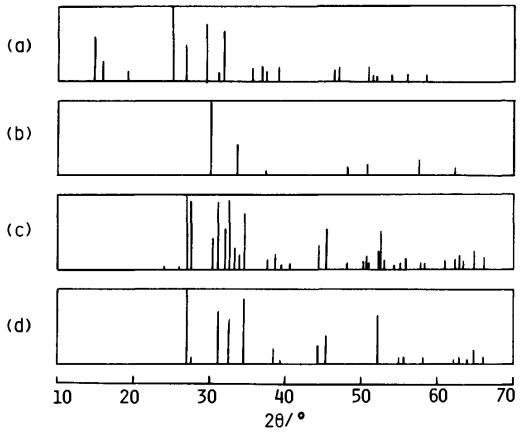

Fig. 8. X-Ray powder diagrams of tin(II) hydroxide oxide precipitated at pH 7.2 (a), and the thermal decomposition products by heating up to, (b) 260 °C; (c) 600 °C; (d) 700 °C.

TABLE 2. MÖSSBAUER PARAMETERS OF TIN(II) CHLORIDE HYDROXIDE PRECIPITATED AT pH 2.4 AND THE THERMAL DECOMPOSITION PRODUCTS BY HEATING UP TO 200, 370, 420, AND 700 °C

Temp	Sn^{II}		Sn^{IV}	Sn^{0}	Existing phase
°C	δ/mm s^{-1}	Δ/mm s^{-1}	δ/mm s^{-1}	δ/mm s^{-1}	
20	3.35	1.85			$Sn_3O(OH)_2Cl_2$
200	3.39	2.39			$Sn_3O_2Cl_2$
	3.52	1.21			
370	3.09	2.16			$Sn_3O_2Cl_2$
	3.61	1.71			
420	3.12	2.05			$Sn_3O_2Cl_2$
	3.73	1.59			
700			0.00	2.54	SnO_2, β-Sn

in Table 2 and Fig. 6, respectively. The final decomposition product heated to 700 °C is a mixture of tin(IV) oxide and β-tin as a consequence of the disproportionation reaction of SnO, which was observed in the DTA curve as the broad peak at about 600 °C.

The Mössbauer spectra and X-ray powder diagrams of tin(II) hydroxide oxide obtained at pH 7.2 and the thermal decomposition products obtained by heating to 260, 600, and 700 °C are shown in Figs. 7 and 8, respectively. The Mössbauer parameters and existing phases are shown in Table 3. The dehydration product heated to 260 °C was SnO, the product heated to 600 °C was a mixture of Sn_2O_3 and β-tin, and the final product obtained by heated to 700 °C is a mixture of SnO_2 and β-tin. Thus, in this hydroxide oxide, the disproportionation of SnO to SnO_2 and β-Sn occurs in two stages *via* Sn_2O_3 and the stages of the thermal decomposition are confirmed as :

$$2Sn_3(OH)_4O \rightarrow 6SnO \rightarrow 2Sn_2O_3 + 2\beta\text{-}Sn \rightarrow 3SnO_2 + 3\beta\text{-}Sn$$

The Mössbauer parameters and X-ray diagrams of tin(II) hydroxide oxide obtained at pH 7.5 and the thermal decomposition products by heating to 250, 420, 620, and 640 °C are shown in Figs. 9 and 10, respectively. The Mössbauer parameters and the existing phases are shown in Table 4. In the Mössbauer spectrum of Fig. 9(a), the area ratio of the tin(IV) impurity to the total was 20%. This suggests that if the

640			0.01	2.67	SnO_2, β-Sn

pH rises above 7.0, the oxidation of tin(II) to tin(IV) proceeds with the increase of pH and the stannic tin is involved in the lattice of hydroxide oxide. The product heated to 250°C, in which the first stage dehydration occurred, gave an amorphous X-ray diagram. This orange amorphous material was stable under an atmosphere of air for two weeks or more in diagreement with the previous report of Donaldson *et al.*[3] The second stage of the dehydration proceeds slowly over the temperature range 250—380°C. The disproportionation reaction of SnO, which was observed as two peaks in the DTA curve of the hydroxide oxide obtained at pH 7.2, collapsed into a small single peak and the residual SnO was still observed in the Mössbauer spectrum of the sample heated to 620°C. The final product was a mixture of SnO_2 and β-Sn and the intermediate Sn_2O_3 was not detected. These differences in the thermal behavior of the tin(II) hydroxide oxide can be ascribed to the change of tin(IV) content with pH.

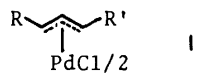
Palladium(II)-Catalyzed Acetoxylation and Chlorination of 2-Alkenyl *p*-Tolyl Sulfones

Katsuyuki OGURA,* Nobuhiro SHIBUYA, Kazumasa TAKAHASHI, and Hirotada IIDA
Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoicho 1-33, Chiba 260
(Received August 5, 1983)

2-Alkenyl *p*-tolyl sulfones were converted into the corresponding 3-acetoxy(or chloro)-1-alkenyl *p*-tolyl sulfones *via* π-allylpalladium complexes which reacted regiospecifically with a nucleophile such as acetate anion or chloride anion in the presence of Cu(II).

π-Allylpalladium complexes (**1**) are usually prepared by various methods starting from alkadienes, alkenes, and 2-alkenyl acetates (or chlorides), and they have often been utilized in organic synthesis.[1] Formally, these complexes



1

may be considered as allyl cation equivalents which react with various nucleophiles. In the course of our investigation to functionalize 2-alkenyl *p*-tolyl sulfones (**2**), we examined generation of di-μ-chlorobis-[1-(*p*-tolylsulfonyl)-π-allyl]dipalladium complexes (**3**) and their reactions with some nucleophiles to give substitution products such as 3-acetoxy-1-alkenyl *p*-tolyl sulfone (**4**) and 3-chloro-1-alkenyl *p*-tolyl sulfone (**5**).[2]

Scheme 1.

Recently, Trost and his coworkers reported on the reaction of 2-alkenyl phenyl sulfones with a Pd(O) complex, where the sulfonyl group behaves as a leaving group to form π-allylpalladium complexes.[3] This is in a sharp contrast with our findings that $PdCl_2$ reacts with **2** to give **3** without loosing the sulfonyl group. We have also found that **3** undergoes regiospecific displacement with acetate anion or chloride anion to give **4** or **5**, respectively.[4]

Results and Discussion

According to Trost's procedure for preparation of π-allylpalladium complexes from alkenes,[5] 2-propenyl *p*-tolyl sulfone (**2a**) was treated with $PdCl_2$ (1 mol equiv), $CuCl_2$ (6.1mol equiv), AcONa (13equiv), and NaCl (13 equiv) in AcOH (60°/16h). Surprisingly, the expected π-allylpalladium complex (**3a**) was not formed, but 3-chloro-1-propenyl *p*-tolyl sulfone (**5a**) and 3-acetoxy-1-propenyl *p*-tolyl sulfone (**4a**) were obtained in 60 and 29% yields, respectively. When the amount of $CuCl_2$ was decreased to 3.4 mol equiv, the acetate **3a** became the predominant product (70% yield). Furthermore, it was found that only a catalytic amount of $PdCl_2$ was needed to transform **2a** into **4a** and/or **5a**. Thus, the reaction proceeded smoothly by the use of 0.10 or 0.03 mol equiv of $PdCl_2$ as shown in Table 1 (Runs 3—5). In these cases, a large excess of $CuCl_2$ appears to oxidize Pd(0) to regenerate Pd(II). Since prolonged reaction did not cause remarkable increase of **4a** (Runs 5 and 6 of Table 1), it was concluded that **4a** is not produced from **5a**. Similar results were also obtained in the reactions of other 2-alkenyl *p*-tolyl sulfones (**2b** and **2c**). In contrast, 3-phenyl-2-propenyl *p*-tolyl sulfone (**2d**) afforded 3-acetoxy-3-phenyl-1-propenyl *p*-tolyl sulfone (**4d**) even when a large excess (6.2—6.9 mol equiv) of $CuCl_2$ was employed (Run 17—19 in Table 1).

Since the amounts of $CuCl_2$ were crucial to the ratio of **4a**:**5a**, we investigated the effect of $CuCl_2$ in more detail. As mentioned above, the acetate **4** was exclusively formed when about 6 mol equiv of $CuCl_2$ was used, whereas, when about 3 mol equiv of $CuCl_2$ was used, predominant formation of the chloride **5** was noted. Table 2 shows that the ratio of **4a**:**5a**, diminishes gradually with increase in the amount of $CuCl_2$ in the given reaction conditions. These phenomena might be attributable to a reversible reaction of $CuCl_2$ with AcONa. This may be supported by the fact that $CuCl_2$ reacted with 2 mol equiv of AcONa in AcOH to give the same mixture as that derived from $Cu(OAc)_2$ and NaCl in the molar ratio of 1:2.[6] This explanation is consistent with the observation that the absence of NaOAc increases the yield of **5a** though the reaction is somewhat slow (Runs 9 and 13 of Table 1).

Preparation of Di-μ-chlorobis[1-(p-tolylsulfonyl)-π-allyl]dipalladium (3a) and Its Reaction with Nucleophiles. As mentioned above, Trost's procedure[5] met with no success in obtaining **3a**. This may be because **3a** undergoes a smooth reaction with the coexisting AcONa in the presence of Cu(II) (*vide infra*). However, the reactions of **3b** and **3d** with nucleophiles appeared to be slow compared to that of **3a**. In fact, **3b** and **3d** were isolated by shortening the reaction time under similar conditions (see Experimental section). Later, it was found that the complex **3a** could also be obtained by treatment of **2a** with 1 mol equiv of $PdCl_2$ and 3 mol equiv of AcONa in AcOH at 60°C for 24 h. The structures of these complexes (**3a**, **3b**, and **3d**) were deduced from their IR spectra and satisfactory elemental analyses. Although **3a** was partially soluble in DMSO, rapid decomposition occurred to give the corresponding 3-hydroxy-1-propenyl *p*-tolyl sulfone. This fact made it difficult to record its NMR spectrum.

a) Stirring in AcOH at 60 °C for 48 h. b) An unidentified complex mixture which might be composed of **3a** and $Cu(OAc)_2$ was formed. c) Treatment of **3a** with 3.0 mol equiv of AcONa in AcOH at 80 °C for 48 h afforded **4a** in 88% yield.

With regard to the reactions of **3a** with acetate anion, it was observed that combined use of AcONa and $Cu(OAc)_2$ was effective to give **4a** (Table 3). Thus, **4a** was obtained in 74% yield on heating a mixture of **3a**, AcONa, and $Cu(OAc)_2$ in AcOH at 60 °C for 48 h. However, treatment of **3a** with either $Cu(OAc)_2$ or AcONa at 60 °C produced only **4a** in low yields. Analogously, stirring of **3a** with NaCl alone in AcOH did not give **5a**, and merely slow reaction of **3a** was noted when it was allowed to react with $CuCl_2$ in AcOH. However, when both $CuCl_2$ and NaCl were added to a solution of **3a** in AcOH, the reaction proceeded smoothly to afford **5a** in 80% yield together with a small amount (9%) of **4a**. In the reaction of **3a** with $Cu(OAc)_2$ and NaCl, both **4a** and **5a** were formed in 29 and 35% yields, respectively. These results indicate that a smooth conversion of **3a** to either **4a** or **5a** can be accomplished in the presence of both Cu(II) and a nucleophile (acetate anion or chloride anion, respectively). This may be interpreted in terms of the following mechanism: Cu(II) contacts the Pd(II)Cl part in **3a** to assist its departure and concurrently the nucleophile attacks the allylic carbon. At the present time, we cannot preclude the possibility that the attack of the nucleophile and the oxidation of Pd(II) of **3a** with Cu(II) occur simultaneously to give directly Pd(0) and the substitution product (**4a** or **5a**). Here it should be noted that the attack of the nucleophiles on **3a** took place at the carbon γ to the sulfonyl group to give **4** and **5**. Since the sulfonyl group is well known as a strong electron-withdrawing group,[7] the γ carbon in the allylic system of **3a** can be considered to be more positive than the α carbon. Therefore, the γ carbon appears to be the favorable site for the approach of a nucleophile.[8]

Requisite Additives for the $PdCl_2$-Catalyzed Conversion of 2 to 4 or 5. For the $PdCl_2$-catalyzed conversion of **2** to **4** or **5**, three steps must be taken into consideration: (i) transformation of **2** into the intermediary π-allylpalladium complex **3**; (ii) the reaction of **3** with a nucleophile to give Pd(0) and the substitution product (**4** or **5**); and (iii) oxidation of Pd(0) to regenerate Pd(II). The final step can be achieved by oxidation

with the coexisting Cu(II). As described previously, Cu(II) and a nucleophile appear to be neccessary to the second step. Of course, it may be also possible that the second and final steps take place simultaneously. Hitherto, Trost and his coworkers reported that three additives, $CuCl_2$, AcONa, and NaCl, were required for efficient production of π-allylpalladium complexes from acyclic and cyclic olefins and $PdCl_2$.[5] This may not be the present case because treatment of **2a** with $PdCl_2$ and AcONa gave **3a** (*vide supra*) and $PdCl_2$ (0.03 mol equiv) could catalyze the transformation of **2a** to **5a** in the presence of $CuCl_2$ (2 mol equiv) and NaCl (3 mol equiv) in AcOH (60°C/48 h: 80% yield).

For the transformation of **2a** into **4a** using 1 mol equiv of $PdCl_2$, combined use of AcONa (2 mol equiv) and $Cu(OAc)_2$ (3 mol equiv) promoted the reaction to give **4a** in 88% yield (60°C/ 48 h). However, the use of a catalytic amount of $PdCl_2$ did not result in complete transformation even in the presence of large amounts of $Cu(OAc)_2$ (4 mol equiv) and AcONa (6 mol equiv). To our surprise, however, Pd(II)-catalysis was successful if NaCl (3 mol equiv)was added. When **2a** was stirred with $PdCl_2$ (0.03 mol equiv), NaCl (3 mol equiv), $Cu(OAc)_2$ (2 mol equiv), and AcONa (6 mol equiv) in AcOH 60°C for 48 h, **4a** was obtained in 92% yield. In the $PdCl_2$-catalyzed conversion of **2a** to **5a** in the copresence of $CuCl_2$ and NaCl, NaCl not only supplies chloride anion but also is essential to the initiation of the reaction. Such a role of NaCl is intriguing, but we so far find no satisfactory interpretation. A possible explanation is that NaCl transforms $PdCl_2$ and $Pd(OAc)_2$, which is produced by oxidation of Pd(0) with $Cu(OAc)_2$, to the soluble palladates formulated as $Na_2[PdCl_n(OAc)_{4-n}]$.[9] Scheme 3 summarizes this proposed mechanism for the conversion of **2** to **4** and/or **5**.

Thus, the $PdCl_2$-catalyzed transformation of **2a** into **4a** or **5a** can be achieved by performing the reaction using $Cu(OAc)_2$-AcONa-NaCl or $CuCl_2$-NaCl, respectively. The reaction was also applied to other 2-alkenyl *p*-tolyl sulfones. The results were summarized in Table 4, showing that the present reaction conditions are general for syntheses of **4** or **5**.

Experimental

Melting points were determined on a hot-stage microscope apparatus (Yanagimoto) and are uncorrected. ^1H NMR spectra were obtained on a Hitachi R-600 spectrometer. Infrared spectra were determined with a JASCO A-200 spectrometer.

Treatment of **2a** *with* $PdCl_2$, $CuCl_2$, *AcONa, and NaCl in AcOH.* *(a) The Use* ca. *3 mol equiv of* $CuCl_2$: After a suspension containing $PdCl_2$ (468 mg: 2.64 mmol), NaCl (1.91 g: 32.7 mmol), AcONa (1.77 g: 21.6 mmol), and $CuCl_2$ (1.18 g: 8.78 mmol) in AcOH (15 ml)-Ac_2O (1.0 ml) was stirred at 90—98°C for 2 h, the suspension was cooled to 60°C. To this, a solution of **2a** (504 mg: 2.62 mmol) in AcOH (10 ml) was added and the resulting mixture was further stirred at 58—64°C for 75 h. Then, water (20 ml) was added and the mixture was extracted with four 35 ml-portions of benzene. The extracts were combined and washed successively with water, saturated aqueous $NaHCO_3$, brine, and water. After being dried over anhydrous $MgSO_4$, the extract was evaporated and separated by column chromatography on silica gel using benzene-dichloromethane (1 : 1) as an eluent to afford **4a** (454 mg: 70% yield): mp 23—24°C; IR (neat) 1745, 1384, 1318, 1303, 1280, 1230, 1148, 1095, 1038, 816, 663 cm^{-1}: ^1H NMR ($CDCl_3$) δ=2.06 (3H, s), 2.43 (3H, s), 4.78 (2H, dd, *J*=0.9 and 3.5 Hz), 6.61 (1H, td, *J*=0.9 and 15 Hz), 7.02 (1H, td, *J*=3.5 and 15 Hz), 7.32 (2H, d, *J*=9 Hz), and 7.79 (2H, d, *J*=9 Hz). Calcd for $C_{12}H_{14}O_4S + 1/20\ C_6H_6$: C, 57.22; H, 5.58%. Found: 57.31; H, 5.58%.

This compound was hydrolyzed to give 3-hydroxy-1-propenyl *p*-tolyl sulfone. A solution containing **3a** (171 mg: 0.67 mmol) and conc. hydrochloric acid (0.5 ml) in methanol (20 ml) was stirred at room temperature for 48 h. After addition of water (20 ml), the mixture was extracted with

a) Using $PdCl_2$ (3 mol%), $Cu(OAc)_2$ (2.0 mol equiv), AcONa (6.0 equiv), and NaCl (3.0 equiv) in AcOH.
b) Using $PdCl_2$ (5 mol%), $CuCl_2$ (3.0 mol equiv), and NaCl (3.0 equiv), in AcOH.

four 30 ml-portions of dichloromethane. The extracts were combined, washed with water, and evaporated under reduced pressure to give colorless crystals (131 mg: 92% yield) which were purified by recrystallization from carbon tetrachloride-dichloromethane to afford colorless needles (100 mg): mp 122—123 °C; IR (KBr) 3605, 1295, 1286, 1274, 1137, 1079, 942, 811, 665, 536, 523 cm^{-1}: ^1H NMR ($CDCl_3$) δ=2.43 (3H, s),4.34 (2H, m), 6.60 (1H, diffused d, J=15 Hz), 7.03 (1H, td, J=3 and 15 Hz), 7.33 (2H, d, J=8 Hz), 7.77 (2H, d, J=8 Hz). Calcd for $C_{10}H_{12}O_3S$: C, 56.59; H, 5.70%. Found: C, 56.61; H, 5.66%.

In the analogous manners, **4b** and **4c** were obtained. **4b**: An oil; IR (neat) 1742, 1373, 1317, 1303, 1235, 1145, 1082, 661, 568, 548, 539 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.36 (3H, d, J=6 Hz), 2.03 (3H, s), 2.41 (3H, s), 5.25—5.72 (1H, m), 6.43 (1H, dd, J=1.6 and 16 Hz), 6.90 (1H, dd, J=4 and 16 Hz), 7.31 (2H, d, J=8 Hz), and 7.73 (2H, d, J=8 Hz). Calcd for $C_{13}H_{16}O_4S$: C, 58.19; H, 6.01%. Found: C, 58.08; H, 6.15%. **4c**: An oil; IR (neat) 3030, 2860, 1748, 1375, 1320, 1301, 1235, 1150, 1087, 665 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.25—1.82 (19H, m), 2.01 (3H, s), 2.44 (3H, s), 5.13—5.56 (1H, diffused s), 6.37 (1H, d, J=15 Hz), 6.83 (1H, dd, J=4 and 15 Hz), 7.31 (2H, d, J=8 Hz), and 7.74 (2H, d, J=8 Hz). Calcd for $C_{13}H_{16}O_4S$: C, 58.19; H, 6.01%. Found: C, 58.08; H, 6.15%.

(b) The Use of ca. *6 mol equiv of* $CuCl_2$: After a suspension containing $PdCl_2$ (370 mg: 2.09 mmol), $CuCl_2$ (1.70 g: 12.7 mmol), AcONa (22.2 g: 27.1 mmol), and NaCl (1.55 g: 26.5 mmol), in AcOH (23.0 ml)-Ac_2O (1.0 ml) was stirred at 90—95 °C for 2 h, **2a** (410 mg: 2.09 mmol), was added along with AcOH (4.0 ml), and the resulting mixture was stirred at 60 °C for 16 h. After addition of water (50 ml) and extraction with four 70-ml portions of benzene-dichloromethane (3:1), the extracts were combined and washed with water, saturated aqueous $NaHCO_3$, and brine. Then, after the extract was dried over anhydrous $MgSO_4$, the solution was evaporated under reduced pressure, and the residue was subjected to column chromatography on silica gel using benzene-hexane and benzene-AcOEt as eluents to give **4a** (156 mg: 29% yield) and **5a** (291 mg: 60% yield). An analytical sample of **5a** was obtained by recrystallization from benzene-hexane: mp 58—59 °C; IR (KBr) 3046, 2921, 1302, 1276, 1141, 861, 709, 587, 530, 501 cm^{-1}: ^1H NMR ($CDCl_3$) δ=2.44 (3H, s), 4.19 (2H, dd, J=1.1 and 5.0 Hz), 6.66 (1H, dd, J=1.1 and 14.8 Hz), 6.97 (1H, dt, J=5.0 and 14.8 Hz), 7.32 (2H, d, J=8.0 Hz), and 7.77 (2H, d, J=8.0 Hz). Calcd for $C_{10}H_{11}O_2ClS$: C, 52.06; H, 4.81%. Found: C, 51.97; H, 4.80%.

Similarly, the following compounds were obtained. **5b**: Mp 37—38 °C (from hexane); IR (KBr) 1315, 1303, 1281, 1145, 1088, 963, 840, 808, 671, 578, 543 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.62 (3H, d, J=6.8 Hz), 2.44 (3H, s), 4.63 (1H, diffused quintet, J=6 Hz), 6.61 (1H, dd, J=14.8 and 0.6 Hz), 6.92 (1H, dd, J=14.8 and 5.6 Hz), 7.37 (2H, d, J=8.3 Hz), and 7.77 (2H, d, J=8.3 Hz). Calcd for $C_{11}H_{13}O_2ClS$: C, 53.99; H, 5.26%. Found: C, 54.02; H, 5.35%.

5c: Mp 30—31 °C; IR (neat) 2925, 2851, 1315, 1302, 1285, 1143, 1186, 811, 653, 588 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.67—1.90 (19H, m), 2.44 (3H, s), 4.44 (1H, dt, J=6.4 and 5.7 Hz), 6.55 (1H, d, J=14.7 Hz), 7.22 (2H, d, J=8.1 Hz), and 7.74 (2H, d, J=8.1 Hz). Calcd for $C_{19}H_{29}O_2ClS$: C, 63.93; H, 8.19%. Found: C, 63.95; H, 8.11%.

Under the similar conditions, 3-phenyl-2-propenyl *p*-tolyl sulfone (**2d**) gave **4d**: mp 108—109 °C; IR (KBr) 3080, 2925, 1739, 1314, 1301, 1236, 1139, 673, 536 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.02 (3H, s), 2.41 (3H, s), 6.18 (1H, dd, J=1.5 and 4.5 Hz), 6.25 (1H, dd, J=1.5 and 15 Hz), 6.99 (1H, dd, J=4.5 and 15 Hz), 7.16—7.61 (7H, broad), and 7.68 (2H, d, J=8 Hz). UV (EtOH) 207 (ε 11700), 239 (12000), and 277 (562) nm. Calcd for $C_{18}H_{18}O_4S$: C, 65.44; H, 5.49%. Found: C, 65.42; H, 5.43%. No **5d** was obtained in this reaction.

Acid hydrolysis of **4d** was also performed by the procedure similar to that of **3a**. 3-Hydroxy-3-phenyl-1-propenyl *p*-tolyl sulfone: mp 134—135 °C; IR (KBr) 3590, 1314, 1307, 1276, 1137, 1078, 975, 813, 756, 704, 691, and 543 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.43 (3H, s), 2.70 (1H, d, J=6 Hz, OH), 5.15—5.49 (1H, m), 6.66 (1H, d, J=16 Hz), 7.18 (1H, dd, J=3.5 and 16 Hz), 7.15—7.46 (7H, m), 7.70 (2H, d, J=8 Hz). Calcd for $C_{16}H_{16}O_3S$: C, 66.64; H, 5.59%. Found: C, 66.79; H, 5.64%.

Isolation of the π-Allylpalladium Complex (3a). A suspension involving **2a** (1.96 g: 10.0 mmol), $PdCl_2$ (1.77 g: 10.0 mmol), and AcONa (1.65 g: 20 mmol) in AcOH (100 ml)-Ac_2O (5 ml) was stirred at 60 °C for 24 h. The deposited solid was collected by filtration and transfered into a beaker. Then, the solid was triturated with benzene (10 ml) and the benzene was discarded by decantation. After this procedure was repeated five times, the solid was washed with five 10 ml-portions of water and dried over sulfuric acid under reduced pressure. An analytical sample was obtained as follows. **3a** was dissolved in DMSO-AcOH (3:2) under ice-cooling and then excess of AcOH was added to deposit **3a**. The solid (**3a**) was filtered and washed with water and dichloromethane: mp 152—164 °C (decomp); IR (KBr) 1310, 1299, 1140, 1092, 820, 802, 788, 656, 573, and 552 cm^{-1}. Calcd for $C_{10}H_{11}O_2ClPdS$: C, 35.63; H, 3.29%. Found: C, 35.23; H, 3.29%.

Isolation of the π-Allylpalladium Complexes (3b and 3d). After a suspension containing $PdCl_2$ (460 mg: 2.59 mmol), NaCl (1.94 g: 23.6 mmol), AcONa (2.77 g: 33.8 mmol), and $CuCl_2$ (943 mg: 7.01 mmol) in AcOH (14 ml)-Ac_2O (3 ml) was stirred at 95—105 °C for 2 h, a solution of **2b** (553 mg: 2.63 mmol) in AcOH (5 ml) was added and the resulting mixture was stirred at 60—65 °C for 76 h. After addition of benzene (20 ml), the mixture was extracted with four 20-ml portions of benzene. The yellow solid floating in the benzene layer was collected by filtration, washed with benzene, and dried in a desiccator to give **3b** (621 mg) as a greenish yellow solid. An analytical sample was obtained by dissolution in DMSO-AcOH (3:1) followed by reprecipitation by addition of water: mp: 168—170 °C; IR (KBr) 3060, 1595, 1308, 1301, 1150, 1079, 820, 806, 799, 654, 566 cm^{-1}. Calcd for $C_{11}H_{13}O_2ClPdS+0.9H_2O$: C, 35.96; H, 4.06%. Found: C, 35.82; H, 3.70%.

The benzene layer was washed with water and saturated aqueous $NaHCO_3$, dried over anhydrous $MgSO_4$, evaporated, and chromatographed on silica gel [elution with benzene- dichloromethane (1:2)] to give **4b** (142 mg: 20% yield).

In the similar manner, **3d** was obtained: mp 193—194 °C (decomp). Calcd for $C_{16}H_{15}O_2ClPdS+0.7H_2O$: C, 45.13; H, 3.88%. Found: C, 45.08; H, 3.69%.

Reaction of 3a with $CuCl_2$ and NaCl. A Typical Procedure: A suspension containing **3a** (506 mg: 1.50 mmol), $CuCl_2$ (404 mg: 3.00 mmol), and NaCl (263 mg: 4.50 mmol) in AcOH (19.5 ml)-Ac_2O (0.7 ml) was stirred at 60 °C for 48 h. After addition of water (40 ml), the mixture was extracted with four 50-ml portions of benzene-dichloromethane (3:1) and the organic layer was washed successively with water, saturated aqueous $NaHCO_3$, brine, and water. The organic layer was dried over anhydrous $MgSO_4$, the solvents were removed, and the resultant residue was subjected to column chromatography on silica gel using hexane-benzene (4:1) and benzene-ethyl acetate (4:1) as eluents to afford **5a** (272 mg), a mixture (6.7 mg) of **5a** and **4a** (9:1), and **4a** (35 mg). The yields of **5a** and **4a** were calculated to be 80 and 9%, respectively.

In the similar manners, **3a** was subjected to the reaction in the presence of various additives. The results were summarized in Table 3.

$PdCl_2$-Catalyzed Conversion of 2a to 4a. A Typical Procedure: A suspension involving **2a** (393 mg: 2.0 mmol), $PdCl_2$ (10.6 mg: 0.06 mmol), $Cu(OAc)_2$ (726 mg: 4.0 mmol), AcONa (985 mg: 12.0 mmol), and NaCl (351 mg: 6.0 mmol), in AcOH (26 ml)-Ac_2O (1 ml) was stirred at 60 °C for 48 h.

After addition of water (40 ml), the resulting mixture was extracted with four 60-ml portions of benzene–dichloromethane (4:1) and then the extract was washed successively with water, saturated aqueous $NaHCO_3$, brine, and water. The extract was dried over anhydrous $MgSO_4$, the solvents were removed, and the resultant residue was subjected to column chromatography on silica gel using hexane–benzene (9:11) and benzene– ethyl acetate (3:2) as eluents to give **4a** (476 mg: 92% yield).

Analogously, **2b** and **2c** were converted to **4b** (90% yield) and **4c** (73% yield), respectively, under the conditions described in Table 4.

$PdCl_2$-Catalyzed Conversion of 2a to 5a. A Typical Procedure: A suspension involving **2a** (1.00 g: 5.1 mmol), $PdCl_2$ (27.1 g: 0.153 mmol), $CuCl_2$ (2.06 g: 15.3 mmol), and NaCl (894 mg: 15.3 mmol) in AcOH (26 ml)–Ac_2O (1 ml) was stirred at 80°C for 30 h. After water (100 ml) was added, the resulting mixture was extracted with four 60-ml portions of benzene–dichloromethane (4:1). Then the organic layers was combined and washed successively with water, saturated aqueous $NaHCO_3$, brine, and water. This layer was dried over anhydrous $MgSO_4$, the solvents were removed, and the resultant residue was subjected to column chromatography on silica gel using hexane–benzene (9:11) and benzene–ethyl acetate (3:2) as eluents to give **5a** (1.09 g: 89% yield).

Similarly, **2b** and **2c** were converted **5b** (68% yield) and **5c** (57% yield), respectively, under the conditions described in Table 4.

Mass Spectra of Butyl Esters and *N*-Trifluoroacetyl Butyl Esters of Some Iminodicarboxylic Acids upon Electron Impact

Katsuhiro KAWASHIRO,* Shiro MORIMOTO, and Hideyuki YOSHIDA

Department of Chemical Engineering, Faculty of Engineering, Tokushima University, Minamijosanjima, Tokushima 770

(Received August 24, 1983)

Mass spectra (electron impact at 20 eV) of butyl esters and *N*-trifluoroacetyl (TFA) butyl esters of some iminodicarboxylic acids (IDCAs) were determined by gas chromatography-mass spectrometry. The IDCAs included iminodiacetic acid (**1**), 2-(carboxymethylamino)propionic acid (**2**), 3-(carboxymethylamino)propionic acid (**3**), 2,2′-iminodipropionic acid (**4**), 2,3′-iminodipropionic acid (**5**), 3,3′-iminodipropionic acid (**6**), *N*-methyliminodiacetic acid (**7**), and nitrilotriacetic acid (**8**). The mass spectra of the butyl ester derivatives are simple, exhibiting the corresponding molecular (M^+) ions with the exception of **5**. The α,α'-IDCAs (**1**, **2**, **4**, **7**, and **8**) are characterized by M^+, M −101 ($COOC_4H_9$) (base peak), and M −157 ($COOC_4H_9+C_4H_8$) ions. The β,β'-IDCA (**6**) is characterized by a more complex spectrum with M^+, M −73 (OC_4H_9), M −115 ($CH_2COOC_4H_9$) (base peak), M −129 ($OC_4H_9+C_4H_9$), and M −171 ($CH_2COOC_4H_9+C_4H_9$) ions. The α,β'-IDCAs (**3** and **5**) in general show spectra in which both ions characteristic of α,α'- and β,β'-IDCAs are observed. The addition of TFA to the imino nitrogens of **1**—**6** increases complexity of the resulting spectra. In these instances, although M^+ ions are usually present, neither M −101 nor M −115 ions are base peaks. The fragmentation pathways of these two volatile derivatives of the IDCAs upon electron impact are discussed.

In connection with chemical evolution, Chadha *et al.*[1] applied a discharge through a simulated Jovian atmosphere. After a reaction mixture was hydrolyzed and derivatized, they identified amino acids such as glycine and alanine, and their *N*-methyl and *N*-acetic acid derivatives (iminodicarboxylic acids, IDCAs) by gas chromatography-mass spectrometry (GC-MS). This result demonstrates that non-protein amino acids such as *N*-alkyl amino acids and IDCAs can be formed along with protein amino acids when amino acid syntheses take place prebiologically from simple molecules or gaseous mixtures *via* a Strecker mechanism. The GC-MS has been shown to be the most suitable method for unequivocal identification of amino acids and related compounds by means of retention times and mass spectral confirmation.[2-5] In these studies, an *N*-trifluoroacetylated *s*-butyl,[2-4] butyl,[1] and isopropyl[5] ester derivatives were used for GC-MS analysis.

Electron impact (EI) mass spectra of *N*-trifluoroacetyl (TFA) butyl esters of protein amino acids[6,7] and certain non protein amino acids[7,8] including β- and γ-, and *N*-alkyl amino acids, have been determined by GC-MS. Recently, Cronin *et al.*[9] have studied GC-MS of the *N*-TFA *s*-butyl esters of five carbon β-, γ-, and δ-amino acids, and presented 70 eV spectra. However, little GC-MS information is available on IDCAs at present. This prompted us to investigate GC-MS of *N*-TFA butyl esters of some IDCAs, as shown in Fig. 1, for unequivocal identification of such IDCAs present in reaction mixtures of prebiological amino acid synthesis. The reason for the *N*-TFA butyl ester derivative to be chosen in the present study, is that not only the derivatives of amino acids have widely been used for GC,[10] but also their fragmentation pathways upon electron impact have been discussed in detail.[6,7,11] Furthermore, previous authors[6,8] have suggested that various alkyl groups used in the esterification gave almost the same fragmentation pathways for amino acids.

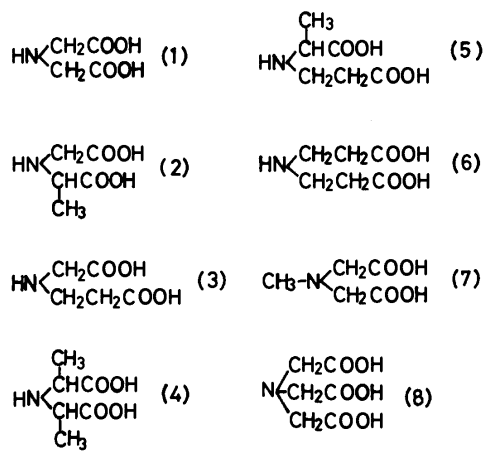

Fig. 1. Iminodicarboxylic acids.

In contrast with common amino acids, the NH of IDCAs is considered to be sterically hindered to some extent, so that trifluoroacetylation at room temperature was found to be incomplete in the case of 2,2′-iminodipropionic acid (**4**). Therefore, GC-MS of butyl ester derivatives was also studied.

The IDCAs studied in the present paper include iminodiacetic acid (**1**), 2-(carboxymethylamino)propionic acid (**2**), 3-(carboxymethylamino)propionic acid (**3**), **4**, 2,3′-iminodipropionic acid (**5**), 3,3′-iminodipropionic acid (**6**), *N*-methyliminodiacetic acid (**7**), and nitrilotriacetic acid (**8**). The structures of **1**—**8** are shown in Fig. 1. They are classified into three groups, α,α'-IDCAs (**1**, **2**, **4**, **7**, and **8**), α,β'-IDCAs (**3** and **5**), and β,β'-IDCA (**6**). Since **7** and **8** are *N*-substituted α,α'-IDCAs, only butyl ester derivatives were studied with them.

Results and Discussion

Gas Chromatography. Figure 2 shows a gas chromatographic separation of a mixture of the butyl esters of **1**—**8**. Although **1**, **2**, and **7** overlapped completely, separate experiments revealed that each IDCA except **4** gives a single GC peak. Compound **4** was found to give two GC peaks, which were evidenced by their mass spectra. This can be ascribed to the separation between diastereomers because **4** has two asymmetric carbon

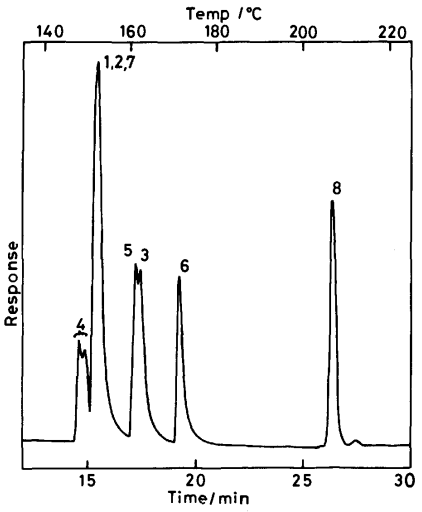

Fig. 2. Gas chromatogram of the butyl esters of **1**—**8**.
Injected: 3.12×10^{-3} μmol of each derivative.
Column: 1.5% OV-101 on Chromosorb G HP (100/120 mesh), 1 m×3 mm I.D. glass. Conditions: initial temperature, 100°C; initial hold, 5 min; program rate, 5°C/min; final temperature, 230°C. Sensitivity: 10×32.

atoms. Figure 3 shows a gas chromatographic separation of a mixture of the *N*-TFA butyl esters of **1**—**6**. Again, each derivative except **4** gave a single GC peak, while **4** gave two GC peaks due to the separation between diastereomers. As expected, the *N*-TFA butyl ester derivatives had somewhat longer retention times than the corresponding butyl ester derivatives.

Mass Spectra. *A) Butyl Ester Derivatives*: Figures 4a—c present the mass spectra of 2,2′-, 2,3′-, and 3,3′-iminodipropionic acid (**4**—**6**). Characteristic ions for **1**—**8** are listed in Table 1. The molecular ions (M^+) are present in all the spectra except **5**. The α,α′-IDCAs give very simple spectra upon electron impact. The base peaks are always M−101 ions which can originate from the following cleavage with charge retention on the nitrogen atoms:

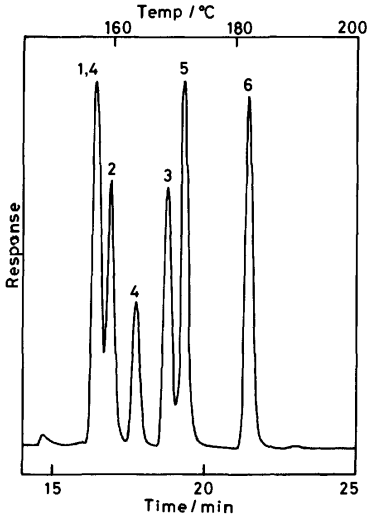

Fig. 3. Gas chromatogram of the *N*-TFA butyl esters of **1**—**6**.

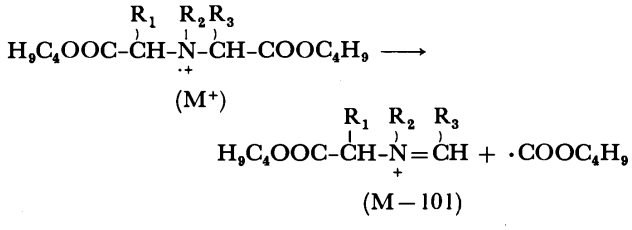
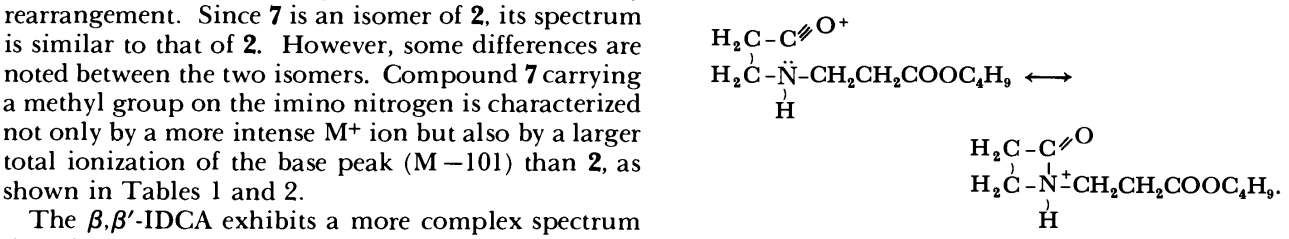
a) Values in parentheses indicate relative intensity. b) The first gas chromatographic peak. c) A tributyl ester.



The predominance of the M−101 ($COOC_4H_9$) ion can be explained in terms of its increased stability due to resonance as described by Biemann *et al.*[12] Another prominent ion for the α,α'-IDCAs, the M−157 ion, results from the M−101 ion by the loss of 1-butene from the residual ester portion *via* a McLafferty rearrangement. Since **7** is an isomer of **2**, its spectrum is similar to that of **2**. However, some differences are noted between the two isomers. Compound **7** carrying a methyl group on the imino nitrogen is characterized not only by a more intense M^+ ion but also by a larger total ionization of the base peak (M−101) than **2**, as shown in Tables 1 and 2.

The β,β'-IDCA exhibits a more complex spectrum than the α,α'-IDCAs (Fig. 4c). The ion at m/z 158 (M−115) is a base peak, which arises from the M^+ ion by the loss of $CH_2COOC_4H_9$ due to alpha-beta bond cleavage (α-cleavage to the imino nitrogen). Because the M−115 ($CH_2COOC_4H_9$) ion resulting from the cleavage is very stable, the fragmentation losing $COOC_4H_9$ from the M^+ ion does not take place to any appreciable extent. Consequently, the M−101 ion typical of the α,α'-IDCAs is of minor importance in this case. The M−115 ion produces the M−171 ion at m/z 102 by the loss of 1-butene from the residual ester portion *via* a McLafferty rearrangement. An important M−73 ion results from the M^+ ion by the loss of OC_4H_9 from either of the two ester portions. This M−73 (OC_4H_9) ion is characteristic of the β,β'- and α,β'-IDCAs, namely those bearing a butoxycarbonyl group at the beta position to the imino nitrogen, and is not present in the spectra of the α,α'-IDCAs (Table 1). One possible explanation for the stability of the M−73 ion has been proposed by Lawless and Chadha[8] as follows:



However, the M−73 peaks observed for **3**, **5**, and **6** are much smaller than those of *N*-TFA-β-amino acid butyl esters reported by Lawless and Chadha.[8] This difference may be explained in terms of the stability of such a cyclized ion as shown above. In the *N*-TFA-β-amino acid butyl esters, the *N*-TFA group is considered to stabilize the resultant cyclized ions through electron-withdrawing. The prominent M−129 ion at m/z 144 originates from the loss of 1-butene from the residual ester portion of the M−73 ion *via* a McLafferty rearrangement. This M−129 ($OC_4H_9 + C_4H_8$) ion is missing in the spectra of the α,β'-IDCAs but present with a low intensity in those of certain α,α'- IDCAs (**1**, **2**, and **8**).

As shown in Fig. 4b, α,β'-IDCAs are characterized by spectra exhibiting both ions typical of the α,α'- and β,β'-IDCAs with the exception of the M−129 ion observed for **6**. However, base peaks are always M−101 and not M−115 ions, indicating that a butoxycarbonyl group (a), defined below, is more preferentially split

TABLE 2. TOTAL IONIZATION OF BASE PEAKS OF THE BUTYL ESTERS OF **1**—**8**

Parent IDCA	Base peak/m/z	Origin	Total ionization/%
1	144	M−101	20
2	158	M−101	38
3	158	M−101	20
4	172	M−101	60
5	172	M−101	42
6	158	M−115	29
7	158	M−101	66
8	258	M−101	42

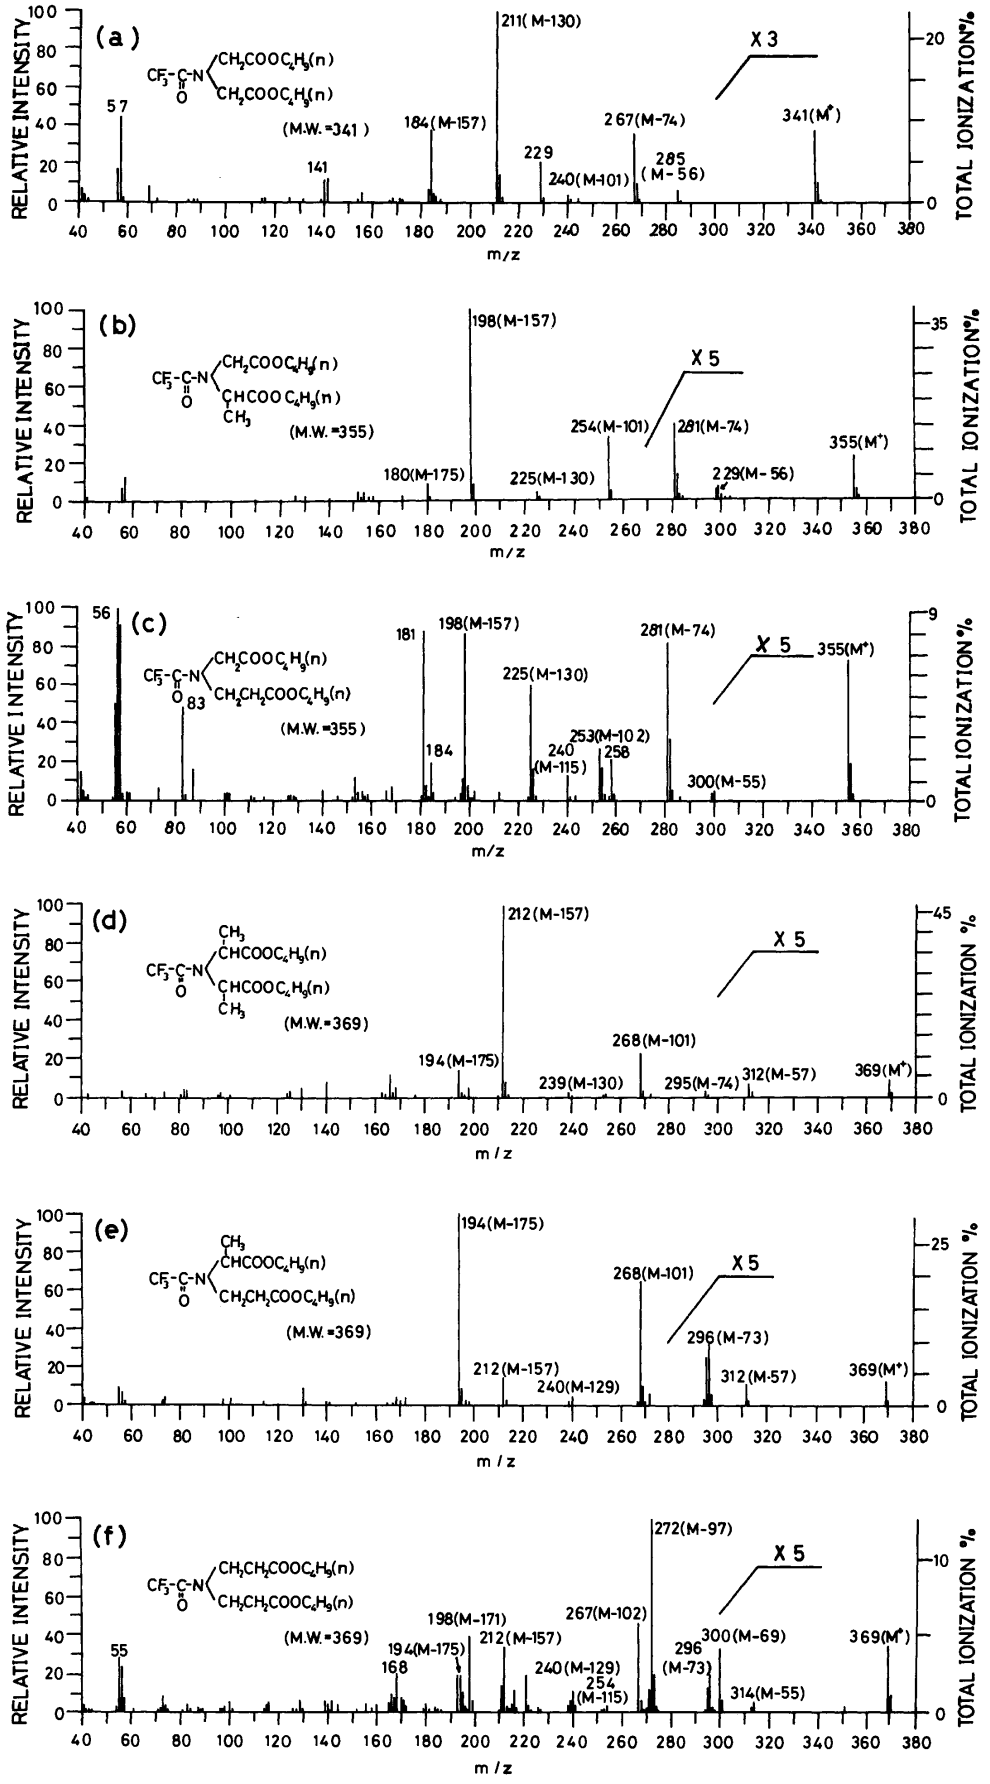


Fig. 5. Mass spectral fragmentations of the *N*-TFA butyl esters of IDCAs. a: **1**, b: **2**, c: **3**, d: **4**, e: **5**, and f: **6**.

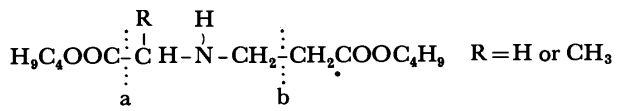
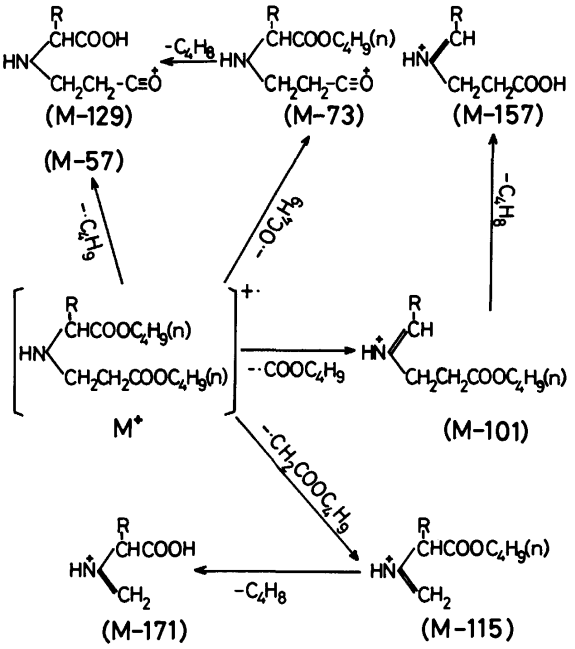


off than a butoxycarbonylmethyl one (b), also defined above, by α-fission to the imino nitrogen atom. A prominent M−175 ion is observed for **3** and **5**, which corresponds to the one resulting from the M−157 ion by the loss of H_2O,[6] or from the M−101 ion by the loss of 1-butanol.[7] Fragmentation pathways for the α,β'-IDCAs are presented in Scheme 1 as an illustrative example, which involves both the pathways characteristic of α,α'- and β,β'-IDCAs.



Scheme 1. Fragmentation pathways of the butyl esters of the α,β'-IDCAs.

As shown in Table 1, the M−57 ion is consistently present in all the spectra, which arises from the loss of a butyl group from the corresponding M^+ ion. The M+1 ion is also observed for **1**—**8**, and in certain instances (**2** and **5**) this ion is more intense than the corresponding M^+ ion.

As shown in Table 2, the total ionization of the base peak (M−101) generally depends on the structure of IDCA. The IDCAs carrying a methyl group on an α-carbon or an imino nitrogen atom have larger total ionization.

In conclusion, the α,α'-IDCAs are characterized by the M^+, M−101 (base peak), and M−157 ions. The β,β'-IDCA is characterized by a more complex spectrum with the M^+, M−73, M−115 (base peak), M−129, and M−171 ions. The α,β'-IDCAs generally show spectra in which both ions characteristic of α,α'- and β,β'-IDCAs are present. The M−101 and not M−115 ion is a base peak for the α,β'-IDCAs.

B) N-TFA Butyl Ester Derivatives: Figures 5a—f show the mass spectra of *N*-TFA butyl esters of **1**—**6**. In general, each spectrum is more complex than that of the corresponding butyl ester derivative. However, M^+ ions are present in all the spectra. The M−101 (loss of a butoxycarbonyl) ion which is a base peak for the butyl ester derivatives with the exception of **6**, becomes less significant in these instances. This may be due to the fact that a strong electron-attractive TFA group attached to an imino nitrogen atom will decrease the stability of the ion. It is noted that the important ions, M−73 (loss of a butoxyl group), M−74 (loss of 1-butanol), M−129 (loss of a butoxyl group and 1-butene), and M−130 are consistently present in all the spectra. The M−130 ion is observed at *m/z* 225 for **3** and its elementary composition was determined to be $C_7H_6NO_4F_3$ by a high-resolution mass measurement, which corresponds to the loss of 1-butanol and 1-butene from the M^+ ion. Accordingly, the M−130 ion is considered to result from the M−74 ion by the loss of 1-butene *via* a McLafferty rearrangement. The M−74 ion arises from the loss of 1-butanol from either of the two ester portions of the M^+ ion. Gelpi *et al.*[6] have found, for the *N*-TFA butyl esters of aspartic and glutamic acids, that the cleavage of one of the butoxyl groups to give the M−73 ion is accompanied by removal of 1-butanol to give the M−74 ion. This fragmentation is significant especially for the *N*-TFA butyl esters of IDCAs, but not for the butyl ester derivatives.

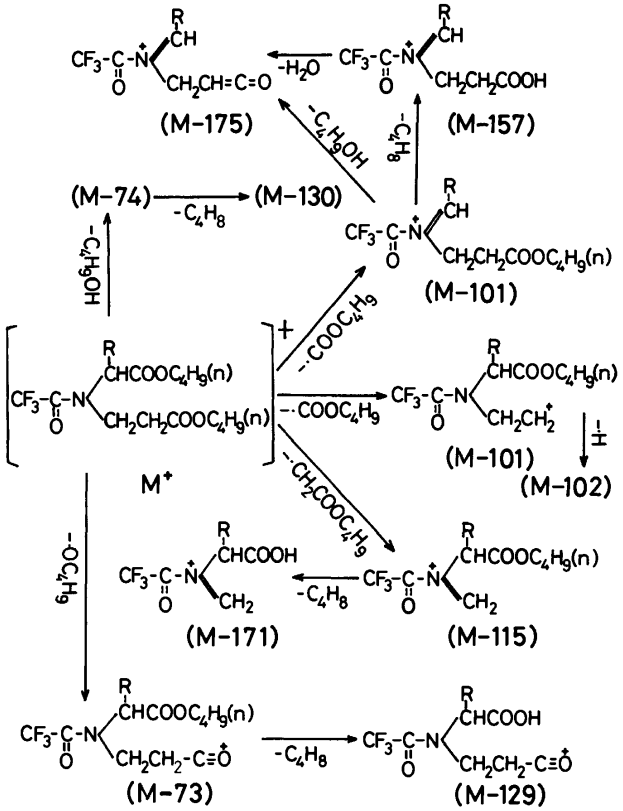
In the high mass region, two ions, M−55 and M−56, are usually present, although not as major peaks in any instances. The former ion may be explained in terms of a double hydrogen rearrangement. The latter ion results from the loss of 1-butene from the M^+ ion *via* a McLafferty rearrangement.

For the α,α'-IDCAs (**1**, **2**, and **4**), the M−74 and M−130 ions are more intense than the M−73 and M−129 ions, respectively. In the case of **1**, the M−130 ion at *m/z* 211 is a base peak. Additional characteristic ions are M−157 (loss of a butoxycarbonyl and 1-butene) and M−175 (loss of a butoxycarbonyl and 1-butanol). The former ion is a base peak for **2** and **4**.

In contrast, the β,β'-IDCA (**6**) shows a more complex spectrum (Fig. 5f) than the α,α'-IDCAs. The base peak at *m/z* 272 corresponds to a fragment, M−97 (CF_3CO), which was confirmed by a high-resolution mass measurement. Other unusual ions are M−69 (CF_3) at *m/z* 300 and M−102 ($COOC_4H_9$+H) at *m/z* 267, the elementary compositions of which were also confirmed by high-resolution mass measurements. The M−102 ion is more intense than the M−101. This fact is in good agreement with results obtained for β-amino acid derivatives,[7,8] since **6** is an *N*-substituted β-alanine. The stability of the M−102 ion for β-amino acids has been explained in terms of resonance by Lawless and Chadha.[8] Additional characteristic ions are M−115 (loss of a butoxycarbonylmethyl) at *m/z* 254 and M−171 (loss of a butoxycarbonylmethyl and 1-butene) at *m/z* 198. The characteristic ions of the α,α'-IDCAs such as the M−157 and M−175 ions are also observed. In contrast with the α,α'-IDCAs, the M−74 and M−130 ions are less intense than the M−73 and M−129 ions, respectively.

For the α,β'-IDCAs (**3** and **5**), fragmentations become more complicated. As shown in Fig. 5c, **3** exhibits a spectrum in which both ions characteristic of the α,α'- and β,β'-IDCAs are present. The elementary composition of an unusual ion at *m/z* 181 was determined to be $C_6H_6NO_2F_3$ by a high-resolution mass measurement, which corresponds to a fragment, M−174

($COOC_4H_9 + OC_4H_9$). The origin and structure of this ion are unkown. On the other hand, **5** exhibits an almost identical spectrum (Fig. 5e) with that of the corresponding α,α'-IDCA (**4**), except that the base peak is M−175 at *m/z* 194, and that the M−74 and M−130 ions are less intense than the M−73 and M−129 ions, respectively. Although the M−102 ion is present with a very low intensity, another ion typical of the β,β'-IDCA, M−115, is not observed. This fact indicates that either of the fragmentation characteristics of α,α'- or β,β'-IDCAs can take place predominantly depending on the structures of α,β'-IDCAs. Fragmentation pathways for the α,β'-IDCAs are presented in Scheme 2 as an illustrative example. The structures of the M−74 and M−130 ions are unknown.



Scheme 2. Fragmentation pathways of the *N*-TFA butyl esters of the α,β'-IDCAs.

Although fragmentation pathways for the *N*-TFA butyl esters of the IDCAs are more complicated than those for the butyl ester derivatives, it seems possible to identify unknown IDCAs by noting the characteristic ions described above.

Experimental

All the melting points were determined with a Yanagimoto micro melting point apparatus and were not corrected. ^1H NMR spectra were measured with a Hitachi R-24B spectrometer using DSS as an internal standard. Thin layer chromatography was carried out on silica gel 60 F_{254} (Merck) using the following solvent system: *n*-BuOH–AcOH–H_2O (4:1:1, v/v).

Preparation of IDCAs. Compound **1** was obtained from Wako Pure Chemical Industries, Ltd. and **8** was prepared by the method reported previously.[13]

2-(Carboxymethylamino)propionic Acid (2). Compound **2**·HCl was prepared from DL-alanine (5.6 g, 63 mmol) and chloroacetic acid (5.9 g, 62 mmol) in the presence of 4 M LiOH (1 M=1 mol dm^{-3}) (46.4 ml) according to the method of Okamoto *et al.*[14] The aqueous solution of **2**·HCl was poured into an ion-exchange column (2.0ϕ×100 cm, Amberlite CG 120 (H form)) and then **2** was eluted with H_2O. The fractions containing **2** were concentrated to give crystals of free **2**: these were recrystallized from H_2O-acetone: yield 2.47 g (27%); mp (decomp) 229—232° (lit,[15] 222—223°C); R_f 0.04. Found: C, 40.55; H, 6.10; N, 9.52%. Calcd for $C_5H_9NO_4$: C, 40.82; H, 6.17; N, 9.52%.

3-(Carboxymethylamino)propionic Acid (3). A solution of *N*-(2-cyanoethyl)glycine[16] (2.56 g, 20 mmol) in 6 M HCl (50 ml) was refluxed on a sand bath for 2 d. The reaction mixture was evaporated to dryness and the residue was dissolved in a minimum amount of H_2O. The solution was treated with Amberlite CG 120 (H form) (2.0ϕ×21 cm) by the method described for **2**. The fractions containing **3** were evaporated to dryness and the residue was recrystallized from H_2O-ethanol: yield 1.29 g (44%); mp (decomp) 195—198°C; R_f 0.07; NMR (trifluoroacetic acid (TFA)) δ=7.86 (2H, br, NH_2^+), 4.22 (2H, t, J=4.7 Hz, N^+CH_2CO), 3.91—3.40 (2H, m, $N^+C\underline{H_2}CH_2$), and 3.10 (2H, t, J=5.4 Hz, $CH_2C\underline{H_2}CO$). Found: C, 40.64; H, 5.96; N, 9.32%. Calcd for $C_5H_9NO_4$: C, 40.82; H, 6.17; N, 9.52%.

2,2'-Iminodipropionic Acid (4). Compound **4**·HCl was prepared from DL-alanine (5.97 g, 67 mmol) and 2-bromopropionic acid (10.2 g, 67 mmol) in the presence of 1 M NaOH (250 ml) according to the procedure of Karrer and Appenzeller.[17] The free acid was obtained by ion-exchange chromatography and then recrystallized from H_2O-acetone: yield 5.09 g (47%); mp (decomp), 250—252°C (lit,[18] 233—235°C); R_f 0.12. Found: C, 44.72; H, 7.02; N, 8.71%. Calcd for $C_6H_{11}NO_4$: C, 44.72; H, 6.88; N, 8.69%.

2,3'-Iminodipropionic Acid (5). Compound **5** was prepared from *N*-(2-cyanoethyl)-DL-alanine[16] (2.84 g, 20 mmol) by the method described for **3**: yield 0.88 g (27%); mp (decomp) 200—203°C; R_f 0.13; NMR (TFA) δ=7.75 (2H, br, NH_2^+), 4.64—4.04 (1H, m, CH), 3.92—3.34 (2H, m, N^+CH_2), 3.09 (2H, t, J=5.8 Hz, CH_2CO), and 1.81 (3H, d, J=7.3 Hz, CH_3). Found: C, 44.84; H, 6.69; N, 8.92%. Calcd for $C_6H_{11}NO_4$: C, 44.72; H, 6.88; N, 8.69%.

N-(2-Cyanoethyl)-β-alanine. This compound was prepared by the cyanoethylation of β-alanine (44.5 g, 0.55 mol) with acrylonitrile (29.2 g, 0.50 mol) according to the procedure of McKinney *et al.*[16] and recrystallized from H_2O-acetone: yield 38.1 g (52%); mp (decomp) 144—146°C; R_f 0.19; NMR (TFA) δ=7.75 (2H, br, NH_2^+), 3.99—3.77 (4H, m, N^+CH_2), and 3.24—2.96 (4H, m, $CH_2CN + CH_2CO$). Found: C, 49.44; H, 7.38; N, 19.03%. Calcd for $C_6H_{10}N_2O_2 \cdot 1/4\ H_2O$: C, 49.14; H, 7.22; N, 19.10%.

3,3'-Iminodipropionic Acid (6). Compound **6** was prepared from *N*-(2-cyanoethyl)-β-alanine (2.84 g, 19.4 mmol) by the method described for **3**. After the hydrolyzate was poured into a column packed with Amberlite CG 120 (H form), the column was washed with H_2O to remove neutrals at first, and then the product was eluted with 2% aq pyridine: yield 1.98 g (63%); mp (decomp) 157—159°C; R_f 0.11; NMR (TFA) δ=7.56 (2H, br, NH_2^+), 3.83—3.30 (4H, m, N^+CH_2), and 3.05 (4H, t, J=7.1 Hz, CH_2CO). Found: C, 44.49; H, 6.91; N, 8.72%. Calcd for $C_6H_{11}NO_4$: C, 44.72; H, 6.88; N, 8.69%.

N-Methyliminodiacetic Acid (7). Compound **7** was prepared from sarcosine (3.0 g, 34 mmol) and chloroacetic acid (3.1 g, 33 mmol) in the presence of 4 M LiOH (16.8 ml) by the method described for **2**. After being recrystallized from H_2O-acetone and dried in a vacuum desiccator at room temperature, the product was identified as a hemihydrate: yield

Table 3. Elution times and relative color constants of some IDCAs on ion-exchange chromatography

IDCA	Elution time/min	Relative color constant[a)]
1	42	0.99
2	42	0.32
5	64	0.009
3	66	0.30
Gly	94	1.00

a) Color constant of Gly: 87.6 μmol^{-1}.

2.50 g (49%); mp (decomp) 231—234 °C (lit,[19] 226—227 °C (free acid)); R_f 0.07; NMR (TFA) δ=8.40 (1H, br, NH^+), 4.38 (4H, s, CH_2CO), and 3.31 (3H, s, N^+CH_3). Found: C, 38.18; H, 6.29; N, 8.72%. Calcd for $C_5H_9NO_4 \cdot 1/2H_2O$: C, 38.46; H, 6.46; N, 8.97%.

Ion-exchange Chromatography. Ion-exchange chromatography was carried out with a Sibata amino acid analyzer AA-600 under the following conditions: Column, 0.25ϕ×50 cm packed with Aminex A-4 (Bio-Rad); flow rate of eluent (pH 3.25 citrate buffer, 0.2 M Na^+), 6 ml/h; flow rate of ninhydrin solution, 3 ml/h; jacket temperature, 30 °C. The time of heating in the reaction bath (100 °C) was designed to be 30 min. Each of the IDCAs was chromatographed separately, and its color constant was calculated by the common $H \times W$ method. Among the IDCAs, **4** and **6** were negative to color development with ninhydrin,[20] so that their elution times could not be determined. The ion-exchange chromatographic data are listed in Table 3. It was unsuccessful to separate a mixture of the IDCAs with the amino acid analyzer.

Derivatization for Gas Chromatography. For the preparation of butyl ester derivatives, each individual IDCA (0.1 mmol) was refluxed for 30 min with 1-butanol (5 ml) which was 5.2 M in dry HCl, and then complete solubilization was achieved. Excess reagent was distilled off at 50 °C under reduced pressure. The residual ester hydrochloride was dissolved in a minimum amount of H_2O. After being made alkaline with K_2CO_3, the solution was repeatedly extracted with CH_2Cl_2 (20 ml×4). The extracted solution was dried (Na_2SO_4), filtered, and then evaporated carefully to dryness at room temperature leaving an oil. The butyl ester derivative was taken up in CH_3NO_2 (2 ml), 1 μl portions of which were usually injected into the gas chromatographic column. For the preparation of *N*-TFA butyl ester derivatives, an ester hydrochloride prepared as above was suspended in CH_2Cl_2 (1 ml), to which $(CF_3CO)_2O$ (0.5 ml) was added. After being left overnight at room temperature, the reaction mixture was carefully evaporated to dryness, and then taken up in CH_3NO_2 (2 ml) for gas chromatography. When $(CF_3CO)_2O$ was added to the ester hydrochlorides of the *N*-substituted IDCAs (**7** and **8**), the corresponding butyl ester derivatives were liberated in the free state. In the case of **4**, trifluoroacetylation with $(CF_3CO)_2O$ at room temperature was incomplete due to steric hindrance. However, it was found that trifluoroacetylation was completed in 60 min at 100 °C; in this experiment 1 ml of $(CF_3CO)_2O$ was added.

Gas Chromatography. Gas chromatography was carried out with a Hitachi gas chromatograph 163 equipped with a flame ionization detector (H_2 flow rate, 35 ml/min). A single column technique was used. The conditions for gas chromatography were as follows: column, 1 m×3 mm I. D. glass packed with 1.5% OV-101 on Chromosorb G HP (100/120 mesh) (Shimadzu); injection port, 200 °C; flow rate of N_2 (carrier gas), 30 ml/min. The column oven was operated isothermally at 100 °C for 5 min after injection and then programmed to be heated up to 230 °C at a rate of 5 °C/min.

Gas Chromatography-Mass Spectrometry. Mass spectra were measured with a JEOL JMS-D 300 mass spectrometer, which was connected through a jet separator (glass) with a JGC-20 KP gas chromatograph. Each volatile derivative was chromatographed on a glass column (1 m×2 mm I. D.) containing 3% OV-101 on Chromosorb G HP (100/120 mesh) (Shimadzu) using He as carrier gas. The GC-MS combination was operated with the following parameters: injection port, 200 °C; separator, 250 °C; ionizing voltage, 20 V; ionizing current, 300 μA; accelerating voltage, 3.0 kV; ion source, 210 °C. The spectrometer was continuously scanned every 5 s.

The authors wish to thank Miss Yasuko Yoshioka, Faculty of Pharmaceutical Sciences, Tokushima University for obtaining mass spectra by gas chromatography-mass spectrometry.

(Received September 2, 1983)

The reaction of *S,S*-diaryl-*N*-(*p*-tolylsulfonyl)sulfilimines and *N*-unsubstituted diaryl-sulfilimines with hyperoxide anion radical ($O_2^{\cdot-}$) in the presence of 18-crown-6 as a catalyst together with 1-bromopropane/benzene, benzoyl chloride/benzene, *p*-tolylsulfonyl chloride/benzene, carbon tetrachloride, chloroform, or dichloromethane, gave the corresponding sulfoximines, through nucleophilic oxidation with an intermediary dioxy species formed upon treatment of organic halides with potassium hyperoxide (KO_2).

Oxidation is considered to be one of the most important class of reactions which take place on the sulfur atom of organosulfur compounds along with substitution and reduction.[1] We have been carrying out systematic investigations on the oxidation of organosulfur compounds of various oxidation states,[2] and suggested that the oxidation which takes place on the sulfur atom is classified mainly into three different types of reactions, based on the electronic demand of the oxidant, *i.e.*, direct one electron transfer oxidation, electrophilic oxidation, and nucleophilic oxidation. The tricoordinate organosulfur species such as sulfoxides[2] and especially thiosulfinic *S*-esters[2] are believed to be good models for studying the mechanism of these oxidations and substantial amount of knowledge has been accumulated on the electrophilic and nucleophilic oxidations.[1] Although sulfilimines are relatively new commers among organosulfur compounds, the chemistry of sulfilimines, isoelectronic species of sulfoxides, has recently been extensively investigated,[3] the oxidation of sulfilimines is the most effective method to prepare sulfoximines which are widely used as important reagents for organic syntheses such as an alkylidene transfer reagent.[4] Sodium hypochlorite[5] and sodium perbenzoate[6] have been shown to be excellent oxidants to convert the sulfilimines to the corresponding sulfoximines. In many cases, however, many other oxidants, which are used in the oxidation of sulfoxide have been found to react with sulfilimines, affording various undesirable products together with the desired products, sulfoximines, as minor products and sometimes not affording the corresponding sulfoximine at all, or not reacting at all with other oxidants, recovering the original sulfilimines.[7] In general, electrophilic oxidation of sulfilimines fails to afford the corresponding sulfoximines, while nucleophilic one is expected to oxidize sulfilimines successfully to the corresponding sulfoximines.

Hyperoxide anion radical ($O_2^{\cdot-}$) is known to be an effective nucleophile in aprotic solvents.[8] Alkyl halide is known to react with hyperoxide anion radical through an S_N2 mechanistic path and yields the alkyl peroxide as an overall product *via* formation of alkylperoxyl radical and alkyldioxy anion[9] in the initial step. The *p*-tolylsulfonyl chloride-potassium hyperoxide reaction yields an intermediate *i.e.*, *p*-tolylsulfonylperoxoate anion which oxidized sulfoxides, phosphines, or electrophilic olefins to afford the corresponding sulfones, phosphine oxides or epoxides.[2] Although *S,S*-diaryl-*N*-(*p*-tolylsulfonyl)-sulfilimines have not been oxidized readily with various oxidizing systems, many of these oxidizing systems are electrophilic oxidants. According to a concept of electrophilic and nucleophilic oxidations,[10] *N*-(*p*-tolylsulfonyl)sulfilimines are liable to be attacked by nucleophilic oxidants, since the central sulfur atom is tricoordinate and hence the electron density around the central sulfinimidoyl sulfur atom is decreased. Meanwhile, since the following dioxy species, *i.e.*, alkyldioxy species (ROO^-), acyldioxy species ($AcOO^-$), or sulfonyldioxy species($TsOO^-$), generated *in situ* in the treatment of alkyl halide, acyl halide, or tosyl chloride with hyperoxide anion radical, are believed to be markedly more nucleophilic oxidizing agents than hyperoxide anion radical alone, even *S,S*-diaryl-*N*-(*p*-tolylsulfonyl)sulfilimines, which are inert to hyperoxide anion radical alone, are expected to be selectively oxidized with the reactive dioxy intermediates to afford the corresponding sulfoximines successfully, as in the nucleophilic oxidation of *S,S*-diaryl-*N*-(*p*-tolylsulfonyl)sulfilimine with such a powerful nucleophilic oxidant as hypochlorite anion.[5b]

This paper describes the successful oxidations of sulfilimines with hyperoxide anion radical in a few reaction systems.

Results and Discussion

S,S-*Diaryl*-N-*(p-tolylsulfonyl)sulfilimine.* Hyperoxide anion radical was generated *in situ* by mixing potassium hyperoxide and 18-crown-6 as a catalyst in an apropriate solvent such as benzene under argon atmosphere. At first,when *S,S*-diphenyl-*N*-(*p*-tolylsulfonyl)sulfilimine was treated with hyperoxide anion radical in the presence of 18-crown-6 as catalyst in benzene without any additive, such as an organic halide, there was no formation of any oxidized pro-

† Present adress; Okayama University of Sciences, Ridai-cho, Okayama 700.

duct, *i.e.*, the corresponding sulfoximine, and the sulfilimine was recovered quantitatively after 24 h. A few additives were examined which are capable of generating more effective dioxy species to convert *S,S*-diphenyl-*N*-(*p*-tolylsulfonyl)sulfilimine to the corresponding sulfoximine selectively. Addition to such an alkyl halide, as 1-bromopropane to the above reaction system in the presence of 18-crown-6 or "dicyclohexyl-18-crown-6" was found to give the corresponding sulfoximine in 91% or 94% yields respectively. Diphenyl sulfoxide, an isoelctromer of the sulfilimine, was also oxidized to diphenyl sulfone in this reaction system. Other additives, such as benzoyl chloride and *p*-tolylsulfonyl chloride, were also found to be effective in the oxidation of *S,S*-diphenyl-*N*-(*p*-tolylsulfonyl)sulfilimine to the sulfoximine under mild conditions. The results are summarized in the following equation 1.

$$\mathrm{Ph\text{-}\underset{\downarrow}{\underset{X}{S}}\text{-}Ph} \xrightarrow[\text{Solvent}]{\mathrm{KO_2/crown/additive}} \mathrm{Ph\text{-}\overset{O}{\overset{\uparrow}{\underset{\downarrow}{\underset{X}{S}}}}\text{-}Ph} \qquad (1)$$

X: $NSO_2C_6H_4CH_3$-*p*, O, NH.
Crown: 18-crown-6, "dicyclohexyl-18-crown-6".
Additive: 1-bromopropane, PhCOCl, TsCl, CH_2Cl_2, $CHCl_3$, CCl_4.
Solvent: benzene.

This oxidation, however, did not proceed at all without the crown ether. Thus, the sulfilimine is considered to be oxidized by the intermediary reactive dioxy anion species, incipiently formed *in situ* in the treatment of these organic halides with hyperoxide anion radical in the presence of the crown ether (Eq. 2).

$$\mathrm{PrBr} + \mathrm{O_2^-} \longrightarrow \mathrm{PrOO^-}$$
$$\mathrm{PrOO^-} + \mathrm{O_2^-} \longrightarrow \mathrm{PrOO^-} + \mathrm{O_2}$$
$$\mathrm{Ph\text{-}\underset{\downarrow}{\underset{NTs}{S}}\text{-}Ph} + \mathrm{PrOO^-} \longrightarrow \mathrm{Ph\text{-}\overset{O}{\overset{\uparrow}{\underset{\downarrow}{\underset{NTs}{S}}}}\text{-}Ph} + \mathrm{PrO^-} \qquad (2)$$

Several other sulfilimines were also converted to the corresponding sulfoximines in good yields. Halogenated solvents such as dichloromethane, chloroform, or carbon tetrachloride[11] were also found to assist the oxidation of this type. These results were summarized in Table 1. *S*-(*p*-Nitrophenyl)-*S*-phenyl-*N*-(*p*-tolylsulfonyl)sulfilimine was found to afford unidentified products. No original sulfilimine was recovered.** *S*-Methyl-*S*-phenyl-*N*-(*p*-tolylsulfonyl)-sulfilimine was not oxidized at all in this system. The original sulfilimine was recovered though the isoelectronic methyl phenyl sulfoxide was readily oxidized to the corresponding sulfone in 78% yield.

a) Isolated yield.

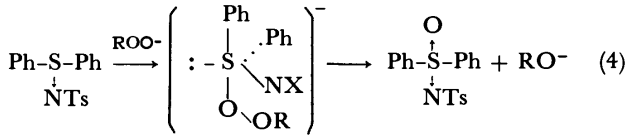
In this reaction, the relatively acidic α-hydrogen atom of this sulfilimine may be immediately deprotonated by hyperoxide anion radical, or peroxyl radical to stop the reaction, because of the formation of the hydroperoxy species (HOO^-) which are incapable of nucleophilic oxidation. Incidentally, acetonitrile was found to react with disulfide in the presence of hyperoxide anion radical to form bis(arylthio)acetonitrile.[2,13] Initial formation of cyanomethyl radical has been proposed for this reaction. The formation of peroxide ion (O_2^{2-}), which may exist in this reaction system by disproportionation of hyperoxide anion (O_2^{2-}) can be ruled out, since the reaction of *S,S*-diphenyl-*N*-(p-tolylsulfonyl)sulfilimine with Na_2O_2 in the presence of 18-crown-6 in benzene under argon atmosphere resulted in the partial reduction of this sulfilimine to give diphenyl sulfide in 30% yield together with the recovered sulfilimine in 70% after 24 h. Dimethyl sulfide and methyl phenyl sulfide were found not to be oxidized at all under these conditions. Thus, treatment of a mixture of *S,S*-diphenyl-*N*-(*p*-tolylsulfonyl)sulfilimine and phenyl *p*-tolyl sulfide with potassium hyperoxide in dichloromethane at 25 °C for 2 h in the presence of catalytic amount of 18-crown-6 in argon atmosphere gave *S,S*-diphenyl-*N*-(*p*-tolylsulfonyl)sulfoximine quantitatively, recovering the added phenyl *p*-tolyl sulfide quantitatively, but not phenyl *p*-tolyl sulfoxide or sulfone (Eq. 3).

$$\mathrm{Ph\text{-}\underset{\downarrow}{\underset{NTs}{S}}\text{-}Ph} + \mathrm{Ph\text{-}S\text{-}Tol}(p\text{-}) \xrightarrow[\mathrm{CH_2Cl_2}]{\mathrm{KO_2/18\text{-}crown\text{-}6}} \mathrm{Ph\text{-}\overset{O}{\overset{\uparrow}{\underset{\downarrow}{\underset{NTs}{S}}}}\text{-}Ph} + \mathrm{Ph\text{-}S\text{-}Tol}(p\text{-}) \qquad (3)$$

Phenyl *p*-tolyl sulfide was not oxidized at all even after prolonged reaction time, 24 h, with this nucleophilic oxidation system. These results strongly support that

** Upon addition of this sulfilimine into the solution of hyperoxide anion in benzene in the presence of 18-crown-6 without any additive, *e.g.*, 1-bromopropane, one finds rapid color change (from colorless heterogeneous solution into dark bluish solution) of the solution, which eventually gave unidentified products, without recovering the starting material. Perhaps, an S_{RN} type substitution reaction[12] of hyperoxide anion radical with this sulfilimine, which is activated by nitro group, would have taken place involving one electron transfer from hyperoxide anion into the sulfilimine, followed by subsequent reaction of the aromatic anion radical with oxygen or hyperoxide anion radical, or subsequent breaking down to give unidentified products.

the reactive dioxy anion species (ROO^-) was initially formed and then oxidized *S,S*-diphenyl-*N*-(*p*-tolylsulfonyl)sulfilimine, but not the sulfide. The hydroperoxide (ROOH) intermediate may not be formed during the reaction, since it would readily oxidize the sulfide but not the sulfilimine in this system. Although there is no legitimate evidence to clarify the mechanism for this oxidation by ROO^-, we propose that this oxidation may involve the initial formation of unstable sulfurane intermediate by the nucleophilic attack of dioxy anion toward the electrophilic center of sulfinimidoyl sulfur atom of the sulfilimine which readily breaks down to the corresponding sulfoximine and alkoxide anion in the subsequent step as shown in Eq. 4. This sulfurane intermediate has been proposed in the nucleophilic oxidation of sulfoxides or sulfilimines with hypochlorite anion.[2,5b] Nor was there any good correlation between the effect of substituent and the yield of the sulfoximine as depicted in Table 1, unlike those of the nucleophilic oxidation of sulfoxides by perbenzoic acid[14] or alkyldioxy anion[14] or of *N*-(arylsulfonyl)sulfilimine by hypochlorite anion[5b] in which fairly good Hammett correlations have been found to hold. A similar phenomenon was observed in the oxidation of sulfoxide with hyperoxide anion radical in the presence of di-*p*-tolyl disulfide,[2] or in the S_N2 type substitution reaction of primary or secondary alkyl halide with hyperoxide anion radical.[9,15]



(4)

Similar dioxy anion species have been postulated in the epoxidation of electrophilic olefins or in the oxidation of sulfoxides to the corresponding sulfones.[16,17] Gibian and Ungermann found that dimethyl sulfoxide used as solvent was oxidized during the reaction of alkyl halide with hyperoxide anion radical by the intermediary active oxidizing species, an alkyldioxy anion.[15]

Thus, in the presence of organic halides and a catalytic amount of the crown ether, potassium hyperoxide was found to oxidize *S,S*-diaryl-*N*-(*p*-tolylsulfonyl)sulfilimines which have no nitro group to the corresponding sulfoximines.

N-Unsubstituted S,S-Diarylsulfilimine. *N*-Unsubstituted diarylsulfilimines were reported to be oxidized selectively to the corresponding sulfoximines by sodium hypochlorite,[5a] potassium permanganate,[7a] and sodium periodate.[16] No good result was obtained by oxidation with *m*-chloroperbenzoic acid,[7a] and hydrogen peroxide in acidic media such as acetic acid[7a] or in neutral media.

In the absence of alkyl halide, unsubstituted diphenylsulfilimine did not react with potassium hyperoxide in the presence of 18-crown-6 in benzene only to afford the recovered sulfilimine even after 24 h. However, the same oxidation in the presence of 1-bromopropane proceeded successfully giving the corresponding sulfoximine in 75% yield. The sulfilimine was also oxidized in dichloromethane which functions both as solvent and reactant, affording the corresponding sulfoximine in a good yield. These results are listed in Table 2. *S*-(*p*-Nitrophenyl)-*S*-phenylsulfilimine reacted with potassium hyperoxide in the absence of alkyl halide to afford various unidentified products, but not afford the corresponding sulfoximine. The oxidation of the unsubstituted sulfilimine is considered to proceed similarly as in the case of *S,S*-diphenyl-*N*-(*p*-tolylsulfonyl)sulfilimine, namely *via* involving sulfurane as an intermediate as shown in equation 4.

Table 2. Oxidation of *N*-unsubstituted sulfilimines

a) Isolated yield.

All these reactions reveal clearly that tricoordinate organosulfur compounds are oxidized to the corresponding tetracoordinate sulfur compounds much more effectively by nucleophilic oxidants as we have anticipated.

In summary, *S,S*-diaryl-*N*-(*p*-tolylsulfonyl)sulfilimines and unsubstituted diarylsulfilimines were selectively oxidized to the corresponding sulfoximines upon treatment with potassium hyperoxide in the presence of organic halides.

Experimental

General. Melting points of the products were measured by Yanaco instrument and were uncorrected. IR spectra were obtained using a Hitachi 215 spectrophotometer. ^1H NMR spectra of all the compounds were obtained with a Hitachi Perkin-Elmer R-20 spectrometer in 20% deuteriochloroform solution using tetramethylsilane as an internal standard. Liquid chromatographs were obtained by Yanaco-L-1030 instrument using methanol as an eluent. Thin layer chromatographs were carried out with Merck DC-Plastikofolien Kieselgel 60 F 254 Art 5735 with fluorescent indicator using various solvents and mixed solvents. Development was followed with UV light or by coloring with iodine. Silica gel used for column chromatography was either of Wako or Merck chromatographic grade. Elemental analyses were carried out by the Chemical Center of this University. Potassium hyperoxide was obtained from Veutron Alfa Products. 18-Crown-6 and "dicyclohexyl-18-crown" were obtained from Wako Pure Chemicals and used after drying *in vacuo* at 60—70°C. Anhydrous dichloromethane, chloroform, and carbon tetrachloride were obtained by distillation of first grade commercial products and then dried over calcium dichloride just before use. Benzene was purified by distillation similarly and dried over metal sodium under nitrogen. *p*-Tolylsulfonyl chloride from Wako Pure Chemicals were used after recrystallization from hexane.

Benzoyl chloride was purified by distillation after dehydration with calcium dichloride. Extra pure reagent 1-bromopropane from Wako Pure Chemicals was used directly without any further treatment. Other chemicals were of reagent grade.

Materials. *N*-(*p*-Toylylsulfonyl)sulfilimines *i.e.*, *S,S*-dimethyl-, *S*-methyl-*S*-phenyl-. *S,S*-diphenyl-, *S*-(*p*-tolyl)-*S*-phenyl-, *S*-(*p*-chlorophenyl)-*S*-phenyl-, *S*-(*p*-nitrophenyl)-*S*-phenyl-*N*-(*p*-tolylsulfonyl)sulfilimines were prepared by treatment of the corresponding sulfides with chloramine-T in methanol, according to the method reported earlier.[19] *N*-Unsubstituted sulfilimines *i.e.*, *S,S*-diphenyl-, *S*-phenyl- *S*-(*p*-tolyl)-, *S*-(p-nitrophenyl)-*S*-phenylsulfilimines were prepared by treatment of the corresponding *N*-(*p*-tolylsulfonyl)sulfilimines with concentrated sulfuric acid and then with aqueous sodium hydroxide solution according to a known method.[7a]

Reaction of S,S-*Diphenyl*-N-(p-*tolylsulfonyl*)*sulfilimine with Potassium Hyperoxide in Benzene in the Presence of 1-Bromopropane and Catalytic Amount of 18-Crown-6.* To a finely powdered potassium hyperoxide (252 mg, 3.5 mmol) was injected a solution of the title sulfilimine (501 mg, 1.4 mmol) and 18-crown-6 (0.08 mmol) in dry benzene and then a solution of 1-bromopropane (260 mg, 2.1 mmol) in the same solvent was added into a two-necked flask under dry argon atmosphere at room temperature. The resulting heterogeneous mixture stirred at the same temperature for 3 h. The reaction was monitored by TLC or HPLC until the substrate disappeared nearly completely. After the reaction, the reaction mixture was poured into a large excess of ice-water, extracted with chloroform, washed with water, and dried over anhydrous magnesium sulfate. The solvent was removed under reduced pressure, and the crude corresponding sulfoximine was obtained. Purification was accomplished by column chromatography through silica gel using chloroform as an eluent. The corresponding sulfoximine was obtained in 91% yield. In the reactions in which *p*-tolylsulfonyl chloride and benzoyl chloride were used as organic halides, the above mentioned procedure was also applied.

Oxidation of S,S-*Diphenyl*-N-(p-*tolylsulfonyl*)*sulfilimine with Potassium Hyperoxide in Dichloromethane in the Presence of 18-Crown-6.* A solution of the title sulfilimine (500 mg, 1.4 mmol) in dry dichloromethane was added to a finely powdered potassium hyperoxide (252 mg, 3.5 mmol) and dry 18- crown-6 (0.07 mmol) in a two-necked flask under dry argon atmosphere at room temperature. The mixture was stirred at the same temperature for 2 h, monitoring by HPLC. After the consumption of the substrate, the work-up described before was carried out. The corresponding sulfoximine was obtained in 97% yield.

Oxidation of N-*Unsubstituted Diphenylsulfilimine with Potassium Hyperoxide in Dichloromethane in the Presence of 18-Crown-6.* To a finely powdered potassium hyperoxide (440 mg, 6.2 mmol) was added a solution of the title sulfilimine (500 mg, 2.5 mmol) and dry 18-crown-6 in dry dichloromethane in a two-necked flask under dry argon atmosphere at room temperature. The heterogeneous solution was stirred at the same temperature for 1 h. After the starting sulfilimine was found to have disappeared, upon monitoring by TLC or HPLC, the reaction mixture was poured into excess water. After the usual work-up and separation by column chromatography, diphenyl sulfide (6%) and diphenylsulfoximine (84%) were obtained.

We express our thanks to Dr. Toshikazu Takata for his collaboration.

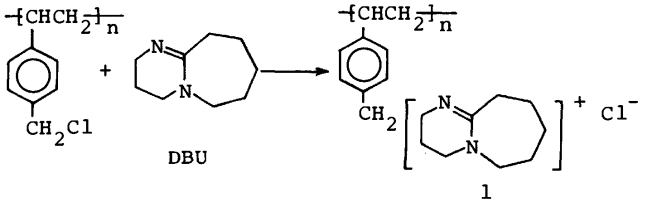
Ion Exchange Resins Anchoring 1,8-Diazabicyclo[5.4.0]undec-7-ene

Tomomichi ISHIKAWA* and Atsushi YONEYAMA
Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received September 13, 1983)

The synthesis of polymeric quaternary ammonium salts linked 1,8-diazabicyclo[5.4.0]undec-7-ene(DBU) to chloromethylated polystyrenes is described. The polymers so obtained become anion exchangers with both quaternary ammonium and tertiary amino groups. The values of the total ion-exchange capacities indicated that the quaternization of the tertiary amino groups on the polymers with hydrochloric acid is difficult. The chloride forms of the resins, in spite of their bulky and steric quaternary ammonium groups containing DBU, were effective as ion exchangers for a variety of bulky anions such as sulfate, oxalate, hexacyanoferrate(II), hexacyanoferrate(III), and tris(oxalato) ferrate(III) ions. The free base forms of the resins gave low reactivity for chloride and sulfate ions. Some examples of the application of the resins is also reported.

Quaternary ammonium polymers have been used as ion exchange resins, catalysts and polyelectrolytes for a long time, and have also generated considerable interest in biological and medical fields in recent years.[1] The reaction of chloromethylated polystyrene with a variety of tertiary amines yields polymeric ammonium salts. On the other hand, "ionen polymers" can be prepared from tertiary diamino compounds with dihaloalkanes. 1,8-Diazabicyclo[5.4.0]undec-7-ene (DBU) possessing two tertiary amino groups is a potent organic base which is useful for the dehydrohalogenation of alkyl halides,[2] the *O*-alkyl cleavage of hindered methyl esters[3] and the oxidative coupling of diphenylmethanimine.[4] Because it is known that one mole of two functional compounds can be reacted with one chloromethyl group on the polymers,[5] anion exchange resins containing both strongly and weakly basic groups will be obtained by treating chloromethylated polystyrene with DBU:



1

We have studied the reactivity of these basic groups, especially the basicity of the weakly basic groups. In this paper we describe new anion exchange resins of this type which have been prepared for the first time, and the properties of these resins have been investigated.

Experimental

Materials. Chloromethylated polystyrenes were prepared by chloromethylation of soluble polystyrene (DP 1100; Asahi Dow Chem. Co.) and 2% divinylbenzene-styrene copolymer(200—400 mesh; Eastman Kodak Co.) according to Ref.[6,7] Commercial DBU (Extra Pure; Sanyo Kasei Kogyo Co.) was purified by distillation; bp 88—89 °C (400 Pa). *N,N*-Dimethylformamide(DMF) was dried by the usual method and distilled befor use. The other materials were of reagent grade.

Preparation of Quaternary Ammonium Polymers. A 300 cm³, four necked round bottomed flask equipped with a stirrer, reflux condenser, and thermometer was charged with the desired amount of chloromethylated polystyrenes, DBU, and DMF. The reaction mixture was stirred at 40 °C for 6—7 h, and then filtered (in the case of the soluble chloromethylated polystyrene, after poured into ethyl acetate) and washed several times with methanol. The product was dried under reduced pressure.

Determination of Ion-exchange Capacities. Salt splitting capacity and total ion-exchange capacity were determined by the general method[8] for strongly and weakly basic anion exchange resins.

General Method of Ion Exchange. About 0.3 g of the chloride forms of the resins was shaken overnight with 100 cm³ of 0.1 mol cm⁻³ salts aq solution, and then recovered by filtration. The resin was washed with water, dried *in vacuo* and submitted to elemental analysis.

Adsorption Measurement. Metalic Salts: About 0.3 g of the chloride forms of the resins was shaken for 4 d with 100 cm³ of 0.1 mol cm⁻³ copper(II) or mercury(II) chloride aq solution, and then recovered by filtration. The resin was washed with water, dried *in vacuo* and submitted to elemental analysis.

Iodine: About 0.1 g of the chloride forms of the resins was shaken overnight with 30 cm³ of the desired concentration of iodine-chloroform solution or iodine-potassium iodide aq solution, and then recovered by filtration. The resin was washed with water, and dried *in vacuo*. The iodine adsorbed was determined by iodometry and elemental analysis.

Results and Discussion

Quaternary Ammonium Polymers. Polymer-supported quaternary ammonium salts were prepared from polystyrenes by a route which involves chloromethylation and subsequent amination. Styrene homopolymer and 2% divinylbenzene-styrene copolymer were used in this work, because higher crosslinking and poorer swelling chloromethylated polystyrenes seem to be insufficient for practical amination with bulky amine such as DBU. Egawa and co-worker[9] also reported that the anion exchange resins derived from the styrene copolymers containing divinylbenzene of less than 2% are useful for the absorption of the metalic ions.

The chloromethylation of styrene homopolymer and 2% divinylbenzene-styrene copolymer gave two chloromethylated polymers containing 19.3 and 21.4% of chlorine, respectively. The chloromethylated polymers were treated with the various amounts of DBU. The yields of the aminated polymers were based

on the chloromethylated polystyrenes. The DBU and chlorine contents of the products were determined by elemental analysis. The results are summarized in Table 1. It is apparent that the chlorine contents are in good agreement with the DBU contents which were calculated on the basis of the nitrogen contents. These results indicate that one molecule of DBU reacted with one chloromethyl group to give the ion pairs of the chloride ion with the quaternary ammonium ion. Notwithstanding that all the chloromethyl groups had reacted, they do not convert quantitatively into quaternary ammonium groups.

The IR spectrum of the quaternary ammonium polymer shows an absorption band at 3350 cm^{-1} (OH of alcohol). On the other hand, the absorption responsible for the C-Cl bond (660 cm^{-1}) in the chloromethylated polystyrenes disappeared.

From these results, all the chloromethyl groups unreacted with DBU appeared to be changed to hydroxymethyl groups by the hydrolysis, perhaps because of the presence of a small amount of water in the reaction mixture. Therefore, the constitutional sequence of the polymers obtained in this work will be presented as Fig. 1.

The value of *l*, *m*, and *n* in the Fig. 1 were determined on the basis of the chlorine contents of the original chloromethylated polystyrenes and the nitrogen contents of the aminated polymers. The results are given in Table 1. In such Runs 1—3 which were carried out in the insufficiently dehydrated DMF, the value of *m* becomes higher than those of Runs 4—7 in the almost anhydrous DMF.

The reaction of the soluble chloromethylated polystyrene with DBU was completed under homogeneous condition in DMF. However, the aminated products, which were precipitated with ethyl acetate and then dried, were insoluble in DMF, perhaps because of the formation of crosslinks.

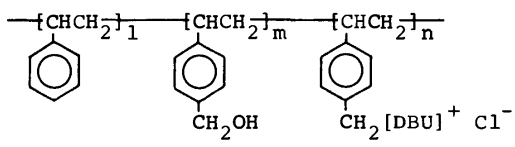

Fig. 1. Constitutional sequence.

Exchange Capacities of Basic Resins. The aminated polymers described in this paper can behave as a strongly basic anion exchanger as well as a weakly basic anion exchanger, because of the presence of both the quaternary ammonium groups and the tertiary amino groups in the polymers. The anion exchange capacities (salt splitting capacities) and total ion exchange capacities are given in Table 2. As can be seen from this table, the values of salt splitting capacity are considerably lower in comparison with the values for commercial strongly basic anion exchange resins. The salt splitting capacity was determined by titrating the sodium hydroxide which is formed according to Scheme 1.

$$\text{(P)-[DBU]}^{+}\text{Cl}^{-} \xrightarrow{\text{NaOH}} \text{(P)-[DBU]}^{+}\text{OH}^{-}$$
1 **2**

$$\xrightarrow{\text{NaCl}} \text{(P)-[DBU]}^{+}\text{Cl}^{-} + \text{NaOH}$$
3

Scheme 1.

Table 2 also gives the DBU and chlorine contents of the starting chloride form **1**, the intermediate free base form **2**, and the resulting chloride form **3** of the polymers in the Scheme 1. It was shown that **2** contained negligible chlorine, showing that all the chloride ions had been virtually displaced by hydroxide ions, while the chlorine content of **3** was extremely low in comparison with that of **1**. From these results, for this polymer the low values of salt splitting capacity seem to be ascribable to the higher selectivity of adsorption of hydroxide ion than that of chloride ion.

The total exchange capacities were calculated from the amounts of hydrochloric acid reacting with the polymer **2** according to Scheme 2.

$$\text{(P)-[DBU]}^{+}\text{OH}^{-} \xrightarrow{\text{HCl}} \text{(P)-[DBU]}_{2}^{2+}\text{H}\ 2\text{Cl}^{-}$$

7	1	0.73	3.64	0.596	3.05	2.98

a) Run number in Table 1. b) In Scheme 1. c) Salt splitting capacity. d) Total ion-exchange capacity. e) Product obtained by treating the chloride forms of the resin with hydrochloric acid.

In the Table 2 the values of the ratio of the total exchange capacities to the number of nitrogen atoms are relatively low in comparison with the value expected from the polymer **4**. This result indicates that the reaction of the tertiary amino groups on the polymer **2** with hydrochloric acid is very difficult. This appears to be caused by an electrostatic effect owing to the close contacts[10] between the quaternary ammonium groups derived from the two tertiary amino groups on the DBU molecule.

The pK_a of DBU was 11.5, while that of the DBU bound on the polymer was 5.1, which is nearly equal to that of pyridine.

Application of Polymer Anchoring DBU. In this work, polymers anchored by bulky quaternary ammonium groups were prepared. Therefore, the ion exchange reactions with a variety of bulky anions such as sulfate, oxalate, hexacyanoferrate(II), hexacyanoferrate(III), and tris(oxalato)ferrate(III) were carried out. The chloride forms of the polymers were used in these reactions. The results are given in Table 3. In the determination of the ion exchange capacity, a difference of less than 5% was found between the values determined by elemental analysis of the Na_2SO_4-treated polymer and by titration of the sodium chloride produced in the solution after treatment. For potassium hexacyanoferrate(III), moreover, the value determined by iodometry of $K_3[Fe(CN)_6]$ remaining in the solution after the treatment was in near agreement with that by elemental analysis of the treated polymer. Therefore, in the other cases the exchange capacities were determined by elemental analysis. The results show that the polymers allow an ion exchange reaction with each bulky anion.

a) The chloride forms of the resin containing 2.89 mequiv g^{-1} of DBU was used. b) Determined by elemental analysis. c) Determined by volumetric analysis.

The absorption of metalic ions with the anion exchange resin bound tetraethylenepentamine has been investigated[9] at various pH values. It is found that the absorption increases with an increase of the pH value; at pH 4.5, it is nearly maximized in mercury(II) chloride but reaches only half a maximum value in copper(II) chloride. Table 4 gives the DBU and chlorine contents of the products obtained by treating the chloride forms

of the aminated polymers with aqueous solutions of mercury(II) or copper(II) chloride at pH 4—5. The values were determined by elemental analysis. The product obtained by treatment with mercury(II) chloride gave a lower DBU content than for the starting polymer. The IR spectrum of this product is shown in Fig. 2; it indicates the characteristic absorption band at 460 cm^{-3}, perhaps on ν_{N-Hg}[11], which is not observed for the starting polymers. These results are probably associated with the formation of a polymer-mercury complex. The mercury content of the product determined by atomic absorption analysis was 2.13 mequiv g^{-1}, which is reasonably consistent with that calculated from the nitrogen content. On the other hand, in the case of copper(II) chloride the DBU and chlorine contents of the product are almost consistent with those of the starting polymer. Both the starting and $CuCl_2$-treated polymers gave identical IR spectra. These results indicate that this resin can be used for separation of mercury and copper ions.

The reaction of iodine with the chloride forms of the aminated polymers was carried out in chloroform or in aqueous solution of potassium iodide. The amounts of iodine adsorbed were determined by elemental analysis and iodometry. The values of the ratio of iodine atoms to one DBU-moiety in the polymers are given in Table 5. In chloroform, the values by iodometry were closely consistent with those calculated from the nitrogen content. In this case, about one molecule of iodine seems to be adsorbed with one DBU-moiety on the polymers. On the other hand, in the KI aq solution the value I/DBU by elemental analysis is about one and a half times the number of the value by iodometry. This result indicates that the chloride ions on the polymer were displaced with triiodide ions formed from iodine and potassium iodide.

Ion Radicals of Organometallic Compounds. III. Positional Effects on the Thermodynamics of Formation and the Kinetics of Decomposition of (Methyl-substituted Benzene)-tricarbonylchromium Cation Radicals

Tamio IKESHOJI† and Vernon D. PARKER*
Laboratory for Organic Chemistry, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim-NTH, Norway
(Received September 17, 1983)

Reversible oxidation potentials, rate constants, and activation parameters are reported for the formation and decomposition reactions of all isomers of (methyl-substituted benzene)tricarbonylchromium cation radicals. The reversible potentials were observed to depend both on the number and the positions of the methyl substituents. It was found that the effects on the reversible potentials of adding single methyl substituents to similar structures were additive. The activation energies and entropies for the decomposition reactions were found to be grouped into four different categories depending upon the numbers of adjacent unsubstituted positions on the methylarene ligands. Within each group the deviations from the averages were less than experimental error. The differences in activation parameters are explained in terms of how effective bonding is between the chromium atom and the arene ligands in the cation radicals.

In previous papers of this series we have examined the thermodynamics and kinetics of the formation and decomposition reactions of (arene)tricarbonylchromium cation radicals in acetonitrile.[1,2] The arene moieties were either methylbenzene[1] or benzenes substituted with heteroatom-containing substituents.[2] The (methyl-substituted benzene)tricarbonylchromium complexes show four main oxidation peaks during linear sweep voltammetry measurements at stationary platinum electrodes.[1] The cation radicals of the complexes are generated at the first reversible oxidation wave (wave I) and decompose by a first order chemical reaction (Eq. 1) followed by electron transfer reaction (Eq. 2),

$$MCr(CO)_3^+ \xrightarrow{k} M + Cr(CO)_n^+ + (3-n)CO \quad (1)$$

$$Cr(CO)_n^+ + MCr(CO)_3^+ \rightleftharpoons Cr(CO)_m^{2+} + MCr(CO)_3 + (n-m)CO \quad (2)$$

i.e. an ECE_h mechanism. Both the activation parameters and the oxidation potentials were observed to be related to the number of methyl substituents. The more highly substituted complexes show the higher activation energies for the decomposition reactions of the cation radicals, *i.e.* form the kinetically more stable cations. For the same cation radicals the more highly substituted ones are formed at the lower potentials, *i.e.* are the more thermodynamically stable. However, a number of discrepancies were observed for the parameters obtained for the 7 complexes studied, $(CH_3)_n$-$C_6H_{6-n}Cr(CO)_3$ with $n=0$ to 6, with one isomer for each value of n. For example, the difference in oxidation potentials of 1,4-$(CH_3)_2C_6H_4Cr(CO)_3$ and 1,3,5-$(CH_3)_3$-$C_6H_3Cr(CO)_3$ was only 1 mV while the difference in activation energies for the decompositions of the corresponding cation radicals was 3.9 kcal mol^{-1}. †† On the other hand the difference in activation energies for the decomposition reactions of the cation radicals of 1,3,5-$(CH_3)_3C_6H_3Cr(CO)_3$ and 1,2,4,5-$(CH_3)_4C_6H_2Cr(CO)_3$ was observed to be only 0.3 kcal mol^{-1}. This suggests that the effects of methyl substitution on the ease of the formation and the ease of the decomposition of the cation radicals differ.

In order to obtain more insight on the effects of methyl substitution on the formations and the decompositions, oxidation potentials and kinetic parameters were obtained for all of the remaining isomers of (methyl-substituted benzene)tricarbonylchromium complexes.

Experimental

All measurements were carried out in acetonitrile with 0.1 mol dm^{-3} *n*-Bu_4NBF_4 and Ag/Ag$^+$ (0.01 mol dm^{-3} $AgNO_3$ in acetonitrile with 0.1 mol dm^{-3} *n*-Bu_4NBF_4) as reference electrode. The concentration of the substrate was 2.0 mmol dm^{-3}. The measurements of reversible oxidation potentials were performed at −10°C in order to attain reversibility over a wide range of sweep rates. The kinetic measure ments of rate constants were performed by derivative cyclic voltammetry (DCV) in the typical temperature range of −10°C to 25°C with an interval of 5°C. Activation energies (E_a) and activation entropies (ΔS^*) were obtained by Arrhenius correlations of rate constants. The details of the measurement procedure were reported in previous papers.[1,3,4]

In this paper the complexes are identified according to the number of the methyl substituents as follows:

(0)=$C_6H_6Cr(CO)_3$,
(1)=$CH_3C_6H_5Cr(CO)_3$,
(1,2), (1,3,), (1,4)=dimethyl-substituted complexes,
(1,2,3), (1,2,4), (1,3,5)=trimethyl-substituted complexes,
(1,2,3,4), (1,2,3,5), (1,2,4,5)—tetramethyl-substituted complexes,
(5)=$(CH_3)_5C_6HCr(CO)_3$,
(6)=$(CH_3)_6C_6Cr(CO)_3$.

Results

Reversible oxidation potentials of the complexes and kinetic parameters for the decomposition reactions of their cation radicals are shown in Table. 1. The reversibility was confirmed from the result that the potential differences of the oxidation and reduction peaks of cyclic voltammograms were close to *ca.*

60 mV at high scan rates where the two peaks were observed to have the same height. In this case these two peaks did not shift according to the chemical reaction (Eq. 1) of the ECE_h mechanism.

Discussion

Reversible Oxidation Potentials of the Complexes. The reversible electrode potentials for the oxidation of all of the complexes in acetonitrile are plotted *vs.* the number of methyl substituents in Fig. 1. Linear regression anaiysis gives a slope of −33.6 mV/methyl group with a correlation coefficient of 0.985. There are differences in oxidation potentials within each group of isomers, *i.e.* those with 2, 3, and 4 methyl substituents. These differences affect the overall correlation. The points represented as black circles in Fig. 1 show the effect of additional methyl groups on two basic structural units, corresponding to 1,3-dimethyl- and 1,3,5-trimethylbenzene complexes.

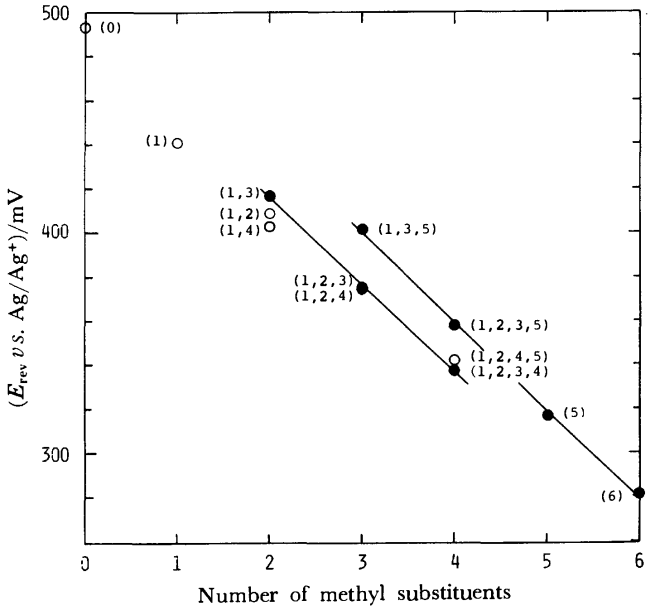

Fig. 1. Relation between reversible oxidation potentials and the structures of the complexes. See text for the structures.
(●) E_{rev} on lines.

The linear regression line for the first case has a slope of −40.0 mV/(additional methyl group) and a correlation coefficient of 0.999. In these cases the effect of additional methyl groups on the reversible oxidation potentials is additive. This suggests that the scatter observed in Fig. 1 is due to the fact that the magnitude of the effect of a methyl substituent is dependent upon the total structure and that the reversible oxidation potentials cannot be considered independent of the substitution existing before the addition of the group.

Another interesting aspect of the correlations in Fig. 1 is that the line for 1,3-substituted complexes lies only 16 mV below the other line on the potential scale. This means that an additional meta methyl substituent has much smaller effect on the reversible oxidation potentials than the addition of substituents ortho to those in the basic structural unit.

Some of the effects of methyl substitution on the reversible oxidation potentials could be due to steric interactions between the methyl groups and the carbonyl groups. In complexes (0)[5-7)] and (6)[8)] the steric configuration of H and CH_3 of the arene in relation to CO is the staggered structure **1**, and in complex (1)[9)] it is the eclipsed form **2** due to electron donation from CH_3.[10)] It is possible that ortho substitution

makes the staggered form energetically more favorable and meta substituents favor the eclipsed form. This effect could cause the difference in the potentials. With regard to conformation, it should be noted that the configuration around the chromium atom in the neutral complexes is tetrahedral, but there is a possibility that the change in oxidation state of chromium in going to the cation radical is accompanied by a change in configuration. Unfortunately the detailed structures of the cation radicals are not known, the rotational barriers in arene-$Cr(CO)_3$ are small,[10)] and thus further discussion of steric effects would be highly speculative.

TABLE 2. GROUPS DIVIDED ACCORDING TO THE ACTIVATION ENERGY AND THE STRUCTURE OF TRICARBONYLCHROMIUM COMPLEXES

Group	Designation	Structures of benzenes in complexes	E_a/kcal mol^{-1}	$-\Delta S^*$/cal K^{-1} mol^{-1}
1	3		8.6 (0.3)	18.2 (0.7)
2	2		10.3 (0.1)	16.2 (0.4)
3	1		14.4 (0.3)	8.1 (1.3)
4	0		17.0 (1.4)	5

Activation Parameters for the Decomposition Reactions of the Cation Radicals. The complexes can be divided into four groups according to the magnitudes of the activation parameters as shown in Table 2 and Fig. 2. These division also correspond to the substitution pattern of the methylarene ligand. Those complexes having three or more adjacent unsubstituted positions form the first group. The activation energies (E_a) for these compounds were found to be 8.6 ± 0.3 kcal mol^{-1} and the corresponding activation entropies (ΔS^*) equal to -18.2 ± 0.7 cal K^{-1} mol^{-1}. The standard deviations are well within the experimental errors for the determination of any of the parameters. This fact implies that the parameters can be considered to be equal for all members of the group. The second group has two adjacent unsubstituted positions and in this case E_a are equal to 10.3 ± 0.1 kcal mol^{-1} and ΔS^* were estimated to be -16.2 ± 0.4 cal K^{-1} mol^{-1}. The complexes in the third group have only H substituents with adjacent methyl substituents and in all these cases there are two or three such H substituents. The activation parameters were estimated to be 14.4 ± 0.3 kcal mol^{-1} (E_a) and -8.1 cal K^{-1} mol^{-1} (ΔS^*). The final group has only two members, the complexes of haxamethyl- and pentamethylbenzene, and the activation energies averaged 17.0 ± 1.4 kcal mol^{-1} and ΔS^* was evaluated as -5 cal K^{-1} mol^{-1} in both cases.

The data in Table 2 conform well to an isokinetic relationship.[11] The data are plotted in Fig. 3. The linear regression slope is equal to 601 K, *i.e.*, the isokinetic temperature, with a correlation coefficient of 0.995. The relationship implies an inversion of relative rate constant at temperatures above and below 601 K. However, the apparent isokinetic temperature is so far removed from the range in which the parameters were determined that we place little significance on it. On the other hand the linear relationship does exist and we point this out without becoming involved in a discussion of the possible significance of the relationship, which is in itself controversial.[11]

The most stable cation radical complex, both from a thermodynamic (E_{rev}) and a kinetic (k and E_a) points of view, is that derived from hexamethylbenzene. The least stable is that from benzene. This fact suggests that steric effects have little to do with the relative stability of the cation radicals. If we assume that the

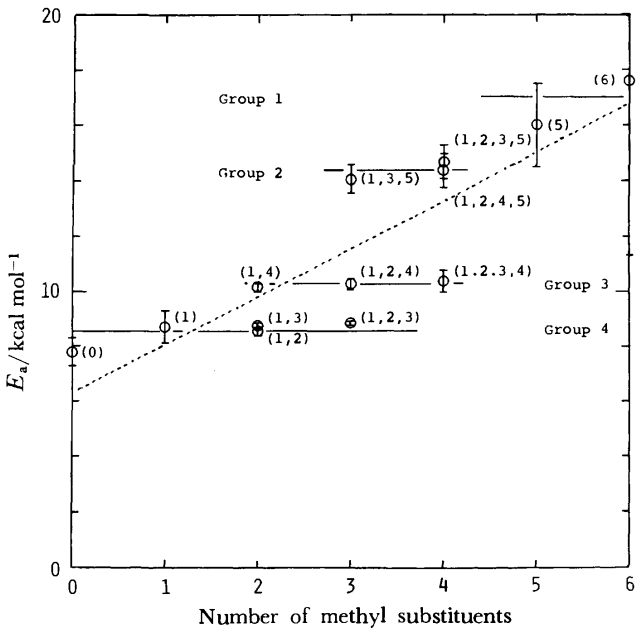

Fig. 2. Relation between activation energies of decomposition reactions of the cation radicals from the complexes and their structures. See text for the structures.
(——) Mean value of E_a in each group. (------) Linear regression line.

(—○—) From Table 2. (●) Each isomer.

most important electronic effect of the methyl substituents is an inductive one, the positions where methyl is attached are the ones most affected by the substituent. All positions in the hexamethylbenzene complex cation radical are affected equally by the methyl groups. This would allow a maximum degree of transmission of the inductive effects of the methyl groups providing that Cr is located with the same relationship to all the C atoms of the benzene ring. Any unsubstituted position brings about a decrease in the donation of electrons from the methylarene ligand to the chromium atom. The complex of pentamethylbenzene forms a less stable cation radical than the corresponding hexamethylbenzene complex. The effect is amplified by having two or three unsubstituted positions as is the case for the group 3 complexes. The difference in stability becomes greater when adjacent positions are unsubstituted as in groups 2 and 1. In these cases the chromium atom could not be located equidistant from all of the ring carbon atoms except in (0) and have the maximum effect of the methyl groups at the substituted positions. There are most likely differences in the geometries of the cation radical complexes depending upon the substitution pattern.

In conclusion the linear relationship observed between the thermodydnamic and kinetic stabilities, with some scattering, can be considered to be due to different but similar aspects in three states. The thermodynamic stabilitites are related to two states of them, *i.e.* neutral complex and cation complex. On the other hand the kinetic stabilites are related to another set of two states, *i.e.* cation complex and transition state to decomposition.

We wish to thank the Royal Norwegian Council for Science and Technology for a fellowship to T.I.

(Received October 26, 1983)

The copper(II)-catalyzed transamination of 2-methyl-3-hydroxy-4-aminomethyl-5-(dodecylthiomethyl)pyridine (C_{12}SPM) with sodium pyruvate was investigated in an aqueous medium at pH 6.8, μ 0.10 (KCl), and 30.0 ±0.1 °C in the presence of molecular aggregates of *N,N*-ditetradecyl-*N*$^{\alpha}$-[6-(trimethylammonio)hexanoyl]-L-alaninamide bromide (N^+C_5Ala2C_{14}), *N,N*-ditetradecyl-*N*$^{\alpha}$-[6-(trimethylammonio)hexanoyl]-L-histidinamide bromide (N^+C_5His2C_{14}), or hexadecyltrimethylammonium bromide (CTAB). The reaction afforded the corresponding pyridoxal analogue (C_{12}SPL) and alanine as the final products upon addition of edta which liberates the copper(II) ion from the coordination sites of the aldimine Schiff-base. The coordination interaction between the copper(II) ion and C_{12}SPM, which takes place prior to the transamination, was clarified by electronic spectroscopy. The reactivity of the 2:1 (ketimine:Cu^{II}) complex was found to be much larger than that of the 1:1 complex in the molecular assemblies of N^+C_5Ala2C_{14} and CTAB, and the formation of the former species was more pronounced in the N^+C_5Ala2C_{14} vesicle. The bilayer vesicle formed with N^+C_5His2C_{14} allowed the formation of the 1:1 complex in preference to that of the 2:1 complex, and the coordination-free imidazolyl group of the amphiphile effectively catalyzed the isomerization as a general base.

Pyridoxal-5′-phosphate (PLP) is known to catalyze various transformation reactions of amino acids such as transamination, elimination, racemization, and decarboxylation as the coenzyme in biological systems.[1] Although most of the PLP-dependent enzymatic reactions can be simulated by nonenzymatic systems,[2] such nonenzymatic reactions are much less efficient than the corresponding enzymatic ones with respect to reactivity, substrate specificity, and reaction selectivity. In order to improve the catalytic efficiency of model systems for the PLP-dependent enzymes, micellar surfactants,[3] synthetic polymers,[4] and macrocyclic compounds[5] have been utilized in recent years to simulate the functions of apoenzymes. We have reported previously that a bilayer membrane composed of a synthetic peptide lipid can provide a reaction field favorable for the transamination of PLP with a hydrophobic amino acid.[6]

In the present work, we prepared hydrophobic vitamin B_6 analogues, C_{12}SPM and C_{12}SPL, and investigated the reaction of C_{12}SPM with pyruvate in single-walled vesicles of N^+C_5Ala2C_{14} and N^+C_5His2C_{14} as effected by the copper(II) ion. The kinetic behavior of the transamination reaction was analyzed in the light of metal-coordination modes observed for C_{12}SPM and its ketimine Schiff-base with the copper(II) ion. The kinetic effect of single-walled vesicles formed with N^+C_5His2C_{14} on the transamination is to be discussed in view of the base catalysis of the histidyl residue.

Experimental

Spectroscopic data were taken on a Union Giken SM-401 UV-visible spectrophotometer and a Hitachi R-24B NMR spectrometer. pH-Measurements were carried out with a Beckman expandomatic SS-2 pH meter equipped with a Metrohm EA-125 combined electrode after calibration with a combination of appropriate standard aqueous buffers. Melting points were measured with a Yanaco MP-S1 apparatus (hot-plate type). Elemental analyses were performed at the Microanalysis Center of Kyushu University.

Hexadecyltrimethylammonium bromide (CTAB) of Nakarai Chemicals was recrystallized from ethanol, mp 237—239 °C (decomp). *N,N*-Ditetradecyl-*N*$^{\alpha}$-[6-(trimethylammonio)hexanoyl]-L-alaninamide bromide (N^+C_5Ala2C_{14}) and *N,N*-ditetradecyl-*N*$^{\alpha}$-[6-(trimethylammonio)hexanoyl]-L-histidinamide bromide (N^+C_5His2C_{14}) were prepared as described elsewhere.[6,7] 2-Methyl-3-hydroxy-4-aminomethyl-5-(dodecylthiomethyl)pyridine dihydrobromide (C_{12}SPM·2HBr) and 2-methyl-3-hydroxy-4-formyl-5-(dodecylthiomethyl)pyridine (C_{12}SPL) were prepared as described below.

2-Methyl-3-hydroxy-4-aminomethyl-5-(bromomethyl)pyridine Dihydrobromide (PMBr). Pyridoxamine dihydrochloride (1.0 g, 4.2 mmol) dissolved in 48% aqueous hydrobromic acid (25 ml) was refluxed for 2 h. After the mixture was evaporated to dryness *in vacuo*, the crude product was dissolved in methanol and purified by reprecipitation with ether; yield 1.3 g (81%), mp 265—270 °C (decomp).

2-Methyl-3-hydroxy-4-aminomethyl-5-(dodecylthiomethyl)pyridine Dihydrobromide (C_{12}SPM·2HBr). A solution of 1-dodecanethiol (530 mg, 2.6 mmol) in dry ethanol (5 ml) was added dropwise to 50 mg of sodium metal dissolved in dry ethanol (5 ml) with stirring under nitrogen atmosphere. PMBr (400 mg, 1.0 mmol) dissolved in dry ethanol (50 ml) was added dropwise to the resulting mixture with stirring under nitrogen at 0 °C. The mixture was evaporated to dryness *in*

vacuo, and the residue was recrystallized from methanol. The crude product dissolved in methanol was treated with 48% aqueous hydrobromic acid, evaporated to dryness, and purified by gel-filtration chromatography on columns of Toyopearl HW-40 fine and Sephadex LH-20 in this sequence with methanol as an eluant to afford a white solid: yield 0.17 g (33%), mp 193— 194 °C (decomp); ^{1}H-NMR (CD_3OD, TMS) δ=0.88 [3H, t, $S(CH_2)_{11}\underline{CH_3}$], 1.27 [20H, m, $SCH_2(\underline{CH_2})_{10}CH_3$], 2.50 [2H, t, $S\underline{CH_2}(CH_2)_{10}CH_3$], 2.67 [3H, s, 2-$\underline{CH_3}$ on pyridine ring], 3.96 [2H, s, $\underline{CH_2}S(CH_2)_{11}CH_3$], 4.39 [2H, s, $\underline{CH_2}NH_3^+$], and 8.16 [1H, s, 6-H on pyridine ring].

Found: C, 47.15; H, 7.72; N, 5.66%. Calcd for $C_{20}H_{36}N_2OS \cdot 2HBr$: C, 46.70; H, 7.45; N, 5.45%.

2-Methyl-3-hydroxy-4-formyl-5-(dodecylthiomethyl)pyridine (C_{12}SPL). A mixture of potassium hydroxide (1.37 g, 9.8 mmol), C_{12}SPM·2HBr (0.10 g, 0.19 mmol), α-oxoglutaric acid (1.46 g, 10 mmol), and zinc nitrate (0.116 g, 0.39 mmol) in methanol (200 ml) was stirred for 24 h at room temperature, and evaporated to dryness *in vacuo*. The residue was suspended in 2 mol dm^{-3} aqueous hydrochloric acid (100 ml), and extracted with chloroform (3 × 50 ml). The chloroform extract was washed with water, dried over anhydrous sodium sulfate, and evaporated to dryness *in vacuo*. The crude product was purified by gel-filtration chromatography on a column of Sephadex LH-20 with methanol as an eluant to afford a pale yellow oil: yield 29 mg (39%); ^{1}H-NMR ($CDCl_3$, TMS) δ=0.89 [3H, t, $S(CH_2)_{11}\underline{CH_3}$], 1.29 [20H, m, $SCH_2(\underline{CH_2})_{10}CH_3$], 2.35 [2H, br s, $S\underline{CH_2}(CH_2)_{10}CH_3$], 2.51 [3H, s, 2-$\underline{CH_3}$ on pyridine ring], 3.90 [2H, s, $\underline{CH_2}S(CH_2)_{11}CH_3$], 7.87 [1H, s, 6-H on pyridine ring], and 10.45 [1H, s, CHO].

Found: C, 68.06; H, 9.46; N, 4.01%. Calcd for $C_{20}H_{33}NO_2S$: C, 68.34; H, 9.46; N, 3.98%.

Kinetic Measurements. The reaction medium was prepared as follows. (i) An appropriate amount of the stock solution of one of the amphiphiles ($N^+C_5Ala2C_{14}$, $N^+C_5His2C_{14}$, and CTAB) in ethanol was placed in a glass vessel, and evaporated *in vacuo* to remove the solvent completely. An aqueous HEPES (2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid) buffer (2.5 mmol dm^{-3}, pH 6.8) containing 0.1 mol dm^{-3} potassium chloride was added to the residue. (ii) An aqueous dispersion of the amphiphile thus prepared was sonicated for 2 min with a probe-type sonicator at 30-W power (W-220F, Heat Systems-Ultrasonics). The resulting vesicle solution was sufficiently clear and gave good kinetic reproducibility. Each run was initiated by adding 20 µl of an aqueous solution of C_{12}SPM (5.0 × 10^{-3} mol dm^{-3}), an appropriate quantity of an aqueous solution of $Cu(ClO_4)_2$ which was standardized by conventional chelatometric titration (1.0 × 10^{-2} mol dm^{-3}), and 100 µl of a freshly prepared aqueous solution of sodium pyruvate (0.1 mol dm^{-3}) to 2.0 ml of the reaction medium which was pre-equilibrated at 30.0 ± 0.1 °C in a thermostated cell set in the spectrophotometer.

Results and Discussion

Spectral Change in the Course of Transamination. The transamination reaction of C_{12}SPM with sodium pyruvate, as effected by the presence of single-walled vesicles of $N^+C_5Ala2C_{14}$ and $N^+C_5His2C_{14}$ as well as by CTAB micelles, was followed spectrophotometrically in the aqueous HEPES buffer at pH 6.8, μ 0.10 (KCl), and 30.0 ± 0.1 °C. Figure 1 shows the spectral change observed along the progress of transamination in the presence of the $N^+C_5Ala2C_{14}$ vesicle. The absorption spectrum of C_{12}SPM in the single-walled vesicle shows a maximum at 293 nm and a shoulder at 315 nm. This indicates the presence of two species which are different in protonation site from each other (Scheme 1).[8,9] The charged form (PM_1) was primarily observed in dioxane-water (1:9 v/v), and the fraction of the neutral

Electronic absorption spectra of C_{12}SPM (5.0×10^{-5} mol dm^{-3}) in an aqueous HEPES buffer (2.5×10^{-3} mol dm^{-3}) at pH 6.8, μ 0.10 (KCl), and 30.0±0.1 °C in the presence of $N^+C_5Ala2C_{14}$ vesicle (1.0×10^{-3} mol dm^{-3}) and varying amounts of $Cu(ClO_4)_2$: 0, 5.1×10^{-6}, 1.0×10^{-5}, 1.5×10^{-5}, 2.0×10^{-5}, 2.5×10^{-5}, 3.0×10^{-5}, and 5.0×10^{-5} mol dm^{-3} (read from A to B).

form (PM_2) increased with an increase in dioxane content. The microenvironmental polarity for the pyridoxamine moiety of C_{12}SPM in the aggregates was evaluated from the relative intensities of the absorption maxima for these species. As a result, both vesicular and micellar systems provide a microenvironment equivalent to that provided by dioxane-water (1:1 v/v) (Kosower's *Z*-value, 87).[10] Addition of $Cu(ClO_4)_2$ resulted in an immediate shift of the absorption maximum to 306 nm along with an increase in intensity as shown in Fig. 2. This spectral change is analogous to that observed for the formation of the Cu^{II}-pyridoxamine complex in methanol[9] and attributed to the formation of the Cu^{II}-C_{12}SPM complex (**1** in Scheme 2). Subsequently, the ketimine Schiff-base complex (**2** in Scheme 2), having an absorption maximum at 305 nm, was formed instantaneously upon addition of sodium pyruvate to the solution. The intensity of this peak decreased with time, isosbestic points being observed at 286 and 335 nm. A new absorption band appeared at 385 nm and increased in intensity as the reaction proceeded. The absorption spectrum observed at the final stage of reaction was identical with that of the copper complex of the aldimine Schiff-base of C_{12}SPL formed with alanine (**3** in Scheme 2). When an aqueous solution of tetrasodium ethylenediaminetetraacetate (edta; 10-fold molar excess over Cu^{II} ion) was added to the final solution, the spectrum changed immediately indicating the formation of the metal-free aldimine Schiff-base of C_{12}SPL formed with alanine. This Schiff-base was hydrolyzed to C_{12}SPL and alanine completely within 1 h. The isomerization of the ketimine Schiff-base to the corresponding aldimine was not observed in the absence of $Cu(ClO_4)_2$. Similar reaction behavior was found in other amphiphile systems of the present study. Table 1 summarizes the spectral parameters for various species formed in the present amphiphile systems.

In the light of these observations, the overall reaction pathway is explicitly given in Scheme 2. Matsumoto *et al.* reported that the reaction of pyridoxamine with

α-keto acids and copper(II) ion yielded the Cu^{II}-aldimine chelates in methanol, but the rate-determining step was not unambiguously defined.[11] In the present transamination reaction, however, the isomerization of the Cu^{II}-ketimine chelate to the Cu^{II}-aldimine chelate is exclusively the rate-determining step without any ambiguity, since the reaction time course was not influenced by the mixing mode of the reactants, simultaneous or sequential, and showed a monophasic kinetic feature. The absorption bands characteristic of the Cu^{II}-ketimine and -aldimine chelates were used to determine the rates of isomerization reaction.

Metal-coordination Behavior of C_{12}SPM. Prior to the transamination reaction, the copper(II) ion undergoes coordination with C_{12}SPM as shown in Scheme 2. The π-π^* transition bands appearing in the 300-nm range are due to the pyridoxamine chromophore of C_{12}SPM in the N^+C_5Ala2C_{14} vesicle, and their intensities increased upon addition of $Cu(ClO_4)_2$ (Fig. 2). The simplest coordination equilibrium would involve the formation of the 1:1 (C_{12}SPM:Cu^{II}) complex (Eq. 1).

$$C_{12}SPM + Cu^{II} \rightleftharpoons Cu^{II}(C_{12}SPM) \quad (1)$$

This is not the case, however, since the value of $[Cu^{II}(C_{12}SPM]/[C_{12}SPM][Cu^{II}]$ varied as the concentration of $Cu(ClO_4)_2$ was changed. Alternatively, the copper-coordination scheme, which involves the formation of both 2:1 and 1:1 (C_{12}SPM:Cu^{II}) complexes (Eq. 2), was utilized to analyze the equilibrium data.

$$2(C_{12}SPM) \underset{K_1}{\overset{Cu^{II}}{\rightleftharpoons}} Cu^{II}(C_{12}SPM)_2 \underset{K_2}{\overset{Cu^{II}}{\rightleftharpoons}} 2\,Cu^{II}(C_{12}SPM) \quad (2)$$

The formation of such 2:1 and 1:1 chelate species has been also reported for the coordination of Cu^{II} ion with pyridoxamine in aqueous media.[12] The observation of an isosbestic point at 286 nm (Fig. 2) assures that the present 2:1 and 1:1 chelates have an identical molar absorption coefficient as given in terms of the C_{12}SPM unit. Now, the respective stability constants (K_1 and K_2), defined by Eqs. 3 and 4, were evaluated by the least-squares analysis in a manner similar to that applied to the zinc(II)-paracyclophane system.[13]

$$K_1 = \frac{[Cu^{II}(C_{12}SPM)_2]}{[C_{12}SPM]^2[Cu^{II}]} \quad (3)$$

$$K_2 = \frac{[Cu^{II}(C_{12}SPM)]^2}{[Cu^{II}(C_{12}SPM)_2][Cu^{II}]} \quad (4)$$

The total concentration of C_{12}SPM bound to Cu^{II} at a given concentration of $Cu(ClO_4)_2$ ($c=[Cu^{II}(C_{12}SPM)]+2[Cu^{II}(C_{12}SPM)_2]$) is calculated by Eq. 5.

$$c = \frac{\Delta A}{A_c - A_f}[C_{12}SPM]_0 \quad (5)$$

Here, A_c and A_f denote the absorbance in the presence of sufficiently excess $Cu(ClO_4)_2$ and that in its absence, respectively, at a selected wavelength close to the absorption maxima of the Cu^{II}-C_{12}SPM complexes; ΔA is the absorbance change with respect to A_f at the intermediate concentration range of $Cu(ClO_4)_2$; and $[C_{12}SPM]_0$ denotes the total concentration of C_{12}SPM. Combining Eqs. 3, 4, and 5, we obtain Eq. 6.

$$(K_1K_2)^{1/2}[C_{12}SPM]([Cu^{II}]_0 - c) + K_1[C_{12}SPM]^2(2[Cu^{II}]_0 - c) = c \quad (6)$$

Here, $[Cu^{II}]_0$ is the initial concentration of $Cu(ClO_4)_2$. This equation is in the form, $aX + bY = Z$, where a and b are $(K_1K_2)^{1/2}$ and K_1, respectively, and X, Y, and Z are experimentally observable. K_1 and K_2 were determined by the least-squares analysis using all the experimental sets of (X, Y, Z) at various concentrations of $Cu(ClO_4)_2$. The results are summarized in Table 2. The observed total concentration of C_{12}SPM bound to Cu^{II} was computationally reproduced quite satisfactorily by the aid of the K_1 and K_2 values determined as above for the whole concentration range of $Cu(ClO_4)_2$ employed in the present study (Fig. 3).

Figure 4 shows the calculated molar distributions of the 2:1 and 1:1 chelate species of C_{12}SPM in the three different molecular assemblies as a function of the Cu^{II} concentration. In both N^+C_5Ala2C_{14} vesicle and CTAB micelle, the fraction of the 2:1 complex is greater than that of the 1:1 complex in a low concentration range of Cu^{II}, while the fraction of the latter exceeds that of the former at higher Cu^{II} concentrations. Meanwhile, the

Table 2. Stability constants for copper(II) complexes of C_{12}SPM in various amphiphile systems at 30.0±0.1 °C[a]

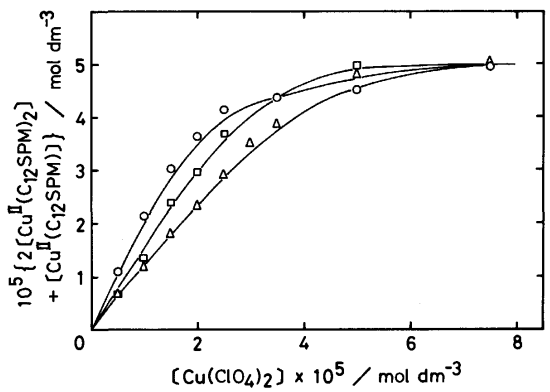

Fig. 3. Correlations between total concentrations of $Cu(ClO_4)_2$ and Cu^{II}-C_{12}SPM complexes in an aqueous HEPES buffer (2.5×10^{-3} mol dm^{-3}) at pH 6.8, μ 0.10 (KCl), and 30.0±0.1 °C in the presence of N^+C_5Ala2C_{14} (○, 1.0×10^{-3} mol dm^{-3}), N^+C_5His2C_{14} (△, 1.0×10^{-3} mol dm^{-3}), and CTAB (□, 3.0×10^{-3} mol dm^{-3}). Solid lines refer to the calculated data by the aid of evaluated stability constants (K_1 and K_2, Table 2); total concentration of C_{12}SPM, 5.0×10^{-5} mol dm^{-3}.

1:1 complex is formed predominantly over the whole concentration range of $Cu(ClO_4)_2$ in the $N^+C_5His2C_{14}$ vesicle. This result strongly indicates that the imidazolyl group of $N^+C_5His2C_{14}$ undergoes coordination with the copper(II) ion which leads to the formation of the 1:1 complex in preference to that of the 2:1 complex.[14]

Kinetic Behavior of Isomerization Reaction. The isomerization of the Cu^{II}-ketimine Schiff-base to the corresponding Cu^{II}-aldimine chelate was followed by means of electronic absorption spectroscopy at 30.0 ± 0.1 °C in the presence of cationic amphiphiles.

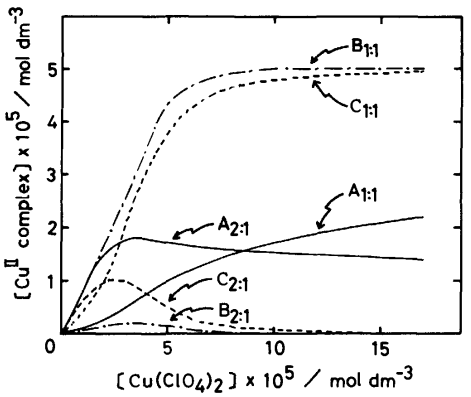

Fig. 4. Distributions of Cu^{II}-$C_{12}SPM$ complexes in an aqueous HEPES buffer (2.5×10^{-3} mol dm^{-3}) at pH 6.8, μ 0.10 (KCl), and 30.0 ± 0.1 °C in the presence of $N^+C_5Ala2C_{14}$ (A, 1.0×10^{-3} mol dm^{-3}), $N^+C_5His2C_{14}$ (B, 1.0×10^{-3} mol dm^{-3}), and CTAB (C, 3.0×10^{-3} mol dm^{-3}). Subscripts 1:1 and 2:1 denote the 1:1 and 2:1 ($C_{12}SPM$:Cu^{II}) complexes, respectively; total concentration of $C_{12}SPM$, 5.0×10^{-5} mol dm^{-3}.

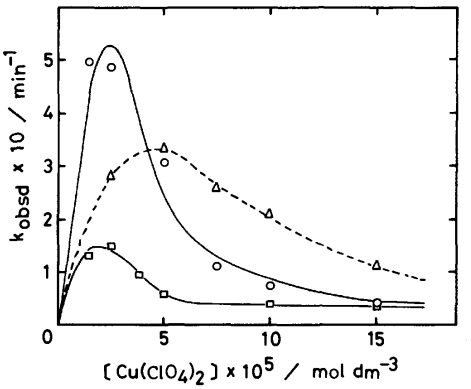

Fig. 5. Correlations between total concentration of $Cu(ClO_4)_2$ and first-order rate constant for the isomerization of Cu^{II}-ketimine to Cu^{II}-aldimine in an aqueous HEPES buffer (2.5×10^{-3} mol dm^{-3}) at pH 6.8, μ 0.10(KCl), and 30.0 ± 0.1 °C in the presence of $N^+C_5Ala2C_{14}$ (○, 1.0×10^{-3} mol dm^{-3}), $N^+C_5His2C_{14}$ (△, 1.0×10^{-3} mol dm^{-3}), and CTAB (□ 3.0×10^{-3} mol dm^{-3}) with initial concentrations: $C_{12}SPM$, 5.0×10^{-5} mol dm^{-3}; sodium pyruvate, 5.0×10^{-3} mol dm^{-3}. Solid lines refer to the calculated data on the basis of Eq. 7 and evaluated kinetic parameters (Table 3).

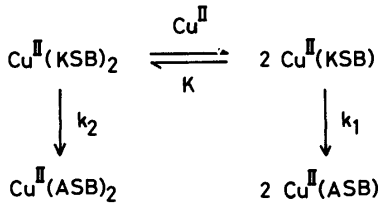
The absorbance increase due to the formation of the Cu^{II}-aldimine chelate was monitored at 385 nm to determine the reaction rate. The observed rate constant, k_{obsd}, was plotted against the total concentration of $Cu(ClO_4)_2$ as shown in Fig. 5.

In both $N^+C_5Ala2C_{14}$ vesicle and CTAB micelle, the rate constant reaches a maximum and then falls down sharply as the Cu^{II} concentration increases. This overall feature is completely reproducible in several sets of kinetic runs. In the light of the coordination behavior of $C_{12}SPM$ with the copper(II) ion, it can be considered that the copper-binding scheme for the formation of Cu^{II}-ketimine Schiff-base complexes involves both 2:1 and 1:1 (ketimine:Cu^{II}) chelate species as shown in Scheme 2. The observed correlations given in Fig. 5 can be reproduced by summing up the reaction rates of both 1:1 and 2:1 complexes; the former and latter complexes are designated as $Cu^{II}(KSB)$ and $Cu^{II}(KSB)_2$ with specific rate constants, k_1 and k_2 (per ketimine Schiff-base), respectively. The specific rate constant for the metal-free ketimine Schiff-base is neglected under the present conditions. The kinetic expression, on the basis of Scheme 3, is given by Eq. 7, where $[Cu^{II}\text{-KSB}]_T$ is the total concentration of the Cu^{II}-ketimine chelates as given in terms of the ketimine Schiff-base unit.



KSB : ketimine Schiff-base
ASB : aldimine Schiff-base

Scheme 3.

$$k_{obsd}[Cu^{II}\text{-KSB}]_T = k_1[Cu^{II}(KSB)] + 2k_2[Cu^{II}(KSB)_2] \quad (7)$$

The concentrations of $Cu^{II}(KSB)$ and $Cu^{II}(KSB)_2$ are interrelated by the stability constant (K) defined by Eq. 8.

$$K = \frac{[Cu^{II}(KSB)]^2}{[Cu^{II}(KSB)_2][Cu^{II}]} \quad (8)$$

The determination of K values was not made by the spectral method which was applied to the Cu^{II}-$C_{12}SPM$ system, because the coordination behavior given by Eq. 8 is accompanied with the isomerization reaction. Accordingly, the values of k_1, k_2, and K were obtained by the regression analysis which minimizes the sum of the squares of errors (U) applied to all the experimental data (Eq. 9).

$$U = \sum \{k_{obsd}[Cu^{II}\text{-KSB}]_T - k_1[Cu^{II}(KSB)] - 2k_2[Cu^{II}(KSB)_2]\}^2 \quad (9)$$

The value of $[Cu^{II}\text{-KSB}]_T$ was evaluated from the final concentration of the Cu^{II}-aldimine Schiff-base

Table 3. Specific rate constants for isomerization reaction of Cu^{II}-ketimine to Cu^{II}-aldimine and stability constants for Cu^{II}-ketimine chelates in amphiphile systems at 30.0±0.1 °C[a)]

Parameter	Amphiphile	
	$N^+C_5Ala2C_{14}$	CTAB
k_1/min^{-1}	0.041	0.036
k_2/min^{-1}	0.70	0.17
K	20	130

a) Cationic amphiphile systems in an aqueous buffer (2.5×10^{-3} mol dm^{-3}) at pH 6.8 and μ 0.10 (KCl): $N^+C_5Ala2C_{14}$, 1.0×10^{-3} mol dm^{-3}; CTAB, 3.0×10^{-3} mol dm^{-3}.

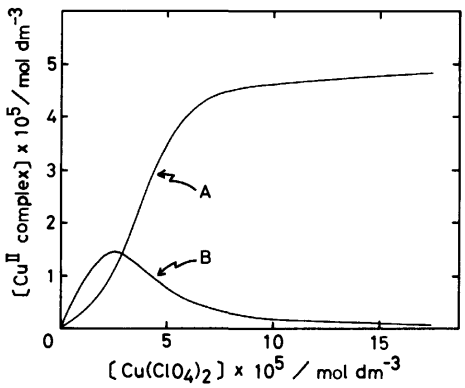


Fig. 6. Distributions of Cu^{II}-ketimine chelates in an aqueous HEPES buffer (2.5×10^{-3} mol dm^{-3}) at pH 6.8, μ 0.10 (KCl), and 30.0±0.1 °C in the presence of $N^+C_5Ala2C_{14}$ vesicle (1.0×10^{-3} mol dm^{-3}): A, 1:1 (ketimine:Cu^{II}) chelate; B, 2:1 chelate. Initial concentrations: $C_{12}SPM$, 5.0×10^{-5} mol dm^{-3}; sodium pyruvate, 5.0×10^{-3} mol dm^{-3}.

produced by the isomerization reaction,[15)] since the Cu^{II}-ketimine chelate was quantitatively converted into the corresponding Cu^{II}-aldimine chelate.

The kinetic parameters thus obtained for the isomerization carried out in the aggregates of $N^+C_5Ala2C_{14}$ and CTAB are listed in Table 3, and the calculated molar distributions of individual chelate species in the $N^+C_5Ala2C_{14}$ vesicle are shown in Fig. 6 as a function of the Cu^{II} concentration. In a manner as observed for the Cu^{II}-$C_{12}SPM$ system, the fraction of the 2:1 complex is greater than that of the 1:1 complex in a low Cu^{II} concentration range. However, the formation of the 1:1 complex is more facilitated with the terdentate ketimine Schiff-base than with the bidentate $C_{12}SPM$. It is noteworthy that the reactivity of the 2:1 complex is much larger than that of the 1:1 complex in the molecular assemblies of $N^+C_5Ala2C_{14}$ and CTAB, and that the formation of the former species is more pronounced in the $N^+C_5Ala2C_{14}$ vesicle. In order that the isomerization must take place (**2** →**3** in Scheme 2), the hydrogen atom substituted on the carbon atom, interposed between the Schiff-base nitrogen and 4-carbon atom of the pyridine ring, needs to be displaced first. The polarization of the C_4'-H bond of a given Schiff-base chelate is important in facilitating its cleavage. Thus, the effective charge on Cu^{II} must exert much effect on the reactivity. The 2:1 complex, in which the carboxylate group of the ketimine Schiff-base is free from coordination, retains positive charge on Cu^{II} more effectively than the 1:1 complex, in which three coordination sites are occupied with the anionic groups. Such a charge effect provided on Cu^{II} has been also claimed for the β-elimination reaction of *O*-phosphoserine with glyoxylate and copper(II) ions.[16)]

As shown in Fig. 5, the correlation between rate and Cu^{II} concentration observed in the $N^+C_5His2C_{14}$ vesicle is considerably different from those in the molecular aggregates of $N^+C_5Ala2C_{14}$ and CTAB. In the light of the coordination behavior of $C_{12}SPM$ with the copper(II) ion, the primary species in a concentration range of $Cu(ClO_4)_2$ higher than 5.0×10^{-5} mol dm^{-3} must be the 1:1 Cu^{II}-ketimine chelate. However, the observed rate constant reaches a maximum at the Cu^{II} concentration of 5.0×10^{-5} mol dm^{-3} and then falls down gradually as the Cu^{II} concentration increases beyond this range. This rate profile can be understood on the basis of the coordination behavior of the imidazolyl group of $N^+C_5His2C_{14}$ with the copper(II) ion. The coordination interaction of the imidazolyl group with Cu^{II} tends to stabilize the 1:1 Cu^{II}-ketimine chelate since the residual coordination site of Cu^{II} in the 1:1 chelate is occupied with the imidazolyl group and to inhibit the formation of the corresponding 2:1 chelate. In a concentration range of $Cu(ClO_4)_2$ lower than 5.0×10^{-5} mol dm^{-3} where all the copper(II) ions are exclusively coordinated to the ketimine Schiff-base, the isomerization reaction of the Cu^{II}-ketimine chelate is catalyzed by the imidazolyl group free from coordination with the copper(II) ion (Fig. 7). We have already confirmed the catalytic assistance of the imidazolyl group as a general base in the transamination reaction of PLP with *N*-dodecyl-L-alaninamide in the $N^+C_5His2C_{14}$ vesicle.[6)] At higher concentrations of $Cu(ClO_4)_2$ beyond 5.0×10^{-5} mol dm^{-3}, the excess copper(II) ion tends to form the Cu^{II}-imidazole complexes to reduce an amount of the free imidazolyl group. On this ground, the reactivity of the

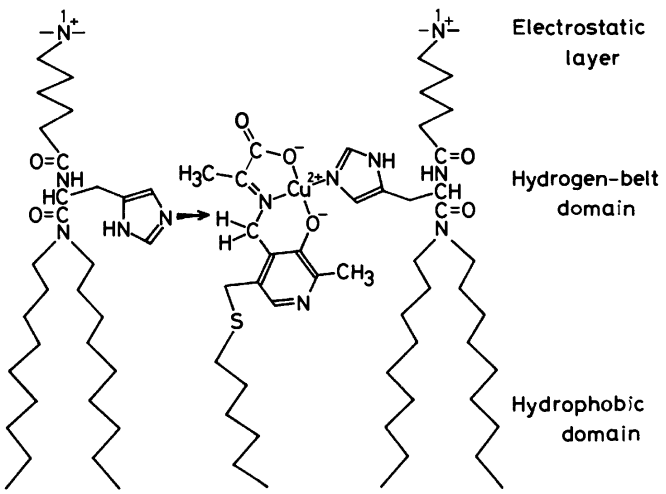

Fig. 7. Schematic representation of the isomerization mechanism for the Cu^{II}-ketimine complex in the $N^+C_5His2C_{14}$ vesicle.

1:1 complex in the $N^+C_5His2C_{14}$ vesicle must be facilitated by the general base catalysis of the metal-free imidazolyl group.

In conclusion, it became apparent that the copper(II)-catalyzed transamination of $C_{12}SPM$ with pyruvate in the cationic vesicles proceeds to give $C_{12}SPL$ and alanine as the final products. The detailed kinetic investigation of the isomerization of the Cu^{II}-ketimine to the corresponding Cu^{II}- aldimine clarified the following aspects. (i) In the bilayer vesicle formed with $N^+C_5Ala2C_{14}$, the formation of the reactive 2:1 (ketimine:Cu^{II}) complex is more favored than in the ordinary cationic micelles. (ii) The bilayer vesicle formed with the amphiphile having the histidyl residue ($N^+C_5His2C_{14}$) allows the formation of the 1:1 complex in preference to that of the 2:1 complex, and the coordination-free imidazolyl group of the amphiphile effectively catalyzes the isomerization as a general base.

The present work was supported in part by Grant-in-Aid for Scientific Research No. 58430016 from the Ministry of Education, Science and Culture.

14) An absorption band appeared in the 620-nm range upon addition of $Cu(ClO_4)_2$ to the $N^+C_5His2C_{14}$ vesicle. This is attributable to the ligand-field band due to the coordinated copper(II) ion. However, quantitative evaluation of the stability constant for the Cu^{II}-$N^+C_5His2C_{14}$ complex was not possible due to insolubility of the complex in aqueous media.

15) Both 2:1 and 1:1 chelate species were assumed to have an identical molar absorption coefficient per aldimine Schiff-base unit in a similar manner as considered for the Cu^{II}-$C_{12}SPM$ complexes.

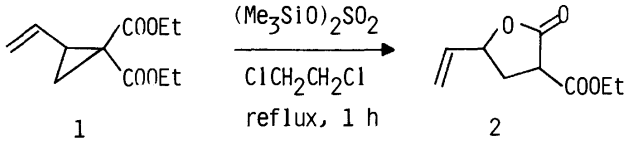
Bis(trimethylsilyl) Sulfate Catalysis in γ-Lactonization of Cyclopropanecarboxylates Activated by Carbonyl Substituents on α-Carbon

Yoshitomi MORIZAWA, Tamejiro HIYAMA,*,† Koichiro OSHIMA, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received October 31, 1983)

The title reaction of 1-carbonyl substituted cyclopropanecarboxylates proceeds under C(1)-C(2) bond cleavage to produce γ-lactones. Stereochemically, the reaction takes two pathways: (1) substrates with a cationstabilizing group like vinyl on C(2) give thermodynamically favored γ-lactones having the thermodynamically more stable arrangement of substituents irrespective of the configuration of the cyclopropane substrates, (2) substrates without such a cation-stabilizing group afford γ-lactones under *ca.* 70% inversion at C(2) reaction center.

Organosilicon reagents such as iodotrimethylsilane or cyanotrimethylsilane are silicon version of hydroiodic acid or hydrocyanic acid and exhibit characteristic Lewis acidity of trimethylsilyl silicon as well as remarkably increased nucleophilicity of iodide or cyanide group.[1-4] Among the silylated inorganic acids bis(trimethylsilyl) sulfate (BTS)[5-7] is characterized by its high Lewis acidity and low nucleophilicity, although the synthetic application of this reagent has been limited so far only to silylation of active hydrogen compounds.[8-10] Previous work has been related to the protective tetrahydropyranylation of alcohols as well as the deprotection.[11] We have found that the appropriately activated cyclopropanecarboxylates are readily transformed into γ-butyrolactones in the presence of BTS.[12]

Transformation of Doubly Activated Cyclopropane into γ-Butyrolactones. Treatment of diethyl 2-vinyl-1,1-cyclopropanedicarboxylate[13] (**1**) with BTS in 1,2-dichloroethane produces the γ-butyrolactone **2** in 98% yield. The reaction of dimethyl 2-vinyl-1,1-



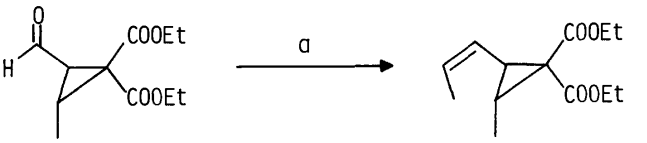
1 2

Scheme 1.

cyclopropanedicarboxylate gave the lactone in a lower yield (46%) after prolonged reaction time (10 h). Other possible product such as ethyl 3-cyclopentene-1,1-dicarboxylate or a seven-membered ring lactone was not detected at all. The BTS catalyst is markedly expedient for this transformation as other Lewis acids induced rearrangement to **3** and/or nucleophilic ring opening leading to **4** at the expence of the yields of **2** as listed in Table 1. Ethyl chrysanthemate, *trans*-2-vinyl-1-(1-oxo-3-phenylpropyl)cyclopropane, and ethyl *trans*-2-phenylcyclopropanecarboxylate did not produce the corresponding γ-lactones. Obviously the *gem*-dicarbonyl substituents on a cyclopropane carbon are required for the lactonization of this kind. Notably, the catalyzed oxavinylcyclopropane rearrangement takes place under mild conditions (40—80 °C) as compared with the purely thermal reaction proceeding at over 280 °C.[14,15]

† Present address: Sagami Chemical Research Center, 4-4-1 Nishiohnuma, Sagamihara, Kanagawa 229.

Extension of the reaction to other cyclopropanecarboxylates are summarized in Table 2. Diethyl *trans*-2-methyl-3-(*cis*-1-propenyl)-1,1-cyclopropanedicarboxylate (**5**) (Scheme 2) was converted into the lactone **6**



5

a: $Ph_3PCH_2CH_3Br$, n-BuLi.

Scheme 2.

of the depicted stereochemistry. Although the *trans* arrangement of the methyl and 1-propenyl appendages in **5** is retained in the product **6**, the isomerization of the *cis* C=C bond to *trans* is remarkable.[16] Retention of the stereochemistry at the cyclopropane carbon occurs also in the transformation of **7**[17] to the lactone **8**. The structure of **8** is based on ^{1}H-NMR spectral data (J_{ab}=6.7 Hz, J_{bc}=6.7 Hz, J_{bd}=3.1 Hz, J_{be}=9.3 Hz). Examination of the molecular model shows that dihedral angle of H_a-C-C-H_b is almost the same as that of H_b-C-C-H_c with respect to **8**. In contrast the *endo*-propenyl isomer of **8** is incapable of giving such a set of coupling constants. This is consistent with the *exo*-1-propenyl structure of **8**. Similar transformation of **9** gives **10** whose stereochemistry of phenyl substituent is tentatively assigned as *exo* on the basis of similar observations.

On the other hand, however, opposite stereochemistry prevails in the reaction of substrates having no cation-stabilizing substituent like 1-propenyl group. The dihydro derivative **11**[17] was transformed into an 82:18 mixture of the *endo*-propyl lactone **12a** and *exo*-isomer **12b**. The stereochemical assignment is

Table 2. Transformation of α-carbonyl substituted cyclopropanecarboxylates into γ-butyrolactone with BTS catalyst[a]

Substrate	Temp/°C	Yield/%	Product(s) (ratio)
 5	40[b]	60(98)[c]	 6
 7	80	39[d]	 8
 9	80	28[f]	 10
 11	80	79[e]	 12a (82 : 18) 12b

Substrate	Temp/°C	Yield/%	Product(s) (ratio)
 13	80	71	 14a (65 : 35) 14b
 15	80	28[d]	14a (23 : 77) 14b
 16	80	8(29)[c]	 17

a) Typically 1 mol of the substrate was heated in the presence of 2 mol of BTS in 1,2-dichloroethane. b) The reaction was carried out in dichloromethane. c) Based on the consumed starting material. d) Other product was polymeric material ($R_f \simeq 0$ on TLC) only. e) BTS (1 mol) was employed. f) A by-product, ethyl 2-benzyl-5-oxo-1-cyclopentene-1-carboxylate 18 (24%), was formed.

based on the fact that the *endo* hydrogen in the bicyclic system appears at higher field than the *exo* one (see experimental part).[18] Similarly, compound **13**[17] gave a 65:35 mixture of **14a** and **14b**. The somewhat sluggish reaction of the *endo* methyl isomer **15** (Scheme 3) gave the *exo* methyl lactone **14b** predominantly. Thus, the γ-lactonization of **11**, **13**, and **15** mostly accompanies the inversion of the configuration at C(2) center. Thermal vinylcyclopropane-cyclopentene rearrangement (*ca.* 300 °C) proceeds with approximately 70% inversion at the migrating terminus.[19,20] Diethyl 1,1-cyclopropanedicarboxylate (**16**) isomerizes to γ-lactone[21] sluggishly.

Experimental

Distillation was carried out in Kugelrohr (Büchi). All mps and bps were not corrected. All ^{1}H-NMR spectra (tetramethylsilane as an internal standard) were obtained on a Varian EM 390 spectrometer, chemical shifts being given in ppm units. The IR spectra of neat liquid film samples (unless otherwise

noted) were measured on a Shimadzu IR-27G spectrometer, MS on a Hitachi RMU-6L spectrometer, and exact mass on a Hitachi M 80 spectrometer. Preparative TLC plates were prepared with Merck Kiesel-gel PF_{254}. Column chromatography was carried out with silica gel (Wakogel C-100) at atmospheric pressure.

Synthesis of Diethyl trans-*2-Methyl-3-(*cis-*1-propenyl)-1,1-cyclopropanedicarboxylate (5).* Butyllithium (1.44 M** hexane solution 3.2 ml, 4.6 mmol) was added to a THF (10 ml) solution of ethyltriphenylphosphonium bromide (1.70 g, 4.6 mmol) at 0 °C. After stirring for 15 min diethyl 2-formyl-3-methyl-1,1-cyclopropanedicarboxylate[22] (0.70 g, 3.1 mmol) in THF (4 ml) was added at 0 °C and the reaction mixture was stirred for 30 min. Workup followed by column chromatography (hexane–ethyl acetate=20:1) gave **5** (0.39 g, 53% yield): bp 70—75 °C (bath temperature)/0.03 Torr***: ^{1}H-NMR (CCl_4) δ=1.12 (*J*=7.2 Hz, 3H), 1.25 (t, *J*=6.0 Hz, 3H), 1.30 (t, *J*=6.0 Hz, 3H), 1.5—2.3 (m+dd (δ=1.77, *J*=1.5, 6.8 Hz), 4H), 2.38 (t, *J*=8.0 Hz, 1H), 3.9—4.3 (m, 4H), 4.91 (ddd, *J*=8.0, 10.5, 1.5 Hz, 1H), 5.48 (dq, *J*=10.5, 6.8 Hz, 1H); IR 2980, 1730, 1370, 1293, 1207, 1140, 1067 cm^{-1}; MS *m/z* (rel intensity) 241 (M^++1, 5), 240 (M^+, 21), 225 (11), 194 (63), 165 (51), 149 (99), 121 (38), 93 (100), 79 (61). Found: C, 65.18; H, 8.61%. Calcd for $C_{13}H_{20}O_4$: C, 64.98; H, 8.39%.

Synthesis of Ethyl endo-*6-Methyl-2-oxobicyclo[3.1.0]hexane-1-carboxylate (15).* Ethyl acetoacetate (0.52 g, 4.0 mmol) dissolved in THF (5 ml) was added to sodium hydride (60% in oil, 0.19 g, 4.8 mmol) suspended in THF (15 ml) at 0 °C. After 20 min butyllithium (1.70 M hexane solution, 2.6 ml, 4.4 mmol) was added and the reaction mixture was stirred for 20 min at 0 °C. (*Z*)-1-Bromo-2-butene (0.60 g, 4.4 mmol) dissolved in THF (3 ml) was then added and stirred for 45 min. Workup and purification by column chromatography (benzene–ethyl acetate=30:1) gave ethyl (*Z*)-3-oxo-6-octenoate (0.65 g, 89% yield): bp 73 °C (bath temperature)/0.03 Torr; ^{1}H-NMR (CCl_4) δ=1.27 (t, *J*=6.9 Hz, 3H), 1.60 (d, *J*=5.1 Hz, 3H), 2.1—2.7 (m, 4H), 3.27 (s, 2H), 4.10 (q, *J*=6.9 Hz, 2H), 5.1—5.7 (m, 2H); IR 2980, 1745, 1326, 1237, 1032 cm^{-1}; MS *m/z* (rel intensity) 184 (M^+, 17), 166 (5), 112 (47), 97 (71), 69 (79), 55 (100). Found: C, 64.97; H, 8.79%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%.

The β-keto ester (0.57 g, 3.1 mmol) was converted into the corresponding diazo compound with *p*-toluenesulfonyl azide (0.64 g, 3.2 mmol) and triethylamine (0.49 ml, 3.5 mmol) in acetonitrile (10 ml) (r.t., 4 h). The diazo compound was then heated in toluene (10 ml) with $Cu(acac)_2$ (0.10 g) at reflux for 8 h. Concentration and column chromatography (benzene–ethyl acetate=30:1) gave **15** (0.36 g, 63% yield): bp 105—109 °C (bath temperature)/1 Torr; ^{1}H-NMR (CCl_4) δ=1.17 (d, *J*=6.6 Hz, 3 H), 1.32 (t, *J*=6.9 Hz, 3H), 1.5—2.7 (m, 6H), 4.12 (q, *J*=6.9 Hz, 2H); IR 3000, 1755, 1730 cm^{-1}; MS *m/z* (rel intensity) 183 (M^++1, 10), 182 (M^+, 10), 154 (44), 137 (88), 136 (86), 112 (100), 80 (66), 57 (97). Found: C, 65.88; H, 7.73%. Calcd for $C_{10}H_{14}O_3$: C, 65.92; H, 7.74%.

Synthesis of Ethyl 6-Phenyl-2-oxobicyclo[3.1.0]hexane-1-carboxylate (9). This compound was prepared similarly starting from (*E*)-3-chloro-1-phenyl-1-propene in 68% overall yield: mp 86.0—86.5 °C (hexane, prism); ^{1}H-NMR ($CDCl_3$) δ=0.88 (t, *J*=7.2 Hz, 3H), 2.0—2.5 (m, 4H), 2.90 (d, *J*=5.4 Hz, 1H), 3.1—3.3 (m, 1H), 3.91 (q, *J*=7.2 Hz, 2H), 7.2—7.4 (m, 5H); IR ($CHCl_3$) 2970, 1746, 1724, 1503, 1375, 1348, 1180, 1036 cm^{-1}; MS *m/z* (rel intensity) 245 (M^++1, 7), 244 (M^+, 20), 198 (53), 170 (30), 157 (28), 129 (100), 115 (43), 91 (40). Found: C, 73.82; H, 6.44%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%.

Transformation of 1 into Ethyl-2-Oxo-5-vinyltetrahydrofuran-3-carboxylate (2). *A Typical Procedure for the Transformation with BTS*: Diethyl 2-vinyl-1,1-cyclopropanedicarboxylate (**1**) (82 mg, 0.4 mmol) dissloved in 1,2-dichloroethane (2 ml) was heated to reflux in the presence of BTS (0.20 g, 0.8 mmol) for 1 h. The reaction mixture was poured into brine (10 ml) and extracted with ethyl acetate (10 ml×3). Column chromatography (silica gel, benzene–ethyl acetate=30:1) gave the γ-butyrolactone (**2**) (70 mg, 98% yield): bp 125—130 °C (bath temperature)/0.06 Torr; ^{1}H-NMR (CCl_4) δ=1.34 (t, *J*=6.9 Hz, 3H), 2.0—2.9 (m, 2H), 3.48 (dd, *J*=9.6, 5.7 Hz, 1H), 4.24 (q, *J*=6.9 Hz, 2H), 4.7—5.2 (m, 1H), 5.2—5.6 (m, 2H), 5.7—6.2 (m, 1H); IR 3000, 1780, 1740, 1162 cm^{-1}; MS *m/z* (rel intensity) 184 (M^+, 3), 183 (2), 155 (18), 137 (51), 110 (100). Found: C, 58.57; H, 6.65%. Calcd for $C_9H_{12}O_4$: C, 58.69; H, 6.57%.

Reaction of Diethyl 2-Vinyl-1,1-cyclopropanedicarboxylate with Sulfuric Acid. The compound **1** (72 mg, 0.34 mmol) dissolved in 1,2-dichloroethane (2 ml) was treated with sulfuric acid (97%, 0.01 ml) at 0 °C for 5 h. Workup and preparative TLC (hexane–ethyl acetate=2:1) gave **2** (R_f 0.40—0.50, 38 mg, 61% yield) and diene **3** (9 mg, 14% yield). The diene **3** gave bp 97 °C (bath temperature)/1 Torr; ^{1}H-NMR (CCl_4) δ=1.29 (t, *J*=6.9 Hz, 3H), 1.32 (t, *J*=6.9 Hz, 3H), 1.91 (d, *J*=6.0 Hz, 3H), 4.16 (q, *J*=6.9 Hz, 2H), 4.20 (q, *J*=6.9 Hz, 2H), 6.17 (dq, *J*=6.0, 15.0 Hz, 1H), 6.50 (dd, *J*=10.5, 15.0 Hz, 1H), 7.11 (d, *J*=10.5 Hz, 1H); IR 2999, 1738, 1728, 1643, 1605, 1240, 1058, 980 cm^{-1}; MS *m/z* (rel intensity) 210 (M^+, 50), 197 (19), 171 (56), 169 (60), 138 (67), 137 (67), 121 (100), 110 (86). Found: *m/z* 212.1054. Calcd for $C_{11}H_{16}O_4$: M, 212.1048.

Reaction of Diethyl 2-Vinyl-1,1-cyclopropanedicarboxylate with Trimethylsilyl Perchlorate. Trimethylsilyl perchlorate was prepared by mixing silver perchlorate (100 mg, 0.48 mmol) and chlorotrimethylsilane (72 mg, 0.48 mmol) in benzene at room temperature for 30 min and filtration of the precipitated salt. To the benzene solution of the catalyst, diethyl 2-vinyl-1,1-cyclopropanedicarboxylate **1** (53 mg, 0.25 mmol) in benzene (2 ml) was added and the mixture was stirred at room temperature for 2 h. Preparative TLC (hexane–ethyl acetate=10:1) gave **2** (18 mg, 39% yield) and **4a** (34 mg, 47% yield). The compound **4a** gave bp 110—113 °C (bath temperature)/0.05 Torr; ^{1}H-NMR (CCl_4) δ=1.23 (t, *J*=7.2 Hz, 4H), 1.24 (t, *J*=7.2 Hz, 2H), 2.4—2.9 (m, 2H), 3.0—3.5 (m, 3H), 4.08 (q, *J*=7.2 Hz, 2.7H), 4.11 (q, *J*=7.2 Hz, 1.3H), 5.3—5.8 (m, 2H), 6.9—7.4 (m, 5H); IR 3000, 1736, 1610, 970, 746, 698 cm^{-1}; MS *m/z* (rel intensity) 291 (M^++1, 1), 290 (M^+, 2), 271 (2), 199 (11), 130 (100), 115 (26), 91 (33). Found: C, 70.59; H, 7.81%. Calcd for $C_{17}H_{22}O_4$: C, 70.32; H, 7.64%.

Reaction of 1 with Iodotrimethylsilane. To diethyl 2-vinyl-1,1-cyclopropanedicarboxylate (0.07 g, 0.33 mmol) dissolved in 1,2-dichloroethane (2 ml), iodotrimethylsilane (0.07 ml, 0.72 mmol) was added at room temperature. The reaction mixture was stirred for 18 h. Column chromatography (silica gel, hexane–ethyl acetate=5:1) gave diethyl (4-iodo-2-butenyl)propanedioate (**4b**) whose structure was assigned spectrometrically (0.10 g, 87% yield): ^{1}H-NMR (CCl_4) δ=1.30 (t, *J*=6.9 Hz, 3H), 2.58 (dd, *J*=6.9, 4.8 Hz, 2H), 3.30 (t, *J*=6.9 Hz, 1H), 3.80 (t, *J*=6.6 Hz, 2H), 4.19 (q, *J*=6.9 Hz, 2H), 5.7—5.9 (m, 2H); IR 3000, 1758, 1738, 1235, 1155, 1035 968 cm^{-1}; MS *m/z* (rel intensity) 249 (14), 213 (M^+−I, 57), 181 (15), 139 (46), 111 (55), 95 (54), 67 (100).

*Ethyl 2-Oxo-5-(*trans-*1-propenyl)tetrahydrofuran-3-carboxylate (6)*: Bp 137—138 °C (bath temperature)/0.055 Torr; ^{1}H-NMR ($CDCl_3$) δ=1.13 (d, *J*=6.0 Hz, 3H), 1.35 (t, *J*=6.9 Hz, 3H), 1.80 (d, *J*=6.3 Hz, 3H), 2.53 (ddq, *J*=6.0, 11.8, 10.4 Hz, 1H, H_b), 3.10 (d, *J*=11.8 Hz, 1H, H_a), 4.24 (q(*J*=6.9 Hz)+dd (H_c), totally 3H), 5.51 (dd, *J*=14.7, 7.2 Hz, 1H), 5.80 (dq, *J*=14.7, 6.3 Hz, 1H); The coupling constant J_{ab}=11.8, J_{bc}=10.4 Hz is consistent to the *trans*-relationship of protons on γ-butyrolactone

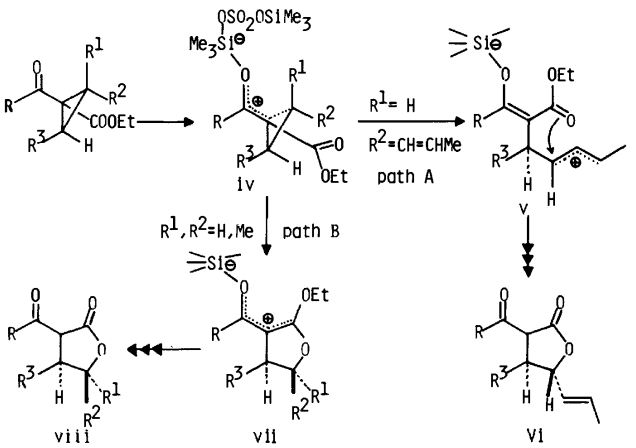
20) Two pathways below stem from the intermediate (iv) and apparently compete each other. When R^2 is propenyl, the path A involving a zwitter ionic intermediate (v) is preferred and cyclizes to give the product (vi) exclusively. As the methyl ester corresponding to **1** reacted reluctantly, liberation of ethyl cation may be crucial at the transformation of v into vi. The substrates without 1-alkenyl group react, in turn, *via* the



path B to give an intermediate vii which then collapse to the product viii. The intermediacy of pentacoordinate silicon species such as iv, v, and vii seems reasonable in view of such pentacoordinate silicon compounds isolated and well-documented. E. L. Klanberg and E. L. Rate and Equilibrium of the Hydration of 1,3-Benzodithiolylium Ion

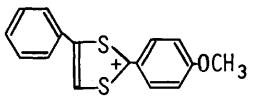
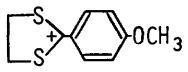
Tadashi OKUYAMA* and Takayuki FUENO
Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received November 12, 1983)

Rates and the equilibrium constant of hydration of 1,3-benzodithiolylium ion were spectrophotometrically measured at 30 °C in aqueous acidic solutions. The hydrate was stable below pH 5 and $pK_R^+ = -0.40$. The cation does not seem to be very stable as compared with the corresponding dithiolanylium ion.

Considerable attention has recently been focused on the chemistry of 1,3-dithiolylium ions[1-3] because of their potential aromaticity and their use in the synthesis of tetrathiafulvalene derivatives. The CMR chemical shifts of the cations were considered to be evidence for the aromaticity by some authors[4,5] while the opposite conclusion was reached from similar results by others.[6] Equilibrium constants of the hydration of some 1,3-dithiolylium ions were measured in 50% ethanol: pK_R^+ of 2-(*p*-methoxyphenyl)-4-phenyl-1,3-dithiolylium ion **1** was found to be 4.11.[7] The saturated dithiolanylium ion **2** has a similar pK_R^+ value (4.1).[8] That is, the π-electonic sextet of the former cation contributes little to its equilibrium stability.

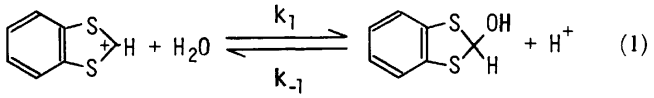


1, $pK_R^+ = 4.11$



2, $pK_R^+ = 4.1$

In the present study, we have measured pK_R^+ and rates of hydration of an easily available cation, 1,3-benzodithiolylium ion **3**, in order to compare its stability with the dithiolanylium analogue.



3 **4** (1)

Results

The cation **3** is stable in strong acid, having UV absorption maxima at 238 (log ε 3.65), 253.2 (3.85), 257.5 (3.81), and 308.5 (3.62) nm. On dilution of acid, the absorption at longer wavelength diminishes with formation of a strong absorption at 226.5 nm (log ε 4.49). The spectrum was stable at least for several days in acid solutions and even in unbuffered water (pH≈5). The spectrum at low acidities closely resembles that of 2-isopentyloxy-1,3-benzodithiole which has absorption maximum at 226 nm with log ε 4.42 in aqueous solution. On acidifying strongly the unbuffered solution of **3**, the absorption at 226.5 nm immediately disappears with simultaneous regeneration of the absorption due to the original cation **3**; *i.e.*, the spectrum change is rapid and reversible. The change must be due to the equilibrium between the cation **3** and its hydrate **4** (Eq. 1). The hydrate **4** must be responsible for the absorption at 226.5 nm.

Absorbance changes at 226 and 330 nm (shoulder of the spectrum of **3**) were measured at 30 °C with changing acidity in hydrochloric and perchloric acid solutions. The absorbance changes are plotted against the acidity function H_R[9,10] in Fig. 1, plots following sigmoid curves with $pK_R^+ = -0.40$.

Rates of the absorbance decrease at 226 nm were measured at 30 °C on a stopped-flow spectrophotometer by mixing a stock solution of **4** obtained by dissolving **3** in unbuffered water and an aqueous perchloric acid solution of an appropriate concentration. Results are given in Table 1. Observed pseudo-first-order rate

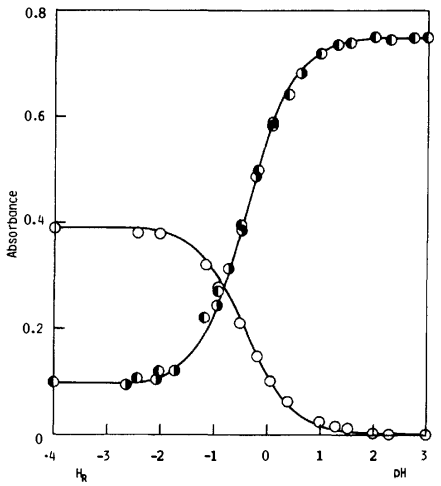


Fig. 1. Absorbance changes measured at 226 nm in HCl (◐) and $HClO_4$ (◑) with the substrate concentration of 2.46×10^{-5} mol dm^{-3} and measured at 330 nm in HCl solutions (○) with the substrate concentration of 1.33×10^{-4} mol dm^{-3}. Solid curves are sigmoid of $pK_R^+ = -0.40$.

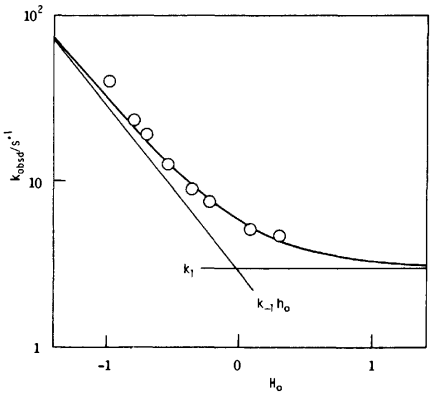

Fig. 2. Plots of log k_{obsd} against H_0. Reaction conditions are given in footnote a of Table 1. The solid curve is calculated with $k_1 = 3.0$ s^{-1} and $k_{-1} = 2.9$ dm^3 mol s^{-1}.

Table 1. Rate constants for reaction 1 at 30 °C

$[HClO_4]$/mol dm^{-3} [a]	k_{obsd}/s^{-1}	[HCl]/mol dm^{-3} [b]	k_{obsd}/s^{-1}
0.391	4.75	1.0×10^{-4}	9.13
0.587	5.20	5.0×10^{-4}	8.75
0.978	7.52	2.5×10^{-3}	9.05
1.174	8.86	5.0×10^{-3}	9.50
1.468	12.8	5.0×10^{-2}	9.18
1.761[c]	19.2	0.25	9.28
1.957[c]	23.5		
2.348[c]	40.0		
2.935[d]	101.9		

a) Rates were measured by the absorbance decrease at 226 nm in aqueous solutions containing 1 vol% of CH_3CN. The initial concentration of the substrate (**4**) was 2.46×10^{-5} mol dm^{-3}. b) Rates were measured by the absorbance decrease at 308 nm in 1 : 1 (v/v) CH_3CN-H_2O of μ=0.25. The initial concentration of the substrate (**3**) was about 1.3×10^{-4} mol dm^{-3}. c) Temperature may slightly higher than 30 °C because of heat of mixing. d) Temperature was about 33 °C owing to heat of mixing.

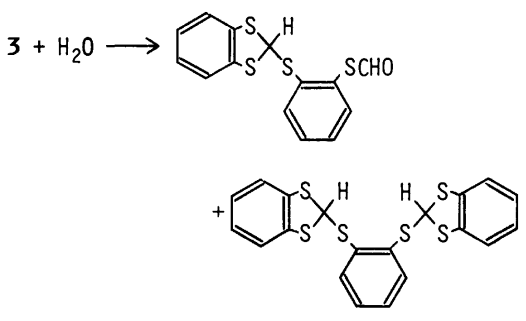
constants k_{obsd} are plotted logarithmically against the acidity function H_0[9,10] Fig. 2.

Disappearance of **3** was also followed at 308 nm by a stopped-flow mixing of a stock solution of **3** in dry acetonitrile and an aqueous hydrochloric acid solution of the ionic strength of 0.50 maintained with KCl, the resultant reaction solution being 1:1 (v/v) CH_3CN-H_2O of μ=0.25. The rate constant was nearly independent of acid concentration [HCl] over the range 1.0×10^{-4}—0.25 mol dm^{-3} as listed in Table 1.

In alkaline solutions, reactions seemed to be somewhat more complicated. When 30μl of the stock solution of **3** in acetonitrile (2×10^{-3} mol dm^{-3}) was added to 3 ml of a borate buffer (pH=9.1) or aqueous NaOH (0.01 mol dm^{-3}), the solution became usually turbid. However, a clear solution of the same composition was always obtained when the aqueous solution (unbuffered) of **3** containing 2 vol% CH_3CN was mixed with an appropriate alkaline solution. The latter solutions in dilute NaOH (0.01—0.1 mol dm^{-3}) showed an absorption maximum at 243 nm, which disappeared in a few hours. The clear borate buffer solution of **3** had the absorption of 226 nm which gradually changed to the absorption of $\lambda_{max}\approx240$ nm and then disappeared, the final spectrum showing no maximum absorption above 220 nm. These spectral changes did not have any clear isosbestic point.

Discussion

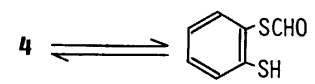
Reaction of the cation **3** with water was previously studied and was found to give dimeric and trimeric products as shown in Eq. 2.[11,12] The reaction was



(2)

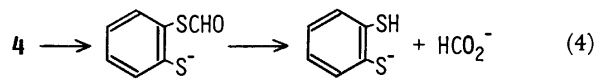
undertaken in relatively high concentration of **3** and a small amount of water, resulting in polymeric products.

The reaction carried out in very dilute solutions at acidic pH is obviously simple and UV spectral and kinetic behavior conforms with the equilibrium hydration (Eq. 1). Ring-opening reaction of the hydrate **4** must be reversible, if occur, and the equilibrium favors the cyclic structure (**4**).



(3)

The reaction seems to proceed further in alkaline solutions, probably to give the ring-open product followed by the hydrolysis of a resultant thioformic acid *S*-ester (Eq. 4). Direct dissolution of a stock solution



(4)

of **3** in CH_3CN into an aqueous alkaline solution, however, resulted in turbidity probably owing to the polymeric products (Eq. 2). Because of very rapid reaction, the local concentration of **3** may be high in this case. Thus, the reaction in always dilute solution which avoids bimolecular reactions between two substrate molecules is distinctly different from that in higher concentrations. Examination of the products in a preparative sense was impossible in the former mild reaction.

The pK_R+ value of **3** (−0.40) is smaller than that of 4-phenyl-1,3-dithiolylium ion (*ca.* 2)[7,13] but seems to be close to that of dithiolanylium ion.[14] The pK_R+ values of 2-(*p*-methoxyphenyl) derivatives of the unsaturated and saturated cations (**1** and **2**) are also similar to each other[7,8] as mentioned above. Equilibrium stabilities of 1,3-dithiolylium and 1,3-benzodithiolylium ions (relative to their hydrates) are not much greater than the corresponding saturated systems (dithiolanylium ions). The π-electronic sextet of the former cations does not seem to be effective in their stabilization in the above sense.

The rate of disappearance of the cation **3** (9.13 s^{-1} in 1 : 1 (v/v) CH_3CN-H_2O at 30 °C) is about 1/10 of that of 2-methyl-1,3-dithiolanylium ion (88 s^{-1}). That is, the

rate of decay of **3** is smaller but that of formation of **3** (from the hydrate) is greater than that of a similar saturated analogue (since the equilibrium constants are similar).

Kinetic measurements were also carried out in essentially aqueous solutions (containing 1 vol% of CH_3CN) at 30 °C with use of a stock solution of the hydrate **4** in water by following its disappearance to form **3** in acidic solutions. The rate constant k_{obsd} for the reversible reaction (Eq. 1) is the sum of the rate constants for the forward and reverse reactions.

$$k_{obsd} = k_1 a_w + k_{-1} h_0 , \quad (5)$$

where a_w and h_0 stand for the activity of water and the acidity function (10^{-H_0}),[9,10] respectively. The value h_0 corresponds to $[H^+]$ in dilute acid. The value a_w diminishes with acidity but it is not smaller than 0.9 in the present acidity range ($H_0 > -1$); the effect of a_w is small. Thus, rate constants k_{obsd} are logarithmically plotted against H_0[10] in Fig. 2. In the acidity scale of H_0, $H_R = -0.40$ (pK_R^+) corresponds to -0.02,[10] where $k_1 a_w = k_{-1} h_0$. The theoretical curve calculated with $k_1 = 3.0\,s^{-1}$ and $k_{-1} = 2.9\,dm^3\,mol^{-1}s^{-1}$ according to Eq. 5 is shown in Fig. 2. The range of acidity examined was necessarily narrow because of no equilibrium formation of **3** at low acidities and of heat of mixing at high acidities. Upward deviations of the observed points at high acidities may in part be due to the temperature rise on mixing.[16]

The rate of decomposition of **3** (k_1) is 1/3 of that observed in 1 : 1 CH_3CN-H_2O. The enhanced rate in the aqueous organic medium may be ascribed to instability of the cation in the less polar solvent.

Experimental

Materials. 2-Isopentyloxy-1,3-benzodithiole and 1,3-benzodithiolylium (**3**) perchlorate were prepared according to the method of Nakayama.[12] Acetonitrile was distilled from P_2O_5. Glass-distilled water was used throughout the work.

Equilibrium Measurements. Hydrochloric and perchloric acid solutions were prepared from concentrated HCl and 70% $HClO_4$, respectively, and concentrations were determined by titration. A stock solution of **3** was obtained by dissolving a weighed amount of the perchlorate in dry CH_3CN, concentration being usually 2.5×10^{-3} mol dm^{-3}. Into 3.0 ml of acid in a quartz cuvette equilibrated at 30 ± 0.1 °C was introduced 30 μl of the stock solution of **3** from a microsyringe and the absorbance was measured on a Shimadzu UV 200 spectrophotometer. Measurements were made in triplicate under the same conditions and averages are plotted in Fig. 1. Other spectral measurements were carried out in a similar way.

Kinetic Measurements. Rates were measured on a Union RS 1100 stopped-flow spectrophotometer at 30 ± 0.2 °C by mixing the acid solution with a dilute stock solution of **3** in CH_3CN or in aqueous solution (as a form of **4**). The aqueous stock solution was prepared by dissolving 1.0 ml of the stock solution of **3** in CH_3CN into water in a 50 ml volumetric flask. Good pseudo-first-order kinetics were observed over 3 halflives. Averages of 4 or 5 measurements are summarized in Table 1.

The authors thank S. Kawao for the preparation of 2-isopentyloxy-1,3-benzodithiole.

Cycloaddition Reactions of Heteroaromatic Thioketones with Maleic Anhydride, Norbornene, Acrylonitrile, Styrene, and 2-Chloroacrylonitrile

Haruo OHMURA and Shinichi MOTOKI*

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received November 18, 1983)

Heteroaromatic thioketones react with maleic anhydride, norbornene, acrylonitrile, and styrene to form the Diels-Alder adducts, respectively. The thioketones also undergo cycloaddition with 2-chloroacrylonitrile followed by elimination of hydrogen chloride to give heteroaromatic analogues of *o*-quinodimethan derivatives. In these reactions, the thioketones act as a heterodiene on the dienophiles to give [4+2]cycloadducts regioselectively.

Recently, it has been found that α,β-unsaturated thiocarbonyl compounds, such as thiochalcone, 2-(arylmethylene)tetralin-1-thione, underwent cycloaddition reactions as reactive heterodienes with various olefins.[1]

On the other hand, the conjugated system made up of an aromatic or heteroaromatic ring and the side chain double bond can react as a diene.[2] For example, styrene has been known to react with dicyanoacetylene in this manner.[3] In 2-vinylfuran or 2-vinylthiophene, two diene systems are present in the molecule but the one involving the side chain is more reactive than heteroaromatic ring toward maleic anhydride.[4] As the heteroaromatic thioketones, aryl 2-furyl thioketones **1** and aryl 2-thienyl thioketones **3**, are relatively stable and readily available, we were interested in their properties as α,β-unsaturated thioketones. Previously, a part of the results of the study was reported.[5]

In the present paper, we wish to describe the detailed results of the cycloaddition reactions of these heteroaromatic thioketones with maleic anhydride, norbornene, acrylonitrile, styrene, and 2-chloroacrylonitrile.

Results and Discussion

1. The Reaction with Maleic Anhydride. The reaction of 2-furyl phenyl thioketone (**1a**) with maleic anhydride gave the cycloadduct **2a**. The structure of **2a** was confirmed by the IR, ^{1}H NMR, and mass spectra and elemental analysis. The IR spectrum of **2a** showed bands at 1860 and 1780 cm^{-1} due to the anhydride linkage. The mass spectrum showed a molecular ion peak at *m/z* 286 and retro Diels-Alder type fragments at *m/z* 188 (thioketone) as base ion peak and *m/z* 98 (maleic anhydride). In the ^{1}H NMR spectrum, the signal at δ 3.80 coupled with H-2, H-3, and H-4 is assigned to H-3a. The double-doublet and doublet at δ 4.05 and 4.24 are assigned to H-4 and H-5, respectively. The two double-doublet at δ 5.72 and 6.76 are assigned to olefinic protons of dihydrofuran ring (H-3 and H-2, respectively). These data and elemental analysis are consistent with the proposed structure **2a**.

2-Furyl mesityl thioketone (**1b**) gave the similar cycloadduct **2b**.

The reaction of aryl 2-thienyl thioketones (**3a**) with maleic anhydride was carried out in refluxing xylene, because the reaction needed prolonged reflux in benzene.

The reaction of phenyl 2-thienyl thioketone (**3a**) with maleic anhydride gave an aromatized cycloadduct **4a**. In the ^{1}H NMR spectrum, the singlet at δ 5.14 is assigned to benzylic proton (H-7). The mass spectrum showed no retro Diels-Alder fragment.

TABLE 1. THE REACTION WITH MALEIC ANHYDRIDE

Thioketone	Ar	Product	Reaction time	Solvent	Yield/%	Mp θ_m/°C
1a	Phenyl	**2a**	10 min	Benzene	56	124—125
1b	Mesityl	**2b**	1 h	Benzene	69	134—135
3a	Phenyl	**4a**	4 h	Xylene	12	146—147
3c	*p*-ClC_6H_4	**4c**	8 h	Xylene	18	193—194

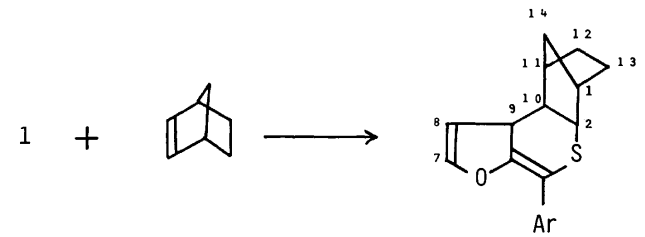
TABLE 2. THE REACTION WITH NORBORNENE

Thioketone	Ar	Product	Reaction time	Solvent	Yield/%	Mp θ_m/°C
1a	Phenyl	**5a**	50 min	Benzene	80	122—125
1b	Mesityl	**5b**	2 h	Benzene	76	121—122
3a	Phenyl	**6a**	20 min	Xylene	60	139—142
3b	Mesityl	**6b**	4 h	Xylene	74	158—160
3c	*p*-ClC_6H_4	**6c**	30 min	Xylene	56	120—121

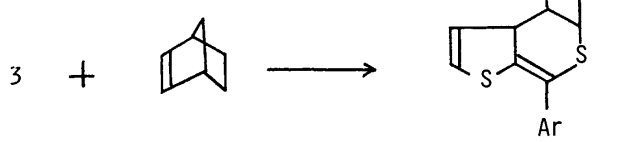
Probably the thioketone reacted with maleic anhydride to give the initial cycloadduct **4a'** which rearranged to aromatized adduct **4a** owing to its tendency to restore the aromatic system.

The reaction of *p*-chlorophenyl 2-thienyl thioketone (**3c**) with maleic anhydride gave a similar aromatized product **4c**. The results are presented in Table 1.

2. The Reaction with Norbornene. The reaction of 2-furyl phenyl thioketone (**1a**) with norbornene gave the cycloadduct **5a**. The IR spectrum of **5a** showed bands at 2960(C-H), 2880(C-H), and 1650(C=C) cm^{-1}. The mass spectrum showed ion peak at *m/z* 282 as parent ion peak and retro Diels-Alder fragment at *m/z* 188 (thioketone) as base ion peak. The ^1H NMR spectrum showed two multiplets at δ 1.08—1.76 and 2.00—2.36 for the signals of aliphatic protons in norbornane moiety, and a double-doublet at δ 2.78 and a double-double-doublet at δ 3.26 ($J_{9,10}$=10.0, $J_{8,9}$=2.1, and $J_{7,9}$=1.5 Hz) for H-2 and H-9, respectively. Two double-doublet at δ 5.52 and 6.64 are assigned to olefinic protons of H-8 and H-7, respectively.



5



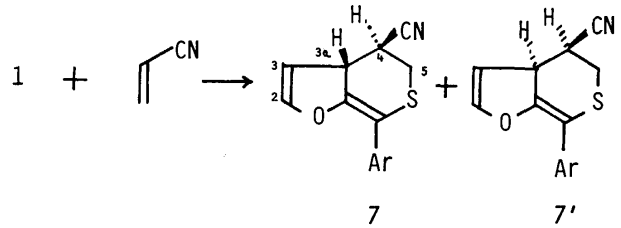
6

The reaction of 2-furyl mesityl thioketone (**1b**), aryl 2-thienyl thioketones **3a**, **3b**, and **3c** with norbornene gave similar cycloadducts **5b**, **6a**, **6b**, and **6c**, respectively. The structures were confirmed on the basis of the spectral data. The results are presented in Table 2.

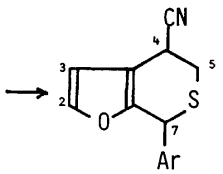
3. The Reaction with Acrylonitrile and Styrene. The reaction of heteroaromatic thioketone with acrylonitrile or styrene gave the sole regioisomeric adduct.

The reaction of 2-furyl mesityl thioketone (**1b**) with acrylonitrile gave the adduct **7b**. In the ^1H NMR spectra of **7b**, the signals of H-2, H-3, and H-4,5 appeared at δ 6.54, 5.50, and 2.52—3.12 and the splitting pattern of H-3a signal ($J_{3a,4}$=10.4, $J_{3,3a}$=2.5, and $J_{2,3a}$=2.1 Hz) was similar to that of H-9 in **5**. These results are consistent with the structure **7b** rather than that of its regioisomer. Besides the adduct **7b**, the stereoisomer **7b'** with respect to H-3a and H-4 ($J_{3a,4}\approx$2 Hz) was separated by column chromatography.

The reaction of 2-furyl phenyl thioketone (**1a**) with acrylonitrile gave 1,3-rearranged product **8a**. The mass spectrum of **8a** showed an ion peak at *m/z* 241 as parent ion peak. In the ^1H NMR spectrum, the multiplet at δ 3.00—3.12 and the double-doublet at δ 4.06 are assigned to H-5 and H-4, respectively. Presence of the singlet at δ 5.00 assignable to H-7 evidently indicates that the product is not the initial adduct **7a** but its rearranged compound **8a**.



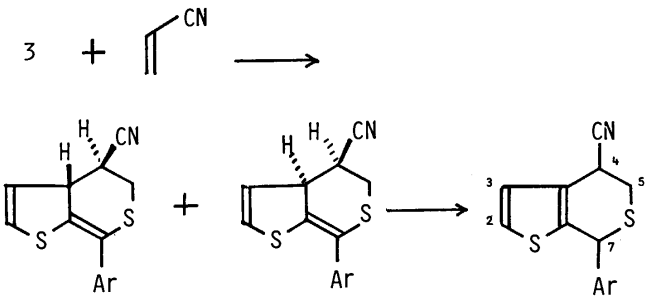
7 7'



8

The reaction of mesityl 2-thienyl thioketone (**3b**) with acrylonitrile gave two stereoisomeric adducts **9b** and **9b'**.

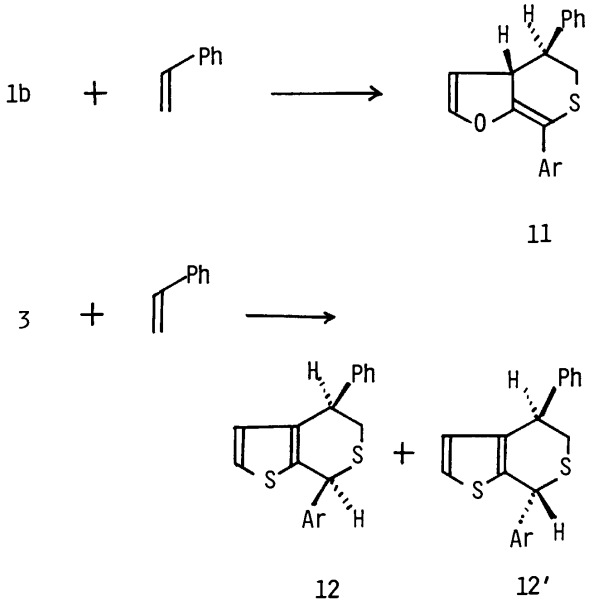
Aromatization of the initial adduct was also observed in the reaction of phenyl 2-thienyl thioketone (**3a**) with acrylonitrile. In this case, the product **10** were separated into two stereoisomers. The ^1H NMR spectra of these



9 9′ 10

isomers showed a singlet at δ 5.20 and 5.25 for the benzylic proton (H-7), respectively. Differences in the ^{13}C NMR spectra were also observed obviously.

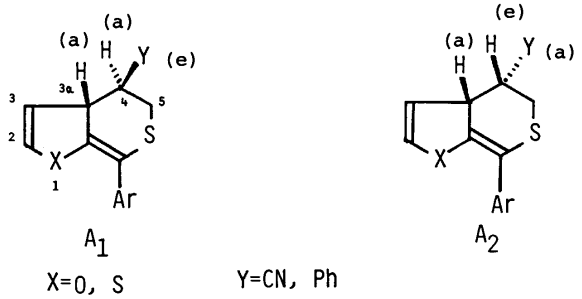
When the reaction of 2-furyl mesityl thioketone (**1b**) with styrene was carried out similarly, a [4+2]-cycloadduct **11b** was obtained. The reaction of aryl 2-thienyl thioketones **3a** and **3c** with styrene gave mixture of the aromatized products **12a** and **12a′**, and of **12c** and **12c′**, respectively. All attempts to isolate two isomers were unsuccessful. In the ^1H NMR spectra, two sets of signals were observed. This indicates that the product is a mixture of stereoisomers, the ratio of which was determined by intensity ratio of the two signals for benzylic proton (1 : 1).



11

12 12′

4. Stereoisomer in the Products. It is possible to consider two diastereomers in the products **7**, **9**, and **11** with respect to each two asymmetric carbon atoms C-3a and C-4 [Type **A**]. The products actually obtained are classified into two groups, those having large coupling constants ($J_{3a,4}$=10.0, 10.4, and 10.4 Hz for **7b**, **9b**, and **11b**, respectively) and those having small coupling constants ($J_{3a,4}\approx$2 and 2.3 Hz for **7b′** and **9b′**, respectively) between H-3a and H-4 in the ^1H NMR spectra. The large J value indicates[6] 3a-4 trans configuration (axial-axial) as represented by the structure $\mathbf{A}_1$ (or its enantiomer) and the small J value indicates 3a—4 cis configuration (structure $\mathbf{A}_2$, axial-equatrial).[7] It can be seen from Table 3 that the cis isomers are preferentially produced in the reaction with acrylonitrile.



A_1 A_2

X=O, S Y=CN, Ph

The products **5** and **6** have each five asymmetric carbon atoms C-1, C-2, C-9, C-10, and C-11 [Type **B**]. However, H-2, H-10 and H-1, H-11 are undoubtedly in cis relationship to each other.[8] Therfore, only four diastereomers are possible in these adducts. All the compounds of Type **B** obtained in the present study had large coupling constant ($J_{9,10}\approx$10 Hz) between H-9 and H-10 which indicates 9-10 trans configuration (structure $\mathbf{B}_1$ or $\mathbf{B}_2$, axial-axial). Chemical shift in the ^{13}C NMR spectra of the bridged carbon (C-14) of norbornane moiety suggests that the product probably has exo configuration ($\mathbf{B}_2$) rather than endo one ($\mathbf{B}_1$).[9]

3b	Mesityl	**9b**	6 h	18	129—130
		9b′		79	194—195

a) The reactions were carried out in refluxing dry benzene. b) As a matter of convenience, the stereoisomeric adducts are represented in this way. However, it is difficult to distinguish clearly between these stereoisomers **10a** and **10a′**.

Table 4. The reaction with styrene

Thioketone	Ar	Product	Reaction time[a]/h	Yield/%	Mp θ_m/°C
1b	Mesityl	**11b**	9	40	144—146
3a	Phenyl	**12a, 12a'**	1	15	—
3c	*p*-ClC_6H_4	**12c, 12c'**	4	17	—

a) The reactions were carried out in refluxing dry benzene.

Table 5. The reaction with 2-chloroacrylonitrile

Thioketone	Product	Reaction time[a]/min	Yield/%	Mp θ_m/°C	IR ν(CN)/cm^{-1}	^{13}C NMR δ C-4
1a	**14a**	10	56	85—87	2190	76.5
1b	**14b**	20	60	135—136	2190	74.6
3a	**16a**	60	63	103—105	2190	80.2
3b	**16b**	120	76	156—158	2190	79.1
3c	**16c**	60	69	165—166	2200	80.8

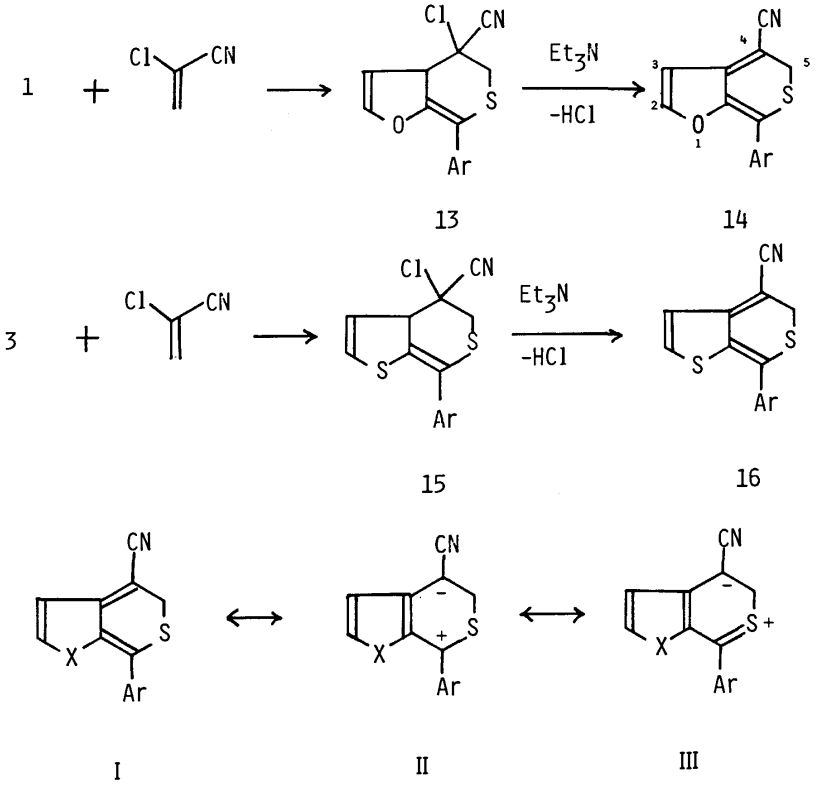
a) The reactions were carried out in refluxing dry benzene.

The adduct with maleic anhydride **2** was found to have 3a-4 trans, 4-5 cis configuration (**B_3**).

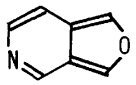
5. The Reaction with 2-Chloroacrylonitrile. The cycloaddition reactions of aryl 2-furyl thioketones **1** or aryl 2-thienyl thioketones **3** with 2-chloroacrylonitrile in refluxing benzene gave an unstable adduct **13** or **15**. As these adducts readily eliminate hydrogen chloride, attempt to isolate them in a pure form was unsuccesful. However, when triethylamine was added to the reaction mixture, the color of the solution turned immediately from yellow to deep red and triethylamine hydrochloride was precipitated. Column chromatography of the mixture gave *o*-quinodimethan-type derivatives of furan and thiophene **14** or **16** as stable red crystals.

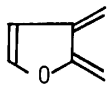
The IR spectra of **14** or **16** showed an intense absorption at 2190—2200 cm^{-1} due to the cyano group and the ^1H NMR spectra showed the singlet at δ 3.68—3.78 for methylene protons (H-5). In the ^{13}C NMR spectra, the C-4 signal is unusually upfield from the one in ordinary olefinic carbons. This suggests a considerable contribution of zwitter ionic structure such as **II** or **III** to the resonance state of **14** or **16**.

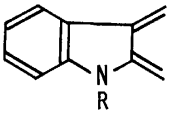
In general, *o*-quinodimethans are generated by flash-vacuum thermolysis[10] or by 1,4-elimination from the ammonium salt.[11] Furo[3,4-*c*]pyridine (**17**), 2,3-dimethylene-2,3-dihydrofuran (**18**),[12] and 2,3-dimethyleneindolin (**19**)[11] are the example of heteroaromatic *o*-quinodimethans. However, all of these compounds are unstable and are isolated only as their dimer or can be trapped by suitable capture. High stabilities of **14** and **16** are presumably ascribed to



the electron-withdrawing effect of cyano group and electron-releasing effect of sulfur atom.







17 18 19

6. Summary. In heteroaromatic thioketones, thiocarbonyl group conjugated with ring double bond reacted preferentially as a diene. The reactivity of these thioketones was in agreement with the extent of the aromaticity of the furan and thiophene ring as expected. Regioselectivity of the reaction of heteroaromatic thioketones agreed with those of previously reported α,β-unsaturated thioketones.[1] It is found that the adduct obtained from mesityl 2-furyl or 2-thienyl thioketones do not tend to undergo 1,3-hydrogen shift.

Experimental

All the melting points are uncorrected. The IR spectra were determined on a Hitachi Model 260-10 infrared spectrometer. The ^{1}H NMR and ^{13}C NMR spectra were recorded on a JEOL JNM-FX 100 spectrometer using Me_4Si as internal standard at 100 MHz or 25 MHz, respectively. The mass spectra were recorded on a Hitachi double-focusing mass spectrometer RMU-7M operating at an ionizing potential of 70 eV. Silica gel (Wako gel C-200) was used for column chromatography.

Heteroaromatic thioketones **1** or **3** were prepared by the reaction of the corresponding ketone and Lawesson reagent [2,4-bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane 2,4-disulfide][13] or P_4S_{10}.[14] The thioketones were purified by column chromatography on Florisil gel (100—200 mesh) using dichloromethane-hexane (1:4) as eluent. 2-furyl phenyl thioketone (**1a**): blue liquid; 2-furyl mesityl thioketone (**1b**): blue liquid; phenyl 2-thienyl thioketone (**3a**): blue liquid (lit,[15] blue liquid); mesityl 2-thienyl thioketone (**3b**): blue liquid; *p*-chlorophenyl 2-thienyl thioketone (**3c**): deep green needles, mp 61—62 °C (lit,[15] mp 63 °C).

Cycloaddition Reaction of Heteroaromatic Thioketone with Dienophile. General Procedure: A solution of the thioketone (5 mmol) and dienophile (5 mmol or slightly excess) in dry benzene or xylene (5 cm^3) was refluxed under a nitrogen atmosphere until all the thioketone was consumed as indicated by TLC. The solvent was evaporated and the residue was recrystallized directly or chromatographed on silica gel to give the cycloadduct.

*7-Phenyl-3a,4-dihydro-5H-thiopyrano[3,4-b]furan-4,5-dicarboxylic Anhydride (**2a**)*: Colorless needles (from benzene-hexane) IR (KBr) 1860 (C=O) and 1780 (C=O) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.80(ddd, J=6.6, 2.2, and 2.2 Hz, 1H), 4.05(dd, J=9.6 and 6.6 Hz, 1H), 4.24 (d, J=9.6 Hz, 1H), 5.72 (dd, J=2.5 and 2.2 Hz, 1H), 6.76 (dd, J=2.5 and 2.2 Hz, 1H), 7.12—7.40 (m, 3H), and 7.60—7.76 (m, 2H); MS m/z (rel intensity) 286 (M$^+$, 8), 188 (thioketone, 100), 160(9), 155(10), and 98 (maleic anhydride, 7). Found: C, 62.92; H, 3.54; S, 11.26%. Calcd for $C_{15}H_{10}O_4S$: C, 62.93; H, 3.52; S, 11.20%.

*7-Mesityl-3a,4-dihydro-5H-thiopyrano[3,4-b]furan-4,5-dicarboxylic Anhydride (**2b**)*: Chromatographed by eluting with benzene; colorless crystals (from benzene-hexane); IR (KBr) 3120, 2980, 1880 (C=O), and 1790 (C=O) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.16 (s, 6H), 2.28 (s, 3H), 3.12 (dd, J=12.0 and 12.0 Hz, 1H), 3.66 (ddd, J=12.0, 3.0, and 2.5 Hz, 1H), 4.20 (d, J=12.0 Hz, 1H), 5.78 (dd, J=3.0 and 3.0 Hz, 1H), 6.68 (dd, J=3.0 and 2.5 Hz, 1H), and 6.84 (broad s, 2H); MS m/z (rel intensity) 328 (M$^+$, 21), 255 (51), 230 (thioketone, 100), 213 (58), 197 (51), and 169 (46). Found: C, 66.10; H, 4.99; S, 9.76%. Calcd for $C_{18}H_{16}O_4S$: C, 65.84; H, 4.91; S, 9.76%.

*7-Phenyl-4,5-dihydro-7H-thieno[2,3-c]thiopyran-4,5-dicarboxylic Anhydride (**4a**)*: Chromatographed by eluting with benzene-hexane (1:1); slightly yellow crystals (from ligroin); IR(KBr) 1870 (C=O) and 1790 (C=O) cm^{-1}; ^{1}H NMR($CDCl_3$) δ=4.48 (d, J=8.5 Hz, 1H), 4.62(dd, J=8.5 and 1.0 Hz, 1H), 5.14(s, 1H), 7.20(broad s, 2H), and 7.31(broad s, 5H); MS m/z (rel intensity) 302(M$^+$, 44), 229(74), 203(14), and 153(100). Found: C, 59.58; H, 3.27; S, 21.05%. Calcd for $C_{15}H_{10}O_3S_2$: C, 59.59; H, 3.33; S, 21.21%.

*7-(p-Chlorophenyl)-4,5-dihydro-7H-thieno[2,3-c]thiopyran-4,5-dicarboxylic Anhydride (**4c**)*: Chromatographed by eluting with benzene; purple crystals (from benzene-hexane); IR(KBr) 1870 (C=O) and 1790 (C=O) cm^{-1}; ^{1}H NMR($CDCl_3$) δ=4.56(d, J=1.0 Hz, 2H), 5.28(s, 1H), and 7.04—7.34(m, 6H); MS m/z (rel intensity) 338(M$^+$, 12), 336(M$^+$, 29), 308(5), 263(54), and 153(100). Found: C, 53.52; H, 2.62; S, 18.59%. Calcd for $C_{15}H_9O_3S_2Cl$: C, 53.49; H, 2.69; S, 19.04%.

*exo-4-Phenyl-6-oxa-3-thiatetracyclo[9.2.1.0^{2,10}.0^{5,9}]tetradeca-4,7-diene (**5a**)*: Chromatographed by eluting with benzene; red crystals (from ethanol); IR(KBr) 2960, 2880, and 1650 cm^{-1}; ^{1}H NMR($CDCl_3$) δ=1.08—1.76(m, 6H), 2.00—2.36(m, 3H), 2.78(dd, J=8.2 and 1.5 Hz, 1H), 3.26(ddd, J=10.0, 2.1, and 1.5 Hz, 1H), 5.52(dd, J=2.1 Hz, 1H), 6.64(dd, J=2.1 and 1.5 Hz, 1H), 7.00—7.36(m, 4H), and 7.68—7.84(m, 1H); MS m/z (rel intensity) 282(M$^+$, 28), 188(thioketone, 100), and 187(48). 4,7-Diphenyl-4,5-dihydro-7H-thieno[2,3-c]thiopyran (12a) and (12a'): Chromatographed by eluting with benzene-hexane (1:3); orange crystals (from ethanol); IR (KBr) 3100, 3060, 3030, 2910, 1600, 730, and 710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.76—3.28 (m, 2H), 4.35—4.45 (m, 1H), 5.24 (s, 0.5H), 5.35 (s, 0.5H), 6.46 (d, J=5.0 Hz, 0.5H), 6.50 (d, J=5.0 Hz, 0.5H), 7.00 (d, J=5.0 Hz, 0.5H), 7.04 (d, J=5.0 Hz, 0.5H), and 7.05—7.40 (m, 10H); MS m/z (rel intensity) 308 (M^+, 53), 262 (49), 230 (42), 204 (thioketone, 100), 203 (97), and 184 (48). Found: C, 73.69; H, 5.11; S, 20.63%. Calcd for $C_{19}H_{16}S_2$: C, 73.98; H, 5.23; S, 20.79%.

7-(p-Chlorophenyl)-4-phenyl-4,5-dihydro-7H-thieno[2,3-c]thiopyran (12c) and (12c'): Chromatographed by eluting with benzene-hexane (2:3); yellow crystals (from ethanol); IR (KBr) 3120, 2910, 1600, and 1490 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.75—3.22 (m, 2H), 4.15—4.45 (m, 1H), 5.20 (s, 0.5H), 5.32 (s, 0.5H), 6.47 (d, J=5.7 Hz, 0.5H), 6.52 (d, J=5.7 Hz, 0.5H), 7.00 (d, J=5.7 Hz, 0.5H), 7.05 (d, J=5.7 Hz, 0.5H), and 7.00—7.40 (m, 9H); MS m/z (rel intensity) 344 (M^+, 17), 342 (38), 296 (21), 264 (37), 261 (42), 238 (54), and 203 (100). Found: C, 66.43; H, 4.32; S, 18.97%. Calcd for $C_{19}H_{15}S_2Cl$: C, 66.55; H, 4.41; S, 18.70%.

Reaction of Heteroaromatic Thioketone with 2-Chloroacrylonitrile. A mixture of heteroaromatic thioketone (5 mmol) and 2-chloroacrylonitrile (1 cm^3) was refluxed in dry benzene (5 cm^3) under a nitrogen atmosphere until all the thioketone had been consumed as evidenced by TLC analysis. The reaction mixture was cooled and triethylamine (2 cm^3) was added in the solution. The solution was refluxed for 30 min. The color of the solution turned immediately deep red. The mixture was cooled to room temperature and the precipitated triethylamine hydrochloride was filtered off. The filtrate was evaporated and the residue was purified by column chromatography. The eluate was evaporated and the residue was recrystallized from ethanol to give **14** or **16**.

4-Cyano-7-phenyl-5H-thiopyrano[3,4-b]furan (14a): Chromatographed by eluting with benzene-hexane (2:1); red needles; IR (KBr) 3150, 3100, 3060, 2190, and 1630 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.68 (s, 2H), 6.26 (d, J=2.7 Hz, 1H), 7.22 (d, J=2.7 Hz, 1H), 7.28—7.48(m, 3H), and 7.60—7.80 (m, 2H); MS m/z (rel intensity) 239 (M^+, 64), 238 (100), 213 (6), 209 (9), 121 (6), and 77 (7). Found: C, 70.33; H, 4.05; N, 6.08; S, 13.24%. Calcd for $C_{14}H_9NOS$: C, 70.27; H, 3.79; N, 5.85; S, 13.40%.

4-Cyano-7-mesityl-5H-thiopyrano[3,4-b]furan (14b): Chromatographed by eluting with benzene-hexane (1:2); red needles; IR (KBr) 3130, 2975, 2920, 2190, 1640, 1610, 1580, 1550, 1150, 860, and 790 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.20 (s, 6H), 2.29 (s, 3H), 3.74 (s, 2H), 6.20 (d, J=2.5 Hz, 1H), 6.87 (broad s, 2H), and 7.08 (d, J=2.5 Hz, 1H); MS m/z 281(M^+, 100), 266 (42), 252 (21), 248 (44), and 238 (20). Found: C, 72.34; H, 5.44; N, 4.79; S, 11.38%. Calcd for $C_{17}H_{15}NOS$: C, 72.57; H, 5.37; N, 4.98; S, 11.39%.

4-Cyano-7-phenyl-5H-thieno[2,3-c]thiopyran (16a): Chromatographed by eluting with benzene-hexane (2:3); red crystals; IR (KBr) 3120, 2190, 1580, 1520, 1490, 1095, 980, 760, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.73 (s, 2H), 6.68 (d, J=7.0 Hz, 1H), 7.10 (d, J=7.0 Hz, 1H), and 7.20—7.60 (m, 5H); MS m/z (rel intensity) 255 (M^+, 80), 254 (100), 229 (7), and 222 (7). Found: C, 65.75; H, 3.28; N, 5.57; S, 25.20%. Calcd for $C_{14}H_9NS_2$: C, 65.85; H, 3.55; N, 5.49; S, 25.11%.

4-Cyano-7-mesityl-5H-thieno[2,3-c]thiopyran (16b): Chromatographed by eluting with dichloromethane-hexane (1:3); reddish purple needles; IR (KBr) 3090, 2970, 2920, 2190, 1610, 1585, 1530, 1505, 1100, 850, and 770 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.19 (s, 6H), 2.28 (s, 3H), 3.78 (s, 2H), 6.63 (d, J=5.9 Hz, 1H), 6.85 (broad s, 2H), and 7.02 (d, J=5.9 Hz, 1H); MS m/z (rel intensity) 297 (M^+, 100), 282 (29), 264 (55), 212 (17), and 178 (M^+—mesityl, 13). Found: C, 68.84; H, 5.03; N, 4.60; S, 21.22%. Calcd for $C_{17}H_{15}NS_2$: C, 68.95; H, 5.08; N, 4.71; S, 21.56%.

7-(p-Chlorophenyl)-4-cyano-5H-thieno[2,3-c]thiopyran (16c): Chromatographed by eluting with dichloromethane-hexane (2:3); red silky needles; IR (KBr) 2975, 2200, 1580, 1490, 1195, 820, and 755 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.76 (s, 2H), 6.70 (d, J=6.3 Hz, 1H), 7.11 (d, J=6.3 Hz, 1H), and 7.20—7.84 (m, 4H); MS m/z (rel intensity) 291 (M^+, 35), 290 (56), 289 (77), 288 (100), 256 (16), 231 (16), and 178 (19). Found: C, 57.99; H, 2.79; N, 4.81; S, 22.03%. Calcd for $C_{14}H_8NS_2Cl$: C, 58.03; H, 2.78; N, 4.83; S, 22.13%.

Quinazoline Derivatives from 2-Phenyl-4-quinazolinylhydrazine

Hassan Ahmed EL-SHERIEF,* Abdalla Mohamed MAHMOUD, and Ahmed Ahmed ESMAIEL

Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt

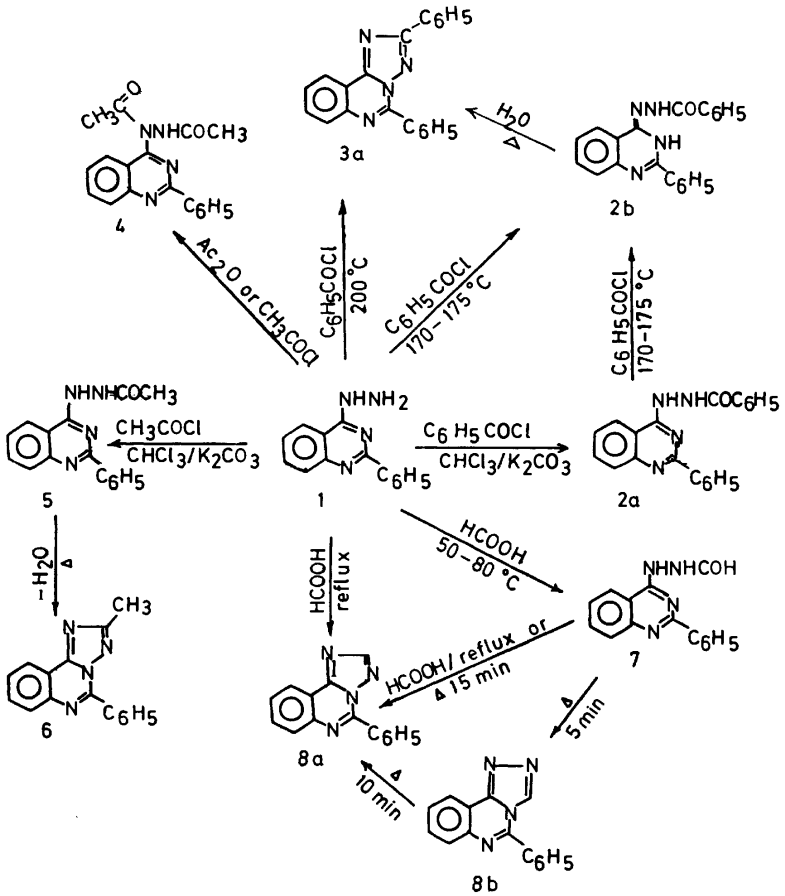
(Received December 1, 1982)

Formic acid and acetyl and benzoyl chloride were treated with 2-phenyl-4-quinazolinylhydrazine (**1**) under mild conditions to afford the corresponding hydrazides which were converted into 5-phenyl[1,2,4]triazolo[1,5-*c*]quinazoline, 2-methyl-5-phenyl[1,2,4]triazolo[1,5-*c*]quinazoline, and 2,5-diphenyl[1,2,4]triazolo[1,5-*c*]quinazoline (**3a**) respectively by heating over their melting points. Reaction of **1** with aldehydes produced the corresponding hydrazones which give the corresponding [1,2,4]triazolo[1,5-*c*]quinazolines (**3a**—**i**) on pyrolysis. Carbon disulfide underwent ring closure with **1** to 5-phenyl-1,2,4-triazolo[4,3-*c*]quinazoline-3-thiol which was readily converted into the corresponding alkylthio compounds by treatment with alkyl halides. Further, 4-(4-arylmethylene-5-oxo-2-phenyl-2-imidazolinylamino)-2-phenylquinazolines were obtained *via* the condensation of 4-arylmethylene-2-phenyl-2-oxazolin-5-ones with **1**.

Literature survey has revealed that some heterocyclic compounds such as 2-hydrazinoquinoxaline which has hydrazino group ortho to ring nitrogen can be cyclized to the corresponding[1,2,4]triazolo[4,3-*a*]quinoxalines[1] *via* the reaction with organic acids, acid chlorides and/or acid anhydrides and the acylated intermediate was not obtained. In some cases, however, only the acylated intermediates were obtained, depending on the nature of heterocyclic compound.[2] The isomerization in ring-fused 1,2,4-triazoles induced by acid or heat has been reported for several of these ring systems.[3,4] A particularly facile isomerization was observed with[1,2,4]triazolo[4,3-*c*]quinazoline system to its [1,2,4]triazolo[1,5-*c*]quinazoline isomer.[5]

It was of interest to mention that the products obtained from the reaction of 2-phenyl-4-quinazolinylhydrazine (**1**) with acyl chlorides, formic acid, or aldehydes depend mainly on the reaction conditions applied.

The reaction of **1** with benzoyl chloride in chloroform containing anhydrous potassium carbonate yielded 2-benzoyl-1-(2-phenyl-4-quinazolinyl)hydrazine (**2a**), while heating a mixture of **1** and benzoyl chloride at 170—175 °C for 1 h, the isomer **2b** was obtained as a major product. Heating of **2a** in benzoyl chloride at 170 °C for 1 h gave the isomer **2b**. Further, heating of both **2a** and **2b** above their melting points for 15 min gave 2,5-diphenyl[1,2,4]triazolo[1,5-*c*]quinazoline (**3a**), which was obtained directly by refluxing a mixture of **1** and benzoyl chloride for 2 h, as shown in



Scheme 1.

Scheme 1.

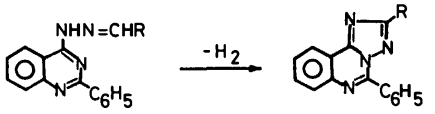
The structures of **2a**, **2b**, and **3a** were established on the basis of their IR, UV, and Mass spectral analysis. Refluxing of **1** with acetic anhydride or acetyl chloride for 2 h gives 1,2-diacetyl-1-(2-phenyl-4-quinazolinyl)hydrazine (**4**). 2-Acetyl-1-(2-phenyl-4-quinazolinyl)hydrazine (**5**) was obtained by the reaction of **1** with acetyl chloride in chloroform containing anhydrous potassium carbonate, which was cyclized to 2-methyl-5-phenyl[1,2,4]triazolo[1,5-*c*]quinazoline (**6**), by heating above its melting point for 15 min (Scheme 1).

It was reported by Potts[5] that 5-phenyl[1,2,4]-triazolo[1,5-*c*]quinazoline (**8a**) was obtained by direct cyclization of **1** with formic acid, while its [4,3-*c*]-quinazoline isomer (**8b**) was achieved by the reaction of **1** with triethyl orthoformate.

In our investigation both isomers **8a** and **8b** were obtained through the formation of *N*-formyl intermediate **7** which was obtained by conducting the reaction of **1** with formic acid at 55—80 °C for 45 min. Heating of **7** over its melting point for 5 min gave **8b**, which was readily isomerized to **8a** by further heating above its melting point for 10 min. On the other hand, **8a** was obtained directly by continuous heating of **7** for 15 min or by refluxing of **7** with formic acid for 1 h.

The UV spectra of **3a**, **6**, and **8a** were characterized by the location of the principal absorption band at shorter wavelength relative to that of **2a**, **5**, and **7** respectively. The observed blue shift (52—58 nm) may be due to the shortening of conjugation as a result of their cyclization to 1,2,4-triazolo ring system.

Reaction of **1** with the appropriate aldehydes in ethanolic solution containing piperidine yielded the corresponding hydrazones (**9a**—**i**). While carrying the same reaction in the absence of solvent at 210—220 °C for 2 h, cyclization took place and the [1,2,4]-triazolo[1,5-*c*]quinazolines (**3a**—**i**) were obtained.



9 3

a: C_6H_5	f: $C_6H_4CH_3$-p
b: C_6H_4Br-p	g: $C_6H_4NO_2$-p
c: C_6H_4Cl-p	h: $C_6H_4NO_2$-m
d: C_6H_4Cl-m	i: 2-thienyl
e: $C_6H_4OCH_3$-p	

On the other hand, heating of **9a** above its melting point for 1 h, it was cyclized to **3a**. The IR spectra of **9a**—**i** revealed an absorption band at 3370—3350 cm^{-1} attributed to NH group, which disappeared in compounds **3a**—**i**. The UV spectra of **9** were characterized by the presence of a principal absorption band at 362—382 nm, while the UV spectra of **3** exhibited a principal absorption band at 300—310 nm. The observed blue shift (62—72 nm), probably due to the shortening of conjugation as a result of cyclization.

The NMR spectrum of **3e** (in DMSO) showed a singlet at δ=3.8 (3H, OCH_3), a multiplet at 6.8—7.8 (9H, aromatic protons) and another multiplet at 8.4—8.6 (4H, of quinazoline ring); while the NMR spectrum of **3f** showed a singlet at δ=2.6 (3H, CH_3), a multiplet at 7.2—7.8 (9H, aromatic protons) and at 8.2—8.5 (4H, of quinazoline ring).

In the mass spectra of these fused ring systems molecular ions were obtained for all compounds studied.

Further, it was reported that carbon disulfide reacted with 2-pyridylhydrazines[2,6] or 2-thiazolylhydrazines[7] to produce 1,2,4-triazolo[4,3-*a*]pyridine-3-thiols and thiazolo[2,3-*c*]-1,2,4-triazole-3-thiols respectively.

Similarly, reaction of **1** with carbon disulfide provided a convenient synthesis of 5-phenyl-1,2,4-triazolo[4,3-*c*]-quinazoline-3-thiol (**10**), which was readily converted to the corresponding 3-alkylthio compounds (**11a**—**e**) with alkyl halides in basic medium.

The NMR spectrum of **11b** (in $CDCl_3$) showed a triplet at δ=1.3 (J=6 Hz, 3H, CH_3), a quartet at 3.3 (J=6 Hz, 2H, CH_2), and a multiplet at 7.5—8.3 (9H, aromatic protons), while the NMR spectrum of **11d** (in $CDCl_3$) showed signals at δ=4.7 (s, 2H, CH_2) and at 7.4—8.8 (m, 14 H, aromatic protons).

Furthermore, the hitherto unreported reaction of **1** with 4-arylmethylene-2-phenyl-2-oxazolin-5-ones (**12**)[8] in benzene or xylene afforded the corresponding 1-(2-phenyl-4-quinazolinyl)-2-(2-benzamido-3-arylacryloyl)-hydrazine (**13**). The IR spectra of **13** showed two bands characteristic of the stretching vibration of two carbonyl groups at 1680—1670 cm^{-1} and at 1650—1640 cm^{-1} in addition to the NH band appeared at 3320—3290 cm^{-1}.

When **12** was allowed to react with **1** in the presence of anhydrous zinc chloride, the corresponding 4-(4-arylmethylene-5-oxo-2-phenyl-2-imidazolin-1-ylamino)-2-phenylquinazolines (**14a—d**) were produced directly.

On the other hand, **14a** was also obtained by heating of **13a** above its melting point for 5 min in the presence of anhydrous zinc chloride. The IR spectra of **14a—d** showed absorption bands at 1690—1680 cm^{-1} and 3280—3240 cm^{-1} which were assigned to C=O and NH stretching frequencies respectively. The mass spectrum of **14c** showed a molecular ion peak at *m/e* 497, which agreed with the molecular weight expected.

Experimental

Melting points reported are uncorrected. Elemental analysis was carried out on a CHN analyzer. IR spectra were recorded on a Perkin-Elmer infracord. NMR spectra were recorded by a Varian EM 60 MHz spectrometer. Mass spectra were taken on MAT 112 Massenspectrometer.

2-Phenyl-4-quinazolinylhydrazine (**1**) was prepared as previously described by Postovskii, mp 215 °C, lit,[9] mp 214—215 °C.

2-Benzoyl-1-(2-phenyl-4-quinazolinyl)hydrazine (**2a**). To a solution of **1** (5.9 g, 0.025 mol) in dry chloroform (100 ml) containing anhydrous potassium carbonate (0.5 g), benzoyl chloride (0.02 mol) was added slowly. After the addition was complete, the reaction mixture was stirred at room temperature for 30 min and then heated on a steam bath for 1 h. The mixture was filtered, evaporated and the crude product was collected and crystallized from ethanol as yellow needles, 7 g (82%); mp 248 °C. IR(KBr), 3360 (NH), 3220(NH), 1650 cm^{-1} (C=O); UV(ethanol), λ_{max} 248 (log ε 4.59), 320(4.0), 356 nm (3.84); MS (70 eV), M^+, *m/e* (rel intensity) 340 (100%), 221(53%), 205(38%), 103 (59%), 102(65%). Found: C, 74.11; H, 4.70; N, 16.45%. Calcd for $C_{21}H_{16}N_4O$: C, 74.10; H, 4.47; N, 16.46%.

The isomer **2b** was obtained by heating a mixture of **1** (0.02 mol) and benzoyl chloride (0.04 mol) at 170—175 °C for 1 h. The product was isolated by pouring the reaction mixture into cooled 5% sodium carbonate solution. The crude product crystallized from ethanol as colorless needles, 4.5 g (66%), mp 260 °C. IR (KBr); 3320(NH), 3210 (NH), 1660 cm^{-1} (C=O); UV (ethanol) λ_{max} 232(log ε 4.56), 256 (4.5), 308 nm(4.06); MS (70 eV), M^+, *m/e* (rel intensity) 340 (80%), 322 (100%), 219(35%). Found: C, 73.92; H, 4.83; N, 16.32%. Calcd for $C_{21}H_{16}N_4O$: C, 74.10; H, 4.74; N, 16.46%.

The same product was also obtained by heating of **2a** (1 g) in benzoyl chloride (5 ml) at 170—175 °C for 1 h.

2,5-Diphenyl[1,2,4]triazolo[1,5-c]quinazoline (**3a**). A mixture of **1** (4.69 g, 0.02 mol) and benzoyl chloride (0.04 mol) was refluxed for 2 h. The product was isolated as before and crystallized from ethanol as colorless needles, 4.6 g (72%).

The same compound was also obtained by heating of **2a** or **2b** (1 g) over their melting points for 15 min, and crystallized from ethanol, 0.5 g (63%). There is no melting point depression and the infrared spectrum was superimposable on that of **3a** prepared according to the above procedure (Table 2).

1,2-Diacetyl-1-(2-phenyl-4-quinazolinyl)hydrazine (**4**). **1** (2.3 g, 0.01 mol) was refluxed with acetic anhydride or acetyl chloride (10 ml) for 2 h. The colorless product separated was collected and crystallized from ethanol as colorless needles, 2.8 g (87%), mp 255 °C; IR (KBr); 3300 (NH), 1700, 1670 cm^{-1} (C=O), NMR, δ=2.5 (s, 3H, CH_3CO), 2.7 (s, 3H, CH_3CO), 3.0 (s, 1H, NH), 7.7—9.0 (m, 9H, aromatic protons).

Found: C, 67.36; H, 5.11; N, 17.28%. Calcd for $C_{18}H_{16}N_4O_2$: C, 67.49; H, 5.03; N, 17.49%.

2-Acetyl-1-(2-phenyl-4-quinazolinyl)hydrazine (**5**). It was prepared from **1** (9.2 g, 0.04 mol) and acetyl chloride (0.02 mol) in chloroform solution containing anhydrous potassium carbonate as previously described in **2a**. The crude product was crystallized from ethanol as pale orange prisms, 2 g (74%), mp 252—253 °C. IR (KBr) 3300, 3220 (NH), 1650 cm^{-1} (C=O).

Found: C, 69.18; H, 5.15; N, 20.46%. Calcd for $C_{16}H_{14}N_4O$: C, 69.05; H, 5.07; N, 20.13%.

Refluxing of **5** (1 g) with acetic anhydride or acetyl chloride (5 ml) for 1 h yielded **4** (0.9 g; 75%).

2-Methyl-5-phenyl[1,2,4]triazolo[1,5-c]quinazoline (**6**). **5** (1 g) was heated above its melting point for 10 min and after cooling to room temperature, crystallized from methanol as colorless needles, 0.6 g (60%), mp 128 °C; IR (KBr) 3050 (C–H), 1615 cm^{-1} (C=N); UV (ethanol) λ_{max} 259 (log ε 4.38), 264(4.25), 294 (4.3) nm; MS (70 eV), M^+, *m/e* (rel intensity) 260 (100%), 219 (36%); NMR, δ=2.7 (s, 3H, CH_3), 7.5—7.8 (m, 5H, C_6H_5), 8.5—8.8 (m, 4H, quinazoline ring).

Found: C, 73.71; H, 4.56, N, 21.31%. Calcd for $C_{16}H_{12}N_4$: C, 73.83; H, 4.65; N, 21.52%.

2-Formyl-1-(2-phenyl-4-quinazolinyl)hydrazine (**7**). A mixture of **1** (1 g) and formic acid (6 ml) was heated at 50—80 °C for 45 min and the excess acid was evaporated under reduced pressure. The crude product was collected and crystallized from ethanol as yellow crystals, 0.8 g (71%), mp 240 °C; IR (KBr) 3270, 3220(NH), 1650 cm^{-1}, (C=O); UV (ethanol), λ_{max} 275 (log ε 3.99), 288 sh (3.86), 350 nm (3.25).

5-Phenyl-1,2,4-triazolo[4,3-c]quinazoline (**8b**). **7** (1 g) was heated above its melting point for 5 min and after cooling, crystallized from ethanol as colorless needles, 0.7 g (77%); mp 207 °C, lit[5] mp 205—206 °C.

Found: C, 73.00; H, 4.38; N, 22.41%. Calcd for $C_{15}H_{10}N_4$: C, 73.16; H, 4.09; N, 22.75%.

5-Phenyl[1,2,4]triazolo[1,5-c]quinazoline (**8a**). Heating of **7** (1 g) as described above for 15 min gave colorless needles from ethanol 0.8 g (88%), mp 185 °C, lit[5] mp 184—185 °C.

The same product was also obtained by refluxing a mixture of **1** (0.5 g) and formic acid (3 ml) for 1 h as described[5] before, or by heating of **8b** (0.5 g) above its melting point for 10 min. UV (ethanol), λ_{max} 249 (log ε 4.22), 292 nm, (3.89).

Found: C, 73.18; H, 4.16; N, 22.54%. Calcd for $C_{15}H_{10}N_4$: C, 73.16; H, 4.09; N, 22.75%.

Reaction of 2-Phenyl-4-quinazolinylhydrazine (**1**) *with Aldehydes* (**9a—i**). A mixture of **1** (0.01 mol), aromatic aldehyde (0.012 mol), ethanol (30 ml), and piperidine (0.2 ml) was refluxed for 4 h. The separated hydrazone was filtered and crystallized from the same solvent as yellow to red needles. The same products were also obtained by fusion of **1** with the appropriate aldehyde for 2 min (Table 1).

2-Aryl-5-phenyl[1,2,4]triazolo[1,5-c]quinazolines (**3a—i**). A mixture of appropriate aldehyde (0.015 mol) and **1** (0.01 mol) was heated at 210—220 °C for 2 h. The pyrolysis residue in the reaction flask was cooled and triturated with cold ethanol. The crude product was dissolved in ethanol–benzene (charcoal), forming colorless needles of **3a—i** (Table 2).

3a was also obtained by heating **9a** for 1 h at 210—215

Effect of Ethanol on the Inclusion Complex Formation between β-Cyclodextrin and Pyrene

Akira NAKAJIMA

Department of Electronic Engineering, Faculty of Engineering, Saitama Institute of Technology, Okabe, Saitama 369-02

(Received June 2, 1983)

Synopsis. The effect of the addition of ethanol on the formation of the inclusion compound between β-cyclodextrin and pyrene in aqueous solution has been studied. Based on the time dependences of the fluorescence spectra of pyrene as a probe, the rate constants estimated for the inclusion and further association in the presence of ethanol have been discussed.

It has been reported[1] that macromolecular inclusion compounds have a considerable effect on the reactivity of the substrates included. Much interest has recently been shown in the inclusion compounds of cyclodextrins,[2,3] since they exhibit appreciable enzyme-like activity, and a variety of practical applications are extending. It seems that few studies have been made on the effect of a third component, though it may occasionally have a significant influence on the enzymatic reactions.

Previously, a system of β-cyclodextrin (βCD) and pyrene in aqueous solution has been investigated utilizing the intensity enhancement phenomenon[4] and the association constant has been estimated.[5] In this work, the effect of ethanol on the rates of inclusion and further association has been studied in the same system.

Experimental

Pyrene was recrystallized and vacuum-sublimed, and βCD was purified by repeated recrystallizations from water. Ethanol was dried and fractionally distilled.

The sample solutions were carefully prepared using deionized water from an aqueous solution of pyrene which was well saturated by allowing it to stand in contact with pyrene microcrystals for more than a week. No excimer-like emission nor impurity emission was detected in these solutions. The initial concentration of pyrene, C_p, was estimated to be 2.5×10^{-7} M (1 M=1 mol dm^{-3}) by measuring the low absorbance at 334 nm. The volumetric preparation of a solution and the subsequent measurement required at least two minutes, after which the spectral changes with time were observed.

Fluorescence spectra were recorded at about 13 °C on a Shimadzu 210A spectrophotometer with some minor modifications. The excitation was made employing a combination of a high-intensity monochromator and a Xe-lamp stabilized over the wavelengths (about 15 nm width) for the second peak of the second absorption band of pyrene (319—322 nm).

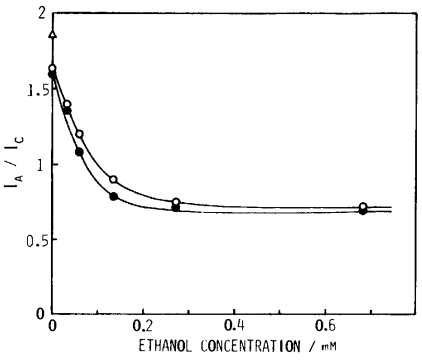

Fig. 1. Changes in I_A/I_C ratios with ethanol concentrations in aqueous solutions of βCD (8.5×10^{-4} M) and pyrene (2.5×10^{-7} M). After 30 min (○) and a week (●), and without βCD (△).

Results and Discussion

It is now well known[4,6,7] that the intensities of vibronic bands in the fluorescence spectrum of pyrene vary strikingly with the solvent polarity and the ratio of the intensity of the band A at 373 nm (I_A) to that of the band C at 384 nm (I_C) can be regarded as a measure of the polarity of medium,[6] the phenomenon being effectively employed here to probe the microenvironments. It is observed that the intensity ratio I_A/I_C is 1.87 in pure water but 0.58 in a nonpolar solvent.

The changes in the I_A/I_C ratios with varying ethanol concentrations in the solutions containing given amounts of pyrene and βCD are illustrated in Fig. 1. As can be seen, the effect of the addition of ethanol is very remarkable; the reaction is considerably speeded at concentrations more than 0.2 M. The ratios are also found to change with time.

The decrease of the I_A/I_C value from 1.87[8] implies that considerable part of pyrene dissolved is included within the βCD cavity, where the environment has a polarity corresponding to an I_A/I_C value of 0.68.[5]

The variations of the I_A/I_C ratios with time for various ethanol concentrations are shown in Fig. 2. Inspection of the behaviors of these curves reveals that they consist of two portions, associated with a fast and a slow process. The fast initial decay, which appears to be almost completed within a minute, is likely due to the inclusion of pyrene by βCD, while the subsequent slow decrease may be ascribed to a

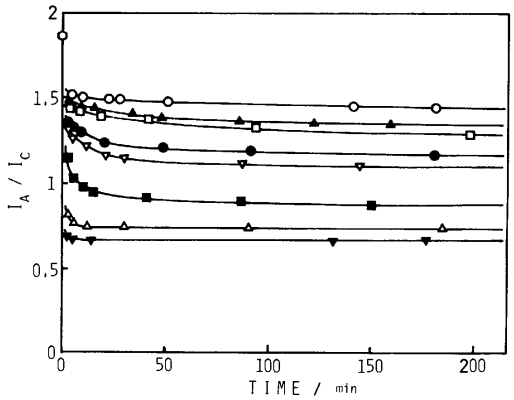

Fig. 2. Variations of I_A/I_C ratios with time in aqueous solutions of βCD (1.9×10^{-3} M) and pyrene (2.5×10^{-7} M). Concentration of ethanol (M): 0 (○), 1.4×10^{-3} (▲), 4.1×10^{-3} (□), 8.2×10^{-3} (●), 1.4×10^{-2} (▽), 4.1×10^{-2} (■), 0.14 (△), 1.7 (▼), and without βCD (0).

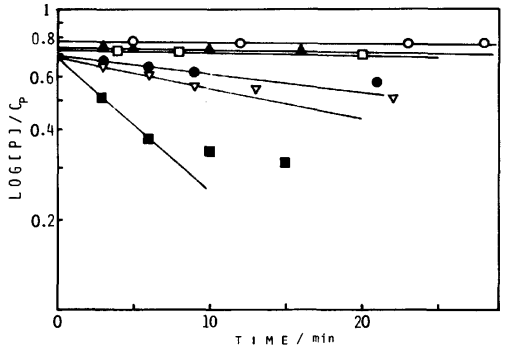

Fig. 3. Plot of log $[P]/C_P$ *vs.* t.

further association of the resulting inclusion compounds. As clearly shown in Fig. 2, the inclusion and the further association are appreciably accelerated by the addition of ethanol.

According to these observations, the reaction scheme may be expressed as follows:

$$P + D \underset{k_2}{\overset{k_1}{\rightleftharpoons}} PD,$$

$$PD + D \underset{k_4}{\overset{k_3}{\rightleftharpoons}} PD_2,$$

where P and D denote pyrene and βCD, respectively, and PD and PD_2 represent respectively the 1:1 and 1:2 complexes formed from them. Though the association may produce various complex species,[8] here PD_2 is taken as most probable. These rate constants are considered as functions of ethanol concentration, [Et].

Thus, the kinetic equations are given by

$$\frac{d[P]}{dt} = -k_1[P][D] + k_2[PD],$$

$$\frac{d[PD]}{dt} = k_1[P][D] - (k_2+k_3[D])[PD] + k_4[PD_2].$$

At relatively short times the term associated with $[PD_2]$ can be neglected and [D] is practically equal to C_D, the total βCD concentration, because of $[P] \ll C_D$.

Then, the solution has the form:

$$[P] = A\exp(-k_+t) + B\exp(-k_-t),$$

where $k_\pm = (a \pm \sqrt{a^2 - 4b})/2,$

$$a = (k_1+k_3)C_D + k_2, \quad b = k_1k_3C_D^2.$$

By using the initial conditions that $[P]=C_P$ and $[PD]=0$ at $t=0$,

$$A = (k_1C_D - k_-)C_P/(k_+ - k_-),$$

$$B = (k_+ - k_1C_D)C_P/(k_+ - k_-).$$

It can be assumed here that $k_1C_D \gg k_2 \approx k_3C_D \gg k_4$.

Accordingly, a rough approximation gives

$$k_+ \approx k_1C_D, \; k_- \approx k_3C_D,$$

$$A \approx C_P, \; B \approx k_2C_P/k_1C_D = C_P/KC_D;$$

$$[P]/C_P \approx \exp(-k_1C_Dt) + \exp(-k_3C_Dt)/KC_D.$$

Thus, the rate constant k_3 together with the equilibrium constant K can be estimated from the slowly decreasing portion of the curves. In the present experiment, however, the value of k_1 cannot be obtained owing to the considerably rapid changes.

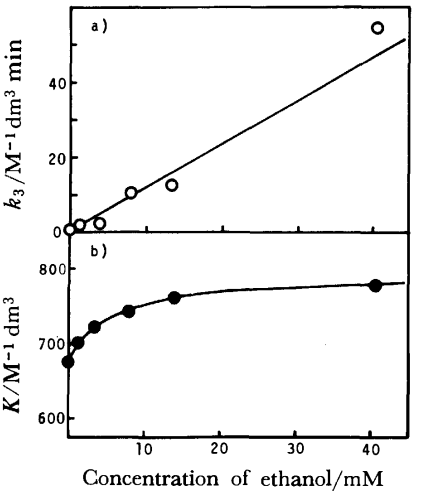

Fig. 4. Plots of k_3 (a) and K (b) against ethanol concentration.

To interpret the time-dependent behaviors on the basis of the above scheme, the concentrations of pyrene dissolved in the water phase, [P], need to be evaluated, and the following formula[5] has been employed:

$$\frac{I_A}{I_C} = \frac{k_P^A\phi_P\varepsilon_P[P] + k_{PD}^A\phi_{PD}\varepsilon_{PD}[PD]}{k_P^C\phi_P\varepsilon_P[P] + k_{PD}^C\phi_{PD}\varepsilon_{PD}[PD]},$$

Where ϕ's are the quantum yields ($\phi_{PD}/\phi_P \approx 1.5$),[5] ε's are the absorption coefficients ($\varepsilon_{PD}/\varepsilon_P \approx 1$),[6] and k^A or k^C represents the fraction of the spectral intensity for the A or C band. The assumption that $[P]+[PD] \approx C_P$ at $t \approx 0$ has been used.

Figure 3 shows plots of log $[P]/C_P$ *vs.* t, which are found to be fairly linear at small t. From the slopes and intercepts of the lines approximate values of k_3 and K are obtained. Furthermore, k_3 as well as K is plotted against the ethanol concentration in Fig. 4. As shown, k_3 appears to depend linearly on [Et], implying the possibility of the formation of a four-component complex PD_2Et.

In constrast to k_3, K does not change so much with [Et] since not only k_1 but k_2 depends on [Et]. Only an order-of-magnitude agreement is obtained between the value of K ($675\,M^{-1}dm^3$) and that ($190\,M^{-1}dm^3$) estimated previously,[5] and the discrepancy may be due largely to the times for measurement, various approximations, different pyrene and βCD concentrations, temperatures, *etc.*

The Crystal Structure of the B′-Form of Heptadecanoic Acid

Midori GOTO* and Eiichi ASADA†
National Chemical Laboratory for Industry, 1-1, Higashi, Yatabe, Ibaraki 305
(Received July 8, 1983)

Synopsis. X-Ray structural determination of the B′-form of heptadecanoic acid showed that the unit cell contains two crystallographically independent molecules. All-trans zigzag chains are found in both molecules.

Odd numbered fatty acids are known to crystallize in three polymorphic forms, named A′, B′, and C′.[1] Informations relating to the properties of these are collected in Table 1. The B′-form of pentadecanoic acid has been studied by von Sydow using two-dimentional X-ray diffraction data.[2] We have now been able to obtain fairly good single crystals of the B′-form of heptadecanoic acid and investigated its crystal structure.

Experimental

The heptadecanoic acid was prepared from methyl heptadecanoate by hydrolysis. The B′-form crystals were obtained by crystallization from a 2,2,4-trimethylpentane solution. A crystal with dimensions of $0.6\times0.3\times0.05$ mm^3 was used for the structure determination. The cell dimensions and the diffraction intensities were measured on a Rigaku-Denki four circle diffractometer by using graphite monochromated Cu-$K\alpha$ radiation at room temperature. Crystal data are as follows: $C_{17}H_{34}O_2$ (B′-form); M.W=270.46; triclinic, $P\bar{1}$; a=5.561(1), b=8.018(1), c=47.90(1)Å; α=114.18(1), β=114.96(1), γ=80.22(1)°; D_x=1.017 g cm^{-3}. All independent reflections within the range of $2\theta\leqq120°$ were collected by the use of the 2θ—ω scan mode with a scanning rate 4° (2θ) min^{-1}. Correction for absorption was not applied. A total 1028 independent reflections with $|F_o|\geqq3\sigma(|F_o|)$ were obtained.

Structure Determination

The positions of the carbon atoms were obtained from three dimensional Patterson maps. The positions of the oxygen atoms were obtained by difference synthesis. The positions of the hydrogen atoms, with the exception of carboxyl hydrogen atoms, were calculated by assuming C-H distances of 1.10 Å and a tetrahedral arrangement. The structure was refined

by the block-diagonal least-squares method using the UNICS III system.[3] The R-value was reduced to 0.077. The final atomic parameters[4] are listed in Table 2.

Results and Discussion

The B′-form of heptadecanoic acid has a characteristic layer structure, such as is usually found in fatty acids. As shown in Fig. 1, the molecules form all-trans zigzag chains, in contrast to the case of the B-form of stearic acid,[5] in which the bond between the second and third carbon atoms takes a gauche conformation. The structural parameters are shown in Table 3. The subcell, *i.e.* the cell which describes the repetition in the hydrocarbon chains,[1] was found to be orthorhombic, with the following dimensions: a_s=5.0 Å, b_s=7.4 Å, and c_s=2.54 Å, similar to that of the B-form of stearic acid.[5]

The conformations of the two molecules (I, II) in the asymmetric unit are similar to each other. These molecules are joined in pairs by hydrogen bonds between the carboxyl groups with the O···O distances of 2.64(1) Å (I-I) and 2.62(1) Å (II-II). The dihedral angles between the planes containing the carboxyl groups was 11° (I-I), and 21° (II-II), nearly the same as those in the other fatty acids.[6,7] The second closest oxygen contact distance is 3.2 Å as shown in Fig. 2.

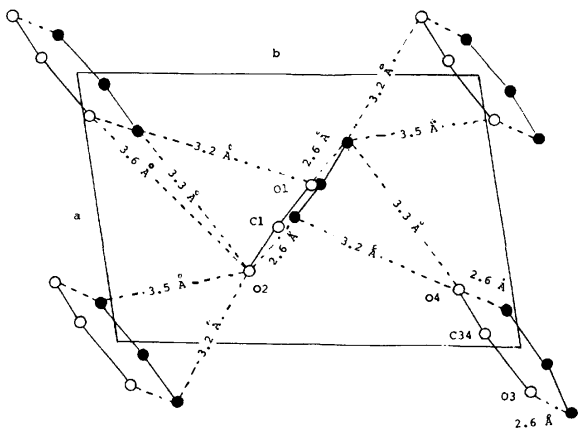

Fig. 2. Carboxyl groups projected along the c* axis.

This value agrees well with that of the B-form of stearic acid.[5] Von Sydow[2] reported that the hydrogen bond was formed between the crystallographically independent molecules (such as I-II) in the structure of the B′-form of pentadecanoic acid. We reinvestigated it and found that the hydrogen bond is formed between the two molecules related by a center of symmetry as in the B′-form of heptadecanoic acid.[8]

It is known that in the odd-numbered fatty acids a transition B′⇄C′ is reversible but in the even numbered ones a transition B⇄C is not.[1] This difference may be related to the fact that in the odd members the molecular conformation of the B′-form is similar to that of the C′-form because both of them have all-trans zigzag chains but in the even members the B-form has a bond of gauche conformation whereas the C-form does not.[5]

We are grateful to Professor Y. Iitaka of the University of Tokyo for his encouragement and helpful discussions. We are indebted to Dr. T. Sakurai and Miss K. Kobayashi of the Institute of Physical and Chemical Research for the programs UNICS III used in this work.

Solvent Effects on the Intensity of the nπ* Absorption Spectra of 1-Phenylethylenetrithiocarbonate and *p*-Benzoquinones

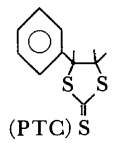
Yasufumi JINNOUCHI, Motohisa KOHNO, and Akira KUBOYAMA*

National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Ibaraki 305

(Received August 22, 1983)

Synopsis. The nπ* absorption intensities of 1-phenylethylene trithiocarbonate (**1**), *p*-benzoquinone (**2**), and 2,5-di-*t*-butyl-p-benzoquinone (**3**) in nonpolar solvents are compared with the theoretical ones calculated by the use of Abe's formula, in which the Onsager-cavity field is used. For **3**, the theoretical intensities are well correlated with the observed ones, whereas for the others there are discrepancies, especially for **1**. These discrepancies are attributed to strong dispersion-force interactions with the solvents.

Experimental data about solvent effects on the intensity of the electronic absorption spectra are still scarce. Previously, however, we found that the intensity of the nπ* absorption spectrum of *p*-benzoquinone (PBQ) in carbon disulfide is far stronger than that in heptane.[1] Recently, we also found that the intensification of the thiocarbonyl nπ* absorption spectrum of 1-phenylethylene trithiocarbonate (PTC) in carbon disulfide is greater than that of PBQ. In the studies of the solvent effects on the intensity of the nπ* absorption spectra PTC is favorable in that the nπ* absorption spectrum is at far longer wavelengths than the longest wavelength ππ* absorption spectrum and in that the steric hindrance about the thiocarbonyl group is small.



Experimental

Measurements. The absorption spectra have been obtained by means of a Cary 14 self-recording spectrophotometer. The integrated absorption intensities of the spectra were obtained by measuring the weight of the section papers, on which the areas are the same as those surrounded by the absorption curves and the baselines. In order to minimize errors which might be caused by any unevenness of the quality of the section papers used, they were calculated from the ratio of the weight of a portion of an absorption spectrum to that of a polygon[2] inscribed in it. In this method, the errors were within 0.4%.

Materials. The PTC (Toyotama Kogyo Co.) was purified by vacuum sublimation (mp 85.0—86.0°C). The PBQ (Tokyo Kasei Kogyo Co.) was purified by sublimation (mp 115.0—116.0°C). The 2,5-di-*t*-butyl-*p*-benzoquinone (2,5-PBQ) (Tokyo Kasei Kogyo Co.) was twice recrystallized from cyclohexane (mp 152.7°C). All the solvents employed, *i.e.*, cyclohexane, benzene, carbon tetrachloride, and carbon disulfide, were of a spectro-grade (all from Wako Pure Chemical Industries Co. except for the carbon disulfide of E. Merck), and were used without further purification. GR-grade 1-methylnaphthalene (Tokyo Kasei Kogyo Co.) was purified by vacuum distillation.

Results and Discussion

The long-wavelength absorption spectra of PTC in several nonpolar solvents in Fig. 1 can safely be assigned to the thiocarbonyl nπ* spectrum[1,3] from their positions and from the intensity and solvent effects on their positions; this nπ* transition has previously been thought to be essentially forbidden, like that of quinones,[1] in view of the weak intensity of these spectra. The intensity of the nπ* spectra of PTC and quinones is thought to be essentially due to the vibronic mixing of the nπ* and the closest allowed ππ* state.[4]

In Tables 1 and 2, the ratios of the *f*-values (oscillator strengths) of the nπ* spectra in various nonpolar solvents and that in cyclohexane are compared with those obtained by means of Abe's formula,[5]

derived with the Onsager-cavity field, on the basis of the quantum-mechanical theory. In obtaining the observed *f*-values, the factor of $(1/n_D^{20})$[2] (n_D^{20}: refractive index of the D-line at 20°C) is included.[5,6] In Abe's work,[5] the formula derived with the Onsager-cavity field best reproduced the observed results among the many formulas thus far derived by many authors. In 2,5-PBQ, the observed results are close to the theoretical ones, while in PTC and PBQ the observed results are far from the theoretical ones, especially in PTC. The above results can be interpreted as follows.

In 2,5-PBQ, solvent molecules can hardly ever approach the carbonyl oxygen atoms because of the heavy steric hindrance caused by the two *t*-butyl groups. In PBQ, the hydrogen atoms attached to the α-carbon atoms cause something of a steric hindrance to the approach of solvent molecules to its carbonyl oxygen atoms. On the other hand, in PTC there is no such steric hindrance. Moreover, in PTC the bond length of the thiocarbonyl C-S bond is longer than that of the C-O bonds of PBQ, and the 3p lone-pair orbital of the sulfur atom is far more spread outward than the 2p lone-pair orbital of the oxygen atoms of PBQ. Therefore, solvent molecules can approach more easily to the thiocarbonyl sulfur atom of PTC than to the oxygen atoms of PBQ.

From the above discussion, the before-mentioned discrepancy of the observed results from the theoretical ones may be concluded to be essentially related to the approachability of solvent molecules to these heteroatoms. As the main interaction between nonpolar solvent molecules and these heteroatoms, which causes the intensification of the $n\pi^*$ spectra, any interaction but the dispersion-force interaction can hardly ever be cited. Previously Koyanagi[7] theoretically proved that the dispersion-force interaction between solvents and a solute may cause mixing between a forbidden state and the allowed states of the solute, resulting in an intensification of the forbidden spectrum, and later Koyanagi *et al.*[7,8] experimentally showed this on the $n\pi^*$ absorption spectra of carbonyl compounds. The dispersion-force interaction is very sensitive to the distance between the component molecules. Moreover, it becomes, in general, stronger with decreases in the ionization potentials of the component molecules. The ionization potential of the 3p lone-pair electron of the thiocarbonyl sulfur atom in PTC is considerably lower than that of the 2p lone-pair electrons of the carbonyl oxygen atoms in PBQ. Consequently, the dispersion-force interaction of PTC with solvents may be considerably stronger than that of PBQ. Therefore, the main cause of the before-mentioned discrepancy of the observed results may be attributed to the strong dispersion-force interaction of PTC and PBQ with the nonpolar solvents.

Generally speaking, the blue-shift of an $n\pi^*$ spectra in a solvent relative to that in saturated hydrocarbons shows that there are some specific interactions between the solvent and the solute, such as hydrogen-bond formation and charge-transfer and electrostatic interactions.[1] The $n\pi^*$ spectrum of PTC in carbon disulfide is at almost the same position as that in cyclohexane.[1] This fact may show that specific interactions between carbon disulfide and PTC are very small. Therefore, the remarkable enhancement of the $n\pi^*$ absorption intensity of PTC in carbon disulfide can hardly ever be attributed to the complex formation between carbon disulfide and PTC.

Freezing of Water as Aggregated with Cationic Surfactants in Deuterochloroform

Junzo SUNAMOTO,* Tomiko HAMADA, and Hiroki KONDO
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received May 25, 1983)

Synopsis. Freezing of water solubilized with the cationic CTAX(hexadecyltrimethylammonium halides) and QDX (dihexadecyldimethylammonium halides) in deuterochloroform was observed by ^{1}H-NMR method. The freezing of water was largely affected by the characteristics of the water-surfactant aggregates by the R-value(=[H_2O]/[surfactant]) and the structure of surfactant. In the 0.20 M (1 M=1 mol dm^{-3}) CTABr/0.16 M H_2O/$CDCl_3$ system, for example, the apparent freezing was observed at about −20 °C.

Various surfactants form aggregates with polar solutes, usually water molecules, in apolar media. People call the aggregates "reversed micelles" sometimes. "The aggregates" can provide specific and restricted reaction field for various chemical reactions[1] irrespectively of the concept of the cmc and aggregation number. In such a specific system equilibria, rates, and pathways of chemical reactions can be controlled by continuously and simultaneously changing the micropolarity and microviscosity of the reaction field and the activity of the cosolubilizates as a function of water content in the system.[2] Extending a series of our studies on the characterization of "the aggregates" or "reversed micelles", in this work, we would like to report an apparent freezing of water in the system. For this purpose, ^{1}H-NMR method for the water proton signal was utilized.[3,4]

Experimental

All the spectra were obtained using a JEOL 100 MHz NMR spectrometer at various probe temperatures with TMS as an internal standard. The probe temperature was calibrated carefully with methanol proton signals before and after measurements. Water content was determined on a Kyoto Electronics MFG Karl-Fischer Moisture Automatic Titrater, Model MK-AIII. Through all the runs deuterochloroform was employed as a bulk solvent to form the water-surfactant aggregates. Surfactants were the same as those used in a previous work.[3]

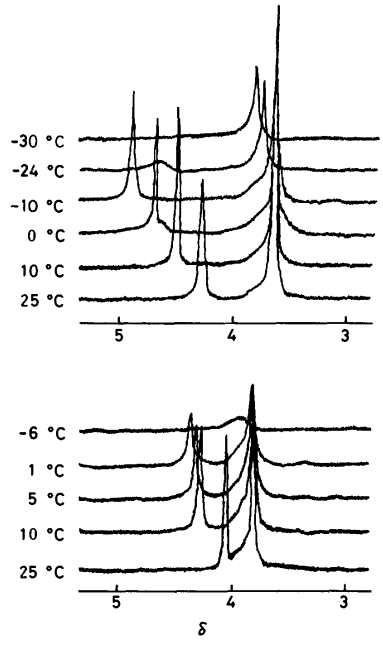

Fig. 1. NMR proton signals of water (lower field) and N-methyl group (upper field) of 0.20 M CTACl/0.444 M H_2O/$CDCl_3$ (top) and 0.10 M QDCl/0.245 M H_2O/$CDCl_3$ (bottom) at various temperatures.

Results and Discussion

Since the life time of both water protons, located in bulk phase and interacting with surfactant, is faster than the NMR time scale, only one signal of water proton was observed by NMR.[3]

First, lowering the probe temperature causes a downfield shift of the water proton signal with a concomitant line-broadening (Fig. 1). Further lowering the temperature shows a sudden and large line-broadening and a shift toward upper magnetic field of the signal. Hence, this point was defined tentatively as the apparent freezing point of water in this system. Second, the chemical shift of water proton siganl was due to both the R-value(=[H_2O]/[surfactant]) and the structure of surfactant.[3,4]

Water in deuterochloroform containing no surfactants shows a signal at 1.96 ppm (25.0 °C). In the cationic surfactant-water aggregates, water molecules interact with the strongly electronegative cation-head of surfactants by means of coordination-type.[3] This means that the water proton signal in micellar system appears downfield far from the value in chloroform: In the present cationic aggregates, the water proton

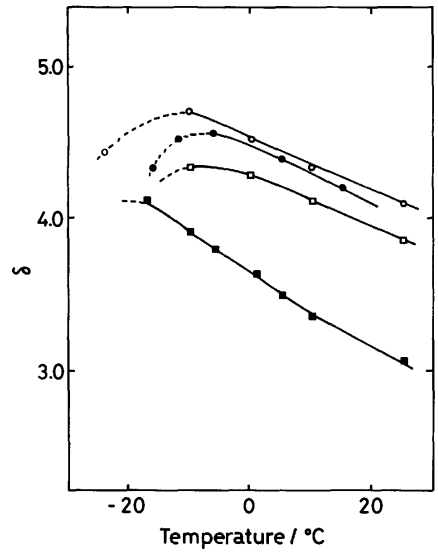

Fig. 2. Chemical shifts of water proton signal in the 0.20 M CTAX/$CDCl_3$ system as a function of the probe temperature: -○-, CTACl (R=2.22); -●-, CTABr (R=2.24); -□-, CTABr (R=2.04); -■-, CTABr (R=0.80), respectively. Drastic line-broadenings were observed over the broken line region.

signals were usually observed around 3—5 ppm (Figs. 1 and 2). Increasing the R-value produces hydrogen bonding between water molecules themselves and causes the paramagnetic shift of the proton signal as seen in Fig. 2. The chemical shift of the water proton under consideration seems to finally reach the value of pure bulk water (4.66 ppm). From the same reason, it is certain that upon lowering temperature the mobility of water molecules decreases and simultaneously both the hydrogen bonding between water molecules and the interaction between water and surfactants become stronger, resulting in further downfield shift of the signal (Fig. 2). Freezing and solubility decrease of water with lowering of temperature lead to a phase separation of the system. This was observed in a drastic change on the chemical shift and line width of the water proton signal. The apparent freezing point thus obtained was largely affected by the R-value, structure of surfactant, and bulk solvent. For example, in the case of CTABr aggregates in $CDCl_3$, the apparent freezing point was about $-20°C$ for $R=0.80$, $-10°C$ for 2.04, and $-6°C$ for 2.22, respectively. For QDBr micelles, it was about $-1°C$ for $R=0.60$ and $0°C$ for 2.45. However, in the case of anionic AOT aggregates in $CDCl_3$, no decrease in the freezing temperature was observed even when the R-value was below unity.

In any event, the nature of water bound to surfactants in apolar media is rather different from that of bulk water. In addition, the present work suggests to us that one can conduct chemical reactions in an aqueous system even below $0°C$ if an appropriate system was provided with the water-surfactant aggregates in apolar media.[5]

ESR Studies of Spin-Spin Dipolar Interaction in Pure and Diluted Phenoxyl Radical Solids

Kazuo MUKAI,* Kyozo UEDA, Kazuhiko ISHIZU, and Seigo YAMAUCHI†
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790
†*Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606*
(Received August 26, 1983)

Synopsis. ESR studies have been carried out on powder samples of pure phenoxyl (2,6-di-*t*-butyl-4-phenylphenoxyl) and 3% phenoxyl diluted in its diamagnetic corresponding phenol matrix. The dipolar splittings due to the spin pairs in closest approach have been observed for both the pure and 3% phenoxyl.

Recently, many investigations have been performed for the magnetic properties of some organic stable neutral radicals, including phenoxyl radicals. The magnetic susceptibility of these radicals deviates from the Curie-Weiss law at low temperatures and shows a broad maximum. This behavior of the paramagnet could be well described by the Heisenberg one-dimensional model or .singlet-triplet equilibrium model with isotropic antiferromagnetic exchange interaction: The value of the spin-spin exchange interaction (J) between neighboring radical molecules in these radical solids has been determined, by comparing experimental curve of susceptibility with theoretical one.[1] However, the examples that the property of the spin-spin dipolar interaction (D) in these radical solids has been clarified are very limited.[2,3] Recently, ESR studies have been carried out on powder samples of pure galvinoxyl and 1% galvinoxyl doped in its diamagnetic corresponding phenol matrix, which has the same crystal structure with that of galvinoxyl at 293 K. The existence of radical pairs in both the pure galvinoxyl and 1% galvinoxyl has been confirmed by the observation of the ESR zero-field splittings at 77 K, and, thus, by comparing the observed zero-field splittings, the mechanism of a first-order phase transition from paramagnetic to diamagnetic (or weak paramagnetic) reported previously for galvinoxyl at 85 K has been discussed.[4,5]

In the present work, in order to clarify the property of the spin-spin dipolar interaction in organic radical solids, we have measured the ESR spectra of powder samples of pure 2,6-di-*t*-butyl-4-phenylphenoxyl[6] (**1**) (abbreviated to phenoxyl hereafter) (see Fig. 1) and 3% phenoxyl diluted in its diamagnetic corresponding phenol matrix in the temperature range 293—77 K and 4.2 K.

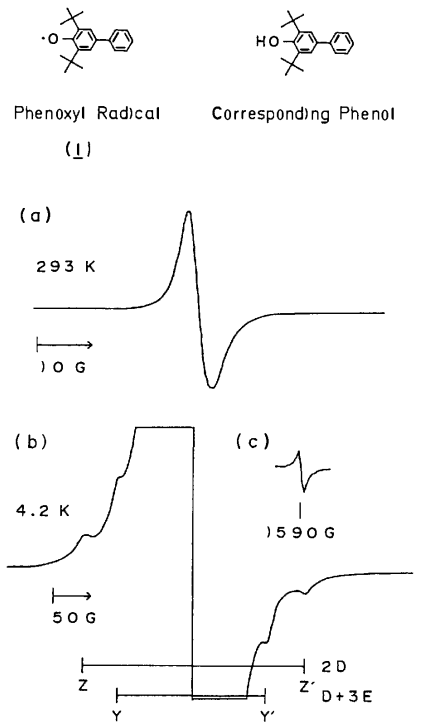

Fig. 1. ESR spectrum of a powder of phenoxyl (**1**); (a) $\Delta m_s=\pm1$ transition spectrum at 293 K, (b) $\Delta m_s=\pm1$ transition spectrum at 4.2 K, and (c) $\Delta m_s=\pm2$ transition spectrum at 4.2 K.

Experimental

Radical concentration of **1** was obtained from the results of the paramagnetic susceptibility measurements at 20°C, after correcting for the diamagnetic contribution ($\chi_{dia}=-0.204\times10^{-3}$ emu/mol) calculated by the Pascal's method. The value was 99% for **1**, assuming the Curie law. The powder sample of 3% phenoxyl diluted in its diamagnetic corresponding phenol matrix was prepared according to the procedure used for diluted galvinoxyl.[4]

Results and Discussion

The ESR spectrum of powder sample of the phenoxyl (**1**) at 293 K shows an exchange-narrowed, Lorentz-type absorption with a width of 4.5 G (1 G=10^{-4} T) located at g=2.0047, as shown in Fig. 1(a). When the temperature is lowered, the linewidth starts to increase gradually, and becomes 6.5 G at 77 K. In addition to the strong central singlet, two pairs of weak, broad side peaks were observed with the same order of intensity at 4.2 K, as shown in Fig. 1(b). The two pairs of absorption lines will be due to zero-field splittings arising from the intermolecular spin-spin dipolar interaction of two electrons in a triplet state.[7] In fact, the forbidden transition ($\Delta m_s=\pm2$) was observed at about 1590 G, as shown in Fig. 1(c). The zero-field splitting parameters and g-tensor values were evaluated as $|D|=148.2\pm0.4$ G and $|E|=17.0\pm0.4$ G and $g_{zz}=2.0027\pm0.0003$ (Z,Z') and $g_{yy}=2.0044\pm0.0003$ (Y,Y'), respectively. This phenomenon will be considered to be similar to the cases of some TCNQ salts and bisgalvinoxyl biradical, which also exhibit ESR zero-field splittings at low temperatures.[3,8] The magnetic susceptibilities of the above TCNQ salts and the bisgalvinoxyl biradical were well explained by singlet-triplet equilibrium model with lower singlet

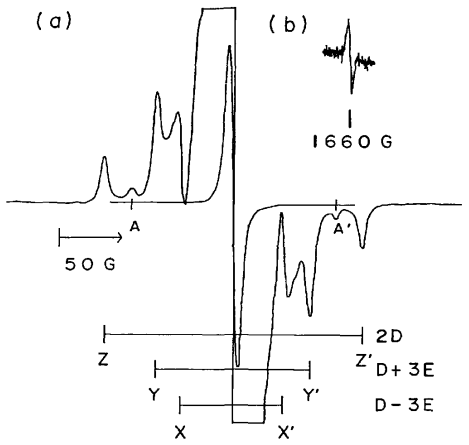

Fig. 2. ESR spectrum of a powder of 3% phenoxyl (**1**) at 293 K; (a) $\Delta m_s=\pm 1$ transition spectrum and (b) $\Delta m_s=\pm 2$ transition spectrum.

and upper triplet states. Therefore, our ESR data of the phenoxyl (**1**) indicate that this radical is a ground singlet with a thermally accessible triplet state.

The ESR spectrum of 3% phenoxyl at 293 K shows three pairs of absorption lines (Z,Z'; Y,Y'; and X,X') with the same order of intensity, as shown in Fig. 2(a). The three pairs of absorption lines apparently represent zero-field splittings arising from the intermolecular dipolar interaction of two electrons in a triplet state; thus, the zero-field splitting parameters and g-tensor values were evaluated as $|D|=101.3\pm 0.4$ G and $|E|=6.9\pm 0.4$ G and $g_{zz}=2.0043\pm 0.0003$ (Z,Z'), $g_{yy}=2.0042\pm 0.0003$ (Y,Y'), and $g_{xx}=2.0045\pm 0.0003$ (X,X'), respectively. In addition, the other weak $\Delta m_s=\pm 1$ absorptions (A,A') with a separation of about 161 G were observed in the ESR spectra, as shown in Fig. 2(a). The weak absorptions may be due to a radical triad.[9]

Careful measurements of the positions of the resonance lines show that this zero-field splitting is linearly temperature-dependent with $d|D|/dT=-(28\pm 2)\times 10^{-3}$ G K^{-1}. In the same way the $|E|$ thermal dependence is estimated to be about $d|E|/dT=-(4\pm 2)\times 10^{-3}$ G K^{-1}. This result may be interpreted as arising from the thermal expansion of the crystal lattice. The zero-field splitting parameters observed at 4.2 K are $|D|=109.3\pm 0.4$ G and $|E|=7.9\pm 0.4$ G. Here, the calculated average interelectronic distances, using a model of two point dipoles, are 6.50 Å at 293 K and 6.34 Å at 4.2 K for 3% phenoxyl. The spectrum at 4.2 K is similar to those above 77 K, and at 4.2 K, no deviation from linear temperature-dependency has been observed in D and E values.

In the present experiments, we observed the dipolar splittings due to the spin-pairs in closest approach for both the pure and 3% phenoxyl (**1**) at 4.2 K.[4] If the crystal structure of the phenol precursor of **1** is the same as that of phenoxyl (**1**), the value of the dipolar splitting observed for the diluted phenoxyl crystals will be considered to be the same as that of the neat phenoxyl crystal. However, the D and E parameters ($|D|=148.2$ G and $|E|=17.0$ G) obtained for pure phenoxyl are very different from those ($|D|=109.3$ G and $|E|=7.9$ G) obtained for 3% phenoxyl (**1**) at 4.2 K. Therefore, at first, we expected that the pure phenoxyl may show a first-order phase transition at low temperature, as observed for galvinoxyl,[5] and measured the Debye-Scherrer X-ray diffraction patterns at 293 K. However, the diffraction patterns observed for the pure phenoxyl and the corresponding phenol did not agree with each other in their diffraction angles and intensities at 293 K, contrary to our expectations. Both the phenoxyl radical (**1**) and the corresponding phenol may be considered to be biphenyl derivatives; the molecule of biphenyl is planar or nearly so in both the solid and triplet state, but twisted 30—40° around the central single bond in the vapor and in solution. Thus, the degree of twisting of biphenyl molecule is clearly due to a delicate balance of nonbonded repulsion and conjugation. In a previous paper,[10] it is reported that the phenoxyl radical (**1**) has planar character, because the inter-ring bond acquires some double-bond character in the phenoxyl radical in view of a valence-bond. On the other hand, the corresponding phenol does not acquire such double bond character, showing different crystal structure with that of the pure phenoxyl.

As described above, we observed the zero-field splittings due to the spin-pairs in closest approach for the pure phenoxyl at 4.2 K; the result indicates that this radical is a ground singlet with a thermally accessible triplet state. However, usually, the powder sample of the radical solids shows an "exchange-narrowed" single ESR absorption line, because of strong spin-spin exchange interaction operating between neighboring radical molecules. Consequently, the examples that the property of the spin-spin dipolar interaction (D) in the radical solids has been clarified are very limited.[2,3] Therefore, the observation of the dipolar splittings in phenoxyls diluted in their diamagnetic corresponding phenol matrices may be of significance.

The authors are much obliged to Professor Noboru Hirota of Kyoto University for the ESR measurements at 4.2 K.

†*NMR Laboratory, Faculty of Engineering, Hokkaido University, Sapporo 060*
(Received July 13, 1983)

Synopsis. The ring proton signals have been assigned for the ^{1}H NMR spectra of the green paramagnetic tetraammine(5-nitrosalicylato)cobalt(III) chloride nitrate hydrate and (quadridentate amine)(5-nitrosalicylato)cobalt(III) chloride nitrate hydrate, $[Co(5\text{-}NO_2sal)L]Cl\cdot NO_3\cdot nH_2O$ (L: $(NH_3)_4$, trien, 2,3,2-tet, and 3,2,3-tet). The ^{1}H NMR spectra indicate that the unpaired electron on the coordinated 5-nitrosalicylato ligand of the title complexes is located over the π-orbital of the chelated ligand

Previously, we have been concerned with the XPS[1,2] of the green paramagnetic tetraammine(5-nitro(or nitroso)salicylato)cobalt(III) complexes, *i.e.*, it has been established that an unpaired electron of these complexes is delocalized partly on the cobalt atom and partly on the chelated ligand (coordinated 5-nitrosalicylato ligand). In the NMR spectra of these complexes, the signals of the ammine proton have been assigned,[3] but the ring proton and carbon signals of the chelated ligand have so far remained unsolved. We have now devised appropriate conditions for the measurement of the NMR spectra of the green paramagnetic cobalt(III) complexes. The present paper deals with the measurement of the ring protons of the green paramagnetic tetraammine(5-nitrosalicylato)cobalt(III) chloride nitrate hydrate and the related compounds.

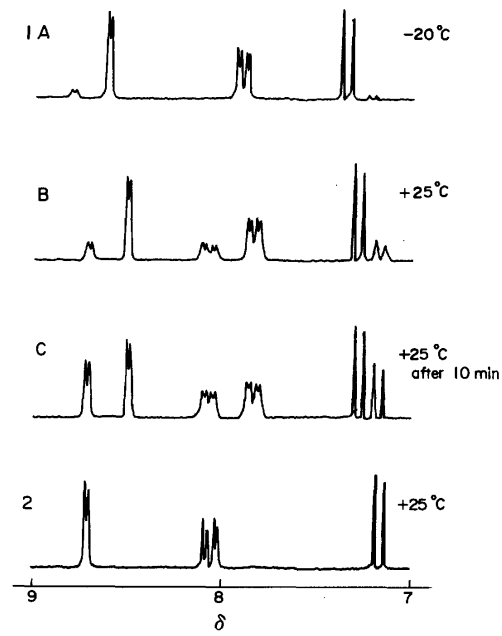

Fig. 1. The ^{1}H NMR spectra of the paramagnetic complex **1** and the diamagnetic complex **2** in 1.8 mol dm^{-3} D_2SO_4.
1A-C: $[Co(5\text{-}NO_2sal)(NH_3)_4]Cl\cdot NO_3\cdot H_2O$,
2: $[Co(5\text{-}NO_2sal)(NH_3)_4]NO_3\cdot H_2O$.

Results and Discussion

The ^{1}H NMR spectra of the chelated ligand of the green paramagnetic tetraammine(5-nitrosalicylato)-cobalt(III) chloride nitrate hydrate, $[Co(5\text{-}NO_2sal)(NH_3)_4]Cl\cdot NO_3\cdot H_2O$ (**1**), have not previously been observed, because the measurement is difficult. However, appropriate conditions for the NMR measurement of the green paramagnetic cobalt(III) complexes are now established as follows: The concentration and solvent, temperature and accumulation number are $4.6\pm0.2\times10^{-2}$ mol dm^{-3} in 1.8 mol D_2SO_4 solution, -20°C and two hundred times, respectively. On the other hand, the ^{13}C NMR spectrum of **1** did not show the expected signals, because of paramagnetism. The ^{1}H NMR spectra of **1**, as is shown in Fig. 1(A), have indicated three ring protons at δ 7.36, 7.91, and 8.61 under the same conditions. This spectrum showed six signals at 25°C as is shown in Fig. 1(B). In addition, after 10 min, as is shown in Fig. 1(C), these signals decrease with increase of the ring proton signals at δ 7.16, 8.05, and 8.71; these are chemical shifts of the ring protons of the corresponding orange diamagnetic nitrate hydrate, $[Co(5\text{-}NO_2sal)(NH_3)_4]NO_3\cdot H_2O$ (**2**). Finally, the ring proton signals of **1** are similar to those of **2**. Thus, the signals at δ 7.36 (d, H), 7.91 (dd, H),and 8.61 (d, H) of **1** have been assigned to the H_3, H_4, and H_6 ring protons, respectively. The chemical shifts and the coupling constants of the ring protons of **1** are closely similar to those of **2** as is shown in Table 1. Thus, the σ-bonds which are formed from protons and carbons (sp^2 configuration) of the chelated ligand of **1** resemble the σ-bonds of **2**, *i.e.*, the partly unpaired electron can not be delocalized over a hydrogen of the chelated ligand and a substituted methyl group[3] of the corresponding green paramagnetic tetraammine(4-methyl-5-nitrosalicylato)cobalt(III) chloride trihydrate, $[Co(4\text{-}Me\text{-}5\text{-}NO_2sal)(NH_3)_4]Cl_2\cdot 3H_2O$ (**3**), previous reported. It can be concluded that the partly unpaired electron on the chelated ligand is localized over the π-orbital of the chelated ligand. This is in agreement with the XPS results,[2] *i.e.*, the C ls binding energy and FWHM of **1** are different from those of **2**. Then, the electronic state of the π-orbital of the chelated ligand of **1** should be different from that of **2**.

The ring proton signals of the corresponding green paramagnetic (5-nitrosalicylato)cobalt(III) complexes with the quadridentate amine ligands such as trien (**4**, **5**), 2,3,2-tet (**6**), and 3,2,3-tet (**7**) were measured under the same conditions and the results are collected in Table 1. The ring proton signals of the chelated ligand

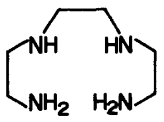
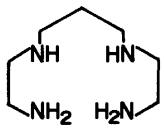
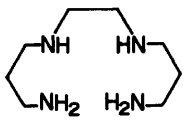
Solvent: 1.8 mol dm^{-3} D_2SO_4; Standard: internal DSS (δ=0). a: broad signal.



trien



2,3,2-tet



3,2,3-tet

of complex **7** are very sharp similar to those of **1**, though those of complex **4** are broad. Thus, the ring proton signals of the chelated ligand of complexes **4**—**7** are sharp with the increase of the total number of the center methylene carbons of the quadridentate amine ligands. This property is attributable to the coordinated quadridentate ligands.[4]

On the other hand, the ammine proton signals at δ 3.44 (s, 6H) and 3.94 (s, 6H) of **1** are similar to those (δ 3.44 (s, 6H) and 3.94 (s, 6H)) of **2** under the same conditions. This result agrees with that of XPS of **2**,[2] *i.e.*, the N ls binding energy of ammine ligands of **1** is similar to that of **2**.

Experimental

Measurements. The NMR spectra were recorded with Varian XL-200 NMR spectrometer.

Complexes. Green paramagnetic tetraammine- or (quadridentate amine)(5-nitrosalicylato)cobalt(III) chloride nitrate hydrate[5] (**1**, **4**—**7**) and orange diamagnetic tetraammine(5-nitrosalicylato)cobalt(III) nitrate hydrate[3] (**2**) were prepared by the methods of the previous papers.

(Received August 3, 1983)

Synopsis. The crystal data for calcium sulfite hemihydrate are orthorhombic, Pbcn, a=10.664(1), b=6.495(1), c=9.823(1) Å, and Z=8. The structure consists of two alternating layers. The calcium ions are coordinated by six O atoms: Five originate from the sulfite ions, and one from the water molecule.

There are only two papers relating the crystal structures of calcium sulfite: One reports the cell dimensions of calcium sulfite hemihydrate crystal[1] and the other the crystal structure of calcium sulfite tetrahydrate.[2]

This study deals with the crystal structure of calcium sulfite hemihydrate obtained as a stable phase in the temperature range from 0 to 98°C.

Experimental

Preparation. Single crystals of the hemihydrate were synthesized from calcium chloride solution(1.0 M, 1M= 1 mol dm^{-3}) and sodium sulfite solution (1.0 M) by the diffusion method (25°C, 4 weeks). Single crystals were obtained in the form of transparent plates with thicknesses of 0.1—0.4 mm. Analysis: Found: CaO, 43.3; SO_2, 49.5; H_2O, 7.1%. Calcd for $CaSO_3 \cdot 0.5H_2O$: CaO, 43.4; SO_2, 49.6; H_2O, 7.0%.

Determination of the Cell Constants and Collection of the Intensity Data. A crystal with the approximate dimension of 0.2×0.1×0.2 mm was used for the determination of cell constants and the collection of intensity data at 18°C. The cell constants were determined by the least-squares method based on the 2θ values of 21 reflections. Crystal data: $CaSO_3 \cdot 0.5H_2O$, $F.W.$=129.1, orthorhombic, space group Pbcn, a=10.664(1), b=6.495(1), c=9.823(1) Å, V=680.4(3) Å^3, Z=8, D_c=2.521, D_m= 2.51 g cm^{-3} (by flotation method). The reflection data for X-ray structural determination were collected with a Rigaku automatic four-circle diffractometer using graphite-monochromatized Cu$K\alpha$ radiation. Background was counted for 5 s at either side of each peak. The fluctuations in intensity of the three standard reflections measured every 50 reflections were about 1.1% during the data collection. Intensities of 741 independent reflections were measured up to θ=70°. Reflections having intensities stronger than four times the respective standard deviations were treated as observed. 519 non-zero reflections were obtained and corrected for Lorentz and polarization factors, but no correction was made for absorption.

Determination and Refinement of the Structure

The structure was determined by the symbolic addition method.[3] All the non-hydrogen atoms in the asymmetric unit were located from the E map. Refinement of atomic parameters was carried out by the full-matrix least-squares method, the quantity minimized being $\sum w(|F_o| - |F_c|)^2$ with w=1.0 for all the reflections. Four cycles of the least-squares refinement of the coordinates with isotropic temperature factors gave an R value of 0.082. Anisotropic temperature factors were introduced for all the atoms except hydrogen atoms, the R value being slightly reduced to 0.081. The atomic scattering factors for S and O were given by Cromer and Mann,[4] and that for Ca by International Tables for X-ray Crystallog-

raphy.[5] The dispersion corrections for atomic scattering factors of Ca and S are 0.3 and 0.3 for $\Delta f'$ and 1.4 and 0.6 for $\Delta f''$, respectively. At the final stage of the refinement the difference Fourier map showed only featureless peaks. For these calculations, computer programs made by Stewart *et al.*[6] were used. Anisotropic temperature factors of the non-hydrogen atoms and the complete F_o-F_c data are deposited as Document No. 8406 at the Office of the Editor of the Bulletin of the Chemical Society of Japan. The final atomic coordinates, their estimated standard deviations, and equivalent isotropic temperature factors are given in Table 1.

Description and Discussion of the Structure

A projection of the structure along the c axis and the numbering of the atoms are shown in Fig. 1. The oxygen atoms O(1)-O(3) belong to the sulfite ion, and the oxygen atom O(4) belongs to the crystal water. The oxygen atoms of water molecules are situated on the twofold axes. No such sulfite ions in a disordered state as observed in the structure of calcium sulfite tetrahydrate[2] exists in that of the hemihydrate crystal. The interatomic distances and angles are given in Table 2. The S-O and O-O interatomic distances and O-S-O bond angles in the $S(1)O_3^{2-}$ ion are 1.502(1)—1.519(1) Å, 2.354(1)—2.414(1) Å, and 102.4(1)—106.3(1)°, respectively. These values are similar to those (1.52(2)—1.53(3) Å, 2.37(1)—2.39(1) Å, 102.2(3)—102.9(4)°) calculated from the atomic coordinates[2] of the sulfite ion in the ordered state in the structure of the tetrahydrate crystal. The coordination of O atoms around the Ca(1) ion is shown in Fig. 2. The calcium ions are coordinated by six O atoms. This number is the same as that of the Ca-coordinated O atoms in the tetrahydrate crystal.[2] Five of them originate from the $S(1)O_3^{2-}$ ions(O(1'), O(2'), O(2''), O(3), O(3')), and the other from the water molecule(O(4)). The Ca(1)-O(4) distance of 2.506(1) Å is longer than the other Ca(1)-O distances(2.305(1)-2.457(1) Å). For the tetrahydrate crystal, contrary to the hemihydrate crystal, the Ca-O(sulfite ion) distances(2.52(1)-2.53(7) Å) are longer than the Ca-O (water) distances (2.38(1)-2.45(1) Å).[2] The average Ca-O distance in the hemihydrate crystal (2.403 Å) is slightly shorter than 2.45 Å in the tetrahydrate crystal.

It can be presumed that the high thermostability of the hemihydrate is caused by the existence of Ca-O bondings stretched like a net all over the crystal and by the absence of the sulfite ions in a disordered state. A stereoscopic view of the crystal structure is shown in Fig. 3. The structure consists of two alternating layers similar to those in the tetrahydrate crystal: One consists of the calcium ions alone, and the other of the sulfite ions and water molecules. They are parallel to the (010) plane.

Application of Liquid Crystals for Gas-Liquid Chromatography

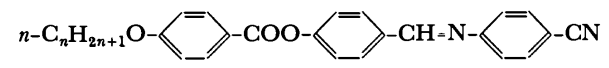
Sakumitsu SAKAGAMI* and Minoru NAKAMIZO
National Industrial Research Institute of Kyushu, Tosu, Saga 841
(Received August 11, 1983)

Synopsis. A liquid crystalline homologous series of *N*-[4-(4-alkoxybenzoyloxy)benzylidene]-4-cyanoanilines was applied as a stationary liquid phase for the gas-liquid chromatographic separation of various positional isomers. It is shown that the nematic phase has higher selectivity for several positional isomers compared with the other mesomorphic phases.

Liquid crystals are anisotropic liquids and they exhibit interesting solvent properties due to the rod-like shape and the ordered arrangement of their molecules. These unique solvent properties of liquid crystals were used for the first time as the stationary phase in gas-liquid chromatography (GLC) for the separation of the positional isomers of various disubstituted benzenes.[1] Recently, the separation of various solutes such as polycyclic aromatic hydrocarbons,[2] steroid epimers,[3] and *Z*/*E* mixtures of fatty alcohols[4] has been carried out with good success using liquid crystalline stationary phases in GLC.

Most GLC studies reported so far have been made with the use of nematic liquid crystals. However, from the viewpoint of practical application there exists a disadvantage that the use of the nematic stationary phases is confined to their limited mesomorphic temperature ranges. In connection with an attempt to obtain liquid crystals with a wide mesomorphic temperature range the smectic[5,6] and re-entrant nematic phases[7] have been recently applied to the separation of the various positional isomers.

In order to develop GLC using liquid crystals as the liquid phase it seems worthwhile to study the solubility and selective affinity of the various solutes in these different liquid crystalline phases. In this report we describe a study of the separation of some positional isomers in different mesomorphic phases by use of a homologous series of *N*-[4-(4-alkoxybenzoyloxy)benzylidene]-4-cyanoanilines.



(n=7, 9, and 12)

Experimental

Materials. 4-Dodecyloxybenzoic acid was synthesized according to the known method[8] while the other lower homologues were commercially obtained. These 4-alkoxybenzoic acids were converted to acid chlorides by treatment with thionyl chloride, and then esterified by a reaction with 4-hydroxybenzaldehyde in ether solution including triethylamine. Finally, the substituted benzaldehydes formed were coupled with 4-cyanoaniline in ethanol solution. The crude liquid crystals were purified by successive recrystallization from ethanol. The solutes chosen were commercially obtained and used without further purification.

Apparatus and Procedure. The liquid crystalline texture and the transition temperatures were determined by a Nikon polarizing microscope equipped with a Mettler FP 52 microfurnace and control unit. Checks on the transition temperatures were made using a Rigaku differential scanning calorimeter.

The support material employed was 100—120 mesh Chromosorb W HP. The support was coated with the liquid crystalline compounds by using chloroform as solvent, followed by gradual elimination of the solvent by evaporation. The concentration of the liquid phase in the packing of the coated support was 2.5 wt%. The columns were conditioned at 240°C for 2 h prior to initial use.

A Hitachi 163 gas chromatograph equipped with a flame-ionization detector was used. The flow-rate of the carrier gas (nitrogen) was measured using a soap-bubble flow meter.

Results and Discussion

The transition temperatures and the liquid crystalline phases of the compounds studied are given in Table 1. The C_7 and C_9 homologues have been reported by Weissflog *et al.*[9] and the transition temperatures determined in this study are in good agreement with the published data. The C_7 member exhibits both the smectic A and nematic phases while another liquid crystalline phase, *i.e.*, re-entrant nematic phase is monotropically observed for the C_9 member. As shown in Table 1, the C_{12} homologue exhibits no nematic phase. This is not surprising because the disappearance of the nematic phase is not unusual, and has been frequently observed as the alkoxy chain length increases in other homologous series of liquid crystalline materials.[10]

To estimate the selective affinity of the different liquid crystalline phases toward the various solutes we have measured relative retention(α) of some positional isomers on the liquid crystalline stationary phases. The chosen solute isomers and their relative retention determined in this study are compiled in Table 2.

The separation of *m*- and *p*-xylenes by GLC is a classically difficult one because of their similar boiling points and polarities. However, it should be stressed that both the nematic phase of the C_7 homologue and the re-entrant nematic phase of the C_9 member can separate this isomeric pair. Separation of compounds on the basis of molecular shape is the most characteristic feature of the liquid crystalline stationary phase in GLC.[11] Roughly, the more rod-like a solute is, the

TABLE 1. TRANSITION TEMPERATURES OF LIQUID CRYSTALS STUDIED (°C)

n	Re-entrant nematic	Smectic C	Smectic A	Nematic	Isotropic
7			(72)	113	264
9	(92)		95	224	246
12		(74)	83		245

The parentheses show the monotropic transition.

TABLE 2. RELATIVE RETENTION OF THE SOLUTE ISOMERS STUDIED

Solutes	Temperature °C	C_7	C_9	C_{12}
m- and *p*- Xylenes	75	1.05(N)	1.02(Re N)	—[a] (S_A)
m- and *p*- Dibromobenzenes	130	1.14(N)	1.08(S_A)	1.09 (S_A)
m- and *p*- Chloroacetophenones	130	1.20(N)	1.14(S_A)	1.14 (S_A)
1- and 2- Chloronaphthalenes	130	1.12(N)	1.07(S_A)	1.07 (S_A)
Phenanthrene and Anthracene	210	1.14(N)	1.12(S_A)	1.12 (S_A)

The relative retention is equal to 1.00 for the *m*- and 1- isomers and phenanthrene, respectively. The parentheses indicate the liquid crystalline phases. N: nematic, S_A: smectic A, Re N: re-entrant nematic.
a) The isomers of *m*- and *p*-xylenes can not be separated at 75 °C in the smectic A phase of C_{12} homologue.

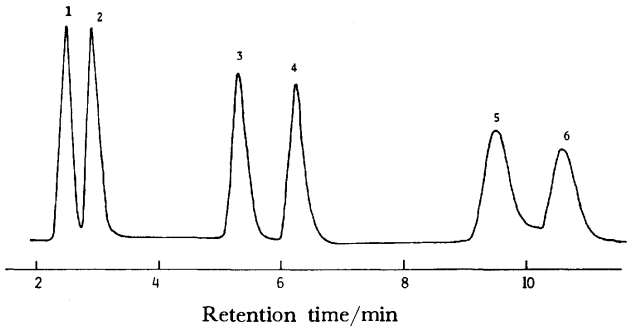


Fig. 1. Gas chromatogram of a mixture of dibromobenzenes, chloroacetophenones and chloronaphthalenes observed in the nematic phase on a C_7 column. Oven temperature, 130°C; injection temperature, 250°C; flame-ionization detector; nitrogen flow-rate, 25 ml/min. Peaks 1: *m*-dibromobenzene, 2: *p*-dibromobenzene, 3: *m*-chloroacetophenone, 4: *p*-chloroacetophenone, 5: 1-chloronaphthalene, 6: 2-chloronaphthalene.

easier it should fit into the liquid crystalline lattice and hence the greater its solubility should be. As is expected, the retention time for the isomer with the more rod-like shape (*p*-isomer) is longer than that for the *m*-isomer. It is also noteworthy to state that the relative retention of xylene isomers observed in the nematic phase is higher than that in the re-entrant nematic state. This result is likely to indicate that the nematic phase has much higher selective affinity toward the positional isomers compared with the re-entrant nematic phase.

Isomeric pairs of dibromobenzenes, chloroacetophenones and chloronaphthalenes can be separated almost completely at 130°C on all the mesomorphic stationary phases studied, as shown in Fig. 1. As mentioned previously, the length to breadth ratio of the molecules plays an important role for the separation of the solute isomers on the liquid crystalline stationary column. It is apparent in Fig. 1 that the isomer with the more rod-like shape (*p*- and 2-isomer) is retained longer than that with less rod-like shape. Similarly, a complete separation of phenanthrene and anthracene can be achieved at 210°C using a liquid crystalline column, as shown in Table 2. In addition, it should be emphasized that a value of relative retention toward all the positional isomers obtained in the nematic phase is much higher relative to the corresponding values found in the smectic A and re-entrant nematic phases.

In conclusion, we believe that the C_7 member of the homologous series studied is likely to be most useful stationary liquid phase in GLC because it exhibits a wide nematic temperature range and a unique selectivity for a mixture of various positional isomers.

Binuclear Metal Complexes. LIV.[1] Strongly Spin-coupled Copper(II)-Iron(III) Complex of a Salen Homolog Containing Pendant Phenolic Group

Wakako KANDA, Hisashi ŌKAWA,* and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashiku, Fukuoka 812
(Received October 27, 1983)

Synopsis. A copper(II)-iron(III) binuclear complex of *N,N'*-disalicylidene-2-methyl-4-(2-hydroxy-5-methylphenyl)-1,2-butanediamine has been prepared and characterized. Cryomagnetic measurements revealed the presence of an antiferromagnetic spin-exchange interaction of $J=-70\,cm^{-1}$ between the metal ions.

Magnetical investigations of copper(II)-iron(III) complexes are of current interest in connection with the models for the active site of cytochrome oxidase where the iron(III) center of cytochrome a_3 and copper(II) are strongly spin-coupled.[2,3] However, only few copper(II)-iron(III) complexes are magnetically characterized.[4-6]

N,N'-Disalicylideneethylenediaminatocopper(II) and its congeners can act as bidentate chelating agents through the phenolic oxygens. Sinn and coworkers have used these complexes to synthesize a number of binuclear and trinuclear metal complexes.[7] However, no polynuclear complexes of salen analogues containing iron(III) have been obtained, mainly because of their low stability. Recently, we synthesized a new salen analogue containing a pendant phenolic group, *N,N'*-disalicylidene-2-methyl-4-(2-hydroxy-5-methylphenyl)-1,2-butanediamine (abbreviated as H_2(sal-Hpen)).[8] Its iron(III) complex Fe(sal-pen) was shown to be of five-coordination with the pendant phenolic oxygen at the apical position.[7] In this study we report the synthesis, characterization, and magnetism of the copper(II)-iron(III) complex Fe(sal-pen)$CuCl_2$.

Experimental

Preparations. H_2(sal-Hpen) and Fe(sal-pen) were prepared by the method in the preceding paper.[8]

Fe(sal-pen)$CuCl_2$. A suspention of Fe(sal-pen) (0.10 g) and anhydrous $CuCl_2$ (0.33 g) in an ethanol-dichloromethane mixture (1:1, 30 cm^3) was refluxed with stirring for 2 d. Reddish purple solution thus obtained was slowly condensed in a vacuum desiccator to give purple brown crystals.

Found: C, 49.41; H, 4.39; N, 4.43%. Calcd for Fe(sal-pen)$CuCl_2 \cdot 3/2H_2O$: C, 49.59; H, 4.47; N, 4.44%.

Magnetic Measurements. Magnetic susceptibilities were measured in the temperature range 80—300 K by the Faraday method, the apparatus being calibrated with $[Ni(en)_3]S_2O_3$.[9] Magnetic moments were calculated by the equation, $\mu_{eff}=2.828(\chi_M \times T)^{1/2}$, where χ_M is the molar susceptibility per iron and copper atoms corrected for diamagnetism by the use of Pascal's constants.

Results and Discussion

The analytical results demonstrate the stoichiometry of the complex to be Fe(sal-pen)$CuCl_2$. However, this does not rule out the possibility of coprecipitation of Fe(sal-pen) and $CuCl_2$. The complexes obtained, however, appeared uniform prismatic crystals under microscopic observation. The color of the dichloromethane solution gradually changed from purple-brown to dark brown, suggesting the decomposition of the complex. Thus, the investigations were carried out on solid samples.

The infrared spectrum of Fe(sal-pen)$CuCl_2$ showed appreciable band shifts compared with that of Fe(sal-pen); the C=N stretching and skeletal bands were shifted from 1610 and 1540 cm^{-1} to 1630 and 1550 cm^{-1}, respectively. The shift of the skeletal band to the higher frequency suggests the binuclear structure bridged by the phenolic oxygens.[10] The magnetic moment of Fe(sal-pen)$CuCl_2$ is 5.2 BM at room temperature, which is lower than that of Fe(sal-pen) (5.8 BM†). The ESR spectrum of Fe(sal-pen)$CuCl_2$ exhibited a very weak signal near $g=2$ and differs from the spectrum of Fe(sal-pen) which exhibits a strong signal near $g=3.7$. All these facts clearly demonstrate that Fe(sal-pen)$CuCl_2$ is a new heteronuclear complex, bridged by the phenolic oxygens of the salen skeleton (Fig. 1).

The magnetic moment of the complex (5.2 BM) is much lower than the spin-only value (6.2 BM) for the high-spin iron(III)-copper(II) system. Further, the moment decreased to 4.7 BM when the temperature was lowered to the liquid nitrogen temperature. These facts suggest the operation of the intramolecular spin-exchange interaction. The magnetic behavior is best understandable by assuming a high-spin iron(III) coupled with copper(II). Such a spin-coupling results in two total spin states $S_T=3$ and $S_T=2$ with an energy gap of $|6J|$ based on the Heisenberg model ($H=-2JS_1 \cdot S_2$). The molar susceptibility can be calculated using the simplified Van Vleck's equation,[11]

$$\chi_M = \frac{Nq^2\beta^2}{kT} \times \frac{5\exp(-6J/kT)+14}{5\exp(-6J/kT)+7} + N\alpha,$$

where β is the Bohr magneton, N Avogadro's constant, k the Boltzmann constant, g the Landé splitting factor,

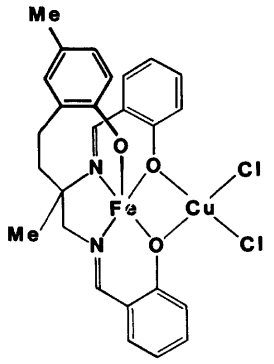

Fig. 1. Possible structure of Fe(sal-pen)$CuCl_2$.

† 1 BM=0.9273×10^{-23} J T^{-1}.

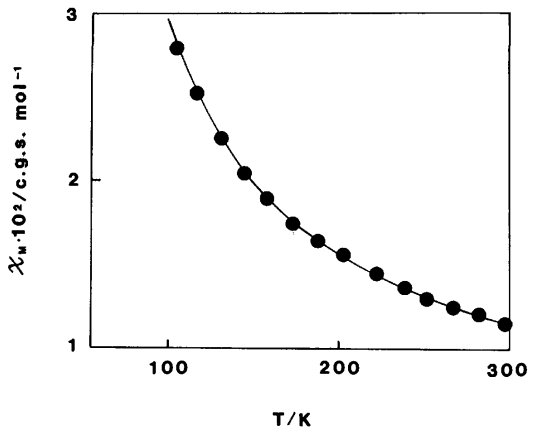

Fig. 2. Temperature-variation of magnetic susceptibility of Fe(sal-pen)$CuCl_2$. The solid curve is drawn based on the theoretical susceptibility equation for the (S=5/2)-(S=1/2) system with the parameters g=1.98, $-J$=70 cm^{-1}, and $N\alpha$=0.

J the exchange integral, and $N\alpha$ the temperature-independent paramagnetism. The experimental χ_M *vs.* T plot was best reproduced by the theoretical curve by assuming $-J$=70 cm^{-1}, g=1.98, and $N\alpha$=0. Thus, the existence of a strong antiferromagnetic spin-exchange interaction between the metal ions in Fe(sal-pen)$CuCl_2$ has been established through the present study.

Thermal Decomposition of *t*-Butyl Heptafluoroperoxybutyrate

Hideo SAWADA,* Hidehiko HAGII, Kazuyoshi AOSHIMA, and (the late) Takeshi ARAI
Chemicals and Explosives Research Laboratory, Nippon Oil & Fats Co., Ltd., Taketoyo, Chita-gun, Aichi 470-23
(Received July 21, 1983)

Synopsis. The decomposition of *t*-butyl heptafluoroperoxybutyrate (TBH) was studied in both toluene and methanol. Kinetic and product studies from the thermolysis showed that this peroxy ester decomposes heterolytically in nonpolar solvents like toluene with homolysis, whereas in methanol this peroxy ester undergoes principally transesterification.

Although the mechanisms for the thermolysis of a series of peroxy esters have been extensively investigated,[1] studies of fluorinated peroxy esters have been few. Bartlett *et al.* reported that the *t*-butyl peroxy esters derived from strong organic acids might well undergo ionic cleavage in polar solvents[2] and *t*-butyl peroxytosylate decomposes heterolytically with Criegee rearrangement in absolute methanol to give acetone dimethyl acetal and toluenesulfonic acids.[3] Hedaya *et al.* reported that 1-methoxy-1-methylethyl *p*-nitroperbenzoate (*p*-$NO_2C_6H_4CO_2OC(CH_3)_2(OCH_3)$) decomposes heterolytically in methanol to give rise to Criegee-type products *via* 1,1-dimethoxyethylium ion intermediate.[4] These results suggest that *t*-butyl peroxy esters derived from perfluorinated organic acids ($R_fCO_2OC(CH_3)_3$, R_f=perfluorinated alkyl, aryl) would decompose similarly to give Criegee-type products. We wish to report herein on the results of the thermal decomposition of *t*-butyl heptafluoroperoxybutyrate (TBH) in both toluene and methanol.

Results and Discussion

The thermal decomposition of TBH was carried out in both toluene and methanol at 10.0—85.0 °C as shown in Table 1. For decomposition of TBH in toluene at 65.0—85.0 °C, autocatalysis was observed in the absence of pyridine and the first-order rate constants could not be obtained. However rates of decomposition following a first-order rate constant were obtained at 10.0—30.0 °C and autocatalysis was not observed. The values of the activation enthalpy and entropy for the thermal decomposition of TBH in toluene and in methanol were $\Delta H^*=89.5\pm4.2$ kJ mol^{-1}, $\Delta S^*=-74.1\pm12.1$ J K^{-1} mol^{-1}, and $\Delta H^*=44.4\pm2.1$ kJ mol^{-1}, $\Delta S^*=-167.8\pm7.1$ J K^{-1} mol^{-1}, respectively.

When TBH decomposed in toluene, 1,2-diphenylethane, which would result from radical cleavage, was obtained as shown in Table 2. Additionally the bulk polymerization of styrene initiated by TBH was studied at 50—60 °C. The thermal polymerization of styrene may be considered negligible at these temperatures. Bulk polymerization of styrene was observed and the rate constants of the polymerization were shown in Table 3. From the rate constants, the value of the activation energy of the polymerization was 94.6 ± 9.2 kJ mol^{-1}, which suggests that the polymerization of styrene initiated by TBH is not cationic but radical.[5] These results indicate that TBH would decompose homolytically in toluene.

On the other hand, the activation parameters for the thermal decomposition of TBH in toluene have small values compared with those of *t*-butyl peroxy esters which are expected to decompose homolytically; for example, *t*-butyl peroxypivalate, in chlorobenzene, $\Delta H^*=125.5$ kJ mol^{-1}, $\Delta S^*=46.4$ J K^{-1} mol^{-1}.[6] The smaller values of the enthalpy and the entropy of activation suggest that TBH would decompose in part with heterolysis. The rates of decomposition followed a first-order rate equation in the presence of pyridine, however, the first-ordsr rate constants drifted upwards remarkably after about 60% reaction at 85 °C. From this result, it can be seen that the autocatalysis was not completely suppressed even when pyridine was present. Decomposition products in toluene at 85 °C in the presence of pyridine were studied and the results were shown in Table 2. Heptafluorobutyric acid resulted from the thermolysis of TBH and reacted with pyridine to give pyridinium heptafluorobutyrate (**3**). Furthermore, 2-methoxy-1-propene (**1**), which would

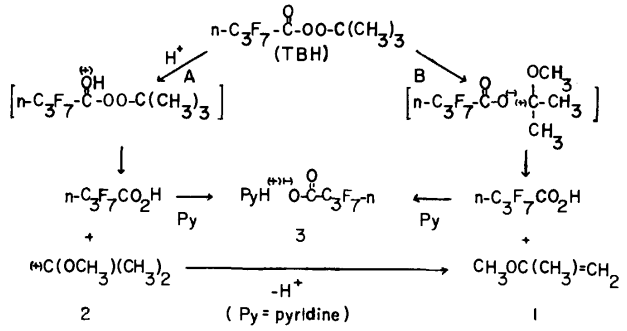
55	12.16±0.84
60	22.43±0.64

result from ionic cleavage, was obtained as shown in Table 2. Olah *et al.* reported that the 1-methoxy-1-methylethylium ion (**2**) can also be isolated by the reaction of *t*-butyl peracetate with magic acid in SO_2ClF at −78 °C.[7] These results indicate that TBH would decompose partially with homolysis and partially with heterolysis which might contain both the autocatalysis (path A) and Criegee rearrangement (path B) according to the Scheme 1.



Scheme 1.

In the thermal decomposition of TBH in methanol, it is of interest that the entropy of activation for the decomposition has a large negative value compared with those of *t*-butyl peroxy esters derived from strong organic acids; TBH $\Delta S^{\ddagger} = -167.8 \pm 7.1\ J\ K^{-1}\ mol^{-1}$; *t*-butyl *p*-nitroperbenzoate, in methanol, $\Delta S^{\ddagger} = -28.0\ J\ K^{-1}\ mol^{-1}$;[8] *t*-butyl peroxytosylate, in metanol, $\Delta S^{\ddagger} = 3.8\ J\ K^{-1}\ mol^{-1}$.[3] From this large negative value of the entropy of activation and the observation of *t*-butyl hydroperoxide in decomposition products as shown in Table 4, it may be concluded that the thermal decomposition of TBH in methanol is principally dependent upon the following transesterification.

$$n\text{-}C_3F_7CO_2OC(CH_3)_3 + CH_3OH \longrightarrow n\text{-}C_3F_7CO_2CH_3 + (CH_3)_3COOH$$

On the other hand, 2,2-dimethoxypropane (**5**) in Table 4, which would result from nucleophilic attack of methanol on the 1-methoxy-1-methylethylium ion (**4**) as shown in Scheme 2, was obtained in 33% yield. The formation of 2,2-dimethoxypropane (**5**) also suggests that TBH would decompose in part with Criegee rearrangement. From the fact that methyl

heptafluorobutyrate (**6**) can be quantitatively obtained by the reaction of heptafluorobutyric acid with methanol even at room temperature, **6** in Scheme 2 would result from the methyl-esterification of heptafluorobutyric acid as well as transesterification.

Experimental

TBH was prepared by the reaction of *t*-butyl hydroperoxide with heptafluorobutyryl chloride in the presence of pyridine and distilled carefully, bp 39.5—40.0 °C/17 mmHg (1 mmHg = 133.322 Pa). The infrared spectra showed the characteristic peroxy ester carbonyl band at 1815 cm^{-1}. ^{1}H-NMR($CF_2ClCFCl_2$) $\delta = 1.36$ (9H s). Mass *m/z* 286(M^+), 271, 197, 169, 150, 119, 100, 73, 69, 58, 57 (base), 55, 50, 45, 43, 42, 41, 39, 31, 29, 27, and 15; Calcd for $C_8H_9O_3F_7$: C, 33.58; H, 3.17%. Found: C, 32.50; H, 2.99%. The rates of decomposition of TBH were measured by iodometric titration or disappearance of the carbonyl stretching peak of the peroxy ester at 1815 cm^{-1}. The products of complete decomposition of TBH in both toluene and methanol were identified from the result obtained by GC/MS and the retention times of GLC compared with authentic samples.

The authors are indebted to Mr. Katsushi Katsura at the Tsukuba Central Research Laboratory of Nippon Oil & Fats Co., Ltd. for GC/Mass spectrometric measurement.

Studies of Bitter Peptides from Casein Hydrolyzate. VIII.[1] Bitter Taste of Cyclic Analog of BPIa (Arg-Gly-Pro-Pro-Phe-Ile-Val)[2]

Ichizo MIYAKE, Katsushige KOUGE, Hidenori KANEHISA, and Hideo OKAI*

Department of Fermentation Technology, Faculty of Engineering, Hiroshima University, Shitami, Saijo-cho, Higashihiroshima 724

(Received September 16, 1983)

Synopsis. In order to elucidate the structure-taste relationship of bitter peptide BPIa (Arg-Gly-Pro-Pro-Phe-Ile-Val), *cyclo*-BPIa was synthesized. The result of both taste and CD examinations suggested that the bitterness of BPIa is caused by its spatial structure, which is analogous to that of *cyclo*-BPIa.

In our synthetic investigations of bitter peptide BPIa isolated from casein hydrolyzate by Minamiura *et al.*,[3] it has been confirmed that N-terminal arginine residue and C-terminal hydrophobic moiety are necessary for an intence bitterness of BPIa and that the spatial structure of whole molecule attributed to prolylproline in the center also contributes to its bitter taste. We also assume that N- and C-terminals of BPIa are situated close together by prolylproline. In order to confirm our assumption, we synthesized *cyclo*-BPIa, in which N-terminal arginine and C-terminal valine residues were combined, and compared its bitter taste with that of BPIa.

The synthetic route for *cyclo*-BPIa is shown in Fig. 1. Boc-Pro-Pro-Phe-Ile-Val-OBzl, which was an intermediate in the synthesis of BPIa,[4] was hydrogenated to yield the corresponding acid (**1**). It was condensed with H-Arg(NO_2)-Gly-OBzl·HCl (**3**) by the DCC-HOBt method and the resulting protected heptapeptide (**4**) was converted to the corresponding acid (**5**) by a saponification reaction. **5** was esterfied by the DCC-HONSu method to afford the corresponding active ester (**6**). After the amino protection of **6** was removed by the action of hydrogen chloride in 98% formic acid, the resulting heptapeptide active ester hydrochloride (**7**) was treated with pyridine under high-dilution conditions for cyclization. The reaction mixture yielded a clude N^G-nitro substituted cyclic heptapeptide (**8**), which was then purified by passing through columns of acidic and basic ion exchangers. **8** thus obtained was hydrogenated in the presence of palladium black to yield *cyclo*-BPIa (**9**). The homogeneity of the final product was confirmed by thin-layer chromatography, amino acid analysis, paper electrophoresis, and elemental analysis.

The taste of *cyclo*-BPIa was organoleptically determined by panel evaluation with four people. *cyclo*-BPIa possessed an extremely bitter taste: its threshold value was 0.02 mM (1 M=1 mol dm^{-3}). The value was of the same level as BPIa; the threshold value of BPIa was 0.05 mM. The CD curves of both *cyclo*-BPIa and BPIa measured in water are presented in Fig. 2. *cyclo*-BPIa has a curve with a negative trough at 202 nm; BPIa possesses a similarly shaped curve.

The results of both taste and CD examinations suggested that the bitter taste of BPIa is caused by its characteristic molecular shape, which is analogous to that of *cyclo*-BPIa.

Experimental

All the melting points are uncorrected. Thin-layer chromatography was carried out on Merck silica gel G with the solvent systems: R_f^1, *n*-BuOH-AcOH-pyridine-H_2O (4:1:1:2, v/v); R_f^2, $CHCl_3$-MeOH (5:1, v/v). Opical rotations were measured on a Union PM-101 polarimeter. Amino acid analysis in acid hydrolyzate with 6 M HCl at 110 °C for 72 h was performed with a Hitachi amino acid analyzer, KLA-5 type. Prior to analyses, the compounds were dried over phosphorus pentaoxide at 66 °C and 2 mmHg (1 mmHg=133.332 Pa) for 2 h.

Boc-Pro-Pro-Phe-Ile-Val-OH (1). This was prepared from Boc-Pro-Pro-Phe-Ile-Val-OBzl[4] (7.62 g, 10 mmol) in

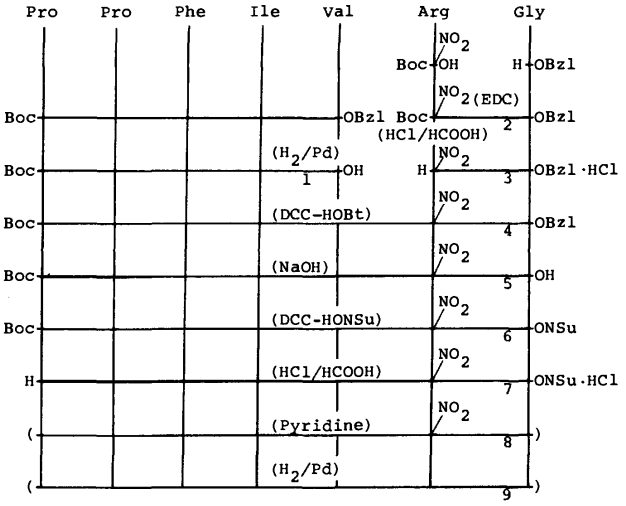

Fig. 1. Synthesis of *cyclo*-BPIa.

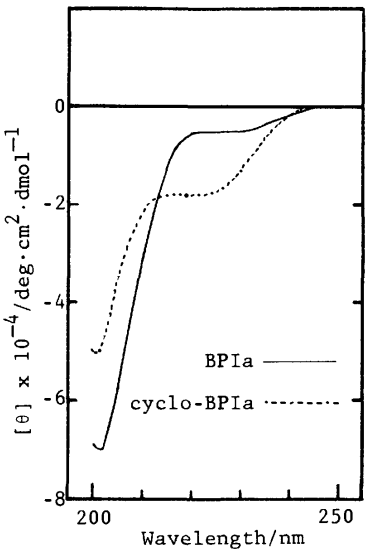

Fig. 2. CD curves of *cyclo*-BPIa and BPIa.

MeOH (30 ml) by hydrogenation in the presence of Pd black; yield 5.95 g (89%); mp 169—171 °C; $[\alpha]_D^{20}$ −96° (*c* 1, MeOH); R_f^1 0.86 and R_f^2 0.73.

Found: C, 62.34; H, 8.16; N, 10.26%. Calcd for $C_{35}H_{53}O_8N_5$: C, 62.57; H, 7.95: N, 10.43%.

Boc-Arg(NO$_2$)-Gly-OBzl (**2**). This was prepared from Boc-Arg(NO_2)-OH (9.60 g, 30 mmol) and H-Gly-OBzl·TsOH (12.12 g, 36 mmol) in acetonitrile (100 ml) by the EDC method;[5] yield 10.85 g (76%); mp 96 °C; $[\alpha]_D^{20}$ −11° (*c* 1, MeOH); R_f^1 0.91 and R_f^2 0.77

Found: C, 51.61; H, 6.31; N, 17.88%. Calcd for $C_{20}H_{30}O_7N_6$: C, 51.49; H, 6.48; N, 18.02%.

H-Arg(NO$_2$)-Gly-OBzl·HCl (**3**). This was prepared from **2** (4.66 g, 10 mmol) by the action of hydrogen chloride in 98% formic acid. The product was obtained as a hygroscopic solid; yield 4.02 g (100%); R_f^1 0.76 and R_f^2 0.31.

Boc-Pro-Pro-Phe-Ile-Val-Arg(NO$_2$)-Gly-OBzl (**4**). This was prepared from **1** (5.38 g, 8 mmol) and **3** (4.02 g, 10 mmol) in DMF (20 ml) by the DCC-HOBt method.[6] The product was recrystallized from hot MeOH; yield 5.14 g (63%); mp 231—232 °C; $[\alpha]_D^{20}$ −41.5° (*c* 1, DMF); R_f^1 0.91 and R_f^2 0.76.

Found: C, 58.59; H, 7.31; N, 15.03%. Calcd for $C_{50}H_{73}O_{12}N_{11}$: C, 58.86; H, 7.21; N. 15.10%.

Boc-Pro-Pro-Phe-Ile-Val-Arg(NO$_2$)-Gly-OH (**5**). Compound **4** (5.1 g, 5 mmol) was saponified with 1 M NaOH (7.5 ml) in MeOH (10 ml). The purification was done by the extraction with *n*-BuOH: yield 4.42 g (97%); mp 105 °C (decomp); $[\alpha]_D^{20}$ −32.3° (*c* 1, DMF); $R_f^1$0.56 and R_f^2 0.21.

Found: C, 54.11; H, 7.27; N, 16.15%. Calcd for $C_{43}H_{67}O_{12}N_{11}\cdot H_2O$: C, 54.47; H, 7.34; N, 16.25%.

Boc-Pro-Pro-Phe-Ile-Val-Arg(NO$_2$)-Gly-ONSu (**6**). To a solution of **5** (1.37 g, 1.5 mmol) and HONSu (0.35 g, 3 mmol) in DMF (5 ml), DCC (0.62 g, 3 mmol) was added with stirring at 0 °C. The reaction mixture was stirred for 3 h at 0 °C, then at room temperature overnight. DCUrea was filtered off and a large amount of ether was poured into the filtrate. The precipitate thus obtained was collected by filtration. It was recrystallized from acetonitrile; yield 1.26 g (82%); mp 193 °C; $[\alpha]_D^{20}$ −46.1° (*c* 0.5, DMF); R_f^1 0.91 and R_f^2 0.81.

Found: C, 54.58; H, 7.15; N, 15.90%. Calcd for $C_{47}H_{70}O_{14}N_{12}\cdot 1/2H_2O$: C, 54.47; H, 6.91; N, 16.22%.

cyclo(*-Arg(NO$_2$)-Gly-Pro-Pro-Phe-Ile-Val-*) (**8**). Compound **6** (0.51 g, 0.5 mmol) was dissolved in 98% formic acid and 3.5 M hydrogen chloride in dioxane (10 ml) at 0 °C. After 30 min, the solution was evaporated *in vacuo* and the oily residue was solidified with ether (yield 0.44 g). The active ester hydrochloride (**7**) thus obtained was dissolved in DMF (5 ml) and the solution was added dropwise to pyridine (250 ml) with stirring. The reaction mixture was stirred for 24 h at room temperature and evaporated *in vacuo*. The residual oil was dissolved in a mixture of dioxane (50 ml) and water (10 ml). The solution was passed successively through columns (1.2 cm×12.5 cm) of Amberlite CG-120 (H^+ form) and Amberlite CG-400 (OH^- form). The columns were washed with the same solvent and the collected effluent was evaporated *in vacuo*; then the product was collected by the aid of water (yield 51 mg). It was recrystallized from MeOH-ether; yield 41 mg (10%); mp 221 °C (decomp); $[\alpha]_D^{20}$ −56.3° (*c* 0.5, MeOH); R_f^1 0.83 and R_f^2 0.65.

Found: C, 52.51; H, 6.98; N, 17.52%. Calcd for $C_{38}H_{57}O_9N_{11}\cdot 3H_2O$: C, 52.70; H, 7.33; N, 17.79%.

cyclo(*-Arg-Gly-Pro-Pro-Phe-Ile-Val-*) (**9**). Compound **8** (40 mg, 0.005 mmol) was dissolved in MeOH (2 ml) and AcOH (2 ml) and hydrogenated in the presence of Pd black for 24 h. The filtrate from catalyst was evaporated *in vacuo* and the oily residue was crystallized by the aid of ether. It was recrystallized from water-acetone; yield 40 mg (97%); mp 198 °C (decomp); $[\alpha]_D^{20}$ −31.4° (*c* 0.5, MeOH); R_f^1 0.57 and R_f^2 0.05. Amino acid ratios in acid hydrolyzate: Arg 1.11, Gly 0.97, Pro 2.01, Phe 1.09, Ile 1.00, Val 0.95.

Found: C, 53.38; H, 7.70; N, 15.30%. Calcd for $C_{38}H_{58}O_7N_{10}\cdot CH_3COOH\cdot 4H_2O$: C, 53.44; H, 7.85; N, 15.58%.

Paper Electrophoresis. This was carried out under the conditions previously reported.[7] *cyclo*-BPIa migrated toward the cathode and revealed a single spot by spraying Sakaguchi reagent; ninhydrin gave the same result. The R_{Arg} value[8] of *cyclo*-BPIa was 0.58.

CD Measurement. This was performed with a JASCO J-20A. A cell of path length 0.2 mm was used and runs were made at ambient temperature.

Sensory Test. Taste of cyclo-BPIa was organoleptically determined in the same manner as described in the previous pepers.[1,4,7]

The authors wish to express their thanks to Associate Professor Michio Kondo of Saga University for the CD measurement. Thanks are also due to Dr. Shinji Okumura of Ajinomoto Co. Inc., for supplying some amino acids.

Silver Ion-induced Allylation of Furan with Cyclopropyl Halides

Nobujiro SHIMIZU,* Kenji WATANABE, and Yuho TSUNO
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
(Received, September 22, 1983)

Synopsis. Allyl species generated from 1-bromo-2-phenylcyclopropane and seven different 1,1-dihalocyclopropanes with the aid of silver perchlorate reacted with furan in a regio- and stereoselective manner to give a series of 2-allylfuran derivatives in fair to good yields.

The S_N1 like reactions of cyclopropyl halides generally proceed *via* a stereoelectronically controlled ring-opening rearrangement to allyl cation intermediates.[1,2] Although this unique behavior of cyclopropyl halides provides a useful synthetic route to cyclic alkenes which are not readily accessible by other methods,[3] only a few examples have been reported on the reactions between the allyl species formed from cyclopropyl halides and substrates other than solvent nucleophiles.[4] Trapping of such the species by furan seems to be of synthetic interest in view of the fact that direct alkylation reactions of furan including allylation often cause extensive resinification.[5,6] We here report the results of the silver ion-induced reaction of furan with various cyclopropyl halides **1a**—h.

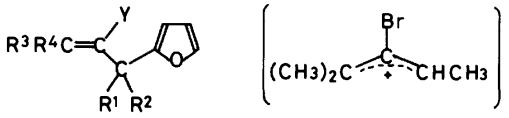
On exposure to silver perchlorate in THF/ether (1:3), 1,1-dibromo-2,2,3,3-tetramethylcyclopropane (**1a**) rapidly reacted with furan at room temperature to give 2-(2-bromo-1,1,3-trimethyl-2-butenyl)furan (**2a**) in 40% isolated yield together with 3-bromo-2,4-dimethyl-1,3-pentadiene (35%) which was shown to be the principal product in the absence of furan. Allyl species formed from cyclopropyl halides **1b**—h and silver perchlorate also reacted with furan to give the corresponding 2-allylfuran derivatives **2b**—h in moderate to good yields. The results are given in Table 1. Typical experimental procedure consists of treating a halide (**1**, 10 mmol) with silver perchlorate (2 equiv.) in THF/ether (1:3) in the presence of excess furan (*ca.* 5 equiv.) and calcium carbonate (as a buffer) at ambient temperature or under reflux.

Among 1,1-dihalocyclopropanes **1a**—g, ease of the reaction decreased in the order **1a**>**1b**≫**1c**—g and prolonged exposure to silver perchlorate was needed for the last series of halides. A marked difference in reactivity was also seen between the two stereoisomers of a cyclopropyl bromide **1h**. Thus, when a mixture of (*E*)-and (*Z*)-**1h** (1:1.47) was treated with silver perchlorate in the presence of furan in THF/ether (1:3) under reflux for 30 min, the (*E*)-isomer was completely consumed to give *trans*-**2h** in excellent yield, whereas the (*Z*)-isomer remained unchanged, in accord with the theoretical prediction.[1]



3 4

Unsymmetrical halides **1b**—f and **1h** are expected to give a regioisomeric product **3** besides **2** but actually, furan preferentially reacted with the less heavily alkylated (or arylated) carbon site of the allyl species generated from these halides yielding **2** as the exclusive product. It should be noted, however, that the silver ion-induced reaction of these halides with methanol in place of furan gave the corresponding methyl ethers of type **3** as the major product.[7] Table 2 shows the change in regioselectivity in the silver ion-induced reaction of **1b** with various substrates. In contrast to methanol, *t*-butyl alcohol preferred the secondary carbon site rather than the tertiary site of the allyl species **4** formed from **1b**. Presumably, a small nucleophile such as methanol would preferentially react with the most electron positive site but the steric effects must be the major factor to control selectivity for bulky substrates including aromatic rings.

It is also worth stating that besides the stereospecific conversion of (*E*)-**1h** to *trans*-**2h**, the formation of **2** from **1d**—f was highly stereoselective yielding a single

TABLE 1. SILVER ION-INDUCED REACTION OF FURAN WITH CYCLOPROPYL HALIDES

a) Reaction were carried out in THF/ether (1 : 3) using **1b**, silver perchlorate, and a nucleophile in the molar ratio 1 : 2 : 5 (0 °C, 45 min). b) A mixture of *p*- and *o*-isomers (1.9 : 1) was obtained in 82% yield. c) The corresponding ethers were formed in high yields.

stereoisomer or near so. The (*Z*)-structure may be deduced for the abundant isomer from the reported stereochemical observation on the Ag(I)-induced solvolysis of 1,1-dihalocyclopropanes.[2] This was in fact true and the reductive dehalogenation of **2e** with LAH in boiling THF[8] gave *trans*-**2h** as the principal product. These results are explicable in terms of the stereocontrolled ring-opening formation of (*Z*)-allyl cations from **1d**—f in preference to the isomeric (*E*)-cations.[1,9]

Experimental

NMR spectra were determined in carbon tetrachloride using a Hitachi R-600 spectrometer. IR spectra were recorded on a Hitachi 260-10 spectrophotometer.

Silver Perchlorate-Induced Reaction of Furan with Cyclopropyl Halides. The following procedure for the preparation of 2-(2-bromo-1,3-dimethyl-2-butenyl)furan (**2b**) is representative.

Into a stirred mixture of silver perchlorate (4.05 g, 20 mmol), furan (3.5 g), and calcium carbonate (2 g) in THF/ether (1 : 3, 20 ml) was added a solution of 1,1-dibromo-2,2,3-trimethylcyclopropane (**1b**, 2.36 g, 9.8 mmol) in ether (2 ml) during the period of 15 min at room temperature. The mixture was stirred for additional 45 min at ambient temperature and quenched with saturated sodium chloride solution. A crude oil obtained after usual workup was distilled to give an allylfuran **2b** (1.76 g, 76%): bp 95—98 °C (14 Torr: 1=Torr 133.3 Pa); IR 3130, 1650, 1505, 1150, 1080, 1010, 910 and 740 cm^{-1}; NMR δ=1.40 (3H, d, J=7 Hz), 1.92 (6H, s), 4.17 (1H, q, J=7 Hz), 6.00 (1H, m), 6.20 (1H, m), and 7.24 (1H, m). Found: C; 52.31, H; 5.74%. Calcd for $C_{10}H_{13}BrO$: C; 52.42, H; 5.72%.

Similarly, furan derivatives **2a** and **2c**—h were obtained and characterized. They showed IR bands near 3130, 1640, 1505, 1150, 1010, 920, and 730 cm^{-1} and NMR signals of the furan ring protons near δ=6.0, 6.2, and 7.2. **2a**: NMR δ=1.20 (3H, s), 1.52 (6H, s), and 1.84 (3H, s). **2c**: bp 97—98 °C (17 Torr); NMR δ=1.90 (6H, s), 3.80 (2H, s) (Found: C; 50.22, H; 5.20%). **2d** (as a mixture of (*E*)- and (*Z*)-isomers in the ratio 1 : 8.7): bp 114—117 °C (3 Torr); NMR (signals of the less abundant isomer were shown in italics.) δ=*2.17* (s) and 2.21 (s) (together 3H), 3.66 (s) and *3.97* (s) (together 2H), and 7.22 (5H, s). **2e**+**3e** (8.4 : 1): bp 123—126 °C (2 Torr); NMR for **2e** δ=3.90 (2H, s), 6.72 (1H, s), and 7.2—7.6 (5H, m) (Found: C; 59.03, H; 4.14%), and for **3e** δ=4.99 (1H, s), 5.45 (1H, s), 5.67 (1H, s), and 7.26 (5H, s). **2f**+**3f** (24 : 1): bp 96—100 °C (14 Torr); NMR for **2f** δ=0.92 (3H, t, J=7 Hz), 1.44 (2H, m), 2.18 (2H, q, J=7 Hz), 3.70 (2H, s), and 5.19 (1H, t, J=6 Hz) (Found: C; 52.18, H; 5.74%), and for **3f** δ=0.95—2.0 (7H, m), 3.56 (1H, t, J=7 Hz), 5.45 (1H, broad s), and 5.65 (1H, broad s). **2g**: bp 85—87 °C (15 Torr); NMR δ=1.23 (3H, s), 1.52 (6H, s), and 1.86 (3H, s) (Found: C; 66.60, H; 7.68%). **2h**: NMR δ=3.51 (2H, d, J=5 Hz), 5.98 (1H, m) 6.18—6.32 (2H, m), 6.60 (1H, d, J=16 Hz), and 7.2—7.4 (6H, m).

Reduction of 2b, 2e, and 2f with LAH. A mixture of **2b** (1.28 g, 15.6 mmol) and LAH (0.5 g) in THF (10 ml) was heated under reflux for 5 h. A crude oil (801 mg) obtained after workup was distilled to give 2-(1,3-dimethyl-2-butenyl)furan (450 mg): bp 105—109 °C (92 Torr); IR 1590, 1010, and 730 cm^{-1}. NMR δ=1.27 (3H, d, J=7 Hz), 1.70 (6H, s), 3.65 (1H, m), 5.15 (1H, d, J=8 Hz), 5.85 (1H, m), 6.15, (1H, m), and 7.20 (1H, m) (Found: C; 79.82, H; 9.42%).

Similarly, **2e** and **2f** were reduced to **2h** and 2-(2-hexenyl)furan, respectively. NMR of the latter compound: δ=1.90 (3H, t, J=7 Hz), 1.42 (2H, m), 2.00 (2H, m) , 3.30 (2H, m), 5.4—5.6 (2H, m), 5.87 (1H, m), 6.16 (1H, m), and 7.20 (1H, m).

Reaction Efficiency of Exciplexes in Singlet Sensitized Decomposition of Dibenzoyl Peroxide

Hiroaki MISAWA, Akihide KITAMURA,† Hirochika SAKURAGI, and Katsumi TOKUMARU*
Department of Chemistry, University of Tsukuba, Sakura-mura, Ibaraki 305
(Received November 5, 1983)

Synopsis. Quantum yields were measured for aromatic hydrocarbon-sensitized decomposition of dibenzoyl peroxide in benzene. For the sensitizers employed, naphthalene, phenanthrene, triphenylene, and chrysene, the ratio of the rate constants for decay and radical formation from intermediate exciplexes was found to be similar (0.2—0.4), indicating that the reactivity of the peroxide moiety in the intermediate is independent of the structural factors of the sensitizers as far as examined.

Exciplexes have been proposed as reactive intermediates in many photochemical reactions though they are not necessarily emissive.[1-3] In some cases the exciplexes may be too reactive to be alive in sufficiently long lifetimes to exhibit emission.[3,4] However, few works have been carried out to actually examine intrinsic reactivity of the exciplexes from the viewpoint of structural factors of sensitizers.[2,5,6]

Previously, singlet excited aromatic hydrocarbons have been revealed to sensitize decomposition of dibenzoyl peroxide (BPO) in solution.[7-9] The reaction was proposed to proceed through short lived reactive exciplexes which either bring about homolytic decomposition of the peroxide moiety into free radicals or deactivate into the original components in the ground state as shown in the following scheme, where Sens and P denote a sensitizer and the peroxide, respectively, and k_q, k_r, and k_d mean the rate constants of the processes concerned.

This paper describes an attempt to determine the relative reactivity of the exciplexes in singlet sensitized decomposition of BPO in relation to structural factors of the hydrocarbon sensitizers.

$$^1\text{Sens}^* + \text{P} \xrightarrow{k_q} {}^1(\text{Sens}\cdot\text{P})^* \quad (1)$$

$$^1(\text{Sens}\cdot\text{P})^* \xrightarrow{k_r} \text{Free radicals} + \text{Sens} \quad (2)$$

$$^1(\text{Sens}\cdot\text{P})^* \xrightarrow{k_d} \text{Sens} + \text{P} \quad (3)$$

Scheme 1.

Results and Discussion

Benzene solutions of a sensitizer (3.0×10^{-3}—3.0×10^{-2} mol dm^{-3}) and varying concentrations of BPO (1.2×10^{-3}—3.1×10^{-2} mol dm^{-3}) were irradiated under argon atmosphere with 366-nm light (for chrysene as sensitizer) or 313-nm light (for triphenylene, phenanthrene, and naphthalene) isolated from a 400 W high pressure mercury lamp, and the quantum yields for decomposition of BPO were determined at low conversion of BPO (less than 20%) using potassium tris(oxalato)ferrate(III) actinometry.[10]

According to Scheme 1, the quantum yield for disappearance of BPO is expressed by Eq. 4, where τ_S^0 means the lifetime of the singlet excited sensitizer in the absence of the peroxide.

$$\Phi^{-1} = (1 + 1/k_q\tau_S^0[\text{P}])(1 + k_d/k_r) \quad (4)$$

For each sensitizer employed, the reciprocal of the quantum yield is linearly correlated with the reciprocal of the peroxide concentration, and the intercept, $(k_r+k_d)/k_r$, exceeds unity (Fig. 1). This means clearly that the reaction proceeds through formation of some reactive intermediates like exciplexes. The results analyzed according to Eq. 4 are summarized in Table 1.

In Table 1 are also listed the $k_q\tau_S^0$ values determined by fluorescence quenching in benzene using the single photon counting technique,[11] the singlet excitation energies[10] and oxidation potentials[12] of the sensitizers. The $k_q\tau_S^0$ value obtained from the quantum yield measurements for each sensitizer satisfactorily agrees well with that from the fluorescence quenching.

As Table 1 indicates, the observed ratios of the rate constants for decay and radical formation from the exciplexes, k_d/k_r, are not significantly varied (0.21—0.41) among the unsubstituted polycyclic aromatic hydrocarbons employed, naphthalene, phenanthrene, triphenylene, and chrysene. This fact indicates that the reactivity of the peroxide moiety in the intermediate does not depend upon such structural factors of the sensitizers as the singlet excitation energies of the sensitizers, E_S, and the extent of charge transfer from the excited sensitizer to BPO in the exciplex, $E_{ox}-E_S$. This observation might be accounted for by the facts that the low energy (*ca.* 31 kcal mol^{-1}, 1 cal=4.184 J)[13] is required for the cleavage of the peroxide linkage compared to the singlet excitation energies of the sensitizers (Table 1) and that the

overall process of the sensitization gives free radical products arising from benzoyloxyl and phenyl radicals, but not any ionic products at all.[7-9]

Attempts to determine the quantum yields by employing other sensitizers like anthracene, 9,10-diphenylanthracene, pyrene, and perylene were abandoned, since these sensitizers were found to be fairly consumed during the reaction in contrast to the above sensitizers which were recovered more than 80% after the reaction.

Experimental

Materials. Dibenzoyl peroxide was purified by reprecipitation from dichloromethane-methanol. Triphenylene was prepared according to literature.[14] The other aromatic hydrocarbons, naphthalene, phenanthrene, chrysene, anthracene, 9,10-diphenylanthracene, pyrene, and perylene, were commercially available. The aromatic hydrocarbons were purified by column chromatography on silica gel with petroleum ether as eluent and recrystallized from hexane. Benzene (special grade) was distilled before use.

Measurement of Quantum Yields. The quantum yields for disappearance of BPO were determined in benzene under argon atmosphere employing potassium tris(oxalato)ferrate(III) as actinometer. Irradiation was carried out with 366-nm light for chrysene, anthracene, 9,10-diphenylanthracene, pyrene, and perylene and with 313-nm light for naphthalene, phenanthrene, and triphenylene. From a 400 W high pressure mercury lamp 366-nm light was isolated through a Toshiba UV-D36B glass filter and 313-nm light through a Toshiba UV-D33S and a K_2CrO_4/Na_2CO_3 solution filter.[10] The amounts of the remaining BPO were determined by HPLC (column: Zorbax ODS, solvent: $CH_3OH-H_2O=85:15$). Although BPO was decomposed on direct irradiation with 313-nm light, its quantum yield was less than 1% compared with the sensitized decompositions and can be satisfactorily neglected in the present investigation.

On the Penetration Rate and the Role of Acids in the Control of Impregnation Profiles

Masaharu KOMIYAMA* and Robert P. MERRILL†
Department of Chemical Engineering, Faculty of Engineering, Tohoku University, Aramaki Aoba, Sendai 980
†*School of Chemical Engineering, Cornell University, Ithaca, New York 14853 U.S.A.*
(Recieved June 2, 1983)

Two factors which play important roles in determining the concentration profiles in the impregnation of porous catalysts, *viz.*, penetration rate of impregnating solution and the use of acids, were examined. The flow rate of impregnating solution into a spherical dry pellet consisting of polydispersed pores obeyed the equation which assumed constant pressure differential at the liquid front independent of its position in the pellet. The adsorption behavior of nickel ions onto γ-alumina strongly depended on the pH of the solution, and very weakly on the kind of acids used. By controlling the pH of the impregnating solution, it was possible to obtain a surface impregnation, a uniform impregnation and a subsurface impregnation for nickel on γ-alumina.

Many catalysts in common use are produced by impregnating a pellet of a porous support with a solution of catalyst precursors. During the impregnation and subsequent drying, small crystallites of the catalyst precursors are deposited on the internal surface of the support material. The mass transfer processes involved in the impregnation and drying steps typically do not reach equilibrium, resulting in non-uniform concentration profiles of impregnant along the radius of the support pellet. The importance of designing and/or controlling these concentration profiles, or impregnation profiles, has been recognized, because optimized impregnation profiles may bring about higher overall reaction rate,[1] better light-off performance,[2,3] longer catalyst life,[3,4] and/or conservation of expensive catalyst metals.[5,6]

In order to design and control the impregnation profiles the factors influencing the profiles must be identified by constructing appropriate impregnation models. The impregnation step involves the time-dependent flow of impregnating solution into a dry pellet and adsorption of impregnant onto the pore wall. The interior dispersal of impregnant during this step has been analyzed in detail by Vincent and Merrill,[7] for single-component impregnation using a single-pore model. Their analysis has since been expanded in two directions: models for single-component impregnation into a porous sphere[8] and the multi-component impregnation using the single-pore model[9] have been presented. This paper examines experimentally two aspects of these two developments.

The expansion of the single-pore model to a three-dimensional porous sphere is like the one-dimensional model based on the analysis of Washburn[10] who assumed a succession of Pourselle steady states. Its derivation involved an assumption, *viz.*, constant pressure differential at the liquid front independent of its position inside the pellet (*cf.* Fig. 1 (a)). Impregnation profiles calculated from this expanded model quantitatively agreed with experimental impregnation profiles,[8] although no theoretical or experimental basis for the assumption was presented. The dynamics of liquid uptake during catalyst impregnation is not well understood, and is at the stage of being closely examined.[11] In the first part of this paper we examine this process, by directly measuring the penetration rate of a liquid into a spherical pellet.

Kulkarni *et al.*[9] have expanded the single-component model to multi-component impregnation using the single-pore model of Vincent and Merrill[7] and assuming competitive adsorption among the impregnants. For the preparation of subsurface impregnation employing various acids, their model calculations were in qualitative agreement with some of the Pt/γ-alumina impregnation profiles reported by Shyr and Ernst,[12] although the sharp breakthroughs observed in Ni/γ-alumina subsurface impregnation profiles[8] (*cf.* Fig. 4) were not reproduced. This may be an indication that for this particular system the mechanism of producing subsurface impregnation by the use of acids may not by a simple competitive adsorption between the nickel ions and the acid species. The latter part of the present paper examines the mechanism of controlling impregnation profiles by the use of acids in the preparation of Ni/γ-alumina catalysts.

Experimental

Spherical γ-alumina pellets of about 4 mm-diameter supplied by Universal Oil Products were employed as the porous support. Their pretreatment and characterization are found elsewhere.[8] The poze size distribution of the alumina support is bimodal, with peak radii at around 2.5 nm (found by nitrogen adsorption) and in between 0.1 to 0.3 μm (observed by scanning electron microscopy, SEM).

The rate of 1-bromonaphthalene penetration into the alumina sphere was examined by using a light microscope with a calibrated eyepiece. 1-Bromonaphthalene was chosen as a model liquid because its refractive index of 1.66 is nearly the same with that of γ-alumina, which is 1.7. Thus alumina contacted with 1-bromonaphthalene becomes transparent, enabling one to observe through a light microscope the position of the penetrating liquid front as a function of time.

Effects of acids on nickel adsorption on γ-alumina were examined by aqueous phase adsorption measurements, which were carried out by soaking powdered (<65 mesh) alumina pellets into solutions of nickel nitrate with or without additives such as citric acid or hydrochloric acid. Adsorption experiments were performed in a constant-temperature bath at 20.0 °C with continuous stirring for 1 h. The temperature and the contact time were chosen to simulate the actual catalyst impregnation. After one hour the alumina powder

was separated from the solution by centrifuge, and the solution pH was measured. The amount of nickel ion adsorbed onto the solid surface was determined spectrophotometrically from the incremental loss of Ni(II) species in the liquid phase by adding an appropriate amount of KCN to the solution, thus converting nickel ion into a cyanide complex, and measuring its absorption at 310 nm.[13] Such a procedure was necessary in order to measure the small difference in nickel concentration caused by its adsorption on γ-alumina, because the absorption sensitivity of nickel aquo complex at around 400 nm was not sufficient to make reliable measurements.

A series of Ni/γ-alumina catalysts, designed to demonstrate the effects of pH on impregnation profiles, were prepared by impregnating alumina pellets with pH-adjusted aqueous solutions of nickel nitrate. Solution pH was adjusted by the addition of citric acid and/or ammonium hydroxide. Detailed procedures for the catalyst preparation are found elsewhere.[8] For the measurements of the impregnation profiles of the finished catalysts, a JEOL JXA 733 electron microprobe was employed. Detailes of sample preparation and procedure for this measurement are also presented elsewhere.[8]

Results and Discussion

Penetration Rate of Impregnating Solution. The three-dimensional impregnation model developed earlier,[8] which is an extension of a single-pore model proposed by Vincent and Merrill,[7] predicts the penetration rate of the liquid front into a spherical pellet by the following equation:

$$(1-\Gamma)^3 = 1-\tau^{1/2}, \qquad (1)$$

where Γ is the reduced radial position in a sphere, or one minus the fractional radius, and τ is the reduced time, or actual time divided by t_L which is the time necessary for the liquid to reach the center of the pellet. It was assumed[8] in deriving the above equation that the pressure differential is constant at the liquid front regardless of its position in the sphere. This assumption is depicted in Fig. 1 (a), where the pressure profiles along the radius of a pellet which is represented by a long single pore of the length of the pellet radius are shown for two positions of liquid front. Also note that pressure differential along the radius of the pellet at any given time is approximated by a linear function.

The validity of this assumption and its physical basis may become clearer by examining directly the actual rate of liquid penetration, or the front velocity of the penetrating liquid, and comparing it with the model prediction. Figure 2 shows measurements of the front positions of 1- bromonaphthalene penetrating into γ-alumina spheres as functions of time τ. Two sets of measurements are shown, which represent the upper and the lower bound of measurements among a number of pellets tested. The solid line in the figure was calculated by using the above Eq.(1) which is non-dimensionalized and thus is applicable to any liquid penetration. The model calculation agrees well with the measured front positions in the range of $\Gamma>0.3$. Where $\Gamma<0.3$, the actual Γ is larger than predicted. This results from very large initial front velocities followed by a period of near zero velocity.

In order to interpret these results consider first a pellet consisting of monodispersed pores, for which

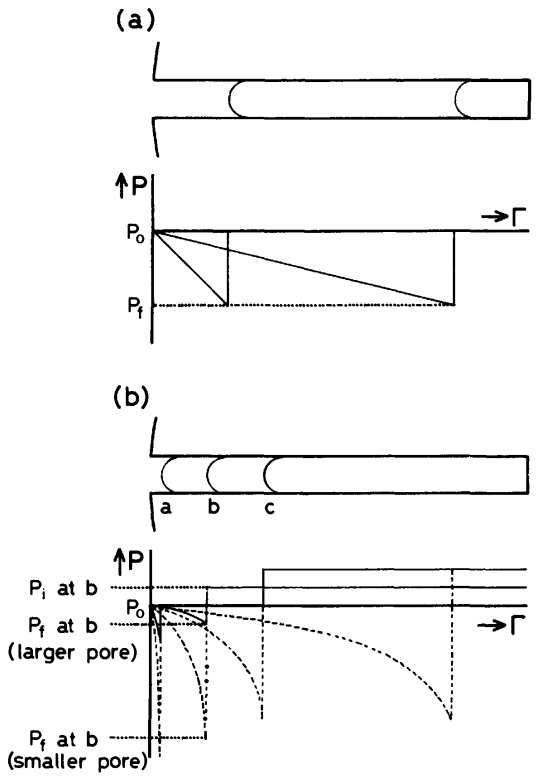

Fig. 1. Pressure profiles in the impregnating solution along the radius of a pellet.
(a) Model profile assumed in the three-dimensional impregnation model; (b) profile concieved from the results of the liquid penetration measurements. Solid lines: larger pores. Broken lines: smaller pores. P_i: Pressure inside the pellet; P_o: pressure outside the pellet; P_f: pressure at the liquid front.

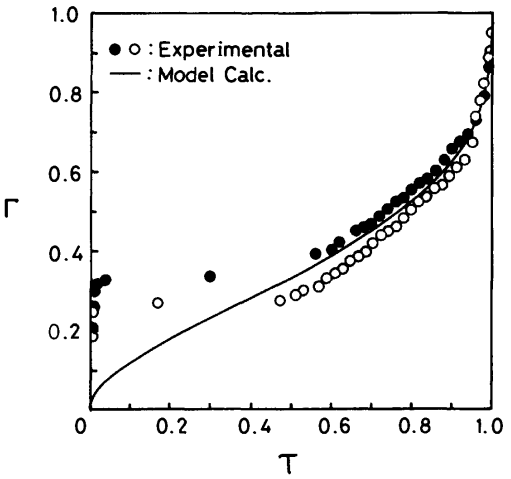

Fig. 2. Non-dimensionalizad penetration depth, $\Gamma=z/L$, of 1-bromonaphthalene into γ-alumina pellet as a function of non-dimensionalized time, $\tau=t/t_L$. Open and closed circles: experimental; solid line: model calculation using Eq. (1).

pressure profiles along the radius of the pellet at various times are represented by solid lines in Fig. 1 (b). For each profile there is a monotonic decrease in pressure up to the meniscus of the liquid front followed by a

discontinuous increase across the meniscus. At the onset of impregnation (point **a** in Fig. 1 (b)), the pressure inside the pellet, P_i, is similar to that outside the pellet, P_o, and the liquid penetrates with the capillary pressure, $(P_i-P_f)\simeq(P_o-P_f)$, as driving force. As the liquid progresses (point **b**), it compresses the air inside the pellet, raising P_i higher than P_o. Since the pressure drop at the liquid front, (P_i-P_f), is fixed for a given pore-liquid system, this higher P_i results in smaller driving force, (P_o-P_f), slowig down the rate of liquid penetration. Penetration will be stopped when P_i is balanced with the capillary pressure, *i.e.*, $P_o=P_f$ (point **c**) and the driving force for flow is zero.

In the case of a pellet consisting of polydispersed pores, such as the present one, the situation will be more complicated. At the early stage of impregnation liquid is mainly carried into the pellet through larger pores which have higher mass flow than smaller pores.[7,8] The flow through these larger pores will eventually be stopped by the process discussed above. The data in Fig. 2 indicate that this happens at $\Gamma\simeq0.3$, which gives P_i of about 3 atmosphere. This corresponds to the capillary pressure of the pores with radius of about 0.7 μm, which is in the larger end of the pore size distribution observed by SEM.

Even after liquid in the larger pores is halted, however, liquid in smaller pores, with pressure profiles represented by the broken lines in Fig. 1 (b), advance due to the higher capillary pressure. Volume occupied by this advancing liquid will be compensated by a receding meniscus in larger pores, keeping P_i constant. As a consequence liquid in larger pores is slowly pushed back, eventually making the pores empty to serve as air-escape channels. In the present system this is a long process as seen from the flat portion of the measured liquid front positions in Fig. 2, *i.e.*, the region where the observed velocity of the front is zero. Note that the wavelength of white light, which was used in the microscope, peaks above 1 μm so that neither the receding meniscus in larger pores nor the advancing meniscus in the smaller pores can be detected. The opening of the air channels is confirmed by air bubbles which are observed to form at the exterior of pellet at *ca.* $\tau=0.5$. Once the air channels are established, P_i will be kept constant at this level by advancing liquid to keep the channels open. Since the pressure drop at the liquid front is fixed for a given liquid-pore system, constant P_i means constant P_f, fulfilling the assumption described above.

It follows from the above discussion that there are two limiting cases in which the assumption of constant P_f holds. One is the early stage of impregnation (*e.g.*, point **a**), where $(P_o-P_f)\simeq(P_i-P_f)$. In this case (P_i-P_o) could be neglected compared to the driving force, (P_o-P_f), and P_f holds approximately constant. Note that this limiting case would dominate the impregnation process if a support consisting of very small pores is used. The pressure balancing in such system would not occur until very late in the impregnation process, *i.e.*, point **c** for example in Fig. 1 (b), which is displaced close to $\Gamma=1$. The other limiting case is the later stage of impregnation, where P_f is kept constant by the mechanism discussed above. Also note here that if a support consisting of relatively large pores is used, the pressure balancing would occur very early stage in the impregnation, *i.e.*, point **c** is displaced close to $\Gamma=0$, and this limiting case will dominate the impregnation. These two limiting cases are obvious in the data shown in Fig. 2, where early stage ($\tau=0$—0.03) corresponds to the former case and later stage ($\tau=0.4$—1) to the latter case. At intermediate level ($\tau=0.03$—0.4) during which either limit is appropriate, there is a transition from the larger pore-dominated region to the smaller pore region.

Effects of Acids on the Adsorption Behavior of Nickel. The effect of nitric acid addition on nickel ion adsorption on γ-alumina powder has already been reported.[8] Its results showed that the amount of nickel ion adsorbed during one hour of contact time is strongly influenced by the pH of the solution. Nickel adsorption on γ-alumina was shown to be inhibited below a pH of about 4, and the amount of nickel adsorption abruptly increased at around a pH of 5.2. The adsorption continuously increased past the pH of pure nickel salt solution to the basic side. While such adsorption behavior was presumed to be a pH effect rather than an example of competitive adsorption, and methods of preparing subsurface impregnation utilizing this pH effect has been demonstrated,[8] these results were not conclusive since it used only one acid species and there still remains the possibility that competitive adsorption of some form is still operative.[9]

In Fig. 3 adsorption as a function of pH is plotted for a number of other acids commonly used to prepare subsurface impregnation of Ni/γ-alumina. In order to simplify the presentation, data points for hydrochloric acid and glicine are replaced by lines connecting through them in the figure, since the scatter in the adsorption data was very small for those acids. Plotted in the figure is the final pH of the solution measured after alumina powder was separated by a centrifuge. It shows that regardless of the kind of acid added to the solution, nickel adsorption abruptly increases at a pH of about 5.2. These results support the previous discussion[8] that nickel adsorption on γ-alumina surface is

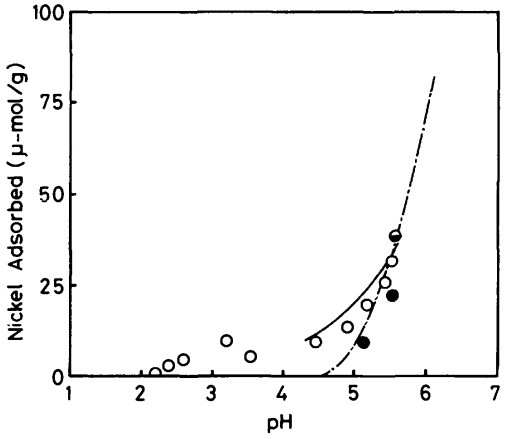

Fig. 3. The effect of pH on $Ni(NO_3)_2$ adsorption on γ-alumina. Initial concentration of $Ni(NO_3)_2$: 0.00988M. Contact time: 1h. Plotted pH are those after the contact. Additives: none (◒), citric acid (○), oxalic acid (●), hydrochloric acid (——), glycine (—·—).

controlled by the pH of the solution and not by competitive adsorption. The kind of acid species used to control pH seems to have little effect on the extent of adsorption.

A close examination of Fig. 3 shows, however, that the acids can be grouped into two types: One that inhibits nickel adsorption completely below pH of about 4, and another that allows weak adsorption even below that pH. Nitric acid,[8] oxalic acid, and glicine belong to the former while citric and hydrochloric acids belong to the latter.

This work is not intended to elucidate the physical chemistry of the pH effect. Some possible explanations have been suggested previously.[8] A detailed discussion on pH-dependent adsorption of metal cations onto oxide surfaces is given by Brunell.[14] Here we concentrate on the utilization of this pH effect for the control of impregnation profiles.

pH-Controlled Catalyst Impregnation. The strong effect of pH upon the amount adsorbed provides a degree of freedom in controlling the concentration profiles in the impregnation of porous catalysts. By exploiting these effects subsurface, uniform and/or surface impregnation can be produced.

The preparation of subsurface impregnation, through manipulating pH, has been demonstrated[8] for Ni/γ-alumina system using nitric acid as pH controller. The effects of concentrations of nitric acid and nickel salt were examined and discussed in detail.[8] When a support immersed in an impregnating solution of low pH, cation adsorption on the pore wall is inhibited at first. If the pH controlling species is adsorbed on the pore wall, then as the solution penetrates the pore its local pH gradually increases. At some point along the axis of the pore the pH may increase to the point where adsorption of the co-impregnated metal cation becomes appreciable. This should result in an outer shell of metal free adsorbate and a subsurface impregnation past the point where the critical pH is achieved, provided that molecular diffusion along the axis of the pore is small enough.

Figure 4 compares the nickel concentration profile of a sample using nitric acid (profile **a**) and citric acid (profile **b**) to suppress adsorption at the exterior of the pellet. In these plots the nickel concentration, determined by X-ray fluorescence, is presented as a function of fractional radius. A value of 1.0 in the radius represent the exterior of the pellet. In profile **b** the open circles are for pellets sectioned after drying and the solid circles are for pellets sectioned before drying. It is clear in profile **b** that the surface enhanced concentration is due to segregation during drying,[8] and therefore not pertinent to this discussion of the impregnation step.

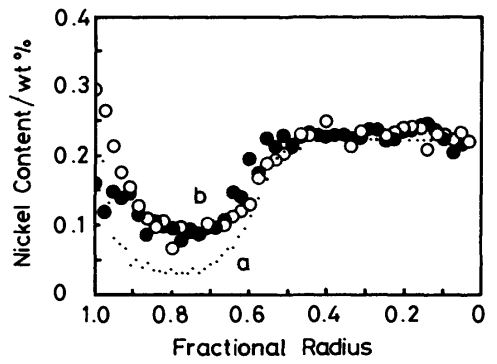

Fig. 4. Nickel subsurface impregnation produced by using nitric acid (profile **a**, dotted line) and citric acid (profile **b**, open and closed circles) as pH controller. Initial concentrations: $Ni(NO_3)_2$, 0.0247 M (1 M= 1 mol dm^{-3}); HCl, 0.000982 M; citric acid, 0.0012 M.

Profiles **a** and **b** are very similar to each other, indicating that both acids play almost identical roles, *i.e.*, pH control, in producing subsurface impregnation.

Two minor differences are noted between these two profiles. First, the acid concentration necessary to create the same thickness for the low metal loading band (fractinal radius>0.6) is higher for citric acid than for nitric acid. This is understood from the above pH-controlled impregnation mechanism, which assumes that the nickel adsorptivity is controlled by local pH. Since the dissociation constant of citric acid is much lower than that of nitric acid, a higher concentration of citric acid is necessary in order to obtain the same pH profile along the radius of the pellet and thus to create the similar nickel concentration profiles. Second, the amount of nickel deposition at the low loading region (0.9>fractional radius>0.6) is higher when citric acid was used as pH-controller than when nitric acid was used. In case of profile **a** in Fig. 4 the deposition in this region was considered to be produced by the overlap of the leading edge of the breakthrough and the tail of the surface-segregated deposition band. A higher loading in the surface region for profile **b** is attributed to the low but non-negligible adsorption below pH=4 for citric acid-controlled adsorption (*cf.* Fig. 3). In contrast to nitric acid,[8] citric acid does not completely inhibit the adsorption of nickel ions in the region where pH of the penetrating solution is still low.

It is expected from the results presented in Fig. 3 and the mechanism of pH-controlled subsurface impregnation deduced from it, that it may also be possible to produce a profile with a high concentration at the surface of the pellet if the pH of the impregnating solution is adjusted to higher side where adsorptivity enhancement is observed instead of inhibition (see Fig. 3). Presented in Fig. 5 are the nickel concentration profiles of the samples impregnated with solutions of varying initial pH. The same concentrations of nickel nitrate and citric acid were employed for all samples in Fig. 5 as well as the sample in Fig. 4, profile **b**, The initial pH was adjusted by adding an appropriate amount of ammonium hydroxide to the solution. Only the initial value of pH is presented in the figure, since it is not possible to determine experimentally the final pH of the solution in the pore at the end of the impregnation. As a control, single-component impregnation was also performed and the resulting profile is shown in Fig. 5 (sample No. F-1). Note that there is no evidence of significant surface segregation in any of these samples. There is no disparity between closed and open circles.

Nickel nitrate at this concentration produces a uniform impregnation profile as shown in Fig. 5, control sample No. F-1. When the initial pH was adjusted to

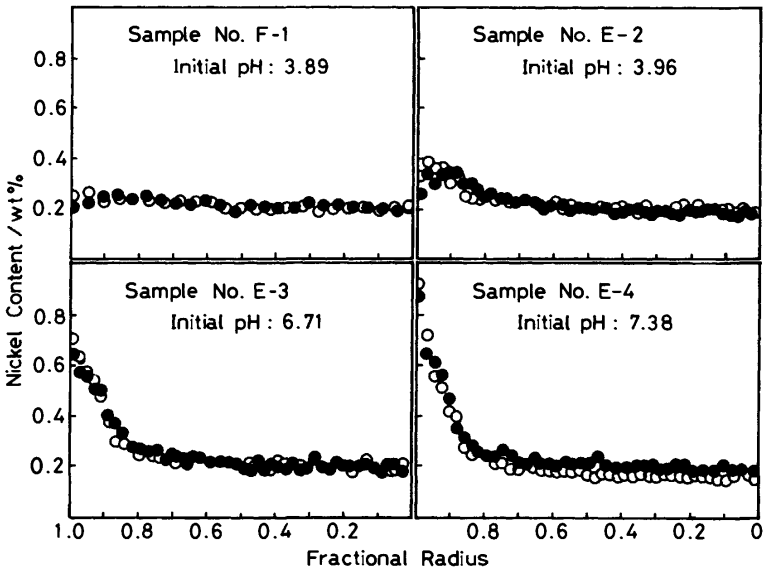

Fig. 5. Nickel concentration profiles impregnated at various initial pH.

the acidic side where adsorption inhibition occurs, subsurface impregnation was produced as discussed above (Fig. 4, profile **b**). When the starting pH was adjusted to higher side where nickel adsorption is enhanced, surface impregnation profiles resulted (Fig. 5, sample Nos. E-2 through E-4). Note that the higher the initial pH of the solution, the larger the nickel concentration near the outer surface of the pellet. The mechanism is exactly the same as that which produced subsurface impregnations except that adsorption enhancement occurs near the external surface of the pellet instead of inhibition.

While this pH effect adds another degree of freedom in engineering impregnation profiles, it also adds complication to the modeling of the impregnation process. Major parameters which play important roles in determining impregnation profiles involve characteristics of metal cation adsorptivity such as maximum amount of adsorption or an adsorption rate coefficient.[7] The consequence of the above pH effect is the dependence on local pH of these otherwise constant parameters. Models for the pH-controlled impregnation must consider these parameters as functions of local pH of the solution in the pore, which depends both on Γ and τ. It is not surprising, therefore, that models describing inhibition *via* competitive adsorption[9] do not predict the sharpness of the concentration.

For subsurface impregnation (acidic side pH control) using nitric acid, the pH effect was represented as a step function,[8] *viz.*, complete inhibition below pH=5.2 and single component behavior above that pH. Such an approach was justified because with this acid the pH dependence of nickel adsorption can be closely approximated by a step function, and also because of the resulting good agreement between the actual impregnation profiles and the ones calculated using this approximation, as reported earlier.[8] Such a treatment, however, may not be appropriate for the case of higher side pH control or acidic side control using acids like citric acid, because the nickel adsorption behavior for these cases cannot be approximated by a step function of pH. Further work is necessary in order to formulate an impregnation model incorporating such pH effects.

The work is partially supported by the Grant for Scientific Research No. 57750699 from the Japanese Ministry of Education, Science and Culture.

Regularity in Homolytic Lattice Energies of Anhydrous Formate, Acetate, Oxalate, and Glycolate of Metals**

Minoru SAKIYAMA* and Shigeo MURATA
Chemical Thermodynamics Laboratory, Faculty of Science, Osaka University, Toyonaka 560
(Received July 30, 1983)

The homolytic lattice energy ΔU_R of an ionic crystal M_xA_y was defined as the standard internal energy change at 298.15 K for the following vaporization process to yield neutral species M and A: $(1/x)M_xA_y(c)=M(g)+(y/z)A(g)$. ΔU_R and $[\Delta U_R-(y/x)\Delta H_f^\circ(A,g)]$ were calculated for formates and acetates and for oxalates and glycolates, respectively, of metals, and were analyzed empirically. ΔU_R(formate)$\simeq\Delta U_R$(acetate) holds for every metal. ΔU_R of oxalates and glycolates may be expressed as follows: ΔU_R(oxalate or glycolate)$=a\Delta U_R$(formate or acetate)$+b(y/x)$, where a is the constant close to unity, and b is the constant which is, possibly, close to zero for oxalates and about 40 kJ mol^{-1} for glycolates. The linear relations in ΔU_R were discussed in relation to crystal structure of the salts and carboxyl O-H bond dissociation energy of the corresponding carboxylic acids.

The cohesion energy of an ionic crystal of formula M_xA_y has been usually expressed as the lattice energy U_L which is defined as the standard internal energy change ΔU° for the following heterolytic (ionic) vaporization of the crystal at 298.15 K:

$$M_xA_y(c) = xM^{m+}(g) + yA^{n-}(g), \quad (1)$$

where m and n are the numbers of ionic charges in the units of e. U_L is given as follows:

$$U_L = x\Delta H_f^\circ(M^{m+}, g) + y\Delta H_f^\circ(A^{n-}, g) - \Delta H_f^\circ(M_xA_y, c) - (x+y)RT. \quad (2)$$

For most of polyatomic anions, reliable experimental data of standard enthalpy of formation in gaseous state are not availble at present. Within the extent of the present compounds, reliable data are available only for acetate anion,[1] so it is impossible to carry out a satisfactory empirical analysis in terms of U_L for the present compounds. On the other hand, reliable data are more abundant for the correseponding gaseous neutral species (free radical). A formed by loss of n electrons from a polyatomic anion A^{n-}. Within the extent of the present compounds, $\Delta H_f^\circ(A,g)$ has been determined precisely for formate and acetate free radicals.[2,3]

Here, the homolytic lattice energy ΔU_R is defined as the standard internal energy change at 298.15 K of the following homolytic (nonionic) vaporization of an ionic crystal M_xA_y (c):

$$(1/x)M_xA_y(c) = M(g) + (y/x)A(g). \quad (3)$$

ΔU_R is given as follows:

$$\Delta U_R = \Delta H_f^\circ(M, g) + (y/x)\Delta H_f^\circ(A, g) - (1/x)\Delta H_f^\circ(M_xA_y, c) - [(x+y)/x]RT. \quad (4)$$

Correspondingly, the heterolytic lattice energy ΔU_I is defined by the equation: $\Delta U_I=(1/x)U_L$. ΔU_I is related with ΔU_R according to:

$$\Delta U_I = \Delta U_R + \sum_1^m I(M, i) + C_1 + (y/x)[\sum_1^n A(A, j) + C_2], \quad (5)$$

where $I(M, i)$ is the i-th ionization energy of species M, $A(A, j)$ is the j-th electron affinity of species A, and C_1 and C_2 are $[\Delta U^\circ(298.15\ K)-\Delta U^\circ(0\ K)]$ for the processes: $M(g)=M^{m+}(g)+me$ and $A(g)+ne=A^{n-}$, respectively where e denotes electron.

** Contribution No. 58 from Chemical Thermodynamics Laboratory, Faculty of Science, Osaka University.

In this paper, ΔU_R of formates and acetates and $[\Delta U_R-(y/x)\Delta H_f^\circ(A, g)]$ of oxalates and glycolates are analyzed empirically and discussed in relation to crystal structure of the salts and O-H bond dissociation energy of the corresponding carboxylic acids.

Procedure and Results

Most of the standard enthalpies of formation used in the present analysis were taken from Ref. 4. The data from other sources are collected in Table 1. From these data, ΔU_R was calculated according to Eq. (4) and presented in Table 2 for formates and acetates. The plot of ΔU_R (acetate) against ΔU_R (formate) is shown in Fig. 1. A straight line passes close to the plots and the origin in

this figure. Linear regression analysis gave the following result:

$$\Delta U_R(\text{acetate})/\text{kJ mol}^{-1} = 0.9818\Delta U_R(\text{formate})/\text{kJ mol}^{-1}, \quad (6)$$

with standard deviation from the fit s_f of 9 kJ mol^{-1}.

It is not possible at present to calculate ΔU_R for oxalates and glycolates, since $\Delta H_f^\circ(g)$ is not available for oxalate and glycolate free radicals. Instead, $[\Delta U_R-(y/x)\Delta H_f^\circ(A, g)]$ calculated according to Eq. (4) was given in Table 2 and plotted against ΔU_R (formate) in Figs. 2 and 3. The upper lines express the results of the linear regression analysis of the data of bivalent metal cations. The lower lines were drawn so that they were parallel with the corresponding upper lines with intercepts 141(=282/2) and 399(=798/2), respectively, in Figs. 2 and 3. Thus, the whole data may be expressed by the following equations:

$$[\Delta U_R(\text{oxalate})-(y/x)\Delta H_f^\circ(O_2CCO_2, g)]/\text{kJ mol}^{-1} = 0.9965\Delta U_R(\text{formate})/\text{kJ mol}^{-1} + 282(y/x), \quad (7)$$

with the maximum deviation of 6 kJ mol^{-1} ands s_f of 5 kJ mol^{-1} for uni- and bivalent metal cations, respectively, and

$$[\Delta U_R(\text{glycolate})-(y/x)\Delta H_f^\circ(HOCH_2CO_2, g)]/\text{kJ mol}^{-1} = 0.9728\Delta U_R(\text{formate})/\text{kJ mol}^{-1} + 399(y/x), \quad (8)$$

with the maximum deviation of 5 kJ mol^{-1} and s_f of 6 kJ mol^{-1} for uni- and bivalent metal cations, respectively.

Similar plots, though not shown, were made for the pairs of oxalate-acetate and glycolate-acetate, with

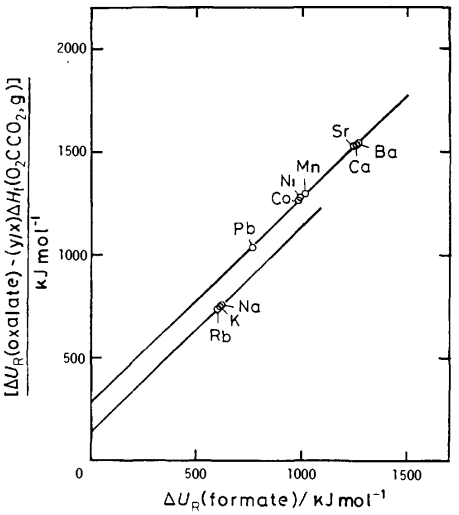

Fig. 2. $[\Delta U_R(\text{oxalate})-(y/x)\Delta H_f^\circ(O_2CCO_2, g)]$ *vs.* ΔU_R (formate) plot.
(y/x) is equal to 1/2 and 1 for mono- and divalent metals, respectively. The straight lines are expressed with the equation: $[\Delta U_R\text{ (oxalate)}-(y/x)\Delta H_f^\circ(O_2CCO_2,g)]=0.9965\Delta U_R\text{ (formate)}+282(y/x)$.

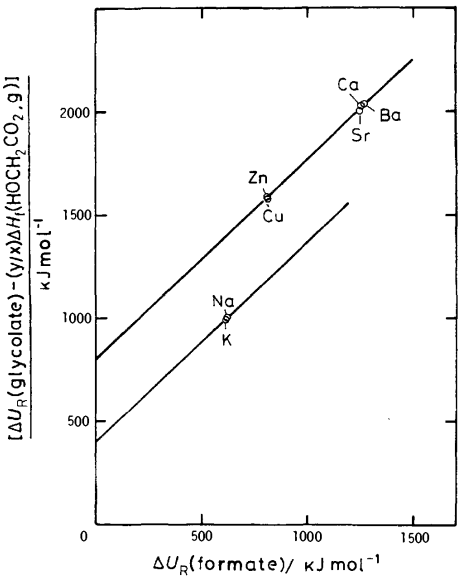

Fig. 3. $[\Delta U_R\text{ (glycolate)}-(y/x)\Delta H_f^\circ(HOCH_2CO_2, g)]$ *vs.* ΔU_R (formate) plot.
(y/x) is equal to 1 and 2 for mono- and divalent metals, respectively. The straight lines are expressed with the equation: $[\Delta U_R\text{ (glycolate)}-(y/x)\Delta H_f^\circ(HOCH_2CO_2, g)]=0.9728\Delta U_R\text{ (formate)}+399(y/x)$.

similar results. The linear relations are expressed as follows:

$$[\Delta U_R(\text{oxalate})-(y/x)\Delta H_f^\circ(O_2CCO_2, g)]/\text{kJ mol}^{-1} = 1.0239\Delta U_R(\text{acetate})/\text{kJ mol}^{-1} + 275(y/x), \quad (9)$$

with the maximum deviation of 8 kJ mol^{-1} and s_f of 8 kJ mol^{-1} for uni- and bivalent metal cations, respectively, and

$$[\Delta U_R(\text{glycolate})-(y/x)\Delta H_f^\circ(HOCH_2CO_2, g)]/\text{kJ mol}^{-1} = 0.9965\Delta U_R(\text{acetate})/\text{kJ mol}^{-1} + 397(y/x), \quad (10)$$

with the maximum deviation of 5 kJ mol^{-1} and s_f of 11 kJ mol^{-1} for uni- and bivalent metal cations, respectively.

While univalent metals are limited to alkali metals for the pairs of oxalate-formate, glycolate-formate, and glycolate-acetate, Ag(I) is also included in the plots of the pair oxalate-acetate. This shows that the linear relation for univalent metals is not specific to alkali metals.

Discussion

Prior to the discussion of each of relations in ΔU_R given in Eqs. (6)—(10), two remarks are presented here. Firstly, it is to be noted that the linear relations hold even for compounds of Mn(II), Co(II), Ni(II), and Cu(II), which are the cations with unfilled 3d orbitals. In order to study the effect of the d-orbital splitting on ΔU_R, the difference in ΔU_I between these compounds and the corresponding Ca compounds Ca_xA_y was calculated using equation (2) and the definition: $\Delta U_I = U_L/x$,

$$\Delta U_I(M_xA_y) - \Delta U_I(Ca_xA_y) = \Delta H_f^\circ(M^{2+}, g) - \Delta H_f^\circ(Ca^{2+}, g) - \Delta H_f^\circ(M_xA_y, c) + \Delta H_f^\circ(Ca_xA_y, c). \quad (11)$$

As shown in Table 3, the difference in ΔU_I changes significantly with cation species, but it barely depends on anion species. Thus, the stabilization energy due to the d-orbital splitting of each cation is nearly independent of anion species. The stabilization energy was evaluated by the crystal field theory,[7] resultant values up to 300 kJ mol^{-1}. More recently, a molecular orbital approach[8] was reported, giving the values of several hundred kJ mol^{-1} or less. Whatever the exact values may be, the conclusion derived above, together with the fact that the coefficients of the first terms on the right-hand sides of Eqs. (6)—(10) are close to unity, shows that even if the effect of the 3d-orbital splitting was corrected, the resultant values would satisfy these equations.

Secondly, the linear relations in ΔU_R given in Eqs. (6)—(10), in connection with Eq. (5), leads to the corresponding linear equations in ΔU_I, although it is unknown whether the proportionality holds for the pair of formate-acetate.

Now, the discussion on each linear relation is started. For the pair of formate-acetate, ΔU_R (formate)$\simeq\Delta U_R$ (acetate) holds. Crystal structure has been determined for formates of Na,[9] Ca,[10,11] Sr,[10] Ba,[11] and Cu(II).[12] These crystals are characterized by the coordination of the metal cations with four or more carboxyl oxygen atoms. Hence, ΔU_R may be divided into two parts: The contribution from metal-oxygen interactions and that from the other interactions, both in the crystalline states. The former is considered to be more dominant than the latter. The observed approximate equality in ΔU_R suggests that the crystal structures of formates and acetates of a metal are similar and, in view of the similarity of chemical structure of the anions, the magnitude of metal-oxygen interaction energy is also similar between formate and acetate of a metal.

Table 3. The difference between heterolytic lattice energy ΔU_I of formate, acetate, oxalate, and glycolate of Mn(II), Co(II), Ni(II), Cu(II), and Zn(II), and ΔU_I of the corresponding Ca compounds

Cation M(II)	$[\Delta U_I(M_xA_y) - \Delta U_I(Ca_xA_y)]$/kJ mol^{-1}			
	Formate	Acetate	Oxalate	Glycolate
Mn(II)	251	262	—	261
Co(II)	402	—	—	406
Ni(II)	489	—	—	500
Cu(II)	522	542	523	524
Zn(II)	457	457	468	—

For the pairs of oxalate-formate and oxalate-acetate, it is clear from Eqs. (7) and (9), that ΔU_R (oxalate) is expressed by a linear function of ΔU_R (formate) or ΔU_R (acetate), with a coefficient close to unity and a second term proportional to (y/x). Furthermore, from the similarity in chemical structure of the anions as a whole, the relation: ΔU_R(formate)$\simeq\Delta U_R$(oxalate)$\simeq\Delta U_R$ (acetate), is expected to hold for every metal. Substitution of an assumed value of ΔH_f° (O_2CCO_2, g)$=-279$ kJ mol^{-1}, into Eqs. (7) and (9), leads to the following approximate equality relations:

$$\Delta U_R(\text{oxalate})/\text{kJ mol}^{-1} = 0.9965\Delta U_R(\text{formate})/\text{kJ mol}^{-1} + 3(y/x), \quad (12)$$

and

$$\Delta U_R(\text{oxalate})/\text{kJ mol}^{-1} = 1.0239\Delta U_R(\text{acetate})/\text{kJ mol}^{-1} - 4(y/x). \quad (13)$$

The assumed value of $\Delta H_f^\circ(HOCH_2CO_2, g)$ was then used to calculate the mean O-H bond dissociation energy $\bar{D}$(O-H) of oxalic acid, which was defined as ΔU° (298.15 K) for the reaction: $(1/2)HO_2CCO_2H(g) = (1/2)O_2COO_2(g) + H(g)$. $\bar{D}$(O-H) was calculated to be 443 kJ mol^{-1}. Similarly, corresponding O-H bond dissociation energies D(O-H) of formic and acetic acids, defined as ΔU°(298.15 K) of the reactions: $RCO_2H(g) = RCO_2(g) + H(g)$, where R is H or CH_3, were calculated to be 443 and 440 kJ mol^{-1}, respectively. Agreement of the calculated value of $\bar{D}$(O-H) of oxalic acid with D(O-H) of formic and acetic acids strongly suggests that $\Delta H_f^\circ(O_2CCO_2, g)\simeq-279$ kJ mol^{-1} and the relation: ΔU_R(formate)$\simeq\Delta U_R$(oxalate)$\simeq\Delta U_R$(acetate) holds. Thus, ΔH_f°(g) of oxalate biradical, which would be determined experimentally only with difficulty, could be estimated with some grounds. In addition, the coefficients of the first terms of Eqs. (11) and (12) which are close to unity, suggest the similarity in the character of crystal structure and the magnitude of metal-oxygen interaction energy of a metal oxalate with formate and acetate of the same metal.

For the pairs of glycolate-formate and glycolate-acetate, Eqs. (8) and (10) show that ΔU_R(glycolate) is expressed by a linear functions of ΔU_R(formate) or ΔU_R(acetate), with a coefficient close to unity and a second term proportional to (y/x). The assumption that ΔU_R(formate)$\simeq\Delta U_R$(glycolate)$\simeq\Delta U_R$(acetate), or equivalently that $\Delta H_f^\circ(HOCH_2CO_2, g) = -398$ kJ mol^{-1}, leads to the result: D(O-H)$=400$ kJ mol^{-1} for carboxyl O-H of glycolic acid. ΔH_f°(g) of glycolic acid used in this calculation was obtained by estimation

using the group contribution method,[13,14] with an estimated value of $[C-(CO)(O)(H)_2]=-34.3$ kJ mol^{-1}. Hence, this value is more uncertain than the rest. Even so, the value of D(O-H) given above is significantly smaller than the corresponding values of formic and acetic acids.

Instead, it was assumed that D(O-H)=443 kJ mol^{-1} for carboxyl O-H of glycolic acid, in accordance with those of formic and acetic acids. This implies that $\Delta H_f^\circ(HOCH_2CO_2, g)=-355$ kJ mol^{-1}. Substitution of this value to Eqs. (8) and (10) leads to the following equations:

$$\Delta U_R(\text{glycolate})/\text{kJ mol}^{-1} = 0.9728\Delta U_R(\text{formate})/\text{kJ mol}^{-1} + 44(y/x), \quad (14)$$

and

$$\Delta U_R(\text{glycolate})/\text{kJ mol}^{-1} = 1.0239\Delta U_R(\text{acetate})/\text{kJ mol}^{-1} + 42(y/x), \quad (15)$$

Among the glycolates, crystal structure has been determined only for Cu(II) glycolate.[15] In this crystal, Cu(II) is coordinated with four carboxyl and two hydroxyl oxygen atoms of glycolate anions, *i.e.* glycolate anion is tridentate, whereas formate and acetate anions are bidentate. In addition, each hydroxyl oxygen atom forms a remarkably short intermolecular hydrogen bond 0.257 nm long to the carboxyl oxygen atom of a second neighbouring complex. The short O-H···O hydrogen bond corresponds to the hydrogen bond energy of about 40 kJ mol^{-1}.

For Cu(II) glycolate, the second terms of Eqs. (14) and (15) may be interpreted in terms of (1) the intermolecular hydrogen bond in the crystal, which is cleaved in the gaseous state, and (2) the change in the electronic structure and probably the molecular structure as well, of the hydroxyl moiety of glycolate anions, accompanying homolytic vaporization. Contributions from these sources to ΔU_R(glycolate) are clearly proportional to (y/x) and independent of metal species. It is to be noted that the contribution from the former source is sufficiently large to account for mostly the second terms by itself. The latter contribution is considered to be smaller than the former. The other possible extra effects arising from the fact that glycolate is a tridentate anion, may not be included in the causes of the second terms, since it seems unlikely that these extra effects are independent of metal species.

Equations (14) and (15) suggest that crystal structure of every glycolate is similar to that of Cu(II) glycolate. Intermolecular hydrogen bond would be present and metal cations would be coordinated with carboxyl and hydroxyl oxygen atoms, in the crystal of every glycolate. The total magnitude of metal-oxygen interaction energy does depend on metal species, but is independent of the kind or the combination of coordinating oxygen atoms (carboxyl and hydroxyl), as is reflected in the coefficients of the first terms which are close to unity.

Thus, it has been shown that the empirical analysis of crystal cohesion energy in terms of ΔU_R can be used to obtain various informations on crystal structure and inter-ion interactions in the crystal, at least within the extent of the present compounds.

Table 4. Estimated standard enthalpies of formation in crystalline state of metal formates, acetates, glycolates, and oxalates

Cathion	$-\Delta H_f^\circ(M_xA_y, c)$/kJ mol^{-1}			
	Formate	Acetate	Glycolate	Oxalate

Hg(II)	711(A)	—	1192(A)	—
Tl(I)	481(A)	—	715(A)	933(A)
Pb(II)	—	—	1347(FA)	—

F, A, and O in the parentheses show that ΔU_R of the corresponding formate, acetate, and oxalate, was used to derive the estimated value, respectively. The values with parenthesized FA are the mean values of those obtained by correlation with ΔU_R of formate and that of acetate.

Apart from the analysis of ΔU_R described so far, the regularity in ΔU_R or $[\Delta U_R-(y/x)\Delta H_f^\circ(A,g)]$ enables us to estimate $\Delta H_f^\circ(c)$ of a compound M_xA_y, from that of another compound of the same metal, by using equations (6)—(10) and then Eq. (4). The estimated values are presented in Table 4.

Photoelectrochemical Oxidation of Alcohols on Polycrystalline Zinc Oxide

Ju-seong LEE,† Tamihiko KATO, †† Akira FUJISHIMA,* and Kenichi HONDA
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received August 29, 1983)

The current doubling behavior of alcohols was studied on an n-type ZnO polycrystalline electrode. The increase in photocurrent due to alcohols on the ZnO depended on pH of the solution. The photocurrent was almost doubled in alkaline solution. It was found that the ZnO photoanode dissolved in the neutral aqueous solution but the dissolution reaction of ZnO was completely suppressed in alkaline solution at a sufficiently large pH. From the experimental results obtained by the rotating ring disk electrode and gas chromatographic and mass spectrometric analyses, a mechanism of the current-doubling reaction is proposed.

Most recent investigations of semiconductor electrodes have been concerned with the utilization of solar energy in which water is photoelectrolyzed to hydrogen and oxygen.[1-8]

Some studies of the electrochemical behavior of organic substances at semiconductor electrodes have been reported.[9-13] For example, Morrison *et al.*[14,15] reported a "current doubling effect" due to the anodic behavior of aqueous formate ion or alcohols at an illuminated zinc oxide single crystal semiconductor electrode. To account for the mechanism of current doubling they suggested that holes formed by photoirradiation of an n-type semiconductor react with the current doubling agent R to give R^{+}, which then donates an electron to the conduction band and becomes R^{2+}. However, the photodissolution reaction of zinc oxide was not mentioned.

Subsequently, similar effects were reported on other semiconductor electrodes. Gerischer *et al.*[16,17] found current doubling behavior on a cadmium sulfide single crystal electrode when alcohols or aldehydes were added to the electrolyte. Tamura *et al.*[18] observed that the photooxidation current for a titanium dioxide single crystal electrode was increased by the addition of alcohols in acidic aqueous solution.

Our earlier studies[19-22] with the zinc oxide electrode in neutral aqueous solution showed that as the photocurrent was increasd, oxygen evolution could not be observed but zinc ions were detected in the electrolyte solution after the photoelectrolysis. The amount of zinc ions dissolved was almost equivalent to the charge of holes that flowed to the zinc oxide surface. These facts indicated that the current doubling effect may not always follow Morrison's mechanism.

In this paper, we re-examine the mechanism of current doubling by using a polycrystalline zinc oxide electrode and alcohols as the current doubling agent in solutions of various pH. Experimental measurements were made by rotating ring-disk electrode (RRDE) and gas chromatographic and mass spectrometric analyses of reaction products produced from a photoelectrolysis.

Experimental

Polycrystalline n-type zinc oxide pellets were made by pressing ZnO powder of reagent grade with a pressure of 0.5 t/cm^2 and then heating the pellets for 3 h at 1300 °C in air.[21] Two kinds of semiconductor electrodes were made; one was of the conventional type and another was for a ring-disk electrode system. The pellet for photoelectrochemical measurements and macrophotoelectrolysis was 17 mm-diameter and about 2 mm-thick. The pellet for a smaller size cell, which was used for mass spectrometric analysis was 8 mm-diameter and about 2 mm-thick. After an ohmic contact was made with an In-Ga alloy, a lead wire was connected with silver paste, and then all surfaces except one side were covered with an epoxy resin.

The pellet for the ring-disk electrode was assembled with a 6 mm-diameter zinc oxide disk and an amalgamated gold ring 7 mm in inner diameter and 9 mm in outer diameter. The ring-disk electrode is schematically shown in Fig. 1 (a). The experimental setup of the RRDE followed previous paper.[23]

The faces of both zinc oxide electrodes, which were exposed to the electrolyte solution, were polished with alumina powder, etched in 1 : 1 HCl-water mixed solution for 10 s, and then washed with distilled water.

A macroelectrolysis cell consisted of two compartments separated by a cation exchange membrane (Asahi Garasu, Selemion CMV). The volumes of anolyte and catholyte chambers were 100 and 80 ml, respectively. As shown in Fig. 1 (b), the cell was equipped with the polycrystalline n-type zinc

oxide working electrode, a platinum wire counter electrode, and a saturated calomel electrode (SCE) as a reference electrode. A smaller size cell, which was used for mass spectrometric analysis, was equipped with two electrodes, such as ZnO photoanode and Pt cathode, and the volume of electrolyte was 1 ml, as shown in Fig. 1 (c).

The light source was a 500 W high pressure mercury arc lamp (Ushio Denki) and the wavelength of the illuminating light was fixed at 360±30 nm by means of a glass filter (Toshiba Kasei, UV-D2). Current-potential behavior of the zinc oxide electrode was measured with a potentiostat/galvanostat system (Hokuto Denko), with a saturated calomel electrode as a reference and platinum as a counter electrode. All chemicals were of reagent grade. The oxygen and organic compounds produced were analyzed by means of gas chromatography (Hitachi Model 163) and mass spectrometry (Ulvac YTP-150). In the case of the gas chromatographic analysis, all liquid compounds except formaldehyde were analyzed by using polyethylene glycol 2000, polyethylene glycol 20 M and Chromosorb 101 (FID, temp 120 °C), and formaldehyde was chromatographed with Porapax N (TCD, temp 100 °C). The electrolyte solutions after electrolysis were injected into the gas chromatograph. Oxygen evolved was analyzed with Molecular Sieve SA on 60/80 mesh. The carrier gas was helium at a flow of 40 ml/min. The zinc ions in the electrolyte solutions were analyzed spectrophotometrically by using Zincon reagent in a pH 9.0 buffer solution. Before all experiments, the solutions were purged with nitrogen gas for more than 30 min.

Results

Typical current-potential curves for the electrolyte solution at pH 6 and 13 are shown in Fig. 2. In the dark, no anodic current was observed in both the presence or the absence of a current doubling agent, such as methyl alcohol. In the solution at pH 6, the anodic photocurrent appeared at −0.45 V *vs.* SCE, and then reached saturation under anodic polarization. With the addition of methyl alcohol to the solution, the saturated photoanodic current was increased by a factor of only 1.1. On the other hand, in the solution at pH 13, the onset potential of the anodic photocurrent was more negative by 0.4 V than the potential in the neutral solution. By addition of methyl alcohol to the alkaline solution, the photocurrent was almost doubled.

The pH dependences of the photocurrent ratio (i/i_0) of ZnO for various alcohols added to solution are shown in Fig. 3, where i and i_0 are the photocurrent in the presence and in the absence of a current doubling agent, respectively. The ratio i/i_0 increased for the solution containing a primary or secondary alcohol above pH 10, whereas the increase was not observed for a tertiary alcohol solution. Thus it was found that the increase in the photocurrent of ZnO for given alcohol depended very much on the pH of the solution, an effect which is important for the discussion of the reaction mech-

anism. In addition to the pH effect, the α hydrogen of alcohols may be involved with the current doubling photoelectrochemical oxidation reaction.

To obtain more information on the current doubling behavior, the rotating disk electrode method was employed. For convenience, the effects of methyl alcohol concentration was evaluated by the parameter $Y=100(i-i_0)/i_0$ which references the increase in current to the photocurrent in an alkaline electrolyte. The dependence of the value of Y on the concentration of methyl alcohol in a solution containing 0.2 M Na_2SO_4+0.1 M NaOH (pH 13) (1 M=1 mol dm^{-3}) is shown in Fig. 4. The maximum Y value of 80% was obtained for CH_3OH at concentrations $\geq 4\times10^{-3}$ M. In case of methyl alcohol, the RRDE technique was applied to determine which reaction occurred on the ZnO photoanode in neutral

Other conditions are the same as in Fig. 5.

and alkaline solutions. The current-potential curves at the disk and the ring electrode in solutions containing 0.2 M Na_2SO_4 are shown for pH 6 and 13 in Figs. 5 and 6, respectively. As shown in Fig. 5, for dark conditions at pH 6, the disk current was negligibly small at the fixed potential of +1.0 V *vs.* SCE, and at the ring electrode hydrogen evolution occurred at potentials more cathodic than −1.5 V *vs.* SCE. Under illumination in the absence of methyl alcohol, an anodic photocurrent flowed at the zinc oxide electrode. At the same time, a reduction current appeared at the ring electrode in the potential ranges more cathodic than −0.2 and −1.0 V, which corresponds to the reduction of oxygen and zinc ion, respectively. By addition of methyl alcohol to the solution, the magnitude of the disk photocurrent increased almost 1.1 or 1.2 times, but the ring current due to the reduction of zinc ion showed little change and the ring current for oxygen reduction disappeared from the current-potential curves.

However, in the alkaline solution (pH 13) the behaviors of the ring and the disk currents were different from those in the neutral solution. As shown in Fig. 6, under illumination on the disk electrode of the ZnO in the absence of methyl alcohol, the ring reduction current due to oxygen appeared from −0.3 V *vs.* SCE but that due to the zinc ion was not observed. The dotted curve 2 of the ring current in Fig. 6 almost coincides with the reduction of oxygen at the dropping mercury electrode reported by Kolthoff.[24] Therefore, the first cathodic wave corresponds to the reduction of dissolved oxygen to hydrogen peroxide and the second wave to the reduction of peroxide to hydroxide ion.

By addition of methyl alcohol to the solution of pH 13, the disk photocurrent increased nearly two times that of the initial photocurrent. At the same time, the reduction current which corresponds to the reduction of oxygen disappeared in the potential range between −0.3 and −1.6 V, but a new wave appeared at a potential of about −1.6 V *vs.* SCE. This new wave might correspond to a reduction current due to formaldehyde formed by photoelectrolysis of methyl alcohol. If dissolution of ZnO photoelectrode occurred in alkaline solution as well as in the neutral solution, the reduction wave of Zn^{2+} should have been observed in Fig. 6. Upon addition of zinc ion to the solution of pH 13, the ring current corresponding to the reduction of Zn^{2+} appeared at a potential of −1.25 V (curve 3 in Fig. 6).

From the experimental results shown in Figs. 5 and 6, it is concluded that the n-type ZnO photoanode dissolved in the neutral aqueous solution but not in the alkaline aqueous solution around pH 13, with or without a current doubling reagent.

In addition to the experimental results of the RRDE measuremnt, the weight changes of the ZnO anode before and after macroelectrolysis under illumination were measured. The weight loss in neutral solution was quantitatively proportional to the quantity of electricity flowed, but a weight change of ZnO could not detect in the alkaline solution at pH 13. Consequently, the ZnO photoanode does not dissolve in adequately alkaline solution during macrophotoelectrolysis, a result which confirms the RRDE measurements.

The data in Table 1 show the results obtained by

Table 1. Photoelectrochemical reaction of polycrystalline *n*-type ZnO electrode in alcoholic solution

macrophotoelecrolysis. In neutral solution in the absence of alcohol, the current efficiencies of evolved oxygen and dissolved Zn^{2+} ion are almost 100%, respectively. On the other hand, in the alkaline solution in the absence of alcohol, the current efficiency for dissolved Zn^{2+} was zero but that of evolved oxygen was maintained at 100%. By addition of alcohols 0.5 M) to the neutral or alkaline solution, oxygen evolution was not observed. In these cases, aldehyde or ketone which corresponds to the oxidation product of a primary or secondary alcohol was observed. During photoelectrolysis the pH of the anolyte decreased gradually in the alkaline alcoholic solution but in the case of the neutral solution the pH of the anolyte was almost constant.

Photoelectrolysis resulted in formation of a small amount of formaldehyde compared with the amount of acetaldehyde or acetone produced. To examine this phenomena, the gas evolved from the electrolyte solution was analyzed by mass spectrometry after the continuous photoelectrolysis to one half the theoretical charge (quantity of electricity) in the alkaline 0.1 M CH_3OH solution (pH 13) using the small size cell. The mass spectrum showed strong signals of H_2 (*m/z* 2), unreacted methyl alcohol (*m/z* 31, 32), formaldehyde (*m/z* 18, 29, 30), CO_2 (*m/z* 44), and a very weak signal of formic acid (*m/z* 46).[25] Hydrogen probably was evolved from the Pt cathode during the electrolysis. The CO_2 is the oxidation product of methyl alcohol on ZnO where part of the formaldehyde produced is oxidized to CO_2.

Discussion

In general, when an oxide or hydrous oxide is immersed in an aqueous solution, protons and hydroxide ions become adsorbed.[26] The pH-dependence of the adsorption on the surface of the ZnO electrode could be explained by assuming reactions (1) and (2) at the electrode surface facing the electrolyte solution, that is, hydroxide ions are adsorbed on Lewis acid sites in alkaline solution and protons are adsorbed on Lewis base sites in weak acid or neutral solution.

$$ZnO + OH^- \longrightarrow ZnO\text{-}OH^- \text{ (in alkaline solution)}, \quad (1)$$

$$ZnO + H^+ \longrightarrow ZnO\text{-}H^+ \text{ (in weak acid or neutral solution)}. \quad (2)$$

The photo-produced holes coming to the ZnO surface may interact with, and oxidize, these adsorbed hydroxide ions or surfaces adsorbed protons. For example, hydroxyl radicals could be produced by reactions (3) and (4)

$$ZnO\text{-}OH^- + h^+ \longrightarrow ZnO + \cdot OH, \quad (3)$$

$$ZnO\text{-}H^+ + h^+ \longrightarrow Zn^{2+} + \cdot OH. \quad (4)$$

Thus the corrosion of the ZnO can occur readily in the neutral solution and be suppressed in alkaline solution. Then, the $\cdot CH_2OH$ radical formed by the reaction between the $\cdot OH$ radical and the α hydrogen of alcohol as in reaction (5) can result in donation of an electron to the conduction band of ZnO, as in reaction (6),

$$\cdot OH + CH_3OH \longrightarrow \cdot CH_2OH + H_2O, \quad (5)$$

$$\cdot CH_2OH + OH^- \longrightarrow HCHO + H_2O + e^-. \quad (6)$$

The net reaction occurring in alkaline solution is obtained by combining reactions (1), (3), (5), and (6)

$$CH_3OH + 2OH^- + h^+ \longrightarrow HCHO + 2H_2O + e^-. \quad (7)$$

The net reaction in weak acid or neutral solution is obtained by combining reactions (2), (4), (5), and (6).

$$ZnO + CH_3OH + h^+ \longrightarrow Zn^{2+} + HCHO + H_2O + e^- \quad (8)$$

Yamase *et al.*,[27] using an esr spin trapping method, detected simultaneously $\cdot OH$ and $\cdot CH_2OH$ radicals as intermediate of the photocatalytic reaction in an aqueous methyl alcohol solution containing polytungstate ion. Thus, reaction (5) is substantiated by their results.

The pH of the alkaline methyl alcohol solution after photoelectrolysis decreased in proportion to the quantity of electricity, but the pH of the neutral solution was much the same as that of the initial solution.

Hence, the observation of current increase (*e.g.* current doubling) makes it clear that hydroxide ion is involved in the reaction mechanism, as in Eq. (6). It is apparent that the current increasing reaction easily takes place in the alkaline solution for which $[OH^-] \geq 10^{-4}$M. In the case of the neutral solution, the small current increasing can be accounted for by the low concentration of hydroxide ions.

As a result of mass spectrometric and chemical analysis, considerable amount of carbon dioxide is detected after photoelectrolysis. This result supported the fact that formaldehyde is produced by oxidation of methyl alcohol on a ZnO photoanode and that the formaldehyde which is produced seems to be oxidized further up to carbon dioxide.

It is also concluded that the n-type ZnO photoanode dissolved in the neutral aqueous solution but not in the alkaline aqueous solution around pH 13, with or without a current doubling reagent.

The Complexation of Zinc Tetraphenylporphyrintrisulfonate by Viologen and Its Role in Photoredox Processes

Ichiro Okura,* Shin Kusunoki, and Shigetoshi Aono
Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152
(Received August 31, 1983)

The formation of the cation radicals of viologen dyes was established when an aqueous solution containing zinc tetraphenylporphyrintrisulfonate (Zn-$TPPS_3$), viologen dye, and 2-mercaptoethanol was irradiated by visible light. The reduction of viologen has been studied kinetically; its reduction rate may be expressed as follows:

$$v = \frac{d[V^+]}{dt} = \left(\frac{k_3[Zn\text{-}TPPS_3]_0}{1+K_1[V^{2+}]+K_2[V^+]}\right)\left(\frac{k_4[V^{2+}]}{k_{-3}+k_4[V^{2+}]}\right)\left(\frac{k_6[RSH]}{k_5[V^+]+k_6[RSH]}\right),$$

where $[V^{2+}]$, $[V^+]$, and [RSH] are the concentrations of the oxidized form and the reduced form of viologen, and 2-mercaptoethanol respectively. On the basis of the rate expression, a reaction mechanism containing the complexation of Zn-$TPPS_3$ by viologen was proposed. On the addition of hydrogenase to the above photo-irradiation system, hydrogen evolution was observed by the irradiation of visible light.

Photochemical redox systems have been developed for the purpose of solar-energy utilization.[1] The systems, containing, as shown in the following scheme, a photosensitizer (S), an electron donor (D), and an electron carrier (C), have been used to evolve hydrogen from water when a suitable catalyst is present:

$$\underset{D_{ox}}{D} \quad \underset{S \xrightarrow{h\nu} S^*}{S^+} \quad \underset{C}{C^+} \quad \text{Catalyst} \quad \underset{1/2H_2}{H^+} \qquad (1)$$

As photosensitizers, metallo-porphyrins have been employed extensively in these studies.[2] As catalysts, hydrogenase and colloidal platinum are predominant. Methylviologen has been used almost exclusively as an electron carrier.

As both the photosensitizer and the electron carrier serve as redox catalysts in the above reaction, the overall reaction may be expressed as follows:

$$D + H^+ \xrightarrow{h\nu} D_{ox} + 1/2H_2. \qquad (2)$$

When EDTA, triethanolamine, or 2-mercaptoethanol (RSH) is used as an electron donor, the following reactions occur:

$$(HOOCCH_2)_2N(CH_2)_2N(CH_2COOH)_2 + H_2O \longrightarrow (HOOCCH_2)_2N(CH_2)_2NHCH_2COOH + CO_2 + HCHO + H_2, \qquad (3)$$

$$N(CH_2CH_2OH)_3 + H_2O \longrightarrow NH(CH_2CH_2OH)_2 + CHOCH_2OH + H_2, \qquad (4)$$

$$2RSH \longrightarrow RSSR + H_2. \qquad (5)$$

The overall reaction shown above, the light-induced oxidation of the electron donor, involves a net solar energy storage, and part of the light energy is also stored. If back reaction proceeds upon the addition of a suitable catalyst and the stored light energy is taken out as heat, the stored solar energy can be used when needed. In the cases of Reactions (3) and (4), complex products with three or four components are formed, and it may not be easy to get the starting materials by means of the back reaction. In the case of Reaction (5), however, the back reaction proceeded easily. When cystine was used as the disulfide (RSSR), the starting material, cysteine, was produced with the palladium catalyst by the hydrogenation of RSSR under mild reaction conditions (at 30 °C; hydrogen pressure: 1 atm). By the conversion of cysteine to cystine and hydrogen, about 30 kJ mol^{-1} of light energy is stored. Therefore, the hydrogen production reaction expressed by Reaction (5) seems to be suitable for a solar-energy-storage system.

The photoreduction of electron carriers should proceed nicely to get an efficient hydrogen evolution, provided the hydrogen evolution rate is determined by the photoreduction of the electron carrier as is shown in Eq. (1). For this purpose, suitable combinations of the components and the optimum reaction conditions are discussed in this study.

Experimental

Materials. All the chemicals, obtained from the Tokyo Kasei Kogyo Co., were of the highest available purity. The ethyl-, propyl-, and butylviologens were synthesized according to the literature.[3] The zinc *meso*-tetraphenylporphyrintrisulfonate (Zn-$TPPS_3$) was synthesized by refluxing $TPPS_3$ and zinc acetate (molar ratio; 1:10) in methanol for 2 h.

Desulfovibrio vulgaris cells (Miyazaki type, which has kindly been provided by Prof. T. Yagi of Shizuoka Univ.) were cultured according to the literature.[4] The hydrogenase [H_2: ferricytochrome C_3 oxidoreductase, EC 1.12.2.1] from *Desulfovibrio vulgaris* was purified according to Yagi's method.[5] The concentration of hydrogenase is not known, but it has the ability to produce 4.88 μmol of hydrogen when this reaction system is used: hydrogenase (0.5 ml)-methylviologen (4.15×10^{-6} mol)-$Na_2S_2O_4$ (2.87×10^{-5} mol) in 6.0 ml of 0.02 mol dm^{-3} of Tris-HCl buffer (pH 7.0) at 30 °C for 10 min.

Measurement Procedure. The sample solution, which consisted of the photosensitizer, the viologen dye, 2-mercaptoethanol, and hydrogenase (if included) in 0.02 mol dm^{-3} of the Tris-HCl buffer (pH 7.0; this value is suitable for hydrogenase), was deaerated by repeated freeze-pump-thaw cycles. A typical experiment was performed as follows under anaerobic conditions. To 8.33×10^{-8} mol dm^{-3} of the photosensitizer, 1.26×10^{-4} mol dm^{-3} of the viologen dye and 0.21 mol dm^{-3} of RSH as a reducing agent in water, 0.5 ml of hydrogenase (if included) was added. The volume of the mixture was then adjusted to 6.0 ml with 0.02 mol dm^{-3} of the Tris-HCl buffer (pH 7.0). In the photolysis with

continuous irradiation, the sample, in a Pyrex cell equipped with a magnetic stirrer, was irradiated with light from a 200-W tungsten lamp. Light at wavelengths less than 390 nm was cut off by a Toshiba L-39 filter. A portion of the evolved hydrogen was collected *via* a sampling valve and analyzed by means of gas chromatography.

Results and Discussion

Photoreduction of Viologen Dyes by RSH. When an aqueous solution containing Zn-TPPS$_3$, viologen dye, and RSH was irradiated, the formation of the viologen cation radical was observed. As is shown in Fig. 1, the concentration of the viologen radical increased rapidly at the beginning of the reaction, and then reached a constant value. When the light was then cut off, the concentration of the cation radical decreased gradually. The difference in the constant values may depend on the difference in the photoinduced viologen-reduction rates and the backward reaction rates in the absence of light.

As is shown in Figs. 2, 3, and 4, the initial rate of cation-radical formation (the slopes of the curves at the beginning of the reaction in Fig. 1) increases at any viologen-dye concentration, and then decreases after a maximum point. To clarify this abnormal phenomenon, the rate decrease at a higher viologen concentration, the following experiments were carried out.

Complexation of Zn-TPPS$_3$ by Viologen Dyes. When Zn-TPPS$_3$ was mixed with ethylviologen, the characteristic Soret absorption band (418 nm) decreased with the increase in the ethylviologen concentration, and a new spectrum appeared which has a characteristic absorption band at 425 nm through the isosbestic point at 422 nm (Fig. 5). Similar complex formations between metalloporphyrins and methylviologen have recently been reported.[6]

When the complex is formed by the following reaction:

$$\text{Zn-TPPS}_3 + \text{EtV}^{2+} \overset{K_1}{\rightleftharpoons} \text{complex} \qquad (6)$$

EtV^{2+}: ethyl viologen,

the equilibrium constant, K_1, is expressed by:

$$K_1 = \frac{[\text{complex}]}{[\text{Zn-TPPS}_3][\text{EtV}^{2+}]}. \qquad (7)$$

This equation can be rewritten as follows by using the initial Zn-TPPS$_3$ concentration, $[\text{Zn-TPPS}_3]_0$:

$$\frac{[\text{Zn-TPPS}_3]_0}{[\text{complex}]} = 1 + \frac{1}{K_1[\text{EtV}^{2+}]}. \qquad (8)$$

As the complex concentration is calculated from the absorbance of the complex, the relation between

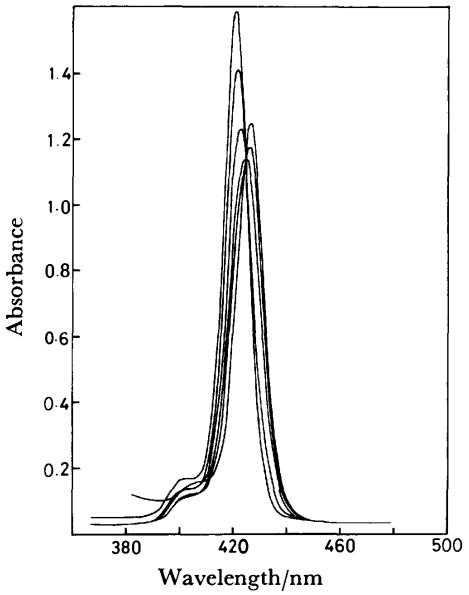

Fig. 5. Spectrum change of Zn-TPPS$_3$ by the addition of ethylviologen.

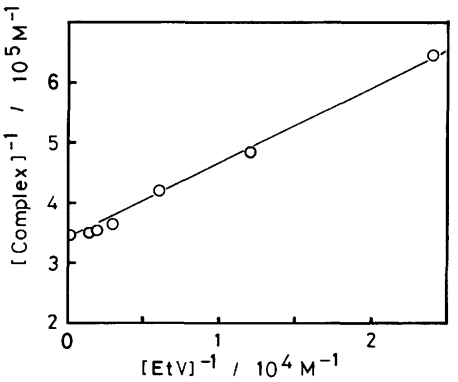

Fig. 6. Relation between [complex]$^{-1}$ and [EtV^{2+}]$^{-1}$.

[complex]$^{-1}$ and [EtV^{2+}]$^{-1}$ can be plotted to as shown in Fig. 6. The good linear relation between [complex]$^{-1}$ and [EtV^{2+}]$^{-1}$ shows the formation of a 1 : 1 complex of Zn-TPPS$_3$ and ethylviologen.

When other viologen dyes were used, the respective complex formation was observed, as is shown in Fig. 7. The equilibrium constants obtained by Eq. (8) are listed in Table 1.

The reduced form of viologen dye also produced a complex with Zn-TPPS$_3$. When the benzylviologen reduced by $Na_2S_2O_4$, for example, was added to Zn-TPPS$_3$, a new spectrum (Fig. 8 Spectrum c) was observed, which shows that Zn-TPPS$_3$ forms a complex with reduced benzylviologen.

Complex formation was also observed when metal-free porphyrin, TPPS$_3$, was used (the data is not shown); this shows that the central metal of the metalloporphyrin does not play an important role in the complex formation, but that the porphyrin ring combines with viologen dye.

Kinetics and Mechanism of Photo-induced Reduction of Viologen Dyes. As has been mentioned above, Zn-TPPS$_3$ forms complexes with both oxidized and

reduced forms of viologen dyes. After comparing the reaction mechanisms reported for similar systems[7] and the above results, the following scheme containing complex-formation processes may be proposed:

$$\text{Zn-TPPS}_3 + \text{V}^{2+} \overset{K_1}{\rightleftharpoons} [\text{Zn-TPPS}_3\ \text{V}^{2+}]_{\text{complex}},$$

$$Zn\text{-}TPPS_3 + V^+ \overset{K_2}{\rightleftharpoons} [Zn\text{-}TPPS_3\ V^+]_{complex},$$

$$Zn\text{-}TPPS_3 \underset{k_{-3}}{\overset{h\nu, k_3}{\rightleftharpoons}} Zn\text{-}TPPS_3^*,$$

$$Zn\text{-}TPPS_3^* + V^{2+} \xrightarrow{k_4} Zn\text{-}TPPS_3^+ + V^+,$$

$$Zn\text{-}TPPS_3^+ + V^+ \xrightarrow{k_5} Zn\text{-}TPPS_3 + V^{2+},$$

$$Zn\text{-}TPPS_3^+ + RSH \xrightarrow{k_6} Zn\text{-}TPPS_3 + 1/2\ RSSR,$$

where V^{2+} and V^+ are oxidized and reduced forms of viologen dyes respectively. K_1 and K_2 are equilibrium constants. k_{-3}, k_4, k_5, and k_6 are rate constants, but k_3 is not, for it is a function of light flux. As the fraction of light absorption is small under these experimental conditions, *i.e.*, as the εCl value is small enough, ΦI_0 can be replaced by k_3[Zn-TPPS$_3$]$_0$.

If the complexes are not effective for viologen photoreduction, and if only free Zn-TPPS$_3$ is effective for this reaction, as Rougee *et al.* have previously established by a similar system,[6a] the following rate expression can be derived on the basis of the above reaction mechanism by the use of the steady-state approximation for [Zn-TPPS$_3$*] and [Zn-TPPS$_3^+$]:

$$v = \frac{d[V^+]}{dt} = \left(\frac{k_3[\text{Zn-TPPS}_3]_0}{1+K_1[V^{2+}]+K_2[V^+]}\right)\left(\frac{k_4[V^{2+}]}{k_{-3}+k_4[V^{2+}]}\right) \times \left(\frac{k_6[RSH]}{k_5[V^+]+k_6[RSH]}\right). \quad (9)$$

At the initial state of the reaction, V^+ grows linearly with the reaction time, for the rate of the back reaction, Zn-TPPS$_3^+$ reduction by V^+, is negligibly small at this stage. Equation (9) is rewritten as follows:

$$v = \left(\frac{k_3[\text{Zn-TPPS}_3]_0}{1+K_1[V^{2+}]}\right)\left(\frac{k_4[V^{2+}]}{k_{-3}+k_4[V^{2+}]}\right), \quad (10)$$

or

$$\frac{1}{v(1+K_1[V^{2+}])} = \left(\frac{1}{k_3[\text{Zn-TPPS}_3]_0}\right)\left(1+\frac{k_{-3}}{k_4[V^{2+}]}\right). \quad (11)$$

According to Eq. (11), $1/v(1+K_1[V^{2+}])$ should be linearly related to $1/[V^{2+}]$, and the intercept, $1/k_3$[Zn-TPPS$_3$]$_0$, should not depend on the type of viologen dye. The good linear relations and the same intercept in the cases of methylviologen and ethylviologen, as shown in Fig. 9, indicate that Eq. (9) is adequate. From the slopes and the intercept of the straight lines, the ratios of such rate constants as k_4/k_{-3} (as shown in Table 1) and k_3 were obtained. By using the values listed in Table 1 and k_3, the relations between v and $[V^{2+}]$ are obtained from Eq. (9); they are shown by the dotted lines in Figs. 2, 3, and 4. The experimental values agree well with the theoretial results except for some deviations in the case of ethylviologen. The good fittings of the curves show that the above-mentioned scheme explains the experimental results satisfactorily.

A typical time dependence of the viologen-radical concentration is shown in Fig. 10. The time course can be obtained by integrating Eq. (9). As $[V^{2+}]_0 \ll [RSH] \simeq$ constant under these experimental conditions, and if $K_1 \simeq K_2$, Eq. (9) can be rewritten as follows:

$$\left(\frac{k_4[V^{2+}]}{k_{-3}+k_4[V^{2+}]}\right)\frac{1}{v} = \left(\frac{k_3[\text{Zn-TPPS}_3]_0}{1+K_1[V^{2+}]_0}\right)^{-1}\left(1+\frac{k_5[V^+]}{k_6[RSH]}\right). \quad (12)$$

This relation is confirmed by the good linearity of the $\left(\frac{k_4[V^{2+}]}{k_{-3}+k_4[V^{2+}]}\right)\frac{1}{v}$ *vs.* $[V^+]$ plot, as is shown in Fig. 11. From the slope and the intercept of the straight line, the ratio of the rate constants, k_5/k_6, is obtained. By

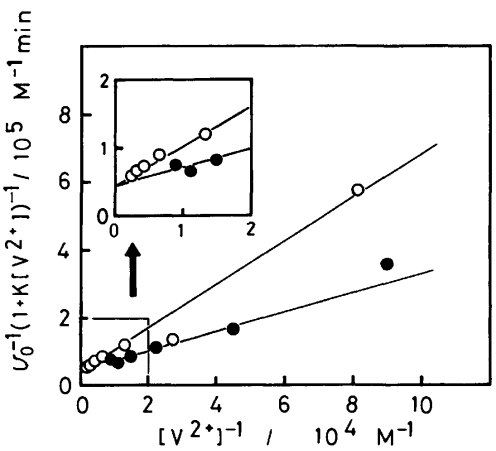

Fig. 9. Relation between $V_0^{-1}(1+K_1[V^{2+}])^{-1}$ and $[V^{2+}]^{-1}$.

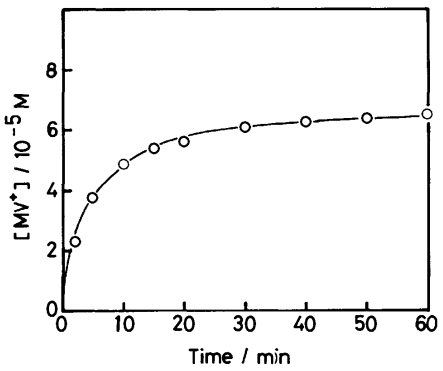

Fig. 10. Time dependence of reduced methylviologen concentration.
Reaction conditions: Zn-TPPS$_3$, 1.31×10^{-7} mol dm^{-3}; RSH, 0.85 mol dm^{-3}; methylviologen, 6.92×10^{-5} mol dm^{-3}, —: calculated; ○: observed.

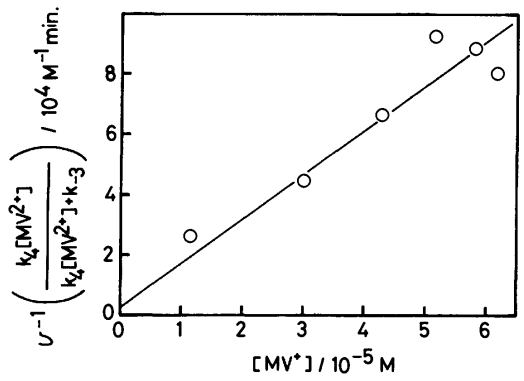

Fig. 11. Relation between $v^{-1}\left(\frac{k_4[MV^{2+}]}{k_4[MV^{2+}]+k_{-3}}\right)$ and $[MV^{2+}]$.

integrating Eq. (11), Eq. (13) can be obtained:

$$\frac{k_5[V^+]^2}{2k_6[RSH]} - \frac{k_{-3}}{k_4}[V^+]\left(1-\frac{k_5}{k_6[RSH]}\right) - \frac{k_4}{k_{-3}}\left(1+\frac{k_5}{k_6[RSH]}\right)\ln\left(\frac{[V^{2+}]_0-[V^+]}{[V^{2+}]_0}\right) = \frac{k_3[Zn\text{-}TPPS_3]_0}{1+K_1[V^{2+}]_0}t. \quad (13)$$

By using the constant values obtained from Figs. 9, 11, and Table 1, the time dependence of $[V^+]$ can be plotted on the basis of Eq. (13), as is shown by the solid line in Fig. 10. The good fit of the observed data (open circles) and the calculated data (solid line) indicates that Eq. (9) is adequate for expressing the kinetic data; it also supports the proposed reaction mechanism.

Photo-induced Hydrogen Evolution with Hydrogenase. As the reduced forms of methy-, ethyl-, propyl-, and benzylviologens have been known to produce hydrogen in the presence of a suitable catalyst, an attempt was made to produce hydrogen by the use of an electron-transfer system conbinning Zn-TPPS$_3$ and viologen dyes.[8]

By the addition of hydrogenase to the system containing RSH, Zn-TPPS$_3$, and viologen dye, photo-induced hydrogen evolution was carried out. Experiments were preformed by using higher initial concentrations of viologen dye in order to minimize the free Zn-TPPS$_3$, where more than 70% of the porphyrin is complexed, and also by using the optimum concentration, where the maximum reduction rate of viologen dye is given as is shown in Figs. 2, 3, and 4. In these experiments, an excess amount of hydrogenase was used to make the rate-determining step of the hydrogen-evolution reaction to the photoreduction of viologen dyes. As is shown in Figs. 12 and 13, a continuous hydrogen evolution was observed in both cases. The higher hydrogen evolution rate was obtained by using the optimum concentration of the viologen dyes.

We wish to express our appreciation to Professor Tominaga Keii and Professor Yoshio One for their stimulating and helpful discussions.

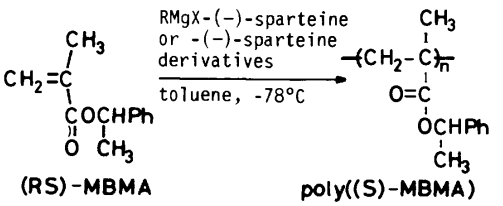
(+)-6-Benzylsparteine (**a**) crystallizes in orthorhombic systems; $P2_12_12_1$, a=10.711(1), b=25.868(4), c=6.804(1) Å, and Z=4; EtMgBr-(+)-6-benzylsparteine (**b**) also belongs to orthorhombic system; $P2_12_12_1$, a=11.020(4), b=23.660(10), c=8.666(6) Å and Z=4; and $MgBr_2$-(+)-6-benzylsparteine toluene solvate (**c**), orthorhombic system; $P2_12_12_1$, a=16.654(3), b=19.723(4), c=8.637(2) Å and Z=4. The structure of **a** was solved by the direct method and those of **b** and **c** by the heavy atom method. Refinements were carried out by the block-diagonal least-squares procedure; R values are: (**a**) 0.055. (**b**) 0.169, and (**c**) 0.118, respectively for 1342, 1445, and 1501 reflections. The **a** molecule takes a one-boat form, whereas by coordination to the Mg atom it changes into all-chair form in **b** and **c** molecules. The Mg atom has a distorted tetrahedral geometry; **b**, Mg-N=2.13(4) and 2.19(4), Mg-C 2.34(5) and Mg-Be=2.506(16) Å and N-Ng-N=83.1(14)°; **c**, Mg-N=2.08(3) and 2.17(3), Mg-Br=2.454(12) and 2.473(12) Å and N-Mg-N=85.8(10)°. The structures of these molecules are compared with those of (−)-sparteine complexes with EtMgBr, t-BuMgCl, and $MgCl_2$. On the basis of the molecular structures determined the activity of these Grignard reagent-(−)-sparteine derivatives for the enantiomer-selective polymerization of MBMA is discussed.

Asymmetric selective (enantiomer-selective) polymerization of racemic (*RS*)-α-methylbenzyl methacrylate (MBMA) has been investigated with homogeneous Grignard reagent-(−)-sparteine derivative catalysts in toluene at −78 °C.[1] Sparteines combined with the Grignard reagents were (−)-sparteine, (−)-α-isosparteine, (−)-6-ethylsparteine, (+)-6-benzylsparteine, (−)-Δ^5-dehydrosparteine, and (−)-$\Delta^{5,11}$-didehydrosparteine. Among the complexes formed between Grignard reagent and (−)-sparteine (or its derivatives), EtMgBr-(−)-sparteine has a high activity, whereas t-BuMgCl-(−)-sparteine and EtMgBr-(−)-α-isosparteine has no activity, in the asymmetric selective polymerization of racemic (*RS*)-MBMA (Table 1). EtMgBr-(+)-6-benzylsparteine was also found active for the polymerization mentioned above but it is less active than EtMgBr-(−)-sparteine.



In order to obtain informations on the structural dependence of the reactivity and monomer-selectivity of these catalysts, molecular structures of EtMgBr-(−)-sparteine[2], t-BuMgCl-(−)-sparteine[3] and related complex $MgCl_2$-(−)-sparteine[3], and EtMgBr-(−)-α-

isosparteine[4] have been determined by means of X-ray diffraction. This paper deals with the molecular structure of EtMgBr-(+)-6-benzylsparteine and related complex $MgBr_2$-(+)-benzylsparteine. Interests on the molecular conformation promoted the crystal structure analysis of (+)-6-benzylsparteine.

Experimental

(+)-6-Benzylsparteine was recrystallized from a methanol solution. EtMgBr-(+)-6-benzylsparteine was prepared by mixing the crystalline powder of (+)-6-benzylsparteine and ether solution of EtMgBr under nitrogen atmosphere, because the reaction of a toluene solution of (+)-6-benzylsparteine and ether solution of EtMgBr gave $MgBr_2$-(+)-6-benzylsparteine instead of EtMgBr-(+)-6-benzylsparteine.

Crystals of (+)-6-benzylsparteine, EtMgBr-(+)-6-benzylsparteine, and $MgBr_2$-(+)-6-benzylsparteine used had approximate dimensions of 0.38×0.25×0.23, 0.68×0.33×0.25, and 0.13×0.25×0.5 mm, respectively. Crystals of EtMgBr-(+)-6-benzylsparteine and $MgBr_2$-(+)-6-benzylsparteine are both sensitive to moisture in air, and they were sealed in glass capillary tubes under nitrogen. Each crystal was mounted on a Rigaku automated, four-circle diffractometer. Nickel-filtered Cu $K\alpha$ radiation (λ=1.5418 Å) was used for the former organic crystal, and graphite monochromatized Mo $K\alpha$ radiation (λ=0.7107 Å) for the later two Mg-complexes, respectively. Unit-cell dimensions of each crystal were determined by the least-squares fit using 2θ values of high order, strong reflections.

Crystal Data. (+)-6-Benzylsparteine (**a**), $C_{22}H_{32}N_2$, M 324.5, orthorhombic, space group $P2_12_12_1$, a=10.711(1), b=25.868(4), c=6.804(1) Å, V=1885.1(4) Å^3, D_c=1.143 g cm^{-3} for Z=4, μ(Cu $K\alpha$)=5.07 cm^{-1}; EtMgBr-(+)-6-benzylsparteine (**b**), $C_{24}H_{37}N_2MgBr$, M 457.8, orthorhombic, space group $P2_12_12_1$, a=11.020(4), b=23.660(10), c=8.666(6) Å, V=2260(2) Å^3, D_c=1.350 g cm^{-3} for Z=4, μ(Mo $K\alpha$)=19.7 cm^{-1}; $MgBr_2$-(+)-6-benzylsparteine toluene solvate(c), $C_{22}H_{32}N_2MgBr_2 \cdot C_7H_8$, $F.W.$ 600.8, orthorhombic, space group $P2_12_12_1$, a=16.654(3), b=19.723(4), c=8.637(2) Å, V=2836.8(9) Å^3, D_c=1.407 g cm^{-3} for Z=4, μ(Mo $K\alpha$)=30.7 cm^{-1}.

Reflection intensities were measured by the θ-2θ scan technique at a 2θ rate of 4° min^{-1}. The scan widths were $\Delta 2\theta$=(2.0+0.3tanθ)° for the former organic crystal and $\Delta 2\theta$=(2.4+0.7tanθ)° for the latter two Mg-complexes. Backgrounds were counted for 7.5 s at both ends of a scan. Four standard reflections were measured after every 60 reflections, which showed less than 5% fluctuations throughout the data collection. A total of 1408 reflections was measured for (+)-6-benzylsparteine, of which 1346 were non-zero reflections. The reflection profiles of EtMgBr-(+)-sparteine were not so sharp, and only 1445 reflections ($|F_o|>3\sigma(F_o)$) out of 2369 measured were used for the structure analysis. For $MgBr_2$-(+)-6-benzylsparteine 2942 reflections were measured but only 1501($|F_o|>3\sigma(F_o)$) could be used. Usual Lp corrections were applied but corrections for absorption and extinction were ignored.

Structure Solution and Refinement

(a) (+)-6-Benzylsparteine. The structure was solved by the direct method (*MULTAN* 78),[5] and all the C and N atoms could be located on the E map. The refinement of the structure was carried out by the block-diagonal least-squares procedure (*HBLS* V).[6] The function minimized was $\sum w(\Delta F)^2$. During the course of the refinement four strong reflections (200, 230, 031, and 160), which were considered largely affected by the extinction, were excluded. Hydrogen atoms were located on a difference Fourier map, which were refined isotropically while the other anisotropically. The final R index was 0.055 (R_W=0.092) for 1342 non-zero reflections. The weighting schemes used at the final stage of the refinement were $w=\{\sigma^2(F_o)+0.01024|F_o|^2\}^{-1}$ for $|F_o|>0$ and w=0.63654 for $|F_o|=0$. The final atomic parameters are listed in Table 2.††††

was located by three-dimensional Patterson function. Positions of the Mg, N, and C atoms except the C(16) were determined by the subsequent Fourier synthesis. The structure was first refined isotropically by the block-diagonal least-squares procedure (*HBLS* V) with unit weight. The temperature factor of the C(1) atom fell on a negative value, and it was corrected and fixed as B=4.67 Å^2 which was derived from the Wilson statistics of structure amplitudes. The C(16) atom could be located on a difference Fourier map and fixed at the position. At the final stage of the anisotropic refinement the anomalous dispersion of all the non-hydrogen atoms was considered. However, the R index converged to a rather high value of 0.169(R_w=0.188) for 1445 reflections. The final atomic parameters are listed in Table 3.††††

(c) $MgBr_2$-(+)-6-benzylsparteine Toluene Solvate. The crystal of this complex was expected as that of EtMgBr-(+)-6-benzylsparteine, but the three-dimensional Patterson function could not be interpreted well. Three big peaks, found on the E map based on the phases using the *MULTAN* 78 program, supported to interprete the Patterson function as the complex was $MgBr_2$-(+)-6-benzylsparteine. The N and C atoms were then located on the Fourier synthesis based on the phases of the Mg and two Br atoms. The structure was refined by the *HBLS* V program with unit weight. Subsequent Fourier and difference syntheses revealed the location of seven C atoms of toluene, the solvent of crystallization. None of the hydrogen atoms could be located. The R index was 0.118 (R_w= 0.126) for 1501 reflections at the final stage of the anisotropic refinement: the anomalous dispersion of Br, Mg, N, and C atoms was considered. The final atomic parameters are given in Table 4.††††

Atomic scattering factors[7] and coefficients of anomalous dispersion[8] used were taken from International Tables for X-Ray Crystallography, Vol. IV. All the computations were done on an ACOS 700S computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University.

Results and Discussion

Molecular Structures. Perspective views(*ORTEP* II)[9] of (+)-6-benzylsparteine, EtMgBr-(+)-6-benzylsparteine, and $MgBr_2$-(+)-6-benzylsparteine molecules are depicted in Figs. 1, 2, and 3, respectively. Bond lengths and bond angles in these complexes are given in Figs. 4, 5 and 6, respectively.

(a) (+)-6-Benzylsparteine: The remarkable feature of the structure is that this molecule takes a one-boat form: six-membered ring made by the C(7), C(8), C(9), C(11), N(1), and C(17) atoms is in a boat form, whereas all of the other rings in chair forms. The C(2)-N(2)-C(6)-[115.5(3)°] and C(11)-N(1)-C(15) angles[111.7(4)°] are respectively larger than the corresponding angles in

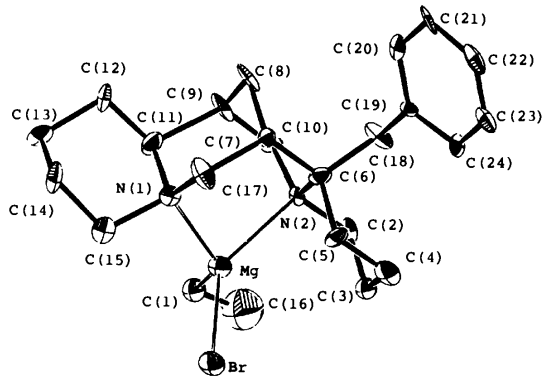

Fig. 2. A perspective view of EtMgBr-(+)-6-benzylsparteine molecule with the numbering scheme of atoms. Non-hydrogen atoms are drawn as thermal ellipsoids with 20% probability level.[9]

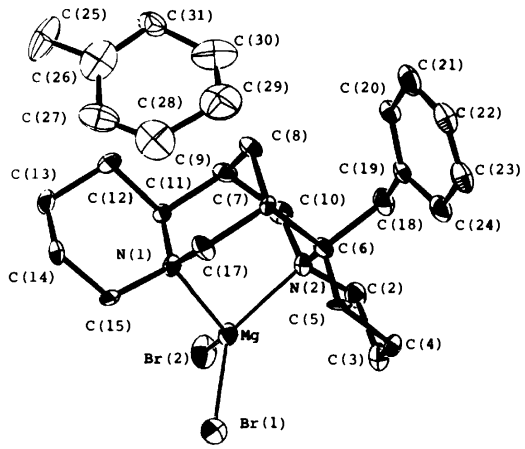

Fig. 3. A perspective view of $MgBr_2$-(+)-6-benzylsparteine and toluene, the crystalline solvent molecules with the numbering scheme of atoms. Non-hydrogen atoms are drawn as thermal ellipsoids with 20% probability level.[9]

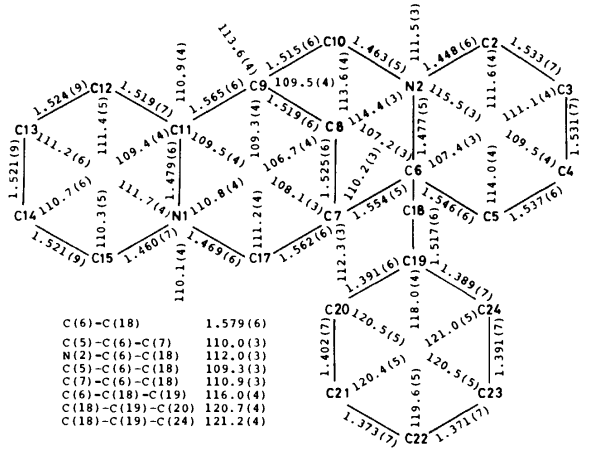

Fig. 4. Selected bond lengths [l/Å] and bond angles [ϕ/°] in (+)-6-benzylsparteine molecule.

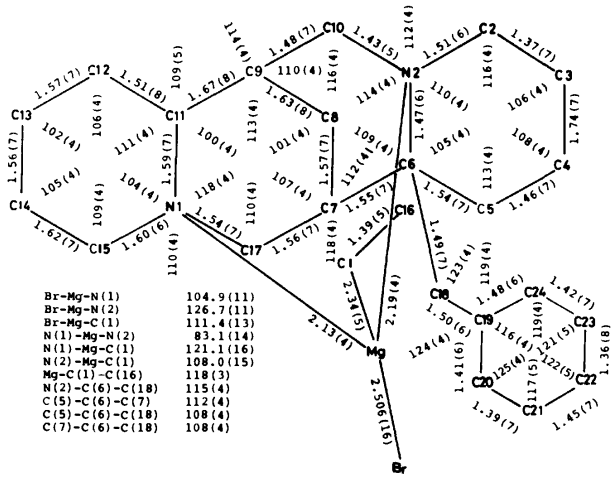

Fig. 5. Selected bond lengths [l/Å] and bond angles [ϕ/°] in EtMgBr-(+)-6-benzylsparteine molecule.

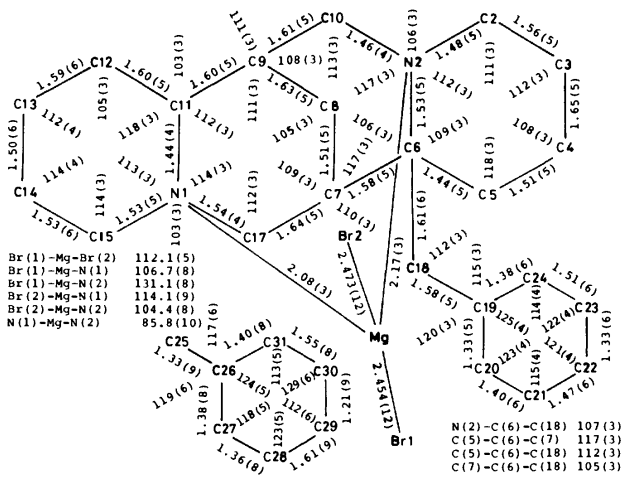

Fig. 6. Selected bond lengths [l/Å] and bond angles [ϕ/°] in $MgBr_2$-(+)-6-benzylsparteine and toluene, the crystalline solvent molecule.

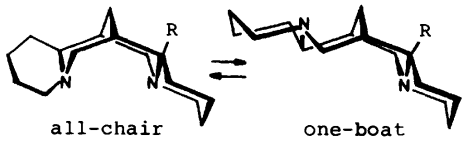
sparteine skeleton in 17β-methylsparteine diperchlorate [109.6(6) and 107.9(5)°][10] and episparteine N(16)-oxide sesquiperchlorate [110.6(3) and 109.0(3)°],[11] of which the sparteine moieties have one-boat form. Whereas the C(5)-C(6)-(7) angle [110.0(3)°] is smaller than those [115.8(7) and 116.5(3)°] in the two sparteine derivatives mentioned below.

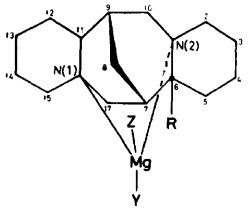


(b) EtMgBr-(+)-6-benzylsparteine: The sparteine skeleton in the (+)-6-benzylsparteine moiety has an all-chair form, and its structure is similar to those found in EtMgBr-(−)-sparteine,[2] *t*-BuMgCl-(−)-sparteine,[3] and $MgCl_2$-(−)-sparteine.[3] The spatial arrangement of the alkyl and halogen ligands the sparteine skeleton through the Mg atom is, similar to that in *t*-BuMgCl-(−)-sparteine,[3] reverse to that in EtMgBr-(−)-sparteine.[2] The coordination geometry around the Mg atom is distorted tetrahedral, which is similar to those observed in Grignard reagent-(−)-sparteine complexes.

(c) $MgBr_2$-(+)-6-benzylsparteine: The sparteine skeleton in the present complex also has an all-chair conformation. Distorted tetrahedral geometry is observed around the Mg atom.

(d) Structure of the Sparteine Skeleton in RMgX-(−)-sparteine Derivative Complexes. Through the five

Table 5. Comparison of the coordination geometry around the Mg atom with estimated standard deviations in parentheses



(a) Bond length[l/Å]

EtMgBr-(−)-α-isosparteine	83.9(5)	106.1(6)	129.7(6)	122.9(4)	101.4(4)	112.1(5)

RMgX-(−)-sparteine derivative complexes except EtMgBr-(−)-α-isosparteine, the (−)-sparteine ligand and sparteine skeleton of (+)-6-benzylsparteine ligand take all-chair form, and all of them have the same structure: corresponding bond lengths and bond angles are respectively equal within the range of error.

The (−)-sparteine ligand (or sparteine skeleton) consists of four fused N-containing six-membered rings; the fusion of N(1)-containing ring to the central symmetrically-fused two rings is different from that of N(2)-containing ring. The approximately Λ-shaped (−)-sparteine ligand has a cavity in which a Mg atom can coordinate. The C(7)-side of the cavity is spatially less open than the C(9)-side because of the unsymmetrical structure of (−)-sparteine ligand.

The (−)-α-isosparteine ligand has a C_2 symmetry. A half of its cavity is very similar to that of the C(7)-side of (−)-sparteine. The whole cavity of this ligand is more likely Λ-shaped and spatially less open than that of (−)-sparteine.

(e) Coordination Geometry around the Mg Atom in RMgX-(-)-sparteine Derivative Complexes: The geometry around the Mg atom is summarized in Table 5. In each complex the Mg atom has a distorted tetrahedral geometry. As shown in Table 5, two Mg-N bond lengths are equal [av. 2.15 Å], and the N-Mg-N angle is sharp and solid [83.1—85.8, av. 84.3°]. Regardless the geometrical relation of the alkyl and halogen ligands to the sparteine skeleton mentioned before, the Y-Mg-N(2) angle is larger than the Y-Mg-N(1), whereas the Z-Mg-N(2) angle is smaller than the Z-Mg-N(1). The Y-Mg-Z angle is slightly larger than the tetrahedral angle. Among the Mg-Y and Mg-Z bond lengths, the Mg-Cl lengths in *t*-BuMgCl-(−)-sparteine [2.332(7) Å] is much longer than those in dichloride, $MgCl_2$-(−)-sparteine [2.269(5) Å]. Similarly, the Mg-Br bond lengths in EtMgBr-(−)-sparteine, EtMgBr-α-isosparteine and EtMgBr-(+)-6-benzylsparteine look like longer than those in dibromide, $MgBr_2$-(+)-6-benzylsparteine though it is not fully significant. The Mg-C bond lengths in four complexes are equal [2.19(2)—2.34(5), av. 2.25 Å] within the range of error.

(f) Structure-dependence of Reactivity of RMgX-(−)-sparteine Derivative Complexes for the Asymmetric Selective Polymerization of (RS)-*MBMA*: In Table 6 summarized are molecular structures of EtMgBr-(−)-sparteine,[2] *t*-BuMgCl-(−)-sparteine,[3] EtMgBr-(+)-6-benzylsparteine (present study), and EtMgBr-(−)-α-isosparteine[4] and also results of enantiomer-selective

TABLE 6. STRUCTURE AND REACTIVITY OF RMgX-(−)-SPARTEINE DERIVATIVE COMPLEXES

Complex	Molecular Structure			Reactivity for the enantiomer selective polymerization of (*RS*)-MBMA (Ref. Table 1)
	Solid ball and spoke model[13]	Space-filling model[13]	Substrate-accomodation in the neighborhood of Mg atom	
EtMgBr-(−)-sparteine			Sufficiently large	Good
t-BuMgCl-(−)-sparteine			No	No
EtMgBr-(+)-6-benzylsparteine			Small	Poor
EtMgBr-(−)-α-isosparteine			No	No

polymerization of (*RS*)-MBMA initiated by these complex catalysts.[1] Discussion will be limited on the structural feature because the activity and selectivity of these complex catalysts has already been discussed in detail.[1]

It has been reported that the polymerization of MBMA proceeds in a coordination mechanism: the structure of the active center, which presumably depend on the structure of the sparteine skeleton and the geometry around the Mg atom, is considered of most importance.

In catalytically active EtMgBr-(−)-sparteine, the Et group coordinates to the Mg atom at the spatially less opened C(7)-side of the cavity (Y=Et) whereas the bulky Br ligand at the more opened C(9)-side. The Et group is not so large. The Mg atom, therefore, has a sufficient space to accommodate the MBMA, the substrate in its neighborhood.

On the other hand, in the inactive *t*-BuMgCl-(−)-sparteine, the bulky *t*-Bu ligand covers the Mg atom at the spatially more opened C(9)-side and the Cl ligand at the C(7)-side of the cavity (Y=Cl and Z=*t*-Bu). The spatial arrangement of alkyl and halogen ligands is reverse to that of EtMgBr-(−)-sparteine. As is clearly seen from the space-filling model[13] of this molecule (Table 6), there is no room spatially to accommodate the substrate in the neighborhood of the Mg atom.

In the poorly active EtMgBr-(+)-6-benzylsparteine, the all-chair form (+)-6-benzylsparteine ligand has a structure very close to the (−)-sparteine ligand except the benzyl group. The cavity under Λ-shaped sparteine skeleton is therefore very close to that of (−)-sparteine ligand. The Et ligand in this complex coordinates to the Mg atom at the more opened C(9)-side of the cavity. The alkyl and halogen ligands spatially arranged reverse to that of EtMgBr-(−)-sparteine (Y=Br and Z=Et).

In EtMgBr-(−)-α-isosparteine, the cavity of (−)-α-isosparteine is less opened than that of (−)-sparteine. The Mg atom coordinate deep in the cavity covered with Et and Br ligands, which leads the inactivity of this complex.

Crystal Structure. The packing of molecules in crystals of (+)-6-benzylsparteine, EtMgBr-(+)-6-benzylsparteine, and $MgBr_2$-(+)-6-benzylsparteine toluene solvate are drawn in Figs. 7, 8, and 9.

(a) (+)-6-Benzylsparteine: Rather loose molecular contacts are observed between carbon atoms of the benzyl group in one molecule and those of bridge-head carbons in the other molecule: The closest intermolecular atomic contact being 3.682(6) Å [C(24) (x, y, z)···C(9) $(-0.5+x, 0.5-y, -z)$].

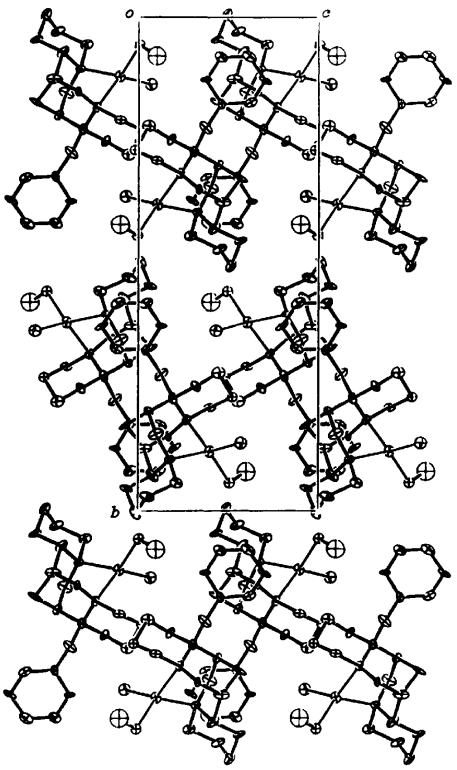

Fig. 8. The crystal structure of EtMgBr-(+)-6-benzylsparteine.[9]

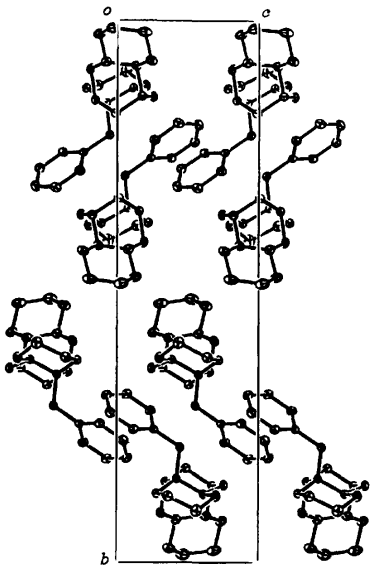

Fig. 7. The crystal structure of (+)-6-benzylsparteine.[9]

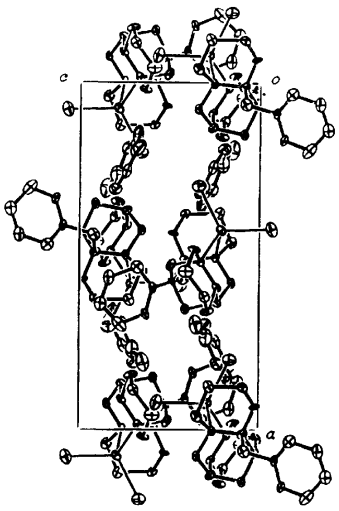

Fig. 9. The crystal structurre of $MgBr_2$-(+)-6-benzylsparteine toluene solvate.[9]

(b) EtMgBr-(+)-6-benzylsparteine: The molecular packing in the crystal is determined by the van der Waals contacts between carbon atoms of the benzyl group in one molecule to those of sparteine skeleton in the other molecule. The shortest intermolecular atomic contact is found between C(22) (x, y, z) and C(10) ($-0.5+x$, $0.5-y$, $1-z$) [3.52(7) Å].

(c) $MgBr_2$-(+)-6-benzylsparteine Toluene Solvate: The Mg complexes in the crystal are loosely bound to toluene molecules by van der Waals forces. The closest intermolecular atomic contact is 3.56(7) Å [both C(30) (x, y, z)···C(8) (x, y, z) and C(31) (x, y, z)···C(4)($-0.5+x$ $0.5-y$, $-z$)], whereas the shortest distance between Mg complexes is 3.74(4) Å [C(9) (x, y, z)···Br ($-0.5+x$, $0.5-y$, $-1-z$)].

A part of the cost of the present study is defrayed by the Grant-in-Aid for Scientific Research (No. 56470069), Ministry of Education, Science and Culture.

Decay Mechanism of the Aromatic Hydrocarbon Biradical, 1,1′-Biacenaphthene-2,2′-diyl. Effects of Solvent and Heavy-atom Perturbation

Harumichi KOBASHI,* Reiko KONDO,† Hiroki IKAWA,† and Toshifumi MORITA
Department of Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376
(Received, November 10, 1983)

Effects of solvents and heavy-atom (H-A) containing compounds on the lifetime of the title biradical (**1**) have been examined to elucidate the decay mechanism of **1** in fluid solutions by means of nanosecond laser spectroscopy. **1** was quenched effectively by H-A compounds such as diethylmercury and iodoethane. The decay rates of **1** showed no explicit correlation with solvent polarities, while a linear correlation was found between the decay rate and the sum of squares of the spin-orbit (S-O) coupling factors of heavy atoms involved in the solvents; chlorobezene, 1,2-dichloroethane, dichloromethane, bromobenzene, and dibromomethane. It has been shown that (i) the biradical lifetime is determined by intersystem crossing (ISC) from the triplet to singlet spin state prior to chemical reactions, (ii) ISC is enhanced by H-A perturbation through the S-O interaction, and (iii) the reactivity of the singlet biradical (^{1}**1**) but not the triplet one (^{3}**1**) sways the product distribution in the triplet-sensitized photodimerization of acenaphthylene.

Since a direct detection of Norrish type II biradicals in fluid solution,[1] dynamic properties of these biradicals have been studied considerably.[2] However, our knowledges about dynamic behavior of aromatic hydrocarbon biradicals have been still scarce in comparison with those for type II biradicals.[3]

Previously we reported an observation of aromatic hydrocarbon biradical **1** as an intermediate in the triplet-sensitized photocycloreversion of trans-dimer (t-D) of acenaphthylene.[4] The biradical **1** is also supposed as an intermediate for the triplet-sensitized photodimerization of acenaphthylene (A).[5,6] This reaction is known to be a typical example of a photochemical H-A effect[7] and to undergo a significant effect of solvent polarity.[6] Therefore, examinations of solvent and H-A effects on the biradical lifetime may be favorable for elucidating the decay behavior of **1** in relation to the dimerization reaction.

This paper deals with a nanosecond laser photolysis study of the biradical **1** under the influence of H-A compounds and solvents with various polarities, in order to clarify the decay mechanism of **1** having a characteristic structure different from the type II biradicals. It was of interest whether the decay rate of a triplet biradical would be determined by a chemical reaction or by ISC prior to chemical reactions. We here make it clear that the decay of **1** proceeds *via* the latter mechanism. We also intend to relate quantitatively the decay rates of **1** to the S-O interaction factors, because the already-known results of H-A effects on biradicals are only qualitative.[1a,3a] The present results show an explicit correlation between them, indicating that the decay rate is enhanced by H-A compounds through the S-O interaction. At the same time, a complex formation between **1** and EtI is proposed and a role of the biradical in the dimerization reaction is also discussed.

Experimental

Materials. The trans-dimer of acenaphthylene (t-D) and benzophenone (BP) were the same as those reported previously.[4] Benzene, toluene, 1,4-dioxane, and acetone were all spectrograde reagents (Dotite). Dibromomethane (Wako, GR grade) was used without further purification. Dichloromethane, 1,2-dichloroethane, chlorobenzene, bromobenzene, pyridine, and acetonitrile were purified by the usual methods. Iodoethane (Wako, GR grade), diethylmercury (Wako, CP grade), and diethyl sulfide (Wako, EP grade) were distilled under vacuum just before use.

Nanosecond Laser Photolysis. The 1,1′-biacenaphthene-2,2′-diyl (**1**) was observed by a nanosecond laser photolysis method at 347 nm.[4] The solutions used contained both t-D ($\geq 2\times10^{-3}$ mol dm^{-3}) and BP ($\approx 4\times10^{-3}$ mol dm^{-3}) as a triplet sensitizer. The lifetime of **1** was measured by monitoring the time-dependent intensity of its characteristic absorption band at 380 nm. When the absorption band of **1** was overlapped by a long-lived absorption of byproduct, *e.g.*, benzophenone ketyl radical, the interference absorption at 380 nm was subtracted from the observed absorption to obtain a true decay time of **1**. The quenching experiments of **1** by Et_2Hg, EtI, and Et_2S were performed in benzene solutions. All solutions were degassed by the usual freeze-pump-thaw method. The lifetime measurements were performed at 20±1 °C.

Results and Discussion

Transient Absorption Spectra. Before examination of the external solvent effects, transient absorption spectra of **1** were observed in each solvent at room temperature. The typical spectra are illustrated in Fig. 1. Figure 1a is the previously observed spectra in benzene given for comparison.[4] Figure 1b shows time-resolved absorption spectra observed in dichloromethane. The spectral profiles resemble well those given in Fig. 1a. Namely, in the early stage of time after excitation, absorption bands due to ^{3}BP and ^{3}t-D are observed around 530 and 450 nm respectively. Both bands decay rapidly and a strong absorption band grows around 380 nm. This is the characteristic absorption band of **1** (Fig. 1b-2). This band decays with the first-order kinetics. Figure 1c pictures the transient spectra in 1,4-dioxane. The absorption of **1** is observed also around 380 nm. In this case, a distinct absorption band with maximum at 545 nm still remains after disappearance of **1**. The absorption band monitored at 545 nm

† Present address: Japan Information Processing Service Co. Ltd., Kabuto-cho, Chuo-ku, Tokyo 103.

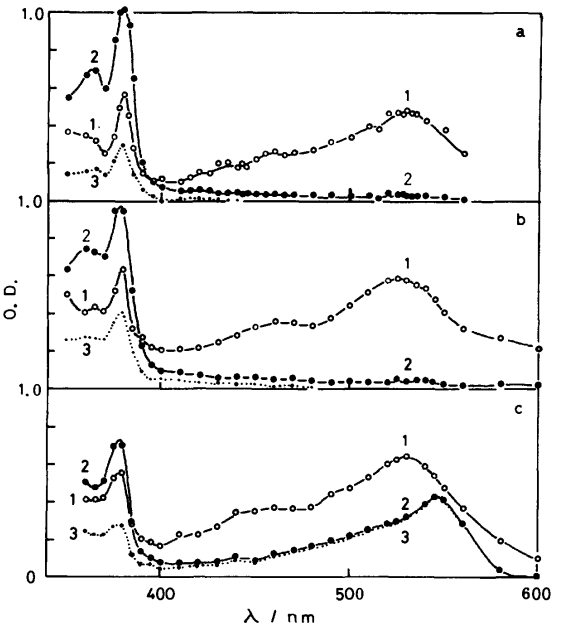

Fig. 1. Transient absorption spectra observed in the BP-t-D system. Solvent and delay time after the beginning of laser oscillation:
a) Benzene; (1) 40 ns, (2) 230 ns, (3) 730 ns, b) dichloromethane; (1) 40 ns, (2) 260 ns, (3) 660 ns, c) 1,4-dioxane; (1) 60 ns, (2) 280 ns, (3) 660 ns.

decayed slowly with the second-order kinetics. This long-lived transient can be identified to benzophenone ketyl radical (BPH·) from comparing the spectrum and decay kinetics with those of BPH· in the literatures.[8] The BPH· observed here is not a transient produced by a reaction between **1** and BP, because the absorbance of BPH· around 545 nm does not increase as the absorbance of **1** at 380 nm decreases during the time interval 280—660 ns (Fig. 1c). Furthermore, if BP in the ground state caused H-atom abstraction from ^{3}t-D, the abstraction reaction should occur in benzene or in dichloromethane as well. But no BPH· absorption is observed in these solvents (Figs. 1a and b). The BPH·, therefore, is not also a transient originated from the reaction between ^{3}t-D and BP. It is considered that BPH· forms through H-abstraction reaction by ^{3}BP from the solvent 1,4-dioxane which is a fairly good H-donor.[9] Because BPH· disappears much slower than **1**, the decay of BPH· is negligible in the time range required to analyze the biradical lifetime (τ_B). Then, the value of τ_B in 1,4-dioxane can be estimated by a simple procedure in which the absorbance of BPH· ($D_{BPH\cdot}$) is subtracted from the observed absorbance (D_{obsd}) using the following equation:

$$D_{obsd} - D_{BPH} = (D^0_{obsd} - D_{BPH\cdot})\exp(-t/\tau_B),$$

where D^0_{obsd} is the observed absorbance at the time origin arbitrarily taken in the time domain where the decay curve is exponential.

Quenching of 1 by H-A Containing Compounds. Figures 2a, 2b, and 2c present the Stern-Volmer plots of lifetimes against concentrations of the quenchers Et_2Hg, EtI, and Et_2S, respectively, in benzene. The quenching by Et_2Hg shows a good linear relation

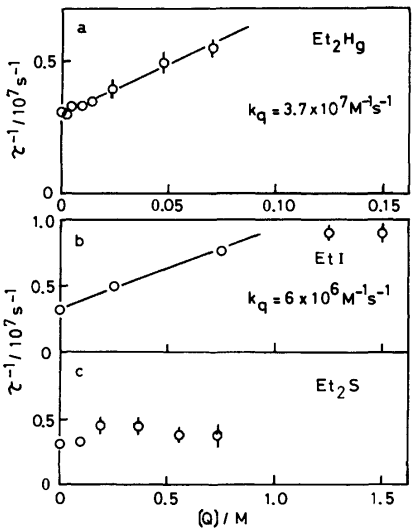

Fig. 2. Stern-Volmer plots of the inverse lifetime τ^{-1} *vs.* quencher concentration [Q]. The quencher Q: a) Et_2Hg, b) EtI, c) Et_2S. (1 M = 1 mol dm^{-3})

with the rate constant k_q: 3.7×10^7 dm^3 mol^{-1} s^{-1} (Fig. 2a). The quenching curve by EtI approaches gradually the maximum value near *ca.* 1×10^7 s^{-1} with increasing [EtI]. In the range of [EtI]<1 mol dm^{-3} the curve can be approximated by a straight line corresponding to k_q: *ca.* 6×10^6 dm^3 mol^{-1} s^{-1}. This line is added into Fig. 2b. Figure 2c indicates that Et_2S is not an effective quencher for **1**. Thus, the quenching efficiencies correspond to the order of magnitude of the atomic number of heavy atoms (Hg, I, and S) in the quenchers, suggesting that the quenching events are caused by external H-A effect.

The nonlinearity of the Stern-Volmer plots, as shown in Fig. 2b, has been frequently observed in the high concentration region of quenchers (>1 mol dm^{-3}). As for the quenching mechanism there are some interpretations in terms of the decrease of the activity coefficients of quenchers,[10] the change of radiationless transition induced by change of solvent composition,[11] and the formation of ground- or excited-state complex.[12,13] In recent studies the exciplex mechanism appears to be an appropriate one to the H-A effect of EtI on the quenching of both excited singlet and triplet states of aromatic hydrocarbons.[14,15] Since **1** is composed of aromatic hydrocarbon moieties similar to chromophores in the exciplex forming systems noted above, a weak complex formation may be expected between **1** and EtI. We attempted to analyze the quenching curve for EtI from a view point of the complex formation, although no explicitly spectral evidence indicating the complex formation was observed up to the heighest concentration (2.5 mol dm^{-3}) of EtI so far as we examined.[16] The quenching curve bending downward suggests the existence of the so-called dynamic equilibrium[17] represented as follows:

$$\mathbf{1} + \mathrm{EtI} \underset{k_b}{\overset{k_a}{\rightleftharpoons}} \mathbf{1}\cdots\mathrm{EtI}, \qquad (1)$$

with τ_B^{-1} and τ_C^{-1}

where τ_B and τ_C are the lifetimes of **1** in the absence of EtI and the complex **1**···EtI respectively, k_a and k_b are the rate constants of association and dissociation processes respectively, and the equilibrium constant K is defined by k_a/k_b. When the dynamic equilibrium condition,

$$k_a[\mathrm{EtI}],\ k_b \gg \tau_B^{-1},\ \tau_C^{-1}, \tag{2}$$

holds completely, the apparent lifetime (τ) of **1** in the presence of EtI should satisfy the following two relations expressed by Ware *et al.*[18] and Rayner and Wyatt[19] respectively:

$$(\tau^{-1}-\tau_B^{-1})^{-1} = (\tau_C^{-1}-\tau_B^{-1})^{-1}(1+K^{-1}[\mathrm{EtI}]^{-1}), \tag{3}$$

and

$$[\mathrm{EtI}]^{-1}(\tau^{-1}-\tau_B^{-1}) = K(\tau_C^{-1}-\tau^{-1}). \tag{4}$$

Although both equations are derived from the same kinetic assumption (Eq. 2), Eq. 3 is sensitive to τ values in the relatively low concentration region of the quencher and Eq. 4 reflects rather well the variation in τ in the relatively high concentration region. Figures 3a and 3b show the relations corresponding to Eqs. 3 and 4 respectively for the lifetimes (τ) measured at 8 different concentrations of EtI in the range of 0.25—2.5 mol dm^{-3}. Both equations fit well the experimental results. The values of K 0.64±0.06 dm^3 mol^{-1} and τ_C 65± 5 ns are obtained from Fig. 3a and K 0.72±0.09 dm^3 mol^{-1} and τ_C 69±13 ns are obtained from Fig. 3b. A good agreement in each K and τ_C values estimated from the two different kinetic expressions suggests strongly the existence of **1**···EtI in the equilibrium as indicated in Eq. 1. The complex formation contributes to enhancement of the biradical decay through the S-O interaction as is indicated later.

Effects of H-A Solvents and Solvent Polarities. Table 1 lists the values of biradical lifetimes (τ_B)

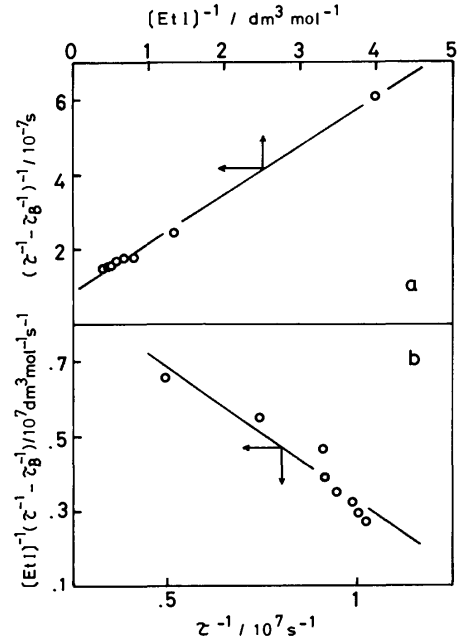

Fig. 3. Kinetic relations corresponding to (a) Eq. 3 and (b) Eq. 4.

Table 1. Decay times of **1** in various solvents at 20 °C

Solvent	ε	$\sum\zeta^2/10^6$ cm^{-2}	τ_B/ns
1,4-Dioxane	2.21		270
Benzene	2.28		300
Toluene	2.38		290
Bromobenzene	5.39	6.05	152
Chlorobenzene	5.71	0.34	289
Dibromomethane	7.04	12.1	84
Dichloromethane	8.93	0.69	295
1,2-Dichloroethane	10.66	0.69	350
Pyridine	13.23		290
Acetone + 1,2-Dichloroethane (1 : 1 in volume)	15.7[a]		380
Acetonitrile + Benzene (1 : 1 in volume)	24.6[a]		310

a) The values of mixed solvents are obtained by assuming additivity: $\varepsilon_{mix}=\sum\chi_i\varepsilon_i$, where χ_i is the molar fraction and ε_i corresponds to ε of i-th component solvent.

measured in several solvents together with those of dielectric constant (ε) of the solvents. The errors in τ_B values are *ca.* 10%. The mixed solvents were employed as highly polar solvents because of low solubility of t-D in neat acetone or acetonitrile. For H-A solvents of bromobenzene, chlorobenzene, dibromomethane, dichloromethane, and 1,2-dichloroethane the sum of squares of S-O interaction factors (ζ) of halogen atoms involved in the solvents are additionally given in Tabel 1.[20] The $\sum\zeta^2$ values are a measure of the magnitude of transition probability induced by S-O interaction; $k_{ISC}\propto\langle^1\phi|H_{SO}|^3\phi\rangle^2\propto\sum\zeta^2$, where k_{ISC} is the probability of ISC induced by heavy atoms and $\langle^1\phi|H_{SO}|^3\phi\rangle$ is the S-O coupling matrix element between singlet and triplet states.

The τ_B values in the H-A solvents decrease with the order of 1,2-dichloroethane, dichloromethane, chlorobenzene, bromobenzene, and dibromomethane. This tendency is parallel to that for the quenching rate constants in the addition effect of H-A compounds. To show this effect quantitatively, Fig. 4 illustrates a relation between τ_B^{-1} and $\sum\zeta^2$. There exists a linear relation. Therefore, it is evident that the S-O interaction is the origin of the H-A solvent effect enhancing the decay rate of **1**. Although the compounds involving Cl- or S-atom show no recognizable H-A effect, this seems due to much smaller S-O interaction factors of these atoms than those of Br- and I-atoms.

Next we notice the effect of solvent polarity on the lifetime. The τ_B values in Table 1 do not show any appreciable correlation with solvent polarities and are close to one another except for the lifetimes in bromobenzene and dibromomethane (H-A solvents). Accordingly, the biradical lifetimes can be regarded to be almost independent on solvent polarity. In contrast, it is known that a lifetime of the Norrish type II biradical **2** derived from 4-methyl-1-phenyl-1-pentanone depends strongly on the polarity and hydrogen-bonding strength of solvents.[1a,2a] Such influence of H-bonding ability is not found for the case of **1**. These different

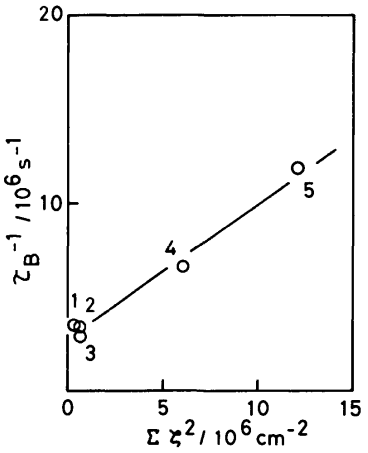

Fig. 4. The relation between the inverse lifetime of **1** (τ_B^{-1}) and the S-O interaction parameter ($\Sigma\zeta^2$); 1) chlorobenzene, 2) dichloromethane 3) 1,2-dichloroethane, 4) bromobenzene, and 5) dibromomethane.

features between **1** and **2** as to the solvent effects seem to arise from difference in their molecular structures. That is, **1** has a structure composed of two identical aromatic π-radical sites with no or weak H-bonding property but **2** consists of two different radical sites one of which has a hydroxyl group to cause readily H-bonding with basic solvents. Besides **1** would have a smaller dipole moment than **2**. Therefore, it is understood that **1** is less sensitive to the solvent polarity as well as H-bonding ability.

Decay Mechanism of 1 and Photodimerization of Acenaphthylene. A previous report[4] demonstrated that (i) **1** is a triplet-derived biradical with a fairly long life, (ii) its decay rate is approximately temperature-independent, (iii) the frequency factor of an Arrhenius plot for the decay rate constant is so small (1.9×10^6 s^{-1} in benzene) as to suggest a spin-forbidden nature of the decay process, and (iv) **1** is quenched by oxygen, a paramagnetic molecule, with a nearly diffusion-controlled rate constant 0.9×10^{10} dm^3 mol^{-1} s^{-1} in benzene at 20 °C. These properties of **1** resemble quite well those of familier triplet state type II biradicals. From these knowledges, **1** has been ascribed to be a biradical in the triplet spin state (^{3}**1**). We here discuss the decay mechanism of ^{3}**1** relating the mechanism of photodimerization of A on the basis of the previously-mentioned results together with already-known results of the photodimerization reaction.

In an examination of solvent effect on the triplet-sensitized dimerization of A, it has been reported that the logarithm of the ratio between the yields of the products t-D and c-D, log[t-D]/[c-D], correlates linearly with the Kirkwood-Onsager parameter $(\rho/M)(\varepsilon-1)/(2\varepsilon+1)$ where ρ is the solvent density and M is the molecular weight of solvent.[6,21] Nevertheless, as seen from Table 1, the decay rate of ^{3}**1** is not governed by the above relation and other solvent polarity parameters. It turns out, therefore, that ^{3}**1** does not concern directly the reaction steps determining the product distribution of c- and t-D. Since the τ_B values are approximately unaltered in the several kinds of light-atom solvents, it is supposed that ^{3}**1** does not react directly with the solvents. The validity of this supposition may be justified by the fact that the material balance of the dimerization reaction is approximately 100% in several solvents; cyclohexane, benzene, and methanol.[5] Because byproduct formation is negligible even in the H-A solvent, 1-bromopropane,[5,22] it may be also plausible that the biradical quenching by the H-A perturbers is not due to chemical reactions between ^{3}**1** and the perturbers. The spin-allowed dissociation of ^{3}**1**$\rightarrow{}^3$A*+A is thermally forbidden, so that this process is difficult to take place. ^{3}**1** is considered to exist in the potential minimum, *i.e.*, the relaxed state, since its lifetime was observably long. Then, a fairly high activation energy (at least, a few kcal mol^{-1}) would be required for the biradical decay if ^{3}**1** caused spin inversion concomitantly with bond beaking (*i.e.*, ^{3}**1**$\rightarrow$2A) in which ^{3}**1** must be activated thermally in the triplet state potential surface to take a conformation favorable for the dissociation yielding 2A. However, no activation energy was observed for the decay rate of ^{3}**1** in benzene.[4] Therefore, the spin-forbidden process of ^{3}**1**$\rightarrow$2A does not seem to participate in the radiationless decay of ^{3}**1**. Hence, the lifetime of ^{3}**1** must be determined by the rate of ISC as a physical process from the triplet to the singlet spin state (^{1}**1**) both in the presence and absence of the perturbers (X). The most reasonable decay routes of ^{3}**1** can be represented as follows:

$$^3\mathbf{1} \xrightarrow[(+X)]{\text{ISC}} {}^1\mathbf{1} \begin{cases} \nearrow \text{c-D} \\ \rightarrow \text{t-D} \\ \searrow 2\text{A} \end{cases}, \qquad (5)$$

where ^{1}**1** decays so rapid as unable to be observed by the nanosecond laser photolysis. Since ^{3}**1** involves no decay process other than ISC, the increase in the rate of ISC induced by the H-A compounds does not lead to increase in the total yield of the dimers in the triplet-sensitized dimerization reaction. This suggestion is consistent with the previous results that a kinetic analysis for the yield of the dimers can be treated without regard to the enhancement of biradical spin relaxation and hence H-A solvents may act only as solvents with certain polarities on the product distribution.[22,23]

It is known that the quantum yields for directly excited photodissociation of c- and t-D, which are assumed to dissociate via respective biradical states in the singlet multiplicity,[24,25] are different from each other.[25-27] These results imply that the reactivity of ^{1}**1** depends strongly on its conformation immediately after generation. Such importance of biradical conformation in determining product distribution has been proposed for type II biradicals.[2b,28] On the other hand, the present result regarding effect of solvent polarity suggests that the conformations of ^{3}**1** in various solvents are not so much different from one another as to vary the ISC rate depending on difference of solvent polarities, since the rate of ISC is determined normally by the magnitude of S-O interaction matrix element which is sensitive to conformation of a biradical. Such circumstance would be the case for ^{3}**1** at the moment when ISC occurs. If the conformation does not change during ISC, the conformations of ^{1}**1** immediately after generation would be nearly identical to one another in different

solvents as the case for ^{3}**1** is so. Therefore, it may be thought that the product distribution of c- and t-D is swayed by the solvent-dependent rate constants of ^{1}**1** producing c- and t-D but not by difference in the conformations of ^{1}**1** immediately after generation.[29] However, further study about dynamic nature of the short-lived singlet biradical ^{1}**1** will be needed to elucidate a detailed mechanism of the solvent effect on the product distribution.

It has been pointed out that two types of spin inversion concerning the mechanism of ISC in a triplet biradical are assumed: One is a spin inversion leading to singlet biradical prior to chemical reactions (Mechanism I) and the other is a spin inversion occuring concurrently with reactions to yield some products of the singlet state (Mechanism II).[30] In the present case, it is clear that ISC corresponds to Mechanism I, since no direct chemical reaction occurs in the triplet biradical while the singlet biradical may be an actual intermediate which plays an essential role in determining the product distribution.

The authors are grateful to Prof. Haruo Shizuka for his interest and critical manuscript reading.

Aqueous Dispersion of Iron Oxide by Acrylic Oligomer Surfactants

Kunio ESUMI,* Kimihiko OGIHARA, and Kenjiro MEGURO
Department of Applied Chemistry and Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received November 18, 1983)

The aqueous dispersion of iron oxide by acrylic oligomer surfactants was examined by particle size and zeta potential measurements. Iron oxide particles were suspended in an aqueous iron(III) chloride solution to render the surface positively charged. The iron oxide particles so prepared were then flocculated by the addition of a small amount of acrylic oligomer surfactant. The flocs of iron oxide could be redispersed by further addition of acrylic oligomer surfactant. The flocculation and the redispersion processes can be explained in terms of a "two-fold adsorption layer" mechanism of the acrylic oligomer surfactant. The concentrations of acrylic oligomer surfactants needed to achieve flocculation and redispersion decreased with an increase in acrylic content of the oligomer surfactants.

Recently, from the standpoint of environment pollution and of conservation of resources, water-base dispersion has become attractive rather than an organic-base one. Thus, it is important to prepare stable dispersions in aqueous solution. Although many kinds of surfactants have been utilized[1-3] for this purpose, they have some deficiencies such as poor film formation and sensitivity to water vapor after drying the film. Of these surfactants, oligomer surfactants[4-7] which exhibit characteristics of low molecular surfactant and of polymer surfactant have been developed and employed for dispersion of pigments due to suitable properties such as improvement of film formation and resistance to water vapor. However, there are few reports concerning dispersion of pigments by oligomer surfactants.

In this work, to elucidate an interaction of oligomer surfactant and pigment, dispersion of iron oxide by acrylic oligomer surfactants in diluted system was studied by measuring the particle size and the zeta potential.

Experimental

Materials. The oligomer surfactants used in this work were synthesized by co-oligomerization[5] of acrylic acid, acrylonitrile, and 1-dodecanethiol, followed by neutralization with potassium hydroxide. The chemical structure and analytical properties of the oligomer surfactants obtained are given in Table 1. All the chemicals were of reagent grade. The water used was purified by passing through Milli-Q Reagent Grade Water Systems until its specific conductivity fell below $10^{-7}\,\Omega^{-1}\,cm^{-1}$. As a pigment, α-Fe_2O_3 was supplied by Titan Chemicals. The specific surface area and isoelectric point of the sample were 6.4 m^2/g and 1.9, respectively.

Procedure. The suspensions of iron oxide were prepared as follows: 0.01 g of solids was added to 150 cm^3 of a desired aqueous solution and treated for 5 min in a Bransonic ultrasonic bath. The particle size distribution was determined by a centrifugal particle size analyzer CP-50 (Shimadzu Seisakusho Co., Ltd.). The zeta potential of the sample was measured with a Laser Zee 500 (Pen Kem Inc.) electrophoresis apparatus.

Results and Discussion

To elucidate the effect of oligomer surfactants on the dispersion of iron oxide, it is necessary to obtain a well dispersed system. For this purpose, iron oxide solids were suspended in aqueous iron(III) chloride solutions. From the facts[8] that the mean particle sizes show a minimum value and the zeta potential of the iron oxide reaches a maximum value at about 0.5 mmol dm^{-3} iron(III) chloride, the stock dispersion in 0.5 mmol dm^{-3} iron(III) chloride was used in further studies.

On the addition of a small amount of oligomer surfactant(I) to aqueous suspensions of iron oxide particles in 0.5 mmol dm^{-3} iron(III) chloride, the iron oxide particles flocculated, but the flocs redispersed on further addition of the same surfactant. The mean particle size of the iron oxide increased with rising concentration of oligomer surfactant(I), reached a maximum value at 0.016 mmol dm^{-3} and then decreased on further addition of oligomer surfactant(I) as shown in Fig. 1(a). The positively charged iron oxide particles in an aqueous iron(III) chloride solution were discharged in the presence of oligomer surfactant(I) and then the charge was reversed to negative on further addition of this surfactant (Fig. 1(b)). The zero point of charge of iron oxide was about 0.016 mmol dm^{-3} of oligomer surfactant(I); this value corresponds to the concentration of oligomer surfactant(I) at which the maximum mean particle size was established.

The flocs formed by the addition of this surfactant could be easily suspended in toluene by shaking, which indicates that the surface of the solids became hydrophobic by adsorption of oligomer surfactant(I). The behavior of the other oligomer surfactants(II)—(V)

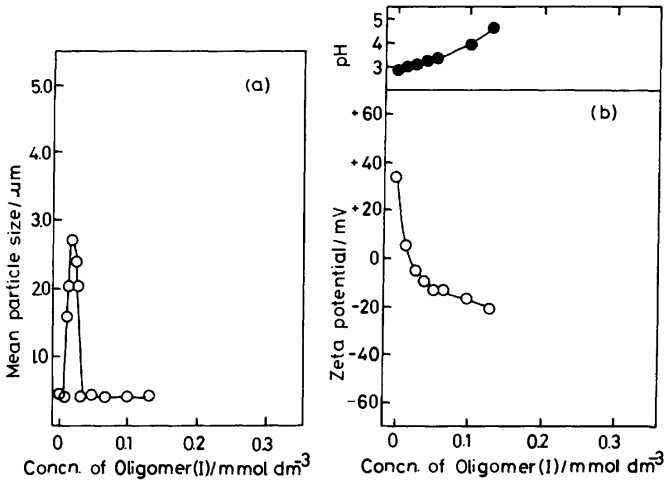

Fig. 1. The variation of the mean particle size and the zeta potential of iron oxide in the presence of 0.5 mmol dm^{-3} iron(III) chloride as a function of added oligomer surfactant(I).

was analogous to that of oligomer surfactant(I).

The redispersion of the iron oxide flocs was investigated by further addition of oligomer surfactant(I). Figure 1(a) shows that the mean particle size of iron oxide flocs decreased with the concentration of the oligomer surfactant(I). The complete redispersion occurred at about 0.029 mmol dm^{-3} of oligomer surfactant(I). In the cases of the other oligomer surfactant(II)—(V), similar results were obtained.

A model for the mechanisms of flocculation and redispersion processes can be explained in terms of the "two-fold adsorption layer" similar to that suggested earlier.[9,10] That is, the iron oxide is positively charged in an aqueous iron(III) chloride solution providing a well dispersed state characterized by a minimum in the mean particle size and a maximum in the zeta potential. On addition of a low concentration of oligomer surfactant(I), the particles are discharged and their size increases. As the hydrocarbon chains of the oligomer surfactant(I) are oriented outward, the particles become hydrophobic and flocculation takes place. On further addition of oligomer surfactant(I), the adsorption of this surfactant occurs by a hydrophobic-hydrophobic interaction resulting in a two-fold layer with the ionized groups of the second layer oriented towards the solution. Accordingly, the particles are recharged and redispersion is achieved, mainly due to the electric repulsion. For the other oligomer surfactant(II)—(V), the mechanism mentioned above can also be applied for the flocculation and the redispersion of iron oxide.

Furthermore, the flocculation and redispersion states of iron oxide by addition of oligomer surfactants were estimated by applying the D.L.V.O. theory.[11] According to the D.L.V.O. theory the total potential energy V between the two particles is obtained by a summation of the repulsive potential V_R and the attractive potential energy V_A:

$$V = V_R + V_A. \tag{1}$$

For this system, V_R for spherical particles is given:

$$V_R = \frac{\varepsilon a \psi_0^2}{2} \ln(1 + e^{-\kappa H}), \tag{2}$$

where ψ_0 is the surface potential of the particles, "a" the particle radius, ε dielectric constant of the medium, κ the reciprocal of the thickness of double layer and H the shortest distance between the two particles. Attractive potential energy V_A is given by the Hamaker equation,[12] assuming the attraction between the particles is entirely based upon the London-van der Waals forces and $H \ll a$,

$$V_A = -\frac{Aa}{12} \frac{1}{H}, \tag{3}$$

where A is the Hamaker constant. Substituting Eq. 2 and Eq. 3 into Eq. 1, we obtain:

$$V = \frac{\varepsilon a \psi_0^2}{2} \ln(1 + e^{-\kappa H}) - \frac{Aa}{12H}. \tag{4}$$

Assuming ψ_0 equals to zeta potential and using the proper value of A, the values of V for all the systems can be obtained from Eq. 4.

The values of V for iron oxide suspensions dispersed with oligomer surfactant(I) in the presence of iron(III) chloride are plotted as a function of H in Fig. 2. Here, the value of A (4.5×10^{-13} erg)[2] is used for number of 1 and 2, and A (4.7×10^{-14} erg)[13] for number of 3 and 4. The latter value was obtained from consideration of the two-fold adsorption layer. In number of 1, the repulsive force operates between the two iron oxide particles when they approach, resulting in the stable suspensions. On the other hand, V becomes negative values over all the H for the concentration of the number of 2 indicating unstable suspensions. In the numbers of 3 and 4, V becomes positive values. This suggests that the suspensions become stable. For the other oligomer surfactants, similar potential curves were obtained like that of oligomer surfactant(I). Thus, the flocculation and redispersion states of iron oxide can be explained

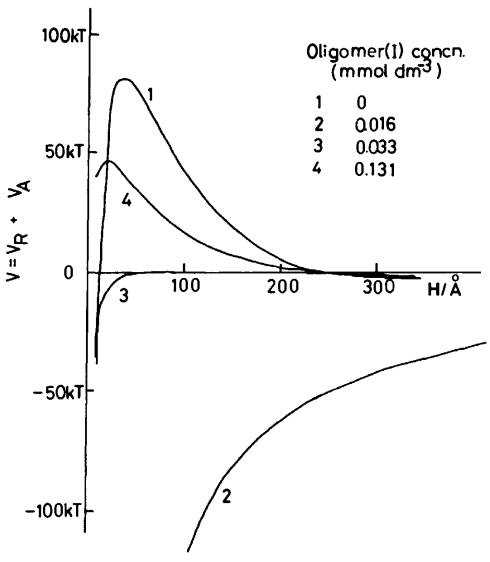

Fig. 2. The relation between V and stability for oligomer surfactant(I).

Table 2. Maximum flocculation and redispersion concentration for iron oxide dispersion

Oligomer	C_{mf}/mmol dm^{-3}	C_{rd}/mmol dm^{-3}
(I)	0.016	0.029
(II)	0.023	0.060
(III)	0.035	0.094
(IV)	0.045	0.061
(V)	0.032	0.10

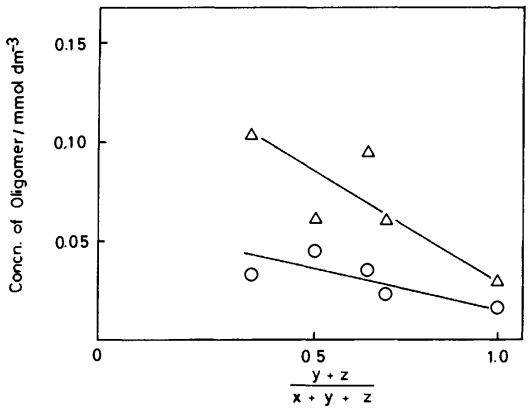

Fig. 3. The variation of the maximum flocculation and the redispersion concentration as a function of acrylic content in oligomer surfactants: (○) maximum flocculation concentration, (△) redispersion concentration.

by the D.L.V.O. theory.

To study the effect of different composition of oligomer surfactants on the dispersion of iron oxide, the maximum flocculation and redispersion concentration values are listed in Table 2 and plotted in Fig. 3. As the acrylic content in the oligomer surfactant molecule increases, the maximum flocculation concentration gradually decreases, while the redispersion concentration decreases more steeply than for the maximum flocculation concentration. The above results suggest that the oligomer surfactant with the higher acrylic content is adsorbed effectively to the positively charged iron oxide, thus resulting in lowering the maximum flocculation concentration. On the other hand, since oligomer surfactants with lower acrylic content seem to be coiled more closely in the solution, the adsorption of a second layer due to hydrophobic-hydrophobic interaction would not occur effectively. Furthermore, as oligomer surfactants with lower acrylic content contain less ionized groups, the second layer of the oligomer surfactant with the lower acrylic content would not enhance electric repulsion significantly. Therefore, to attain redispersion by adding oligomer surfactant with a lower acrylic content, more dense adsorption at the second layer is required. Thus, the redispersion concentration with oligomer surfactant with lower acrylic content becomes higher. It is found that a different composition of the oligomer surfactant molecule on the dispersion of iron oxide provides a different flocculation and a redispersion concentration.

The authors express their thanks to Miss S. Oguro and Miss A. Miyamoto for their assistance through this work.

Catalytic Activity of MoO_3 and V_2O_5 Highly Dispersed on TiO_2 for Oxidation Reactions

Takehiko Ono,* Yoshiro Nakagawa, Hisashi Miyata, and Yutaka Kubokawa
Department of Applied Chemistry, University of Osaka Prefecture, Sakai, Osaka 591
(Received December 3, 1983)

The structure of Mo-Ti oxide catalysts has been investigated by using IR and XRD techniques. At a low Mo content, MoO_3 is highly dispersed on TiO_2, an amorphous phase being formed. Simultaneously, a shift of the Mo=O band from 995 cm^{-1} to 950 and 905 cm^{-1} takes place. The maximum rate of the oxidation of C_2H_5OH and C_3H_6 over Mo-Ti-6(atom% of Mo) is attributable to the weakening of the Mo=O bond. The ^{18}O tracer and kinetic studies of the oxidation of C_3H_6 over Mo-Ti and V-Ti oxides suggest that a redox mechanism is applicable, the rate constants of reduction and reoxidation step being determined. The promoter action of TiO_2 support is attributed mainly to the increase in the rate of reduction step.

Previously we have reported that the promoter effect observed with V-Sn and Mo-Sn oxide catalysts in C_3H_6 oxidation arises from the formation of an amorphous material between each component in those composite catalysts.[1-3] It has been also shown that an amorphous phase formed with V-Ti oxides[4] at a low vanadium content is characterized by vanadate dispersed on TiO_2 in a monolayer, its distorted structure bringing about the weakening of V=O bond, *i.e.*, enhancement of the activity for the oxidative dehydrogenation of C_2H_5OH. As regards Mo-Ti oxide catalysts, a number of workers have studied the correlation between the surface structure and the catalytic activity by means of various techniques such as XRD,[5] IR,[5,6,7] XPS,[8] and *etc.*[7,9] Our understanding of this problem, however, is very far from complete.

In this work, the structure of Mo-Ti oxide catalysts have been investigated in a similar manner to that used in the studies of V-Ti oxides,[4] its correlation with the activity for the oxidative dehydrogenation of C_2H_5OH being examined. With V-Sn and V-Mo oxide catalysts, the nature of the oxygen species responsible for C_3H_6 oxidation has been recently discussed on the basis of the results of ^{18}O tracer and kinetic studies.[2] Similar studies have been extended to Mo-Ti as well as V-Ti oxide catalysts, since such studies are expected to provide information on the nature of the active phase of those catalysts.

Experimental

Materials. Mo-Ti oxides were prepared as follows: The slurry containing desired quantities of TiO_2 (p-25, Degussa) and ammonium heptamolybdate was evaporated with constant stirring. The dried product was calcined at 400 °C. MoC_3 was prepared by heating ammonium heptamolybdate at 450 °C. The surface area of the catalysts determined by the BET method were as follows: TiO_2, 45; Mo-Ti-3 (containing Mo in 3 atom%), 43; Mo-Ti-6, 41; Mo-Ti-24, 30; Mo-Ti-55, 15; MoO_3, 2 m^2/g. The V-Ti oxide catalysts used were the same as those in the previous paper.[4] $^{18}O_2$(99.1 atom%) was obtained from B.O.C. Limited (U. K.).

Apparutus and Procedures. The catalytic oxidation of C_3H_6 and C_2H_5OH was carried out in a closed circulation system (*ca.* 290 cm^3). The reaction products such as CH_2=CHCHO, CO, CO_2, CH_3CHO, and CH_3COCH_3, were analyzed by gas chromatography. The ^{18}O% in the reaction products were determined with a Hitachi RMU-6E mass spectrometer using the following ionization voltage: 80 eV for CO and CO_2, 15.5 eV for H_2O, and 15 eV for CH_2=CHCHO. X-Ray diffraction patterns (XRD) of the catalysts were obtained on both Rigaku Denki D-3F and RAD-rA diffractometers using Cu $K\alpha$ radiation with a Ni filter. With RAD-rA, the goniometer moter system and the signal were interfaced with a versatile data-aquisition system. The RAD-rA diffractometer can detect a small amount of crystalline MoO_3 at a lower Mo content. IR spectra of Mo-Ti oxides were recorded on a Hitachi EPI-G2 infrared spectrometer.

Results and Discussion

Structure of Mo-Ti Oxides. XRD patterns of Mo-Ti oxides showed only lines due to MoO_3 and TiO_2 phases. Figure 1 shows the XRD patterns of MoO_3 phase in Mo-Ti-3 and -6 as well as in their corresponding mechanical mixtures of pure MoO_3 and TiO_2. The intensities of the diffraction lines due to MoO_3 in the Mo-Ti catalysts are much smaller than those of the corresponding mixtures. With Mo-Ti-3, about 100% of the Mo oxide is present as an amorhous phase and

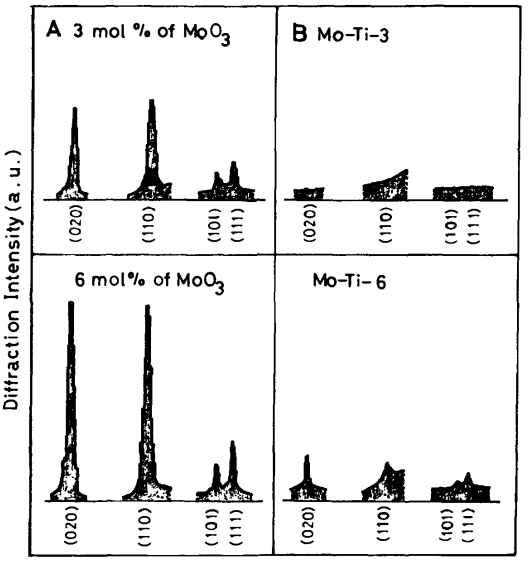

Fig. 1. X-Ray diffraction intensities of Mo-Ti oxides. (A) Mechanical mixtures of molybdenum and titanium oxides; (B) Mo-Ti oxide catalysts. (*hkl*) denote the crystal planes of MoO_3. Each diffraction line was integrated at 0.05° intervals of diffraction angle for 20 s.

with Mo-Ti-6 about 80—90%. Figure 2 shows the average intensities with Mo-Ti-24 and -55 together with the corresponding values for Mo-Ti-3 and -6. With Mo-Ti-24 and -55 catalysts MoO_3 crystals are somewhat oriented in a particular direction. As shown in Fig. 2, most of MoO_3 is amorphous at a low Mo content, its crystallinity increasing at a higher Mo content.

The IR spectra of Mo-Ti oxides containing more than 24 atom% of Mo show sharp bands at 995 and 885 cm^{-1} due to MoO_3(Fig. 3c, d). With Mo-Ti-3 and -6, these band are scarcely observed (Fig. 3 a, b). As has been done in the case of V-Ti oxides,[4], the TiO_2 disk, the weight of which corresponds to the TiO_2 content in the Mo-Ti oxides, was placed in the reference beam in order to offset the absorption due to TiO_2. As shown in Fig. 3e, f, the new bands at 950 and

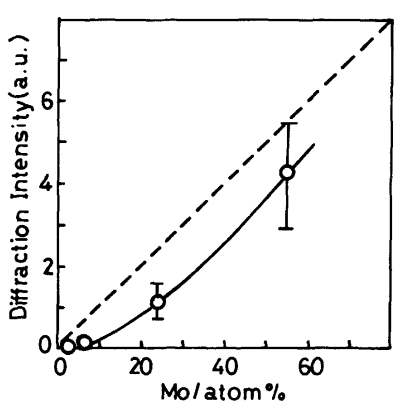

Fig. 2. X-Ray diffraction intensities of MoO_3 in the TiO_2-MoO_3 mixtures (dotted line) and in Mo-Ti catalysts (solid line) as a function of Mo content.

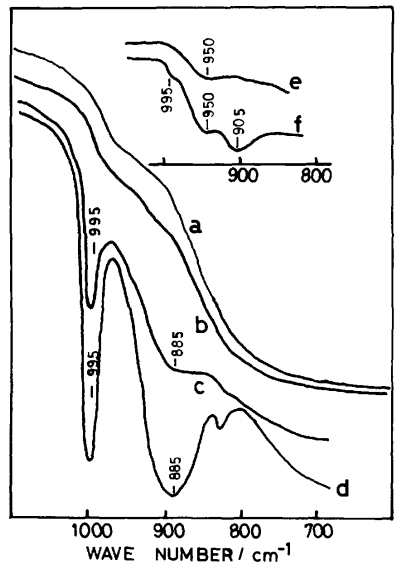

Fig. 3. IR spectra of Mo-Ti oxides. (a) Mo-Ti-3; (b) Mo-Ti-6; (c) Mo-Ti-24; (d) Mo-Ti-55; (e) and (f) the absorption due to TiO_2 were subtracted from (a) and (b) by placing the disk in the reference beam, respectively. 75 mg of KBr disk in 1 wt% of sample was used.

905 cm^{-1} appear with Mo-Ti-3 and -6 catalysts.

According to a number of workers,[10-13] the Raman spectra of various molybdenum-oxygen polyanions show two or three bands in each frequency region of about ≈200, 310—370, 500—600, 700—850, and 900—1000 cm^{-1}; the bands in the last region have been assigned to the stretching vibration of terminal Mo=O groups.[14] From these results the bands at 950—900 cm^{-1} observed with Mo-Al oxide catalysts have been attributed to the surface molybdate on alumina by Jezirowski *et al.*[14] A similar assignment has been made with the bands around 970 cm^{-1} for Mo-Si oxide catalysts.[15,16] Thus the two bands at 950 and 905 cm^{-1} seem to be assigned to terminal Mo=O stretches of the surface molybdate on TiO_2.

The bands at 995(s), 885(s), 820(w), 600(s), and 480(w) cm^{-1} are observed with IR spectra of crystalline MoO_3, while the bands at 995(m), 821(s), 668(w), and 494(vw) cm^{-1} appear in its Raman spectra.[16,17] The band at 995 cm^{-1} appears in both spectra, while the band at 885 cm^{-1} in the IR alone, suggesting that the vibrational modes attributable to both bands appear to be different from each other. Since it has been established that the band at 995 cm^{-1} is assigned to the Mo=O stretching vibration, some other assignment should be made for the band at 885 cm^{-1}.

From these facts it is concluded that with Mo-Ti oxide catalysts at a low Mo content, MoO_3 is highly dispersed on TiO_2 and present as an amorphous state which is characterized by the surface molybdate on TiO_2. Its formation results in distortion of the structure, *i.e.*, shift of the Mo=O band from 995 cm^{-1} to 950 and 905 cm^{-1}. A similar conclusion has been drawn for V-Ti oxides where formation of surface vanadate on TiO_2 brings about the shift of the V=O band from 1020 to 980 cm^{-1}.[4]

Oxydative Dehydrogenation of C_2H_5OH over Mo-Ti Catalysts. Figure 4 shows the rate of oxydative dehydrogenation of C_2H_5OH and the selectivity towards CH_3CHO formation as a function of Mo content at 180 °C. The major product is CH_3CHO, the remainder being $CH_3COOC_2H_5$ and trace of CO_2. The rate passes through a maximum around Mo-Ti-6. The maximum rate is *ca.* 4 times and 30—40 times larger than that at MoO_3 and TiO_2, respectively. There is no marked difference between the rates of oxidation in the presence and absence of oxygen (Fig. 4). Furthermore, essentially the same selectivities towards CH_3CHO formation is obtained with both oxidations. This suggests that lattice oxygen is responsible for the oxydative dehydrogenation over Mo-Ti oxide catalysts.

The rate measurements at various O_2 and C_2H_5OH pressures showed that with MoO_3 the order of the reaction is −0.5 in C_2H_5OH and zero in O_2, while with Mo-Ti-3 and Mo-Ti-6 the corresponding order is zero and 0.2—0.3, respectively. This suggests that the kinetics observed with MoO_3 is in disagreement with what is expected from a redox mechanism; the negative order in C_2H_5OH might arise from its strong adsorption.

As described above, with Mo-Ti-3 and -6 almost the whole MoO_3 is present as the amorphous surface species, while with Mo-Ti oxides containing more than

above 20 atom% of Mo, a considerable fraction MoO_3 consists of crystalline MoO_3.

Accordingly, in the region of a low Mo content, the activity of Mo-Ti oxides for the dehydrogenation of C_2H_5OH increases with increasing Mo content owing to the increase in the concentration of amorphous surface species. In the region of a high Mo content, the increase in the Mo content will cause an increase in the fraction of crystalline MoO_3 which is less active than the surface molybdate species. Thus, it is explicable that the oxidation activity passes through a maximum around 6 atom% of Mo. Such a feature is the same as that with V-Ti oxide catalysts as reported previously.[4]

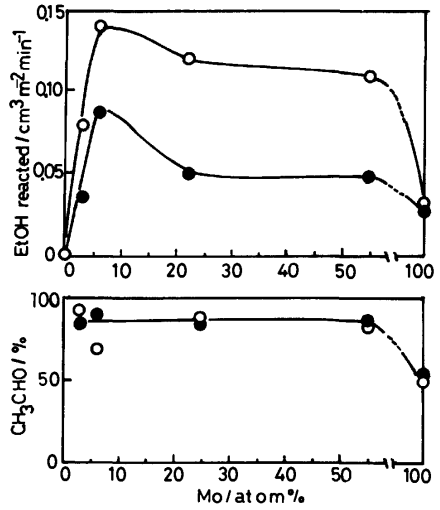

Fig. 4. Oxydative dehydrogenation of C_2H_5OH over Mo-Ti oxide catalysts at 180°C. (○) $P(C_2H_5OH)=6$ Torr and $P(O_2)=18$ Torr; (●) $P(C_2H_5OH)=6$ Torr and $P(N_2)=20$ Torr; 1 Torr=133.3 Pa.

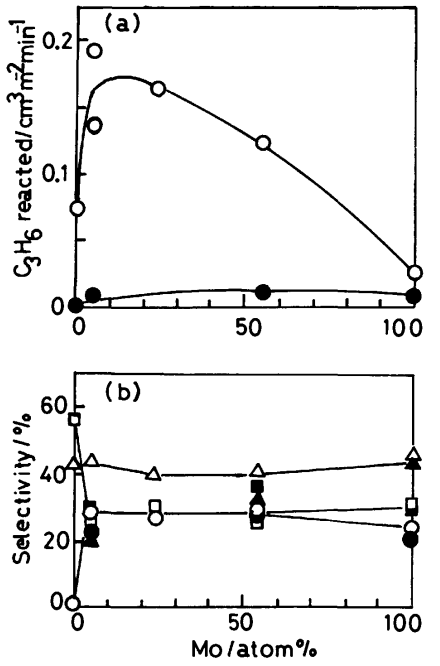

Fig. 5. Rates and product selectivities in C_3H_6 oxidation as a function of Mo content at 400°C. (a) ○ $P(C_3H_6)=23$ Torr and $P(O_2)=25$ Torr, ● $P(C_3H_6)=23$ Torr. (b) ○●, CH_2=CHCHO; □■ CO_2; △▲ CO. Solid symbols denote the results in the absence of gaseous oxygen.

C_3H_6 Oxidation over Mo-Ti and V-Ti Catalysts. Figure 5 shows the rates of C_3H_6 oxidation and the product selectivities as a function of Mo content at 400 °C. The rate of oxidation passes through a maximum around Mo-Ti-6. Almost the same distribution of the products is obtained in the whole range of the Mo content, *i.e.*, the selectivity towards CH_2=CHCHO formation is 25—30%, the remainder being CO, CO_2, and traces of CH_3COCH_3. With TiO_2, there is no formation of CH_2=CHCHO. With MoO_3 and Mo-Ti-6, essentially the same distribution of the products was obtained with both oxidations in the presence and absence of oxygen.

Similar studies have been extended to V-Ti oxide catalysts. The rate of oxidation at 320 °C also passed through a maximum around V-Ti-10 (atom% of V) catalyst. The selectivity towards CH_2=CHCHO formation decreased with decreasing vanadium content from 15—20% for V_2O_5 to 2—3% for V-Ti-10, the remainder being CO and CO_2. No formation of CH_2=CHCHO was observed with TiO_2. The rate of oxidation over V-Ti-10 is *ca.* 4 times higher than that over V_2O_5 and *ca.* 60 times than over TiO_2.

The dependence of the rate of oxidation upon O_2 and C_3H_6 pressure has been investigated with Mo-Ti as well as V-Ti oxides. As shown in Fig. 6, with increasing O_2 pressure, the rate of oxidation increases markedly for Mo-Ti-6 and V-Ti-10, while a slight increase in the rate is observed for MoO_3 and V_2O_5. There was no marked difference in the dependence of the rate of oxidation on C_3H_6 pressure over V-Ti-10 and V_2O_5. The situa-

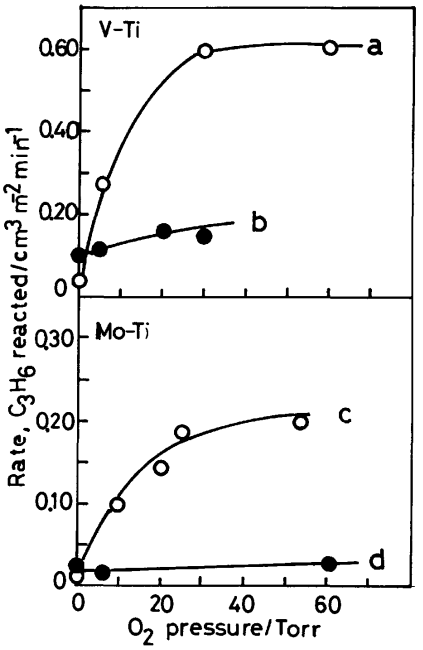

Fig. 6. Rates of C_3H_6 oxidation as a function of oxygen pressure. (a) and (b) are for V-Ti-10 and V_2O_5, respectively, at 320°C and (c) and (d) for Mo-Ti-6 and MoO_3 at 400°C. $P(C_3H_6)=23$ Torr.

tion, however, was different with Mo-Ti-6 and MoO_3, *i.e.*, the order in C_3H_6 was *ca.* 0.3 for Mo-Ti-6 but *ca.* 0.9 for MoO_3.

^{18}O Tracer and Kinetic Studies of C_3H_6 Oxidation. A large dependence of the rate of C_3H_6 oxidation on oxygen pressure observed with Mo-Ti-6 and V-Ti-10 suggests the possibility of participation of adsorbed oxygen in the oxidation. In order to obtain information on the nature of oxygen species responsible for the C_3H_6 oxidation over those catalysts, the oxidation of C_3H_6 has been investigated using $^{18}O_2$ tracer (99 atom%) with the results shown in Table 1 and Fig. 7. Little or no change in the ^{18}O content of the oxygen occurred during the reaction. According to the work of Blanchard *et al.*,[18] the exchange of oxygen through CO_2 appears to be negligible under the present experimental conditions.

In spite of the use of 99% of $^{18}O_2$, the ^{18}O content in the products at the initial stages of the reaction ranges from 20 to 30% for Mo-Ti-6 and MoO_3 and 15 to 20% for V-Ti-10 and V_2O_5. This indicates that the lattice oxygen(^{16}O) is responsible for the oxidation over both oxide catalysts. As has been done by Keulks *et al.*,[19] assuming uniform distribution of the incorporated ^{18}O among the sublayer of the oxides and the number of oxygen atoms in unit area (20 μmol/m^2), the extent of participation has been determined as follows: V_2O_5(*ca.* 10 layers)>V-Ti-10(*ca.* 5 layers)>V-Ti-2(*ca.* 1 layer) and Mo-Ti-6(*ca.* 5 layers)=MoO_3(*ca.* 5 layers).

As described previously,[2] even in the case where the surface anion vacancies are not refilled from gaseous oxygen, the following equation based on a simple redox mechanism holds, as far as the diffusion of the oxide ion is rapid as compared to the surface reduction;[2]

$$k_1P(C_3H_6)\theta = k_2P(O_2)^{0.5}(1-\theta), \quad (1)$$

where k_1 is the rate constant for reduction step and k_2 for reoxidation step. θ and $1-\theta$ refer to the surface oxide ions and anion vacancies, respectively, which corresponds to the surface Mo=O species and anion vacancies formed by oxygen removed from it, respectively, in view

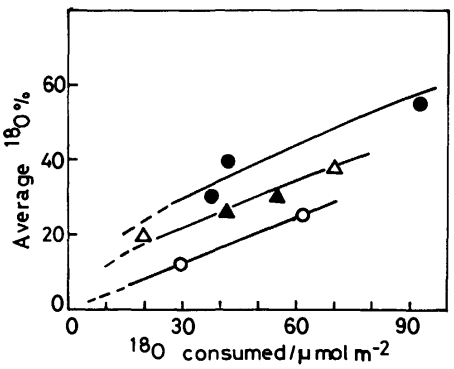

Fig. 7. Average ^{18}O%[a] in the products *vs.* amount of ^{18}O consumed[b] in C_3H_6 oxidation. V-Ti-10(●) and V_2O_5(○) at 320°C, Mo-Ti-6(▲) and MoO_3 (△) at 400°C. a),b) See Table 1.

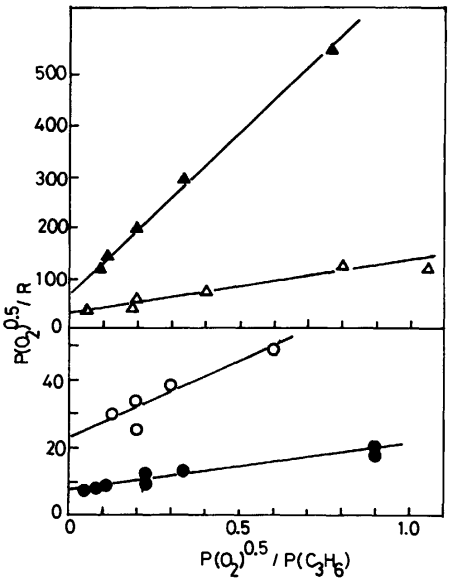

Fig. 8. Plots of $P(O_2)^{0.5}/R$ *vs.* $P(O_2)^{0.5}/P(C_3H_6)$ for MoO_3(▲), Mo-Ti-6(○), V_2O_5(△), and V-Ti-10 (●).
Experimental conditions are the same as in Fig. 5 for Mo–Ti oxides and in Fig. 6 for V-Ti oxides, respectively. R denotes the rate of C_3H_6 oxidation.

Table 1. ^{18}O contents in the products of C_3H_6 oxidation over Mo-Ti and V-Ti oxide catalysts

Catalyst	Temp °C	React. time min	Products/μ mol m^{-2} and ^{18}O content/%[a]				Total yield[c] μ mol-oxygen atoms m^{-2}	Average[d] ^{18}O %	Lattice oxygen[e] participated layers
			CO_2	CO	H_2O[b]	CH_2=CHCHO			
Mo-Ti-6	400	3	7.4(24)	7.1(34)	17(—)	3(19)	42	26	*ca.* 5

of the importance of the Mo=O species in the oxidation. The following rate equation results:

$$R = \frac{k_1 k_2 P(C_3H_6) P(O_2)^{0.5}}{k_1 P(C_3H_6) + k_2 P(O_2)^{0.5}}. \quad (2)$$

As shown in Fig. 8, the plots of $P(O_2)^{0.5}/R$ *vs.* $P(O_2)^{0.5}/P(C_3H_6)$ is approximately linear, suggeting that this equation is applicable to the results. Table 2 shows the values of k_1 and k_2 thus obtained.

Both k_1 and k_2 values increase on going from MoO_3 to Mo-Ti-6 and from V_2O_5 to V-Ti-10. The increase in the k_1 value is much larger than that for the k_2 value. Thus, the promoter action of TiO_2 in V-Ti and Mo-Ti oxides is attributed mainly to the increase in the rate of reduction step. Such a relative change of k_1 and k_2 is expected from the weakening of the Mo=O bond as described above. Thus, the rate maximum observed with both oxidation (Figs. 4 and 5) are explicable on the same basis. A large dependence of the rate of oxidation on oxygen pressure over Mo-Ti-6 and V-Ti-10 catalysts is also explicable from high values of k_1/k_2, *i.e.*, the high reducibility of surface molybdate or vanadate on TiO_2. The maximum rate of oxidation for Mo-Ti-6 and V-Ti-10 is explicable in a manner similar to that with the oxydative dehydrogenation of C_2H_5OH, *i.e.*, by the change in the concentration of the surface species with the Mo or V content.

Recently a number of workers have investigated the promoter effect observed with V-Ti oxides in the oxidation reaction, making various proposals.[20-24] The results described above indicate that similar mechanisms are involved in the promoter effects with both Mo-Ti and V-Ti oxides; The role of TiO_2 support in those oxide catalysts is to enhance the activity per one site in addition to the increase in the number of active sites. From the results in the present work together with those obtained previously,[4] it might be concluded that the promoter action due to formation of the amorphous phase (a highly dispersed oxide catalyst) is expected for other composite oxide catalysts.

Akimoto *et al.*[6] have reported that both adsorbed molecular oxygen and lattice oxygen participates in the production of maleic anhydride from 1,3-C_4H_6 over Mo-Ti catalysts. In the case of V-Sn oxide catalysts at a low V content, we have also suggested the participation of both adsorbed and lattice oxygens in the oxidation on the basis of the results of ^{18}O tracer as well as kinetic studies.[2] With Mo-Ti and V-Ti oxide catalysts, however, it seems unnecessry to take into account the possibility of adsorbed oxygen, since the dependence of the rate of oxidation on O_2 and C_3H_6 pressure is explicable by the concept that only lattice oxygen participates in the oxidation.

With the C_3H_6 oxidation over Mo-Ti oxide, there is a marked difference between the rates of oxidation in the presence and absence of oxygen. Such a feature is contrast with a slight difference between the both rates for the oxydative dehydrogenation of C_2H_5OH. It should be noted that the number of lattice oxygen atoms consumed on the oxidation of one molecule is 1—2 with C_2H_5OH but 9—10 with C_3H_6, the lattice oxygen producing CO, CO_2, H_2O, and CH_2=CHCHO for C_3H_6 oxidation. Furthermore, the reaction temperature is much higher for the C_3H_6 oxidation. Accordingly, the extent of oxygen removed from the Mo=O species during the reaction is expected to be much smaller for C_2H_5OH dehydrogenation than for the C_3H_6 oxidation. Thus, a small enhancement of the rate of C_2H_5OH dehydrogenation by the presence of oxygen is explicable.

The authors wish to thank Mr. Makoto Sakaguchi for carrying out part of the experiments.

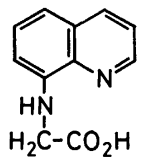
(Received August 3, 1983)

Stopped-flow kinetic and equilibrium studies have been made of the formation of a cobalt(II) complex with *N*-(8-quinolyl)aminoacetic acid in 0.10 mol dm^{-3} aqueous sodium chloride containing 12 vol% ethanol at 25 °C. Octahedral mono- and bis-ligand complexes were formed *via* the two pathways of the reactions of deprotonated and monoprotonated ligand species with the aquacobalt(II) ion. The coordination mechanism is discussed.

It is interesting to study spectrochemically the coordination characteristics of aromatic multidentate ligands to matal ions, which take several kinds of coordination geometry depending on the ligand employed, because the ligating groups are incorporated into the rigid frame of the aromatic ligand and because the electronic absorption spectrum of the ligand reflects its coordination mode. Furthermore, the nature of the ligating groups and the steric restriction due to the planarity of the ligand qualify the coordination behavior and mechanism of the metal ion.



Hqaa

The present study relates to the formation of a cobalt(II) complex with *N*-(8-quinolyl)aminoacetic acid (Hqaa).[1] In order to obtain detailed information on the coordination reaction characteristics, the coordination state of cobalt(II) and the coordination behavior of the ligand were spectrochemically and kinetically investigated. There has been only one paper concerning the ligand based on potentiometry.[2]

Experimental

Reagents. The ligand, QAA,[1] was synthesized by the condensation of chloro- or bromoacetic acid with 8-aminoquinoline in an alkaline medium, with some modifications of the literature procedure.[2] It was obtained as a monohydrochloride salt and was purified by repeated crystallizations from an aqueous solution. Calcd for $C_{11}H_{10}N_2O_2 \cdot HCl$: C, 55.35; H, 4.64; N, 11.73%. Found: C, 55.63; H, 4.59; N, 12.02%.

An aqueous cobalt(II) solution was prepared from analytical grade chloride salt from the Wako Pure Chemicals Ind. Co., Ltd., Osaka, and was acidified slightly with HCl to prevent its hydrolysis. It was then standardized by titration with EDTA. All the other chemicals were of an analytical or equivalent grade and were used without further purification.

Measurements. Electronic absorption spectral measurements were made with JASCO spectrophotometers, models UVIDEC-1 and SS-25, to the latter of which were attached a stopped-flow apparatus, Model SFC-5; a data processor, Model DP-500; and a RIKADENKI X-Y recorder, Model RW-11. The protonation and stability constants were determined spectrophotometrically at 340 nm in the former and at 303.5 nm in the latter in a 0.10 mol dm^{-3} aqueous sodium-chloride solution containing 12 vol% ethanol at 25.0±0.1 °C. Nitrogen gas was passed through the solution before the absorption spectral measurements to avoid any possible oxidation of cobalt(II). Kinetic runs were made at 303.5 nm under a pseudo-first-order kinetic condition with respect to the metal-ion or ligand concentration. The rate constant, k_{obsd}, was calculated from this relation:

$$\ln \{A_{eq}/(A_{eq}-A_t)\} = k_{obsd} \cdot t,$$

where A_t and A_{eq} stand for the absorbances at 303.5 nm at time t and at equilibrium respectively. The hydrogen-ion concentration was calculated from the measured pH value, pH_{meas}, with a HORIBA pH meter, Model F7-SS, with glass and 3.33 mol dm^{-3} potassium chloride calomel electrodes, according to this relation:

$$-\log [H^+] = pH_{meas} + \log f_{H^+}.$$

The activity coefficient of the hydrogen ion, f_{H^+}, was estimated by defining a 12 vol% ethanol aqueous solution containing 0.0100 mol dm^{-3} HCl and 0.0900 mol dm^{-3} NaCl as $-\log [H^+] \equiv 2.00$. The f_{H^+} value estimated under these conditions agreed well, within the limits of experimental error, with the literature data of 0.83.[3] The hydrogen-ion concentration was adjusted mainly with an acetic acid-sodium acetate buffer solution, whose concentration was maintained as low as possible (usually less than 0.5×10^{-2} mol dm^{-3}) in order to confirm that there was no meaningful influence on the complex formation of cobalt(II) with QAA under the equilibrium and kinetic conditions adopted.

Results and Discussion

Electronic Absorption Spectra. Figures 1 and 2 show the electronic absorption spectra of QAA and its cobalt(II) complexes respectively. The qaa^- species gives two distinct absorption maxima, at 29.20×10^3 and 39.40×10^3 cm^{-1}, due to the $\pi\rightarrow\pi^*$ transitions, which shift bathochromically on protonation at the heterocyclic nitrogen atom (Fig. 1). The coordination of the terdentate ligand qaa^- to cobalt(II) brings about remarkable spectral features; several absorption maxima in the $(31.70—33.70)\times10^3$ cm^{-1} region and a maximum at 43.20×10^3 cm^{-1} are characteristic of the mono-QAA complex, and there are in addition a maximum at 39.53×10^3 cm^{-1} and a shoulder around

† Present address: Yokkaichi Works, Japan Synthetic Rubber Co., Ltd., Yokkaichi, Mie 510.

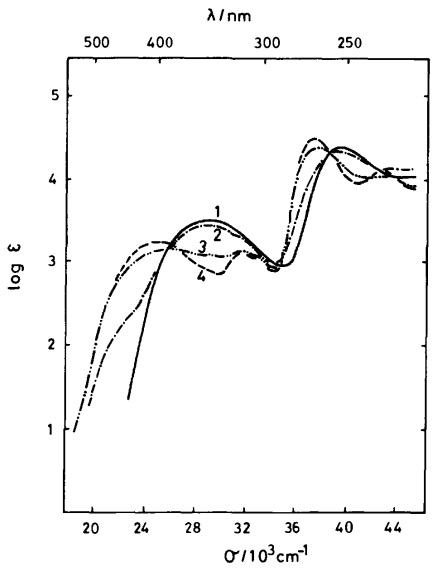


Fig. 1. Absorption spectra of QAA. 1: pH 9.70 (qaa^-); 2: pH 4.50; 3: pH 2.86; and 4: pH 0.38 ($H_3\ qaa^{2+}$).

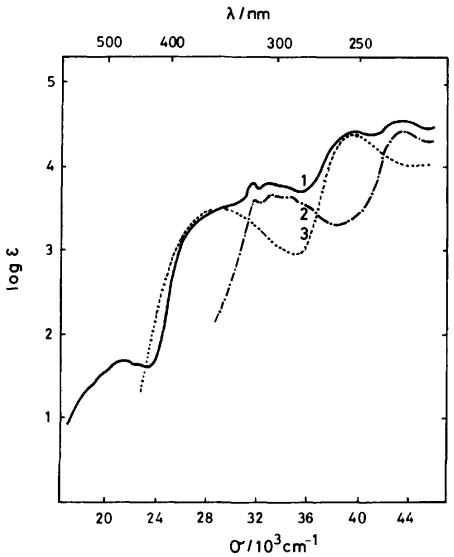

Fig. 2. Absorption spectra of the QAA complex. 1: $[Co(qaa)_2]$; 2: $[Co(qaa)(H_2O)_3]^+$; and 3: qaa^-.

$29.07\times10^3\ cm^{-1}$ of the bis-QAA complex. This shows that the transitions of π electrons related to the coordinated ligand are influenced by the numbers and arrangement of its chromophores.

The electronic absorption spectra in the d-d transition region of the bis-QAA complex and a typical cobalt(II) complex with octahedral coordination are given in Fig. 3. The absorption spectrum of the bis-QAA complex can be well correlated to that of a Schiff-base complex of the $[Co(N)_4(O)_2]$ type,[4] and the absorption maxima at 10.20×10^3 and 21.19×10^3 cm^{-1} of the bis-QAA complex can be assigned to the $^4T_{1g}(F)$-$^4T_{2g}(F)(O_h)$ and $^4T_{1g}(F)$-$^4T_{1g}(P)(O_h)$ transitions respectively.

Hence, it can be concluded that the QAA complex has an octahedral coordination and that the mono-

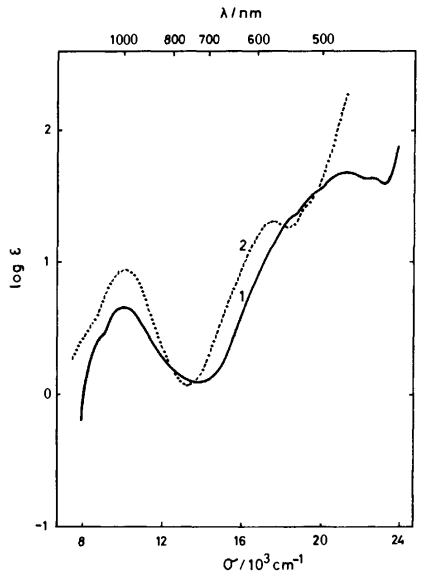

Fig. 3. Absorption spectra in the d-d transition region of $[Co(qaa)_2]$ and a Schiff base complex, $[Co(L)_2(py)_2]^+$, with octahedral coordination.[4] 1: $[Co(qaa)_2]$ and 2: $[Co(L)_2(py)_2]^+$, L: *ortho*-$OC_6H_4CHN(CH_2)_3CH_3$.

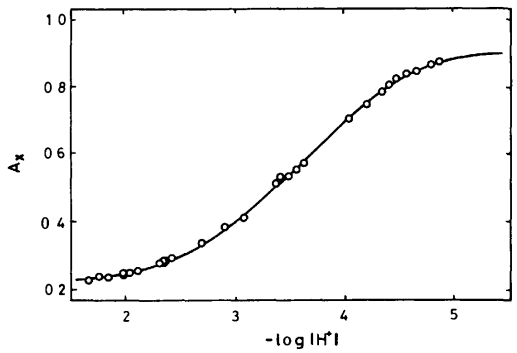

Fig. 4. Relation between A_x and $-\log[H^+]$ for QAA. Concentration of QAA, 1.41×10^{-4} mol dm^{-3}. Bald line is a theoretical curve drawn by using K_{a1} of $10^{4.04}$ and K_{a2} of $10^{2.99}$.

and bis-QAA complexes can be expressed as $[Co(qaa)(H_2O)_3]^+$ and $[Co(qaa)_2]$ respectively.

Stability. The protonation constants of QAA were determined by the use of the following relation (*cf.* Appendix I):

$$A_x = A_2 + \frac{(A_0-A_2)+(A_1-A_2)K_{a1}[H^+]}{1+K_{a1}[H^+]+K_{a1}K_{a2}[H^+]^2}. \quad (1)$$

Here, K_{a1} (=[Hqaa]/[H^+][qaa^-]) and K_{a2} (=[H_2qaa^+]/[H^+][Hqaa]) are the protonation constants related to the heterocyclic nitrogen base and the carboxylate group;[5] A_0 and A_2 are absorbances corresponding to the qaa^- and $H_2\ qaa^+$ species; A_1 is an intrinsic absorbance of the Hqaa species, and A_x is an absorbance when these ligand species coexist. Equation (1) was solved by the curve-fitting method[6] with a normalized curve of:

$$Y = \{(A_0-A_2)+bt\}/(1+at+t^2) \text{ and } X = \log t, \quad (2)$$

with $\log K_{a1}K_{a2}=2(X-\log[H^+])$, $\log K_{a1}/K_{a2}=2\log a$,

Table 1. Protonation constants of QAA

4.82±0.05	9.51±0.10	27.5±0.3	54.3±0.6	0.10 mol dm^{-3} aqueous sodium chloride containing 12 vol% ethanol, 25 °C spectrophotometry	Present work

a) Calculated by this relation: $-\Delta G^\circ_{1j}=RT\ln\beta_{1j}$ without the extrapolation of β_{1j} to the zero ionic strength ($j=1$ and 2).

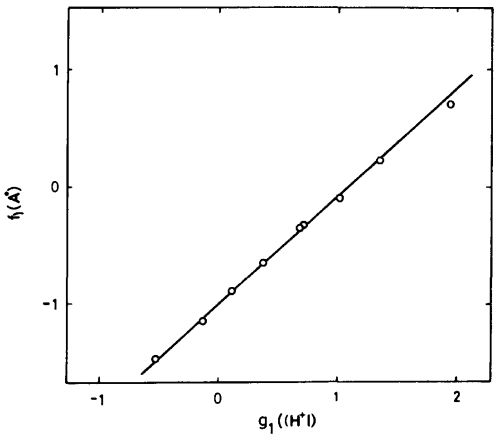

Fig. 5. Relation between $f_1(A')$ and $g_1([H^+])$. $f_1(A')\equiv \log\{(A'-A_{11g})/(A_{m.c}-A')\}$, $g_1([H^+])=-\log\{[H^+]-(K_{a2}[H^+]+1+1/K_{a1}[H^+])\}$. C_M, 1.60×10^{-2} mol dm^{-3} and C_L, 1.60×10^{-4} mol dm^{-3}.

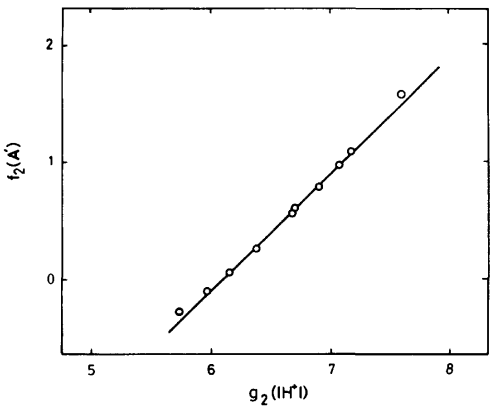

Fig. 6. Relation between $f_2(A')$ and $g_2([H^+])$. $f_2(A')\equiv \log\{(A'-A_{11g})/(A_{b.c}-A_{11g})\}-3\log\{(A_{b.c}-A')/((A_{b.c}-A_{11g})\}$, $g_2(H^+])\equiv-2\log\{[H^+](K_{a2}[H^+]+1+1/K_{a1}[H^+])\}$. C_M, 8.02×10^{-5} mol dm^{-3} and C_M, 1.60×10^{-4} mol dm^{-3}.

and $\log(A_1-A_2)=\log b+(1/2)(\log K_{a2}/K_{a1})$. Figure 4 shows the results, from which the K_{a1} and K_{a2} values were calculated; they are summarized in Table 1, together with those in the literature.[2]

The stability constants were determined by means of this relation:

$$\log\{(A'-A_{11g})/(A_{m.c}-A')\} = \log\beta_{11}C_M/K_{a1} - \log\{[H^+](K_{a2}[H^+]+1+1/K_{a1}[H^+])\}, \quad (3)$$

for the mono-QAA complex (β_{11}) under the condition of $C_M\gg C_L$, and by this relation:

$$\log\{(A'-A_{11g})/(A_{b.c}-A_{11g})\} - 3\log\{(A_{b.c}-A')/(A_{b.c}-A_{11g})\} = \log 4\beta_{12}C_M^2/K_{a1}^2 - 2\log\{[H^+](K_{a2}[H^+]+1+1/K_{a1}[H^+])\}, \quad (4)$$

for the bis-QAA complex (β_{12}) under the condition of $2C_M=C_L$ (*cf.* Appendix II). Here, C_M and C_L are the total concentrations of cobalt(II) and QAA respectively; A_{11g}, $A_{m.c}$, and $A_{b.c}$ denote absorbances corresponding to the ligand, the mono-QAA complex, and the bis-QAA complex respectively, and A' is the absorbance when the ligand and the complex coexist. Figures 5 and 6 show the findings on the relation between the absorbance term and the hydrogen-ion-concentration term in Eqs. (3) and (4), from which β_{11} and β_{12} were determined; they were summarized in Table 2, together with those in the literature.[2]

It is noteworthy that the stability constant of the mono-QAA complex is very close to the second step-by-step stability constant (β_{12}/β_{11}), as given in Table 2; this differs from general tendency for the step-by-step stability constants to decrease with increased

numbers of the coordinated ligands.[7] The molecular model reveals that there are no steric factors in QAA to bring about this particular aspect and that there are more possible geometrical isomers for the bis than for the mono-QAA complex, *i.e.*, six for the former and two for the latter. The relatively large values of the second step-by-step stability constant as compared with the first one may reflect either the bis-QAA complex being in equilibrium for some of its geometrical isomers or the mutual stabilizing interactions between the coordinated ligands in the bis-QAA complex.

Kinetics. By taking into consideration the protonation constants of QAA, the hydrolysis constant of cobalt(II) ($\log K_{OH}=-9.85$ (0 mol dm^{-3}, 25 °C) or -9.82 (1.0 mol dm^{-3}($NaClO_4$), 25 °C), $K_{OH}=[[Co(OH)(H_2O)_5]^+][H^+]/[[Co(H_2O)_6]^{2+}]$,[8] the stability constants of the mono- and bis-QAA complexes, and the rapid attainment of equilibria for the protolytic processes[9] as compared with the complex formation processes, which proceed at pH 2—5, the reaction pathways of the QAA complex can be given as follows (j=0—2);

$$[Co(H_2O)_6]^{2+} + H_jqaa^{(j-1)+} \xrightarrow{k_{0j}} [Co(qaa)(H_2O)_3]^+ + jH^+, \quad (\mathbf{I})$$

$$[Co(qaa)(H_2O)_3]^+ + H_jqaa^{(j-1)+} \xrightarrow{k_{1j}} [Co(qaa)_2] + jH^+. \quad (\mathbf{II})$$

In case the rate-determining step is in Stage **I**, Eqs. 6 and 7 can be deduced under the pseudo-first-order kinetic conditions with respect to the cobalt(II) and QAA concentrations (*cf.* Appendix III);

$$\begin{aligned} &d[[Co(qaa)(H_2O)_3]^+]/dt \\ &= k^M_{obsd}([[Co(qaa)(H_2O)_3]^+]_{eq} - [[Co(qaa)(H_2O)_3]^+]) \\ &= (k_{02}[H_2qaa^+] + k_{01}[Hqaa] + k_{00}[qaa^-])[[Co(H_2O)_6]^{2+}] \\ &\quad - (k_{-02}[H^+]^2 + k_{-01}[H^+] + k_{-00})[[Co(qaa)(H_2O)_3]^+], \end{aligned} \quad (5)$$

$$k^M_{obsd} = \{C'_M/(K_{a1}K_{a2}[H^+]^2 + K_{a1}[H^+] + 1) + 1/\beta_{11}\} \times (k_{02}K_{a1}K_{a2}[H^+]^2 + k_{01}K_{a1}[H^+] + k_{00}), \quad (6)$$

$$\begin{aligned} &d[[Co(qaa)_2]]/dt \\ &= k^L_{obsd}([[Co(qaa)_2]]_{eq} - [[Co(qaa)_2]]), \end{aligned}$$

$$k^L_{obsd} = \frac{\{C'_L/(K_{a1}K_{a2}[H^+]^2 + K_{a1}[H^+] + 1)\}^2 + 1/\beta_{12}}{C'_L/(K_{a1}K_{a2}[H^+]^2 + K_{a1}[H^+] + 1)} \times (k_{02}K_{a1}K_{a2}[H^+]^2 + k_{01}K_{a1}[H^+] + k_{00}), \quad (7)$$

where k^M_{obsd} and k^L_{obsd} are the observed rate constants under the condition of $C_M' \gg C_L'$ and $C_L' \gg C_M'$; k_{0j} is the forward rate constant for the pathway of $[Co(H_2O)_6]^{2+}$ and $H_j qaa^{(j-1)+}$; k_{-0j} is the backward rate constant for the same pathway; C_M' and C_L' are the total concentrations of cobalt II and QAA, and the suffix "eq" denotes the equilibrium state. Under the pseudo-first-order kinetic condition with respect to the ligand, Stage **II** may possibly be the rate-determining step and Eq. 8 can be deduced analogously:

$$k^L_{obsd} = \{C'_L/(K_{a1}K_{a2}[H^+]^2 + K_{a1}[H^+] + 1) + \beta_{11}/\beta_{12}\} \times (k_{12}K_{a1}K_{a2}[H^+]^2 + k_{11}K_{a1}[H^+] + k_{10}), \quad (8)$$

where k_{1j} is the forward rate constant for the pathway of $[Co(qaa)(H_2O)_3]^+$ and $H_j qaa^{(j-1)+}$. Hence, the reaction pathways can be deduced by plotting the $[H^+]$ dependence of $k^M_{obsd}{}'$ and $k^L_{obsd}{}'$, which are defined as follows;

$$k^M_{obsd}{}' \equiv k^M_{obsd}/\{C'_M/(K_{a1}K_{a2}[H^+]^2 + K_{a1}[H^+] + 1) + 1/\beta_{11}\}, \quad (6')$$

$$k^L_{obsd}{}' \equiv k^L_{obsd}\{C'_L/(K_{a1}K_{a2}[H^+]^2 + K_{a1}[H^+] + 1)\}/[\{C'_L/(K_{a1}K_{a2}[H^+]^2 + K_{a1}[H^+] + 1)\}^2 + 1/\beta_{12}], \quad (7')$$

or:

$$k^L_{obsd}{}' \equiv k^L_{obsd}/\{C'_L/(K_{a1}K_{a2}[H^+]^2 + K_{a1}[H^+] + 1) + \beta_{11}/\beta_{12}\}. \quad (8')$$

Figures 7 and 8 depict the $[H^+]$ dependences of $k^M_{obsd}{}'$ and $k^L_{obsd}{}'$ respectively, as defined by Eq. 7′. No meaningful result was obtained when $k^L_{obsd}{}'$ was defined by means of Eq. 8′. It can be concluded that the rate-determining step for both the mono- and bis-QAA complexes are in Stage **I** and that the reaction pathways of $[Co(H_2O)_6]^{2+}$ with Hqaa and with qaa^- really hold true. The rate constants and related data are summarized in Table 3.

The rate constants for the octahedral cobalt(II) complexes abstracted in Table 4 have been reported. All these ligands form cobalt(II) complexes by means of the preliminary formation of an outer-sphere complex, followed by transformation to the inner-sphere complex; then the chelate complexes are formed with a liberation of the coordinated water from the outer-sphere complex as the mechanistic rate-determining step.[10-19] The two exceptions are β-alaninate and 3-aminobutyrate, which show the chelate-ring closure as the rate-determining step.[16,17] In this reaction mechanism, the formation rate constant (k_f) can be equated with a product of the

formation constant of the outer-sphere complex (K_{os}) and the rate constant for the liberation of the coordinated water from the cobalt(II) ion (k^{-H_2O}), which then should be independent of the entering ligands. Table 4 reveals that the formation-rate constant for the complex with qaa$^-$ is in line with those for the complexes with glycinate, α-alaninate, *etc.*, even with no calculation of k^{-H_2O} from the estimated K_{os} and k_f values. Hence, it can be concluded that QAA forms a cobalt(II) complex in a "normal substitution" mode[16,17] through the preliminary formation of the outer-sphere complex, followed by the substitution of the coordinated water, with its liberation as the ultimate rate-determining step.

A comparison of k_{01} and k_{00} in Table 3 reveals that, as in the case of glycinate,[11] the carboxylato group of QAA coordinates more feasibly than does the heterocyclic nitrogen atom. The molecular model shows that the imino nitrogen atom may be less easily coordinated because its accessibility toward the metal atom is less than that of any other donor atoms in the ligand. Therefore, it can be stated that the carboxylato group of QAA coordinates first to the aquacobalt(II) ion as a unidentate ligand, followed by the donations of imino and heterocyclic nitrogen atoms to complete two five-membered chelate rings; this is followed by the coordination of the second QAA in a more rapid manner because of the labilization of the remaining coordinated water,[11] thus completing the bis-QAA complex.

Appendix

In this section, M, ML, ML_2, L, HL, and H_2L are used as simplified expressions of $[Co(H_2O)_6]^{2+}$, $[Co(qaa)(H_2O)_3]^+$, $[Co(qaa)_2]$, qaa^-, Hqaa, and H_2qaa^+; the molar absorption coefficients of the last five of those are ε_{11}, ε_{12}, ε_0, ε_1, and ε_2 respectively.

I. The following relations are given based on definitions in the text and the materials balance:

$$A_x = \varepsilon_0[L] + \varepsilon_1[HL] + \varepsilon_2[H_2L], \quad (A\text{-}1)$$

$$A_0 = \varepsilon_0[L]_m = \varepsilon_0 C_{11g}, \quad (A\text{-}2)$$

$$A_1 = \varepsilon_1[HL]_m = \varepsilon_1 C_{11g}, \quad (A\text{-}3)$$

$$A_2 = \varepsilon_2[H_2L]_m = \varepsilon_2 C_{11g}, \quad (A\text{-}4)$$

$$C_{11g} = [L] + [HL] + [H_2L] = [L]_m = [HL]_m = [H_2L]_m, \quad (A\text{-}5)$$

where C_{ug} is the total concentration of QAA. The suffix m specifies the portion of the concentration, in which only the unique ligand species is present. By taking K_{a1} and K_{a2} into consideration and by inserting Eqs. A-2—A-5 into Eq. A-1 with suitable rearrangements, Eq. 1 can be derived.

II. In an acidic solution of pH 2—5, where the complex formation proceeds, the following relations hold for the equilibrium:

$$C_M = [M] + [ML] + [ML_2], \quad (A\text{-}6)$$

$$C_L = [L] + [HL] + [H_2L] + [ML] + 2[ML_2] = [L]_i + [HL]_i + [H_2L]_i, \quad (A\text{-}7)$$

$$A' = \varepsilon_0[L] + \varepsilon_1[HL] + \varepsilon_2[H_2L] + \varepsilon_{11}[ML] + \varepsilon_{12}[ML_2], \quad (A\text{-}8)$$

$$A_{b.c} = \varepsilon_{12} C_M, \quad (A\text{-}9)$$

$$A_{11g} = \varepsilon_0[L]_i + \varepsilon_1[HL]_i + \varepsilon_2[H_2L]_i. \quad (A\text{-}10)$$

Here, the suffix i specifies the initial concentration of the ligand. Under the condition of $2C_M = C_L$, the bis-QAA complex is assumed to be dominant over the mono-QAA complex. Hence, the following relations are derived from Eqs. A-6—A-10 by taking K_{a1} and K_{a2} into consideration:

$$[L] = (C_L - 2[ML_2])/(1 + K_{a1}[H^+] + K_{a1}K_{a2}[H^+]^2), \quad (A\text{-}11)$$

$$[M] = \{(A_{b.c} - A')/(A_{b.c} - A_{11g})\} C_M, \quad (A\text{-}12)$$

$$[ML_2] = \{(A' - A_{11g})/(A_{b.c} - A_{11g})\} C_M, \quad (A\text{-}13)$$

The application of Eqs. A-11—A-13 into Eq. A-14:

$$\beta_{12} = [ML_2]/[M][L]^2, \quad (A\text{-}14)$$

and suitable rearrangements give us Eq. 4.

III. When Stage **I** is the rate-determining step, the following relations can be given under the condition of $C_M' \gg C_L'$:

$$C_M' = [M] + [ML] \approx [M] = [M]_{eq}, \quad (A\text{-}15)$$

$$C_L' = [L] + [HL] + [H_2L] + [ML] = [L]_{eq} + [HL]_{eq} + [H_2L]_{eq} + [ML]_{eq}. \quad (A\text{-}16)$$

By using Eqs. A-15 and A-16 together with Eq. A-17:

$$\beta_{11} = [ML]_{eq}/[M]_{eq}[L]_{eq}. \quad (A\text{-}17)$$

Equation 5 can be transformed into Eq. A-18:

$$\begin{aligned} d[ML]/dt &= (k_{02}K_{a1}K_{a2}[H^+]^2 + k_{01}K_{a1}[H^+] + k_{00}) \times ([M][L] - [ML]/\beta_{11}) \\ &= (k_{02}K_{a1}K_{a2}[H^+]^2 + k_{01}K_{a1}[H^+] + k_{00}) \times \{C_M'/(K_{a1}K_{a2}[H^+]^2 + K_{a1}[H^+] + 1) + 1/\beta_{11}\} \times ([ML]_{eq} - [ML]). \end{aligned} \quad (A\text{-}18)$$

A comparison of Eq. A-18 with Eq. 5 gives Eq. 6, which can be rewritten as:

$$k_{02}K_{a1}K_{a2}[H^+]^2 + k_{01}K_{a1}[H^+] + k_{00} = k^M_{obsd}', \quad (A\text{-}19)$$

by using the definition given in Eq. 6′. It was used for the data analysis.

Equations 7 and 8 can be derived from Eq. 5 in an analogous way.

Kinetic Studies of the Hydrolysis of Diketene Catalyzed by the Chloropalladium(II) Complex

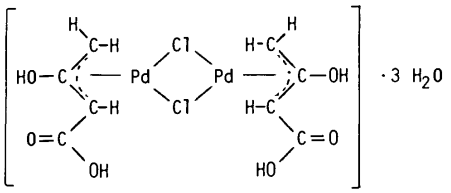
Seichi OKEYA* and Shinichi KAWAGUCHI*,†

Faculty of Education, Wakayama University, Fukiage, Wakayama 640
†*Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558*

(Received September 12, 1983)

When diketene and sodium tetrachloropalladate(II) are mixed in aqueous solution, color of the solution changes promptly from dark red to yellow. During this fast primary reaction about one equivalent of diketene is consumed and acetoacetic acid (H_2A) is retained as a trihapto ligand in $[PdCl_2(HA)]^-$ (**2**). The succeeding steady hydrolysis of diketene (S) proceeds as a pseudo first-order reaction, obeying the rate law: $-d[S]/dt=k_{obsd}[S]=(k_0+k_{cat})[S]$, $k_{cat}=k_{obsd}-k_0=(k_1+k_2/[H^+])[Pd^{II}]/[Cl^-]$, where $k_1=2.0\times10^{-5}$ s^{-1} and $k_2=2.96\times10^{-6}$ mol dm^{-3} s^{-1} at 0 °C and $\mu=1.0$ mol dm^{-3} ($HClO_4$ and $NaClO_4$). A mechanism which postulates complex **2** as the effective catalyst is proposed to explain the observed two-term rate equation.

Diketene consists of a four-membered lactone ring adjacent to a vinyl function and suffers attack of various nucleophiles and electrophiles to cleave the ring.[1] Tezuka *et al.* found that sodium tetrachloropalladate catalyzes the alcoholysis of diketene to afford acetoacetic esters.[2] Ethyl acetoacetate (etacH) forms a stable dinuclear palladium(II) complex $[PdCl(etac)]_2$, in which the β-keto ester ligand was confirmed by X-ray analysis to be coordinated with palladium in the η-allylic fashion.[3] Okeya *et al.* also found that the solvolysis reactions of diketene in water and acetone are catalyzed by palladium(II) complexes.[4] Palladium(II) complexes of the reaction products, acetoacetic acid and 2,2,6-trimethyl-4*H*-1,3-dioxin-4-one, were characterized and inferred to have the η-allylic structure. In fact the crystal and molecular structure of the former complex (**1**) was determined by X-ray crystallography.[5]



1

Palladium(II) forms a lot of organometallic compounds and is useful as catalysts for synthetic reactions.[6] As is exemplified by the famous Wacker reaction,[7] palladium participates in redox processes in most of the catalytic reactions. The spontaneous reaction of diketene with water is very slow[8] but is catalyzed by acids to produce acetone and carbon dioxide *via* acetoacetic acid.[9] The tetrachloropalladate(II) is very effective as a catalyst for this hydrolysis reaction but shows no sign of redox process involved. With the aim of elucidating the mechanism of this interesting catalysis a kinetic study was undertaken.

Experimental

Materials. A stock aqueous solution of sodium tetrachloropalladate(II) was prepared by dissolving palladium(II) chloride and sodium chloride in the mole ratio of 1 : 5. The exact concentrations of palladium and total chloride were determined by chemical analysis. Diketene (99.9% in purity) was supplied by Daicel Co., Ltd. and vacuum-distilled just before use. Other reagents such as perchloric acid, sodium perchlorate, sodium hydroxide, sodium chloride, and palladium(II) chloride as well as analytical reagents and indicators were of the AR grade and used as supplied.

Kinetic Measurement. A mixture of diketene and sodium tetrachloropalladate(II) in aqueous solution was stirred in a thermostated (±0.3 °C) reaction vessel. The solution was kept at $\mu=1.0$ mol dm^{-3} by virtue of sodium perchlorate and perchloric acid. By one minute after admixing the substrate with the catalyst color of the solution changed from dark red to yellow, indicating variation in the palladium(II) coordination sphere. Time zero for the steady reaction was set at this point and an aliquot was taken out from the reaction mixture and poured into an ethanol solution of about twice equivalents of dimethylglyoxime to quench the reaction. The mixture was titrated with a sodium hydroxide solution (0.1 mol dm^{-3}). Bromothymol Blue was used as an indicator (color changing from yellow to green) and the solution was kept throughout in ice and handled promptly. The initial concentration of diketene (S) for the steady reaction was calculated from Eq. 1,

$$[S]_0 = [S]_a - \{[NaOH]_0 - 2[Pd^{II}] - [HClO_4]\}, \quad (1)$$

where $[S]_a$ stands for the total concentration of diketene employed initially and $[NaOH]_0$ gives the concentration of alkali solution needed for neutralization of the aliquot. The amount of diketene consumed in the primary process is nearly equivalent to $[Pd^{II}]$. For each kinetic run diketene was used to make the $[S]_0$ value be in the region 0.15—0.20 mol dm^{-3}. Progress of the reaction thereafter was followed by taking aliquots at appropriate time intervals and titrating them in a similar way. The spontaneous hydrolysis of diketene in the absence of palladium(II) was also studied analogously.

Determination of the Hydrogen and Chloride Concentrations. It is usually rather difficult to determine accurately the hydrogen ion concentration in a solution with high ionic strength.[10] In this study an empirical method was used to relate an observed pH value to the hydrogen ion concentration. Solutions of hydrochloric acid at various concentrations were adjusted to $\mu=1.0$ mol dm^{-3} with sodium perchlorate and their pH values were determined. A calibration curve was thus drawn and the pH values of reaction mixtures were applied to this curve to evaluate their hydrogen ion concentrations.

As will be discussed shortly, the palladium(II) complex involved in the steady reaction is presumed to be $[PdCl_2(HA)]^-$ (H_2A=acetoacetic acid) and the concentration

of free chloride ions was calculated from the equation,

$$[Cl^-] = [Cl^-]_t - 2[Pd^{II}],$$

where $[Cl^-]_t$ represents the total concentration of chloride ions inclusive of those retained in the palladium(II) coordination sphere.

Instruments. The pH determination was performed with a Hitachi-Horiba M-5 pH meter. A reference electrode of the double junction type was used in order to prevent the perchlorate interference. Absorption spectra were measured by means of a Hitachi EPS-3T recording spectrophotometer.

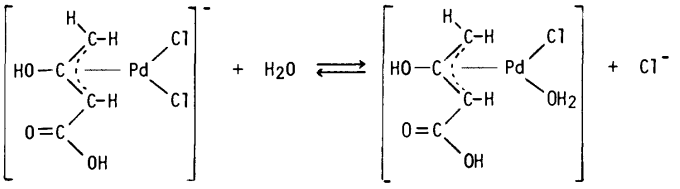
Results and Discussion

Spontaneous hydrolysis of diketene in the absence of the palladium(II) catalyst proceeds as a first order reaction and $k_0=1.67\times10^{-5}$ s^{-1} at 0 °C and $\mu=1.0$ mol dm^{-3}. Addition of hydrochloric acid slightly lowers the rate, k_0 for example being 1.44×10^{-5} s^{-1} when [HCl] is 0.05 mol dm^{-3}. On the other hand the reaction is accelerated very remarkably by addition of sodium hydroxide.

The stepwise stability constants (K_n in dm^3 mol^{-1}) of the complexes $PdCl_n(H_2O)_{4-n}^{(2-n)+}$ were determined by Elding[11] at 25 °C and $\mu=1.00$ mol dm^{-3}: $K_1=(2.98\pm0.06)\times10^4$, $K_2=(1.92\pm0.13)\times10^3$, $K_3=(2.6\pm0.2)\times10^2$, and $K_4=(2.37\pm0.10)\times10$. When the chloride ion concentration lies in the 0.02—0.2 mol dm^{-3} region as is the case for the present study, the chloropalladium(II) complex seems to exist as a mixture of $[PdCl_4]^{2-}$, $[PdCl_3(H_2O)]^-$, and $[PdCl_2(H_2O)_2]$.

When an aqueous solution of diketene is added to an aqueous solution of $Na_2[PdCl_4]$, color of the solution changes in one minute from dark red to yellow. The absorption spectrum of this solution has a maximum at 360 nm (ε=*ca.* 1200), and does not change during the progress of reaction. As is seen in Fig. 1, the λ_{max} slightly shifts to longer wave length side with increasing chloride concentration. It may be presumed that the dichloropalladium(II) complex coordinated with acetoacetic acid in an η-allylic fashion, $[PdCl_2(HA)]^-$ (**2**), is produced by the following fast reactions and works as an effective catalyst for the succeeding steady reaction. Complex **2** may be contaminated with a small amount of aqua counterpart **2′** in equilibrium 3. Since the chloride ion is a weaker ligand than the aqua ligand in the spectrochemical series, shift of the equilibrium 3 to the left hand side causes red shift of the absorption maximum. Thus $[PdCl(H_2O)(en)]^+$ and $[PdCl_2(en)_2]$ absorb at 360 and 370 nm, respectively.[12]

$$\left.\begin{aligned}
[PdCl_4]^{2-} + S + H_2O &\xrightarrow{\text{fast}} [PdCl_2(HA)]^- + H^+ + 2Cl^- \\
[PdCl_3(H_2O)]^- + S &\xrightarrow{\text{fast}} [PdCl_2(HA)]^- + H^+ + Cl^- \\
[PdCl_2(H_2O)_2] + S &\xrightarrow{\text{fast}} [PdCl_2(HA)]^- + H^+ + H_2O
\end{aligned}\right\} \quad (2)$$



2 **2′** (3)

When diketene is used up, color of the solution returns to red gradually. On being cooled below 0 °C the yellow solution deposits complex **1** but the red solution does not. The ^{1}H NMR assay indicates that complex **1** is converted into **2** in aqueous solution containing excess chloride ions, but either of them is not thermodynamically stable under these circumstances. Even when sodium acetoacetate is added to aqueous solution of $Na_2[PdCl_4]$, no sign of reaction is observed. Thus complex **2** is not formed by the reaction of $[PdCl_4]^{2-}$ with acetoacetic acid, but seems to be involved as an intermediate in the catalytic reaction.

The succeeding rather slow hydrolysis of diketene was followed by the titration method. The hydrogen ion concentration of the reaction mixture remained almost constant during the progress of reaction, indicating that acetoacetic acid, the reaction product, hardly ionizes in the acidic solution. Contributions from added perchloric acid and produced hydrochloric acid were subtracted from the observed hydrogen ion concentration, and the remaining part was related to the ionization of the η^3-coordinated acid in complex **2**.

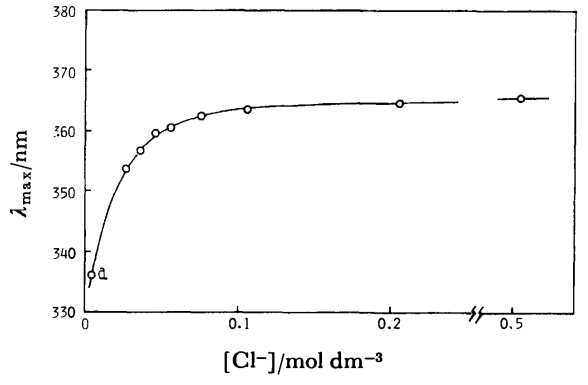


Fig. 1. Variation of λ_{max} of the reaction mixture with the concentration of chloride ions. Point a shows the λ_{max} of a solution containing complex **1** and diketene.

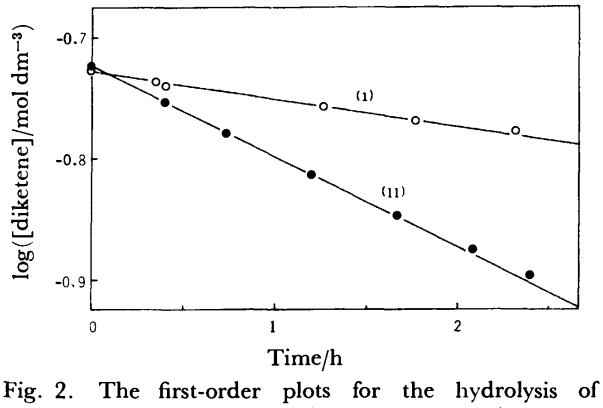

Fig. 2. The first-order plots for the hydrolysis of diketene in the absence (i) and presence (ii) of the Pd^{II} catalyst at 0 °C and $\mu=1.0$ mol dm^{-3}. $[Cl^-]=0.050$ mol dm^{-3}, $[H^+]=0.021\pm0.001$ mol dm^{-3}, and $[Pd^{II}]=0.0100$ mol dm^{-3}.

In this way the acid dissociation constant K_a (1) of **2** was estimated to be in the range 10^{-2}—10^{-3} mol dm^{-3} and is a little smaller than that of complex **1** (3.2×10^{-2} mol dm^{-3} at 18 °C).[4,5]

As is shown in Fig. 2, the reaction proceeds as a pseudo first order reaction up to 30—50% conversion. Since the spontaneous uncatalyzed hydrolysis is also a first order reaction, contribution of the catalyzed reaction is given by Eq. 4.

$$-\frac{d[S]}{dt} = k_{obsd}[S] = (k_0+k_{cat})[S],\ k_{cat} = k_{obsd} - k_0. \quad (4)$$

Both of the rate constants k_{obsd} and k_0 for the overall and uncatalyzed reactions, respectively, were measured more than four times under the same conditions and averaged.

Figures 3 and 4 show that $(k_{obsd}-k_0)$ is proportional to the palladium(II) concentration and also to reciprocal of the chloride concentration. Dependence of $(k_{obsd}-k_0)$ on the hydrogen ion concentration at constant palladium(II) and chloride concentrations is shown in Fig. 5. If the rate constants are plotted against the reciprocal of hydrogen ion concentration, a straight line is obtained (Fig. 6). Thus the pseudo first order rate constant for the catalyzed reaction is expressed by Eq. 5, and k_1= 2.0×10^{-5} s^{-1} and k_2=2.96×10^{-6} mol dm^{-3} s^{-1} at 0 °C and μ=1.0 mol dm^{-3}.

$$k_{obsd} - k_0 = \left(k_1+\frac{k_2}{[H^+]}\right)\frac{[Pd^{II}]}{[Cl^-]}. \quad (5)$$

The Eyring plots of rate data in Table 1 for the catalyzed and spontaneous reactions gave $\Delta H^{\ddagger}$=53 kJ mol^{-1} for both reactions. It should be added that the rate data reported in this paper may be accurate to ±10%.

Mechanism of Catalyzed Hydrolysis. Hydrolysis reactions of aliphatic lactones in weakly acidic solutions have been studied rather extensively.[13] For example, rates of hydrolysis of β-propiolactone and

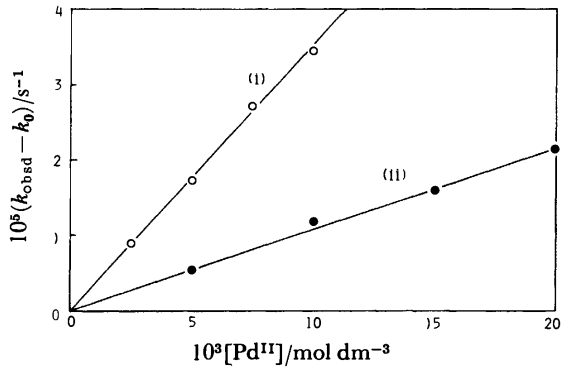

Fig. 3. Dependence of $(k_{obsd}-k_0)$ on the palladium(II) concentration at 0 °C, μ=1.0 mol dm^{-3}, and [H$^+$]=0.021±0.001 mol dm^{-3}. (i) [Cl$^-$]=0.050 mol dm^{-3}. (ii) [Cl$^-$]=0.180 mol dm^{-3}.

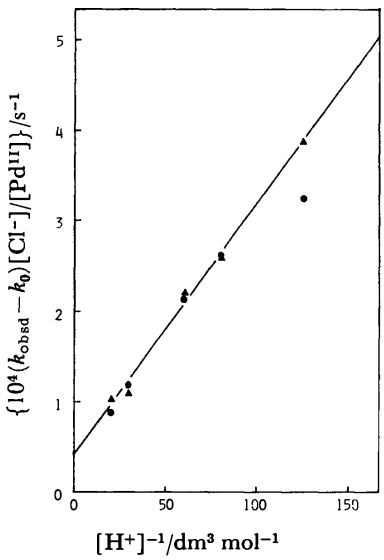

Fig. 6. Plot of $(k_{obsd}-k_0)[Cl^-]/[Pd^{II}]$ against reciprocal of the hydrogen ion concentration. Rate data are the same as those of Fig. 5, [Cl$^-$] being 0.015(●) or 0.045(▲)mol dm^{-3}.

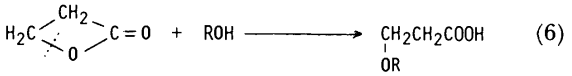
Table 1. Rates of hydrolysis of diketene at various temperatures and $\mu=1.0$ mol dm^{-3}, $[Cl^-]=0.195$ mol dm^{-3}, $[H^+]=0.008$ mol dm^{-3}

T/K	$10^5 k_0$/s^{-1}	$10^5 k_{obsd}$/s^{-1}	$10^3(k_{obsd}-k_0)/[Pd^{II}]$[a]/dm^3 mol^{-1} s^{-1}
303	17.3	27.2	19.8
293	8.45	13.3	9.70
283	3.76	5.89	4.26
278	2.34	3.74	2.80
273	1.56	2.37	1.62

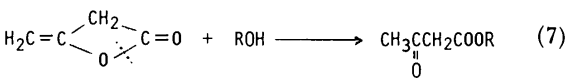
a) $[Pd^{II}]=0.0050$ mol dm^{-3}.

γ-butyrolactone were reported to be 1.88×10^{-4} and 5.00×10^{-5} s^{-1}, respectively, in neutral solutions at 37 °C.[14] The β-lactone is usually less stable and hydrolyzed more readily than the γ-lactone. In the molecule of diketene, the C=C function is attached to the β-lactone ring and the strain energy was estimated[15] as 94.1 kJ mol^{-1}. The rotational spectrum suggested that diketene is not planar.[16] Thus diketene is thermodynamically less stable and more reactive than β-propiolactone. In fact the hydrolysis rate of diketene was reported by van Duuren *et al.*[14] to be 2.0×10^{-3} s^{-1} at 25 °C and pH 7. This value is much larger than the present data in Table 1, but does not allow a direct comparison because of lacking in description of ionic strength. Higher ionic strength decreases the hydrolysis rate, k_0 at 0 °C being 3×10^{-5} s^{-1} at $\mu\approx0$ and 1.56×10^{-5} s^{-1} at $\mu=1.0$ mol dm^{-3}.

β-Propiolactone reacts with alcohol both in the absence and presence of acid catalysts to give 3-alkoxypropionic acid.[17] The alkyl-oxygen bond seems to be cleaved in this reaction (Eq. 6) as well as in hydrolysis.[18] On the other hand the reaction between diketene and alcohol results in the acetoacetic ester[1] probably by virture of the acyl-oxygen fission (Eq. 7).



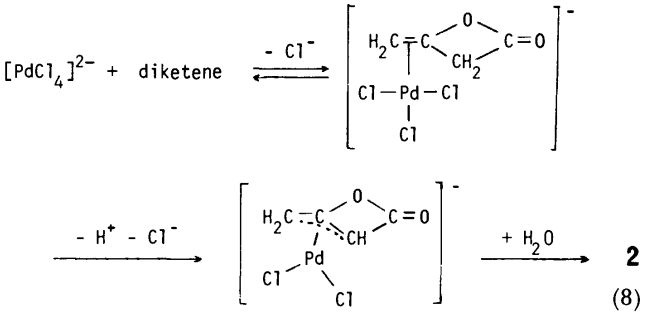
(6)



(7)

Alcoholysis of diketene catalyzed by palladium(II) seems to proceed according to the same mechanism and analogously hydrolysis of diketene both in the absence and presence of palladium(II) may involve the acyl-oxygen fission.

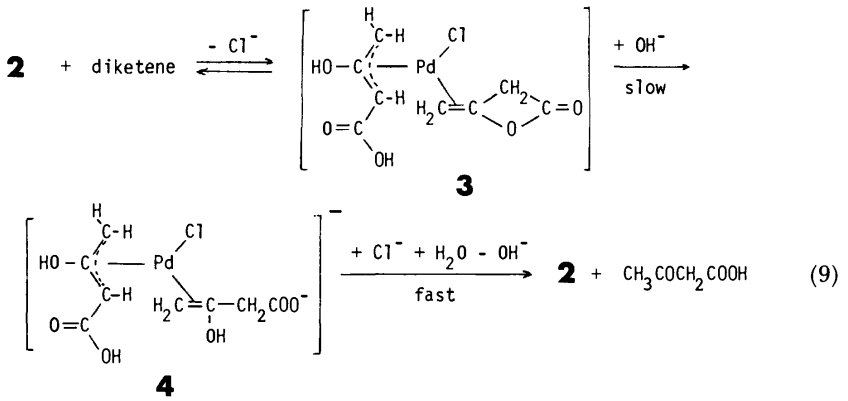
Since either of β-propiolactone and γ-butyrolactone shows no sign of interaction with $[PdCl_4]^{2-}$ in aqueous solution, diketene must coordinate with palladium(II) not through the oxygen atom(s) but through the C=C bond in the primary step of catalysis. Displacement of two chloride ligands and a methylene proton of diketene may give rise to a trihapto complex of the diketene anion, which in turn will be hydrolyzed rapidly to give complex **2** (Eq. 8).



(8)

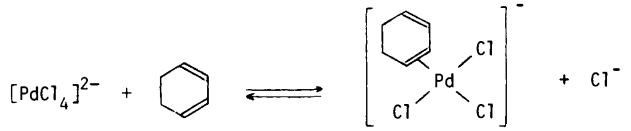
The succeeding steady reaction obeys the two term rate equation 5. The rate-determining step may be the nucleophilic attack of a water molecule (k_1) or a hydroxide anion (k_2) on the diketene ligand in the intermediate complex **3** as is shown in Eq. 9 for the k_2 path.

The enol tautomer of acetoacetic acid in the presumed complex **4** must be very unstable and rapidly displaced by a chloride anion to recover complex **2** and the product acetoacetic acid. Although the intermediate complexes postulated in this scheme have not been characterized, the rate equation 5 is readily interpreted on the assumption that complex **2** functions as the effective catalyst for hydrolysis of diketene. Pietropaolo *et al.*[19] studied kinetically the reaction between $[PdCl_4]^{2-}$ and 1,3-cyclohexadiene to form an η-allylic complex and proposed the following mechanism which involves the nucleophilic attack of methanol on the coordinated olefinic double bond as the rate-determining step in accordance with the observed rate law, rate$=k[PdCl_4^{2-}][\text{diene}]/[Cl^-]$. The mechanism is

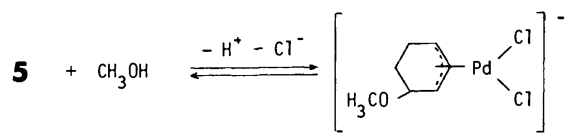


(9)

quite similar to that proposed here for the steady hydrolysis of diketene.



5



6

We thank Daicel, Ltd. for the generous gift of diketene.

Phase Equilibria in the Ln_2O_3-V_2O_3-V_2O_5 (Ln=Dy and Ho) Systems at 1200 °C

Kenzo KITAYAMA* and Takashi KATSURA
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received October 4, 1983)

Phase equilibria in the systems, Dy_2O_3-V_2O_3-V_2O_5 and Ho_2O_3-V_2O_3-V_2O_5, were established at 1200 °C by changing the oxygen partial pressure from 4.32 to −7.50 Pa in terms of $\log P_{O_2}$. In both systems, Ln_2O_3, $LnVO_4$, $LnVO_3$, V_nO_{2n-1}(n=2—7), VO_2, and $Ln_8V_2O_{17}$($4Ln_2O_3 \cdot V_2O_5$) are stable, and compounds with mole ratio Ln_2O_3/V_2O_5=5/1 are not stable under the present experimental conditions. On the basis of the established phase diagrams, the standard Gibbs energies of reactions, (1) $3\,Dy_2O_3+2\,DyVO_3+O_2=Dy_8V_2O_{17}$, (2) $DyVO_3+1/2\,O_2=DyVO_4$, (3) $3\,Ho_2O_3+2\,HoVO_3+O_2=Ho_8V_2O_{17}$, and (4) $HoVO_3+1/2\,O_2=HoVO_4$, were determined to be −278, −123.8, −277, and −122.4 kJ, respectively. $LnVO_4$, $Ln_8V_2O_{17}$, V_2O_3, and VO_2 have nonstoichiometric compositions. $\Delta G°$ values for reactions (2) and (4) fit well on the linear line presented by us.

The phase equilibria in the Ln_2O_3-V_2O_3-V_2O_5 systems[1-8] at 1200 °C were established by changing the oxygen partial pressures from 4.32 (air) to −7.50 or −8.00 Pa in terms of $\log P_{O_2}$. These established phase diagrams showed different patterns one another because of the differences of compounds coexisting under the experimental conditions although systems with Gd_2O_3[4] and Eu_2O_3[8] showed a similar pattern. Besides, the standard Gibbs energies of reactions found in the established diagrams and crystallographic data of the compounds presented for the systems have been obtained. It has also been established that the relationship between the ionic radius and $\Delta G°$ of reaction, $LnVO_3+1/2\,O_2=LnVO_4$, is linear provided that the lanthanoid elements can be divided into two groups.

In the present study, Dy_2O_3 and Ho_2O_3 were chosen as Ln_2O_3. In the Dy_2O_3-V_2O_5 and Ho_2O_3-V_2O_5 systems, compounds with mole ratio Ln_2O_3/V_2O_5 4/1 and 5/1 were stable[9] in the air from 600 to 1500 °C in addition to the well-known $LnVO_4$. So new types of phase equilibria will be expected.

Only one report was available about Dy_2O_3-V_2O_3 system,[10] in which one compound $DyVO_3$ with the congruent melting point at 2100 °C was found and it is nonstoichiometric toward V_2O_3 side in the temperature range from about 1800 to 2000 °C. The Ho_2O_3-V_2O_3 system has not been completely studied on account of the instability of V_2O_3 in the air, but $HoVO_3$ is well-known as a stable phase.

The crystallographic properties of $DyVO_3$, $HoVO_3$, $DyVO_4$, and $HoVO_4$ were investigated by many researchers.[11-14]

The objectives of the present study are: (1) preparation of the detailed phases diagrams of both systems at 1200 °C in order to determine the stable compounds under the present experimental conditions, (2) calculation of the standard Gibbs energies of reactions appeared in the established phase diagrams, and (3) examination of the fitness of present data on the linear relationship between the standard Gibbs energies of reactions and the ionic radius of the lanthanoid elements.

Experimental

Analytical grades of Dy_2O_3 (99.9%), Ho_2O_3 (99.9%), and V_2O_5, which was made by heating NH_4VO_3 of the guaranteed grade at 500 °C in the air for about 24 h, were used as the starting materials. Desired Dy_2O_3/V_2O_5 and Ho_2O_3/V_2O_5 mole ratios of samples were obtained by mixing appropriate quantities throughly in an agate motar under ethyl alcohol. The mixtures were treated by the procedures described in the previous paper.[1] The apparatus and procedures for controlling the oxygen partial pressures and keeping a constant temperature, the method of thermogravimetry, the criterion for an equilibrium establishment, the method of measurement of the actual oxygen partial pressure, and the method of chemical analysis are the same as those reported in the previous papers.[1,15-19]

Results and Discussion

Phase Equilibria. It was ascertained by the preliminary studies that Dy_2O_3 is stable under the present experimental ranges of the oxygen partial pressure. Seven samples with Dy_2O_3/V_2O_5 mole ratios 85/15, 8/2, 7/3, 65/35, 1, 35/65, and 15/85 were prepared to be used in the thermogravimetric experiments. The thermogravimetric results for three samples with mole ratios 85/15, 7/3, and 35/65 are shown in Fig. 1 as representative. In Fig. 1 the ordinate is the oxygen partial pressure represented in $\log P_{O_2}$ in the Pa unit and the abscissa is the composition shown by W_{O_2}/W_T, where W_{O_2} is the weight gain of the samples from the reference weight at $\log P_{O_2}$=−7.50, which is a point in the oxygen partial pressures where Dy_2O_3, $DyVO_3$, and V_2O_3 are stable, and W_T is the total weight increase of samples which might get if V_2O_3 in the samples at the reference state changed to V_2O_5 in the higher oxygen partial pressures. The W_{O_2}/W_T ratio was usually shown in the range from 0.995 to 1.00 in the air. Figure 1 shows the different patterns one another, and in the oxygen partial pressure range from $\log P_{O_2}$=−7.50 to −4.85 (Fig. 1a) the weight change was not observed. The value of $\log P_{O_2}$=−4.85 is the oxygen partial presure of the gas phase in equilibrium with the phase assemblages R+A_2+

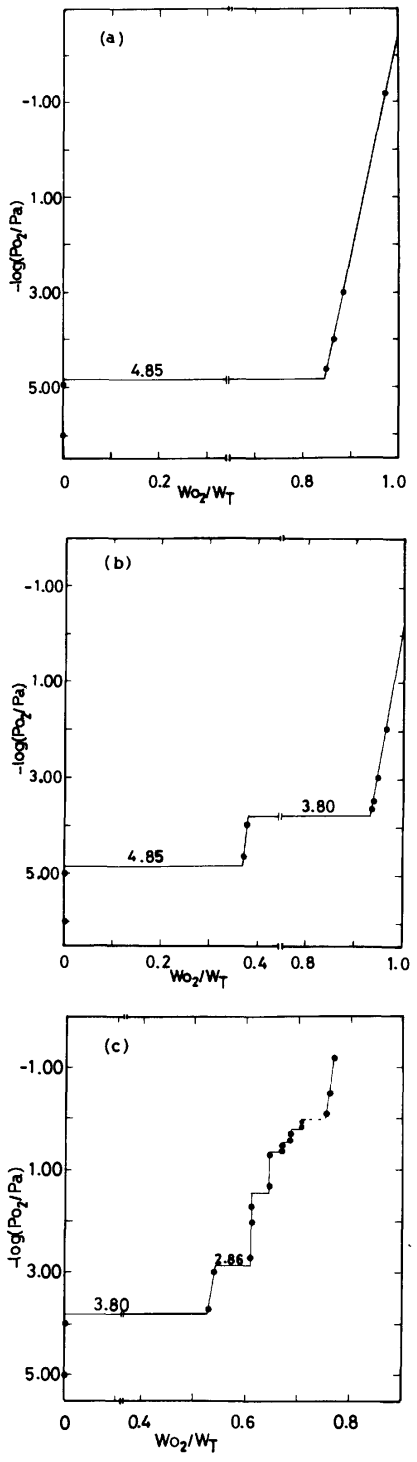

Fig. 1. The relationships between $-\log(P_{O_2}/\text{Pa})$ and the compositions, W_{O_2}/W_T, of the samples.
(a) $Dy_2O_3/V_2O_5=85/15$, (b) $Dy_2O_3/V_2O_5=7/3$, (c) $Dy_2O_3/V_2O_5=35/65$.

C which symboles will be shown in Table 2. In the range higher than $\log P_{O_2}=-4.85$, the weight changes linearly with the change in oxygen partial pressures. Figure 1b shows two oxygen partial pressures, −4.85 and −3.80 in $\log P_{O_2}$, in equilibrium. The latter corresponds to that of Reaction (2) in Table 4, and Fig. 1c have six oxygen partial pressures in equilibrium

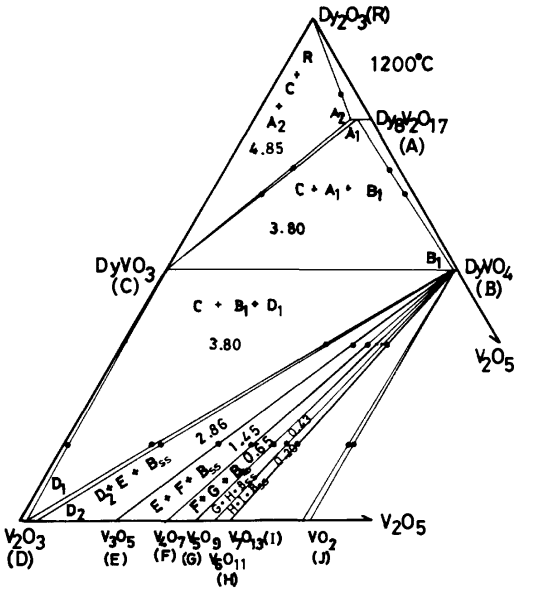

Fig. 2. Phase equilibria in the Dy_2O_3-V_2O_3-V_2O_5 system at 1200 °C. Numerical values in the three solid phases regions are the oxygen partial pressures in equilibrium in $-\log P_{O_2}$. Symbols are the same as those in Table 2.

in which five values correspond to those of the reactions in the V-O system.[1)]

In Table 1 the results of identification of phases are shown. In the first column are shown the compositions of the starting materials in mole%, in the second the experimental conditions of the oxygen partial pressure in terms of $\log P_{O_2}$ in Pa, in the third the experimental durations in hours, and in the last the phases that were found in the respective quenched samples using X-ray powder diffractometer with Cu $K\alpha$ radiation.

Based upon the above thermogravimetric results and the results of identification of phases, a phase diagram of the system can be constructed and is shown in Fig. 2. The following phases are stable; $V_nO_{2n-1}(n=2—7)$, VO_2, Dy_2O_3, $DyVO_4$, $DyVO_3$, and $Dy_8V_2O_{17}(4Dy_2O_3\cdot V_2O_5)$. The compound $5Dy_2O_3\cdot V_2O_5$ reported by Brusset *et al.*[9)] as the stable phase was not found.

The stability of Ho_2O_3 under the present experimental conditions was confirmed by preliminary experiments. Seven samples with Ho_2O_3/V_2O_5 mole ratios 85/15, 8/2, 7/3, 6/4, 1, 35/65, and 15/85 have also been used in the thermogravimetric experiments. The value of $\log P_{O_2}=-7.50$ was selected as the reference oxygen partial pressure by the similar reason as described above. In Fig. 3 the relationships between the oxygen partial pressure and the composition of samples are shown as those in Fig. 1 with the representative samples having mole ratios 85/15, 6/4, and 15/85. Figure 3 shows similar patterns to Fig. 1.

Quenched samples were used for the identification of phases and the phases were identified by X-ray powder diffractometer with Cu $K\alpha$ radiation. The results are shown in Table 1 together with those of the Dy_2O_3-V_2O_3-V_2O_5 system. Figure 4 was depicted by using

above experimental results as those in Fig. 2. Figures. 2 and 4 give similar patterns each other. In addition to the seven oxides in the V_2O_3-V_2O_5 system, Ho_2O_3, $HoVO_4$, $HoVO_3$, and $Ho_8V_2O_{17}$($4Ho_2O_3 \cdot V_2O_5$) are stable. These phase diagrams are very simple having only one compound between Ln_2O_3 and $LnVO_4$. This type of the phase diagram was found in the systems of Eu, Gd, and Er. It was very interesting that

		−0.50	32	$HoVO_4+VO_2$

these elements are located in the middle of the lanthanoid.

$DyVO_4$, $HoVO_4$, $Dy_8V_2O_{17}$, and $Ho_8V_2O_{17}$ have nonstoichiometric compositions, and the relationships between the oxygen partial pressure and the compositions were obtained as follows: $N_O/N_B=4.23\times10^{-3}\log P_{O_2}-1.38\times10^{-4}$ for $DyVO_4$, $N_O/N_L=8.80\times10^{-3}\log P_{O_2}+6.37\times10^{-3}$ for $HoVO_4$, $N_O/N_A=0.045\log P_{O_2}-0.098$ for $Dy_8V_2O_{17}$, and $N_O/N_K=0.079\log P_{O_2}-0.023$ for $Ho_8V_2O_{17}$, where N_O is the mole fraction of oxygen atom in the compounds and N_A, N_B, N_K, and N_L are the mole fractions of the $Dy_8V_2O_{17}$, $DyVO_4$, $Ho_8V_2O_{17}$, and $HoVO_4$ components in the compounds, respectively.

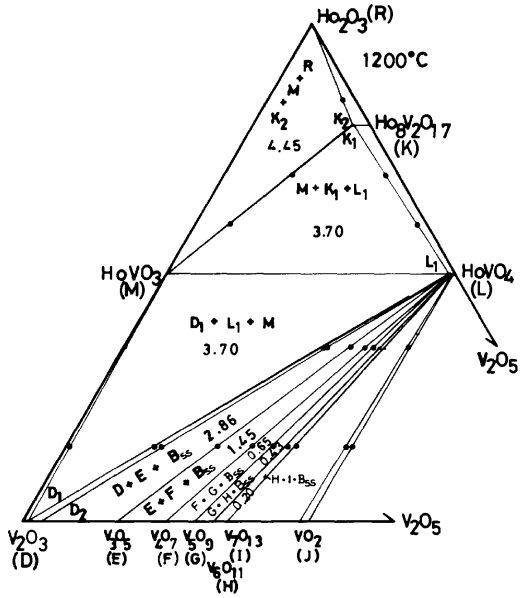

Fig. 4. Phase equilibria in the Ho_2O_3-V_2O_3-V_2O_5 system at 1200 °C. Numerical values in the three solid phases regions are the oxygen partial pressures in equilibrium in $-\log P_{O_2}$. Symbols are the same as those in Table 2.

Table 2 lists the compositions of the compounds at various oxygen partial pressures, stability ranges of the compounds in terms of $\log P_{O_2}$, the symbols of the compounds, and the activities of the components described above. The activities of the components in the solid solutions were calculated by means of the Gibbs-Duhem equation with the data of thermogravimetry, for example N_O/N_A *vs.* $\log P_{O_2}$ described above. A detailed method of the calculation has been discussed in the previous paper.[18]

Lattice constants of the compounds $DyVO_3$, $DyVO_4$, $Dy_8V_2O_{17}$, $HoVO_3$, $HoVO_4$, and $Ho_8V_2O_{17}$ are tabulated in Table 3. Present values are in good agreement

Table 2. Compositions, symbols, stability ranges in the oxygen partial pressures, and activities of component in the solid solutions

Component	Composition	Symbol	$-\log(P_{O_2}/\text{Pa})$	$-\log a_i$
$Dy_8V_2O_{17}$	$Dy_8V_2O_{17.0}$	A	-2.1[a]$-$$-4.32$	0.55

(4) $HoVO_3+1/2\,O_2=HoVO_4$	3.70±0.03	122.4±0.5

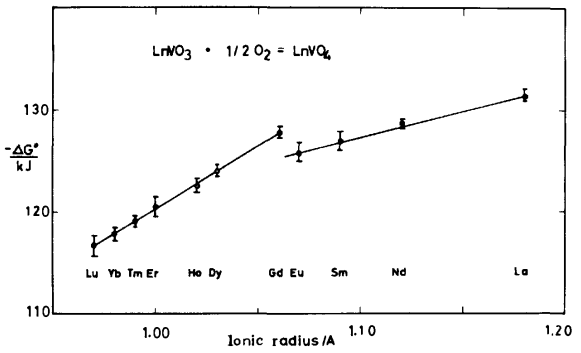

Fig. 5. The relationship between the ionic radius of lanthanoid elements with eight coordination and the ΔG° values of reaction, $LnVO_3+1/2\,O_2=LnVO_4$.

with those quoted in the Table. There are no considerable differences in values of the samples which were prepared under the different conditions of oxygen partial pressures. Lattice constants of $Dy_8V_2O_{17}$ and $Ho_8V_2O_{17}$ were determined with the data of $4\,Tm_2O_3 \cdot V_2O_5$.[20] Experimental errors are still large compared with the data of other compounds.

Calculation of the Standard Gibbs Energies of Reactions. On the basis of the present phase equilibria, the standard Gibbs energies of the reactions appeared in the systems, except for the partial system of V_2O_3-V_2O_5, can be calculated by an equation, $\Delta G^\circ=-RT\ln K$, where R is the gas constant, T, the absolute temperature, and K, the equilibrium constant of each reaction. Chemical reactions appeared in the phase diagrams, the oxygen partial pressures in equilibrium for each reaction, and ΔG° values obtained are shown in Table 4. Activities of each component in solid solutions, which are necessary for the calculation, are given in Table 2.

The Relationship between ΔG° and Ionic Radius. In the series of Ln_2O_3-V_2O_3-V_2O_5 system, the common reaction, $LnVO_3+1/2\,O_2=LnVO_4$, appeares in all the systems. It is very interesting to correlate the ΔG° values of reactions with some properties of lanthanoid elements. In a previous report,[7] we have graphically presented the linear relationship between ΔG° values and the ionic radius of lanthanoid elements with eight coordination, provided that the lanthanoid series was subdivided into two groups. The present program is to ascertain whether or not the data obtained in the present systems fit well to the previous linear relation. The values of the present systems are plotted in Fig. 5 with open circles. These circles are well fit on the line which has been drawn using the data of previous results of another systems.

Synthesis and Stereoselectivity of Cobalt(III) Complexes of Quadridentate Ligands Possessing SNNS Array of Donor Atoms

Kazuaki YAMANARI,* Norimatsu TAKESHITA, and Yoichi SHIMURA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received November 17, 1983)

Several thiolato complexes of $[Co(SNNS)(diamine)]^+$ type were prepared (diamine stands for en=1,2-ethanediamine, *R*-pn=(*R*)-1,2-propanediamine, and *RR*-chxn=(*R*,*R*)-1,2-cyclohexanediamine) and characterized from their visible-UV absorption, circular dichroism, and ^{13}C NMR spectra, where SNNS denotes two kinds of open-chain quadridentate ligands, H_2endet=3,6-dimethyl-3,6-diazaoctane-1,8-dithiol and *R*-H_2pndet=(*R*)-3,4,6-trimethyl-3,6-diazaoctane-1,8-dithiol. Both the SNNS ligands gave the two geometrical isomers, *cis*-α(dark green) and *cis*-β(dark violet), whereas 3,7-dimethyl-3,7-diazanonane-1,9-dithiolate(2−) ligand gave no stable monomeric complex. Interestingly, stereoselective complex formation was found in *Δ*-*cis*-α-[Co(*R*-pndet)(en or *RR*-chxn)]$^+$, *Δ*(S^NR^N)-*cis*-β-[Co(endet)(*R*-pn or *RR*-chxn)]$^+$, and *Δ*(S^NR^N)-*cis*-β-[Co(*R*-pndet)(en or *RR*-chxn)]$^+$, the *Δ*-*cis*-α configuration of the former complex being the novel one having the equatorially-oriented terminal chelate rings on the tertiary nitrogen atoms.

In a previous communication, we reported the stereochemistry of cobalt(III) complexes with a quadridentate ligand having SNNS donor set. Two geometrical isomers of the $[Co(N)_4(thiolato)_2]^+$ type complex were first separated by column chromatography.[1] The earlier attempt to prepare this type of complexes using bidentate ligand was unsuccessful in spite of the chromatographic analysis.[2] These circumstances show that the quadridentate ligand possessing SNNS donor set is promising for the stereochemical investigation of cobalt(III) complexes.

In this paper, three kinds of open-chain SNNS quadridentate ligands 3,6-dimethyl-3,6-diazaoctane-1,8-dithiol(H_2endet), 3,7-dimethyl-3,7-diazanonane-1,9-dithiol(H_2tndet), and (*R*)-3,4,6-trimethyl-3,6-diazaoctane-1,8-dithiol(*R*-H_2pndet) were used to prepare several cobalt(III) complexes $[Co(SNNS)(diamine)]^+$ (diamine=en, *R*-pn, and *RR*-chxn), $[Co(SNNS)(CN)_2]^-$, and [Co(SNNS)(aet)].[3] The complexes were separated, optically resolved by the chromatographic techniques, and characterized from their visible-UV absorption, circular dichroism(CD), and ^{13}C NMR spectra. For the complex $[Co(SNNS)(diamine)]^+$, the two geometrical isomers, *cis*-α and *cis*-β, are possible as shown in Fig. 1. This type of geometrical isomers were found for the endet and *R*-pndet ligands, whereas no stable mononuclear complex was detected for the tndet ligand. Furthermore, the optically active *R*-pndet ligand showed complete stereoselectivity in *cis*-α and *cis*-β-[Co(*R*-pndet)(en or *RR*-chxn)]$^+$.

Experimental

Preparation of Ligand. *3,6-Dimethyl-3,6-diazaoctane-1,8-dithiol(H_2endet), $[HSCH_2CH_2N(CH_3)CH_2-]_2$*: The ligand was prepared from thiirane[4] and *N*,*N*′-dimethyl-1,2-ethanediamine as described by Karlin and Lippard.[5] ^{13}C NMR (benzene): δ=22.99 ($CH_2\underline{C}H_2SH$), 42.66 ($N\underline{C}H_3$), 55.72 ($N\underline{C}H_2CH_2SH$), and 61.13 ($N\underline{C}H_2CH_2N$). Found: C,48.25; H,9.53; N,13.05%. Calcd for H_2endet·1/6 C_6H_6=$C_9H_{21}N_2S_2$: C, 48.53; H,9.56; N,12.65%. A solution of H_2endet (1 mmol) in methanol (5 cm^3) was added to a warm solution of $Ni(CH_3CO_2)_2\cdot 4H_2O$ (1 mmol) in methanol (10 cm^3). The brown solid, which separated immediately, was filtered, washed with ethanol, and vacuum dried. Found: C, 36.24; H, 6.85; N, 10.56%. Calcd for [Ni(endet)]=$C_8H_{18}N_2S_2Ni$: C, 36.25; H, 6.85; N ,10.57%.

3,7-Dimethyl-3,7-diazanonane-1,9-dithiol(H_2tndet), $[HSCH_2CH_2N(CH_3)CH_2-]_2CH_2$: This ligand was obtained in the same manner as that of H_2endet, where *N*,*N*′-dimethyl-1,3-propanediamine[6] is substituted for *N*,*N*′-dimethyl-1,2-ethanediamine. ^{13}C NMR (benzene): δ=23.10 ($CH_2\underline{C}H_2SH$), 25.70 ($NCH_2\underline{C}H_2CH_2N$), 42.34 ($N\underline{C}H_3$), 55.67 ($N\underline{C}H_2CH_2SH$), and 60.87 ($N\underline{C}H_2CH_2CH_2N$). Found: C,51.01; H, 9.85; N,12.09%. Calcd for H_2tndet·1/6 C_6H_6=$C_{10}H_{23}N_2S_2$: C, 51.02; H, 9.85; N, 11.90%. A solution of H_2tndet (1 mmol) in methanol (5 cm^3) was added to a warm solution of $Ni(CH_3CO_2)_2\cdot 4H_2O$ (1 mmol) in methanol (10 cm^3). To this mixture was added 0.3 g of $NaClO_4$ dissolved in 2 cm^3 of methanol. The resulting solution was concentrated by a rotary evaporator to give dark brown crystals, which were collected by filtration and washed with ethanol. Found: C, 26.52; H, 5.06; N, 6.91%. Calcd for $[Ni\{Ni(tndet)\}_2](ClO_4)_2$=$C_{18}H_{40}N_4S_4O_8Cl_2Ni_3$: C, 26.50; H, 4.94; N, 6.87%.

(R)-*3,4,6-Trimethyl-3,6-diazaoctane-1,8-dithiol(*R*-H_2pndet), $HSCH_2CH_2N(CH_3)CH(CH_3)CH_2N(CH_3)CH_2CH_2SH$*: The ligand was prepared from thiirane and (*R*)-*N*,*N*′-dimethyl-1,2-propanediamine[7] according to the same method. The purity was relatively low compared with those of H_2endet and H_2tndet and therefore checked by the nickel(II) complex formation. The dark brown Ni(II) trimer was obtained in a similar way by the method of the above tndet complex. Found: C, 28.22; H, 5.51; N, 6.92%. Calcd for $[Ni\{Ni(R\text{-pndet})\}_2]Br_2\cdot CH_3OH$=$C_{19}H_{44}N_4S_4Br_2ONi_3$: C, 28.22; H, 5.48; N, 6.93%.

Preparation and Separation of the Cobalt(III) Complexes. cis-α- *and cis*-β-*[Co(endet)(diamine)]ClO_4 (diamine=en, R-pn, and RR-chxn)*: To a solution of 3.15 g of $[Co(en)_3]Cl_3\cdot 3H_2O$ in 20 cm^3 of water was added a mixture of 1.74 g of H_2endet and 0.6 g of NaOH in 20 cm^3 of water. The mixed solution was stirred for 2 h at room temperature. After filtration of the gummy precipitate, the resulting dark green filtrate was poured onto a column of SP-Sephadex C-25 (Na^+ form 4×50 cm), washed with water, and eluted with 0.1 mol

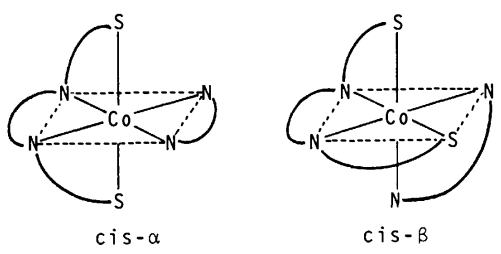

Fig. 1. Two geometrical isomers of $[Co(SNNS)(diamine)]^+$.

dm^{-3} $NaClO_4$. Two partly overlapping bands, dark green and dark violet, were eluted in this order. The total yield of the desired products was *ca.* 30% and the amount of the former isomer was somewhat higher than that of the latter one. As described later, the dark green and the dark violet isomers were assigned to *cis*-α- and *cis*-β-[Co(endet)(en)]$^+$, respectively. Each eluate was concentrated in a vacuum evaporator to give crystals of the desired perchlorate salt. Found for the dark green isomer (*cis*-α): C, 28.33; H, 6.20; N, 13.12%. Found for the dark violet isomer (*cis*-β): C, 28.17; H, 6.22; N, 13.17%. Calcd for [Co(endet)(en)]ClO_4=$C_{10}H_{26}N_4S_2O_4CoCl$: C, 28.27; H, 6.17; N, 13.19%. The perchlorate salt was converted into the corresponding chloride salt using a column of QAE-Sephadex A-25 (Cl^- form). The highly soluble chloride salt was used for ^{13}C NMR measurements.

The complexes containing *R*-pn or *RR*-chxn ligand were prepared and separated in the same manner as described above except for the use of Δ-[Co(*R*-pn)$_3$]$^{3+}$ or Δ-[Co(*RR*-chxn)$_3$]$^{3+}$, respectively, as a starting material. The two geometrical isomers, dark green and dark violet, were obtained in each case. Found for the dark green *R*-pn isomer: C, 29.59; H,6.34; N, 12.41%. Calcd for *cis*-α-[Co(endet)(*R*-pn)]$ClO_4\cdot 0.5H_2O$=$C_{11}H_{29}N_4S_2O_{4.5}CoCl$: C, 29.50; H, 6.53; N, 12.51%. Found for the dark violet *R*-pn isomer: C, 30.35; H, 6.51; N, 12.80%. Calcd for *cis*-β-[Co(endet)(*R*-pn)]ClO_4=$C_{11}H_{28}N_4S_2O_4CoCl$: C, 30.10; H, 6.43; N, 12.77%. Found for the dark green *RR*-chxn isomer(*cis*-α): C, 35.10; H, 6.75; N, 11.70%. Found for the dark violet *RR*-chxn isomer(*cis*-β): C, 35.14; H, 6.74; N, 11.60%. Calcd for [Co(endet)(*RR*-chxn)]ClO_4=$C_{14}H_{32}N_4S_2O_4CoCl$: C, 35.11; H, 6.73; N, 11.70%.

Diastereomer Separation of cis-α- *and* cis-β-*[Co(endet)(diamine)]*$^+$*(diamine=*R-*pn and* RR-*chxn)*: The general procedure in chromatography was as follows: Small amount of each isomer was dissolved in water, adsorbed onto a column of cation exchanger (Dowex 50W×2, Na^+ form; 3×15 cm) and eluted with 0.3 mol dm^{-3} Na_2SO_4. The eluate was collected into 5 cm^3 portions and the CD spectra of the fractions were measured. Two diastereomers were confirmed in each of *cis*-α-[Co(endet)(*R*-pn)]$^+$ and *cis*-α-[Co(endet)(*RR*-chxn)]$^+$, though the elution order is reversed, namely the last eluted isomer $(-)^{CD}_{570}$-*cis*-α-[Co(endet)(*R*-pn)]$^+$ corresponding to the first eluted one $(-)^{CD}_{570}$-*cis*-α-[Co(endet)(*RR*-chxn)]$^+$. On the other hand, both *cis*-β-[Co(endet)(*R*-pn)]$^+$ and *cis*-β-[Co(endet)(*RR*-chxn)]$^+$ gave the only one diastereomer, which showed the two negative CD bands in the first d-d absorption band region. In the cases of *cis*-α complexes, the oxidation products, probably sulfenato complexes, partly overlapped on the front of the first eluted band, which was collected and rechromatographed in the same manner. The diastereomer separation using SP-Sephadex C-25(Na^+ form) gave almost the same results even when the optically active reagents such as *RR*-$C_4H_4O_6^{2-}$ and [Sb_2(*RR*-$C_4H_2O_6)_2$]$^{2-}$ were used as an elution agent. These chromatographic results were supported by the ^{13}C NMR data as shown later.

cis-α *and* cis-β-*Na[Co(endet)(CN)$_2$]*: To a suspension of Na[$CoBr_2(CN)_2(NH_3)_2$](2.19 g) in 50 cm^3 of water, which was prepared by treating *cis(CN)-cis(SO$_3$)-trans(NH$_3$)*-[$Co(CN)_2(SO_3)_2(NH_3)_2$]$^{3-}$ [8] with a HBr solution, was added a solution of H_2endet (1.39 g) and NaOH (0.53 g) in 15 cm^3 of water and the mixture was stirred for 3 h. After filtration of the precipitate, the filtrate was poured onto a column of QAE-Sephadex A-25 (Cl^- form, 3×50 cm), washed with water, and eluted with 0.08 mol dm^{-3} NaCl. The two bands, red purple and light brown, were eluted in this order. Each band was concentrated, reloaded onto a column of Sephadex G-15 to remove the NaCl, and eluted with water. The eluate was evaporated to dryness because of high solubility in water or ethanol. Found for the red purple isomer: C, 26.90; H, 4.99; N, 12.50%. Calcd for *cis*-α-Na[Co(endet)$(CN)_2$]$\cdot 2H_2O\cdot 1.2$NaCl=$C_{10}H_{22}N_4S_2O_2CoNa_{2.2}Cl_{1.2}$: C, 26.90; H, 4.97; N, 12.55%. Found for the light brown isomer: C, 32.33; H, 5.84; N, 14.72%. Calcd for *cis*-β-Na[Co(endet)$(CN)_2$]$\cdot 2H_2O$=$C_{10}H_{22}N_4S_2O_2CoNa$: C, 31.91; N, 5.89; N, 14.89%.

fac(S)-*[Co(endet)(aet)]*: To a solution of $[Co(NH_3)_6]Cl_3$ (0.53 g) in 10 cm^3 of water was added a solution of H_2endet (0.46 g) and Haet (0.15 g) in 10 cm^3 of water and the mixture was stirred 2 h at room temperature. After filtration of the precipitate, the filtrate was poured onto a column of Sephadex A-25 (Cl^- form), and eluted with water. The dark green band was collected and evaporated to dryness below 20 °C. Found: C, 34.88; H, 7.06; N, 12.24%. Calcd for *fac(S)*-[Co(endet)(aet)]=$C_{10}H_{24}N_3S_3Co$: C, 35.18; H, 7.08; N, 12.31%.

Complexes Containing tndet Ligand: The same preparative method as that of [Co(endet)(en)]$^+$ was applied to this system. The solution of $[Co(en)_3]Cl_3$ became temporarily dark green by the addition of tndet ligand but then changed to dark brown to give a large amount of a gummy precipitate. The column chromatograph of the filtrate gave no desirable monomeric species in this system. The change of diamine from en to *R*-pn or *RR*-chxn led to similar results.

cis-α- *and* cis-β-*[Co(*R*-pndet)(diamine)]*$^+$*(diamine=en and* RR-*chxn)*: The complexes were prepared in the same manner as that of [Co(endet)(diamine)]$^+$ where *R*-H_2pndet was substituted for H_2endet. The column chromatography using Dowex 50W×2 (Na^+ form, 3×15 cm; 0.4 mol dm^{-3} NaCl) gave the two geometrical isomers, green and violet in this order, for both [Co(*R*-pndet)(en)]$^+$ and [Co(*R*-pndet)(*RR*-chxn)]$^+$. The earlier eluted green band was rechromatographed to remove the partly overlapping oxidation products. Each band was fractionated into 5 cm^3 portions and their CD spectra were checked. Interestingly, each band was composed of a single species, that is, complete stereoselectivity was observed in *cis*-α(green)- and *cis*-β(violet)-[Co(*R*-pndet)(diamine)]$^+$ (diamine=en and *RR*-chxn). No solid complex was isolated because of their low yield. The concentration value for the CD intensity determination was calculated from the measured absorbance using the absorption coefficient of *cis*-α- or *cis*-β-[Co(endet)(*R*-pn)]$^+$.

cis-α- *and* cis-β-*[Co(endese)(en)]*$^+$ *and* cis-α- *and* cis-β-*[Co(endesi)(en)]*$^+$ *(endese=3,6-dimethyl-3,6-diazaoctane-1,8-disulfenic acid, [HOSCH$_2$CH$_2$N(CH$_3$)CH$_2$-]$_2$ and endesi=3,6-dimethyl-3,6-diazaoctane-1,8-disulfinic acid, [HO$_2$SCH$_2$CH$_2$N(CH$_3$)CH$_2$-]$_2$)*: A stoichiometric amount of 0.6% aqueous H_2O_2 (1.76×10^{-2} mmol) was added to a solution of *cis*-α- or *cis*-β-[Co(endet)(en)]ClO_4(0.88×10^{-2} mmol) in 5 cm^3 of water, leading to an orange-red solution instantly. The oxidation was followed by the absorption spectral measurements. The absorption spectra of *cis*-α- and *cis*-β-[Co(endese)(en)]$^+$ in Table 1 were measured when the absorption intensity became maximum in the region of 380—420 nm, which is the characteristic region to the coordinated sulfenato group. The formation of the corresponding sulfinato complex was negligible because the oxidation from the coordinated sulfenato to the sulfinato group proceeds approximately 10^3 times slower than that from the coordinated thiolate to the sulfenate.[9]

The corresponding sulfinato complex *cis*-α- or *cis*-β-[Co(endesi)(en)]$^+$ was prepared in the same manner using a large excess of 30% H_2O_2 and kept to standing for 1 or 2 d to complete the reaction. In the case of *cis*-α-[Co(endesi)(en)]$^+$ the desired solid complex was obtained. Found: C, 23.73; H, 5.40; N, 10.98%. Calcd for *cis*-α-[Co(endesi)(en)]$ClO_4\cdot H_2O$ =$C_{10}H_{28}N_4S_2O_9CoCl$: C, 23.70; H, 5.57; N, 11.05%. The data of *cis*-β-[Co(endesi)(en)]$^+$ in Table 1 were calculated by assuming that the absorption coefficient at 31250 cm^{-1} is

the same as that of the *cis*-α isomer at 28380 cm^{-1}.

Measurement. The visible and ultraviolet absorption spectra were measured on a Hitachi 330 spectrophotometer and CD spectra with a JASCO MOE-1 spectropolarimeter in aqueous solutions. The ^{13}C NMR spectra were recorded with a JEOL FX-90Q NMR spectrometer.

Results and Discussion

Characterization of Geometrical Isomers. The *cis*-α and *cis*-β isomers (Fig. 1) of the $[Co(endet)(en)]^+$ complex have C_2 and C_1 symmetries, respectively, and are assignable on the basis of ^{13}C NMR spectra. The dark green isomer showed five signals (26.30, 45.21, 52.53, 62.25, and 72.71 ppm) and therefore is assigned to the *cis*-α geometry. The dark violet isomer showed ten signals (17.74, 26.60, 29.20, 42.37, 46.76, 47.11, 58.24, 63.88, 64.34, and 70.89 ppm), which is consistent with the *cis*-β geometry. The absorption spectra of

a) Shoulder. b) See Experimental section. c) This band may be due to the oxidized impurities.

$[Co(N)_4(S)_2]$ type complexes are shown in Fig. 2 and Table 1. The first d-d absorption band of each isomer is composed of two components. Since the interval between the components is larger for the dark green isomer than for the dark violet, the former isomer can be assigned to the *cis-α* structure of *trans(S)* chromophore and the latter to the *cis-β* of *cis(S)*. The complexes showed an intense band in 29000—34000 cm^{-1} region, which is assigned to the $Co(\sigma^*) \leftarrow S(\sigma)$ ligand-to-metal charge transfer (LMCT) transition.[10] The LMCT band of the *cis-α* isomer appears at 29690 cm^{-1} but that of the *cis-β* at 33500 cm^{-1} with its splitting component at 35210 cm^{-1}. Such a difference has been observed between geometrical isomers having two sulfide (thioether)[11] or sulfito[12] donor atoms: In general the charge transer (CT) band of *trans(S)* isomer locates at lower energy than that of *cis(S)* one. Thus the relative positions of CT bands confirm the above structural assignments. This criterion is also valid for the other complexes $[Co(endet)(R\text{-pn})]^+$, $[Co(endet)(RR\text{-chxn})]^+$, $[Co(R\text{-pndet})(en)]^+$, and $[Co(R\text{-pndet})(RR\text{-chxn})]^+$: the first eluted green isomer has the *cis-α* geometry and the second eluted violet one the *cis-β* geometry.

The absorption spectra of other thiolato complexes $[Co(endet)(CN)_2]^-$ and [Co(endet)(aet)] are shown in Fig. 3. In $[Co(endet)(CN)_2]^-$ three geometrical isomers, *cis-α*, *cis-β*, and *trans(CN)*, are possible. The red purple isomer exhibited the single LMCT band at 32450 cm^{-1} and therefore is assigned to the *cis-α* geometry. If the initial *cis(CN)*-configuration of the starting material $Na_3[Co(CN)_2(SO_3)_2(NH_3)_2]$ is retained after the reaction, the light brown isomer should have the *cis-β* geometry in agreement with the presence of two LMCT components at 34570 and 38300 cm^{-1}. The green isomer of [Co(endet)(aet)] showed the very similar absorption spectrum to *fac(S)*-$[Co(aet)_3]$ and *fac(S)*-$[Co(L\text{-cysteinato})_3]^{3-}$.[10] Thus this isomer can be assigned to the *fac(S)* geometry with *cis-β* configuration of the quadridentate ligand. The *mer(S)* configuration is very novel for a $[Co(N)_3(thiolato)_3]$ type complex and there has been no example except *mer(S)*-[Co(2-pyridinethiolato)$_3$].[13]

Figure 4 presents the absorption spectra of $[Co(endese)(en)]^+$ and $[Co(endesi)(en)]^+$. The usual oxidation reactions with H_2O_2 do not involve Co-S cleavage[9,10,14] and the initial geometrical structures should be retained. In fact, both the *cis-α* sulfenato and *cis-α* sulfinato complexes showed the intense CT band at lower energy side than the corresponding *cis-β* complexes, respectively (Table 1).

Synthesis and Stereochemistry of the Complexes of Sulfur-containing Quadridentate Ligand. Several cobalt(III) complexes with quadridentate ligands possessing NSSN array of donor atoms, $NH_2(CH_2)_xS(CH_2)_yS(CH_2)_zNH_2$, have been studied so far.[15] The results showed that only the *cis-α* isomer is formed in the case of $x=y=z=2$ and only the *cis-β* and *trans* isomers in the case of $x=z=2$ and $y=3$ for the mononuclear $[Co(NSSN)X_2]$ complexes. The skeleton of present thiolato ligands $HS(CH_2)_xN(CH_3)(CH_2)_yN(CH_3)(CH_2)_z$-SH is similar to the above one except for the position of sulfur atoms. However, the present SNNS ligands gave both *cis-α* and *cis-β* isomers in the case of $x=y=z=2$ (endet and *R*-pndet) and no mononuclear species in the case of $x=z=2$ and $y=3$ (tndet). Such striking difference can be attributable to the high bridging ability of thiolato groups and the special property of the tndet ligand described below.

Nickel(II) acetate reacted with H_2endet in methanol solution to give the brown complex [Ni(endet)]. However, the tndet ligand did not give the mononuclear complex but the trimeric one $[Ni\{Ni(tndet)\}_2](ClO_4)_2$. A similar Ni(II) trimer has been reported on the occasion of the detritylation of 1,9-bis(tritylthio)-3,7-diazanonane),[16] the trimer being probably in equilibrium with the monomer in methanol. This was confirmed from the synthesis of some mixed-metal trimer by allowing the Ni(II) trimer to react with Pd^{2+} or Cd^{2+}.[17] The synthesis of $[Co(tndet)(diamine)]^+$ was unsuccessful and some kind of polynuclear complex, whose composition was poorly characterized, was formed in the present case. Recently, Lippard and his co-workers prepared the iron complexes of H_2endet and H_2tndet ligands. Zubieta and his co-workers also reported the molybdenum complexes of the same ligands. In

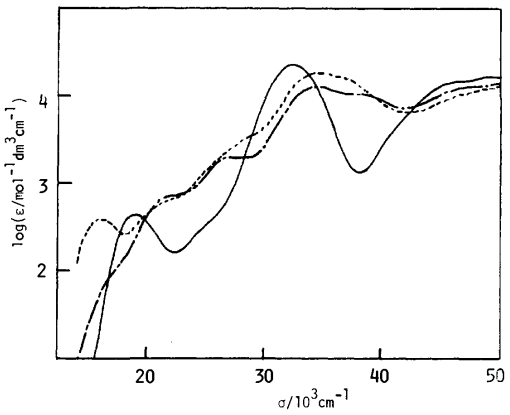

Fig. 3. Absorption spectra of *cis-α*-$[Co(endet)(CN)_2]^-$ (——), *cis-β*-$[Co(endet)(CN)_2]^-$ (– – – –), and *fac(S)*-[Co(endet)(aet)] (----).

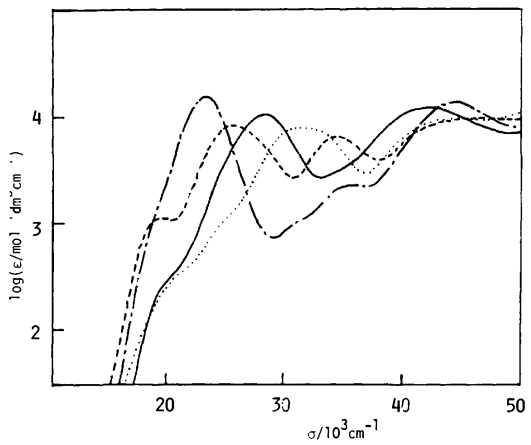

Fig. 4. Absorption spectra of *cis-α*-$[Co(endese)(en)]^+$ (– – – –), *cis-β*-$[Co(endese)(en)]^+$ (----), *cis-α*-$[Co(endesi)(en)]^+$ (——), and *cis-β*-$[Co(endesi)(en)]^+$ (……).

these investigations, some unusual structures were found for the complexes containing tndet ligand: The pseudo tetrahedral complex [Fe(Htndet)$(NO)_2$] has a 12-membered chelate ring in which the two nitrogen atoms of the quadridentate ligand are not coordinated to the iron atom.[18] A similar feature of the structure was found in [Mo_2O_4(Htndet)$_2$].[19] In these cases the tndet ligand is protonated to produce a six-membered ring $\underline{\text{N-C-C-C-N-H}}$ with a chair conformation, which is responsible for the poor complex formation in the present tndet ligand.

The synthetic efforts was also made for [Co(endet)X_2], where X_2 denotes 2(NH_3), 2(NO_2^-), $C_2O_4^{2-}$, $CH_3COCHCOCH_3^-$, CO_3^{2-}, 2(CN^-), and aet^-, all preparations except the latter two ligands producing no mononuclear cobalt(III) complex. This fact means that the stable complex is formed only when the remaining two coordination sites are occupied by such tightly bound ligands as 2(CN^-) and aet^-.

Stereoselective Formation of Diastereomers. Figure 5 shows the ^{13}C NMR spectra of *cis*-α- and *cis*-β-[Co(endet)(*RR*-chxn)]$^+$. The *cis*-α isomer exhibited twelve signals (24.73 (strong), 25.60, 27.06, 33.46, 34.54, 52.25, 52.69, 59.35, 61.52 (strong), 63.58, 72.19, and 73.38 ppm in D_2O), which imply the *cis*-α isomer having C_2 symmetry is a diastereomeric mixture of $\Delta(R^NR^N)(R^CR^C)$ and $\Lambda(S^NS^N)(R^CR^C)$. On the other hand, the *cis*-β isomer showed fourteen signals (23.79, 24.22, 25.85, 28.72, 32.24, 34.30, 45.13, 50.55, 56.84, 61.66, 62.14, 62.96, 65.83, and 69.13 ppm in DMSO-d_6), which indicate the stereoselective formation of single C_1 *cis*-β diastereomer. These results are completely in accord with those of the chromatographic separation: Two diastereomers were confirmed for *cis*-α-[Co(endet)(*R*-pn)]$^+$ and *cis*-α-[Co(endet)(*RR*-chxn)]$^+$, whereas the single diastereomer was found for *cis*-β-[Co(endet)(*R*-pn)]$^+$ and *cis*-β-[Co(endet)(*RR*-chxn)]$^+$.

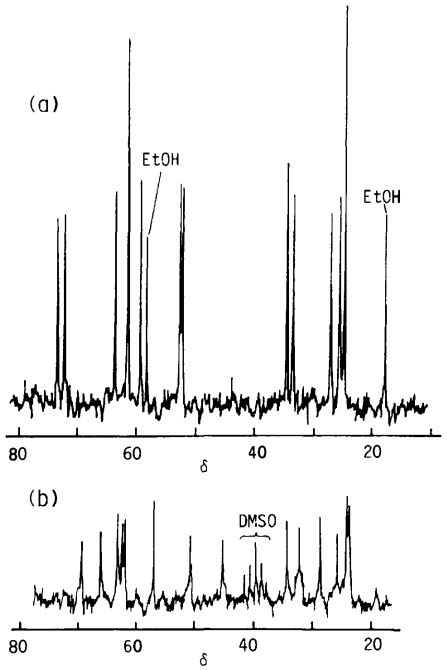

Fig. 5. ^{13}C NMR spectra of [Co(endet)(*RR*-chxn)]$^+$: (a) *cis*-α in D_2O; ethanol(δ 58.27 vs Me_4Si) was used as the internal standard. (b) *cis*-β in DMSO-d_6; DMSO (δ 39.5 vs Me_4Si) was used as the internal standard.

The CD spectra of *cis*-α diastereomers are shown in Figs. 6 and 7. The earlier eluted *R*-pn isomer *cis*-α-$(+)^{CD}_{600}$-[Co(endet)(*R*-pn)]$^+$ corresponds to the later eluted *RR*-chxn one *cis*-α-$(+)^{CD}_{600}$-[Co(endet)(*RR*-chxn)]$^+$ (Fig. 6). Both the *cis*-α-$(+)^{CD}_{600}$ isomers showed a positive dominant CD band in the first absorption band region and therefore are assigned to the $\Lambda(S^NS^N)$ absolute

a) Shoulder.

configuration concerning the skew pair of chelate rings and the tertiary nitrogen atoms. The remaining diastereomers *cis*-α-$(-)^{CD}_{570}$-[Co(endet)(*R*-pn)]$^+$ and *cis*-α-$(-)^{CD}_{570}$-[Co(endet)(*RR*-chxn)]$^+$ exhibited a negative main CD band in the same region, which are assigned to the $\Lambda(R^NR^N)$ absolute configuration.

Each single diastereomer was found in *cis*-α-[Co(*R*-pndet)(en)]$^+$ and *cis*-α-[Co(*R*-pndet)(*RR*-chxn)]$^+$. When the methyl group on the medial chelate ring of quadridentate ligand takes an equatorial position, the medial chelate ring is fixed to the most stable λ conformation. Therefore, two diastereomers, $\Delta\lambda(R^NR^CR^N)$ and $\Lambda\lambda(S^NR^CS^N)$, are possible for *cis*-α-[Co(*R*-pndet)(diamine)]$^+$ in Fig. 8. Each the obtained diastereomer showed three CD bands, (+), (−), and (+), from the lower energy side in the first absorption

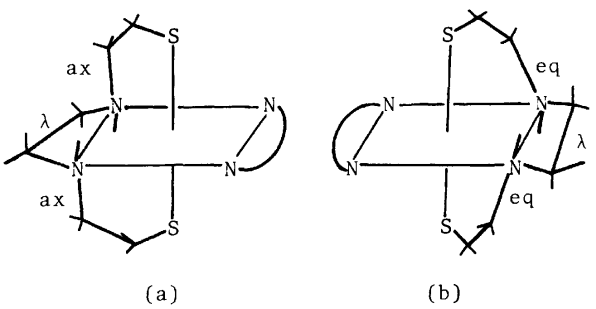

Fig. 8. Two diastereomers of *cis*-α-[Co(*R*-pndet)(diamine)]$^+$: (a) $\Lambda\lambda(S^NR^CS^N)$ and (b) $\Delta\lambda(R^NR^CR^N)$.

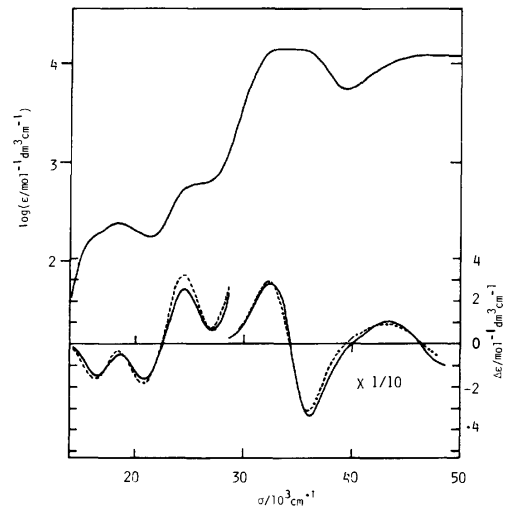

Fig. 9. Absorption and CD spectra of *cis*-β-[Co(endet)(diamine)]$^+$: diamine=*R*-pn (——) and *RR*-chxn (----).

band region (Fig. 7). Since the negative CD band becomes dominant, the complexes can be assigned to the $\Delta\lambda(R^NR^CR^N)$ absolute configuration which has the equatorially oriented terminal chelate rings on the tertiary nitrogen atoms. It has long been generally thought that the configuration $\Lambda\lambda(S^NR^CS^N)$ is more preferable in *cis*-α geometry because the configuration $\Delta\lambda(R^NR^CR^N)$ suffers the greatest ring strain in the backbone and two adjacent chelate rings. However, the latter $\Delta\lambda(R^NR^CR^N)$ or the related $\Delta\lambda(R^NR^CR^CR^N)$ configuration has been recently reported in several chromium(III) and cobalt(III) complexes containing the quadridentate ligands such as (*S*)-*N*,*N*′-bis(2-pyridylmethyl)-1,2-propanediamine, (1*S*,2*S*)-*N*,*N*′-bis(2-pyridylmethyl)-1,2-cyclohexanediamine(abbrev. *SS*-picchxn),[20] and (1*R*,2*R*)-*N*,*N*′-dimethyl-1,2-cyclohexanediamine-*N*,*N*′-diacetate (*N*,*N*′-Me$_2$-*RR*-chxnda).[21] The configurations of Λ-*cis*-α-[CrCl$_2$(*RR*-picchxn)]-

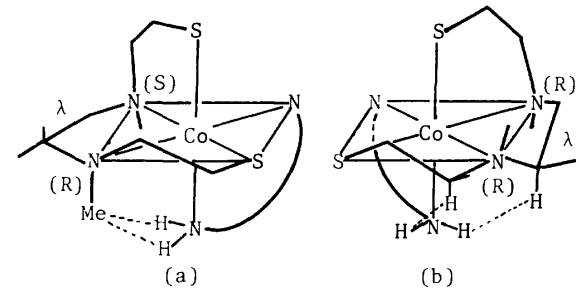

Fig. 11. Possible diastereomers of *cis*-β-[Co(*R*-pndet)(diamine)]$^+$: (a) $\Delta\lambda(S^NR^CR^N)$ and (b) $\Delta\lambda(R^NR^CR^N)$.

ClO$_4$[22] and Δ-*cis*-α-[Co(*N*,*N*′-Me$_2$-*RR*-chxnda)(en)]ClO$_4$[23] have been explicitly determined by the X-ray structure analysis. The CD spectral patterns of *cis*-α-[Co(*R*-pndet)(en)]$^+$ and *cis*-α-[Co(*R*-pndet)(*R*-chxn)]$^+$ are very similar to that of Δ-*cis*-α-[Co(*N*,*N*′-Me$_2$-*RR*-chxnda)(en)]$^+$, especially in the first absorption band region.[20] This fact supports that the present *cis*-α complexes have the rare $\Delta\lambda(R^NR^CR^N)$ configuration.

The CD spectra of the *cis*-β complexes, [Co(endet)(*R*-pn)]$^+$, [Co(endet)(*RR*-chxn)]$^+$, [Co(*R*-(pndet)(en)]$^+$, and [Co(*R*-pndet)(*RR*-chxn)]$^+$ are shown in Figs. 9 and 10. They are very resemble to one another all over the regions measured. The results indicate that each the *cis*-β diastereomer is formed stereoselectively in agreement with the ^{13}C NMR results and has the same absolute configuration. The Δ configuration is assigned to these complexes on the basis of the net negative CD sign in the first absorption band region.

In *cis*-β-[Co(*R*-pndet)(diamine)]$^+$, only two diastereomers, $\Delta\lambda(S^NR^CR^N)$ and $\Lambda\lambda(R^NR^CR^N)$, are possible owing to the λ conformation of the medial chelate ring as in Fig. 11. In the $\Lambda\lambda(R^NR^CR^N)$ structure(b), there is a steric repulsion between the two amine protons of bidentate diamine and the two methylene protons adjacent to the tertiary amine of the quadridentate. On the other hand, the steric crowding between the methyl group on the *R*-N atom and the amine protons of bidentate diamine in the $\Delta\lambda(S^NR^CR^N)$ structure(a) can be eliminated partly by the conformational change of the terminal chelate ring. Therefore the actual diastereomer is limited to the $\Delta\lambda(S^NR^CR^N)$ configuration. In conclusion, all the four *cis*-β complexes obtained stereoselectively can be assigned to $\Delta(S^NR^N)$ configuration on the basis of the analogous CD patterns.

Isolation and Assignment of Two Isomers of *trans*(NO_2)-Dinitrobis-[(*S*)-2-aminomethylpyrrolidine]-cobalt(III) Perchlorate

Masahiko SABURI,* Yasuhiko YOKOWO, and Sadao YOSHIKAWA*
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received November 18, 1983)

Two possible isomers (trans,cis and trans,trans) of *trans*-(NO_2)-[($Co(NO_2)_2$(ampr)$_2$]ClO_4 (ampr= (*S*)-2-aminomethylpyrrolidine) were isolated separately by fractional recrystallization. The dinitro complexes were converted to the corresponding *trans*(Cl,NO_2)-[$CoCl(NO_2)$(ampr)$_2$]$^+$ complexes. Based on the circular dichroism and ^{13}C-NMR spectral data, it was shown that the less soluble dinitro complex gave the single isomer of the chloronitro complex, while the more soluble one yielded two diastereomeric chloronitro complexes. Thus, the former is assigned to the trans,cis configuration, and the latter to the trans,trans, taking the geometries of the complexes into consideration.

Two stereoisomers, designated as trans,trans and trans,cis,[1] are possible for the *trans*(X)-[$CoX_2(N\text{-}N')_2$]$^{n+}$ complexes, where *N*-*N*′ refers to an unsymmetrical diamine ligand (see Fig. 1). Each pair of two equivalent amino groups, *N* and *N*′, disposes in trans fashion for the trans,trans and in cis for the trans,cis isomer, respectively. 1,2-Propanediamine, one of the representative unsymmetrical diamine, has been shown to give the trans,trans isomer for its dichlorocobalt(III) complex with the optically active form.[2]

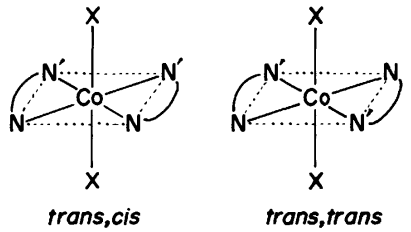

Fig. 1. Two possible isomers of *trans*(X)-[CoX_2-$(N\text{-}N')_2$]$^{n+}$ ion.

Although the formation of *trans,cis*-[$CoCl_2$((*R*)-pn)$_2$]$^+$ ion ((*R*)-pn=(*R*)-1,2-propanediamine) was claimed,[3] no detailed spectral evidence has been reported.

Most of mono-N-alkyl-substituted 1,2-diamines gave rise to the trans,trans configuration, as exemplified by *N*-methyl-1,2-ethanediamine,[1,4] (*S*)-1-methylamino-2-propanamine,[5] and (*S*)-1-ethylamino-2-propanamine.[6] It was found that (*R*)-*N*,*N*′-dimethyl-1,2-propanediamine afforded both of the trans,trans and trans,cis isomers of dinitrocobalt(III) complex.[7] This is the sole example reported so far, where the two possible isomers were isolated separatly.

In a previous paper,[8] we reported on the cobalt(III) complexes of (*S*)-2-(methylaminomethyl)pyrrolidine (=*N*-Meampr), which is a chiral unsymmetrical 1,2-diamine derived from (*S*)-proline. The [CoX_2(*N*-Meampr)$_2$]$^+$ (X=NO_2^- or Cl^-) complexes take specifically the trans,cis configuration.[8] We supposed that the unique predominance of the trans,cis isomer over the trans,trans for *N*-Meampr complexes was due, at least in part, to the presence of pyrrolidine ring in the ligand. With a view to elucidate the effect of pyrrolidinyl moiety build in a diamine molecule, the stereochemical features of cobalt(III) complexes with (*S*)-2-amino-methylpyrrolidine (=ampr) were investigated in this study. If the steric effect of pyrrolidine ring supresses any other factors controlling the geometry of complexes, the trans,cis isomer would be exclusively formed even for the ampr complexes.

Experimental

trans,cis-*Dinitrobis[(S)-2-aminomethylpyrrolidine]cobalt(III) Perchlorate,* trans,cis-*[Co(NO_2)$_2$(ampr)$_2$]ClO_4.* Sodium hexanitrocobaltate(III) (4.04 g; 0.01 mol) was added to a solution of ampr (2.00 g; 0.02 mol) in water (30 cm^3), and the resultant solution was heated at 60—65 °C for 15 min. Sodium perchlorate (4.0 g) dissolved in water (4 cm^3) was added, and the solution was cooled in a refrigerator overnight. Yellow crystals were filtered off, washed with ethanol and diethyl ether, and air-dried. Yield; 1.5—2.0 g. The filtrate (designated as F-1) was kept for obtaining the trans,trans isomer.

The crystals obtained above were recrystallized fractionally from warm water (80 °C). Less soluble yellow fine needle crystals were collected, washed with ethanol and diethyl ether, and air-dried. Yield; 0.5—0.8 g. Found: C, 26.24; H, 5.64; N, 18.82%. Calcd for $C_{10}H_{24}N_6O_8ClCo$: C, 26.65; H, 5.37; N, 18.65%.

trans,trans-*Dinitrobis[(S)-2-aminomethylpyrrolidine]cobalt(III) Perchlorate,* trans,trans-*[Co(NO_2)$_2$(ampr)$_2$]ClO_4.* The filtrate from the trans,cis isomer was gradually evaporated at room temperature to separate out brown crystals (0.5—1.0 g) after several days. The same product was also obtained from the filtrate F-1. Brown crystals were recrystallized from warm water (80 °C). Found: C, 26.92; H, 5.75; N, 18.39%. Calcd for $C_{10}H_{24}N_6O_8ClCo$: C, 26.65; H, 5.37; N, 18.65%.

trans,cis-*Chloronitrobis[(S)-2-aminomethylpyrrolidine]cobalt-(III) Perchlorate,* trans,cis-*[CoCl(NO_2)(ampr)$_2$]ClO_4 (Chloronitro-1).* *trans,cis*-[$Co(NO_2)_2$(ampr)$_2$]ClO_4 (0.65 g) was added to 1 M HCl (10 cm^3; 1 M=1 mol dm^{-3}), and heated for 5 min at 65 °C with occasional stirring. To the mixture was added $LiClO_4$ (1.0 g), and cooled in an ice bath. The crystals were filtered off, washed with ethanol and diethyl ether, and air-dried. Yield; 0.55 g. The crude product was recrystallized from hot water. Found: C, 27.07; H, 5.38; N, 16.01%. Calcd for $C_{10}H_{24}N_5O_6ClCo$: C, 27.28; H, 5.50; N, 15.91%.

trans,trans-*Chloronitrobis[(S)-2-aminomethylpyrrolidine]cobalt(III) Perchlorate,* trans,trans-*[CoCl(NO_2)(ampr)$_2$]ClO_4 (Chloronitro-2).* *trans,trans*-[$Co(NO_2)_2$(ampr)$_2$]ClO_4 (7.8 g) was

added to 8 M HCl (27 cm^3), and the mixture was heated at 70—75 °C for 5 min with occasional stirring. To the mixture was added $LiClO_4$ (4 g), and the whole was cooled in an ice bath for 3 h. Orange-red precipitate thus formed was filtered off, and washed with ethanol and diethyl ether. Yield; *ca.* 5 g. The precipitate was dissolved in warm water (80 cm^3 at 70 °C), and filtered while hot. To the filtrate was added concd. HCl (5 cm^3), and cooled in a refrigerator overnight. Orange-red crystals were collected, washed with ethanol and diethyl ether, and air-dried. Found: C, 27.22; H, 5.11; N, 15.48%. Calcd for $C_{10}H_{24}N_5O_6Cl_2Co$: C, 27.28; H, 5.50; N, 15.91%.

trans,trans-*Chloronitrobis[(S)-2-aminomethylpyrrolidine]cobalt(III) Chloride,* trans,trans-*[CoCl(NO$_2$)(ampr)$_2$]Cl (Chloronitro-3).* The filtrate after the removal of crude *trans,trans*-$[CoCl(NO_2)(ampr)_2]ClO_4$ mentioned above was poured into a mixture of ethanol (100 cm^3) and diethyl ether (500 cm^3), and the mixture was cooled in a refrigerator. Reddish pink precipitate deposited was collected and washed with diethyl ether. The crude product was recrystallized from methanol and diethyl ether. Found: C, 31.52; H, 6.16; N, 18.47%. Calcd for $C_{10}H_{24}N_5O_2Cl_2Co$: C, 31.93; H, 6.44; N, 18.62%.

trans,cis-*Dichlorobis[(S)-2-aminomethylpyrrolidine]cobalt(III) Perchlorate,* trans,cis-*[CoCl$_2$(ampr)$_2$]ClO$_4$.* *trans,cis*-$[Co(NO_2)_2(ampr)_2]ClO_4$ (1.5 g) was added to concd HCl (15 cm^3) and heated on a steam bath, until deep green crystals began to appear. The mixture was cooled in a refrigerator overnight, and the crystals were collected and washed with ethanol and diethyl ether. Yield; 0.75 g. The crude product was recrystallized from concd HCl. Found: C, 27.91; H, 5.78; N, 13.39%. Calcd for $C_{10}H_{24}N_4O_4Cl_3Co$: C, 27.94; H, 5.63; N, 13.05%.

trans,trans-*Dichlorobis[(S)-2-aminomethylpyrrolidine]cobalt(III) Perchlorate,* trans,trans-*[CoCl$_2$(ampr)$_2$]ClO$_4$.* *trans,trans*-$[Co(NO_2)_2(ampr)_2]ClO_4$ (3.3 g) was added to concd HCl (35 cm^3), and heated on a steam bath, until the solution became deep green. To the solution was added 70% $HClO_4$ (5 cm^3), and the whole was cooled in a refrigerator overnight. Green crystals were collected and washed in a usual way. Yield; 0.9 g. Found: C, 27.69; H, 5.59; N, 12.98%. Calcd for $C_{10}H_{24}N_4O_4Cl_3Co$: C, 27.94; H, 5.63; N, 13.05%.

Measurements. Visible and ultraviolet absorption spectra were obtained with a Hitachi 340 spectrophotometer. Circular dichroism spectra were recorded with a JASCO J-500 spectropolarimeter. ^{13}C-NMR spectra were obtained on a JEOL PFT-100 spectrometer (24.75 MHz), using TMS as an external reference.

Results and Discussion

It was demonstrated that $[Co(NO_2)_2(ampr)_2]ClO_4$, the dinitrocobalt(III) complex of ampr prepared by a reaction of ampr with $Na_3[Co(NO_2)_6]$ and succesive addition of $NaClO_4$, could be fractionated into two distinct crystalline products from aqueous solution; *i.e.* less soluble brownish yellow needles and more soluble brown blocks. Both forms equally showed the elemental analytical data corresponding to the formula $[Co(NO_2)_2(C_5H_{12}N_2)_2]ClO_4$, and, further, exhibited almost identical electronic absorption spectra. The spectra showed the absorption band characteristic of cobalt(III) complexes with the nitro group at 29000 cm^{-1}, so that the nitro ligands were considered to locate at the trans position to each other in the two forms.[1,5] The circular dichroism (CD) spectra of these dinitro complexes were, however, apparently different to each other as shown in Fig. 2. The numerical spectral data are summarized in Table 1. These findings unambiguously indicated that the two possible isomers of *trans*(NO_2)-$[Co(NO_2)_2(ampr)_2]ClO_4$ (illustrated as structures **a** and **b** in Fig. 3) were isolated.

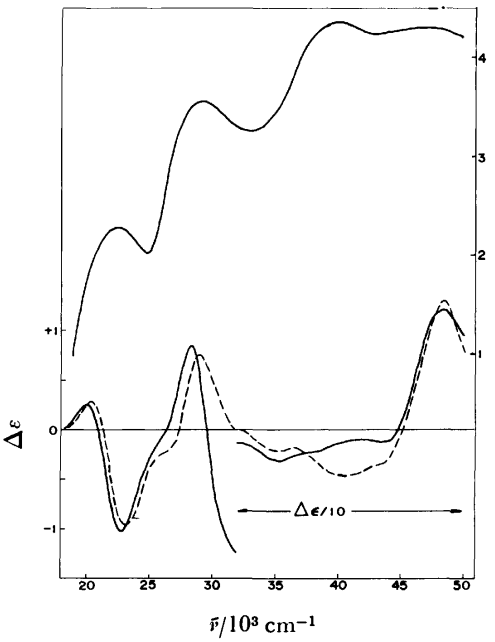

Fig. 2. Electronic absorption and CD spectra for the less soluble (trans,cis isomer; ——) and the more soluble form (trans,trans isomer; — — —) of *trans*-$(NO_2)[Co(NO_2)_2(ampr)_2]ClO_4$.

With a view to assign both the fractions of *trans*-(NO_2)-$[Co(NO_2)_2(ampr)_2]ClO_4$ to either of structure **a** (trans,cis) and **b** (trans,trans), the dinitro complexes were converted into the chloronitro complexes. Figure 3 suggests that *trans,cis*-$[Co(NO_2)_2(ampr)_2]^+$ ion gives the single species of *trans,cis*-$[CoCl(NO_2)(ampr)_2]^+$ ions (structure **c**), while *trans,trans*-$[Co(NO_2)_2(ampr)_2]^+$ ion yield, in principle, two diastereomeric *trans,trans*-$[CoCl(NO_2)(ampr)_2]^+$ ions (structure **d** and **e**). In practice, the less soluble dinitro complex gave a chloronitro complex as perchlorate (chloronitro-1) in an almost quantitative yield, and the more soluble dinitro complex also afforded another chloronitro complex as perchlorate (chloronitro-2). It was interestingly found that the third chloronitro complex could be isolated from the filtrate of chloronitro-2 as chloride salt (chloronitro-3).

It was reported that *trans*- and *cis*-$[CoCl(NO_2)(en)_2]^+$ ion (en=1,2-ethanediamine) showed the absorption bands assignable to the d-d transition at 21600 and 20100 cm^{-1}, respectively.[9] The absorption spectra of chloronitro complexes of ampr resembled to one another, and exhibited the first absorption bands at *ca.* 20900 cm^{-1} (Fig. 4 and Table 1). It is certain that the ligand field provided by ampr, an *N*-substituted 1,2-diamine, is somewhat weaker than that of en,[10] so that three chloronitro complexes could be reasonably assigned to the *trans*(Cl,NO_2) configuration.

a) In H_2O. b) In 1 M NaCl. c) In methanol. d) Shoulder.

Further, the CD spectra of chloronitro complexes were obviously different from one another, and did not change after recrystallization. This means that the three possible diastereomer of *trans*(Cl,NO_2)-$[CoCl(NO_2)(ampr)_2]^+$ ion could be isolated separately. Thus, the more soluble dinitro complex, which gave rise to two isomers of chloronitro complex, should have the trans,trans structure, and, therefore, the less soluble dinitro complex should take the trans,cis configuration.

If the above mentioned assignments are valid, chloronitro-1 must have the trans,cis configuration (structure **c**), in which the two ampr ligands are in unequal circumstances due to the C_1 symmetry of **c**. On the other hand, chloronitro-2 and -3 are considered to adopt either of the trans,trans configurations (structure **d** or **e**) with C_2 symmetry. In those structures, the two ampr molecules should be situated in the identical environment, though the environment of ampr in **d** is intrinsically different from that in **e**. In order to make sure the assignment, ^{13}C-NMR spectra of chloronitro complexes were examined.

The ^{13}C-NMR spectrum of chloronitro-3 was obtained in 1 M DCl solution, the data being given in Table 2. The spectrum showed five resonances, with the incidental overlap of two signals at 49.8 ppm. This support that chloronitro-3 certainly adopts the trans,trans configuration and consists of the single species, though the exact structure, **d** or **e**, of this isomer has not been established. The chloro-

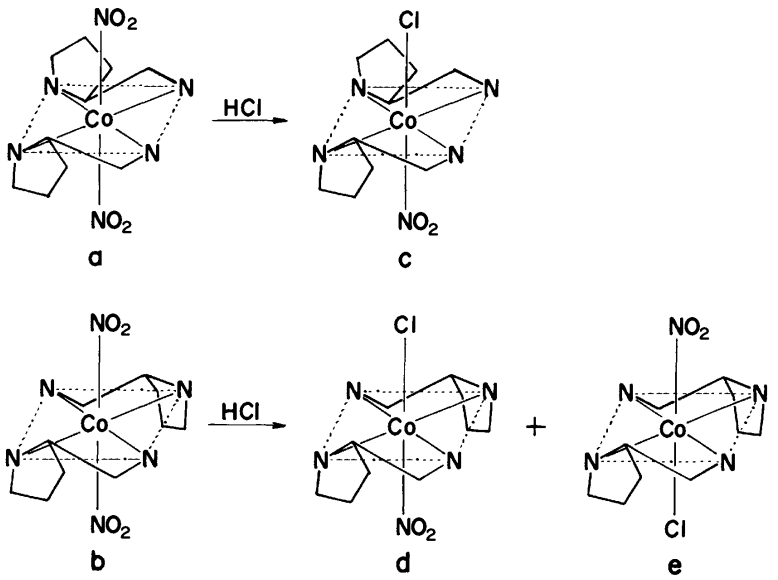

Fig. 3. Structures of *trans,cis*-$[Co(NO_2)_2(ampr)_2]^+$ ion (**a**), *trans,trans*-$[Co(NO_2)_2(ampr)_2]^+$ ion (**b**), *trans,cis*-$[CoCl(NO_2)(ampr)_2]^+$ ion (**c**), and *trans,trans*-$[CoCl(NO_2)(ampr)_2]^+$ ion (**d** and **e**).

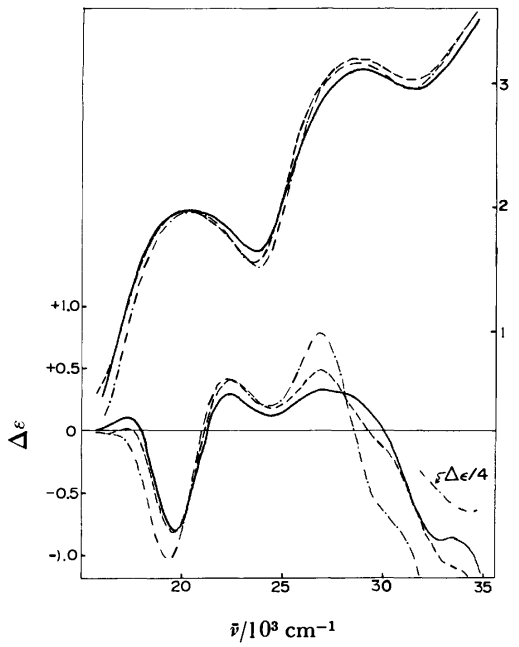

Fig. 4. Absorption and CD spectra of chloronitro-1 (——), chloronitro-2 (— — —), and chloronitro-3 (—·—·—).

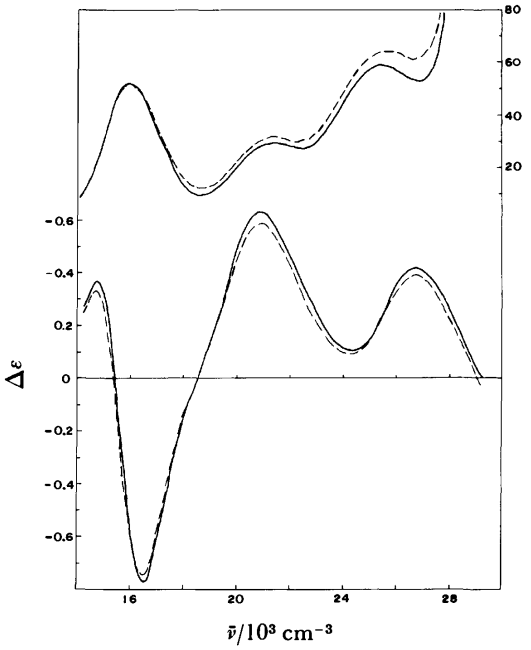

Fig. 5. Visible absorption and CD spectra of *trans,cis*-$[CoCl_2(ampr)_2]ClO_4$ (——), and *trans,trans*-$[CoCl_2(ampr)_2]ClO_4$ (— — —).

nitro-1 and -2 provided no satisfactory spectra in DCl solution because of the low solubility of the complexes and structural changes (the aquation of the chloride ligand and/or trans-cis isomerization) occured during the measurements.

The ^{13}C-NMR spectrum of chloronitro-1 could, however, be taken in a mixture of 1 M DCl and acetone. Although a few signals were occasionally overlapped, the spectrum could be analyzed to be composed of ten resonances as given in Table 2. This means that two ampr ligands are in the different circumstances, being consistent with the expected stereochemical requirements from the structure **c**. Thus, the ^{13}C-NMR features of chloronitro complexes, as well as the absorption and CD spectral data, confirmed without conflict that the less soluble dinitro complex adopted the trans,cis configuration, while the more soluble one took the trans,trans configuration.

It is clarified, therefore, that both trans,cis and trans,trans isomers exist with respect to ampr complexes. The steric effects brought about by pyrrolidine ring appeared not to be so significant in ampr complexes, compared with those found in *N*-Meampr complexes, where only the trans,cis isomer is existent. This is possibly due to the difference in the steric repulsions

Table 2. ^{13}C-NMR spectral data[a] of chloronitro complexes

trans,trans-$[CoCl(NO_2)(ampr)_2]Cl$[b] (chloronitro-3)	*trans,cis*-$[CoCl(NO_2)(ampr)_2]ClO_4$[c] (chloronitro-1)	Assignments[d]

27.68 (1)	27.35 (1)	
	27.78 (1)	
49.81 (2)	49.24 (1)	C_1, C_5
	50.10 (3)	
65.41 (1)	65.04 (1)	
	65.47 (1)	C_2

a) Ppm from TMS (external). b) Measureed in 1 M DCl. c) Measured in a mixture of 1 M DCl and acetone. d) The order of carbon atoms in ampr is as follows;  . e) The values in parentheses are approximate relative intensities of the signals.

between pyrrolidinyl moiety and *N*-methylamino (-NH(CH_3)) group in *N*-Meampr complexes, and between pyrrolidinyl and primary amino (-NH_2) group in ampr complexes, particularly in the trans,trans configuration. The steric repulsion must be considerably severer in *N*-Meampr complexes than in ampr complexes. Hence, it is shown that the steric effect of pyrrolidine ring is not so pronounced as to give solely the trans,cis isomer for complexes with any diamines having this ring.

Finally, both of the dinitro complexes were converted into the corresponding *trans*(Cl)-dichloro complexes. No configurational change was expected during this conversion, as the cases of other *N*-substituted 1,2-diamine complexes.[1,5,6] The absorption and CD spectra of two isomers resembled closely to each other, though slight differences were still acknowledged (Fig. 5). This displays a novel example of isolation of two diastereomers possible for *trans*(Cl)-$[CoCl_2(N\text{-}N')_2]^+$ ion.

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received December 8, 1983)

A large number of mixed-ligand $[Pd(N)_n(O)_{4-n}]$-type complexes (n=1—4) which contain at least one optically active ligand were synthesized and isolated in a systematic manner. (*S*)-Propylenediamine, (2*S*)-N^1,N^1-diethyl-1,2-propanediamine, and (*S*)-amino carboxylates were employed as one ligand, which is optically active; ammonia, diamines, amino carboxylates, acetates, and dicarboxylates as the other ligand occupying the remaining coordination sites. Isomerism could be detected in the mixed complexes of an unsymmetrical diamine and an amino carboxylate and has been discussed on the basis of ^{13}C NMR and CD spectra. Moreover, the influence of optically inactive ligands on the vicinal CD spectra has been examined, and also the additivity of vicinal CD contributions of two different optically active ligands has been demonstrated.

The electronic structure of d^8 square-planar complexes has been studied most extensively on $[MCl_4]^{2-}$ (M=Pt and Pd)[1] which are easy to deal with theoretically and experimentally. In a separate paper,[2] we reported on the electronic structures of *cis*- and *trans*-$[Pd(Cl)_2(N)_2]$-type complexes. An extension of the work to complexes containing nitrogen and oxygen atoms which are most popular as coordinating atoms is desirable to understand systematically the electronic structure of square-planar palladium(II) complexes. Although it is desired to use as simple ligands as possible in order to study the d-d absorption spectra, there have been known few examples of the isolation of mixed-ligand palladium(II) complexes comprising of such *N*- and/or *O*-ligands. This seems to be ascribed to the lability of palladium(II) complexes and to retarded development of systematized synthetic routes. Unavailability of ion exchange column chromatography, which serves as a very powerful tool for separating some chemical species in the case of cobalt(III), chromium(III), rhodium(III) complexes *etc.*, is also responsible for the situation.

In 1932, Drew *et al.*[3] isolated $[Pd(en)(NH_3)_2]Cl_2$, $[Pd(en)(py)_2]Cl_2$, and $[Pd(NH_3)_2(py)_2]Cl_2$ and observed that the former two complexes were obtained only by the action of ammonia or pyridine(py) on $[PdCl_2(en)]$, the action of ethylenediamine(en) on $[PdCl_2(NH_3)_2]$ or $[PdCl_2(py)_2]$ causing disproportionation to give $[Pd(NH_3)_4]Cl_2$ or $[Pd(py)_4]Cl_2$ as well as $[Pd(en)_2]Cl_2$, respectively. According to these investigations $[Pd(NH_3)_2(py)_2]Cl_2$ can be obtained either from $[PdCl_2(NH_3)_2]$ or from $[PdCl_2(py)_2]$, where excess pyridine is necessary in the case of the former starting material but in the latter case the calculated quantity of ammonia must be used because excess ammonia replaces the coordinated pyridine molecules. These observations suggest that the order of introduction of ligands is important in the synthesis of mixed-ligand palladium(II) complexes.

Although the kinetics of the mixed-ligand palladium(II) complexes of ethylenediamine and a variety of amino carboxylates has been systematically investigated by Lim,[4] no isolation and spectroscopic studies of the complexes have been undertaken at all. The examples of the isolation of $[Pd(N)_2(O)_2]$-type complexes with simple ligands are limited to $[Pd(ox)(NH_3)_2]$[5] and $[Pd(CH_3CO_2)_2L_2]$ (L=py, $NH(C_2H_5)_2$, $N(C_2H_5)_3$, and (bipyridine)$_{1/2}$)[6] except bis(amino carboxylato) complexes.[7,8] None of these complexes, however, are suited for investigation of d-d spectra because of low solubility, isomerization reaction, and/or the presence of the low energy intraligand transitions. As to the mixed-ligand palladium(II) complexes of an amino carboxylate and a (di)carboxylate, no reports could be found even on the preparation.

This paper deals with the synthesis and isolation of mixed-ligand $[Pd(N)_n(O)_{4-n}]$-type complexes (n=1—4) containing (di)amine(s) as an *N*-ligand, (di)carboxylate(s) as an *O*-ligand, and an amino carboxylate as an *N*,*O*-ligand. Then, the mixed-ligand complexes comprising of (*S*)-propylenediamine or (2*S*)-N^1,N^1-diethyl-1,2-propanediamine and an unsymmetrical bidentate ligand such as an amino carboxylate should exhibit isomerism; this could be actually detected in the amino carboxylato complexes, and has been discussed on the basis of ^{13}C NMR and CD spectra. Moreover, we have examined the additivity of vicinal CD contributions of two optically active ligands and the influence of optically inactive ligands on the vicinal CD spectra. The following abbreviations are used for ligands in the present paper: *S*-pn, (*S*)-propylenediamine $NH_2CH_2CH(CH_3)NH_2$; tn, trimethylenediamine $NH_2CH_2CH_2CH_2NH_2$; N^1,N^1-Et_2-(*S*)-pn, (2*S*)-N^1,N^1-diethyl-1,2-propanediamine $NH_2CH(CH_3)CH_2N(C_2H_5)_2$; *N*,*N*-$Me_2$en, *N*,*N*-dimethylethylenediamine $NH_2CH_2CH_2N(CH_3)_2$; *N*,*N*-Et_2en, *N*,*N*-diethylethylenediamine $NH_2CH_2CH_2N(C_2H_5)_2$; Hgly, glycine $NH_2CH_2CO_2H$; β-Hala, β-alanine $NH_2CH_2CH_2CO_2H$; *S*-Hala, (*S*)-alanine $NH_2CH(CH_3)CO_2H$; *S*-Hpro, (*S*)-proline $\overline{NHCH_2CH_2CH_2CHCO_2H}$; *S*-Hser, (*S*)-serine $NH_2CH(CH_2OH)CO_2H$; *S*-Hleu, (*S*)-leucine $NH_2CH\{CH_2CH(CH_3)_2\}CO_2H$; *S*-Hhpro, (*S*)-hydroxyproline $\overline{NHCH_2CH(OH)CH_2CHCO_2H}$; H(*N*,*N*-$Me_2$gly), *N*,*N*-dimethylglycine $N(CH_3)_2CH_2CO_2H$; H_2ox, oxalic acid HO_2CCO_2H; H_2mal, malonic acid $HO_2CCH_2CO_2H$; Ham,amino carboxylic acid.

Experimental

[Pd(N)$_4$]-type Complexes. *1) [Pd(S-pn)(NH$_3$)$_2$]Cl$_2$*: Concentrated aqueous ammonia (*ca.* 26.5%, 120 mg) was added to a suspension of 400 mg of [PdCl$_2$(*S*-pn)][2] in 15 cm^3 of water, with stirring at room temperature. The resulting clear solution was evaporated to 1—2 cm^3 under reduced pressure and then diluted with 5 cm^3 of methanol. After removal of a small amount of [PdCl$_2$(*S*-pn)] reproduced, the solution was mixed with one drop of concentrated aqueous ammonia and 3 cm^3 of ether, and allowed to stand at room temperature. White crystals were collected, washed with a mixture of methanol—ether, and dried in air. Yield: 310 mg. Found: C, 12.57; H, 5.65; N, 19.42%. Calcd for $C_3H_{16}N_4Cl_2Pd$: C, 12.62; H, 5.65; N, 19.62%.

2) [Pd(S-pn)(en)]Cl$_2$: An aqueous solution containing 73 mg of ethylenediamine was mixed with 300 mg of [PdCl$_2$(*S*-pn)] suspended in 10 cm^3 of water and the mixture was stirred at 40 °C. The resulting solution was filtered and concentrated to a small volume under reduced pressure. Addition of ethanol to the concentrate warmed gave white precipitate, which was collected, washed with a mixture of water-ethanol, and dried *in vacuo*. Yield: 290 mg. Found: C, 18.67; H, 5.92; N, 17.34%. Calcd for [Pd(*S*-pn)(en)]Cl$_2$·0.5H$_2$O=$C_5H_{19}N_4Cl_2O_{0.5}Pd$: C, 18.73; H, 5.97; N, 17.48%.

3) [Pd(S-pn)$_2$]Cl$_2$: This complex was obtained from [PdCl$_2$(*S*-pn)] by the same method as in *2)*, in a 72% yield. The content of water of crystallization is different from that reported for [Pd(*R*-pn)$_2$]Cl$_2$.[9] Found: C, 21.68; H, 6.20; N, 16.81%. Calcd for [Pd(*S*-pn)$_2$]Cl$_2$·0.5H$_2$O=$C_6H_{21}N_4Cl_2O_{0.5}Pd$: C, 21.54; H, 6.33; N, 16.75%.

4) [Pd(S-pn)(tn)]Cl$_2$: An aqueous solution containing this complex was prepared in the same way as in *2)*. The solution was evaporated under reduced pressure to give a sirup, which was dissolved in ethanol. After filtration the ethanol solution was mixed with ether and allowed to stand in a refrigerator. The desired product was obtained as white crystals in an 82% yield. Found: C, 21.04; H, 6.37; N, 16.35%. Calcd for [Pd(*S*-pn)(tn)]Cl$_2$·H$_2$O=$C_6H_{22}N_4Cl_2OPd$: C, 20.97; H, 6.45; N, 16.31%.

5) [Pd(N^1,N^1-Et$_2$-(S)-pn)(NH$_3$)$_2$]Cl$_2$: A suspension of 610 mg of [PdCl$_2$(*N*^{1},*N*^{1}-Et$_2$-(*S*)-pn)][10] in 10 cm^3 of water was mixed with concentrated aqueous ammonia (*ca.* 26.5%, 300 mg) and the mixture was stirred at 40 °C. An evaporation of the resulting pale yellow solution gave a sirup, which was dissolved in a mixture of ethanol-ether and stored in a freezer for 4 d. Yellow blocks deposited were mechanically separated from a small amount of white powder and identified as [PdCl(NH$_3$)(*N*^{1},*N*^{1}-Et$_2$-(*S*)-pn)]Cl by the absorption spectrum and elemental analysis (yield: 370 mg). Found: C, 25.99; H, 6.48; N, 12.97%. Calcd for [PdCl(NH$_3$)(*N*^{1},*N*^{1}-Et$_2$-(*S*)-pn)]Cl=$C_7H_{21}N_3Cl_2Pd$: C, 25.90; H, 6.52; N, 12.95%. Its electronic absorption(AB) and CD data in a 0.10 M KCl aqueous solution (1 M=1 mol dm^{-3}) were as follows in $\sigma_{max}/10^3$ cm^{-1} (ε/mol^{-1} dm^3 cm^{-1}) and $\sigma_{ext}/10^3$ cm^{-1} ($\Delta\varepsilon$/mol^{-1} dm^3 cm^{-1}), respectively; AB: 29.3 (346), 47.8 (17000) and CD: 23.6 (−0.027), 27.9 (+0.12), 32.0 (−0.73).

The monochloro complex (220 mg) was dissolved in a minimum quantity of warm water and diluted with 3 cm^3 of ethanol containing one drop of concentrated aqueous ammonia. The resulting almost colorless solution was mixed with ether to give faint yellow needles, which were washed with a mixture of 95%-ethanol-ether and dried in air. Yield: 140 mg. Found: C, 23.46; H, 7.33; N, 15.38%. Calcd for [Pd(*N*^{1},*N*^{1}-Et$_2$-(*S*)-pn)(NH$_3$)$_2$]Cl$_2$·H$_2$O=$C_7H_{26}N_4Cl_2OPd$: C, 23.38; H, 7.29; N, 15.58%. This complex is liable to decompose even in the crystalline state.

6) [Pd(N^1,N^1-Et$_2$-(S)-pn)(tn)]Cl$_2$: An aqueous solution of 130 mg of *N*^{1},*N*^{1}-Et$_2$-(*S*)-pn was added to 250 mg of [PdCl$_2$(tn)] suspended in 13 cm^3 of water, with stirring at *ca.* 55 °C. The resulting solution was evaporated to dryness and the residue was dissolved in a small amount of warm methanol. After filtration the methanol solution was mixed with acetone and allowed to stand in a refrigerator to give faint yellow crystals, which were washed with a mixture of water-acetone and dried *in vacuo*. Total yield: 300 mg. Found: C, 31.42; H, 7.38; N, 14.75%. Calcd for $C_{10}H_{28}N_4Cl_2Pd$: C, 31.47; H, 7.39; N, 14.68%.

7) [PdL(S-pn)]Cl$_2$ (L=N^1,N^1-Et$_2$-(S)-pn and N,N-*Et$_2$en)*: These complexes were prepared from [PdCl$_2$(*S*-pn)] by a method similar to that in *6)*, but crystallized from ethanol by adding acetone. Yield: 75—85%. Found: C, 28.77; H, 7.66; N, 13.46%. Calcd for [Pd(*N*^{1},*N*^{1}-Et$_2$-(*S*)-pn)(*S*-pn)]Cl$_2$·2H$_2$O=$C_{10}H_{32}N_4Cl_2O_2Pd$: C, 28.76; H, 7.72; N, 13.41%. Found: C, 27.71; H, 7.29; N, 14.29%. Calcd for [Pd(*N*,*N*-Et$_2$en)(*S*-pn)]Cl$_2$·1.25H$_2$O=$C_9H_{28.5}N_4Cl_2O_{1.25}Pd$: C, 27.71; H, 7.36; N, 14.36%.

*8) [PdL(N^1,N^1-Et$_2$-(S)-pn)]Cl$_2$ (L=*N,N-*Et$_2$en and* N,N-*Me$_2$en)*: Each of these complexes was obtained from [PdCl$_2$L][11] in a manner similar to that in *6)*, but crystallization was performed from warm ethanol or methanol by adding ether. Yield: 80—85%. Found: C, 36.87; H, 8.06; N, 13.32%. Calcd for [Pd(*N*,*N*-Et$_2$en)(*N*^{1},*N*^{1}-Et$_2$-(*S*)-pn)]Cl$_2$=$C_{13}H_{34}N_4Cl_2Pd$: C, 36.85; H, 8.09; N, 13.22%. Found: C, 33.40; H, 7.60; N, 14.29%. Calcd for [Pd(*N*,*N*-Me$_2$en)(*N*^{1},*N*^{1}-Et$_2$-(*S*)-pn)]Cl$_2$=$C_{11}H_{30}N_4Cl_2Pd$: C, 33.39; H, 7.64; N, 14.16%.

9) Other Complexes: The complex [Pd(*N*^{1},*N*^{1}-Et$_2$-(*S*)-pn)$_2$]Cl$_2$ was prepared according to the method reported,[10] but the content of water of crystallization was different. Found: C, 35.57; H, 8.47; N, 11.82%. Calcd for [Pd(*N*^{1},*N*^{1}-Et$_2$-(*S*)-pn)$_2$]Cl$_2$·2H$_2$O=$C_{14}H_{40}N_4Cl_2O_2Pd$: C, 35.49, H, 8.51; N, 11.82%. The complex [Pd(*N*^{1},*N*^{1}-Et$_2$-(*S*)-pn)(en)]Cl$_2$ was prepared in our previous work.[11]

[Pd(N)$_3$(O)]-type Complexes. *1) [Pd(gly)(S-pn)]ClO$_4$*: A suspension of 400 mg of [PdCl$_2$(*S*-pn)] in 15 cm^3 of water was mixed with an aqueous solution (5 cm^3) containing 120 mg of glycine and 65 mg of sodium hydroxide. The mixture was stirred for 30 min at 45 °C to turn into a clear lemon yellow solution, which was treated with 200 mg of sodium perchlorate and evaporated to dryness under reduced pressure. After washing with cold water, the crude product was recrystallized from warm water by adding methanol. Yield: 270 mg. Found: C, 17.03; H, 4.01; N, 11.87%. Calcd for $C_5H_{14}N_3ClO_6Pd$: C, 16.96; H, 3.99; N, 11.87%.

*2) [PdL(en)]ClO$_4$ (L=*S-*ala and* S-*ser)*: These complexes were prepared from [PdCl$_2$(en)] by the same method as in *1)*, in a 75—80% yield. Found: C, 17.05; H, 4.08; N, 11.85%. Calcd for [Pd(*S*-ala)(en)]ClO$_4$=$C_5H_{14}N_3ClO_6Pd$: C, 16.96; H, 3.99; N, 11.87%. Found: C, 16.43; H, 3.89; N, 11.35%. Calcd for [Pd(*S*-ser)(en)]ClO$_4$=$C_5H_{14}N_3ClO_7Pd$: C, 16.23; H, 3.81; N, 11.36%.

3) [Pd(S-ala)(tn)]ClO$_4$: Silver oxide (380 mg) was mixed with 400 mg of [PdCl$_2$(tn)] suspended in 12 cm^3 of water and the mixture was stirred at room temperature for 20 min in the dark. After the silver chloride had been filtered off, perchloric acid (60%, 266 mg) and (*S*)-alanine (141 mg) were successively added to the filtrate. The reaction mixture was stirred for 20 min and evaporated to dryness. A water-methanol (1:9) solution of the residue was mixed with ether and allowed to stand in a refrigerator, giving pale yellow crystals, which were washed with a mixture of methanol-ether and dried *in vacuo*. Yield: 510 mg. Found: C, 18.83; H, 4.76; N, 10.91%. Calcd for [Pd(*S*-ala)(tn)]ClO$_4$·H$_2$O=$C_6H_{18}N_3ClO_7Pd$: C, 18.67; H, 4.70; N, 10.88%.

4) [Pd(β-ala)(S-pn)]ClO$_4$: This complex was prepared by a method similar to that in *3)*, but crystallization was performed in an aqueous medium by adding ethanol carefully and

allowing to stand at room temperature for 4 d. Yield: 190 mg. Found: C, 19.33; H, 4.55; N, 11.12%. Calcd for [Pd(β-ala)(*S*-pn)]$ClO_4 \cdot 0.5H_2O$=$C_6H_{17}N_3ClO_{6.5}Pd$: C, 19.11; H, 4.54; N, 11.14%.

5) [Pd(S-leu)(en)]ClO_4: This was obtained in the same manner as in *3)*, but ethanol was used in place of ether in crystallization. Yield: 75%. Found: C, 24.34; H, 5.12; N, 10.54%. Calcd for $C_8H_{20}N_3ClO_6Pd$: C, 24.26; H, 5.09; N, 10.61%.

6) [Pd(S-ala)(S-pn)]ClO_4: Silver perchlorate (290 mg) and silver oxide (165 mg) were successively added to a suspension of 350 mg of [$PdCl_2$(*S*-pn)] in 12 cm^3 of water and the mixture was stirred at room temperature for 15 min in the dark. The silver chloride was filtered off and the filtrate was mixed with an aqueous solution (3 cm^3) containing 124 mg of (*S*)-alanine. After 20 min of stirring the mixture was evaporated under reduced pressure to give a sirup, which was dissolved in a methanol-ethanol (1:4) mixture (6 cm^3) and allowed to stand at room temperature. The desired product separated was washed with a mixture of methanol-ethanol and dried *in vacuo*. Yield: 370 mg. Found: C, 19.61; H, 4.40; N, 11.35%. Calcd for $C_6H_{16}N_3ClO_6Pd$: C, 19.58; H, 4.38; N, 11.42%.

7) [Pd(S-pro)(S-pn)]ClO_4: This complex was prepared by the same method as in *6)*, but a mixture of methanol-ethanol (1:1) was used as the solvent for crystallization. The crude product was recrystallized from warm water by adding acetone. Yield: 25%. Found: C, 24.48; H, 4.67; N, 10.65%. Calcd for $C_8H_{18}N_3ClO_6Pd$: C, 24.38; H, 4.60; N, 10.66%.

8)[PdL(en)]ClO_4 *(L=S-pro and S-hpro)*: Each of these complexes was prepared from [$PdCl_2$(en)] in the same way as in *6)*, but crystallized from hot water by adding ethanol. Yield: 85—90%. Found: C, 22.18; H, 4.28; N, 11.02%. Calcd for [Pd(*S*-pro)(en)]ClO_4=$C_7H_{16}N_3ClO_6Pd$: C, 22.12; H, 4.24; N, 11.06%. Found: C, 21.29; H, 4.13; N, 10.57%. Calcd for [Pd(*S*-hpro)(en)]ClO_4=$C_7H_{16}N_3ClO_7Pd$: C, 21.23; H, 4.07; N, 10.61%.

*9) [Pd(*N,N-*Me*$_2$*gly)(*N^1,N^1-*Et*$_2$-(S)-*pn)]*ClO_4: A suspension of 470 mg of [$PdCl_2$(N^1,N^1-Et_2-(*S*)-pn)] in 15 cm^3 of water was treated with 320 mg of $AgClO_4$ and 180 mg of Ag_2O in the same manner as in *6)*. The resulting solution was mixed with an aqueous solution of 215 mg of *N,N*-dimethylglycine hydrochloride pre-neutralized with Ag_2O. The mixture was stirred at room temperature for 1 h and evaporated to dryness. The crude product was recrystallized from hot water; yield 410 mg. Found: C, 30.34; H, 5.95; N, 9.51%. Calcd for $C_{11}H_{26}N_3ClO_6Pd$: C, 30.15; H, 5.98; N, 9.59%.

10) [Pd(β-ala)(N^1,N^1-*Et*$_2$-*(S)-pn)]*ClO_4: This complex was obtained in the same manner as in *9)*, using β-alanine in place of *N,N*-dimethylglycine hydrochloride and silver oxide, in a 65% yield. Found: C, 28.19; H, 5.79; N, 9.82%. Calcd for $C_{10}H_{24}N_3ClO_6Pd$: C, 28.32; H, 5.70; N, 9.91%.

cis-[Pd(N)$_2$*(O)*$_2$*]-type Complexes.* *1) [Pd*$_2$*(μ-OH)*$_2$*(S-pn)*$_2$*](*ClO_4*)*$_2$: This complex could be isolated as an intermediate product in the preparation of [Pd(amino carboxylato)(*S*-pn)]ClO_4.

A suspension of 300 mg of [$PdCl_2$(*S*-pn)] in 12 cm^3 of water was treated with 250 mg of $AgClO_4$ and 145 mg of Ag_2O in the same way as described for [Pd(*S*-ala)(*S*-pn)]ClO_4. The resulting solution was evaporated to dryness under reduced pressure and the residue was dissolved in a small amount of methanol. After filtration the methanol solution was mixed with ethanol and chilled in an ice-bath to give yellow precipitate, which was collected after 1.5 h, washed with ethanol and ether, and dried *in vacuo*. Yield: 230 mg. Found: C, 12.18; H, 3.82; N, 9.11%. Calcd for $C_6H_{22}N_4Cl_2O_{10}Pd_2$: C, 12.13; H, 3.73; N, 9.43%. This complex, as well as the corresponding nitrate and hydrogencarbonate salts described below, tends to decompose in an ethanol solution and is sensitive to heat.

2) [Pd$_2$*(μ-OH)*$_2$*(S-pn)*$_2$*](*NO_3*)*$_2$: This was prepared by a method similar to that in *1)* using $AgNO_3$ in place of $AgClO_4$. Crystallization was performed from water by adding acetone at room temperature. The solubility of this complex exhibits a negative temperature gradient in a solvent system of water-acetone. Yield: 35%. Found: C, 13.78; H, 4.32; N, 15.87%. Calcd for $C_6H_{22}N_6O_8Pd_2$: C, 13.88; H, 4.27; N, 16.19%. The nitrate is most unstable among the three kinds of the dimer salts.

3) [Pd$_2$*(μ-OH)*$_2$*(S-pn)*$_2$*](*HCO_3*)*$_2$: The mixture [$PdCl_2$(*S*-pn)] (250 mg) and Ag_2CO_3 (95%, 290 mg) suspended in 15 cm^3 of water was stirred for 15 min at 55—60 °C. The AgCl was filtered off in hot and the filtrate was chilled in an ice-bath. Yellow crystals were collected, washed with cold water, methanol, and ether, and dried *in vacuo*. Yield: 100 mg. Found: C, 18.34; H, 4.50; N, 10.72%. Calcd for $C_8H_{24}N_4O_8Pd_2$: C, 18.58; H, 4.68; N, 10.83%. This complex was also obtained by adding aqueous solution of $NaHCO_3$ to that containing [Pd_2(μ-OH)$_2$(*S*-pn)$_2$]$(ClO_4)_2$.

4) [Pd(CH_3CO_2*)*$_2$*(S-pn)]*: A suspension of 350 mg of [$PdCl_2$(*S*-pn)] in 10 cm^3 of water was stirred with 330 mg of Ag_2O for 15 min at room temperature. After removal of AgCl, to the solution was added 167 mg of acetic acid diluted with 2 cm^3 of water. The mixture was stirred for 15 min at *ca.* 55 °C and then evaporated to a small volume under reduced pressure and chilled in an ice-bath to give yellow crystals. The crystals were washed with cold methanol and ether, and dried *in vacuo*. Total yield: 320 mg. Found: C, 28.10; H, 5.40; N, 9.38%. Calcd for $C_7H_{16}N_2O_4Pd$: C, 28.15; H, 5.40; N, 9.38%.

5) [PdL(S-pn)] (L=ox and mal): These complexes were obtained by the same method as in *4)*, but crystallized from a more dilute solution. Yield: 75—80%. Found: C, 22.41; H, 3.75; N, 10.44%. Calcd for [Pd(ox)(*S*-pn)]=$C_5H_{10}N_2O_4Pd$: C, 22.36; H, 3.75; N, 10.43%. Found: C, 25.39; H, 4.25; N, 9.92%. Calcd for [Pd(mal)(*S*-pn)]=$C_6H_{12}N_2O_4Pd$: C, 25.50; H, 4.28; N, 9.91%. The oxalato complex was also obtained by a reaction of [$PdCl_2$(*S*-pn)] with silver oxalate.

6) [Pd(ox)(N^1,N^1-*Et*$_2$-*(S)-pn)]*: A suspension of 300 mg of [$PdCl_2$(N^1,N^1-Et_2-(*S*)-pn)] in 15 cm^3 of water was treated with 300 mg of silver oxalate. The solution filtered was evaporated to dryness under reduced pressure and the crude product was recrystallized from a minimum amount of warm water by adding acetone; yield 110 mg. Found: C, 33.24; H, 5.60; N, 8.60%. Calcd for $C_9H_{18}N_2O_4Pd$: C, 33.29; H, 5.59; N, 8.63%.

[Pd(N)(O)$_3$*]-type Complexes.* *1) K[Pd(*CH_3CO_2*)*$_2$*(S-ala)]*: An aqueous solution (18 cm^3) containing K[$PdCl_2$(*S*-ala)][8] (360 mg) and acetic acid (144 mg) was cooled in an ice-bath and then stirred with 285 mg of freshly prepared silver oxide for 8 min in the dark. After removal of AgCl the solution was evaporated to a small volume and mixed with acetone. On standing in a refrigerator overnight, the desired product was obtained as orange-brown crystals, which were washed with a mixture of water-acetone and dried *in vacuo*. Total yield: 210 mg. Found: C, 23.64; H, 3.44; N, 4.00%. Calcd for $C_7H_{12}NO_6KPd$: C, 23.91; H, 3.44; N, 3.98%. This complex is thermally labile and decomposes gradually even at room temperature in an aqueous solution.

2) K[Pd(mal)(S-ala)]: The crude poduct was obtained in the same manner as in *1)* using malonic acid in place of acetic acid, and recrystallized from water by adding acetone; yield 30%. Found: C, 21.41; H, 2.47; N, 4.13%. Calcd for $C_6H_8NO_6KPd$: C, 21.47; H, 2.40; N, 4.17%

Measurements. Electronic absorption spectra were recorded with a Hitachi 330 spectrophotometer and CD spectra with a JASCO MOE-1 spectropolarimeter. Unless otherwise noted, all the measurements were made in aqueous solutions

at room temperature. A 10-cm cell was employed for the CD measurements in the long wavelength region in order to acquire a higher precision. ^{13}C NMR spectra were taken on a JEOL FX-90Q NMR spectrometer in D_2O containing 1,4-dioxane as an internal standard (δ=67.40).

Results and Discussion

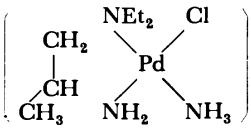
Synthesis of the Mixed-ligand Complexes. In the synthesis of palladium(II) complexes comprising of two kinds of ligands, a ligand possessing higher affinity for palladium [which we will call a higher-affinity ligand hereafter] should be introduced firstly, as the study by Drew *et al.*[3] suggests. When the order is reversed, a disproportionation reaction tends to occur, affording the complexes each having one kind of ligands. Generally, *N*-ligands coordinate to palladium more strongly than *O*-ligands; then, $[Pd(N\text{-}O)(N\text{-}N)]^+$ and $[Pd(O\text{-}O)(N\text{-}N)]$ complexes should be synthesized from $[PdCl_2(N\text{-}N)]$, and $[Pd(O\text{-}O)(N\text{-}O)]^-$ should be from $[PdCl_2(N\text{-}O)]^-$. The order of the affinity with respect to diamine ligands was obtained from the observation of the disproportionation in the course of the synthesis of $[Pd(N)_4]$-type complexes, being as follows:

en ≈ *S*-pn > tn > *N*,*N*-Me$_2$en
> N^1,N^1-Et$_2$-(*S*)-pn ≈ *N*,*N*-Et$_2$en ≫ NH_3.

The disproportionation reaction proceeded also when excess lower-affinity ligand was allowed to react with a dichloro complex of higher-affinity ligands. All the $[Pd(N)_4]$-type complexes under investigation were obtained in accord with the above order of affinity. The reaction of ammonia with $[PdCl_2(N^1,N^1\text{-Et}_2\text{-}(S)\text{-pn})]$ apparently does not proceed by one step but by two steps [Eq. (1)], that is, the intermediate product

$$[PdCl_2(N^1,N^1\text{-Et}_2\text{-}(S)\text{-pn})] \xrightarrow{NH_3} \mathbf{I} \xrightarrow{NH_3} [Pd(NH_3)_2(N^1,N^1\text{-Et}_2\text{-}(S)\text{-pn})]Cl_2 \quad (1)$$

where **I** is



$[PdCl(NH_3)(N^1,N^1\text{-Et}_2\text{-}(S)\text{-pn})]Cl$ was isolated. The action of twice the equimolar quantity of ammonia on the dichloro complex gave only the intermediate chloroammine complex, indicating that the remaining chloro ligand is resistant to the substitution with ammonia. Judging from this observation, the intermediate is supposed to possess structure **I** because an ammine ligand is considered to be more bulky than a chloro ligand.

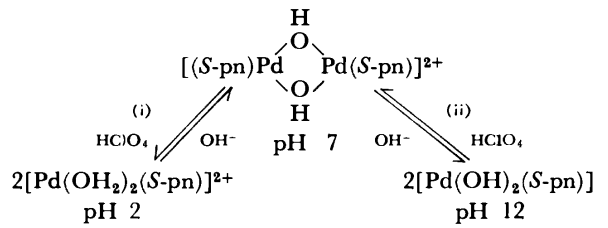
$[Pd(N)_3(O)]$-type complexes were synthesized by the following three methods [Eqs. (2)—(4)]. The method of Eq. (2) is useful only when a desired product crystallizes with ease and is sufficiently less soluble than sodium chloride (*e.g.* $[Pd(gly)(S\text{-pn})]ClO_4$ and $[Pd(S\text{-ala})(en)]ClO_4$). When the complexes are highly soluble, the method of Eq. (3), where both perchloric acid and amino carboxylic acid are employed in an equimolar amount with the starting dichloro complex is effective. The method of Eq. (4) is essentially the same as that of Eq.(3), but it is noticed that all the reactions proceed under nearly neutral conditions.

$$[PdCl_2(N\text{-}N)] + H(N\text{-}O) + NaOH \xrightarrow[H_2O]{NaClO_4} [Pd(N\text{-}O)(N\text{-}N)]ClO_4 + 2NaCl \quad (2)$$

$$[PdCl_2(N\text{-}N)] + Ag_2O \xrightarrow[H_2O]{} \frac{1}{2}\left[\begin{array}{c}H\\O\\ \left(N\diagdown Pd\diagup N\right)\\ \left(N\diagup O\diagdown N\right)\\H\end{array}\right](OH)_2 + 2AgCl \xrightarrow[H_2O]{H(N\text{-}O)+HClO_4} [Pd(N\text{-}O)(N\text{-}N)]ClO_4 \quad (3)$$

$$[PdCl_2(N\text{-}N)] + AgClO_4 + \frac{1}{2}Ag_2O \xrightarrow[H_2O]{} \frac{1}{2}\left[\begin{array}{c}H\\O\\ \left(N\diagdown Pd\diagup N\right)\\ \left(N\diagup O\diagdown N\right)\\H\end{array}\right](ClO_4)_2 + 2AgCl \xrightarrow[H_2O]{H(N\text{-}O)} [Pd(N\text{-}O)(N\text{-}N)]ClO_4 \quad (4)$$

The di-μ-hydroxo complex of *S*-pn, which is an intermediate in the reactions of Eqs.(3) and (4), could be isolated as nitrate and hydrogencarbonate, as well as perchlorate. The following equilibria with regard to the dimer perchlorate were confirmed by absorption and CD spectral measurements [See also Fig. 1; the shoulder at 45.5×10^3 cm^{-1} of the dimer complex is assigned to a charge transfer transition, Pd← O(μ-OH)]. The equilibrium constant of equilibrium (i) for the corresponding en complexes has been determined by Lim and Martin.[12]



The preparation of $[Pd(S\text{-ala})(NH_3)_2]ClO_4$ was attempted according to both Eqs. (3) and (4), but the contamination with the bis(alaninato) complex prevented the isolation of the pure product. The purity was not improved by recrystallization. This seems to be primarily caused by the mechanism that the ammonia liberated during the course of recrystallization promotes a disproportionation reaction.

cis-$[Pd(N)_2(O)_2]$-type complexes could not be obtained by the method of Eq. (5). The reaction proceeded only incompletely even by the use of excess dicarboxylate, which indicates high affinity of a chloro ligand over *O*-ligands for palladium. Thus it is necessary that chloride ions are removed from the

$$[PdCl_2(S\text{-pn})] + M_2(O\text{-}O) \xrightarrow[H_2O]{} [Pd(O\text{-}O)(S\text{-pn})] + 2MCl \ (M=\text{alkali metal}) \quad (5)$$

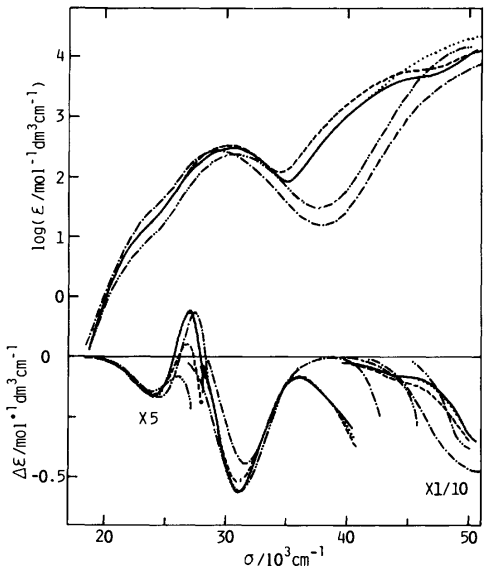


Fig. 1. Absorption and CD spectra of $[Pd_2(\mu\text{-}OH)_2(S\text{-}pn)_2]X_2$. ——: X=$ClO_4$ in H_2O, —·—: X=ClO_4 in 0.01 M $HClO_4$ (=2×[$Pd(OH_2)_2$(S-pn)]$(ClO_4)_2$), —··—: X=ClO_4 in 0.01 M NaOH (=2×[$Pd(OH)_2$(S-pn)], ----, X=HCO_3 in H_2O, and ……: X=NO_3 in H_2O.

reaction system. The method of Eq. (6) satisfies this

$$[PdCl_2(S\text{-pn})] + Ag_2O \xrightarrow[H_2O]{} \frac{1}{2}[(S\text{-pn})Pd(\mu\text{-}OH)_2Pd(S\text{-pn})](OH)_2 + 2AgCl$$

$$\xrightarrow[H_2O]{H_2(O\text{-}O)} [Pd(O\text{-}O)(S\text{-pn})] \quad (6)$$

requirement. The calculated quantity of a dicarboxylic acid is sufficient here, and a desired product can be isolated from the salt free system. The method of Eq. (7)

$$[PdCl_2(S\text{-pn})] + Ag_2(O\text{-}O) \xrightarrow[H_2O]{} [Pd(O\text{-}O)(S\text{-pn})] + 2AgCl \quad (7)$$

was also effective for the synthesis of the oxalato complex. Attempts to synthesize the carbonato complex by this method, however, were unsuccessful, and the hydrogen carbonate salt of the same di-μ-hydroxo complex as is seen in Eq. (6) was obtained instead. The same material was also obtained by metathesis of an authentic sample of the corresponding perchlorate with sodium hydrogencarbonate.

[Pd(N)(O)$_3$]-type complexes could not be obtained by reaction (8) but by (9) in analogy with the case of

$$K[PdCl_2(S\text{-ala})] + M_2(O\text{-}O) \xrightarrow[H_2O]{} K[Pd(O\text{-}O)(S\text{-ala})] + 2MCl \quad (8)$$

$$K[PdCl_2(S\text{-ala})] + Ag_2O + H_2(O\text{-}O) \xrightarrow[H_2O]{} K[Pd(O\text{-}O)(S\text{-ala})] + 2AgCl \quad (9)$$

cis-[Pd(N)$_2$(O)$_2$]-type complexes. Chloro ligands must be removed in the presence of a dicarboxylic acid because otherwise some decomposition occurs and it seems to be concerned with the instability of the di-μ-hydroxo complex [(S-ala)Pd(μ-OH)$_2$Pd(S-ala)] in a basic solution [Eq. (10)]. The malonato complex

$$K[PdCl_2(S\text{-ala})] + Ag_2O \xrightarrow[H_2O]{} \frac{1}{2}[(S\text{-ala})Pd(\mu\text{-}OH)_2Pd(S\text{-ala})] + KOH + 2AgCl \quad (10)$$

obtained according to Eq. (9) had been somewhat contaminated by the disproportionation products, but it could be purified by recrystallization. The use of oxalic acid in place of malonic acid gave only a mixture of the disproportionation products. The direct method where silver oxalate is used as in Eq. (7) also led to the same result.

Isomerism. As both S-pn and am$^-$ are unsymmetrical bidentate ligands, their mixed-ligand complexes should exhibit geometrical isomerism. We will call the configurations of two isomers *cis*(CH$_3$,O) and *trans*(CH$_3$,O) by considering the relative positions between the methyl group of S-pn and the coordinating oxygen atom of am$^-$. The ^{13}C NMR spectra of the β-ala, S-pro, and S-ala complexes varied with time, which was ascribed to the variation of distribution of such isomers: the β-ala and S-pro complexes comprise exclusively one isomer in the crystalline state and the S-ala complex also roughly so, whereas in solution each of them changes slowly into a mixture of the two isomers (approximately equimolar). The gly complex was found to be such a mixture even in the crystalline state. All the resonances were assigned on the basis of comparison with those of the related complexes[13] and by the INEPT method[14] (Table 1). The chelate ring carbons C(1) and C(2) of S-pn exhibit different

chemical shifts between a pair of isomers, and this is also the case for the carbonyl carbon C(c) of the gly complex and the methyl carbon C(3) of *S*-pn in the β-ala complex. For example, the ^{13}C NMR specirum of the β-ala complex showed six signals correspoding to six different carbons when it was recorded immediately after dissolution; whereas after equilibration (110 h) it showed three additional signals, which are assigned to C(1), C(2), and C(3) (Fig. 2 and Table 1). The variable distribution of the isomers could be also detected by CD spectra. The main negative CD band in the d-d transition region increased in intensity with time after dissolution in the β-ala and *S*-pro complexes, but decreased in the *S*-ala complex

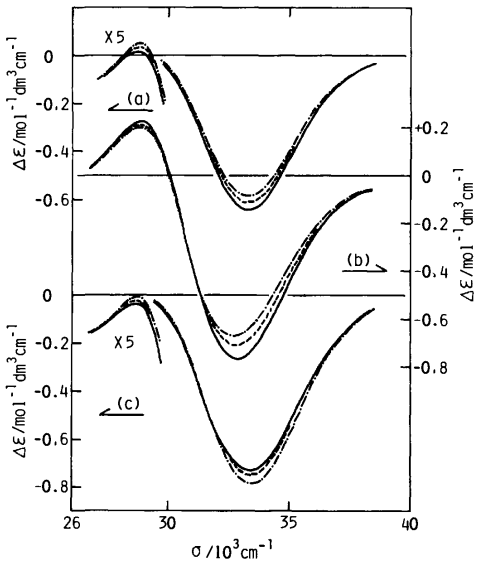

Fig. 3. CD spectral variation with time after dissolution for [PdL(*S*-pn)]ClO_4. (a) L=β-ala; —·—: 0 h, ----: 24 h, and ——: 110 h (in equilibrium). (b) L=*S*-pro; —·—: 0 h, ----: 5 h, and ——: 30 h (in equilibrium). (c) L=*S*-ala; —·—: 0 h, ----: 5 h, and ——: 12 h (in equilibrium).

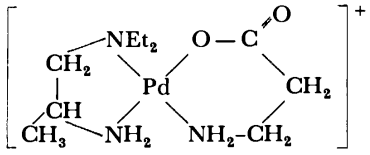
(Fig. 3). This suggests that the configuration of the isomer predominant in the crystalline state of the former complexes is different from that of the latter complex, which is compatible with the deduction from the ^{13}C NMR spectra. In one isomer of every complex, the difference in chemical shifts between C(1) and C(2) is small (*ca.* 1.3, 1.0, and 1.2 ppm for the β-ala, *S*-pro, and *S*-ala complexes, respectively), and in the other isomer it is large (*ca.* 6.1, 5.1, and 5.2 ppm, respectively). The predominant isomer in the crystalline state is the former for the β-ala and *S*-pro complexes, and the latter for the *S*-ala complex (Table 1).

The configuration was determined by examination of the time-dependent ^{13}C NMR and CD spectra of [Pd(β-ala)(N^1,N^1-Et_2-(*S*)-pn)]$^+$. In the NMR spectrum recorded immediately after dissolution, each of the α- and β-carbon of β-ala showed two signals; and after 120 h (in equilibrium) one of the two signals disappeared and the remaining one increased in intensity (Fig. 2). This fact suggests that the complex comprises a mixture of a pair of isomers in the crystalline state, but in solution isomerizes slowly to the more stable isomer.[15] The steric interaction between the amino group of β-ala and the diethylamino group of N^1,N^1-Et_2-(*S*)-pn is expected to be more significant than that between the carboxyl oxygen of β-ala and the diethylamino group.[16] Therefore, structure **II** can be assigned to the more stable isomer.



II *trans*(CH_3,*O*)

Although the CD variation with time was unexpectedly small, it was reproducible: +0.021→+0.014 (at 350 nm) and −0.919→−0.903 (at 299 nm), given as $\Delta\varepsilon$/mol^{-1} dm^3 cm^{-1} for 0 h→120 h (See also Fig. 8). Thus, the main band varies in the positive direction. This variation can be correlated to the isomerization of the *cis*(CH_3,*O*) to the *trans*(CH_3,*O*) isomer on the basis of the above structural assignment. Therefore, the predominant isomer in the crystalline state of [Pd(*S*-ala)(*S*-pn)]ClO_4, which exhibits the same CD variation as [Pd(β-ala)(N^1,N^1-Et_2-(*S*)-pn)]ClO_4, is *cis*-(CH_3,*O*); and those of [Pd(β-ala)(*S*-pn)]ClO_4 and [Pd(*S*-pro)(*S*-pn)]ClO_4, which exhibit the reverse CD variation, are *trans*(CH_3,*O*). These results are summarized in Table 2.

It is worth noting that the complexes with a six-membered amino carboxylato chelate ring isomerize evidently more slowly than those with a five-membered one, and have comparable rate of isomerization (or racemization) with the [Pd(N)$_4$]-type complexes with two five-membered chelate rings.[11] Although [Pd(N)$_4$]-type complexes such as [Pd(N^1,N^1-Et_2-(*S*)-pn)(*S*-pn)]$^{2+}$ should also exhibit similar isomerism, it could be detected by neither of ^{13}C NMR nor CD spectra.

^{13}C NMR Spectra. A convenient rule concerning ^{13}C NMR spectra is derived from the assignment of isomers given in the preceding section: A carbon atom adjacent to the coordinated *N*-atom resonates at *ca.* 1 ppm higher or lower magnetic field when an *O*-atom occupies the coordination site trans or cis to the *N*-atom, respectively, in comparison with the case that an *N*-atom occupies the same site instead of *O*-atom (Compare the data for a pair of isomers of [Pd(am)(*S*-pn)]$^+$ with those for [Pd(en)(*S*-pn)]$^{2+}$). Using this rule, two carbon signals of en in the [Pd(*S*-am)(en)]$^+$ complexes can be readily assigned on reference to that of en in [Pd(en)(*S*-pn)]$^{2+}$ (46.57

Table 2. Isomerization of [Pd(N)$_3$(O)]-type complexes[a]

ppm). Accordingly, the signals at *ca.* 45.7 and 47.8 ppm are assigned to the carbon atom adjacent to the *N*-atom trans and cis to the *O*-atom, respectively.

CD and Absorption Spectra. 1) [Pd(N)$_4$]-type Complexes: The spectra of the complexes containing *S*-pn and N^1,N^1-Et$_2$-(*S*)-pn as an optically active ligand are shown in Figs. 4 and 5, respectively; the numerical data being given in Tables 3 and 4. The absorption curves are composed of an unsymmetrical broad band and a lower-lying shoulder in the d-d transition region, the latter being a spin-forbidden d-d band. The shape of the spin-allowed d-d band can be characterized by the half-value width parameters and the unsymmetry parameter.[2] These parameters for the complexes studied in this paper are listed in Table 5.

The CD spectra in the spin-forbidden d-d region show two negative bands, more distinctly in the N^1,N^1-Et$_2$-(*S*)-pn complexes. In the spin-allowed d-d region, all complexes of the [Pd(N)$_4$]-type show only one negative band except the tn complexes, which exhibit an additional weak positive band in the lower energy side. The intensity of the main negative band is lower for the ammine complexes than for the en and tn complexes and it is almost equal for the latter two complexes, when compared within one of the series of *S*-pn or N^1,N^1-Et$_2$-(*S*)-pn complexes (Figs. 4 and 5). The main CD band lies at higher energy by (0.5—1.1) $\times 10^3$ cm^{-1} than the spin-allowed d-d absorption peak for all the complexes including the tn complexes. Thus, it is expected that the complexes other than the tn complexes also have another transition component in the lower energy side of the main band. The CD band for the lower energy component is, however, undetectable probably because of its low intensity. The minimum of $|\Delta\varepsilon|$ around 30×10^3 cm^{-1} seems to arise from such a CD band, and is included in Table 4. This and the main negative band

a) m: The minimum of $|\Delta\varepsilon|$ (See text); sh: shoulder ($\Delta\varepsilon$ is given for the value σ given). b) Water of crystallization is omitted (See Table 3).

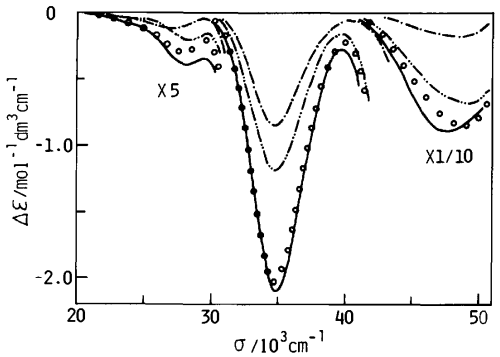

Fig. 6. CD spectra of $[Pd(N,N\text{-}Et_2en)(S\text{-}pn)]Cl_2$ (—·—), $[Pd(N,N^1\text{-}Et_2\text{-}(S)\text{-}pn)(en)]Cl_2$ (—··—), and $[Pd(N^1,N^1\text{-}Et_2\text{-}(S)\text{-}pn)(S\text{-}pn)]Cl_2$ (——); and CD curve calculated from $[\Delta\varepsilon(\text{—·—})+\Delta\varepsilon(\text{—··—})]$ (oooo).

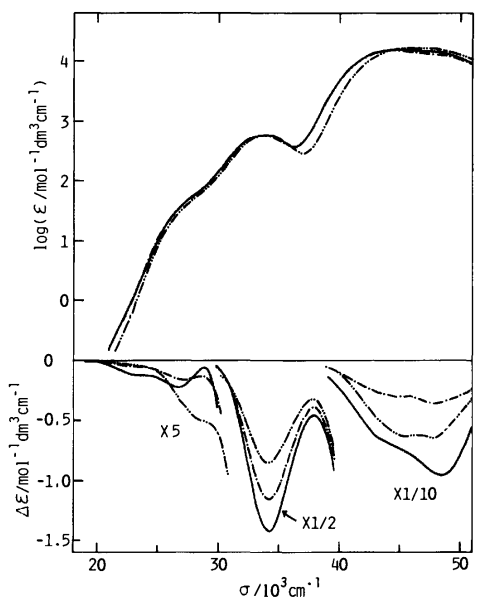

Fig. 7. Absorption and CD spectra of $[Pd(N^1,N^1\text{-}Et_2\text{-}(S)\text{-}pn)_2]Cl_2$ (——), $[Pd(N,N\text{-}Et_2en)(N^1,N^1\text{-}Et_2\text{-}(S)\text{-}pn)]Cl_2$ (—·—), and $[Pd(N,N\text{-}Me_2en)(N^1,N^1\text{-}Et_2\text{-}(S)\text{-}pn)]Cl_2$ (—··—).

are assigned to $^1A_{2g}$ and $^1E_g \leftarrow {}^1A_{1g}$ (D_{4h}), respectively, and it is expected that the $^1B_{1g} \leftarrow {}^1A_{1g}$ transition, which is magnetic dipole forbidden, occurs at higher energy than the $^1E_g \leftarrow {}^1A_{1g}$ transition as in $[PdCl_4]^{2-}$ and *cis*-$[Pd(Cl)_2(N)_2]$-type complexes.[1,2]

The CD spectrum of $[Pd(N^1,N^1\text{-}Et_2\text{-}(S)\text{-}pn)(S\text{-}pn)]^{2+}$ comprising two different optically active ligands can be reproduced well by the sum of the CD curves of $[Pd(N,N\text{-}Et_2en)(S\text{-}pn)]^{2+}$ and $[Pd(N^1,N^1\text{-}Et_2\text{-}(S)\text{-}pn)(en)]^{2+}$, which have the same structure as the first complex except for the disposition of *C*-methyl group (Fig. 6). Thus the two optically active ligands contribute independently to the optical activity of $[Pd(N^1,N^1\text{-}Et_2\text{-}(S)\text{-}pn)(S\text{-}pn)]^{2+}$. The complexes having two *N*,*N*-dialkylethylenediamine ligands exhibited a splitting with the absorption and CD bands which are assigned to Pd←N(σ) charge transfer(CT) transitions (Fig. 7). The complexes with only one *N*,*N*-dialkylethylenediamine

ligand exhibited no such splitting (Fig. 5). Therefore, the splitting seems to be concerned with the structure that two dialkylamino groups occupy the trans sites. However, none of the complexes showed any splitting of the spin-allowed d-d band unlike the *trans*-$[Pd(Cl)_2(N)_2]$-type complexes.[2] The CD intensity of $[Pd(N,N\text{-}Et_2en)(N^1,N^1\text{-}Et_2\text{-}(S)\text{-pn})]^{2+}$ is smaller than a half of that of $[Pd(N^1,N^1\text{-}Et_2\text{-}(S)\text{-pn})_2]^{2+}$, additivity not holding (Fig. 7). This fact can be explained by supposing some difference between the ligand-ligand interactions of the two complexes. The explanation is also applicable to the significantly different CD curves of the *N,N*-Et_2en and the *N,N*-Me_2en complex.

2) [Pd(N)$_3$(O)]-type Complexes: The absorption and CD spectra are shown in Figs. 8—10 and the numerical data in Tables 6 and 7. It is noteworthy that the CD patterns of the complexes with *S*-pn or N^1,N^1-Et_2-(*S*)-pn are very similar to those of the corresponding [Pd(N)$_4$]-type complexes. Namely, the CD patterns of $[Pd(gly)(S\text{-pn})]^+$ and $[Pd(\beta\text{-ala})(S\text{-pn})]^+$ are similar to those of $[Pd(en)(S\text{-pn})]^{2+}$and $[Pd(tn)(S\text{-pn})]^{2+}$, respectively, and those of $[Pd(\beta\text{-ala})(N^1,N^1\text{-}Et_2\text{-}(S)\text{-pn})]^+$ and $[Pd(N,N\text{-}Me_2gly)(N^1,N^1\text{-}Et_2\text{-}(S)\text{-pn})]^+$ to those of $[Pd(tn)(N^1,N^1\text{-}Et_2\text{-}(S)\text{-pn})]^{2+}$ and $[Pd(N,N\text{-}Me_2en)(N^1,N^1\text{-}Et_2\text{-}(S)\text{-pn})]^{2+}$, respectively. The intensity of the main CD band (in the spin-allowed d-d region) for the [Pd(N)$_3$(O)]-type complexes was *ca.* 60—80% comparing with the corresponding [Pd(N)$_4$]-type complexes. Thus, two types of complexes seem to possess much the same electronic structure, but their CD intensities are influenced not only by the kind of the coordinating atoms but also by the chelate ring size and the con-

formation of an optically inactive ligand.

The vicinal CD caused by an optically active amino carboxylate ligand possesses a pattern of + and − from lower energy in the spin-allowed d-d region for all the (*S*)-amino carboxylato complexes studied here, but the intensity ratio of the positive to the negative band is diverse (Figs. 9 and 10). The *S*-pro and *S*-hpro complexes exhibited a positive band with a high intensity relative to the other amino carboxylato complexes. This phenomenon is characteristic of the complexes with a coordinated asymmetric *N*-atom.[17,18] Moreover, the CD corresponding to the absorption band at *ca.* $51\times10^3\,cm^{-1}$ also showed different features from those for the other complexes in agreement with the assignment of the band to a Pd←N(σ) CT transition.

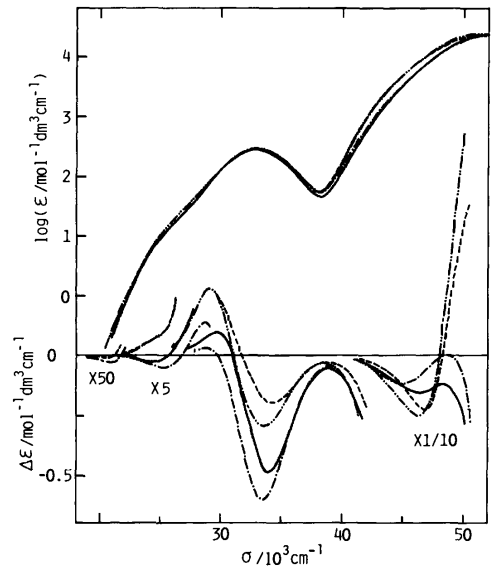

Fig. 9. Absorption and CD spectra of [PdL(en)]-ClO_4. ——: L=*S*-ser, —·—: L=*S*-leu, —··—: L=*S*-pro, and ----: L=*S*-hpro.

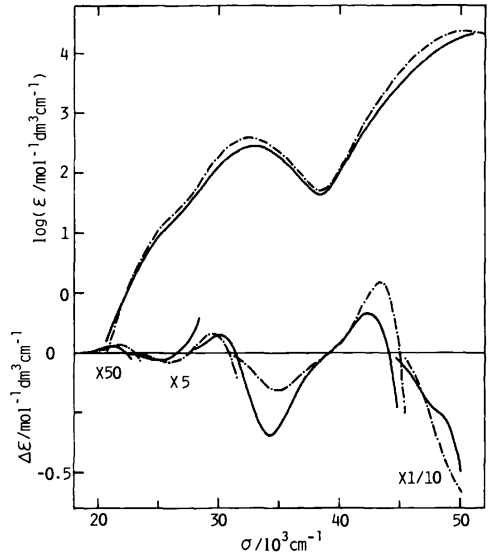

Fig. 10. Absorption and CD spectra of [Pd(*S*-ala)L]-ClO_4. ——: L=en and —·—: L=tn

The pattern of the vicinal CD of the *S*-ala complexes does not depend on the ring size of optically inactive diamine ligands, but the intensity does, particularly in the spin-allowed d-d region (Fig. 10). This situation contrasts with that in the corresponding *S*-pn complexes of $[Pd(N)_4]$-type (Fig. 4). A positive CD band occurring at the lower edge of the Pd←N(σ) CT absorption band is a general characteristic of the palladium(II) complexes containing *S*-ala. Although the corresponding absorption band was observed as a shoulder in $[Pd(S\text{-ala})_2]$,[19] it was hardly detected in the complexes containing only one *S*-ala ligand. The band is assigned to an orbitally-forbidden CT transition rather than a spin-forbidden CT one because the band differs in CD sign from the adjacent allowed CD band.

The additivity of the vicinal CD contributions of *S*-pn and *S*-am was demonstrated with regard to the *S*-ala and *S*-pro complexes (Fig. 11). The almost perfect additivity may be expected since a ligand-ligand interaction is considered to be smaller in these cases than in $[Pd(N^1,N^1\text{-Et}_2\text{-}(S)\text{-pn})(S\text{-pn})]^{2+}$, even for which such an additivity holds. However, it should be noted that the CD data of $[Pd(S\text{-am})(S\text{-pn})]^+$ used in the analysis was taken for an approximately equimolar mixture of the geometrical isomers.

As $[Pd(gly)(S\text{-pn})]^+$ and $[Pd(S\text{-ala})(en)]^+$ are considered to have almost the same electronic energy level scheme, some informations will be obtained about the vicincal effects of *S*-pn and *S*-ala by comparing the CD spectra of the two complexes. We previously de-

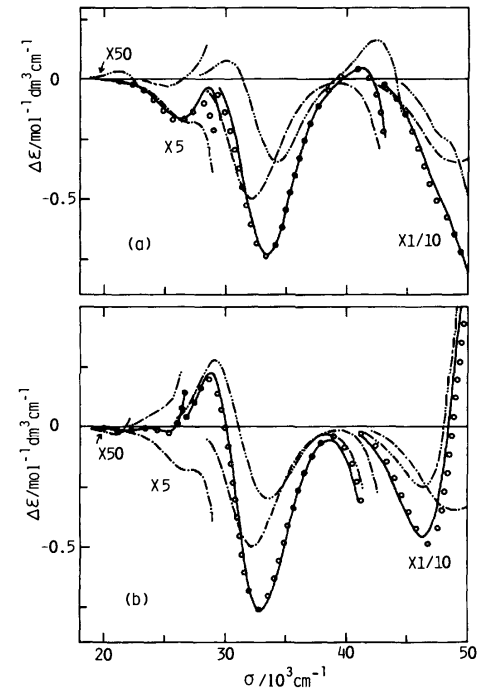

Fig. 11. CD spectra of $[Pd(gly)(S\text{-pn})]ClO_4$ (—·—), $[PdL(en)]ClO_4$ (—··—), and $[PdL(S\text{-pn})]ClO_4$ (——), all in the isomer equilibrium; and CD curves calculated from $[\Delta\varepsilon(\text{—·—})+\Delta\varepsilon(\text{—··—})]$ (oooo). (a) L=*S*-ala and (b) L=*S*-pro.

monstrated with regard to [$PdCl_2$(*S*-pn)] that the main negative CD band in the spin-allowed d-d region was primarily based on the $^1E_g \leftarrow {}^1A_{1g}$ transition, although it included a minor contribution by the $^1B_{1g} \leftarrow {}^1A_{1g}$ transition (D_{4h}).[2] This situation seems to be also the case for the *S*-pn complexes of various types, [Pd(*S*-pn)$(N)_n(O)_{2-n}$] (n=0—2), from an examination of the absorption and CD data (Figs. 4, 8, and 12). On the other hand, the main negative CD band of [Pd(*S*-ala)(en)]$^+$ shows a shift by *ca.* 2×10^3 cm^{-1} to higher energy than that of [Pd(gly)(*S*-pn)]$^+$, although the corresponding absorption band does not (Fig. 11a). Thus, it is reasonable to consider that the vicinal contribution by *S*-ala exhibits a dispersion pattern of + and − from lower energy for the $^1E_g \leftarrow {}^1A_{1g}$ transition (D_{4h}). The CD spectrum of [$Pd(CH_3CO_2)_2$(*S*-ala)]$^-$ supports this deduction (*vide infra*).

3) cis-[Pd(N)$_2$(O)$_2$]-type Complexes: The absorption and CD spectra are shown in Fig. 12 and the numerical data in Tables 8 and 9. The absorption and CD spectra of [$Pd(CH_3CO_2)_2$(*S*-pn)] measured in H_2O are different from those in the aqueous solutions containing acetate ions. It seems that the coordinated acetate ions are released by aquation in H_2O, judging from the similarity of the absorption and CD spectra to those of [$Pd(OH_2)_2$(*S*-pn)]$^{2+}$ (Fig. 1). The enhancement of absorbance around 40×10^3 cm^{-1} in H_2O is ascribable to the di-μ-hydroxo complex formed partly.

The CD pattern in the spin-allowed d-d region is various, depending upon the optically inactive ligands: + and −; − and +; and − for the CH_3CO_2, ox, and mal complexes, respectively. The complexes containing monodentate ligands exhibit a positive CD band in the lower energy side of the main negative CD band. This situation differs from that found in the [$Pd(N)_4$]- and [$Pd(N)_3(O)$]-type complexes. The ox complex exhibits a positive CD band in the higher energy side of the main negative CD one, being unique in the series of *S*-pn complexes. It is reasonable to assign the CD band to the $^1B_{1g} \leftarrow {}^1A_{1g}$ transition (D_{4h}) from its position and low intensity. If this is true, it is a very unique example that the CD band for the transition was observed definitely. Although the corresponding band did not appear in [Pd(ox)(N^1,N^1-Et_2-(*S*)-pn)], the CD features are very similar to those of [Pd(ox)(*S*-pn)] in the spin-allowed d-d region, particularly in the width of the main band. Thus it is likely that the CD band of interest is canceled out by the main band.

4) [Pd(N)(O)$_3$]-type Complexes: The absorption and CD spectra are shown in Fig. 13 and the numerical data

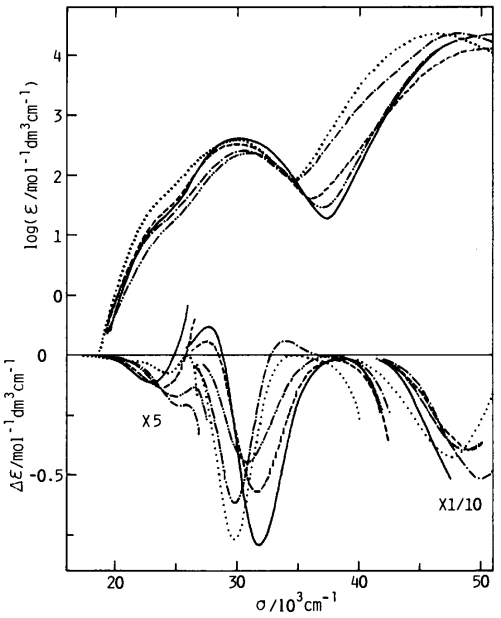

Fig. 12. Absorption and CD spectra of [PdL(*S*-pn)] and [Pd(ox)(N^1,N^1-Et_2-(*S*)-pn)] (·····). L=$(CH_3CO_2)_2$ in 0.50 M CH_3CO_2Na (—·—) and in H_2O (----); L=ox in H_2O (—·—); and L=mal in H_2O (—··—).

a) As in Table 4. b) $\Delta\varepsilon$ is based on palladium.

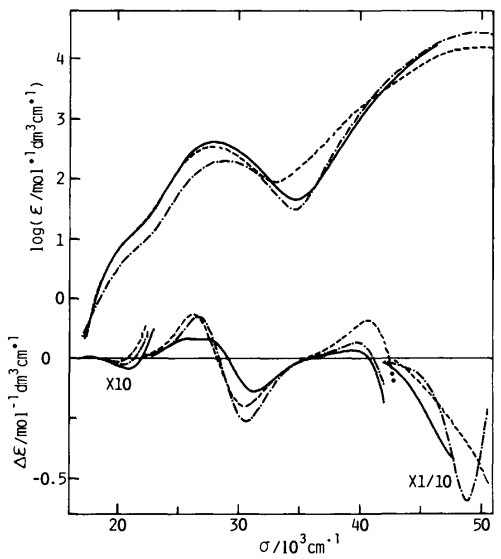

Fig. 13. Absorption and CD spectra of K[PdL(*S*-ala)]. L=$(CH_3CO_2)_2$ in 0.50 M CH_3CO_2Na (——) and in H_2O (----); and L=mal in H_2O (—·—).

in Tables 8 and 9. The K[Pd(CH_3CO_2)$_2$(*S*-ala)] complex aquates in water free from acetate ions similarly to [Pd(CH_3CO_2)$_2$(*S*-pn)]; the band ascribed to the di-μ-hydroxo complex was obviously observed as a shoulder around 40×10^3 cm^{-1}. Both the absorption and CD spectra of the acetato complex were essentially the same in 0.50 and 1.0 M CH_3CO_2Na. The CD spectrum showed a pattern of +, +, and − from lower energy in the spin-allowed d-d region; the lowest-lying positive band is assigned to the $^1A_{2g}\leftarrow{}^1A_{1g}$ transition and the following dispersion is to the $^1E_g\leftarrow{}^1A_{1g}$ one (D_{4h}). Apparently, only one positive band is observed in the other alaninato complexes including the [Pd(*S*-ala)(N)$_2$]-type ones, which is ascribed to the overlapping of the two positive bands. This explanation implies a relatively large separation between the $^1A_{2g}$ and $^1E_g\leftarrow{}^1A_{1g}$ transitions in $[Pd(CH_3CO_2)_2(S\text{-ala})]^-$, being compatible with the large value of unsymmetry parameter (Table 5). Consequently, the vicinal CD caused by *S*-ala ligand is considered to exhibit the definite pattern over the d-d and CT transition region, irrespective of the other ligand coordinated together. Similar CD spectra have been also observed in [Pd(*S*-ala)$_2$] and $[PdCl_2(S\text{-ala})]^-$.[19]

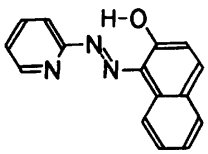
Kinetics and Mechanism of Complex Formation of Nickel(II) with 1-(2-Pyridylazo)-2-naphthol in Acetic Acid[1)]

Akiharu HIOKI, Shigenobu FUNAHASHI, and Motoharu TANAKA*
Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received December 15, 1983)

The complex formation reactions of nickel(II) nitrate, nickel(II) acetate, and nickel(II) chloride with 1-(2-pyridylazo)-2-naphthol (PAN) in acetic acid (HOAc) to form the 1:1 nickel(II)–PAN complex have been studied kinetically by using a stopped-flow technique. The second-order rate constants and activation parameters at 25 °C are $k=(1.4\pm0.1)\times10^4$ mol^{-1} kg s^{-1}, $\Delta H^*=51.2\pm1$ kJ mol^{-1}, $\Delta S^*=6.4\pm4$ J mol^{-1} K^{-1}, and $\Delta V^*=23.4\pm2.4$ cm^3 mol^{-1} for $Ni(NO_3)_2$, $k=(1.1\pm0.1)\times10^4$ mol^{-1} kg s,$^{-1}$, $\Delta H^*=49.5\pm1$ kJ mol^{-1}, $\Delta S^*=-1.3\pm4$ J mol^{-1} K^{-1}, and $\Delta V^*=15.5\pm2.6$ cm^3 mol^{-1} for $Ni(OAc)_2$, and $k=(4.8\pm0.1)\times10^4$ mol^{-1} kg s^{-1}, $\Delta H^*=51.4\pm1$ kJ mol^{-1}, $\Delta S^*=17.0\pm4$ J mol^{-1} K^{-1}, and $\Delta V^*=35.4\pm5.5$ cm^3 mol^{-1} for $NiCl_2$. The positive value of ΔV^* strongly suggests a dissociative mode of activation.

Kinetics of the complexation of nickel(II) ion has been studied extensively in aqueous solution and it has proved that the reactions proceed *via* the Eigen mechanism.[2-4)] On the other hand, studies in nonaqueous solvents are not numerous.[5-7)] Acetic acid has been utilized as a useful solvent in the titration of weak bases since Conant and Hall,[8)] and the acid-base equilibria in this solvent have been studied first by Kolthoff and Bruckenstein,[9a)] and later by Tanaka and Nakagawa.[9b)] There are not many studies on the complex formation of metal ions in acetic acid.[10)] We have recently reported the solvent-exchange rate on copper(II) acetate[11)] and manganese(II) perchlorate[12)] in acetic acid.

In this paper we describe the rates of reactions of nickel(II) species ($Ni(NO_3)_2$, $Ni(OAc)_2$, and $NiCl_2$) with 1-(2-pyridylazo)-2-naphthol (PAN or Hpan) in acetic acid. This is the first kinetic study on complex formation of a simple metal ion with an acyclic ligand in acetic acid.[13)]



PAN or Hpan

Experimental

Reagents. In order to keep the reaction medium as dry as possible, extreme care was taken in the purification and preparation of all reagents and compounds. All reagents and solutions were stored in a glove box or a desiccator.

Acetic Acid: The purification of acetic acid was described previously.[14)] The water content of acetic acid and acetic acid solutions was confirmed to be less than 5×10^{-3} mol kg^{-1} by the Karl-Fisher titration.

PAN: PAN (Dojindo Laboratories, Kumamoto) was purified by sublimation.

Nickel(II) Salts: Hydrated nickel(II) nitrate (reagent grade) was recrystallized from distilled water. The hydrate was dissolved in acetic acid containing a small amount of nitric acid. Acetic anhydride equivalent to the water involved was added to the nickel(II) nitrate solution. Anhydrous nickel(II) nitrate precipitates. The precipitate was washed with acetic anhydride and then with acetic acid. This compound is formulated as $Ni(NO_3)_2\cdot6HOAc$.[15)] The crystals of nickel(II) acetate and nickel(II) chloride were prepared similarly and solvated salts may be formulated as $Ni(OAc)_2\cdot4HOAc$ and $NiCl_2\cdot4HOAc$. Each nickel solution was prepared by dissolving these crystals in acetic acid.

Lithium Salts: Reagent grade lithium perchlorate, lithium nitrate, and lithium chloride were recrystallized from distilled water and dried at 170, 130 and 120 °C respectively. Perchloric acid solution and lithium acetate were prepared by the methods described previously.[10)]

Measurements. A highly sensitive spectrophotometer (SM 401, Union Giken Co. Ltd., Osaka) and a Carl Zeiss spectrophotometer (Model PMQ II) were used for the measurements of absorption spectra. Reaction rates at atmospheric pressure were measured by means of a highly sensitive stopped-flow spectrophotometer.[10,16)] The temperature of the reaction cell was maintained to within ±0.1 °C. At high-pressures up to 55 MPa the reactions were followed by using a high-pressure stopped-flow apparatus.[17)] At 25 °C acetic acid freezes at 55 Mpa.

Equilibria in Acetic Acid. In acetic acid almost all substances exist as the non-dissociating form because of its low dielectric constant ($\varepsilon=6.18$ at 20 °C).[18)] Thus it is important to consider separately the ionization and dissociation. Overall dissociation of AB is expressed by Eq. 1.

$$AB \overset{K_i}{\rightleftharpoons} A^+B^- \overset{K_d}{\rightleftharpoons} A^+ + B^- \quad (1)$$

An overall dissociation constant K_D is defined by Eq. 2.

$$K_D = \frac{[A^+][B^-]}{[AB]+[A^+B^-]} = \frac{K_iK_d}{1+K_i}, \quad (2)$$

where K_i is an ionization constant and K_d is a dissociation constant.[9a)] Available values of K_D are $10^{-12.53}$ for H_2O,[19)] $10^{-10.1}$ for HNO_3,[20)] $10^{-8.55}$ for HCl,[9a)] $10^{-5.87}$ for $HClO_4$,[21)] $10^{-6.79}$ for LiOAc,[21,22)] $10^{-7.1}$ for LiCl,[21,23)] $10^{-5.80}$ for $LiClO_4$,[24)] and $10^{-7.63}$ for $Ni(OAc)_2$ ($Ni(OAc)_2\rightleftharpoons NiOAc^+ + OAc^-$).[25)] K_d can be calculated by an equation of the type derived by Fuoss and Kraus for ion-pair formation,[26)] at least to a correct order of magnitude. The K_d value is estimated to be about 10^{-6} mol dm^{-3} for all of these 1:1 electrolytes. Then values of K_i are estimated to be $10^{-6.5}$ (H_2O), $10^{-4.1}$ (HNO_3), $10^{-2.5}$ (HCl), $10^{-0.7}$ (LiOAc), $10^{-1.1}$ (LiCl), and $10^{-1.6}$ ($Ni(OAc)_2$).

From the K_i value of $Ni(OAc)_2$, it may be concluded that two OAc^- ions in $Ni(OAc)_2$ exist in the first coordination sphere of nickel(II). Since the Edwards E_n value[27)] (the electron-donating property) of chloride ion (1.24) is similar to that of

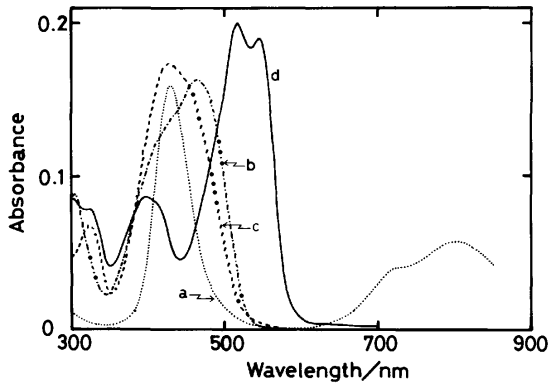


Fig. 1. Absorption spectra of nickel(II) chloride, the acid and base forms of PAN, and the nickel(II)-PAN complex in acetic acid.
a: $[NiCl_2]=1.12\times10^{-2}$ mol kg^{-1}; b: $[PAN]=9.43\times10^{-6}$ mol kg^{-1}; c: $[PAN]=9.43\times10^{-6}$ mol kg^{-1}, $[HClO_4]=5.5\times10^{-5}$ mol kg^{-1}; d: $[PAN]=9.43\times10^{-6}$ mol kg^{-1}, $[Ni(OAc)_2]=2.02\times10^{-4}$ mol kg^{-1}.

Each point is an average of several determinations. The straight lines are calculated by using the ΔV^* values in Table 2.

acetate ion (0.95), two chloride ions in $NiCl_2$ are thought also to be in the first coordination sphere of nickel(II). The absorption spectra of nickel(II) nitrate, acetate, and chloride in acetic acid show their typical octahedral geometry (see Fig. 1-a for $NiCl_2$).[28] The molar absorption coefficients of nickel(II) solutions are independent of concentration of nickel(II) salts. The complexation rate of $Ni(NO_3)_2$ does not change even in the presence of HNO_3 up to 10^{-3} mol kg^{-1} (*vide infra*). These facts are consistent with solvolysis of nickel(II) salts not occurring in acetic acid.

The addition of perchloric acid (the strongest acid) to an acetic acid solution of PAN changes PAN to its acid form (see Fig. 1), protonated at nitrogen of the pyridyl group of PAN, while the addition of lithium acetate, the strongest base, causes little change in the absorption spectrum. From the change of the spectra the mole fraction of ionized PAN ([HpanH$^+$OAc$^-$]+[HpanH$^+$])/[Hpan] is estimated to be about 0.05 at most. Thus PAN exists practically as the base

$$\text{Hpan} + \text{HOAc} \rightleftharpoons \text{HpanH}^+\text{OAc}^- \rightleftharpoons \text{HpanH}^+ + \text{OAc}^- \quad (3)$$

form (Hpan) in acetic acid.

Absorption spectrum was measured for mixtures of the 2×10^{-5} mol kg^{-1} PAN solution with the 2×10^{-5} to 2×10^{-3} mol kg^{-1} nickel(II) solution. At the nickel(II) concentration higher than 2×10^{-4} mol kg^{-1}, the complexation of PAN is quantitative and the reverse reaction can be neglected. The reaction system is expressed by Eq. 4.

$$\text{Hpan} + NiX_2 \longrightarrow \text{Ni(pan)X} + \text{HX}, \quad (4)$$

where X^- is NO_3^-, OAc^-, or Cl^-. The spectrum of the 1:1 nickel(II)-PAN complex is shown in Fig. 1-d. The pan$^-$ ion is a tridentate ligand. The 1:1 nickel(II)-PAN complex tends to decompose slowly with half-life of several hours.

Results and Discussion

Kinetic measurements were carried out at 516, 544, and 554 nm for $Ni(NO_3)_2$, at 516 nm and 544 nm for $Ni(OAc)_2$, and 516 nm and 540 nm for $NiCl_2$ in large excess nickel concentration over PAN. The change in absorbance at each wavelength as a function of reaction time was satisfactorily fitted to the pseudo-first-order rate law. A conditional first-order rate constant k_0 involving the nickel(II) concentration was obtained by the relation: $\ln(A_\infty-A_t)=\ln(A_\infty-A_0)-k_0t$, where A_0, A_t, and A_∞ denote the absorbances at initial time, at time t, and at infinite time, respectively.

The rate of formation of the 1:1 nickel(II)-PAN complex is first order with respect to PAN. Conditional first-order rate constants under various conditions are summarized in Table 1. The plots of k_0 against the nickel(II) concentration are given in Fig. 2. The effect of water in acetic acid on k_0 was checked by the addition of various amounts of water up to 6×10^{-2} mol kg^{-1}. Though k_0 decreases slightly with increasing water concentration, the presence of water up to 5×10^{-3} mol kg^{-1} does not affect the rate. At lower concentrations of the nickel(II) the data show a linear relationship through the origin and then $k_0=kC_{Ni}$, where k is a second-order rate constant and C_{Ni} is a total concentration of nickel(II). At higher C_{Ni} the data deviate from the straight line. This deviation will be considered later in detail.

The activation parameters obtained from the temperature dependence of k (17.0—35.0 °C), *i.e.* the Eyring plot, are tabulated in Table 2. By the transition state

theory, the relation between k and pressure P is given as $(\partial \ln k/\partial P)_T=-\Delta V^{\neq}/RT$. As apparent from Fig. 3, the rate constant varies linearly with pressure: the activation volume, $\Delta V^{\neq}$, is independent of pressure. The values of $\Delta V^{\neq}$ are also summarized in Table 2.

Since the reactions of $Ni(NO_3)_2$ and $NiCl_2$ with PAN produce HNO_3 and HCl, respectively, the effect of these acids on the reaction rate was examined. When these acids are added to the acetic acid solution of PAN, PAN changes into an acid form. From the change of the absorption spectra, the equilibrium constants of Eq. 5, $K_{PAN\text{-}HX}$, were calculated to be 4.3×10^2 mol^{-1} kg for HNO_3 and 4.2×10^4 mol^{-1} kg for HCl.

$$Hpan + HX \overset{K_{PAN\cdot HX}}{\rightleftharpoons} HpanH^+X^- \quad (5)$$

Moreover under conditions where $[Ni(NO_3)_2]=2.04\times10^{-3}$ mol kg^{-1} and $[PAN]=1.15\times10^{-5}$ mol kg^{-1}, the presence of 100-fold excess of HNO_3 over [PAN] did not affect the reaction rate as expected from the $K_{PAN\text{-}HNO_3}$ value. Under conditions where $[NiCl_2]=2.60\times10^{-4}$ mol kg^{-1} and $[PAN]=1.15\times10^{-5}$ mol kg^{-1}, the addition of HCl twice as much as PAN decreased the reaction rate by *ca.* 6%. After all the reaction rate is not affected by HNO_3 or HCl generated by the complexation.

The addition of various amounts of lithium perchlorate and lithium acetate to a PAN solution resulted in the change in the spectra with an isosbestic point at 456 nm. The reaction corresponds to equilibrium 6.

$$Hpan + Li^+ClO_4^- + HOAc \rightleftharpoons HpanH^+ClO_4^- + LiOAc \quad (6)$$

Table 2. Activation parameters for the complex formation of nickel(II) with PAN in acetic acid

Reaction	k(25 °C) / mol^{-1} kg s^{-1}	$\Delta H^{\neq}$ / kJ mol^{-1}	$\Delta S^{\neq}$ / J mol^{-1} K^{-1}	$\Delta V^{\neq}$ / cm^3 mol^{-1}
$Ni(NO_3)_2$+PAN	$(1.4\pm0.1)\times10^4$	51.2±1	6.4±4	23.4±2.4
$Ni(OAc)_2$+PAN	$(1.1\pm0.1)\times10^4$	49.5±1	−1.3±4	15.5±2.6
$NiCl_2$+PAN	$(4.8\pm0.1)\times10^4$	51.4±1	17.0±4	35.4±5.5

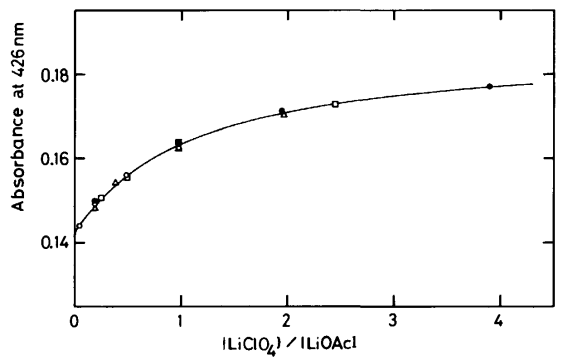

Fig. 4. Effect of lithium acetate and lithium perchlorate on spectra of PAN.
[PAN] = 1.53×10^{-5} mol kg^{-1}, [$LiClO_4$]/mol kg^{-1} = 1.59×10^{-4} (○); 3.17×10^{-4} (△); 7.90×10^{-4} (□); 3.16×10^{-3} (●).

Taking into consideration the ionization of PAN shown by Eq. 3, the equilibrium constant for Eq. 6 was determined to be [HpanH$^+$$ClO_4^-$][LiOAc][Hpan]$^{-1}$×[Li$^+$$ClO_4^-$]$^{-1}$=0.91±0.03 by analyzing the change in absorbance at 426 nm (see Fig. 4). The similar phenomena have been reported previously.[29,30]

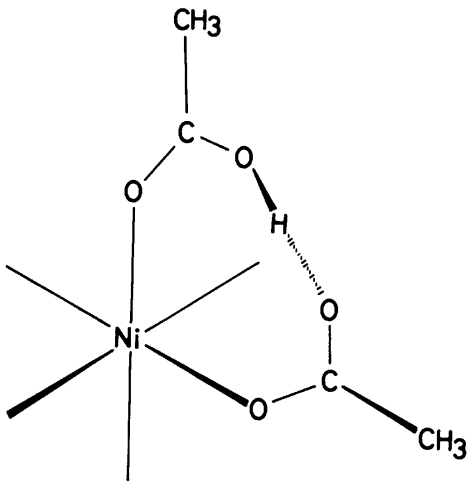
As apparent from Fig. 2, the plots for nickel(II) nitrate and nickel(II) chloride deviate from the straight line with increasing nickel(II) concentration. The deviation is thought to be due to a fast equilibrium in which PAN interacts with nickel(II) species to form a nonreactive species. The nonreactive species of PAN seems to be a quadrupole ion-pair of the acid form of PAN, similar to the species that Bruckenstein and Kolthoff have shown for Methyl Yellow.[31] It is reasonable that the extent of the deviation, *i.e.*, the ion-pair formation, parallels the ionization constants K_{PAN-HX} for HOAc,[32] HNO_3, and HCl. The conditional first-order rate constant is given by the relation: $k_0 = kC_{Ni}/(1+KC_{Ni})$, where K is a formation constant of a nonreactive ion-pair. The value of K for $Ni(NO_3)_2$ is 92 mol^{-1} kg at 25.0 °C and those for $NiCl_2$ are 1206, 1007, 927, and 842 mol^{-1} kg at 17.0, 25.0, 30.0, and 35.0 °C, respectively.

The reactivity of nickel(II) chloride is higher than the hexasolvento nickel(II) involved in the nitrate. This is just as expected from the following equation:[33]

$$\log k_{ML}^{-S} = \log k_M^{-S} + \gamma E(L), \quad (7)$$

where k_{ML}^{-S} and k_M^{-S} denote the rate constants of solvent exchange at ML and M, respectively, E(L) the electron donating ability of L, and γ a constant characteristic of the metal ion M.

As stated earlier, the electron donating ability (E_n) of chloride (1.24) is not much different from that of acetate (0.95). Although a similar enhancement of reactivity is expected for nickel acetate, nickel acetate is the least reactive among these three nickel species. This may be due to the coordination of acetate with nickel as a hydrogen bridged dimer bidentate as follows:[34]



Therefore the reactivity of the acetate is anticipated to be less than expected from its E_n value: we observe hardly the bound ligand effect for the acetate in its complexation in acetic acid. The E_n value for acetate (0.95) is not for the dimeric acetate but for the simple acetate.

The values of activation enthalpy are much the same for the present three systems (see Table 2). The parallel relation between ΔV^* and ΔS^* is observed. Since the activation volumes are positive and considerably large, these reactions are concluded to proceed via a dissociative-interchange mechanism. The dissociative character increases in the order: acetate<nitrate<chloride.

Oxidation of Lipids. V. Oxidation of Methyl Linoleate in Aqueous Dispersion

Yorihiro YAMAMOTO, Shunichi HAGA, Etsuo NIKI,* and Yoshio KAMIYA
Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received August 9, 1983)

The rate and products of oxidation of methyl linoleate dispersed in water by Triton X-100 were measured at 50 °C. The oxidation was initiated by water- or oil-soluble azo-initiators. The oxidation proceeded smoothly by both types of initiators without any noticeable induction period and a constant rate of oxygen uptake was observed. Conjugated diene hydroperoxides were formed almost quantitatively. The oxidizability for methyl linoleate in aqueous dispersion was obtained as $k_p/(2k_t)^{1/2}=0.032(\text{s}\cdot\text{mol/L-oil})^{-1/2}$ where k_p and k_t are the rate constants for propagation and termination reactions, respectively. This value was similar to that observed in the homogeneous oxidation in chlorobenzene. L-Ascorbic acid inhibited the oxidation initiated by water-soluble initiator but it could not inhibit the oxidation initiated by oil-soluble initiator. 2,6-Di-*t*-butyl-4-methylphenol inhibited the oxidation initiated by both initiators. On the other hand, α-tocopherol was effective for the oxidation initiated by oil-soluble initiator and it incompletely inhibited the oxidation initiated by water-soluble initiator.

The oxidation of polyunsaturated fatty acids has received renewed attention recently in connection with the deterioration of foods and oils and with the peroxidation in biological systems.[1-6] In the course of our study on the oxidation of lipids and its inhibition,[7-10] we have extended the work to the oxidation of methyl linoleate in water dispersion. Methyl linoleate was chosen as a substrate since its oxidation proceeds by a straightforward mechanism to give four isomeric hydroperoxides quantitatively at the initial stage.[7,9,11-20] The azo compounds were used as a radical initiator in order to obtain a constant rate of chain initiation.

Experimental

Material. Methyl linoleate was obtained from Sigma Chemical Co. and used as received. Prior to the oxidation, little conjugated diene hydroperoxides were observed by HPLC analysis (see later text). Ethyl palmitate was purchased from Tokyo Kasei Kogyo Co. and used as received. 2,2′-Azobis(2,4-dimethylpentanenitrile) (AMVN) and 2,2′-azobis(2-amidinopropane) hydrochloride (AAPH) used as a radical initiator were obtained from Wako Pure Chemical Industries. L-Ascorbic acid and Triton X-100 were their highest grade available. Commercial 2,6-di-*t*-butyl-4-methylphenol (BMP) was recrystallized from methanol. Natural D-α-tocopherol was kindly supplied from Eisai Co.

Procedure. Appropriate amounts of methyl linoleate, ethyl palmitate, and AMVN (and, if necessary, benzene solution of BMP and α-tocopherol) were taken into a 30 ml Pyrex glass ampoule and dissolved into benzene. The ampoule was connected to the water aspirator and benzene was removed at room temperature. The removal of benzene was checked by the weight. Five ml of 0.01 M (1 M=1 mol dm^{-3}) aqueous Triton X-100 (when necessary, L-ascorbic acid was dissolved in this solution) was added into the ampoule and shaken vigorously on Vortex mixer for two minutes. The oxidation initiated by a water-soluble initiator, AAPH, dissolved in an aqueous Triton X-100 was carried out by a similar procedure.

The ampoule was degassed and then oxygen was introduced into the vessel. The oxidation was carried out at 50 °C under atmospheric pressure of oxygen for the desired time. The rate of oxygen uptake was followed by pressure decrease using a pressure transducer connected to the vessel.

The oxidation was ceased by cooling the ampoule, then methanol was added into the ampoule in order to homogenize the aqueous dispersion. The consumption of methyl linoleate was measured by GLC. An aliquot of methanol solution was evacuated using the evaporator and the reside was dissolved in hexane. This hexane solution was analyzed by HPLC to determine the amounts of hydroperoxides formed, using a silica-gel column and hexane/isopropyl alcohol/acetic acid (1000:10:1, v/v/v) as the eluent. The extinction coefficient was taken from the literature.[12]

Results and Discussion

Oxidation of Methyl Linoleate (LH) Micelle Initiated by Oil-soluble Initiator. Table 1 shows the results of AMVN-initiated oxidation of LH in an aqueous dispersion at 50 °C. As shown in Fig. 1 (Run 2), the oxidation of LH proceeded smoothly without any noticeable induction period and a constant rate of oxygen uptake was observed.

The oxidation of LH initiated by oil-soluble initiator (IN_2I) proceeds by the mechanism[9] shown below:

$$\text{initiation} \quad (IN_2I)_{oil} \longrightarrow 2eI\cdot + N_2 + (1-e)\text{I-I}, \quad (1)$$

$$I\cdot + O_2 \xrightarrow{LH,\ O_2} IOOH + LO_2\cdot, \quad (2)$$

$$\text{propagation} \quad LO_2\cdot + LH \xrightarrow{k_p} LOOH + L\cdot, \quad (3)$$

$$L\cdot + O_2 \rightleftharpoons LO_2\cdot, \quad (4)$$

$$\text{termination} \quad LO_2\cdot + LO_2\cdot \xrightarrow{k_t} \text{nonradical products.} \quad (5)$$

The rate of oxygen uptake ($-dO_2/dt$) is given by

$$-dO_2/dt = R_i^{1/2}[LH]k_p/(2k_t)^{1/2}, \quad (6)$$

where k_p, k_t, and R_i are the rate constants for Reactions 3 and 5, and rate of initiation, respectively. The rate of initiation was measured by the Eq. 7 from the induction period (t_{inh}) observed in the presence of inhibitor (InhH). The constant n is the number of peroxyl radicals trapped by one inhibitor and it was assumed to be 2.[21]

$$R_i = n[\text{InhH}]/t_{inh}. \quad (7)$$

a) The numbers in the parentheses are the rate of oxidation and kinetic chain length during the induction period.

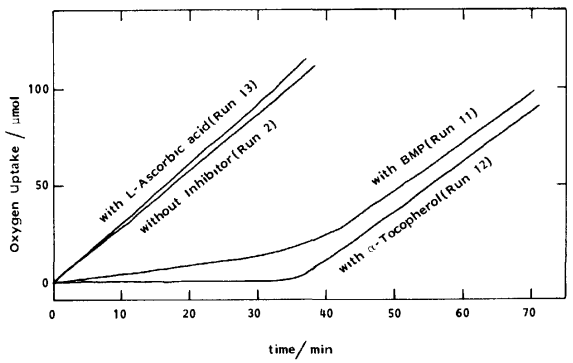

Fig. 1. Rate of oxygen uptake in the AMVN-initiated oxidation of methyl linoleate dispersed in aqueous Triton X-100 at 50 °C.

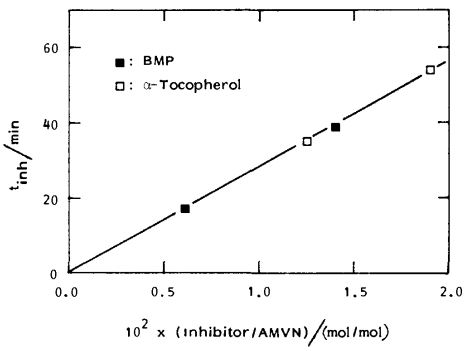

Fig. 2. Plot of induction period(t_{inh}) against the ratio of inhibitor to AMVN concentration in the AMVN-initiated oxidation of methyl linoleate in aqueous dispersion at 50 °C.

Figure 1 shows that the induction period was observed in the presence of BMP or α-tocopherol (Runs 11 and 12). The induction period is produced because BMP or α-tocopherol scavenges the chain carrying peroxyl radicals by Reactions 8 and 9, and suppresses

$$LO_2\cdot + InhH \xrightarrow{k_{inh}} LOOH + Inh\cdot, \quad (8)$$

$$LO_2\cdot + Inh\cdot \longrightarrow Inh\text{-}OOL, \quad (9)$$

the oxidation. As the inhibitor consumed, the rate of oxidation increases and when all the inhibitor is exhausted the oxidation proceeds at the same rate as that in the absence of an inhibitor; that is, the lines for Runs 11 and 12 after the induction period are parallel with the line for Run 2.

Table 2 summarizes the effect of inhibitors on the AMVN-initiated oxidation of LH in an aqueous dispersion. The rate of oxidation during the induction period was smaller when α-tocopherol was used as the inhibitor than when BMP was used. This is the reason why α-tocopherol traps the chain carrying peroxyl radicals faster than BMP.[8,21)]

Figure 2 shows the induction period changes as a

function of the ratio of inhibitor to AMVN. A good linear correlation was observed and the slope for α-tocopherol was identical with that for BMP, suggesting the same stoichiometric number n for both inhibitors.

Equation 6 suggests that the rate of oxygen uptake is the first order with respect to the concentration of the substrate. Figure 3 shows the plot of $-dO_2/dt$ as a function of [LH] $R_i^{1/2}$ and a linear correlation was obtained. This also supports that the oxidation proceeds by the Reactions 1 to 5. The slope gives the oxidizability, $k_p/(2k_t)^{1/2}$, as 0.032 $(s \cdot mol/L\text{-}oil)^{-1/2}$.

Oxidation of Methyl Linoleate(LH) Micelle Initiated by Water-soluble Initiator. A constant rate of oxygen uptake was observed in the oxidation of LH micelle initiated by AAPH as shown in Fig. 4 (Run 23), which indicates that the rate of radical formation in the oil region of micelle was constant nevertheless radicals were initially formed in the aqueous phase.[22]

Table 3 summarizes the effect of Triton X-100 on the AAPH-initiated oxidation of LH in an aqueous dispersion. When Triton X-100 was not added and LH was floating on the water-air interface, little oxygen uptake was observed (Run 15). The rate of oxygen uptake increased with an increase in the concentration of Triton X-100 (Runs 16—19). However, an appreciable rate of oxygen uptake was observed in the oxidation of 0.1 M aqueous Triton X-100 alone (Run 20), therefore the concentration of Triton X-100 was kept constant at 0.01 M.

Table 4 summarizes some representative results of the AAPH-initiated oxidation of LH dispersed in 5 ml of 0.01 M aqueous Triton X-100 at 50 °C. The rate of initiation (R_i) was calculated from the induction period (t_{inh}) produced in the presence of BMP (see later results). The oxidizability, $k_p/(2k_t)^{1/2}$, was calculated from equa-

tion 6 as 0.032 (s·mol/L-oil)$^{-1/2}$ on the average of Runs 17, 22, 23, and 24. This value agreed well with that obtained in the AMVN-initiated oxidation of LH dispersed in an aqueous Triton X-100. These values were also in good agreement with the oxidizability obtained in the oxidation of LH in chlorobenzene at 50 °C; 0.033 (M·s)$^{-1/2}$.[23)]

The effect of inhibitors on the AAPH-initiated oxidation of LH in an aqueous dispersion is summarized in Table 5 and Fig. 4. Water-soluble inhibitor, L-ascorbic acid, suppressed the oxidation (Runs 29 and 30). BMP also inhibited the oxidation (Runs 26 and 27) and we can calculated the concentration of radical produced in the oil region of micelle in an unit time (R_i) from the induction period (T_{inh}) by Eq. 7. Figure 5 shows the plot of t_{inh} against the ratio of BMP to AAPH and a linear correlation was obtained. On the other hand, α-tocopherol inhibited the oxidation incompletely as shown in Fig. 4.

Products. Table 6 summarizes the oxygen uptake, substrate reacted, and the formation of hydroperoxides in the oxidation of methyl linoleate (LH) in an aqueous dispersion at 50 °C. As observed in the oxidation of LH in an homogeneous solution, the major products were for isomeric conjugated diene hydroperoxides: (9*Z*,11*E*)-13-hydroperoxy-, (9*E*,11*E*)-13-hydroperoxy-, (10*E*,12*Z*)-9-hydroperoxy-, and (10*E*,12*E*)-9-hydroperoxyoctadecadienoic acid methyl esters. The amounts of oxygen uptake, substrate disappearance, and the formation of hydroperoxides agreed fairy well with each other. Figure 6 shows the dependence of *cis,trans*-LOOH/*trans,trans*-LOOH ratio on the concentration of substrate in the oil phase. The intersections and the slopes were the same independent of the initiators. Furthermore, the *cis,trans* to *trans,trans* ratios were similar to those obtained in the homogeneous oxidation of LH in solution at 50 °C.[9)]

In conclusion, the oxidation of methyl linoleate dispersed in an aqueous Triton X-100 was initiated by not only oil-soluble initiator but also water-soluble initiator, and a constant rate of oxygen uptake was observed. Water-soluble inhibitor, L-ascorbic acid, inhibitd the oxidation initiated by water-soluble initiator but it could not inhibited the oxidation initiated by

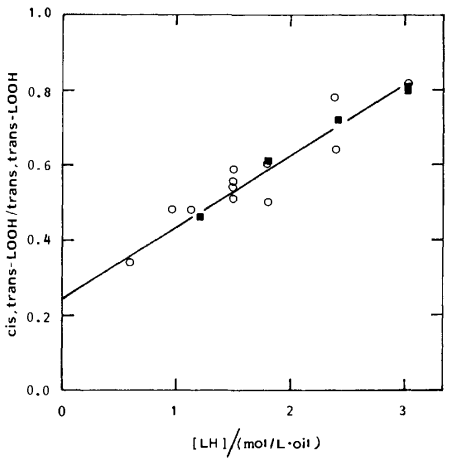

Fig. 6. Plot of *cis,trans*-LOOH/*trans,trans*-LOOH ratio against methyl linoleate (LH) concentration in the AMVN-(○) and AAPH-(■) initiated oxidation of LH in aqueous dispersion at 50 °C.

oil-soluble initiator. Oil-soluble inhibitor, BMP and α-tocopherol, inhibited the oxidation initiated by both inhibitors. The oxidizability for methyl linoleate in an aqueous dispersion was similar to that observed in the homogeneous oxidation in chlorobenzene. Furthermore, conjugated diene hydroperoxides were formed almost quantitatively and *cis,trans/trans,trans* ratios were similar to those obtained in the homogeneous oxidation. Thus, the oxidation of methyl linoleate in an aqueous dispersion proceeds in the oil region by the similar rate and mechanism as in homogeneous solution.

A gift of α-tocopherol from Eisai Co. Ltd. is gratefully acknowledged.

(Received September 17, 1983)

This paper describes the synthesis of 3-(3-*t*-butoxypropyl)-6-hydroxy-2,5-piperazinedione derivatives by the hydroxylation of the corresponding 2,5-piperazinedione with *N*-bromosuccinimide (NBS) in the presence of water and the subsequent cyclization to 2-oxa-7,9-diazabicyclo[4.2.2]decane-8,10-dione derivatives (**11**). The reversible interconversion between the spiro[oxolane-2,2′-piperazine]-3′,6′-dione prepared previously and the bicyclo compound **11** was established. The formation mechanisms and the structural confirmation of **11** and the other products are discussed.

Bicyclomycin, produced by *Streptomyces (St.) sapporonensis*[1] and *St. aizunensis*,[2] is found to have an interesting bicyclostructure and a marked bioactivity.[3-6] The very interesting and important investigation on the correlation between the structure and the bioactivity attracked and prompted us to synthesize the bicyclomycin and its analogs. Many workers have attempted the synthesis of bicyclomycin,[7-12] more recently, it has been reported that Nakatsuka *et al.* have succeeded in the total synthesis.[13] We also reported briefly the facile conversion of 1-benzyl-3-(3-hydroxypropyl)-2,5-piperazinedione (**3**) (2,5-piperazinedione=PDO) derivative to the corresponding bicyclo compound.[10]

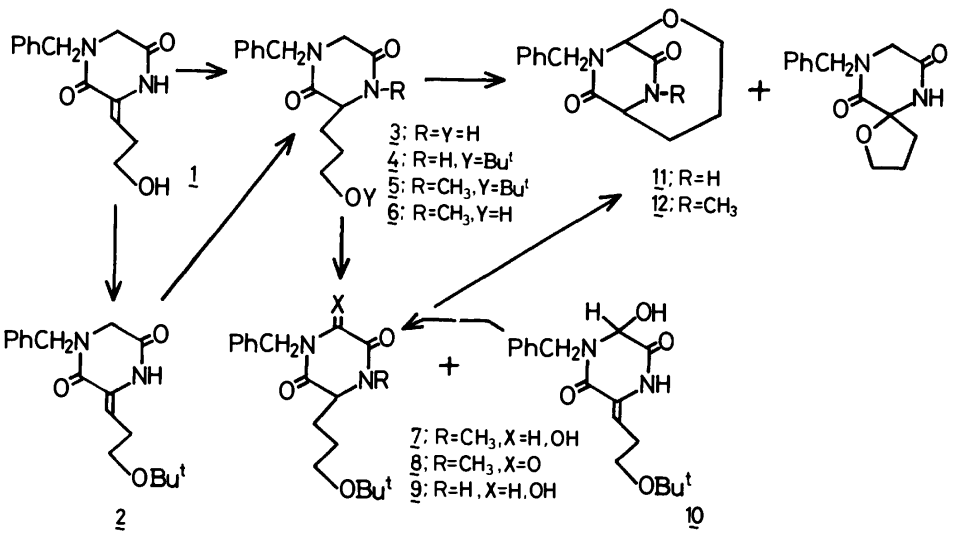
In the present paper, we wish to report in detail the synthesis of the main framework of bicyclomycin. The structural determination and the formation mechanisms are discussed.

Results and Discussion

Synthesis of 3,6-Bridged PDO. The starting 1-benzyl-3-(3-hydroxypropylidene)-PDO (**1**), derived by the cyclization of diethyl (*Z*)-2-chloroacetylamino-2-pentendioate[14,15] with benzylamine and the reduction of the resulting 3-[2-(ethoxycarbonyl)ethylidene]-PDO derivative with $LiAlH_4$,[14] was treated with isobutene to give 1-benzyl-3-(3-*t*-butoxypropylidene)-PDO (**2**). The subsequent hydrogenation of **2** with 10% Pd/C gave 1-benzyl-3-(3-*t*-butoxypropyl)-PDO (**4**) in a good yield.

According to the method for the selective hydroxylation of 6-position of PDO derivative reported recently,[14] the compound **4** was treated with *N*-bromosuccinimide (NBS) in a mixture of chloroform and water to give reaction products as a mixture. The crude mixture thus obtained was chromatographed on a silica-gel column to give three fractions, from which the compounds **2**, **10**, and **9** were in turn obtained in 28, 21, and 29% yields respectively. The latter two were identified as 1-benzyl-3-(3-*t*-butoxypropylidene)-6-hydroxy-PDO (**10**) and 3-(3-*t*-butoxypropyl)-6-hydroxy-PDO (**9**). In addition, the compound **9** separated above and newly obtained by the catalytic hydrogenation of **10** with 10% Pd/C was found to be comprised of two stereoisomers, which could be separated purely to give **9a** and **9b** (*ca.* 1:1 ratio).

On the other hand, in order to block the 4-position,



Scheme 1.

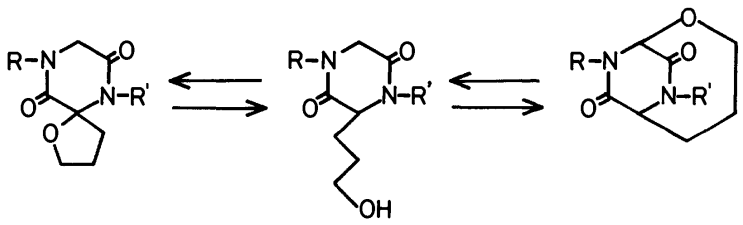


Fig. 1.

according to the method reported previously,[16] the compound **4** was subjected to the methylation with methyl iodide, followed by the reaction of the resulting 1-benzyl-3-(3-*t*-butoxypropyl)-4-methyl-PDO (**5**) with NBS in the presence of water. The reaction products thus obtained as a mixture were separated on a silica-gel column to give two kinds of colorless crystals, which were identified as 1-benzyl-5-(3-*t*-butoxypropyl)-4-methyl-2,3,6-piperazinetrione (**8**) and the corresponding 6-hydroxy-PDO (**7**) obtained in a 26% and a 40% yield respectively.

In order to examine whether or not the *N*-unmasked **3**[14] can be hydroxylated at the 6-position, the substrate **3** was also made to react with NBS in the presence of water. As a result, the expected hydroxylation of **3** took place. The resulting product, yielded as an intermediate, was cyclized to give the 3,6-bridged PDO and spiro-PDO derivatives. The two products thus obtained were readily characterized to be 9-benzyl-2-oxa-7,9-diazabicyclo[4.2.2]decane-8,10-dione (**11**) and 4'-benzylspiro[oxolane-2,2'-piperazine]-3',6'-dione[14] in a 28% and a 38% yield respectively.

On the other hand, the similar reaction of **3** with NBS in chloroform in the absence of water gave an oily product, which was assigned to be a mixture of 3-, 6-bromo, and 3,6-dibromo derivatives of **3** based on the spectroscopic analyses. However, the attempts to separate the above mixture purely have been unsuccessful so far. Consequently, the hydroxylation mechanism is supposed to be the bromination of **3** in the first step and then the substitution of bromine with hydroxyl group at 3- and 6-positions. Furthermore, from the above results and the fact that the spiro compound easily converted into **3**,[14] the reversible interconversion route between the spiro and 3,6-bridged compounds (**11**) *via* **3** was first ascertained and established here, as is illustrated in Fig. 1.

In addition, in order to obtain **11** in a higher yield, the cyclization of 1-benzyl-6-hydroxy-3-(3-hydroxypropyl)-PDO *in situ*, formed as an intermediate by the treatment of **9** with trifluoroacetic acid, was successful. **11** was obtained in a 95% yield from **9a** and in a 90% yield from **9b**. **7** was similarly worked up to give 7-methyl derivative of **11** (**12**) in a quantitative yield. Therefore, the formation mechanisms of **11** and **12** could be unambiguously concluded to be the decomposition of *t*-butoxyl group of **7** and **9** with trifluoroacetic acid to hydroxyl group, followed by the immediate cyclization by the intramolecular dehydration between 3-(3-hydroxypropyl) and 6-hydroxyl groups.

The yields, physical constants, and spectral data of **4**—**8** and **9** are summarized in Table 1.

In the NMR spectrum of **11**, the signal of the proton at the 1-position appeared in the δ 4.20 as a multiplet and the signal at δ 5.01 is attributable to 6-proton, which is splitting as a doublet (J=1.2 Hz) of the long range coupling due to the *W*-letter relationship between NH and 1-proton. In consequence, the 3,6-bridged PDO (**11** and **12**) thus obtained was found to have a boat structure, as in the corresponding spiro derivative;[14] this is illustrated in Fig. 2.

Synthesis of 3-Methoxy-3,6-bridged PDO. To

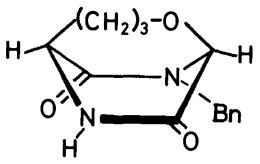

Fig. 2.

generalize the synthesis of the 3,6-bridged PDO, 3-alkoxy- and 3-hydroxy-3-(3-*t*-butoxypropyl)-PDO derivatives newly synthesized here were made to undergo the cyclization reaction. According to the method reported previously,[17] the compound **2** was treated with NBS in a mixture of dioxane and water to give colorless crystals, which were identified as 1-benzyl-3-(1-bromo-3-*t*-butoxypropyl)-3-hydroxy-PDO (**14**) in a 97% yield. In this case, the hydroxylation at the both 3- and 6-positions of **2** did not take place, but only **14** was obtained selectively. The subsequent hydrogenolysis of bromine on **14** with 10% Pd/C gave the corresponding 3-(3-*t*-butoxypropyl)-3-hydroxy-PDO derivative (**16**) in a 94% yield.

On the other hand, the methoxylation of **2** with NBS in methanol was also achieved, followed by the similar hydrogenolysis of the resulting 3-(1-bromo-3-*t*-butoxypropyl)-3-methoxy-PDO derivative (**13**) gave 1-benzyl-3-(3-*t*-butoxypropyl)-3-methoxy-PDO (**15**) in a 95% yield. For the purpose of the conversion of *t*-butoxyl group, **15** was treated with organic acid such as glacial acetic acid; the unexpected elimination of methanol readily occurred to give the starting material **2** quantitatively. Hence, to prevent the methoxyl group from being eliminated it is necessary to protect the 4-position of **15**.[14] The methylation of **15** with methyl iodide[16] gave the corresponding 4-methyl-PDO derivative of **15** (**17**) in a 71% yield.

Next, the reaction of **17** with NBS in a mixture of chloroform and water was performed to obtain a crystalline product as a mixture. Subsequently, by the usual column chromatograph method, the crude mixture was separated purely to give two fractions: The first fraction gave colorless crystals, identified as the corresponding 2,3,6-piperazinetrione derivative of **17** (**18**) in a 23% yield, while the second one gave a colorless syrup, which was also identified as the corresponding 6-hydroxy-PDO derivative of **17** (**19**) in a 40% yield. Although the compounds **17** and **19** thus obtained did not give satisfactory elemental analyses because of the difficulty of purification, their structures could be exactly confirmed by the further transformation to **18** and to the 6-acetoxy derivative of **19** (**20**) respectively.

In order to activate the 6-hydroxyl group, the compound **19** was acetylated by the usual method, followed by the treatment of **20** obtained with trifluoroacetic acid. As a result, the cyclization proceeded quickly to give the reaction products as a mixture. The subsequent separation of the mixture on a silica-gel column gave a syrup from the first fraction and colorless crystals from the second one. These compounds were characterized to be 9-benzyl-6-methoxy-7-methyl-2-oxa-7,9-diazabicyclo[4.2.2]decane-8,10-dione (**22**) in a 54% yield and the authentic 4'-benzyl-5'-hydroxy-1'-methylspiro-[oxolane-2,2'-piperazine]-3',6'-dione (**23**)[14] in a 32% yield respectively.

From the above results, interestingly, even if both 3- and 4-positions were protected with methoxyl and methyl groups respectively, it was found that the spiro formation reaction could be carried out to give **23**.

The yields, physical constants, and spectral data of **13**—**19**, and **20** are summarized in Table 2.

From the NMR spectral data of **22**, the disappearance of the signals due to *t*-butyl of 3-*t*-butoxypropyl at the 3-position and those due to methyl of acetoxyl groups at the 6-position, and the appearance of methylene protons at δ 2.95 (dd, J=5.0 Hz, J=7.5 Hz), 4-methyl protons at δ 2.95 (s), 3-methyl group at δ 3.32 (s), and 6-proton at δ 5.07 (s) indicate unambiguously the formation of the expected bicyclo compound (**23**).

Further work including the cyclization of **16** and **21** is now in progress and the results will be published later.

Experimental

All the boiling and melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-G3 Spectrometer. The NMR spectra were measured with a JNM-PS-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd), using tetramethylsilane as an internal standard.

Preparation of **2**. Into a solution of **1** (3.0 g, 11.54 mmol) in CH_2Cl_2 (250 ml), we stirred concentrated H_2SO_4 (1.2 ml). Isobutene gas was then introduced into the resultant solution under cooling, till the volume of the solution became about 350 ml. After the mixture was allowed to stand at room temperature overnight, an aqueous solution of $NaHCO_3$ (100 ml) was added with vigorous stirring. The organic layer was washed with water and then dried over anhydrous Na_2SO_4. Removal of CH_2Cl_2 gave crystals, which were recrystallized from dibutyl ether to give colorless prisms. Yield 88%, mp 123—125 °C. IR (KBr): 3180 (NH), 1680, 1635 (CO) cm^{-1}. NMR ($CDCl_3$): δ=1.24 (s, Bu^t), 6.28 (t, -CH=, J=8.0 Hz), 9.56 (bs, NH). Found: C, 67.82; H, 7.84; N, 8.78%. Calcd for $C_{18}H_{24}N_2O_3$: C, 68.33; H, 7.65; N, 8.85%.

Preparation of **4**. A solution of **2** (1.2 g, 3.80 mmol) in methanol (60 ml) was hydrogenated catalytically with 10% Pd/C (120 mg) at room temperature for 30 min. After filtering off Pd/C, the methanol solution was concentrated to give crude crystals, which were recrystallized from dibutyl ether to give colorless needles. IR (KBr): 3240 (NH), 1695, 1660 (CO) cm^{-1}.

Preparation of **5**. Into a solution of **4** (450 mg, 1.41 mmol) in DMF (5 ml), we stirred 55% NaH (74 mg, 1.70 mmol) at room temperature. After the evolution of hydrogen ceased, methyl iodide (240 mg, 1.69 mmol) was added to the resulting solution, with stirring for 15 min. Into the reaction solution was added ice water (20 ml) and then the resulting solution was extracted twice with benzene (30 ml). The benzene layer was washed twice with water and then dried over anhydrous Na_2SO_4. Removal of benzene gave crystals, which were recrystallized from hexane to give colorless needles. IR (KBr): 1650 (CO) cm^{-1}.

Preparation of **6**. After a solution of **5** (400 mg, 1.20 mmol) in trifluoroacetic acid (3 ml) was allowed to stand at room temperature for 2 h, the resulting solution was concentrated under reduced pressure to give a residual product. The residue thus obtained was purified on a silica-gel column using a mixture of chloroform and acetone (5:1 v/v) as the eluent. Concentration of the fraction obtained gave crude crystals, which were recrystallized from benzene-hexane to give colorless prisms. IR (KBr): 3350 (OH), 1660 (CO) cm^{-1}.

Reaction of **4** *with NBS-Water*. Into a solution of **4** (2.0 g, 6.29 mmol) in chloroform (200 ml) was added water (20 ml) and NBS (1.34 g, 7.55 mmol) at room temperature. After stirring for 2 h, the organic layer which separated was washed with water and then dried over anhydrous Na_2SO_4. After removal of chloroform, the residue was chromatographed on a silica-gel column using a mixture of chloroform and acetone (10:1 v/v) as the eluent. Four fractions thus obtained were concentrated under reduced pressure and each resulting product was purified by means of the recrystallization or on the silica-gel column to give **2**, **10**, **9a**, and **9b** respectively. **2**; Yield 28%. **9a**; IR (KBr): 3200, 1705, 1670, 1665, and 1630 cm^{-1}. **9b**; IR: 3250, 1680 cm^{-1}. **10**; Yield 21%, mp 134—136 °C (colorless prisms from benzene-hexane). IR (KBr): 3300 (OH), 3200 (NH), 1690 (CO), 1620 (C=C) cm^{-1}. NMR ($CDCl_3$): δ=1.22 (s, 9H, Bu^t), 5.06 (bs, 1H, 6-H), 5.7—6.0 (OH), 6.30 (t, -CH=, J=8.0 Hz), 9.70 (bs, NH). Found: C, 65.08; H, 7.22; N, 8.49%. Calcd for $C_{18}H_{24}N_2O_4$: C, 65.04; H, 7.28; N, 8.43%.

Hydrogenation of **10**. A solution of **10** (225 mg, 0.678 mmol) in methanol (20 ml) was catalytically hydrogenated with 10% Pd/C (30 mg) at room temperature for 30 min to give a mixture of **9a** and **9b** (*ca.* 1:1) in a 93% yield.

Reaction of **5** *with NBS-Water*. Into a solution of **5** (1.0 g, 3.01 mmol) in a mixture of chloroform (20 ml) and water (5 ml), we stirred NBS (643 mg, 3.61 mmol) at room temperature for 6 h. The resulting chloroform layer was washed with water and then dried over anhydrous Na_2SO_4. After removal of chloroform, the residue obtained was chromatographed on a silica-gel column using a mixture of

chloroform and acetone (20:1 v/v) as the eluent. The two fractions thus obtained were concentrated to give **8** and **9** respectively. **8**; IR (KBr): 1720, 1690 (CO) cm^{-1}. **9**; IR: 3170 (OH), 1675, 1650 (CO) cm^{-1}.

Reaction of 3 with NBS-Water. In a similar manner, the treatment of **3** (800 mg, 3.05 mmol) with a solution of NBS (600 mg, 3.37 mmol) in a mixture of chloroform (30 ml) and water (3 ml) was worked up for 3 h to give two kinds of products, **11** and the corresponding spiro derivative[14] in a 28 and a 38% yield respectively. **11**; Mp 200—202 °C (colorless prisms from benzene-hexane). IR (KBr): 3230 (NH), 1800 1670 (CO) cm^{-1}. NMR ($CDCl_3$): δ=1.7—2.3 (m, 4H, $-CH_2-$), 3.4—4.0 (m, 2H, $-O-CH_2-$), 4.20 (m, 1H, $-C\underline{H}-CH_2-$, 6-H), 5.01 (d, 1H, $-C\underline{H}-OCH_2-$, $J_{3\text{-H,NH}}$=1.2 Hz, 3-H), 7.68 (s, NH). Found: C, 65.01; H, 6.34; N, 10.66%. Calcd for $C_{14}H_{16}N_2O_3$: C, 64.60; H, 6.20; N, 10.76%.

Cyclization of 9a and 9b. A solution of **9** (300 mg, 0.898 mmol) in CF_3COOH (2 ml) was allowed to stand at room temperature for 2 h. After removal of CF_3COOH, the residual product was dissolved in benzene (20 ml) and the resulting solution was washed with water and then dried over anhydrous Na_2SO_4. Concentration of the solution gave **11** in a 95% yield from **9a** and in a 90% yield from **9b**.

Preparation of 12. From 6: The treatment of **6** (110 mg, 3.99 mmol) with NBS (71 mg, 3.99 mmol) in chloroform (10 ml) was carried out under reflux for 1 h to give **12** as an unstable colorless crystals. Yield 48%. IR (KBr): 1670 (CO) cm^{-1}. NMR ($CDCl_3$): δ=1.5—2.4 (m, 4H, $-CH_2-$), 2.96 (s, 3H, $N-CH_3$), 3.3—3.9 (m, 2H, $-O-CH_2-$), 4.12 (dd, 1H, $-C\underline{H}-CH_2-$, J=3.0, 4.5 6-H), 5.12 (s, 1H, $-C\underline{H}-OCH_2-$, 3-H).

From 7: Treatment of **7** (240 mg, 6.89 mmol) in CF_3COOH (2 ml) at room temperature for 2 h gave **12** in a 98% yield.

Preparation of 13. Into a mixture of **2** (900 mg, 2.85 mmol) in methanol (10 ml), we stirred NBS (507 mg, 2.85 mmol) at room temperature for 10 min. After removal of methanol, the residue was dissolved in chloroform (20 ml) and the resulting solution was washed twice with water and then dried oved anhydrous Na_2SO_4. Concentration of the solution gave crystals, which were recrystallized from benzene-hexane to give colorless needles. IR (KBr): 3160 (NH), 1680 (CO) cm^{-1}.

Preparation of 14. Similarly, the treatment of **2** (900 mg, 2.85 mmol) with NBS (507 mg, 2.85 mmol) in a mixture of dioxane (10 ml) and water (5 ml) was worked up to give **14** as colorless needles from CCl_4. IR (KBr): 3200 (NH, CO), 1660 (CO) cm^{-1}.

Preparation of 15. A solution of **13** (900 mg, 2.11 mmol) in methanol (50 ml) was catalytically hydrogenated with 10% Pd/C (100 mg) in the presence of triethylamine (220 mg, 2.18 mmol) at room temperature for 15 min. After the Pd/C was filtered off, the methanol solution was concentrated. The residue was dissolved in CH_2Cl_2 (50 ml) and the resulting solution was washed twice with water and then dried over anhydrous Na_2SO_4. After removal of CH_2Cl_2, the residual syrup thus obtained was purified on a silica-gel column using a mixture of chloroform and acetone (10:1 v/v) as the eluent. Evaporation of the solvent gave **15** as a colorless syrup. IR (KBr): 3220 (NH), 1680 (CO) cm^{-1}.

Preparation of 16. Similarly, the hydrogenation of **14** (1.1 g, 2.66 mmol) with 10% Pd/C (100 mg) in methanol (60 ml) in the presence of triethylamine (270 mg, 2.66 mmol) was performed to give **16** as colorless needles from benzene. IR (KBr): 3240 (OH, NH), 1690, 1640 (CO) cm^{-1}.

Preparaation of 17. Into a solution of **15** (1.2 g, 3.45 mmol) in THF (40 ml), we stirred 55% NaH (150 mg, 3.45 mmol) at room temperature. After the evolution of hydrogen ceased, methyl iodide (580 mg, 4.08 mmol) was added to the resulting solution with stirring. After continuing the stirring for 1 h, the reaction solution was neutralized with acetic acid. After removal of THF, the residue obtained was dissolved in ethyl acetate (30 ml) and the resulting solution was washed twice with water and then dried over anhydrous Na_2SO_4. Concentration of the solution gave the residual syrup, which was purified on a silica-gel column using a mixture of chloroform and acetone (30:1 v/v) to give **17** as a colorless syrup. IR (KBr): 1660 (CO) cm^{-1}.

Reaction of 17 with NBS-Water. Into a solution of **17** (850 mg, 2.35 mmol) in a mixture of chloroform (20 ml) and water (5 ml), we stirred NBS (460 mg, 2.58 mmol) at room temperature overnight. The resulting organic layer was washed with water and dried over anhydrous Na_2SO_4 and finally concentrated. The residue thus obtained was chromatographed on a silica-gel column using a mixture of chloroform and acetone (20:1 v/v) as the eluent. The first fraction gave trione derivative **18**, and the second one gave 6-hydroxy derivative **19**. **18**; IR (KBr): 1745, 1685 (CO) cm^{-1}. **19**; IR: 3300 (OH), 1660 (CO) cm^{-1}.

Acetylation of 19. A solution of **19** (700 mg, 1.85 mmol) in acetic anhydride (5 ml) in the presence of sodium acetate (3 mg) was heated at 100 °C for 1 h. After removal of acetic anhydride under reduced pressure, the residue was purified on a silica-gel column using a mixture of chloroform and acetone (30:1 v/v) as the eluent. The fraction was concentrated under reduced pressure to give the corresponding acetyl derivative (**20**). IR (KBr): 1760, 1690 (CO) cm^{-1}.

Cyclization of 20. A solution of **20** (650 mg, 1.55 mmol) in CF_3COOH (5 ml) was allowed to stand at room temperature for 2 h. The reaction solution was concentrated under reduced pressure and the residue was chromatographed on a silica-gel column using a mixture of chloroform and acetone (10:1 v/v) as the eluent. The first fraction gave bicyclo compound **22** and the second one gave the spiro compound **23** in a 32% yield. **22**: Yield 54%, syrup. IR (KBr): 1680 (CO) cm^{-1}. NMR ($CDCl_3$): δ=1.3—1.9 (m, 2H, $-CH_2-$), 2.16 (dd, 2H, $-CH_2-$, J=5.0, 7.5 Hz), 2.95 (s, 3H, $N-CH_3$), 3.32 (s, 3H, OCH_3), 3.3—4.0 (m, 2H, $-OCH_2-$), 5.07 (s, 1H, $-C\underline{H}-OCH_2-$, 3-H). Found: N, 9.20%. Calcd for $C_{16}H_{20}N_2O_4$: N, 8.98%.

The Reaction of 5-Benzylidene-2,3,4,5-tetrahydropyridine with Some Nucleophiles

Yujiro NOMURA, Takashi BANDO, Yoshito TAKEUCHI,* and Shuji TOMODA
Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received September 30, 1983)

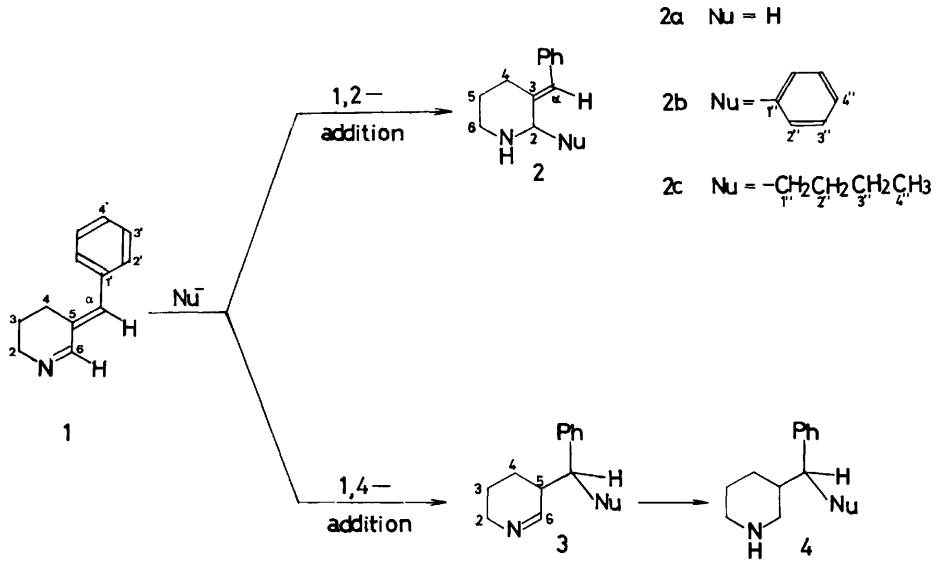
The reaction 5-benzylidene-2,3,4,5-tetrahydropyridine (**1**) with nucleophilic reagents, such as sodium tetrahydroborate, lithium tetrahydridoaluminate, organometallic reagents, pyrrole, or ethyl propiolate, has been studied. The reaction of **1** with sodium tetrahydroborate, lithium tetrahydridoaluminate, phenylmagnesium bromide, butyllithium gave exclusively respective 1,2-adducts. The reaction with pyrrole gave a tricyclic 1:1 adduct while **1** formed a 1:2 adduct with ethyl propiolate.

As an extension of our recent work directed toward the synthesis of 5-benzylidene-2,3,4,5-tetrahydropyridine (**1**)[1] which is featured with the α, β-unsaturated imine moiety fixed in *s-trans* conformation, we have investigated its reactivity toward nucleophiles. Two reaction modes are *a priori* expected: 1,2-addition of a nucleophile (Nu^-) to the C=N bond would provide a 2-substituted 3-benzylidenepiperidine (**2**), whereas conjugate addition (1,4-addition) of a nucleophile would afford 5-(α-substituted benzyl)-2,3,4,5-tetrahydropyridie (**3**) (Scheme 1). Compounds having the general structure **2** have recently attracted considerable attention in view of their potential clinical application as antihistamine and anticholine drugs.[2] On the other hand, the cyclic imine **3** may serve as a useful precursor to a variety of piperidine alkaloids and other natural alkaloids.[3] Herein we wish to report the results of such reactions of **1** with several nucleophiles which have been carried out in an attempt to synthesize these compounds (**2** and **3**).

Results and Discussion

Hydride Reduction of 1. Reduction of the C=N bond of **1** with a hydride reagent (1,2-addition) would produce 3-benzylidenepiperidine (**2a**, Nu=H), to which access has thus far been difficult using the conventional synthesis methodology.[1] On the other hand, 1,4-reduction would ultimately afford 3-benzylpiperidine (**4**) *via* partially reduced 5-benzyl-2,3,4,5-tetrahydropyridine (**3a**, Nu=H). It is generally accepted that in the reduction of α,β-unsaturated ketones 1,4-reduction tends to be more preferred with sodium tetrahydroborate than with lithium tetrahydridoaluminate.[4] In practice, however, the reduction of **1** with either reagent gave exclusively desired **2a** in 90% ($NaBH_4$, methanol, r.t.) or 85% ($LiAlH_4$, ether, 0 C). Structural identification of **2a** was based on spectral data (MS, IR, and ^1H and ^{13}C NMR). A molecular ion peak at *m/z* 173 in the mass spectrum was consistent with the molecular formula ($C_{12}H_{15}N$). ^1H NMR spectrum showed a characteristic singlet at δ 6.27 due to the benzylidene proton and one exchangeable proton at δ 2.13 (NH) in addition to eight methylene and five aromatic protons. The IR spectrum indicated a medium band at 1650 cm^{-1} due to the C=C bond conjugated with the phenyl group. In line with these data, its ^{13}C NMR spectrum exhibited ten peaks, six of which showed up in the sp^2-C region (δ 123.03—139.72), suggesting the presence of one C=C bond besides the aromatic ring.

Such a selective 1,2-hydride reduction of **1** is surprising for two reasons; (a) as described earlier, sodium



Scheme 1.

tetrahydroborate reduction of α,β-unsaturated ketones or aldehydes normally gives a mixture of 1,2- and 1,4-reduction products with the latter being predominant.[4] (b) lithium tetrahydridoaluminate reduction of 3-phenyl-2-propenal shows a discrete tendency depending on the reaction temperature; 3-phenyl-2-propen-1-ol is produced at −10 °C as a result of preferential 1,2-reduction,[5] whereas at 25 °C in diethyl ether 3-phenyl-1-propanol is obtained exclusively.[6] It should be noted here that in the case of **1** possessing an α,β-unsaturated imine structure with a phenyl group at the β-carbon, the reduction with lithium tetrahydridoaluminate at higher temperature (tetrahydrofuran, reflux, 0.5 h) resulted in the same product **2a** (79% yield); neither **3a** nor **4** was detected.

Reaction with Organometallic Compounds. The less reactive trend of the benzylidene C=C bond of **1** toward nucleophiles in comparison with α,β-unsaturate aldehyde was exposed more clearly by the reaction with organometallic compounds. Thus the reaction of **1** with excess phenylmagnesium bromide in diethyl ether at room temperature provided 3-benzylidene-2-phenylpiperidine (**2b**, Nu=Ph) exclusively in 56% yield. The structure of the product **2b** was confirmed by combustion analysis and spectral data (MS, IR, ^{1}H and ^{13}C NMR). The molecular formula ($C_{18}H_{19}N$) was established by elemental analysis (C, H, and N) and mass spectral molecular weight, *m/z* 249 (M^+). The assigned structure was compatible with the ^{1}H NMR spectrum which revealed characteristic signals at δ 1.93 (br s, 1H, NH, exchangeable with D_2O) and δ 5.90 (br s, 1 H, benzylidene proton) in addition to aromatic and alicyclic protons.

An analogous reaction mode was observed in the reaction of **1** with *n*-butyllithium at −78 °C in THF which resulted in the formation of 3-benzylidene-2-butylpiperidine (**2c**; Nu=*n*-Bu) in 95% yield. The structure of **2c** was characterized by the spectral data (MS, IR, ^{1}H and ^{13}C NMR). The ^{13}C NMR showed eight aliphatic carbons (δ 14.14—61.33) and six sp^2-carbons (δ 122.00—137.82); the peak due to the C=N bond was not detected, suggesting that the 1,2-adduct was the sole product. In agreement with this conclusion, the ^{1}H NMR indicated one benzylidene proton (δ 6.27). but no peak around δ 8 due to azomethine proton was detected.

It is noteworthy that both phenylmagnesium bromide and phenyllithium react with α,β-unsaturated imines, which can assume an *s-cis* conformation, to provide 1,4-adducts exclusively.[7] The above reaction therefore suggests an important synthetic approach for introduction of various alkyl or aryl substituent at C2 of the piperidine bearing exocyclic double bond at C3. Hence the present two-step sequence for preparation of such compounds (**2b**, **2c**) starting from 2,3,4,5-tetrahydropyridine[1,8] is much simpler and more economical than the previous methods.[9,10]

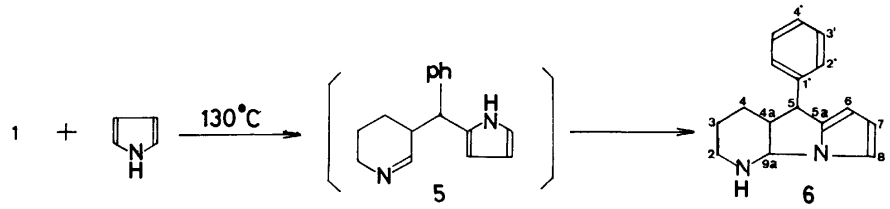
In order to prepare compounds of type **3**, we examined the reaction of organocuprates (I) (Li[R_2Cu], R=alkyl or aryl). However, desired 1,4-adducts could not be obtained under various conditions; only the starting material was recovered unchanged.

Reaction with Other Nucleophiles. The pronounced tendency of 1,2-addition of the above anionic nucleophiles could be reversed by the use of nonanionic nucleohiles, such as pyrrole. The reaction of **1** with excess pyrrole at 130 °C for 14 h gave 5-phenyl-1,3,4,4a, 5,9a-hexahydro-2*H*-pyrrolo[1',2':1,5]pyrrolo[2,3-*b*]pyridine(**6**) in 32% yield. Structural assignment was based on analytical and spectral data (MS, IR, ^{1}H and ^{13}C NMR). The presence of the fused pyrrole ring was evident by IR (1490 cm^{-1}, pyrrole ring skeletal vibration) as well as by ^{13}C NMR spectrum (four sp^2-carbons at δ 101.51(d), 111,85(d), 111.85(d)† and 142.32(s)). In its ^{1}H NMR spectrum, the three olefin protons absorbed at δ 5.83(d, *J*=3 Hz), 6.27(t, *J*=3 Hz) and 6.70(d, *J*=3 Hz) and two protons at δ 5.10(d, *J*=6 Hz) and 4.01(d, *J*=6 Hz) were assigned to the benzylic proton and the methine proton adjacent to the two nitrogen atoms, respectively. These NMR data were consistent with the tricyclic structrue **6**. This was also supported by analytical and mass spectral data.

Structure **6** suggested possible intervention of intermediate **5**, which may have been formed by 1,4-addition of pyrrole to the conjugated imine system of **1** (scheme 2). The reaction may be regarded as an electrophilic substitution of **1** with pyrrole which usually undergo such reactions preferentially at C2. This reaction therefore presents striking contrast to the previously mentioned examples of 1,2-addition of charged nucleophiles. It is very interesting that such a complex heterocyclic system can be constructed in one step by this reaction.

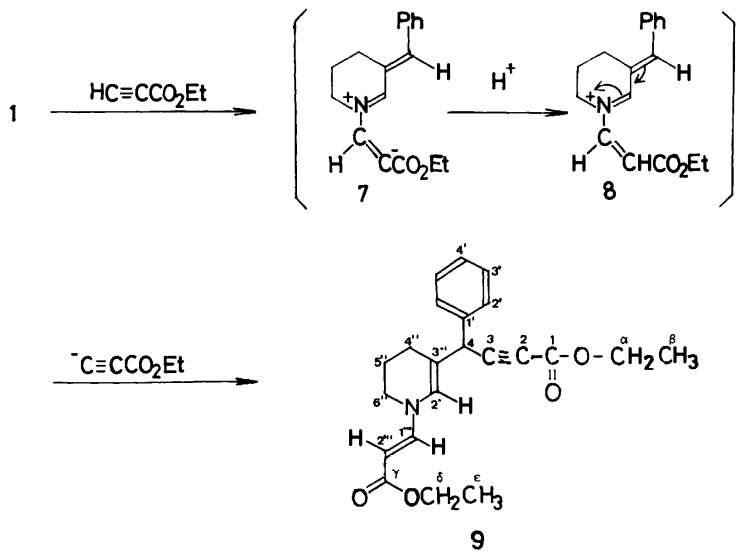
The other uncleophile examined was ethyl propiolate which is usually regarded as an electrophile because of its electron deficient triple bond. However, its conjugate base often functions as a nucleophile.[11]

Thus the reaction of **1** with ethyl propiolate (r.t., 13h, 73%; reflux, 0.5 h, 68%) afforded **9**. The structural elucidation of ethyl 4-[1-(2-ethoxycarbonylvinyl)-1,4,5,6-tetrahydro-3-pyridyl]-4-phenyl-2-butynoate (**9**) was based on spectroscopic data (MS, IR, ^{1}H and ^{13}C NMR). The mass spectral molecular ion peak (M^+=367) as well



Scheme 2.

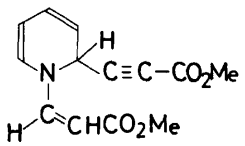
† Two signals are degenerated at the decoupling condition (see Experimental).



Scheme 3.

as ^{13}C NMR spectrum (a total of 20 peaks) established the molecular formula ($C_{22}H_{25}O_4N$). The presence of a *trans* C=C bond was suggested by ^{13}C NMR (δ 88.58 (d) and 150.33 (d)) and ^1H NMR (δ 4.85 (d, J=12 Hz) and 7.42 (d, J=12 Hz)).[12] The proton absorption at δ 4.85 disappeared upon addition of D_2O in agreement with the general behavior of the β-proton of an enamine system.[13] The other double bond was identified as a part of the endocyclic enamine segment on the basis of ^{13}C NMR (δ 127.42 or 127.96 (d) and 133.54 (s)) and ^1H NMR (δ 4.76(s)). The triple bond was evident by ^{13}C NMR (δ 77.47 (s) and 82.67 (s)) as well as by IR (2220 cm^{-1}).

The formation of **9** could be most simply rationalized by initial attack of one molecule of ethyl propiolate at the nitrogen of **1** to form the zwitter ion **7** and subsequent 1,6-addition of a second molecule of the acetylenic ester *via* the nitrilium ion intermediate **8**.[12] A similar reaction has previously been observed between pyridine and metyl propiolate to afford the 1,2-dihydropyridine **10**.[14]



10

In summary, although our intention to synthesize both **2** and **3** could not entirely be satisfied in the present investigation, compounds **2** are potentially useful as anticholine or antihistamine drugs and the unanticipated formation of compounds **6** and **9** is intriguing not only because of the initial mechanism (1,4-addition) of their formation, but also because of their unique structural feature which is otherwise only difficultly accessible.

Experimental

All reactions were performed under dry inert conditions. Solvents used were purified by distillation over appropriate drying agent under dry nitrogen atmosphere. Mass spectra were measured on a Hitachi-Perkin Elmer RMU-6D spectrometer. Infrared spectra were recorded on a JASCO DS-403G spectrometer. ^1H NMR spectra were obtained with a JEOL MH-100 spectrometer. ^{13}C NMR spectra were recorded on a JEOL FX-90Q spectrometer operated at 22.5 MHz. Typical acquisition parameters were spectral width 5000 Hz, flip angle 30° and pulse delay 2s with 8192 data points. The ^{13}C NMR spectral data of the products (**2a**, **2b**, **2c**, **6**, and **9**) were collected in Table 1 and assignments were rationalized at the end of this section. All chemical shifts were reported in δ relative to internal tetramethylsilane.

5-Benzylidene-2,3,4,5-tetrahydropyridine (1).[1] A mixture of 2,3,4,5-tetrahydropyridine trimer (α-isomer) (32.5 g, 0.131 mol) and benzaldehyde (45.6 g, 0.430 mol) in absolute methanol (500 ml) was heated under reflux for 4 h. After removal of the solvent *in vacuo*, the residue was fractionally distilled to afford 28.0 g(42%) of 5-benzilidene-2,3,4,5-tetrahydropyridine (**1**): bp 108—110 °C (0.25 mmHg)

Reaction of 1 with Sodium Tetrahydroborate. Sodium tetrahydroborate (509 mg, 13.5 mmol) dissolved in methanol (20 ml) was added dropwise with stirring to a solution of **1** (1.085 g, 6.35 mmol) in methanol (30 ml) at ambient temperature. After additional 2 h stirring, concentrated hydrochloric acid (10 ml) was added to the reaction mixture. After removal of the solvent, water (15 ml) was added to the residue. The resultant solution, saturated with potassium carbonate, was extracted with diethyl ether. After drying the extract over anhydrous sodium sulfate and subsequent removal of ether *in vacuo*, 3-benzylidenepiperidine (**2a**) (984 mg, 90%) was obtained as colorless oil. ^1H NMR($CDCl_3$): δ 1.57(quintet, J=6 Hz, 2H), 2.13(s, 1H), 2.50(t, J=6 Hz, 2H), 2.90(t, J=6 Hz, 2H), 3.37(s, 2H), 6.27(s, 1H), and 7.00—7.40(m, 5H); IR(neat): 745 and 700 cm^{-1}; MS: M^+=173.

Reaction of 1 with Lithium Tetrahydroaluminate. A): A solution of **1** (983 mg, 5.75 mmol) in absolute ether (10 ml) was added dropwise with stirring to dry dietyl ether (15 ml) suspended with lithium tetrahydridoaluminate (500 mg, 13.2 mmol) at 0 °C. After additional 2 h stirring, ice-water was added to the reaction mixture. The organic layer was separated, dried with anhydrous sodium sulfate, and evapo-

a) Measured in $CDCl_3$ on a JEOL FX-90Q spectrometer operated at 22.5 Hz (See Experimental section for acquisition conditions). b, c) Assignments may be reversed.

rated to afford **2a** (843 mg, 85%).

B): A solution of **1** (529 mg, 3.09 mmol) in dry tetrahydrofuran (10 ml) was added to dry tetrahydrofuran (15 ml) suspended with lithium tetrahydridoaluminate (494 mg, 13.0 mmol) under reflux. After continued reflux for 30 min, ice-water was added to the reaction mixture. The organic layer was separated, dried with anhydrous sodium sulfate, and evaporated to leave **2a** (421 mg, 79%).

Reaction of 1 with Phenylmagnesium Bromide. A solution of bromobenzene (2.5 ml, 23.9 mmol) in absolute dietyl ether (14 ml) was added under nitrogen atmosphere to magnesium powder (600 mg, 24.7 mmol) to form phenylmagnesium bromide. Subsequently, a solution of **1** (1.070 g, 6.26 mmol) dissolved in absolute ether (6 ml) was added to the Grignard reagent. The mixture was stirred for 14 h at ambient temperature and then poured into ice-cold 10% hydrochloric acid. The usual work-up followed by purification by silica-gel column chromatography using diethyl ether/dichloromethane (1 : 1) as an eluant afforded 3-benzylidene-2-phenylpiperidine (**2b**) (870 mg, 56%); mp 60.0—60.5 °C (sublimed, uncorrected); ^{1}H NMR ($CDCl_3$) δ 1.67 (quintet, J=6 Hz, 2H), 1.93 (broad s, 1H), 2.17—3.00 (m, 4H), 4.43 (broad s, 1H), 5.90 (broad s, 1H) and 7.00—7.56 (m, 10H); IR (KBr) 754, and 692 cm^{-1}; MS m/z 249 (M^+); Found: C, 86.71; H, 7.47; N, 5.85%. Calcd for $C_{18}H_{19}N$: C, 86.70; H, 7.68; N, 5.62%.

Reaction of 1 with Butyllithium. Butyllithium dissolved in hexane (1.51 mol/l, 4 ml) was added under nitrogen atmosphere to a cold (−78 °C) solution of **1** (500 mg, 2.92 mmol) in tetrahydrofuran (10 ml) and stirred for 45 min at −78 °C. The reaction was quenched with 10 ml of water and the resultant solution, saturated with potassium carbonate, was extracted with ether. The extract was dried over anhydrous sodium sulfate and the ether removed *in vacuo*. 3-Benzylidene-2-butylpiperidine (**2c**) was obtained as colorless oil. ^{1}H NMR ($CDCl_3$) δ 0.93 (t, 3H), 1.01—2.00 (m, 8H), 2.20 (broad, 1H), 2.33—3.33 (m, 4H), 3.60 (t, 1H), 6.27 (broad s, 1H) and 7.20 (m, 5H); IR (neat) 740 and 695 cm^{-1}; MS m/z 229 (M^+).

Reaction of 1 with Pyrrole. **1** (989 mg, 5.78 mmol) was dissolved in pyrrole (10 ml) and heated under reflux for 14 h. After removal of excess pyrrole *in vacuo*, the residue was purified by dry alumina column chromatography using hexane-dichloromethane-diethyl ether (1 : 1 : 1) as an eluent to afford 5-phenyl-1,3,4,4a,5,9a-hexahydro-2*H*-pyrrole[1',2' : 1,5]-pyrrolo[2,3-*b*]pyridine (**6**) (442 mg, 32%); mp 82.5—83.0 °C (sublimed, uncorrected); ^{1}H NMR ($CDCl_3$) δ 1.20—2.23 (m, 5H), 2.40—3.00 (m, 3H), 4.01 (d, J=6 Hz, 1H), 5.10 (d, J=6 Hz, 1H), 5.83 (d, J=3 Hz, 1H), 6.27 (t, J=3 Hz, 1H) 6.70 (d, J=3 Hz, 1H) and 7.00—7.57 (m, 5H); IR (KBr) 1490 (pyrrole ring), 748, 733, 720, 705 and 672 cm^{-1}; MS m/z 238 (M^+); Found (Calcd): C 80.63 (80.63), H 7.55 (7.61), N 11.91 (11.75).

Reaction of 1 with Ethyl Propiolate. A): A mixture of ethyl propiolate (9.77 mmol) and **1** (500 mg, 2.92 mmol) dissolved in benzene (20 ml) was heated under reflux for 30 min under nitrogen atmosphere. After removal of solvent *in vacuo*, the residue was purified by dry silica-gel column chromatography using hexane-dichloromethane-diethyl ether (2 : 1 : 1) as an eluant to afford ethyl 4-[1-(2-ethoxycarbonylvinyl)-1,4,5,6-tetrahydro-3-pyridyl]-4-phenyl-2-butynoate (**9**) (725 mg, 68%).

B): A mixture of ethyl propiolate (9.77 mmol) and **1** (456 mg, 2.67 mmol) dissolved in benzene (20 ml) was stirred under nitrogen atmosphere at ambient temperature for 13 h. After removal of solvent *in vacuo*, the residue was purified as described above to provide **9** (713 mg, 73%). ^{1}H NMR ($CDCl_3$) δ 1.20 (t, J=7 Hz, 3H), 1.25 (t, J=7 Hz, 3H), 1.43—2.00 (m, 2H), 2.20—2.60 (m, 1H), 2.70—3.00 (m, 1H), 3.33 (t, 2H), 4.12 (q, J=7 Hz, 2H), 4.20 (q, J=7 Hz, 2H), 4.76 (s, 1H), 4.85 (d, J=12 Hz, 1H exchangeable with D_2O), 6.50 (broad s, 1H), 7.00—7.47 (m, 5H) and 7.42 (d, J=12 Hz, 1H); IR (neat): 2220 (-C≡C-), 1710 (-C=C-CO-O-), 748, and 698 cm^{-1}; MS m/z 367(M^+).

^{13}C NMR Spectra. ^{13}C NMR chemical shift values are tabulated in Table 1. The assignment was made chiefly by the splitting pattern under off-resonance decoupling

conditions and by comparison with the compounds having similar (or partially similar) structures. The numbering of carbon atoms (see the structures in the schemes) is in some cases provided only for the sake of easy comparison.

5-Benzylidene-2,3,4,5-tetrahyropyridine (1): The low field signal of imine carbon atom was already described.[1] The assignment of C2′ and C3′ signals was based on the spin-lattice relaxation times (T_1). Thus, it is expected that C3′ relax faster than C2′. The chemical shift data for styrene[15] was also taken into consideration.

3-Benzylidenepiperidines (2a—c): Comparison with the δ values for **2a—c** with those of **1** leaves little uncertainty in the assignment except that the assignment for C2′ and C3′ may be reversed. The differentiation of signals due to two aromatic rings of **2b** was made based on the assumption that C1′—C4′ resonances are in much the same field among three compounds **2a—c**.

5-Phenyl-1,3,4,4a,5,9a-hexahydro-2H-pyrrolo[1′,2′:1,5]pyrrolo-2,3-b]pyridine (6): Of the two monoprotonated carbon resonances at δ 47.00 and δ 50.66, the latter can be assigned to C4a because of apparently shorter relaxation time due to the greater number of protons in the vicinity. Of the four sp^2-carbons of pyrrole moiety, two give a degenerate signal at δ 111.85, which should inevitably be assigned to C6 and C8 from chemical shift consideration. This assignment was confirmed by the observation that under weak decoupling condition the peak split into a pair of doublet with different splitting which reflects the distance between the carbon in question and the nitrogen atom. A high-field shift of unprotonated α-carbon resonance into protonated β-carbon region seems characteristic of α-carbons of 1,2-disubstituted pyrrole.[16]

Ethyl-[1-(2-ethoxycarbonylvinyl)-1,4,5,6-tetrahydro-3-pyridyl]-4-phenyl-2-butynoate (9): There are in **9** four sp^2-hydridized enamine carbon atoms, of which the signal due to the unprotonated C3″ is assigned based on chemical shift consideration. Peaks at δ 88.58 and 150.33, are assigned to C2‴ and C1‴, respectively, since the corresponding carbon nuclei of enamino ester resonate at δ 84.0 and 160.6, respectively.[17] Hence, the peak at δ 127.42 or 127.96 is due to C2‴, an unsaturated α-carbon of 1,2,3,4-tetrahydropyridine moiety which resonates at δ 132—133.[18]

Of the two signals at δ 77.47 and 82.67 due to two sp-hybridized carbons, the latter which shows a small coupling with H4 is assigned to C3. Of the signals due to two sets of OCH_2-CH_3 moiety, peaks at δ 13.98 and 62.19 are assigned to Cβ and Cα, respectively, based on comparison with the δ values for ethyl propiolate.[19] Similarly, C=O signal in higher field as an ester carbonyl carbon (δ 153.04) was assigned to C1.[19] This is an additional support for the presence of -C≡CCOO- moiety.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 443007 from the Ministry of Education, Science and Culture.

The Willgerodt-Kindler Reaction between Polycyclic Aromatic Amines and Benzaldehyde. Formation of 1,3-Thiazines

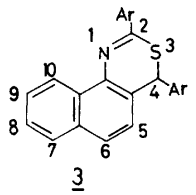
Yujiro NOMURA, Takashi HAYAMA, Yoshito TAKEUCHI,*
Shuji TOMODA, and Yuko KATO
Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received December 15, 1983)

The title reaction performed under typical conditions of the Willgerodt-Kindler reaction afforded "abnormal" product 1,3-thiazines. A mechanism involving the Diels-Alder reaction between *N*-benzylidenearylamine and thiobenzaldehyde has been suggested to explain the formation of 1,3-thiazines.

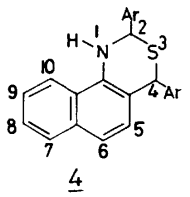
The Willgerodt-Kindler reaction,[1] in which ketones or aldehydes are allowed to react with amines in the presence of elemental sulfur under thermal conditions, is well known as an effective method for the preparation of thioamides. We now report the formation of abnormal products, 1,3-thiazines in the reaction between benzaldehyde and polycyclic aromatic amines under the typical Willgerodt-Kindler conditions[2] and present evidence for the possible intervention of thiobenzaldehyde, an elusive species which has attracted considerable attention in recent years.[3]

Results and Discussion

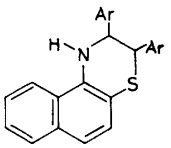
Typical reaction conditions are illustrated by the reaction between 1-naphthylamine (**1**) and benzaldehyde (**2a**). A mixture of **1**, **2a** and an excess powdered sulfur was heated at 140—150 °C for 48 h under a nitrogen atmosphere. Brisk evolution of hydrogen sulfide was evident by the positive test on lead tetraacetate paper during the reaction. The dark viscous reaction mixture was purified by column chromatography to give 2,4-diphenyl-4*H*-naphtho[1,2-*d*][1,3]thiazine (**3a**, 29% yield) and *N*-(1-naphthyl)thiobenzamide (48% yield)[2] in addition to two minor products, 2,4-diphenyl-1,4-dihydro-2*H*-naphtho[1,2-*d*][1,3]thiazine (**4a**, 6% yield) and an unidentifiable compound (11% yield).



3



4



4′

The structures of the 1,3-thiazine (**3a**) and dihydrothiazine (**4a**) were assigned by spectral data (IR, ^{1}H and ^{13}C NMR, MS) and elemental analysis. With regard to the structure of dihydrothiazine (**4a**), the position of the heteroatoms in the thiazine ring system was determined by its ^{1}H NMR data. The proton of C-2 showed up as a doublet (δ 5.26, J=5.5 Hz), whereas that of C-4 appeared as a singlet (δ 5.41). This indicated that the structure of **4a** is more consistent with the 1,3-thiazine ring system represented by formula **4** (Ar=Ph) than structure **4′**. The most explicit evidence for the structure of thiazine (**3a**) was obtained by dehydrogenation of dihydrothiazine (**4a**) over elemental sulfur in refluxing pyridine: **4a** was converted into **3a** in 80% yield.

The reactions between **1** and *p*-substituted benzaldehydes (**2**) are summarized in Table 1. The yield of **3** varies from 24 to 35%. The structures of these compounds **3** were assigned on the basis of spectral (^{1}H and ^{13}C NMR, IR, MS) and analytical data. Although these reactions afforded thioamides as the major product, the formation of **3** is significant since such an easy preparation of 1,3-thiazines has not been reported to date.[4]

Table 1. Synthesis of 1,3-thiazines (**3**, **12**, **13**, and **14**) from aromatic amines (**1**, **9**, **10**, and **11**)

Amine	ArCHO(**2**)[a]	Reagent/mmol			Conditions	1,3-Thiazine	Yield/%[b]
		1	**2**	S	Temp/°C, Time/h		
1	**2a**	10	20	30	150, 48	**3a**	29

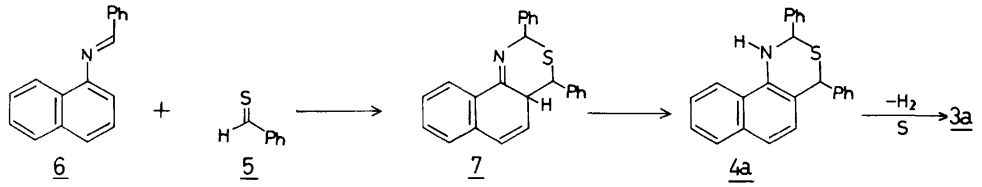
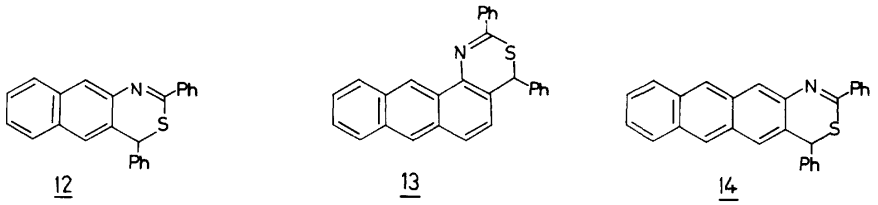
11	**2a**	2.8	6.8	6.3	145, 24[c]	**14**	22

a) **2a**: Benzaldehyde, **2b**: *p*-chlorobenzaldehyde, **2c**: *p*-bromobenzaldehyde. b) Isolated, unoptimized yield. c) In 4-Methylpyridine.



(Eq. 1)



With a view to extend this reaction to other amines, we were particularly intrigued by the mechanism which might involve thiobenzaldehyde (**5**): It was anticipated that 1,3-thiazine might have arisen from the Diels-Alder reaction between **5** and *N*-benzylidene-1-naphthylamine **6**, a 2-aza-1,3-butadiene in which the C=C bond is incorporated in the naphthalene ring. It is well established that aldehydes react with hydrogen sulfide in the presence of amine to afford thioaldehydes.[5] As shown in Eq. 1, thermal cycloaddition between **5** and **6** would give rise initially to **7**, which undergoes 1,3-H shift to afford dihydrothiazine **4a** (Eq. 1).

Conversion of **4** into **3** under the reaction conditions may be readily understood since **4** was transformed to **3** upon dehydrogenation with elemental sulfur as described earlier. In order to demonstrate possible intervention of **5**, **6** was allowed to react with **5** generated *in situ* from *S*-benzyl phenylmethanethiosulfinate (**8**).[3a] Indeed, when a mixture of **6** and a large excess **8** in toluene was heated at 100 °C for 20 h in the presence of 4A Molecular Sieves, **4a** was isolated in 47% yield. Mixed melting point as well as spectral data (^{1}H NMR and IR) unequivocally established the structure of this product. The formation of the thioamide was not observed in this reaction. It should be noted here that the reaction of 2-aza-1,3-butadiene and thiocarbonyl compound has not previously been reported.[6]

Synthesis of 1,3-thiazines under Willgerodt-Kindler conditions can also be applied to other aromatic amines, such as 2-naphthylamine (**9**), 1-anthrylamine (**10**) and 2-anthrylamine (**11**) (Table 1). Structure assignments of the products (**12**, **13**, and **14**) were based on spectral data (NMR, IR and MS) and combustion analysis. In the cases of **9** and **11**, the structures of the 1,3-thiazines (**12** and **14**, respectively) were more consistent with formulas **12** and **14** rather than with **12'** and **14'**. The absence of IR band near 810 cm^{-1} precluded the possibility of 1,2,3,4-tetrasubstituted benzene ring structures.

In summary, while the yield of 1,3-thiazines is not high, the present reaction as well as the reaction between 2-aza-1,3-diene and thiocarbonyl compound may suggest a useful general entry to 1,3-thiazine system, to which access has been difficult,[4] by appropriate choice of reaction conditions.

Experimental

All reactions were performed under dry nitrogen. Mass spectra were measured with a Hitachi RMU-6MG Spectrometer. ^{1}H NMR and ^{13}C NMR spectra were measured with a Varian EM-390 spectrometer and a JEOL FX-90Q spectrometer, respectively, using $CDCl_3$ as solvent. Chemical shifts were recorded in δ scale relative to internal tetramethylsilane. IR spectra were recorded on a JASCO A-102 Spectrometer and the frequencies are given in reciprocal centimeter.

General Procedure of the Willgerodt-Kindler Reactions. The ratio of the reagents and reaction conditions are included in Table 1. Solvent was not used except for the preparation of **13** and **14**, for which 4-methylpyridine was used as the solvent. To a mixture of arylamine and benzaldehyde was added powdered sulfur and the mixture was stirred at 140—150 °C for 7—48 h in an oil bath under a nitrogen atmosphere. The resulting dark brown mixture was dissolved in dichloromethane and the unchanged sulfur was removed by filtration. The filtrate was concentrated and chromatographed on a silica-gel column (dichloromethane:hexane= 1—2:5) to give 1,3-thiazine in the yield shown in Table 1. In the case of **2a**, dihydro-1,3-thiazine **4a** was also separated.

Spectral and analytical data of 1,3-thiazine and **4a** now follow;

3a: Mp 175—176 °C; MS (70 eV) *m/z* 351 (M^+); ^{1}H NMR ($CDCl_3$) δ=5.40 (s, 1H, H-4), 7.15 (s, 5H, Ph), 7.4—7.9 (m, 10H, Ar), and 8.93—9.06 (m, 1H, Ar); ^{13}C NMR ($CDCl_3$) δ=158.4 (s), 141.8 (s), 139.5 (s), 138.5 (s), 133.8 (s), 131.5 (d), 130.5 (s), 128.7 (d), 128.5 (d), 127.8 (d), 127.7 (d), 127.6 (d), 127.4 (d), 126.5 (d), 125.6 (d), 124.1 (d), 117.3 (s), and 45.8 (d); IR (KBr) 1540, 1490, 1450, 1235, 940, and 810 cm^{-1}.

Found: C, 82.12; H, 4.89; N, 3.90; S, 9.06%. Calcd for $C_{24}H_{17}NS$: C, 82.02; H, 4.88; N, 3.99; S, 9.12%.

4a: Mp 182—183 °C; MS (70 eV) *m/z* 353 (M^+); ^{1}H NMR ($CDCl_3$) δ=4.80 (br s, 1H), 5.26 (d, *J*=5.5 Hz, 1H), 5.41 (s, 1H), and 7.20—7.96 (m, 16H); ^{13}C NMR ($CDCl_3$) δ=145.2 (s), 139.7 (s), 138.9 (s), 133.8 (s), 129.6 (d), 129.2 (d), 128.9 (d), 128.8 (d), 128.5 (d), 127.7 (d), 127.2 (s), 126.6 (d), 126.3 (d), 125.8 (d), 125.3 (d), 120.3 (d), 118.8 (d), 115.5 (s), 57.5 (d), and 48.2 (d); IR (KBr) 3400, 1565, 1510, 1460, 1400, 1110, and 800 cm^{-1}.

Found: C, 81.54; H, 5.22; N, 3.77;, S, 8.69%. Calcd for $C_{24}H_{19}NS$: C, 81.55; H, 5.42; N, 3.96; S, 9.07%.

3b: Mp 161—162 °C; MS (70 eV) *m/z* 420 (M^+); ^{1}H NMR ($CDCl_3$) δ=5.41 (s, 1H), 6.9—8.1 (m, 13H), and 8.97—9.16 (m, 1H); ^{13}C NMR ($CDCl_3$) δ=156.6 (s), 140.1 (s), 139.3 (s), 137.7 (s), 136.6 (s), 133.8 (s), 130.4 (s), 129.9 (s), 129.5 (d), 128.9 (d), 128.7 (d), 128.2 (d), 127.6 (d), 126.7 (d), 125.4 (d), 123.9 (d), 116.6 (s), and 45.0 (d); IR (KBr) 1535, 1483, 1232, 1167, 1089, 1010, and 930 cm^{-1}.

Found: C, 68.57; H, 3.45; N, 3.27; S, 7.95; Cl, 17.14%. Calcd for $C_{24}H_{15}NSCl_2$:C, 68.58; H, 3.60; N, 3.33; S, 7.63; Cl, 16.87%.

3c: Mp 140—141 °C; MS (70 eV) *m/z* 509 (M^+); ^{1}H NMR ($CDCl_3$) δ=5.35 (s, 1H), 6.85—8.10 (m, 13H), and 8.76—8.96 (m, 1H); ^{13}C NMR ($CDCl_3$) δ=140.6 (s), 137.1 (s), 133.8 (s), 131.7 (d), 130.2 (s), 129.6 (d), 129.0 (d), 128.2 (d), 127.6 (d), 126.7 (d), 126.3 (s), 125.3 (d), 124.6 (s), 123.9 (d), 121.8 (s), 116.6 (s), and 45.1 (d); IR (KBr) 1575, 1540, 1483, 1391, 1235, 1070, 1007, and 930 cm^{-1}.

Found: C, 56.64; H, 2.85; N, 2.66; S, 6.40; Br, 31.71%. Calcd for $C_{24}H_{15}NSBr_2$: C, 56.60; H, 2.97; N, 2.75; S, 6.30; Br, 31.38%.

12: Mp 201—202 °C; MS (70 eV) *m/z* 351 (M^+); ^{1}H NMR ($CDCl_3$) δ=6.10 (s, 1H), 7.00 (br s, 5H), 7.47 (m, 5H), 7.92 (m, 4H), and 8.18 (m, 2H); ^{13}C NMR ($CDCl_3$) δ=158.7, 141.9, 130.0, 133.6, 131.5, 130.3, 129.3, 129.1, 129.0, 128.8, 128.4, 128.4, 127.6, 127.1, 127.0, 126.9, 125.6, 123.2, 115.3, and 41.1; IR (KBr) 1540, 1490, 1445, 1260, 1240, 1195, 975, and 915 cm^{-1}.

Found: C, 82.15; H, 4.67; N, 3.98; S, 9.12%. Calcd for $C_{24}H_{17}NS$: C, 82.02; H, 4.88; N, 3.99; S, 9.12%.

13: Mp 185—186 °C; ^{1}H NMR ($CDCl_3$) δ=5.46 (s, 1H), 7.2 (br s, 6H), 7.41—7.62 (m, 5H), 7.85—8.43 (m, 6H), and 9.54 (s, 1H); IR (KBr) 1541, 1490, 1445, 1230, 1173, 1133, 939, and 795 cm^{-1}.

Found: C, 83.76; H, 4.50; N, 3.75; S, 8.21%. Calcd for $C_{28}H_{19}NS$: C, 83.76; H, 4.77; N, 3.49; S, 7.98%.

14: Mp 250—251 °C; ^{1}H NMR ($CDCl_3$) δ=6.26 (s, 1H), 7.2—8.2 (m, 16H), 8.49 (s, 2H); IR (KBr) 1540, 1492, 1447, 1255, 1170, and 965.

Found: C, 83.55; H, 4.48; N, 3.49; S, 8.23%. Calcd for $C_{28}H_{19}NS$: C, 83.76; H, 4.77; N, 3.49; S, 7.98%.

*Reaction of **4a** with Sulfur to Give **3a**.* To a solution of **4a** (35 mg, 0.1 mmol) in dry pyridine (10 mL) was added excess powdered sulfur and the mixture refluxed for 20 h. The resulting dark resinous material was dissolved in dichloromethane (60 mL). The solution was washed with water, 1 M hydrochloric acid (60 mL), aqueous sodium hydrogencarbonate, and water, dried over magnesium sulfate, and concentrated. The residue was chromatographed on a silica-gel column to give **3a** (28 mg, 80% yield), which was identified by comparison of spectral (IR and ^{1}H NMR) data of authentic **3a**.

*Synthesis of **4a** from **6** and **5** Generated from **8**.* A mixture of **6** (0.39 g, 1.7 mmol) and **8** (4.37 g, 17 mmol)[3a] in toluene (5 ml) was placed in a tube and 4A Molecular Sieves (4 g) was added. The tube was thoroughly purged with dry nitrogen and heated at 100 °C for 20 h. The reaction mixture was filtered to remove the molecular sieves and the filtrate concentrated in vacuo. It was then subjected to column chromatographic separation on silica gel (80 g) eluting with hexane:dichloromethane (10:3) to afford **4a** (280 mg, 47% yield). Mixed melting point, IR and ^{1}H NMR spectral comparison unambiguously established its structure.

1-Propyl-1,4-dihydronicotinamide (PNAH), 1-(3-phenylpropyl)-1,4-dihydronicotinamide (**1a**), 1-(2-phenylthioethyl)-1,4-dihydronicotinamide (**1b**), and 1-(4-phenylthiobutyl)-1,4-dihydronicotinamide (**1c**) and their 4-deuterated analogs are synthesized as NAD(P)H-models and subjected to the reduction of *m*-nitro-α,α,α-trifluoroacetophenone in the presence or absence of magnesium ion in acetonitrile. Kinetics at 323 K have been studied. Kinetic isotope effect is small (2.33) only when **1a** or **1b** is employed for the reduction in the presence of magnesium ion, whereas it appears large (≈3.2) under other conditions. The result has been interpreted in terms of steric interference by a proximate phenyl group on the approach of the substrate to form a binary (in the absence of magnesium ion) or ternary (in the presence of magnesium ion) complexes. Thermodynamic parameters for the formation of complexes between the models and magnesium ion have been studied. It has been elucidated that enthalpy of complexation is small for **1a** than others. However, the small enthalpy of complexation is compensated by small entropy of complexation affording almost constant free-energy of complexation throughout the models studied.

In a series of reports from our laboratory, we have emphasized that a complex of 1,4-dihydropyridine derivative and magnesium ion plays an important role in biomimetic reductions with NAD(P)H-models. The magnesium ion assists polarization of electron cloud on dihydropyridine moiety to migrate an electron onto a substrate.[1,2]

X-Ray crystallography and other evidence have revealed that zinc ion in certain liver alcohol dehydrogenases (LADH) is tetrahedrally coordinated by cysteinyl SH and/or histidinyl nitrogen.[3,4] It is commonly accepted that the zinc ion in the enzyme behaves as a Lewis acid to polarize the carbonyl group of a substrate.[5] However, it is not obvious whether tetrahedrally coordinated zinc ion in an enzyme can accommodate a carbonyl group as an extra ligand.[6] At least in the mimetic reactions, metal ions with an chelating reagent exerted no catalytic activity.[1]
