Partial structure **B**. Another spin system $(CH_3)_2C=CH_bCH_gH_h$ was identified by spin decoupling. The methylene protons (H_n and H_o) hidden among other multiplets were revealed by irradiation of the equivalent allylic methylene protons (H_g and H_h, δ 1.91) and analysis of the COSY spectrum (Fig. 3). The multiplicities of H_n (δ 1.32, d, J=15 Hz) and H_o (δ 1.21, d,J=15 Hz) in the spin decoupled spectrum showed that the methylene group (CH_nH_o) was connected to a quaternary carbon atom.

Partial structure **C**. The starting point in the analysis of this spin system was the two nonequivalent methylene protons, (H_c, δ 3.78) and (H_d (δ 3.50), of the hydroxymethyl group. For this analysis the COSY spectrum (Fig. 3) was very efficient and the spin network $HOCH_2CHCH_2CH_2$ was deduced as the sole spin system consistent with the observation of the cross peaks, H_c-H_d, H_c-H_i, H_d-H_i, H_i-H_p, H_p-H_k, H_p-H_m, H_p-H_l, H_k-H_l, and H_k-H_m, Extensive decoupling

experiments revealed the multiplicities and the coupling constants of these protons. In particular, irradiation of H_l, (δ 1.35) and H_m (δ 1.35) observed in a highly congested region changed the signal patterns of H_p, (δ 1.07, dddd, J=15, 11, 10, and 4 Hz), H_k (δ 1.48, ddd, J=13, 11, and 4 Hz),[9] and H_i (δ 1.75, tt, J=10 and 4 Hz) into a double doublet (J=11 and 10 Hz), a doublet (J=11), and a triple doublet (J=10 and 4 Hz; two

of the six-lines in higher field part were hidden among the olefinic methyls), respectively. The values of the geminal and vicinal coupling constants indicated that this grouping could be part of a five or six-membered ring system. The multiplicities of H_i and H_k suggested that both the methine (CH_i) and the methylene (CH_kH_l) groups had a quaternary carbon neighbor.

The following mass spectral analysis (Fig. 4) was very indicative of the connections among the spin systems (partial structures **A**—**E**) separated by the quaternary carbon atoms. Oxidation of magydardienediol (**1**) with Jones reagent, followed by methylation with diazomethane, gave a diastereomeric mixture (*ca.* 1 : 1) of tetrahydrofuran derivatives, **5a** and **5b**. The tetrahydrofuran ring moiety can be derived from either partial structure **F** (**A**+**D**) or **F'** (**B**+**D**).[2,11] Both the mass spectra of **5a** and **5b** exhibited two characteristic intense peaks at *m/z* 250 (ion **a** (R=CO_2CH_3)) and *m/z* 167 (ion **b** (R=CO_2CH_3)). The complete lack of the peaks at *m/z* 143 (ion **c**) and 209 ([M−143]$^+$) expected for partial structure **G'** disproved the presence of partial structure **F'** in **1**.[12] Ion **b** may be formed by cleavage of the tetrahydrofuran ring moiety followed by loss of the 4-methyl-3-pentenyl side chain.[13,14] Thus, it was shown that partial structures **F** and **B** were present in the diterpene (**1**).

From the foregoing evidence either **1** or **1'** could be deduced as the gross structure of magydardienediol. The diol (**1**) exhibited an IR absorption at 3520 cm^{-1} (5×10^{-3} mol dm^{-3} in CCl_4) due to an intramolecular hydrogen bond.[15] As the hydroxymethyl group has already been shown to be equatorial (*i.e.* axial H_i), only **1** can take up a conformation in which the hydroxyl groups are sufficiently close in space for intramolecular hydrogen bonding. In further support of the structure, the proximity of the hydroxymethyl group to $C_{(1)}$-CH_3 was ascertained by the NOE experiments (Figs. 5(iii) and 7) and the long-range spin couplings between H_k and $C_{(3)}$-CH_3 and between H_j and $C_{(1)}$-CH_3 were shown in the COSY (Fig.3) and the proton-proton long-range COSY[16] spectra.

The stereochemistry of magydardienediol (**1**) was established as that shown in Fig. 8 based on the NOE difference spectra and the NOESY spectral analysis (Fig. 7). When $C_{(3)}$-CH_3 was irradiated the $C_{(1)}$-CH_3 and the H_p signals were enhanced (Fig. 5(i)) and furthermore when H_p was irradiated both the peaks of the tertiary methyls were enhanced (Fig. 5(ii)); this indicated that the tertiary methyls and H_p were 1,3-diaxially oriented on a chair cyclohexane ring. The

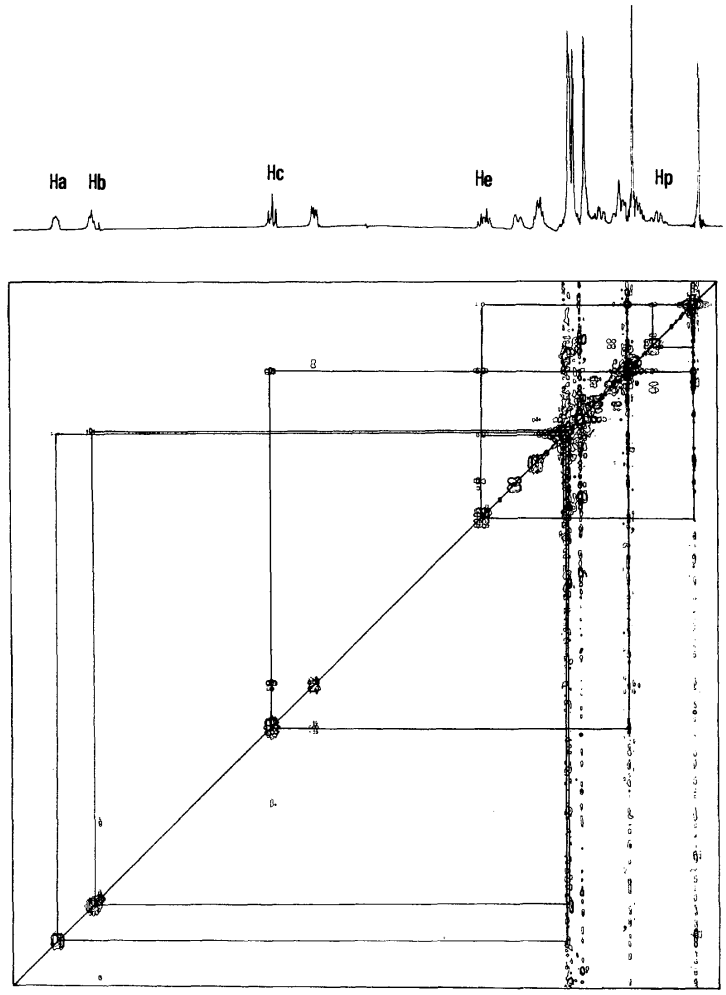

Fig. 7. Contour plot of the two-dimensional NOE spectrum (NOESY) of magydardienediol (**1**). The spectral width was 2000 Hz (1024×512 data points). Pulse delay and mixing times were 5 s and 1000 ms, respectively.

W-rule long-range spin coupling between $C_{(3)}$-CH_3 and the axial proton H_k (Fig. 3) gave additional evidence of the axial nature of the tertiary methyl.

As for the torsional isomerism about the single bond between the equatorial hydroxymethyl group and $C_{(6)}$, the intramolecular hydrogen bonding favored the conformation in which H_c and H_i were in antiperiplanar relation. This conformation was defined by the value of the vicinal coupling constant (J=10 Hz) observed between H_c and H_i and was well consistent with the NOE connectivities of H_c to $C_{(1)}$-CH_3 and H_p (Fig. 5(ii)(iii)).[15]

Finally, the *cis* relation of the 3-methyl-2-butenyl side chain to the tertiary methyls was revealed by the NOE experiments (Fig. 5(i) (iv)) which showed the proximity of H_e to the tertiary methyls. The axial nature of H_j was further shown by the W-rule long-range spin coupling between the axial $C_{(1)}$-CH_3 and H_j. The preferred conformation of the 3-methyl-2-butenyl side chain and the assignment of H_e and H_f were deduced as shown in Fig. 8 based on the NOE difference and NOESY experiments (Figs. 5(i) (iv), 6, and 7). The lower shift of the olefinic methyl resonance (δ 1.71) may be due to an anisotropy of the tertiary hydroxyl group in close proximity.[10]

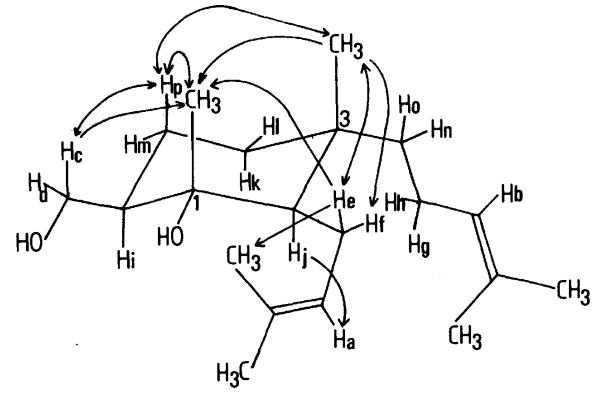

Fig. 8. Conformation and NOE connectivities of magydardienediol (**1**) (arrow heads show enhanced signals in the NOE difference spectra). The NOESY spectrum showed cross peaks corresponding almost to the above connectivities.

The structure of magydardienediol (**1**), a diterpene with a novel carbon skeleton, was thus established as *t*-6-hydroxymethyl-1,*t*-3-dimethyl-*t*-2-(3-methyl-2-butenyl)-3-(4-methyl-3-pentenyl)-*r*-1-cyclohexanol.

Experimental

Both ^{1}H-NMR and ^{13}C-NMR spectra were recorded on a JEOL GX-400 spectrometer with tetramethylsilane as internal standard. Mass and IR spectra were obtained using JEOL DX-300 and JASCO A-3 spectrometers, respectively.

^{13}C-NMR Spectral Data of Magydardienediol (1) Derived from the Complete Decoupling and INEPT Spectroscopies (100 MHz, $CDCl_3$). δ 132.10 (C=), 131.30 (C=), 126.42 (CH=), 124.79 (CH=), 78.87 ($C_{(1)}$), 65.73 (CH_2OH), 54.81 (CH), 49.90 (CH), 43.81 (CH_2), 37.20 ($C_{(3)}$), 36.96 (CH_2), 25.91 (CH_3), 25.74 (CH_3), 23.92 (CH_2), 22.65 (CH_2), 22.00 (CH_2), 20.47 (CH_3), 19.11 (CH_3), 18.04 (CH_3), and 17.65 (CH_3).

Preparation of 5a and 5b. Magydardienediol (**1**) (15 mg) was treated with an excess of Jones reagent and the resulting carboxylic acids were methylated with diazomethane in ether. The crude product was chromatographed on silica gel (1 g) using hexane–ethyl acetate (3:1) as eluent to give a mixture of **5a** and **5b** (3 mg); one spot on TLC; IR spectrum of the mixture (neat): 3460 and 1730 cm^{-1}; GLC: retention times, 14.8 (**5a**) and 18.8 (**5b**) min (Carbowax 20M (20%, 2 m), 200 °C); GC–MS (Carbowax 20M (1.2 m), 70 eV) *m/z* (rel intensity) 352 (M^+; 0.7 (**5a**) and nil (**5b**)), 337 ($[M-CH_3]^+$; 1 (**5a**) and 1 (**5b**)), 334 ($[M-H_2O]^+$; 3.6 (**5a**) and 0.4 (**5b**)), 321 ($[M-OCH_3]^+$; 3 (**5a**) and 3 (**5b**)), 294 (12 (**5a**) and 15 (**5b**)), 250 (27 (**5a**) and 24 (**5b**)), 167 (41 (**5a**) and 30 (**5b**)), and 69 (100 (**5a**) and 100 (**5b**)); High-resolution mass spectrum of the mixture *m/z* 337.2369 (Calcd for $C_{20}H_{33}O_4$: *m/z* 337.2378), 250.1906 (Calcd for $C_{16}H_{26}O_2$: 250.1932), and 167.1069 (Calcd for $C_{10}H_{15}O_2$: 167.1071).

Phenanthraquinone Monothiosemicarbazone as Sensitive Reagent for the Spectrophotometric Determination of Zinc(II)

Prem Prakash SINHA, Sharwan Kumar SINDHWANI,* and Rajendra Pal SINGH
Department of Chemistry, University of Delhi, Delhi-7, India
(Received April 23, 1983)

Phenanthraquinone monothiosemicarbazone has been found to be a sensitive and selective reagent for the spectrophotometric determination of zinc(II) in the pH range 7.0—8.6. The red complex formed shows maximal absorbance at 510 nm. Beer's law is obeyed up to 1.96 ppm and optimum range of concentration being 0.22—1.70 ppm. The sandell sensitivity is 0.0018 μg Zn^{II} cm^{-2}, with molar extinction coefficient being 3.52×10^4 mol^{-1} cm^{-1}. The method has been applied to the determination of zinc in 6% Zn–Al alloy.

Several organic reagents[1] have been used for the determination of micro amounts of zinc. Recently introduced reagents are 5,10,15,20-tetrakis(1-methylpridinium-4-yl)porphine,[2] 2-(3-sulfobenzoyl)pyridine thiosemicarbazone,[3] and 2-(5-nitro-2-pyridylazo)-1-naphthol.[4] But most of them suffer from various disadvantages.

Preliminary investigations have shown that phenanthraquinone monothiosemicarbazone (PTS) forms coloured complexes with several metal ions such as iron (II and III) (λ_{max}=510 nm), cobalt(II) (λ_{max}=500 nm), nickel (II) (λ_{max}=520 nm), copper (I and II) (λ_{max}=530 nm), cadmium(II) (λ_{max}=500 nm), ruthenium(III) (λ_{max}=660 nm), rhodium(III) (λ_{max}=510 nm), palladium(II) (λ_{max}=590 nm, when the final concentration of hydrochloric acid is in the range 0.28—1.14 M+ and λ_{max}=540 nm at pH 8.0—9.5), osmium(VIII) (λ_{max}=530 nm), iridium(III) (λ_{max}=520 nm) and platinum(IV) (λ_{max}=510 nm). The present study deals with spectrophotometric determination of zinc with PTS. Zinc(II) reacts with PTS and forms red complex which is soluble in methanol and shows maximum absorbance at 510 nm.

Experimental

Apparatus. A Unichem SP 600 spectrophotometer with matched glass cells of 10 mm light path was used for absorbance measurements. An ECIL (PH 821 A) expanded scale pH-meter was used for pH measurements.

Reagents. *Synthesis of PTS*: Phenanthraquinone monothiosemicarbazone (PTS) was prepared by refluxing equimolar amounts of phenanthraquinone and thiosemicarbazide in methanol for 3 h on a boiling water bath. The hot solution was filtered under suction and cooled in refrigerator. Red crystals of PTS obtained, were recrystallized from methanol (yield, 80%). The purity was checked by thin-layer chromatography and elemental analysis. A 2.5×10^{-3} M PTS solution was prepared in *N*,*N*-dimethylformamide (DMF). Though the solution is stable for at least two days, a fresh solution was prepared each day to avoid possible decomposition.

Zinc(II) Solution. 0.1 M zinc (II) solution was prepared by dissolving zinc sulfate heptahydrate (AnalR BDH) in double distilled water, containing 0.5 ml of sulfuric acid in one liter of the solution. The solution was standardized volumetrically.

Sodium Tetraborate Solution. 0.01 M in double distilled water. All other solutions of cations and anions were prepared from A.R. grade chemicals in double distilled water.

Separation of Zinc. The separation of zinc from other cations by diethyldithiocarbamate has been suggested.[5] Zinc (II) solution was buffered with ammonium citrate and ammonium hydroxide at pH 8.5; the final solution containing approximately 1% citrate. The solution was then extracted with 5.0 ml portions of diethyldithiocarbamate in chloroform until the chloroform no longer changes colour. Zinc was again re-extracted from the combined chloroform extact with aqueous 0.16 M hydrochloric acid and determined spectrophotometrically with PTS.

Recommended Procedure for the Determination of Zinc. To an aliquot containing 2.24 to 17.0 μg of zinc(II), add 1 ml of 2.5×10^{-3} M PTS solution in DMF. Adjust the pH between 7.0—8.6 with 0.01 M sodium tetraborate. Add 5 ml of methanol and dilute the solution to 10 ml with distilled water. Measure absorbance at 510 nm against corresponding reagent blank prepared under identical conditions. Calculate the amount of zinc from the calibration curve.

Determination of Zinc in 6% Zn–Al Alloy (BCS No. 300). Dissolve 0.1 g alloy in about 5 ml of aqua regia and evaporate to almost dryness. Dissolve the residue in about 2 ml of hydrochloric acid and dilute to 100 ml . Take suitable aliquot and determine the amount of zinc following the recommended procedure after masking iron with fluoride.

The results obtained for three determinations are shown in Table 1.

TABLE 1. DETERMINATION OF ZINC IN 6% Zn–Al ALLOY

Composition of 6% Zn–Al alloy (%)	Zinc found (ppm)	Zinc calculated (ppm)	Error (%)
C=1.28, Mn=0.41	0.594	0.598	−0.67
Si=0.16, Mg=2.76 Fe=0.30, Ti=0.15	0.890	0.897	−0.78
Zn=5.98, Cr=0.15 Pb=0.003 and Sn=0.006	1.122	1.196	−0.53

Results

Absorbance Spectra and Stability of the Complex. A study of the effect of pH on the complexation of zinc(II) with PTS showed that the red complex gives maximum absorbance at 510 nm (Fig. 1) which is constant in the pH range 7.0—8.6 (Fig. 2). Subsequent studies were carried out at pH 7.5±0.1. The complex is stable for 2 h.

* 1M=mol dm^{-3}.

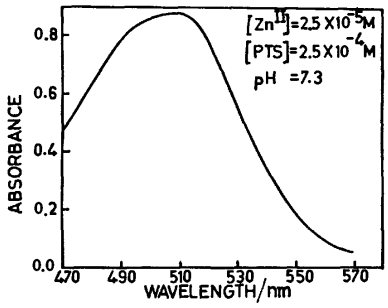

Fig. 1. Absorption spectra of Zn^{II}–PTS complex.

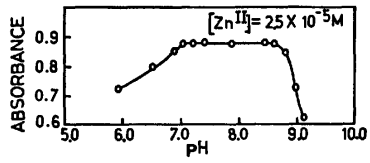

Fig. 2. Effect of pH on Zn^{II}–PTS compex.

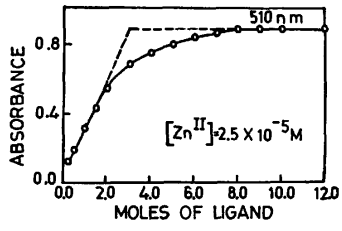

Fig. 3. Composition of Zn^{II}–PTS complex by mole ratio method.

Effect of Reagent Concentration. The ratio of reagent to metal ion necessary for maximum colour formation was ascertained. It was found that eight fold excess of reagent is required for the complete complexation (Fig. 3) but however 10 times PTS was used during all studies. Since the absorbance of the ligand at 510 nm is very small therefore the excess of the reagent is not critical.

Physical Constants of the Complex. Under the optimal conditions describred above, Beer's law obeyes up to 1.96 ppm of zinc(II). The potimum range of concentration of zinc(II) for accurate determination, as deduced from Ringbom plot[6] (Fig. 4) is 0.22—1.70 ppm. The molar absorptivity is 35200 l mol^{-1} cm^{-1} at 510 nm with Sandell's sensitivity of 0.0018 μg Zn cm^{-2} for log I_0/I=0.001.

Precision of the Method. Measured under optimum conditions, eight samples containing 1.63 ppm of zinc, the average relative deviation was found to be 0.26% with maximum relative deviation of 0.41% and mean absorbance of 0.880. The standard deviation is 5.4×10^{-3}.

Stoichiometry of the Complex. The stoichiometry of the complex was determined by Job's method of continuous variations[7] (Fig. 5) and mole ratio method[8] (Fig. 3). Both showed the formation of 1:3 complex (metal:ligand).

Effect of Diverse Ions. Synthetic solutions containing 1.63 ppm of zinc(II) and different amounts of diverse ions were prepared and analyzed by the

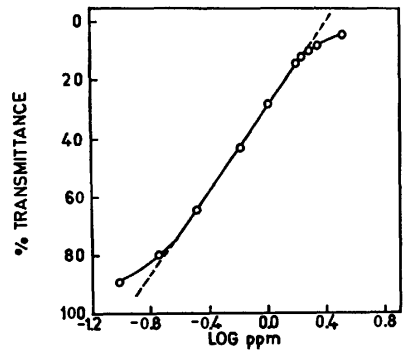

Fig. 4. Ringbom plot for Zn^{II}–PTS complex.

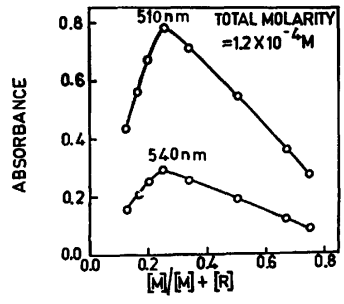

Fig. 5. Composition of Zn^{II}–PTS complex by Job's method.

recommended procedure. An error of ±2% absorbance reading was neglected. The amounts (in ppm) of ions tolerated with masking ion if any, are given in parentheses:

Chloride, bromide, and nitrate (1000 each); fluoride and thiourea (700 each); nitrite (350); thiocyanate (250); tartrate (100): iodide (100); thiosulfate (300); oxalate (30); sulfite (500); magnesium(II), calcium (II), barium(II), and strontium(II) (150 each); aluminium(III) (75); uranyl(VI) (100); molybdenum (VI) and tungsten(VI) (50 each); manganese(II) (F^-, 15); vanadium(V) (F^-, 20); thorium(IV) and titanium(IV) (50 each); silver(I) (Cl^-, 10); rhodium (III) (thiourea, 5); iridium(III) (SCN^-, 1); osmium (VIII) (SCN^-, 5); platinum(IV) (I^-, 5); nickel(II) (SCN^-, 10); lead(II) (15); tin(II) (10); copper(II) (thiourea, 2); iron(II) (F^-, 5); mercury(II) (I^-, 10); cadmium(II) ($C_2O_4^{2-}$, 5) and chromium(III) (5).

EDTA, phosphate, citrate, and cyanide interfere seriously.

Discussion

Among various reagents reported for the determination of zinc, dithizone[9-11] is notable. The reagent is highly sensitive but excess of dithizone has to be removed by shaking with very dilute ammonia solution which can often contain traces of zinc. It is important in the determination of traces of zinc and the procedure is tedious. Zincon[12,13] is another important reagent but the sensitivity is low, and a large number of metals interfere, making it necessary to separate the zinc first. PAN[14,15] and Chrome Azurol S[16] are sensitive reagents but highly unselective. The disadvantage of 5, 10, 15, 20-tetrakis-(1-methyl-

TABLE 2. SENSITIVITIES OF REAGENTS FOR THE SPECTROPHOTOMETRIC DETERMINATION OF ZINC(II)

Reagent	Sensitivity (μg Zn cm^{-2})
Dithizone	0.0007/538 nm
Zincon	0.0032/625 nm
1-(2-Pyridylazo)-2-naphthol	0.0012/550 nm
Chrome Azurol S	0.0015/510 nm
Methylthymol Blue	0.0047/584 nm
2-(2-Pyridylazo)-*p*-cresol	0.0022/580 nm
Arsenazo III	0.0023/570 nm
Thiodibenzoylmethane	0.0019/410 nm
Biacetyl bis[4-phenyl-(thiosemicarbazone)]	0.003/440 nm
2-(3-Sulfobenzoyl)pyridine thiosemicarbazone	0.0022/390 nm
5,10,15,20-tetrakis-(1-methyl-pyridinium-4-yl)porphine	0.0028/437 nm
Phenanthraquinone monothiosemicarbazone (PTS)	0.0018/510 nm

pyridinium-4-yl) porphine[2] is that free reagent which absorbs at 423 nm has to be removed by forming the lead complex (λ_{max}=476 nm) before measuring the absorbance of the zinc complex. Among thiosemicarbazones, 2-(3-sulfobenzoyl) pyridine thiosemicarbazone[3] is fairly sensitive but effect of diverse of ions, in the determination of zinc, has not been investigated.

In the present investigation, PTS compares favourably with other well-known reagents. The procedure is simple and large amounts of ligand do not interfere, which is an advantage over dithizone. The reagent is more selective than PAN and Chrome Azurol S. There is no extraction *etc.* which is an advantage over other methods. Although small amounts of the metals such as copper, iron, nickel *etc.* can be masked, they should be separated if present in large amounts before the determination of zinc. The sensitivity of the different methods for the determination of zinc are compared in Table 2.

One of the authors (PPS) is thankful to University Grants Commission, New Delhi, India for the award of a teacher fellowship to him.

A Rapid Pulse Nebulization Technique for Flame Atomic Fluorescence Spectrometry

Edet Joseph EKANEM
School of Basic Studies, Ahmadu Bello University, Zaria, Nigeria
(Received July 21, 1983)

A simple and rapid pulse nebulization technique in which 200 μl sample volume is injected and aspirated into a flame-nebulizer is described for the determination of cadmium by line source atomic fluorescence spectrometry (AFS) and for magnesium and other elements by continuum source AFS. The volume of blood and serum samples required for replicate analysis is reduced below 1 ml; nebulizer clogging by heavy sample matrices is reduced; small volumes of rare samples can be analysed in the same batch as bulky samples using this technique. The technique is also applicable to flame AES which can also be performed with the instrumentation used in this work.

In the flame atomic fluorescence spectrometric determination of cadmium, the high sample uptake rate of about 9 ml min^{-1} requires large sample volumes for replicate analysis. In the nitric acid deproteinisation procedure already reported for the determination of low cadmium levels in blood,[1] a 2 ml minimum blood volume was required for replicate analysis by continuously aspirating the analytical sample into the nitrogen-separated air-acetylene flame. This demand on sample is unsatisfactory for rare samples especially in cases like cadmium determination where sample dilution must be minimised to improve analytical sensitivity. The possibility of using a pulse nebulization technique with small sample volumes has, therefore, been explored in the line source AFS determination of cadmium and the continuum source AFS determination of other elements as exemplified by magnesium in clinical samples.

The application of pulse nebulization to flame spectrometry has been reported by various workers[2–11] and reviewed by Berndt *et al.*[11] This includes microsampling techniques employing small Teflon funnels[9] and a Teflon sampling manifold for use with small sample injections.[10] Applications specific to flame AFS have also been reported.[2,8]

Experimental

Chemicals and Samples. The procedure reported was applied to whole blood, serum, and urine samples after appropriate pretreatment, Whole blood and serum samples were deproteinised by shaking the sample and 2 M† nitric acid in equal volumes and centrifuging. The supernatant was analyzed for cadmium by line source AFS without further dilution; it was, however, further diluted 100 times with deionised water before determining magnesium by continuum source AFS. Urine samples were only acidified to 0.04 M with hydrochloric acid for cadmium determination, while they were diluted 200 times with deionised water and similarly acidified for magnesium analysis. It has previously been shown that hydrochloric acid enhances the measurement sensitivity for both cadmium[12] and magnesium.[1]

Instrumentation. The spectrometer used for these studies was the laboratory-constructed one already described.[1,12] It consisted of a SPEX double monochromator with a photomultiplier detector and a Brookdeal 5C14 photon counter for signal processing. A nitrogen-separated air-acetylene flame was used as atom cell. A thermostated electrodeless discharge lamp excited by microwave in a 3/4 wave Broida cavity was used as a line source. The continuum source was a 300 W Xenon arc lamp. For line source AFS, a mechanical chopper was applied for background correction by intensity modulation while, for continuum source AFS, the rotating circular quartz plate with different quadrant thicknesses[13] was used for background correction by wavelength modulation. Though the continuum source was used as a primary source in continuum source work, it was also employed as a secondary source for effecting scatter correction in line source AFS work, operating at low power. The layout of the spectrometer for line source and continuum source AFS is presented in Figs. 1 and 2 respectively.

To modify the spectrometer for pulse nebulization, a polypropylene micro-pipette tip was attached to the nebulizer capillary tubing as shown in Fig. 3 to serve as a sample pulse reservoir, taking care to obtain a leakproof connection. It was ensured that the end of the capillary tubing did not project into the pipette tip so that each sample pulse injected into it was completely uptaken into the nebulizer without any dead volume. Micro-pipettes of various volumes were employed to deliver sample pulses into the reservoir. Figure 3 is not drawn to scale but typical dimensions for the device are indicated.

Procedure. The instrument was aligned and optimised for line source AFS, continuum source AFS, or flame AES as required. The measurement cycle time, usually 1 s, for collecting the signals was selected on the photon counter as explained later and the optimum uptake rate was measured. An aliquot of the sample to be measured was injected rapidly into the sample reservoir from a micropipette so that it was aspirated into the nebulizer in a single unbroken stream. The highest signal displayed soon after the injection was recorded. This was repeated for 3 or 4 aliquots of each sample and the mean signal for the sample was obtained as the average of the 3 or 4 replicate results. Between injections, deionised water or an appropriate blank solution was continuously aspirated to prevent inter-sample memory effects. A sample blank was also analyzed by the same procedure and its signal was subtracted from all sample results.

Alternatively the signal from each aliquot was traced on a chart recorder. It was then necessary to determine the appropriate measurement cycle time to obtain a representative signal trace.

Optimization of Measurement System. The optimum measurement cycle time constant was selected from a range of options provided on the photon counter. The optimum time constant, however, depended on other system para-

† 1 M = 1 mol dm^{-3}.

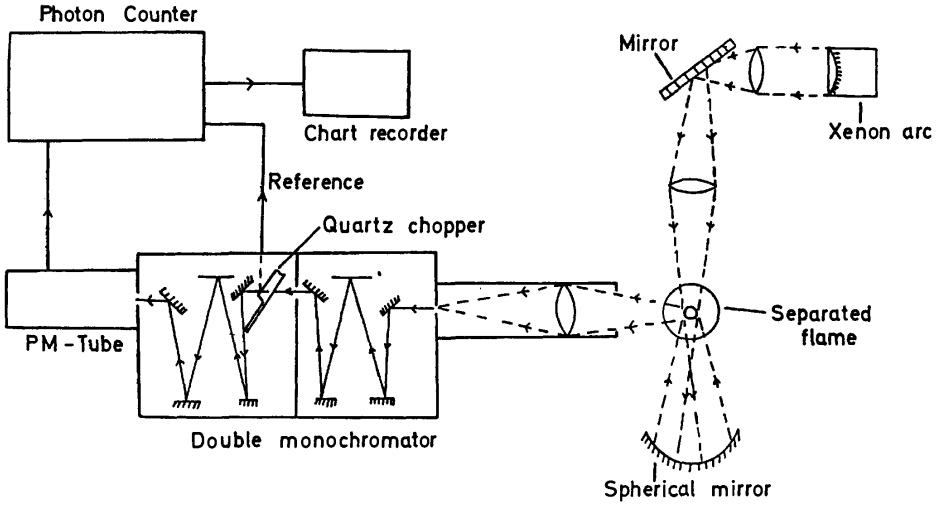

Fig. 2. The modified instrumentation for continuum source AFS.

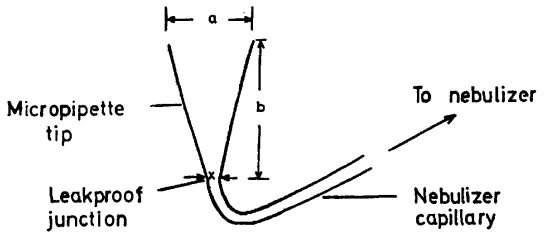

Fig. 3. Reservoir for sample injection. (a)=0.6 cm (b)=5 cm x=0.5 mm

meters defined below for purposes of this pulse nebulization technique.

Uptake Rate (R_u): The optimum uptake rate was similar to that obtained for continuous sample aspiration. It was measured at the nebulizer screw setting that gave the highest signal for pulses of a suitable standard solution.

Sampling Time (t_s): This was the time required for a sample pulse to be completely sucked up from the reservoir. It was measured approximately with a stopwatch and averaged for a large number of equal pulses; it was directly related to the sample uptake rate and pulse volume as

$$t_s = \frac{V_p}{R_u}, \tag{1}$$

where V_p is the pulse volume; and R_u is the uptake rate.

Peak Time (t_p): This was the total time required to attain a peak analyte concentration in the measurement zone of the flame, after sample injection into the reservoir. Usually this time was slightly longer than t_s as in the expression

$$t_p = t_s + x.$$

where x is the time between the complete uptake of the pulse and the attainment of a stable peak signal level in the flame.

Readout Time (t_r): This was the period between sample injection and the digital display of the relevant signal. The value of t_r depended on the measurement cycle time constant selected on the photon counter.

For a given sample pulse volume and uptake rate, some measurement cycle time constants were more suitable than others. The option selected for a given application was determined by the way in which the signal was obtainable from pulse operation.

From a measurement of the uptake rate (R_u), Eq. 1 could be used to derive t_s for any pulse volume used. t_r could be measured directly for a given uptake rate and pulse volume. Usually t_r exceeded t_s by a fraction that could be estimated, the excess depending solely on the measurement cycle time selected.

At the measurement zone, the atoms from a pulse just injected arrived according to the profile illustrated in Fig. 4 and a peak signal was observed for a pulse only if t_r bracketted t_p.

In selecting the measurement cycle time (t_{mc}), three possibilities could be applied as follows:

I. $t_{mc} \ll t_p$: During the period t_p, when the pulse is passing through the measurement zone, a counting cycle is executed and repeated many times with progressively increasing total counts as t_p is approached and progressively decreasing totals as t_p is exceeded. These signals which are digitally displayed in sequence can be plotted to obtain a peak profile as shown in Fig. 4. Alternatively the signals accumulated during t_p may activate a chart recorder to plot a peak as in the profile. For a pulse volume of 200 μl and the 9 ml min^{-1} uptake rate routinely employed in these measurements, the 0.1 s measurement cycle typified this condition.

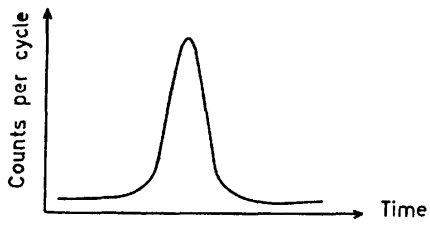

Fig. 4. The Peak Profile when $t_{mc} \ll t_p$.

II. $t_{mc} \gg t_p$: In this case the sample passes through the flame rather quickly while the counting continues for much longer. The signal collected during a short period is ascribed to a much longer period during most of which sample is not passing through the measurement zone. Sensitivity is poorer and higher chances exist of noise signals being counted. The 10 s measurement cycle typified this condition.

III. $t_{mc} \approx t_p$: In this option, sample presentation may get so locked to the measurement cycle that signal collection takes place only at the time when sample is passing the measurement zone. The signal is registered as one total at the end of the measurement cycle and offers increased sensitivity. The 1 s count time was typical.

It is to be noted that in case I where a definite peak can be traced as the measurement is repeated many times while sample is passing through the flame, the peak value does not follow the sample presentation immediately. There are a number of lower signals before the peak value. Therefore the peak signal needs to be selected from others that arise from the same sample pulse. Alternatively the signal is traced on a chart recorder and the peak height measured from the trace. In the other cases, the signal displayed immediately following the injection of the sample pulse is the peak signal. Only one measurement cycle is executed while sample is passing through the measurement zone and only one signal is output at the end of the cycle. This signal, however, is much higher than even the peak value in case I.

In this instrumentation, all three options are possible but only option III provides good sensitivity and precision. Option I suffers from reduction in sensitivity because of a reduced counting time, while option II suggests lower precision.

Results and Discussion

Line Source AFS. The experimental conditions of the flame are shown in Table 1. The sample uptake rate and other parameters for signal retrieval were measured with a stopwatch for a measurement cycle time of 1 s. Pulses of a 10 μg l^{-1} Cd standard solution were injected while adjusting the uptake rate until a maximum signal was obtained. The uptake rate was then measured by continuous nebulization. The sampling time, t_s, was measured by noting the time between the sample delivery into the reservoir and sample disappearance from the reservoir into the nebulizer capillary tubing. The calculated values also shown in Table 2 were based on the measured uptake rate of 9.2 ml min^{-1}. The readout time, t_r, was measured by noting the time between the delivery of the pulse into the reservoir and the display of the relevant signal on the photon counter readout. The mean values of these parameters were based on 15 measurements of each and are reported in Table 2.

The Optimum Pulse Volume and Measurement Cycle. Measurements were repeated for various pulse volumes of an aqueous 4 μg l^{-1} cadmium standard solution and the results shown in Table 3 were obtained for measurement times of 1 s and 0.1 s. The trends were similar for both measurement cycle times and also for a 10 μg l^{-1} cadmium standard solution.

In the 20—200 μl range of pulse volumes, the 200 μl pulse produced the highest sensitivity. As indicated in Table 3, it also yielded a more satisfactory detection limit than smaller sample volumes investigated. So

Table 1. Optimised flame conditions

Factor	Optimum values
Flame type	Nitrogen-separated air-acetylene flame
Flame composition	Stoichiometric-fuel rich
Nitrogen pressure	1 psi
Acetylene back pressure	12 psi
Acetylene feed pressure	8 psi
Air feed pressure	40—45 psi
Flame height	28 mm

Table 2. Parameters for signal retrieval

Parameter	Pulse volume/μl	Measured	Calculated
t_s	200	1.31 s	1.30 s
t_s	50	—[a)]	0.33 s
t_r	200	1.58 s	
R_u		9.2 ml min^{-1}	

a) t_s was too short to measure accurately for 50 μl pulses.

TABLE 3. VARIATION OF Cd FLUORESCENCE SENSITIVITY WITH PULSE VOLUME AND COUNTING TIME CONSTANTS

Pulse volume	Signal (counts/cycle)		Detection limit/μg l^{-1}	
μl	1 s cycle	0.1 s cycle	1 s cycle	0.1 s cycle
200	226	42	0.76	1.36
100	65	35	2.66	1.63
50	54	21	3.21	2.72
20	51	8	3.41	7.14

the 200 μl pulse volume was selected for routine analysis. For similar reasons, a measurement time of 1 s was preferred to 0.1 s. In this case, the measurement time was similar in magnitude to t_s and t_p. That t_s, t_p, and t_r exceeded the measurement cycle time, t_{mc}, of 1 s offered optimum sensitivity as it ensured that sample was present in the measurement zone throughout the counting cycle. Otherwise there would be no sample in the flame for some part of the counting cycle and reduced sensitivity would result.

Measurements With a Chart Recorder. The smallest pulse volume that gave a trace with well defined peaks was the 200 μl pulse volume. Only the 0.1 s time constant yielded peak traces. The precision and the linearity of calibration curves were satisfactory but the detection limit was three times worse than that obtained when the signal was obtained directly from the photon counter display using a 1 s measurement time constant. The value increased from 0.7 μg l^{-1} to 2.0 μg l^{-1} for cadmium. Samples could still be compared by this procedure if they contained more than the 2 μg l^{-1} level.

Comparison of Procedures. Pulse nebulization was compared with continuous nebulization by applying each sampling technique to exactly the same solutions, instrumental settings and analysis conditions. A measurement time of 1 s and 200 μl sample were employed for all pulse nebulization measurements. Parameters considered for comparison included overall sensitivity, precision, accuracy, detection limit, and linear range of calibration curve.

To compare overall sensitivity, a number of samples were measured using both techniques and the signal levels were compared. The detection limits calculated for each sample introduction technique were also compared.

Pulse nebulization generally provided 40—52% less sensitivity than continuous nebulization when 200 μl sample pulses were applied. As shown in Table 4, detection limits were twice worse for pulse nebulization than for continuous nebulization.

Precisions calculated as relative standard deviations for 15 replicate measurements were compared for pulse and continuous nebulizations. Very similar results were obtained for the two techniques.

The calibration curve obtained for pulse operation was linear up to 8 ppm, while the linear range for continuous nebulization was only up to 2 ppm.

Larger Pulse Volumes. The disparity indicated between pulse and continuous nebulization was further investigated by observing pulse volumes above 200 μl.

TABLE 4. COMPARISON OF DETECTION LIMIT FOR CADMIUM

Sample	Detection limit/ppb	
	Pulse nebulization	Continuous nebulization
Aqueous	0.11	0.05
Water diluted blood	0.48	0.24
Blood Deproteinate	0.22	0.11
Urine	0.16	0.08

TABLE 5. DEPENDENCE OF ANALYTICAL FIGURES OF MERIT ON PULSE VOLUMES

Pulse volume	Signal	Detection limit	Precision
μl	(counts/s^{-1})	μg l^{-1}	%
100	80	0.39	4.9
200	223	0.11	3.6
400	285	0.08	3.1
600	401	0.05	2.9
700	398	0.05	3.1
800	396	0.05	3.1
1000	409	0.05	2.4
1200	420	0.05	2.9
1500	406	0.05	3.2

The respective signals for an aqueous 4 μg l^{-1} cadmium standaed solution and the corresponding detection limits are shown in Table 5; the measurement precision provided by each pulse volume is also indicated. A 1 s measurement cycle was employed in all cases.

As can be seen from Table 5, the sensitivity was improved with the increase of pulse volume and became constant over about 600 μl. There was a progressive improvement in both measurement precision and detection limit until 600 μl. Thereafter these parameters attained identical values to those obtained by continuous nebulization. Then, the nebulization ceased to be strictly pulse but semicontinuous, as the sample volume was enough to maintain a steady signal level over several counting cycles. Instead of achieving reasonable sensitivity and precision using a microvolume of rare samples, 600 μl of sample, when continuously aspirated, became insufficient for three replicate measurements as achieved by the pulse technique.

Comparison of Accuracy. The same whole blood samples were analyzed for cadmium by flame AFS employing pulse and continuous nebulization in turn and the results are campared in Table 6. A comparison of other results for cadmium in whole blood obtained by this pulse AFS technique with those obtained independently in a different laboratory by carbon furnance AAS showed satisfactory agreement. Whole blood samples which had been analyzed for cadmium by many laboratories were also analyzed by this pulse AFS technique and the results were in good agreement with the laboratory means.

Continuum Source AFS. The application of pulse nebulization to the continuum source AFS technique was also investigated in detail for the determination of magnesium. Various pulse volumes of a 400 μg l^{-1} Mg aqueous standard were measured by the con-

Table 6. Determination of cadmium in whole blood by pulse and continuous nebulization

Sample No.	Concentration/μg l^{-1}	
	Pulse nebulization	Continuous nebulization
1	15.4	21.4
2	10.8	8.0
3	10.0	8.8
4	14.8	14.8
5	27.0	29.2

Table 7. Comparison of analytical results for magnesium by pulse continuous nebulization

Sample	Mg results/μg ml^{-1}	
	Pulse nebulization (y)	Continuous nebulization (x)
Blood 1	40.5	40.5
Blood 2	40.7	40.8
Blood 3	47.5	47.3

tinuum source AFS procedure using the measurement cycles of 0.1 and 1 s. From the results, the 1 s counting time provided higher sensitivity than the 0.1 s counting time. The 200 μl pulse volume was also superior to smaller pulse volumes in sensitivity and precision. As in the determination of cadmium by pulse nebulization, the detection limit, overall sensitivity, and precision for magnesium were improved with increasing pulse volume and were similar to values obtained by continuous nebulization for pulse volumes larger than 600 μl.

Using 200 μl pulses and a measurement cycle of 1 s, the pulse technique was employed to determine magnesium in various samples which were also measured by continuous nebulization. A comparison of the results is presented in Table 7. The blood, serum, and urine samples were appropriately diluted and acidified with hydrochloric acid as already described. The calibrations were achieved for all samples using aqueous magnesium standards acidified to 0.04 M with hydrochloric acid. The linear range extended from 4 μg l^{-1} to 10 μg ml^{-1} for pulse nebulization while it was in the range of 2 μg l^{-1}—2 μg ml^{-1} for continuous nebulization.

Other Applications. A broader scope for pulse nebulization in AFS and other techniques developed with the present instrumentation was demonstrated in other application as summarized in Table 8. A pulse size of 200 μl was employed in all cases. The technique was suitable for the determination of both major and minor elements in clinical samples.

Table 8. Other applications of pulse nebulization

Element	Technique	Detection limit μg l^{-1}	% Precision at (aqueous level)
Mg	CSAFS	4	2.5 (400 μg l^{-1})
Zn	CSAFS	80	2.3 (500 μg l^{-1})
Fe (248.3 nm)	CSAFS	10	2.6 (500 μg l^{-1})
Na (589 nm)	FAES	3	1.8 (10 μg ml^{-1})
P (246.4 nm)	FMFS	21000	2.3 (200 μg ml^{-1})

(FMFS) = Flame molecular fluorescence spectrometry.

Conclusion

The pulse nebulization device was very simple and easily attached to the pneumatic nebulizer, yielding zero dead volume during operation. The sensitivity and analytical precision were comparable to those attainable with large sample volumes aspirated continuously. The procedure was rapid and the volume of sample required for replicate analysis was effectively reduced. Employing the deproteinisation procedure for blood sample pretreatment, this sample introduction technique reduced system clogging with heavy sample matrices, compared to the normal continuous nebulization since less total amount of matrix per sample was introduced into the system. Accuracy was not impaired by the pulse technique.

A New Synthesis of Pyrazolo[3,4-*b*]quinoline Derivatives†

D. C. Holla and S. Seshadri*

Dyes Research Laboratory, University Department of Chemical Technology, Matunga, Bombay 400019, India

(Received August 29, 1983)

A new synthesis of pyrazolo[3,4-b]quinoline-4-carboxylic acid derivatives is described. This involves the Pfitzinger reaction of pyrazolone derivatives with isatic acid under controlled conditions. The pyrazoloquinolinecarboxylic acids were converted to their corresponding amides and nitriles, and their absorption and emission characteristics are recorded.

The use of pyrazolo[3,4-*b*]quinoline derivatives as fluorescent brighteners is well known.[1] The major synthetic approach has been the cyclization of appropriately substituted *N*-(1-alkyl-5-pyrazolyl)anthranilic acids by phosphoryl chloride. 5-Chloro-4-formylpyrazoles and substituted aromatic amines on heating form respective 1-phenylpyrazolo[3,4-*b*]-quinoline derivatives which are reported[2,3] to be optical brightening agents.

An obvious alternate synthetic route would be the reaction of pyrazolone derivatives with isatin under the Pfitzinger conditions which would yield the pyrazolo [3,4-*b*]quinoline-4-carboxylic acid. Rather surprisingly, this simple synthetic scheme has not been previously described in the literature. This synthetic scheme has the advantage that different pyrazolones can be employed and further the resultant carboxylic acid could also be further converted to different derivatives such as amide or nitrile.

The Pfitzinger reaction on 3-methyl-1-phenyl-5-pyrazolone (**IIb**) was carried out under normal conditions, employing isatin (**I**) in 40% sodium hydroxide solution. Under these conditions the reaction did not occur even when the reaction mixture was heated for several hours. It was thought that the failure of the reaction might be due to the existence of the pyrazolone in the enolic form in the alkaline conditions, tending to make the pyrazolone inactive for the reaction with isatic acid (2-aminophenylglyoxylic acid). We, therefore carried out the reaction at a certain level of basicity (pH 10—11) so that the enolization would not be complete and the active methylene group would be able to react with isatic acid. Indeed, under these conditions the reaction did take place and on work-up by acidification a yellow product was obtained which was characterized as the expected 3-methyl-1-phenyl-pyrazolo[3,4-*b*]quinoline-4-carboxylic acid (**IIIb**). The structure of this product was established by its acidic character, infrared spectrum (carboxylic acid at 1695 cm^{-1}) and elemental analysis and also by conversion into its derivatives like amide (**IVb**) and nitrile (**Vb**).

Rather surprisingly, the fluorescence of this acid was weak and we therefore wished to study the fluorescence of the derivatives of this acid. Thus the amide (**IVb**) was prepared by the usual method and the amide (**IVb**) was converted to nitrile (**Vb**). The nitrile (**Vb**) was expected to show enhanced fluorescence compared to the carboxylic acid (**IIIb**) but we found that there was no improvement in the fluorescence intensity.

We then proceeded to synthesise other pyrazolo [3,4-*b*]quinoline derivatives by this route. Thus, 3-methyl-5-pyrazolone (**IIa**) was reacted with isatin and 1-unsubstituted pyrazoloquinolinecarboxylic acid (**IIIa**) was obtained. This was further alkylated by dimethyl sulfate to yield the *N*-methyl derivative (**VIa**) and by acrylonitrile to yield *N*-(2-cyanoethyl) derivative (**VIb**). The alkylation products have been given the structures as indicated since there was only a slight bathochromic shift on alkylation. Alkylation on the 2-nitrogen atom would have yielded a quinonoid structure, which would have given a larger bathochromic shift. Thus the compounds (**IIIa, VIa, VIb, IIIb**) showed absorption maxima 382, 386, 392, and 386 nm respectively whereas 2-phenyl derivative (**X**) prepared by us earlier[4] had maximum at 420 nm (Chart 2).

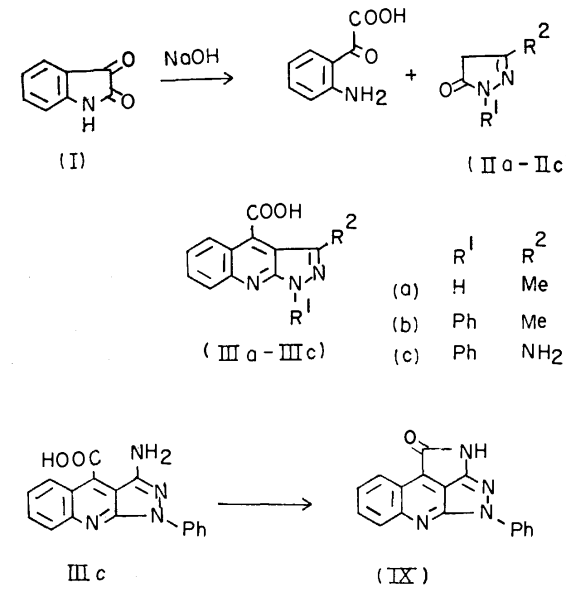

Chart 1.

We found to our satisfaction that the *N*-alkyl derivatives showed much stronger fluorescence and even the *N*-unsubstituted derivative (**IIIa**) showed stronger fluorescence than the *N*-phenyl derivative (**IIIb**). The N-unsubstituted pyrazoloquinolinecarboxylic acid and the two *N*-alkyl derivatives were also converted into the corresponding amides (**VIIa** and **VIIb**) and nitriles (**VIIIa** and **VIIIb**). The absorption and fluorescence efficiencies of these compounds were also studied (Table 1)

From our studies, it can be seen that the *N*-alkylpyrazolo[3,4-*b*]quinoline derivatives are strong

fluorophores but comparison with a commercial fluorescent brightener (7-diethylamino-4-methylcoumarin) showed them to be very much inferior. These compounds were also evaluated by application to polyester fibre but they did not produce significant brightening.

We also carried out the Pfitzinger reaction on 3-amino-1-phenyl-5-pyrazolone (**IIc**) and the product obtained was the expected 3-aminopyrazolo[3,4-*b*]-quinoline-4-carboxylic acid (**IIIc**) as shown by its amphoteric properties, infrared spectrum (doublet for the amino group at 3200 and 3100 cm^{-1} and carboxyl carbonyl at 1650 cm^{-1}) and elemental analysis. This compound could be converted to the lactam (**IX**) by treatment with conc. hydrochloric acid. The structure of the lactam (**IX**) was established by elemental analysis and infrared spectrum (lactam carbonyl at 1720 cm^{-1}). The amino acid (**IIIc**) and the lactam (**IX**) were strongly colored and did not show any fluorescence (Chart 1).

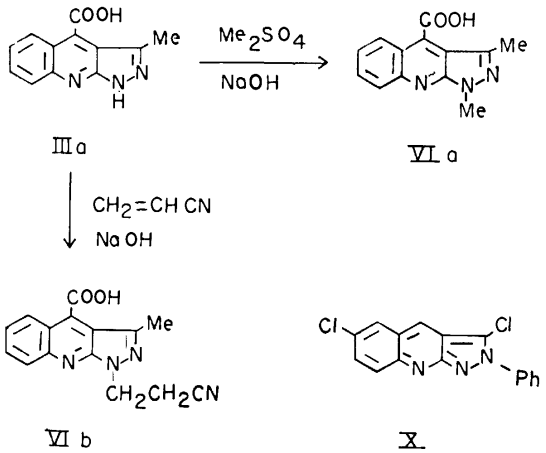

Chart 2.

Experimental

All melting points are uncorrected. The IR spectra were recorded on different spectrophotometers as Nujol mull and the UV spectra were recorded on Pye-Unicam SP8000.

General Procedure for the Synthesis of Pyrazolo[3,4-b]quinoline Derivatives. To a clear solution of isatin (6.8 mmol) in NaOH (10 ml, 10%) pyrazolone derivative (**IIa—IIc**) (7 mmol) was added and stirred till a homogeneous solution was obtained. The pH of the solution was adjusted between 10 and 11 by adding a few drops of HOAc. The solution was refluxed for 5 to 6 h and cooled . On acidification (with HCl 1:1 in the case of 3-Methyl-1-phenyl-5-pyrazolone and 3-methyl-5-pyrazolone and with HOAc to pH 6 in the case of 3-amino-1-phenyl-5-pyrazolone). The products separated were isolated. The yield, mp, recrystallization solvent and molecular formula are given in the Table.

*1,3-Dimethylpyrazolo[3,4-b]quinoline-4-carboxylic Acid (**VIa**).* To the solution of **IIIa** (4.4 mmol) in NaOH (20 ml, 5%) dimethyl sulfate (5.3 mmol) was added and the reaction mixture was heated in a water bath at 60—70 °C for 2 h. The resulting yellow solution was cooled and acidified with dil. HCl (2M). A yellow precipitate of **VIa** was obtained in 86% yield and was recrystallized from ethanol as yellow crystals mp >300° (Found: C, 65.1; H, 4.9; N, 17.1%, Calcd for $C_{13}H_{11}N_3O_2$: C, 65.0, H, 4.6, N, 17.5%).

*1-(2-Cyanoethyl)-3-methylpyrazolo[3,4-b]quinoline-4-carboxylic Acid (**VIb**).* To the solution of **IIIa** (4.4 mmol) in NaOH (20 ml, 5%) containing 0.1 g of Triton B as the catalyst acrylonitrile (5.3 mmol) was added and the reaction mixture was stirred at room temperature for 3 h. The sodium salt that separated was acidified with dil. HCl (2M (1M=1 mol dm^{-3})) and the product **VIb** was obtained in 89% yield. This was recrystallized from ethanol mp >236—237 °C (Found: N, 19.7%, Calcd for $C_{15}H_{12}N_4O_2$: N, 20.0%).

*Synthesis of the Lactam (**IX**).* The acid **IIIc** (3.2 mmol) was taken in concd HCl (10 ml) and kept at room temperature for 3 to 4 h. It was diluted with water, when a brown-colored solid **IX** was obtained in 74% and was recrystallized from EtOAc mp >300 °C (Found: N. 19.1%, Calcd for $C_{17}H_{10}N_4O$: N, 19.6%).

General Procedure for the Synthesis of Pyrazolo[3,4-b]quinoline-4-carboxamides. A mixture of the acid (1 g), dry benzene (5 ml), and freshly-distilled thionyl chloride (10 ml) was refluxed for 2 to 3 h. The acid chloride, obtained after removing excess thionyl chloride and benzene, was

treated with liquid ammonia and kept overnight at room temperature. The amide obtained was filtered. The yield, mp, recrystallization solvent, molecular formula of the various amides prepared are given in the Table.

General Procedure for the Synthesis of Pyrazolo[3,4-b]quinoline-4-carbonitriles. These were prepared by refluxing the amide (1 g) with $POCl_3$ (6 ml) in an oil bath at 110—115 °C for 2 h. After the usual work-up, the product separated was isolated. The yield, mp, recrystallization solvent, molecular formula of the various nitriles prepared are given in the Table.

We are thankful to Prof. M.R. Padhye for recording the IR and UV spectra and to the Microanalytical section of our department for the analyses. One of us (D.C.H.) is thankful to C.S.I.R., New Delhi for the award of a junior research fellowship.

The Self-condensation of Methyl Iodide. The Intermediacy of Methylium Ions in C-C Bond Formation

Yoshio ONO* and Masahiko KOGAI

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 22, 1983)

Synopsis. Hydrocarbons are formed by the reaction of methyl iodide vapor with solid-silver dodecatungstophosphate. The self-condensation is plausibly initiated by the attack of the methylium ion on the C-H bond of methyl iodide. It is suggested that the methylium ion is a key intermediate also in the conversion of methanol into hydrocarbons.

Since the conversion of methanol into hydrocarbons over ZSM-5 zeolites was discovered, many discussions have been reported on the mechanism of the reaction, especially with regard to the first C-C bond formation.[1] As for the first C-C bond formation, three major intermediates proposed are carbenoid species,[2] the trimethyloxonium ion,[3] and the methylium ion.[4]

Ono and Mori[4] proposed the intermediacy of the methylium ion, which attacks the C-H bond of methanol or dimethyl ether by forming a three center-two electron bond. The methylium ion would be generated by the reaction of the acidic sites and methanol (or dimethyl ether).

$$H^+ + CH_3OH \longrightarrow CH_3^+ + H_2O$$

$$CH_3^+ + CH_3OR \longrightarrow \left[\begin{array}{l} H \\ CH_3 \end{array}\!\!>\!\!\!-\!\!-CH_2OR\right]^+$$

$$\longrightarrow CH_3CH_2OR + H^+$$

The carbon-carbon bond formation *via* the direct attack of the methylium ion on a C-H bond has been established in superacid chemistry, as examplified by the polymerization of methane.[5] According to the above shceme, the C-C bond formation should occur even without acid centers if the methylium ion is provided in some another way. We have attempted such experiments.

As the source of methylium ions, the reaction of methyl iodide and silver cation was selected, since combinations of methyl iodide and a metal cation are known to be good methylating reagents.

$$CH_3I + Ag^+ \longrightarrow CH_3^+ + AgI \qquad (1)$$

As a silver salt, silver dodecatungstophosphate ($Ag_3PW_{12}O_{40}$, AgTP) was selected. The ease of the reaction between methyl iodide and AgTP is evidently shown by the fact that the immediate precipitation of silver iodide is observed when methyl iodide is added to a methanol solution of AgTP at room temperature.

If methylium ions are generated by Reaction (1), they would attack C-H bonds of methyliodide molecules to form C-C bonds.

We wish to report here the formation of hydrocarbons by the reaction of methyl iodide vapor with solid AgTP.

The reaction was carried out as follows: The powder of AgTP (1 g=8.3×10^{-4} mol of Ag^+) was placed in a reactor which was a part of a closed-recirculation system (dead volume, 234 ml), heated under a vacuum at 573 K, and then kept at the reaction temperature. Methyl iodide vapor (17.7×10^{-4} mol) was then admitted to the system, and the change in the gas phase composition was monitored with the time by withdrawing small portions of the gas at appropriate intervals.

In Fig. 1, the amount of methyl iodide which disappeared from the gas phase and the amount of hydrocarbons which appeared in the gas phase at 373 K are plotted as functions of the reaction time. The distribution of hydrocarbons produced is also shown. Both the yield and the distribution of hydrocarbons are expressed on a carbon-number basis. The amount of methyl iodide consumed and that of hydrocarbons produced increased gradually with the time, until the reaction almost ceased after 5 h, when hydrocarbons amounting to 6.6×10^{-4} mol of carbon atoms appeared in the gas phase. This amount corresponds to about 80% of that Ag^+ ions in the salt, indicating that the reaction is a stoichiometric one.

The amount of methyl iodide disappearing from the gas phase was more than the amount of hydro carbons and even more than the amount of Ag^+ in the salt. The difference may be due to the sorption of unreacted methyl iodide in the bulk of the solid and/or the accumulation of part of the hydrocarbon prod-

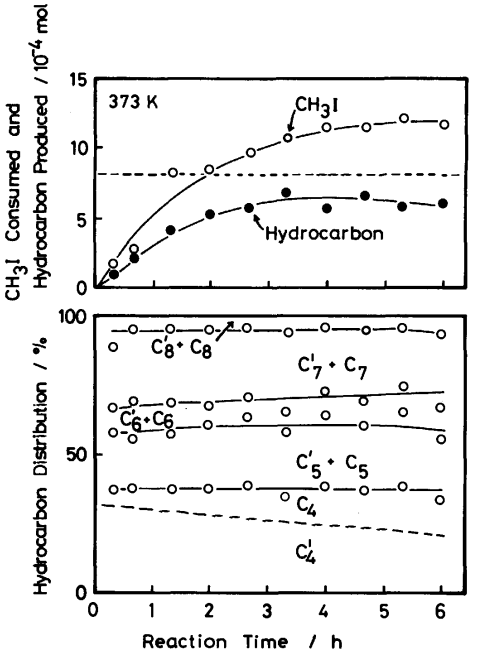

Fig. 1. Change in the amount of CH_3I consumed and hydrocarbons produced with time in the reaction of CH_3I and $Ag_3PW_{12}O_{40}$ at 373 K.

ucts in the solid. The main hydrocarbon products at this temperature are aliphatic hydrocarbons with carbon atoms of 4—7.

At 423 K, the reaction procceded faster. The methyl iodide disappearing from the gas phase amounted to 10.6×10^{-4} mol after 1.5 h. The amount of hydrocarbon produced was 8.3×10^{-4} mol after a reaction of 15 min.

At 573 K, the stoichiometric amount of methyl iodide was consumed within 5 min, as is shown in Fig. 2. The further consumption of methyl iodide continued for another 30 min, even though the amount of hydrocarbons in the gas phase did not increase any longer. At this temperature, the main hydrocarbon products were propane and isobutane. Propylene and butenes found at the early stage disappeared after 1 h, probably because of their further reactions with methyl iodide. This may be account for the consumption of methyl iodide beyond the stoichiometry based on the silver cation.

The fact that hydrocarbons are formed from methyl iodide in the presence of AgTP strongly indicates the importance of the methylium ion in forming C–C bonds from one-carbon molecules. The reaction is essentially a stoichiometric one. The reaction mechanism may be expressed as follows:

$$CH_3I + Ag^+ \longrightarrow CH_3^+ + AgI$$

$$CH_3^+ + CH_3I \longrightarrow \left[\begin{array}{l} H \\ CH_3 \end{array}\!\!>\!\!\cdots CH_2I\right]^+ \longrightarrow CH_3CH_2I + H^+$$

$$CH_3CH_2I + Ag^+ \longrightarrow CH_2{=}CH_2 + AgI + H^+$$

$$CH_2{=}CH_2 + CH_3I \longrightarrow CH_3CH_2CH_2I$$

$$n CH_3I + n Ag^+ \longrightarrow (CH_2)_n + n AgI \text{ (overall)}$$

Besides the reactions described above, various reactions involving carbenium-ion intermediates, like H-transfer, alkylation, and dimerization, may well occur, resulting in the formation of paraffins. It should be noted that a similar mechanism for the C–C bond formation has been proposed for the self-condensation of methyl fluoride in neat antimony fluoride.[9,10]

AgTP is an effective catalyst for converting methanol into hydrocarbons.[11–13] It has been eatablished that the active centers in this system are Brönsted-acid sites, which are produced by the reduction of silver cations by hydrogen molecules (or atoms) provided by the partial decomposiiton of methanol under the present reaction conditions.[12–14]

The distribution of hydrocarbons in the catalytic conversion of methanol over AgTP at 573 K is very similar to that in the stoichiometric reaction of methyl iodide and AgTP at the same temperature, indicating that the mechanism of the propagation of the C–C chain is the same in the two systems. This again argues favorably for the intermediacy of

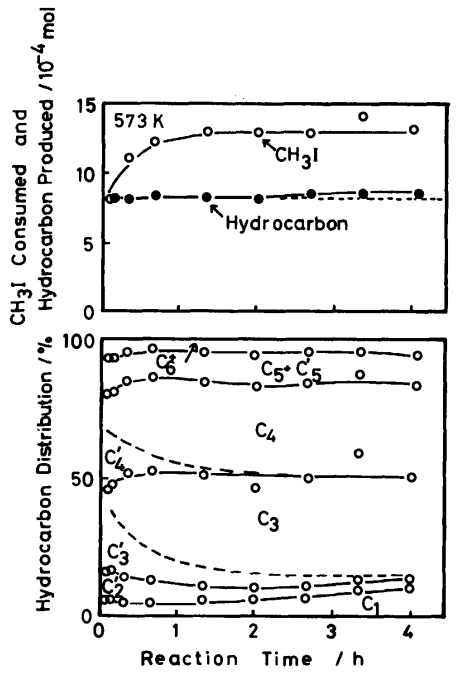

Fig. 2. Change in the amount of CH_3I consumed and hydrocarbons produced with time in the reaction of CH_3I and $Ag_3PW_{12}O_{40}$ at 573 K.

methylium ions in the conversion of methanol into hydrocarbons over acidic catalysts.

It is important to note that hydrocarbons are formed from methyl iodide at temperature at which the hydrocarbon formation from methanol over zeolites or heteropolyacids is practically unobservable. The easier formation of the C–C bonds in the methyl iodide-Ag^+ system may be attributed to the facile generation of incipient methylium ions.

Formation of Aluminosilicate by Adsorption of Silicic Acid on Aluminium Hydroxide

Takushi YOKOYAMA,* Osamu NAKAMURA,† and Toshikazu TARUTANI
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashiku, Fukuoka 812
(Received February 15, 1984)

Synopsis. When monosilicic acid was adsorbed on aluminium hydroxide, allophane-like compound rapidly formed and the monosilicic acid adsorbed was consumed by the formation of the allophane-like compound until the Si/Al mole ratio of the sample reached 0.33—0.39. Above these ratio, the formation of polysilicic acid occured.

Some reports have been published on the formation of surface products by adsorption of silicic acid on solids. Huang[1] suggested the formation of phyllite sheets on γ-alumina from a kinetic study. Muraishi and Kitahara[2] confirmed the formation of magnesium silicate on the surface of magnesium hydroxide by differential thermal analysis (DTA) and infrared absorption.

In a previous paper,[3] the authors reported that aluminium hydroxide, which had adsorbed monosilicic acid, showed an endothermic peak between 100 and 300 °C and an exothermic peak at around 1000 °C on the DTA curve. The DTA curve is similar to the thermal curve of allophane, indicating amorphous aluminosilicate.[4]

In this paper, the formation of an allophane-like compound by the adsorption of monosilicic acid on aluminium hydroxide and the effect of the composition of the samples on the exothermic peak intensity are discussed.

Experimental

All the reagents used were of analytical reagent grade. Monosilicic acid solution and aluminium hydroxide were prepared as described previously.[3,5]

Adsorption experiments were carried out using a batch method[3] and a continuous flow method.[5] In the batch method, a known amount of aluminium hydroxide was introduced into a monosilicic acid solution (500 cm^3) of pH 5. In the continuous flow method, aluminium hydroxide was introduced into a flask and then 150 ppm (SiO_2) monosilicic acid solution of pH 5 was continuously flowed through the flask with a flow rate of 2 dm^3/d. Adsorption experiments were carried out at 25 °C. In both methods, after 5 h or at appropriate intervals, an aliquot of aluminium hydroxide, which had adsorbed silicic acid, was pipetted and filtered, and the composition of the sample was determined. The sample dried at 25 °C for 10 d was used for differential thermal analysis. Si(M)/Al(A) and Si(T)/Al(A) ratios are the mole ratios of monosilicic acid and total silicic acid to aluminium in the sample, respectively. The difference between the two ratios indicates the formation of polysilicic acid on the aluminium hydroxide. Si/Al(MR) ratio is the mole ratio of monosilicic acid to aluminium hydroxide in the initial solution in the batch method.

Differential thermal analysis was performed using a Rigaku Denki Thermoflex 8002 H/D thermoanalyzer. The sample (13.5 mg) in a shallow platinum crucible was heated in air at a heating rate of 10 °C/min. The water content was almost the same in all samples (*ca.* 40%). The reference material was γ-alumina.

Results and Discussion

In a preliminary experiment, it was found that the exothermic peak height decreased steeply with increasing pH of the mother solutions over the pH range 5—10. Therefore, the adsorption experiments were carried out at pH 5. A DTA curve of the sample prepared at pH 5 is shown in Fig. 1. In this study the exothermic peak similar to that of allophane was observed for all samples.

The adsorption experiment (batch method) was carried out under the condition of a 2.1 Si/Al(MR) ratio. The results of the differential thermal analysis of the samples are shown in Fig. 2. The exothermic peak height increased with adsorption time and attained a constant value after 2 h. This indicates that the allophane-like compound rapidly formed by the reaction of the adsorbed monosilicic acid and aluminium hydroxide.

In order to examine the effect of the Si(T)/Al(A) ratio of a sample on the exothermic peak height, adsorption experiments (batch method) were carried out by changing the Si/Al(MR) ratio in 100 and 300 ppm (SiO_2) monosilicic acid solutions. Figure 3 shows the variation of the exothermic peak height with the Si(T)/Al(A) ratio. The maximum peak height occurred at a 0.33 Si(T)/Al(A) ratio. The sample (Si(T)/Al(A)=0.36, Si(M)/Al(A)=Si(T)/Al(A))

† Present address: Department of Commerce and Industry, Fukuoka Prefectual Government, Hakataku, Fukuoka 812.

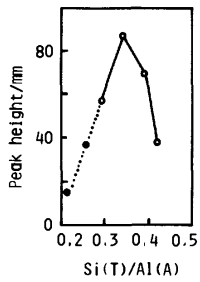

Fig. 3. Variation of exothermic peak height with Si(T)/Al(A) ratio. Initial monosilicic acid concentration: ···●··· 100 ppm, —○— 300 ppm. Reaction time: 5 h. pH: 5.

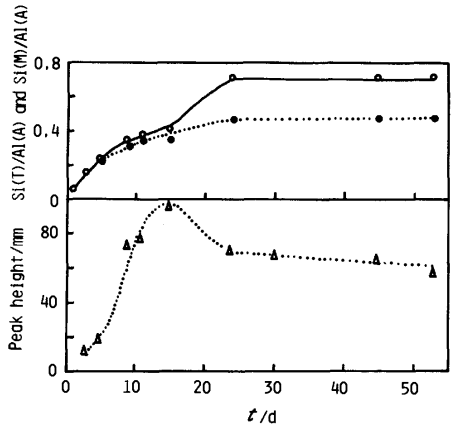

Fig. 4. Variations with time of Si(M)/Al(A) and Si(T)/Al(A) ratios and exothermic peak height. Flowing solution: 150 ppm monosilicic acid solution of pH 5. ···●···: Si(M)/Al(A), —○—: Si(T)/Al(A), ···△···: Exothermic peak height.

was heated at 1000°C for 5 h and the heated sample was analyzed by powder X-ray diffraction. The diffractogram showed the formation of mullite ($3Al_2O_3 \cdot 2SiO_2$). This result also suggests that the sample is an allophane-like compound.[4]

The results obtained by the continuous flow method are shown in Fig. 4. The exothermic peak height increased steeply until the Si(T)/Al(A) ratio reached 0.39 and then declined with further increase in the Si(T)/Al(A) ratio. At an early stage of adsorption the Si(T)/Al(A) and Si(M)/Al(A) ratios increased with time, and the Si(T)/Al(A) ratio was nearly equal to the Si(M)/Al(A) ratio below 15 d. Subsequently the Si(T)/Al(A) ratio became larger than the Si(M)/Al(A) ratio with time, indicating that a part of the silicic acid adsorbed on the aluminium hydroxide polymerized.

As shown in Figs. 3 and 4, the exothermic peak height was strongly influenced by the Si(T)/Al(A) ratio of the sample and the maximum peak height occurred at Si(T)/Al(A) ratios of 0.33 and 0.39. These values are similar to that of mullite. In the sample having the 0.33 Si(T)/Al(A) ratio, the largest amount of the allophane-like compound may exist.

The behavior of monosilicic acid adsorbed on aluminium hydroxide can be explained as follows. When monosilicic acid is adsorbed on aluminium hydroxide, the allophane-like compound rapidly forms and the adsorbed monosilicic acid is consumed by the formation of an allophane-like compound until the Si(T)/Al(A) ratio reaches 0.33. Most of the aluminium hydroxide transforms to the allophane-like compound after a short time. Monosilicic acid is still adsorbed on the allophane-like compound formed, and the adsorbed monosilicic acid polymerizes with time above a Si(T)/Al(A) ratio of *ca.* 0.4.

Solvent Effects on the $n\rightarrow\pi^*$ Absorption Intensities of Acetone and Cyclopentanone

Tai-ichi SHIBUYA

Department of Chemistry, Faculty of Textile Science and Technology, Shinshu University, Ueda, Nagano 386

(Received April 13, 1984)

Synopsis. The recently proposed theory [*J. Chem. Phys.* **78**, 5175 (1983)] for the solvent effect on the absorption intensity has been successfully applied to the $n\rightarrow\pi^*$ bands of acetone and cyclopentanone in various organic solvents observed by Nakashima, *et al.* [*Bull. Chem. Soc. Jpn.* **55**, 415 (1982)].

Nakashima *et al.*, in their recent paper,[1] correlated the intensities of the $n\rightarrow\pi^*$ absorption bands of acetone and cyclopentanone in various organic solvents to $(\bar{\alpha}/\bar{r}^6)^2$ of the solvents, $\bar{\alpha}$ being the mean molecular polarizability of the solvent and $\bar{r}$ the mean distance between the solute and solvent molecules.[2] The $n\rightarrow\pi^*$ absorption of ketones is usually observed as very weak bands. It is electric-dipole forbidden, but is vibrationally induced.[3,4]

Recently we[5] have shown that the energy density of light acting on the solute molecule is different from that outside of the solution and that the ratio of the observed oscillator strength (f'') to the *true* oscillator strength (f) of the solute molecule is given by

$$f''/f = [s(n^2-1)+1]^2/n. \quad (1)$$

In this expression, n is the refractive index of the medium, and s is a shape parameter between zero and unity depending upon the shape of the cavity in which the solute molecule is supposed to lie and upon the relative direction of the transition moment in the cavity. Eq. (1) may also be written as

$$\sqrt{nf''} = \sqrt{f}s(n^2-1) + \sqrt{f}, \quad (2)$$

which expresses a linear relationship between $\sqrt{nf''}$ and (n^2-1).

Nakashima *et al.*, measured absorption spectra at room temperature. The observed oscillator strengths (f'') of acetone and cyclopentanone in various solvents were estimated from Figs. 6 and 7 in their paper.[1] These values are listed in Table 1. Also listed are the refractive indices (n_{20}^{D}) of these solvents measured[6] at 20°C with the Na-D line. Using these values for n in Eq. (2), we plotted $\sqrt{nf''}$ *vs.* n^2-1 in Figs. 1 and 2. The least-squares fittings give s=0.88 and $f=1.80\times10^{-4}$ for acetone and $s=0.71_5$ and $f=2.27\times10^{-4}$ for cyclopentanone.

These values of s are reasonable since the transition moments of the vibrationally induced $n\rightarrow\pi^*$ transitions of these molecules are supposed to be perpendicular to the plane of the sp^2-hybrid planar structure in the carbonyl group. Note that $s=1$ if the flat molecule is very large compared with the size of the solvent molecules and that $s=1/3$ when the cavity is spherical.[5]

The relation Eq. (1) or (2) was derived in Ref. 5 on the assumptions (i) that both solute and solvent are nonpolar and mutually innert and (ii) that the absorption band is strong enough so that the imaginary part of the polarizability in the frequency region of the absorption is well approximated by this absorption band alone. These conditions are not strictly satisfied here, but the reasonable results obtained here imply that these conditions are fairly well satisfied. It may be interesting to compare the values of f with the gas-phase oscillator strengths ($f°$). Values of $f°$ are, however, not known for the $n\rightarrow\pi^*$ transitions of these molecules.

Solvent effects on the absorption intensity are of two-fold:[5] (a) The effective density of radiation energy "seen" by the solute molecule is different from the energy density when the dielectric medium is eliminated, and (b) the transition moment and the absorption frequency of the solute molecule are different from one solution to another and also different from those of the isolated molecule because of the solute-solvent interaction in the solution systems. In the present paper, only the solvent effect of type (a) was considered. On the other hand, the effect considered

a) Estimated from Figs. 6 and 7 in Ref. 1. b) The numbering of solvents coincides with that of Ref. 1. Here, solvents are in the order of increasing n. c) Refractive indices of solvents, n_{20}^{D} taken from Ref. 6.

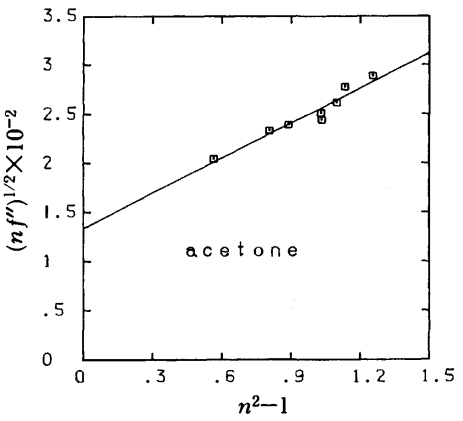

Fig. 1. Plot of $\sqrt{nf''}$ *vs.* n^2-1 for the $n\rightarrow\pi^*$ transition of acetone in various organic solvents. The solid line indicates the least-squares fitted Eq.(2) with $s=0.884$ and $f=1.80_1\times10^{-4}$.

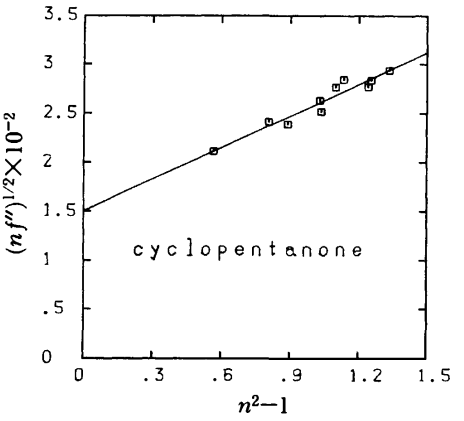

Fig. 2. Plot of $\sqrt{nf''}$ *vs.* n^2-1 for the $n\rightarrow\pi^*$ transition of cyclopentanone in various organic solvents. The solid line indicates the least-squares fitted Eq. (2) with $s=0.715$ and $f=2.27_0\times10^{-4}$.

by Nakashima *et al.*[1] is of type (b). The fact that the linearity of Eq. (2) has been observed fairly well as shown in Figs. 1 and 2 indicates that the effect of type (a) is significant in the solution systems studied here. This, however, does not exclude the possibility that f may be significantly different from f° as the result of the solvent effect of type (b). It is therefore desirable to have experimental values of f° for the $n\rightarrow\pi^*$ transitions of acetone and cyclopentanone.

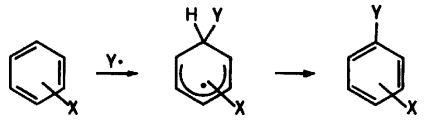
A Molecular Orbital Study of the 1,2-Migration Reaction of Substituted Cyclohexadienyl Radicals

Osamu KIKUCHI* and Satoshi SHIMOMURA
Department of Chemistry, The University of Tsukuba, Sakura, Ibaraki 305
(Received April 20, 1984)

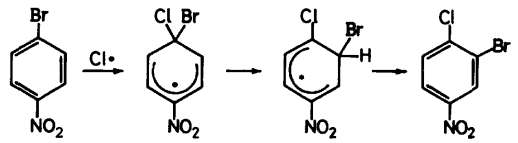
Synopsis. The 1,2-migration reaction of cyclohexadienyl radicals was examined on the basis of an open-shell restricted self-consistent field (SCF) MINDO/3 calculation. For the NO_2- and OH-substituted cyclohexadienyl radicals, the 6-substituted isomers (**1**; X=H, Y=NO_2 or OH) were calculated to be the least stable and apt to undergo a 1,2-hydrogen shift. The electron-withdrawing groups were predicted to have high migratory aptitude.

The cyclohexadienyl radical, **1**, is considered to be an intermediate in the radical aromatic substitution reaction.[1] The isomer distribution of the reaction products in the radical substitution reaction of substituted benzenes is affected by the stabilities of isomeric cyclohexadienyl radicals.[2]



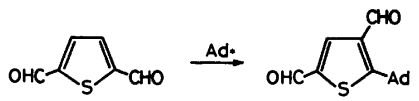
1

Another factor which affects the product distribution is the 1,2-migration reaction of the intermediate radical to give another cyclohexadienyl radical. *p*-Bromonitrobenzene reacts with the Cl radical to give 2-bromo-1-chloro-4-nitrobenzene.[3]



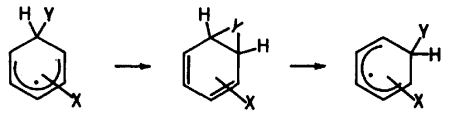
2 **3**

This suggests that the intermediate ipso radical, **2**, rearranges to **3** by the bromo 1,2-shift. The reaction of the adamantyl radical with **4** to give **5** also suggests the 1,2-shift of the CHO group in the intermediate ipso radical.[4]



4 **5**

In this note the 1,2-migration reaction of cyclohexadienyl radicals is examined theoretically. The open-shell restricted SCF method[5] with MINDO/3 approximation[6] was applied to substituted cyclohexadienyl radicals, **1**, and to the bridged radicals, **6**, which are the transition states of the 1,2-migration reaction.



1 **6**

Results and Discussion

1,2-Shift of Cyclohexadienyl Radical. The structures of unsubstituted cyclohexadienyl radical, **1** (X=Y=H), and the transition state bridged radical, **6** (X=Y=H), were optimized by assuming a planar carbon skeleton,[7] C_{2v} symmetry for **1** and C_s symmetry for **6**. The structures obtained are shown in Fig. 1. Structure **II** is that of the transition state, since a small deviation of the migrating H atom out of the C_s symmetry plane results in energy lowering. The schematic representation of the singly-occupied molecular orbitals (SOMO) of **I** and **II** are shown in Fig. 2. The energy difference between **I** and **II**, 156 kJ/mol, is the activation energy of the 1,2-hydrogen shift of **I**.

Substituent Effect. The substituent effect on the 1,2-hydrogen shift was examined by using the NO_2 and OH groups as the substituent. The **I** and **II** structures were employed and partial optimization was performed for the substituent structure. The calculated heats of formation are listed in Table 1. The activation energies are shown in Fig. 3. For the NO_2- and OH-substituted cyclohexadienyl radicals, the 3-substituted isomer was predicted to be the most stable, while the 6-substituted isomer was the least stable. The stability of the 3-substituted isomer may be understood from the interaction between the SOMO of **I** (Fig. 2-a) and the substituent. The energy differences among the transition states are small in comparison with those among the reactant isomers, suggesting that the liability of the 1,2-shift is determined by the instability of the reactant radical.

Migratory Aptitude. The migratory ability of migration groups was estimated from the energy differences between **1** (X=H) and **6** (X=H) for Y=CH_3, H, NO_2, and CHO. The structure of **6** was optimized for each migration group. The calculated activation energies are listed in Table 2. The activation energies for the 1,2-shift of electron-withdrawing groups (NO_2 and CHO) are smaller than those for the H and CH_3 groups. This trend is well explained by the stability of the SOMO at the transition state. In the H shift, the unpaired electron localizes on the six-membered carbon ring (Fig. 2-b). On the other hand, in the case of the CHO shift, the unpaired electron delocalizes into the antibonding π-orbital of the carbonyl group (Fig. 4); this delocalization lowers the SOMO energy. The easy transformation of the electron-withdrawing

group, as is observed in the **4**→**5** reaction, is caused by the stabilization of the transition state due to the delocalization of the unpaired electron into the migrating group.

The Cooperative Binding Isotherms of Sodium Alkanesulfonates to Poly(1-methyl-4-vinylpyridinium chloride)

Iwao SATAKE,* Katumitu HAYAKAWA, Mayumi KOMAKI, and Tamaki MAEDA
Department of Chemistry, Faculty of Science, Kagoshima University, Korimoto, Kagoshima 890
(Received May 1, 1984)

Synopsis. Binding isotherms of nonane-, decane-, and undecane- sulfonate ions to poly (1-methyl-4-vinylpyridinium chloride) were determined by using nitrobenzene-membrane electrode. It was shown that an increase in alkyl chain length is accompanied not only by a rapid increase in the cooperativity parameter but by a regular decrease in an equilibrium surfactant concentration at half binding.

Recently, much attention has been paid to the potentiometric determination of the cooperative binding isotherms of the surfactant ion to polyions such as ionic polypeptide,[1,2] synthetic polyelectrolyte,[3-7] polysaccharide,[5-8] and DNA.[9] In all cases, the binding isotherm has been found to rise steeply in quite narrow range of the equilibrium surfactant concentration. It is now well recognized that the hydrophobic interaction among the bound surfactant molecules plays an important role in determining the nature of the cooperative binding isotherm. In order to make this point clear, we studied in this communication the effect of the surfactant chain length on the cooperative binding isotherm of sodium alkanesulfonate to poly (1-methyl-4-vinylpyridinium chloride) (PVMP) in the presence of added salt.

Experimental

Sodium alkanesulfonates (SAS) with carbon atoms (n) of 9, 10, and 11 were synthesized from the alkyl bromides purified by vacuum distillation.[10] The products were purified by the recrystallization from water, then from methanol and finally by extraction with petroleum ether for 20 h. PVMP was prepared by quaternization of poly (4-vinylpyridine) with methyl bromide.[11] The product was then converted to the chloride through dialysis against NaCl solution. An infrared spectrum showed that virtually all of the pyridine moiety was quaternized. The concentration (C_p) of PVMP in molarity of ionic groups was determined by titrating the corresponding polybase with HCl.

The binding isotherm of SAS to PVMP was determined potentiometrically at 25 °C by using the following cell. Reference electrode (Ag-AgCl)| NH_4NO_3 agar bridge| Reference solution (SAS, C_r)| Nitrobenzene (DTAAS, 1×10^{-4} mol dm^{-3})| Sample solution (PVMP, C_p; SAS, C; NaCl, C_s)| NH_4NO_3 agar bridge| Reference electrode (Ag-AgCl) where DTAAS denotes an ion exchanger, dodecyltrimethylammonium alkanesulfonate, and C_r and C the concentrations of SAS in reference and sample solutions, respectively. The concentrations of PVMP and NaCl were kept constant throughout whole experiments. The electromotive force (E) of the cell was measured with an Orion digital pH meter model 701 A with an accuracy of ±0.1 mV.

Results and Discussion

Prior to the measurements on PVMP solutions, the membrane electrode was calibrated with solutions of SAS. In the absence of PVMP, a plot of E *vs.* log C gave a straight line with a slope of 58.6 mV for n=9, 58.8 mV for n=10, and 59.7 mV for n=11, respectively. The linear relation was found to hold in the concentration range above 2×10^{-5} mol dm^{-3} for n=11 and 10, and 2×10^{-4} mol dm^{-3} for n=9. These calibration curves permit the determination of an equilibrium surfactant concentration (C_f) in solution of SAS with PVMP. The degree of binding of the surfactant ion by PVMP (β) can then be given by $\beta=(C-C_f)/C_p$.

The binding isotherms of SAS to PVMP thus determined are shown in Fig. 1. In conformity with the results obtained for a variety of surfactant ion-polyion systems,[1-9] the binding isotherm rises steeply in narrow range of C_f, reflecting the highly cooperative nature of the binding process of alkanesulfonate ion to PVMP. An important feature of Fig. 1 is the striking effect of the surfactant chain length on the critical range of C_f where the steep rise in binding isotherm occurs. Indeed, the successive decrease in n causes approximately four-fold increase of the value of C_f at β=0.5. Moreover, the steepness of the binding isotherm tends to decrease regularly with decreasing alkyl chain length. According to the theoretical treatment of the surfactant ion-polyion interactions, the surfactant ion is considered to cluster side by side onto the ionic groups of the polyion.[1] Hence, the regular dependence of the cooperativity on alkyl chain length may reasonably be ascribed to a change in hydrophobic interaction among the bound surfactant ions.

The cooperative binding isotherm in excess salt solution can well be described by the following expressions.[1]

$$2\beta - 1 = (y-1)/[(1-y)^2+4y/u]^{1/2} \quad (1)$$

$$KuC_f(\beta=0.5) = 1 \quad (2)$$

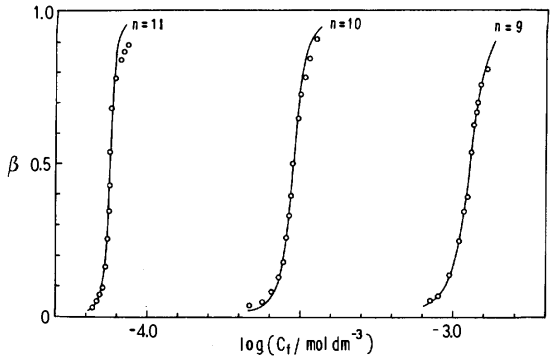

Fig. 1. The binding isotherms of alkanesulfonate ions to PVMP at 25 °C. $C_p=2.55\times10^{-4}$ mol dm^{-3}, $C_s=2.12\times10^{-2}$ mol dm^{-3}. O, observed; solid line, calculated isotherm from Eq. 1 with u=220 for n=9, 480 for n=10, and 2000 for n=11, respectively.

Here, y refers to $C_f/[C_f(\beta=0.5)]$, K is the apparent binding constant of the surfactant ion to a site which has two unoccupied neighbors, and Ku is that to a site which has one or more occupied neighboring sites, respectively. Equation 1 can easily be rearranged to

$$2\beta - 1 = u^{1/2}(y-1)[\beta(1-\beta)/y]^{1/2}. \quad (3)$$

This equation implies that the plot of β *vs.* $(y-1)[\beta(1-\beta)/y]^{1/2}$ gives a straight line with a slope of, $u^{1/2}/2$. As is shown in Fig. 2, such a plot gives in fact a straight line over a wide range of β. A least squares treatment leads to the most reliable value of the cooperativity parameter, u, of 220 for n=9, 480 for n=10, and 2000 for n=11, respectively. The calculated binding isotherms from Eq. 1 with the values of u so determined are shown in Fig. 1. In all cases, the agreement is satisfactory up to about β=0.8. As may be expected, the value of u increases rapidly with increasing alkyl chain length. This, in turn, suggests that the hydrophobic interaction among the bound surfactant ions is of primary importance in determining the cooperativity of the binding process of a homologous series of surfactant ions to a given polyion. An interesting comparison may be made here among the values of u for surfactant ions with the same alkyl chain length. For example with sodium decyl sulfate, the value of u was found to be 77 for helical poly(L-ornithine),[1] 161 for poly (D,L-ornithine),[1] and 26 for a copolymer of diallyldimethylammonium chloride and sulfur dioxide.[3] In the case of cationic surfactants, the value of u was estimated to be 40 for decylammonium chloride in a helical poly (L-glutamic acid) solution[2] and 200 for 1-decylpyridinium bromide in a sodium poly (vinyl sulfate) solution.[4] These observations indicate that the cooperativity parameter depends also on the polyion conformation as well as the hydrophobic character of the polyion residue.

According to Eq. 2, the logarithm of C_f (β=0.5) is anticipated to depend linearly on n, since an increment in $-RT$ ln Ku per CH_2 group represents the free energy of transfer, w, of a methylene group from aqueous medium to the surfactant ion cluster on the polyion. Indeed, the plot of ln $[C_f(\beta=0.5)/\text{mol dm}^{-3}]$ *vs.* n gives a straight line with a slope of -1.36 which corresponds to w of -3370 J mol^{-1} at 25 °C. The fact that the estimated value of w is comparable to that of -3700 J mol^{-1} from aqueous medium to liquid hydrocarbons[12] reflects well the hydrophobic character of the bound surfactant ion cluster on the polyion chain. In their study

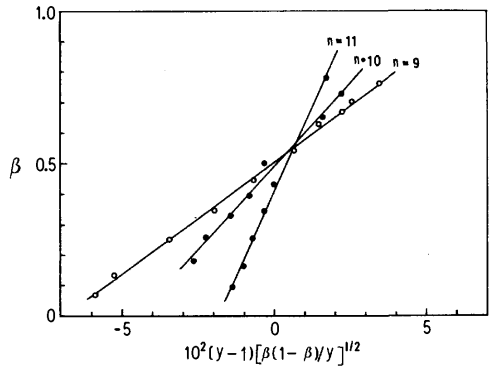

Fig. 2. Plots of β *vs.* $(y-1)[\beta(1-\beta)/y]^{1/2}$.

of the cooperative binding isotherms of dodecyl- and tetradecyltrimethylammonium ions to alginate, pectate, and carboxymethylcellulose, Hayakawa *et al.*[7] obtained the values of w of $-$(3150—3330) J mol^{-1} at 30 °C. Thus, the local environment around the alkanesulfonate ions bound to PVMP is supposed to be similar in its hydrophobicity to those around the alkyltrimethylammonium ions bound to the ionic polysaccharides.

Fermi Resonance Effects on the ν_1 Raman Bands of Liquid CH_2Br_2 and CH_3Br

Kazuyoshi FUJITA, Takuya FUKUDA, Kohji FUKUSHI, and Masao KIMURA*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received May 16, 1984)

Synopsis. Applying Fermi-resonance-band-shape functions to the isotropic Raman band profiles of liquid CH_2Br_2 and CH_3Br in the ν_1 region, the peak frequencies, band-widths, and coupling constants of the ν_1 and combination vibrations have been determined.

In a previous paper on the Raman spectra of halogenated methanes in the liquid state,[1] Fukushi and Kimura have proposed the interpretation that the band around 2990 cm^{-1} of CH_2Br_2 is caused by Fermi resonance (FR) between the fundamental ν_1 and combination $2\nu_3+\nu_8+\nu_9$ vibrations. This interpretation was made on the basis of the fact that the band was observed in both the liquid[1] and solid[2] states as a doublet comprized of two components with comparable intensities. The band around 2960 cm^{-1} of liquid CH_3Br has an unsymmetric profile with a satellite on the high-frequency side.[1] The band was also considered to be a FR band between the ν_1 and $\nu_3+\nu_5+\nu_6$ vibrations, because its profile did not vary much with the temperature.[3] The decomposition of these bands into two components with the Voigt profile yielded the half-widths at half-height (hwhh) of 4.2 and 2.4 cm^{-1} for CH_2Br_2 and CH_3Br respectively.[4] These values are quite different from each other even though the bands belong to the same vibrational species. However, the Fermi-resonance band must be described by a linear combination of two Lorentzians and an unsymmetric function,[5] and the hwhh and peak frequency of each Lorentzian component are not equivalent to those of either the active or the passive band. Therefore, the hwhh values previously reported, especially for CH_2Br_2, may not be true, but only apparent. Thus, these bands have been reanalyzed using functions for the Fermi-resonance band shape (FRBS) proposed previously.[5]

Experimental and the Results of Band Analysis

The details of the experimental unit and technique have been published elsewhere.[1,3] The true power spectra were determined from the observed spectra by deconvoluting a slit function.

TABLE 1. RESULTS OF ANALYSIS FOR THE ν_1 ISOTROPIC RAMAN BANDS OF CH_2Br_2 AND CH_3Br(in cm^{-1} units)

	CH_2Br_2[a]		CH_3Br[a]	
	F[b]	L[c]	F[b]	L[c]
Ω^A	2988.0	2987.9	2956.1	2956.0
Ω^P	2989.3	2989.0	2963.5	2959.5
Γ^A	2.3	3.9	2.3	2.3
Γ^P	6.6	—	8.9	—
$\lvert\omega_\lambda\rvert$	6.2	4.6	4.1	2.1

a) Apparent peak frequencies: CH_2Br_2, 2983 and 2993 cm^{-1}; CH_3Br, 2955 cm^{-1}. b) Fermi-resonance-band shape (Figs. 1a and 2a). c) Two Lorentzians (Figs. 1b and 2b).

The band parameters of the two Lorentzian components; the hwhh, Γ_+ and Γ_-, the peak frequencies, Ω_+ and Ω_-, and the integrated intensities S_+ and S_-, are related to those for active (A) and passive (P) bands in the uncoupled state by these equations:[5]

$$\Gamma_\pm = \bar{\Gamma}_+/2 \pm (1/\sqrt{2})[(u^2+v^2)^{1/2}-v]^{1/2},$$

$$\Omega_\pm = \bar{\Omega}_+/2 \pm (1/\sqrt{2})[(u^2+v^2)^{1/2}+v]^{1/2},$$

$$S_\pm = (1/2) \pm [\bar{\Omega}_- u/2+\bar{\Gamma}_- v/2][u^2+v^2]^{-3/4},$$

where $\bar{\Gamma}_\pm=\Gamma^A\pm\Gamma^P$, $\bar{\Omega}_\pm=\Omega^A\pm\Omega^P$, $u=[\bar{\Omega}_-/2]^2-\bar{\Gamma}_-^2+|\omega_\lambda|^2$, and $v=2\bar{\Omega}_-\bar{\Gamma}_-$, and where ω_λ is the coupling constant. The unsymmetric part is also expressed in terms of these parameters.[5] The parameter values were determined by the least-squares method applied to the band profiles. The true peak frequencies and band-widths for the active and passive modes and the coupling constants were calculated from the $\Gamma_\pm$, $\Omega_\pm$, and $S_\pm$ values thus obtained; they are listed in Table 1, Column F. Table 1, Column L, lists peak frequencies and band-widths obtained by analyzing the bands with two Lorentzians and the coupling constants estimated using equation usually quoted.[6] Figures 1 and 2 show the results of simulation for the ν_1 bands of CH_2Br_2 and CH_3Br at 290 K respectively, while (a) and (b) compare the results from the FRBS and Lorentz functions.

Discussion

As may be seen in Fig. 1, it is clear that the ν_1 band of CH_2Br_2 cannot be described as a superposition of two independent Lorentzians. The unsymmetric component of the FRBS makes a fairly large contribution to the whole band shape. The apparent band-widths, Ω_+ and Ω_- and the relative intensity of the two symmetric components, S_+ and S_-, shown in Figs. 1 (a) and (b) are not very different from each other, but the resulting band-widths, Γ^A, and coupling constants, $|\omega_\lambda|$, are quite different, as Table 1 shows.

For the ν_1 band of CH_3Br, both theoretical curves seem to reproduce the experiment, as is shown in Figs. 2 (a) and (b). On close examination, however, a difference between the two sets of results appears in the high-frequency region. In the results of analysis with the FRBS function, the unsymmetric component contributes significantly to the band profile and, as a result, the peak frequency of the satellite band, Ω^P, is high and the coupling constant, $|\omega_\lambda|$, is large compared with the results based on the two Lorentzians. The unperturbed frequency of the passive mode obtained by the FRBS analysis, 2963.5 cm^{-1}, is very close to the frequency of the combination band, $\nu_3+\nu_5+\nu_6$, calculated from the fundamental frequencies, 2965 cm^{-1}. As far as the Ω^A and Γ^A values are concerned, both analyses yielded the same results. The present results for CH_3Br are also coincident with the results obtained in the previous study,[3] where the band was

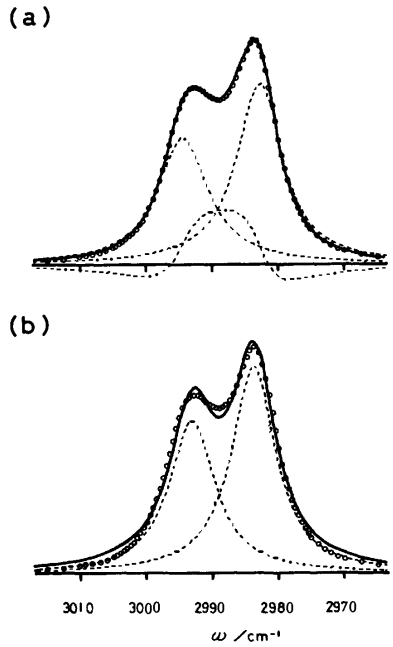

Fig. 1. Band simulation for the ν_1 isotropic Raman band of CH_2Br_2 with (a) Fermi resonance band shape function and (b) two Lorentzians; o observed, —— simulated curves, and ---- components.

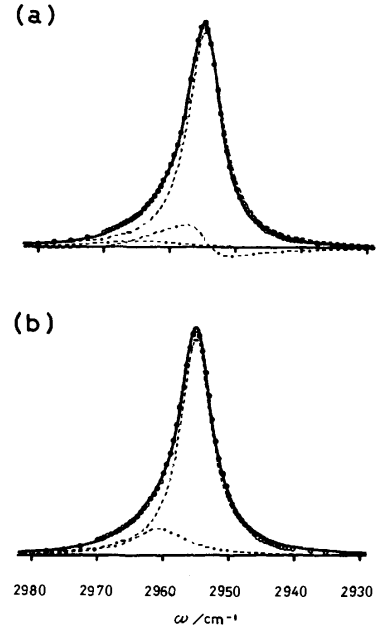

Fig. 2. Band simulation for the ν_1 isotropic Raman band of CH_3Br with (a) Fermi resonance band shape function and (b) two Lorentzians; o observed, —— simulated curves, and ---- components.

not deconvoluted and was analyzed with two Voigt functions. This indicates that the Fermi resonance effect on the band shape is insignificant for two bands with such a large separation and a weak coupling. The hwhh values of the ν_1 bands obtained for CH_2Br_2 and CH_3Br agree perfectly with each other. This suggests that the vibrational relaxation mechanisms of the ν_1 modes are similar to each other.

A Modification of the Method of Spectrophotometric Determination of Iron with Ethylenediamine-*N,N'*-bis(2-hydroxyphenylacetic acid)

Tetsuo KATSUYAMA* and Kyoko WATANABE
Department of Basic Technology, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992
(Received January 9, 1984)

Synopsis. Etylenediamine-*N,N'*-bis(2-hydroxyphenylacetic acid) (H_4eddha) reacts with iron to form a 1:1 complex having an absorption maximum at 480 nm. The method of the spectrophotometric determination of iron with eddha was modified by heating the colored solution in a boiling water bath for a few minutes. The molar absorption coefficient of the Fe^{III}-eddha complex formed was 4.72×10^3 l mol^{-1} cm^{-1} and the relative standard deviation for determination of 5.90×10^{-5} mol dm^{-3} (3.29 μg cm^{-3}) of iron was 0.21%. The effect of 45 diverse ions was examined; only a few metal ions interfered. Aluminium alloys were analyzed for iron by the present method.

Ethylenediamine-*N,N'*-bis(2-hydroxyphenylacetic acid) (H_4eddha) has been used for the spectrophotometric determination of iron.[1-4] This reagent reacts with either iron(III) or iron(II) in the molar ratio 1:1 to form a red iron (III) complex.[5] The stability constant of the Fe^{III}-eddha complex is particularly large among metal-eddha complexes,[6] and the iron(III) complex is so stable that the color development is maximal over a wide pH range and a large excess of the reagent is not necessary for the determination.

This reagent has desirable properties for the spectrophotometric determination of iron. However it is not widely used for this purpose in spite of it being available for analytical use at a reasonable cost. This can be attributed to the following facts. (1) The color reaction of eddha with iron is slow; (2) the effect of diverse ions has not previously been examined sufficiently.

Gordon V. Johnson *et al.* reported that when the resultant colored solution was allowed to stand 18 h before absorbance was measured, the adverse effect of foreign metals on the accuracy of the analysis could be minimized.[4] However, their method is not convenient for usual spectrophotometric analysis since the color-developing period is long. Recently we have found that when the resultant colored solution not showing maximum color intensity was heated in a boiling water bath for a few minutes, the maximum color development was obtained and the color, once developed, was stable. Further, when the heating treatment was used, the existence of moderately large amounts of diverse ions was permited and accurate results were obtained. The present method can be also applied to the determination of iron in aluminium alloys.

Experimental

Reagents. A 1×10^{-2} M (1 M=1 mol dm^{-3}) iron(III) solution was prepared by dissolving guranteed reagent grade iron(III) nitrate in 0.02 M nitric acid. The concentration of the iron(III) ion was determined titrimetrically with edta. This solution was diluted with 0.02 M nitric acid as required.

A 1×10^{-3} M eddha solution was prepared by dissolving the known amount of the reagent obtained from Dojindo Laboratories in dilute sodium hydroxide solution; the molar ratio of eddha to sodium hydroxide was one to two. The reagent solution is colorless. However it changes to light yellow on standing for about 15 d. Thus it is recommended that fresh reagent solution be prepared every two weeks.

Apparatus. Absorbance and absorption spectra were measured with a Hitachi Perkin Elmer 139 spectrophotometer using 10 mm quartz cells. The pH values were measured with a Toa Electronics Model HM-15A digital pH-meter.

Standard Procedure. A sample solution containing less than about 8 μmol (450 μg) of iron was taken into a 50 cm^3 Erlenmeyer flask. Then, 12 cm^3 of 1×10^{-3} M eddha, 2 cm^3 of 1 M acetic acid, and 5 cm^3 of 1 M sodium acetate were added to the solution. After the Erlenmeyer flask was kept for three minutes in a boiling water bath, the solution was cooled with running water. The cooled solution was then transfered to a 50 cm^3 volumetric flask and diluted to the mark with water; final pH was 5.1. The absorbance of the solution was measured at 480 nm against water.

Results and Discussion

The solutions for absorbance measurements were prepared by the heating method unless otherwise stated.

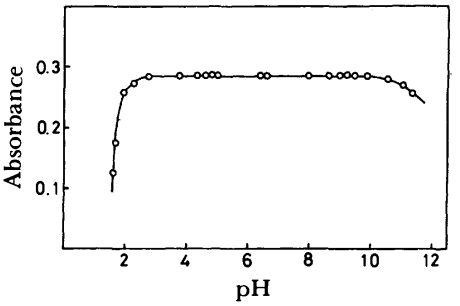

Fig. 1. Effect of pH on formation of the Fe^{III}-eddha complex.
Fe^{III}: 6.04×10^{-5} M (3.37 μg cm^{-3}), eddha: 2.40×10^{-4} M, wavelength: 480 nm, reference: water.

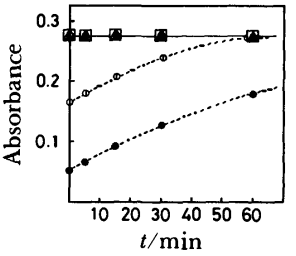

Fig. 2. The changes in absorbance of iron(III) eddha solution with time.
Fe^{III}: 5.83×10^{-5} M eddha: 2.40×10^{-4} M, Ni^{II}: 1.70×10^{-2} M pH: 5.0, room temperature (20 °C), wavelength: 480 nm, reference: water.
Heating time: ---●---, 0 min; ---Ⓘ---, 1 min; —▲—, 2 min; —○—, 3 min; —△—, 5 min; —□—, 8 min.
The quantity of the solution heated was 25 cm^3.

Absorption Spectra and Effect of pH. The solution of Fe^{III}-eddha had an absorption maximum at 480 nm. The absorbance of the solution at 480 nm remained constant over a wide pH range 2.5—10.0 (Fig. 1).

Color Development. Without the heat treatment, the time to obtain the maximum color development was varied by changing the conditions.[7] However, when the solution not showing maximum color intensity was kept for a few minutes in a boiling water bath the color reaction was completed. Examples are shown in Fig. 2, in which it is seen that the maximum color development is obtained by the heat treatment of two minutes and above. As a rule, a heat treatment of three minutes was adequate for full color development if the quantity of the solution for the color reaction was less than 40 cm^3. The color, once developed, was stable; the absorbance remained constant over a period of 5 h. The absorbance was independent of the temperature of measurement (10—35 °C).

Composition of the Complex and Effect of eddha Concentration. The composition of the complex was determined by a molar ratio study: The absorbance was plotted as ordinate against the [eddha]/[Fe^{III}] ratio (iron concentration constant; ratio, 0.3—6.0). The absorbance increased linearly with the ratio but became constant above a ratio of unity. This suggests that iron(III) forms a 1:1 complex with eddha and a large excess of reagent is not needed for full color development.

Effects of Amount of Buffer Solution and Ionic Strength. A buffer solution was prepared by mixing 1 M acetic acid solution with 1 M sodium acetate solution in 1:2.5 ratio. The color intensity of the iron(III) complex was not affected by the addition of from 2 to 20 cm^3 of the buffer solution (for 2.95 μmol of iron(III) in 50 cm^3 solution). The color intensity of the iron(III) complex was also not affected by an ionic strength change of from 0.1 to 1.4 M.

Calibration Curve. The calibration curve under the conditions described in the standard procedure was linear in the concentration range 1×10^{-5}—1.6×10^{-4} M (0.6—9 μg cm^{-3}) of iron(III). The molar absorption coefficient of the Fe^{III}-eddha complex was 4.72×10^3 l mol^{-1} cm^{-1} (at 480 nm). These values are somewhat smaller than those reported in the literature,[1] in which it is stated that the linear concentration range and the molar absorption coefficient of the Fe^{III} -eddha complex are 0—2.5×10^{-4} M and about 5.6×10^{-3} l mol^{-1} cm^{-1} (at 470) respectively. The relative standard deviation of the absorbance was 0.21% for 5.90×10^{-5} M (3.29 μg cm^{-3}) of iron(III) (12 determinations). This value is smaller than that of the method of A. L. Underwood (0.5%).[1]

Effect of Diverse Ions. The effect of 45 diverse ions was examined by the standard procedure stated. The ion in question was introduced into the iron sample solution before addition of other reagents. The results are shown in Table 1.

A. L. Underwood tested several metal ions for interference in the measurement of 5.4 μmol (in 50 ml) of iron(III);[1] it was shown that the presence of the metal ions in the following amounts did not interfere with the determination of the iron(III). Ca^{2+}, 5000 μmol; Cu^{2+}, 32 μmol; Hg^{2+}, 100 μmol; Mg^{2+}, 8200 μmol; Mn^{2+}, 3600 μmol; Ni^{2+}, 34 μmol; Pb^{2+}, 97 μmol; UO_2^{2+}, 8 μmol; Zn^{2+}, 31 μmol; Al^{3+}, 7400 μmol; Th^{4+}, 9 μmol in 50 ml. Comparing Table 1 with the results tested by A. L. Underwood, it seems that in many cases the interferences in the present method are smaller than those in A. L. Underwood's results. Thus, it may be said that the tolerance limit of diverse ions increases by use of heat treatment.

TABLE 1. EFFECT OF DIVERSE IONS ON THE DETERMINATION OF IRON(III)[a]

Ions added	Tolerance amount added to 50 cm^3 / μmol
K^+, Li^+, Na^+, NH_4^+, Rb^+, Tl^+, Ba^{2+}, Be^{2+}, Ca^{2+}, Cd^{2+}, Mg^{2+}, Pb^{2+}, Sr^{2+}, Zn^{2+}, Ce^{3+}, La^{3+}	6000[b]
Al^{3+}	5400
Mn^{2+}	3000
Th^{4+}	1800
Ni^{2+}	1200
Hg^{2+}	900
Ag^+	450
UO_2^{2+}, Cu^{2+}	80
Co^{2+}, Cr^{3+}	3
Br^-, Cl^-, ClO_3^-, ClO_4^-, HCO_3^-, CH_3COO^- I^-, NO_3^-, $H_2PO_4^-$, SCN^-, SO_4^{2-}, thiourea	6000[b]
F^-	3000
tartrate	1500
citric acid, $P_2O_7^{4-}$	300
NO_2^-, oxalate	90
CN^-	60

a) Iron(III) taken in 50 cm^3 was 2.95 μmol (165 μg). The tolerance limit was taken as the value in which an error is not more than 1%. Foreign ions were added as nitrates and sodium salts except following: K^+, KCl; NH_4^+, NH_4Cl; Hg^{2+}, $HgCl_2$; Al^{3+}, $K_2Al_2(SO_4)_4$; SCN^-, NH_4SCN; CN^-, KCN; tartrate, sodium potassium tartrate. b) Maximum tested.

Determination of Iron in an Aluminium Alloy. Aluminium alloys furnished by the National Bureau of Standards were analyzed for iron. The sample solution was prepared by dissolving the aluminium alloy (NBS 85: 1.2 g, NBS 87a: 0.5 g) in perchloric acid using the method described previously.[8] The results of the three repeated determinations of iron (starting from the weighing of the alloy) were as follows. NBS 85 (certified, 0.24%): 0.24, 0.23, and 0.24%. NBS 87a (certified, 0.61%): 0.61, 0.61, and 0.61%. Satisfactory results were obtained.

(Received February 23, 1984)

Synopsis. The wet method to convert chemically prepared manganese dioxides (MnO_2s) into β-MnO_2 was reported. Chemically prepared MnO_2s, such as I. C. Sample Nos. 5, 8, 11, and 12, were converted into β-MnO_2 by using a proton-assisted rearrangement reaction in a boiling dil. H_2SO_4 solution containing Mn^{2+} ion at 100±10 °C.

In a previous paper,[1] the wet method to change crystal structures from several MnO_2s, such as δ-MnO_2, α-MnO_2, electrolytic MnO_2s (EMDs) and heat-treated EMDs to β-MnO_2 was reported and a complex situation in classifying artificial MnO_2s, especially prepared by wet methods, was discussed. In recent years, so-called chemically prepared MnO_2s (CMDs) in addition to EMDs became available for experimental use in batteries. In this paper, we report an extension of the method to some CMDs.

Experimental

CMDs, I. C. Sample Nos. 5, 8, 11, and 12, obtained from the International MnO_2 Sample Office (c/o Union Carbide Corp., Parma Technical Center, P. O. Box 6116, Cleveland, Ohio 44101, USA) were used as received. A reaction vessel was consisted of a 500 ml round-bottom flask joined to a condenser with the standard taper joint and a heating mantle at the bottom. A 250 ml of 0.5 mol dm^{-3} H_2SO_4 with 10 g of $MnSO_4$ (4—5)H_2O in a round-bottom flask was heated at 100±10 °C and then 10 g of MnO_2 sample was added into the flask. After the reaction period of a week, a reaction product was filtered and well-washed with cool distilled water. The washed reaction product was dried at about 60 °C in the air.

X-Ray data on starting materials and reaction products were obtained by using a Shimadzu XD-3A X-ray diffractometer with iron $K\alpha$ radiation (30 kV, 10 mA) filtered with manganese.

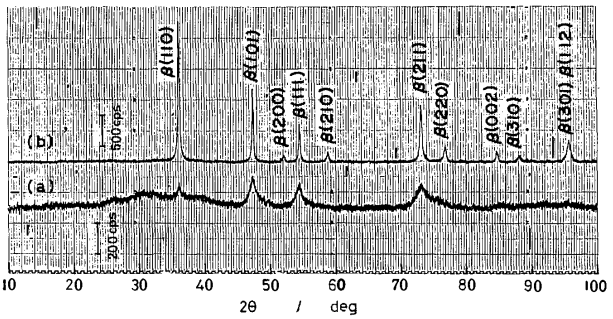

Fig. 1. X-Ray diffractional patterns of I.C. Sample No. 5 (a) and a reaction product (b) after the acid digestion of I.C. Sample No. 5 in 0.5 M H_2SO_4 (1 M= 1 mol dm^{-3}) with $MnSO_4$ at 100±10 °C for a week.

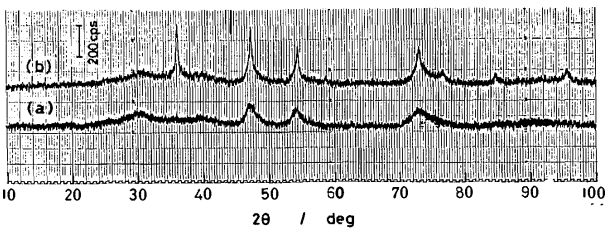

Fig. 2. X-Ray diffractional patterns of I.C. Sample No. 8 (a) and a reaction product (b) after the acid digestion of I.C. Sample No. 8 in 0.5 M H_2SO_4 with $MnSO_4$ at 100±10 °C for a week.

Since the location of line in terms of diffraction angle (2θ) and the shape of line were important in identifying the crystal structure of MnO_2, observed XRD patterns are shown in Figs. 1—4. The reaction product was identified as β-MnO_2 (pyrolusite) from both 2θ value (tetragonal system, a=4.39 Å and c=2.87 Å) and the intensities of lines ($P4_2/mnm$-D_{4h}^{14} with the positional parameter of anion u=0.31), and the indices (h, k, l) are given in figures.

CMDs, such as I. C. Sample Nos. 5, 8, and 12, have almost the same XRD patterns, which may be

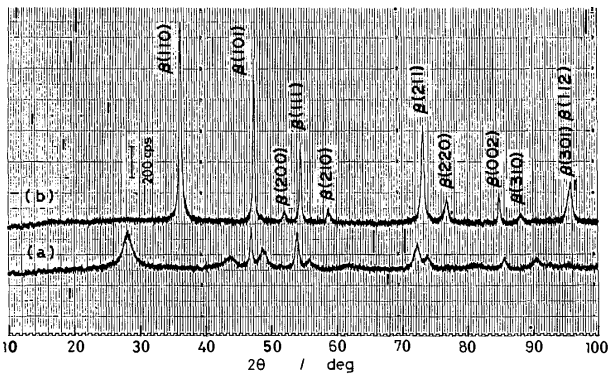

Fig. 3. X-Ray diffractional patterns of I.C. Sample No. 11 (a) and a reaction product (b) after the acid digestion of I.C. Sample No. 11 in 0.5 M H_2SO_4 with $MnSO_4$ at 100±10 °C for a week.

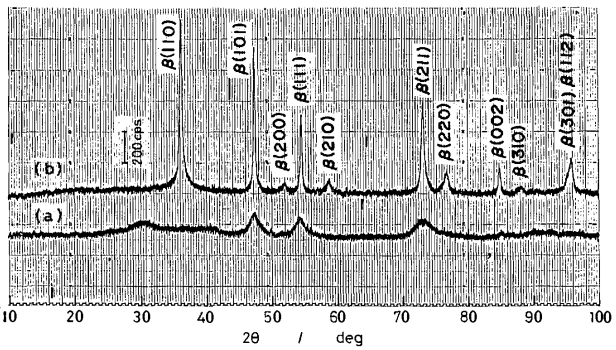

Fig. 4. X-Ray diffractional patterns of I.C. Sample No. 12 (a) and a reaction product (b) after the acid digestion of I.C. Sample No. 12 in 0.5 M H_2SO_4 with $MnSO_4$ at 100±10 °C for a week.

characterized by diffused lines at *ca.* 30 and 40° as shown in Figs. 1, 2, and 4. According to Gattow and Glemser,[2] they may be classified as γ-MnO_2.

The XRD pattern of I. C. Sample No. 11 has almost the identical 2θ values with those of ramsdellite[3] but the intensities are quite different, suggesting that the crystal structure is very close to ramsdellite but not exactly the same, which is probably due to the intergrowth of pyrolusite and ramsdellite domains[4] like nsutite.[5]

As can be seen in Figs. 1, 3, and 4, both types of CMDs, *i.e.*, I. C. Sample Nos. 5, 11, and 12, were converted into β-MnO_2. Although the XRD pattern of β-MnO_2 uncontaminated by the lines of starting material has not been obtained yet for some reasons, I. C. Sample No. 8 seems to be converted into β-MnO_2 after the acid digestion as is shown in Fig. 2. Without addition of $MnSO_4$ in a reaction mixture, none of the changes in XRD patterns was observed after the acid digestion.

Then, we conclude that CMDs available in the I. C. Sample Office can be converted into β-MnO_2 by using the proton-assisted rearrangement reaction in a boiling dil. H_2SO_4 solution containing Mn^{2+} ion at 100 ± 10°C. The mechanism of the proton-assisted rearrangement reaction with Mn^{2+} ion is still under investigation by using spectro-electrochemical techniques combined with conventional analytical techniques.

The authors wish to thank Mr. I. Matsuhisa and Mr. K. Ogino for their assistance in sample preparation. This work was partially supported by a grant in aid for Scientific Research from the Ministry of Education, Science and Culture.

A Study of Inorganic Ion Exchangers. IX.[1] The Synthesis of $Al_xZrH_{2-3x}(PO_4)_2 \cdot yH_2O$ and Its Characteristics

Etsuro KOBAYASHI

National Chemical Laboratory for Industry, Yatabemachi, Tsukuba-gun, Ibaraki 305

(Received April 9, 1984)

Synopsis. To make a material with specific functions such as those of a catalyst, a layer-structure compound with the formula of $Al_xZrH_{2-3x}(PO_4)_2 \cdot yH_2O$ ($x \leqq 2/3$) was synthesized by a hydrothermal reaction between $ZrOCl_2 \cdot 8H_2O$ and $Al(H_2PO_4)_3$ at 200—270 °C. The product had a layer spacing of 7.75 Å, slightly longer than α-$Zr(HPO_4)_2 \cdot H_2O$ (7.62 Å), and fairly good thermal stability at 250—500 °C. However, the above objective was not attained by ion-exchange between various zirconium phosphates and an aqueous solution of aluminium chloride.

Inorganic layer-structure compounds with thermal stability have specific functions of ion-exchangers or catalysts. In this study, crystalline alminium zirconium phosphate, $Al_xZrH_{2-3x}(PO_4)_2 (x \leqq 2/3)$, was synthesized by the hydrothermal reaction of zirconium(IV) chloride oxide with tris(dihydrogenphosphate) aluminium, and the properties of the product were examined. An attempt was also made to obtain such a material by means of ion exchange between various zirconium phosphates and aluminium chloride.

Experimental

The reaction product, $Al_xZrH_{2-3x}(PO_4)_2 \cdot yH_2O$, was synthesized by means of a hydrothermal reaction between $ZrOCl_2 \cdot 8H_2O$ and an $Al(H_2PO_4)_3$ aqueous solution (P_2O_5, 34.8%; Al_2O_3, 8.6%; specific gravity, 1.499; Nippon Chemical Co.) in an autoclave, according to the previously reported method.[1]

The formation of $Al_xZrH_{2-3x}(PO_4)_2$ was also examined by means of ion exchange between one gram of α-$Zr(HPO_4)_2 \cdot H_2O$. γ-$Zr(HPO_4)_2 \cdot 2H_2O$, or $Zr[(C_4H_9)_3NH]_xH_{2-3x}(PO_4)_2$[1] and 100 cm^3 of M/10 (1 M=1 mol dm^{-3}) $AlCl_3$. In this process, the pH change of the mother liquor was measured for 18 h at 20 °C, and the Al^{3+} ions adsorbed onto the zirconium phosphate were determined. The analysis of the above products was carried out as follows. The H_2O was estimated from the weight loss of the sample heated at 800 °C. After the heated product had been dissolved by alkali fusion, the ZrO_2, Al_2O_3, and P_2O_5 components were separated from each other and determined by means of gravimetric analysis. The reaction products were characterized by means of X-ray diffraction and thermal analysis (DTA, TG).

Results and Discussion

The conditions for the hydrothermal reaction of $ZrOCl_2$ with $Al(H_2PO_4)_3$ and the analytical data of the products are shown in Table 1.

The influence of the reaction temperatures was examined in Nos. 1—4 of Table 1. An amorphous product was formed in the mother liquor at temperatures lower than 150 °C. The crystallinity was augmented, and a crystalline product was obtained at 200 °C or higher.

The influence of the Al $(H_2PO_4)_3/ZrOCl_2$ (Al/Zr) mole ratios on the hydrothermal reaction was examined in Nos. 2, 5—7; the X-ray diffraction patterns of the reaction products are shown in Fig. 1.

At an Al/Zr mole ratio of 3 (No. 5), an amorphous product was formed, though the crystalline product was obtained with an increase in the mole ratio. However, the diffraction peaks (2θ; 20.6°, 26.3°) attributed to $Al_2(HPO_4)_3$ appeared in the X-ray diffraction pattern of the product at an Al/Zr mole ratio of 12 (No. 7). Thus, the reaction product is apparently intermingled with $Al_2(HPO_4)_3$. This is also evident from the increase in the Al_2O_3 content of the reaction product. Under suitable conditions (200—250 °C, Al/Zr=8) for the synthesis, the $ZrO_2 : P_2O_5$ mole ratio of the reaction product was 1:1, and then the Al^{3+}-ion content was about 5%. The product composition can be written as $Al_{0.2-0.3}ZrH_{2-3(0.2-0.3)}(PO_4)_2 \cdot 0.7-1.4H_2O$.

The X-ray diffraction pattern of this product was quite similar to that of α-$Zr(HPO_4)_2 \cdot H_2O$, but the layer

a) Aqueous solution of $Al(H_2PO_4)_3$ containing 34.8% of P_2O_5 and 8.6% of Al_2O_3.

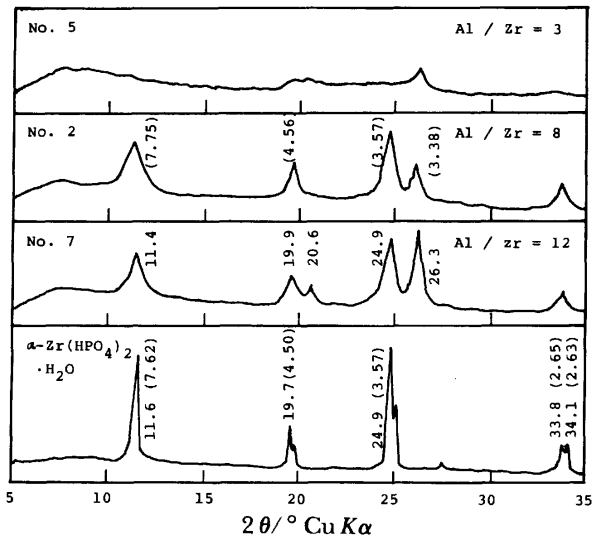

Fig. 1. X-Ray diffraction patterns of $Al_xZrH_{2-3x}(PO_4 \cdot yH_2O$ and α-$Zr(HPO_4)_2 \cdot H_2O$. Effect of $Al(H_2PO_4)_2$ mole/$ZrOCl_2$ mole (Al/Zr) on the synthesis Numerals on peaks indicate 2θ/degrees and lattice distances Cl/Å).

spacing of 7.75 Å, determined from the first d value (002) of the reaction product, was slightly longer than that of 7.62 Å for α-$Zr(HPO_4)_2 \cdot H_2O$.

The results of adding $Al(OH)_3$ (No. 9), or $(C_4H_9)_3N$ (No. 10) to this reaction system were investigated. The pH of the reaction mixture containing $Al(OH)_3$ was slightly higher than that to which no addition was made, but the reaction product was possibly contaminated by metal ions dissolved by the corrosion of the autoclave. The X-ray diffraction patterns of the reaction products of Nos. 9 and 10 were shown to be intermingled with $Al_2(HPO_4)_3$ as a by-product. In Experiment No. 10, the crystalline zirconium phosphate connected to $(C_4H_9)_3N$ could not be obtained as a result of the formation of an oily tertiary amine phosphate.

The DTA and TG curves of $Al_xZrH_{2-3x}(PO_4)_2 \cdot H_2O$ and α-$Zr(HPO_4)_2 \cdot H_2O$ are shown in Fig. 2.

The thermal decomposition in the reaction product showed a behavior similar to that of α-$Zr(HPO_4)_2 \cdot H_2O$. A broad endothermic peak attributed to the dehydration of the water of layer spacing appeared at 130—150 °C. The change in the weight of the heating

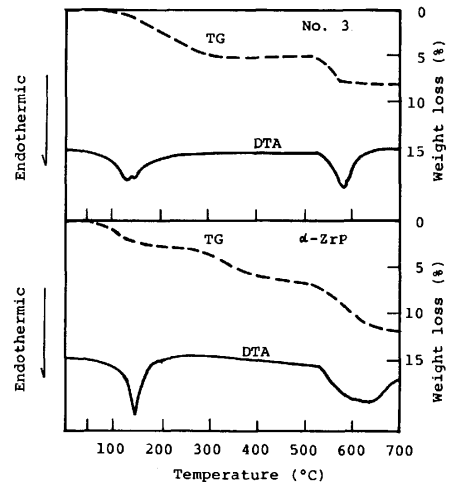

Fig. 2. DTA and TG curves of $Al_xZrH_{2-3x}(PO_4 \cdot yH_2O$ and α-$Zr(HPO_4)_2 \cdot H_2O$.

product could not be detected on the TG curve at 250—500 °C. In this temperature range, the condensation was obstructed by aluminium ions present in the layer-spacing of the phosphate. The thermal stability of $Al_xZrH_{2-3x}(PO_4)_2 \cdot yH_2O$ at 250—500 °C could also be observed from the X-ray diffraction pattern of the heated product.

When a reaction between zirconium phosphate and aluminium ions occurs easily, the method of synthesizing $Al_xZrH_{2-3x}(PO_4)_2 \cdot yH_2O$ directly becomes less necessary. Accordingly, the reactions of zirconium phosphates (α-$Zr(HPO_4)_2 \cdot H_2O$, γ-$Zr(HPO_4)_2 \cdot 2H_2O$ or $Zr[(C_4H_9)_3NH]_xH_{2-x}(PO_4)_2 \cdot yH_2O$) with an aqueous solution of $AlCl_3$ were examined. The pH values were found to decrease from about 4.5 to 2.5, followed by the adsorption of Al^{3+} ions onto the solid phase by 1.66% in the case of the butyl amine salt (17.0 Å), 0.81% for γ-$Zr(HPO_4)_2 \cdot 2H_2O$ (12.3 Å), and 0.24% for α-$Zr(HPO_4)_2 \cdot H_2O$ (7.6 Å). The adsorbed Al^{3+} ions slightly increased in proportion to the layer-spacing of the phosphates. Thus, the direct synthesis is significant for the indicated purpose.

(Received May 1, 1984)

Synopsis. TG-DTA studies revealed that the complexes CoX_2L_2 (L=tmu, dmeu or dmpu (see text); X=Cl, Br or I) decompose into CoX_2 and 2L by slight heating. The ease of this decomposition decreases in the orders of tmu>dmeu>dmpu and Cl>Br>I, corresponding to the orders of coordination abilities of these ligands.

In connection with the recent studies of Kuya *et al.* on the cobalt (II) halide complexes of dimethyl ethyleneurea (dmeu) and dimethyl trimethyleneurea (dmpu),[1,**] we carried out a comparative study on the thermal behaviors of these complexes and also those of the corresponding complexes of tetramethylurea (tmu), reported formerly by King.[2] All these complexes are of the general formula CoX_2L_2 (L= tmu, dmeu or dmpu; X=Cl, Br or I), and their spectral, magnetic and conductometric studies indicated that they are composed of tetrahedral, high-spin and uncharged species, *i.e.*, $[CoX_2L_2]$, in which the L molecules are coordinated to Co (II) at their C=O groups.[1,2]

Experimental

Preparation of the Complexes. The complexes of dmpu, and the Cl- and Br-complexes of dmeu, were prepared as reported elsewhere.[1] The remaining complexes were prepared by stirring anhydrous CoX_2 with 1,2-dichloroethane, in which it is nearly insoluble, and dropping L into the mixture, until complete dissolution of CoX_2 took place. The blue or bluish green solution formed was then evaporated under vacuum, until large crystals of the same color separated out. The purity of the crystals was confirmed by elementary analysis, and also by the TG data (especially Δw in vacuum; *cf.* Table 1).

TG-DTA Measurements. The thermogravimetric (TG) and differential thermal analysis (DTA) measurements were carried out with a Sinku-Riko TGD-3000 Differential Thermobalance, in static air, in flowing N_2 (flow rate: 50 $cm^3 min^{-1}$) and in vacuum (3 Torr; 1 Torr=133 $N m^{-2}$). 15—20 mg of the sample was taken for each run, and heated at a rate of 4 °C min^{-1}.

Results and Discussion

Figure 1 shows the TG curves of the dmpu complexes, and the DTA curve of $[CoBr_2(dmpu)_2]$, both measured in flowing N_2. The TG and DTA curves of the remaining complexes are essentially similar to these. All the TG curves show a wide decomposition step, and the weight loss for it agrees, in each case, reasonably well with the stoichiometry of the following decomposition (1):

$$[CoX_2L_2] \longrightarrow CoX_2 + 2L, \quad (1)$$

in which all the organic ligands are driven off in the gas phase, leaving cobalt halides behind. On the other hand, the DTA curves are composed of a sharp endothermic peak appearing at 90—150 °C, and another endothermic peak near the end of the decomposition step on the TG curve. Visual observation confirmed that the former corresponds to the melting point; the fact that it is so low indicates that these complexes are essentially molecular crystals, supporting their formulation.[1,2] The latter corresponds apparently to the absorption of heat of the decomposition, together with the heat of vaporization of evolved L. In certain cases, another very weakly endothermic peak appears before melting (mostly at 70—80 °C), which may be due to some phase transition in the solid.

Comparing all these data, which are also summarized in Table 1, we can readily recognize that the ease of the reaction (1) in N_2 decreases in the following orders of L and X:

L: tmu>dmeu>dmpu

X: Cl>Br>I

The meaning of these orders can be explained as follows. In the course of the decomposition (1), the ligands L are driven out of the coordination sphere, but the driving force for it must be the attack by the anions X^- belonging to the surrounding complexes, which tend to form Co-X-Co bridges leading, eventually, to the formation of the layer lattice structure of CoX_2. In other words, we can say that the ligands L are squeezed out of the coordination sphere by the anions X^-. The ease of the decomposition will then increase with the

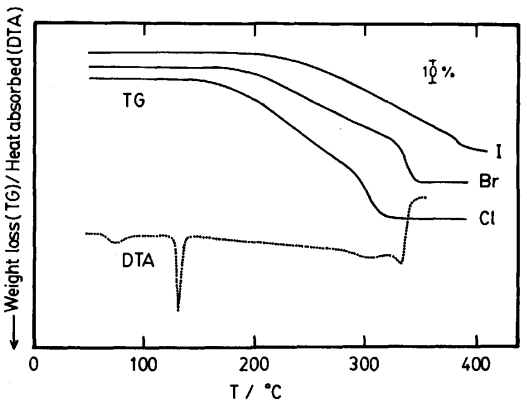

Fig. 1. TG curves of the dmpu complexes, and DTA curve of $[CoBr_2(dmpu)_2]$, in flowing N_2.

**) According to the IUPAC nomenclature, dmeu and dmpu are 1,3-dimethyl-2-imidazolidinone and 1,3-dimethylhexahydro-2-pyrimidinone, respectively.

TABLE 1. TG-DTA DATA OF THE COMPLEXES: TEMPERATURE RANGES AND WEIGHT LOSSES(Δw) FOR THE DECOMPOSITION STEP, AND DTA PEAK POSITIONS

Complex	In N_2			In vacuum		Δw/% (Calcd)[b]
	Temp range/°C	Δw/%	DTA peaks[a]/°C	Temp range/°C	Δw/%	
$[CoCl_2(tmu)_2]$	80—260	61.4	*91*, 239	50—205	64.7	64.1
$[CoBr_2(tmu)_2]$	100—300	48.5	*97*, 289	65—180	49.2	51.5
$[CoI_2(tmu)_2]$	120—380	46.6	*131*, —[c]	85—245	41.3	42.6
$[CoCl_2(dmeu)_2]$	125—350	60.0	(76), *127*, 252	70—220	62.0	63.7
$[CoBr_2(dmeu)_2]$	125—310	49.4	(72), *138*, 290	85—255	48.9	51.1
$[CoI_2(dmeu)_2]$	110[d]—430	43.0	*134*, —[c]	70—245	41.4	42.2
$[CoCl_2(dmpu)_2]$	120—340	64.9	(101), *127*, 313	85—220	65.2	66.4
$[CoBr_2(dmpu)_2]$	150—365	52.8	(70), *130*, 344	100—260	53.0	54.0
$[CoI_2(dmpu)_2]$	170—410	45.2	*146*, 384	115—250	43.6	45.0

a) The peaks for melting points are italicized, and those for solid phase transitions are in parentheses. b) Calculated according to the eq.(1). c) Scarcely perceptible. d) Sizable decomposition begins at *ca.*160°C.

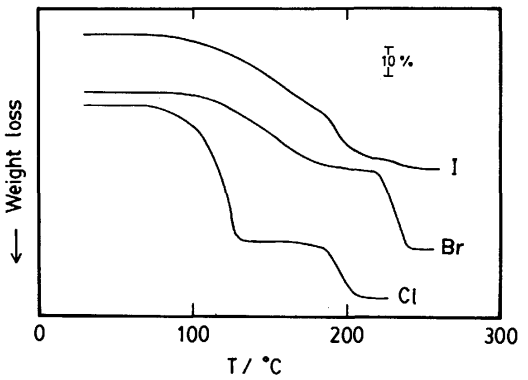

Fig. 2. TG curves of the dmeu complexes in vacuum.

increase of the coordination ability of X^-, *i.e.*, in the direction of $I^- \rightarrow Br^- \rightarrow Cl^-$, and also with the decrease of the coordination ability of L. As one can easily see from their dipole moments (tmu: 3.49D, dmeu: 4.09D, dmpu: 4.23D; solvent: dioxane, 1 D=3.33×10^{-30} Cm), the latter ability will be the lowest with tmu, and will increase through dmeu to dmpu.[3,4]

Similar measurements were also made in static air and in vacuum. The data in air was found to be essentially similar to those in N_2, but those in vacuum were notably different. As can be seen from Table 1, the temperature range for the decomposition is notably lowered by evacuation, and, although the general appearance of the TG curves indicate that the two orders of L and X still approximately hold, small shoulders indicating stepwise release of L are observed on most of them. The most significant ones are those of $[CoX_2(dmeu)_2]$ shown in Fig. 2, which reveal that Cl- and Br-complexes of definite intermediate compositions, *i.e.*,$CoCl_2(dmeu)_{2/3}$ and $CoBr_2(dmeu)$, are formed in the course of the decomposition (1). Intermediate complexes of similar stoichiometries, with probably polymeric structures, have been observed in the thermal decompositions of other CoX_2L_2-type complexes.[5,6] The DTA curves in vacuum are rather complicated, with several endothermic peaks corresponding to the successive steps.

We can thus conclude that this decomposition can be understood as the competition of the coordination tendencies of the leaving and entering groups, as is commonly encountered among the ligand exchange reactions.[7,8]

8) It may be added that the fully alkylated ureas studied here are all liquids which boil near or above 200°C, and are thermally very stable. Further decomposition of the released ligand will thus be quite unlikely, at least for the most part of the decomposition step.

A Solubility Phase Diagram Study on Optical Resolution of Bis(ethylenediamine)oxalatocobalt(III) (1+) by L-α-Amino Dicarboxylate(1−)

Kazuaki YAMANARI,* Michihito IGAKI,† and Yoichi SHIMURA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received May 1, 1984)

Synopsis. The binary and ternary solubility phase diagrams for the system of Δ- and Λ-[Co(ox)(en)$_2$]X (X=L-glutamate (L-Hglu$^-$) and L-aspartate (L-Hasp$^-$)) were determined in water. It was found that the former anion L-Hglu$^-$ behaves as an excellent resolving agent for [Co(ox)(en)$_2$]$^+$ but the latter anion L-Hasp$^-$ forms a pseudoracemate *rac*-[Co(ox)(en)$_2$](L-Hasp).

An application of L-amino acid cation as a resolving agent for metal complexes has been reported.[1] In this note, L-α-amino acid anion, L-glutamate (L-Hglu$^-$) and L-aspartate (L-Hasp$^-$), are examined as a resolving agent for the resolution of [Co(ox)(en)$_2$]$^+$, the former anion leading to the successful optical resolution. The binary and ternary solubility phase diagrams of these systems are presented here.

Experimental

Δ- and Λ-[Co(ox)(en)$_2$](L-Hglu)·5.5H$_2$O: To a solution of *rac*-[Co(ox)(en)$_2$]CH$_3$CO$_2$[2] (100 g, 0.307 mol) dissolved in 300 cm^3 of water was added a solution of Na(L-Hglu)·H$_2$O (57.4 g, 0.307 mol) in 200 cm^3 of water. The mixed solution was evaporated to *ca.* 450 cm^3 and cooled in an ice bath. The less soluble Λ-diastereomer deposited was filtered, washed with methanol and acetone and then air-dried at room temperature. Further concentration of the filtrate gave the second crop (the final filtrate was reserved for Δ-diastereomer). The total yield was 72 g. The diastereomer was recrystallized from hot water. Found: C, 25.97; H, 6.78; N, 13.64%. Calcd for Λ-[Co(ox)(en)$_2$](L-Hglu)·5.5H$_2$O=C$_{11}$H$_{35}$N$_5$O$_{13.5}$Co: C, 25.79; H, 6.89; N, 13.67%. $\Delta\varepsilon_{523}$=+2.88 and ε_{497}=119.6 mol^{-1} dm^3 cm^{-1}.

An excess of conc. HCl was added to the above filtrate to give Δ-[Co(ox)(en)$_2$]Cl·3H$_2$O. The chloride salt was converted into the L-Hglu salt using a column of QAE-Sephadex A-25 (L-Hglu$^-$ form). Found: C, 25.94; H, 6.73; N, 13.63%. Calcd for Δ-[Co(ox)(en)$_2$](L-Hglu)·5.5H$_2$O=C$_{11}$H$_{35}$N$_5$O$_{13.5}$Co: C, 25.79; H, 6.89; N, 13.67%. $\Delta\varepsilon_{523}$=−2.91 and ε_{497}=120.3 mol^{-1} dm^3 cm^{-1}.

rac-, Δ-, *and Λ-[Co(ox)(en)$_2$](L-Hasp)·nH$_2$O*: The same process as described above except for the use of Na(L-Hasp)·H$_2$O instead of Na(L-Hglu)·H$_2$O gave the pseudoracemate *rac*-[Co(ox)(en)$_2$](L-Hasp). Found: C, 29.96; H, 5.57; N, 17.52%. Calcd for *rac*-[Co(ox)(en)$_2$](L-Hasp)=C$_{10}$H$_{22}$N$_5$O$_8$Co: C, 30.08; H, 5.55; N, 17.54%. ε_{497}=119.4 mol^{-1} dm^3 cm^{-1}.

The active diastereomers Δ-and Λ-[Co(ox)(en)$_2$](L-Hasp) were prepared from the corresponding active complexes Δ-[Co(ox)(en)$_2$]Cl·3H$_2$O and Λ-[Co(ox)(en)$_2$](L-Hglu)·5.5H$_2$O, respectively, using a column of QAE-Sephadex A-25 (L-Hasp$^-$ form). Found for Δ-diastereomer: C, 26.66; H, 6.22; N, 15.56%. Found for Λ-diastereomer: C, 26.69; H, 6.20; N, 15.55%. Calcd for [Co(ox)(en)$_2$](L-Hasp)·3H$_2$O=C$_{10}$H$_{28}$N$_5$O$_{11}$Co: C, 26.50; H, 6.23; N, 15.45%. $\Delta\varepsilon_{523}$=−2.86 and ε_{497}=119.3 mol^{-1} dm^3 cm^{-1} for Δ-diastereomer, and $\Delta\varepsilon_{523}$=+2.85 and ε_{497}=118.7 mol^{-1} dm^3 cm^{-1} for Λ- one.

Measurement. Solubility in water was determined according to the previously reported method.[3] The solid phases were identified by elemental analysis, absorption,

and circular dichroism (CD) spectra. Optical densities were measured with a Hitachi 330 spectrophotometer and CD with a JASCO MOE-1 spectropolarimeter.

Results and Discussion

The solubility data for the binary and ternary systems are given in Tables 1 and 2, respectively.

System containing L-*Hglu*$^-$. The binary solubility curves are shown in Fig. 1. The solubility of *Δ*-diastereomer is very higher than that of *Λ*-one at 5—60 °C. The *Δ*-diastereomer showed an inflection at *ca.* 21.5 °C, where solid phase changes from 5.5-hydrate to 4.5-hydrate. A similar inflection appeared at *ca.* 53.5 °C for *Λ*-diastereomer, corresponding to the transition from 5.5-hydrate to 3.5-hydrate. The ternary isotherm at 15 °C showed one invariant point E near the *Δ*-diastereomer side (Fig. 2). Therefore, when an aqueous solution of pseudoracemic mixture is concentrated at 15 °C, the less soluble *Λ*-diastereomer will be obtained as solid deposit. The maximum yield of optical resolution calculated from the liquid phase composition at point E is 89%,[4] which ranks with those of the most excellent resolving agents such as *Δ*(or *Λ*)-[Co(edta)]$^-$(93%) and hydrogen tartrate (*R,R*)-C$_4$H$_5$O$_6^-$ (79%).[3]

System containing L-*Hasp*$^-$. The binary solubility curves are shown in Fig. 1. The solubility of *Δ*-diastereomer is the highest among three complexes. The curve of pseudoracemate intersects that of *Λ*-diastereomer at *ca.* 19 °C, the solubility of the latter being less than that of the former below this temperature. The ternary isotherm at 25 °C (Fig. 2) showed two invariant points H and I in agreement with the preparative formation of pseudoracemate *Δ*-[Co(ox)(en)$_2$]· *Λ*-[Co(ox)(en)$_2$](L-Hasp)$_2$=*rac*-[Co(ox)(en)$_2$](L-Hasp). The fundamental feature of the ternary isotherm was unaltered at 2 °C in equilibrium conditions. However, certain metastable states, which were at least maintained for several hours, were observed at this temperature. Especially, it is noteworthy that the curve I'K' intersects the racemic line AS, which means that the pseudoracemic mixture is optically resolvable in metastable state at 2 °C.

4) The general equation of resolution yield in ternary system has been given by A. Fuyuhiro (D. Thesis, Univ. of Osaka (1982), p. 95). If the angle between AE and AS in Fig. 2 is θ, the resolution yield is represented as follows: yield(%)=$\{\sin\theta/(\cos\theta/2\sqrt{3}+\sin\theta/2)\}\times 100$.

Immunoassay Using a Metal-complex Compound as a Chemiluminescent Catalyst. IV. The Investigation of a Metal Porphine Complex as a Labeling Reagent

Tadashi HARA,* Motohiro TORIYAMA, Hisayo MIYOSHI, and Shinji SYOGASE
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
(Received May 7, 1984)

Synopsis. Among the metal porphine and phthalocyanine complexes synthesized by the present authors, a iron(III) complex of 5,10,15,20-tetrakis(4-carboxyphenyl)-porphine was found to be most sensitive for the chemiluminescence reaction of luminol-H_2O_2; it was successfully used in the determination of albumin as a protein model, with a detection limit of about 130 pg.

A chemiluminescence complex catalyst immunoassay (CLCCIA), in which a synthesized iron(III) phthalocyanine complex compound, acting as a catalyst in the chemiluminescence(CL) reaction of 5-amino-2,3-dihydro-1,4-phthalazinedione(luminol) hydrogen peroxide(H_2O_2), was used as a labeling reagent, was previously described for practical use by the present authors.[1-3] This method has the advantages of being sensitive and of enabling one to select the desired chemical structure of the labeling reagent[2] since it is based on the use of the catalytic reaction of a synthesized metal-complex compound. In order to make this method very useful as an immunoassay, the preparation of a more sensitive complex compound than a iron(III) phthalocyanine complex compound as a labeling reagent is necessary.

It is well known that the natural substances having a porphine skeleton in their active centers, that is, peroxidase, microperoxidase, hemin, and hematin, act as sensitive catalysts for the CL reaction of luminol-H_2O_2. Several metal porphine complexes with a skeleton similar to those of the above natural substances were, therefore, synthesized by the present authors, and their catalytic activities were compared with each other; our studies included hematin, which had been previously reported[4] to show the highest catalytic activity among the above natural substances. Here, the catalytic activity was compared for a liberated catalyst and a catalyst-albumin conjugate obtained by the carbodiimide method.

Experimental

A metal 5,10,15,20-tetrakis(4-carboxyphenyl)porphine (TCPP) complex was prepared by synthesizing TCPP by Adler's procedure[5] and by reacting it with the desired metal salt under refluxing in an acetic-acid medium.[6] The labeling of human serum albumin(HSA) as a protein model with a metal-complex compound except for iron(III) 1,8,15,22-tetracarboxyphthalocyanine (TCP-Fe(III)) was carried out by the carbodiimide method used by Karube *et al.*[7] Here, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC) or *N*-cyclohexyl-*N'*-(2-morpholinoethyl)carbodiimide-methyl *p*-toluenesulfonate(CMC) as a water-soluble carbodiimide was used and the column charged with TOYOPEARL HW-50 was used for the gel filtration. The labeling of TCP-Fe(III) was carried out as follows: A 5-cm³ phosphate buffer solution(pH 7.2) containing 25 mg of HSA was added to the solution immediately after 5 mg of iron(III) 1,8,15,22-tetrakis (chlorocarbonyl)phthalocyanine had been dissolved in 1 cm³ of dimethyl sulfoxide. The contents were made to react at room temperature for 1 h and then at 4 °C for 18 h. Thereafter, the contents were treated much as in the method used by Karube *et al.*

The catalytic activity was measured by diluting a sample solution with a borate buffer solution(pH 10.2) and by subjecting the diluted solution to the flow-injection analysis apparatus shown in Fig. 1. By the use of the peristaltic pumps (d) in Fig. 1, a 1.0×10^{-3} mol/dm³ luminol solution (pH 10.2) (a), a 7.5×10^{-3} mol/dm³ H_2O_2 solution(b), and a borate buffer solution (pH 10.2) (c) were delivered at the rate of 2.5 cm³/min. A definite volume of the sample solution was taken by means of the sampling loop (200 mm³) (f) and injected into the flow line by operating a six-way cock (e). Then the CL emitted was measured with a photon counter (Hamamatsu TV, C-1230, R-464) (i).

Results and Discussion

It has been established that the salts of Fe^{III}, Co^{II}, and Os^{VIII}, belonging to the eighth-group of the periodic table, and natural substances with a iron porphine skeleton, such as peroxidase, microperoxidase, hemoglobin, hematin, and hemin, show high catalytic activities for the CL reaction of luminol-H_2O_2. Several water-soluble porphine complexes of the eighth-group elements were synthesized, and their catalytic activities were examined. A useful labeling reagent for CLCCIA was required to satisfy the following conditions: 1) the labeling reagent should be soluble in an alkaline solution when the CL of luminol-H_2O_2 gave a high quantum yield, and 2) the labeling reagent should contain a functional group by which the labeling reagent could be covalently bonded to the desired constituent, such as protein, under mild conditions. From these points of view, the TCPP complex was selected as the labeling reagent in the pres-

O: TCPP-Fe(III), ◑: TCPP-Pd(II), ◐: TCPP-Pt(II), and ●: TCP-Fe(II).

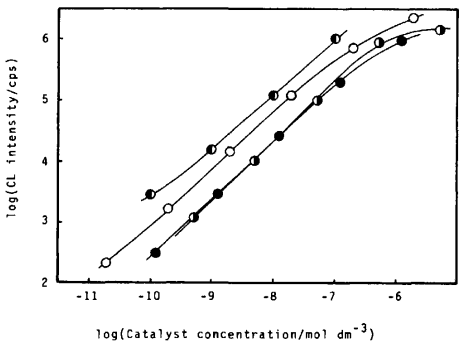

Fig. 3. The catalytic activities of labeled HSA on the basis of catalyst concentration.
Liberated TCPP-Fe(III) (◐), and HSA labeled with TCPP-Fe(III) (O), TCP-Fe(III) (●), and hematin (◑), respectively, by the use of CMC as a carbodiimide.

ent study. Though Co^{II} belonged to the eighth-group, its complexes[1] did not show very high catalytic activity. The catalytic activities of the TCPP complexes of Fe^{III}, Pt^{II}, and Pd^{II}, all belonging to the eighth-group, were examined (Fig. 2). The TCPP-Fe(III) was found to be most sensitive among them; its catalytic activity was higher than that of TCP-Fe(III),[1] which had been previously reported to be most sensitive, and that of hematin,[4] which had been reported to be the most sensitive among the natural-substance catalysts. The TCPP complexes of Mn^{III} and Sn^{IV} other than the eighth-group elements were also synthesized in order to examine their catalytic activities. The catalytic activity of TCPP-Mn(III) was about one-three hundredth that of TCPP-Fe(III), and TCPP-Sn(IV) showed a slight catalytic activity.

HSA as a model protein, was labeled with TCPP-Fe(III), TCP-Fe(III), and hematin, and the catalytic activities of the labeled HSA were examined. Each concentration of the HSA and the catalyst in the labeled HSA was determined by the use of the calibration curves of TCPP-Fe(III) at 414 nm and 280 nm, of TCP-Fe(III) at 637 nm and 280 nm, of hematin at 384 nm and 280 nm, and of HSA at 280 nm, on the assumption that the absorption of each constituent remained unchanged before and after the labeling. The catalytic activities of the labeled HSA are shown in relation to

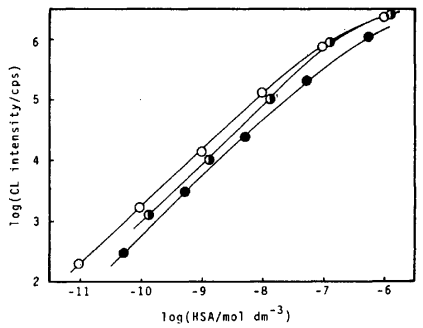

Fig. 4. The catalytic activities of labeled HSA.
HSA labeled with TCPP-Fe(III) (O), TCP-Fe(III) (●), and hematin (◑), respectively, by the use of CMC as a carbodiimide.

the catalyst concentration in Fig. 3. It was concluded from the absorbance measurement that the mole ratio of HSA to TCPP-Fe(III) was 1:3 or 1:2 for the HSA labeled with TCPP-Fe(III) by the use of EDC or CMC as a carbodiimide. The HSA labeled with TCPP-Fe(III) was not so sensitive as the value to be expected from the above mole ratio. As can be seen from Fig. 3, the catalytic activities of a liberated TCPP-Fe(III) and the TCPP-Fe(III) labeled onto HSA were not as similar as TCP-Fe(III) and hematin.

The catalytic activities of TCPP-Fe(III), TCP-Fe(III), and hematin, based on the HSA concentration, were also compared with each other (Fig. 4). The detection limit of the HSA labeled with TCPP-Fe(III) gave the lowest value among them, and a linear calibration curve was obtained at the concentration range of 9.4×10^{-12}—9.4×10^{-8} mol/dm^3-labeled HSA, with a detection limit of about 130 pg HSA. The HSA labeled with TCPP-Fe(III) was about 5.6 times as sensitive as the HSA labeled with TCP-Fe(III), since the detection limit of the latter was about 730 pg; it was also about twice as sensitive as the HSA labeled with hemin reported by Ikariyama *et al.*[8]

It was concluded from the above results that TCPP-Fe(III) was a more sensitive and more excellent labeling reagent for the determination of protein than those reported so far, though the catalytic activity of TCPP-Fe(III) was lowered by the labeling, unlike the case of the other chemiluminescence complex catalysts.

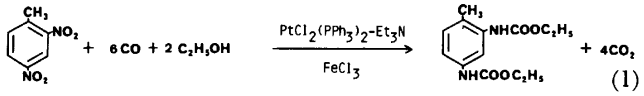
The Platinum Complex-catalyzed Reductive *N*-Carbonylation of Dinitroarenes to the Biscarbamates

Yoshihisa WATANABE,* Yasushi TSUJI, and Ryo TAKEUCHI
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received December 21, 1984)

Synopsis. Dichlorobis(triphenylphosphine) platinum(II) shows good catalytic activity for the reductive *N*-carbonylation of dinitroarenes in ethanol in the presence of a Lewis acid and triethylamine. From 2,4-dinitrotoluene, diethyl 4-methyl-1,3-phenylenebiscarbamate is obtained in 50% yield at 190 °C under carbon monoxide pressure of 60 kg cm^{-2}.

Much attention has been paid to the reductive *N*-carbonylation of dinitroarenes and intensive effort is focused on finding an effective catalyst system.[1] We have recently demonstrated that a homogeneous platinum catalyst system including tertiary amine and a Lewis acid has high catalytic activity for the reductive *N*-carbonylation of mononitroarenes,[2] where ethyl phenylcarbamate derivatives are obtained in high yields in ethanol medium. In the present paper, dinitroarenes such as 2,4-dinitrotoluene, 2,6-dinitrotoluene, and *m*-dinitrobenzene are employed as a substrate (Eq. 1).



(1)

Results and Discussion

Dichlorobis (triphenylphosphine) platinum(II) is effective for the catalytic transformation of 2,4-dinitrotoluene into diethyl 4-methyl-1,3-phenylenebiscarbamate in the presence of tertiary amine and a Lewis acid. The combination of the platinum complex with a Lewis acid, tertiary amine, and triphenylphosphine is essential for the high catalytic activity , as in the previous paper.[2] The effectiveness of the catalyst system is highly affected by the nature of and the ratio between those components.

The most dominant factor is the nature of a Lewis acid (Table 1). Without a Lewis acid, the platinum catalyst system does not show any catalytic activity and dinitroarenes are recovered unchanged. Iron(III) chloride is the most favorable for giving the biscarbamate, diethyl 4-methyl-1,3-phenylenebiscarbamate, in a good yield (Run 1). Different from the previous paper,[2] tin(IV) chloride and aluminum chloride are less effective. The additions of vanadium(V) trichloride oxide or titanium(IV) chloride were also less effective. With iron(II) chloride trihydrate or pentacarbonyliron(0) or molybdenum(V) chloride, the biscarbamate is not obtained.

The catalytic activity is strongly influenced by the amount of the Lewis acid in the catalytic system (Table 2). The yield of the biscarbamate was nearly zero and only 8% with a small amount of iron(III) chloride. In order to maintain the high catalytic activity, more than tenfold excess of the Lewis acid to the platinum complex is required.

The molar ratio of triethylamine to iron(III) chloride is also a major factor determining the catalytic activity (Fig. 1). The yield of the biscarbamate showed a maximum at the molar ratio of 1.8. The biscarbamate was not obtained at all at the molar ratio over 3. Excess triethylamine would coordinate the platinum complex and saturate the active catalyst sites.

The reaction proceeded with reasonable conversion at 180 °C and 190 °C. At lower temperatures, the yield of the biscarbamate is low and cannot be improved by prolonging the reaction time. The reaction completed at 190 °C for 4 h. Elevating the reaction temperature to 200 °C decreased the yield of biscarbamate to 37%. The optimum initial carbon monoxide pressure is 60 kg cm^{-2}. Under both lower and higher pressures the yield of biscarbamate decreased (yield 29% both under 85 and 45 kg cm^{-2}). The reaction was performed with other dinitroarenes. *m*-Dinitrobenzene and 2,6-dinitrotoluene were converted to the corresponding biscarbamate, although the yields were rather low (diethyl 1,3-phenylenebiscarbamate 28%, diethyl 2-methyl-1,3-phenylenebiscarbamate 30%).

a) A mixture of 2, 4-dinitrotoluene(10 mmol), [$PtCl_2(PPh_3)_2$](0.1 mmol; 1 mol% based on 2, 4-dinitrotoluene used), Lewis acid(2.0 mmol), triethylamine(3.6 mmol) and ethanol(20 ml) was stirred under 60 kg cm^{-2} carbon monoxide. b) Product: Diethyl 4-methyl-1, 3-phenylenebiscarbamate. Determined by HPLC based on the amount of 2, 4-dinitrotoluene charged. c) Iron(III) chloride(1.0 mmol), triethylamine(1.8 mmol).

Table 2. The effect of molar ratio of iron(III) chloride to platinum complex[a]

Run	Molar ratio of $[PtCl_2(PPh_3)_2]$ to Iron(III) Chloride	Yield[b]/%
7	1: 2	0
8	1: 5	8
9	1:10	44
3	1:20	44
10	1:40	40

a) 2, 4-Dinitrotoluene(10 mmol), $[PtCl_2(PPh_3)_2]$(0.1 mmol), iron(III) chloride(0.2-4 mmol), triethylamine(0.36-7.2 mmol; fixing $FeCl_3/Et_3N=1/1.8$), EtOH(20 ml) at 180 °C for 4 h under 60 Kg cm^{-2}. b) Product: Diethyl 4-methyl-1, 3-phenylenebiscarbamate. Determined by HPLC based on the amount of 2, 4-dinitrotoluene charged.

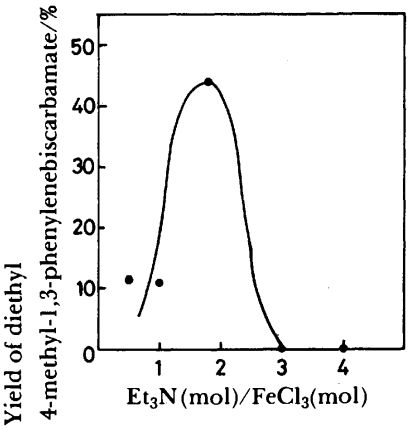

Fig 1. The *N*-Carbonylation of 2,4-Dinitrotoluene. The Effect of the Molar Ratio, $Et_3N/FeCl_3$. 2,4-Dinitrotoluene (10 mmol), $PtCl_2(PPh_3)_2$ (0.1 mmol), $FeCl_3$ (1.0 mmol), triethylamine (0.5—4.0 mmol), EtOH (20 ml) at 180 °C for 4 h under the initial pressure of 60 kg cm^{-2} carbon monoxide. Yields are determined by HPLC based on the amount of 2,4-dinitrotoluene charged.

In the present *N*-carbonylation, the nitrene intermediate would be generated by the deoxygenation of dinitroarene with carbon monoxide, and the carbonylation of the nitrene intermediate will follow (Eq. 2).[2]

$$ArNO_2 \xrightarrow[-CO_2]{+CO} (ArN)(Pt) \xrightarrow{+CO} (ArNCO)(Pt) \xrightarrow{+EtOH} ArNHCOOEt + (Pt) \quad (2)$$

Experimental

General Procedure. A glass liner was set in a 100 ml stainless steel autoclave. The reagents were charged in the following order: Dinitroarene (10 mmol), ethanol (20 ml), triethylamine (0.25 ml, 1.8 mmol), $[PtCl_2(PPh_3)_2]$ (79 mg, 0.1 mmol), and $FeCl_3$ (162 mg, 1.0 mmol). After being sealed and flushed with carbon monoxide, the reactor was pressurized with carbon monoxide to 60 kg cm^{-2}. The autoclave was heated to 190 °C in 20 min and then held at this temperature for 4 h.

Product Isolation. Ethanol was removed from the reaction mixture *in vacuo* at 50 °C. Then, benzene was added to the residue. Aminoarenes were extracted by 60 ml of 10% HClaq three times and the aqueous layer was discharged. Evaporation of benzene afforded the biscarbamate.

Analytical Procedure. The melting points were uncorrected. The HPLC analysis was performed on a Shimadzu LC-5A equipped with a column (μ-Bondapak C_{18}) and $MeOH/H_2O=6/4$ as an eluent. Naphthalene was employed as an internal standard and the yield of the product was determined according to the calibration curve obtained for each sample. The IR spectra were measured on a Hitachi model 215 grating spectrophotometer. The ^{13}C and ^1H-NMR spectra were recorded at 25.05 MHz and 100 MHz respectively with a JEOL JNM FX- 100 spectrometer. Elemental analyses were performed at the Microanalytical Center of Kyoto University. The mass spectra were recorded on a JMS OISG mass spectrometer.

The analytical data of the products are described below. The phenyl carbon resonances in the ^{13}C-NMR spectra were tentatively assigned by calculating their chemical shifts with additive parameters.[4]

Diethyl 4-Methyl-1,3-phenylenebiscarbamate. White crystals, mp 136—138 °C. A Convenient Method for the Preparation of Conjugated Olefins from Allylic Acetates and Aldehydes. Synthesis of Pellitorine

Yuhko TSUKAHARA, Hideki KINOSHITA,* Katsuhiko INOMATA, and Hiroshi KOTAKE
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received March 28, 1984)

Synopsis. A variety of allylic acetates were treated with sodium bromide and triphenylphosphine in the presence of 5 mol% of [Pd(PPh$_3$)$_4$] to give the phosphonium salts, which were converted to the ylids *in situ* and allowed to react with various aldehydes to afford the corresponding conjugated olefins in good yields. Furthermore, this procedure was applied to the synthesis of an insecticidal substance, Pellitorine.

In the previous paper,[1] it was reported that the reaction of allylic acetates with sodium *p*-toluenesulfinate in THF–MeOH catalyzed by [Pd(PPh$_3$)$_4$] gave regiocontrolled allylic sulfones in good yields. On the basis of this finding, we thought that the reaction of allylic acetates with alkali halides such as NaBr and LiI instead of sodium *p*-toluenesulfinate would give the corresponding allylic halides under the same reaction conditions. When geranyl acetate was treated with NaBr in the presence of a catalytic amount of [Pd(PPh$_3$)$_4$] and one equiv of triphenylphosphine, the corresponding phosphonium salt (**1**) was actually isolated.[2]

In this paper, we wish to report an efficient procedure for the preparation of conjugated olefins in one-pot from allylic acetates *via* the formation of the triphenylphosphonium salts (**1**). Thus, to a solution of one equiv of PPh$_3$ and 5 mol% of [Pd(PPh$_3$)$_4$] in dry THF were added a solution of one equiv of cinnamyl acetate in dry THF and a solution of two equiv of NaBr in dry MeOH under N_2. After the reaction mixture was stirred for 1.5 h at room temperature, it was successively treated with 1.2 equiv of BuLi and 1.1 equiv of benzaldehyde at −17 °C and stirred for 4 h at room temperature. The usual work-up gave the desired 1,4-diphenyl-1,3-butadiene (**2a**) in 83% yield.

In a similar manner, various conjugated olefins (**2b—g**) were prepared in good yields as shown in Table.

Next, the present method was applied to the synthesis of Pellitorine (**5**),[3] a crystalline insecticidal substance isolated from *Anacyclus pyrethrum DC.* roots, from the allylic acetate(**4**) prepared by oxidation of (*E*)-*N*-isobutyl-2-butenamide (**3**) and hexanal according to the following scheme. Pellitorine (**5**, 2*E*, 4*E*-) and its 2*E*,4*Z*-isomer were obtained in 31% and 24% yields, respectively. The latter isomer could be converted into Pellitorine (**5**) in a quantitative yield by treatment with a catalytic amount of I_2.

As mentioned above, the present method proved to be a very useful procedure for the preparation of conjugated olefins[4] from easily available acetates.

Experimental

HPLC analyses were performed with a Waters M6000 A instrument using a 30 cm×3.9 mm column (μ-Polasil, particle size-10 μm, detection 254 nm). Thin-layer chromatography (TLC) was performed on Merck's silica gel 60 PF_{254}

(Art. 7749).

Preparation of Conjugated Olefins (2a—g). **2a**: To a solution of PPh_3 (131 mg, 0.5 mmol) and $[Pd(PPh_3)_4]$ (29 mg, 0.025 mmol) in dry THF (1.5 ml) were added a solution of cinnamyl acetate (88 mg, 0.5 mmol) in dry THF (0.5 ml) and a solution of NaBr (103 mg, 1 mmol) in dry MeOH (2 ml) under N_2. After stirring for 1.5 h at room temperature, the reaction mixture was cooled to −17 °C and a hexane solution (*ca.* 15%) of 1.2 equiv of BuLi was added at the temperature. The mixture was stirred for 30 min at room temperature and cooled to −17 °C again. Then, a solution of benzaldehyde (59 mg, 0.55 mmol) in dry THF (0.5 ml) was added. The reaction mixture was gradually warmed and kept at room temperature for 4 h. After quenching the reaction with aq KCN (7 mg, 0.1 mmol), the product was extracted with AcOEt and subjected to preparative TLC (solvent; hexane) to give **2a** consisting of two isomers in 83% yield (86 mg). They were separable with a pre-coated TLC plate (Merck's silica gel $60F_{254}$, Art.5715, solvent; hexane) and their stereochemistry was assigned by comparison of UV spectra and melting point with those reported in literatures. Ratio of the isomers was determined by HPLC analysis of the crude product (solvent; hexane, flow rate 1 ml/min). 1*E*,3*E*-isomer: Mp 144—149 °C (lit, 147—149 °C).[5] UV (hexane) 329 nm (lit, 328 nm).[6] 1*E*,3*Z*-isomer: An oil; IR (neat) 980, 745, 720, 692, and 680 cm^{-1}. The 1*E*,3*Z*-isomer was readily converted to the 1*E*,3*E*-isomer with the aid of a catalytic amount of I_2 in benzene-ether.

2b: Mp 177.0—178.5 °C (lit, 172 °C).[7]

2c: Ratio of the isomers was determined by HPLC analysis using "iso-octane" as eluent. The stereochemistry of the isomers was assigned by UV spectra comparing with the reported ones.[8]

2d: An oil. The stereochemistry and ratio of the isomers were determined by 100 MHz ^{1}H-NMR spectrum. 1*E*,3*E*-isomer: NMR ($CDCl_3$) δ=1.05 (t, *J*=7.4 Hz, 3H), 2.17 (m, 2H), 5.85 (dt, *J*=6.3, 14.8 Hz, 1H), 6.18 (dd, *J*=9.4, 14.8 Hz, 1H), 6.42 (d, *J*=15.4 Hz, 1H), 6.76 (dd, *J*=9.4, 15.4 Hz, 1H), and 7.10—7.45 (m, 5H). 1*E*,3*Z*-isomer: NMR ($CDCl_3$) δ=1.05 (t, *J*=7.4 Hz, 3H), 2.17 (m, 2H), 5.54 (dt, *J*=7.4, 10.5 Hz, 1H), 5.98—6.25 (m, 1H), 6.42 (d, *J*=15.4 Hz, 1H), 6.76 (dd, *J*=9.4, 15.4 Hz, 1H), and 7.10—7.45 (m, 5H). MS (of the mixture) *m/z* 158 (M^+) and 129 ($M^+-C_2H_5$). IR (of the mixture, neat) 980 736, and 680 cm^{-1}.

2e: An oil. Ratio of the isomers was determined by HPLC analysis (solvent; "iso-octane." flow rate 0.5 ml/min). 1*E*,3*E*-isomer: IR (neat) 951, 740, and 680 cm^{-1}.[2] 1*Z*,3*E*-isomer: IR (neat) 790 and 690 cm^{-1}; NMR ($CDCl_3$) δ=1.60 (s, 3H), 1.68 (s, 3H), 1.81 (s, 3H), 2.00—2.30 (m, 4H), 5.04 (br, 1H), and 5.83—7.57 (m, 8H). MS (of the mixture) *m/z* 226 (M^+) and 157 ($M^+-CH_2CH{=}C(CH_3)_2$).

2f: An oil. Ratio of the isomers was determined by GLC analysis (Shimazu GC 6A, 10% Silicone SE-30 on 60-80 mesh Shimalite W, 210 °C). The mixture was separated by preparative TLC (30% silver nitrate-impregnated silica gel). 6*E*,8*E*,10*E*-isomer: IR (neat) 986 and 951 cm^{-1}.[2] 6*E*,8*Z*,10*E*-isomer: IR (neat) 760 cm^{-1}. NMR (of the mixture, $CDCl_3$) δ=1.58 (s, 6H), 1.65 (s, 6H), 1.73 (s, 6H), 1.93—2.30 (m, 8H), 5.05 (br, 2H), and 5.07—6.50 (m, 4H).

2g: An oil. Determination of the stereochemistry and ratio of the isomers were performed as described for **2e**. 1*E*-isomer: IR (neat) 980 and 950 cm^{-1}.[3] 1*Z*-isomer: IR (neat) 783, 740, and 686 cm^{-1}. MS (of the mixture) *m/z* 158 (M^+) and 143 (M^+-CH_3). NMR (of the mixture, $CDCl_3$) δ=1.80 (s, 6H), and 5.72—7.63 (m, 8H).

(E)-N-Isobutyl-2-butenamide (3). To a solution of triethylamine (1.518 g, 15 mmol) and isobutylamine (1.646 g, 22.5 mmol) in dry CH_2Cl_2 (20 ml) was added dropwise a solution of crotonoyl chloride (1.568 g, 15 mmol) in dry CH_2Cl_2 (10 ml) at 0 °C under N_2. Usual work-up gave the desired product which was recrystallized from hexane. Yield, 2.063 g (97%). Mp 70.5—72.0 °C. IR (KBr) 3240, 2960, 1660, 1615, 1550, 1230, and 978 cm^{-1}. NMR ($CDCl_3$) δ=0.92 (d, *J*=6.5 Hz, 6H), 1.47—2.26 (m, 1H), 1.83 (dd, *J*=2.0, 7.0 Hz, 3H), 3.13 (dd, *J*=6.0, 6.0 Hz, 2H), 5.87 (dd, *J*=2.0, 15.0 Hz, 1H), 6.14 (br, 1H), and 6.81 (dq, *J*=7.0, 15.0 Hz, 1H). Found: C, 67.78; H, 10.89; N, 9.74%. Calcd for $C_8H_{15}NO$: C, 68.04; H, 10.71; N, 9.92%.

(E)-Isobutyl-4-acetoxy-2-butenamide (4). A mixture of **3** (565 mg, 4 mmol), acetic anhydride (449 mg, 4.4 mmol), water (73 mg, 4 mmol), and acetic acid (5 g, 83 mmol) was refluxed for 75 min under N_2. Selenium(IV) oxide (533 mg, 4.8 mmol) was added to it by portions. The mixture was refluxed for about 10 h and worked up in the usual way. The product was isolated by preparative TLC (solvent; hexane:AcOEt= 1:1 v/v). Yield, 120 mg (15%). IR (neat) 3293, 2960, 1740, 1670, 1630, 1550, 1270, 1235, and 980 cm^{-1}; NMR ($CDCl_3$) δ=0.92 (d, *J*=6.5 Hz, 6H), 1.47—2.14 (m, 1H), 2.07 (s, 3H), 3.11 (dd, *J*=6.0, 6.0 Hz, 2H), 4.65 (dd, *J*=1.5, 5.0 Hz, 2H), 6.06 (dd, *J*=2.0, 15.4 Hz, 1H), 6.12 (br, 1H), and 6.73 (dt, *J*=5.0, 15.4 Hz, 1H); CI-MS *m/z* 200 (M^++1).

Preparation of Pellitorine (5). To a solution of PPh_3 (110 mg, 0.42 mmol) and $[Pd(PPh_3)_4]$ (42 mg, 0.036 mmol) in dry THF (1.5 ml) were added a solution of **4** (71 mg, 0.36 mmol) in dry MeOH (3 ml) and a solution of NaBr (86 mg, 0.84 mmol) in dry MeOH (1.5 ml) under N_2. The mixture was refluxed for 4 h and cooled to −17 °C. Then, a hexane solution of BuLi (0.396 mmol) was added with vigorous stirring followed by the addition of a solution of hexanal (40 mg, 0.396 mmol) in dry THF (1 ml). The reaction mixture was gradually warmed up to room temperature and worked up in the usual way. Two fractions were obtained by preparative TLC (Merck's Aluminum oxide 60 PF_{254}, Type E, solvent; benzene:AcOEt=8:1 v/v). From the first fraction of lower R_f value, Pellitorine (**5**) was obtained in 31% yield (25 mg). Its Mp, IR, and NMR data were identical with those of the reported ones.[9] Mp 89—90 °C (lit, 89—90 °C). 4*Z*-isomer was obtained from the second fraction of higher R_f value as an oil. It could be converted to Pellitorine in a quantitative yield by treatment with a catalytic amount of I_2 in benzene for 1 h at room temperature. Yield, 19 mg (24%, an oil); IR (neat) 3250, 1635, 1598, 1528, 1262, 982, and 858 cm^{-1}; NMR ($CDCl_3$) δ=0.66—1.10 (t, 3H), 0.92 (d, *J*=6.0 Hz, 6H), 1.10—2.53 (m, 9H), 3.12 (dd, *J*=6.0, 6.0 Hz, 2H), 5.37—6.27 (m, 4H), and 7.27—7.70 (m, 1H); MS *m/z* 223 (M^+).

(Received March 29, 1984)

Synopsis. The reaction of pyrazine 1-oxide with phosphoryl chloride gave a 49% yield of 2-chloropyrazine and a small amount of 2-aminopyrazine. The precursor of aminopyrazine was elucidated to be a 1-(2-pyrazinyl)-pyrazinium salt. The orientation of substitution in the formation of the salt was determined by reaction of deuterium labelled pyrazine *N*-oxides with phosphoryl chloride.

As part of our continuing program directed toward the reaction of pyrazine *N*-oxides,[1] we now report a novel formation of 2-aminopyrazine (**3**) from the reaction of pyrazine 1-oxide (**1**) with phosphoryl chloride.

It has been known that treatment of pyrazine 1-oxide **1** with two equivalents of phosphoryl chloride at 55 °C followed by brief reflux gives a 25% yield of 2-chloropyrazine (**2**).[2] The yield of **2**, however, was increased to 49% when **1** was treated in a large excess of the reagent at 70 °C for 2 h. Surprisingly, a small amount of 2-aminopyrazine (**3**) was isolated on hydrolytic workup of the reaction mixture. The precursor of **3** was elucidated to be a 1-(2-pyrazinyl) pyrazinium salt (**4**) from the ^{1}H NMR spectrum of the reaction mixture prior to hydrolysis (see Fig.). The doublet of doublets having the coupling constants of 4.5 and 1.5 Hz at δ 9.47 and 8.76, which correspond to C-2,6 and C-3,5 protons of the pyrazinium moeity of **4**, respectively, are characteristic for those of pyrazine 1-oxide **1** or 1-methylpyrazinium iodide.[3] Presumably the counter ion of **4** is the chloride ion but it was not established because of difficult separation of **4** from the reaction mixture. Thus, **3** was formed by decomposition of the pyrazinium group of the salt **4** under hydrolytic conditions. In addition, the NMR spectrum of the reaction mixture indicated that **2** and **4** were formed in 50% yields each. These results are illustrated in Scheme 1.

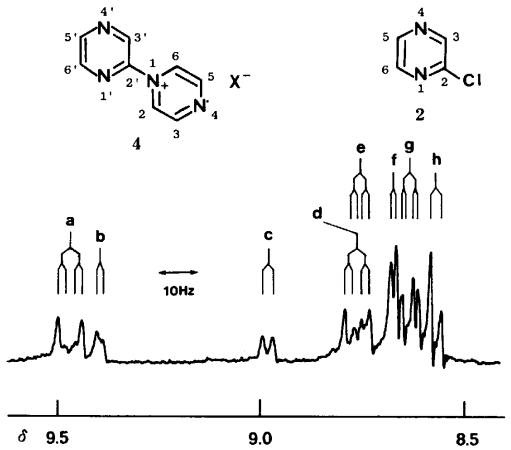

Fig. 1. The ^{1}H NMR spectrum (100 MHz) of reaction mixture formed by treatment of **1** with phosphoryl chloride at 70 °C for 2 h. Assignment of signals: a, δ 9.47, H-3,5 of **4**; b, 9.40, H-3′ of **4**; c, 8.98, H-5′ of **4**; d, 8.76, H-2,6 of **4**; e, 8.75, H-6′ of **4**; f, 8.68, H-3 of **2**; g, 8.63, H-6 of **2**; h, 8.57, H-5 of **2**. The counter ion of **4**, X^-, is chloride ion or an unidentified ion.

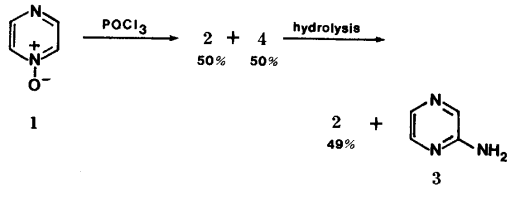
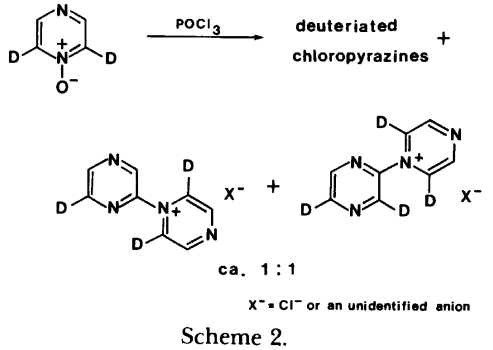
The pyrazinium salt **4** having the counter ion of $P_2O_3Cl_2^-$, which would seem to consist of several complex hydrolysates of phosphoryl chloride,[4] was isolated from the reaction mixture of **1** with phosphoryl chloride at room tempeature for 30 min. The isolated salt **4** gave satisfactory analysis for C, H, and N, and ^{1}H and ^{13}C NMR spectra. The other products of the reaction at room temperature were a 13% yield of **2**, and an approximate 30% yield of the hydrochloride of **1**.

The direction of substitution in formation of the salt **4** was significantly demonstrated by reactions of deuterium labelled *N*-oxides, pyrazine-2,6-d_2 and -3,5-d_2 1-oxides, which were obtained by treatment of the corresponding dichloropyrazine 1-oxides with deuterium. The NMR spectra of those reaction mixtures showed that the substitution reaction took place at carbons both α and β to the *N*-oxide function, and the pyrazinium nitrogen atom was derived from the nitrogen atom originally oxidized in another molecule of **1**. For example, pyrazine-2,6-d_2 1-oxide gave a pair of isomers (*ca.* 1:1) of the salts as shown in Scheme 2.

1-(2-Pyridyl)pyridinium salts have been prepared by treatment of pyridine 1-oxide with tosyl chloride in pyridine, and the hydrolysis of these salts gives aminopyridines.[5] The formation of the salt is believed to involve the nucleophilic attack of pyridine on (1-pyridinio) tosylate. The regiospecificity of the pyrazinium nitrogen of **4**, however, rules out the mechanism in which pyrazine is formed by deoxygena-



Scheme 1.



Scheme 2.

tion of the *N*-oxide **1** with phosphoryl chloride. In addition, the basicity (pK_a 0.65)[6] of the nitrogen in pyrazine is not enough to bring about the nucleophilic attack of the nitrogen atom on pyrazine *N*-phosphorodichloridate which initially formed, or chloropyrazine **2**. Actually, no incorporation of unlabelled pyrazine was observed when the reaction of deuteriopyrazine *N*-oxide was conducted in the presence of unlabelled pyrazine. We have not yet determined the mechanism which accounts for the observed regiochemistry but now the work is in progress.

Experimental

Materials. Phosphoryl chloride was used after being distilled twice at 106—107°C. Pyrazine 1-oxide (**1**) was prepared according to the procedure of Koelsch and Gumprecht.[7] The crude product was extracted with hot benzene, and the solution was passed through a column of 100/200 Florisil eluted with chloroform to remove a small amount of pyrazine 1,4-dioxide. Further purifications were carried out by sublimation at *ca.* 100°C/1 Pa and recrystallization from benzene to give **1** of mp 113—114°C (lit, 113—114°C;[7] ^{1}H NMR ($CDCl_3$): δ=8.50 (2H, dd, J=3.4 and 1.6 Hz), 8.17 (2H, dd). Deuterium labelled pyrazine 1-oxides were prepared by replacement of the corresponding dichloropyrazine *N*-oxides[8,9] (0.01 mol) in acetonitrile (50 ml) with deuterium (99.5 atom% D, 1.1 equivalents) in the presence of 5% palladium on carbon (0.1 g/1.0 g) and triethylamine (1.05 equivalents) under atmospheric pressure at 20°C. The mixture was filtered and evaporated to dryness *in vacuo*. The residue was worked up by our earlier procedure[10] to give 60—70% of the labelled *N*-oxide, which was purified by sublimation at *ca.* 100°C/1 Pa. Isotopic purity was determined by ^{1}H NMR spectrum to be 80%d_2 and 95%d_2 for pyrazine-2,6-d_2 and -3,5-d_2 1-oxides, respectively. The starting material for pyrazine-3,5-d_2 1-oxide, 3,5-dichloropyrazine 1-oxide, was prepared by N-oxidation of 2,6-dichloropyrazine with peracetic acid in acetic acid but the yield was very low (1.2—4%).[8,9] We found that the *N*-oxide was obtained in 64% yield by treatment of the dichloropyrazine with *m*-chloroperbenzoic acid (1.2 equivalents) in chloroform (reflux, 24 h).

Reaction of 1 with Phosphoryl Chloride. At 70°C for 2 h: A mixture of **1** (0.480 g, 5.0 mmol) in 9.0 ml of phosphoryl chloride was stirred and heated at 70°C for 2 h. After cooling to room temperature, the solution was poured into ice-water and basified at pH 9 with 30% aqueous sodium hydroxide. The solution was extracted with four 10-ml portions of chloroform, and the extracts were washed with two 20-ml portions of water and dried over magnesium sulfate. The yield of **2** was determined by GLC analysis of the chloroform extract.[11] The aqueous layer and washings were further basified at pH 10 with sodium carbonate and evaporated to dryness *in vacuo*. The residue was sublimed at 100°C/1 Pa to give 0.026 g (11%) of **3**, mp 114—116°C. This compound was identified by comparison with the IR and NMR spectra of the authentic sample, mp 119—120°C, purchased from Aldrich Chem. Co.

At Room Temperature: A mixture of **1** (0.480 g, 5.0 mmol) in 9.0 ml of phosphoryl chloride was stirred at room temperature for 30 min, and then 20 ml of dry chloroform was added to the mixture. Insoluble material was collected by filtration and the filtrate was worked up as described. The insoluble material was dried at room temperature *in vacuo* and triturated in dry nitromethane. Insoluble material (hydrochloride of **1**, 0.2 g, 30%; Found: C, 35.73; H, 3.67; N, 21.13; Cl, 26.97%. Calcd for $C_4H_5N_2OCl$: C, 36.24; H, 3.80; N, 21.14; Cl,26.75%) was collected by filtration, and dry carbon tetrachloride was added to the filtrate to give 0.44 g of **4**. Several purifications in the predescribed fashion gave an unstable solid of **4**, mp 126—128°C (decomp); IR (KBr): 1606 cm^{-1} (P=O); ^{1}H NMR (nitromethane-d_3): δ=9.51 (2H, dd, J=4.5 and 1.5 Hz), 9.41 (1H, d, J=1.5 Hz), 9.02 (1H, d, J=2.6 Hz), 8.84 (2H, dd, J=4.5 and 1.5 Hz), 8.80 (1H, dd, J=2.6 and 1.5 Hz); ^{13}C NMR (nitromethane-d_3): 149.5, 145.2, 141.4 (C-3′, 4′, 5′), 147.3 (C-2′), 139.0, 138.7 (C-2,6 and C-3,5); Found: C, 28.30; H, 2.38; N, 16.69; Cl, 19.46%. Calcd for $C_8H_7N_4P_2O_3Cl_2$: C, 28.26; H, 2.08; N, 16.48; Cl, 20.85%.

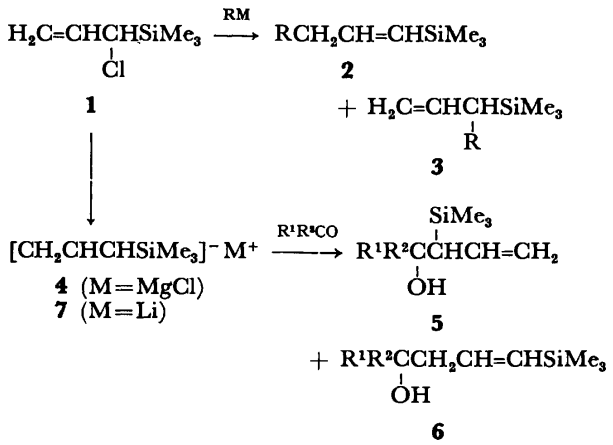
Synthesis and Reactions of 1-(Trimethylsilyl)allyl Chloride[1]

Nobujiro SHIMIZU,* Fumihiro SHIBATA, and Yuho TSUNO
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
(Received April 13, 1984)

Synopsis. 1-(Trimethylsilyl)allyl chloride prepared conveniently from 1,3-dichloropropene reacted smoothly with organocopper compounds yielding terminal alkenylsilanes, while its Grignard reactions with carbonyl compounds gave the corresponding alcohols with the regioselection depending sensitively on substrates.

Silylated allyl halides are useful synthetic intermediates.[2] 3-Silylallyl halides are obtainable from allylsilanes or 3-silylallyl alcohols[3,4] but no practical method is so far available for 1-silylallyl halides, although 3-chloro-3-(trimethylsilyl)allyltriphenyllead was reported to yield 1-(trimethylsilyl)allyl chloride (**1**) as a minor product on treating with butyllithium followed by hydrolysis.[5,6] We here describe a convenient route to **1** and several reactions of this material.

1,3-Dichloropropene reacted with chlorotrimethylsilane on mixing in the presence of magnesium at room temperature in a THF/ether (1:1) solution to give **1** in 40% yield.[7] The product contained a small amount of 1-chloro-3-trimethylsilylpropene as an impurity which was difficult to be removed.[8]



Treatment of **1** with organocopper compounds led to the regioselective γ-alkylation affording terminal alkenylsilanes **2** (**2**/**3**>97/3 in most cases) in good yields. The results are given in Table 1. Stereochemistry of the product **2** was dependent on the organometallic species involved. For example, lithium dibutylcuprate(I) reacted with **1** to give *trans*-1-trimethylsilylheptene predominantly, whereas butylcopper yielded the *cis*-isomer as the major product. In the alkylation with Grignard reagents (RMgX) in the presence of a catalytic amount of copper(I) iodide, *cis*-products significantly increased when RMgX was slowly added to a mixture of **1** and CuI instead of the addition of **1** to an admixture of RMgX and CuI. Probably, RCu is involved as a reactive species under the former conditions; a cuprate(I) may be operative under the latter conditions.

A Grignard reagent **4** prepared from **1** added regioselectively to aldehydes to give the corresponding α-alcohols **5** together with a small amount of regioisomeric γ-alcohols **6**. Low reaction temperature favored the formation of **5** and so did THF as compared to ether as solvent. In contrast, the reagent **4** reacted with ketones yielding **6** exclusively irrespective of the reaction conditions, as shown in Table 2. The silylated carbon terminus of the species **4** is probably more electronegative than is the unsubstituted CH_2-terminus; so electronically a carbonyl group would preferentially attack the former site, as is indeed observed for aldehydes. A marked change in the regioselectivity for ketones presumably arises from the steric hindrance around a carbonyl group. The regioselection also depends on a counter cation of the allyl anion. Thus, the present results contrast with the fact that a related species **7** reacts with both aldehydes and ketones to give **6** as the sole product.[9] This is probably associated with the difference in the ionic character of a carbon-metal bond.

TABLE 1. REACTIONS OF **1** WITH ORGANOMETALLIC REAGENTS[a]

Reagent	Yield/% of **4**[f]	Isomer ratio (*Z*)/(*E*)
n-BuMgBr/CuI (10 mol%)	83	0.72[i], 0.43[j]

Experimental

NMR spectra were determined in carbon tetrachloride solutions with a Hitachi R-600 spectrometer and IR spectra were recorded on a Hitachi 260-10 spectrophotometer.

1-(Trimethylsilyl)allyl Chloride (1). A mixture of 1,3-dichloropropene (Tokyo Chemical Industry, 43 g, 0.39 mol), chlorotrimethylsilane (42 g, 0.39 mol), and 1,2-dibromoethane (0.1 cm^3) was added to a stirred mixture of magnesium (13 g) and chlorotrimethylsilane (20 g) in THF/ether (1:1) (400 cm^3) over a period of 4 h at room temperature. The mixture was stirred for further 4h at room temperature and quenched with a sodium hydrogencarbonate solution. Usual workup gave a colorless oil (23 g), bp 73—76 °C (100 Torr: 1 Torr=133.3 Pa), which was a mixture of **1** and 1-chloro-3-trimethylsilylpropene in the ratio 93:7. The spectral data for these two compounds were superimposable with those reported.[5,10]

Reactions of 1 with Organometallic Reagents. The following example is representative.

Butylmagnesium bromide (16 mmol) in THF (20 cm^3) was added to a mixture of **1** (0.79 g, 5.3 mmol), copper(I) iodide (0.3 g, 1.5 mmol), and ethylbenzene (50 mg, as an internal standard) in THF (5 cm^3) over a period of 15 min at 0 °C. Aqueous workup of the mixture gave 1.01 g of 1-trimethylsilylheptene (*E*/*Z*=1.08) (37%; 84% based on GLC), bp 90—97 °C (47 Torr) (Found: C, 70.50; H, 13.06%). An analytical sample of each isomer was obtained by GLC. (*E*): IR 1620 (C=C) cm^{-1}; NMR δ=0.03 (9H, s), 0.7—1.6 (9H, m), 1.8—2.3 (2H, m), 5.48 (1H, d, *J*=17 Hz), 5.7—6.2 (1H, m). (*Z*): IR 1610 cm^{-1}; NMR δ=0.09 (9H, s), 0.7—1.6 (9H, m), 1.75—2.35 (2H, m), 5.35 (1H, d, *J*=13 Hz), 6.25 (1H, d of t, *J*=13 and 6 Hz).

Similarly, the following alkenylsilanes (RCH_2CH=$CHSiMe_3$) were prepared and characterized. R=*t*-Bu (*E*/*Z*=1.6), bp 100—107 °C (135 Torr) (Found: C, 70.84; H, 13.02%): NMR (Signals for the (*Z*)-isomer were shown in italics.) δ= 0.03 and *0.10* ($SiMe_3$), *5.46* (d, *J*=14 Hz) and 5.55 (d, *J*=18 Hz) (=$CHSiMe_3$). R=*c*-C_6H_{11} (*E*/*Z*=1.3), bp 102—107 °C (11 Torr): NMR δ=0.03 and *0.08* ($SiMe_3$), *5.37* (d, *J*=13 Hz) and 5.46 (d, *J*=18 Hz) (=$CHSiMe_3$). R=CH_2CN (*E*/*Z*=1.3), bp 134—136 °C (82 Torr) (Found: C, 62.50; H, 9.85; N, 9.01%): NMR δ=0.08 and *0.15* ($SiMe_3$), *5.66* (d, *J*=14 Hz) and 5.4—6.1 (complicated due to coalescence of the two olefinic protons) (=$CHSiMe_3$). R=Ph (*E*/*Z*=0.7), bp 95—99 °C (25 Torr): NMR δ=0.05 and *0.17* ($SiMe_3$), *5.55* (d, *J*=13 Hz) and 5.60 (d, *J*= 16 Hz) (=$CHSiMe_3$). These alkenylsilanes showed an IR band (C=C) near 1605 (for *Z*-isomer) or near 1620 cm^{-1} (for *E*-isomer). R=PhCOCHEt: IR 1680 and 1620 cm^{-1}; NMR δ=−0.04 (9H, s), 0.87 (3H, t), 1.7 (2H, m), 2.4 (2H, m), 3.37 (1H, m), 5.4—6.1 (2H, m), 7.3—8.0 (5H, m)

Reactions of 1-(Trimethylsilyl)allylmagnesium Chloride (4) with Carbonyl Compounds. The Grignard reagent **4** prepared from **1** (0.4 g, 2.7 mmol) in ether (20 cm^3) was added to a solution of isobutyraldehyde (240 mg) and decane (54 mg, internal standard) in ether (10 cm^3) at 0 °C. Usual workup gave 127 mg of two isomeric alcohols **5** and **6** (R^1=*i*-Pr, R^2=H) (76:24), bp 95—96 °C (41 Torr). Each alcohol was isolated by GLC. **5**: IR 3500, 1635 cm^{-1}; NMR δ=0.02 (9H, s), 0.7—1.0 (6H, m), 3.1—3.5 (1H, m), 4.6—5.1 (2H, m), 5.5—6.2 (1H, m) (Found: C, 64.04; H, 11.87%). **6**: IR 3410, 1625 cm^{-1}; NMR δ=0.05 (9H, s), 0.88 (6H, d, *J*=6 Hz), 2.20 (2H, m), 3.30 (1H, m), 5.64 (1H, d, *J*=18 Hz), 5.6—6.4 (1H, m).

The following alcohols were also characterized. **5** (R^1=Ph, R^2=H): IR 3400, 1620 cm^{-1}; NMR δ=−0.02 (9H, s), 1.7 (1H, broad s), 1.88 (1H, d of d, *J*=9 and 6 Hz), 4.2—6.2 (3H, m), 7.2 (5H, s). **6** (R^1=Ph, R^2=Me): IR 3450, 1620 cm^{-1}; NMR δ=0.09 (9H, s), 1.7 (1H, s), 2.55 (2H, m), 5.6—5.9 (2H, m), 7.1—7.5 (5H, m) (Found: C, 71.49; H, 9.47%).

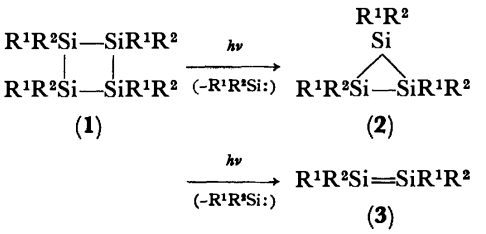
(Received May 16, 1984)

Synopsis. Photolyses of a series of octaalkylcyclotetrasilanes (**1**) in a hydrocarbon solvent successively afforded hexaalkylcyclotrisilanes (**2**) and tetraalkyldisilenes (**3**). Compounds **2** and **3** were found to exhibit their absorption bands corresponding to the lowest energy transitions at λ_{max} 300—330 and 390—440 nm, respectively.

Recently we succeeded to isolate the first peralkylcyclotrisilane, hexaneopentylcyclotrisilane $[(Bu^tCH_2)_2Si]_3$ which gave on photolysis the first peralkyldisilene, tetraneopentyldisilene $(Bu^tCH_2)_2Si{=}Si(CH_2Bu^t)_2$.[1,2] It was found that the both Si_3 and Si=Si frameworks behave as chromophores *per se*, showing their longest-wavelength absorption maxima at λ_{max} 310 and 400 nm, respectively. Further, it was also demonstrated in our subsequent work that irradiation of octaisopropylcyclotetrasilane $[Pr^i_2Si]_4$ successively yielded hexaisopropylcyclotrisilane $[Pr^i_2Si]_3$ (λ_{max} 300—330 and tetraisopropyldisilene $(Pr^i_2Si{=}SiPr^i_2)$ (λ_{max} 400 nm).[3] Shortly after our publication,[1] Masamune and coworkers reported that photolysis of 5,6-benzo-2,2,3,3-tetra-*t*-butyl-2,3-disilabicyclo[2.2.2]octa-5,7-diene leads to the formation of tetra-*t*-butyl-disilene $(Bu^t_2Si{=}SiBu^t_2)$ (λ_{max} 433 nm),[4] and also that hexakis(1-ethylpropyl)cyclotrisilane $[(Et_2CH)_2Si]_3$ (λ_{max} 328 nm) undergoes photolysis to furnish the corresponding peralkyldisilene (λ_{max} 390 nm).[5] This note describes a photochemical reaction of peralkylcyclotetrasilanes $[R^1R^2Si]_4$ having various alkyl groups other than isopropyl group in order to observe spectrophotometric properties of cyclotrisilane (Si_3) and disilene (Si=Si) frameworks.

Photolyses of peralkylcyclotetrasilanes (**1a—1e**) were carried out by using a cyclohexane solution in an evacuated UV cell, as shown previously.[3] In general, upon irradiation (254 nm) at room temperature, the longest-wavelength absorption band (290—310 nm) of a starting cyclotetrasilane diminished rapidly and a new intense band appeared at λ 300—330 nm. The intensity of the band increased and attained the highest value. This band began to diminish and instead a new weak band at λ 390—400 nm appeared. The colorless solution turned to yellow and the new band became more intense. On further irradiation, the both bands completely dissipated and the solution became colorless again, showing an absorption band in a shorter wavelength region (<275 nm). This spectral change during the irradiation was similar to that of octaisopropylcyclotetrasilane.[3] Thus, it is clearly demonstrated that the two absorption maxima at λ 300—330 nm and 390—400 nm regions in the present cases are also due to peralkylcyclotrisilanes $[R^1R^2Si]_3$ (**2a—2e**) and peralkyldisilenes $[R^1R^2Si{=}SiR^1R^2]$ (**3a—3e**), respectively. The absorption bands observed for these cyclotrisilanes and disilenes, together with the data reported by Masamune and coworkers,[4,5] are summarized in Table 1.



a: $R^1{=}Bu^t$, $R^2{=}Me$ **b**: $R^1{=}Bu^t$, $R^2{=}Pr^n$
c: $R^1{=}R^2{=}Bu^s$ **d**: $R^1{=}R^2{=}Bu^t$
e: $R^1{=}R^2{=}Me_3SiCH_2$

The absorption wavelength for tetra-*t*-butyldisilene[4] in Table 1 is longer than those for the other disilenes and comparable with those for peraryldisilenes (420—440 nm).[6] Masamune *et al.* interpreted this red shift in terms of the molecular geometry for the former disilene and also suggested that the four quaternary carbon atoms of the bulky substituents may not attain coplanality due to steric repulsion.[4]

Our previous observation that peralkylcyclotetrasilanes undergo photolysis to yield successively cyclotrisilanes and disilenes with extrusion of dialkylsilanediyls (eqn) was further confirmed in the present study.

TABLE 1. SPECTRAL BEHAVIORS OF CYCLOTRISILANES AND DISILENES (ABSORPTION BANDS CORRESPONDING TO LOWEST ENERGY TRANSITIONS)

Experimental

Melting points are uncorrected. UV spectra were obtained by using a Hitachi 200-100 spectrometer. IR spectra were recorded on a JASCO A-102 spectrometer. NMR spectra were recorded in $CDCl_3$ at 400 MHz for ^1H NMR and 22.6 MHz for ^{13}C NMR by using a JEOL JNM FX-400FT and a Hitachi R-90H FT spectrometer, respectively. MS spectral analyses were conducted by using a JEOL JMS-07 spectrometer.

Materials. Octaalkylcyclotetrasilanes $[R^1R^2Si]_4$ ($R^1=R^2=Pr^i$;[7] $R^1=R^2=Bu^i$;[7] $R^1=R^2=Bu^s$; $R^1={}^t$Bu, $R^2=$Me;[7,8] $R^1=Bu^t$, $R^2=Pr^n$[7]) were prepared by the method described in the literatures.

$[(Me_3SiCH_2)_2Si]_4$: Bis(trimethylsilylmethyl)dichlorosilane $[(Me_3SiCH_2)_2SiCl_2]$ (bp 110—130 °C/55 Torr(1 Torr≈133.322 Pa)) (2.74 g, 10 mmol) and lithium (0.16 g, 23 mg-atom) in THF (20 ml; anhydrous and oxygen-free) was allowed, under Ar, to react with magnetic stirring at room temperature for 3 h, during which time the mixture was dark-brown in color and at the end of this time, the starting chlorosilane was consumed completely (by GLC analyses). After addition of cyclohexane (10 ml), the resulting light-yellow mixture gave on standing a yellow viscous liquid containing crystalline solid. Upon trituration with a small amount of hot ethanol, the crystalline solid was obtained, which was recrystallized from ethanol to give colorless fine needles of octakis(trimethylsilylmethyl)cyclotetrasilane $[(Me_3SiCH_2)_2Si]_4$; 0.25 g (12%), mp 290—301 °C (sealded capillary); UV (cyclohexane), λ_{max} 308 (ε 260), 263 sh (1800), and 223 nm (31000); ^1H NMR ($CDCl_3$) δ=0.106 (s, 16H, CH_2) and 0.094 (s, 72H, CH_3); ^{13}C NMR ($CDCl_3$) δ=2.47 ($\underline{C}H_3$, q) and 1.25 ($\underline{C}H_2$ t); IR (KBr pellet) 2960 s, 2900 m, 1440 m, 1400 w, 1350 w, 1242 vs (SiMe), 1043 sh, 1038 s, 990 w, 845 s, 770 s, 746 s, and 683 m cm^{-1}; MS (23 eV) *m/z* 810 M^+ (21), 289 (5), 217 (21), 201 $[(Me_3SiCH_2)_2\text{-}1]^+$ (100), 145 (19), and 73 $[Me_3Si]^+$ (14). Found; C, 47.87; H, 11.41%. Calcd for $C_{32}H_{88}Si_{12}$: C, 47.45; H, 10.95%.

$[Bu^tPr^nSi]_4$: UV (cyclohexane) λ_{max} 294 (ε 370), 257 sh (2600), and 217 nm (16900).

Photolyses of $[R^1R^2Si]_4$ giving $[R^1R^2Si]_3$ and $R^1R^2Si{=}SiR^1R^2$. All the photolyses of peralkylcyclotetrasilanes were performed by a similar manner to that for octaisopropylcyclotetrasilane $[Pr^i_2Si]_4$.[3]

We are grateful to Mr. M. Yanagisawa and Ms. K. Hiraizumi of the National Chemical Laboratory for Industry for the measurements of the high-resolution ^1H NMR spectra.

N-Allylation of Imides Catalyzed by Palladium(0)

Yoshio INOUE,* Masaaki TAGUCHI, Masanori TOYOFUKU, and Harukichi HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aoba, Aramaki, Sendai 980
(Received May 18, 1984)

Synopsis. Palladium(0)-triphenylphosphine complexes catalyzed the allylic exchange reaction of allylic esters, phenyl ethers, and isoureas with imides such as phthalimide to give *N*-allylic products. Among them, *O*-allylic isoureas were most effective in exchanging the allylic group of more complex structure. *N*-Allylic derivatives were also obtained by the telomerization of butadiene or allene with phthalimide catalyzed by a palladium(0) species.

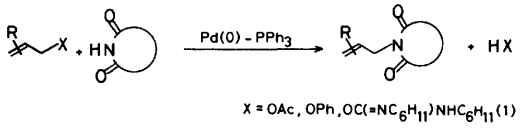
Palladium-catalyzed allylic exchange reaction of esters and ethers with various nucleophiles occurs smoothly usually in the presence of bases. Alcohols, amines, active methylene compounds, and carboxylic acids are typical nucleophiles.[1] However there are no reports so far on the use of imides as the nucleophile. If it could be achieved, the product would be *N*-allylic imide. The removal of the dioyl group affords the primary allylic amine. The overall procedure is a modification of the Gabriel synthesis to obtain a primary amine. Primary allylic amine function exists in many natural products and is considerably of preparative importance.[2]

On the other hand, the dimerization of 1,3-butadiene or allene by palladium catalysts occurs with incorporation of various nucleophiles to produce functionalyzed allylic derivatives.[1] The similar nucleophiles to those employed in the allylic exchange reaction can be used. In this paper we describe the *N*-allylation of imides through allylic exchange reaction or through telomerization of dienes with imides catalyzed by a palladium(0) species.

Results and Discussion

Allylic Exchange Reaction. Allylic esters and phenyl ethers underwent allylic exchange reaction with imides such as phthalimide and succinimide to yield the *N*-allylic imides in the presence of palladium(0)-triphenylphosphine species. Although *N*-allylation of saccharin was achieved by this catalyst system, amides such as benzamide and acetanilide did not participate in the reaction. Results are shown in Table 1. The feature of this reaction is that this proceeds even in the absence of bases. The employment of phthalimide potassium salt affords the product in an increased yield. Allylic acetate needed slightly severe conditions to carry out the reaction compared to allyl phenyl ether.

2-Cyclohexenyl, geranyl, and linaryl acetate did not give the products. The lack of regio- and stereoselectivity shown in the case of crotyl acetate and the dull reactivity mentioned above indicated that the reaction using allylic acetate had limited value.



X = OAc, OPh, OC(=NC6H11)NHC6H11 (1)

To overcome these defects, *O*-allylic isourea **1** was employed as the allylating reagent, which was formed[3] by treating the allylic alcohol with dicyclo-

TABLE 1. *N*-ALLYLATION OF IMIDES

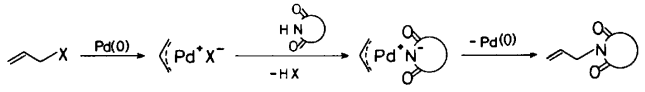
Imide (10 or 5 mmol), allylic compound (1 equiv), $Pd(PPh_3)_3$ (2 mol%), DMF (20 or 10 cm^3); 5 h: a) Pth=phthaloyl, Suc=succinyl; all gave satisfactory elemental and spectral data. b) $Pd(dba)_2$ (2 mol%)(dba=dibenzylideneacetone) and PPh_3 (4 mol%) were used; 10 h. c) Phthalimide potassium salt (5 mmol) was used in place of phthalimide. d) In addition, (*E*)-and (*Z*)-2-butenyl isomers were formed in 6 and 4% yield, respectively. e) A mixture of (*E*)-2,7-octadienyl propionate (69%) and 1-vinyl-5-hexenyl propionate (30%). f) **2**:**3**=61:39.

hexylcarbodiimide. The reaction of geranyl and neryl derivatives of **1** with phthalimide proceeded smoothly at 60 °C regio- and stereo-selectively with the deposition of *N,N'*-dicyclohexylurea.

This reaction presumably proceeds by oxidative addition to the allylic substrate to palladium(0) to generate a π-allylpalladium species followed by nucleophilic attack of the imide to give the product.[1] Phthalimide and succinimide are quite acidic and cannot be nucleophiles. So the actual attacking species is the imide anion arised intermediately from the abstraction of the imide hydrogen by the allylic leaving group. The more basic the anion X^- is, the more facile the generation of the imide anion is. The increased reactivity of **1** is ascribed to the high basicity of the dicyclohexylurea anion[4] generated intermediately.



Telomerization of Dienes with Phthalimide. The reaction of 1,3-butadiene with phthalimide took place in the presence of $Pd(PPh_3)_3$ yielding *N*-(2,7-octadienyl)phthalimide (**2**) and *N*-(1-vinyl-5-hexenyl)-phthalimide (**3**). The reaction was rather sluggish at 100 °C. Employment of a slightly higher temperature (120 °C) and addition of 10 mol% of phthalimide potassium salt gave reasonable yields of the telomers, **2** and **3**. Longer reaction time (20 h) caused the degradation of the products.[5] Telomerization of isoprene with phthalimide did not occur even under forced conditions. Allene also reacted with phthalimide at 100 °C to give *N*-(3-methy-2-methylene-3-butenyl)phthalimide (**4**) by $Pd(PPh_3)_3$ catalyst in a moderate yield.

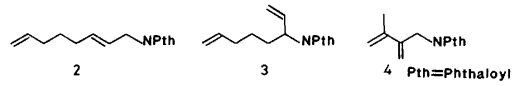


TABLE 2. TELOMERIZATION OF BUTADIENE WITH PHTHALIMIDE

Reaction temp/°C	Reaction time/h	Total yield/%[a]	Composition **2**:**3**
100	5	24	58:42
100	5	39[b]	58:42
120	5	74[b]	44:56
100	20	7	78:22

Butadiene (14—22 mmol), phthalimide (5 mmol), $Pd(PPh_3)_3$ (0.1 mmol), DMF (10 cm^3): a) Based on phthalimide. b) Phthalimide potassium salt (0.5 mmol) was added.

Experimental

General Procedure for the Allylic Exchange Reaction of Allylic Ester, Phenyl Ether, and Isourea with Imide. Imides and allylic compounds were reacted in DMF under nitrogen atmosphere in the presence of Pd(0)-PPh_3 catalyst. After the reaction, the DMF was evaporated under reduced pressure. The residue was taken up in benzene (*ca.* 10 cm^3) and the mixture was filtered to eliminate the unreacted imide. The pure products were obtained by column chromatography on silica gel.

N-Geranylphthalimide. Mp: 58.5—59.2 °C (60—61.5 °C).[6] Anal. ($C_{18}H_{21}NO_2$) C, H, N. IR (KBr) 1760 and 1700 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.52 (3H, s), 1.58 (3H, s), 1.79 (3H, s), 2.02 (4H, m), 4.02 (2H, d, J=7.2 Hz), 4.92—5.42 (2H, m), and 7.68 (4H, m). ^{13}C NMR ($CDCl_3$) δ=167.68, 140.29, 133.52, 132.35, 131.38, 123.72, 118.07, 39.42, 35.72, 26.31, 25.49, and 17.54.

N-Nerylphthalimide. Mp: 57.3—58.1 °C (59—60.5 °C).[6] Anal. ($C_{18}H_{21}NO_2$) C, H, N. IR (KBr) 1765 and 1700 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.65 (3H, s), 1.68 (3H, s), 1.70 (3H, s), 2.24 (4H, m), 4.27 (2H, d, J=7.2 Hz), 4.97—5.50 (2H, m), and 7.72 (4H, m). ^{13}C NMR ($CDCl_3$) δ=166.09, 140.48, 133.66, 131.91, 131.31, 123.87, 123.04, 118.90, 35.67, 32.06, 26.61, 25.68, 23.29, and 17.69.

Reaction of Butadiene with Phthalimide. The reaction was carried out in DMF in the presence of $Pd(PPh_3)_3$ in an autoclave. The products were purified by column chromatography on silica gel (benzene).

N-[(E)-2,7-Octadienyl]phthalimide (2). Liquid. Anal. ($C_{16}H_{17}NO_2$) C, H, N. IR (neat) 1770, 1700, 1640, 1470, 1420, 990, 960, and 910 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.2—1.6 (2H, m), 1.7—2.2 (4H, m), 4.1 (2H, d), 4.6—5.05 (2H, m), 5.1—6.0 (3H, m), and 7.65 (4H, m).

N-(1-Vinyl-5-hexenyl)phthalimide (3). Liquid. Anal. ($C_{16}H_{17}NO_2$) C, H, N. IR (neat) 1770, 1700, 1640, 1470, 990, and 910 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.1—1.7 (2H, m), 1.7—2.3 (4H, m), 4.6 (1H, m), 4.85 (1H, d), 4.86 (1H, d), 5.05 (1H, d), 5.15 (1H, d), 5.7 (1H, m), 6.15 (1H, m), and 7.65 (4H, m).

Reaction of Allene with Phthalimide. Phthalimide (5.0 mmol), $Pd(PPh_3)_3$ (0.1 mmol), and allene (10.0 mmol) were reacted in DMF (10 cm^3) at 100 °C for 5 h in an autoclave. Isolation by column chromatography on silica gel (hexane: ethyl acetate=10:1) gave the product, *N*-(3-methyl-2-methylene-3-butenyl)phthalimide (**4**); yield 0.56 g (49 %). Mp: 108.0—109.0 °C. Anal. ($C_{14}H_{13}NO_2$) C, H, N. IR (KBr) 1770, 1700, 1430, and 880 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.9 (3H, s), 4.5 (2H, s), 4.95 (2H, m), 5.25 (2H, m),and 7.8 (4H, m).

Second-order Rate Constants for the Decomposition of Methyl Iodide in Different Rare Gases

Ko SAITO,* Hiroyuki TAHARA, and Ichiro MURAKAMI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received February 24, 1984)

Synopsis. The thermal gas-phase decompostion of methyl iodide was studied in He and Kr over the temperature range of 1025—1520 K and the total-density range of (0.96—2.3)×10^{-5} mol cm^{-3}. The results showed that, at high temperatures, these inert gases act as "weak colliders." From the low-pressure limit rate constants, the relative values of the collision efficiency, β_c(M), were evaluted as;

$$\beta_c(\mathrm{He}):\beta_c(\mathrm{Ar}):\beta_c(\mathrm{Kr})=1.7:1.0:0.46$$

by connecting them with the previously reported data for an Ar mixture.

Studies of thermal decomposition in the low-pressure region provide important information of collisional intermolecular energy transfers. Although, at low temperatures, inert gas effects have been reported in many thermal systems,[1] at high temperatures (above 1000 K), only a few data are available from shock-tube studies, mostly in rare gases.[2]

In our previous study,[3] the thermal decomposition of methyl iodide in Ar was found to be controlled by the collisional activation step at temperatures above 1000K and at around atmospheric pressure. On the basis of the kinetic data, weak collision parameters were evaluated, and the energy-transfer behavior in collisions was discussed. In the present work, further investigations are made with regard to the thermal decomposition of CH_3I in Kr and Kr–He systems.

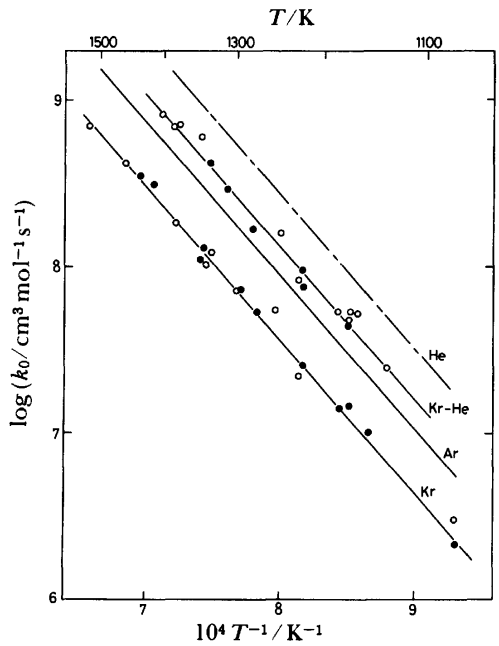

Fig. 1. Arrhenius plots of k_0 for different heat bath gases. Total density; ●: (1.0±0.1)×10^{-5} mol cm^{-3}, ○: (2.2± 0.1)×10^{-5} mol cm^{-3}. k_0(Ar) was cited from Ref. 3.

Experimental

The experiments were performed in a shock tube 9.4 cm in inner diameter. A detailed explanation of the equipment and the procedures has been given in the previous paper.[3] The decomposition rate of CH_3I was measured by monitoring the time dependent UV absorption at 275 nm.

Purified methyl iodide was diluted by the use of Kr (>99.95%) and He (>99.995%). As it was difficult to generate adequate shock conditions in He, a mixture of 50%Kr—50%He was used as the diluent to obtain the rate data in He. The temperature range behind the shock waves was from 1025 to 1520K, while the total density range was 9.6×10^{-6}—2.3×10^{-5} mol cm^{-3}.

Results and Discussion

The absorption profiles of methyl iodide behind the shock waves in Kr and Kr–He were essentially the same as those of the experiment in Ar.[3] In the present experiment, Lambert-Beer's law was also ascertained to hold in the present concentration range. In Fig. 1, Arrhenius plots of the second-order rate constants, $k_0=k/[\mathrm{M}]$, are shown for the different systems, where $k=\ln([CH_3I]_0/[CH_3I]_t)/t$ and where [M] denotes the concentration of the diluent gas M. The data for the Ar mixture, which were measured in the previous work, are also included in Fig. 1. From the facts that, in the Ar system, the decomposition occurred in the low-pressure region and that the k_0 values in Kr and Kr–He are of the same order as those of the Ar system, the decomposition in the present systems may be regarded as being in the low-pressure region. In fact, the estimated high-pressure rate constant was higher than the k_0 value by more than two orders of magnitude.

In the Kr and Kr–He systems, the reaction scheme for the overall decomposition is considered to be the same as in the Ar system, for there is no reason to consider that some of the secondary reactions are greatly enhanced by the change in the diluent gas from Ar to Kr or He. Thus, we obtain the low-pressure rate constants for the initiation reaction in Kr and He in the same manner as in the Ar system. The decomposition rate at the early stage of the reaction is written for the Kr system as;

$$-\mathrm{d}[CH_3I]/\mathrm{d}t = k_0(\mathrm{Kr})[CH_3I][\mathrm{Kr}],$$

where

$$k_0(\mathrm{Kr}) = 10^{15.0}\exp(-178\ \mathrm{kJ\ mol^{-1}}/RT)\ \mathrm{cm^3\ mol^{-1}\ s^{-1}}.$$

On the other hand, for the Kr–He system the decomposition rate is expressed as;

$$-d[CH_3I]/dt = k_0(Kr)[CH_3I][Kr] + k_0(He)[CH_3I][He],$$

provided that there are no additional interactions due to the mixing of the rare gases. Thus, the value of k_0(He) was evaluated from k_0(Kr) and k_0(Kr–He) as;

$$k_0(He) = 10^{15.88} \exp(-178\,kJ\,mol^{-1}/RT)\ cm^3\ mol^{-1}\ s^{-1}.$$

These rate constants have error limits of 20% in the temperature range of 1100—1500 K. In Fig. 1, the k_0(He) value is shown by a dashed line.

The collision efficiency, β_c, and the average energy, $<\Delta E>$, transferred per activating and deactivating collision were evaluated by the procedure described in the previous paper.[3,4] In Table 1, the evaluated values for these parameters are listed at four temperatures; the data for the Ar system are included. From Table 1, the importance of the weak collision effects is clearly demonstrated in these systems by the fact that $\beta_c \ll 1$. The temperature dependence of β_c for these weak colliders is expressed as $\beta_c \propto T^{-2}$, as in the previous papers.[3,5] This temperature dependence is larger than the theoretical prediction ($\beta_c \propto T^{-1}$).[6] Accordingly, we have found the temperature dependence of $<\Delta E>$ to be proportional to T^{-1} for the present systems. Large temperature dependences of $<\Delta E>$ are not unusual in the case of low collision effciencies at high temperatures.[7]

In general, the relative ordering of the energy-transfer efficiency in different bath gases depends on several limitations on the effective collisions, such as the relative masses, the relative translational energy of the colliding molecules, and the direction of the colliding molecules or the local position to be attacked. In the present systems, the ordering is β_c(He)$>\beta_c$(Ar)$>\beta_c$(Kr); this is the same as for the $-<\Delta E>$ values. That is, the average energy transferred per collision is larger for a lighter collision partner in the decomposition of CH_3I. This means that a fast collision is more effective in the enrgy transfer between translation and vibration modes. In this respect, it is of interest to compare the present results with such similar molecule-Ar systems as CH_3Cl–Ar[5] and CF_3I–Ar.[8] In the CH_3Cl–Ar system, $-<\Delta E>$ is as twice as large as that in the CH_3I–Ar system.[9] On the other hand, in the CF_3I–Ar system, $<\Delta E>$ is nearly the same as that in the CH_3I–Ar system. These facts also establish the effectiveness of fast collisions in T–V energy transfers at high temperatures in these systems. For different types of reactions, however, fast collisions are not necessarily dominant. For example, in the data for the decomposition of triatomic molecules, such as N_2O, NO_2, NOCl, and O_3, in different heat baths, Ar is less effective than Kr (except for N_2O).[2] This seems to suggest that some other factors are more important in these systems.

Table 1. Weak collision parameters

Dynamic NMR as a Nondestructive Method for the Determination of Rates of Dissociation. VIII. Proton Affinities of Anions Derived from Strong Acids in Chloroform[1)]

Michinori Ōki* and Manabu Ohira
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received April 11, 1984)

Synopsis. Dynamic NMR study of topomerization by dissociation of *N,N*-dibenzylanilinium salt was applied to the determination of proton affinities of anions derived from strong acids in chloroform-*d*. The total line shape analysis of the benzylic proton signals gave the following order of proton affinity:

$$Cl^- > p\text{-}CH_3C_6H_4SO_3^- > CH_3SO_3^- > Br^-.$$

In a previous paper, we reported that the rates of proton exchange between *p*-substituted *N,N*-dibenzylanilinium and chloride ions could be determined by the dynamic NMR technique.[2)] That paper was concerned about the proton affinity of amines affected by substituents. However, it is expected that we can determine the proton affinity of anions, if we fix the *N,N*-dibenzylanilinium ion and vary the anion which forms an ion pair with the former, because the anion in the ion pair is the proton acceptor in the exchange reaction. In turn, the proton affinity of anions affords information about the acidity of the conjugate acids. Although it is possible to titrate acids in nonaqueous solutions against indicators, the knowledge of "intrinsic acidity", that means the acidity without foreign materials, will be of value, especially because acids very often act as catalysts in organic reactions. To contribute to this area, we have compared proton affinity of chloride, bromide, methanesulfonate, and *p*-toluenesulfonate anions. This paper is to report the results.

The kinetic parameters for the proton exchange between *N,N*-dibenzylanilinium ion and some anions are summarized in Table 1. Although iodide salt was also prepared, it discolored easily. The data are not included in Table 1 because of the low reliability, but broadening of lines was observed at temperatures close to the boiling point of chloroform. The coalescence temperature was estimated to be 70—80 °C.

The results indicated that the bromide ion has less proton affinity than the chloride anion and probably the iodide ion has the least proton affinity among the anions examined. This result is in conformity with the acidity data in water.[3)]

Comparison of the proton affinity of sulfonate anions and halide anions in water has some difficulty. Although Bessière calculated pK_a's of various inorganic acids and sulfonic acids from the data in trifluoroacetic acid,[4)] the p*Ka*'s are not in conformity with other standard values. One point which is certain from the report by Bessière is that methanesulfonic acid and *p*-toluenesulfonic acid have comparable acidity. Our data confirm this point and establish that the acidity of the sulfonic acids can be placed between hydrochloric acid and hydrobromic acid in chloroform. The order of acidity, $HBr > CH_3SO_3H > HCl$, obtained by titration in chloroform,[5)] agrees with the present results as well.

The interesting point in the kinetic data is that, whereas the anilinium halides give large positive entropy of activation, the sulfonates give small negative entropy of activation. We have shown that an ammonium perchlorate gives negative entropy of activation on dissociation of the C–N bond in it and have developed a hypothesis that the origin of the negative entropy of activation is the loss of freedom of motion of the perchlorate ion in the transition state.[1)] The data shown in Table 1 suggest that the negative entropy of activation is common when the anion carries more than two negatively charged, equivalent oxygens. The reason for this must be, as suggested in the previous paper, the loss of freedom of motion of the anion in the transition state by forming a partial O–H bond, whereas the anion is rotating in the ground state due to the presence of three or four negatively charged oxygen atoms. We may now conclude that the entropy of activation for the dissociation of the N–H or N–C bond in ammonium salts is large positive when the anion is halide, while it is small negaitve if the anion is sulfonate or perchlorate.

So far, we have discussed the proton exchange of *N,N*-dibenzylanilinium ions and anions. The data are confined to strong acids. This has a special meaning because it is difficult to obtain exact p*Ka* values of strong acids in water. A book which compiles acidities of organic substances cites the p*Ka* of methanesulfonic acid (−1∼−2) as uncertain.[6)] This technique is expected to provide a method of approach to acidities of very strong acids.

Table 1. Kinetic parameters and related data for the proton exchange between *N,N*-dibenzylanilinium ion and anions derived from strong acids in chloroform-*d*

Anions	Cl^-[b)]	Br^-	$CH_3SO_3^-$	$p\text{-}CH_3C_6H_4SO_3^-$
T_c/°C	−0.7	47.8	12.3	10.6
Correlatior Coeff.	0.999	0.998	0.999	0.999
ΔH^*/kcal mol^{-1}[a)]	18.5±0.7	21.1±1.1	14.1±0.3	11.6±0.5
ΔS^*/e.u.	18.0±2.6	15.5±3.3	−0.2±1.2	−8.9±1.7
ΔG^*_{273}/kcal mol^{-1}	13.6	16.9	14.2	14.0

a) 1 cal=4.184 J. b) The data were obtained in the previous paper.[2)]

However, this technique should not be limited to the anilinium salt. If a more basic amine, which fulfil the following conditions, is used, the proton affinity of anions, of which conjugate acid is less acidic than those described here, should be obtained. The necessary conditions are, 1) possession of diastereotopic nuclei which are NMR-active, and 2) exchange of their sites by dissociation followed by inversion. Thus this technique is potentially useful for determining acidity of various acids in aprotic solvents.

Experimental

N,N-Dibenzylaniline was commercially available from Tokyo Kasei Co. and was used as received. Preparation and acquisition of kinetic data of hydrochloride were described in the previous paper.[2]

Hydrobromide was prepared by mixing 1 g of *N,N*-dibenzylaniline in 50 mL of carbon tetrachloride with 2 mL of 47% hydrobromic acid followed by recrystallization of the precipitate from tetrahydrofurane–hexane, colorless crystals. ^{1}H NMR ($CDCl_3$, δ): 4.72 and 5.03 (4H, m), 7.1—7.7 (15H, m).

Hydriodide was prepared similarly from 57% hydriodic acid. It discolored easily under normal protections against oxygen and light. Removal of the brown color was difficult, brown crystals. ^{1}H NMR ($CDCl_3$, δ): 4.79—5.11 (4H, m), 7.0—7.8 (15H, m).

p-Toluenesulfonate was prepared by mixing an ethanolic solution of *N,N*-dibenzylaniline with *p*-toluenesulfonic acid in ethanol. The salt was recrystallized from chloroform–hexane, colorless crystals which discolor easily. ^{1}H NMR ($CDCl_3$, δ): 2.36 (3H, s), 4.88 (4H, br s), 7.0—8.0 (19H, m).

Methanesulfonate was prepared similarly, colorless oil. ^{1}H NMR ($CDCl_3$, δ): 2.97 (3H, s), 4.83 (4H, br s), 7.0—7.4 (15H, m).

Dynamic NMR measurement was performed as reported previously with chloroform-*d* solutions.[2] The following chemical shift differences ($\Delta\nu_{AB}$) and coupling constants (J_{AB}) were used throughout the total line shape analyses because they did not change at several temperatures where the exchange of protons was negligibly slow. J_{AX} and J_{BX} of which low temperature values are shown below, were treated as reciprocally variable with temperature.

HBr salt: $\Delta\nu_{AB}$ 25.9 Hz, J_{AB} −12.7 Hz, J_{AX} 3.2 Hz, J_{BX} 7.0 Hz.

CH_3SO_3H salt: $\Delta\nu_{AB}$ 34.0 Hz, J_{AB} −12.5 Hz, J_{AX} 2.4 Hz, J_{BX} 7.3 Hz.

p-$CH_3C_6H_4SO_3H$ salt: $\Delta\nu_{AB}$ 33.0 Hz, J_{AB} -12.5 Hz, J_{AX} 2.4 Hz, J_{BX} 7.3 Hz.

The following rate constants (s^{-1}) were obtained (temperature in °C in parentheses).

HBr salt: 28.0 (40.5), 39.0 (42.9), 49.0 (45.5), 63.0 (47.8), 81.0 (50.2), 107.0 (52.7)

CH_3SO_3H salt: 24.0 (-0.7), 37.0 (3.6), 40.0 (4.5), 49.0 (6.7), 57.0 (8.4), 72.0 (11.0), 82.0 (12.3), 103.0 (14.5)

p-$CH_3C_6H_4SO_3H$ salt: 30.0 (-2.4), 40.0 (1.0), 54.0 (4.9), 65.0 (6.7), 77.0 (9.7), 85.0 (10.6), 106.0 (13.6)

The kinetic parameters were obtained by the usual manner with the use of these rate constants and temperatures.

This work was supported by a Grant in Aid from Ministry of Education, Science and Culture.

Effect of Hydrogenation on Solubility of Carbonized Pitch

Yoshio YAMADA,* Minoru SHIRAISHI, Takeshi FURUTA,
Toshio YAMAKAWA, and Yuzo SANADA†
National Research Institute for Pollution and Resources, Yatabe, Ibaraki 305
(Received December 12, 1983)

The effect of hydrogenation of carbonized pitch on its solubility in quinoline was investigated in connection with structural changes of the pitch during carbonization. Naphtha-tar pitch (NTP) and acenaphthylene were carbonized at 673 and 703 K, respectively, for various periods of time. The pitches thus heat-treated were hydrogenated by BenKeser reaction and the amount of quinoline insolubles (QI) in the hydrogenated pitch was determined. An acenaphthylene pitch (ACP) heat-treated for 24 h was rendered completely soluble into quinoline by the hydrogenation, whereas a considerable amount of insolubles was left in the case of NTP treated for longer residence times than 8 h. This can be explained in terms of the difference in interaction among aromatic molecules constituting the QI components derived from NTP and ACP. ACPs doped with elemental sulfur left a significant quantity of QI after the hydrogenation. The addition of sulfur is considered to form crosslinking bonds between aromatic molecules through hydrogen abstraction by the sulfur. When QI separated from carbonized NTP was hydrogenated, the degree of conversion into quinoline solubles (QS) was low as compared with that for the whole sample of the same NTP. The presence of QS in the pitch plays a very important role for the hydrogenation.

Since mesophase transformation occurring in the early stage of carbonization of pitch is a key step to determine physical and chemical properties of resultant coke and carbon products, much attention has so far been focused on the carbonization behavior of various pitches and related materials. The texture of optically anisotropic mesophase formed during the carbonization process is influenced by various factors, *e.g.*, molecular structures, their distribution in starting materials, and the fluidity of the system.[1] One of procedures controlling mesophase textures is modification by means of hydrogenation of pitch.[2,3] The effect of the hydrogenation is considered as increasing the fluidity of the system in the temperature range where mesophase is formed and thereby developing optical textures.

Hydrogenation under severe conditions such as high temperature and high pressure of hydrogen induces cracking and consequently, gives products different from original constituents. On the other hand, a mild reaction using lithium in ethylenediamine, *i.e.*, the BenKeser reduction, is suitable for modification of pitch[4] because aromatic rings in molecules are converted mainly to hydroaromatics in which hydrogens attached to naphthenic rings are transferrable during the carbonization. Such a hydrogenation of heat-treated pitch which contains partly anisotropic textures in an isotropic matrix, is also effective for controlling the development of mesophase by converting all anisotropic textures into isotropic ones.[5]

In this study, in order to obtain structural information on mesophase, pitches have been subjected to heat-treatment to different degrees prior to hydrogenation and then hydrogenated by the BenKeser reaction. The solubility of pitches thus obtained was determined for quinoline. In addition, influences on the hydrogenation have been investigated of sulfur doped in acenaphthylene pitch and of quinoline-soluble components in naphtha-tar pitch.

Experimental

Carbonization. Naphtha-tar pitch (NTP) obtained by thermal cracking of naphtha was supplied from Kureha Chemical Industry. Acenaphthylene of reagent grade was commercially available from Tokyo Kasei Kogyo Co., Ltd. and used without further purification. NTP and acenaphthylene were carbonized at 673 and 703 K, respectively, at a heating rate of 3 K min^{-1} and maintained at each temperature for 1—24 h in a nitrogen stream. Sumatora Light (Minas) vacuum residue (SL) treated at 703 K for 1—24 h[6] was used for comparison.

Doping of sulfur into acenaphthylene pitch (ACP) was carried out in the following way: Elemental sulfur was added to acenaphthylene with a ratio of 1 : 5 by weight and the mixture was heat-treated at 623 K for 3 h in a nitrogen atmosphere in an autoclave with a magnetic stirrer. After the treatment unreacted sulfur was removed by washing with ethanol. The pitch obtained was carbonized in a similar procedure as described above.

Hydrogenation. These pitches carbonized as above were hydrogenated by a method reported by Brooks and Silberman:[7] Lithium was added in small portions to a stirred suspension of a finely ground sample in anhydrous ethylenediamine in a nitrogen atmosphere. The weight of lithium was equal to that of the pitch. After 3 h reaction, the mixture was cooled and hydrolyzed with ice and water. The reaction product was recovered by centrifugation and washed repeatedly with water until lithium ion was removed. The product was dried below 383 K for 24 h in an oven.

Determination of Quinoline Insolubles (QI) and Elemental Analysis. The amount of QI was determined according to the filtration method of JIS-K2425. Analysis of carbon, hydrogen, and nitrogen was carried out with a Yanaco MT-3 CHN Corder and sulfur content was measured by using a LECO Corporation IR-33.

X-Ray Diffraction. The average size of molecules for carbonized pitches was calculated from the (11) band of X-ray diffraction profile according to Diamond's method.[8]

Results

Structural Change with Carbonization. Amounts

† Present address: Hokkaido University, Faculty of Engineering, Sapporo 060.

of quinoline insolubles in NTP and ACP carbonized at 673 and 703 K, respectively, are plotted against carbonization time in Fig. 1, together with those for hydrogenated pitches described in the next section. NTP forms easily QI at a higher rate than ACP does in spite of its lower carbonization temperature. Both pitches consist of almost all QI components at longer residence times. In order to obtain structural information on heat-treated pitches, the average size of molecules, *La*, was calculated from the (11) band of X-ray diffraction pattern (Table 1). It seems that the molecular size increases with residence time although the values listed in Table 1 somewhat scatter. An obvious difference between NTP and ACP is that NTP before carbonization is composed of larger molecules (10.2 Å). This is because the original pitch was subjected to thermal treatment at a higher temperature.[9] The number of stacking units as obtained from the (002) band of X-ray profile for the carbonized pitches of NTP ranges from 2.4 to 2.8 under these experimental conditions.*1)

samples are plotted against residence time in Fig. 2. Values for SL pitch obtained in the same procedure are added there for comparison. When carbonized pitches of NTP and ACP were hydrogenated, the H/C ratio increased from 0.5 to 0.8—1.0. The number of hydrogen atoms introduced per 100 carbon atoms can be calculated from the difference between measurements of elemental analysis. The data are shown in Fig. 3. ACP maintains almost a constant value over the ranges of residence time adopted. On the other hand, the hydrogenation susceptivity of NTP is different from that of ACP; a remarkable hydrogen addition for NTP was recognized with its pitches produced in the early stage of carbonization. After a maximum was reached near 4 h carbonization, the number of hydrogens introduced was caused to decrease with residence time. SL exhibits a similar curve with a steeper slope than NTP.

When a series of ACPs heat-treated for various periods of time was hydrogenated, all carbonization products were completely converted to QS even in the case of the ACP carbonized at 703 K for 24 h, which consisted entirely of quinoline-insoluble fractions (Fig. 1). On the other hand, the whole components of the NTP samples carbonized at shorter residence times than 4 h were made soluble in quinoline by the hydrogenation, but further heat-treatment left a considerable amount of QI in the hydrogenated pitches, as can be seen in Fig. 1 and Table 2. The values designated in parentheses in Table 2 represent the amounts of QI when the insolubles isolated from NTP pitches were hydrogenated. When the whole NTP pitch treated for 10 or 16 h and the QI separated from the corresponding sample were hydrogenated, there was no significant difference between them. In the case of NTP carbonized for 4 or 8 h, however, a considerable difference is recognized between them (Table 2).

The ACP containing sulfur was prepared in order to investigate the effect of sulfur doping on carbonization. The amount of residual sulfur in the pitch is given in the last column of Table 3. The amount of the sulfur remaining increased with residence time, but after the hydrogenation the sulfur content in the pitch decreased because part of the sulfur had reacted with hydrogen to produce hydrogen sulfide. Values of QI for these pitches are given in Table 4. In contrast to the data of ACPs without sulfur (Fig. 1), ACPs containing sulfur left a large amount of QI after the hydrogenation.

Discussion

The structure and reactivity of insolubles present in original pitches have been investigated in detail by Mochida *et al.*[10,11] They found that the QI fraction with optical isotropy is different in chemical structure from the other fractions and can be modified by means of reductive alkylation and hydrogenation. Since the QI matters generated in the carbonization process of pitch are anisotropic in optical texture, they are fundamentally different from QIs involved in pitches without

heat-treatment. Therefore, it is interesting to consider structural changes associated with the increase in QI on the basis of the extent of hydrogenation of NTP and ACP carbonized to different degrees.

According to the pyrolysis scheme of acenaphthylene reported by Singer and Lewis[12] and others,[13,14] acenaphthylene polymerizes when subjected to heat-treatment at lower temperatures than 503 K, and then decomposes to produce fluorocyclene, decacyclene, *etc.* when heated over a temperature range of 600 to 650 K. As the temperature is raised further, zethrene which has a unit structure favorable for formation of higher aromatic sheet molecules, appears from 703 to 723 K. It was found from the X-ray result (Table 1) that a series of ACPs carbonized at 703 K for various periods of time has average sizes of 9.6—11.4 Å, which are roughly comparable to the size of zethrene-like molecules (≈10.6 Å). The hydrogen to carbon atomic ratios are kept at almost the same values (Fig. 2), whereas the QI content steadily increases with residence time (Fig. 1). These results suggest that the treatment for a prolonged period at this temperature does not bring about any drastic structural change in the constituent molecules of QI.[15] When the carbonized pitches of ACP were hydrogenated, the number of hydrogens introduced into aromatic molecules was almost constant over the carbonization-time range of 1—24 h and the whole samples were completely rendered soluble in quinoline. The above evidence suggests that the arrangement of aromatic molecules would be destroyed by the hydrogenation due to a reduction in the interaction among the molecules. Thus, it seems that the QI matters of ACP consist of components with such smaller molecular weights as to get dissolved into quinoline by the BenKeser reaction.

In contrast, hydrogenated NTP and SL behave in a manner different from that of ACP described above. Since both samples originate from petroleum oil, they contain alkyl chains attached to hydroaromatic rings before the carbonization. The less degree of hydrogenation on the pitches without heat-treatment might result from the presence of the alkyl groups inhibiting the effective hydrogenation of aromatic ring molecules.[7] When they are heat-treated, elimination and/or cyclization of the alkyl groups occur and at the same time the resultant molecules become more aromatic.

It is well known that the BenKeser reaction mainly converts aromatic hydrocarbons into partially hydrogenated ones without cleavage of rings.[4,7] However, the stronger the interaction between aromatic layers becomes, the lower the degree of hydrogenation is rendered because of the decrease in the dispersibility of molecules in solvent. Therefore, the considerable decrease in the ratio H/C of NTP and SL for longer residence times (Fig. 2) may suggest the presence of such a strong intermolecular force among aromatic layers in QI. In fact, the aromaticity of NTP carbonized at 673 K for 16 h was estimated to be roughly unity from data of H/C and helium density.[16] This value is higher than that obtained for ACP treated at 703 K for 24 h (0.95). Therefore, as the residence time becomes longer, NTP is considered to produce matters with high contents of QI, in which the interaction among stacked molecules is strong enough to prevent the solvent penetration. In other words, the degree of solubility in quinoline after the hydrogenation may reflect the quality of QI in pitch before the hydrogenation.

The influence of the sulfur present in the original NTP was taken into account as another factor in order to understand the difference in hydrogenation behavior between NTP and ACP. As already described, the result in Table 4 reveals that the sulfur addition to ACP produces residues which leave some amounts of QI after the hydrogenation. It may be associated with formation of crosslinkages during carbonization.[17]

Marsh and Crawford[18] reported that mesophase spherules formed in the early stage of carbonization include small soluble molecules between lamellae. When the carbonized pitch is treated with quinoline, the small molecules incorporated between mesophase layers are considered to get dissolved into quinoline. Consequently, it is expected that the interaction between the layers becomes stronger and that the solvent such as ethylenediamine cannot penetrate into these layers on the hydrogenation. Hydrogenation of only the QI fraction from NTP carbonized for 4 or 8 h left a considerable amount of insolubles (Table 2). Thus, the result supports the above assumption and furthermore, suggests that the soluble components in the present system contribute to the solubility of QI after the hydrogenation, as pointed out by Mochida *et al.*[11]

(Received December 28, 1983)

The decomposition process of orthorhombic hydrogen molybdenum bronze, $H_{0.30}MoO_3$, was studied by the temperature programmed decomposition (TPD) technique *in vacuo* and in helium gas. The only gas liberated during the decomposition was H_2O and no other gas was detected. The TPD spectrum above 150 °C was composed of three bands (PII, PIII, and PIV). The PII band corresponded to the process from $H_{0.30}MoO_3$ to $H_{0.21}MoO_{2.95}$ without any structural change. The PIII band corresponded to the process from $H_{0.21}MoO_{2.95}$ to $H_{0.06}MoO_{2.88}$ with the structural change and the PIV band, to the process from $H_{0.06}MoO_{2.88}$ to $MoO_{2.85}$.

It is well known that hydrogen molybdenum bronzes are formed by reduction of MoO_3 in an aqueous medium[1] or by atomic hydrogen.[2] There are many phases which may be formulated as $H_xMoO_3(0<x\leqq2.0)$. The existence of four phases has been confirmed by Birtill and Dickens.[3] According to them, the ranges of homogeneity of these phases with the approximate limits are as follows; (i) blue orthorhombic ($0.23<x<0.40$), (ii) blue monoclinic ($0.85<x<1.04$), (iii) red monoclinic ($1.55<x<1.72$), and (iv) green monoclinic ($x=2.0$). In the hydrogen molybdenum bronze, hydrogen is inserted into the MoO_3 layers as atoms[4-6] and occupies available sites near the zigzag oxygen atoms of the intralayers.[6]

The authors have studied the structural and compositional changes of the blue orthorhombic bronze heated *in vacuo* and found that the bronze is decomposed to a nonstoichiometric compound with a rhombic MoO_3 structure with the evolution of H_2O.[7]

Sermon *et al.*[8] and Marcq *et al.*[9] studied the catalytic hydrogenation reaction for 1-pentene and ethylene on the red monoclinic bronze, $H_{1.6}MoO_3$, obtained from Pt-supported MoO_3 by hydrogen spillover. They concluded that atomic hydrogen plays an important role in the catalytic hydrogenation. The hydrogen in the blue orthorhombic bronze is also effective for 1-butene isomerization.[10]

It is important in studying the catalytic reaction to reveal the decomposition process of the bronze and the behavior of hydrogen in the bronze on heating. The authors have reported[11] the kinetics of isothermal decomposition of the blue orthorhombic bronze. In the present work, the decomposition was studied by the temperature programmed decomposition (TPD) technique *in vacuo* and in helium gas.

Experimental

The sample was prepared by the Glemser's method.[1] Its structure was confirmed by X-ray diffraction analysis to be identical with the blue orthorhombic phase reported by Birtill and Dickens.[3] The composition was determined to be $H_{0.30}MoO_3$ by chemical analysis[12] and by thermogravimetry.

A conventional high vacuum system equipped with a Cahn microbalance, a Pirani gauge, and a quadrupole gas analyzer was used for the measurements of the changes in weight and pressure. The rate of heating, β, was controlled by a temperature programmed controller.

The decomposition of the blue orthorhombic bronze on heating in helium gas was also studied by a gas chromatograph.

A differential scanning calolimeter (DSC) was used for measuring the heat of decomposition in helium gas.

Results

Temperature Programmed Decomposition in vacuo (TPD(v)). The bronze, $H_{0.30}MoO_3$, was degassed at room temperature under a vacuum of 10^{-4} Torr for 2 h and then heated at various heating rates (β=3.5—13.7 °C min^{-1}). The change in pressure was recorded with a Pirani gauge. The TPD(v) spectra at the various heating rates are shown in Fig. 1. A small band appeared below 150 °C. The TPD (v) spectrum above 150 °C showed clearly three peaks as the rate of heating was slow. Indeed, the spectrum obtained at a heating rate of 3.5 °C min^{-1} showed three distinct peaks, suggesting that the spectrum may be composed of three bands and the line shapes of each band may

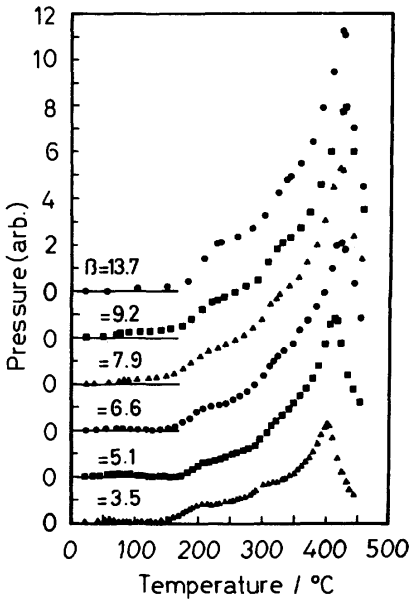

Fig. 1. TPD(v) spectra of the blue orthorhombic bronze, $H_{0.30}MoO_3$.

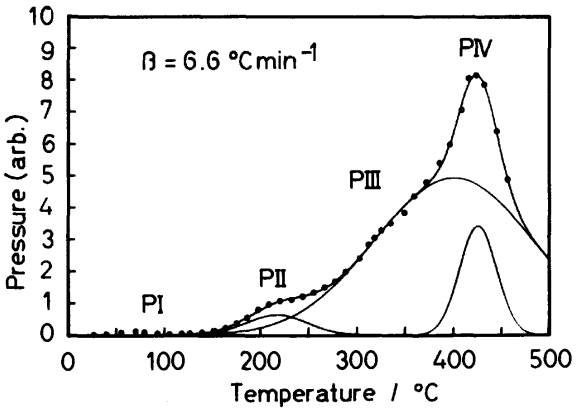

Fig. 2. Analysis of TPD(v) spectrum of the blue orthorhombic bronze, $H_{0.30}MoO_3$.

be symmetrical. Therefore, the spectra above 150 °C could be analyzed by a curve resolver. One of the results is shown in Fig. 2. This shows that the spectrum above 150 °C consists of three bands (PII, PIII, and PIV). All the spectra in Fig. 1 were analyzed by the same technique. The shifts of each peak temperature (Tm) to higher temperatures were observed when the heating rates were increased. The peak temperatures, Tm(II) of the PII band appeared over a temperature range of 185—238 °C. Tm(III) of the PIII band and Tm(IV) of the PIV band appeared at 356—408 and 392—429 °C, respectively.

The gas liberated in these experiments was H_2O and no other gas was detected by the quadrupole gas analyzer. The above results suggest that hydrogen in the bronze reacted with the lattice oxygen to produce H_2O in three steps.

Activation energies of 18.4(PII), 28.4(PIII), and 39.6(PIV) kcal mol^{-1} were estimated from the shifts of the peak temperatures (Tm(II), Tm(III), and Tm (IV)).[13]

Thermogravimetry. The weight-loss of the blue orthorhombic bronze was measured by a Cahn microbalance at various heating rates (β=3.5—13.7 °C min^{-1}) *in vacuo*. The X-ray and thermogravimetric results showed that on the vacuum heating the bronze transformed to $MoO_{2.85}$, a nonstoichiometric compound with rhombic MoO_3 structure, through a mixture of the orthorhombic and rhombic structures[7] as follows;

$$\text{(I)}\quad H_{0.30}MoO_3\cdot nH_2O \xrightarrow{\text{below 150 °C}} H_{0.30}MoO_3$$

$$\text{(II)}\quad \xrightarrow{\approx 286\ ^\circ C} H_{0.21}MoO_{2.95}^{**}$$

$$\text{(III)}\quad \xrightarrow{\approx 390\ ^\circ C} H_{0.06}MoO_{2.88}^{***}$$

$$\text{(IV)}\quad \xrightarrow{\approx 446\ ^\circ C} MoO_{2.85}\ .$$

**: Orthorhombic bronze with the lowest hydrogen content.

***: Isomorphous with rhombic MoO_3.

The rising temperature technique has been widely used in kinetic investigation of thermal decomposition and other reactions of solid.[13-16] By this technique, Ozawa[16] formulated a simple and useful method to analyze the thermogravimetric data and determined the activation energies of the decomposition of calcium oxalate and the degradation of Nylon 6. According to his method, activation energies are easily determined as follows; initially the fraction reacted, α, is plotted against the reciprocal absolute temperature ($1/T$), and the value of $1/T$ corresponding to $1-\alpha$ of each heating rate curve can be estimated. Secondly, the activation energies can be determined from the plots of the logarithms of the heating rate, $\log \beta$, *vs.* $1/T$ obtained from the above plots.

Figure 3 shows the typical thermogravimetric curves of the bronze plotted against $1/T$. If the decomposition proceeds in one step, activation energies estimated from the plots of $\log \beta$ *vs.* $1/T$ should be equal at every α. However, the results suggest that the activation energies for different α differ from one another. The value of $1-\alpha$ at the peak temperatures (Tm(II), Tm(III), and Tm(IV)) of each band of the TPD(v) spectra were 0.86±0.05(PII), 0.31±0.08(PIII), and 0.12±0.03(PIV), respectively. Figure 4 shows the plots of $\log \beta$ *vs.* $1/T$ which gives the same value of $1-\alpha$, corresponding to Tm(II), Tm(III), and Tm(IV). From these

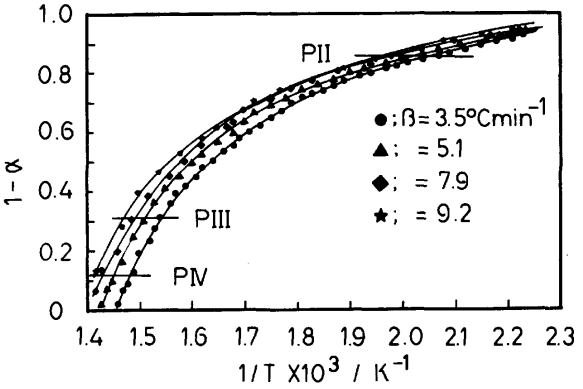

Fig. 3. The thermogravimetric curves of $H_{0.30}MoO_3$ plotted against the reciprocal absolute temperatures.

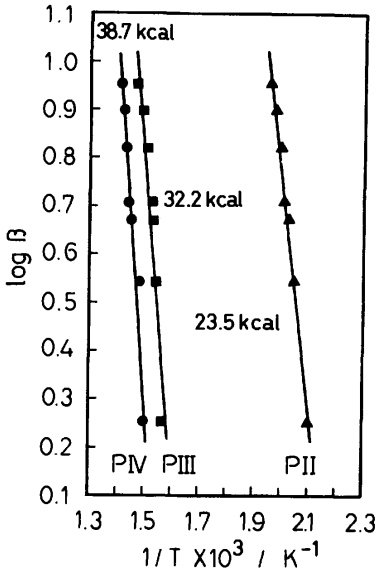

Fig. 4. The plots of logarithms of heating rates against the reciprocal absolute temperatures.

plots, the activation energies were determined to be 23.5(PII), 32.2(PIII), and 38.7(PIV) kcal mol^{-1}, respectively. These values are in good agreement with those determined from the TPD(v) spectra.

Temperature Programmed Decomposition in Helium Gas (TPD(h)). The bronze was also heated in helium gas with the flow rate of 90 ml min^{-1} and was studied by means of the gas chromatograph. The heating rates employed were 3, 7.5, and 10 °C min^{-1}. No peak appeared below 200 °C. Above this temperature, however, three peaks appeared as in the case of vacuum heating. The range of Tm(II) was 259—283 °C, which was higher compared with that obtained by TPD(v) spectra. Those of Tm(III) and Tm(IV) were 296—315 and 352—380 °C. These were lower than those obtained by TPD(v) spectra. These differences in Tm may be attributed to the difference in the experimental methods.

The activation energies were also estimated from the shifts of Tm and the heating rates and were determined to be 27.5(PII), 32.2(PIII), and 38.0(PIV) kcal mol^{-1}, respectively. The activation energy of PII is a little higher than those determined by TPD(v) spectra and by thermogravimetry, but those of PIII and PIV are in good agreement.

DSC Measurement. The heat of decomposition of the bronze was measured by DSC with the heating rates of 5, 7, and 10 °C min^{-1}, which were treated in helium gas with the flow rate of 90 ml min^{-1}. Three endothermal peaks appeared at 240—250, 310—321, and 353—364 °C, and were in good agreement with those of the Tm(II), Tm(III), and Tm(IV) of TPD(h) spectra obtained by heating in helium gas. The total endothermal heat was determined by the peak area to be 5.82±0.13 cal g^{-1}. If this value were proportioned to each band area of PII, PIII, and PIV, the alloted values would be 0.81±0.02(PII), 1.98±0.04(PIII), and 3.03±0.07(PIV) cal g^{-1}, respectively. These energies produce many effects; heat of reaction between hydrogens and lattice oxygens, heat of desorption of H_2O, *etc.* Therefore, it is difficult to conclude that the endothermal heats are directly related to the binding energies of hydrogen in the bronze.

Discussion

Figure 5(A) shows the typical TPD(v) spectrum obtained by the Pirani gauge, while Fig. 5(B) is the differential curve calculated from the weight change (Fig. 5(C)) of the bronze on vacuum heating. As shown in Fig. 5(B), the fluctuation is recognized above 250 °C and it is difficult to obtain a smooth curve. On the other hand, the TPD(v) spectrum is very smooth. However, the Tm's are somewhat higher than those obtained from the differentiation of the weight changes. The pirani gauge method to detect pressure change is somewhat different from the microbalance for measuring weight changes and, therefore, there might be a temperature lag between the both measurements. However, the Tm's obtained from both measurements might occur with a similar temperature lag in all the steps. The TPD method gives the smooth spectrum, and is the simplest and most useful method for studying the decomposition of the bronze.

According to the proton NMR result,[11] there is no difference in the behavior of the protons in the original bronze and in the bronze treated at 350 °C under a vacuum of 10^{-4} Torr (1 Torr=133.322 Pa). This suggests that the environment surrounding the protons does not change during heating at 350 °C. The hydrogen atom sites in the bronze are surrounded by oxygen atoms making zigzag chains in the MoO_3 layers, as is illustrated in Fig. 6(A). Two hydrogen atom sites on a given O···O line are too close for two hydrogen atoms to occupy them simultaneously and inelastic neutron scattering has confirmed that there is no OH_2 groups in this phase.[17] If one hydrogen atom occupied the A site near oxygen (B) as shown in Fig. 6(B), there would be four available sites for the hydroxyl hydrogen.[6] Most of the hydrogen atom must have a neighbouring site 1 in

pairs.[6] Therefore, the most available site must be the site 1 or 4 as shown in Fig. 6(C).

The PI band which appears below 150 °C in the TPD(v) spectra may result from the desorption of a small amount of adsorbed water. This corresponds exactly to the I process.

The orthorhombic bronze retains its original crystal structure up to about 287 °C although the hydrogen content (x) changes from 0.30 to 0.21. This suggests that the reaction occurs sporadically and the nearest two hydrogen atoms in the sites 1 and 4 react with the nearest lattice oxygens to produce H_2O. This temperature range falls in that of the PII band in the TPD spectra and, therefore, the PII band corresponds to the PII process.

The weight-loss in the temperature range of about 287 and 390 °C was about a half of the total weight-loss, and the product was confirmed to be the mixture of the orthorhombic and rhombic MoO_3 structures. It might be considered that the dehydration of the PII process involves nucleation and the nuclei produced might accelerate the dehydration successively. On the other hand, the PIII band is broad and the integrated area is much larger than those of the PII and PIV. Considering the above results, it is concluded that the PIII band corresponds to the PIII process.

$H_{0.06}MoO_{2.88}$ was isomorphous with the rhombic MoO_3 and the hydrogen atoms were considered to be sparsely distributed. Therefore, even though $H_{0.06}MoO_{2.88}$ was decomposed completely to $MoO_{2.85}$ at about 446 °C with the evolution of H_2O, no structural change was observed. The decrease in weight was small and the PIV band was narrow and small. It is reasonable to conclude that the PIV band corresponds to the IV process.

The authors thank to Professor Makoto Kaburagi of Kobe University for writing the program to analyze TPD spectra.

Fluorescence of Europium Tris(bromate) Enneahydrate with Ar^+ Laser Excitation

Masahiko HASUNUMA, Keiko OKADA,* and (the late) Yoshifumi KATO
Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657
(Received January 9, 1984)

The (f,f^*) transitions of europium tris(bromate) enneahydrate crystal between 12000 and 20000 cm^{-1} were measured at 95 K by laser-excited fluorescence spectroscopy. The crystal field components of the ground ($^7F_{0,1\cdots6}$) and the excited states ($^5D_{0,1}$) participating in the transitions were analyzed in terms of the tensor-operator method. Besides electric-dipole transitions, a number of magnetic-dipole transitions were detected in compliance with the selection rule. The theory could reproduce the observed wavenumbers and intensities both for the σ- and π-transitions. The population ratio of the $^5D_0$ to the $^5D_1$ was estimated to be 14.1 from the intensity calculations and the observed results. The result suggests that mixing of g-orbitals is significant for the forced electric-dipole transitions.

The trivalent europium ion of $4f^6$ electronic configuration has a ground ^7F multiplet with a width of about 5000 cm^{-1} and the next low energy levels of ^5D multiplet about 17000—24000 cm^{-1} above. The Eu^{3+} ion in crystals displays characteristic emission in the visible region which arises from the (f,f^*) transitions between these states. In the last decade, a considerable number of studies have been made on the fluorescence of Eu^{3+} doped in a variety of host lattices. So far, however, no work has been reported on the electronic structure of europium tris(bromate) enneahydrate crystals of $Eu(BrO_3)_3\cdot9H_2O$, which has a typical coordination structure of $[Eu(OH_2)_9]^{3+}$. In a previous work,[1] the fluorescence spectrum excited by an Ar^+ laser on the europium tris(ethyl sulfate) enneahydrate crystal (Eu(ES)) was studied. In this structure the Eu^{3+} ion is in the C_{3h} crystal field of $[Eu(OH_2)_9]^{3+}$. Besides the confirmation of the crystal field splittings of the ground ^7F multiplet and the excited $^5D_0$ and $^5D_1$ states, a successful interpretation of the spectral intensities was made by applying the Judd-Ofelt theory.[2,3]

The present study is concerned with the electronic structure of $Eu(BrO_3)_3\cdot9H_2O$ obtained by analysing the laser-excited fluorescence spectra. In this host, the Eu^{3+} ion is in the D_{3h} crystal field of $[Eu(OH_2)_9]^{3+}$ according to X-ray crystallography.[4,5] The transition probabilities for both the electric-dipole (ED) and magnetic-dipole (MD) transitions were also calculated by using the tensor-operator method. Some discussions are given of the calculated and observed relative intensities.

Experimental

Single crystals of $La(BrO_3)_3\cdot9H_2O$ and $Eu(BrO_3)_3\cdot9H_2O$ were prepared by the method described in a previous paper.[6] The fluorescence spectra of the crystals were measured through an analyser to obtain polarization of the emitted radiations whose polarizing planes are perpendicular (σ-) and parallel (π-spectrum) to the principal axis of the crystal. The experimental procedure was the same as in our previous report.[1]

Results and Discussion

Selection Rules. In view of the X-ray crystallographic studies,[4,5] it may appear adequate to assume the D_{3h} crystal field of $[Eu(OH_2)_9]^{3+}$. However, D_3 symmetry was adopted for the theoretical calculations, since it is convenient for the spectral assignments. The crystal field mixes the states which differ in J and J_z, whereupon J and J_z cease to be good quantum numbers. Then the crystal quantum number μ is used to classify the crystal field energy levels. The classification of the crystal quantum number for different

Spectra. The fluorescence spectra of $Eu(BrO_3)_3 \cdot 9H_2O$ at 95 K excited by a 457.9 nm line of an Ar^+ laser are shown in Figs. 1 and 2. The Raman lines of the vibrational modes were distinguished from the fluorescence lines by reference to the spectrum of $La(BrO_3)_3 \cdot 9H_2O$, which is isomorphous with $Eu(BrO_3)_3 \cdot 9H_2O$ and gives no (f,f^*) transitions, since it has no f-electron in the ground configuration. The σ- and π-polarized spectra exhibit fluorescence lines at the same wavenumbers but with different relative intensities. The intensities were measured by the areas under the curves of the spectra. The lines were assigned to ED and MD transitions between "crystal field levels" on the basis of the selection rules and the calculated transition energies and intensities. The observed wavenumbers and relative intensities of the fluorescence lines of $Eu(BrO_3)_3 \cdot 9H_2O$ are listed in Table 3. Eight strong MD transitions are allowed according to the selection rules for the "ion levels" (*i.e.* $|\Delta J| \leqq 1$) and 12 weak MD transitions are forbidden transitions with $|\Delta J|>1$. While the former strong transitions were already reported by Hellwege,[9] Axe,[10] and Sayre and Freed[11] for Eu(ES), the latter weak transitions were first observed in our previous research applying the laser as a light source.[1] The forbidden transitions occur when there exists a considerable interaction of the free ion with the crystal field, that is, when the influence of J-mixing is appreciable. Table 4 summarizes the crystal field levels of $Eu(BrO_3)_3 \cdot 9H_2O$ determined by the present analysis.

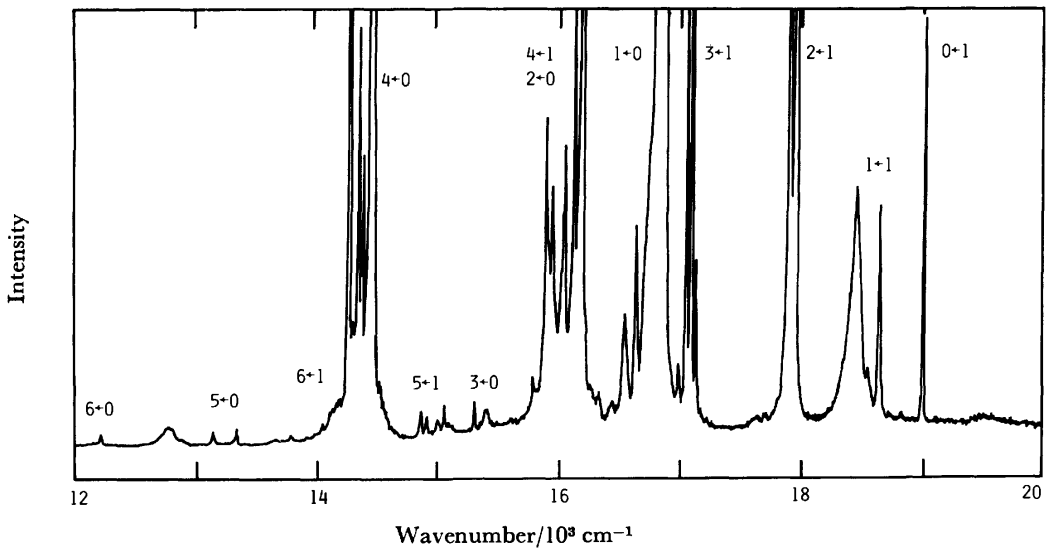

Fig. 1. σ-polarized fluorescence spectra of $Eu(BrO_3)_3 \cdot 9H_2O$ at 95 K excited by the 457.9 nm line of Ar^+ laser. Fluorescence lines assigned to the transitions between the ground ($^7F_{J'}$) and excited substates (^5D_J) are shown as ($J' \leftarrow J$).

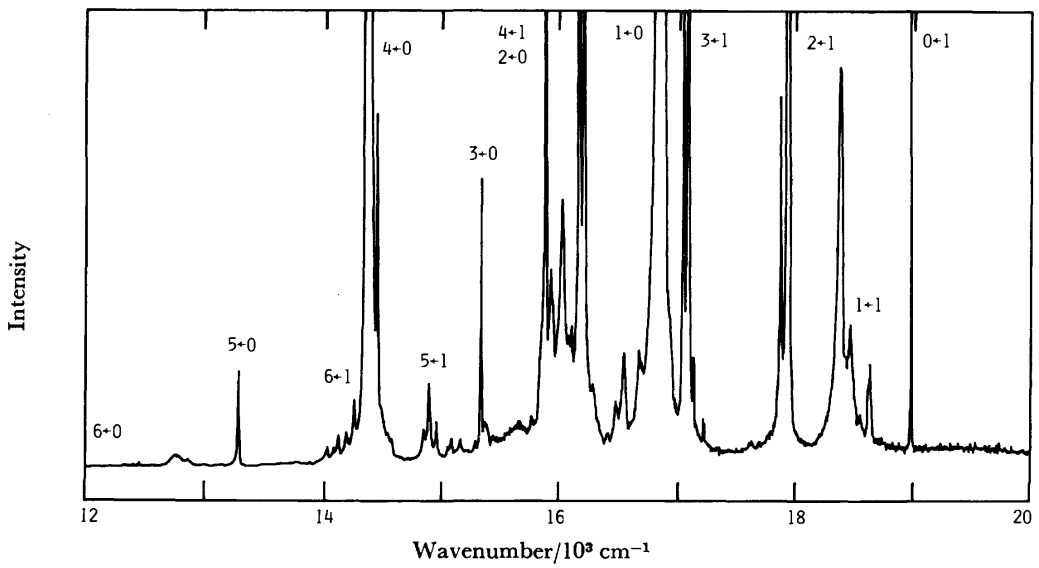

Fig. 2. π-polarized fluorescence spectra of $Eu(BrO_3)_3 \cdot 9H_2O$. Notations are the same as in Fig. 1.

Energy Levels. The procedure for calculating the energies of the 4*f*-orbitals in $[Eu(OH_2)_9]^{3+}$ will be briefly described here. In the case of strong spin-orbit interactions, the wavefunctions for the electrons of the free ion can be written as

$$|\phi) = \sum_n C_n |f^N : qSLJ), \quad (1)$$

where q is an additional quantum number specifying the state. In the presence of the crystal field, the wavefunctions should be rewritten as

$$|\psi_a) = \sum_i a_i |f^N : qSLJM). \quad (2)$$

In taking the summation, a basis set was restricted to the 64 states strongly interacting with ^5D_J and ^7F_J, that is, ^7F_J, $3(^5D_J)$, $2(^5F_J)$, $3(^5G_J)$, ^5H_J, $6(^3P_J)$, ^3D_J, ^3F_J, and ^3H_J states, where the numbers in front of the parentheses are the numbers of states with different q in Eqs. 1 and 2.[12]

The total Hamiltonian of a rare earth ion placed in a crystal field may be written as

$$H = H_{ion} + H_{cry}, \quad (3)$$

where H_{ion} is the Hamiltonian of the free ion and H_{cry} is the potential term provided by the crystal environment around the ions of interest. H_{ion} can be split into

$$H_{ion} = H_0 + H_{es} + H_{so}, \quad (4)$$

where H_0 is the sum of the kinetic energy and the potential energy due to the field of all the inner shell electrons and the nucleus, H_{es} is the electrostatic repulsive potential due to the coulomb and exchange interactions between pairs of the outer shell electrons, and H_{so} is the spin-orbit interaction. H_0 contributes only to a common energy shift for all the levels of a given configuration. Hence the energy levels of the $4f^6$ configuration can be evaluated by diagonalizing the interaction matrix elements of $H_{es}+H_{so}+H_{cry}$. The electrostatic interaction and the spin-orbit interaction can be expressed by a linear combination of the terms of the

Slater radial integrals F_n (n=2, 4, 6) and the spin-orbit coupling constant ζ_{4f}, respectively. The scalar two-body electrostatic interactions arising from the second-order perturbation energies were next considered. They give an additional term to H_{ion} with three configuration interaction (CI) parameters α, β, and γ.[8] The crystal field potential for D_3 symmetry may be expanded in terms of the tensor operator $C_n^{(k)}$ to give in which B_n^k is a

$$H_{cry} = B_0^2C_0^2 + B_0^4C_0^4 + B_3^4(C_3^4+C_{-3}^4) + B_0^6C_0^6 + B_3^6(C_3^6+C_{-3}^6) + B_6^6(C_6^6+C_{-6}^6), \quad (5)$$

crystal field parameter to be determined. First, the matrix concerned with the free ion part was diagonalized by fitting the calculated ion levels to the experimental centers of gravity of the J-manifolds. Next, the crystal field parameters were determined to reproduce the observed crystal field levels for each ion level. Finally, the matrix as a whole was diagonalized by readjusting all the parameters. Table 5 lists the optimum parameters thus obtained. The calculated eigenvalues are in close agreement with the observed ones within root mean square (rms) deviations of 24.0 cm^{-1} and 5.6 cm^{-1} for ion levels and crystal field levels, respectively.

The wavefunctions thus obtained were used to calculate the transition probabilities between crystal field levels.

Intensities. The intensity of radiation for the $\psi_b \leftarrow \psi_a$ transition is given by

$$I(\psi_a:\psi_b) \propto \sigma^4 g(\psi_a)N(\psi_a)[|(\psi_a|\boldsymbol{D}_e|\psi_b)|^2 + |(\psi_a|\boldsymbol{D}_m|\psi_b)|^2]/(2J+1), \quad (6)$$

where σ is the transition energy in wavenumber, $g(\psi_a)$ and $N(\psi_a)$ are the degeneracy and the population of the initial state ψ_a, and $\boldsymbol{D}_e$ and $\boldsymbol{D}_m$ are the ED and MD operators, respectively. The ED operator is written as

$$\boldsymbol{D}_e = -e\sum_i \boldsymbol{r}_i(\mathbf{C}_\rho^{(1)})_i, \tag{7}$$

where $\mathbf{C}_\rho^{(1)}$ is an irreducible tensor of rank 1. The z-component of the ED moment corresponding to the π-polarized emission is obtained with $\rho=0$, and the $(x\pm iy)$-components corresponding to the σ-polarized emission are obtained with $\rho=\pm1$. The ED mechanism of the (f,f^*) transitions has been considered to be of a forced electric dipole origin by Judd[2] and Ofelt.[3] They occur due to the mixing of $nl^{N-1}n'l'$ configurations of opposite parity through the odd terms of the crystal field potential V_{odd}. Then the perturbed state $|\psi_a'\rangle$ is expressed as

$$|\psi_a'\rangle = |\psi_a\rangle - \sum_\eta \left[\frac{(nl^{N-1}n'l':\eta|V_{odd}|\psi_a)}{\Delta E(\eta)}\right]|nl^{N-1}n'l':\eta), \tag{8a}$$

$$\Delta E(\eta) = E(nl^{N-1}n'l':\eta) - E(\psi_a) \simeq \Delta E(n'l'), \tag{8b}$$

where the perturbing potential V_{odd} is defined by

$$V_{odd} = \sum_i \sum_{t,p} A_{tp}\boldsymbol{r}_i^t(\mathbf{C}_p^{(t)})_i. \tag{9}$$

For D_3 symmetry the odd potential has the form

$$V_{odd}(D_3) = \sum_i \sum_t A_{t3}\boldsymbol{r}_i^t(\mathbf{C}_3^{(t)} - \mathbf{C}_{-3}^{(t)})_i. \tag{10}$$

The matrix elements of $\boldsymbol{D}_e$ may be expanded in terms of LS multiplets by the application of the tensor-operator technique to yield

$$\begin{aligned}(\psi_a'|\boldsymbol{D}_e|\psi_b') = {} & \sum_{i,j}\sum_\lambda\sum_{t,p} a_i^* b_j (-1)^{2J+S+L'+\lambda-M+p+\rho}\delta(S,S') \\ & \times (2\lambda+1)[(2J+1)(2J'+1)]^{1/2} \\ & \begin{bmatrix}1 & \lambda & t\\ \rho & -p-\rho & p\end{bmatrix}\begin{bmatrix}J & \lambda & J'\\ -M & P+\rho & M'\end{bmatrix} \\ & \times \begin{Bmatrix}J & J' & \lambda\\ L' & L & S\end{Bmatrix} T_c(t,\lambda)(qSL||\boldsymbol{U}^{(\lambda)}||q'SL'),\end{aligned} \tag{11a}$$

$$\begin{aligned}T_c(t,\lambda) = {} & A_{tp_{l'}}\sum(-1)^{l+l'}2(2l+1)(2l'+1)\begin{bmatrix}l & l & l'\\ 0 & 0 & 0\end{bmatrix}\begin{bmatrix}l & t & l'\\ 0 & 0 & 0\end{bmatrix} \\ & \times \begin{Bmatrix}1 & \lambda & t\\ l & l' & l\end{Bmatrix}(R_{nl}|r|R_{n'l'})(R_{n'l'}|r^t|R_{nl})/\Delta E(\eta),\end{aligned} \tag{11b}$$

where A_{tp} is a perturbing crystal field parameter. From the triangular condition for n-j symbols with $l=3$, Eq. 11 has nonzero matrix elements only if

$$\lambda = 2,\ 4,\ 6,\quad t = \lambda\pm1,\quad l' = 2,\ 4. \tag{12}$$

Therefore, the five parameters $T_c(3,2)$, $T_c(3,4)$, $T_c(5,4)$, $T_c(5,6)$, and $T_c(7,6)$ are required. The $T_c(t,\lambda)$ contains theoretically undeterminable factors by the present method, namely, the crystal field parameter A_{tp}, the radial wavefunction and the energy of the $n'l'$ orbital. Hence, an alternative parametrization proposed by Axe[10] was adopted; this is appropriate to describe the relative intensities of transitions between the crystal field levels by taking the $T_c(t,\lambda)$ as adjustable parameters. A line strength[13] for transitions between ion levels was defined by Judd-Axe[2,10] as

$$S(\phi_nJ:\phi_mJ') = \sum_t\sum_\lambda (2\lambda+1)T_i(t,\lambda)^2|(\phi_nJ|\boldsymbol{U}^{(\lambda)}|\phi_mJ')|^2/(2t+1). \tag{13}$$

The $T_i(t,\lambda)$ is a parameter concerned with the transition between ion levels and should be distinguished from $T_c(t,\lambda)$ for the crystal field levels. The matrix elements of the unit tensor of rank λ can be calculated using the eigenvectors in Eq. 1:

$$\begin{aligned}(\phi_nJ|\boldsymbol{U}^{(\lambda)}|\phi_mJ') = {} & \sum_{n,m} c_n^* c_m \delta(S,S')(-1)^{S+L'+J-\lambda} \\ & \times [(2J+1)(2J'+1)]^{1/2} \\ & \times \begin{Bmatrix}J & J' & \lambda\\ L' & L & S\end{Bmatrix}(f^N:qSL||\boldsymbol{U}^{(\lambda)}||f^N:q'SL').\end{aligned} \tag{14}$$

Consequentry, the parameters $T_i(t,\lambda)$ may be estimated from the observed line strengths using Eq. 13:

$$\begin{aligned}&T_i(3,2) = \pm0.58,\quad T_i(3,4) = \pm0.20,\quad T_i(5,4) = \pm2.39,\\ &T_i(5,6) = \pm0.05,\quad T_i(7,6) = \pm1.46.\end{aligned} \tag{15}$$

An MD transition within the $4f^N$ configuration is allowed since an MD operator $\boldsymbol{D}_m$ is of even parity having the form

$$\begin{aligned}\boldsymbol{D}_m &= -\beta(2S+L),\\ \beta &= -e\hbar/(4\pi mc).\end{aligned} \tag{16}$$

The matrix element of $\boldsymbol{D}_m$ reduces to

$$\begin{aligned}(\psi_a|(\boldsymbol{D}_m)_\rho|\psi_b) = {} & \sum_{i,j} a_i^* b_j (-1)^{J-M}\begin{bmatrix}J & 1 & J'\\ -M & \rho & M'\end{bmatrix} \\ & \times (f^N:qSLJ||\boldsymbol{D}_m||f^N:q'S'L'J'),\end{aligned} \tag{17}$$

where $\rho=0$ and ±1 correspond to σ- and π-polarized radiations, respectively, contrary to ED transitions. According to Condon and Shortley,[13] the matrix elements are nonzero only when they are diagonal in the quantum numbers q, S, and L, and furthermore J satisfies the following three cases ($\Delta J=0,\ \pm1$):

1) $J'=J$,

$$(qSLJ||\boldsymbol{D}_m||qSLJ') = g[J(J+1)(2J+1)]^{1/2}, \tag{18}$$

where

$$q = 1 + [J(J+1) + S(S+1) - L(L-1)]/[2J+1].$$

2) $J' = J-1$,

$$(qSLJ||\boldsymbol{D}_m||qSLJ') = \left[\frac{(S+L+J+1)(S+L+1-J)(J+S-L)(J+L-S)}{4J}\right]^{1/2}. \tag{19}$$

3) $J' = J+1$,

$$(qSLJ||\boldsymbol{D}_m||qSLJ') = \left[\frac{(S+L+J+2)(S+J+1-L)(L+J+1-S)(S+L-J)}{4(J+1)}\right]^{1/2}. \tag{20}$$

Thus, the MD transition probability can be evaluated straightforwardly by using Eqs. 1 and 2 for ion levels and crystal field levels, respectively.

The calculated values of the relative line strengths are contrasted with the observed ones in Table 6. The comparison enables us to estimate the population of the initial levels by Eq. 6. The two components of the $^5D_1$ state, $^5D_1(0)$ and $^5D_1(\pm1)$, were assumed to be equal in population since they are separated by only 8.6 cm^{-1}. On the other hand, the $^5D_0(0)$ state lies about 1750 cm^{-1}

below the $^5D_1$ state. The ratio of the population of $^5D_0$ to that of $^5D_1$ is given by

$$\frac{N(^5D_0)}{N(^5D_1)} = \frac{S_{obsd}(^5D_0:{}^7F_J)/S_{calcd}(^5D_0:{}^7F_J)}{S_{obsd}(^5D_1:{}^7F_{J'})/S_{calcd}(^5D_1:{}^7F_{J'})} = R(^5D_0 \rightarrow {}^7F_J:{}^5D_1 \rightarrow {}^7F_{J'}), \quad (21)$$

where $N(^5D_J)$ stands for the sum of populations overall the components of the J-manifold. Since the fluorescence intensity is proportional to the population difference between the initial and the final states, the population ratio can be estimated from the intensities of two transitions involving the same final state. Thus, the population ratio was calculated from the line strengths in Table 6 to be

$$R(^5D_0 \rightarrow {}^7F_2:{}^5D_1 \rightarrow {}^7F_2) = 14.1, \quad (22a)$$

$$R(^5D_0 \rightarrow {}^7F_4:{}^5D_1 \rightarrow {}^7F_4) = 15.5, \quad (22b)$$

$$R(^5D_0 \rightarrow {}^7F_6:{}^5D_1 \rightarrow {}^7F_6) = 12.6. \quad (22c)$$

The average of these values gives 14.1 as the population ratio $^5D_0$ to $^5D_1$. The result differs from the Boltzmann distribution at 77k.

The values of $T_i(t,\lambda)$ of Eq. 15 for free ion levels were revalued for crystal field levels by a least-squares method.

$$T_c(3,2) = 0.25,\quad T_c(3,4) = -0.10,\quad T_c(5,4) = -2.71,$$
$$T_c(5,6) = -0.02,\quad T_c(7,6) = -0.10. \quad (23)$$

The calculated relative intensities are compared with the observed ones in Table 7, where the intensity of the line $^7F_0(0^+) \leftarrow {}^5D_1(\pm 1)$ is taken to be unity. The observation is well reproduced by the calculation.

Since $T_c(t,\lambda)$ is related to the radial wavefunction $R_{n'l'}$, the contribution of the admixing orbital $n'l'$ can be estimated. Then a parameter

$$\Gamma = \sum_{n'} \Omega(n'g)/[\sum_{n'} \Omega(n'g) + \sum_{n'} \Omega(n'd)], \quad (24)$$

proposed by Axe[10] may be introduced, where

$$\Omega(n'l') = (R_{4f}|r|R_{n'l'})(R_{n'l'}|r^t|R_{4f})/\Delta E(n'l'). \quad (25)$$

The parameter Γ may be considered as a kind of measure of the contribution of the admixing orbital $n'l'$, *i.e.*, if only d-orbitals contribute, Γ=0, and if only g-orbitals contribute, Γ=1. Approximate ratios between $T_c(t,\lambda)$ values given by Eq. 11b are shown as function of Γ as

$$\frac{T_c(3,4)}{T_c(3,2)} = \frac{1.95-1.42\Gamma}{1.0+1.44\Gamma}, \quad (26a)$$

$$\frac{T_c(5,6)}{T_c(5,4)} = \frac{6.08-6.19\Gamma}{1.0+5.00\Gamma}. \quad (26b)$$

From the $T_c(t,\lambda)$ values in Eq. 23 the value of Γ was calculated to be 0.968 and 0.987 for the t=3 (Eq. 26a) and t=5 (Eq. 26b), respectively. Consequently, it is concluded that the $n'g$-orbital plays a dominant role in configuration mixing for ED transitions.

Crystal absorption spectra of the two modifications of the perylene-TCNQ (7,7,8,8-tetracyanoquinodimethan) complex were derived from reflection spectra by the Kramers-Kronig transformation and are discussed in relation to the differences in the crystal structures. The spectral response of photoconduction does not show any efficient photocarrier generation in the lowest charge-transfer band region in either modification. However, the rise of the photocurrent of both modifications was found to obey an empirical equation, $Y \propto (E-E_{th})^{2.5}$, where Y is the quantum yield of the photocarrier generation, E is the photon energy, and E_{th} is the threshold energy. E_{th} of the two modifications is almost the same and falls in the energy region a little above the lowest charge-transfer band. Efficiencies of the carrier generation, on the other hand, are quite different for the two modifications. These photoelectrical characters are discussed in connection with the optical spectra and also with the data of photoelectron emission.

Photoconduction in the charge-transfer (CT) complex has been studied for a number of complexes since Akamatu and Kuroda reported the photoconduction in the complexes of pyrene with some electron acceptors.[1-17] As for the mobility of the charge carriers, some features arising from the one-dimensionality of the crystal structure have been observed for some complexes.[15-17] However much less has been known about the mechanism of the carrier generation.[14] Photoelectric responses have been observed for some complexes in the region of the lowest CT-band, while some other complexes show photoelectric response only in the higher-energy regions. It has been inferred that the higher CT-states, in which the charge transfer occurs to acceptor molecules farther than the nearest neighbor of a donor, play an important role in the carrier generation.[10] However, no clear evidence has been obtained for such an inference.

Perylene and TCNQ have been found to form a 3:1 complex[18] as well as the well known 1:1 modification.[7,19] The crystal structure of the former (Fig. 1b)[20] has two characteristics as compared with the usual CT-complexes. First, the stacks of perylene-the donor(D)- and TCNQ-the acceptor(A)- are composed of DAD units. The CT-interaction between the donor and acceptor molecules seems to be confined within a DAD unit. Secondly, there are additional arrays of perylene molecules between the stacks of perylene and TCNQ, the orientation of those perylene molecules being almost perpendicular to the molecules forming the stacks. Consequently, the interaction between the stacks is blocked by those additional perylene molecules, which are hereafter called *interstitial* perylene molecules.

In this paper, we report the reflection and photoconduction spectra of the single crystals of the two modifi-

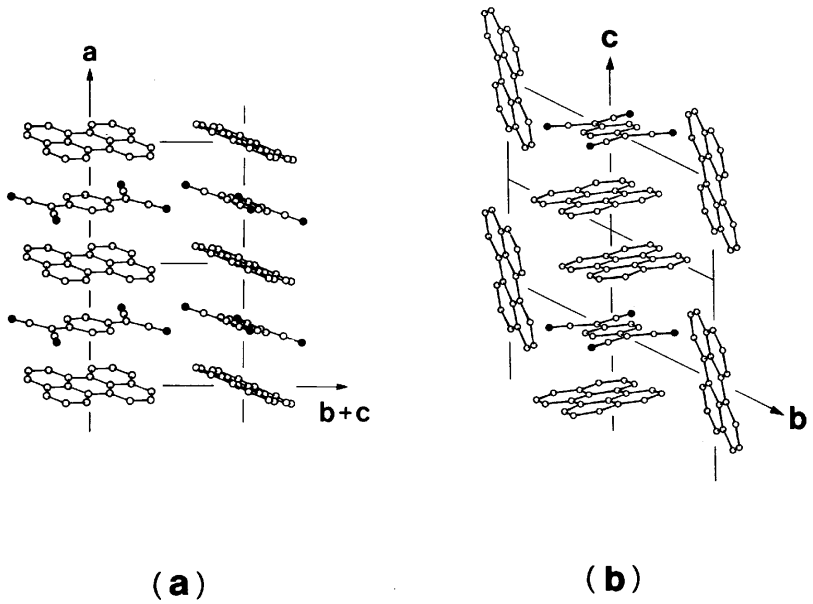

Fig. 1. Crystal structures of the two modifications of the perylene-TCNQ complex, (a) 1 : 1, (b) 3 : 1.

cations of the perylene-TCNQ complex, and discuss the threshold energies of the photocarrier generation in these crystals. The nature of the higher CT-states and the process of the carrier generation through those states are also discussed in connection with the crystal structures.

Experimental

Perylene was purified from Aldrich gold-label reagent by column chromatography on active alumina using xylene as the eluent, and then by the sublimation in the vacuum. TCNQ obtained from Tokyo Kasei was purified successively by the recrystallization from acetonitrile and by the repeated sublimation in the vacuum.

Crystals of the 1:1 modification were obtained by the recrystallization from an equimolar solution in tetrahydrofuran or by the sublimation in the vacuum. Crystals of the 3:1 modification were obtained by the diffusion method in benzene or by the recrystallization in the same solvent. In the diffusion method, perylene and TCNQ were separately charged in two branches of a sealed U-shaped tube filled with benzene, and then it was maintained at about 30 °C for several weeks. The 3:1 modification was also obtained by slowly evaporating the benzene solution containing an excess amount of perylene.

Both the 1:1 and 3:1 crystals were dark-blue crystals with metallic lusters, but their crystal-formation habits were totally different. The 1:1 modification usually crystallizes as needle-like crystals elongated along the c-axis, whereas the 3:1 modification crystallizes as small blocks. The above-mentioned two kinds of crystals were confirmed by X-ray diffraction to be identical with the known 1:1 and 3:1 modifications.[19,20]

Polarized reflection spectra of single crystals of the two modifications were measured at room temperature with a microspectrophotometer, details of which have been previously reported.[21] Single crystals of silicon were used as the standard of the reflectivity.[22]

The photocurrent of the single crystals was measured at room temperature with a Keithley 602 electrometer or a Cary 401 vibrating-reed electrometer by a two-probe method with an arrangement of the so-called surface type. Electrical contacts onto the crystals were made with colloidal silver. Typical conditions of the electric field and the cross section of the crystal were 100 V across an electrode gap of 1 mm and 0.2 mm^2. Measurements were carried out in a nitrogen atmosphere. Spectral response of the photocurrent was measured with a monochromatized light source equipped with a 150 W tungsten-iodine lamp and a neutral filter with a variable density. It gave a constant flux of photons at any wavelength in the visible and near-infrared regions. The spectral width of the monochromator was about 6 nm (240 cm^{-1}) at 500 nm.

Results and Discussion

Reflection Spectra. Figures 2 and 3 show the reflection spectra of the (01$\bar{1}$) face of the 1:1 modification and of the (100) face of the 3:1 modification, respectively. Each figure shows the spectra measured respectively for the light polarizations parallel and perpendicular to the stacking axis (a-axis of the 1:1 modification and c-axis of the 3:1 modification). Recently, Bandrauk and his coworkers[23] reported the reflection spectra of the two modifications of the perylene-TCNQ complex. Their results are different in some respects from ours. In their c-polarized spectrum of the bc-plane of the 3:1 modification, the peak reflectances of the

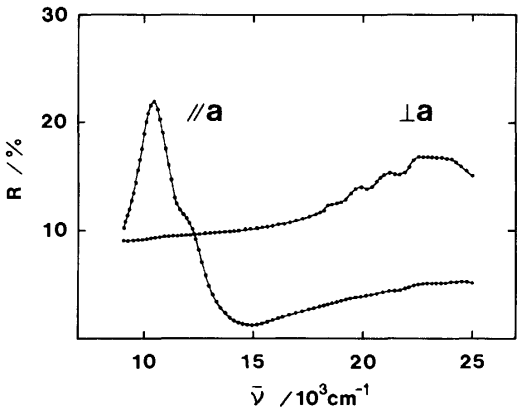

Fig. 2. Reflection spectra of the (01$\bar{1}$) face of the 1 : 1 modification with the polarizations along and perpendicular to the stacking axis (a-axis).

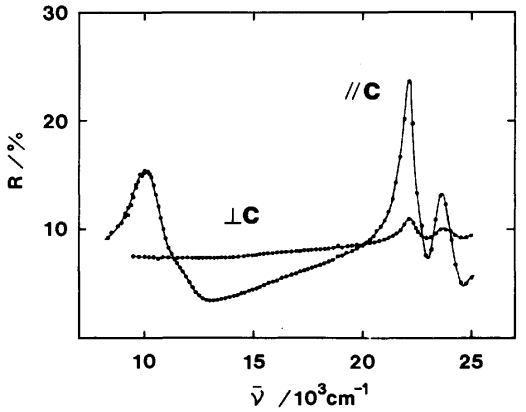

Fig. 3. Reflection spectra of the (100) face of the 3 : 1 modification with the polarizations along and perpendicular to the stacking axis (c-axis).

CT-band as well as those of the local-excitation bands are much smaller than our results. In addition, there appears a small dispersion around 500 nm in their spectrum obtained for another light polarization on the same crystal plane. We could not observe such a dispersion for any light polarization on the (100) face (bc-plane) of the 3:1 modification, but observed a similar dispersion in the spectra taken on another crystal face which is considered to be the (00$\bar{1}$) face (ab-plane).

From the observed reflectivity data, we calculated the optical constants by the Kramers-Kronig transformation, assuming simple dispersions of the optical constants outside of the energy region where the measurement was carried out.[21] Optical constants near the upper limit of the experiment (25×10^3 cm^{-1}), therefore, naturally contain some ambiguity on account of this assumption. Absorption spectra thus calculated of the (01$\bar{1}$) face of the 1:1 modification are shown in Fig. 4. The lowest-energy band is almost completely polarized along the stacking axis (a-axis). It has the peak at 10.6×10^3 cm^{-1} and a shoulder around 12×10^3 cm^{-1}. The peak molar extinction coefficient is 2.4×10^4 dm^3 mol^{-1} cm^{-1}. According to the polarization, this band must arise from the CT-transition between the perylene and TCNQ stacking in a column.

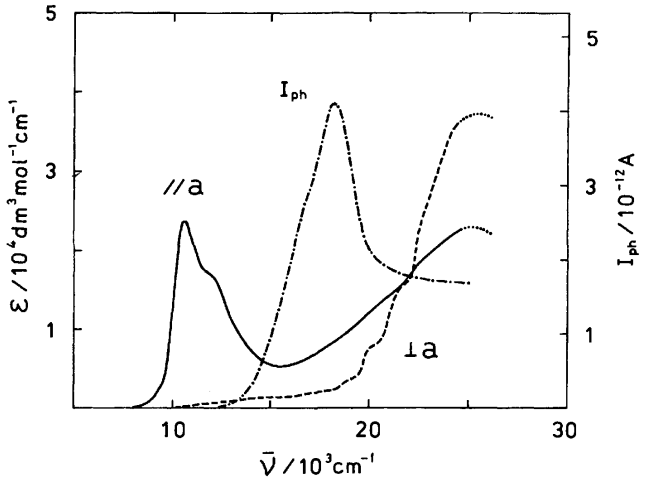

Fig. 4. Absorption spectra on the (01$\bar{1}$) face of the 1 : 1 modification with the polarization along (——) and perpendicular (----) to the stacking axis (a-axis), and photoelectric response (—·—) of the same modification.

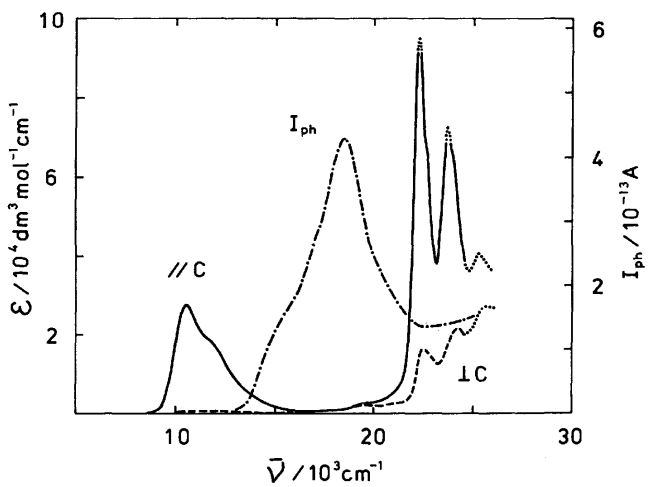

Fig. 5. Absorption spectra on the (100) face of the 3 : 1 modification with the polarizations along (——) and perpendicular (----) to the stacking axis (c-axis), and photoelectric response (—·—) of the same modification.

The energy difference between the peak and the shoulder suggests that this shoulder may be a vibrational structure, but there remains a possibility that it is related to a higher CT-state. The nature of this shoulder will be discussed later in connection with the spectrum of the 3:1 modification. As is seen in the ⊥a spectrum, local-excitation transitions of the perylene and TCNQ arise above 19×10^3 cm^{-1}. Note that the absorption at the higher-energy side of the CT-band in the //a spectrum does not completely decay but is followed by an absorption which gradually increases its intensity until the local-excitation region above 19×10^3 cm^{-1}. This implies that, in the above-mentioned region, there are some more electronic transitions polarized along the stacking axis. They may be mixed states between higher CT-states and the local-excitation states.

Absorption spectra on the (100) face of the 3:1 modification were similarly calculated from the reflection spectra (Fig. 5). The lowest-energy band of this modification, polarized along the c-axis, has a strong resemblance to the corresponding band of the 1:1 modification, and can be assigned to the CT-transition between perylene and TCNQ stacking in a column. It has the peak at 10.5×10^3 cm^{-1} and a shoulder around 12×10^3 cm^{-1}. The peak molar extinction coefficient is 2.8×10^4 dm^3 mol^{-1} cm^{-1}. The higher-energy side of the above shoulder decays clearly, and does not show any absorption which continues to the local-excitation region.

The similarity and the differences between the CT-bands of these two modifications may be understood by comparing their crystal structures[19,20] which have already been described. Electronic overlaps between the donor and acceptor of the nearest neighbor are similar in the two modifications. However, the interactions with the molecules in the second nearest unit and the farther units are by no means the same. It is therefore inferred that the lowest CT-states in the two modifications are similar, but that some differences may be seen for the higher CT-states. These are the features seen in the observed spectra if we consider that the shoulders around 12×10^3 cm^{-1} are the vibrational structures of the lowest CT-bands and that the absorption in the region of 15×10^3—20×10^3 cm^{-1} in the //a spectrum of the 1:1 modification is associated with the higher CT-states. Very weak absorption in the same region in the spectra of the 3:1 modification suggests the small transition probabilities to the higher CT-states in this modification.

Pronounced peaks are seen in the local-excitation region in the //c spectrum of the 3:1 modification. The peak wave numbers, 22.2 and 23.7×10^3 cm^{-1}, fall between the corresponding wave numbers[24] of the absorption peaks of perylene in the solution and the α-perylene crystal which is composed of perylene molecules with a dimer-type conformation. Taking account of the polarization of the above peaks and the crystal structure, those peaks are assigned to the transitions in the interstitial perylenes. Molar extinction coefficients at the peaks of these bands could not be estimated accurately because the interval of the experimental points of the reflection spectrum was not small enough compared with the band width. However, they seem to be almost three times as large as the extinction coefficients of the corresponding peaks in the solution spectrum,[24] which is in harmony with a simple expectation based on the oriented-gas model. These observations indicate the weakness of the interaction of the interstitial perylenes with other molecules in the stacks.

Photoconduction of the 1:1 Modification. The spectral response of the photocurrent of the 1:1 modification obtained by the recrystallization from tetrahydrofuran is shown in Fig. 4. A crystal obtained by the sublimation method gave an almost similar result. These spectral-response curves qualitatively agree with those of needle crystals reported by Vincent and Wright.[7,25] The curve shows a peak around 18×10^3

cm^{-1} with a long tail in the small wave-number side. Note that excitation in the lowest CT-band region seemingly does not give rise to a photocurrent efficiently. The photocurrent, I_{ph}, changed nonlinearly against the intensity of the excitation light, L, as follows:

$$I_{ph} = aL^n, \tag{1}$$

where a is a constant and n was 0.4—0.6 depending on the crystal. This result indicates that the steady-state photocurrent in our crystals was affected by the presence of charge-carrier traps.[26] However the dominant mechanism of the carrier generation may not be the detrapping of the carriers by the excitons, because no large photoelectric response was observed around the lowest CT-band region.

Energy for the charge-carrier generation in molecular crystals has been estimated by Lyons' scheme.[27,28] This scheme also seems applicable to weak molecular complexes.[29,30] Figure 6 illustrates this idea for the perylene-TCNQ complexes, where I_c=5.7 eV[31] is the adiabatic photoelectron-emission threshold and E_A=2.8 eV[32] is the electron affinity of TCNQ. Since the direct measurement of P^-, the polarization energy of the TCNQ anion in the complex, is practically difficult,[30] we roughly estimated it by assuming that P^- is the same as P^+, the polarization energy of the perylene cation in the complex. The latter was estimated to be 1.2 eV from the difference between I_c and the ionization potential of perylene molecule.[33-35] Thus the energy for generating a pair of thermally relaxed charge carriers, $I_c - E_A - P^-$, is estimated to be 1.7 eV (14×10^3 cm^{-1}). The photocurrent in Fig. 4 does not show efficient response at this energy. One must, however, examine the threshold region of the spectral response more precisely.

It has been empirically found[27] that the quantum yield, Y, of the photocarrier generation in some molecular crystals around the threshold is given by

$$Y = b(E - E_{th})^{2.5}, \tag{2}$$

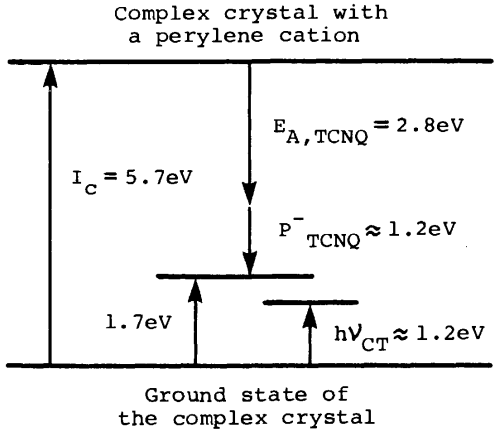

Fig. 6. Energy diagram for estimating the threshold energy of the carrier generation in the 1 : 1 modification, where I_c is the ionization potential of the 1 : 1 complex, $E_{A,TCNQ}$ is the electron affinity of TCNQ, and P^-_{TCNQ} is the assumed polarization energy for $TCNQ^-$ in the complex crystal (see the text). Threshold energy is estimated to be 1.7 eV. $h\nu_{CT}$ shows the approximate level of the lowest CT-state.

where E is the photon energy, E_{th} is the threshold energy of the carrier generation, and b is a constant. In our experiment, we utilized a light source by which a constant photon flux, L_0, was obtained at each wavelength studied. The photocurrent spectrum reflects, then, the quantum yield of the carrier generation, as follows:

$$I_{ph}(E) = c\{L_0 Y(E)\}^n, \tag{3}$$

where n is the number appeared in Eq. (1), and c is a constant. We therefore plotted $I_{ph}^{1/2.5n}$ against the photon energy. Curve A in Fig. 7 shows the result thus plotted in the threshold region for the 1 : 1 modification. A straight line can been seen in the region above 14×10^3 cm^{-1}. Extrapolation of this line gives the value of E_{th} to be 13.8×10^3 cm^{-1} (1.71 eV). Deviation from the line in the smaller-energy region may arise from some extrinsic carrier generations which involve the carrier traps at the impurity sites. The E_{th} value obtained above agrees well with the energy for the carrier generation estimated from the photoemission data and is a little larger than the peak energy of the lowest CT-band.

CT-Excitons have the character of a Wannier exciton. If one took a one-electron scheme,[27] the threshold of the carrier generation might be found at an energy where the series of the higher CT-states (larger Wannier excitons) converges. A simple consideration indicates that the lowest CT-state is more stable by approximately $e^2/2\varepsilon R$ than this energy, where R is the distance between the nearest donor-acceptor couple and ε is the dielectric constant of the crystal along the stacking axis. This difference may be as large as 1 eV. The threshold of the photoconduction, then, would be expected at an energy much higher than the lowest CT-band. This does not agree with the experimental observation. This discrepancy may be understood if one thinks about the relaxation from higher CT-states to the pair of the thermally relaxed charge carriers. In CT-complexes, CT-excitations contribute an non-negligible amount to the total polarizability of the crystal.[21] The polarization energy gained by localizing a unit charge in a molecular crystal is as large as 1 eV.[34]

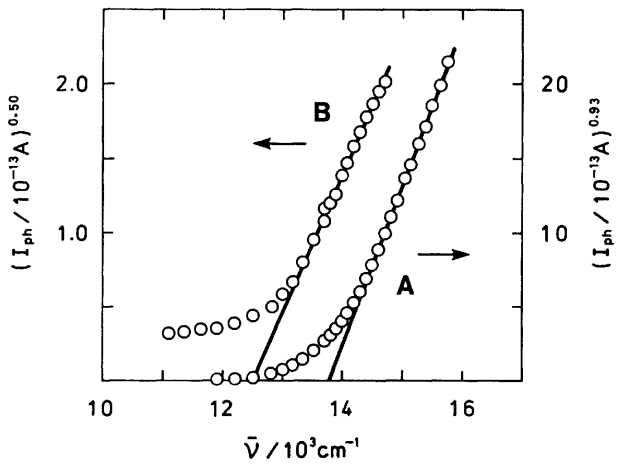

Fig. 7. (A) Plot of $I_{ph}^{1/2.5n}$ for the 1 : 1 modification. The number n (see the text) was 0.43 for this crystal. (B) $I_{ph}^{1/2.5n}$ for the 3 : 1 modification. n was 0.80 for this crystal.

Then the energy gain by relaxing the higher CT-states to a pair of charge carriers may be as large as several tenths of 1 eV. This energy may compensate a considerable part of the energy difference between the higher CT-states and the lowest CT-state. This may be the reason why we observed the threshold of the photocarrier generation only a little above the lowest CT-band.

Photoconduction of the 3:1 Modification. The spectral response of the photoconduction of the 3:1 modification is shown in Fig. 5. Although this spectrum is similar to that of the 1:1 modification, the photocurrent is smaller by one or two orders of magnitude, though the experimental conditions were similar. $I_{ph}^{1/2.5n}$ plotted for the threshold region is shown in Fig. 7 (curve B). There seems a threshold of the carrier generation at 12.5×10^3 cm^{-1} (1.55 eV). Small shoulders of photocurrent are seen around 15 and 17×10^3 cm^{-1} in Fig. 5. They suggest that some density of states related to the initial step of carrier generation are located around those energies. These may be mixed states of the higher CT-states and the local-excitation states. The threshold energy is smaller than that of the 1:1 modification, but the difference is not large. This is reasonable because the stabilization of the valence electrons in the crystal and also the polarization energies of the charge carriers are inferred to be almost the same in the two modifications.

The spectral response shows that the efficiency of the photocarrier generation is small around the threshold region and larger in the region of the higher CT-states. This may be easily understood if one considers a competition between the carrier generation through the CT-states and the deactivation of these states. The molar extinction coefficient of the lowest CT-band is very large although it is an intermolecular transition. Then, the radiative deactivation may be fast and the probability of the carrier generation from this state may be small, even if the thermal energy required to activate the carrier generation from this state were very small. For the higher CT-states, the transition dipoles to the ground state are small, and the thermal relaxation easily causes the localization of the electron and generates the charge carriers.

The small photoelectric response of the 3:1 modification compared with the 1:1 modification may be explained in terms both of the carrier generation and of the mobility. The weak absorption in the intermediate region between the lowest CT-band and the local excitation region in the absorption spectra of the 3:1 modification (Fig. 5) seems to indicate the small transition probabilities to the higher CT-states and then the smaller probability of the photocarrier generation. The crystal structure of the 3:1 modification obviously does not favor the carrier transport either.

35) Valence electrons in the highest occupied molecular orbital of the donor are considered to be stabilized by the CT-interaction with the acceptor and are by no means the same as in the free donor molecule. This stabilization seems small in the weak CT-complexes studied before (Refs. 28, 29), but it is uncertain in the complexes studied here. However, we have tried to estimate the threshold energy of the photocarrier generation very roughly in this paper.

The Crystal Structure of 13*H*-Dibenz[*a*,*de*]anthracen-13-one

Isao OONISHI,* Shoji FUJISAWA, Junji AOKI, Yuji OHASHI,† and Yoshio SASADA†

Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274

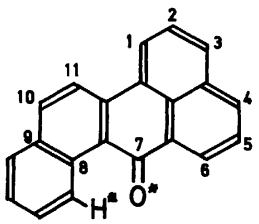
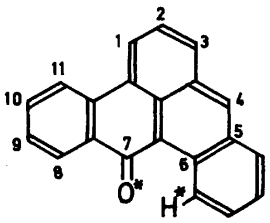
(Received February 27, 1984)

Crystals of the title compound, $C_{21}H_{12}O$, are orthorhombic, belong to the space group $Pn2_1a$, have lattice constants of a=14.227(3), b=15.551(4), c=12.436(3) Å, and also have Z=8. The structure was determined using the direct method and was refined by using a full-matrix least-squares method to an R value of 0.106 on the basis of 1964 reflections with $|F_o|>3\sigma(|F_o|)$. The molecules is slightly distorted from the planar conformation owing to a steric repulsion between the O and H atoms. The molecules are stacked in pairs and two pairs with different overlapping modes are randomly arranged with different populations. It has been qualitatively explained that the populations of disordered molecules reflect the difference in their lattice energies.

It has been assumed that the glycerol condensation of benz[*a*]anthracene-9,10-dione results in the formation of two isomeric products: 7*H*-benzo[*h*,*i*]chrysen-7-one (8,9-BzBT)†† and 13*H*-dibenz[*a*,*de*]anthracen-13-one (5,6-BzBT)††. The crystal and molecular structure of 8,9-BzBT has been determined using the X-ray diffraction method.[1] The molecule is distorted from the planar conformation owing to a steric repulsion between the O* and H* atoms. Around an inversion center, the molecules are stacked in pairs. Two pairs with different overlapping mode are randomly arranged with different populations. The present work was undertaken to confirm the structure of another isomer, 5,6-BzBT, and to compare its crystal and molecular structure with that of 8,9-BzBT.



7*H*-benzo[*h*,*i*]chrysen-7-one (8,9-BzBT)††



13*H*-dibenz[*a*,*de*]anthracen-13-one (5,6-BzBT)††

Scheme

†† The names in common use.

Experimental

The title compound was prepared by a method which has been reported previously.[1] The crystals used for X-ray work were grown by slow sublimation in a sealed glass tube with a nitrogen atmosphere (100 Pa). Crystal data are as follows: $C_{21}H_{12}O$; M.W. 280.1; orthorhombic; a=14.227(3), b=15.551(4), c=12.436(3) Å, and U=2751.4(9) Å^3; D_x=1.352 g cm^{-3}; Z=8; space group $Pn2_1a$; μ(Cu $K\alpha$)=42.6 cm^{-1}. The intensity data were collected on a Rigaku automated four-circle diffractometer using the $\omega/2\theta$ scan technique with a scanning rate of 4°(2θ) min^{-1}. The dimensions of the crystal used for data collection were 0.4×0.35×0.3 mm. A total of 2569 independent reflections were measured (up to 2θ=125.0°) using graphite monochromated Cu $K\alpha$ radiation, of which 1694 reflections with $|F_o|>3\sigma(|F_o|)$ were used for the analysis. Corrections were made for Lorentz and polarization factors, but not for absorption.

Structure Determination

Systematic absences of $0kl$, $k+l=2n+1$ and $hk0$, $h=2n+1$ indicated the space group to be Pnma or $Pn2_1a$. The packing consideration suggested a non-centrosymmetric arrangement and the structure was successfully refined on the basis of the space group $Pn2_1a$. There are two crystallographically independent molecules in an asymmetric unit, which are denoted as A and B. The structure was determined using the direct method, with the MULTAN 78 program.[2] This structure was refined using the block-diagonal least-squares method with isotropic thermal parameters. After 6 cycles of refinement (R=0.20), 20 small peaks due to the disordered B molecule were found on the difference map*. This molecule is denoted as C. Further refinement was performed using the full-matrix least-squares method with the SHELX 76 program.[3] The anisotropic thermal parameters were used for the non-hydrogen atoms of the A and B molecules and the isotropic thermal parameters were used for the atoms of the C molecules and H atoms. The C molecule was constrained to have the same structure as that of A. The final R became 0.106. The population factors of the B and C molecules were refined to be 0.80(1) and 0.20(2), respectively. No peaks higher than 0.3 eÅ^{-3} were found on the final difference map. The atomic scattering factors were taken from Ref. 4. The final atomic parameters with their standard deviations are listed in Table 1.**

Results and Discussion

Figure 1 illustrates the crystal structure of 5,6-BzBT viewed along the b axis. One of the two crystallographically independent molecules takes a disordered structure, B and C, which are situated on nearly the same plane and have different orientations. The two

* No diffuse scattering was observed on the Weissenberg photographs.

** Lists of the observed and calculated structure factors, anisotropic thermal parameters for non-H atoms and positional parameters for H atoms are deposited as Document No. 8444 at the office of the Chemical Society of Japan.

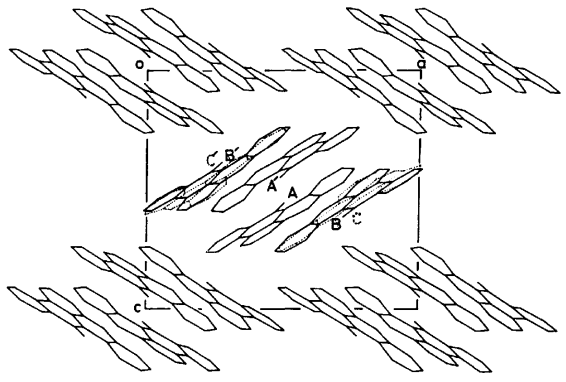

Fig. 1. Projection of the crystal structure along the b axis.
A and B′, and A and C′ form dimer pairs; A and A′ *etc.* are related to each other by the symmetry 2_1.

crystallographically independent molecules are stacked on each other as shown in Fig. 2. The mean interplanar distances between A and B′, and A and C′, are 3.47(2) and 3.58(2) Å, respectively, which are similar to 3.47(1) and 3.52(3) Å observed in the 8,9-BzBT crystal.[1] There is no unusually short contacts between the molecules.

The deviations of the atoms from the mean molecular plane are shown in Fig. 3. The bond distances and angles are listed in Tables 2 and 3, respectively. The molecules are significantly distorted from a planar conformation owing to the overcrowding around the O atom, which is also found in the 8,9-BzBT crystal. The steric repulsion between O and C(21)–H(21) is released mainly by the enlargement of the O–C(7)–C(16) angle and the twisting of the C(7)–O and C(6)–C(21) bonds. The angle of O–C(7)–C(16) and the twisting angle of O–C(7)···C(6)–C(21) are 126° and 8.2° in A, and 125° and 6.3° in B, respectively. They are comparable to 123° and 6° in 8,9-BzBT.

The interplanar distances between A and B′ or A and C′ seems to indicate that the interaction between the two molecules should be weak. This suggests that the difference in populations of the disordered molecules, B and C, is brought about by the crystalline field. A similar disordering is also found in the 8,9-BzBT

crystal. In order to clarify the effect of the crystalline field, the lattice energies were calculated for the two ordered structures using the program PCK5;[5] one is composed of A and B, and the other of A and C. Only the nonbonded interatomic repulsive force was taken into account. The orientation and translation of the molecules were refined to obtain the minimum lattice energy, the molecular geometry being fixed. Several starting structures were constructed by rotating and translating the molecules to a small extent from the position determined by X-ray analysis. Figure 4 shows the structures with the minimum lattice energies and the structure studied by X-ray analysis. The structure

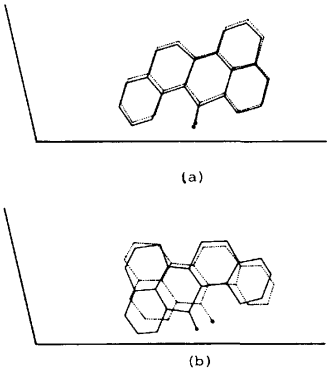

Fig. 5. Results of the packing analysis for 8,9-BzBT. (a) and (b) correspond to the molecules (I) and (II),[1] respectively.
The stuctures with minimum energies and the ones obtained by the X-ray analysis are dotted and solid lines, respectively.

calculated for B is considerably different from the X-ray structure. The lattice energies calculated are 25.1 and 31.8 KJ mol^{-1} for (a) and (b), respectively. This result qualitatively explains the smaller population of the C molecule.

Similar calculations were also performed for the disordered structure of 8,9-BzBT. In this case, the asymmetric unit of the space group $P2_1/c$ contains one molecule, which is disordered with a ratio of about 4:1. Figure 5(a) shows the structure obtained by X-ray analysis and by the minimum-energy calculation for the molecule with the greater population, whereas Fig. 5(b) is the corresponding one for the molecule with the smaller population. The minimum lattice energies are 13.8 and 31.0 KJ mol^{-1} for (a) and (b), respectively. These results suggest that several packing modes have energies similar to each other in the crystals of such condensed polycyclic aromatic compounds and the populations of the disordered molecules reflects the difference in their lattice energies.

Temperature Effect on Decay of Ions and Radicals in Supercooled Liquids as Studied by Pulse Radiolysis and γ-Radiolysis: 1-Propanol and Ethanol

Noriyuki KATO,* Tetsuo MIYAZAKI, Yukihiro KAWAI, and Kenji FUEKI
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
(Received March 9, 1984)

The decay-rate constants, k, of dipentyl disulfide anions or benzyl radicals in 1-propanol and ethanol were measured over a temperature range of 107—230 K by pulse- and γ-radiolysis method. The decay-rate constants were found to range over nine orders of magnitude. The decay kinetics is a composite first-order reaction. Since the decay rates of reaction intermediates observed are diffusion-controlled, the decay-rate constants represent directly the rates of molecular transport in the supercooled liquids. It was found that the temperature dependence of the decay-rate constants could be expressed by the following equation.

$$\log\frac{k}{T} = -\frac{A}{T-T_g} + B,$$

where T is the absolute temperature, A and B are constants. T_g is the glass transition temperature. The molecular diffusion of the ions or radicals in the supercooled liquids was completely suppressed at the glass transition temperature. The temperature dependence of the decay-rate constant was compared with that of the viscosity of the matrix. It was found that the temperature, at which the molecular diffusion is completely suppressed is much higher than the temperature at which the viscosity is infinite.

1-Propanol and ethanol form supercooled liquids at low temperature. Reaction intermediates, such as ions and free radicals, are produced in these alcohols by exposure to γ-rays or high-energy electrons. When the ions or radicals do not react with the solvent, they diffuse in the solvent to recombine with other reactive species. The diffusion of the reaction intermediates in the supercooled liquids is an important process in condensed-phase radiation chemistry.

The temperature dependence of the rate constants of reaction intermediates in condensed media has been studied by several workers: Leone and Hamill,[1] Fuller *et al.*,[2] Gilles and Boyd,[3] and Čerček[4] reported that the rate constants for reactions of ionic species produced by pulse radiolysis were correlated with the viscosity of the solvents. The decay of free radicals produced by γ-radiolysis of organic solutions has been investigated at low temperatures by Dainton *et al.*[5] and Willard *et al.*[6] Since the previous studies on the decay of reaction intermediates were undertaken only by the use of either pulsed-electron beams or γ-rays, the decay-rate constants were obtained over at most three orders of magnitude.

Recently we have reported the decay-rate constants of solute ions produced by both the pulse- and γ-radiolysis of 2-methyltetrahydrofuran(MTHF) and of a methylcyclohexane(MCH)-2-methylbutane(2MB) mixture over wide temperature (88—230 K) and viscosity ranges.[7] By use of both pulse- and γ-radiolysis the decay-rate constants of the reaction intermediates were obtained over the range of nine orders of magnitude, and then it was found that the temperature dependence of the decay-rate constants is closely related to the glass transition temperature, T_g, of the solvents. However, the relation between the decay-rate constants and the viscosity could not be discussed in the previous paper,[7] since the viscosity of MTHF or a MCH–2MB mixture was not known over a wide temperature range.

The viscosity of 1-propanol or ethanol was measured over a wide temperature range.[8,15] In order to compare the decay-rate constants of reaction intermediates with the viscosity, we have now studied the decay of ions and radicals produced in the temperature range 107—230 K. The decay-rate constants were also obtained over nine orders of magnitude. The decay-rate constant of reaction intermediates represents directly a microscopic molecular transport property, while the viscosity reflects a macroscopic transport phenomenon. Thus, it was found that the diffusible behavior obtained by the measurement of such rate constants provides us with direct information on microscopic molecular transport in the supercooled liquid, in contrast to the viscosity behavior as a macroscopic transport phenomenon in the supercooled liquid.

Experimental

Spectrograde ethanol, supplied by Nakarai Kagaku Co., and standard pure 1-propanol, supplied by Hayashi Junyaku Co., were used as received. Standard pure dipentyl disulfide (DPDS) was used after the distillation *in vacuo* and standard pure benzyl chloride was used without further purification. The sample was degassed on a vacuum line and sealed off.

Pulsed-electron beams were generated with a Febetron 707 accelerator operated at an electron energy of 2 MeV, and the duration time of a pulse was 20 ns. The radiation dose of one pulse is about 6×10^4 rad. The dose was controlled by inserting a brass mesh between the sample and the electron beam exit. The sample, sealed into a quartz cell, is fixed in a sample holder of a metal Dewar which was described in a previous paper.[9] The temperature of the sample can be controlled within an error limit of ±0.1 K. The temperature rise of the sample was less than 0.5 K immediately after the pulse irradiation. An apparatus for optical absorption measurements consists of a Xenon lamp, a monochromator, a photomultiplier, an oscilloscope, and a polaroid camera.[10] The signals obtained from pulse radiolysis were analyzed by use of a UP10E personal computer (Nippon Univac Co., Ltd.).

γ-Irradiation was made with ^{60}Co γ-rays at a dose rate of 5×10^5 rad/h. The dose given to the n-C_3H_7OH–DPDS system

was 3.5×10^5 rad, while that of the n-C_3H_7OH-$C_6H_5CH_2Cl$ and the C_2H_5OH-$C_6H_5CH_2Cl$ system was 1.0×10^5 rad.

After γ-irradiation in liquid nitrogen at 77 K, the sample was stored in liquid methane (100—111 K) or a liquid isopentane-methane mixture (112—120 K). The temperature of the liquid methane or liquid isopentane-methane mixture was controlled by addition of liquid nitrogen. The temperature of the sample can be fixed within an error limit of ±0.5 K. All optical absorption measurements on γ-irradiated samples were carried out at 77 K.

Results

Figure 1 shows optical absorption spectra of the irradiated n-C_3H_7OH containing 1 mol% DPDS (Fig. 1-a) and 3 mol% $C_6H_5CH_2Cl$ (Fig. 1-b). The absorption observed in the γ-radiolysis, shown by a solid line, was obtained at 77 K. Absorption bands around 420 nm (Fig 1-a) and 318 nm (Fig. 1-b) are attributed to DPDS anions[11] and benzyl radicals,[12] respectively. The absorption observed in the pulse radiolysis at 140 K, denoted by circles, indicates clearly the formation of DPDS anions (Fig. 1-a) and benzyl radicals (Fig. 1-b). When the C_2H_5OH-$C_6H_5CH_2Cl$ (3 mol%) system was irradiated by γ-rays at 77 K or pulsed-electron beams in the temperature ranges of 125—200 K, the optical absorption spectrum of benzyl radicals was also observed.

The decay of DPDS anions or benzyl radicals in the present systems, represented by the optical density of their absorption maxima, were similar to those of pyrene anions observed in the MCH-2MB(3:1 in volume)-pyrene and the MTHF-pyrene systems.[7]

Discussion

Decay Kinetics of Dipentyl Disulfide Anions and Benzyl Radicals. When DPDS anions and benzyl radicals decay by a first-order reaction or a second-order reaction, the decay should be described by Eq. 1 for the first-order reaction or Eq. 2 for the second-order reaction.

$$\log (OD/OD_o) \propto -kt, \quad (1)$$

$$(1/OD) - (1/OD_o) \propto kt, \quad (2)$$

where OD_o is the initial optical density of the absorption of the anions or radicals, and OD is the optical density at a time, t, after irradiation. Figure 2 shows $[(1/OD)-(1/OD_o)]$ of DPDS anions against time in the radiolysis of n-C_3H_7OH-DPDS(1 mol%) at 140 K. The slope at a dose of 1.7×10^4 rad does not coincide with that at 6×10^4 rad, indicating that the slope depends upon the initial concentration of DPDS anions. Thus, the second-order reaction plays a minor role in the decay of DPDS anions. Figure 3 shows $\log (OD/OD_o)$ of DPDS anions against time in the radiolysis of n-C_3H_7OH-DPDS(1 mol%) at 140 K. The decay curves at different initial anion concentrations (resulting from different doses) roughly superimposed on each other, but show a curvature convex to the origin, rather than the straight line for a "pure" first-order decay. Thus, the DPDS anions in n-C_3H_7OH decay by a composite first-order kinetics which was proposed previously by Willard *et al.* for the decay of alkyl radicals in γ-irradiated alkyl iodides.[13] The decay of benzyl radicals in the radiolysis of n-C_3H_7OH-$C_6H_5CH_2Cl$(3 mol%) and C_2H_5OH-$C_6H_5CH_2Cl$(3 mol%) was also expressed by a composite first-order kinetics. As was reported in our previous paper,[7] the pyrene anions in MTHF and in a MCH-2MB mixture decay by a composite first-order kinetics. Thus, it can be said that the anions and radicals in the supercooled liquids, such as 1-propanol, ethanol, MTHF, and a MCH-2MB mixture, do not decay by a simple first-order process but a composite first-order process.

Since the shape of the composite first-order decay curve probably arises from various distances of intraspur diffusion before reactions, the observed decay curve consists of a differential decay rate. For analytical convenience the apparent decay-rate constants, k_{75}, k_{50}, and k_{35} are defined here to be $(-\ln 0.75)/t_{75}$, $(-\ln 0.5)/t_{50}$, and $(-\ln 0.35)/t_{35}$, where t_m is the time required for the decay to m% of the initial amount of ions or radicals.

OD and OD_0 are the optical density at time t and the initial optical density, respectively.

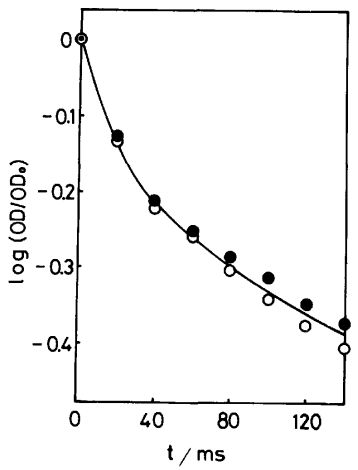

Fig. 3. The first-order kinetics plots of the decay of dipentyl disulfide anions in the pulse radiolysis of 1-propanol-dipentyl disulfide (1 mol%) at 140 K. ●: Irradiation dose; 6×10^4 rad, ○: Irradiation dose; 3.1×10^4 rad. OD and OD_0 are the optical density at time t and the initial optical density, respectively.

Since the temperature dependences of k_{75} and k_{35} coincide with that of t_{50}, the discussion on the decay-rate constant is limited here to k_{50}.

Decay of Dipentyl Disulfide Anions in Irradiated 1-Propanol. The formation of DPDS anions in the radiolysis of n-C_3H_7OH–DPDS(1 mol%) are described by the following reactions:

$$n\text{-}C_3H_7OH \rightsquigarrow n\text{-}C_3H_7OH^+ + e^-, \quad (3)$$

$$e^- + DPDS \longrightarrow DPDS^-. \quad (4)$$

They decay by the following neutralization reaction.

$$DPDS^- + M^+ \longrightarrow P, \quad (5)$$

where M^+ means the n-C_3H_7OH cation or DPDS cation formed by hole capture, and P denotes some products. Since the DPDS anions decay by a composite first-order reaction, they decay by recombination with cationic species in a spur. That is, most of DPDS anions decay by recombination with M^+ in close proximity.

An apparent activation energy, E, for the decay of DPDS anions is evaluated by $E=R\times d(\ln k)/d(1/T)$, where R is the gas constant. k is the apparent decay-rate constant for DPDS anions, defined by $(\ln 2)/t_{1/2}$ (*cf.* previous section). Then E=17, 29, and 71 kJ mol^{-1} are obtained for the temperature ranges of 170—155 K, 155—135 K, and 125—111 K, respectively. This implies that the Arrhenius-type activation energy is inappropriate to be defined under our experimental conditions. Since recombination of the anions in reaction (5) needs no activation energy, the apparent activation energy for the decay of DPDS anions arises from the diffusion controlled processes before recombination. The apparent activation energy (71 kJ mol^{-1}) for the decay of DPDS anions at 125—111 K may correspond to the barrier height for the molecular diffusion of DPDS anions at low temperature rather than for the tunneling neutralization. The tunneling neutralization may play a minor role in the decay of DPDS anions.

The temperature effect on the decay of reaction intermediates in the radiolysis will be discussed in terms of the relation between the decay-rate constant and the viscosity. When the rate constant for a bimolecular diffusion-controlled process expressed by Eq. 6 is connected with the diffusion coefficient expressed by the Stokes-Einstein relation (Eq. 7), Eq. 8 can be obtained.

$$k = 4\pi r_{ab} D_{ab}, \quad (6)$$

$$D = k_B T/6\pi r\eta, \quad (7)$$

$$k/T \propto \eta^{-1}, \quad (8)$$

where r_{ab} is the separation distance between two molecular species in collision, and $D_{ab}=D_a+D_b$ is the relative diffusion coefficient of the two species (a, b), and k_B is the Boltzmann's constant, r is the radius of a molecular species as a moving sphere, and η is the viscosity of solvent. The viscosity is related to the solvent-solvent molecular interaction, whereas the diffusion processes of reaction intermediates are related to the solute-solvent interaction. Equation 9 applies to the latter case.

$$k/T \propto \eta^{-n}, \quad (9)$$

where n is equal to or less than unity.[2]

Since the decay of pyrene anions in the irradiated MTHF or a MCH–2MB mixture can be expressed by the Doolittle-type equation[7,14] which has often been used for relaxation phenomena in supercooled liquids, we will examine whether the temperature effect on the decay-rate constant for DPDS anions can also be expressed by this type of equation (Eq. 10).

$$\log\frac{k}{T} = -\frac{A}{T-T_d^\circ} + B, \quad (10)$$

where A and B are constants. T_d° is the temperature at which the molecular transport of reaction intermediates is completely suppressed. T_d°, A, and B were

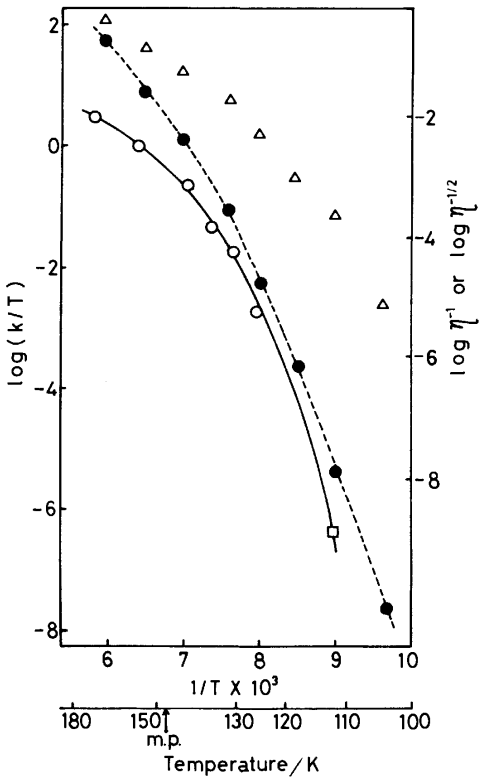

Fig. 4. Temperature dependence of the decay-rate constant of dipentyl disulfide anions in the irradiated 1-propanol-dipentyl disulfide (1 mol%). ○: Pulse radiolysis, □: γ-radiolysis, ——: Eq. 11 in text, ●: $\log \eta^{-1}$, ----: Eq. 12 in text, △: $\log \eta^{-1/2}$. The viscosity, η (in poise), of 1-propanol was quoted from Ref. 8.

determined so that they could best reproduce the experimental decay-rate constants.

Equation 11 is obtained for the decay of DPDS anions in n-C_3H_7OH which is illustrated by a solid line in Fig. 4.

$$\log \frac{k}{T} = -\frac{157.6}{T-94} + 2.577, \qquad (11)$$

where k is in units of s^{-1}. The error limit of T_g is ±2 K. The curve drawn by using Eq. 11 fits well the experimental (k/T) (*cf.* Fig. 4). The reported viscosity[8] of n-C_3H_7OH is also shown in the figure. It is well-known that the viscosity can be expressed by the Doolittle-type equation,[14] in which T_g in Eq. 10 is replaced by T_v°, a characteristic temperature in viscosity. The reported viscosity,[8] η (in poise), of n-C_3H_7OH can be expressed by the following equation as a function of temperature.

$$\log \eta^{-1} = -\frac{409.3}{T-75} + 3.501 \qquad (12)$$

Figure 4 shows that the temperature dependence of $\log (k/T)$ is different from those of $\log \eta^{-1/2}$ and $\log \eta^{-1}$.

Decay of Benzyl Radicals in Irradiated 1-Propanol and Ethanol. When n-C_3H_7OH containing 3 mol% $C_6H_5CH_2Cl$ or C_2H_5OH containing 3 mol% $C_6H_5CH_2Cl$ is irradiated by pulsed-electron beams or γ-rays, benzyl

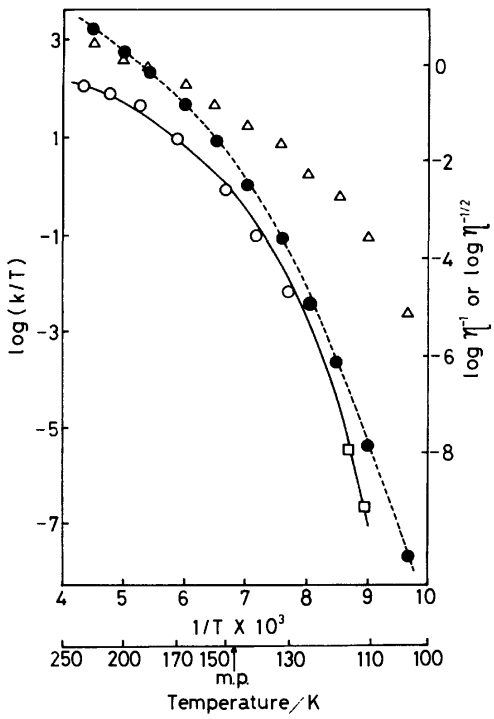

Fig. 5. Temperature dependence of the decay-rate constant of benzyl radicals in the irradiated 1-propanol-benzyl chloride (3 mol%). ○: Pulse radiolysis, □: γ-radiolysis, ——: Eq. 14 in text, ●: $\log \eta^{-1}$, ----: Eq.12 in text, △: $\log \eta^{-1/2}$. The viscosity, η (in poise), of 1-propanol was quoted from Ref. 8.

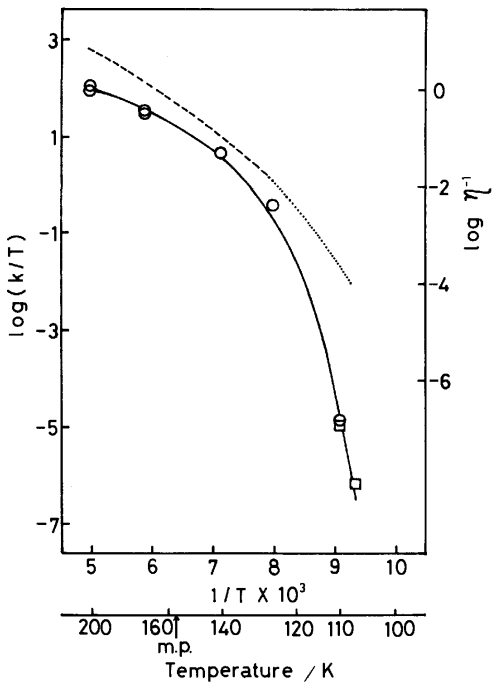

Fig. 6. Temperature dependence of the decay-rate constant of benzyl radicals in the irradiated ethanol-benzyl chloride (3 mol%). ○: Pulse radiolysis, □: γ-radiolysis, ——: Eq.15 in text, ----: $\log \eta^{-1}$, ·····: $\log \eta^{-1}$ extrapolated by Eq. 16, see text. The viscosity, η (in poise), of ethanol was quoted from Ref. 15.

radicals are produced by the dissociative electron attachment.

Since the benzyl radicals decay by a composite first-order reaction, they may decay by the following geminate recombination with the Cl^- ion rather than random recombination with other radicals.

$$C_6H_5CH_2 + Cl^- \longrightarrow C_6H_5CH_2Cl^- \quad (13)$$

Willard *et al.* reported previously that the C_2H_5 radicals produced from dissociative electron capture by ethyl iodide at 77 K decay by geminate recombination of the $(C_2H_5+I^-)$ pair.[13] $C_6H_5CH_2Cl^-$ produced by reaction (13) decays by the recombination with n-$C_3H_7OH^+$ or $C_2H_5OH^+$. Another possibility that the benzyl radicals react with a small amount of impurities, such as oxygen, in the alcohol cannot be ruled out in this system. Since the reaction of a benzyl radical with 1-propanol or ethanol is endothermic, the benzyl radical cannot react with the solvent at such low temperatures as those in the present experiments.

Though ethanol is liquid at 170 K, the viscosity (0.62 poise) at this temperature is much higher than that (0.01 poise) at room temperature.[15] Thus, the random diffusion of benzyl radicals may be suppressed at 170 K, resulting in geminate recombination.

Figure 5 shows the apparent decay-rate constants ($\log(k/T)$) for benzyl radicals in the n-C_3H_7OH-$C_6H_5CH_2Cl$ (3 mol%) system. The experimental (k/T) can be well expressed by the following equation, as shown by a solid line.

$$\log\frac{k}{T} = -\frac{202.6}{T-92} + 3.500, \quad (14)$$

where k is in units of s^{-1}. It is noted that the value of T_d° (92 K) in Eq. 14 is approximately the same as that in Eq. 11 (T_d°=94 K) within an error limit.

Figure 6 shows the apparent decay-rate constants of benzyl radicals in the C_2H_5OH-$C_6H_5CH_2Cl$ (3 mol%) system. It is noted that the decay-rate constant at 110 K obtained by pulse radiolysis almost agrees with that by the γ-radiolysis. Equation 15 is obtained for the decay of benzyl radicals in the C_2H_5OH-$C_6H_5CH_2Cl$ system

$$\log\frac{k}{T} = -\frac{115.9}{T-95} + 3.144, \quad (15)$$

where k is expressed in units of s^{-1}. It was reported that the viscosity, η (in poise), of C_2H_5OH at the temperature T K can be expressed by Eq. 16 in the temperature range of 124—273 K.[15]

$$\log\eta^{-1} = -\frac{343.8}{T-59.7} + 3.325 \quad (16)$$

The temperature dependence of the viscosity is shown by a dashed line in Fig. 6. The viscosity values extrapolated below 124 K by using Eq. 16 are also shown by a dotted line. The temperature dependence of $\log(k/T)$ for the decay of benzyl radicals is different from that of $\log\eta^{-1}$ for C_2H_5OH.

Molecular Transport of Reaction Intermediates and Viscosity in Supercooled Liquids. The decay of reaction intermediates represents directly their molecular transport properties. It should be emphasized that the decay-rate constants in the supercooled liquids can be expressed by Eq. 10 over the wide temperature range in which the decay-rate constants change by nine orders of magnitude. Table 1 shows T_d° obtained from Eq. 10 together with the reported glass transition temperatures, T_g, of the supercooled liquids. It is interesting to note that T_d° corresponds well to T_g, though the reported values of T_g slightly differ to each other due to the different methods of measurement. Thus, Eq. 10 can be rewritten as follows:

TABLE 1. CHARACTERISTIC TEMPERATURE, T_d°, T_g, AND T_v° IN SUPERCOOLED LIQUIDS

Solvent	Diffusible intermediate	T_d°/K[a]	T_g/K	T_v°/K[b]
n-C_3H_7OH	Dipentyl	94	86—100[c], 93—100[d]	75
	Disulfide anion		94[e], 98[f]	
	Benzyl radical	92		
C_2H_5OH	Benzyl radical	95	90—96[c], 92—96[g]	60
			93—97[h], 93[e], 95[i], 96[f]	
MCH-2MB	Pyrene anion	80[j]	81[k]	63
MTHF	Pyrene anion	88[j]	88[l]	—

a) T_d° is the temperature at which the molecular diffusion of reaction intermediates is completely suppressed (*cf.* Eq. 10 in text). The error limit of T_d° is ± 2 K. b) The viscosity can generally be expressed by the Doolittle-type equation of $\log\eta^{-1}=C/(T-T_v^\circ)+D$ where C and D are constants. T_v° is the temperature at which the viscosity is infinite. c) W. Kauzmann, *Chem. Rev.*, **43**, 219 (1948). d) The value was obtained from specific heat measurements (G. S. Parks and H. M. Huffmann, *J. Phys. Chem.*, **31**, 1842 (1927)). e) The value was taken as the temperature at which the viscosity is $\approx 10^{13}$ poise, based on data in Ref. 9. f) The value quoted from Ref. 17. g) The value was obtained from specific heat measurements (G. S. Parks, *J. Am. Chem. Soc.*, **47**, 338 (1925)). h) The value was obtained from specific heat measurements (K. K. Kelley, *J. Am. Chem. Soc.*, **51**, 779 (1929)). i) The value was determined from the differential thermal analysis method (O. Haida, H. Suga, and S. Seki, *Proc. Japan Acad.*, **48**, 683 (1972)). j) The value was obtained from Ref. 7. k) The glass transition temperature of the mixture was estimated by interpolation from the T_g values of neat MCH and 2MB (*cf.* C. A. Angell, J. M. Sare, and E. J. Sara, *J. Phys. Chem.*, **82**, 2622 (1978)). l) The value was taken as the temperature at which the viscosity is $\approx 10^{13}$ poise, based on data from A. C. Ling and J. E. Willard (*J. Phys. Chem.*, **72**, 3349 (1968)).

$$\log\frac{k}{T} = -\frac{A}{T-T_g} + B. \quad (17)$$

Therefore, it is concluded that the decay-rate constant for reaction intermediates in the supercooled liquids can be expressed by Eq. 17 and that the molecular diffusion is completely suppressed at the glass transition temperature.

The viscosity can be expressed by the Doolittle-type equation, and the temperature, T_v^0, at which the viscosity is infinite, is also shown in Table 1. It is interesting to note that T_g^0 (or T_g) does not agree with T_v^0. It should be pointed out that the viscosity represents a macroscopic transport property of the solvent, while the decay rate of reaction intermediates represents the microscopic molecular transport of solutes in the solvent.

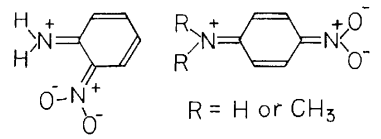
Thermochemical Studies on 3- and 4-Nitroanilines and Their *N,N*-Dimethyl Derivatives†

Junichi FURUKAWA, Shigeo MURATA, Minoru SAKIYAMA,* and Syûzô SEKI**
Chemical Thermodynamics Laboratory and Department of Chemistry, Faculty of Science, Osaka University, Toyonaka 560
(Received April 2, 1984)

Standard enthalpies of combustion and of sublimation at 298.15 K were determined and standard enthalpies of formation in crystalline and gaseous states were derived for *N,N*-dimethyl-3- and *N,N*-dimethyl-4-nitroanilines by calorimetric measurements. Stabilization energies due to the intramolecular interaction between substituents were evaluated and discussed for these compounds and 3- and 4-nitroanilines.

For most of disubstituted benzenes, dipole moment in benzene solution may be approximated by the vector sum of the dipole moments of the appropriate monosubstituted benzenes.[1] However, there are a group of exceptional compounds, 2- and 4-nitroanilines and *N,N*-dimethyl derivative of the latter being examples of such compounds. Observed dipole moments in benzene solution are by 16 and 20 per cent higher than the calculated values for 2- and 4-nitroanilines, respectively, whereas that of 3-nitroaniline is only 3 per cent higher than the calculated value.[1] The corresponding deviations are 23 and 4 per cent for *N,N*-dimethyl-4- and *N,N*-dimethyl-3-nitroanilines, respectively.[1]

The unusual dipole moments were attributed to the enhanced contribution of the following polar ortho- and para-quinonoid resonance structures to the ground state configurations of these molecules:[2]



These resonance structures are characterized by the intramolecular charge transfer interaction between (dimethyl) amino and nitro substituents through the benzene ring. In this sense, the resonance has been called "interaction resonance" or "through resonance" between "push" (electron-donating) and "pull" (electron-accepting) substituents. For 3-nitroaniline and its *N,N*-dimethyl derivative, meta-quinonoid structures are available, but their contributions to the ground state configurations were considered to be small owing to the presence of a transannular bond. The normal dipole moments of 3-nitroaniline and its *N,N*-dimethyl derivative were explained along this line.

In a previous paper,[3] standard enthalpies of formation at 298.15 K were reported for 3- and 4-nitroanilines (**1** and **2**, respectively) in gaseous state by the present authors. In this paper, standard enthalpies of combustion and sublimation are reported and standard enthalpies of formation in crystalline and gaseous states are derived for *N,N*-dimethyl-3- and *N,N*-dimethyl-4-nitroanilines (**3** and **4**, respectively). Stabilization energies have been evaluated and discussed for these molecules.

Experimental

Materials. Commercial **3** (Tokyo Kasei, G.R.) was purified by recrystallization from ethanol solution, preliminary sublimation *in vacuo*, zone melting, and fractional sublimation *in vacuo*. Commercial **4** (Tokyo Kasei, G.R.) was purified by recrystallization from ethanol, ethyl acetate, and benzene solutions, and fractional sublimation *in vacuo*. The purified sample of **4** is highly pure as revealed by the results of CO_2 determination to be shown later. That of **3** is slightly less pure as compared with the former, judging from DSC curves in the melting region.

Combustion Calorimetry. A constant temperature jacket type rotating bomb calorimeter with a platinum-lined bomb, described elsewhere,[4] was used without rotating the bomb. The calorimeter was calibrated by burning thermochemical standard benzoic acid (N. B. S. SRM 39i) under certificate conditions. Mean and standard deviation of mean of observed energy equivalents for the empty calorimeter were (15161.76±0.90) J K^{-1} (8 experiments) and (15162.9±1.3) J K^{-1}(4 experiments) for 3 and 4, respectively. In contrast to **1** and **2**,[3] **3**, and **4** in pellet form could be burnt completely without using a promoter, in most cases, in an ordinary open crucible at 3 MPa of oxygen pressure. Carbon monoxide was barely detected for **3** and **4**. Nitric acid was determined by titration with aqueous sodium hydroxide. For **4**, carbon dioxide recovery was determined by the method described elsewhere.[4b]

Sublimation Calorimetry. A sublimation calorimetric system incorporating a Calvet microcalorimeter, described elsewhere,[5] was employed. Apparatus Mark II with sample containers Mark B and apparatus Mark I with sample containers Mark A were used for **3** and **4**, respectively.

Auxiliary Quantities. Relative atomic masses were taken from the recommendation of IUPAC Commission on Atomic Weights (1977). Densities, specific heat capacities,

and $(\partial U/\partial P)_T$ values, which were used to reduce weights to masses in vacuum and to deduce standard energies of combustion from calorimetric data, are presented in Table 1. Other auxiliary quantities are as follows: T_h=298.15 K, V(bomb)=0.3469 dm^3, and $\Delta U_c^\circ/M$(fuse)=−16507 J g^{-1}.

Results

Standard Energies of Combustion. Molar standard energies and enthalpies of combustion, given in this paper, refer to the following idealized combustion reactions at 298.15 K:

$$C_8H_{10}O_2N_2(c) + (19/2)O_2(g) = 8CO_2(g) + 5H_2O(l) + N_2(g).$$

Details of the combustion calorimetric results are presented in Table 2 and 3 for **3** and **4**, respectively. Most of the symbols in these tables are similar to those used by Hubbard *et al.*[6] Mean and standard deviation of the mean for the observed standard energies of combustion, ΔU_c°(c), were −(4555.91±0.66) and −(4540.63±0.22) kJ mol^{-1}, for **3** and **4**, respectively. Relative total carbon dioxide recovery, [m(CO_2, obsd)/m(CO_2, calcd)], where m(CO_2, obsd) and m(CO_2, calcd) are the observed and calculated total masses of recovered carbon dioxide, respectively, was (1.0000±0.0002) for **4**, where uncertainty is the standard deviation of the mean.

Standard Enthalpies of Sublimation. Details of the sublimation calorimetric results are presented in Table 4 for both compounds. Observed enthalpies of sublimation for each substance were subjected to a regression analysis for linear relations between two variables.[7] Derived expressions are as follows:

and

$$\Delta H^{\circ}_{sub}(T)/\text{kJ mol}^{-1} = -(0.031\pm0.012)(T/\text{K}) + (111.9\pm4.5), \quad (2)$$

for **3** and **4**, respectively, where associated uncertainties are those at the 95 per cent confidence level. Estimated standard deviation from the fit, s_f, was 0.04 kJ mol^{-1} and 0.22 kJ mol^{-1}, for **3** and **4**, respectively. ΔH°_{sub} (298.15 K) values, obtained by extrapolation of the fits given above to 298.15 K, were (92.72±0.27) kJ mol^{-1} and (102.7±1.0) kJ mol^{-1} for **3** and **4**, respectively.[8]

Standard Thermodynamic Quantities. Derived thermodynamic quantities are presented in Table 5. Uncertainties for ΔU°_{c}(c) and ΔH°_{c}(c) are the uncertainty intervals, defined by Rossini.[9] CODATA key values for thermodynamics[10] were used to calculate ΔH°_{f}(c). Uncertainties for ΔH°_{f}(c) and ΔH°_{f}(g) were calculated by using the equation of error propagation.

a) Both the diameter and the depth of the orifice were 1.0 mm. b) The diameter and the depth of the orifice were 2.0 and 0.1 mm, respectively, for experiments at 350 and 373 K, and 2.0 and 0.1 mm, respectively, for experiments at 402 K.

Table 5. Derived standard thermodynamic quantities at 298.15 K of *N,N*-dimethyl-3-nitroaniline (**3**) and *N,N*-dimethyl-4-nitroaniline (**4**)

	3	**4**
$-\Delta U^{\circ}_{c}$(c)/kJ mol^{-1}	4555.9±1.5	4540.63±0.94
$-\Delta H^{\circ}_{c}$(c)/kJ mol^{-1}	4557.2±1.5	4541.87±0.94
$-\Delta H^{\circ}_{f}$(c)/kJ mol^{-1}	20.1±1.8	35.4±1.4
ΔH°_{sub}/kJ mol^{-1}	92.72±0.27	102.7±1.0
ΔH°_{f}(g)/kJ mol^{-1}	72.6±1.8	67.3±1.7

Discussion

For **3** and **4**, neither ΔH°_{f}(c) nor ΔH°_{f}(g) has been reported. ΔH°_{f}(g) values reported in the previous paper[3] are (62.5±1.8) kJ mol^{-1} and (55.2±1.8) kJ mol^{-1} for **1** and **2**, respectively.

The difference in ΔH°_{f} (g) between **1** and **2** and between **3** and **4** are (7.3±2.5) kJ mol^{-1} and (4.7±2.5) kJ mol^{-1}, respectively. This shows that **2** and **4** are significantly more stable than **1** and **3**, respectively, in accordance with the resonance picture in terms of the quinonoid structures.

In this paper, stabilization energies E_{stb} of the disubstituted benzenes due to the intramolecular interaction between the substituents are defined as ΔH° (=ΔU°) at 298.15 K of the following type of hypothetical gas-phase redistribution reaction:

where R is H or CH_3. This type of reactions involves the fission and formation of a C_{ar}–NO_2 (or C_{ar}–NR_2) bond and a C_{ar}–H bond ,where C_{ar} denotes the aromatic ring carbon atom. The kind and number of the cleaved bonds are identical with those of the formed ones; the only change being the one from di- and un-substituted benzenes on the left-hand side to two mono-substituted benzenes on the right-hand side. In this sense, ΔH° of this type of reaction may be considered to be a reasonable measure of the degree of intramolecular interaction between the substituents through a benzene ring leading to the stabilization of the disubstituted benzene molecule with reference to benzene, aniline (or *N,N*-dimethylaniline), and nitrobenzene molecules.

Derived (E_{stb}/kJ mol^{-1}) values are (9.3±2.2), (16.6±2.2), (12.6±3.0), and (17.9±3.5) for **1**, **2**, **3**, and **4**, respectively. The following [ΔH°_{f}(g)/kJ mol^{-1}] values were employed in this calculation: (67.6±1.0),[11] (87.8±0.8),[11] (100.5±2.9),[12] and (82.9±0.3)[11] for nitrobenzene, aniline, *N,N*-dimethylaniline, and benzene, respectively.

Parr and Wasylishen briefly reported the result of MINDO/3 calculation on **2**.[13] The reported value of ΔH°_{f}(g) was 26.51 kJ mol^{-1}, which is by 29 kJ mol^{-1} less positive than the value reported by the present authors.[3] Hehre *et al.*[14] calculated the interaction energy of **2**, which may be identified with ΔH° (=ΔU°) at 0 K of the redistribution reaction described above, from calculated atomization energies of the relevant species based on *ab initio* MO theory, employing the STO-3G minimal set. They reported 9.2 and 12.6 kJ mol^{-1} for pyramidal and planar forms of the amino group, respectively. These values are comparable with the present result.

Comparison of E_{stb} between **1** and **3** and between **2** and **4** shows that the effect of *N,N*-dimethyl substitution on E_{stb} is not significant. It is to be noted that **1** and **3** as well as **2** and **4** have been shown to have positive stabilization energies by the present analysis. From the viewpoint of the resonance theory, the 1,3-isomers are expected to be barely stabilized with respect

to benzene, aniline (or its *N,N*-dimethyl derivative), and nitrobenzene, since the contribution from the meta-quinonoid resonance structure would be small. The present result is not in accord with this expectation.

Kinetic Study of Excited Diatomic Molecules of Krypton and Xenon

Yoshiro Ito and Shigeyoshi Arai*
The Institute of Physical and Chemical Research, Wako-shi, Saitama 351-01
(Received April 17, 1984)

Excited diatomic molecules of krypton and xenon in $1^3\Sigma_u^+$ states, Kr_2^* and Xe_2^*, were produced by irradiating krypton and xenon in the presence of an excess of argon with short electron-beam pulses. The kinetic behaviors of Kr_2^* and Xe_2^* (monitored by near-IR absorption spectrophotometry) are explained quantitatively in terms of mechanisms involving three-body association and radiative decay. The rate constants were found to be $(6.5\pm0.8)\times10^{-33}$ cm^6 s^{-1} for $Kr^*+Kr+Ar\rightarrow Kr_2^*+Ar$ and $(1.6\pm0.3)\times10^{-32}$ cm^6 s^{-1} for $Xe^*+Xe+Ar\rightarrow Xe_2^*+Ar$. The rate constants for the quenching reactions of Kr_2^* were determined for Xe, H_2, O_2, N_2, CO, and NO.

The irradiation of rare gases with ionizing radiations results in the formation of excited atoms *via* direct excitation or ionization followed by charge neutralization. When pressures of rare gases are sufficiently high (10^2 Torr or higher), excited atoms are rapidly converted into excited diatomic molecules in a three-body association reaction involving one excited and two ground-state atoms.[1-3] Excited diatomic molecules of rare gases have broad and continuous vacuum UV emissions, which are attributed to the optical transitions between the bound excited and repulsive ground states.[4,5] Arai, Firestone, and their co-workers have demonstrated that rare gases irradiated with electron pulses exhibit two types of intense transient absorptions due to excited diatomic molecules in the near-IR region.[6-9] A comparison of the observed optical data with theoretical values leads to an assignment of the first absorption (at shorter wavelengths) and the second absorption (at longer wavelengths) to the transition $1^3\Sigma_u^+$ to $2^3\Pi_g$ and $1^3\Sigma_g^+$, respectively (potentical curves of diatomic molecules).[10] The two near-IR absorptions and the principal vacuum UV emission originate from a molecule in the same electronic state, *i.e.*, the lowest triplet state $1^3\Sigma_u^+$.

By observing the time dependence of the first absorption, several kinetic parameters have been determined for the excited diatomic molecules of rare gases in the $1^3\Sigma_u^+$ state.[7,9,11,12] The parameters are the rate constants of the formation and decay processes, together with quenching processes by many simple molecules. The absorption spectrophotometric method has also been applied to the kinetic study of helium molecules in the $1^3\Sigma_u^+$ state.[13]

The present paper reports on the kinetic parameters of the excited diatomic molecules of krypton and xenon. These parameters were determined by time-dependent observations of their first absorptions under various experimental conditions. The chemical reactions of excited atoms or excited diatomic molecules of rare gases should be studied more extensively, since information from such studies is important for constructing or testing theoretical models used in chemical kinetics.

Experimental

The experimental apparatus and procedures are essentially the same as those described in previous studies.[8,9,11-13] Therefore, only a few fundamental points will be briefly described.

All the samples were irradiated with 600-keV electron pulses generated from a Febetron 706. The profile had a pulse width of about 5 ns. The absorptions due to excited diatomic molecules of rare gases were measured spectrophotometrically as a function of time under various experimental conditions. The photomultiplier used was a Hamamatsu TV R316. The total rise time of the detection system was about 20 ns. Molecular absorptions were measured at a slit width of 0.30 mm, *i.e.*, a wavelength resolution of about 0.9 nm using a Narumi R23 monochromator. The widths of the 983-nm band due to an excited krypton molecule and the 1032-nm band due to an excited xenon molecule are much larger than the wavelength resolution.

Krypton and xenon purchased from Teikoku Sanso Co. and Takachiho Shoji Co., respectively, were of the highest grade and were used without further purification. The krypton used in the previous study contained xenon as an impurity. For the krypton used here, however, we could not detect any absorption due to an excited xenon atom, when 800 Torr (1 Torr=133.322 Pa) of krypton was irradiated with electron pulses. Since the energy transfer from excited krypton to xenon occurs very efficiently, the absence of excited xenon guarantees the high purity of krypton. Argon purchased from Nihon Sanso Co. did not show any sign of an impurity throughout all the observations. The other gases were obtained from Takachiho Shoji Co. and were used without further purification.

Results and Discussion

In this paper, the excited rare-gas atoms with an electronic configuration of $np^5(n+1)s^1$ are denoted by $X^*(^1P_1)$, $X^*(^3P_0)$, $X^*(^3P_1)$, and $X^*(^3P_2)$ in the L-S coupling notation, where X is a rare-gas atom and n is the principal quantum number of the outer shell of the ground state atom X. The excited diatomic molecules in the $1^3\Sigma_u^+$ state are denoted by X_2^*.

Formation of Excited Diatomic Molecules in Mixtures. The formation processes of Kr_2^* and Xe_2^* in the presence of excess argon were studied by measuring their near-IR absorptions as a function of time. Kr_2^* has its first absorption bands at 965.5, 974.3, 983.3, and 988.6 nm, and Xe_2^* has corresponding bands in the region of 1000—1120 nm.[6-9] The time dependencies of the absorptions were monitored at 983.3 nm for Kr_2^* and at 1032.0 nm for Xe_2^*. No change in shape was observed for the first absorption bands of Kr_2^* and Xe_2^* through their formation and decay processes in previous studies.[8,9]

Although the ionizing radiation interacts mainly

with the excess argon at an initial stage, excitation energies are expected to be transferred rapidly to krypton and xenon in the mixtures examined here. For example, the energy-transfer rates from $Ar^*(^3P_0)$ and $Ar^*(^3P_2)$ to $Kr(^1S_0)$ are estimated to be 1.5×10^6 and 3.7×10^6 s^{-1}, respectively, in a mixture of 930-Torr argon and 20-Torr krypton.[14] Our time-dependent absorption measurements for $Ar^*(3p^54s^1)$ indicated a rapid disappearance (within 1 μs or so) after a pulse in the same mixture. Chang and Setser have measured two-body deactivation rate constants for $Ar^*(3p^54p^1)$, which were produced by the laser-pulse excitation of $Ar^*(3p^54s^1)$.[15] The constants range from 1×10^{-10} to 2×10^{-11} cm^3 s^{-1}. Therefore, the lifetimes of $Ar^*(3p^54p^1)$ are estimated to be less than about 2 ns in 760-Torr argon at room temperature. We observed several visible and near-IR emission lines originating from $Ar^*(3p^54p^1)$ and $Kr^*(4p^55p^1)$ in irradiated argon-krypton mixtures. In all the mixtures examined, emissions terminated immediately after irradiation ceased. The excited argon and krypton atoms in higher states are, if produced, degraded almost instantaneously into those in the four lower states *via* radiative or collision processes. Although there are many visible and near-IR emission lines caused by excited rare-gas atoms at various high levels, such lines have not been observed in electron-irradiated rare gases at about 760 Torr except for those by $X^*(np^5(n+1)p^1)$.[6] The energy-transfer rate from Ar_2^* to $Kr(^1S_0)$ is 6.4×10^7 s^{-1} in a mixture of 930-Torr argon and 20-Torr krypton.[11]

Charged species disappear very rapidly after irradiation ceases. Ion recombination coefficients for X_2^+ and e^- have been summerized in the review by Bardsley and Biondi.[16] The coefficients are 7.5×10^{-7} cm^3 s^{-1} for Ar_2^+, 12×10^{-7} cm^3 s^{-1} for Kr_2^+, and 14×10^{-7} cm^3 s^{-1} fox Xe_2^+. Assuming that the electron pulse has an accelerating energy of 600 keV, a total output of 10 J, and a beam cross section of 2 cm^2, one can roughly estimate the initial ion concentration (n_0) from the energy loss of the incident electrons in 950-Torr argon.[17] The calculated initial lifetimes of X_2^+, *i.e.*, (recombination coefficient$\times n_0)^{-1}$ are less than 0.22 ns, indicating a rapid disappearance of charged species.

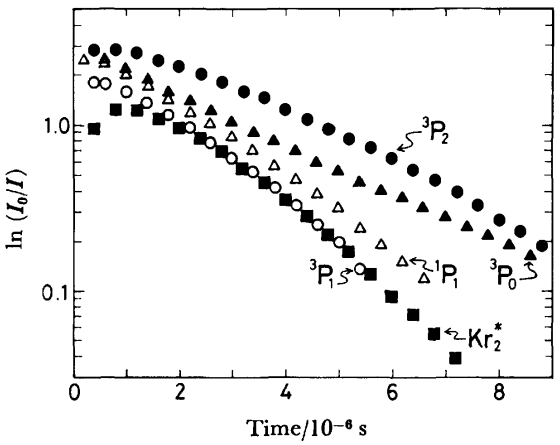

Fig. 1. Logarithmic plots of optical densities against time for Kr_2^* and $Kr^*(^1P_1, ^3P_0, ^3P_1,$ and $^3P_2)$ in the mixture of 60 Torr Kr and 890 Torr Ar. I_0, intensity of analyzing light transmitted in the absence of absorbing species; I, that in the presence of absorbing species. Absorption measurements, see text.

Figure 1 shows logarithmic plots of optical densities *vs.* time for Kr_2^*, $Kr^*(^1P_1)$, $Kr^*(^3P_0)$, $Kr^*(^3P_1)$, and $Kr^*(^3P_2)$ in the mixture of 890-Torr argon and 60-Torr krypton. $Kr^*(^1P_1)$, $Kr^*(^3P_0)$, $Kr^*(^3P_1)$, and $Kr^*(^3P_2)$ were monitored by observing absorption lines at 828.1, 785.4, 819.0, 892.9 nm, respectively (Fig. 1). The apparent lifetimes of these excited species range from 1.5 to 3 μs in the mixture. However, the Lambert-Beer law does not hold between optical density and concentration, because the bandpass of analyzing light used here (*i.e.*, about 0.35 nm) is larger than the widths of the atomic absorption lines. The net lifetimes should be shorter than the apparent ones by a factor between 1 and 2.[18]

The time dependence of the concentration of an excited diatomic molecule in a mixture can be explained by the following mechanism:

$$\text{X in excess argon} \rightsquigarrow X^* \tag{1}$$

$$X^* \longrightarrow X, \tag{1}$$

$$X^* + X + M \longrightarrow X_2^* + M, \tag{2}$$

$$X_2^* \longrightarrow 2X + h\nu, \tag{3}$$

where M is a third body. The mechanism leads to the equation:

$$[X_2^*] = \frac{k_2[X][M][X^*]_0}{k_1+k_2[X][M]-k_3}\{\exp[-k_3t] - \exp[-(k_1+k_2[X][M])t]\}, \tag{4}$$

where k_n is the rate constant of the corresponding reaction and $[X^*]_0$ is an initial concentration of X^*. The absorption intensity *vs.* time curves observed for Kr_2^* and Xe_2^* exhibit an early growth and a subsequent slow decay after passing a maximum. The apparent decay and growth should correspond to the first and second exponential terms of Eq. 4, respectively, in the high-pressure region where $\{k_1+k_2[X][M]\}$ is larger than k_3. On the other hand, the relation is reversed in the low-pressure region where $\{k_1+k_2[X][M]\}$ is smaller than k_3, since the sign of Eq. 4 changes. As the result, the apparent first-order decay rate is equal to $\{k_1+k_2[X][M]\}$.

On the basis of Eq. 4, we have analyzed a series of absorption-intensity *vs.* time curves obtained with Kr_2^* and Xe_2^* in mixtures, where the total pressures were kept nearly constant and the partial pressures of krypton and xenon were varied over a wide range. In fact, the observed curves were found to approximately fit the difference of the two exponential terms, as shown in Fig. 2. Since the partial pressures of krypton and xenon are relatively low, the apparent first-order decay rates obtained here are expected to correspond to $\{k_1+k_2[X][M]\}$ in the second term. We determined the first-order decay rates from late portions of absorption-intensity *vs.* time curves, *i.e.*, portions later than 2 μs after pulses. Figures 3 and 4 present plots of $\{k_1+k_2[X][M]\}$ against [X] for krypton and xenon, respectively, where good linear relations are seen for both gases. The radiative decay rates, *i.e.*, k_3's of Kr_2^*

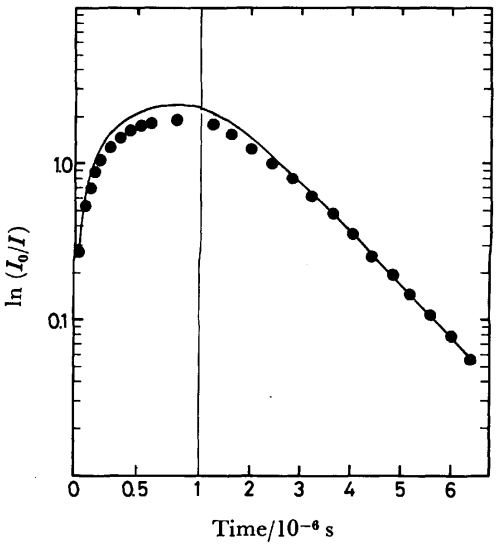

Fig. 2. Logarithmic plots of optical density at 983.3 nm against time for Kr_2^* in the mixture of 76 Torr Kr and 874 Torr Ar. Time scales are different between the regions before and after 1 μs. Solid curve was calculated from Eq. 4, where $k_3=1.8\times10^6$ s^{-1} and $k_1+k_2[M][Kr]=7.7\times10^5$ s^{-1}.

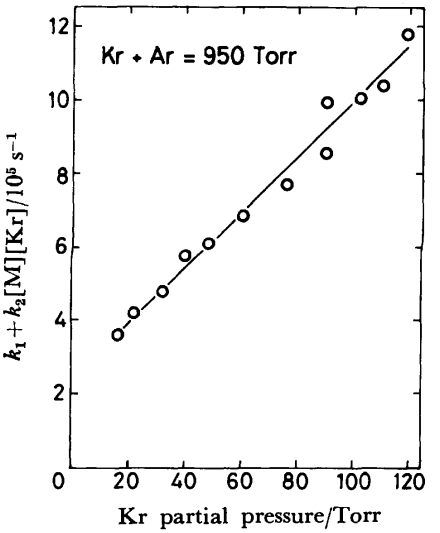

Fig. 3. Plot of $k_1+k_2[M][Kr]$ against partial pressure of Kr.

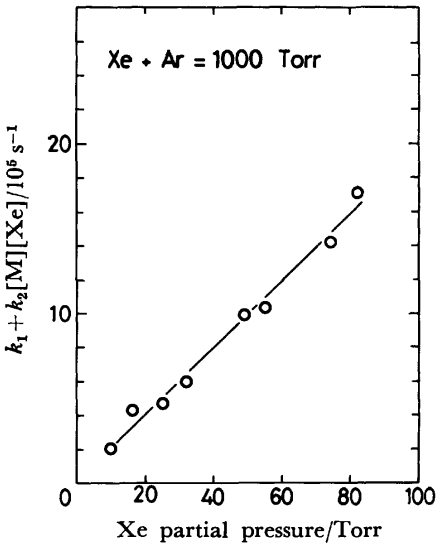

Fig. 4. Plot of $k_1+k_2[M][Xe]$ against partial pressure of Xe.

and Xe_2^* have been reported to be 2.83×10^6 s^{-1} and 1.0×10^7 s^{-1}, respectively.[7,19] The decay rates are much larger than the apparent first-order decay rates shown in Figs. 3 and 4. The rate constants for the formation of Kr_2^* and Xe_2^* are tabulated in Table 1, together with those reported previously.[3,20,21] The rate constant determined here for Xe_2^* is a little smaller than that reported in the vacuum UV-emission study by Rice and Johnson.[20] However, it agrees with more recent determination by Gleason *et al.* within the error limits.[21]

It is generally accepted that the precursor responsible for the formation of X_2^* in the $1^3\Sigma_u^+$ state is one or more of the excited atoms $X^*(^1P_1)$, $X^*(^3P_0)$, $X^*(^3P_1)$, and $X^*(^3P_2)$. The observed results presented in Figs. 3 and 4 indicate that X_2^* is produced in a three-body reaction involving X, X*, and M, where the rate constant is given by the slope in each figure. If two or more precursors are involved in the formation of X_2^*, the corresponding three-body reactions should have almost the same rate constant among different precursors. There might be a possibility that some collisional processes induce the degradation of higher excited atoms, *i.e.*, $X^*(^1P_1)$, $X^*(^3P_0)$, and $X^*(^3P_1)$ into $X^*(^3P_2)$, and the resulting excited atom $X^*(^3P_2)$ acts as a precursor in the formation of X_2^*. However, it seems difficult to reconcile such a complicated mechanism with the simple relations presented in Figs. 3 and 4, except for the extreme case that collisional processes proceed much more rapidly than the three-body formation process of X_2^*. The results (Fig. 1) are inconsistent with the extreme case. The excited diatomic molecule in the $1^3\Sigma_u^+$ state is correlated to $X^*(^3P_2)$ and $X(^1S_0)$ at an infinite nuclear distance in theoretical studies.[10,22-27] The molecule in the $1^1\Sigma_u^+$ state is correlated to $X^*(^3P_1)$ and $X(^1S_0)$. Further, the combination of $X^*(^1P_1)$ and $X(^1S_0)$ leads to molecules in other states and that of $X^*(^3P_0)$ and $X(^1S_0)$ leads to repulsive potentials. These studies suggest that the most probable precursor is $X^*(^3P_2)$. The other excited atoms do not contribute appreciably to the formation of $X_2^*(1^3\Sigma_u^+)$, although they might produce $X_2^*(1^1\Sigma_u^+)$ in a similar three-body reaction.

Quenching Reactions of Excited Krypton Molecule. Excited diatomic molecules of rare gases are very reac-

tive with other molecules since they have large internal excitation energies. The energies are estimated to be 16.1 eV for Ne_2^*, 10.8 eV for Ar_2^*, 9.2 eV for Kr_2^*, and 7.7 eV for Xe_2^*. These values can be derived from the well depths of excited molecules in the $1^3\Sigma_u^+$ state and energy levels of excited atoms in $^3P_2$ states.[10,25,27,28] Rate constants of quenching reactions of He_2^*, Ne_2^*, and Ar_2^* by a number of simple gases were already determined using an absorption spectrophotometric technique.[11-13] However, those of Kr_2^* have been scarcely known in both absorption and emission studies.

The decay rate of Kr_2^* in pure krypton increases with increasing pressure of krypton (at low pressures). The apparent decay reflects the three-body association (similarly for the mixtures of argon and krypton). However, the decay becomes constant at pressures above 600 Torr. The radiative process now corresponds to the observed decay in the pressure region. This result is consistent with the previous one.[7] The rate was found to be 2.9×10^6 s^{-1}. In 800-Torr krypton, Kr_2^* is produced much more rapidly as compared with the radiative decay process. The addition of a small amount of quenchers into 800-Torr krypton enhanced the decay rate of Kr_2^*. Plots of decay rates against partial pressures of quenchers gave straight lines for the quenchers examined here. Table 2 tabulates the rate constants and cross-sections obtained with Xe, H_2, O_2, N_2, CO, and NO. The reactivities of Kr_2^* toward these gases are more or less similar to those of Ar_2^*; the rate constants are relatively small for H_2 and N_2 in both Kr_2^* and Ar_2^*.[11]

Table 2. Rate constants and cross sections of quenching reactions of $Kr_2^*(1^3\Sigma_u^+)$

Quencher	Rate constant 10^{-11} cm^3 s^{-1}	Cross section 10^{-2} nm^2
Xe	14±3	40±8
H_2	4.0±0.8	2.2±0.4
N_2	0.62±0.12	1.1±0.2
O_2	37±7	70±14
CO	12±2	21±4
NO	35±7	65±13

Photocatalytic Reactions of Azide Ions on Platinized Titanium Dioxide Powders in Solutions

Yoshio NOSAKA,* Yutaka ISHIZUKA, Kohji NORIMATSU, and Hajime MIYAMA
Department of Chemistry, The Technological University of Nagaoka, Kamitomioka, Nagaoka 949-54
(Received April 28, 1984)

Ammonia was formed photocatalytically from an aqueous solution of azide ion by using illuminated Pt/TiO_2 semiconductor powder. The reaction products, NH_3, N_2, and small amounts of N_2O and NO_3^-, were detected. Hydrogen, O_2 and N_2H_4 were not formed in the primary reaction products. From these results, together with photoelectrochemical measurements, a mechanism of the ammonia formation from azide ion and water is presented.

From the viewpoint of the chemical conversion of solar energy, much attention has been paid to the synthesis of ammonia from molecular nitrogen and water with the aid of light energy. Photocatalytic synthesis of ammonia from N_2 on illuminated semiconductors has been reported by several researchers.[1-5] Schrauzer and Guth[1] first reported the ammonia synthesis on moist iron doped TiO_2 powders. Miyama *et al.*[2] described the synthesis of ammonia from N_2 saturated water by using various kinds of semiconductors as photocatalysts. Recently, $SrTiO_3$ doped with RuO_2 and NiO has been used by Tamaru and coworkers.[5] Yoneyama *et al.*[6] described the formation of a considerable amount of ammonia from nitrogen monoxide instead of N_2. Nitrogenase, which is a well known catalyst for ammonia synthesis, catalyzes the ammonia production from N_3^- and other nitrogen compounds as well as from N_2.[7] Since N_3^-, which is a halogen-like ion, has an oxidized state between N_2 and NH_3, it may be expected to have some connection with intermediate spieces of the NH_3 synthesis from N_2. However, there has been no report for the photocatalytic reaction of aqueous azide ions. Therefore, we studied the photocatalytic ammonia synthesis from N_3^- aqueous solution and examined the reaction mechanism.

Experimental

The platinized TiO_2 used in the present study was prepared by the following procedure. Titanium dioxide powder (anatase, 99.95%, Kojundo Kagaku Co., Ltd.) was mixed with a platinum tetrachloride aqueous solution, dried and fired at 600 °C in flowing argon. Then, the powder was reduced in flowing hydrogen at 600 °C for 4 h. The catalysts were washed thoroughly with pure water. The 5%-platinized TiO_2 was used, unless otherwise stated. In a typical experiment, 0.2 g of catalyst and 10 cm^3 of 0.1 mol/dm^3 sodium azide solution was placed in a Pyrex vessel of 30 mm diameter, and the mixture was vigorously stirred throughout the reaction. Irradiation was performed with a 500 W high pressure mercury lamp focused through two water-filled round flasks. The temperature of the reaction mixture was about 43 °C. The catalyst in the reaction tube was removed with a centrifuge before the quantitative analysis of the products in the solution. The amount of ammonia was determined by measuring the absorbance at 640 nm after the reaction with Indophenol Blue. Hydrazine and NO_3^- were analysed from the absorbance at 458 nm and 410 nm with *p*-dimethylaminobenzaldehyde and brucine, respectively. The amount of unreacted N_3^- was determined as FeN_3^{2+} with 460-nm absorbance, which was formed by passing N_3H gas evolved by heating the acidified sample solution through a $Fe(NO_3)_3$ solution. Gaseous products were analyzed by gas chromatography with a thermal conductivity detector. A molecular sieve 5A column was used for the analysis of H_2, O_2, and N_2. For N_2O an active carbon column was used. The carrier gases were argon and helium for the analysis of H_2 and the other gases, respectively. Ammonia could not be detected by the columns used in the present study.

The TiO_2 film electrodes used for electrochemical measurements were prepared by painting $TiCl_4$ solution on polished titanium plate and firing at 500 °C. The platinization on the electrode was performed by a similar method described above for TiO_2 powder. The method of the electrochemical measurements is the same as described previously.[8]

Results

Table 1 summarizes a part of experimental results. Platinization of TiO_2 caused marked ammonia formation from N_3^-. The effect of platinization could be observed for the catalyst made by mixing in an agate mortar. The activity of the catalysts prepared by the impregnation method was comparable to those by the photodeposition method.[9] Accordingly, the impregnation method was used in further experiments because of the simplicity of the preparation. The reproducibil-

a) Unless otherwise remarked, platinization of TiO_2 powder was done by the impregnation method, and 1 mmol N_3^-, 10 cm^3 water, and 0.2 g of catalysts were used. b) These catalysts were prepared in the same process.

ity in the activity measurements was within ±5% for the same catalysts. However, the activity of catalysts was different from preparation to preparation up to about 3 times. The maximum quantum yield obtained for the ammonia production was estimated to be about 0.5%. The effect of different compounded metals on the catalytic activity has been described already.[10] The activity of 1.0% platinized TiO_2 is much smaller than that of 3.0% or 5.0% platinized TiO_2. Sakata *et al.*[11] reported the effect of the platinum content on the photocatalytic activity for hydrogen evolution from alcohol and water. They have shown that the activity increases rapidly with the amount of platinum up to 0.05%, and the increase becomes gradual above this content. The difference in the dependence of the platinum content on the catalytic activity may be attributed to the difference in platinization method. The dependence on the platinum content is similar to that of the photoconductivity of Pt/TiO_2 powders prepared by the impregnation method.[12] One of the factors controlling the photoconductivity is the rate of recombination of photoinduced electron-hole pairs. Therefore, the present result suggests that the rate of the decomposition of N_3^- is determined by the separation of the photoinduced electron-hole pairs, as has been proposed in the previous paper.[10]

When the reaction mixture had been deaerated, the rate of ammonia formation increased to three times that for the aerated conditions. This indicates that reduction of N_3^- competes with that of O_2 in the air. In order to clarify this observation, photocatalytic reaction was performed in various atmospheres with the same Pt/TiO_2 catalyst. The product yields are shown in Table 2 and the growth features of gaseous products are shown in Fig. 1. In the He atmosphere, N_2O was formed gradually with irradiation time. When the reactant mixture was bubbled with O_2 gas thoroughly, the amount of ammonia formed was very low. In this case, a large amount of N_2O was formed. In a N_2O atmosphere, the N_2 yield did not increase, although the ammonia yield was greater than that in the O_2 atmosphere, indicating that N_2O formed in the reaction with O_2 was not responsible for the decrease in the ammonia yield. Under any reaction conditions, O_2 and H_2 were not detected as a primary product. After the mitigation of the evolution of N_2, molecular hydrogen was observed in the He atmosphere. Since aqueous ammonia is known to be decomposed into N_2 and H_2 with photocatalysts,[5] the delayed formation of H_2 is attributed to the decomposition of the ammonia produced. The amount of remaining N_3^- was measured at the end of the growth of N_2 in the reaction under He atmosphere. The amount of N_3^- was 100 μmol when 1240 μmol of N_2 and 180 μmol of ammonia had been

produced. Since the initial amount of N_3^- has been 1 mmol, this result suggests that all of the consumed N_3^- turned into ammonia or N_2. For confirmation, the by-products possibly formed in the solutions were analyzed. Hydrazine was not detected to a sensitivity of about 0.01 μmol, and the amount of NO_3^- was less than 0.5 μmol. Under the aerated conditions, these nitrogen compounds were not increased.

In order to clarify the mechanism of the photocatalytic reaction, electrode reactions were measured with a platinized TiO_2 polycrystalline film electrode. For aqueous solutions of 0.1 mol/dm^3 NaN_3 and 0.05 mol/dm^3 Na_2SO_4, current-potential curves were measured and some of them are shown in Fig. 2. The pH value of sulfate solution had been adjusted to that of azide solution (pH 8.4) by the addition of a small amount of KOH. A reduction current accompanied by the evolution of a gas was observed at less cathodic potential in the presence of N_3^-. After the reduction with the Pt/TiO_2 electrode, ammonia was detected in the solution. The gas evolved was determined to be nitrogen by a separate experiment using a platinum electrode. By the irradiation on the Pt/TiO_2 electrode, the feature of the reduction current was almost unchanged. On the other hand, at anodic potentials photoinduced oxidation currents were observed for both of the solutions. In the presence of N_3^-, the photocurrent appeared at less anodic potential, indicating that N_3^- is more easily oxidized than OH^- at TiO_2 surface. This experimental result is consistent with the report for the oxidation of N_3^- on platinum electrodes.[13]

Discussion

Bard has pointed out that an illuminated platinized TiO_2 powder works as a microelectrode.[14] Consequently, the surface reactions on the photocatalyst are predicted by those of cathodic and anodic processes observed in the photoelectrochemical measurements. In the present study, the current-potential curves in Fig. 2 show that N_3^- is oxidized before the oxidation of OH^-. The oxidation potential of N_3^- on a platinum electrode is 0.78 V (*vs.* SCE).[13] The azide radical, $N_3\cdot$, formed by the oxidation of N_3^- becomes, instantly, the dimer, $(N_3)_2$, followed by the evolution of N_2.[13] Therefore, at the oxidation site on the photocatalysts the following reaction is expected to occur.

$$2N_3^- \longrightarrow 3N_2 + 2e^- \quad (1)$$

On the other hand, the reduction of N_3^- aqueous solution on solid electrodes has not been reported. However, Fig. 2 shows that N_3^- is reduced before the formation of H_2. Since the formation of adsorbed hydrogen atoms precedes the evolution of H_2, the hydrogen atoms seem to react with N_3^-. The reductive decomposition may occur in succession as indicated by the current-potential curve having no shoulder. As mentioned above, the evolution of N_2 gas was observed during the electrode reduction, then the reduction of N_3^- accompanied by the reaction with water may be expressed by Eq. 2;

$$N_3^- + 3H_2O + 2e^- \rightarrow NH_3 + N_2 + 3OH^-. \quad (2)$$

The standard potential for the electrode reduction of N_3H was reported to be 1.82 V (*vs.* NHE) in acidic solution,[15] so that of Eq. 2 can be estimated as 0.97 V at pH 8.4. At this pH, the standard potential for the reduction of water is −0.50 V. Therefore, from a thermodynamical view point, Eq. 2 is more likely to occur than the reduction of water.

The total stoichiometric equation for the photocatalytic reaction of N_3^- and water should be expressed by the combination of Eqs. 1 and 2; *viz.*,

$$3N_3^- + 3H_2O \longrightarrow NH_3 + 4N_2 + 3OH^-. \quad (3)$$

This equation is consistent with the present experimental results that the formation of ammonia involves N_2 gas evolution and that N_2 has not been detected for the undoped TiO_2 photocatlyst which did not yield ammonia. This stoichiometric equation implies that the ratio of the products $N_2 : NH_3$ is to be 4:1. The experimental result in Table 2 shows that the amount of ammonia formed was really about a quarter of that of N_2 in the early stage of the reaction. However, in the later stage, the amount of ammonia was smaller than that of stoichiometry. This may be attributed to the decomposition of produced ammonia into N_2 and H_2, as mentioned above.

In the helium atmosphere, N_2O was the major by-product. The formation of N_2O from N_3^- aqueous solution was studied by the method of radiolysis.[16] As a reaction intermediate, the presence of HNO, which gives $H_2N_2O_2$ followed by the formation of N_2O, has been assumed. When this assumption is adopted in the present system, the intermediate HNO may arise from N_3OH^- which is formed from $N_3\cdot$ and OH^-. The formation of N_3OH^- is probable,[17] because N_3^- is known to behave in chemical properties like halogen ions.[15] Since the yield of N_2O was very low, it is also probable that the oxygen of N_2O may originate from the possible absorbed oxygen on the catalysts.

In the oxygen atmopsphere, the NH_3 yield was very low while N_2O was formed largely. This indicates that at the reduction site the reactions of Eqs. 4 and 5 may happen instead of Eq. 2.

$$O_2 + H^+ + e^- \longrightarrow HO_2\cdot \quad (4)$$

$$2HO_2\cdot \longrightarrow H_2O_2 + O_2 \quad (5)$$

The hydrogen peroxide may produce N_2O by the following exothermic reactions[16];

$$H_2O_2 + N_3^- \longrightarrow HNO + N_2 + OH^- \quad (6)$$

$$2HNO \longrightarrow N_2O + H_2O. \quad (7)$$

Since N_2O is considered to be formed through some intermediates, there must be a delay for the formation of N_2O. Fig. 1 shows that the formation of N_2O delays from that of N_2. This reaction mechanism for N_2O formation predicts that the product ratio of $N_2 : N_2O$ is 8:1. The observed ratio was, however, nearly equal to 5:1. Then, another process such as the reaction of $N_3\cdot$ radical with O_2 at the oxidation site may be taken into account.

Since the standard free energy change for Eq. 3 is negative, the photocatalytic ammonia production *via*

azide ion is not suitable for storage of solar energy. Further investigation concerning the mechanism of the formation of ammonia may provide a clue to improving the yield of ammonia synthesis from N_2 and water.

This work was supported in partly as Grants-in-Aid for Scientific Research (No. 57045043 and 58045056) from the Ministry of Education, Science and Culture.

The Crystal Structure of 3-(Adenin-9-yl)-*N*-(2-succinimidyl)-propionamide and Hydrogen Bonding Scheme of Anticonvulsant Drugs with Adenine

Midori TAKIMOTO, Akio TAKENAKA, and Yoshio SASADA*
Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227
(Received May 28, 1984)

3-(Adenin-9-yl)-*N*-(2-succinimidyl)propionamide† has been synthesized as a model for studying the interaction between cyclic ureide and adenine, and its crystal structure examined. The crystals are monoclinic, the space group $P2_1/c$, with unit-cell dimensions of a=10.861(1), b=12.766(1), c=9.753(1) Å, β=91.10(1)°, and Z=4. The ureide moiety is hydrogen bonded to adenine with NH···N(1) (2.903(3) Å) and O···HN(6) (2.955(3) Å). A comparison of the hydrogen bonding patterns of the related compounds with adenine suggests that cyclic ureide anticonvulsant drugs possess the capability of interacting with N(1) and N(6) sites of adenine.

Many compounds containing cyclic ureide skeleton, such as barbiturate, hydantoin and succinimide derivatives, have been used extensively as anticonvulsant and antiepileptic drugs.[1] It is known that barbiturate/hydantoin derivatives form stronger hydrogen bonds with adenine than the other nucleic acid bases.[2] This is an interesting observation because it is suspected that some adenine-related complexes play a role in nerve transmission.[3]

To understand the structural aspects of their interaction, we have synthesized 3-(adenin-9-yl)-*N*-(2-succinimidyl)propionamide as a model and determined its crystal structure.

Experimental and Structure Determination

3-(Adenin-9-yl)propionic acid (**1**) was prepared by the method reported by Kondo, Miyata, and Takemoto[4] and DL-asparagine methyl ester hydrochloride (**2**) was derived from DL-asparagine. The condensation of **1** and **2** by dicyclohexylcarbodiimide method gave *N*-[3-(adenin-9-yl)propionyl]-DL-asparagine methyl ester, and the product was spontaneously converted into 3-(adenin-9-yl)-*N*-(2-succinimidyl)propionamide in a methanol solution saturated with ammonia.

Colourless plate crystals were obtained from an aqueous solution. Density was measured by flotation in a mixture of cyclohexane and carbon tetrachloride. A crystal, 0.35×0.35×0.1 mm³ in size, was mounted on a Rigaku automated four-circle diffractometer. Nickel-filtered Cu $K\alpha$ radiation (λ=1.54184 Å) was used. The accurate unit-cell dimensions were derived from the 2θ values of 34 high-angle reflexions. Crystallographic data are summarized in Table 1. Intensities were measured on the diffractometer by means of ω scanning ($2°<2\theta<125°$), the scan speed being 4°/min and scan width 1.2° plus α_1–α_2 divergence. Five reference reflexions monitored periodically showed no significant intensity deterioration. Corrections were made for Lorentz and polarization factors, but not for absorption effects. A total of 2153 independent reflexions were obtained, 378 of which had no net intensities; the observational threshold value, F_{lim}, was 1.96. The standard deviations were estimated by the equations $\sigma^2(F_o)=\sigma_P^2(F_o)+qF_o^2$, where $\sigma_P(F_o)$ was evaluated by counting statistics and q(1.22×10^{-5}) was derived from the variations of the monitored reflexions.

TABLE 1. CRYSTAL DATA FOR 3-(ADENIN-9-YL)-*N*-(2-SUCCINIMIDYL)PROPIONAMIDE

Chemical formula: $C_{12}H_{13}N_7O_3$	
Space group: $P2_1/c$	
a/Å=10.861(1)	V/Å³=1683.5(1)
b/Å=12.766(1)	Z=4

β/°=91.10(1)	D_x/g cm^{-3}=1.490

† 2-Succinimidyl=2,5-dioxo-3-pyrrolidinyl

The structure was solved by the direct method using MULTAN 78 programme[5] and the atomic parameters were refined by the full-matrix least-squares method. The quantity minimized was $\sum\omega(|F_o|-|F_c|)^2$, where $\omega=1/\sigma^2(F_o)$. In the refinement, the zero-reflexions with $|F_c|>F_{lim}$ were included by assuming $F_o=F_{lim}$ and $\omega=\omega(F_{lim})$. All the hydrogen atoms were found on a difference map and included in the refinement.

The final R value was 0.059 for 1875 reflexions with $|F_o|>3\sigma(F_o)$; the maximum shift of parameters in the last cycle was 0.1σ for C, N, O, and 0.3σ for H. Atomic scattering factors were taken from Ref. 6. The atomic parameters of the non-hydrogen atoms are listed in Table 2.[7]

Results and Discussion

Molecular Structure. Figure 1 shows a stereoscopic view of 3-(adenin-9-yl)-*N*-(2-succinimidyl)propionamide molecule. Bond lengths and angles are shown in Fig. 2.

The dimensions of the adenine moiety are in good agreement with those found in 9-methyladenine,[8] 3-(adenine-9-yl)propionamide[9] and 3-(adenin-9-yl)propionic acid.[10] The adenine moiety is planar with maximum displacement of 0.016 Å for N(9) from the least-squares plane. The bond lengths and angles of the succinimide moiety are similar to those found in 2-(3-bromo-4-ethoxyphenyl)succinimide.[11] The succinimide moiety has a half-chair form; the value of P defined by Pitzer and Dorath[12] is −13.3°, which is between those of E_2 and ${}_1T_2$. The deviations of C(15) and C(16) from the plane [C(17), N(18), C(19)] are 0.150 Å and −0.083 Å, respectively. This conformation is different from the envelope form of 2-(3-bromo-4-ethoxyphenyl)succinimide. The dihedral angle between two amide planes [C(19), O(19), N(18)] and [C(17), O(17), N(18)] is 5.7°.

As shown in Fig. 1, the molecule is extended; torsion

angles, N(9)-C(11)-C(12)-C(13) and C(11)-C(12)-C(13)-N(13) are 69.5° and −149.5°, respectively. The conformation is similar to that found in the complex 3-(adenin-9-yl)propionamide : 1-methylthymine dihydrate[13] and 3-(adenin-7-yl)propionamide monohydrate.[14] The dihedral angle between the adenine and the mean plane of succinimide moiety (C(15), C(16), C(17), O(17), N(18), C(19), O(19)) is 6.2(1)°.

The equivalent isotropic temperature factors are calculated from anisotropic thermal parameters using the equation $B=8\pi^2(U_1+U_2+U_3)/3$, where U_1, U_2, and U_3 are principal components of the mean square displacement matrix U. Values in ⟨ ⟩ are anisotropicity defined by $(\Sigma(B-8\pi^2U_i)/3)^{1/2}$ and those in ( ) are e.s.d.'s; they refer to the last decimal places.

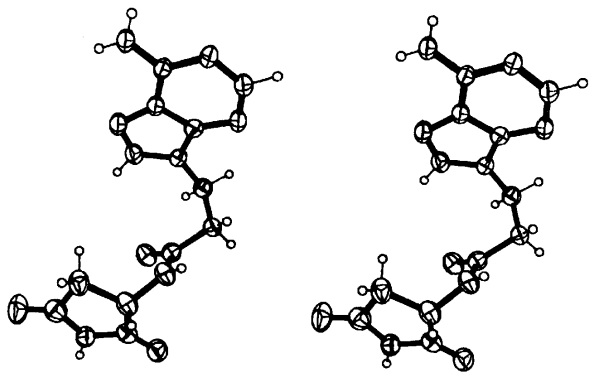

Fig. 1. Stereoscopic view of 3-(adenin-9-yl)-*N*-(2-succinimidyl)propionamide with 50% probability ellipsoids.

Crystal Structure. The crystal structure viewed along the b axis is shown in Fig. 3. The geometries of hydrogen bonds are given in Table 3. The succinimide moiety is linked to the adenine moiety at (1+*x*, 1/2−*y*, 1/2+*z*) by the hydrogen bonds, N(18)H···N(1) and O(19)···HN(6). The dihedral angle between the least-squares planes of these two moieties is 5.2(1)°. These and the N(6)H···N(3) hydrogen bonds between the molecules related by the two-fold screw make sheets parallel to (101) as shown in Fig. 4.

Another hydrogen bond N(14)H···O(13) between peptide groups links the sheets together. This N(14)H seems to make a bifurcated hydrogen bond, though the N(14)H···O(17) distance is rather long (3.297(4) Å).

The adenine moieties related by the c glide are stacked on each other at the distance of 3.558(5) Å for C(2)···C(8) and 3.412(4) Å for N(1)···C(8). Another closest contact is 3.456(4) Å between C(6) at (*x*, *y*, *z*) and C(8) at (−1+*x*, *y*, *z*).

Interaction between Cyclic Ureide and Adenine. Figure 5 shows the hydrogen bonding patterns found

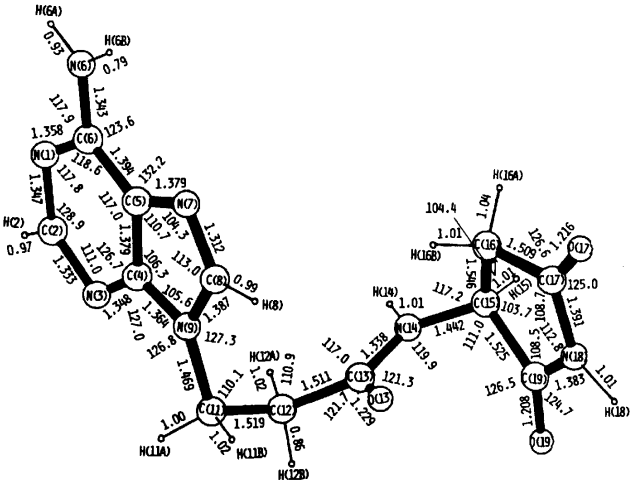

Fig. 2. Atomic numbering and bond lengths (*l*/Å) and angles (*φ*/°) in 3-(adenin-9-yl)-*N*-(2-succinimidyl)-propionamide. E.s.d.'s for bond lengths and angles are 0.004–0.005 Å and 0.3°, respectively.

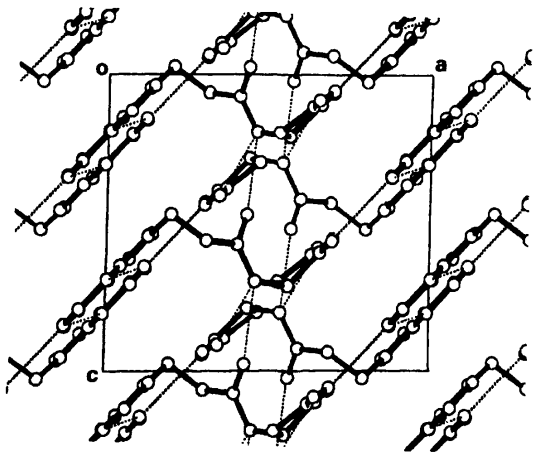

Fig. 3. Crystal structure of 3-(adenin-9-yl)-*N*-(2-succinimidyl)propionamide projected along the b axis.

in the adenine complexes with several cyclic ureide derivatives. Barbiturates interact with adenine through the two kinds of double hydrogen bonds; type 1 is a combination of NH···N(1) and O···HN(6) and type 2 is NH···N(7) and O···HN(6).[15,16] The present crystal exhibits the hydrogen bonds of type 1, while the scheme in parabanic acid with a similar cyclic ureide skeleton is type 2.[17] Recently it has been reported that 2-thiohydantoin interacts with adenine at the N(3) or N(7) site.[18]

In order to examine the preferential hydrogen bonding sites of adenine, the formation energies of possible complexes were calculated by CNDO/2 approximation[19] (Table 4). The formation energies with barbi-

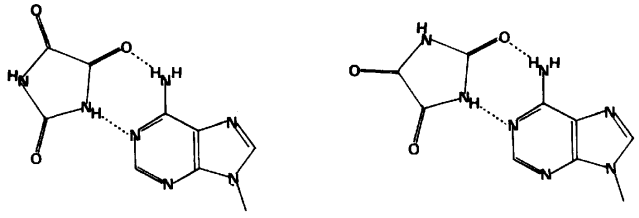
Table 4. The difference in formation energy (ΔE/kcal mol^{-1}) between type 1 and type 2 of some cyclic ureides and 9-methyladenine by CNDO/2 calculation

Type 1 is a combination of NH···N(1) and O···NH(6) and type 2 is NH···N(7) and O···NH(6). 1 cal=4.186 J.

	Barbiturate	Parabanic acid	2-Methylsuccinimide
E(Type 2)-*E*(Type 1)	+0.2	−1.6(I) −2.0(I')	−0.4

In the calculation, hydrogen bond geometries are taken from Ref. 15, Ref. 17, and the present study. Type 1 of parabanic acid (two modes, I and I') and type 2 of 2-methylsuccinimide are hypothetical structures.



(I) (I')

turate are almost the same for the two types of hydrogen bonding. In the case of the parabanic acid, however, the type 1 is distinctly less stable than the type 2. These results are consistent with the hydrogen bonding patterns found in the respective crystals, suggesting that the hydrogen bonding scheme in model crystals comes from the inherent nature of the components. In the present combination of adenine and succinimide, there is no significant difference in formation energy so that the other type (type 2) would be found if the crystallizing condition is adjusted suitably.

While barbiturate and succinimide derivatives have anti-convulsant effect, parabanic acid and 2-thiohydantoin containing similar molecular skeleton do not exhibit such effect.[1] Activity and inactivity seem to be associated with the different hydrogen bonding patterns; that is cyclic ureide anticonvulsant drugs possess the capability of interacting with N(1) and N(6) sites of adenine.

Recently, it has been reported that diphenyl hydantoin and pentobarbital inhibit the protein synthesis in rat brain.[20-22] This side effect can be explained by the argument that they might interact with adenine at N(1) and N(6), which are the sites forming the Watson-Crick base pair.

Acid Dissociation Constants of Alkyl Xanthic Acids and Formation Constants of Cadmium(II) and Zinc(II) Xanthato Complexes in 1:1 v/v H_2O-DMF Medium

Kenjiro HAYASHI,* Yoshiaki SASAKI, Shigehiro INOMATA, and Takagimi YANAGIDANI
Department of Chemistry, Faculty of Science, Yamaguchi University, Yoshida, Yamaguchi-shi 753
(Received December 27, 1983)

The overall formation constants, β_3, of cadmium(II) and zinc(II) complexes with alkyl xanthates (*O*-alkyl dithiocarbonates) were determined by polarography in the 1:1 v/v water-*N*,*N*-dimethylformamide mixture. The values of these constants increase in the order, methyl<ethyl<propyl<butyl<2-methylpropyl<1-methylethyl xanthate. This order agrees entirely with the order of the basicity of alkyl xanthates determined by using the kinetic parameter of the acid decomposition of xanthates.

Alkyl xanthates (*O*-alkyl dithiocarbonates, $ROC(S)S^-$, abbreviated as X^-) have been used as chelating reagents for the solvent extraction of metal ion.[1] However, the thermodynamical property of the metal xanthato complexes has not yet become clear sufficiently.

The present authors have studied the solvent extraction of several metal xanthato complexes, and reported the compositions and the formation constants of the extracted complexes.[2-5] Furthermore, the water-soluble complexes having a formula MX_3^- or MX_4^{2-} ($M=Cd^{2+}$, Zn^{2+}) were found to be formed only with methyl and ethyl xanthates in the presence of a large excess of xanthate[6,10].

All the cadmium(II) and zinc(II) xanthato complexes formed in the water-*N*,*N*-dimethylformamide(DMF) mixture were soluble in this mixture. Therefore, the compositions and the stability constants of these soluble complexes were determined by polarography. The apparent acid dissociation constants of alkyl xanthic acids (*O*-alkyl dithiocarbonic acids, HX) in the same medium were also determined, and the effect of the basicity of the ligand on the stability of the complex was studied.

Experimental

Reagents. Potassium salts of alkyl xanthates were synthesized from corresponding alkanols, carbon disulfide, and potassium hydroxide as described previously.[6] The solutions of xanthates were prepared immediately before use.

The stock solutions (0.02 mol dm^{-3}) of cadmium(II) and zinc(II) were prepared by dissolving each nitrate salt in 0.1 mol dm^{-3} nitric acid. These solutions were standardized volumetrically with EDTA.

Apparatus and Procedures. (1) The decomposition rate of xanthate in the 1:1 v/v water-DMF medium was measured spectrophotometrically at 305 nm which is an absorption maximum wavelength of xanthate on a Hitachi Model 139 spectrophotometer (for moderate decomposition) and a Union Giken Model RA-401 stopped-flow spectrophotometer (for fast decomposition). Each cell chamber was thermostated at 25 °C with a water jacket. The ionic strength of test solutions was kept at 0.4 mol dm^{-3} with potassium chloride (the use of nitrate salt was unfavorable because of the absorption of light in ultraviolet region and the oxidation of the xanthates in an acid solution). The pH of the solutions was controlled by using the potassium acetate-hydrochloric acid buffer solution.

(2) Direct current polarographic waves were recorded with a Yanaco Model P8 polarograph using a three-electrodes format with mercury as an auxiliary electrode and saturated calomel electrode as a reference electrode. The dropping mercury electrode used had an m value of 1.18 mg s^{-1} and a drop time of 5.67 s at open circuit at a height of mercury reservoir of 69.0 cm. All polarographic measurements were made in the 1:1 v/v water-DMF medium containing 5×10^{-4} mol dm^{-3} metal ion, proper amount of xanthate, and 0.002% Triton X-100 as a maximum suppressor at 25.0±0.2 °C under the air-free condition. The ionic strength of the test solutions was made 0.4 mol dm^{-3} by the addition of potassium nitrate, and pH was adjusted with nitric acid or potassium hydroxide solution.

Results and Discussion

(1) Acid Dissociation Constant of Xanthic Acid. Alkyl xanthates are quite unstable in an acid solution and decompose. The dissociation constant of xanthic acid in the water-DMF mixture system was determined according to the method of Iwasaki and Cooke,[7] who determined the constant in an aqueous medium.

The decomposition rate equation introduced by them is as follows:

$$-\frac{d\ln([X^-]+[HX])}{dt}=\frac{k_3}{1+K_a[H^+]^{-1}}\equiv\kappa \quad (1)$$

or

$$\log\frac{(\text{Absorbance})_1}{(\text{Absorbance})_2}=\frac{\kappa}{2.303}(t_2-t_1), \quad (2)$$

where k_3 and K_a are the decomposition rate and dissociation constants of xanthic acid, and $(\text{Absorbance})_1$ and $(\text{Absorbance})_2$ denote the absorbances at time t_1 and t_2, respectively.

A linear relationship of Eq. (2) held between the time elapsed after the preparation of xanthate solution and the absorbance at 305 nm. It is satisfactory to consider that Eq. (2) is valid not only in an aqueous medium but also in the 1:1 v/v water-DMF mixture.

The log-values of κ were calculated on the basis of the slopes of plots according to Eq. (2) and are given in Table 1. The acid dissociation and decomposition rate constants of xanthic acids were obtained by the analysis of $\log\kappa$ as a function of pH according to Eq. (1). Results are given in Table 2.

TABLE 1. LOG-VALUE OF κ/min^{-1} AS A FUNCTION OF pH

Methyl xanthate		Ethyl xanthate		Propyl xanthate		1-Methylethyl xanthate		Butyl xanthate		2-Methylpropyl xanthate	
pH	log κ	pH	log κ	pH	log κ	pH	log κ	pH	log κ	pH	log κ
1.23	1.47	1.23	1.39	1.23	1.40	1.20	1.35	1.17	1.40	1.20	1.17
1.57	1.39	1.57	1.33	1.57	1.34	1.73	1.31	1.70	1.33	1.70	1.12
1.76	1.32	1.76	1.29	1.76	1.31	2.00	1.26	2.40	1.05	1.95	1.10
1.99	1.21	1.99	1.20	1.99	1.23	2.20	1.14	2.70	0.83	2.23	0.98
2.52	0.84	2.52	0.90	2.52	0.97	2.65	0.87	3.25	0.39	2.70	0.72
2.75	0.63	2.75	0.68	2.75	0.79	2.94	0.68	3.45	0.16	2.95	0.53
2.93	0.57	2.93	0.63	2.93	0.65	3.06	0.56	4.07	−0.40	3.15	0.38
4.45	−0.89	4.47	−0.83	4.50	−0.89	4.47	−0.81	4.50	−0.82	4.50	−0.92
5.08	−1.49	5.11	−1.50	5.19	−1.50	5.08	−1.45	5.28	−1.62	5.08	−1.44
5.80	−2.24	5.82	−2.21	5.84	−2.19	5.80	−2.17	5.82	−2.18	5.84	−2.20

(2) Formation Constant of Metal Xanthato Complex. The polarographic determination of the compositions and the formation constants of the cadmium and zinc xanthato complexes was carried out by using Lingane's equation:[8]

$$(E_{1/2})_s - (E_{1/2})_c = \frac{2.303RT}{nF}\log\beta_j + j\frac{2.303RT}{nF}\log[X^-], \quad (3)$$

assuming the activity and diffusion coefficients of the simple and complexed metal ions to be equal to each other; where n is the number of moles of electrons involved in the electrode reaction, F the faraday, R the gas constant, T the absolute temperature, j the number of ligands coordinated to metal ion, and β_j the overall formation constant of MX_j. $(E_{1/2})_s$ and $(E_{1/2})_c$ denote the half-wave potentials of the simple and complexed metal ions, respectively.

The effect of pH on the diffusion current and the half-wave potential of simple metal ions was preliminarily studied. The half-wave potential was not affected by pH but the diffusion current decreased in a higher pH region than 8.2 for cadmium ion and 7.5 for zinc ion. Polarography for the metal xanthato complexes was therefore carried out in the pH ranging from 7.0 to 8.0 for the cadmium(II) system and from 7.0 to 7.3 for the zinc(II) system. The reversible half-wave potential was obtained graphically by the method of Matsuda and Ayabe.[9]

As shown in Figs. 1 and 2, there was a linear relationship between the half-wave potential and the logarithm of the free xanthate ion concentration which was estimated by subtracting three times of metal concentration from the total concentration of xanthate. The values of the slope of these plots obtained for the cadmium(II) system were 90, 88, 91, 89, 88, and 89 mV for methyl, ethyl, propyl, 1-methylethyl, butyl, and 2-methylpropyl xanthates, respectively. And the values for the zinc(II) system were 85, 93, 96, 95, 94, and 91 mV, respectively. These values of the slope were in agreement with those expected from Eq. (3) in which j was 3. The overall formation constants, β_3, calculated from Eq. (3) are given in Table 2.

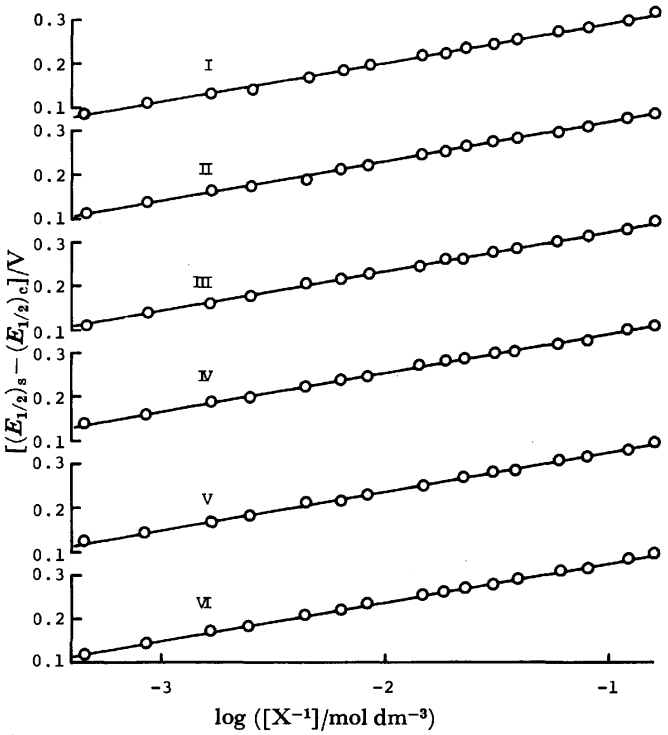

Fig. 1. Shift in the half-wave potential of cadmium(II) ion by the presence of alkyl xanthates in the 1 : 1 v/v water–DMF mixture.
I: methyl xanthate, II: ethyl xanthate, III: propyl xanthate, IV: 1-methylethyl xanthate, V: butyl xanthate, VI: 2-methylpropyl xanthate.

One of the authors (K. H.) has already studied the formation of ethyl xanthato complexes of cadmium and zinc in the 1 : 1 v/v water–DMF medium.[10] According to him, the β_3 values for cadmium and zinc complexes were $10^{14.40}$ and $10^{4.63}$, respectively. The β_3 value for cadmium in Table 2 was in fair agreement with the above value, but the β_3 value for zinc complex obtained in this work was significantly larger than that reported previously. In the previous paper, lithium perchlorate (0.5 mol dm^{-3})–potassium nitrate (1.0—1.5 mol dm^{-3}) was used as the supporting electrolyte for the cadmium system, while potassium chloride (0.5—1.0 mol dm^{-3})

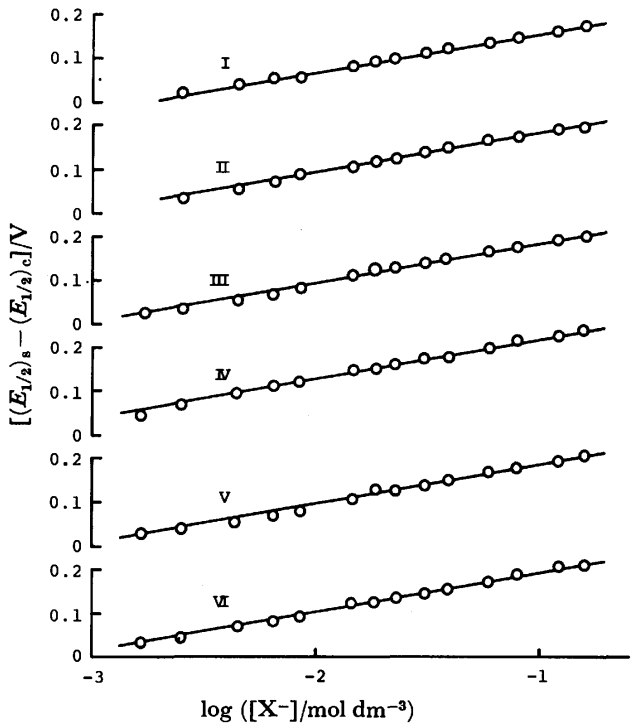

Fig. 2. Shift in the half-wave potential of zinc (II) ion by the presence of alkyl xanthates in the 1 : 1 v/v water-DMF mixture.
I: methyl xanthate, II: ethyl xanthate, III: propyl xanthate, IV: 1-methylethyl xanthate, V: butyl xanthate, VI: 2-methylpropyl xanthate.

was employed for the zinc system. Therefore, the apparent inconsistency seems to be caused by the formation of a zinc–chloro complex which was not considered in the previous paper.

As shown in Table 2, the basicity of xanthates increased in the order, methyl<ethyl<propyl<butyl<2-methylpropyl<1-methylethyl. This order is in agreement with the order reported in the aqueous medium[11] except for 2-methylpropyl and 1-methylethyl derivatives. The stability of complexes increased in the same order of the basicity of the ligands (Table 2), and this result is quite reasonable because a metal ion should form a more stable complex with a more basic ligand.

Table 2. Acid dissociation constant(K_a) and decomposition rate constant(k_3) of alkyl xanthic acid, and formation constant(β_3) of cadmium and zinc xanthato complexes

Xanthate	pK_a	k_3 / min^{-1}	log β_3 (for Cd)	log β_3 (for Zn)
Methyl	2.07	32.4	12.86	8.05
Ethyl	2.20	26.3	13.87	8.93
Propyl	2.22	27.5	13.94	9.00
1-Methylethyl	2.44	14.8	14.55	10.15
Butyl	2.23	27.5	14.04	9.04
2-Methylpropyl	2.25	26.9	14.04	9.20

The decomposition rate constant of methyl xanthate was the maximum and that of 1-methylethyl derivative was the minimum, and it can be said roughly that more basic xanthate is more stable in an acid solution.

The complexes of cadmium are always more stable than the corresponding zinc complexes. The difference in log β_3 was about 4.8. As cadmium(II) ion is more "soft" as Lewis acid than zinc(II) ion, the former should give a more stable complex with xanthate which coordinates through two sulfur atoms.

Structural Characterization of Several Metal(II) 2-Methyl-8-quinolinolato Complexes in Several Organic Solvents

Hiroyuki NARIAI,* Yoshitaka MASUDA,† and Eiichi SEKIDO†
Department of Chemistry, College of General Education, Kobe University, Tsurukabuto, Nada-ku, Kobe 657
†*Department of Chemistry, Faculty of Science, Kobe University, Rokkodai-cho, Nada-ku, Kobe 657*
(Received February 3, 1984)

Bivalent metal complexes of cobalt(II), nickel(II), copper(II), and zinc(II) with 2-methyl-8-quinolinol (2MeHql) were prepared. Their properties, such as those shown by thermogravimetry (TG) and differential thermal analysis (DTA), X-ray diffraction, magnetic susceptibility, and the optical spectra, were measured and compared with those of 8-quinolinolato complexes. All the metal complexes prepared here are monohydrates, whereas their 8-quinolinolato complexes are dihydrates. The methyl group at the 2-position of the quinoline ring caused a shift of about 40—80 °C in the dehydration temperature, and, as a result of the dehydration, a dimer anhydrate was produced. The dimer-formation conditions were established in chloroform and dioxane solutions. However, the addition of such basic solvents as pyridine, water, and methanol cleaved the bridge linkages in complexes and produced a distorted octahedral configuration by solvent-binding in the axial position. The existence of a copper complex with a dimer structure such as has been shown in other metal complexes was not verified in any of the solvents used here.

8-Quinolinol (Hql) has been widely used as a useful analytical reagent to evoke insoluble stoichiometric precipitation with many bivalent metals.[1-5] Many studies have been done on the absorption spectra and the infrared (IR) analysis of their metal complexes.[6-10] However, from the standpoint of explaining the reaction mechanism involved in solvent extraction, the investigation of the solution state of their metal complexes in organic solvents has come to be especially important. However, there have been few reports on them.[11-13] In this work, 2-methyl-8-quinolinolato complexes of bivalent metals (Co, Ni, Cu, and Zn) have been prepared and studied in relation to their physical and chemical properties, their characterization in several organic solvents, and the mechanism of adduct formation. Furthermore, they have been compared with the metal 8-quinolinolato complexes.

Experimental

Reagents. The organic solvents, *e.g.*, chloroform, dioxane, and methanol, were of a reagent grade and were used after further purification, according to the handling methods of Sekido and Kunikida[13] or of Fieser.[14] The other reagents were of an analytical grade.

Preparation of Complexes. Preparation of several metal 2-methyl-8-quinolinolates: $M(2Meql)_2 \cdot H_2O$ (M=Co, Ni, Cu, and Zn). A definite quantity of each metal salt was placed in an acetic acid-acetate buffer solution at pH 5.0 (cobalt(II) and nickel(II)) or 6.2 (copper(II) and zinc(II)), and then the solution was added to an ethanolic 2-methyl-8-quinolinol solution to cause stoichiometric precipitation; the precipitate was filtered, washed several times with hot water to remove the excess 2-methyl-8-quinolinol, and dried in air. Their metal-complex anhydrates were prepared after heating their hydrates at a constant temperature (cobalt(II): 250 °C, nickel(II): 300 °C, copper(II): 150 °C, and zinc(II): 200 °C) for 3 h.

Apparatus and Procedures. A Rigaku Denki Differential Thermobalance TG-DSC was used for the measurement of the TG and DTA. A portion of about ten grams of each complex was heated in a small platinum dish in air and at the heating rate at 10 °C min^{-1}.

X-Ray analysis was carried out with a Rigaku Denki Geigerflex D-1 X-ray Diffractometer, using nickel-filtered Cu $K\alpha$ radiation, except for the cobalt(II) complexes, for which iron-filtered Co $K\alpha$ radiation was used.

The magnetic susceptibilities were measured by means of the Gouy method at room temperature.

The visible and ultraviolet spectra were measured with a Hitachi-124 Spectrophotometer, using the pure solvent as a blank, for cell path-lengths of 1, 10, 50, and 100-mm. A definite amount of a metal-complex anhydrate was dissolved in the appropriate solvent to give the desired concentration. The visible and ultraviolet spectra of the solution were measured within three hours after it had been prepared with the above method. Measurements with other solvents, *e.g.*, dioxane, pyridine, methanol, and their mixed solvents, were carried out with the same procedure.

Results and Discussion

Physical Properties of Several Metal 2-Methyl-8-quinolinolato Complexes. TG and DTA: Typical representative TG and DTA curves of the prepared complexes ($Co(2Meql)_2 \cdot H_2O$ and $Ni(2Meql)_2 \cdot H_2O$) are shown in Fig. 1. It can be seen that one molecule of hydration water is lost in the first step in the range of 170—210 °C for the cobalt(II) complex and in that of

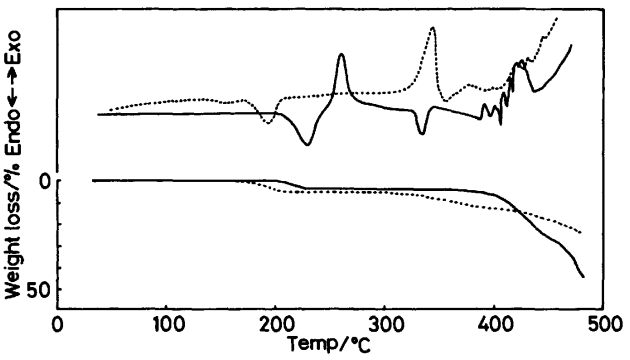

Fig. 1. TG and DTA curves of $Ni(2Meql)_2 \cdot H_2O$(——) and $Co(2Meql)_2 \cdot H_2O$(----) in air.

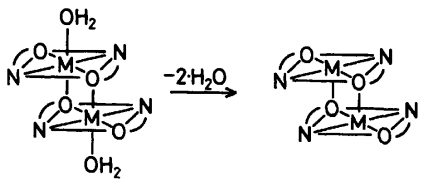
200—230 °C for the nickel(II) complex. The same patterns were also obtained for other metal (copper(II) and zink(II)) complexes. The composition and range of the dehydration temperatures of the hydrated complexes are shown in Table 1. As a reference, those of 8-quinolinolate hydrates are shown, too. From a comparison with hydrated 8-quinolinolato complexes, it can be seen, first, that hydrated 2-methyl-8-quinolinolato complexes have one molecule of hydration water and that the dehydration temperatures were 40—80 °C higher than those of the 8-quinolinolato complex dihydrates. This shows that the steric hindrance of the 2-methyl group prevents the complex formation;[15] consequently, the bond strength and length of M-N and M-O are rather weakened and lengthened in comparison with those of the 8-quinolinolato complex dihydrates, resulting in an increase in the bond strength from the axial directions; in other words, coordination becomes easier. The above discoveries enhanced the possibility of the formation of dimerization or polymer complexes and an adduct with a basic substance.

Second, the complexes which have one hydrated water molecule, $M(2Meql)_2 \cdot H_2O$, probably prefer a dimer geometry coordinated with two molecules of hydrated water above and below the two molecules of metal as is shown in Scheme 1, to a five-coordinated geometry (square pyramidal). However, since the dehydration temperature was much higher (about 200—230 °C) than those of other metal complexes, since the exothermic peak appeared upon dehydration, and since no loss in gravimetric quantity involving the exothermic reaction was observed, the geometry of the nickel(II) complex may be different from the structure described above (Scheme 1). The X-ray diffraction pattern of the amorphous sample and exchange by means of dehydration with heating, were not observed; still, it seems that dimer anhydrates were formed as a result of the dehydration of water coordinated above and below the metals.



Scheme 1.

Table 1. Thermal analytical data

Molecular formula	Range of dehydration (°C)
$Cu(2Meql)_2 \cdot H_2O$	100—120
$Zn(2Meql)_2 \cdot H_2O$	130—160
$Co(2Meql)_2 \cdot H_2O$	170—210
$Ni(2Meql)_2 \cdot H_2O$	200—230
$Cuql_2 \cdot 2H_2O$	50— 80
$Znql_2 \cdot 2H_2O$	80—120
$Coql_2 \cdot 2H_2O$	110—145
$Niql_2 \cdot 2H_2O$	110—145

Susceptibility of Complexes: Table 2 shows the results of elemental analysis, the magnetic moments of metal 2Meql complex monohydrates, and their anhydrates compared with those of the 8-quinolinolato complexes. All the metal complexes have a high-spin magnetic moment;[16] these results suggest the possibility of dimer geometry.

X-Ray-diffraction-pattern Analysis: Figures 2 and 3 shows the X-ray diffraction patterns of metal 2Meql complex monohydrates and anhydrates. All the patterns of the cobalt(II), copper(II), and zinc(II) complex monohydrates, except for the nickel(II) complex, are similar, with some peaks of the same diffraction angles; the nickel(II) complex displayed different, rather complicated patterns. Metal-complex anhydrates of cobalt(II), copper(II), and zinc(II), except for nickel(II), also show very similar patterns; three peaks appeared at about $2\theta=10°$, and three or five peaks, at about $2\theta=30—40°$.

The Characterization of Several Metal 2Meql Complexes in Aqueous and Organic Solvents. Optical Spectra of 2MeHql in Aqueous Solutions: Figure 4 shows the optical spectra of 2MeHql in aqueous solutions. From the increase in the basicity of the oxygen and nitrogen atoms upon the substitution of the 2-position with the methyl group, the peaks showed a blue shift.[17] The substitution of the methyl group for hydrogen at the 2-position brought about an increase in the basicity of oxygen and nitrogen, resulting in a blue shift.

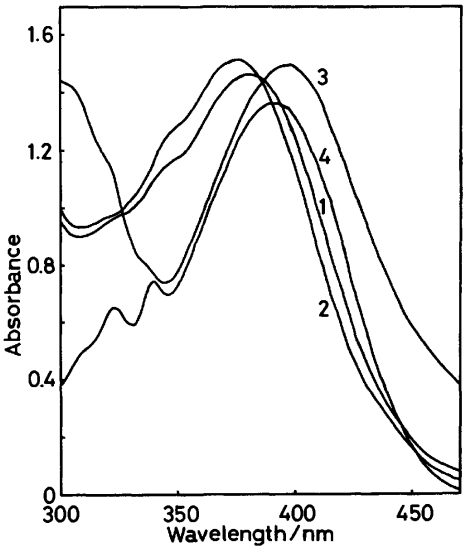

Fig. 5. Optical spectra of some metal(II) 2-methyl-8-quinolinolato complexes in chloroform. 1: Co(2.66×10^{-4} M), 2: Ni(3.04×10^{-4} M), 3: Cu(3.00×10^{-4} M), 4: Zn(3.04×10^{-4} M).

Optical Spectra of the Complexes in a Pure Organic-solvent Medium: It is important, from the standpoint of explaining the reaction mechanism involved in solvent extraction, to know whether or not the dimeric geometry of the cobalt(II), nickel(II), copper(II), and zinc(II) 2Meql complexes in organic solvents is kept. Figure 5 shows the optical spectra of the complexes in chloroform. In a previous paper,[13] Sekido and Kunikida have reported that a trace amount of water affects the optical spectra of nickel 8-quinolinolate anhydrate. We have been measured the optical spectra of metal complexes in chloroform treated with various desiccants; we have found that the red shifts of the optical maximum increase in this order: Ni(376 nm)<Co(381 nm)<Zn(391 nm)<Cu(397 nm), and that a variety of desiccants does not affect the optical spectra; that is, the dimer geometry of an anhydrate is maintained in a chloroform solution. Further, the behavior of the optical spectra in a dioxane solution is the same as in chloroform.

Optical Spectra of the Complexes in Mixed Solvents: From the viewpoint of adduct formation and configuration variation, the optical spectra of mixed solvents-in dioxane-pyridine, dioxane-methanol, and dioxane-water systems, were examined using the same preparing procedure in a chloroform solvent.[18] For example, the optical spectra of copper complexes are shown in Figs. 6, 7, and 8. In Fig. 6, with an increase in the amount of pyridine, the optical maximum at about 400 nm shifted toward 385 nm, involving only one isosbestic point at 394 nm. In Fig. 7, with an increase in the amount of methanol, the absorption maximum at about 400 nm shifted toward 385 nm, while the optical density decreased, and then the optical maximum at 339 nm turned into a shoulder. Isosbestic points were observed at 386 and 330 nm, so at least two species of metal complexes were present. In Fig. 8, a similar behavior of the optical spectra was

observed in dioxane-water; however, the optical maximum at 339 nm completely disappeared. In this system, the precipitation of hydrate was observed at a water concentration of about 33.3 M (1M=1 mol dm^{-3}). From the results of the optical spectra of other mixed-solvent systems, it seems that the optical spectra of complex anhydrates depend upon their nature, the molar ratio, the concentration of the solvents, and the analytical concentration of the complexes. The results of the optical spectra of complex anhydrates in various organic solvents are shown in Table 3. The optical spectra in the dioxane solution of copper-

(sh: shoulder).

(II) complex anhydrates were changed upon the addition of basic solvents, which resulted in a shifting of the isosbestic point. In other words, the configuration of the complex anhydrates in a dioxane solution turned into something else. However, in the case of other metal-complex anhydrates, upon the addition of basic solvents a new isosbestic point appears, so two equilibrium states at least are present. Depending on the amount of basic solvents added, the configuration of the complex anhydrate [1] in a dioxane solvent turns into a different structure [3a, 3b, or 3c] through a middle species [2a, 2b, or 2c] as is shown in Fig. 9. The amount of Lewis base added depended upon the strength of the basicity; it was preferred to the order of pyridine<water<methanol. For example, in nickel-complex anhydrate, the amounts of the basic solvents needed to change from one configuration to another were 2.5×10^{-3} M for pyridine, 1.1 M for water, and 4.9 M for methanol.

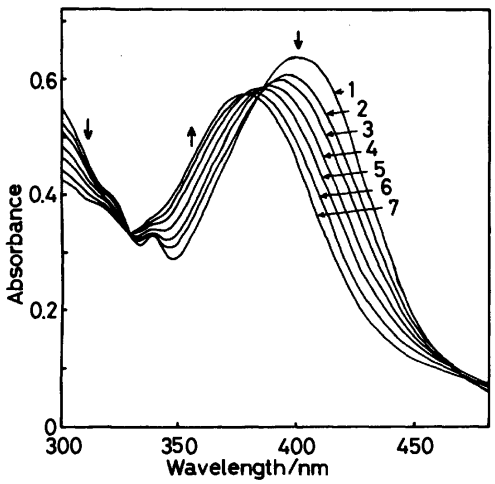

Fig. 8. Optical spectra of $Cu(2Meql)_2$ in dioxane containing various amounts of water. 1: $[H_2O]=0$ M, 2: 2.78 M, 3: 5.56 M, 4: 11.11 M, 5: 16.67 M, 6: 22.22M, 7: 27.78 M. $[Cu(2Meql)_2]=1.13\times10^{-4}$ M. Trends of spectral change with increase in base concentration are shown by arrows.

Effect of the Concentration of a Complex on Its Optical Spectra: The optical spectra of the nickel(II) 8-quinolinolato complex at various concentrations in dried chloroform were examined in a previous paper.[13] The monomer complex exists below 1×10^{-5} M, but the binuclear or trinuclear complex exists at concentrations above 1×10^{-5} M, and for the binuclear complex, the formation constant was calculated at $K=2000$:

$$2\cdot Niql_2 \overset{K}{\rightleftharpoons} (Niql_2)_2.$$

In the case of the metal 2Meql complexes, not enough change in the optical spectra upon the addition of basic solvents was obtained, so the equilibrium constant could not be calculated accurately. However, the dimeric complex of cobalt(II), nickel(II), or zinc(II) probably exists at concentrations above 2×10^{-5} M. The solvents added at lower concentrations coordinated at the axial positions of the dimer complex, and at higher concentrations the bridge linkages by 2Meql were broken by added solvents (refer to Fig. 9) and the axial positions were coordinated, resulting in a distorted octahedral geometry, as is shown in Fig. 9. The stability of dimer geometry increased in the order of: cobalt(II)≃nickel(II)>zinc(II); the dimer⇄monomer order

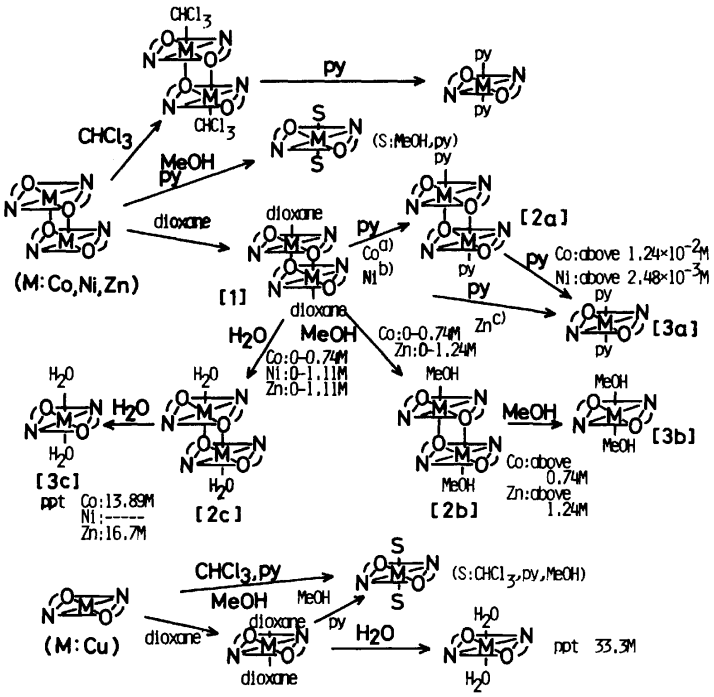

Fig. 9. Proposed structures of several metal(II) 2-methyl-8-quinolinolato complexes in various organic solvents. a) Co: 0—1.24×10^{-2} M, b) Ni: 0—2.48×10^{-3} M, c) Zn: above 0.743×10^{-3} M.

was affected by the nature of the basicity, and the dimer formed rapidly at low concentrations when a strong base such as in the pyridine solvent, was added. On the other hand, in the case of the copper(II) complex, from the optical spectra of all the organic solvents used here and the variation in the concentration of the copper(II) complex, it seems that the dimer structure did not exist; that is, an adduct complex with a planar geometry has formed.

This work was presented in part at the 37th Annual Meeting of the Chemical Society of Japan, Yokohama, April, 1978, Abstr. No. 2I29.

Kinetics of Ligand Exchange of Tris(β-diketonato)iron(III) with Acetylacetone, Trifluoroacetylacetone, and 2-Thenoyltrifluoroacetone in Carbon Tetrachloride

Tatsuya SEKINE* and Kazuho INABA
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received February 17, 1984)

The ligand of tris(β-diketonato)iron(III) with acetylacetone (Hacac), trifluoroacetylacetone (Htfa), or 2-thenoyltrifluoroacetone (Htta) in carbon tetrachloride was exchanged with another ligand among these. The rate was measured in order to learn about the reaction mechanism in this medium; one in which no intermediates with the solvent molecules were expected. From the dependence of the rate on the particular leaving and entering ligand and from the values of ΔH^* and ΔS^*, it was concluded that in an exchange involving [Fe(acac)$_3$] there is always a proceeding dissociative mechanism and for [Fe(tta)$_3$] and [Fe(tfa)$_3$] with Hacac there is an interchange mechanism. Exchanges with a fluorinated β-diketone is thought to have a character intermediate to these two mechanisms.

Kinetic studies on the ligand exchange of metal complexes have been, in most cases, carried out in aqueous solutions and several explanations for models in which the solvent molecules also react as ligands to form intermediate species have been proposed from the experimental results. When nonpolar- and non-solvating-type solvents are employed instead of water, however, it is expected that more direct information about the effects of the chemical properties of the leaving and entering ligand on the reaction mechanism can be obtained.[1,2] For this reason, the rates of nonisotopic ligand exchanges for three tris(β-diketonato)iron(III) complexes in carbon tetrachloride were determined in the present study. Considerations are made on the reaction mechanism for situations where the effect of the solvent molecules is considered slight.

Experimental

Materials. All reagents were reagent grade. The β-diketones, 2,4-pentanedione (acetylacetone; Hacac), 1,1,1-trifluoro-2,4-pentanedione (trifluoroacetylacetone; Htfa), and 1-(2-thienyl)-4,4,4-trifluoro-1,3-butanedione (2-thenoyltrifluoroacetone; Htta) were supplied by Dojindo Co., Kumamoto. The Htta was recrystallized from benzene–petroleum ether before use. Iron(III) complexes of these β-diketones were synthesized by the conventional method[3] and recrystallized from benzene–petroleum ether. The purity was checked by an elementary analysis as: [Fe(acac)$_3$] (Found: C 51.25, H 6.02%, Calcd: C 51.01, H 5.99%), [Fe(tfa)$_3$] (Found: C 34.95, H 2.34, F 33.10%, Calcd: C 34.98, H 2.35, F 33.20%), and [Fe(tta)$_3$] (Found: C 40.11, H 1.71, S 13.25, F 23.62%, Calcd: C 40.07, H 1.68, S 13.37, F 23.77%). The carbon tetrachloride was washed three times with water, treated with a dehydrating resin, (SK1B, Mitsubishi Kasei Co., Tokyo) and distilled.

Procedures. The experiments were carried out in a thermostated bath (±0.3 K) located in a thermostated room (±0.6 K). A carbon tetrachloride solution containing 1×10^{-5} to 4×10^{-4} mol dm^{-3} of one of the iron(III) complexes (FeA$_3$) and an excess amount of the ligand (HA) was mixed with a solution containing 1×10^{-4} to 1 mol dm^{-3} of another entering ligand (HB). In order to study ligand exchange equilibrium, the mixed solution was left standing and its optical absorption was measured at 375 nm (exchange of [Fe(acac)$_3$] with Htfa), or 550 nm (for all of the other reactions) after it had become a certain constant value. This was repeated for several molar ratios of the two ligands, HA and HB. While the rate of ligand exchange was being studied, the optical absorption of the solution was measured several times.

Data Treatment. The exchange equilibrium of the iron(III) complex with the entering ligand in the solution may be expressed as;

$$FeA_3 + nHB \rightleftharpoons FeA_{3-n}B_n + nHA$$
$$K_n = [FeA_{3-n}B_n][HA]^n[FeA_3]^{-1}[HB]^{-n}. \quad (1)$$

The optical absorption of the solution at equilibrium is given by;

$$E = [Fe(III)](\varepsilon_0+\varepsilon_1K_1R+\varepsilon_2K_2R^2+\varepsilon_3K_3R^3) \times (1+K_1R+K_2R^2+K_3R^3)^{-1}, \quad (2)$$

where ε_n is the molar extinction coefficient of the $FeA_{3-n}B_n$ complex and R is the concentration ratio (R=[HB][HA]$^{-1}$). The values of K_n and ε_n were obtained by analyzing the data using a successive-approximation program.[4]

The kinetic data on ligand exchange can be treated as follows. When the whole exchange reaction is controlled by the exchange of the first ligand of FeA$_3$, the successively formed three species, FeA$_2$B, FeAB$_2$, and FeB$_3$, should be in equilibrium with each other. Under such conditions, the following conditional over-all extinction coefficient can be defined if R is kept constant, since the molar ratios of the three successive complexes should always be constant;[5]

$$\varepsilon_T = (\varepsilon_1K_1R+\varepsilon_2K_2R^2+\varepsilon_3K_3R^3)(K_1R+K_2R^2+K_3R^3)^{-1}. \quad (3)$$

This conditional constant can be calculated on the basis of Eqs. 1 and 2 and, at the same time, can be determined from the absorption at equilibrium if the starting complex, FeA$_3$, is nearly completely changed into the ligand exchanged species. Thus, from information on absorption and the total concentration of iron(III) in the solution, the concentration of the FeA$_3$ species after a certain time interval can be written as;

$$[FeA_3] = (E-\varepsilon_T\times[Fe(III)])(\varepsilon_0-\varepsilon_T)^{-1}. \quad (4)$$

From the decrease in the FeA$_3$ concentration, the rate of ligand exchange can be expressed as;

$$V = -d[FeA_3]/dt = k_{obsd}[FeA_3], \quad (5)$$

where k_{obsd} is the observed rate constant of the exchange reaction.

Results

Ligand Exchange Equilibria. From the absorption data of the equilibrated solutions, the values of K_n and ε_n were obtained as listed in Table 1.

Rate of Ligand Exchange of [Fe(acac)$_3$]. The rate of ligand exchange of [Fe(acac)$_3$] with Htfa or Htta was found to be first order with respect to [Fe(acac)$_3$] and independent of the leaving ligand. Figure 1 gives the results as a function of the concentration of the entering ligand at 298 K. When the entering ligand was Htta, the value of k_{obsd} was independent of its concentration in the range of 10^{-3} to 10^{-2} mol dm^{-3}, though a first-order dependence appeared below and above this range. When the entering ligand was Htfa, on the other hand, no region was apparently found where the rate was independent of its concentration. However, both data could be explained well by assuming the same type of reaction if the effect of the entering ligand as an acid catalyzer, as will be described later, is corrected.

Rate of Ligand Exchange of [Fe(tfa)$_3$]. In the course of the study of the ligand exchange of [Fe(tfa)$_3$] with Hacac, it was found that absorption at 375 nm rapidly increased just after the addition of a Hacac solution to the [Fe(tfa)$_3$] solution. This enhancement in the absorption was concluded to be due to an association of [Fe(tfa)$_3$] and Hacac which proceeded much more rapidly than the ligand exchange. Spectrometric data were analyzed after a correction for this intermediate was made. Figure 2 gives the results at 298 K as a function of the entering ligand. In the higher ligand concentration range, the value of the observed rate constant is independent of the entering ligand, but in the lower region it is proportional to its concentration.

Rate of Ligand Exchange of [Fe(tta)$_3$]. A similar type of increased absorption at 550 nm was also found upon the addition of Hacac to the [Fe(tta)$_3$] solution. The rate of ligand exchange of [Fe(tta)$_3$] with Hacac or Htfa was found to be first order with respect to the iron(III) complex and independent of the leaving ligand. The dependence on each entering ligand was first order when the concentration was lower than 0.2 mol dm^{-3} and independent above this value. Figure 3 gives the results.

The results in Figs. 1 to 3 can be represented by the following general equation;

$$k_{obsd} = \frac{k_A(1+k_C[HB])[HB]}{k_B+[HB]}. \quad (6)$$

TABLE 1. SUMMARY OF EQUILIBRIUM CONSTANTS

	[Fe(acac)$_3$] +Htfa (375 nm)	[Fe(acac)$_3$] +Htta (550 nm)	[Fe(tfa)$_3$] +Htta (550 nm)

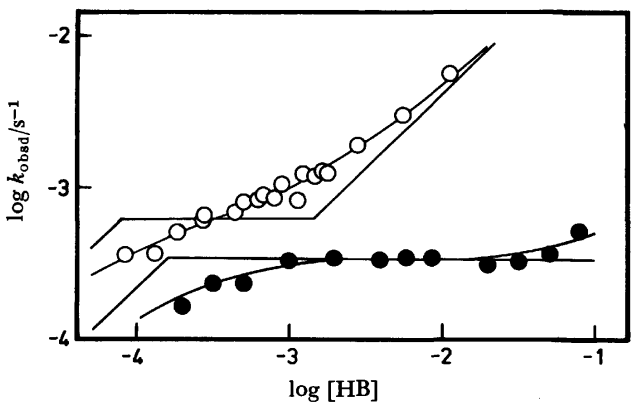

Fig. 1. Rate of [Fe(acac)$_3$] reaction with Htfa (○) and Htta (●) as a function of the entering ligand concentration at 298 K. The curves are caluclated by introducing the constants in Table 2 into Eq. 6. The straight lines are the asymptotes for the curves.

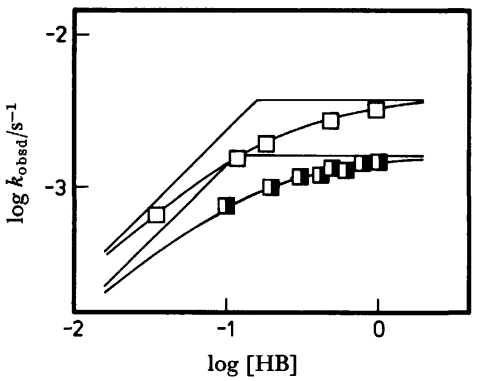

Fig. 3. Rate of [Fe(tta)$_3$] reaction with Hacac (■) and Htfa (□) as a function of the entering ligand concentration at 298 K. The curves are calculated by introducing the constants in Table 2 into Eq. 6. The straight lines are the asymptotes for the curves.

TABLE 2. SUMMARY OF CONSTANTS AND ACTIVATION PARAMETERS

	$[Fe(acac)_3]$		$[Fe(tfa)_3]$		$[Fe(tta)_3]$	
	+Htfa	+Htta	+Hacac	+Htta	+Hacac	+Htfa
$\log (k_A/s^{-1})$	−3.2	−3.5	−2.6	−2.1	−2.8	−2.4
$\log (k_B/\text{mol dm}^{-3})$	*ca.* −4	*ca.* −4	−0.8	0.3	−0.9	−0.8
$\log (k_C/\text{mol}^{-1}\text{ dm}^3\text{ s}^{-1})$	2.8	0.7	—	—	—	—
$\Delta H^*/\text{kJ mol}^{-1}$ †	83	82	56	63	62	68
$\Delta S^*/\text{J K}^{-1}\text{ mol}^{-1}$ †	−27	−38	−106	−74	−89	−64

† The estimated errors of ΔH^* and ΔS^* for the reactions of $[Fe(tfa)_3]$ and $[Fe(tta)_3]$ are around ±1 and ±5 while that for the reactions of $[Fe(acac)_3]$ are ±5 to 10 and ±20 to 30, respectively.

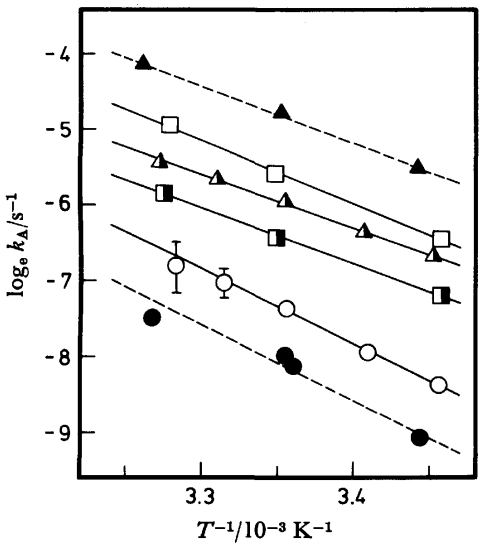

Fig. 4. Arrhenius plot of the rate constant k_A of the reaction of $[Fe(acac)_3]$ with Htfa (○) and Htta (●), $[Fe(tfa)_3]$ with Hacac (△) and Htta (▲), and $[Fe(tta)_3]$ with Hacac (◨) and Htfa (□).

From the information in Fig. 1, the value of the constant k_C was obtained. From the results expressed in Figs. 2 and 3, this term was concluded to be negligible. The values of the constants obtained are listed in Table 2.

Activation Parameters of Ligand Exchange Reactions. The rate of ligand exchange was also measured at 288 and 306 K (and 293 and 302 K for $[Fe(acac)_3]$ and Htfa or $[Fe(tfa)_3]$ and Hacac reaction). Figure 4 gives the $\log_e k_A$ *vs.* $1/T$ plot. The results regarding the reaction of $[Fe(acac)_3]$ with Htfa and Htta were found to be somewhat more erroneous than those of other reactions, especially at higher temperatures. The activation parameters, ΔH^* and ΔS^*, obtained from these data are listed in Table 2.

Effect of Trichloroacetic Acid. In a previous study, it was found that the rate of ligand exchange of $[Fe(acac)_3]$ with Htta in carbon tetrachloride was accelerated by the presence of several acids.[2] In the present study, the effect of trichloroacetic acid was measured. The reactions of $[Fe(acac)_3]$ with both Htta and Htfa were accelerated by trichloroacetic acid already at a concentration of 10^{-5} mol dm^{-3} and that of $[Fe(tta)_3]$ with Htfa was also accelerated by a presence of 10^{-3} mol dm^{-3}. The rates of other reactions were not affected by trichloroacetic acid in a concentration range of 10^{-5} to 10^{-3} mol dm^{-3}.

Discussion

It was concluded from the absorption data of the mixed sample solutions at equilibrium that more than 99% of the starting complex, FeA_3, had been changed to the ligand exchanged species under the conditions of the R employed for the kinetic experiments. Thus from the total concentration of iron(III) and the absorption at equilibrium, the value of ε_T in Eq. 3 should be obtained. This was confirmed since the values calculated by introducing the constants in Table 1 into Eq. 3 agreed well with this observed value. From this, the analysis of the kinetic data in the present study by using Eq. 4 and the values of ε_T should be reasonable.

Some experiments were made under conditions of R where the chemical species formed from FeA_3 were only of the FeA_2B type complex and $FeAB_2$ and FeB_3 were negligible. The rate was always similar to that obtained at values of R where exchange was complete. Thus, the rates of ligand exchange of the FeA_2B and of $FeAB_2$ species were much higher than that of the FeA_3 species. This should support the assumption already made that the rate was, in all the cases, not affected by the concentration of the leaving ligand and, consequently, the controlling step was the exchange of the first ligand of FeA_3. Thus, the discussion below is made on the basis of this assumption.

In the present study, it is assumed that (i) the solvation with carbon tetrachloride should be very weak and, thus, any intermediate species containing the solvent molecules is negligible, and (ii) the presence of any charged species is negligible in the solution. The results in Figs. 1 to 3 are generally represented by Eq. 6, but since the term k_C represents a catalytic effect with the entering ligand itself, as will be seen later, the results should be given by the following equation if this effect is statistically substracted;

$$k_{obsd} = \frac{k_A[HB]}{k_B + [HB]}. \quad (7)$$

This equation suggests that the reaction may possibly proceed by two types of ligand-exchange mechanisms. One is the dissociative mechanism which is represented by;

$$MA_3 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} MA_3^* \xrightarrow[+HB]{k_2} MA_2B + HA,$$

where the superscript "*" denotes a complex one of whose chelate ring is open. When the rate constant for the ring opening is given by k_1, that for its backward reaction by k_{-1} and that for the entering of HB by k_2, the following equation is obtained;

$$V = \frac{k_1[\mathrm{HB}][\mathrm{FeA_3}]}{(k_{-1}/k_2)+[\mathrm{HB}]}. \quad (8)$$

The other is the interchange mechanism which is represented by;

$$\mathrm{MA_3} + \mathrm{HB} \overset{K}{\rightleftharpoons} \mathrm{MA_3{*}HB} \overset{k}{\longrightarrow} \mathrm{MA_2B} + \mathrm{HA},$$

$$V = \frac{k[\mathrm{HB}][\mathrm{FeA_3}]}{K^{-1}+[\mathrm{HB}]}. \quad (9)$$

Here, MA_3 is in equilibrium with its associate with HB and the reaction is controlled by the formation of the first chelate ring with the anion of the entering ligand B^- involving a proton-transfer from the entering HB to the leaving A^-.

It is known that if a reaction proceeds by a dissociative mechanism, the value of ΔH^* is large and ΔS^* is positive or nearly zero while if it proceeds by an interchange mechanism, the ΔH^* is smaller than that by a dissociative mechanism and the ΔS^* is negative. After observing this general tendency and the values in Table 2, it may be concluded that the ligand exchange of the [Fe(acac)$_3$] complex proceeds by a dissociative mechanism while that of [Fe(tfa)$_3$] and [Fe(tta)$_3$] proceeds by an interchange mechanism, although the ligand exchange of [Fe(tta)$_3$] with Htfa may have an intermediate character of these two becasue of the intermediate magnitude of the values of ΔH^* and ΔS^*. Although the reactions of [Fe(acac)$_3$] with Htta and Htfa are assumed to proceed by a dissociative mechanism, the values of k_1 are not similar. One explanation for this may be that the amount and/or the effect on the rate of the minor contents in the systems such as water, impurities in the reagents *etc.*, are not identical. However, further experiments seem to be necessary in order to solve this problem.

It seems to be reasonable that a catalytic effect of the acids, including that with the entering β-diketone to the complex which is also a weak acid, appears only in the exchange reaction of [Fe(acac)$_3$] with the fluorinated β-diketones and not in the exchange of [Fe(tta)$_3$] or [Fe(tfa)$_3$] with acetylacetone or with the other fluorinated β-diketone if the former reaction proceeds by a dissociative mechanism and the latter by an interchange mechanism. When the reaction proceeds by a dissociative mechanism, the leaving ligand, $acac^-$, easily accepts a proton from a stronger acid. This should help in the dissociation of the ligand from the complex, but acetylacetone in an acid form, Hacac, may not give up a proton so easily to the leaving ligand. On the other hand, when the reaction proceeds by an interchange mechanism and when the dissociation of the proton from the entering ligand which is accompanied by the closure of the chelate ring controls the whole reaction, another acid whether it is stronger or weaker can not assist the leaving of the proton and, thus, can not catalyze the reaction.

The enhancement of the absorption properties of a solution of [Fe(tfa)$_3$] or [Fe(tta)$_3$] just after the addition of acetylacetone has been explained by a mechanism involving the interaction of the complex with the β-diketone from the statistical treatment of optical data. This may support the conclusion that the ligand exchange in these cases proceeds by an interchange mechanism, although such a change was not clearly observed with the addition of Htfa to the [Fe(tta)$_3$] solution or with the addition of Htta to the [Fe(tfa)$_3$] solution. A similar change in the absorption, but probably due to a somewhat different cause, was also found in the "inert" solvent, benzene, in the previous paper.[6]

Adduct formation of uncharged chelate complexes in nonpolar solvents with an uncharged ligand has been studied from the stand point of the "synergistic effect" of solvent extraction.[7] The tendency of metal chelates with acetylacetone to accept a neutral ligand is generally smaller than of those with fluorinated β-diketones. It is also known that the neucleophilic tendency of ligands to form such adducts is greater with those ligands to form more stable complexes and, thus, Hacac should be more neucleophilic than the other two. From these, the interactions of the complex and the entering ligand should be stronger with the chelates with the fluorinated β-diketones and, thus, it seems to be reasonable that they tend to exchange by an interchange mechanism while that with acetylacetone exchanges by a dissociative mechanism. The values k_B for the reaction of [Fe(tfa)$_3$] and [Fe(tta)$_3$] in Table 2 correspond to the inverse of the formation constant of the interacted species. The value is smaller for reactions with [Fe(tfa)$_3$] with Hacac than with Htta (the former forms a larger amount of interacted species), and is nearly the same in the reactions of [Fe(tfa)$_3$] and [Fe(tta)$_3$] with Hacac and, thus, the adducts are similarly stable.

In the previous work,[2] a set of values of ΔH^* and ΔS^* for the ligand exchange of [Fe(acac)$_3$] with Htta in carbon tetrachloride was reported. However, from recalculations made using data obtained in both the previous and present work, it was concluded that the values in Table 2 should be employed. In the present study, the results of experiments with Htta were found to be less reproducible than those with other β-diketones.

In aqueous solutions, the water molecules might also act as an entering ligand whose concentration is constant and much higher than any other entering ligands present. Thus, formation of intermediates with water molecules is expected prior to the entrance of the ligand to be studied. Since no such intermediates with solvent molecules could be formed in carbon tetrachloride, the effect of the chemical properties of the ligands on the reaction mechanism could be recognized more clearly than in aqueous solutions. The use of benzene in the kinetic study of the ligand exchange of iron(III) complexes was reported[6] but since the ligands are different, no direct comparison of this previous study with the present one seems to be possible.

Isotopic ligand exchange of tris(acetylacetonato)-iron(III) in an acetylacetone medium was studied and the reaction mechanism was reported to be associative.[3] However, since the nature of the solvent and the enter-

ing ligand is different, the present results may not be compared directly with the previous study.

In a previous kinetic study of the isotopic ligand exchange of aluminium(III), indium(III), gallium(III), and beryllium(II) complexes where the ligand was 2,4-pentanedione, 1-phenyl-1,3-butanedione, or 1,3-diphenyl-1,3-propanedione in tetrahydrofuran, the rate was always lower when the acidity of the ligand was weaker (pK_a is greater).[8]

There have been other reports on the isotopic and non-isotopic ligand exchange of complexes of other metal ions in organic solvents (for example Refs. 9—14). However, direct comparison of the present data with these previous results does not seem to be possible because of the difference of the medium.

We are grateful to Dr. Shigeru Suzuki of the Tokyo College of Pharmacy, for the elementary analysis of the complexes.

Preparation of {*N*-(2-Aminoethyl)-1,3-propanediamine}(diethylenetriamine)-cobalt(III) Complex, and Separation and Optical Resolution of the Isomers

Minoru Ishii

Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi-ikebukuro, Toshima-ku, Tokyo 171

(Received February 24, 1984)

The mixed ligand complex {*N*-(2-aminoethyl)-1,3-propanediamine}(diethylenetriamine)cobalt(III) was prepared. Of the five possible geometrical isomers, two were isolated by column chromatography; their formation ratio was *ca.* 6:4. Both isomers were completely resolved by chromatography. Their configurations were assigned to the meridional type on the basis of electronic, infrared, and circular dichroism spectroscopy, and the X-ray analysis data.

The linear triamine, *N*-(2-aminoethyl)-1,3-propanediamine ($NH_2CH_2CH_2CH_2NHCH_2CH_2NH_2$; abbreviated as aepn), can act as a terdentate ligand. It coordinates to the central metal ion in two topological ways. The mixed complex, $[Co(aepn)(dien)]^{3+}$ (dien; diethylenetriamine), exists in five geometrical isomers: Three *facial* (*fac*) isomers and two *meridional* (*mer*) isomers (Fig. 1). The difference between the two *mer*-geometries arises from the orientation of the N (secondary)–H bond in the dien ligand. Further, there are the optically active antipodes arising from an alternative configuration (*R*/*S*) of the secondary nitrogen atom in the aepn (Fig. 2). Thus, this isomerism can be expected to hold for the *mer*-isomers, and it should be recognized as a new type.

As a few examples of complexes which can be expected to show similar stereochemistry and isomerism, $[Co(dien)_2]^{3+}$,[1] $[Co(dema)(dien)]^{3+}$, $[Co(dema)_2]^{3+}$ (dema; *N*-methylbis(2-aminoethyl)amine),[2] and $[Co(dpt)_2]^{3+}$ (dpt; bis(3-aminopropyl)amine)[3] have been prepared and their spectroscopic data reported. Among these complexes, all three of the possible isomers of $[Co(dien)_2]^{3+}$ were isolated,[1] and the molecular structures were determined by the X-ray analysis of the *sym-fac*-$[Co(dien)_2]Br_3$,[4] $(-)_{589}$ *unsym-fac*-$[Co(dien)_2][Co(CN)_6]\cdot 2H_2O$[5] and $(+)_{589}$ *mer*-$[Co(dien)_2]Br_3\cdot 1.6H_2O$[6] crystals.

Various types of optically active complexes also have been reported recently and studied for their stereochemical geometries. With respect to the polyamine cobalt(III) complexes, a considerable number of determinations of absolute configurations were accomplished by an X-ray analysis technique. On the basis of these results, attempts to relate the spectroscopic data with the geometrical structures were carried out. Hence, it has become feasible to discuss quantitative details, such as the relationship between the absolute configuration and the circular dichroism (CD) spectrum, and the estimation of the contributions in the CD spectrum. This discussion is, however, limited to special types. Most of the empirical and quasi-empirical rules are useful for the complexes containing a five-membered chelate or planar six-membered chelate rings, but no

rule is useful for the nonplanar six-membered chelate and larger chelate ring systems. In the [Co(aepn)(dien)]$^{3+}$ complex, three five-membered chelate rings and a six-membered one may coexist and be fused. From this viewpoint, it seemed that it would be interesting to investigate this complex. Moreover, the very fact that this is a new type of isomerism for the *mer*-isomers is worth noting.

In this paper, the preparation of [Co(aepn)(dien)]$^{3+}$, and its d-d absorption, CD and infrared spectra will be presented.

Experimental

Ligands and Reagents. The aepn and dien ligands were obtained from the Aldrich Chemical Co., Inc., and the Tokyo Kasei Co., Inc., respectively, and were used without further purification. The *mer*-[$CoCl_3$(dien)] complex was prepared according to the method described in the literature.[7] An ion-exchange resin (SP-Sephadex C-25) was obtained from Pharmacia Fine Chemicals Co., Inc. All the other reagents were obtained commercially.

Measurements. The elution curves were recorded with a Hitachi Perkin Elmer 139 spectrophotometer. The visible and near-ultraviolet absorption spectra were measured with a Hitachi EPS 3T spectrophotometer using 10-mm quartz cells. The CD spectra were obtained on a JASCO J-500 automatic spectropolarimeter using attached 10-mm quartz cells. The infrared spectra were measured with a JASCO A 202 infrared spectrophotometer by using Nujol mulls. All the spectral measurements were carried out at room temperature.

Analytical. The content of cobalt was colorimetrically determined by the nitroso-R method, while the contents of the other elements, C, H, N, and Cl, were measured at the Organic Analysis Center of the Institute of Physical and Chemical Research.

Preparation of the Complex, and Separation and Resolution of the Isomer. To 2.7 g of finely ground *mer*-[$CoCl_3$(dien)][7] suspended in 5 cm^3 of dimethyl sulfoxide (DMSO), 1.5 g of aepn was added in small portions, after which the mixture was stirred for 3 h at room temperature. The resulting orange solution was diluted with a small amount of water, and then the unreacted material was filtered off rapidly. The filtrate was poured into a SP-Sephadex C-25 column (H^+ form, ϕ 4 cm×*ca.* 30 cm) in several portions. After washing with 1.0 dm^3 of water and 1.0 dm^3 of 0.01 mol dm^{-3} hydrochloric acid, the elution was carried out with 0.10 mol dm^{-3} hydrochloric acid. The eluate was collected and evaporated to dryness with an evaporator (35 °C) to remove the hydrochloric acid. The residue was dissolved in a small amount of water. Upon the addition of $NaClO_4$, the resulting solution gave 3.7 g of the desired product in a 64% yield for perchlorate. This product was then dissolved in a small amount of water, and the solution was poured into a column containing the SP-Sephadex C-25 resin (H^+ form, ϕ 2.0 cm×*ca.* 100 cm) and washed with a large amount of water. When the elution was carried out with an acidic solution (pH≈2, 0.20 mol dm^{-3} Na_2SO_4+H_2SO_4), two orange-colored bands descended (the elution order: I, II).[8] The two eluates of these bands were independently collected and once more charged on a column of SP-Sephadex C-25 resin (H^+ form, ϕ 2.0 cm×*ca.* 100 cm). By elution with a 0.20 mol dm^{-3} sodium bis[(+)$_{589}$tartrato]diantimonate(III) solution, the two orange bands were separated. The four layers thus obtained (I-(1), I-(2), II-(1), and II-(2)) were optically active. The four eluents corresponding to these layers were independently collected and poured into a column of SP-Sephadex C-25 resin (H^+ form, ϕ 4.0 cm×*ca.* 30 cm). After having been washed with 2.0 dm^3 of water and 1.0 dm^3 of 0.01 mol dm^{-3} hydrochloric acid, elution with 0.10 mol dm^{-3} hydrochloric acid was carried out. The eluted solutions were evaporated to dryness at a low temperature (35 °C) and *in vacuo*. After the removal of the hydrochloric acid by evaporation, the residue was dissolved in a small amount of water. To this orange solution, $NaClO_4$ was added, after which the mixture was kept in a refrigerator. The orange precipitate was recrystallized from warm water. The analytical data of the four isomers thus obtained (I-(1), I-(2), II-(1), and II-(2)) are listed in Table 1.

Results and Discussion

The elution curves obtained at each step are shown in Fig. 3. Only two single bands are found in the first elution as shown in Fig. 3 (a) (the area ratio I:II is *ca.* 6:4); no indication of further separation can be recognized. On the preparation of complexes containing diverse ligands, it is generally known that a series of complexes which differ in the composition of the ligands is obtained as by-products. However, in the present reaction, there is little expectation that any [Co(dien)$_2$]$^{3+}$[9] and [Co(aepn)$_2$]$^{3+}$[10] can be obtained. In order to examine the behavior of these impurities in SP-Sephadex chromatography, these complexes were added beforehand to [Co(aepn)(dien)]$^{3+}$, and then the mixed samples (Fig. 4 (a), (b)) and a sample containing [Co(dien)$_2$]$^{3+}$ (Fig. 4 (c)) were eluted independently in a manner similar to the above. It was found that the behavior of *mer*-[Co(dien)$_2$]$^{3+}$ and the mixture of

The eluent is 0.20 mol dm^{-3} $Na_2SO_4+H_2SO_4$ acidic solution (pH≈2).

isomers of [Co(aepn)$_2$]$^{3+}$ was somewhat analogous to that of the I and II isomers in chromatogram. However, careful and repeated elution of the I and II isomers of [Co(aepn)(dien)]$^{3+}$ did not provide any evidence indicating any further separation of other species. In the following elution, two bands with the area ratio of *ca.* 1:1 descended (Fig. 3 (b), (c)). From these facts, it was concluded that little or no [Co-(dien)$_2$]$^{3+}$ and [Co(aepn)$_2$]$^{3+}$ were obtained by this synthetic process; hence, the process was effective for the preparation of [Co(aepn)(dien)]$^{3+}$.

The absorption and CD spectra of the isolated isomers in the visible and near-ultraviolet region (18000—46000 cm^{-1}) are shown in Figs. 5 and 6 respectively, while their spectroscopic data are listed in Table 2. Among the absorption spectra, the positions and intensities of all the bands were approximately the same. In the three isomers (*mer-*, *unsym-fac-*, and *sym-fac-*) of [Co(dien)$_2$]$^{3+}$,[1] differences in the maxima of the absorption bands were observed. These facts indicate that the four isomers (I-(1), I-(2), II-(1), and II-(2)) of [Co(aepn)-(dien)]$^{3+}$ have a structural resemblance. Compared with the known complexes of the [Co(triamine)$_2$]$^{3+}$ type, the maximum of the first absorption band is at a lower energy side than those of the three isomers of [Co(dien)$_2$]$^{3+}$[1] and at a higher energy side than those of

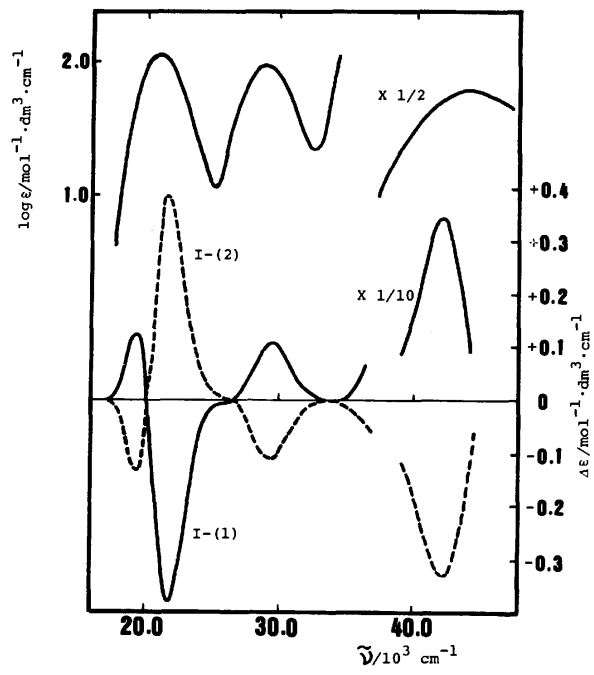

Fig. 5. Absorption and CD spectra of isomer I of [Co(aepn)(dien)]$^{3+}$.

$[Co(aepn)_2]^{3+}$ [10] and *mer*-$[Co(dpt)_2]^{3+}$.[3] These differences in absorption bands were concluded to be due to aepn which was located at a lower position than dien and at a higher position than dpt in the spectrochemical series. In a series of complexes of the $[Co(en)_x(tn)_y(tmd)_z]^{3+}$ type (x=0—3, y=0—3, z=0—3, $x+y+z$=3: tn=1,3-propanediamine, tmd=1,4-butanediamine), it was observed by Kojima *et al.*[11] that the maximum of the absorption bands shifted to the lower energy side as the number of ring members increased. A similar shift is observed for the complexes of the $[Co(triamine)_2]^{3+}$ type as the number of ring members increases from 5 to 6.

In the CD spectra as well as in the absorption spectra, a similarity in the band positions is also found for the four isomers. The pattern and magnitude of two pairs of the spectra, (I-(1) and I-(2), and II-(1) and II-(2)), are mirror images of each other. These findings indicate that they are two pairs of enantiomers with a structural resemblance; this fact agrees with the results obtained from chromatography.

The present author and his associates have already determined the molecular and absolute structures of the I-(1) isomer to be *mer-trans*-δ-NH(R) (corresponding to the *mer*-I type in Fig. 2 (a)) by the X-ray crystal analysis of the iodide monohydrate crystal.[12] Therefore, the structure of the antipode I-(2) can naturally be assigned to *mer-trans*-λ-NH(S) and, further, that of other pair (II-(1) and II-(2)), to the *mer*-II type isomers (Fig. 2 (c), (d)). The magnitudes of the CD spectra are rather weaker than those of the tris(chelate)cobalt(III) complexes in the d-d transition region. The values of $\Delta\varepsilon$ are of the same order of magnitude as those of the optically active forms of *mer*-$[Co(dien)_2]^{3+}$,[1] *mer*-[Co(dema)(dien)]$^{3+}$,[2] and *mer*-$[Co(dpt)_2]^{3+}$,[3] except that the major peak in the first absorption band region is somewhat intense. This finding is consistent with the assignment of the configuration presented above.

The infrared spectra of the I and II isomers are shown in Fig. 7. The similarity of these spectra also indicates that the structures of the two isomers

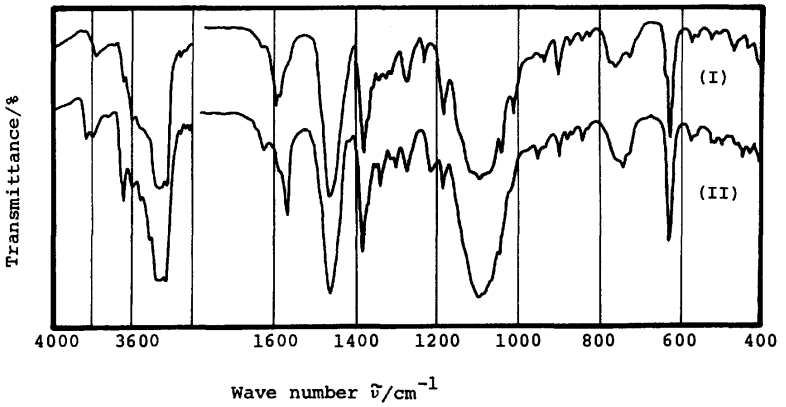

Fig. 7. Infrared spectra of *mer*-[Co(aepn)(dien)]$^{3+}$.

resemble each other. In $[Co(dien)_2]^{3+}$, Yoshikawa and Yamasaki[1] identified the absorption bands at 1610—1550 cm^{-1} as antisymmetric NH_2 bending vibrations and observed a larger splitting for the *mer*-isomer. In the case of $[Co(aepn)(dien)]^{3+}$, similar splitting was observed (I; 1585, 1595, 1625 cm^{-1}, II; 1570, 1585(sh), 1625 cm^{-1}). This observation confirmed that I and II are *mer*-type isomers.

Yoshikawa and Yamasaki investigated in detail the isomeric ratio of $[Co(dien)_2]^{3+}$[1] and $[Co(dema)(dien)]^{3+}$[2] using several synthetic pathways, and reported that the use of *mer*-$[CoCl_3(dien)]$ as a starting material gave the *mer*-isomer in an overwhelming yield. This agrees with the results obtained in the present paper. Thus, in the *mer*-$[CoCl_3(dien)] \rightarrow [Co(aepn)(dien)]^{3+}$ process, clearly no rearrangement of the configuration occurred. Therefore, the remaining three *fac*-isomers were not obtained through this synthetic pathway. The *fac*-$[CoCl_3(dien)]$ complex seems to be one of the most suitable starting materials for the *fac*-$[Co(aepn)(dien)]^{3+}$; unfortunately, this complex is not yet well known. The present author's attempts to obtain this complex were unsuccessful. Some synthetic attempts to obtain these *fac*-$[Co(aepn)(dien)]^{3+}$ were, therefore, carried out with the use of typical compounds as raw materials.

1) The oxidation of a mixture containing equivalent amounts of $CoCl_2 \cdot 6H_2O$, dien, and aepn with an air stream in the presence of active charcoal.

2) The stirring of a mixture containing equivalent amounts of $[CoCl(NH_3)_5]^{2+}$, dien, and aepn.

Both methods were carried out in aqueous solutions and gave large amounts of the by-products, $[Co(dien)_2]^{3+}$ and $[Co(aepn)_2]^{3+}$, and a small amount of $[Co(aepn)(dien)]^{3+}$. The $[Co(aepn)(dien)]^{3+}$ thus obtained was chromatographically identified as consisting of *mer*-isomers. The *fac*-isomers were never isolated or detected, however. For both synthetic pathways, further attempts were carried out in the nonaqueous solvent DMSO. The reaction, however, did not proceed, and $[Co(aepn)(dien)]^{3+}$ was not obtained. Therefore, no *fac*-$[Co(aepn)(dien)]^{3+}$ has yet been isolated, though there may be a possibility of formation *via* other pathways. However, in the case of the $[Co(triamine)_2]^{3+}$ complexes, it is known that the *mer*-isomer is obtained as the chief product. In particular, it has been observed that any attempts to prepare $[Co(dpt)_2]^{3+}$ gave only the *mer*-isomer.[3] These facts suggest that the probability of obtaining the *fac*-$[Co(aepn)(dien)]^{3+}$ isomers is low.

The CD spectrum of the I-(1) isomer has a small positive peak on the lower energy side of the first absorption band region and a main negative peak on the higher energy side. As has been mentioned before, Okiyama *et al.* determined the molecular structure of a similar *mer*-type complex, *mer*-$[Co(dien)_2]^{3+}$, by the X-ray analysis of the $(+)_{589}$ *mer*-$[Co(dien)_2]Br_3 \cdot 1.6H_2O$ crystal; the absolute configuration of this antipode, which showed a main negative peak in the first absorption band region (19500 cm^{-1} $\Delta\varepsilon$=+0.096 mol^{-1} dm^3 cm^{-1}, 21900 cm^{-1} $\Delta\varepsilon$=−0.181 mol^{-1} dm^3 cm^{-1}), was assigned to *trans*-λ-NH. In the present work, an obvious inversion was observed for the CD pattern between *mer-trans*-δ-NH-$[Co(dien)_2]^{3+}$ and *mer-trans*-δ-NH(*R*)-$[Co(aepn)(dien)]^{3+}$ (or *mer-trans*-λ-NH-$[Co(dien)_2]^{3+}$ and *mer-trans*-λ-NH(*S*)-$[Co(aepn)(dien)]^{3+}$). At first sight, *mer*-$[Co(dien)_2]^{3+}$ appears to have pseudo-planes of symmetry and two-fold axes of rotation in the octahedral situation. However, the possibility of a second source of asymmetry arises in this situation. Since the conformations of the two fused five-membered chelate rings must be δ and λ, the chiral contribution from the conformational effects may be cancelled out. The net chirality in the optically active geometry probably comes from the stereochemical relationship between the two N(secondary)–H bonds of two dien ligands. In contrast to this simple model, the chirality of *mer*-$[Co(aepn)(dien)]^{3+}$ may be complicated by the presence of the six-membered chelate ring of the aepn ligand; that is, the contributions coming from the asymmetric secondary nitrogen of aepn and from the remaining conformational effect must be applied. As has been mentioned above, the isomerism of *mer*-$[Co(aepn)(dien)]^{3+}$ is a new type. For example, in the case of the $[Co(triamine)_2]^{3+}$ complex, neither theoretical attempts nor empirical attempts to estimate these contributions were carried out. However, it will be possible to find, in the complexes containing quadridentate tetramine ligands, convenient models which possess this geometrical feature in common with the *mer*-$[Co(aepn)(dien)]^{3+}$. Among these models, *trans*-(*R*,*R*)-$[Co(3,2,3\text{-tet})XY]^{n+}$ (n=1, 2, 3: X, Y=unidentate ligands: 3,2,3-tet=4,7-diazadecane-1,10-diamine; Fig. 8) could be one of the complexes which would supply useful clues. Since the 3,2,3-tet moiety of this complex coincides with those of the aepn of *mer-trans*-δ-NH(*R*) (Fig. 2 (a), *mer*-I) and *mer-trans*-λ-NH(*R*)-$[Co(aepn)(dien)]^{3+}$ (Fig. 2 (c), mer-II), there are extensive similarities between the geometries of these species. Bosnich and Harrowfield[13] have studied in detail the spectra of *trans*-(*R*,*R*)-$[Co(3,2,3\text{-tet})XY]^{n+}$. In the case of X=Y=$NH_3$, a typical CoN_6 species, they found that *trans*-(*R*,*R*)-$[Co(3,2,3\text{-tet})(NH_3)_2]^{3+}$ had a main negative peak in the first absorption band region. From the structure shown in Fig. 8, it is clear that the chirality of the 3,2,3-tet complex arises exclusively from the contributions of the configurations of the asymmetric nitrogen atoms and the conformations of the chelate rings. Thus, the main negative peak can be expected to reflect these contributions exactly. The chirality of

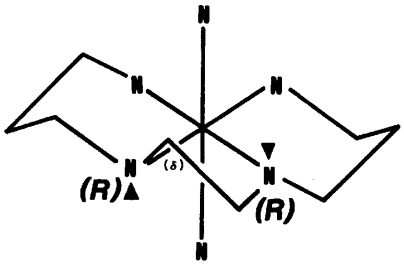

Fig. 8. Conformation of *trans*-(*R*,*R*)-$[Co(3,2,3\text{-tet})(NH_3)_2]^{3+}$.

mer-[Co(aepn)(dien)]$^{3+}$ came from the effects of the relationships between the two *trans*-NH bonds, the configuration of the asymmetric atom, and the conformation of the chelate rings, as has previously been described. In the first absorption band region, the main negative peak observed for *mer-trans-δ*-NH(*R*)-[Co(aepn)(dien)]$^{3+}$ suggests that the last two contributions may be superior to the first. It is clear that the inversion of the CD pattern in this region is attributable to differences between the magnitudes of these contributions. This finding can help us establish the relationships between the sign of the CD main peak in the first absorption band region and the situation of aepn. By the use of these relationships, the following structures of the remaining enantiomers can be assigned: II-(1); *trans-λ*-NH(*R*), and II-(2); *trans-δ*-NH(*S*).

In *mer*-[Co(dpt)$_2$]$^{3+}$, Yamada *et al.*[3] obtained a CD spectrum with an extraordinarily small value of $\Delta\varepsilon$ and predicted a decrease in the contribution from the two N-H bonds as a result of a flattering of the four six-membered rings. For *mer*-[Co(aepn)(dien)]$^{3+}$ also, such a decrease can be expected.

The author gratefully acknowledges the valuable discussions and encouragement to Professor M. Nakahara of Rikkyo (St. Paul's) University during the course of this work.

8) By the use of a 0.20 mol dm^{-3} Na_2SO_4 solution (pH≈7) as an eluent, two bands were also eluted from the column of the Na^+ from. However, they isomerized to each other while being purified. When the elution was carried out with a 0.20 mol dm^{-3} Na_2SO_4+H_4SO_4 acidic solution (pH≈2), a mixture of the isomers was separated into two bands which behaved chromatographically like the I and II isomers. In an earlier paper (Ref. 12), the present author and his associates reported a separation into four layers. It seems clear that this earlier report overlooked this isomerization and so should be amended here.

9) The [Co(dien)$_2$]$^{3+}$ was prepared according to Method C described in Ref. 1 of this paper.

10) A paper to be submitted to *Bull. Chem. Soc. Jpn.*, will describe the preparation and isolation of the isomers in detail. Under these conditions, the [Co(aepn)$_2$]$^{3+}$ showed no separation. The absorption spectroscopic data of the mixture are as follows: 20900 cm^{-1} (log ε=1.95 mol^{-1} dm^3 cm^{-1}), 29000 cm^{-1} (log ε=2.08 mol^{-1} dm^3 cm^{-1}).

(Received February 24, 1984)

The crystal structure of $(-)^{CD}_{474}$ *mer*-[Co{*N*-(2-aminoethyl)-1,3-propanediamine}(diethylenetriamine)]$I_3 \cdot H_2O$ has been determined by means of X-ray diffraction. The crystal is monoclinic, with a space group of $P2_1$, a=9.662 (2), b=14.602(2), c=8.201(3), β=112.87(4)°, and Z=2. The structure was solved by the Patterson-Fourier method and refined by the full-matrix least-squares method, which yielded an R value of 0.060 for the 2441 observed reflections. Each ligand molecule acts as a terdentate with meridional configurations. The absolute configuration of the coordinated asymmetric nitrogen atom in *N*-(2-aminoethyl)-1,3-propanediamine was determined to be *R*. The six-membered chelate ring in *N*-(2-aminoethyl)-1,3-propanediamine adopts a chair conformation, and the conformation of the five-membered chelate ring is δ. The conformations of the two five-membered chelate rings formed by diethylenetriamine are δ and λ, and the N(secondary)-H bond is oriented toward the six-membered chelate ring formed by *N*-(2-aminoethyl)-1,3-propanediamine.

Two linear triamines, *N*-(2-aminoethyl)-1,3-propanediamine ($NH_2CH_2CH_2CH_2NHCH_2CH_2NH_2$: abbreviated as aepn) and diethylenetriamine ($NH_2CH_2CH_2NHCH_2CH_2NH_2$; abbreviated as dien), can act as terdentate ligands and coordinate to the central metal ion in two topological modes. The cobalt(III) complex, $[Co(aepn)(dien)]^{3+}$, which contains three five-membered chelate rings and one six-membered ring, can exist in five geometrical isomers, as is shown in Fig. 1. The two *mer*-isomers differ in the orientation of the N(secondary)–H bond in the dien ligand. Further, the optical isomers arising from the alternative disposition of the N–H bond of the secondary nitrogen atom in aepn (*R*/*S*) can be expected for each of the two *mer*-geometries (Fig. 2).

Three *mer* type complexes, *mer*-$[Co(dien)_2]^{3+}$,[1] *mer*-[Co(dema)(dien)]$^{3+}$ (dema; *N*-menthylbis(2-aminoethyl)-amine),[2] and *mer*-$[Co(dpt)_2]^{3+}$ (dpt; bis(3-aminopropyl)amine),[3] have been prepared. The crystal structure of $(+)_{589}$*mer*-$[Co(dien)_2]Br_3 \cdot 1.6H_2O$ has previously been determined, and the absolute configuration of the complex ion has been identified as *trans*-λ-NH.[4]

Complexes with five-membered chelate rings have been extensively studied, but little is known concerning the complexes involving a six-membered chelate ring. Thus, it is of interest to study the stereochemistry

of $[Co(aepn)(dien)]^{3+}$.

In this paper, the structure and the absolute configuration of $(-)^{CD}_{474}$ *mer*-{*N*-(2-aminoethyl)-1,3-propanediamine}(diethylenetriamine)cobalt(III) iodide monohydrate, $(-)^{CD}_{474}$ *mer*-[Co(aepn)(dien)]$I_3 \cdot H_2O$ are reported.

Experimental

The $[Co(aepn)(dien)]^{3+}$ complex was prepared by the method described in the literature.[5] Of the two fractions obtained by means of SP-Sephadex C-25 ion-exchange chromatography, the faster one was collected and resolved by this chromatography. The $(-)^{CD}_{474}$ isomer was converted into iodide in the anion-exchange region (I^- form, ϕ 1.0 cm×30 cm), and the effluent was evaporated to a few cm^3 under reduced pressure. Crystals were grown from an aqueous solution acidified with acetic acid, and elemental analyses gave:

Found: C, 15.87; H, 4.30; N, 12.54%. Calcd for $Co(C_9H_{28}N_6)I_3 \cdot H_2O$: C, 15.94; H, 4.46; N, 12.39%.

The crystals are orange-red, transparent hexagonal prisms. They are monoclinic. The observed systematic absences on Weissenberg photographs, *0, k, 0* for $k=2n$, indicated that the possible space group was $P2_1$ or $P2_1/m$. Since the crystal was optically active, the space group was uniquely determined to be $P2_1$.

Crystal data:

$(-)^{CD}_{474}$*mer*-[Co(aepn)(dien)]$I_3 \cdot H_2O$, $Co(C_9H_{28}N_6)I_3 \cdot H_2O$ $M_w=678.02$, monoclinic, $a=9.662(3)$, $b=14.602(2)$, $c=8.201(3)$ Å, $\beta=112.87(4)°$, $V=1065.9(4)$ Å^3, $Z=2$, $D_m=2.19$ ($D_c=2.11$) g cm^{-3}, μ for Mo $K\alpha$ ($\lambda=0.7107$ Å) $=51.10$ cm^{-1}, space group $P2_1$.

A crystal with dimensions of *ca.* 0.4×0.2×0.15 mm^3 was used for the intensity measurements. The intensities were collected on a PHILIPS 1100 four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation up to $2\theta=70°$, the θ-2θ scan technique being employed. Independent 2441 reflections with $|F_o|<3\sigma(|F_o|)$ were used for the structure determination. The usual corrections were made for the Lorentz, polarization, and absorption factors, but no correction was applied for extinction. The structure was solved by the Patterson-Fourier method with a local version of UNICS.[6] The calculations were carried out on a FACOM M-160F computer at the Institute for Solid State Physics (The University of Tokyo) and on a HITAC 200H computer at the Computer Center of the University of Tokyo.

Determination and Refinement of the Structure

The positions of the I and Co atoms were deduced from three-dimensional Patterson maps, while the positions of all the non-hydrogen atoms were derived by the Fourier method. They were refined by the block-diagonal least-squares method with anisotropic thermal parameters. At the stage of $R=0.074$, eight hydrogen atoms among the twenty-eight hydrogen atoms (except for those of the water molecule) were found from a different synthesis. The positions of the remaining twenty hydrogen atoms were located theoretically. The final refinement was carried out using the full-matrix least-squares program LINUS[7] with anisotropic thermal parameters for non-hydrogen atoms and isotropic ones for hydrogen atoms. The final R and R_2 values were 0.060 and 0.073 respectively.[8]

The absolute structure was determined by the anomalous-scattering technique. Some $h\ k\ l$ and $h\ \bar{k}\ l$ pairs were examined on Weissenberg photographs recorded using Cu $K\alpha$ radiation. As is shown in Table 1, a comparison of the observed and calculated differences between $|F(hkl)|$ and $|F(h\bar{k}l)|$ indicates that the calculated values differ by more than 10%. The concordance in Table 1 indicates that the $(-)^{CD}_{474}$-isomer has the absolute configuration illustrated in Fig. 4. The enantiomeric structure was refined in the same way and converged at residuals $R=0.061$ and $R_2=0.074$. The application of the R-factor ratio test[9] showed that the latter can be rejected at the 0.05 significance level in favor of the former.

The final atomic parameters and thermal factors of non-hydrogen atoms and hydrogen atoms are given in Tables 2 and 3 respectively.[10]

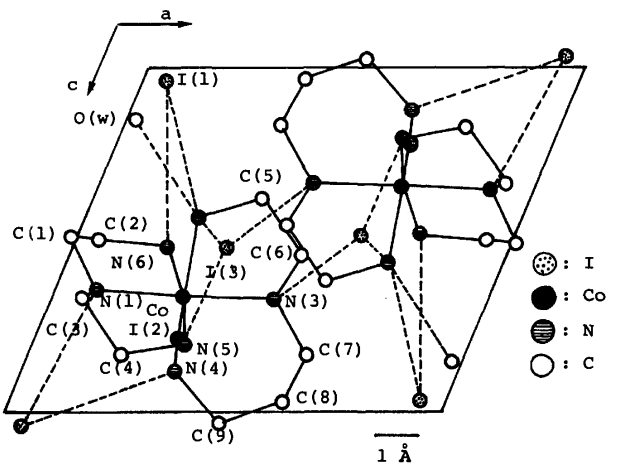

Fig. 3. A projection of the crystal structure along *b*.

cation, $(-)^{CD}_{474}$ *mer*-[Co(aepn)(dien)]$^{3+}$ corresponds to the *mer*-I type (Fig. 2 (a)). The absolute configuration of the asymmetric nitrogen atom (N(3)) was determined to be *R*.[11] The structure shown in Fig. 4 was assigned to *trans*-δ-NH(*R*) (Fig. 2 (a)).[12] The conformations of the two fused five-membered chelate rings in dien were δ and λ, in agreement with the observation for $(+)_{589}$ *mer*-[Co(dien)$_2$]Br$_3\cdot$1.6H$_2$O.[4] The conformation of the six-membered chelate ring formed by aepn was chair (Fig. 5), and the conformation of its five-membered chelate ring was δ.

The bond distances and angles in the complex ion are listed in Table 4, together their estimated standard deviations.

The Co-N(secondary) bond distance in dien (Co-N(1)) is significantly shorter than the Co-N(terminal) bond distances (Co-N(5), Co-N(6)). Such a trend was also observed for $(+)_{589}$ *mer*-[Co(dien)$_2$]Br$_3\cdot$1.6H$_2$O[4] and $(-)_{589}$*unsym-fac*-[Co(dien)$_2$][Co(CN)$_6$]$\cdot$2H$_2$O.[13] In contrast to this, the three Co-N distances (Co-N(2), Co-N(3), and Co-N(4)) in aepn are within 1.0σ of each other.

The N(terminal)-Co-N(terminal) angles in the five-membered chelate rings (N(1)-Co-N(6), N(1)-Co-N(5), and N(2)-Co-N(3)) are smaller than 90°, in agreement with the result obtained for similar complexes containing five-membered chelate rings.[14]

N (4) - Co - N (6)	88.8 (5)	N (1) - C (3) - C (4)	104.1 (11)
N (5) - Co - N (6)	169.4 (5)	N (2) - C (5) - C (6)	107.6 (13)
		N (3) - C (6) - C (5)	107.1 (11)
Co - N (1) - C (1)	111.7 (10)	N (3) - C (7) - C (8)	112.2 (14)
Co - N (1) - C (3)	109.4 (9)	N (4) - C (9) - C (8)	112.1 (14)
Co - N (2) - C (5)	108.6 (9)	N (5) - C (4) - C (3)	106.5 (14)
Co - N (3) - C (6)	107.7 (8)	N (6) - C (2) - C (1)	105.2 (11)
Co - N (3) - C (7)	120.3 (10)		
Co - N (4) - C (9)	119.8 (9)	C (7) - C (8) - C (9)	112.0 (15)
Co - N (5) - C (4)	111.3 (10)		
Co - N (6) - C (2)	110.8 (10)		

In the six-membered ring, this angle (N(3)-Co-N(4)) is slightly greater than 90°. The Co-N-C angles (Co-N(3)-C(7), Co-N(4)-C(9)) are larger by 10% than the other bond angles in the chelate ring. The six-membered chelate ring is thus flattened like those in $[Co(tn)_3]^{3+}$.[15]

The N(terminal)-Co-N(terminal) angles in both ligands (N(5)-Co-N(6), N(2)-Co-N(4)) are obviously smaller than 180°, whereas the N(secondary)-Co-N(secondary) angle (N(1)-Co-N(3)) is nearly 180°. The three ligating nitrogen atoms of each ligand and the cobalt atom are nearly co-planar, and the two coordination planes are perpendicular. These observations suggest that the presence of the six-membered chelate ring does not introduce much distortion into the octahedral geometry of the complex cation and that any such distortion is relieved by the flexibility of the six-membered ring.

The relevant interatomic distances of less than 3.9 Å between complexes, along with the estimated standard deviations, are listed in Table 5. The bond length of I(1)-N(4) (3.55(2) Å) is clearly shorter than the sum of the ionic radii. This might lead to the hydrogen bond formation of N-H···I.

Appendix

Remarks on Chirality Specification. The four isomers of *mer*-[Co(aepn)(dien)]$^{3+}$ shown in Fig. 2 can be specified easily by means of common chirality descriptors. Without any consideration of the conformations of the chelate rings, the chirality of these isomers can be said to arise from the dissymmetric disposition of the two coordinated NH groups and from the dissymmetry around the secondary nitrogen atom of aepn. If we employ the same descriptor as was used for *mer*-[Co(dien)$_2$]$^{3+}$,[4] they can be denoted by:

(a) *trans*-δ-NH(R), (b) *trans*-λ-NH(S), (c) *trans*-λ-NH(R), (d) *trans*-δ-NH(S),

where δ or λ refers to the non-oriented N-N and H-H lines defined by the two N-H groups under consideration and where R or S represents the absolute configuration of the asymmetric nitrogen atom of aepn. Recently, Damhus and Schäffer proposed a new reference system consisting of oriented lines.[16] When this new system is employed, the four isomers can be represented as follows:

(a) $\vec{\Lambda}(R)$, (b) $\vec{\Delta}(S)$, (c) $\vec{\Delta}(R)$, (d) $\vec{\Lambda}(S)$.

Formation of an *N,N*-Bidentate Chelate, Bis[4-(4-methyl-2-pyridylazo)resorcinol]nickel(II) Perchlorate, in Dioxane

Yoshihiro KUDO, Noboru YOSHIDA, Taira IMAMURA, and Masatoshi FUJIMOTO*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received February 29, 1984)

The formation of a new *N,N*-bidentate complex of nickel(II) perchlorate with an *N,N,O*-terdentate ligand, 4-(4-methyl-2-pyridylazo)resorcinol (4-MePAR), was first detected in dioxane spectrophotometrically. The stability of the *N,N*-bidentate species in dioxane is strongly affected by the presence of a proton acceptor such as water, ethanol, imidazole, and Cl^-, which promote the coordination of the *ortho* phenolic oxygen in the ligand to form the *N,N,O*-terdentate complex. The new complex was isolated from dioxane solution and identified to be an *N,N*-bidentate complex salt, $[Ni(4\text{-mepar})_2](ClO_4)_2$, having two counter ions, ClO_4^-. A distorted-planar configuration of the complex was suggested on the basis of IR, X-ray photoelectron spectroscopic, and magnetic measurements.

o-(Pyridylazo)phenol compounds coordinate to metal ions to form *N,N,O*-terdentate complexes in aqueous media.[1,2] Kinetic studies on the reactions of 4-(2-pyridylazo)resorcinol (PAR)[3] and 1-(2-pyridylazo)-2-naphthol (β-PAN)[4] with nickel(II) ion in aqueous solution suggested the following reaction mechanism involving the formation of an *N,N*-bidentate complex (II) as an intermediate. However, the intermediate complex II presumed in the scheme 1 has not been detected so far.[5]

In the present study, the formation of the *N,N*-bidentate complex II of nickel(II) perchlorate with 4-(4-methyl-2-pyridylazo)resorcinol (4-MePAR) was first detected spectrophotometrically in an aprotic solvent, 1,4-dioxane. The stability of the *N,N*-bidentate complex strongly depends on the solvent basicity and/or the presence of a proton acceptor.

The intermediate bidentate complex II was first isolated as a perchlorate from dioxane solution and identified.

PAR: R=H; 4-MePAR: R=Me

Experimental

Materials. Deionized water was distilled. Reagent grade materials were used unless otherwise specified.

Nickel(II) perchlorate monohydrate was obtained by heating recrystallized hexahydrate at 90±5 °C for 5 h *in vacuo* and kept in a desiccator over P_2O_5. The nickel(II) content in the monohydrate was determined titrimetrically with EDTA. The concentrations of the solutions were calculated from the weighed amount.

The ligands, 4-MePAR,[6] 4-(2-pyridylazo)phenol (*p*-PAP),[7] and 5-dimethylamino-2-(2-pyridylazo)phenol (DAPAP),[8] were synthesized as described in the literature. The concentrations of the solutions were calculated from the weighed amount.

In order to remove peroxides, dioxane (Wako) was passed through a column of basic alumina, dried with sodium metal, and distilled under argon immediately before use.

Syntheses of the Nickel(II) Complexes. *1)* N,N,O-*Terdentate Complex*: $[Ni(LH^*)_2]^0$. The complex was prepared by mixing an aqueous solution of nickel(II) chloride (3.1 mmol) with that of 4-MePAR (3.9 mmol). The red-dish brown complex was identified to be $Ni(C_{12}H_{10}N_3O_2)_2$ by elemental analysis.

2) N,N-*Bidentate Complex*: $[Ni(LHH^*)_2](ClO_4)_2$. 4-MePAR (200 mg, 0.87 mmol) was dissolved in dioxane (*ca.* 200 cm^3) under argon atmosphere. To the solution $Ni(ClO_4)_2 \cdot H_2O$ (100 mg, 0.36 mmol) suspended in dioxane (*ca.* 100 cm^3) was slowly added. The mixture was stirred for several hours and allowed to stand overnight in the dark under argon atmosphere. The yellowish red precipitate was filtered, washed with dioxane, and dried for 2 d *in vacuo* over P_2O_5. Yield *ca.* 40%. Found: C, 40.01; H, 3.19; N, 11.49; Cl, 8.83%.[9] Calcd for $Ni(C_{12}H_{11}N_3O_2)_2(ClO_4)_2$: C, 40.26; H, 3.10; N, 11.74; Cl, 9.90%.

3) Other Nickel(II) Complexes. The 1:2 complex of nickel(II) with *p*-PAP, $[Ni(pap)_2]^0 \cdot H_2O$, was synthesized as reported in the literature.[7] The *N,N*-bidentate nickel(II) complex of DAPAP was prepared and purified by the same method as that for the synthesis of $[Ni(LHH^*)_2](ClO_4)_2$. The isolated complex was identified to be $Ni(C_{13}H_{14}N_4O)_2(ClO_4)_2 \cdot 2H_2O$ by elemental analysis.

Measurements. Since most of the reagents used in the study were moisture-sensitive, all measurements were performed under dry argon atmosphere. All sample solutions were prepared in a glove bag filled with dry argon.

Visible absorption spectra were measured at 25.0±0.3 °C with a Hitachi EPS-3T recording spectrophotometer.

The IR spectra were measured with a JASCO IR-G infrared spectrophotometer in the region 4000—400 cm^{-1} with use of

† The ligand is abbreviated as LHH*, where H and H* denote the protons of the *ortho* and the *para* hydroxyl group, respectively.

the KBr pellet technique. The KBr disk was carefully prepared under dry argon atmosphere. The influence of the moisture during the measurements was negligibly small.

X-Ray photoelectron spectra were obtained for powdered samples using an electron spectrometer Model VG ESCA 3. Mg *Kα* (1253.6 eV) X-ray radiation was used as the excitation source. The measurements were conducted at room temperature under a vacuum of *ca.* 10^{-6} Pa.

The magnetic susceptibilities of the nickel(II)-4-MePAR complexes were measured at room temperature using Gouy method. Diamagnetic corrections for the ligands were calculated from Pascal's constants; -32.0×10^{-6} c.g.s emu mol^{-1} was used as the correction for perchlorate ion.[10]

The ^1H NMR data for the dioxane solution of the new complex were not obtained owing to very low solubility.

The pH* of the aqueous dioxane solution was measured at 25 °C with a Hitachi-Horiba pH-meter Model F-7ss. The values of pC_H (=$-\log C_H$) were calculated by the following relationship between pH-meter readings (pH*) and the values of $\log U_H$: $pC_H=pH^*+\log U_H$.[11]

Results and Discussion

Spectral Changes in the Complex Formations of Nickel(II) Perchlorate with 4-MePAR. Figure 1(a) shows the spectral changes in the complex formation of nickel(II) perchlorate with 4-MePAR in 10%(v/v) dioxane–water at pH* 4.2. Upon addition of nickel(II) perchlorate to the solution of 4-MePAR, the absorption around 380 nm due to 4-MePAR decreased with the increase of a new absorption at 511 nm; a well-defined isosbestic point was observed at 465 nm, which indicates the presence of a simple equilibrium. Molar ratio method indicates the formation of a 1:2 nickel(II) complex. The feature of the final spectrum of the complex (Curve 5) is essentially the same as the absorption spectrum of the *N,N,O*-terdentate 1:2 complex of PAR in 10%(v/v) dioxane–water,[12] namely, the final spectrum is ascribed to the *N,N,O*-terdentate complex, $[Ni(LH^*)_2]^0$.

In neat dioxane, different spectral changes were observed. Figure 1(b) shows the spectral changes observed upon addition of nickel(II) perchlorate to the dioxane solution of 4-MePAR. The absorption around 380 nm due to the free ligand decreased with the increase of new absorption around 420 and 480 nm with a single isosbestic point at 399 nm (Curves 1→3) in the region of the low concentrations of nickel(II) perchlorate ($[Ni(II)]_t/[4\text{-MePAR}]_t\leqq0.3$). With further increase in the concentration of nickel(II) perchlorate, a new absorption peak appeared (λ_{max}=430 and 470 nm (sh)) with another set of isosbestic points at 400 and 471 nm (Curves 4→6). These spectral changes suggest the existence of two successive equilibria.

Molar ratio method indicated the formation of a 1:3 and a 1:2 nickel(II) complex in the first and the second step of the reaction, respectively.[13] The final spectrum of the 1:2 nickel(II) complex (Curve 6) clearly differs from the spectrum characteristic of the *N,N,O*-terdentate 1:2 complex (Curve 5 in Fig. 1(a)).

Electronic Spectra of the Isolated Nickel(II) Complexes in Dioxane. Figure 2 shows the electronic spectra in dioxane of the free ligand 4-MePAR, the isolated new yellowish red complex, $[Ni(C_{12}H_{11}N_3O_2)_2](ClO_4)_2$, and the terdentate complex, $[Ni(LH^*)_2]^0$.

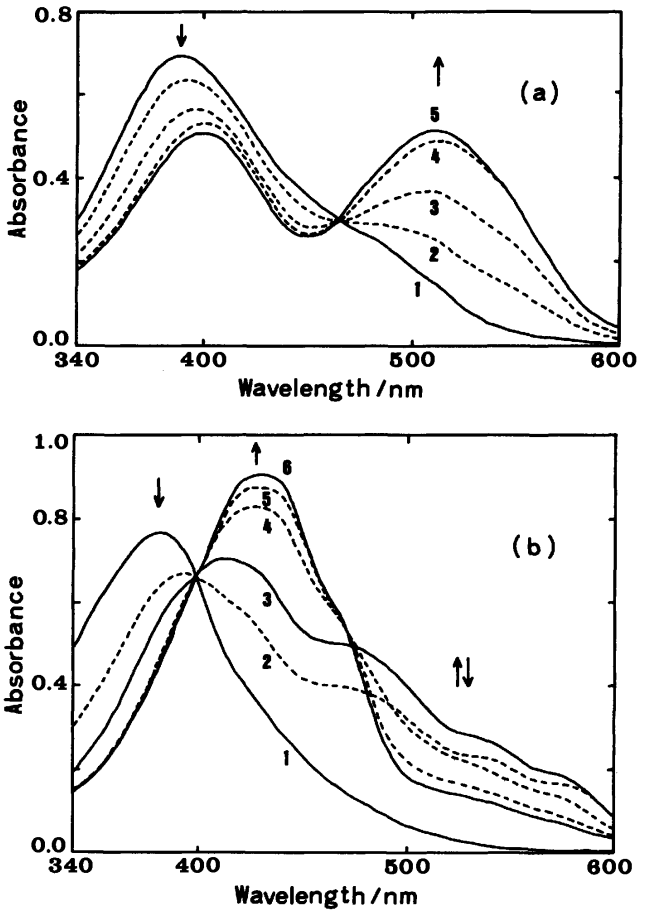

Fig. 1. (a) Spectral change upon addition of nickel(II) perchlorate to the 10% (v/v) dioxane–water solution of 4-MePAR at pH*=4.2, I=0.1 mol dm^{-3} ($NaClO_4$), and 25 °C.
$[4\text{-MePAR}]_t=3.67\times10^{-5}$ mol dm^{-3} ([ ]$_t$ denotes the total concentration). $[Ni(II)]_t$=0.00 (1), 0.48 (2), 0.95 (3), 3.17 (4), and 15.8×10^{-5} mol dm^{-3} (5).
(b) Spectral change upon addition of nickel(II) perchlorate to the dioxane solution of 4-MePAR at 25 °C.
$[4\text{-MePAR}]_t=3.65\times10^{-5}$ mol dm^{-3}. $[Ni(II)]_t$=0.00 (1), 0.41 (2), 1.03 (3), 1.64 (4), 1.97 (5), and 19.7×10^{-5} mol dm^{-3} (6).

The absorption spectrum of the free ligand has a single peak at 381 nm ($\varepsilon_{max}=2.10\times10^4$ mol^{-1} dm^3 cm^{-1}) (Curve 1). The spectra of the complexes show the large bathochromic shifts compared with the spectrum of the free ligand. The spectrum of the new complex with a single peak at 426 nm ($\varepsilon_{max}=3.90\times10^4$ mol^{-1} dm^3 cm^{-1}) and a shoulder around 470 nm ($\varepsilon_{sh}=3\times10^4$ mol^{-1} dm^3 cm^{-1}) (Curve 2) essentially coincides with that of the dioxane solution prepared by mixing a large excess of nickel(II) perchlorate with 4-MePAR (Curve 6 in Fig. 1(b)). The spectrum of the bis-terdentate complex, $[Ni(LH^*)_2]^0$, has two absorption bands at 400 ($\varepsilon_{max}=3.2\times10^4$) and 542 nm ($\varepsilon_{max}=3.2\times10^4$ mol^{-1} dm^3 cm^{-1}) in dioxane (Curve 3).

The feature of the absorption spectrum with two bands is characteristic of the coordination of the *ortho* phenolic oxygen in the ligand. The spectrum of the new complex is quite different from that of the *N,N,O*-

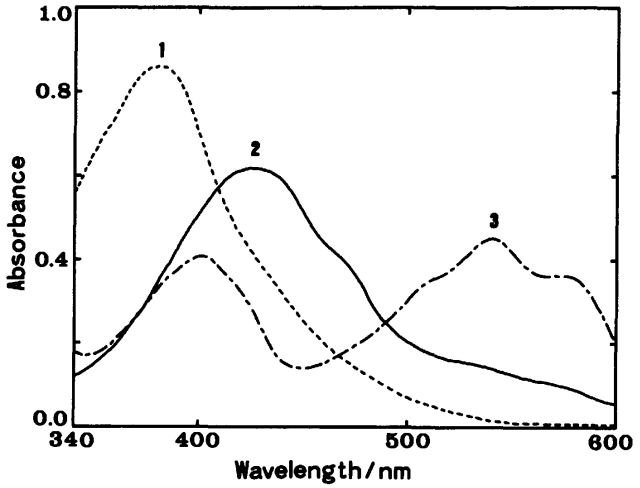

Fig. 2. Electronic spectra of the free ligand 4-MePAR and its nickel(II) complexes at 25 °C in neat dioxane. (1) 4-MePAR: $[LHH^*]_t = 4.09 \times 10^{-5}$ mol dm^{-3}; (2) the new complex: $[Ni(C_{12}H_{11}N_3O_2)_2(ClO_4)_2]_t = 1.57 \times 10^{-5}$ mol dm^{-3}; (3) the *N,N,O*-terdentate complex: $[Ni(LH^*)^0_2]_t = 1.3 \times 10^{-5}$ mol dm^{-3}.

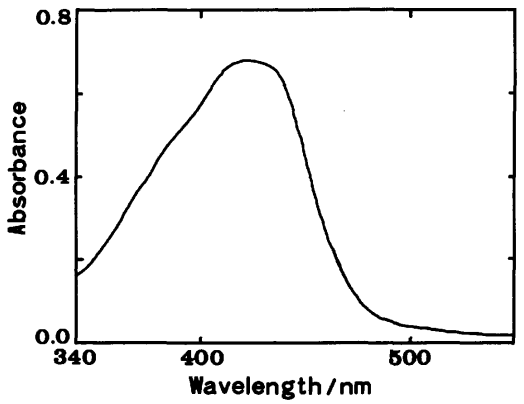

Fig. 3. Electronic spectrum of the *N,N*-bidentate chelate between nickel(II) perchlorate and *p*-PAP at 25 °C in dioxane.
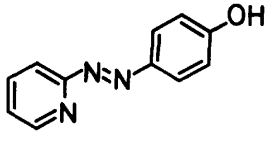
$[Ni(II)]_t = 5.25 \times 10^{-5}$ mol dm^{-3}, $[p\text{-PAP}]_t = 3.63 \times 10^{-5}$ mol dm^{-3}.

terdentate complex, $[Ni(LH^*)_2]^0$. Furthermore, the spectrum of the new complex is similar to that of the *N,N*-bidentate 1:2 nickel(II) complex of *p*-PAP with no coordinating *o*-hydroxyl group (Fig. 3).



p-PAP

These observations indicate that the new complex has an *N,N*-bidentate structure with uncoordinated *ortho* phenolic oxygen. This conclusion is also supported by the elemental analysis; the isolated new complex is $[Ni(LHH^*)_2](ClO_4)_2$ having two perchlorate ions as counter ions.

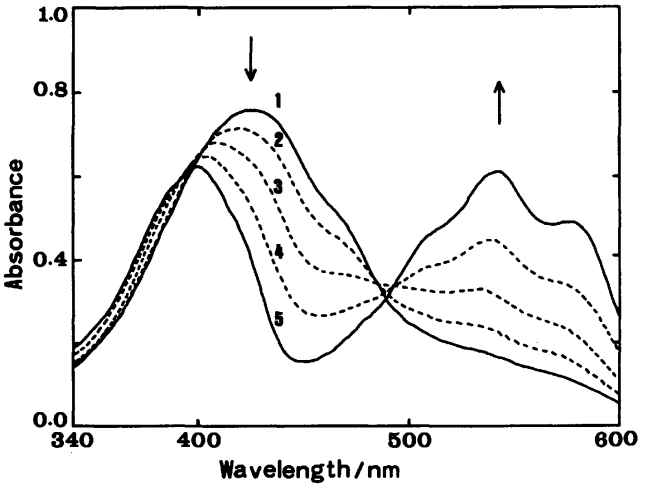


Fig. 4. Spectral change observed on addition of imidazole to the 1.52×10^{-5} mol dm^{-3} dioxane solution of the new complex at 25 °C.
$[Imidazole]_t = 0.00$ (1), 0.60 (2), 1.19 (3), 2.09 (4), and 7.46×10^{-5} mol dm^{-3}.

Reactions of Brønsted Bases with the New Bidentate Complex. The formation of the *N,N*-bidentate complex in dioxane was seriously influenced by the presence of a Brønsted base as a proton acceptor which would promote the release of the *ortho* phenolic proton and the subsequent formation of the *N,N,O*-terdentate complex.

Upon addition of a nitrogen base, imidazole, to the dioxane solution of the new complex, the yellow solution turned pink. Figure 4 shows the spectral change upon addition of imidazole to the solution of the new complex; two-step reactions were demonstrated by two sets of isosbestic points at 403 and 485, and 392 and 493 nm. The final spectrum essentially coincides with the spectrum of the dioxane solution of the *N,N,O*-terdentate complex, $[Ni(LH^*)_2]^0$, isolated from aqueous solution. This indicates that the observed spectral change results from the coordination of the *ortho* phenolic oxygen of the ligand; imidazole acts as a proton acceptor and not as a ligand.

The stoichiometry of the two-step reaction between the bidentate complex and imidazole, B, was found to be 1:1 for the first step and 1:2 for the overall reaction by molar ratio method. The feature of the spectral change is explained by the following reaction scheme,

$$[Ni(LHH^*)_2]^{2+} \xrightarrow[HB^+]{B} [Ni(LHH^*)(LH^*)]^+ \xrightarrow[HB^+]{B} [Ni(LH^*)_2]^0. \quad (2)$$

yellow orange pink

The same spectral change was observed upon addition of water or ethanol to the dioxane solution of the new complex. The addition of tetrabutylammonium chloride to the dioxane solution of the new complex also gave the similar spectral change. This result suggests a role as a proton acceptor of chloride ion.[14]

Liberation of ortho *Protons from the New Bidentate Complex in Aqueous Media.* In the solution pre-

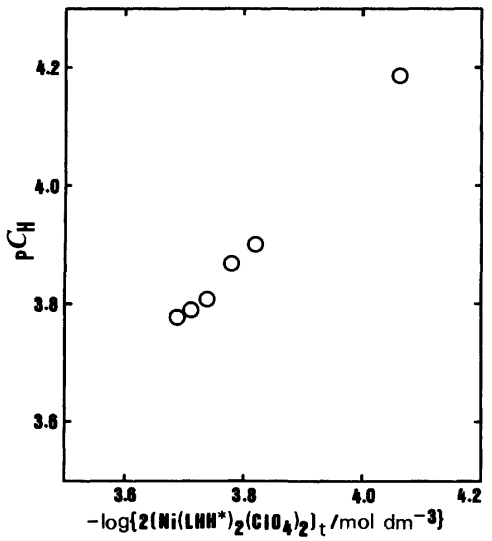

Fig. 5. Plot of pC_H *vs.* $-\log\{2[Ni(LHH^*)_2(ClO_4)_2]_t\}$ in 10%(v/v) dioxane-water at 25 °C.

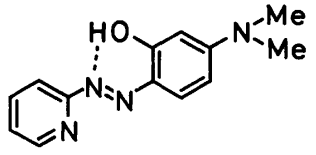
pared by dissolving the new complex in 10%(v/v) dioxane-water the characteristic absorption peak at 426 nm of the new complex was not observed, instead, the two absorption bands around 400 and 511 nm were observed, which were ascribed to the *N,N,O*-terdentate complex, $[Ni(LH^*)_2]^0$. The pH* values of the solutions were lowered in accordance with the amount of the dissolved new complex. The plot of the values of pC_H against $-\log\{2[Ni(LHH^*)_2(ClO_4)_2]_t\}$ demonstrates the liberation of two protons from the new complex (Fig. 5). The liberation of protons should be owed to the *ortho* protons of the *N,N*-bidentate complex: $[Ni(LHH^*)_2]^{2+}+2H_2O\rightarrow[Ni(LH^*)_2]^0+2H_3O^+$, since the *para* protons of the terdentate complex, $[Ni(LH^*)_2]^0$, could not be dissociated under the experimental conditions.[15] In addition, the spectral and pH measurements in the similar experiments with the nickel(II) complex, isolated from dioxane, of DAPAP having no *p*-hydroxyl group gave the same results as those for the new bidentate complex, $[Ni(LHH^*)_2](ClO_4)_2$.



DAPAP

From these results, we concluded that the new yellowish red complex is the *N,N*-bidentate intermediate complex II proposed in the Scheme 1.

Possible Configuration of the Isolated New Complex. The IR spectrum of the new complex perchlorate, $[Ni(LHH^*)_2](ClO_4)_2$, shows a single strong broad band at 1060—1150 cm^{-1}, which corresponds to the $\nu_{Cl\text{-}O}$ of the free perchlorate ion, ClO_4^-. This indicates that the perchlorate anions do not coordinate to the central nickel(II) atom.[16]

The binding energy of Ni(II)($2p_{3/2}$) bonded to the same ligands under different geometries increases in general in the order of a square-planar (*ca.* 853—854 eV), a tetrahedral (*ca.* 853—854 eV), and an octahedral configuration (*ca.* 855 eV).[17]

Table 1. Core electron binding energies and magnetic moments of the free ligands and their nickel(II) complexes

Species	Binding energy[a]/eV			μ_{eff}[b]/BM
	N(1s)	O(1s)	Ni($2p_{3/2}$)	
LHH*	395[c]	528		
	398.3[c]	531.3		
$[Ni(LHH^*)_2](ClO_4)_2$	400.0[c]	—[d]	853	3.04
$[Ni(LH^*)_2]^0$	400.3[c]	528	856	3.08
		532.1		
p-PAP	399.2[c]	531.2

		520.4		
$[NiCl_2(phen)_2]^0\cdot 4H_2O$[e]	398.3		854.1	
Bpy[f]	398.6			
$[NiCl_2(bpy)_2]^0$[e]	399.1		854.9	

a) All raw binding energies were corrected to hydrocarbon C(1s) value of 285.0 eV.[20] b) Measured at 290 K. c) Ref. 19. d) Unable to measure due to the strong O(1s) signal of the perchlorate ion. e) Ref. 17. f) Ref. 18.

The X-ray photoelectron spectral data of the free ligands and their nickel(II) complexes are summarized in Table 1 together with the data of magnetic moments. The increase in the binding energy of N(1s) of the ligand on the formation of the complexes, $[Ni(LH^*)_2]^0$,[19] $[Ni(pap)_2]^0\cdot H_2O$,[19] and $[NiCl_2(bpy)_2]^0$,[17] is due to the coordination of the nitrogen atoms to the nickel(II) atom.[20] A positive chemical shift in the N(1s) binding energy observed in the new complex suggests the coordination of the nitrogen atoms to nickel(II) in the complex, $[Ni(LHH^*)_2](ClO_4)_2$. The Ni(II)($2p_{3/2}$) binding energy of the new complex formulated as $[Ni(LHH^*)_2](ClO_4)_2$ is in good agreement with that of a four-coordinated complex, $[Ni(pap)_2]^0\cdot H_2O$, and is obviously lower than that of the typical octahedral complexes, $[Ni(LH^*)_2]^0$, $[NiCl_2(phen)_2]^0\cdot 4H_2O$,[17] and $[NiCl_2(bpy)_2]^0$.[17]

These X-ray photoelectron spectral data strongly suggest the four-coordinated *N,N*-bidentate structure for the complex, $[Ni(LHH^*)_2](ClO_4)_2$.

The magnetic moments, μ_{eff}, of four-coordinated nickel(II) complexes in general depend on its spin-state and ligand field symmetry.[21] The magnetic moment of $[Ni(LHH^*)_2](ClO_4)_2$ was found to be 3.04 BM at 290 K. This value suggests that the new complex, $[Ni(LHH^*)_2](ClO_4)_2$, has a distorted-planar structure.

The authors thank Professor Isamu Toyoshima and Dr. Katsumi Tanaka at the Research Institute for Catalysis for help in the measurements of X-ray photoelectron spectra. They also thank Professor Yoshio Matsunaga for the kindness in the measurements of magnetic susceptibilities.

13) The formation of a 1:3 nickel(II) complex of 4-MePAR will not be discussed here in detail.

14) The formation of the new complex was not observed also in the reactions of nickel(II) chloride, acetate, and nitrate with 4-MePAR in neat dioxane. These results indicate the role of the counter-ion, Cl^-, CH_3COO^-, and NO_3^-, as a proton acceptor in dioxane. However, perchlorate ion, ClO_4^-, does not act as a proton acceptor in dioxane.

15) The pK_{a1} and pK_{a2} values in 10%(v/v) dioxane-water for the dissociation of the two *p*-hydroxyl protons in the bis-terdentate complex, $[Ni(LH^*)_2]^0 \overset{pK_{a1}}{\rightleftharpoons} [Ni(LH^*)L]^- + H^+ \overset{pK_{a2}}{\rightleftharpoons} [NiL_2]^{2-} + 2H^+$, were determined by pH titration to be 5.82 and 7.09, respectively. Preparation and Stereochemistry of Bis(ethylenediamine)-cobalt(III) Complexes with Selenium Donor Atom

Takumi KONNO,* Ken-ichi OKAMOTO, and Jinsai HIDAKA
Department of Chemistry, University of Tsukuba, Sakura, Ibaraki 305
(Received March 29, 1984)

Five optically active cobalt(III) complexes of [Co(bidentate-*N,Se*)(en)$_2$] type were prepared; here bidentate-*N,Se* denotes 2-aminoethaneselenolato (aes), 2-aminoethaneselenenato (aesee), 2-(methylseleno)ethylamine (mseea), 2-(ethylseleno)ethylamine (eseea), and 2-(benzylseleno)ethylamine (bseea). These complexes were characterized from their absorption, CD and ^{1}H NMR spectra. Of these complexes, the crystal structure of $(+)^{CD}_{500}$-[Co(mseea)(en)$_2$](ClO$_4$)$_3$ was determined by the X-ray diffraction method. The red plate crystal was orthorhombic, space group $P2_12_12_1$, a=12.220(15), b=19.224(7), c=8.977(11) Å, Z=4, and the final R value was 0.087. The coordinated selenium atom takes the (*R*) configuration for the *Λ* isomer. The absorption and CD spectra of the five complexes are discussed in comparison with those of the corresponding cobalt(III) complexes containing a coordinated sulfur atom.

A few cobalt(III) complexes with selenium-containing ligand have been investigated,[1-4] but little information concerning their spectrochemical and stereochemical properties has been reported up to now. It is favorable to compare the properties of cobalt(III) complexes containing a selenium donor atom with those of the corresponding complexes containing a sulfur donor atom, which have been extensively studied.[5-13]

This work is concerned with the preparation and stereochemistry of cobalt(III) complexes with a coordinated selenium atom. The cobalt(III) complex with 2-aminoethaneselenolato ($NH_2CH_2CH_2Se^-$), $[Co(aes)(en)_2]^{2+}$, was optically resolved, and the optically active cobalt(III) complexes with 2-aminoethaneselenenato ($NH_2CH_2CH_2SeO^-$), $(+)^{CD}_{500}\cdot(-)^{CD}_{360}$-[Co(aesee)(en)$_2$]$^{2+}$, 2-(methylseleno)ethylamine ($NH_2CH_2CH_2SeCH_3$), $(+)^{CD}_{500}$-[Co(mseea)(en)$_2$]$^{3+}$, 2-(ethylseleno) ethylamine ($NH_2CH_2CH_2SeC_2H_5$), $(+)^{CD}_{500}$-[Co(eseea)(en)$_2$]$^{3+}$, and 2-(benzylseleno)ethylamine ($NH_2CH_2CH_2SeCH_2C_6H_5$), $(+)^{CD}_{500}$-[Co(bseea)(en)$_2$]$^{3+}$, were derived from $(+)^{CD}_{500}$-[Co(aes)(en)$_2$]$^{2+}$.[14] The crystal structure of the selenoether complex, $(+)^{CD}_{500}$-[Co(mseea)(en)$_2$]$^{3+}$, was determined by X-ray diffraction and was compared to that of the corresponding thioether complex, [Co(mea)(en)$_2$]$^{3+}$ (mea=2-(methylthio)ethylamine).[9] This is the first example of the structural analysis of the cobalt(III) complex with a selenoether donor atom. The absorption and CD spectra of the present complexes are discussed in comparison with those of the corresponding [Co(bidentate-*N,S*)(en)$_2$] type complexes.[9-13]

Experimental

1) Preparation and Resolution of the Complexes. a) $(+)^{CD}_{500}$-(2-Aminoethaneselenolato)bis(ethylenediamine)cobalt(III) Perchlorate. $(+)^{CD}_{500}$-[Co(aes)(en)$_2$](ClO$_4$)$_2$: [Co(aes)(en)$_2$](NO$_3$)$_2$ was prepared by the method of Deutsch *et al.*[1] A solution containing 2.0 g of $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$ in 20 cm^3 of water was added with stirring to a solution containing 2.4 g of [Co(aes)(en)$_2$](NO$_3$)$_2$ in 80 cm^3 of water at 50 °C. The solution was stirred for 5 min, though fine dark brown crystals soon began to appear. The crystals were collected by filtration and it was found from a CD measurement that the crystals were the $(+)^{CD}_{500}$ diastereomer with a small amount of the $(-)^{CD}_{500}$ type. After the $(-)^{CD}_{500}$ diastereomer contamination was removed by grinding in a mortar several times with 10 cm^3 of an aqueous solution of NaClO$_4$ (1.5 mol dm^{-3}), the remaining $(+)^{CD}_{500}$ diastereomer was dissolved in an aqueous solution of NaClO$_4$. The solution was concentrated with a rotary evaporator until fine needle crystals of the selenolato complex appeared. After cooling in a refrigerator, crystals of $(+)^{CD}_{500}$-[Co(aes)(en)$_2$](ClO$_4$)$_2$ were collected by filtration, and washed with ethanol and ether. Found: C, 14.81; H, 4.32; N, 13.96%. Calcd for $(+)^{CD}_{500}$-[Co(aes)(en)$_2$](ClO$_4$)$_2$=$C_6H_{22}N_5O_8Cl_2SeCo$: C, 14.38; H, 4.42; N, 13.97%.

b) $(+)^{CD}_{500}\cdot(-)^{CD}_{360}$-(2-Aminoethaneselenenato)bis(ethylenediamine)cobalt(III) Perchlorate. $(+)^{CD}_{500}\cdot(-)^{CD}_{360}$-[Co(aesee)(en)$_2$](ClO$_4$)$_2$: A calculated amount of 0.31 cm^3 of 1% aqueous H_2O_2 was added dropwise to a solution containing 0.05 g of $(+)^{CD}_{500}$-[Co(aes)(en)$_2$](ClO$_4$)$_2$ in 1 cm^3 of water and the solution was stirred for 15 min. An orange-yellow precipitate was obtained from the reaction solution after the addition of 2-propanol. This complex was recrystallized from a small amount of water by adding ethanol. The selenenato complex obtained showed the identical absorption and CD spectra with those of the reaction solution, indicating that the $(+)^{CD}_{500}\cdot(-)^{CD}_{360}$ isomer was selectively formed. Found: C, 13.96; H, 4.04; N, 13.35%. Calcd for $(+)^{CD}_{500}\cdot(-)^{CD}_{360}$-[Co(aesee)(en)$_2$](ClO$_4$)$_2$=$C_6H_{22}N_5O_9Cl_2SeCo$: C, 13.93; H, 4.28; N, 13.54%.

c) $(+)^{CD}_{500}$-(2-(Methylseleno)ethylamine)bis(ethylenediamine)cobalt(III) Perchlorate. $(+)^{CD}_{500}$-[Co(mseea)(en)$_2$]ClO$_4$)$_3$: To a solution containing 0.05 g of $(+)^{CD}_{500}$-[Co(aes)(en)$_2$](ClO$_4$)$_2$ in 1 cm^3 of water was added 1 cm^3 of dimethyl sulfate. The mixture was allowed to stand in a refrigerator overnight and separated into two layers. The orange-red upper layer was poured onto a column of QAE-Sephadex A-25 (ClO$_4^-$ form, 2 cm×20 cm), and the column was eluted with water. The eluate was concentrated with a rotary evaporator until red crystals appeared. The resultant red complex was recrystallized from a small amount of water and obtained as fairly large plate crystals. A piece of a crystal was used in the X-ray diffraction study. Found: C, 13.89; H, 3.94; N, 11.39%. Calcd for $(+)^{CD}_{500}$-[Co(mseea)(en)$_2$](ClO$_4$)$_3$=$C_7H_{25}N_5O_{12}Cl_3SeCo$: C, 13.65; H, 4.09; N, 11.37%.

d) $(+)^{CD}_{500}$-(2-(Ethylseleno)ethylamine)bis(ethylenediamine)cobalt(III) Perchlorate. $(+)^{CD}_{500}$-[Co(eseea)(en)$_2$](ClO$_4$)$_3$: To a solution containing 0.05 g of $(+)^{CD}_{500}$-[Co(aes)(en)$_2$](ClO$_4$)$_2$ in 2 cm^3 of *N,N*-dimethylformamide was added 0.25 g of ethyl iodide. The mixture was allowed to stand in a refrigerator for two days, whereupon the color of the solution turned from dark brown to dark red. *N,N*-Dimethylformamide and unreacted ethyl iodide were extracted into ether and to the remaining dark red oil was added a small amount of water. This solution was poured onto a column of QAE-Sephadex

A-25 (ClO_4^- form, 2 cm×20 cm) and the column was eluted with water. The eluate was concentrated almost to dryness with a rotary evaporator and to this was added a small amount of ethanol. After cooling in a refrigerator, the resultant crystals were collected by filtration and washed with ethanol–ether (1:1) and ether. Found: C, 15.15; H, 4.19; N, 10.98%. Calcd for $(+)^{CD}_{500}$-[Co(eseea)(en)$_2$]$(ClO_4)_3$= $C_8H_{27}N_5O_{12}Cl_3SeCo$: C, 15.26; H, 4.32; N, 11.12%.

e) $(+)^{CD}_{500}$-(2-(Benzylseleno)ethylamine)bis(ethylenediamine)cobalt(III) Perchlorate. *$(+)^{CD}_{500}$-[Co(bseea)(en)$_2$]$(ClO_4)_3$*: This complex was prepared by a procedure similar to that used for $(+)^{CD}_{500}$-[Co(eseea)(en)$_2$]$(ClO_4)_3$ described in *d*), using benzyl chloride instead of ethyl iodide. Found: C, 21.57; H, 4.11; N, 9.88%. Calcd for $(+)^{CD}_{500}$-[Co(bseea)(en)$_2$]$(ClO_4)_3\cdot 1.5H_2O$= $C_{13}H_{29}N_5O_{12}Cl_3SeCo\cdot 1.5H_2O$: C, 21.73; H, 4.49; N 9.74%.

f) $(+)^{CD}_{500}$-(2-Aminoethanethiolato)bis(ethylenediamine)cobalt(III) Perchlorate. *$(+)^{CD}_{500}$-[Co(aet)(en)$_2$]$(ClO_4)_2$*: This complex was prepared by a procedure similar to that used for $(+)^{CD}_{500}$-[Co(aes)(en)$_2$]$(ClO_4)_2$ described in *a*). $(+)^{CD}_{500}$-[Co(aet)-(en)$_2$]$(ClO_4)_2$ showed the same CD pattern as that of *Λ*-[Co-(aet)(en)$_2$]$^{2+}$ reported by Yamanari *et al.*,[5] but the CD intensity of the former ($\Delta\varepsilon_{522}$=+1.37) are much higher than that of the latter ($\Delta\varepsilon_{522}$=+0.54). Found: C, 15.86; H, 4.90; N, 15.51%. Calcd for $(+)^{CD}_{500}$-[Co(aet)(en)$_2$]$(ClO_4)_2$=$C_6H_{22}N_5O_8SCl_2Co$: C, 15.86; H, 4.88; N, 15.42%.

g) $(+)^{CD}_{500}$·$(+)^{CD}_{360}$- and $(+)^{CD}_{500}$·$(-)^{CD}_{360}$-(2-Aminoethanesulfenato)-bis(ethylenediamine)cobalt(III) Perchlorate. *$(+)^{CD}_{500}$·$(+)^{CD}_{360}$- and $(+)^{CD}_{500}$·$(-)^{CD}_{360}$-[Co(aese)(en)$_2$]$(ClO_4)_2$*: A calculated amount of 1.24 cm^3 of 1% aqueous H_2O_2 was added dropwise to a solution containing 0.2 g of $(+)^{CD}_{500}$-[Co(aet)(en)$_2$]$(ClO_4)_2$ in 4 cm^3 of water and the mixture was stirred for 15 min. An orange precipitate was obtained from the reaction solution after adding a large amount of 2-propanol. This complex was dissolved in a small amount of water and then 2-propanol was added until fine orange crystals began to appear. After cooling in a refrigerator overnight, the crystals of $(+)^{CD}_{500}$·$(+)^{CD}_{360}$-[Co(aese)(en)$_2$]$(ClO_4)_2$ was collected by filtration. $(+)^{CD}_{500}$·$(-)^{CD}_{360}$-[Co(aese)(en)$_2$]$(ClO_4)_2$ was obtained from the filtrate by the addition of 2-propanol. These two isomers were recrystallized twice from water by adding 2-propanol. $(+)^{CD}_{500}$·$(+)^{CD}_{360}$ and $(+)^{CD}_{500}$·$(-)^{CD}_{360}$ aese isomers showed the same CD spectra as *Λ*-(*S*)- and *Λ*-(*R*)-[Co(aese)(en)$_2$]$^{2+}$, respectively, reported by Kita *et al.*[11] The formation ratio of the two isomers, *Λ*-(*S*) : *Λ*-(*R*), was about 1:3, which was evaluated from the CD spectra of the reaction solution. Found for $(+)^{CD}_{500}$·$(+)^{CD}_{360}$ isomer: C, 15.52; H, 4.52; N, 14.68%. Found for $(+)^{CD}_{500}$·$(-)^{CD}_{360}$ isomer: C, 15.45; H, 4.47; N, 14.77%. Calcd for $(+)^{CD}_{500}$·$(+)^{CD}_{360}$- and $(+)^{CD}_{500}$·$(-)^{CD}_{360}$-[Co(aese)(en)$_2$]$(ClO_4)_2$=C_6H_{22}-$N_5O_9SCl_2Co$: C, 15.32; H, 4.71; N, 14.89%.

h) $(+)^{CD}_{500}$-(2-(Methylthio, Ethylthio or Benzylthio)ethylamine)-bis(ethylenediamine)cobalt(III) Nitrate. *$(+)^{CD}_{500}$-[Co(mea, eea or bea)(en)$_2$]$(NO_3)_3$*: These thioether complexes were prepared by a procedure similar to those used for selenoether complexes described in *c*)—*e*), using $(+)^{CD}_{500}$-[Co(aet)(en)$_2$]-$(ClO_4)_2$ instead of $(+)^{CD}_{500}$-[Co(aes)(en)$_2$]$(ClO_4)_2$. The nitrate salts were obtained by the use of an anion exchange resin (QAE-Sephadex A-25, NO_3^- form). $(+)^{CD}_{500}$-[Co(mea or eea)-(en)$_2$]$(NO_3)_3$ showed the same CD spectra as *Λ*-(*R*)-[Co(mea or eea)(en)$_2$]$^{3+}$, reported by Yamanari *et al.*[5] Found for $(+)^{CD}_{500}$ mea complex: C, 18.68; H, 5.53; N, 24.45%. Calcd for $(+)^{CD}_{500}$-[Co(mea)(en)$_2$]$(NO_3)_3$=$C_7H_{25}N_8O_9SCo$: C, 18.42; H, 5.52; N, 24.55%. Found for $(+)^{CD}_{500}$ eea complex: C, 21.00; H 5.92; N, 22.97%. Calcd for $(+)^{CD}_{500}$-[Co(eea)(en)$_2$]$(NO_3)_3\cdot 0.25C_2H_5OH$= $C_8H_{27}N_8O_9SCo\cdot 0.25C_2H_5OH$: C, 21.19; H, 5.96; N, 23.25%. Found for $(+)^{CD}_{500}$ bea complex: C, 28.23; H, 5.66; N, 20.23%. Calcd for $(+)^{CD}_{500}$-[Co(bea)(en)$_2$]$(NO_3)_3\cdot H_2O$=$C_{13}H_{29}N_8O_9$-$SCo\cdot H_2O$: C, 28.37; H, 5.68; N, 20.36%.

2) General Data. The electronic absorption spectra were recorded with a JASCO UVIDEC-1 spectrophotometer, and the CD spectra with a JASCO J-20 spectropolarimeter. All measurements were carried out in an aqueous solution at room temperature. The ^{1}H NMR spectra were recorded in deuterium oxide on a JEOL JNM-FX-100 NMR spectrometer at probe temperature. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal reference. The calculations were carried out on a FACOM M-200 computer at University of Tsukuba.

3) X-Ray Characterization. The unit cell parameters and intensity data were measured on a Rigaku-denki four circle diffractometer (AFC-5) with a graphite-monochromatized Mo *Kα* radiation. The unit cell parameters were determined by least-squares refinement based on 24 reflections. The systematic absences led to the space group $P2_12_12_1$. Crystal data: $C_7H_{25}N_5O_{12}Cl_3SeCo$, *M.W.*=615.6, *a*=12.220 (15), *b*=19.224(7), *c*=8.977(11) Å, *V*=2108.9(11) Å^3, orthorhombic, space group $P2_12_12_1$, d_x=1.91 g cm^{-3}, d_c=1.92 g cm^{-3}, and *Z*=4.

The intensity data were collected by the ω–2θ scan technique up to 2θ=60° with a scan rate of 4° min^{-1}. The intensity data were converted to the F_o data in the usual manner. Absorption corrections were not applied. A total of 2176 independent reflections with $|F_o|>3\sigma(|F_o|)$ were considered as 'observed' and used for the structure analysis.

4) Determination of the Crystal Structure. The positions of the cobalt and selenium atoms were obtained from the three-dimensional Patterson function. The difference-Fourier maps based on the cobalt and selenium positions revealed all non-hydrogen atom. The structure was refined by a full-matrix least-squares refinement of the positional and anisotropic thermal parameters of all the non-hydrogen atoms (program RFINE by L. W. Finger, which was modified by H. Horiuchi, was used). The neutral atomic scattering factors for all the non-hydrogen atoms were taken from the literature.[15] The final residual values were *R*=0.090 and R_w=0.119, respectively. We attempted to determine the absolute configuration of the complex cation by an anomalous-scattering technique. When the refinements were carried out by use of a set of the atomic parameters containing the *Λ* configuration of the complex cation, the residual values converged to *R*=0.087 and R_w=0.114, respectively. On the contrary, the refinements in the enantiomeric atomic parameters (the *Δ* corfiguration) resulted in the residual values of *R*=0.095 and R_w=0.124, respectively. These facts suggest that the former is probably the correct choice, namely, the complex cation has the *Λ* configuration. This absolute configuration coincides with the result that $(+)^{CD}_{500}$-[Co-(mseea)(en)$_2$]$^{3+}$ is assigned to the *Λ* configuration based on the CD spectral behavior (*vide infra*).

The final positional parameters are listed in Table 1. List of structure factors (Table A), anisotropic thermal parameters (Table B), bond lengths and angles for perchlorate ion (Table C), and the projected figure of the crystal structure, which indicated distance in the range of 2.90—3.04 Å, are kept at the Chemical Society of Japan (Document No. 8445).

Results and Discussion

Structure of $(+)^{CD}_{500}$-[Co(mseea)(en)$_2$]$^{3+}$. The perspective drawing of the $(+)^{CD}_{500}$-[Co(mseea)(en)$_2$]$^{3+}$ ion is shown in Fig. 1. The bond lengths and angles are summarized in Table. 2. The coordination geometry around the cobalt atom is approximately octahedral. The selenium atom coordinates to the cobalt atom and the mseea ligand acts as a bidentate. The asymmetric selenium atom in $(+)^{CD}_{500}$-[Co(mseea)(en)$_2$]$^{3+}$, which has the *Λ* configuration, takes the (*R*) configuration. This result supports the prediction that a steric inter-

action occurs between the methyl group and the ethylenediamine chelate ring, N2-C4-C5-N3, if the asymmetric selenium donor atom takes the (*S*) configuration. The methyl group of this isomer takes the axial orientation, which causes the chelate ring of 2-(methylseleno)ethylamine, Se-C2-C3-N1, to have the gauche form with λ conformation (Fig. 1 and Table 3), though the methyl group is expected to take the equatorial orientation in general.[16,17] This fact seems to point out that the methyl group and the amino groups, N3 and N4, repel each other, if the methyl group takes the equatorial orientation. The ethylenediamine chelate ring, N4-C6-C7-N5, takes the reasonable gauche form with δ conformation (Fig. 1 and Table 3). The other ethylenediamine chelate ring, N2-C4-C5-N3, takes the unusual gauche form with λ conformation (Fig. 1 and Table 3).

The bond lengths and angles are similar to those for the [Co(L)(en)$_2$] type complexes, where L denotes selenium- or sulfur-containing ligand such as 2-aminoethaneselenolato,[1] 2-aminoethaneseleninato,[2] and 2-(methylthio)ethylamine.[9] The average Co-N

The *X*, *Y*, and *Z* coordinates in Å are referred to the crystallographic axes.

length is 1.959 Å and no significant trans effect is observed, as well as the cobalt(III) complexes with coordinated thioether sulfur atom.[9,18] The bond lengths of Co–Se, Se–Cl, and Se–C2 (2.386, 1.999, and 1.952 Å) are longer than the bond lengths of Co–S (2.267) and S–C (1.817 and 1.834 Å) in the corresponding [Co(mea)(en)$_2$]$^{3+}$,[9] and this results in a smaller bond angle of Co–Se–C2 (91.6°) that the angle of the corresponding Co–S–C (97.9°).[9] The other two bond angles around the selenium atom (Co–Se–Cl=107.1° and Cl–Se–C2=102.3°) are reasonable for the tetrahedral geometry in contrast to those around the sulfur atom in [Co(mea)(en)$_2$]$^{3+}$ (Co–S–C=114.2° and C–S–C=99.4°).[9] This fact seems to depend on the longer bond lengths of Se–Co and Se–Cl.

Absorption and CD Spectra. The electronic absorption and CD spectra of the selenolato complex, $(+)^{CD}_{500}$-[Co(aes)(en)$_2$]$^{2+}$, selenenato complex, $(+)^{CD}_{500}\cdot(-)^{CD}_{360}$-[Co(aesee)(en)$_2$]$^{2+}$, and selenoether complexes, $(+)^{CD}_{500}$-[Co(mseea)(en)$_2$]$^{3+}$, $(+)^{CD}_{500}$-[Co(eseea)(en)$_2$]$^{3+}$, and $(+)^{CD}_{500}$-[Co(bseea)(en)$_2$]$^{3+}$, are shown in Figs. 2—5, together with those of the corresponding [Co(bidentate-*N*,*S*)(en)$_2$] type complexes; the data are summarized in Tables 4 and 5. The absorption spectral behavior of the cobalt(III) complexes which belong to [Co(*N*)$_5$(*Se*)] type is quite similar to those of the corresponding [Co(*N*)$_5$(*S*)] type complexes (Figs. 2—6).[5,9-12] The intense absorption bands at around 32—36×10^3 cm^{-1} are assigned to the charge transfer ones due to the coordinated selenium atom, which correspond to the so-called sulfur-to-metal charge transfer band.[5,9-12] The charge transfer bands of the selenolato, selenenato and selenoether complexes commonly shift to a lower energy than those of the corresponding thiolato, sulfenato and thioether ones, respectively (Figs. 2—6).[5,9-12] Of these complexes, [Co(aesee)(en)$_2$]$^{2+}$ shows another intense band at 27.55×10^3 cm^{-1} (Fig. 3). This band corresponds well with the characteristic band (*ca.* 27.0×10^3 cm^{-1}) of the sulfenato complex, [Co(aese)(en)$_2$]$^{2+}$ (Fig. 3).[10-12] Therefore, the band at 27.55×10^3 cm^{-1} seems to be characteristic for the selenenato complex as well as for the sulfenato complex.

In the first absorption band region, [Co(aes)(en)$_2$]$^{2+}$ shows an explicit shoulder on the lower energy side of the major peak (*ca.* 16.6×10^3 cm^{-1}) as well as [Co(aet)(en)$_2$]$^{2+}$ (Fig. 2).[5] This kind of shoulder was also observed in the absorption spectra of the cobalt(III) complexes with thiolato-type ligand such as L-cysteinate[7,8] and D- or L-penicillaminate,[8,13] and

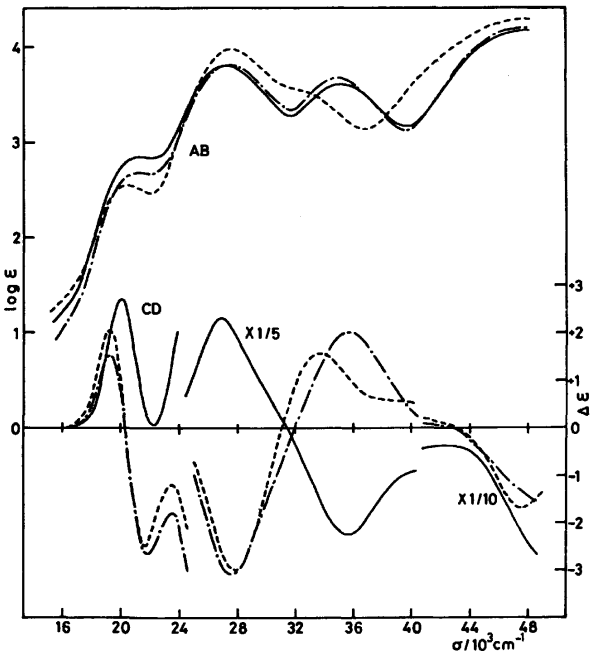

Fig. 3. Absorption and CD spectra of $(+)^{CD}_{500}\cdot(-)^{CD}_{360}$-[Co(aesee)(en)$_2$]$^{2+}$ (----), $(+)^{CD}_{500}\cdot(-)^{CD}_{360}$-[Co(aese)(en)$_2$]$^{2+}$ (—·—) and $(+)^{CD}_{500}\cdot(+)^{CD}_{360}$-[Co(aese)(en)$_2$]$^{2+}$ (——).

accordingly, this band seems to be also characteristic for the selenolato coordination. The mseea, eseea and bseea complexes show a rather sharp first absorption band without a shoulder as the case of the corresponding thioether complexes (Figs. 4—6).[5,9]

Wave numbers and $\Delta\varepsilon$ values (in parentheses) are given in 10^3 cm^{-1} and mol^{-1} dm^3 cm^{-1}, respectively. Sh denotes a shoulder.

The aesee complex shows the first absorption band with a large molar absorption coefficient and it seems to be affected by the intense charge transfer band at 27.55×10^3 cm^{-1} (Fig. 3). The first absorption bands of the selenolato, selenenato, and selenoether complexes shift to a lower energy than those of the corresponding thiolato, sulfenato, and thioether complexes,[5,9-12] respectively (Figs. 2—6), indicating that the order of the ligand field strength is *S*>*Se*.

The *Δ* and *Λ* isomers are possible for [Co(aes)(en)$_2$]$^{2+}$. As shown in Fig. 2, the CD spectrum of $(+)^{CD}_{500}$-[Co(aes)(en)$_2$]$^{2+}$ agrees with that of *Λ*-$(+)^{CD}_{500}$-[Co(aet)(en)$_2$]$^{2+}$ in the whole region,[5] and then the $(+)^{CD}_{500}$ aes isomer is assignable to the *Λ* configuration. Taking the asymmetric selenium donor atom, (*R*) and (*S*), into consideration, four isomers, *Λ*-(*R*), *Λ*-(*S*), *Λ*-(*R*), and *Λ*-(*S*), are possible for each of [Co(aesee)(en)$_2$]$^{2+}$, [Co(mseea)(en)$_2$]$^{3+}$, [Co(eseea)(en)$_2$]$^{3+}$, and [Co(bseea)(en)$_2$]$^{3+}$. In contrast to the fact that two isomers, *Λ*-(*R*) and *Λ*-(*S*), were formed for [Co(aese)(en)$_2$]$^{2+}$ (*Λ*-(*R*):*Λ*-(*S*)=3:1), $(+)^{CD}_{500}\cdot(-)^{CD}_{360}$-[Co(aesee)(en)$_2$]$^{2+}$ was selectively formed by the stoichiometric oxidation reaction of *Λ*-$(+)^{CD}_{500}$-[Co(aes)(en)$_2$]$^{2+}$ with H_2O_2. The $(+)^{CD}_{500}\cdot(-)^{CD}_{360}$ aesee isomer shows quite similar CD spectrum to that of the *Λ*-(*R*) aese isomer (Fig. 3),[11] and then it is suggested that the $(+)^{CD}_{500}\cdot(-)^{CD}_{360}$ aesee isomer takes the *Λ*-(*R*) configuration. This stereoselectivity may suggest that there is an intramolecular hydrogen bond between the selenenato or sulfenato oxygen atom and the adjacent amino proton in *Λ*-(*R*)-[Co(aesee or aese)(en)$_2$]$^{2+}$ and the hydrogen bond stabilizes the *Λ*-(*R*) configuration. The hydrogen bond is more favorable for the *Λ*-(*R*) aesee isomer than for the *Λ*-(*R*) aese one, because the bond lengths of Co–Se and Se–O are longer than those of Co–S and S–O, respectively.[1,2] The $(+)^{CD}_{500}$ mseea, eseea and bseea isomers, which were derived from *Λ*-$(+)^{CD}_{500}$-[Co(aes)(en)$_2$]$^{2+}$, show a positive CD band (*ca.* 19.7×10^3 cm^{-1}) whose intensity decreases with the order of the mseea, eseea, and bseea isomers, though the bseea isomer shows a weak negative CD band at the higher energy side in the first absorption band region. A similar CD spectral behavior was observed for a series of the corresponding thioether isomers, $(+)^{CD}_{500}$ mea, eea, and bea (Fig. 6). Taking these facts and the assignments of the $(+)^{CD}_{500}$ mea and eea isomers[5] into consideration, the $(+)^{CD}_{500}$ mseea, eseea, bseea, and bea isomers are assigned to the *Λ* configuration. The ^{1}H NMR spectrum of the $(+)^{CD}_{500}$ mseea

isomer exhibits a single peak in the methyl protons region (2.26 ppm from DSS) and that of the $(+)_{500}^{CD}$ eseea isomer one set of triplet peaks (centered at 1.57 ppm). The $(+)_{500}^{CD}$ bseea isomer shows a single peak due to the aromatic protons (7.52 ppm). The ^1H NMR spectral behavior of the selenoether isomers is in line with that of the corresponding thioether isomers.[5,9] Molecular model constructions of the selenoether and thioether complexes reveal that the *Λ*-(*R*) configuration is preferable, because the *Se*- or *S*-alkyl group in the *Λ*-(*S*) configuration have a nonbonding interaction with the adjacent ethylenediamine chelate ring. Moreover, the X-ray structural analysis indicates that the $(+)_{500}^{CD}$ mseea isomer has the (*R*) configuration for the coordinated selenium atom when the isomer takes the *Λ* configuration. Based on these results, it is suggested that the $(+)_{500}^{CD}$ selenoether and thioether isomers take selectively the *Λ*-(*R*) configuration in solution.

In the charge transfer band region, the *Λ*-(*R*) selenoether and thioether isomers show one positive CD band, while *Λ*-[Co(aes)$(en)_2$]$^{2+}$, *Λ*-[Co(aet)$(en)_2$]$^{2+}$ and *Λ*-[Co(aesi-*N,S*)$(en)_2$]$^{2+}$ (aesi=2-aminoethanesulfinato),[2] which have no chirality due to the chalcogen donor atom, show a negative one (Figs. 2 and 4—6). This fact suggests that the CD band in this region is contributed by not only the configurational chirality due to the skew pair of chelate rings but also the chirality of the selenium or sulfur donor atom.

Preparation and Characterization of Cobalt(III) Complexes with *S,S*-Bridge *R,S*-Sexidentate-N_2,S_2,O_2 Type Ligands. Crystal Structure of $(+)^{CD}_{560}$-((2*R*,9*S*)-Diamino-3,3,8,8-tetramethyl-4,7-dithia-1,10-decanedioato)cobalt(III) Ion

Mikako KANESAKA, Ken-ichi OKAMOTO,* Masayo NOMOTO, and Jinsai HIDAKA
Department of Chemistry, University of Tsukuba, Sakura, Ibaraki 305
(Received April 12, 1984)

[Co(*R,S*-sexidentate-N_2,S_2,O_2)] and [Co(*R*-terdentate-*N,S,O*)(*S-terdentate-N,S,O*)] type complexes, including the title complex cation, [Co(*R,S*-ebp)]$^+$, were prepared and resolved. The crystal structure and absolute configuration of the $(+)^{CD}_{560}$-[Co(*R,S*-ebp)]$^+$ isomer were determined by X-ray diffraction. The complex cation has an [*S*] configuration. The *R,S*-ebp coordinates as a sexidentate, of which two sulfur donor atoms take selectively *R*(*S*). The absorption and CD spectra are discussed in comparison with those of the related complexes.

In a previous paper,[1] we reported the preparation, CD spectra, and stereochemistry of [Co(LL-sexidentate-N_2,S_2,O_2)] and [Co-(L-terdentate-*N,S,O*)$_2$] type complexes. Regarding the CD spectral analysis of these complexes, the CD contribution due to *S*(*C*) of the ligand was troublesome. This paper deals with the preparation and resolution of [Co(*R,S*-sexidentate-N_2,S_2,O_2)] type complex cations, [Co(OOCCH(NH_2)C(CH_3)$_2$S(CH_2)$_n$SC(CH_3)$_2$CH(NH_2)COO)]$^+$ (n=2, *R,S*-ebp; n=3, *R,S*-tbp; n=4, *R,S*-tetp),[2] and (*S*-methyl-*R*-penicillaminato)(*S*-methyl-*S*-penicillaminato)cobalt(III), [Co(*R*-smp)(*S*-smp)]$^+$, and with the X-ray crystal structure analysis of $(+)^{CD}_{560}$-[Co(*R,S*-ebp)]$^+$. The reaction of *cis*·*cis*·*cis*-(*R*-penicillaminato)(*S*-penicillaminato)cobaltate(III),[3] [Co(*R*-pen)(*S*-pen)]$^-$, with Br(CH_2)$_n$Br (n=2, 3, and 4) spanned with ethylene, trimethylene, or tetramethylene the thiolato type sulfur donor atoms of the *R*- and *S*-pen to give an *R,S*-ebp, *R,S*-tbp, or *R,S*-tetp complex. The reaction of *cis*·*cis*·*cis*-[Co(*R*-pen)(*S*-pen)]$^-$ with dimethyl sulfate gave *cis*·*cis*·*cis*-[Co(*R*-smp)(*S*-smp)]$^+$, and the oxidation reaction of a cobalt(II) ion with the *R*- and *S*-smp gave *cis*·*cis*·*cis*- and *trans*·*trans*·*trans*-[Co(*R*-smp)(*S*-smp)]$^+$. The *cis*·*cis*·*cis* isomers of the above complexes were resolved into their optical isomers, which can be designated as [*R*] and [*S*] based on the chiral arrangement of the coordinated atoms.[4]

Experimental

1) Preparation of the Ligand. *a)* *S*-Methylpenicillamine was prepared by a procedure similar to that used for *S*-benzylpenicillamine.[5] Found: C, 44.95; H, 8.20; N, 9.36%. Calcd for $C_6H_{13}NO_2S$: C, 44.14; H, 8.02; N, 8.58%.

2) Preparation and Resolution of Complexes. *b) [Co(*R,S*-ebp)]Br.* An excess (5 cm^3) of 1,2-dibromoethane was added to a solution containing 0.8 g of *cis*·*cis*·*cis*-K[Co(*R*-pen)(*S*-pen)]·2H_2O[3] in 14 cm^3 of dimethyl sulfoxide. The mixture was stirred at room temperature for a few minutes and allowed to stand for about 1 d. The color of the solution changed from green to dark-red, and then to a deep-red. Dimethyl sulfoxide and unreacted 1,2-dibromoethane were extracted with ether several times. To the remaining dark-red solution a small amount of water was added. This solution was then poured onto a column of SP-Sephadex C-25 (Na^+ form, 4.0 cm×25 cm). After the column had been swept with water, the adsorbed band was eluted with a 0.05 mol dm^{-3} aqueous solution of NaBr. Only one red-violet band was eluted and fractionated. It was found, from the absorption spectral measurements, that all the eluates contained only [Co(*R,S*-ebp)]$^+$. The eluates were combined and concentrated to a small volume with a rotary evaporator at a temperature below 25 °C. The deposited NaBr was filtered off. The filtrate was poured onto a column of Sephadex G-10 (3.0 cm×85 cm) and eluted with water. The eluate was concentrated to a small volume again and an appropriate amount of ethanol was added to the solution. The resulting red-violet crystals were collected by filtration, recrystallized from water by adding ethanol, and washed with ethanol and ether. Found: C, 27.21; H, 5.65; N, 5.28%. Calcd for [Co(*R,S*-ebp)]Br·4H_2O=$CoC_{12}H_{22}N_2O_4S_2Br$·4$H_2O$: C, 27.02; H, 5.65; N, 5.25%.

To a solution containing 86 mg of the racemic [Co(*R,S*-ebp)]Br·4H_2O and 32.4 mg of $(+)_{546}$-K[Co(edta)]·2H_2O[6] (edta; ethylenediaminetetraacetate) in a small amount of water were added 14 mg of silver acetate and 17 mg of silver perchlorate. After the mixture was stirred for 10 min, the precipitated silver bromide and potassium perchlorate were filtered off. After the filtrate had been concentrated to a small volume, the concentrated solution, to which was added a small amount of ethanol, was kept in a refrigerator for 5 d. The less-soluble diastereomer (violet needle crystals) was recrystallized from water by adding ethanol. A piece of a crystal was used for an X-ray diffraction study. By use of the anion exchange column (Br^- form), the diastereomer was converted into the bromide salt, $(+)^{CD}_{560}$-[Co(*R,S*-ebp)]Br. The $\Delta\varepsilon$ values were evaluated from the absorption spectral data.

*c) [Co(*R,S*-tbp)]Br.* The $(-)^{CD}_{560}$-[Co(*R,S*-tbp)]$^+$ complex was prepared and resolved by a procedure similar to that used for [Co(*R,S*-ebp)]Br described in *b)*, using 1,3-dibromopropane instead of 1,2-dibromoethane. Found for the *R,S*-tbp complex: C, 30.79; H, 5.48; N, 5.50%. Calcd for [Co(*R,S*-tbp)]Br·2H_2O=$CoC_{13}H_{24}N_4O_4S_2Br$·2$H_2O$: C, 30.54; H, 5.52; N, 5.28%. Found for the less-soluble diastereomer: C, 35.05; H, 4.95; N, 6.91%. Calcd for [Co(*R,S*-tbp)][Co(edta)]·2.5H_2O=$Co_2C_{23}H_{36}N_6O_{12}S_2$·2.5$H_2O$: C, 35.07; H, 5.25; N, 7.11%.

The bromide salt was obtained by the same procedure as in *b)* and the $\Delta\varepsilon$ values were also evaluated from the absorption spectral data.

*d) [Co(*R,S*-tetp)]Br.* The $(+)^{CD}_{560}$-[Co(*R,S*-tetp)]$^+$ complex was prepared and resolved by a procedure similar to that used for [Co(*R,S*-ebp)]Br as in *b)*, using 1,4-dibromobutane instead of 1,2-dibromoethane, and $(-)_{546}$-K[Co(edta)]·2H_2O as resolving agent. Found for the *R,S*-tetp complex: C, 32.55; H, 5.41; N, 5.41%. Calcd for [Co(*R,S*-tetp)]Br·

$1.5H_2O$=$CoC_{14}H_{26}N_2O_4S_2Br \cdot 1.5H_2O$: C, 32.56; H, 5.65; N, 5.42%. The bromide salt and the $\Delta\varepsilon$ values were obtained by the same procedure as in *b)*.

Here, it is noted that for the *S,S*-bridge complex, the [*S*]-$(+)_{560}^{CD}$ *R,S*-ebp isomer forms the less-soluble diastereomer with $(+)_{546}$-[Co(edta)]$^-$, whereas the [*R*]-$(-)_{560}^{CD}$ *R,S*-tbp isomer forms the less-soluble diastereomer with $(+)_{546}$-[Co(edta)]$^-$ and the [*S*]-$(+)_{560}^{CD}$ *R,S*-tetp isomer with $(-)_{546}$-[Co(edta)]$^-$.

*e) [Co(*R*-smp)(*S*-smp)]NO_3. Method 1.* This complex was prepared by a procedure similar to that used for [Co(*R*-smp)(dien)]$^+$ [7] and [Co(*S*-smp)$_2$]$^+$,[8] namely, *cis·cis·cis*-[Co(*R*-smp)(*S*-smp)]$^+$ was obtained by the reaction of the coordinated thiolato type donor atoms of *cis·cis·cis*-[Co(*R*-pen)(*S*-pen)]$^-$ [3] with dimethyl sulfate. It was confirmed using a cation exchange column chromatography (Dowex 50W-X8, 200—400 mesh, Na^+ form, 3.5 cm×20 cm) that no isomerization had taken place. Found: C, 29.60; H, 5.77; N, 8.60%. Calcd for [Co(*R*-smp)(*S*-smp)]$NO_3 \cdot 2.5H_2O$ =$CoC_{12}H_{24}N_3O_7S_2 \cdot 2.5H_2O$: C, 29.39; H, 5.96; N, 8.57%.

Method 2. The [Co(*R*-smp)(*S*-smp)]$^+$ complex was also prepared by a procedure similar to that used for [Co(L-met)$_2$]$^+$,[9] using *S*-methylpenicillamine instead of L-methionine. The reaction mixture was filtered to remove any insoluble material. The filtrate was allowed to stand at room temperature overnight and was then poured onto a column of Dowex 50W-X8 (200—400 mesh, Na^+ form, 3.5 cm×60 cm). After the column had been swept with water, the adsorbed band was eluted with a 0.1 mol dm^{-3} aqueous solution of NaCl. Three colored bands, dark-violet (F-1), reddish violet (F-2), and violet (F-3), were eluted in this order and were in the ratio of about F-1:F-2:F-3=1:5:3. From their absorption spectral measurements, it was found that F-1 and F-2 eluates contained *trans·trans·trans-* and *cis·cis·cis*-[Co(*R*-smp)(*S*-smp)]$^+$ isomers, respectively. The F-3 eluate showed the same spectrum as the *trans*(*S*)-[Co(*S*-smp)$_2$]$^+$ isomer,[8] but did not exhibit the optical activity, indicating it was a mixture of *trans*(*S*)-[Co(*S*-smp)$_2$]$^+$ and *trans*(*S*)-[Co(*R*-smp)$_2$]$^+$. Each of the F-1 and F-2 eluates was concentrated to a small volume with a rotary evaporator at a temperature of about 20 °C. The deposited NaCl was filtered off. As the amount of the earlier eluate (F-1) was very small, it could not be obtained as in crystal form. The absorption spectrum of the *trans·trans·trans*-[Co(*R*-smp)(*S*-smp)]$^+$ was measured with the solution and it is illustrated with an arbitrary scale in Fig. 3.

The F-2 eluate, which showed the same absorption spectrum as that in *Method 1*, was poured onto a column of SP-Sephadex C-25 (Na^+ form, 3.0 cm×90 cm). After the column had been swept with water, the adsorbed band was eluted with a 0.03 mol dm^{-3} aqueous solution of K_2[Sb$_2$(*d*-tart)$_2$]·$3H_2O$. After circulating the eluates in the same column two times, they separated into two reddish violet bands and fractionated. Each of the fractions was concentrated to a small volume with a rotary evaporator at a temperature of about 20 °C and the deposited K_2[Sb$_2$(*d*-tart)$_2$] was filtered off. The filtrate was converted into the bromide salt using a column of QAE-Sephadex A-25 (Br^- form) and the CD spectra were measured with its solutions. The earlier eluate contained $(-)_{560}^{CD}$-*cis·cis·cis*-[Co(*R*-smp)(*S*-smp)]$^+$ and the later contained $(+)_{560}^{CD}$ one. The $\Delta\varepsilon$ values were also evaluated from the absorption spectral data.

3) General Data. The electronic absorption spectra were recorded with JASCO UVIDEC-1 and UVIDEC-610 spectrophotometers and the CD spectra with a JASCO J-20 spectropolarimeter. All measurements were carried out in aqueous solutions at room temperature. The calculations were carried out on a FACOM M-200 computer at University of Tsukuba.

4) X-Ray Characterization. The unit cell parameters and intensity data for the single crystal (*ca.* 0.12×0.18×0.35 mm^3) were measured on a Rigaku-denki automated four circle diffractometer (AFC-5) with graphite-monochromatized Mo $K\alpha$ radiation. The unit cell parameters were determined by a least-squares refinement based on 38 reflections. The systematic absence led to the space group $P2_12_12_1$. Crystal data: $Co_2C_{22}H_{44}N_4O_{17}S_2$, *M.W.*=818.6, orthorhombic, space group $P2_12_12_1$, a=13.215(5), b=37.035(12), c=6.527(2) Å, V=3194.1(18) Å^3, D_m=1.72 g cm^{-3} (by the flotation), D_x=1.70 g cm^{-3}, Z=4, and μ(Mo $K\alpha$)=12.9 cm^{-1}.

Intensity data up to 2θ=60° were collected by the ω-2θ scan technique with a scan rate of 3° min^{-1}. During the course of the data collection, three reflections were monitored every 40 reflections. The intensity data were converted into F_o data in the usual manner. Absorption corrections were not applied. A total of 2322 independent reflections with $|F_o|>3\sigma(|F_o|)$ was observed and used for the structure analysis.

5) Determination of the Crystal Structure. The positions of two cobalt atoms were obtained from the three dimensional Patterson function. The difference Fourier maps, based on the cobalt positions, revealed all the non-hydrogen atoms. The structure was refined by a full-matrix least-squares refinement of the positional and anisotropic thermal parameters of all the non-hydrogen atoms (program RFINE by L. W. Finger was used). The neutral atomic scattering factors for all the non-hydrogen atoms were taken from the literature.[10] The final R value converged to 0.088. The absolute configuration could not be determined by the anomalous scattering technique, using Cu $K\alpha$ radiation, but it was determined on the basis of the known configuration of the $(+)_{546}$-[Co(edta)]$^-$.[6] The final atomic parameters with their estimated standard deviations are given in Table 1. A list of structure factors, anisotropic thermal parameters of non-hydrogen atoms, and the projected figure of the crystal structure, which indicated distance in the range of 2.63—3.02 Å, are kept at the Chemical Society of Japan as Document No. 8446.

Results and Discussion

Description of the Structure. The perspective drawings of the complex cation and anion are given in Figs. 1 and 2, respectively, together with their numbering scheme. The bond lengths and angles with their estimated standard deviations in the complex ions are listed in Table 2. The cobalt atom in the complex cation is surrounded by two *cis* sulfur, two *cis* oxygen, and two *cis* nitrogen atoms, and the *R,S*-ebp coordinates to cobalt atom as a sexidentate. The [Co(*R,S*-ebp)]$^+$ complex, was resolved into the optical isomers, which are designated as [*R*] and [*S*] configurations based on the chiral arrangement of the coordinated atoms.[4] The absolute configuration of the $(+)_{560}^{CD}$-[Co(*R,S*-ebp)]$^+$ isomer was determined to be the [*S*] configuration (Fig. 1) on the basis of the known configuration, Δ, of the $(+)_{546}$-[Co(edta)]$^-$ (Fig. 2).[6] Both of the chiral sulfur donor atoms take selectively the *R*(*S*)[4] configuration and the *S,S*-bridged five-membered chelate ring has a gauche form with the λ conformation (Fig. 1 and Table 3). The remaining chelate rings of the $(+)_{560}^{CD}$-[Co(*R,S*-ebp)]$^+$ isomer show similar conformations to those of the cobalt(III) complexes having the same framework as the penicillamine moiety.[3,11-13] The bond lengths and angles for the $(+)_{560}^{CD}$-[Co(*R,S*-ebp)]$^+$ isomer are quite similar to those

of the parent complex, *cis·cis·cis*-[Co(*R*-pen)(*S*-pen)]$^-$.[3] These facts suggest that the two sulfur atoms of the parent complex anion react with 1,2-dibromoethane to give an *S,S*-bridged five-membered ring without any strain. It is noted that the Co–S bond lengths of 2.199(7) and 2.221(8) Å for the $(+)^{CD}_{560}$ *R,S*-ebp isomer are significantly shorter than those of the thioether type complexes such as *trans*(*S*)-bis(*S*-methyl-L-cysteinato)cobalt(III)[11] and *trans*(*O*)-*N,N'*-ethylenebis(*S*-methyl-L-cysteinato)cobalt(III),[12] which have a similar framework to the penicillamine moiety of the *R,S*-ebp.

a) B_{eq} is the equivalent isotropic temperature factors defined by Hamilton.[16]

The bond lengths and angles in the $(+)_{546}$-[Co(edta)]$^-$ isomer agree well with the data for [Co(sarmp)$(NH_3)_3$]·$(+)_{546}$-[Co(edta)] (sarmp; *N*-(2-carboxyethyl)-sarcosinate) (Table 2).[6] The crystal structure consists of the complex cations and anions, and water molecules. The several hydrogen bonds are recognized between the complex ions and/or water molecules (Fig. A).

Absorption and CD Spectra. The electronic absorption and CD spectra of the non-bridge complex, [Co(*R*-smp)(*S*-smp)]$^+$, and the S,S-bridge complexes, [Co(*R,S*-ebp)]$^+$, [Co(*R,S*-tbp)]$^+$, and [Co(*R,S*-tetp)]$^+$, are shown in Figs. 3 and 4, and their spectral data are summarized in Table 4. Two geometrical isomers, *cis·cis·cis* and *trans·trans·trans*, are possible for the non-bridge complex, [Co(*R*-smp)(*S*-smp)]$^+$. In the first absorption band region, the F-1 isomer exhibits well separated two absorption components, while the F-2 isomer exhibits a sharp band (Fig. 3 and Table 4). These absorption spectral patterns indicate that the F-1 isomer takes the *trans·trans·trans* configuration and the F-2 isomer takes the *cis·cis·cis* configuration.

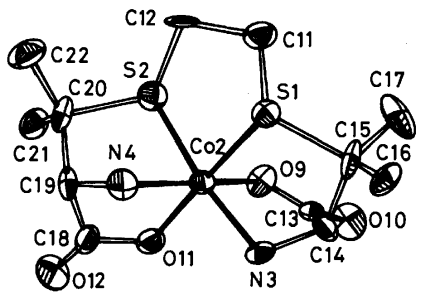

Fig. 1. A perspective drawing of [*S*]-$(+)^{CD}_{560}$-[Co(*R,S*-ebp)]$^+$ with the numbering scheme of atoms.

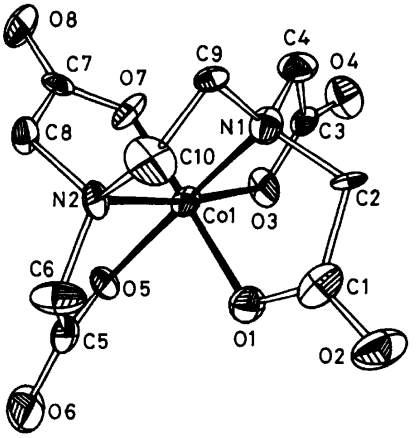

Fig. 2. A perspective drawing of Λ-$(+)_{546}$-[Co(edta)]$^-$ with the numbering scheme of atoms.

Furthermore, the maximum positions of their thioether charge transfer bands ($29.59\times10^3\,cm^{-1}$ for F-1 and $32.95\times10^3\,cm^{-1}$ for F-2) also support the geometries which *trans(S)* is for F-1 isomer and *cis(S)* for F-2 one. These absorption spectra agree well with those of $[Co(aeta)_2]^+$ and $[Co(aetp)_2]^+$ (aeta; (2-aminoethylthio)acetate and aetp; 3-(2-aminoethylthio)propionate).[14] All the *S,S*-bridge complexes exhibit similar absorption spectral patterns over the whole region to that of the *cis·cis·cis*-[Co(*R*-smp)(*S*-smp)]$^+$ isomer, indicating the same geometrical arrangements with respect to the coordinated atoms. The *R,S*-ebp, *R,S*-tbp, and *R,S*-tetp complexes exhibit a sharp first absorption band at *ca.* $19\times10^3\,cm^{-1}$, regardless of their *S,S*-bridged backborn rings (five-, six-, and seven-membered ones, respectively). On the contrary, the absorption maxima of the sulfur-to-metal charge tansfer bands are shifted to lower energy in the order of *R,S*-ebp>*R,S*-tbp>*R,S*-tetp≈non-bridge complex, as shown in Figs. 3 and 4, and Table 4. This order seems to run parallel to the rigidity of the *S,S*-bridged backborn rings.

The $(+)^{CD}_{560}$-[Co(*R,S*-tbp)]$^+$ and $(+)^{CD}_{560}$-[Co(*R,S*-tetp)]$^+$ isomers exhibit quite similar CD spectral patterns over the whole region to that of [*S*]-$(+)^{CD}_{560}$-[Co(*R,S*-ebp)]$^+$, accordingly, it is assigned that the $(+)^{CD}_{560}$ *R,S*-tbp and $(+)^{CD}_{560}$ *R,S*-tetp isomers also take an [*S*] configuration, respectively. Similarly, the $(+)^{CD}_{560}$-*cis·cis·cis*-[Co(*R*-smp)(*S*-smp)]$^+$ isomer can be tentatively assigned to an [*S*] configuration by comparing its CD spectrum with that of the [*S*]-$(+)^{CD}_{560}$-[Co(*R,S*-ebp)]$^+$ isomer, though a little difference from that of the *R,S*-ebp isomer is observed (Fig. 3).

In order to estimate the absolute configuration of

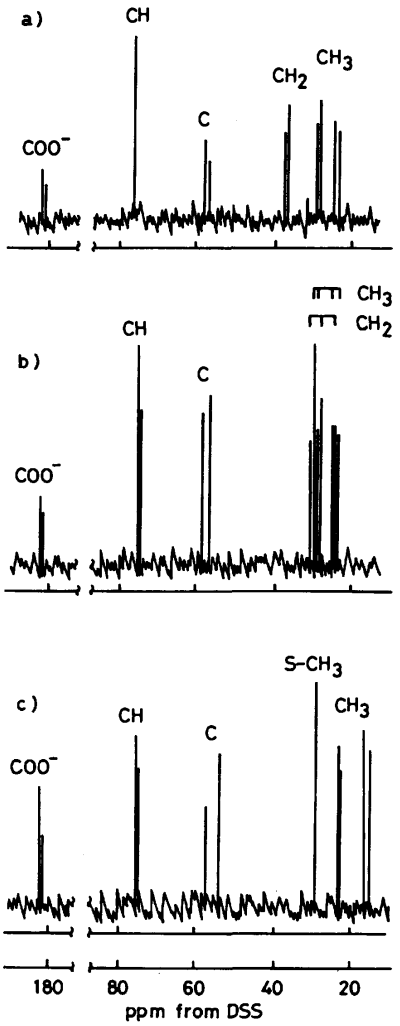

Fig. 5. ^{13}C NMR spectra of the complexes: (a) $(+)^{CD}_{580}$-[Co(*R*,*S*-ebp)]$^+$, (b) $(-)^{CD}_{580}$-[Co(*R*,*S*-tbp)]$^+$, and (c) $(-)^{CD}_{560}$-*cis*·*cis*·*cis*-[Co(*R*-smp)(*S*-smp)]$^+$.

$(-)^{CD}_{560}$-[Co(*R*,*S*-tbp)]$^+$ (thirteen lines for thirteen carbons) and [*R*]-$(-)^{CD}_{500}$-*cis*·*cis*·*cis*-[Co(*R*-smp)(*S*-smp)]$^+$ (eleven lines for twelve carbons) isomers, as shown in Fig. 5. Further, the ^{1}H NMR spectrum of the $(-)^{CD}_{560}$-*cis*·*cis*·*cis*-[Co(*R*-smp)(*S*-smp)]$^+$ isomer shows two sharp signals (2.27 and 2.03 ppm) due to the *S*-methyl protons. Stereomodel examination elucidates these results as follow; namely, the $S(S)_D$,$S(S)_L$ configuration is assigned for [*R*]-$(-)^{CD}_{560}$-[Co(*R*,*S*-tbp)]$^+$. The $R(S)_D$, $S(S)_L$ configuration is probable for the [*R*]-$(-)^{CD}_{560}$-*cis*·*cis*·*cis*-[Co(*R*-smp)(*S*-smp)]$^+$ isomer because of the steric interaction between the two *S*-methyl groups, though an $S(S)_D$,$S(S)_L$ configuration is also possible for the isomer. The CD spectrum of the $(+)^{CD}_{560}$-*cis*·*cis*-[Co(*R*-smp)(*S*-smp)]$^+$ isomer, which was assigned to the same [*S*] configuration as the $(+)^{CD}_{560}$ *R*,*S*-ebp isomer, differs partially from that of the latter, as mentioned above. A similar difference was observed between the CD spectra of the *trans*(*O*)-[Co(L-smp)$_2$]$^+$ and *trans*(*O*) *S*,*S*-bridge isomers, *trans*(*O*)-[Co(LL-sexidentate-N_2,S_2,O_2)].[1] Taking the results from the ^{1}H and ^{13}C NMR spectral behavior of the present isomers into consideration, it is possible to consider that the difference is related to the additional CD contribution due to the fixation of two sulfur donor atoms located in the *cis* position.

The authors wish to express thanks to Miss Hiroko Nishimoto for her aid in the experiment.

Dynamic NMR as a Nondestructive Method for the Determination of Rates of Dissociation. IX. Rates of Dissociative Reactions of the Coordinated Form of [*o*-(Diethylaminomethyl)-phenyl]halodimethyl(or diphenyl)stannanes[1,2]

Michinori Ōki* and Manabu Ohira
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received April 11, 1984)

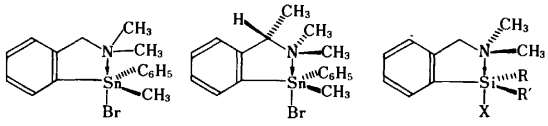
The coordinated form of [*o*-(diethylaminomethyl)phenyl]halodimethyl(or diphenyl)stannanes was found to exhibit dynamic behaviors in their ^{1}H NMR spectra. Examination of a series of halogen compounds by total line shape analysis of the diastereotopic methylene proton signals revealed that, at 10 °C, the rates of dissociation were 11.7, 22.9, 28.6, and 73.3 s^{-1} for fluoro, chloro, bromo, and iodo compounds, respectively: The results are in conformity with the expectation from the electronegativity of halogens. The relatively small differences in the activation parameters in the whole series may include contribution by solvation energies. The diphenyl compound exhibited fast exchange rates relative to the corresponding dimethyl compound. This was attributed to the steric factor rather than the $p\pi$-$d\pi$ interaction.

The ligand exchange is one of the fundamental reactions in coordination chemistry. The dissociative reactions are often found in the ligand exchange and have been the target of many investigations.[3] As to the methodology for the determination of the rates of exchange, not only classical chemical reactions but also the dynamic NMR technique played an important role, because the latter affords data which are too fast for the ordinary laboratory time scale. Among many others we can pick up following examples which dealt with the coordination chemistry of amine ligands by dynamic NMR in the literature.

After the pioneering work by Mole,[4] various groups of investigators studied the exchange reactions of trivalent aluminium-amine complexes.[5,6] This technique was extended to boron-amine[7] and gallium-amine[8] complexes. An amine-sulfur dioxide complex was also studied.[9] These classic literatures use excess of substrates, usually the base, to observe coalescence of complexed and uncomplexed signals. Thus it may be said that these techniques determine the rates of exchange, either dissociative or associative, in the presence of excess of other reagents than the solvent concerned.

Observation of the dissociative processes in the absence of foreign materials is important, since it affords information about the "intrinsic" dissociative nature of the complex concerned. This is, on one hand, possible by observing the spin-spin coupling between the central metal atom in a complex and the atom, which has non-zero nuclear spin, in the ligand because the coupling disappears on dissociation. This technique has been reviewed.[10] Although the most of ligands contain atoms, which have non-zero nuclear spin, such as hydrogen, the central atom is not necessarily NMR-active. Therefore, the observation of spin-spin couplings has limitation in this respect.

Since we have been able to show that dissociation rates of a type of ammonium salts could be followed by the dynamic NMR method,[11] we are interested in applying this method to the problem in coordination chemistry. The necessary conditions for detection by this procedure are that 1) the compound in question has a pair of diastereotopic NMR-active nuclei, 2) the diastereotopic nuclei exchange their sites by dissociation, and 3) preferably the ligand which dissociates is singular. Literature search revealed that there were some examples which are similar but not exactly the same with our topomerization technique. van Koten and associates found that spin-exchange between the diastereotopic methyl protons in the coordinated form of bromo[*o*-(dimethylaminomethyl)phenyl]methylphenylstannane (**1**) was observed by the dynamic NMR technique.[12] They further elaborated to show that a diastereomer of bromo[*o*-[1-(dimethylamino)ethyl]-phenyl]methylphenylstannane (**2**) isomerized to another slowly at a low temperature.[13] These phenomena can be explained by dissociation of the amine ligand followed by internal rotation, inversion of amine and religation (or alternatively the chiral center of tin racemizes after dissociation of the ligand). Corriu *et al.* reported the similar phenomenon in the corresponding silicon compounds (**3**),[14] although they postulated that coordinated and decoordinated forms were observed. We believe our explanation of dissociation-topomerization is more likely than the postulate by Corriu *et al.*

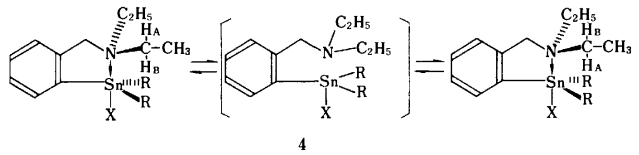


1 2 3

van Koten *et al.* extended their work further to more complicated tin compounds in which a 6-membered ring was formed by ligation.[15] Deeming and Rothwell were able to show dynamic nature of an amine ligand in a similar situation in palladium complexes, although they postulated that the mechanism of the exchange is different from that discussed here.[16]

The works cited above were possible because the metal atom was a chiral center. However, the diastereotopic nature does not require the presence of a chiral center. Therefore, by designing a proper molecule, we

should be able to observe topomerization by dissociation in a compound which has no chiral center. This will broaden the scope of the technique and is worthwhile to be tried. We designed bromo[*o*-(diethylaminomethyl)phenyl]dimethylstannane (**4**: R=CH_3, X=Br) because the methylene protons in the ethyl group should be diastereotopic when the amine coordinates but it topomerizes when the ligand dissociates, internal rotation takes place, the amine inverts, and then the ligand recoordinates (Scheme 1).



4

Scheme 1.

This paper reports successful observation of topomerization in **4** and discusses the effect of the substituents on the rates of topomerization.

Experimental

N,N-Diethylbenzylamine (**5**) was prepared by adding 20 g of diethylamine in 30 mL of acetone to 25.0 g of benzyl chloride and 30 g of potassium carbonate in 50 mL of water and 100 mL of acetone and heating the mixture for 5 h. The yield was 54%. Colorless oil, bp 60—62 °C/3.5 mmHg (lit,[17] bp 211—212 °C). ^{1}H NMR ($CDCl_3$, δ): 1.01 (6H, t, J=7 Hz), 2.49 (4H, q, J=7 Hz), 3.53 (2H, s), 7.1—7.4 (5H, br s).

Bromo[o-(diethylaminomethyl)phenyl]dimethylstannane (4: R=CH$_3$, X=Br). To a mixture of 20 mL of dry ether and 5 mL of 1.5 M butyllithium (1M=1 mol dm^{-3}) in hexane, 1.2 g (7.4 mmol) of *N,N*-diethylbenzylamine was added with stirring. The mixture was stirred at room temperature under a nitrogen atmosphere until the Gilman color test II[18] became negative. This required 7—10 d. The solution of *o*-lithio-*N,N*-diethylbenzylamine was added to a solution of 2.4 g (7.8 mmol) of dibromodimethylstannane in 20 mL of dry ether during the course of 1 h with stirring. The stirring was continued for further 3 h and the solvents were evaporated. The residue was taken up in benzene and evaporated. Recrystallization of the product from benzene-hexane gave 0.5 g (17%) of the desired compound, mp 145—146 °C. Found: C, 40.01; H, 6.00; N, 3.48; Br, 20.66%. Calcd for $C_{13}H_{22}$BrNSn: C, 39.94; H, 5.67; N, 3.58; Br, 20.44%. ^{1}H NMR ($CDCl_3$, δ): 0.92 (6H, s), 0.99 (6H, t, J=7 Hz), 2.65 (4H, q, J=7 Hz), 3.65 (2H, s), 6.9—7.4 (3H, m), 8.23 (1H, m). ^{1}H NMR (toluene-d_8, δ): 0.43 (6H, t, J=7 Hz), 0.73 (6H, s), 2.03 (4H, q, J=7 Hz), 3.03 (2H, s), 6.5—7.4 (3H, m), 8.62 (1H, m).

Chloro[o-(diethylaminomethyl)phenyl]dimethylstannane (4: R=CH$_3$, X=Cl), mp 150—151 °C, was similarly prepared in 30% yield. Found: C, 44.92; H, 6.65; N, 3.87; Cl, 10.70%. Calcd for $C_{13}H_{22}$ClNSn: C, 45.07; H, 6.40, N, 4.04; Cl, 10.23%. ^{1}H NMR ($CDCl_3$, δ): 0.80 (6H, s), 0.99 (6H, t, J=7 Hz), 2.64 (4H, q, J=7 Hz), 3.64 (2H, s), 6.9—7.5 (3H, m), 8.18 (1H, m).

Chloro[o-(diethylaminomethyl)phenyl]diphenylstannane (4: R=C$_6$H$_5$, X=Cl), mp 135—136 °C, was similarly prepared in 9% yield. Found: C, 58.49; H, 5.62; N, 3.10; Cl, 7.67%. Calcd for $C_{23}H_{26}$ClNSn: C, 58.70; H, 5.57; N, 2.98; Cl, 7.53%. ^{1}H NMR ($CDCl_3$, δ); 0.70 (6H, t, J=7 Hz), 2.24 (4H, q, J=7 Hz), 3.59 (2H, s), 7.1—7.9 (13H, m), 8.47 (1H, m).

Iodo[o-(diethylaminomethyl)phenyl]dimethylstannane (4: R=CH$_3$, X=I). To a solution of 0.30 g (0.87 mmol) of compound **4** (R=CH_3, X=Cl) in 20 mL of ethyl acetate was added 0.13 g (0.87 mmol) of sodium iodide in 20 mL of ethyl acetate. The precipitate of sodium chloride was filtered off and the filtrate was concentrated. The residue was purified by recrystallization from dichloromethane-pentane to give 0.34 g (90%) of the desired compound, mp 140—141 °C. Found: C, 35.60; H, 5.45; N, 3.16; I, 28.42%. Calcd for $C_{13}H_{22}$INSn: C, 35.66; H, 5.06; N, 3.20; I, 28.98%. ^{1}H NMR ($CDCl_3$, δ): 1.01 (6H, t, J=7 Hz), 1.12 (6H, s), 2.68 (4H, q, J=7 Hz), 3.68 (2H, s), 6.9—7.5 (3H, m), 8.32 (1H, m).

Fluoro[o-(diethylaminomethyl)phenyl]dimethylstannane (4: R=CH$_3$, X=F). A solution of 0.28 g of **4** (R=CH_3, X=I) in 20 mL of methanol was mixed with 0.10 g of potassium fluoride in 5 mL of water and the whole was refluxed for 3 h. The solvents were evaporated and the residue was taken up in benzene. The benzene solution was evaporated and the residue was recrystallized from ether-hexane to afford the desired compound, mp 74—77 °C, in 80% yield. Found: C, 47.10; H, 6.75; N, 4.28%. Calcd for $C_{13}H_{22}$FNSn: C, 47.31; H, 6.71; N, 4.24%. ^{1}H NMR ($CDCl_3$, δ): 0.62 (6H, d, J_{HF}=4.2 Hz), 1.00 (6H, t, J=7 Hz), 2.66 (4H, q, J=7 Hz), 3.64 (2H, s), 7.0—7.5 (3H, m), 7.99 (1H, m).

Dynamic NMR Measurement. The measurement was carried out on a JEOL FX-400 NMR spectrometer which operates at 400 MHz for protons. The samples were dissolved in chloroform-*d* to make up *ca.* 100 mmol/L solutions. The data were accumulated for 200 times. Temperature was calibrated by the chemical shift differences of methanol protons. The chemical shift differences of the AB protons and the coupling constants at *ca.* −50 °C are summarized in Table 1. J_{AX} and J_{BX} were constant at 7.2—7.3 Hz for all the compounds examined.

Total Line Shape Analysis and Kinetic Parameters. The line shapes were analyzed by computer simulation with the use of the modified Binsch program.[19] The spectra were analyzed as an AB part of an ABX_3 system. The coupling constants were constant throughout the temperature range examined but the chemical shift differences drifted as temperature changed but one case, compound **4** (R=CH_3, X=I). Thus for those which gave drifts in chemical shift differences, the chemical shift differences were checked at several temperatures where the rates of exchange were negligibly small. The chemical shift change was found to be linearly correlated with temperature and the following equations gave chemical shift differences at a given temperature. T_2 was estimated from the

4: R=C_6H_5, X=Cl

$$\Delta\nu_{AB} = -0.409T + 62.66 \quad (r=0.996)$$

4: R=CH_3, X=Br

$$\Delta\nu_{AB} = -0.0170T + 26.74 \quad (r=1.000)$$

Table 1. Chemical shift differences of the methylene protons in ethyl groups and coupling constants at *ca.* −50 °C at 400 MHz

R	X	$\Delta\nu_{AB}$/Hz	J_{AB}/Hz
CH_3	F	19.3	−13.7
CH_3	Cl	27.0	−13.7
CH_3	Br	27.6	−13.7
CH_3	I	27.8	−13.7
C_6H_5	Cl	82.8	−13.9

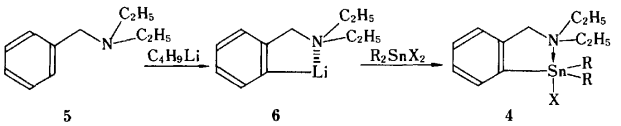
line widths of benzyl protons and was assumed to be constant at 0.16 s. The calculated spectra and the observed ones were matched by the visual method. The agreement of the both spectra were excellent. The following rate constants were obtained (k/s^{-1} and T/°C in parentheses are given). For **4** (R=C_6H_5, X=Cl), see Fig. 1.

4 (R=CH_3, X=F): 6.1 (5.1), 12.0 (10.5), 27.0 (16.2), 35.0 (18.1), 47.0 (20.7), 58.0 (22.6).
4 (R=CH_3, X=Cl): 7.0 (1.9), 11.5 (5.0), 22.0 (9.2), 42.0 (14.5), 75.0 (18.7), 98.0 (21.5), 120.0 (22.8).
4 (R=CH_3, X=Br): 7.5 (1.3), 16.0 (6.6), 25.0 (9.0), 33.0 (10.9), 45.0 (12.7), 62.0 (21.5), 118.0 (20.0).
4 (R=CH_3, X=I): 4.0 (−8.4), 8.0 (−4.5), 18.0 (0.7), 36.0 (5.1), 78.0 (10.5), 90.0 (11.3), 175.0 (16.2).

The rate constants thus obtained were put into the Eyring equation to obtain the activation parameters. The rate constants and free energies of activation at a given temperature were calculated with the use of these activation parameters.

Results and Discussion

The first point which we wish to raise is the steric effect in the synthesis of the compounds which was performed as is shown in Scheme 2. Although lithiation of *N,N*-dimethylbenzylamine with butyllithium



Scheme 2.

proceeded smoothly and the Gilman color test II became negataive after a day or so at room temperature,[20] the same lithiation of *N,N*-diethylbenzylamine (**5**) required 7—10 d to give the negative Gliman test II. We were not able to lithiate completely the ortho position of *N,N*-diisopropylbenzylamine. It seems that the steric effect in the coordinated form (**6**) which stabilizes the lithiated compound is severely affected by the bulkiness of the substituent on the nitrogen.

The ^{1}H NMR spectra of **4** at 60 or 90 MHz gave a simple A_2X_3 quartet for the methylene protons of the ethyl groups. This could mean either the rate of exchange was large on the NMR time scale or the chemical shift differences were too small to detect, although the exchange rate was small. A ^{1}H NMR spectrum at 60 MHz at −50 °C showed essentially no change from that at room temperature. Summing up this result and the data reported by van Koten *et al.*,[12] we concluded that the chemical shift differences of the AB protons were too small for a spectrometer operating at 60 MHz. Then we shifted to a spectrometer operating at 400 MHz.

The AB part of the spectrum of **4** (R=CH_3, X=Br) at 400 MHz showed a barely resolved signal at room temperature but it became a distinct AB part of the ABX_3 system when the spectrum was determined at lower temperatures. The other compounds showed the similar trend. Since the spectral change due to temperature for **4** (R=CH_3, X=Br) is given in a preliminary note,[2] the temperature dependent spectra of **4** (R=C_6H_5, X=Cl) are shown in Fig. 1 together with the calculated spectra. Activation parameters obtained from the rate constants and temperatures are summarized in Table 2 together with $\Delta G^{\ddagger}$'s and k's at 10 °C, which were obtained by calculation, for comparison. The correlation coefficients were very close to 1 and we may discuss the effect of substituents with the use of these data.

The first point we wish to discuss is that argument, saying that the results by van Koten *et al.*[12,13] and

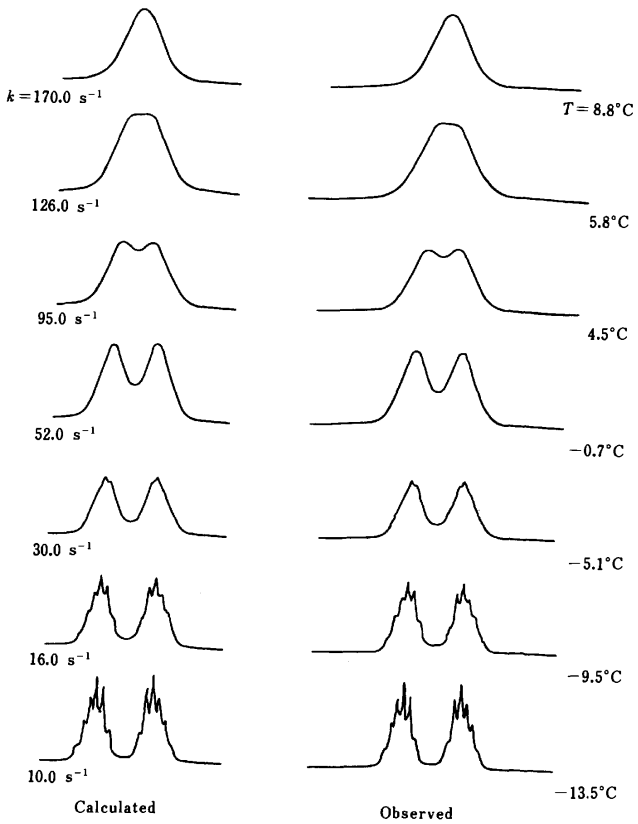


Fig. 1. Calculated and observed spectra of the AB part of ABX_3 patterns in **4** (R=C_6H_5, X=Cl) at various temperatures.

Corriu *et al.*[14] could be caused by the fluxional behavior of the complexes, can be denied by the present results. The X-ray crystallography of compound **1** was carried out and concluded that nitrogen and bromine occupy the apical positions.[21] Although electronegative groups favor to be in the apical positions in trigonal bipyramid complexes, this general trend cannot rule out the possibility that a configuration in which nitrogen or bromine occupies the basal position is present in solution. However, in our cases, if it were the fluxional behavior of the complexes, the coalescence of the AB proton signals could not have been observed for the following reasons. The AB protons at a site (that is either apical or basal) give their own chemical shifts but they are still diastereotopic in another site unless they dissociate and inversion of nitrogen takes place. Therefore, the fluxional behavior could explain the change in the chemical shift differences due to temperature but not the coalescence of the diastereotopic proton signals. Topomerization by dissociation is the process we observe.

The common feature of the activation parameters for compound **4** is that large positive entropies of activation are observed. The feature of the entropy of activation gives suggestions in diagnosing the rate-determining step of the observed topomerization processes. As stated earlier, there are four steps involved in the observation: Dissociation of the amine ligand, rotation about the NCH_2–phenyl bond, inversion of amine, and religation. Inversion of the amine is easily rejected, because the free energy of activation for the observed process is 14—15 kcal/mol at 283 K, whereas that for nitrogen inversion in dibenzylmethylamine is 6.6 kcal/mol at 132 K[22] and that for diethylmethylamine is 7.9 kcal/mol at 160 K.[23] Ruling out the NCH_2–phenyl rotation from being the possible rate-determining step is difficult: *o,o'*-disubstituted neopentylbenzenes are known to show a barrier to rotation about the C_{CH_2}–C_{Ar} bond of 13—15 kcal/mol[24] but the effect of removing one *o*-substituent is not known, in addition to the fact that the effect of the stannyl substituent on the barrier is unknown. However, it scarcely happens that the internal rotation of a molecule shows a large positive entropy of activation. Therefore, being a rate-determining step for the NCH_2–phenyl rotation is less likely. The third possibility, that the religation is the rate-determining step, can also be ruled out because we observe only the ligated form: We should have been able to observe the dissociated form, if the barrier to religation were high relative to that for dissociation of the ligand. Then the most probable rate-determining step for the observed topomerization is the dissociation of the ligand.

The same trend, a large positive entropy of activation, was also observed for the dissociation of anilinium ions.[11] The increase in the entropy in the transition state of a reaction seems to be a commonly observed feature when we go from an ionic ground state to a less ionic transition state. This has been attributed to the increase in the freedom of motion of solvent molecules.[25]

When we descend the periodic table from fluorine to chlorine, to bromine, and then to iodine, the free energy of activation at 10 °C decreases and consequently the rates of topomerization increase in this order. This is reasonable in the sense that a more electronegative halogen causes a stronger N–Sn bond than a less electronegative halogen. However, when we see the ΔH^*'s and ΔS^*'s which are obtained by division of the free energies of activation at various temperatures, we notice that things are not so simple as are expected from the electronegativity. As far as numericals concern, the fluoro compound gives a rather small enthalpy of activation and the bromo and iodo compounds give large enthalpies of activation. The increase in entropy seems to be large in the bromo and iodo compounds relative to the fluoro compound. Since the division of free energy of activation into enthalpy and entropy terms may include errors, we may not be able to get further into insight. However, it is tempting to consider that solvent molecules and/or the stages of the transition state play important roles in determining the activation parameters.

In view of the fact that topomerization by dissociation of an amine ligand in coordination compounds involves a large positive entropy of activation, it is dangerous to compare free energies at different temperatures. In our examples, the fluoro compound gave the smallest $\Delta\nu_{AB}$ (Table 1) among the compounds examined. This will necessarily make the coalescence temperature low. Since the free energy of activation calculated by the coalescence method is a function of T, the low temperature tends to give a small free energy of activation. The smallest free energy of activation in the fluoro compound in a series of silicon compounds[14] may have the origin in this area. Reexamination is awaited.

The data for **4** (R=C_6H_5, X=Cl) suggest that topomerization in this compound is much faster than others: The enthalpy of activation is definitely smaller and the increase in entropy in the transition state seems to be smaller than others. It may be possible to attribute the small ΔH^* to the decrease in acidity of the tin atom due to pπ-dπ interactions but out choice is the steric effect. Firstly, the d orbital which interacts with the 2p orbital of the phenyl group is 5d. This will make the overlap of the orbitals less effective. Secondly, the phenyl group is large. This will make the steric repulsion significant when the coordination bond is formed. The small entropy of activation seems to support the idea, together with the small enthalpy of activation. The steric interactions will make the Sn–N bond long, thus making the Sn–N bond less ionic. The latter factor should contribute to lessen the entropy of activation, because the freedom of motion of solvent molecules in the ground state will be large, relative to a strongly ionic case, if the ionic nature of a bond is weak.

Finally we wish to discuss the steric effects of the alkyl groups on the nitrogen atom. From the chemical shift differences of diastereotopic methyl protons in **1** and coalescence temperature (30 °C), the free energy of activation for topomerization of **1** is calculated as 15.4 kcal/mol. If we calculate the free energy of activation for topomerization of **4** (R=CH_3, X=Br) at the same

temperature, we obtain 14.0 kcal/mol which is much less than the value for **1**. One would argue on the basis of various factors, but we believe this is due to the steric effects (or entropic effects) of the ethyl group. One of the bases on which we postulate the steric effect is a preliminary study on the rates of topomerization of a compound in which one of the ethyl groups in **4** (R=CH_3, X=Br) is replaced by a methyl group. This compound gave free energy of activation of 15.2 kcal/mol at 33.5 °C by the coalescence method. Thus replacing the ethyl group by a small methyl group caused the raise of the activation energy.

So far we have discussed on the dissociation of amine ligands. Although this technique cannot be applied to phosphines and arsines due to their slow inversion rates, there is a possibility that this affords information on the dissociation of sulfur or oxygen ligands. Exchange of oxygen ligands in borane–ether complexes is reported,[26] by looking at the coalescence of ^{19}F signals due to $(CH_3)_2O \cdot BF_3$ and $(C_2H_5)_2O \cdot BF_3$. It might be possible to study the dissociation of their complexes without foreign materials by this technique. There is one point which should be kept in mind, however, when we apply the topomerization technique to the dissociation of oxygen or sulfur ligands. That is to distinguish dissociation from inversion. It is clear that the postulate by Brownstein that he observed inversion of pyramidal oxygen and sulfur[27] should be reexamined. We now plan to extend the technique to these areas.

We wish to thank Professor Haruo Seto and Mr. Kazuo Furihata of Institute of Applied Microbiology, The University of Tokyo, for their technical assistance in measuring the 400 MHz spectra. Our thanks are also due to the Ministry of Education, Science and Culture for a Grant in Aid for Scientific Research which supported this work.

Chemical Effects on the X-ray *K* Emission Spectra of Phosphorus in Organic Compounds

Seiji YASUDA
The Government Industrial Research Institute, Kyushu, Shuku-machi, Tosu-shi, Saga 841
(Received April 21, 1984)

Spectral changes in the P $K\alpha$ and P $K\beta$ X-ray emission lines of solid organic phosphorus compounds were measured with a two-crystal X-ray spectrometer. The P $K\alpha$ line shifted to higher energies with an increasing number of oxygen atoms attached directly to a phosphorus atom. Similar shifts were found in the P $K\alpha$ satellites, which were always 1.5—2.0 times larger than those of the parent $K\alpha$ line. There was no simple correlation for relating the P $K\beta_1$ shift to the phosphorus form. The P $K\beta$ profiles of organic phosphorus seemed to be characterized by the surrounding atoms or groups. The appearance of the $K\beta'$ band offered possible evidence for the existence of phosphorus–oxygen bonding in the samples.

It has been found that the chemical bonding forms of phosphorus affect the wavelenghts, spectral profiles and intensities of the phosphorus X-ray emission lines to a measurable degree.[1-5] These phenomena have received considerable attention from analytical chemists, since they can offer much direct information about phosphorus forms in unknown samples.[6,7] Most of the published work on the spectral changes in the P $K\alpha$ and P $K\beta$ lines has been concentrated on inorganic phosphorus compounds such as phosphides, phosphates and glasses.[8-11] However, so far as organic phosphorus is concerned, there is a lack of the experimental evidence for the chemical shifts and profile changes in the P K emission lines. Only a few measurements on the P $K\beta$ profile changes have been directed to the theoretical interpretation of the phosphorus–ligand bonding in certain organic coordination compounds.[12,13]

In a preceding paper,[14] more reliable data related to the chemical shifts of the sulfur $K\alpha$ and $K\beta$ lines from many organic compounds were shown together with certain regularities in their profile changes. The present paper deals in an analogous way with several solid organic phosphorus compounds. The observed spectral changes are discussed qualitatively with regard to phosphorus bonding forms.

Experimental

The P $K\alpha$ and P $K\beta$ spectra were automatically measured by a step-scanning method at regular intervals of 0.005° or 0.01° 2θ using a Rigaku SX X-ray fluorescence spectrometer equipped with a two-crystal spectrometer. Ge(111) ($2d$= 6.5327 Å) analyzer crystals and a flow proportional counter were used. The primary radiation used for exciting the spectrum was provided by a chromium X-ray tube operated at 50 KV, 35 mA. The 2θ positions of the P $K\alpha$, its satellite and P $K\beta$ lines were determined by averaging the goniometer settings at which the same intensity was measured on either side of the peak at the approximately 90% of the maximum intensity. The values of the chemical shifts of the P $K\alpha$ and P $K\alpha_4$ satellite were determined as an energy difference between a compound and red phosphorus and those of the P $K\beta_1$ were determined in relation to that of Li_3PO_4. At least three independent measurements were made for each compound. The experimental errors were estimated to be nearly 0.01 eV for the P $K\alpha$ shifts and 0.04 eV for the other shifts. Background corrections were made regarding the intensity measurements.

Organic phosphorus compounds used in this study were of the highest commercial grade available. Each sample was prepared by pressing a fine powder into an aluminium ring using a sample preparation kit. All compounds were confirmed by X-ray diffraction or IR analysis.

Results and Discussion

P K$\alpha_{1,2}$ *Spectrum.* The P $K\alpha_1$ and P $K\alpha_2$ emission lines appeared as an unresolved $K\alpha_{1,2}$ doublet under the present experimental conditions. By convention, this doublet is designated as P $K\alpha$ throughout this paper. The P $K\alpha$ width, at half-maximum intensity, was constant at about 1.78 eV in all compounds and red phosphorus. This suggests that the compounds used were not contaminated by significant amounts of phosphorus in a different bonding form. Table 1 lists the data of the P $K\alpha$ chemical shifts of organic phosphorus compounds and some inorganic phosphorus compounds chosen as a difference, together with their P $K\alpha_4$ and P $K\beta_1$ shifts to be discussed below.

TABLE 1. THE CHEMICAL SHIFTS OF THE PHOSPHORUS $K\alpha$ AND $K\beta$ LINES

Compound	Chemical shift/eV		
	$K\alpha$	$K\alpha_4$	$K\beta_1$
P	0	0	+2.36
Ph_3P	+0.02	+0.20	+0.91
Ph_3PO	+0.37	+0.76	+0.43
Ph(H)PO(OH)	+0.47	+0.83	−0.43
$PhPO(OH)_2$	+0.62	+1.03	+0.53
$PhPO(ONa)_2 \cdot xH_2O$	+0.66	+1.06	+0.05
$(PhO)_3PO$	+0.74	+1.16	−0.10
$PhOPO(OH)_2$	+0.78	+1.16	+0.55
$PhOPO(ONa)_2 \cdot xH_2O$	+0.78	+1.19	+0.55
$NO_2PhOPO(ONa)_2 \cdot 6H_2O$	+0.78	+1.19	+0.58
$C_{12}H_{25}OPO(ONa)_2$	+0.78	+1.19	+0.58
$NH_2CONH_2 \cdot H_3PO_4$	+0.78	+1.19	+0.58
$NaPH_2O_2 \cdot H_2O$	+0.46	+0.90	−0.43
$NaPHO_3$	+0.62	+1.03	−0.05
Na_2HPO_4	+0.81	+1.19	+0.24
Li_3PO_4	+0.81	+1.26	0

The P $K\alpha$ line of all compounds investigated here shifted to higher energies than that of red phosphorus. A relatively small shift of +0.02 eV was obtained for triphenylphosphine, Ph_3P. For triphenylphosphine oxide, Ph_3PO (in which one oxygen is attached directly to phosphorus) the P $K\alpha$ line moved +0.37 eV. A further positive shift was observed for phenylphosphinic acid, Ph(H)PO(OH), in which two oxygen atoms are bonded directly to phosphorus. The observed P $K\alpha$ shift of +0.47 eV for this acid agreed closely to that of sodium phosphinate. Phenyl phosphonic acid, $PhPO(OH)_2$, and its disodium salt (with three adjacent oxygen atoms) exhibited P $K\alpha$ shifts of +0.62 and +0.66 eV, respectively. These are almost comparable to that of sodium hydrogenphosphate. Except for triphenyl phosphate, $(PhO)_3PO$, with a P $K\alpha$ shift of +0.74 eV, the remaining organic phosphates gave a constant P $K\alpha$ shift of +0.78 eV. The data were slightly less than those for inorganic phosphates. More recently, Maekawa *et al.*[16] reported a significant difference in the P $K\alpha$ shifts among inorganic phosphates. However, such differences were not found in most organic phosphates of interest here.

From the above results, it is concluded that the P $K\alpha$ line of organic phosphorus compounds is successively shifted to higher energies with an increase in the number of oxygen atoms bonded directly to a phosphorus atom. Therefore, the data on the P $K\alpha$ shifts (listed in Table 1) can be expected to be utilized to analyze phosphorus forms in unknown organic samples.

P $K\alpha_{3,4}$ *Satellite Spectrum.* The P $K\alpha_{3,4}$ group of satellites was observed on the high-energy tails of the parent $K\alpha$ line. Figure 1 shows the spectral profiles of the P $K\alpha_{3,4}$ satellites for several compounds. In every case, three components $K\alpha_4$, $K\alpha_3$, and $K\alpha'$ could be resolved from the high-energy side, but the remaining components, $K\alpha_3'$ and $K\alpha''$, reported in the literature[17,18] were obscure. The intensity of the $K\alpha_4$ or $K\alpha_3$ satellite was approximately 4% of that of the parent $K\alpha$, whereas the $K\alpha'$ satellite was quite low in intensity, and sometimes even ambiguous. Spectral changes related to phosphorus bonding forms were observed in the relative intensities and energy positions of the resolved satellites. The intensity ratio, $K\alpha_4/K\alpha_3$, at each peak position increased slightly with an increasing number of oxygen atoms attached directly to the phosphorus. The ratio changed from nearly 0.57 in Ph_3P to 0.85 in Ph_3PO and to 0.90 in phosphates. A similar trend has been found in the sulfur $K\alpha_{3,4}$ satellites of organic sulfur compounds.[14]

The P $K\alpha_{3,4}$ satellites moved as a group with an almost constant offset of about 2.56 eV between $K\alpha_4$ and $K\alpha_3$ and of about 5.10 eV between $K\alpha_3$ and $K\alpha'$. Therefore, only the P $K\alpha_4$ shift of each compound relative to red phosphorus is shown in Table 1. The direction of the P $K\alpha_4$ shift was quite similar to that of the parent P $K\alpha$ line, while the data of the $K\alpha_4$ shifts were always 1.5—2.0 times larger than those of the P $K\alpha$ line. This result supports the general prediction[17] that the chemical shift of the $K\alpha$ satellites should be much more sensitive to the chemical-bonding forms of elements than is the parent $K\alpha$ line. However, more valuable information about the phosphorus forms than those from P $K\alpha$ shifts could not be obtained from the spectral changes in the P $K\alpha$ satellites.

P $K\beta$ *Spectrum.* The high-resolution P $K\beta$ spectra of organic phosphorus compounds revealed very complex band structures, composed of several strongly overlapping lines caused by transitions involving valence-band electrons.[9] In this study, some attempts were made to reveal possible regularities in the chemical shift of the $K\beta_1$ and in the P $K\beta$ profile changes. The most intense peak in each spectrum was noted to be $K\beta_1$ and additional low-energy bands were noted to be $K\beta_x$ and $K\beta'$. As shown in the last column of Table 1, the observed P $K\beta_1$ chemical shifts of organic phosphorus compounds relative to that of Li_3PO_4

varied from −0.43 eV for Ph(H)PO(H) to +0.91 eV for Ph_3P. However, a simple correlation between the P $K\beta_1$ shifts and the chemical-bonding forms of phosphorus could not be found.

The P $K\beta$ profiles of organic phosphorus varied from compound to compound. Some of them are shown in Figs. 2 and 3. Each spectrum was normalized relative to the maximum intensity of $K\beta_1$. The $K\beta$ profiles of red phosphorus and inorganic phosphorus compounds tested here are almost identical to those reported by Fichter[9]; therefore, they are not shown. The first characteristic feature of the P $K\beta$ profile change was the occurrence of a low-energy band $K\beta'$ in the $K\beta$ spectra involving compounds with phosphorus–oxygen bonding. This band was observed at about 13.5—14.0 eV below $K\beta_1$ and its intensity increased slightly with an increasing number of oxygen atoms attached directly to the phosphorus. Consequently, it seems reasonable to assume that the appearance of the $K\beta'$ band can offer evidence for phosphorus–oxygen bonding. This feature was the only possible regularity obtained in the present study on the P $K\beta$ profile changes of organic phosphorus compounds. Such a feature is also supported by the fact that the $K\beta'$ band disappeared in the $K\beta$ spectra involving red phosphorus and Ph_3P. However, in the $K\beta$ spectrum of Ph_3PO with a phosphorus–oxygen bonding, the $K\beta'$ band became obscure and its $K\beta$ profile was rather closer to that of Ph_3P which exhibited a clearly resolved high-energy band at about 2.6 eV above $K\beta_1$.

The next interesting feature of the P $K\beta$ profile change was the behaviour of the low-energy band $K\beta_x$ adjacent to $K\beta_1$. For phenyl dihydrogenphosphate, $PhOPO(OH)_2$, and $PhPO(OH)_2$, the $K\beta_x$ band was clearly resolved at about 2.7 eV below $K\beta_1$. However, this band was no longer detectable in the $K\beta$ spectra from their disodium salts in which two hydrogen atoms in hydroxyl groups are substituted by two sodium atoms. These salts exhibited a relatively sharp $K\beta_1$ with a nearly symmetrical structure. Similar $K\beta$ profiles were obtained for the other disodium salts such as $NO_2PhOPO(ONa)_2 \cdot 6H_2O$ and $C_{12}H_{25}OPO(ONa)_2$. Such a behaviour of the $K\beta_x$ band suggests that this band may be associated with bonding between phosphorus and a hydroxyl group. This feature was supported by the appearance of a $K\beta_x$ band from urea phosphate, which involves three hydroxyl groups. However, in the $K\beta$ spectrum from Ph(H)PO(OH), which has one hydroxyl group attached to phosphorus, the $K\beta_x$ band was unclear or extremely weak. The high-energy subband $K\beta''$ has been frequently resolved from the $K\beta$ spectra of third-period elements[15] in certain compounds such as sulfites, sulfoxides and chlorates. However, the corresponding $K\beta''$ band was not discernible in the P $K\beta$ spectra of any of the compounds studied here.

The present study does not cover more extensive organic phosphorus compounds and, hence, there is a lack of data for certain forms of organic phosphorus. Consequently, a clear rule for relating the P $K\beta$ profile changes to various phosphorus forms could not be established. However, it seems possible to predict phosphorus forms of unknown samples by a comparison with the P $K\beta$ profiles shown in Figs. 2 and 3.

Stability Constants of Some Bivalent Metal Chelates of 3-Aryl-2,4-pentanedione in 75% v/v 1,4-Dioxane-Water Medium

Yoshito WAKUI, Katsunori YANO, Yoshiharu NAKANO, Kousaburo OHASHI,* and Katsumi YAMAMOTO
Department of Chemistry, Faculty of Science, Ibaraki University, Mito 310
(Received April 19, 1984)

A new ligand, 3-(1-naphthyl)-2,4-pentanedione, was prepared. Concentration proton-dissociation constants of 3-aryl-2,4-pentanedione (aryl group; phenyl, 2,4-dinitrophenyl, and 1-naphthyl) and concentration stability constants of some bivalent metal chelates of 3-aryl-2,4-pentanedione were determined in a 75% v/v 1,4-dioxane-water medium containing 0.05 mol dm^{-3} sodium perchlorate by a pH-titrimetric method. The dissociation constant (pK_a) of 3-(2,4-dinitrophenyl)-2,4-pentanedione, 2,4-pentanedione, 3-phenyl-2,4-pentanedione, and 3-(1-naphthyl)-2,4-pentanedione were found to be 8.87, 10.93, 11.50, and 11.71, respectively. The order of acidity in 2,4-pentanedione was explained by the field effect of the aryl group. The stability constants of the bivalent metal chelates of these ligands were in accord with the Irving-Williams series. The stepwise stability constant of the chelate increased with an increasing pK_a value of 3-aryl-2,4-pentanedione. This result cannot be explained by the steric and solvation effect of an aryl substituent.

There have been a large number of articles describing the preparation of 2,4-pentanedione derivatives, their proton-dissociation[1,2] and partition[3,4] equilibrium constants, stability and partition equilibrium[5] constants of their metal chelates, and solvent extraction[6] of metal ions with 2,4-pentanedione derivatives. The investigations involving metal chelates of 3-substituted 2,4-pentanedione seem to be rare compared to those involving metal chelates of 1-substituted 2,4-pentanedione.

The effect of alkyl substituents at the 1-position of 2,4-pentanedione on the stability constant of a metal chelate has been studied.[1,2] An alkyl substituent lowers the acidity, and the stability constants of copper(II) chelates are generally smaller than expected on the basis of a pK_a–log β (overall stability constant) relationship.

Martin and Martin[7] studied the steric and solvation effect of an alkyl substituent at the 3-position of 2,4-pentanedione on the chelating tendency and found that there was no linear pK_a–log β relationship for bivalent metal chelates of 3-alkyl-2,4-pentanedione. They assert that the effect of an alkyl substituent at the 3-position on the chelating tendency is complicated, and that the solvation effect may be more important than the steric effect.[7]

When methylene-hydrogen of 2,4-pentanedione was substituted with an aryl group, the aromatic ring of an aryl group should adopt a conformation perpendicular to the 2,4-pentanedione ring, and all mesomeric effects of the aromatic ring shold be excluded. The authors' interest lies in clarifying the effect of the aryl group on the proton-dissociation constant and the stability constant of bivalent metal chelates of 3-aryl-2,4-pentanedione.

Experimental

Synthesis of 3-(1-Naphthyl)-2,4-pentanedione. A mixture of 1-naphthylacetonitrile (100 g, 0.60 mol) and ethyl acetate (60 cm^3) was added to a 1-butanol solution of butoxide (sodium metal 7.1 g +1-butanol 100 cm^3) while being stirred. After the reaction mixture was warmed to 80 °C, it was allowed to cool to room temperature while being stirred. The whole mixture became a gray cake. It was dissolved in water and acidified. The oily layer was extracted with ether and the ether was evaporated. A mixture of acetic acid, water, and sulfuric acid (520 cm^3 each) was added to the crude product. The resulting mixture was refluxed for 6 h. Black oil was extracted with ether and crude 1-naphthylacetone was obtained after the usual work-up. 40.5 g (32.4%), bp 115—120 °C /0.1 mm Hg. The 1-naphthylacetone was treated with a mixture of acetic anhydride (55.1 cm^3, 0.59 mol) and a BF_3–acetic acid complex (264 g) at 50 °C for 20 h. To the reaction mixture was added 1100 cm^3 of a sodium acetate solution (about 8%) and the resulting mixture was refluxed for 2 h. A crude product was extracted with ether, transferred to an aqueous sodium hydroxide solution (5%) and then the resultant alkaline solution was acidified with 5 mol dm^{-3} hydrochloric acid. Crude 3-(1-naphthyl)-2,4-pentanedione precipitated was recrystallized from ethanol: Yield 20.0 g (14.7%). It was further chromatographed (Wako gel C-200). mp 105.0—106.5 °C, IR (KBr): 3020, 2930, 1600 cm^{-1}; ^{1}H-NMR ($CDCl_3$, δ): 17.02 (s, 1H), 8.0—7.3 (m, 7H), 1.75 (s, 6H); MS: m/z 226 (parent), 211, 183, 165 (base), 43. Anal ($C_{15}H_{14}O_2$) C,H.

Since the ^{1}H-NMR spectrum showed intramolecular hydrogen-bonded *OH proton equivalent to about one proton* in $CDCl_3$, 3-(1-naphthyl)-2,4-pentanedione should adopt the enol form. The fact that two methyl ring are magnetically equivalent, suggests that an aromatic ring of substituent is perpendicular to the 2,4-pentanedionate ring and 2,4-pentanedione is in equilibrium between the tautomeric isomers at a more rapid rate than NMR time scale.

Materials. 3-(2,4-dinitrophenyl)-2,4-pentanedione was prepared by a method described in the reference,[8] and identified by its melting point, ^{1}H-NMR and IR spectra, and a chemical analysis of carbon, nitrogen, and hydrogen, Reagent-grade 3-phenyl-2,4-pentanedione (Tokyo Kasei Co., Ltd.) was used without purification. Reagent-grade 2,4-pentanedione (Wako Co., Ltd.) was distilled before use. Reagent-grade 1,4-dioxane (Kanto Co., Ltd.) was shaken with solid potassium hydroxide, refluxed with sodium metal for 10 h, and distilled. The distilled 1,4-dioxane was preserved in a nitrogen atmosphere. Sodium perchlorate was recrystallized from an aqueous solution and dissolved in redistilled and decarbonized water. The concentration of the sodium perchlorate solution was determined by the titration of the hydrogen ion concentration after an aliquot of the perchlorate solution was passed through a column of cation-exchange resin in the hydrogen from. The solutions of metal

perchlorate were prepared by converting the metal powder (Mitsuwa Co., Ltd.) to metal perchlorate. Their concentrations were determined by EDTA titration using appropriate indicators. The concentration of the perchloric acid in a metal perchlorate solution was determined by the method similar to that used for the determination of sodium perchlorate.

pH Measurement. The pH measurement was conducted using a Hitachi-Horiba model F-7 type pH meter. A Horiba glass-electrode type 1026-05T was used. A Horiba 2535A-06T type reference electrode, with a double-junction mantle with 3.33 mol dm^{-3} potassium chloride in water and 0.05 mol dm^{-3} sodium perchlorate in 75% v/v 1,4-dioxane-water as an internal solution, was used. The pH meter was standardized using buffer solutions (pH 4.01, 6.86, 10.02 at 25 °C). A fifty-cm^3 portion of 75% v/v 1,4-dioxane-water containing $(1.5—2.0)\times10^{-3}$ mol dm^{-3} metal ion, $(5.0—6.5)\times10^{-3}$ mol dm^{-3} ligand, 0.003 mol dm^{-3} perchloric acid, and 0.05 mol dm^{-3} sodium perchlorate was placed in a 100-cm^3 tall beaker shielded with copper plates and thermostated at 25±0.1 °C. The solution was titrated with 0.02 mol dm^{-3} sodium hydroxide solution containing 0.03 mol dm^{-3} sodium perchlorate. The solution was agitated continuously by passing pure nitrogen. The titration was started 2 h after the electrodes were thermostated in the solution. The response of the electrode was very slow in the 75% v/v 1,4-dioxane-water medium. It took less than 20 min to get a constant reading after each addition of titrant.

Calculation of the Results. A. personal computer (PC 8001 mk II (NEC Co., Ltd.)) was used for the calculatation of the results. N_{80}-basic was used as the language.

Results and Discussion

Determination of pK_a of 3-Aryl-2,4-pentanedione. The concentration of hydrogen ions (pH_c) in 1,4-dioxane-water could not be directly determined from the reading of the pH meter. A potentionmetric titration method modified by Ohtaki[9] was used to find the hydrogen ion concentration in a 75% v/v 1,4-dioxane-water medium. When the concentration of the bulk electrolyte was larger than that of the hydrogen ion concentration, the activity coefficient of the hydrogen ion became constant. The pH_c value can be calculated using the analytical hydrogen ion concentration. The pH_c values are related to the reading of the pH meter, pH_R, by

$$pH_c = pH_R + \Delta pH, \quad (1)$$

ΔpH depending on the concentration of 1,4-dioxane, the ionic strength, *etc.* The ΔpH value obtained using Gran's plot[10] was +0.13±0.04. The electrode worked well enough to obtain the proton-dissociation and stability constants. The concentration of deprotonated 3-aryl-2,4-pentanedione can be given by $a=h-[ClO_4^-]+[Na^+]-K_w h^{-1}$ where h and K_w are the hydrogen ion concentration and the ion product of water in 75% v/v 1,4-dioxane-water medium (3.45×10^{-19})[11] and the proton-dissociation constant can be represented by $K_a=ah/[HL]$. The ratio of $[HL]:[HL]_T$ can be represented as follows:

$$Z = \frac{(C_L - a)}{C_L},$$

where C_L represents the total concentration of 3-aryl-2,4-pentanedione. This ratio was calculated by the hydrogen ion concentration and the proton-dissociation constant as follows:

$$Z = \frac{10^{x+p}}{1+10^{x+p}},$$

where $x=\log h$, $p=\log K_a$ ($\equiv -pK_a$). Normalized curve Z is obtained as follows:

$$Z = \frac{10^x}{1+10^x}. \quad (3)$$

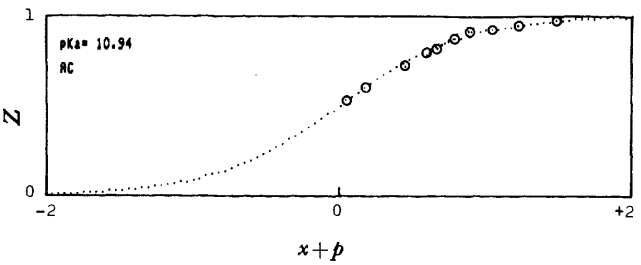

Fig. 1. Determination of pK_a value of 2,4-pentanedione by curve-fitting method (in 75% v/v 1,4-dioxane-water medium containing 0.05 mol dm^{-3} $NaClO_4$, 25 °C). (·····): Normalized curve, (⊙⊙): Experimental data.

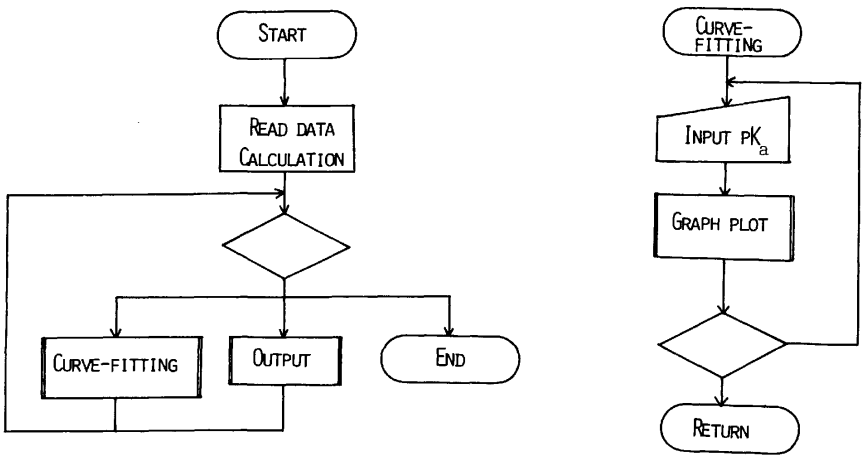

Fig. 2. Block flow chart of program used for dtermination of proton-dissociation constant of 3-aryl-2,4-pentanedione.

A plot of the experimental data Z ($=10^{x+p}/1+10^{x+p}$) was adjusted to coincide with a normalized curve Z until a best fit was obtained. Then, the x value coinciding with $X=0$, $p=-x$ was read. In this work, we attempted to determine the proton-dissociation constant using a program for curve-fitting.[12] The procedure for obtaining the best fit was performed on the display unit of a microcomputer. Fugure 1 shows plots of Z *vs.* $(x+p)$ and a normalized curve of $Z=10X/1+10X$. Thus, the pK_a value of 2,4-pentanedione was obtained to be 10.93±0.08 which is in good agreement with that obtained graphically. Figure 2 represents the block flow chart of the program used for the determination of the proton-dissociation constant of 3-aryl-2,4-pentanedione. The values of pK_a of 3-aryl-2,4-pentanedione are listed in Table 1.

Determination of the Stability Constant. The reaction of the chelate formation of bivalent metal ions with 3-aryl-2,4-pentanedione can be represented by Eqs. 4 and 5:

$$M + L \overset{K_1}{\rightleftharpoons} ML, \tag{4}$$

$$ML + L \overset{K_2}{\rightleftharpoons} ML_2, \tag{5}$$

where K_1 and K_2 represent the stepwise stability constants of 1:1 and 1:2 metal chelates. The average number of 3-aryl-2,4-pentanedione bound per metal ion, Z, is related with K_1 and K_2:

$$Z = \frac{K_1a + 2K_2a^2}{1+K_1a+K_2a}. \tag{6}$$

This formula is derived to

$$Z = \frac{p_2 10^{x+p_1} + 2(10^{x+p_1})^2}{1+p_2 10^{x+p_1} + (10^{x+p_1})^2}, \tag{7}$$

where notations are: $x=\log a$, $p_1=1/2 \log K_2$, $p_2=K_1 \cdot K_2^{-1/2}$. The normalized curve Z is represented as

$$Z = \frac{p_2 10^{X} + 2(10^{X})^2}{1+p_2 10^{X} + (10^{X})^2}. \tag{8}$$

In order to find the required parameters, experimental data Z should be moved along the X axis until the best fit is found. The $\log K_2$ values are then determined by reading $\log a$ at $X=0$. Again the curve-fitting

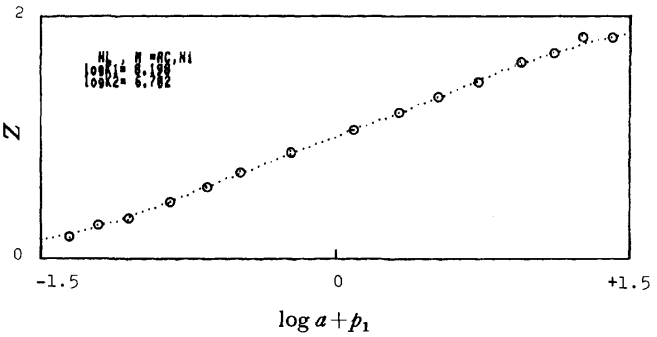

Fig. 3. Determination of concentration stability constant of nickel(II) chelate of 2,4-pentanedione by curve-fitting method (in 75% v/v 1,4-dioxane-water medium containing 0.05 mol dm^{-3} $NaClO_4$, 25 °C). (·····): Normarized curve, (⊙⊙): Experimental data.

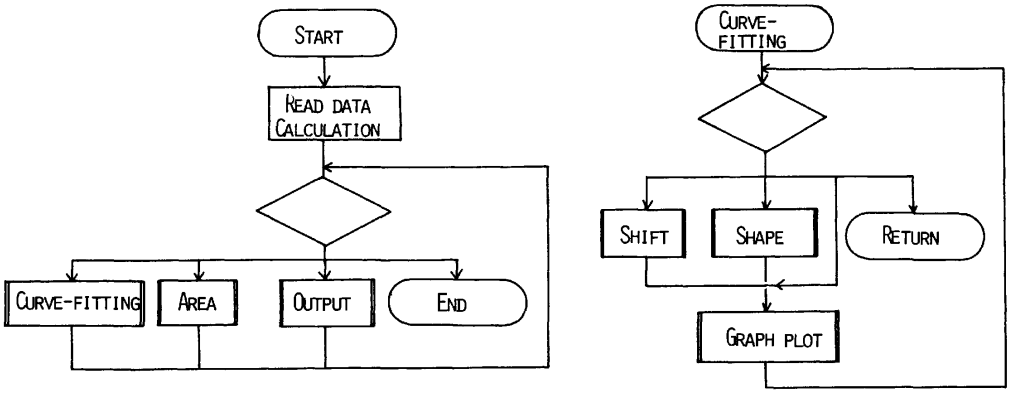

Fig. 4. Block flow chart of program used for determination of stability constant of bivalent metal chelates of 3-aryl-2,4-pentanedione.

Table 1. Concentration proton-dissociation constants and stability constants of some bivalent metal chelates of 3-aryl-2,4-pentanedione (in 75% v/v 1,4-dioxane-water medium, 25 °C)

3-aryl-2,4-pentanedione	pK_a	Co(II)		Ni(II)		Cu(II)		Zn(II)	
		$\log K_1$	$\log K_2$	$\log K_1$	$\log K_2$	$\log K_1$	$\log K_2$	$\log K_1$	$\log K_2$
2,4-pentanedione	10.93	7.8	6.6	8.2	6.7	10.5	9.1	7.6	7.0

was performed on the display unit of a microcomputer. The plot of Z *vs.* log $a+p_1$ is shown in Fig. 3. The obtained values of K_1 and K_2 agreed with those obtained graphically. A block flow chart of the program for the determination of the stepwise stability constants, K_1 and K_2, is shown in Fig. 4.

The thermodynamic proton-dissociation constant (pK_a) of 2,4-pentanedione and stability constant of bivalent metal chelates of 2,4-pentanedione in 75% v/v 1,4-dioxane–water medium, which were obtained by van Uitert and his colaborators,[13] were larger than those obtained in this study. The difference in the results may be ascribed to a difference in experimental conditions. Since the keto-enol tautometric equilibrium of these 3-aryl-2,4-pentanedione in 75% v/v 1,4-dioxane–water is not known, the thermodynamic proton-dissociation and stability constants could not be determined. Manome and Saito[11] found that the pK_a value and the stability constant of the 1:1 bivalent metal chelates of 1,3-diphenyl-1,3-propanedione obtained under almost the same experimental conditions as ours were smaller than thermodynamic data obtained by van Uitert.[13]

The pK_a value of 3-aryl-2,4-pentanedione obtained in the present study increased in the following order: 3-(2,4-dinitrophenyl)-2,4-pentanedione<2,4-pentanedione<3-phenyl-2,4-pentanedione≲3-(1-naphthyl)-2,4-pentanedione. Since the aromatic ring of the substituent should adopt a conformation perpendicular to the 2,4-pentanedione ring, all the mesomeric effect of aryl group may be excluded for these 3-aryl-2,4-pentanedione.

The pK_a values of acetic acid, cyclohexyl acetic acid, and phenyl acetic acid were 4.75, 4.80, and 4.31, respectively.[14] Acidity of these acetic acid derivatives was explained in terms of the inductive effect or the field effect, that is, the interaction between the dipole of the substituent and dissociatable hydrogen through an intervening medium.[14] As mentioned above, there should be no mesomeric effect of 3-aryl group for 3-aryl-2,4-pentanedione. The pK_a value of 3-aryl-2,4-pentanedione and 2,4-pentanedione indicates the order opposit to the case of acetic acid derivatives. Consequently, the order of the acidity of 2,4-pentanedione and 3-aryl-2,4-pentanedione cannot be explained by the inductive effect of an aryl group. For 3-phenyl-2,4-pentanedione and 3-(1-naphthyl)-2,4-pentanedione, the field effect may be an important factor controlling the acidity rather than the inductive effect. Thus, phenyl and naphthyl groups which are rich in π-electrons would be considered to destabilize the conjugate base and decrease the acidity. In the case of 3-(2,4-dinitrophenyl)-2,4-pentanedione having π-electron-withdrawing nitro groups, benzene moiety of 2,4-dinitrophenyl ring may become electron defficient. The positively polarized benzene ring would interact with 2,4-pentanedione moiety. The interaction stabilizes the conjugate base to make the acidity greater than 2,4-pentanedione.

The stepwise stability constants of the 1:1 and 1:2 bivalent metal chelates are in accord with the Irving-Williams series.[15] The relationship between pK_a and

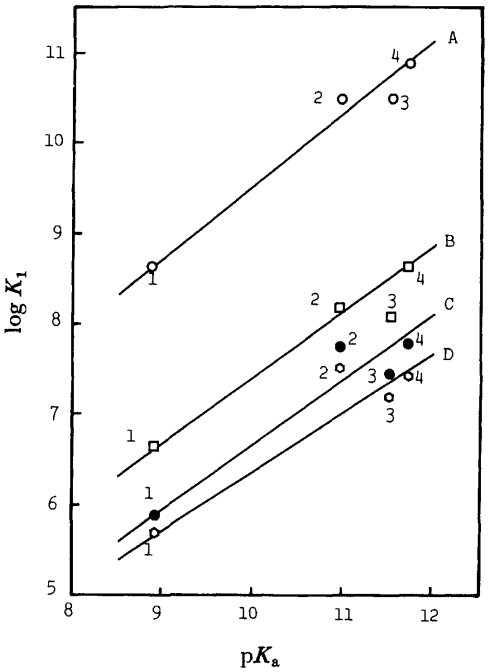

Fig. 5. Variation of log K_1 of bivalent metal chelates as a function of pK_a for 3-aryl-2,4-pentanedione. Metal ion: A, copper(II); B, nickel(II); C, cobalt(II); D, Zinc(II). 3-aryl-2,4-pentanedione: 1) 3-(2,4-dinitrophenyl)-2,4-pentanedione; 2) 2,4-pentanedione; 3) 3-phenyl-2,4-pentanedione; 4) 3-(1-naphthyl)-2,4-pentanedione.

log K_1 for 3-aryl-2,4-pentanedione is shown in Fig. 5, indicating that there is no linear relationship between pK_a and the stability constant, log K_1. However, the stability constant increased with increasing pK_a value of 3-aryl-2,4-pentanedione. Also, a similar result was obtained for the 1:2 metal chelates. The linear relationship between pK_a and the overall stability constant, log β, has been observed for the copper(II) chelates of 2,4-pentanedione derivatives (1,1,1-trifluro-2,4-pentanedione, 2,4-pentanedione, 1-phenyl-1,3-butanedione, and 3-methyl-2,4-pentanedione).[16]

Though the pK_a value of 3-phenyl-2,4-pentanedione was larger than that of 2,4-pentanedione by 0.6, the stability constants of these metal chelates of 3-phenyl-2,4-pentanedione were found to be smaller than those of 2,4-pentanedione or to be of the same magnitude.

The linear pK_a–log β relationship was not observed for copper(II) and other bivalent metal chelates of 3-alkyl-2,4-pentanedione,[3] as mentioned above. The hydrophobic character of the ligand was proposed as one reason for the above results. However, it may be very difficult to clearly explain the effect of a substituent at the 3-position of 2,4-pentanedione on the stability constant at the present stage.

3-(2,4-dinitrophenyl)-2,4-pentanedione can be a useful extractant for metal ions because of the complex formation of metal chelates in an acidic medium and the large hydrophobic character.

The authors wish to thank Dr. Toshitaka Terasaka for his kind and useful advice on data analysis using a

microcomputer.

Solvent-extraction Behavior of Molybdenum(VI) with 1,5-Diphenylcarbazone and the Extraction-spectrophotometric Determination of Molybdenum(VI)

Kousaburo OHASHI,* Kiichiro NAGASHIMA, Rumiko SEITA, and Katsumi YAMAMOTO
Department of Chemistry, Faculty of Science, Ibaraki University, Mito 310
(Received May 7, 1984)

The solvent extraction of molybdenum(VI) with 1,5-diphenylcarbazone (Hdpco) into chloroform, benzene, or tributyl phosphate (tbp) was studied. The molar ratio of molybdenum(VI):1,5-diphenylcarbazone in the complex extracted into chloroform or benzene in the range from 1.0 mol dm^{-3} HNO_3 to pH 1.9 was found to be 1:2. The extracted complex was estimated to be $MoO_2(dpco)_2$. On the other hand, molybdenum(VI) may be extracted into tbp as a mixture of $MoO_2(dpco)_2$ and $MoO_2(dpco)(OH)(tbp)$. The extraction constants, K_{ex} ($=[MoO_2(dpco)_2]_o/[Mo(OH)_6][Hdpco]_o^2$), were determined to be 7.9×10^6 and 3.8×10^8 mol^{-2}dm^6 for chloroform and benzene respectively. A black complex formulated as $MoO_2(dpco)_2\cdot5H_2O$ was formed. Molybdenum(VI) can be determined over the range from 1.50 to 19.0 μg/10 cm^3 within a relative error of ±4%. The interference of diverse ions will be described.

Extraction-spectrophotometric determinations of molybdenum(VI) have been extensively investigated.[1] However, there have been few reports describing a detailed extraction behavior of molybdenum(VI) compared to those of other metal ions because of the diversity of molybdenum(VI) species in an aqueous solution. Molybdenum(VI) was extracted as $MoO_2(tta)_2$ and $HMoO_2(tta)_3$ with 4,4,4-trifluoro-1-(2-thienyl)-1,3-butanedione (tta) from 6.0 mol dm^{-3} hydrochloric acid and 0.05 mol dm^{-3} sulfuric acid solutions respectively.[2] In some cases, molybdenum(VI) is reduced by chelating extractants with a sulfur atom to give a molybdenum(V) complex.[3] Thus, the solvent extraction of molybdenum(VI) is characterized by varied extraction behavior.

1,5-diphenylcarbazone, which has a structure similar to that of 3-mercapto-1,5-diphenylformazan, reacts with a large number of metal ions to form intensively colored complexes. However, because of the poor extractability and instability of the molybdenum(VI)–dpco complex, dpco has not been employed as the extractant for molybdenum(VI). The unstable cadmium(II)- and manganese(II)–dpco complexes in benzene were stabilized by the addition of tbp.[4]

The present work describes the extraction behavior of molybdenum(VI) with Hdpco, the preparation of $MoO_2(dpco)_2$, and the determination of molybdenum(VI).

Experimental

Apparatus. A Hitachi 170-30-type atomic-absorption spectrophotometer was used for the determination of molybdenum(VI). A Hitachi 200-10-type automatic-recording absorption spectrophotometer was used to measure the absorption spectra of molybdenum(VI)–dpco complexes. The pH measurements were made by using a Hitachi-Horiba M-7-type pH meter.

Reagents. *Standard Molybdenum(VI) Solution*: A 0.10-mol dm^{-3} molybdenum(VI) solution was prepared by dissolving 2.419 g of sodium molybdate-water (1/2) (Kanto Co. Ltd.) in 100 cm^3 of a sodium hydroxide solution (pH 9). The working solutions were prepared by diluting the stock solution with redistilled water.

Standard Hdpco Solution: Hdpco (GR. grade, Tokyo Kasei Co., Ltd.) was purified by the method described in the literature.[5] A 1.00×10^{-2}-mol dm^{-3} Hdpco solution was prepared by dissolving 0.240 g of Hdpco in 100 cm^3 of an organic solvent.

Organic Solvent: Chloroform, benzene, and tbp of a reagent grade were purified by distillation and then saturated with redistilled water.

All the other reagents were of a guaranteed reagent quality.

Procedure for the Extraction. A 10-cm^3 portion of a 8.00×10^{-5} mol dm^{-3} molybdenum(VI) solution was placed in a 100-cm^3 separatory funnel. To the solution, 10 cm^3 of a given concentration of Hdpco in an organic solvent was added. The pH of the molybdenum(VI) solution was adjusted with nitric acid. The solutions were vigorously shaken for 60, 30, and 10 min for chloroform, tbp, and benzene respectively. After the phases had been allowed to separate, the pH of the aqueous phase was measured. The pH change was negligibly small during the extraction. The distribution ratio of molybdenum(VI) was determined by measuring the molybdenum(VI) in the aqueous phase .

Preparation of $MoO_2(dpco)_2\cdot5H_2O$. A 400-cm^3 portion of a 0.20-mol dm^{-3} molybdenum(VI) aqueous solution and a 400-cm^3 portion of a 1.0×10^{-2} mol dm^{-3} Hdpco in benzene were placed in a 1-dm^3 separatory funnel. The pH of the molybdenum(VI) solution was adjusted to 2.0 with nitric acid. The solutions were vigorously shaken for 30 min. After the separation, the benzene was distilled out quickly. Black crystals were recrystallized from benzene–heptane (yield, 0.6 g). Found: C, 49.80; N, 17.43; H, 4.20%. Calcd for $MoC_{26}N_8O_7H_{28}$: C, 49.69; N, 17.82; H, 4.49%.

Procedure for the Determination of Molybdenum(VI). A 10-cm^3 portion of a sample solution containing up to 19.0 μg was placed in a 100-cm^3 separatory funnel. To the solution, 10 cm^3 of 3.00×10^{-3} mol dm^{-3} Hdpco in benzene was then added. The pH of the solution was adjusted to 2.0 before placing the molybdenum(VI) solution in the separatory funnel. The solutions were vigorously shaken for 10 min. After the phase separation, the organic phase was transferred to a 10-mm cell. Within 30 min after the separation, the absorbances of the organic phases were measured at 545 nm against a reagent blank obtained in the same way.

Results and Discussion

Extraction of Molybdenum(VI) with Hdpco. Figure 1 represents the effect of the pH on the extraction of 8.00×10^{-5} mol dm^{-3} molybdenum(VI) with $(1-3)\times10^{-3}$ mol dm^{-3} Hdpco into chloroform. The optimum pH range is 2—3. The extractability decreased on both sides of the optimum pH range. Similar results were

obtained for benzene and tbp. For 8.00×10^{-5} mol dm^{-3} molybdenum(VI), the distribution curve of the Mo-$(OH)_6$ species[7] was very similar to these extraction—pH curves.

The proton-dissociation constant (pK_a) of Hdpco in an aqueous solution has been reported to be about 8.[8] Under these experimental conditions, all the species of Hdpco distributed in the aqueous phase should exist in a neutral form. The extraction—pH curve shown in Fig. 1 can not be explained by considering the equilibrium of the proton-dissociation of Hdpco in the aqueous phase. The results obtained indicates that a species of $Mo(OH)_6$ other than the molybdenum(VI) species such as $Mo(OH)_5(H_2O)^+$ and $Mo(OH)_5O^-$ is responsible for the extraction of molybdenum(VI) with Hdpco.

The number of molecules of Hdpco involved in the molybdenum(VI)-dpco complex extracted can be obtained from the slope of a plot of log D *vs.* log $[Hdpco]_0$. The result is shown in Fig. 2. The straight lines with the slope of 2.0 suggest that two molecules of Hdpco are involved in the extraction

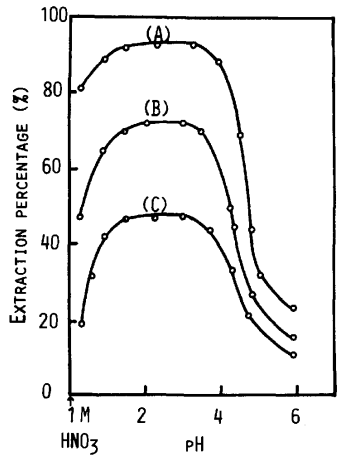

Fig. 1. Effect of pH on extraction of molybdenum(VI) with Hdpco into chloroform.
Mo^{VI}: 8.00×10^{-5} mol dm^{-3}. Hdpco: (A), 3.00×10^{-3} mol dm^{-3}; (B), 2.00×10^{-3} mol dm^{-3}; (C), 1.00×10^{-3} mol dm^{-3}.

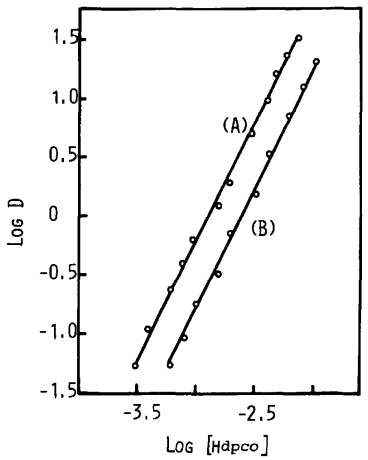

Fig. 2. Relationship between log D and log [Hdpco].

of one molybdenum(VI) atom. Similarly, a straight line with a slope of 2.0 was also obtained for benzene. Thus, the ratio of molybdenum(VI):dpco in the molybdenum(VI)-dpco complex extracted into chloroform and benzene agreed with that of the isolated complex, $MoO_2(dpco)_2$. For tbp, on the other hand, the plots of log D *vs.* log [Hdpco] gave straight lines with a slope between 1.2 and 1.7 over the range from 1.0 mol dm^{-3} HNO_3 to pH 4.3 (Fig. 3). Molybdenum(VI) may be extracted with Hdpco into tbp as a mixture of $MoO_2(dpco)_2$ and $MoO_2(dpco)$-(OH)(tbp).

Absorption Spectra of Molybdenum(VI)-dpco Complex. The absorption maximum of isolated $MoO_2(dpco)_2$ appeared at 545 nm in chloroform, benzene, or tbp. However, the absorption spectra of the molybdenum-

Mo^{VI}: 4.00×10^{-5} mol dm^{-3}. HNO_3: 0.10 mol dm^{-3}; Organic solvent: chloroform. Hdpco: (A) 1.00×10^{-3} mol dm^{-3}; (B) 1.50×10^{-3} mol dm^{-3}; (C) 3.00×10^{-3} mol dm^{-3}.

(VI)-dpco complex extracted into chloroform depended on the (1—3)$\times10^{-3}$ mol dm^{-3} Hdpco concentration (Fig. 4) and also on the pH (Fig. 5). The absorption spectrum of the molybdenum(VI) dpco complex extracted with 2.00×10^{-3} mol dm^{-3} of Hdpco at pH 2.3 gave the three peaks at 470, 500, and 610 nm. The absorption maximum of the molybdenum(VI)-dpco complex extracted with 3.00×10^{-3} mol dm^{-3} of Hdpco into tbp (Fig. 6) and benzene appeared at *ca.* 545 nm. The absorption spectra of the extracted molybdenum-(VI)-dpco complex depended on the organic solvent used. The addition of an excess Hdpco to isolated

Mo^{VI}: 2.00×10^{-5} mol dm^{-3}. Hdpco: 3.00×10^{-3} mol dm^{-3}. pH: (A) 1.9; (B) 0.30 mol dm^{-3} HNO_3; (C) 1.0 mol dm^{-3} HNO_3; (D) 4.4.

$MoO_2(dpco)_2$ in chloroform, benzene, or tbp caused an absorption spectral change, giving spectra similar to those of the molybdenum(VI)-dpco complex extracted with 3.00×10^{-3} mol dm^{-3} of Hdpco. This abnormal absorption spectral behavior probably results from the reaction of the extracted $MoO_2(dpco)_2$ with free Hdpco in the organic phase. The structure and composition of the molybdenum(VI)-dpco complex extracted with a large excess of Hdpco were not ascertained.

In general, molybdenum(VI) complexes of organic ligands involve a *cis*-MoO_2^{2+} structure.[9,10] A *cis*-MoO_2^{2+} structure for $MoO_2(dpco)_2$ may be proposed in spite of the lack of any direct proof supporting a *cis*-structure.

Extraction Constant for the Extraction of $Mo(OH)_6$ with Hdpco. As has been mentioned above, $Mo(OH)_6$ would be a more reactive species toward Hdpco than $Mo(OH)_5(H_2O)^+$ and $Mo(OH)_5O^-$, which exist at pH 2.0. At the optimum pH of 1.9—2.5, molybdenum(VI) is present predominantly as $Mo(OH)_6$.[7] Therefore, the equation which best represents the extraction equilibrium at pH 2.0 is perhaps:

$$Mo(OH)_6 + 2Hdpco \overset{K_{ex}}{\rightleftharpoons} MoO_2(dpco)_2,$$

with the extraction constant:

$$K_{ex} = \frac{[MoO_2(dpco)_2]_o}{[Mo(OH)_6][Hdpco]_o^2},$$

where the subscript o refers to the organic phase. The values of K_{ex} for chloroform and benzene were determined to be 7.9×10^6 and 3.8×10^6 mol^{-2} dm^6, respectively at 20 °C. The value of K_{ex} for benzene was about 50 times that for chloroform. It was also found that the extractability of the molybdenum(VI)-dpco complex into chloroform was better than that into tbp, though the K_{ex} for tbp was not determined.

Back-extraction of Molybdenum(VI)-dpco Complex. The back-extraction of the molybdenum-(VI)-dpco complex extracted into chloroform, benzene, or tbp with aqueous solutions of various pHs was studied by the following procedure. Ten cm^3 of a molybdenum(VI)-dpco complex solution, which had

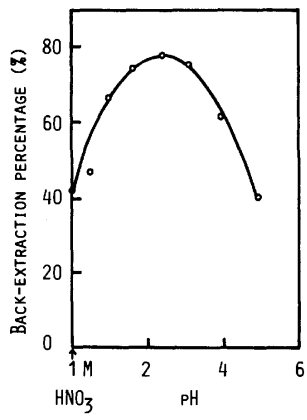

Fig. 7. Effect of pH on back-extraction of molybdenum-(VI)-dpco complex extracted into chloroform.
Mo^{VI}: 8.00×10^{-5} mol dm^{-3}. Hdpco: 2.00×10^{-3} mol dm^{-3}. pH values were adjusted by using nitric acid solution.

been prepared by shaking 8.00×10^{-5} mol dm^{-3} of molybdenum(VI) solution with 2.00×10^{-3} mol dm^{-3} of Hdpco in an organic solvent at pH 1.9, was shaken with 10-cm^3 portions of aqueous solutions of various pHs for 60 min. The results are shown in Fig. 7. The back-extraction–pH curve, was quite similar to that of the forward-extraction–pH curve, indicating that the extraction equilibrium is reversible. For benzene and tbp, similar results were obtained.

Infrared Spectrum of MoO_2(dpco)$_2$. The infrared spectrum of $MoO_2(dpco)_2$ was distinctly different from that of Hdpco. The free Hdpco showed the strong band assigned to the carbon–oxygen vibration at 1705 cm^{-1}. In the case of $MoO_2(dpco)_2$, the band of the carbon–oxygen vibration disappeared completely. The dpco in $MoO_2(dpco)_2$ must be present in the enol configuration. The infrared spectrum of $MoO_2(dpco)_2$ was quite similar to that of $Cr(dpco)(H_2O)_4^{2+}$.[11] The three weak bands at 620, 610, and 595 cm^{-1} for $Cr(dpco)(H_2O)_4^{2+}$ were ascribed to the vibrational chromium–oxygen band.[6] The two weak bands at 600 and 630 cm^{-1} for $MoO_2(dpco)_2$ may be assigned to the vibrational molybdenum–oxygen bands. The molybdenum(V) oxo complexes of 2-methyl-8-quinolinol, $(C_{10}H_8NO)_4Mo_2O_3$, $(C_{10}H_8NO)_2MoO(OH)$, and $(C_{10}H_8NO)_2Mo_2O_4$, showed vibrational molybdenum–oxygen bands at 932—945, 935—945, and 930—945 cm^{-1} respectively.[11] The strong broad band between 900 and 940 cm^{-1} for $MoO_2(dpco)_2$ may be assigned to the molybdenum–oxygen stretching.

Determination of Molybdenum(VI). Molybdenum(VI) was determined based on the foregoing procedure. The method obeyed Beer's law at molybdenum(VI) concentrations from 1.50 to 19.0 μg/10 cm^3, within a relative error of ±4%. The molar extinction coefficient was 5.1×10^4 dm^3 mol cm^{-1} at 545 nm. The effects of various metal ions on the determination of 9.6 μg/10 cm^3 molybdenum(VI) were also examined. The presence of such metal ions as cobalt(II), zinc(II), nickel(II), manganese(II), lead(II), and tungsten(VI) can be tolerated in amounts up to 2.5×10^2 μg/10 cm^3, within a relative error of ±5%. The presence of amounts of iron(III), tin(II), and zirconium(IV) equal to that of molybdenum(VI) can be tolerated below a relative error of 5%. The interference of 20 μg/10 cm^3 of copper(II) can be masked in the presence of 0.01 mol dm^{-3} of sodium hydrogensulfite. The present method was more sensitive than the thiocyanate method[12], the dithiol method[13], the oxinate method[14], and the flavon-3-ol-2′-sulfonate method[10], but less sensitive than the pyrogallol red method[15] and 3,4-dihydroxyazobenzene method.[16]

Preparation, and Thermal and Electronic Properties of Double Complex Salts and Cyanide-bridged Complexes Containing Cationic Copper(II) Complexes and Hexacyanoferrate(II) Ion

Masatatsu SUZUKI and Akira UEHARA*

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received May 26, 1984)

Reaction of copper(II) ion with hexacyanoferrate(II) ion, $[Fe(CN)_6]^{4-}$, in an aqueous solution containing such an amine as en (1,2-ethanediamine), tn (1,3-propanediamine), dien (bis(2-aminoethyl)amine), or dpt (bis(3-aminopropyl)amine), gave two types of complexes: Double complex salts, $[Cu(en \text{ or } tn)_2]_2[Fe(CN)_6]\cdot nH_2O$ (n=5—8), and cyanide-bridged complexes, $[(Cu(dien \text{ or } dpt))_2(NC)_2Fe(CN)_4]\cdot 4H_2O$. The infrared spectra of the complexes in the ν_{CN} region revealed that the complexes, $[(Cu(dien \text{ or } dpt))_2(NC)_2Fe(CN)_4]\cdot 4H_2O$, contain cyanide bridges, while in $[Cu(en \text{ or } tn)_2]_2[Fe(CN)_6]\cdot nH_2O$, no cyanide bridge is present. The thermal reactions of the complexes in the solid state were investigated by means of derivatography under dynamic conditions (D conditions). It was found that dehydration from $[Cu(en)_2]_2[Fe(CN)_6]\cdot nH_2O$ resulted in formation of cyanide bridge in the apical position of square planer $[Cu(en)_2]^{2+}$. For $[(Cu(dien \text{ or } dpt))_2(NC)_2Fe(CN)_4]\cdot 4H_2O$, dehydration resulted in the formation of additional cyanide bridges. All the complexes showed metal to metal (iron(II) to copper(II)) charge-transfer transitions (MMCT) in the near ultraviolet or visible region. The complexes, $[Cu(en \text{ or } tn)_2]_2[Fe(CN)_6]\cdot nH_2O$, exhibited the outer sphere iron(II) to copper(II) charge-transfer bands (OSMMCT) in the near ultra-violet region. $[(Cu(dien \text{ or } dpt))_2(NC)_2Fe(CN)_4]\cdot 4H_2O$ and the dehydrated complexes prepared by thermal reaction showed the inner-sphere iron(II) to copper(II) charge transfer bands (ISMMCT) in the visible region. A good correlation was observed between the energies of the MMCT and the d-d band maxima of copper(II) ions.

Reaction of various metal ions with $[Fe(CN)_6]^{4-}$ forms a series of Prussian Blue type complexes which have cyanide-bridged structure and are polymeric in nature.[1-4] It is also known that $[Fe(CN)_6]^{4-}$ forms cation-anion ion pair with various cationic complexes in solution and they tend to form so called double complex salts or cyanide-bridged complexes which consist of discrete structural units.[5-7] These complexes are of paticular interest in studying the electron-transfer phenomena in the solid state. Unfortunately, no well characterized complex has been known except for those containing cationic Ru^{III} complexes as counter part or counter ion.[5-7] Further studies are needed for advanced elucidation of the solid state electron transfer of metal complexes. In this study, we prepared new double complex salts and cyanide-bridged complexes containing cationic copper(II) complexes and hexacyanoferrate(II) anion, $[Cu(en \text{ or } tn)_2]_2[Fe(CN)_6]\cdot nH_2O$ (n=5—8) and $[(Cu(dien \text{ or } dpt))_2(NC)_2Fe(CN)_4]\cdot 4H_2O$, where en represents 1,2-ethanediamne, tn 1,3-propanediamine, dien bis(2-aminoethyl)amine, and dpt bis(3-aminopropyl)amine. Their structures and electronic properties were investigated by means of infrared and electronic spectroscopies.

Uehara *et al.* demonstrated that the thermal reaction of the double complex salts such as $[(Cr \text{ or } Co)(OH_2)(NH_3)_5][(Cr \text{ or } Co)(CN)_6]$ in the solid state afforded various types of the cyanide-bridged complexes.[8,9] The thermal cyanide-bridging reactions are highly dependent on the nature of the metal ions contained in the cationic and anionic moieties. It is well known that the stereochemistry of the copper(II) complexes is flexible with respect to the coordination number and geometry.[10] Therefore, the solid state thermal reaction of the present double complex salts and cyanide-bridged complexes containing copper(II) ions is also expected to form various types of cyanide-bridged complexes. The thermal cyanide-bridging reaction of the present complexes is also one of the subjects of this study.

Experimental

Preparation of Complexes. *$[Cu(en)_2]_2[Fe(CN)_6]\cdot nH_2O$ (**1a**) (n=5—8).* To a solution of 1 mmol of $K_4[Fe(CN)_6]\cdot 3H_2O$ in 20 cm^3 of water was added a solution containing 2 mmol of $Cu(NO_3)_2\cdot 6H_2O$ and 5 mmol of en in 20 cm^3 of water. To the resulting mixture was added 10 cm^3 of methanol with stirring. The solution was allowed to stand overnight to give violet crystals, which were collected by filtration, washed with cold water, and air-dried. The complex salt contained 5—8 mol of water depending on the experimental conditions. Found: C, 24.95; H, 6.33; N, 29.45%. Calcd for the penta hydrate $C_{14}H_{42}N_{14}O_5Cu_2Fe$ (MW 669.57): C, 25.11; H, 6.32; N, 29.29%.

*$[Cu(tn)_2]_2[Fe(CN)_6]\cdot 5H_2O$ (**2a**).* The complex was prepared in a similar way to that of **1a**. Dark blue crystals were collected by filtration, washed with cold water, and air-dried. Found: C, 29.98; H, 6.92; N, 27.13%. Calcd for $C_{18}H_{50}N_{14}O_5Cu_2Fe$ (MW 725.67): C, 29.79; H, 6.94; N, 27.03%.

*$[(Cu(dien))_2(NC)_2Fe(CN)_4]\cdot 4H_2O$ (**3a**).* To a solution of 1 mmol of $K_4[Fe(CN)_6]\cdot 3H_2O$ in 20 cm^3 of water was added a solution containing 2 mmol of $Cu(NO_3)_2\cdot 6H_2O$ and 2.5 mmol of dien in 20 cm^3 of water. After a few minutes dark green crystals began to appear. The crystals deposited were collected by filtration, washed with cold water, and air-dried. Found: C, 27.08; H, 5.57; N, 27.30%. Calcd for $C_{14}H_{34}N_{12}O_4Cu_2Fe$ (MW 617.48): C, 27.23; H, 5.50; N, 27.23%.

*$[(Cu(dpt))_2(NC)_2Fe(CN)_4]\cdot 4H_2O$ (**4a**).* The complex was prepared in a similar way to that of **3a**. Dark green crystals deposited from an aqueous solution turned blue upon drying in air. Found: C, 32.05; H, 6.02; N, 25.13%. Calcd for $C_{18}H_{42}N_{12}O_4Cu_2Fe$ (MW 673.59): C, 32.09; H, 6.29; N, 24.69%.

Dehydrated Complexes. The dehydrated complexes, **1b**, **3b**, and **4b**, were obtained by heating **1a**, **3a**, and **4a**, respectively, for a given period of time at constant temperature with thermobalance (*vide infra*). Since the dehydrated

complexes were hygroscopic more or less, the measurements were carried out as soon as possible after preparations.

Measurements. The thermal reactions of the complexes were traced under dynamic conditions (D conditions) by using MOM Type-OD-102 Derivatograph. The measurements were carried out under a constant flow of nitrogen gas at heating rate of 2 °C min^{-1}. The electronic spectra in solution and nujol mull were measured with a Jasco UVIDEC 505 UV/VIS recording digital spectrophotometer and those in powder on a Hitachi EPU-2A spectrophotometer. Infrared spectra were obtained by a KBr-disk method with a Jasco A-3 infrared spectrophotometer.

The electronic spectra of **1a**, **2a**, and **4a** in aqueous solution were measured by the addition of 0.1 mol equivalent (against Cu^{II} concentration) of the corresponding amine to suppress the formation of reddish brown colloidal suspension, which is probably $Cu_2[Fe(CN)_6]\cdot nH_2O$. The electronic spectrum of **3a** in an aqueous solution could not be obtained because of its low solubility.

Results and Discussion

Derivatography. The derivatograms of the en complex, **1a**, revealed that the complex contains 5—8 mol of water depending on the preparative conditions. The representative derivatogram of the pentahydrate complex is given in Fig. 1. The TG curve of the complex shows weight loss at 60—100 °C and then a clear plateau is obtained. This weight loss corresponds to evolution of water molecules. The dpt complex, **4a**, also shows a similar behavior to that of **1a**: Four moles of water are evolved at 30—100 °C and then a clear plateau appears. The appearance of the clear plateaus in the TG curves indicates that the dehydrated complexes of **1a** and **4a** are easily obtained by thermal reaction. For the dien complex, **3a**, the evolution of 4 mol of water is seen up to *ca.* 130 °C, immediately followed by a slow successive weight loss. Therefore, it seems difficult to obtain the dehydrated complex in pure state under dynamic conditions. Preliminary experiments, however, showed that the isothermal heating of the complex at 120 °C for 5 h gave considerably pure anhydrous complex, which was used for infrared and electronic spectral measurements. The complicated TG curve of the tn complex, **2a**, suggests that it is difficult to obtain the dehydrated complex. All the complexes decomposed in complicated manners after dehydration. Although the decomposition products could not be characterized, the compounds obtained by heating at 200 °C for 0.5 h still showed the strong ν_{CN} bands at 2080—2040 cm^{-1}, which are indicative of the presence of $[Fe(CN)_6]^{4-}$ moiety.[11] This implies that the decompositions occur in the Cu^{II} moieties, but not in $[Fe(CN)_6]^{4-}$ moiety.

It should be noted that the decompositions of

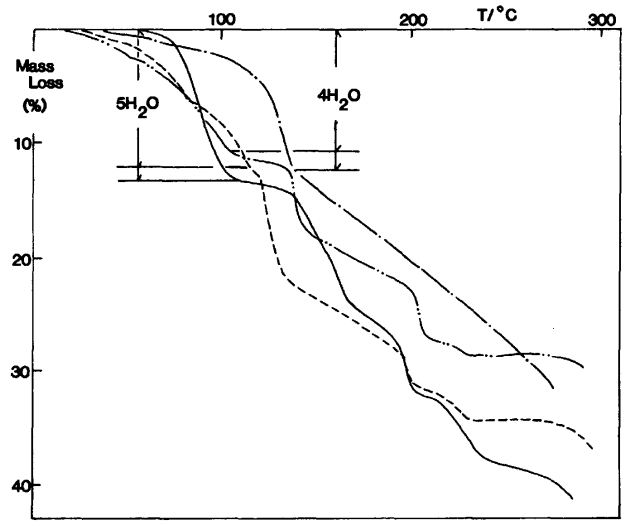

Fig. 1. Derivatograms of $[Cu(en)_2]_2[Fe(CN)_6]\cdot 5H_2O$ (**1a**) (——), $[Cu(tn)_2]_2[Fe(CN)_6]\cdot 5H_2O$ (**2a**) (----), $[(Cu(dien))_2(NC)_2Fe(CN)_4]\cdot 4H_2O$ (**3a**) (—·—), and $[(Cu(dpt))_2(NC)_2Fe(CN)_4]\cdot 4H_2O$ (**4a**) (—··—).

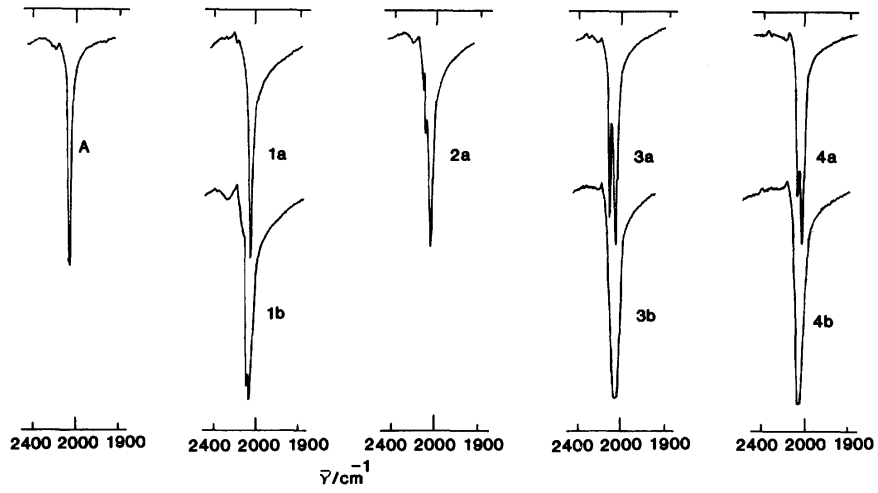

Fig. 2. Infrared spectra of $K_4[Fe(CN)_6]\cdot 3H_2O$ (**A**), $[Cu(en)_2]_2[Fe(CN)_6]\cdot 5H_2O$ (**1a**), dehydrated complex (**1b**) of **1a**, $[Cu(tn)_2]_2[Fe(CN)_6]\cdot 5H_2O$ (**2a**), $[(Cu(dien))_2(NC)_2Fe(CN)_4]\cdot 4H_2O$ (**3a**), dehydrated complex (**3b**) of **3a**, $[(Cu(dpt))_2(NC)_2Fe(CN)_4]\cdot 4H_2O$ (**4a**), and dehydrated complex (**4b**) of **4a**.

$[Cu(en)_2]^{2+}$ and $[Cu(tn)_2]^{2+}$ moieties began to take place at *ca.* 140 °C and 120 °C, respectively. $[Cu(en)_2]SO_4$ and $[Cu(tn)_2]SO_4$ have been shown to be stable up to 250 °C and 200 °C, respectively.[12] It is well known that the thermal stabilities of complexes are highly dependent on the counter ion.[12] Low stabilities of the present complexes may be attributable to an effect of the counter ion, $[Fe(CN)_6]^{4-}$, *i.e.*, it is likely that coordination ability of nitrogen atom of NC-Fe to copper(II) ion is strong enough to weaken the Cu-en and Cu-tn bonds (*vide infra*). This is in line with the fact that the complexes easily decomposed in an aqueous solution to form reddish brown colloidal suspension, which is probably $Cu_2[Fe(CN)_6]\cdot nH_2O$.

$[Cu(en\ or\ tn)_2]_2[Fe(CN)_6]\cdot nH_2O$. The infrared spectrum of $[Cu(en)_2]_2[Fe(CN)_6]\cdot 5H_2O$ is given in Fig. 2. The complex shows a strong ν_{CN} band at 2040 cm^{-1}, which is essentially identical to that of $K_4[Fe(CN)_6]\cdot 3H_2O$. This clearly indicates that no significant interaction is present between $[Cu(en)_2]^{2+}$ and $[Fe(CN)_6]^{4-}$ moieties, and the complex can be formulated as double complex salt, $[Cu(en)_2]_2[Fe(CN)_6]\cdot 5H_2O$. The electronic spectrum of the complex in the solid state exhibits a band at 18300 cm^{-1} and a shoulder at *ca.* 25000 cm^{-1} (Fig. 3). The former band is assigned to the d-d transitions of $[Cu(en)_2]^{2+}$ moiety. A shoulder at *ca.* 25000 cm^{-1} is not observed in the electronic spectra of the individual complexes, $[Cu(en)_2]^{2+}$ and $[Fe(CN)_6]^{4-}$. Therefore, this shoulder can be assigned to the outer sphere metal to meal (iron(II) to copper(II)) charge transfer transition (OSMMCT). The electronic spectrum in water (*ca.* 5×10^{-3} M. (1 M=1 mol dm^{-3})) exhibits two bands at 17800 cm^{-1} and 31200 cm^{-1} with a very small shoulder at *ca.* 24000 cm^{-1} (Fig. 3). The two bands are due to the d-d transitions of $[Cu(en)_2]^{2+}$ and $[Fe(CN)_6]^{4-}$, respectively. The very small shoulder at *ca.* 24000 cm^{-1} is assigned to OSMMCT. Such low intensity of the shoulder is ascribed to the low ion pair formation under the experimental conditions and to the low oscillator strength expected for the OSMMCT.[13]

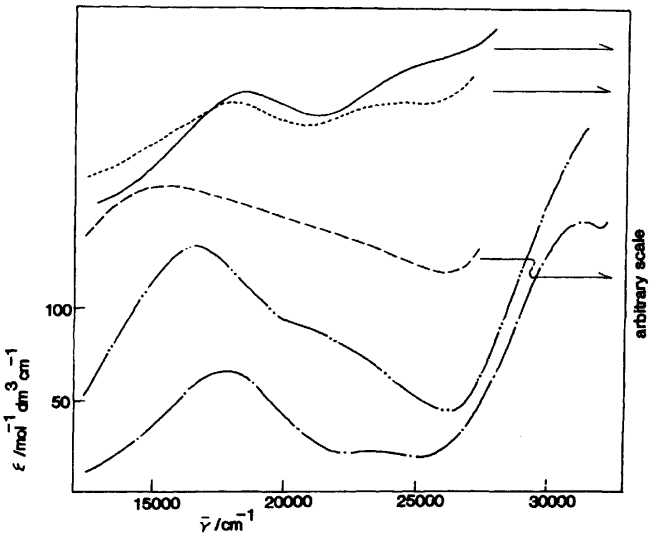

Fig. 3. Nujol mull spectra of $[Cu(en)_2]_2[Fe(CN)_6]\cdot 5H_2O$ (**1a**) (——), dehydrated complex (**1b**) of **1a** (·····), and $[Cu(tn)_2]_2[Fe(CN)_6]\cdot 5H_2O$ (**2a**) (----), and absorption spectra of $[Cu(en)_2]_2[Fe(CN)_6]\cdot 5H_2O$ (**1a**) (—·—) and $[Cu(tn)_2]_2[Fe(CN)_6]\cdot 5H_2O$ (**2a**) (—···—) in water.

As was mentioned before, 5 mol of water of **1a** is evolved at 60—100 °C in the solid state. During the dehydration process, the original violet complex turned blue. The dehydrated complex, **1b**, shows two ν_{CN} bands at 2065 cm^{-1} and 2040 cm^{-1} (main band) (Fig. 2). It is well known that if the M-CN group forms a M-CN-M′ type bridge, ν_{CN} shifts in a higher wave number region.[14] Thus in the dehydrated complex, Fe-CN-Cu type bridge is formed, *i.e.*, nitrogen atom of NC-Fe coordinates to the apical position of square planer $[Cu(en)_2]^{2+}$. At the present stage, however, it is not clear whether the cyanide bridges are formed in both of $[Cu(en)_2]^{2+}$ ions. A coordination to the apical position of square planer copper(II) complex has been known to be weak and termed as "semi-coordination".[15] A splitting of ν_{CN} band of the dehydrated complex, **1b**, (*ca.* 25 cm^{-1}) is much smaller than that of the dien complex, **3a**, (*ca.* 60 cm^{-1}). This smaller splitting of ν_{CN} band of **1b** may be interpreted in terms of a weaker coordination of nitrogen atom of NC-Fe to copper(II) ion (*vide infra*).

The dehydrated complex, **1b**, shows two bands at 17700 cm^{-1} and 23800 cm^{-1} in the solid state (Fig. 3). The former band is assigned to the d-d transitions of $[Cu(en)_2]^{2+}$ and the latter is ascribed to inner sphere MMCT (ISMMCT). The red shift of the d-d band maximum of Cu^{II} moiety in the dehydrated complex also supports a coordination of nitrogen atom of NC-Fe to the apical position of $[Cu(en)_2]^{2+}$. Hathaway *et al.* studied the electronic spectra of various $[Cu(en)_2]X_2$ type complexes (X=Cl^-, Br^-, NO_3^-, *etc.*).[16] The energies of the d-d band maxima of the complexes have been shown to be highly dependent on the degree of interaction between X and $[Cu(en)_2]^{2+}$ in the apical position. The energy of the band maximum of the hydrated complex, **1a**, is comparable to that of $[Cu(en)_2](NO_3)_2$, where NO_3^- ions weakly coordinate to the square planer $[Cu(en)_2]^{2+}$ in the apical position. Thus it is probable that in the hydrated complex, semi-coordination of water molecules to $[Cu(en)_2]^{2+}$ in the apical position is present. During the dehydration process, water molecules coordinated are removed and subsequently nitrogen atom of NC-Fe comes into the apical position of $[Cu(en)_2]^{2+}$. The observed red shift of the d-d band maximum of $[Cu(en)_2]^{2+}$ moiety upon semi-coordination of nitrogen atom of NC-Fe implies that the ligand field strength of nitrogen atom of NC-Fe is stronger than that of H_2O. A color change from violet to blue was also observed in the solid **1a** on standing it for several days at room temperature without weight loss. This fact suggests that the coordination ability of nitrogen atom of NC-Fe is stronger than that of H_2O.

The tn complex, **2a**, shows a strong ν_{CN} band at 2040 cm^{-1} with two small bands at 2150 and 2080 cm^{-1} (Fig. 2). The small bands may be ascribed not to cya-

nide bridge, but to lower symmetry of $[Fe(CN)_6]^{4-}$ moiety in the crystals. Therefore, we believe that no significant interaction between $[Cu(tn)_2]^{2+}$ and $[Fe(CN)_6]^{4-}$ moieties is present and the complex can be formulated as double complex salt, $[Cu(tn)_2]_2[Fe(CN)_6]\cdot 5H_2O$. The electronic spectrum of the complex in the solid state exhibits a very broad band in the visible region, which may be due to an overlapping of the d-d band of $[Cu(tn)_2]^{2+}$ and OSMMCT (Fig. 3). The position of the OSMMCT is not clear in this complex. On the other hand, the electronic spectrum in an aqueous solution shows the d-d band of $[Cu(tn)_2]^{2+}$ at 16700 cm^{-1} and a shoulder at *ca.* 22000 cm^{-1}, which is assigned to the OSMMCT.

[(Cu(dien or dpt))$_2$(NC)$_2$Fe(CN)$_4$]·4H$_2$O. The dien complex, **3a**, shows a splitting of ν_{CN} band at 2110 and 2050 cm^{-1} (main band), indicating the presence of cyanide bridge (Fig. 2). A possible structure of this complex is a discrete trinuclear Cu-NC-Fe-CN-Cu structure. The splitting of the ν_{CN} (60 cm^{-1}) is much larger than that of the dehydrated en complex, **1b**. Such a large difference in ν_{CN} splitting between **1b** and **3a** seems to be attributable to a strength of copper(II)-nitrogen bonding (Cu-NC-Fe), *i.e.*, the stronger the Cu-NC bonding, the larger the ν_{CN} splitting. In the case of the en complex, **1b**, nitrogen atom of NC-Fe binds to d_{z^2} orbital of square planar $[Cu(en)_2]^{2+}$ (out of plane bonding), whereas it is possible that in the dien complex, **3a**, nitrogen atom of NC-Fe binds to $d_{x^2-y^2}$ orbital (in plane bonding); the inplane bonding is much stronger than the out of plane bonding.

The complex shows the d-d band maximum of Cu^{II} moiety at 15900 cm^{-1} and the ISMMCT at 22000 cm^{-1} in the solid state (Fig. 4). In general, tridentate ligands such as dien and dpt tend to adopt a meridional form in copper(II) complexes.[17] Although a square planar structure having N_4 (dien and NC-Fe) donor set might be a plausible one, the energy of the d-d band maximum of the complex seems to be low for sqaure planar copper(II) complexes with N_4 (dien and NC-Fe) donor set, and this probably suggests that water molecules coordinate to copper(II) ion to form octahedral or five-coordinate structure. The dehydration from the complex caused a color change from green to blue. For the dehydrated complex, **3b**, the splitting of ν_{CN} disappears and the ν_{CN} band becomes broad (Fig. 2). In the dehydrated complex, two more coordination sites are available for the coordination of NC-Fe; therefore, it is likely that in the dehydrated complex, additional one or two cyanide bridges are formed and the strength of Cu-N (NC-Fe) bondings are not identical, resulting in an observed broadening of ν_{CN} band because of overlapping of various ν_{CN} bands. The complex may be polymeric. The d-d band of Cu^{II} moiety of the dehydrated complex becomes a shoulder and ISMMCT shifts to red (Fig. 4).

The dpt complex, **4a**, exhibits a splitting of ν_{CN} band (2090 and 2050 cm^{-1} (main band)) (Fig. 2). The splitting (*ca.* 40 cm^{-1}) is, however, smaller than that of the dien complex (*ca.* 60 cm^{-1}). This implies that the coordination of NC-Fe to Cu^{II} ion is weaker than that in the dien complex, **3a**, *i.e.*, cyanide bridge seems to occur in the apical position. The dpt complex is soluble in water, whereas the dien complex is insoluble at all. This remarkable difference in solubility may reflect a change in structure. This would be reconciled with the result derived from the above infrared spectra.

The bands at 15300 and 19400 cm^{-1} are ascribed to the d-d transitions of Cu^{II} moiety and the ISMMCT, respectively (Fig. 4). The fact that the dpt complex shows the d-d band in lower energy side than the dien complex is attributable to weaker ligand field strength of dpt than that of dien. In the dehydrated complex, **4b**, the splitting of ν_{CN} also disappears

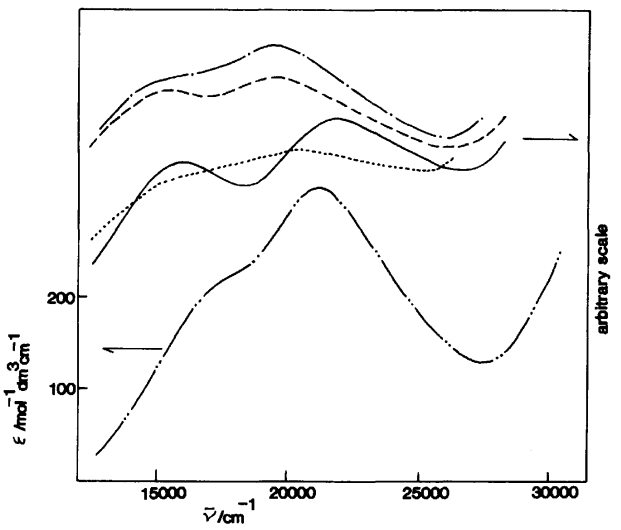

Fig. 4. Nujol mull spectra of $[(Cu(dien))_2(NC)_2Fe(CN)_6]\cdot 4H_2O$ (**3a**) (——), dehydrated complex (**3b**) of **3a** (·····), $[(Cu(dpt))_2(NC)_2Fe(CN)_4]\cdot 4H_2O$ (**4a**) (----), and dehydrated complex (**4b**) of **4a** (—·—), and absorption spectrum $[(Cu(dpt))_2(NC)_2Fe(CN)_4]\cdot 4H_2O$ (—···—) in water.

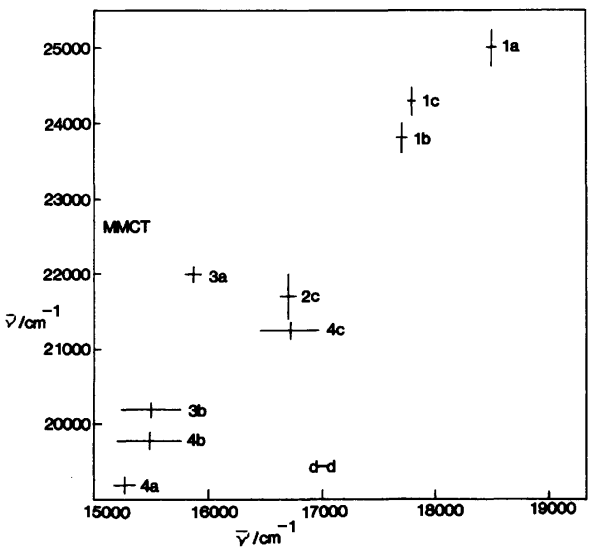

Fig. 5. Correlation between the energies of the d-d band maxima of Cu^{II} moieties and the energies of MMCT.

and the band becomes broad as well as that of the dien complex (Fig. 2). This broadening of ν_{CN} may be also due to the formation of additional cyanide bridges.

The electronic spectrum in an aqueous solution exhibits a strong band at 21300 cm^{-1} with a shoulder at *ca.* 17000 cm^{-1} (Fig. 4). The band at 21300 cm^{-1} is assigned to MMCT. This MMCT band is much more intense than those of the en and tn complexes. This is reasonably interpreted in terms of the presence of Cu-NC-Fe bridge in an aqueous solution as was found in the solid state.

Correlation between MMCT and d-d Transitions. Figure 5 shows a correlation between the energies of MMCT and the d-d band maxima of Cu^{II} moieties. A good correlation is observed. The MMCT of the presnt complexes are assigned to one-electron jump from the t_{2g} orbital of the low spin iron(II) to the $e_g(d_{x^2-y^2})$ orbital of copper(II) ion in octahedral symmetry.[2] Therefore, the energies of the MMCT depend on the energy difference between the $d_{x^2-y^2}$ orbital energy of Cu^{II} ion and t_{2g} orbital energy of Fe^{II} ion. Assuming that the t_{2g} orbital energies of Fe^{II} ions in the present complexes are almost constant, the energies of the MMCT are mainly dependent on the $d_{x^2-y^2}$ orbital energies of Cu^{II} ions; the higher the energy of the d-d band maximum of Cu^{II} moiety, the higher the $d_{x^2-y^2}$ orbital energy and the higher the energy of the MMCT.

Our thanks are due to Prof. R. Tsuchiya for his helpful discussions and encouragement throughout this study.

Dianionocobalt(III) complexes of the $[CoX_2(edpp)_2]^+$-type (X=Cl^-, Br^-, I^-, NCO^-, NCS^-, N_3^-, NO_2^-) have been prepared, where edpp is (2-aminoethyl)diphenylphosphine. The corresponding $[CoX_2(en)(dppe)]^+$ complexes are rather unstable and have been obtained only for X=Cl^-, Br^-, and NCS^-, where en and dppe denote ethylenediamine and 1,2-bis(diphenylphosphino)ethane, respectively. Except for the NCS^- complex of edpp, only one geometrical isomer has been obtained for all the complexes. Two geometrical isomers of $[Co(NCS)_2(edpp)_2]^+$ have been isolated, and crystal structures of *trans*(NCS,NCS),*cis*(P,P)-$[Co(NCS)_2(edpp)_2]Br\cdot 3H_2O\cdot(CH_3)_2CO$ and *cis*(NCS,NCS),*trans*(P,P)-$[Co(NCS)_2(edpp)_2]Br\cdot CH_3OH$ have been determined by X-ray analyses. The NCS^- ions in these complexes coordinate to the cobalt(III) ion through their nitrogen atoms with nearly linear Co-N-C-S fragments. The Co-P distances in the isomers are similar to one another, but the average Co-NH_2 and Co-NCS distances in the *trans*(NCS,NCS) isomer (2.010 and 1.882 Å) are longer and shorter than those of the *cis*(NCS,NCS) isomer (1.970 and 1.960 Å), respectively. Absorption spectra of all the complexes in solution have been recorded and the results compared with those of related dianionocobalt(III) complexes.

In previous papers, we have reported the preparation[1] and molecular structure[2] of *trans*(Cl,Cl),*cis*(P,P)-$[CoCl_2(edpp)_2]^+$ (edpp=$NH_2CH_2CH_2P(C_6H_5)_2$). The complex will be a useful starting material for preparing various bis(edpp) complexes. For example, it easily reacts with chelate ligands such as acetylacetonate or oxalate ions to afford the $[Co(O-O)(edpp)_2]^{n+}$-type complexes.[1] This paper deals with the $[CoX_2(edpp)_2]$-type complexes obtained by reactions of the dichloro complex with various unidentate anions X^-. There are five possible geometrical isomers of $[CoX_2(edpp)_2]^+$. Except for the NCS^- complex, however, only one isomer has been obtained for all of the complexes. For the NCS^- complex, two geometrical isomers have been isolated and the crystals subjected to X-ray structure analysis in order to determine the geometrical configuration as well as the linkage isomerism of the NCS^- ligand. Some structurally related $[CoX_2(en)(dppe)]^+$ complexes (en=$NH_2CH_2CH_2NH_2$, dppe=$(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2$) have been prepared. Absorption spectra of all the complexes have been recorded and the results compared with those of related diacidato cobalt(III) complexes.

Experimental

The edpp ligand was prepared by the literature method,[3] and handled under a nitrogen atmosphere until it formed cobalt(III) complexes. The dppe ligand was purchased from Strem Chemicals Inc. and used as received. Absorption spectra of the complexes were recorded on a Hitachi 323 spectrophotometer.

The starting complexes, *trans*(Cl,Cl)-$[CoCl_2(edpp)_2]ClO_4$, *trans*-$[CoCl_2(en)(dppe)]ClO_4\cdot H_2O$, *trans*-(P,N)-$[CoCO_3(edpp)_2]$-$Cl\cdot 3.5H_2O$, and $[CoCO_3(en)(dppe)]ClO_4$ were prepared by methods reported previously.[1]

trans*(Br,Br)-[CoBr$_2$(edpp)$_2$]Br·2H$_2$O*. To a methanol solution (20 cm³) of *trans*(P,N)-$[CoCO_3(edpp)_2]Cl\cdot 3.5H_2O$ (100 mg) was added 47% HBr (1.0 cm³) at 5 °C. The resulting brown solution turned green on heating at 60 °C, and then was cooled in an ice bath. On addition of a small amount of water yellow-green crystals were precipitated, collected, washed with water and diethyl ether, and air-dried. Yield: 65 mg(55%). Found: C, 42.12; H, 4.30; N, 3.45%. Calcd for $C_{28}H_{36}N_2Br_3CoO_2P_2$: C, 42.40; H, 4.57; N, 3.53%. The complex is soluble in methanol and CH_2Cl_2, but insoluble in water and diethyl ether.

[CoI$_2$(edpp)$_2$]I. A methanol solution (20 cm³) of *trans*(P,N)-$[CoCO_3(edpp)_2]Cl\cdot 3.5H_2O$ (100 mg) was degassed with nitrogen. To the solution was added colorless 57% HI (2.1 g) purified by passing a column of Dowex 1×8 (I^- form) dropwise at room temperature with stirring in an atmosphere of nitrogen. The color of the solution changed from red to brown, and a brown precipitate appeared. After 30 min the precipitate was filtered, washed with water and diethyl ether, and air-dried. Yield: 47 mg(35%). Found: C, 37.45; H, 3.99; N, 2.99%. Calcd for $C_{28}H_{32}N_2I_3CoP_2$: C, 37.44; H, 3.59; N, 3.12%.

cis*(NCS,NCS)-[Co(NCS)$_2$(edpp)$_2$]Cl·H$_2$O and* trans*(NCS,NCS)-[Co(NCS)$_2$(edpp)$_2$]Cl·1/2(NaCl)·H$_2$O*. A methanol solution (300 cm³) containing *trans*(Cl,Cl)-$[CoCl_2(edpp)_2]ClO_4$ (500 mg) and KNCS (200 mg) was stirred overnight at room temperature. The color of the solution slowly changed from green to dark red. The resulting solution was diluted with methanol (200 cm³) and water (1 dm³), and applied on a column (ϕ3 cm×10 cm) of SP-Sephadex C-25. The adsorbed product was eluted with 0.1 mol dm^{-3} NaCl in water–methanol (1:1), and the eluate was evaporated to half of its original volume at 35 °C under reduced pressure. The complex in the concentrate was extracted with CH_2Cl_2, and the extract was evaporated

to dryness under reduced pressure. The residue was dissolved in the minimum amount of benzene–methanol (3:1), and the solution was chromatographed by use of a column (ϕ3 cm×50 cm) of Sephadex LH-20 and an eluent, benzene–methanol (3:1). The column showed two separate bands, the first orange and the second red bands, the complexes in which were determined to have the *cis*(NCS,NCS) and *trans*-(NCS,NCS) structures, respectively, by X-ray structure analysis (*vide infra*). Each eluate of the two bands was evaporated to dryness under reduced pressure, and the complex was dissolved in a small amount of methanol. The solution was mixed with an aqueous NaCl solution and stored in a refrigerator to yield crystals of the chloride of the complex, which were filtered, washed with water, and air-dried. Yield: The *cis*(NCS,NCS) isomer=94 mg(19%), the *trans*(NCS,NCS) isomer=184 mg (35%). Found for the *cis*(NCS,NCS) isomer: C, 52.07; H, 4.67; N, 7.79%. Calcd for $C_{30}H_{34}N_4ClCoOP_2S_2$: C, 52.44; H, 4.98; N, 8.15%. Found for the *trans*(NCS,NCS) isomer: C, 50.21, H, 4.44; N, 7.64%. Calcd for $C_{30}H_{34}N_4Cl_{1.5}CoNa_{0.5}OP_2S_2$: C, 50.30; H, 4.78; N, 7.82%. These complexes are soluble in acetone, alcohols, and CH_2Cl_2, but insoluble in water and diethyl ether.

trans*(NCO,NCO)*-*[Co(NCO)$_2$(edpp)$_2$]Cl·3.5H$_2$O.* This complex was prepared by the same method as that for the NCS^- complex, using *trans*(Cl,Cl)-$[CoCl_2(edpp)_2]ClO_4$ (200 mg) and KNCO (80 mg). A very small orange band assignable to the *cis*(NCO,NCO) isomer was observed in column chromatography, but the complex could not be isolated. Yield: 41 mg(20%). Found: C, 51.37; H, 5.21; N, 7.72%. Calcd for $C_{30}H_{39}N_4ClCoO_{5.5}P_2$: C, 51.47; H, 5.61; N, 8.00%. The complex is purplish red in color, and its solubility is similar to that of the NCS^- complex chloride.

trans*(N$_3$,N$_3$)*-*[Co(N$_3$)$_2$(edpp)$_2$]Cl·NaCl.* A methanol solution (80 cm^3) containing *trans*(Cl,Cl)-$[CoCl_2(edpp)_2]ClO_4$ (100 mg) and NaN_3 (80 mg) was stirred at 50 °C for 1 h. The resulting greenish-brown solution was evaporated to dryness under reduced pressure, and the residue was mixed with water (100 cm^3) to yield a greenish-brown precipitate, which was collected and dissolved in a small amount of methanol. The solution was mixed with an aqueous NaCl solution and allowed to stand to yield a yellow-green crystalline precipitate, which was collected, washed with water and diethyl ether, and air-dried. In column chromatography of the product, no fraction indicative of other isomers was observed. Yield: 45 mg(45%). Found: C, 48.36; H, 4.78; N, 15.82%. Calcd for $C_{28}H_{32}N_8Cl_2CoNaP_2$: C, 48.36; H, 4.64; N, 16.11%. The complex is soluble in methanol and CH_2Cl_2, but insoluble in water and diethyl ether.

trans*(NO$_2$,NO$_2$)*-*[Co(NO$_2$)$_2$(edpp)$_2$]Cl·H$_2$O.* The complex in solution is photosensitive, and the following procedures should be carried out in the dark. A mixture of *trans*-(Cl,Cl)-$[CoCl_2(edpp)_2]ClO_4$ (300 mg) and $NaNO_2$ (160 mg) in methanol (220 cm^3) was stirred at 40 °C for 40 min to give a yellow solution. On further heating at 40 °C for 20 min the solution gave a yellow precipitate, and then Dowex 1×8 in the chloride form (1.0 g) was added to it. The mixture was stirred overnight at room temperature and filtered. The filtrate was diluted with water (1 dm^3), and the solution was applied on a column (ϕ3 cm×40 cm) of SP-Sephadex C-25. By elution with 0.05 mol dm^{-3} NaCl in methanol–water (1:4), a yellow, a very small yellow-orange, and a large brown bands were eluted separately. The eluate of the first yellow band was evaporated to a small volume under reduced pressure. The concentrate was mixed with NaCl and stored in a refrigerator to yield yellow crystals, which were filtered, washed with a small amount of cold water and diethyl ether, and air-dried. Yield: 18 mg (6.2%). Found: C, 50.59; H, 4.96; N, 8.17%. Calcd for $C_{28}H_{34}N_4ClCoO_5P_2$: C, 50.73; H, 5.17; N, 8.45%. The complex is soluble in water, methanol, and ethanol, but insoluble in diethyl ether.

The complex in the second yellow-orange band could not be isolated because of a small amount. The color of the last band became faint during the elution.

trans-*[CoBr$_2$(en)(dppe)]ClO$_4$.* To a methanol solution (15 cm^3) of $[CoCO_3(en)(dppe)]ClO_4$ (100 mg) was added dropwise 47% HBr at 20 °C. The resulting brown solution turned green on warming at 40 °C on a water bath. The green solution was further warmed at 45 °C for 2 min, and then $NaClO_4·H_2O$ (1 g) was added. After cooling to room temperature, the precipitated green crystals were filtered, washed with water, and air-dried. Yield: 44 mg(40%). Found: C, 44.06; H, 4.31; N, 3.56%. Calcd for $C_{28}H_{32}N_2Br_2ClCoO_4P_2$: C, 43.30; H, 4.15; N, 3.56%. The complex is soluble in methanol and CH_2Cl_2, but insoluble in water and diethyl ether.

trans-*[Co(NCS)$_2$(en)(dppe)]Cl·1.5H$_2$O.* This complex was prepared by a method similar to that for the $[Co(NCS)_2(edpp)_2]^+$ complex, using *trans*-$[CoCl_2(en)(dppe)]ClO_4·H_2O$ and KNCS. Yield: 23%. Found: C, 51.93; H, 4.86; N, 7.95%. Calcd for $C_{30}H_{35}N_4ClCoO_{1.5}P_2S_2$: C, 51.77; H, 5.07; N, 8.05%. The complex is red in color and its solubility is similar to that of *trans*(NCS,NCS)-$[Co(NCS)_2(edpp)_2]Cl·1/2(NaCl)·H_2O$. In column chromatography a trace of an orange complex assignable probably to the cis isomer was observed, but it could not be isolated.

Attempts to prepare the $[CoX_2(en)(dppe)]^+$-type complexes with other X^- ions such as I^-, NCO^-, N_3^-, or NO_2^- were all unsuccessful.

a) Diffraction data at 168 K. Unit cell parameters at 292 K are $a=23.232(3)$, $b=17.621(3)$, $c=9.827(2)$ Å, $\beta=105.45(1)°$, $V=3877(1)$ Å^3. b) Diffraction data at 173 K. Unit cell parameters at 293 K are $a=13.194(2)$, $b=14.239(2)$, $c=9.808(1)$ Å, $\alpha=105.15(1)$, $\beta=97.27(1)$, $\gamma=103.66(2)°$, $V=1693.0(5)$ Å^3. c) At 298 K. d) At 293 K. e) The weight (ω) was taken as $\omega=[\sigma_c^2+(0.0151|F_o|)^2]^{-1}$, where σ_c denotes a standard deviation of F_o calculated from counting statistics.

X-Ray Analyses. For X-ray studies, the bromides of *trans*(NCS,NCS)- and *cis*(NCS,NCS)-$[Co(NCS)_2(edpp)_2]^+$ were prepared by methods similar to those for the corresponding chlorides, using KBr instead of NaCl. Single crystals of *trans*(NCS,NCS)-$[Co(NCS)_2(edpp)_2]Br \cdot 3H_2O \cdot (CH_3)_2CO$ (**1**) and *cis*(NCS,NCS)-$[Co(NCS)_2(edpp)_2]Br \cdot CH_3OH$ (**2**) were obtained by recrystallizing the respective bromides from methanol–acetone (1:1) and methanol–water (2:1) solutions, respectively.

Diffraction data were collected on a Rigaku AFC-5 four-

circle diffractometer with use of graphite-monochromatized Mo-$K\alpha$ radiation at 168K for complex **1** and at 173K for complex **2**. The low-temperature measurements were made with an attached Rigaku variable-temperature apparatus based on a cold nitrogen gas stream method. The procedures used for data collections as well as the methods used in the solution and refinement of the structure were standard and have been described previously.[4] The intensity data were corrected for Lorentz-polarization effects and for absorption. Non-hydrogen and hydrogen atoms were refined anisotropically and isotropically, respectively. Pertinent crystallographic data are summarized in Table 1. Tables 2 lists positional parameters for non-hydrogen atoms in complexes **1** and **2**. In complex **2** the bromide ion and the oxygen atom of methanol are disordered and located at two positions with occupancy factors (P) of $P_{Br(A)}$=0.94 and $P_{Br(B)}$=0.06, and $P_{O(A)}$=0.84 and $P_{O(B)}$=0.16, respectively. The F_o-F_c data, final thermal parameters, and hydrogen atomic coordinates are preserved by the Chemical Society of Japan (Document No. 8450).

All the calculations were carried out on a HITAC M-200H computer at the Computer Center of the Institute for Molecular Science with the Universal Computation Program System UNICS III.[5]

Results and Discussion

Structure of trans*(NCS,NCS)*,cis*(P,P)-[Co(NCS)$_2$(edpp)$_2$]Br·3H$_2$O·(CH$_3$)$_2$CO (1) and* cis*(NCS,NCS)*,trans*-(P,P)-[Co(NCS)$_2$(edpp)$_2$]Br·CH$_3$OH (2).* Figures 1 and 2 show stereoviews of the complex cations in **1** and **2**, respectively. The relevant bond lengths and bond angles based on the atomic numbering scheme in these figures are listed in Tables 3 and 4. All the cations have a distorted octahedral coordination with two P and four N atoms, the NCS^- ions coordinating to the cobalt(III) ion through their N atoms.

In complex 1 the complex cation has a *trans*(NCS, NCS),*cis*(P,P) configuration. The two edpp chelate rings adopt a skew (gauche) conformation of $\delta\delta$ or $\lambda\lambda$ chirality (racemic).[6] The same structure has been found for the bis(edpp) moiety of *trans*(Cl,Cl),*cis*(P,P)-[CoCl$_2$(edpp)$_2$][CoCl$_4$]$_{1/2}$,[2] (complex **3**). The orientation of phenyl groups on the P atoms in complex **1** is also very similar to that in complex **3**. The average Co–P distance of 2.270 Å in complex **1** is slightly longer than that in complex **3** (2.255 Å), whereas the average Co–NH_2 distance (2.010 Å) is slightly shorter than that in complex **3** (2.024 Å), although the differences may be less meaningful on the statistical ground. The average P–Co–P angle in complex **1** (103.3°) is also widened as has been seen in complex **3** (103.1°) to alleviate the overcrowding due to bulky substituents on the P atoms. Other structural parameters on the edpp chelate ligand are almost similar to those in complex **3**. The NCS^- ions are almost linear and coordinate to the cobalt(III) ion through their N atoms with a slightly bent structure, the Co–N–C angles ranging from 171.8—176.2°. The Co–NCS distances (1.881, 1.883 Å) are nearly the same as those reported for *trans*-[Co(NCS)$_2${P(OC$_2$H$_5$)$_3$}$_4$]$^+$ (1.838, 1.874 Å) and *trans*-[Co(NCS)$_2$(trien)]$^+$ (1.901, 1.884 Å; trien=triethylenetetramine).[8]

On the other hand, complex **2** has a *cis*(NCS,NCS), *trans*(P,P) structure. The formation of only *trans*(P,P) isomer in *cis*(NCS,NCS)-[Co(NCS)$_2$(edpp)$_2$]$^+$ is rather unusual, since complexes of the [Co(O–O)(edpp)$_2$]$^{n+}$ type, where O–O is a bidentate ligand such as an oxalate or acetylacetonate ion, form always the *trans*(P,N) isomer in the largest abundance among three possible isomers, *trans*(P,P), *trans*(P,N), and *trans*(N,N).[1] The Co–P distances (2.263, 2.275 Å) in complex **2** are nearly the same as those in complex **1** (2.272, 2.268 Å), despite the two trans-labilizing P donor atoms are in the trans positions to each other. On the other hand, the Co–NH_2 distances (1.976, 1.982 Å) are fairly shorter than those in complex **1** (2.003, 2.016 Å) and are nearly the same as those in cobalt(III) diamine complexes such

as $[Co(en)_3]^{3+}$ (1.978 Å).[9] The elongation of Co-NH_2 distance in complex **1** is attributable to trans influence of the P atom.[2,10] The Co-NCS fragment is nearly linear geometry similar to those in complex **1**, but significant differences in bond distance are found between the two isomers. The average Co-N distance in complex **2** (1.960 Å) is longer than that in complex **1** (1.882 Å), whereas the average N-C distance in the former (1.049 Å) is shorter than that in the latter (1.124 Å). No significant difference is found for the C-S distance between complex **1** (1.650 Å) and complex **2** (1.674 Å). The octahedral angles around the cobalt(III) ion in complex **2** are not largely deviated from the right angle (85.3—96.5°). The two edpp chelate rings take δ and λ conformations, and the complex ion can be designated as a *lel·ob* isomer.

Complexes **1** and **2** include acetone and methanol, respectively as organic solvents of crystallization. Such inclusion of organic solvents in crystals has often been found in metal complexes containing bulky organic groups such as -PPh_2. Nonbonded distances in the crystals and stereoviews of the crystal structures are given in the supplementary materials (Document No. 8450).

Preparation and Absorption Spectra of the Complexes. The $[CoX_2(edpp)_2]^+$-type complexes (X=NCO^-, NCS^-, N_3^-, NO_2^-) were obtained by substitution reactions between *trans*(Cl,Cl)-$[CoCl_2(edpp)_2]^+$ and MX (M=Na or K) in methanol. The Br^- and I^- complexes were prepared by treating *trans*(P,N)-$[CoCO_3(edpp)_2]^+$ with HBr and HI, respectively, in order to avoid the contamination of mixed-halogeno complexes. The reaction for the I^- complex was carried out under an atmosphere of nitrogen to prevent oxidation of I^- to I_3^- which forms a quite insoluble salt with $[CoI_2(edpp)_2]^+$. For each complex only one isomer was obtained except for the NCS^- complex. It formed two isomers, *trans*-(NCS,NCS),*cis*(P,P)- and *cis*(NCS,NCS),*trans*(P,P)-isomers as described in the preceeding section. The formation ratio of the two isomers, trans:cis was *ca.* 2:1 under the given experimental conditions. Both isomers in ethanol are stable and do not isomerize even at a boiling point.

Attempts to prepare the corresponding $[CoX_2(en)(dppe)]^+$ complexes were made by procedures similar to those for $[CoX_2(edpp)_2]^+$, using *trans*-$[CoCl_2(en)(dppe)]^+$ and MX (M=Na or K, X=NCO^-, NCS^-, N_3^-, NO_2^-), and $[CoCO_3(en)(dppe)]^+$ and HX (X=Br, I). However, the complexes obtained are only those of Br^-

and NCS^-. No reaction took place between *trans*-$[CoCl_2(en)(dppe)]^+$ and KNCO at room temperature, reactions at higher temperatures or in the presence of large excess of KNCO causing reduction of cobalt(III) to cobalt(II). A dark-geen complex assignable to $[Co(N_3)_2(en)(dppe)]^+$ was yielded by a similar reaction with NaN_3, but the complex decomposed in the course of purification. In the case of the I^- complex, orange-yellow crystals were obtained from the reaction mixture. However, elemental analysis revealed the product to be the composition of $Co(dppe)_2I$. The reaction with $NaNO_2$ resulted in the formation of *trans*-$[Co(NO_2)_2(en)_2]^+$ and $[Co(NO)_2(dppe)]^+$.[11]

Figure 3 shows absorption spectra of $[CoX_2(edpp)_2]^+$ in methanol for X=Cl^- and Br^-, and in CH_2Cl_2 for X=I^-. Spectral data are given in Table 5. The near infrared spectra of the Cl^- and Br^- complexes were obtained in CH_2Cl_2 solutions. The structure of the Cl^- complex has been determined by X-ray analysis to have a *trans*-(Cl,Cl),*cis*(P,P) configuration.[2] Thus the Br^- complex which gives a spectrum similar to that of the Cl^- complex can be assigned to the *trans*(Br,Br),*cis*(P,P) isomer. The bands around 16000 cm^{-1} of these Cl^- and Br^- complexes are assigned to the split component (Ia) of the first d-d absorption band from a comparison with the spectrum of *trans*-$[CoCl_2(en)_2]^+$.[12] The I^- complex shows a broad spectrum with no peak except the band at 10200 cm^{-1} which can be assigned to the spin-forbidden d-d band described below, the spin-allowed, first d-d band being hidden by strong I^- to Co^{III} charge-transfer bands.[13] Thus the structure of this complex can not be assigned unequivocally from the spectrum. No good NMR spectrum of the complex was obtained because of its instability. The infrared spectrum somewhat differs from those of *trans*(X,X)-$[CoX_2(edpp)_2]X$ (X=Cl^-, Br^-). The structure of the I^- complex remains unknown at present.

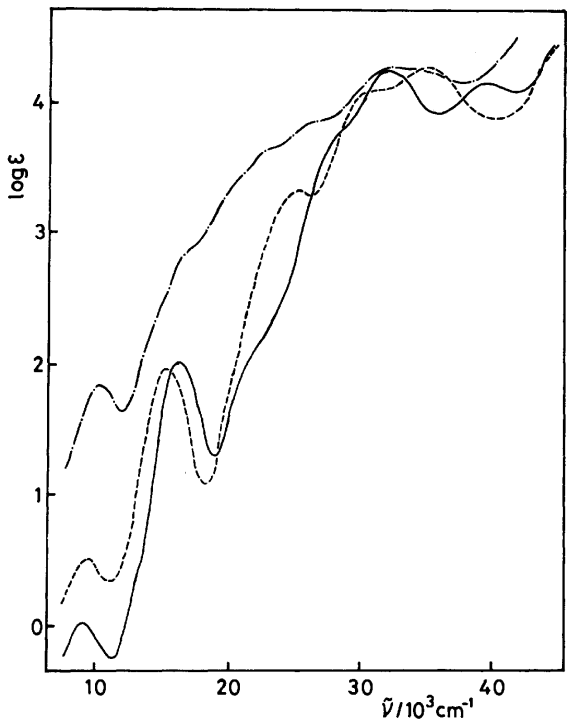

Fig. 3. Absorption spectra of *trans*(X,X)-$[CoX_2(edpp)_2]^+$: X=Cl^- (——), Br^- (----), and I^- (—·—).

All of the halogen complexes of edpp show a distinct band around 10000 cm^{-1}. The peak positions are not much different among the complexes, and the band intensities increase in the order of the Cl^-<Br^-<I^- complexes. These features are similar to those of the spin-forbidden d-d bands in the series of cobalt(III) halogeno complexes such as $[CoX(NH_3)_5]^{2+}$ (*ca.* 11000 cm^{-1})[14] or $[CoX(CN)_5]^{3-}$ (*ca.* 20000 cm^{-1}).[15] Thus the bands around 10000 cm^{-1} in the present halogeno complexes can be assigned to the spin-forbidden d-d band. The yellow-green $[CoBr_2(en)(dppe)]^+$ complex is assigned to the trans isomer, since the spectrum quite resembles that of *trans*-$[CoCl_2(en)(dppe)]^+$[1] as shown in Fig. 4. The corresponding X^- complexes of dppe and edpp show spectra similar to each other.

In Fig. 5 are compared absorption spectra of *trans*-(NCS,NCS),*cis*(P,P)- and *cis*(NCS,NCS),*trans*(P,P)-$[Co(NCS)_2(edpp)_2]^+$ and $[Co(NCS)_2(en)(dppe)]^+$ in methanol solutions. The spectrum of the dppe complex is very similar to that of the *trans*(NCS,NCS),*cis*-(P,P) isomer of the edpp complex, and the complex can be assigned to the trans isomer. The first d-d band of the *cis*(NCS,NCS),*trans*(P,P) isomer is observed as a shoulder absorption at *ca.* 20000 cm^{-1}. The shoulder

* Shoulder absorption

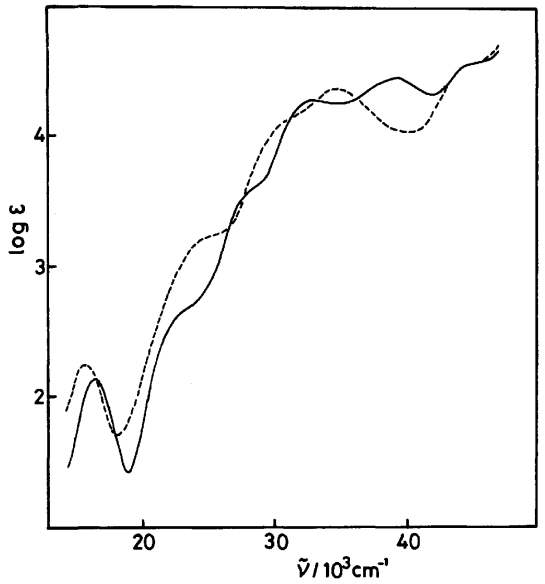

Fig. 4. Absorption spectra of *trans*-$[CoX_2(en)(dppe)]^+$: X=Cl^- (——), and Br^- (----).

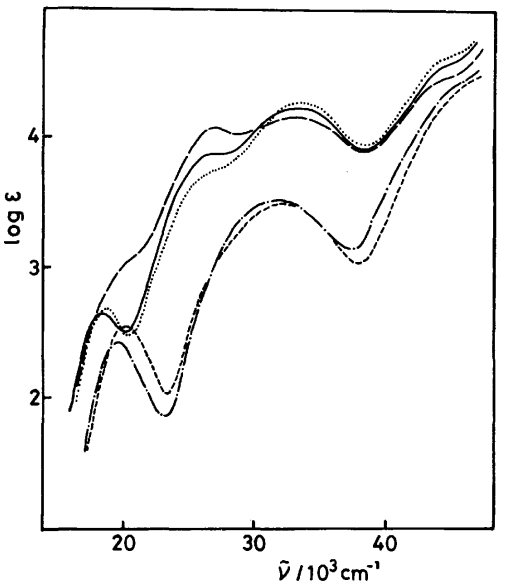

Fig. 5. Absorption spectra of bis(isothiocyanato) complexes: *trans*(NCS, NCS), *cis*(P,P)-$[Co(NCS)_2(edpp)_2]^+$ (——), *cis*(NCS, NCS), *trans*(P,P)-$[Co(NCS)_2(edpp)_2]^+$ (— —), *trans*-$[Co(NCS)_2(en)(dppe)]^+$ (……), *trans*-$[Co(NCS)_2(en)_2]^+$ (—·—), and *cis*-$[Co(NCS)_2(en)_2]^+$ (----).

lies in the high energy side and its intensity is fairly strong as compared with the first d-d band of the *trans*-(NCS,NCS),*cis*(P,P) isomer. A similar spectral difference has been reported between the first d-d bands of *cis*- and *trans*-$[Co(NCS)_2(en)_2]^+$ (cis isomer: 20400 cm^{-1}, log ε=2.54; trans isomer: 19700 cm^{-1}, log ε=2.44).[16] However, the difference in band intensity between the two isomers of the edpp complex is remarkable. The strong intensity of the cis isomer may be attributable to the *trans*(P,P) configuration involved in this isomer, since *trans*(P,P)-$[Co(C_2O_4)(edpp)_2]^+$ shows the first d-d

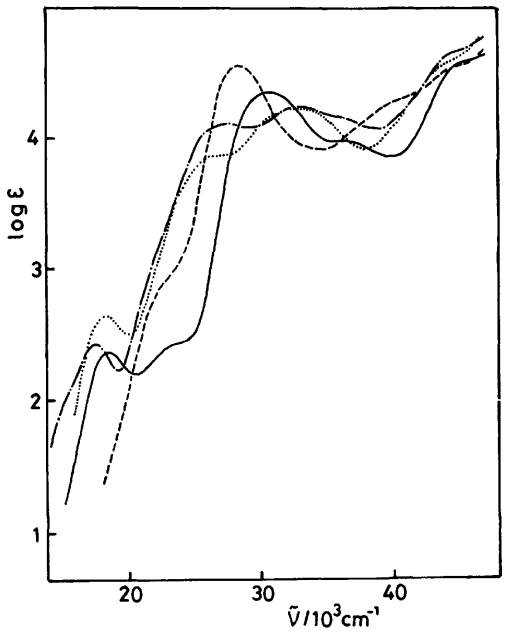

Fig. 6. Absorption spectra of $[CoX_2(edpp)_2]^+$: X= NCO^- (——), N_3^- (—·—), NO_2^- (----), and NCS^- (……).

band (20400 cm^{-1}, log ε=3.08) much stronger than that of the corresponding *trans*(P,N) isomer (20000 cm^{-1}, log ε=2.54).[1]

Figure 6 compares absorption spectra of $[CoX_2(edpp)_2]^+$ (X=NCO^-, N_3^-, and NO_2^-) in methanol solutions with that of *trans*(NCS,NCS),cis(P,P)-$[Co(NCS)_2(edpp)_2]^+$. At present, we can not assign geometrical structures of the complexes unequivocally on the basis of these spectra. In column chromatography using SP-Sephadex C-25 or Sephadex LH-20, however, any fractions of each of these complexes did not show optical activity, while *cis*(NCS,NCS),*trans*(P,P)-$[Co(NCS)_2(edpp)_2]^+$ was partially resolved by similar chromatography. Further, complexes of the $[CoX_2(edpp)_2]^+$ type seem to be more stable in the *trans*(X,X) isomer than the *cis*(X,X) one as exemplified by the formation ratio of the NCS^- complex. On the basis of these facts, all the complexes in Fig. 6 may be assigned to the *trans*(X,X) isomer. That the first d-d band of the N_3^- complex is at lower energy than that of the NCS^- complex is consistent with the ranking of N_3^- in the spectrochemical series.[17] The d-d band positions of the NCO^- and NO_2^- complexes clearly indicate the isocyanato and nitro coordination modes, respectively. The observed shoulder at *ca.* 24000 cm^{-1} in the NCO^- complex may be assigned to the second d-d band, although the energy separation between this shoulder and the first band is rather small. In general, the separation between the first and second d-d bands in cobalt(III) phosphine complexes has been reported to become small.[18] The intensities of d-d bands of the NCO^- and N_3^- complexes are not so strong as that of *cis*(NCS,NCS),*trans*(P,P)-$[Co(NCS)_2(edpp)_2]^+$. Thus the complexes will have the *trans*(X,X),*cis*(P,P) configuration. The NO_2^- complex shows the first absorp-

tion band with fairly strong intensity, and the spectral pattern in this band region resembles that of *cis*(NCS, NCS),*trans*(P,P)-[Co(NCS)$_2$(edpp)$_2$]$^+$, indicating the *trans*(NO$_2$,NO$_2$),*trans*(P,P) configuration. Examination of molecular models indicates that the NO_2^- ligands in the *trans*(NO$_2$,NO$_2$),*cis*(P,P) configuration cause a big hindrance with the phenyl groups, while such a hindrance is much reduced in the *trans*(NO$_2$, NO$_2$),*trans*(P,P) configuration. In fact, the [CoX$_2$(en)-(dppe)]$^+$- and [CoX$_2$(dpee)$_2$]$^+$-type complexes (dpee= *cis*-1,2-bis(diphenylphosphino)ethylene)[19], where the PPh$_2$ groups are in the cis positions, do not form stable complexes with NO_2^- ions.

For a given X$^-$ ligand, the first d-d band of *trans*-(X,X)-[CoX$_2$(edpp)$_2$]$^+$ is observed at slightly lower energy than that of *trans*(X,X)-[CoX$_2$(en)(dppe)]$^+$ (X= Cl$^-$, Br$^-$, NCS$^-$), and at similar energy to that of *trans*-(X,X)-[CoX$_2$(dpee)$_2$]$^+$ (X=Cl$^-$, Br$^-$, NCO$^-$, N$_3^-$).[19] The NCS$^-$ complex of dpee is reported to show the band at anomalously low energy (16800 cm^{-1}).[19] The corresponding *trans*(X,X)-[CoX$_2$(en)$_2$]$^+$ complex gives the first d-d band at the highest energy among these edpp, dppe, and dpee complexes.

In the ultraviolet region, the present phosphine complexes exhibit strong absorption bands due to charge-transfer transitions between the X$^-$, PPh$_2$, and NH$_2$ groups and cobalt(III). In order to assign properly these spectra, more spectral data will be needed.

(Received May 21, 1984)

Lanthanoid complexes with 1-*l*-menthyloxy-3-benzoylacetone, [Ln(*l*-moba)$_3$(H$_2$O)$_n$] (Ln=La, Pr, Nd, Eu, Dy, Ho, Tm; n=0, 1, or 2), have been synthesized and characterized by elemental analyses, molecular weight determinations, and electronic, circular dichroism, and luminescence spectra. The molecular weight determinations suggest that the complexes are in a monomer-dimer equilibrium in nondonating solvents while they are monomeric in donating solvents. The complexes exhibit fairly intense circular dichroisms at the f-f band region, demonstrating the stereoselective formation of an enantiomer. The stereoselectivities have been discussed in terms of the intramolecular interligand CH/π-interaction operating between the phenyl and the menthyl groups of the ligands. [Eu(*l*-moba)$_3$(H$_2$O)] shows luminescence at the $^5D_0 \rightarrow {}^7F_1$ and $^5D_0 \rightarrow {}^7F_2$ transitions in benzene. Based on the concentration dependence of the luminescence, it is demonstrated that dimerization facilitates nonradiative relaxation and greatly reduces the quantum efficiency of luminescence.

Lanthanoid complexes with 1,3-diketones have been the subject of current studies because of the utility in NMR spectroscopy as shift reagents[2] and the interest in photoluminescence.[3,4] Recently much attention has been paid to the lanthanoid complexes with chiral 1,3-diketones in connection with the chirality recognition of enantiomers[5,6] and stereoselectivity of the complexes.[7] It is known, however, that the lanthanoid complexes with 1,3-diketones derived from *d*-camphor exhibit no optical activity in the f-f transition region.[8] This is probably due to the absence of the interligand interaction within a molecule because of the larger ionic radius of the lanthanoid ions.

In the previous paper of this series,[9] we reported that tris(1-*l*-menthyloxy-3-benzoylacetonato)M(III) complexes, [M(*l*-moba)$_3$] (M=Co, Cr, Mn) (Fig. 1), prefer a *cis*-Δ-configuration. The stereoselectivity was attributed to an intramolecular interligand CH/π-interaction between the *l*-menthyl and the phenyl residues of the ligand (Fig. 2). Similar stereoselectivities were also observed for tris(1-*l*-menthyloxy-3-acetylacetonato)M(III) [M(*l*-moac)$_3$] (M=Co, Cr)[10] and tris{1-*l*-methyloxy-3-(2-naphthoxyl)acetonato}M(III) [M(*l*-mona)$_3$] (M=Co, Cr, Mn).[11] It is particularly noteworthy that [Mn(*l*-moba)$_3$] and [Mn(*l*-mona)$_3$] are readily obtained as an optically active form without any effort to resolution, though tris(1,3-diketonato)manganese(III) complexes have been believed to be hardly resolved owing to the lability of manganese(III) for ligand substitution.[12] These findings prompted us to synthesize the lanthanoid complexes with *l*-moba$^-$ and study their property and stereochemistry to see the effect of the intramolecular interligand CH/π-interaction.

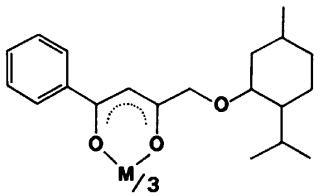

Fig. 1. Chemical structure of [M(*l*-moba)$_3$].

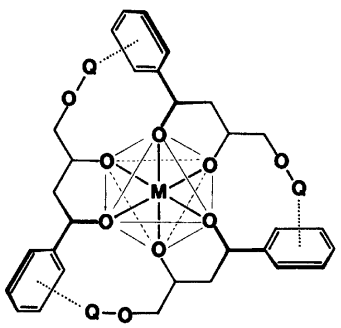

Fig. 2. Schematical representation of interligand CH/π-interaction supposed for [M(*l*-moba)$_3$] (Q=*l*-menthyl).

Experimental

Syntheses. Synthetic method of H(*l*-moba) was described in the preceding paper.[9] The lanthanoid complexes were obtained in a similar way. The procedure is exemplified by Eu^{III} complex. H(*l*-moba) (1.0 g) and NaOH (0.133 g) were dissolved in ethanol (10 cm^3). To this solution was added an ethanolic solution of EuCl$_3$·6H$_2$O (0.40 g), and the mixture was stirred for a few minutes and filtered. To the filtrate were added water (50 cm^3) and ether (100 cm^3), and the mixture was vigorously shaken. The ether layer was separated, shaken three times with water, and dried over sodium sulfate. On evaporating the solvent at room temperature, a yellow precipitate was obtained. It was collected and dried *in vacuo* over phosphorus pentaoxide.

Elemental analyses of the complexes thus prepared are given in Table 1.

Physical Measurements. Molecular weights were determined with a Hitachi Perkin-Elmer 115 Molecular Weight Apparatus in benzene and in ethanol. Electronic spectra were measured on a Shimadzu UV-visible Recording Spectrometer Model UV-240 in benzene. Circular dichroism spectra were recorded on a JASCO J-500C Spectropolarimeter in benzene. Luminescence spectra were recorded on a Hitachi Fluorescence Spectrophotometer in benzene with the excitation at 392.5 nm. The elemental analyses were carried out at

Results and Discussion

The lanthanoid(III) complexes of *l*-moba$^-$ were isolated as anhydrates, monohydrates, or dihydrate. The complexes of the first half of the lanthanoid series formed hydrates while the complexes of the latter half of the series formed anhydrates. This trend may be rationalized in terms of the lanthanoid contraction. That is, it is likely that in the complexes of the smaller metal ions the crowding of the hydrophobic residues of the ligand around the metal acts as an insulating sheath which interferes with the hydration, while such a steric effect is not so large as to hinder the hydration in the complexes with the large metal ions.

In donating solvents tris(1,3-diketonato) lanthanoid(III) complexes readily expand their coordination number from six to seven, eight, or nine by linking solvent molecules. In nondonating solvents, the complexes tend to dimerize (or polymerize) to achieve a higher coordination number than six by sharing the oxygen atoms of the ligand.[13] Hence, lanthanoid complexes with 1,3-diketones are in a monomer-dimer equilibrium in nondonating solvents.[6,7] In order to obtain an evidence for the equilibrium, molecular weights were determined in benzene over the concentration range 0.1—1.0 wt%. The results are shown in Fig. 3. Since each molecular weight increases with the increase of the concentration, the complexes evidently exist in a monomer-dimer equilibrium in benzene: 2[Ln(*l*-moba)$_3$]$\rightleftarrows$[Ln$_2$(*l*-moba)$_6$].[14]

As seen from Fig. 3, the dependency of molecular weight on concentration varies with the metal ions. The La^{III}, Pr^{III}, and Eu^{III} complexes show a large dependency on concentration, and almost all the molecules are dimerized at 1.0 wt%. It is likely that these complexes readily dimerize to achieve a higher coordination number owing to a relatively small interligand repulsion associated with the larger metal ions. Thus, the dimerization of these complexes is in line with their tendency to form hydrates. On the other hand, the molecular weights of the Dy^{III}, Ho^{III}, and Tm^{III} complexes show little dependency on concentration, and they are all monomeric in the concentration range examined. Since the size of the metal ion is relatively small, the bulky hydrophobic residues of the ligands

would cover the metal center and interfere with the dimerization. The Nd^{III} complex showed a concentration-dependence of molecular weight similar to those of the Dy^{III} and Ho^{III} complexes, though Nd^{III} is rather similar to Pr^{III} and Eu^{III} in ionic size. It is likely that the Nd^{III} complex is of eight-coordination with two water molecules and thence exhibits a low tendency to dimerize.

In donating solvents tris(1,3-diketonato) lanthanoid-(III) complexes form solvent adducts to achieve a higher coordination number.[15] Such adducts formation would interfere with the dimerization of tris(1,3-diketonato)lanthanoid(III). Thus, we have measured the molecular weights of the *l*-moba complexes in ethanol, a donating solvent. The results indicate that the molecular weights are almost independent of concentration and fall in the range 1100—1200. It is obvious that the complexes forms adducts with one or two molecules of ethanol.

Difference spectral data of the complexes determined in benzene are given in Table 2. Each spectrum can be interpreted by means of free ionic terms. CD spectral data are also included in Table 2, and some of the spectra are shown in Figs. 4—6 as examples.

According to Richardson,[16] the interaction mechanisms between a metal ion and dissymmetric environment are classified into three: *i.e.*, (1) vicinal effect (chirality induced at the metal by the mere presence of asymmetric atom in the ligand), (2) conformational

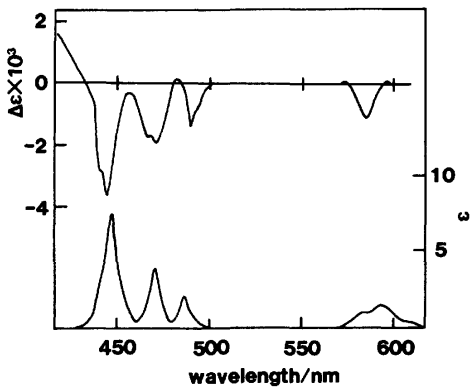

Fig. 4. Electronic and CD spectra of [Pr(*l*-moba)$_3$-(H_2O)] in benzene.

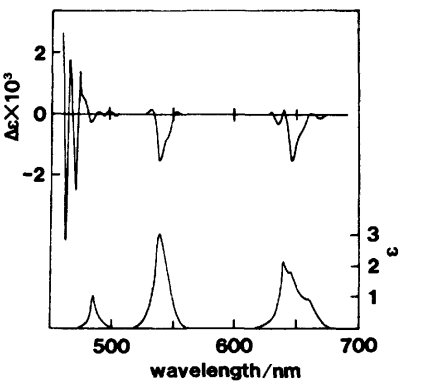

Fig. 5. Electronic and CD spectra of [Ho(*l*-moba)$_3$] in benzene.

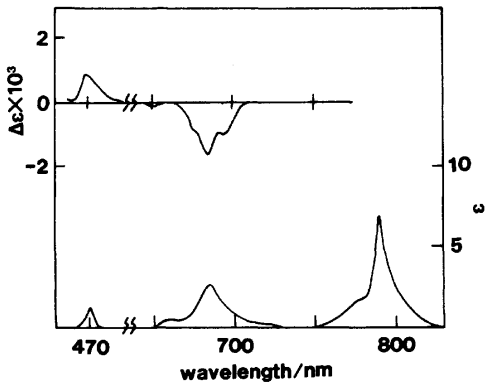

Fig. 6. Electronic and CD spectra of [Tm(*l*-moba)$_3$] in benzene.

effect (chilarity arising from the asymmetric atom in a chelate ring), and (3) the configurational effect (chirality due to an asymmetric disposition of chelate rings about the metal). In general, optical activity arising from the vicinal effect is at least one order of magnitude smaller than that from the conformational effect[17] and two orders of magnitude smaller than that from the configurational effect.[18]

In the present complexes the chiral group is out of the chelate ring and far apart from the metal ion. Hence, the optical activity induced at the f-f transition region by its vicinal effect would be supposed to be very small on this ground. However, the CD intensities observed for the present complexes are considerably high and comparable to those of the complexes with L-amino acidate ions.[19,20] This clearly indicates that the optical activities of the complexes are caused by the configurational effect. Therefore the present study has revealed that the interligand noncovalent interaction can bring about a stereoselectivity of lanthanoid complexes in spite of the lability of lanthanoid ions for ligand substitutions. In the cases of the Dy^{III}, Ho^{III}, and Tm^{III} complexes, the main species present in benzene is monomeric anhydrate at the concentration ($\approx 10^{-2}$M 1M=1 mol dm^{-3}) for the CD measurements. Thus, it is quite reasonable to assume that the interligand CH/π-interaction operating between the *l*-menthyl and phenyl residues of *l*-moba$^-$ (Fig. 2) causes the stereoselectivity producing the *cis*-Δ isomer, by analogy with the cases of the 3d-transition metal complexes with *l*-moba.[9,11]

On the other hand, the Pr^{III} and Eu^{III} complexes are substantially dimeric in benzene solution at the concentration for the CD measurements. Observations of considerably intense CD bands in the f-f transition region for these complexes indicate the existence of a stereoselectivity in the dimers. The stereoselectivities in the dimers can also be attributed to the interligand noncovalent interaction, though the detail of the interaction in the dimers is not clear at present because of the lack of crystallographic data.

It is expected that the stereoselectivity effected by the interligand noncovalent interactions also takes place in the solvent adducts of the *l*-moba complexes. We measured CD spectrum of [Dy(*l*-moba)3] as a representative example in ethanol and compared it

with the spectrum in benzene (Fig. 7). The CD spectrum in ethanol markedly differs from that of the monomeric [Dy(*l*-moba)$_3$] in benzene, implying the configurational change by the adduct formation. The considerably intense CD's in ethanol are indicative of a stereoselectivity in [Ln(*l*-moba)$_3$(EtOH)$_n$]. A similar stereoselectivity in the solvent adducts has been recognized for the lanthanoid complexes with the chiral 1,3-diketones derived from *d*-camphor.[4,15]

It is well known that Eu^{III} complexes with 1,3-diketones exhibit luminescence at the $^5D_0 \rightarrow {}^7F_1$ and $^5D_0 \rightarrow {}^7F_2$ transitions.[15,21-23] [Eu(*l*-moba)$_3$(H_2O)] also emits luminescence at 586 and 609 nm corresponding to the above transitions, respectively (Fig. 8). Interestingly, the intensity of the luminescence in benzene dramatically increases with the decrease of the concentration. Taking into account the monomer-dimer equilibrium of the complex, it is evident that the luminescence occurs only on the monomer. In relation to this, it should be noted that the Eu^{III} complexes with 1,3-diketones generally show only weak luminescence in nondonating solvents but its intensity is much enhanced on the addition of dimethyl sulfoxide to the solution.[15] Further, the adduct formations with "synergic agents" such as trioctylphosphine, tributyl phosphate, or dihexyl sulfoxide have been used to improve the quantum efficiency of luminescence[21]. Such enhancement of luminescence in these complexes can also be rationalized in terms of the shift of the monomer-dimer equilibrium to the monomeric species caused by the adduct formation with the solvent molecules or the synergic agents. It is generally accepted that the quantum efficiency of luminescence of lanthanoid complexes decreases when radiationless energy loss occurs in the excited state through the contact with other molecules, quenching impurities, or undesirable solvent molecules.[21] Therefore, the present results suggest that dimerization also facilitates nonradiative relaxation and thence greatly reduces the quantum efficiency of luminescence.

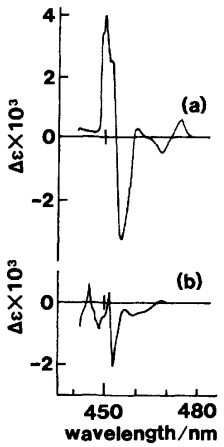

Fig. 7. CD spectra of [Dy(*l*-moba)$_3$]; (a) in benzene and (b) in ethanol.

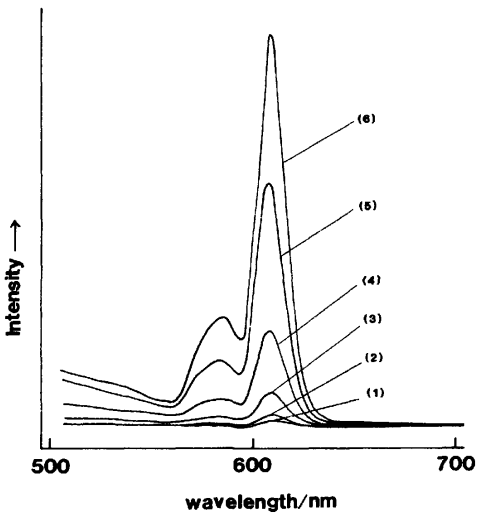

Fig. 8. Relative intensities of luminescence of [Eu(*l*-moba)$_3$(H_2O)] at various concentrations: (1): 3.681×10^{-2}, (2): 1.841×10^{-2}, (3): 1.104×10^{-2}, (4): 7.362×10^{-3}, (5): 3.681×10^{-3}, and (6): 1.472×10^{-3} M.

In conclusion the present study has shown that the interligand CH/π-interaction causes the stereoselectivity in the monomers, dimers, and solvent-adducts of the lanthanoid complexes. Further, it is suggested that the interligand CH/π-interaction forms an insulating sheath to protect the complexes from dimerization and solvation, especially in the cases of smaller lanthanoid ions and in dilute solutions.

The authors wish to thank to Dr. K. Yoshimura of Kyushu University for the measurements of luminescence spectra.

Synthetic Photochemistry. XXVIII.[1] A Photochemical C_5-Homologation of 4-Isopropenyltoluene with Methyl 2,4-Dioxopentanoate to Isolaurene and a Formal Synthesis of Cuparene

Hitoshi TAKESHITA,* Akira MORI, and Satoshi NAKAMURA†

Research Institute of Industrial Science, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816

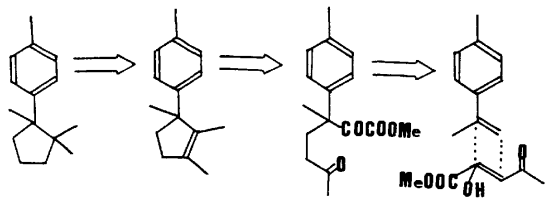
†*Graduate School of Engineering Sciences, 39, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816*

(Received March 8, 1984)

Starting from the photocycloaddition of methyl 2,4-dioxopentanoate with 4-isopropenyltoluene, isolaurene was synthesized, and its further conversion to 5-cuparenone constituted the formal synthesis of cuparene. For the first time, the *proto*-(2+2)π cycloadduct, a β-keto cyclobutanol derivative, has been isolated from the product mixture.

Recently, we have extended the use of the photocycloadducts of methyl 2,4-dioxopentanoate (**1**) with olefins to a facile cyclopentane ring construction.[2] The method must be applicable to a synthesis of laurenoids or cuparenoids.

An advantage of using **1** as a photocycloaddend is a capability of reaction with conjugated olefins; with cyclopentadiene[2] and with cycloheptatriene,[3] it gave the (2+2)π cycloadducts in addition to the (2+4)π and/or (2+6)π cycloadducts. Even with an acyclic diene, isoprene, **1** smoothly produced the (2+2)π cycloadducts, from which sesquiterpenoids, geijerone and an elemene derivative,[4] and monoterpenoids, dehydroiridodial, and chrysomelidial,[5] have been synthesized. This constitutes a proper head-to-tail homologation of terpenoids with the C_5-unit. Based on this method, cuparenoids and migrated cuparenoids, many of which are physiologically active, can be constructed as shown in the following *retro*-synthetic scheme (Scheme 1).



Scheme 1.

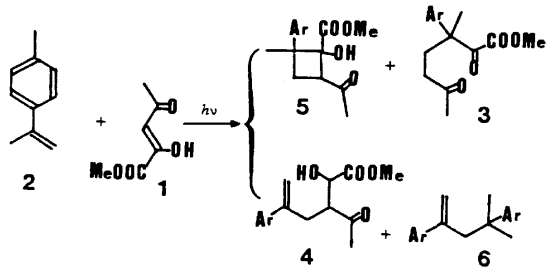
Since indene was photochemically reactive with **1**,[6] 4-isopropenyltoluene (**2**) should also be reactive enough to form the photoadduct (**3**) which could be just the proper starting material for the purpose.

When an ethyl acetate solution of **1** and **2** was internally irradiated by means of a high-pressure mercury lamp, formation of four photoproducts was recognized, as shown in Scheme 2. The major product (48% yield) was the desired (2+2)π cycloadduct (**3**). Its ^{1}H-NMR spectrum showed signals ascribable to the *p*-tolyl, acetyl, and methoxycarbonyl groups. Another compound (**4**, 10% yield) showed not only the NMR signals of acetyl and methoxycarbonyl groups, but those of a methine proton on the carbon bearing the methoxycarbonyl and hydroxyl groups and a terminal methylene group. Therefore, **4** must be an ene-reaction product.[7]

Another product (**5**), 0.2% yield, exhibited the $\nu_{C=O}$ band in the IR spectrum, and was converted into **3** under somewhat strong conditions. Therefore, **5** must be the *proto*-(2+2)π adduct. It is surprising that an intensive use of silica-gel column chromatography in the workup has not completed the *retro*-aldolization of such a strained aldol, **5**.

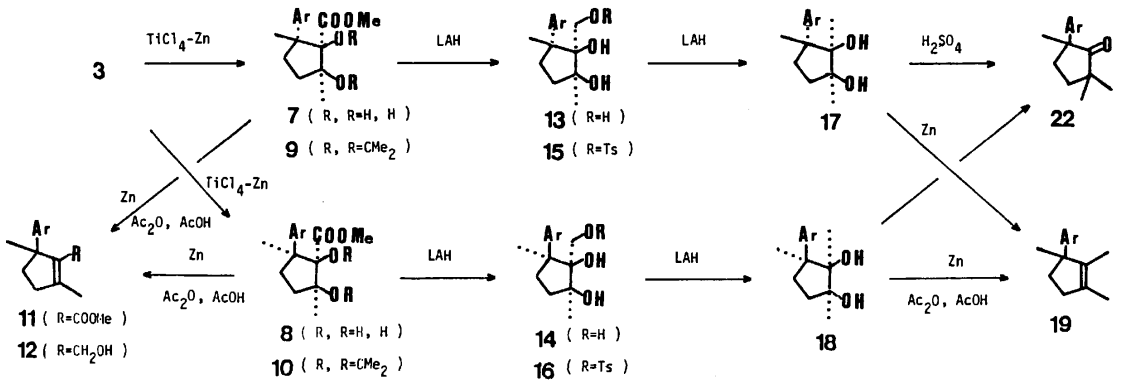
Although we have previously isolated the *proto*-(4+2)π[2] and (6+2)π[3] cycloadducts of **1** with conjugated olefins, this is the first example of an isolation of a *proto*-(2+2)π adduct.

From the less polar photoproduct mixture, 23% of a hydrocarbon (**6**) has been isolated; its NMR analysis determined the structure to be the ene-type dimer of **2**.



Scheme 2.

The formation of **3** from **2** can be regarded as a C_5 homologation of a monoterpene to sesquiterpenoid derivatives; subsequent transformations of **3**, in Scheme 3, may lead to a fundamental laurenoid skeleton. When **3** was treated with titanium(II) chloride,[5,8,9] generated *in situ* from titanium(IV) chloride and zinc dust, two *cis*-glycol derivatives (**7** and **8**) were formed in good yields. Both **7** and **8** formed the dioxolane derivatives (**9** and **10**) by treatment with 2,2-dimethoxypropane in the presence of pyridinium *p*-toluenesulfonate (PPTS) in benzene. Relative configurations of **7** and **9** *vs.* **8** and **10** were determined by the ^{1}H-NMR comparisons; the methoxyl signals of the ester groups of **7** and **9** appeared at δ=3.27 and 3.21, while those of **8** and **10** at 3.80 and 3.76, and the difference can be explained in terms of the anisotropic high-field shift due to the proximate aromatic ring in the formers. Therefore, the *p*-tolyl and the methoxycarbonyl groups of **7** and **9** are in *cis*-rela-



Scheme 3.

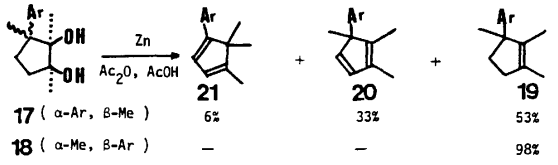
tionship.

The zinc-in-acetic acid reduction of both **7** and **8** afforded the same cyclopentene derivative (**11**), whose LAH (lithium aluminum hydride) reduction to an allyl alcohol (**12**) was unsatisfactory because of a low yield. Alternatively, **7** and **8** were at first reduced to the triols (**13** and **14**), and then their tosylates (**15** and **16**) were reduced again with LAH to the diols (**17** and **18**). The ^{1}H-NMR spectrum of **18** was identical with that of the osmium(VIII) oxide oxidation product of isolaurene, although the original workers[11] did not specify the stereochemistry.[11]

The reduction of **18** with zinc in acetic acid[12] gave a hydrocarbon (**19**) in 98% yield, whose reported NMR data in carbon tetrachloride was identical with isolaurene.[10] Consequently, an alternative synthesis of **19** has been completed.

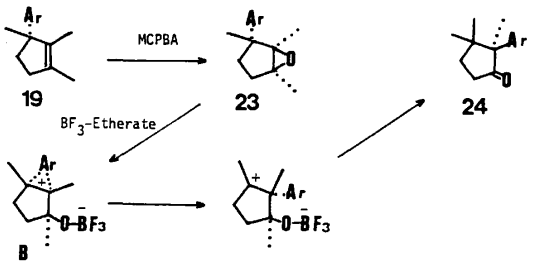
On the other hand, the same treatment of **17** yielded **19** in a lower yield, 53%, together with the formation of two cyclopentadiene derivatives (**20** and **21**) in 33 and 6% yields. The structures of **20** and **21** were clarified by the NMR analysis; the formation of **20** from **17** in a substantial amount confirmed the assignment for the stereochemistry of the glycols, **7** and **8** (Scheme 4).

Following the conversion of **18** to 2,5,5-trimethyl-2-(*p*-tolyl)cyclopentanone (**22**),[10] **17** was also treated with methanolic sulfuric acid briefly; an exclusive product was the cyclopentanone (**22**) whose structure was firmly established by the NMR comparisons. In any case, the protic acid-induced rearrangement of **17** and **18** never furnished the cuparene skeleton. Probably, this comes from a preferential protonation to the C-3 hydroxyl groups over the C-2 hydroxyl group on steric grounds.



Scheme 4.

These results of the protic acid-catalyzed dehydration of **17** and **18** made us examine the Lewis acid-promoted reaction of an oxygenated isolaurene derivative. Indeed, when an epoxide (**23**) prepared from **19** and *m*-chloroperbenzoic acid (MCPBA) was treated with boron trifluoride etherate in benzene, a facile rearrangement occurred. The sole product formed was a cyclopentanone derivative (**24**) whose NMR data measured in carbon tetrachloride were identical with those of 2,3,3-trimethyl-2-(*p*-tolyl)cyclopentanone (5-cuparenone) already prepared by de Mayo and Suau.[13] As proposed in Scheme 5, the rearrangement of **23** to **24** involved migrations of the *p*-tolyl and the methyl groups *via* formation of the spirocyclic phenonium ion (**B**). Since cuparene[14] has been synthesized from **24**,[13] the present study constitutes another total synthesis of it.



Scheme 5.

Experimental

The elemental analyses were performed by Miss M. Yamaguchi of This Institute. The NMR spectra were measured by an FX 100 Model spectrometer, JEOL, in $CDCl_3$ solutions unless otherwise specified, and the chemical shifts were expressed in δ units from the internal Me_4Si. The mass spectra were measured by an O1SG Model spectrometer, JEOL, and the IR spectra were taken either in solution (CCl_4 or $CHCl_3$) or as KBr disks, by an A 102 Model spectrometer, JASCO.

Photocycloaddition Reaction of 4-Isopropenyltoluene (2) with 1. An EtOAc solution (50 cm^3) of **2** (27.6 g) and **1** (9.2 g) was placed in an immersion well cooled with running water, and was internally irradiated with a 400-W high-pressure mercury lamp with an occasional check of the reaction with $FeCl_3$ coloration. After 25 h, the mixture was evaporated *in vacuo* at room temperature to remove the volatile material, and fractionated with benzene and aqueous Na_2CO_3. The organic layer containing the photoadducts was then dried on $MgSO_4$, and chromatographed on a silica-gel column; from the least polar fractions eluted with hexane was the hydrocarbon, **6**, 10.2 g (23%) [Found: M$^+$, 264.1857. Calcd for $C_{20}H_{24}$: M$^+$, 264.1875. δ=1.16 (6H, s), 2.24 (3H, s), 2.75 (2H, s), 4.70 (1H, dm, J=2 Hz), 5.09 (1H, d, J=2 Hz), and 6.8—7.2 (8H, m). δ(C)=20.8, 21.0, 28.8 (2C), 38.3, 49.6, 116.2, 125.9 (2C), 126.5 (2C), 128.7 (2C), 128.9 (2C), 134.8, 136.5, 140.8, 146.7, and 146.8. ν: 3200—2800, 1625, 1520, 900, 830, 817 cm^{-1}].

From the subsequent fractions eluted by hexane-EtOAc (9:1) gave a colorless oil, **3**, 8.0 g (48%). Cold finger distillation of a part of this sample yielded the analytical specimen, a colorless liquid [Found: C, 69.58; H, 7.36%. M^+, 276.1361. Calcd for $C_{16}H_{20}O_4$: C, 69.54; H, 7.30%; M^+, 276.1361. δ=1.57 (3H, s), 1.99 (3H, s), 2.0—2.3 (4H, m), 2.26 (3H, s), 3.50 (3H, s), and 7.07 (4H, s). δ(C)=20.8, 21.0, 29.6, 31.4, 38.3, 52.0, 52.8, 126.5 (2C), 129.5 (2C), 136.9, 137.0, 162.7, 197.3, and 207.1. ν: 1743, 1722 cm^{-1}].

Subsequently, the fractions from hexane-EtOAc (8:2) yielded a pale yellow oil, **4**, 1.7 g (10%) [Found: C, 69.47; H, 7.39%. M^+, 276.1358. δ=2.10 (3H, s), 2.34 (3H, s), 2.8—3.2 (4H, m, diminished to 3H by adding D_2O), 3.69 (3H, s), 4.21 (1H, d, J=3.2 Hz), 5.13 (1H, d, J=1.3 Hz), 5.53 (1H, d, J=1.3 Hz), and 6.8—7.3 (4H, m). δ(C)=21.1, 30.4, 33.8, 52.5, 53.0, 70.9, 115.0, 126.0 (2C), 129.3 (2C), 136.7, 137.7, 144.5, 173.8, and 210.9. ν: 3500, 1740, 1715 cm^{-1}]. An oily material obtained from more polar fractions was further purified by means of preparative thin-layer chromatography (PTLC) to yield a colorless oil, **5**, 29 mg (0.2%) [Found: M^+, 276.1367. Calcd for $C_{16}H_{20}O_4$: 276.1362. δ=1.44 (3H, s), 2.10 (3H, s), 2.0—2.4 (4H, m, diminished to 3H by adding D_2O), 2.31 (3H, s), 3.83 (3H, s), and 6.8—7.2 (4H, m). δ(C)=21.2, 24.8, 30.2, 31.5, 37.7, 39.7, 52.6, 62.3, 129.5 (2C), 129.8 (2C), 136.4, 173.3, and 208.7. ν: 3460, 1725, 1710 cm^{-1}].

Conversion of 5 to 3. A benzene solution (2 cm^3) of **5** (5 mg) and TsOH (1 mg) was refluxed for 1 h. PTLC of the reaction mixture afforded **3**, 3.5 mg (70%), whose identity with the authentic sample was confirmed by direct comparisons.

Reductive Cyclization of 3. Formation of 7 and 8. To an anhydrous tetrahydrofuran (THF, 60 cm^3) of $TiCl_4$ (650 mg), Zn (450 mg) and pyridine (240 mg) were added at 0 °C. The mixture, containing Ti(II) salt, was then cooled by ice-water, and a THF solution (20 cm^3) of **3** (631 mg) was added for 0.5 h at 0 °C with vigorous stirring. After 3 h, the mixture was poured into ice-water, and extracted with ether, and the ether extract was chromatographed on a silica-gel column with hexane-EtOAc (3:1) to give colorless crystals, mp 126—126.5 °C, **7**, 213 mg (34%) [Found: C, 69.29; H, 8.01%; M^+, 278.1509. Calcd for $C_{16}H_{22}O_4$: C, 69.04; H, 7.97%; M^+, 278.1520. δ=1.12 (3H, s), 1.50 (3H, s), 2.26 (3H, s), 2.4—2.8 (4H, m), 3.27 (3H, s), 3.4 (1H, br. s, disappeared by adding D_2O), 4.24 (1H, br. s, disappeared by adding D_2O), and 6.8—7.2 (4H, m). δ(C)=20.8, 25.5, 28.0, 32.9, 35.8, 51.8, 52.1, 80.3, 89.4, 124.9 (2C), 128.5 (2C), 135.0, 144.8, and 175.4. ν=3460, 1720, 1515, 1260 cm^{-1}], and a colorless oil, **8**, 219 mg (35%) [Found: M^+, 278.1520. δ=1.23 (3H, s), 1.37 (3H, s), 1.8—2.2 (3H, m), 2.28 (3H, s), 2.4—2.8 (2H, m), 3.48 (1H, br. s), 3.80 (3H, s), and 7.04 (4H, m). δ(C)=20.8, 25.4, 26.8, 34.6, 37.7, 52.3 (2C), 81.4, 88.6, 127.6 (2C), 128.4 (2C), 135.7, 141.7, and 174.1. ν: 3470, 1515, 1250 cm^{-1}].

Isopropylidenedioxy Derivative (9) from 7. To an anhydrous benzene solution (2 cm^3) of **7** (27.6 mg), 2,2-dimethoxypropane (2 cm^3) and PPTS (10 mg) were added at once, this mixture was kept at 15—25 °C for 8 h. It was then diluted with ether and washed with aqueous K_2CO_3 solution. PTLC of the organic extracts with hexane-EtOAc (4:1) yielded a colorless oil, 15 mg (55%), **9** [Found: M^+, 318.1839. Calcd for $C_{19}H_{26}O_4$: M^+ 318.1831. δ=1.38 (3H, s), δ=1.45 (3H, s), 1.50 (3H, s), 1.63 (3H, s), 1.8—2.9 (4H, m), 2.27 (3H, s), 3.21 (3H, s), and 7.03 (4H, s). δ(C)=21.0, 27.4, 27.6, 28.1, 28.4, 37.1, 39.6, 51.2, 54.5, 93.7, 100.0, 115.4, 125.3 (2C), 128.6 (2C), 135.2, 144.7, and 172.7. ν: 1750 cm^{-1}].

Isopropylidenedioxy Derivative (10) from 8. Similarly, **8** (52 mg) was converted to **10**, a colorless oil, 67.5 mg (74%) [Found: M^+, 318.1839. δ=1.28 (3H, s), 1.35 (6H, s), 1.58 (3H, s), 1.6—2.0 (4H, m), 2.29 (3H, s), 3.76 (3H, s), and 7.08 (4H, s). δ(C)=20.9, 24.9, 26.9, 27.2, 27.4, 34.7, 38.8, 51.6, 54.6, 93.4, 95.7, 109.8, 126.5 (2C), 128.6 (2C), 135.5, 141.5, and 171.8. ν: 1720 cm^{-1}].

Reduction of 7 with Zinc in Acetic Acid. To a mixed solution of Ac_2O (18 cm^3) and AcOH (9 cm^3) of **7** (142.5 mg), powdered Zn (3 g) was added in portions while refluxing for 6 h. The mixture was then evaporated *in vacuo* to remove the solvent, and the residue was poured into ice-water, and extracted with benzene. The extracts were purified by PTLC to give a colorless oil, 80 mg (64%), **11** [Found: M^+, 244.1463. Calcd for $C_{16}H_{20}O_2$: M^+, 244.1463. δ=1.61 (3H, s), 1.8—2.3 (4H, m), 2.14 (3H, s), 2.27 (3H, s), 3.50 (3H, s), and 7.0—7.1 (4H, m). δ(C)=16.9, 20.9, 25.0, 37.8, 42.5, 50.5, 53.8, 125.4 (2C), 128.7 (2C), 134.7, 135.1, 146.1, 155.1, and 166.3. ν: 1715, 1520, 1268 cm^{-1}].

Reduction of 8 with Zinc in Acetic Acid. Similarly, **8** (41 mg) was reduced with powdered Zn (670 mg) in Ac_2O (4 cm^3) and AcOH (2 cm^3) for 9.5 h to give a colorless oil, 35 mg (85%), which was identical with the sample of **12** obtained from the reduction of **7**.

LAH-Reduction of 11 to Give 12 An anhydrous ether solution (25 cm^3) of **11** (46.5 mg) was treated with LAH (22 mg) at 15—25 °C for 1.5 h. The mixture was then treated with EtOAc, and poured into ice-water, and extracted with ether. The PTLC of the extracts with hexane-EtOAc (3:1) gave a colorless oil, 2.4 mg (6%), **12** [Found: M^+, 216.1514. Calcd for $C_{15}H_{20}O$: M^+, 216.1514. δ=1.51 (3H, s), 1.83 (3H, s), 2.30 (3H, s), 3.83 (1H, d, J=12.5 Hz), 4.05 (1H, d, J=12.5 Hz), and 7.0—7.2 (4H, m). δ(C)=14.4, 20.9, 25.1, 36.1, 41.7, 53.9, 57.2, 125.9 (2C), 128.9 (2C), 135.2, 138.4, 141.1, and 146.1. ν: 3420, 1520 cm^{-1}].

LAH-Reduction of 7. Formation of 13. An anhydrous ether solution (30 cm^3) of **7** (188 mg) was treated with LAH (102 mg) at 15—25 °C for 0.5 h, and subsequently refluxed for 5 h. The mixture was then poured into ice-water and extracted with ether. Silica-gel column chromatography of the extracts yielded colorless needles, mp 126—127 °C, 168 mg (99%), **13** [Found: C, 72.09; H, 8.90; M^+, 250.1569. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%; M^+, 250.1569. δ=1.12 (3H, s), 1.43 (3H, s), 1.8—2.4 (5H, m, diminished to 4H by adding D_2O), 2.29 (3H, s), 2.74 (1H, br. s, disappeared by adding D_2O), 3.33 (1H, d, J=12 Hz), 3.53 (1H, d, J=12 Hz), 3.84 (1H, br. s, disappeared by adding D_2O), and 7.0—7.2 (4H, m). δ(C)=20.8, 26.2, 26.7, 33.6, 38.0, 51.3, 64.7, 81.4, 83.3, 127.2 (2C), 129.0 (2C), 136.0, and 143.6. ν: 3500, 1360 cm^{-1}].

LAH-Reduction of 8. Formation of 14. Similarly, **8** (679 mg) was converted by the LAH reduction to colorless needles, mp 107—108 °C, 605 mg (99%), **14** [Found: C, 71.99; H, 8.98%; M^+, 250.1563. δ=1.35 (3H, s), 1.41 (3H, s), 2.0—2.3 (4H, m), 2.29 (3H, s), 3.00 (3H, br. s, disappeared by adding D_2O), 3.55 (1H, d, J=12 Hz), 3.70 (1H, d, J=12 Hz), and 6.8—7.2 (4H, m). δ(C)=20.7, 24.7, 25.4, 35.9, 38.7, 50.7, 63.1, 81.1, 81.2, 127.8 (2C), 128.5 (2C), 135.8, and 142.1. ν: 3450, 3300, 1510 cm^{-1}].

LAH-Reduction of a Monotosylate (15) Derived from 13. Preparation of 17. To a cold pyridine solution (5 cm^3) containing TsCl (380 mg), **13** (331 mg) was added and kept at 10—15 °C for 24 h. The mixture was then heated *in vacuo* to remove the volatile material, and the residue was washed with water, and extracted with $CHCl_3$. The extracts yielded colorless oily monotosylate, **15**, 528 mg (99%) [δ=1.18 (3H, s), 1.36 (3H, s), 1.6—2.3 (4H, m), 2.28 (3H, s), 2.41 (3H, s), 2.68 (1H, d, J=10 Hz), 2.83 (2H, br. s), 3.91 (1H, d, J=10 Hz), and 6.9—7.5 (8H, m). δ(C)=20.8, 21.6, 26.1, 26.5, 32.8, 38.1, 51.6, 72.0, 80.8, 81.8, 126.6 (2C), 127.8 (2C), 128.7 (2C), 129.6 (2C), 131.9, 135.6, 142.3, and 144.6. ν: 3500, 1360 cm^{-1}], on silica-gel column chromatography. Subsequently, **15** (145 mg) was dissolved in an anhydrous ether (10 cm^3), and was reduced with LAH (30 mg) in ether (25 cm^3) at 15—25 °C for 3 h. Then, the mixture was treated with EtOAc, poured into ice-water, and

extracted with ether. The extracts were chromatographed on a silica-gel column to give colorless needles, mp 91—92 °C, 81 mg (96%), **17** [Found: M^+, 234.1621. Calcd for $C_{15}H_{22}O_2$: M^+, 234.1620. δ=0.78 (3H, s), 1.21 (3H, s), 1.42 (3H, s), 1.8—2.1 (4H, m), 2.30 (3H, s), 2.6 (2H, br. s, disappeared by adding D_2O), and 7.0—7.2 (4H, m). δ(C)=21.0, 22.4, 25.5, 26.5, 31.9, 37.1, 51.7, 80.4, 82.5, 126.3 (2C), 128.6 (2C), 135.1, and 145.4. ν: 3600—3300, 1510 cm^{-1}].

Reduction of 14 to 18 via *Monotosylate (16).* Similarly, **14** (558 mg) was converted to a monotosylate (**16**), a colorless oil, 887 mg (99%) [δ=1.32 (3H, s), 1.41 (3H, s), 1.8—2.3 (4H, m), 2.27 (3H, s), 2.37 (3H, s), 2.62 (2H, br. s), 4.09 (1H, d, J=10 Hz), 4.23 (1H, d, J=10 Hz), and 7.0—7.5 (8H, m). δ(C)=20.8, 21.6, 24.2, 25.7, 36.7, 39.1, 50.8, 71.4, 80.6, 80.7, 126.6 (2C), 127.8 (2C), 128.6 (2C), 129.8 (2C), 132.4, 136.1, 140.8, and 144.9. ν: 3500, 1360 cm^{-1}]. Then, an anhydrous ether solution (30 cm^3) of **16** (465 mg) was reduced by LAH (95 mg) to a colorless oil, 268 mg (99%), **18** [Found: M^+, 234.1622. δ=1.12 (3H, s), 1.28 (3H, s), 1.34 (3H, s), 2.0—2.3 (4H, m), 2.30 (3H, s), 2.6 (2H, br. s, disappeared by adding D_2O), and 7.1—7.3 (4H, m). δ^{CCl_4}=1.08 (3H, s), 1.20 (3H, s), 1.29 (3H, s), 1.8—2.3 (4H, m), 2.30 (3H, s), and 7.0—7.1 (4H, m). δ(C)=19.4, 20.8, 25.6, 26.1, 33.9, 38.3, 51.4, 80.9, 82.4, 127.3 (2C), 128.9 (2C), 136.0, and 141.9. ν: 3450, 1515 cm^{-1}], of which the NMR taken in CCl_4 was in accord with that (lit, mp 114—116 °C) prepared by Irie *et al.*[10]

Reduction of 17 with Zinc in Acetic Acid. Formation of 19, 20, and 21. To a mixed solution of Ac_2O (12 cm^3) and AcOH (6 cm^3) of **17** (145 mg), powdered Zn (617 mg) was added in portions, and the mixture was refluxed for 3 h. It was then filtered, and the residue was washed with water, dil HCl, and ether. The filtrate was extracted with ether, and the combined organic layer was evaporated *in vacuo* to remove the volatile material. Then the residue was chromatographed on a silica-gel column. From the less polar fractions, a hydrocarbon, **19**, a colorless oil, 65 mg (53%) [Found: M^+, 200.1575. Calcd for $C_{15}H_{20}$: 200.1563. δ=1.37 (3H, s), 1.39 (3H, s), 1.71 (3H, s), 2.0—2.3 (4H, m), 2.30 (3H, s), and 7.07 (4H, s). δ^{CCl_4}=1.32 (3H, s), 1.35 (3H, s), 1.69 (3H, s), 1.8—2.3 (4H, m), 2.26 (3H, s), and 6.92 (4H, s). δ(C)=10.3, 14.3, 20.9, 34.3, 35.9, 41.6, 54.6, 126.1 (2C), 128.7 (2C), 131.8, 134.6, 137.5, and 146.2], was isolated, and was in accord with isolaurene in respects of the reported NMR.[10] From the more polar fractions, other hydrocarbons, **20**, 42 mg (33%) [Found: M^+, 198.1406. Calcd for $C_{15}H_{18}$: 198.1406. δ=1.44 (3H, s), 1.55 (3H, s), 1.85 (3H, s), 2.28 (3H, s), 6.10 (H, d, J=6.5 Hz), 6.28 (1H, d, J=6.5 Hz), and 6.9—7.05 (4H, m). ν: 2960, 2930, 1510, 815 cm^{-1}], and **21**, 7 mg (6%) [Found: M^+, 198.1392. δ=1.19 (6H, s), 1.87 (3H, d, J=2 Hz), 2.30 (3H, s), 5.94 (1H, quint, J=2 Hz), 6.53 (1H, d, J=2 Hz), and 7.05—7.35 (4H, m). δ(C)=12.4, 21.0, 22.5 (2C), 53.0, 123.3, 125.2, 125.8 (2C), 128.9 (2C), 133.6, 135.6, 145.1 and 155.5], were isolated.

Reduction of 18 with Zinc in Acetic Acid to 19. Similarly, **18** (231.5 mg) was refluxed with powdered Zn (980 mg) in Ac_2O (20 cm^3) and AcOH (10 cm^3) for 3 h. The mixture was then washed with water and with dil HCl, and extracted with ether. The ether extracts were heated *in vacuo* to remove the solvent, and the residue was chromatographed on a silica-gel column to give a colorless oil, **19**, 194 mg (98%) which was identical with the sample obtained from **17**.

Sulfuric Acid Treatment of 17. A methanolic H_2SO_4 solution (10%, 2 cm^3) of **17** (26.5 mg) was treated at 20—25 °C for 5 min. The mixture was then poured into water and extracted with benzene. The extracts were purified by PTLC to give **22**, 23.2 mg (95%) [Found: M^+, 216.1508. Calcd for $C_{15}H_{20}O$: M^+, 216.1514. δ=1.00 (3H, s), 1.14 (3H, s), 1.37 (3H, s), 1.6—2.3 (4H, m), 2.30 (3H, s), and 7.05—7.2 (4H, m). δ^{CCl_4}=0.94 (3H, s), 1.08 (3H. s), 1.29 (3H, s), 1.6—2.3 (4H, m), 2.28 (3H, s), and 6.95—7.1 (4H, m). δ(C)=20.9, 25.1, 25.5, 26.5, 34.7, 34.9, 45.5, 53.4, 126.3 (2C), 129.4 (2C), 136.2, 140.6, and 224.7. ν: 1735 cm^{-1}], which was identical with the product prepared by Irie *et al.* from **18**.[10]

Epoxidation of 19 to 23. A CH_2Cl_2 solution (25 cm^3) of **19** (200 mg) was mixed with MCPBA (90%, 345 mg), and kept at 15—25 °C for 24 h. After filtration of the resultant *m*-chlorobenzoic acid, the filtrate was washed with aqueous $NaHCO_3$, and chromatographed on a silica-gel column to give a colorless oil, 147 mg (68%), **23** [Found: M^+, 216.1512. Calcd for $C_{15}H_{20}O$: M^+, 216.1512. δ=1.12 (3H, s), 1.47 (3H, s), 1.49 (3H, s), 1.8—2.8 (4H, m), 2.32 (3H, s), and 7.0—7.1 (4H, m). δ(C)=11.7, 15.9, 20.2, 20.9, 31.8, 37.3, 48.5, 70.4, 72.7, 125.8 (2C), 129.0 (2C), 135.4, and 143.8. ν: 3150—2800, 1520, 1243, 815 cm^{-1}].

BF_3-Catalyzed Rearrangement of 23. Formation of 24. An anhydrous benzene solution (1 cm^3) of **23** (11.9 mg) was mixed with BF_3 etherate (0.05 cm^3), and kept at 20—25 °C for 5 min. The mixture was then poured into ice-water and extracted with $CHCl_3$. The extracts were chromatographed on a silica-gel column to give a colorless oil, 10.9 mg (92%), **24** [Found: M^+, 216.1512. Calcd for $C_{15}H_{20}O$: M^+, 216.1512. δ=0.67 (3H, s), 1.06 (3H, s), 1.32 (3H, s), 1.8—2.8 (4H, m), 2.30 (3H, s), and 6.95—7.1 (4H, m). δ^{CCl_4}=0.65 (3H, s), 1.04 (3H, s), 1.24 (3H, s), 1.8—2.8 (4H, m), 2.28 (3H, s), and 6.92 (4H, s). δ(C)=19.3, 20.9, 23.9, 26.5, 33.5, 36.0, 42.7, 59.9, 127.7 (2C), 128.4 (2C), 135.9, 137.9, and 222.1. ν: 3200—2800, 1742, 1510 cm^{-1}], which was in good agreement with the reported NMR data (in CCl_4) of de Mayo and Suau.[13]

The authors are grateful to the Ministry of Education, Science, and Culture for a Grant to H. T. (No. 57218019).

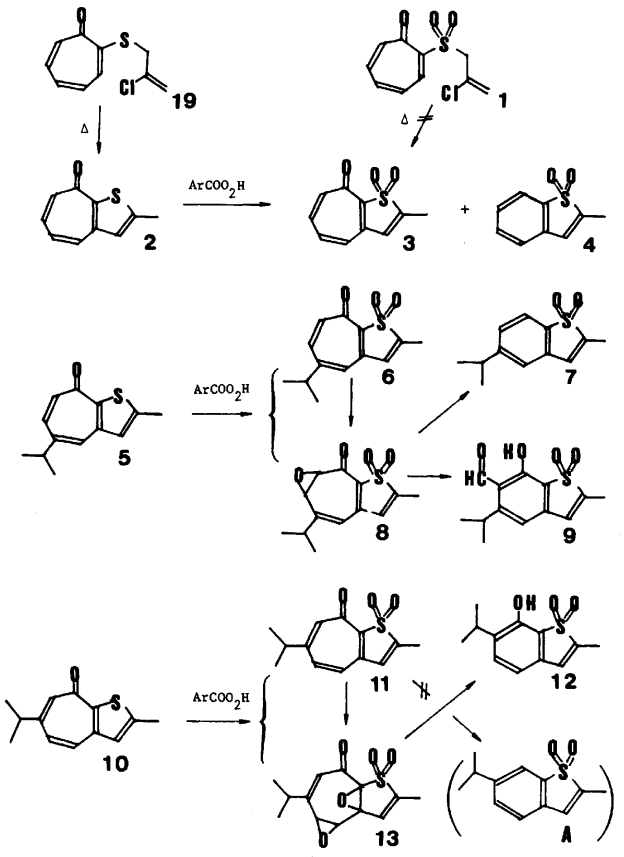
The MCPBA-oxidation of 8*H*-Cyclohepta[*b*]thiophen-8-ones to Their 1,1-Dioxides and Further Ring-contracted Benzo[*b*]thiophene Derivatives

Hitoshi TAKESHITA,* Hideshi MOTOMURA,† and Hiroaki MAMETSUKA
Research Institute of Industrial Sciece, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816
†*Graduate School of Engineering Sciences, 39, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816*
(Received May 4, 1984)

Upon MCPBA-oxidation, several 8*H*-cyclohepta[*b*]thiophen-8-ones yielded the 8*H*-cyclohepta[*b*]thiophen-8-one 1,1-dioxides and their epoxides. The latters were shown to be convertible to several ring-contracted derivatives, the benzo[*b*]thiophene 1,1-dioxides and/or their corresponding phenol and salicylaldehyde derivatives.

Recently, we have reported[1,2] a series of thermal rearrangement of functionalized 2-(allylthio)tropone derivatives. In connection with this, the thermolysis of the sulfonyl derivatives, *i.e.*, 2-(allylsulfonyl)tropones, should be of interest concerning potential precursors for α-keto sulfene intermediates. However, the sulfones have been shown to be stable around 110 °C, where the corresponding sulfinyl derivatives are reactive. Herein we wish to describe an unprecedent oxidative ring contraction to a variety of benzenoid derivatives from the isopropyltropone derivatives in the preparation of the 8*H*-cyclohepta[*b*]thiophen-8-one 1,1-dioxides.

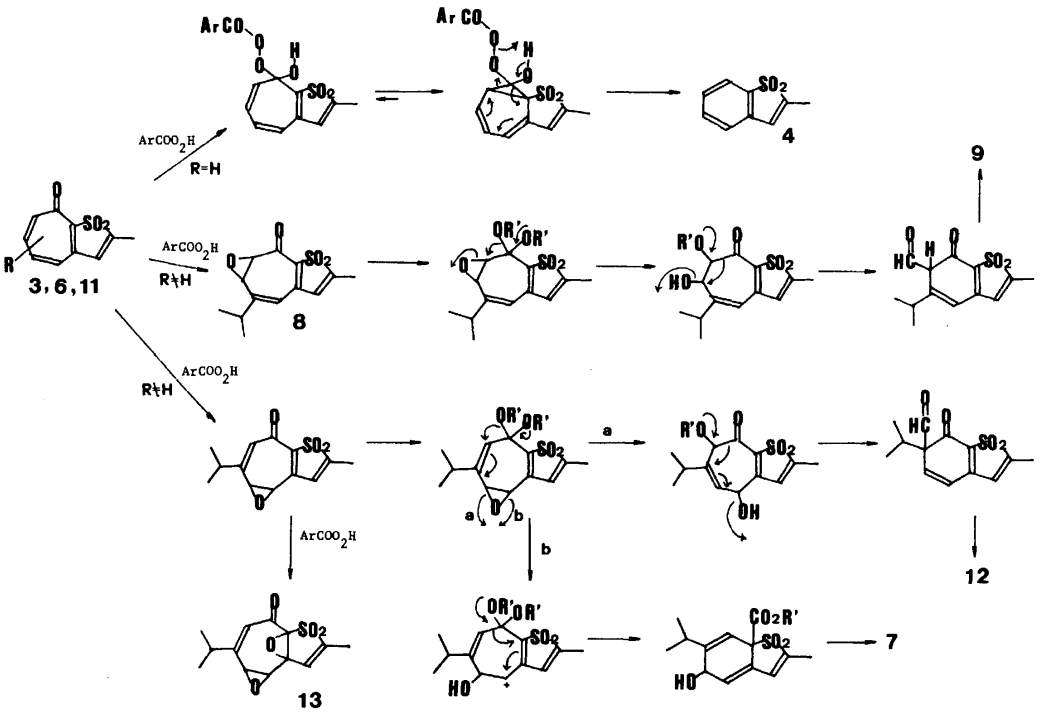
In a hope to obtain thienotropone dioxide *via* a "*sulfono*"-Claisen rearrangement, 2-(2-chloro-2-propenylsulfonyl)tropone (**1**) was heated at 110 °C for 10 min, but no reaction occurred at all. However above 180 °C, a decomposition of the material gradually took place although no definite product could be isolated. Obviously, an alternative route must be the *m*-chloroperbenzoic acid (MCPBA)-oxidation of 2-methyl-8*H*-cyclohepta[*b*]thiophen-8-one (**2**).[1] In fact, oxidation in chloroform yielded two products (**3** and **4**); the NMR spectrum of the major product (**3**) indicated the retention of the seven-membered ring, and the IR spectrum showed absorptions due to the newly formed sulfonyl group. Therefore, it must be the expected product. However, the minor product (**4**), analyzing for $C_9H_8O_2S$ on the basis of the mass spectrum, was 2-methylbenzo[*b*]thiophene 1,1-dioxide, and the ^{1}H-[3] and ^{13}C-NMR[4] were in good agreement with the data already reported. A further MCPBA-oxidation of **3** under similar conditions gave **4**. This unexpected occurrence of a novel ring contraction prompted us to investigate the reaction in more detail.



Scheme 1.

Accordingly, the oxidation of 5-isopropyl derivative (**5**)[1] was investigated. The four products identified were the corresponding isopropyl derivatives (**6** and **7**) of **3** and **4** together with two new products (**8** and **9**), which were isolated by preparative thin-layer chromatography (PTLC). One (**8**) of the minor products was assumed to be a further epoxidation product of **6** on the basis of its spontaneous conversion to **7** and **9**. Its extreme instability is not surprising because of a thiophene 1,1-dioxide structure. Nevertheless, the NMR spectrum of **8** showed a pair of *AB*-type signals at δ=3.71 and 4.08, of which the former was further spin-coupled to the other methine proton at δ=6.12, and showed a magnetically nonequvalent pair of doublet methyls, indicating a presence of sp^3-carbons in the vicinity of the isopropyl group. No other characterization was successful due to its rapid decomposition to **7** and **9**. The further MCPBA oxidation of **6** indicated a formation of **8** in substantial amount. Therefore, its structure is shown to be 6,7-epoxy-5-isopropyl-2-methyl-6,7-dihydro-8*H*-cyclohepta[*b*]thiophen-8-one 1,1-dioxide.

Another product, **9**, was 6-formyl-7-hydroxy-5-isopropyl-2-methylbenzo[*b*]thiophene 1,1-dioxide; the NMR spectrum exhibits only one phenyl proton as a singlet, and the isopropyl and thiophene 1,1-dioxide moieties still remained. In addition, there are characteristic signals at δ=10.36 and 12.58 ascribable to the



Scheme 2.

salicylaldehyde function. Since the chemical shift of the C-4 proton of the phenyl ring, δ=6.80, was higher than that of **7**, $\Delta\delta$=0.30, this should eliminate an alternative, 6-hydroxy-7-formyl structure.

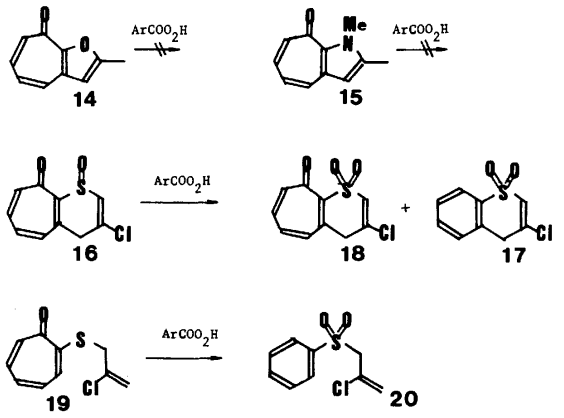
On the other hand, the 6-isopropyl derivative (**10**)[1] gave the corresponding dioxide, 6-isopropyl-2-methyl-8*H*-cyclohepta[*b*]thiophen-8-one 1,1-dioxide (**11**), in good yield, but the ring-contracted 6-isopropyl-2-methylbenzo[*b*]thiophene 1,1-dioxide (**A**) was undetectable. Instead of this, a phenol (**12**) and an epoxide, 3a,8a:4,5-diepoxy-6-isopropyl-2-methyl-3a,4,5,8a-tetrahydro-8*H*-cyclohepta[*b*]thiophen-8-one 1,1-dioxide (**13**),[5] were obtained. The ^{1}H-NMR spectrum of **13** also showed the *AB*-signals due to epoxy methine protons and a nonequivalent pair of methyl doublets. The ^{13}C-NMR spectrum showed only five sp^2-carbons, and the mass spectrum indicated its composition to be $C_{13}H_{14}O_5S$. Moreover, **13**, unlike **8**, was relatively stable under the reaction conditions. Therefore, **13** could be formulated as shown.

The remaining product, **12**, was also identified from the NMR analysis to be 7-hydroxy-6-isopropyl-2-methylbenzo[*b*]thiophene 1,1-dioxide. Unlike **9**, **12** possesses the isopropyl group at C-6, and the α-formylcyclohexadienone as an intermediate could not be enolized to yield the salicylaldehyde derivative. Therefore, a mechanism for this eliminative rearrangement could be proposed as shown in Scheme 2.

It is not surprising that the substituent on the tropone ring determined the site of the reaction, and the subtle difference of such chemical properties leads to entirely different results. Another interesting feature is that, from the same type of precursors (the epoxycycloheptadienones), the formation of aromatic compounds at a different oxidation level, *i.e.*, benzene, phenol, and salicylaldehyde derivatives, occurred. Moreover, there must be two different mechanisms operative for the benzene formation; one is, operative in the parent tropone derivatives, the oxidative decarbonylation *via* the 7-acyldioxy-7-hydroxytropylidenes,[6] and the other is hydrolytic ring contraction of the epoxycycloheptadienones as verified in cases of the isopropyl derivatives.

To gain insight into the scope and limitations of this reaction, we have examined other heterocylic troponoids. 2-Methyl-8*H*-cyclohepta[*b*]furan-8-one (**14**)[7] resulted in a recovery of the starting **14**. On the other hand, the oxidation of 1,2-dimethyl-8*H*-cyclohepta[*b*]pyrrol-8-one (**15**)[8] should be of interest since it should at first be oxidized to an *N*-oxide, which resembles sulfonyl derivatives in respect to having a positive, formal charge on the C-2 substituent. An extensive decomposition occurred under thse conditions, and only a small amount of **15** was recovered. However, 3-chlorocyclohepta[*b*]thiopyran-9(4*H*)-one 1-oxide (**16**)[2] afforded 3-chloro-4*H*-benzo[*b*]thiopyran 1,1-dioxide (**17**) and 3-chlorocyclohepta[*b*]thiopyran-9(4*H*)-one 1,1-dioxide (**18**). From this, it seems to be characteristic for 2-sulfonyltropones. Indeed, when 2-(2-chloro-2-propenylthio) tropone (**19**) was oxidized with an excess of MCPBA, (2-chloro-2-propenylsulfonyl) benzene (**20**) was obtained as the by-product of **1** after a prolonged period.

Several examples on the ring contractions of troponoids or tropylidenes to benzene derivatives have been reported in the literature. Beside the well-known rearrangement of 2-halogeno- and 2-alkoxytropones to benzoic acid derivatives on base-treatment,[9] Mukai *et al.* have reported a thermolysis of tropone (**B**) to benzene (**C**) above 600 °C,[10] and Volpin *et al.*[11] have



Scheme 3.

observed the formation of **C** in the hydrogen peroxide oxidation of the tropylium salt; probably, this would be a cheletropic fragmentation of tropyl hydroperoxide *via* the valence isomer, 7-hydroperoxybicyclo[4.1.0]-hepta-2,4-diene. A similar mode to this ring contraction to condensed benzenoid was also found in the MCPBA-oxidation of condensed polycyclic tropylium salt as well as the parent tropylium tetrafluoroborate.[12] However, no precedence has been known for the oxidative formation of benzenes from the tropones. In the concomitant formation of **C** and **B** from tropylidene during the sensitized photooxygenation, an intermediacy of **B** for **C** has been disproven by us.[13] Therefore, the present oxidation is the first example of that reaction.

Experimental

The mps were measured by a Yanagimoto Micro mp apparatus and not corrected. The elemental analyses were performed by Miss M. Yamaguchi and Miss S. Hirashima of this Institute. The high-resolution mass spactra were obtained with a JEOL OSIG Model spectrometer. The NMR spectra were taken with a JEOL FX 100 Model spectrometer in $CDCl_3$ solutions otherwise specified under the Fourier transform mode, and the chemical shifts expressed were δ unit from the internal Me_4Si. The IR spectra were measured either as KBr disk or CCl_4 solution with a Jasco IR 101 Model spectrophotometer.

Preparation of 2-(2-Chloro-2-propenylsulfonyl) tropone (1). A $CHCl_3$ solution (3 cm^3) of **19** (204 mg), prepared from 2-mercaptotropone and 2,3-dichloropropene,[1] was treated with MCPBA (534 mg) at 20 °C for 20 h. The mixture was then washed with aqueous $NaHCO_3$, and extracted with $CHCl_3$. The organic extracts were fractionated with silica-gel column to isolate **1**, 204 mg (87%), pale yellow needles, mp 79—80 °C [Found: C, 48.95; H, 3.48%. Calcd for $C_{10}H_9O_3SCl$: C, 49.08; H, 3.71%. δ=4.55 (2H, s), 5.48 (2H, s), 7.0—7.4 (4H, m), and 8.16 (1H, dd, J=8, 2 Hz). δ(C)= 63.3, 122.0, 128.9, 131.7, 136.1, 139.9, 140.8, 144.1, 146.2, and 182.3. ν: 1630, 1520, 1310, 1140, 900, and 790 cm^{-1}].

Attempted Thermolysis of 1. a) An *N,N*-dimethylformamide (DMF) solution (0.5 cm^3) of **1** (30 mg) was heated in a sealed NMR tube at 110 °C for 1 h. No appreciable change was detected.

b) A DMF solution (0.4 cm^3) of **1** (25 mg) was heated in a sealed NMR tube at 180 °C for 10 min. The NMR spectroscopy revealed an extensive decomposition to intractable material.

MCPBA-oxidation of 2-Methyl-8H-cyclohepta[b]thiophen-8-one (2).[1] A $CHCl_3$ solution (3 cm^3) of **2** (128 mg) was mixed with MCPBA (394 mg, 2.5 mol equiv) and kept at 15—25 °C for 48 h. The mixture was then washed with aqueous $NaHSO_3$ and $NaHCO_3$, and extracted with $CHCl_3$. PTLC of the extracts on silica gel gave **3**, 66 mg (44%), yellow needles, mp 192—193 °C [Found: C, 57.38; H, 3.95%. Calcd for $C_{10}H_8O_3S$: C, 57.68; H, 3.87%. δ=2.27 (3H, d, J=2 Hz), 6.62 (1H, q, J=2 Hz), and 6.9—7.4 (4H, m). δ(C)=9.5, 124.6, 132.2, 135.7, 140.0, 140.1, 140.9, 146.5(2C), and 177.3. m/z, 208 (M^+). ν: 1620, 1580, 1520, 1460, 1300, 1240, 1140, 860, and 800 cm^{-1}], **4**, colorless needles, mp 105—106 °C, 10 mg (8%) [δ=2.20 (3H, d, J=2 Hz), 6.74 (1H, q of quint, J=2, 1 Hz), and 7.2—7.7 (4H, m), δ(C)=9.1, 121.4, 124.2, 125.8, 129.2 131.6, 133.5, 136.4, and 140.9. ν: 1445, 1285, 1140, and 750 cm^{-1}].

Further Oxidation of 3 to 4. A $CDCl_3$ solution (0.3 cm^3) of **3** (16 mg) and MCPBA (34 mg, 2.1 mol equiv) was kept at 15—25 °C for 72 h. The NMR spectroscopy indicated the partial formation of **4**, 33%.

MCPBA-oxidation of 5-Isopropyl-2-methyl-8H-cyclohepta[b]-thiophen-8-one (5) to 6, 7, 8, and 9. A $CHCl_3$ solution (3 cm^3) of **5** (200 mg) was mixed with MCPBA (497 mg, 2.5 mol equiv) and kept at 15—20 °C for 72 h with stirring. After filtration of the resultant MCBA, the filtrate was chromatographed on a silica-gel column to give colorless needles, mp 53—54 °C, **7**, 3 mg (1.5%) [Found: M^+, 222.0712. Calcd for $C_{12}H_{14}O_2S$: M^+, 222.0715. δ=1.25 (6H, d, J=7 Hz), 2.21 (3H, d, J=2 Hz), 2.94 (1H, sept, J=7 Hz), 6.71 (1H, m), 7.10 (1H, d, J=1.5 Hz), 7.26 (1H, dd, J=8, 1.5 Hz), and 7.60 (1H, d, J=8 Hz). δ=9.2, 23.7 (2C), 34.5, 121.6, 122.6, 126.1, 127.4, 141.2, and 155.5. ν: 2975, 1295, 1145, and 825 cm^{-1}], and yellow needles, mp 196—197 °C, **6**, 124 mg (54%) [Found: C, 62.54; H, 5.68%. Calcd for $C_{13}H_{14}O_3S$: C, 62.38; H, 5.64%. δ=1.26 (6H, d, J=7 Hz), 2.28 (3H, d, J=2 Hz), 2.87 (1H, sept, J=7 Hz), 6.64 (1H, quint, J=2 Hz), 6.86 (1H, dd, J=2, 1.5 Hz), 7.08 (1H, dd, J=12, 1.5 Hz), and 7.22 (1H, dd, J= 12, 2 Hz). δ(C)=9.4, 22.5 (2C), 39.0, 125.7, 128.0, 137.7, 138.5, 140.8, 145.7, 146.2, 162.9, and 176.8. m/z, 250 (M^+). ν: 2980, 1620, 1560, 1300, 1140, and 870 cm^{-1}].

The combined filtrates were further purified by PTLC to give minor products, an unstable yellow oil, **8**, 13.6 mg (5.6%) [δ=1.27 (3H, d, J=7 Hz), 1.28 (3H, d, J=7 Hz), 2.22 (3H, d, J=2 Hz), 2.84 (1H, sept, J=7 Hz), 3.71 (1H, dd, J=4, 2 Hz), 4.08 (1H, d, J=4 Hz), 6.12 (1H, dd, J=2, 1 Hz), and 6.38 (1H, q, J=2 Hz)], and pale yellow needles, **9**, mp 166—167 °C, 9.7 mg (4%) [Found: M^+, 266.0591. Calcd for $C_{13}H_{14}O_4S$: M^+, 266.0608. δ=1.35 (6H, d, J=7 Hz), 2.24 (3H, d, J=2 Hz), 3.68 (1H, sept, J=7 Hz), 6.69 (1H, q, J=7 Hz), 6.80 (1H, s), 10.38 (1H, s), and 12.58 (1H, s). δ(C)=9.5, 22.4 (2C), 24.0, 113.0, 118.2, 124.5, 140.5, 146.6, 157.9, 161.4, and 216.7. ν: 2975, 1650, 1300, 1140, and 905 cm^{-1}].

Further MCPBA-oxidation of 6. A $CHCl_3$ solution (5 cm^3) of **6** (29 mg) was mixed with MCPBA (64 mg) and was kept at 15—25 °C for 72 h. The NMR spectral analysis of the mixture indicated the formation of **8**, 35%.

Spontaneous Conversion of 8 to 7, and 9. A neat liquid of **8** (10.7 mg) was kept in a glass vessel at 15—25 °C for 20 h. The resultant crystals thus formed were collected by filtration to give **9**, 4.2 mg (39%), and liquid chromatographic analysis of the filtrate, *ca.* 6 mg, indicated the composition of **7** and **9** as 53:47.

MCPBA-oxidation of 6-Isopropyl-2-methyl-8H-cyclohepta[b]-thiophen-8-one (10) to 11, 12, and 13. A $CHCl_3$ solution (3 cm^3) of **10** (206 mg) was mixed with MCPBA (523 mg, 2.5 mol eq) and kept at 15—20 °C for 72 h. After removal of MCBA by filtration, the filtrate was chromatographed on a silica-gel column to give yellow needles, **11**, mp 179—180 °C, 141 mg (60%) [Found: C, 62.10; H, 5.64%. δ=1.24 (6H, d, J= 7 Hz), 2.26 (3H, d, J=2 Hz), 2.78 (1H, sept, J=7 Hz), 6.68

(1H, q, J=2 Hz), 7.02 (1H, dd, J=11, 1 Hz), 7.12 (1H, dd, J=1.5, 1 Hz), and 7.22 (1H, dd, J=11, 1.5 Hz). δ(C)=9.5, 22.5 (2C), 38.7, 124.8, 131.0, 139.9, 140.2, 142.7 (2C), 146.2, 156.9, and 177.1. *m/z*, 250 (M^+). ν: 2970, 1615, 1580, 1305, 1140, and 880 cm^{-1}].

From more polar fractions, the minor products, yellow needles, **13**, mp 133—134 °C, 3 mg (1.2%) [Found: M^+, 282.0555. Calcd for $C_{13}H_{14}O_5S$: M^+, 282.0562, δ=1.20 (3H, d, J=7 Hz), 1.21 (3H, d, J=7 Hz), 2.09 (3H, d, J=2 Hz), 2.63 (1H, sept, J=7 Hz), 3.42 (1H, dd, J=4, 1 Hz), 3.90 (1H, d, J=4 Hz), 6.04 (1H, t, J=1 Hz), and 6.61 (1H, q, J=2 Hz). δ(C)=9.7, 20.9, 21.1, 37.5, 54.8, 55.1, 65.2, 124.9, 127.3, 147.1, 157.3, and 185.6. δ(C)C_6D_6=9.1, 20.5, 20.7, 36.8, 54.3 (2C or 3C), 63.8, 126.0, 147.6, 155.9, and 185.7. ν: 2980, 1165, 1325, 1295, and 1150 cm^{-1}], and colorless needles, **12**, mp 119—120 °C, 2.2 mg (1%) [Found: M^+, 238.0671. Calcd for $C_{12}H_{14}O_3S$: M^+, 238.0690. δ=1.24 (6H, d, J=7 Hz), 2.17 (3H, d, J=2 Hz), 3.22 (1H, sept, J=7 Hz), 6.67 (1H, q, J=7 Hz), 6.76 (1H, d, J=8 Hz), and 7.27 (1H, d, J=8 Hz). δ(C)=9.0, 22.6, 26.9, 116.9, 126.5, 130.5, 131.9, 133.2, 139.1, 140.2, and 149.5. ν: 3420, 2960, 1470, 1290, 1140, and 880 cm^{-1}], were isolated by further PTLC.

Further MCPBA-oxidation of 11. A $CHCl_3$ solution (5 cm^3) of **11** (132 mg) was mixed with MCPBA (287 mg) and was kept at 15—25 °C for 72 h. The HPLC analysis of the mixture revealed a formation of **12**, 21%, and **13**, 4%, together with the recovered **11**, 63%.

Attempted MCPBA-oxidation of 2-Methyl-8H-cyclohepta[b]furan-8-one (14). A $CDCl_3$ solution (2 cm^3) of **14** (52 mg) was mixed with MCPBA (147 mg, 2.0 mol equiv) and kept at 15—25 °C for 48 h. The NMR spectroscopy revealed no appreciable change.

Attempted MCPBA-oxidation of 1,2-Dimethyl-8H-cyclohepta-[b]pyrrol-8-one (15). A $CHCl_3$ solution (1 cm^3) of **15** (60 mg) and MCPBA (160 mg, 2.1 mol equiv) was kept at 15—25 °C for 24 h in an NMR tube. The ^{1}H-NMR spectrum of the mixture was complicated; the strongest signals were those of the starting compound, **15**. No further work was attempted.

MCPBA-oxidation of 3-Chloro-9-oxo-4H,9H-cyclohepta[b]-thiopyrane-1-oxide (16). A $CHCl_3$ solution (4 cm^3) of **16** (163 mg) and MCPBA (342 mg, 2.2 mol equiv) was kept at 15—20 °C for 72 h. The mixture was fractionated on a silica-gel column to give **17**, 8 mg (10%), colorless needles, mp 106—107 °C [Found: C, 50.43; H, 3.52%. Calcd for $C_9H_7O_2SCl$: C, 50.35; H, 3.29%. δ=4.53 (2H, d, J=2 Hz), 7.13 (1H, m), and 7.2—7.7 (4H, m). δ(C)=34.8, 121.7, 125.4, 129.0, 130.3, 130.5, 134.0, 137.3, and 140.6. *m/z*, 214 (M^+). ν: 1450, 1295, 1150, and 770 cm^{-1}], **18**, pale yellow fine needles, mp 130—132 °C (decomp), 39 mg (46%) [Found: C, 49.59; H, 2.98%. Calcd for $C_{10}H_7O_3SCl$: C, 49.49; H, 2.91%. $\delta^{(CD_3)_2CO}$=4.70 (2H, d, J=2 Hz), 7.0—7.6 (4H, m), and 7.36 (1H, t, J=2 Hz). δ(C)=34.8, 126.8, 131.9, 135.9, 138.7, 140.2, 146.0, 146.9, and 177.3. *m/z*, 242 and 244 (M^+). ν: 3100, 1615, 1580, 1310, 1140, and 800 cm^{-1}], and the recovered **16**, 85 mg (52%). On contact of **18** with water hydrolytic decomposition to an unidentifiable compound occurred.

Prolonged MCPBA-oxidation of 2-(2-Chloro-2-propenylsulfonyl)tropone (1). A $CHCl_3$ solution (2 cm^3) of **1** (106 mg) was kept at 15—20 °C for 95 h. The mixture was then washed with aqueous Na_2CO_3, and extracted with $CHCl_3$. The extracts were fractionated by PTLC to colorless needles, **20**, mp 45—46 °C, 9 mg (19%) [Found: C, 49.87; H, 4.15%. Calcd for $C_9H_9O_2SCl$: C, 49.88; H, 4.19%. δ=4.05 (2H, s), 5.34 (1H, d, J=1 Hz), 5.49(1H, d, J=1 Hz), and 7.4—8.0 (4H, m). δ(C)=64.6, 121.8, 128.5, 128.7, 129.1, 134.1, and 137.7. *m/z*, 216 and 218 (M^+)], and the recovered **1**, 50 mg (47%).

Alternative Preparation of 20. An EtOH solution (5 cm^3) of benzenethiol (119 mg) was mixed with 2,3-dichloropropene (106 mg) and refluxed for 2 h. The mixture containing **20** thus formed was then evaporated, dissolved in $CHCl_3$ (5 cm^3), and kept at 15—25 °C for 24 h with MCPBA (550 mg, 2.5 mol equiv). The colorless needles (20.7 mg, 97%) were identical with **20** in respects of mp, mass, and NMR spectra.

The authors are grateful to the Ministry of Education, Science and Culture for operating a Grant to H. M. (No. 58740235).

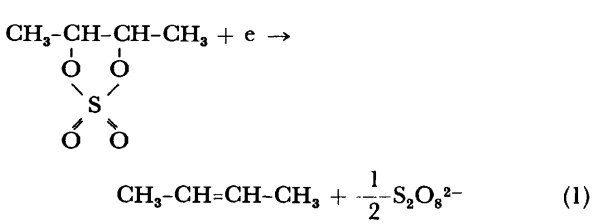
(Received April 11, 1984)

It was confirmed that cyclic and acyclic sulfates of diols and monoalcohols could be reduced at cathodes in nonaqueous solvents. The reduction products were greatly affected by the molecular structures of the sulfates. The reduction of the cyclic sulfates of 1,2-diols yielded the corresponding alkenes and disulfate dianions of the parent diols in high yields and current efficiencies were based on one-electron reduction. On the other hand, the cyclic sulfates of 1,3- and 1,4-diols were also reduced by one-electron transfer under similar conditions, but the cycloalkanes expected were not formed and the products were cyclic ethers along with acyclic alkane or unsaturated alcohol. The reduction of the cyclic sulfate of hydrated formaldehyde, which is regarded as a 1,1-diol, did not give any identified products except for a small amount of methane. Finally, acyclic dialkyl sulfates were reduced by one-electron transfer to give complicated mixtures consisting of monomeric alkanes and alkenes, dimeric alkanes, ethers, and/or alkyl metals. Based on the results obtained, the mechanism of reduction of sulfates (mainly cyclic sulfates of 1,2-diols) is discussed.

It is known that 1,2-diols themselves are electrochemically reduced only with great difficulty. However when the hydroxyl groups are derivatized to a good "leaving group" -OR, reduction leads to alkenes or alkanes. The diacetate of hydrobenzoin is reduced to bibenzyl in the presence of proton donors,[1] while the dioxalate also is reduced at a relatively low potential to give stilbene.[2] Highly aryl-substituted epoxides are reduced but selectivities for the corresponding alkenes are low.[3]

The above examples show that derivatives of only 1,2-diols involving di- or higher aryl-substituents can be reduced. This may suggest considerable difficulty in the reduction of derivatives of 1,2-diols which are not aryl-substituted. In fact, only one successful result had been reported prior to our previous report. Dey and Sullivan[4] found that propylene carbonate was reduced not directly but indirectly with electrogenerated lithium metal.

In previous works,[5,6] we showed the first example of the direct reduction of derivatives of 1,2-diols which are not aryl-substituted,[7] and the following points were established: (a) The sulfate was coulometrically reduced by one-electron transfer and (b) the yield of 2-butene formed did not exceed 50% based on the starting sulfate. Equation 1 was tentatively given as a stoichiometry for this reduction, postulating the elimination of radical anion $SO_4^{\cdot-}$ and its dimerization. This is distinguished by the one-electron transfer reduction, as contrasted to the four-[1] and two-electron[2-4] transfer reductions of other 1,2-diol derivatives.



$$CH_3\text{-}CH=CH\text{-}CH_3 + \frac{1}{2}S_2O_8^{2-} \qquad (1)$$

More detailed examination of the reduction of sulfate of 2,3-butanediol and extension of the reduction to sulfates of other 1,1-, 1,2-, 1,3-, and 1,4-diols and of monoalcohols are reported here.

Results an Discussion

Reduction of the Cyclic Sulfate of 2,3-Butanediol. Stoichiometry: In order to establish the stoichiometry, the separation of products containing sulfur was attempted.

When the sulfate was reduced at a mercury cathode in Et_4NClO_4/DMF, very small amounts of precipitates, which decomposed in acid solutions, were formed. They were presumed to be a mercury salt of an oxyacid containing sulfur, *e.g.* Caro's acid,[9] from their properties.

If peroxodisulfate ions were formed according to Eq. 1, they would be present as the tetraethylammonium salt (soluble in DMF) and should be easily reduced to sulfate ions.[10] In fact, it was confirmed that ammonium peroxodisulfate was reduced consuming 2F (1F=96480C)/mole of charge at a less negative potential than the cyclic sulfate of 2,3-butanediol.

Peroxodisulfate ion can be regarded as equivalent to sulfate anion radical ($SO_4^{\cdot-}$) in some cases. Therefore, it was attempted to trap the anion radical in electrolyses in the presence of aniline[11] and styrene,[12] but the yield of 2-butene was not affected in both cases and also in the latter case neither styrene oxide nor polystyrene could not be detected.

A further investigation was made of products which are soluble in the catholyte and not volatile. After a complicated work-up procedure of the catholyte, the bis(tetrabutylammonium) salt of the acyclic disulfate dianion (**1**) of 2,3-butanediol was separated and derivatized to the dipotassium salt. The molecular structure of the dipotassium salt was confirmed by spectral and analytical data, and by the recovery of 2,3-butanediol and sulfuric acid after its hydrolysis. These results indicate Eq. 2 to be the most likely stoichiometry for the main reaction. The yield of **1** separated as the dipotassium salt was 42% according to Eq. 2; such a value lower than 100% seemed to be due to mainly to material loss in the complicated multi-step procedure for the separa-

tion. On the other hand, yields of 2-butene, which were tentatively reported to be lower (39—49%) than 50% according to Eq. 1 in the previous work,[5] can be re-evaluated as 78—99% according to Eq. 2.

1

Reaction Mechanism: The initial steps of the reduction were investigated by voltammetric methods. As shown in Fig. 1, cyclic voltammetry indicated a totally irreversible process, since a more negative shift of reduction peak potentials at higher sweep rates and no oxidation peak were observed. The cyclic sulfate also gave a single polarographic wave ($E_{1/2}$ −1.86 V *vs.* Ag^+/Ag), the wave height of which was proportional to concentration and had a linear relationship to the square root of the mercury column height. The wave analysis of the polarograms gave a slope of *ca.* 160 mV. Since it has been confirmed that the cyclic sulfate undergoes one-electron reduction, the slope larger than 59 mV should indicate that the electron transfer step is also irreversible. Combining this result with that of cyclic voltammetry, a possible reaction route from the cyclic sulfate to a ring-opened anion radical (**3**) *via* another one (**2**) is shown in Scheme 1. This manner of ring-opening should be more favorable than others, in view of the higher electron negativity of oxygen than carbon and the strong electron-withdrawing power of the $-SO_2-$ part of **3**.

As the simplest route from **3** to the final products (2-butene and **1**), disproportionation (route A in Scheme 1) of **3** is conceptually proposed without either highly negative or positive experimental evidence. Since it is known that a radical with a leaving group at its β-position looses the latter as a radical and yields an olefin,[13] **3** may loose $SO_4^{\cdot-}$ to give 2-butene (route B). Although it has been confirmed by the electrolysis in the presence of $SO_4^{\cdot-}$ trapping reagents that the reaction does not involve any free $SO_4^{\cdot-}$ in the bulk of the catholyte, the formation of **1** by addition reaction of $SO_4^{\cdot-}$ to **3** or 2-butene in cathode interface can not be excluded in a case where the trapping reagents can

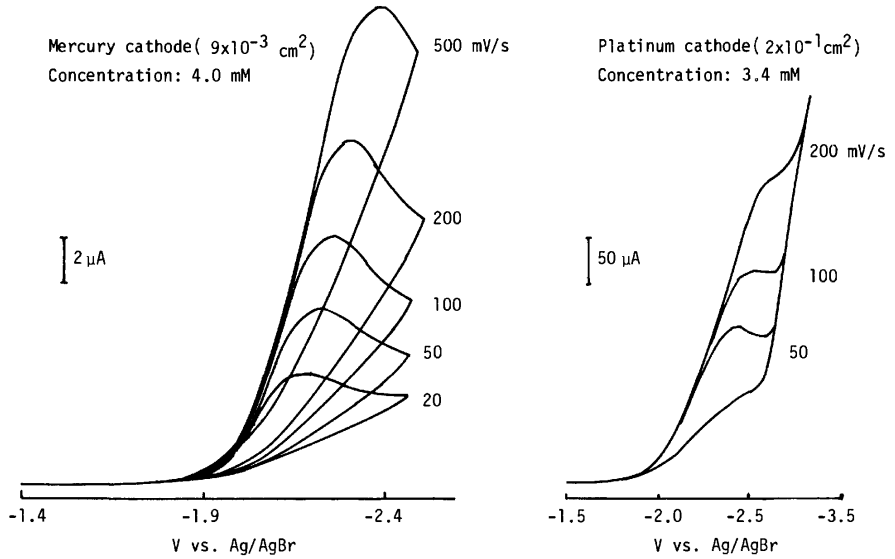

Fig. 1. Cyclic voltammograms of cyclic sulfate of 2,3-butanediol at various potential sweep rates in 0.2 M tetrabutylammonium perchlorate/DMF.

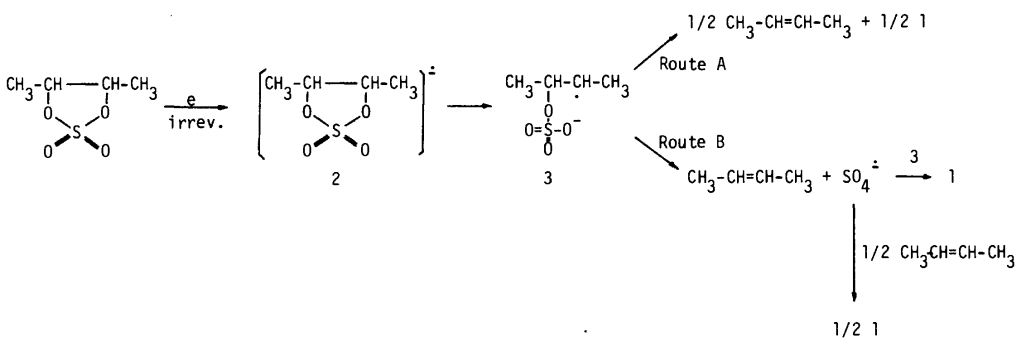

Scheme 1.

not enter the interface. However, it may be difficult to explain why $SO_4^{\cdot-}$, a strong oxidizing reagent, could not be reduced if it had been formed; a rationalization is possible if the rate of the addition reaction is very much higher than that of the reduction. In such a case, there should be no apparent difference between routes A and B, and at least they can not be distinguished by ordinary means. The reaction of $SO_4^{\cdot-}$ with mercury, if it occurred, should be considered separately from the main pathways.

Reduction of Cyclic Sulfates of 1,2-Diols Other Than 2,3-Butanediol. *i-E* Curves of the cyclic sulfate of four kinds of 1,2-diols including 2,3-butanediol were measured by a stationary method. As shown in Fig. 2, the reduction potential of the sulfates was apparently affected by steric hindrance of the diol molecules.

Table 1 shows results of controlled potential electrolyses of the sulfates at a mercury cathode in Et_4NClO_4/DMF. Yields and current efficiencies of the corresponding alkenes formed were estimated according to the stoichiometry of Eq. 2.

The cyclic sulfate of 1,2-ethanediol showed a unique phenomenon in the current-time relation during electrolysis. As shown in Fig. 3, the current decreased rapidly to the background level when the electrolysis was carried out at −1.3 V *vs.* Ag^+/Ag and only 0.6 F/mole of charge was passed. The current efficiency for ethene in this period was 22%. When the applied potential was reset now at −1.6 V, the current increased. Additional 0.3 F/mole of charge could be passed at this potential, till the current decreased again. The current efficiency in this period was 42%. The current could be increased again by resetting the potential at −1.8 V and 0.2 F/mole of charge was passed. The current efficiency was 44%. No more significant increase of the current was observed, when the potential was changed more cathodically after diminution of the current at −1.8 V. The overall current efficiency and total yield were 30 and 34%, respectively. No original sulfate remained unreacted. The above phenomenon is very intriguing but it seems difficult to explain; an attempted explanation is that electrogenerated species might initiate polymerization of the cyclic sulfate to form linear poly(1,2-ethanediol sulfate)s whose reduction

potentials are more negative than that of the cyclic sulfate, depending on the degree of polymerization.

Beside the results given above, here, some informations about the reduction of the cyclic sulfate of 2,3-butanediol are supplemented. As shown in Table 1, a lower current efficiency and yield of 2-butene was obtained at a less negative potential at a mecury cathode; such a dependence of the efficiency and yield on the potential was not observed at a platinum cathode. This fact may suggest the occurrence of side reaction of **3** with a less negatively polarized mercury cathode. A gas chromatogram of the catholyte just after the electrolysis showed only a very small peak for 2-butanone(in addition to 2-butene), while the catholyte treated with aqueous sulfuric acid at 70 °C gave several small peaks which could not be identified. This result also suggests occurrence of side reactions.

The cyclic sulfate of 2,3-dimethyl-2,3-butanediol could be coulometrically reduced by one-electron transfer to give 2,3-dimethyl-2-butene in current efficiency and yield lower than those in the reduction of the sulfate of 2,3-butanediol. The tetrabutylammonium salt of the disulfate dianion of 2,3-dimethyl-2,3-butanediol could be separated pure from a catholyte consisting of Bu_4NClO_4 and acetonitrile.

The cyclic sulfate of *trans*-1,2-cyclohexanediol was reduced at such a negative potential(−2.4 V *vs.* Ag^+/Ag) that supporting electrolyte cation (Et_4N^+) was discharged; amalgam formation was observed indicating that indirect reduction with electrogenerated amalgam occurred simultaneously. The yield of cyclohexene was 100% when 2.3 F/mole of charge were passed.

Reduction of Cyclic Sulfates of Diols Other Than 1,2-Diols. The cyclic sulfate of hydrated formaldehyde, so-called methylene sulfate, can be regarded as the cyclic sulfate of a 1,1-diol and presents as an equilibrium mixture with the cyclic dimer.[14] As the sulfate decomposed exothermically in DMF, acetonitrile was used as a solvent for the electrolysis. The *i-E* curve of the sulfate is shown in Fig. 4, together with that of sulfates of other diols. As shown in Figs. 2 and 4, it is plain that the sulfate of 1,1-diol can be reduced at a considerably less negative potential than that required for any other diols, though different cathodes and/or solvents were used. The two-step reduction wave of the sulfate of the 1,1-diol may be due to the monomer/dimer equilibrium described above. The sulfate was reduced consuming coulometrically 1.0 F/mole of charge at −1.0 V *vs.* Ag^+/Ag corresponding to the first reduction wave at a mercury cathode in acetonitrile, but no product could be detected by gas-chromatographic analysis. When 0.9 F/mole of charge was coulometrically passed at a more negative potential (−1.8 V) corresponding to the second wave, small amounts (2% yield) of methane were formed. Using a platinum cathode, similar results were given. Because no ethene could be detected in any case, the generation of a carbene as an intermediate was not be verified.

The cyclic sulfate of 1,3-propanediol was reduced consuming 1 F/mole of charge at −1.9 V *vs.* Ag^+/Ag at mercury and platinum cathodes in DMF. The former cathode gave no gas-chromatographically detectable

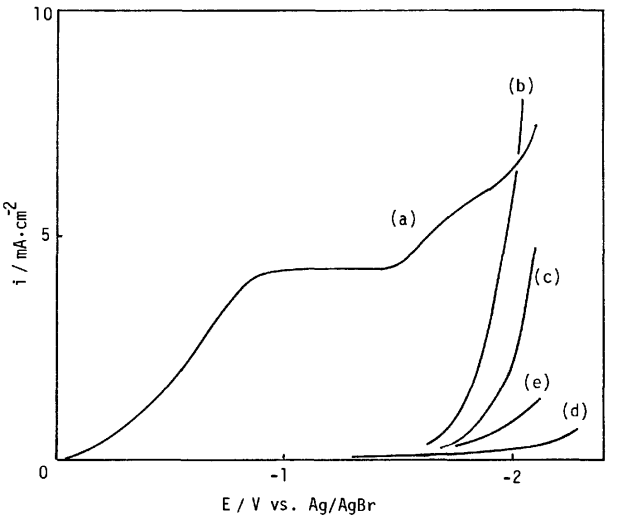

Fig. 4. *i-E* Curves of cyclic sulfates of 1,1-, 1,3-, and 1,4-diols.

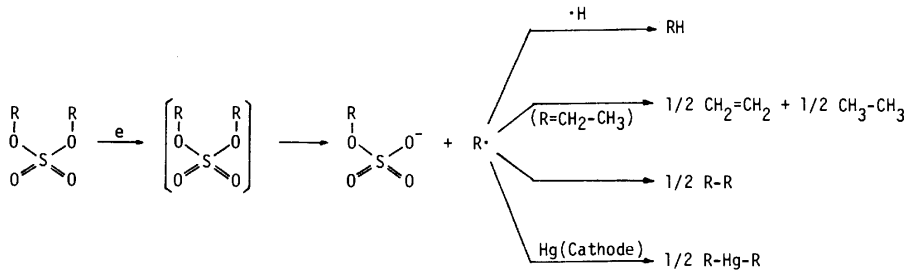
product, while the latter gave allyl alcohol in 10% yield and one more product which had the same molecular weight as allyl alcohol but was not either propylene oxide or oxetane.

The reduction of the cyclic sulfate of 1,4-butanediol at a mercury cathode gave a result similar to that of 1,3-propanediol under the same conditions. Reduction at a platinum cathode resulted in the formation of



Scheme 2.

butane(16% yield) and THF(11%).

Although there have been some ambiguous points in the reduction of the cyclic sulfates of diols other than 1,2-diols, it is interesting to note that the manner of the reduction was quite different from that of 1,2-diols.

Reduction of Acyclic Sulfates of Monoalcohols. *i-E* curves of dialkyl sulfates are shown in Fig. 5. Dimethyl sulfate was reduced at a less negative potential than diethyl sulfate.

Dimethyl sulfate was completely reduced by about 1 F/mole at −1.9 V *vs.* Ag^+/Ag at a mercury cathode in DMF. The products detected were dimethyl ether and dimethylmercury. At a platinum cathode, methane(6% yield) was formed in addition to dimethyl ether(13%). Diethyl sulfate also was reduced by 1 F/mole at a mercury cathode to give diethyl ether in 38% yield, but the presence of diethylmercury was not checked. The reduction at a platinum cathode resulted in the formation of a variety of products: Diethyl ether (17% yield), ethanol(12%), ethane(37%), ethene(16%), and butane(trace). The formation of hydrocarbons and dialkylmercury in the reduction of dialkyl sulfates suggests the generation of alkyl radicals as intermediates, shown in Scheme 2. On the other hand, it seems difficult, just as in the reductions of the cyclic sulfates of diols other than 1,2-diols, to propose specific routes for the products containing oxygen from dialkyl sulfates; they may involve alkoxyl radicals, alkoxide anions and/or alkyl radicals.

Conclusions

This comparative study of the electrochemical reduction of a variety of types of organic sulfates leads to the following principal conclusions:

(a) All the sulfates used were reduced by one-electron transfer.

(b) The reduction products were greatly affected by the type of sulfates; cyclic/acyclic, diol/monoalcohol, and 1,1-/1,2-/1,3-/1,4-diols.

(c) Among the cyclic sulfates of diols, those of 1,2-diols were reduced in a unique manner to give the corresponding alkenes and 1,2-disulfate dianions.

Experimental

Voltammetry. Cyclic voltammograms were recorded at room temperature in 0.1—0.2 M† Bu_4NClO_4/DMF by using a potentiostat (Nikko Keisoku Co. Model MPGS-301), a function generator (Nikko Keisoku Co. Model NPS-2) and an X-Y recorder (Rikendenshi Co. Model F-3DH). Polarograms were measured using Yanaco Model P-1100. Working electrodes for the voltammetries were a platinum wire (diameter, 0.04 cm; length, 1.5 cm; area, 2×10^{-1} cm²), a hanging mercury electrode (drop weight, 1.1 mg; area, 9×10^{-3} cm²) and a dropping mercury electrode (drop weight at −2.10 V *vs.* Ag^+/Ag and 43.5 cm mercury column height, 1.3 mg; area, 1×10^{-2} cm²). Cathodic potentials were referred to a silver bromide electrode in 0.1 M Bu_4NClO_4/DMF. Three-electrode systems with large platinum counter electrodes were employed for all measurements.

Steady state *i-E* curves were measured by using the equipment and solutions similar to those used in the preparative electrolyses described below.

Preparative Electrolyses. An H-type divided cell, a potentiostat (Wenking Model ST-72 or Hokutodenko Model HA-105) and a coulometer (Hokutodenko Model HF-201) were used for electrolyses which were carried out at constant potentials at a mercury pool cathode (diameter, 4 cm; area, 12.5 cm² or diameter, 3 cm; area, 7.1 cm²) and a platinum plate cathode (3×4 cm; area, 12 cm²) at 20 °C. Catholytes were 50 cm³ of DMF or acetonitrile containing 0.4 M Et_4NClO_4 or 0.5 M Bu_4NClO_4 and 0.04—0.10 M starting sulfates.

Product Analyses. Gaseous products were introduced into a gas burette with a nitrogen stream and analyzed by gas chromatography (Porapak Q, 2 m, 40—100 °C). Products in the catholytes also were analyzed by gas chromatography (Porapak Q, 2 m, 100—200 °C for dimethyl ether, diethyl ether, THF, oxetane, propylene oxide, styrene oxide, ethanol and 2,3-butanediol; PEG 20M, 0.5 and 2 m, 30—150 °C for butane, 2-butene, 2-butanone, cyclohexene, 2,3-dimethyl-2-butene and allyl alcohol). Mass spectra were measured by a spectrometer (Jeol Model D-100) connected with gas chromatograph (Joel Model GJC-20K) or none.

The separation of salts of the acyclic disulfate dianion (**1**) of 2,3-butanediol from the catholytes and their identification were carried out by the following procedures: After the electrolysis of the cyclic sulfate of 2,3-butanediol, DMF was evaporated at 50 °C under reduced pressure from the catholyte containing tetrabutylammonium perchlorate; water was added to the residue. The perchlorate was removed from the resulting mixture by extraction with dichloromethane. The aqueous layer was evaporated to dryness under reduced pressure. The residual white solid, which was contaminated with water and DMF, seemed to consist mainly of the bis(tetrabutylammonium) salt of **1** (IR spectrum), but it could not be purified enough to confirm the molecular structure. Next, the separation from a catholyte containing acetonitrile instead of DMF was attempted in a different procedure. Acetonitrile was evaporated at room temperature under reduced pressure and then 30 cm³ of water and 9 cm³ of 0.5 M perchloric acid were added to the residue. The resulting mixture was extracted with two potions of 20 cm³ of dichlo-

† 1 M=1 mol dm^{-3}.

romethane to remove the tetrabutylammonium perchlorate. The aqueous layer was neutralized (pH 7.0) with potassium hydroxide solution and concentrated at room temperature under reduced pressure. The precipitated potassium perchlorate was removed from the solution by filtration. To the filtrate was added ethanol, and the precipitated potassium salt of **1** as white crystals was collected on a filter paper and washed repeatedly with ethanol. Yield, 42%; mp, 249.0—252.5 °C (dec); IR (KBr), 3010 (ν_{C-H}) and 1220—1290 cm^{-1} ($\nu_{S=O}$) MS (70 eV), *m/z* 88 (corresponding to the molecular weight of 3,4-dimethyldioxetane) and 72 (2,3-epoxybutane); ^{1}H-NMR (in D_2O), δ=1.37 (m, 6H) and 4.55 (m, 2H) (multiplet signals may be due to stereoisomers, *dl/meso*, of **1**); flame test, violet (potassium). Found: C, 14.82; H, 2.66; S, 18.80%. Calcd for $C_4H_8S_2O_8K_2$: C, 14.72; H, 2.47; S, 19.64%. Further confirmation of the structure was obtained by hydrolysis. 0.192 g (0.59 mole) of the potassium salt of **1** was heated for 6 h at 95 °C in 2 cm^3 of water containing three drops of 2 M hydrochloric acid. 2,3-Butanediol (45% yield) in the reaction mixture was detected by gas chromatography and barium sulfate (52% yield) was precipitated by addition of barium chloride solution.

A small amount of the bis(tetrabutylammonium) salt of the acyclic disulfate dianion of 2,3-dimethyl-2,3-butanediol also could be separated fairly pure from the corresponding catholyte of DMF. Mp, 94.5—95.0 °C; IR(KBr), 1110—1240 cm^{-1} ($\nu_{S=O}$). Found: C, 59.57; H, 11.24; N, 4.36; S, 9.02%. Calcd for $C_{38}H_{84}N_2S_2O_8$: C, 59.96; H, 11.12; N, 3.68; S, 8.42%.

Partial confirmation of the composition of the suspended pale gray particles formed in the electrolysis of the cyclic sulfate of 2,3-butanediol in DMF was made as follows: The particles were collected on a filter paper and washed with DMF and water. The fine powder thus obtained dissolved in dilute nitric acid generating gas. From the resulting nitric acid solution, black and yellow powders precipitated by adding to it aqueous solutions of sodium sulfide and potassium iodide, respectively. The former and the latter seemed to be probably HgS and β-HgI_2 which latter was slightly soluble in ether. The original powder also seemed to decompose in dilute sulfuric and hydrochloric acids and be transposed to finer white powders. The resulting acid solution did not oxidize iodide ions. The original powder was not organic as judged by the IR spectrum. The properties of the powder indicated that it was an inorganic mercury salt. Identification as $HgSO_4$ and $Hg(ClO_4)_2$ was excluded by comparison with authentic samples. From these results, the powder was presumed to be a mercury salt of an oxyacid containing sulfur, *e.g.* Caro's acid. No further structure determination of this powder was made, since, because of the very small quantity involved it should not be important in determining the main reaction paths.

Dimethylmercury was analyzed by mass spectroscopy combined with gas chromatography: MS (20 eV), *m/z* 234 (M^+), 232 (M^+), 231 (M^+), 230 (M^+), 229 (M^+), 219 (M^+-CH_3), 217 (M^+-CH_3), 216 (M^+-CH_3), 215 (M^+-CH_3), 214 (M^+-CH_3) and 213 (M^+-CH_3).

Materials. Chemicals, except for the cyclic sulfates, were commercially supplied from Tokyo Kasei Kogyo Co., Ltd., Aldrich Chemical Co. and Pfaltz & Bauer, Inc. The cyclic sulfates mentioned below, unless stated otherwise, were prepared by literature methods: The cyclic sulfates of 1,2-ethanediol,[15] 2,3-butanediol,[16] 2,3-dimethyl-2,3-butanediol,[17] *trans*-1,2-cyclohexanediol,[18] and hydrated formaldehyde.[19]

Cyclic Sulfate of 1,3-Propanediol: To a suspension of 42.6 g (0.56 mole) of 1,3-propanediol in 200 cm^3 of dichloromethane was dropwise added 72.6 g (0.62 mole) of thionyl chloride; the reaction mixture was reluxed for 1 h. The mixture was poured into 100 cm^3 of ice water and the organic layer was washed with 100 cm^3 of water and aqueous sodium hydrogencarbonate, and again with water. The organic layer was dried over anhydrous magnesium sulfate and evaporated under reduced pressure. By fractional distillation of the residual oil the cyclic sulfite of 1,3-propanediol was obtained. Yield, 71%; bp, 52—54 °C/ 8 Torr (1 Torr= 101×325/760 Pa); IR (liquid film), 1180 cm^{-1} ($\nu_{S=O}$). To a solution of 20.0 g (0.16 mole) of the cyclic sulfite in 150 cm^3 of acetic acid was added dropwise below 14 °C a solution of 20.0 g (0.13 mole) of potassium permanganate in 200 cm^3 of water. After the reaction mixture was stirred for 1 h at room temperature, 100 cm^3 of water was added and then a solution of sodium sulfite until the precipitating manganese dioxide disappeared. When the mixture was neutralized with sodium carbonate, considerable amounts of the cyclic sulfate of 1,3-propanediol precipitated as white solid. The mixture was thoroughly extracted with ether and the resulting ethereal solution after being washed with water was dried over anhydrous magnesium sulfate. The solution was evaporated and the recrystallization of the residual white solid from a mixture of ether and hexane afforded the pure sulfate of 1,3-propanediol as white needles. Yield, 20%; mp, 60.5—62.0 °C (lit,[20], 63 °C); IR(KBr), 1380 and 1190 cm^{-1} ($\nu_{S=O}$). Found: C, 26.11; H, 4.54; S, 23.25%. Calcd for $C_3H_6SO_4$: C, 26.01; H, 4.38; S, 23.21%.

Cyclic Sulfate of 1,4-Butanediol: Prepared by a procedure similar to that for the cyclic sulfate of 1,3-propanediol. The cyclic sulfite of 1,4-butanediol: Yield, 67%; bp, 71.0—72.0 °C/ 6 Torr (lit,[18], 90.5—91.0 °C/13 Torr); IR (liquid film), 1200 cm^{-1} ($\nu_{S=O}$). The cyclic sulfate of 1,4-butanediol (recrystallized from a mixture of benzene and hexane): Yield, 50% (based on the sulfite); mp, 41.5—43.0 °C (lit,[18] 44—45 °C); IR(KBr), 1360—1395 and 1195 cm^{-1} ($\nu_{S=O}$). Found: C, 31.41; H, 5.41; S, 20.81%. Calcd for $C_4H_8SO_4$: C, 31.57; H, 5.50; S, 21.07%.

We thank Mr. Kwangho Park, UCLA, for performing some of the analyses and Dr. Yoshio Saito, UCLA, for valuable suggestions. We are also grateful to the Solar Energy Research Institute (Subcontract XB-1-9039-1), U.S.A. and the Japanese Ministry of Education, Science, and Culture for making possible Nonaka's participation at an initial period of this study in U.S.A.

Studies on *N*-Glycopeptides. II. Separation of α- and β-Amide of *N*-(L-Aspartyl)-β-D-glucopyranosylamine Obtained *via* *N*-(Benzyloxycarbonyl)-L-aspartic Anhydride

Masahiro TAMURA, Hiroshi NISHIZAKI, Chiemi MIYAZAKI, and Hideo OKAI*
Department of Fermentation Technology, Faculty of Engineering, Hiroshima University, Shitami, Saijo-cho, Higashihiroshima 724
(Received April 28, 1984)

A mixture of *N*-(L-α-aspartyl)- and *N*-(L-β-aspartyl)-β-D-glucopyranosylamine was obtained by the condensation of *N*-(benzyloxycarbonyl)-L-aspartic anhydride with β-D-glucopyranosylamine. Attempts to separate the mixture by using cation-exchange chromatography, a copper(II) complex, and fractional recrystallization were carried out. These separations gave good yields of the desired β-amine.

In a previous paper, we reported the preparation of nine *N*-glycopeptides, obtained by the condensation of *N*-hydroxysuccinimide esters of aspartyltripeptides with three glycosylamines.[1] This active ester method realized a carbohydrate–peptide linkage formation reaction, which was scarce in the *N*-glycopeptide synthesis. However, another synthetic route is necessary in order to prepare more complex *N*-glycopeptides for which demand has been increasing. Preparations of aspartylpeptides *via* *N*-(benzyloxycarbonyl)-L-aspartic anhydride have also been reported. Hirata *et al.* condensed *N*-(benzyloxycarbonyl)-L-aspartic anhydride with a L-histidine benzyl ester, and separated the α- and β-isomer from the reaction mixture.[2] If an efficient separation of aspartyl α- and β-amide is established, this anhydride method can be applied to *N*-glycopeptide synthesis.

Jeanloz *et al.*, actually, prepared 2-acetamido-3,4,6-tri-*O*-acetyl-1-*N*-[*N*-(benzyloxycarbonyl)-L-β-aspartyl]-2-deoxy-β-D-glucopyranosylamine and some of their analogs by the condensation of *N*-(benzyloxycarbonyl)-L-aspartic anhydride with glycosylamines and the following fractional recrystallization or silica-gel column chromatography.[3] They however, carried out the condensation using fully *O*-protected glycosylamine, and so, the separation technique was limited. Moreover, de-*O*-acetylation at the final step requires an alkaline treatment which usually harms the aspartyl linkage. We have attempted to resolve this problem by condensing glycosylamine possessing unprotected hydroxyl groups. Futhermore, applying this idea to the synthesis of *N*-glycopeptide *via* *N*-(benzyloxycarbonyl)-L-aspartic anhydride should reap a greater variety of separations of the α- and β-aspartyl isomer than Jeanloz *et al.* has attempted. We prepared *N*-(L-α-aspartyl)cyclohexylamine, *N*-(L-β-aspartyl)cyclohexylamine, *N*-(L-α-aspartyl)-β-D-glucopyranosylamine, and *N*-(L-β-aspartyl)-β-D-glucopyranosylamine as models of carbohydrate-asparagine compounds. We then examined several separations by using cation-exchange resine chromatography, a copper (II) complex, and fractional recrystallization to find the most efficient ones.

Mixtures were prepared as shown in Schemes 1 and 2. *N*-(Benzyloxycarbonyl)-L-aspartic anhydride (**1**) was condensed with cyclohexylamine to give a mixture of **2a** and **2b**. This was hydrogenated in the presence of palladium black, and the desired mixture of **3a** and **3b** was obtained. *N*-(Benzyloxycarbonyl)-L-aspartic anhydride (**1**) was also condensed with β-D-glucopyranosylamine (**5**), which was prepared by the hydrogenation of β-D-glucopyranosyl azide[1] (**4**) in the presence of Adams' catalyst (PtO_2), to give a mixture of **6a** and **6b**. Hydrogenation of the mixture in the presence of palladium black gave the desired mixture of **7a** and **7b**.

It should be noted here that Kornguth *et al.* reported

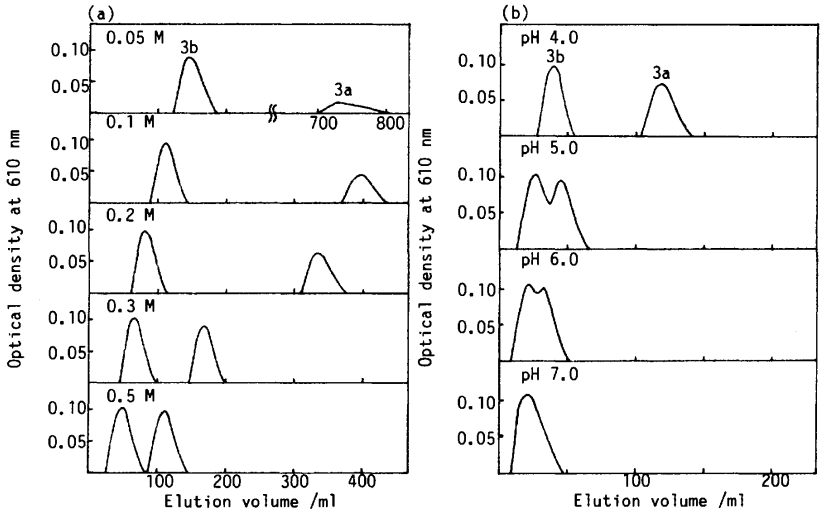

Fig. 1. Effect of salt concentration (a) and pH (b) in pyridinium acetate solvent system on separation of *N*-(L-α-aspartyl)cyclohexylamine (**3a**) and *N*-(L-β-aspartyl)cyclohexylamine (**3b**).

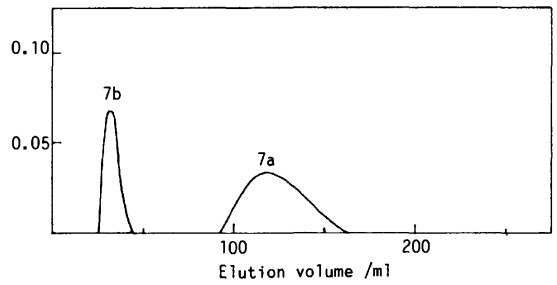

Fig. 2. Separation of *N*-(L-α-aspartyl)-β-D-glucopyranosylamine (**7a**) and *N*-(L-β-aspartyl)-β-D-glucopyranosylamine (**7b**) on a small column.
Amberlite CG-120 type II (pyridinium form, 1.2× 10 cm) Buffer solution ; 0.1 M pyridinium acetate (pH 4.0).

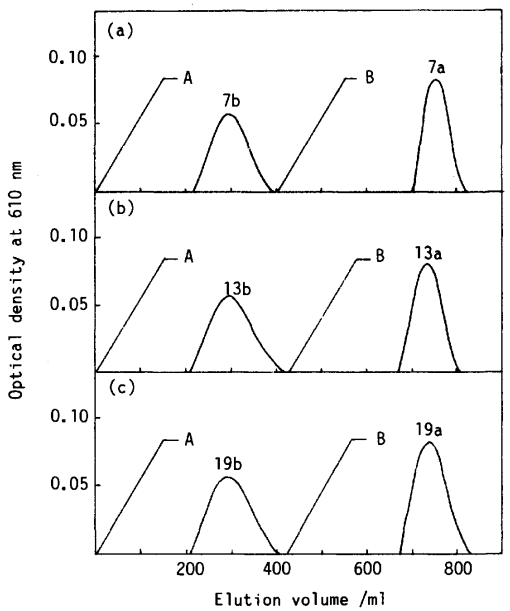

Fig. 3. Preparative separation of **7a** and **7b** (a), **13a** and **13b** (b), and **19a** and **19b** (c).
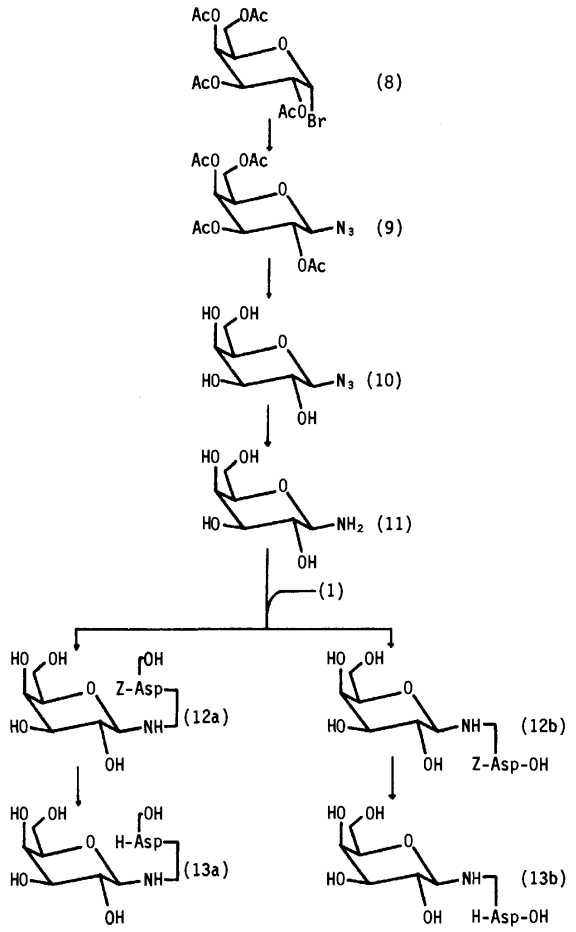
Amberlite CG-120 type I (pyridinium form, 2.8× 50 cm) Buffer solution ; A : 0.1 M pyridinium acetate (pH 4.0) B : 0.2 M pyridinium acetate (pH 4.0).

the separation of a mixture of ε-(L-α-glutamyl)-L-lysine and ε-(L-γ-glutamyl)-L-lysine using an amino-acid analyzer,[4] and Hirata *et al.* reported the separation of a mixture of L-α-aspartyl-L-histidine and L-β-aspartyl-L-histidine, or L-α-glutamyl-L-histidine and L-γ-glutamyl-L-histidine using a cation-exchange resin.[2] With this in mind, we first examined the separation of mixtures **3a** and **3b**, and **7a** and **7b** by cation-exchange resin chromatography. Preliminary experiments on a mixture of **3a** and **3b** were performed with a small column of Amberlite CG-120 using pyridinium acetate buffers at different pH and salt concentrations in order to find an optimal condition for the separation. The elution patterns of a mixture composed of **3a** and **3b** are indicated in Figs. 1-a and 1-b. 0.1 M† Pyridinium acetate (pH 4.0) separated the mixture most effectively. We then attempted to separate a mixture of **7a** and **7b** using the same solvent. As shown in Fig. 2, **7a** and **7b** were separated completely.

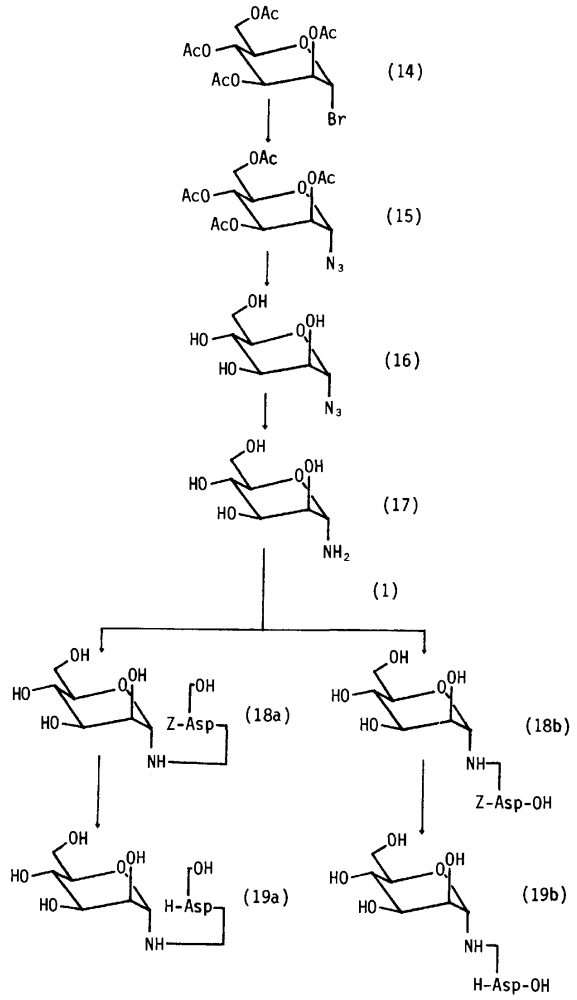
As a large-scale experiment we attempted to separate material composed of **7a** and **7b** into α- and β-amide with a large column (2.8×54 cm) of Amberlite CG-120, using 0.1 M pyridinium acetate (pH 4.0) as an eluent. After the first peak was eluted, the eluent was changed to 0.2 M pyridinium acetate (pH 4.0). Compounds **7a** and **7b** were separated completely (see Fig. 3-a) and provided high yields (250 mg and 120 mg, respectively).

We further prepared mixtures of α- and β-amide of β-D-galactopyranosylamine and α-D-mannopyranosylamine as shown in Schemes 3 and 4, and treated them using the same method as described for the separation of **7a** and **7b** in order to investigate the limit of separation using a cation-exchange resin. Both galactosyl (**13a** and **13b**) and mannosyl (**19a** and **19b**) derivatives were separated completely, as shown in Figs. 3-b and 3-c. From these results, the usefulness of the separation of

† 1M=1 mol dm^{-3}.



Scheme 3.



Scheme 4.

α- and β-amide of aspartyl residue from the reaction mixture (obtained by the condensation of *N*-(benzyloxycarbonyl)-L-aspartic anhydride with various glycosylamines) by the use of cation-exchange resin chromatography was proved.

We next applied a mixture of **7a** and **7b** to an amino acid analyzer. Compounds **7a** and **7b** were separated completely (see Fig. 4). The percentage of color yield of **7a** and **7b**, based on L-aspartic acid as 100%, were observed to be 89% and 162%, respectively. We used an amino acid analyzer to check the purity of the mixture after the following separations.

Secondly, we examined a separation using a copper (II) complex. By the addition of dicopper carbonate dihydroxide to **7a** and **7b**, 6-membered and 5-membered rings were formed, respectively. It is well-known that a 5-membered copper (II) complex is more stable than a 6-membered salt (see Fig. 5). We tried to separated **7a** and **7b** using the difference in their stabilities. The experiment was performed as shown in Scheme 5. The crystals (II) obtained were de-salted and apllied to an amino acid analyzer. We found that purification was as follows: **7a**:**7b**=9:91. The purification by the differential stability of copper (II) salts of **7a** and **7b** may be suitable in the preparation of *N*-glycopeptide.

Thirdly, we attempted to isolate **6b** from the mixture by fractional recrystallization. We prepared diastereomeric salts of **6a** and **6b** with cyclohexylamine and dicyclohexylamine, and these salts were recrystallized from methanol. The crystals obtained were hydrogenated, applied to an amino acid analyzer to confirm the purity of the mixture, and the results are listed in Table 1. We discovered an interesting and useful fact; the dicyclohexylammonium salt of **6b** is more soluble than

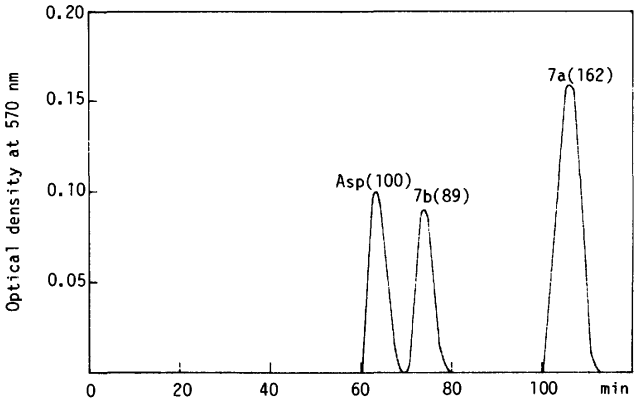


Fig. 4. Elution pattern of aspartic acid, *N*-(L-β-aspartyl) β-D-glucopyranosylamine (**7b**), and *N*-(L-α-aspartyl)-β-D-glucopyranosylamine (**7a**) by amino acid analyzer. Sample; 0.1 μmol/ml solution.

that of **6a**, whereas the cyclohexylammonium salt of **6b** is less soluble than that of **6a**. These facts were applied to separate a mixture of **6a** and **6b**. At the outset, we attempted to obtain **6b** by the repetitious recrystallization of a cyclohexylammonium salt as shown in Scheme 6, however, pure **6b** was obtained in a very low yield. Therefore, we used both a cyclohexylammonium salt and a dicylohexylammonium salt (shown in Scheme 7) to obtain a pure cyclohexylammonium salt of **6b** with a high yield.

We considered that fractional recrystallization has several merits, to wit; (a) fractional recrystallization is performed in organic solution, in which aspartyl residue is more stable than an acidic or basic solution of water, and (b) the resulting β-amide is suitable to elongate the peptide chain toward the C-terminal since fractional recrystallization is carried out using an *N*-protected aspartyl derivative.

We established separation techniques to obtain β-amide formed by the reaction of *N*-(benzyloxycarbonyl)-L-aspartic anhydride with glycosylamine. Each separation gave a good yield and compared favorably with that of Jeanloz *et al.* Additionally,and equally important, is the fact that this method goes to lesser extremes, yet is much more refined than the method of Nerberger *et al.* in which they condensed *N*-(benzyloxycarbonyl)-L-aspartic acid α-benzyl ester with 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosylamine in the presence of dicyclohexylcarbodimide.[5]

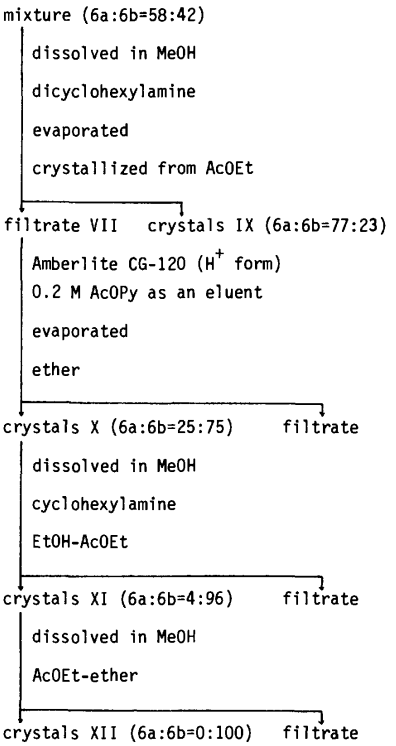

Scheme 7.

Experimental

All the melting points were uncorrected. The optical rotations were measured on a Union PM-101 Polarimeter. IR spectra were taken on a Jasco spectrophotometer Model IRA-1. Thin-layer chromatography was carried out on a Kieselgel G nach Stahl (Type 60) with 1-butanol–acetic acid–pyridine–water (4:1:1:2 v/v). Spots of material possessing a free amino group in a thin-layer plate were detected by ninhydrin, and those of the amino group-blocked material by spraying 25% HBr/AcOH and then ninhydrin. A quantitative analysis of the aspartyl derivatives was performed with a Hitachi Model KLA-5 amino acid analyzer. The amounts of color developed were determined using an Atago AG-4 Densitometer (slit 1×18 mm, 610 nm). Samples for elemental analysis were dried at 60 °C over phosphorus pentaoxide *in vacuo*.

Preparation of Mixtures. N-*(L-α-Aspartyl)- and* N-*(L-β-Aspartyl)cyclohexylamine (**3a** and **3b**)*: A solution of *N*-(benzyloxycarbonyl)-L-aspartic anhydride[6] (**1**) (1.25 g) in tetrahydrofuran (5 ml) was added to a solution of cyclohexylamine (0.7 ml) and triethylamine (0.56 ml) in tetrahydrofuran (5 ml) under vigorous stirring at room temperature overnight. The reaction mixture was evaporated to dryness and the residue was dissolved in ethyl acetate. The solution was washed with 4% sodium hydrogencarbonate and water, successively, dried over anhydrous sodium sulfate, and evaporated. A solid of **2a** and **2b** (1.40 g, 80%) was obtained by the aid of ether–petroleum ether.

The mixture of **2a** and **2b** (0.70 g) was dissolved in acetic acid (30 ml) and treated with hydrogen in the presence of palladium black. The filtrate from the catalyst was evaporated to dryness and a mixture of **3a** and **3b** was obtained after crystallization from ether; yield, 0.43 g.

Found: C, 56.00; H, 8.49; N, 13.01%. Calcd for $C_{10}H_{18}N_2O_3$: C, 56.05; H, 8.47; N, 13.08%.

N*[N-(Benzyloxycarbonyl)-L-α-aspartyl]- and* N-*[N-(Benzyloxycarbpnyl)-L-β-aspartyl]-β-D-glucopyranosylamine (**6a** and **6b**)*: To a solution of *β*-D-glucopyranosylamine[1] (**5**) (4.30 g), obtained by the hydrogenation of *β*-D-glucopyranosyl azide[1] (**4**), and triethylamine (3.36 ml) in water (20 ml), a solution of **1** (4.98 g) in tetrahydrofuran (20 ml) was added under vigorous stirring at room temperature. The stirring continued overnight. The reaction mixture was evaporated to dryness and the residue was dissolved in water (40 ml). The solution was adjusted to pH 4.0 by the addition of 2% hydrochloric acid and extracted with ethyl acetate (total 500 ml). The organic layer was dried over anhydrous sodium sulfate and evaporated. The residual oil was crystallized using ether; yield, 4.79 g (56%); R_f 0.79 (**6a**) and 0.72 (**6b**).

Found: C, 50.49; H, 5.66 N, 6.52%. Calcd for $C_{18}H_{24}N_2O_{10}$ C, 50.49; H, 5.65; N, 6.54%.

N-*(L-α-Aspartyl)- and* N-*(L-β-Aspartyl)-β-D-glucopyranosylamine (**7a** and **7b**)*: A mixture of **6a** and **6b** (1.28 g) was dissolved in methanol and hydrogenated in the presence of palladium black. After 4 h, the catalyst was filtered off and the filtrate was evaporated to dryness. A mixture of **7a** and **7b** was crystallized using ethanol; yield 0.58 g (66%); R_f 0.34.

Found: C, 40.14; H, 6.17; N, 9.52%. Calcd for $C_{10}H_{18}N_2O_8$: C, 40.18; H, 6.17; N, 9.52%.

*Tetra-O-acetyl-β-D-galactopyranosyl Azide (**9**)*: This compound was prepared by the method of W. Pfleiderer and B. Bühler.[7] The yield was 84% and the product had a mp of 92—93 °C; lit,[7] mp 96 °C. ν_{max}^{KBr} 1760 (OAc) and 2100 cm^{-1} (N_3).

Found: C, 45.00; H, 5.14; N, 11.22%

N-*(L-α-Aspartyl)- and* N-*(L-β-Aspartyl)-β-D-galactopyranosylamine (**13a** and **13b**)*: Compound (**9**) (7.46 g) was dissolved in methanol (20 ml) saturated with dry ammonia at 0 °C and was stored in a glass-stoppered bottle at room temperature overnight. The reaction mixture was then evaporated *in vacuo*. The residual oil was dissolved in methanol and hydrogenated in the presence of PtO_2. The filtrate from the catalyst was evaporated to dryness and the residue was solidified using ethanol; yield, 2.45 g.

This *β*-D-galactopyranosylamine (**11**) (4.30 g) and **1** (4.98 g) were treated as described for the preparation of a mixture of **6a** and **6b**, to give **12a** and **12b**; yield, 4.54 g (53%); R_f 0.82 (**12a**) and 0.74 (**12b**).

A mixture of **12a** and **12b** (1.28 g) was hydrogenated as described for the preparation of **7a** and **7b**; yield, 0.52 g (59%); R_f 0.38.

Found: C, 40.13; H, 6.19; N, 9.56%. Calcd for $C_{10}H_{18}N_2O_8$: C, 40.18; H, 6.27; N, 9.52%.

*Tetra-O-acetyl-α-D-mannopyranosyl Azide (**15**)*: This was prepared by the method of Paulsen *et al.*[8] The yield was 71% and the product had $[\alpha]_D^{20}$ +87° (*c* 1, chloroform): lit,[8] $[\alpha]_D^{20}$ +91° (*c* 1, dioxane), ν_{max}^{nujol} 1750 (OAx) and 2110 cm^{-1} (N_2).

Found: C, 45.12; H, 5.11; N, 11.21%.

N-*(L-α-Aspartyl)- and* N-*(L-β-Aspartyl)-α-D-mannopyranosylamine (**19a** and **19b**)*: **15** (7.46 g) was de-*O*-acetylated and hydrogenated as described for preparation of **11** to give **17**. **17** (4.30 g) and **1** (4.98 g) were treated as described for preparation of the mixture of **6a** and **6b**; yield, 4.88 g (57%); R_f 0.68 (**18a**) and 0.64 (**18b**).

A mixture of **18a** and **18b** (1.28 g) was hydrogenated as described for the preparation of **7a** and **7b**; yield, 0.51 g (58%); R_f 0.31.

Found: C, 40.22; H, 6.20; N, 9.50%. Calcd for $C_{10}H_{18}N_2O_8$: C, 40.18; H, 6.17; N, 9.52%.

*Separation of α- and β-Amide by Cation-exchange Resin Chromatography. Separation of **3a** and **3b** on a Small Column*: A column (1.2×10 cm) with Amberlite CG-120 (pyridinium form) was equilibrated by washing with pyridinium acetate (pH 4.0) of a definite salt concentration (0.05 M, 0.1 M, 0.2 M, 0.3 M, or 0.5 M) or 0.2 M pyridinium acetate of definite pH (4.0, 5.0, 6.0, or 7.0), and the mixture was applied to a column. The column was eluted with the same buffer at room temperature, and two ml fractions were collected at a flow rate of about 10 ml/h. Approximately 0.01 ml from each tube was spotted on a strip of filter paper. The strip was dried at 100 °C for 5 min, immersed in a 0.2% ninhydrin–acetone solution, and again heated. The degrees of coloration developed were determined by a densitometer. The resulting patterns are shown in Fig. 1.

*Separation of **7a** and **7b** on a Small Column*: A mixture of **7a** and **7b** (50 mg) was treated on a column of Amberlite CG-120 (pyridinium form) in same manner as the saparation of **3a** and **3b** using 0.1 M pyridinium acetate (pH 4.0). The resulting patterns are shown in Fig. 2.

*Preparative Separation of **7a** and **7b***: A mixture of **7a** and **7b** (500 mg) was applied to a large column (2.8×54 cm) of Amberlite CG-120 (pyridinium form) using 0.1 M pyridinium acetate (pH 4.0) as an eluent. For the elution of the slower peak, 0.2 M pyridinium acetate (pH 4.0) was used as an eluent. The elution patterns are shown in Fig. 3-a.

7a: Yield 256 mg (51%); mp 183—185 °C (decomp); $[\alpha]_D^{20}$ +13.5° (*c* 2, water). ν_{max}^{KBr} 3300 (broad OH and NH) and 1630 cm^{-1} (CONH).

Found: C, 40.90; H, 6.14; N, 9.51%. Calcd for $C_{10}H_{18}N_2O_8$: C, 40.81; H, 6.17; N, 9.52%.

7b: Yield, 120 mg (24%); mp 204 °C (decomp) $[\alpha]_D^{20}$ −5.5° (*c* 2, water). ν_{max}^{KBr} 3300 (broad OH and NH) and 1650 cm^{-1} (CONH).

Found: C, 40.87; H, 6.15; N, 9.49%. Calcd for $C_{10}H_{18}N_2O_8$: C, 40.81; H, 6.17; N, 9.52%.

Preparative Separation of 13a and 13b: A mixture of **13a** and **13b** (500 mg) was treated in same manner as has been described for the separation of **7a** and **7b**. The elution patterns are shown in Fig. 3-b.

13a: Yield, 211 mg (42%); mp 186—189 °C (decomp); $[\alpha]_D^{20}$ +16.5° (*c* 2, water). ν_{max}^{KBr} 3300 (broad OH and NH) and 1640 cm^{-1} (CONH).

Found: C, 40.84; H, 6.14; N, 9.55%. Calcd for $C_{10}H_{18}N_2O_8$: C, 40.81; H, 6.17; N, 9.52%.

13b: Yield, 163 mg (33%); mp 202—216 °C (decomp); $[\alpha]_D^{20}$ −6.0° (*c* 2, water). ν_{max}^{KBr} 3300 (broad OH and NH) and 1650 cm^{-1} (CONH).

Found: C, 40.81; H, 6.14; N, 9.51%. Calcd for $C_{10}H_{18}N_2O_8$: C, 40.81; H, 6.17; N, 9.52%.

Preparative Separation of 19a and 19b: A mixture of **19a** and **19b** (500 mg) was treated in the same manner as for the separation of **7a** and **7b**. The elution patterns are shown in Fig. 3-c.

19a: Yield, 158 mg (52%); mp 187—188 °C (decomp); $[\alpha]_D^{20}$ +16.5° (*c* 2, water). ν_{max}^{KBr} 3300 (broad OH and NH) and 1640 cm^{-1} (CONH).

Found: C, 40.79; H, 6.16; N, 9.54%. Calcd for $C_{10}H_{18}N_2O_8$: C, 40.81; H, 6.17; N, 9.52%.

19b: Yield, 119 mg (39%); mp 204—221 °C (decomp); $[\alpha]_D^{20}$ −4.0° (*c* 2, water). ν_{max}^{KBr} 3300 (broad OH and NH) and 1660 cm^{-1} (CONH).

Found: C, 40.85; H, 6.16; N, 9.50%. Calcd for $C_{10}H_{18}N_2O_8$: C, 40.81; H, 6.17; N, 9.52%.

Separation of α- and β-Amide by Copper (II) Complex. To a solution of **7a** and **7b** (**7a**:**7b**=55:45, 294 mg) in water (6 ml), dicopper carbonate dihydroxide (66 mg) was added. The solution was heated for 5 min and then 45% acetic acid was added. It was maintained at pH 4.0 onernight. Type-I crystals (139 mg, 43%) were obtained using methanol. A small amount of these were treated on a column of Amberlite CG-120 (H^+ form) (1.3×8.0 cm) with water and 0.2 M pyridinium acetate (pH 5.0) as an eluent. The eluting fraction was collected and evaporated to dryness. The residue was applied to an amino acid analyzer (**7a**:**7b**=36:64).

Type-I crystals were dissolved in hot water and 45% acetic acid was added to the solution. The mixture was maintained at pH 4.0 overnight. Type-II crystals (46 mg, 33%) were obtained using methanol-acetone. A small amount of these were treated on a column of Amberlite CG-120 (H^+ form) as described above (**7a**:**7b**=9:91).

Separation of α- and β-Amide by Fractional Recrystallization. Preliminary Experiments: To a solution of **6a** and **6b** (428 mg) in methanol (5 ml), cyclohexylamine or dicyclohexylamine (2 mmol each) was added. Crystals were obtained using ether (5 ml), and the filtrates were evaporated. Crystals were obtained using ether–petroleum ether as second crop. These crystals were dissolved in methanol, and hydrogenated in the presence of palladium black. Filtrates from the catalyst were evaporated and applied to an amino acid analyzer. The results are listed in Table 1.

Separation of 6a and 6b by the Use of Cyclohexylammonium Salt: A mixture of **6a** and **6b** (**6a**:**6b**=58:42, 428 mg) was dissolved in methanol (5 ml) and cyclohexylamine (0.23 ml) was added to the solution. Type-III crystals (295 mg, 56%) were obtained using ethyl acetate-ether. A small amount of these crystals were dissolved in methanol and hydrogenated in the presence of palladium black. The catalyst was filtered off the filtrate was evaporated. The residual oil was applied to an amino acid analyzer (**6a**:**6b**=47:53).

Type-III crystals were dissolved in methanol (5 ml) in methanol (5 ml) and type-IV crystals (210 mg, 71%) were obtained using ethyl acetate–ether. A small amount of these crystals were hydrogenated as described above, and applied to an amino acid analyzer (**6a**:**6b**=41:59).

Type-IV crystals were dissolved in methanol (5 ml) and type-V crystals (152 mg, 72%) were obtained using ethyl acetate–ether. A small amount of these crystals were hydrogenated and applied to an amino acid analyzer (**6a**:**6b**=15:85).

Type-V crystals were treated as described for the prepartion of type-IV crystals, and type-VI crystals (107 mg, 70%, **6a**:**6b**=6:94) was obtained.

Type-VI crystals were treated as described for the preparation of type-VI crystals, and type-VII crystals (75 mg, 70%, **6a**:**6b**=0:100) were obtained.

Separation of 6a and 6b by the Use of Both Cyclohexylammonium and Dicyclohexylammonium Salt: To a solution of **6a** and **6b** (428 mg, **6a**:**6b**=58:42) in methanol (5 ml), dicyclohexylamine (0.197 ml) was added. The mixture was evaporated to dryness and type-IX crystals (396 mg, 65%) were obtained by the recrystallization from hot ethyl acetate. A small amount of type-IX crystals were hydrogenated, applied to an amino acid analyzer (**6a**:**6b**=77:23).

A filtrate (VIII) was evaporated to dryness, and residual oil was dissolved in water (10 ml). The solution was treated on a column Amberlite CG-120 (H^+ form) using 0.2 M pyridinium acetate (pH 5.0) as an eluent. The eluting fractions was collected and evaporated to dryness. Type-X cryltals (123 mg, 29%) were obtained using ether. A small amount of type-X crystals were hydrogenated and applied to an amino acid analyzer (**6a**:**6b**=25:75).

Type-X crystals were dissolved in methanol (3 ml) and cyclohexylamine (0.05 ml) was added to the solution. The solution was evaporated to dryness and the residual oil was crystallized from ethanol–ethyl acetate to give type-XI crystals (120 mg, 79%). A small amount of type-XI crystals were hydrogenated and applied to an amino acid analyzer (**6a**:**6b**=4:96).

Type-XI crystals were dissolved in methanol (3 ml) and the solution was evaporated to dryness. Type-XII crystals (103 mg, 86%) were obtained using ethyl acetate–ether. A small amount of type-XII crystals were hydrogenated and applied to an amino acid analyzer (**6a**:**6b**=0:100).

Liquid Crystal Materials with Sulfur Atoms Incorporated in the Principal Structure 2. New Liquid Crystal Compounds; 2-Substituted-5-(*p*-substituted phenyl)-1,3-dithianes

Yuichiro HARAMOTO,* Koji AKAZAWA, and Hiroyoshi KAMOGAWA
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400
(Received May 7, 1984)

2-Substituted-5-(*p*-substituted phenyl)-1,3-dithianes (**8**), new liquid crystals, were synthesized. The mesomorphic properties of these compounds were compared with those of the corresponding 2-(*p*-substituted phenyl)-5-alkyl-1,3-dithianes (**9**). The main difference found between these two liquid-crystal compounds was that some of **8** exhibited both monotropic nematic and smectic liquid-crystal phases but **9** exhibited only the monotropic nematic phase. This difference seems to originate in somewhat increased lateral interactions between molecules. Even for the three-ring compounds, many of them exhibited the monotropic liquid-crystal behavior. This should mean that these 1,3-dithiane compounds strongly tend to exhibit the monotropic liquid-crystal behavior.

In recent years, 2,5-disubstituted 1,3-dithianes and 1,3-oxathianes have been reported as new types of liquid-crystal materials.[1,2] Since these structures are quite novel as liquid crystals, we wish to report information on a further synthesis of 2-substituted-5-(*p*-substituted phenyl)-1,3-dithianes and to compare their liquid-crystal behavior with that of the 2-(*p*-substituted phenyl)-5-alkyl-1,3-dithianes previously reported.

Results and Discussion

2-Substituted-5-(*p*-substituted phenyl)-1,3-dithianes were synthesized *via* the following route.

In the synthesis of **2**, both esterification and etherification were done in one step. In step **2**→**3**, it was necessary to keep the reaction temperature at 190—200 °C for about 30 min under a reduced pressure (15 mmHg (1 mmHg=133.322 Pa)) for the complete evolution of carbon monoxide. This evolution of CO allowed us to check and control the progress of the reaction.

In step **4**→**5**, PBr_3 must be used for *p*-ethoxy compounds to prevent the cleavage of the ether bond, but in the case of *p*-methyl compounds $HBr-H_2SO_4$ could be used under conventional conditions. **8** was purified mostly by means of recrystallizations from hexane. Those compounds which could not be purified by recrystallization were purified first by column chromatography, then by recrystallization from hexane until only a single spot in TLC was obtained.

Thus synthesized **8**, were all colorless and odorless crystals or powders which were soluble in common organic solvents.

Absorption of C2 and C4, C6 carbons of the 1,3-dithiane ring in ^{13}C-NMR, as determined by ^1H-complete decoupling (COM), ^1H-off resonance decoupling (OFR), and ^1H-selective decoupling (SEL) procedures, are located at δ=47.46 and 37.06, respectively, for a 1,3-dithiane (R=C_2H_5O, R'=C_7H_{15}). According to Eliel, in the 1,3-dithiane substituted at the C2 carbon by the methyl group, the equatorial isomer absorbs at about 5 ppm lower field than the axial isomer does.[3] Since this compound exhibits liquidcrystal phases and any absorption does not exist between δ 47.46 and 63.39, it should be the pure equatorial isomer without contamination with the axial one.

Mesomorphic ranges of the synthesized 2-substituted-5-(*p*-substituted phenyl)-1,3-dithiane **8** and the corresponding 2-(*p*-substituted phenyl)-5-alkyl-1,3-dithiane **9** are given in Table 1.

Measurements of the mesomorphic ranges and the assignment of the mesophases were carried out by means of a micro melting-point apparatus equipped with polarizers. To decide on the type of smectic phase, a comparison was made of these smectic phases with the color photography found in the literature.[4]

The difference between **8** and **9** are : (1) Some of **8** exhibited smectic A, but **9** not at all and (2) **8** exhibited liquid-crystal phases down to temperatures lower than those corresponding to **9**.

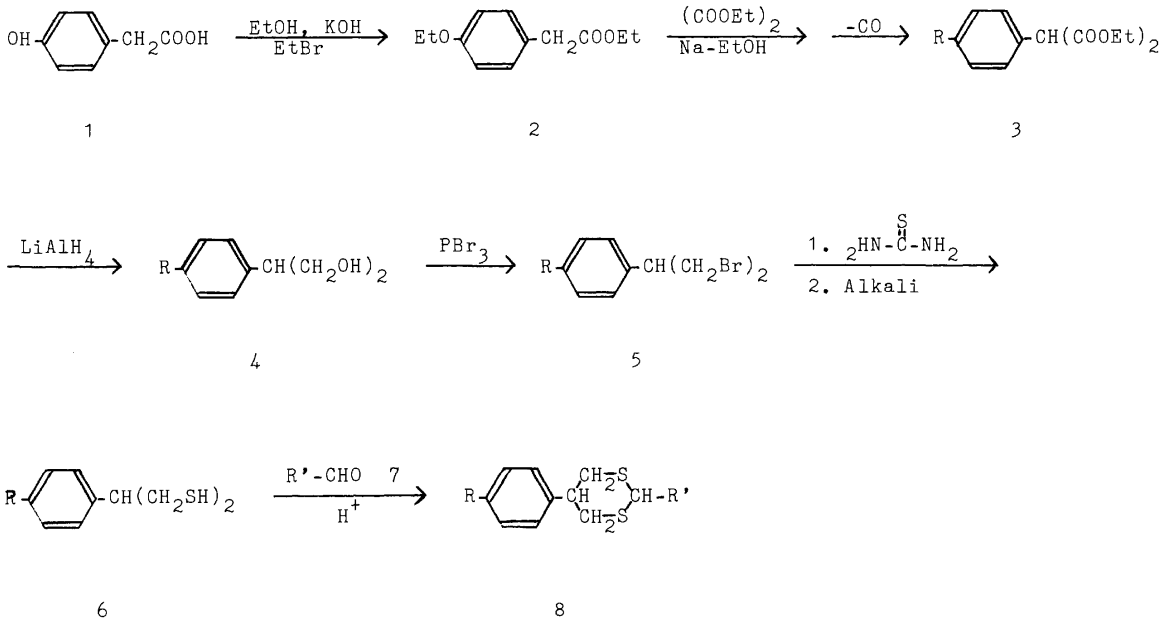
Generally, the smectic phase appears by increasing the attractive side interactions between molecules. The difference in structure between **8** and **9** involves the position of the sulfur atoms. This difference seems to increase side interactions between **8**. That is, in **9**, S-atoms are located more closely to the benzene ring than in **8**, so that the steric effect which decreases lateral interactions seems to become more effective.

Since sulfur atoms are located more closely to the electron-withdrawing benzene ring in **9** than in **8**, this electron withdrawal might be responsible for the lower dipole moment and dispersion force of the C–S bond. In **8**, C–S bonds are more distant from the benzene ring than in the case of **9**, so that this diminishing effect may be very small. Therefore, lateral interactions in **9** should be smaller than those in **8**.

ΔH_{C-1} of the compound **8-5** and **8-6** are 4.97 kcal/mol (1 cal=4.184 J) and 5.90 kcal/mol, and ΔS_{C-1} of them are 15.0 cal/mol/K 17.6 cal/mol/K respectively. These values are somewhat smaller than those of other common liquid-crystal materials.[5]

Even in the three-ring compounds, many of them exhibit the monotropic liquid-crystal behavior. This fact indicates that the 1,3-dithiane compounds of the present study strongly tend to exhibit the monotropic liquid-crystal behavior.

Three-ring compounds having the 5-(*p*-ethoxyphenyl) group (**8-8**, **-10**, **-11**) have a stronger tendency to



R: OC_2H_5, CH_3.
R′: C_2H_5, *n*-C_3H_7, *n*-C_5H_{11}, *n*-C_6H_{13}, *n*-C_7H_{15}, *n*-C_8H_{17}, $C_6H_4OC_2H_5$(*p*-), $C_6H_4OC_3H_7^n$(*p*-), $C_6H_4OC_4H_9^n$(*p*-), $C_6H_4OC_5H_{11}^n$(*p*-), $C_6H_4CH_3$(*p*-), C_6H_4CN(*p*-).

Fig. 1.

exhibit the enantiotropic liquid-crystal behavior than those having the 5-(*p*-methylphenyl) group (**8-13, -14, -15**). All of **8** which do not exhibit any liquid-crystal phases exhibited remarkable supercooling states. This property is common to both **8** and **9**.

Experimental

IR, ^{1}H-NMR, ^{13}C-NMR, and Mass spectra were obtained with a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, a JNM FX 90Q FT-NMR spectrometer, and a Hitachi RMU-6 MG spectrometer, respectively. Elemental analyses were carried out with a Perkin-Elmer 250 instrument. Mesomorphic phases and the transition temperature were determined by means of both a Mitamura Riken micro melting-point apparatus equipped with polarizers and a differential scanning calorimeter. The rate of cooling was fixed to 1 °C/min.

Diethyl p-*Ethoxyphenylmalonate (3).* A conventional procedure was used for the syntheses of **3**.[6] Yield 60—70% Bp 160—163 °C/3—5 mmHg IR ($CHCl_3$) 2850—3000 (alkyl), 1740 (C=O), 1600 (Ar), 1260 (ether) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=1.3 (q, 9H, CH_3), 3.9—4.5 (m, 6H, O-CH_2), 4.6 (s, 1H, CH), 6.8—7.6 (q, 4H, ArH).

Diethyl p-*Methylphenylmalonate (3′).* Yield 50—60% Bp 137—140 °C/5—8 mmHg IR ($CHCl_3$) 2850—3000 (alkyl), 1740 (C=O), 1600 (Ar) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=1.25 (t, 6H, CH_2-CH_3), 2.3 (s, 3H, CH_3), 4.25 (q, 4H, O-CH_2), 4.6 (s, 1H, CH), 7.2 (s, 4H, ArH).

*2-(*p-*Ethoxyphenyl)-1,3-propanediol (4).* $LiAlH_4$-reduction of **3** in ether at 35 °C for 18 h provided **4**. Yields ranged from 90 to 95%. IR ($CHCl_3$) 3600 (OH), 2850—3000 (alkyl), 1605 (Ar), 1250 (ether) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ= 1.4 (t, 3H, CH_3), 2.5—4.3 (m, 9H, CH_2-O, CH, OH), 7.05 (q, 4H, ArH).

*2-(*p-*Methylphenyl)-1,3-propanediol (4′).* Yield 90%. IR ($CHCl_3$) 3600 (OH), 2850—3000 (alkyl), 1600 (Ar) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=2.3 (s, 3H, CH_3), 2.5—4.0 (m, 7H, CH_2-O, OH), 7.2 (s, 4H, ArH).

*2-(*p-*Ethoxyphenyl)-1,3-dibromopropane (5).* To a solution of PBr_3 (0.03 mol), anhyd benzene (10 ml), and pyridine (0.8 g) cooled in an ice bath were added, dropwise, a solution of **4** (0.04 mol), anhyd benzene (10 ml), and pyridine (0.3 g) (30 min.). The solution was kept at 0—5 °C for 1 h, then at 30—40 °C for 15 h. The reaction mixture was poured into ice water (400 ml) and extracted twice with ether (400 ml). The extract was washed with cold water, dried over anhyd Na_2SO_4, and evaporated *in vacuo* at 30 °C.

Yield 53%. IR ($CHCl_3$) 2800—3000 (alkyl), 1600 (Ar), 1250 (ether) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=1.4 (t, 3H, CH_3), 3.0—4.5 (m, 7H, CH_2-O, CH_2-Br, CH), 7.0 (q, 4H, ArH).

*2-(*p-*Methylphenyl)-1,3-dibromopropane (5′).* To a solution of 48% HBr (50g) and concd H_2SO_4 (15 g) cooled in an ice bath were added successively **4′** (0.1 mol) and concd H_2SO_4 (25g). The solution was kept at 95—100 °C for 18 h. The reaction mixture was then poured into water (200g). The mixture was stirred for a while and extracted twice with ether (each 400 ml). The extract was washed with cold 10% aq $NaHCO_3$, and concentrated on a rotary evaporator at 30 °C. The residue was distilled *in vacuo* to afford a transparent liquid in a 50% yield.

Bp 125—130 °C/1 mmHg. IR ($CHCl_3$) 2850-3000 (alkyl), 1600 (Ar) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=2.3 (s, 3H, CH_3), 2.8—4.0 (m, 5H, CH_2, CH), 7.2 (s, 4H, ArH).

*2-(*p-*Ethoxyphenyl)-1,3-propanedithiol (6).* To a solution of thiourea (0.064 mol, 4.9 g) in triethylene glycol (8 ml) kept at 75 °C was added **5** (0.016 mol) under the nitrogen atmosphere followed by stirring at 75 °C for 18 h.

Tetraethylenepentamine (0.016 mol, 3.03 g) was then added, and the mixture was stirred at 75 °C for 2 h under the nitrogen atmosphere. The reaction mixture was poured into ice water (200 g) and extracted twice with ether (each 300 ml). The extract was dried over anhyd Na_2SO_4, and evaporated *in vacuo* at 30 °C.

Yield 55%. IR ($CHCl_3$) 2800—3000 (alkyl), 1600 (Ar), 1250 (ether) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=1.0—1.7 (m, 5H, SH, CH_3), 2.9 (s, 4H, CH_2-S), 3.0—3.6 (m, 1H, CH), 4.05 (q, 2H,

CH_2-O), 7.0 (q, 4H, ArH).

2-(p-Methylphenyl)-1,3-propanedithiol (6′). Yield 66% IR ($CHCl_3$) 2800—3000 (alkyl), 1600 (Ar) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=0.9—1.5 (m, 2H, SH), 2.3 (s, 3H, CH_3), 2.5—3.7 (m, 5H, CH, CH_2-S), 7.1 (s, 4H, ArH).

2,5-Disubstituted 1,3-Dithianes (8). To a solution of **6** (0.004 mol) and aldehyde **7** (0.004 mol) in anhyd $CHCl_3$ (200 ml) cooled in an ice bath were added BF_3-$(C_2H_5)_2O$ (0.5 g) and Molecular Sieve (3A, 1/15; 3g). The mixture was stirred at 0—5 °C for 8 h and then at 20—25 °C for 18h. The solution was washed with 10% $NaHCO_3$ (400 ml), then with water (400 ml), dried over anhyd Na_2SO_4, and evaporated *in vacuo* at 40 °C. The crude product was purified by alumina column chromatography to collect the hexane-benzene=1:1 eluate.

Upon evaporation of the eluate *in vacuo*, the residue was purified by recrystallization from hexane.

2-Alkyl-5-(p-ethoxyphenyl)-1,3-dithianes. IR ($CHCl_3$) 2800—3000 (alkyl), 1600 (Ar), 1250 (ether) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=0.7—2.0 (m, alkyl), 2.6—3.4 (m, 5H, CH_2-S, CH), 3.8—4.3 (m, 3H, CH_2-O, $\overset{S}{S}$>CH-), 7.0 (q, 4H, ArH).

2-Ethyl-5-(p-ethoxyphenyl)-1,3-dithiane (8-1): Yield, 28%. Found: C, 62.51; H, 7.915. Calcd for $C_{14}H_{20}S_2O$: C, 62.71; H, 7.51%. MS (*m/z*) 268 (M^+).

2-Propyl-5-(p-ethoxyphenyl)-1,3-dithiane (8-2): Yield 27%. Found: C, 63.56; H, 7.55%. Calcd for $C_{15}H_{22}S_2O$: C, 63.78; H, 7.85%. MS (*m/z*) 282 (M^+).

2-Butyl-5-(p-ethoxyphenyl)-1,3-dithiane (8-3): Yield, 17%. Found: C, 64.94; H, 8.15%. Calcd for $C_{16}H_{24}S_2O$: C, 64.82; H, 8.16%. MS (*m/z*) 296 (M^+).

2-Pentyl-5-(p-ethoxyphenyl)-1,3-dithiane (8-4): Yield, 16%. Found: C, 65.97; H, 8.70%. Calcd for $C_{17}H_{26}S_2O_1$: C, 65.76; H, 8.44. MS (*m/z*) 310 (M^+).

2-Hexyl-5-(p-ethoxyphenyl)-1,3-dithiane (8-5): Yield, 15%. Found: C, 66.75; H, 8.68. Calcd for $C_{18}H_{28}S_2O$: C, 66.61; H, 8.70%. MS (*m/z*) 338 (M^+). ^{13}C-NMR ($CDCl_3$) δ=47.46 (C2), 37.06 (C4, C6), 42.86 (C5).

2-Heptyl-5-(p-ethoxyphenyl)-1,3-dithiane (8-6): Yield, 15%. Found: C, 67.17; H, 8.96%. Calcd for $C_{19}H_{30}S_2O$: C, 67.40; H, 8.93%. MS (*m/z*) 338 (M^+). NMR ($CDCl_3$) δ=47.46 (C2), 37.06 (C4, C6), 42.86 (C5).

2-Octyl-5-(p-ethoxyphenyl)-1,3-dithiane (8-7): Yield, 21%. Found: C, 68.01; H, 9.17%. Calcd for $C_{20}H_{32}S_2O$: C, 68.13; H, 9.15%. MS (*m/z*) 352 (M^+).

2-(p-Alkoxyphenyl)-5-(p-ethoxyphenyl)-1,3-dithiane. IR ($CHCl_3$) 2800—3000 (alkyl), 1600 (Ar), 1250 (ether) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=0.7—2.0 (m, -OH_2C-R), 2.8—3.5

(m, 5H, CH_2-S, CH), 4.0 (m, 4H, CH_2-O), 5.25 (s, 1H, $\overset{S}{S}$>CH-), 6.8—7.7 (m, 8H, ArH).

2,5-Bis(p-ethoxyphenyl)-1,3-dithiane (8-8): Yield, 28%. Found: C, 66.58 ;H, 6.71%. Calcd for $C_{20}H_{24}S_2O_2$: C, 66.63; H, 6.71%. MS (*m/z*) 360 (M^+).

2-(p-Propoxyphenyl)-5-(p-ethoxyphenyl)-1,3-dithiane (8-9): Yield, 47%. Found: C, 67.38; H, 7.16%. Calcd for $C_{21}H_{26}S_2O_2$: C, 67.34; H, 7.00%. MS (*m/z*) 374 (M^+).

2-(p-Butoxyphenyl)-5-(p-ethoxyphenyl)-1,3-dithiane (8-10): Yield, 39%. Found: C, 67.70; H, 7.29%. Calcd for $C_{22}H_{28}S_2O_2$: C, 68.00; H, 7.26%. MS (*m/z*) 388 (M^+).

2-(p-Pentyloxyphenyl)-5-(p-ethoxyphenyl)-1,3-dithiane (8-10): Yield, 31%. Found: C, 68.36; H, 7.81%. Calcd for $C_{23}H_{30}S_2O_2$: C, 68.61; H, 7.51%. MS (*m/z*) 402 (M^+).

2-(p-Methoxyphenyl)-5-(p-ethoxyphenyl)-1,3-dithiane (8-12): Yield, 38%. Etsuo NIKI,* and Yoshio KAMIYA
Department of Reaction Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Tokyo 113
(Received May 7, 1984)

Decompositions of methyl linoleate hydroperoxide (LOOH) induced by di-*t*-butyl diperoxyoxalate and cobalt ions were investigated in benzene at 50 °C under vacuum to elucidate the degradation mechanism. The major products were dimer (LOOL), oxodiene, hydroxydiene and epoxyhydroxyene (and/or epoxyoxoene). It was suggested that these products were formed by the recombination of L· and LOO· radicals, β-scission of LO· radical, hydrogen abstraction of LO· radical, and intramolecular epoxidation of LOO· radical, respectively. The decomposition of methyl linolenate hydroperoxide (L'OOH) was also studied. The major products were dimer, oxotriene, hydroxytriene, and thiobarbituric acid reactive substances, which were suggested to be formed by the intramolecular cyclization of L'OO· radical.

Polyunsaturated fatty acids (PUFA), which are present as phosphoglyceride esters in biological membranes, are quite susceptible to oxidation.[1] The oxidation of PUFA gives peroxides as primary products,[2] and it is suggested that the formation of so-called "lipid peroxides" is associated with aging and the appearance of geriatric disorders such as heart attack, stroke, diabates, *etc.*[3-8] Therefore, it is very important to understand the formation and the decomposition of the lipid peroxide in the living system. The oxidation of PUFA and behavior of hydroperoxides derived from PUFA are also important subjects in food chemistry.[5,6]

The decomposition of peroxides is important since it can contribute to chain initiation of lipid peroxidation and xenogenous toxicity. It has been reported that the decomposition of linoleic acid hydroperoxide gave various products such as oxodiene,[9-16] epoxyhydroxyene,[10,12-14,16-18] epoxyoxoene,[10,14,16,17] trihydroxyene,[10,14] peroxide-bridged dimer,[14] carbon-carbon bridged dimer,[19] hydroxydiene,[12] oxodihydroxyene,[14] oxohydroxyene,[10,16] and hydroperoxyoxoene.[17] The distribution of products is dependent on experimental variables such as atmosphere, catalysts, absence and presence of hydrogen donors and reductants, and pH.

In this study, we undertook a simple system in order to elucidate the mechanism of homolytic decomposition of linoleate and linolenate hydroperoxides induced by radicals and metal ions in a homogeneous solution.

Experimental

Material. Methyl linoleate (LH) was obtained from Sigma Chemical Co. and used as received. Little peroxide was observed by HPLC analysis.[21,22] Methyl linoleate hydroperoxide (LOOH) was synthesized[22,23] from LH by the action of soybean lipoxygenase (Sigma Chem. Co.) and purified by passing through a silica-gel column using hexane and ether as eluent. It was found by HPLC analysis that the ratio of (9*Z*,11*E*)-13-hydroperoxy-9,11-octadecadienoic acid methyl ester to total peroxide was higher than 95%. LOOH was stored as a benzene solution below 0 °C. Under these conditions, the decomposition and isomerization[22] of LOOH were very slow.

Methyl linolenate(L'H) was obtained from Sigma Chemical Co. and purified by silica-gel column chromatography. Methyl linolenate hydroperoxide (L'OOH) was also prepared using soybean lipoxygenase. It was purified with a silica-gel column and stored as a benzene solution below 0 °C to avoid the decomposition and isomerization of hydroperoxide. More than 95% of hydroperoxide was found to be (9*Z*,11*E*, 15*Z*)-13-hydroperoxy-9,11,15-octadecatrienoic acid methyl ester by HPLC analysis.[24]

Di-*t*-butyl diperoxyoxalate (DBPO) was prepared by the reaction of oxalyl chloride and *t*-butyl hydroperoxide followed by recrystallization from pentane.[25] α-Methylstyrene (α-MS) was purified by the conventional method; washing with alkali and distillation. 2,6-Di-*t*-butyl-4-methylphenol (BMP) was recrystallized from methanol. Bis (acetylacetonato) cobalt (II) ($Co(acac)_2$) and benzene were those of the highest grade available.

Procedure. A 3 ml of benzene solution of LOOH was taken into a 30 ml Pyrex glass ampoule with additives, if necessary, such as DBPO and $Co(acac)_2$. The ampoule was degassed by freeze and thaw method and sealed by a Teflon valve (6VD type, Nupro Co.). Then the ampoule was put into a water bath kept at 50 °C for desired time. The reaction mixture was stirred vigorously.

After the reaction, the ampoule was cooled by liquid nitrogen, opened, and then warmed up to the room temperature. The reaction mixture was analyzed by TLC and HPLC. A portion of the reaction mixture was evacuated to remove the solvent on water aspiration, then hexane was added. UV absorbances of the hexane solution at 235 and 270 nm were measured to determine the conjugated diene and oxodiene; their extinction coefficients were taken from the literature[20,26] as 28000 and 20000 $M^{-1}\,cm^{-1}$, respectively.

Analytical Method. Merck Silica-Gel 60 plate and hexane/ether/acetic acid (60/40/1, by volume) eluent were used for the TLC analysis. Spots were visualized by iodine vapour. TLC/FID analyzer (IATRON model TH-10) was applied for quantitative measurement. HPLC analysis was described in the previous paper.[21] GPC spectra were measured on a Simadzu LC model 830 equipped with a UV detector, Shimadzu model UV 202. Shimadzu GPC columns, HSG 15 and 30, were used in series and eluent was tetrahydrofuran. The formation of α-methylstyrene oxide was determined by GLC. 2-Thiobarbituric acid reactive substances (TBARS) were measured by the conventional

† Presented at the Annual Meeting of the Chemical Society of Japan, August, 1983.

photometric method.[2] Molecular weight of a dimer was measured with a vapour pressure osmometer in benzene at 40 °C. ^{1}H NMR spectroscopy was performed on a Varian 360 spectrometer.

Results and Discussion

Table 1 shows the result of DBPO-induced decomposition of LOOH in 3 ml benzene *in vacuo* at 50 °C for 5 h. LOOH was thermally stable in benzene *in vacuo* at 50 °C (Run 1). However, LOOH was decomposed when incubated with DBPO (Run 2). The half life of DBPO is 23.1 min at 50 °C,[25] therefore more than 99% of DBPO decomposes in 5h at 50 °C. The amount of LOOH decomposed was almost twice as that of DBPO added, which is quite reasonable since DBPO produces 2 moles of *t*-butoxyl radical as discussed later in the text. Table 2 summarizes the result of cobalt-catalyzed decomposition of LOOH in 3 ml benzene *in vacuo* at

a) Numbers show μmols in 3 ml. b) 2,6-Di-*t*-butyl-4-methylphenol. c) Bis(acetylacetonato) cobalt(II). d) Same as footnote. f) In Table 1. e) Assumed to be epoxide (see text and Fig. 1). f) Ratios of dimer, oxodiene + LOH, and **5** were 1.0/3.1/1.2 by TLC/FID. g) Under air.

50 °C for 2h. LOOH was decomposed completely in every run, which suggests that $Co(acac)_2$ decomposes LOOH catalytically.

Figure 1 shows the thin layer chromatograms of initial LOOH and decomposition products. As shown, chromatograms were clear. Thin layer chromatography of the reaction mixture was carried out with larger scale than that shown in Fig. 1, and each spot was collected, analyzed, and found as dimer, oxodiene, LOH, and unknown product **5** by the following results.

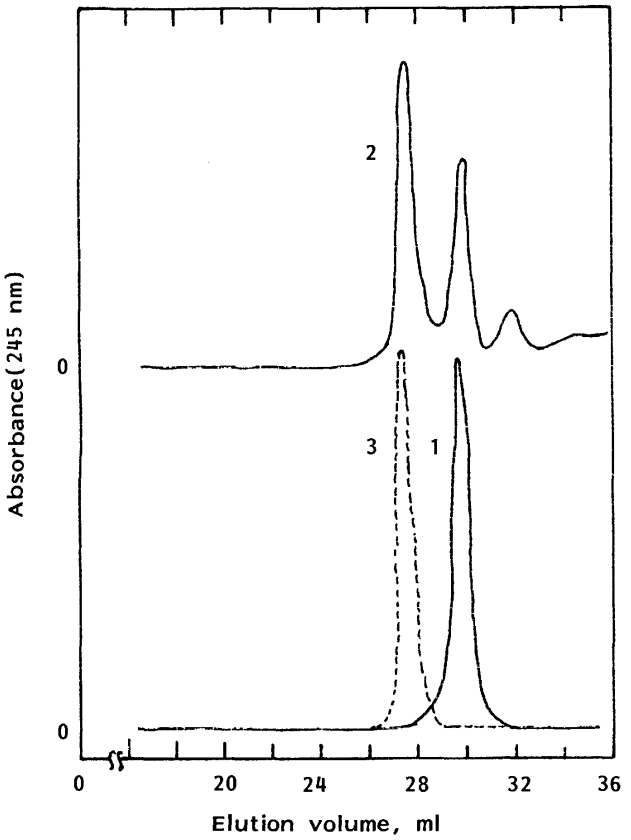

Fig. 2. Gel permeation chromatograms of initial LOOH-(**1**), reaction product of Run 2(**2**), and isolated dimer-(**3**).

2: Figure 2 shows the gel permeation chromatograms of initial LOOH (line 1), reaction mixture of Run 2 (line 2), and isolated **2** (dotted line 3). As shown, a new peak (elution volume=27.5 ml) was observed in the reaction mixture and **2** gave an identical chromatogram. The molecular weight of **2**, as measured with a vapour pressure osmometer, was 619±15. **2** has a strong absorption at 231.5 nm and its extinction coefficient was about 40000 $M^{-1}cm^{-1}$, suggesting that **2** has two conjugated dienes in a molecule. ^1H NMR spectra $\delta(CCl_4)$; 3.63 (s, 6H,$OC\underline{H}_3$), 4.1—4.5 (m, 2H, O-C-$\underline{H}$), 5.2—6.3 (m, 8H, $(C\underline{H}=C\underline{H})_2$) indicate that **2** is a peroxide-bridged dimer LOOL. The calculated molecular weight for LOOL is 619.

3: **3** has a strong characteristic UV absorption at 270 nm and R_f value(0.42) is between those of LOOH(0.33) and LH(0.83). By comparing with the previous results,[14,26] **3** was attributed to oxodiene, $-C(O)-(C=C)_2-$.

4: R_f value of **4** was identical with that of the products obtained by reduction of LOOH with triphenylphosphine. Therefore, **4** must be hydroxyoctadecadienoic acid methyl ester, LOH.

The decrease of LOOH and the formation of LOH shown in Tables 1 and 2 were measured by HPLC. The decrease of conjugated diene and the increase of oxodiene were determined by UV absorbance at 235 and 270 nm, respectively. The yields of dimer and **5** were estimated by the deepness of the color of the spot. The ratios of dimer, oxodiene, LOOH, LOH, and **5** were also measured by TLC/FID in Runs 2 and 5. In other Runs, LH and α-MS disturbed the TLC/FID analysis. α-Methylstyrene oxide was determined by glc.

As shown in Table 1 and Fig. 1, the major products of DBPO-induced decomposition of LOOH were dimer and the unknown compound **5**. The addition of methyl linoleate (LH) decreased **5** (Run 3), while it increased

Table 3. DBPO-induced and Cobalt-catalyzed decomposition of methyl linolenate hydroperoxide (L'OOH) in benzene *in vacuo* at 50 °C[a]

Dimer[c]	−	++	+++++	++	+++	−	±

a) Numbers in μmol. b) Thiobarbituric acid reactive substances. c) Same as footnote f) in Table 1. d) Under air.

the dimer. The major products of cobalt-catalyzed decomposition of LOOH were dimer, oxodiene, hydroxydiene (LOH), and **5**. Oxodiene and LOH were not observed in the DBPO-induced decomposition of LOOH. The yield of dimer was increased by the addition of LH (Run 6) and decreased by the addition of BMP (Run 7). Furthermore, little dimer was observed in the decomposition of LOOH under air (Run 8). The yield of **5** decreased by the addition of LH and BMP, and by changing the atmosphere to air (Runs 6—8). Little TBARS was observed in the decomposition of LOOH.

Table 3 summarizes the results of DBPO-induced and cobalt-catalyzed decomposition of methyl linolenate (L'OOH) in benzene *in vacuo* at 50 °C. L'OOH was thermally stable in benzene *in vacuo* at 50 °C (Run 10). The DBPO-induced decomposition of L'OOH gave dimer and TBARS. In addition to them, hydroxytriene (L'OH) and oxotriene were produced in the cobalt catalyzed decomposition of L'OOH. The yield of dimer was increased by the addition of methyl linoleate (LH) (Runs 12 and 14) and decreased by the addition of BMP (Run 15) and by changing the atmosphere to air (Run 16).

The results and discussion described above suggest that the decompositions of LOOH and L'OOH proceed by the scheme shown below. DBPO decomposes to give *t*-butoxyl radical (*t*-BuO·) and carbon dioxide (Eq. 1).

$$\text{DBPO} \longrightarrow 2\,t\text{-BuO}\cdot + 2CO_2, \quad (1)$$

$$t\text{-BuO}\cdot + \text{LOOH} \longrightarrow t\text{-BuOH} + \text{LOO}\cdot, \quad (2)$$

$$\text{LOOH} + Co^{2+} \longrightarrow \text{LO}\cdot + OH^- + Co^{3+}, \quad (3)$$

$$\text{LOOH} + Co^{3+} \longrightarrow \text{LOO}\cdot + H^+ + Co^{2+}, \quad (4)$$

$$\text{LOO}\cdot \rightleftharpoons \text{L}\cdot + O_2, \quad (5)$$

$$\text{LOO}\cdot + \text{L}\cdot \longrightarrow \text{LOOL}, \quad (6)$$

$$2\text{LOO}\cdot \longrightarrow \text{LOH} + \text{Oxodiene} + O_2, \quad (7)$$

$$\text{LOO}\cdot \longrightarrow \mathbf{5}\ (\text{epoxyhydroxyene and/or epoxyoxoene}), \quad (8)$$

$$\text{LO}\cdot \xrightarrow{\text{LOOH, LH, BMP}} \text{LOH}, \quad (9)$$

$$\text{LO}\cdot \longrightarrow \text{Oxodiene}, \quad (10)$$

$$\text{L'OO}\cdot + \text{L'}\cdot \longrightarrow \text{L'OOL'}, \quad (11)$$

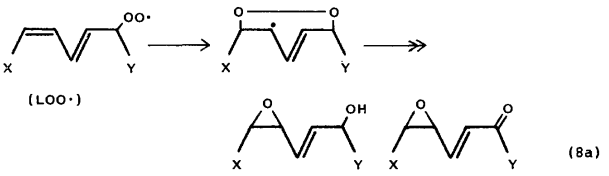
$$\text{L'O}\cdot \xrightarrow{\text{L'OOH, LH, BMP}} \text{L'OH}, \quad (12)$$

$$\text{L'O}\cdot \longrightarrow \text{Oxotriene}, \quad (13)$$

$$\text{L'OO}\cdot \longrightarrow \text{TBARS}, \quad (14)$$

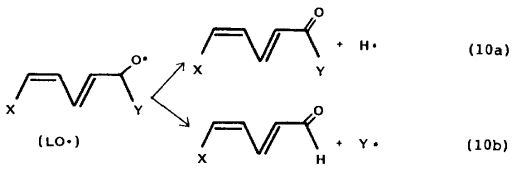
t-Butoxyl radical abstracts hydrogen from LOOH to give peroxyl radical LOO·(Eq. 2). Equations 3 and 4 show the redox decomposition of LOOH by cobalt ions. Therefore, LOO·radical is a key intermediate in the DBPO-induced decomposition of LOOH. Under low concentration of oxygen, LOO·radical liberates oxygen and gives resonance-stabilized alkyl radical, L·(Eq. 5). The recombination of peroxyl radical and alkyl radical is quite fast and consequently dimer, LOOL, is formed (Eq. 6). The presence of oxygen must suppress the formation of dimer, since the bimolecular interaction of peroxyl radicals gives LOH and oxodiene (Eq. 7) rather than LOOL. Reaction 7 is not important under low concentration of oxygen.[21] In fact, the amounts of LOH and oxodiene were very small in Run 2.

Unknown product **5** is also produced from peroxyl radical (Eq. 8). The formation of α-methylstyrene oxide in the presence of α-methylstyrene (Runs 4 and 9) and the low R_f value of **5** suggest that **5** is an epoxide such as epoxyhydroxyene and/or epoxyoxoene produced by intramolecular epoxidation of LOO·radical as shown below.[27]



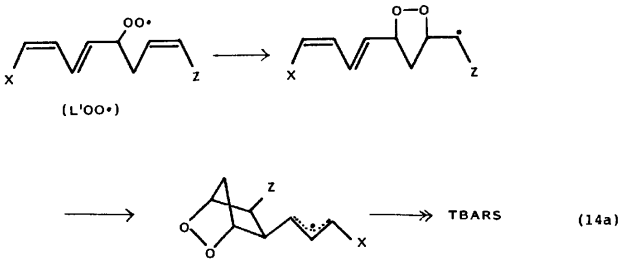
$X=(CH_2)_7COOCH_3$, $Y=(CH_2)_4CH_3$

In addition to peroxyl radical, alkoxyl radical, LO·, plays an important role in the redox decomposition of LOOH and gives LOH and oxodiene by hydrogen abstraction (Eq. 9) and β-scission (Eq. 10), respectively. BMP acts as an efficient hydrogen donor to oxygen radicals and increases LOH.



$X=(CH_2)_7COOCH_3$, $Y=(CH_2)_4CH_3$

The decomposition of L'OOH proceeds similarly as LOOH; peroxyl radical, L'OO·gives dimer (Eq. 11) and alkoxyl radical, L'O·gives hydroxytriene, L'OH, (Eq. 12) and oxotriene (Eq. 13). However, TBARS was produced instead of **5**, probably by intramolecular cyclization of peroxyl radical (Eq. 14a).[30-32]



$X=(CH_2)_7COOCH_3$, $Z=CH_2CH_3$

In conclusion, the homolytic decomposition of linoleate hydroperoxide gave dimer, oxodiene, hydroxydiene, and epoxyhydroxyene (and/or epoxyoxoene) and that of linolenate hydroperoxide gave dimer, oxotriene, hydroxytriene, and TBARS.

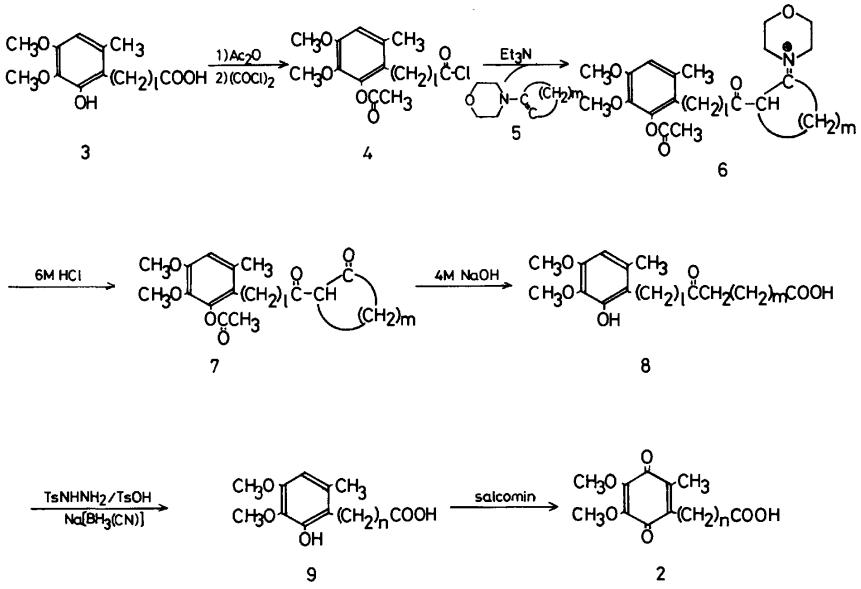
(Received May 10, 1984)

ω-(1,4-Benzoquinon-2-yl)alkanoic acids, 2-[10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decyl]-3-hydroxytetracosanoic acid, all-*trans*-5,9,13,17-tetramethyl-4,8,12,16-octadecatetraenoic acid, and stearic acid were coupled to the 6-*O*-position of the carbohydrate moiety of muramyl dipeptide alkyl esters, and 6-*O*-aminoacyl-muramyl dipeptide methyl esters. The aminoacyl residues used were Gly, Leu, Ahx, and Aud. New synthetic methods were developed for ω-(1,4-benzoquinon-2-yl)alkanoic acids such as 22-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)docosanoic acid, and the α-branched ω-(1,4-benzoquinone-2-yl) β-hydroxy acid, 2-[10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decyl]-3-hydroxytetracosanoic acid. The effects of the resulting quinonyl, multiprenylacetyl, and stearoylmuramyl dipetides on the induction of delayed-type hypersensitivity to ABA-Tyr in guinea pigs and the tumor(meth-A)-suppressive activity in syngeneic BALB/c female mice were measured. The results revealed that all these muramyl-dipeptide derivatives retained the adjuvant activity whereas the potent tumor-suppressive activity was observed only in quinonylmuramyl dipeptides, indicating that the 5,6-dimethoxy-3-methyl-1,4-benzoquinone ring is a requisite for the manifestation of the tumor-suppressive activity. The lipophilicity-hydrophilicity balance of the molecule was also important. Among the compounds tested, *N*-acetyl-6-*O*-[10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decanoyl]muramyl-L-valyl-D-isoglutamine methyl ester showed the most potent tumor-suppressive activity. This compound also showed tumor-regressive activity in guinea pigs, and hence is a good candidate for further studies.

The immunotherapy of cancer, especially with *Mycobacterium tubeculosus Bacillus Calmette-Guèrin* (BCG), originally incorporated into clinical studies by Mathé and his colleagues, was investigated in many centers.[2)] The observation that BCG has serious side effects has stimulated clinical trials of less toxic material such as the cell wall skelton of BCG and that of *Nocardia*;[3)] the potent immunological activity of these materials is well established.[4)] Consequently, the discovery that *N*-acetylmuramyl-L-alanyl-D-isoglutamine (MDP) is able to replace mycobacterial whole cells in Freund's complete adjuvant stimulated efforts to develop a new antitumor agent by modifying this immunoactive minimal component of the cell wall peptidoglycan.[5)] In 1980 McLaughlin *et al.* reported that some synthetic MDP analogues, when administered in combination with trehalose dimycolate (TDM) as oil-in-water emulsion, caused line-10 hepatocellular-carcinoma regression in strain 2 guinea pigs.[6)] It was postulated that the presence of TDM enabled the water-soluble MDP analogues to disperse efficiently in the organic phase, and hence facilitated their antitumor activity. In an earlier attempt, Yamamura *et al.* reported that the incorporation into the MDP molecule of mycolic acid, a lipophilic constituent of the mycobacterial cell wall, resulted in a weak, compared with BCG cell wall skeleton, but distinct manifestation of the antitumor activity as determined by Meth-A fibrosarcoma suppression in syngeneic BALB/c female mice.[7)] Later, Kusumoto *et al.* found that the Meth-A fibrosarcoma suppressive effect of the 6-*O*-mycoloyl derivatives of MDP was unaffected when mycolic acid was replaced by a synthetic mycolic acid-mimic α-branched β-hydroxy fatty acid with 48 carbon atoms.[8)] These findings suggest that the lipophilicity-hydrophilicity balance of the molecule may be required for antitumor activity and the application of an MDP derivative with more favorable characteristics for cancer immunotherapy is possible.

In our efforts to obtain an agent for cancer immunotherapy, we tried to incorporate immunologically active lipophilic carboxylic acids, such as quinonyl[9)] and multiprenylacetic acids,[10)] into the MDP molecule using 6-*O*-aminoacyl MDP intermediates, which provided an effective means for introducing these labile carboxylic acids.[11)] Most of the resulting compounds, especially those having a 10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decanoyl group, exhibited a favorable biological effect on the induction of delayed-type hypersensitivity to *N*-acetyl-3-(4-arsonophenylazo)-L-tyrosine (ABA-Tyr) in guinea pigs.[11)] The apparent tumor-suppressive effect of the methyl esters of these derivatives has also been established.[12)] In this paper, we describe further the synthesis and immunological activities of quinonyl muramyl dipeptide alkyl ester derivatives **1** and a new general procedure for the synthesis of quinonyl acids, including mycoloyl-type quinonyl acid, having a long hydrocarbon chain. [A mycoloyl-type quinonyl acid (quinonylmycolic acid in this paper) is an α-branched β-hydroxyalkanoic acid having a quinone ring at the ω-position (**25**).]

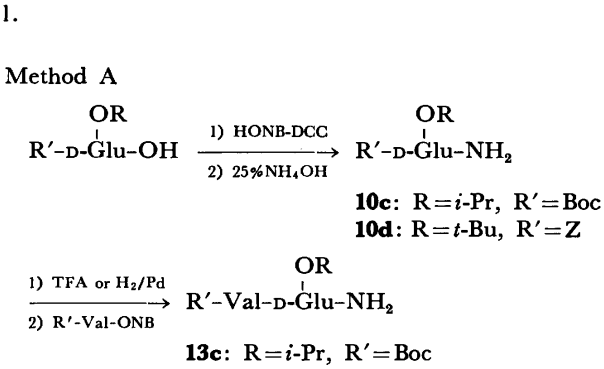
Chemistry. Six ω-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)alkanoic acids, QS-3, 6, 10, 16, 22, and 34 (**2**)[13)] and quinonylmycolic acid (**25**) were prepared. QS-3 (**2a**), 6 (**2b**), and 10 (**2c**) were prepared by the reported procedure.[14)] Since a convenient synthetic sequence of QS-16 (**2d**), 22 (**2e**), and 34 (**2f**) with long hydrocarbon chains has not been described, we developed a general synthetic method for those quinonyl acids (Scheme 1): ω-(3,4-dimethoxy-2-hydroxy-6-methylphenyl)alkanoic acid **3**[14)] was acetylated and then converted to the carbonyl chloride **4** by treatment with oxalyl dichloride. The chloride **4** was condensed



Scheme 1.

with an enamine **5**,[15] having an appropriate ring size, to give a condensation product **6**. After successive hydrolysis with 6 M HCl and 4 M NaOH, the carbonyl group of **8** was reduced with sodium cyanotrihydroborate in the presence of *p*-toluenesulfonohydrazide[16] to give **9**. When a 6-membered enamine (1-morpholinocyclohexene **5a**, m=4) and a 12-membered enamine (1-morpholinocyclododecene **5b**, m=10) are used, 6 and 12 carbon atoms can be extended, respectively [**3a**(1=9)→**9a**(n=15) and **3a**→**9b**(n=21)], in this conversion. By oxidation of **9a** with (*N*,*N*′-disalicylideneethylenediaminato)cobalt(II) (salcomin)[17] the target compound **2** was obtained. In this oxidation, potassium nitrosodisulfonate (Fremy's salt) used for the synthesis of quinonyl acids, such as QS-10 with a short hydrocarbon chain, could not be used for the synthesis of those with a long hydrocarbon chain because the yield was low or the reaction failed to proceed.[14] Compound **9b** (n=21), newly obtained by this procedure, was used as the starting material to synthesize **2f** (n=33). These findings demonstrate the accomplishment of a facile chain elongation of the alkyl side chain in quinonyl acids.

The synthesis of partially protected muramyl dipeptide alkyl esters **16** and their condensation with these carboxylic acids were carried out as outlined in Schemes 2 and 3: Secondary and tertiary alkyl ester analogues **13c** and **d** were prepared in a manner similar to the synthesis of the methyl ester analogue **13a**,[18] *i.e.* D-Glu was esterified at the γ-carboxyl group initially. After α-amino protection and amidation, either Boc-Val-ONB or *Z*-Val-ONB was coupled with α-amino-deprotected D-isoGln isopropyl and *t*-butyl ester to give **13c** and **d**, respectively (Scheme 2, Method A). Other Boc-Val-D-isoGln alkyl ester analogues (**13b**, **e**, and **f**) were prepared by esterification of Boc-Val-D-isoGln (**12**) with an appropriate alcohol; 6-chloro-1-(*p*-chlorophenylsulfonyloxy)benzotriazole (CCBT)[19]



Scheme 2.

was used as a coupling agent. Dipeptide **12** was obtained by catalytic hydrogenolysis from Boc-Val-D-isoGln benzyl ester (**11**)[18] (Scheme 2, Method B).

Boc-Val-D-isoGln alkyl esters **13** thus obtained were deblocked by TFA and coupled with the 1-*O*-benzyl-4,6-*O*-benzylidene-*N*-acetyl-α-muramic acid HONB ester (**14**).[18] In the case of compound **13d**, the *Z* group was removed by hydrogenolysis. The 4,6-*O*-benzylidene group of the muramyl moiety of the resulting protected glycopeptide **15** was removed by treatment with hot 75% acetic acid to give the partially protected muramyl dipeptide alkyl esters **16**, to which were condensed the above-mentioned quinonyl acids **2** by DCC in a mixture of pyridine and DMF. The yield from this procedure of quinonyl acids having short

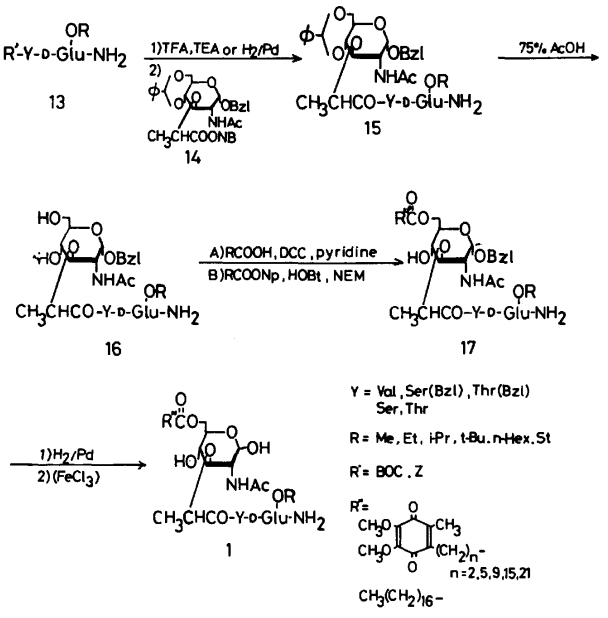
a) *c* 0.5. b) Temperature=21 °C. c) *c* 0.4; Temperature=24 °C.

alkyl chains (**2a**: n=2; **2c**: n=9) reached up to 70%. The yield of quinonyl acids with long alkyl chains (**2d**: n=15; **2e**: n=21) was 35 and 25%, respectively, and that of **2f** (n=33) was much lower. Stearic acid was also condensed to *N*-acetyl-1-*O*-benzyl-α-muramyl-L-valyl-D-isoglutamine methyl ester (**16a**) in a similar manner to obtain *N*-acetyl-6-*O*-stearoylmuramyl-L-valyl-D-isoglutamine methyl ester (**1o**) to evaluate the effect of the quinonyl moiety on biological activities.

Alternatively, the partially protected muramyl dipeptide alkyl esters **16** were condensed with the *p*-nitrophenyl ester of the quinonyl acids in the presence of HOBt and NEM in DMF at room temperature for 2 d. This procedure was also used for the condensation of benzyloxycarbonyl amino acids with the partially protected muramyl dipeptide **16a** to obtain compounds with a linking amino acid between a lipophilic carboxylic acid and muramyl dipeptide moiety[10] (Scheme 6, **16a**→**33**). The protected quinonyl muramyl dipeptide alkyl esters **17** were then hydrogenated in acetic acid or methanol with palladium black as a catalyst. The hydroquinonyl group was oxidized by $FeCl_3$ in methanol to the desired 6-*O*-quinonyl-*N*-acetylmuramyl-L-valyl-D-isoglutamine alkyl esters **1** (Scheme 3). Compound **1h** was obtained in a moderate yield directly by the coupling of quinonyl acid **2b** (n=5) with *N*-acetylmuramyl-L-valyl-D-isoglutamine methyl ester[18] using DCC as a condensing agent. Compounds **1m** and **n** having a Ser of Thr residue instead of the Val residue of **1a** were synthesized similarly with Boc-Ser(Bzl)-D-isoGln methyl ester (**11g**) or Boc-Thr(Bzl)-D-isoGln methyl ester (**11h**) as a starting material, respectively.



Scheme 3.

We also developed a novel general synthetic route for quinonylmycolic acid **25** with 10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decyl acetate (**18**)[14] as a starting material (Scheme 4). Compound **18** was hydrogenated and the hydroxyl groups of the resulting hydroquinone were methoxymethylated by methoxymethyl chloride in the presence of NaH and subsequent hydrolysis with 4M NaOH gave the protected quinonyl alcohol **19**. Compound **19** was oxidized with

dimethyl sulfoxide using pyridine-sulfur trioxide complex to the aldehyde **20**, which was then condensed with the ethyl 3-oxoalkanoate **21**[20] in the presence of acetic acid-piperidine to produce the condensation product **22**. Catalytic hydrogenation of the double bond of **22** and subsequent reduction with sodium borohydride afforded the protected quinonylmycolic acid ethyl ester **23**, which was then hydrolyzed with 3M NaOH to yield

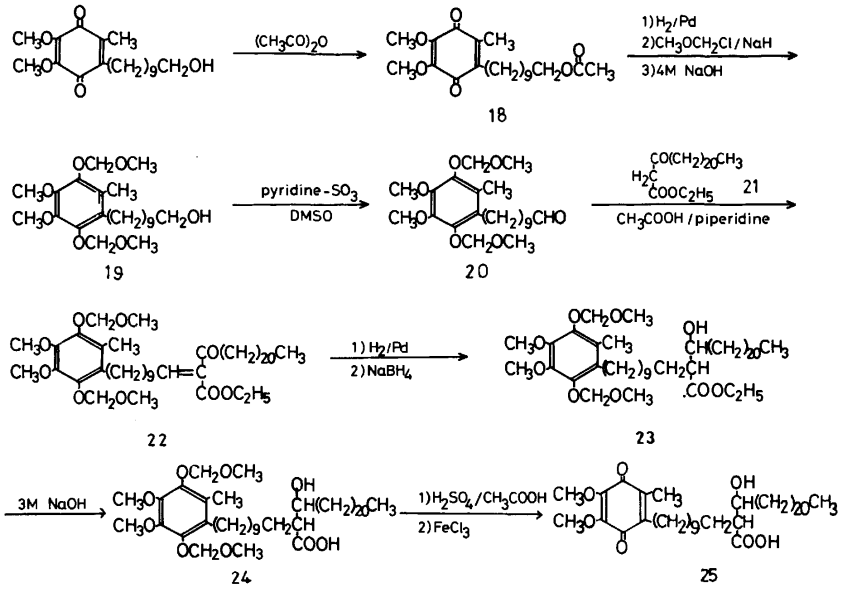
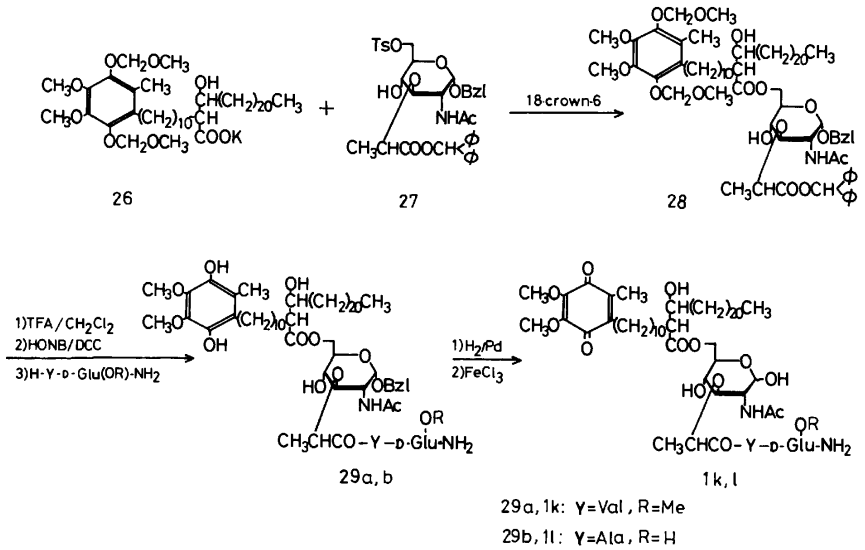


Scheme 4.



Scheme 5.

24. The protecting methoxymethyl group of **24** was then removed by heating at 100 °C for 10 min in a mixture of 2M H_2SO_4 and acetic acid. The resulting hydroquinone was reoxidized with $FeCl_3$ in dioxane to the desired quinonylmycolic acid **25**.

The synthesis of 6-*O*-quinonylmycoloylmuramyl dipeptides **1k** and **l** was carried out as shown in Scheme 5 as in the case for the synthesis of 6-*O*-mycoloylmuramyl dipeptides,[7] since the condensation of **25** with *N*-acetyl-1-*O*-benzyl-α-muramyl dipeptides by DCC in a mixture of pyridine and DMF did not proceed. Protected quinonylmycolic acid **24** was converted to the potassium salt **26**, which was then condensed with *N*-acetyl-1-*O*-benzyl-6-*O*-tosyl-α-muramic acid diphenylmethyl ester (**27**)[7] in the presence of 18-crown-6. The diphenylmethyl and methoxymethyl protecting groups of **28** were then removed by TFA. The resulting carboxylic acid was activated by the HONB-DCC method[21] and condensed *in situ* with the dipeptides to give the protected quinonylmycoloylmuramyl dipeptide **29**. The removal of the benzyl protecting group by catalytic hydrogenolysis and reoxidation of the hydroquinone ring by $FeCl_3$ produced target compound **1**.

The methyl ester with a linking amino acid between a lipophilic acid and the muramyl dipeptide moiety **33a—d** were prepared by acylating the corresponding 6-*O*-aminoacylmuramyl dipeptide methyl esters **31** with *p*-nitrophenyl ester of 10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decanoic acid (Scheme 6). *N*-Acetyl-6-*O*-(all-*trans*-5,9,13,17-tetramethyl-4,8,12,16-octadecatetraenoyl-L-leucyl)muramyl-L-valyl-D-isoglutamine methyl ester (**33e**) was also obtained in this procedure. The esters **33a** and **b** could also be obtained by treating the corresponding γ-carboxyl-free derivatives **32** with diazomethane in methanol as exemplified in Scheme 7. The γ-carboxyl-free derivatives **32** were obtained according to the procedure reported earlier.[11]

The purification of all these desired products **1** was carried out by column chromatography on silica

gel and Sephadex LH-20. The physicochemical properties of the intermediates and the desired MDP derivatives are shown in Tables 1—5.

Measurement of Adjuvant and Tumor Suppressive Activities. The adjuvant activity of the synthetic MDP derivatives **1** and **33** on the induction of delayed-type hypersensitivity to ABA-Tyr in guinea pigs was assayed by the following method.[12] Hartley guinea pigs each weighing 300—500 g were immunized in the footpads (all four) with a total of 50 μg of ABA-Tyr in Freund's incomplete adjuvant containing the synthetic MDP derivatives. Five animals were used per group. Control groups were immunized with ABA-Tyr alone in Freund's incomplete adjuvant (Control 1) or with Freund's incomplete adjuvant alone (Control 2). After 2 weeks, skin tests were performed with 50 or 100 μg of ABA-Tyr-bovine serum alubmin (ABA-BSA) prepared by the method of Tabachnick and Sobotka.[22] Skin reaction were measured 24 and 48 h after an intradermal injection of the test antigen. The results are shown as the average diameter (mm) ± the standard error (SE) of the skin reaction (induration) of five guinea pigs.

The evaluation of the suppressive activity on a transplantable tumor in syngeneic mice was carried out according to the procedure reported previously.[12] A mixture of tumor cells (Meth-A, 1×10^5 cells) and the synthetic MDP derivatives suspended in phosphate-buffered saline was inoculated intradermally into the flanks of BALB/c female mice. Tumor size at the site of the inoculation and survival rates were examined every week. The results were obtained 4 weeks after the fibrosarcoma inoculation. Animals with tumors less than 2 mm were considered to be tumor free; such mice were then rechallenged by Meth-A (1×10^5 cells) and observed for an additional 2 weeks to confirm the immunotherapeutic activity of the test materials.

Results and Discussion

Some lipid-soluble vitamins, such as retinol, α-tocopherol, and ubiquinones, are known to exert diverse immunological effects.[23] The metabolites of ubiquinones and their synthetic related compounds are also lipophilic and possess various biological characteristics of ubiquinones including the enhancement of humoral immune response.[24] It has been argued that, among a series of MDP derivatives, the lipophilicity or lipophilicity-hydrophilicity balance is a fundamental requirement for the expression of the antitumor activity.[8,25] It was reported that 6-*O*-mycoloyl-MDP exhibited a tumor-suppressive effect, but was unable to

enhance humoral antibody formation.[26] Therefore, the incorporation of lipophilic and immunologically active quinonyl acids, which enhance humoral immune response,[24] may produce some additional favorable effects in MDP. These were the considerations that led us to synthesize several quinonyl derivatives of MDP in the hope of creating an effective antitumor agent. We examined the adjuvant activity of the compounds on the induction of delayed-type hypersensitivity to ABA-Tyr in guinea pigs. The suppression test of a transplantable tumor in syngeneic mice was carried out on those compounds that exhibited potent adjuvant activity. In this study, the Ala residue in MDP was replaced mostly with the Val residue since *N*-acetylmuramyl-L-valyl-D-isoglutamine showed the most potent activity on inducing delayed-type hypersensitivity.[18] Some other lipophilic MDP analogues, such as **1o** and **33e**, were also synthesized and tested to evaluate the effect of the quinonyl group on the adjuvant and tumor-suppressive activities.

Compounds **1a—f** were synthesized and examined to assess the effect produced by varying the ester substituent at the γ-carboxyl group of the isoglutamine moiety. Ester functionality was varied in the sequence of methyl, ethyl, isopropyl, *t*-butyl, hexyl, and stearyl (octadecyl). As shown in Table 6 (Expt. 1), the adjuvant activity of all the ester derivatives were more potent than MDP; the isopropyl homologue **1c** showed maximum activity. Although an ester substituent bigger than the *t*-butyl group (**1d**) caused a slight decrease in activity, there was little variation in activity between each ester set. This indicates a reduced dependence of the adjuvant activity on steric factors and/or the lipophilicity of the ester substituents at the γ-carboxyl group of the isoglutamine moiety.

The extent of increase in the adjuvant activity was appreciably affected by the chain length in the quinonyl acid moiety (Table 6; Expt. 2). Among the normal alkyl groups investigated (**1a**, and **1g—j**), activity was optimal for the decanoyl derivative **1a** and decreased for the longer chain derivatives **1i** and **1j**. Decreasing activity was a function of chain length. Compounds with shorter chain length, **1g** and **1h**, also exhibited less potent adjuvant activity than **1a**. The lower activity of these compounds could be interpreted as a consequence of either an inadequate lipophilicity of the molecule or an inadequate spacial arrangement of the quinone ring and MDP moiety. In the quinonylmycoloyl series, the adjuvant activity of the methylated Val derivative **1k** is less potent than even MDP whereas the γ-carboxyl-free MDP derivative **1l** showed the most potent activity (Table 6; Expt. 2). This finding also indicates that excess lipophilicity of the molecule causes decreased adjuvant activity.

In the tumor-suppressive activity, as in the adjuvant activity, most of the ester homologues showed comparable potent activity whereas the chain length of the quinonyl acid moiety greatly affected the activity; thus some parallelism exists between the adjuvant and the tumor-suppressive activity (data not shown). Among the quinonyl muramyl dipeptide ester derivatives,

methyl ester homologue **1a** showed the most potent activity when 5×10^5 Meth-A cells were used (Table 7). Therefore, compound **1a** was further modified and tested for adjuvant and tumor-suppressive activity. The compounds synthesized for this purpose were those in which the Val residue of **1a** was replaced with Ser (**1m**) and Thr (**1n**), and those having a linking amino acid between the quinonyl acid and muramyl-dipeptide moiety (**33**).

The effects of these synthetic MDP derivatives **1m**, **1n**, and **33** together with those of the most immunoadjuvant active analogues of MDP, *N*-acetylmuramyl-L-valyl-D-isoglutamine (**34**) and its methyl ester (**35**),[18] on the induction of delayed-type hypersensitivity to ABA-Tyr is shown in Table 8. The results for 6-*O*-stearoyl (**1o**) and 6-*O*-multiprenyl (**33e**) derivatives, and nonmethylated quinonyl MDP derivatives having Gly (**32a**) and Leu (**32b**) as the linking amino acids are also included for comparison. The effect on Meth-A suppression is shown in Table 9.

The 10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decanoyl group incorporated directly into the 6-*O*-position of the muramyl moiety (**1a**) maintained the adjuvant activity of the parent molecules **34** and **35**. Differences in activity among **1a**, **1m**, and **1n**, in which the Ala of MDP was replaced with Val, Ser, and Thr, reflect differences in activity observed among the corresponding parent MDP analogues, *i.e.*, *N*-acetylmuramyl-L-valyl, L-seryl, and L-threonyl-D-isoglutamine.[18] These derivatives also showed potent tumor-suppressive activity even though they were administered as a suspension in phosphate-buffered saline whereas mycoloyl-MDP was reported to be active when administered as an oil-in-water emulsion.[7] The activity developed by **1m** and **1n** was somewhat lower than that of **1a**. The potency of all three derivatives was in good accordance with that of their adjuvant activity when 5×10^5 Meth-A cells were used (Table 9, Expt. 1). A dose response was obtained for **1a** (Table 9, Expt. 2). The induction of systemic tumor immunity that suppressed tumor growth in mice was demonstrated by the reinoculation of 1×10^5 Meth-A cells. The adjuvant activity of stearoyl-MDP derivative **1o** diminished slightly and its apparent low tumor-suppressive activity indicated that not only lipophilicity but some other biological

activities rendered by quinonyl moiety, such as interaction with the cell surface membranes, are necessary for the development of tumor-suppressive activity.

Most of the quinonyl muramyl dipeptides with a linking amino acid between the quinonyl acid and the muramyl moiety (**33**) also exhibited adjuvant activity comparable to that of **34**. The lower activity of **33d**, with 11-aminoundecanoic acid as a linking unit, is compatible with the result obtained for nonmethylated quinonyl muramyl dipeptides with a long chain linking unit.[9] The tumor-suppressive activity of these quinonyl muramyl dipeptides **33** was also demonstrated (Table 9, Expt. 3). Compounds **33c** and **33d** are equipotent in tumor-suppressive activity in spite of the latter's diminished adjuvant activity. Among these quinonyl muramyl dipeptides with a linking amino acid, **33b** is almost as active as **1a**. The result for **33a** was variable. The retention of the adjuvant activity by the multiprenyl derivative **33e** showed that the quinonyl moiety is not a requisite for maintaining the induction activity for delayed-type hypersensitivity. The low activity in tumor suppression of **33e**, however, indicated the importance of the quinonyl moiety for the development of tumor suppression as observed in the case of stearoyl-MDP **1o**. Parent muramyl dipeptide analogues **34** and **35** did not cause any tumor-suppressive activity either.

From these results, we conclude that quinonyl muramyl dipeptide **1a** has the most potent adjuvant and tumor-suppressive activities. It is of particular interest that **1a**, when injected into the established tumor as an oil-in-water emulsion on day 2, 5, 8, and 15 after intradermal inoculation, caused complete regression of the line-10 hepatocellular carcinoma in strain 2 guinea pigs.[27] Metastasis was not observed. Although more extensive search to find an effective immunotherapeutic agent for cancer by modifying natural MDP is required, the potent adjuvant, tumor-suppressive, and tumor-regressive effects of **1a** make it a good candidate for further studies.

Experimental

Melting points were taken in open capillaries and are uncorrected. Optical rotations were determined with a Perkin Elmer model 141 polarimeter. ^{1}H NMR spectra were obtained on a Varian EM-390 spectrometer with tetramethylsilane as an internal standard. All chemicals and solvents were of reagent grade and were used without further purification. The reactions were monitored by TLC on Merck F_{254} silica gel pre-coated plates, which were generally developed with $CHCl_3$–acetone–EtOH (70:30:3, v/v) for compound **11**, $CHCl_3$–acetone–MeOH (10:3:2, v/v) for **1**, **15**, **16**, **17**, **30**, and **33**, AcOEt–pyridine–H_2O–AcOH (30:10:5:3, v/v) for **1**, **31**, and **33**, and *n*-BuOH–AcOH–AcOEt–H_2O (1:1:1:1, v/v) for **1** and **33**. Solution were concentrated in a rotary vacuum evaporator under reduced pressure at temperatures below 45 °C.

*10-(2-Acetoxy-3,4-dimethoxy-6-methylphenyl)decanoyl Chloride (**4a**).* A solution of 10-(3,4-dimethoxy-2-hydroxy-6-methylphenyl)decanoic acid (**3a**)[14] (12.6 g, 37.1 mmol) in Ac_2O (30 ml) was combined with concd H_2SO_4 (1 ml), and the mixture was stirred for 1.5 h at room temperature. Water (10 ml) was then added carefully and the stirring was continued for 2 h. After the removal of the solvent, the residue was dissolved in AcOEt (100 ml), and the solution was washed with 5% $NaHCO_3$. The aqueous layer was back-washed with AcOEt (100 ml). The extracts were combined, washed successively with 1M HCl and water, and dried ($NaSO_4$). The solvent was evaporated to give an oily acetyl compound (13.5 g, 95.6%) which was dissolved in benzene (20 ml). To this was added oxalyl dichloride (9.25 ml, 0.1 mol) dropwise at room temperature, then the mixture was stirred at 50 °C for 1 h. After the removal of the solvent, the residue was flushed with benzene, and dried (NaOH pellets): 13.0 g (91.8%) ^{1}H NMR ($CDCl_3$): δ=1.28—1.90 (14H, m), 2.25—2.73 (8H, m), 2.91 (2H, t), 3.85 (3H, s), 3.90 (3H, s), and 6.72 (1H, s).

*22-(3,4-Dimethoxy-2-hydroxy-6-methylphenyl)-13-oxodocosanoic Acid (**8b**).* A solution of **4a** (7.98 g, 20 mmol) in $CHCl_3$ (4 ml) was added dropwise to a mixture of 1-morpholinocyclododecene (**5b**)[28] (6.29 g, 24 mmol) and Et_3N (3.08 ml, 22 mmol) at 0 °C over a period of 30 min, and the reaction mixture was stirred at room temperature for 15 h. To this were added $CHCl_3$ (5 ml) and 6M HCl (10 ml); the mixture was heated under reflux for 5 h, cooled to room temperature, diluted with water (20 ml), and extracted with $CHCl_3$ (2×30 ml). The combined extracts were washed with water, and dried (Na_2SO_4). After the removal of the solvent, the residue was purified by column chromatography (6×11 cm) on silica gel using $CHCl_3$ as an eluant to give 2-[10-(2-acetoxy-3,4-dimethoxy-6-methylphenyl)decanoyl]cyclododecanone (**7b**): 8.63 g (79.2%). Then, a solution of compound **7b** in EtOH (8 ml) was added to hot 4M NaOH (7.8 ml) and the mixture was heated for 10 min under reflux, cooled to room temperature, acidified to pH 2 with 6M HCl, and extracted with AcOEt (30 ml). The extract was washed with water, dried (Na_2SO_4), and concentrated to give the residue, which was recrystallized from ether–petroleum ether: 6.12 g (74.4%). mp 63—64 °C. ^{1}H NMR ($CDCl_3$): δ=1.17—1.90 (32H, m), 2.22—2.78 (11H, m), 3.88 (3H, s), 3.92 (3H, s), and 6.40 (1H, s).

Found: C, 71.57; H, 10.17%. Calcd for $C_{31}H_{52}O_6$: C, 71.50; H, 10.07%.

*16-(3,4-Dimethoxy-2-hydroxy-6-methylphenyl)-7-oxohexadecanoic Acid (**8a**).* This compound was synthesized from **4a** and **5a** in a manner similar to that of **8b**: 35.9%. mp 55—57 °C.

Found: C, 68.64; H, 9.40%. Calcd for $C_{25}H_{40}O_6$: C, 68.77; H, 9.23%.

*34-(3,4-Dimethoxy-2-hydroxy-6-methylphenyl)-13-oxotetracontanoic Acid (**8c**).* This compound was synthesized from **4b**, which was derived from **3b** and **5b** in a manner similar to that of **8b**: 32.7%. mp 92—93 °C.

Found: C, 74.88; H, 11.29%. Calcd for $C_{43}H_{76}O_6$: C, 74.95; H, 11.12%.

*22-(3,4-Dimethoxy-2-hydroxy-6-methylphenyl)docosanoic Acid(**9b**).* Compound **8b** (5.21 g, 10 mmol), *p*-toluenesulfonohydrazide (2.33 g, 12.5 mmol) and cyclohexane (25 ml) were added to a solution of DMF–sulfolane (25 ml—25 ml) containing *p*-toluenesulfonic acid (250 mg) at 100 °C. After 5 min, Na[BH_3(CN)] (2.51 g, 41 mmol) was added. The mixture was stirred for 20 min at the same temperature and the solution was diluted with brine, and extracted with ether (2×100 ml). The extracts were combined, washed with water, 0.5M HCl and water successively, and dried (Na_2SO_4). After the removal of the solvent, the residue was recrystallized from a small amount of ether: 3.13 g (58.6%). mp 67—68 °C (lit,[14] mp 67—68 °C).

Found: C, 73.76; H, 10.78%. Calcd for $C_{31}H_{54}O_5$: C, 73.47; H, 10.74%.

*16-(3,4-Dimethoxy-2-hydroxy-6-methylphenyl)hexadecanoic Acid (**9a**).* This compound was synthesized from **8a** in a manner similar to that of **9b**: 57.4%. mp 45 °C.

Found: C, 71.13; H, 10.13%. Calcd for $C_{25}H_{42}O_5$: C, 71.05;

H, 10.02%.

*34-(3,4-Dimethoxy-2-hydroxy-6-methylphenyl)tetracontanoic Acid (**9c**).* This compound was synthesized from **8c** in a manner similar to that of **9b**: 70.6%. mp 93 °C.

Found: C, 76.73; H, 11.91%. Calcd for $C_{42}H_{78}O_5$: C, 76.50; H, 11.65%.

*22-(5,6-Dimethoxy-3-methyl-1,4-benzoquinon-2-yl)docosanoic Acid (**2e**).* A mixture of **9b** (2.0 g, 3.95 mmol) and (N,N'-disalicylideneethylenediaminato)cobalt(II) (salcomin 325 mg, 1 mmol) in DMF (10 ml) was stirred under oxygen at room temperature for 24 h. The solvent was evaporated and the residue was dissolved in AcOEt (50 ml). The insolubles were filtered and the filtrate was washed succesively with 0.5 M HCl and water, and dried (Na_2SO_4). After the removal of the solvent, the residue was purified on a column (4.5×11 cm) of silica gel using $CHCl_3$ as an eluent and then recrystallized from EtOH: 1.04 g (50.6%). mp 83—84 °C (lit,[14] mp 86—87 °C).

Found: C, 71.44; H, 10.18%. Calcd for $C_{31}H_{52}O_6$: C, 71.50; H, 10.07%.

*16-(5,6-Dimethoxy-3-methyl-1,4-benzoquinon-2-yl)hexadecanoic Acid (**2d**).* This compound was synthesized from **9a** in a manner similar to that of **2e**: 58.9%. mp 70—71 °C.

Found: C, 68.89; H, 9.30%. Calcd for $C_{25}H_{40}O_6$: C, 68.77; H, 9.23%.

*34-(5,6-Dimethoxy-3-methyl-1,4-benzoquinon-2-yl)tetracontanoic Acid (**2f**).* This compound was synthesized from **9c** in a manner similar to that of **2e**: 21.3%. mp 89—90 °C.

Found: C, 74.73; H, 11.09%. Calcd for $C_{43}H_{76}O_6$: C, 74.95; H, 11.12%.

N-(t-Butoxycarbonyl)-D-glutamic Acid γ-Isopropyl Ester DCHA Salt. Thionyl chloride (2 ml, 27 mmol) was added dropwise to isopropyl alcohol (40 ml) at −10 °C. To this was added D-glutamic acid (3.0 g, 20 mmol), and the mixture was stirred at room temperature for 3 days. After the insolubles were removed by filtration, ether (200 ml) was added to the filtrate to give D-glutamic acid γ-isopropyl ester HCl salt (1.6 g, 35.4%). Without further purification, the salt (1.5 g, 6.64 mmol) was dissolved in water (5 ml) and the resulting solution was combined with DMF solution (5 ml) of *O-t*-butyl *S*-(4,6-dimethyl-2-pyrimidinyl) thiocarbonate (1.91g, 7.97 mmol). Et_3N (1.84 ml) was then added at 4 °C, and the mixture was stirred at room temperature for 20 h, diluted with water (20 ml), and extracted with ether (2×30 ml). The pH of the aqueous layer was adjusted to 2 with 2M HCl under cooling and the mixture was extracted with AcOEt (50 ml). The AcOEt layer was washed with 1M HCl and water succesively, and dried (Na_2SO_4). After the removal of the solvent, the residue (1.90 g) was converted to DCHA salt in ether by adding DCHA (1.3 ml): 2.50 g (80.0%). mp 131 °C. $[\alpha]_D^{23}$ −7.1° (*c* 0.5, DMF).

Found: C, 63.57; H, 10.01; N, 6.08%. Calcd for $C_{25}H_{46}N_2O_6$: C, 63.80; H, 9.85; N, 5.95%.

*N-(t-Butoxycarbonyl)-D-isoglutamine Isopropyl Ester (**10c**).* *N*-(*t*-Butoxycarbonyl)-D-glutamic acid γ-isopropyl ester DCHA salt (704 mg, 1.5 mmol) was converted to free carboxylic acid by the usual method. The resulting oil and *N*-hydroxysuccinimide (207 mg, 1.8 mmol) were dissolved in CH_3CN (10 ml). To this was added DCC (371 mg, 1.8 mmol) at 4 °C, and the mixture was stirred at room temperature for 2 h. After the removal of the precipitates by filtration, 25% aqueous ammonia (0.6 ml) was added under cooling and the mixture was stirred at 4 °C for 30 min. The solvent was evaporated and the resulting crystals were washed with hot water: 375 mg (86.8%). mp 148—150 °C. $[\alpha]_D^{23}$ −3.2° (*c* 0.5, DMF).

Found: C, 54.60; H, 8.75; N, 9.63%. Calcd for $C_{13}H_{24}N_2O_5$: C, 54.15; H, 8.39; N, 9.72%.

*N-(Benzyloxycarbonyl)-D-isoglutamine t-Butyl Ester (**10d**).* This compound was synthesized in a similar manner to that described for 10c: 67.8%. mp 113 °C. $[\alpha]_D^{22}$ −2.5° (*c* 0.5, DMF).

Found: C, 61.13; H, 7.23; N, 8.36%. Calcd for $C_{17}H_{24}N_2O_5$: C, 60.70; H, 7.19; N, 8.33%.

*N-(t-Butoxycarbonyl)-L-valyl-D-isoglutamine (**12**).* *t*-Butoxycarbonyl-L-valyl-D-isoglutamine benzyl ester (**11**)[18] (7.50 g, 17.2 mmol) was hydrogenated in MeOH (150 ml) using palladium black as a catalyst at room temperature for 6 h. After the removal of the catalyst by filtration, the filtrate was concentrated to give the residue which was reprecipitated from AcOEt–petroleum ether: 6.00 g (quantitative). mp 89—90 °C. $[\alpha]_D^{23}$ +5.8° (*c* 0.5, DMF).

Found: C, 51.96; H, 8.10; N, 12.11%. Calcd for $C_{15}H_{27}N_3O_6$: C, 52.16; H, 7.88; N, 12.17%.

*N-(t-Butoxycarbonyl)-L-valyl-D-isoglutamine Isopropyl Ester (**13c**).* Compound **10c** (173 mg, 0.6 mmol) was treated with TFA (2 ml) at room temperature for 20 min. After the removal of TFA, the residual oil was washed with a mixture of ether and petroleum ether (1 : 1, v/v) by decantation. The resulting oil was then dissolved in CH_3CN (5 ml) together with *N*-(*t*-butoxycarbonyl)-L-valine HONB ester (277 mg, 0.6 mmol), Et_3N (0.1 ml) was added, and the mixture was stirred at room temperature for 15 h. After the usual work-up, the product was crystallized from petroleum ether: 185 mg (79.6%). The physicochemical data are given in Table 1.

*N-(Benzyloxycarbonyl)-L-valyl-D-isoglutamine t-Butyl Ester (**13d**).* Compound **10d** (202 mg, 0.6 mmol) was hydrogenated in MeOH (10 ml) with palladium black as a catalyst at room temperature for 3 h. After the removal of the catalyst by filtration, the fltrate was concentrated to dryness. The residue was dissolved in CH_3CN (10 ml) together with *N*-(benzyloxycarbonyl)-L-valine HONB ester (248 mg, 0.6 mmol), and the mixture was stirred at room temperature for 15 h. To this was added 5% citric acid solution, and the resulting crystals were collected by filtration and recrystallized from MeOH–AcOEt–petroleum ether: 178 mg (68.1%). The physicochemical data are given in Table 1.

*N-(t-Butoxycarbonyl)-L-valyl-D-isoglutamine Octadecyl Ester (**13f**).* Compound **12** (1.73 g, 5 mmol) was combined with Et_3N (0.84 ml, 6 mmol) in DMF (5 ml) at 4 °C, and to this was added 6-chloro-1-(*p*-chlorophenylsulfonyloxy) benzotriazole[19] (2.06 g, 6 mmol) with stirring. Soon after, the mixture became clear and stirring was continued at room temperature for 4 h. A solution of 1-octadecanol (4.05 g, 15 mmol) and Et_3N (0.7 ml) in CH_2Cl_2 (30 ml) was then added at 4 °C and the mixture was stirred at room temperature for additional 24 h. After the usual work-up, the residue was recrystallized from AcOEt–petroleum ether: 1.10 g (37.0%).

Compounds **13b** and **e** were prepared similarly from appropriate alcohols and **12**. The yields and physicochemical data are given in Table 1.

*N-(t-Butoxycarbonyl)-O-benzyl-L-seryl-D-isoglutamine Methyl Ester (**13g**).* *N*-(*t*-Butoxycarbonyl)-D-isoglutamine methyl ester[18] (0.65 g, 2.5 mmol) was treated with TFA (5 ml) at room temperature for 20 min. After the removal of TFA, the residue was triturated with ether. The resulting oily D-isoglutamine methyl ester trifluoroacetate was dried over NaOH pellets, dissolved in AcOEt (5 ml), and neutralized with Et_3N (0.35 ml) under cooling. A solution of *N*-(*t*-butoxycarbonyl)-*O*-benzyl-L-serine HONB ester (1.14 g, 2.5 mmol) in AcOEt (5 ml) was then added, and the mixture was stirred at room temperature for 16 h. After the usual work-up, the residue was recrystallized from AcOEt–ether: 776 mg (71.2%).

Compound **13h** was prepared in a similar manner. The yield and physicochemical data are given in Table 1.

*N-Acetyl-1-O-benzyl-4,6-O-benzylidene-α-muramyl-L-valy-D-isoglutamine t-Butyl Ester (**15d**).* Compound **13d** (160

mg; 0.38 mmol) was hydrogenated in MeOH (20 ml) with palladium black as a catalyst at room temperature for 2 h. After the removal of the catalyst by filtration, the filtrate was concentrated to give the residue which was dissolved in CH_3CN (10 ml) together with **14** (240 mg, 0.38 mmol). The mixture was left at room temperature for 15 h, then the resulting crystals were collected and recrystallized from CH_3CN–ether: 216 mg (75.3%). The physicochemical data are given in Table 2.

N-Acetyl-1-O-benzyl-4,6-O-benzylidene-α-muramyl-O-benzyl-L-seryl-D-isoglutamine Methyl Ester (15g). Dipeptide **11h** (0.44 g, 1 mmol) was treated with TFA (6 ml) at room temperature for 20 min. After the removal of TFA, the residue was triturated with a mixture of ether and petroleum ether (1:1, v/v). The resulting powder was filtered, dried over NaOH pellets, and dissolved in THF (4 ml). After neutralization with Et_3N (0.14 ml) under cooling, this was combined with a solution of *N*-acetyl-1-*O*-benzyl-4,6-*O*-benzylidene-α-muramic acid HONB ester (**14**) (0.63 g, 1 mmol) in THF (2 ml). The mixture was then stirred at room temperature for 16 h, and the gel was filtered and washed thoroughly with THF. The solid obtained was reprecipitated from EtOH–DMF: 0.55 g 80.0%.

Compounds **15a—c**, **e**, **f**, and **h** were prepared in a similar manner. The yields and physicochemical data of **15** are given in Table 2.

N-Acetyl-1-O-benzyl-α-muramyl-L-valyl-D-isoglutamine Methyl Ester (16a). *N*-Acetyl-1-*O*-benzyl-4,6-*O*-benzylidene-α-muramyl-L-valyl-D-isoglutamine methyl ester[18] (10.1 g, 14.4 mmol) in 75% acetic acid (200 ml) was heated in a boiling water bath for 20 min. After the removal of the solvent, the residue was flushed with water and then toluene, and reprecipitated from EtOH–ether: 0.84 g (73.0%).

Compound **16b—h** were prepared in a similar manner. The yields and physicochemical data of **16** are given in Table 2.

N-Acetyl-1-O-benzyl-6-O-[10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decanoyl]-α-muramyl-L-valyl-D-isoglutamine Methyl Ester (17a). *Method A.* Compound **16a** (1.25 g, 2 mmol) in DMF (10 ml) and 10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decanoic acid (0.85 g, 2.4 mmol) in dry pyridine (4 ml) was combined. To this was added DCC (0.83 g, 4 mmol) under cooling and the mixture was stirred at 4 °C for 6 d. After the usual work-up, the crude material was recrystallized from a mixture of MeOH and ether: 1.47 g (75.8%). *Method B.* Compound **16a** (0.25 g, 0.4 mmol) and 10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decanoic acid *p*-nitrophenyl ester (0.38 g, 0.8 mmol), HOBt (0.22 g, 1.6 mmol), and NEM (0.21 g, 1.6 mmol) were dissolved in DMF (2 ml) and the mixture was stirred at room temperature for 2 d. After the removal of the solvent, the residue was applied onto a silica-gel column which was eluted with $CHCl_3$–MeOH–AcOH (18:2:1, v/v) as an eluting solvent. The resulting **17a** was further purified by column chromatography of Sephadex LH-20 (1.5×90 cm) with EtOH as an eluent: 0.19 g (49.1%).

Compounds **17b—g**, **i**, and **j** were synthesized in a manner similar to that described in method B. Compounds **17k—m** were synthesized in a manner similar to that described in method A and purified as described in method B. The yields and physicochemical data of **17** are given in Table 3.

N-Acetyl-6-[10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decanoyl]muramyl-L-valyl-D-isoglutamine Methyl Ester (1a). Compound **17a** (192 mg, 0.2 mmol) was hydrogenated in MeOH (4 ml) with palladium black as a catalyst at room temperature for 4 h and the catalyst was removed. The methanol solution of the resulting hydroquinone was combined with an aqueous solution of $FeCl_3 \cdot 6H_2O$ (1 g), and the mixture was stirred at room temperature for 30 min. To this was added AcOEt (50 ml), and the AcOEt layer was washed with water (15 ml) and dried (Na_2SO_4). After the removal of the solvent, the crystalline residue was purified by column chromatography of Sephadex LH-20 (1.8×44 cm) with a mixture of EtOH and 0.1 M AcOH (3:2, v/v) as an eluent. Recrystallization from EtOH–ether–petroleum ether gave **1a**: 127 mg (73.0%).

Compounds **1b—g** and **i—m** were synthesized in a similar manner. The yields and physicochemical data of **1** are given in Table 4.

N-Acetyl-6-O-[6-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)hexanoyl]muramyl-L-valyl-D-isoglutamine Methyl Ester (1h). 6-(5,6-Dimethoxy-3-methyl-1,4-benzoquinon-2-yl)hexanoic acid (**2b**) (35.6 mg, 0.12 mmol) and *N*-acetylmuramyl-L-valyl-D-isoglutamine methyl ester[18] (53.3 mg, 0.1 mmol) were dissolved in a mixture of DMF and pyridine (0.4 ml each). To this was added DCC (41.2 mg, 0.2 mmol), and the solution was stirred at room temperature for 30 h. The precipitate formed was filtered and the filtrate was concentrated to give the residue which was purified by column chromatography on silica gel (15 g) using $CHCl_3$–MeOH–acetone (50:9:6, v/v) as an eluant. Recrystallization from EtOH–ether gave **1h**: 31.5 mg (38.8%). The physicochemical data are given in Tabel 4.

Ethyl 3-Oxotetracosanoate (21).[20] A solution of diethyl malonate (21.7 g, 0.12 mol) in EtOH (13 ml) was slowly added dropwise to a suspension of magnesium (4.1 g, 0.17 mol) in a mixture of EtOH (4 ml) and CCl_4 (0.2 ml), maintaining a vigorous reaction. Ether (50 ml) was then added, and the mixture was refluxed for 3 h. After the removal of the solvent, the residue was flushed with benzene to remove EtOH and the residue was dissolved in ether (60 ml). To this was added over a period of 30 min an ethereal solution (50 ml) of docosanoyl chloride (0.15 mol), and the mixture was stirred at 50 °C for 2 h and at room temperature for 15 h. After 1M H_2SO_4 (300 ml) was added carefully, the mixture was extracted with ether (300 ml). The organic layer was washed with water, dried (Na_2SO_4), and concentrated to give 2-ethoxycarbonyl-3-oxotetracosanoic acid ethyl ester (75.4 g, 93.5%). This was dissolved in DMSO (50 ml) containing *p*-toluenesulfonic acid (2.1 g) and the mixture was heated at 200—210 °C in an oil bath for 20 min. After the evolution of CO_2 gas had ceased, the mixture was allowed to cool to room temperature, diluted with water (500 ml), and extracted with ether (500 ml). The extract was washed with water, dried (Na_2SO_4), and concentrated to give the residue, which was purified by column chromatography on silica gel (700 g) using hexane–diisopropyl ether (9:1, v/v) as an eluting solvent: 27.9 g (45.2%).

Found: C, 76.31; H, 12.23%. Calcd for $C_{26}H_{50}O_3$: C, 76.04; H, 12.27%.

10-(5,6-Dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decyl Acetate (18). A solution of 10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)-1-decanol[14] (50.4 g, 0.15 mol) and pyridine (48.6 ml, 0.6 mol) in CH_2Cl_2 (250 ml) was combined with acetic anhydride (42.6 ml, 0.45 mol) at 4 °C, and the mixture was stirred at room temperature for 15 h. Water (50 ml) was then added and the mixture was stirred at room temperature for 30 min. After the removal of the solvent, AcOEt (300 ml), $NaHCO_3$ (60 g) and water (200 ml) were added to the residue, and the mixture was stirred at room temperature for additional 1 h. The organic layer was washed succesively with 1M HCl and water, and dried (Na_2SO_4). After the removal of the solvent, the residue was triturated with petroleum ether to give **18** as a crystal: 51.5 g (90.7%). mp 39—40 °C.

Found: C, 66.35; H, 8.53%. Calcd for $C_{21}H_{32}O_6$: C, 66.30; H, 8.48%.

10-(3,4-Dimethoxy-2,5-dimethoxymethyloxy-6-methylphenyl)-1-decanol (19). Compound **18** (30.3 g, 80 mmol) was

hydrogenated in DMF (300 ml) with 5% palladium on carbon as a catalyst at room temperature for 2 h and the catalyst was removed by filtration. To the filtrate was added NaH (7.04 g, 0.18 mol) under nitrogen. After being stirred for 30 min, the mixture was combined with methoxymethyl chloride (13.4 ml, 0.18 mol) at 4 °C, and the stirring was continued at room temperature for additional 15 h. The reaction mixture was then diluted with water (2 l) and extracted with ether (500 ml). The extract was concentrated to give an oil (40 g) which was dissolved in EtOH (200 ml) and treated with 4M NaOH (60 ml). The mixture was stirred at room temperature for 15 h, diluted with water (1 l), and extracted with ether (300 ml). The extract was washed with water, dried (Na_2SO_4), and concentrated to give a residue which was purified by column chromatography on silica gel (300 g) with $CHCl_3$–MeOH (50:1, v/v) as an eluting solvent: 27.4 g (80.3%).

Found: C, 63.24; H, 9.35%. Calcd for $C_{23}H_{40}O_7 \cdot 1/2H_2O$: C, 63.13; H, 9.45%.

*10-(3,4-Dimethoxy-2,5-dimethoxymethyloxy-6-methylphenyl)-decanal (**20**).* A solution of pyridine-sulfur trioxide complex (30.7 g, 0.19 mol) in DMSO (120 ml) was added dropwise to a solution of **19** (27.4 g, 64.2 mmol) and Et_3N (44.9 ml, 0.32 mol) in DMSO (60 ml) over a period of 1 h, and the mixture was stirred at room temperature for 1 h. The mixture was poured into ice-cold water (500 ml) and extracted with ether (500 ml). The extract was washed with water, dried (Na_2SO_4), and concentrated to give a residue which was purified by column chromatography on silica gel (300 g) with $CHCl_3$: 22.1 g (81.1%).

Found: C, 64.29; H, 9.07%. Calcd for $C_{23}H_{38}O_7$: C, 64.76; H, 8.98%.

*2-[10-[3,4-Dimethoxy-2,5-bis(dimethoxymethoxy)-6-methylphenyl]decylidene]-3-oxotetracosanoic Acid Ethyl Ester (**22**).* A solution of **21** (14.4 g, 35 mmol) and **20** (14.9 g, 35 mmol) in anhydrous benzene (40 ml) was combined with AcOH (0.35 ml) and piperidine (0.18 ml), and the mixture was heated under reflux to remove the water formed azeotropically. After the removal of the solvent, the residue was purified by column chromatography on silica gel (450 g) with $CHCl_3$–MeOH (9:1, v/v): 18.8 g (65.6%). ^1H NMR ($CDCl_3$): δ=0.88 (3H, t), 1.10—1.72 (57H, b), 2.20 (3H, s), 2.34—2.81 (4H, m), 3.59 (6H, s), 4.20 (2H, q), 5.03 (4H, s), 5.33—5.71 and 6.60—7.00 (1H, m).

Found: C, 71.18; H, 10.53%. Calcd for $C_{49}H_{89}O_9 \cdot 1/2H_2O$: C, 71.06; H, 10.46%.

*2-[10-[3,4-Dimethoxy-2,5-bis(dimethoxymethoxy)-6-methylphenyl]decyl]-3-hydroxytetracosanoic Acid Ethyl Ester (**23**).* Compound **22** (18.4 g, 22.5 mmol) was hydrogenated in a mixture of dioxane (200 ml) and EtOH (150 ml) with palladium black as a catalyst at room temperature for 8 h. The catalyst was removed by filtration and the filtrate was concentrated. The resulting residue was dissolved in a mixture of dioxane (120 ml) and MeOH (40 ml), and to this was added $NaBH_4$ (851 mg, 22.5 mmol) with stirring. After 30 min, the pH of the mixture was adjusted to 3 with 5% citric acid. The mixture was then diluted with water (200 ml) and extracted with AcOEt (200 ml). The extract was washed with water, dried (Na_2SO_4), and concentrated to give a crystalline residue which was recrystallized from MeOH: 16.9 g (91.2%). mp 42—44 °C.

Found: C, 71.75; H, 11.30%. Calcd for $C_{49}H_{90}O_9$: C, 71.48; H, 11.02%.

*2-[10-[3,4-Dimethoxy-2,5-bis(dimethoxymethoxy)-6-methylphenyl]decyl]-3-hydroxytetracosanoic Acid (**24**).* A solution of **23** (16.5 g, 20 mmol) in a mixture of EtOH (70 ml) and dioxane (50 ml) was combined with 3M NaOH (30 ml), and the mixture was heated under reflux for 2 h. After the solution was cooled to room temperature, the pH was adjusted to 3 with 10% citric acid. The mixture was diluted with water (300 ml) and extracted with AcOEt (150 ml). The extract was washed with water, dried (Na_2SO_4), and concentrated to give a residue which was purified by column chromatography on silica gel (200 g) with $CHCl_3$–MeOH (50:1, v/v): 14.3 g (89.9%). mp 60 °C. ^1H NMR ($CDCl_3$): δ=0.87 (3H, t), 1.07—1.80 (58H, broad s), 2.20 (3H, s), 2.34—2.82 (3H, m), 3.28—3.50 (1H, m), 3.59 (6H, s), and 5.00 (4H, s).

Found: C, 70.86; H, 11.01%. Calcd for $C_{47}H_{86}O_9$: C, 70.99; H, 10.90%.

*2-[10-(5,6-Dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decyl]-3-hydroxytetracosanoic Acid (**25**).* A solution of **24** (1.59 g, 2 mmol) in hot AcOH (20 ml) was combined with 2M H_2SO_4 (2 ml), and the mixture was stirred at 100 °C for 10 min. After the removal of the solvent, the residue was dissolved in AcOEt (50 ml) and the solution was washed with water. The solvent was evaporated and the residue was dissolved in dioxane (30 ml). To this was added a solution of $FeCl_3 \cdot 6H_2O$ (2.70 g, 10 mmol) in water, and the mixture was stirred at room temperature for 1 h, diluted with water (100 ml), and extracted with AcOEt (50 ml). The extract was washed with water, dried (Na_2SO_4), and concentrated to give a residue which was crystallized from MeOH: 1.03 g (73.1%). mp 72—73 °C ^1H NMR ($CDCl_3$): δ=0.89 (3H, t), 1.10—1.67 (58H, broad s), 2.00 (3H, s), 2.30—2.61 (3H, m), 3.73—3.93 (1H, m), and 3.98 (6H, s).

Found: C, 73.01; H, 10.87%. Calcd for $C_{43}H_{76}O_7$: C, 73.25; H, 10.87%.

*N-Acetyl-1-O-benzyl-6-O-[2-[10-[3,4-dimethoxy-2,5-bis(dimethoxymethoxy)-6-methylphenyl]decyl]-3-hydroxytetracosanoyl]-α-muramic Acid Diphenylmethyl Ester (**28**).* A solution of **24** (3.18 g, 4 mmol) in $CHCl_3$ (30 ml) was made basic to phenolphthalein with a solution of 0.5 M KOH in MeOH (8.1 ml) and then the solvent was removed to give a waxy potassium salt **26**. This salt (833 mg, 1 mmol) was dissolved, together with *N*-acetyl-1-*O*-benzyl-6-*O*-(*p*-tolyluenesulfonyl)-α-muramic acid diphenylmethyl ester (**27**)[7] (703 mg, 1 mmol) and 18-crown-6 (60 mg, 0.23 mmol), in anhydrous toluene (40 ml). After being stirred at 80 °C for 4 h, the mixture was concentrated to give a residue which was purified by column chromatography on silica gel (30 g) with $CHCl_3$–MeOH (99:1, v/v): 1.05 g (79.1%).

Found: C, 69.47; H, 9.03; N, 1.10%. Calcd for $C_{78}H_{119}NO_{16} \cdot H_2O$: C, 69.66; H, 9.07; N, 1.04%.

*N-Acetyl-6-O-[2-[10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decyl]-3-hydroxytetracosanoyl]muramyl-L-valyl-D-isoglutamine Methyl Ester (**1k**).* A solution of **28** (1.0 g, 0.75 mmo) and anisole (1.1 ml) in CH_2Cl_2 (10 ml) was combined with TFA (10 ml) at 4 °C with stirring and the stirring was continued for additional 1 h. After the removal of the solvent, the residue was dissolved in ether (30 ml) and the solution was washed with water, dried (Na_2SO_4), and concentrated. The residue was purified by column chromatography on silica gel (20 g) with $CHCl_3$–acetone–MeOH (10:3:2, v/v) as an eluting solvent to give *N*-acetyl-1-*O*-benzyl-6-*O*-[2-[10-(2,5-dihydroxy-3,4-dimethoxy-6-methylphenyl)decyl-3-hydroxytetracosanoyl]-α-muramic acid (500 mg, 62.2%). This acid (214 mg, 0.2 mmol) was dissolved in THF (3 ml) together with L-valyl-D-isoglutamine methyl ester hydrochloride (65 mg, 0.27 mmol), Et_3N (38 μl, 0.27 mmol), and HONB (54 mg, 0.3 mmol). To this was added DCC under cooling, and the mixture was stirred at room temperature for 15 h. After the removal of the precipitate by filtration, the filtrate was concentrated and the residue was dissolved in AcOEt (30 ml). The solution was washed successively with 5% citric acid and water, dried (Na_2SO_4), and concentrated to give a residue which was purified by column chromatography on silica gel (5 g) with $CHCl_3$–MeOH (97:3, v/v) as an eluant. The resulting crystalline

protected glycopeptide **29a** (106 mg) was hydrogenated in a mixture of THF (2 ml) and AcOH (1 ml) with palladium black as a catalyst at room temperature for 3 h and the free glycopeptide obtained was dissolved in dioxane (10 ml). To this was added a solution of $FeCl_3 \cdot 6H_2O$ (270 mg, 1 mmol) in a small amount of water, and the mixture was stirred at room temperature for 3 min to oxidize the hydroquinone ring. After the removal of the solvent, the residue was dissolved in AcOEt (20 ml). The solution was washed with water, dried (Na_2SO_4), and concentrated to give a residue which was lyophilized from *t*-BuOH: 88 mg (33.0%). The physicochemical data are given in Table 4.

N-Acetyl-6-O-[2-[10(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decyl]-3-hydroxytetracosanoyl]muramyl-L-alanyl-D-isoglutamine (11) was synthesized in a manner similar to that of **1k**. The yield and physicochemical data are given in Table 4.

N-Acetyl-1-O-benzyl-6-O-(benzyloxycarbonyl-L-leucyl)-α-muramyl-L-valyl-D-isoglutamine Methyl Ester (30b). A mixture of **16a** (31.2 g, 5 mmol), benzyloxycarbonyl-L-leucine *p*-nitrophenyl ester (3.86 g, 10 mmol), HOBt (2.70 g, 20 mmol) and NEM (2.56 ml, 20 mmol) in DMF (50 ml) was stirred at room temperature for 60 h. After the removal of the solvent, the residue was purified by column chromatography of silica gel with $CHCl_3$–MeOH (19:1, v/v) as an eluent. Reprecipitation from MeOH–ether gave **30b**: 3.1 g (71.7%).

Compounds **30a**, **c**, and **d** were synthesized in a similar manner. The yields and physicochemical data are given in Table 5.

N-Acetyl-6-O-(L-leucyl)muramyl-L-valy-D-isoglutamine Methyl Ester (31b). Compound **30b** (0.3 g, 0.35 mmol) was hydrogenated in AcOH (10 ml) with palladium black as a catalyst at room temperature for 4 h, and the catalyst was removed by filtration. After the removal of the solvent, the residue was reprecipitated from a mixture of MeOH and ether: 0.19 g (82.6%).

Compounds **31a**, **c**, and **d** were synthesized in a similar manner. The yields and physicochemical data are given in Table 5.

N-Acetyl-6-O-[10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decanoyl-L-leucyl]muramyl-L-valyl-D-isoglutamine Methyl Ester (33b). *Method A.* A mixture of **31b** (51.8 mg, 0.08 mmol), 10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decanoic acid *p*-nitrophenyl ester (41.7 mg, 0.088 mmol), and NEM (0.012 ml, 0.09 mmol) in DMF (0.5 ml) was stirred at room temperature for 60 h. After the removal of the solvent, the residue was applied onto a silica-gel column (2× 12 cm) which was eluted with AcOEt–pyridine–H_2O–AcOH (130:10:5:3, v/v). The resulting crude **33b** was further purified by column chromatography of Sephdex LH-20 (1.5×90 cm) with EtOH–0.1 M AcOH (3:2, v/v) as an eluent and lyophilized from *t*-BuOH: 32 mg (40.7%). *Method B.* *N*-Acetyl-6-*O*-[10-(5,6-dimethoxy-3-methyl-1,4-benzoquinon-2-yl)decanoyl-L-leucyl]muramyl-L-valyl-D-isoglutamine[29] (32b, 20 mg) was dissolved in MeOH (0.3 ml). To this was added excess ethereal diazomethane solution dropwise under cooling and the mixture was stirred at 4 °C for 30 min. After the removal of the solvent, the residue was purified as described in method A: 13.8 mg (67.0%).

Compounds **33a**, **c**, and **d** were synthesized in a similar manner as described in method A, and compounds **33a** and **e** in method B. The yields and physicochemical data of **33** are given in Table 5.

We wish to thank Professor T. Shiba of Osaka University for discussions and Dr. J. Miller for reviewing the manuscript.

Structure-taste Relationships of Aspartyl Tripeptide Esters

Yasuo Ariyoshi

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki-ku, Kawasaki 210

(Received May 18, 1984)

A series of twenty four analogues of L-α-Asp-Gly-Gly-OMe has been synthesized in relation to structural features of sweet peptides. The rule in the structure-taste relationships of dipeptides is held in the sweet aspartyl tripeptide esters. In order for the aspartyl tripeptide esters to be sweet, the second amino acid must have a D-configuration and a small, compact alkyl group (Me, Et, or *i*-Pr) at R^2. An L-configuration of the third amino acid is required for a potent sweet taste. It has been concluded that the small alkyl group at R^2 participates in binding with the receptor through a hydrophobic interaction and increases the sweetness potency.

A wide variety of structural features have been known in sweet-tasting compounds. Attempts to elucidate the structural features necessary to elicit a sweet taste have been made, and several molecular theories have been proposed to relate the various structural features[1].

Since the discovery[2] of a sweet taste in L-α-Asp-L-Phe-OMe, a large number of analogues have been synthesized in an attempt to elucidate structure-taste relationships, and to obtain more potent and stable sweet peptides. It has been demonstrated that the L-Asp moiety in the original L-α-Asp-L-Phe-OMe molecule is restricted to L-aspartic acid[2] or aminomalonic acid[3] but that considerable modification can be made to the L-Phe-OMe moiety. The L-Phe-OMe has been successfully replaced by alkyl- and arylamines,[4] D-and L-amino acid esters,[2,5] D-amino acid alkylamides,[6] D-amino acid derivatives,[7] and aminomalonic acid diesters.[8] The importance of the peptide bond has also been demonstrated, since any modification in its structure results in a complete loss of sweetness.[9]

The sweetness potency in L-α-aspartyl dipeptide analogues has been quantitatively analyzed in relation to structural, electronic, and hydrophobic parameters.[10] A possible sweet conformation of L-α-Asp-L-Phe-OMe has also been determined by an NMR study, a potential energy calculation,[11] and an examination of L-α-Asp-Δ^z-Phe-OMe.[12]

In a previous paper,[13] the tastes of aspartyl dipeptides were relationalized through Fischer projection formulas. In this paper, these formulas have been translated into the structure shown in Fig. 1.

The structural features of sweet aspartyl dipeptide esters have been successfully explained on the basis of the general structure (Ia),[13a] in which the carboxyl and amino groups serve as a proton acceptor and a proton donor, respectively, in the hydrogen bonding with the receptor. The small hydrophobic side chain (S) is considered to participate in the hydrophobic interaction

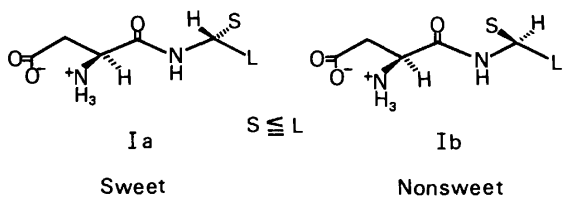

Fig. 1. General structure for sweet aspartyl dipeptide esters: S=small hydrophobic group (1—4 atoms); L=larger hydrophobic group (3—6 atoms).[13a]

with the receptor and to increase the sweetness potency. The larger hydrophobic group (L) seems to be associated with the conformation and hydrophilic-hydrophobic balance of the whole molecule. The hydrophilic-hydrophobic balance in a molecule is another important factor. Space-filling properties are also important, since the receptor site seems to be in the shape of a deep narrow cleft,[11] a pocket,[13b] or a hydrophobic tube[14] with the binding sites inside it.

In an attempt to extend the general structure (Ia) for sweet dipeptides to tripeptides, several aspartyl tripeptides have been synthesized and tested.[13b] The sweetness potencies were weak, 1—3 times sweeter than sucrose.

In order to confirm our previous conclusion on the roles of the S and L groups in the structure (Ia) and to extend the general structure (Ia) to tripeptides, various aspartyl tripeptide esters were synthesized, and several intensely-sweet tripeptides were obtained after an examination of the sweet structure (Ia) and a consideration of the hydrophilic-hydrophobic balance in a sweet molecule.

Synthesis

The protected dipeptides in Table 1 were prepared by the dicyclohexylcarbodiimide (DCC) method.[15] When the dipeptides (**1**, **3**, **5**) were obtained as oily residues, a *t*-butoxycarbonyl (Boc) group of these peptides was deprotected with hydrogen chloride in methanol and the resulting hydrochlorides (**2**, **4**, **6**) were crystallized. Compound **7** was left over from a previous experiment. The Boc group of the protected dipeptides in Table 1 was removed with *p*-toluenesulfonic acid monohydrate[16] in methanol, and the resulting dipeptide ester *p*-toluenesulfonates were used for the next step without further purification. The protected tripeptides in Table 2 were prepared by condensation of β-benzyl *N*-benzyloxycarbonyl-L-aspartate with the appropriate dipeptide ester using DCC. Compounds **42**—**44**, **47**—**49**, and **51** were prepared by the active ester method,[17] in which *N*-benzyloxycarbonyl-L-aspartic acid β-benzyl α-succinimido ester was coupled with the appropriate dipeptide ester. The desired tripeptide esters in Table 3 were obtained by deprotection of the benzyloxycarbonyl and benzyl groups from the protected tripeptides in Table 2 by hydrogenation over Pd/C.

Results and Discussion

In order to evaluate contributions of the side chains

Table 1. Protected dipeptides

II

Fig. 2. L-α-Aspartyl tripeptide esters.

of each amino acid, the substituents R^1—R^5 of II were systematically modified. The results are summarized in Table 4. In the relationships between the sweet dipeptides (Ia) and tripeptides (II), S (a small hydrophobic group) of Ia corresponds to R^2 (a small alkyl group) of II, and L (a larger hydrophobic group) corresponds to $-CONHCR^3(R^4)COOR^5$. In systematic structural variation of the tripeptides (II), it was assumed that R^2 (a small alkyl group) in II was one of the groups responsible for sweetness, through a hydrophobic interaction with the receptor.

As reported previously,[13b] L-α-Asp-Gly-Gly-OMe (**76**), which is tasteless (Table 4), was selected as a standard of tripeptides because it has the simplest structure and a correlation with other tripeptides is easy.

As the first step, the contribution of the third amino acid to sweetness was evaluated. The introduction of a methyl group at R^4 of **76** gave a weakly sweet peptide (**52**). When the methyl group of **52** was introduced on the opposite side (R^3), the resulting peptide (**53**) was also weakly sweet. Replacement of the methyl group in

52 by an isopropyl or an isobutyl group gave **54** and **55**, respectively, which were bitter. These results show that a modification of the third amino acid alone does not effect elicitation of sweetness.

Secondly, the contribution of the second amino acid to sweetness was evaluated. As mentioned above, it seems that a small alkyl group (Me, Et or *i*-Pr) at R^2 is required for sweetness. Therefore, in this experiment, a small alkyl group was introduced at R^2 so as to meet the sweet structure (Ia), in which S corresponds to R^2 of II in the configuration. As reported previously, replacement of a methyl group at R^2 of **76** gave **77**,[13b] which was 3 times sweeter than sucrose. Replacement of the methyl group by an ethyl or an isopropyl group gave **78** and **79**,[13b] which were sweet and tasteless, respectively. The ethyl ester analogue (**80**)[13b] of **79** was also tasteless. As described above, the modification of the second amino acid alone gave a similar result in the case of the modification of the third amino acid.

Thirdly, the combined contribution of the second and third amino acids was evaluated. In this experiment, a small alkyl group of the second amino acid was also introduced at R^2 by the reason mentioned above. Introduction of an alkyl group to the α-carbon of Gly in L-α-Asp-D-Ala-Gly-OMe (**77**) significantly increased the sweetness potency (**56—60**). The potent sweetness seems to result from an increased hydrophobicity as compared with **77**. The sweet taste changed to a bitter taste (**61**) with increasing hydrophobicity of the group (R^4). In the same way, when a small alkyl group was introduced to the α-carbon of Gly in L-α-Asp-D-Val-Gly-OMe (**79**), the resulting peptides (**62—65**) became intensely sweet. Compound **66** may be too hydrophobic to taste sweet. A substituent at R^2 is considered to be a small, compact alkyl group, such as Me, Et or *i*-Pr, from the previous work on the dipeptide sweeteners, especially in L-α-Asp-D-amino acid esters. A need for the small alkyl group (R^2) was confirmed by the fact that L-α-Asp-D-Leu-L-Ala-OMe (**67**) was not sweet but bitter. The *i*-Bu group in **67** seems to be too bulky to interact effectively at the sweet receptor site. These observations suggest that the hydrophilic-hydrophobic balance in a molecule and the space-filling properties are important. It is interesting that the sweetness potencies were significantly changed by altering the configuration of the third amino acid (**52** and **53**; **56** and **57**; **62** and **63**). The observation shows that the L-configuration of the third amino acid is

required for a potent sweet taste. The importance of the spacial orientation of the side chain may suggest another hydrophobic interaction at R^4 with the receptor site. The sweet receptor is considered to be a protein,[18] therefore, such an interaction appears to occur possibly at the receptor site.

Finally, in order to reconfirm the required configurations (R^2=small alkyl group; R^1=H) at the second amino acid, several tripeptides having opposite configurations at this chiral center were synthesized. All of the peptides (**68—75**) were essentially tasteless or bitter. Among them, however, compounds **71**, **73**, **74**, and **75** were bitter-sweet. The sweetness of these compounds did not come from contamination of their sweet isomers. Compound **74** was found by thin-layer chromatography (TLC) and high-performance liquid chromatography (HPLC) to be free from **64**. TLC analyses of **71**, **73**, and **75** showed no other compounds to be detectable. The weak sweet taste observed in compounds **71**, **73**, **74**, and **75** with all L-configurations may show that sweetness cannot necessarily be correlated with D-isomerism at the second amino acid. These four compounds, however, were essentially bitter. It is therefore concluded that the general structure (Ia) for sweet dipeptides is extended to that for sweet tripeptides (II), in which R^1 is H and R^2 is a small alkyl group. Exceptions that **71**, **73**, **74**, and **75** with the L-configuration at the second amino acid showed a weak sweet taste along with a bitter taste may be interpreted in terms of their conformations, in which a certain conformer may possibly fit the narrow receptor pocket.

Summary

A series of twenty four analogues of L-α-Asp-Gly-Gly-OMe (**76**) has been synthesized in relation to our previous conclusion that the small alkyl group (S) of the sweet dipeptides (Ia) increases the sweetness potency through a hydrophobic interaction with the receptor. It has been concluded that the small alkyl group at R^2 in the tripeptides (II) participates in binding with the receptor through the hydrophobic interaction and increases the sweetness potency. In order for the tripeptides to be sweet, the second amino acid must have the D-configuration and a small, compact alkyl group (Me, Et or *i*-Pr) at R^2. The L-configuration of the third amino acid is required for a potent sweet taste. This suggests another hydrophobic interaction at R^4. The rule in the general structure (Ia) for the sweet dipeptides is held in the sweet tripeptides (II). The sweetness potencies of the tripeptides obtained here, however, were lower than those of aspar-

tyl dipeptides. This result suggests the importance of the hydrophilic-hydrophobic balance and space-filling properties (shape, size, length, and conformation) in a sweet peptide. The tripeptides are generally more hydrophilic than potent sweet dipeptides and the hydrophilic property will cause the decreased sweetness potency. The receptor site for sweet amino acids and peptides seems to be not a plane but the shape of a pocket[13b] or a similar one as mentioned before. With increasing length of a peptide, it becomes difficult to fit such a narrow site. The decreased binding of the sweet molecule to the receptor reduces the potency.

Experimental

All melting points were taken on a Yanagimoto capillary melting point apparatus Model MP-21 and are uncorrected. Optical rotations were measured on a JASCO DIP-140 digital polarimeter with a 10-cm cell at room temperature and a 1% concentration. TLC was performed on precoated silica gel $60F_{254}$ plates (E. Merck) and spots were detected with ninhydrin or I_2 vapor. All compounds were essentially homogeneous on TLC. HPLC was carried out on a Hitachi 635A instrument with a Unisil Q C-18 reverse-phase column (4 mm ×25 cm) eluting with 23% methanol in pH 3.5 NaH_2PO_4 buffer at a flow rate of 0.8 ml/min. Sweetness potency was not evaluated by the panel method due to quantities available. In general, a panel evaluation needs a large quantity of sample. The yield, after purification, of each sweet peptide (Table 3) was less than 0.5 g. The quantity of tripeptides obtained here was insufficient for the panel evaluation. Therefore, sweetness evaluation was carried out by the author by matching a threshold concentration of each compound with that of sucrose. Test solutions of the tripeptides were made up at several concentrations. A series of the solutions were tasted up and down. Thus, it was possible to reproducibly determine the concentration which matched a 0.6% aqueous solution of sucrose. In order to confirm the sweetness values, compounds **56**, and **62—65** were also evaluated by a well trained sensory panelist, and the potencies were in fair agreement with those listed in Table 4. Therefore, it has been considered that the sweetness potencies in Table 4 are reproducible and reliable enough to discuss the functions of a small hydrophobic group.

Materials: Boc-amino acids were purchased from Peptide Institute Inc., except for Boc-L-Abu (Kokusan Chemical Works Ltd.). Esters of Gly, D-Ala, L-Phe, and L-Val were synthesized in our laboratory. Z-L-Asp(OBzl)-OH and esters of L-Ala and L-Leu were purchased from Kokusan Chemical Works Ltd.

Boc-Dipeptide Esters (1, 3, 5, 8—27). A typical run (**11** in Table 1) was as follows: To an ice-cooled stirred solution of H-L-Val-OMe·HCl (2.77 g, 16.5 mmol) and triethylamine (Et_3N) (1.67 g, 16.5 mmol) in 40 ml of chloroform was added Boc-D-Ala-OH (2.84 g, 15 mmol), followed by DCC (3.09 g,

15 mmol). The resulting mixture was stirred in an ice-bath for 1 h and then kept standing overnight, after which a few drops of acetic acid were added to the reaction mixture. The mixture was then stirred for 15 min and filtered. The filtrate was washed successively with water, a 10% citric acid solution, a 5% sodium hydrogencarbonate solution and water and then concentrated under reduced pressure to give an oily product. The oil was crystallized from ethyl acetate–hexane to give 2.77 g (61.1%) of Boc-D-Ala-L-Val-OMe (**11**) as plates. Recrystallization was effected from the same solvent. The data are given in Table 1.

Protected Tripeptide Esters (28—51). a) The DCC Method. A typical run (**35** in Table 2) was as follows: To a solution of Boc-D-Ala-L-Val-OMe (**11**, 2.23 g, 7.38 mmol) in 20 ml of methanol was added *p*-toluenesulfonic acid monohydrate (TosOH·H_2O) (1.78 g, 9.4 mmol). The mixture was stirred at 30 °C for 5 h. The solvent was evaporated under reduced pressure at a bath temperature of 50 °C to give H-D-Ala-L-Val-OMe·TosOH as an oily residue. The residue was used for the next step without further purification. H-D-Ala-L-Val-OMe·TosOH thus obtained was dissolved in 40 ml of chloroform and neutralized with Et_3N (0.95 g, 9.4 mmol) in an ice-bath. To the stirred ice-cooled solution was added Z-L-Asp(OBzl)-OH (2.50 g, 7 mmol), followed by DCC (1.44 g, 7 mmol). The mixture was stirred while cooling for 1 h and at room temperature for 3 h and then kept standing overnight. A few drops of acetic acid were then added to the reaction mixture. The mixture was stirred at room temperature for 15 min and then filtered. The filtrate was washed successively with water, 1M HCl (twice), a 5% sodium hydrogencarbonate solution (twice) and water, and then concentrated under reduced pressure to leave an oily product. The oil was crystallized from ethyl acetate–hexane to give Z-L-Asp(OBzl)-D-Ala-L-Val-OMe (**35**) as needles. Recrystallization was carried out from the same solvent. The data are given in Table 2.

b) The active ester method. A typical run (**51** in Table 2) was as follows: DCC (3.10 g, 15 mmol) was added to an ice-cooled mixture of Z-L-Asp(OBzl)-OH (5.36 g, 15 mmol) and *N*-hydroxysuccinimide (2.07 g, 18 mmol) in 50 ml of chloroform with stirring. The mixture was stirred in an ice-bath for 1 h and at room temperature for 3 h and then kept standing overnight. A few drops of acetic acid were then added to the reaction mixture, which was stirred at room temperature for 15 min and filtered. The filtrate was washed successively with water, a 5% sodium hydrogencarbonate solution and water, and then concentrated under reduced pressure to leave an oily product, which turned to crystals upon standing. Recrystallization from ethyl acetate–hexane gave Z-L-Asp(OBzl)-ONSu as needles; yield, 4.75 g (69.7%); mp 83—84 °C; $[\alpha]_D^{24}$ −19.1° (*c* 1, ethyl acetate). To a solution of Boc-L-Val-L-Leu-OMe (**27**, 3.10 g, 9 mmol) in 20 ml of methanol was added TosOH·H_2O (2.05 g, 10.8 mmol). The mixture was stirred at 30 °C for 5 h. The solvent was evaporated under reduced pressure at a bath temperature of 50 °C to give H-L-Val-L-Leu-OMe·TosOH as an oily residue. The oil was dissolved in 40 ml of chloroform and cooled in an ice-bath. To this solution was added Et_3N (1.10 g, 10.8 mmol), followed by Z-L-Asp(OBzl)-ONSu (3.79 g, 8.34 mmol) with stirring. The mixture was stirred at room temperature for 3 h and then kept standing overnight. The reaction mixture was worked up as a) to give Z-L-Asp(OBzl)-L-Val-L-Leu-OMe (**51**) as crystals, which were recrystallized from ethyl acetate—hexane to give **51** as needles. Recrystallization was carried out from the same solvent. The data are given in Table 2.

Tripeptide Esters (52—75). A typical run (**59** in Table 3) was as follows: Z-L-Asp(OBzl)-D-Ala-L-Val-OMe (**35**, 1.85 g) was dissolved in a mixture of acetic acid (40 ml) and water (10 ml), and hydrogenated in the presence of 5% Pd/C (0.6 g) with stirring at atmospheric pressure and room temperature for 6 h. The reaction mixture was filtered and the filtrate was concentrated under reduced pressure to dryness. The residue was dissolved in water and the solvent was evaporated under reduced pressure to remove remaining acetic acid. The procedure was repeated three times. The crystalline residue, thus obtained, was recrystallized from water–acetone to give 0.76 g (63.3%) of L-α-Asp-D-Ala-L-Val-OMe·$2H_2O$ (**59**) as needles. Recrystallization from water afforded 0.26 g of pure **59** dihydrate as needles. The data are given in Table 3. In another experiment, the peptide (**59**) was recrystallized from water to give **59** monohydrate as needles; mp 160—161 °C.

The author wishes to thank Mr. T. Takemoto for HPLC analyses and Dr. S. Yamaguchi for sensory evaluation.

Asymmetric Catalytic Hydrogenations of Chiral α-Keto Amides

Kaoru HARADA* and Toratane MUNEGUMI
Department of Chemistry, The University of Tsukuba, Sakura-mura, Niihari, Ibaraki 305
(Received May 21, 1984)

Asymmetric catalytic hydrogenations of chiral pyruvamides were carried out using palladium on charcoal (Pd-C) as a catalyst to give lactamides with the diastereoisomeric purities (d.p.) of up to 62%. It was found that there was a linear correlation between the d.p. and the dielectric constant of the solvents used in the hydrogenations of chiral pyruvamides. The results were explained by employing the chelation model and the adsorption of the phenyl group in the substrate molecule on the catalyst. The temperature effect on the d.p. of the product was also examined. The catalytic hydrogenations of chiral benzoylformamides were also performed to give low d.p. presumably, the chelation complexes of the substrates could not take a predominant conformation with the catalyst.

Several studies on the asymmetric catalytic hydrogenations of α-keto acid derivatives have been performed.[1-7] However, a few examples of the asymmetric catalytic hydrogenations of chiral α-keto amides have been reported.[1,7,8] Mitsui and Kanai carried out[1] the hydrogenations of *N*-[(*S*)-α-methylbenzyl]benzoylformamide in ethanol over palladium catalysts. Ojima *et al.* performed[7] the hydrogenations of pyruvamides employing an amino acid ester as the chiral source with palladium on charcoal. In the previous study,[8] we reported the stereochemistry in the catalytic hydrogenations of three pyruvamides whose chiral sources were (*S*)-α-methylbenzylamine, (*S*)-α-ethylbenzylamine, and (*S*)-α-(1-naphthyl)ethylamine. The steric courses in the catalytic hydrogenations could be explained by the formation of a five-membered substrate-catalyst complex-(chelation mechanism[8-17]). It was considered that the complexes were stabilized by the adsorption of the phenyl group in the chiral source, on the catalyst.[8]

In this paper, we wish to describe the stereochemistry on the catalytic hydrogenations of three types of chiral α-keto amides (**3**, **5**, and **10** as shown in Scheme 1—4) over palladium on charcoal using several solvents, in connection with the adsorption of phenyl group on the catalyst. We also would like to correct the analytical data reported in the previous paper,[8] by means of a more accurate analytical method.[17]

In the catalytic hydrogenations of substrates **5** and **10**, it was found that there was a linear correlation between the diastereoisomeric purities(d.p.) of the products and the dielectric constant of the solvents used.

Results and Discussion

Catalytic Hydrogenations of Benzoylformamides **3**. The substrates **3a—c** were prepared as shown in Scheme 1, and were hydrogenated over palladium on charcoal-(Pd-C) at 30 °C in several solvents. The d.p. of the products are listed in Table 1, along with optical purities(o.p.) of mandelic acid obtained through the hydrolyses of the products. The d.p. of the products were determined by the gas chromatographic separation of diastereomeric mandelamides.

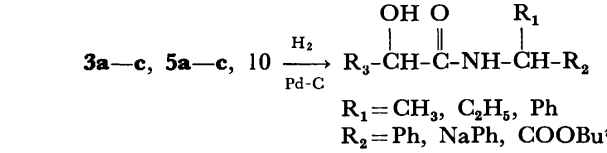
Scheme 3.

All the hydrogenations of substrate **3a** gave (*R*)-mandelic acid (*S*)-amide [(*R*,*S*)-mandelamide] preferentially. And all the hydrogenations of substrate **3b** gave (*S*)-mandelic acid (*S*)-amide [(*S*,*S*)-mandelamide] preferentially. However, the d.p. of the products were too low (1.3—7.7%) to discuss the steric courses of the catalytic hydrogenations by using these experimental data(Table 1). The reason for the low d.p. could be caused by the adsorption of phenyl group, which attached to the carbonyl carbon, on the catalyst surface, and the adsorbed substrate-catalyst complex could not take a predominant conformation.



Scheme 4.

The catalytic hydrogenations of substrates **3a—b** were carried out in methanol at various temperatures. The temperature effect on d.p. of the products is shown in Table 2. The hydrogenations of substrate **3a** at low temperature mainly gave (*S*,*S*)-mandelamide slightly in excess. The hydrogenation of substrate **3b** at −10 °C

gave (*S,S*)-mandelamide in up to 9.8%. However, detailed discussion could not be made on the temperature effect, because the d.p. of mandelamides were so low.

Catalytic Hydrogenations of Substrates 5a—c. This section describes the catalytic hydrogenations of three chiral pyruvamides **5a—c**. (*S*)-α-Methylbenzylamine, (*R*)-α-ethylbenzylamine, (*R*)-1-(1-naphthyl)-ethylamine were used as the chiral sources of pyruvamides.

The substrates were prepared by the coupling of pyruvic acid and the chiral amines with dicyclohexylcarbodiimide (DCC) in the presence of *N*-hydroxysuccinimide (HOSu) as shown in Scheme 2.

The results of the catalytic hydrogenations of substrates **5a—c** at 30 °C in several solvents are listed in Table 3. The d.p. of the products are plotted against the dielectric constants of the solvents used for the hydrogenation as shown in Fig. 1.

Substrate **5a** whose chiral moiety was (*S*)-α-methylbenzyl amine gave *N*-[(*S*)-lactoyl]-(*S*)-amide [(*S,S*)-lactamide] in excess. Substrate **5b** whose chiral moiety was (*R*)-α-ethylbenzylamine and substrate **5c** whose chiral moiety was (*R*)-1-(naphthyl)ethylamine, preferentially gave *N*-[(*R*)-lactoyl]-(*R*)-amide [(*R,R*)-lactamide]. The d.p. of the products in the hydrogenations of substrate **5a** were higher than the results in the hydrogenations of other substrates in all solvents, and the order of the d.p. was as follows: **5a**>**5b**>**5c**.

When *N,N*-dimethylformamide (DMF) was used as the solvent, the d.p. of (*S,S*)-lactamide reached to 62%. When benzene was used as the solvent, substrate **5a** gave (*R,S*)-lactamide in excess contrary to the results obtained with alcoholic solvents. Hydrogenation of substrate **5a** in MeOH–H_2O (7:3) gave (*S,S*)-lactamide with 21% d.p.

The linear correlation beween the dielectric constant of the solvents and the d.p. of the products was explained by using the chelation mechanism as shown in Fig. 2. The chelation mechanism involves a two step adsorption of the substrate during the catalytic hydrogenations. In the first step, the substrate molecule forms a five-membered chelated intermediate with the catalyst surface. In the second step, the resulting chelated intermediate is adsorbed on the catalyst from the less bulky side of the substrate and then hydrogenated. The *s-cis* conformation shown in Fig. 2 could be the first stage of the adsorption of the substrate (the chelated intermediate) in the chelation mechanism. The stereochemistry in the catalytic hydrogenation would be determined by the conformation of the first adsorption (the chelated intermediate). The *s-trans* conformation in Fig. 2 shows the mechanism involving one step adsorption on the catalyst. Since the d.p. of the hydrogenation of substrate **5a** was larger than those of **5b** and **5c**, the asymmetric induction would not be caused by the difference of bulkiness between H and alkyl(R_1) groups. Therefore, *s-trans* adsorption state which produces (*S,S*)-lactamide in excess would not affect largely on the asymmetric induction. The steric courses of these reactions could be interpreted by means of three *s-cis* (chelation) adsorption states (conformer A, B, and C)

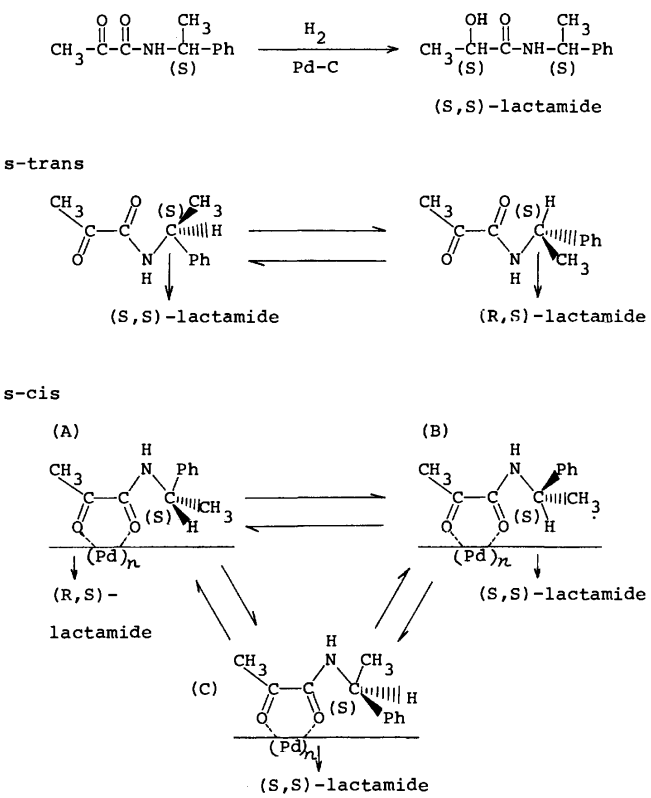

Fig. 2. Possible steric course in the catalytic hydrogenation of substrate **5a**.

in Fig. 2.

Conformer A produces (*R,S*)-lactamide and conformer B and C produces (*S,S*)-lactamide preferentially. Since the hydrogenations of substrate **5a** in the polar solvents gave (*S,S*)-lactamide, the substrate molecule would be hydrogenated mainly through conformer B and C. The decrease of d.p. of (*S,S*)-lactamide with the decrease of dielcectric constant of the solvents could be interpreted by the increase of the proportion of conformer A. In polar solvents, the substrate molecule would tend to take conformer B or C, because of the adsorption of the phenyl group on the catalyst or the phenyl group's escaping from the polar solvent. On the other hand, since the interaction between the phenyl group and the solvent would be stronger in less polar solvents than in polar solvents, the proportion of substrate molecule taking conformation A would increase. Therefore, d.p. of (*S,S*)-lactamide would increase with the increase of the dielectric constant of the solvent used.

The adsorption of the phenyl group on the catalyst could be confirmed by the result obtained by the hydrogenation of substrate **5a** using benzene as a solvent. The hydrogenation of substrate **5a** in benzene gave (*R,S*)-lactamide in excess (17% d.p.) contrary to the results in the hydrogenation in alcoholic solvents [(*S,S*)-lactamide in excess]. Since the phenyl group in the substrate molecule would interact with benzene, the substrate molecule would tend to take conformation A and then be hydrogenated to afford (*R,S*)-lactamide in excess.

The decrease of d.p. in the hydrogenation in

MeOH–H_2O (7:3), which is a very polar solvent system, could not be explained by means of the polarity of the solvent.

It was found that d.p. obtained by the hydrogenations in polar solvents were high (up to 62%) in spite of 1,4-asymmetric induction. These results suggested that the chelated intermediate (conformer B or C) were stable. If the two carbonyl groups were not fixed in *s-cis* conformation by the chelation to the catalyst, these high d.p. of the products would not be obtained.

The catalytic hydrogenations of substrates **5a—c** in methanol were carried out at various temperatures. The results of the hydrogenations are listed in Table 4. (*S,S*)-Lactamide was obtained in excess from substrate **5a** at all temperatures. (*R,R*)-Lactamide was obtained in excess from substrate **5b**. However, the temperature effect was rather low on the d.p. of the resulting (*S,S*)-lactamide or (*R,R*)-lactamide.

Catalytic hydrogenations of substrate ***10***. High d.p. in the catalytic hydrogenations of substrates **5a—c** were explained by the chelation of the two carbonyl groups and the adsorption of the phenyl group included in the chiral moiety, on the catalyst. The solvent effect of the catalytic hydrogenations of substrate **10** clarifies the adsorption of the phenyl group, on the catalyst.

Substrate **10** was prepared by oxidation of *N*-lactoyl-(*S*)-phenylglycine ester as shown in Scheme 3. The catalytic hydrogenations were carried out over palladium on charcoal in several solvents. The results of the hydrogenations are listed in Table 5. The hydrogenations of substrate **10** in all solvents gave *N*-[(*R*)-lactoyl]-(*S*)-phenylglycine ester [(*R,S*)-lactamide] in excess. The d.p. of the product [(*R,S*)-lactamide] increased with the increase of the dielectric constant of the solvents. Thus, there was a linear correlation between d.p. and the dielectric constant (Fig. 1).

In the previous paper[15] on the hydrogenations of *N*-pyruvoyl-(*S*)-amino acid esters, we have reported a similar relationship between d.p. and the dielectric

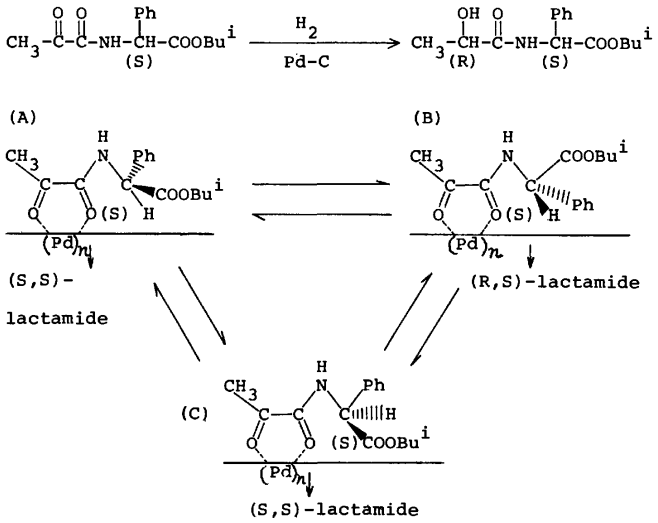

Fig. 3. Possible steric course in the catalytic hydrogenation od substrate **10**.

constant (Fig. 1). The substrates containing (*S*) 2-aminoalkanoic acid isobutyl ester as a chiral source, gave (*R,S*)-lactamide preferentially in polar solvents. And the d.p. of (*R,S*)-lactamide increase with the increase of the dielectric constant of the solvent. However, d.p. in the hydrogenations of substrate **10** were higher (up to 55%) than those in the hydrogenations[15] of other *N*-pyruvoyl-(*S*)-amino acid esters. These results were explained by the adsorption of the phenyl group on the catalyst (Fig. 3). In polar solvents, adsorption of the phenyl group of substrate **10** on the catalyst would be strong as well as substrate **5a**. The affinity between the phenyl group and the catalyst would be weaker with the decrease of the dielectric constant of the solvent. And the affinity between the COOBu^i and the catalyst would be stronger with the decrease of the dielectric constant of the solvents.[15] The proportion of conformer C (Fig. 3) of substrate **10** would increase in less polar solvents.

Therefore, d.p. of (*R,S*)-lactamide obtained from the hydrogenations of substrate **10** were smaller than those of (*S,S*)-lactamide obtained from the hydrogenations of substrate **5a**. (Substrate **5a** does not have an ester group in its chiral moiety.)

In other experiments, the catalytic hydrogenations of substrate **10** in methanol were also carried out at various temperatures. The temperature effect is shown in Table 5. (*R,S*)-Lactamide was preferentially obtained in all temperatures. However, the temperature effect was rather small on the d.p. of the resulting (*R,S*)-lactamide.

Experimental

All the melting points were uncorrected. Optical rotations were measured with a JASCO DIP-181 Digital Polarimeter. All the gas chromatographic analyses were carried out with a Hitachi 163 gas chromatograph, and the peaks on the chromatograms were integrated with a Hitachi 834-30 chromatoprocessor. NMR spectra were measured with a Hitachi R-24 High Resolution NMR spectrometer. IR spectra were measured with a Hitachi 260-50 infrared spectrometer.

Benzoylformyl Chloride[19,20] *1.* A mixture of benzoylformic acid (23.7 g, 158 mmol) and oxalyl chloride (80 g, 630 mmol) was refluxed for 6 h, and the extra oxalyl dichloride was distilled off. The residue was distilled under reduced pressure (68 °C/4 mm Hg (1 mm Hg=133.322 Pa)), and pale yellow liquid was obtained (14.8 g, 56%). IR, 1690 cm^{-1} (C=O), 1780 cm^{-1} (C=O).

Chiral Amines 2a—c. Chiral amine **2a** was purchased from Aldrich Chemical Company, Inc. $[\alpha]_D^{20}$ −39.0° (neat). Chiral amine 2b was obtained by the optical resolution[22] of racemic amine which was prepared by the method reported in the literture.[23] $[\alpha]_D^{20}$ −21.3° (*c* 1.53, benzene). Chiral amine 2c was purchased from Sigma Chemical Company. $[\alpha]_D^{25}$ −59.0° (*c* 1.0, ethanol).

(S)-Phenylglycine 6. $[\alpha]_D^{20}$ +155.6° (*c* 1.0, 1 mol dm^{-3} HCl).

N-[(S)-α-Methylbenzyl]benzoylformamide[1] *3a.* To a cooled dry benzne solution (200 ml) in which benzoylformyl chloride (7.30 g, 43.5 mmol) was dissolved, (*S*)-α-methylbenzylamine (5.27 g, 43.5 mmol) and triethylamine (4.41 g, 43.5 mol) were added dropwise. The reaction mixture was stirred for 2 h at 5—10 °C and 12 h at room temperature. After the reaction, the resulting white precipitate was filtered off and was washed with benzene. The benzene solution was extracted with three 150 ml portions of 1 mol dm^{-3} HCl, saturated $NaCO_3$ aqueous solution and brine respectively. The benzene layer was dried with $MgSO_4$. After drying agent was filtered off, the solution was evaporated *in vacuo*. The oil was purified with silica-gel flash chromatography[24] (eluent; ethyl acetate-hexane (1:9)). The fraction which contained the product were evaporated and the resulting crude white solid was recrystallized from chloroform-hexane. Yield, 7.41 g (67%). Mp, 111—112 °C (lit,[1] 110—111 °C). R_f= 0.28 (silica gel TLC; developing solvent, ethyl acetate-hexane (1:9)). $[\alpha]_D^{25}$ −106° (*c* 1.0, ethanol). NMR (CCl_4): δ=1.5 (3H, *J*=7 Hz), 5.0 (1H, m), 7.25 (9H, m), 8.25 (2H, m). Calcd for $C_{16}H_{15}NO_2$: 75.86; H, 5.96; N, 5.52%. Found: C, 75.86; H, 5.92; N, 5.49%.

N-[(S)-α-Ethylbenzyl]benzoylformamide 3b. To a cooled dry benzene solution (180 ml) in which benzoylformyl chloride (6.17 g, 36.8 mmol) was dissolved, (*S*)-α-ethylbenzylamine (4.98 g, 36.8 mmol) and triethylamine (3.72 g, 36.6 mmol) were added dropwise. The crude product was synthesized and purified by the similar manner in the preparation of 3a. Yield, 5.39 g (55%). Mp, 88.5—89.5 °C. R_f=0.28 (silica gel TLC; developing solvent, ethyl acetate-hexane (1:9)). $[\alpha]_D^{24}$ −107° (*c* 1.0, ethanol). NMR ($CDCl_3$): δ=0.9 (3H, t, *J*=7.5 Hz), 1.9 (2H, q, *J*=7.5 Hz), 4.9 (1H, m), 7.35 (9H, m), 8.3 (2H, m). Calcd for $C_{17}H_{17}NO_2$, C, 76.38; H, 6.41; N, 5.23%. Found: C, 76.31; H, 6.40; N, 5.30%.

N-[(S)-1-(1-Naphthyl)ethyl]benzoylformamide 3c. To a cooled dry benzene solution (30 ml) in which benzoylformyl chloride (1.00 g, 6.00 mmol) was dissolved, (*S*)-1-(1-naphthyl)ethylamine (1.02 g, 6.00 mmol) and triethylamine (0.60 g, 6.00 mmol) were added dropwise. After the reaction, usual treatment was carried out. An oily product was obtained. Yield, 0.92 g (51%). R_f=0.24 (ethyl acetate-hexane (9:1)). $[\alpha]_D^{23.5}$ +0.8° (*c* 1.0, ethanol). $[\alpha]_D^{22.5}$ −46.8° (*c* 1.0, benzene). NMR (CCl_4); δ=1.6 (3H, d, 7 Hz), 5.9 (1H, m), 7.9 (13H, br). Calcd for $C_{20}H_{17}NO_2$: C 79.18; H, 5.64; N, 4.61%. Found: C, 78.04; H, 5.70; N, 4.53%.

Pyruvamides 5a—c. Chiral pyruvamides **5a**—c were prepared by the same manner as shown in the literatures.[8,21]

(S)-Phenylglycine Isobutyl Ester p-Toluenesulfonate[10]. (*S*)-Phenylglycine (3.02 g, 20.0 mmol), *p*-toluenesulfonic acid monohydrate (4.19 g, 22.0 mmol), and isobutyl alcohol (20 ml), were mixed in benzene (80 ml). The mixture was

refluxed for 58 h, and the water formed during the esterification was distilled off by the azeotropic method. Crude white product obtained after evaporation of the reaction mixture was recrystallized from ethanol–ether. Yield, 7.95 g (89%). Mp, 180—181 °C. $[\alpha]_D^{25}$ +67.0° (*c* 1.04, ethanol). R_f=0.60 (1-buthanol–acetic acid–water (4:1:2)). Calcd for $C_{19}H_{25}NO_5S$: C, 60.13; H, 6.64; N, 3.69%. Found: C, 60.26; H, 6.68; N, 3.67%.

N-Pyruvoyl-(S)-phenylglycine Isobutyl Ester **10**. To a cooled ethyl acetate solution of **8** (2.26 g, 5.67 mmol), racemic lactic acid (0.50 g, 5.67 mmol), triethylamine (0.57 g, 5.6 mmol), and *N*-hydroxysuccinimide (0.8 g, 6.9 mmol), dicyclohexylcarbodiimide (1.3 g, 6.3 mmol) was added. After the usual treatment of the reaction product, a crude oily product was obtained. The oily product was purified with silica-gel column chromatography (eluent; ethyl acetate–benzene (1:1)). A white solid was obtained by the evaporation of the fraction containing the product. Yield, 1.34 g (85%). This white solid (1.00 g, 3.58 mmol) was dissolved in 30 ml of acetone. To this solution, water (10 ml), acetic acid (1 ml), and $KMnO_4$ (1.0 g) was added under cooling in an ice–water bath. The reaction was carried out for 4 h in an ice–water bath and for 20 h at room temperature. After the reaction was over, MnO_2 was filtered off and the solution was extracted with three 50 ml of portions of benzene. The benzene layer was dried with $MgSO_2$, and then evaporated to afford crude oily product. This was purified with silica-gel column chromatography (benzene–ethyl acetate (19:1)). Yield, 0.28 g (28%). Mp, 63—64 °C. NMR ($CDCl_3$): δ=0.81 (6H, d, J=6 Hz), 1.9 (1H, m), 2.45 (3H, s), 3.92 (2H, d, J=6Hz), 5.49 (1H, d, J=8 Hz), 7.35 (5H, s), 7.85 (1H, br). $[\alpha]_D^{24}$ +114° (*c* 1.1, ethanol). Calcd for $C_{15}H_{19}NO_4$: C, 64.96; H, 6.90; N, 5.05%. Found: C, 64.91; H, 6.91; N, 5.01%.

Hydrogenations of **3a—c** *and Hydrolyses of the Products.* Substrates **3a—c** (500 mg) were dissolved in 10 ml of solvents [methanol (MeOH), ethanol (EtOH), 2-propanol (Pr^iOH), 2-methyl-2-propanol (Bu^tOH), 2-methyl-2-butanol ($C_5H_{11}{}^tOH$), and benzen] and were hydrogenated over 5% palladium on charcoal (purchased from Nippon Engelhald) at 30 °C. After 8—10 h reaction, the catalyst was filtered off, and the reaction mixtures were evaporated *in vacuo* to afford oily products. To these oily products, 20 ml of 6 mol dm^{-3} HCl was added and the mixtures were refluxed for 6 h. After hydrolysis, the reaction mixture was extracted with three 30 ml portions of ether. The ether layer was dried with $MgSO_4$ and the ether layer was evaporated to white solids. Chemical yields were determined by the measurement of the weight of the white solids and the optical purities of mandelic acid were determined by the measurement of the optical rotation.

Hydrogenations of **3a—c** *and Derivatization of the Products for GC Separation.* Substrates **3a—c** (25 mg, 0.10 mmol) were dissolved in 3 ml of solvents [MeOH, EtOH, Pr^iOH, Bu^t, ethyl acetate (AcOEt)] and were hydrogenated over 5% palladium on charcoal at 30 °C. After 8—10 h reaction, the catalyst was filtered off, and the reaction mixtures were evaporated to dryness. The chemical yields of the products were determined by the GC analyses of the residues. A portion of the residue was derivatized to *O*-TFA lactamide by the manner as described in the literature.[18] D. p. was determined by the GC separation of the *O*-TFA derivatives of diastereomeric mandelamides with a chiral stationary phase (Chirasil-Val).[18,25]

Catalyic Hydrogenations of Substrates **5a—c**[9] *and* **10**. Substrates **5a—c** (20 mg, 0.1 mmol) were dissolved in 3 ml of solvents [MeOH, EtOH, Pr^iOH, Bu^tOH, AcOEt, benzene, and *N,N*-dimethylformamide (DMF)], and were hydrogenated at 30 °C over 5% palladium on charcoal (100 mg) for 12—48 h. After the catalyst was filtered off, the reaction mixtures were evaporated to dryness. Both chemical yields[21] and d.p.[18] of the resulting lactamides were determined by the similar manner in the hydrogenations of substrates **3a—c**.

Studies on Peptide Antibiotic "Gratisin"

Makoto TAMAKI
Department of Chemistry, Faculty of Science, Toho University, Miyama, Funabashi-shi, Chiba 274
(Received June 1, 1984)

According to a primary structure proposed for an antibiotic peptide, gratisin, four peptides containing respectively partial sequences, L-Phe-L-Pro-L-Tyr, D-Phe-L-Pro-L-Tyr, L-Phe-L-Pro-D-Tyr, and D-Phe-L-Pro-D-Tyr, were synthesized by a liquid phase method. Among them, *cyclo*(-L-Val-L-Orn-L-Leu-D-Phe-L-Pro-D-Tyr-)$_2$ showed the strongest activity against the Gram-positive microorganisms tested. The activity toward *Bacillus subtilis* was similar to that of gramicidin S. Therefore, it is quite possible that natural gratisin is identical to this peptide. To facilitate a further investigation of the structure-activity relationship, four additional analogs were prepared. The results of their antibiotic activities showed that an interchange of D-Phe residues with D-Tyr residues caused the decrease of activity, and that the hydroxyl group of D-Tyr residues had no important role in this activity. The peptides possessing partial sequences, D-Phe-D-Tyr-L-Pro and L-Pro-D-Phe-D-Phe, exhibited strong activity. These facts show that the positions of Pro residues are not restricted to 5 and 5′ for the exhibition of the activity. The CD spectra of these synthetic peptides in an aqueous solution reflected the partial sequences around Pro residues, which affect largely the conformation of these synthetic antibiotics. The temperature dependence of these CD spectra indicated that the conformation of biologically active peptides is more stable than those of less active peptides.

An antibiotic peptide, gratisin, showing activity toward *Bacillus subtilis* 720 was isolated from *Bacillus brevis* Y-33 by Silaev *et al.*[1] It is a cyclododecapeptide composed of two each of Val, Orn, Leu, Phe, Pro, and Tyr residues. From an analogy of the primary structure of gramicidin S (GS) produced by *Bacillus brevis* ATCC 9999, the primary structure of gratisin was proposed (as shown in Fig. 1).[2,3] However, the configuration of each amino acid residue has not yet been established.

In this paper, the synthesis of several gratisin peptides shown in Fig. 2[4] and the relationship between structure and antibiotic activity will be described.

In the first of a series of studies on gratisin, gratisin peptide **I** consisted of only L-amino acid residues and gratisin peptide **II**, which has a structure analogous to GS containing D-Phe residues at positions 4 and 4′, were synthesized and the antibiotic activities of these peptides were examined.[5,6] Peptide **II** showed an activity against the Gram-positive microorganisms tested, but was less potent than GS. On the other hand, peptide **I** showed little activity. To study configurations of amino acid residues following Pro residues, peptide **III** having a Phe-Pro-D-Tyr partial sequence and peptide **IV** having a D-Phe-Pro-D-Tyr partial sequence were synthesized.[7,8] Peptide **III** was almost inactive. On the other hand, peptide **IV** showed a marked activity against the Gram-positive microorganisms tested. Its activity against *Bacillus subtilis* was similar to that of GS and stronger than that of peptide **II**. Peptide **V** having a D-Tyr-Pro-D-Phe partial sequence and peptide **VI** having a D-Phe-Pro-D-Phe partial sequence were synthesized in order to investigate the role of the side chain of D-Phe residues at 4 and 4′, and D-Tyr residues at 6 and 6′. A Pro residue is frequently found in β-turns in naturally occuring proteins[9] and peptides[10–12], and is known to play an important role in stabilizing their conformations. To investigate the roles of Pro residues in gratisin, peptide **VII** having Pro residues at positions 6 and 6′, and peptide **VIII** having Pro residues at 4 and 4′ were synthesized.

Abbreviations with no prefix show L-amino acid residue.

Results and Discussion

Synthesis of Gratisin Peptides I—VIII. Each cyclododecapeptide **I—VIII** consists of two identical hexapeptide sequences (Fig. 2). Therefore, these peptides were synthesized according to the following three steps: 1) synthesis of hexapeptides by stepwise elongation; 2) synthesis of dodecapeptides by condensation between two of the fragment hexapeptides; 3) cyclization of the dodecapeptides by an azide or active-ester method. In the synthesis of these peptides, Pro residue was chosen as the C-terminal amino acid in order to avoid racemization in the fragment

condensation and the cyclization step. The benzyl (Bzl) group was used as the protector of the carboxyl groups. α-amino groups were protected by a *t*-butoxycarbonyl (Boc) group. The δ-amino group of Orn residue was protected by a benzyloxycarbonyl (Z), and the hydroxyl group of Tyr residue by a benzyl (Bzl) group or a 2,6-dichlorobenzyl ($BzlCl_2$) group. In the synthesis of gratisin peptides **I**—**VIII**, each Boc-hexapeptide benzyl ester was synthesized by stepwise elongation using dicyclohexylcarbodiimide (DCC) or 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (WSCD) and 1-hydroxybenzotriazole (HOBt) (Scheme 1). Throughout the synthesis of each Boc-hexapeptide benzyl ester, intermediates were purified by only washing with 5% citric acid and 5% Na_2CO_3. The purities of the intermediates were confirmed by thin-layer chromatography with several solvent systems. Finally, each Boc-hexapeptide benzyl ester was purified by silica-gel column chromatography followed by recrystallization. The homogeneity of each Boc-hexapeptide benzyl ester was confirmed by thin-layer chromatography, amino acid analysis and elemental analysis.

i) Synthesis of Gratisin Peptide I. Three different procedures were examined for the synthesis of gratisin peptide **I**. In the first trial, Pro residue was chosen as the C-terminal amino acid of the dodecapeptide, and cyclization was carried out by an azide method. However, the cyclization of H-[Tyr(Bzl)-Val-Orn(Z)-Leu-Phe-Pro-]$_2$-N_3, did not proceed under the usual conditions. In the pathway of the biosynthesis of GS and tyrocidine in *Bacillus brevis*, they are produced by cyclization of the linear decapeptide with a Leu residue at the C-terminal.[13,14] In the imitation of the biosynthesis, a Leu residue was chosen as the C-terminal residue and the cyclization was also tried using an azide method *via* H-[Phe-Pro-Tyr(Bzl)-Val-Orn(Z)-Leu-]$_2$-N_3. Though this trial was also unsuccessful, it afforded a ninhydrin-negative compound. In an amino acid analysis of the acid hydrolysate of this product, each value of Val, Orn, Phe, Pro, and Tyr was in good agreement with the value expected for the gratisin peptide, but the value obtained by Leu was one-half of the value. The results of amino acid and elemental analyses of this product can be explained by giving it the following tentative structure; *cyclo*[-Phe-Pro-Tyr-(Bzl)-Val-Orn(Z)-Leu-Phe-Pro-Tyr(Bzl)-Val-Orn(Z)-

$$\begin{array}{l} CH_2\text{-}CH(CH_3)_2 \\ | \\ NH\text{-}CH\text{-}NH\text{-}CO\text{-} \end{array}$$

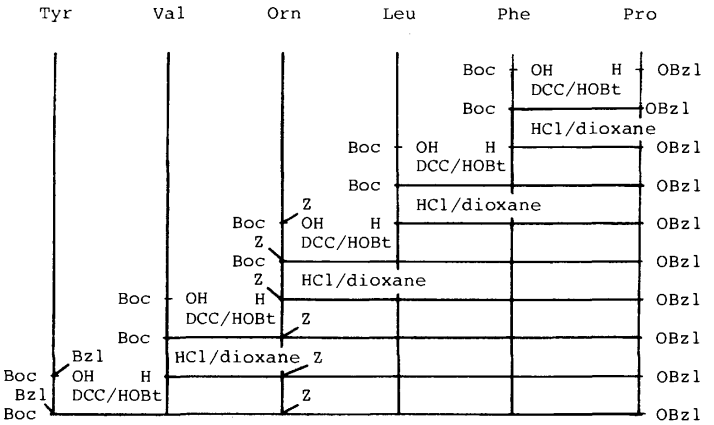
].

The cyclization to give peptide **I** was finally achieved using an active-ester method, according to Scheme 2. The active ester (**Id'**) was prepared by the following procedure. The coupling of Boc-hexapeptide hydrazide (**Ib**) with H-Tyr(Bzl)-Val-Orn(Z)-Leu-Phe-Pro-OH derived from **Ic** was carried out by an azide method. The product was purified by Sephadex LH-20 gel filtration, which was very effective for the removal of the contaminating amine and acid components. The Boc-dodecapeptide (**Id**) was converted into the corresponding active ester by WSCD and *N*-hydroxysuccinimide (HOSu). The active ester (**Id'**) was deprotected with trifluoroacetic acid (TFA) in the presence of anisole and then subjected to cyclization at 60 °C for 3 h under high dilution in pyridine ($<3\times10^{-3}$ M 1 M=1 mol dm^{-3}) to minimize intermolecular reactions. The product was purified by chromatography on a silica-gel column followed by recrystallization. The yield of the cyclization was 29%. The removal of the protecting groups of cyclododecapeptide (**Ie**) by hydrogenolysis in methanol containing hydrogen chloride afforded peptide **I**.

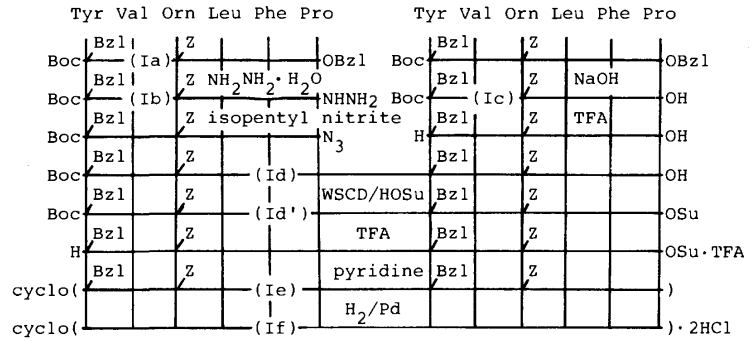
In the synthesis of gratisin peptide **III**, cyclization *via* the azide, H-[D-Tyr($BzlCl_2$)-Val-Orn(Z)-Leu-Phe-Pro-]$_2$-N_3, did not proceed. Hence, cyclization was carried out using an active-ester method similar to that described in the synthesis of gratisin peptide **I**. The desired peptide was obtained at a yield of 60%.

Peptides **VII** and **VIII** were also synthesized in a similar manner. The yields of cyclization by an active-ester method were 62% (peptide **VII**) and 57% (**VIII**).

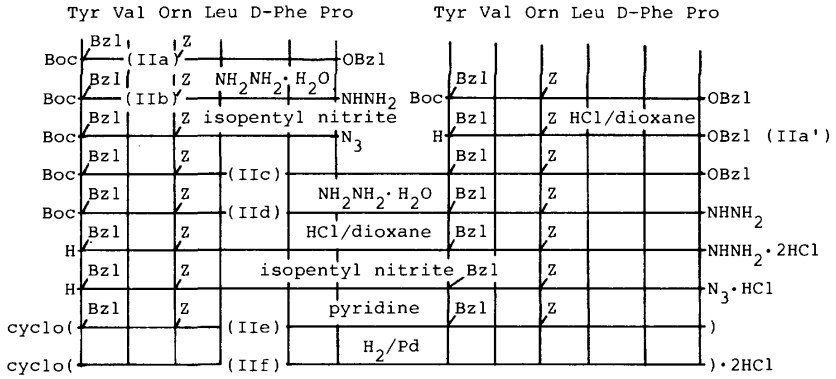
ii) Synthesis of Gratisin Peptide II. Peptide **II** was prepared according to Scheme 3. Boc-dodecapeptide benzyl ester (**IIc**) was obtained by the coupling of two hexapeptides (**IIa'** and **IIb**). The product was



Scheme 1. Synthesis of Boc-Tyr(Bzl)-Val-Orn(Z)-Leu-Phe-Pro-OBzl (**Ia**).
* Each hexapeptide (**IIa**—**VIIIa**) was synthesized by a similar method.
WSCD was used the coupling reagent in synthesis of **IVa**—**VIIIa** instead of DCC.



Scheme 2. Synthesis of *cyclo*(-Tyr-Val-Orn-Leu-Phe-Pro-)$_2$·2HCl (**If**).
* Gratisin peptides **III**, **VII**, and **VIII** were synthesized by a similar manner.



Scheme 3. Synthesis of *cyclo*(-Tyr-Val-Orn-Leu-D-Phe-Pro-)$_2$·2HCl (**IIf**).
* Gratisin peptides **IV**—**VI** were synthesized by a similar manner.

purified by Sephadex LH-20 gel filtration and silica-gel column chromatography. **IIc** was converted into hydrazide **IId**. Then, it was treated with 4M HCl/dioxane in the presence of anisole, and converted into an azide with isopentyl nitrite at −20 °C for 15 min. The azide could be cyclized under high dilution in pyridine at 0 °C for 3 d. The resulting product was purified by silica-gel column chromatography following recrystallization. The yield of cyclization was 43%. The removal of all masking groups by hydrogenolysis yielded peptide **II**.

Peptides **IV**—**VI** were synthesized by a method similar to that described for peptide **II**. The yields of cyclization by the azide method were 63 (peptide **IV**), 29 (**V**), and 41% (**VI**).

The homogeneity of peptides **I**—**VIII** was confirmed by means of thin-layer chromatography, electrophoresis, amino acid analysis and elemental analysis (Table 1 and 3). The molecular weight of the fully protected cyclic peptides were measured by a vapor-pressure osmometer and were in good agreement with the respective calculated values.

In the synthesis of peptides **I**—**IV**, cyclization was carried out by an azide method in the first trial. In the case of peptides **II** and **IV**, both having a D-Phe-Pro partial sequence, the cyclization proceeded satisfactorily. On the other hand, the cyclization of peptides **I** and **III**, both having a L-Phe-Pro partial sequence, did not proceed well by this method. The investigation of CPK molecular models of these four sequences elucidated that the β-methylene group

Table 1. Amino acid analysis of gratisin peptides **I**—**VIII**

of L-Phe residue preceding Pro residue collides with the δ-methylene group of the Pro residue if the L-Phe-Pro sequence take GS-like β-turn. On the other hand, the D-Phe-Pro sequence seems to favor the formation of β-turn. A similar tendency to β-turn formation was also reported for cyclic hexapeptides containing a D-Phe-Pro sequence by Kopple *et al.*[15], and on GS analogs and linear tetrapeptides with partial sequences related to the β-turn part of GS by Nagai *et al.*[16,17] The feasibility of the cyclization in the preparation of peptides **II** and **IV** by an azide method might result from such a β-turn preference in their primary structure containing a D-Phe-Pro sequence. The synthesis of peptides **I** and **III** was finally accomplished by an active-ester method. Under the conditions of this method, the degree of conformational freedom of the corresponding linear peptides

a) Minimum inhibitory concentration in μg/ml: The minimum amount of the compounds necessary for the complete inhibition of the growth was determined by an agar dilution method with 10^6 organisms per milliter.

was enhanced as compared with that in an azide method, because the reaction was performed at a higher temperature. The increase of a chance collision between N- and C-terminals in the linear peptides might explain why cyclization by an active-ester method proceeded better than with an azide method.

Antibiotic Activity. The antibiotic activities of synthetic peptides **I—VIII** are shown in Table 2. Peptides **I—IV** have the amino acid sequence proposed by Silaev *et al.*, although the configurations of the amino acid residues preceding and following the Pro residue differ from each other. The extent of the activities of these pepides is influenced by the configuration of the amino acid residues. Peptide **I** and **III** having, respectively, L-Phe-Pro-L-Tyr and L-Phe-Pro-D-Tyr partial sequences showed little activity. Peptide II containing a D-Phe-Pro-L-Tyr partial sequence was active toward Gram-positive miroorganisms tested, but its activity against *Bacillus subtilis* was 1/16 of that of GS. On the other hand, peptide **IV** possessing a D-Phe-Pro-D-Tyr partial sequence was most active in peptides **I—IV**, and its activity against *Bacillus subtilis* was similar to that of GS. These results indicated that the presence of D-Phe residues at 4 and 4′ is important for activity, and D-residues at positions 6 and 6′ also contribute to activity. Although we have had no opportunity to directly compare our synthetic peptides with natural gratisin, it is quite possible that synthetic peptide **IV** possessing D-residues in positions 4, 4′, 6, and 6′ is identical with the natural antibiotic.

The activity of peptide **V** was 1/2—1/8 of that of peptide **IV**. This result points out the significance of the D-Phe residues at 4 and 4′ regarding activity. Similar results have been obtained for GS analogs.[18–20] For example, [D-Tyr$^{4,4'}$]-GS containing D-Tyr residues in place of D-Phe residues displayed only about 1/3 of the activity of GS.[18] On the other hand, peptide **VI** showed a similar activity to that of peptide **IV**. The result suggests that the hydroxyl groups of D-Tyr residues in the 6 and 6′ positions are not necessary for activity.

Peptide **VII** showed the highest activity among peptides **I—VIII**, and its activity against *Bacillus subtilis* was the same as that of GS. The activity of peptide **VIII** against *Bacillus subtilis* was also the same as that of GS, but the activity against other microorganisms was a little less compared to peptides **IV** and **VII**. It is an unexpected result that peptides **VII** and **VIII**, in which the Pro residues occupy positions different from 5 and 5′, showed a strong antibiotic activity, considering the restriction of the sequence in GS for its activity.[21] Supposing that the action mode of gratisin is the same as that of GS[22], this result suggests that the presence of additional amino acid residures, D-Tyr or D-Phe, in gratisin peptides make them more likely to adopt a conformation suitable for the antibiotic action regardless of the transfer of Pro residue, in comparison with rigidity of the structure of GS.

Secondary Structure-Activity Relationship. CD spectra of GS and synthetic peptides **I—VIII** (dihydrochloride) in aqueous solution are shown in Figs. 3 and 4. These spectra are classified into four groups according to their configuration around the Pro residue (Fig. 3). The spectrum of gratisin peptide **I** was characterized by a small negative band near 211 nm and a shoulder near 230 nm (Fig. 3-a), and resembles that of [L-Ala$^{4,4'}$]-GS.[16] The spectrum of peptide **II** showed double-minima in a similar region to that of GS, although its ellipticity was less (Fig. 3-b). Since peptide **II** has a D-Phe-Pro partial sequence similar to GS, these two peptides seem to adopt an analogous conformation to give similar CD spectra. A similar result was obtained by Takiguchi *et al.*[23] in a study on an analog of GS with a larger ring size. Their analog (*iso*-GS) involves two amide bonds between the carboxyl groups of Val residues and the δ-amino groups of Orn residues and, hence, the number of ring members of this analog is equal to that of peptide **II**. This analog showed an ORD spectrum similar to that of GS, but its trough was shallower than that of GS. The CD pattern of peptide **VII** is also similar to that of GS. (Fig. 3-b) and might result from the presence of a D-X-Pro-L-Y partial sequence in the peptide. The spectrum of peptide **III** showed negative bands near 199 nm and 230 nm, and a shoulder near 215 nm (Fig. 3-c). The CD spectrum of peptide **VIII** was characterized by a positive band at 217 nm and a shoulder near 205 nm, but was similar in shape to that of peptide **III**. The spectra of peptides **IV—VI** resembled each other and were characterized by negative bands near 200 nm and shoulders near 220 nm (Fig. 3-d). Some differences were found in ellipticities near 200 nm. However, no relationship between the depth of the trough in these CD spectra and antibiotic activity could be found.

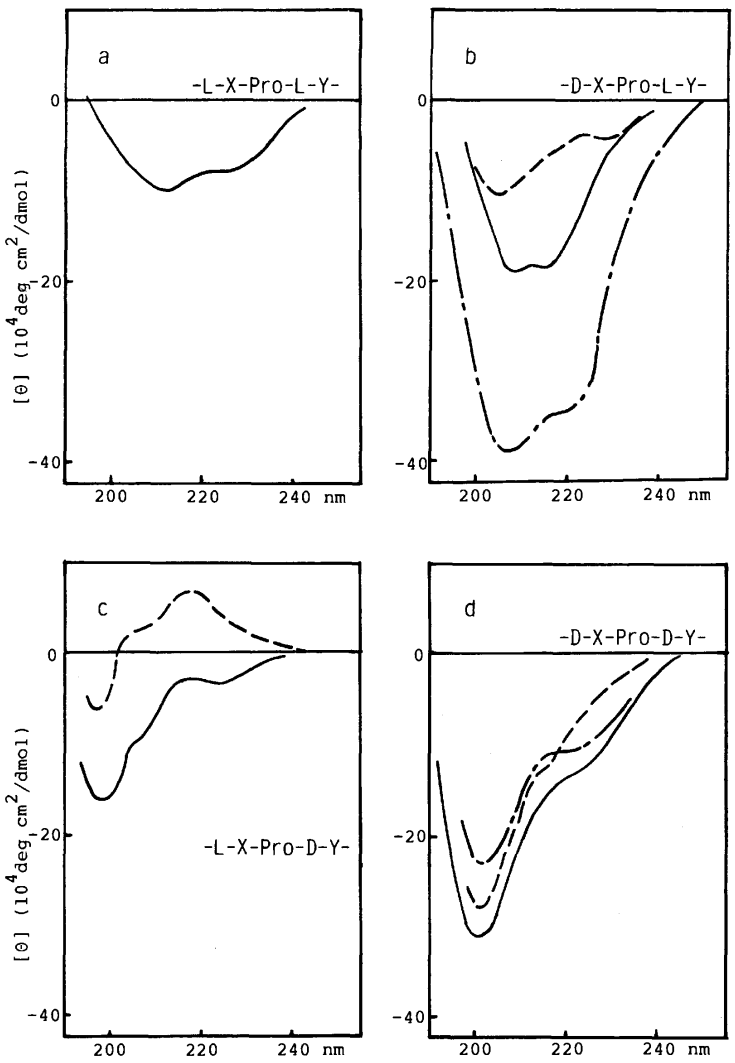

Fig. 3. CD spectra of GS and gratisin peptides **I**—**VIII** in aqueous solution. (a) **I**. *cyclo*(-Val-Orn-Leu-Phe-Pro-Tyr-)$_2$ ——; (b) **II**. *cyclo*(-Val-Orn-Leu-D-Phe-Pro-Tyr-)$_2$ ——, **VII**. *cyclo*(-Val-Orn-Leu-D-Phe-D-Tyr-Pro-)$_2$ ——, GS. *cyclo*(-Val-Orn-Leu-D-Phe-Pro-)$_2$ ——; (c) **III**. *cyclo*(-Val-Orn-Leu-Phe-Pro-D-Tyr-)$_2$ ——, **VIII**. *cyclo*(-Val-Orn-Leu-Pro-D-Phe-D-Phe-)$_2$ ——; (d) **IV**. *cyclo*(-Val-Orn-Leu-D-Phe-Pro-D-Tyr) ——, **V**. *cyclo*(-Val-Orn-Leu-D-Tyr-Pro-D-Phe-)$_2$ ——, **VI**. *cyclo*(-Val-Orn-Leu-D-Phe-Pro-D-Phe-)$_2$ ——.

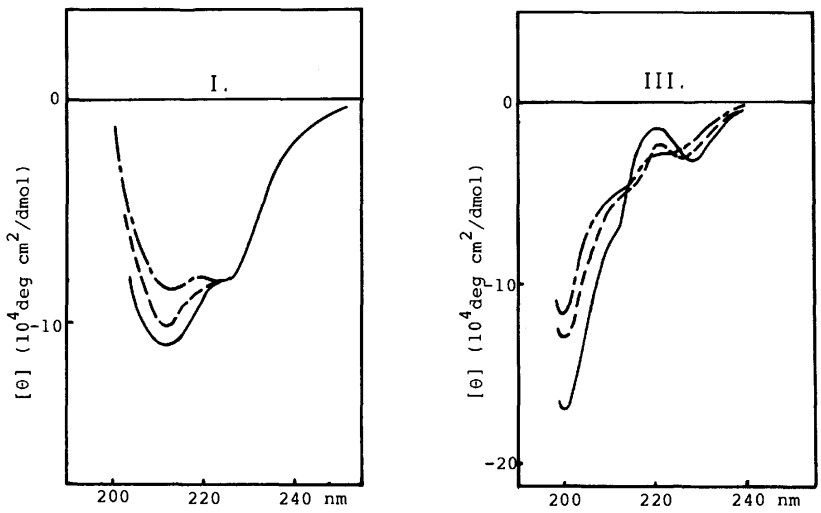

Fig. 4. CD spectra of gratisin peptides **I** and **III** at different temperature. 24 °C ——, 40 °C —— 60 °C —·—.

The shapes of CD spectra of active peptides **IV**, **VII**, **VIII**, and GS (Fig. 3) differ from each other, and no relationship between the pattern of the CD spectra in an aqueous solution and antibiotic activity could be found. These results indicate that these peptides have a different conformation in an aqueous solution. However, it is likely that when these peptides interact with a cell membrane of a target microorganisms, they adopt a GS-like conformation and exhibit antibiotic activities.

The CD spectroscopic study indicated that the partial sequence around a Pro residue is important for the conformation of these peptides. The significance of the sequence for conformation was similarly reported by Blout *et al.* on cyclic hexapeptides[24] and by Nagai *et al.* on linear tetrapeptides.[17]

The CD spectra of these synthetic peptides **I**—**VIII** in aqueous solutions were obtained at different temperatures (24, 40, and 60 °C) (Fig. 4). The CD spectra of peptides **II** and **IV**—**VIII** did not vary between 24 and 60 °C, indicating that the conformations of these peptides were stable within this temperature range. On the other hand, the ellipticities of peptides **I** and **III** decreased with a rise in temperature (Fig. 4). These results indicate that the conformations of peptides **I** and **III** with smaller activities are more labile than those of active peptides **II** and **IV**—**VIII**.

Experimental

All the melting points are uncorrected. CD spectra were obtained with a JASCO spectropolarimeter (model J-20 or J-500). The CD spectroscopy of gratisin peptides **I**—**VIII** was carried out using aqueous solutions of their dihydrochlorides. The molecular weights of the protected cyclododecapeptides were determined by a Hitachi-Perkin-Elmer vapor-pressure osmometer (model 115) using DMF as a solvent. Amino acid analyses were carried out using an ATTO MLC-703, after hydrolysis of the peptides in 6 M HCl at 110 °C for 24 h. Thin-layer chromatography was performed on Merck silica-gel F_{254} plates with the following solvent systems (v/v): R_f^1, $CHCl_3$–MeOH (9:1); R_f^2, $CHCl_3$–MeOH–AcOH (95:5:3); R_f^3, *n*-BuOH–AcOH–H_2O (4:1:1); R_f^4, *n*-BuOH–pyridine–AcOH–H_2O (4:1:1:2). Yields, physical properties and analytical data of peptides **I**—**VIII** and the intermediary products are summarized in Table 3. The yield of each benzyl ester of Boc-hexapeptide was calculated on the basis of the amount of Pro-OBzl used as a starting material.

*Boc-Tyr(Bzl)-Val-Orn(Z)-Leu-Phe-Pro-OBzl (**Ia**).* DCC (2.06 g, 10 mmol) was added to a solution of Boc-Phe (2.65 g, 10 mmol), HOBt (1.48 g, 11 mmol), Pro-OBzl·HCl (2.42 g, 10 mmol) and TEA (1.39 ml) in $CHCl_3$ (50 ml) at 0 °C. This solution was stirred for 2 h at 0 °C and overnight at room temperature. After the reaction mixture was concentrated *in vacuo*, AcOEt (20 ml) was added to the residue and insoluble substances were removed by filtration. The filtrate was then diluted with AcOEt (150 ml). The solution was washed successively with 5% citric acid, water, 5% Na_2CO_3 and water, and then dried over sodium sulfate. After removal of the drying agent, the solvent was evaporated *in vacuo*. The residue was dissolved in 4 M HCl/dioxane (20 ml) containing anisole (0.5 ml) at 0 °C. After stirring for 30 min at room temperature, the solution was concentrated *in vacuo*. The residue was dissolved in $CHCl_3$ (30 ml). The solution was washed with 10% Na_2CO_3 and water under cooling with an ice bath. To this solution were added Boc-Leu (2.4 g, 10 mmol), HOBt (1.48 g, 11 mmol) and DCC (2.06 g, 10 mmol) at 0 °C. The same procedure as described above was repeated for this reaction mixture. Further, Boc-Orn(Z), Boc-Val, and Boc-Tyr(Bzl) were successively coupled by the same method. All reactions were followed by TLC on a silica-gel plate. The crude protected hexapeptide obtained from the final reaction mixture was purified by chromatography on a silica-gel column (1.2×60 cm) using a solvent system of $CHCl_3$–MeOH (50:1). The fractions containing the desired product were combined and concentrated. The product was reprecipitated from AcOEt–ether; overall yield, 5.49 g (47% from Pro-OBzl).

Compounds **IIa**—**VIIIa** were prepared in a similar manner. In the synthesis of **IVa**—**VIIIa**, WSCD·HCl was used instead of DCC as the coupling reagent.

*Boc-Tyr(Bzl)-Val-Orn(Z)-Leu-Phe-Pro-NHNH$_2$ (**Ib**).* A solution of **Ia** (2.3 g, 2.1 mmol) and hydrazine hydrate (2 ml) in DMF (15 ml) was allowed to stand for 5 d at room temperature. The solution was concentrated, and then water was added to the residue. The resulting solid product was collected by filtration; yield, 1.5 g (71%).

Compounds **IIb**—**VIIIb** were prepared in a similar manner.

*Boc-Tyr(Bzl)-Val-Orn(Z)-Leu-Phe-Pro-OH (**Ic**).* In a solution of **Ia** (1.75 g, 1.5 mmol) in MeOH (24 ml) and dioxane (12 ml), 2 M NaOH (1.5 ml) was added. The solution was then stirred for 12 h at room temperature. After the addition of water (10 ml), the solution was concentrated *in vacuo* at a low temperature, and then water (50 ml) was added to the residue. The resulting solid product was collected by filtration, washed with water and dried. The product was recrystallized from MeOH–ether; yield 1.43 g (88%).

Compounds **IIIc**, **VIIc**, and **VIIIc** were prepared in a similar manner.

*Boc-[Tyr(Bzl)-Val-Orn(Z)-Leu-Phe-Pro-]$_2$-OH (**Id**).* Compound **Ic** (0.86 g, 0.8 mmol) was dissolved in TFA (15 ml) containing anisole (0.5 ml) at 0 °C. After stirring at room temperature for 30 min, the solution was concentrated *in vacuo*. Ether (50 ml) was added to the residue, and the resulting solid, H-Tyr(Bzl)-Val-Orn(Z)-Leu-Phe-Pro-OH·TFA, was collected by filtration. To a solution of **Ib** (0.87 g, 0.8 mmol) in DMF (10 ml) were added 4.4 M HCl/dioxane (0.54 ml, 2.4 mmol) and isopentyl nitrite (0.12 ml, 0.9 mmol) at −40 °C. After stirring at −20 °C for 20 min, TEA (0.34 ml, 2.4 mmol) was added at −40 °C. This mixture was combined with a solution of the total amount of H-Tyr(Bzl)-Val-Orn(Z)-Leu-Phe-Pro-OH·TFA prepared above and NMM (0.09 ml) in DMF (10 ml). The mixture was stirred at 0 °C for 3 d and concentrated. A solution 10% citric acid (50 ml) was added to the residue and the resulting product was collected by filtration, washed with water and dried. The product was purified by gel filtration on a Sephadex LH-20 column (2.5×120 cm) using DMF as a solvent. The fractions containing the desired product were then combined and concentrated. The product was recrystallized from hot EtOH; yield 1.1 g (67%).

Compounds **IIId**, **VIId**, and **VIIId** were prepared in a similar manner. In the removal of the Boc group of compounds **VIIc** and **VIIIc**, 4 M HCl/dioxane was used instead of TFA.

cyclo[-*Tyr(Bzl)-Val-Orn(Z)-Leu-Phe-Pro-*]$_2$ (**Ie**). *Active-Ester Method.* To a solution of **Id** (300 mg, 0.14 mmol) in DMF (10 ml) was added HOSu (32 mg, 0.28 mmol) and WSCD·HCl (53 mg, 0.28 mmol) at 0 °C, and then the mixture was stirred for 7 h at room temperature. The solvent was evaporated and then water was added to the residue. The resulting solid product was collected by filtra-

tion, washed with water and dried. It was dissolved in TFA (5 ml) containing a few drops of anisole at 0 °C. The mixture was stirred for 30 min at room temperature and then concentrated. The residue, trifluoroacetate of dodecapeptide active ester, was triturated with ether, collected by filtration and dissolved in DMF (10 ml). The solution was added, dropwise, to pyridine (150 ml) at 60 °C. After stirring for 3 h at 60 °C and overnight at room temperature, the solvent was evaporated, and then water was added to the residue. The resulting solid product was collected by filtration, washed with water and dried. The crude product was purified by chromatography on a silica-gel column (1.2×30 cm) using a solvent system of $CHCl_3$–MeOH (50:1). The fractions containing the desired product were combined and concentrated. The product was recrystallized from EtOH–ether; yield, 83 mg (29%).

Compounds **IIIe**, **VIIe**, and **VIIIe** were prepared in a similar manner.

A Trial by an Azide Method. The cyclization of H-[Phe-Pro-Tyr(Bzl)-Val-Orn(Z)-Leu-]$_2$-$NHNH_2$ with an azide method was attempted by a procedure (described later) used in the preparation of compound **IIe**. In the purification of the product by column chromatography on silica-gel, a small amount of ninhydrin negative substance was isolated. The analytical results of the product are as follows: amino acid ratios in acid hydrolyzate; Phe 1.10, Pro 0.96, Tyr 0.86, Val 1.01, Orn 1.01, Leu 0.56. Elemental analysis: C, 66.61; H, 7.10; N, 10.81%. These results are not in agreement with the values expected for the desired product, *cyclo*[-Phe-Pro-Tyr(Bzl)-Val-Orn(Z)-Leu-]$_2$, but coincide with the following value calculated for the tentative urea-type structure described earlier: amino acid ratios; Phe 1, Pro 1, Tyr 1, Val 1, Orn 1, Leu 0.5. Calcd for $C_{108}H_{135}N_{15}O_{18}\cdot H_2O$: C, 66.54; H, 7.08; N, 10.77%.

cyclo*(-Tyr-Val-Orn-Leu-Phe-Pro-)$_2$·2HCl (If).* Compound **Ie** (50 mg, 0.026 mmol) was dissolved in a mixture of 90% MeOH (30 ml), dioxane (5 ml), and 1 M HCl (0.1 ml). It was hydrogenated in the presence of palladium black for 15 h at room temperature. After removal of the catalyst, the filtrate was concentrated *in vacuo*. The product was recrystallized from EtOH-ether; yield, 38 mg (94%).

Gratisin peptides, **IIIf**, **VIIf**, and **VIIIf** were prepared in a similar manner.

Boc-[Tyr(Bzl)-Val-Orn(Z)-Leu-D-Phe-Pro-]$_2$-OBzl (IIc). Compound **IIa** (1.17 g, 1 mmol) was dissolved in 4 M HCl/dioxane (20 ml) containing anisole (0.5 ml) at 0 °C. After stirring at room temperature for 30 min, the solution was concentrated *in vacuo*. Ether (50 ml) was added to the residue, and the resulting solid, H-Tyr(Bzl)-Val-Orn(Z)-Leu-D-Phe-Pro-OBzl·HCl, was collected by filtration. To a solution of **IIb** (1.1 g, 1 mmol) in DMF (10 ml) were added 8.83 M HCl/dioxane (0.34 ml) and isopentyl nitrite (0.15 ml, 1 mmol) at −40 °C. After stirring at −20 °C for 15 min, the solution was cooled again to −40 °C and neutralized with TEA (0.42 ml, 3 mmol). This solution was combined with a chilled solution of H-Tyr(Bzl)-Val-Orn(*Z*)-Leu-D-Phe-Pro-OBzl·HCl mentioned above and NMM (0.11 ml, 1 mmol) in DMF (10 ml). The reaction mixture was stirred at 0 °C for 3 d, and then concentrated. The residue was dissolved in AcOEt (150 ml), and the solution was washed with 5% citric acid, water, 5% Na_2CO_3 and water, and dried over sodium sulfate. After concentrating the solution, the residue was purified by gel filtration on a Sephadex LH-20 column (2.5×120 cm) using DMF as solvent, and the fractions containing the desired product were combined and concentrated. Further purification was performed by chromatography on a silica-gel column (1.2×30 cm) using a solvent system of $CHCl_3$–MeOH (50:1), following by recrystallization from hot EtOH; yield, 1.23 g (60%).

Compounds **IVc**, **Vc**, and **VIc** were prepared in a similar manner. But the gel filtration on a Sephadex LH-20 column was not required for purification.

Boc-[Tyr(Bzl)-Val-Orn(Z)-Leu-D-Phe-Pro-]$_2$-$NHNH_2$ (IId). Compound **IIc** (1.1 g, 0.5 mmol) was treated with hydrazine hydrate (1.5 ml) as described for the preparation of **Ib**. The product was purified by gel filtration as described in the preparation of **Id**; yield, 0.96 g (94%).

Compound **IVd**, **Vd**, and **VId** were prepared in a similar manner.

cyclo*[-Tyr(Bzl)-Val-Orn(Z)-Leu-D-Phe-Pro-]$_2$ (IIe).* Compound **IId** (500 mg, 0.24 mmol) was dissolved in 4 M HCl/dioxane (15 ml) containing anisole (0.5 ml). The mixture was stirred for 40 min at room temperature and then concentrated *in vacuo*. The residue was triturated with ether and collected by filtration. To a solution of the hydrochloride of the dodecapeptide hydrazide in DMF (10 ml) was added 8.8 M HCl/dioxane (0.09 ml) and isopentyl nitrite (0.036 ml, 0.27 mmol) at −40 °C. After 15 min, the mixture was poured, dropwise, into pyridine (200 ml) at 0 °C. After stirring for 3 d at 0 °C, the solution was concentrated. Addition of water to the residue afforded a precipitate, which was filtrated and washed with water. Purification was performed by chromatography on a silica-gel coulmn (1.2×30 cm) using a solvent system of $CHCl_3$–MeOH (50:1), followed by recrystallized from hot EtOH; yield 198 mg (43%).

Compounds **IVe**, **Ve**, and **VIe** were prepared in a similar manner. In removal for Boc group of compounds **IVd** and **Vd**, TFA was used instead of 4 M HCl/dioxane.

cyclo*(-Tyr-Val-Orn-Leu-D-Phe-Pro-)$_2$·2HCl (IIf).* Compound **IIe** (100 mg, 0.052 mmol) was dissolved in 90% MeOH (20 ml), and then 1 M HCl (0.15 ml) was added to the solution. The mixture was hydrogenated in the presence of palladium black for 15 h. After removing the catalyst, the filtrate was concentrated *in vacuo*. The product was purified by gel filtration on a Sephadex LH-20 column (1×150 cm) using EtOH as solvent, and by reprecipitation from EtOH–ether; yield, 72 mg (90%).

Compounds **IVf**, **Vf**, and **VIf** were prepared in a similar manner. But, in this case, the gel-filtration purification procedure was not required.

Cellulose Plate Electrophoresis. Electrophoresis of the products was carried out with a cellulose (Avicel) plate and with a solvent system of HCOOH–AcOH–MeOH–H_2O (1:3:6:10 v/v, pH 1.3) for 2 h at 500 V/20 cm. Each of the peptides **I**—**VIII** revealed a single spot, the mobility being the same as that of GS.

The author wishs to express his sincere thanks to Professor Ichiro Muramatsu, Rikkyo University, for his kind guidance throughout this work, and to Professor Michiaki Takimoto, Toho University, for his encouragement. He is also grateful to Associate Professor Shosuke Sofuku, Rikkyo University, for his helpful discussions. He is indebted to the members of the Research Laboratories of Toyo Jozo Co. for their elemental analyses and microbiological assays and to Professor Yasutomo Sugimura, Toho University, for performing amino acid analyses.

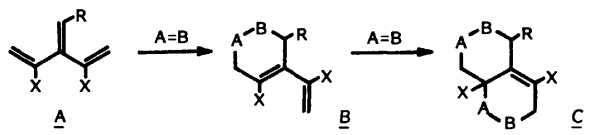
Diene-transmissive Diels-Alder Cycloaddition Reaction of Bis(silyloxy) Cross-conjugated Trienes

Otohiko Tsuge,* Eiji Wada, Shuji Kanemasa, and Hirohiko Sakoh
Research Institute of Industrial Science, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences Kyushu University, Kasugakoen, Kasuga 816
(Received June 18, 1984)

Multiple Diels-Alder reaction of bis(silyloxy) cross-conjugated trienes is presented. Two trienes, 3-benzylidene- and 3-(methoxymethylene)-2,4-bis(trimethylsilyloxy)-1,4-pentadiene, undergo two sequential Diels-Alder cycloadditions with a variety of dienophiles forming hydronaphthalene rings. Some characteristics of this reaction have been discussed in terms of stereo-, regio-, and chemoselectivity. It is proposed that this process is referred to as "diene-transmissive Diels-Alder reaction".

There have been reported numerous processes by which ring systems can be prepared. Although each has the characteristic advantages, one of the most reliable processes is the Diels-Alder cycloaddition that generally proceeds in a highly diastereoselective manner.[1] Recently a process that produces more than one ring in a single reaction has been often requested in elaborating complex natural products. Attracting is the use of the Diels-Alder reaction as a part of ring construction steps. Some examples are known for the multiple sequence of the Diels-Alder cycloaddition and called Domino,[2] Timed,[3] and Tandem Diels-Alder reaction.[4,5] However, their applications in organic synthesis are rare.

We have found a new process of multiple sequence of the Diels-Alder reaction. The process, referred to as "diene-transmissive Diels-Alder reaction",[6] involves two sequential cycloadditions of cross-conjugated triene: A part of the triene **A** undergoes the first cycloaddition to a dienophile (A=B) forming a six-membered ring **B** with an endocyclic double bond which serves as a part of diene for the following reaction. The second cycloaddition gives a bis-cycloadduct **C**. The cross-conjugated triene **A** of our choice carries two silyloxy moieties (X=OTMS, TMS: trimethylsilyl) as diene-activating and directing substituents.

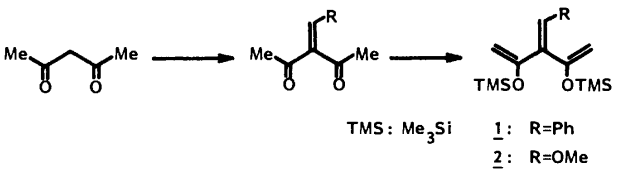


A B C

The present paper describes the full detail of our investigation on the diene-transmissive Diels-Alder reactions of bis(silyloxy) cross-conjugated trienes, a part of which has been already reported as preliminary communications.[6-8]

Results and Discussion

Synthesis of Bis(silyloxy) Cross-conjugated Trienes. Blomquist[9] and Bailey[10] have reported the first examples of diene-transmissive Diels-Alder reaction using the parent cross-conjugated triene, 3-methylene-1,4-pentadiene. However, this elegant ring formation has long discouraged its application in organic synthesis because of tough handling, ready polymerization, low reactivity as a diene, and difficult structural modification of the triene. Our bis (silyloxy) cross-conjugated trienes can be synthesized in two steps from readily available 2,4-pentanedione, and a variety of substituents may be introduced from aldehydes.



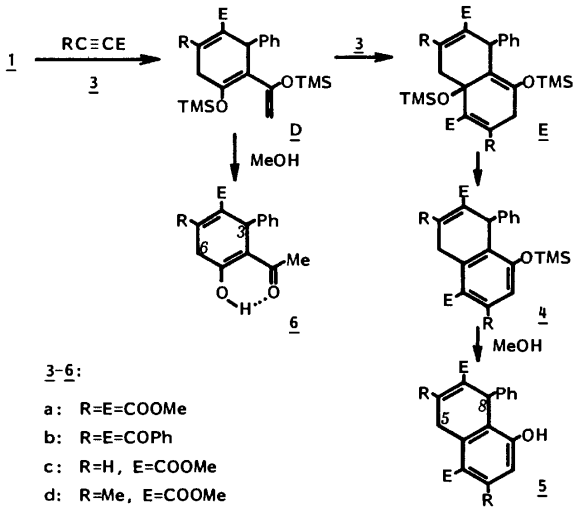
Scheme 1.

Scheme 1 illustrates the synthesis of trienes, 3-benzylidene- **1** and 3-(methoxymethylene)-2,4-bis(trimethyl silyloxy)-1,4-pentadiene **2**. The condensation products of 2,4-pentanedione with benzaldehyde and trimethyl orthoformate were silylated with chlorotrimethylsilane giving **1** and **2**. The use of 1,8-diazabicyclo-[5.4.0]undec-7-ene in dichloromethane[11] for **1** and of triethylamine together with a catalytic amount of zinc chloride in benzene[12] for **2** gave the best results.

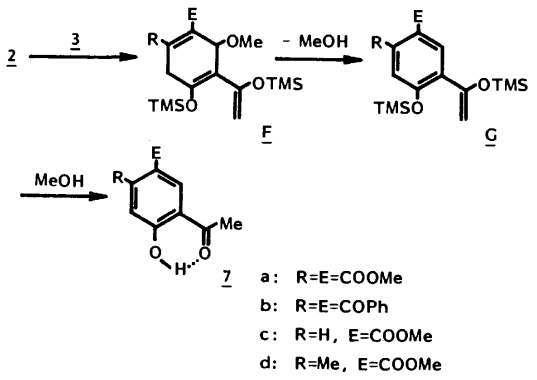
The trienes **1** and **2** are stable enough to be purified by a vacuum distillation and chromatographed over silica gel if carefully handled.[13] In the absence of moisture, they may be stored for a long time without decomposition and polymerization.[14] Such thermal stability of **1** and **2** is a great advantage over the parent triene.

Cycloadditions to Acetylenic Dienophiles. The reaction of **1** with dimethyl acetylenedicarboxylate **3a** (five equiv) under reflux in benzene gave a desilylated bis-adduct **5a** after the usual work-up with methanol (Scheme 2 and Table 1). As shown in Scheme 2, the first Diels-Alder reaction between **1** and **3a** forms a mono-cycloadduct **D** that bears a diene functionality activated by two silyloxy moieties. The second reaction occurs smoothly affording a bis-cycloadduct **E**. Aromatization of the secondarily formed ring induces the elimination of trimethylsilanol leading to **4a**. On work-up with methanol, **4a** is desilylated into **5a**. As the diene function in **D** is highly activated by two silyloxy substituents, the second cycloaddition is even more accelerated than the first, only a trace of mono-adduct **6a** being formed.

The diene-transmissive Diels-Alder reaction of **1** with an unsymmetrical acetylene provides another advan-



Scheme 2.



Scheme 3.

tage. The reaction with methyl propiolate **3c** gave bis-cycloadducts **4c** and **5c** besides a poor yield of mono-adduct **6c**, meaning that both the first and second cycloadditions proceeded in a highly regioselective manner. That is, the silyloxy groups in **1** serve not only as diene-activating substituents but also as directing ones.

Dibenzoylacetylene **3b** and methyl 2-butynoate **3d** failed in the formation either mono- or bis-adducts.

The other triene **2** was found much more reactive than **1**. It reacts with **3a** and **3b** even at room temperature, however the only products were mono-adducts **7a** and **7b** (Scheme 3 and Table 1). The exclusive formation of mono-adduct **7** from a reactive triene **2** remarkably contrasts with the predominant formation of bis-adduct **5** from a rather sluggish triene **1**. This is because of the ready elimination of methanol from the initially formed mono-cycloadduct **F**. ^{1}H-NMR spectral analysis of the reactions indicated that the methanol elimination occurred even at room temperature.

The triene **2** is a well designed conjugation system. Since it carries three alkoxyl groups, any two in a 1,3-relationship, both the first and second cycloadditions are highly accelerated and also regioselective. In addition, the methoxyl group is eliminated after the cycloaddition is complete, adding an unsaturation to the cycloadduct.

The reactions with **3c** and **3d**, under harder reaction conditions, provided regioselective mono-adducts **7c** and **7d**, respectively.

Cycloadditions to Cyclic Olefinic Dienophiles. To investigate the stereochemical aspect of diene-transmissive Diels-Alder reaction the cycloadditions with cyclic olefinic dienophiles were carried out.

The reaction of **1** with excess of *N*-methylmaleimide **8a** under reflux in benzene and the work-up with methanol gave a bis-adduct **10a** together with low yields of two isomeric mono-adducts **11a** and **12a** (Scheme 4 and Table 2). The minor products were assigned as the 3a,4-*cis*- **11a** and 3a,4-*trans*-hydroisoindolinedione **12a**, respectively, on the basis of the spectral data, especially of the coupling constants between 3a-H and 4-H (**11a**: 6.0 Hz; **12a**: 2.0 Hz) as well as the chemical shifts of *N*-Me (**11a**: δ 2.38; **12a**: δ 3.00). The cis and trans mono-adducts correspond to the products derived through an endo and an exo approach of dienophile **8a** across the trans diene part of **1**, respectively.[15] In the present paper, therefore, the compound of type **11a** is to be called an endo adduct and **12a** an exo adduct.

Stereochemistry of the bis-adduct **10a** has been determined at two stages, the first Diels-Alder reaction (from **1** to the mono-cycloadduct) and the second reaction (the path to the second cycloadduct). Main path of the first cycloaddition should be endoselective since **11a** was only isolated in the reaction of **1** with **8a** at room temperature (Table 2). The ^{1}H-NMR spectrum con-

Table 1. Reactions of **1** and **2** with acetylenic dienophiles **3**

Triene	Acetylene (equiv)	Reaction Conditions			Product (yield/%)[a]

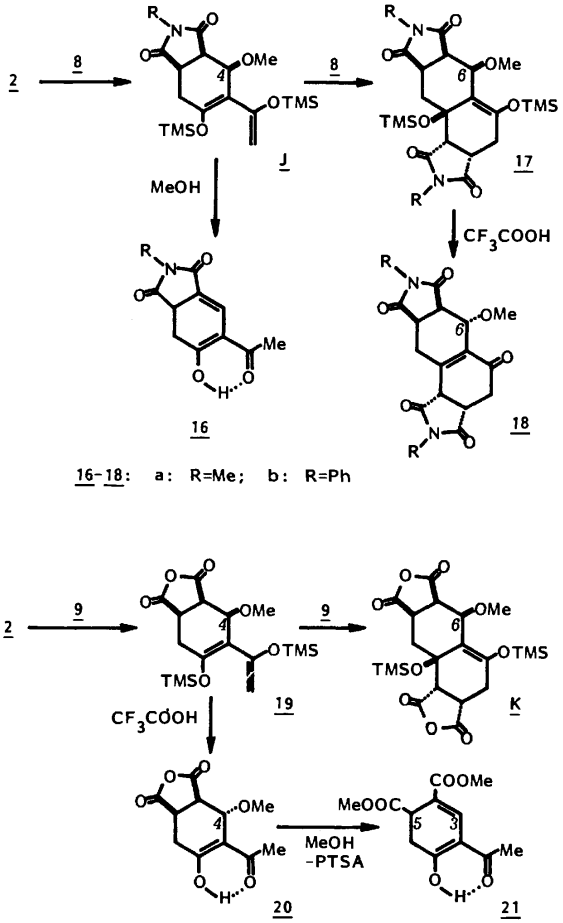

Scheme 5.

firmed cis configuration at the 6- and 6a-positions of **10a** (J_{6-6a}=6.0 Hz; *N*-Me: δ 2.33). Although the stereochemistry at the 3a- and 10b-junctions could not be determined only on the basis of the spectral data, it was tentatively assigned according to the probable reaction pathway shown in Scheme 4. The first cycloaddition of **1** to **8a** is highly endoselective leading to an endo mono-cycloadduct **H** (X=NMe). The second molecule of **8a** approaches across the diene conjugation of **H** in an endo fashion from the less hindered side (the opposite side of the fused maleimide ring and the phenyl) forming a stereoselective skeleton of bis-cycloadduct **I** (X=NMe). When treated with methanol, desilylation occurs to give a fused cyclohexenone ring **10a**.

Similar results were given in the reaction of **1** with *N*-phenylmaleimide **8b** as shown in Scheme 4 and Table 2.

Maleic anhydride **9** was found much more reactive than the maleimides. Triene **1** reacted with two equivalents of **9** under reflux in benzene forming **I** (X=O) as a major product, which was found composed of two isomers of bis-cycloadducts. The followed esterification with methanol in the presence of *p*-toluenesulfonic acid gave two isomeric decarboxylated bis-adducts **13** and **14** besides a small amount of exo mono-adduct **15**. Even with less than one equivalent of **9** at room temperature, **I** was only obtained in a good yield. It is surprising that the second cycloaddition of **9** has shown such a low stereoselectivity. The reason has not been clarified yet.

One of the four expected ester groups in the esterified bis-adducts was missing. It was eliminated during the hydrolysis of two anhydride rings in **I** (X=O). On the basis of the ^{1}H-NMR spectrum which showed no methylene multiplets upfield of δ 2.0,[16] it was confirmed that the lost carboxyl group had been at the 4-position. Among four positions (3-, 4-, 6-, and 7-positions), a carbanion that is expected to form on decarboxylation would be best stabilized at the 4-position.

The activated cross-conjugated triene **2** readily reacts with **8** and **9** under mild reaction conditions in a highly chemoselective manner. Type of products is dependent upon the amount of dienophile as well as the reaction conditions as shown in Scheme 5 and Table 2.

The reaction of **2** with an equivalent of **8a** in benzene at room temperature was followed by the work-up with methanol giving only a mono-adduct **16a** in a good yield. As **16a** was accompanied with the elimination of methanol, stereoselectivity in the first cycloaddition leading to a mono-cycloadduct **J** is not clear. With two equivalents of **8a** under reflux in benzene, a stereoselective bis-cycloadduct **17a** was isolated as the single product. Desilylation readily took place giving a bis-adduct **18a** when **17a** was treated with a catalytic amount of trifluoroacetic acid in benzene. Interesting is that the configuration at the 6-position of **17a** was inverted at the acid-catalyzed desilylation stage, probably through an elimination-addition mechanism.

As the structure of **17a** could not be determined only on the basis of spectral data, it was tentatively assigned by the following discussion: Molecular model inspection indicates that the most stable conformation for **J** is an envelope type in which a bulky substituent **R'** (=OMe) occupies an axial position in order to minimize the steric repulsion to the 3-carbonyl and the protruding silyloxy groups (Fig. 1). Although both sides of diene in the exo mono-cycloadduct exo-**J** as well as the upper side of the endo one endo-**J** are sterically hindered for the approach of **8a**, an endo approach from the bottom side of diene in endo-**J** looks quite easy. This approach must be the reaction leading to the stereoselective bis-cycloadduct **17a**. Thus, **17a** was assigned as a bis-cycloadduct formed via the endo mono-cycloadduct endo-**J**. On the other hand, the stereochemistry at the 6- and 6a-positions of **18a** was easily determined as trans on the basis of small J_{6-6a} (4.0 Hz) since this ring has an envelope conformation with an axial 6-methoxyl substituent.

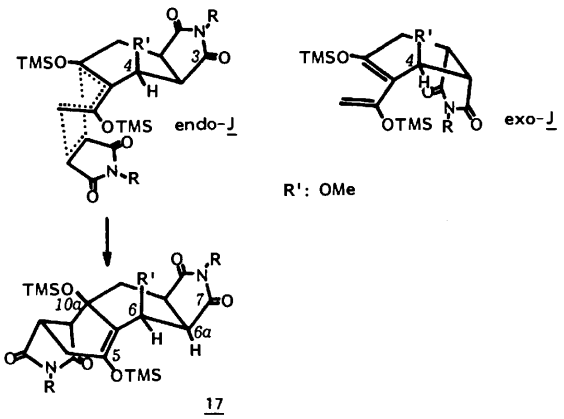

Fig. 1. Possible configuration and conformation for mono-cycloadduct **J**, and stereochemistry for second cycloaddition.

Similarly the stereoselective mono- **16b** and bis-adducts **17b** and **18b** were selectively formed in the reactions with *N*-phenylmaleimide **8b**. The stage of desilylation of **17b** into **18b** was also accompanied with the inversion of methoxyl moiety.

The reaction of **2** with an equivalent of maleic anhydride **9** was so rapid as to be completed in 10 min at room temperature forming a quantitative yield of endo mono-cycloadduct **19**. Treatment of **19** with trifluoroacetic acid in benzene provided a desilylated mono-adduct **20** while the usual work-up with methanol gave a mixture of two isomeric half esters. Esterification of **20** with methanol in the presence of *p*-toluenesulfonic acid led to a methanol eliminated mono-adduct **21** that was also obtained directly from **19** under the same conditions. Although the quantitative formation of a bis-cycloadduct **K** was confirmed in the reaction between **2** and two equivalents of **9**, neither its purification nor the conversion into isolable derivatives was successful.

To be emphasized are given as follows: 1) The first cycloaddition of both **1** and **2** is highly endoselective and the second reaction selectively takes place with an endo approach of dienophiles from the less hindered side of diene moiety. 2) The double cycloaddition sequence of **2** is highly chemoselective. Either the mono- or bis-cycloadduct is selectively formed depending upon the amount of dienophiles. 3) The elimination of methanol in the reactions of **2** adds an unsaturation to the products.

Cycloadditions to Acyclic Olefinic Dienophiles. Compared with such highly reactive dienophiles as **3**, **8**, and **9**, acyclic olefinic dienophiles show a low reactivity toward the trienes **1** and **2**. The first cycloaddition slowly proceeds with a poor stereoselec-

Its isolation failed.

tivity, a mixture of endo and exo mono-cycloadducts being formed in a comparable ratio. Regardless of the stereochemistry of mono-cycloadduct, the second cycloaddition is extremely slow probably because the initially formed six-membered ring takes a half-chair conformation which is hardly favored for the approach of the second molecule of dienophile. Therefore, the major products in the diene-transmissive Diels-Alder reactions with acyclic olefinic dienophiles are mono-adducts.

The reaction of **1** with dimethyl maleate **22** (large excess) gave an exo mono-adduct **15** that was identical with the minor product in the reaction of **1** with **9** (Scheme 6 and Table 3). On the other hand, with dimethyl fumarate **23a** under the same reaction conditions, an exo- **24a** and an endo mono-adduct **25a** were obtained together with a mixture of two isomeric bis-adducts **26**. In this case also the exo adduct **24a** was the major product. When the same reaction was carried out under harder conditions (under reflux in toluene), the yield of **26** increased up to 88% and those of both **24a** and **25a** decreased. These results indicate that two isomers of bis-adducts **26** carry different stereochemistry in the initially formed ring, and further indicate that both the endo and exo mono-cycloadducts **L** can undergo the second cycloaddition with a comparable easiness.

The most stable conformation for the six-membered rings of **15**, **24a**, and **25a** is a half-chair type.[17] Molecular model inspection shows that the bulky phenyl substituent at the 3-position occupies an axial position to avoid the steric hindrance to the adjacent acetyl moiety. Consequently an axial substituent at the 5-position, which is in a 1,3-relationship to the phenyl, faces closely to the phenyl plane and therefore is magnetically shielded. Thus the isomer with a shielded ester group (COOMe: δ 3.32) was assigned to **24a**, and then the other **25a**.

Two conformers of the exemplified compound **14** are illustrated in Fig. 2. It is clear that not the adjacent but the next ester is most intensely shielded when it is sitting cis to the axial phenyl. The following six compounds give good examples for the chemical shifts of a variety of ester methyls and the coupling constants J_{3-4} of cyclohexene ring systems of related compounds. These values agree with the ones estimated on the axial-phenyl conformation model.

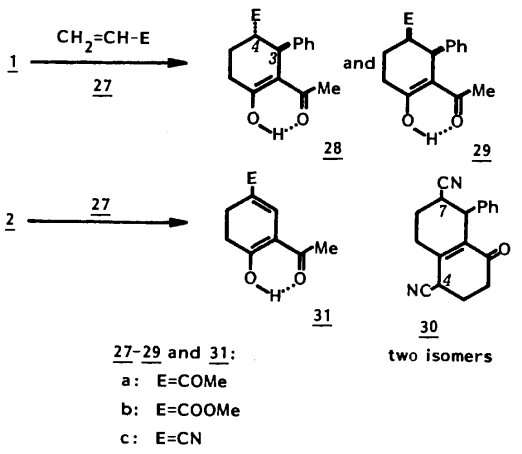
Fumaronitrile **23b** also reacted with **1** under reflux in toluene giving a mixture of two isomeric mono-adducts **24b** and **25b**, but in this case the endo adduct **25b** was the major product.

The same methanol-eliminated mono-adduct **21** was yielded both in the reaction of **2** with the fumarate **22** and in that with the maleate **23a**. As have been shown in Scheme 5, this compound **21** is also obtainable from **2** and maleic anhydride **9**. In the prolonged reaction with excess of **22**, a quantitative formation of exo mono-cycloadduct **M** was confirmed by ^{1}H-NMR spectroscopy, no trace of either bis-adduct or endo mono-adduct being formed. These results indicate that the reaction of activated triene **2** with **22** takes place in a highly chemoselective (selective mono-cycloadduct formation) and exoselective manner, and that the methanol elimination occurs only after the desilylation. When the cycloadduct **M** was treated with methanol, **21** was obtained in a good yield.

Both trienes **1** and **2** reacted with unsymmetrical olefinic dienophiles such as methyl vinyl ketone **27a**, methyl acrylate **27b**, and acrylonitrile **27c** in a highly regioselective manner, but its stereoselectivity was low. So far as these reactions were carried out around 80 °C, only the mono-adducts were afforded.

Even with large excess of **27**, the reactions of **1** under reflux in benzene or in a dienophile itself (**27c**) gave only the mono-adducts as mixtures of exo **28** and endo isomers **29** (Scheme 7 and Table 3). In all cases, the exo isomers were the major products. Their structures were based on the chemical shifts of substituents at the 4-position as well as the coupling constants between 3-H and 4-H. When the reaction with **27c** was carried out under harder conditions (at 110 °C in a shield tube for 5 d), a mixture of two isomeric bis-adducts **30** was obtained in a fair yield. They are the isomers which have different configurations in the initially formed six-membered ring.



Scheme 7.

In the similar reactions of **2** with **27**, the only obtained products were the regioselective mono-adducts **31**. These products were also accompanied with methanol elimination, the stereochemical selectivity of mono-cycloadduct formation being ambiguous.

Experimental

General. Melting points were determined on a Yanagimoto micro melting point apparatus and uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-102 spectrometer. ^{1}H-NMR spectra were recorded on a Hitachi R-40 or a JEOL FX-100 instrument and ^{13}C-NMR spectra were obtained on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane. Mass spectra were measured with a JEOL JMS-01SG-2 spectrometer at 75 eV of ionization energy. Elementary analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck) or on 0.2 mm precoated plates of aluminum oxide 60 F-254 type E (Merck). Visualization was with ultraviolet light (254 and 365 nm) and iodine. Wakogel C200 and C300 (Wako) were used for preparative column chromatography. Preparative high performance liquid chromatography (HPLC) was carried out on a Kusano KHLC-201 apparatus with a UV-detector Uvilog-III using a column (22×300 mm) packed with silica gel (Wakogel LC-50H). Micro vacuum distillation was performed with a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type V at about 50 °C unless otherwise stated.

Benzene and toluene were purified by the distillation of the predried commercial solvents and stored on sodium wire. Dichloromethane was dried on calcium chloride and then distilled on calcium hydride.

Materials. 3-Benzylidene-[18] and 3-(methoxymethylene)-2,4-pentanedione[19] were prepared by the condensations of 2,4-pentanedione with benzaldehyde in the presence of piperidine and with trimethyl orthoformate in the presence of acetic anhydride, respectively. Dibenzoylacetylene **3b**[20] was synthesized from the bromination and dehydrobromination procedure of *trans*-1,2-dibenzoyl-ethene. Methyl propiolate **3c**[21] and 2-butynoate **3d** were obtained by the esterification of the corresponding acids with methanol in the presence of *p*-toluenesulfonic acid. Propynoic acid was commercially available and 2-butynoic acid[22] was prepared by the reaction of propyne with butyllithium and then with carbon dioxide.

As for the following reagents, the ones of commercial grade were purified by distillation or crystallization: Triethylamine: distilled on potassium hydroxide and stored on the same agent; 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU): distilled and stored on molecular sieves 5A; zinc chloride: crystallized from anhydrous dioxane and dried over phosphorus pentaoxide under vacuum; dimethyl acetylenedicarboxylate **3a**, methyl vinyl ketone **27a**, methyl acrylate **27b**, and acrylonitrile **27c**: distilled; maleic anhydride **9**: distilled under vacuum and stored in a bottle with a tightly-fitting stopper. The other reagents were all commercially available and no further purification was needed.

3-Benzylidene-2,4-bis(trimethylsilyloxy)-1,4-pentadiene **1**. To a mixture of 3-benzylidene-2,4-pentanedione (9.41 g, 0.1 mol) and DBU (15.22 g, 0.1 mol) in dry dichloromethane (25 ml) was added chlorotrimethylsilane (13.9 ml, 0.11 mol) at room temperature. The mixture was heated at 40 °C under dry atmosphere for 20 h and then all the volatile materials were removed *in vacuo*. The residue was triturated with dry hexane (100 ml) and the hexane separated from the insoluble DBU·HCl was concentrated *in vacuo* to give 15.05 g (91%) of crude **1**. This crude triene **1** was purified by a column chromatography over silica gel (Wako C200) using a mixture of benzene–hexane (1:9) as an eluent affording pure **1** (9.45 g, 57%) as a colorless liquid: bp 115 °C (107 Pa) (bulb-to-bulb); IR (neat) 1625, 1595 (C=C), 1245, and 830 cm^{-1} (TMS); ^{1}H-NMR (CCl_4) δ=0.17, 0.27 (each 9H, s, TMS), 4.17, 4.38 (each 1H, d, J=1.0 Hz, 1- and/or 5-CH_2), 4.35, 4.69 (each 1H, dd, J=1.0 and 0.6 Hz, 1- and/or 5-CH_2), 6.72 (1H, t, J=0.6 Hz, phC<u>H</u>=), and 7.00—7.46 (5H, m, ArH); ^{13}C-NMR (CCl_4) δ=0.00, 0.10 (each q, TMS), 94.83, 95.95 (each t, 1- and 5-C), 153.06, and 155.30 (each s, 2- and 4-C); MS m/z (rel. intensity) 332 (M^+; base peak), 241 (M^+−92, 25) and 73 (TMS^+, 79).

Found: C, 64.74; H, 8.60%; M^+, 332. Calcd for $C_{18}H_{28}O_2Si_2$: C, 65.00; H, 8.49%; M, 332.

Another procedure for **1** was briefly presented in the preceding communication.[6]

3-(Methoxymethylene)-2,4-bis(trimethylsilyloxy)-1,4-pentadiene **2**. A mixture of dry zinc chloride (0.57 g) and triethylamine (31.17 g, 0.31 mol) was vigorously stirred at room temperature for 1 h and mixed with a solution of 3-(methoxymethylene)-2,4-pentanedione (9.95 g, 0.07 mol) and chlorotrimethylsilane (35.5 ml, 0.28 mol) in dry benzene (50 ml). The resultant mixture was heated at 40 °C for 24 h and cooled to room temperature. The salt precipitated was filtered off and the filtrate was concentrated *in vacuo* to afford a yellow residue. Vacuum distillation of the residue gave 16.44 g (82%) of triene **2** as colorless liquid: bp 72 °C (240 pa); IR (neat) 1685—1600 (C=C), 1250, and 840 cm^{-1} (TMS); ^{1}H-NMR ($CDCl_3$) δ=0.18, 0.23 (each 9H, s, TMS), 3.65 (3H, s, OMe), 4.13, 4.26, 4.40, 4.49 (each 1H, s, =CH_2), and 6.40 (1H, s, C<u>H</u>OMe); ^{13}C-NMR ($CDCl_3$) δ=0.15, 0.24 (each q, TMS), 60.47 (q, OMe), 91.52, 97.27 (each t, =CH_2), 117.34 (s, 3-C), 145.38 (d, C<u>H</u>OMe), 150.92, and 153.79 (each s, 2- and 4-C); MS m/z 286 (M^+), 271 (M^+−15, base peak), 147, 63, and 45.

Found: m/z 286.1435. Calcd for $C_{13}H_{26}O_3Si_2$: M, 286.1420.

Cycloaddition of **1** *to* **3a** *Leading to* **5a**. A mixture of freshly distilled **1** (0.64 g, 1.92 mmol) and **3a** (1.37 g, 9.6 mmol) in dry benzene (5 ml) was refluxed under nitrogen for 72 h, the benzene was evaporated *in vacuo*, and the residue was treated with methanol (10 ml) at room temperature overnight. The methanol was completely removed off *in vacuo* to give a viscous oil which was then chromatographed over silica gel using chloroform–hexane (1:1) as an eluent. Crude **5a** (0.438 g, 51%) was purified by crystallization from ether–hexane.

5a: Colorless prisms; mp 171—173 °C; IR (KBr) 3360 (OH), 1725, 1715, 1665 (C=O), 1590, 1280, and 1245 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=3.64 (1H, dd, J_{5-8}=2.8 and J_{gem}=21.8 Hz, one of 5-CH_2), 3.64, 3.74, 3.76, 3.89 (each 3H, s, COOMe), 3.95 (1H, dd, J_{5-8}=4.0 and J_{gem}=21.8 Hz, the other of 5-CH_2), 5.30 (1H, dd, 8-H), and 7.04—7.16 (6H, m, ArH and 2-H); ^{13}C-NMR ($CDCl_3$) δ=29.12 (t, 5-C), 42.08 (d, 8-C), 52.55, 52.80 (each q, COO<u>Me</u>), 114.78 (d, 2-C), 153.99 (s, 1-C), 166.27, 167.74, 168.15, and 169.43 (each s, <u>C</u>OOMe); MS m/z (rel. intensity) 454 (M^+, 10), 423 (M^+−31, 39), 422 (M^+−32, 75), 363 (79), 345 (base peak), 313 (11), 304 (16), and 189 (10).

Found: C, 63.15; H, 4.98%; M^+, 454. Calcd for $C_{24}H_{22}O_9$: C, 63.43; H, 4.88%; M, 454.

Cycloaddition of **1** *to* **3c** *Leading to* **4c**, **5c**, *and* **6c**. A mixture of **1** (0.685 g, 2.06 mmol) and **3c** (2.0 g, 23.8 mmol), both freshly distilled, in dry benzene (3 ml) was refluxed under nitrogen for 168 h. When all the volatile materials were removed off *in vacuo* and the residue was treated with methanol (10 ml), colorless solid of **4c** (0.313 g, 37%) was precipitated. The methanol filtrate was stirred at room temperature overnight and then evaporated *in vacuo*. The viscous oil obtained was chromatographed over silica gel with chloroform–hexane (1:1) to give **5c** (0.07 g, 10%) and **6c** (0.01 g, 2%). Repeated chromatography provided a pure sample of **4c**; **5c** was purified by crystallization from ether–hexane to give colorless prisms; **6c** was distilled on a micro distillation apparatus.

4c: Colorless solid; mp 143—145 °C; IR (KBr) 1720, 1700 (C=O), 1250, 875, and 840 cm^{-1} (TMS); ^{1}H-NMR ($CDCl_3$) δ=0.13 (9H, s, TMS), 3.67, 3.83 (each 3H, s, COOMe), 4.09 (1H, dt, J_{5-6}=J_{5-8}=3.3 and J_{gem}=22.5 Hz, one of 5-CH_2), 4.15 (1H, ddd, J_{5-6}=5.2, J_{5-8}=2.6, and J_{gem}=22.5 Hz, the other of 5-CH_2), 5.30 (1H, dd, 8-H), 6.62 (1H, d, J_{2-3}=8.5 Hz, 2-H), 7.00—7.30 (6H, m, ArH and 6-H), and 7.76 (1H, d, 3-H); ^{13}C-NMR ($CDCl_3$) δ=0.00 (q, TMS), 30.41 (t, 5-C), 39.69 (d, 8-C), 51.25 (q, COO<u>Me</u>), 115.43 (d, 2-C), 120.77 (s, 4-C), 135.80 (d, 6-C), 156.34 (s, 1-C), 166.03, and 167.14 (each s, <u>C</u>OOMe); MS m/z (rel. intensity) 411 (M^++1, 30), 410 (M^+, base peak), 379 (15), 378 (13), 351 (16), 334 (17), 333 (68), 301 (43), and 73 (40).

Found: C, 67.41; H, 6.44%; M^+, 410. Calcd for $C_{23}H_{26}O_5Si$: C, 67.29; H, 6.38%; M, 410.

5c: Colorless prisms (from ether–hexane); mp 179—181 °C; IR (KBr) 3230 (OH), 1720—1660 (C=O), 1575, 1250, and 1225 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=3.67, 3.84 (each 3H, s, COOMe), 4.08 (1H, dt, J_{5-6}=J_{5-8}=3.2 and J_{gem}=23.0 Hz, one of 5-CH_2), 4.15 (1H, ddd, J_{5-6}=5.2, J_{5-8}=2.6, and J_{gem}=23.0 Hz, the other of 5-CH_2), 5.41 (1H, dd, 8-H), 6.60 (1H, d, J_{2-3}=8.5 Hz, 2-H), 7.00—7.34 (6H, m, ArH and 6-H), and 7.76 (1H, d, 3-H); ^{13}C-NMR ($CDCl_3$) δ=30.65 (t, 5-C), 39.39 (d, 8-C), 51.78 (q, COO<u>Me</u>), 113.31 (d, 2-C), 120.30 (s, 4-C), 136.85 (d, 6-C), 157.04 (s, 1-C), 166.85, and 167.73 (each s, <u>C</u>OOMe); MS m/z (rel. intensity) 339 (M^++1, 19), 338 (M^+, 83), 307 (M^+−31, 23), 306 (M^+−32, 20), 279 (21), 278 (32), 261 (64), 260 (31), 247 (64), 229 (base peak), 191 (25), 189 (41) and 115 (21).

Found: C, 70.93; H, 5.39%; M^+, 338. Calcd for $C_{20}H_{18}O_5$: C, 70.99; H, 5.36%; M, 338.

6c: Colorless viscous liquid; bp 120 °C (200 Pa) (bulb-to-bulb); IR (neat) 3400 (OH), 1720, 1660 (C=O), 1600, and 1245 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.05 (3H, s, COMe), 3.27 (1H, ddd, J_{6-3}=3.0, J_{6-5}=4.8, and J_{gem}=22.0 Hz, one of 6-CH_2), 3.37 (1H, ddd, J_{6-5}=3.2, J_{6-3}=3.7, J_{gem}=22.0 Hz, the other of 6-CH_2), 3.68 (3H, s, COOMe), 4.83 (1H, dd, 3-H), 6.83 (1H, dd, 5-H), 7.10-7.24 (5H, br. s, ArH), and 15.96 (1H, br. s, OH); ^{13}C-NMR ($CDCl_3$) δ=25.60 (t, 6-C), 32.58 (1, CO<u>Me</u>), 41.80 (d, 3-C), 51.72 (q, COO<u>Me</u>), 109.56 (s, 2-C), 165.68 (s, <u>C</u>OOMe), 177.89 (s, <u>C</u>OMe), and 199.20 (s, 1-CO); MS m/z (rel. intensity) 273 (M^++1, 17), 272 (M^+, base peak), 254 (M^+−18, 34), 222 (22), 213 (31), 197 (29), 195 (34), 129 (40), and 128 (17).

Found: C, 70.45; H, 6.08%; M^+, 272. Calcd for $C_{16}H_{16}O_4$: C,

70.57; H, 5.92%; M, 272.

Cycloaddition of 2 to 3a Leading to 7a. A solution of **2** (0.85 g, 3.0 mmol) and **3a** (0.843 g, 6.0 mmol), both freshly distilled, in dry benzene (4 ml) was stirred at room temperature under nitrogen for 24 h. After evaporation of all the volatile materials, the residue was treated with methanol (10 ml) at room temperature overnight. The methanol was completely evaporated *in vacuo* to give a residue which was then chromatographed over silica gel using chloroform–ethyl acetate (3:1) as an eluent. Colorless needles (from aqueous methanol) of **7a** (0.425 g, 57%) were obtained:

7a: Colorless needles from aqueous methanol; mp 77 °C; IR (KBr) 1720 and 1645 cm^{-1} (C=O); ^1H—NMR ($CDCl_3$) δ= 2.67 (3H, s, MeCO), 3.87, 3.90 (each 3H, s, COOMe), 7.02 (1H, s, 6-H), 8.27 (1H, s, 3-H), and 12.50 (1H, s, OH); MS *m/z* 252 (M^+), 237 (M^+-15), and 221 (M^+-31, base peak).

Found: C, 56.93; H, 4.87%; M^+, 252. Calcd for $C_{12}H_{12}O_6$: C, 57.14; H, 4.80%; M, 252.

Cycloaddition of 2 to 3b Leading to 7b. Similar reaction between **2** (0.547 g, 1.9 mmol) and **3b** (0.447 g, 1.9 mmol) in 3 ml of benzene under the conditions shown in Table 1 gave 0.31 g (47%) of **7b** which was precipitated on the work-up with methanol.

7b: Colorless leaflets from dichloromethane–methanol; mp 189-190 °C; IR (KBr) 1670—1640 cm^{-1} (C=O); ^1H-NMR ($CDCl_3$) δ=2.60 (3H, s, COMe), 7.07 (1H, s, 6-H), 7.20—7.70 (10H, m, ArH), 8.02 (1H, s, 3-H), and 12.60 (1H, s, OH); MS *m/z* 344 (M^+) and 267 (M^+-77, base peak).

Found: C, 76.47; H, 4.75%; M^+, 344. Calcd for $C_{22}H_{16}O_4$: C, 76.73; H, 4.68%; M, 344.

Cycloaddition of 2 to 3c Leading to 7c. Similar reaction starting from **2** (0.573 g, 2.0 mmol) and **3c** (0.336 g, 4.0 mmol) under the conditions shown in Table 1 gave 0.134 g (35%) of **7c**, after a chromatography over silica gel with chloroform.

7c: Colorless needles from aqueous methanol; mp 99—99.5 °C; IR (KBr) 1720 cm^{-1} (C=O); ^1H-NMR ($CDCl_3$) δ=2.68 (3H, s, COMe), 3.90 (3H, s, COOMe), 6.96 (1H, d, J_{6-5}=9.0 Hz, 6-H), 8.06 (1H, dd, J=9.0 and 2.0 Hz, 5-H), 8.42 (1H, d, J= 2.0 Hz, 3-H), and 12.60 (1H, s, OH); MS *m/z* 194 (M^+) and 179 (M^+-15, base peak).

Found: C, 62.09; H, 5.14%; M^+, 194. Calcd for $C_{10}H_{10}O_4$: C, 61.85; H, 5.19%, M, 194.

Cycloaddition of 2 to 3d Leading to 7d. Similar reaction between **2** (0.886 g, 3.1 mmol) and **3d** (0.607 g, 6.2 mmol) under the conditions of Table 1 gave 0.045 g (8%) of **7d**, after a chromatography over silica gel with chloroform.

7d: Colorless needles from aqueous methanol; mp 70 °C; IR (KBr) 1720 and 1635 cm^{-1} (C=O); ^1H-NMR ($CDCl_3$) δ=2.60 (3H, s, 5-Me), 2.64 (3H, s, COMe), 3.87 (3H, s, COOMe), 6.77 (1H, s, 6-H), 8.36 (1H, s, 3-H), and 12.42 (1H, s, OH); MS *m/z* 208 (M^+) and 193 (M^+-15, base peak).

Found: 63.17; H, 5.99%; M^+, 208. Calcd for $C_{11}H_{10}O_4$: C, 63.45; H, 5.81%; M, 208.

Cycloaddition of 1 to 8a Leading to 10a, 11a, and 12a. A solution of **1** (0.43 g, 1.29 mmol) and **8a** (0.333 g, 3.0 mmol) in dry benzene (1.5 ml) was stirred at room temperature under nitrogen for 48 h. The benzene was evaporated *in vacuo* and the residue was treated with methanol (10 ml) at room temperature overnight. The methanol was removed *in vacuo* to afford a viscous residue, it was treated with water, extracted with chloroform, the chloroform was dried over magnesium sulfate, and finally evaporated *in vacuo*. Trituration of the viscous oil obtained with ether–hexane gave 0.089 g (23%) of **11a**.

11a: Colorless prisms from ether–hexane; mp 163—165 °C; IR (KBr) 1775, 1700 (C=O), and 1610 cm^{-1}; ^1H-NMR ($CDCl_3$) δ=2.04 (3H, s, COMe), 2.38 (3H, s, NMe), 2.80 (1H, dd, J_{gem}=21.0 and J_{7-7a}=12.5 Hz, one of 7-CH_2), 3.00—3.45 (3H, m, the other of 7-CH_2, 3a-, and 7a-H), 4.38 (1H, d, J_{4-3a}=6.0 Hz, 4-H), and 6.80—7.30 (5H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=24.07 (7-C), 24.54 (NMe), 27.53 (COMe), 37.05, 41.33 (3a- and 7a-C), 46.15 (4-C), 108.38 (5-C), 127.99, 128.40, 128.69, 137.20, 176.84 (CON-), 178.01 (CON-), 182.71 (COMe), and 197.03 (6-C); MS *m/z* (rel. intensity) 299 (M^+, 27), 281 (25), 256 (19), 131 (22), 126 (30), 115 (26), and 77 (22).

Found: C, 68.37; H, 5.80; N, 4.63%; M^+, 299. Calcd for $C_{17}H_{17}NO_4$: C, 68.21; H, 5.73; N, 4.68%; M, 299.

A solution of **1** (0.475 g, 1.43 mmol) and **8a** (0.477 g, 4.29 mmol) in dry benzene (5 ml) was refluxed under nitrogen for 72 h. The benzene was evaporated *in vacuo* to give a residue which solidified on treatment with methanol (15 ml). This colorless solid of **10a** (0.21 g) was collected on a filter and washed with another 5 ml of methanol. The combined methanol filtrate was stirred at room temperature overnight, evaporated *in vacuo*, and the residue obtained was chromatographed over silica gel. The fraction with chloroform–hexane (2:1) gave 0.055 g of mixture between **11a** (2%) and **12a** (3%), from which only **12a** was isolated by crystallization from ether–hexane. The fraction with chloroform–ethyl acetate 19:1 afforded 0.14 g of **10a**. Total amount of **10a** was 0.35 g (60%).

10a: Colorless prisms from benzene–hexane; mp 213—215 °C; IR (KBr) 1760, 1675 (C=O), and 1420 cm^{-1}; ^1H-NMR ($CDCl_3$) δ=2.33 (3H, s, NMe), 2.53 (1H, dd, J_{gem}=17.0 and J_{10-9a}=9.0 Hz, one of 10-CH_2), 2.95 (1H, dd, J_{gem}=17.0 and J_{10-9a}=4.5 Hz, the other of 10-CH_2), 3.04 (3H, s, NMe), 3.20—3.75 (5H, m, 4-CH_2, 3a-, 6a-, and 9a-H), 3.92 (1H, d, J_{10b-3a}=8.0 Hz, 10b-H), 4.70 (1H, dd, J_{6-6a}=6.0 and J_{6-9a}=2.0 Hz, 6-H), and 6.70—7.22 (5H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=23.90 (t, 10-C), 25.36, 25.48 (each q, NMe), 34.64 (t, 4-C), 36.99, 38.34 (each d, 3a-, 6a-, and 9a-C), 44.09 (d, 10b-C), 44.50 (d, 6-C), 127.75 (d), 128.46 (d), 135.80 (s), 136.27 (s), 146.13 (s), 174.37, 176.66, 178.59 (each s, CON-), and 190.98 (s, 5-CO); MS *m/z* (rel. intensity) 393 (M^++1, 33), 392 (M^+, base peak), 374 (59), 289 (35), 280 (29), 203 (25), 178 (28), 167 (22), 165 (28), and 115 (25).

Found: C, 67.59; H, 5.25; N, 7.14%; M^+, 392. Calcd for $C_{22}H_{20}N_2O_5$: C, 67.33; H, 5.14; N, 7.14%; M, 392.

12a: Colorless solid from ether–hexane; mp 126—128 °C; IR (KBr) 3420 (OH) and 1690 cm^{-1} (C=O); ^1H-NMR ($CDCl_3$) δ=2.11 (3H, s, COMe), 2.54 (1H, dd, J_{gem}=19.5 and J_{7-7a}= 9.0 Hz, one of 7-CH_2), 2.76 (1H, dd, J_{gem}=19.5 and J_{7-7a}=2.3 Hz, the other of 7-CH_2), 3.00 (3H, s, NMe), 3.19 (1H, dt, J_{7a-7}=J_{7a-3a}=9.0 and J_{7a-7}=2.3 Hz, 7a-H), 3.60 (1H, dd, J_{3a-7a}=9.0 and J_{3a-4}=2.0 Hz, 3a-H), 4.68 (1H, d, J_{4-3a}=2.0 Hz, 4-H), and 7.04—7.43 (5H, m, ArH); MS *m/z* (rel. intensity) 300 (M^++1, 17), 299 (M^+, 87), 281 (base peak), 170 (32), 142 (28), and 126 (42).

Found: C, 68.37; H, 5.79; N, 4.80%; M^+, 299. Calcd for $C_{17}H_{17}NO_4$: C, 68.21; H, 5.73; N, 4.68%; M, 299.

Cycloaddition of 1 to 8b Leading to 10b, 11b, and 12b. A solution of **1** (0.665 g, 2.0 mmol) and **8b** (0.692 g, 4.0 mmol) in 6 ml of dry benzene was stirred at room temperature under nitrogen for 120 h. The benzene was evaporated *in vacuo* and the residue was treated with methanol (15 ml) overnight to precipitate 0.18 g (26%) of **11b** which was collected and washed with another portion (5 ml) of methanol. The combined methanol filtrate was evaporated *in vacuo* and the viscous oil obtained was triturated with ether to give 0.135 g (13%) of **10b**.

10b: Colorless solid from chloroform–hexane; mp 278—280 °C; IR (KBr) 1770, 1700 (C=O), 1585, 1375, and 1175 cm^{-1}; ^1H-NMR ($CDCl_3$) δ=2.63 (1H, dd, J_{gem}=16.5 and J_{10-9a}=9.0 Hz, one of 10-CH_2), 3.05 (1H, dd, J_{gem}=16.5 and J_{10-9a}=5.5 Hz, the other of 10-CH_2), 3.20—3.85 (5H, m, 4-CH_2, 3a-, 6a-, and 9a-H), 3.96 (1H, d, J_{10b-3a}=8.0 Hz, 10b-H), 4.86 (1H, d, J_{6-6a}=6.5 Hz, 6-H), and 6.37—7.60 (15H, m, ArH); MS *m/z* 516 (M^+).

Found: C, 74.13; H, 4.82; N, 5.32%; M+, 516. Calcd for $C_{32}H_{24}N_2O_5$: C, 74.40; H, 4.68; N, 5.42%; M, 516.

11b: Colorless needles from ether-hexane; mp 188—190 °C; IR (KBr) 1770, 1700 (C=O), 1600, 1380, 740, and 695 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.05 (3H, s, COMe), 2.88 (1H, m, one of 7-CH_2), 3.20—3.62 (3H, m, the other of 7-CH_2, 3a-, and 7a-H), 4.48 (1H, m, 4-H), 6.40—7.32 (10H, m, ArH), and 16.02 (1H, s, OH); ^{13}C-NMR ($CDCl_3$) δ=24.72 (q, COMe), 27.53 (t, 7-C), 37.28, 41.57 (each d, 3a- and 7a-C), 45.62 (d, 4-C), 108.73 (s, 5-C), 126.23 (d), 128.11 (d), 128.69 (d), 128.93 (d), 129.10 (d), 131.10 (s), 137.56 (s), 175.66, 177.18 (each s, CON-), 182.00 (s, COMe), and 197.62 (s, 6-C); MS *m/z* (rel. intensity) 362 (M^++1, 26), 361 (M^+, base peak), 343 (57), 318 (47), 199 (27), 188 (48), 131 (32), 91 (29), and 77 (23).

Found: C, 72.94; H, 5.56; N, 3.87%; M+, 361. Calcd for $C_{22}H_{19}NO_4$: C, 73.11; H, 5.30; N, 3.88%; M, 361.

A mixture of **1** (0.345 g, 1.04 mmol) and **8b** (0.519 g, 3.0 mmol) in dry benzene (6 ml) was refluxed under nitrogen for 48 h. The benzene was removed off *in vacuo*, the residue was treated with methanol (15 ml) at room temperature for 5 h, the methanol was completely evaporated *in vacuo*, and finally the viscous oil obtained was chromatographed over silica gel. The fraction with chloroform gave 0.042 g of mixtrure of **11b** (3%) and **12b** (6%), from which only **12b** was isolated by crystallization from chloroform-hexane. Continued elution with chloroform-ethyl acetate (9:1) afforded 0.43 g (80%) of **10b**.

12b: Colorless prisms from ether-hexane; mp 204—206 °C; IR (KBr) 3400 (OH), 1700 (C=O), and 1380 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.13 (3H, s, COMe), 2.60 (1H, dd, J_{gem}=16.5 and J_{7-7a}=8.5 Hz, one of 7-CH_2), 2.84 (1H, dd, J_{gem}=16.5 and J_{7-7a}=2.0 Hz, the other of 7-CH_2), 3.34 (1H, ddd, J_{7a-7}=8.5, J_{7a-7}=2.0, and J_{7a-3a}=9.0 Hz, 7a-H), 3.82 (1H, dd, J_{3a-7a}=9.0 and J_{3a-4}=2.0 Hz, 3a-H), 4.77 (1H, d, J_{4-3a}=2.0 Hz, 4-H), 7.00—7.56 (10H, m, ArH), and 15.86 (1H, s, OH); ^{13}C-NMR ($CDCl_3$) δ=22.54 (COMe), 33.35 (7-C), 38.28, 39.99 (3a- and 7a-C), 46.26 (4-C), 107.09 (5-C), 126.28, 126.64, 127.28, 128.87, 129.22, 131.57, 139.79, 177.36 (CON-), 188.40 (COMe), and 191.87 (6-C); MS *m/z* 361 (M^+).

Found: C, 73.07; H, 5.33; N, 3.80%; M+, 361. Calcd for $C_{22}H_{19}NO_4$: C, 73.11; H, 5.30; N, 3.88%; M, 361.

Cycloaddition of ***1*** *to* ***9*** *Leading to* ***1(X=O)***, ***13***, ***14***, *and* ***15***. A solution of **1** (0.267 g, 0.83 mmol) and **9** (0.174 g, 1.77 mmol) in dry benzene (5 ml) was refluxed under nitrogen for 48 h. The benzene was evaporated off *in vacuo* and the residue was heated under reflux in methanol (60 ml) in the presence of *p*-toluenesulfonic acid (0.2 g) for 24 h. The methanol was removed off *in vacuo*, the residue was treated with water, extracted with ether, the ether was dried over magnesium sulfate, and finally evaporated *in vacuo* to give a viscous oil. This oil was chromatographed over silica gel using chloroform-hexane (1:2) as an eluent. The first fraction gave 0.02 g (7%) of **15** and the second 0.263 g of mixture between **13** (57%) and **14** (22%) which were separated by repeated chromatography over silica gel with ether-hexane (1:1) and crystallization.

13: Colorless needles from hexane; mp 141—143 °C; IR (KBr) 1720, 1650 (C=O), 1430, 1200, 1170, and 1000 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.25—3.85 (9H, m, CH_2 and CH), 3.10, 3.62, 3.70 (each 3H, s, COOMe), 4.13 (1H, br. d, J_{8-7}=7.5 Hz, 8-H), and 6.80—7.30 (5H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ= 30.65 (t), 33.47 (t), 38.46, 39.51, 40.51, 42.27, 46.09, 51.02 (q), 52.13 (q), 126.35 (d), 127.34 (d), 127.93 (d), 132.62 (s), 140.61 (s), 155.58 (s), 171.90 (s), 172.67 (s), 173.25 (s), and 193.86 (s); MS *m/z* (rel. intensity) 401 (M^++1, 25), 400 (M^+, base peak), 341 (17), 340 (34), 281 (52), 249 (29), and 221 (47).

Found: C, 65.75; H, 6.08%; M+, 400. Calcd for $C_{22}H_{24}O_7$: C, 65.99; H, 6.04%; M, 400.

14: Colorless solid from hexane; mp 114—116 °C; IR (KBr) 1740, 1725, 1660 (C=O), 1440, 1200, and 1040 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.35—3.50 (9H, m, CH_2 and CH), 3.15, 3.59, 3.75 (each 3H, s, COOMe), 4.14 (1H, br. d, J_{8-7}=7.0 Hz, 8-H), and 6.90—7.30 (5H, m, ArH); MS *m/z* (rel. intensity) 401 (M^++1, 45), 400 (M^+, base peak), 369 (27), 340 (33), 309 (66), 281 (78), 277 (25), 249 (59), and 221 (91).

Found: C, 65.95; H, 6.15%; M+, 400. Calcd for $C_{22}H_{24}O_7$: C, 65.99; H, 6.04%; M, 400.

15: Colorless prisms from ether-hexane; mp 153—155 °C; IR (KBr) 1720 (C=O), 1600, and 1250—1200 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.90 (3H, s, COMe), 2.48—2.97 (2H, m, one of 6-CH_2 and 5-H), 3.06 (1H, dd, J_{gem}=20.0 and J_{6-5}=12.6 Hz, the other of 6-CH_2), 3.37 (1H, dd, J_{4-3}=2.3 and J_{4-5}= 3.2 Hz, 4-H), 3.62, 3.70 (each 3H, s, COOMe), 4.50 (1H, d, J_{3-4}=2.3 Hz, 3-H), 7.10—7.40 (5H, m, ArH), and 15.95 (1H, s, OH); ^{13}C-NMR ($CDCl_3$) δ=25.42 (q, COMe), 29.36 (t, 6-C), 34.64, 42.33 (each d, 4- and 5-C), 48.50 (d, 3-C), 52.08, 52.37 (each q, COOMe), 106.27 (s, 2-C), 127.34 (d), 127.75 (d), 128.98 (d), 142.55 (s), 171.67, 172.61 (each s, COOMe), 179.95 (s, COMe), and 200.90 (s, 1-C); MS *m/z* (rel. intensity) 332 (M^+, 5), 301 (M^+—31, 3), 213 (21), 115 (26), 59 (20), and 43 (base peak).

Found: C, 65.19; H, 6.12%; M+ 332. Calcd for $C_{18}H_{20}O_6$: C, 65.05; H, 6.07%; M, 332.

A solution of **1** (0.37 g, 1.11 mmol) and **9** (0.226 g, 2.3 mmol) in dry benzene (5 ml) was refluxed under nitrogen for 48 h. The residue obtained by evaporation of the benzene *in vacuo* was triturated with benzene-hexane (1:9) to give 0.48 g (82%) of **I** (X=O) as colorless solid. The product **I** was found to contain two isomers (2.5:1) on the basis of ^{1}H-NMR spectrum (δ_{TMS}: the major isomer: 0.00 and 0.26; the minor isomer: −0.30 and 0.27). The bis-cyclo-adduct mixture **I** (X=O) (0.265 g, 0.5 mmol) was heated in water (30 ml) under reflux for 24 h. The water was evaporated to dryness *in vacuo* and the residue was washed with benzene to give 0.17 g (95%) of tricarboxylic acid. This acid (0.155 g, 0.43 mmol) was heated under reflux in methanol (100 ml) in the presence of *p*-toluenesulfonic acid (0.15 g) for 48 h. The methanol was evaporated *in vacuo*, the residue was treated with water, extracted with ether, the ether was washed with aqueous sodium hydrogencarbonate, dried over magnesium sulfate, and evaporated *in vacuo*. The residue was chromatographed over silica gel using ether-hexane (1:1) as an eluent to give 0.088 g (51%) of **13** and 0.033 g (19%) of **14**.

Similarly, **1** (0.70 g, 2.1 mmol) and **9** (0.149 g, 1.52 mmol) were stirred in dry benzene (2 ml) at room temperature under nitrogen for 72 h. The reaction mixture was added to a large quantity of hexane to precipitate colorless solid of **I** (0.25 g, 63%) which was composed of two isomers (3:1).

Cycloaddition of ***2*** *to an Equivalent of* ***8a*** *Leading to* ***16a***. A mixture of **1** (0.662 g, 2.3 mmol) and **8a** (0.257 g, 2.3 mmol) in 1 ml of dry benzene was stirred at room temperature under nitrogen for 24 h. After evaporation of the solvent *in vacuo*, the residue was treated with methanol (15 ml) at room temperature overnight to precipitate 0.278 g of **16a**. The methanol separated from the solid was evaporated completely *in vacuo* and the viscous oil obtained was chromatographed over silica gel with hexane-ethyl acetate (3:1) to give 0.048 g of **16a**. Total amount of **16a** was 0.326 g (64%).

16a: Colorless needles from aqueous methanol; mp 186 °C; IR (KBr) 1755, 1685 (C=O), and 1640-1580 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.28 (3H, s, COMe), 2.54 (1H, dd, J_{gem}=17.0 and J_{7-7a}=15.0 Hz, one of 7-CH_2), 3.02 (1H, dd, J_{gem}=17.0 and J_{7-7a}=7.0 Hz, the other of 7-CH_2), 3.05 (3H, s, NMe), 3.60 (1H, ddd, J_{7a-7}=15.0, 7.0, and J_{7a-4}=2.5 Hz, 7a-H), 7.32 (1H, d, J_{4-7a}=2.5 Hz, 4-H), and 15.94 (1H, s, OH); ^{13}C-NMR ($CDCl_3$) δ=20.35 (q, COMe), 24.77 (q, NMe), 35.18 (t, 7-C),

38.12 (d, 7a-C), 108.01 (s, 5-C), 119.77 (s, 3a-C), 127.07 (d, 4-C), 167.83, 174.89 (each s, CON-), 186.07 (s, COMe), and 199.19 (s, 6-C); MS *m/z* 221 (M^+, base peak).

Found: C, 59.77; H, 4.93; N, 6.26%; M^+, 221. Calcd for $C_{11}H_{11}NO_4$: C, 59.73; H, 5.01; N, 6.33%; M, 221.

Cycloaddition of **2** *to two Equivalents of* **8a** *Leading to* **17a** *and* **18a**. Triene **2** (0.989 g, 3.5 mmol) and **8a** (0.767 g, 7.0 mmol) were heated under reflux in dry benzene (3 ml) under nitrogen for 24 h. After cooled to room temperature, the solution was treated with 10 ml of hexane at room temperature for 0.5 h to precipitate 1.104 g (63%) of **17a**. To a solution of **17a** (0.204 g, 0.4 mmol) in 2.5 ml of dry benzene was added a drop of trifluoroacetic acid, and immediately colorless solid of **18a** was precipitated (0.125 g, 90%).

17a: Colorless solid; mp 185—187 °C; IR (KBr) 1775, 1700 (C=O), 1250, and 880 cm^{-1} (TMS); ^{1}H-NMR ($CDCl_3$) δ=0.15, 0.21 (each 9H, s, TMS), 2.26—3.65 (8H, m, CH_2 and CH), 2.88, 2,96 (each 3H, s, NMe), 3.09 (3H, s, OMe), and 4.70 (1H, d, J_{6-6a}=3.6 Hz, 6-H); ^{13}C-NMR ($CDCl_3$) δ=0.17, 2.17 (each q, TMS), 24.66, 24.95 (each q, NMe), 29.59, 33.35 (each t, 4- and 10-C), 36.17, 39.04, 44.50, 54.01 (each d, 3a-, 6a-, 9a-, and 10b-C), 55.72 (q, OMe), 71.10 (d, 6-C), 73.86 (s, 10a-C), 113,84 (s, 5a-C), 152.35 (s, 5-C), 175.72, 177.13, 179.01, and 180.47 (each s, CON-); MS *m/z* 508 (M^+), 493 (M^+-15), and 73 (base peak).

Found: C, 54.37; H, 7.14; N, 5.37%; M^+ 508. Calcd for $C_{23}H_{36}N_2O_7Si_2$: C, 54.30; H, 7.13; N, 5.51%; M, 508.

18a: Colorless prisms; mp 180—182 °C; IR (KBr) 1780 and 1720—1640 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.50—3.90 (8H, m, CH_2 and CH), 2.97, 3.00 (each 3H, s, NMe), 3.05 (3H, s, OMe), and 5.00 (1H, d, J_{6-6a}=4.0 Hz, 6-H); ^{13}C-NMR ($CDCl_3$) δ=24.83, 25.42 (each q, NMe), 26.42, 34.05 (each t, 4- and 10-C), 36.64, 37.57, 43.97, 45.91 (each d, 3a-, 6a-, 9a-, and 10b-C), 57.54 (q, OMe), 68.46 (d, 6-C), 135.15 (s, 5a-C), 153.00 (s, 10a-C), 173.72, 175.83, 176.71, 178.83 (each s, CON-), and 191.04 (s, 5-CO), MS *m/z* 346 (M^+), 331, 316 (base peak), and 314 (M^+-32).

Found: C, 58.94; H, 5.19; N, 8.47%; M^+, 346. Calcd for $C_{17}H_{18}N_2O_6$: C, 58.96; H, 5.24; N, 8.09%; M, 346.

Cycloaddition of **2** to an Equivalent of **8b** *Leading to* **16b**. A solution of **2** (0.741 g, 2.6 mmol) and **8b** (0.448 g, 2.6 mmol) in dry benzene (2 ml) was stirred at room temperature under nitrogen for 20 h and the benzene was evaporated *in vacuo*. When the residue was treated with methanol (15 ml), colorless solid of **16b** (0.536 g, 73%) was immediately separated.

16b: Colorless leaflets from dichloromethane-methanol; mp 227 °C; IR (KBr) 1765 and 1710—1610 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.25 (3H, s, COMe), 2.64 (1H, dd, J_{gem}=16.2 and J_{7-7a}=14.4 Hz, one of 7-CH_2), 3.07 (1H, dd, J_{gem}=16.2 and J_{7-7a}=7.1 Hz, the other of 7-CH_2), 3.73 (1H, ddd, J_{7a-7}=14.4, 7.1, and J_{7a-4}=2.4 Hz, 7a-H), 7.22 (1H, d, J_{4-7a}=2.4 Hz, 4-H), 7.20—7.50 (5H, m, ArH), and 16.00 (1H, s, OH); MS *m/z* 283 (M^+) and 136 (base peak).

Found: C, 67.83; H, 4.54; N, 5.05%; M^+, 283. Calcd for $C_{16}H_{13}NO_4$: C, 67.84; H, 4.63; N, 4.94%; M, 283.

Cycloaddition of **2** *to two Equivalents of* **8b** *Leading to* **17b** *and* **18b**. Triene **2** (0.515 g, 1.8 mmol) and **8b** (0.623 g, 3.6 mmol) in dry benzene (2 ml) was heated at 50 °C under nitrogen for 20 h. After cooled to room temperature, the reaction mixture was triturated with 6 ml of hexane to separate colorless precipitation of **17b** (0.704 g, 62%). To a solution of **17b** (0.19 g, 0.3 mmol) in 2.5 ml of dry benzene was added a drop of trifluoroacetic acid. The mixture was stirred at room temperature for 15 min and treated with hexane to precipitate 0.125 g (89%) of **18b**.

17b: Colorless solid; mp 188—190 °C; IR (KBr) 1775, 1705 (C=O), 1250, and 845 cm^{-1} (TMS); ^{1}H-NMR ($CDCl_3$) δ=0.19, 0.25 (each 9H, s, TMS), 2.48—3.80 (8H, m, CH_2 and CH), 3.20 (3H, s, OMe), 4.91 (1H, d, J_{6-6a}=3.5 Hz, 6—H), and 7.00—7.52 (10H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=1.00, 2.23 (each q, TMS), 29.77, 33.35 (each t, 4- and 10-C), 36.46, 39.16, 44.91, 54.01 (each d, 3a-, 6a-, 9a, and 10b-C), 55.95 (q, OMe), 71.74 (d, 6-C), 74.03 (s, 10a-C), 113.66 (s, 5a-C), 126.23, 126.64, 128.34, 128.98, 129.28, 131.51, 132.27, 152.76 (s, 5-C), 174.89, 176.30, 178.01, and 179.48 (each s, CON-); MS *m/z* 632 (M^+), 617 (M^+-15), and 73 (base peak).

Found: C, 62.64; H, 6.37; N, 4.65%; M^+, 632. Calcd for $C_{33}H_{40}N_2O_7Si_2$: C, 62.63; H, 6.37; N, 4.43%; M, 632.

18b: Colorless prisms; mp 148—150 °C; IR (KBr) 1775 and 1720—1660 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.45—3.92 (8H, m, CH_2 and CH), 3.12 (3H, s, OMe), 5.10 (1H, d, J_{6-6a}=4.0 Hz, 6-H), and 7.10—7.60 (10H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=26.36, 34.23 (each t, 4- and 10-C), 36.34, 37.93, 44,03, 45.85 (each d, 3a-, 6a-, 9a-, and 10b-C), 57.65 (q, OMe), 68.75 (d, 6-C), 126.05, 126.52, 128.22, 128.63, 129.10, 129.22, 131.10, 131.92, 134.97 (s, 5a-C), 152.76 (s, 10a-C), 172.67, 175.01, 175.48, 178.07 (each s, CON-), and 190.86 (s, 5-CO); MS *m/z* 438 (M^+-32).

Found: C, 68.45; H, 4.61; N, 6.05%. Calcd for $C_{27}H_{22}N_2O_6$: C, 68.93; H, 4.71; N, 5.95%.

Cycloaddition of **2** *to an Equivalent of* **9** *Leading to* **19**, **20**, *and* **21**. A mixture of **2** (0.904 g, 3.2 mmol) and **9** (0.309 g, 3.2 mmol) was allowed to stand at room temperature for 10 min. ^{1}H-NMR measurement of this mixture showed that **19** was formed in a quantitative yield. It was isolated as unstable liquid by vacuum distillation on a micro distillation apparatus (0.469 g, 39%). To the mixture of each equivalent of **2** and **9** was added a drop of trifluoroacetic acid, and then hexane to precipitate colorless solid of **20**.

19: Yellow liquid; bp 180 °C (133 Pa) (bulb-to-bulb); IR (neat) 1860, 1785 (C=O), 1250, and 850 cm^{-1} (TMS); ^{1}H-NMR ($CDCl_3$) δ=0.24 (18H, s, TMS), 2.48 (1H, dd, J_{gem}=16.5 and J_{7-7a}=10.0 Hz, one of 7-CH_2), 2.85 (1H, dd, J_{gem}=16.5 and J_{7-7a}=7.5 Hz, the other of 7-CH_2), 3.12 (1H, dd, J_{3a-4}=3.5 and J_{3a-7a}=10.0 Hz, 3a-H), 3.17 (3H, s, OMe), 3.47 (1H, dt, J_{7a-7}=7.5, 10.0 and J_{7a-3a}=10.0 Hz, 7a-H), 4.37, 4.63 (each 1H, d, J_{gem}=1.0 Hz, =CH_2), and 4.65 (1H, d, J_{4-3a}=3.5 Hz, 4-H); ^{13}C-NMR ($CDCl_3$) δ=0.59, 0.94 (each s, TMS), 28.42 (t, 7-C), 37.28, 47.26 (each d, 3a- and 7a-C), 55.83 (q, OMe), 73.27 (d, 4-C), 93.82 (t, =CH_2), 114.60 (s, 5-C), 151.36 (s, 6-C), 171.02, and 173.90 (each s, COO-); MS *m/z* 384 (M^+), 369 (M^+-15), and 73 (base peak).

20: Colorless needles from chloroform; mp 117—118 °C; IR (KBr) 1850, 1770 (C=O), and 1600 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.20 (3H, s, COMe), 2.54 (1H, dd, J_{gem}=16.5 and J_{7-7a}=9.0 Hz, one of 7-CH_2), 2.96 (1H, dd, J_{gem}=16.5 and J_{7-7a}=8.0 Hz, the other of 7-CH_2), 3.14 (3H, s, OMe), 3.26 (1H, dd, J_{3a-4}=3.0 and J_{3a-7a}=11.0 Hz, 3a-H), 3.55 (1H, m, 7a-H), 4.70 (1H, d, J_{4-3a}=3.0 Hz, 4-H), and 15.80 (1H, s, OH); ^{13}C-NMR ($CDCl_3$) δ=20.20 (q, COMe), 32.53 (t, 7-C), 35.53, 47.14 (each d, 3a- and 7a-C), 55.31 (q, OMe), 73.45 (d, 4-C), 105.27 (s, 5-C), 170.55, 173.01 (each s, COO-), 185.17 (s, COMe), and 195.91 (s, 6-C); MS *m/z* 240 (M^+), 209 (M^+-31), and 43 (base peak).

Found: C, 55.27; H, 5.03%; M^+, 240. Calcd for $C_{11}H_{12}O_6$: C, 55.00; H, 5.04%; M, 240.

Crude **19**, which had been prepared from **2** (0.749 g, 2.6 mmol) and **9** (0.256 g, 2.6 mmol), was heated under reflux in methanol (50 ml) in the presence of *p*-toluenesulfonic acid (0.1 g) for 24 h. The methanol was evaporated *in vacuo* and the residue was dissolved in ether. The ether was washed with aqueous sodium hydrogencarbonate (5%), dried over magnesium sulfate, and then evaporated *in vacuo* to give viscous oil which was chromatographed over silica gel using chloroform–ethyl acetate (9:1). Colorless solid of **21** was obtained (0.371 g, 56%).

21: Colorless needles from hexane; mp 92—92.5 °C; IR

(KBr) 1725, 1690 (C=O), and 1610 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.14 (3H, s, COMe), 2.71 (1H, dd, J_{gem}=17.5 and J_{6-5}=7.0 Hz, one of 6-CH_2), 2.94 (1H, dd, J_{gem}=17.5 and J_{6-5}=3.2 Hz, the other of 6-CH_2), 3.64, 3.77 (each 3H, s, COOMe), 3.94 (1H, dd, J_{5-6}=7.0 and 3.2 Hz, 5-H), 7.54 (1H, s, 3-H), and 15.94 (1H, s, OH); ^{13}C-NMR ($CDCl_3$) δ=19.96, 37.22, 38.40, 51.96, 52.49, 107.13, 117.48, 134.56, 166.20, 172.37, 184.76, and 198.14; MS *m/z* 254 (M^+) and 195 (M^+−59, base peak).

Found: C, 56.59; H, 5.51%; M^+, 254. Calcd for $C_{12}H_{14}O_6$: C, 56.69; H, 5.55%; M, 254.

Cycloaddition of 2 to two Equivalents of 9 Leading to K. The reaction of **2** (0.10 g, 0.3 mmol) with **9** (0.068 g, 0.6 mmol) in benzene-d_6 (3 ml) was followed by ^{1}H-NMR spectroscopy. After 4 h at room temperature, both the starting materials were consumed and the following signals were observed: δ=0.06, 0.11 (each 9H, s, TMS), 2.10—3.50 (8H, m, CH_2 and CH), 3.00 (3H, s, OMe), and 4.75 (1H, d, J_{6-6a}=3.5 Hz, 6-H).

Cycloaddition of 1 to 22 Leading to 15. A solution of **1** (0.53 g, 1.59 mmol) and **22** (1.44 g, 10.0 mmol) in dry benzene (5 ml) was refluxed under nitrogen for 7 d. The usual work-up with methanol as described above and the followed column chromatography over silica gel gave 0.25 g (45%) of **15**.

Cycloaddition of 1 to 23a Leading to 24a, 25a, and 26. A solution of **1** (0.365 g, 1.1 mmol) and **23a** (0.476 g, 3.3 mmol) in dry benzene (5 ml) was refluxed under nitrogen for 7 d. After evaporation of all the volatile materials *in vacuo*, the residue was treated with methanol (10 ml) at room temperature overnight. The methanol was evaporated off *in vacuo* and the viscous oil obtained was chromatographed over silica gel. The fraction eluted with chloroform-hexane (1:1) afforded a mixture (0.24 g, 65%) of **24a** and **25a**. The ratio was determined by ^{1}H-NMR spectroscopy (**24a**: 55%; **25a**: 11%). They were separated into each isomer by a preparative thin-layer chromatography (silica gel) using chloroform as an eluent and purified by crystallization. The fraction with chloroform gave 0.13 g (25%) of **26**.

24a: Colorless prisms from ether-hexane; mp 83—84 °C; IR (KBr) 3400 (OH), 1725 (C=O), 1600, and 1240 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.77 (3H, s, COMe), 2.50—3.32 (4H, m, 6-CH_2, 4-, and 5-H), 3.32, 3.65 (each 3H, s, COOMe), 4.32 (1H, m, 3-H), and 7.00—7.40 (5H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=26.01 (s, COMe), 30.88 (t, 6-C), 39.10, 42.86 (each d, 4- and 5-C), 50.49 (d, 3-C), 51.96, 52.31 (each s, COOMe), 107.79 (s, 2-C), 127.05, 127.81, 128.09, 142.55 (s), 172.31, 173.19 (each s, COOMe), 179.30 (s, COMe), and 200.56 (s, 1-C); MS *m/z* 332 (M^+), 257, 195, 115, and 43 (base peak).

Found: C, 65.14; H, 6.09%; M^+, 332. Calcd for $C_{18}H_{20}O_6$: C, 65.05; H, 6.07%; M, 332.

25a: Colorless prisms from ether-hexane; mp 153—155 °C; IR (KBr) 3400 (OH), 1725 (C=O), 1600, and 1230 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.90 (3H, s, COMe), 2.58 (1H, dd, J_{gem}=18.5 and J_{6-5}=11.3 Hz, one of 6-CH_2), 2.70—3.40 (3H, m, the other of 6-CH_2, 4-, and 5-H), 3.53, 3.65 (each 3H, s, COOMe), 4.31 (1H, d, J_{3-4}=5.0 Hz, 3-H), and 7.10-7.35 (5H, m, ArH); MS *m/z* (rel. intensity) 332 (M^+, 20), 314 (21), 301 (26), 289 (62), 257 (45), 213 (26), 195 (25), and 43 (base peak).

Found: C, 64.88; H, 6.21%; M^+, 332. Calcd for $C_{18}H_{20}O_6$: C, 65.05; H, 6.07%; M, 332.

26: Colorless liquid as a mixture of two isomeric bis-adducts (the isomer ratio was about 6—7:1). The spectral data for the major product are given as follows: ^{1}H-NMR ($CDCl_3$) δ=2.40—4.00 (8H, m, CH_2 and CH), 3.32, 3.57, 3.67, 3.83 (each 3H, s, COOMe), 4.26 (1H, br. d, J_{8-7}=5.5 Hz, 8-H), and 6.80—7.30 (5H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ= 31.00, 37.13 (each t, 2- and 5-C), 39.67, 41.42, 42.35, 48.68 (each d, 3-, 4-, 6-, and 7-C), 49.61 (d, 8-C), 52.00, 52.53, 52.87 (each q, COOMe), 126.55, 127.53, 128.31, 134.50, 141.90, 149.40 (s, 4a-C), 170.99, 172.06, 172.70, 173.33 (each s, COOMe), and 192.48 (s, 1-CO); MS *m/z* 459 (M^+).

Found: C, 63.66; H, 5.78%; M^+, 459. Calcd for $C_{24}H_{26}O_9$: C, 63.87; H, 5.72%; M, 459.

Similar reaction of **1** (1.57 g, 4.72 mmol) with **23a** (2.16 g, 15.0 mmol) under reflux in dry toluene (10 ml) for 7 d and the same work-up as mentioned gave a mixture of **24a** (10%) and **25a** (2%), and **26** (88%).

Cycloaddition of 1 to 23b Leading to 24b and 25b. Triene **1** (0.75 g, 2.25 mmol) and **23b** (0.527 g, 6.75 mmol) in toluene (6 ml) were allowed to react under the conditions shown in Table 3. The usual work-up with methanol and the followed chromatography over silica gel with chloroform afforded a mixture (0.386 g, 64%) of **24b** and **25b**. The isomer ratio was found be 2:11 (**24b**: 10%; **25b**: 55%). Only the major product **25b** was isolated as colorless solid which solidified when the above mixture was treated with methanol.

25b: Colorless needles from methanol; mp 210—211.5 °C; IR (KBr) 3400 (OH), 2250 (CN), and 1590 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.76 (3H, s, COMe), 2.80—3.00 (4H, m, 6-CH_2, 4-, and 5-H), 4.33 (1H, d, J_{3-4}=8.5 Hz, 3-H), and 7.10—7.44 (5H, m, ArH); MS *m/z* (rel. intensity) 267 (M^++1, 12), 266 (M^+, 40), 248 (61), 221 (26), 195 (21), 170 (28), 168 (36), 167 (26), 155 (27), 145 (28), 117 (27), 81 (24), and 43 (base peak).

Found: 71.88; H, 5.20; N, 10.28%; M^+, 266. Calcd for $C_{16}H_{14}N_2O_2$: C, 72.16; H, 5.30; N, 10.52%, M, 266.

Cycloaddition of 2 to 22 Leading to M and 21. A mixture of **2** (0.779 g, 2.7 mmol) and **22** (0.392 g, 2.7 mmol) in dry benzene (3 ml) was heated under reflux under nitrogen for 48 h. The benzene was evaporated *in vacuo*, the residue was treated with methanol (15 ml) at room temperature overnight, and the methanol was removed off *in vacuo*. Viscous oil obtained was chromatographed over silica gel using chloroform-ethyl acetate (9:1) to give 0.293 g (42%) of **21** which was identical with a product given in the reaction of **2** with maleic anhydride **9**.

Similar reaction of **2** with three equivalents of **22** was carried out under reflux in dry benzene for 72 h. After all the volatile materials were removed off *in vacuo*, the residue was submitted for ^{1}H-NMR measurement. The spectrum showed the quantitative formation of exo mono-cycloadduct M: ^{1}H-NMR ($CDCl_3$) δ=0.18, 0.23 (each 9H, s, TMS), 2.20—3.50 (4H, m, 6-CH_2, 4-, and 5-H), 3.37 (3H, s, OMe), 3.60, 3.69 (each 3H, s, COOMe), 4.40, 4.60 (each 1H, s, =CH_2), and 4.48 (1H, d, J_{3-4}=2.8 Hz, 3-H).

Cycloaddition of 2 to 23a Leading to 21. Similar reaction starting from **2** (0.461 g, 1.6 mmol) and **23a** (0.234 g, 1.6 mmol) under the conditions shown in Table 3 and the same work-up as mentioned above gave 0.336 g (82%) of **21**.

Cycloaddition of 1 to 27a Leading to 28a and 29a. Triene **1** (0.92 g, 2.72 mmol) and **27a** (5 ml, large excess) in dry benzene (3 ml) were refluxed under nitrogen for 6 d. After all the volatile materials were evaporated *in vacuo*, the residue was treated with methanol (20 ml) at room temperature overnight. The methanol was removed off *in vacuo* and the residue was chromatographed over silica gel using chloroform-hexane (1:1) to give 0.34 g (48%) of **28a** and then 0.14 g (20%) of **29a**.

28a: Colorless prisms from hexane; mp 31—32 °C; IR (KBr) 3400 (OH), 1700 (C=O), and 1598 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.75—2.00 (2H, m, 5-CH_2), 1.85, 2.15 (each 3H, s. COMe), 2.42 (2H, m, 6-CH_2), 2.74 (1H, dt, J_{4-5}=5.2 and J_{4-3}=4.0 Hz, 4-H), 4.31 (1H, d, J_{3-4}=4.0 Hz, 3-H), and 7.00—7.40 (5H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=19.55 (t, 5-C), 25.71 (q, COMe), 28.24 (t, 6-C), 28.36 (q, COMe), 40.92 (d, 4-C), 55.31 (d, 3-C), 108.14 (s, 2-C), 126.70, 127.69, 128,69, 144.48, 180.47 (s, 2-COMe), 200.90 (s, 4-COMe), and 208.47 (1-CO); MS *m/z* (rel. intensity) 258 (M^+, 16), 215 (49), 197 (33), 173 (21), 155 (31), and 43 (base peak).

Found: C, 74.62; H, 6.97%; M+, 258. Calcd for $C_{16}H_{18}O_3$: C, 74.39; H, 7.02%; M, 258.

29a: Colorless grains from hexane; mp 81—82 °C; IR (KBr) 3400 (OH), 1700 (C=O), and 1590 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.80—2.30 (2H, m, 5-CH_2), 1.85, 1.88 (each 3H, s, COMe), 2.55 (2H, m, 6-CH_2), 2.83 (1H, ddd, J_{4-5}=4.0, 12.1, and J_{4-3}=4.9 Hz, 4-H), 4.26 (1H, d, J_{3-4}=4.9 Hz, 3-H), 6.90—7.36 (5H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=17.79 (t, 5-C), 25.36, 28.83 (each q, COMe), 29.82 (t, 6-C), 42.74 (d, 4-C), 52.66 (d, 3-C), 109.73 (s, 2-C), 127.34 (d), 128.46 (d), 128.93 (d), 139.73 (s), 180.59 (s, 2-COMe), 200.79 (s, 4-COMe), and 209.65 (s, 1-CO); MS *m/z* (rel. intensity) 259 (M^++1, 48),258 (M^+, base peak), 215 (63), 197 (41), 187 (23), 173 (23), 155 (27), 131 (22), and 43 (61).

Found: C, 74.39; H, 7.01%; M+, 258. Calcd for $C_{16}H_{18}O_3$: C, 74.39; H, 7.02%; M, 258.

Cycloaddition of 1 to 27b Leading to 28b and 29b. Similar reaction of **1** (0.376 g, 1.13 mmol) with **27b** (2 ml) in benzene (6 ml) followed by the work-up with methanol afforded the crude product which was then chromatographed over silica gel. The fraction eluted with chloroform-hexane (3:7) gave 0.11 g of **28b** and the continued fraction 0.15 g of mixture between **28b** and **29b** (**28b**: 35%; **29b**: 13%). The fraction with chloroform-hexane (1:1) provided 0.028 g of **29b**. Total amount of **28b** was 0.22 g (70%) and that of **29b** was 0.068 g (22%).

28b: Pale yellow liquid by repeated column chromatography; IR (neat) 3400 (OH), 1720 (C=O), and 1595 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.60—2.10 (2H, m, 5-CH_2), 1.88 (3H, s, COMe), 2.30—2.60 (2H, m, 6-CH_2), 2.76 (1H, dt, J_{4-5}= 4.5 and J_{4-3}=3.4 Hz, 4-H), 3.71 (3H, s, COOMe), 4.40 (1H, d, J_{3-4}=3.4 Hz, 3-H), and 7.00—7.40 (5H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=18.85 (t, 5-C), 25.60 (q, COMe), 27.95 (t, 6-C), 41.92 (d, 4-C), 47.03 (d, 3-C), 52.08 (q, COOMe), 107.68 (s, s, 2-C), 126.87 (d), 127.81 (d), 128.75 (d), 143.96 (s), 173.66 (s, COOMe), 180.94 (s, COMe), and 201.08 (s, 1-CO); MS *m/z* 274 (M^+), 231, and 196.

Found: C, 70.19; H, 6.67%; M+, 274. Calcd for $C_{16}H_{18}O_4$: C, 70.05; H, 6.61%; M, 274.

29b: Colorless prisms from ether-hexane; mp 93—95 °C; IR (KBr) 3400 (OH), 1730 (C=O), 1600, 1400, and 1220 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.70—3.04 (5H, m, 5-, 6-CH_2, and 4-H), 1.89 (3H, s, COMe), 3.56 (3H, s, COOMe), 4.29 (1H, d, J_{3-4}=5.0 Hz, 3-H), and 6.90-7.35 (5H, m, ArH); MS *m/z* (rel. intensity) 275 (M^++1, 18), 274 (M^+, base peak), 231 (58), 197 (37), 155 (20), 145 (21), and 42 (53).

Found: C, 69.93; H, 6.87%; M+ 274. Calcd for $C_{16}H_{18}O_4$: C, 70.05; H, 6.61%; M, 274.

Cycloaddition of 1 to 27c Leading to 28c and 29c. Triene **1** (0.65 g, 1.95 mmol) was heated under reflux in freshly distilled **27c** (5 ml) under nitrogen for 58 h. The crude product obtained by the usual work-up with methanol was chromatographed over silica gel. The fraction eluted with chloroform-hexane (2:1) afforded 0.084 g of **28c**, and then 0.21 g of **28c** and **29c** (3.3:1). The other fraction with chloroform gave 0.045 g of **29c**. Total amount of **28c** was 0.245 g (54%) and that of **29c** was 0.094 g (18%).

28: Colorless prisms from ether-hexane; mp 153—155 °C; IR (KBr) 3400 (OH), 2230 (CN), 1590, 1410, 1240, and 960 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.60-2.10 (2H, m, 5-CH_2), 1.88 (3H, s, COMe), 2.48 (1H, dt, J_{gem}=19.0 and J_{6-5}=4.5 Hz, one of 6-CH_2), 2.86 (1H, dt, J_{gem}=19.0 and J_{6-5}=9.0 Hz, the other of 6-CH_2), 3.00 (1H, dt, J_{4-5}=4.1 and J_{4-3}=2.7 Hz, 4-H), 4.20 (1H, d, J_{3-4}=2.7 Hz, 3-H), and 7.00—7.44 (5H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=18.85 (t, 5-C), 25.42 (t, 6-C), 27.30 (q, COMe), 33.17 (d, 4-C), 43.44 (d, 3-C), 105.97 (s, 2-C), 120.59 (s, CN), 127.89, 129.10, 141.25, 180.18 (s, COMe), and 201.03 (s, 1-CO); MS *m/z* (rel. intensity) 241 (M^+, 28), 214 (26), 196 (23), 187 (22), 155 (37), 145 (35), 115 (29), 77 (26), and 44 (base peak).

Found: C, 74.88; H, 6.34; N, 5.84%; M+, 241. Calcd for $C_{15}H_{15}NO_2$: C, 74.66; H, 6.27; N, 5.81%; M, 241.

29c: Colorless prisms from ether-hexane; mp 144—146 °C; IR (KBr) 3400 (OH), 2220 (CN), 1600, 1410, 1240, and 940 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.86 (3H, s, COMe), 1.94 (2H, m, 5-CH_2), 2.59 (2H, dd, J_{6-5}=6.1 and 7.1 Hz, 6-CH_2), 3.10 (1H, m, 4-H), 4.09 (1H, d, J_{3-4}=4.9 Hz, 3-H), and 7.10—7.50 (5H, m, ArH); ^{13}C-NMR ($CDCl_3$) δ=18.85 (t, 5-C), 25.48 (t, 6-C), 29.30 (q, COMe), 32.25 (d, 4-C), 41.63 (d, 3-C), 108.03 (s, 2-C), 119.77 (s, CN), 128.16, 128.63, 129.34, 138.09, 179.18 (s, COMe), and 200.85 (s, 1-CO); MS *m/z* (rel. intensity) 241 (M^+, 35), 214 (22), 187 (21), 155 (33), 145 (32), and 77 (23).

Found: C, 74.68; H, 6.31; N, 5.83%; M+, 241. Calcd for $C_{15}H_{15}NO_2$: C, 74.66; H, 6.27; N, 5.81%; M, 241.

Similar reaction of **1** (0.769 g, 2.3 mmol) with **27c** (3.1 ml, 46 mmol) was carried out in a sealed tube (At 110 °C for 5 d in 6 ml of dry benzene). The usual work-up with methanol gave viscous oil which was purified by chromatography over silica gel. The fraction eluted with hexane-ethyl acetate (4:1) afforded 0.116 g of **28c** and 0.065 g of mixture between **28c** and **29c** (1:1). The continued elution with hexane-ethyl acetate (2:1) gave 0.243 g of **30**. Total amounts were as follows: **28c**: 0.149 g (27%); **29c**: 0.033 g (6%); **30**: 0.243 g (38%). The bis-adduct **30** was found to be a mixture of two isomers whose ^{1}H-NMR spectrum was given as shown below: ^{1}H-NMR ($CDCl_3$) δ=1.68—2.10 (2H, m, CH_2), 2.10—3.10 (7H, m, CH_2 and CH), 3.44—3.80 (1H, m, CHCN), 4.37 (1H, br. CHPh), and 6.80—7.44 (5H, m, ArH).

Cycloaddition of 2 to 27a Leading to 31a. A solution of **2** (0.856 g, 3.0 mmol) and freshly distilled **27a** (1.2 ml, 15 mmol) was heated under reflux in dry benzene (3 ml) under nitrogen for 48 h. The usual work-up with methanol gave the crude product. It was chromatographed over silica gel using hexane-chloroform (3:1) to give 0.325 g (60%) of **31a**.

31a: Colorless prisms from ether-hexane; mp 42—44 °C; IR (KBr) 1680—1540 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.28, 2.36 (each 3H, s, COMe), 2.50—2.70 (4H, m, CH_2), 7.32 (1H, br. s, 3-H), and 16.23 (1H, s, OH); ^{13}C-NMR ($CDCl_3$) δ=20.14 (t, CH_2), 20.31, 24.95 (each q, COMe), 34.05 (t, CH_2), 107.56 (s), 129.81 (s), 133.27 (d, 3-C), 185.40 (s, 2-COMe), 196.50 (s, 4-COMe), and 199.91 (s, 1-C); MS *m/z* 180 (M^+), 137 (M^+−43), and 43 (base peak).

Found: C, 66.91; H, 6.79%; M+, 180. Calcd for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71%; ,M, 180.

Cycloaddition of 2 to 27b Leading to 31b. Similar procedure starting from **2** (0.81 g, 2.8 mmol) and **27b** (0.73 g, 8.4 mmol) and the followed column chromatography over silica gel using chloroform gave 0.367 g (66%) of **31b**. The reaction conditions were listed in Table 3.

31b: Colorless needles from aqueous methanol; mp 60 °C; IR (KBr) 1700 and 1640—1580 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.23 (3H, s, COMe), 2.40—2.80 (4H, m, CH_2), 3.75 (3H, s, COOMe), 7.40 (1H, br. s, 3-H), and 16.07 (1H, s, OH); ^{13}C-NMR ($CDCl_3$) δ=20.20 (q, COMe), 21.37, 34.35 (each t, CH_2), 51.72 (q, COOMe), 107.73 (s), 120.00 (s), 132.74 (d, 3-C), 167.14 (s, COOMe), 184.64 (s, COMe), and 199.79 (s, 1-CO); MS *m/z* 196 (M^+), 181 (M^+−15), and 43 (base peak).

Found: C, 61.07; H, 6.23%; M+, 196. Calcd for $C_{10}H_{12}O_4$: C, 61.22; H, 6.16%; M, 196.

Cycloaddition of 2 to 27c Leading to 31c. The same procedure using **2** (0.765 g, 2.7 mmol) and **27c** (0.88 ml, 13.5 mmol) and the followed column chromatography over silica gel using dichloromethane gave 0.316 g (73%) of **31c**. The reaction conditions were shown in Table 3.

31c: Colorless prisms from dichloromethane-hexane; mp 108—109 °C; IR (KBr) 2200 (CN) and 1680—1500 cm^{-1}

(C=O); ^{1}H-NMR ($CDCl_3$) δ=2.20 (3H, s, COMe), 2.60 (4H, m, CH_2), 7.04 (1H, s, 3-H), and 16.03 (1H, s, OH); ^{13}C-NMR ($CDCl_3$) δ=20.14 (q, COMe), 23.78, 33.58 (each t, CH_2), 107.73 (s, 2-C), 111.96 (s), 119. 65 (s, CN), 137.67 (d, 3-C), 184.70 (s, COMe), and 198.03 (s, 1-CO); MS *m/z* 163 (M^+, bask peak).

Found: C, 66.38; H, 5.65; N, 8.43%; M^+, 163. Calcd for $C_9H_9NO_2$: C, 66.25; H, 5.56; N, 8.58%; M, 163.

Cross Diene-transmissive Diels-Alder Cycloaddition Reaction of Bis(silyloxy) Cross-conjugated Trienes

Otohiko TSUGE,* Shuji KANEMASA, Hirohiko SAKOH, and Eiji WADA

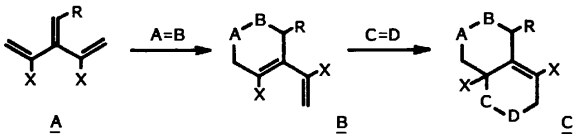
(Received June 18, 1984)

Cross type of diene-transmissive Diels-Alder cycloaddition has been demonstrated by using two bis-silyloxy cross-conjugated trienes. The first cycloaddition stage of cross reaction, which has to be highly selective in the formation of mono-cycloadducts, has been performed by the reactions of an activated triene with cyclic olefins or those of trienes with acyclic olefins. The secod cycloadditions with a variety of dienophiles provide cross types of bis-adducts. The characteristics of these cross reactios are discussed.

The diene-transmissive Diels-Alder reaction is a process that involves two sequential Diels-Alder cycloadditions of cross-conjugated triene.[1] Of great value as a synthetic tool is the cross type of diene-transmissive Diels-Alder reaction in which each different dienophile participates in each stage of cycloadditions leading to the formation of cross bis-cycloadduct (**A**→**B**→**C**). Success of the cross reaction mainly depends upon the chemoselective formation of mono-cycloadduct **B**. This selectivity may be conveniently called "monoselectivity" in the present paper.



A B C

The preceding paper has dealt with the diene-transmissive Diels-Alder reaction of bis (silyloxy) cross-conjugated trienes, 3-(methoxymethylene)- **1** and 3-benzylidene-2,4-bis(trimethylsilyloxy)-1,4-pentadiene **2**.[1] The reaction of **1** with an equivalent of cyclic olefinic dienophiles was highly monoselective, while with two equivalents the bis-cycloadducts were exclusively formed. On the other hand, the reaction of either **1** or **2** with acyclic olefinic dienophiles below 80 °C was also monoselective even if excess of dienophiles was used.

Therefore, the cross type of diene-transmissive Diels-Alder reaction may be achieved through the following two possible approaches: The first method involves the initial formation of the mono-cycloadducts between **1** and cyclic olefinic dienophiles and the followed second cycloaddition with appropriate dienophiles. The second method is initiated by the initial cycloaddition of either **1** or **2** with acyclic olefinic dienophiles and followed by the second cycloaddition with highly reactive dienophiles.

Results and Discussion

The most promising cross process of diene-transmissive Diels-Alder reaction may be achieved by use of the activated triene **1**. When an equivalent of **1** is used, the cycloadduct to cyclic olefinic dienophiles is highly monoselective forming endo mono-cycloadducts. The endo approach of the second molecule of dienophiles from the less hindered side easily occurs giving stereoselective bis-cycloadducts when another equivalent of dienophiles is added.[1]

Each equivalent of **1** and *N*-phenylmaleimide **3a** in benzene was allowed to react at room temperature for 20 h during which time the endo mono-cycloadduct **D** was formed. After the addition of dimethyl acetylenedicarboxylate **4a** (1.5 equivalent) as the second dienophile, the reaction was continued under reflux for an additional 20 h. The usual desilylating work-up with methanol gave a cross bis-adduct **5aa** (Scheme 1 and Table 1). It was assigned that the initially formed ring of **5aa** had trans configuration on the basis of the coupling constant between 3a-H and 4-H (J_{3a-4}=3.0 Hz) This means that the stereochemistry at the 4-position of mono-cycloadduct **D** was inverted. Such inversion, which must have occurred at or later the desilylation stage, has been generally observed in the reactions of **1** with cyclic olefinic dienophiles.[1]

Similar reaction of **1** with *N*-methylmaleimide **3b** and then with **4a** or that of **1** with **3b** and then with dibenzoylacetylene **4b**, under the reaction conditions shown in Table 1, gave the cross bis-adduct **5ba** or **5bb**, respectively.

When maleic anhydride **3c** was used as the first dienophile, the cycloaddition was completed in 2 h at room temperature. The second cycloaddition with **4a** was followed under reflux in benzene for 24 h. Esterification of the reaction mixture with methanol in the presence of *p*-toluenesulfonic acid gave two isomeric cross bis-adducts **6ca** and **7ca**. Their ratio is not so important because **6ca** gradually changes into **7ca** when heated or treated with methanol in the presence of *p*-toluenesulfonic acid. The structures were confirmed on the basis of the coupling constant between 1-H and 2-H (**6ca**: 6.0 Hz; **7ca**: 3.0 Hz).

^{1}H-NMR analysis of the reaction of isolated mono-cycloadduct **D** (X=O) with **4a** showed the formation of aromatized cross bis-adducts **F** and **G** (R=E=COOMe) whose isolation failed. Their ratio was found to change depending upon the reaction temperature and time: Only **F** (after 24 h at room temperature), a mixture of **F** and **G** (4:3, after 24 h under reflux in benzene), and only **G** (after a week at room temperature or after 3 d under reflux in benzene) were formed, indicating that the endo bis-cycloadduct **F** and the exo one **G** are kinetically and thermodynamically controlled products, respectively.

Thus, in the cross cycloadditions of **1** with cyclic

olefinic dienophiles and then with acetylenic ones, the first stage is an endoselective cycloaddition leading to **D**. The acetylenes approach from the less hindered side, opposite to the 4-MeO and fused maleimide ring, forming the stereoselective cross bis-cycloadducts **E** which are immediately aromatized by the elimination of a silanol. The inversion of 4-MeO substituent starts giving more stable isomers probably through an elimination-addition mechanism. In the cases of maleimides, only the inverted bis-adducts **5** were isolated, and in the case of maleic anhydride, a mixture of bis-adducts **6** and **7** was yielded.

Similar reaction of **1** with **3c** and then with **4b**, under similar reaction conditions (Table 1), gave an exo cross bis-adduct **7cb** together with a methanol-eliminated bis-adduct **8cb**, no trace of endo bis-adduct **6cb** being obtained.

As the diene moiety of mono-cycloadduct **D** carries two silyloxy substituents in a 1,3-relationship, the second cycloaddition to unsymmetrically substituted dienophiles should be regioselective.[2] As expected, the reaction of **1** with **3c** and then with methyl propiolate **4c** gave a regioselective methanol-eliminated cross bis-adduct **8cc**, but in a low yield.

Olefinic dienophiles can be employed as well in the second cycloaddition. Thus, the endo mono-cycloadduct **D** (X=O), which had been formed in the initial cycloaddition of **1** to **3c**, was allowed to react with **3b** and the reaction mixture was treated with trifluoroacetic acid. The only product isolated in 38% yield was a stereoselective cross bis-adduct **9** which was accompanied with the inversion at the 6-position. Although the configuration at the points of fusion (the 3a and 10b positions) was not clear only on the basis of the spectral data, it was tentatively assigned as shown in Scheme 2 according to the most likely approach of **3b**. The second olefinic dienophile **3b** must have approached to **D** in an endo fashion from the opposite side to the 4-MeO and the fused maleimide ring, giving a stereoselective bis-cycloadduct **H**.

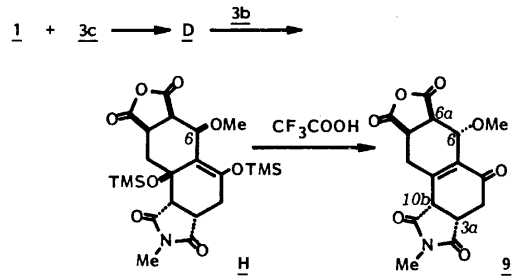


Scheme 2.

Table 1. Cross cycloadditions of **1** to cyclic olefins **3** and then acetylenes **4**

Olefin (equiv)	Acetylene (equiv)	Reaction Conditions[a] 1st Reaction	2nd Reaction	Product (yield/%)[b]
3a (1.0)	**4a** (1.5)	24 h at r.t.	20 h under Reflux	**5aa** (49)
3b (1.0)	**4a** (1.5)	24 h at r.t.	20 h under Reflux	**5ba** (41)
3b (1.0)	**4b** (1.0)	24 h at r.t.	36 h under Reflux	**5bb** (47)
3c (1.0)	**4a** (1.4)	2 h at r.t.	24 h under Reflux	**6ca** (14), **7ca** (19)
3c (1.0)	**4b** (1.0)	2 h at r.t.	24 h at r.t.	**7cb** (33)[c], **8cb** (6)
3c (1.0)	**4c** (2.0)	2 h at r.t.	48 h under Reflux	**8cc** (15)

a) All the reactions were carried out in dry benzene. The first and second reactions were performed in the same flask. When **3c** was used as the first dienophile, esterification procedure was followed after the second cycloaddition was complete (under reflux in methanol for 24 h in the presence of *p*-toluenesulfonic acid). b) All isolated yields based on **1**. c) A part of **7cb** was isolated as a silylated derivative **G** (R=E=COPh).

As the cross bis-cycloadducts and also their derivatives formed in the cross reactions of **1** with two different cyclic olefinic dienophiles were found all quite labile, the cross reactions with such combinations were not further investigated.

As described in the preceding paper,[1] both trienes **1** and **2** react with acyclic olefinic dienophiles affording only the mixture of endo and exo mono-cycloadducts, even when excess of the dienophiles is used. But, the prolonged reactions at higher temperature produce poor yields of bis-cycloadducts, indicating that the cross type of diene-transmissive Diels-Alder reaction may be achieved by reacting the triene **1** or **2** with acyclic olefins as the first dienophiles and then with highly reactive second dienophiles.

The triene **1** reacted with excess of methyl acrylate **10a** under reflux in benzene for 48 h. It was found from the separate experiment that two isomeric mono-cycloadducts **I** (isomer ratio=1:2)[3] were formed in good yields in this reaction mixture. After the solvent and the excess dienophile **10a** were completely removed, the residue was allowed to react further with the second dienophile **4a** under the conditions shown in Table 2. The work-up with methanol gave two isomeric cross bis-adducts **11aa** and **12aa** (Scheme 3). Again in this case, the isomer ratio is not important because they are interconvertible each other.

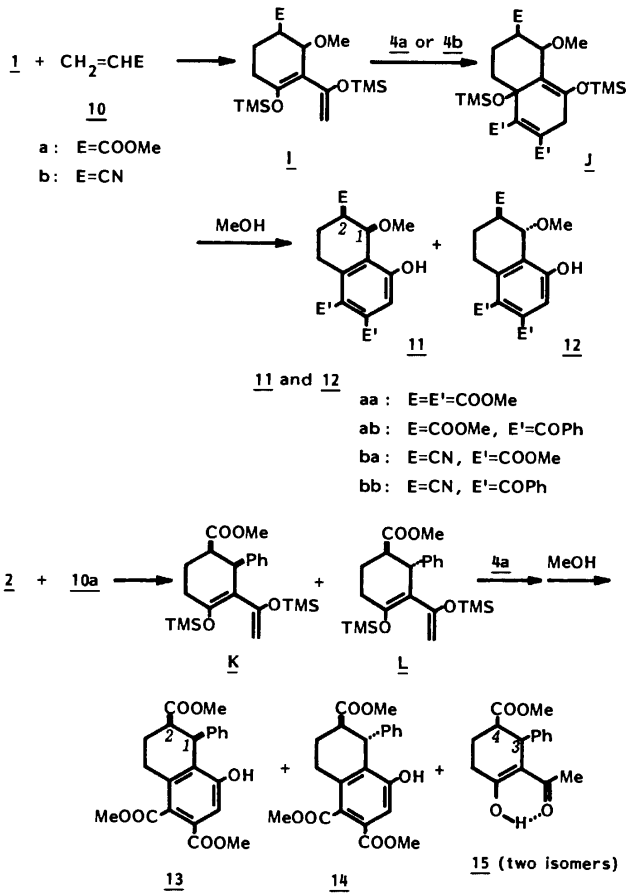
Similar cross reactions were performed by using **10a** or acrylonitrile **10b** as the first dienophile and **4a** or **4b** as the second. Results obtained are listed in Table 2.

In the cross cycloaddition of triene **1**, the use of unsymmetric dienophiles does not make any trouble since the both stage of double Diels-Alder reactions are highly regioselective. Disadvantage is that mono-cycloadducts to acyclic olefins take a half-chair conformation which disturbs the approach of the second dienophiles.[4] This sluggish second cycloaddition is often accompanied with some side reactions. One of them is the Michael reaction. In the reaction of mono-cycloadduct **I** (E=CN) with **4a**, a considerable amount of Michael adduct was obtained.[5]

Heating the triene **2** in large excess of **10a** for a long time (5 d at 80 °C) produces endo- **K** and exo mono-cycloadduct **L** in 22 and 70% yields, respectively.[6] When this mixture was allowed to react with **4a**, two isomeric cross bis-adducts **13** (endo, 10%) and **14** (exo, 36%) were yielded besides the mono-adducts **15** (6%, endo:exo=1:3). This result indicates that the endo mono-cycloadduct **K** cycloadds to **4a** as slowly as the exo one **L** does.

In the cross type of diene-transmissive Diels-Alder reactions using acyclic olefins, the second dienophiles are required to be highly reactive. Although the use of cyclic olefins as the second reagent led to the formation of rather unstable cross bis-adducts such as **9**, their high reactivity is still attracting.

The regioselective mono-cycloadduct **I** formed in the reaction of **1** with **10a** was allowed to react with an equivalent of **3b** under reflux in benzene for 24 h. The

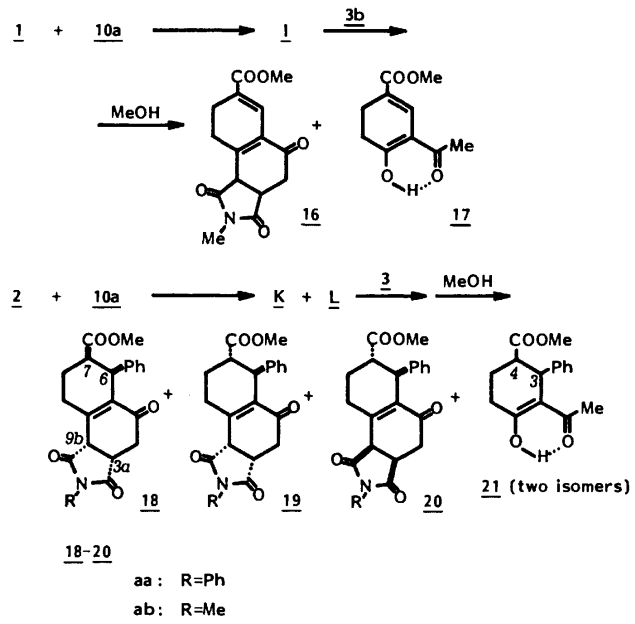


Scheme 3.

Table 2. Cross cycloadditions of **1** and **2** to acyclic olefins **10** and then acetylenes **4**

Triene	Olefin (equiv)	Acetylene (equiv)	Reaction Conditions[a] 1st Reaction	Reaction Conditions[a] 2nd Reaction	Product (yield/%)[b]
1	**10a** (3.0)	**4a** (1.1)	48 h at 80 °C	48 h under Reflux	**11aa** (21), **12aa** (8)
1	**10a** (3.0)	**4b** (1.0)	48 h at 80 °C	48 h under Reflux	**11ab** (15), **12ab** (21)
1	**10b** (5.0)	**4a** (2.0)	48 h at 75 °C	48 h under Reflux	**11ba** (23), **12ba** (12)
1	**10b** (5.0)	**4b** (1.0)	48 h at 75 °C	48 h under Reflux	**11bb** (28), **12bb** (10)
2	**10a** (20.0)	**4a** (1.1)	120 h at 80 °C	48 h under Reflux	**13** (10)[c], **14** (36)[c]

a) After the first cycloadditions in dry benzene was complete, the solvent and excess dienophiles **10** were completely removed off. To the residue were added dry benzene and acetylenes **4**, and the mixture was allowed to react under the shown conditions. b) All isolated yields based on the trienes. c) Separation was unsuccessful. Accompanied with the formation of mono-adduct **15** (endo : exo = 1 : 3, in 6% yield).



Scheme 4.

usual work-up with methanol gave a cross bis-adduct **16** (25%) together with the mono-adduct **17** (28%) which was derived from unreacted **I** (Scheme 4). There are no ambiguities on the stereochemistry of **16** since methanol elimination as well as desilylation has occured. Due to the instability, it failed to purify **16**.

Similar cross reactions were investigated by using triene **2**. When a mixture of **K** (endo) and **L** (exo) (**K**:**L**=22:70) was reacted with an equivalent of **3a** under reflux in benzene for 48 h, three kinds of cross bis-adducts **18aa**, **19aa**, and **20aa** were formed in 49% yield (**18aa**:**19aa**:**20aa**=2:14:3) besides a small amount of isomeric mono-adducts **21** (11%, endo:exo=1:5). Only the major product **19a** was isolated in pure form from a mixture of the other two. The structural assignment was based on the coupling constants between 6-H and 7-H as well as the stereochemical aspect of the reaction paths.[7]

The endo/exo ratio in the mono-cycloadducts (**K**:**L**=22:70) was found quite different from that in the products. The ratio of all the products from **K** to those from **L** was 7:53. This is probably because all of the cross bis-adducts **18aa**—**20aa** are labile. Actually they were partly decomposed when chromatographed over silica gel or heated in methanol. Under the same conditions, the second cycloaddition with **3b** recovered relatively large amount of the mono-cycloadducts **K** and **L** in the forms of **21** (38%, endo:exo=1:3) together with three cross bis-adducts **18ab**, **19ab**, and **20ab** (26%, **18ab**:**19ab**:**20ab**=1:4:2). The isomer ratios of unreacted mono-cycloadducts (endo/exo ratios of **21**) are about the same to the ratio between **K** and **L**, meaning that there is little difference of reactivity between the exo- **K** and endo mono-cycloadduct **L** in the cycloadditions to such cyclic olefins.

Experimental

General and Materials. Melting points were determined on a Yanagimoto micro melting point apparatus and uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-102 spectrometer. ^{1}H-NMR spectra were recorded on a Hitachi R-40 or a JEOL FX-100 instrument and ^{13}C-NMR spectra were obtained on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane. Mass spectra were measured with a JEOL JMS-01SG-2 spectrometer at 75 eV of ionization energy. Elementary analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck) or on 0.2 mm precoated plates of aluminum oxide 60 F-254 type E (Merck). Visualization was made with ultraviolet light (254 and 365 nm) or iodine. Wako gel C200 and C300 (Wako) were used for preparative column chromatography. Preparative high performance liquid chromatography (HPLC) was carried out on a Kusano KHLC-201 apparatus with a UV-detector Uvilog-III using a column (22×300 mm) packed with silica gel (Wako gel LC-50H). Micro vacuum distillation was performed with a Sibata GTO-250R Kugelrohr distilling apparatus in a glass tube oven. When this apparatus was used, boiling points were expressed with the oven temperature. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type V at about 50 °C unless otherwise stated.

Benzene was purified by the distillation from sodium and stored on sodium wire. Both trienes, 3-(methoxymethylene)-**1** and 3-benzylidene-2,4-bis(trimethylsilyloxy)-1,4-pentadiene **2**, were prepared by the silylation of 3-(methoxymethylene)- and 3-benzylidene-2,4-pentanedione with chlorotrimethylsilane, respectively, as shown in the preceding paper.[1] The commercial materials of maleic anhydride **3c**, dimethyl acetylenedicarboxylate **4a**, methyl acrylate **10a**, and acrylonitrile **10b** were purified by distillation. The commercial grades of *N*-phenyl- **3a** and *N*-methylmaleimide **3b** were used without further purification. Dibenzoylacetylene **4b** was synthesized from 1,2-dibenzoylethene.[8] Methyl propiolate **4c** was obtained by the esterification of the commercial propiolic acid in the presence of *p*-toluenesulfonic acid.[9]

Cycloaddition of 1 to 3a and then 4a Leading to 5aa. A solution of freshly distilled **1** (0.773 g, 2.7 mmol) and **3a** (0.425 g, 2.5 mmol) in dry benzene (3 ml) was stirred at room temperature under nitrogen for 24 h. After **4a** (0.523 g, 3.7 mmol) was added, the resulting mixture was heated under reflux for 20 h. All the volatile materials were evaporated *in vacuo* and the residue obtained was stirred in methanol (10 ml) overnight. Evaporation of the methanol *in vacuo* left the residue which was then chromatographed over silica gel using chloroform–ethyl acetate (5:1) to give 0.524 g (49%) of **5aa**. The analytical sample of **5aa** was available through the repeated chromatography since its purification by crystallization was unsuccessful.

5aa: Colorless leaflets; mp 230 °C; IR (KBr) 3400 (OH); 1775, 1720, and 1685 cm^{-1} (C=O); ^{1}H-NMR (CDCl$_3$+DMSO-d_6) δ=2.70—3.90 (4H, m, 9-CH$_2$, 3a-, and 9a-H), 3.11 (3H, s, OMe), 3.81, 3.82 (each 3H, s, COOMe), 5.40 (1H, d, J_{4-3a}= 3.0 Hz, 4-H), and 7.10—7.56 (7H, m, ArH, 6-H, and OH); ^{13}C-NMR (CDCl$_3$+DMSO-d_6) δ=23.01, 35.75, 44.09, 50.96, 54.84, 68.10, 113.31, 123.47, 124.49, 125.34, 126.87, 127.40, 128.46, 130.98, 135.27, 154.58, 164.56, 167.03, 173.95, and 177.01; MS *m/z* 439 (M$^+$), 408 (M$^+$−31), and 228 (base peak).

Found: C, 62.78; H, 4.70; N, 3.67%; M$^+$, 439. Calcd for $C_{23}H_{21}NO_8$: C, 62.87; H, 4.82; N, 3.19%; M, 439.

Cycloaddition of 1 to 3b and then 4a Leading to 5ba. A solution of freshly distilled **1** (0.455 g, 1.6 mmol) and **3b** (0.161 g, 1.4 mmol) in dry benzene (2 ml) was stirred at room temperature under nitrogen for 24 h. After **4a** (0.309 g, 2.2 mmol) was added, the mixture was heated under reflux for 20 h. All the volatile materials were evaporated *in vacuo* and the residue was stirred in methanol (10 ml) overnight. Evapo-

ration of the methanol *in vacuo* left viscous oil which was then chromatographed over silica gel using chloroform–ethyl acetate (3:1) to give 0.266 g (41%) of **5ba**. It was purified by repeated chromatography.

5ba: Colorless solid; mp 248 °C; IR (KBr) 3420 (OH), 1785, 1725, and 1670 cm^{-1} (C=C); ^1H NMR (DMSO-d_6) σ=2.60—3.20 (4H, m, 9-CH_2, 3a-, and 9a-H), 2.88 (3H, s, NMe), 3.00 (3H, s, OMe), 3.80 (6H, s, COOMe), 5.23 (1H, d, J_{4-3a}=3.0 Hz, 4-H), 7.28 (1H, s, 6-H), and 8.24 (1H, s, OH); ^{13}C-NMR (DMSO-d_6) δ=24.32, 36.84, 44.98, 52.34, 52.58, 55.85, 68.90 (d, 4-C), 114.32 (d, 6-C), 124.46 (s), 129.72 (s), 136.73 (s), 155.74 (s, 5-C), 165.78, 168.02 (each s, COOMe), 176.01 and 179.18 (each s, 1- and 3-CO); MS *m/z* 377 (M^+), 346 (M^+−31), and 228 (base peak).

Found: C, 57.01; H, 4.92; N, 3.81%; M^+, 377. Calcd for $C_{18}H_{19}NO_8$: C, 57.29; H, 5.07; N, 3.71%; M, 377.

Cycloaddition of 1 to 3b and then 4b Leading to 5bb. A solution of fresh **1** (0.521 g, 1.8 mmol) and **3b** (0.202 g, 1.8 mmol) in dry benzene (3 ml) was stirred at room temperature under nitrogen for 24 h. To this solution was added **4b** (0.426 g, 1.8 mmol) and the mixture was refluxed under nitrogen for 36 h. All the volatile materials were removed off *in vacuo* and the residue was stirred in methanol (10 ml) at room temperature overnight. The methanol was completely evaporated *in vacuo* to afford viscous oil which was chromatographed over silica gel with chloroform–ethyl acetate (4:1). Analytical sample of **5bb** (0.402 g, 47%) was obtained by repeated chromatography.

5bb: Colorless solid; mp 160—162 °C; IR (KBr) 3400 (OH), 1775, and 1705—1650 cm^{-1} (C=O); ^1H-NMR (DMSO-d_6) δ=2.64—3.40 (4H, m, 9-CH_2, 3a-, and 9a-H), 2.84 (3H, s, NMe), 3.10 (3H, s, OMe), 5.34 (1H, d, J_{4-3a}=3.5 Hz, 4-H), 7.00 (1H, s, 6-H), 7.32—7.80 (10H, m, ArH), and 10.58 (1H, s, OH); ^{13}C-NMR (DMSO-d_6) δ=24.31 (q, NMe), 24.83 (t, 9-C), 36.99, 45.09 (each d, 3a- and 9a-C), 55.95 (q, OMe), 69.04 (d, 4-C), 115.43 (d, 6-C), 124.82 (s), 128.16 (d), 128.40 (d), 128.63 (s), 129.57 (s), 130.28 (d), 136.33 (d), 137.27 (s), 137.91(s), 138.79 (s), 155.05 (s, 5-C), 176.01, 179.06 (each s, 1- and 3-CO), 195.27, and 196.56 (each s, COPh); MS *m/z* 469 (M^+), 437 (M^+−32), and 105 (base peak).

Found: C, 71.45; H, 4.89; N, 3.04%; M^+, 469. Calcd for $C_{28}H_{23}NO_6$: C, 71.63; H, 4.94; N, 2.98%; M, 469.

Cycloaddition of 1 to 3c and then 4a Leading to 6ca and 7ca. A solution of freshly distilled **1** (0.579 g, 2.0 mmol) and **3c** (0.18 g, 1.8 mmol) in dry benzene (2 ml) was stirred at room temperature under nitrogen for 2 h. To this solution was added **4a** (0.391 g, 2.8 mmol) and the mixture was heated under reflux for 24 h. After all the volatile materials were evaporated *in vacuo*, the residue was refluxed in methanol (50 ml) in the presence of *p*-toluenesulfonic acid (0.1 g) for 24 h. The residue obtained after evaporation of the methanol *in vacuo* was dissolved in chloroform (30 ml), the chloroform solution was washed with 5% aqueous sodium hydrogen carbonate, dried over magnesium sulfate, and evaporated *in vacuo* to give viscous oil which was found to contain **6ca** and **7ca** in a ratio of 2:3 by ^1H-NMR spectroscopy. The oil was separated into **6ca** (0.1 g, 13%) and **7ca** (0.146 g, 19%) by column chromatography over silica gel using chloroform–ethyl acetate (4:1).

6ca: Colorless solid from chromatography; mp 129—130 °C; IR (KBr) 3280 (OH) and 1720 cm^{-1} (C=O); ^1H-MNR ($CDCl_3$) δ=2.85—3.92 (4H, m, 4-CH_2, 2-, and 3-H), 3.64 (3H, s, OMe), 3.67, 3.72, 3.83, 3.87 (each 3H, s, COOMe), 4.90 (1H, d, J_{1-2}=6.0 Hz, 1-H), 7.23 (1H, s, 7-H), and 8,78 (1H, s, OH); ^{13}C-NMR ($CDCl_3$) δ=25.48, 39.45, 41.68, 51.96, 52.43, 56.95, 79.43, 116.36, 122.76, 126.40, 129.22, 134.33, 157.46, 165.91, 169.43, 169.61, and 172.20; Ms *m/z* 410 (M^+), 378 (M^+−32), and 287 (base peak).

Found: C, 55.33; H, 5.37%; M^+, 410. Calcd for $C_{19}H_{22}O_{10}$: C, 55.61; H, 5.40%; M, 410.

7ca: Colorless leaflets from aqueous methanol; mp 173—174 °C; IR (KBr) 3410 (OH) and 1720 cm-$^{-1}$ C=O)); ^1H-NMR ($CDCl_3$) δ=2.90—3.96 (4H, m, 4-CH_2, 2-, and 3-H), 3.48 (3H, s, OMe), 3.60, 3.74, 3.80, 3.88 (each 3H, s, COOMe), 5.08 (1H, d, J_{1-2}=3.0 Hz, 1-H), 7.19 (1H, s, 7-H), and 7.53 (1H, br. s, OH); ^{13}C-NMR ($CDCl_3$) δ=25.07 (t, 4-C), 36.34, 43.03 (each d, 2- and 3-C), 52.25, 52.60 (each q, COOMe), 72.21 (d, 1-C), 114.49 (d, 7-C), 125.17 (s), 126.99 (s), 129.34 (s), 134.92 (s), 156.41 (s, 8-C), 166.15, 169.43, 170.84, and 173.55 (each s, COOMe); MS *m/z* 410 (M^+), 378 (M^+−32), and 287 (base peak).

Found: C, 55.82 H, 5.40%; M^+, 410. Calcd for $C_{19}H_{22}O_{10}$: C, 55.61; H, 5.40%; M, 410.

Methanol Elimination of 7ca into 8ca. When **7ca** (0.14 g, 0.34 mmol) was heated under reflux in toluene (10 ml) for 48 h and then cooled to room temperature, colorless solid of **8ca** (0.088 g, 68%) was precipitated. It was washed with ether to give pure sample of **8ca**.

8ca: Colorless solid; mp 222—224 °C; IR (KBr) 3460 (OH) and 1710 cm^{-1} (C=O); ^1H-NMR ($CDCl_3$+DMSO-d_6) δ=2.90 (1H, dd, J_{gem}=16.8 and J_{vic}=8.0 Hz, one of CH_2), 3.28 (1H, dd, J_{gem}=16.8 and J_{vic}=3.5 Hz, the other of CH_2), 3.60—3.90 (1H, m, CHCOOMe), 3.56, 3.79, 3.82 (each 3H, s, COOMe), 7.25 (1H, s, ArH), and 7.90 (1H, s, =CH); ^{13}C-NMR ($CDCl_3$+DMSO-d_6) δ=28.06 (t, CH_6), 37.28 (q, OMe), 51.84, 51.96, 52.13, 52.43 (each q, COOMe), 115.01 (d), 122.12 (s), 124.35 (s), 126.87 (s), 130.46 (s), 130.57 (s), 133.74 (s), 155.74 (s), 165.62, 165.91, 167.97, and 171.73 (each s, COOMe); MS *m/z* 378 (M^+).

Found: C, 57.26; H, 4.82%; M^+, 378. Calcd for $C_{18}H_{18}O_9$: C, 57.14; H, 4.80%; M, 378.

Cycloaddition of 1 to 3c and then 4b Leading to G (R=E=COPh), 7cb, and 8cb. A solution of fresh **1** (0.545 g, 1.9 mmol) and **3c** (0.187 g, 1.9 mmol) in dry benzene (2 ml) was stirred at room temperature under nitrogen for 2 h. After **4b** (0.446 g, 1.9 mmol) was added, the resultant mixture was continued to stir at the same temperature under nitrogen for additional 24 h. All the volatile materials were evaporated *in vacuo* and the residue was treated with methanol (10 ml) to precipitate 0.274 g (27%) of **G** (R=E=COPh). It was collected on a filter and washed with a small amount of methanol (20 ml). To the filtrate was added 80 ml of methanol and this solution was refluxed in the presence of *p*-toluenesulfonic acid (0.1 g) for 24 h. The same work-up as mentioned above gave viscous oil which was chromatographed over silica gel using chloroform–ethyl acetate (4:1) to afford a mixture of **7cb** and **8cb** (0.102 g, 11%, 1:1). Repeated chromatography gave pure **8cb**, but **7cb** was always contaminated with a trace of **8cb**.

G (R=E=COPh): Colorless solid; mp 199—200 °C; IR (KBr) 1860, 1780, 1650 (C=O), 1250, and 845 cm^{-1} (TMS); ^1H-NMR ($CDCl_3$) δ=0.32 (9H, s, TMS), 2.90—3.36 (4H, m, 9-CH_2, 3a-, and 9a-H), 3.20 (3H, s, OMe), 5.38 (1H, d, J_{4-3a}= 3.2 Hz, 4-H), 6.93 (1H, s, 6-H), and 7.24—7.72 (10H, m, ArH); MS *m/z* 528 (M^+), 429 (base peak), and 105.

Found: C, 68.24; H, 5.36%; M^+, 528. Calcd for $C_{30}H_{28}O_7Si$: C, 68.16; H, 5.34%; M, 528.

7cb: Colorless solid; IR (KBr) 3200 (OH), 1730, 1710, and 1640 cm^{-1} (C=O); ^1H-NMR ($CDCl_3$+DMSO-d_6) δ= 2.60—3.80 (4H, m, 4-CH_2, 2-, and 3-H), 3.56 (6H, s, COOMe), 3.67 (3H, s, OMe), 5.10 (1H, d, J_{1-2}=3.0 Hz, 1-H), 6.96 (1H, s, 7-H), and 9.80 (1H, br. s, OH); MS *m/z* 470 (M^+), 411 (M^+−59, base peak), 105, and 77.

8cb: Colorless solid; mp 142—145 °C; IR (KBr) 3100 (OH), 1705, and 1640 cm^{-1} (C=O); ^1H-NMR ($CDCl_3$+ DMSO-d_6) δ=2.82 (1H, dd, J_{gem}=17.0 and J_{vic}=7.5 Hz, one of CH_2), 3.06 (1H, dd, J_{gem}=17.0 and J_{vic}=3.3 Hz, the other of CH_2), 3.67—3.90 (1H, m, CH), 3.41, 3.78 (each 3H,

s, COOMe), 7.00 (1H, s, ArH), 7.20—7.72 (10H, m, ArH), and 7.99 (1H, s, =CH); MS *m/z* 470 (M^+), 411 (M^+-59, base peak), and 105.

Found: C, 70.94; H, 4.79%; M^+, 470. Calcd for $C_{28}H_{22}O_7$: C, 71.48; H, 4.71%; M, 470.

Methanol elimination of **7cb** into **8cb** was achieved as follows: The comound **7cb** (0.125 g, 0.25 mmol) was heated under reflux in toluene for 24 h. Colorless solid which was precipitated on cooling was collected on a filter and washed with ether to give pure **8cb** (0.096 g, 0.204 mmol, 82%).

Cycloaddition of 1 to 3c and then 4c Leading to 8cc. Triene **1** (0.845 g, 2.9 mmol) was treated with **3c** (0.289 g, 2.9 mmol) and then **4c** (0.496 g, 5.8 mmol) in dry benzene (3 ml) under the conditions shown in Table 1. The benzene was removed off *in vacuo*, the residue was refluxed in methanol (50 ml) in the presence of *p*-toluenesulfonic acid (0.1 g), and the methanol was evaporated *in vacuo*. The residue was treated in the usual way as mentioned above and chromatographed over silica gel using chloroform–ethyl acetate (5:1) to give 0.14 g (15%) of **8cc**. It was purified by repeated column chromatography.

8cc: Colorless solid; mp 182—183 °C, IR (KBr) 3340 (OH), 1720, 1700, and 1675 cm^{-1} (C=O); ^{1}H-NMR (DMSO-d_6) δ= 2.92—4.20 (3H, m, CH_2 and CH), 3.50, 3.73, 3.77 (each 3H, s, COOMe), 6.80, 7.70 (each 1H, d, J_{vic}=9.0 Hz, ArH), 7.86 (1H, s, =CH), and 10.92 (1H, s, OH); ^{13}C-NMR (DMSO-d_6) δ=28.06 (t, CH_2), 37.16 (d, CH), 51.67, 51.84, 52.02 (each q, COOMe), 113.60 (d), 119.18 (s), 119.42 (s), 124.64 (s), 131.10 (d), 133.74 (d), 138.67 (s), 158.11 (s), 166.09, 166.32, and 172.49 (each s, COOMe); MS *m/z* 320 (M^+), 261 (M^+-59), and 229 (base peak).

Found: C, 59.85; H, 4.82%; M^+, 320. Calcd for $C_{16}H_{16}O_7$: C, 60.00; H, 5.03; M, 320.

Cycloaddition of 1 to 3c and then 3b Leading to 9. Triene **1** (0.587 g, 2.0 mmol) and **3c** (0.201 g, 2.0 mmol) were stirred in dry benzene (2 ml) at room temperature under nitrogen for 2 h. To this solution was added **3b** (0.228 g, 2.0 mmol) and the mixture was refluxed for 20 h, cooled to room temperature, treated with a few drops of trifluoroacetic acid, and then triturated with hexane. Colorless precipitate of **9** (0.257 g, 38%) was collected on a filter and washed with ether-hexane.

9: Colorless solid; mp 186—188 °C; IR (KBr) 1885, 1780, and 1720—1640 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$+DMSO-d_6) δ=2.70—4.10 (8H, m, 4-, 10-CH_2, 3a-, 6a-, 9a-, and 10b-H), 2.95 (3H, s, NMe), 3.07 (3H, s, OMe), and 4.92 (1H, d, J_{6-6a}=3.7 Hz, 6-H); ^{13}C-NMR (DMSO-d_6) δ=24.19, 32.82, 35.29, 36.17, 42.74, 45.62, 55.95 (OMe), 66.93 (6-C), 131.98 (5a-C), 151.53 (10a-C), 169.67, 172.72, 172.84, 176.01 (COO- and CON-), and 190.51 (5-CO); MS *m/z* 333 (M^+), 301 (M^+-32), and 230 (base peak).

This compound **9** was too unstable to provide an analytically pure sample by chromatography or crystallization. No satisfied analytical data were available.

Cycloaddition of 1 to 10a and then 4a Leading to 11aa and 12aa. A solution of freshly distilled **1** (0.877 g, 3.1 mmol) and **10a** (0.81 ml, 9.2 mmol) in dry benzene (3 ml) was heated at 80 °C under nitrogen for 48 h. The solvent and excess of **10a** were all evaporated completely *in vacuo* and the residue was dissolved in another 3 ml of dry benzene containing **4a** (0.435 g, 3.4 mmol). This solution was refluxed for 48 h. The usual work-up with methanol and column chromatography over silica gel with hexane–ethyl acetate (2:1) gave 0.228 g (21%) of **11aa**. Continued elution with the same solvent afforded 0.086 g (8%) of **12aa**.

11aa: Colorless prisms from benzene–hexane; mp 116—116.5 °C; IR (KBr) 3370 (OH) and 1715 cm^{-1} (C=O) ^{1}H-NMR ($CDCl_3$) δ=1.80—2.30, 2.64—2.88 (each 2H, m, 3- and 4-CH_2), 3.08 (1H, ddd, J_{2-3}=4.0, 10.8, and J_{2-1}=9.0 Hz, 2-H), 3.28 (3H, s, OMe), 3.78, 3.87, 3.89 (each 3H, s, COOMe), 5.36 (1H, d, J_{1-2}=9.0 Hz, 1-H), 7.28 (1H, s, 7-H), and 8.21 (1H, s, OH); ^{13}C-NMR ($CDCl_3$) δ=24.07, 25.60 (each t, 3- and 4-C), 42.33 (d, 2-C), 52.31, 52.55 (each q, COOMe and OMe), 75.80 (d, 1-C), 115.48 (d, 7-C), 124.00 (s), 126.46 (s), 129.45 (s), 136.85, 157.28 (s, 8-C), 166.03, 169.49, and 173.55 (each s, COOMe); MS *m/z* 352 (M^+) and 320 (M^+-32).

Found: C, 58.06; H, 5.81%; M^+, 352. Calcd for $C_{17}H_{20}O_8$: C, 57.95; H, 5.72%; M, 352.

12aa: Colorless needles from aqueous acetone; mp 185—186 °C; IR (KBr) 3260 (OH) and 1710 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.92—2.24 (2H, m, 3- or 4-CH_2), 2.40—3.04 (3H, m, 3- or 4-CH_2 and 2-H), 3.42 (3H, s, OMe), 3.74, 3.84, 3.87 (each 3H, s, COOMe), 5.04 (1H, d, J_{1-2}=4.5 Hz, 1-H), 7.24 (1H, s, 7-H), and 7.37 (1H, s, OH); ^{13}C-NMR ($CDCl_3$) δ=17.58, 24.98 (each t, 3- and 4-C), 43.47 (d, 2-C), 51.34, 51.99, 52.46, 58.27 (each q, COOMe and OMe), 70.13 (d, 1-C), 112.75 (d, 7-C), 125.26 (s), 127.25 (s), 128.31 (s), 135.94 (s), 156.43 (s, 8-C), 165.65, 168.46, and 172.58 (each s, COOMe); MS *m/z* 352 (M^+) and 320 (M^+-32).

Found: C, 58.07; H, 5.84%; M^+, 352. Calcd for $C_{17}H_{20}O_8$: C, 57.95; H, 5.72%; M, 352.

Cycloaddition of 1 to 10a and then 4b Leading to 11ab and 12ab. Under the same conditions as shown above (see Table 1), triene **1** (1.249 g, 4.4 mmol) was allowed to react with **10a** (1.2 ml, 13.1 mmol) and then **4b** (1.021 g, 4.4 mmol). The crude product was chromatographed over silica gel using hexane–ethyl acetate (1:1) to give 0.295 g (15%) of **11ab** and then 0.415 g (21%) of **12ab**.

11ab: Colorless prisms from dichloromethane–hexane; mp 133—135 °C; IR (KBr) 3300 (OH), 1725, 1655 (C=O), and 1580 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.80—2.20, 2.50—2.74 (each 2H, m, 3- and 4-CH_2), 3.10 (1H, ddd, J_{2-3}=4.0, 10.8, and J_{2-1}=9.0 Hz, 2-H), 3.34 (3H, s, OMe), 3.76 (3H, s, COOMe), 5.44 (1H, d, J_{1-2}=9.0 Hz, 1-H), 6.97 (1H, s, 7-H), 7.20—7.80 (10H, m, ArH), and 8.32 (1H, s, OH); ^{13}C-NMR ($CDCl_3$) δ= 24.25, 26.18 (each t, 3- and 4-C), 42.45 (d, 2-C), 52.25, 52.96 (each q, COOMe and OMe), 75.91 (d, 1-C), 116.25 (d, 7-C), 123.17, 128.11, 128.98, 129.99, 131.86, 132.86, 133.09, 136.68, 137.67, 137.91, 138.56, 156.67 (s, 8-C), 173.61 (s, COOMe), 195.56, and 198.09 (each s, COPh); MS *m/z* 444 (M^+) and 412 (M^+-32).

Found: C, 72.78; H, 5.42%; M^+, 444. Calcd for $C_{27}H_{24}O_6$: C, 72.96; H, 5.44%; M, 444. **12ab**: Colorless prisms from aqueous acetone; mp 194—195.5 °C; IR (KBr) 3440 (OH), 1715, 1655 (C=O), and 1580 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.80—3.04 (5H, m, 3-, 4-CH_2, and 2-H), 3.50 (3H, s, OMe), 3.72 (3H, s, COOMe), 5.07 (1H, d, J_{1-2}=4.5 Hz, 1-H), 6.90 (1H, s, 7-H), and 7.20—7.80 (11H, m, ArH and OH); ^{13}C-NMR (DMSO-d_6) δ=17.79, 25.71 (each t, 3- and 4-C), 43.62 (d, 2-C), 51.31, 58.53 (each q, COOMe and OMe), 70.57 (d, 1-C), 114.19 (d, 7-C), 126.58, 128.52, 129.57, 130.69, 132.92, 136.56, 137.27, 137.67, 155.70 (s, 8-C), 172.61 (s, COOMe), 195.32, and 197.27 (each s, COPh); MS *m/z* 412 (M^+-32).

Found: C, 72.96; H, 5.44%. Calcd for $C_{27}H_{24}O_6$: C, 72.90; H, 5.45%.

Cycloaddition of 1 to 10b and then 4a Leading to 11ba and 12ba. Triene **1** (1.306 g, 4.6 mmol) and **10b** (1.5 ml, 22.8 mmol) were heated at 75 °C in dry benzene (3 ml) under nitrogen for 48 h. All the volatile materials were completely evaporated off *in vacuo* and the residue was allowed to react with **4a** (1.296 g, 9.1 mmol) in benzene (3 ml) under reflux for 48 h. After the reaction mixture was subjected to the usual work-up with methanol, it was chromatographed over silica gel with hexane–ethyl acetate (2:1) to give 0.336 g (23%) of **11ba** and 0.175 g (12%) of **12ba**.

11ba: Colorless prisms from benzene–hexane; mp 163—164 °C; IR (KBr) 3400 (OH), 2240 (CN), and 1700 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.80—2.40, 2.70-3.00 (each 2H, m, 3-

and 4-CH_2) 3.24 (1H, ddd, J_{2-3}=4.0, 6.5, and J_{2-1}=5.5 Hz, 2-H), 3.46 (3H, s, OMe), 3.85, 3.88 (each 3H, s, COOMe), 4.91 (1H, d, J_{1-2}=5.5 Hz, 1-H), 7.24 (1H, s, 7-H), and 7.50 (1H, s, OH); ^{13}C-NMR (DMSO-d_6) δ=18.32, 22.37 (each t, 3- and 4-C), 27.01 (d, 2-C), 52.19, 52.60, 57.54 (each q, COOMe and OMe), 70.28 (d, 1-C), 113.13 (d, 7-C), 119.71 (s, CN), 124.70 (s), 124.94 (s), 129.22 (s), 134.86 (s), 157.46 (s, 8-C), 165.73, and 168.26 (each s, COOMe); MS *m/z* 319 (M^+) and 287 (M^+−32).

Found: C, 60.09; H, 5.41; N, 4.65%; M^+, 319. Calcd for $C_{16}H_{17}NO_6$: C, 60.18; H, 5.37; N, 4.39%; M, 319.

12ba: Colorless needles from aqueous acetone; mp 158—159 °C; IR (KBr) 3300 (OH), 2250 (CN), and 1720 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.80—3.40 (5H, m, 3-, 4-CH_2, and 2-H), 3.68 (3H, s, OMe), 3.84, 3.87 (each 3H, s, COOMe), 4.82 (1H, d, J_{1-2}=4.5 Hz, 1-H), 7.23 (1H, s, 7-H), and 7.87 (1H, s, OH); ^{13}C-NMR ($CDCl_3$) δ=21.61, 24.01 (each t, 3- and 4-C), 30.24 (d, 2-C), 52.66, 58.18 (each q, COOMe and OMe), 73.45 (d, 1-C), 115.43 (d, 7-C), 118.83 (s, CN), 123.94, 129.57, 134.68, 156.70 (s, 8-C), 165.97, and 169.43 (each s, COOMe); MS *m/z* 319 (M^+) and 287 (M^+−32).

Found: C, 59.90; H, 5.34; N, 4.49%; M^+, 319. Calcd for $C_{16}H_{17}NO_6$: C, 60.18; H, 5.37; N, 4.39%; M, 319.

Cycloaddition of ***1*** *to* ***10b*** *and then* ***4b*** *Leading to* ***11bb*** *and* ***12bb***. The same procedure as described above (see Table 1) starting from **1** (1.13 g, 3.9 mmol), **10b** (1.3 ml, 19.7 mmol), and **4b** (0.924 g, 3.9 mmol) gave 0.458 g (28%) of **11bb** and 0.168 g (10%) of **12bb**. The latter was purified by repeated chromatography.

11bb: Colorless needles from ethyl acetate-hexane; mp 220 °C; IR 3300 (OH), 2240 (CN), 1665, 1645 (C=O), and 1585 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.80—2.36, 2.60—2.80 (each 2H, m, 3- and 4-CH_2), 3.22 (1H, ddd, J_{2-3}=3.5, 8.5, and J_{2-1}=6.5 Hz, 2-H), 3.54 (3H, s, OMe), 5.04 (1H, d, J_{1-2}=6.5 Hz, 1-H), 6.96 (1H, s, 7-H), and 7.20—7.76 (11H, m, ArH and OH) ^{13}C-NMR (DMSO-d_6) δ=18.55, 23.01 (each t, 3- and 4-C), 27.12 (d, 2-C), 57.65 (q, OMe), 70.57 (d, 1-C), 114.54 (d, 7-C), 119.89 (s, CN), 124.05 (s), 128.52 (d), 128.69, 129.69, 130.51 (s), 133.09 (d), 135.39 (s), 136.59 (s), 137.73 (s), 137.85 (s), 156.70 (s, 8-C), 195.32, and 197.09 (each s, COPh); MS *m/z* 411 (M^+), 379 (M^+−32), and 105 (base peak).

Found: C, 75.65; H, 5.12; N, 3.65%; M^+, 411. Calcd for $C_{26}H_{21}NO_4$: C, 75.90; H, 5.14; N, 3.40%; M, 411.

12bb: Colorless solid; mp 186—189 °C; IR (KBr) 3280 (OH); 2240 (CN); 1660, 1635 (C=O), and 1580 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.70—3.00 (4H, m, 3- and 4-CH_2), 3.10—3.40 (1H, m, 2-H), 3.69 (3H, s, MeO), 4.86 (1H, d, J_{1-2}=4.5 Hz, 1-H), 6.90 (1H, s, 7-H), 7.10—7.90 (10H, m, ArH), and 8.28 (1H, s, OH); ^{13}C-NMR ($CDCl_3$+DMSO-d_6) δ=20.02, 24.95 (each t, 3- and 4-C), 30.71 (d, 2-C), 59.42 (q, OMe), 69.10 (d, 1-C), 114.19 (d, 7-C), 120.06 (s, CN), 124.41 (s), 127.58, 127.81, 128.22, 129.22, 130.57, 132.22, 132.45, 134.56, 136.27, 137.32, 137.56, 155.63 (s, 8-C), 195.03, and 197.27 (each s, COPh); MS *m/z* 379 (M^+−32) and 105 (base peak).

Found: C, 75.41; H, 5.18; N, 3.52%. Calcd for $C_{26}H_{21}NO_4$: C, 75.90; H, 5.14; N, 3.40%.

Cycloaddition of ***2*** *to* ***10a*** *and then* ***4a*** *Leading to* ***13*** *and* ***14***. A solution of **2** (0.895 g, 2.7 mmol), **10a** (4.9 ml, 54 mmol), and a catalytic amount of 1,4-benzenediol in dry benzene (10 ml) was refluxed under nitrogen for 5 d. All the volatile materials were completely evaporated *in vacuo* and the residue was dissolved in dry benzene (3 ml) containing **4a** (0.421 g, 3.0 mmol). This solution was refluxed under nitrogen for 48 h and the benzene was evaporated *in vacuo*. The residue was treated with methanol (20 ml) at room temperature overnight and the methanol was removed off. The viscous oil obtained was chromatographed over silica gel. The fraction eluted with hexane-ethyl acetate (4:1) afforded 0.045 g (6%) of **15**. The continued elution with hexane-ethyl acetate (2:1) gave a mixture of **13** and **14** (0.496 g, 46%). Both column chromatography over silica gel and high performance liquid chromatography were not effective for the separation of **13** and **14**.

13+14: Colorless solid (**13**:**14**=2:7, mp 77—83 °C); IR (KBr) 3400 (OH) and 1720 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.80—2.20 (2H, m, CH_2), 2.60—3.00 (3H, m, CH_2 and CH), 3.53, 3,62, 3.76, 3.84, 3.92 (9H, each s, COOMe), 4.75 (1H, br. d, 1-H), 6.40 (1H, s, OH), and 6.80-7.32 (5H, m, ArH); MS *m/z* 398 (M^+).

Cycloaddition of ***1*** *to* ***10a*** *and then* ***3b*** *Leading to* ***16***. Triene **1** (0.94 g, 3.3 mmol) and fresh **10a** (0.89 ml, 9.9 mmol) were heated under reflux in dry benzene (3 ml) under nitrogen for 48 h. All the volatile materials were evaporated off *in vacuo* and the residue was then heated together with **3b** (0.401 g, 3.6 mmol) in dry benzene (3 ml) under reflux for 24 h. The usual work-up of the reaction mixture with methanol gave viscous oil of crude product. It was chromatographed over silica gel using hexane-ethyl acetate (4:1) to afford 0.182 g (28%) of **17**. The continued elution with hexane-ethyl acetate (1:1) gave 0.233 g (25%) of **16** (mp 45—55 °C). During the purification of **16** by column chromatography under the same conditions, only one third of the charged amount was recovered and the purity of **16** was not so improved (mp 55—60 °C). Some spectral data of **16** are given below.

16: ^{1}H-NMR ($CDCl_3$) δ=2.40—3.20 (6H, m, CH_2), 3.00 (3H, s, NMe), 3.40—3.92 (2H, m, CH), 3.76 (3H, s, COOMe), and 7.44 (1H, br. s, 6-H); ^{13}C-NMR ($CDCl_3$) δ=20.49, 25.42, 27.24, 33.70, 37.46, 44.68, 51.90, 127.52, 128.93, 130.98, 150.59, 166.97, 173.72, 176.77, and 190.46; MS *m/z* 289 (M^+) and 274 (M^+−15).

Cycloaddition of ***2*** *to* ***10a*** *and then* ***3a*** *Leading to* ***18aa, 19aa, and 20aa***. A solution of **2** (0.895 g, 2.7 mmol), fresh **10a** (4.8 ml, 54 mmol), and 1,4-benzenediol (trace) in dry benzene (10 ml) was refluxed under nitrogen for 5 d. All the volatile materials were evaporated *in vacuo* and the residue was dissolved in another 3 ml of benzene containing **3a** (0.513 g, 3.0 mmol). The resulting solution was again refluxed for 48 h. The mixture was subjected to the usual work-up with methanol and then the column chromatography over silica gel. The fraction eluted with hexane-ethyl acetate (4:1) afforded **21** (0.082 g, 11%, endo:exo=1:5). The continued elution with hexane-ethyl acetate (1:1) gave 0.156 g (13%, 2:3) of a mixture of **18aa** and **20aa**, and then 0.413 g (36%) of **19aa**. The separation of **18aa** and **20aa** was unsuccessful (^{1}H-NMR ($CDCl_3$) δ=1.60—3.92 (9H, m, CH_2 and CH), 3.52 (3×0.4H, s, COOMe of **18aa**), 3.57 (3×0.6H, s, COOMe of **20aa**), 4.52 (1×0.6H, br. s, 6-H of **20aa**), 4.56 (1×0.4H, d, J_{6-7}=6.0 Hz, 6-H of **18aa**), and 6.80—7.60 (10H, m, ArH)).

19aa: Colorless solid from HPLC; mp 80—83 °C; IR (KBr) 1775, 1720, and 1670 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.70—3.84 (9H, m, CH_2 and CH), 3.67 (3H, s, COOMe), 4.45 (1H, br. s, 6-H), and 6.88-7.60 (10H, m, ArH); MS *m/z* 429 (M^+, base peak).

Found: M^+, *m/z* 429.1583. Calcd for $C_{26}H_{23}NO_5$: M, 429.1576.

Cycloaddition of ***2*** *to* ***10a*** *and then* ***3b*** *Leading to* ***18ab, 19ab, and 20ab***. Similar procedures using **2** (0.479 g, 1.4 mmol), **10a** (2.6 ml, 28 mmol), and a trace of 1,4-benzenediol in dry benzene (the first reaction: under reflux for 5 d; the second reaction: under reflux for 48 h) gave viscous oil of crude product. It was chromatographed over silica gel using hexane-ethyl acetate as an eluent to afford 0.15 g (38%) of **21** (endo:exo=1:3). The continued elution with hexane-ethyl acetate (1:1) gave a mixture of **18ab**, **19ab**, and **20ab** (0.138 g, 26%, **18ab**:**19ab**:**20ab**=1:4:2). The separation

of these isomers by column chromatography over silica gel was unsuccessful. Pure **18ab** and **19ab** were obtained through HPLC using dichloromethane-ethyl acetate (2:1) as an eluent.

18ab: Colorless solid from HPLC; mp 225—228 °C; IR (KBr) 1775, 1735, 1700, and 1675 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.60—2.04 (2H, m, CH_2), 2.10—3.82 (7H, m, CH_2 and CH), 3.00 (3H, s, NMe), 3.52 (3H, s, COOMe), 4.52 (1H, d, J_{6-7}=5.5 Hz, 6-H), and 6.80—7.36 (5H, m, ArH); MS *m/z* 367 (M^+, base peak).

19ab: Colorless plates from ether-hexane; mp 82—85 °C; IR (KBr) 1775 and 1720—1665 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.60—3.60 (9H, m, CH_2 and CH), 3.05 (3H, s, NMe), 3.65 (3H, s, COOMe), 4.41 (1H, br. s, 6-H), and 6.84—7.36 (5H, m, ArH), MS *m/z* 367 (M^+).

Found: M^+, *m/z* 367.1413. Calcd for $C_{21}H_{21}NO_5$: M, 367.1418.

Some characteristic signals of crude **20ab** in the ^{1}H-NMR spectrum in $CDCl_3$ are given as follows: δ=3.00 (3H, s, NMe), 3.60 (3H, s, COOMe), and 4.44 (1H, br. s, 6-H).

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 58750694 from the Ministry of Education, Science and Culture to E. W.

2) S. Danishefsky, T. Kitahara, C. F. Yan, and J. Morris, *J. Am. Chem. Soc.* , **101**, 6996 (1979).

3) After the reaction of **1** with **10a** was complete (reflux in dry benzene for 48 h), all the volatile materials were evaporated *in vacuo* and the residue was subjected to ^{1}H-NMR measurement. The spectrum was very clean and showed that only two isomeric mono-cycloadducts were formed in quantitative yields (isomer ratio was 1:2). the major isomer: δ=0.16, 0.22 (each 9H, s, TMS), 3.36 (3H, s, OMe), and 3.66 (3H, s, COOMe); the minor isomer: δ= 0.18, 0.24 (each 9H, s, TMS), 3.36 (3H, s, OMe), and 3.72 (3H, s, COOMe).

4) According to the molecular model inspection, the approach of the second dienophile across the diene part of mono-cycloadduct is sterically hindered, on both sides, when the cycloadduct has a half-chair conformation. On each side, there are each two repulsive axial substituents in this conformation, disturbing the approach of dienophile.

5) A mixture of two Michael adducts of mono-cycloadduct to **4a** was obtained in 22% yield. The Michael addition of enol silyl ethers is known: K. Yamamoto, S. Suzuki, and J. Tsuji, *Chem. Lett.* , **1978**, 649.

6) When the reaction mixture was treated with methanol at this stage, the endo and exo mono-adducts were isolated in 22 and 70% yields, respectively (see Ref. 1).

7) The configuration of the initially formed six-membered rings was determined on the basis of the coupling constants J_{6-7}. The stereochemistry of fused maleimide rings was based on the stereochemical characteristics of diene-transmissive Diels-Alder cycloaddition.

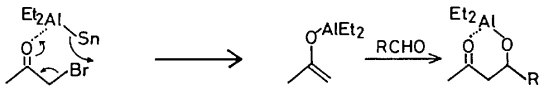
Reformatsky Type Reaction with New Aluminium Reagents Containing Al-Sn or Al-Pb Linkage[1)]

Seijiro MATSUBARA, Noriyuki TSUBONIWA, Yoshitomi MORIZAWA, Koichiro OSHIMA,* and Hitosi NOZAKI
Department of Industrial Chemistry, Faculty of Engineering Kyoto University, Yoshida, Kyoto 606
(Received June 28, 1984)

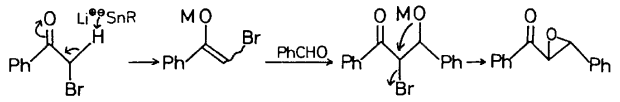
Treatment of α-bromo carbonyl compounds with the reagent prepared from *n*-Bu_3SnLi and Et_2AlCl or from $SnCl_2$ and Et_2AlCl affords enolates which react with ketone or aldehyde to give β-hydroxy carbonyl compounds in good to excellent yields. The reactions proceed similarly with the reagents which are generated from R_3PbLi (R=Ph, *n*-Bu) and Et_2AlCl. Catalysis by the added $Pd(PPh_3)_4$ complex promotes the reduction effectively and improves the yields of the desired adducts. The regio- and stereoselectivities are disclosed.

Cross aldol condensation is one of the most versatile method of making a carbon–carbon bond. The old procedures, however, have some drawbacks of accompanying self aldol condensation and retro-aldol reaction, which provide undesired by-products.[2)] During the past decade, numerous efforts have been made to overcome these shortages.[3)] Among many metal enolates such as Li,[2)] Mg,[2)] Zn,[2)] Ti,[4a)] B,[4b)] Al,[4c,4d,4e)] Si,[4f)] and Sn,[4g)] having been explored, aluminium enolate is suitable for trapping the initially formed aldol adducts as stable chelates.[4c)] Previously reported[4c)] aldol reaction is based on the generation of the regiospecific aluminium enolate by the coupled attack of Et_2AlCl and Zn on the α-halo carbonyl compounds. Here we wish to describe another effective method for the regioselective formation of aluminium enolates which are sufficiently reactive to attack carbonyl components under mild conditions.

A novel reagent which is believed to have an aluminium-tin single bond[5)] is produced by treatment of *n*-Bu_3SnLi[6)] with an equimolar amount of Et_2AlCl. The aluminium atom should behave as a Lewis acid center, which will coordinate the carbonyl oxygen and will give rise to *n*-Bu_3Sn anion acting as a potent reductant (Scheme 1). In fact, treatment of an α-bromo carbonyl compound with this reagent gave an enolate which reacted with a ketone or aldehyde to afford a β-hydroxy carbonyl compound in good yield after aqueous work-up. The success is ascribed to the strong affinity of tin for bromine[7)] as well as that of aluminium for oxygen. Actually, treatment of a mixture of α-bromoacetophenone and benzaldehyde with *n*-Bu_3SnLi alone gave a small amount of β-hydroxy ketone (<5%) in addition to 1,3-diphenyl-2,3-epoxy-1-propanone (33% yield), a Darzens type product.[8)] The latter compound was produced exclusively in 63% yield in the reaction of *n*-Bu_3SnLi–Me_3Al combination instead of *n*-Bu_3SnLi–Et_2AlCl. Strong basicity of the Sn^- anion accompanying Li^+ ion explains the observed results (Scheme 2).



Scheme 1.



Scheme 2.

As shown in Table 1, the *n*-Bu_3SnLi–Et_2AlCl reagent can be applied equally well to the Reformatsky reaction[9–11)] of α-bromo esters. Reactions of methyl γ-bromocrotonate shown in Scheme 3 gave the α-adducts exclusively in contrast to the normal Reformatsky reactions producing mixtures of α-adducts and γ-adducts in roughly 7:3 ratios.[12)] This high regioselectivity is a characteristic of the aluminium dienolate.[4c,4e)]

a) These compounds gave satisfactory specra data. See Ref. 4c. b) A catalytic amount of $Pd(PPh_3)_4$ (5 mol%) was added. c) No 1,4-adduct was detected among the reaction mixture. d) The ratio of the stereoisomers (erythro and threo) was determined by an absorption due to the benzylic proton. See Ref. 4 g. e) This compound was identical with the authentic sample. See Ref. 4f. f) Determined by nmr analysis. See Ref. 4f.

Table 2. Reformatsky type reactions with $SnCl_2$-Et_2AlCl system

Run	Bromo ketone or bromo ester	Ketone or aldehyde	Additive	Products	Yield/%
1	$PhCOCH_2Br$	PhCHO	—		70
2	$PhCOCH_2Br$	PhCHO	$Pd(PPh_3)_4$[a]		91
3	Ethyl bromoacetate	Cyclohexanone	$Pd(PPh_3)_4$[a]		89
4	Ethyl bromoacetate	PhCHO	$Pd(PPh_3)_4$[a]		88
5	Ethyl bromoacetate	Cyclohexanone	$Pd(PPh_3)_4$[a]		61
6	2-Bromocyclohexanone	PhCHO	$Pd(PPh_3)_4$[a]		95 (31/69)[b]
7	*Methyl γ-bromo*-crotonate	PhCHO	—[c]		80 (41/59)[d]

a) A catalytic amount of $Pd(PPh_3)_4$ (5 mol%) was added. b) The ratio of the stereo isomers (erythro and threo) was determined by an absorption due to the benzylic proton. See Ref. 4g. c) Palladium catalyst was not effective. d) Erythro/threo ratio was determined by an absorption due to the methoxyl proton. See Ref. 4c.

TABLE 3. REFORMATSKY TYPE REACTIONS WITH R_3PbLi-Et_2AlCl SYSTEM

Run	Bromo ketone or bromo ester	Ketone or aldehyde	Reagent	Products	Yield/%
1	$PhCOCH_2Br$	PhCHO	A	$PhCCH_2CHPh$ (O, OH)	86
2	$PhCOCH_2Br$	PhCHO	B	$PhCCH_2CHPh$ (O, OH)	78
3	$PhCOCH_2Br$	Cyclohexanone	A		61
4	$PhCOCH_2Br$	Cinnamaldehyde	B[a]	$PhCCH_2-CH-CH=CHPh$ (O, OH)	84
5	2-Bromocyclohexanone	PhCHO	A		77 (28/72)[b]
6	Methyl γ-bromo-crotonate	Cyclohexanone	A[a]		74
7	Methyl γ-bromo-crotonate	Cyclohexanone	A		56

Reagent A: n-Bu_3PbLi-Et_2AlCl; Reagent B: Ph_3PbLi-Et_2AlCl. a) A catalytic amount of $Pd(PPh_3)_4$ (5 mol%) was added. b) The ratio of the stereo isomers (erythro and threo) was determined by an absorption due to the benzylic proton. See Ref. 4g.

The regioselectivity of the reaction was demonstrated by the following two examples (Scheme 4). Treatment of a mixture of 2-bromo-2-methylcyclohexanone[13] and benzaldehyde with n-Bu_3Sn-$AlEt_2$ gave the expected β-hydroxy ketone I.[4a] Meanwhile, the reaction of 2-bromo-6-methylcyclohexanone[14] provided the regioisomer II[4a] exclusively. Each product I or II was obtained as a single product without any contamination of the opposite regioisomer. Since the starting bromides are prepared with high regioselectivity, the present method provided us with a simple route to the β-hydroxy ketones I and II.

It should be noted that these reactions proceeded more effectively in the presence of a catalytic amount of $Pd(PPh_3)_4$ (Run 5, 7, 11, 13, and 16). For instance, the yield of the adduct of α-bromoacetophenone and cinnamaldehyde was increased from 54% to 75% in the presence of a catalytic amount of $Pd(PPh_3)_4$.[15] We may safely assume that Pd(0) facilitates the reduction of bromo ketone[16] to the aluminium enolate.

The addition of a hexane solution of Et_2AlCl to a suspension of anhydrous $SnCl_2$ in dichloromethane gave a dark red homogeneous solution.[17] The reagent thus prepared also was found to be effective for the Reformatsky type reaction (Table 2). The stereochemistry of the adducts and the regiochemistry of these reactions are similar to those with n-Bu_3SnLi-Et_2AlCl reagent (Run 6, 7).

The use of $PhMe_2SiLi$[18] and Ph_3GeLi[19] instead of n-Bu_3SnLi resulted in a formation of only a small amount of desired β-hydroxy ketone in addition to unidentified products. The combination of R_3PbLi-Et_2AlCl[20] (R=n-Bu, Ph), however, proved to be as effective as n-Bu_3SnLi-Et_2AlCl system (Table 3). The stereochemical outcomes were almost same as those with n-Bu_3SnLi-Et_2AlCl system.

Experimental

The IR spectra were determined on a Shimadzu IR-27-G spectrometer, the mass spectra on a Hitachi M-80 machine, and the NMR spectra on a Varian EM-390 spectrometer. The chemical shifts are given in δ, with TMS as an internal standard. The analyses were carried out by the staff at the Elemental Analyses Center of Kyoto University. Tetrahydrofuran was freshly distilled from sodium benzophenone ketyl. Purification of products were performed by column chromatography on silica gel (Wakogel C-100) or preparative thin-layer chromatography (TLC). Analytical GLPC was performed with a Yanagimoto GCG-550-F and a Shimadzu GC-4CPT.

Preparation of β-Hydroxy Carbonyl Compounds with the Reagent Prepared from n-*Bu₃SnLi–Et₂AlCl.* A hexane solution of butyllithium (1.6 M†, 3.8 ml, 6.0 mmol) was added to a suspension of anhydrous tin(II) chloride (0.38 g, 2.0 mmol) in THF (4 ml) at 0 °C. After being stirred for 20 min, the reaction mixture was treated with a hexane solution of diethylaluminum chloride (1.0 M, 2.0 ml, 2.0 mmol) at 0 °C. After the resulting mixture was stirred for another 20 min, a mixture of α-bromo carbonyl compound (1.0 mmol) and ketone or aldehyde (1.0 mmol) in THF (3 ml) was added [$Pd(PPh_3)_4$ (58 mg, 0.05 mmol) was added successively, if necessary] and the whole was stirred for 30 min. The reaction mixture was poured into 1M hydrochloric acid (20 ml) and

† 1 M=1 mol dm^{-3}.

extracted with ether. The combined organic layers were washed with brine, dried over anhydrous sodium sulfate, and concentrated. The crude product was purified by silica-gel column chromatography (hexane–ethyl acetate, 2:1).

3-Hydroxy-1-phenyl-1-undecanone: Mp 41.5 °C (pentane); IR (nujol) 3500, 1672, 1205 cm^{-1} NMR (CCl_4): δ=0.90 (t, J=6 Hz, 3H), 1.05—1.70 (m, 14H), 2.80—3.20 (m, 3H), 3.85—4.25 (m, 1H), 7.20—7.60 (m, 3H), 7.75—8.00 (m, 2H); MS m/z (%): 244 (30; M^+-18), 220 (34), 120 (35) 105 (100); Found: C, 77.75; H, 10.22%. Calcd for $C_{17}H_{26}O_2$: C, 77.82; H, 9.99%.

(E)-3-Hydroxy-1-phenyl-4-hexen-1-one: Bp 80 °C (bath temp, 1 Torr††); IR (neat): 3350, 2875, 1700, 1660, 1428 cm^{-1}; NMR (CCl_4) δ=1.68 (d, J=5.7 Hz, 3H), 2.80 (bs, 1H), 3.02 (d, J=6.0 Hz, 2H), 4.40—4.70 (m, 1H), 5.36—5.90 (m, 2H), 7.2—7.65 (m, 3H), 7.75—8.05 (m, 2H); MS m/z (%) 172 (2, M^+-18), 120 (30), 105 (100), 77 (52); Found: C, 75.60; H, 7.50%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

Ethyl (E)-3-Hydroxy-5-phenyl-4-pentenoate: Bp 75 °C (bath temp, 1 Torr); IR (neat): 3400, 1705, 1150, 1020, 960 cm^{-1}; NMR (CCl_4): δ=1.25 (t, J=7.5 Hz, 3H), 2.50 (d, J=6 Hz, 2H), 2.90 (bs, 1H), 4.10 (q, J=7.5 Hz, 2H), 4.35—4.75 (m, 1H), 6.33 (d,d, J=6.7 Hz, 15.3 Hz, 1H), 6.90—7.40 (m, 6H); MS m/z (%): 220 (19, M^+), 202 (25), 174 (15), 129 (71), 104 (100), 91 (19); Found: C, 71.04, H, 7.50%. Calcd for $C_{13}H_{16}O_3$: C, 70.89, H, 7.32%. Saponification and dehydration gave 5-phenylpentadienoic acid, which was identical with an authentic sample.[21]

1-Hydroxy-1-phenyl-3-nonanone: Bp 104 °C (bath temp, 0.7 Torr); IR (neat): 3400, 2899, 1679, 1443 cm^{-1}; NMR (CCl_4): δ=0.90 (t, J=6 Hz, 3H), 1.05—1.70 (m, 8H), 2.35 (t, J=6.6 Hz, 2H), 2.60 (d, J=6 Hz, 1H), 2.63 (d, J=7.5 Hz, 1H), 3.15—3.45 (m, 1H), 4.8—5.1 (m, 1H), 6.95—7.30 (m, 5H); MS m/z (%): 234 (0.5, M^+), 216 (3.8), 146 (69), 131 (100), 77 (13), 58 (26); Found: C, 77.05, H, 9.60%. Calcd for $C_{15}H_{22}O_2$: C, 76.88, H, 9.46%.

1-(1-Hydroxycyclohexyl)-2-octanone: Bp 58 °C (bath temp, 1 Torr); IR (neat): 3455, 1690, 1400, 970 cm^{-1}; NMR (CCl_4): δ=0.90 (t, J=6 Hz, 3H), 1.0—2.0 (m, 18H), 2.30 (t, J=6.6, 2H), 2.40 (s, 2H), 3.30 (bs, 1H); MS m/z (%): 226 (15, M^+), 208 (35), 156 (8), 113 (100), 99 (51); Found: C, 74.38, H, 11.87%. Calcd for $C_{14}H_{26}O_2$: C, 74.29, H, 11.58%.

Methyl 2-(1-Hydroxycyclohexyl)-3-butenoate: Bp 51 °C (bath temp, 0.7 Torr); IR (neat): 3450, 1700, 1620, 1155, 985, 905 cm^{-1}; NMR (CCl_4): δ=0.80—1.90 (m, 10H), 2.82 (bs, 1H), 2.91 (t, J=9 Hz, 1H), 3.67 (s, 3H), 5.07 (d,d, J=16.5, 1.5 Hz, 1H), 5.13 (d,d, J=7.5, 1.5 Hz, 1H), 5.90 (d,d,d, J=16.5, 7.5, 1.5 Hz, 1H); MS m/z (%): 198 (0.76, M^+), 183 (2.5), 155 (10), 100 (100), 99 (92), 81 (36), 69 (17), 68 (29); Found: C, 77.05, H, 9.60%. Calcd for $C_{11}H_{18}O_3$: C, 76.88, H, 9.46%.

Preparation of β-Hydroxy Carbonyl Compounds with the Reagent Prepared from $SnCl_2$–Et_2AlCl. A hexane solution of diethylaluminum chloride (1.0 M, 2.0 ml, 2.0 mmol) was added to a suspension of anhydrous tin (II) chloride (0.38 g, 2.0 mmol) in CH_2Cl_2 (5 ml) at 0 °C. The solution turned to red immediately. After being stirred for 20 min, a mixture of α-bromo carbonyl compound (1.0 mmol) and ketone or aldehyde (1.0 mmol) in CH_2Cl_2 (3 ml) was added [$Pd(PPh_3)_4$ (58 mg, 0.05 mmol) was added at the same time, if necessary] and the whole was stirred for 1 h. The reaction mixture was poured into 1M hydrochloric acid (30 ml) and extracted with ether. The combined organic layers were washed with brine, dried over anhydrous sodium sulfate, and concentrated. The crude product was purified by silica-gel column chromatgraphy (hexane–ethyl acetate, 2:1).

Preparation of β-Hydroxy Carbonyl Compounds with the Reagent Prepared from R_3PbLi–Et_2AlCl. A hexane solution of butyllitium (1.6 M, 3.8 ml, 6.0 mmol) or an ether solution of phenyllilitum (2.7 M, 2.2 ml, 6.0 mmol) was added to a suspension of a lead (II) chloride (0.56 g, 2.0 mmol) in THF (4 ml) at 0 °C. After being stirred for 20 min, the whole was cooled to −20 °C, and a hexane solution of diethylaluminum chloride (1.0 M, 2.0 ml, 2.0 mmol) was added at the same temperature. After the resulting mixture was stirred for another 20 min, a mixture of α-bromo carbonyl compound (1.0 mmol) and ketone or aldehyde (1.0 mmol) in THF (3 ml) was added [$Pd(PPh_3)_4$ (58 mg, 0.05 mmol) was added at this time, if necessary] and the whole was warmed up to 0 °C and stirred for 30 min. The reaction mixture was poured into 1 M hydrochloric acid and extracted with ether. The combined organic layers were washed with brine, dried over anhydrous sodium sulfate, and concentrated. The residual liquid was submitted to silica-gel column chromatgraphy with hexane–ethyl acetate=2:1 as an eluent.

Darzens Type Reactions with n-Bu_3SnLi–Me_3Al System. A hexane solution of trimethylaluminium (1.0 M, 2.0 ml, 2.0 mmol) was added to a solution of *n*-Bu_3SnLi prepared from *n*-BuLi (6.0 mmol) and $SnCl_2$ (0.38 g, 2.0 mmol) as described above, in THF (3.0 ml) at 0 °C. After stirring for 2 h, a mixture of α-bromoacetophenone (0.20 g, 1.0 mmol) and benzaldehyde (0.11 g, 1.0 mmol) in THF (2.0 ml) was added at 0 °C and the resulting mixture was stirred for another 20 min. The reaction mixture was poured into 1 M hydrochloric acid (30 min) and extracted with ether. The combined organic layers washed with brine, dried and concentrated. Purification by preparative TLC on silica-gel (hexane-ethyl acetate, 5:1) gave 1,3-diphenyl-2,3-epoxy-1-propanone in 63% yield.

1,3-Diphenyl-2,3-epoxy-1-propanone: Mp 88.5 °C (CH_2Cl_2/penthane); IR (CCl_4): 3000, 1680, 1590, 1500, 1210, 1000, 890 cm^{-1}; NMR (CCl_4): δ=3.90—4.05 (m, 2H) 6.90—7.60 (m, 3H), 7.27 (s, 5H), 7.80-8.10 (m, 2H); MS m/z (%): 224 (12.4, M^+), 165 (9), 105 (100), 91 (23), 77 (64), 65 (16), 51 (31); Found C, 79.87, H, 5.30. Calcd for $C_{15}H_{12}O_2$: C, 80.34, H, 5.39%.

Financial support by the Ministry of Education, Science and Culture, Japanese Government (Grant-in Aid for Special Project Reserch 58110005) is acknowledged. We also thank Toyo Stauffer Chemical Company for a gift of Et_2AlCl.

Electroluminescent Properties of *n*-GaAs in Peroxodisulfate Solutions. Transient Behavior and Carrier Concentration Effect on Emission Spectra

Kohei UOSAKI* and Hideaki KITA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 12, 1984)

Electroluminescence (EL) due to band-to-band transition was observed for *n*-GaAs in solutions containing peroxodisulfate ions. Digital simulation shows that the observed transient current and EL intensity stimulated by negative potential pulses can be explained by assuming that the surface concentration of $S_2O_8^{2-}$ was zero during potential pulses and that the EL intensity was proportional to the surface concentration of SO_4^{-} (generated by the one-electron reduction of $S_2O_8^{2-}$). Surface composition change seems to be the main reason for the relation between the potential and EL intensity. A hydrogen evolution reaction reduces the EL efficiency at relatively negative potentials. Although the potential and time had no observed effect on the shape of the EL spectra, the carrier concentration affected the peak position and the full width at half maximum (FWHM) of the EL spectra. For greater carrier concentrations, the wavelength of the EL peak became shorter and the FWHM became larger. These results agree with those reported regarding solid-state luminescence and can be explained by the filling of the conduction band states by electrons (Burnstein-Moss shift).

The luminescent properties of semiconductors in solutions have proved to be useful in understanding the mechanism of electrochemical reactions at semiconductor electrodes.[1-10] Photoluminescence (PL) measurements are often used to determine the quantum efficiency of photoelectrochemical reactions[11-13] and electroluminescence (EL) measurements are used to probe the intermediates of reactions and the surface states of semiconductors.[14-18]

Gallium arsenide (GaAs) has been one of the most frequently studied semiconductors and its luminescent properties at p/n and semiconductor/metal junctions have become well known.[19-25] The luminescent properties of GaAs in solution, however, have been studied less. Recently, Hobson and Ellis thoroughly studied the photoluminescent properties of *n*-GaAs in a solution containing Te^{2-}/Te_2^{2-}.[26] Only a few reports are available involving the electroluminescence properties of GaAs.[27-30]

In this paper, we describe the transient behavior of the current and the EL intensity of *n*-GaAs electrodes in solutions containing $S_2O_8^{2-}$ and the effect of carrier concentration on the EL spectra.

Experimental

Materials. Four types of *n* -GaAs single crystals with different carrier concentrations were used in the present study. Their properties are summarized in Table 1. Ohmic contacts to the crystals were obtained using an In-Ga alloy. The procedure for mounting the electrodes was similar to one reported before.[31] The electrode surface was etched in HNO_3-HCl (1:1) before each experiment. Reagent-grade NaOH and $K_2S_2O_8$, and water purified using a Milli-Q water purification system (Millipore Corp.) were used to prepare electrolyte solutions.

Electrochemical and Luminescent Measurements. The potential of the electrode was controlled with a potentiostat (Hokuto Denko, HA-301) with respect to an Ag/AgCl reference electrode. A large Pt foil, which surrounded a GaAs working electrode, was used as a counter electrode. The EL intensity was monitored with a photomultiplier (Hamamatsu TV Co. Ltd., R406) having a response similar to S-1. A programmable function generator (Hokuto Denko, HB-105) and a wave-memory unit (NF Electronic Co. Ltd., WM-811 with an 8-bit resolution) were used to study the transient behavior of the EL intensity and current. Both the function generator and the wave-memory unit were controlled by a personal computer (Nippon Electronic Co. Ltd., PC-8801) *via* a GP-IB interface and a PIO interface with TTL signals, respectively. After each measurement, data were transferred to the computer and, to improve the signal-to-noise ratio, the data were averaged 2—64 times. The averaged data were then transferred to and stored on a floppy disc. The time sequence for the transient behavior measurements is shown in Fig. 1(a).

Time-resolved EL spectra were obtained by pulsing the potential between −0.5 V and −3.65 V, following the time sequence shown in Fig. 1(b). In this case, the computer was used to provide potential pulses *via* a 12-bit D/A convertor, to collect the photomultiplier (PMT) response which was amplified by a fast-response amplifier (NF Electronic Co. Ltd., LI-75A, 1 MHz, gain=100) *via* a 12-bit D/A convertor every 10 msec and to control a monochromator (Ritsu Oyo Kogaku Co. Ltd., MC-20N, having a grating with 1200 grooves/mm blazed at 0.75 μm). After the EL intensity was measured and averaged at one wavelength, the monochromator was driven to make measurements at a new wavelength. After all the measurements were completed, the EL data were trans-

ferred to and stored on a floppy disc.

Similar arrangements were employed to study the potential dependence of the EL spectra. The time sequence for this type measurement is shown in Fig. 1(c). The potential was pulsed between −0.5 V and a given potential. The resulting PMT response was observed at a given wavelength 10 msec after the potential step, amplified by the LI-75A amplifier, monitored by a 12-bit A/D convertor and stored in the computer. After measurements at a given potential were completed, measurements at new potentials were carried out. Measurements were repeated at 2.5 or 5 nm intervals. After all the measurements were completed, the EL data were transferred to and stored on a floppy disc.

Digital simulation was carried out using the computer and calculated results were plotted on an X-Y plotter (RY 11Z, Rika Denki Co. Ltd.).

Results

The Transient behavior and Potential Dependence of Current and EL Intensity. Typical EL-i-t relations of *n*-GaAs (sample No.4) in a solution containing 5 M NaOH (1 M=1 mol dm^{-3}) and 0.10 M $K_2S_2O_8$ for potential pulses of 300 msec are shown in Fig. 2. The electrode potential was kept at −1.0 V for about 1 min before each potential pulse. As the pulse was made more negative, the maximum EL intensity became

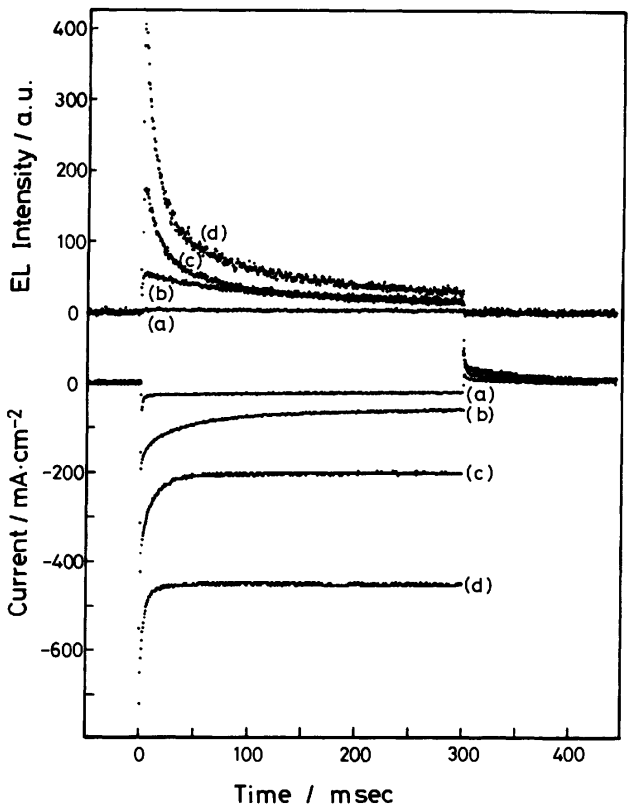

Fig. 2. EL-i-t relations of *n*-GaAs (Te doped, 0.96×10^{18} cm^{-3}) in a solution containing 5 M NaOH and 0.10 M $K_2S_2O_8$ for potential pulses from −1.0 V (1 min) to a given potential (300 msec). (a): −1.5 V, (b): −2.0 V, (c): −2.5 V, (d): −3.0 V.

greater and the maximum cathodic current became larger. The potential dependence of the EL intensity is, in general, not so simple. The EL intensity and the current at 50, 100, 200, and 295 msec after the cathodic potential pulse was applied are plotted against the pulsed potential (Fig. 3). The EL intensity was made to increase by applying a more negative cathodic pulse, until *ca.* −1.9—−2.0 V. However, it decreased between −2.0 and −2.2 V and then increased again.

EL Spectra. The EL Spectra of *n*-GaAs (sample No.4) in a solution containing 5 M NaOH and 0.15 M $K_2S_2O_8$ at 10, 30, 50, and 70 msec after a potential was pulsed from −0.5 V to −3.65 V are shown in Fig. 4(a). The EL peak appeared at 855 nm (1.45 eV), which is in good agreement with the band-gap energy of GaAs.[32] There seems to be no spectral change within this time domain, which is clearly seen in Fig. 4(b) where the EL spectra are normalized to the peak intensity of each spectrum.

To study the potential dependence of the EL spectra, only data 10 msec after the pulses were applied were obtained for four GaAs samples, since there was no spectral change during the potential pulse. Typical EL spectra are shown in Fig. 5(a). Normalized spectra are shown in Fig. 5(b). No potential effect on EL spectra was observed in any of the four samples.

The relation of carrier concentration on the EL spectra was also studied. Since no time or potential depen-

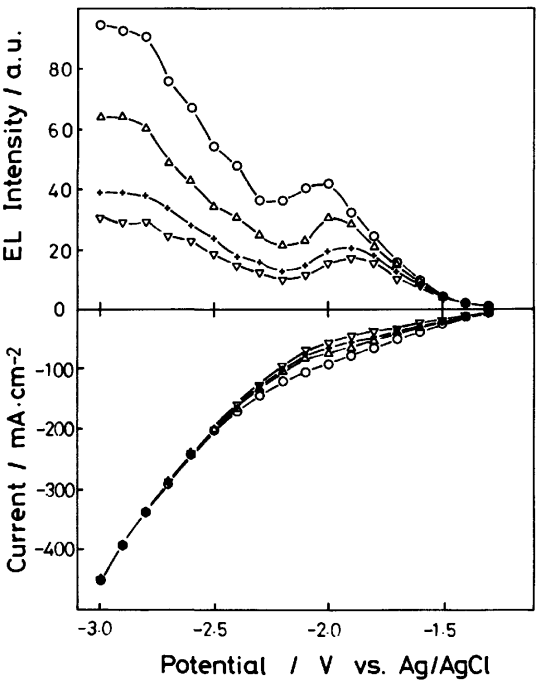

Fig. 3. Pulsed potential dependence of EL intensity and current at 50 (○), 100 (△), 200 (+), and 295 (▽) msec after potential was stepped from −1.0 V. Other experimental conditions are as same as those of Fig. 2.

dencies were observed, only the normalized EL spectra obtained 10 msec after the potential was pulsed from −0.5 V to −3.5 V are shown in Fig. 6. For higher carrier concentrations, the peak energy increased and the FWHM of the EL spectra became larger. It was rather difficult to study the effect of carrier concentration on EL intensity quantitatively because the surface area of the electrodes and the alignment varied from experiment to experiment. The effect of a dopant on spectral shape was negligible, as far as a comparison between Si and Te was concerned.

Although Pettinger *et al.* reported that sub-band emission is much stronger than band-edge emission for *n*-GaAs,[27] we observed only small, if any, sub-band emission. Because of the poor sensitivity of the PMT employed in this study at wavelengths longer than 1000 nm, it is not possible to quantitatively compare the intensity of the band-edge emission to that of the sub-band emission.

Discussion

It is well known that the EL of *n*-type semiconductors in solutions containing $S_2O_8^{2-}$ is predominanly caused by the following reactions[6]

$$S_2O_8^{2-} + e_c^- \longrightarrow SO_4^{\cdot-} + SO_4^{2-}, \quad (1)$$

$$SO_4^{\cdot-} \longrightarrow SO_4^{2-} + p_v^+. \quad (2)$$

Thus, $S_2O_8^{2-}$ is first reduced by electrons of the conduction band, e_c^-, producing $SO_4^{\cdot-}$ which is a strong oxidant to be able to inject holes into the valence band of semiconductors, p_v^+. A part of p_v^+ recombine radiatively

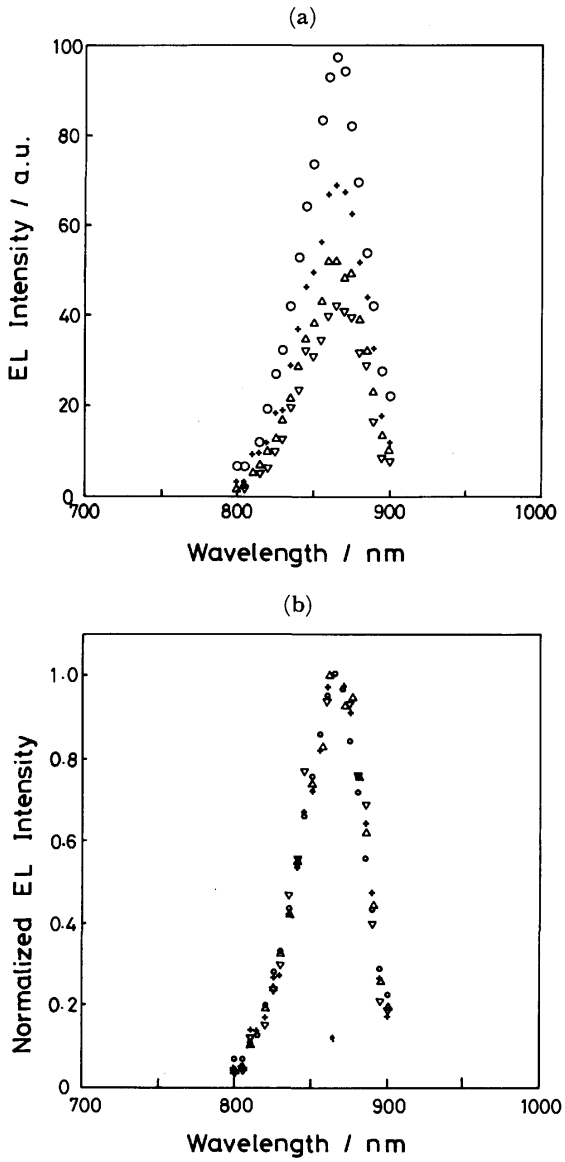

Fig. 4. EL spectra (a) and normalized EL spectra (b) of *n*-GaAs (Te doped, 0.96×10^{18} cm^{-3}) in a solution containing 5 M NaOH and 0.15 M $K_2S_2O_8$ at 10 (○), 30 (+), 50 (△), and 70 (▽) msec after potential was pulsed from −0.5 V to −3.65 V.

with e_c^- either directly or *via* intermediate levels such as surface states, lattice defects or impurity states. The former process generates edge emission and the latter sub-band emission. As mentioned before, the energy of the major peak in the EL spectra of GaAs in this study coincides with the energy gap of GaAs, suggesting that the band-to-band transition is the dominant process in the generation of EL.

The transient behaviors of the EL of *n*-ZnO and of ZnS were studied by Yamase and Gerischer[5] and by Fan *et al.*[7], respectively, but that of *n*-GaAs is not available. The potential dependence of the transient behavior of EL and current is more clearly seen by studying the transient behavior of EL efficiency, which is the ratio of the EL intensity to current, as shown in Fig. 7. The S/N ratio at relatively positive potentials was low because of

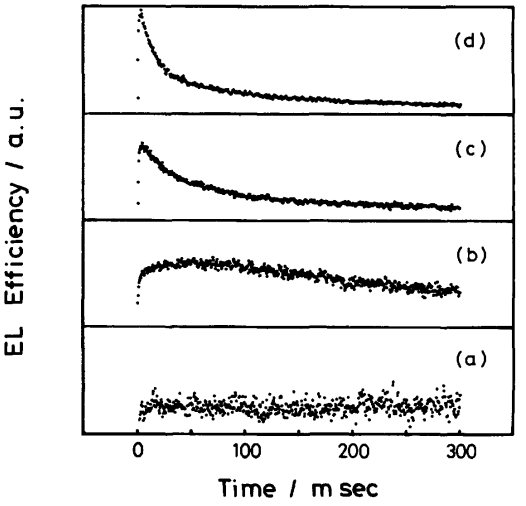

Fig. 7. Transient behavior of EL efficiency calculated from the data in Fig. 2.

the small values of EL intensity and current. It is, however, clear that while the efficiency was almost constant at -1.5 V, it gradually increased and then decreased with time at -2.0 V. A similar trend was observed at more negative potentials but the time to reach the maximum intensity was smaller at more negative potentials. The EL efficiency-potential relations for different time domains are shown in Fig. 8. There is a clear maximum in each relation around -2.2 V. Similar results were reported for n-GaAs in solutions containing several hole-injecting species,[30] for n-InP in dilute nitric acid[10] and for ZnO in a solution containing $S_2O_8^{2-}$.[5] Two reasons should be considered. One is the depletion of $S_2O_8^{2-}$ near the electrode surface and the other is a change in surface characteristics. At the beginning of the potential pulse, no $SO_4^{\cdot-}$ exists and, therefore, no EL is observed. $SO_4^{\cdot-}$ is generated by the reaction (1) and the EL intensity increases. However, $S_2O_8^{2-}$ is depleted at the surface and eventually $SO_4^{\cdot-}$ also decreases. Thus, the EL intensity decreases. This can be formulated, semiquantitatively, by assuming that the surface concentration of $S_2O_8^{2-}$ is zero during the potential pulse, *i.e.*, the rate of reaction (1) is controlled by diffusion of $S_2O_8^{2-}$, and EL intensity is proportional to $SO_4^{\cdot-}$ concentration. The surface concentration of $SO_4^{\cdot-}$, c_s, is given by solving

$$\frac{dc_s}{dt} = \frac{\sqrt{D}c^*}{\sqrt{\pi t}} - k_1 c_s, \tag{3}$$

where D and c^* are the diffusion coefficient and bulk concentration of $S_2O_8^{2-}$, respectively, k_1 is the rate constant for reaction (2) and t is the time after potential is

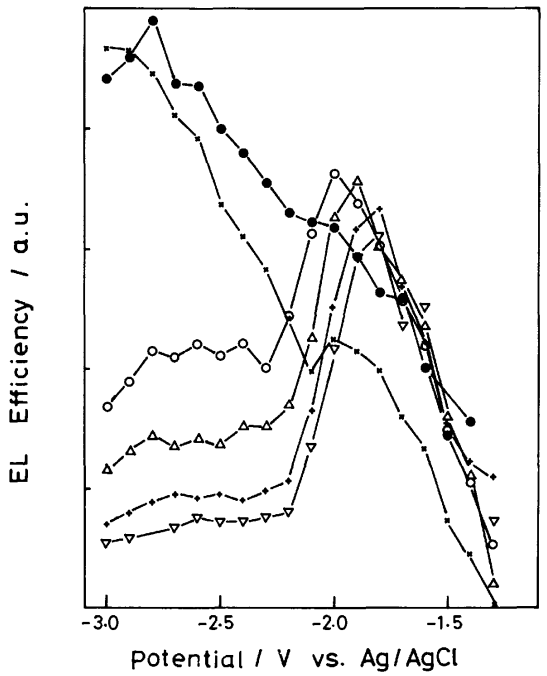

Fig. 8. Pulsed potential dependence of EL efficiency at 1 (▲), 10 (×), 50 (○), 100 (△), 200 (+), and 295 (▽) msec after potential was stepped from −1.0 V. Other experimental conditions are as same as those of Fig. 2.

pulsed. The EL intensity, I_{EL}, is given by

$$I_{EL} = \eta k_1 c_s, \tag{4}$$

where η is the EL efficiency. η should be determined by surface characteristics. To see if this simple model could explain the EL-t relations, Eq. 3 was solved using a digital-simulation technique. Figure 9(a) shows k_1c_s, which is proportional to I_{EL} if η is assumed to be constant, and $\frac{\sqrt{D}c^*}{\sqrt{\pi t}}+k_1c_s$, which is proportional to the current due to reduction of both $S_2O_8^{2-}$ and $SO_4^{\cdot-}$, against time for several values of k_1. The time dependence of the relative EL efficiency, *i.e.*, $k_1c_s/(\frac{\sqrt{D}c^*}{\sqrt{\pi t}}+k_1c_s)$, is shown in Fig. 9(b). The results in Fig. 9 prove that EL-i-t and EL efficiency-t relations can be explained by just considering a simple concentration profile change as a function of time. Of course, a hydrogen evolution reaction becomes a dominant process when $S_2O_8^{2-}$ is depleted, particularly at relatively negative potentials and its contribution to the EL efficiency should be taken into account in a more thorough examination.

Although the time dependence of the EL can be explained by just considering the depletion of $S_2O_8^{2-}$ (as shown above), the potential dependence of EL intensity and EL efficiency needs other explanations. When the potential was made more negative, band bending and the concentration of electrons in the conduction band near the surface became greater. Since the radiation recombination of electrons in the conduction band and holes in the valence band is more effective at a higher concentration of electrons in the conduction band and holes in the valence band,[21] the EL efficiency should be higher at more negative potentials. The EL-V and EL efficiency-V relations show that this is not so. Around −2.0 V, the EL starts to decrease after applying a more negative potential.

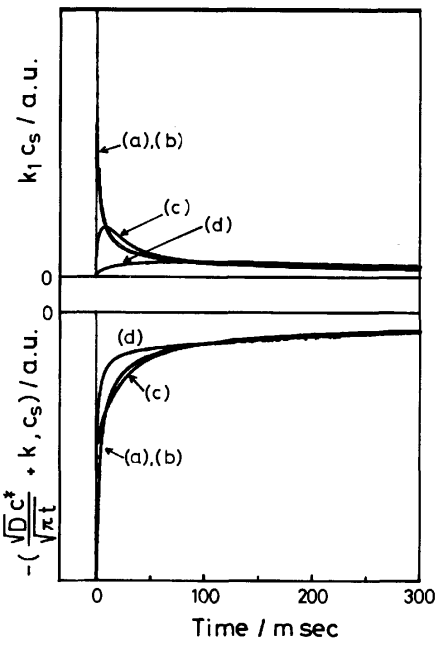

Fig. 9(a). Time dependence of $\left(-\frac{\sqrt{D}c^*}{\sqrt{\pi t}}+k_1c_s\right)$ which is propotional to current and k_1c_s which is propotional to EL intensity.
$D=10^{-5}$ cm^2 s^{-1}. $c^*=10^{-3}$ M. $k_1=10000$ s^{-1} (a), 1000 s^{-1} (b), 100 s^{-1} (c), and 10 s^{-1} (d).

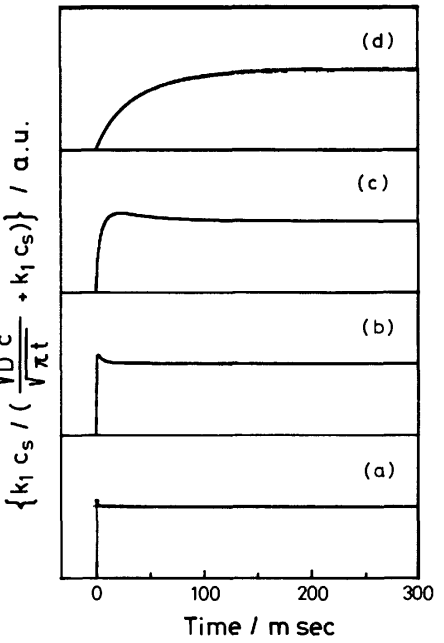

Fig. 9(b). Time dependence of $\left\{k_1c_s/\left(\frac{\sqrt{D}c^*}{\sqrt{\pi t}}+k_1c_s\right)\right\}$ which is propotional to EL efficiency. Parameters for the calulation are as same as those of Fig. 9(a).

Decker *et al.* proposed that a compositional change in the semiconductor surface, which was suggested for GaAs by Gerischer and Mattes,[33] causes the EL quenching for GaAs in solutions containing various redox agents.[30] Thus, the present GaAs was also covered with an oxide layer at −1.0 V and the potential pulse to −2.1—−2.2 V introduced unsaturated surface states (dangling bonds) which acted as recombination centers and reduced radiation recombination. Thus, η in Eq. 4 first increases with a more negative polarization due to a larger band bending while the surface characteristics remain constant. However, η starts to decrease beyond *ca.* −2.0 V because of the introduction of the recombination centers. When the potential is pulsed in this region, a change in the surface composition is initiated. Since composition change needs some time, EL intensity (efficiency) is high even at this potential region just after the pulse is applied. When the potential becomes much more negative (*e.g.* −2.3 V), the surface states are restabilized by hydride formation and η, *i.e.*, EL intensity, again increases, although the EL efficiency measured later than 50 msec after the potential pulse is applied does not increase even at these potentials, because the hydrogen evolution reaction becomes dominant.

Although Bard *et al.* reported that the EL spectral shape of ZnS was affected by current (*i.e.*, potential) and time,[7] no such effect was observed in our experiment. This difference is reasonably understood since only the potential dependence on the band-edge emission spectra was investigated in the present study, while the EL observed at ZnS was the sub-band emission. There could be some effect in the sub-band emission region even in the present arrangement, but it was not detected clearly enough to be analysed.

The carrier concentration dependence of the cathode- and photo-luminescent spectra of GaAs have been measured using p/n and Schottky junctions, but no report on EL in a solution is available. The results in Fig. 6, *i.e.*, a blue shift of the peak energy and a widening of the peak at highly doped GaAs, are, however, in good agreement with the results reported for solid-state luminescence[22] and can be explained by the filling of the conduction band sates by electrons (Burnstein-Moss shift).[34] These results again confirm that the EL spectra obtained are due to band-edge emission and suggest that the EL study at a semiconductor/solution interface conveniently provides information on band-edge energy.

The present work was partialy supported by a Grant-in-Aid for Scientific Research, Ministry of Education, Science and Culture. We gratefully acknowledge stimulating discussions with Prof. A. B. Ellis and Dr. W. S. Hobson of the University of Wisconsin at Medison where the preliminary part of this work was carried out by one of us (K.U.) supported by the Japan/U.S. Cooperative Program on Solar Energy Conversion by Photosynthesis. We are also grateful to Prof. A. B. Ellis and Dr. W. S. Hobson for donating several semiconductors.

Enhanced Circular Dichroism and Phase Separation of Azobenzene-Containing Chiral Bilayer[1)]

Naotoshi NAKASHIMA, Kozo MORIMITSU, and Toyoki KUNITAKE*
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812
(Received May 30, 1984)

An azobenzene-containing chiral amphiphile showed a drastic enhancement of circular dichroism (CD) due to formation of the rigid bilayer assembly. The drastic CD change was caused by phase transition of the matrix bilayer in the case of mixed bilayers with dihexadecyldimethylammonium bromide, but was caused by phase transition of the chiral component in the case of the single component bilayer. Both CD and absorption spectra of the azobenzene-containing chiral bilayer were used for detecting phase separation of mixed membranes. It was pointed out that the CD technique is widely applicable to phase separation studies.

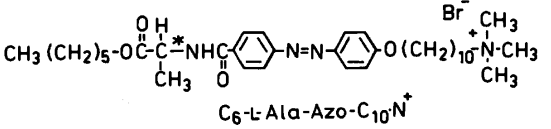
We have shown that synthetic amphiphiles undergo spontaneous formation of bilayers in water.[2,3)] Double-chain ammonium salts are typical examples. In these cases, introduction of the amino acid residue often gives rise to well-developed bilayer assemblies.[4—6)] The amino acid-derived chiral bilayer was found to display very peculiar circular dichroism when the aromatic chromophore was present.[7)] The same is true with bilayers of single-chain amphiphiles, as briefly described.[8)]

Phase separation is one of the most fundamental characteristics of bilayers. The bilayer of the biomembrane is composed of various lipid constituents and their distribution plays critical roles in the control of the physiological function. Detection of the phase separation in the biomembrane has been conducted by calorimetry,[9,10)] the spin probe technique,[11,12)] freeze-fracture electron microscopy,[13)] and recently, by neutron small-angle scattering.[14,15)] In the synthetic system, the spectral shift of the azobenzene chromophore was shown to be especially useful for its detection,[16)] and this technique has been applied to examinations of the interaction of the surface receptor[17)] and of the cluster formation of the reacting species in the catalytic hydrolysis.[18)] The excimer formation of the benzene chromophore was also useful for this purpose.[19)]

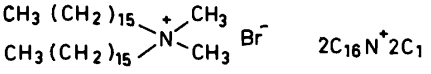
In the present paper, we wish to demonstrate that circular dichroism is a convenient technique for studying phase separation. The large CD enhancement of the chiral bilayer arises from the interaction of spatially fixed chromophores in the gel state and is not observed for fluid (non-interacting) chiral components.[7,8)] Therefore, the CD enhancement can be associated with the cluster formation (in the rigid bilayer matrix). The probe amphiphile used in this study is C_6-L-Ala-Azo-$C_{10}N^+$, and the matrix membrane is $2C_{16}N^+2C_1$. Since this bilayer-forming amphiphile is chiral and contains the azobenzene chromophore, both of CD and absorption spectra are used for detecting phase separation. A comparison of the two spectral methods is discussed.

Experimental

Materials. *p*-(*p*-Hydroxyphenylazo)benzoic acid was prepared by the procedure of Cohen and McGilbery,[20)] mp 246→264 °C (dec) (The arrow indicate the liquid-crystalline range), lit,[20)] mp 268 °C.



C_6-L-Ala-Azo-$C_{10}N^+$



$2C_{16}N^+2C_1$

The benzoic acid was allowed to react with 1,10-dibromodecane to give *p*-[*p*-(10-bromodecyloxy)phenylazo]-benzoic acid in 54% yield after recrystallization from acetic acid/ethyl acetate, mp 195→225 °C. The Williamson product (1 g, 2.2 mmol) and 0.5 g of Na_2CO_3 were added to 10 cm^3 of $SOCl_2$. After the mixture was refluxed for 2 h, excess $SOCl_2$ was removed, and the red-brown residue was condensed with 0.7 g (2.2 mmol) of hexyl-L-alaninate *p*-toluenesulfonate in dry tetrahydrofuran(THF) to give 0.4 g (30% yield) of hexyl *N*-[*p*-[*p*-(10-bromodecyloxy)phenylazo]-benzoyl] alaninate, mp 100—103 °C. Quaternization of this product with trimethylamine in THF produced C_6-L-Ala-Azo-$C_{10}N^+$ in 46% yield, mp room temp→117 °C. The final product was identified by IR and NMR spectroscopies and by elemental analyses. Found: C, 61.2; H, 8.30; N, 8.00%. Calcd for $C_{35}H_{55}N_4O_4Br \cdot H_2O$: C, 61.39; H, 8.24; N, 8.18%.

Preparation of $2C_{16}N^+2C_1$ was described elsewhere.[21,22)]

Measurement. Electron microscopy was performed with a Hitachi H-500 instrument as described before.[2,3)] Differential scanning calorimetry(DSC) was carried out for 20-mmol·dm^{-3} samples with a Daini-Seikosha SSC/560 instrument. The temperature was raised from 0 °C at a rate of 2 °C/min. The details have been described.[22)]

For spectral measurements of single-component bilayers, 5—10 mg of C_6-L-Ala-Azo-$C_{10}N^+$ were dissolved in $CHCl_3$, thin films of the amphiphile obtained by solvent removal were added with distilled water, and the mixture was sonicated for 30 s (Bransonic Cell Disruptor 185) to obtain clear dispersions (5×10^{-4} M, 1 M=1 mol dm^{-3}) and used for spectral measurements after aging for 30 min in ice water.

Aqueous samples of mixed bilayers were similarly prepared from C_6-L-Ala-Azo-$C_{10}N^+$ (5.0×10^{-4} M) and $2C_{16}N^+2C_1$ (5.0×10^{-3} M). The solutions were aged for 10 min at 60 °C and spectral measurements were made after slowly cooling to given temperatures and aging for 20 min. The spectral measurement was subsequently done in the heating process in similar manners.

The absorption and circular dichroism spectra were obtained on a Hitachi 220A spectrophotometer and a JASCO J-40AS spectropolarimeter, respectively. They were equipped with cell holders. The path length of the cell was 1 mm.

Results and Discussion

Electron Microscopy and DSC Study. We have shown that many azobenzene-containing, single-chain amphiphiles form bilayer aggregates.[23] Figure 1 is an electron micrograph of aqueous bilayer of C_6-L-Ala-Azo-$C_{10}N^+$. It is clear that the layered aggregate is formed. The DSC measurement indicates that the aqueous bilayer possess the crystal-to-liquid crystal phase transition at 57 °C (transition range, 40—65 °C) with the enthalpy change of 19.2 kJ/mol.

Absorption and CD Spectra. The absorption spectrum of C_6-L-Ala-Azo-$C_{10}N^+$ possesses maxima at 358 and 234 nm in ethanol and at 359 and 238 nm in the aqueous hexadecyltrimethylammonium bromide (CTAB, 10 mM) micelle, and does not vary with temperature. In contrast, small temperature dependence was found for the aqueous bilayer: λ_{max} are located at 351 and 252 nm at low temperatures and absorption intensities decrease upon raising temperature (Fig. 2a). These reversible spectral changes are apparently related to the phase transition of the bilayer.

The CD spectrum of the amphiphile has the following characteristics: $[\theta]_{355}=+2{,}000$ (maximum) in ethanol, and $[\theta]_{360}=+3{,}000$ (maximum) in CTAB micelle. It is enormously intensified in water as shown in Fig. 2b. At low temperatures, $[\theta]$ is 5.0×10^5 deg·cm^2 dmol^{-1} at 365 nm (maximum) and is -2.9×10^5 at 332 nm (minimum). The spectral intensity decreases drastically at high temperatures (50—70 °C) with sign reversal: $[\theta]_{366}=-1.0\times10^4$ and $[\theta]_{330}=+8.0\times10^3$. The CD enhancement due to temperature reaches fifty fold in magnitude.

The absorption near 350 nm is associated with the transition moment along the long axis of the azobenzene moiety.[24] Therefore, the shape of the low-temperature CD spectrum in this region is indicative of strong exciton coupling among the electric transition moments.[25] The 250-nm absorption corresponds to the transition moment along the short axis of azobenzene. The CD enhancement in this region is smaller by an order of magnitude compared with that in the 350-nm region: $[\theta]_{267}=-50{,}000$ and $[\theta]_{250}=-18{,}000$. However, these values are still greater than those in ethanol (no bilayer formed) or those at high temperatures. The exciton coupling is also apparent.

Figure 3 is obtained by plotting $[\theta]_{365}$ against temperature. The $[\theta]_{365}$ value remains constant at 10—35 °C and drastically decreases at 45—50 °C. As mentioned in the previous section (DSC data), the phase transition of the C_6-L-Ala-Azo-$C_{10}N^+$ bilayer starts at 45 °C and the DSC peak is located at 57 °C. Therefore, the CD enhancement is lost almost completely at the temperature region where the chain melting starts. Virtually the same change is observed in the heating cycle, and hysteresis is essentially absent. It must be noted, however, that the CD in-

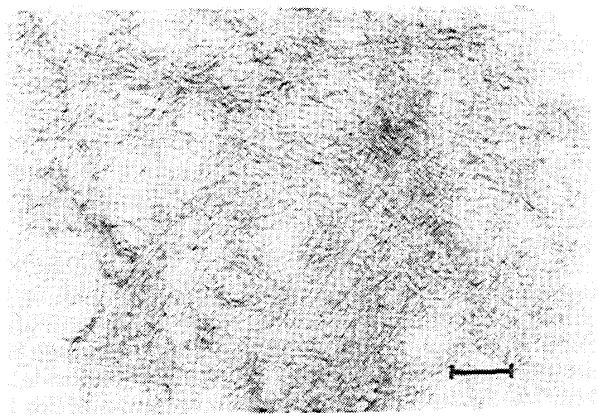


Fig. 1. Electron micrograph of C_6-L-Ala-Azo-$C_{10}N^+$ stained by uranyl acetate, 10 mM; initial magnification, × 40,000, scale bar indicates, 1000 Å.

tensity of the liquid-crystalline bilayer is larger than that of the isolated molecule in ethanol or in CTAB micelle.

These results (exciton coupling and temperature dependence) are essentially the same as those described briefly for bilayers of a biphenyl-containing single-chain amphiphile (C_{12}–Bph–L-Ala–C_2N^+)[8] and a benzene-containing double-chain amphiphile ($2C_{12}$–L-Glu–ph–C_4N^+).[7]

Spectral Changes of Mixed Bilayer. Table 1 summarizes the $[\theta]_{365}$ values of mixed bilayers of C_6–L-Ala–Azo–$C_{10}N^+$ and $2C_{16}N^+2C_1$ at 10 °C. The $[\theta]_{365}$ value decreases with decreasing molar ratios of the chiral component. The CD enhancement is observed, when the molar ratio is not smaller than 1/10.

The enhancement is totally lost with the molar ratios of less than 1/20. As discussed above, the CD enhancement is produced by the exciton coupling of the fixed azobenzene chromophores. Therefore, the CD enhancement in the two-component bilayer indicates the presence of the cluster of the chiral amphiphile. The data of Table 1 suggest that the cluster is only partially formed at the molar ratio of 1/10, and this molar ratio was used in the subsequent experiments.

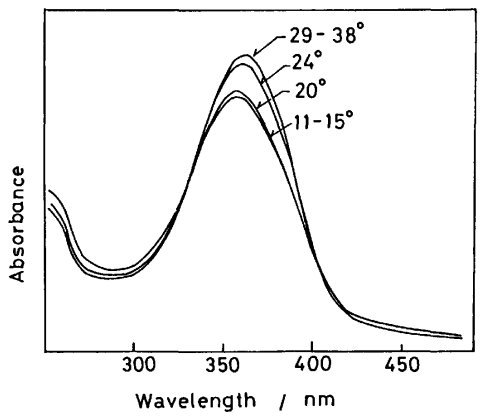

Fig. 4. Temperature dependence of absorption spectra of mixed bilayers. C_6–L-Ala–Azo–$C_{10}N^+$, 5×10^{-4} M, $2C_{16}N^+2C_1$, 5×10^{-3} M, cooling process.

A mixed (1:10) bilayer of C_6–L-Ala–Azo–$C_{10}N^+$ and $2C_{16}N^+2C_1$ was subjected to aging at 60 °C, and absorption and CD spectra were measured in the cooling and, subsequently, heating processes. The absorption spectra in the cooling process are displayed in Fig. 4. Although the overall spectral change is not remarkable, its temperature dependence is more clearly seen in Fig. 5 by plotting the maximum absorbance (A_{max}) and the location of λ_{max} against temperature. Both of A_{max} and λ_{max} change critically at 20—25 °C. Virtually the same temperature dependence was observed in the heating process. The CD spectral shape of the mixed bilayer is the same as those illustrated in Fig. 2b, however, its temperature dependence is different. In the cooling process, the enhanced CD is not observed from 60 °C to 26 °C, and the enhancement starts at *ca.* 22 °C. The temperature dependence of $[\theta]_{365}$ of the mixed bilayer in this process is illustrated in Fig. 6, together with that in the heating process (from 10 °C). The $[\theta]_{365}$ value drastically changes at *ca.* 25 °C in both processes, and this critical temperature agrees with those in absorption spectra (Fig. 5). The hysteresis is small in this system as well.

The 1:10 mixed bilayer gives an DSC peak at 28 °C. This T_c value is almost identical with that of the single-component bilayer of $2C_{16}N^+2C_1$.[22] The DSC peak corresponding to the bilayer of C_6–L-Ala–Azo–$C_{10}N^+$ (57 °C) was not detected. Apparently the two components exist as separate clusters in the rigid bilayer matrix of $2C_{16}N^+2C_1$, but the chiral component cannot form separate domains in the fluid $2C_{16}N^+2C_1$ matrix.

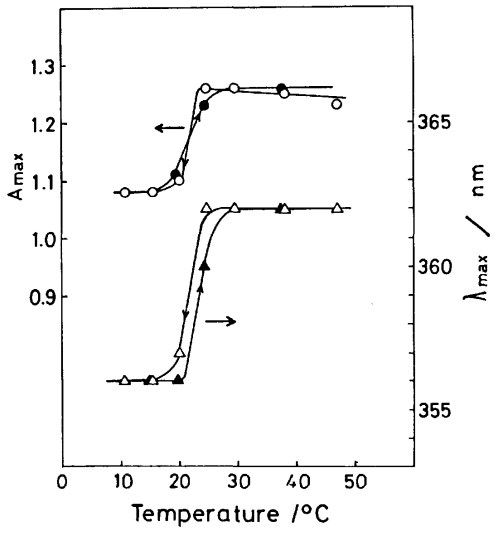

Fig. 5. Plots of A_{max} and λ_{max} against temperatures. C_6–L-Ala–Azo–$C_{10}N^+$, 5×10^{-4} M, $2C_{16}N^+2C_1$, 5×10^{-3} M, ○: cooling process, ●: heating process.

Phase Separation and CD Enhancement. The DSC behavior of the mixed bilayer is consistent with the spectral data. The CD enhancement is not observed at 30—40 °C where DSC data suggest dispersion of C_6-L-Ala-Azo-$C_{10}N^+$ molecules in the fluid $2C_{16}N^+2C_1$ bilayer. The bilayer cluster of the chiral amphiphile would have produced enhanced CD at these temperatures (see Fig. 2b). The phase separation occurs at 22—26 °C where the $2C_{16}N^+2C_1$ bilayer undergoes the liquid crystal-to-crystal phase transition. The domain of the C_6-L-Ala-Azo-$C_{10}N^+$ bilayer is in the crystalline state at these temperatures, and therefore, enhanced CD results. It is noteworthy that the drastic CD change is caused by *phase transition of the matrix bilayer* in the case of the mixed bilayer, but that it is caused by *phase transition of the chiral component* in the single-component bilayer system. It is possible, therefore that mixed bilayers are selected in such a way that large CD changes occur at desired temperatures. These situations are illustrated schematically in Fig. 7.

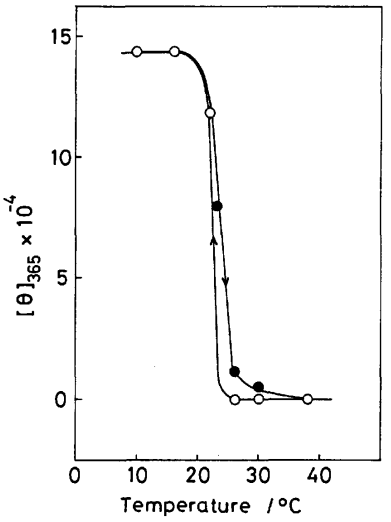

Fig. 6. Temperature dependence of $[\theta]_{365}$ of the mixed bilayer.

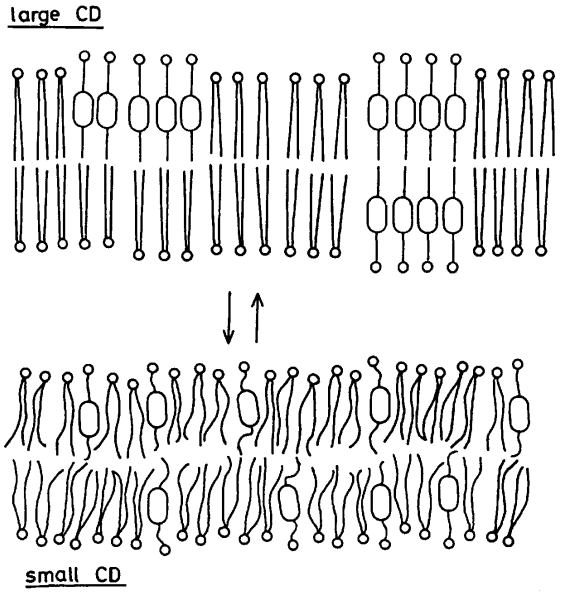

Fig. 7. Schematic illustration of the phase separation.

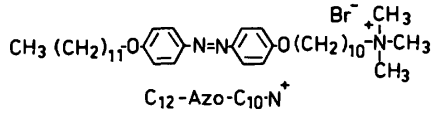
It was reported from these laboratories that azobenzene-containing bilayers give rise to varied spectral characteristics depending on membrane physical states and chemical structures of the component.[23] For instance, C_{12}-Azo-$C_{10}N^+$ possesses λ_{max} at 330 nm as bilayer clusters and λ_{max} at 355 nm as an isolated chromophore. This spectral shift has been used to detect phase separation. The azobenzene amphiphile used in this study unfortunately displays only a very small difference in absorption spectra, which is not sensitive enough to probe phase separation. Instead, much enhanced CD spectra of the rigid chiral bilayer are a powerful tool for phase separation studies.



C_{12}-Azo-$C_{10}N^+$

Conclusion

An azobenzene-containing, chiral amphiphile exhibited remarkable CD enhancements due to formation of rigid bilayers. This phenomenon was used to study the phase separation behavior in mixed bilayers. Phase separation of synthetic bilayers has been examined by the DSC technique,[18,19] absorption spectroscopy,[16] and excimer formation.[19] The CD technique becomes the fourth methods. The present CD results are consistent with those of the absorption spectrum of the azobenzene chromophore in that phase separation is induced by the liquid crystal-to-crystal phase transition of the matrix bilayer. The spectral shift of chromophores is usually not large enough to made detection of phase separation possible. In contrast, the CD enhancement is observed for many chiral bilayers which possess aromatic chromophores. This indicates that the CD technique is widely applicable to phase separation studies.

We are grateful to Professor K. Yamafuji for the use of a spectropolarimeter.

The Specific Heat Capacities of D-Glucose and D-Xylose in Water-Ethanol System

Fumio KAWAIZUMI,* Nobuo SASAKI, Yasushi OHTSUKA,
Hiroyasu NOMURA, and Yutaka MIYAHARA
Department of Chemical Engineering, School of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
(Received June 5, 1984)

Using an isoperibol twin calorimeter the specific heat capacities of solutions of D-glucose and D-xylose dissolved in water-ethanol mixtures (10, 20, 30, and 50 wt% of ethanol) have been measured at temperature close to 30 °C and the apparent molar heat capacity of te solutes ϕ_{C_p} has been calculated. Dependence of ϕ_{C_p} upon solute concentration varied markedly with the solvent composition but the variation was similar for both solutes. The infinite dilution values of $\phi_{C_p}^{\circ}$ *i.e.* $C_{p,2}^{\infty}$ are higher for D-glucose than for D-xylose at any compositions of the solvent system. The $C_{p,2}^{\infty}$ decreased first noticeably with the amount of ethanol in the solvent, reaching a minimum value at approximately 20 wt% of ethanol, then it increased. Values of the parameter $\Delta C_{p,2}^{\infty}=C_{p,2}^{\infty}-C_{p,2}^{*}$, where $C_{p,2}^{*}$ is the specific heat capacity of the solute in the solid state, are negative in 10, 20, and 30 wt% of ethanol, while it is positive in 50 wt%. The values of $\Delta C_{p,2}^{\infty}$ have been discussed in its connection with the degree of structuring of the solvents.

To date we have measured the specific heat capacity, C_p, of aqueous solutions of hexose (D-fructose, D-galactose, D-glucose, and D-mannose,[1] pentose (D-xylose, D-arabinose, D-ribose, and L-arabinose),[2] as well as several kinds of commercial samples of dextran[3] which is an anhydroglucose polymer. The solute-solvent interaction between these saccharide molecules and solvent water has been discussed on the basis of the partial molar heat capacity at infinite dilution, $C_{p,2}^{\infty}$, calculated from our experimental results.

As a continuation of the above-mentioned measurements we will describe in this paper the results of determination of the specific heat capacities of solutions of D-glucose and D-xylose in the mixed solvent consisting of water and ethanol (10, 20, 30, and 50 wt% of ethanol).

Addition of ethanol to the aqueous solution of saccharides will result in the precipitation of saccharides. This phenomenon can be considered as a result of removal of hydrated water by the added ethanol. In fact, compressibility measurements[4,5] have shown that in pure water the partial specific compressibility, $\bar{\kappa}_2^{\circ}$, of D-glucose and dextran is negative, showing the hydration of these solutes, but that the $\bar{\kappa}_2^{\circ}$ increases with increasing content of ethanol and it becomes a constant positive value in the solvents containing more than 20 wt% of ethanol. In such solvents water molecules preferentially hydrated to saccharides are completely removed by the action of ethanol, then the values of $\bar{\kappa}_2^{\circ}$ correspond to the compressibility of the solutes themselves. Measurements of specific heat capacity and those of compressibility are complementary in elucidating the solute-solvent interaction. The former results seem to give more direct information on the structural change of solvent caused by the addition of solutes.[1-3]

Experimental

Materials. Commercially available guaranteed grade D-glucose and D-xylose were dried in an electric vacuum oven and used without further purification. The ethanol used for preparation of the mixed solvents was obtained by drying by anhydrous $CaSO_4$ and then distilling the guaranteed pure-grade reagents.

Calibration of the Calorimeter and Measurements. Specific heat capacities of solutions were determined using an isoperibol twin calorimeter of dry-shield type. Details concerning this calorimeter and procedures of measurements have been reported earlier.[1] However, the manipuration has been modified slightly. Preliminary experiment of this work demonstrated that introduction of 100 g each of solution to be examined and a reference liquid into each Dewar vessel does not give a successful result. This is due to the large variation of density with the composition of the water-ethanol mixture. The difference in the volume of two liquids leads immediately to the difference in the surface area not immersed in liquids in the two Dewar vessels. To reduce the relative magnitude of the heat leak through the inner surface of the vessels, we have increased the amount of sample solution and reference liquid in each Dewar vessel to 150 g. Following the

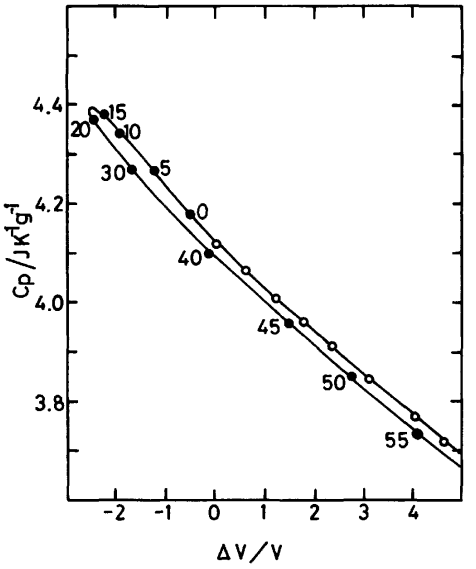

Fig. 1. Calibration curve of the twin calorimeter using 150 g of aqueous solutions of sodium chloride and of ethanol. ΔV is the change of potential of the thermistor bridge during 5 min. ○: sodium chloride, ●: ethanol.
The rotational rate of the stirring system is at 450 min.$^{-1}$ The numeral in the figure refers to the weight per cent of ethanol in the solvent.

procedures described in our early work,[1] we have carried out calibration of the calorimeter using aqueous solutions of ethanol and sodium chloride, whose specific heat capacities are given in the literature.[6] Results of calibration are illustrated schematically in Fig. 1. In principle, the calibration based on the C_p data of aqueous solutions of ethanol and sodium chloride should give an identical curve. This is not the case in Fig. 1. It may be noted here, however, that the calibration using 100 g of sample and reference liquids led to much larger differences between the two sets of calibration than those shown in Fig. 1. Increase of the rotational rate of the stirrer from 450 to 600 min^{-1} resulted in a minor effect on the general features illustrated in Fig. 1.

Dissolution of D-glucose and D-xylose in the solvent system concerned in this work always results in the lowering of the C_p value of the solutions. We, therefore, used the upper curve for the measurements in 10 wt% of ethanol, while the lower calibration curve was adopted for the determination of C_p in 20, 30, and 50 wt% of ethanol. Measurement was not done in 40 wt% of ethanol, for in this mixed solvent the potential difference ΔV to be detected is very small (see, Fig. 1) and desired precision of the measurement could not be attained. On the other hand, measurements in ethanol-rich solvents are also difficult owing to the limited solubility of the solutes D-glucose and D-xylose.

Measurements of C_p have been done at six to eight different concentrations of solute at temperature close to 30 °C and the infinite dilution values of the partial molar heat capacity $C_{p,2}^{\infty}$ have been determined.

Results and Discussion

C_p Data and Determination of $C_{p,2}^{\infty}$. In view of the paucity of the C_p data of solutions in general, and especially in mixed solvent system, presentation of our experimental results in an original numerical form seems worthy. All the C_p values determined in this study are summarized in Tables 1 and 2. From these data the apparent molar heat capacity of solute, ϕ_{C_p}, at solute concentration of molality m was calculated using the equation,

$$\phi_{C_p} = \frac{1}{m}[(1000 + mM_2)C_p - 1000C_{p,1}], \quad (1)$$

where $C_{p,1}$ is the specific heat capacity of the solvent system and M_2 is the molar mass of the solute. The values of ϕ_{C_p} at infinite dilution, $\phi_{C_p}^{\circ} = C_{p,2}^{\infty}$, were deter-

mined from the least-squares fitting of the experimental data.[1,2]

Concentration Dependence of ϕ_{Cp}. The coefficient related with concentration dependence of ϕ_{Cp} of a nonelectrolyte has significances physically similar to the first order parameter, B_c, of the following expression used in the case of ϕ_{Cp} of electrolytic solutes:

$$\phi_{C_p} = C^{\infty}_{p,2} + A_c m^{1/2} + B_c m, \quad (2)$$

where A_c is a parameter derived from the Debye-Hückel theory. In numerous papers describing the determination of C_p and ϕ_{Cp} of solutions which have hitherto been published, those making reference to the concentration dependence of ϕ_{Cp} are rather few in number.[7-10] The concentration dependence coefficient of ϕ_{Cp} should not be treated as a mere adjustable parameter to reproduce the experimental results. More attention must be paid to this coefficient, as it can serve as a clue in elucidating the nature of solute-solute-solvent interactions. Unfortunately, no theoretical prediction of this coefficient has been put forth. Experiments have shown that it is positive or negative, depending on the circumstances. The values of the coefficients listed in Table 3 are those obtained as first-order coefficients of the function $\phi_{Cp}(m)$ with respect to the molality m. The purpose of this work is chiefly the determination of $C^{\infty}_{p,2}$ rather than that of the concentration dependence of ϕ_{Cp}. Although the values shown in Table 3 are not so precise as to deserve a detailed discussion of these values, the general trend of the concentration dependence of ϕ_{Cp} in the aqueous mixed solvent system is clearly seen in Table 3; solute concentration dependence of ϕ_{Cp} varies remarkably with the solvent system but the variation is qualitatively the same for D-glucose and D-xylose. Table 3 suggests that with variation of the media surrounding the solute, the degree of solute-solute-solvent interactions varies in a similar fashion for D-glucose and D-xylose dissolved in the water-ethanol mixture.

$C^{\infty}_{p,2}$ and $\Delta C^{\infty}_{p,2}$. The values of $\phi_{Cp}{}^{\circ}=C^{\infty}_{p,2}$ determined in this work and those in pure water obtained in our previous work,[1,2] are presented in Table 4. It is noteworthy in Table 4 that the $C^{\infty}_{p,2}$'s of D-glucose are always higher than those of D-xylose in any compositions of the solvent system, showing the positive contribution of $C^{\infty}_{p,2}$ (-CH(OH)-) in water-ethanol system. Variation of $C^{\infty}_{p,2}$ with the content of ethanol in the solvent given in Table 4 is more easily understood by the aid of Fig. 2. Here again similar variation can be observed for both solutes and the minimum appears at about 20 wt% of ethanol. This behavior differs

a) Ref. 1. b) Ref. 2.

significantly from the case of the partial specific compressibility $\bar{\kappa}_2^\circ$ which, as stated in the introductory part of this paper, takes a constant positive value at above 20 wt% of ethanol.[4,5] In this connection it is remembered that in water the $\bar{\kappa}_2^\circ$ gave the hydration number of saccharides which is not proportional to the number of monomer unit contained in the saccharides, whereas the $\Delta C_{p,2}^\infty$, a quantity which will be mentioned immediately below, increases linearly with the molecular dimension from mono- to trisacharides.[1] According to the Kirkwood-Buff solution theory[11] the isothermal compressibility of a binary solution is describable in terms of the pair correlation function. On the other hand, an extended treatment of the Kirkwood-Buff theory[12] has proved that the specific heat capacity of pure liquids at constant volume contains contributions from three- and four-particle distribution function. Differences in adiabatic and isothermal compressibility, or heat capacity at constant pressure and at constant volume are essentially indifferent in the present consideration. Hence, it seems reasonable to consider that the $\bar{\kappa}_2^\circ$ reflects predominantly the interaction in the vicinity of solute molecules, while the partial molar heat capacity is concerned with the long range molecular interaction in solutions and is pertinent to the discussion of the structural change of the solvent system.

Ben-Naim[13] proposed a theory to analyse the relation between ϕ_{C_p} of non-polar gases and the equilibrium species in the two-state model of water. However, his theory was unsuccessful even to predict the definite sign of the quantity ϕ_{C_p}. As before,[1-3] we prefer to use the quantity $\Delta C_{p,2}^\infty$ in discussing the structural change of the solvent system. The $\Delta C_{p,2}^\infty$ is defined as

$$\Delta C_{p,2}^\infty = C_{p,2}^\infty - C_{p,2}^*, \tag{3}$$

where $C_{p,2}^*$ in the specific heat capacity of the pure solute. In water we have classified the "structure-forming" and "structure-breaking" effects of solute according to the sign of the $\Delta C_{p,2}^\infty$. With the same criteria as in water, D-glucose and D-xylose are working as structure-breaking solutes in solvents containing 10, 20, and 30 wt% of ethanol, while they are structure-forming solutes in water and 50 wt% (presumably also at 40 wt%, see Fig. 2) of ethanol. This conclusion is simple but is not persuasive. Rather, the following interpretation seems more plausible; the structure of solvent is different for each solvent system and we are observing a structuring of the respective solvent systems through the parameter $\Delta C_{p,2}^\infty$. Consequently, the positive value of $\Delta C_{p,2}^\infty$ at 50 wt% of ethanol does not correspond straightfowardly to the structure promotion by the added solutes D-glucose or D-xylose, but it shows that the promoted structure exists even before addition of the solutes. The promoted structure in the water-ethanol system is expected, for example, from viscosity data of this mixture which shows the very high peak at *ca.* 45 wt% of ethanol. Values of the concentration dependence of ϕ_{C_p} in water-ethanol system as shown in Table 3 may also be related to the structure promotion in this aqueous mixed solvent.

Combination of the results of $\bar{\kappa}_2^\circ$ and $C_{p,2}^\infty$ leads to the following conclusion; addition of ethanol in the aqueous solutions of D-glucose and D-xylose gives rise to the removal of preferentially hydrated water molecules and at the same time the structuring of the solvent system as a whole decreases. With increasing ethanol content in the solvent, the structure promotion in water-ethanol system becomes progressively predominant up to certain ethanol content. Owing to this process the minimum appears and $\Delta C_{p,2}^\infty$ again takes a positive value at 50 wt% of ethanol.

The authors wish to express their thanks to Mr. Ko-hei Itano for his efforts in carrying out supplementary measurements.

(Received June 9, 1984)

The crystal structure determination of the title compound (abbreviated as α-LiPt(mnt) has been performed at room temperature and 153 K. The $[Pt(mnt)_2]^{n-}$ (mnt=1,2-dicyano-1,2-ethylenedithiolato, $C_4N_2S_2^{2-}$) anions stack face-to-face along the c-axis with Pt···Pt distance of 3.6 Å. The room temperature structure and the average structure of the 153 K superstructure are almost the same. The room temperature conductivity of α-LiPt(mnt) is about 200 S cm^{-1}, and the compound undergoes a metal-insulator transition (Peierls transition) at 220 K. In α-LiPt(mnt) the conduction pathway is through the ligand-centered π-system which is composed of predominantly S $3p_z$ orbitals. Oscillation photographs about the c-axis show strong satellite spots on the layerlines of $(0.41+n)c^*$ and $(0.59+n)c^*$ (n=0, ±1, ±2, ···). The content of Li cation reveals that these satellite spots can be described as $2k_F$ spots. The regular appearance of characteristic satellite reflections indicates that α-LiPt(mnt) has a sinusoidally modulated lattice. The wave vector of the lattice modulation wave is $\mathbf{k}=0.15\mathbf{b}^*+0.59\mathbf{c}^*$ and the amplitude of the lattice modulation wave is $0.045\,\boldsymbol{a}/a+0.13\boldsymbol{b}/b+0.060\boldsymbol{c}/c$ Å. The overlap integrals along face-to-face stacking directions are much larger than the interstack overlap integrals and the resulting large anisotropy indicates that α-LiPt(mnt) is a one-dimensional metal.

The crystal structures, syntheses and electrical conduction properties of 1,2-dithiolene complexes have been extensively studied.[1-3] Recently a new type one-dimensional partially oxidized $[M(mnt)_2]^{n-}$ (M= Ni, Pd, Pt; mnt=1,2-dicyano-1,2-ethylenedithiolato, $C_4N_2S_2^{2-}$) complex has been reported.[4,5] Metallic behavior has been found for crystals of $(H_3O)_{0.33}Li_{0.8}[Pt(mnt)_2]\cdot 1.67H_2O$, which is abbreviated as α-LiPt(mnt).[4-6]† Its room temperature conductivity, 200 S cm^{-1} is as large as that of $K_2[Pt(CN)_4]\cdot Br_{0.3}\cdot 3.2H_2O$ (KCP(Br)). Although the $[Pt(mnt)_2]^{n-}$ anions stack face-to-face with a Pt···Pt distance of 3.639 Å, the partially oxidized 1,2-dithiolene complexes have a conduction pathway based on the ligand-centered π-system (predominantly sulfur $3p_z$ orbitals). This is in contrast to the high conductivity of inorganic one-dimensional metals containing tetracyano-platinate and bis(oxalato)platinate anions which arises from a partially occupied Pt $5dz^2$ electron energy band.

α-LiPt(mnt) undergoes a metal-insulator transition at about 220 K.[4] The static magnetic susceptibility of α-LiPt(mnt) has been measured from 2—300 K by J. R. Cooper *et al.*[6] Above 150 K, the conduction electron paramagnetism $X_p=X_s-C/T$ gradually develops. It shows a sharp knee at 220 K corresponding to metal-semiconductor phase transition.

In this paper we report the crystal structures of α-LiPt(mnt) at room temperature and at 153 K. The 153 K superstructure corresponds to a so-called Peierls structure.

Experimental

Crystal Preparation, Data Collection, and Structure Solution. Slow aerial oxidation of a 50% aqueous acetone solution of $H_2[Pt(mnt)_2]$ and LiCl gave $Li_xH_y[Pt(mnt)_2]\cdot nH_2O$ as a black microcrystalline product containing small shining black needle crystals (α-LiPt(mnt))[7] and plate crystals (β-LiPt(mnt)).[8] The needle crystals were used in this experiment. Details concerning crystal characteristics and X-ray diffraction methodology are shown in Table 1. Intensities were measured on a Rigaku automated four-circle diffractometer with Mo $K\alpha$ radiation at room temperature and at 153 K. Graphite-monochromatized Mo $K\alpha$ radiation (0.71073 Å) was used for data collection. Intensities were collected by using a $\omega-2\theta$ scan technique. The scan width was determined for each reflection according to the formula $w=(A+B\tan\theta)°$. Three standard reflections monitored every 50

† This compound was initially reported to be $Li_x[Pt(mnt)_2]\cdot 2H_2O$ (where $x\approx 0.8$) but has recently been shown to contain protons in the lattice.[7]

(at room temperature) and every 100 (at 153 K) measurements, and their intensities remained essentially constant during the data collection. The data was corrected for Lorentz and polarization. The crystal was covered with epoxy resin for measurements at room temperature and was sealed in a glass capillary for measurements at 153 K. At 153 K, the relatively weak satellite reflections were observed, but these were not included in the analyses of the average structure. The structure was solved by the heavy-atom method and refined to $R=0.065$ and $R=0.068$, $w=1/[\sigma^2+0.01|F_o|^2]$ for $|F_o|\geqq 15$, $w=0.2$ for $|F_o|<15$ using 1686 and 2015 independent reflections for which $I>3\sigma(I)$ at room temperature and at 153 K, respectively. Absorption corrections were performed in both cases, but did not result in much improvement of the room temperature structure because the crystal used for the data collection was twinned.

The c*-axis projection of the structure of α-LiPt(mnt) is shown in Fig. 1. Atomic parameters are shown in Table 2. The thermal parameters and F_o-F_c tables are kept at the office of this Bulletin as Document No. 8451.

Results and Discussions

The Room Temperature Structure and the Average Structure of the 153 K Superstructure. The crystal structures of α-LiPt(mnt) at both temperatures are almost the same. The planar $[Pt(mnt)_2]^{n-}$ anions stack face-to-face along the c-axis with an eclipsed configuration to form a columnar stacked structure. The interplanar distance between the $[Pt(mnt)_2]^{n-}$ anions are 3.592 and 3.537 Å, and the Pt···Pt distances are 3.639 and 3.597 Å, at room temperature and at 153 K respectively. In α-LiPt(mnt), all the inter-anion distances within the stack are equal. This is different from the structures found for the similar $[Pt(mnt)_2]$ complexes $Rb[Pt(mnt)_2]\cdot 2H_2O$[9] and β-LiPt(mnt),[8] both of which possess dimeric structures. In $Rb[Pt(mnt)_2]\cdot 2H_2O$ the interplanar spacing within the dimer is 3.356 Å and between dimers 3.512 Å. In β-LiPt(mnt) the interplanar spacing within the dimer is 3.346 Å and between dimers 3.631 Å and 3.643 Å. In both compounds the anions are arranged along the column in a fully eclipsed configuration, which is a characteristic of $M_x[Pt(mnt)_2]$ compounds containing small cations. Mono-anion salts with bulky organic cations often pos-

sess columnar stacks containing anion dimers with a staggered configuration.[10] The $[Pt(mnt)_2]^{n-}$ anion is almost planar with average bond lengths (in Å) Pt–S 2.271(2), 2.267(3), S–C 1.722(8), 1.705(10), and C–C 1.360(16), 1.365(18), at room temperature and at 153 K, respectively. The bond lengths and angles are compared in Table 3.

In $Rb_{1.67}[Pt(C_2O_4)_2]\cdot 1.5H_2O$,[11] intermolecular distances are much shortened by the formation of the Pt···Pt bonds. The Pt···Pt distances are modulated by the Peierls distortion and the molecular plane is concave in order to reduce the steric hindrance with the ligands of the neighbouring molecules. Terminal oxygen atoms of the ligands are deviated 0.4—0.5 Å from the plane. However, in α-LiPt(mnt) the molecule is almost planar both at room temperature and at 153 K probably because of the large intermolecular separation. The equations of the best planes and the perpendicular distances from these planes are deposited and kept at the office of this Bulletin.

Intermolecular short contacts are also shown in Fig 1. The transverse interatomic distances between the S atoms are considerably shortened in the low temperature. Close S···S contacts of less than 3.8 Å are shown in Table 4. The short interatomic distances between the S atoms on adjacent molecules in adjacent stacks are 3.686, 3.724, and 3.743 Å at room temperature and 3.622, 3.674, and 3.676 Å at 153 K. Close S···S contacts in the transverse direction of the Pt chain have been also found in α-LiPt(mnt) and $Rb[Pt(mnt)_2]\cdot 2H_2O$. There are two Li sites in the unit cell. The Li ions are disordered and the occupancy probability of the Li site is 40%. The Li ions are six-coordinated and Li···N(O) distances vary from 1.94 to 2.69 Å at room temperature and 2.06 to 2.54 Å at 153 K. There are two oxygen atoms and $0.8Li^+$ cations in the unit cell. They are located in-between the $[Pt(mnt)_2]$ anions along the a-axis. As mentioned before, the results of the chemical analysis of α-LiPt(mnt) have shown that the unit cell should contain 0.33 H_3O^+ but the crystal structure analyses could not distinguish the sites of H_3O^+ from those of H_2O. Table 5 lists short interatomic distances of less than 3.0 Å within the coordination spheres around the Li cation and the oxygen atom of the water molecule (or hydroxonium ion).

Measurements of satellite reflections by oscillation photographs. We examined temperature dependence of intensities of X-ray reflections within the temperature range between 90 K and 300 K. An oscillation photograph around the c-axis shows that the strong satellite spots appear on the layer lines of $(0.41+n)c^*$, or $(0.59+n)c^*$ ($n=0, \pm1, \cdots$) (Fig. 2). The cation content revealed that these satellite spots can be described as $2k_F$ spots.[7] The satellite reflections show that α-LiPt(mnt) has a sinusoidally modulated lattice. Figure 3 shows the temperature dependence of intensities of the satellite spots ($\xi\ \eta\ \zeta$). The intensities of satellite reflections, (−13, −2.85, −0.41), (6, 3.85, 0.41), and (13, 2.15, 0.59)

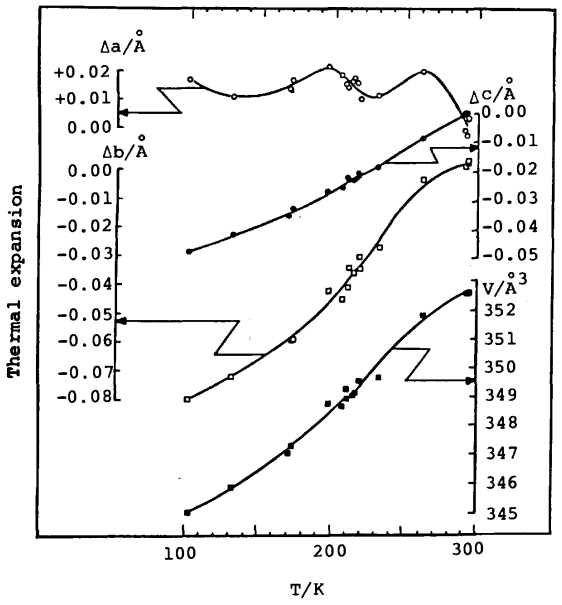

Fig. 4. Temperature dependence of the cell parameters.

were measured under the same conditions as the main reflections. The intensities are roughly proportional to $\sqrt{T-T_c}$ (T_c=213 K).

Temperature Dependence of the Cell Parameters. The temperature dependence of the cell parameters are shown in Fig. 4. The cell constants b and c are shortened by 8 and 5% within the temperature range between 300 K and 90 K and a is expanded by up to 2%.

It is worth noticing that the contraction of the transverse direction b, is larger than the change in a and c. The stack of the $[Pt(mnt)_2]$ complexes is parallel to the c axis. The large contraction of b indicates that the S···S interaction in the transverse direction of complexes are strengthened in the low temperature.

The Analysis of the Modulation wave in the Peierls Structure. As is well-known, the one-dimensional metallic state is not stable at low temperature. The system tends to be distorted periodically in order to gain electronic energy. The lattice instability brings about the superstructure and characteristic X-ray diffuse scatterings appear below transition temperature (T_c). The lattice-modulation wave with the wave number of $2k_F$ develops below T_c.

When the lattice is sinusoidally modulated, the position of the j-th atom of the n-th cell, $\mathbf{r}_{jn}$, is given by $\mathbf{r}_{jn}=\mathbf{R}_n+\mathbf{d}_j+\mathbf{P}\sin(2\boldsymbol{k}_F\cdot\mathbf{R}_n)$, where $\mathbf{R}_n$ is the lattice vector of the n-th lattice point of the average structure, $\mathbf{P}$ is an amplitude of the modulation wave, and $\boldsymbol{k}_F$ is the wave vector of the modulation wave. The intensity formula of X-ray diffraction by the crystal with sinusoidal modulation waves whose fundamental lattice contains only one molecule, is as follows

$$I(\xi\eta\zeta) = |F(\xi\eta\zeta)|^2, \tag{1}$$

$$F(\xi\eta\zeta) = \sum_{n_1}\sum_{n_2}\sum_{n_3} F_o(\xi\eta\zeta)\exp[2\pi i(\xi n_1+\eta n_2+\zeta n_3)] \times \exp[2\pi i(p_1\xi+p_2\eta+p_3\zeta)] \times \sin 2\pi(\phi_1 n_1+\phi_2 n_2+\phi_3 n_3), \tag{2}$$

where scattering vector $\mathbf{s}=2\pi(\xi\boldsymbol{a}^*+\eta\boldsymbol{b}^*+\zeta\boldsymbol{c}^*)$, $2\boldsymbol{k}_F=2\pi(\phi_1\boldsymbol{a}^*+\phi_2\boldsymbol{b}^*+\phi_3\boldsymbol{c}^*)$, and $F_o(\xi\ \eta\ \zeta)$ is the scattering amplitude of the averaged structure without modulation wave. $I(\xi\ \eta\ \zeta)$ can be written as follows by the use of Bessel functions which satisfy the equation $\exp[x/2-(t-t^{-1})]=\sum_{n=-\infty}^{\infty} J_n(x)t^n$. Intensities of main reflections and satellite reflections $I(\xi\ \eta\ \zeta)$ can be written

$$I(\xi\eta\zeta) \propto |F_o(hkl)|^2 J_o^2[2\pi(p_1h+p_2k+p_3l)]\cdots\cdots(hkl) \tag{3}$$

$$\propto |F(h+m\phi_1, k+m\phi_2, l+m\phi_3)|^2 \times J_m^2\{2\pi[p_1(h+m\phi_1)+p_2(k+m\phi_2)+p_3(l+m\phi_3)]\}\cdots\cdots(h+m\phi_1, k+m\phi_2, l+m\phi_3). \tag{4}$$

The intensities of the m-th satellite spots are proportional to the square of the m-th Bessel functions. In the case of $2\pi(\phi_1\boldsymbol{a}^*+\phi_2\boldsymbol{b}^*+\phi_3\boldsymbol{c}^*)=2\boldsymbol{k}_F$ the first satellite reflections are called $2k_F$ spots and the second satellite reflections appear at the $(h+4\pi\phi_1,\ k+4\pi\phi_2,\ l+4\pi\phi_3)$ in the reciprocal space. Since the amplitude of the periodical lattice modulation wave is small, $2\pi(p_1\xi+p_2\eta+p_3\zeta)(=x)$ is much less than 1.0 and $J_o(x)^2 \gg J_1(x)^2 \gg J_2(x)^2 \gg \cdots$. Therefore the intensities of the higher order satellite reflections are much smaller than those of the 1-st order satellite reflections. In facts, 2-nd order reflections can be scarecely seen on the Weissenberg photographs. When $x \ll 1$, $J_1(x)\simeq(1/2)x$ and the intensity formula becomes very simple.

If the periodical lattice distortion wave of α-LiPt(mnt) can be described in terms of the simple sinusoidal wave, A, defined by the following equation,

$$A = \sum_{\xi\eta\zeta}(|F_{obs}(\xi\eta\zeta)| - kS(\xi\eta\zeta)|F_{calc}(\xi\eta\zeta)|\times 2\pi(p_1\xi+p_2\eta+p_3\zeta)/2)^2$$

must be minimized. $F_{obsd}(\xi\ \eta\ \zeta)$ is an observed structure amplitude of the first order satellite reflection. $F_{calcd}(\xi\ \eta\ \zeta)$ is a structure amplitude calculated from the atomic parameters of the average structure and $S(\xi\ \eta\ \zeta)(=\mathrm{sign}(p_1\xi+p_2\eta+p_3\zeta))$ was easily determined by the examination of the intensity distribution of the 1337 satellite reflections. The conditions for the data collection were the same as those used in

determining the average structure at 153 K.

Figure 5 shows the examples of the intensity distributions of the observed structure amplitude of $|F(h+\phi_1, k+\phi_2, l+\phi_3)|$. The distribution of the $|F(\xi\ \eta\ \zeta)|$ is divided into two regions where the values of the $|F(\xi\ \eta\ \zeta)|$ are not zero. The position of this boundary changes according to ζ and forms a plane in the three dimensional reciprocal space. The intensities of satellite reflections are proportional to $|J_1(x)|^2$. When x is constant, $2\pi(p_1\xi+p_2\eta+p_3\zeta)(=x)$ represents one plane and intensities of satellite reflections are zero at the points of the reciprocal space where $(p_1\xi+p_2\eta+p_3\zeta)=0$. The intensities become stronger according to the departure from this plane. The sign of the satellite reflection is changed on this plane. Thus $S(\xi\ \eta\ \zeta)$ values in one region are determined +1 and those in the other region are −1. On the whole the intensity of satellite reflection becomes weaker, when $(\xi\ \eta\ \zeta)$ departs from the origin of the reciprocal space. p_1, p_2, and p_3 are determined by the minimization of A. From $\partial A/\partial p_1=0$, $\partial A/\partial p_2=0$, $\partial A/\partial p_3=0$, we obtain

$$\sum_{\xi\eta\zeta}(|F_o|-\pi kS|F_c|(p_1\xi+p_2\eta+p_3\zeta))\xi = 0,$$
$$\sum_{\xi\eta\zeta}(|F_o|-\pi kS|F_c|(p_1\xi+p_2\eta+p_3\zeta))\eta = 0,$$
$$\sum_{\xi\eta\zeta}(|F_o|-\pi kS|F_c|(p_1\xi+p_2\eta+p_3\zeta))\zeta = 0. \quad (5)$$

We used the scale factor k obtained in the structure determination of the averaged structure at 153 K. Based on the 1337 satellite reflections, p_1, p_2, and p_3 were determined as 0.045 Å, 0.137 Å, and 0.060 Å. The phase parameters (ϕ_1, ϕ_2, ϕ_3) were determined from the positions where the satellite reflections have maximum intensities in the reciprocal space. The four-circle diffractometer was scanned varying the indices of the reflections at intervals of 0.01 around the main reflections in order to gain the diffraction maxima of the satellite reflections. The diffraction maxima corresponding to Eqs. 3 and 4 represent main and satellite reflections which appear regularly at intervals of $|\phi_1 a^*+\phi_2 b^*+\phi_3 c^*|$. The measurement of the coordinates of the reflections in the reciprocal space gave $\phi_1=0.0$, $\phi_2=0.15$, $\phi_3=0.59$. The reliability factor R of 1337 satellite reflections was 0.18. Considering that R was calculated on the basis of the considerably weak satellite reflections, this result is satisfactory. The modulation wave of α-LiPt(mnt) is shown in Fig. 6. The amplitude of the modulation wave of α-LiPt(mnt) is 0.14 Å, which is similar to those of $Rb_{1.67}[Pt(C_2O_4)_2]\cdot 1.5H_2O$ (Rb-OP)[11] and $K_{1.81}[Pt(C_2O_4)_2]\cdot 2H_2O$ (γ-K-OP).[12] Comparison of the struc-

tural data of the superstructures of platinum complexes is shown in Table 6. It may be of interest that in one-dimensional platinum complexes the lattice distortion wave gives rise to a periodical variation of the charge density along the Pt chains. The phase of the periodical distortion wave is considered to be governed by the interchain Coulomb coupling and the Pt chains are anti-phase ordered so as to minimize the Coulomb energy.[11] In α-LiPt (mnt), anti-phase ordering does not hold, perhaps due to the fairly strong transverse S···S interactions.

MO Calculation. We calculated the intermolecular overlap integrals(S) between LUMO of the neutral $Pt(mnt)_2$ molecule, obtained by means of the extended Hückel method. The molecule was idealized to have D_{2h} symmetry. The overlap integrals were calculated from Slater type orbitals. The semiempirical parameters are listed in Table 7. The overlap integrals along the face-to-face stacking direction are much larger than the interstack overlap integrals. The LUMO of the neutral $[Pt(mnt)_2]^0$ is b_{3g}, which agrees with the results of Schrauzer[17] and Yamatera.[18] Further the LUMO is consistent with the change of the bond distances obtained by the structure determination of $Ni(mnt)_2^{2-}$ and $Ni(mnt)_2^{1-}$.[10] The overlap integral of dz^2 orbital in the platinum chain in α-LiPt(mnt) is one-tenth of those of one-dimensional platinum complexes of tetracyanates or bisoxalates because of the large Pt··· Pt distance in α-LiPt(mnt). On the other hand, the intrastack overlap integrals of S atoms are the same order as those of the dz^2 orbitals of tetracyanoplatinates or bis(oxalato)platinates. The intermolecular overlap integrals between the b_{3g} LUMO of the neutral molecules were calculated and the values obtained are shown in Table 8. The overlap integrals along face-to-face stacking S(**c**) (intrastack) is much larger than the interstack overlap integrals S(***b***) or S(***b***+**c**), S(***b***−**c**). The large anisotropy indicates this compound is a one-dimensional metal. The value of S(**c**) indicates that the band width may be about 0.5 eV. Magnetic susceptibility measurements by J. R. Cooper show the conduction electron bandwidth ($4t_{//}$) in a tight binding model is 0.66 eV. This value is about a factor of 2.5 larger than that determined from the plasma frequency (0.26 eV).[6] The plasma frequency of this compound is much smaller than that observed for the usual platinum complexes of tetracyanates or bisoxalates.

Role of the Interchain Transverse S···S Contacts. The electrical conductivity of one-dimensional platinum complexes such as tetracyanoplatinates and bis(oxalato)platinates is strongly dependent on the periodicity of the Pt chain. Similar correlation between the electrical properties and the periodicity of the Pt chains can be also seen in $[Pt(mnt)_2]$ complexes. α-LiPt(mnt) is metallic at room temperature and at 213 K(T_c) a metal-insulator transition is observed. Since the $[Pt(mnt)_2]^{n-}$ are stacked regularly above T_c, the band is partially (59%) filled and one-dimensional metallic properties are observed. In $Rb[Pt(mnt)_2]\cdot 2H_2O$,[9] the band is half filled, which is consistent with the dimer structure and the semiconducting resistivity (≈10^5 Ωcm). In the case of β-LiPt(mnt)[8] the band is 1/4 (or 3/4) filled and the Peierls distortion produces a fourfold structure with a band gap at the Fermi level resulting in semiconducting properties which agree with the temperature dependence of its conductivity (≈10^{-3} Scm^{-1}). Though $M_x[Pt-$

$(mnt)_2$] has one-dimensional stacks of the platinum complexes, it cannot be regarded as typical one-dimensional system. In a one-dimensional system, the relationship between the band gap (2Δ) and the metal-insulator transition temperature (T_c) formed for the system without fluctuations, $2\Delta/T_c=3.73$, cannot be applied because the $2k_F$ lattice distortion does not develop until the temperature is lowered to as low as $T \lesssim T_c/3$ (hence $2\Delta/T_c \gtrsim 10$). In α-LiPt(mnt), $2\Delta/T_c$ is 3.95, which is close to the value derived from the mean field theory 3.73. The reason for the depression of the fluctuations of the lattice distortion wave lies in the characteristic interchain transverse contacts due to S atoms. Thus, despite of the one-dimensional nature of the electronic structure, α-LiPt(mnt) does not behave as one-dimensional system in the presence of the lattice distortion mode.

This work was supported by the Grant-in-Aid for special Research Projection "The Properties of Molecular Assembly" (No. 58218008), from the Ministry of Education, Science and Culture.

7) A. E. Underhill and P. E. Clemenson, to be published. Recent investigation of average charge on the anion by treating the compound with an excess of iodine and back titrating the iodine with sodium thiosulphate, showed that the average charge on the anion appears to be 1.15. Further pH titrations on solutions of the salt revealed that there are approximately 0.33 protons per platinum in two different samples. Elemental analysis of Li was performed and the contents of Li was obtained as 0.75 with the aid of atomic emission spectrometry. On the other hand, we observed $2k_F$ satellite spots to appear on the layer lines of $(0.41\pm n)c^*$, or $(0.59\pm n)c^*$ (n=0,1,..) on the oscillation photograph around the c-axis. From the X-ray experiment total charge of the anion is supposed to be 0.82 or 1.18. The value of 1.18 is good agreement with the value of 1.15 obtained from the chemical analysis. Therefore the chemical formula of α-LiPt(mnt) is considered to be $(H_3O)_{0.33}Li_{0.8}[Pt(mnt)_2]\cdot 1.67H_2O$.

On the basis of the intensity formula and the properties of Bessel funtions $J_m^2(X)=1$, some simple relations between Bessel functions and the relative intensities of the main and satellite reflections are derived. In the case of $K_{1.81}[Pt(C_2O_4)_2]\cdot 2H_2O$ we obtained the amplitude of the modulation wave using these simple relations. Satellite reflections were recorded on equi-inclination Weissenberg photographs and visually estimated.

The Molecular Structure of Trimethylamine-Borane as Studied from Gas Electron Diffraction and Spectroscopic Data

Kinya IIJIMA, Nobuhiro ADACHI, and Shuzo SHIBATA*
Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422
(Received June 18, 1984)

The molecular structure of trimethylamine-borane $(CH_3)_3N \cdot BH_3$ has been determined from gas electron-diffraction data with spectroscopic data. The molecular parameter values and their uncertainties are r_g(B-H)= 1.261±0.006 Å, r_g(N-B)=1.656±0.002 Å, r_g(C-N)=1.485±0.001 Å, r_g(C-H)=1.108±0.002 Å, ∠HBH=112.8±0.4°, and ∠CNC=109.2±0.2°. The potential barrier around the N-B bond has been estimated to be larger than 5 kcal mol^{-1} (1 cal=4.183 J). The isotope effects on the B-D bond distance and the DBD angle have also been estimated to be −0.006 Å and 0.4°, respectively, in r_a^0 parameters.

Trimethylamine-borane $(CH_3)_3N \cdot BH_3$ is one of stable molecular complexes, and the gaseous molecular structure has been determined from microwave spectroscopic data by two research groups.[1,2] The N-B distances obtained from both studies, 1.609 and 1.638 Å, are considerably different from each other. On the other hand the N-B distances in $(CH_3)_3N \cdot BX_3$ (where X is F, Cl, Br, and I), on which we have studied by electron diffraction,[3] fall into the range of 1.65—1.67 Å. The N-B distances of $(CH_3)_3N \cdot BH_3$ obtained by MW spectra are out of this range, though it appears to be difficult to determine precisely the molecular parameters of this compound from MW data because only one rotational constant is available for one isotope species and the center of mass in this compound locates close to the nitrogen atom.

The acceptor power of borane for trimethylamine or pyridine has been discussed in relation with heat of formation,[4,5] dipole moment,[6] chemical shift of NMR spectra,[7] and displacement reaction.[8] We have also reported that on complex formation the changes of molecular structure of the donor and the acceptor molecules have some relation with the acceptor power of boron trihalides.[3] In order to discuss the acceptor power of borane in this point of view, it is necessary to know the precise values of molecular parameters of $(CH_3)_3N \cdot BH_3$. We undertook thus the structure analysis by a gas electron-diffraction method in combination with microwave spectroscopic data.

Experimental

The sample of trimethylamine-borane was purified by sublimation in vacuum. Electron diffraction photographs were taken by the use of an r^3-sector on Kodak Electron-Image plates at camera distances of 293.30 and 143.60 mm. The sample is highly volatile and a nozzle was heated at 346 K to introduce the vaporized sample to vacuum from a warmed sample holder. An accelerating voltage was 40 kV and the wavelength was determined from the diffraction patterns of thallium(I) chloride.[9] The exposure times were about 135 and 280 s for the long and short camera distance photographs, respectively, with an electron-beam current of 0.8 μA. The pressure in the diffraction chamber was 5×10^{-6} Torr (1 Torr=133.322 Pa) during the experiment. Three plates and four plates were selected for the long and short camera distance photographs, respectively, and their optical densities were measured at 0.4 mm intervals by the use of a digital microphotometer. The electron diffraction unit and the digital microphotometer used in the present study have been described elsewhere.[10]

Analysis and Results

Molecular Intensity and Radial Distribution. The scattering intensities in the range of s=2.8—16.5 Å^{-1} were obtained from the long camera-distance plates and those in the range of s=10.1—33.3 Å^{-1} from the short camera-distance plates. They were leveled by using theoretical backgrounds, and the intensities for each camera distance were averaged. The elastic and inelastic scattering factors were taken from the tables prepared by Schäfer *et al.*[11] and by Cromer and Mann,[12] respectively. The inelastic scattering factor for the hydrogen atom was taken from the table by Tavard *et al.*[13] The experimental background curve was drawn smoothly,[14] and the experimental molecular intensities obtained are shown in Fig. 1. Figure 2 shows the experimental radial distribution function calculated from the experimental molecular intensities. The molecular model of $(CH_3)_3N \cdot BH_3$ and the numbering of the atoms are shown in Fig. 3.

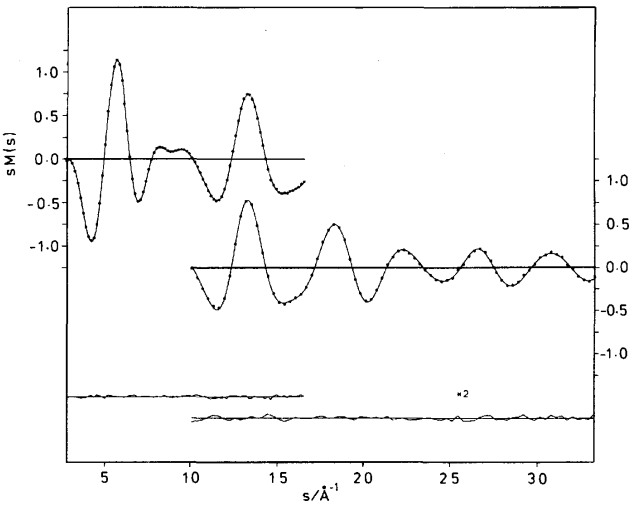

Fig. 1. Molecular intensities for trimethylamine-borane. The two upper curves are long and short camera-distance data. Dots represent observed intensities, solid curves calculated intensities, and the lower curves are their residuals.

Vibrational Amplitude and Shrinkage Correction. Root-mean-square amplitudes of the atomic pairs in $(CH_3)_3N \cdot BH_3$ with the staggered form were calculated by using the Urey-Bradley force field for related molecules,[3] which was changed slighly so as to obtain better agreement with the observed mean amplitudes. The force constants are listed in Table 1, and the calculated mean amplitudes and the shrinkage corrections, $r_a - r_\alpha$,[15] are listed in Table 2.

The height of the rotational barrier around the N-B bond, V_3, was estimated to be about 10 kcal mol^{-1} from the force constant of Y by the relation $V_3=(2/9)Y$. The lower limit was calculated to be 5 kcal mol^{-1} from the lower limit of the Y value which was estimated from the error of the observed mean amplitude of the *gauche* $C_2 \cdots H_1$ atomic pair, because the Y value has the main contribution to the mean amplitude of that atomic pair.[16]

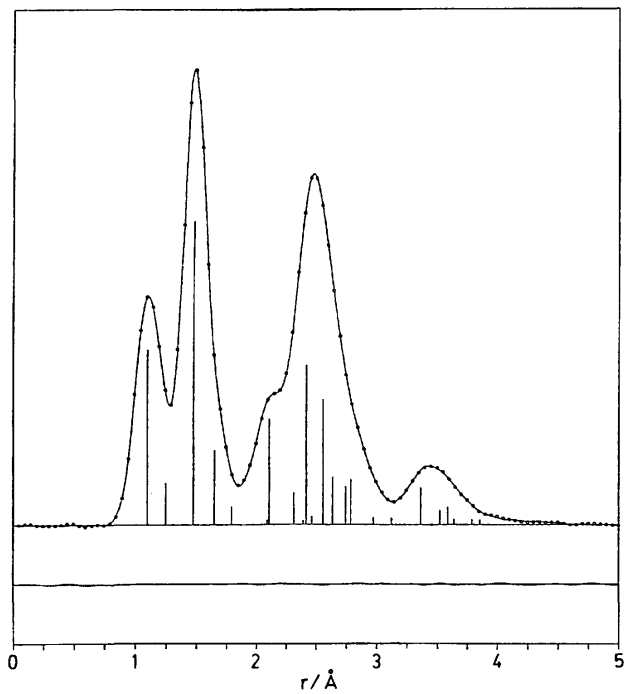

Fig. 2. Radial distribution for trimethylamine–borane. Dot represents the experimental one, the solid curve the calculated one, and the difference is shown below. The vertical bars represent bond distances and the scattering powers.

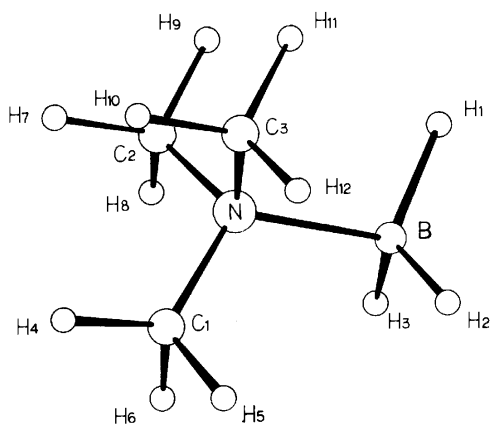

Fig. 3. Numbering of atoms in trimethylamine–borane.

Analysis of Electron Diffraction Intensities and Rotational Constant. At first the molecular parameters of $(CH_3)_3N \cdot BH_3$ were determined by the least-squares analysis of the molecular intensities. Here it was assumed that the molecule has the C_{3v} symmetry in a staggered form, and the methyl and the borane groups also have the C_{3v} symmetry. The geometrical parameters and the root-mean-square amplitudes listed in Tables 3 and 4 were refined. The mean amplitudes of the other atomic pairs and the shrinkage corrections were fixed to the calculated values listed in Table 2. The asymmetry parameters, κ, for the B-H, N-B, C-N, and C-H bonds were estimated to be 21, 4.7, 2.1, and 12×10^{-6} Å, respectively, by the diatomic approximation[17] and were fixed throughout the analysis. Those for the other atomic pairs were ignored.

Table 1. Urey-Bradley force field for $(CH_3)_3N \cdot BH_3$

K(N-B)	1.0	H(HCH)	0.4
K(B-H)	4.0	H(NCH)	0.3

B$\cdots$$H_4$	1127	61	C_1-H_4	774	247
B$\cdots$$H_5$	1785	−7	$C_1\cdots H_7$	1673	9
$H_1\cdots H_2$	1354	200	$C_1\cdots H_8$	1669	10
$H_1\cdots$N	1144	78	$C_1\cdots H_9$	1051	70
$H_1\cdots C_1$	1149	44	$H_4\cdots H_5$	1264	353
$H_1\cdots C_2$	1676	−8	$H_4\cdots H_7$	2470	−33
$H_1\cdots H_4$	1457	77	$H_4\cdots H_8$	2594	−72
$H_1\cdots H_5$	1805	56	$H_4\cdots H_9$	1780	76
$H_1\cdots H_7$	1859	48	$H_5\cdots H_8$	1775	76
$H_1\cdots H_8$	2532	−67	$H_5\cdots H_9$	1369	103
$H_1\cdots H_9$	2500	−58	$H_5\cdots H_{12}$	2461	−30

The numbering of the atoms is shown in Fig. 3. The mean amplitudes and shrinkage corrections were calculated for the same temperature (346 K) as in the experiment.

The r_α parameters for bonds obtained by the analysis of electron diffraction data were transformed to r_α^0 parameters at 0 K by the relation $r_\alpha^0 = r_\alpha + K_T - K_0 - 3/2\, a(l_T^2 - l_0^2)$,[15] and the angle parameters were assumed to be equal to those at 0 K. The rotational constant, B_α^0, which was calculated from these r_α^0 parameters was 0.15065(68) cm^{-1}. The rotational constant observed for the normal species was 0.1506482 cm^{-1},[2] and the value corrected for the vibrational effect, B_z,[18] was 0.150629 (19) cm^{-1}, as listed in Table 5. The uncertainty in the correction was tentatively assumed to be 100%. Although the B_α^0 value from the electron diffraction data was in agreement with the observed one, B_z, within the limits of error, the joint analysis of electron diffraction data and rotational constant was performed. The relative weight for the observed rotational constant in the least-squares calculation was estimated to be 1×10^7 in such a way that 2.6 times the standard deviation of the rotational constant obtained from the least-squares calculation is nearly equal to the uncertainty in B_z. The r_α^0 parameters and the mean amplitudes obtained from the joint analysis are listed in Tables 3 and 4, respectively, with their errors. The random errors were 2.6 times as large as the errors estimated by the least-squares calculations. The systematic errors were estimated from the errors in both the measurements of camera distance (0.03%) and wavelength (0.08%). The best-fit molecular intensities and the theoretical radial distribution function are shown in Figs. 1 and 2, respectively. The experimental intensities, the experimental smooth backgrounds, and the correlation matrix for the molecular parameters are deposited as Document No. 8452 at the Office of the Editor of the Bulletin of the Chemical Society of Japan. The least-squares calculations were carried out on a HITAC M-200H computer in the Computer Center of the University of Tokyo.

Table 6 lists the observed rotational constants of the isotope species[2] and the corresponding ones calculated by the use of the r_α^0 parameters in Table 3. The

calculated rotational constants of the species with deuterium are significantly different from the observed ones, while those of the other species are in good agreement with the observed ones. These differences may indicate isotope effects on the B-D bond and the DBD angle. However, they cannot be estimated only from the rotational constant of $(CH_3)_3N\cdot BD_3$. The isotope effect on the B-D bond was thus estimated by the diatomic approximation and Δr_a^0 (=r_a^0(B-D)−r_a^0(B-H)) was assumed to be equal to Δr_g^0 (=r_g^0(B-D)−r_g^0(B-H)), because the force field used is not so reliable to calculate the precise perpendicular amplitude of the B-H bond, as described later. Thus, Δr_g^0 was obtained from $(3/2)a[l_0(\text{B-D})^2-l_0(\text{B-H})^2]$,[19] where a is Morse constant and was assumed to be 2.0 Å^{-1}. The mean amplitudes of the B-D and the B-H bonds at 0 K were calculated from the relation of $l_0^2=h/8\pi^2\mu c\nu$,[20] where h is Planck constant, μ is reduced mass, c is light velocity, and ν is the wave number for B-D (1656 cm^{-1}) or B-H (2267 cm^{-1}) bond stretching.[21] The isotope effect on the B-D bond distance was −0.006 Å. Then the isotope effect on the DBD angle was estimated so as to give the best agreement of the calculated rotational constant of $(CH_3)_3{}^{14}N\cdot{}^{11}BD_3$ with the observed one, and resulted in the value (=∠DBD−∠HBH) of 0.4±0.1°, where 100% uncertainty was assumed for the isotope correction to the B-D bond.

Discussion

The N-B bond distance of $(CH_3)_3N\cdot BH_3$, 1.656± 0.002 Å, is nearly equal to those of trimethylamine-boron trihalides, which were also determined by an electron-diffraction method,[3] as listed in Table 7. On the complex formation the B-H and the C-N bond distances of the complex increase by 4.4 and 1.6%, respectively, and the HBH and the CNC angles of the complex decrease by 6.1 and 1.1%, respectively, comparing the molecular parameters of $(CH_3)_3N\cdot BH_3$ with those of its component molecules,[22,23] in which BH_3 refers to the terminal part of diborane. These relative changes of the molecular parameters are nearly equal to the corresponding ones in $(CH_3)_3N\cdot BF_3$.[3] This seems to show that the acceptor power of borane is similar to that of boron trifluoride in accord with the result from the measurement of the enthalpy change.[5]

The rotational barrier around the N-B bond of this complex is higher than 5 kcal mol^{-1} and it seems to be larger than the barrier of a methyl group.[24] We deduced the V_3 value from the Y value, which was adjusted so that the calculated mean amplitude of the *gauche* $C_2\cdots H_1$ atomic pair agree with the observed one. Force constants for angle deformation, H(CNB) and H(NBH), also contributed to the mean amplitude of the *gauche* $C_2\cdots H_1$ pair. In the present study the H(CNB) was reasonably estimated from the observed mean amplitude of the C···B pair, but the H(NBH) could not be optimized. Therefore the deduced value of V_3 is not a reasonable one. However it should be noticed that the configuration around the nitrogen atom of this complex is nearly regular tetrahedral, but the observed mean amplitude of the C···B pair, 0.091± 0.005 Å, is considerably larger than that of the C···C pair, 0.080±0.003 Å. This fact shows that the BH_3 group vibrates more than the CH_3 group. Thus the mobility of the borane group seems to hinder the rotation around the N-B bond and increase the barrier height.

The isotope effects were found on the B-D bond distance and the DBD angle and they were estimated to be −0.006 Å and 0.4°, respectively, though the isotope effect on the B-D bond distance depends on the assumption of the diatomic approximation with the anharmonic constant of 2.0 Å^{-1}. The isotope effect on the C-D bond distance in CD_4 and that on the N-D bond distance in ND_3 have been estimated to be both −0.004 Å.[25,26] The isotope effect on the B-D bond distance of $(CH_3)_3N\cdot BD_3$ is comparable with them while the isotope effect on the DBD angle differs from that on the DND angle of ND_3, in which the DND angle is nearly equal to the HNH angle of NH_3.[26] It seems that in ND_3 the DND angle remains unchanged in spite of the shortening of the N-D distance because of the strong repulsion between the lone paired electrons of the N atom and the paired electrons of the N-D bond.

(Received January 12, 1984)

Phosphorylation of nucleosides with sodium *cyclo*-triphosphate (P_{3m}) was studied under various conditions (mixing ratio of P_{3m} to nucleoside, pH, reaction temperature and time). 1) Adenosine, cytidine, guanosine, and uridine were easily phosphorylated by P_{3m} to form selectively nucleoside 2′-monophosphates, 3′-monophosphates, and 2′,3′-cyclic monophosphates. On the other hand, 2′-deoxyadenosine, 3′-deoxyadenosine, 2′-deoxycytidine, and thymidine could not be phosphorylated by P_{3m}. 2) The phosphorylation of adenosine, cytidine, guanosine, and uridine varied strongly, depending on the reaction conditions; mixing ratio, pH, reaction temperature and time. Under conditions of a high mixing ratio of P_{3m} to nucleoside (5:1—10:1), high pH (12—14), high temperature (70—100 °C) for a short time (1—2 d) or low temperature (room temperature) for a long time (70—150 d), nucleoside 2′- and 3′-monophosphate could be obtained in high yield (about 50—100%). 3) At the initial stage of the phosphorylation reactions of adenosine, cytidine, and guanosine with P_{3m}, nucleoside 2′,3′-cyclic monophosphates were formed, though a small amount (about 1—3%), but in the course of the reaction for a long time, they were hydrolyzed to nucleoside 2′- and 3′-monophosphates. 4) 2′-deoxyadenosine, 3′-deoxyadenosine, 2′-deoxycytidine, and thymidine could not be phosphorylated by P_{3m}. This means that the presence of hydroxyl groups at the 2′- and 3′-positions of the ribose was necessary for the phosphorylation of nucleosides with P_{3m}. 5) Phosphorylation of nucleosides with short-chain phosphates (ortho-, pyro-, and triphosphate) could not be observed at all. 6) The mechanism of formation of nucleoside 2′-monophosphates, 3′-monophosphates, and 2′,3′-cyclic monophosphates in the phosphorylation of nucleosides with P_{3m} was discussed.

Nowadays, as phosphorylating agents for nucleosides and related organic compounds are usually used phosphoryl chloride, polyphosphoric acid[1-4] and various organic phosphorus compounds.[5-8] However, the phosphorylation of nucleosides with such reagents is generally a tedious operation. Feldmann[9] has reported that sodium *cyclo*-triphosphate(P_{3m}) reacted with alcohol or sugar in an alkaline solution to form its monophosphate or triphosphate derivatives. Also, Schwartz[10] and Saffhill[11] have reported that, by the phosphorylation of nucleosides with condensed phosphates, nucleosie 2′-, 3′-, and 5′-monophosphates were obtained. However, their formation conditions and the reaction mechanism are scarcely known at present. The present authors[12] have already reported that inosine was easily phosphorylated by P_{3m} at 2′- and 3′-positions of the ribose to form selectively inosine 2′-monophosphate(2′-IMP) and 3′-monophosphate(3′-IMP). Accordingly, in the present study adenosine, 2′- and 3′- deoxyadenosine, cytidine, 2′-deoxycytidine, guanosine, uridine, and thymidine were phosphorylated with P_{3m} under various experimental conditions, and the reaction products as well as the reaction mechanism were investigated.

Experimental

1) Phosphorylation of Adenosine with cyclo-*Triphosphate.* With 50 cm^3 of 0.2 mol dm^{-3} aqueous sodium *cyclo*-triphosphate(P_{3m}) solution were mixed 50 cm^3 of adenosine solutions of various concentrations ranging from 0.02 to 0.04 mol dm^{-3}, and each mixed solution (molar ratio P_{3m}: adenosine=5:1—10:1) was adjusted to the prescribed pH value (14, 12, 10, 7, and 2) by use of sodium hydroxide or hydrochloric acid solution and was allowed to react at 100 °C, 70 °C, and room temperature. Because the pH of the mixed solution decreased with the progress of the reaction, the pH of the solution was kept always at the prescribed value using sodium hydroxide solution.

2) Phosphorylation of Cytydine with cyclo-*Triphosphate.* With 50 cm^3 of 0.5 mol dm^{-3} aqueous P_{3m} solution were mixed 50 cm^3 of aqueous cytidine solution of various concentrations ranging from 0.1 to 0.5 mol dm^{-3}, and each mixture (P_{3m}: cytidine=1:1—5:1) was allowed to react at pH 14—2, at room temperature and 70 °C.

3) Phosphorylation of Guanosine with cyclo-*Triphosphate.* With 50 cm^3 of 0.2 mol dm^{-3} aqueous P_{3m} solution was mixed 50 cm^3 of 0.04 mol dm^{-3} guanosine solution and the mixture (P_{3m}: guanosine=5:1) was allowed to react, similarly to the experiments of adenosine and cytidine series.

4) Phosphorylation of Uridine with cyclo-*Triphosphate.* With 50 cm^3 of 0.05—0.5 mol dm^{-3} aqueous P_{3m} solutions was mixed 50 cm^3 of 0.05 mol dm^{-3} aqueous uridine solution, and each mixed solution (P_{3m}:uridine=1:1—10:1) was allowed to react at pH 12 and 70 °C.

5) Phosphorylation of Thymidine with cyclo-*Triphosphate.* With 50 cm^3 of 0.2 mol dm^{-3} aqueous P_{3m} solution was mixed 50 cm^3 of 0.04 mol dm^{-3} aqueous thymidine solution, and the mixed solution (P_{3m}: thymidine=5:1) was allowed to react at pH 12—14 and 70 °C.

6) Phosphorylation of 2′- or 3′-Deoxyadenosine with cyclo-*Triphosphate.* With 50 cm^3 of 0.2 mol dm^{-3} aqueous P_{3m} solution was mixed 50 cm^3 of 0.04 mol dm^{-3} aqueous solution of 2′- or 3′-deoxyadenosine, the mixture was adjusted to pH 12 with 6 mol dm^{-3} sodium hydroxide solution and was allowed to react at 70 °C.

7) Phosphorylation of 2′-Deoxycytidine with cyclo-*Triphosphate.* With 50 cm^3 of 0.5 mol dm^{-3} aqueous P_{3m} solution was mixed 50 cm^3 of 0.1 mol dm^{-3} aqueous 2′-deoxycytidine solution, and the mixture was allowed to react at pH 12 and 70 °C.

8) Phosphorylation of Nucleosides with Ortho-, Pyro-, or Triphosphate. With 50 cm^3 of 0.2 mol dm^{-3} aqueous solution of a short-chain sodium ortho-, pyro-, or triphosphate was mixed 50 cm^3 of 0.04 mol dm^{-3} aqueous solutions of adenosine, cytidine, guanosine, uridine and thymidine, and each mixture was allowed to react at pH 12 and 70 °C, similarly to the phosphorylation of nucleosides with P_{3m}.

Chemicals. Sodium *cyclo*-triphosphate hexahydrate, $Na_3P_3O_9 \cdot 6H_2O$, was prepared by the procedure described in the previous paper[13] and recrystallized five times from an aqueous solution. Guaranteed grade adenosine, 2'- and 3'-deoxyadenosine, cytidine, 2'-deoxycytidine, guanosine, uridine, and thymidine from Sigma Chemical Company were used without purification.

Anion-exchange Chromatography. A column of 1.5X64 cm packed with an anion-exchange resin Dowex 1X2 (formate form) of 200—400 mesh was employed. The eluent used in the experiments of adenosine series was 0.3 mol dm^{-3} formic acid solution, pH being about 2.1. The sample solution (1 cm^3) was injected into a column, and the eluate was fractionated in 10-g fractions with a fraction collector of the weight type. Adenosine, adenosine 2'-monophosphate (2'-AMP), adenosine 3'-monophosphate(3'-AMP), and 2', 3'-cyclic monophosphate(2', 3'-cAMP) were determined by means of spectrophotometry at 260 nm.

In experiments of cytidine series, a mixture of 0.05 mol dm^{-3} formic acid with equal volume of 0.01 mol dm^{-3} sodium formate solution was used as the eluent. The pH of the mixed solution was about 3.0. The absorbance was measured at 279 nm.

In experiments of guanosine series, an equal volume mixture of 1 mol dm^{-3} formic acid and 0.15 mol dm^{-3} sodium formate solution was used as the eluent. The pH of the mixed solution was about 2.7. The absorbance was measured at 255 nm.

The eluent used in experiments of uridine and thymidine series was an equal volume mixture of 1 mol dm^{-3} formic acid and 0.1 mol dm^{-3} sodium formate solution. The pH of the mixed solution was about 2.5. The absorbance was measured at 260 and 267 nm in experiments of uridine and thymidine series, respectively.

High Performance Liquid Chromatography (HPLC).[12] HPLC was carried out by use of a Shimadzu LC-3A, under the following conditions: packing material Lichromosorb H_2N (5 μm, E. Merck), column size 250X4.6 mm I.D., pressure 70 kg/cm^2, column temperature 40 °C, eluent 0.015 mol dm^{-3} ammonium dihydrogen orthophosphate, flow rate 1.0 cm^3/min.

Thin-layer Chromatography (TLC). Plates used were DC-Alufolin cellulose F_{254} and DC-Fertigplatten cellulose F (E. Merck). As the developer was used a mixture solution consisting of saturated ammonium sulfate, 1 mol dm^{-3} ammonium acetate solution, and 2-propanol, in the ratio of 80:18:12.

Results and Discussion

Phosphorylation of Adenosine with P_{3m}. With 50 cm^3 of 0.2 mol dm^{-3} aqueous P_{3m} solution was mixed 50 cm^3 of 0.02 mol dm^{-3} aqueous adenosine solution (P_{3m}:adenosine=10:1) and the mixture was allowed to react at pH 12 and 70 °C. The pH of the mixture decreased gradually and reached to about 7.5 after 1 d. This fact suggests that P_{3m} reacted with water or adenosine to form linear phosphates or their derivatives. As an example, results of anion-exchange chromatography of the reaction products are shown in Fig. 1. As can be seen from Fig. 1, after 1 d peaks corresponding to adenosine 2'-monophosphate(2'-AMP), adenosine 3'-monophosphate(3'-AMP), and adenosine 2', 3'-cyclic monophosphate(2', 3'-cAMP) were observed at about 700, 1070, and 1200 cm^3 of the effluent, respectively. Reaction products of adenosine with P_{3m} were only 2'-AMP, 3'-AMP, and 2', 3'-cAMP. On the other hand, the peak of adenosine appeared at 70 cm^3 of the effluent. The products obtained in the reaction were identified to be 2'-AMP, 3'-AMP, and 2', 3'-cAMP, by comparing their data of anion-exchange chromatography, HPLC, and TLC with those of the authentic samples, as well as by chemical analysis of the reaction products. Also, it is found that the amounts of 2'-AMP and 3'-AMP increase with the reaction time.

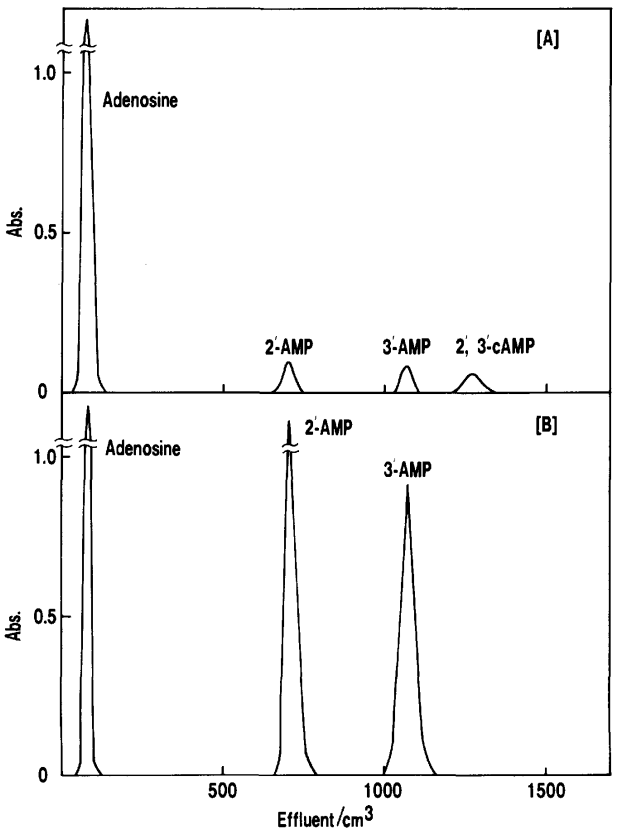

Fig. 1. Elution patterns for the reaction products of P_{3m} with adenosine at 70 °C and pH 12.
P_{3m}: Adenosine=10:1, (A): After 1 d, (B): After 17 d.

In Fig. 2, the amounts of 2'-AMP, 3'-AMP, and 2', 3'-cAMP, formed by the reaction of P_{3m} with adenosine (mixing ratio=10:1) at pH 12 and 70 °C, are plotted as a function of time. With the progress of the reaction, amounts of 2'-AMP and 3'-AMP increased gradually to maximum values, about 37 and 45% after 17—25 d respectively, and then decreased slowly. On the contrary, the amount of 2',3'-cAMP was largest (about 3%) after 1 d, and decreased rapidly with the reaction time, and finally became entirely zero after 8 d. On the other hand, with the increase of 2'-AMP and 3'-AMP formation, the starting material(adenosine) decreased.

Further, after a long reaction time (more than 30 d) the amounts of decomposition products of adenosine, 2′-AMP, and 3′-AMP increased gradually.

Figure 3 shows the change of the amounts of 2′-AMP and 3′-AMP in the reaction of P_{3m} with adenosine under conditions of mixing ratio 5:1, pH 12, and room temperature. The decrease in the mixing ratio as well as the lowering of the reaction temperature caused to decrease extremely the formation rate and the yields of products. Further, formation of 2′,3′-cAMP observed at the initial stage of the reaction, was so little that it was omitted in Fig. 3.

The amounts of 2′-AMP, 3′-AMP, and 2′, 3′-cAMP obtained by the phosphorylation of adenosine with P_{3m} under various conditions are summarized in Table 1. As can be seen, the phosphorylation of adenosine with P_{3m} could not proceed at pH 7 or less, namely in neutral or acidic medium. The larger the ratio of P_{3m} to adenosine, the higher the pH and the higher the reaction temperature are, the larger are the amounts of 2′-AMP and 3′-AMP formed.

The phosphorylation of 2′-deoxyadenosine, 3′-deoxyadenosine, and adenine (purine base of adenosine) with P_{3m} were also investigated under conditions similar to those for the phosphorylation of adenosine with P_{3m}. However, these compounds could not be phosphorylated at all. Results of the phosphorylation of 2′- and 3′-deoxyadenosine are also shown in Table 1 for reference.

Based on above-described results, 2′-AMP and 3′-AMP could be selectively obtained by the phosphorylation of adenosine with P_{3m} under conditions of high mixing ratio (P_{3m}:adenosine=5:1—10:1), high pH (pH 10—14), and high temperature (70—100 °C). Also, 2′, 3′-cAMP was formed in a short period (1—3 d) after the reaction, but it was easily decomposed with time and thus its amount was so little as about 3% at the highest. Based on the fact that 2′,3′-cAMP is easily hydrolyzed under the present experimental conditions to form 2′-AMP and 3′-AMP, 2′, 3′-cAMP formed at the initial stage of the reaction is considered to be hydrolyzed.

From the above results, the optimum conditions for the phosphorylation of adenosine with P_{3m} are found to be mixing ratio 10:1, pH 12, and 70 °C. Further, the fact that 2′- and 3′-deoxyadenosine cannot be phosphorylated at all with P_{3m} may suggest that the presence of hydroxyl groups at both 2′- and 3′-positions of the

ribose is required for the phosphorylation of nucleosides with P_{3m}.

Phosphorylation of Cytidine with P_{3m}. In Fig. 4 are shown the results of anion-exchange chromatography of the reaction products in the phosphorylation of cytidine with P_{3m}. Peaks corresponding to cytidine 2′-monophosphate(2′-CMP), cytidine 3′-monophosphate(3′-CMP), and cytidine 2′,3′-cyclic monophosphate(2′,3′-cCMP) appeared at about 740, 930, and 1300 cm^3 of the effluent, respectively. These products were identified by comparing their data of anion-exchange chromatography, HPLC, and TLC with those of the authentic samples. The peak of cytidine appeared also at about 80 cm^3 of the effluent. Further, a large peak (about 180 cm^3) appeared between those of cytidine and 2′-CMP was proved to correspond to the decomposition product of cytidine by the experiment, in which cytidine alone was treated at pH 12 and 70 °C. As the decomposition product is, however, not identified yet and is beyond the purpose of the present study, it is not described here.

The reaction products of the phosphorylation of cytidine with P_{3m} were only 2′-CMP, 3′-CMP, and 2′, 3′-cCMP. In the reaction for a long time, 2′-CMP and 3′-CMP were formed markedly.

Yields of 2′-CMP, 3′-CMP, and 2′, 3′-cCMP in the phosphorylation of cytidine or 2′-deoxycytidine with P_{3m} are summarized in Table 2. At pH 14 and 70 °C, cytidine was phosphorylated with P_{3m} in a short time (10—24 hr), namely about 55% of the starting material (cytidine) was phosphorylated after 1 d. With the elapse of the reaction time, however, 2′-CMP and 3′-CMP once formed were hydrolyzed, and as the result, the amounts of them decreased rapidly. At the same reaction temperature, the phosphorylation of cytidine with P_{3m} became slower with the decrease of pH, and the phosphorylation did not proceed under acidic conditions. 2′, 3′-cCMP was easily formed at the initial stage of the reaction, but with the elapse of reaction time, 2′, 3′-cCMP was hydrolyzed to form 2′-CMP and 3′-CMP. 2′,3′-cCMP was well formed at pH 12 and room temperature (about 4.2%).

			7	24	35	0
P_{3m}: 2′-Deoxycytidine						
5 : 1	12	70		—	0	—

At pH 12 and room temperature after a long time(65 d), about 80% of cytidine was phosphorylated to form about 35 and 45% of 2′-CMP and 3′-CMP, respectively. As can be seen from Table 2, at such a high pH as 14 and at high temperature (70 °C), 2′-CMP and 3′-CMP once formed were easily hydrolyzed.

The optimum conditions for the phosphorylation of cytidine with P_{3m} are either at pH 12 and room temperature for a long time (65—70 d) or at pH 14 and 70 °C for a short time (12—24 h). Cytidine, differing from adenosine series, was found to be phosphorylated even at pH 7, though small in amount. On the other hand, the phosphorylation of 2′-deoxycytidine with P_{3m} could not be observed at all, similarly to the cases of 2′-deoxyadenosine and 3′-deoxyadenosine. For the phosphorylation of cytidine, the presence of hydroxyl groups at both 2′- and 3′-positions of the ribose was also suggested to be necessary. The basis of this conclusion will be discussed later in detail.

Phosphorylation of Guanosine with P_{3m}. An example of the results of anion-exchange chromatography of the reaction products obtained in the phosphorylation of guanosine with P_{3m} is shown in Fig. 5-(A). Guanosine was easily phosphorylated with P_{3m} to form chiefly guanosine 2′-monophosphate(2′-GMP) and guanosine 3′-monophosphate (3′-GMP). Also in the phosphorylation of guanosine, the formation of guanosine 2′, 3′-cyclic monophosphate(2′,3′-cGMP), though small in amount, was observed at the initial stage of the reaction. Amounts of 2′-GMP and 3′-GMP obtained under various conditions are summarized in Table 3. The optimum conditions for the phosphorylation of guanosine with P_{3m} are found to be the mixing ratio 5:1, pH 12, room temperature, and long reaction period (70 d).

Phosphorylation of Uridine with P_{3m}. Figure 6 shows the results of HPLC of the reaction products in the phosphorylation of uridine with P_{3m}. Comparing the data with those of the authentic samples, the main reaction products were uridine 2′-monophosphate (2′-UMP) and uridine 3′-monophosphate(3′-UMP).

	2	70	30	0	0	0

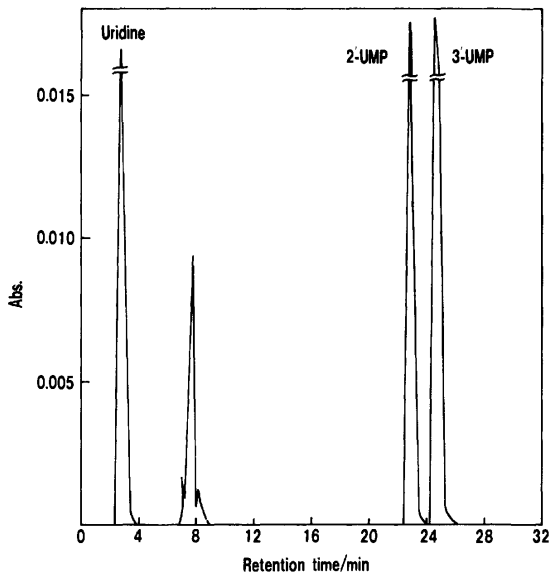

Fig. 6. Elution profile of the reaction products of P_{3m} with uridine at 70 °C and pH 12.
P_{3m}: Uridine=10 : 1, after 49 d.

Three small peaks, appeared between those of the starting material (uridine) and 2′-UMP, were proved to be those of decomposition products of uridine, based on the experiment carried out with uridine alone under the same conditions (pH 12 and 70 °C). On the other hand, 2′-UMP and 3′-UMP was not separated by anion-exchange chromatography under the above-described conditions, as shown in Fig. 5-(B). Further, the formation of 2′, 3′-cUMP could not be ascertained by means of HPLC and anion-exchange chromatography. It is not clear yet whether 2′, 3′-cUMP was not formed originally or 2′, 3′-cUMP once formed at the initial stage of the reaction, being very unstable, was easily hydrolyzed. It may be reasonable, however, to consider that the latter is more probable, similarly to the case of adenosine, cytidine, and guanosine series.

In Table 4 are shown the results of phosphorylation of uridine with P_{3m} under various conditions. Under the conditions of P_{3m}:uridine=10:1, pH 12, and room temperature, uridine is phosphorylated with P_{3m} completely (100%) after 140 d. Thus, the starting material (uridine), 2′-UMP, and 3′-UMP were not hydrolyzed at all at room temperature.

Phosphorylation of Thymidine with P_{3m}.[14] Thymidine, one of 2′-deoxynucleosides, was not phosphorylated at all under above-described conditions. This fact may be explained similarly to the above-described cases of 2′- and 3′-deoxyadenosine and 2′-deoxycytidine. The reasons will be discussed later in detail.

Phosphorylation of Nucleosides with Ortho-, Pyro-, and Triphosphate. The phosphorylation of nucleosides with short-chain phosphates such as ortho-(P_1), pyro-(P_2), and triphosphate(P_3) was also investigated under similar experimental conditions to those with P_{3m}, but the phosphorylation of nucleosides with short-chain phosphates was not observed at all.

Mechanism of Phosphorylation of Nucleosides with P_{3m}. The mechanism of the phosphorylation of adenosine, cytidine, guanosine, and uridine with P_{3m} is summarized in Fig. 7. First, a hydrogen bond is formed between the hydroxyl group at the 2′- or 3′-position of ribose of nucleoside and an oxygen atom of P_{3m}. Then, by the attack of the corresponding oxygen atom of the hydroxyl group at 3′- or 2′-position upon a phosphorus atom of P_{3m}, the ring of P_{3m} is opened to give an intermediate product, a triphosphate derivative of nucleoside. This triphosphate derivative, however, is immediately hydrolyzed to give nucleoside 2′- or 3′-monophosphate and P_2. On the other hand, the mechanism of formation of nucleoside 2′,3′-cyclic monophosphate may be as follows: As shown in Fig. 7, the intermediate, nucleoside 2′- or 3′- triphosphate formed first by the reaction of nucleoside with P_{3m}, is attacked by the hydroxyl group at 3′- or 2′- position, to give 2′,3′-cyclic monophosphate and P_2. Nucleoside 2′,3′-cyclic monophosphate thus formed is hydrolyzed to give 2′- and

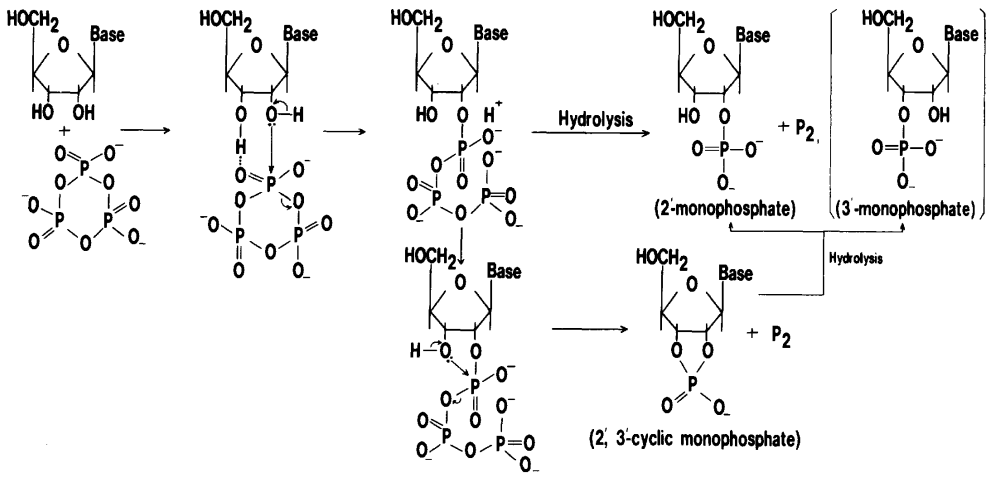

Fig. 7. Mechanism of phosphorylation of nucleosides with P_{3m}.

3'-monophosphate.

As can be seen from above-mentioned experimental results, nucleoside 2'- and 3'-monophosphates, formed by the phosphorylation of adenosine, cytidine, guanosine or uridine with P_{3m}, are nearly equal in amount. This means that the probability to form a hydrogen bond between the hydroxyl group at 2'- or 3'-position of the ribose and an oxygen atom of P_{3m} are practically equal. Further, based on the fact that 2'-deoxyadenosine, 3'-deoxyadenosine, 2'-deoxycytidine, and thymidine cannot be phosphorylated with P_{3m} at all, the presence of hydroxyl groups at both 2'- and 3'-positions of the ribose is suggested to be indispensable for the phosphorylation. In this connection, formation of the above-mentioned hydrogen bond between the hydroxyl group at 2'- or 3'- position and an oxygen atom of P_{3m} is considered to be really possible in aqueous solution, because the bond length of P=O in crystalline sodium *cyclo*-triphosphate is 1.48 Å,[9] while that of C–C bond at 2'- and 3'-positions of ribose in nucleoside is 1.53 Å.[15]

Potassium-ion Exchange on α-Hafnium Phosphate

Isao TOMITA,* Masaru BANJU,† Katsumi NOGUCHI,† and Toshihiro NAKAMURA†

Tokyo University of Fisheries, Konan, Minato-ku, Tokyo 108

†*Department of Industrial Chemistry, Faculty of Engineering, Meiji University, Higashi-Mita, Tama-ku, Kawasaki 214*

(Received April 16, 1984)

Forward and backward pH titration curves were measured for potassium-ion exchange on crystalline α-hafnium phosphate which had been prepared by the direct-precipitation method. Exchange in each direction proceeded in two steps, and the hysteresis was observed in the region of smaller loadings of the potassium ions. Exchange in the ternary H^+–Li^+–K^+ system was also preliminarily investigated, the selectivity of the potassium and lithium ions was what would be expected from the results of the binary hydrogen ion-alkali metal ion systems.

Lithium-ion-exchange behavior on crystalline α-hafnium bis(hydrogenphosphate) monohydrate, $Hf(HPO_4)_2 \cdot H_2O$, was reported in a previous paper[1], where this compound was considered not to form as many exchanged phases as α-zirconium phosphate because of the single-step lithium-ion exchange.

In contrast to the lithium-ion exchange, the potassium-ion exchange proceeds step-by-step as is the case for α-zirconium phosphate, but considerable difference is observed in the forward and backward titrations. Detailed experiments were thus carried out for K^+- and H^+-ion exchange, as well as for ternary-ion exchange (H^+–Li^+–K^+), and will be reported in this paper. The α-hafnium phosphate employed here had been synthesized by the direct-precipitation method. Comparison between the ion exchangers prepared by the reflux method and by the direct-precipitation method was also made.

Experimental

Ion-exchangers. Alberti and Torracca[2] prepared α-zirconium phosphate by the direct-precipitation method. Hasegawa and Kuwayama,[3] and Inoue and Yamada[4] have further developed methods for α-zirconium phosphate. There has been no data for the direct precipitation of α-hafnium phosphate, but a method similar to α-zirconium phosphate preparation can be expected to be useful. For the preparation of α-hafnium phosphate, the methods adopted by the above-mentioned authors were applied to the hafnium compound with some modifications. Hafnium tetrachloride was dissolved in hydrofluoric acid. To this we then added phosphoric acid, the concentrations of the resulting solutions were 0.13 mol·dm^{-3} in Hf^{IV}, 0.76 mol·dm^{-3} in HF, and 2.5 mol·dm^{-3} in H_3PO_4. The solution was transferred into a polyethylene bottle and placed in a water bath kept at 56 °C; then prehumidified air was passed through for more than 100 h. The crystalline precipitates thus formed were centrifuged and washed with deionized water until the pH of the supernatant solution became 4.5. The product was stored over silica gel, and characterization was made by means of X-ray powder diffractometry and thermal analysis (TG, DTA).

The potassium form of α-hafnium phosphate was prepared from α-hafnium phosphate by the batch method in the presence of 0.033 mol·dm^{-3} KCl and 0.067 mol·dm^{-3} KOH. The potassium salt employed in the backward titration was a monohydrate of the dipotassium salt of α-hafnium phosphate.

Ion-exchange Experiment. This experiment was carried out by the batch method. In the binary K^+–H^+ forward experiment, mixed solutions of 0.1 mol·dm^{-3} KCl and 0.1 mol·dm^{-3} KOH at variable mixing ratios were used to give solutions with differing pH values, while the K^+ ion concentration was kept constant. A weighed amount (150 mg) of α-hafnium phosphate was placed in contact with each of the above-mentioned solutions (15 cm^3) in a stoppered Erlenmeyer flask, and the mixture was shaken for 5 d at 25 °C. After equilibration, the solution was centrifuged, and the supernatant was subjected to pH measurement, as well as to the determination of potassium by means of gravimetry with sodium tetraphenylborate.[5] The analytical data for potassium were used for the calculation of the K^+ ionic fraction ($\overline{XK}$) of the exchanger. The solid phase was analyzed by means of X-ray powder diffractomety with a Shimadzu X-ray diffractometer, XD-3A. The samples were either in a slightly wet state before mesurement or in a completely dry state after having been placed over silica gel. Thermogravimetry and differential thermal analysis were carried out with a Shimadzu thermal analyzer, DT-30.

In the backward titration, a 180-mg portion of potassium salt was taken, the amount being equivalent to 150 mg of α-hafnium phosphate. Fifteen-cm^3 portions of the mixed solutions of 0.1 mol·dm^{-3} KCl and 0.1 mol·dm^{-3} HCl at variable mixing ratios were placed in contact with the potassium form for 5d at 25 °C.

In the case of the ternary H^+–Li^+–K^+ system, a 150-mg portion of α-hafnium phosphate was equilibrated with mixed solutions of 0.1 mol·dm^{-3} LiCl, 0.1 mol·dm^{-3} LiOH, 0.1 mol·dm^{-3} KCl, and 0.1 mol·dm^{-3} KOH at 25 °C. The equilibration time was 5 d. The lithium in the supernatant was determined by means of flame photometry with a Hitachi atomic absorption spectrophotometer, 170-50A.

Results and Discussion

Synthesis of α-Hafnium Phosphate by the Direct-precipitation Method. The X-ray powder diffraction data of the α-hafnium phosphate prepared by the direct-precipitation method are given in Table 1, together with those obtained for that prepared by the reflux method.[6] A very good agreement is seen between the *d*-spacings measured for both specimens. The relative intensities of some diffraction lines differ considerably, however; especially, the reflection from the (002) plane is very strong in the specimen obtained by the direct-precipitation method as compared to that obtained by the reflux method, in which the reflection from the (112) plane is the most intense. The results of TG and DTA are shown for both specimens in Fig. 1. The dehydration of 1 mol

of water takes place at about 170 °C in both cases, but the sample prepared by the direct-precipitation method is dehydrated very slowly until it has released 1 mol of water up to 550 °C. The finely powdered specimen gave the same result.

Forward K^+–H^+ Ion Exchange. The pH-titration curve for K^+ ion exchange is shown in Fig. 2. The forward exchange, where H^+ ions of α-hafnium phosphate were replaced by K^+ ions, proceeded in two steps. The first plateau, in the Region I at a pH value of around 2.7, corresponds to the existence of two phases, namely, α-hafnium phosphate and monopotassium salt. Slightly before a half exchange, the pH values increased rather abruptly and attained the second plateau at a pH value of around 7.3. The second plateau is very flat and corresponds to the stage where the mono- and dipotassium salts coexist. The titration curve is completed at approximately the theoretical exchange capacity of 5.15 meq·g^{-1} α-hafnium phosphate. This dibasic feature of the curve has not been observed in the case of Li^+ ion exchange on α-hafnium phosphate.[1]

a) α-Hafnium phosphate prepared by refluxing in 12 mol·dm^{-3} H_3PO_4 for 245 h. b) The *hkl* indices are tentatively assigned by referring to the powder data of α-zirconium phosphate (JCPDS 22-1022, 1971), with small modifications.

The X-ray powder patterns of the exchanger at every stage of the forward exchange were measured in the wet and dry states of the sample and are represented in Figs. 3 and 4 respectively. In the case of the exchanger in the wet state, the diffraction line from the (002) plane(d=7.6 Å) decreased in intensity as the K^+-ion exchange proceeded, and the line at 8.1 Å appeared. This indicates the formation of the monohydrate of monopotassium salt. At the ionic fraction ($\overline{XK}$) of 0.44, the 7.6 Å peak appears to have increased again, but this is due to the overlapping of the reflection because the anhydride of monopotassium salt has almost the same d value, as will be described later. On the further progress of the K^+-ion exchange, the second plateau of the titration curve started, and the dipotassium salt with the interlayer distance of 10.8 Å soon appeared. This means that the trihydrate of dipotassium salt formed after the half exchange. Figure 4 shows the powder patterns which have been measured on the exchangers dried over silica gel. A considerable variation of the patterns with the drying conditions of the samples can be seen. Thus, the monohydrate of monopotassium salt loses 1 mol of water on standing over silica gel at room temperature, and it gives anhydride with the interlayer distance of 7.6 Å. Similarly, the trihydrate of dipotas-

sium salt is converted into monohydrate with the interlayer distance of 9.2 Å. The water content has been confirmed by thermogravimetry. The above results may be summarized as follows:

$$\underset{(7.6\,\text{Å})}{Hf(HPO_4)_2\cdot H_2O} \longrightarrow$$

$$\begin{array}{ccc} Hf(KPO_4)(HPO_4)\cdot H_2O & \longrightarrow & Hf(KPO_4)_2\cdot 3H_2O \\ (8.1\,\text{Å}) & & (10.8\,\text{Å}) \\ \downarrow & & \downarrow \\ Hf(KPO_4)(HPO_4) & & Hf(KPO_4)_2\cdot H_2O \\ (7.6\,\text{Å}) & & (9.2\,\text{Å}) \end{array}$$

Backward K^+–H^+-ion Exchange. The pH titration curve of the backward process is given in Fig. 2. A two-step ion exchange is clearly observed. The plateau at a pH value of around 7.0 corresponds to the coexistence of the dipotassium salt and the monopotassium salt. The forward and backward curves practically coincide in this region (Region II in the figure), indicating that the process is reversible, not only in the ion-exchange reaction, but also in the structural change of the exchanger. An abrupt change in the pH at the half exchange shows the existence of a single monopotassium salt phase. This has been confirmed by the X-ray powder data which will be shown below. As the exchange progressed, the deviation of the backward curve from the forward one became remarkable. This kind of hysteresis can often be observed in alkali-metal ion exchange on α-zirconium phosphate; it suggests that the formation of the dihydrogen form does not always result in a α-type crystal. It is further noted that a small fraction of the K^+ ions could not be released with 0.1 mol·dm^{-3} HCl within 5d.

The X-ray powder patterns of the exchanger at every stage of the backward exchange in wet and dry states are given in Figs. 5 and 6 respectively. The starting exchanger has an interlayer distance of the monohydrate of dipotassium salt of 9.2 Å instead of the 10.8 Å of the trihydrate, because it was necessary to weigh the exchanger in the dry state. As may be seen in Fig. 5, up to $\overline{XK}$=0.57 the 9.2 Å peak disappeared, and the reflection lines from the monopotassium salt appeared. At about a half exchange, two reflections at 2θ=11° amd 11.6° corresponding to the monohydrate (d=8.1 Å) and the anhydride (d=7.6 Å) of monopotassium salt, were observed. The relative intensities of the two peaks depended on how wet the X-rayed specimens were. As K^+ ions in the exchanger were replaced by H^+ ions, however, the position of the lowest-angle reflection remained essentially unchanged, suggesting that the 8.1 Å peak still predominated even if the monopotas-

sium salt was converted into the dihydrogen form. This fact correlates with the deviation of the forward and the backward curves from each other; it can be considered that, in the backward process, the solid-solution formation takes place, that is H^+ ions are incorporated with the monopotassium form without any esssential change in the crystal structure. In α-zirconium phosphate, it is known that a wider range of the solid-solution formation is observed as the degree of crystallinity becomes poorer. The same trend may be thought to be found in α-hafnium phosphate. The complete desorption of K^+ ions was not possible under the experimental conditions used, but it was confirmed that some portion of the exchanger was converted into α-hafnium phosphate. In this case, the diffraction line around $2\theta=25°$ ($d=3.5$ Å) is useful in identifying α-hafnium phosphate, because the line at $2\theta=11.6°$ ($d=7.6$ Å) overlapped with that of the anhydride of monopotassium salt. In the same way, the monopotassium-salt phase can be differentiated from α-hafnium phosphate for the forward process (Fig. 3). The backward exchange can be shown as follows:

$$\begin{array}{ccccc} \underset{(10.8\,\text{Å})}{Hf(KPO_4)_2\cdot 3H_2O} & \longrightarrow & \underset{(8.1\,\text{Å})}{Hf(KPO_4)(HPO_4)\cdot H_2O} & \longrightarrow & \left\{\begin{array}{l} \underset{(8.1\,\text{Å})}{Hf(HPO_4)_2\cdot xH_2O} \\ \\ \underset{(7.6\,\text{Å})}{Hf(HPO_4)_2\cdot H_2O} \end{array}\right. \\ \downarrow & & \downarrow & & \\ \underset{(9.2\,\text{Å})}{Hf(KPO_4)_2\cdot H_2O} & & \underset{(7.6\,\text{Å})}{Hf(KPO_4)(HPO_4)} & & \end{array}$$

Ternary H^+–Li^+–K^+ Ion Exchange. Figure 7 shows the titration curve for Li^+–H^+ and K^+–H^+ binary ion exchange on α-hafnium phosphate in the forward direction obtained by the present authors. From the selectivity point of view, it is clear that the exchanger prefers K^+ ions to Li^+ ions up to an ion-exchange capacity of around 2 meq $M^+\cdot g^{-1}$ α-hafnium phosphate, where M^+ denotes the Li^+ or K^+ ion. Above this capacity, the selectivity is reversed until the completion of the exchange. However, this argument has to be examined experimentally, because, in the ternary H^+–Li^+–K^+ system, some new solid phases including Li^+ and K^+ ions might be formed, and this might affect the selectivity of two ions. On the other hand, if no such new solid phases are formed, the selectivity should follow those obtained in the binary systems. Figure 8 gives the variation in the alkali-metal-ion uptake with the pH. Thus, up to an ion-exchange capacity of about 2 meq $\cdot g^{-1}$ exchanger, K^+ ions were preferably taken up, whereas Li^+ ion remained in the equilibrating

solution. Above this point, *i.e*, above $\overline{XK}$=0.43, the Li^+-ion uptake started and the pH value of the solution rose steeply. The lithium-ion uptake proceeded as not

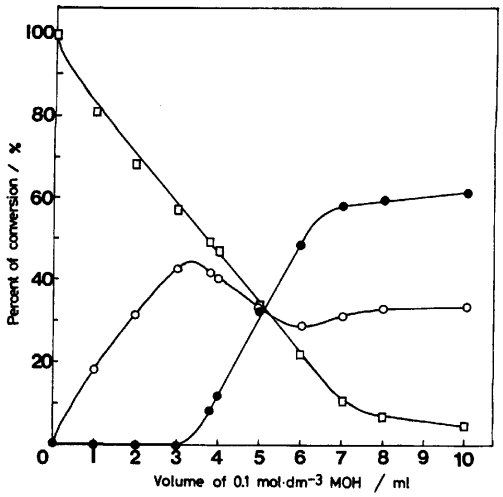

Fig. 9. Distribution of H^+, Li^+, and K^+ ions on α-hafnium phosphate at different hydroxide concentrations.
□: H^+, ●: Li^+, ○: K^+.

only H^+ ions but also K^+ ions were replaced by Li^+ ions. The pH-titration curve thus behaved differently from that for the binary system after the half exchange, but the selectivity sequence of the K^+ and Li^+ ions is almost exactly the one expected from the binary systems. Figure 9 represents the distribution of H^+, Li^+, and K^+ ions on α-hafnium phosphate at varying hydroxide concentrations. Thermogravimetry showed that the final product of the titration was dehydrated over the range of 120—400 °C. Its chemical composition was $Hf(K_{0.67}Li_{1.23}H_{0.10})(PO_4)_2 \cdot 1.17H_2O$. However, the X-ray patterns showed that the reflections were rather broad and that the crystallinity had deteriorated. The sample in the wet state had one broad line at 2θ=11° (d=8 Å), whereas that in the dry state had two lines, at about 11° and 10.3° (d=8.6 Å). The formation of a phase having a larger interlayer distance than that in the wet state can not be the consequence of dehydration. There is some possibility that an amorphous form was converted into the crystalline form during storage and drying, but no definite assignment to the known phase is possible at present.

Steam Reforming of Hydrocarbons and Water Gas Shift Reaction Through a Wall of Stabilized Zirconia Used as Hydrogen Separator

Kiyoshi Otsuka,* Seiichiro Yokoyama, and Akira Morikawa
Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received October 28, 1983)

Steam reforming of CH_4 and C_2H_4 or water gas shift reaction was allowed to occur through a wall of stabilized zirconia acting as hydrogen separator. The reactions proceed *via* transport of oxygen ions in the zirconia lattice from cathode to anode of the wall, accompanying an electron transfer in the reverse direction through the outer lead wire. Hydrogen without CO_2, CO, or hydrocarbons can be obtained directly by each reaction at the cathode side. The rate of hydrogen production increases exponentially with a rise in applied potentials *via* chromel-constantan thermocouples. The presence of reducing gas such as CO, CH_4, or H_2 at the anode side will decrease considerably the applied potential required to produce hydrogen at the same rate. A tentative reaction mechanism is proposed on the basis of kinetic information of the reaction.

Steam reforming or partial oxidation of hydrocarbons is at present the most efficient and economical process for hydrogen manufacture. The product gas, often called synthesis gas, is converted to high-content hydrogen through water gas shift reaction with simultaneous production of carbon dioxide. Removal of carbon dioxide, carbon monoxide, and hydrocarbons from make-gas is indispensable for getting high-purity hydrogen, which will inevitably raise the hydrogen cost. Under these circumstances, it is desired that high-purity hydrogen should be obtained directly by steam reforming of hydrocarbons or by water gas shift reaction without any removal processes for carbon dioxide, unreacted hydrocarbons, and carbon monoxide. We describe in this report a simple method to obtain pure hydrogen without carbon dioxide, carbon monoxide, or hydrocarbons by running water gas shift reaction or steam reforming of methane and ethylene with the aid of stabilized zirconia. The calcia-stabilized and yttria-stabilized zirconia used in this work are well known as solid electrolytes in which conduction is due almost entirely to oxygen ion transport in a lattice with anion vacancies.[1)]

The basic concept of the method will be explained by Fig. 1. At the anode, CH_4, C_2H_4, and CO are oxidized by oxygen ion as follows:

$$\text{Anode:}\quad CH_4 + 4O^{2-} \rightarrow CO_2 + 2H_2O + 8e^-, \quad (1)$$

$$C_2H_4 + 6O^{2-} \rightarrow 2CO_2 + 2H_2O + 12e^-, \quad (2)$$

$$CO + O^{2-} \rightarrow CO_2 + 2e^-. \quad (3)$$

The electrode works not only as an accepter of electrons liberated but also as a catalyst for the reaction. The electrons are transported through the lead wire connecting both the electrodes of anode and cathode. At the cathode, water vapor is reduced by the electrons transported from the anode, producing only hydrogen:

$$\text{Cathode:}\quad H_2O + 2e^- \rightarrow H_2 + O^{2-}. \quad (4)$$

The overall reactions can be written as follows:

From Eqs. 1 and 4,

$$CH_4 + 2H_2O \rightarrow CO_2 + 4H_2. \quad (5)$$

From Eqs. 2 and 4,

$$C_2H_4 + 4H_2O \rightarrow 2CO_2 + 6H_2. \quad (6)$$

From Eqs. 3 and 4,

$$CO + H_2O \rightarrow CO_2 + H_2. \quad (7)$$

Equations 5 and 6 represent steam reforming of methane and ethylene, respectively. Equation 7 is water gas shift reaction. By the method described above, we can get pure hydrogen directly by steam reforming of hydrocarbons or water gas shift reaction without any separation processes for CO_2, CO, and hydrocarbons.

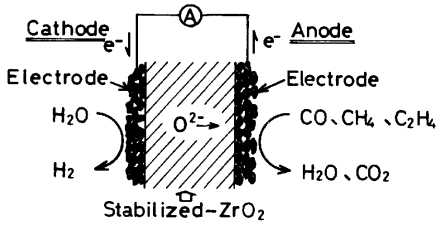

Fig. 1. Schematic model of reactions proceeding through the wall of stabilized zirconia.

Experimental

The calcia-stabilized zirconia (CSZ) and yttria-stabilized zirconia (YSZ) used were obtained from Nippon Kagaku Togyo Company. The contents of CaO and Y_2O_3 were 11 and 8 mol%, respectively. The geometry of the reactor used is illustrated in Fig. 2. The outer diameter of the zirconia tube was 21 mm and its thickness was 2.5 mm. The length of the tube was 300 mm. The outer diameter of the reactor was 30 mm. The electrodes were affixed on to the zirconia tube by wetting the tube with a suspension of powders of metal oxide in acetone followed by evaporation of the acetone. The metallic electrodes were prepared by decomposition or reduction of the oxides at 873 K in a flow of helium or hydrogen before use. The apparatus employed was a glassmade flow reactor system operated at atomospheric pressure. The reaction temperatures were 873—1273 K. Water vapor (usually 2.7 kPa) carried by helium was fed into the reactor. The feed rate of water vapor was usually 23 μmol min^{-1}. Pure H_2, CH_4, CO, and C_2H_4 were used as anode gases usually without dilution. The flow rate of anode gas was 0.22—2.2 mmol min^{-1}.

Results and Discussion

Electrode Material. Table 1 shows the efficiency of electrode materials for either the cathode or anode of CSZ. The reactivity test on electrode materials was carried out by using aged silver (Ag*), which had been used for reaction at 973 K for more than 20 h, on one side of the electrodes. The geometric area of the zirconia surface coated with Ag* was 80.1 cm^2. The areas of the electrode materials tested were 52.8 cm^2. Hydrogen was used as a test anode gas. For every electrode pair given in Table 1, hydrogen was produced according to the theory described above. This was confirmed by the fact that the amount of hydrogen produced at the cathode side (analyzed by gas chromatography) corresponded well to those calculated from currents measured with the ampere meter A in Fig. 1. Moreover, the reaction ceased and resumed in correspondence to disconnecting and connecting the lead wires for both the electrodes, respectively.

The results in Table 1 indicate that Ag, Ni, Pt, Pd, and In_2O_3-SnO_2 are all good electrodes as far as the efficiency of hydrogen formation is concerned. However, Ni, Pt, Pd, and In_2O_3-SnO_2 could not be attached firmly to the zirconia tube by the method described in the experimental section. In contrast, the silver electrode may be ascribed to a solid contact of silver particles on the zirconia surface.

The high efficiency of hydrogen production for the fresh silver pair (Ag-Ag) decreased considerably after 20 h reaction at 973 K (Ag*-Ag*) probably because of the sintering of silver particles during the reaction. After 20 h, however, the electrode pair Ag*-Ag* showed a reproducible activity when the reaction had been run below 973 K. Hence, the following studies were carried out with the electrode pair of Ag*(cathode)-Ag*(anode).

Table 1. Comparison of efficiencies of electrode materials on CSZ at 973 K

Electrode material		Rate of H_2 formation at cathode/μmol min^{-1}
Cathode	Anode	
Ag	Ag	2.62
Ag	Ag*	1.88
Ag*	Ag*	0.68
In_2O_3-SnO_2	Ag*	0.15
Ni	Ag*	1.34
Pt	Ag*	1.22
Pd	Ag*	1.11
Ag*	In_2O_3-SnO_2	1.12
Ag*	Ni	1.59
Ag*	$PrCoO_3$	0.81
Ag*	Pt	0.75
Ag*	Pd	0.75

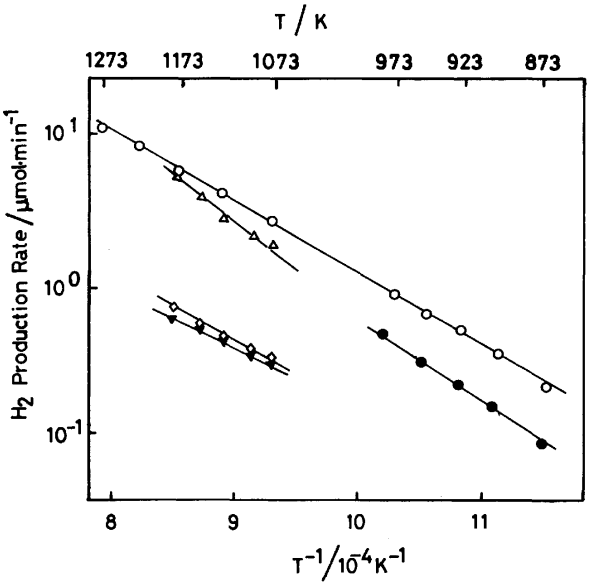

Fig. 3. The rates of hydrogen formation as functions of temperature for different anode gases. The flow rate of anode gas was 0.63 mmol min^{-1}. Anode gas; ○: H_2(using YSZ), ●: H_2(using CSZ), △: C_2H_4(YSZ), ◇: CO(YSZ), ▼: CH_4(YSZ).

Comparison of Efficiencies of Anode Gases for YSZ and CSZ. The effect of anode gases on the rate of hydrogen formation was examined for both YSZ and CSZ. Rates of hydrogen production using different reducing gases on the anode side are plotted in Fig. 3. as a function of reaction temperature. The results in Fig. 3 show that there are large differences among the efficiencies of the anode gases for the production of hydrogen in both the cases of YSZ or CSZ used. The apparent activation energies calcu-

lated from the slopes in Fig. 3 are 79 (YSZ; anode gas, H_2), 94 (YSZ; C_2H_4), 77 (YSZ; CO), and 70 kJ mol^{-1} (YSZ; CH_4). The activation energy for CSZ with H_2 as anode gas (closed circles) is 80 kJ mol^{-1} which is very close to that for the YSZ–H_2 system (open circles). Moreover, there are not so much differences between the rates for YSZ (open circles) and for CSZ (closed circles); the ratio of the rates is less than 2.6.

Effect of Applied Potential from Thermocouples. The maximum rate of hydrogen formation observed in this work (Fig. 3; YSZ at 1273 K with anode gas of H_2) is 10.8 μmol min^{-1} corresponding to a current density of 0.72 mA cm^{-2}. This value is far too low for the application of the method to practical use. Therefore, in order to enhance the rate of hydrogen formation, we attempted to apply an electric potential between both the electrodes. Electric energy was supplied on the Seebeck effect from the heat stored in the furnace of reactor *via* 30 pairs of chromel-constantan thermocouples connected in series. Figure 4 shows a sharp increase in the rate of hydrogen formation as a function of effective applied potentials from the thermocouples. The rate increases exponentially with a rise in the applied potential for all the cases using different anode gases. Although the efficiency of thermoelectric generation of electricity is still low,[2,3] the method can easily be applied and utilization of waste heat from chemical plants may be feasible. Whatever the primary energy source of electricity may be or whatever the method for final conversion of energy into electricity may be, the results of Fig. 4 suggest that the applied potential required to yield the same rate of hydrogen formation is caused to decrease when a reducing gas is present at the anode side of the stabilized zirconia, as compared with the value in the case of helium as anode gas (the arrows in Fig. 4 indicate an example of differences in the potentials required). From a viewpoint of electrochemical decomposition of water vapor, the results are taken to indicate that the reducing gas would favorably reduce the consumption of electric power.

Although the efficiency of hydrogen production is still far low for practical use, we have been able to demonstrate that the method proposed in this work can be used for the production of pure hydrogen. Higher temperatures, higher pressures of steam and anode gas, greater electric applied potentials, thinner thicknesses of stabilized zirconia, and higher surface areas of zirconia and electrodes, must improve the efficiency remarkably.

Effects of Concentrations of Gases at Anode and Cathode. Effects of concentrations of anode gases are shown in Fig. 5. The conversion of water to hydrogen depends strongly on the concentration of anode gas irrespective of the presence or absence of electric potential applied. On the other hand, the rate of water decomposition does not depend on the concentration of water vapor (cathode gas) as shown in Fig. 6. The conversion of anode gases is in the range 0.02—0.92% depending on reaction conditions as seen from Figs. 5 and 6. The conversion of water vapor to hydrogen does not depend much on the flow rate of anode gas in the range between 2.2 and 0.22 mmol min^{-1}. Thus, the conversion of pure hydrogen as anode gas increases from 0.26 to 2.4% when the flow rate of anode gas has been decreased from 2.2 to 0.22 mmol min^{-1}.

The rate of hydrogen formation, *viz.*, the current during reaction, increases exponentially with a rise in the applied potential (Fig. 4). If the diffusion of oxygen ion is the rate determining step, Ohm's law should be observed. Hence, the results in Fig. 4 suggest that the rate determining step is of electrochemical reaction. The results that the conversion of water vapor depends on the kind of anode gas (Fig. 3)

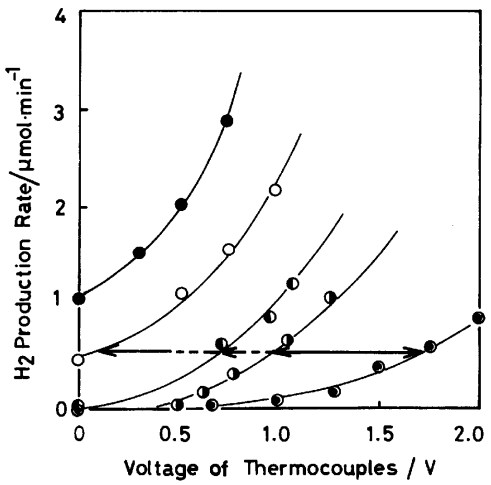

Fig. 4. Rate of hydrogen formation as functions of applied potential from thermocouples using different anode gases. The reactions were carried out at 973 K. The flow rate of anode gas was 0.63 mmol min^{-1}. Anode gas; ●: H_2(using YSZ), ○: H_2(CSZ), ◐: CO(CSZ), ◑: CH_4(CSZ), ⊙: He(CSZ).

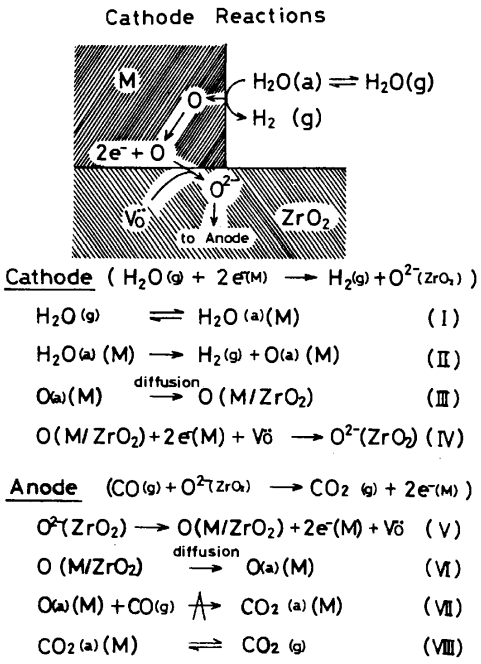

Fig. 7. The reaction mechanism.

and on the concentration of anode gas (Fig. 5), suggest that the rate determining step is the oxidation process of anode gas by oxygen at the surface of silver electrode. The oxygen is transported from the cathode through the stabilized zirconia. The ion conductivity of oxygen in YSZ is 9 to 11 times as high as that in CSZ in the temperature range between 873 K and 973 K.[4] However, the rate of hydrogen formation on YSZ is no more than 2.6 times that on CSZ (Fig. 3). This obsevation together with the results in Figs. 3, 4, and 5 excludes the possibility that the diffusion of the oxygen ion is the rate determining step under the reaction condition in this work. The diffusion may become the rate determining step when the rate of overall reaction has been increased remarkably.

The reaction mechanism which we have in mind is shown in Fig. 7. At the cathode side, the oxygen atom formed through decomposition of the adsorbed water (Eq. II) on silver electrode (M) diffuses through the surface or bulk of the electrode (Eq. III). The oxygen atom is transfered into the stabilized zirconia through the reaction with anion vacancies (Vö) and electrons which have been supplied from the anode *via* the outer circuit (Eq. IV). The reactions of Eqs. V to VIII occur at the anode side. Equations V and VI are the reverse reactions of Eqs. IV and III, respectively. Equation VII is the reaction when carbon monoxide is used as anode gas. Similar reactions can be considered when hydrogen, ethylene, or methane instead of carbon monoxide is used. The oxidation of anode gas by the adsorbed oxygen atom (Eq. VII) is assumed to be the rate determining step. The applied potential between the anode and cathode would increase the activity of oxygen at the anode, thus enhancing the rate of hydrogen production exponentially (Fig. 4). Further studies are needed to confirm the mechanism proposed in Fig. 7.

In conclusion, the method examined in this work can be used in principle for the production of pure hydrogen. However, much more improvement in the efficiency of hydrogen production is needed for practical application of the method.

Synergistic Effect of Alcohol-Benzene Mixtures for Coal Extraction

Masashi IINO* and Minoru MATSUDA
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980
(Received February 25, 1984)

Coals were extracted with alcohol-benzene mixtures at room temperature. For coals of high oxygen content, Yallourn and Taiheiyo coals, the extraction yields for the mixtures were much greater than those for alcohols and benzene alone. This synergistic effect was more marked for less bulky alcohols: The order was methanol>ethanol>isopropyl alcohol>*t*-butyl alcohol. The degree of swelling and the apparent density of the coals in alcohols were measured. The results show that smaller alcohols may permeate into pores of the coals more extensively and cause greater swelling than larger alcohols. It is reasonable to consider that this swelling of the coals then facilitates the extraction with benzene or alcohol-benzene mixtures, which are better solvents in solubility for coal molecules than alcohols. For Shin-yubari coal having low oxygen content, no such a synergistic effect was observed, probably due to the lower degree of swelling of this coal.

Solvent extraction at room temperature, which causes no chemical change of coals, provides useful knowledge about coal structure through the studies on extraction mechanism and the characterization of extracts, even though extraction yields are usually low. It is also connected with coal liquefaction, which includes a step of coal dissolution with a suitable solvent under pyrolysis conditions. Many studies on solvent extraction have been reported[1] and attempts have been made to explain the extraction mechanism.

Dryden[2] has extensively studied solvent extraction; he used about 30 British coals and many organic solvents at or above room temperature. His conclusion concerning extraction yield is that a good solvent contains a nitrogen atom or an oxygen one (less efficient than nitrogen) possessing an unshared pair of electrons. He has also found that the quantity of imbibition of solvents used, which correlates to the swelling degree of coals in the solvents, is related to extract yields.

Marzec and coworkers[3] have presented a model for extraction of coal: Coal consists of a macromolecular network and extractable substances filling the pores of a network; the donor-acceptor interactions proposed by Gutmann[4] are responsible for binding together the network and the extractable substances. According to their model, solvent extraction is a substitution reaction in which extractable substances are replaced by a solvent molecule through donor-acceptor interaction of solvent and network or solvent and extractable substances.

Another approach to the extraction mechanism is a theoretical one from thermodynamics, namely, a correlation between the solubility parameter, δ, and the coal extractability or the solubility of coal-derived matter.[5] This theory states that a solvent having a δ value like that of the coal used will give the highest extraction yield. Hombach[6] has reported a result which may demonstrate the theory by using mixtures of solvents having different δ values. δ also has been found to be related to the swelling of coals.[5b,7]

However, there are some examples[8,9] indicating insufficient extraction which means that considerable amount of substances soluble in the solvent still exists in coal after the extraction. For example, the carbon disulfide-soluble part of pyridine extract is 4% based on coal, but the yield in a direct extraction of the same coal with carbon disulfide is only 0.2%.[8] Similarly, 13% is the chloroform-soluble part of the pyridine extract, but only 2.4% is the chloroform extraction yield.[9] Insufficient permeation into coals may be responsible for this result.

A mixed solvent is considered to be a powerful means in the elucidation of such a complex extraction mechanism, especially when this shows a large synergistic effect. We have reported[10] that the carbon disulfide-pyridine mixture shows a very large synergistic effect for extractions of bituminous coals. For Shin-yubari coal, the extraction yields for 1 h at room temperature are 0.9, 3.0, and 28.7% for carbon disulfide, pyridine, and their 1 : 1 mixture, respectively. The mechanism for this extraction is not clear at present. In this study we will report the mechanism of the extractions with alcohol-benzene mixtures. Alcohol-benzene mixtures are well known to show synergistic effects for coal extractions[11] and are often used to obtain wax and other coal-derived materials from brown coals.[12]

Experimental

Materials. Yallourn, Taiheiyo, and Shin-yubari coals, stored in water, were dried in air, ground, and sieved to <60 mesh. The coals were further dried at 107 °C under nitrogen atmosphere to constant weight (usually 1—2 h). The proximate and ultimate analyses (daf) are shown in Table 1.

All the solvents for extraction studies were reagent-grade (>98%) and were used without purification.

General Solvent Extraction Procedure of Coals. 4 g of coal sample was extracted with 100 ml of a solvent or a solvent mixture with stirring using a magnetic stirrer in an Erlenmeyer flask for 1 h at room temperature. After separation by centrifugation and filtration, the solvent was removed from the solution by a rotatory evaporater. The extract and the residue were dried *in vacuo* at 80 °C to constant weight. Extraction yield (daf) were determined from Eq. 1 and ash % is the value on dry-base. The yields were reproduced within ±10% for repeated runs.

Table 1. Ultimate and proximate analyses of coals

Coal	Proximate analysis (wt%)				Ultimate analysis (wt/%, daf)				
	Moisture	VM[a]	FC[b]	Ash	C	H	N	S	O[c]
Yallourn	14.3	47.3	37.6	0.8	66.1	5.3	0.6	0.3	27.7
Taiheiyo	4.4	49.2	34.1	12.3	75.4	7.0	1.2	0.3	16.1
Shin-yubari	0.9	38.0	54.1	7.0	86.7	6.2	1.7	0.3	5.1

a) Volatile matter. b) Fixed carbon. c) Difference.

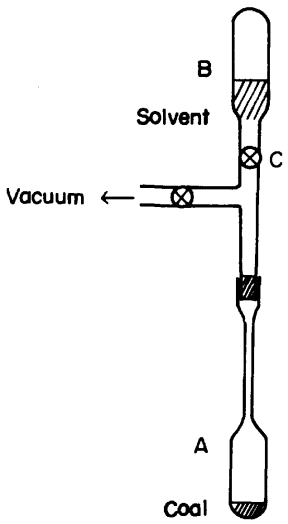

Fig. 1. The apparatus for apparent density measurement.

$$\text{Extraction yield (\%)} = \frac{\text{extract (g)} \times 100}{(1-\text{ash(\%)}/100) \times \text{coal feed (g)}} \quad (1)$$

For the extraction with alcohols, benzene, and their mixtures the recoveries of extracts+residues are always nearly or below 100%, indicating negligible inclusions of solvents in extracts and residues.

Relative Swelling Degree Measurement of Coals. The method reported by Hombach[6] was used. 600 mg of ground coal sample (<170 mesh) was placed in a cylindrical glass tube (d=10 mm, l=170 mm). 1.5 ml of solvent was added and the tube was immersed in a thermostat regulated at 30 °C, occasionally shaking the mixture to remove the gas which evolved. The height of the coal powder layer was measured after 1 and 24 h, respectively. The relative swelling degree for a solvent was estimated from the ratio of the height for a solvent to that for hexane as a standard and was reproduced within ±10% for repeated runs. The measurements at a time longer than 24 h showed no significant change. This rather simple method enables the relative swelling degree of a coal immersed in a solvent to be estimated easily.

Apparent Specific Gravity Measurement of Coals. 10 g of coal sample was charged into a glass ampoule, A, with a glass tube of 4 mm i.d. in Fig. 1. After evacuation for 3 h at room temperature the solvent in a tube, B, which was connected with a needle valve, C, was introduced into the ampoule, A, and the ampoule was immersed in a water bath regulated at 30 °C for 20 h. Then the position of the meniscus of the solvent was marked. The quantity of the solvent introduced was measured gravimetrically. The volume, V, of the coal-solvent mixture was determined by replacing it with distilled water, measuring the volume of water from its weight and specific gravity. A temperature of 30 °C was used, since t-butyl alcohol has freezing point higher than 25 °C. The apparent density was determined from Eq. 2 and was reproduced within ±5% for repeated runs.

$$\text{Apparent density (g/ml)} = \frac{\text{coal feed (g)}}{V\ \text{(ml)} - \text{volume of the solvent (ml)}} \quad (2)$$

Results

Extraction with Alcohol-Benzene Mixtures at Room Temperature. Figure 2 shows the effect of solvent composition of methanol-benzene mixture on extraction yields. For Yallourn and Taiheiyo coals, the yields for the mixture are higher than those for methanol and benzene alone. No such synergistic effect was observed for Shin-yubari coal.

Table 2 shows the effect of the structure of the alcohols on the extraction yields for Yallourn and Taiheiyo coals. The yields increase in the order of methanol>ethanol>isopropyl alcohol>t-butyl alcohol for the cases of the alcohol alone and of the mixture with benzene. The degree of the synergistic effect was estimated from the ratio of the yield for the mixtures to the sum of those for the alcohol and benzene alone; this is listed in the parentheses of the third and fifth columns in Table 2. These values also increase with decreasing the bulkiness of the alcohols used here.

Hexane[d]	(1.0)	(1.0)	(1.0)	(1.0)	(1.0)	(1.0)
Benzene	1.0_0	1.1_0	1.1_5	1.1_5	1.0_5	1.1_0

a) −170 mesh. b) 95% alcohol. c) Insufficient sedimentation. d) A standard solvent.

The extract from Taiheiyo coal with 1:1 methanol–benzene mixture is soluble in benzene and almost insoluble in methanol. Its carbon and hydrogen % (daf), 81.0 and 10.4%, are higher than those for the raw coal, indicating that a hydrocarbon-like extract was obtained. The extraction yields increase with decreasing particle size, namely 0.3_0, 0.5_5, 1.4_0, and 3.3_5% for 9—16, 16—60, 60—100, and 100—170 mesh, respectively, probably due to the increase of the surface area of the coal. The extraction for 3 h gave a little higher yield (5%) than that for 1 h, in the extraction with 1:1 methanol–benzene mixture.

Shin-yubari coal showed no synergistic effect for other alcohols than methanol.

Relative Swelling Degrees and Apparent Densities in Alcohols. Table 3 shows that relative swelling degrees in alcohols were in the order of ethanol> methanol≃isopropyl alcohol>*t*-butyl alcohol≃benzene≃hexane for Yallourn and Taiheiyo coals, and benzene>methanol≃ethanol≃isopropyl alcohol≃ hexane>*t*-butyl alcohol for Shin-yubari coal. Here hexane is known to be inert for swelling of coals. It is clear from Table 3 that alcohols induce a swelling of Yallourn and Taiheiyo coals, but not for Shin-yubari coal, and that this swelling is generally more marked for less bulky alcohols.

Apparent densities measured at 30 °C are summarized in Table 4. This apparent density is considered to reflect the extent of permeation of a solvent into coal; greater density may correspond to greater permeation of a solvent. Table 4 shows that the order of the densities among the alcohols is the same as that of the extraction yields for Yallourn and Taiheiyo coals (Table 2). Namely, smaller alcohols have greater permeation and extraction yield than larger alcohols. Table 4 also shows that apparent densities for Taiheiyo coal were greater than those for Shin-yubari coal in all solvents measured. Toda, Yoshida, Honda, and Hatami[13] have obtained a similar result in their extensive studies on pore structures of various coals that Taiheiyo coal (*C*%, 77.8%) has greater apparent densities than Yubari coal (*C*%, 86.2%) both for methanol and hexane solvents. They discussed these results from the viewpoints of the true densities of the coals and the permeation of the solvents into the coals.

Table 4. Apparent densities of taiheiyo and shin-yubari coals in alcohols and hexane at 30 °C

Solvent	Density (g/cm³)	
	Taiheiyo[a]	Shin-yubari[a]
Methanol	1.425	1.321
Ethanol[b]	1.390	1.305
Isopropyl alcohol	1.348	1.275
t-Butyl alcohol	1.322	1.253
Hexane	1.369	1.313

a) −60 mesh. b) 95% alcohol.

Extraction with Various Methanol-organic Solvent Mixtures. Various methanol-organic solvent

Pyridine	7.3 (105) [d)]	6.8 (102) [d)]	6.4 (110) [d)]	4.4 (104) [d)]	3.0 (101) [d)]	0.7 (101) [d)]

a) 4.0 g of coal (−60 mesh) in 100 ml of the solvent for 1 h at room temperature. b) The solvent in the first column was used. c) 1:1 mixture by volume with methanol was used. d) [(extract+residue) (g)/coal feed (g)] × 100.

mixtures were examined. The results are summarized in Table 5, together with the result for methanol-benzene mixture. For Yallourn and Taiheiyo coals, methanol mixtures with carbon tetrachloride, benzene, carbon disulfide, and tetrahydrofuran gave higher extraction yields than these organic solvents alone. For Shin-yubari coal, carbon disulfide and pyridine gave higher and lower yields for the mixture with methanol, respectively.

Discussion

Synergistic Effect of Alcohol-Benzene Mixtures. Figure 2 and Table 2 show that the synergistic effect for alcohol-benzene mixtures was observed for Yallourn and Taiheiyo coals; this was more marked for less bulky alcohols. Tables 3 and 4 show that smaller alcohols may permeate into pores of a coal more extensively and may cause greater swelling than larger alcohols. It is not unreasonable to consider that this swelling, in turn, may facilitate an extraction with another solvents.[14)] The solubility test for the extracts of Taiheiyo coal with methanol-benzene mixture indicates that benzene has a greater solubility than alcohols. Swelling with alcohols may facilitate extraction with benzene or alcohol-benzene mixtures. In the case of Yallourn coal, an extracting solvent may be alcohol-benzene mixtures, not benzene alone, since 15% of the extract was not soluble in benzene nor methanol. Swelling has been suggested by Dryden[2)] to be an important factor for extraction. Pajak and Marzec[15)] have also reported that the extraction yields with solvents of low extraction power, for example, benzene and diethyl ether, increased when a coal (*C*% 80.7%) was pre-swollen with methanol, tetrahydrofuran, dimethyl formamide, or pyridine.

For Shin-yubari coal, on the other hand, neither swelling by alcohols nor any synergistic effect were observed. This may be attributed to low content of hydroxyl groups, which is deduced from the IR spectrum and from the oxygen content of Shin-yubari coal. Nelson, Mahajan, and Walker[16)] have found that methanol-induced swelling increases linearly with the oxygen content of coals, due to an increased affinity of coal molecules for methanol.

Patel and coworkers[17)] have reported that the solubility of solvent-refined coal and solvent-refined lignite in benzene or chloroform increased from 50—60 to 80—100% upon either acetylation or silylation and this can be explained by the disruption of the intermolecular hydrogen bond in coal. The similar increase of benzene or chloroform extract yield has been reported by Liotta and coworkers[18)] in alkylation of coal which proceeds under mild conditions; this is again ascribed to the reduction of intermolecular associations in coals. In our case, hydrogen bonding between coal molecules in Yallourn and Taiheiyo coals may be broken by hydrogen bonding with the permeating alcohols and the swelling of coal may thus be induced.

Although the extraction yields in our experiments are low, the mechanism proposed here may apply to other solvent systems and may be one example where bulkiness of solvents plays an important role in extraction.

Extraction with Various Methanol-organic Solvent Mixtures. Table 5 shows that the recovery of extract+residue considerably exceeds 100% in extractions of Yallourn and Taiheiyo coals with methanol-pyridine mixture. Collins and coworkers[19)] have reported that pyridine and ethylenediamine were retained in both the extract and residue even after washing with benzene. In our case the solvent may be retained in the extract and residue. Other solvents in Table 5 than pyridine showed nearly 100% recovery. The increased yields for the methanol mixtures with carbon tetrachloride in Yallourn and Taiheiyo coals may be caused by the same mechanism as in the case of the mixture with benzene. On the other hand, decreased yields in the case of pyridine for Shin-yubari coal may be caused by its hydrogen bonding with methanol. Dryden[2)] has reported that ethylenediamine loses its high extractability when it contains water, since it forms hydrogen bonds with the nitrogen atoms of ethylenediamine.

Carbon disulfide seems to be different from other solvents listed in Table 5, in that its mixture with methanol is effective for all the coals in Table 5. We have found and reported that carbon disulfide–pyridine mixture is a very efficient solvent for Shin-yubari coal: It gives about 40% extraction yield at room temperature.[10)]

Unstable Excimer Formation in *cis*-1,2-Di(2-naphthyl)cyclobutane

Shinzaburo ITO,* Masahide YAMAMOTO, and Yasunori NISHIJIMA
Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received May 10, 1984)

An unstable intramolecular excimer which is formed in an excited state of *cis*-1,2-di(2-naphthyl)cyclobutane is investigated. The excimer formation-rate constants and dissociation-rate constants in fluid solutions at low temperatures were determined by picosecond time-resolving measurements. The formation processes are interpreted in relation to the bending motion of the cyclobutane ring. Photophysical characteristics of unstable excimers are shown in this system.

Intramolecular excimer formation has been investigated in a number of compounds having two or more aromatic chromophores in a molecule. Since Hirayama's noted work for various diphenylalkanes, it has been confirmed that the most favorable geometry for a stable excimer is a symmetrical sandwich-like parallel arrangement of aromatic planes at a distance of 0.3—0.4 nm. This is easily achieved for a compound in which two chromophores along the alkane chain are separated by three carbon atoms.[1] This result was also confirmed for naphthalene derivatives.[2,3]

But, the existence of an unstable excimer, besides the stable excimer, was found in poly(*N*-vinylcarbazole).[4,5] It has been reported that the unstable excimer, which is often called a second excimer, comes from a partially overlapping structure of two aromatic rings. Much attention has been paid to the unstable excimers since their photophysical behavior is closely related to the relaxation processes of excitation energy in polymer systems. Recently, unstable excimer formation was reported in a few bichromophoric model compounds.[6,7] Studies on such compounds are useful in clarifying the geometry and conformation of the unstable excimer due to the well defined molecular structure and simple relaxation process.[8]

In the present work, we report on a new kind of unstable excimer formed in the compound *cis*-1,2-di(2-naphthyl)cyclobutane. Its detailed photophysical characteristics and excimer formation mechanisms are elucidated by means of photostationary and time-resolving measurements. This information will be important for interpreting the excited-state kinetics in more complex polymer systems.

Experimental

Materials. *cis*-1,2-Di(2-naphthyl)cyclobutane (DNCB) was prepared by the photodimerization of 2-vinylnaphthalene in a benzene solution.[9] The products were fractionated by column chromatography on silica gel with hexane–dichloromethane (7:1) as the eluent. The obtained DNCB was recrystallized from methanol solution prior to use: mp 95—97 °C; NMR (CCl_4) δ=2.5—2.7 (2H, m), 4.1—4.3 (1H, m), and 6.8—7.6 (7H, m). 2-Ethylnaphthalene (Aldrich Chemical Co.) was used as a monomeric model compound. Spectrograde hexane (Nakarai Chemicals Ltd.) was used as a solvent without further purification.

Measurements. All spectroscopic measurements were carried out in hexane solutions degassed by repeated freeze-thaw cycles at *ca.* 10^{-3} Pa. The concentrations were adjusted to 10^{-4} mol dm^{-3}, at which intermolecular excimer formation was negligible. Fluorescence spectra were measured with a Shimadzu RF-502 spectrofluorophotometer whose spectral response was calibrated according to a standard tungsten lamp. The quantum yields of fluorescence were determined relative to that of quinine sulfate in 0.5 mol dm^{-3} sulfuric acid.[10] The decay curves of fluorescence were measured by a single photon counting technique (Ortec Inc., 9200 nanosecond fluorescence spectrometer). For the measurements of the rise and decay curves in the picosecond time region, the 4th harmonic (266 nm, 20 ps) of a passively mode-locked Nd^{3+}:YAG laser was used as an exciting light source. The emission was detected by a Hamamatsu Photonics streak camera (C979) and digitized by a TV camera/microcomputer system (C1000).[11,12] Suitable combinations of optical filters were used in order to isolate the monomer fluorescence and the excimer fluorescence.

Results

The absorption spectra of DNCB and 2-ethylnaphthalene are very similar, although a slight red shift of 1.5—2 nm is observed for DNCB. Such a red shift has been reported for a similar compound, *cis*-1,2-diphenylcyclopentane,[13] and observed for compounds in which plural naphthyl groups are closely linked intramolecularly, *e.g.*, poly(2-vinylnaphthalene).

The fluorescence spectra of DNCB in hexane at various temperatures are shown in Fig. 1. The spectra clearly show broad excimer emission at 400 nm in the low-temperature range, but the excimer emission is not observed either at room temperature or at 77 K in a rigid glass solvent. The fluorescence excitation spectra for the excimer emission band and for the monomer emission band at a wavelength of about 330 nm agree well with the absorption spectrum. Quantum yields of the monomer and excimer emission are shown in Fig. 2, together with the monomer emission quantum yields of 2-ethylnaphthalene. The quantum yields of excimer emission (Φ_D) have the largest value at an extremely low temperature, −95 °C, which is the freezing point of the solvent. As the temperature increases, Φ_D decreases monotonously, and the quantum yields of monomer emission (Φ_M) increase slightly because of the dissociation of excimer. A further increase of temperature rapidly quenches both of the monomer and excimer fluorescence. The total emission quantum yields of DNCB show much smaller values than those of 2-ethylnaphthalene in the high-temperature region, shown in Fig. 2. These results show that DNCB is able

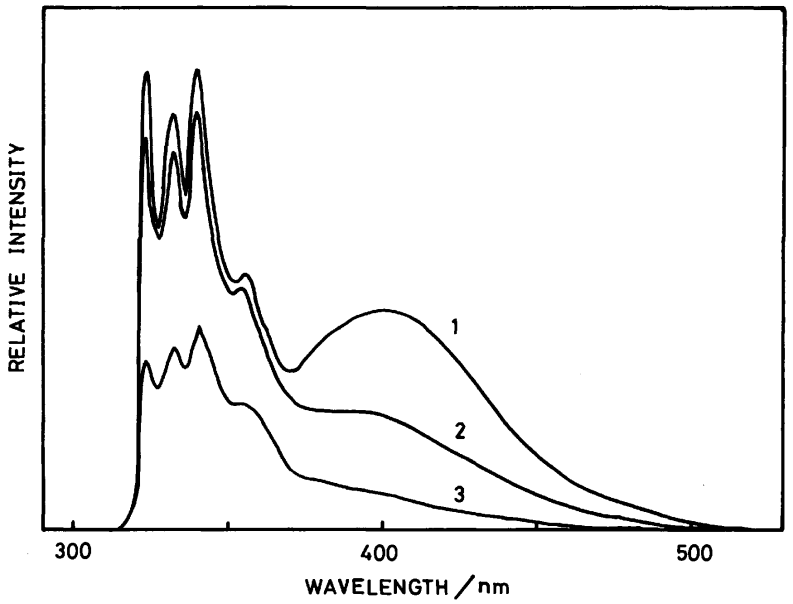

Fig. 1. Fluorescence spectra of DNCB in hexane. 1: −80 °C, 2: −50 °C, and 3: −20 °C.

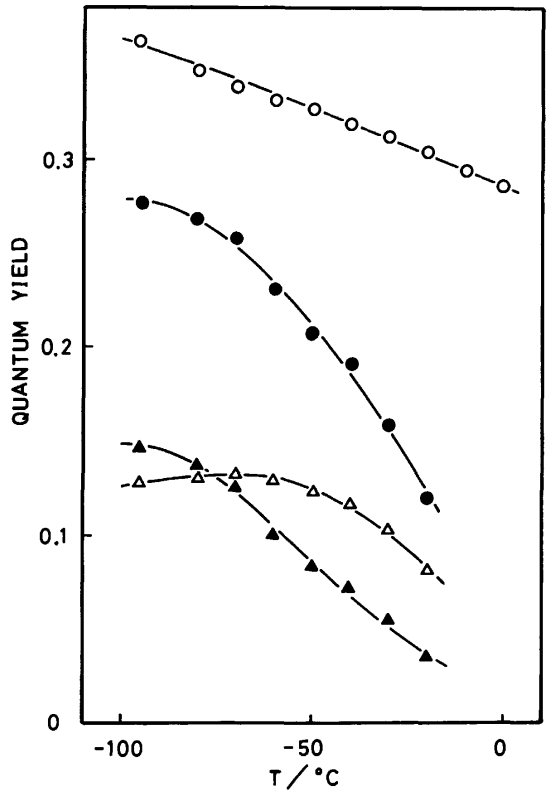

Fig. 2. Fluorescence quantum yields of monomer emission (△), excimer emission (▲) and total emission (●) of DNCB, and quantum yields of monomer emission of 2-ethylnaphthalene (○).

to form an intramolecular excimer by a dynamic process after photoexcitation. The formation process can be achieved by a little conformational change whose rate is very fast even at low temperatures. Since the formed excimer state is not stable, it dissociates to the monomer state or deactivates to the ground state radiationlessly, with increasing temperature.

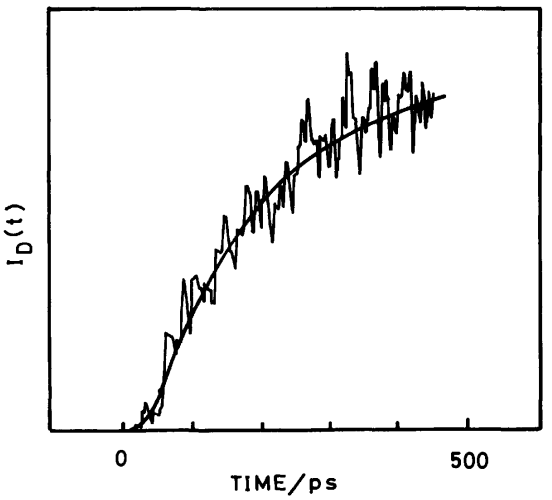

Fig. 3. Rise curve of excimer fluorescence of DNCB at −37°C.
The solid line shows the curve simulated by the function of $I_D(t) = \exp(-t/63\text{ ns}) - \exp(-t/0.16\text{ ns})$.

The dynamic process of excimer formation is well confirmed by time-resolved measurements for monomer and excimer fluorescence. Figure 3 shows a rise curve of excimer emission of DNCB in the picosecond time region. The measurements were carried out at various temperatures and the rise-time constants were determined by a simulation method. The decay-time constants were also obtained by the single photon counting technique in the nanosecond region. For the monomer fluorescence, the decay curve should be given as a double exponential decay function, but it could not be confirmed by the picosecond time-resolving measurements because of the weak signal intensities. Decay times for the monomer emission in the nanosecond region are the same as those of excimer emission in the observed temperature range. This fact shows that the

association and dissociation rate constants of the excimer are fairly large compared with the other rate constants. Thus, the dynamic equilibrium between the excited monomer state and the excimer state is achieved before deactivation to the ground state. The observed rise- and decay- time constants are summarized in Fig. 4.

Discussion

The naphthyl groups of DNCB come face to face with each other without a deformation of the aromatic rings, as shown in Fig. 5. The pair of naphthyl groups can be expected to form an intramolecular excimer since the aromatic rings can achieve an arrangement similar to the sandwich-type conformation. However, the interaction between two naphthyl groups in the ground state is too weak to make a dimeric complex which would give a different absorption spectrum from an isolated naphthalene unit.[14] Furthermore, the monomer fluorescence spectrum of DNCB is similar to that of 2-ethylnaphthalene. From these facts, it can be concluded that the excited state immediately after photoexcitation is the monomer state and the intramolecular excimer is formed from this excited state by some dynamic processes accompanied by conformational changes of the cyclobutane ring.

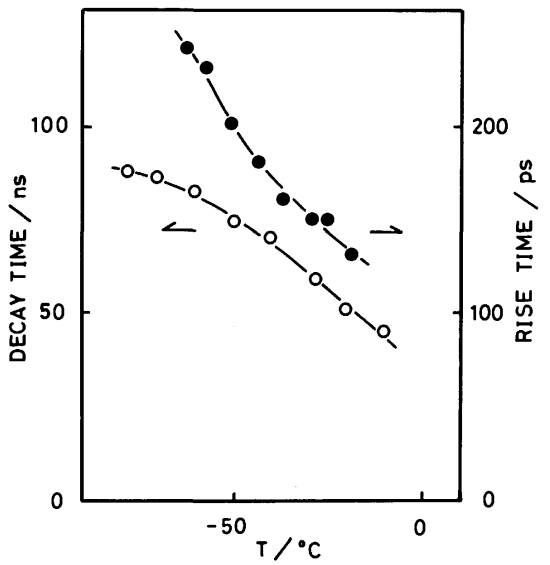

Fig. 4. Temperature dependence of rise and decay time constants.

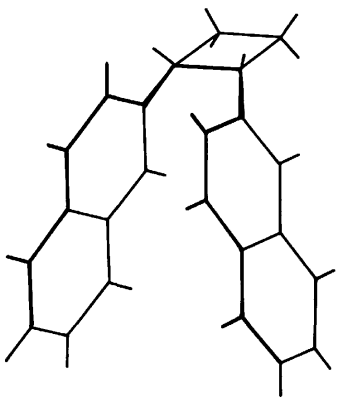

Fig. 5. Schematic molecular structure of DNCB at the planar conformation of cyclobutane ring.

We can obtain the excimer-formation rate constant by time-resolving measurements. The kinetic scheme of this system, and the notation of rate parameters are written as follows.

$$\begin{aligned}
&M + h\nu \longrightarrow M^* \\
&M^* \longrightarrow M + h\nu_1 && k_{01}^f \\
&M^* \longrightarrow M && k_{01}^n \\
&M^* \longrightarrow D^* && k_{21} \\
&D^* \longrightarrow M^* && k_{12} \\
&D^* \longrightarrow M + h\nu_2 && k_{02}^f \\
&D^* \longrightarrow M && k_{02}^n
\end{aligned}$$

where M and M* represent the naphthyl group in the ground state and the excited state, respectively, and D* is the intramolecular excimer. In the present system, the dynamic equilibrium conditions[15] are satisfied: k_{21}, $k_{12} \gg k_{01}$, k_{02}, where $k_{01}=k_{01}^f+k_{01}^n$, and $k_{02}=k_{02}^f+k_{02}^n$. The rate constants, k_{01} and k_{02}, for the naphthyl groups have previously been reported to be of the order of $10^7\ s^{-1}$.[16] Judging from the fast rise times of excimer emission and its slow decay, the rate constants k_{21} and k_{12} are larger than k_{01} and k_{02} by a factor of at least 100. Under dynamic equilibrium conditions, the following equations are used.

$$\lambda_2 = k_{21} + k_{12}$$
$$\Phi_M = k_{01}^f k_{12}/\lambda_1\lambda_2$$

where λ_1 and λ_2 are the decay time constant and rise time constant, respectively, in the excimer response function,

$$I_D(t) = \exp(-\lambda_1 t) - \exp(-\lambda_2 t).$$

The value of k_{01}^f was determined by measurements of the fluorescence quantum yield and lifetime for 2-ethylnaphthalene in the same temperature range: $k_{01}^f=4.2-4.4\times10^8\ s^{-1}$. From the data, λ_1, λ_2, Φ_M, and k_{01}^f, the excimer formation and dissociation rate constants, k_{21} and k_{12} can be determined. Errors in this calculation come mainly from the simulated values of λ_2, and these are of the order of several per cent. The Arrhenius plots of thus-obtained k_{21} and k_{12} are shown in Fig. 6. From the slopes of these plots, the activation energy of the excimer formation process, E_{21} was found to be 5.0 kJ/mol, and that of the dissociation process, E_{12} was 8.4 kJ/mol (with an error of about ±0.5 kJ/mol). Then, the formation- and dissociation-rate constants are expressed by,

$$k_{21} = 5.1\times10^{10}\exp(-5.0\times10^3/RT)$$
$$k_{12} = 1.6\times10^{11}\exp(-8.4\times10^3/RT)$$

where R is the gas constant. The enthalpy change for the excimer formation in DNCB is given as the difference between E_{21} and E_{12}: $\Delta H=-3.4$ kJ/mol. This value is much smaller than the reported ΔH value

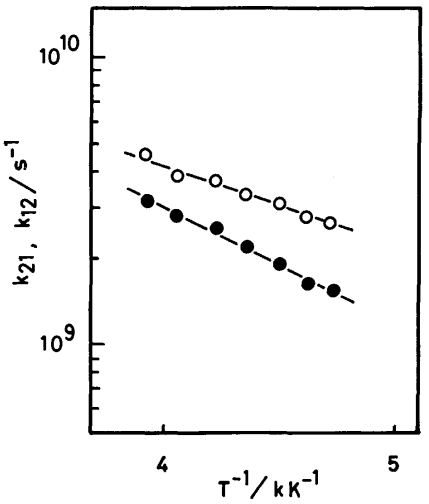

Fig. 6. Arrhenius plots of k_{21}(○) and k_{12}(●).

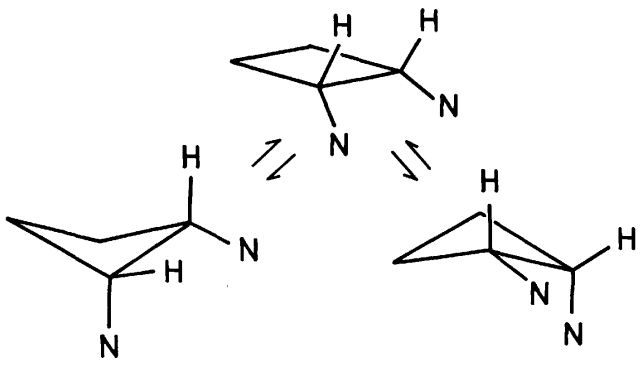

Fig. 7. Bending motion of cyclobutane ring. N: 2-Naphthyl.

for the stable excimer of 2-ethylnaphthalene: −18 kJ/mol.[3,17] Thus, the intramolecular excimer of DNCB has a very weak binding energy and exists only in the low-temperature region in contrast to the stable excimers formed in various dinaphthylalkanes.[16]

The excimer formation and dissociation processes seem to correspond with the bending motion of the cyclobutane ring between puckered forms, as shown in Fig. 7. Two naphthalene rings of DNCB can take an overlapped arrangement at the planar form of cyclobutane ring as shown in Fig. 5, which is attained in the course of the bending motion. The planar conformation has been said to be in a little higher energy state, *ca.* 6.2 kJ/mol than the puckered forms studied by Raman spectroscopy.[18] The overlapping arrangement at the planar form of the cyclobutane ring is not a parallel-sandwich arrangement with respect to the naphthyl groups. Assuming the angle, N-C-H, to be 110°, and the distances, C(aliphatic)-C(aliphatic)=0.155 nm, C(aliphatic)-C(aromatic)=0.152 nm, and C(aromatic)-C(aromatic)=0.139 nm, the planes of naphthalene rings come face to face with each other at an angle, *ca.* 50°. This means their C(aliphatic)-C(aromatic) in-plane axes are inclined at an angle *ca.* 50°, and the distance between the two naphthalene rings is estimated to be 0.28 nm and 0.67 nm for the nearest and farthest aromatic

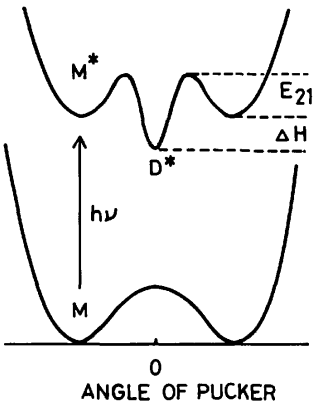

Fig. 8. Schematic potential energy diagram of DNCB.

carbon atoms, respectively. The instability of the excimer state is due to this structural restriction which prevents the naphthalene rings from forming the stable parallel sandwich conformation at the distance of 0.3—0.4 nm. The transition rate of the two puckered forms has been assumed to be considerably fast because of the low barrier energy for the ring inversion. In the present work, it is clear that the rate of bending motion is in the order of 10^9 s^{-1}, thus the conformational lifetime of a puckered form is less than a few hundred picoseconds.

According to the above discussion, the schematic potential energy diagram is illustrated in Fig. 8. The photophysical properties of this unstable excimer are noted: 1) small enthalpy gain for the formation process, 2) large dissociation rate to the excited monomer state even in low temperatures, 3) increase of radiationless dissipation to the ground state at high temperatures. Similar properties have been observed for the unsymmetrical naphthalene excimers formed in 1-(1-naphthyl)-3-(2-naphthyl)propane, whose binding energy was found to be 8.8 kJ/mol.[19] These characteristics seem to be common to the unstable intramolecular excimers. It has often been reported that unstable excimers give somewhat blue shifted fluorescence spectra compared with the stable excimer. But, DNCB shows the same excimer emission band as the stable excimer in spite of its instability. The wavelength of excimer fluorescence should be determined by the difference between the excited state electronic energy and the ground state energy of the excimer geometry. If the ground state energy becomes higher than that of the stable excimer, it is possible that the unstable excimer shows longer wavelength emission than that of the stable excimer. In the present case, the cyclobutane ring at the planar conformation forces the naphthyl groups to have a higher energy geometry both in the ground state and in the excimer state. Therefore, the emission band of excimers seems to be unsuitable as a measure of instability.

The authors wish to express their gratitude to Professor Keitaro Yoshihara and Associate Professor Nobuaki Nakashima, Institute for Molecular Science, for their kind co-operation in picosecond time-resolving mea-

surements. This work has partially been supported by the Fuji Xerox Academic Research Found.

(Received June 21, 1984)

Assignments of the out-of-plane normal vibrations of [$^1H_4$]- and [$^2H_4$]pyrimidines were reexamined through studies of the polarized Raman, time-resolved phosphorescence and polarized dark sublevel phosphorescence spectra. The vibrational analyses of the phosphorescence spectra based on their polarization behavior indicate that the appearance of the strong 0-0 and totally symmetric vibronic bands in the dark sublevel phosphorescence spectra is attributed to the distortion of the molecular structure along the b_1 normal coordinates in the lowest triplet state.

The phosphorescence spectrum of pyrimidine has been studied by many workers and the emitting triplet state of this molecule was assigned to $^3B_1$ (n, π^*).[1-4] Nishi *et al.*[5] observed the phosphorescence spectrum at 4.2 K and pointed out that the 0-0 and totally symmetric vibronic bands arise from the T_z (B_2) and T_y (A_1) sublevels of the lowest triplet state, while the out-of-plane vibronic bands arise, very likely, from the dark T_x (A_2) sublevel, where the x and z axes were taken as the direction normal to the molecular plane and the C_2 axis, respectively. Chan and Sharnoff[6] determined the ordering of the sublevels of the lowest triplet state in pyrimidine to be T_x, T_y, and T_z using the microwave optical double-resonance technique. Burland and Schmidt[7] investigated the dynamic behavior of the pyrimidine molecule in the lowest triplet state using the microwave-induced delayed phosphorescence technique and pointed out that the populating rate for the T_x sublevel was unexpectedly high. Recently, Inoue and Lim[8] observed the zero-field electron paramagnetic resonance transitions among the sublevels of the lowest triplet state of pyrimidine in a benzene host crystal at 1.6 K by the optical detection of the resonance transitions and suggested that the unusually high T_x population is associated with the pseudo-Jahn-Teller distortions of the potential surfaces in the $^3A_1$ (π, π^*) and $^3B_2$ (π, π^*) states perturbed by a close-lying $^3A_2$ (n, π^*) state.

In this paper, the vibrational analyses of the phosphorescence spectra of [$^1H_4$]- and [$^2H_4$]pyrimidines will be reexamined through the studies of the polarized T_x sublevel phosphorescence spectra in benzene host crystals and the polarized Raman spectra in single crystals. The molecular structure in the lowest triplet state will be also discussed.

Experimental

Chemicals. [$^1H_4$]Pyrimidine, obtained from Nakarai Chemicals, was purified by repeated distillation under reduced pressure. [$^2H_4$]Pyrimidine, which was kindly supplied by Professor Lionel Goodman of Rutgers University, was purified by vacuum distillation. Methylcyclohexane and benzene of Dotite Spectrosol Grade were used without further purification.

Optical Measurements. The time-resolved phosphorescence spectra and the phosphorescence lifetimes of [$^1H_4$]- and [$^2H_4$]pyrimidines were studied in methylcyclohexane and benzene matrices at various temperatures between 4.2 and 1.4 K. Liquid helium in the Dewar vessel, where the sample was held, was pumped out with a rotary pump of 1000 L min^{-1} displacement, and the sample was kept at desired temperatures by controlling the speed of evacuation of helium gas with a valve placed between the pump and the Dewar vessel. The temperature of the sample was determined by measuring the vapor pressure of helium in the top of the Dewar vessel. The short-lifetime phosphorescence was observed in the following way. The sample was excited for 10 ms. Two ms after the excitation ceased, the phosphorescence was sampled for 10 ms. The long-lifetime phosphorescence was observed at exciting, waiting, and sampling times of 200, 200, and 200 ms, respectively.

The polarized long-lifetime phosphorescence spectra were observed in a benzene host crystal at 1.4 K. The single-crystal specimen was obtained as follows. Single crystals of benzene doped with [$^1H_4$]- and [$^2H_4$]pyrimidines, were made by the Bridgman method at low temperature. Well grown single crystals examined under polarized light were cut about 2 mm in thickness along a cleavage plane with a razor blade in a cold room kept at −15 °C and suspended in an inner Dewar vessel precooled to −30 °C. Liquid nitrogen was poured into an outer Dewar vessel and the Dewar vessels were allowed to stand for about 10 h. Then, after pouring liquid helium very gradually into the inner Dewar vessel, the samples were examined again under polarized light. Only the crystals which were not cracked were used for the measurement of the polarized spectrum. Since we had no crystallographic knowledge about the cleavage plane cut out from the benzene single crystal, the polarized phosphorescence spectrum was observed with a rotatable polarizer whose orientation was set in such a way that the intensity of the 0-0 band of the long-lifetime phosphorescence spectrum became the strongest and the rotation of the polarizer by 90° gave the weakest intensity. The spectra observed at the former and latter orientations of the polarizer are drawn with solid and dotted lines (referred to as A and B spectra, respectively). The optical and electronic arrangements used for the measurements of the time-resolved phosphorescence spectrum, the polarized phosphorescence spectrum and the phosphorescence lifetimes are exactly the same as those described previously.[9,10]

The polarized Raman spectra of [$^1H_4$]- and [$^2H_4$]pyrimidine single crystals were observed at −30 °C in the crystal orientation where the Raman bands observed at 395 cm^{-1} for [$^1H_4$]-pyrimidine and at 365 cm^{-1} for [$^2H_4$]pyrimidine showed drastic change of polarization behavior by rotating the polarizer under the same way as described previously.[11]

The Raman spectrum polarized parallel to the crystal growth direction is referred to as // spectrum and the spectrum polarized perpendicular to as ⊥ spectrum.

Results and discussion

Out-of-plane Normal Vibrations. Although the normal vibrations of [$^1H_4$]- and [$^2H_4$]pyrimidines have been studied by many workers,[12-15] the assignments given for the normal vibrations, especially for the out-of-plane vibrations, do not agree with each other. Therefore, the out-of-plane vibrations were reexamined by studing the polarized Raman spectrum and normal coordinate calculations. The normal coordinate calculation for the out-of-plane vibrations was carried out with a valence force field and the ϕ-type torsional coordinate using the same method as described previously.[16] Values of the force constants are given in Table 1, where the notations Q, q, P, p, and t are the same as those given by Whiffen.[17] Calculated vibrational frequencies and modes for [$^1H_4$]- and [$^2H_4$]pyrimidines are listed in Tables 2 and 3, respectively.

The polarized Raman spectra of [$^1H_4$]- and [$^2H_4$]-pyrimidines are shown in Fig. 1. As can be seen in this figure, the non-totally symmetric Raman bands, which are depolarized in molten phase, are classified into three types (I, II, and III) based on their polarization behavior. In the first type, the intensity of the ⊥ band is stronger than that of the // band. In the second type, the intensity of the // band is stronger than that of the ⊥ band, and in the third type the intensity of the ⊥ band is much stronger than that of the // band. A comparison of the polarization behavior of the Raman bands with the band contours of the corresponding infrared bands observed in a vapor phase[12] indicates that the type-I and-II Raman bands should be assigned to vibrations belonging to b_2 and b_1 symmetry species, respectively. Hence, the type-III Raman bands are assigned to a_2 species.

C′ is the carbon atom placed between the two N atoms.
H′ is the hydrogen atom bonded to the C′ atom.

The Raman bands of [$^1H_4$]pyrimidine observed at 345, 725, 775, and 982 cm^{-1} showed type-II polarization behavior and, thus, these were assigned to the ν_{16b}, ν_{11}, ν_4, and ν_{17b} vibrations of b_1 species, respectively. The vibrational modes were determined based on the normal coordinate calculation and also through the analysis of the phosphorescence spectrum. The bands observed at 395 and 1004 cm^{-1} showed type-III polarization and, thus, they were assigned to the ν_{16a} and ν_{17a} vibrations of a_2 species, respectively. The Raman bands of [$^2H_4$]pyrimidine observed at 300, 553, 675, 720, and 850 cm^{-1} showed type-II polarization behavior and the bands at 365 and 807 cm^{-1} showed type-III polarization. Thus, the former were assigned to the ν_{16b}, ν_{11}, ν_{10b}, ν_4, and ν_{17b} vibrations and the latter to the ν_{16a} and ν_{17a} vibrations, respectively. The ν_{10b} vibration of [$^1H_4$]pyrimidine could not be identified in the polarized Raman spectrum. The out-of-plane normal vibrations thus assigned are given in Tables 2 and 3, together with those given by previous workers.[12-15] Our assignments explain well the observed polarization behavior of the phosphorescence spectra (described later).

Phosphorescence Spectrum. The temperature dependence of the relative intensities of the ν_{17b}, ν_{11}, and ν_{16b} bands with respect to the 0-0 band in the long-lifetime phosphorescence and that of the lifetime of the long-lifetime phosphorescence observed in methylcyclohexane are shown in Figs. 2 and 3, respectively. As can be seen in these figures, the relative intensity and the lifetime became almost

constant at temperatures below 2 K. This indicates that the spin lattice relaxation, involving the dark T_x sublevel of the lowest triplet state, hardly takes place at temperatures below 2 K within the lifetime of the T_x sublevel. Thus, one can conclude that the long-lifetime phosphorescence observed at 1.4 K arises directly from the T_x sublevel.

The lifetimes of the lowest triplet sublevels at 1.4 K are given in Table 4, together with the values measured by Burland and Schmidt.[7] The lifetime of the T_x sub-

level is so long compared with those of the T_y and T_z sublevels that the long-lifetime phosphorescence spectrum can easily be separated out from the short-lifetime T_y and T_z spectra. While the T_z sublevel spectrum could not be separated from the T_y spectrum under our experimental technique due to very close lifetimes of these two sublevels.

The time-resolved phosphorescence spectra of [$^1H_4$]- and [$^2H_4$]pyrimidines observed in methylcyclohexane matrix at 1.4 K are shown in Figs. 4 and 5, respectively. Intensity ratio of the 0-0 bands of the "long-" and "short-" lifetime spectra extrapolated at t=0 ms, that is, when the excitation light was cut off, was determined to be about 1/100. The

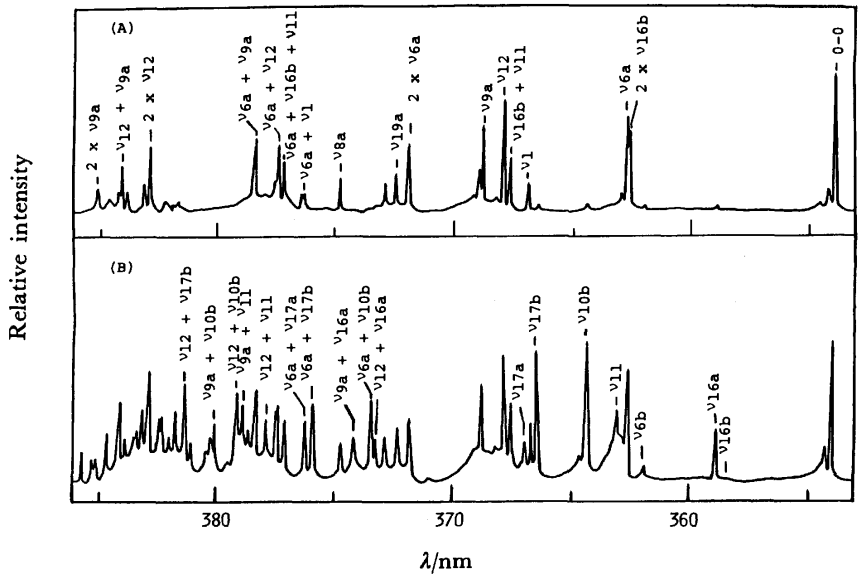

Fig. 4. Short (A) and long (B) lifetime phosphorescence spectra of [$^1H_4$]pyrimidine in methylcyclohexane at 1.4 K.

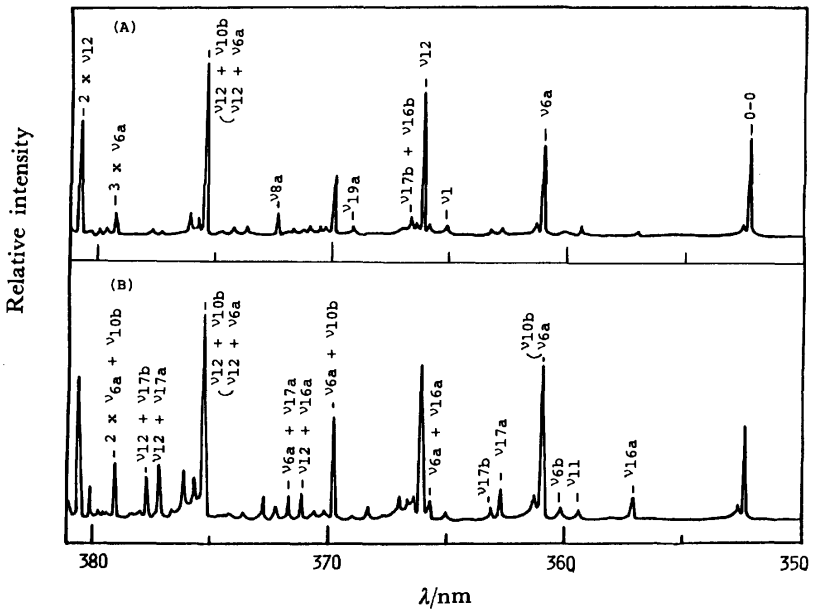

Fig. 5. Short (A) and long (B) lifetime phosphorescence spectra of [$^2H_4$]pyrimidine in methylcyclohexane at 1.4 K.

spectra shown in Figs. 4 and 5 were drawn after the observed intensities of the 0-0 bands in both the spectra were normalized to unity. Vibrational analysis made on the appreciably intense bands in the short-lifetime phosphorescence spectrum was the same as that given by Nishi *et al.*[5] and Hochstrasser and Marzzacco[18] for the phosphorescence spectrum observed at 4.2 K. Although the long-lifetime phosphorescence gave essentially the same spectral structure as that of the short-lifetime phosphorescence, the most characteristic feature of the long-lifetime spectrum was a remarkable increase of the relative intensities of some vibronic bands with respect to the 0-0 band.

The short-and long-lifetime phosphorescence spectra observed in a benzene matrix at 1.4 K showed essentially the same spectral structure as those observed in methylcyclohexane. The polarized long-lifetime phosphorescence spectra of [$^1H_4$]- and [$^2H_4$]-pyrimidines doped in a benzene host single crystal are given in Figs. 6 and 7, respectively. The bands in the polarized phosphorescence spectrum can be classified into two types. In the first type, the intensity of the A spectrum is stronger than that of the B spectrum while in the second type the intensity relation is *vice versa*. Based on the polarization behavior of the bands, vibrational analyses of the phosphorescence spectra of [$^1H_4$]- and [$^2H_4$]pyrimidines were carried out.

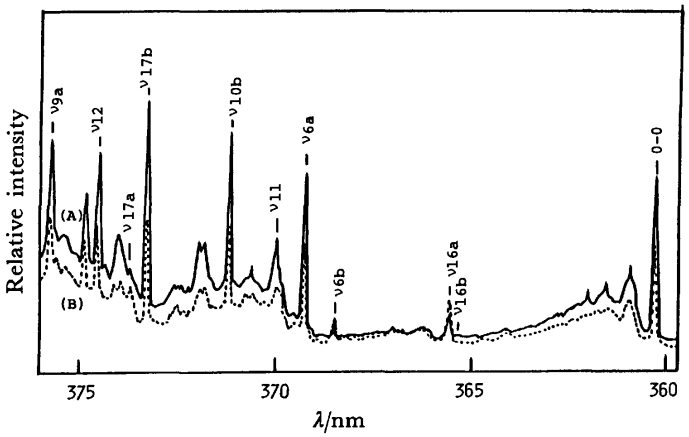

Fig. 6. Polarized long-lifetime phosphorescence spectrum of [$^1H_4$]pyrimidine in benzene host crystal at 1.4 K. A and B are referred to the paper.

[$^1H_4$]Pyrimidine: The phosphorescence bands separated by 392, 618, 716, 804, 962, 1005, 1465, 1484, 1533, 1646, 1795, 1861, 1876, 1940, and 2030 cm^{-1} from the 0-0 band are much intensified relative to the 0-0 band in the long-lifetime spectrum compared with the short-lifetime spectrum. Among them the 392, 618, 1005, 1465, and 1533 cm^{-1} bands showed the second-type polarization behavior in the polarized long-lifetime phosphorescence spectrum, while the other showed the first-type polarization. By referring the polarized Raman spectrum and the normal coordinate calculation, 392, 618, 716, 804, 962, and 1005 cm^{-1} bands were assigned to the ν_{16a}, ν_{6b}, ν_{11}, ν_{10b}, ν_{17b}, and ν_{17a} vibrations, respectively. Hence, it is concluded that the intensified bands showing the first-type polarization behavior can be assigned to the b_1 vibronic bands, while those showing the second-type polarization to the a_2 or b_2 bands. The other intensified bands were assigned to combination bands involving these out-of-plane vibrations based on their polarization behaviors. Generally, the H wagging vibrations are the most effective for the vibronic coupling between (n, π^*) and (π, π^*) states and thus the H wagging vibrations are expected to be observed with fairly strong intensity in the dark sublevel phosphorescence spectrum. Therefore, intensified bands in the dark T_x sublevel phosphorescence spectrum could be assigned to the H wagging vibrations. Our assignment given for the modes of the out-of-plane vibrations were made based on this point.

[$^2H_4$]Pyrimidine: The phosphorescence bands separated by 374, 556, 608, 669, 800, 833, 1029, 1323, 1421, 1465, 1720, and 1857 cm^{-1} from the 0-0 band in methylcyclohexane are intensified relative to the 0-0 band in the long-lifetime spectrum. Among them the 374, 608, 800, 1029, 1421, 1465, and 1857 cm^{-1} bands showed the second-type polarization behavior in the polarized phosphorescence spectrum and the

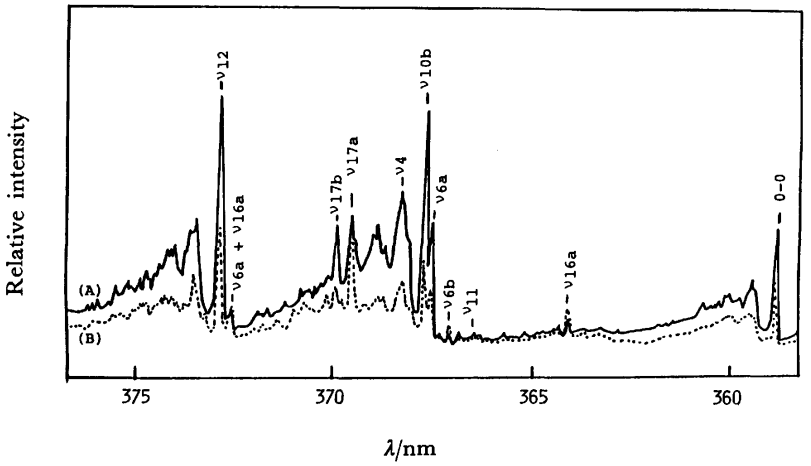

Fig. 7. Polarized long-lifetime phosphorescence spectrum of [$^2H_4$]pyrimidine in benzene host crystal at 1.4 K.

others showed the first-type polarization. The 374, 608, and 800 cm^{-1} bands were assigned to the ν_{16a}, ν_{6b}, and ν_{17a} vibrations, respectively, and the 556, 669, and 833 cm^{-1} bands to the ν_{11}, ν_{10b}, and ν_{17b} vibrations, respectively, by referring Table 3. As in the case of [$^1H_4$]pyrimidine, the first-type polarization behavior in the phosphorescence spectrum is attributed to the b_1 vibronic bands and the second type to the a_2 or b_2 bands. It should be noted that the 0-0 and totally symmetric vibronic bands showed the first type, that is, b_1 polarization behavior in the long-lifetime phosphorescence spectra of [$^1H_4$]- and [$^2H_4$]pyrimidines as can be seen in Figs. 6 and 7. Detailed vibrational analyses are given in Figs. 4 and 5.

Molecular Structure in the Lowest Triplet State. It is quite impossible that the a_1 and b_1, and also a_2 and b_2 vibronic bands show the same polarization behavior, respectively, so far as the molecular geometry of pyrimidine keeps the point group C_{2v} in the lowest triplet state even if the pyrimidine molecules take any orientations in a benzene host crystal. We will now discuss the orientation of the pyrimidine molecule in a benzene host single crystal. Hong and Robinson[19] observed two spectral origins in the phosphorescence of pyrazine in a benzene host crystal, where one is much stronger than the other, and suggested that most of the pyrazine molecules preferentially occupy the substitutional site of the host crystal with a certain fixed orientation. Since the molecular structure of pyrimidine is similar to that of pyrazine and the phosphorescence spectrum in a benzene host crystal shows single origin and distinct polarization behavior as can be seen in Figs. 6 and 7, it is believed that almost all pyrimidine molecules are oriented in a single way in a benzene host crystal. If the pyrimidine molecule, which belongs to the point group C_{2v}, deforms along the normal coordinates of a_2 symmetry species, the molecular symmetry reduces to the point group C_2 and thus a_1 and a_2 symmetry species go into a species, and b_1 and b_2 species into b species. On the other hand, if the molecule deforms along the b_1 normal coordinates the molecular symmetry reduces to the point group C_s, where the plane perpendicular to the original molecular plane and involving the z axis is the symmetry plane. In this case, a_1 and b_1 symmetry species go over into a′ species, and a_2 and b_2 species into a″ species. Thus the symmetrically forbidden transition in the C_{2v} molecular geometry becomes allowed if the molecular structure deforms to the point group C_2 or C_s.

The transitions from the T_x sublevel in the lowest triplet state to the totally symmetric vibrational levels in the ground state are strictly forbidden when the molecule has the C_{2v} geometry, while the transitions become allowed with z-polarization when the molecule deforms along the a_2 normal coordinates. In this case, the transitions from the T_x sublevel to the b_1 and b_2 vibrational levels of the ground state have x- and/or y-polarization, while transitions to the a_1 and a_2 levels have z-polarization. On the other hand, if the molecule deforms along the b_1 normal coordinates, the transitions from the T_x sublevel to the a_1 and b_1 vibrational levels have y-polarization, while the transitions from the T_x sublevel to the a_2 and b_2 levels have x- and/or z-polarization. These polarization behaviors are illustrated in Fig. 8.

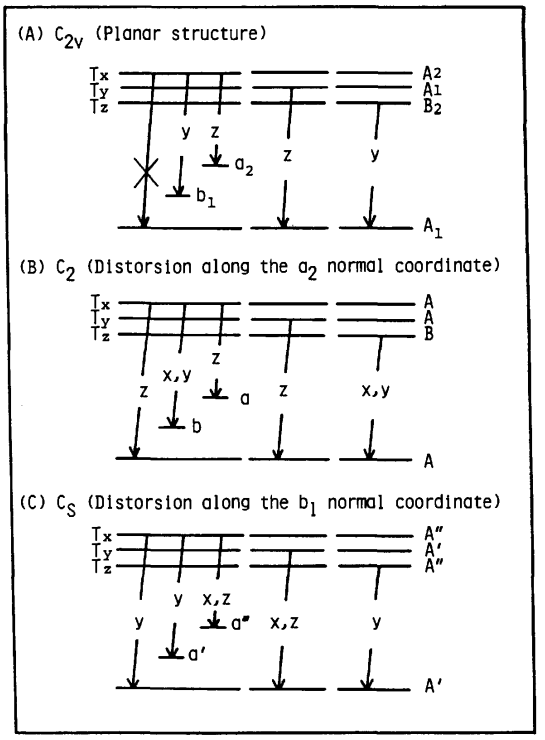

Fig. 8. Polarization directions of the phosphorescence bands emitted from each sublevels of the lowest triplet state in C_{2v} molecular geometry (A), in C_2 geometry (B), and in C_s geometry (C).

Since the 0-0 and totally symmetric vibronic bands show the same polarization behavior as that of the b_1 vibronic bands, as described above, one can understand that the direction of the transition moments of the 0-0 and totally symmetric vibronic bands coincide with that of the b_1 vibronic bands. Thus, one could conclude that the appearance of the 0-0 and totally symmetric bands in the long-lifetime phosphorescence spectrum is responsible for the molecular distortion along the b_1 normal coordinates in the lowest triplet state. This conclusion was supported by the fact that the b_2 and a_2 vibronic bands showed the same polarization behavior in the polarized long-lifetime phosphorescence spectrum, as described above.

We would like to express our thanks to Mr. Shoji Kizuki for his great help in the experiment. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (No. 57470013).

Synthesis and Characterization of Iron(III) Complexes with Unsymmetrical Quadridentate Schiff Bases, and Spin Equilibrium Behavior in Solution[1)]

Naohide MATSUMOTO,* Kazuhiro KIMOTO, Akira OHYOSHI, and Yonezo MAEDA†
Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
†*Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812*
(Received March 23, 1984)

Several iron(III) complexes with planar unsymmetrical quadridentate Schiff bases composed of 1:1:1 condensation products of acetylacetone, ethylenediamine, and each of salicylaldehyde and *o*-hydroxyacetophenone have been prepared and characterized, where the Schiff bases are abbreviated as [H_2salacen] and [H_2hapacen], respectively. The effective magnetic moment of [FeCl(hapacen)] increases gradually from 3.46 BM at 80 K to 5.31 BM at 301 K, and was interpreted by a spin-spin interaction model based on a binuclear structure with an antiferromagnetic interaction parameter of $J=-10$ cm^{-1} ($S_1=S_2=5/2$), while the magnetic moment for [FeCl(salacen)] is 5.86 BM at 80 K and 5.96 BM at 302 K, indicating that the complex is a monomeric species of high-spin type. The bis(imidazole)iron(III) complexes [Fe(im)$_2$(salacen)]$BPh_4\cdot CH_3OH$ and [Fe(im)$_2$-(hapacen)]$BPh_4\cdot 2CH_3OH$ showed a striking thermochromic behavior in various organic solvents, changing from dark red to green with decrease of the temperature. The complexes are essentially of low-spin type in solids, where im and BPh_4 denote imidazole and tetraphenylborate, respectively. Electronic, ^{1}H NMR (Evans method), and ESR spectra confirmed that the thermochromism is caused by spin-equilibrium between high-spin($S=5/2$) and low-spin($S=1/2$) states of iron(III).

Several iron(III) complexes such as tris(dialkyldithiocarbamato)iron(III) and iron(III) complexes with hexadentate Schiff bases or porphyrin derivatives have been known as examples of cross-over complexes in solids.[2)] Spin-equilibrium behavior attributable to high-spin($S=5/2$)$\rightleftharpoons$low-spin($S=1/2$) of iron(III) in solution has been observed in iron(III) hemoproteins such as methemoglobin and cytochrome peroxidase,[3)] and synthetic iron(III) complexes with hexadentate Schiff bases.[4)] In order to develop a model complex for the spin-equilibrium behavior of natural products, it is desirable to study iron(III) complexes with planar quadridentate ligands exhibiting spin-equilibrium in solution.

Nishida *et al.*[5)] investigated the magnetic properties of the iron(III) complexes [Fe(im)$_2$(sal$_2$en)]BPh_4 and [Fe(im)$_2$(ac$_2$en)]BPh_4 with ligand structures of **1** and **3** of Fig. 1, and elucidated that the complexes [Fe(im)$_2$-(sal$_2$en)]BPh_4 and [Fe(im)$_2$(ac$_2$en)]BPh_4 are of high-spin and low-spin type in solids, respectively. When the discussion is limited to bis(imidazole)iron(III) complexes with similar types of ligand systems, a complex with a ligand field strength intermediate between those of **1** and **3** is expected to be a candidate for a spin cross-over complex. The in-plane ligand field strength can be estimated by the positions of d-d band maxima of the corresponding copper(II) complexes, where the d-d band maxima of the copper(II) complexes are given in parentheses in Fig. 1.[6)] The position of the d-d band maximum of the unsymmetrical quadridentate copper(II) complex of **2** is intermediate between those of **1** and **3**, as would be predicted by the ligand structures. Based on the criterion described above, the ligands **4** and **5**,

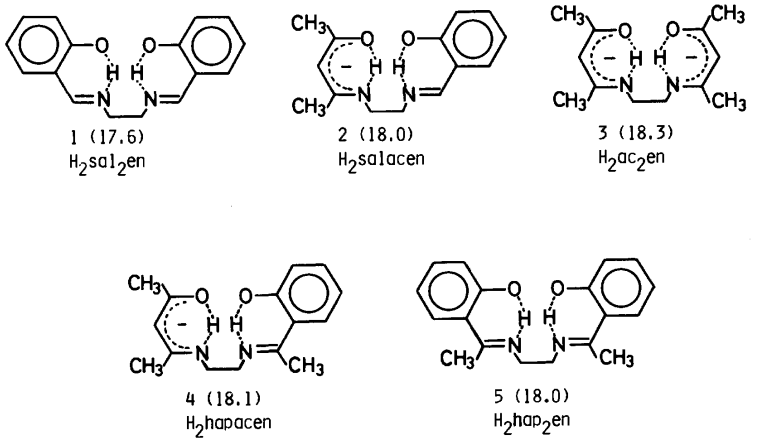

Fig. 1. Structures of [H_2sal$_2$en] (**1**), [H_2salacen] (**2**), [H_2ac$_2$en] (**3**), [H_2hapacen] (**4**), and [H_2hap$_2$en] (**5**). The positions of d-d band maxima of the corresponding copper(II) complexes are given in parentheses (10^3 cm^{-1}).

in addition to the ligand **2**, were selected, where the structures of the ligands, along with the positions of d-d band maxima of the corresponding copper(II) complexes in parentheses, are shown in Fig. 1.

In this study, bis(imidazole)iron(III) complexes with ligands **2**, **4**, **5** along with their chloro iron(III) complexes, were prepared and characterized by elemental analyses, melting points, magnetic susceptibilities, and ESR spectra. The bis(imidazole)iron(III) complexes with unsymmetrical quadridentate ligands (**2**, **4**) showing a striking thermochromism in solution were investigated by electronic, ESR, and ^{1}H NMR (Evans method)[7] spectra.

Experimental

Physical Measurements. Melting points were measured on a Yanagimoto melting points apparatus and are uncorrected. Elemental analyses were performed by Mr. Shinichi Miyazaki at the Technical Service Center of Kumamoto University. Thermogravimetric analysis (TGA) was carried out on a Shimadzu TGC-20 type microthermobalance at a heating rate of 5 °C min^{-1}, using *ca.* 10 mg of a sample for each run. Magnetic moments for the bis(imidazole)iron(III) complexes in dichloromethane were obtained by using the Evans ^{1}H NMR technique at ambient temperature (28 °C),[7] a JEOL MH 100 spectrometer being used at 100 MHz. Electronic spectra in Nujol mull were recorded on a Shimadzu spectrophotometer UV 200, while electronic spectra in solution at room temperature and *ca.* 200 K were recorded on a Hitachi recording spectrophotometer 323, where a jacketed, insulated quartz cell was used, and the temperature was monitored by a YEW Type 2572 digital thermometer. Variable temperature spectra were obtained on a Hitachi 340 spectrophotometer, where the temperature of a sample solution was thermostated within ±0.1 °C by use of a temperature controlled circulating bath, Neslab RTE-8, and measured immediately before and after each spectral measurement with a copper-constantan thermocouple and a digital thermometer, Takeda TR-2121.[8] ESR spectra were measured at ambient temperature and liquid nitrogen temperature on a JEOL JES-FEAX (X-band), using Mn^{2+} doped in MgO as reference. Magnetic susceptibilities on polycrystalline samples were determined by the Faraday method, using an electrobalance Type 2002 (Cahn Instrument) with an electromagnet (8000 G) operated at 20 A. The temperature was controlled over 78—300 K by using a digital temperature controller, Model 3700 (Scientific Instrument). $HgCo(NCS)_4$ was used as a calibration substance. The effective magnetic moment was calculated by the formula of $\mu_{eff}=2.828\sqrt{\chi_A T}$, where χ_A is a molar susceptibility after diamanetic correction.

Synthesis. Ligands. Unsymmetrical quadridentate Schiff base ligands (**2**, **4**) were prepared by the demetallation reaction of the corresponding copper(II) complexes with gaseous hydrogen sulfide in dichloromethane solution, according to the method reported earlier,[9] and identified by the ^{1}H NMR spectra. Symmetrical quadridentate Schiff base **5** was prepared by the method of literature.[10]

Chloroiron(III) Complexes. The preparative methods of the chloroiron(III) complexes [FeCl(salacen)], [FeCl(hapacen)], and [FeCl(hap$_2$en)] are similar, so that only the synthesis of [FeCl(salacen)] is described in detail. To a solution of [H_2salacen] (10 mmol) in 50 cm^3 of absolute methanol was added a solution of anhydrous iron(III) chloride (10 mmol) in 50 cm^3 of absolute methanol. To this mixture, triethylamine (20 mmol) was added. The resulting solution was stirred at 60 °C for 1 h and allowed to stand for several hours at room temperature. The black crystals which separated were filtered, washed with absolute methanol and diethyl ether, and dried *in vacuo*.

Bis(imidazole)iron(III) Complexes. The preparative methods of the bis(imidazole)iron(III) complexes [Fe(im)$_2$(salacen)]BPh_4, [Fe(im)$_2$(hapacen)]BPh_4, and [Fe(im)$_2$(hap$_2$en)]BPh_4 are similar, and only the synthesis of [Fe(im)$_2$(salacen)]BPh_4 is exemplified in detail. The mixture of [FeCl(salacen)] (2 mmol) and imidazole (4 mmol) in 150 cm^3 of absolute methanol was stirred at 60 °C for 20 min, and the solution was filtered while hot. The filtrate was added to a solution of sodium tetraphenylborate (30 mmol) in 10 cm^3 of absolute methanol, and the resulting red solution was allowed to stand overnight to precipitate green crystals. The green needle crystals were filtered, washed with a small amount of absolute methanol and diethyl ether, and dried *in vacuo*. They were recrystallized from a mixture of dichloromethane and absolute methanol.

Results and Discussion

Analytical data and melting points are given in Table 1. As indicated by the elemental analyses, the bis(imidazole) iron(III) complexes tend to crystallize as solvates. The number of solvent molecule of crystallization was evaluated by thermogravimetric analysis (TGA), where the weight losses estimated by the elemental analyses were observed.

Magnetic Properties in Solids. Chloroiron(III) Complexes. The value of the effective magnetic moment of [FeCl(salacen)] is 5.86 BM at 80 K and 5.96 BM at 302 K, indicating that the complex is a mononuclear species with a high-spin state of iron(III). On the other hand, the effective magnetic moment of [FeCl(hapacen)] increases gradually from 3.46 BM at 80 K to 5.31 BM at 302 K (see Fig. 2). Magnetic susceptibility data for [FeCl(hapacen)] were analyzed with

TABLE 1. ELEMENTAL ANALYTICAL DATA AND MELTING POINTS[a]

Compound	C (%)	H (%)	N (%)	Mp θ_m/°C
[FeCl(salacen)]	49.69 (50.11)	4.82 (4.81)	8.19 (8.35)	213
[FeCl(hapacen)]	51.49 (51.53)	5.27 (5.09)	7.82 (8.01)	244
[FeCl(hap$_2$en)]	54.41 (54.64)	4.86 (5.31)	6.97 (6.91)	>290
[Fe(im)$_2$(salacen)]$BPh_4\cdot CH_3OH$	68.77 (68.63)	6.00 (6.14)	10.69 (10.67)	125
[Fe(im)$_2$(hapacen)]$BPh_4\cdot 2CH_3OH$	67.33 (67.72)	6.26 (6.53)	9.94 (10.08)	118
[Fe(im)$_2$(hap$_2$en)]$BPh_4\cdot 2CH_3OH$	68.81 (69.06)	6.09 (6.26)	9.82 (9.66)	131

a) Calcd values are in parentheses.

a spin-spin interaction model based on the spin Hamiltonian $-2JS_1 \cdot S_2$ ($S_1=S_2=5/2$). The susceptibility per iron atom of a binuclear species is given in Eq. 1.[11]

$$\chi_A = Ng^2\beta^2[55+30\exp(10x)+14\exp(18x)+5\exp(24x)+\exp(28x)]/kT[11+9\exp(10x)+7\exp(18x)+5\exp(24x)+3\exp(28x)+\exp(30x)] \quad (x=-J/kT) \quad (1)$$

Assuming an isotropic g value of 2.00, the J value obtained by the best-fit of the susceptibility data to Eq. 1 is $-10\ cm^{-1}$.[12] Figure 2 shows the experimental effective magnetic moments and the theoretical curve with the bast-fit value of J. The J value of $-10\ cm^{-1}$ is comparable to the J values of chloro(*N*,*N*-disalicylideneethylenediaminato)iron(III) ([FeCl(sal$_2$en)]) and analogous complexes.[13] Figure 3 shows a proposed structure of [FeCl(hapacen)], based on the structure of [FeCl(sal$_2$en)].[13]

Bis(imidazole)iron(III) Complexes. The effective magnetic moments for [Fe(im)$_2$(salacen)]BPh$_4$·CH$_3$OH and [Fe(im)$_2$(hapacen)]BPh$_4$·2CH$_3$OH are 3.02 and 3.20 BM at 301 K, respectively, indicating that the complexes are essentially of low-spin type in the solid state. ESR spectra for [Fe(im)$_2$(salacen)]BPh$_4$·CH$_3$OH and [Fe(im)$_2$hapacen]BPh$_4$·2CH$_3$OH in the solid state showed a single signal at *ca.* g=2.1 at 298 K, and the signal split into three components at liquid nitrogen temperature, which is characteristic of low-spin iron(III) complexes.[14] Experimental anisotropic g values are listed in Table 2. The nature of the ground state Kramers doublet of the ^{2}T of pseudo-octahedral iron(III) complexes can be elucidated by using the anisotropic g values. In this calculation, the spin-orbit coupling interaction and the crystal field distortion are considered. The eigenfunctions of a $(t_2)^1$ configuration may be written as

$$\Psi_i^+ = A_i|1^+> + B_i|\zeta_1^-> + C_i|-1^+>$$
$$\Psi_i^- = A_i|-1^-> - B_i|\zeta_1^+> + C_i|+1^->,$$

where $|1>=-(d_{xz}+id_{yz})/\sqrt{2}$, $|-1>=(d_{xz}-id_{yz})\cdot\sqrt{2}$, $|\zeta_1>=id_{xy}$, i=1, 2, 3, and the superscripts + and − mean the α-spin and β-spin wave functions. The Kramers doublet will be split by the magnetic field interaction $\mathbf{H}=\beta(k\mathbf{l}+2\hat{s})\mathbf{H}$, where k, the orbital reduction factor, is fixed at 0.9 in this calculation. The g values for the ground state level may be given as[14]

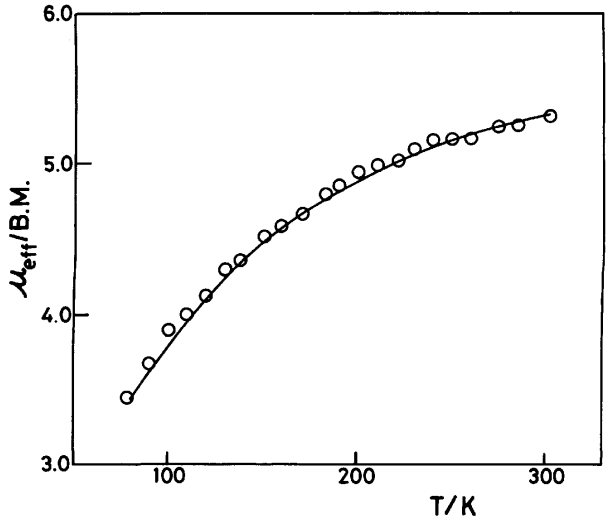

Fig. 2. Temperature dependence of the effective magnetic moment for [FeCl(hapacen)] (o), where the solid line represents theoretical curve of Eq 1 with the parameters of J=10 cm^{-1} and g=2.00.

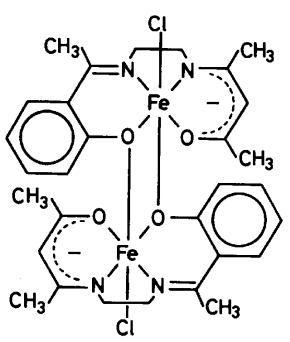

Fig. 3. A proposed structure for [FeCl(hapacen)].

Table 2. ESR parameters and occupied orbital of unpaired electron for [Fe(im)$_2$(salacen)]BPh$_4$·CH$_3$OH (**1**) and [Fe(im)$_2$(hapacen)]BPh$_4$·2CH$_3$OH (**2**)

	(**1**)	(**2**)
g_x	2.349	2.322
g_y	2.138	2.155
g_z	1.938	1.931
A_1	0.104	0.105
B_1	0.995	0.993
C_1	−0.036	−0.028
unpaired electron orbital	d_{xy}	d_{xy}

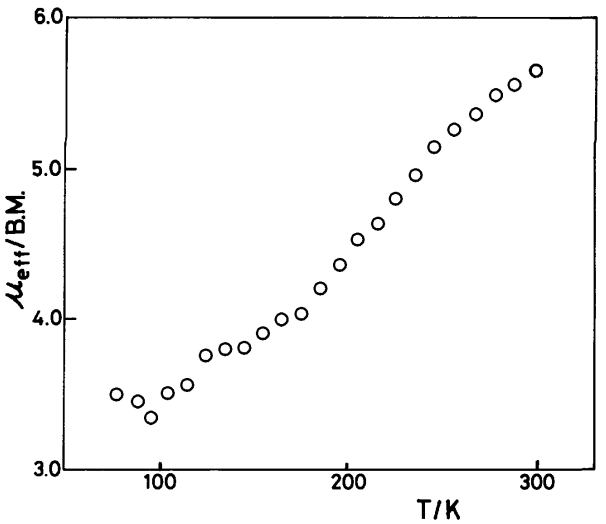

Fig. 4. Temperature dependence of the effective magnetic moment for [Fe(im)$_2$(hap$_2$en)] BPh$_4$·2CH$_3$OH (○).

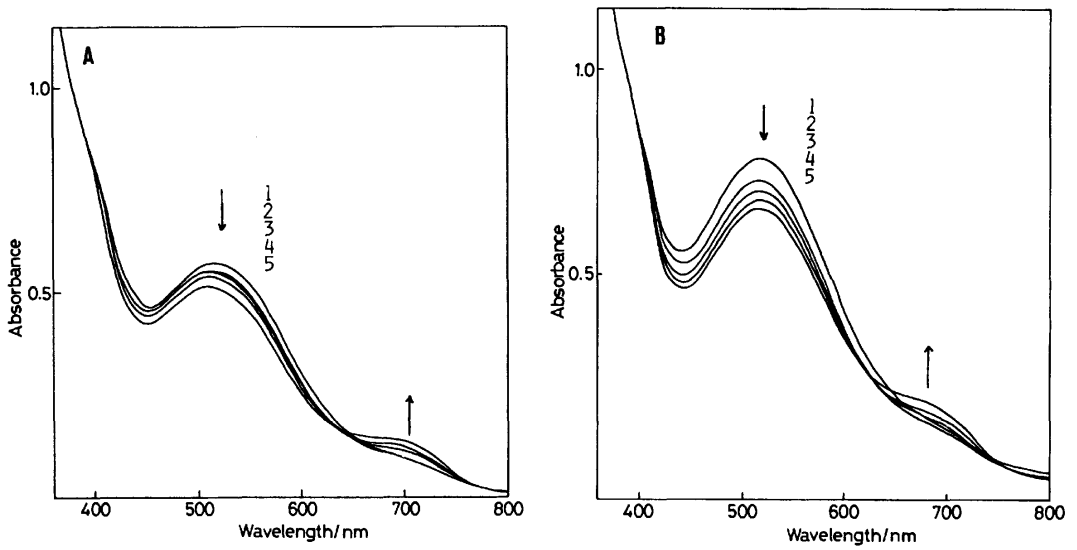

Fig. 5. Absorption spectra of [Fe(im)$_2$(salacen)] $BPh_4 \cdot CH_3OH$ (**A**) (3.098×10^{-4} mol dm^{-3}) and [Fe(im)$_2$(hapacen)]$BPh_4 \cdot 2CH_3OH$ (**B**) (2.735×10^{-4} mol dm^{-3}) in dichloromethane solution at various temperatures (301 (**1**), 288 (**2**), 273 (**3**), 263 (**4**), 251 (**5**) K).

$$g_z = 2[A^2 - B^2 + C^2 + k(A^2 - C^2)]$$
$$g_x = 2[B^2 - 2AC + \sqrt{2}kB(A - C)]$$
$$g_y = 2[B^2 + 2AC + \sqrt{2}kB(A + C)]$$
$$A^2 + B^2 + C^2 = 1$$

The values of A, B, and C are selected to solve the above equations by using the experimental anisotropic g values. Since the signs of the observed g values are not determined experimentally, the values of A, B, and C are not obtained unequivocally, so that it is necessary to try many assignments to solve the equations. The reasonable solutions[14] are selected and listed in Table 2. As shown in Table 2, the ground state Kramers doublet consists mainly of the state wherein the unpaired electron remains in the d_{xy} orbital, because the B value is nearly equal to 1.

Figure 4 shows the temperature dependence of the magnetic moment of [Fe(im)$_2$(hap$_2$en)]$BPh_4 \cdot 2CH_3OH$ in the solid state. The value of the effective magnetic moment increases gradually from 3.50 BM at 78 K to 5.64 BM at 298 K. This behavior is attributable to a spin-equilibrium between high-spin an low-spin states of iron(III).

Thermochromic Behavior in Solution. Green needle crystals of [Fe(im)$_2$(salacen)]$BPh_4 \cdot CH_3OH$ and [Fe(im)$_2$(hapacen)]$BPh_4 \cdot 2CH_3OH$ are dissolved in various organic solvents such as acetone, dichloromethane, chloroform, *N,N*-dimethylformamide, and acetonitrile, to change their colors to dark red at room temperature. At *ca.* 200 K (Dry Ice/acetone bath), the color changes from dark red to green, showing a striking thermochromic behavior. It should be noted that such a thermochroism was not observed for the symmetrical complexes [Fe(im)$_2$(sal$_2$en)]BPh_4 and [Fe(im)$_2$(hap$_2$en)]$BPh_4 \cdot 2CH_3OH$. Temperature dependence of the electronic spectra of [Fe(im)$_2$(salacen)]$BPh_4 \cdot CH_3OH$ and [Fe(im)$_2$(hapacen)]-

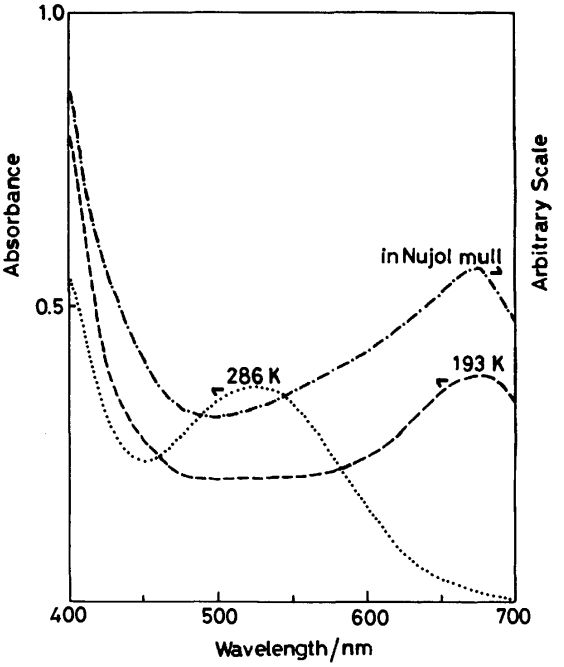

Fig. 6. Electronic absorption spectra of [Fe(im)$_2$(hapacen)]$\cdot 2CH_3OH$ in dichloromethane at 286 and 193 K, along with the spectrum in Nujol mull.

$BPh_4 \cdot 2CH_3OH$ in dichloromethane over the temperature range of *ca.* 300—250 K is shown in Fig. 5. The spectrum of [Fe(im)$_2$(hapacen)]$BPh_4 \cdot 2CH_3OH$ in dichloromethane at 286 and 193 K, along with the spectrum in Nujol mull at room temperature is shown in Fig. 6. As shown in Fig. 5 and 6, the spectrum of [Fe(im)$_2$(hapacen)]$BPh_4 \cdot 2CH_3OH$ at 300 K exhibits an absorption band at 520 nm with an extinction coefficient on the order of *ca.* 2500 mol^{-1} dm^3 cm^{-1}. With a lowering of the temperature, this band decreases its intensity and a new band

appears at 680 nm. The electronic spectrum of [Fe(im)$_2$(hapacen)]BPh$_4$·2CH$_3$OH at 193 K in dichloromethane resembles that in Nujol mull at room temperature, where the complex is confirmed to be a low-spin type in the solid state on the basis of the magnetic moment and the ESR spectrum, as described earlier. Therefore the lower energy band around 680 nm is due to a low-spin species. The magnetic moments for [Fe(im)$_2$(salacen)]BPh$_4$·CH$_3$OH and [Fe(im)$_2$(hapacen)]BPh$_4$·2CH$_3$OH in dichloromethane at 301 K were estimated by the Evans ^{1}H NMR method to be 5.45 and 5.60 BM, respectively, which lie in the range expected for high-spin iron(III) complexes, so that the higher energy band around 520 nm is due to a high-spin species.

The authors wish to express their thanks to Dr. Tasuku Ito of the Institute for Molecular Science and Mr. Toshiaki Kanao of Kumamoto University, for the measurements of the variable temperature electronic spectra.

Ozonization of Triphenylmethane Dyes

Masaki MATSUI,* Hideki NAKABAYASHI, Katsuyoshi SHIBATA, and Yoshimi TAKASE
Department of Industrial Chemistry, Faculty of Engineering, Gifu University, Yanagido, Gifu 501-11
(Received November 21, 1983)

The reaction of Malachite Green (MG, **1a**), a model compound of triphenylmethane dye, with ozone proceeded *via* two paths. The first path involved an ozone attack at the dimethylamino moiety to give a *N*-formylmethylamino derivative **4a**. The second path produced 4-(dimethylamino)benzophenone (**2a**) and *p*-(dimethylamino)phenol (**6**). Other ozonized products, **3a** and **5a** were also detected. The following is a discussion of the ozonization mechanism.

The reactions of dyes with ozone have been studied from the point of dye-wastewater treatment. Currently, such reactions are being looked at in terms of the decrease in the chemical oxygen demand (COD) and decolorization.[1] However, the ozonization mechanism has scarcely been touched. In this respect, the ozonization reactions of pyrazolone,[2] azo,[3-6] indigoid,[7] and diphenylmethane[8] dyes have been reported.

Reactions involving triphenylmethane dyes have been discussed regarding photo-fading. The photoreaction of MG in water was reported to give 4-(dimethylamino)benzophenone, the carbinol base of MG, and *p*-(dimethylamino)phenol.[9] The photoreactions of Crystal Violet (CV) have been reported to give *p*-(dimethylamino)phenol, 4,4′-bis(dimethylamino)benzophenone, the leuco and demethylated derivatives of CV, *etc.*[10-12]

The ozonization reaction of MG, a model compound of the triphenylmethane dye, is discussed.

Experimental

General. Ozone was generated by a Nihon ozon 0-1-2 type ozonizor. IR, NMR, and mass spectra were recorded on a Hitachi EPI-S2 spectrometer, a Hitachi R-24 spectrometer, and a Hitachi M-52 spectrometer, respectively. Melting points were measured with a Yanagimoto micro-melting-point apparatus. Gas chromatography was performed using Shimadzu 3AH and 4C-PF gas chromatographs. Purity of the materials used was confirmed by gas chromatography.

Materials. The materials which were used are shown in Figure 1. **1a** (MG, Nakarai Chemicals, Ltd.) was recrystallized from benzene-ethanol; ^{1}H ($CDCl_3$) δ=3.35 (12H, s) and 6.8—7.9 (13H, m). **1b** was synthesized as described in the literature;[13] ^{1}H NMR ($CDCl_3$), δ=2.88 (12H, s), 3.53 (3H, s), and 6.5—7.1 (12H, m). **1c** was also synthesized as described in the literature;[13] ^{1}H NMR ($CDCl_3$) δ=3.00 (12H, s) and 7.0—8.0 (12H, m). **1d** (CV, Nakarai Chemicals, Ltd.) was recrystallized from water; ^{1}H NMR ($CDCl_3$) δ=3.28 (18H, s) and 6.9—7.4 (12H, dd). Dimethylaminobenzophenones **2a—c** were synthesized as described in the literature,[14] and recrystallized from ethanol. 4-(Dimethylamino)benzophenone (**2a**); mp 87.5—89.0 °C (lit 89.5—90.5 °C).[14] 4-Dimethylamino-4′-methoxybenzophenone (**2b**); mp 131.4 °C (lit 133 °C).[15] 3-Nitro-4′-(dimethylamino)benzophenone (**2c**); mp 173.6 °C (lit 173 °C).[15] 4,4′-Bis(dimethylamino)benzophenone (**2d**) was synthesized by the oxidation of Auramine 0;[16] mp; 171.0—172.3 °C (lit 172—174 °C).[17] *N*-Formylmethylaminobenzophenones **3a—d** were synthesized by the oxidation of the corresponding *p*-(dimethylamino)benzophenones **2a—d** with Collins reagent[18] and purified by column chromatography (silica gel, acetone). 4-(*N*-Formylmethylamino)benzophenone (**3a**); mp 188.5 °C; ^{1}H NMR ($CDCl_3$) δ=3.42 (3H, s), 7.3—8.0 (9H, m), and 8.75 (1H, s); MS (20 eV) *m/z* (rel intensity) 239 (M^+; 26), 238 (1), 162 (26), 134 (24), 105 (44), and 77 (100); IR (KBr disk) 1600 cm^{-1} (C=O). 4-(*N*-Formylmethylamino)-4′-methoxybenzophenone (**3b**); mp 132.8 °C; ^{1}H NMR ($CDCl_3$) δ=3.35 (3H, s), 3.38 (3H, s), 6.9—7.9 (8H, m), and 8.63 (1H, s); MS (20 eV) *m/z* (rel intensity) 269 (M^+; 37), 268 (1), 162 (20), 135 (100), and 107 (17); IR (KBr disk) 1600 cm^{-1} (C=O). 3-Nitro-4′-(*N*-formylmethylamino)benzophenone (**3c**); mp 145.4 °C; ^{1}H NMR ($CDCl_3$) δ=3.38 (3H, s), 7.2—8.6 (8H, m), and 8.73 (1H, s); MS (20 eV) *m/z* (rel intensity) 284 (M^+; 30), 162 (26), 150 (9), 134 (100), and 122 (4); IR (KBr disk) 1605 (C=O), 1530, and 1320 cm^{-1} (NO_2). 4-(Dimethylamino)-4′-(*N*-formylmethylamino)benzophenone (**3d**); mp 170.1 °C; ^{1}H MNR ($CDCl_3$) δ=3.08 (3H, s), 3.40 (6H, s), 7.3—7.9 (8H, m), and 8.63 (1H, s); MS (20 eV) *m/z* (rel intensity) 282 (M^+; 63), 281 (13), 267 (54), 162 (4), 148 (100), 134 (33), and 120 (8); IR (KBr disk) 1600 cm^{-1}

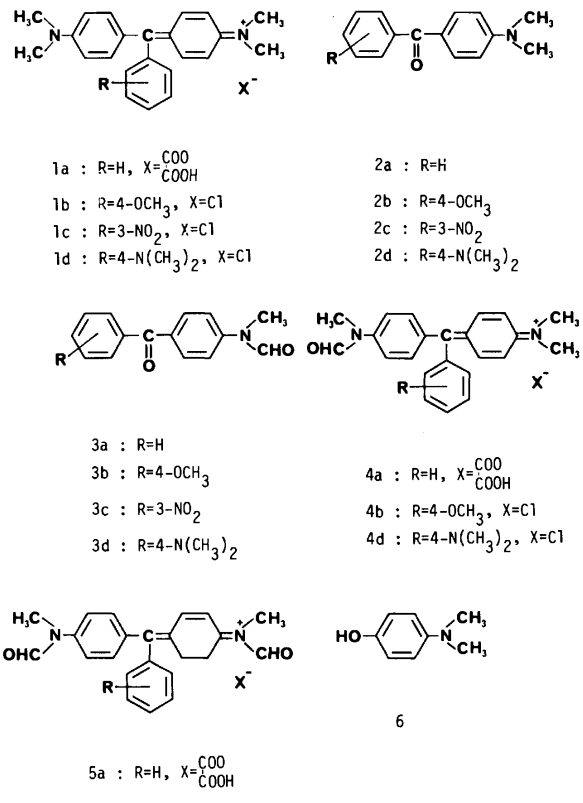

Fig. 1. Materials.

(C=O). **4a** was synthesized by the oxidation of **1a** with Collins reagent and purified by column chromatography (silica gel, acetone); ^{1}H NMR ($CDCl_3$) δ=2.90 (3H, s), 3.25 (6H, s), 7.0—7.6 (13H, m), and 8.42 (1H, s); MS (20 eV) *m/z* (rel intensity) 344 (100), 343 (10), 267 (60), and 210 (50). **4b** was isolated by the ozonization of **1b** and purified by column chromatography (silica gel, methanol:acetone=1:3); ^{1}H NMR ($CDCl_3$) δ=2.93 (6H, s), 3.38 (3H, s), 3.78 (3H, s), 6.7—7.4 (12H, m), and 8.40 (1H, s); MS (20 eV) *m/z* (rel intensity) 374 (100), 373 (17), 267 (15), and 240 (46). **4d** was synthesized by the oxidation of **1d** with Collins reagent; ^{1}H NMR ($CDCl_3$) δ=2.98 (12H, s), 3.05 (3H, s), 6.6—7.1 (12H, m), and 8.41 (1H, s); MS (20 eV) *m/z* (rel intensity) 387 (35), 386 (15), 267 (50), 253 (100), 134 (25), and 120 (60). **5a** was synthesized by a further oxidation of **1a** with Collins reagent; ^{1}H NMR ($CDCl_3$) δ=3.20 (6H, s), 7.0—7.5 (13H, m), and 8.30 (2H, s); MS (20 eV) *m/z* (rel intensity) 358 (3), 357 (10), 224 (6), 134 (22), and 77 (100). *p*-(Dimethylamino)phenol (**6**) was synthesized as described in the literature;[9] mp 74.1 °C (lit 74—76 °C).[19] The mass spectra of **4a**, **4b**, **4d**, and **5a** were recorded as the leuco derivatives.

Ozonization. The method of ozonization was the same as that described in a previous paper.[8] Ozonization was carried out with an ozone-oxygen mixture (ozone: 9.0 mg min^{-1}, oxygen: 200 cm^3 min^{-1}) on 0.136 mmol of substrate in 10 ml of solvent. Excess ozone was determined by iodometric titration. The ozonization products were analyzed using gas chromatography and identified by comparing their mass spectra with those of authentic samples. Yields were determined by comparisons with standard solutions of known compounds by GLC using 2% Silicone OV-1, 2% FFAP, and Chromosorb 101 columns.

Results and Discussion

When MG (**1a**) was ozonized, 4-(dimethylamino)benzophenone (**2a**), 4-(*N*-formylmethylamino)benzophenone (**3a**), *N*-formylmethylamino derivative **4a**, *N,N'*-diformylmethylamino derivative **5a**, and *p*-(dimethylamino)phenol (**6**) were detected. The result is shown in Table 1. In each case, a trace amount of **5a** was detected. Since no significant difference between the distribution of the products found in methanol and that found in dichloromethane was observed (runs 1 and 2), the possibility that a reaction of **1a** with the peroxides formed through the ozonization of methanol yielded the products was excluded. The reaction of **1a** with ozone proceeds *via* two paths. The first path produces **4a** *via* an ozone attack at the dimethylamino moiety of **1a**. The second path produces **2a** and **6** *via* an ozone attack at the carbon adjacent to the triphenylmethyl carbon of **1a**. **2a**, and **4a** are further ozonized to give **3a**, **5a**, and **6**. The ratio of the ozone attack on each position was calculated from the yields of **4a** and **2a**. The results are also shown in Table 1. The ratio N/C decreased with increasing temperature (runs 1, 3, and 4), since the reactivity of **2a** with ozone increases with decreasing temperature. Yields of the products decreased as the ratio of water in methanol increased (runs 4, 5, 6, 7, and 8). Ozone decomposes easily in water to give an hydroxyl radical which is a strong oxidizing agent.[20] The products detected by the ozonization of **1a**, however, were not obtained in the reaction of **1a** with Fenton's reagent, which generates a hydroxyl radical. The ratio of ozone(consumed)/**1a**(reacted) increased as the ratio of water in methanol became greater (runs 4, 5, 6, 7, and 8). From these results, it was found that the added water played only a role involving the acceleration of the decomposition of ozone to give a hydroxyl radical. Then, yields of the ozonization products decreased.

The substituent effect on the ozonization of **1a** is shown in Table 2. When **1c** was ozonized, ketone **2c** and *p*-(dimethylamino)phenol (**6**) were predominantly produced. On the other hand, ozonization of **1d** preferentially afforded *N*-formylmethylamino derivative **4d**. When **1a** and **1b** were ozonized, the ketones, the *N*-formylmethylamino derivative, and *p*-(dimethylamino)phenol were detected, respectively. The ratio N/C changed drastically and was in the order **1c**< **1a**<**1b**<**1d**, which consists with that of electron-donative ability of the substituent. This result suggests that an electrophilic ozone attack takes place on the dimethylamino nitrogen.

The probable ozonization mechanism of the dimethylamino moiety of **1a** is proposed in Scheme 1, by reference to the ozonization mechanism of aromatic

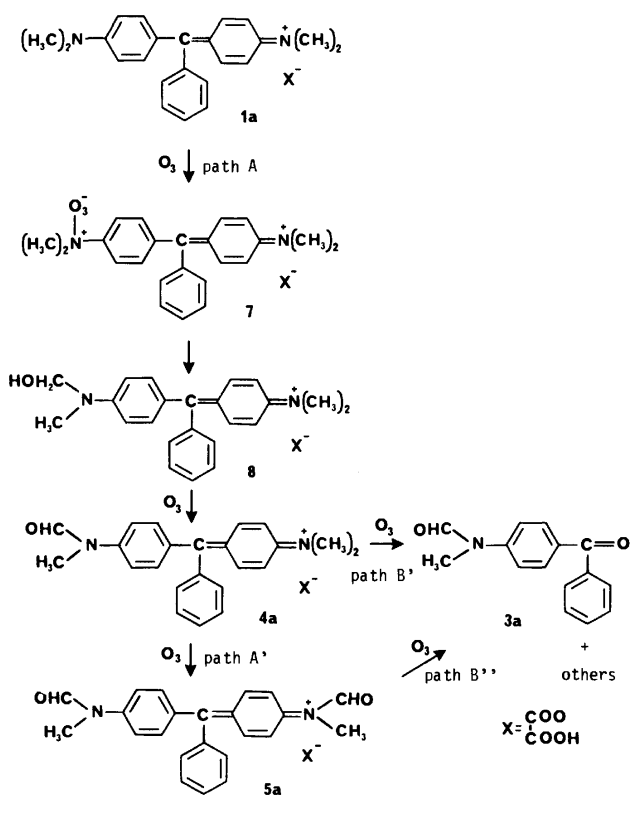


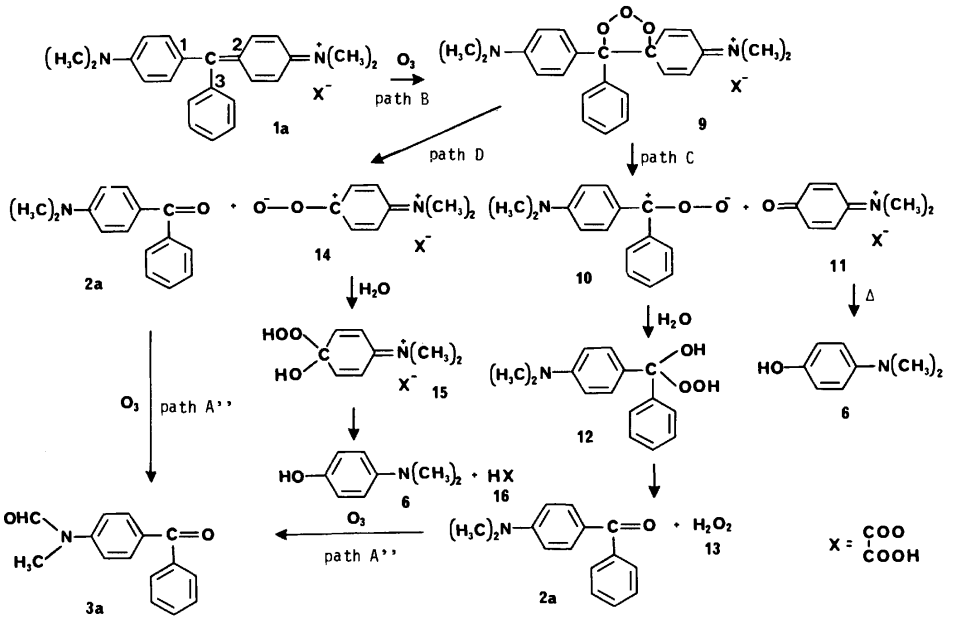
Scheme 1.

tertiary-amines.[21,22)] Ozone electrophilically attacks the dimethylamino nitrogen to give **1a**-ozone adduct **7**, which is converted into *N*-hydroxymethyl-*N*-methylamino derivative **8** [path A]. Since the value of the ratio ozone(consumed)/substrate(reacted) of **1d**, whose dimethylamino moiety is preferentially attacked by ozone was 1.7 (Table 2, run 4), it was concluded that the *N*-hydroxymethyl-*N*-methylamino derivative **8** is further ozonized to give the *N*-formylmethylamino derivative **4a**. Some radical process in which an oxygen molecule takes part may be involved. The *N*-formylmethylamino derivative **4a** is further ozonized to give either *N*,*N*'-diformylmethylamino derivative **5a** [path A'] or the ketone **3a** and *p*-(dimethylamino)phenol (**6**) [path B']. The *N*,*N*'-diformylmethylamino derivative **5a** is further ozonized to give the ketone **3a** [path B"].

A mechanism for the ozone attack on the skeleton of **1a** is proposed in Scheme 2. Except for the primary ozonides of α,β-unsaturated carbonyl compounds, certain allylic compounds, and certain substituted cinnamic esters, primary ozonides decompose into the corresponding carbonyl oxides and carbonyl compounds.[23)] In Scheme 2, carbons C1 and C2 are considerably more negative than carbon C3, due to the mesomeric effect produced by the dimethylamino groups. When ozone electrophilically attacks C1 and C2, a primary ozonide **9** is formed [path B]. The direction of the cleavage of the primary ozonide **9** follows two possible paths. The primary ozonide **9** can cleave to carbonyl oxide **10** and ketone **11** [path C]. The carbonyl oxide **10** reacts with water to give 4-(dimethylamino)benzophenone (**2a**) and hydrogen peroxide (**13**) *via* hydroperoxide **12**. The ketone **11** can be converted into *p*-(dimethylamino)phenol (**6**) at the injection room of the gas chromatograph during analysis.

In contrast, the primary ozonide **9** can decompose to 4-(dimethylamino)benzophenone (**2a**) and carbonyl oxide **14**, which reacts with water to give *p*-(dimethylamino)phenol (**6**) and oxalic acid (**16**) *via* hydroperoxide **15** [path D].

In fact, the presence of a small amount of water (*ca.* 0.2%) was confirmed by gas chromatography. In order to differentiate path C from path D, the following experiments were carried out. If the primary ozonide **9** had cleaved by path C, hydrogen peroxide (**13**), which is formed from the hydroperoxide **12**, should have been detected. Unfortunately, it was impossible to differentiate the hydrogen peroxide (**13**) from the peroxides formed by the ozonization of methanol which was used as a solvent. On the other hand, if the primary ozonide **9** had cleaved by path D, the phenolic proton of *p*-(dimethylamino)phenol would have come from the water. The relative yield of *p*-(dimethylamino)phenol-*d* for *p*-(dimethylamino)phenol produced by the ozonization of **1a** in the presence of heavy water is shown in Fig. 2. For a greater ratio of heavy water, the relative yield of *p*-(dimethylamino)phenol-*d* also increased. However, this result does not sufficiently prove that the primary ozonide **9** cleaves mainly by path D. Since even in the presence of *ca.* 70 molar equivalents of heavy



Scheme 2.

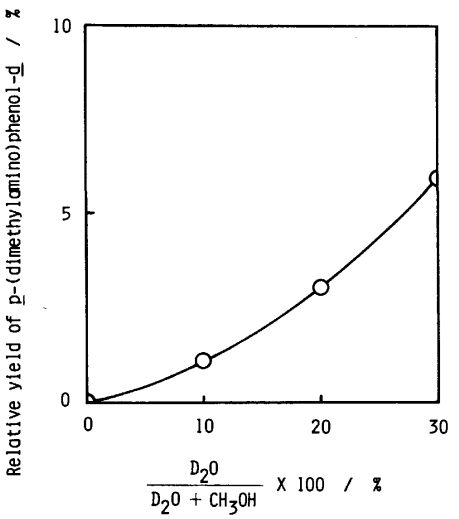


Fig. 2. Relative yield of *p*-(dimethylamino)phenol-*d* in the ozonization of **1a**.

water (30%), only 6% of *p*-(dimethylamino)phenol-*d* was observed. It was thus concluded that the primary ozonide **9** mainly cleave by way of path C and to a lesser extent by way of path D. The result is consistent with the general rule that a primary ozonide cleaves to a carbonyl oxide whose carbocation is more liable to be stabilized by the mesomeric effect.[24] 4-(Dimethylamino)benzophenone (**2a**) was further ozonized to give 4-(*N*-formylmethylamino)benzophenone (**3a**) [path A"].

The authors are grateful to Professor Teijiro Kitao, Associate Professor Masaru Matsuoka, and Dr. Hiroyuki Nakazumi of the University of Osaka Prefecture for useful discussion.

The Synthesis of Partially-protected 2′-Deoxyribonucleotide Dimers by the Selective Phosphorylation of Stannylated Nucleosides[1)]

Masajiro KAWANA,* and Hiroyoshi KUZUHARA
Riken (The Institute of Physical and Chemical Research), Wako-shi, Saitama 351-01
(Received June 30, 1984)

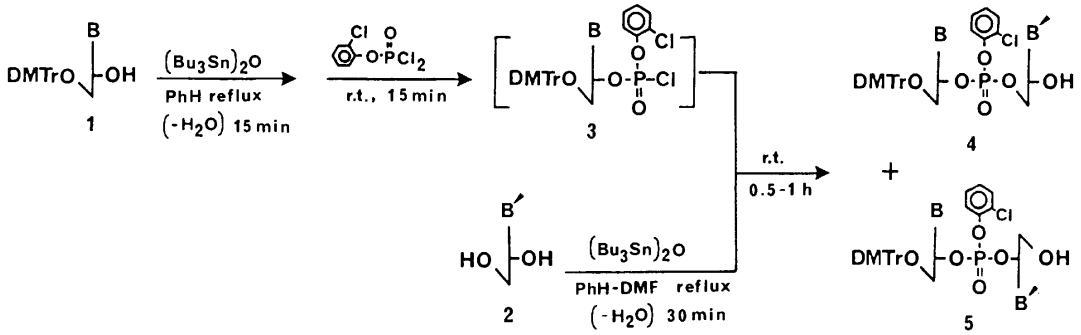
A new method for the synthesis of the title compounds is described. The activation of the hydroxyl moieties of 5′-*O*-dimethoxytrityl and 3′,5′-*unprotected* 2′-deoxyribonucleosides, which were appropriately protected on their base residues, was done with bis(tributyltin) oxide in separate flasks. The resulting stannylated nucleosides were coupled with 2-chlorophenyl phosphorodichloridate to form the dimers with 3′→5′ internucleotide linkages in yields of more than 71%, along with the corresponding 3′→3′ isomers in yields of less than 10%. The method of Cashion *et al.* was also evaluated, in which up-to-date protecting groups were employed.

The formation of internucleotide linkages by the coupling of two nucleoside components which have minimum protecting groups on their hydroxyl functions is, in principle, very attractive for the rapid synthesis of the nucleotide dimers that have been useful for the preparation of oligonucleotides of defined length and sequence.[2a,b)] Cashion *et al.*[3)] have reported on such method. Thus, 3′→5′ linked 2′-deoxyribonucleotide dimers were synthesized in a one-pot procedure by phosphorylation of 5′-*O*-methoxytritylated nucleosides with 4-chlorophenyl phosphorodi-1,2,4-triazolidate, followed by condensation with 3′-terminal units of 3′,5′-*unprotected* nucleosides: The starting nucleosides were appropriately protected on their base residues. A phosphomonotriazolide intermediate produced in this reaction was activated by the addition of a large amount of 1-methyimidazole. Later, Agarwal *et al.*[4)] reported that triethylammonium benzenesulfonate was also effective for this activation. Even though the 5′-(primary hydroxyl) group of the incoming nucleoside in this coupling reaction is more reactive than its 3′-(secondary hydroxyl) one, there is the possibility that an undesired isomeric dimer with a 3′→3′ internucleotide linkage is produced.

We wish to report herein the evaluation of Cashion's method using up-to-date protecting groups for the synthesis of oligodeoxynucleotides, and our alternative approach to the dimers by the activation of hydroxyl functions with bis(tributyltin) oxide. Recently, metal-mediated phosphorylation by activating the hydroxyl groups in nucleosides has been shown to be useful for the synthesis of deoxyribonucleotides.[5)] The reaction proceeded smoothly without the activation of a phosphotriester intermediate. It is well known that organic tin compounds have been used effectively for the selective activation of hydroxyl groups in ribofuranosides[6)] and glycopyranosides.[7)]

Results and Discussion

We first examined the synthetic reaction of the partially-protected thymidylyl(3′→5′)thymidine (**4a**) (Scheme 1). A mixture of 1 mol equiv of 5′-*O*-dimethoxytritylthymidine (**1a**) and 0.6 mol equiv of bis(tributyltin) oxide in benzene was refluxed for 15 min with an azeotropic removal of water; a clear solution was obtained and no decomposition of the starting nucleoside was observed. Similarly, a mixture of 1.5 mol equiv of thymidine (**2a**) and 0.9 mol equiv of bis(tributyltin) oxide in benzene containing a small amount of *N*,*N*-dimethylformamide (DMF) was treated for 30 min. The stannylated derivative prepared in the first solution was then phosphorylated with 1.4 mol equiv of 2-chlorophenyl phosphorodichloridate at room temperature. The reaction was completed within 15 min, as judged by its TLC analysis; we could detect no formation of a 3′→3′ dimer at this step. To this solution was added the second solution containing the incoming nucleoside. The coupling reaction was over



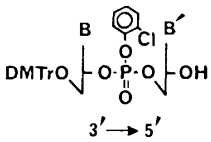
BB′=TT (**a** series), CT, AT, TC, AC, or TA.
T=thymin-1-yl; C=4-*N*-benzoylcytosin-1-yl; A=6-*N*-benzoyladenin-9-yl; DMTr=4,4′-dimethoxytrityl.

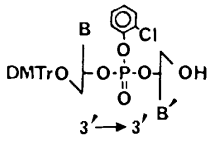
Scheme 1.

at room temperature in 30 min. Evaporation of the benzene followed by chromatography gave **4a** in a 94% yield (93% purity), while the 3′→3′ dimer (**5a**) was formed in a yield of less than 3%. These yields were not appreciably changed, when the amount of the tin compound required for the activation of **2a** was increased to 1.5 mol equiv, which was enough to derivatize its 3′ and 5′-hydroxyl groups into their stannylated functions (Table 2, the second line).

On the other hand, according to the slightly modified procedure of Cashion *et al.* using the same protecting groups as ours, **4a** was prepared in a 73% yield, while a large amount (15%) of **5a** was also isolated. The ^{1}H NMR spectrum of **4a** prepared by this procedure was identical with that from ours except difference in the intensity of signals between two diastereoisomers due to the chirality of the phosphorous triester. The 3′→5′ dimer could easily be distinguished from its 3′→3′ isomer by means of their TLC and ^{1}H NMR spectroscopic analyses (Tables 2 and 3). These analyses also showed that **4a** from our procedure contained a very small amount (less than 3 mol%) of an unidentified tin compound,[8] which could not be excluded without loss of the desired dimer. However, it seemed that this contamination did not interfere with further reaction.[9]

Table 1. The yields(%) of the partially-protected nucleotide dimers





BB′ [a]	Tin method[b] 3′→5′	Tin method[b] 3′→3′	Triazolide method[b] 3′→5′	Triazolide method[b] 3′→3′
TT	94	<3	73 (92) [c]	15
CT	81	6	59	9
AT	76	<3	59	12
TC	77	7	57 (90) [c]	20
AC	71	10	50	16
TA	75	<3	66 (90) [c]	7

a) T=thymin-1-yl; C=4-*N*-benzoylcytosin-1-yl; A=6-*N*-benzoyladenin-9-yl; DMTr=4,4′dimethoxytrityl. b) The dimers were obtained as foams, which were dried at room temperature over diphosphorus pentaoxide *in vacuo* for 4 h; the purity of the 3′→5′ dimers was grater than 90%, as judged by their ^{1}H NMR spectroscopic assay. c) The value in the parentheses is the original data of Cashion *et al.* (Ref. 3) with the following protecting groups: 4-Chlorophenyl for the phosphate; 4-methoxytrityl for the 5′-hydroxyl group; anisoyl for the cytosine residue; benzoyl for the adenine residue. No data for the corresponding 3′→3′ isomers are described in their paper.

Our method was successfully applied to the synthesis of five partially-protected dinucleotides of d(CT), d(AT), d(TC), d(AC), and d(TA) in yields of more than 71%. Both results from the procedure of Cashion *et al.* and ours are summarized in Table 1. The formation of a relatively large amount of the 3′→3′ dimers was observed in the former procedure. Originally, they have used the 4-chlorophenyl protecting group for the phosphate moiety, instead of the present 2-chlorophenyl group, and have obtained the partially-protected 3′→5′ dimers of d(TT), d(TC), d(TA), and d(AG) in about 90% yields (Table 1). It is considered that subtle changes in the protecting groups at the 5′-position and the base residue (from the original nucleoside to the present one) did not exert an important effect upon the reactivity of the coupling reaction, since the changed moieties are located far from the reaction center. Therefore, it seemed likely that the 2-chlorophenyl group was not suitable for the original procedure, presumably because of its steric reason.

Our method with bis(tributyltin) oxide has improved not only regarding yields of the desired 3′→5′ dimers, but also regarding selectivity of the coupling reaction with the 3′,5′-unprotected nucleosides as far as the six dimers are concerned. However, the synthetic reactions for ten other possible dimers still have problems to be solved. There are mainly due to the lower reactivity of the phosphorochloridate intermediates (**3**) with incoming stannylated nucleosides.

a) For the abbreviations and protecting groups of the dimers, see the footnote in the Table 1. b) Used for the 5′-protected component. c) Used for the 3′,5′-unprotected component. d) See the Experimental section. e) TLC on silica gel with chloroform-methanol (9:1). Broad spots due to the diastereoisomers were observed.

Experimental

The ^{1}H NMR spectra were recorded on a JEOL JNM-GX 400 spectrometer, with tetramethylsilane as the internal standard. Merck silica gel GF_{254} was used for TLC, and the compounds were detected by heating after spraying them with a methanol-sulfuric acid-4-methoxybenzaldehyde mixture (85:15:5, v/v) or 5% ethanolic solution of molybdophosphoric acid. Merck silica gel 60 (0.063—0.29 mm) was utilized for column chromatography.

The protected nucleosides were prepared according to known procedures.[10] Bis(tributyltin) oxide and 1-methylimidazole, as well as 4-chlorophenyl phosphorodichloridate and 1*H*-1,2,4-triazole, were purchased from Tokyokasei Co., Ltd. (Tokyo, Japan) and Dojindo Lab. (Kumamoto, Japan), respectively.

The General Procedure for the Synthesis of Partially-protected 2'-Deoxyribonucleotide Dimers. Some of the results and reaction conditions are described in Tables 1 and 2, while the ^{1}H NMR spectral data are summarized in Table 3.

(A) The Method with Bis(tributyltin) Oxide. A mixture of 5'-*O*-(4,4'-dimethoxytrityl)nucleoside (0.5 mmol) and bis(tributyltin) oxide (0.3—0.5 mmol) in benzene (20 ml) was refluxed at 110 °C (bath temperature) for 15 min with azeotropic removal of water by means of a Dean-Stark apparatus. The resulting solution was concentrated to *ca.* 5 ml (solution A). Similarly, a mixture of 3',5'-unprotected nucleoside (0.75 mmol) and bis(tributyltin) oxide (0.45—0.75 mmol) in benzene (20 ml) and dry DMF (1—2 ml) was refluxed at 110 °C (bath temperature) for 30 min with a water trap. The resulting solution was concentrated to *ca.* 5 ml (solution B). To solution A was added a solution of 2-chlorophenyl phosphorodichloridate[11] (0.6—0.7 mmol) in dry benzene (1 ml) at room temperature under an atmosphere of dry nitrogen. The solution was stirred for *ca.* 15 min. Solution B was then added at room temperature, and the mixture was stirred for 0.5—1 h. Dry pyridine (0.2 ml) was added, and the benzene was then removed at room temperature *in vacuo*. The residue was chromatographed on a silica-gel (65 ml) column made up in benzene-ethyl acetate-pyridine (20:20:1). The tin compounds were first eluted successively with the same solvent system (150 ml) and benzene-ethyl acetate-methanol (20:20:1, 130 ml), and the dimers were then eluted with the latter solvent system (5:5:0.8—5:5:1). Under these conditions for the chromatography, the isolated 3'→5' dimers of d(AT) and d(AC) were still contaminated with a small amount of the starting 3',5'-unprotected nucleosides. The thymidine in the former was removed by washing a chloroform solution of the dimer with 0.5 M† phosphate buffer (KH_2PO_4-K_2HPO_4, pH 5.0), and 4-*N*-benzoyl-2'-deoxycytidine in the latter was taken off by means of rechromatography on a silica-gel (20 ml) column with chloroform-methanol (95:5).

(B) The Slightly Modified Method of Cashion *et al.*[3] The nucleosides used in this procedure had been dried by means of azeotropic distillation with dry pyridine.

To a solution of 1*H*-1,2,4-triazole (2.8 mmol, 4 equiv) and triethylamine (2.8 mmol, 4 equiv) in dry pyridine (4 ml) there was added 2-chlorophenyl phosphorodichloridate (0.84 mmol, 1.2 equiv) at room temperature with stirring under an atmosphere of dry nitrogen. After 3 min, 1-methylimidazole (11.2 mmol, 16 equiv) was added, and the stirring was continued for another 5 min. To this mixture was added a solution of 5'-*O*-(4,4'-dimethoxytrityl)nucleoside (0.7 mmol, 1 equiv) in dry pyridine (2.5 ml) at room temperature. After the mixture had been stirred for 30 min, a solution of the 3',5'-unprotected nucleoside (1.4 mmol, 2 equiv) in dry pyridine (3 ml) was added. In the case of the deoxycytidine derivative, a mixture of dry pyridine (3 ml) and dry DMF (2 ml) was used. The mixture was stirred at room temperature for 4—5 h, quenched with 50% aqueous pyridine, and diluted with chloroform (100 ml). The mixture was washed, successively, with 0.5M phosphate buffer (KH_2PO_4-K_2HPO_4, pH 5.0, 30 ml×2) and brine (30 ml), dried over magnesium sulfate, and concentrated. The pyridine was removed below 45 °C *in vacuo* by co-evaporation with toluene. The residue was chromatographed on a silica-gel (100 ml) column with chloroform-methanol (97:3→9:1) to give the dimers.

(Received December 3, 1983)

Synopsis. The conformational equilibria of 1,2-dichloroethane and 1,2-dibromoethane have been investigated through a study of the pressure and temperature dependences of these materials in pure liquid states. The volume changes estimated here under a trans-gauche transformation of 1,2-dichloroethane and 1,2-dibromoethane are -2.7 ± 0.4 and -5.2 ± 0.5 cm³/mol, respectively.

Many compounds, as mixtures of conformers, have vibrational modes characteristic to each conformer. Measurements of the quantitative intensity of certain vibrations as a function of the variation in pressure and temperature provided volume and enthalpy differences between the conformers.

In the present work, the enthalpy and volume differences between the trans and gauche conformers of 1,2-dichloroethane and 1,2-dibromoethane in a neat liquid state were determined by means of Raman spectroscopy. The trans conformer of 1,2-dichloroethane and 1,2-dibromoethane has one Raman-active C–X (X= halogene) stretching vibration (A_g species) at 754 cm^{-1} and 658 cm^{-1}, respectively. The gauche form exhibited two bands which were assigned to the symmetric and antisymmetric stretching vibrations, respectively (655 cm^{-1} and 678 cm^{-1} for 1,2-dichloroethane and 522 cm^{-1} and 588 cm^{-1} for 1,2-dibromoethane).[1,2]

The Raman spectra under high pressure were recorded using a Laser Raman Spectrometer consisting of an argon-ion laser (NEC, GLG 3200, 2W) and a Spec 1403 double monochromater. The high-pressure Raman cell used is shown in Fig. 1. This high-pressure optical cell with three quartz glass windows (10× 10 mmϕ) is made of stainless steel, SUS 630 (Hitachi PSL stainless steel). The cell is similar to that used by Taniguchi *et al.*[3] Sample liquids were inserted directly into the cell and compressed hydrostatically by a piston (Hand pump. UP-21, Rikenkiki Co., Ltd.) connected to a intensifier (Model 15770-1, manufactured by Haskel Co., Ltd.). The pressure was measured using a Heise precision Bourdon-type guage (Heise Guage, Model CM, manufactured by Dresser Co., Ltd.). This guage works well up to 7.0×10^8 Pa, with a scale graduated to 5×10^5 Pa. The measurements involving pressure effects were carried out at room temperature (about 298 K) for 1,2-dichloroethane, but at 323 K for 1,2-dibromoethane since 1,2-dibromoethane solidifies at about 7×10^7 Pa at room temperature. The spectra were recorded at intervals of about 2.5×10^7 Pa. The temperature dependence of the Raman spectra was also measured at atmospheric pressure. Temperatures ranged from 292 to 363 K. A variable-temperature cell of the Harney-Miller type was used. The spectra were recorded three to five times at each temperature and pressure. The integrated intensities of each band were determined by weighting five Xerox copies of the spectral charts.

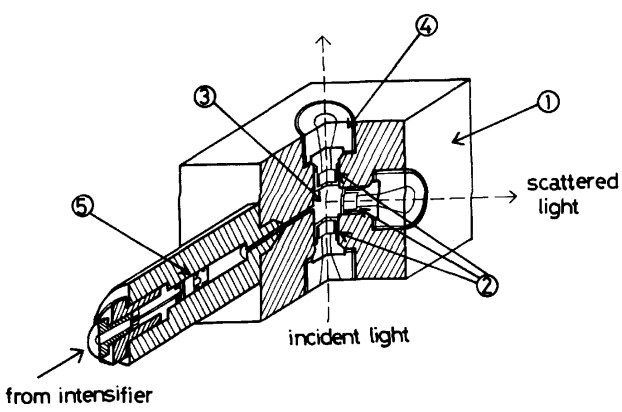

Fig. 1. High pressure optical cell.
1: Pressure bomb, 2: Quartz glass winodw, 3: Sample room, 4: Plug, 5: Piston.

The ratios of the sum of the integrated intensities of the two C–X stretching bands of the gauche form (I_g) to the intensity of the C–X stretching band of the trans form (I_t) were obtained as a function of temperature and pressure.

The enthalpy and volume differences between the two conformers can be estimated by the following equations.

$$\Delta H = -8.31 \times \left(\frac{\partial \ln [I_g/I_t]}{\partial \ln [1/T]}\right)_P \quad \text{[J/mol]} \qquad (1)$$

$$\Delta V = -8.21 \times 10^6 T\left(\frac{\partial \ln [I_g/I_t]}{\partial P}\right)_T \quad \text{[cm³/mol].} \qquad (2)$$

Figure 2 shows $\ln[I_g/I_t]$ *vs.* P plot for 1,2-dichloroethane. The open circles indicate the paralell components and the solid ones are those for the perpendicular components, using 90° scattering and linearly polarized light. As is seen in Fig. 2, a linear relationship was obtained within the experimental error and the slopes for different polarization components coincide with each other. The volume changes obtained here for the trans-gauche transformation of 1,2-dichloroethane and 1,2-dibromoethane are -2.7 ± 0.4 and -5.2 ± 0.5 cm³/mol, respectively. The enthalpy differences of 1,2-dichloroethane and 1,2-dibromoethane are 0.0 and 3.6 ± 0.6 kJ/mol, respectively and are in good agreement with those reported previously.[4–6]

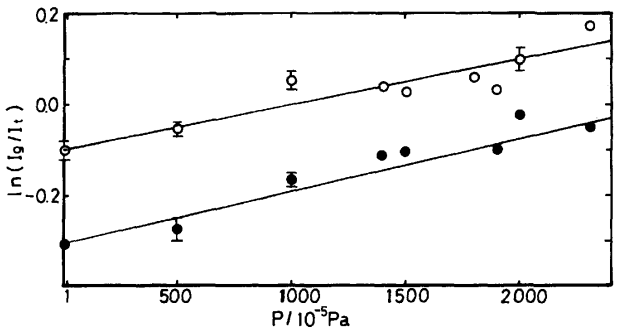

Fig. 2. Relationship between the logarithmic ratio of the integrated intensities of C–Cl stretching bands of *gauche-* and *trans-* 1,2-dichloroethane against the pressure at room temperature.
○: Parallel scattered light, ●: polarized scattered light.

If we assume that $V=M/d$, where d is the bulk density of liquid, the volume change ratios, $\Delta V/V$'s are $-3.4\pm0.5\%$ for 1,2-dichloroethane and $-6.0\pm0.6\%$ for 1,2-dibromoethane. The value of 1,2-dibromoethane is in good agreement with that obtained by ultrasonic work,[7] but that of 1,2-dichloroethane is about a half of the one obtained by their method.[8] At this stage, the discrepancy can not be interpreted.

Devaure and Lascombe,[9] starting from a thermodynamical consideration, derived the following equation for the relation between the enthalpy and volume differences of the conformational equilibria in liquids.

$$\Delta H_{liq} - \Delta H_{gas} = RT^2\left(\frac{\partial f}{\partial T}\right)_\rho + \Delta V_{liq}\frac{\alpha}{\beta}T \qquad (3)$$

where α and β are the expansion coefficient and isothermal compressibility, respectively and f is $\ln[K/K_0]$, in which K is the equilibrium constant in liquid state and K_0 in gaseous state. They claimed that the first term in Eq. 3 is negligible, as predicted by Pratt-Chandler's theory.[10]

The enthalpy differences of the trans-gauche transformation of 1,2-dichloroethane and 1,2-dibromoethane in a gaseous state, ΔH_{gas}, have been found to be 5.10 and 6.94 kJ/mol (on the average),[4-6] respectively. We can estimate the left hand side of Eq. 3, $\Delta=\Delta H_{liq}-\Delta H_{gas}$, to be -5.10 and -3.34 kJ/mol for 1,2-dichloroethane and 1,2-dibromoethane, respectively. The second term of the right hand side of Eq. 3 can also be calculated, from data on thermal-expansion coefficients[11] and isothermal compressibilities (where isothermal compressibility was calculated from the data of adiabatic compressibility,[12] β_s, heat capacity,[13] C_p, and molar volume, V using the equation of $\beta=\beta_s+\frac{TV\alpha^2}{C_p}$). The values of $\Delta V_{liq}\frac{\alpha}{\beta}T$ were -1.15 and -2.12 kJ/mol for 1,2-dichloroethane and 1,2-dibromoethane, respectively. Comparing the values of Δ with $\Delta V_{liq}\frac{\alpha}{\beta}T$, the first term in the right hand side of Eq. 3 can not be neglected in comparison with the second term, at least in this case, even if taking into account of the experimental errors.

The authors should like to express their appreciation to Prof. Y. Taniguchi of Ritsumeikan University for advices in designing the high pressure optical cell.

Hydrogenation of 3-Ethoxy-1-propene Catalyzed by Supported Nickel Catalysts

Hiromi MATSUHASHI and Hideshi HATTORI*
Department of Chemistry, Faculty of Science, Hokkaido University Sapporo 060
(Received March 15, 1984)

Synopsis Nickel catalysts supported on different kinds of metal oxides were prepared to search for active catalysts for 3-ethoxy-1-propene hydrogenation. Ni/ThO_2 and Ni/SiO_2–Al_2O_3 catalysts exhibited high activity and selectivity for 1-ethoxypropane, while Ni/MgO, Ni/CaO, and Ni/La_2O_3 catalysts preferentially catalyzed double bond migration to 1-ethoxy-1-propene which undergo hydrogenation with difficulty.

In contrast to extensive studies of hydrogenation of olefins, less attention has been given to hydrogenation of unsaturated compounds containing hetero atoms. We have reported that for the hydrogenation of unsaturated compounds containing nitrogen the activities of nickel catalysts varied considerably with the type of support and the support acted as one function in bifunctional catalysis.[1)]

For unsaturated compounds containing oxygen, hydrogenation of allyl alcohols has been studied with heterogeneous catalysts to some extent.[2)] However, hydrogenation of allyl ethers has been studied only with Raney Ni[3)] and NiB.[4)] The present study was undertaken to understand more about hydrogenation of allyl ethers on supported Ni catalysts. Ten kinds of metal oxides were selected as supports for Ni, and used for hydrogenation of 3-ethoxy-1-propene. It was found that the Ni catalysts supported on ThO_2 and SiO_2–Al_2O_3 were highly active and selective.

Supported Ni catalysts were prepared by an impregnation method. The metal oxides used as support, and their surface areas, were MgO (84 m^2/g), CaO (16 m^2/g), La_2O_3 (43 m^2/g), ThO_2 (42 m^2/g), ZrO_2 (65 m^2/g), TiO_2 (85 m^2/g), Al_2O_3 (227 m^2/g), SiO_2 (333 m^2/g), and SiO_2–Al_2O_3 (278 m^2/g). Prior to impregnation, there metal oxides were calcined at 773 K in air for 6 h. The metal oxides were suspended in aqueous nickel nitrate, and the water was evaporated to dryness over a water bath. The nickel nitrate on the metal oxides was then decomposed at 773 K in air for 3 h. Prior to the reaction, the catalysts were reduced with hydrogen at 773 K. The Ni content was 9.1—9.2 wt% for all catalysts except Ni/Al_2O_3. The Ni/Al_2O_3 contained 10 wt% Ni.

A greaseless closed recirculation reactor was used for carrying out the reaction. A mixture of 1.3 kPa 3-ethoxy-1-propene and 2.6 kPa hydrogen was allowed to react with *ca.* 100 mg of catalyst (24—32 mesh grain) at 273 K or 323 K. The products were analyzed by GLC. Identification was by NMR for separately collected products.

The amount of hydrogen adsorbed on catalysts was measured volumetrically at 273 K. The saturated amounts of hydrogen were calculated by applying the adsorption isotherm to the Langumuir equation for dissociative adsorption.

Time dependences of the composition in the reaction are shown in Fig. 1 for Ni/Al_2O_3 and in Fig. 2 for Ni/ThO_2 and Ni/SiO_2–Al_2O_3. Over Ni/Al_2O_3, 3-ethoxy-1-propene underwent both hydrogenation to 1-ethoxypropane and double bond migration to (*E*)- and (*Z*)-1-ethoxy-1-propene when the reaction was carried out at 273 K. 3-Ethoxy-1-propene disappeared after 240 min. As the reaction temperature was raised to 323 K, 1-ethoxy-1-propene underwent appreciable hydrogenation. This feature of the time dependence was commonly observed for all catalysts except for Ni/SiO_2–Al_2O_3, though the relative rate of hydrogenation to that of double bond migration varied with the type of catalyst. For instance, over Ni/La_2O_3, the double bond migration was very fast as compared with hydrogenation. Over Ni/ThO_2, hydrogenation was

Reaction temperature; 273 K; reaction time; 60 min.

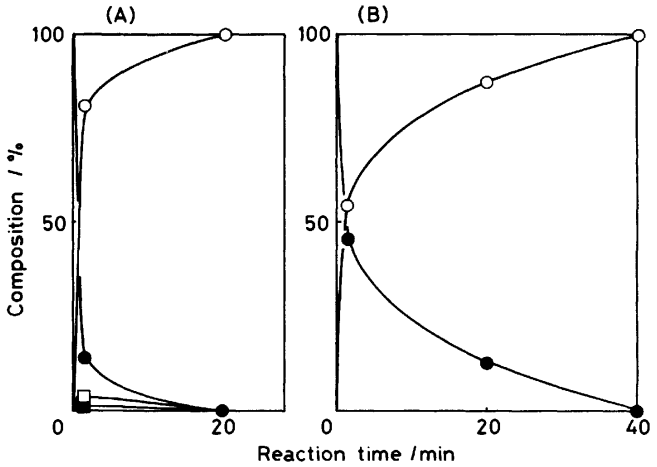

Fig. 2. Time dependences of the composition in the hydrogenation of 3-ethyoxy-1-propene over Ni/ThO_2 (A) and Ni/SiO_2–Al_2O_3 (B).
○: 1-Ethyoxypropane, ●: Ethyoxy-1-propene, □: (*Z*)-1-Ethyoxy-1-propene, ■: (*E*)-1-Ethyoxy-1-propene.

complete in 20 min, and the amount of 1-ethoxy-1-propene formed was very small as shown in Fig. 2(A). The characteristic feature with Ni/SiO_2–Al_2O_3 is seen in Fig. 2(B); double bond migration to 1-ethoxy-1-propene did not occur.

The composition of the products after 60 min when reactions were carried out at 273 K over *ca.* 100 mg of catalyst samples are summarized in Table 1. Other products such as ethanol and propane were not detected. The amounts of hydrogen adsorbed are also included. The Ni/ThO_2 and Ni/SiO_2–Al_2O_3 exhibited high activity; giving 100% hydrogenated product in 60 min. In particular, the Ni/ThO_2 gave 100% hydrogenated product even in 20 min. The hydrogenation activities were low for the catalysts other than Ni/ThO_2 and Ni/SiO_2–Al_2O_3. With Ni/MgO, Ni/CaO, and Ni/La_2O_3, large amounts of 1-ethoxy-1-propene resulted from the double bond migration. 1-Ethoxy-1-propene undergoes hydrogenation at a much slower rate than 3-ethoxy-1-propene does. To obtain a faster hydrogenation rate, catalysts are desirable that do not catalyze the double bond migration of 3-ethoxy-1-propene. The low hydrogenation activities of Ni/MgO, Ni/CaO, and Ni/La_2O_3 are considered to be due to the high activity of the supports for double bond migration.[5]

The active catalysts, Ni/ThO_2 and Ni/SiO_2–Al_2O_3, adsorbed relatively large amount of hydrogen. Although Ni/SiO_2 adsorbed large amounts of hydrogen but showed low activity, a capability of adsorption of a large amount of hydrogen may be required for a catalyst to be active for hydrogenation.

Heats of Solution of Bolaform Electrolytes in Water. II. Polymethylenebis(trimethylammonium) Dibromides

Kunio TAMAKI* and Rie FURUYA
Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama 236
(Received May 21, 1984)

Synopsis. The heats of solution of polymethylenebis(trimethylammonium) dibromides $[(CH_3)_3N(CH_2)_nN(CH_3)_3]Br_2$ (n=3—6, 8, 10, and 12) and alkyltrimethylammonium bromides $C_nH_{2n+1}N(CH_3)_3Br$ (n=2—6) in water were measured at 15, 25, and 35 °C. The hydrophobic character of the polymethylene groups was compared with that of alkyl groups on the basis of the changes in the heat capacity for dissolution, which were obtained from the relation between the heats of solution and the temperature.

In a previous paper,[1] the heats of solution for two series of bolaform electrolytes, polymethylenediammonium dichlorides and disodium polymethylene disulfates, in water were reported, and hydrophobic character of polymethylene groups in bolaform electrolytes was compared with that of alkyl groups for corresponding monovalent electrolytes, alkylammonium chlorides and sodium alkyl sulfates, respectively. The present paper is the extension of the previous work, and the heats of solution for a series of polymethylenebis(trimethylammonium) dibromides ($[(CH_3)_3N(CH_2)_nN(CH_3)_3]Br_2$, which will be abbreviated as, MeC_nMe) and for comparison for a series of alkyltrimethylammonium bromides ($C_nH_{2n+1}N(CH_3)_3Br$, which will be abbreviated as, C_nMe) in water will be reported. The changes in the heat capacity for dissolution in water, $\Delta C_p°$, for MeC_nMe and C_nMe were obtained from the relation between the heats of solution and the temperature, and the hydrophobic character of the polymethylene groups in MeC_nMe was compared with that of the alkyl group in C_nMe.

Experimental

Materials. MeC_nMe were prepared by the reactions of the α,ω-dibromoalkane with an excess of trimethylamine in ethanol.[3] The salts, except for $MeC_{12}Me$, were purified several times by recrystallization from ethanol. $MeC_{12}Me$ was recrystallized from an ethyl acetate–ethanol solution. C_nMe were prepared by the reactions of alkyl bromides with an excess of trimethylamine in ethanol. The salts were recrystallized several times from ethanol. All the salts were dried *in vacuo* at room temperature for several days, and were analyzed for bromide ion by argentometric titration. All the salts were found to have a purity greater than 99.6%. Water was triply distilled.

Calorimetry. The heats of solution were measured by a method similar to that described in previous papers.[1,2]

Results and Discussion

Heat-of-solution measurements have been carried out over the concentration range of 8×10^{-4}—3×10^{-3} mol dm^{-3}. In this concentration range, any dependence of the heats of solution on the concentration is within the limit of experimental error, so the average of three or more measurements was taken as the heats of solution at infinite dilution, $\Delta H_s°$. The $\Delta H_s°$ values of MeC_nMe and C_nMe are listed in Table 1. The $\Delta H_s°$ values were used to calculate the changes in the heat capacity, $\Delta C_p°$, in going from the pure compounds to an aqueous solution at infinite dilution:

$$\Delta C_p° = d\Delta H_s°/dT,$$

where T is the temperature. The magnitude and sign of $\Delta C_p°$ can be taken as relative measure of the solute-solvent interaction.[4-6] The $\Delta C_p°$ values of simple salts indicate negative values, whereas the $\Delta C_p°$ values of hydrophobic solutes indicate positive values.

Table 1. Heats of solution and heat-capacity change

n	$\Delta H_s°$/kJ mol^{-1}			$\Delta C_p°$/J K^{-1} mol^{-1}
	15 °C	25 °C	35 °C	25 °C
	$C_nH_{2n+1}N(CH_3)_3Br$			
2	17.11	17.15	16.95	0
3	9.43	10.12	10.77	67
4	9.65	10.54	11.49	92
5	18.44	20.47	22.40	198
6	11.06	13.59	16.31	262
	$[(CH_3)_3N(CH_2)_nN(CH_3)_3]Br_2$			
3	21.70	19.97	18.47	−162
4	25.84	24.87	24.00	−92
5	27.05	26.77	26.76	−14
6	31.01	31.56	32.07	53
8	27.14	28.94	30.58	172
10	24.87	27.91	30.80	297
12	38.04	42.15	46.69	433

The $\Delta C_p°$ values obtained at 25 °C are listed in Table 1. As may be seen in Table 1, for the MeC_nMe series, MeC_3Me, MeC_4Me, and MeC_5Me show the negative $\Delta C_p°$ values. Therefore, the electrostrictive hydration due to the charge-bearing groups $-N(CH_3)_3^+$ may interfere with the interaction of the hydrophobic $-(CH_2)_n-$ group of the lower homologs with water. In the case of MeC_6Me and larger MeC_nMe homologs, the $\Delta C_p°$ values become positive and they increase with an increase in the chain length. They are classified as hydrophobic structure-makers.

With the C_nMe series, the $\Delta C_p°$ value for tetramethylammonium bromide ($(CH_3)_4NBr$, abbreviated as C_1Me in this paper) was reported to be −42 J K^{-1} mol^{-1} by Sarma, Mohanty, and Ahluwalia[7] and −47 J K^{-1} mol^{-1} by Arnett and Campion.[4] Table 1 indicates that the $\Delta H_s°$ values of C_2Me are virtually independent of the temperature, for which electro-

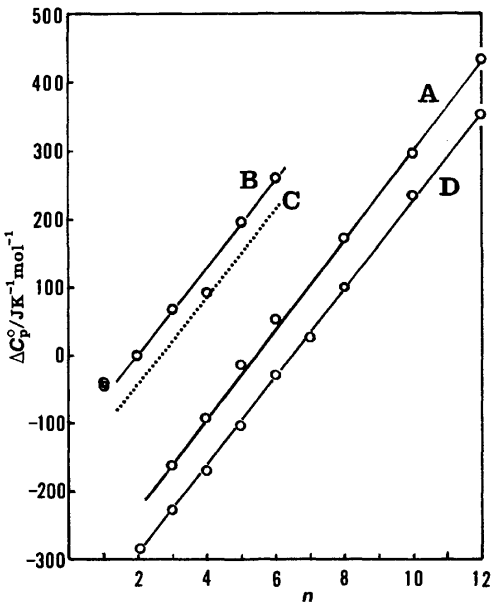

Fig. 1. Plot of ΔC_p° against n. A: $[(CH_3)_3N(CH_2)_n$-$N(CH_3)_3]Br_2$, B: $C_nH_{2n+1}N(CH_3)_3Br$, C: $-(CH_2)_n$-$N(CH_3)_3Br$, D: $[H_3N(CH_2)_nNH_3]Cl_2$.

strictive and hydrophobic hydration balance each other. In the case of C_3Me and higher homologs, the ΔC_p° values become positive, and they are hydrophobic structure-makers.

The ΔC_p° values are plotted against the number of carbon atoms, n, in the polymethylene or alkyl group for MeC_nMe and C_nMe in Fig. 1. If we take one-half the ΔC_p° values for MeC_nMe, the ΔC_p° values for a series of $-(CH_2)_nN(CH_3)_3Br$ can be estimated. The ΔC_p° *vs.* n relation thus obtained is plotted as a dotted line in Fig. 1. It is found that for the same number of n, the ΔC_p° values for $-(CH_2)_nN(CH_3)_3Br$ are lower than those for C_nMe. With the same ΔC_p° values, the difference in n between the two ΔC_p°-*vs.*-n lines for C_nMe and $-(CH_2)_nN(CH_3)_3Br$ corresponds to about 0.8. Therefore, the hydrophobic character of the polymethylene chain in MeC_nMe is considerably diminished below that of alkyl chain in monovalent C_nMe salts with the same number of n.

In Fig. 1, a plot of the ΔC_p° values against n for polymethylenediammonium dichlorides reported in a previous paper[1] is also included. For the same number of n, the ΔC_p° values for MeC_nMe are larger by about 75 J K^{-1} mol^{-1} than those for polymethylenediammonium dichlorides. This may be mainly attributed to the hydrophobic effect of the methyl groups attached to the two terminal nitrogen atoms, because the difference in ΔC_p° values due to the variation in halide ions for the same cations is very small.[6]

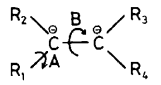
Internal Rotation of Tetraphenylethylene Dianion as Studied by H-1 and C-13 NMR

Masaru MORIKAWA, Hideki MATSUI, Akihiro YOSHINO, Kensuke TAKAHASHI,* and Goh MIYAJIMA†
Department of Industrial Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
†*Naka Works, Hitachi Ltd., Ichige-cho 882, Katsuta-shi, Ibaraki 312*
(Received May 25, 1984)

Synopsis. The line-shape analyses of the ^{1}H NMR spectra of the title anion have been made by means of a program of DNMR3. The thermodynamical parameters thus obtained are discussed in terms of counterions and other additives.

The ^{1}H NMR spectra of the title dianion has been reported previously.[1] A pictorial description of the dianion studied is shown in Scheme 1. As shown in the scheme, two internal rotations, A and B, exist in the carbanion. This study aims to obtain the thermodynamical parameters of these internal rotations. Our preliminary results have previously been reported.[2]



$R_1=R_2=R_3=R_4=C_6H_5$

Scheme 1.

Experimental

The strarting material (Tetraphenylethylene) was a commercial one and was used without further purification except for degassing by repetitive melting and freezing in a vacuum. The procedures for preparing the carbanion were the same as those previously reported.[1]

The H-1 and C-13 NMR measurements were carried out on a Hitachi R-20B spectrometer at 60 MHz and on a Hitachi R-900 FT spectrometer at 22.6 MHz. The sample concentration was about 1.0 mol dm^{-3} in the case of the potassium salt in THF-d_8. The H-1 and C-13 chemical shifts were evaluated with the high-field solvent peaks of THF-d_7 and -d_8 used as internal references. They were taken to be 1.75 and 25.2 ppm respectively with respect to TMS.

The temperature-dependent H-1 NMR spectra were analyzed by using the program of DNMR3 (QCPE No. 165).[3] In the original program, the maximum dimension of the B submatrices has been fixed at 48 and the maximum line number, at 136. For the analysis of the present material, it was necessary to expand them to 100 and 210 respectively. The calculations were carried out by a HITAC-8400 computer system installed in this Institute.

Results and Discussion

H-1 and C-13 NMR Spectra. The spectra of the title dianion have been observed at temperatures from 31.5 to −90 °C, with potassium as counterions in THF-d_8. The C_o signals in the temperature-dependent C-13 NMR spectra have decreased in height at −50 °C, been broadened at −60 °C, and clearly split into doublets at −74 °C. The H-1 NMR spectra of the carbanion were analyzed by the LAOCN3 program.[4] The coupling constants and the chemical shifts thus obtained are tabulated in Table 1. The H-1 and C-13 chemical-shift differences at low temperatures are about δ 1.35 and 0.07 for the H_o and H_m, and δ 2.3 and 1.2 for the C_o and C_m, respectively. The comparatively large difference in chemical shift between two H_o peaks can be explained by the ring-current effect of the phenyl groups.[5]

Line-shape Analyses. The temperature-dependent H-1 and C-13 NMR spectra were measured by using the same sample sealed in a 5-mm O.D. tube. Therefore, the C-13 NMR spectra were not suitable for the line-shape analyses because of their low signal-to-noise ratio. However, the proton-decoupled C-13 spectra were so simple that a rough estimate of the two-site exchange problem using a computer program, CLATUX[6] was possible, giving the activation energy of about 34 kJ mol^{-1}. The H-1 NMR line-shape analyses, however, could give a more exact activation energy. The rate constants for the two-site-five-spin exchange problem are given in Table 2 for various temperatures. The calculated and corresponding observed spectra are given in Fig. 1 for three typical temperatures. From the values in Table 2, the thermodynamical parameters tabulated in Table 3 are obtained. The values are compared with those

39.8±1.5	27.1±0.8	37.9±1.5	−25.7±6.6

reported for the phenylmethanide and diphenylmethanide ions.[7-12] The activation energy observed in this study is the smallest value reported thus far. This may be attributed to the fact that the carbanion is sterically inhibited from having the planar structure rather than to its resonance stabilization in the ground state.

Effects of Counterions and Other Additives. The coalescence temperatures of the H_o in the carbanion are affected by the counterions. Several attempts were made to obtain the exact thermodynamical parameters. However, the solubilities of the lithium and sodium salts are too small for us to obtain good line-shaped spectra in THF at low temperatures. Therefore, the line-shaped analyses described above are possible only for the potassium salt. The coalescence temperatures are estimated to be about −40, −55, and −60 °C for the K^+, Na^+, and Li^+ counterions respectively. The temperatures decrease with a decrease in the metal radius and with an increasing proximity of the metal to the active carbon site. The coalescence temperatures can be used to estimate the changes in the free energy of activation for the rotation A in the carbanions using the following equation:

$$\Delta G_c^{\ddagger}=aT_c[9.972+\log(T_c/\Delta\nu_{ab})],$$

where T_c, $\Delta\nu_{ab}$, and a are the coalescence temperature, the chemical-shift difference of two exchanging sites, and a constant of 19.14 J mol^{-1} respectively.[13] In the case of the sodium salt, the $\Delta G_c^{\ddagger}$ value is 43.7 kJ mol^{-1} when the values of T_c and $\Delta\nu_{ab}$ are adopted as *ca.* 218 K and 67 Hz. This value is reasonable as compared with that obtained for the potassium salt (43.9 kJ mol^{-1} at 233.2 K). Hexamethylphosphoric triamide (HMPA) was used to check the effect of other additives, because it has a high dielectric constant. The effect of HMPA caused a rise in the coalescence temperature by about 5 K in the potassium and sodium salts. Therefore, the effect appears as an increase in the activation energy of the rotation A. This is consistent with that observed for diphenylmethanide ions by Olah and Watkins.[12]

Vibrational Distributions of CO^+ (A) Produced from the Charge-transfer Reactions of Ne^+ and He^+ with OCS at Thermal Energy

Hiroshi Sekiya,* Masaharu Tsuji, and Yukio Nishimura
Research Institute of Industrial Science, and Department of Molecular Science and Technology, Graduate School of Engineering Sciences, Kyushu University, Kasuga-shi, Fukuoka 816
(Received June 15, 1984)

Synopsis. The Ne^++OCS and He^++OCS charge-transfer reactions have been studied by emission spectroscopy in a flowing afterglow. The relative vibrational populations of $CO^+(A^2\Pi)$ were determined by observing the $CO^+(A^2\Pi-X^2\Sigma^+)$ emission system produced from the above reactions. The populations decrease approximately exponentially with the vibrational quantum number.

Optical spectroscopic studies on the thermal-energy charge-transfer (CT) reactions between Ne^+ and small molecules are limited,[1,2] although those on the reactions between He^+ and small molecules have been made extensively.[3,4] Previously we have reported on the $CO^+(A^2\Pi-X^2\Sigma^+)$ emission produced from the Ne^++OCS CT reaction in a flowing afterglow.[1] The $CO^+(A\text{-}X)$ emission arises also from the He^++OCS CT reaction.[5] In order to understand the overall CT process, it is important to determine the internal energy state distribution of the products resulting from the thermal-energy CT reactions between rare gas ions and small molecules. In this Note we describe the vibrational distribution of $CO^+(A)$ produced from the Ne^++OCS reaction in comparison with that produced from the He^++OCS reaction. To our knowledge, this is the first report on the vibrational distribution of a product resulting from the Ne^+ CT reaction.

Experimental

The flowing afterglow apparatus is essentially identical to that described previously.[1] Active species of Ne and He were generated in a 2450 MHz microwave discharge. The Ne and He pressures ranged from 80 to 87 Pa (1 Pa=7.5×10^{-3} Torr). Emission spectra were observed on a Nippon Jarrell Ash 1-m monochromator equipped with either a HTV R376 or a HTV R585 photomultiplier. The relative sensitivity of the detection system was calibrated by a halogen lamp.

Results and Discussion

The $CO^+(A\text{-}X)$ emission system was observed in both Ne and He afterglows together with numerous emission systems which have been reported in the earlier papers.[1,5] The $CO^+(A\text{-}X)$ emission systems observed in the above two afterglows arise from the following CT reactions, respectively:

$$Ne^+ + OCS \longrightarrow CO^+(A) + S + Ne,$$
$$CO^+(A) \longrightarrow CO^+(X) + h\nu. \quad (1)$$
$$He^+ + OCS \longrightarrow CO^+(A) + S + He,$$
$$CO^+(A) \longrightarrow CO^+(X) + h\nu. \quad (2)$$

The recombination energies of $Ne^+(^2P_{1/2,3/2})$ are 21.66 and 21.56 eV, while that of the ground-state $He^+(^2S)$ is 24.58 eV.[6] Meanwhile, the calculated minimum energy required for the formation of $CO^+(A)$ from OCS is 19.73 eV, which is obtained on the assumption that sulfur atoms are formed in the ground ^3P state.[7] In Fig. 1 is shown a typical emission spectrum of the $CO^+(A\text{-}X)$ in the He afterglow, where a pulsed modulation system[5,8] was employed to eliminate the emissions due to the $He(2^3S)$+OCS Penning ionization. The $CO^+(B\text{-}A)$ emission has been observed in the $He(2^3S)$+CO Penning ionization.[9] However, no $CO^+(B\text{-}A)$ emission could be identified in the He^++OCS reaction, although weak $CO^+(B\text{-}X)$ emission could be identified.[5] Accordingly, the contribution of the $CO^+(B\text{-}A)$ cascade to the production of $CO^+(A)$ is very small in the He^++OCS reaction. The identified vibrational levels of $CO^+(A)$ range from $v'=0$ to $v'=5$ in the Ne^++OCS reaction[1] and from $v'=0$ to $v'=11$ in the He^+ +OCS reaction. In the Ne^++OCS reaction, as a partner of $CO^+(A)$ for $v'=0$—4, sulfur atoms in the ^3P and ^1D states are energetically possible, while sulfur atoms only in the ^3P state are energetically possible as a partner of $CO^+(A)$ for $v'=5$. On the other hand, in the He^++OCS reaction sulfur atoms in the ^3P, ^1D, and ^1S states are energetically accessible as a partner of $CO^+(A)$ for $v'=0$—11.

The relative vibrational populations were obtained from the emission spectra by means of a procedure reported in the previous paper.[8] The contribution of the vibrational relaxation of $CO^+(A)$ has been examined in the He pressures ranging from 80 to 800 Pa: Little difference has been found between the vibrational populations observed at 80 Pa and those extrapolated to zero He pressure. In the Ne^++OCS reaction, no pressure dependence of the vibrational populations of $CO^+(A)$ could be examined owing to the low intensity of the $CO^+(A\text{-}X)$ emission. We regarded the vibrational distribution of $CO^+(A)$ measured at 80 Pa as an approximate initial distribution in both Ne^++OCS and He^++OCS reactions. The relative vibrational populations of $CO^+(A)$, N_v, thus obtained are shown in Fig. 2. It should be

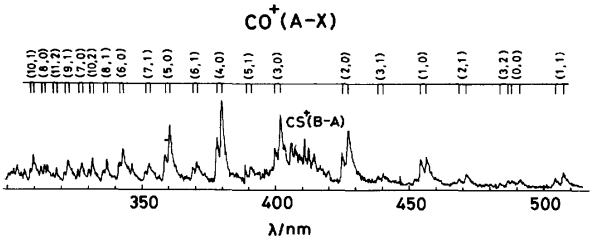

Fig. 1. A typical emission spectrum resulting from the He^++OCS CT reaction in a He afterglow.

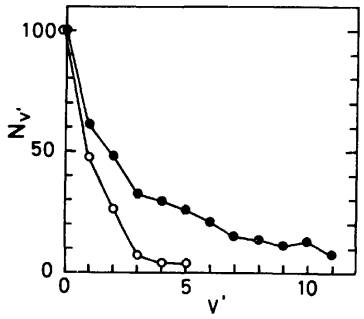

Fig. 2. Relative vibrational distribution of CO^+ (**A**). ○: Produced from the Ne^++OCS reaction, ●: Produced from the He^++OCS reaction.

noted that $N_{v'}$ decreases approximately exponentially with v' not only in the He^++OCS reaction but also in the Ne^++OCS reaction. Assuming a Boltzmann distribution for the vibrational levels, the effective vibrational temperatures are estimated to be 3400±400 K and 10100±1000 K for the Ne^++OCS and He^++OCS reactions, respectively. No photoelectron spectroscopic experiment has been reported on the excited electronic states of OCS^+ lying above 20 eV, which would be optically inaccessible states. The precursor states leading to the $CO^+(A)$ state in the Ne^++OCS and He^++OCS reactions would be optically forbidden multiple-electron-transition states of OCS^+ lying above 20 eV, which have been identified by Carnovale *et al.*[9] through electron-ion coincidence.

Photoinduced Potential Changes across Poly(vinyl chloride)/Crown Ether Membranes. Membrane Potential in the Presence of Alkaline Earth Metal Cations

Jun-ichi ANZAI, Hiroshi SASAKI, Akihiko UENO, and Tetsuo OSA*
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980
(Received June 15, 1984)

Synopsis. The potential change across poly(vinyl chloride)/crown ether membrane was induced by photoirradiation in the presence of alkaline earth metal cations. The photoresponse of the membrane potential depended markedly on the kind and concentration of the cation species, the magnitude of the potential shift lying in the order of $Mg^{2+}>Ca^{2+}\approx Sr^{2+}>Ba^{2+}$.

We[1-3] and Shinkai *et al.*[4-8] have reported independently that the cation binding and transporting properties of azobenzene-modified crown ethers are successfully regulated by photoirradiation. Recently, we have found that the potential across the poly(vinyl chloride) (PVC)/4,4′-bis[3,4-(1,4,7,10,13-pentaoxatridecane-1,13-diyl)benzyloxycarbonyl]azobenzene (**1**) membrane changes reversibly upon alternate UV and visible light irradiation in the presence of alkali metal chloride.[9-11] The photoresponse of the membrane potential has been explicated based on the surface potential changes originating from the enhanced uptake of the alkali metal cation onto the membrane surface by photogenerated *cis*-**1**. The purpose of this note is to describe a different aspect in the photoresponse of the potential across PVC/**1** membrane with alkaline earth metal chloride.

Experimental

Materials. PVC (molecular weight of *ca.* 70000) was purchased from Wako Pure Chemical Industry Ltd. and used without further purification. Dibutyl phthalate (DBP), tetrahydrofuran (THF), and alkaline earth metal chloride are of extra pure reagent grade. The synthetic procedure and analytical data of **1** were reported previously.[2,3]

Membrane Preparation. PVC/**1** membrane of *ca.* 0.1 mm thickness was prepared by pouring the mixture of 235 mg of PVC, 0.54 ml of DBP, 1.3 mg of **1**, and 20 ml of THF onto a flat Petri dish (9.2 cm diameter) and allowing the solvent to evaporate.

Membrane Potential Measurement. All measurements were conducted at 25 °C. The composition of the electrochemical cell for the membrane potential measurements was as follows; Hg, Hg_2Cl_2(s)|KCl(sat.)|0.1 mol dm^{-3} $(CH_3)_4NCl$| electrolyte solution (c_1)|PVC/**1** membrane| electrolyte solution (c_2)|0.1 mol dm^{-3} $(CH_3)_4NCl$|KCl(sat.)|Hg_2Cl_2(s), Hg. The electrode in the c_1 compartment was earthed. Photoirradiation was carried out with 500 W xenon lamp with cut-off filters Toshiba UV D-35 and Corning 3-74 to isolate UV ($320\,nm<\lambda<400\,nm$) and visible ($\lambda>410\,nm$) light, respectively.

Results and Discussion

In the previous papers[9-11] we have reported that the membrane potential across PVC/**1** membrane interposed between two alkali metal chloride solutions changes upon photoirradiation. The magnitude and sign of the photoinduced potential shift, $\Delta(\Delta\Phi)$, were dependent on the kind and concentration of the cations, **1** content in the membrane, and the direction from which the membrane was irradiated. The photoresponsive behavior of the membrane potential was explained based on the surface potential change of the membrane, which was caused by the charge density change of the membrane surface through the photoinduced variation in the binding ability of **1** for alkali metal cations. The photoresponse was presumed to arise from the formation of sandwich-type complexes in which *cis*-**1** trapps a cation by its two crown-ether moieties.

Figure 1 illustrates the photoresponse of the membrane potential in the presense of $MgCl_2$. After a steady state potential difference, $\Delta\Phi$, had been reached under dark conditions, a negative shift of the potential was induced upon UV irradiation from the c_2 compartment

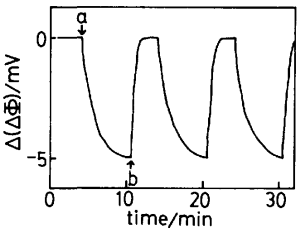

Fig. 1. Photoresponse of the membrane potential upon alternate UV (a) and visible (b) light irradiation. c_1; $[MgCl_2]=1\times10^{-3}$ mol dm^{-3}. c_2; $[MgCl_2]=5\times10^{-1}$ mol dm^{-3}.

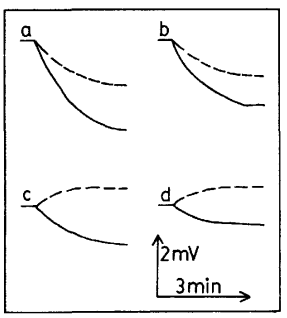

Fig. 2. Effect of the ionic concentration on the photoresponse in the presence of $MgCl_2$. Photoirradiation was conducted from c_1 (----) and c_2 (——) compartment sides. c_1; $[MgCl_2]=1\times10^{-2}$ (a), 1×10^{-1} (b), 5×10^{-1} (c), 1 (d) mol dm^{-3}. c_2; $[MgCl_2]=$ 1 mol dm^{-3}.

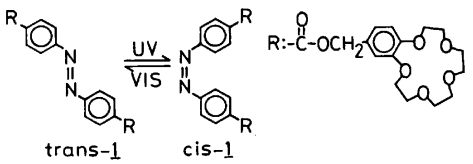
side. About 6 min sufficed to attain a steady state potential under UV light and the initial potential was recovered rapidly by switching the UV light to the visible one. The on-off cycle of the membrane potential was fairly reversible.

The effect of the ionic concentration on the photoresponse of the potential was examined by irradiating the membrane from the direction c_1 or c_2 compartment side. When the membrane was irradiated by UV light from the direction of c_2 compartment, the negative shift of the potential was always induced. The $\Delta(\Delta\Phi)$ values related closely to the ionic concentration in c_1 compartment. Larger $\Delta(\Delta\Phi)$ values were obtained in the case that the concentration gradient between the two solutions was increased. Even when the concentration gradient was zero ($c_1=c_2=1$ mol dm^{-3}), the potential shift was observed. On the other hand, the photoresponse was not simple when the membrane surface facing the compartment with a lower electrolyte concentration (c_1) was exposed to UV light. Under the conditions that the concentration gradient between the two electrolyte solutions was large, the membrane potential shifted to the negative direction (Figs. 2-a and 2-b). On the contrary, the positive shift of the potential was observed when the concentration gradient was small (Fig. 2-c). In the case of $c_1=c_2=1$ mol dm^{-3} (Fig. 2-d), the $\Delta(\Delta\Phi)$ value was equal in magnitude but opposite in sign to that obtained by irradiating from the c_2 side. This photoresponsive behavior was much the same as that observed for alkali metal cations.[9-11] We can explained the phenomena similarly to the case of alkali metal cations, that is, (i) the membrane potential changes are resulting from the fact that the charge density of the membrane surface (*i.e.*, surface potential) is perturbed by the photoinduced change in the binding ability of **1** for cations, (ii) the magnitude of the charge density changes of the membrane surface is determined by both factors of *trans*-**1**/*cis*-**1** ratio at the membrane surface and the ionic concentration in the solution, (iii) the



trans-**1**/*cis*-**1** ratio at one surface of the membrane is different from that of the opposite surface under UV light. The third argument can be the reason why the membrane potential changed even when no concentration gradient existed between the two solutions.

Figure 3 shows the photoresponse for $MgCl_2$, $CaCl_2$, $SrCl_2$, and $BaCl_2$. In the high c_2/c_1 regions, the larger $\Delta(\Delta\Phi)$ values were obtained for all salts. The magnitude of the $\Delta(\Delta\Phi)$ values lies in the order of $MgCl_2>CaCl_2\approx SrCl_2>BaCl_2$. This dependence of $\Delta(\Delta\Phi)$ values on the kind of cation species does not coincide with the order expected from the fitness between each cation and *cis*-**1**; the diameters of Mg^{2+}

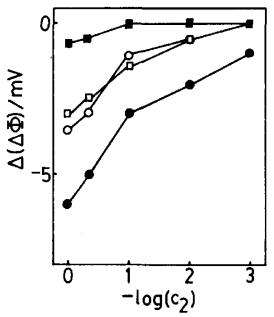


Fig. 3. Effect of the ionic concentration on the potential shift.
c_1; [Metal chloride]$=1\times10^{-3}$ mol dm^{-3}.
■; $BaCl_2$, □; $SrCl_2$, ○; $CaCl_2$, ●; $MgCl_2$.

and Ca^{2+} (1.22 Å and 1.98 Å, respectively) seem too small to form the sandwich-type complex, but the size of Ba^{2+} is appropriate (2.70 Å).[12] The data are incompatible with those obtained for alkali metal cations, where larger $\Delta(\Delta\Phi)$ values were observed for K^+ and Rb^+ which have suitable ionic sizes to form stable sandwich-type complexes with *cis*-**1**. Considering from these facts, any other factors, though not clear in the present stage, may participate in determining the binding ability of **1** for alkaline earth metal cations at the membrane/solution interface.

Thus, it became obvious that the potential across the PVC/**1** membrane interposed between two aqueous alkaline earth metal chloride changed upon photoirradiation in the different manner from that for alkali metal chloride although the factors governing the binding ability of **1** for alkaline earth metal cations at the membrane/solution interface remain equivocal.

(Received January 5, 1984)

Synopsis. The 4-methoxybenzyloxycarbonyl group of 7-[D-2-(4-hydroxyphenyl)-2-(4-methoxybenzyloxycarbonylamino)acetamido]cephalosporanic acid was effectively removed with *p*-toluenesulfonic acid in acetonitrile. The mechanism of the deprotection is discussed and the role of acetonitrile can reasonably be explained in terms of the Ritter reaction.

In a previous report[1] of our screening study, we reported that the 4-methoxybenzyloxycarbonyl group [Z(OMe)] of 7-[D-2-(4-hydroxyphenyl)-2-(4-methoxybenzyloxycarbonylamino)actamido]cephalosporanic acid (**1**) could be successfuly removed by trifluoroacetic acid without adverse effect on the compound. Trifluoroacetic acid is conveniently used in laboratory synthesis, but its use for a large-scale preparation is undesirable because of its irritation on mucous membrane.

We now report a practical deprotection of the Z(OMe) group of **1** which has given a solution to this problem. The deprotection is accomplished by treatment of **1** with *p*-toluenesulfonic acid or methanesulfonic acid in

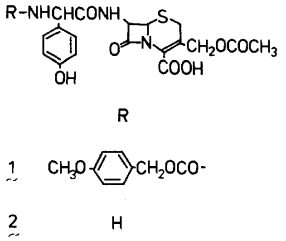

Table 1. Conditions for removal of Z(OMe) group and ratios of **1** and **2**

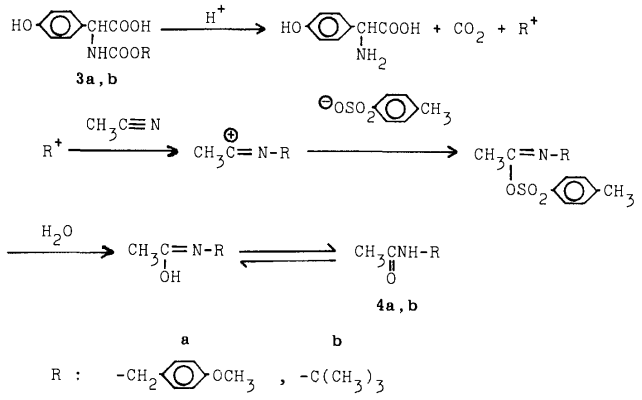
acetonitrile. The deprotection extremely depended on the nature of solvents tested and acetonitrile was found to be the most effective solvent (Table 1). Removal of the Z(OMe) group of **1** was completed within 60 min by using two equivalents of *p*-toluenesulfonic acid at 20—25 °C in acetonitrile–acetone (9:1, v/v). Addition of acetone or dioxane to acetonitrile in a small ratio was useful for preventing deposits from separating out of reaction mixtures as the removal reaction proceeded, but their addition in increased ratios slowed down the reaction. The reaction was also slowed down when smaller amounts of *p*-toluenesulfonic acid or lower reaction temperatures were used. Addition of excess water to acetonitrile interfered with the deprotection. Methanesulfonic acid also removed the Z(OMe) group, but a slightly longer reaction time was required than for the use of *p*-toluenesulfonic acid.

The role of acetonitrile was made clear as follows: A treatment of *N*-Z(OMe)-*p*-hydroxyphenylglycine (**3a**) with *p*-toluenesulfonic acid in acetonitrile gave *N*-(4-methoxybenzyl)acetamide (**4a**) in 49% yield as well as *p*-hydroxyphenylglycine *p*-toluenesulfonic acid salt in 93% recovery. This result suggests that the Ritter reaction occurs in this deprotection. Chauvette *et al.*[2] reported that a Boc group was effectively removed in acetonitrile by treatment with *p*-toluenesulfonic acid. But the mechanism was not cleared. A treatment of *N*-Boc-*p*-hydroxyphenylglycine (**3b**) under similar conditions also gave the corresponding acetamide **4b** in 51% yield. In both cases, the role of acetonitrile can reasonably be explained on the basis of the mechanism shown in Scheme 1, although the yields of **4a** and **4b** were not quantitative.



Scheme 1.

This deprotection has successfully been applied to a several-hundred-gram scale preparation of cefpiramide,[3] a new broad-spectrum cephalosporin with antipseudomonal activity.

Although acetonitrile has not been a common solvent in peptide synthesis, this procedure using acetonitrile may be recommended for efficient deprotection of a Z(OMe) or a Boc group.

Experimental

Melting points were determined in open capillary tubes with a Thomas-Hoover Uni-Melt apparatus and are uncorrected. ^{1}H NMR spectra were recorded on a JEOL FX-90Q (90 MHz) spectrometer with TMS used as internal standard; all chemical shifts are reported in δ values. Separation and quantitative analysis were performed with a high performance liquid chromatograph (Model No. ALC/GPL 204, Japan Waters, Ltd.) equipped with a LiChrosorb RP-8 column (10 μm particle size, 30 cm by 4 mm).

Removal of a Z(OMe) Group of 7-[D-2-(4-Hydroxyphenyl)-2-(4-methoxybenzyloxycarbonylamino)acetamido]cephalosporanic Acid (1). A mixture of compound **1**[1] (0.5 g), solvent (5 ml), and *p*-toluenesulfonic acid or methanesulfonic acid was stirred under the conditions given in Table 1. A part of the reaction mixture was sampled and analyzed by HPLC. The mobile phase used was a mixture of 0.01 M (1M=1 mol dm^{-3}) phosphate buffer (pH 6.8) and MeOH (6:4 by volume). The ratios of **1** and **2** in Table 1 were determined from each peak area corrected for the UV sensitivity of each compound.

Removal of a Z(OMe) Group of D-2-(4-Hydroxyphenyl)-2-(4-methoxybenzyloxycarbonylamino)acetic Acid (3a). To a solution of **3a** (1.0 g, 3 mmol) in MeCN (40 ml) was added a solution of *p*-toluenesulfonic acid monohydrate (1.15 g, 6 mmol) in MeCN (15 ml). The mixture was stirred at room temperature for 3.5 h. The *p*-hydroxyphenylglycine *p*-tolenesulfonic acid salt precipitated was collected by filtration, washed with MeCN (10 ml) and dried *in vacuo*: yield 0.95 g (93%); mp 222—223 °C (dec.) (lit,[6] 229 °C).

The combined filtrate and washings were concentrated *in vacuo*. To the residue was added a solution of sodium bicarbonate (0.507 g) in water (15 ml) and the mixture was extracted successively three times with diethyl ether (15 ml) and twice with ethyl acetate (15 ml). The extracts were combined, dried over $MgSO_4$, and the solvent removed *in vacuo*, leaving a yellow solid. It was chromatographed on a thin layer (Merck; pre-coated TLC plate Silica Gel $60F_{254}$, 20×20 cm, of layer thickness 0.50 mm) with EtOAc to give *N*-(4-methoxybenzyl)acetamide (0.195 g, 36.0%): mp 95—96 °C (lit,[4] 95—97 °C). The content of this compound in the reaction mixture was 0.27 g (49%) as determined by an HPLC analysis using a mobile phase consisting of 0.01 M phosphate buffer (pH 6.8) and MeOH (1:1 by volume).

A similar treatment of D-*N*-Boc-*p*-hydroxyphenylglycine (**3b**) with *p*-toluenesulfonic acid in acetonitrile gave *N*-(*t*-butyl)acetamide in 51% yield, which was identified by elemental analysis and by comparison of its melting point and ^{1}H NMR spectrum with those of an authentic sample.[5]

The authors wish to thank Dr. Masataka Fukumura for his useful suggestions on this report. The authors also wish to thank Mr. Kenzo Hosotani for his excellent technical assistance in the synthesis.

Synthesis of 2,4-Di(*p*-formyl)-α-truxillic Acid by Crystal Engineering

Fusae NAKANISHI,* Michiko ISHII, and Hachiro NAKANISHI
Research Institute for Polymers and Textiles 1-1-4 Yatabe-Higashi, Tsukuba, Ibaraki 305
(Received February 21, 1984)

Synopsis. *p*-Formycinnamic acid, which usually crystallizes in either the β-form or γ-form of packing, was converted into its diethyl acetal. The introduction of such bulky groups onto a benzene ring successfully provided us with the α-form of packing, from which the desired photodimer, 2,4-di(*p*-formyl)-α-truxillic acid (*c*-2, *t*-4-bis(*p*-formylphenyl)-*r*-1,*t*-3-cyclobutanedicarboxylic acid) was obtained with a yield of 85—90%.

We have previously reported[1] the preparation of 3,4-di(*p*-formyl)-β-truxilic acid (*t*-3, *t*-4-bis(*p*-formylphenyl)-*r*-1, *c*-2-cyclobutanedicarboxylic acid) from *p*-formylcinnamic acid (*p*-FCA)crystals using irradiated light. Two polymorphic forms of *p*-FCA were found, each depending on recrystallization conditions: β-form; photo-reactive and γ-form; photostable. Attempted recrystallization using various kinds of solvents did not provide for the formation of α-form crystals, the photodimerization of which gives us 2,4-di(*p*-formyl)-α-truxillic acid **3** (*c*-2, *t*-4-bis(*p*-formylphenyl)-*r*-1-, *t*-3-cyclobutanedicarboxylic acid). The synthesis of **3** is of considerable interest since it might be converted into the same compound as the photodimer of diethyl 3,3′-(*p*-phenylene)diacrylate and the crystal structure and the photoreactivity of this dimer might provide us with crucial information on the mechanism of the four-center type photopolymerization,[2] *i.e.*, a kind of crystal transition reaction from the monomer to the polymer.

This report is concerned with the successful formation of **3** by crystal engineering. The data on the crystal structure of cinnamic acid derivatives suggest that the introduction of a bulky group onto a benzene ring of cinnamic acid may lead to the formation of α-form crystals since the steric hindrance of a bulky group avoids the β-type packing. We have chosen a diethyl acetal group as an example of such a bulky group since it is easy to introduce and to retrieve.

First, preparation of **1** of *p*-FCA was attempted by the usual method, using various kinds of acids. The results are shown in Table 1. In the presence of a strong acid, such as conc. sulfuric acid, *p*-FCA was almost converted into **1**. However, the crystals of the diethyl acetal derivative, thus obtained, were unstable and were readily hydrolyzed by moisture in the air. Presumably the crystals were contaminated with acid residues. Even an attempted neutralization of the reaction mixture by washing was not effective in the interior of the crystals and an attempted improvement of the yield was unsuccessful. By means of acetic acid catalysis, the acetal formed was stable to moisture, but *p*-FCA still remained in a considerable amount and, moreover, separation of the acetal from the reaction mixture was rather difficult. Therefore, the following method was carried out in order to improve the preparation. After exposure to hydrogen chloride gas, acidified β-form crystals of *p*-FCA were suspended in ethanol at 15 °C. The UV spectrum of these suspended crystals gradually changed. The maximum of the UV absorption gradually shifted from 295 nm (*p*-FCA) to 276 nm. The crystals obtained at this stage were colorless with a mp of 142 °C, and were identified as **1** of *p*-FCA on the basis of elemental analysis and spectroscopic data (IR, UV, and NMR). This simple reaction proceeded under mild conditions, and side reactions, such as esterification, were not observed and quite pure **1** was obtained. It should be noted that the photostable γ-form of crystalline *p*-FCA was not converted into the acetal under the same conditions. These results suggest that the reaction was controlled by the crystal structure, that is, a topochemical reaction. The crystal structure of β-form of *p*-FCA[3] showed that formyl groups were exposed on the well-developed crystal face. Though we can not establish the mechanism of this reaction in detail because of lack of the data on the crystal structure of γ-form of *p*-FCA, it seems that the reaction proceeds from a well-developed crystal face through an attack by an ethanol molecule, in a mechanism similar to that proposed for the solid-gas reaction of carboxylic acid with ammonia.[4] The diethyl acetal crystals were found to be photoreactive. The absorption peak of the UV spectrum of irradiated diethyl acetal crystals in ethanol deceased gradually to a small peak with λ_{max} around 269 nm. At this stage, no absorption peak ascribed to double bonds was observed in the IR spectrum of irradiated crystals. In the NMR spectrum of irradiated crystals in DMSO-d_6, double bonds peaks disappeared and new peaks appeared at δ 3.7—4.6. The proton ratio of each peak in the NMR spectrum (benzene : methine : methylene and new peaks :

TABLE 1. PREPARATION OF ETHYL ACETAL OF *p*-FORMYLCINNAMIC ACID (*p*-FCA)

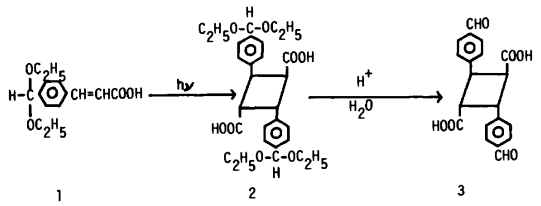
methyl) was found to be 8:2:12:12. New peaks (4 protons) were assingned as cyclobutane ring protons, based on a comparison with the reported data on cyclobutane rings.[5] These facts suggest that dimer **2** was formed by cycloaddition of **1**. In order to hydrolyze to a formyl derivative, diethyl acetal groups of the dimer **2** were treated with hydrochloric acid. Formation of dimer **3** was supported by elemental analysis, IR and NMR spectra. The configuration of the cyclobutane ring of **3** was determined by comparing the shape and the mid-point of symmetrical spin patterns of the cyclobutane rings in the NMR spectrum with those of reported cyclobutane rings. According to the report by Ben-Efraim *et al.*,[5] mid-points of cyclobutane ring proton patterns of *α*-truxillic acid, *β*-truxinic acid and *μ*-truxinic acid (*t*-3, *c*-4-diphenyl-*r*-1, *t*-2-cyclobutanedicarboxylic acid) have the same position. As shown in Fig. 1, the cyclobutane ring patterns of **3**, (B), were mirror-symmetrical but the shape was different from those of 3,4-di(*p*-formyl)-*β*-truxinic acid,[1] (A). The mid-points of both spin patterns were the same value (4.16). These facts suggest that **3** was either *α*-truxillic acid or a *μ*-truxinic acid-type dimer. The cyclobutane ring patterns of **3** are similar to those of *α*-truxillic acid.[5] Based on these facts, it was certain that product **3** was an *α*-truxillic acid-type dimer. The over-all reaction is shown in Scheme 1. This is the first preparation of *α*-truxillic acid carrying formyl groups on benzene rings.



Scheme 1.

Experimental

p-FCA was prepared according to Wiely.[6] It crystallized into two different modifications, depending on the crystallization solvent. *β*-Form crystals were obtained from ethanol and *γ*-form from acetone. Both forms have the same melting point, 249 °C, but they have different X-ray diffraction patterns.

Preparation of Diethyl Acetal of p-*Formylcinnamic Acid.* *β*-Form crystals of *p*-FCA (2 g) were exposed to anhydrous hydrogen chloride gas for 30 min and the crystals were acidified. They were suspended in ethanol (30 ml) while stirring at 15 °C. At this temperature, 10% of the *p*-FCA crystals were dissolved in the ethanol. In order to determine the progress of reaction, the UV spectrum of the suspended crystals was occasionally measured while in the ethanol. When the absorption peak of the crystals ceased to shift, the crystals were collected by filtration. Some of diehyl acetal of *p*-FCA was further obtained by the evaporation of the mother liquor. The combined yield was 2.5 g. Found: C, 67.02; H, 6.93%. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%. Mp 142 °C (from ethanol-hexane); UV_{max} (EtOH) 276 nm; ^1H NMR (DMSO-d_6); δ=1.2 (6H, t, $-CH_3$) 3.3—3.7 (4H, q, $-CH_2-$), 5.5 (1H, s, -CH), 6.4—7.9 (2H, d, -CH=CH-), 7.3—7.8 (4H, m, aromatic proton).

Photodimerization of Diethyl Acetal of p-*FCA in the Crystalline State.* Diethyl acetal crystals (100 mg) of *p*-FCA were suspended in hexane (100 ml) and irradiated with a 500 W xenon lamp at 15—20 °C. After 6 h diethyl acetal of *p*-FCA was changed to the dimer in the yield of 85—90%. Mp 230—232 °C; ^1H NMR (DMSO-d_6); δ=1.15 (12H, t, $-CH_3$), 3.3—3.7 (8H, q, $-CH_2-$), 5.5 (2H, s, -CH), 3.7—4.6 (4H, m, cyclobutane proton), 7.3 (8H, m, aromatic proton).

Dimer **2** (100 mg) was suspended in dil HCl (50 ml) for a few hours while stirring. By this treatment dimer **3** was obtained. Mp 273—275 °C (from ethanol-water); UV_{max} (EtOH) 264 nm; Found: C, 68.17; H, 4.68%. Calcd for $C_{20}H_{16}O_6$: C, 68.18; H, 4.58%. ^1H NMR (DMSO-d_6); δ=3.7—4.6 (4H, m, cyclobutane proton), 7.4—8.0 (8H, m, aromatic proton), 10.0 (2H, s, -CHO).

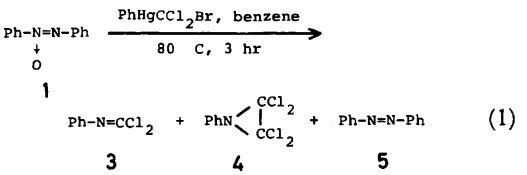
Reactions of Azoxybenzene with Dichlorocarbene in the Phase-transfer-catalyzed System

Shizen SEKIGUCHI,* and Tomohisa FUJIU
Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Ten-jin cho, Kiryu, Gunma 376
(Received March 8, 1984)

Synopsis. Azoxybenzene (**1**) reacted with dichlorocarbene (**2**) at 40 °C in the presence of a phase-transfer catalyst (18-crown-6 or tributylamine) in a binary solvent ($CHCl_3$–aqueous KOH), giving 2,2,3,3-tetrachloro-1-phenylaziridine (**4**), azobenzene (**5**), and 2-hydroxy-1-phenylbenzimidazole.

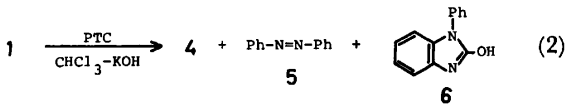
The phase-transfer technique has been regarded as a useful tool in improving the preparative processes and syntheses used in laboratories. Although the reactions of dihalocarbenes with olefins,[1-3] amides,[4] imines,[5] alcohols[6] and adamantane[7] have already been studied, only a few studies involving the addition of dichlorocarbenes to -N(O)=N- (azoxy) bonds have been published.

Seyferth and his coworkers have reported the reaction of azoxybenzene (**1**) with dichlorocarbene (**2**) in benzene, in which phenyl(bromodichloromethyl)mercury ($PhHgCCl_2Br$) was used as a source reagent of **2**. They found that 1,1-dichloro-*N*-phenylmethanimine (**3**, yield 3%), 2,2,3,3-tetrachloro-1-phenylaziridine (**4**, yield 12%) and azobenzene (**5**, yield 6%) were formed (Eq. 1).[8]



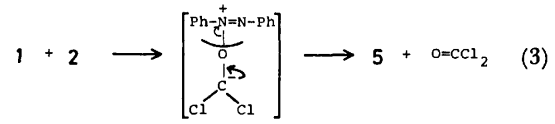
(1)

We have also carried out a reaction of **1** with **2** in the presence of 18-crown-6 or tributylamine as a phase-transfer catalyst (PTC) under the phase-transfer-catalyzed conditions (50% aqueous KOH–$CHCl_3$), in which the different products, except for **4** and **5**, were formed (Eq. 2). The results are indicated in Table 1.



(2)

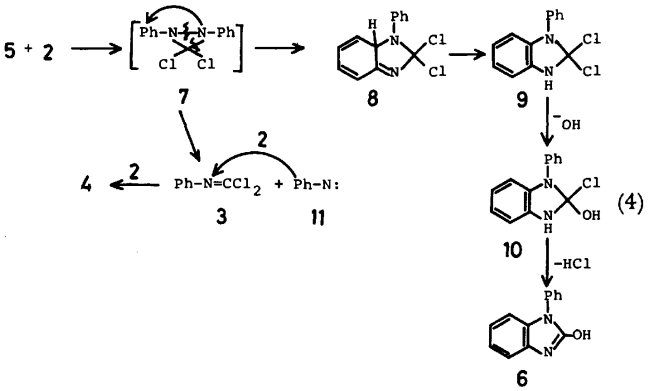
Azobenzene (**5**) is probably formed *via* the following path (Eq. 3).[9,10] In such polar solvents as chloroform



(3)

the intermediate shown in the bracket (Eq. 3) might reasonably be considered to intervene with the electrophilic character of **2**.

Further, in order to elucidate the formation path of **4** and **6**, a reaction of **5** with **2** under the same conditions described in Table 1 (PTC tributylamine; temp 40 °C; time 4 h) was carried out, in which **4** and **6** were formed in 31.0 and 15.5% yields (based on **5** consumed), respectively. These results would indicate that **4** and **6** are formed *via* the following path (Eq. 4).[11]



(4)

It is not clear, at present, whether the N-N bond fission in **7** is heterolytic or homolytic. The intermediacy of **7**, however, is reasonable from considering the formation of **4** and **6**.[11,12] As is shown in Eq. 3, the abstraction of an oxygen atom by **2** is interesting and such a reductive function of **2** would be excepted to attract attention.

TABLE 1. REACTION OF AZOXYBENZENE WITH DICHLOROCARBENE IN THE PRESENCE OF PHASE TRANSFER CATALYSTS

1 mmol	$CHCl_3$ mmol	aq KOH (50%) mmol	Temp °C	Time h	Product/%[a] 4	5	6	Conv. %
					18-Crown-6[b]			
30.0	419	446	40	10	36.8	3.0	1.7	35.0
					Tributylamine[c]			
			40	4	42.0	5.3	8.5	37.6
			10	24	32.2	6.1	4.2	37.1

a) Based on the azoxybenzene consumed. b) 18-Crown-6 0.76 mmol. c) Tributylamine 0.76 mmol.

Experimental

General Comments. The products were identified using NMR and MS spectrometers, UV and IR spectrophotometers, and elemental analyses. All the capillary melting points were uncorrected.

Preparation of Azoxybenzene (1). Following a method described in the literature,[12] **1** was prepared from nitrobenzene, diarsenic trioxide, and sodium hydroxide (yield 65%): mp 34—35 °C (35.5—36.6 °C).[12]

Reaction of Azoxybenzene (1) with Dichlorocarbene (2) for Isolation of the Products. The preparative procedure was as follows: A solution of 5.95 g (30.0 mmol) of **1**, 0.204 g (0.76 mmol) of 18-crown-6, and 50.0 g (446 mmol) of aqueous KOH (50%) was added to an Erlenmeyer flask with a reflux condenser and a thermometer placed on a heating plate. The flask was covered with aluminium foil in order to shield it from light.

After the chloroform layer was filtered and concentrated, by aqueous H_2SO_4 (5N) and extracted with chloroform. Then, the extract was dried overnight over anhydrous $MgSO_4$. After the chloroform layer was filtered and concentrated, the residue was processed by column chromatography (silica gel [Wako gel C-200]-benzene).

In addition, **4** was seperated from unreacted **1**, **5**, and **6**, using a column [silica gel-ligroin (bp 80—100 °C)], and purified by reduced distillation [bp 70—72 °C/2.66 Pa[8]].

The ligroin fraction containing unreacted **1**, **5**, and **6** was processed by column chromatography [firstly, silica gel-benzene-ligroin (4:1 v/v), and secondly, silica gel-benzene-acetone (9:1 v/v)] giving the **6** fraction. It was concentrated and the residue was recrystallized from acetone, giving pure **6**.

After the residual ligroin fraction was concentrated, the residue was subjected to fractional crystallization from methanol, giving pure **1** (mp 35—36 °C) and **5** (mp 67.5—68 °C).

2,2,3,3-Tetrachloro-1-phenylaziridine (4); bp 70—72 °C/2.66 Pa (70—72 °C/Pa).[8]

2-Hydroxy-1-phenylbenzimidazole (6); mp 210 °C; M^+ 210; NMR (DMSO-d_6) δ=11.1 (1H, s, broad, OH and NH), 7.7 (5H, s, 1-phenyl), and 7.2—7.5 (4H, m, phenyl); IR (KBr) 3400, 3100, 1750—1660, 1600, 1450, 760, 740, and 690 cm^{-1}; Anal. ($C_{13}H_{10}N_2O$) C. H. N. The chemical shift at δ=11.1 and the absorption band at 1750—1660 cm^{-1} clearly indicate that there are two tautomers (**6** and 2-oxo-1-phenyl-2,3-dihydrobenzimidazole).

Reaction of Azobenzene (5) with Dichlorocarbene (2) for Isolation of the Products. The preparative procedure was the same as that involved in the reaction of **1** with **2**.

Determination of Products. After the reaction was completed, the mixture was neutralized with aqueous H_2SO_4 (5M (1M=1 mol dm^{-3})) to pH 6—7 and extracted with two 200 ml portions of chloroform. Then, the chloroform layer was dried over anhydrous $MgSO_4$.

After the chloroform layer was filtered and the filtrate was concentrated, the residue was diluted exactly to 50 ml with a mixed solvent [methanol-chloroform (7:3 v/v)]. A 5-ml portion of the solution was analyzed by HPLC under the following conditions to determine **6**: Column JASCO SC-02L (silica gel) 0.46ϕ×25 cm, flow rate 1.0 ml/min, wave length 290 nm, solvent methanol-H_2O (6:4 v/v), internal standard biphenyl.

The residual 45-ml solution was concentrated and subjected to column chromatography [silica gel (Wako gel C-200)-benzene] to remove residual tarry matter.

After the eluent was concentrated, it was diluted to 20 ml with a mixed solvent [methanol-chloroform (7:3 v/v)]. The solution was subjected to GLC (HITACHI 164) to determine **4**, unreacted **1**, and **5**. The operating conditions were as follows: column (0.5ϕ×100 cm) Celite 545 impregnated with SE-30 (silicone) (10 wt%), column temperature 120 °C (for **4**) and 250 °C (for **1** and **5**), flow rate 20 (for **4**) and 10 ml/min (for **1** and **5**), carrier gas He; internal standard azobenzene (**5**) (for **4**) and benzyl benzoate (for **1** and **5**).

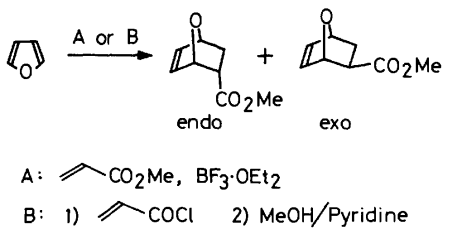
Preparatively Useful Method for the Synthesis of Diels-Alder Adducts between Furan and Methyl Acrylate

Hiyoshizo KOTSUKI,* Kazuhiko ASAO, and Hiroyuki OHNISHI
Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780
(Received March 15, 1984)

Synopsis. The Diels-Alder adducts of furan with methyl acrylate were successfully prepared by two methods on a preparative scale. The $BF_3 \cdot OEt_2$-catalyzed reaction of furan with methyl acrylate gave a 7:3 mixture of endo and exo adducts in 75.7% yield. When acryloyl chloride was used as a dienophile, after esterification with methanol, a 3:7 mixture of the same adducts was obtained in 76.5% overall yield.

The 7-oxabicyclo[2.2.1]heptyl system has been widely employed as a source of important intermediates in natural product syntheses.[1] The most straightforward approach to the construction of the 7-oxabicyclo[2.2.1]heptyl system takes advantage of the Diels-Alder reaction between furan and a suitable dienophile. However, the Diels-Alder reaction of furan with conventional dienophiles is usually sluggish because of the aromatic character of the furan ring (resonance energy *ca.* 25 kcal/mol).[2]

Previously, we have demonstrated the solution to this problem by the application of high-pressure technique.[3] Recently, however, it has been reported that some Lewis acid catalysts could provide an alternative approach to realize these Diels-Alder reactions.[4] These results prompt us to report our preliminary finding for a convenient preparation of Diels-Alder adducts between furan and methyl acrylate in preparatively useful amounts.



Firstly, the Lewis acid-catalyzed method is described. Among several Lewis acids, $BF_3 \cdot OEt_2$ was found to be a most effective catalyst for this reaction (Table 1). Thus, when the mixture of freshly distilled furan and methyl acrylate was catalyzed with 0.1 equiv of $BF_3 \cdot OEt_2$ *without solvent* at 5 °C for 10 h under nitrogen atmosphere , the desired endo and exo Diels-Alder adducts were obtained in 75.7% combined yields *with high endo selectivity* (endo:exo=7:3). For instance, the reported yield of the adducts is 55% using ZnI_2 as catalyst[4b] or 62% at 15 kbar pressure[3b] (endo:exo= 1:2 for the former or 6:4 for the latter). So the newly developed method considerably improves both the yield and the endo selectivity as the result of the kinetically controlled reaction.[5] Other Lewis acids such as $AlCl_3$, $SnCl_4$, and $ZnCl_2$ gave only resinous products and with other dienophiles such as methyl vinyl ketone, acrylonitrile, and dimethyl maleate either the reaction was not catalyzed or polymerization was predominant. Reaction with 2-methylfuran gave adducts in low yield and 2,5-dimethylfuran gave no adducts.

An alternative procedure is the use of a strongly reactive dienophile of acryloyl chloride. It has been known that acryloyl chloride reacts with furan in high yield.[6] However, the detailed experimental procedure has not been published. We found the reaction was greatly improved by addition of propylene oxide as a hydrogen chloride scavenger. Thus, the reaction of furan with acryloyl chloride in the presence of a few drops of propylene oxide gave adducts in high yield by ^1H NMR measurement. Esterification of the product with absolute methanol followed by purification gave the endo and exo adducts in 76.5% overall yield *in high exo selectivity* (endo:exo= 3:7), in contrast to the former case. This is probably due to the thermodynamic stability of the exo adduct. The reaction with 2-methylfuran gave the known Michael adduct[6,7] and 2,5-dimethylfuran gave no adducts.

By these two methods Diels-Alder adducts of furan with methyl acrylate have become available in large quantity. Both endo and exo stereoisomers are readily separable by column chromatography; for the preparation of the endo-isomer the first procedure is preferred and the second one is convenient for the exo-isomer.

TABLE 1. DIELS-ALDER REACTION OF FURAN WITH METHYL ACRYLATE

Experimental

^{1}H NMR spectra were obtained on a JEOL MH-100 spectrometer and the IR spectra were recorded on a JASCO IRA-1. All reactions were carried out in the presence of a catalytic amount of hydroquinone (HQ) under N_2 atmosphere. Furan and methyl acrylate were freshly distilled prior to use. $BF_3 \cdot OEt_2$ was fractionally distilled from CaH_2. Acryloyl chloride was prepared from acrylic acid according to the literature[8] and was freshly distilled prior to use. Column chromatography was performed with Wakogel C-200. Merck's precoated silica-gel 60 F-254 plates (0.25 mm) were used for monitoring the reactions.

Evaporation of the excess reagents or solvents was performed *in vacuo* below 35 °C. All the products were identified by comparing their spectral data with those of authentic samples.

Methyl 7-Oxabicyclo[2.2.1]hept-5-ene-2-carboxylate. *A) With $BF_3 \cdot OEt_2$ Catalyst:* To a mixture of furan (24 g; 0.353 mol) and methyl acrylate (10 g; 0.116 mol) 1.5 ml of $BF_3 \cdot OEt_2$ was added *via* syringe at −20 °C with stirring. Thereafter, the reaction was allowed to proceed in the refrigerator (<5 °C) for 10 h. During the reaction, the solution color changed to pale yellow and a small amount of brown deposit formed. After evaporation of the excess reagents, the residue was poured into CH_2Cl_2 and washed successively with water, satd $NaHCO_3$, and satd NaCl, dried over $MgSO_4$, and concentrated. Purification of the oily product (14 g) by silica-gel column chromatography gave 9.86 g (55.1%) of endo-adduct and 3.69 g (20.6%) of exo-one. With hexane–AcOEt the endo-isomer was obtained from earlier fractions.

B) With Acryloyl Chloride: A mixture of furan (21.6 g; 0.32 mol), acryloyl chloride (10.2 g; 0.113 mol), and 3—4 drops of propylene oxide was stirred in the dark at room temperature for 48 h. After evaporation of the excess reagents, 15.6 g of the product was obtained as a dark yellow oil. The product was esterified conventionally with abs. MeOH (10 ml) using 3 equiv of pyridine at room temperature for 36 h and then quenched with ice-water. The excess MeOH was removed and the aqueous phase was extracted with AcOEt. The combined extracts were washed successively with water, 2M HCl (1 M=1 mol dm^{-3}), satd $NaHCO_3$, and satd NaCl, dried over $MgSO_4$, and concentrated. The yellowish product (14.16 g) was purified as above to afford 3.72 g (21.4%) of endo-adduct and 9.42 g (54.1%) of exo-one.

3-(5-Methyl-2-furyl)propanoyl Chloride. A mixture of 2-methylfuran (3 g; 37 mmol), acryloyl chloride (3 g; 33 mmol), and 2—3 drops of propylene oxide was stirred at room temperature for 24 h. Evaporation of the excess reagents gave an almost pure product (4.64 g; 81.5%), bp 95—100 °C/15 mmHg (lit,[7] 99 °C/15 mmHg; 1 mmHg=133.322 Pa).

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 5874025).

Preparation of Tetraalkylammonium *N*-Chloro-*p*-toluenesulfonamides and Their Application to Imination of Phosphorus Compounds and Sulfides

Tamotsu YAMAMOTO,* Daisaburo YOSHIDA, Jun HOJYO, and Hiranari TERAUCHI
Department of Industrial Chemistry, Faculty of Engineering, Kanto Gakuin University, Mutsuura, Kanazawa-ku, Yokohama 236
(Received April 5, 1984)

Synopsis. Tetraalkylammonium *N*-chloro-*p*-toluenesulfonamides were prepared from chloramine T and tetraalkylammonium chlorides as a substance corresponding to anhydrous chloramine T, and found to give rise to the effective tosylimination of phosphorus compounds and diaryl sulfides.

Chloramine T (sodium *N*-chloro-*p*-toluenesulfonamide **1**) is a useful reagent for tosylimination but commercially available as its trihydrate. In general the tosylimination is effectively accomplished using the trihydrate in water or alcohol containing water. With triphenyl phosphine, however, the trihydrate gives a phosphonium salt [$(Ph_3P^+\text{-}NHTs)_2NTs^{2-}$] in stead of the phosphine imide, while the anhydrous **1** gives the latter product.[1]

$$Ph_3P + \mathbf{1}(H_2O)_0 \longrightarrow Ph_3P{=}NTs$$

$$Ph_3P + \mathbf{1}(H_2O)_3 \longrightarrow (Ph_3P^+\text{-}NHTs)_2NTs^{2-}$$

$$Ts = p\text{-}CH_3C_6H_4SO_2$$

Furthermore, with the special sulfides, such as 2-haloethyl phenyl sulfides, the tosylimination using the anhydrous **1** has been known to give better result than that using the trihydrate.[2]

On the other hand, recently Sharpless *et al.* have developed a new use of the anhydrous chloramine T, allylic amination of olefins.[3]

As described above, the anhydrous chloramine T is very interesting. However, it is explosive and is not easily available. On the basis of the fact that most quaternary ammonium salts are anhydrous, we tried to prepare tetraalkylammonium *N*-chloro-*p*-toluenesulfonamides (**2**) and to apply to imination of phosphorus compounds and sulfides.

Results and Discussion

Preparation of Tetraalkylammonium N-Chloro-p-toluenesulfonamides (2). Initially tetrabutylammonium *N*-chloro-*p*-toluenesulfonamide (**2a**) was prepared by the ion-exchange reaction of chloramine T trihydrate with tetrabutylammonium halides (chloride and bromide) in water. For obtaining well crystallizable **2a**, the use of tetrabutylammonium chloride and an excess amount of **1** to the ammonium salt are required.

Similarly other tetraalkylammonium *N*-chloro-*p*-toluenesulfonamides (**2b—2e**) were prepared from the corresponding tetraalkylammonium chlorides and chloramine T trihydrate.

$$\mathbf{1}(H_2O)_3 + \underset{\mathbf{3}}{R^1{}_3R^2N^+X^-} \longrightarrow \underset{\mathbf{2}}{R^1{}_3R^2N^+N(Cl)\text{-}Ts^-}$$

X=Cl, Br

Although these ammonium salts **2** were obtained in solid state, the purification by recrystallization was unsuccessful. The structures of **2** were confirmed by IR and NMR spectra and determination of active chlorine. The results are given in Table 1.

To know the thermal stability of **2** their decomposition temperatures were measured by a thermal differential analyzer. As shown in Table 1, the compounds **2** have such high decomposition temperatures, but they gradually decompose even at room temperature and so the storing in a freezer is recommended.

Tosylimination of Phosphorus Compounds and Tosylimination of Phosphorus Compounds and Sulfides Using 2a. The reaction of **2a** with triphenylphosphine (**4a**) in dichloromethane was carried out at room temperature for 5 h to give *N*-(*p*-tolylsulfonyl)-*P,P,P*-triphenylphosphine imide (**5a**) in a 96% yield. This shows that **2a** can be used as an alternate to the anhydrous chloramine T. Similarly the reactions of **2a** with tributyl (**4b**) and triphenyl phosphites (**4c**) gave the corresponding phosphorimidates, (**5b**)[4] and (**5c**), in 91 and 96% yields, respectively.

a) A, B, C and D show the methods using **2a**, $1(H_2O)_3$ (in MeOH, 40 °C, 5 h), $1(H_2O)_3$ (presence of AcOH in MeOH, 40 °C, 5 h), and $1(H_2O)_0$ (in absolute EtOH), respectively. b) D. S. Tarbell *et al.*, *J. Am. Chem. Soc.*, **63**, 2939 (1941). c) F. G. Mann *et al.*, *J. Chem. Soc.*, **121**, 1052 (1922). d) I. W. J. Still, *et al.*, *Synthesis*, **1978**, 540. e) T. Yamamoto *et al.*, *Chem. Lett.*, **1975**, 581. f) From Ref. 2.

For the reactions of **2a** with sulfides (**6**), seven kinds of sulfides listed in Table 2 were chosen. The reactions were carried out at 35—40 °C for 5 h, the resulting mixture worked up in common way. The results together with those obtained in the reactions using chloramine T trihydrate in methanol with or without acetic acid, are given in Table 2. The yields of sulfilimines (**7**) using **2a** are almost independent of their structures.

$$\underset{\mathbf{6}}{R^1SR^2} + \mathbf{2a} \xrightarrow{CH_2Cl_2} R^1S(R^2)=NTs + n\text{-}Bu_4N^+Cl^- \quad \mathbf{7}$$

This is contrasted with hydrated chloramine T, the reactions of which with diaryl sulfides give the corresponding sulfilimines only in low yields. In addition the *S*-imination of 2-bromoethyl phenyl sulfide (**6g**) with **2a**, is more effective than that with anhydrous **1**.[5] The *S*-imination of diaryl sulfides using **2a** may be more effective than that using trihydrated **1** in the presence of acetic acid.[6] Such an effective tosylimination by **2a** may be brought *via* radical mechnism in which more active species (radical) than *N*-chloro-*p*-toluenesulfonamide[6] is included, since **2a** decolors the violet of *N,N*-diphenyl-*N'*-picryl hydrazyl and in the presence of H·donor (hydroquinone) does not give rise to the tosylimination of diaryl sulfides.

Experimental

All melting points are not corrected. The ^{1}H-NMR spectra were measured with a JEOL JNM-PMX60 spectrometer using TMS as the internal standard. The mass spectra were obtained on a JEOL JMS-D300 mass spectrometer with an ionizing potential of 70 ev. The decomposition temperatures were obtained with a Rigaku Denki E-1 thermal differential analyzer.

Preparation of Tetraalkylammonium N-*Chloro*-p-*toluenesulfonamides* (**2**). *General Procedure*: To a stirred solution of 12—18 mmol of **1** $(H_2O)_3$ in 20 ml of water was dropped 10 mmol of tetraalkylammonium chloride in 20 ml of water below 5 °C. After stirring below 5 °C for 5 h, the resulting mixture was extracted with CH_2Cl_2 and dried over anhydrous sodium sulfate. The dried solution was evaporated to dryness under vacuum to give **2**.

Tosylimination of Phosphorus Compounds Using **2a**. To a stirred solution of 3.3 mmol of **2a** in 15 ml of CH_2Cl_2 was added a solution of 3.0 mmol of phosphorus compound **4** in 15 ml of CH_2Cl_2. After the solution was stirred at 35—40 °C for 5 h, the resulting solution was washed with water and dried over anhydrous sodium sulfate. The dried solution was evaporated to dryness and the residue obtained was triturated or washed with ether. **5a**: Yield 96%; mp 186—188 °C (from EtOH)(187 °C);[1] IR (KBr): 1140 cm^{-1} (P=N). **5b**: Yield 91%; oil (after several washing with ether). IR (NaCl): 1310 and 1130 (SO_2), 1150 (P→N), and 1020 cm^{-1} (P-O-C), NMR ($CDCl_3$): δ=0.89 (t, 9H J=5 Hz), 1.0—1.9 (m 12H), 2.35 (s 3H), 4.05 (m 6H), 7.21 (d 2H J=8 Hz), and 7.79 (d 2H J=8 Hz). MS *m/z* (%): 419 (M^+ 11), 364 (28), 363 ($M^+-C_4H_8$ 90), and 251 (100). **5c**: Yield 96%; oil (after several washing with ether). IR (NaCl): 1270 and 1140 (SO_2), 1180 (P-O-C), and 1160 cm^{-1} (P=N). NMR ($CDCl_3$): δ=2.21 (s 3H), 7.06 (d 2H J=8 Hz), 7.64 (d 2H J=8 Hz), and 7.21 (broad s 15H). MS *m/z* (%): 479 (M^+ 19), 386 ($M^+-C_6H_5O$ 90), 385 ($M^+-C_6H_6O$ 95), and 325 (100).

Tosylimination of Sulfides. General Procedure: To a stirred solution of 3.3 mmol of **2a** in 15 ml of CH_2Cl_2 was added a solution of 3.0 mmol of sulfide **6** in 15 ml of CH_2Cl_2. After the solution was stirred at 35—40 °C for 5 h, the resulting solution was washed with water and dried over anhydrous sodium sulfate. The dried solution was evaporated to dryness and the residue obtained was triturated with ether. **7e**: Yield 93%; mp 123—124 °C (from MeOH). IR (KBr): 1290 and 1135 (SO_2), and 968 cm^{-1} (S=N). NMR ($CDCl_3$): δ=2.37 (s 3H), 7.24 (d 2H J=8 Hz), 7.2—7.7 (m 8H), and 7.73 (d 2H J=8 Hz). Found: C, 53.45; H, 3.56; N, 3.56%. Calcd for $C_{19}H_{15}Cl_2NO_2S_2$: C, 53.77; H, 3.57; N, 3.30%. **7f**: Yield 90%; mp 131—132 °C (from MeOH). IR (KBr): 1520 and 1342 (NO_2), 1298 and 1140 (SO_2), and 960 cm^{-1} (S=N), NMR ($CDCl_3$): δ=2.37 (s 6H), 7.13 (d 2H J=8 Hz), 7.24 (d 2H J=8 Hz), 7.52 (d 2H J=8 Hz), 7.69 (d 2H J=9 Hz), 7.78 (d 2H J=8 Hz), and 8.22 (d 2H J=9 Hz). Found: C, 57.78; H, 4.36; N, 6.66%. Calcd for $C_{20}H_{18}N_2O_4S_2$: C, 57.95; H, 4.39; N, 6.76%.

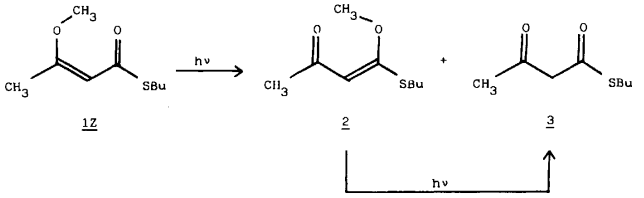
Photoreaction of *S*-Butyl 3-Methoxy-2-butenethioate. Competitive 1,5-Methyl Migration and *O*-Demethylation

Tadashi HASEGAWA,* Kazuhiko IWASAKI, and Nobutoshi YOSHIHARA
Department of Chemistry, Tokyo Gakugei University, Nukuikitamachi, Koganeishi, Tokyo 184
(Received April 12, 1984)

Synopsis. Irradiation of *S*-butyl (*Z*)-3-methoxy-2-butenethioate (**1Z**) gave the 1,5-methyl migration product **2** and the *O*-demethylation product **3**. The photo-1,5-methyl migration occured competitively with the *O*-demethylation from the π, π^* excited triplet state of **1Z**. The migration product **2** underwent the secondary photoreaction to **3** in a nondegassed benzene solution.

Recently we reported the photoreaction of *S*-alkyl 3-oxobutanethioates to the corresponding disulfides.[1] The photoreaction occurred only from the keto form though the 3-oxobutanethioates exhibit keto-enol tautomerism. Irradiation of a model compound for the enol form, *S*-butyl (*Z*)-3-methoxy-2-butenethioate (**1Z**), under nitrogen gave no disulfides but an *O*-demethylated product. Although the photoreactions of enol esters have been well studied,[2] those of enol ethers have received only little attention.[3] We investigated the further details of the enol ether **1Z** and found thst **1Z** underwent the unusual 1,5-methly migration competing with the *O*-demethylation. The migration was followed by the secondary photoreaction in the presence of dissolved oxygen. In this paper we will descrive these results of the photoreaction of **1Z**.

Irradiation of a degassed benzene solution of **1Z** in a sealed Pyrex tube with a 450 W high-pressure mercury lamp gave 4-butylthio-4-methoxy-3-butene-2-one (**2**) and *S*-butyl 3-oxobutanethioate (**3**) in 65 and 25% yield, respectively.[4] The structure of **2** was elucidated by spectral data and by elemental analysis. The IR spectrum of **2** showed the characteristic absorption of α,β-unsaturated carbonyl at 1680 cm^{-1}. The ^1H NMR spectrum of **2** showed two singlets at δ 2.28 and 3.64, attributable to the acetyl and the methoxyl group, respectively. The peak at δ 3.64 underwent large upfield shift in benzene-d_6 and was observed at δ 2.94. The ^1H NMR spectra of α,β-unsatulated compounds undrego large chaneges when these substances are dissolved in aromatic solvents.[5] The solvent effect of **2** can be explained in terms of the diamagnetic anisotropy of the aromatic nucleus in the intermolecular complex between the α,β-unsatulated carbonyl compounds and the aromatic solvent. The ^{13}C NMR spectrum of **2** showed a doublet at δ 99.3 and singlets at δ 169.9 and 187.8 attributable to α-, β-, and carbonyl carbon, respectively. These results supported the structure of **2**.



The photochemical reaction of **1Z** was pursured by quantitative analysis of the products and the starting material. The time-conversion curves are given in Figs 1 and 2. Since no quantitative measurement was taken of the intensity of the light for irradiation and absorption of the light by the enol form of the product 3-oxobutanethioate **3**, only the relative reactivity will be discussed here. Figure 1 shows that both the compound **2** and **3** were formed even at low conversion percentage of **1Z**. The figure also shows that the amount of **2** and **3** were nearly constant after the staring material had completly disappaered. Therefore, the migration from **1Z** to **2** competes with the demethylation to **3**. The formation of both **2** and **3** from **1Z** were efficiently and equally quenched with 1,3-pentadiene and sensitized with *p*-methoxy acetophenone, so that both **2** and **3** formations take place from the same triplet state of **1Z**.

The ratio of photoproduct **2** to **3** was strongly affected by the irradiation conditions. Figure 2 shows that compound **2** converts to compound **3** by prolonged

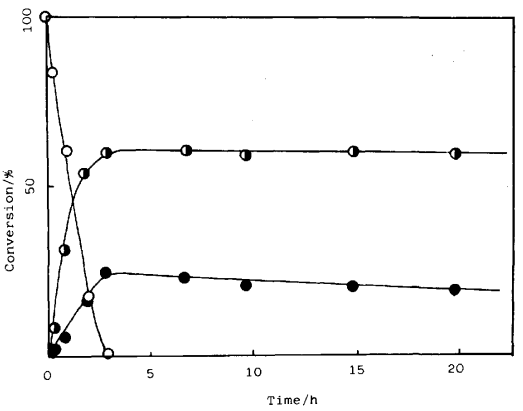


Fig. 1. Time-conversion curves for the photochemical reaction of **1Z** in degassed benzene-d_6

—○—: 1Z, —◑—: 2, —●—: 3.

iradiation in a nondegassed benzene solution. Dissolved oxyen might causes the transformation of **2** to **3**. The Figure also shows that the rate of disappearance of the starting compound **1Z** is enhanced in the nondegased benzene. Ethyl bromide also accelerated the photoreaction of **1Z** and the secondary photoreaction of **2**. The compounds containing heavy atoms enhance the rate of π,π^* S→T* intersystem crossing, and no heavy-atom enhancement of the rate of intersystem crossing takes place in the n,π^* excited state of ketones.[6] The external heavy atom effects on photoreactions of **1Z** and **2** suggest both the primary and the secondary photoreaction proceed from the π,π^* excited triplet state. Dissolved oxygen in solution probably operates through the catalysed intersystem crossing.[7]

The formation of **3** can be explained in terms of homolytic carbonoxygen bond cleavage from the π,π^* excited triplet state of **1Z**. Biphenyl could be detected by GLC analysis of a reaction mixture of a degassed benzene solution of **1Z**. This result supports the above mechanism for the formation of **3**. The formation of the methyl migration product **2** may be explained in terms of either the concerted 1,5-sigmatropic reaction or the nonconcerted radical rearrangement. Although the 1,5-sigmatropic reactions with inversion at the migration center are photochemically allowed,[8] the reactions in general do not take place from the $^3\pi,\pi^*$ states.[9] Therefore, the nonconcerted radicalrearrangement seems to be probable for the mechanism of the 1,5-methyl migration of **1Z**.

Irradiation of a benzene solution of the *E*-isomer 1E gave the *O*-demethylated product **3** in 58% yield.[10] No methyl migration products could be detected. Abcence of the methyl migration products in photolysis of the *E*-isomer seems to be explained in terms of the principle of least motion.[11] The distance separating the methoxyl and the carbonyl group should be larger in the *E*-isomer than in the *Z*-isomer. Therefore, the 1,5-methyl migration occurs easily in the case of the *Z*-isomer. The cage radical pair from the *E*-isomer seems to diffuse to free radicals.

Experimental

The IR spectra were recorded on a JASCO A-3 spectrometer. The UV spectra were taken on a JASCO HUN-790 spectrometer. The ^{1}H and the ^{13}C NMR spectra were measued on a JEOL FX-90Q spectrometer using TMS as an internal standard. Irradiation was carried out with an Ushio 450 W high-pressure mercury lamp.

Chemicals. The butenethioate **1Z** and **1E** were prepared by treatment of the 3-oxobutanethioate **3** with diazomethane in the usual way.[12] The *E*- and *Z*-configuration were deduced by ^{1}H NMR spectroscopic data.[13]

S-Butyl (E)-3-Methoxy-2-butenethioate (1E): Mp 44.6—45 °C; IR (KBr) 1430, 1510, 1660 cm^{-1}; UV λ_{max}^{EtOH} 293 nm (ε 6360); ^{1}H NMR ($CDCl_3$) δ=0.91 (3H, t, CH_3), 1.1—1.8 (4H, m, CH_2), 2.14 (3H, s, CH_3), 2.82 (2H, t, SCH_2), 3.83 (3H, s, OCH_3), 5.68 (1H, s, olefinic); ^{13}C NMR ($CDCl_3$) δ= 13.6 (q), 22.0 (t), 28.3 (t), 30.5 (q), 31.7 (t), 58.2 (q), 97.7 (d), 173.8 (s), 194.3 (s); Found: C, 57.23; H, 8.64%. Calcd for $C_9H_{16}O_2S$: C, 57.41; H, 8.65%.

S-Buthyl (Z)-3-Methoxy-2-butenethioate (1Z): Mp 41.5—42 °C; IR (KBr) 1380, 1600, 1660 cm^{-1}; UV λ_{max}^{EtOH} 273 nm (ε 6960); ^{1}H NMR ($CDCl_3$) δ=0.91 (3H, t, CH_3), 1.1—1.8 (4H, m, CH_2), 2.01 (3H, s, CH_3), 2.86 (2H, t, SCH_2), 3.85 (3H, s, OCH_3), 5.24 (1H, s, olefinic); ^{13}C NMR ($CDCl_3$) δ= 13.7 (q), 18.7 (q), 22.1 (t), 28.0 (t), 32.0 (t), 56.2 (q), 105.1 (d), 165.1 (s), 186.1 (s); Found: C, 57.24; H, 8.60%. Calcd for $C_9H_{16}O_2S$: C, 57.41; 8.65%.

Preparative Irradiation of 1Z. A solution of **1Z** (300 mg, 1.60 mmol) in benzene (5 cm^3) was placed in a 15×150 mm Pyrex culture tube. The solution was degassed by three freeze-pump-thaw cycles, sealed and irradiated for 2 h with a high-pressure mercury lamp. After removal of the solvent, the residual oil was chromatographed on silica gel. Elution with benzene–ethyl acetate (4:1) gave **2** (195 mg, 65%) and **3** (70 mg, 25%). **2**: bp 220 °C/10 Torr (1 Torr≈ 133.322 Pa); IR (neat) 1680 cm^{-1}; UV λ_{max}^{EtOH} 263 nm (ε 5360); ^{1}H NMR ($CDCl_3$) δ=0.92 (3H, t, CH_3), *ca.* 1.2—1.8 (4H, m, CH_2), 2.28 (3H, s, CH_3CO), 2.88 (2H, t, SCH_2), 3.64 (3H, s, OCH_3), 5.39 (1H, s, olefinic); ^{1}H NMR (C_6D_6) δ=0.81 (3H, t, CH_3), *ca.* 1.1—1.7 (4H, m, CH_2), 2.28 (3H, s, CH_3CO), 2.88 (3H, s, OCH_3), 2.94 (2H, t, SCH_2), 5.26 (1H, s, olefinic); ^{13}C NMR ($CDCl_3$) δ=13.7 (q), 19.7 (q), 22.1 (t), 28.4 (t), 32.2 (t), 55.4 (q), 99.3 (d), 169.9 (s), 187.8 (s); Found: C, 57.51; H, 8.61%. Calcd for $C_9H_{16}O_2S$: C, 57.41; H, 8.56%.

Preparative Iradiation of 1E. A solution of **1E** (12 mg, 0.65 mmol) in benzene (5 cm^3) was irradiated for 10 h with a high-pressure mercury lamp. The usual work-up gave the unreacted **1E** (62 mg) and **3** (32 mg, 58%).

Quantitative Analysis of Photoreaction of 1Z. A degassed/nondegassed benzene-d_6 solution of **1Z** (0.30 mol/L) in a sealed NMR tube was irradiated. The amounts of **1Z**, **2**, and **3** were determined by ^{1}H NMR spectroscopy.

Reaction of Allene with Water Catalyzed by Palladium(0) in the Presence of Carbon Dioxide

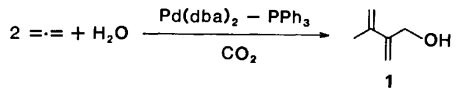
Yoshio INOUE,* Yukihiro OHTSUKA, and Harukichi HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Tohoko University, Aoba Aramaki Sendai 980
(Received April 14, 1984)

Synopsis. A novel reaction involving allene and water took place using palladium(0)-triphenylphosphine as a catalyst in the presence of carbon dioxide to yield 3-methyl-2-methylene-3-buten-1-ol, selectively. A related reaction of allene with methanol or ethanol was found to occur without carbon dioxide.

It has been reported that the dimerization of allene by palladium catalysts involves the incorporation of nucleophiles. The reaction produces functionalized 2,3-dialkyl-1,3-butadiene derivatives. The nucleophiles used so far has been carboxylic acids,[1] amines,[2] and active methylene compounds.[2] Triethylsilane also adds to allene to form triethylallylsilane.[2] In connection with the reaction of 1,3-diene with water,[3] we have studied the reaction of allene with water in the presence of palladium(0) catalysts and have found that a novel reaction took place under a carbon dioxide (CO_2) atmosphere to yield 3-methyl-2-methylene-3-buten-1-ol (**1**). The effect of CO_2 on the reaction of 1,3-butadiene with water has also been reported.[4] The related reaction of allene with alcohols, such as methanol and ethanol, was found to occur in the absence of CO_2. In this paper we describe the scope of the reaction.

Results and Discussion

It is possible to react allene with water in the presence of $Pd(dba)_2$–triphenylphosphine [dba=dibenzylideneacetone] (the catalyst) under a certain pressure of CO_2 to give 3-methyl-2-methylene-3-buten-1-ol (**1**). Allene oligomers were also formed in small amounts as by-products. Without CO_2 the reaction was very sluggish and gave only a trace amount of **1**.



1

Results are shown in Table 1. Generally ethers, such as tetrahydrofuran (THF) and 1,4-dioxane, were suitable as the solvent for the formation of **1**, except diethyl ether. Among them, THF was the best with respect to yield and selectivity toward **1**. Employment of a large excess of water (water/allene=10) did not give rise to **1**.

A reaction temperature of 80—90 °C and a reaction time of 1 h were the most suitable conditions. Longer reaction times caused a decrease in the yield, indicating that the product underwent further reaction.

The effect of the molar ratio $PPh_3/Pd(dba)_2$ on the reaction was investigated. The best result was obtained at a P/Pd ratio of 3 with 63% yield and 93% selectivity toward **1** at 80 °C in THF. A further addition of phosphine (P/Pd=4) led to a pronounced reduction of **1** (yield only 5%). When a molar ratio P/Pd=1 was used, a solvent-insoluble allene-polymer was formed at the expense of **1** (yield of **1**, 25%). The IR spectrum of the allene-polymer showed peaks at 1630, 1420, and 890 cm^{-1} indicating its structure as $[-CH_2C(=CH_2)-]_n$.[5]

The effect of diphosphines of the structure $Ph_2P(CH_2)_nPPh_2$ (n=1, 2, 3, 4, 6, 10, 12) was also examined under standard reaction conditions (diphosphine/Pd=1, THF, 80 °C, 1 h). Generally, these diphosphines retarded the formation rate of **1** (yield< 23%), especially with n=2 and 3, the reaction stopped. These observations may be explained by the chelating

Table 1. Reaction of allene with water[a]

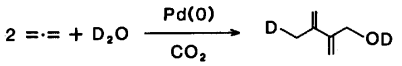
a) Allene (1.0 g, 24.9 mmol) in most cases. $Pd(dba)_2$(0.5 mmol), H_2O(50 mmol), solvent(10 cm^3), CO_2(10 atm). b) Based on allene charged. c) Apparent selectivity based on the area ratio in the glc chart. d) $(CH_3OCH_2CH_2)_2O$.

effect of the diphosphine ligands. They occupy coordination sites of the metal and prevent allene from occupying sufficient coordination sites for the reaction.

The introduction of CO_2 changes the acidity of the medium. Thus, further studies examined the effects of acids and bases. The addition of an acid such as $BF_3 \cdot OEt_2$ (10 equiv with respect to Pd) or trifluoroacetic acid (1.5 equiv) inhibited the formation of alcohol **1**. The formation of **1** was also inhibited by $NaHCO_3$ (2 equiv with respect to Pd) or NaOH (10 equiv). Interestingly, the catalytic activity was restored by the introduction of CO_2 in the case of $NaHCO_3$. The effect of CO_2 was characteristic.

Apparently hydrogen in the water was incorporated into the C_6 moiety of dienol **1**. ^1H NMR analysis clearly showed that a deuterium migrated into the methyl group of product **1** obtained from the experiment employing D_2O. However the reaction mechanism



cannot be easily delineated by this observation alone, because such an incorporation of hydrogen may occur *via* a variety of mechanisms including the bis(σ-allyl)palladium intermediate.[2] At present we hesitate to propose a conclusive mechanism.

Unlike the allene–water reaction, the related reaction of allene with alcohol took place in the absence of CO_2. The product was 4-alkoxy-2-methyl-3-methylene-1-butene (**2**). The results are summarized in Table 2. The introduction of CO_2 led to a decreased formation of **2**,

2a R=Me
b R=Et

contrary to the case of water. The reaction was markedly effected by the molecular weight of the alcohol employed. Thus, methanol gave rise to a higher yield of **2a**, whereas 1-butanol gave this product only in trace amounts. Since there is only a little difference in the acidity constant among the alcohols used, steric factors may be responsible for such an effect.

Table 2. Reaction of allene with alcohol[a]

a) Allene(1.0 g, 24.9 mmol) in most cases. $Pd(dba)_2$ (0.5 mmol), PPh_3(1.0 mmol); 100 °C, 2 h. b) Based on allene charged. c) Apparent selectivity based on the area ratio in the glc chart. d) Under CO_2 pressure (10 atm). e) CH_3ONa(5.0 mmol) was added. f) Under CO_2 pressure(10 atm) in the presence of CH_3ONa(5.0 mmol).

Experimental

Reaction of Allene with Water. Typically, allene (1.0 g, 24.9 mol) was allowed to react with H_2O (50 mmol) in THF (10 cm³) in the presence of $Pd(dba)_2$ (0.5 mmol) and PPh_3 (1.0 mmol) at 80 °C for 1 h under CO_2 pressure (10 atm) in an autoclave. After the reaction, the mixture was filtered to remove allene polymers, if any. The filtrate was analyzed by glc; Silicone GE SE-52, 90 °C.

Isolation of 3-Methyl-2-methylene-3-buten-1-ol (1). The products of several experiments were combined. The solvent (THF) was removed by distillation under a reduced pressure at room temperature. The residue was subjected to flash-distillation under reduced pressure. The distillate consisted of organic and water layers. Glc analysis showed that the organic layer contained dienol **1** with a purity of ≈93% (area ratio). This organic sample yielded the following data: IR (neat) 3300, 1600, 1440, 1380, 1040, and 890 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.62 (s, 1H), 1.94 (s, 3H), 4.36 (s, 2H), 5.08 (m, 2H), and 5.23 (m, 2H). ^{13}C NMR ($CDCl_3$) δ=21.05 (q), 63.88 (t), 112.52 (t), 112.66 (t), 140.78 (s), and 145.60 (s). MS (20 V) *m/z* 98 (M^+), 79, 69, and 55.

Reaction of Allene with Deuterium Oxide. This reaction was carried out in a manner similar to that described for the reaction of water with allene (1.0 g, 24.9 mmol), $Pd(dba)_2$ (0.5 mmol), PPh_3 (1.0 mmol), and D_2O (0.9 cm³) in THF (10 cm³) under CO_2 pressure (10 atm) at 80 °C for 1 h. Isolation by flash-distillation gave 0.27 g (22%) of the deuterated dienol in 95% purity. ^1H NMR analysis revealed that the incorporation of deuterium was exclusively on the methyl carbon, δ=1.95 (br. s, ≈2H).

Reaction of Allene with Methanol and Ethanol. The reaction was performed in a manner similar to that described above for the corresponding reaction of water employing allene (1.0 g, 24.9 mmol), $Pd(dba)_2$ (0.5 mmol), PPh_3 (1.0 mmol), and methanol (or ethanol) (5 cm³) in THF (5 cm³) at 100 °C for 2 h. The product analysis was carried out by glc.

Isolation of 4-Methoxy-2-methyl-3-methylene-1-butene (2a) and 4-Ethoxy-2-methyl-3-methylene-1-butene (2b). Most of the THF was removed by distillation under reduced pressure. The flash-distillation of the residue gave a mixture of **2a** and methanol (or **2b** and ethanol). A pure product was obtained by preparative glc. **2a**: IR (CCl_4) 1595, 1085, and 890 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.90 (s, 3H), 3.31 (s, 3H), 4.10 (s, 2H), 5.00 and 5.10 (m, 2H), and 5.20 (s, 2H). MS (20 V) *m/z* 112 (M^+), 97, 82, 79, and 67. **2b**: IR (CCl_4) 1590, 1090, and 890 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.21 (t, 3H), 1.92 (s, 3H), 3.50 (q, 2H), 4.16 (s, 2H), 5.00 and 5.10 (m, 2H), and 5.22 (s, 2H).

Efficient Preparation of 3-Alkyl(or Aryl)thio-1(or 2)-propenyl *p*-Tolyl Sulfones

Katsuyuki OGURA,* Teruyuki IIHAMA, Kazumasa TAKAHASHI, and Hirotada IIDA
Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoicho 1-33, Chiba 260
(Received April 27, 1984)

Synopsis. Synthetic routes from 3-chloro-1-propenyl *p*-tolyl sulfone to 3-(*p*-tolylthio)-1(or 2)-propenyl *p*-tolyl sulfone, 3-isopropylthio-1(or 2)-propenyl *p*-tolyl sulfone, and 3-methylthio-2-propenyl *p*-tolyl sulfone were exploited.

In connection with 1,3-bis(methylthio)-2-propenyllithium, an synthetic equivalent of 2-formylethenyl carbanion,[1] our attention was focused on the utilization of 3-alkyl(or aryl)thio-1(or 2)-propenyl *p*-tolyl sulfone (**1** or **2**) as a new type of synthetic reagent.[2] Since these compounds (**1** and **2**) were unknown in the literature,[3] an effective method for the preparation of **1** and **2** first had to be secured in order to accomplish organic syntheses utilizing them. Hence, we chose (*E*)-3-chloro-1-propenyl *p*-tolyl sulfone (**3**)[4] as a starting material.

1 **2**

a: R = Tol b: R = i-Pr c: R = CH_3

[Tol = p-tolyl]

In the reaction of **3** with a thiolate anion, displacement of chlorine atom by alkyl(or aryl)thio group and the Michael-type addition of a thiol (**4**) to the C–C double bond of **3** are anticipated to take place. Furthermore, migration of the C–C double bond of the displacement product (**1**) must be taken into consideration.[5,6] As is apparent from Table 1, the ratio of the products depended on the employed solvent and reaction time. In the reaction of **3** with **4a** and K_2CO_3 in DMF or CH_3CN, the displacement product (**1a**) was predominantly formed at the first stage, but the proportion of **2a** increased as the reaction proceeded. In contrast, the employment of THF as a solvent afforded **1a** in 90% yield even after a prolonged reaction time. This is probably because the solubility of K_2CO_3 in THF is too low to catalyze the migration of the C–C double in **1a**.

Compared with **4a**, **4b** produced a significant amount of the Michael-type adduct (**5b**) as shown in Table 1. Especially, the yield of **5b** was 70% in the reaction conducted in THF. Scheme 2 shows the whole

Scheme 2.

sequence for the conversion of **3** to **1** and **5**, where a thiolate anion (**4'**) is in equilibrium with **4** and **4'** reacts reversibly with **3** to form the carbanion (**5'**) of **5**. The reaction of **3** with lithium 2-propanethiolate in THF resulted in the exclusive formation of a cyclopropane derivative (**7b**) through an intramolecular cyclization of the intermediary carbanion (**5'b**). This fact suggests that the displacement reaction leading to **1** is relatively slow and **5'** is indeed produced under the present reaction conditions. Since **4b** is a relatively weak acid, the most part of the employed **4b** might remain unchanged to serve as a proton source. The insolubility of K_2CO_3 in THF seems to increase the population of **4b** to cause the rapid protonation of **5'b** resulting in the predominant formation of **5b**. We tried to facilitate the displacement reaction by utilizing of 3-iodo-1-propenyl *p*-tolyl sulfone (**8**). The starting material (**8**) was easily obtained on treatment of **3** with KI in refluxing acetone. In fact, when **8** was subjected to the reaction with **4b** (1.0 mol-equiv) and $NaHCO_3$ (1.0 mol-equiv) in DMF at room temperature, **1b** was cleanly produced in 82% yield.

In the reaction of **3** with **4c**, a commercially available 15% aqueous solution of sodium methanethiolate could be used as a source of methanethiolate

a) At room temperature. b) Mol-equiv to **3**. c) (*E*)-isomer. d) The value in the parenthesis is the ratio of the (*Z*)- and (*E*)-geometrical isomers (by ^1H NMR analysis). e) **3** was recovered in 15% yield.

anion to give **2c** as the only isolable product, but its yield was relatively low (72% in DMF, 38% in CH_3CN, and 46% in methanol). Hence, the Schneider's method[7] was applied to the preparation of **1c** or **2c**. Thus, a 1:10 mixture of **3** and dimethyl sulfide was stirred at room temperature for 4 d, but no reaction occurred. In contrast, the addition of KI (3 equiv) accelerated the reaction to form a 42:58 mixture of **1c** and **2c**. The complete conversion of this mixture to **2c** was readily achieved by treatment with K_2CO_3 in CH_3CN at room temperature. The overall yield of **2c** from **3** was 92%.

Experimental

Reaction of **3** with p-*Toluenethiol* (**4a**). *A Typical Procedure.* To a solution of **4a** (126 mg: 1.01 mmol) in CH_3CN (10 ml) were added K_2CO_3 (137 mg: 1.01 mmol) and **3**[4] (231 mg: 1.00 mmol), and the resulting mixture was stirred at room temperature for 10 h under an atmosphere of nitrogen. Then, saturated aqueous NH_4Cl (30 ml) was added and the mixture was extracted with CH_2Cl_2 (3× 40 ml). The extracts were combined, washed with water, and dried (Na_2SO_4). After evaporating the solvent, the residual yellow solid was subjected to column chromatography on silica gel [hexane–benzene(2:1)] to give 3-(*p*-tolylthio)-2-propenyl *p*-tolyl sulfone (**2a**) (317 mg; 99% yield) as a mixture of two geometrical isomers (*Z*:*E*=63:37). The (*Z*)-isomer was obtained in a pure form by recrystallization from EtOH. (*Z*)-**2a**: colorless crystals; mp 78—79 °C; IR (KBr) 1605, 1595, 1290, 1124 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.29 (3H, s), 2.42 (3H, s), 4.01 (2H, d, *J*=8 Hz), 5.69 (1H, dt, *J*=10, 8 Hz), 6.45 (1H, d, *J*=10 Hz), 7.00 (4H, s), 7.30 (2H, d, *J*=8 Hz), 7.80 (2H, d, *J*=8 Hz). Anal. ($C_{17}H_{18}O_2S_2$) C, H. The (*E*)-isomer of **2a** was isolated by recrystallization of a mixture of two geometrical isomers (*Z*:*E*=43:57) given in the reaction of **3** with **4a** in DMF. (*E*)-**2a**: colorless crystals; mp 109—110 °C (from EtOH); IR (KBr) 1603, 1598, 1302, 1129 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 2.33 (3H, s), 2.46 (3H, s), 3.78 (2H, d, *J*=7.4 Hz), 5.54 (1H, dt, *J*=15.5, 7.4 Hz), 6.18 (1H, d, *J*=15.5 Hz), 7.0—7.45 (6H, m), 7.72 (2H, d, *J*=7.5 Hz). Anal.($C_{17}H_{18}O_2S_2$) C, H.

1a: colorless crystals; mp 77—78 °C (from EtOH); ^1H NMR ($CDCl_3$) δ=2.25 (3H, s), 2.44 (3H, s), 3.51 (2H, d, *J*=7 Hz), 6.14 (1H, d, *J*=15 Hz), 6.88 (1H, dt, *J*=15, 7 Hz), 6.97 (2H, d, *J*=7 Hz), 7.14 (2H, d, *J*=7 Hz), 7.31 (2H, d, *J*=7.2 Hz), 7.60 (2H, d, *J*=7.2 Hz). Anal.($C_{13}H_{18}O_2S_2$) C, H.

Reaction of **3** *with Lithium 2-Propanethiolate.* To a solution of 2-propanethiol (421 mg: 5.52 mmol) in THF (5 ml), was added a 1.5 mol/l hexane solution (3.9 ml) of butyllithium (6.0 mmol) under ice-cooling, and the resulting mixture was stirred at room temperature for 1 h. After the addition of **3** (1.28 g: 5.53 mmol), the mixture was further stirred under ice-cooling for 2 h. The aqueous workup and column chromatography on silica gel [benzene–hexane (1:1)] gave **7** (834 mg: 56%) as colorless crystals: mp 58 °C (from benzene–hexane); ^1H NMR ($CDCl_3$) δ=1.20 (3H, d, *J*=6.6 Hz), 1.23 (3H, d, *J*=6.6 Hz), 1.45—1.85 (2H, m), 2.45 (3H, s), 2.40—3.05 (4H, m), 7.29 (2H, d, *J*=7.8 Hz), 7.71 (2H, d, *J*=7.8 Hz). Anal.($C_{13}H_{18}O_2S_2$) C, H.

Preparation of (E)-*1b via 3-Iodo-1-propenyl* p-*Tolyl Sulfone* (*8*). A mixture of **3** (932 mg: 4.04 mmol) and KI (2.01 g: 12.1 mmol) in acetone (30 ml) was refluxed for 3 h. The aqueous workup gave crude **8** as a pale yellow solid. After a mixture of 2-propanethiol (91 mg: 1.2 mmol) and $NaHCO_3$ (103 mg: 1.22 mmol) in DMF (10 ml) was stirred at room temperature for 30 min, the crude **8** (382 mg: 1.18 mmol) was added and the resulting mixture was further stirred at room temperature for 12 h under an atmosphere of nitrogen. The usual workup followed by column chromatography gave 263 mg (82% yield) of **1b** as colorless crystals.

Reaction of **3** *with Sodium Methanethiolate.* To a solution of **3** (387 mg: 1.68 mmol) in DMF (10 ml), was added a 15% aqueous solution (1.73 g: 4.13 mmol) of sodium methanethiolate (Tokyo Kasei Inc.) under an atmosphere of nitrogen, and the resulting mixture was stirred at room temperature for 3 h. The aqueous workup and the subsequent separation by column chromatography on silica gel [hexane–benzene (1:2)] to afford **2c** (290 mg: 71% yield) as a mixture of two geometrical isomers (*Z*:*E*=27:73). Rechromatography of this mixture and recrystallization gave pure (*Z*)-**2c** and pure (*E*)-**2c**. (*E*)-**2c**: colorless crystals; mp 79—80 °C (from ethanol); ^1H NMR ($CDCl_3$) δ=2.23 (3H, s), 2.46 (3H, s), 3.77 (2H, d, *J*=7.5 Hz), 5.35 (1H, dt, *J*=16, 7.5 Hz), 6.13 (1H, d, *J*=16 Hz), 7.35 (2H, d, *J*=8.5 Hz), and 7.73 (2H, d, *J*=8.5 Hz). Anal.($C_{11}H_{14}O_2S_2$) C, H. (*Z*)-**2c**: a colorless oil; ^1H NMR ($CDCl_3$) δ=2.12 (3H, s), 2.44 (3H, s), 3.94 (2H, d, *J*=7.5 Hz), 5.54 (1H, dt, *J*=7.5 Hz), 6.25 (1H, d, *J*=9 Hz), 7.29 (2H, d, *J*=8.5 Hz), 7.72 (2H, d, *J*=8.5 Hz). Anal.($C_{11}H_{14}O_2S_2$) C, H.

Reaction of **3** *with Dimethyl Sulfide* A mixture of dimethyl sulfide (41.8 g: 0.25 mol), **3** (15.4 g: 0.067 mol), and KI (33.7 g: 0.020 mol) was stirred at room temperature for 7 d. After the addition of water (100 ml), the resulting mixture was extracted with CH_2Cl_2 (3×80 ml). The extracts were combined, washed with saturated aqueous $NaHSO_3$, dried (Na_2SO_4), and evaporated. The residue was dissolved in CH_3CN (50 ml) and K_2CO_3 (929 mg: 6.70 mmol) was added. The mixture was stirred at room temperature for 1 d and water (100 ml) was added. The usual workup followed by column chromatography gave **2c** (14.94 g: 92% yield) (*Z*:*E*=28:72).

Alkoxylation of Ferrocene by Photolysis of Haloferrocenes in Aqueous Alcohols

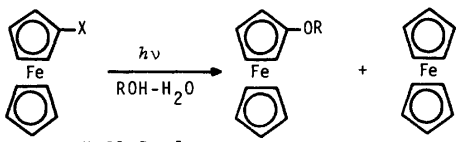
Katsuyoshi SHIBATA,* Yoshiyuki SAITO, Masaki MATSUI, and Yoshimi TAKASE
Department of Industrial Chemistry, Faculty of Engineering, Gifu University, Yanagido, Gifu 501-11
(Received May 4, 1984)

Synopsis. The UV irradiation of haloferrocenes in aqueous alcohols resulted in an alcoholysis with the formation of the corresponding alkoxyferrocenes accompanied by the formation of ferrocence. The order of the reactivities of haloferrocenes was I>Br>Cl.

Considerable attention has been directed to the realm of photosubstitution of aromatic compounds.[1] However, photosubstitution of ferrocene derivatives has not been extensively studied.[2] In this paper, we report the photolysis of haloferrocenes in aqueous alcohols. The photochemical substitution of halogens with alkoxyl groups occurred.

The irradiation of an aqueous methanol solution of bromoferrocene in the presence of sodium carbonate afforded methoxyferrocene(60%) and ferrocene(8%). Similarly, iodo- and chloroferrocenes produced methoxyferrocene. Photolysis of these haloferrocenes in other alcohols also gave mixtures of the corresponding alkoxyferrocenes and ferrocene.

The photoreactions are generalized in Scheme 1. The results are summarized in Table 1. The reactivities of halogens are I>Br>Cl for both photosubstitution and photoreduction.



Scheme 1.

TABLE 1. PHOTOCHEMICAL REACTIONS OF HALOFERROCENES WITH ALCOHOLS

FcX[a] X	ROH[b] R	Time of irradn/h[c]	Conversion/%	Yield/%[d] FcOR	Yield/%[d] FcH

	Et	1.5	75	37	10
	n-Pr	1.5	59	14	13
	i-Pr	1.5	64	21	15
	t-Bu	1.5	45	8	18
I	Me	1.0	93	47	25
	i-Pr	1.0	74	18	28

a) [FcX] = 1.8 mmol dm^{-3}. b) The solutions contained 10% of water and 10 mmol dm^{-3} of Na_2CO_3. c) High pressure Hg arc lamp with a Pyrex filter. d) Yields were determined by GLC and based on unrecovered haloferrocene.

The nucleophilic substitution of ferrocene derivatives takes place with difficulty, and few cases have been reported.[3] The alkoxyferrocenes, other than methoxyferrocene, have not been synthesized. This type of reaction affords a new route for the introduction of alkoxyl groups into the ferrocene ring: The reactivity of chloroferrocene is too small. The reaction of iodoferrocene gave a considerable amount of ferrocene. Consequently, bromoferrocene is adequate for the synthesis of alkoxyferrocenes.

Experimental

The melting points were measured with a Mettler FR-2 melting point apparatus and are uncorrected. IR spectra were obtained with a JASCO A-302 spectrometer. ^{1}H NMR spectra were taken with a Hitachi R-22 apparatus an chemical shifts are given in ppm from TMS internal standard. GLC analysis were carried out by means of a Shimadzu 4C-PF apparatus. Mass spectra were obtained using a Hitachi M-52 mass spectrometer at 20 eV.

Materials. Bromo- and iodoferrocenes were synthesized by the reaction of *N*-halosuccinimides with ferrocenylmercury(II) chloride.[4] Bromoferrocene; mp 31.5—32 °C (lit,[4] 30—31 °C). Iodoferrocene; mp 46—47 °C (lit,[4] 45.5—46 °C). Chloroferrocene was prepared by refluxing iodoferrocene with copper(I) chloride in pyridine.[5] mp 57—57.5 °C (lit,[5] 56—56.5 °C).

Irradiation of Haloferrocenes. A solution of haloferrocene(1.8 mmol dm^{-3}) in alcohol-water(9:1 v/v, 200 cm^3) in the presence of sodium carbonate(5 mmol dm^{-3}) was irradiated in a Pyrex vessel with a 300 W high pressure Hg arc lamp (Eikosha) externally at room temperature. The reaction mixture was extracted with benzene, and resultant benzene solution was washed with water and dried (Na_2SO_4). After removal of the solvent, products were isolated by means of preparative TLC (Merck Silica Gel 60 PF_{254}-hexane).

Methoxyferrocene: Mp 40—41 °C (lit,[4] 39—40.5 °C). Found: M$^+$ 216.

Ethoxyferrocene: An orange oily substance. IR (neat) 3120, 2995, 1108, 1025, 1003, 816, 688 (Fc ring), 2950, 1476, 1382, 1251, and 1065 cm^{-1} (EtO); ^{1}H NMR ($CDCl_3$) δ=1.32 (t, 3H), 3.81 (q, 2H), 3.75—3.95 (m, 2H), 4.0—4.15 (m, 2H) and 4.16 (s, 5H); MS *m/z* (rel intensity) 230 (M$^+$, 100), 202 (76), 172 (33), and 121 (33). Found: C, 62.38; H, 6.01. Calcd for $C_{12}H_{14}OFe$: C, 62.64; H, 6.13.

Propoxyferrocene: An orange oily substance; IR (neat) 3105, 2970, 1104, 1000, 815, 682 (Fc ring), 2940, 2880, 1472, 1387, 1250, and 1060 cm^{-1} (*n*-PrO); ^{1}H NMR ($CDCl_3$) δ=1.00 (t, 3H), 1.73 (sex, 2H), 3.76 (t, 2H), 3.86 (s, 2H), 4.10 (s, 2H), and 4.20 (s, 5H); MS *m/z* (rel intensity) 244 (M$^+$, 59), 202 (75), 172 (18), and 121 (100). Found: C, 63.62; H, 6.45. Calcd for $C_{13}H_{16}OFe$: C, 63.96; H, 6.61.

Isopropoxyferrocene: An orange oily substance; IR (neat) 3120, 3000, 1003, 819, 629 (Fc ring), 2955, 2870, 1388, 1378, 1255, 1122, 1045, and 918 cm^{-1} (*i*-PrO); ^{1}H NMR ($CDCl_3$) δ=1.28 (d, 6H), 3.8—4.0 (m, 2H), 4.0—4.2 (m, 3H), and 4.19 (s, 5H); MS *m/z* (rel intensity) 244 (M$^+$, 100), 202 (76), 172 (33), and 121 (33). Found:

C, 63.57; H, 6.48. Calcd for $C_{13}H_{16}OFe$: C, 63.96; H, 6.61.

t-Butoxyferrocene: mp 68—68.5 °C; IR (KBr) 3110, 2995, 1110, 1012, 802 (Fc ring), 2950, 2880, 1460, 1373, 1365, 1246, and 1055 cm^{-1} (*t*-BuO); ^1H NMR ($CDCl_3$) δ=1.13 (s, 9H), 3.8—4.0 (m, 2H), and 4.05—4.3 (m, 7H), MS *m/z* (rel intensity) 258 (M^+, 100), 202 (98), 172 (50), and 121 (33). Found: C, 65.01; H, 7.07. Calcd for $C_{14}H_{18}OFe$: C, 65.14; H, 7.03.

A Synthesis of *dl*-Pumiliotoxin-C

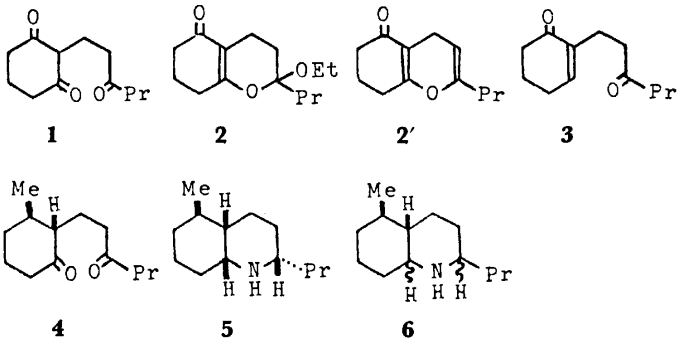
Kyo Abe,* Teruhisa Tsugoshi, and Nobuo Nakamura
Department of Chemistry, Osaka City University, 3-3-138 Sugimoto-cho, Sumiyoshi-ku, Osaka 558
(Received May 5, 1984)

Synopsis. Reductive aminocyclization of trans-2-(3-oxohexyl)-3-methyl-1-cyclohexanone (**4**) with sodium cyanotrihydroborate and ammonium bromide gave *dl*-pumiliotoxin-C (**5**) and its stereochemical isomer (**6**) in a ratio of 48:52.

Recently, we have reported of reductive aminocyclization of 2,6-alkanediones with sodium cyanotrihydroborate and ammonium bromide to afford *cis*-6-alkyl-2-methylpiperidine as a sole product.[1]

This experimental fact stimulated us to synthesize **5**, a minor component of the frog Dendrobates pumilio,[2] although many chemists have already reported on its synthesis.[3–6]

This paper reports of experimental results and discussion of our synthesis of **5**.



Results and Discussion

For reductive aminocyclization, *trans*-2-(3-oxohexyl)-3-methyl-1-cyclohexanone (**4**) was prepared from 1,3-cyclohexanedione in 4 steps: In the first step, 1,3-cyclohexanedione was alkylated with 1-chloro-3-hexanone under alkaline conditions to afford 2-(3-oxohexyl)-1,3-cyclohexanedione (**1**) in 40% yield. **1** was refluxed in ethanol and benzene with a catalytic amount of *p*-toluenesulfonic acid to give 2-ethoxy-2-propyl-7,8-dihydro-5(6*H*)-chromanone (**2**) quantitatively. The structure of **2** was confirmed from the following two experimental facts: even when **2** was treated with an excess amount of lithium aluminum hydride, 2-(3-oxohexyl)-2-cyclohexen-1-one (**3**) as a sole product was given in 80% yield; **2** was easily converted to 2-propyl-5,6,7,8-tetrahydro-4*H*-chromen-5-one (**2′**) on distillation. The enone **3** was treated with lithium dimethylcuprate(**I**) in dry ether to give **4** in 90% yield. The stereochemical correlation between the methyl and 3-oxohexyl groups must be trans configuration. Thus **4** was treated with sodium cyanotrihydroborate and ammonium bromide in dry methanol at room temperature for 4 d and worked up to give a basic yellow oil in 88% crude yield. A GLC analysis showed that the basic oil consisted of two components in a ratio of 48:52 at R_t's 4.5 and 4.8 min, respectively. The first peak was identical with an authentic sample of **5** as revealed by the co-injection method. They were separated by means of preparative GLC using a glass column packed with 5% Silicone OV-1. Each of them was converted to its hydrochloride. The salt of the first peak component was identical with an authentic sample of *dl*-pumiliotoxin-C hydrochloride as revealed by comparison of their melting points and ^{13}C NMR spectra. The hydrochloride of the second one had the same chemical formula as the hydrochloride of **5** as a result of elemental analysis and melted at 246—250 °C. These facts suggest that the second one **6** seems to be a stereochemical isomer of **5**. But we could not determine its stereochemistry.

Experimental

All melting and boiling points are uncorrected. ^1H and ^{13}C NMR spectra were measured with a JEOL PS-100 and a JEOL FX-100, respectively, using tetramethylsilane as internal standard.

2-(3-Oxohexyl)-1,3-cyclohexanedione (1). Into 30 ml of aqueous solution of potassium hydroxide (8.4 g, 0.15 mol) was dissolved solid 1,3-cyclohexanedione (10.8 g, 0.15 mol). Then a solution of 1-chloro-3-hexanone (20.3 g, 0.15 mol) in methanol (75 ml) was added into it. The reaction mixture was stirred for 24 h at room temperature and then concentrated to one fifth volume. It was made alkaline with aqueous solution of potassium hydroxide and then extracted with ether several times. The aqueous layer was acidified with hydrochloric acid and then extracted with ether (30 ml×5). The ethereal extract was washed with brine and dried over anhydrous sodium sulfate. After removal of the solvent, the residue became crystalline, which was recrystallized from hexane to give **1** (7.5 g, 40% yield): mp 87—88 °C; IR (CCl_4) 3150, 1680, and 1600 cm^{-1}; UV (EtOH) 263 nm (1.5×10^4); MS 210 (M^+); ^1H NMR ($CDCl_3$) δ=0.93 (t, J=7 Hz, 3H), 1.42—2.20 (m, 5H), 2.20—2.60 (m, 8H), and 2.60—2.81 (m, 2H): Found C, 68.54; H, 8.63. Calcd for $C_{12}H_{18}O_3$: C, 68.56; H, 8.72.

2-Ethoxy-2-propyl-7,8-dihydro-5(6H)-chromanone (2). A mixture of **1** (4 g, 19 mmol), a catalytic amount of *p*-toluenesulfonic acid, ethanol (60 ml), and benzene (180 ml) was slowly refluxed in a Dean-Stark apparatus to remove deposited water azeotropically. It was washed with 10% aque-

ous solution of sodium hydroxide three times and with brine, and dried over anhydrous sodium sulfate. After removal of the solvent, the residue obtained was used for the next step without further purification. When it was distilled under reduced pressure, it decomposed to 2-propyl-5,6,7,8-tetrahydro-4*H*-chromen-5-one (**2'**): Crude yield 4.5 g, quantitative; IR (neat) 1700, 1650, 1620, 1380, 1220, 1180, and 1130 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.95 (t, J=7 Hz, 3H), 1.10 (t, J=7.5 Hz, 3H), 1.2—1.7 (m, 4H), 1.7—2.1 (m, 4H0, 2.25 (t, J=7 Hz, 6H), and 3.45 (q, J=7.5 Hz, 2H).

2-Propyl-5,6,7,8-tetrahydro-4H-chromen-5-one (2'). ^1H NMR ($CDCl_3$) δ=0.93 (t, J=7 Hz, 3H), 1.50 (sex, J=7 Hz, 2H), 1.90 (t, J=7 Hz, 2H), 2.88 (t, J=7 Hz, 4H), and 4.70 (t, J=4.5 Hz, 1H).

2-(3-*Oxohexyl*)-2-*cyclohexen*-1-*one* (**3**). To a stirred suspension of lithium aluminum hydride (0.83 g, 0.02 mol) in dry ether (50 ml) was added dropwise a solution of **2** (2.38 g, 0.01 mol) in dry ether (50 ml). The mixture was stirred for 3 h at room temperature and then treated carefully with water. The white solid formed was filtered through Celite and washed successively with ether. The filtrate was washed with brine. After removal of the solvent, the residue was distilled under reduced pressure to give **3** (15.6 g, 80% yield): bp 81—90 °C (0.01 mmHg) (1 mmHg=133.322 Pa); IR (neat) 1700, 1660, 1610, 1440, 1410, 1370, 1250, 1170, 1130, 1100, 1080, 1000, and 900 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 0.9 (t, J=7.5 Hz, 3H), 1.55 (t, J=4.5 Hz, 2H), 2.00 (m, 2H), 2.15—2.60 (m, 1H), and 6.70 (t, J=4.5 Hz, 1H); MS 119 (M^+). Found: C, 74.19; H, 9.14. Calcd for $C_{12}H_{18}O_2$: C, 73.76; H, 9.35.

2-(3-Oxohexyl)-3-methyl-1-cyclohexanone (4). To a suspension of copper(I) iodide (5.73 g, 0.03 mol) in dry ether (100 ml) was added an ethereal solution of methyllithium (0.06 mol) at −15 °C in an argon atmosphere. When the mixture became transparent, a solution of **3** (3.88 g, 0.02 mol) in dry ether (60 ml) was added at −15 °C. The reaction mixture was stirred for 30 min and then treated with aqueous solution of ammonium chloride. The ethereal layer was washed with brine and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was distilled under reduced pressure to give **4** (3.8 g, 91% yield): bp 85—89 °C (0.03 mmHg); IR (neat) 1720, 1700, 1450, 1400, 1370, 1130, and 1040 cm^{-1}. ^1H NMR ($CDCl_3$) δ=9.25 (t, 7.5 Hz, 3H), 1.33 (d, J=7.5 Hz, 3H), 1.20—2.00 (m, 9H), and 2.20—2.70 (m, 7H). Found: C, 74.04; H, 10.53. Calcd for $C_{13}H_{22}O_2$: C, 74.24; H, 10.54.

Reductive Aminocyclization of 4 to dl-*Pumiliotoxin-C (5) and its Stereochemical Isomer (6).* To a suspension of **4** (2.38 g, 0.023 mol) and ammonium bromide (2.22 g, 0.023 mol) in dry methanol (30 ml) was added all at once sodium cyanotrihydroborate (0.71 g, 0.012 mol). The reaction mixture was stirred at room temperature for 4 d. Then it was acidified with conc. hydrochloric acid (pH 3) and stirred for additional 30 min. After evaporation of solvent from the reaction mixture under reduced pressure, the residue was washed with ether several times and then dissolved in water. The aqueous solution was extracted with ether by using an eternal extactor. The extracted ethereal solution was dried over anhydrous sodium sulfate and condensed to give a yellow oil (crude 2.93 g, 88% yield), which was offered for preparative GLC.

Preparative GLC of the Basic Yellow Oil. The GLC was carried out with a AEROGRAPH Model 920 (glass column, 5 mm×3 M, packed with 5% Silicone OV-1 on 80—100 mesh Chomosorb W, oven temp, 145 °C; injection temp, 160 °C). Two peaks appeared at R_t's 4.5 and 4.8 min in a ratio of 48:52, respectively. The first peak was identical with an authentic sample of **5**. The preparative GLC was carried out under the same conditions. The first component was converted to its hydrochloride in a usual manner: mp 230 °C [lit,[6] 232 °C]; ^{13}C NMR ($CDCl_3$) δ=13.19, 19.83, 20.63, 23.19, 25.29, 27.28, 29.15, 34.18, 34.69, 58.04, and 60.10. The second component also was converted to its hydrochloride, which was recrystallized from ethyl acetate and isopropyl alcohol (5:1): mp 246—250 °C (white needle); ^{13}C NMR ($CDCl_3$) δ=13.33, 18.28, 24.09, 25.29, 28.02, 29.89, 34.92, 36.56, 44.42, 58.12, and 61.70; Found: C, 67.26; H, 11.38, N, 5.94. Calcd for $C_{13}H_{26}ClN$: C, 67.39; H, 11.23; N, 6.05.

The authors wish to thank Drs. Toshiro Ibuka and Takashi Tokuyama for their offer of the precious sample of *dl*-pumiliotoxin-C, and also Mr Jun'ichi Goda for conducting the elemental analysis.

(Received May 17, 1984)

Synopsis. Various alkyl aryl trithiocarbonates may readily be synthesized in good yield at low temperatures such as 20 °C by allowing trioctylmethylammonium chloride (phase-transfer catalyst) to catalyze reaction of benzenethiols and alkyl halides with carbon disulfide.

Much attention has been focused on the synthesis of trithiocarbonates, which are very important intermediates for the preparation of insecticides and oil additives.[1] Some procedures for the synthesis of trithiocarbonates have been developed which employ reactions of sodium trithiocarbonates with alkyl halides,[2] thiophosgene with benzenethiols,[3] aryl chlorodithioformates with alkanethiols,[4] and lithio-2-alkyl thio-1,3-dithiolanes with alkyl halides.[5] Wepplo and Wright[6] synthesized alkyl cyanoalkyl trithiocarbonates *via* reaction of alkanethiols and haloalkanenitriles with carbon disulfide in the presence of tetrabutylammonium sulfate, but they were unable to obtain alkyl aryl trithiocarbonates.[6] These known procedures are not preferrable with respect to various points such as synthetic convenience, intractability of reagents and substrates, and availability of starting materials. In the course of our investigations on the chemistry of organosulfur compounds,[7] we have studied on the development of a new synthetic method for alkyl aryl trithiocarbonates. Here we wish to report of a convenient one-pot synthesis of trithiocarbonates from benzenethiols, carbon disulfide, and alkyl halides in the presence of a phase-transfer catalyst such as trioctylmethylammonium chlorid (TOMAC), the reaction sequence being summarized by Eqs. 1 and 2. Results obtained for the reaction of benzenethiol and carbon disulfide with methyl iodide are listed in Table 1. It should be noted that only a trace of trithiocarbonate is obtained in the absence of phase-transfer catalyst (run 5), whereas in the presence of 0.3 mmol TOMAC the desired trithiocarbonate **2a** is formed in a yield of 64% (run 6). Thus, a remarkable accelerating effect of TOMAC is found for this reaction. Moreover, a higher yield of trithiocarbonate **2a** is obtained with decreasing temperature (runs 3 and 4). This phenomenon is not unexpected since the intermediate, anion **1**, may be considered to be unstable at higher temperatures.

thesized *via* the reaction of benzenethiols with alkyl halides and carbon disulfide in the presence of TOMAC. As shown in Table 2, methyl 4-methylphenyl trithiocarbonate **2k** and benzyl 4-methylphenyl trithiocarbonate **2o** were obtained especially in high yields, 72 (run 12) and 85% (run 16), respectively. Trithiocarbonates bearing an electron-withdrawing group such as chlorine, however, were formed in low yield by this procedure (run 15). A plausible pathway for this reaction may comprise a nucleophilic attack of the thiolate anion moiety of intermediate **1** on the carbon atom of alkyl halides in the presence of TOMAC, as shown in Eqs. 1 and 2. The above results demonstrate that the catalytic approach utilized in this study may be of significant value for the preparation of alkyl aryl trithiocarbonates.

Experimental

IR spectra were obtained on a JASCO IR-G spectrophotometer. NMR spectra were measured with a Hitachi R-20B spectrophotometer (60 MHz) in $CDCl_3$ using TMS as internal standerd.

General Procedure. Carbon disulfide (20 mmol) and TOMAC (0.3 mmol) were added to a solution of benzenethiol (10 mmol) in aq NaOH (10 mmol) and after 2 h stirring at room temperature, alkyl halide (10 mmol) in benzene (10 ml) was added and stirring was continued for 3 h at room temperature. After completion of reaction the benzene layer was dried on sodium sulfate and then concentrated by evaporation of benzene under vacuum. Alkyl aryl trithiocarbonates **2a—o** and alkyl aryl sulfides **3a—o** were obtained by vacuum distillation and column chromatography on silica-gel (Wako Gel C-300) using hexane-chloroform (9:1) as eluent.

*Physical Properties of **2a—o**.* *Methyl Phenyl Trithiocarbonate (**2a**)*: Bp 142—6 °C (2 mmHg) (1 mmHg=133.322 Pa); IR 1048 and 1076 cm^{-1}; NMR ($CDCl_3$) δ=2.46 (S, 3H) and 7.39 (s, 5H). Found: C, 48.13; H,4.26. Calcd for $C_8H_8S_3$: C, 47.96; H, 4.03.

*Benzyl Phenyl Trithiocarbonate (**2b**)*: Bp 130—2 °C (2 mmHg); IR 1048 and 1062 cm^{-1}; NMR ($CDCl_3$) δ=4.46 (s, 2H) and 7.0—7.3 (m, 10H). Found: C, 60.52; H, 4.12. Calcd for $C_{14}H_{12}S_3$; C, 60.83; H, 4.38.

*Ethyl Phenyl Trithiocarbonate (**2c**)*: Bp 144—7 °C (2 mmHg); IR 1056 and 1072 cm^{-1}; NMR ($CDCl_3$) δ=1.12 (t, 3H), 3.12 (t, 2H), and 7.3—7.5 (m, 5H). Found: C, 51.14; H, 4.73. Calcd for $C_9H_{10}S_3$: C, 50.43; H, 4.70.

*Phenyl Propyl Trithiocarbonate (**2d**)*: Bp 145—9 °C (2 mmHg); IR 1037 and 1065 cm^{-1}; NMR ($CDCl_3$) δ=0.83 (t, 3H), 1.2—1.9 (m, 2H), 3.13 (t, 2H), and 7.0—7.5 (m, 5H). Found: C, 52.74; H, 5.52. Calcd for $C_{10}H_{12}S_3$: C, 52.59; H, 5.30.

*Isopropyl Phenyl Trithiocarbonate (**2e**)*: Bp 130—2 °C (2 mmHg); IR 1042 and 1062 cm^{-1}; NMR ($CDCl_3$) δ=1.22 (d, 6H), 4.00 (m, 1H), and 7.2—7.4 (m, 5H). Found: C, 52.73; H, 5.56. Calcd for $C_{10}H_{12}S_3$: C, 52.59; H, 5.30.

*Butyl Phenyl Trithiocarbonate (**2f**)*: Oil; IR 1060 and 1040 cm^{-1}, NMR ($CDCl_3$) δ=0.90 (t, 3H), 1.4—1.8 (m, 4H), 3.21 (t, 2H), and 7.45 (s, 5H). Found: C, 54.96; H, 5.96. Calcd for $C_{11}H_{14}S_3$: C, 54.55; H, 5.79.

*Pentyl Phenyl Trithiocarbonate (**2g**)*: Oil; IR 1060 and 1040 cm^{-1}; NMR ($CDCl_3$) δ=0.90 (t, 3H), 1.3—1.5 (m, 6H) and 7.48 (s, 5H). Found: C, 56.67; H, 6.20. Calcd for $C_{12}H_{16}S_3$: C, 56.25; H, 6.25.

*Isopentyl Phenyl Trithiocarbonate (**2h**)*: Oil; IR 1056 and 1045 cm^{-1}; NMR ($CDCl_3$) δ=0.92 (d, 6H), 1.4—1.7 (m, 3H), 3.22 (t, 2H), and 7.47 (s, 5H). Found; C, 56.61; H, 6.34. Calcd for $C_{12}H_{16}S_3$: C, 56.25; H, 6.25.

*Hexyl Phenyl Trithiocarbonate (**2i**)*: Oil; IR 1062 and 1040 cm^{-1}; NMR ($CDCl_3$) δ=0.88 (t, 3H), 1.25—1.6 (m, 8H), 3.21 (t, 2H), and 7.48 (s, 5H). Found: C, 58.04; H, 6.71. Calcd for $C_{15}H_{22}S_3$: C, 57.78; H, 6.67.

*Octyl Phenyl Trithiocarbonate (**2j**)*: Oil; IR 1063 and 1045 cm^{-1}; NMR ($CDCl_3$) δ=0.88 (t, 3H), 1.25—1.6 (m, 10H), 3.20 (t, 2H), and 7.45 (s, 5H). Found: C, 60.68; H, 7.36. Calcd for $C_{15}H_{22}S_3$: C, 60.40; H, 7.38.

*Methyl 4-Methylphenyl Trithiocarbonate (**2k**)*: Bp 152—157 °C (2 mmHg); IR 1048 and 1074 cm^{-1}; NMR ($CDCl_3$) δ=2.29 (s, 3H), 2.42 (s, 3H), and 7.2—7.4 (m, 4H). Found: C, 50.86; H, 4.65. Calcd for $C_9H_{10}S_3$: C, 50.43; H, 4.70.

*Methyl 2-Methylphenyl Trithiocarbonate (**2l**)*: Mp 49.2—49.5 °C; IR 1048 cm^{-1}; NMR ($CDCl_3$) δ=2.42 (s, 3H), 2.58 (s, 3H), and 7.4—7.3 (t, 4H). Found: C, 50.63; H, 4.73. Calcd for $C_9H_{10}S_3$: C, 50.43; H, 4.70.

*Methyl 3-Methylphenyl Trithiocarbonate (**2m**)*: Oil; IR 1072 and 1044 cm^{-1}; NMR ($CDCl_3$) δ=2.36 (s, 3H), 2.52 (s, 3H), and 7.3-7.2 (d, 4H). Found: C, 49.90; H, 4.83. Calcd for $C_9H_{10}S_3$: C, 50.43; H, 4.70.

*4-Chlorophenyl Methyl Trithiocarbonate (**2n**)*: Bp 152—159 °C (4 mmHg); IR 1050 and 1078 cm^{-1}; NMR ($CDCl_3$) δ=2.60 (s, 3H) and 7.43 (s, 4H). Found: C, 40.27; H, 3.15. Calcd for $C_8H_7S_3Cl$: C, 40.93; H, 3.01.

*Benzyl 4-Methylphenyl Trithiocarbonate (**2o**)*: Oil; IR 1040 and 1065 cm^{-1}; NMR ($CDCl_3$) δ=2.34 (s, 3H), 4.40 (s, 2H) and 7.17—7.46 (m, 9H). Found: C, 62.06; H, 4.84. Calcd for $C_{15}H_{14}S_3$: C, 62.02; H, 4.87.

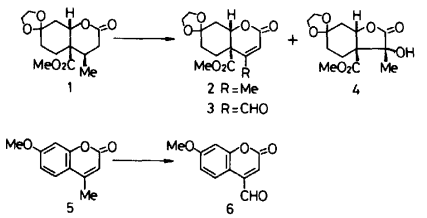
Oxidation Products of β-Methyl-substituted δ-Lactones Using Benzeneseleninic Anhydride and Selenium Dioxide

Takanao MATSUI,* Shuji TAHARA, and Mitsuru NAKAYAMA†
Faculty of Engineering, Miyazaki University, Miyazaki 880
†*Faculty of Science, Hiroshima University, Hiroshima 730*
(Received May 31, 1984)

Synopsis. When 9,9-ethylenedioxy-6-methoxycarbonyl-5-methyl-2-oxabicyclo[4.4.0]decan-3-one was treated with benzeneseleninic anhydride and selenium dioxide, the former yielded preferentially the 4,5-dehydrogenated compound (**2**) together with small amounts of the 5-formyl compound (**3**) and the contraction product (**4**) of the δ-lactone ring, while the latter produced solely **2** in a poor yield.

Utility of benzeneseleninic anhydride (BSA) as an oxidizing reagent has been growing in organic synthesis concerning the preparation of aldehydes and ketones from alcohols and benzylic hydrocarbons.[1] More recently, Barton *et al.* have reported that δ-lactones such as 4-oxa-5α-cholestan-3-one reacted with BSA to form the α,β-unsaturated lactones,[2] but there has been relatively few utilization of BSA as dehydrogenating reagent for lactones and lactams. In addition to the examples, we also wish to report the pretty preparation of 9,9-ethylenedioxy-6-methoxycarbonyl-5-methyl-2-oxabicyclo[4.4.0]dec-4-en-3-one (**2**)[3] from its 4,5-dihydro compound (**1**) by the use of BSA and the investigation of the oxidation products from cyclic lactones (**1**, **2**, and **5**) with BSA and SeO_2.



Scheme 1.

Oxidation reaction of **1** with 1.3 molar equivalent of BSA in chlorobenzene at 80—85 °C for 42 h under N_2 afforded the dehydrogenated compound **2** in 70% yield along with small amounts of the aldehyde **3** and contraction product, 4,4-ethylenedioxy-9-hydroxy-1-methoxycarbonyl-9-methyl-7-oxabicyclo[4.3.0]nonan-8-one (**4**) (Run 2). This method represented better yield of **2** and one-step preparation of α,β-unsaturated δ-lactone in comparison with the previous result due to oxidation-fragmentation of the phenylseleno derivative of **1**.[3] Some results obtained from the reactions which were carried out under a range of the reaction conditions as discussed below are shown in Table 1. The longer reaction time, 95—96 h at 82—90 °C (Run 4, 5) seemed to afford improvement of the yield of **2**, but when performed with more than 1.3 molar equivalent of BSA and refluxing conditions the yield of **2** became somewhat lower (Run 10). Attempts to effect a progressive preparation of **3** from **1** or **2** by utilizing BSA under various reaction conditions were unsuccessful, suggesting little participation of BSA itself in the formation of **3**. In contrast with BSA, using SeO_2 to the oxidation of **1** and **2** under refluxing conditions afforded **2** in *ca.* 17% yield (Run 15) and **3** in *ca.* 26% yield (Run 13), respectively. These results noted that the methyl group on C-5 of **2** was considerably oxidizable with SeO_2. Furthermore, a similar allylic oxidation reaction of an α,β-unsaturated δ-lactone moiety such as 7-methoxy-4-methylcoumarin (**5**) in hot chlorobenzene containing SeO_2 gave an excellent yield (89%) of its 4-formyl compound **6**. All the products **2**, **3**, **4**, and **6** gave satisfactory spectroscopic data and elemental analyses. In addition, the molecular of **4** was established unambiguously by an X-ray crystal structure analysis of its acetate (Fig 1).[5]

A pathway for the formation of **2** and **4** from **1** by the use of BSA can be explained on the basis of that for BSA oxidation proposed by Barton *et al.* (Scheme 2).[2,6] On the other hand, the case of **3** is considered that it was likely produced by further oxidation of **2** with some selenoxide species such as an analog of SeO_2 which would be allowed in the course of the oxidation reaction in the presence of BSA.

Thus, the use of BSA seems to be an effective way in view of the simple handling procedure in order to obtain α,β-unsaturated δ-lactones from its saturated lactones. It was also found that BSA is not convenient

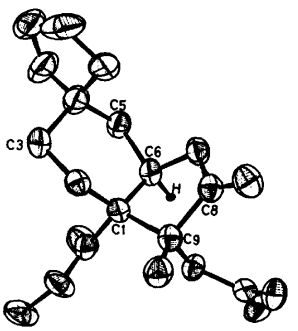


Fig. 1. ORTEP drawing of the molecular structure of acetate of **4**.[4]

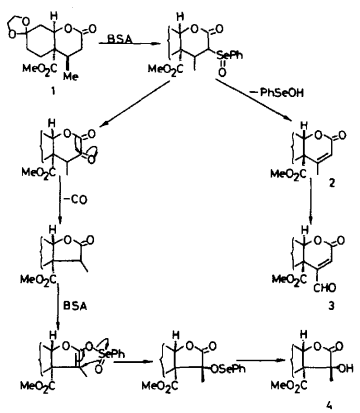

Scheme 2.

Table 1. Yields of 2 and 3[a]

Run	Compd	BSA or SeO_2[b]	Reaction temp/°C and time/h	Yield[c]/%	
				2	3
1[d]	1	1.30 BSA	65—67 40	17	None
2	1	1.30 BSA	80—85 42	70	Trace
3	1	1.29 BSA	90—95 42	69	Trace
4	1	1.30 BSA	82—88 95	75	Trace
5	1	1.30 BSA	78—90 96	78	Trace
6[d]	1	0.51 BSA	83—88 44	26	None
7[d]	1	0.86 BSA	82—87 42	41	None
8[d]	1	1.13 BSA	84—88 42	50	Trace
9	1	1.31 BSA	Reflux 20	41	6
10	1	2.50 BSA	Reflux 20	33	7
11[d]	2	1.28 BSA	Reflux 20		7
12[d]	2	2.50 BSA	Reflux 20		5
13[d]	2	1.25 SeO_2	Reflux 20		26
14[d]	1	2.50 SeO_2	Reflux 20	9	None
15[d]	1	1.20 SeO_2	Reflux 20	17	None

a) The reactions were carried out in chlorobenzene except those of Run 13 and 15 in *o*-xylene. b) Molar ratio of BSA or SeO_2 to the starting material. c) Determined by column chromatographic separation. d) These reactions, Run 1, 6—8, and 11—15 gave recovery of the starting material in 59, 51, 35, 44, 26, 68, 53, and 51%, respectively.

for the oxidation of allylic methyl group in comparison with SeO_2.

Experimental

IR and NMR spectra were measured in $CHCl_3$ and $CDCl_3$, respectively. Chemical shifts are given in δ values (ppm) downfield from the internal TMS reference. The X-ray diffraction data were obtained on an Enraf-Nonius CAD-4 automated four-circle diffractometer with a SDP program package.

General Procedure for the Oxidation of δ-Lactones Using BSA. A mixture of starting material and BSA in dry chlorobenzene was stirred under N_2. After removal of the solvent *in vacuo*, the residue was separated and purified by chromatographic work-up on silica gel with a mixture of benzene and ethyl acetate. **2**: Colorless plates, mp 105—107 °C (ethyl acetate–hexane); IR: 1735, 1720, and 1645 (weak) cm^{-1}; ^{1}H-NMR: 1.4—1.8 and 2.0—2.2 (6H, m, 3X-CH_2-), 2.07 (3H, s, C_5-CH_3), 3.76 (3H, s, -CO_2CH_3), 3.96 (4H, s, ethylenedioxy group), 5.04 (1H, dd, J=6 and 10 Hz, C_1-H), and 5.96 (1H, s, C_4-H); ^{13}C-NMR: 19.9 (q, C_5-CH_3), 26.9, 31.5, and 37.2 (each t, C_7, C_8, and C_{10}), 49.8 (s, C_6), 53.2 (q, -$CO_2\underline{C}H_3$), 64.6 (t, ethylenedioxy group), 77.6 (d, C_1), 107.1 (s, C_9), 120.0 (d, C_4), 155.2 (s, C_5), 162.7 (s, C_3), and 171.9 (s, -$\underline{C}O_2CH_3$); MS: *m/z* 282 (M^+); Found: C, 59.79; H, 6.51%. Calcd for $C_{14}H_{18}O_6$: C, 59.56; H, 6.43%. **3**: Colorless needles, mp 144—145.5 °C (ethyl acetate–hexane); IR: 2850, 2750 (weak), 1740, 1720, and 1620 (weak) cm^{-1}; ^{1}H-NMR: 1.3—1.6, 1.9—2.3, and 2.4—2.7 (6H, m, 3X-CH_2-), 3.75 (3H, s, -CO_2CH_3), 3.98 (4H, s, ethylenedioxy group), 5.04 (1H, dd, J=6 and 8 Hz, C_1-H), 6.76 (1H, s, C_4-H), and 9.73 (1H, s, -CHO); ^{13}C-NMR: 26.0, 31.1, and 37.2 (each t, C_7, C_8, and C_{10}), 47.3 (s, C_6), 53.4 (q, -$CO_2\underline{C}H_3$), 64.9 (t, ethylenedioxy group), 79.4 (d, C_1), 106.8 C_9), 134.0 (d, C_4), 150.0 (s, C_5), 161.9 (s, C_3), 171.0 (s, -$\underline{C}O_2CH_3$), and 191.3 (d, -CHO); MS: *m/z* 296 (M^+); Found: C, 56.93; H, 5.55%. Calcd for $C_{14}H_{16}O_7$: C, 56.75; H, 5.44%. **4**: Colorless plates, mp 183.5—185.5 °C (ethyl acetate–hexane); IR: 3600, 1780, and 1740 cm^{-1}; ^{1}H-NMR: 1.5—2.3 (6H, m, 3X-CH_2-), 1.50 (3H, s, C_9-CH_3), 3.21 (1H, s, OH), 3.78 (3H, s, -CO_2CH_3), 3.92 (4H, s, ethylenedioxy group), and 5.20 (1H, t, J=4 Hz, C_6-H); ^{13}C-NMR: 17.7 (q, C_9-CH_3), 25.2, 30.8, and 33.9 (each t, C_2, C_3, and C_5), 52.5 (q, -$CO_2\underline{C}H_3$), 55.2 (s, C_1), 64.2 and 64.7 (each t, ethylenedioxy group), 77.5 (d, C_6), 78.6 (s, C_9), 106.3 (s, C_4), 170.5 (s, -$\underline{C}O_2CH_3$), and 174.8 (s, C_8); MS: *m/z* 286 (M^+); Found: C, 54.61; H, 6.35%. Calcd for $C_{13}H_{18}O_7$: C, 54.55; H, 6.29%. This compound was obtained in less than 10% yield. Acetate of 4: Colorless plates, mp 129—130.5 °C (ethyl acetate–hexane); IR: 1790, 1750, and 1740 cm^{-1}, ^{1}H-NMR: 1.5—2.3 (6H, m, 3X-CH_2-), 1.66 (3H, s, C_9-CH_3), 2.00 (3H, s,-$OCOCH_3$), 3.79 (3H, s, -CO_2CH_3), 3.92 (4H, s, ethylenedioxy group), and 5.15 (1H, t, J=4 Hz, C_6-H); MS: *m/z* 328 (M^+); Found: C, 54.96; H, 5.85%. Calcd for $C_{15}H_{20}O_8$: C, 54.87; H, 6.14%.

4-Formyl-7-methoxycoumarin (6). A mixture of **5** (480 mg, 2.53 mmol), SeO_2 (400 mg, 3.60 mmol; purified by sublimation method) in dry chlorobenzene (70 ml) was refluxed for 20 h under N_2. After the usual work-up, the crude solid was chromatographed on silica gel using dichloromethane as the eluent to afford 460 mg of **6**; yellow needles, mp 204—206 °C recrystd from dichloromethane (lit,[7] mp 195 °C). IR: 2850, 2750 (weak), 1750 sh, 1720, and 1615 cm^{-1}; ^{1}H-NMR: 3.89 (3H, s, -OCH_3), 6.76 (1H, s, C_3-H), 6.91 (1H, d, J=3 Hz, C_8-H), 7.02 (1H, dd, J=3 and 8 Hz, C_6-H), 8.54 (1H, d, J=8 Hz, C_5-H), and 10.14 (1H, s, -CHO), MS: *m/z* 204 (M^+); Found: C, 64.92; H, 3.90%. Calcd for $C_{11}H_8O_4$: C, 64.70; H, 3.95%.

The authors appreciate to the Research Center for Material Analysis in Miyazaki University for the NMR and MS measurements and the X-ray crystallographic analyses.

Deoximation of Oxime *O*-Acetates, Oximes, and Oxime Ethers by Nonacarbonyldiiron or Pentacarbonyliron. An Electronic Effect for the N-O Bond Cleavage[1)]

Makoto NITTA,* Ichiro SASAKI, Hiroyuki MIYANO, and Tomoshige KOBAYASHI
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160
(Received June 5, 1984)

Synopsis. The reaction of $[Fe_2(CO)_9]$ or $[Fe(CO)_5]$ with oxime *O*-acetates, oximes, and oxime ethers under photoirradiation or thermal conditions undergoes deoximation to give the corresponding ketones. The oxime *O*-acetate was found to be the most reactive class of these compounds. A proposed mechanism involves an initial complexation of the $[Fe(CO)_4]$ species to the nitrogen atom of the oxime group, and the subsequent N-O bond cleavage to give an imido complex. Then the imido complex could collapse to the corresponding ketone via an imine intermediate in protic media.

Previous works in this series have included the papers involving a system which formally contains a C=N-O group.[2,3)] The reaction of substituted 2-isoxazolines with $[Fe_2(CO)_9]$ or $[Fe(CO)_5]$ in methanol under thermal conditions or photoirradiation has been shown to undergo the N-O and C_4-C_5 bond cleavages to give two fragments of aldehydes and the complexed nitrenes, which could collapse to ketones in protic media.[2,4)] Under similar reaction conditions, substituted isoxazoles could undergo a reductive cleavage of the N-O bond to give β-amino enones in good yields.[3)] Although the transformation of oximes to the corresponding ketones has been accomplished thermally by $[Fe(CO)_5]$-$BF_3 \cdot OEt_2$[5)] or $[Fe(CO)_5]$[6)] in anhydrous solvent, the role of $BF_3 \cdot OEt_2$ or the electronic factor controlling the N-O bond cleavage is ambiguous.

In this paper we report on the deoximation of oxime *O*-acetates **1a—d**, oximes **2a—d**, and oxime ethers **3a,c** by $[Fe_2(CO)_9]$ or $[Fe(CO)_5]$ in methanol under thermal conditions or photoirradiation, and suggest that the greater pertinence of the N-O bond cleavage for the oxime *O*-acetates may lead to the corresponding ketones **4a—d**. The reaction conditions and the yields of the products are summarized in Table 1.

Thermal reaction of oxime O-acetates **1a—d** with $[Fe_2(CO)_9]$ in methanol at 60 °C for 1 h afforded the corresponding ketones **4a—d** in good yields (Table 1, entries 1—4). Similarly, photoirradiation of **1a—d** with $[Fe(CO)_5]$ in methanol at the ambient temperature afforded the ketones and the remainder being unreacted starting materials (entries 5—8). On the other hand, thermal reaction of oximes **2a—d** (entries 9—12) or oxime ether **3a** (entry 17) with $[Fe_2(CO)_9]$ proceeded slowly and afforded the corresponding ketones, along with the unreacted starting materials. Furthermore, photoreaction of **2a—d** (entries 13—16) or **3c** (entry 18) with $[Fe(CO)_5]$ also proceeded very slowly as compared to the cases of **1a—d** (5—8). The oximes of conjugated ketones (entries 13 and 14) seem to be less reactive than those of nonconjugated ketones (entries 15 and 16). Regarding the reaction time and the yields of the

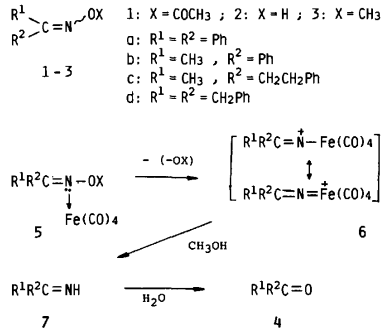
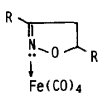
ketones, the oxime *O*-acetates are very labile as compared to the oximes or oxime ethers under both the thermal and photoirradiation conditions. Therefore, the deoximation of oxime *O*-acetates by $[Fe_2(CO)_9]$ under thermal conditions appears most promising.

The present reactions are best explained by the mechanism shown in Scheme 1. Free or solvated $[Fe(CO)_4]$ species have been generally assumed to be the reactive common intermediate in the photolysis[7] or thermolysis ($\geq$80 °C) of $[Fe(CO)_5]$ and thermolysis ($\geq$20 °C) of $[Fe_2(CO)_9]$.[8] Therefore, thermally or photochemically generated $[Fe(CO)_4]$ species could be a reasonable intermediate in the present deoximation reactions.[2,3] The initial step could be a complexation to give **5**. The subsequent N–O bond cleavage could give imido complex **6**.[2] In methanol, the nitrogen moiety of **6** could be reduced by iron moiety,[2,4] and the subsequent protonation could give an imine such as **7**,[6] which could collapse to the ketones by stray water or under workup conditions.



Scheme 1.

2-Isoxazoline is a cyclic ether of oximes, and it undergoes facil N–O and C-4–C-5 bond cleavages to give an aldehyde and a complexed nitrene intermediate which collapses to the corresponding ketone.[2] However, the reactions of oximes **2a-d** as well as oxime ethers **3a,c** are not completed after prolonged heating or photoirradiation (Table 1). Regarding the rigid *N*-complexed C=N–O group (formal hetero-analogue of an allylic anion) of **8** (R=Phenyl or Alkyl), the delocalization of π-d electron from the iron to the π^* orbital of the C=N–O group was suggested to weaken the N–O bond.[2]



8 R = Ph or Alkyl

This electronic effect allowing a facile N–O bond cleavage seems to be reduced by a free rotation across the N–O bond in the cases of oximes and oxime ethers as well as oxime *O*-acetates. The higher reactivity of oxime *O*-acetate as compared to oximes or oxime ethers could be ascribed to the large leaving ability of the OAc group as compared to the OH or OR group.

The reductive[9] or oxidative[10] transformation of oximes to the corresponding ketones has been accomplished. The reductive deoximation of oxime *O*-acetates has also been accomplished by chromium(II) acetate.[11] The present reaction of oxime *O*-acetates could also serve as a convenient method for the deoximation reaction.

Experimental

$[Fe(CO)_5]$ (Strem Chemical Inc.) is a commercial sample. $[Fe_2(CO)_9]$ was prepared by the standard method.[12] All of the reactions were carried out under a dry nitrogen atmosphere. The photoirradiation was carried out using Rayonet Photoreactor fitted with RPR-350 lamps through a Pyrex filter. The oximes and oxime O-acetates were prepared by the standard method. The oxime ethers were prepared by a phase transfer method.[13]

General Procedure for the Deoximation of Oxime O-Acetates 1a—d, Oximes 2a—d, and Oxime Ether 3a with $[Fe_2(CO)_9]$ under Thermal Conditions. A solution of **1a—d**, **2a—d**, or **3a** (1 mmol) and $[Fe_2(CO)_9]$ (437 mg, 1 mmol) in 10 cm^3 of anhydrous methanol was heated at 60 °C for an adequate period. After removal of the methanol, the residue was dissolved in 30 cm^3 of a benzene–hexane mixture (2/1) and filtered through Celite to remove insodluble materials. Then the filtrate was concentrated and the resulting residue was separated by TLC on silica gel using benzene as the eluent to give the corresponding ketones and unreacted starting materials. The results are summarized in Table 1.

General Procedure for the Deoximation of Oxime O-Acetates 1a—d, Oximes 2a—d, and Oxime Ether 3c with $[Fe(CO)_5]$ under Photoirradiation. A solution of **1a—d**, **2a—d**, or **3c** (1 mmol) and $[Fe(CO)_5]$ (392 mg, 2 mmol) in 10 cm^3 of anhydrous methanol was irradiated for an adequate period. After the methanol was evaporated, the residue was dissolved in 30 cm^3 of a benzene–hexane mixture (2/1). Then the solution was filtered through Celite to remove insoluble materials. After evaporating the filtrate the resulting residue was separated by TLC on silica gel using benzene as the eluent to give the corresponding ketones and unreacted starting materials. The results are summarized in Table 1.

The Reductive Amination of Carbonyl Compounds Using Sodium Hydrogentelluride as a Reducing Reagent

Masakazu YAMASHITA,* Mamoru KADOKURA,† and Rikisaku SUEMITSU
Department of Applied Chemistry, Doshisha University, Kamikyo-ku, Kyoto 602
(Received July 11, 1984)

Synopsis. Carbonyl compounds were aminated to secondary amines in moderate yields under mild conditions using sodium hydrogentelluride as a reducing reagent.

Sodium hydrogentelluride (NaTeH, **1**) has been known as a useful reducing reagent and has been used for the reduction of *vic*-dibromo compounds,[1] α,β-unsaturated carbonyl compounds,[2] nitro compounds,[3] α,β-epoxy ketones,[4] *gem*-dibromocyclopropanes,[5] and α-halo carbonyl compounds.[6]

In this paper, we wish to report that **1** is also useful for the reductive amination of carbonyl compounds to secondary amines (Eq. 1).[7]

$$\begin{matrix} R^1 \\ R^2 \end{matrix}\!\!>\!C{=}O + R^3NH_2 \xrightarrow[\text{EtOH, r.t.}]{1} \begin{matrix} R^1 \\ R^2 \end{matrix}\!\!>\!CH\text{-}NHR^3 \qquad (1)$$

For example, benzaldehyde (2 mmol) and butylamine (2 mmol) were added to an ethanolic solution of **1** prepared *in situ* from tellurium and $NaBH_4$, and the mixture wes stirred at room temperature for 20 h. The usual subsequent work-up gave *N*-butylbenzylamine in an 88% yield. The results are summarized in Table 1. As can be seen from Table 1, aliphatic amines afforded the products in good yields, although the yields of the products derived from aniline were rather low. However, when two equivalents of aniline were used, the yield of the corresponding amine was improved (Run 2). In these cases, unreacted aniline and carbonyl compounds were recovered, and no by-product was formed. When glutaraldehyde was treated with amines, *N*-substituted piperidines were obtained as the sole reaction product (Table 2). When 2,5-hexanedione was used, the yield of the pyrrolidine derivative was less than 10%.

Generally, Schiff bases are considered as intermediate of the reductive amination reaction of carbonyl compounds,[7] therefore, in this reaction, the base is also assumed to be formed as an intermediate. In fact, *N*-benzylideneaniline, a representative Schiff base, was reduced by **1** to *N*-benzylaniline in a 70% yield under same reaction conditions.

The good yields of the products, the ease of the reaction procedure, the mildness of the reaction conditions, and the absence of any side reaction make it possible to utilize this reaction for the one-pot synthesis of secondary amines.

Experimental

General. The nuclear magnetic resonance (^1H NMR) spectra were recorded on Hitachi R-600 FT-NMR spectrometer (60 MHz), using Me_4Si as the internal standard. The mass spectra were recorded on a Hitachi RM-50 GC-MS spectrometer. The infrared spectra (IR) were recorded on a Hitachi 260-10 infrared spectrometer. Thin-layer chromatography was performed on Merck Silica Gel.

Materials. The tellurium powder and $NaBH_4$ were purchased from Nakarai Chemicals in an extra pure grade and were used without further purification. The ethanol was distilled and stored over 3A molecular sieves. The *N*-benzylideneaniline was synthesized according to the method in the literature.[8] The glutaraldehyde was available as a 25 wt% solution in water and was used without distillation. All the other compounds in this report were commercial products and were used without further purification.

General Procedure for Reductive Amination. Finely divided tellurium powder (0.65 g, 5 mmol) and $NaBH_4$ (0.45 g, 11 mmol) were placed in a two-necked flask containing a

a) Isolated yield based on starting carbonyl compounds.

Teflon-covered stirring bar. The system was then evacuated and filled with argon. Dry ethanol (25 ml) was injected by means of a syringe, and the suspension was heated at 45 °C until a purple solution was formed. The evolution of hydrogen occurred in this period. This solution was cooled to −20 °C, and then 1 ml of acetic acid in 4 ml of ethanol was injected.[9)]

To a solution of NaTeH, prepared *in situ* as above, a carbonyl compound (2 mmol) and an amine (2 mmol) were added at −20 °C. The resulting mixture was stirred for 20 h at room temperature. The tellurium thus precipitated was filtered, and the filtrate was concentrated *in vacuo*. The residue was dissolved in 20 ml of ethyl acetate and acidified with 3 mol dm^{-3} hydrochloric acid. The combined aqueous layer was made basic with NaOH and extracted with two 30-ml portions of ethyl acetate. The extract was dried over anhydrous Na_2SO_4, concentrated, and purified by TLC (elution with hexane and ethyl acetate). The products were identified by a comparison of their NMR, IR, and mass spectra with those of authentic samples.

O- and *C*-Perfluoroalkylations of Phenol System with (Perfluoroalkyl)phenyliodonium Triflates

Teruo UMEMOTO,* and Osamu MIYANO
Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229
(Received March 23, 1984)

Synopsis. The reaction of FITS reagents with the phenols bearing bulky substituents at *C*-positions yielded *O*- and *C*-perfluoroalkylation products whose ratios were dependent on the steric bulkiness of the substituents or the perfluoroalkyl groups and the reaction temperature.

It is well known that both *O*- and *C*-alkylations occur when phenoxide anions are allowed to react with electrophilic agents such as alkyl halides.[1] However, similar alkylations utilizing perfluoroalkyl halides have never been reported. This may be because the perfluoroalkyl halides would not be effective electrophilic reagents, since the perfluoroalkyl (Rf) group has an extraordinary high electronegativity (3.45).[2]

In 1977, Shreeve and Kitazume reported that phenol reacted with bis(trifluoromethyl)bis(trifluoromethoxy)-sulfurane to give trifluoromethoxybenzene.[3] They, however, proposed a mechanism involving the intramolecular displacement of the phenolic hydroxyl group with the trifluoromethoxyl group *via* an electrocyclic process. Accordingly, their reaction may not be the electrophilic perfluoroalkylation of phenol. Such perfluoroalkylations would be realized only when very efficient electrophilic perfluoroalkylating agents have been developed.

In recent years,[4] we have developed an effective perfluoroalkylating agents, *i.e.* (perfluoroalkyl)phenyliodonium triflates (FITS reagents). In the previous paper,[5] it was demonstrated that the FITS reagent reacts with phenol at its aromatic ring to afford perfluoroalkylphenols. In the present paper, it is shown that both *C*- and *O*-alkylations take place when alkylphenols are allowed to react with FITS reagents.

Results and Discussion

Phenol reacted with FITS-2 or 3*i* in acetonitrile in the presence of pyridine at room temperature to produce a mixture of *C*-Rf phenols without occurrence of *O*-perfluoroalkylation (Eq. 1). The use of FITS-3*i* diminished the formation of the *o*-isomer, suggesting

(1)

FITS-2 (Rf = C_2F_5) 53% (o-/p- = 1)
FITS-3i (Rf = i-C_3F_7) 51% (o-/p- = 0.67)

TABLE 1. *O*/*C*-PERFLUOROALKYLATIONS OF **1** WITH FITS-3*i* OR -3

Run	FITS	Solvent	Temp/°C	Yield/% 2	3	1 (Recovered)	Ratio 2/3
1	-3*i*	CH_2Cl_2	−78→R.t.[a]	11	48	24	0.23
2	-3*i*	CH_3CN	R.t.	26	24	22	1.1
3	-3*i*	CH_2Cl_2	R.t.	27	21	30	1.3
4	-3*i*	CH_2Cl_2	Reflux	28	17	29	1.6

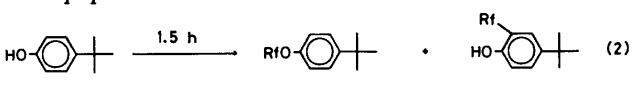
7	-3	CH_2Cl_2	R.t.	9	41	23	0.22
8	-3	$ClCH_2CH_2Cl$	Reflux	14	29	31	0.48

a) Addition of FITS was carried out at −78 °C and the reaction mixture was gradually warmed to room temperature overnight.

that steric repulsion between the bulky perfluoroisopropyl and the hydroxyl groups influenced the proportions of the products formed.

When 4-*t*-butylphenol **1** having a bulky substituent at the *p*-position was allowed to react with FITS-3*i* or

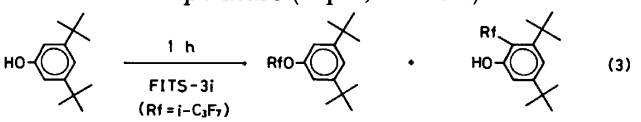


(2)

1 FITS-3i 2a (Rf = i-C_3F_7) 3a
FITS-3 2b (Rf = n-C_3F_7) 3b

-3, *O*-perfluoroalkylation was found to take place in addition to *C*-perfluoroalkylation. The reaction was carried out under several conditions and the results are shown in Table 1. The formation of the *O*-isomer **2a** exceeded that of *C*-isomer **3a** in the reaction of FITS-3*i* at room temperature, while the proportion of the *O*-isomer **2b** by FITS-3 was very low (Run 2 or 3, and 7). It may be attributed to the lesser bulk of the perfluoropropyl group of FITS-3 compared with that of the perfluoroisopropyl group of FITS-3*i*. The ratios of *O*/*C*-Rf phenols were also dependent on the reaction temperature. In the case of FITS-3*i*, **3a** was produced as a major component at low temperature, whereas elevated temperature gave predominantly **2a**. However, the amount of **2b** formed by FITS-3 was less than half of that of **3b** even at the elevated temperature (Run 8). On the other hand, the change in polarity of solvents brought about no significant difference in the ratios of **2**/**3**. From the above results, the appearance of *O*-perfluoroalkylation in the case of the phenol **1** would be mainly ascribed to the steric factor between the bulky substituent at an aromatic ring of **1** and the other bulky FITS reagents.

As expected, 3,5-di-*t*-butylphenol **4** where the *C*-positions are more hindered by two bulky substituents provided the higher proportion of *O*-perfluoroalkylation, but the *O*/*C* ratios were little affected by change in the reaction temperature (Eq. 3, Table 2).



(3)

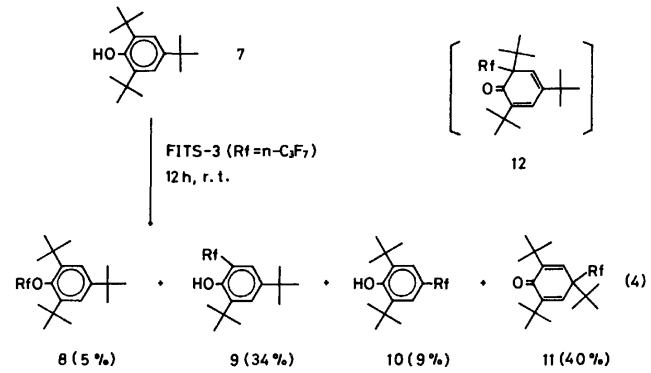
4 5 6

Furthermore, 2,4,6-tri-*t*-butylphenol **7** where all the reactive *C*- and *O*-positions are blocked gave three *C*-Rf compounds **9**—**11** and a small amount of *O*-Rf

TABLE 2. *O*/*C*-PERFLUOROALKYLATIONS OF **4** WITH FITS-3*i*

Run	Solvent	Temp	Yield/% 5	6	4 (Recovered)	Ratio 5/6
1	CH_2Cl_2	R.t.	50	15	10	3.3
2	$ClCH_2CH_2Cl$	Reflux	56	16	18	3.5

phenol **8** (Eq. 4). The reaction proceeded smoothly at room temperature with change of color. Addition of FITS-3 to a solution of **7** in dichloromethane in the presence of an equivalent amount of pyridine produced a blue color, which soon faded. No color developed in the reactions with phenol, **1**, and **4**. From this fact, it appears that the reaction mechanism of the hindered phenol **7** with FITS is different from that of phenol, **1**, and **4**. The appearance of the color may suggest that the reaction of **7** proceeds *via* a radical cation generated by a one electron transfer from **7** to FITS. It is reasonable that **9** and **10** are formed through cyclohexadienone **12** and **11** with loss of *t*-butyl groups, respectively. The former **12** was not isolated.



Experimental

NMR spectra were measured in $CDCl_3$ and ^{19}F chemical shifts were given in ppm upfield from $CFCl_3$ as an internal standard. A gas chromatograph with a column of 20% Apiezon grease L on Uniport B or 2% Silicone OV-1 on Chromosorb WAW DMCS was used for analysis of the products. All the reactions were done under argon atmosphere. FITS-2, -3, and -3*i* were prepared by the method described in our first paper.[4] Reaction solvents were purified and dried by the usual methods.

Reaction of Phenol with FITS-2 or -3i. *Typical Procedure*: Into a solution of 376 mg (4 mmol) of phenol and 162 μl (2 mmol) of pyridine in 8 ml of acetonitrile, 944 mg (2 mmol) of FITS-2 was added in several portions at room temperature. The mixture was stirred for 0.5 h at room temperature. After evaporation of the solvent, the residue was column chromatographed on silica gel using dichloromethane as an eluent to give 120 mg (28%) of the *o*-isomer and 107 mg (25%) of the *p*-isomer. The *m*-isomer could not be isolated. The gas chromatography showed the corresponding small peak. *o*-C_2F_5-phenol: Slightly yellow oil. Adsorption Effects of Highly Polarizable Organic Compounds on Electrode Kinetics

Osamu IKEDA,* Ken-ichi WATANABE, Yasuhiko TANIGUCHI, and Hideo TAMURA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, 2-1 Yamadaoka, Suita, Osaka 565
(Received January 17, 1984)

Adsorption effects of ureas and thioureas on electrode kinetics were studied by using the electrode reactions of $Zn^{2+}/Zn(Hg)$ and Eu^{3+}/Eu^{2+}. The standard rate constant for $Zn^{2+}/Zn(Hg)$ is controlled by the inner-layer permittivity. The effect of this permittivity has been explained in terms of the solvent reorganization energy. The effect of the adsorbates on the electrode kinetics of Eu^{3+}/Eu^{2+} cannot be explained in terms of the inner-layer permittivity. These two results suggest different locations for the formation of the activated complex: Inside the adsorption layer for Zn^{2+} and just outside layer for Eu^{3+}.

Various factors governing electrode kinetics have been reviewed with respect to the electroreduction of inorganic cations in the presence of organic adsorbates.[1,2] In general, organic adsorbates lower the electroreduction rate, but some adsorbates increase the rate; especially markedly thiourea accelerates the reduction of In^{3+},[3] H_3O,[4] and Zn^{2+} and Bi^{3+}.[2] No satisfactory explanation, however, has yet been given to this accelerating action of thiourea. Recently, Sykut *et al.*[5] found that the acceleration of the electroreduction of Zn^{2+} and Bi^{3+} requires both that the capacity of adsorbate solution should be larger than that of base electrolyte solution and that lone pair electrons should be present in the adsorbate, and they termed this cooperative action the "cap-pair" effect. This effect is speculated to be correlated intimately to a larger permittivity of the surface adsorption layer. Then, this effect was studied more precisely by using highly polarizable organic compounds: thiourea (TU), 1,1-dimethylthiourea (DMTU), tetramethylthiourea (TMTU), urea (U), 1,1-dimethylurea (DMU), and tetramethylurea (TMU). The electrode reactions of $Zn^{2+}/Zn(Hg)$ and Eu^{3+}/Eu^{2+} were chosen as representative of reactions of deposition and simple charge-transfer types, respectively.

Experimental

Most of the organic compounds used as adsorbates were of high-purity reagent grade, but they were further purified by double distillation (TMU) or double recrystallization from methanol (DMU) or distilled water (U, TU, TMTU, and DMTU). Only DMTU was synthesized by reaction of dimethylcyanamide with thiourea.[6]

Since the double-layer parameters for the adsorbates have been obtained mainly in 0.5 M NaF solution (1 M=1 mol dm^{-3}), the electrode reaction of $Zn^{2+}/Zn(Hg)$ was studied in 0.5 M NaF solutions containing 1.0×10^{-3} M of Zn^{2+} and an adsorbate at various concentrations. On the other hand, the electroreduction of Eu^{3+} was carried out in 0.5 M aqueous $NaClO_4$ containing 0.93×10^{-3} M of Eu^{3+} and an adsorbate at different concentrations, because Eu^{3+} formes a precipitate of EuF_3 in the aqueous NaF solution. In this case, the double-layer parameters for the adsorbates are assumed not to differ from those in 0.5 M NaF.

Polarographic measurements were carried out with a three-electrode system consisting a polarograph (Yanaco, P-8 Polarograph) equipped with a dropping mercury electrode at 25 °C, and the instantaneous current at the end of drop life was recorded. The drop time was mechanically adjusted to 3.5 s, and the flow rate of mercury was 3.03 mg s^{-1}. The apparent standard rate constant k_s^{app} for $Zn^{2+}/Zn(Hg)$ with the standard electrode potential −1.003 V *vs.* SCE[7] was evaluated according to the analytical procedure for quasi-reversible systems.[8,9] When the concentration of thioureas (TU, DMTU, and TMTU) exceeds the level corresponding to surface coverage about 0.3, the systems yield reversible current-potential curves. For such systems, only the standard rate constant at full coverage was evaluated by the faraday impedance method.[10] On the other hand, k_s^{app} for Eu^{3+}/Eu^{2+} with the standard potential −0.600 V *vs.* SCE[11] was evaluated according to the equation for irreversible systems.[8]

Results and Discussion

Adsorption Behavior of Adsorbates. According to adsorption behavior the adsorbates used in the present study can be classified into two groups, ureas (U,[12] DMU,[13] and TMU[14]) and thioureas (TU,[15,16] DMTU,[13] and TMTU[17]). The orientation common to the ureas at the mercury/aqueous solution interface is the positioning of the C=O bond nearly parallel to the electrode surface. The fit to the Langmuir isotherm observed for U and DMTU indicates the absence of interaction between adsorbed molecules. However, only TMU, which shows a fit to the Frumkin isotherm, exhibits a small positive interaction parameter, which means an attractive interaction between adsorbed molecules around the potentials where the reductions of Zn^{2+} and Eu^{3+} take place.

On the other hand, the orientation common to the thioureas is the positioning of the C=S bond fully vertical to the electrode surface. A repulsive interaction between adsorbed molecules is indicated by the positive values of the second virial coefficient for TU[16] and the negative values of the interaction parameters for DMTU and TMTU.

Effects of Adsorbates on Electrode Kinetics of $Zn^{2+}/Zn(Hg)$. Figure 1 shows the variation of the apparent standard rate constant k_s^{app} due to adsorption of the ureas and thioureas. Only with TMU, a remarkable lowering in the reduction rate was

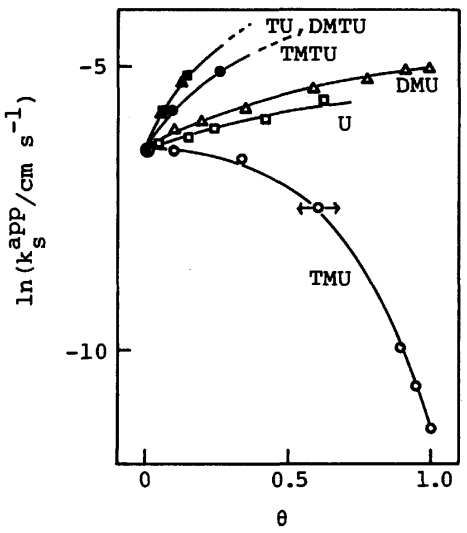

Fig. 1. Variation of ln k_s^{app} for Zn^{2+}/Zn(Hg) with suraface coverage at various adsorbates. Adsorbates: TU (thiourea, ■), DMTU (1,1-dimethylthiourea, ▲), TMTU (tetramethylthiourea, ●), U (urea, □), DMU (1,1-dimethylurea, △), and TMU (tetramethylurea, ○). Arrows representing a speculated coverage for TMU are due to a mixed adsorption consisting of similar two orientations differed in the occupied srera.[17]

observed, but U and DMU accelerated the reaction slightly with an increase in the coverage. The thioureas showed a strong accelerating action even at lower coverages. Since the rate constants at higher coverages could not be evaluated owing to a change into a reversible system, the standard rate constant at the full coverage was estimated by the faraday impedance method[10] only with TMTU and DMTU. The results are summarized in Table 1 together with various double-layer parameters at the full coverage, the values of which are estimated at each apparent half-wave potential $E_{1/2}$, because the rate constants were evaluated around this potential and the plot of these rate constants against potential was then extrapolated to the standard electrode potential to obtain k_s^{app}.

The results relating to the potential drop across the diffuse double layer $\Delta_S^2\phi$ suggest that the reduction rate is not controlled by the Frumkin effect.[18] The effect of adsorbate's dipole charges located at the solution side upon the surface concentration of reacting ion, which is to be considered for the reduction of Eu^{3+} in the subsequent section, is not operative either for the reduction of Zn^{2+}. The electrode process of Zn^{2+}/Zn(Hg) seems to proceed in the adsorption layer. However, it is found that the ϕ_1 potential ($\Delta_1^M\phi$) in the adsorption layer[19] cannot explain the large change in ln k_s^{app} with adsorbates, in analogy with the ϕ_2 potential ($\Delta_2^M\phi$) at the Helmholtz plane. One of interfacial properties susceptible to a large change with adsorbates is the permittivity of the adsorption layer or the inner-layer permittivity ε_1, as can be seen from Table 1. Then, the effect of this permittivity on the rate constant was examined more precisely. For a thin adsorption layer with lower permittivity than that in the solution bulk, Afanas'ev and Damaskin[20] treated the above effect as the work involved in transferring a reacting ion from the solution bulk into the structured surface layer. But, we have treated this effect simply as the work for the activation of Zn^{2+} in the adsorption layer.

When the interaction between reactant and electrode is negligibly weak and the activation free energy is mainly controlled by the solvent reorganization energy, the Marcus theory[21,22] predicts the following simplified relation for the standard rate constant:

$$\ln k_s^{app} = \text{const} - \lambda_o/4kT, \quad (1)$$

where λ_o is a quantity relating to the solvent reorganization energy and represented by

$$\lambda_o = (ne)^2(1/2a - 1/4R)(1/\varepsilon_o - 1/\varepsilon_s), \quad (2)$$

where ne is the charge transferred, a the radius of the reacting ion, R the distance between the center of reacting ion and the electrode surface, and ε_o and ε_s are the optical and static permittivities of medium, respectively. If a and R can be assumed to be constant for the same reaction, one may obtain the following equation related to the permittivity of the medium:

$$\ln k_s^{app} = \text{const} - (1/4kT)(ne)^2(1/2a - 1/4R)(1/\varepsilon_o - 1/\varepsilon_s). \quad (3)$$

a) C_{org}^f and α^{app} mean the concentration corresponding to full coverage and the apparent transfer coefficient, respectively. $\Delta_S^2\phi$, K_1^i, d_1, ε_1, and P_1 are the potential drop across the diffuse layer, the integral inner-layer capacity, the thickness of the inner layer, the permittivity of the inner layer, and the dipole moment of an adsorbed molecule at saturation with the adsorbate, respectively. The double-layer parameters are estimated at each half-wave potential $E_{1/2}$. A positive (negative) value of P_1 corresponds to an orientation having the positive (negative) end of dipole directing toward the electrode surface. b) The values for TMTU and DMTU were evaluated from the data obtained by the faraday impedance method, while those for TMU, DMU, and H_2O by d.c. polarography.

One can assume the surface layer formed by adsorbates to be the medium for the electroreduction of Zn^{2+}. In general, the permittivity of the surface adsorption layer on the electrode is quite different from that of the bulk.[23] When electrode processes occur in this surface adsorption layer, therefore, we have to use the permittivity of this layer. This permittivity of the surface layer or the inner-layer permittivity at saturation with an adsorbate, ε_1, can be estimated from the integral inner-layer capacity $K_1^i(=\varepsilon_1/d_1)$ and the thickness of the inner layer, d_1. The definition of K_1^i is

$$K_1^i = \sigma/(\Delta_2^M\phi_\sigma - \Delta_2^M\phi_{\sigma=0}), \quad (4)$$

where σ is the surface charge density on the electrode, and $\Delta_2^M\phi_\sigma$ and $\Delta_2^M\phi_{\sigma=0}$ are the potential drops across the inner layer at an arbitrary charge density and at the zero charge density, respectively. When the reorientation of adsorbate is not so significant, Eq. 4 can be approximated to[24]

$$1/K_1^i = 1/K_1^{i(\text{ion})} - 1/K_1^{i(\text{dipole})}. \quad (5)$$

Since the first term of the right hand side of Eq. 5 is due to the free charges on the electrode and is affected by the electronic polarizability of the adsorbate, and the second term is due to the dipole orientation, Eq. 5 can be reduced to

$$1/\varepsilon_1 = 1/\varepsilon_o - 1/\varepsilon_s, \quad (6)$$

which means that one may obtain $(1/\varepsilon_o - 1/\varepsilon_s)$ from $1/\varepsilon_1$ which can be estimated from the integral inner-layer capacity. The contribution of ε_s to the inner-layer permittivity has been considered to be minor,[23] which in fact is the case with TMTU.[17]

A plot of $\ln k_s^{app}$ against $1/\varepsilon_1$ is shown in Fig. 2. In this figure, no points for U and TU are included for the lack of ε_1 in the literature, and the point for H_2O refers to the surface layer covered with water molecules only, *i.e.*, the surface layer corresponding to the base 0.5M NaF solution containing no adsorbates.

The plot in Fig. 2 shows a linear relation, which verifies the validity of Eq. 3. However, the slope gives R=1.1 nm on the assumption of $a=R$. This value is rather too large, because R is expected to be 0.3—0.4 nm by taking into account the water layer thickness (0.31 nm) and the ionic radius of Zn^{2+} (0.074—0.088 nm).

Several reasons will be given for the unexpected value of R: (i) neglect of the work, U_i, for transferring reactants from the solution bulk to the discharge site; (ii) no distinction between two layers with different permittivities; (iii) neglect of the thickness of the adsorption layer, d_1; (iv) probable change in a and R during the electrode process. Kharkats[25] discussed effects of two layers with different permittivities and d_1 on the solvent reorganization energy E_s and U_i, and represented E_s and U_i as functions of a, R, d_1, and permittivity.

In the calculation of E_s and U_i, the static permittivity for the adsorption layer is assumed to be 10 times the optical one, and the optical and static permittivities for the water layer adjacent to the adsorption layer are taken as 6.3×10^{-11} and 70×10^{-11} Fm^{-1}, respectively. When the energies controlling the electrode process are concentrated on E_s and U_i, $\ln k_s^{app}$ can be given by

$$\ln k_s^{app} = \text{const} - (E_s+U_i)^2/4E_skT. \quad (7)$$

Figure 3 shows the plot of $\ln k_s^{app}$ for $Zn^{2+}/Zn(Hg)$ against $(E_s+U_i)^2/E_s$, for which 0.4 nm is chosen for a and R so that the experimental slope may agree with the

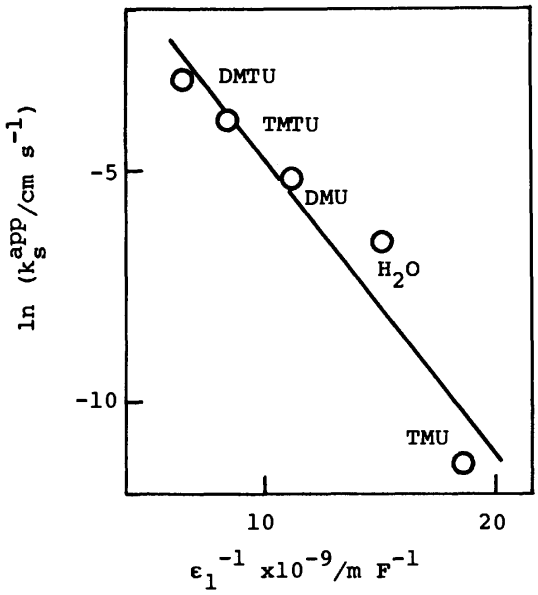

Fig. 2. Plot of $\ln k_s^{app}$ for $Zn^{2+}/Zn(Hg)$ against ε_1^{-1} at saturation with various adsorbates.

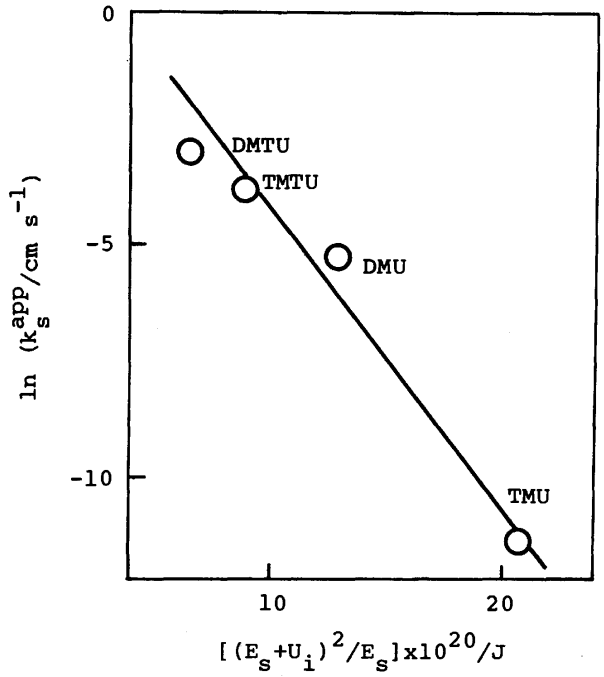

Fig. 3. Plot of $\ln k_s^{app}$ for $Zn^{2+}/Zn(Hg)$ against $(E_s+U_i)^2/E_s$ at saturation with various adsorbates.

a) C_{org} and θ represent the concentration and surface coverage of adsorbate, respectively. The meanings of the other notations are the same as those in Table 1. b) All the values were evaluated from data obtained by d.c. polarography.

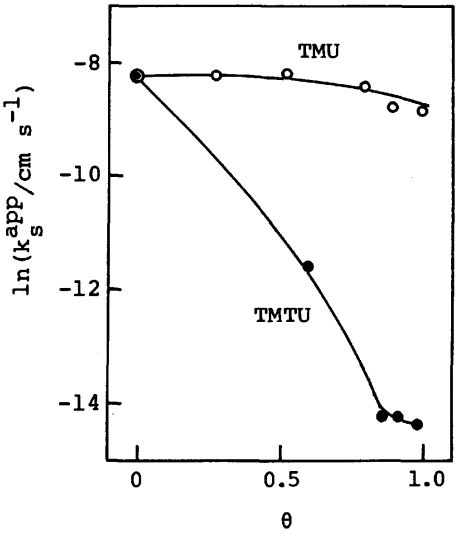

Fig. 4. Variation of ln k_s^{app} for Eu^{3+}/Eu^{2+} with surface coverage at TMU and TMTU.

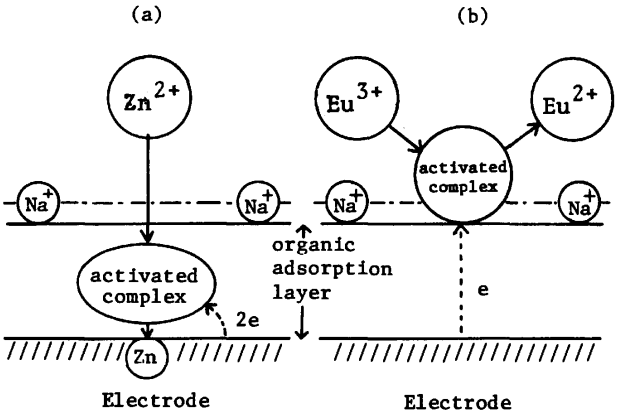

Fig. 5. Reaction paths elucidated for the reductions of (a) Zn^{2+} and (b) Eu^{3+}.

theoretical one ($1/4kT$). The above value $a=R=0.4$nm is in fair agreement with the expected value of 0.3—0.4nm. However, the point for H_2O is excluded from the plot in Fig. 3, because $(E_s+U_i)^2/E_s$ calculated for H_2O was an unreasonable value. Probably, the discharge site would be located just outside the water adsorption layer, and the selected values might be different from those for the bulk water.

Effects of Adsorbates on Electrode Kinetics of Eu^{3+}/Eu^{2+}. Figure 4 shows the variation of ln k_s^{app} for Eu^{3+}/Eu^{2+} with the adsorption of TMU and TMTU. The kinetic data and double-layer parameters at each $E_{1/2}$ are summarized in Table 2. The effect of TMU and TMTU on the reduction rate of Eu^{3+} is in quite a contrast to that on the reduction rate of Zn^{2+}; TMTU increases the reduction rate of Zn^{2+} but lowers the rate of Eu^{3+} significantly. The nearly constant values of ln k_s^{app} at higher coverages suggest a tunneling transition[26] through the adsorption layer to the strongly hydrated Eu^{3+} ion.[27] The estimate of ln [k_s^{app} (TMU)/k_s^{app} (TMTU)] on the basis of the tunneling transition,[28] however, is 0.6, which is rather a small value as compared with the experimental value of 5.6. The Frumkin correction for the surface concentration of Eu^{3+} cannot explain the above experimental value, either. As a matter of course, the permittivity effect predicts an opposite result to the experimental one. It is most likely that the adsorbate's dipole charges located at the solution side affect the surface concentration of Eu^{3+}, because such charges are positive for TMTU and negative for TMU as can be seen from the value, P_1, of dipole moment of an adsorbed molecule in Table 2.

Reaction Paths. A comparison of the two types of electrode reactions has led us to assign the reaction paths shown in Fig. 5 to the reductions of Zn^{2+} and Eu^{3+}. In Fig. 5, the locations where the activated complex is formed are different: (a) Inside the adsorption layer for Zn^{2+} and (b) just outside the layer for Eu^{3+}.

The hydration structure of Zn^{2+} in 0.5M aqueous NaF solution is considered to be $[ZnF(H_2O)_3]^+$.[29] We could detect no clear complex formation of Zn^{2+} with the ureas or thioureas used as adsorbates, because no change was caused in the UV-visible spectrum for the 1.0×10^{-3}M Zn^{2+}+0.5M NaF solution by addition of the adsorbates. This result does not deny the possibility that the complex is formed during the transfer of Zn^{2+} into the surface adsorption layer. When thioureas formes a strong complex with a reacting ion such as Cu^{2+} or Cd^{2+}, however, it is well known that the

reduction rate of these ions is caused to decrease.[2] These results suggest that any complexation of Zn^{2+} occurs with the thioureas or ureas neither in the solution bulk nor in the adsorption layer.

The characteristics of the UV-visible spectrum for the case of Eu^{3+} are similar to those for Zn^{2+}. Since water molecule also is a ligand, we believe that Eu^{3+} in a dilute aqueous solution of any one of the thioureas and ureas will form no complex with them.

Interactions of Excited Lithium Atom with Molecular Hydrogen. II. Properties of Wave Functions in the Potential Crossing Region

Kimiko MIZUTANI,* Takakazu YANO,† Atsushi SEKIGUCHI,†† Kazuko HAYASHI,††† and Shiro MATSUMOTO
Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157
(Received January 31, 1984)

To elucidate the electronic mechanism of the quenching of electronically excited Li atoms by H_2 molecules, CASSCF calculations were made regarding the Li-H_2 system with various geometries. Special attention was payed to the electronic structure of the system in the crossing, or pseudocrossing, region of the potential energy surfaces. Simple CASSCF functions do not have a satisfactory spacial symmetry when the upper and the lower states are almost degenerate in energy, and need to be refined by the addition of a nonorthogonal CI. In the crossing region, electron density maps have shown that the Li atom is bonded more strongly to the nearer H atom than to the farther H atom in the ground state, whereas the opposite is the case for an excited state. Such properties of the wave function lead naturally to a picture of a nonadiabatic process occurring in the crossing region. The pseudocrossing of the first excited and the ground state potential energy surfaces has also been found for all geometries midway between the C_{2v} and $C_{\infty v}$ symmetries.

In a previous report,[1] we have shown that for the Li-H_2 system, the lowest $^2A_1$ and $^2B_2$ potential energy surfaces cross in a line located in an energetically accessible region. This has been determined as being the critical region where the nonadiabatic transition between an excited state and the ground state occurs with fair probability. However, the C_{2v} geometry seems to be too restrictive to describe the whole nonadiabatic process occurring in the system. It has thus become desired that the calculation be extended to more general geometries. Extensive calculations for the Li-H_2 system have been reported by P. J. A. Ruttink and J. H. van Lenthe,[2] and A. F. Wagner and A. C. Wahl[3] using large basis functions. Quite recently, Hobza and Schleyer[4] have reported calculations on the ground state of a Li-H_2 complex with MP2/6—311G (2d, 2p). These calculations, however, do not include any description concerning nonadiabatic transitions.

We report, in this paper, the results of further calculations using more general geometries[5] in order to search for other channels of the nonadiabatic transitions. The properties of the electronic wave function with regard to the geometries around the critical region were studied in some detail. The low-lying potential energy surfaces with a $C_{\infty v}$ geometry did not come close to each other. However pseudocrossing regions did exist for geometries intermediate between the C_{2v} and $C_{\infty v}$ symmetries, although they were located at somewhat higher energies. The MCSCF wave function, including insufficient CSF's, showed inappropriate properties in the critical region. The defect could be corrected by including an additional nonorthogonal configuration interaction.[11c] However, an examination of the crude wave functions led to a new schematic view of the nonadiabatic process. Meyer *et al.*[6] recently reported results of studies on the Na-H_2 system which were conducted for a similar reason as the one reported here. Our results for Li-H_2 parallel theirs in many respects.

Method of Calculation

Geometric parameters were taken as shown in Fig. 1. The bases were minimal STO-3G[7] functions, the electronic wave functions were computed with a CASSCF method,[8] and all orbitals other than the core orbital (1a′) were included in the active space. Computational details and notations are the same as those previously described.[1] The convergence of the MCSCF calculations was judged by the sum: $\sum_p \sum_{q(\neq p)} \langle \phi^p | \hat{R} | \phi^q \rangle^2$, as well as by the steadiness of the energy expectation values. In the above sum, ϕ^p denotes the p-th orbital function just computed, and $\hat{R}$ is the coupling operator.[1] Summations are taken over all the different pairs of orbitals. The value of the sum is denoted as the "residue" below, which should vanish at complete self-consistency. Iterations were continued until the residue value fell below 10^{-20} (hartree)^2. Good convergence was essential for assuring the quality of the wave functions. In one instance, a wave function with a residue value of 10^{-14} (hartree)^2 gave density maps that were quite different from those obtained from a wave function well converged to a residue value of less than 10^{-20} (hartree)^2.

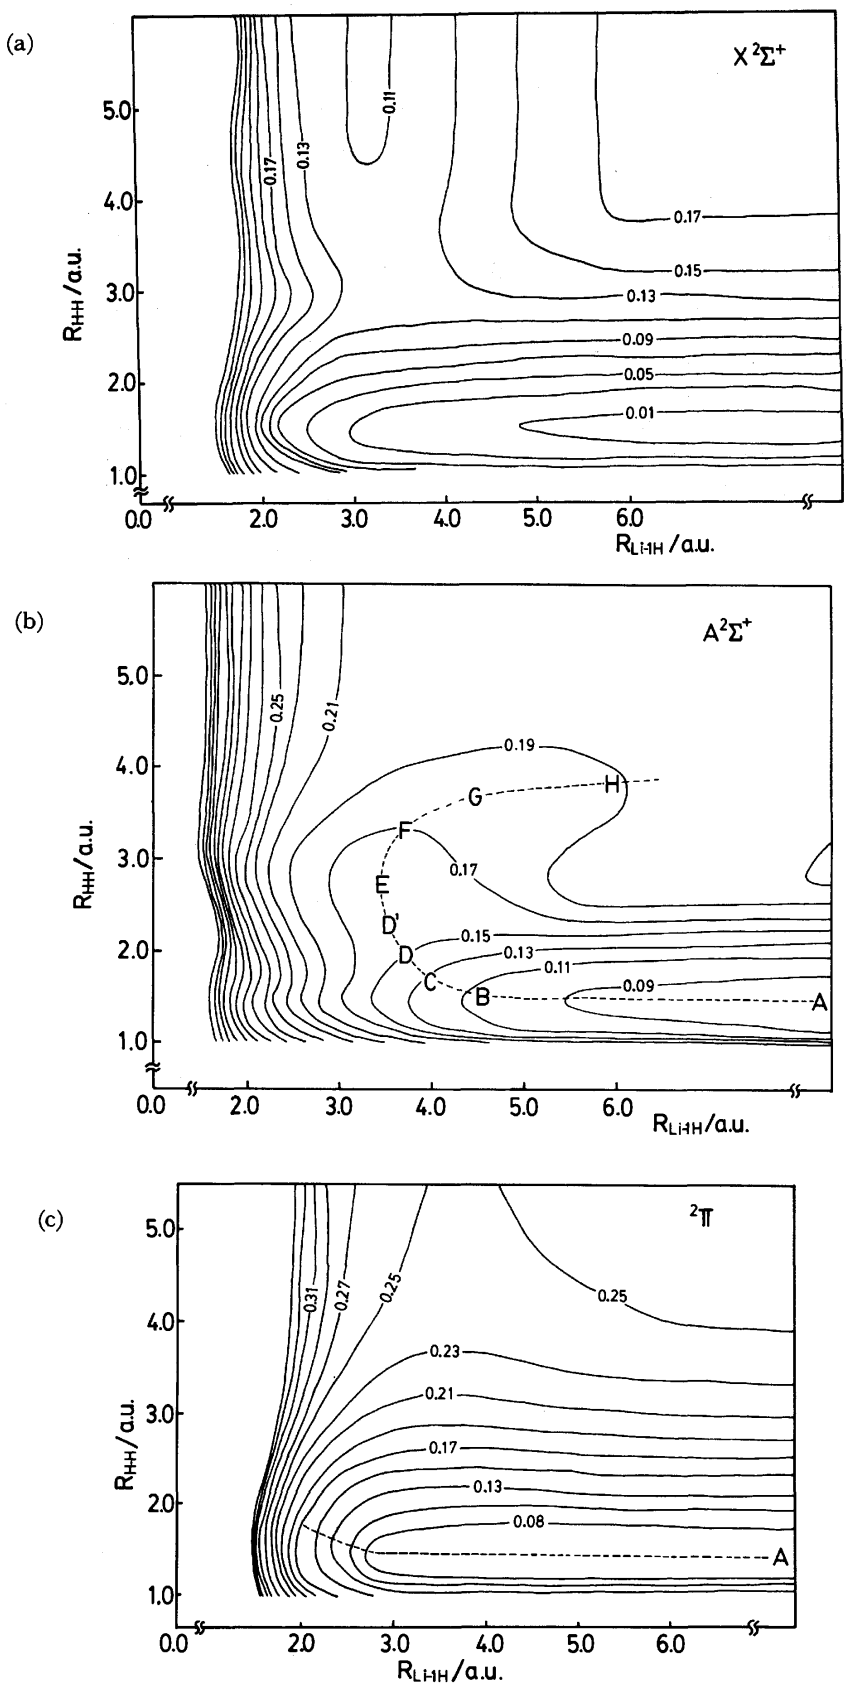

Fig. 2. Two-dimensional potential energy surfaces for the collinear geometry $\theta=90°$; (a) X $^2\Sigma^+$, (b) A $^2\Sigma^+$, and (c) $^2\Pi$. Energies are given in hartrees minus −8.47 on each curve (dashed line is the minimum energy reaction path on the A$^2\Sigma^+$ surface and on the $^2\Pi$ surface, A, B, ···, H are several selected points on the curve).

Results and Discussion

Potential Energy Surfaces in $C_{\infty v}$ Geometry. Figure 2(a) shows the ground state potential energy surface. Figures 2(b) and 2(c) are the two excited state potential energy surfaces leading to a ground hydrogen and to the $2\,^2P$ lithium atom computed with $C_{\infty v}$ symmetry. It can be seen that neither of the excited potential energy surfaces come close to the ground state surface, unlike in the case with a C_{2v} geometry.[1] The minimum energy path, starting from isolated H_2 ($X\,^1\Sigma_g$) and Li ($2\,^2P$) is shown by a dashed line on each excited state surface. The energy differences between the ground and the excited states along these lines are shown in Fig. 3. It seems, therefore, that a $C_{\infty v}$ geometry is far less favored for the quenching process of a $2\,^2P$ Li atom than the C_{2v} geometry,at least at moderate temperatures.

Potential Energy Surfaces for θ=45°. The ground and the first excited state potential energy surfaces for the arrangement θ=45° are shown in Fig. 4. Both states belong to the A′ representation of the C_s point group, and cannot intersect with each other. However, the surfaces come close together in the region shown by short dashed lines in Fig. 4. Figure 5 shows a cross section of the potential surfaces parallel to the ordinate. The potential curves display features of pseudocrossing. It is tempting, therefore, to speculate that nonadiabatic transitions may occur around these geometries, although their energies are somewhat higher than in the C_{2v} case.

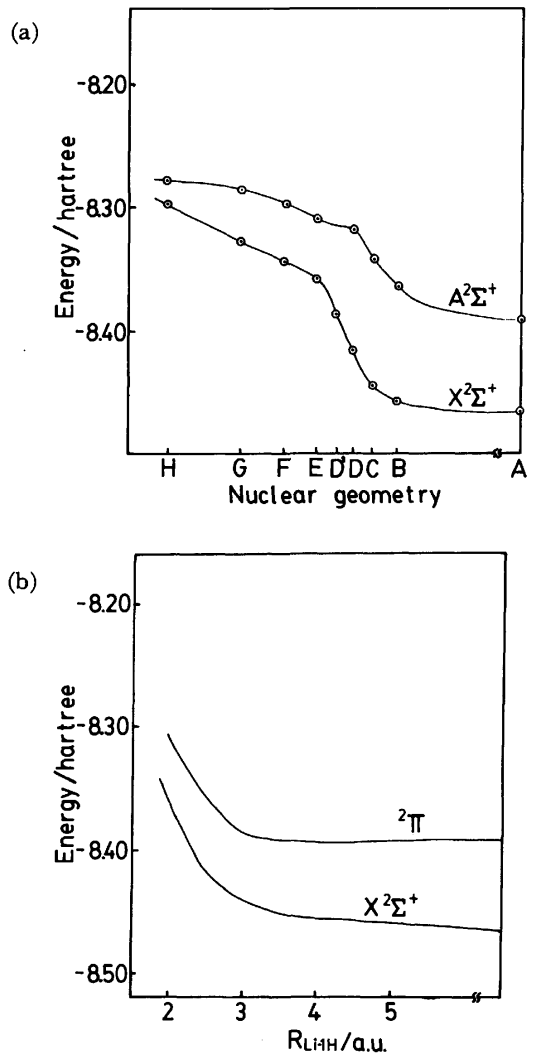

Fig. 3. Energies along the minimum energy path in Fig. 2(b) and 2(c), respectively; (a) $X\,^2\Sigma^+$, $A\,^2\Sigma^+$, and (b) $X\,^2\Sigma^+$, $^2\Pi$. Nuclear geometries A, B, ···, H in Fig. 3(a) correspond to those in Fig. 2(b).

Properties of Potential Energy Surfaces Near the Critical Region of C_{2v} Potential Crossing. It is important to examine the wave function of the system for all the variations of nuclear geometry in the critical region in order to obtain a picture of the nonadiabatic process and to have an estimate of its occurrence probability. Even for the present simplest system, there are three degrees of freedom of the nuclei, and this is a nontrivial task. As an attempt, we selected "normal coordinates" around a geometrical point which seemed to be characteristic of the crossing (or pseudocrossing) region. The central point may be appropriately assigned to the lowest point (hereafter called "point P") on the intersection line of $^2B_2$ and $^2A_1$ surfaces (Figs. 2 and 3 of Ref. 1). By transforming the coordinate system ($R_{\text{Li-H}_2}$, $R_{\text{H-H}}$) to a mass-weighted system ($(m_{\text{Li}}\, m_{\text{H}_2}/(m_{\text{Li}}+m_{\text{H}_2}))^{1/2}\, R_{\text{Li-H}_2}$, $(m_{\text{H}}/2)^{1/2}\, R_{\text{H-H}}$), and by drawing a tangent and a normal at point P to the potential contour line passing through P, we obtained a type of normal coordinate system (Fig. 6). We had, of course, two different coordinate systems depending on which of the potential surfaces we utilized. In practice, the two sets of directions turned out to be not very different, and we took the one constructed on the $^2B_2$ surface, as we expected the process to be occurring from the excited state. Calculations with a larger basis sets[9] revealed the same feature. We shall call the normal direction as the reaction coordinate and the tangential direction as the direction of C_{2v} vibration, for convenience. Another vibrational degree of freedom is an antisymmetric stretching mode (b_2) analogous to that of a stable isosceles triangular molecule. It coincides to the first order with a θ-deformation (*i.e.* rotation by θ (Fig.1) of the H_2 molecule about its center while the center and the inter-hydrogen distance are fixed). Thus, we have taken the angle θ as the third parameter describing the nuclear geometry for visual simplicity and for later conveniences of discussing rotational perturbation separately. The normal vibration of the C_{2v} symmetry plays a role which becomes important only for more quantitative calculations of transition probabilities. Thus, we defer its inclusion until the results of more quantitative calculations are discussed. Figure 7 shows potential energy curves for a θ-deformation at point P,[10] and at several points along the reaction coordinate. The potential curve at P consists virtually of two quasiparabolas crossing at P and symmetrically placed

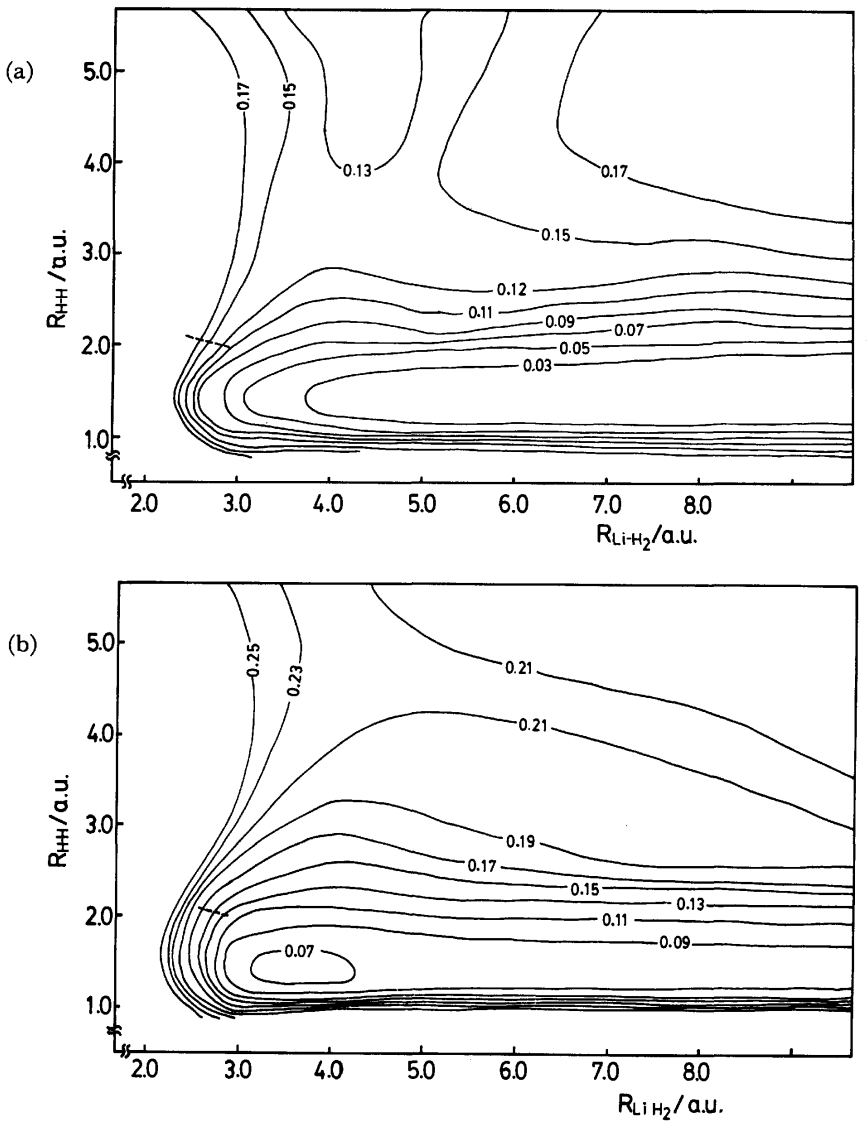

Fig. 4. Potential energy surfaces for C_s geometry $\theta=45°$; (a) lowest $^2A'$ and (b) 2nd. $^2A'$. Energies are given in hartrees minus −8.47 on each curve.

with respect to the ordinate. The points of energy minima lie only slightly lower than P, but they are distinctly displaced from the ordinate. The ground state potential energy curves at points on the reaction coordinate other than P have similar minima, while each of their excited counterparts has a single minimum at $\theta=0°$. It will be noticed that while the ground state potential energy curves at Q''' and R''' have cusps at $\theta=0°$, other ground state curves passing through points more distant from P look smooth at $\theta=0°$. This fact is related to with the quality of our MCSCF wave functions and will be discussed in the next section.

Singularity of MCSCF Wave Functions in a Critical Region. The electron density maps of the 3a′ natural orbitals of the two (nearly)[10] degenerate MCSCF wave functions at point P were obtained by CASSCF calculations and are shown in Fig. 8. As may be apparent from the figures, these two wave functions are in themselves neither symmetric nor antisymmetric with respect to the xz-plane, but are mutually symmetric with respect to this plane, in contradiction to group theoretical requirements. The mirror image relationship is also seen in the 1a′ core orbitals of both wave functions (Tables 1 and 2). A similar dissymmetry of the wave functions is observed when the ground state potential energy curves display cusps, as shown in Fig. 7. In separate CASSCF calculations we obtained MCSCF wave functions while constraining the orbitals to belong to irreducible representations of the C_{2v} point group. The energies of the resulting two wave functions ($^2A_1$ and $^2B_2$) again agreed to 10^{-9} hartree, but were somewhat higher than those without the symmetry constraints on the orbitals. These phenomena have resulted from the near degeneracy of the 3a′ and 4a′ orbitals[11c] and/or the imperfectness of the CSF's involved in the calculation. They may be of the same sort as the doublet instability[11] found for

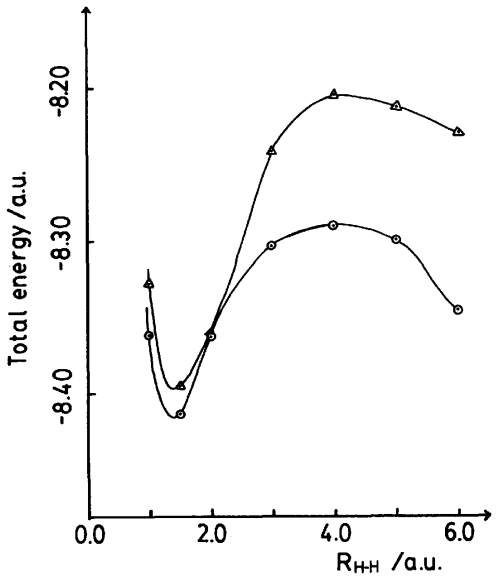

Fig. 5. A cross section of the potential energy surfaces of Fig. 4 cut by a plane perpendicular to the sheet and parallel to and apart by 3.0 bohr from ordinate. ⊙: lowest $^2A'$, ▲: 2nd. $^2A'$.

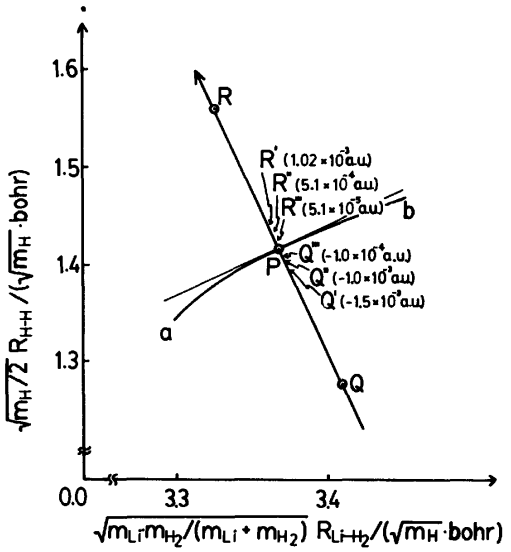

Fig. 6. Normal coordinate system at the lowest point P of the crossing seam of the lowest $^2A_1$ and $^2B_2$ surfaces, displayed in mass weighted scale. *aPb* is the energy contour line through P and *QPR* corresponds to the reaction coordinate on the $^2B_2$ surface. The figures beside letters *R'*, *R''*, *etc.* are the distances from point P.

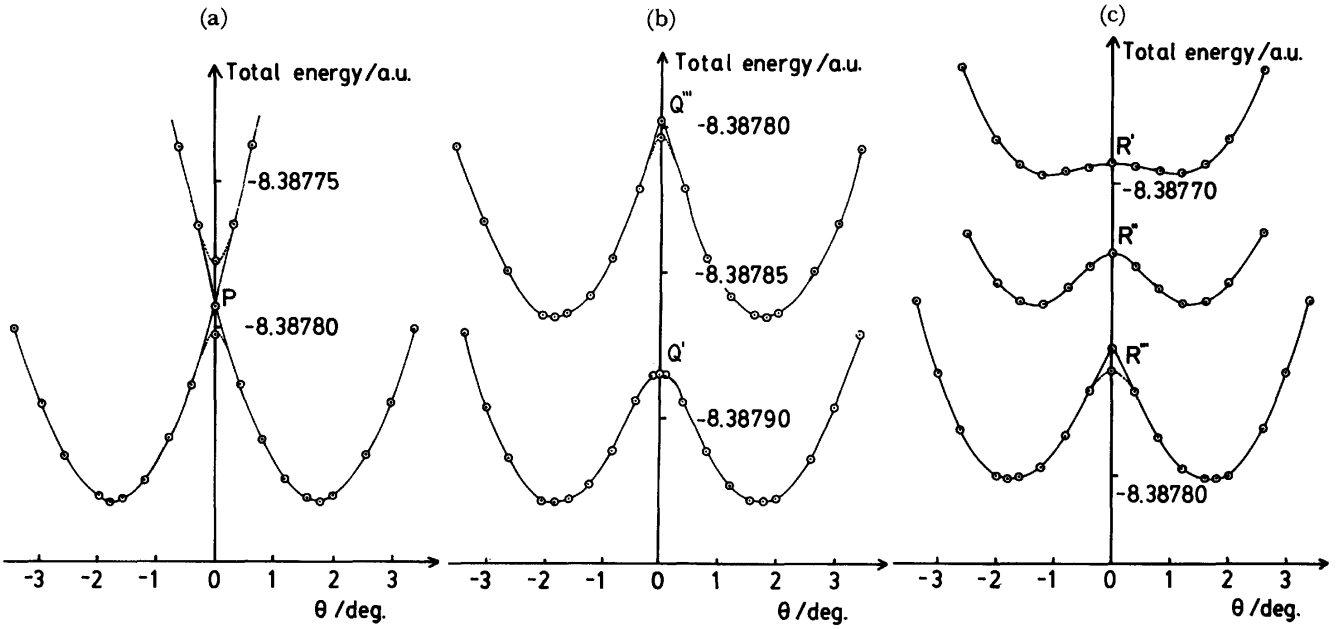

Fig. 7. Total energy *versus* C_s deformation angle from C_{2v} geometry passing: (a) *P*, (b) *Q'*, and *Q'''*, and (c) *R'*, *R''*, *R'''*. The locations of *P*, *Q'*, *Q'''*, *R'*, *R''*, and *R'''*, are shown in Fig. 6. In (b) and (c), only the lower state curves are shown. As to the dashed curves see text.

some stable molecules. Thus, MCSCF wave functions composed of only limited CSF's should be handled with care near geometries where potential crossing occurs, though those functions are quite good in other regions as will be shown below. One remedy is to perform an additional nonorthogonal CI[11c] between the wave functions. Thus, at P two wave functions are obtained, each belonging to one of the irreducible representations of the symmetry point group. The results of this treatment are shown in Fig. 9 and by dashed lines in Fig. 7(a). The energy displacements were of the order of 10^{-6} hartree at point P. Thus, the two curves crossing at P separate out into two smooth pseudocrossing curves. The same smoothing out of the potential curves passing through *Q'''* and *R'''* is shown in Fig. 7 as dashed lines. It will be noted, from the figure, that though the singularity is marked, qualitatively, it is relatively insignificant, quantitatively. Energy shifts resulting from the additional nonorthogonal CI are only remarkable (though the actual values are quite small) near the degenerate point, and do not alter the gross appearance of the MCSCF potential surfaces. The insignificance of the additional CI outside the critical region is seen from the data shown in Table 3.

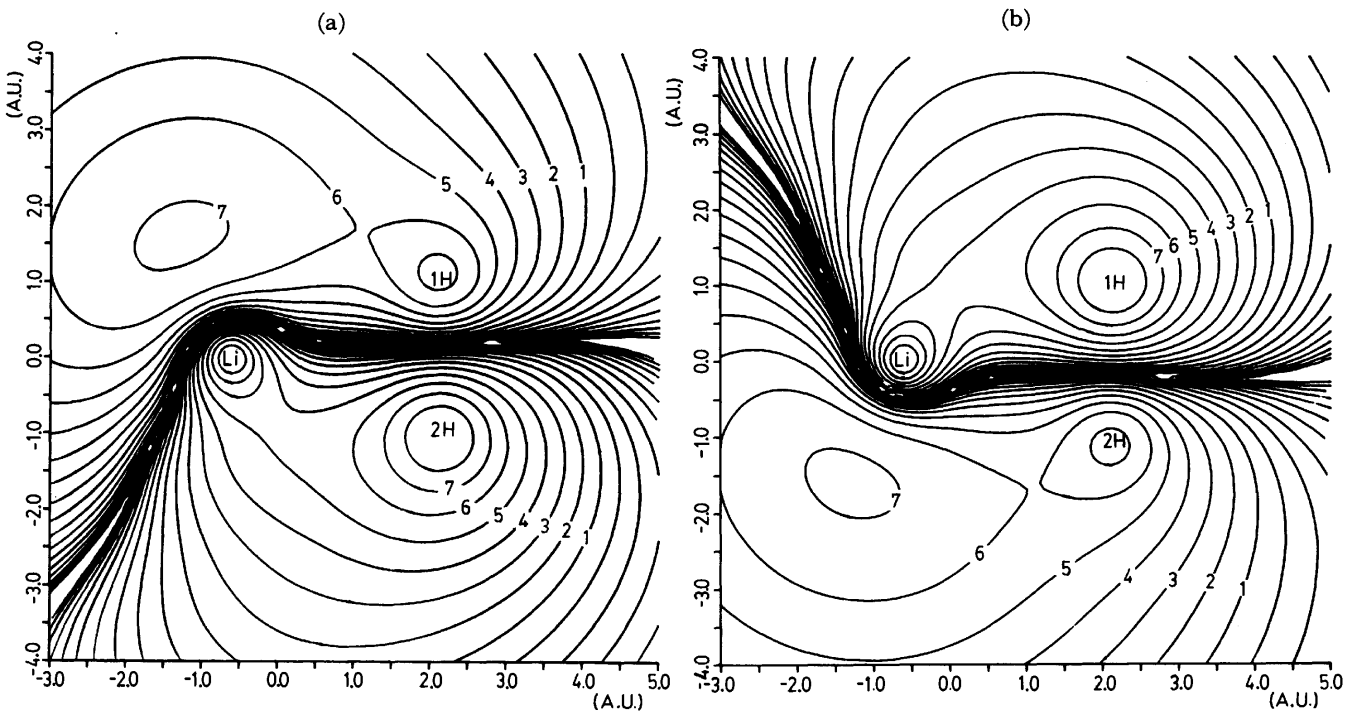

Fig. 8. Contour plots of 3a′ natural orbital electron density of simple MCSCF functions at P; each of (a) and (b) displays either one of the mutually symmetric pair functions degenerate at P. They correspond two states shown by the two curves in Fig. 7(a). The numbers 1, 2, ···, and 7 beside the contours indicate electron density of 3.5565×10^{-4}, 6.3246×10^{-4}, 1.1247×10^{-3}, 2.000×10^{-3}, 3.5565×10^{-3}, 6.3246×10^{-3}, 1.1247×10^{-2} electrons/bohr^3, respectively.

1H	1s	0.0030	0.5329	−0.3180	−0.9401
2H	1s	0.0022	0.5111	0.1835	1.0163

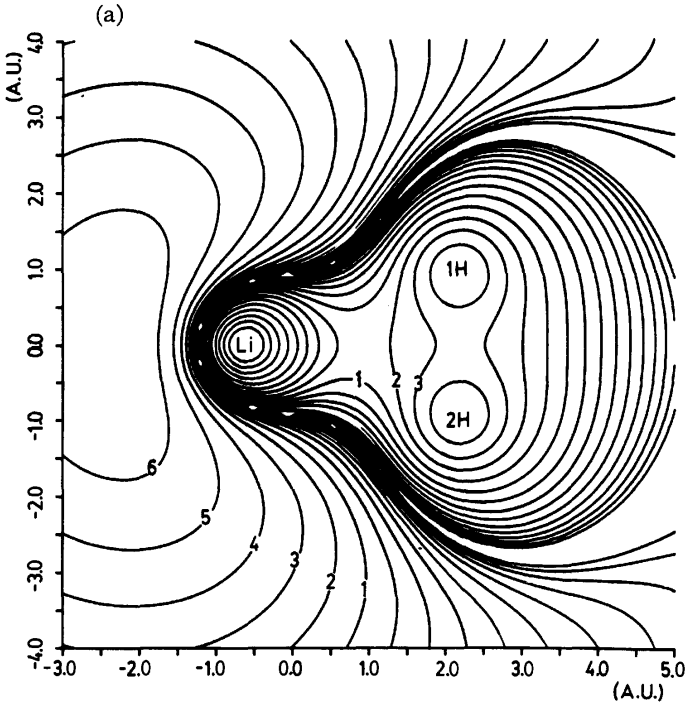
Table 2. Natural orbitals of the other wave function of the degenerate states at point P

Basis	MO	$\phi_{1a'}$	$\phi_{2a'}$	$\phi_{3a'}$	$\phi_{4a'}$
Li	1s	0.9956	−0.1087	−0.1069	0.0567
Li	2s	0.0216	0.0931	0.6076	−0.3182
Li	$2p_x$	−0.0036	0.1039	−0.2871	0.1676
Li	$2p_y$	−0.0022	−0.0076	0.6304	−0.3310
1H	1s	0.0022	0.5111	0.1835	1.0163
2H	1s	0.0030	0.5329	−0.3180	−0.9401

Full CI calculations are also feasible with the small basis set used here. Preliminary results of the full CI calculation[12] closely parallel those of the above CI-corrected functions.

Bond Exchange View of the Nonadiabatic Transition. The "primitive MCSCF function" shown in Figs. 7(a) and 8 have certain defects. They are, however, illustrative of an important property of the adiabatic function near the crossing. The electronic wave function should belong to one of the representations of the C_{2v} point group when the nuclear arrangement has that symmetry. It is more properly described as a linear combination of two mutually symmetric components having the features shown in Fig. 8, rather than by a single one of them. As the nuclear geometry is deformed by a very small angle θ[13] from a precise isosceles structure, one of the components rapidly reveals its predominance, as is be apparent from the small separation of the dashed lines from the solid lines in Fig. 7(a). For example, when θ is slightly positive, the electronic structure is characterized by a 3a′ natural orbital closely resembling that in Fig. 8(a). The 3a′ orbital bonds Li more strongly to the nearer 1H than to the farther 2H, and forces the geometry farther to the potential minima at a positive θ value. The feature of the corresponding excited state in this situation is characterized by the 3a′ natural orbital essentially of the form of Fig. 8(b). In this state, the distant 2H atom is more strongly bonded to the Li than the nearer 1H. In this sense, the nonadiabatic transition near point P may be viewed as a bond-type change, which occurs smoothly. It is noted that the potential curves in Fig. 7(a) (and more schematically in Fig. 10) are similar to those used to schematize a bimolecular replacement reaction.[14]

A rapid change in the mixing coefficients of the wave functions of the type represented in Fig. 8(a) and those in Fig. 8(b) as we pass through $\theta=0°$ means there is a strong dependence of the wave function on the nuclear geometry. That is a condition[15] which is necessary for the electronic transitions caused by nuclear motion. More specifically, we can view each single state of Fig. 7(a) as a kind of diabatic state[16] appropriate to describing the nonadiabatic transition at P (or its



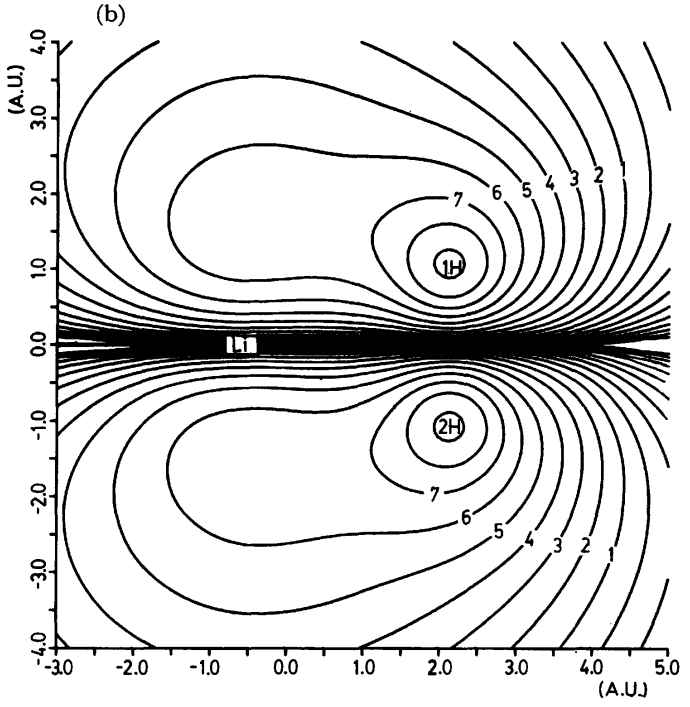


Fig. 9. Contour plots of 3a′ natural orbital electron density of wave functions at P, corrected by an additional CI; (a) upper state and (b) lower state. Figures besides contours have the same meaning as in Fig. 8.

Table 3. Energy difference and energy shifts after an additional nonorthogonal CI

$E_2^0-E_1^{0a)}$	$<1.0\times10^{-10}$	7.4×10^{-5}	7.9×10^{-3}	4.3×10^{-2}
$\lvert\Delta E_1\rvert$	5.8×10^{-6}	1.6×10^{-7}	8.5×10^{-10}	$<1.0\times10^{-15}$

a) Energy difference between the excited $^2A'$ state and the ground $^2A'$ state before an additional CI. Energy unit is hartree.

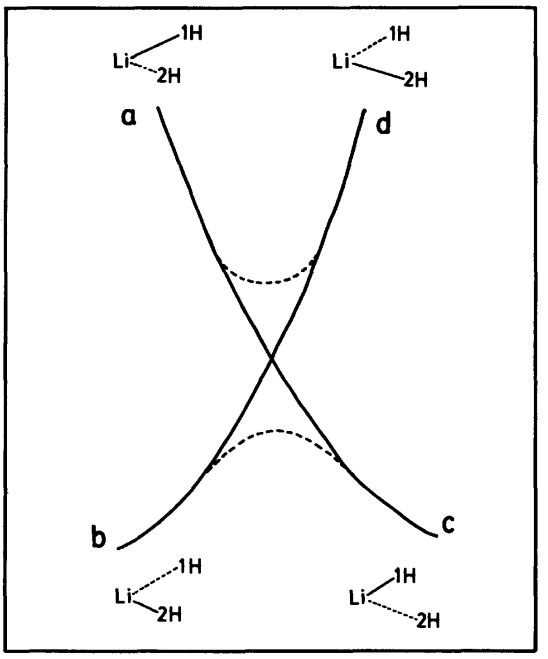

Fig. 10. Schematic representation of potential curves in the pseudocrossing region.

neighborhood) caused by a θ vibration.[11c] Thus as θ changes from a negative to a positive value with a finite velocity, there is a finite probability that the state of the system will follow the diabatic curve from *a* to *c* rather than the adiabatic curve (dashed line) from *a* to *d* (Fig. 10). In other words, there is a finite probability that the system changes from a state in which a more distant atom pair is bonded to a state of the inverse bonding mode.

The presence of cusps in the potential curve at $\theta=0°$ (Fig. 7) is related to the singularity of the density map at $\theta=0°$. The density maps of the 3a′ natural orbitals for points Q', R', and R'', where virtually no cusps are discernible, have a C_{2v} symmetry, while those for points Q''' and R''' have more or less similar abnormal features found at P. We made careful calculations at numerous points along the reaction coordinate and found that the change from the normal behaivor at points far from P to the abnormal one near P was, in reality, continuous. Moreover, the same series of converging functions were obtained irrespective of the starting 0-th approximation of the wave function. Thus, it seems that the singularity seen in the wave function obtained at P and its neighborhood was not the result of pathological progressions of iterations, but the result of an inappropriate form of wave function, as noted above.

Figure 11 shows the potential energy contour maps, thus computed, on the QR-θ plane. Figure 12 is a wide view comprising θ values up to 90°. It shoud be noticed that the shallow channels located at both sides of the reaction coordinate in Fig. 11 are quite immaterial in the gross potential surface (Fig. 12). The depth of the channels was only of the order of

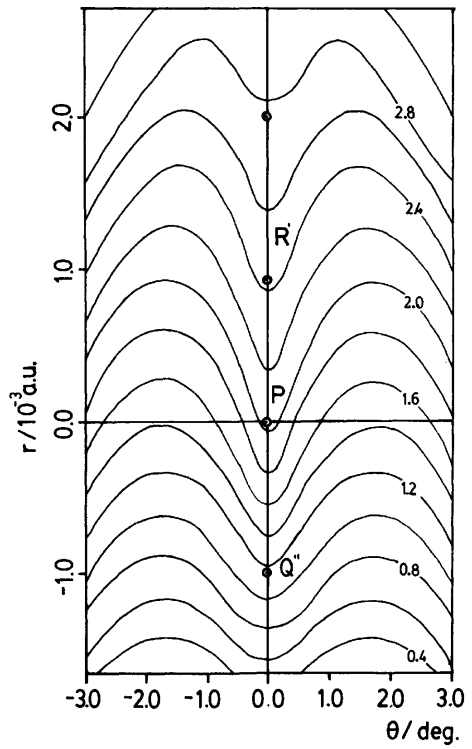

Fig. 11. Contour plots of the potential energy surface of the lowest $^2A'$ state near point P for C_s deformation (finer view). Abscisa: angle of deformation from C_{2v}. Ordinate: reaction coordinate. Figures beside curves indicate the values (E_{total}+8.3880 hartrees)/(10^{-4} hartree).

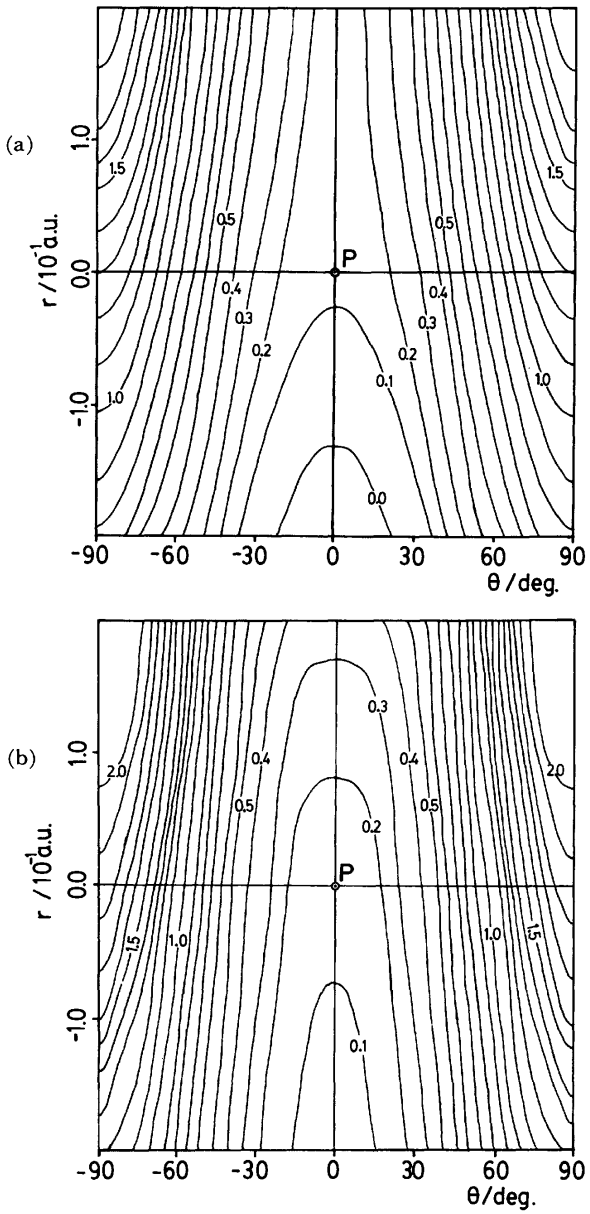

Fig. 12. Contour plots of the potential energy surfaces of the two lowest $^2A'$ states for C_s deformation from C_{2v}. (wider view). Abscisa: deformation angle from C_{2v}. Ordinate: reaction coordinate. (a) lowest $^2A'$ and (b) 2nd. $^2A'$. Figures beside curves indicate the values (E_{total}+8.4000 hartree)/(10^{-1} hartree).

50 cal/mol in this calculation. It may be neglected compared to thermal energy in the usual quenching experiments. The steep ascent of the potential surface to the θ direction implies the energetic disadvantages of a transition through a skewd geometry, as described at the beginning of this discussion. It is interesting that even for linear arrangement of the nuclei, the 3a' natural orbital shows similar bond exchange features as found above for the nearly C_{2v} geometry. Figure 13 shows electron density maps at point F of Fig. 2, and is compared with features shown in Figs. 8 and 9. The whole view of the first and second potential energy surfaces displayed with R_{LiH_2} and θ as parameters may be sketched roughly as in Fig. 14. They touch conically near point P in this dimension.

Conclusions

Potential energy surfaces of a system consisting of an $X^1\Sigma_g^+H_2$ and a Li atom in either 2^2S or 2^2P state come close or even cross, aside from collinear arrangement, for almost all inclination angles of the H_2 axis relative to the direction joining the components. Quenching of the excited Li atom by the H_2 molecule is expected to occur along any of the paths passing through these crossing regions. Among these paths, the ones having an isosceles or nearly isosceles geometry seem to be energetically most favorable. CASSCF wave functions,in which all the orbitals other than the core are included as active states, are almost as good as the full CI wave functions for every nuclear geometry in describing the finer electron density profiles as well as the energetic behavior of the system, except for small cririca regions where crossing or pseudocrossing occur. In the latter regions it is necessary to perform an additional nonorthogonal configuration interaction, or full CI if possible. Energetic corrections are quite small in these regions. The primary wave functions, themselves, reveal characteristic electronic properties of the system in the crossing region. Around the pseudocrossing point, ground state potential curves for

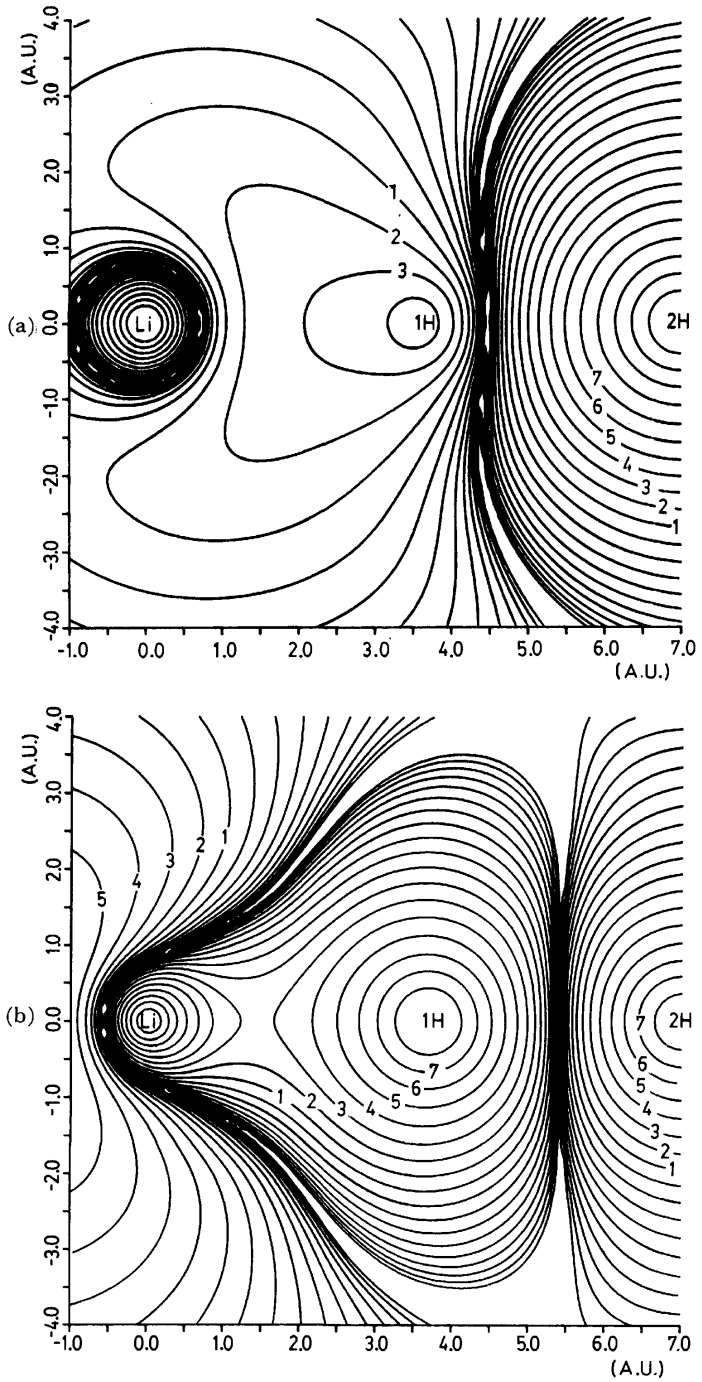

Fig. 13. Contour plots of 3a′ natural orbital electron density map for collinear geometry θ=90°, $R_{Li\text{-}H_2}$= 3.7 bohr, $R_{H\text{-}H}$=3.3 bohr. (a) lowest $^2\Sigma^+$ and (b) 2nd. $^2\Sigma^+$. Figures beside curves have the same meaning as in Fig. 8.

a θ-deformation from the C_{2v} geometry have shallow but distinct minima located at a few degrees on both sides. The whole potential curves may be viewed as resulting from a resonance splitting of the two crude "diabatic" curves, each describing one of the two modes of bonding. In this connection, electron density maps reveal features of bond type alternation upon nonadiabatic transitions induced by the b_2 vibration of the complex. These features resemble the mechanism of a bimolecular exchange reaction.

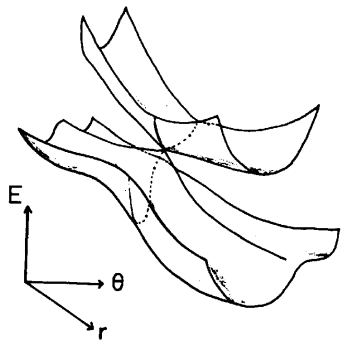

Fig. 14. Schematic view of the $1^2A'$ and the $2^2A'$ adiabatic potential energy surfaces in θ and r dimensions near the conical touch points.

We thank Professor Keiji Morokuma and Dr. Shigeki Kato of the Institute for Molecular Science for their helpfull suggestions, discussions and encouragement. Calculations were carried out at the Computer Center of the IMS, Okazaki National Research Institutes, at the Computer Center of the University of Tokyo, and at the Aoyama Gakuin University Computer Center. Thanks are due to Mr. Toyama for his help in these calculations. The present work was partially supported by a Grant-in-Aid for Scientific research No. 57740248 from the Ministry of Education, Science and Culture.

(Received March 5, 1984)

The ^{14}N and ^{35}Cl NQR and ^{14}N spin-lattice relaxation have been studied at various temperatures on the 1:2 molecular complex of 1,4-diazabicyclo[2.2.2]octane (DABCO) with $CHCl_3$. Two transitions have been observed near 123 K and 138 K. In the lowest temperature phase a minimum in the T_1 was observed and attributed to the axial reorientation of DABCO molecules. The activation energy for this motion was determined to be 12.1 ± 1.2 kJ mol^{-1}. The electron population is discussed for the DABCO complexes with $CHCl_3$ and $CDCl_3$ using the Townes-Dailey treatment.

DABCO has been known to form a molecular complex with chloroform by charge transfer from the former to the latter. The crystal structure of this complex has not been determined as yet. DABCO itself is well known as a plastic crystal and its motions have been studied in detail by NMR and NQR.[1,2] Since DABCO is globular, its motion in the complex will offer information about intermolecular interactions and, consequently, a clue to the molecular structure. Lucus and Guibé have already measured ^{14}N and ^{35}Cl NQR of this complex.[3] They reported the average ^{14}N NQR frequency and three ^{35}Cl NQR lines at liquid nitrogen temperature. We observed the temperature dependence of the ^{14}N and ^{35}Cl NQR lines and the ^{14}N spin-lattice relaxation times of the complex in order to examine the molecular motions and intermolecular interactions.

Experimental

The molecular complex was prepared by adding chloroform to DABCO purified by sublimation in an evacuated vessel and then cooling the mixture gently below 250 K. ^{14}N NQR measurements were carried out using a pulsed NQR spectrometer.[4] On the other hand, ^{35}Cl NQR spectra were observed using a superregenerative spectrometer. The temperature was measured by the use of a copper-constantan thermocouple. The frequency was checked by means of a frequency counter.

Results and Discussion

Temperature Dependence of ^{14}N and ^{35}Cl NQR Lines.

TABLE 1. ^{14}N NQR PARAMETERS IN DABCO COMPLEXES AT LIQUID NITROGEN TEMPERATURE

Complex	ν_-/kHz[a]	ν_+/kHz[a]	η/%	(e^2Qq/h)/kHz
$C_6H_{12}N_2 \cdot 2CHCl_3$	3551.0		0	4734.7
	3545.8	3583.9	1.603	4753.1
	3532.7	3567.5	1.470	4730.9
	3528.9	3562.2	1.409	4734.7
$C_6H_{12}N_2 \cdot 2CDCl_3$	3553.1		0	4737.5
	3551.1	3587.6	1.534	4759.1
	3535.9	3571.9	1.519	4738.5
	3532.8	3564.5	1.340	4731.5

a) Experimental error is within ±0.1 kHz.

Tables 1 and 2 show the NQR frequencies for the DABCO complexes at liquid nitrogen temperature. Seven ^{14}N and eleven ^{35}Cl resonance lines were observed for the complex of DABCO with $CHCl_3$ whereas seven ^{14}N and ten ^{35}Cl resonance lines were observed for the complex of DABCO with $CDCl_3$.

In the complex of DABCO with $CHCl_3$, the average frequency of four ^{14}N NQR lines (except three ν_+ lines) is 3.5396 MHz and agrees well with the value of 3.5397 MHz reported by Lucus and Guibé.[3] For ^{35}Cl NQR lines, frequencies of three among eleven resonance lines coincide approximately with the three frequencies, 37.666, 37.853, and 37.955 MHz, reported by Lucus and Guibé.[3] It is not possible at present to interpret the discrepancy in the number of ^{35}Cl resonance lines between the present study and Ref. 3.

Figure 1 shows the temperature dependence of ^{14}N NQR frequencies in the $CHCl_3$ complex. Seven resonance lines at liquid nitrogen temperature are denoted as (a), (b), (c), ···, and (g) as shown in Fig. 1. (a) and (b) as well as (e) and (f) approached each other with increasing temperature and coincided at about 123 K. The intensity of (d) was about twice as strong as those of the rest at liquid nitrogen temperature. As the temperature was raised, (d) became weak from 115 K and faded out near 123 K. Therefore, the seven resonance lines reduced to four near 123 K. These lines disappeared at 138 K but one broad line 50 kHz wide appeared just above this temperature as shown by the solid line in Fig. 1. As the temperature was raised, the

TABLE 2. ^{35}Cl NQR FREQUENCIES OF DABCO COMPLEXES AT LIQUID NITROGEN TEMPERATURE

Complex	ν/MHz[a]		
$C_6H_{12}N_2 \cdot 2CHCl_3$	37.122	37.360	37.402

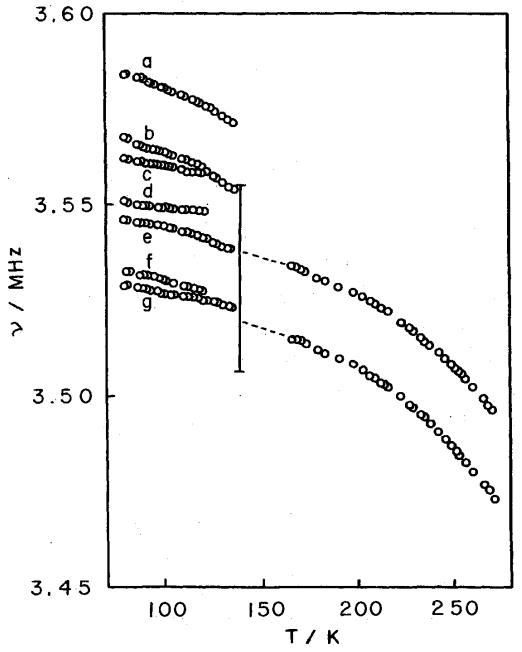

Fig. 1. Temperature dependence of ^{14}N NQR frequencies in $C_6H_{12}N_2 \cdot 2CHCl_3$.

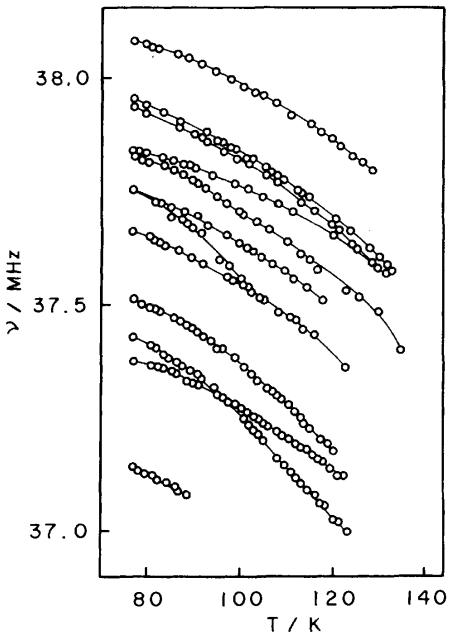

Fig. 2. Temperature dependence of ^{35}Cl NQR frequencies in $C_6H_{12}N_2 \cdot 2CHCl_3$.

linewidth decreased gradually and near 165 K the broad line split into two components. Since it was impossible to determine the resonance frequency with accuracy over the temperature range from 138 K to 165 K, the resonance lines are shown by the dotted lines in Fig. 1.

On the other hand, the temperature dependence of ^{35}Cl NQR frequencies in the $CHCl_3$ complex is shown in Fig. 2. Eleven resonance lines were observed at liquid nitrogen temperature, indicating that there are at least four $CHCl_3$ molecules in this complex. By analogy with ^{14}N resonance lines, the number of ^{35}Cl resonance lines decreased to half near 123 K and faded out

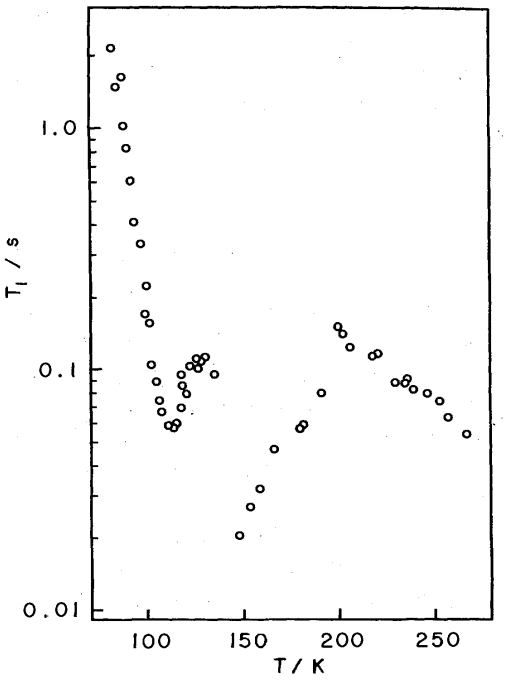

Fig. 3. Temperature dependence of ^{14}N spin-lattice relaxation times in $C_6H_{12}N_2 \cdot 2CHCl_3$. The spin-lattice relaxation times were measured for the (e) line between 80 K and 138 K and for the higher resonance line above 138 K.

near 138 K. However, no ^{35}Cl resonance lines appeared above 138 K up to the melting point (*ca.* 273 K).

^{14}N Spin-Lattice Relaxation Time. Figure 3 shows the temperature dependence of ^{14}N spin-lattice relaxation time in the complex of DABCO with $CHCl_3$. In the temperature range from 80 K to 123 K, the most remarkable feature is the appearance of the T_1 minimum at about 115 K. This process can be attributed to the reorientation of the DABCO molecule about its three-fold axis. The activation energy for this motion was calculated. In this case, the dominant relaxation mechanism can be regarded as magnetic dipole-dipole interaction between ^{14}N and nearby protons. Then, the relaxation time is given by the following equation:[1]

$$1/T_1 = C\tau/(1+\omega_Q^2\tau^2), \quad (1)$$

where C is a constant related to the intrinsic nature of the molecular motion. τ is the correlation time of the motion, and ω_Q is the resonance angular frequency. Assuming that the Arrhenius' relation for the correlation time, the following equation holds:

$$\tau = \tau_0 \exp(E_a/RT), \quad (2)$$

where τ_0 is the inverse frequency factor and E_a is the activation energy for the motion. E_a was calculated to be 12.1±1.2 kJ mol^{-1} for this motion from Eqs. 1 and 2 and the observed T_1 values. In the case of DABCO itself, the activation energy about the N-N axis was found to be 34.2±1.3 kJ mol^{-1} by Zussman *et al.*[1] This

value is nearly three times as large as that of the present complex. This finding suggests that the packing of the molecules is somewhat loose in the complex because the DABCO molecule lies between two bulky chloroform molecules.

At T_1 minimum, $\omega_Q\tau=1$ and the following equation holds:[1]

$$T_1^{min} = (8/81)(\omega_Q r_{NH}^6/\gamma_N^2\gamma_H^2\hbar^2), \quad (3)$$

where r_{NH} is the N-H distance in DABCO. γ_N and γ_H are the gyromagnetic ratio of nitrogen and hydrogen, respectively. Assuming that the structure of DABCO in the complex is the same as that in the pure DABCO crystal,[1] the value of T_1 minimum was calculated to be 60 ms. This is in good agreement with the observed value, 63 ms.

Bond Nature. In the case of the ^{14}N resonance, a pair of resonance lines, ν_- and ν_+, are observed and their frequencies are expressed as follow:

$$\nu_\pm = (e^2Qq/4h)(3\pm\eta), \quad (4)$$

where e^2Qq/h and η are the quadrupole coupling constant and the asymmetry parameter, respectively. In the complex of DABCO with $CHCl_3$, two ^{14}N resonance lines at temperatures above 138 K were found to be one pair of ν_- and ν_+ by measuring their Zeeman effect. Below 138 K the small intensity and small spacing of the multiple resonance lines make the measurement of the Zeeman effect unavailable. However, the temperature dependence of the ^{14}N and ^{35}Cl resonance frequencies makes their assignment to resonance lines possible. Since there are at least four crystallographically nonequivalent $CHCl_3$ molecules at liquid nitrogen temperature as described above, four nonequivalent nitrogen atoms should exist: There are seven ^{14}N resonance lines consisting of three pairs of ν_- and ν_+ and one single line. Between 123 K and 138 K, there are four ^{14}N and six ^{35}Cl resonance lines, indicating the presence of two nonequivalent nitrogen and chloroform. Since (b) and (f) lines coincided to (a) and (e) lines, respectively, at the first transition point as shown in Fig. 1, (a) and (e), (b) and (f), and (c) and (g) are paired. The asymmetry parameters and quadrupole coupling constants obtained by this pairing are listed in Table 1.

^{14}N resonance lines of the complex of DABCO with $CDCl_3$ are also listed in Table 1 together with the asymmetry parameters and quadrupole coupling constants evaluated by the same pairing as that of the $CHCl_3$ complex. The ^{14}N resonance frequencies of the $CDCl_3$ complex shift to the higher frequency region than those of the complex with $CHCl_3$ in the same manner as the ^{35}Cl resonance frequencies. In both complexes the nitrogen atoms are considered to form sp^3 hybrid orbitals. Three hybrid orbitals form N-C sigma bonds and the rest is a lone pair nonbonding orbital. Therefore, the quadrupole coupling constant is given by,[6]

$$e^2Qq/h = (3/4)(m-n)e^2Qq_0/h, \quad (5)$$

where m and n are the electron population in the lone pair and sigma bond orbitals, respectively, and e^2Qq_0/h is the quadrupole coupling constant by a 2p electron of nitrogen and is assumed to be 11.3 MHz.[7] From Eq. 5 and the average coupling constant, the value of $(m-n)$ is computed to be 0.5599 and 0.5595 for the $CHCl_3$ and $CDCl_3$ complexes, respectively. This indicates that the electron population in the lone pair nonbonding orbital in the $CDCl_3$ is larger by 0.0004 than those in the $CHCl_3$ if the frequency difference is taken to arise only from hydrogen bonding formation.

Behavior of Benzo-18-crown-6 Complexes with Alkali Metal Ions in Various Nonaqueous Solvents

Yasuyuki TAKEDA,* Yoshihiko OHYAGI, and Sadatoshi AKABORI†
Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260
†*Department of Chemistry, Toho University, Funabashi, Chiba 274*
(Received March 13, 1984)

The formation constants for 1 : 1 complexes of benzo-18-crown-6 (B18C6) with alkali metal ions and the solubility of B18C6 in various solvents were determined at 25 °C by conductometry and spectrophotometry, respectively. In general, the selectivity of B18C6 for alkali metal ions is governed primarily by the size relationship between cations and the B18C6 cavity. For a given alkali metal ion, the solvation ability of the solvent plays the most important role in determining stability sequences of the B18C6 complex in the solvents. Transfer activity coefficients of B18C6-alkali metal ion complexes were calculated. The transfer activity coefficient of the B18C6 complex from methanol to aprotic solvents somewhat varies with alkali metal ions in the B18C6 cavity. The magnitudes of the transfer activity coefficients of the B18C6 complex from acetonitrile and propylene carbonate to DMF and DMSO are determined mainly by the relative strength of the solvation ability of the former group and the latter group for the alkali metal ion in the B18C6 cavity. In methanol, due to the hydrogen bonds between ether oxygen atoms of B18C6 and methanol, the B18C6 complex is more strongly solvated than the corresponding alkali metal ion, compared to the case of the aprotic solvents.

In a previous paper,[1] various factors, which affect stabilities of 18-crown-6 (18C6) and dibenzo-18-crown-6 (DB18C6) complexes with alkali metal ions in several protic and aprotic solvents, were systematically investigated from a thermodynamic point of view. These factors are (1) the relative sizes of the alkali metal ions and the crown ether cavity, (2) the solvation ability of a solvent for the alkali metal ions, (3) the electron density of the crown ether cavity, and (4) the ligand-ring flexibility.

The behavior of 18C6 and DB18C6 complexes with alkali metal ions in a variety of solvents was studied by conductometry.[1-3] In each case of propylene carbonate[3] and *N,N*-dimethylformamide (DMF),[1] the mobilities of 18C6 complexes with alkali metal ions (Na^+, K^+, Rb^+, Cs^+) were nearly equal. Although the sizes of the 18C6-K^+ complex and $(n\text{-}C_4H_9)_4N^+$ are almost identical, the 18C6 complex in H_2O and CH_3OH does not enforce the hydrogen-bonded structure around the complexed ion as $(n\text{-}C_4H_9)_4N^+$ does.[2] It was proved from Walden products that the behavior of the 18C6-K^+ complex regarding transport phenomena is much the same in protic and aprotic solvents, as is the DB18C6-K^+ complex.[2] In order to obtain information about solute-solvent interactions with regard to 18C6[4,5] and DB18C6[6] complexes with univalent metal ions dissolved in various solvents, transfer activity coefficients of the complexes were determined. The solvation properties of the complexes are discussed in detail.

The structure of benzo-18-crown-6 (B18C6) is intermediate between 18C6 and DB18C6. In analytical chemistry, B18C6 is widely used as a moiety of bis(crown ether)s,[7] a pendant of polymers,[8] and colorimetric extraction-reagents[9] in order to achieve high selectivity for a given metal ion. Only a few thermodynamic studies have, however, been reported on B18C6 complexes with metal ions in solutions.[10-12]

In the present work, formation constants for 1:1 complexes of B18C6 with alkali metal ions and the solubility of B18C6 in protic and aprotic solvents were determined at 25°C by conductometry and spectrophotometry, respectively. The transfer activity coefficients of the B18C6 complexes with alkali metal ions were calculated from these data and values found in the literature regarding the transfer activity coefficients of alkali metal ions. The stabilities and solvation behavior of the B18C6 complexes in solutions are discussed.

Experimental

Materials. Benzo-18-crown-6 was prepared according to Pedersen.[13] The product was recrystallized three times from heptane and dried at 40 °C in a vacuum oven before use. Its purity was checked by melting point, elemental analysis, NMR, and conductometry.

Extremely pure sodium, potassium, rubidium, and caesium chlorides were obtained from Merck Japan Ltd., and were used without further purification. Rubidium and caesium perchlorates were prepared by adding a little excess of perchloric acid to aqueous solutions of rubidium and caesium chlorides, respectively. Sodium and potassium perchlorates were purchased from Merck Japan Ltd. All the perchlorates were recrystallized four times from distilled water and, prior to use, dried at 150 °C in a vacuum oven.

The method of purification of acetonitrile,[2] propylene carbonate,[3] methanol,[14] DMF,[1] and dimethyl sulfoxide (DMSO)[2] was previously described. For these five solvents, the middle 70% of the distillate was used. The conductivities of these final products of acetonitrile, propylene carbonate, methanol, DMF, and DMSO were less than 3×10^{-7}, 6×10^{-8}, 2×10^{-7}, 3×10^{-7}, and 7×10^{-8} $\Omega^{-1}cm^{-1}$, respectively.

Alkali metal chlorides were employed for the methanol system and alkali metal perchlorates for the other solvent systems.

Apparatus and Procedure. The conductance measurements were made on a Fuso conductivity apparatus,

model 362A, in a water bath thermostated at 25±0.005°C. Three cells were used with cell constants of 0.059705, 0.093939, and 0.097761 cm^{-1}. The experimental procedure to obtain formation constants of B18C6 complexes with alkali metal ions was almost the same as that described in a previous paper.[3]

Solubilities of B18C6. Solubilities of B18C6 in acetonitrile (275nm), propylene carbonate (275nm), methanol (225nm), DMF (278nm), and DMSO (276nm) were determined spectrophotometrically at 25±0.02°C. They are 2.8×10^{-1}, 2.4, 2.9, 3.0, and 2.8M (1 M=1 mol dm^{-3}) for acetonitrile, propylene carbonate, methanol, DMF, and DMSO, respectively.

Results and Discussion

The procedure for obtaining formation constants (K_{ML^+}) of B18C6 complexes with alkali metal ions was the same as that described in a previous work,[3] where $K_{ML^+}=[ML^+]/[M^+][L]$. M^+ and L designate an alkali metal ion and a crown ether, respectively. In the present study, it is assumed that the association between a cation and an anion is negligible under the highly dilute experimental conditions (total concentration of an alkali metal ion$\approx5\times10^{-4}$ M) and that B18C6 forms a 1:1 complex with an alkali metal ion. Since the B18C6 concentration was kept below 2.5×10^{-3}M during the experiments, corrections for viscosity changes were neglected. The log K_{ML^+} values are listed in Table 1, together with the literature values.

The molar conductivity (Λ) *vs.* $[L]_t/[M]_t$ plots for propylene carbonate and DMF systems at 25°C are illustrated in Figs. 1 and 2, where $[L]_t$ and $[M]_t$ denote total concentrations of B18C6 and the alkali metal ion, respectively. Since the Λ *vs.* $[L]_t/[M]_t$ curves for the other solvent systems are similar, they have been omitted. Every plot of Λ *vs.* $[L]_t/[M]_t$, except for the $NaClO_4$–DMSO system, shows a decrease in Λ with an increase in the B18C6 concentration. This indicates that the alkali metal ion complexed by B18C6 is less mobile than the corresponding free alkali metal ion. For the $NaClO_4$–DMSO system, the change in Λ was so small in spite of an increase in the B18C6 concentration that the complex-formation constant could not be determined conductometrically. It can be seen from Fig. 1 that, in the cases of Na^+, K^+, and Rb^+, the slope of each curve changes sharply at $[L]_t/[M]_t=1$. The same

tendency was observed for the Na^+-, K^+- acetonitrile, and the Na^+-, K^+-, Rb^+-methanol systems. For the other systems, no such clear breaking point was observed. These data indicate that the following three factors play an important role in causing the clear breaking point. (1) Benzo-18-crown-6 forms a stable complex with an alkali metal ion (log $K_{ML^+}\geqq4.5$). (2) The difference in mobility between the B18C6-alkali metal ion complex and the corresponding free alkali metal ion is large. (3) A higher-order B18C6 complex such as a 1:2 sandwich complex of an alkali metal ion with B18C6 is not formed.

Stability Constants. It can be seen from Table 1 that the log K_{ML^+}-value sequences of B18C6 complexes with K^+, Rb^+, and Cs^+ for the same solvent are $K^+>Rb^+>Cs^+$. This indicates that the selectivity tendency of B18C6 (18C6 cavity radius: 1.34—1.43 Å[20]) agrees well with the size-fit concept. Among all the B18C6 complexes with alkali metal ions (Na^+, K^+, Rb^+, Cs^+), the log K_{ML^+} value of the Na^+-B18C6 complex is the second largest for acetonitrile and propylene carbonate, the third largest for methanol, and the smallest for DMF and DMSO. This reflects the fact that in every one of these solvents Na^+ is the most strongly solvated of all the alkali metal ions (Na^+, K^+, Rb^+, Cs^+), and that the differences in the free energies of the solvation of Na^+ and K^+, Na^+ and Rb^+, and Na^+ and Cs^+ are much smaller for acetonitrile and propylene carbonate than for the other solvents.[1] A similar tendency to that described above was observed for the stabilities of 18C6 and DB18C6 complexes with alkali metal ions in various solvents.[1]

Since an aliphatic ether oxygen atom is more basic than an aromatic ether oxygen atom, the interaction of an alkali metal ion with the former is stronger than that with the latter. Benzo-18-crown-6 and DB18C6 have two and four aromatic ether oxygen atoms, respectively. Thus, it can be expected that the stabilities of the complexes of these three crown ethers with the same alkali metal ion in a given solvent decrease in the order 18C6>B18C6>DB18C6. The data in Table 1 are in good accord with this expectation except for the Na^+-acetonitrile, methanol, DMF, and DMSO systems. For propylene carbonate, however, the difference in the log K_{ML^+} values of Na^+ between 18C6 and B18C6 (0.4), and that between B18C6 and DB18C6 (0.1) are both small compared to the other alkali metal ions (K^+, Rb^+, Cs^+). Since Na^+ is smaller than the 18C6 cavity and has the greatest charge density of all the alkali metal ions (Na^+, K^+, Rb^+, Cs^+), Na^+ held in the cavity may attract the donor oxygen atoms of the crown ether much more strongly than the other alkali metal ions. It follows from this that the complexation reaction of Na^+ with a flexible crown ether causes the largest ligand-ring conformational change among all the alkali metal ions. Consequently, the more flexible is a crown ether, the more destabilized is the Na^+ complex with the crown ether on account of entropy contribution. It thus appears from Table 1 that the stability sequences of Na^+ complexes with 18C6, B18C6, and DB18C6 for the same solvent largely depend on competition between the ligand-ring flexibility and the electron density of the crown ether cavity.

For acetonitrile and propylene carbonate, the log K_{ML^+} value of Na^+ with DB18C6 is the largest; while, those with B18C6 and 18C6 are the second largest. For methanol, the log K_{ML^+} values of Na^+ with DB18C6, B18C6, and 18C6 are the second largest, the second smallest, and the smallest, respectively. For DMF and DMSO, the log K_{ML^+} value of Na^+ with DB18C6 is the second largest; while, those with B18C6 and 18C6 are the smallest. For the same solvent, the difference in the log K_{ML^+} values of the same crown ether between Na^+ and the other alkali metal ion, which forms a more stable complex with the crown ether compared to Na^+, increases in the order DB18C6<B18C6<18C6; that between Na^+ and the other alkali metal ion, which forms a less stable complex with the crown ether compared to Na^+, decreases in the order DB18C6>B18C6>18C6. These results indicate that, on moving from DB18C6 to 18C6, the Na^+ complex is much more destabilized than the other alkali metal ion complexes on account of entropy contribution because the ligand-ring flexibility increases in the order DB18C6<B18C6<18C6.

Solvation-ability sequences of the solvents for the same alkali metal ion are as follows:

Na^+: PC < AN < CH_3OH ≪ DMF < DMSO,
K^+ : CH_3OH < PC < AN ≪ DMF < DMSO,
Rb^+: CH_3OH < PC ≦ AN ≪ DMF ≦ DMSO,
Cs^+ : CH_3OH < PC ≦ AN ≪ DMF < DMSO.[1]

Log K_{ML^+}-value sequences of the B18C6 complex with the same alkali metal ion for the solvents are as follows:

Na^+: PC > AN > CH_3OH ≫ DMF,
K^+ : CH_3OH > PC ≧ AN ≫ DMF > DMSO,
Rb^+: CH_3OH > PC ≧ AN ≫ DMF > DMSO,
Cs^+ : CH_3OH > AN > PC ≫ DMF > DMSO,

where PC and AN denote propylene carbonate and acetonitrile respectively (Table 1). This shows that, for the same alkali metal ion, the log K_{ML^+}-value sequences of B18C6 for the solvents are completely the reverse of the solvation-ability sequences of the solvents except for the log K_{ML^+}-value sequence of Cs^+ for acetonitrile and propylene carbonate. For the solvents used in this work, there exists a very large difference in the solvation ability for the same alkali metal ion between the group of methanol, propylene carbonate, and acetonitrile, and that of DMF and DMSO,[1] and also a large difference in the log K_{ML^+} values of B18C6 about the same alkali metal ion. From the above discussion, it can be concluded that, for the same alkali metal ion, the solvation ability of a solvent plays the most important role in determining the stability sequences of the B18C6 complex for the solvents. A similar conclusion to that mentioned above was obtained for 18C6 and DB18C6.[1]

Transfer Activity Coefficient. The transfer activity coefficient ($\log {}^{s_1}\gamma^{s_2}(ML^+)$) of a B18C6-alkali metal ion complex between the solvent S_1 and the solvent S_2 is calculated by Eq. 1.

$$\log {}^{s_1}\gamma^{s_2}(ML^+) = (\log K_{ML^+})_{s_1} - (\log K_{ML^+})_{s_2} + \log {}^{s_1}\gamma^{s_2}(L) + \log {}^{s_1}\gamma^{s_2}(M^+) \quad (1)$$

These values are listed in Table 2.

It is noted that, although ether oxygen atoms of B18C6 form hydrogen bonds with methanol, the solubility of B18C6 for methanol is approximately equal to those for the aprotic solvents other than acetonitrile. The $\log {}^{CH_3OH}\gamma^s(L)$ value of B18C6 is much larger than the corresponding $\log {}^{CH_3OH}\gamma^s(L)$ value of DB18C6, indicating that B18C6 is much more soluble in methanol than in the aprotic solvents, as compared to DB18C6. This is ascribed to the fact that, since DB18C6 has one more benzo group than B18C6, enforcement of a hydrogen-bonded structure of methanol for the hydrophobic benzo group more decreases the solubility of DB18C6 in methanol than that of B18C6. From Table 2, when s=PC, DMF, and DMSO, $\log {}^{CH_3OH}\gamma^s$(B18C6)−$\log {}^{CH_3OH}\gamma^s$(DB18C6) is of the order of 1, whereas, only for acetonitrile, that is of the order of 2.

In general, in the case of B18C6, $\log {}^{CH_3OH}\gamma^s(ML^+)$ values for the same aprotic solvent of K^+ and Rb^+ are nearly equal to each other; however, they are somewhat different from those of Na^+ and Cs^+. These results reflect the following fact. The sizes of K^+ and Rb^+ are nearly identical with that of the B18C6 cavity; Cs^+ is larger than the B18C6 cavity. Since Na^+ is smaller than the B18C6 cavity, it shifts up and down in the direction perpendicular to the plane of oxygen atoms of B18C6. Thus, the surface charge of K^+ and Rb^+ held in the B18C6 cavity is more effectively screened by the B18C6 from surrounding solvent molecules than that of Na^+ and Cs^+. Consequently, both B18C6 complexes with K^+ and Rb^+ exhibit apparently similar chemical nature; however, the Na^+ and the Cs^+ complexes show somewhat different chemical nature from the others.

From $\log {}^{CH_3OH}\gamma^s(ML^+)$ values in Table 2, solvation-ability sequences of the solvents for the same B18C6-alkali metal ion complex are as follows:

Na^+-B18C6: AN < PC < CH_3OH < DMF,
K^+-B18C6 : AN < PC < CH_3OH < DMSO < DMF,
Rb^+-B18C6: AN < PC < CH_3OH < DMSO < DMF,
Cs^+-B18C6 : AN < CH_3OH ≈ PC ≪ DMF < DMSO.

For the aprotic solvents, the solvation ability of DMF and DMSO for the same B18C6-alkali metal ion

a) Acetonitrile. b) Propylene carbonate.

complex is relatively larger than that of AN and PC; similarly, that of DMF and DMSO with respect to the same alkali metal ion is much greater than that of PC and AN. When s_1=AN and PC and s_2=DMF and DMSO, $\log^{s_1}\gamma^{s_2}(M^+\text{-B18C6})$ is much smaller than $\log^{s_1}\gamma^{s_2}$(B18C6). This indicates that, in DMF and DMSO, a B18C6-alkali metal ion complex much more strongly undergoes solvation than a free B18C6, in comparison with the cases of AN and PC. From the above data, it can be concluded that there is an appreciable interaction between the alkali metal ion held in the B18C6 cavity and solvent molecules, and, furthermore, that, when s_1=AN and PC and s_2=DMF and DMSO, the magnitude of the $\log^{s_1}\gamma^{s_2}(ML^+)$ value is determined mainly by the relative strength of solvation ability of s_1 and s_2 for the alkali metal ion in the B18C6 cavity. $\text{Log}^{PC}\gamma^{AN}(ML^+)-\log^{PC}\gamma^{AN}(L)$ values of B18C6 for Na^+, K^+, and Cs^+ are negative, and that for Rb^+ is nearly equal to zero. Although an alkali metal ion is more strongly solvated in acetonitrile than in propylene carbonate, the reverse is true for a B18C6-alkali metal ion complex. This may be attributed to the fact that B18C6 itself is comparatively more soluble in propylene carbonate than in acetonitrile ($\log^{PC}\gamma^{AN}$(B18C6)=0.93).

The solvation ability of methanol for K^+, Rb^+, and Cs^+ is the lowest of all the solvents used in this work; however, that for the B18C6 complexes with K^+, Rb^+, and Cs^+ is the third largest. $\text{Log}^{CH_3OH}\gamma^s(ML^+)-\log^{CH_3OH}\gamma^s(M^+)$ values for B18C6 are positive except the Na^+-PC system. These results reflect the fact that, in methanol, on account of hydrogen bonds between ether oxygen atoms of B18C6 and methanol molecules, a B18C6-alkali metal ion complex is more strongly solvated than the corresponding alkali metal ion, compared to the case of the aprotic solvent.

Values of $\log^{CH_3OH}\gamma^s(M^+\text{-B18C6})-\log^{CH_3OH}\gamma^s(M^+\text{-DB18C6})$ are 2.8—3.0, 1.1—1.6, 0.9—2.0, and 0.9—1.9 for s=AN, PC, DMF, and DMSO, respectively (Table 2). Generally, these values are nearly equal to the corresponding values of $\log^{CH_3OH}\gamma^s$(B18C6)$-\log^{CH_3OH}\gamma^s$(DB18C6). Since s is an aprotic solvent, this may be largely due to the entropy effect[4] caused by the enforcement of a hydrogen-bonded structure of methanol for the benzo group, as is mentioned above.

The authors thank Mr. Takaya Yusa of this laboratory for his experimental assistance in conductance measurements.

A Study of the Charge-Discharge Characteristics of the Lithium-Polyacetylene Battery by Means of the FFT Impedance Measurement

Tetsuya OSAKA* and Takashi KITAI
Department of Applied Chemistry, School of Science and Engineering, Waseda University, Okubo, Shinjuku-ku, Tokyo 160
(Received March 13, 1984)

The charge-discharge characteristics of the anion-doped lithium-polyacetylene [$(CH)_x$] battery was investigated by means of the FFT impedance method, by which the impedance-frequency dispersion could be measured by very high speed. The charging and self-discharging of the Li-$(CH)_x$ battery were represented by the Randles-type equivalent circuit, added with the corrective term concerned with surface roughness. These processes and their doping states of the $(CH)_x$ film were readily detected by the variation in the resistive component, *Rr*, in the equivalent circuit. The *Rr* value of the self-discharge process was clearly correlated to the open-circuit voltage, *Voc*, regardless of the charging current; furthermore, it was strongly indicated that the self-discharge process is mainly caused by the dopant diffusion from the interface into the interior part of $(CH)_x$ films. For the discharging process, another mechanism, closely concerned with dopant diffusion, was suggested by the impedance results.

The electrochemical doping-undoping method in polyacetylene has been of much interest when applied for lightweight rechargeable batteries.[1,2] The MacDiarmid group[1] indicated the high potential on rechargeable battery by using 6% ClO_4^- doped polyacetylene as a cathode-active material. Moreover, they[2] summarized some characteristics of the lithium-polyacetylene battery in which 7% doped polyacetylene was used as the cathode. The electrochemical doping-undoping processes of polyacetylene have already been studied by FFT impedance measurement[3] and the basic doping-undoping process could readily be analysed by means of the resistive component measured by the FFT impedance measurement at a high speed. In this paper, we wish to report the charge-discharge and self-discharge characteristics of the ClO_4^- doped lithium-polyacetylene battery as established by means of electrochemical measurements, especially by the FFT impedance method.[4]

Experimental

The *cis*-polyacetylene films 0.1 mm thick (weight density, 0.44 g cm^{-3}) were prepared by the Sirakawa method.[5] The cell construction, composed of 8 mmϕ *cis*-$(CH)_x$ working and Li counter electrodes attached to platinum plates, without any reference electrode, is shown schematically in Fig. 1. The volume of the cell was 0.283 cm^3. The polyacetylene working and lithium counter electrodes were fixed by the use of stainless steel SUS 304 fittings with O-rings for sealing. One mol dm^{-3} $LiClO_4$ electrolyte and propylene carbonate (PC) were purified and handled in the usual method.[6] The Li-*p*-$(CH)_x$ battery was galvanostatically charged or discharged using the step-by-step or the consecutive method. The doping level of the $(CH)_x$ film was calculated according to Eq. 1; one percent of the doping level for the film corresponded to 278 mC. The doping was carried out conveniently until the 6% level was reached by referring the Refs. 1 and 2 in order to avoid the irreversible oxidation of the $(CH)_x$ film. The cell impedance was measured from 0.001 to 2.5 kHz by means of the on-line FFT impedance meter constructed by the authors' laboratory.[4] All the experiments were carried out in a dry and inert Ar gas atmosphere.

Results and Discussion

Open-circuit Voltage, Voc, *on Charging-Discharging Process of ClO_4^- Doped Li-$(CH)_x$ Battery.* The relations between the open-circuit voltage, *Voc*, and the doping level, *y*, for the step-by-step charging-discharging process of lithium/1 mol dm^{-3} $LiClO_4$ in the propylene carbonate/$(CH)_x$ battery have already been reported by several workers.[1,2] The basic charging process for the ClO_4^- anion doping into the $(CH)_x$ film is represented by:

$$(CH)_x + xyClO_4^- \longrightarrow [CH^{y+}(ClO_4^-)_y]_x + xye. \quad (1)$$

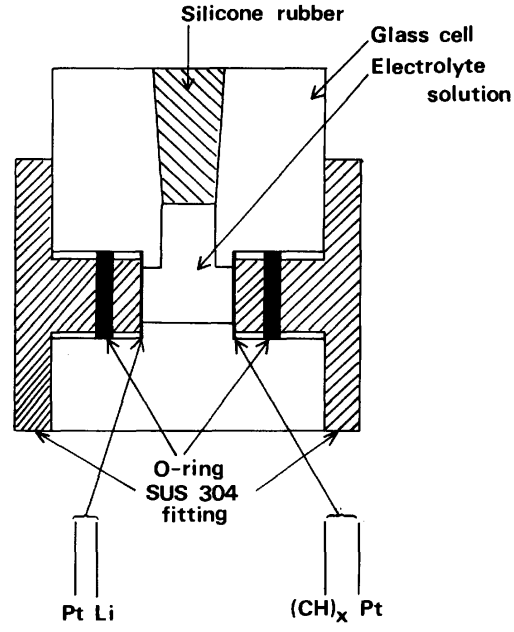

Fig. 1. Schematic cell construction of Li/1 mol dm^{-3} in PC/$(CH)_x$.

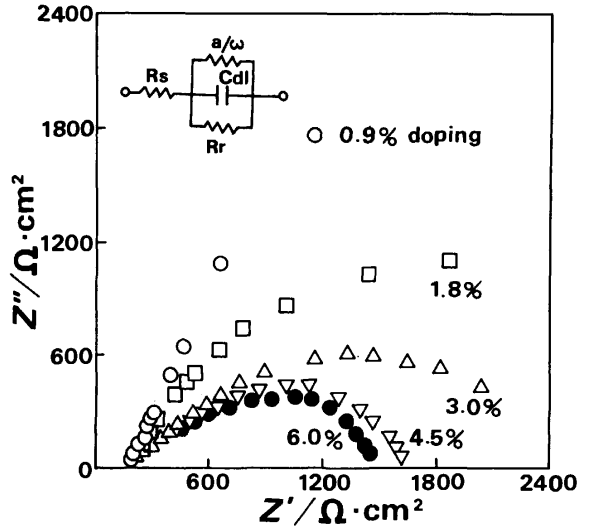

Fig. 2. Cell-impedance representation of charging process for Li-$(CH)_x$ battery step-by-step-charged at 0.5 mA cm^{-2}, where the cell impedance was measured after 24h at each doping level.

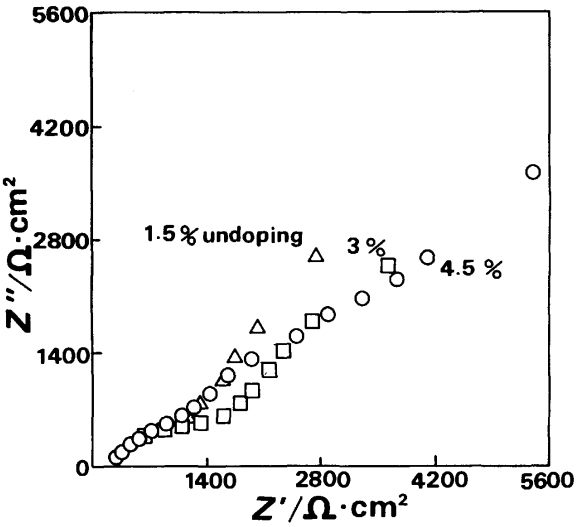

Fig. 3. Cell-impedance representation of the 6% ClO_4^- doped Li-$(CH)_x$ battery for discharging process at 0.5 mA cm^{-2}, where the cell impedance was measured after 24h at each undoping level.

The reduction of Li^+ to metallic Li occurs simultaneously:

$$Li^+ + e \longrightarrow Li. \quad (2)$$

In our experiments, results identical to those in the previous papers[1,2] were obtained. In particular, the *Voc* decrease after charging and the *Voc* increase after discharging were clearly observed. For example, for the charging process, the *Voc*-charged values after 2h were always higher than those after 24h, while for the discharging process, the reverse was true. By considering the previously reported finding[2,3] that a quick charging process causes a nonequivalent concentration gradient of the doped ion in the $(CH)_x$ film for the depth profile, the above results can be interpreted by the facts that most of the ClO_4^- dopant exists near the surface region of the $(CH)_x$ film just after the charging process and, furthermore, that the dopant at the surface diffuses into the film interior with the passage of time. Thus, the *Voc* value is controlled by the dopant concentration at the surface. On the other hand in the discharging process, an immediate discharge produces a decrease in the dopant concentration at the surface region, but the passage of time after discharging process causes a increase in diffusion from the interior to the exterior parts of films.

Impedance Measurement of Charging-Discharging Process using Li-$(CH)_x$ Battery. The impedance-frequency dispersions for the Li-$(CH)_x$ at various charging levels were measured by the FFT impedance method. The cell-impedance representation for the battery galvanostatically charged step by step at 0.5 mA cm^{-2} is shown in Fig. 2. The cell-impedance measurement was done after 24h at each doping level. The cell-impedance representation becomes an inclined semicircle, like the behavior of the polyacetylene film itself.[3] Since two electrode reactions, (1) and (2), in the charging process occur simultaneously at the anode and the cathode respectively, the cell impedance should represent the whole reaction of the Li-$(CH)_x$ battery. However, the cell impedance can be regarded as mainly due to the polyacetylene electrode reaction (1), because the impedance due to the lithium-electrode reaction can almost be ignored because its value is lower than that due to the polyacetylene reaction (*i.e.*, the former reaction rate is faster than the latter). In practice, the semicircle impedance plots are somewhat distorted as compared with those of the $(CH)_x$ film itself,[3] so the influence of the Li-electrode reaction on the cell-impedance behavior may be somewhat contained. The Randles-type equivalent circuit shown in the insert of Fig. 2, which has already been discussed in a previous paper,[3] is applied to the frequency-dispersion behavior showing a semicircle. The components, *Rs*, *Rr*, *Cdl* and $a\ \omega^{-1}$ (ω: angular frequency), are the solution resistance, the resistive component due to the electrode reaction and the film conductivity, the double-layer capacitance, and the corrective term concerned with the surface roughness. The polyacetylene film surface may be porous, for it is composed of fibril units, so that the term concerned with surface roughness should be assumed, and the *Cdl* value becomes the total value of each pore's double-layer capacitance. In these components, the *Rr* value, which corresponds to the semicircle's diameter of impedance behavior, greatly reflects the change in the charging or doping level. Therefore, the charging process of the Li-$(CH)_x$ battery can be pursued and discussed in terms of the variation in the *Rr* value as well as that of the $(CH)_x$ film itself. The resistive component, *Rr*, arises mainly from the two factors of the partial oxidation (or doping) reaction and of the film resistivity itself; it

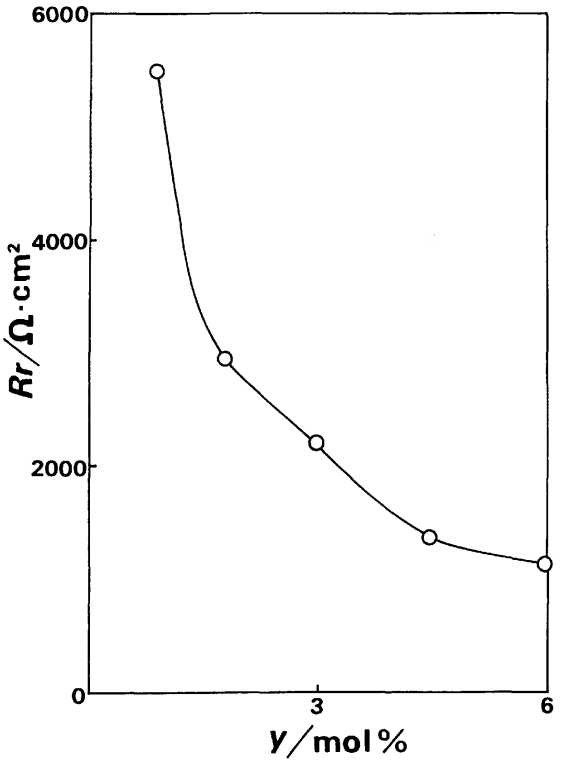

Fig. 4. Relation between resistive component, *Rr*, in the equivalent circuit and doping level, *y*, of the Li-$(CH)_x$ battery step-by-step-charged at 0.5 mA cm^{-2}, where the data were calculated from those in Fig. 2 at each doping level.

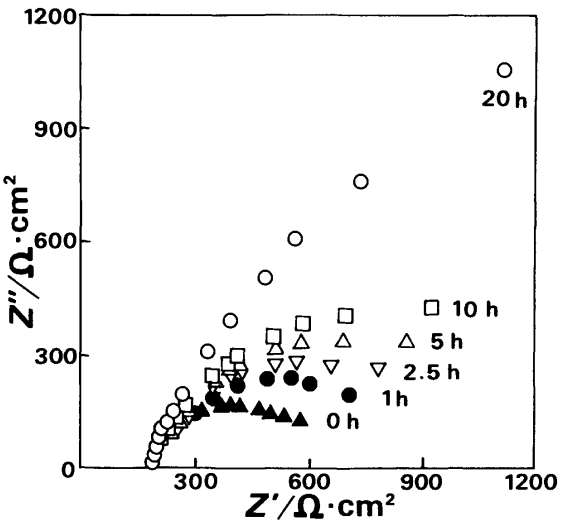

Fig. 5. Cell-impedance representation for self-discharge of Li-$(CH)_x$ battery after consecutive-charged at 0.1 mA cm^{-2}, up to the 6% ClO_4^- doping level.

greatly reflects the dopant concentration not of the whole amount of the charge, but of the amount at the surface region of the $(CH)_x$ film, as is discussed in our previous paper.[3)]

Figure 3 shows the cell-impedance representation for the discharging process of the Li-$(CH)_x$ battery at 0.5 mA cm^{-2} on various undoping levels from the 6% ClO_4^- doped polyacetylene. Each plot was also measured 24 h after the end of discharge. In the discharging process, there was observed to be no difference in cell-impedance behavior between measurements immediately after and 24 h later. Furthermore, the frequency-dispersion behavior of cell impedance is almost independent of the undoping level, as may be seen in Fig. 3. The cell-impedance behavior in the discharging process displays two regions of semicircles at higher frequencies and a linear line at lower frequencies. The linear region is usually concerned with the diffusion process, so the dopant diffusion at the interface is considered to be greatly concerned with and to control the discharging process of the Li-$(CH)_x$ battery.

Figure 4 shows a typical variation in the *Rr* value as a function of the doping level, *y*, on a step-by-step-charging process at 0.5 mA cm^{-2}, which is derived from the data in Fig. 2. The results indicate a good correlation between *Rr* and *y*; namely, the *Rr* value decreases with the increase in the doping level, *y*. The *Rr* decrease tends to change sharply at the initial doping stage.

Impedance of Self-discharge for the Li-$(CH)_x$ Battery after Consecutive Charging up to the 6% ClO_4^- Doping Level. Since the self-discharge phenomenon was observed after charging the ClO_4^- doped Li-$(CH)_x$ battery, the time dependence of impedance for the battery after it had been charged up to the 6% doping level was examined in order to clarify this phenomenon.

Figure 5 shows the cell-impedance representation of the self-discharge of the Li-$(CH)_x$ battery after it has been charged at 0.1 mA cm^{-2} up to the 6% ClO_4^- doping level. The frequency dispersion of the impedance loci becomes a semicircle, just as in Fig. 2. Similar the cell-impedance behavior was also observed in the cases of the 0.2 and 0.5 mA cm^{-2} charging currents. The *Rr* value in the equivalent circuit, corresponding to the semicircle's diameter in the cell-impedance representation, increases with the passage of time. These results can be explained by the fact that the dopant diffuses from the exterior into the interior parts of the $(CH)_x$ film with the increase in time, as well as by the *Voc* results previously discussed.

Figure 6 presents the time dependence of the resistive component, *Rr*, and the open-circuit voltage, *Voc*, for the self-discharge of the Li-$(CH)_x$ battery after it has been charged up to the 6% ClO_4^- doping level. The *Rr* value shown in Fig. 6a increases with an increases in the time after the charging process, finally reaching the maximum constant value of *ca.* 3500 Ωcm^2. The time required to reach the maximum constant value, *tm*, becomes longer with the increase in the charging-current value. This indicates that the dopant diffusion into the $(CH)_x$ film occurs until it reaches a dopant-concentration equivalent to the 6% doping level, whose state is established after the *tm* value, and also that the lower charging-current value produces the more uniform doping state. The behavior of the *Voc* value

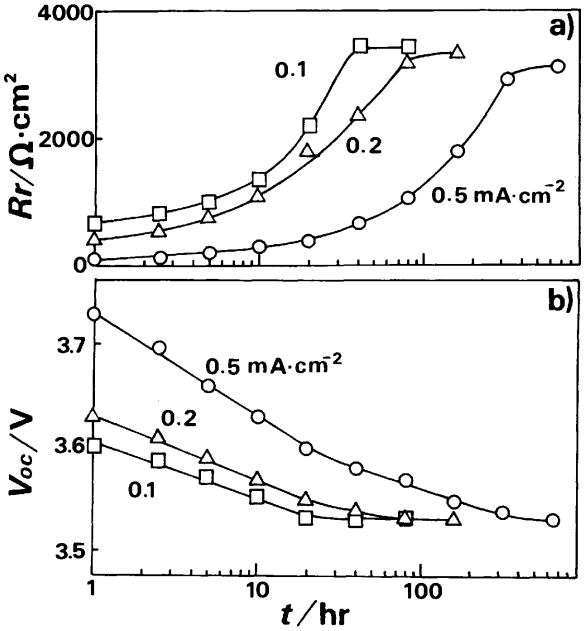

Fig. 6. Time dependence of resistive component, *Rr*, and open-circuit voltage, *Voc*, for self-discharge of Li-$(CH)_x$ after consecutive-charged at various current densities up to the 6.0% ClO_4^- doping level.

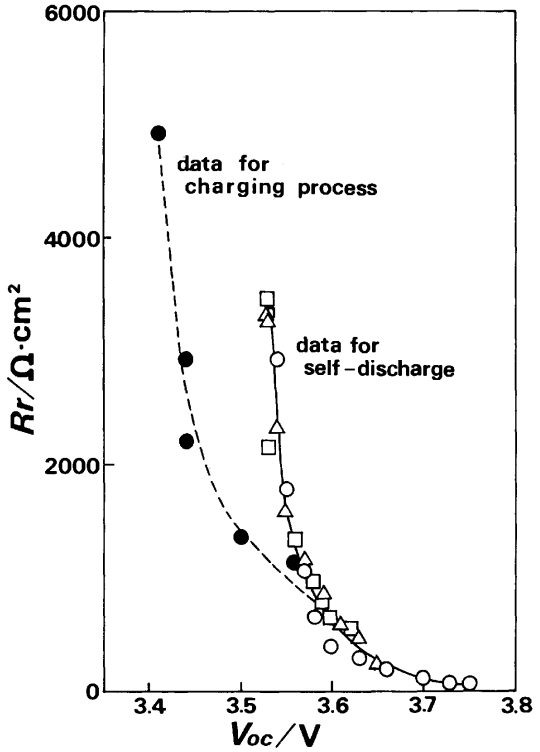

Fig. 7. Relation between resistive component, *Rr*, and open-circuit voltage, *Voc*, for self-discharge after consecutive-charged up to the 6.0% ClO_4^- doping level (*cf.*, Fig. 6), and for step-by-step-charging process (*cf.*, Fig. 2).
○: 6.0% doped at 0.5 mA cm^{-2}, △: 0.2 mA cm^{-2}, □: 0.1 mA cm^{-2}, ●: 0.9—6.0% stepwise-doped at 0.5 mA cm^{-2}.

shown in Fig. 6b displays almost the same trend as that of the *Rr* value in Fig. 6a; that is, the *Voc* value gradually decreases with the passage of time, finally reaching the almost constant value of 3.53 V. The higher charging current makes the *tm'* (the time required to reach a constant *Voc*) longer at the same 6% doping level. The time, *tm*, in the *Rr-t* relation corresponds nearly to the time, *tm'*, in the *Voc-t* relation. The *Voc* value is entirely almost determined by the dopant concentration at the $(CH)_x$ surface[1,2], thus, it may be concluded from the dependence of *tm* or *tm'* on the charging current that the higher charging current produces the higher dopant-concentration gradient for the depth profile, and, furthermore, that the doping states in the $(CH)_x$ film can be evaluated sensitively from the *Rr*-value behavior.

Since the correlation between *Rr* and *Voc* can be presumed from the data in Fig. 6, the relation between *Rr* and *Voc* obtained by the time dependence of *Rr* and *Voc* after charging up to the 6% doping is obtained as shown in Fig. 7. In Fig. 7, there are two kinds of data for the self-discharge process after consecutive charging up to the 6% ClO_4^- doping level, calculated from the data in Fig. 6, and for the step-by-step-charging process from the 0.9 to the 6% doping level, calculated from the data in Fig. 2. For the self-discharge process, there clearly appears a correlation between *Rr* and *Voc*, regardless of the charging current. The *Voc* for the self-discharge process becomes close to the equivalent value of *ca.* 3.5 V for the 6% doping level regardless of the charging current. The *Voc* value higher than 3.5 V clearly means that the doped-ion-concentration gradient occurs at the surface. For the step-by-step charging, the same *Rr* value as that for the self-discharge process correlates with the lower *Voc* value, and the final *Voc* value at the 6% doping level shows the equivalent value of *ca.* 3.5 V, so that the slow step-by-step charging is suitable for uniform doping with no occurrence of the higher dopant-concentration gradient producing the self-discharge. Finally, the *Rr* value after the charging process not only reflects closely the doping states of the $(CH)_x$ film, but can also be used to investigate the self-discharge conditions of the Li-$(CH)_x$ battery.

Conclusion

Charge-discharge and self-discharge characteristics of the ClO_4^- anion-doped lithium-polyacetylene battery were studied by means of the FFT impedance measurement. The impedance-frequency dispersion for charging and self-discharging of the battery was basically interpreted by the Randles-type equivalent circuit. The conditions of the charged battery and the self-discharge were strongly correlated to the resistive component, *Rr*, in the equivalent circuit. The discharging process was observed to behave differently from the charging process. In conclusion, the nonequivalent states of the doped-ion-concentration gradient of the polyacetylene film were readily checked by the *Rr* component, and the large self-discharge

phenomenon was produced by the nonequivalent states of the doped ions.

The authors would like to thank Mr. Yoshimitsu Sawada, Showa Denko Co., Ltd., for providing the polyacetylene samples and for his valuable discussion.

The Excited-state Absorption and Phosphorescence of Rhodium(III) Compounds at Room Temperature

Takeshi OHNO* and Shunji KATO
Chemistry Department, College of General Education, Osaka University, Toyonaka, Osaka 560
(Received March 21, 1984)

The excited states of rhodium(III) compounds including $[Rh(4,7\text{-diphenyl-}1,10\text{-phenanthroline})_3]^{3+}$ ($[Rh(dp\text{-}phen)_3]^{3+}$), $[Rh(1,10\text{-phenanthroline})_3]^{3+}$ ($[Rh(phen)_3]^{3+}$), $[RhCl_2(dp\text{-}phen)_2]^+$, and $[RhCl_2(phen)_2]^+$, have been investigated by means of emission spectroscopy and laser photolysis spectroscopy. The transient species with the lifetime of 0.055—72 μs are identified as the triplet (π-π^*) excited state of the ligand for $[Rh(dp\text{-}phen)_3]^{3+}$ and $[Rh(phen)_3]^{3+}$ and as the triplet ligand-field excited states for $[RhCl_2(dp\text{-}phen)_2]^+$ and $[RhCl_2(phen)_2]^+$. The molar absorption coefficients of the excited states are 9600 $M^{-1}cm^{-1}$ at 550 nm for $[Rh(dp\text{-}phen)_3]^{3+}$, 2750 $M^{-1}cm^{-1}$ at 560 nm for $[RhCl_2(dp\text{-}phen)_2]^+$, 2300 $M^{-1}cm^{-1}$ at 510 nm for $[Rh(phen)_3]^{3+}$, and 1600 $M^{-1}cm^{-1}$ at 550 nm for $[RhCl_2(phen)_2]^+$. The lifetime of the ligand-field excited state of $[RhCl_2(phen)_2]^+$ (700 ns in acetonitrile) decreases to 55 ns in water.

It has been found that the phosphorescent states of metal complexes containing 2,2′-bipyridine* or 1,10-phenanthroline* as ligands have unusual long lifetimes enabling them to undergo bimolecular electron-transfer reactions. The luminescence or the excited-state absorption (ESA) has been utilized to investigate the photochemical reactions of ruthenium(II),[1] chromium(III),[2,3] and rhodium(III) compounds.[4-6] The lifetime and the quenching reaction of the excited state can be derived from the luminescence measurement. Meanwhile, the formation of the excited state can be determined from the measurement of ESA using the molar-absorption coefficient. Provided that the molar-absorption coefficient of the reaction product is also available, one can estimate the efficiency of the product formation in the quenching of the excited state. However, only a few studies of the elementary reactions of excited-metal complexes have been done, since the molar-absorption coefficients of metal complexes are unknown except for the phosphorescent states of $[Ru(bpy)_3]^{2+}$,[7] $[Cr(bpy)_3]^{3+}$,[3] and $[Cr(4,7\text{-diphenyl-}1,10\text{-phenanthroline}^*)_3]^{3+}$.[3] As for rhodium(III), ESA are known only for $[RhBr_2(bpy)_2]^+$[8] and $[RhCl(NH_3)_5]^{2+}$.[9] We will report here the ESA of four rhodium(III) compounds, ···$[Rh(dp\text{-}phen)_3]^{3+}$, $[RhCl_2(dp\text{-}phen)_2]^+$, $[Rh(phen)_3]^{3+}$, and $[RhCl_2(phen)_2]^+$, which are known to be photoactive.[4,5,10] The molar-absorption coefficients of ESA are also determined for the dp-phen complexes which can be efficiently excited by the second harmonics of a ruby laser (347 nm). The phosphorescences of the rhodium(III) compounds at room temperature are also described for purposes of comparison. The solvent dependence of the lifetimes of the ligand-field excited states at room temperature is discussed in connection with the photo-substitution reaction.

Experimental

Apparatus. An NEC SLG-2018 Q-switched ruby laser capable of providing up to 0.17 J per flash at 347 nm was used. The details of the laser apparatus and the monitoring device have been described elsewhere.[3,11] Transient changes in the absorption and decay of luminescence were fed into a Iwatsu 8123 Storagescope, followed by computer analysis using a NEC PC8001 MKII microcomputer. A Hitachi 323 Spectrophotometer and a Hitachi MPF-2A Spectrofluorophotometer were used for the measurements of the absorption and the luminescence spectra, respectively.

Materials. $[Rh(phen)_3]Cl_3\cdot 3H_2O$ was prepared by the method of Harris and McKenzie.[12] $[RhCl_2(phen)_2]Cl\cdot 3H_2O$ was prepared by a catalytic method in the literature,[13] which was applied to the preparation of $[Rh(dp\text{-}phen)_3](ClO_4)_3\cdot 4H_2O$ and $[RhCl_2(dp\text{-}phen)_2]Cl\cdot 3H_2O$. The crude sample were purified by recrystallization; $[Rh(phen)_3]Cl_3\cdot 3H_2O$ and $[RhCl_2(phen)_2]Cl\cdot 3H_2O$ from the aqueous solution, $[Rh(dp\text{-}phen)_3](ClO_4)_3\cdot 4H_2O$ from the ethanol solution (Found; C, 58.79; H, 3.45; N, 5.72. Calcd for $C_{72}H_{56}N_6Cl_3O_{16}Rh$: C, 58.81; H, 3.84; N, 5.72%), and $[RhCl_2(dp\text{-}phen)_2]Cl\cdot 3H_2O$ from the acetonitrile solution (Found: C, 61.40; H, 4.06; N, 5.98. Calcd for $C_{48}H_{38}N_4Cl_3O_3$: C,62.12; H, 4.13; N, 6.04%). Free ligands of dp-phen and phen of analytical grade were used without further purification. Acetonitrile (AN), methanol, and ethanol of G. R. grade were used as supplied by Wako Pure Chemical Co. Water was purified by passing it through a Millipore deionizer and filter. The test solution were deaerated by purging for 15—20 min with nitrogen.

Measurements. All the measurements were done at 13±2 °C, unless otherwise noted. The molar absorption coefficients of the excited states were obtained on the assumption that all the molecules in the 10—40 μM (1 M=1 mol dm^{-3}) of $[Rh(dp\text{-}phen)_3]^{3+}$ or $[RhCl_2(dp\text{-}phen)_2]^+$ were excited to the phosphorescent state by one shot of the laser. The complete excitation of the compounds to the phosphorescent state was ascertained by a constant production of the transient absorption, accompanied by an attenuation of the laser intensity.

The decay of ESA was monitored at 500 nm for $[Rh(phen)_3]^{3+}$ and at 560 nm for $[RhCl_2(phen)_2]^+$, $[Rh(dp\text{-}phen)_3]^{3+}$, and $[RhCl_2(dp\text{-}phen)_2]^+$. The decay of the phosphorescence was monitored using an interference filter with the maximum transparency at 510 nm for $[Rh(dp\text{-}phen)_3]^{3+}$, at 597 nm for $[Rh(phen)_3]^{3+}$, or at 669 nm for $[RhCl_2(dp\text{-}phen)_2]^+$ and $[RhCl_2(phen)_2]^+$.

Results

$[Rh(dp\text{-}phen)_3]^{3+}$. The title compound exhibited

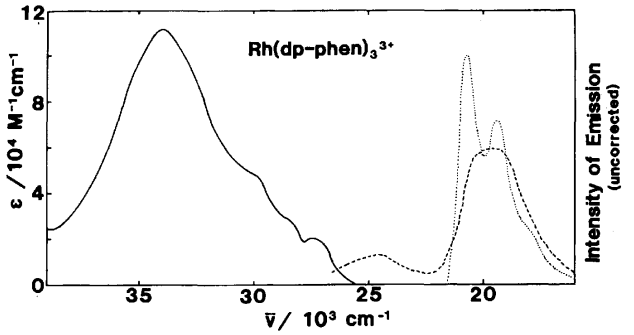

Fig. 1. Absorption and emission spectra of [Rh(dp-phen)$_3$]$^{3+}$.
The full line; the absorption of the 50% AN aqueous solution, the broken line; the emission of the 50% AN aqueous solution (11.4 μM), and the dotted line; the emission of the ethanol-methanol (4:1 by volume) solution (40 μM) at 77 K.

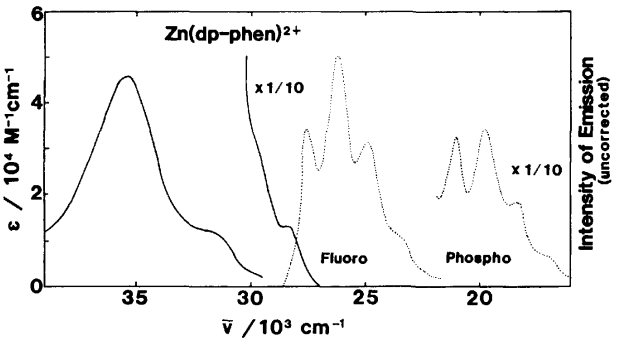

Fig. 2. Absorption and emission spectra of [Zn(dp-phen)]$^{2+}$.
The full line; the absorption of sample containing $Zn(NO_3)_2$ of $(1—5)\times10^{-4}$ M and dp-phen of $(0.2—2)\times10^{-4}$ M in AN-water (1:1) and the dotted line; the emission of the sample containing $Zn(NO_3)_2$ of 2×10^{-4} M and dp-phen of 10^{-4} M in methanol-water (4:1) at 77 K.

almost the same absorption spectrum as the dp-phen coordinated to the zinc(II) ion**, as is shown in Figs. 1 and 2, which is essentially ascribed to the π-π^* transitions of the ligand. The weak band of the free dp-phen at 28800 cm^{-1} (ε=440 M^{-1}cm^{-1}) is strengthened in Zn(dp-phen)$^{2+}$ and [Rh(dp-phen)$_3$]$^{3+}$ by three to thirteen times. As the luminescence spectra in Figs. 1 and 2 show, the coordination of dp-phen to the rhodium(III) ion enormously strengthens the π-π^* phosphorescence, which is shifted to a lower energy with the same fine structure as the phosphorescence of [Zn(dp-phen)]$^{2+}$. While a rise in the temperature weakens the phosphorescence of [Rh(dp-phen)$_3$]$^{3+}$, a phosphorescence with a lifetime of 72 μs and a quantum yield of -10^{-4} is still observed at room temperature. The phosphorescent state of $^3(\pi$-$\pi^*)$ was observed as an absorption by means of laser-photolysis spectroscopy at room temperature. The laser excitation of [Rh(dp-phen)$_3$]$^{3+}$ of 11 μM gives rise to an transient absorption, as is shown in Fig. 3. This transient absorption has the same lifetime (63 μs) as the phosphorescence, so it may be concluded that it is due to the triplet π-π^* state ($^3(\pi$-$\pi^*)$). The molar-absorption coefficient of the $^3(\pi$-$\pi^*)$ is obtained as 9600 M^{-1}cm^{-1} at 550 nm on the condition that the [Rh(dp-phen)$_3$]$^{3+}$ of 11 μM are completely excited to $^3(\pi$-$\pi^*)$ by one shot of the laser, as Fig. 4 shows. The wide ESA of $^3(\pi$-$\pi^*)$ compared to that of the excited free dp-phen indicates the appearance of a new transition. The lifetime of $^3(\pi$-$\pi^*)$ increased by 25% with the increase in the water content in the solvent.

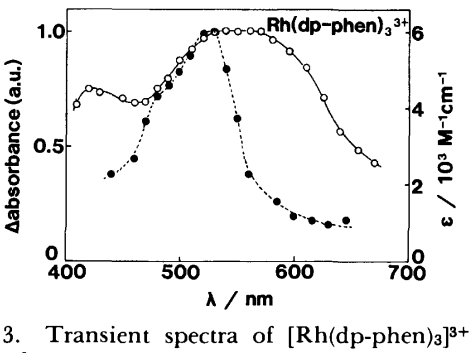

Fig. 3. Transient spectra of [Rh(dp-phen)$_3$]$^{3+}$ and dp-phen.
The full line; [Rh(dp-phen)$_3$]$^{3+}$ of 11.4 μM in AN-water (1:1) and the broken line; dp-phen of 1.21 mM in AN.

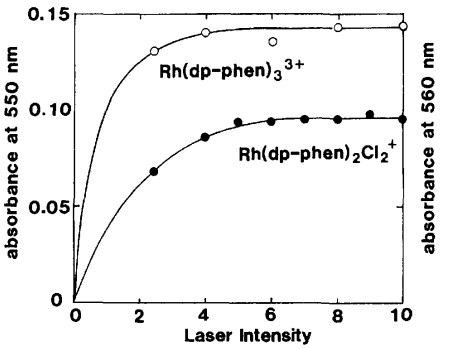

Fig. 4. Dependence of the transient absorbance on the laser intensity.
The open circle; [Rh(dp-phen)$_3$]$^{3+}$ of 11.4 μM in AN-water (1:1) (the left ordinate) and the closed circle; [RhCl$_2$(dp-phen)$_2$]$^+$ of 40 μM in AN (the right ordinate).

[RhCl$_2$(dp-phen)$_2$]$^+$. The pale yellow AN solution of [RhCl$_2$(dp-phen)$_2$]$^+$ emits a weak and broad phosphorescense with a maximum at 690 nm at room temperature (Fig. 5); this can presumably be assigned to the ligand-field phosphorescence ($^3T_1\rightarrow{}^1A_1$)***. It resembles the low-temperature emission of [RhCl$_2$(phen)$_2$]$^+$, with a maximum at 704 nm.[14,15] The lifetime of [RhCl$_2$(dp-phen)$_2$]$^+$ is 1.1 μs at room temperature in AN several hundred times as long as those of [RhX$_2$(NH$_3$)$_4$]$^+$ (X=Cl$^-$ and Br$^-$) in water.[5]

The excited state of $^3T_1$ was also detected by means of laser-photolysis spectroscopy. The transient absorption of the AN solution (Fig. 6) is identified as $^3T_1$ because its lifetime (1.0 μs) is close to that of the phosphorescence. The molar absorption coefficient was obtained as 2750 M^{-1}cm^{-1} at 560 nm from the complete conversion to $^3T_1$, which is ascertained by

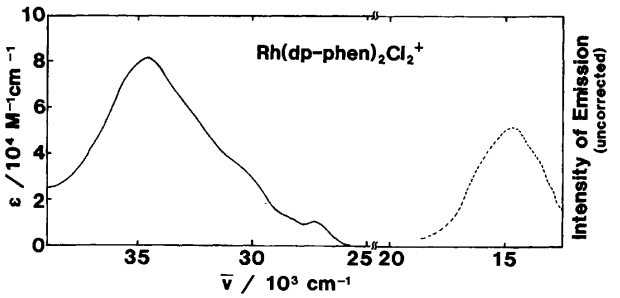

Fig. 5. Absorption spectrum (solid line) and emission spectrum (broken line) of $[RhCl_2(dp\text{-}phen)_2]^+$ in AN.

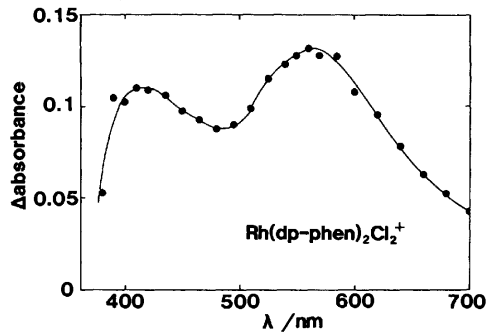

Fig. 6. Transient absorption spectra of $[RhCl_2(dp\text{-}phen)_2]^+$ (50 μM) in AN.

the saturation of the transient absorbance with an attenuation of the laser intensity, as is shown in Fig. 4. The lifetime of $^3T_1$ becomes shorter with the water content in the solvent; the lifetime of 1.02 μs in the AN solution decreases to 340 ns in the 50% AN aqueous solution and to 127 ns in the 20% AN aqueous solution.

$[Rh(phen)_3]^{3+}$. The coordination of phen to the rhodium(III) ion strengthens the lowest transition of free phen by thirteen times, which is symmetry forbidden.[16] On excitation with the second harmonics of the ruby laser, a transient species with an absorption maximum at 510 nm was observed in an alcoholic solvent at room temperature, as well as they at 77 K, as is shown in Fig. 7. Since the transient absorption has as long a lifetime as the phosphorescence (48 ms) from $^3(\pi\text{-}\pi^*)$ at 480 nm,[15] the transient absorption is ascribed to $^3(\pi\text{-}\pi^*)$. The molar-absorption coefficient of the ESA in water was obtained as 2300 $M^{-1}cm^{-1}$ from the complete conversion to the excited state. The lifetime of the $^3(\pi\text{-}\pi^*)$, as monitored by the ESA, decreased at room temperature to 60 ns in methanol, 85 ns in AN–water (4:1), and 440 ns in water. Correspondingly, the $\pi\text{-}\pi^*$ phosphorescence was replaced by a broad emission with the maximum at 580 nm, which has been assigned by Bolleta[17] to the phosphorescence from $^3T_1$. The same lifetime of the phosphorescence from $^3T_1$ as the ESA of $^3(\pi\text{-}\pi^*)$ supports the idea that the thermal activation from $^3(\pi\text{-}\pi^*)$ to $^3T_1$ is responsible for the broad phosphorescence at room temperature.[17] The $^3(\pi\text{-}\pi^*)$ in water has the longest lifetime, in contrast to the triplet ligand-field excited states of $[RhCl_2(dp\text{-}phen)_2]^+$ and $[RhCl_2(phen)_2]^+$, which have the shortest

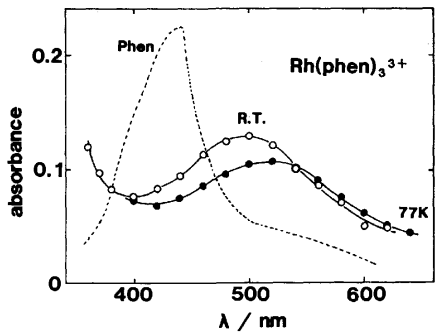

Fig. 7. Transient absorption spectra of $[Rh(dp\text{-}phen)_3]^{3+}$ and free phen.
The open circle; $[Rh(dp\text{-}phen)_3]^{3+}$ of 100 μM in water, the closed circle; $[Rh(dp\text{-}phen)_3]^{3+}$ of 100 μM in ethanol-methanol (4:1) at 77 K, the solid line; phen of 0.04 M in AN.

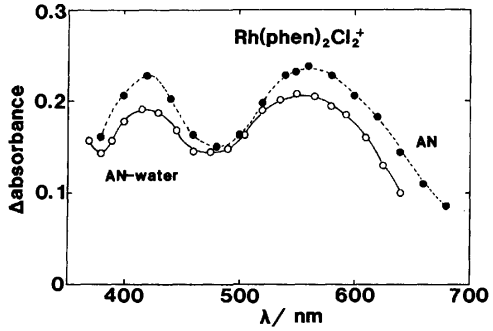

Fig. 8. Transient absorption spectra of $[RhCl_2(phen)_2]^+$ (200 μM) in AN–water (1:1) (open circle) and AN (closed circle).

lifetime in water (*vide infra*). It should be noted that the ESA of $[Rh(phen)_3]^{3+}$ disagrees with that of free phen, with the maximum at 440 nm.

$[RhCl_2(phen)_2]^+$. The lowest excited state of $[RhCl_2(phen)_2]^+$ is $^3T_1$ of the ligand-field excitation, which emits a broad phosphorescence at 77 K.[14,15] The weak phosphorescnce with the lifetime of 680 ns in the AN solution was observed at room temperature, too. The ESA of $^3T_1$ with the molar absorption coefficient of 1600 $M^{-1}cm^{-1}$ at 550 nm is also observed by means of laser photolysis spectroscopy as Fig. 8 shows; it is independent of the solvent. The lifetime of the ESA in the AN solution (700 ns) agrees with that of the ligand field phosphorescence and becomes as short as to 200 ns in the 50% AN aqueous solution and 55 ns in the aqueous solution.

Discussion

The $^3(\pi\text{-}\pi^*)$ of $[Rh(dp\text{-}phen)_3]^{3+}$ and $[Rh(phen)_3]^{3+}$ have some different characters from those of the ligand-field excited states of $[RhCl_2(dp\text{-}phen)_2]^+$ and $[RhCl_2(phen)_2]^+$. The $^3(\pi\text{-}\pi^*)$ of $[Rh(dp\text{-}phen)_3]^{3+}$ has a longer lifetime and a larger molar absorption than the $^3T_1$ of the $[RhCl_2(dp\text{-}phen)_2]^+$. The longest phosphorescent lifetime of $[Rh(dp\text{-}phen)_3]^{3+}$ can be explained as follows. The $^3(\pi\text{-}\pi^*)$ of $[Rh(dp\text{-}phen)_3]^{3+}$

is localized in the large ligand of dp-phen so that the spin-orbit interaction due to the rhodium(III) ion is not effective on the internal conversion ($^3(\pi\text{-}\pi^*) \rightarrow {}^1A_1$). The much shorter lifetimes of the ligand-field triplet-excited states in the aqueous solution may be closely related to the aquation reaction of $[RhCl_2(phen)_2]^+$.[5,18] It can be explained in terms of a competition between the phosphorescence and the aquation that $[RhCl_2(phen)_2]^+$, with less photoactivity (ϕ=0.01),[10] has a longer lifetime (55 ns) than that (1 ns)[5] of *cis*-$[RhBr_2(NH_3)_4]^+$ in the aqueous solution, which undergoes a photoaquation reaction with the quantum yield of 0.3.

The $^3T_1$ of $[RhCl_2(dp\text{-}phen)_2]^+$ and $[RhCl_2(phen)_2]^+$ have large molar-absorption coefficients (2750 $M^{-1}cm^{-1}$ and 1600 $M^{-1}cm^{-1}$, respectively), which can be explained not by the parity-forbidden ligand-field transition, but by a charge-transfer transition ($\pi \rightarrow d_\pi$). As for $[Rh(dp\text{-}phen)_3]^{3+}$, the wide absorption of $^3(\pi\text{-}\pi^*)$ with the absorption coefficient of 9600 $M^{-1}cm^{-1}$ indicates the appearance of a charge-transfer transition ($d_\pi \rightarrow \pi^*$) in addition to the ($\pi\text{-}\pi^*$) transition of the excited free ligand. Such an appearance of the charge-transfer transition ($\pi \rightarrow d_\pi$) in the ESA also has been proposed in the cases of excited doublet states of chromium(III) compounds.[3] By using these large molar-absorption coefficients, one can estimate the formation of the excited state on photoexcitation. The formation of the excited state is indispensable to an estimation of the efficiency of product formation in the quenching process of the excited rhodium(III) compound, which has been qualitatively studied by several workers.[4,19] Both $^3(\pi\text{-}\pi^*)$ and $^3T_1$ of the rhodium(III) compounds studied are subjected to electron-transfer quenching by some aromatic amines. The efficiencies of product formation in the quenching are calculated to be more than 0.1 by using these absorption coefficients. The details of the electron transfer quenching will be reported elsewhere.

(Received March 28, 1984)

An improved method for the determination of the orientation distribution function of a powder consisting of preferentially oriented plate-like and needle-like particles was reported. Using this method, the coarse and fine powders of benzamide and α-2-pyrazinecarboxamide were investigated. It was found that the domains (a domain is defined as a collection of particles having the same preferred orientation plane or axis) of preferentially oriented particles exhibit two distinct changes when undergoing grinding of the powder. One change involves a decrease and the other an increase in volume, indicating that the particles in the domain showing the former change transform into those in the domain showing the latter change following grinding. The increase in volume of the domain can be well explained in relation to the existence of molecular layers connected to each other by weak van der Waals force in the crystal.

Takaki and Yamaguchi[1] reported a process for the determination of an orientation distribution function for preferentially oriented plate-like particles by the usual reflection-type powder diffractometry. The orientation distribution function, $N(\alpha)$, is defined in such a way that the fractional number of plate-like particles whose normals are contained in a solid angle $d\Omega$ at an angle α to the direction normal to the sample-holder is given by $N(\alpha)d\Omega$. They showed that $N(\alpha)$ can be obtained from the distribution function $\rho(\alpha)$

$$\rho(\alpha) = K \cdot N(\alpha) = I_{pre}(\alpha)/I_{ran}(\alpha), \quad (1)$$

where K is a constant, $I_{pre}(\alpha)$ is the intensity for an hkl reflection from preferentially oriented particles, $I_{ran}(\alpha)$ is that from randomly oriented particles and α is an angle between an hkl plane and the plane of preferred orientation.

As for the analytical approximation to the mean distribution function $N(\alpha)$, Uda and Sasa[2-5] and Toraya and Marumo[6] have shown in their studies on preferred orientation in inorganic powder samples that a Gaussian-type function

$$N(\alpha) = C_0 + C_1 \exp(-P\alpha^2) \text{ and } C_0 + C_1 = 1 \quad (2)$$

gives an excellent approximation to the distribution of oriented plate-like particles. The first term is a constant which is responsible for the random orientation of particles in a powder, the second term is a mean distribution function for preferentially oriented particles and P represents the degree of preferred orientation. On the other hand, Yamaguchi *et al.*[7] have shown that a Cauchy-type function

$$N(\alpha) = C_0 + C_1\{1/[1+P\alpha^2] + 1/[1+P(\pi-\alpha)^2]\} \quad (3)$$

gives a good approximation to the distribution function in γ_{II}-Li_2ZnSiO_4 and *p*-iodobenzamide powder samples.

We have found that the above function is unsuitable to express the distribution for very poorly oriented plate-like particles since, for a very small value of P, the value of $N(\alpha)$ at $\alpha=0$ is smaller than that at $\alpha=\pi/2$. Therefore, we will use the following revised distribution function

$$N(\alpha) = C_0 + C_1/[1+P\alpha^2], \quad (4)$$

where the first and the second terms express contributions from randomly oriented and preferentially oriented particles, respectively.

Then, using distribution functions of the above Gaussian (2) and Cauchy (4) types, we reexamined the preferred orientations in several inorganic and organic substances of which X-ray powder-diffraction data or observed orientation-distribution curves have been given.[3-12] The results indicate that, as has already been reported,[6] the Gaussian-type function is superior to the Cauchy-type function in representing the distribution of plate-like particles for exceedingly oriented powders,[3,4,6] while the Cauchy-type function gives a good approximation for all the other poorly oriented powder samples.

Similar to the case of plate-like particles, the distribution of preferentially oriented needle-like particles may be obtained from the distribution function

$$\rho(\beta) = K \cdot N(\beta) = I_{pre}(\beta)/I_{ran}(\beta), \quad (5)$$

where β is the acute angle between the axis normal to an hkl plane and that of preferred orientation. Function $N(\beta)$ can then be obtained[6] in the form

$$N(\beta) = C_0 + C_1'/[1+P'(\pi/2-\beta)^2]. \quad (6)$$

The preferred orientation of needle-like particles in an *m*-iodobenzoic acid powder sample has been well explained using expression (6).

Recently, Yamaguchi *et al.*[8] and Kurisu *et al.*[9] have

extended the above treatment to include domains with different preferred orientations, where a domain is defined as a collection of particles having the same preferred orientation plane or axis. The orientation distribution functions given by them are:

$$N(\alpha) = C_0 + \sum C_n/[1+P_n\alpha_n^2], \quad (7a)$$

for plate-like particles and

$$N(\beta) = C_0 + \sum C_n'/[1+P_n'(\pi/2-\beta_n)^2], \quad (7b)$$

for needle-like particles. Here $N(\alpha)\equiv N(\alpha_1, \alpha_2, \cdots, \alpha_n, \cdots, \alpha_m)$ and $N(\beta)\equiv N(\beta_1, \beta_2, \cdots, \beta_n, \cdots, \beta_m)$, where m is the number of preferred orientation planes (or axes), α_n is the acute angle between an hkl reflection plane and the nth plane of preferred orientation and β_n is the acute angle between the axis normal to an hkl reflection plane and the nth axis of preferred orientation.

Here, we have extended the above treatment to include the case where domains with plate-like and needle-like particles coexist in a powder. The distribution function is then given by

$$N(\alpha, \beta) = C_0 + \sum C_n/[1+P_n\alpha_n^2] + \sum C_m'/[1+P_m'(\pi/2-\beta_m)^2], \quad (8)$$

where the second and the third terms give contributions from plate-like and needle-like particles, respectively.

The relative volumes of domains in a powder sample are obtained from the following expressions:[9]

$$V_0 = 4\pi C_0 \int_0^{\pi/2} \sin\alpha d\alpha = 4\pi C_0, \quad (9)$$

$$V_n = 4\pi C_n \int_0^{\pi/2} \{1/[1+P_n\alpha_n^2]\} \sin\alpha d\alpha, \quad (10a)$$

for plate-like particles and

$$V_m = 4\pi C_m' \int_0^{\pi/2} \{1/[1+P_m'(\pi/2-\beta_m)^2]\} \sin\beta d\beta, \quad (10b)$$

for needle-like particles, where V_0, V_n, and V_m are normalized in such a way that

$$V_0 + \sum V_n + \sum V_m = 1.$$

In this paper we apply the above treatment to coarse and fine powders of benzamide[13] and α-2-pyrazinecarboxamide[14] and examine the change in the preferred orientation of particles following a grinding of the powder.

Experimental

Powder samples were prepared by grinding an aggregate of each crystal in an agate mortar. X-Ray powder diffraction patterns were taken with an X-ray powder diffractometer (Rigaku-Denki, D-2F) with Cu$K\alpha$ radiation using a divergence slit of 1° and a scanning speed of 1° (2θ/min). Each powder sample was packed in a standard specimen holder without any special treatment and was pressed gently to make a flat surface at constant pressure. Diffraction-intensity measurements were made by cutting out the background-subtracted peak areas from each trace and weighing.

Intensities, I_{ran}, were calculated from the following expression:

$$I_{ran} = m \cdot Lp \cdot F_o^2, \quad (11)$$

where F_o's are observed or calculated structure factors, m is multiplicity and Lp is Lorentz-polarization factor. Low-angle reflections (2θ<13°) were not used for least-squares calculations since the intensities of these reflections were

TABLE 1. PREFERRED ORIENTATION PARAMETERS FOR BENZAMIDE POWDER SAMPLES. E.S.D.'S ARE GIVEN IN PARENTHESES.

	C_0[a]	C_1[a]	P_1	C_2[a]	P_2	V_0[b]	V_1[b]	V_2[b]	R[c]	R_0[d]
Orientation plane		(001)		($\bar{1}$04)						
Coarse powder	0.00(1)	0.92(3)	18(1)	0.08(1)	12(5)	0.02	0.88	0.10	0.06	0.60
Fine powder	0.02(1)	0.70(5)	6.4(5)	0.28(2)	4.7(4)	0.09	0.61	0.30	0.05	0.44

a) Parameters C_j's are so normalized that $C_0+C_1+C_2=1$. b) V_0, V_1, and V_2 are relative volumes of domains. c) $R=\sum|I_{pre}-I_{ran}\cdot N(\alpha)|/\sum I_{pre}$. d) R_0 is the initial value of R.

seriously affected by the size of the divergence-slit.

Powder-intensity profiles were calculated from the following expression:

$$y_i = \sum\left[\frac{2}{3}I_nL(2\theta_i, 2\theta_{n1}) + \frac{1}{3}I_nL(2\theta_i, 2\theta_{n2})\right] \quad (12)$$

where y_i is the intensity at a given point $2\theta_i$ in a profile.

The summation is taken over all possible contributing reflections at $2\theta=2\theta_i$; I_n is the intensity for the nth reflection from preferentially oriented particles; $L(2\theta_i, 2\theta_{n1})$ and $L(2\theta_i, 2\theta_{n2})$ are line shape functions for Cu $K\alpha_1$ and Cu $K\alpha_2$, respectively, and are represented by a Cauchy function with the half width of the diffraction peak, H_n. The angular dependence of H_n is represented by

$$H_n^2 = U\cdot\tan^2\theta_n + V\cdot\tan\theta_n + W \quad (13)$$

where U, V, W are constants.

Results and Discussion

Benzamide. Figure 1 shows the intensity pattern for randomly oriented particles calculated from observed F_o's for 42 reflections.[13] X-Ray intensity patterns taken at two different stages of grinding are shown in Fig. 2. Comparing Figs. 1 with 2(a), one can see that the intensities of both the 004 and 008 reflections are prominently enhanced in Fig. 2(a), indicating that the 001 plane is a plane of preferred orientation.

To obtain the distribution function $\rho(\alpha)$, we selected 23 reflections from diffraction peaks in each of the two powder patterns; seven reflections, 012, 013, $\bar{1}$04, 110, 200, 008, 017, with single peaks, five pairs of reflections (100, 004), (102, 011), ($\bar{1}$11, 111), ($\bar{1}$13, 113), ($\bar{1}$08, 108), and two triad reflections ($\bar{1}$14, $\bar{1}$06, 106), (204, 020, 021) with overlapped peaks.

Preferred orientation parameters of $N(\alpha)$ for the 001 preferred orientation plane for the two powder samples were determined by a least-squares technique using a modified program based on one written by Kurisu *et al.*[9] At this stage, we calculated the intensity pattern using the above preferred-orientation parameters and found that the observed intensity for the $\bar{1}$04 reflection was still remarkably strong (especially in the fine powder) as compared with the corresponding intensity in Fig. 1, suggesting that the $\bar{1}$04 plane is another plane of preferred orientation. The final preferred orientation parameters obtained from the above two preferred orientation planes are listed in Table 1. Calculated intensity patterns are shown in Fig. 2.

In Fig. 2, one finds that the calculated intensity patterns are in good agreement with the observed patterns for both the coarse and fine powders. As seen in Table 1, the value of P_1 for the 001 preferred orientation plane decreases from 18 (coarse powder) to 6.4 (fine powder). Similarly, the value of P_2 for the $\bar{1}$04 plane decreases from 12 to 4.7.

The relative volume of V_1 decreases from 0.88 to 0.61, while that of V_2 increases significantly from 0.10 to 0.30. This suggests that a considerable part of the particles in the domain of V_1 change with grinding into those having the $\bar{1}$04 preferred-orientation plane. The existence of this preferred-orientation plane can well be explained from the fact that molecular layers parallel to ($\bar{1}$04) in the crystal are connected with each other by weak van der Waals force.[13]

A microscopic examination revealed that the majority of particles in the coarse powder were thin plates. Comparing the above result, one may say that these plates would probably be those with (001) well developed.

α-2-Pyrazinecarboxamide. Takaki *et al.*[14] have reported that crystals obtained from crystal growth are colorless needles elongated along the c axis and sometimes laths with (010) well developed. A microscopic observation of a coarse powder showed many typical needles. Therefore, it is very interesting to examine the change in the preferred-orientation parameters for needle-like particles following the grinding of the powder.

A total of 16 reflections were used for obtaining preferred-orientation parameters. There included four reflections, 310, 410, $\bar{4}$01, 320, with single peaks, three pairs of reflections, (210, 400), (600, 510), ($\bar{2}$10, 001), and a hexad of reflections (201, 610, $\bar{1}$11, $\bar{2}$11, 220, 011) with overlapped peaks.

Preferred-orientation parameters for coarse and fine powders were obtained by introducing two kinds of domains with preferentially oriented particles; one was the domain with the c preferred orientation axis and the other was that with the 100 preferred orientation plane. Final parameters are listed in Table 2. Figure 3(a) shows the intensity pattern for randomly oriented particles calculated from observed F_o's for 53 reflections.[14] The observed and calculated intensity patterns for the fine powder are shown in Fig. 3(b).

As seen in Table 2, all P values decreased upon grinding. The relative volume of the domain with the c preferred orientation axis decreased from 0.58 (coarse powder) to 0.42 (fine powder), indicating that many of

the needle-like particles obtained from crystal growth retained their shape unchanged, although they diminished in size upon grinding. On the other hand, the domain with the 100 preferred orientation plane increased noticeably in volume from 0.23 to 0.42. The above results may suggest that particles in domains V_0 and V_1 change into those having the 100 preferred orientation plane upon grinding. The existence of the 100 preferred orientation plane can be well explained in terms of the layer structure of the crystal.[14]

Concluding Remarks

In Table 3, we give preferred orientation parameters obtained by use of the Gaussian-type function for the above fine-powder samples. Comparing the parameters in Tables 1 and 2 with those in Table 3, one may find that the R values for both benzamide and α-2-pyrazinecarboxamide fine powders are smaller than the corresponding values in Table 3, showing that in this case also a Cauchy-type function gives a good approximation for representing distribution function of preferentially oriented particles. It is to be noted that significant discrepancies can be found in the values of C_0 for two types of distribution functions, owing to the characteristic features of the Cauchy and Gaussian functions.

Determination of the Vapor Pressures of Lithium Iodide and Potassium Chloride by Molecular Beam Surface Ionization

Hiroyuki KAWANO* and Tsutomu KENPŌ

Department of Chemistry, Faculty of Science, Ehime University, 2-5, Bunkyō-chō, Matsuyama 790

(Received March 30, 1984)

Combined techniques of molecular beam effusion from a Knudsen cell and of positive surface ionization on a heated polycrystalline rhenium filament were employed to determine the vapor pressures P (in atm) of LiI and KCl as a function of cell temperature T (in K), thereby yielding the equations:

$$\log_{10} P(\mathrm{LiI}) = (7.498 \pm 0.046) - (9254 \pm 30)/T \text{ for } 583—717 \text{ K},$$

$$\log_{10} P(\mathrm{KCl}) = (7.210 \pm 0.058) - (11135 \pm 45)/T \text{ for } 687—877 \text{ K}.$$

The present data on the pressure and on both entropy and enthalpy of sublimation are compared with others in literature.

In the research fields of thermochemistry and molecular beam chemistry, it is one of the important problems to know the accurate value of vapor pressure at a given temperature. From this point of view, we have been trying to determine the vapor pressures of alkali-metal halides after having developed a technique of molecular beam surface ionization, and we have already published some of the results thus obtained with CsF and CsCl[1] and with LiCl and NaBr.[2] In this paper we describe the experimental results obtained with LiI and KCl.

Experimental

In the same manner as in the previous works,[1,2] a molecular beam of an alkali-metal halide (MX) effusing from a Knudsen cell heated to a temperature (T) was directed onto a polycrystalline rhenium filament (F) kept at a high temperature (T_F) in the residual gas pressue of about 3×10^{-5} Pa. The total ion current ($I^+(M^+)$) of an alkali-metal ion (M^+) emitted from F was measured as a function of T or T_F. The samples of LiI and KCl used in this work were obtained from Aldrich Chem. Co., Inc. and Wako Pure Chem. Ind., Ltd., respectively.

Results and Discussion

In order to find a filament temperature suitable for producing M^+ from MX under study, $I^+(M^+)$ was measured as a function of T_F while the Knudsen cell was kept at a constant temperature such as T=766, 761, 686, or 627 K for LiI or as T=877, 874, or 763 K for KCl. Two examples of the results thus obtained are illustrated in Fig. 1. The reason why the two are quite different in emission pattern may be explained reasonably[3] by our previous theory[4] that the degrees of both dissociation of MX and ionization of M depend upon the effective work function for positive surface ionization. As may be seen in Fig. 1, $I^+(Li^+)$ and $I^+(K^+)$ are virtually constant at 3.10 ± 0.08 and 13.1 ± 0.4 nA in the ranges $T_F\simeq1280$—1390 and $\gtrsim1050$ K, respectively. These results indicate that the ionization efficiencies of LiI and KCl incident upon F are virtually unity in the respective ranges. Consequently, F was kept at a constant temperature in either of the above ranges, and $I^+(M^+)$ was measured as a function of T. The vapor pressure is given by[1]

$$P(\mathrm{MX}) = 0.0144\, S_C^{-1}[M(\mathrm{MX})\, T]^{1/2}\, I^+(\mathrm{M}^+), \quad (1)$$

where $P(\mathrm{MX})$ and $I^+(M^+)$ are expressed in atm and ampere, respectively, and $M(\mathrm{MX})$ is the molecular weight of MX. The values of the effusing slit area S_C were 1.13×10^{-2} and 1.46×10^{-2} cm^2 in the experiments with LiI and KCl, respectively.

The data on $P(\mathrm{MX})$ determined in this work are summarized in Table 1, and they are illustrated in Figs. 2 and 3, leading to a general expression:

$$\log_{10} P(\mathrm{MX}) = A - B/T. \quad (2)$$

*1 cal=4.184 J.

The values of A and B determined by the present and other workers are summarized in Table 2. The entropy and enthalpy changes due to sublimation at the mean temperature ($\bar{T}$) in the range (T_R) covered in each measurement and also those at 300 K were evaluated from Eqs. 3—6, respectively, in order to compare the latter with literature values at the same temperature (see Table 2).

$$\Delta S(\bar{T}) = 4.575\,A \text{ cal mol}^{-1}\text{ K}^{-1}, \quad (3)$$

$$\Delta H(\bar{T}) = 4.575\times10^{-3}\,B \text{ kcal mol}^{-1}, \quad (4)$$

$$\Delta S(300) = \Delta S(\bar{T}) + \int_{300}^{\bar{T}}\left[\frac{C_p(c)-C_p(g)}{T}\right]dT \simeq \Delta S(\bar{T}) + aR[\ln\bar{T}-\ln 300], \quad (5)$$

$$\Delta H(300) = \Delta H(\bar{T}) + \int_{300}^{\bar{T}}[C_p(c)-C_p(g)]dT \simeq \Delta H(\bar{T}) + aR[\bar{T}-300]. \quad (6)$$

Here, 1 cal is equal to 4.184 J, and $C_p(c)$ and $C_p(g)$ are the specific heats of MX at crystalline and gaseous states at 1 atm, respectively. On the basis of data on the heats,[5] the values of a in the ranges 300—650 and 300—850 K may be taken as 2.35 and 2.28 for LiI and KCl, respectively.

The values of T_F in the present works indicated as (a)—(e) in the last column in Table 2 were 1309, 1299, 2113, 1588, and 1193 K, respectively. The present works (A) and (B) indicate the mean values of those (a) and (b) and those (c)—(e), respectively.

To the best of our knowledge, it is from Refs. 5 and 6 alone that the data on P(LiI) below a melting point (719 K) are available today. As may be seen in Fig. 2 and Table 2, the data on P(LiI) do not agree well with each other among the three, suggesting the necessity of further measurements by many workers using various experimental methods. Both Fig. 3 and Table 2 show that the values of P(KCl) measured in this work are very close to those in Refs. 5, 6, and 13, and also suggest that the data in Refs. 7 and 10 are very poor in reliability probably because of systematic errors.

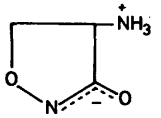
Pulse Radiolysis of Cycloserine in Aqueous Solutions. One-Electron Oxidation by OH Radicals

Masako TANAKA,* Hiroshi SAKUMA,† Osamu KOHANAWA,†† Seijun FUKAYA,††† and Meiseki KATAYAMA
Department of Atomic Science and Nuclear Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received May 23, 1984)

The reaction of (*R*)-4-amino-3-isoxazolidinone (cycloserine) with OH radicals was studied in aqueous solutions by optical pulse radiolysis at pHs 6.5—12. It was concluded, from a comparison of the transient spectra with those obtained in a reaction with N_3 radicals, that OH radicals attacked at the dissociated peptide group, $-N^-CO-$, and an oxidized radical, $-\dot{N}CO-$, was produced through one-electron oxidation. From a kinetic analysis, the reaction was considered to have proceeded by two steps: The first step was the formation of OH adducts, where the rate constant, k(OH+cycloserine), was 8×10^9 mol^{-1} dm^3 s^{-1} for the zwitterion form of cycloserine at pH 6.5 and 1.2×10^{10} mol^{-1} dm^3 s^{-1} for anion form at pHs 8—10. The second step was the formation of oxidized radicals at a rate of $3—4\times10^6$ s^{-1}. These radicals decayed with a second-order rate, suggesting a radical-radical recombination. D-Serine was detected as the major product.

The hydroxyl (OH) radical is one of the most reactive species generated in irradiated water. A number of investigations have been carried out on its reaction with peptides in aqueous solutions, and it has been established that the abstraction of hydrogen from the carbon adjacent to the peptiede nitrogen is the major reaction for linear peptides as well as cyclic dipeptides.[1-6] For the series of five-membered cyclic compounds containing one peptide linkage, such as pyrrolidinone derivatives, the reaction of OH radicals is known to be essentially the same as that on linear peptides.[7] Cycloserine, 4-amino-3-isoxazolidinone (I), which is one of the broad-spectrum antibiotics and is known as an effective inhibitor of transaminase enzyme systems, has a cyclic structure containing one peptide linkage. The sturcture of cycloserine in aqueous solution is a zwitterion as described in (I), the pK values of which are 4.4 and 7.4, respectively.[8] Therefore, it is



Cycloserine (I)

expected that this compound has a high reactivity toward OH radicals and that the OH radicals will attack the dissociated pepetide groups at around biological pHs. In this work we investigated the site of attack of OH radicals and the reaction mechanism of intermediates by studying the transient spectra and kinetics with pH dependence of them.

Experimental

The 45 MeV linac of Hokkaido University, producing 10 ns pulses of 45 MeV electrons, was used for the optical pulse radiolysis experiments. The dose per pulse was 80—100 Gy, which was measured by the KCNS method. The optical detection system was basically the same as that designed by Hunt and Thomas.[9] The light from a high-pressure mercury lamp (HB-50101, Ushio) was chopped by a rotating chopper at 25 Hz and focused at an irradiation cell of which the optical path length was 2 cm. The absorption signals, after passing through a monochromator, were detected by a photomultiplier (R928, Hamamatsu TV), then followed on a transient digitizer (DM901, Iwatsu) and recorded on an X-Y recorder. The range of wavelengths examined was 270 to 350 nm.

The (*R*)-cycloserine was supplied by Aldrich. NaN_3 and other reagents were supplied by Wako Junyaku. All reagents were used without further purification. Solutions were prepared by using triply distilled water the day before the experiment and kept in a refrigirator. The pH values of the solutions were adjusted by adding sodium hydroxide and were determined with a pH meter (pH501, Yokogawa). Solutions were saturated with N_2O gas (1 atm, (N_2O)= 2.5×10^{-2} mol dm^{-3}) just before irradiation in order to prevent the reaction by e_{aq}^-, in which N_2O converts them into OH radicals.

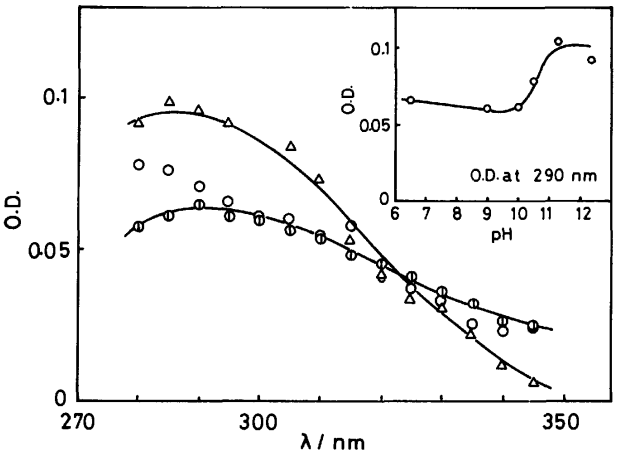


Fig. 1. The transient spectra produced on pulse radiolysis of 10^{-3} mol dm^{-3} cycloserine in presence of N_2O at pH 6.5 (○), 9.0 (◐), and 12.4 (△). The insert shows the pH dependence of the absorbance at 290 nm.

The radiolytic yield of serine, which was the major product, was determined as follows. A solution of 10^{-3} mol dm^{-3} cycloserine (saturated with N_2O) was irradiated by the γ rays of ^{60}Co for 10 min at a dose rate of 3×10^{3} Gy/h. The total absorption dose corresponded to a 10% conversion. Then, the solution was dried in a vacuum and the residue was dissolved in a buffer solution and passed through a conventional automatic aminoacid analyzer (JLC-6AH, JEOL). Upon elution with a buffer solution (pH 3.2), serine and 3-(aminooxy)alanine (which was produced by the hydrolysis of cycloserine in an acidic buffer solution) were separated. Cycloserine was separated by the buffer solution of pH 7.3. The evaluations of G(serine) and G(−cycloserine) were made after the correction for 3-(aminooxy)alanine. The optical isomerism of serine was examined by IR spectra using KBr discs of the residues. In this case, the N_2O saturated solutions of 2×10^{-2} mol dm^{-3} were γ-irradiated for 10 h at a dose rate of 3×10^{3} Gy/h and dried. The irradiation time was chosen so that most of the cyclsoerine could be decomposed.

Results

Transient Absorption Spectra. The absorption spectra were obtained 1.25 μs after a pulse for solutions containing 1.0×10^{-3} mol dm^{-3} cycloserine with various pH values from 6.5 to 12 and are presented in Fig. 1. The spectra, except the one at pH 6.5, have a broad maximum at 290 nm. The band maximum was not observed in the spectrum at pH 6.5. The insert in Fig. 1 shows the change of absorbance at 290 nm with pH. The increase in absorbance was observed above pH 10. The spectra shown in Fig. 1 were compared with those obtained in a reaction with N_3 radicals. The concentration of the N_3^- ion added was 10^{-2} mol dm^{-3}, and the spectra were obtained 10 μs after a pulse in order to avoid the contribution of the absorption due to the remaining N_3 radicals. Transient spectra are shown in Fig. 2. All the spectra at pH 6.5 to 12 showed broad absorption maxima at around 290 nm and were very similar to the spectra shown in Fig. 1. However, as shown in the insert of Fig. 2, the absorbance at 290 nm

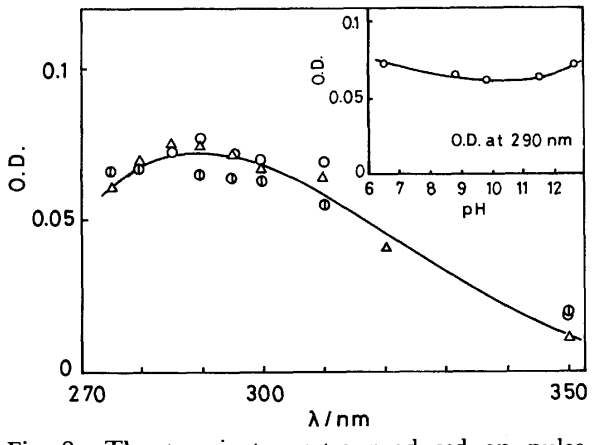

Fig. 2. The transient spectra produced on pulse radiolysis of 10^{-3} mol dm^{-3} cycloserine with 10^{-2} mol dm^{-3} NaN_3 in presence of N_2O at pH 6.5 (○), 9.0 (⦶), 12.4 (△). The insert shows the pH dependence of absorbance at 290 nm.

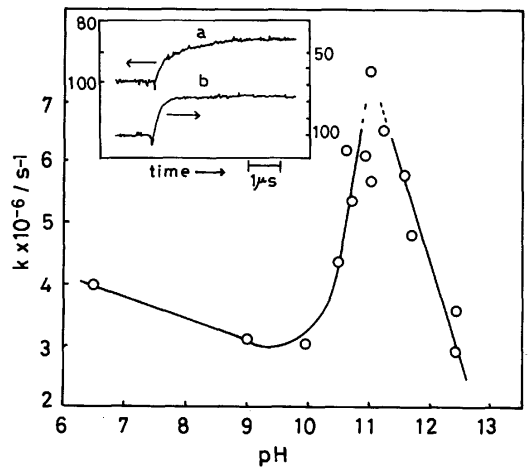

Fig. 3. The pH dependence of rate of formation of the intermediates measured at 290 nm on pulse radiolysis of 10^{-3} mol dm^{-3} cycloserine. The insert shows the example of signal traces at pH 9.9 (a) and 11.3 (b). The ordinates indicate the transmission, %.

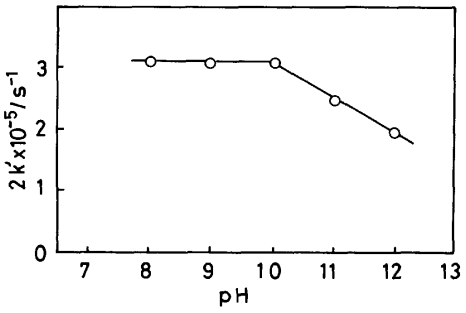

Fig. 4. The pH dependence of the decay rate measured in absorbance on pulse radiolysis of 10^{-3} mol dm^{-3} cycloserine. The true second-order decay rate, $2k$, is related with $2k'$ as follws: $2k=2k'\varepsilon_{290}l$, where ε_{290} is the molar extinction coeffident of intermediate at 290 nm and l is the optical path length.

did not change within the whole pH range examined.

Kinetics of the Formation and Decay of Intermediates. The rates of formation of transient species, shown in Fig. 1, were determined from the growth of the absorption signals at 290 nm for solutions of various pHs. The results are shown in Fig. 3. The insert presents a typical example of the signal traces of growth after pulse. The first-order rate constants are $3-4\times10^{6}$ s^{-1} between neutral and pH 10, increased between pH 10 and 11 and decreased above pH 11. It appeared that the base-catalyzed reaction, or deprotonation, occurred between pH 10 and 11.

The absorbance at 290 nm decayed by second-order kinetics. The pH dependence of the relative decay rates is shown in Fig. 4. The rates decreased above pH 10. The intermediates observed in the reaction of N_3 radicals also decayed by a similar second-order rate.

Determination of k(OH+cycloserine). The reaction rates of OH radicals with cycloserine were determined for solutions of various pHs by using the KCNS method.[10,11] The concentrations of cycloserine and KCNS used were 0.5 to 1.0×10^{-3} mol dm^{-3} and

1.0×10^{-3} mol dm^{-3}, respectively. The absorption due to the $(CNS)_2^-$ radical ions was measured at 475 nm. As the observed rates of growth of $(CNS)_2^-$ did not show simple first-order kinetics, the rate constants were evaluated by fitting the theoretical kinetic expressions to observed data. When the solution contained both cycloserine and CNS^-, the following competitive reactions occurred:

$$OH + CNS^- \xrightarrow{k_1} CNS + OH^-, \quad (1)$$

$$CNS + CNS^- \xrightarrow{k_2} (CNS)_2^-, \quad (2)$$

$$OH + \text{cycloserine} \xrightarrow{k_c} \text{product}, \quad (3)$$

where k_1, k_2, and k_c are the rate constants in these reactions. The time dependence of the concentration of $(CNS)_2^-$ after pulse is given by the following equation, which is derived from the competitive reaction mechanism involving Reactions 1, 2, and 3,

$$\{(CNS)_2^-\}_t = \frac{k_1'k_2'(OH)_0}{k_2'-(k_c'+k_1')}\left\{-\frac{e^{-(k_c'+k_1')t}}{k_c'+k_1'}+\frac{e^{-k_2't}}{k_2'} + \frac{k_2'-(k_c'+k_1')}{k_2'(k_c'+k_1')}\right\}, \quad (4)$$

where $k_1'=k_1(CNS^-)$, $k_2'=k_2(CNS^-)$, and $k_c'=k_c$(cycloserine), and $(OH)_0$ is the initial concentration of OH radicals which was estimated from the maximum absorbance at 475 nm reached after pulse in the solution without cycloserine. The values of k_1 and k_2 were determined by fitting Eq. 4 with $k_c'=0$ to the observed traces of the build-up signal in the solution containing only CNS^- ions. These values are $k_1=1.0\times10^{10}$ mol^{-1}dm^{3}s^{-1} and $k_2=6\times10^9$ mol^{-1}dm^{3}s^{-1}, respectively, which agreed well with reported values.[12] The values of the k_c's are determined by fitting Eq. 4 to the observed traces of growth in solutions containing CNS^- and cycloserine with various pHs. The results are listed in Table 1. The data of pH 12 was estimated by assuming the $k_1=1.0\times10^9$ mol^{-1}dm^{3}s^{-1}.[10] The rates obtained at pHs 8 to 11 are $1.2-1.3\times10^{10}$ mol^{-1}dm^{3}s^{-1}, and did not show the increase between 10 and 11 as observed in the formation rates in Fig. 3. The slightly slow rate obtained at pH 6.5 is reasonable because the net charge is zero at this pH.

Detection of Serine. The radiolytic yield of serine, G(serine), was determined to be 2.5 at pH 6.5—10, and 1.0 at pH 11. The yield of the decrease of cycloserine, G(−cycloserine), was also determined to be approximately 10.0 at pH<10. The IR spectra of the dried residues of the irradiated solution in which cycloserine mostly decomposed showed that the main product was D-serine.

Table 1. The rate constants of the reaction of OH radicals with cycloserine ($\times10^{10}$ mol^{-1}dm^{3}s^{-1})

pH	k_1	k_2	k_c
6.5	1.0	0.65	0.8
9.0	1.0	0.65	1.2
10.0	1.2	0.65	1.3
11.3	1.2	0.65	1.2
12.5	0.1		0.13*

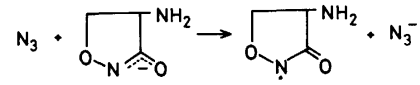
* This value was calculated by the comparison of absorbances at 475 nm in the experiment for only CNS^- with that for CNS^-+cycloserine, assuming $k_1=1.0\times10^9$ mol^{-1}dm^{3}s^{-1} as calculated by Simic and coworkers.[1-3]

Discussion

Upon the irradiation of solutions containing N_3^- ions, N_3 radicals are known to be produced from a reaction of OH radicals with the N_3^- ions,[13] as follows:

$$N_3^- + OH \rightleftharpoons N_3 + OH^-, \quad k(N_3^- + OH) = 1.2\times10^{10}\ \text{mol}^{-1}\ \text{dm}^3\ \text{s}^{-1}. \quad (5)$$

It is also known that the reaction of N_3 radicals is exclusively one-electron oxidation and it is inert toward aliphatic H atoms, whereas the typical reaction of OH radicals is radical addition or H-atom abstraction. The intermediate, which is produced through one-electron oxidation of the isoxazolidinone ring by N_3 radicals, should be the isoxazolidinone radical (II) as described in Reaction 6.



(6)

(II)

Under our experimental conditions, the production of N_3 radicals was completed within a pulse. The contribution of the absorption due to the N_3 radical (absorption maximum is 270 nm) to the transient spectra was negligible 10 μs after the pulse. Thus, the species responsible for the absorption band shown in Fig. 2 was the oxidized radical (II). Since the transient spectra at pH 8 to 10 shown in Fig. 1, where cycloserine exists as anion, are very similar to those in Fig. 2, we attributed the absorption band in Fig. 1 to the oxidized radical (II). Therefore, the site of attack of OH radicals was the dissociated peptide group, $-N^-CO-$, and the radicals were produced through one-electron oxidation by OH radicals. The spectrum at pH 6.5 was slightly different from others. Taking into account the slow k(OH+cycloserine), this would be induced by the lowered selectivity of OH radicals to the peptide group owing to the protonated amino groups, producing different species.

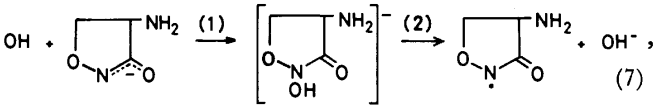
The absorbance at 290 nm in Fig. 1 and the rate of formation in Fig. 3 increased at the same pH range, pH 10—11, in the reaction of OH radicals, whereas these changes were not observed in the reaction with N_3 radicals. These results suggest that the change in the site of attack of OH radicals occur within this pH range. Since this pH range corresponds to the pK of the OH radical, $OH \rightleftharpoons O^- + H^+$, p$K$=11.9,[14] H-atom abstraction by O^- is expected to occur. As shown in Fig. 4, the rate of radical recombination was also found to decrease at this pH range, which suggested the formation of radical anions as intermediates in this pH region. There is one

possibility that the amino groups were attacked by O^- or OH radicals, producing the anion radicals, since dehydrogenation of N-H bonds by these radicals in aliphatic amines on γ-radiolysis[15] and in simple aminoacids on pulse radiolysis[16] in alkaline solutions has been reported. Taking into account the increase in the rate-of-formation of the intermediates, it is also conceivable that the dehydrogenation by OH or O^- radicals occurred on the carbon adjacent to the amino group. In this case, the amino groups may be prompted to deprotonate and the intermediates of anion form could be produced. It is known that the peptide hydrogen adjacent to a radical carbon can dissociate upon pulse radiolysis of the derivatives of 2,5-piperazindione, in which the pK value of the radical is 9.6.[3] The result that pH dependence was observed in the rates-of-formation of the oxidized radical, as shown in Fig. 3, whereas the values of k(OH+cycloserine) were independent of pH, as shown in Table 1, implies that the oxidized radicals observed in Fig. 1 were not formed immediately as the result of the attack of OH radicals, but were formed from a precursor, OH adducts of cycloserine, and therefore k(OH+cycloserine) represents the rate of the formation of OH adduct. This implication is supported by the fact that the rate-of-formation of the oxidized radicals did not change significantly in 10^{-2} mol dm^{-3} solutions.

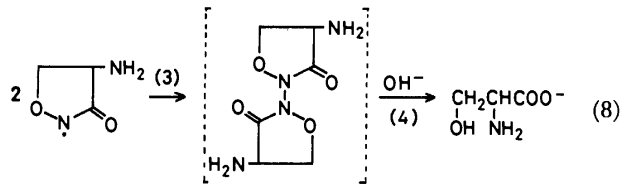
As the oxidized radicals decayed by second-order kinetics, the reaction mechanism of these species was considered to be predominantly through radical-radical recombination. Probably, two oxazolidinone rings become linked through N atoms to lead to the formation of a hydrazine-type bond. This was assumed from the analogy with the previous report that the oxidation of *N*-acyl-*O*-alkylhydroxylamine, RCONHOR$^-$, resulted in the formation of a hydrazine-type compound through N-N coupling.[17]

In this experiment, the value of G(OH) was the sum of $G(e_{aq}^-)$ and the original G(OH), that is, 5.6. If the OH radicals react with cycloserine quantitatively and the decomposition of one hydrazine-type intermediate produce two serine molecules, G(serine) and G(−cycloserine) will be equal to G(OH). However, the radiolytic yield of serine was roughly a half of G(OH) and G(−cycloserine) was higher than G(OH). Thus, the one molecule of serine would be formed through the deomposition of one dimerized intermediate, and some additional cycloserine molecules would react secondarily with the entity which remained after the elimination of serine from the dimerized species.

On the basis of the above considereation, the whole reaction scheme of the radiolysis of the cycloserine anion by OH radicals can be described according to reactions (7) and (8) at a pH range from 8 to around 10:



(7)



(8)

The rate constants of step (1) and (2) were 1.2×10^{10} mol^{-1}dm^{3}s^{-1} and $3-4\times10^6$s^{-1}, respectively. The second-order rate constant of step (3), $2k$, is equal to the products of the apparent rate constant, $2k'$, the molar extinction coefficinent of the oxidized radical (II) at 290 nm, ε_{290}, and the optical path length of the cell. The value of $2k'$ was 3×10^5s^{-1}, as shown in Fig. 4. The value of ε_{290} was roughly estimated to be 630 mol^{-1}dm^{3}cm^{-1} by using the absorbance of the oxidized radical in the reaction of N_3 radicals observed in Fig. 2 and the initial concentration of OH radicals which was estimated to be 5.6×10^{-5} mol dm^{-3} in the pulse of 100 Gy. The resulting rate constant of step (3) was $2k=3.8\times10^8$ mol^{-1}dm^{3}s^{-1} at pH range of 8 to 10.

It is considered that complex processes, such as the attack of OH or O^- radicals on multiple sites, may be occurring at a pH above or around 11.

The authors wish to thank Dr. Takeaki Enoto and Messers. Hiroaki Tanida and Koichi Sato for the help in operating the linac, and Miss Yumiko Misu for the analysis of aminoacids.

Mercury- and Cadmium-photosensitized Reactions of γ-Butyrolactone

Shunzo YAMAMOTO,* Shuzo MATSUDA, Chihiro OZAKI, Hiroshi TAKAHOSO, and Norio NISHIMURA
Department of Chemistry, Faculty of Science, Okayama University, 3-1-1, Tsushima-naka, Okayama 700
(Received May 1, 1984)

The mercury- and cadmium-photosensitized reactions of γ-butyrolactone have been compared. The products obtained in the two photosensitizations were quite different. The gaseous products from the mercury-photosensitized reaction were carbon dioxide, cyclopropane, and propylene, while the products obtained in the cadmium-photosensitized reaction were carbon monoxide and ethylene. This difference suggests that the decomposition of γ-butyrolactone takes place through different intermediates in the two reactions. Possible mechanisms are discussed.

Numerous studies of chemical reactions induced by excited atoms have been published. Cadmium-photosensitized reactions have often been compared with mercury-photosensitized reactions to obtain information about the detailed mechanism of the reaction. It is generally accepted that these reactions are the same by nature, and that a difference in quantum yields of products can be explained by the difference in their excitation energies.

We studied the mercury- and cadmiun-photosensitized reactions of γ-butyrolactone and found quite different products in these reactions. In a previous short communication,[1] we reported briefly the results of these studies. The present paper will report the details of the reactions.

Experimental

The mercury-photosensitized reaction was studied at 125 °C in a cylindrical quartz cell, 4cm in diameter and 10 cm long, fitted with plane quartz windows. A spiral quartz mercury discharge lamp filled with 670Pa Ar was used. The 184.9nm resonance line was filtered out by a Vycor filter. Light intensity absorbed by mercury atoms at 253.7nm was determined by ethylene actinometry.[2]

The cadmium-photosensitized reaction was studied at 300°C in a cylindrical Pyrex cell, 2cm in diameter and 20cm long. A U-shaped cadmium discharge lamp made of Pyrex, filled with 670Pa Ar, was used. Absorbed light intensity at 326.1nm was determined by *cis*-2-butene actinometry.[3]

Product analysis was done by fractionation at −196 and −60°C, and measurement with gas burette and gas chromatography, using a 12m column of VZ-7 (Gasukuro Kogyo Co., LTD) at 0°C.

γ-butyrolactone (Tokyo Kasei Ind., E.P. grade) was purified by trap-to-trap distillation. Liquid butyrolactone was injected into the cell by a microsyringe, and was fully degassed by many careful freeze-pump cycles. *cis*-2-Butene (Nihon Tokushu Gasu K. K., pure-grade) and N_2O (Nihon Sanso K. K., pure-grade) were used as supplied.

Results and Discussion

The Mercury-photosensitized Reaction. Since the vapor pressure of butyrolactone is low at room temperature, it is necessary to elevate the reaction temperature in order to obtain sufficient vapor pressure. The thermal decomposition of butyrolactone at 125°C was found to be negligible.

The major products were carbon dioxide, cyclopropane, and propylene, while carbon monoxide and hydrogen were minor products. These major products were also observed by Simonatis and Pitts[4] and Krull and Arnold,[5] in mercury-photosensitized reaction of γ-butyrolactone. These products are also those which originate from the triplet manifold of lactone in the direct photolysis.[4] This is reasonable, because sensitization by $Hg(^3P_1)$ is expected to give triplet lactone due to spin conservation.

Yields of Carbon dioxide, cyclopropane, and propylene increased linearly with reaction time and light intensity. This shows that carbon dioxide, cyclopropane, and propylene are primary products. Quantum yields of product formation are shown in Fig. 1 as a function of lactone pressure; the quantum yield of carbon dioxide is independent of lactone pressure, while that of cyclopropane increases and that of propylene decreases with increasing lactone pressure. The quantum yield of carbon dioxide was only 0.25, even at the lowest pressure examined. This suggests that most of the triplet lactone formed undergoes the other reactions. As no products volatile at −60°C were obtained except for carbon dioxide, cyclopropane, and propylene, the isomerization to succinaldehyde which was obtained in the direct photolysis of γ-butyrolactone[4] and the process that the triplet lactone loses its excitation energy without forming any products seem to be important.

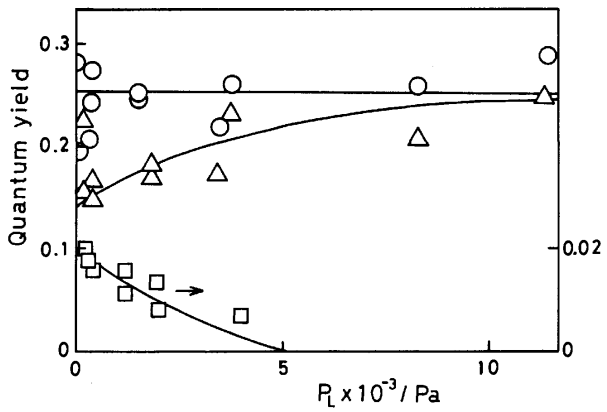

Fig. 1. Pressure dependence of quantum yields of CO_2 (○), cyclopropane (△), and propylene (□) in the mercury-photosensitized reaction of γ-butyrolactone.

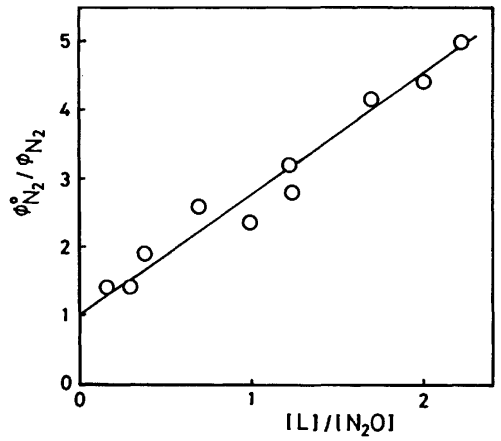

Fig. 2. Competitive quenching plots for lactone.

The quenching cross-section for lactone was obtained from competitive rates of the mercury-photosensitized reactions of lactone and N_2O. Figure 2 shows the competitive quenching plots for lactone. Yields of nitrogen from N_2O are expressed by the expression;

$$\frac{\phi^\circ_{N_2}}{\phi_{N_2}} = 1 + \beta\frac{[L]}{[N_2O]}, \tag{1}$$

where $\phi^\circ_{N_2}$ and ϕ_{N_2} are quantum yields in the absence and in the presence of lactone. The best straight line was obtained by the method of least squares. The quenching cross-section for lactone can be calculated by the following equation;[6]

$$\frac{\sigma^2_L}{\sigma^2_{N_2O}} = \beta\left(\frac{1+M_{Hg}/M_{N_2O}}{1+M_{Hg}/M_L}\right)^{-1/2}, \tag{2}$$

where $\sigma^2_{N_2O}$ is the cross-section for N_2O and we used the value of 18.0 Å^2. The value of 41 Å^2 for lactone was obtained and it can be compared with that for acetone (53 Å^2) and for acetoaldehyde (41 Å^2). In the presence of N_2O, the observed decrease in the quantum yield of cyclopropane agreeds with that expected from competitive quenching within the limits of experimental error.

The following set of reactions is proposed to explain our results:

$$Hg + h\nu\ (253.7\,nm) \longrightarrow Hg(^3P_1), \tag{3}$$

$$Hg(^3P_1) + L \longrightarrow Hg + {}^3L, \tag{4}$$

$${}^3L \longrightarrow CO_2 + C_3H_6^*, \tag{5}$$

$${}^3L \longrightarrow \text{other reactions}, \tag{6}$$

$$C_3H_6^* \longrightarrow CH_3CH{=}CH_2, \tag{7}$$

$$C_3H_6^* + L \longrightarrow \text{cyclo-}C_3H_6 + L. \tag{8}$$

Here, ^3L denotes triplet lactone and $C_3H_6^*$ is a "hot" cyclopropane intermediate. From this mechanism the quantum yields of products should be given by

$$\phi_{CO_2} = \frac{k_5}{k_5+k_6}, \tag{9}$$

$$\phi_{CH_2CH=CH_2} = \frac{k_5}{k_5+k_6}\frac{k_7}{k_7+k_8[L]}, \tag{10}$$

$$\phi_{\text{cyclo-}C_3H_6} = \frac{k_5}{k_5+k_6}\frac{k_8[L]}{k_7+k_8[L]}. \tag{11}$$

These equations explain the observed pressure dependence of the quantum yields.

The Reaction, L→cyclo-C_3H_6+CO_2, is endothermic by about 29 kJ mol^{-1}.[4] Since the excitation energy of $Hg(^3P_1)$ is 469 kJ mol^{-1}, the energy to be distributed among the products is greater than 440 kJ mol^{-1}. This value is almost the same as that estimated for the average energy transferred to the cyclobutanone molecule from the $Hg(^3P_1)$ atom.[7] Photosensitized reaction of cyclobutanone has been reported to yield vibrationally excited cyclopropane and carbon monoxide, and the former is known to isomerize to propylene. In this case a propylene/cyclopropane ratio of 0.58 at about 1330 Pa was obtained. As is shown in Fig. 1, however, propylene was only about one-fifteenth of the cyclopropane at the same pressure. In order to explain this difference, it is suggested that if triplet carbon dioxide (with an energy of about 356 kJ mol^{-1} [18]) is formed in Reaction 5, the energ content of cyclopropane would be greatly reduced, making the isomerization impossible. If the reaction, $^3L \rightarrow {}^3CO_2$+cyclo-C_3H_6 (5′), is added to the mechanism, the following relation can be derived.

$$\frac{\phi_{\text{cyclo-}C_3H_6}}{\phi_{CH_2CH=CH_2}} = \frac{k_{5'}}{k_5} + \left(1+\frac{k_{5'}}{k_5}\right)\frac{k_8}{k_7}[L] \tag{12}$$

From the intercept of the straight line shown in Fig. 3, a value of $k_{5'}/k_5$ of about 12 is obtained. Thus the reaction which produces excited carbon dioxide, is the main process. Simonaitis and Pitts also pointed out the possibility of the formation of triplet carbon dioxide in the direct photolysis of γ-butyrolactone at 210 to 260 nm.[4] A value of 3.45×10^{-4} Pa^{-1} for k_8/k_7 ratio is also obtaine from the intercept and the slope of the straight line. This gives the value of k_7 as 2.75×10^8 s^{-1} by adopting 9.5×10^4 s^{-1} as the kinetic collision frequency at 1 Pa and by assuming unit collisional deactivation efficiency for lactone. The excess energy of energized cyclopropane can be estimated by the equation given by Rabinovitch and Diesen:[9]

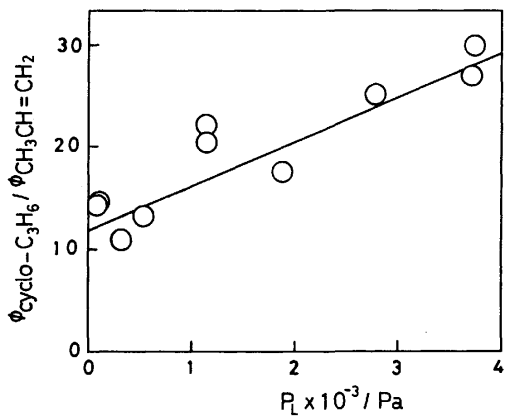

Fig. 3. Plots of $\phi_{\text{cyclo-}C_3H_6}/\phi_{CH_3CH=CH_2}$ against lactone pressure.

TABLE 1. COMPARISON OF EXCESS ENERGY OF CYCLOPROPANE

Compounds	Reactions	E / kJ mol^{-1}
γ-butyrolactone	Hg($^3P_1$)photosensitization	339
cyclobutanone	Hg($^3P_1$)photosensitization[a]	314±21
1-pyrazoline	direct photolysis(312.6 nm)[b]	314
tetrahydrofuran	direct photolysis(197.3 and 194.2 nm)[c]	331

a) Ref. 7. b) P. Cadman, H. M. Meunier, and A. P. Trotman-Dickenson, *J. Am. Chem. Soc.*, **91**, 7640 (1969). c) B. C. Roquitte, *J. Am. Chem. Soc,*. **91**, 7664 (1969).

$$k_7 = A'\left[\frac{E-E_0+a^+E_z^+}{E+aE_z}\right]^{s-1}. \quad (13)$$

Using experimental value of k_7 and substituting $A'=10^{15.80}s^{-1}$, E_0=262.4 kJ mol^{-1}, E_z=205.2 kJ mol^{-1}, E_z^+=179.1 kJ mol^{-1}, s=21, and a and a' which were obtained by being extrapolated from those given in Ref. (10), the value of E was found to be 339 kJ mol^{-1}. This corresponds to about 83% of the total energy (440 kJ mol^{-1}) to be distributed among the products. A comparison of the excess energy of cyclopropane in different systems is given in Table 1. As is shown in Table 1, the value of E in the present system is in fair agreement with those in other system, showing our result is reasonable.

The Cadmium-photosensitized Reaction. In the cadmium-photosensitized reaction, it is necessary to raise the reaction temperature to get a sufficient vapor pressure of cadmium. The thermal decomposition at 300 °C was found to give a small amount of carbon dioxide and cyclopropane, but not to give carbon monoxide and ethylene. The main products in the cadmium-photosensitized reaction were carbon monoxide and ethylene, quite different from those in the mercury-photosensitized reaction. To make sure that the difference between the two reactions is not owing to the difference in temperature, we examined the two reactions at the same temperature (235 °C), and obtained the same results as those obtained under the conditions mentioned above. If the triplet state of lactone lies at about 439 kJ/mol above the ground state, as Simonatitis and Pitts estimated,[11] it can not be formed by reaction of Cd($^3P_1$) which has energy of only 367 kJ mol^{-1}. This probably accounts for the difference between the mercury- and cadmium-photosensitized reactions of lactone. In the presence of a large pressure of nitrogen, oxetane was also observed.

Yields of carbon monoxide and ethylene increased linearly with reaction time, showing that those are primary products. The quantum yields of carbon monoxide and ethylene are shown in Fig. 4 as a function of lactone pressure. The yield of ethylene decreases a little more rapidly than that of carbon monoxide with increasing pressure.

When *cis*-2-butene was added to lactone, the quantum yields of the decomposition products decreased as the quantum yield of *trans*-2-butene formation increases. From the slope of the reciprocal plot of the quantum yield of *trans*-2-butene *vs.* the lactone/*cis*-2-butene ratio (Fig. 5), the quenching efficiency of lactone relative to that of *cis*-2-butene was estimated to be 0.92±0.10. This value is close to those for ethylene (1.03±0.09[12]), propylene (1.18±0.04[12]), and cyclopentanone (0.8±0.2[13]). Figure 6 shows the effect of *cis*-2-butene on the yields of carbon monoxide and ethylene. Solid line shows the relative quantum yields calculated using the relative quenching efficiency of lactone obtained above. As Fig. 6 shows, the decrease in the quantum yields of carbon monoxide and ethylene observed in the presence of *cis*-2-butene can be explained by competitive quenching of triplet lactone alone; *i.e.* the nature of the decomposition was not affected.

In order to explain the experimental results, the following set of reactions is proposed:

$$Cd(^1S_0) + h\nu\ (326.1\ nm) \longrightarrow Cd(^3P_1), \quad (14)$$

$$Cd(^3P_1) + L \longrightarrow CdL^*, \quad (15)$$

$$CdL^* \longrightarrow \cdot COCH_2CH_2CH_2O\text{-}Cd\cdot, \quad (16)$$

$$CdL^* \longrightarrow \text{other reactions}, \quad (17)$$

$$CdL^* + L \longrightarrow Cd + 2L, \quad (18)$$

$$\cdot COCH_2CH_2CH_2O\text{-}Cd\cdot \longrightarrow CO + \cdot CH_2CH_2CH_2O\text{-}Cd\cdot, \quad (19)$$

$$\cdot CH_2CH_2CH_2O\text{-}Cd\cdot \longrightarrow CH_2{=}CH_2 + CH_2O + Cd, \quad (20)$$

$$\cdot CH_2CH_2CH_2O\text{-}Cd\cdot + M \longrightarrow \underline{CH_2CH_2CH_2O} + Cd + M. \quad (21)$$

Here, CdL* stands for a transient complex between the excited cadmium atom and a lactone molecule, which is tentatively proposed to explain the difference between the mercury- and cadmium-photosensitized reactions of lactone. Formation of a similar complex between excited cadmium and saturated alcohols and ethers was suggested previously.[14] Formation of an O-Cd bond in Reactions 17 and 20 was assumed, because the excitation energy of Cd($^3P_1$) alone is not enough to produce biradicals $\cdot COCH_2CH_2CH_2O\cdot$ and $\cdot CH_2CH_2CH_2O\cdot$, as is shown in Table 2.

From this mechanism the following relation can be derived:

$$\frac{\phi_{CO}}{\phi_{C_2H_4}} = 1 + \frac{k_{21}}{k_{20}}[M]. \quad (23)$$

A plot of $\phi_{CO}/\phi_{C_2H_4}$ *vs.* lactone pressure is presented in Fig. 7, from which $k_{21}/k_{20}=1.3\times10^{-5}$ Pa^{-1}. The low value implies a relativly short lifetime for the biradical, $\cdot CH_2CH_2CH_2O\text{-}Cd\cdot$.

From the proposed mechanism, it is expected that the yield of oxetane should increases with increasing lactone pressure. We obtained only small amounts of oxetane in the pure lactone, and found that the yield was independent of lactone pressure. In the presence of a large pressure of nitrogen, however, we obtained

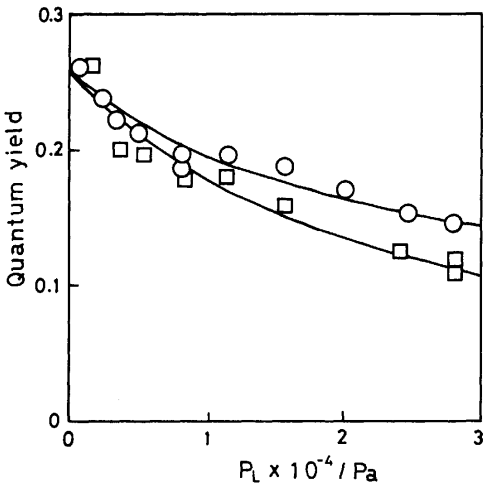

Fig. 4. Pressure dependence of quantum yields of CO (○) and ethylene (□) in the cadmium-photosensitized reaction of γ-butyrolactone.

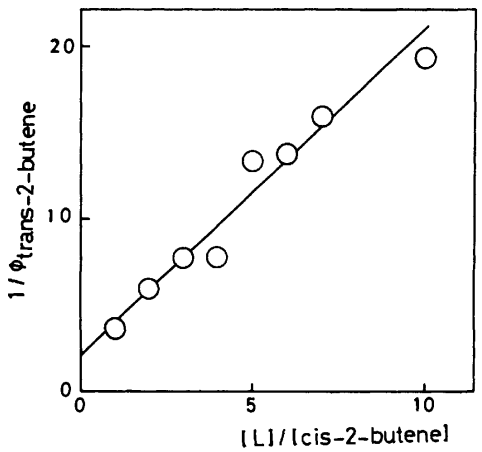

Fig. 5. Plots of the reciplocal of the quantum yield of *tran*-2-butene against the lactone/*cis*-2-butene pressure ratio.

a considerably more oxetane and found that the yield increased with increasing nitrogen pressure. These findings suggest that the biradical produced in Reaction 20 may react with lactone, limiting the yields of oxetane in the pure lactone.

In general, excitation of an ester molecule can be followed by any of three possible bond cleavages (processes I, II, and III); I and II would be indistinguishable for the usual experimental conditions, since radical decomposition (RCO_2 and R'OCO) would be very rapid.[15]

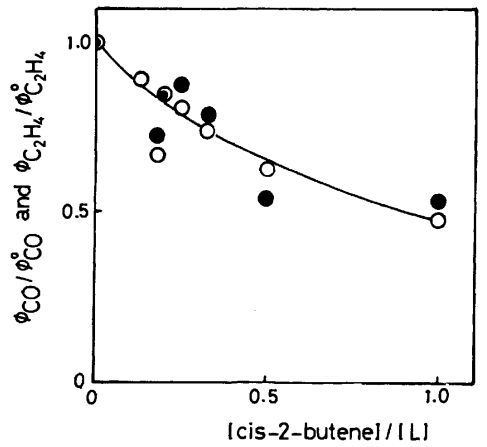

Fig. 6. Quantum yields of CO (○) and ethylene (●) in the cadmium-photosensitized reaction of γ-butyrolactone in the presence of *cis*-2-butene.

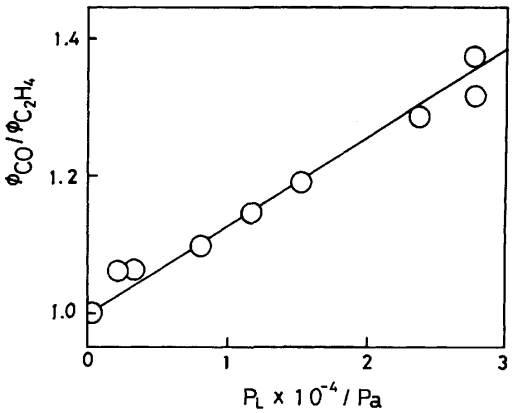

Fig. 7. Plots of $\phi_{CO}/\phi_{C_2H_4}$ against lactone pressure.

RCOOR' + $h\nu$

$\longrightarrow$ RCO_2 + R' ($\longrightarrow$ R + CO_2 + R'), I

$\longrightarrow$ R + CO_2R' ($\longrightarrow$ R + CO_2 + R'), II

$\longrightarrow$ RCO + OR' ($\longrightarrow$ R + CO + OR'). III

Mercury-photosensitized reaction of lactone seems to proceed by process I and/or II, while cadmium-photosensitized reaction seems to proceed by process III. The bond dissociation energies of some bonds in lactone were estimated by thermochemical data given by Benson:[16]

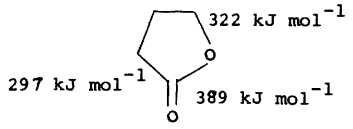

TABLE 2. ENTHALPY CHANGES FOR SOME REACTIONS BETWEEN γ-BUTYROLACTONE AND $Cd(^3P_1)$[a]

Reaction		ΔH / kJ mol^{-1}
$CH_2CH_2CH_2OCO+Cd(^3P_1)$	$\rightarrow \cdot COCH_2CH_2CH_2O\cdot+Cd$	22.2
	$\rightarrow \cdot COCH_2CH_2CH_2O\text{-}Cd\cdot$	−350.3
	$\rightarrow CO+\cdot CH_2CH_2CH_2O\cdot+Cd$	56.9
	$\rightarrow CO+\cdot CH_2CH_2CH_2O\text{-}Cd.$	−315.6

a) We used the value of 372.5kJ mol^{-1} for the bond energy of Cd-O. J. C. Bailar, H. J. EMeteus, Sir Ronald Nyholm, and A. F. Trotman-Dickenson, "Comprehensive Inorganic Chemistry," Vol. III, Pergamon Press, Oxford (1973).

It is easy to understand the mercury-photosensitized reaction of lactone, since the excitation energy of $Hg(^3P_1)$ is sufficiently large. Although the excitation energy of $Cd(^3P_1)$ is smaller than the bond energy of CO–O, the CO–O bond must break at first to produce carbon monoxide. Therefore, we assumed formation of an O–Cd bond in Reaction 16.

Colloid Chemical Studies on the Aggregation of Phospholipid Vesicles with Metal Cations

Kunio FURUSAWA,* Hiroyuki KAKOKI, and Hideo MATSUMURA†
The University of Tsukuba, Department of Chemistry, Sakura-Mura, Ibaraki 305
†*Electrotechnical Laboratory, Sakura-Mura, Ibaraki 305*
(Received May 22, 1984)

Aggregation behavior of phosphatidylethanolamine (PE) and Phosphatidylserine (PS) vesicles that have resulted with various metal cations, has been studied to determine their adsorption characteristics. The critical flocculation concentration of these cations for both vesicles was determined by two techniques, *i.e.*, by the kinetic method in which the rate of flocculation was measured turbidimetrically, and by the traditional static method. The results have been analysed by the usual stability concept in the colloid chemistry, and these analyses revealed that there are two mechanisms in the vesicle aggregation. One is the charge neutralization of the polar groups on the vesicle surface, which is induced by the adsorption of multivalent cations (Th^{4+}, La^{3+}), and the other is the interparticle binding (or the interparticle bridging) caused by the divalent cations (Ca^{2+}, Mg^{2+}).

The importance of the interaction of metal cations with natural membranes has been pointed out by many authors in connection with ion permeability through membranes,[1] membrane stability[2-4] and ion adsorption on the membranes,[5] *etc.* In order to obtain some insight into the mechanism of ionic interaction with biological membranes, several authors have investigated the surface potential of monolayers[6,7] made of phospholipids in various ionic environments. Bangham *et al.*[8] observed the different effects of various divalent cations on the surface potential of acidic phospholipid monolayers. Mclaughlin *et al.*[9] obtained the association constants of various divalent cations by measuring the conductance of phosphatidylserine membranes. Barton[10] determined the degree of divalent cation association with phosphatidylserine membranes by measuring the electrophoretic mobility of phospholipid vesicles.

Only a few colloid chemical studies on the aggregation of phospholipid vesicles have been reported. It has generally been observed that acidic phospholipid vesicles, such as phosphatidylserine and phosphatidylethanolamine vesicles, are very sensitive to multivalent cations;[11,12] the addition of relatively small amounts of cations can cause them to aggregate. In this study, the aggregation behavior of phosphatidylethanolamine and phosphatidylserine vesicles have been studied using various metal cations as coagulants and the experimental results have been analysed by the stability concept in the colloid chemistry.[13]

The concentration of the counter ions required to aggregate the colloidal dispersion is called the critical flocculation concentration(CFC) or flocculation value (C_{CFC}). The CFC depends on a number of factors, such as the nature of colloid particles, the surface charge, the double layer thickness of the particles, and the valence and nature of the counter ions. The procedures for measuring the CFC can be divided into (1) the kinetic method and (2) the static method. In the kinetic method, the initial rate of aggregation is measured turbidimetrically as a function of the concentration of the coagulation agent at which further increase of the coagulant produces no further speeding up of the aggregation process. For a better understanding of colloid stability, measurements in the period immediately after mixing were indispensable because these results are more suitable to interpretation in terms of the particle-particle interaction than those obtained by the static method.

In the static method, a row of glass tubes including the colloidal suspension is prepared, increasing amounts of the coagulant are added and the CFC is determined after waiting a few hours. This method has the drawback that the stability criterion is somewhat arbitrary, but the advantage is that, if properly done, a time scale can be used to attain adsorption equilibrium between the colloidal particles and the coagulation agent. The turbidimetric titration technique can be regarded as a static method, if the titrants are added slowly to attain the adsorption equilibrium.

In this work, two types of measurement on the CFC of the phospholipid vesicles have been undertaken, and the resulting data have been analysed systematically. From these analyses, it appeared that these two techniques give independently important knowledge on the interaction of metal cations with phospholipid membrane.

Experimental

Materials. Bovine brain phosphatidylethanolamine (PE) and phosphatidylserine(PS) were used as the phospholipids which were purchased from Sigma Chemical Co., Ltd (U. S. A.). Other reagents used were of an analytical grade. All the solutions of these materials were made with deionized and doubly distilled water.

Vesicle Preparation. PE and PS vesicles were prepared by the sonication method at 4°C without using any buffer to reduce the spurious effects of the included buffer ions.[14] After the removal of the undispersed materials by the centrifugation (26000g, 1h), the dispersion was filtered through a membrane filter (0.1 μm pore size).

Turbidimetric Titration. Turbidimetric titration was carried out at 25°C under a nitrogen atmosphere using a Hirama automatic recording titrator (Tokyo Japan). The

transmittance (or turbidity) of the vesicle dispersion (30 ml, $1-8\times10^{-2}$ g/dl) was measured at the wavelength of 517 nm. The titrant solution (0.01—0.3 mol dm^{-3} salt solution) was added very slowly (0.01 ml/min) to the vesicle dispersion to attain the adsorption equilibrium between the vesicle surface and the titrant ions. As the titration proceeds, the dispersion begins to become turbid, and the transmittance reaches a minimum at a certain titrant volume (V_{min}) from which we have calculated the CFC on each condition.[12]

Measurements of Aggregation Rate. A Union stopped-flow spectrophotometer (Tokyo, Japan) with a 1 cm path length cell was used in the measurements. In this apparatus, the liquids to be mixed are contained in two syringes. By using a pressure actuator, equal volumes (1.5 ml) of each solution are reproducibly mixed within a very short time (10 ms). The turbidity of the mixture can be recorded on an attached recorder and the initial slope of the optical density (A) *vs.* time (t) curves can be measured. The CFC-value can be determined by plotting the logarithm of the reciprocal slope (log dt/dA) against log c, where c is the coagulant concentration. The measurements are carried out at room temperature and at a wavelength of 517 nm.

Electrophoresis. The electrophoretic mobilities of large vesicles were determined at various pH values in an aqueous solution at 25 °C. The measurements were performed in a Rank brother micro-electrophoretic apparatus (MK-2) using a rectangular glass cell.

Adsorption Experiments. Ten ml of vesicle dispersion (0.05 g/dl) were mixed with the various salt solutions containing different ion concentrations and left standing for one night at 25 °C. Only the vesicle particles were separated from the medium by ultrafiltration (Millipore PTGC) and the concentration of metal cations remaining in the filtrate as well as in the initial solution was measured analytically by means of the Inductively Coupled Argon Plasma Method (Jarrell-Ash 975). From the difference in the concentration before and after the adsorption process, the amounts of adsorption per unit of the vesicle weight (Ap) were calculated.

Membrane Potential Measurements. Monolayers of phospholipids were prepared by spreading chloroform–methanol (3:1) solution of phospholipid on the surface of subphase solution at the neutral pH in 80 ml Teflon trough. After a concentrated salt solution containing the metal cations was added to the subphase solution, the subphase solution was stirred for more than 30 min with a glass-sealed needle (5 mm length) by means of a magnetic stirrer. Thereafter, the surface potentials of the monolayer were measured as a function of salt concentration with a vibrating electrode against an Ag–AgCl reference electrode. All the monolayers used in these experiments have a packing density of 1/60(molecule/Å).

Results and Discussion

Static Method. In Fig. 1, some typical turbidimetric titration curves of PS vesicles with an added $ThCl_4$ aqueous solution are shown as a result of changing the vesicle concentration (C_p). As the titration proceeds, the vesicle dispersion begins to become turbid and the transmittance reaches a minimum at a certain titrant volume (V_{min}), from which we can calculate the CFC for each condition by connecting for the total volume of the sample solution and the added titrant. The V_{min} (or CFC)-value is much dependent on the C_p and the plot of the V_{min} (or CFC) against the C_p shows a straight line passing through the origin as shown in Fig. 2. This indicates that PS vesicles are quantitatively coagulated with Th^{4+} ions. We previously found that phosphatidylcholine (PC) vesicles are also coagulated quantitatively with trimethylammonium glycol-chitosan iodide (TAGC) and concluded that the vesicle coagulation with TAGC is based on a new salt-linkage formation between the phosphate group of PC and the trimethylammonium group in TAGC.[15] From the colloid chemical aspect, this phenomena can be explained as follows: The negative charge on the vesicle particle is neutralized by the adsorption of Th^{4+} ions, and the vesicle particles with zero-charge start to coagulate by the London-Vander Waals attraction forces.[13] In Fig. 2, a relation between the CFC and the C_p of PE vesicles is also plotted. A comparison of these two curves, reveals that the CFC for PS vesicles is always higher than the value of PE vesicles at a constant C_p. This difference will be based on the molecular structure of these phospholipids; the PS molecule has two species of the acidic polar groups (carboxyl and phosphate groups), and the PE molecule has only one group (phosphate group). Therefore, to complete the charge neutralization of the PS molecule, twice the number of cations will be necessary compared to

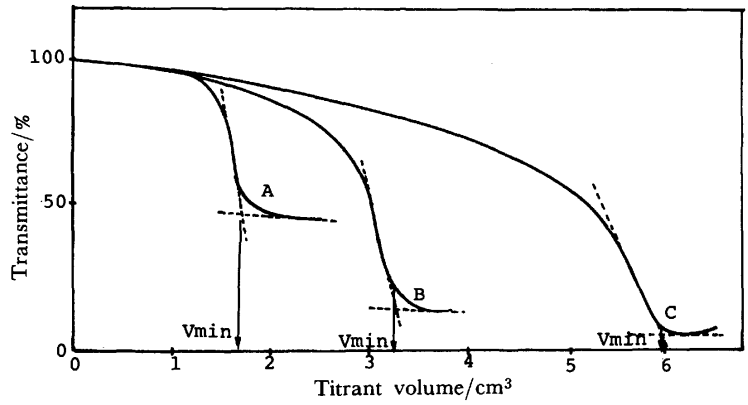

Fig. 1. Typical turbidimetric titration curves of PS vesicles with $ThCl_4$ solution. A: C_p=0.014 g/dl, B: C_p=0.0423 g/dl, C: C_p=0.0750 g/dl.

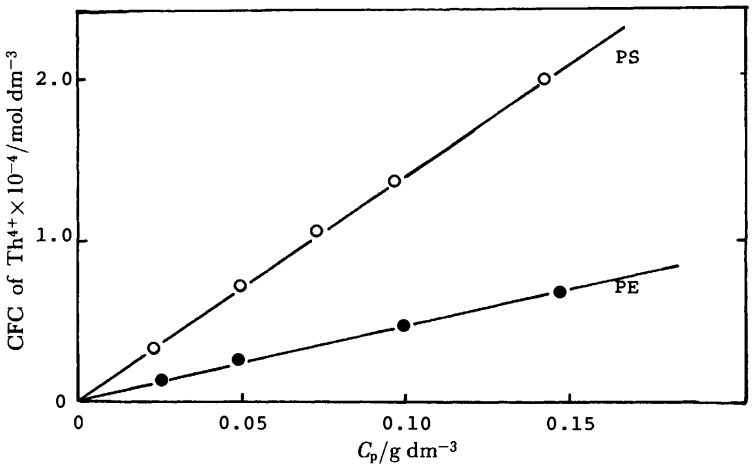

Fig. 2. Relations between the CFC of $ThCl_4$ and the C_p of PS and PE vesicles (pH 4.0).

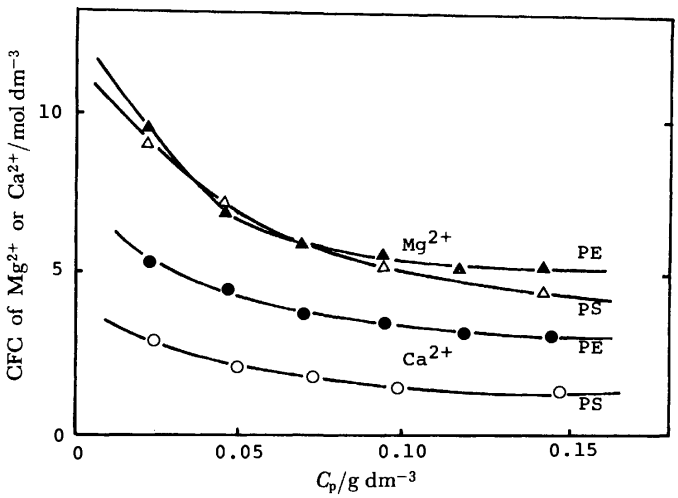

Fig. 3. Relations between the CFC of divalent cations and the C_p of PS and PE vesicles (pH 4.0).

the PE molecule. The tendency of Fig. 2 accords approximately with this assumption, and indicates again that the vesicle coagulation in these systems will be based on the charge neutralization of polar groups on the vesicle surface.

In Fig. 3, the relations between the CFC of divalent cations and the C_p of PE and PS vesicles are plotted. In contrast to Fig. 2, all the curves are decreasing with increasing the C_p. It means that a vesicle suspension with a high C_p can be coagulated by a lower salt solution than the suspension with a low C_p. Furthermore, the relation between the CFC-values of PE and PS vesicles is the reverse of the relation in Fig. 2. These results will oblige us to adopt a different coagulation mechanism from one in Fig. 2. The new mechanism will be an interparticle binding (or an interparticle bridging) caused by the addition of a divalent cation. Existense of the new mechanism is also confirmed by observation of the vesicle aggregates formed by the addition of the various metal cations, *i.e.*, the aggregates formed by Th^{4+} are compact and relatively small flock, while the aggregates formed by Ca^{2+} are large and loose in structure. The existence of two such aggregation mechanisms will be based on the different binding affinity of the added metal cations. Figure 4 shows the initial slope of adsorption isotherms of various metal cations to PE vesicles. The

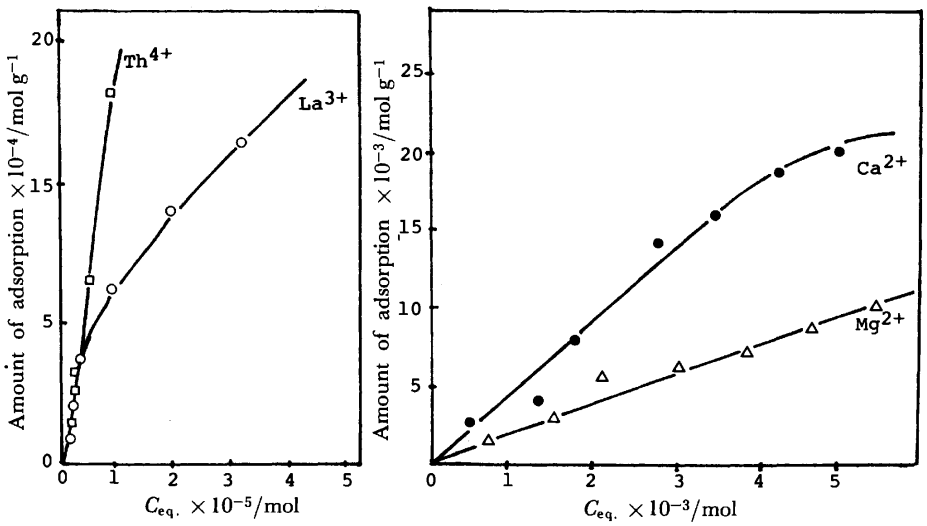

Fig. 4. Initial slope of adsorption isotherms of various metal cations to PE vesicles.

affinity is much dependent on the valence of the cation and especially Th^{4+} and La^{3+} ions show high affinities. From a comparison of Fig. 4 with Fig. 2(or Fig. 3), it is apparent that Th^{4+} or La^{3+} ion with a high adsorption affinity causes the vesicle aggregation due to the charge neutralization, and Ca^{2+} or Mg^{2+} ion with a moderate affinity brings to the aggregation based on the interparticle bridging. In the latter mechanism, the aggregation efficiency will increase by increasing the particle concentration, which is the same tendency with the result found in Fig. 3. Furthermore, this analysis explains reasonably the difference of coagulation behavior of Ca^{2+} and Mg^{2+} ions (see Fig. 3), *i.e.*, Ca^{2+} will make a bridge in higher efficiency than Mg^{2+} by its high adsorption affinity and such a tendency will appear definitely on PS vesicles with two acidic groups. Thus, Ca^{2+} ion has a lower CFC than Mg^{2+} ion, especially for PS vesicles.

Kinetic Method. Figure 5 shows some typical curves of optical density (A) *vs.* time (t), obtained by adding $CaCl_2$ aq solution to PE vesicles. In this figure, the salt concentrations indicated are the final concentrations after mixing by the stopped-flow method. It is clear from these curves that the initial portions are sufficiently linear in agreement with theoretical expectations.[16] The deviation from linearity is due to the non validity of the assumption that the scattering from aggregates is the same as that from spherical particles of the same total weight. By increasing the salt concentrations, the initial slope increases until finally a maximum region is attained where the coagulation rate becomes independent over the wide range of salt concentrations. The CFC is easily determined by plotting the logarithm of the reciprocal slope at the initial time (log dt/dA) which is proportional to the theoretical stability ratio,[13] against log c, where c is the coagulant concentration. In Fig. 6, the plots of log dt/dA *vs.* log c are given for PE and PS vesicles using $CaCl_2$ as the coagulant. The curves obtained are not of the forms predicted by the simple stability theory. They are linearly decreasing in the slow coagulation range and, after staying at a minimum value, they increase again in the high concentration region of $CaCl_2$. Each inflection point in the slow coagulation range is nearly equal to the CFC obtained from the turbidimetric titration.

The occurrence of the minimum stability ratio can be explained in terms of the interparticle bridging of Ca^{2+} ion, because the particle coagulation due to the bridging is a bimolecular process, the rate must be proportional to the product, $\theta(1-\theta)$, of the fraction of covered (θ) and uncovered ($1-\theta$) with adsorbed Ca^{2+} ions.[17] As may be seen in Fig. 6, the experimental points for both vesicles lie within experimental error on a parabola, corroborating the bimolecular coagulation,[18] *i.e.*, the rapid coagulation rate in the middle concentration region, changes again to the slow rate to lose the fraction of uncovered particle. The difference in

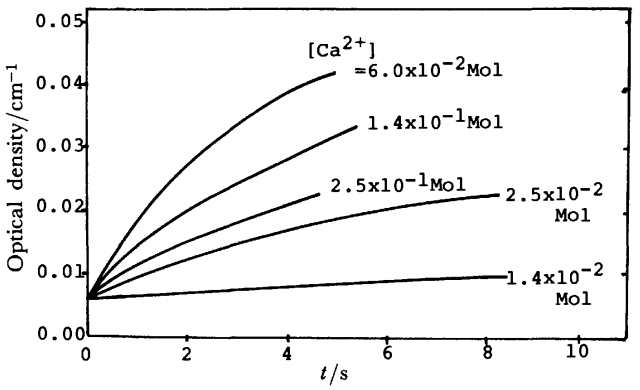

Fig. 5. Optical density (A) *vs.* mixing time curves for PE vesicles.

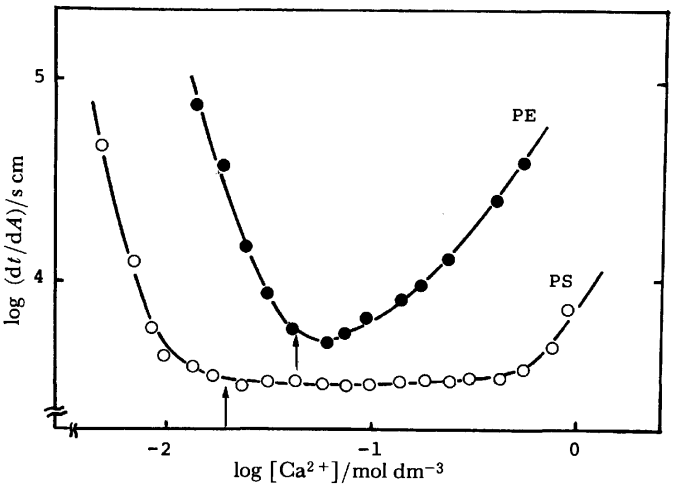

Fig. 6. Plots of logdt/dA *vs.* log[Ca^{2+}] for PE and PS vesicles (pH 4.0)

the stability curves of PE and PS vesicles in Fig. 6, may be explained by the different adsorption capacities of Ca^{2+} for both vesicles. In other words, the number of adsorption sites on PS vesicles is more than the site on PE vesicles. This is testified by the measurements of membrane potential for PE and PS monolayers. Figure 7 shows the membrane potential change (ΔV) of both monolayers with respect to the $CaCl_2$ concentration. Increasing the $CaCl_2$ concentration induces a gradual increase in ΔV and above 5×10^{-2} mol, the ΔV attains respective plateaus which will be proportional to the number of adsorption sites of Ca^{2+}. As may be seen from Fig. 7, the number of sites on the PS membrane is about double number of sites on the PE monolayer, which is an essential reason why PE and PS vesicles would take different aggregation behavior. Further, the detailed analysis between the experimental points of stability and the theoretical curve, will be discussed in the next paper of this series.

In Fig. 8, the stability curves for PE and PS vesicles using $LaCl_3$ are given. The curves of stability, especially for PS vesicles, have a form predicted from the simple stability theory,[19] *i.e.*, it is linear in the slow coagulation range and becomes parallel to the abscissa in the rapid coagulation range. However, the stabil-

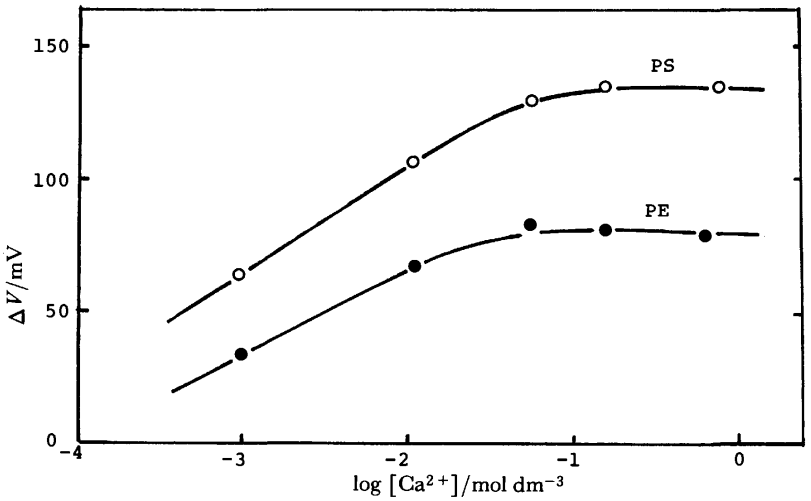

Fig. 7. Membrane potential change (ΔV) of PS and PE monolayers with $CaCl_2$ concentrations (pH 6—pH 8, 25°C).

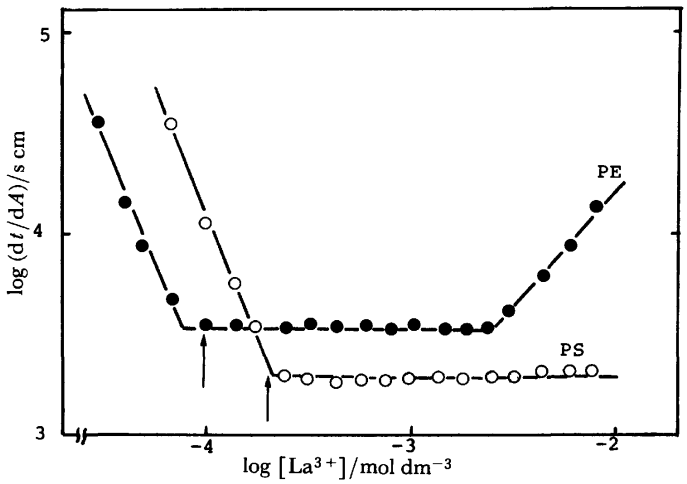

Fig. 8. Plots of log dt/dA *vs.* log[La^{3+}] for PE and PS vesicles (pH 4.0).

ity curve for PE vesicles has a slightly different form from the curve for PS vesicles, and is scarcely increased again in the high concentration region of the salt. As the vesicle coagulation with $LaCl_3$ is based on charge neutralization of polar groups on the surface, this difference between PE and PS vesicles in Fig. 8, must be explained in terms of electrostatic interaction between the particles. Figure 9 shows of zeta-potential *vs.* log molar concentration of $LaCl_3$ for PE and PS vesicles. As the concentration of $LaCl_3$ increases, the zeta-potential gradually decreases with the different slope in PE and PS vesicles; PS vesicles kept slightly negative values until the concentration of 1×10^{-2}mol $LaCl_3$, while, PE vesicles approach to zero and finally become to positive zeta-potential at the same $LaCl_3$ concentration. These electrophoretic results for PE vesicles suggest that the stability behavior in Fig. 8 is due to the reversal of vesicle charge. On the other hand, PS vesicles hardly reverse their electric sign and continue a low stability value over the wide range of $LaCl_3$ concentrations.

In conclusion, it may be said that the usual coagulation technique in the colloid chemistry is the best suitable for studying the properties of the membrane surface, and this gives important knowledge on the conformation and functionality of the polar head groups on the surface of the membrane.

The Dispersion Stability of Colloidal Particles in Dioxane-Water Mixtures

Kazuhiko KANDORI,* Kijiro KON-NO, and Ayao KITAHARA
Department of Industrial Chemistry, Institute of Surface and Colloid Chemistry, Science University of Tokyo, Kagurazaka 1-3, Shinjuku-ku, Tokyo 162
(Received May 24, 1984)

The dispersion stability of titanium dioxide particles and two kinds of iron(III) oxide particles in dioxane-water mixtures was studied as a function of the dielectric constant(ε=2.2—78). The sedimentation of dispersions, the adsorption of sodium 1,2-bis(2-ethylhexyloxycarbonyl)ethanesulfonate (Aerosol OT or AOT) on the particles, and the zeta potential were measured. In the absence of AOT, the dispersions of all the particles were rapidly flocculated over all of the region of the dielectric constant, and little effect of the dielectric constant on the dispersibility was observed. In the presence of AOT, however, the dispersions of all the kinds of particles used were stabilized at both the lower(ε=2.2) and higher(ε=60—78) regions of the dielectric constant by the adsorption of AOT on the particles. However, the flocculation was accelerated for all kinds of particles, and AOT molecules were not at all, or scarcely, adsorbed on the particles in the middle region of the dielectric constant(ε=10—50). This behavior of the dispersibility corresponded with the results of the dynamic light scattering of the AOT solution, which reveal the aggregation of AOT molecules at various dielectric constants. The zeta potential changed from a positive sign to a negative sign with the increase in the dielectric constant, and the isoelectric dielectric point (IED), which means a zero value of the zeta potential, appeared. The order of the values of IED among the three kinds of particles agrees with the order of the isoelectric points(IEP) of the particles. This result can, therefore, be explained by the concept of the acid-base interaction between a particle and a solvent in dioxane-water mixtures.

The theory of the stability of colloidal dispersions in water based on the DLVO theory[1] has been extended to that in nonpolar organic media, and many data on the stability in nonpolar organic media have been accumulated for spherical particles, such as titanium dioxide.[2-7] On the other hand, the dispersion stability of pigments in polar organic media, (*e.g.*, magnetic paints) has recently drawn much attention. The dispersibility of the needle-like particles of iron oxide is very important for magnetic paints. The present authors have previously studied the stability of dispersions of magnetic and nonmagnetic iron(III) oxides and carbon-black particles in 2-butanone as a polar organic medium.[8-11] However, it is difficult to explain the dispersion stability of colloidal particles in several polar organic media, because there are some differences in the characteristics, *i.e.*, the dielectric constant, the solubility parameter, the viscosity, the density, and so on. Lyklema *et al.* have investigated the properties of the electric double layer of the silver iodide particles in a water-ethylene glycol mixture by means of the parameter of the dielectric constant.[12-14] In their study, the dielectric constant, however, was only varied between 38 and 78, and the dispersion stability in the region of low dielectric constants, especially in nonpolar organic media, was not discussed.

In this paper, the dispersions of two kinds of needle-like particles of Fe_2O_3-A, B and the spherical particle of TiO_2 for comparison in dioxane-water mixtures were used in order to discuss the effect of AOT as a dispersant. The dielectric constant of dioxane-water mixtures has been reported by Fuoss *et al.*[15] Systems of dioxane-water mixtures have various advantages; for example, water and dioxane mix in all proportions, so that it is possible to connect the aqueous and nonaqueous (nonpolar) systems.

Experimental

Materials. Two kinds of needle-like iron(III) oxides, A and B, and spherical titanium dioxide (Ishihara Sangyo Co., NR, rutile-type) were used. The two kinds of iron(III) oxides A and B, were prepared according to the references.[16-18] The properties of these three samples are shown in Table 1. They were purified by washing with solvents[8-11] and stored in a desiccator before use.

The dioxane used as a solvent was purified and dried from the GR-grade sample as usual and finally treated with Molecular Sieve 4A to remove any trace of water. The deionized water was distilled in Pyrex glass. The conductivity of the water used was less than 1×10^{-6}mho·cm^{-1}. The AOT used as a dispersant was purified according to an extraction method using a mixture of solvents.[19]

Preparation of Dispersions. The dispersions in media of

TABLE 1. PROPERTIES OF THREE KINDS OF PARTICLES

Sample	Class	Shape	Specific surface area (m^2/g)	Axis length or diameter (Å)	Density (g/cm^3)
Fe_2O_3-A	α-Fe_2O_3	Needle	108	1610×142	3.9
Fe_2O_3-B	α-Fe_2O_3	Needle	10.3	6770×765	3.9
TiO_2	Rutile	Spherical	3.1	2330	4.2

various dielectric constants were prepared under ultrasonic irradiation at 20 kHz 150 W for 5 min. The particle concentration was 0.2 wt%. The dielectric constant of the dispersion medium was changed by changing the mixing ratio of dioxane and water.[15]

Estimation of Dispersion Stability. The stability of a dispersion was estimated by means of the sedimentation experiment described in previous papers;[8-11] *i.e.*, the sedimentation velocity is the gradient of the time profiles of the sharp boundary between supernatant and sediment.

Measurement of Adsorption of AOT and Zeta Potential. The amount of adsorption was determined from the measurement of the equilibrium concentrations of AOT in the supernatant with an ultraviolet spectrometer (UV-200S, Shimadzu Co.).[11]

The zeta potential was measured by microelectrophoresis with the laser Zee TM Model 500 (PEN KEM Co.).[8-11]

Measurement of Dynamic Light Scattering. Dust and other extraneous matter were excluded from the solvents through a millipore filter (pore size=0.2 μm). The scattered light of each sample solution was measured in a cell which had been rinsed repeatedly with dust-free ethanol. The hydrodynamic radius of a micelle (r_h) was calculated from Einstein-Stokes' equation ($r_h=kT/6\pi\eta D$). The diffusion coefficients (D) for various dielectric constant solutions of AOT were measured by means of a dynamic light-scattering instrument at 30±0.1 °C. The wave length of the Ar laser used was 4880 Å.

Calculation of Potential Energy

The potential energy between particles at various dielectric constants was calculated according to the following equations in order to evaluate the dispersibility of three kinds of particles. The needle-like particles (A and B of Fe_2O_3) used in this study were assumed to be cylindrical, and parallel interaction was considered only for the cylindrical particles, because it is clear that parallel interaction is more predominant than head-tail interaction between the cylindrical particles.[9,20]

Three kinds of potential energies of the interaction between a pair of particles were considered; steric repulsion between adsorbed layers (V_R^{en}), electrostatic double-layer repulsion (V_R^{el}), and van der Waals attraction (V_A^L or V_A^δ). They are expressed in the following equations (1)—(6).

For Needlelike Particles: *i)* Steric repulsion between adsorbed layers: Here, Ottewill-Walker's equation was utilized:[21]

$$V_R^{en} = \frac{2kTC_v^2}{v_1\rho_2^2}\cdot(\psi_1-\kappa_1)\cdot V, \tag{1}$$

where V is the total volume of the overlapping zone of the adsorbed layer; C_v, the concentration of AOT in the adsorbed layer; v_1, the molecular volume of a solvent; ρ_2, the density of AOT, and ψ_1 and κ_1 the entropic and enthalpic parameters of mixing proposed by Flory.

ii) Electrostatic double-layer repulsion:[9,20]

$$V_R^{el} = \frac{\varepsilon\sqrt{h\kappa}\Psi_0^2}{2\pi}\left[\frac{2}{3}\left(\frac{1}{\exp(\kappa H+1)+1}-\frac{1}{\exp(\kappa H)+1}\right)\times(1+3\kappa H)+2\left\{\left(\frac{1}{\exp(\kappa H)+1}-\frac{1}{\exp(\kappa H+1)+1}\right)\kappa H+\frac{1}{\exp(\kappa H)+1}\right\}+1.142\exp(-\kappa H)-2\exp(-\kappa H-1)\right], \tag{2}$$

where h is the radius of the cylinder of a needlelike particle, H is the shortest distance between the particle surface, and κ is the reciprocal Debye length, expressed as follows:

$$\kappa = \sqrt{\frac{8\pi n\bar{Z}^2e^2}{\varepsilon kT}}. \tag{2}'$$

Equation (2), introduced under an assumption of $\kappa h>1$ in the previous paper,[9] was assumed to be useful for the system of the dielectric constant at ε=2.2 ($\kappa h<1$). This assumption is permissible because the contribution of this repulsion is comparatively small in nonpolar organic media.[20]

iii) Van der Waals attraction:[1]

$$V_A^L = -\frac{A}{48\pi}\left\{\frac{1}{(H/2)^2}+\frac{1}{(H/2+h)^2}-\frac{2}{(H/2+h/2)^2}\right\}, \tag{3}$$

where A is the Hamaker constant of the oxide in dioxane–water mixtures. Here, the effect of the adsorbed layer was neglected.

For the Spherical Particle (TiO_2): *i)* Steric repulsion between adsorbed layers:[21]

$$V_R^{en} = \frac{4\pi kTC_v^2}{3v_1^2\rho_2^2}\cdot(\psi_1-\kappa_1)\cdot\left(\delta-\frac{H}{2}\right)^2\cdot\left(3a+2\delta+\frac{H}{2}\right), \tag{4}$$

where H is the shortest distance between the particle surfaces, a, the radius of a particle, and δ, the thickness of an adsorbed layer.

ii) Electrostatic double-layer repulsion:[22]

$$V_R^{el} = \frac{\varepsilon a\zeta^2}{2}\ln\{1+\exp(-\kappa H)\}, \tag{5-1}$$

$$V_R^{el} = \frac{\varepsilon a^2\zeta^2}{2a+H}\exp(-\kappa H), \tag{5-2}$$

where ζ is the zeta potential. Eq. (5-1) and Eq. (5-2) were used for the dispersion systems of ε=10—78 and ε=2.2 respectively.

iii) Van der Waals attraction: Here Vold's equation was used, considering the effect of the adsorbed layer:[23]

$$V_A^\delta = -\frac{1}{12}\left\{(\sqrt{A_{22}}-\sqrt{A_{33}})^2\frac{a+\delta}{H}+(\sqrt{A_{33}}-\sqrt{A_{11}})^2\frac{a}{H+2\delta}+4a(\sqrt{A_{22}}-\sqrt{A_{33}})(\sqrt{A_{33}}-\sqrt{A_{11}})\frac{a+\delta}{(H+\delta)(2a+\delta)}\right\}, \tag{6}$$

where A_{11}, A_{22}, and A_{33} are the Hamaker constants of the TiO_2, a solvent, and the AOT adsorbed respectively.

Results

Effect of AOT on the Stability. In order to examine the effect of the AOT concentration on the dispersibility and the zeta potential, measurements of the sedimentation and zeta potential were carried out in dioxane (ε=2.2) and water (ε=78) systems for the three kinds of particles. The dependence of the sedimentation velocity and the zeta potential on the AOT concentration for Fe_2O_3-A is shown as an example in Figs. 1(a) and (b). The dispersion stability of both systems is markedly improved by the addition of a small amount of AOT. Similar results were also observed for the Fe_2O_3-B and TiO_2 particles.

The zeta potential showed a maximum in the curves for the dioxane system at the AOT concentration of 3mM (1M=1 moldm^{-3}), which approximately coincides with the concentration at which the dispersion stability was attained. On the other hand, it suddenly increased to a constant value upon the addition of a small amount of AOT to the water system.

Effect of Dielectric Constant on the Dispersibility. In order to examine the effect of the dielectric constant on the dispersibility and the zeta potential, measurements of the sedimentation and the zeta potential were carried out for various dielectric constants for the three kinds of particles. Here, the systems were examined in both the absence and presence of 20mM AOT. The dependence of the sedimentation velocity and the zeta potential on the dielectric constant is shown as the series of (a) and (b) in Figs. 2, 3, and 4.

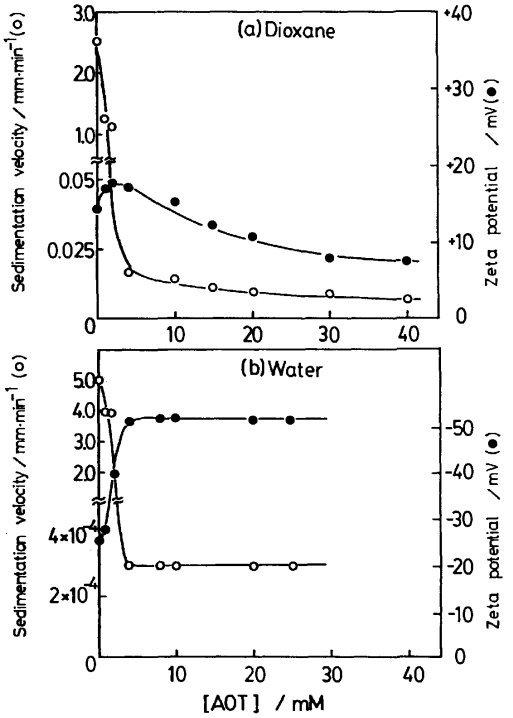

Fig. 1. Plots of the sedimentation velocity and zeta potential *vs.* AOT concentration of Fe_2O_3-A particles for dioxane system(a) and water system(b).

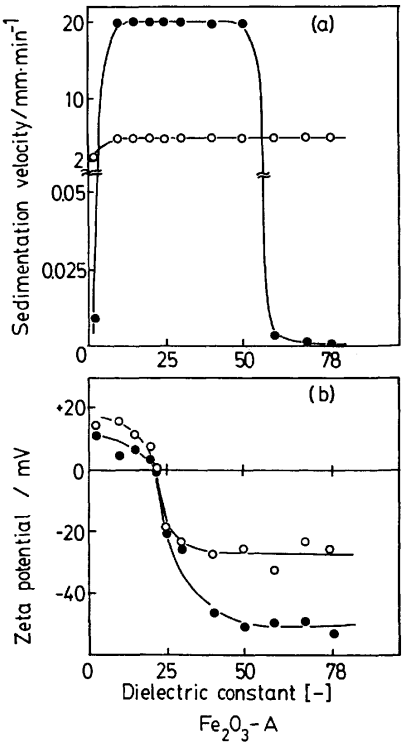

Fig. 2. Change of the sedimentation velocity(a) and zeta potential(b) as a function of the dielectric constant for Fe_2O_3-A particle.
O: In the absence of AOT, ●: In the presence of AOT.

The effect of AOT on the stability of the dispersion is remarkable; the sedimentation velocity is very low in the regions of the lower (at ε=2.2) and higher dielectric

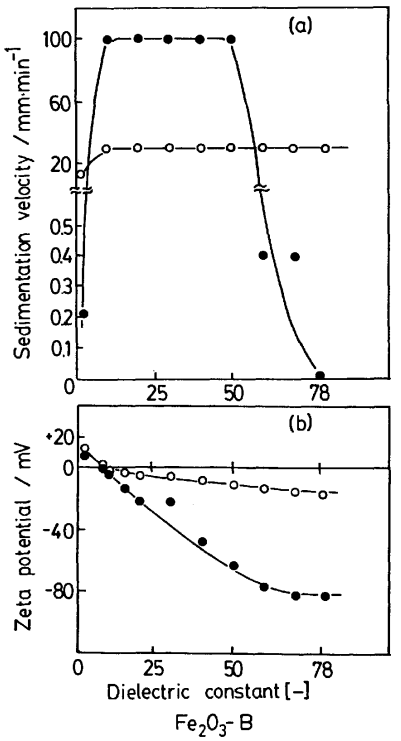

Fig. 3. Change of the sedimentation velocity(a) and zeta potential(b) as a function of the dielectric constant for Fe_2O_3-B particle.
O: In the absence of AOT, ●: In the presence of AOT.

○: In the absence of AOT, ●: In the presence of AOT.

constants (at ε=60—78), but it suddenly increases in the middle region of the dielectric constants (at ε=10—50). This characteristic flocculation of particles in the presence of AOT had previously been observed for carbon-black particles in polar organic media (2-butanone; ε=15.45).[20] On the other hand, in the absence of AOT, the sedimentation velocity is approximately constant, showing the occurrence of considerable flocculation over all of the regions of dielectric constants for the three kinds of particles.

Figures 2, 3, and 4 show that the value of the zeta potential is inverted from a positive sign to a negative sign with the increase in the dielectric constant and that it converges to the zeta potential of the water system for all of the particles. The absolute value of the zeta potential in the presence of AOT is larger than that in the absence of AOT above the isoelectric dielectric point (abbreviated as IED). The order of the magnitude of IED is as follows:

$$Fe_2O_3\text{-B}\ (8) \ll Fe_2O_3\text{-A}\ (22) < TiO_2\ (24). \qquad (A)$$

The figures in brackets show the IED. It is noticeable that the zeta potentials are approximately equal in the neighborhood of the IED for the systems in both the presence and absence of AOT. This result corresponds with the results of the adsorption experiment, which will be shown in Fig. 5.

Effect of Dielectric Constant on Adsorbability of AOT. The adsorption isotherms of AOT for the Fe_2O_3-A particle at various dielectric constants are shown in

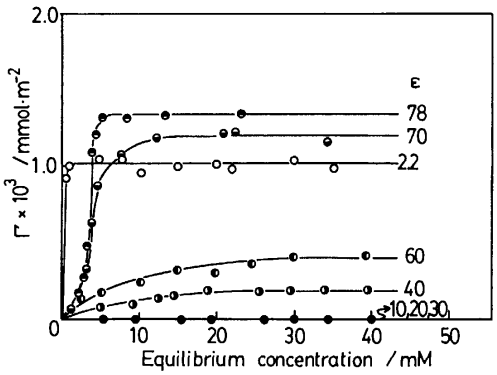

Fig. 5. The adsorption isotherms of AOT for Fe_2O_3-A particle at the various dielectric constants.

TABLE 2. THE DIFFUSION COEFFICIENT (D) MEASURED BY A DYNAMIC LIGHT-SCATTERING METHOD AND THE RESULTING HYDRODYNAMIC DIAMETER (d_h) OF MICELLES AT THE VARIOUS DIELECTRIC CONSTANTS

ε (—)	η (cP)	n (—)	$D\times10^6$ (cm²/s)	d_h (Å)
2.2	1.087	1.4221	1.83	22.0
10	1.445	1.4060	—	—
20	1.672	1.3926	4.08	6.4
30	1.673	1.3807	5.11	5.2
40	1.538	1.3696	2.06	13.8
50	1.339	1.3595	2.10	15.4
60	1.139	1.3493	2.04	18.8
70	0.945	1.3392	1.62	28.4
78	0.894	1.3300	1.65	29.8

Fig. 5. It is characteristic that AOT molecules are not adsorbed in the region of ε=10—30. Furthermore, in the region of ε=40—60, the adsorption isotherms are of the Langmuirian type, but their initial slopes are low and the saturation values of adsorption (Γ_m) are smaller than that of ε=2.2. On the other hand, in the region of ε=70—78, the adsorption isotherms are S-shaped, but the saturation values are higher, belonging to Type I in the Gile-MacEwan-Nakhwa-Smith classification.[24] Hence, in the region of ε=70—78, the most probable orientation of the first layer is with the nonpolar group outside, while the second layer is adsorbed by interchain cohesion with nonpolar groups and ionic groups outside. This observation agrees with the dispersibility of the particles and the zeta potential as shown in Figs. 2, 3, and 4. The amount of AOT adsorbed on Fe_2O_3-B and TiO_2 could not be measured by the ultraviolet method because of their low specific surface areas.

Effect of Dielectric Constant on Micelle Formation. The diffusion coefficient (D) and the hydrodynamic diameter of micelles (d_h) at various dielectric constants, as obtained by the dynamic light-scattering method, are listed in Table 2. As may be seen in Table 2, the values of d_h at ε=2.2, 70, and 78 are 22, 28.4, and 29.8Å respectively. Hence, it can be considered that AOT molecules form the reversed micelles at ε=2.2 and ordinary micelles at ε=70 and 78, because the length of a AOT molecule is approximately 15Å.

On the other hand, the diffusion coefficient (D)

TABLE 3. NUMERICAL VALUES OF Γ_m, C_v, v_1 AND δ USED FOR EQS.(1) AND (4)

ε (−)	$\Gamma_m \times 10^3$ (mmol/m²)	C_v (g/cm³)	v_1 (cm³)	δ (Å)
2.2	1.02	0.302	1.46×10^{-22}	15
10	0	0	1.26×10^{-22}	0
20	0	0	1.09×10^{-22}	0
30	0	0	9.40×10^{-23}	0
40	0.19	0.056	8.00×10^{-23}	15
60	0.41	0.122	5.40×10^{-23}	15
70	1.20	0.178	4.20×10^{-23}	30
78	1.35	0.200	3.00×10^{-23}	30

could not be measured at ε=10, and the values of d_h are very small at ε=20 and 30. These facts suggest that AOT molecules do not form micelles, but exist as monomers. The values of d_h are 13.8—18.8Å in the region of ε=40—60. This suggests that a small part of the AOT molecules associates as dimers or trimers. This change in the aggregation of AOT with the dielectric constant agrees with the results of Elworthy *et al.* for lecithin[25] and Kitahara *et al.* for AOT.[26]

Potential Energies of the Three Kinds of Particles. The dispersibility of the three kinds of particles at various dielectric constants in the presence of 20mM of AOT could be evaluated quantitatively from the magnitude of the total potential energy by the use of Eqs. (1)—(6).

The numerical values used for each equation were as follows: In Eqs. (1) and (4), $\psi_1-\kappa_1=0.1$,[27] a=1165Å and ρ_2=1.0g/cm³,[28] while C_v was calculated from the following equation for each particle: $C_v=\Gamma_m/\delta\cdot S_o$, where δ is the thickness of the adsorbed surfactant molecules and S_o is the specific surface area of each particle. Γ_m, C_v, v_1, are δ are listed in Table 3. The amount of AOT adsorbed for Fe_2O_3-B and TiO_2 could not be measured, but it was assumed that the values of Γ_m for the two particles were equal to that for the Fe_2O_3-A particle. In Eqs. (2) and (5), ζ and κ are listed in Table 4. Here, κ was calculated for each particle from Eq. (2)′ with the ion concentration (n) obtained from the electric conductivity (k). The values of k and κa and κh are also listed in Table 4. Here, Walden's law was adopted for the system of the solvent mixture.[14] In Eqs. (3) and (6), the Hamaker constants were as follows. The values of A, 4.6×10^{-20}J, in Eq. (3) for the Fe_2O_3 particle were calculated from the following equation: $A=(\sqrt{A_{11}}-\sqrt{A_{22}})^2$. $A_{11}=22.6\times10^{-20}$J for the TiO_2 particle,[29] $A_{22}=5.9\times10^{-20}$J for the solvent[29] (the values of water and dioxane are equal), and $A_{33}=2.5\times10^{-20}$J for the adsorbed layer.[27]

The results of the calculation for the three kinds of particles are shown in Figs. 6, 7, and 8 as the respective potential energy curves respectively. The dispersibility of the three kinds of particles and the effect of the dielectric constant can be discussed quantitatively on the basis of these results.

Discussion

Effect of AOT on the Dispersibility in Dioxane and Water System. As may be seen in Fig. 1(a) and (b), the dispersion stability of the dioxane and water systems is markedly improved by the addition of a small amount of AOT (4—5mM). This concentration is of the same order as the critical micellar concentrations of AOT in dioxane and water, which are 5mM and 5.5 mM respectively.[30] Furthermore, at these concentrations of AOT, the adsorption reaches saturation for both systems, as is shown in Fig. 5. This correspondence illustrates the effect of AOT molecules adsorbed on the Fe_2O_3-A particles in both systems.

The appearance of the maximum of the zeta potential in the dioxane system (in the nonpolar system), as is seen in Fig. 1(a), may be explained as follows. At a lower concentration of AOT, the counter ions of the AOT molecules (Na^+) are preferentially adsorbed on the particle, thus increasing the positive change of the zeta potential, followed by the adsorption of the negative ion ($-SO_3^-$), which decreases the zeta potential as the concentration of AOT increases.[31]

Effect of AOT on the Dispersibility of Three Kinds of Oxides at Various Dielectric Constants. As may be seen from the series of (a) in Figs. 2, 3, and 4, the effect of AOT is remarkable for all the particles. This fact is correlated with the adsorbability and micelle formation of AOT molecules, as may be seen in Fig. 5

TABLE 4. THE RESULTS OF ζ- POTENTIAL AND κ FOR THE THREE KINDS OF PARTICLES OBTAINED FROM THE ELECTRIC- CONDUCTIVITY METHOD AT VARIOUS DIELECTRIC CONSTANTS (20mM AOT system)

ε	ζ-potential(mV)			k	κ	Fe_2O_3-A	Fe_2O_3-B	TiO_2

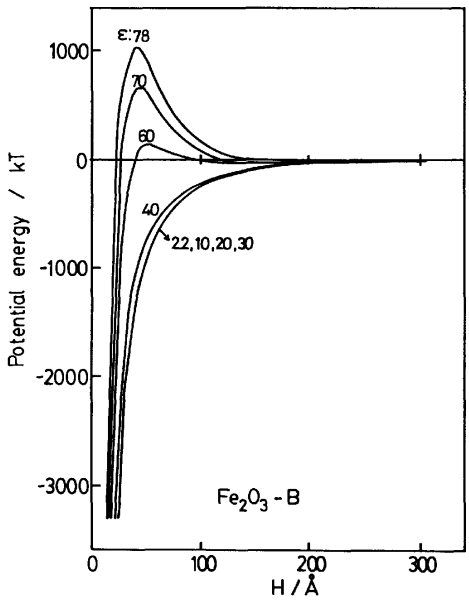

Fig. 7. Potential energy curves for Fe_2O_3-B particle.

and Table 2.

The flocculation of particles in the middle region of the dielectric constants in the presence of AOT is considered to be due to the following reasons. AOT molecules are not at all (at ε=10—30) or only a little (at ε=40, 60) adsorbed on the particle surface (Fig. 5). Hence, the particles can not be stabilized by the steric repulsion of the adsorbed layer of AOT. Therefore, the counter ion (Na^+) works as an indifferent ion in the middle region of the dielectric constant and the electric double layer is compressed.[20] This fact can be seen from κ in Table 4. Therefore, the particles can not be stabilized by the electric double-layer repulsion, either.

As may be seen in Figs. 6, 7, and 8, the potential curves for the three kinds of particles are very similar. That is, in the lower region of the dielectric constants (ε=2.2—40), the potential energy is attractive for all

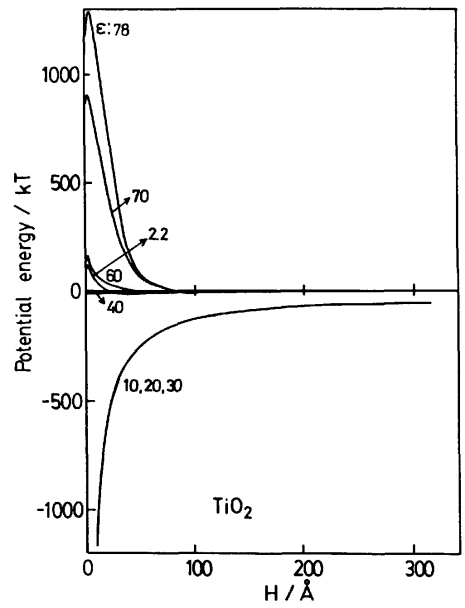

Fig. 8. Potential energy curves for TiO_2 particle.

distances, and the maxima of the potential curves do not appear except at ε=2.2 for the TiO_2 system. On the other hand, in the region of higher dielectric constants (ε=60—78), the maxima of the potential energy (V_{max}) appear in the potential curves. Moreover, the V_{max} increases with the increase in the dielectric constant. These results agree with the results of the dispersion stability of the three kinds of particles, as may be seen in Figs. 2, 3, and 4, except that ε=2.2 for A and B particles of Fe_2O_3. Furthermore, these results also agree with the results of the adsorbability and micelle formation of AOT molecules, shown in Fig. 5 and Table 2, except for ε=2.2. The exception at ε=2.2 is due to the use of Eq. (2) for cylindrical particles at ε=2.2, though $\kappa h<1$, as is shown in Table 4.

Concept of IED. The appearance of IED as seen in Figs. 2, 3, and 4 would be considered on the basis of the concept of acid-base interaction between a particle surface and a solvent as follows. The surface charge is caused by the acid-base interaction between a particle surface and a solvent expressed as Eq. (7):[22]

$$SH_2^+ + OH^- \overset{(a)}{\rightleftharpoons} SH + H_2O \overset{(b)}{\rightleftharpoons} S^- + H_3OH^+, \quad (7)$$

where SH is the surface of a particle and H_2O is either a solvent itself or the water contained in a solvent. If a particle surface is more basic than a solvent, reaction(a) occurs to make the surface positive. In the opposite case, reaction(b) occurs to make the surface negative.

In the region of lower dielectric constants (lower than IED), reaction(a) will occur to make the zeta potential positive, because dioxane is a weakly basic solvent.[32,33] With the increase in the concentration of water, reaction(a) will shift to reaction(b) to make the zeta potential negative, because water is a strongly basic solvent.[34] Hence, the appearance of the IED for all of the particles is considered to result from the shift of

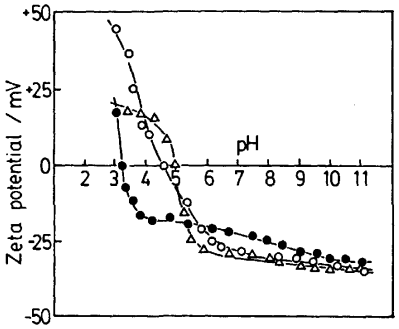

Fig. 9. Change of the zeta potential with pH of the dispersion medium at 20°C.
○: Fe_2O_3-A, ●: Fe_2O_3-B, ▲: TiO_2.

the reaction from (a) to (b).

Comparison of IED for Three Kinds of Particles. The result of (A) expressing the difference of IED can be explained by the following discussion using the above idea of acid-base interaction. The isoelectric points (IEP) of the three kinds of particles were also measured in order to evaluate the acidity or basicity of each particle. This experiment was done by the measure of the zeta potential under the change in the pH of a dispersion medium by the use of aqueous solutions of 10^{-3}M NaOH and 10^{-3}M HCl. The effect of the ionic strength on the zeta potential was neglected in order to see the zeta potential quantitatively.

The changes in the zeta potential with the pH for the three kinds of particles are shown in Fig. 9. The order of the magnitude of the IEP in Fig. 9 is as follows:

$$Fe_2O_3\text{-B}\ (3.2) < Fe_2O_3\text{-A}\ (4.5) < TiO_2\ (5.0), \qquad (B)$$

IEP can be explained by the concept of an acid-base interaction between a particle and a solvent containing the potential-determining ions (H^+, OH^-).[35] The surface of the Fe_2O_3-B particle is more acidic than that of the Fe_2O_3-A particle. Moreover, the surfaces of Fe_2O_3-A and B are more acidic than TiO_2 particle. This differences is probably due to the conditions of the preparation of the particles and the treatment of the particles.[36,37]

The order of the magnitude of result (A) agrees very well with result (B). Therefore, the order of IED can be explained by the concept of acid-base interaction between a particle surface and a solvent.

The authors wish to express their thanks to Dr. Kenji Kubota and Professor Yasunori Tominaga, Department of physics, Faculty of Science, Ochanomizu Women's University, for measuring the dynamic light scattering.

Stability Constants of Scandium Complexes. II. Dicarboxylate Complexes Species

Hisako Itoh, Yukihiro Ikegami, and Yasuo Suzuki*
Department of Industrial Chemistry, Faculty of Engineering, Meiji University, Higashi-mita, Tama-ku, Kawasaki 214
(Received April 14, 1984)

The stability constants of scandium complexes with malonate, maleate, itaconate, glutarate, adipate, and succinate ligands were determined titrimetrically at 25.0 °C and at an ionic strength of 0.1. The chelate effect was negligible for the stability of the scandium complexes with the dicarboxylate ligands studied in contrast with the lanthanoid complexes. The complex formation of scandium might be explained by an electrostatic ionic bond similar to ones exhibited in the lighter rare-earth complexes, due to linear relationships between the stability constants and the ionic potential Z^2/r.

Scandium has been known for almost one hundred years, although its chemistry, particularly its coordination chemistry, has been little studied. In 1970, a review[1] was given on its coordination chemistry. The lack of attention has probably been due to the difficulty, until recently, of obtaining a pure source, though the metal and the oxide are now commercially available in high purity.

In our previous paper,[2] stability constants of scandium complexes with some monobasic acids were reported and compared with those of the lanthanoid complexes. The constants of the scandium complexes were appreciably greater than those of the corresponding lanthanoid complexes, as expected from the smaller ionic radius. The scandium complexes were thought to be similar to the lighter rare-earth complexes with regard to coordinating characteristics and to the degree of cationic hydration. In this study, the stability constants of scandium complexes with some dicarboxylic acids were determined titrimetrically and compared with those of the lanthanoid complexes.

Experimental

Reagents and Apparatus. A scandium nitrate solution was prepared as described previously.[2] Stock solutions of dicarboxylic acids were prepared using analytical reagents and were standardized by potentiometric titration with a standard solution of sodium hydroxide. The pH-measuring system consisted of an Orion model 701A digital pH/mV meter, an Orion 91-01 glass electrode and a Beckman 39400 reference electrode. The instrument is capable of measuring the pH of a solution with an accuracy of 0.001 unit.

Procedure and Calculations. To determine the stability constants, solutions containing a ligand acid, scandium nitrate and potassium nitrate were titrated with standard sodium hydroxide. The solutions were stirred continuously and the temperature was maintained at 25.0 °C during the titrations. Sufficient time was allowed between successive additions of the base in order to obtain constant pH readings. The titrations were continued until precipitation occurred. The constants were calculated by the Bjerrum method.[3] The values of $\bar{n}$ and [A] calculated by the following equations were taken at or near $\bar{n}$=0.5 and 1.5,

$$[A] = \frac{(2-a)A_t - [H] + [OH]}{2[H]^2/K_{a1}K_{a2} + [H]/K_{a2}}$$

$$\bar{n} = \frac{A_t - ([H]^2/K_{a1}K_{a2} + [H]/K_{a2} + 1)[A]}{M_t},$$

where [A] is the concentration of free ligand acid, $\bar{n}$ is the ligand number, A_t and M_t are the total concentration of the ligand acid and scandium metal, respectively, K_{a1} and K_{a2} are the first and second dissociation constants of the acid, respectively, and a is the mole number of the sodium hydroxide added to one mole of the ligand acid. The acid-dissociation constants were determined in a similar way to the stability constants, as described above.

Results and Discussion

Depending on the basicity and the content of hydroxyl and iminodicarboxyl groups, organic ligands exhibit different stabilities and different numbers of binding sites. When only carboxyl and hydroxyl groups are present, the ligands are usually bidentate, tridentate and, in some cases, monodentate. Monobasic acids, including those containing hydroxyl groups, form complexes of the type ScL^{2+}, dibasic acids form ScL'^{+}, while the formation of the acid ion $ScHL''^{+}$ is characteristic of tribasic acids.

The acid-dissociation constants obtained are listed in Table 1. The experimental data for the titrations of the stability constants are shown as plots of $\bar{n}$ *vs.* log[A]

Table 1. Dissociation constants of dicarboxylic acids

Acid	pK_{a1}	pK_{a2}
Malonic acid	2.69	5.48
Maleic scid	1.84	5.83
Itaconic acid	3.68	5.23
Glutaric acid	4.19	5.09
Adipic acid	4.29	5.09
Succinic acid	4.00	5.29

Table 2. Stability constants of scandium complexes

Acid	log K_1		log K_2	
	This work	Previous work	This work	Previous work
Malonic acid	6.78	5.87[4]	5.12	4.25[4]
Maleic acid	5.98	5.34[5]	4.27	
Itaconic acid	4.77		4.00	
Glutaric acid	5.21	4.82[6]	3.70	
Adipic acid	5.25		3.50	
Succinic acid	5.55		3.88

d: Maleate, e: Adipate, f: Itaconate.

in Figs. 1 and 2. In the [A]-region investigated, the first and second complexes were formed and no evidence for the formation of higher complexes was found. Acid complexes were formed for the itaconato complexes, as can be seen from the formation curves and from the stability constants[4] of the lanthanoid-itaconato complexes.

The stability constants obtained are listed in Table 2, together with previously reported values.[5-7] The

values of log K_1 for scandium complexes of some mono- and dicarboxylate ligands are plotted as a function of pK_{a1} for the monocarboxylates and pK_{a2} for the dicarboxylates in Fig. 3. The plots of mono- and dicarboxylate ligands are located on the same straight line, indicating that the chelate effect would be negligible for the scandium complexes and that the hydroxyl groups play an important role in the formation of scandium complexes. The difference of log K_1 of two lines is approximately 3.5, corresponding to a hydrogen-bond energy of about 21 kJ mol^{-1}. The greater stability of ligands containing OH groups compared with those without OH groups would contribute to the intermolecular hydrogen bond between the OH groups and the carboxylate oxygen of the former ligands.

The relationship between the stability constants and ring size is shown in Fig. 4. The stability constant of an oxalato complex (having a five-membered ring)

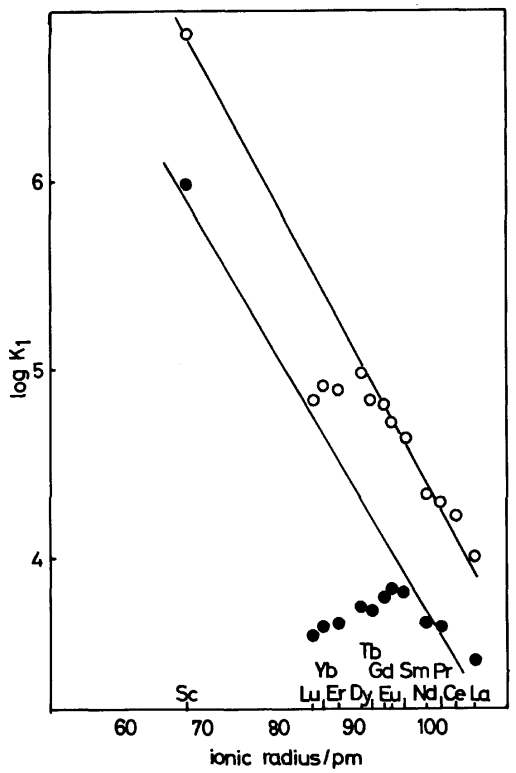

Fig. 5. Relation between stability constants and ionic radius.
○: Malonate, ●: Maleate.

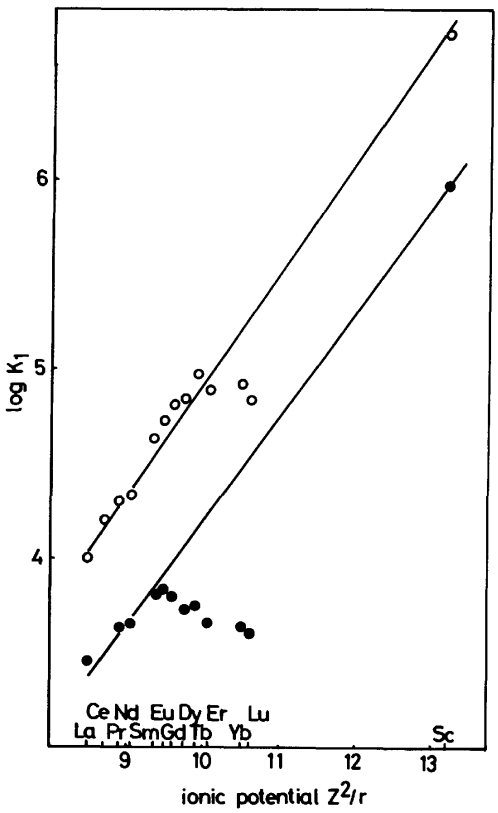

Fig. 6. Relation between stability constants and ionic potential (Z^2/r).
○: Malonate, ●: Maleate.

gives the greatest values (decreasing with increasing ring size). The greater stability of the malonato complex compared to the maleato, glutarato and adipato complexes indicates that the malonato complex forms six-membered rings while the maleato, glutarato, and adipato complexes have seven-, eight-, and nine-membered rings, respectively.

The relation between the stability constant (log K_1) of the scandium and lanthanoid complexes and the ionic radius are shown in Fig. 5. As well as the monobasic acids described before,[2] the stability constants of the scandium complexes with malonic and maleic acids are on the extrapolated lines of the lighter rare-earth complexes rather than those of the heavier rare earths. In the case of the itaconato, glutarato, adipato and succinato complexes, such relationships were not obtained due to a lack of the values for the corresponding lanthanoid complexes.

When a bond between metal and a ligand is purely ionic, the bond strength increases linearly with increasing ionic potential Z^2/r (Z: ionic charge, r: ionic radius), according to Born's equation. The relationships between the stability constants of the rare-earth complexes and the ionic potential are shown in Fig. 6. The linearity was obtained for the scandium and lighter rare-earth complexes, but not for the heavier rare-earth complexes.

Since there is a regular decrease in the crystal radii of rare-earth metal ions, simple electrostatic theory predicts a direct relationship betweeen the atomic number of the rare-earth ion and the stability constants. In nearly all complexes which have been studied, this relationship was precisely found for the values of log K_1 for complexes of the lighter rare earths. This simple relationship was, however, not generally found when the heavier rare-earth ions were considered. The trends in the stability constants for the heavier rare-earth elements can be divided qualitatively into three types. The first group contains those ligands for which there is a regular increase in the values of the stability constants. This does not imply that these ligands follow the simple electrostatic model, since the slope of a plot of log K_1 *vs.* r is usually not the same as for the lighter rare earths. Ligands for which this trend is observed are glycolic, α-hydroxyisobutyric, and mandelic acids. The only obvious similarity among these ligands is that each has at least one OH group. The ligands in the second classification form complexes for which the stability constants of the heavier rare earths have nearly the same values from gadolinium to lutetium. These ligands are acetic, propionic and isobutyric acids. The third group contains dicarboxyllic acids, such as malonic and maleic acids. The stability-constant values for the complexes of these ligands increase with the first elements beyond gadolinium and then show a slight decrease to lutetium. The position of scandium with respect to the relationship between the stability constant and ionic radius is of interest.

The studies with lanthanoid perchlorates and oxygen donor ligands have shown that the coordination number varies with ionic size (values from six to twelve being reported).[8-14] In view of the smaller size of the scandium ion compared with any of the trivalent lanthanoid ions, scandium exhibits a maximum coordination number of six on the low end of the range observed for the heavier rare earths.

The complex formation of scandium with any of the three types of ligands might be explained by an electrostatic ionic bond similar to ones exhibited in the lighter rare-earth complexes, although the coordination number of scandium differs from the lighter rare earths. Other factors besides the purely electrostatic bond might be incorporated in the complex formation of the heavier rare earths.

Studies of the Metal Complexes of Cyclohexane Derivatives. VIII.[1] Preparation and Properties of Platinum(II) and Cobalt(III) Complexes Containing (1*R*,2*S*,3*S*)- or (1*S*,2*R*,3*R*)-3-Methyl-1,2-cyclohexanediamine

Reiko SAITO* and Yoshinori KIDANI†

Aichi Junior College of Nursing, Kamishidami, Moriyama-ku, Nagoya 463

†*Faculty of Pharmaceutical Siences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467*

(Received May 23, 1984)

(1*RS*,2*SR*,3*SR*)-3-Methyl-1,2-cyclohexanediamine (3m-chxn), a methyl derivative of *cis*-1,2-cyclohexanediamine, was prepared and optically resolved. The absolute configurations of the enantiomers obtained were assigned on the basis of the Cotton effect of the *trans*-dichlorobis(diamine) complexes, each containing active 3m-chxn. The complexes of the $[Pt(NH_3)_2L]^{2+}$, $[Pt(en)L]^{2+}$, and $[CoL_3]^{3+}$ types (en=1,2-ethanediamine, L=*R,S,S*- or *S,R,R*-3m-chxn) were also synthesized and characterized on the basis of their absorption, CD, and ^{13}C NMR spectra. It has been found that the chelate rings adopted by *R,S,S*- and *S,R,R*-3m-chxn predominantly take the δ and λ conformations respectively, because of the preferred equatorial orientation of the C_2–C_3 bond of the cyclohexane ring. The four diastereomers of $[Co(R,S,S\text{-3m-chxn})_3]^{3+}$ were chromatographically isolated and assigned to *fac*-$\Lambda(lel_3)$, *mer*-$\Lambda(lel_3)$, *fac*-$\Delta(ob_3)$, and *mer*-$\Delta(ob_3)$.

There have been many studies of the correlation between the conformations of the 1,2-diamine chelate ring and the steric structures of the ligands, but they have almost all been on the effects by the substituents attached to the diamine chelate ring.[2,3] The influences on complex formation of the substituents bonded to the carbon atom outside the chelate ring have not been so widely studied. Recently we ourselves have reported the properties of the complex containing (1*R*,2*S*)-1-aminomethyl-2-methylcyclohexylamine (*R,S*-2m-amcha).[1] The methyl group of this ligand, that is in the β-position to one of the donor atoms, strongly affects the conformation of the chelate ring. The conformation in which the C_1–C_2 bond of the cyclohexane ring is equatorially oriented with respect to the chelate ring is much more favorable than the other one which requires the methyl group to occupy a position over the chelate ring. In this study, we have prepared some Pt^{II} and Co^{III} complexes of (1*R*,2*S*,3*S*)- or (1*S*,2*R*,3*R*)-3-methyl-1,2-cyclohexanediamine (*R,S,S*- or *S,R,R*-3m-chxn). The methyl group is presumed to be situated in an equatorial position in the chair conformation of the cyclohexane ring. Its steric influence on the conformational preference in complex formation is considered to be similar to that of *R,S*-2m-amcha. Another concern of this paper is to obtain experimental data about the properties of the complexes of *cis*-1,2-cyclohexanediamine (*cis*-chxn) derivatives. Little investigatory work has been done on the Pt^{II} and Co^{III} complexes of this series of diamines compared with the *trans*-chxn derivatives.[4–6]

Experimental

Preparation and Resolution of the Ligands. *C*-3-Methyl-4-ene-*r*-1,*c*-2-cyclohexenedicarboxylic acid was prepared according to the procedure in the literature.[7] The reduction of the product with hydrogen in the presence of the rhodium catalyst gave the saturated dicarboxylic acid. A Schmidt reaction[8] of the reduced diacid yielded (1*RS*,2*SR*,3*SR*)-3-methyl-1,2-cyclohexanediamine. Optical resolution was performed using (2*R*,3*R*)-di-*O*-benzoyltartaric acid. From the less soluble diastereomeric salt ($[\alpha]_D=-76°$ (*c* 1.1, CH_3OH)), (+)-3m-chxn·2HCl was isolated. Found: C, 41.77; H, 8.96; N, 13.66%. Calcd for $C_7H_{18}N_2Cl_2$: C, 41.80; H, 9.02; N, 13.93%. $[\alpha]_D=2.9°$ (*c* 10, H_2O). In spite of its low $[\alpha]_D$ value, it is considered to be optically pure and is assigned to (1*R*,2*S*,3*S*)-3m-chxn·2HCl on the basis of the CD spectrum of *trans*-$[CoCl_2((+)\text{-3m-chxn})_2]^+$.[9] The decomposition of the more soluble diastereomeric salt ($[\alpha]_D=-96°$ (*c* 0.43, H_2O)) gave (−)-3m-chxn·2HCl, assignable to (1*S*,2*R*,3*R*). Found: C, 41.60; H, 9.21; N, 13.76%. Calcd for $C_7H_{18}N_2Cl_2$: C, 41.80; H, 9.02; N, 13.93%. $[\alpha]_D=-2.9°$ (*c* 10, H_2O).

Preparation of Complexes. *$[Pt(NH_3)_2L]Cl_2$ and $[Pt(en)L]Cl_2$(en=1,2-ethanediamine, L=*R,S,S- *or* S,R,R-*3m-chxn)*: $[Pt(NH_3)_2L]Cl_2$ and $[Pt(en)L]Cl_2$ were prepared by the reaction of $[PtCl_2L]$ with an aqueous ammonia and an en solution respectively in a manner similar to the procedure in the literature.[10,11] Found: $[Pt(NH_3)_2(R,S,S,\text{-3m-chxn})]Cl_2$, C, 19.26; H, 5.01; N, 12.71%, $[Pt(NH_3)_2(S,R,R\text{-3m-chxn})]Cl_2$, C, 19.02; H, 5.08; N, 12.65%. Calcd for $[Pt(NH_3)_2L]Cl_2\cdot 0.5H_2O=C_7H_{22}N_4Cl_2Pt\cdot 0.5H_2O$: C, 19.23; H, 5.30; N, 12.81%. Found: $[Pt(en)(R,S,S\text{-3m-chxn})]Cl_2$, C, 23.41; H, 5.23; N, 12.41%, $[Pt(en)(S,R,R\text{-3m-chxn})]Cl_2$, C, 23.62; H, 5.30; N, 12.45%. Calcd for $[Pt(en)L]Cl_2=C_9H_{24}N_4Cl_2Pt$: C, 23.79; H, 5.32; N, 12.33%.

trans-*$[CoCl_2L_2]ClO_4$*: An attempt to synthesize these complexes from $CoCl_2\cdot 6H_2O$ and the respective active diamine by the usual air oxidation was unsuccessful. Therefore, they were prepared by a method similar to that used for *trans*-$[CoCl_2(trans\text{-chxn})_2]^+$, using $[CoCO_3(NH_3)_4]NO_3\cdot 0.5H_2O$ as the starting material.[12] The resulting product seemed to be a mixture of *cis*- and *trans*-dichlorobis (diamine) complexes. The expected complexes were obtained by refluxing a methanol solution of a mixture by a method described in the literature.[13] Found: *trans*-$[CoCl_2(R,S,S\text{-3m-chxn})_2]ClO_4$, C, 34.01; H, 6.71; N, 11.13%, *trans*-$[CoCl_2(S,R,R\text{-3m-chxn})_2]ClO_4$, C, 34.39; H, 6.66; N, 11.31%. Calcd for $[CoCl_2L_2]ClO_4\cdot 0.5H_2O=C_{14}H_{32}N_4O_4Cl_3Co\cdot 0.5H_2O$: C, 33.99; H, 6.72; N, 11.32%.

Four Isomers of [Co(R,S,S-*3m-chxn)$_3$]Cl_3*: These complexes

were synthesized in a manner similar to that described previously.[1] The resulting product prepared from *trans*-$[CoCl_2py_4]Cl$ (1.3mmol) and *R,S,S*-3m-chxn (6.5mmol), was adsorbed on SP-Sephadex C-25. This resin was loaded on the top of an SP-Sephadex C-25 column (2.7cm×95cm) and eluted with a 0.2mol/dm³ Na_2SO_4 solution. The four bands which appeared, were named B'-1, B'-2, B-3, and B-4 in the order of elution. The B'-1 and B'-2 bands overlapped each other and contained only a small amount of the complexes. After six chromatographic runs, the combined fractions of B'-1 and B'-2 were evaporated to afford an orange solid. This solid was then chromatographed again using an SP-Sephadex C-25 column (2.7cm×95cm) with a 0.15mol/dm³ Na_3PO_4 solution. Two bands well-separated appeared, they were called B-1 and B-2 in the order of elution. The B-1, B-2, B-3, and B-4 complexes were obtained as chlorides by a procedure similar to that described in a previous report.[1] Yields: B-1; *ca.* 30mg, B-2; *ca.* 60mg, B-3; *ca.* 1300mg, B-4; *ca.* 1600mg. They were dissolved in a small amount of water and recrystallized by adding a 6mol/dm³ hydrochloric acid solution. The B-1, B-2, B-3, and B-4 complexes were obtained as red orange needles, a red orange crystalline powder, an orange crystalline powder, and orange needles respectively. Found: B-1, C, 42.56; H, 8.36; N, 14.11%, B-2, C, 42.28; H, 8.25; N, 14.13%. Calcd for $[CoL_3]Cl_3\cdot 0.5H_2O\cdot HCl=C_{21}H_{48}N_6Cl_3Co\cdot 0.5H_2O\cdot HCl$: C, 42.36; H, 8.46; N, 14.11%. Found: B-3, C, 41.13; H, 9.11; N, 13.86%. Calcd for $[CoL_3]Cl_3\cdot 3.5H_2O=C_{21}H_{48}N_6Cl_3Co\cdot 3.5H_2O$: C, 41.15; H, 9.04; N, 13.71%. Found: B-4, C, 41.88; H, 9.00; N, 14.17%. Calcd for $[CoL_3]Cl_3\cdot 3H_2O=C_{21}H_{48}N_6Cl_3Co\cdot 3H_2O$: C, 41.76; H, 9.01; N, 13.91%.

Measurements: A JASCO J-40 spectropolarimeter and a Shimadzu UV-210-A spectrometer were used to measure the CD and absorption spectra respectively. The optical rotation at 589nm were measured with a JASCO DIP-4 polarimeter. The ^{13}C NMR spectra were recorded on a JEOL JNM-FX-100 spectrometer, with D_2O as a solvent. The chemical shifts were measured with dioxane (δ 67.70ppm) as the internal reference.

Results and Discussion

Conformation of the Chelate Ring of the Pt^{II} Complexes. A representative ^{13}C NMR spectrum of the Pt^{II} complexes prepared in this study is shown in Fig. 1, while the numerical data are given in Table 1. The peak at around 32ppm was assigned to the C_3 carbon by the aid of the off-resonance proton-decoupling technique. The signal at around 27ppm is attributable to the resonance of the C_6 carbon, because it is expected to appear in a lower field than those of the C_4 and C_5 carbons. In the *R,S,S*- or *S,R,R*-3m-chxn Pt^{II} complexes, the C_3 carbon exhibited $^3J_{Pt-C}$ values of 37—38Hz. They were smaller than that of [Pt(bpy)(*trans*-chxn)]$^{2+}$ (52Hz)(bpy=2,2'-bipyridine),[5] whose chelate ring takes a rigid conformation, and also smaller than the two-folded $^3J_{Pt-C}$ values of [Pt(NH₃)₂(*cis*-chxn)]$^{2+}$ and [Pt(en)(*cis*-chxn)]$^{2+}$[14] (25—26Hz)(Table 1). In the *cis*-chxn complex, the two λ and δ conformations are feasibly interconvertible, with a simultaneous inversion of the cyclohexane ring. The $^3J_{Pt-C_3}$ values for the present complexes were found to be almost identical with those of [Pt(bpy)(pn)]$^{2+}$ (38Hz)(pn=1,2-propanediamine)[5] and [Pt(bpy)(2m-amcha)]$^{2+}$ (34Hz).[1] On the other hand, no satellite peaks due to the coupling with ^{195}Pt and the C_6 carbon were observed.

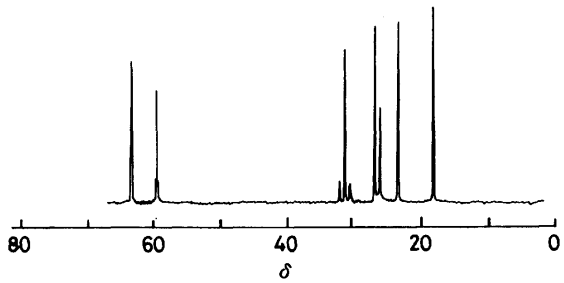

Fig. 1. ^{13}C NMR spectrum of [Pt(NH₃)₂(*S,R,R*-3m-chxn)]$^{2+}$.

The *R,S,S*- and *S,R,R*-3m-chxn ligands are assumed to have the same configuration as that of the *c*-3-methyl-*r*-1,*c*-2-cyclohexanedicarboxylic acid used for the preparation.[7] The possible conformations of *S,R,R*-3m-chxn are shown in Fig. 2. The cyclohexane ring of the ligand is presumed to exist predominantly

a, b: The conformational pair of *S,R,R*-3m-chxn, c, d: λ and δ conformations of *S,R,R*-3m-chxn complex.

in the conformation shown in Fig. 2, a, because the preference for the diequatorial-axial conformation (a) over the diaxial-equatorial conformation (b) seems very reasonable. The λ and δ conformations of the *S,R,R*-3m-chxn complex are also shown in Fig. 2. If the cyclohexane is assumed to take the more stable conformation (Fig. 2, a), then the chelate ring is seen necessarily to exist in the λ conformation (c). The δ conformation (d), in which the cyclohexane ring is assumed to adopt an unstable conformation (b), is disadvantageous. In addition, the steric hindrance caused by the methyl group located above the chelate ring may destabilize the δ conformation. This unfavorable steric effect attributable to the methyl group seemed to be similar to that of the higher-energy conformer of the *R,S*-2m-amcha complex.[1] The empirical result that no $^3J_{Pt\text{-}C_6}$ was detected indicates

that the distribution of the less favorable conformer in the $\lambda \rightleftharpoons \delta$ equilibrium is very small. The smaller ^3J values for the present complexes should be ascribed to the unsymmetrical structure distorted from the idealized gauche form illustrated in Fig. 2, as has been described by Yano *et al.*[15] Therefore, it is concluded that the chelate ring of *S,R,R*-3m-chxn complexes

preferrentially adopts the λ conformation, with the C_2–C_3 bond equatorially oriented.

Absolute Configulation of the Ligands. It has been established that the CD spectra of the *trans*-[$CoCl_2$(1,2-diamine)$_2$]$^+$ complexes, were 1,2-diamine=C-substituted optically active 1,2-diamine, were mainly due to the conformational effect.[16–18] In order to assign the configurations of the resolved (+)- and (−)-3m-chxn ligands, we synthesized the two enantiomers, *trans*-[$CoCl_2$((+)-3m-chxn)$_2$]$^+$ and *trans*-[$CoCl_2$((−)-3m-chxn)$_2$]$^+$. The electronic and CD spectra are shown in Fig. 3, while the numerical results are given in Table 2. The CD signs of *trans*-[$CoCl_2$((−)-3m-chxn)$_2$]$^+$ were observed to be positive in the I_a (16200 cm^{-1}) region and negative in the I_b (21600cm^{-1})

a) Shoulder.

region. Accordingly, this complex was supposed to have the λ conformation, like the *trans*-$[CoCl_2(R\text{-pn})_2]^+$ complex.[17,18] Since the λ conformation is much more favorable for the *S,R,R*-3m-chxn complex than for the *R,S,S*-3m-chxn complex (Fig. 2), the configuration of the (−)-diamine is identified as (1*S*,2*R*,3*R*). The other (+)-ligand is naturally deduced to have the (1*R*,2*S*,3*S*) configuration.

The CD Spectra of the Pt^{II} *Complexes.* The present complexes have two asymmetric carbons, with the *S,R*- or *R,S*- configuration,in their chelate ring, in contrast to the well-studied complexes, which have one *R(S)* or two *R,R(S,S)* chiral carbon(s) in the diamine ring. The electronic and CD spectra of $[Pt(NH_3)_2(R,S,S\text{-3m-chxn})]^{2+}$ and $[Pt(en)(S,R,R\text{-3m-chxn})]^{2+}$ are shown in Fig. 4. The three main bands (Table 3) observed at around 3500, 4100, and 4500 cm^{-1} were tentatively assigned to the $^1A_{1g}\rightarrow{}^3E_g$, $^1A_{1g}\rightarrow{}^1A_{2g}$, and $^1A_{1g}\rightarrow{}^1E_g$ transitions respectively.[4,19,20] According to the assignment by Nakayama *et al.*, however, the last band possibly includes a weak band due to the $^1A_{1g}\rightarrow{}^1B_{1g}$ transition.[21] The Cotton effects of the $^1A_{1g}\rightarrow{}^3E_g$ and $^1A_{1g}\rightarrow{}^1E_g$ transitions of the C-substituted diamine complexes with the *R*-configuration and the λ conformation have been known to be positive. Both the signs and the CD strengths of the ^1E_g and ^3E_g bands in $[Pt(NH_3)_2(S,R,R\text{-3m-chxn})]^{2+}$ and $[Pt(en)(S,R,R,\text{-3m-chxn})]^{2+}$ were similar to those in *R*-pn analogs.[4] These results indicate that, in the above transitions, the contribution to the Cotton effects imposed by the asymmetric α-carbons is small. On the basis of the signs of these bands, two series of Pt^{II} complexes, both containing *S,R,R*- and *R,S,S*-3m-chxn, were found to have λ and δ conformations respectively, as concluded from the CD spectra of the *trans*-$[CoCl_2L_2]^+$ complexes.

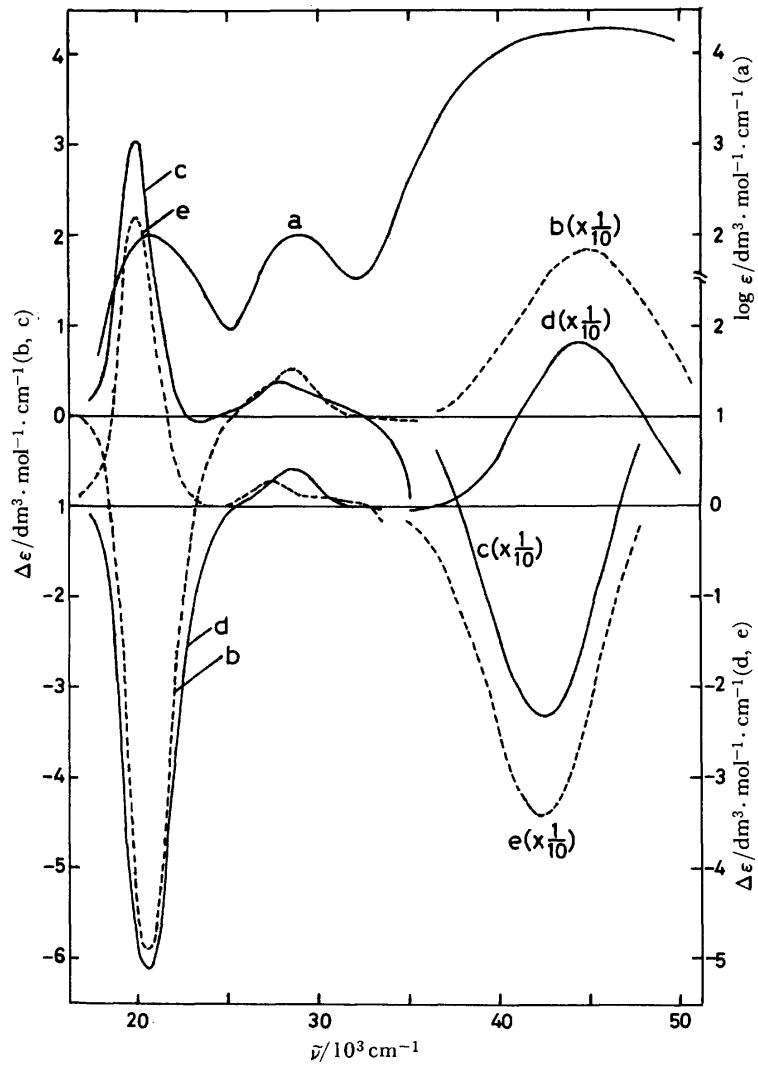

Fig. 6. Electronic spectrum of B-4 (a) and CD spectra of B-1, B-2, B-3, and B-4 (b, d, e, c).
a: *fac*-$\Lambda(lel_3)$-$[Co(R,S,S\text{-3m-chxn})_3]^{3+}$ (B-4), b: *fac*-$\Lambda(ob_3)$-$[Co(R,S,S\text{-3m-chxn})_3]^{3+}$ (B-1), c: *fac*-$\Lambda(lel_3)$-$[Co(R,S,S\text{-3m-chxn})_3]^{3+}$ (B-4), d: *mer*-$\Lambda(ob_3)$-$[Co\text{-}(R,S,S\text{-3m-chxn})_3]^{3+}$ (B-2), e: *mer*-$\Lambda(lel_3)$-$[Co(R,S,S\text{-3m-chxn})_3]^{3+}$ (B-3).

*The Isomers of [Co(*R,S,S-*3m-chxn)$_3$]$^{3+}$.* The [Co(*R,S,S*-3m-chxn)$_3$]$^{3+}$ is expected to contain four isomers. The complexes named B-3 and B-4 were isolated by SP-Sephadex C-25 chromatography, using a Na_2SO_4 solution as an eluent. The isomers named B-1 and B-2, obtained in much lower yields, were not separated from each other with the same eluent.

Figure 5 shows their ^{13}C NMR spectra. Since seven and six signals were observed for the B-1 and B-4 complexes respectively, both complexes were assigned to the *fac*-isomers (C_3-symmetry). Both the B-2 and B-3 complexes were assignable to the *mer*-isomers (C_1-symmetry) because of the inequality of each carbon in their spectra. The resonances for the methine carbon of the *lel* chelate ring in the analogous diamine complexes have been reported to appear in a lower field than those of the *ob* chelate ring.[22,23] The C_1 and C_2 signals of the B-3 isomer appeared at a slightly lower field than those of the B-2 isomer. Similar downfield shifts at the corresponding methine carbons of the B-4 complex were observed compared to the B-3 complex. From these results, in combination with the relative yield, the B-1, B-2, B-3, and B-4 complexes can be assigned to *fac*-(*ob*$_3$), *mer*-(*ob*$_3$), *mer*-(*lel*$_3$), and *fac*-(*lel*$_3$) respectively.

Sakakibara *et al.*[24] reported that the relative rate of the elution of $[CoN_6]^{3+}$-type-complex isomers was influenced by both the interaction between SP-Sephadex and the complex cation and that between the complex cation and the eluent anions, and presented an empirical rule for the elution order of the above type of complexes. However, the present *lel*$_3$ complexes did not follow this rule, being eluted extraordinarily slowly with a Na_3PO_4 solution. This may be caused by the considerably stronger interactions between the complex and SP-Sephadex resulting from the bulky ligand.

The absorption and CD spectra of these complexes are shown in Fig. 6, while the spectral data are summarized in Table 2. The CD spectra of the B-3 and B-4 complexes showed a positive peak in the first-absorption-band region, while those of the B-1 and B-2 complexes showed a very strong negative peak in the same region. Applying the empirical rule on the relationship between the absolute configuration of the tris diamine complex and the CD sign of the first absotption band[25,26] to these complexes, it is concluded that the B-1 and B-2 complexes have the *Δ* configuration, while the B-3 and B-4 have the *Λ* configuration. Since the chelate ring of the *R,S,S*-3m-chxn is restricted to the *δ* conformation, we have assigned the B-1, B-2, B-3, and B-4 complexes to *fac*-*Δ*(*ob*$_3$), *mer*-*Δ*(*ob*$_3$), *mer*-*Λ*(*lel*$_3$), and *fac*-*Λ*(*lel*$_3$) respectively.

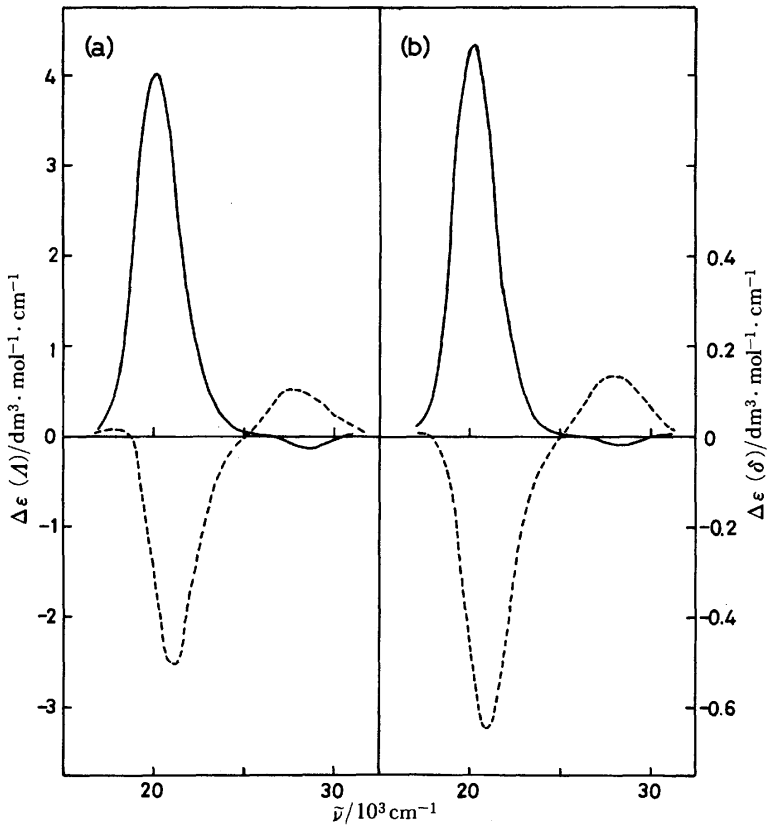

Fig. 7. Configurational effect of CD (*Δ* ε (*Λ*)) (—) and vicinal effect of CD (*Δ* ε (*δ*)) (--) of [Co(*R,S,S*-3m-chxn)$_3$]$^{3+}$.
a—: Calculated *Δ* ε (*Λ*)=1/2{*mer*-*Λ*(*lel*$_3$)−*mer*-*Δ*(*ob*$_3$)}, --: Calculated *Δ* ε (*δ*)=1/6{*mer*-*Λ*(*lel*$_3$)+*mer*-*Δ*(*ob*$_3$)}, b—: Calculated *Δ* ε (*Λ*)=1/2{*fac*-*Λ*(*lel*$_3$)−*fac*-*Δ*(*ob*$_3$)}, --: Calculated *Δ* ε (*δ*)=1/6{*fac*-*Λ*(*lel*$_3$)+*fac*-*Δ*(*ob*$_3$)}.

As is shown in Fig. 7, the configurational and vicinal CD curves derived from the *fac*-isomers resembled the respective curves from the *mer*-isomers. The CD strengths of the vicinal effect of the *tris*(*R,S,S*-3m-chxn) complexes were very similar to those of $[Co(R\text{-pn})_3]^{3+}$,[26-29] and $[Co(R\text{-chxn})_3]^{3+}$.[29] The *R,S,S*-3m-chxn complexes, as well as other related complexes involving cyclohexane rings in their structure, such as $[Co(R\text{-chxn})_3]^{3+}$,[29] $[Co(cis\text{-chxn})_3]^{3+}$,[30,31] and $[Co(R,S\text{-2m-amcha})_3]^{3+}$,[1] showed quite a large configurational effect.

We wish to thank the Instrument Center, Institute for Molecular Science, for the use of a NMR spectrometer (JEOL JNM-FX-100). We are also grateful to Misses Shizuko Iwauchi and Toshiko Naito of the Analytical Center of the Nagoya City University for their elemental analyses.

Studies of the Hydrous Tin(IV) Oxide Ion-exchanger. III. Affinity for Cations and Some Applications

Yasushi INOUE* and Hiromichi YAMAZAKI
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980
(Received June 5, 1984)

The distribution coefficients of hydrous tin(IV) oxide for various cations were measured. The affinity series for alkali-metal ions and alkaline-earth-metal ions were $Li^+ \gg Na^+ > K^+ > Rb^+ \geqq Cs^+$ and $Mg^{2+} > Ca^{2+} > Sr^{2+} \approx Ba^{2+}$ respectively; the values decreased in the order of the increasing crystal radii of the cations. For transition-metal ions, which showed a markedly high affinity, the distribution coefficients had a strong correlation with the hydrolysis constants of the cations and the stability constants of their acetato complexes. Based on these findings, the transition-metal ions are considered to be adsorbed on the exchanger by a bond partially covalent in character, rather than by a pure ionic bond. By using NH_4Cl and $HClO_4$ solutions as eluants, nearly quantitative separations of Cs-Na-Li and Cs-Na-Sr were effected with a relatively small column. The applicability of the exchanger to the group separation of actinoids from long-lived fission products was also suggested.

Through a comprehensive study aimed at preparing a hydrous tin(IV) oxide ion-exchanger, the best conditions for synthesizing the exchanger were established; they have been reported previously. The method has the merits of simplicity and good reproducibility. The exchanger in the H^+ form prepared by this method has a composition of $SnO_2 \cdot 2.18H_2O$ and an ion-exchange capacity of 1.18 mmol Na^+ g^{-1} (at pH 11.3). The adsorption of cations on this material was confirmed to occur by means of an ion-exchange reaction, as shown by the fact that the equivalent amount of the hydrogen ion was released by the uptake of a definite amount of alkali-metal or alkaline-earth-metal ions. The material is an amphoteric ion-exchanger possessing at least two kinds of weakly dissociable ion-exchange sites. Other important properties of the exchanger, such as stability against various chemicals, stability during storage, dependence of the water content on the ionic composition, and physical properties, were also investigated, as has been described in the foregoing reports.[1]

The affinity of the exchanger for various cations is important in understanding the characteristic of the exchanger. There have, however, been only a few reports on the selectivity of the hydrous tin(IV) oxide. Fuller and Donaldson reported this selectivity series: $Cu(II) > Zn(II) > Co(II) \geqq Fe(II) > Ni(II) > Mn(II)$ and attempted the column separation of these transition-metal ions.[2] However, such data for deducing the ion-exchange mechanism are conspicuously lacking at the present time.

The purpose of the present investigation is to understand the cation-exchange reaction of the exchanger through the examination of the distribution coefficients of various cations as a function of the pH, and to show the applicability of the exchanger to the selective separation of actinoids in high-level radioactive waste and to the chromatographic separation of alkali-metal and alkaline-earth-metal ions.

Experimental

Reagents and Apparatus. The hydrogen-ion and sodium-ion forms of the hydrous tin(IV) oxide were prepared by the procedure recommended previously.[1] The exchanger in the Na^+ form was then converted to the NH_4^+ form by means of the column method; a solution of 0.3% NH_3 aq and 0.1 mol dm^{-3} NH_4Cl (pH 10.4) was passed through a column containing the Na^+-form exchanger until no sodium ion was detected in the effluent. The composition of the exchangers thus prepared is shown in Table 1. All the reagents used were of the highest-purity grade obtained from Wako Pure Chemical Industries, Ltd., or E. Merck AG. A well-type NaI (Tl) scintillation counter (Fuji Denki Model NHS-2) was used for the measurement of the γ-radioactivity. All the other apparatuses were the same as described previously.[1]

Distribution Coefficients. The distribution coefficient, K_d, was determined in the following way unless otherwise noted.

A 0.50-g portion of the exchanger in the desired ionic form was placed in contact, in a thermostatted water bath at 25 °C, with 20 cm^3 of a suitable solution containing 1×10^{-4} mol dm^{-3} of the cation in question until the concentration of the cation in the supernatant solution became constant (about 3 to 14 d). The pH and the concentration of the cation in the solution were then measured. The K_d value was calculated by

TABLE 1. COMPOSITION OF THE EXCHANGERS

Ionic form	M^+ content	Water content[1]	Composition (molar ratio)		
	mmol/g M^+form	wt%	SnO_2	M_2O	H_2O
H^+	—	20.51	1	—	2.16
Na^+	1.22	16.81	1	0.116	1.77
NH_4^+	0.86	20.24	1	0.081	1.66

1): Calculated from weight loss when 0.50 g of exchanger was calcinated at 850 °C.

means of the following equation:

$$K_d = \frac{C_i - C_f}{C_f} \cdot \frac{V}{m} \ (\mathrm{cm^3\ g^{-1}}),$$

where C_i and C_f are, respectively, the initial and the final concentration in the solution; V, the volume of the solution in cm^3, and m, the weight of the exchanger in g.

The metal ions were added as their chlorides, except Fe^{3+}, Cr^{3+}, Th^{4+}, and UO_2^{2+}, for which the corresponding nitrates were used. The pH was adjusted by using a desired combination of 0.3 moldm^{-3} $NaClO_4$, and 0.3 moldm^{-3} $HClO_4$ or 0.3 moldm^{-3} NaOH (ionic strength, 0.09). The analyses of Cs, Sr, Ba, Mn, Fe, Co, Cu, Zn, Sc, Y, La, Ce, Eu, Np, and Am were carried out radiometrically using ^{137}Cs, ^{85}Sr, ^{133}Ba, ^{54}Mn, ^{59}Fe, ^{60}Co, ^{64}Cu, ^{65}Zn, ^{46}Sc, ^{88}Y, ^{140}La, ^{144}Ce, ^{152}Eu, ^{239}Np, and ^{241}Am respectively as tracers. Their radioactive purity was confirmed by means of gamma-ray spectrometry. The ^{239}Np tracer was prepared by milking from ^{243}Am by the method of Sill.[3] The oxidation state of neptunium at the tracer concentration was adjusted by the method of Inoue and Tochiyama.[4] The Th^{4+} and UO_2^{2+} were analyzed spectrophotometrically using arsenazo III[5] and 2-(5-bromo-2-pyridylazo)-5-(diethylamimo)phenol[6] respectively as coloring reagents, while the concentration of the other cations were determined by means of atomic-absorption spectrophotometry.

Column Operation. To 2g of the exchanger in the NH_4^+ form was added a suitable amount of the solution used for converting the exchanger to the NH_4^+ form, and the slurry was poured into a glass column, 0.6cm in inside diameter. The column thus prepared had a height of 4.5cm. A solution containing 10 mequivdm^{-3} of the desired cation was passed through the column at a flow rate of 0.1 $cm^3 min^{-1}$.

Results and Discussion

Distribution Coefficients. Figure 1 shows the K_d values for Co^{2+} as a function of the loading at a nearly constant pH value (2.03—2.07). The K_d values were nearly constant lower than 4×10^{-5} mequivg^{-1}, wherefrom they decreased with an increase in the loading of the exchanger.

The cation-exchange reaction between A^+ and M^{n+} is expressed as:

$$n\overline{A}^+ + M^{n+} = \overline{M}^{n+} + nA^+, \quad (1)$$

for which the equilibrium constant, K, can be written as:

$$K = \frac{\bar{a}_M a_A^n}{\bar{a}_A^n a_M} = \frac{\bar{\gamma}_M[\overline{M}]\gamma_A^n[A]^n}{\gamma_M[M]\bar{\gamma}_A^n[\overline{A}]^n}. \quad (2)$$

In Eq. 2, a bar refers to the exchanger phase; a denotes the activity; [ ], the concentration, and γ, the activity coefficient. For the sake of simplicity, the charge in the cations is omitted in this expression. The distribution coefficient of M^{n+} is expressed as:

$$K_d = [\overline{M}]/[M] \ (\mathrm{cm^3\ g^{-1}}). \quad (3)$$

When the amount of M^{n+} uptaken is extremely small as compared with that of A^+ in the exchanger, $\bar{a}_A$ and $\bar{\gamma}_M$ are regarded as constant. Moreover, γ_M/γ_A^n is also constant if the ionic strength of the solution is kept constant. Under such conditions, the following equation holds:

$$\log K_d = \text{const.} - n \log [A], \quad (4)$$

which implies that a plot of log K_d *vs.* log [A] should be linear with a slope of $-n$.

The pH-dependency of the K_d values for Co^{2+}, Sr^{2+}, and Y^{3+} is shown in Fig. 2 for varying concentration of the cations in the solutions. The linear relation between log K_d and pH was observed as predicted from Eq. 4. The slopes of the straight lines, however, depended on the concentration and approached n only when the concentration became extremely dilute: For Co^{2+} and Sr^{2+}, $\leqq10^{-7}$ moldm^{-3}; for Y^{3+}, the tracer concentration. This strong dependency of the K_d values on the concentration of the cations may be ascribed to the limited amount of the cation-exchange sites in the

pH region adopted in the present experiment, since the isoelectric point of the exchanger is around pH 4, as has been reported previously.[1] Because of this observation, it is preferable to use a concentration lower than 10^{-7} mol dm^{-3} in making a strict comparison of the selectivity of the exchanger between various cations. The lack of the sensitivity of the analytical methods for some cations, however, makes this very difficult. As the next best way, the distribution coefficients for various cations were compared at the lowest possible concentration and the constant initial concentration of the cations in solution, 1×10^{-4} mol dm^{-3}.

Figure 3 shows the pH-dependency of the K_d values for uni- and bivalent cations. Based on the selectivity, these cations can be grouped into three classes: transition metal>alkaline earth metal>alkali metal, in the same manner as ion-exchange resin. However, the order of selectivity for the alkaline-earth-metal ions, $Mg^{2+}>Ca^{2+}>Sr^{2+}\approx Ba^{2+}$, is the exact reverse of what would be expected from the ion-hydration theory, which claims that the strength of the electrostatic interaction between a hydrated cation and a fixed anionic group determines the ion-exchange selectivity of the strongly acidic resin; in fact, the selectivity coefficients for ions with the same charge increase with a decrease in the hydrated ionic radius. The selectivity series for transition-metal ions was $Cu^{2+}\geqq UO_2^{2+}>Zn^{2+}\geqq Co^{2+}>Mn^{2+}\geqq Ni^{2+}$. Figure 4 shows the results for tervalent transition-metal ions. When these results are compared with those for bivalent transition-metal ions, the affinity of these ions is not so great as would be expected from their charge. These affinity series, together with those for alkaline-earth-metal ions, show that the selectivity is higher for metal ions of a smaller crystalline radius than for those of a larger one; this cannot be explained by the ion-hydration theory. The slopes of the straight lines were smaller than the expected n, which is predicted from Eq. 4, as is shown in Figs. 3 and 4.

Since the amount of alkali-metal ions uptaken was very small in an acidic medium, a comparison of the affinity for these ions cannot be made by the use of the hydrogen-ion form. Thus, the ion-exchange reactions between Na^+ and the other alkali-metal ions were examined in an alkaline medium, as is shown in Fig. 5. This figure indicates that linear relationships with a slope of −1 held between the log K_d for alkali metal ions and the logarithm of the concentration of Na^+ in the solution; this agrees well with Eq. 4. This agreement appears unreasonable, however, because the decrease in the concentration of Na^+ from 0.1 mol dm^{-3} to 0.01 mol dm^{-3} will increase the activity coefficient of the cations and decrease the concentration of Na^+ in the exchanger. The change in log γ_M/γ_{Na}, however, is estimated to be smaller than 0.02 from the Debye-Hückel equation. The decrease in Na^+ in the exchanger was analyzed and found to be smaller than 0.04 mmol g^{-1}. Consequently, the present experimental conditions satisfy the assumptions made for deducing Eq. 4. Figure 5 also indicates that the order of the selectivity is: $Li^+\gg K^+>Rb^+\geqq Cs^+$. The distribution coefficients for Li^+, Na^+, and Cs^+ on the exchanger in NH_4^+ form were measured by the column method described in the experimental section; the results are presented in Table 2, along with the experimental conditions. The order of the selectivity, $Li^+\gg Na^+>Cs^+$, like that observed in Fig. 5, is the reverse of what would be expected from the ion-hydration theory.

Thus, the ion-exchange reaction may be brought

about by an electrostatic interaction between an unhydrated cation and the negatively charged site in the exchanger, similar to a weakly acidic resin, such as the carboxylic-acid and phosphonic-acid types. Such interaction would be closely related to the ionic potential of the cations. Figure 6 shows the correlation between log K_d at pH 3 and the ionic potential. Here, the ionic radii used were those obtained by using crystals in which the ion has the coordination number of 6,[7] while the log K_d values which could not be obtained by the experiment were those estimated from the extrapolation of the linear log K_d *vs.* pH plot. The correlation coefficient (R) is 0.76. At pH 2 and 4, the R values were 0.65 and 0.83 respectively. Therefore, as a whole, the affinity of the exchanger for various cations is associated with the electrostatic interaction between an unhydrated cation and the anionic site in the exchanger. However, the selectivity series for transition-metal ions deviates markedly from this relation; these ions have high K_d values, even in such an acidic medium as when a negligible amount of the representative element is adsorbed. This finding compels us to consider that factors other than the electrostatic force may play an important part in deciding the selectivity of the exchanger. In order to know such factors, the K_d values for metal ions at pH 3 were compared with their first hydrolysis constants[8] (Fig. 7) and the first stability constants of their acetato

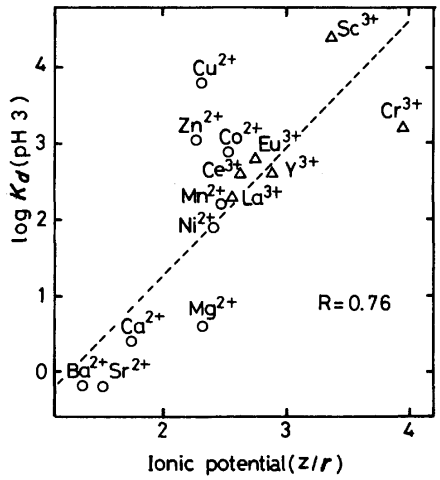

Fig. 6. Relation between logK_d and ionic potential of cation.

complexes[9] (Fig. 8). As can be seen from Fig. 7, the K_d values have a strong correlation with the hydrolysis constant (R_1=0.90). Also, the softness of metal ions as Lewis acid affects the correlation: metal ions with characteristics between hard and soft acids, Cu^{2+}, Zn^{2+}, Co^{2+}, Ni^{2+}, and Mn^{2+}, show larger K_d values than on hard acids, such as uranyl(VI), lanthanoid, and alkaline-earth-metal ions. When metal ions are divided into two such groups, the K_d values can be more closely related to the hydrolysis constants and the first stability constants of acetato complexes (R_2, R_3). Consequently, we can conclude that the formation of a covalent bond between the anionic sites in the exchanger and metal ions plays a part in determining the selectivity of the exchanger, along with the remote coulombic interaction.

The Separation of Actinoids from Fission Products. As the K_d values for UO_2^{2+} are considerably higher than those for other transition-metal ions, it is considered possible to use the exchanger for separating actinoids from fission products in radioactive liquid waste. For this purpose, it is necessary to examine the selectivity for actinoids in a concentrated nitrate medium. Figure 9 shows the pH-dependency of the K_d values for Th^{4+}, UO_2^{2+}, NpO_2^+, NpO_2^{2+}, and Am^{3+} in a 1 mol dm^{-3} nitrate medium at 50 °C. Tracer concentrations of neptunium and americium were used, whereas the concentrations of Th^{4+} and UO_2^{2+} were 9.5×10^{-5} mol dm^{-3} and 1.1×10^{-5} mol dm^{-3} respectively, because of the limited sensitivity of the analytical method used for the present experiment. If we consider the dependency of the K_d values on the concentration (Figs. 1 and 2), the K_d values for these last two elements will be higher than those in Fig. 9 when their concentrations are at a tracer level. Thus, the difference in affinity between Th^{4+} and other actinoid ions is much greater than that shown in Fig. 9. For the same reason, the U(VI) ion shows an affinity higher than that indicated in the figure. The Np(V) ion showed a K_d value higher than 10^4 cm^3 g^{-1} at pH 3 where the uptake of alkali-metal ions was negligibly small. The Np(VI) ion also showed a high affinity, similar to that of the U(VI) ion, but it did not differ so markedly from the Np(V) ion as would be expected from the difference in charge. The high affinities for uranyl and neptunyl species cannot be explained only in terms of the electrostatic interaction between the ions and the anionic sites in the exchanger; it must also be ascribed to the formation of a bond with a partially covalent character, as has been mentiond before. On the other hand, Am^{3+} and Eu^{3+} exhibited almost the same affinity as the Np(VI) ion. Similar to Sr^{2+}, Co^{2+}, or Y^{3+} in a tracer concentration, the slopes of the straight lines of the log K_d *vs.* pH plot were found to be +1 and +2 for the Np(V) and Np(VI) ions respectively. For the Np(VI) ion, the plot deviated from linearity above pH 2.6. This deviation is probably due to a hydrolysis of the ions. The slope of this plot for Am^{3+} and Eu^{3+} was not 3, but about 2, despite the tracer concentration. Korotkin

reported, in his study of the hydrolysis of Am(III) at concentrations lower than 10^{-6} mol dm^{-3}, that Am(III) exists as $Am(NO_3)^{2+}$ in a 0.1 mol dm^{-3} nitrate solution.[10] Based on this view, it may be considered that the nitro complexation is responsible for the behavior of Am^{3+} and Eu^{3+} similar to that of a double-charged cation such as NpO_2^{2+}.

As has been mentiond above, the exchanger exhibits a high selectivity for actinoids in a 1 mol dm^{-3} nitrate

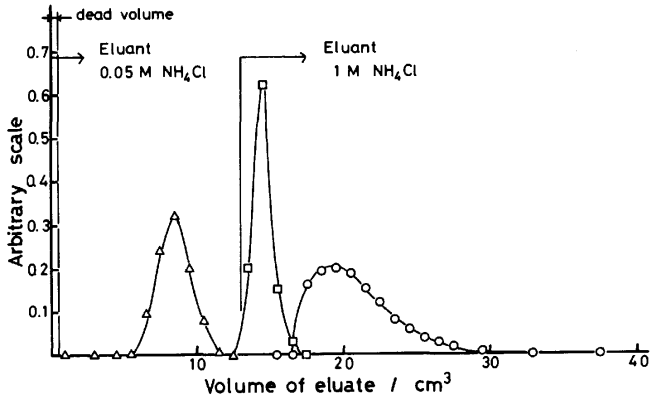

Fig. 11. Separation of Cs^+-Na^+-Li^+ by NH_4^+-form exchanger.

medium, regardless of their oxidation states. Hence, actinoids may be selectively separated from such long-lived fission-products as ^{137}Cs and ^{90}Sr. The uptake of UO_2^{2+} and Sr^{2+}, both of 10^{-3} mol dm^{-3}, was measured in a 1 mol dm^{-3} nitrate medium at varying pH values, as is shown in Fig. 10. This figure shows that UO_2^{2+} could be separated nearly quantitatively from Sr^{2+} by a single-batch-operation at pH 2.8. As the exchanger exhibits a higher affinity for Sr^{2+} than for Cs^+, the quantitative separation of UO_2^{2+} will be much easier from Cs^+ than from Sr^{2+}. These facts suggest the applicability of the exchanger for separating actinoids from ^{137}Cs and ^{90}Sr, which are the major constituents of fission products in aged, high-level liquid wastes.

Separation of Li-Na-Cs and Na-Cs-Sr. In order to confirm the applicability of the exchanger to chromatographic separation, attempts were made to separate Li^+, Na^+, Cs^+, and Sr^{2+} by using the exchanger in a salt form which exhibits different affinities for these ions. The results are presented in Fig. 11. In this experiment, the exchanger in the NH_4^+ form was used. Cs^+ was quantitatively eluted with a 0.05 mol dm^{-3} NH_4Cl solution, while Na^+ and Li^+ were eluted with a 1 mol dm^{-3} NH_4Cl solution, in that order. The yield of the sodium ion was 99% at the eluate volume where Li^+ elution commenced. Lithium ions, however, showed a heavy tailing, which indicates that the neutral solution of ammonium salt was less effective. Figure 12 shows the separation of Na^+, Cs^+, and Sr^{2+}. After Cs^+ and Na^+ had been eluted with the NH_4Cl solution in a manner similar to that shown in Fig. 11, a 0.1 mol dm^{-3} $HClO_4$ solution was passed through, and then the Sr^{2+} was quantitatively eluted with 21 cm^3 of this eluant.

(Received June 25, 1984)

New acetylacetonato (acac) chromium(III) complexes of the type, $[Cr(acac)_{3-n}L_n]^{n+}$ (n=1 and 2), where L denotes a seven-membered chelate ligand, 2,2′-bipyridine *N,N′*-dioxide (bpdo) or 3,3′-dimethyl-2,2′-bipyridine *N,N′*-dioxide (*rac*- or *R*-mbdo), were prepared. Optically active $[Cr(acac)_2(R\text{-mbdo})]^+$ and $[Cr(acac)(R\text{-mbdo})_2]^{2+}$ yielded only one isomer and were assigned to $\Delta(\lambda)(lel)$ and $\Delta(\lambda\lambda)(lel_2)$, respectively, on the basis of the circular dichroism spectra and molecular models. The $[Cr(acac)(mbdo)_2]^{2+}$ complex prepared from *rac*-mbdo formed two racemates of diastereomers, $lel_2(\Delta(\lambda\lambda), \Lambda(\delta\delta))$ and $lel\cdot ob$ $(\Delta(\lambda\delta), \Lambda(\delta\lambda))$, whereas $[Cr(acac)_2(bpdo)]^+$ formed only $lel(\Delta(\lambda), \Lambda(\delta))$ isomer which was resolved by column chromatography. Both *rac*- and $(-)_{589}$-$[Cr(acac)(bpdo)_2](ClO_4)_2\cdot H_2O$ resolved by a chemical method were found to crystallize in lel_2 isomer, but isomerize to the isomer in aqueous solution with the rate of 3.31×10^{-3} s^{-1} at 295.2 K, the rate constant for racemization ($\Delta \rightleftarrows \Lambda$) being 1.08×10^{-4} s^{-1} at 295.2 K. An intramolecular conformational inversion of the bpdo chelate ring for the isomerization and an intramolecular twist mechanism for the racemization were proposed.

In a metal complex, 2,2′-bipyridine *N,N′*-dioxide (bpdo) forms a skew seven-membered chelate ring of which conformation can exist in a pair of enantiomers, δ and λ (Fig. 1).[1] For a tris-bpdo complex, there are four possible racemic pairs of diastereomers (conformational isomers), $lel_3(\Delta(\lambda\lambda\lambda), \Lambda(\delta\delta\delta))$, $lel_2\cdot ob(\Delta(\lambda\lambda\delta), \Lambda(\delta\delta\lambda))$, $lel\cdot ob_2(\Delta(\lambda\delta\delta), \Lambda(\delta\lambda\lambda))$, and $ob_3(\Delta(\delta\delta\delta), \Lambda(\lambda\lambda\lambda))$, and the diastereomerism is analogous to that in $[M(en)_3]^{n+}$ (en=ethlyenediamine).[2] However, it was found that tris-type chromium(III) complexes with bpdo[3] and its derivative, 3,3′-dimethyl-2,2′-bipyridine *N,N′*-dioxide (mbdo)[4] give one and three diastereomers, respectively, and that $[Cr(bpdo)_3]^{3+}$ racemizes spontaneously in aqueous solution.[3] These results indicate that the bpdo chelate ring is flexible and changes its conformation ($\delta \rightleftarrows \lambda$) very easily. On the other hand, the mbdo chelate ring can not change its conformation because of the steric hindrance due to the methyl groups.[4]

This paper describes the preparation and stereochemistry of chromium(III) complexes of the type, $[Cr(acac)_{3-n}L_n]^{n+}$ (n=1, 2; L=bpdo, mbdo). Since the acac chelate ring is assumed to be planar, $[Cr(acac)_2L]^+$ and $[Cr(acac)L_2]^{2+}$ (L=bpdo or mbdo) have two $[lel(\Delta(\lambda), \Lambda(\delta))$ and $ob(\Delta(\delta), \Lambda(\lambda))]$ and three $[lel_2(\Delta(\lambda\lambda), \Lambda(\delta\delta))$, $lel\cdot ob(\Delta(\lambda\delta), \Lambda(\delta\lambda))$, and $ob_2(\Delta(\delta\delta), \Lambda(\lambda\lambda))]$ possible racemic pairs of diastereomers, respectively. In a preliminary paper, we have reported that the $[Cr(acac)(bpdo)_2]^{2+}$ complex isomerizes and racemizes spontaneously in aqueous solution at room temperature.[5] Kinetic studies for these reactions will be also described in detail in this paper.

Experimental

Since the new complexes are photosensitive causing hydrolysis, the following experiments were carried out in the dark.

Preparation and Resolution of $[Cr(acac)_2(bpdo)]^+$ and $[Cr(acac)_2(mbdo)]^+$. The complexes were prepared from $[Cr(acac)_3]$ and bpdo or mbdo according to a method similar to that for $[Cr(acac)_2(phen)]^+$ (phen=1,10-phenanthroline).[6] $[Cr(acac)_3]$ (4.0 g, 11.5 mmol) was added to 90% ethanol (400 cm^3) containing bpdo·H_2O[7] (2.4 g, 11.6 mmol) or racemic mbdo[4] (2.5 g, 11.6 mmol). The solution was adjusted to pH *ca.* 2 with hydrochloric acid and kept at 80 °C with stirring for 2d. The resulting solution was evaporated to a small volume under reduced pressure. The residue was diluted with water (500 cm^3) and the solution was applied on a column (ϕ3.0×50 cm) of SP-Sephadex C-25. The adsorbed species were eluted with a 0.8 mol/dm^3 NaCl solution to give three separate bands. The second green and the last green bands were found to contain bis-bpdo (or bis-mbdo) and tris-bpdo (or tris-mbdo) complexes, respectively. The first violet eluate was collected and mixed with $NaClO_4$ to give violet crystals, which were filtered, washed with a small amount of cold water, and recrystallized from warm water. Yield: bpdo-complex, 3.4g (54%); mbdo-complex, 1.6g (25%). Found for the bpdo complex: C, 44.67; H, 4.00; N, 5.26%. Calcd for $[Cr(acac)_2(bpdo)]ClO_4=C_{20}H_{22}N_2O_{10}ClCr$: C, 44.66; H, 4.12; N, 5.21%. Found for the mbdo complex: C, 46.69; H, 4.62; N, 4.94%. Calcd for $[Cr(acac)_2(mbdo)]ClO_4=C_{22}H_{26}N_2O_{10}ClCr$: C, 46.69; H, 4.63; N, 4.95%. Each of the bpdo and mbdo complexes gave only one racemic pair of diastereomers, no indication for the formation of the other isomer being detected on column chromatograms.

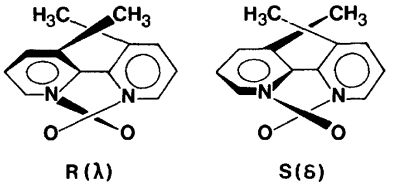

Fig. 1. A pair of enantiomers of mbdo.

The bpdo complex was resolved by DEAE-Sephadex A-25 column chromatography. The perchlorate of the complex (0.08g) was dissolved in water and the solution was applied on a column (ϕ3.8×140cm) of DEAE-Sephadex A-25 in the $[Sb_2(d\text{-tartrato})_2]^{2-}$ form.[8] The complex was eluted with

water, but only one band was observed on the column. However the front and rear fractions of the band showed positive and negative rotations at 546nm, respectively. Each of these fractions was collected separately and chromatographed repeatedly until no further increase in specific rotations at 546nm was observed. Each of the optically pure isomers was isolated as the perchlorate. The $(+)_{546}$- and $(-)_{546}$-isomers showed the following molar rotations in aqueous solutions: $[M]_{546}=+5750°$, $[M]_{546}=-5780°$. Found: C, 43.80; H, 3.94; N, 5.07%. Calcd for $(+)_{546}$-$[Cr(acac)_2(bpdo)]ClO_4\cdot 0.5H_2O=C_{20}H_{23}N_2O_{10.5}ClCr$: C, 43.93; H, 4.24; N, 5.12%.

The resolution of the mbdo complex was not achieved by the same chromatographic method. The optically pure mbdo complex was obtained from optically active mbdo[4] and $[Cr(acac)_3]$.

Preparation of $(+)_{546}$-*[Cr(acac)*$_2$*(R-mbdo)]*$^+$. The complex was obtained by the same method as that for the racemic complex using *R*-mbdo.[4] The perchlorate of the complex was obtained as violet crystals. Found: C, 46.62; H, 4.60; N, 4.75%. Calcd for $(+)_{546}$-$[Cr(acac)_2(R\text{-mbdo})]ClO_4=C_{22}H_{26}N_2O_{10}ClCr$: C, 46.69; H, 4.63; N, 4.95%.

Preparations of [Cr(acac)(bpdo)$_2$*]*$^{2+}$ *and [Cr(acac)(mbdo)*$_2$*]*$^{2+}$. The complexes were prepared by a method similar to that for the above bis-acac complexes using $[Cr(acac)_3]$ (4.0g, 11.5mmol) and bpdo·H_2O (4.8g, 23.3mmol) or racemic mbdo (5.2g, 24.0mmol). The complexes were obtained from the second green band on an SP-Sephadex column chromatograph (ϕ3.0×50cm, 0.8mol/dm^3 NaCl) and isolated as the perchlorate. Yield: bpdo-complex, 2.5g (29%); mbdo-complex, 2.8g (30%). Found for the bpdo complex: C, 40.51; H, 2.91; N, 7.24%. Calcd for $[Cr(acac)(bpdo)_2](ClO_4)_2\cdot H_2O=C_{25}H_{25}N_4O_{15}Cl_2Cr$: C, 40.33; H, 3.39; N, 7.53%. Found for the mbdo complex: C, 42.38; H, 4.35; N, 6.80%. Calcd for $[Cr(acac)(mbdo)_2](ClO_4)_2\cdot 2H_2O=C_{29}H_{35}N_4O_{16}Cl_2Cr$: C, 42.56; H, 4.31; N, 6.85%. For $[Cr(acac)(bpdo)_2]^{2+}$, attempts to separate possible diastereomers were all unsuccessful by column chromatography because of rapid isomerization of the complex (*vide post*). The $[Cr(acac)(mbdo)_2]^{2+}$ complex obtained from racemic mbdo was found to consist of two racemic pairs of diastereomers.[5]

Separation of Diastereomers of [Cr(acac)(mbdo)$_2$*]*$^{2+}$. The $[Cr(acac)(mbdo)_2]^{2+}$ complex (0.05g) was loaded on a column (ϕ2.2×130cm) of SP-Sephadex and eluted with a 0.1mol/dm^3 Na_2SO_4 solution. The column gave two bands, I and II in the order of elution. Each eluate was collected, diluted with water, and applied again on a small column (ϕ2.2×3cm) of SP-Sephadex. The adsorbed complex was eluted with a 1 mol/dm^3 NaCl solution. The eluate was collected and mixed with $NaClO_4$ to give crystals which were recrystallized from warm water. Found for isomer I: C, 42.53; H, 4.46; N, 6.77%. Calcd for $[Cr(acac)(mbdo)_2](ClO_4)_2\cdot 2H_2O=C_{29}H_{35}N_4O_{16}Cl_2Cr$: C, 42.56; H, 4.31; N, 6.85%. Found for isomer II: C, 43.50; H, 3.90; N, 6.77%. Calcd for $[Cr(acac)(mbdo)_2](ClO_4)_2\cdot H_2O=C_{29}H_{33}N_4O_{15}Cl_2Cr$: C, 43.51; H, 4.16; N, 7.00%. The formation ratio, I:II, was about 1:1.

Preparation of $(-)_{589}$-*[Cr(acac)(R-mbdo)*$_2$*]*$^{2+}$. The complex was prepared by the same method as that for the racemic complex using *R*-mbdo and isolated as the perchlorate. Found: C, 43.48; H, 3.96; N, 6.81%. Calcd for $(-)_{589}$-$[Cr(acac)(R\text{-mbdo})_2](ClO_4)_2\cdot H_2O=C_{29}H_{33}N_4O_{15}Cl_2Cr$: C, 43.51; H, 4.16; N, 7.00%. The absorption spectrum of this complex coincides with that of isomer II. The complex corresponding to isomer I was not formed.

Resolution of [Cr(acac)(bpdo)$_2$*]*$^{2+}$. The resolution was achieved by use of the perchlorate of the complex and potassium $(+)_{589}$-tartratoantimonate(III). The resolving agent (0.9g, 1.3mmol) was added to a hot aqueous solution (70°C, 50 cm^3) of the complex (1g, 1.3mmol). The mixture was cooled in an ice bath with stirring to give white precipitate of $KClO_4$. The precipitate was filtered off and methanol (150 cm^3) was added to the filtrate. The resulting solution was cooled in a refrigerator to give green crystals, which were collected, washed with 80% methanol and then methanol, and air-dried. An aqueous solution of these crystals showed a negative rotation at 589nm but lost gradually the activity. Yield: 1.1g. Found: C, 33.63; H, 2.98; N, 4.58%. Calcd for $(-)_{589}$-$[Cr(acac)(bpdo)_2][Sb_2(d\text{-tartrato})_2]\cdot 6H_2O=C_{33}H_{39}N_4O_{24}CrSb_2$: C, 33.84; H, 3.36; N, 4.78%. The crystals were dissolved in a small amount of ice-cold water, and immediately $NaClO_4$ was added to the solution with stirring. Green crystals which resulted were collected, washed with ice-cold water and then ethanol, and air-dried. The complex showed a negative rotation at 589nm in aqueous solution but rapidly lost the activity. Found: C, 40.41; H, 2.94; N, 7.36%. Calcd for $(-)_{589}$-$[Cr(acac)(bpdo)_2](ClO_4)_2\cdot H_2O=C_{25}H_{25}N_4O_{15}Cl_2Cr$: C, 40.33; H, 3.39; N, 7.53%.

Kinetic Runs. All kinetic experiments were carried out in the dark. Both racemic and $(-)_{589}$-$[Cr(acac)(bpdo)_2](ClO_4)_2\cdot H_2O$ in aqueous solutions show a rapid absorption spectral change. The change of absorbance at 620nm was continuously recorded in the temperature range of 15.8—34.6°C on a Shimadzu MPS-50L spectrophotometer with a cell jacket to maintain the temperature constant within ±0.3°C. The pH and ionic strengths of the solutions were adjusted with an aqueous solution of NaCl-HCl. The complex concentrations were in the range of 1.8—2.8mmol/dm^3. The rate of change obeyed the first order kinetic law and the observed rate constant (k_{obsd}) is expressed as follows: $k_{obsd}=-\ln[(A_t-A_\infty)/(A_0-A_\infty)]/t$ where A's are absorbances at the time denoted by suffixes.

A decrease in optical activity at 589nm of $(-)_{589}$-$[Cr(acac)(bpdo)_2](ClO_4)_2\cdot H_2O$ in aqueous solution was observed by similar procedures as described above using a Union PM-101 desital polarimeter. The temperature and the complex concentrations were in the range of 17.2—35.0°C and 1.4—2.5mmol/dm^3, respectively. The complex lost the optical activity in two steps with different rates, the first rapid and the subsequent slow steps (*vide post*).[5] In the latter step, the rate of decrease obeyed the first order kinetic law and the observed rate constant (k_{obsd}) is also expressed by the above equation where A's are degrees of optical rotation.

All kinetic data were treated by a least-squares method and all estimated errors are standard deviations.

Measurements. Absorption and circular dichroism (CD) spectra were recorded on a Shimadzu MPS-50L spectrophotometer and a Jasco J-40 spectropolarimeter, respectively. Optical rotations were measured with a Union PM-101 desital polarimeter.

Results and Discussion

Preparation and Characterization of the Complexes. Four new complexes, $[Cr(acac)_{3-n}L_n]^{n+}$ (n=1 and 2; L= bpdo or mbdo) were prepared from $[Cr(acac)_3]$ and the dioxide ligand in 90% ethanol by a method similar to

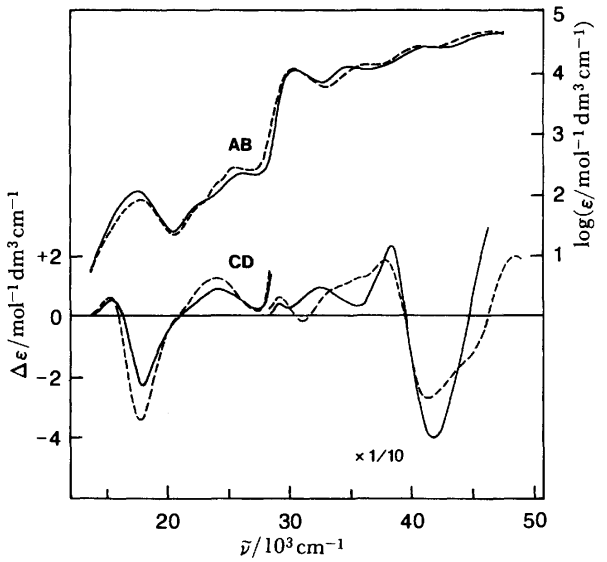

Fig. 2. Absorption (AB) and CD spectra of $(+)_{546}$-$[Cr(acac)_2(R\text{-mbdo})]^+$ (——) and $(+)_{546}$-$[Cr(acac)_2(bpdo)]^+$ (-----) in water.

that for $[Cr(acac)_2(phen)]^+$.[6] Each of the complexes was purified by SP-Sephadex column chromatography and isolated as the perchlorate. The complexes in aqueous solutions are stable in the dark, but undergo gradual hydrolysis in the light.

Both $[Cr(acac)_2L]^+$ complexes of bpdo and racemic mbdo form only one racemic pair of diastereomers of two possible ones, *lel* and *ob*. No indication for the formation of the other isomer was found by column chromatography. The optical resolution of the bpdo complex was achieved by DEAE-Sephadex A-25 ($[Sb_2(d\text{-tartrato})_2]^{2-}$ form) column chromatography with water as an eluent, although repeated chromatography was necessary to obtain the optically pure isomers. On the other hand, the mbdo complex was hardly resolved by the same chromatographic method. Hence the optically pure mbdo complex was prepared from optically active *R*-mbdo.[4] The obtained *R*-mbdo complex gave also only one isomer and its absorption spectrum coincides with that of the racemate prepared from racemic mbdo. The active bpdo and mbdo complexes are optically stable in aqueous solution.

Figure 2 shows the absorption and CD spectra of $(+)_{546}$-$[Cr(acac)_2(R\text{-mbdo})]^+$ and $(+)_{546}$-$[Cr(acac)_2(bpdo)]^+$. The spectral data are given in Table 1. Both absorption spectra are nearly the same over the whole region. The bands at 17530cm^{-1} and 17670cm^{-1} for the mbdo and bpdo complexes, respectively, can be assigned to the first absorption band ($^4T_{2g}\leftarrow{}^4A_{2g}$). The band at *ca.* 26000cm^{-1} for each complex shows a clear shoulder on the low energy side and the band shape is similar to that of $[Cr(acac)_3]$, which was assigned to the $\pi^*\leftarrow\pi$ or $\pi^*\leftarrow n$ transition of acac$^-$.[9,10] The position of the second band ($^4T_{1g}\leftarrow{}^4A_{2g}$) is uncertain because of overlapping with this band. In the ultraviolet region, the complexes exhibit a strong band at 30300cm^{-1} which was also found in $[Cr(acac)_3]$ and assigned to involve both the $\pi^*\leftarrow\pi$ transition of acac$^-$ and the charge transfer (acac$^-$ to metal) transition.[9,10] In the higher energy region, the complexes show three strong bands characteristic of the chelated dioxide ligands.[3,4]

The CD spectra of the two $(+)_{546}$-isomers show a similar pattern over the whole region. This suggests that the isomers have the same absolute configuration including chirality of the skew dioxide chelate ring. The CD patterns in the region of the first absorption band are very similar to those of $(-)_{589}$-$[Cr(acac)_3]$,[11] $(-)_{546}$-$[Cr(acac)_2en]^+$,[10] and $(+)_{589}$-$[Cr(acac)_2tn]^+$ (tn= trimethylenediamine),[12] all of which were reported to have the *Δ* configuration. Thus both $(+)_{546}$-isomers of the dioxide complexes can be assigned to the *Δ* configuration. In the ultraviolet region, the isomers do not show clear exciton CD bands due to two acac$^-$ ligands in the region of 30000 to 35000cm^{-1}.[10-12]

As stated previously, *R*-mbdo forms a *λ* skew chelate ring in a complex.[4] Thus $(+)_{546}$-$[Cr(acac)_2(R\text{-mbdo})]^+$ can be assigned to the *Δ*(*λ*)(*lel*) isomer. The $(+)_{546}$-isomer of the bpdo complex which shows a CD spectrum very similar to that of the *R*-mbdo complex can be assigned to the same isomer. Thus both bpdo and *R*-mbdo complexes form only a *lel* isomer stereoselectively. The $[Cr(en)_2(bpdo)]^{3+}$[3] and $[Co(en)_2L]^{3+}$ complexes (L=2,2′-diaminobiphenyl[13,14] and its 6,6′-dimethyl derivative;[13] these ligands form a skew seven-membered chelate ring similar to the dioxide) give also only a *lel* isomer. On the other hand, bis-(2,2′-bipyridine) and bis(1,10-phenanthroline) chromium(III) complexes containing bpdo or mbdo give only an *ob* isomer.[15] Examination with molecular models indicates that the difference in selectivity seems to come from steric conditions among the ligands.

Although $[Cr(acac)(rac\text{-mbdo})_2]^{2+}$ has three possible racemic pairs of diastereomers, lel_2, *lel*·*ob*, and ob_2, the complex yielded two racemic pairs of diastereomers, isomer I and II. The formation ratio of the isomers, I:II was about 1: 1. On the other hand, the optically active $[Cr(acac)(R\text{-mbdo})_2]^{2+}$ complex prepared from *R*-mbdo gave only one isomer of two possible ones, *Δ*(*λλ*)(lel_2) and *Λ*(*λλ*)(ob_2), and its absorption spectrum coincides with that of isomer II. Since molecular models show that the ob_2 isomer has an extremely crowded structure, the *R*-mbdo complex can be assigned to the *Δ*(*λλ*)(lel_2) isomer. Therefore isomer I and II can be assigned to have the *lel*·*ob* and lel_2 structures, respectively. Attempts to resolve both isomers, I and II, were all unsuccessful. Isomer I and II are stable and the active *R*-mbdo complex is optically stable in aqueous solutions.

Figure 3 shows the absorption spectra of the two isomers of $[Cr(acac)(rac\text{-mbdo})_2]^{2+}$ and the CD spectrum of $(-)_{589}$-$[Cr(acac)(R\text{-mbdo})_2]^{2+}$. The spectral data are given in Table 1. The absorption spectra of the two isomers fairly differ from each other in the visible region, while those in the ultraviolet region are similar. The absorption bands at 17390cm^{-1} with a shoulder

b) The $\Delta\varepsilon$ values were extrapolated to time zero. sh: Shoulder.

(16500cm^{-1}) and at 16180cm^{-1} with a shoulder (17000 cm^{-1}) for isomer I and II, respectively, can be assigned to the first absorption band ($^4T_{2g}\leftarrow{}^4A_{2g}$). The band of isomer II (*lel*$_2$) is more intense than that of isomer I (*lel·ob*). The *lel*$_3$ isomer of [Cr(mbdo)$_3$]$^{3+}$ also shows the most intense and the narrowest first absorption band among those of the three isomers, *lel*$_3$, *lel*$_2$*·ob*, and *lel·ob*$_2$.[4]

Figure 4 compares the absorption and CD spectra of a series of [Cr(acac)$_{3-n}$(*R*-mbdo)$_n$]$^{n+}$ (n=0—3). The first absorption band shifts to lower wavenumbers by replacing acac with mbdo. The intensities of bands in the region from 23000 to 50000 cm^{-1} are related to the number of dioxide and acac ligands. The CD spectra in the region of the first absorption band show a gradual change with an increasing number of n in [Cr(acac)$_{3-n}$(*R*-mbdo)$_n$]$^{n+}$, indicating the same absolute configuration. The $(-)_{589}$-[Cr(acac)$_3$][11] and [Cr(*R*-mbdo)$_3$]$^{3+}$[4] complexes have been assigned to the Δ and $\Delta(\lambda\lambda\lambda)$(*lel*$_3$) configurations, respectively. Thus our preceding assignments of $\Delta(\lambda)$(*lel*) and $\Delta(\lambda\lambda)$(*lel*$_2$), respectively, for [Cr(acac)$_2$(*R*-mbdo)]$^+$ and [Cr(acac)(*R*-

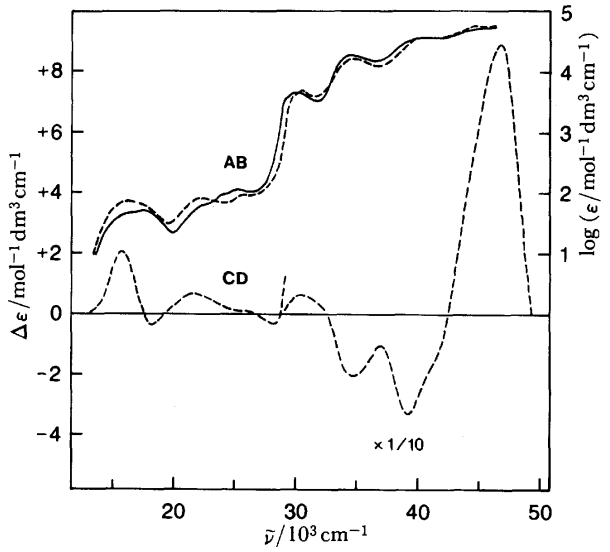

Fig. 3. Absorption (AB) spectrum of $[Cr(acac)(R\text{-mbdo})(S\text{-mbdo})]^{2+}$ (isomer I) (——), and absorption and CD spectra of $(-)_{589}$-$[Cr(acac)_2(R\text{-mbdo})_2]^{2+}$ (isomer II) (-----) in water.

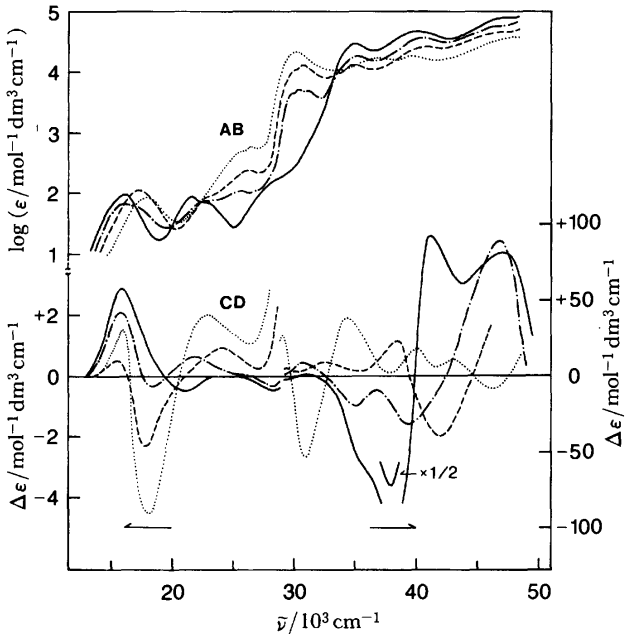

Fig. 4. Absorption (AB) and CD spectra of a series of Δ-$[Cr(acac)_{3-n}(R\text{-}mbdo)_n]^{n+}$ complexes in water; $(-)_{589}$-$[Cr(R\text{-mbdo})_3]^{3+}$ (——), $(-)_{589}$-$[Cr(acac)(R\text{-mbdo})_2]^{2+}$ (-·-·-), $(+)_{546}$-$[Cr(acac)_2(R\text{-mbdo})]^{+}$ (-----), and $(-)_{589}$-$[Cr(acac)_3]$ in ethanol (·····).[11]

mbdo)$_2$]$^{2+}$ are consistent with these CD spectra. The CD strength of the negative component in $[Cr(acac)_3]$ is gradually reduced by replacing acac with *R*-mbdo, $[Cr(R\text{-mbdo})_3]^{3+}$ showing only positive CD band. A similar CD change occurring with replacement of a seven-membered chelate ligand is observed in CD spectra of a series of $[Co(en)_x(tn)_y(tmd)_z]^{3+}$ $(x+y+z=3)$, where tmd denotes tetramethylenediamine which forms a seven-membered chelate ring upon coordination.[16]

The $[Cr(acac)(bpdo)_2]^{2+}$ complex has three possible racemic pairs of diastereomers as well as the corresponding *rac*-mbdo complex. However, attempts to separate such isomers were all unsuccessful by column chromatography because of rapid isomerization of the complex (*vide post*).[5] The optically active complex which was obtained by the chemical method with $K_2[Sb_2(d\text{-tartrato})_2]$ loses gradually its activity in aqueous solution at room temperature.

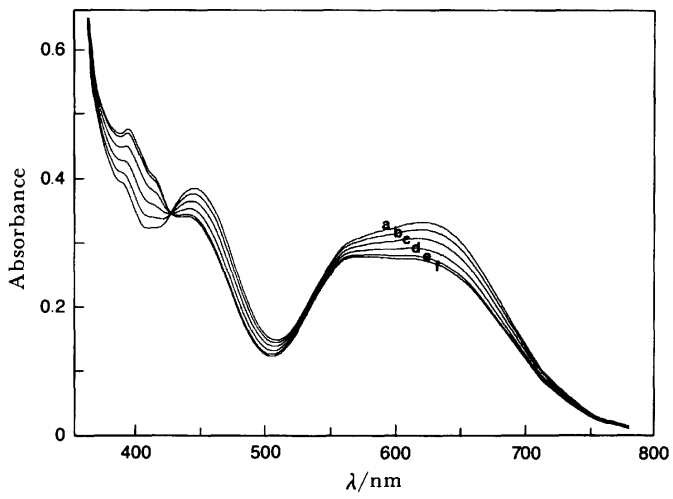

Fig. 5. Absorption spectral change of $[Cr(acac)(bpdo)_2]$-$(ClO_4)_2\cdot H_2O$ in water (pH 7) at 18.0 °C. Reaction time (min): a, 1; b, 3; c, 6; d, 12; e, 24; f, ∞.

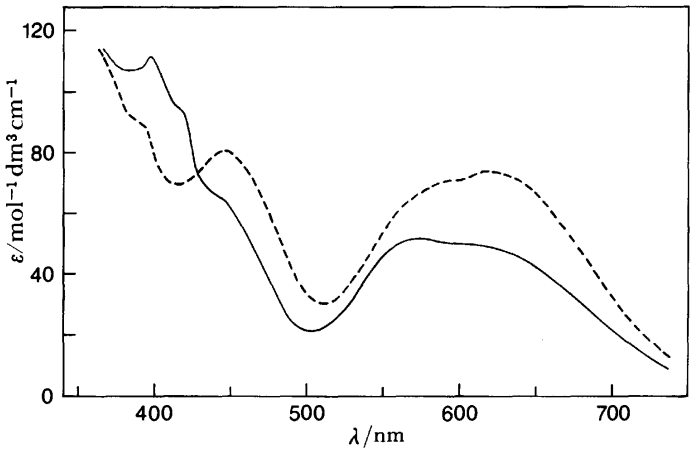

Fig. 6. Absorption spectra of two diastereomers of $[Cr(acac)(rac\text{-mbdo})_2]^{2+}$ in the visible region in water; isomer I(*lel·ob*) (——) and isomer II(lel_2) (-----).

Both racemic and $(-)_{589}$-$[Cr(acac)(bpdo)_2](ClO_4)_2$-$H_2O$ in aqueous solution show a rapid absorption spectral change with an isosbestic point at 427 nm as Fig. 5 shows. The complexes are not hydrolyzed during the change of spectra, since any hydrolyzed product was not detected in the resulting solutions by column chromatography. The species corresponding to absorption spectra a and f in Fig. 5 can be assigned by comparing these spectra with those of the isomers of $[Cr(acac)(rac\text{-mbdo})_2]^{2+}$ in Fig. 6. Spectrum a quite resembles that of the lel_2 isomer of the mbdo complex, and spectrum f seems to be an intermediate one between

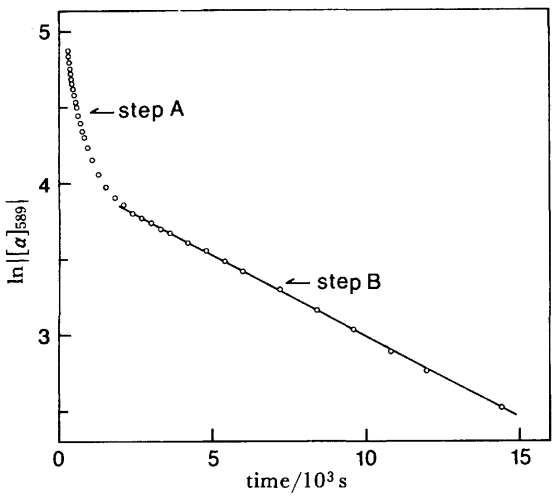

Fig. 7. Decrease in optical rotation of $(-)_{589}$-[Cr(acac)(bpdo)$_2$](ClO$_4$)$_2$·H$_2$O with time in water (pH 7) at 22.0 °C.

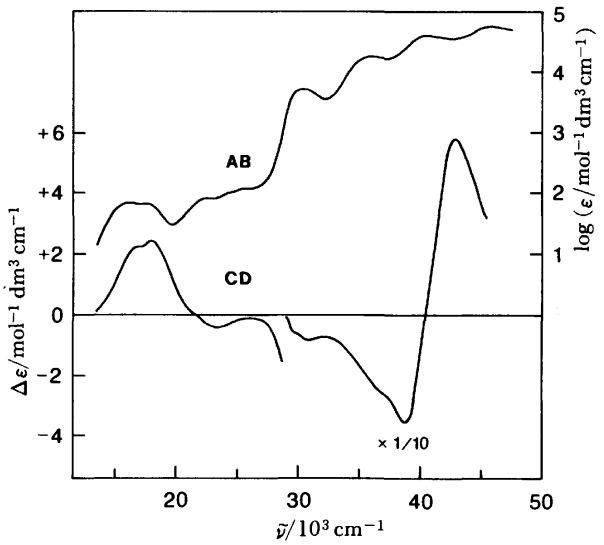

Fig. 8. Absorption (AB) and CD spectra of $(-)_{589}$-[Cr(acac)(bpdo)$_2$]$^{2+}$ in water. These were recorded after an equilibrium of *lel*$_2$ ⇌ *lel·ob* had been reached, and the CD spectrum was corrected for racemization (see text).

those of the two isomers (*lel*$_2$ and *lel·ob*). Thus the spectral change should be caused by isomerization of the complex, *lel*$_2$ ⇌ *lel·ob*. The bpdo chelate ring was shown to be flexible and change its conformation, $\delta \rightleftharpoons \lambda$, very easily.[2,3] Molecular models indicate that the *lel*$_2$ isomer seems to isomerize easily to the *lel·ob* one and *vice versa*, but the *ob*$_2$ isomer will be never formed because of its crowded structure.

As shown in Fig. 7, an aqueous solution of $(-)_{589}$-[Cr(acac)(bpdo)$_2$](ClO$_4$)$_2$·H$_2$O loses the optical activity in two steps with different rates, the first rapid (step A) and the subsequent slow (step B) steps.[5] In step A, the decrease in optical activity accompanies the absorption spectral change, while no spectral change is observed in step B. These results suggest that step A involves the isomerization reaction between the diastereomers, *lel*$_2$ ⇌ *lel·ob*, and step B the racemization reaction between the enantiomers, $\Delta \rightleftharpoons \Lambda$, of the complex.

Figure 8 shows the absorption spectrum of $(-)_{589}$-[Cr(acac)(bpdo)$_2$]$^{2+}$ in aqueous solution at 31 °C at 20 min after dissolution, when no more change in the absorption spectrum was observed. After the equilibrium was reached, the CD spectrum changed with time by step B (the racemization, $\Delta \rightleftharpoons \Lambda$), thus it was extrapolated to time zero by using the k_{obsd}(racemization) value (*vide post*). The corrected CD spectrum is also shown in Fig. 8. The spectral data are given in Table 1. The absorption spectrum in the ultraviolet region is also an intermediate one between those of the *lel*$_2$ and *lel·ob* isomers of [Cr(acac)(mbdo)$_2$]$^{2+}$. The first absorption band gives two components at 16340 and 17240 cm^{-1}. Corresponding to these components, the complex shows two positive CD bands and can be assigned to the Δ configuration. Thus it is concluded that $(-)_{589}$-[Cr(acac)(bpdo)$_2$](ClO$_4$)$_2$·H$_2$O crystallizes in the $\Delta(\lambda\lambda)$-(*lel*$_2$) structure and isomerizes in aqueous solution to the $\Delta(\lambda\delta)$(*lel·ob*) structure in step A.

Kinetics of Isomerization and Racemization of [Cr(acac)(bpdo)$_2$]$^{2+}$. The kinetic experiments were carried out in the dark so as to avoid photoinduced reactions.

The rate of the isomerization of [Cr(acac)(bpdo)$_2$]$^{2+}$, *lel*$_2$ ⇌ *lel·ob*, was followed by monitoring the absorption spectral change at 620 nm with time (in step A) in aqueous solution under the conditions described in Experimental part. The rate of spectral change obeyed the first order kinetic law for at least four half-lives and the rate constant (k_{obsd}) was obtained from the slope of $\log(A_t - A_\infty)$ *vs.* time where A's are absorbances at 620 nm. The rate for the $(-)_{589}$-isomer agreed with that for the racemate within the experimental error. The values of k_{obsd} are given in Table 2. Arrhenius treatment of $\log(k_{obsd})$ *vs.* T^{-1} yielded an activation energy of (77.3±1.2) kJ mol^{-1}) and Eyring treatment of $\log(k_{obsd}/T)$ *vs.* T^{-1} gave an activation enthalpy of (74.9±1.1) kJ mol^{-1} and an activation entropy of (−38.5±3.7) JK^{-1}mol^{-1}. The rate was independent of concentrations of H$^+$ and the free ligands. Hence it is suggested that the isomerization proceeds by an intramolecular mechanism. The small negative activation entropy value seems to reflect such a mechanism. This is consistent with the preceding conclusion that the isomeri-

zation occurs by the conformational inversion ($\lambda \rightleftharpoons \delta$) of the bpdo chelate ring in the $\Delta(\lambda\lambda)(lel_2)$ isomer to afford the $\Delta(\lambda\delta)(lel\cdot ob)$ isomer. The difference in free energy between the lel_2 and $lel\cdot ob$ isomers of the complex is small in aqueous solution because of the almost equal formation ratio between the two isomers of $[Cr(acac)(rac\text{-mbdo})_2]^{2+}$.

For $(-)_{589}$-$[Cr(acac)(bpdo)_2](ClO_4)_2 \cdot H_2O$ in aqueous solution, the rate of decrease in optical activity was followed under the conditions described in experimental part. As Fig. 7 shows, the rate in step B obeyed the first order kinetic law for at least three half-lives and the rate constant (k_{obsd}) was obtained from the slope of $\log|\alpha_t|$ *vs.* time where α is degrees of optical rotation at 589 nm. The values of k_{obsd} are given in Table 3. The estimated values of activation energy, enthalpy, and entropy are (84.8±1.2) kJ mol^{-1}, (82.4±1.2) kJ mol^{-1}, and (−41.7±3.9) J K^{-1} mol^{-1}, respectively. The rate was independent of concentrations of H^+ and the free ligands. Thus the racemization ($\Delta \rightleftharpoons \Lambda$) will also proceed by an intramolecular mechanism. In a previous paper,[3] the rate of racemization of $[Cr(bpdo)_3]^{3+}$ in aqueous solution was found to be 1.40×10^{-4} s^{-1} at 26.9 °C with an activation energy and entropy of 81.3 kJ mol^{-1} and −49 J K^{-1} mol^{-1}, respectively, and the racemization was suggested to proceed *via* an intramolecular twist mechanism from a comparison of these kinetic parameters with those of other complexes such as $[Cr(phen)_3]^{3+}$,[17] for which the same mechanism was proposed. The rate constant and the activation parameters of $[Cr(acac)(bpdo)_2]^{2+}$ are very similar to those of $[Cr(bpdo)_3]^{3+}$, and the racemization will also proceed *via* a twist mechanism. The small negative activation entropy value seems to be consistent with such an intramolecular twist mechanism.

Tables 2 and 3 show that the rate of racemization ($\Delta \rightleftharpoons \Lambda$) is 30 times slower than that of the isomerization ($\delta \rightleftharpoons \lambda$); the complex in aqueous solution isomerizes from the lel_2 isomer to the $lel\cdot ob$ one prior to the racemization. Several different twist mechanisms have been proposed for the intramolecular racemization of a tris(chelate)-type complex.[18] However, it is difficult to determine which mechanism is the most probable for the racemization of the present complex.

Oxygen-plasma Treatment of Packing Materials for Gas Chromatography. The Incorporation of Oxygen into the Hydrocarbon Liquid Phase and the Formation of Crosslinked Products on the Support Surface

Yukio YAMAMOTO,* Seiji OKA, and Koichiro HAYASHI
The Institute of Scientific and Industrial Research, Osaka University, 8-1 Mihogaoka, Ibaraki, Osaka 567
(Received June 27, 1984)

The oxygen-plasma treatment of column packings for gas chromatography was examined with diatomaceous earth coated with several kinds of stationary liquid phases from the point of view of the modification of their chromatographic properties. A remarkable effect on the gas chromatograms of polar compounds was observed for the packings with nonpolar liquids, such as squalane and Apiezon L. The elimination of tailing and the improvement of the resolution by the plasma treatment were attributed to the incorporation of oxygen into the hydrocarbon liquids and the formation of crosslinked products covering the adsorptive support surface. These results were compared with the previous data on argon-plasma treatment.

Recently, we have examined the argon-plasma treatment of packing materials for gas chromatography.[1-3] It was found that the plasma treatment is effective for reducing the tailing of chromatographic peaks on several kinds of packings, such as squalane, Apiezon L, Silicone DC, and dioctyl phthalate on diatomaceous earth. The effect has been attributed to the formation of an inert coating on the adsorptive support surface. Because the distributed liquid of packings is thin and has a large surface area exposed to plasma, plasma treatment provides an effective means of modifying the chromatographic properties of the packings.

In the present study, the oxygen-plasma treatment of packings was undertaken in order to investigate its effect on gas chromatograms and the reactions in the stationary liquid phase caused by the oxidizing plasma. The results are compared with our previous data on the argon-plasma treatment.

Experimental

The column packings (60/80 mesh) were obtained from Wako Pure Chemical Industry. The apparatus and experimental details of the plasma treatment were described previously.[2] The oxygen-plasma treatment was carried out at a pressure of 0.1 Torr (13 Pa) by means of a radiofrequency generator operated at 13.56 MHz and with an output of 50 W. The gas-chromatographic test of the treated packing was also carried out as has been described previously; the packing was packed into a 1m×3mm i.d. stainless tube, and the nitrogen flow rate was 30 ml/min.

The molecular-weight distribution of the liquid extracted from the plasma-treated squalane on Chromosorb W was measured by means of a gel-permeation chromatograph (Toyo Soda HLC-801) in tetrahydrofuran (THF). A differential refractometer and two 2-ft columns, TSK-Gel G2000H8 and G4000H8, connected in series, were used for the measurement. The IR spectrum of the extracted liquid was recorded on a Hitachi Model 295 spectrometer using NaCl plates.

Results

A remarkable effect was observed on the gas chromatograms of polar compounds when the packings with nonpolar liquids, such as squalane and Apiezon L, were treated with the oxygen plasma. Figure 1 shows the gas chromatograms of alcohols and aromatic ketones on Chromosorb W (non-acid washed (NAW))

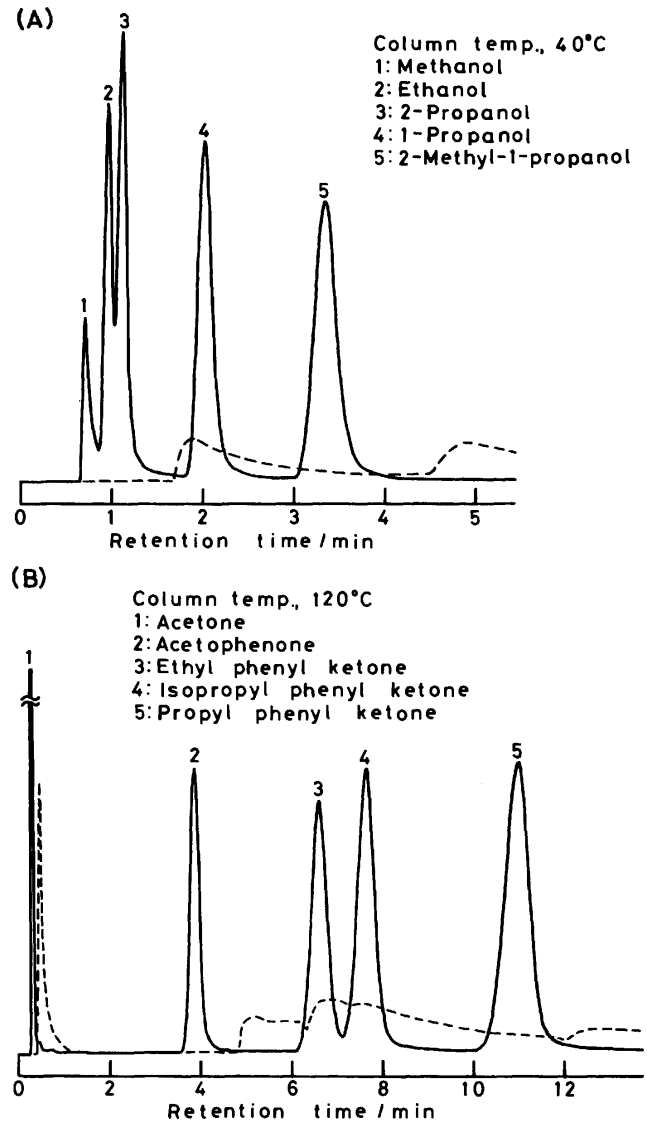

Fig. 1. Gas chromatograms on Chromosorb W (NAW) coated with 5% squalane: solid line, 10 min plasma treated; dotted line, untreated.

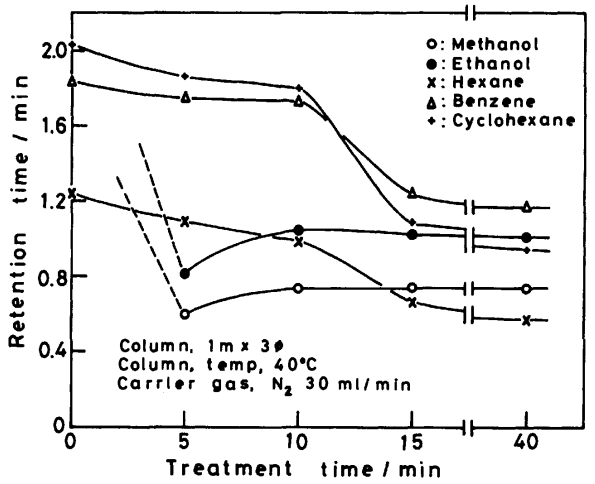

Fig. 2. Change in retention time by plasma treatment.

coated with 5% squalane before (dotted line) and after (solid line) the plasma treatment for 10min. Sharp and well-separated peaks are obtained on the plasma-treated packing, whereas the peaks are very broad, with extensive tailing, on the untreated packing. The best peak separation was attained at the treatment time of 10min. The changes in the retention times of several alcohols and hydrocarbons by the plasma treatment are compared in Fig. 2. The retention times of methanol and ethanol are significantly decreased during the first 5min and then slightly increased during the next 5min. On the other hand, the retention times of hexane, benzene, and cyclohexane slowly decreased with the increase in the treatment time. The effect of the plasma treatment was similar for 5% Apiezon L on Shimalite (NAW), as is illustrated in Fig. 3. By the plasma treatment, the retention time of ethanol is decreased much more than those of hexane and benzene, and the tailing of its peak is effectively reduced. Symmetrical and separated peaks are also obtained for the aromatic ketones on the plasma-treated packing.

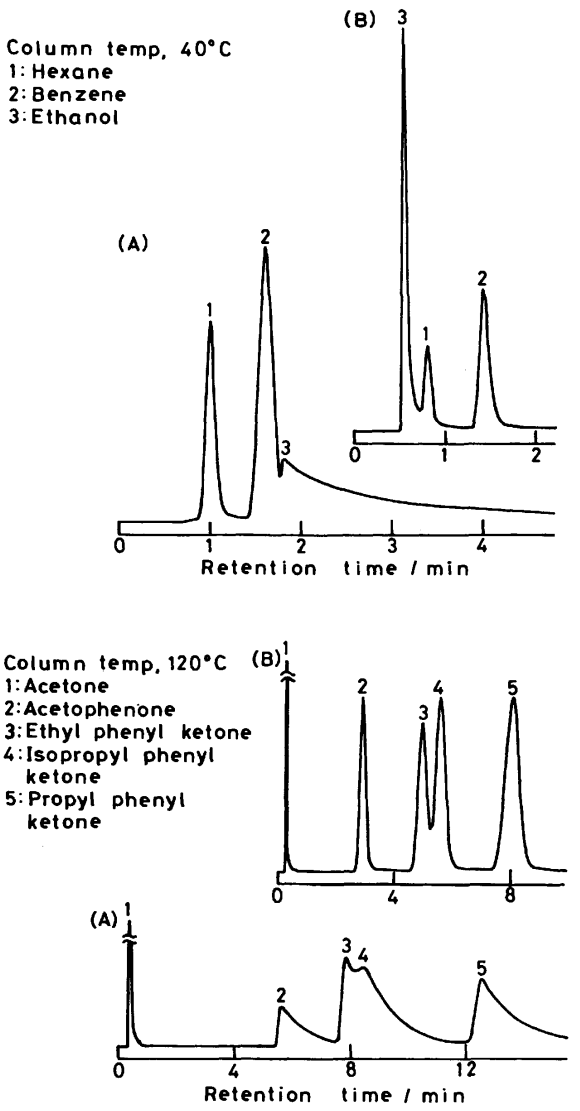

Fig. 3. Gas chromatograms on Shimalite (NAW) coated with 5% Apiezon L: (A) untreated; (B) 10min plasma treated.

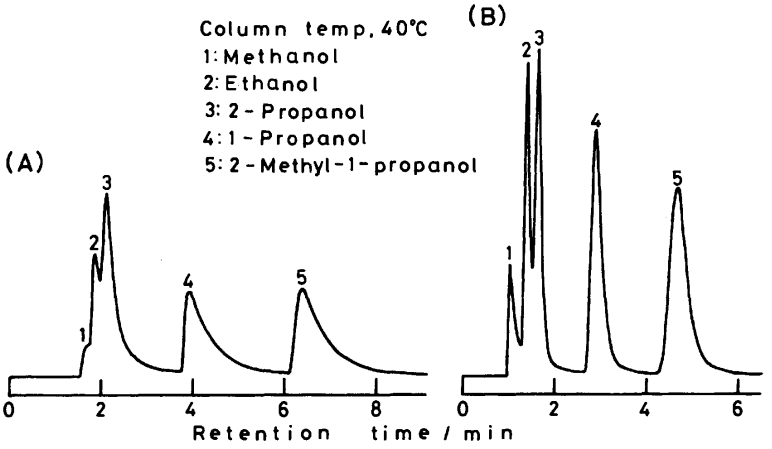

Fig. 4. Gas chromatograms on Chromosorb W (NAW) coated with 10% dioctyl phthalate: (A) untreated; (B) 10min plasma treated.

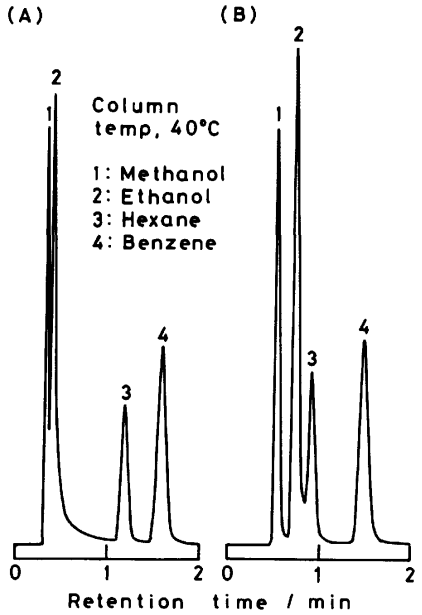

Fig. 5. Gas chromatograms on Chromosorb W (AW-DMCS) coated with 5% squalane: (A) untreated; (B) 10 min plasma treated.

Figure 4 shows the effect of the plasma treatment of Chromosorb W (NAW) coated with 10% dioctyl phthalate on the gas chromatogram of alcohols. Although the effect is less significant than those for the packings described above, the plasma treatment is effective for reducing the tailing. When packings coated with Silicone DC and polyethylene glycol were treated with the oxygen plasma for 10 min, only a slight decrease in retention time was observed, but there was no appreciable improvement in the resolution.

The oxygen-plasma treatment was also examined with acid-washed and dimethyldichlorosilane-treated (AW-DMCS) Chromosorb W coated with 5% squalane; the results are shown in Fig. 5. It can be seen that, by the plasma treatment, the retention times of methanol and ethanol are increased and the tailing of their peaks is eliminated. On the contrary, the retention times of hexane and benzene are decreased by the plasma treatment.

With a packing consisting of 5% squalane and Chromosorb W (NAW), experiments to elucidate the reactions caused by the oxygen-plasma treatment were carried out. After the plasma treatment, the distributed liquid was extracted from the packing with THF by using a Soxhlet extractor and refluxing for 5 h. The extract was submitted to gel-permeation chromatography. The molecular-weight distributions at different treatment times are shown in Fig. 6. These are normalized to the peak height at 28.5 counts corresponding to squalane itself. It is evident that the distributed liquid is polymerized during the plasma treatment. The yields of the higher-molecular-weight products increase with the increase in the treatment time. On the other hand, the formation of the polymerized products is limited in the case of the argon-

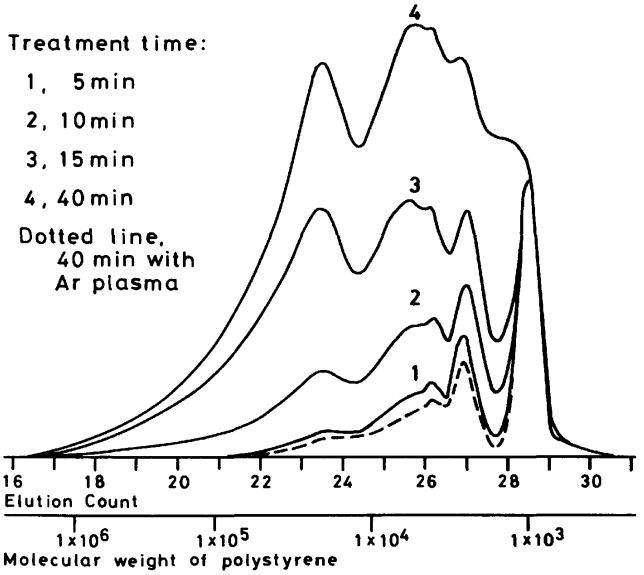

Fig. 6. Molecular weight distribution curves for liquids extracted from plasma treated packings (Chromosorb W (NAW) coated with 5% squalane).

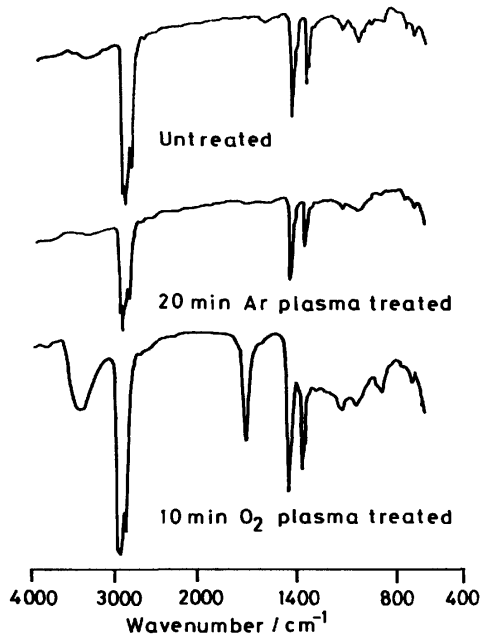

Fig. 7. IR spectra of the liquids extracted from packings (Chromosorb W (NAW) coated with 5% squalane).

plasma treatment, even at the longest treatment time examined, 40 min (dotted line).

The IR spectrum of the extracted liquid, which was measured after evaporating the THF from the extract, is shown in Fig. 7, together with those of the liquids extracted from the untreated and argon-plasma-treated packings. The IR spectrum for the oxygen-plasma treated packing shows the presence of carbonyl and hydroxyl groups, whereas there is no appreciable difference in the spectra between the untreated and argon-plasma-treated packings.

The support recovered from the packing by extract-

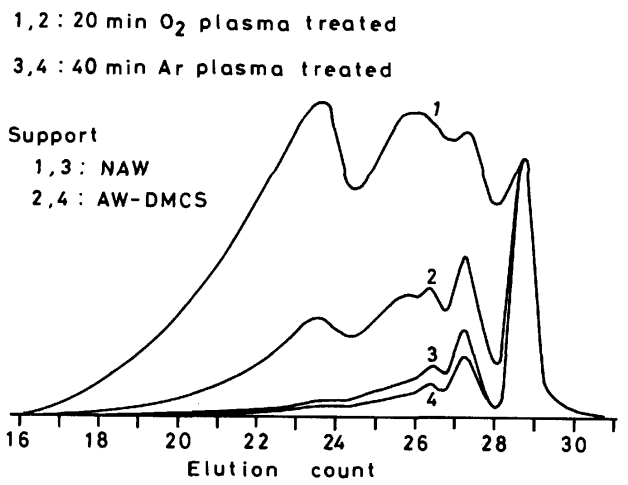

Fig. 8. Comparison of molecular weight distributions of extracted liquids for NAW and AW-DMCS supports.

ing the distributed liquid was dried under vacuum and then weighed to determine the weight loss of the packing due to the extraction. The weight loss decreased with the increase in the treatment time, much as in the case of the argon-plasma treatment,[2] indicating the formation of products not extracted with THF. The yield of such insoluble products, based on the distributed liquid, was 34.5% at a treatment time of 20min, which is comparable to that in the argon-plasma treatment, 31.7%.

For the sake of comparison, the molecular-weight distribution of the extracted liquid was measured for the packing with the AW-DMCS support. The formation of the soluble polymer depends on the support, as is shown in Fig. 8; that is, it is more pronounced on the NAW support in both the oxygen and argon-plasma treatments. Furthermore, the yields of the insoluble products remaining on the AW-DMCS support at the plasma-treatment time of 20min were 26.5 and 18.8% for the oxygen and argon-plasma treatments respectively. These yields are smaller than those on the NAW support.

Discussion

When a hydrocarbon substrate such as polyethylene is exposed to an oxygen plasma, the incorporation of oxygen and crosslinking are known to occur on the substrate surface.[4,5] Similar reactions are considered to occur in the hydrocarbon-liquid phase of the packing when it is treated with the oxygen plasma. The results for the packing with squalane demonstrate the incorporation of oxygen in the form of carbonyl and hydroxyl and the crosslinking to yield the high-molecular-weight products.

The formation of an inert coating on the support surface is considered to play an important role in the elimination of the tailing of chromatographic peaks, much as in the case of the argon-plasma treatment.[1-3] The yields of both the types of polymerized products, those extractable and unextractable with THF, on the NAW support were higher than those on the AW-DMCS support in the oxygen and argon-plasma treatments. Therefore, it seems likely that their formation is promoted by the NAW support surface and that the highly crosslinked products effectively cover it. It is also believed that the increase in the polarity of the liquid phase by the incorporation of oxygen reduces the adsorption of solutes on the support surface because of the increased interaction of the liquid with the support surface. Thus, the remarkable decrease in the retention times of the alcohols and aromatic ketones and the elimination of their tailing (Figs. 1 and 2) are attributable to the reduction of the support adsorptivity toward the solutes.

Another effect of the increase in the polarity of the distributed liquid is an increase in the retention times of the alcohols, resulting in a higher peak separation. This was observed for the packing with the NAW support during the second 5min of treatment (Fig. 2) and also for the packing with the AW-DMCS support (Fig. 5).

The formation of the soluble polymerized products was much more pronounced in the oxygen-plasma treatment than in the argon-plasma treatment. This can be explained by the reactions of oxygen with radical species inhibiting the crosslinking and/or initiating oxidative decomposition of the polymerized products.

Quantum Chemical Consideration of Substituent Effects on Tautomeric Properties of 2-Pyridones–2-Pyridinols

Masayuki KUZUYA,* Akihiro NOGUCHI, and Takachiyo OKUDA
Gifu Pharmaceutical Uuiversity, 6-1, Mitahora-higashi 5-Chome, Gifu 502
(Received January 5, 1984)

The tautomeric properties of 2-pyridones–2-pyridinols exerted by the substituent effect were discussed on the basis of quantum chemical quantities deduced from molecular orbital (MO) calculations. A substituent at the 6-position has the greatest stabilizing effect. The magnitude of this effect was greater on the 2-pyridinol form than the 2-pyridone form, irrespective of the nature of the substituent. This led to a large predominance of the 2-pyridinol form on the 6-polar-substituted derivatives to such an extent that it was observed by conventional UV measurements at ambient temperature. In the 6-methyl derivative, the 2-pyridinol form was not observed by a similar measurement due to the weak substituent effect. The association ability is still an important factor in determining tautomeric equilibrium in a solution, resulting in a strong lability to the molecular environment. The substituent effects on the stabilities of both tautomers were shown to be correlated with the N-atomic charges and ring structural modifications of the tautomers.

2-Pyridone–2-pyridinol (**1**) has been one of the basic tools in a number of studies on tautomeric equilibria, the properties of which are of interest regarding the structure-reactivity relationship and is of potential biological significance for understanding mutation due to base mispairing and enzymic reactions related to the bifunctional catalysis.[1,2] Thus, the study of 2-pyridone (**1**) has been attracting many investigators from more than one area.

Scheme 1.

It has now become well established that **1** exists very largely in the 2-pyridone tautomeric form (**1a**) in solution[1] and in the solid state,[3] but that there is no significant difference in the fundamental stabilities of the tautomers in the gas phase (ΔH=1.3±10 kJ mol^{-1}).[2] It was also been shown that self-association and/or solvation significantly affect tautomeric equilibria.[2,4]

A number of quantum chemical studies on the energetics of the tautomeric properties for **1** have already been published, but those studies have led to various diverse results regarding the energetics of tautomeric equilibria.[5] This may be mainly due to the differences in the method of calculation and the molecular geometric parameters employed. Recently, *ab initio* studies with extended basis sets, including full geometry optimization, were reported and the calculated tautomeric energy difference was shown to be in good agreement with experimental values related to the gas phase.[5k,5l,5m] The details of the substituent effects on the tautomeric properties of **1**, however, have yet been fully elucidated.

We felt it would be important and useful to investigate the substituent effect in order to achieve a full understanding of the factors which influence tautomeric equilibria. In fact, several derivatives of **1** which bear a polar substituent at the 6-position are known to favor the 2-pyridinol form over the 2-pyridone form,[1,6] and the substituent effects have been ascribed to the electron-withdrawing property.

Molecular orbital calculations are particularly useful for such studies since they can provide much information about less-abundant tautomeric species. It is now apparent that nonempirical *ab initio* calculations with extended basis sets must be used to achieve a high accuracy regarding the energetics of tautomeric equilibria.[5k,5l,5m] A large amount of computational time, however, is neccessary for such calculations for a large molecule. Thus, we systematically performed molecular orbital calculations supported by the CNDO/2 and MINDO/3 methods on various substituted 2-pyridones. We believe that the semiempirical method can provide a sufficient fundamental insight into the substituent effects on the relative stability and electronic structure of each tautomeric form.

In this paper, we present the special features disclosed by the calculations and discussed the substituent effects with the quantum chemical quantities derived from such calculations.

In order to obtain experimental data to support the calculated quantities, the IR spectra of several methyl derivatives of 2-pyridones were also measured in a CCl_4 solution.

Experimental

2-Pyridone was commercially available. The preparation of other substituted 2-pyridones is described in the literature.[7]

The infrared spectra were recorded with a JASCO 403G infrared spectrophotometer. The solvent of carbon tetrachloride (spectroscopic grade) was dried over molecular sieves. Solute concentrations were 5×10^{-4} M† (20mm NaCl cells). The cell was heated with a heat gun (PLAJET PJ-206,

†1M=1 mol dm^{-3}.

Ishizaki-Denki Co. Ltd.) to above 60°C. Then, heating was discontinued and the spectra in the 3200—3800cm^{-1} region were measured at *ca.* 50°C. The temperature, measured by a digital thermometer with a thermocouple directly fixed to the cell, was constant during the measurement. The intensities were determined to be given by $\log_{10}(T_0/T)$, where T_0 and T are the apparent intensities of the incident and transmitted radiation at the maximum wave number, respectively.

Calculations

All calculations were carried out on a FACOM M-382 computer at the Computation Center of Nagoya University. The CNDO/2,[8] MINDO/3,[9] MNDO,[10] and MNDOC[11] calculations were performed with the original standard parametrizations, respectively. Geometrical parameters were taken from the results of X-ray crystallographic studies on 2-pyridone[12] and 6-bromo-2-pyridinol[13] for the CNDO/2 and the MINDO/3 calculations with a fixed geometry. Standard bond lengths and bond angles[14] were used as the geometrical parameters of the substituents. The MINDO/3 calculation, with full geometry optimization, was carried out on the structures within C_s symmetry by the RPI/MINDO/3 which contains a convergence-forcing procedure.[15]

Results and Discussion

The molecular-orbital calculations were carried out for a set of 2-pyridones and 2-pyridinols substituted at various positions with methyl, cyano, and methoxy groups.

The computed results by the CNDO/2 method (with a fixed geometry) did not afford satisfactory substituent effects for the relative stability of the two tautomeric forms of the 6-substituted derivatives, which is experimentally known to favor the pyridinol form.[1,6] In contrast, the MINDO/3 method did afford satisfactory results for the substituent effect on the 6-position (*vide infra*). The introduction of substituents can also be expected to alter the ring geometries of both tautomeric forms. Thus, to obtain more precise information on the nature of substituent effects on tautomeric properties, MINDO/3 calculations (with full geometry optimization) were carried out. Details of the results, thus obtained, are presented and discussed in the following subsections.

Energetic Features. The heat-of-formation values (H_f) of a parent compound (**1**) were calculated to be −142.9 and −127.3 kJmol^{-1} for the pyridone form and the pyridinol form, respectively. The calculated energy difference between the two tautomeric forms (15.6kJmol^{-1}) was somewhat greater than the experimental value (1.3±10 kJmol^{-1}).[2]

However, the calculated relative energies (ΔH_f) compared to that of a parent compound (**1**) are a measure of the net substituent effect and are presented in Table 1.

The relative energies, thus obtained, clearly indicate that the 6-substituted derivatives in each tautomeric form are the most stable among the ones bearing the same substituent irrespective of the nature of the substituent. This fact might be rationalized in terms of the *ortho*-position relative to the nitrogen atom, which has a greater electron-accepting property. Thus, the 6-substituent has the greatest interaction with the ring system. Also, the greater stabilizing effect of the 6-substituents on the 2-pyridinol form than on the 2-pyridone form was also shown. This can be understood from the larger C_6–N double-bond character of the former as compared with that of the latter.

As for the effect of the substituent at the 5-position, the 5-methoxy substituent is as effective as 6-polar substituents in a shift of the tautomeric equilibria leading to the predominance of the 2-pyridinol form.

The 5- and 6-chloro derivatives have been shown by IR spectra to favor the 2-pyridinol form over the 2-pyridone form, compared with the 3- and 4-chloro derivatives.[6d] A similar effect of the ortho substituent

to the nitrogen atom has also been shown for 4-pyridones.[6c] Due to the similarity of the net electronic-substituent effect between the methoxy group and the halogen atom (σ-inductive and π-donative), the calculated substituent effects of the methoxy derivatives on the relative stabilities between the two tautomeric forms seem to be in accord with the experimental evidence.

The methyl-substituent effect on the relative energetics of the tautomers has been calculated to be not so strong. In fact, it is the 2-pyridone form that is observed in the UV spectral measurement of these derivatives in a nonpolar solvent. However, some supportive experimental data for such an effect were obtained by IR spectral measurements of several methyl derivatives in a CCl_4 solution (5×10^{-4} M) at *ca.* 50 °C, although, in the solutions, these derivatives exist largely as the self-associated 2-pyridone form and the intensities of the nonassociated species are fairly weak. The observed intensity ratio (I_{OH}/I_{NH}) of the O–H and N–H stretching bands (around 3580 and 3410cm , respectively) of the nonassociated species were 0.08, 0.06, 0.14, 0.10, and 0.19 for unsubstituted-, 4-methyl-, 5-methyl-, 6-methyl-, and 5,6-dimethyl-2-pyridones, respectively. Although the absorption coefficient for the same type of vibration may vary from one molecule to another, the difference in the observed intensity ratio could qualitatively represent the greater stabilization of the corresponding 2-pyridinol form in that order.

Electronic Features. It is known that the introduction of electron-donating substituents at the 2- and 4-positions of pyridine, especially at the 2-position, renders a stabilizing effect. Such effects were ascribed to be the consequence of an increase in the N-atomic electron densities.[16]

Thus, the redistributions of atomic electron densities, resulting from the introduction of substituents, were examined. The differential electron densities of substituted 2-pyridones and 2-pyridinols relative to parent compounds are shown in Fig. 1.

An interesting point regarding Fig. 1 is that the largest increments of electron density on the nitrogen atom were shown on each tautomeric form of the 6-substituted derivatives regardless of the nature of the substituent. This is atributable to the lower core potential (large electronegativity) of the nitrogen atom and the ortho-position against the nitrogen atom. On the other hand, the substituents at the 3-, 4-, 5-positions in both tautomeric forms are primarily explained in terms of the general electronic effects for an aromatic system, that is, the *ortho-* and *para*-orientation for electron-donating substituents and the *meta*-orientation for electron withdrawing substituents. As a result, the 4-cyano and 3- and 5-methoxy substituents lead to the smallest electron densities on the nitrogen atom.

The relationship between the relative N-atomic electron densities (ΔQ_N) and the relative energies (ΔH_f) was examined for each substituent (Fig. 2).

It is clear from Fig. 2 that the increments of the electron densities on the nitrogen atom are in parallel to the trend of the relative total energy gain.[17] The magnitude of this increment was greater for the 2-pyridinol form in the case of methyl and methoxy derivatives. However, the nature of the electron density on the nitrogen atom differs from each other between the tautomeric forms, and also between the substituents. Based on an analysis which divided the electron charge increments into the σ- and π-electron character, the contribution of the σ-electron was found to be greater in methyl derivatives, while in the methoxy and cyano derivatives some greater contributions of the π-electron were found. These differences in the contribution of the σ- and π-electron may cause some deviations from

the correlations in cyano and methoxy derivatives in Fig. 2.

Structural Features. The experimental geometries of 2-pyridones and 2-pyridinols have been reported for 2-pyridone,[3,12)] 5-chloro-2-pyridone,[18)] 6-chloro-2-pyridinol,[12,19)] and 6-bromo-2-pyridinol[13)] by the X-ray crystal structure analyses. The optimized geometries derived by the MINDO/3 method show good agreement with experimental facts. The optimized geometric parameters for the ring part of 2-pyridinol were nearly identical with the result for pyridine by the same method.[20)]

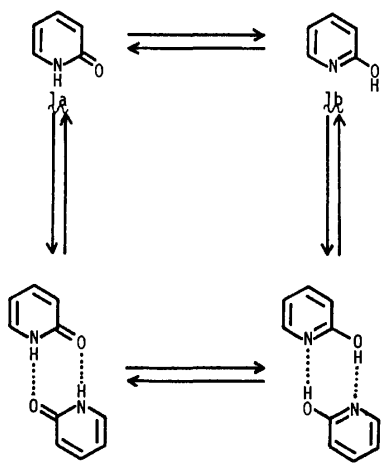
The computed bond lengths of the various substituted 2-pyridones and 2-pyridinols obtained by the MINDO/3 method with geometry optimization are summarized in Tables 2 and 3, respectively.

The ring structural perturbation due to an introduction of the substituents can be understood, on the whole, by an increase in bond lengths, including that of the atom attached to the substituent by about 2.0 pm. Also, the O–H bond lengths are nearly constant and variations in the C–O and C–N bond lengths are small. They seemed not to be associated with the tautomeric properties.

Here, it may be interesting to inspect the substituent effects, combining the structural features with the electronic effects described in a previous subsection. The geometric perturbations indicated that the C_3–C_4 bond length had a greater effect on the stabilities of the 2-pyridone and 2-pyridinol forms than the other bond length, considering that the energy gains by the geometrical optimizations in the 3-, or 4-substituted derivatives were greater than those in 5-, or 6-substitution. But, when a comparison between the energy gains in the two forms was made, it was found that the lengthening of the C_5–C_6 bond had an effect on stabilizing the 2-pyridinol form more than the 2-pyridone form (Table 1) (*vide supra*).

As a result of the C_5–C_6 bond lengthening, some parts of the electron density forming the C_5–C_6 bond must be transferred to the rest of the molecule. Among those, the nitrogen atom would naturally gain the greater part of the electron, resulting in the increment in the N-atomic electron densities.

Self-association. The hydrogen-bonded dimeric structure of 2-pyridones is well known from crystallographic[3,12,18] and thermodynamic studies.[21] The dimeric structure of the 2-pyridinol form with a centrosymmetry is also known through X-ray studies of 6-halo-2-pyridinols.[13,19] Thermodynamic parameters, such as the association constant, have been studied for 6-chloro-2-pyridinol[4] and results indicate that the association energies of the 2-pyridinol form are relatively smaller than those for the 2-pyridone form. The importance of self-association in the tautomeric equilibria of 2-pyridones (**1**) has also been stressed by P. Beak *et al.*[2,4] and O. Bensaude *et al.*,[22] and the mechanism by which the tautomerism occurs is widely accepted to be through the dimer. Although the OH proton in the pyridinol form is more acidic than the NH-proton in the pyridone form, based on both charge densities and bond-order terms, the relevant site for the self-association in the pyridone form is more sterically favorable over that in pyridinol form. The net effect of this may be that the pyridone-pyridone dimer is more feasible. Accordingly, the larger association energies of the 2-pyridone form result in a shift in the tautomeric equilibria of **1**, leading to the predominance of the 2-pyridone form (**1a**).



Scheme 2.

Thus, the substituent effect on the association energy of each tautomeric form is considered to be directly related to tautomeric equilibria. However, there is very little experimental or theoretical in formation available on this matter.

The defects of the MINDO/3 and MNDO methods for the evaluation of intermolecular interactions, particularly in the case of hydrogen-bonding interactions, have already been pointed out.[23,24] In fact, attempts to reproduce the self-association energies of the 2-pyridone (**1a**) and 2-pyridinol (**1b**) form by the MINDO/3 method (employing geometries based on the crystalline structures) resulted in the destabilization of 53.1 kJ mol^{-1} in the former and 74.4 kJ mol^{-1} in the latter.

Furthermore, in calculations related to the optimization of intermolecular distances, including those of NH and OH, energy minima were found at unrealistic interatomic distance between the nitrogen and the oxygen: 4.87 Å in 2-pyridone and 7.80 Å in 2-pyridinol, respectively.[25]

Although there are also documented failures of the CNDO/2 scheme's ability to acount correctly for hydrogen bonding or nonbonded interaction,[26] for certain limited structures set on specific association orientations, one can evaluate the relative energetics by the CNDO/2 method.

In fact, it has been reported that the CNDO/2 method has given the correct self-association energy values for formamide[27] and for several other cases of intermolecular systems such as those involving large contribution due to electrostatic interactions.[28]

Recently, Inuzuka *et al.* have reported the self-association energy of 2-pyridone supported by the CNDO/2 method with a geometry optimization, but without referring to the interrelation to the tautomerism.[29] The reported self-association energy was 147.7 KJ mol^{-1}. They deduced a corrected value of 68.2 kJ mol^{-1}, based on comparisons with several organic compounds. This was compatible with the experimental value (65.3 kJ mol^{-1}) obtained by the NMR technique.[29]

We have also evaluated the self-association energies

of various substituted 2-pyridone forms and 2-pyridinol forms on the dimeric structure experimentally determined by X-ray analyses[13,18] (Table 4).

In the present calculations, the self-association energy of the 2-pyridone form (**1a**) was 71.6 kJ mol^{-1}, which is in fairly satisfactory agreement with the above-mentioned experimental value (65.3 kJ mol^{-1}).[30] This value was greater than that of the 2-pyridinol form (**1b**) by 7.6 kJ mol^{-1}, proving a qualitative validity of this method.

However, when comparisons are made of the values between the 2-pyridone form and the 2-pyridinol form of such derivatives (as shown in Table 4), those of the former value were all greater than those of the latter by about 2.9—10.5 kJ mol^{-1}. This was even true for the case of the derivatives which exist very largely in the 2-pyridinol form (to such an extent as can be observed in conventional UV measurements). Therefore, the association ability seems not to be closely related to the tautomerism of the derivatives bearing a polar substituent at the 6-position, although the tautomerism is well known to occur *via* the dimer. On the other hand, parent and methylated derivatives exist largely in the 2-pyridone form due to the greater association energies compared to the tautomeric-energy differences.

Table 4. Dimerization energies calculated by the CNDO /2 method

Substituent	E_{dim}/kJ mol^{-1}	
	2-Pyridones	2-Pyridinols

6-CN	70.2	61.8
3-OMe	70.3	62.9
4-OMe	74.2	66.4
5-OMe	70.7	62.5
6-OMe	69.6	66.4

Conclusion

It is often observed that the substituent effect on stability and reactivity can not be easily predicted and interpreted in a simple manner since the factors at play (steric, inductive, conjugative and others) may act in opposing ways. Nevertheless, the present studies considerably enhanced our understanding of the nature of the substituent effect on the tautomeric properties of 2-pyridone–2-pyridinol.

The conclusion reached from the present studies may be represented as follows: From calculations, the substituent at the 6-position have been shown to exert the strongest influence on the relative energetics of the tautomers, irrespective of the nature of the substituents. The introduction of polar substituents at this position stabilized the 2-pyridinol form much more than the 2-pyridone form. This effect is well correlated by N-atomic electron densities and ring structural modifications of the tautomers.

Thus, in this type of derivative, the association ability is not an important factor in controlling the tautomeric euilibria in solution, unlike unsubstituted 2-pyridone, although the association energies have been shown to vary with such substituents.

The introductin of a 6-alkyl substituent, such as a methyl group, also similarly resulted in a greater stabilization of the 2-pyridinol form than of the 2-pyridone form. However, due to the small difference in such a relative energetic of the tautomers, the 2-pyridinol forms were not observed by conventional UV spectral measurements, and the association abilities still play an important role in determining the tautomeric equilibria in solution. The tautomerism of these derivatives, therefore, can be considered to be more susceptible to their environmental conditions than that of unsubstituted 2-pyridone.

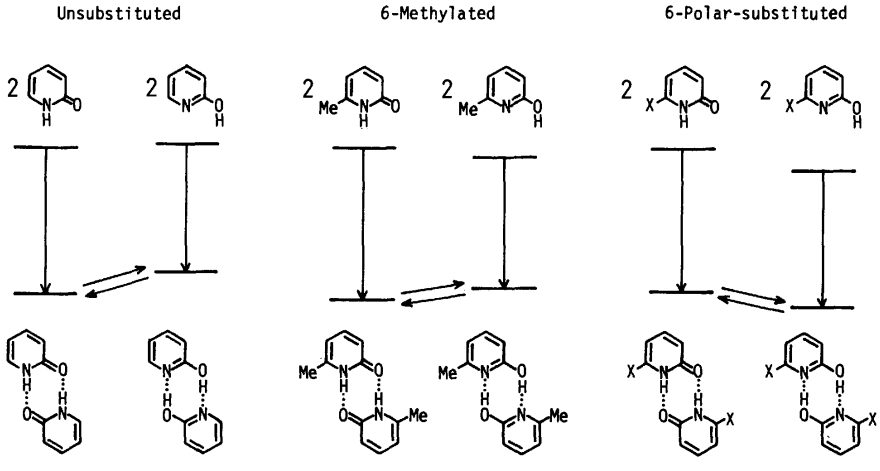

Fig. 3. Qualitative representations for 6-substituent effect on the relative stability of the two tautomers. 6-Polar substituent, **X**, denotes strong electron-withdrawing and donating substituents.

A comparison of the qualitative energy diagrams in the interrelation of the tautomer and dimer forms in solution is illustrated in Fig. 3.

Effects and Role of the Substituents upon 2-Pyridone-catalyzed Mutarotation of 2,3,4,6-Tetra-*O*-methyl-D-glucose

Masayuki KUZUYA,* Akihiro NOGUCHI, and Takachiyo OKUDA
Gifu Pharmaceutical Uuiversity, 6-1, Mitahora-higashi 5-Chome, Gifu 502
(Received January 13, 1984)

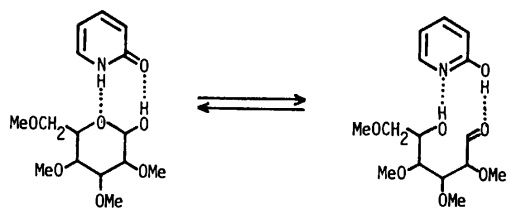
We have studied the catalytic activities of various substituted 2-pyridones on the mutarotation of 2,3,4,6-tetra-*O*-methyl-D-glucose (TMG). The results in an acetone solution at 37 °C showed that an introduction of the polar substituents into the 5- or 6-position, regardless of the nature of the substituents, retarded the relative rate of the mutarotation as compared to a parent compound, while that of alkyl substituents accelerated such rates. Further striking rate enhancements were observed in 5,6-dimethyl-substituted derivatives. Based on experimental results, we concluded that the 2-pyridones which can act as an effective catalyst are such that the 2-pyridone tautomeric form predominantly exists in solution due to its greater association ability and that the 2-pyridinol tautomeric form is energetically more stable for a lower activation energy of the double-proton transfer process in the 2-pyridone-TMG complex.

In a previous paper,[1] we described the influence on the tautomeric properties of 2-pyridones–2-pyridinols exerted by the introduction of substituents on the basis of the quantum mechanical quantities obtained from semiempirical molecular orbital calculations.

The importance of simultaneous two-proton transfers in a bifunctional catalysis is well known in relation to the enzymatic catalysis, and many related systems have been studied along these lines.[2] Among those is the classical 2-pyridone-catalyzed mutarotation of 2,3,4,6-tetra-*O*-methyl-D-glucose (TMG), which is of continued interest and is still under active investigations because of its high catalytic activity. Its very high catalytic efficiency can not be explained by the concerted general acid-base concept, since 2-pyridone is a relatively weak acid and base. Also, the reported rationalization of the catalytic functions are somewhat controversial. This indicates that a delicate balance of many blends of the effects can affect catalytic activities, and that the phenomenon can not be explained in a simple manner.

Tautomeric properties are considered to be of particular importance related to the efficiency of bifunctional catalytic activities, yet full details of the relationship to the tautomeric properties have not yet been understood. Part of our efforts in this area have involved an attempt to explore the substituent effects on the rate of the 2-pyridone-catalyzed mutarotation of TMG.

We report here on the interesting features of such effects and discuss the relations to the tautomeric properties. We also discuss the mechanism on the mutarotations with the aid of quantum mechanical quantities reported in a previous paper.[1]



Scheme 1.

Experimental

^{1}H-NMR spectra were obtained on a Hitachi R-20 spectrometer (60 MHz), in $CDCl_3$ with tetramethylsilane (TMS) as an internal standard. All chemical shifts are in parts per million (δ) from TMS. IR spectra were taken on KBr disks with a JASCO A-102 spectrophotometer and were calibrated against polystyrene. UV spectra were measured in cyclohexane with a Hitachi 323 spectrophotometer. Mass spectra were obtained at 70 eV with a JEOL JMS-D300 spectrometer. Elemental analyses were carried out by the Microanalytical Laboratory, Gifu Pharmaceutical University. All melting points are uncorrected.

2-Pyridone (**1**) and 6-chloro-2-pyridinol (**17**) were commercially available. 3-Methyl- (**2**), 4-methy- (**3**), 5-methyl- (**4**), 6-methyl- (**5**), and 4,6-dimethyl-2-pyridone (**7**) were prepared by diazotization of the corresponding substituted 2-pyridinamine, respectively.[3] 3,5-Dimethyl-2-pyridone (**6**) was prepared from 3,5-lutidine *N*-oxide according to the method of Bain and Saxtone.[4] 4,5,6-Trimethyl-2-pyridone (**9**),[5] 5-bromo-3-methyl-2-pyridone (**13**),[6] 3-methyl-5-nitro-2-pyridone (**14**),[7] 2,3-dihydro-4-methylfuro[2,3-*b*]pyridin-6-ol (**15**),[8] and 6-methoxy-2-pyridinol (**16**)[9] were prepared according to reported procedures. 2,3,4,6-Tetra-*O*-methyl-D-glucose (TMG) was prepared according to a method found in the literature.[10] All compounds used for the present study gave satisfactory spectral properties and elemental analyses.

Preparation of 2-Pyridones (10, 11, and 12). General Procedure: To polyphosphoric acid (125 g) were added the β-ketonitrile (0.05 mol)[11,12] and the ketone (0.05—1.10 mol). The mixture was stirred at 70 °C for 1.5 h, then at 100—120 °C for 1.5 h. The dark mixture was then added to crushed ice (*ca.* 1 Kg) while stirring. Then, ether (500 ml) was added. The resulting mixture was stirred for 30 min. The aqueous layer was neutralized with solid sodium hydrogencarbonate. The precipitated solid was collected and recrystallized from ethanol to give the 2-pyridones.

3,4,5,6-Tetramethyl-2-pyridone (10): Colorless plates, mp 255—256 °C. Found: C, 71.27; H, 8.80; N, 9.04%. Calcd for $C_9H_{13}NO$: C, 71.49; H, 8.67; N, 9.26%. ^{1}H-NMR: δ=1.98 (s, 3H, 3-Me), 2.11 (s, 6H, 4-Me and 5-Me), 2.32 (s, 3H, 6-Me), 13.0 (br, s, 1H, NH); IR: 3200—2200 (br, NH), 1630 cm^{-1} (C=O); UV: 237 (ε 6600), 304 nm (ε 6500); EIMS: *m/z* (% of base) 151 (M^+, 100), 123 (20), 122 (75), 108 (35).

3,5,6-Trimethyl-4-phenyl-2-pyridone (11): Colorless plates, mp

216—217 °C. Found: C,78.98; H, 7.21; N, 6.64%. Calcd for $C_{14}H_{15}NO$: C, 78.84; H, 7.08; N, 6.56%. ^{1}H-NMR: δ= 1.67 (s, 3H, 3-Me), 1.85 (s, 3H, 5-Me), 2.35 (s, 3H, 6-Me), 13.2 (s, 1H, NH); IR 3200—2400 (br, NH), 1640cm^{-1} (C=O); EIMS: *m/z* (% of base) 213 (M^+, 62), 212 (100), 194 (17), 184 (11), and 167 (13).

*3-Methyl-4-phenyl-2*H*-cyclopenta[*b*]pyridin-2-one (12)*: Colorless needles, mp 213—215 °C. Found: C, 79.94; H, 7.76; N, 6.13%. Calcd for $C_{15}H_{15}NO$: C, 79.97; H, 6.71; N, 6.22%. ^{1}H-NMR: δ=1.98 (s, 3H, 3-Me), 2.02 (br, m, 2H, CH_2), 2.46 (br, t, J=6Hz, 2H, CH_2), 2.97 (br, t, J=9Hz, 2H, CH_2), 7.05—7.63 (m, 5H, Ar), 13.35 (br s, 1H, NH); IR: 3200—2200 (br, NH), 1630cm^{-1} (C=O); UV: 228 (ε 14800), 319nm (ε 5600); EIMS: *m/z* (% of base) 225 (M^+, 57), 224 (100), 216 (15), 196 (7).

Rate Measurements. The solvents of acetone and benzene (Extra-pure grade, Wako-pure Chemicals, Ltd.) were purified by distillation before use. The rate of mutarotation was followed using a JASCO DIP-4 digital polarimeter. The rate measurements were carried out according to the method of Smith and Hearn.[13] The pseudo first-order rate constants for the mutarotation were calculated by a least-squares method.

Infrared Spectral Measurements for Intensities of the Monomeric NH Stretching Bands (log I_o/I*).* The solvent of carbon tetrachloride (spectroscopic grade) was dried over molecular sieves. Measurements were made with a JASCO DS-403G Infrared Grating spectrophotometer using a 20mm NaCl cell. The infrared spectra (3600—3200cm^{-1}) were recorded with solvent compensation using a five-fold-scale expansion in transmittance at room temperature.

Results and Discussion

For the substituent effects of 2-pyridones on the mutarotation of TMG, only the study of each of its four monomethyl-substituted 2-pyridones in the 3-, 4-, 5- or 6-position and electron-withdrawing groups in the 5-position has been reported as far as we are aware.[13] It has been shown that the electron-withdrawing groups in the 5-position retarded the rate of mutarotation and that the active catalyst was in the 2-pyridone form. The tautomeric properties are considered to be an important factor in determining the reaction rate. All the 2-pyridones examined, however, were those known to exist largely in the 2-pyridone form in a polar solvent.

Substituent Effect of 2-Pyridone on the Catalytic Activity. We have studied the substituent effects on the rate of the mutarotation of TMG in acetone using various substituted 2-pyridones including compounds (**15**—**17**) whose tautomeric equilibria are experimentally known to favor the 2-pyridinol form in solution.[14] Acetone was chosen as a solvent because of the high solubility of the substituted 2-pyridones.

The rate-constants obtained at 37 °C are listed in Table 1.

Table 1 shows that the catalytic activities of 2-pyridones are not amenable to a simple rationalization and discloses several interesting features. The derivatives (**13**—**17**) which possess a polar substituent at the 5- or 6-position regardless of the electron-withdrawing or -donating substituents showed much less catalytic activity compared to that of the parent compound; the compounds bearing a rather strong electron-withdrawing group at the 5-position (**13**, **14**), which favor the 2-pyridone form over the 2-pyridinol form,[14] and the ones bearing a polar substituent (-OMe and -Cl) at the 6-position (**15**—**17**), which exist very largely in the 2-pyridinol form,[14] are both poor catalysts.

Hence, it appears that the catalytic activity of 2-pyridones on the mutarotation of TMG is not simply related to the apparent abundance of either of the tautomeric forms.

In contrast, the alkylated derivatives (**2**—**12**) were shown to display higher catalytic activities than the parent compound (**1**). Among them, the 6-methyl substituent seems to exert the strongest influence on the rate acceleration.[15] Further striking rate enhancements were observed in derivatives bearing methyl substituents at both the 5- and 6-positions (**8**—**10**).

It is known that each of 2-pyridones and TMG undergoes self-association by hydrogen bonding in nonpolar solvents[16] and that the tautomerisms occur *via* a dynamic process involving double proton transfers in self-association forms.[17] However, the initial stage of the 2-pyridone-catalyzed mutarotations of TMG must involve the formation of a hydrogen-bonded complex between 2-pyridone and TMG. Therefore, the association ability should closely be related to the catalytic activity of the 2-pyridones.

The self-association abilities can be regarded as an experimental criteria for the 2-pyridone-TMG association ability. Such abilities of several methyl derivatives were measured by IR spectra based upon the intensity of the NH stretching band (around 3400cm^{-1}) of the monomeric species as log (I_o/I).

The relative catalytic activities (k_r) in Table 1 were plotted against log (I_o/I), and are shown in Fig 1.

It can be seen from Fig. 1 that the abundance of the monomeric form in a series of 6-methy derivatives (**5** and **7**—**10**) is obviously small. This fact is also consistent with the greater self-association ability of these derivatives deduced from the CNDO/2 calculations previously reported.[1] Although the data, thus measured, are not of high accuracy due to experimental limitations, the relative catalytic activities (k_r) of **1**—**7** were shown to be considerably well correlated with log (I_o/I), as indicated in Fig. 1. Thus, it seems reasonable, to a first approximation, to consider that the catalytic activity of the 2-pyridone is proportional to its association ability.

However, the large deviation of 5,6-dimethyl derivatives (**8**—**10**) from the line strongly indicated that other factors could contribute to the higher catalytic activities of this series.

Concerning a Pronounced Effect of 5,6-Dimethyl Substitutions. In view of the observations that the association abilities of the 6-methyl (**5**) and (**7**), and

a) [TMG]=0.09 M and [2-pyridones]=0.005 M. (1 M=1 mol dm^{-3}) b) Correlation coefficient. c) $k_{obsd}/k_{obsd(parent)}$

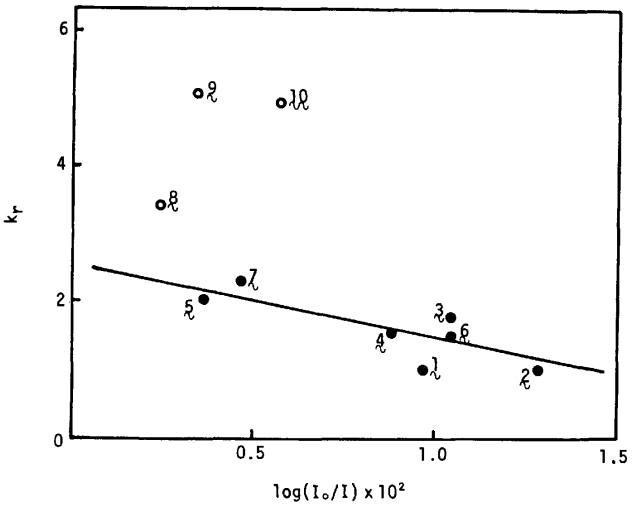

Fig. 1. Plot of the relative catalytic activities (k_r) *vs.* the intensities of the monomeric NH stretching band ($\log(I_0/I)$).
The straight line obtained by a least squares method of **1**—**7** may be expressed as $Y(k_r)=-1.2131\,X(\log(I_0/I))+2.6677$ and the correlation coefficient (r) was obtained as $r=-0.8126$.

5,6-dimethyl derivatives (**8**—**10**) are more or less the same (Fig. 1), such abilities do not account for the striking rate enhancement of a series of 5,6-dimethyl derivatives (**8**—**12**).

The 6-methyl substituent has been shown to render the effect in nature similar to the polar substituents on the relative energetic between the two tautomers (*i.e.* the greater stabilization of 2-pyridinol form), but to a much lesser extent and, to make the tautomeric equilibria labile to the molecular environment. It has also been shown that this propensity was further strengthened by 5,6-dimethyl substitutions.[1)] The origin of these particular substituent effects can be interpreted as due to bond lengthenings at the C_5–C_6 bond, which apparently weaken the diene character to lead to the more 2-pyridinol-like ring structure.

The ring structural difference between the two tautomeric forms should also be related to the kinetics of the tautomerization. Such may be inversely proportional to each other based on the principle of least nuclear motion,[18)] and the derivatives, which require less structural variations during the tautomerization, may be of small activation energies.

Thus, the further acceleration of the rate of the mutarotation catalyzed by 2-pyridones is ascribed to the tautomeric properties, since such reactions proceed with the tautomerization of 2-pyridones.

Inversely, the extremely large predominance to either of the two tautomeric forms induced by an introduction of polar substituents would lead to a retardation of the dynamic process involving the double proton transfers. This rationalization is consistent with the fact that 2-pyridones bearing 6-polar substituents were poor catalysts (*vide supra*), and no further rate enhancement of the mutarotation was observed in the cyclopenta-derivative (**12**) as compared to that of the other derivatives bearing two methyl groups at both 5- and 6-positions, since the C_5–C_6 bond in **12** is no longer lengthened due to the absence of the buttressing effects of the methyl group on each other.

Reactions in Benzene. We have measured the rate of the TMG-mutarotations on several methyl derivatives (**1**, **5**, and **8**) in benzene at various temperatures (10 °C—38 °C) because of the greater tendency for the enhancement of the association in a nonpolar solvent. The pseudo first-order kinetics (k_{obsd}) are summarized in Table 2 along with the correlation coefficient (r) of the least-squares treatment at each temperature.

Table 2 clearly indicated that a considerable rate

a) [TMG]=0.09 M and [2-pyridones]=0.002 M. b) Correlation coefficient.

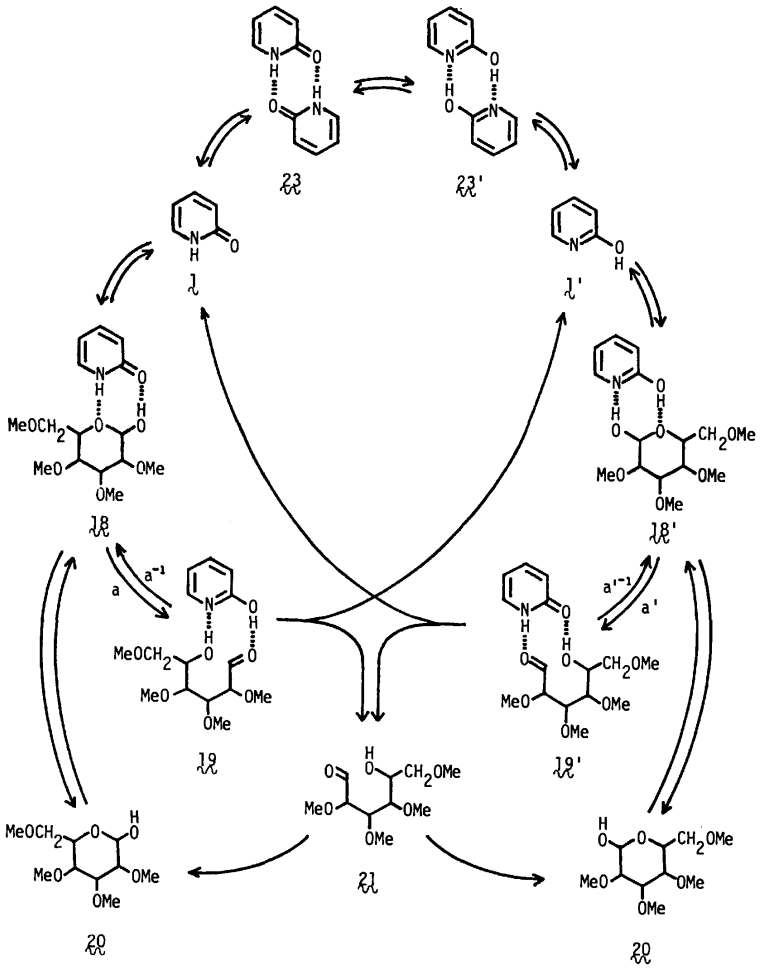
enhancement was observed in a benzene solution as compared to those in acetone at the same temperature. The solvent effect of acetone upon the lower rate can be rationalized in terms of the lower concentration of the 2-pyridone–TMG complex and a higher activation energy of the double proton-transfer process by the greater solvation in such a complex.

Conclusions

On the basis of the results and discussion described above, we deduced the sequences for the mutarotation of TMG catalyzed by 2-pyridones as shown in Scheme 2 for a parent compound (**1**) as an example.

In Scheme 2, the ring-opening processes, ***a*** and ***a'***, include the breaking of the σ-bond in TMG and are considered to require the largest activation energy, and to be important in determining the rate of mutarotation. Of these, process ***a*** is apparently important due to the greater association ability of the pyridone form and the activation energy is considered to be dependent on the relative energetics of **18** and **19**.

It can be concluded, therefore, that for the 2-pyridones to be effective catalysts, the 2-pyridone form predominantly exists in solution due to a greater self-association ability (for higher concentration of the complex (**18**)), and the 2-pyridinol tautomeric form is intrinsically more stable (for a lower activation energy of process ***a***). The tautomeric properties of 6-methyl derivatives, especially 5,6-dimethyl and 4,5,6-trimethyl derivatives, meet the above mentioned requirements[1)]



Scheme 2.

and, indeed, these derivatives were all effective catalysts.

Synthetic Studies on the Ochtodane Type Terpenes I. Stereoselective Construction of the Ochtodane Skeleton from Myrcene

Yukio MASAKI,* Kinji HASHIMOTO, Kazuhiko SAKUMA, and Kenji KAJI
Gifu Pharmaceutical University, 5-6-1 Mitahora Higashi, Gifu 502
(Received May 4, 1984)

The ochtodane skeleton, the Carbon framework of 1,1-dimethyl-3-ethylcyclohexane (**1**) was constructed highly stereoselectively by the acid-catalyzed ($SnCl_4$ or CF_3CO_2H) cyclization of the terminally functionalized myrcene derivatives, the benzenesulfenyl chloride adduct (**7**), the terminal β-hydroxy sulfide (**8**) derived from **7**, and myrcene 6,7-epoxide (**10**). The stereoselectivity of the 3-exo-double bond in **1** formed concomitantly in the cyclization reaction was found to depend remarkably upon the reaction temperature and the 85—94% of *E*-stereoselectivity was attained at −78 °C. By the method, the ochtodane derivatives with the sulfur- or oxygen-functional groups on the C(6)-position were obtained. Synthetic applications of the ochtodane type compounds (**12**) and (**19**) to the aldehyde component (**4**) of the pheromone of the male boll weevils and to an ochtodane type terpene (**26**) isolated from the red alga *Ochtodes crockeri*, are reported.

In 1975 novel dihalogenated dimethylhexahydrobenzofurans including chondrocole A (**2**) were isolated by Moore from Hawaiian red alga *Chondrococcus hornemanni*.[1a] Recently, Fenical and coworkers have found a variety of polyhalogenated and/or oxygenated cyclic monoterpenes possessing the ring system of 1,1-dimethyl-3-ethylcyclohexane (**1**) in red seaweeds (Rhodophyta) of the genera *Chondrococcus* and *Ochtodes* (Rhizophyllidaceae),[1b] and they suggested the name "ochtodane" for the skeleton (**1**). They also reported that some of the ochtodane type monoterpenes appear to function as herbivore feeding deterrents in the marine environment and that a certain polyhalogenated compound of this class shows strong anti-bacterial activity. Interestingly, the less functionalized compounds (*Z*-**3**) and (*E*- and *Z*-**4**) with the carbon skeleton (**1**) already have been isolated and recognized by Tumlinson and coworkers in 1969 as the sex attractant and aggregating pheromonal components of the insect boll weevils *Anthonomus grandis* Boheman.[2a] These terpenes have been suggested to be biosynthesized from myrcene (**5**) directly or *via* the corresponding oxygenated or halogenated precursors in organisms.[1a,3] In the context, a unique sesquiterpene pleraplysillin-1 (**6**) isolated from a marine sponge *Pleraplysilla spinifera* may be classified as the higher homologue of the ochtodane type terpenes.[4]

Because of the practical interest in the agricultural purpose for extermination of noxious insects, a lot of synthetic efforts have focused on the pheromonal components (**3**) and (**4**).[2,5,6a] The biogenetic type cyclization of acyclic 1,5-dienes affording terpenoid-carbocycles was pioneered by Eschenmoser[7a] and by Stork,[7b] and has been extensively studied on not only the non-functionalized but also functionalized polyolefins.[7] In addition to the nonbiogenetic type synthetic route consisting of the two-carbons homologation of 3,3-dimethylcyclohexanone which in general appears non or less stereoselective concerning the geometry of the exocyclic double bond in (**3**) and (**4**),[2b,5] several routes utilizing the biogenetic type cyclization of acyclic monoterpenes including myrcene (**5**) have been reported: Acid-catalyzed cyclization of γ-geraniol,[6a] tricarbonyl myrcene iron,[6b] and 3,10-dihydromyrcene;[6c] and brominative cyclization of myrcene (**5**) using 2,4,4,6-tetrabromo-2,5-cyclohexadien-1-one.[6d] None of these precedents, however, has offered satisfactory stereoselectivities and requisite functionalizations for synthesis

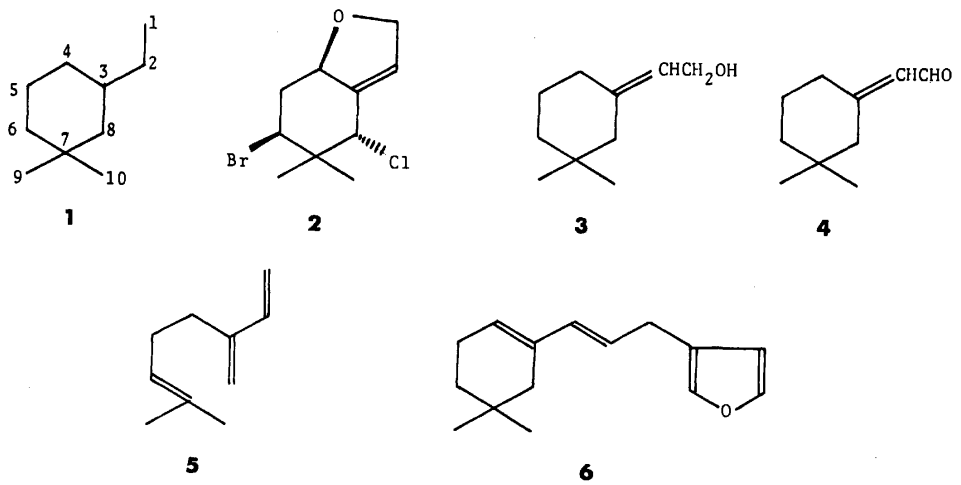

Chart 1.

of the highly functionalized ochtodane type terpenes. Here we disclose new biogenetic type and stereoselective cyclizations of myrcene (**5**) *via* the benzenesulfenyl chloride (PhSCl) adduct (**7**) or the epoxide (**10**) effectively affording the functionalized ochtodanes (**11—15, 17**) which are expected to be the promising intermediates for a variety of ochtodane type terpenes.[8]

Results and Discussion

In a general consideration concerning the possible acid- catalyzed cyclization of myrcene (**5**), the generated terminal tertiary cation (**i**) would cyclize to give the ochtodane type skeleton (**1**) and the other tertiary cation (**ii**), if generated, would form the cyclobutane framework (**iii**) found in glandisol which has been recognized to be the major pheromonal constituent of male boll weevils.[2] Wolinsky has examined the cyclization reaction of γ-geraniol (**iv**) and methyl γ-geranate (**v**) under acidic conditions and reported exclusive formation of the cyclohexane framework (**1**) so far.[6a] We also investigated in the preliminary experiments acid-catalyzed reactions of myrcene (**5**) itself under several conditions involving CF_3CO_2H (CH_2Cl_2/−20°C), $SnCl_4$ (CH_2Cl_2/0°C), 90% HCO_2H (reflux), and polyphosphoric acid (130°C), but the reactions produced complicated and intractable mixtures in all cases examined. Then we turned our attention to the examination of cyclization reaction of the terminally functionalized myrcene derivatives.

1) Acid-catalyzed Cyclization of Terminally Sulfur-substituted Myrcene Derivatives (Scheme 1). Mustafaeva reported that methyl geranate (**vi**) gave the cyclized product (**viii**) on treatment with PhSCl in the presence of $AgSbF_6$ in nitromethane by way of the *in situ* formed terminal adduct (**vii**)[9a] and Weiler also found that the PhSCl-adduct (**x**) of methyl 7-methyl-3-oxo-7-octenoate (**ix**) cyclized to give a cyclohexane derivative (**xi**) by refluxing with silica gel in CH_2Cl_2.[9b] Also we have observed the acid-catalyzed cyclization of terminally sulfur-functionalized geraniol and nerol derivatives (**xii, xiii**) affording the cyclohexane derivatives (**xiv, xv**).[10] Findings in the literatures[9] and our observations[10] prompted us to investigate the behaviors of the terminally sulfur-functionalized myrcene derivatives in the acid-catalyzed cyclization conditions.

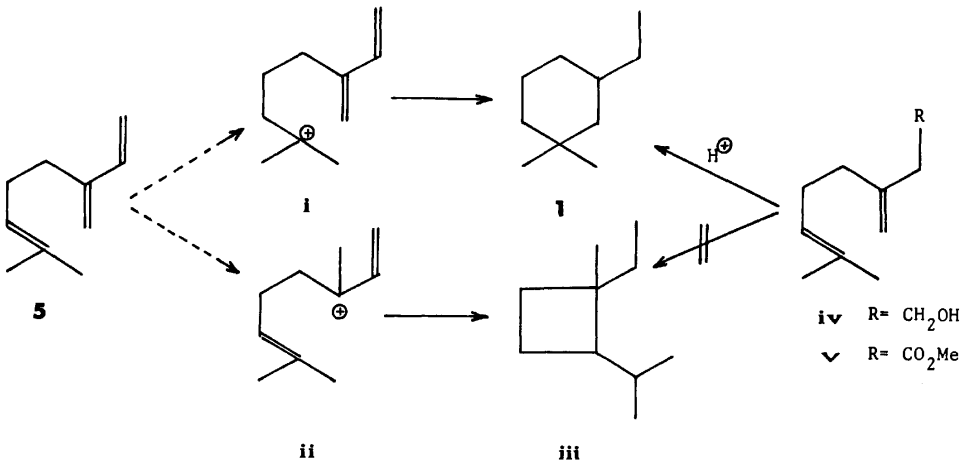

Chart 2.

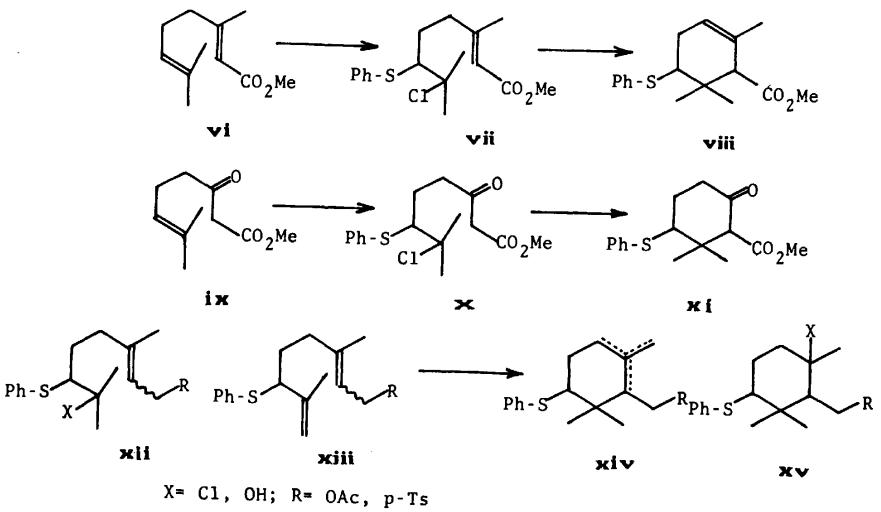

Chart 3.

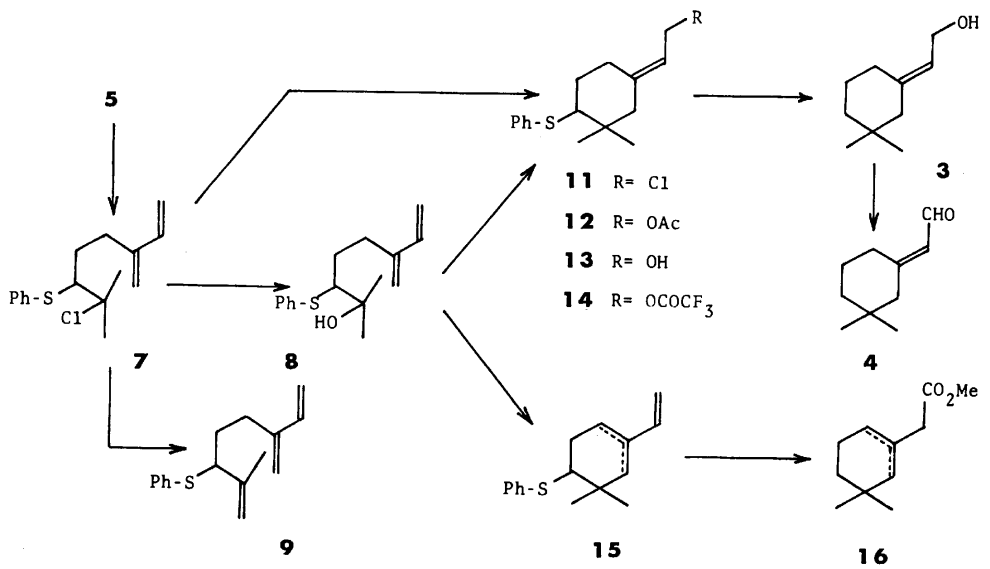
The substrates, PhSCl-adduct (**7**), β-hydroxy sulfide (**8**), and terminal methallylic sulfide (**9**) was prepared from myrcene (**5**) by the method recently developed[11] for the terminal functionalzation of acyclic isoprenoids.

The crude adduct (**7**) was treated with 0.2equiv of $SnCl_4$ in CH_2Cl_2 at −20°C to produce expectingly the cyclized products (**11**) whose ^{1}H-NMR exhibited mainly sharp singlets at δ 0.69 and 1.16 assignable to the gem-dimethyl groups on the cyclohexane ring and a set of a doublet and a triplet respectively at δ 3.95 and 5.31 with the identical coupling constant (8.0Hz) assignable to the primary allylic chloride functionality. The crude product, without further purification, was converted to the corresponding acetate (**12**) by treatment with an excess amount of AcONa in *N,N*-dimethylformamide (DMF) at 60°C for 16h. Purification of the product by column chromatography on silica gel gave a stereoisomeric mixture of acetates (*E*-**12**) and (*Z*-**12**) in 58% overall yield from **5**. ^{1}H-NMR showed signals for one of the geminal methyl groups on the cyclohexane ring at δ 0.92 at a overlaped singlet and for the other one at δ 1.14 and 1.18 as the separate singlets in a ratio 75:25, the peaks which proved to be the diagnostic peaks representing the isomeric ratio. All of the other signals in ^{1}H-NMR, the molecular ion peak at *m/z* 304 in the mass spectrum, and the IR band at 1720cm^{-1} supported the structure of the acetate (**12**). The stereoisomeric ratio was finally determined by ^{1}H-NMR analysis of the aldehyde (**4**) derived from the acetate (**12**) by a sequence of reactions, *vide infra*. After alkaline hydrolysis of the acetate (**12**), desulfurization of the alcohol (**13**) obtained with Li in liquid NH_3 gave the sulfur-free alcohol (**3**) in 65% overall yield from **12**. Oxidation of the alcohol (**3**) with active MnO_2[12] led in 85% yield to the stereoisomeric mixture of α,β-unsaturated aldehydes (**4**), which are the components of the male boll weevil pheromone.[2] The *E/Z*-ratio of the aldehyde (**4**) was determined as 75:25 on the basis of its ^{1}H-NMR analysis: The diagnostic isolated allylic C(8)-methylene protons of each component were clearly observed as a couple of singlets at δ 2.05 (major) and 2.47 (minor) which had been assigned to that of the *E*- and *Z*-component respectively.[2,6a] On the detailed examination of the cyclization conditions, it was found that the stereoselectivity of the concomitant formation of the double bond in the present cyclization reaction is dependent upon the reaction temperature. Thus, cyclization of the adduct (**7**) using $SnCl_4$ (0.2equiv) at 0°C gave the *E/Z*-mixture of the acetate (**12**) in a ratio 59:41 after the subsequent acetoxylation of the crude chloride (**11**), and at −78°C yielded the *E/Z*-ratio of 85:15 contrastingly.

The cyclization reaction was investigated also on the β-hydroxy sulfide (**8**). On treatment of **8** with an excess amount of CF_3CO_2H in CH_2Cl_2 at −20°C, the cyclized trifluoroaceate (**14**) (62%) was obtained, whose isomeric ratio was tentatively estimated as 77:23 on the basis of ^{1}H-NMR analysis: The diagnostic signals of singlets indicating the isomeric ratio appeared at δ 1.16 (major) and 1.20 (minor) assignable to the one of the gem-dimethyl groups on the cyclohexane ring. The ratio was also verified by derivatization of **14** to the aldehyde (**4**) *via* hydrolysis of **14** leading to the alcohol (**13**). The analogous tendency of dependence of the stereoselectivity on the reaction temperature as described for the cyclization of the adduct (**7**) was observed and cyclization of **8** using CF_3CO_2H at 0°C gave a poor *E/Z*-ratio 64:36 of the trifluoroacetate (**14**). On the other hand, treatment of **8** with concd H_2SO_4 in Et_2O at room temperature afforded in this case a high yield (80%) of the regioisomeric cyclized diene mixture (**15**) in a ratio of 60:40 analyzed from its ^{1}H-NMR. The structure of **15** was confirmed by conversion to the regioisomeric mixture of the carboxylic ester



Scheme 1.

Table 1. Acid-catalyzed cyclization of the terminally sulfur-functionalized myrcene derivatives (**7**) and (**8**)

Substrate	Acid (mole equiv)	Reaction Conditions Solvent,	Temp	Time	Product (Ratio)	yield %	*E/Z*-ratio

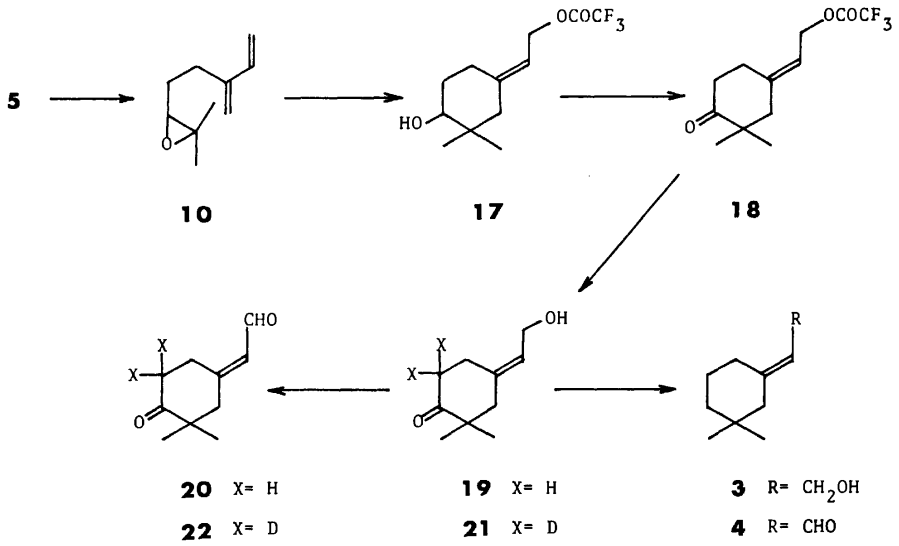
a) The crude adduct was used. b) The primary product (**11**) was not isolated and directly led to **12**.



Scheme 2.

(**16**), which have been reported by Wolinsky,[6a] by a sequence of reactions involving hydroboration, desulfurization, Jones oxidation, and then esterification.

On the substrate terminal methallylic sulfide (**9**), unfortunately, all the several attempted conditions (1.0equiv $SnCl_4/CH_2Cl_2/0$—15°C/1 h; excess H_2SO_4/Et_2O/15°C/2 h; excess CF_3CO_2H/CH_2Cl_2/15°C/1 h) were not effective for the expected cyclization and gave recovery of the starting material. Results of the cyclization reactions examined on the PhSCl-myrcene adduct (**7**) and the β-hydroxy sulfide (**8**) are summarized in Table 1.

II) Cyclization of Myrcene 6,7-Epoxide (Scheme 2). The terminal epoxide functionality has been utilized in the carbocyclization of acyclic polyisoprenoids as much more general and efficient initiator.[7d] To our knowledge, however, the acid-catalyzed carbocyclization of myrcene 6,7-epoxide (**10**) has never been precedented in the literature. In order to construct the functionalized ochtodane skeleton, cyclization of **10** appeared to be one of the attractive candidates. Thus, the epoxide (**10**) was stirred with an excess amount of CF_3CO_2H in CH_2Cl_2 at −20°C. The structural analysis of the product (**17**) obtained in 54% yield revealed that the desirable cyclization was realized. All the data including the IR band at 3400 and 1780 cm^{-1}, M^+ peak at *m/z* 266 in the mass spectrum, and ^{1}H-NMR signals for the gem-dimethyl groups at δ 0.81 and 0.91, the primary allylic trifluoroacetate system at δ 4.77 (2H, d) and 5.28 (1H, t), and the secondary hydroxyl functionality at δ 1.89 (OH) and 3.40 (1H, ABXq) fully supported the structure (**17**) although the stereoisomeric ratio could not be estimated. Oxidation of the alcohol (**17**) with pyridinium chlorochromate (PCC) afforded the ketone (**18**) in 87% yield. In ^{1}H-NMR the ketone (**18**) exhibited sharp singlets at δ 1.04 and 1.07 in a ratio of intensity 87:13 which was supposed to represent the *E/Z*-stereoisomeric ratio of **18**. Exact determination of the ratio was perfomed by the ^{1}H-NMR analysis of the keto aldehyde (**20**) and its dideuterated derivative (**22**) as described below. The compound (**18**) was subjected to alkaline hydrolysis to lead to the keto alcohol (**19**) (92%) which was oxidized to the keto aldehyde (**20**) in 78% yield with active MnO_2. Also in this compound, separate singlets were observed at δ 1.10 and 1.13 in a ratio 87:13 of intensity in ^{1}H-NMR. Correspondence of the ratio to the stereochemistry of the bouble bond in **20** was clearly attained by the ^{1}H-NMR analysis of the 5,5-dideuterio keto aldehyde (**22**) derived by the deuterium

Table 2. Cyclization of myrcene 6, 7-epoxide (**10**) using CF_3CO_2H[a)]

Reaction Temp (°C)	Product	Yield/%	*E*/*Z*-ratio
−5	**17**	53	83:17
−20	**17**	54	87:13
−78	**17**	43	94:6

a) The reaction was carried out in CH_2Cl_2 for 30 min by using 5.0 equiv of CF_3CO_2H.

exchange reaction[13)] of the keto alcohol (**19**) in MeOD with Na followed by oxidation of the 5,5-dideuterio keto alcohol (**21**) with active MnO_2. Generally, the γ-*cis*-methylene protons of α,β-unsaturated aldehydes and esters are known to appear in lower ^{1}H-NMR chemical shifts than the corresponding γ-*trans*-methylene protons by the paramagnetic deshielding effect of the spatially proximate carbonyl group.[2,6a,14)] Thus, the major pair of 2H-signals at δ 2.48 and 3.09 proved to be assigned to the C(8)- and C(4)-methylenes of the *E*-component (*E*-**22**) and the minor pair of 2H-signals at δ 2.67 and 2.86 to the C(4)- and C(8)-methylenes of the *Z*-component (*Z*-**22**), and therefore, the *E*/*Z*-ratio of **22** was determined clearly as 87:13, which was well consisted with the estimation on the trifluoroacetoxy ketone (**18**). The identical *E*/*Z*-ratio was indicated by ^{1}H-NMR analysis of the aldehyde (**4**) derived from the keto alcohol (**19**) *via* deoxygenation[15)] of the corresponding tosylhydrazone with $NaBH_4$ providing the allylic alcohol (**3**). The stereoselectivity in this cyclization also proved to be dependent upon the reaction temperature. As shown in Table 2, the lower temperature resulted in the formation of the *E*-component (*E*-**17**) in higher proportion.

We propose that the higher *E*-stereoselectivity in the trisubstituted double bond formation at the lower temperature in these cyclizations ascribes to the preferential tandem cyclization of the cation (**A**) with the *s*-*trans*-1,3-diene system and concerted formation of the exo-double bond to the reaction of the other cation (**B**) bearing the *s*-*cis*-1,3-diene system.

III) Synthesis of an Oxygenated Ochtodane Type Terpene, (±)-(2Z)-2,4-Ochtodadiene-1,6-diol (26) (Scheme 3). A simple and successful application of the functionalized ochtodanes (**12**) and (**19**) obtained was achieved in the stereoselective synthesis of a diol component (**26**) isolated from the red alga *Ochtodes crockeri*.[1b)] Oxidation of the 6-phenylthio derivative (**12**) (*E*:*Z*=85:15) with 30% H_2O_2 in AcOH followed by heating the intermediate sulfoxide in xylene gave the diene acetate (**23**) in 79% yield from **12**. The structure of the compound (**23**) was supported by the spectral analysis: The M^+ ion was observed at *m*/*z* 194 in the mass spectrum, and the signals of the newly formed C(4)-allylic methylene at δ 2.78 (major (*E*-**23**)) and 2.70 (minor (*Z*-**23**)) as broad singlets and of the C(5)- and C(6)-olefinic protons at δ 5.40—5.60 were detected in ^{1}H-NMR. On treatment of the diene (**23**) with an

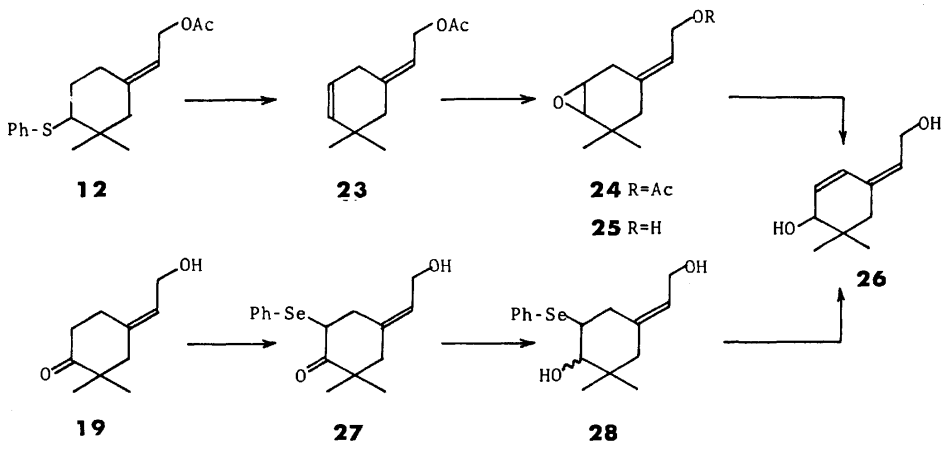
R= Ph, X= S
or
R= H, X= O

Chart 4.

equimolar amount of *m*-chloroperbenzoic acid in CH_2Cl_2 at −20°C, a selective epoxidation proceeded to lead in 59% yield the 5,6-epoxide (**24**), ^{1}H-NMR of which indicated that the allylic acetate system remained intact. Although the *E*- and *Z*-component of **24** were separable by column chromatography on silica gel, the tedious separation of the stereoisomers turned out to be not necessary for the synthesis of the target compound (**26**) because a unexpected kinetic stereoselection in the base promoted epoxide opening reaction of the epoxy alcohol (**25**) was observed. Thus, after alkaline hydrolysis of **24** (*E*:*Z*=15:85), the resulted epoxy alcohol (**25**) was treated with 2.5 equiv of lithium diisopropylamide (LDA) in THF at −78—−20°C for 2 h to furnish the desired diol (**26**) as the single stereoisomer in 73% yield and a small amount of recovery (less than 10%) of the starting epoxy alcohol which was substantially enriched in the *E*-isomr.[16)] The dienediol (**26**) obtained was identified with the natural one[1b)] by spectral comparisons.

The dienediol (**26**) was also synthesized alternatively from the keto alcohol (**19**) *via* a tandem procedure of selenylation and elimination of selenenic acid.[17)] Selenylation of **19** was carried out with LDA and diphenyl diselenide to give the seleno keto alcohol (**27**) (70%). Reduction of **27** with $LiAlH_4$ afforded in 84% yield the selenodiol (**28**), which was treated with $NaIO_4$ in aqueous MeOH at room temperature providing the diol (**26**) in 61% yield.

In conclusion, we established a facile stereoselective method providing the ochtodane skeleton with the functional group on the C(6)-position. The compounds obtained are claimed to be the promising



Scheme 3.

intermediates for the synthesis of a variety of natural ochtodane type terpenes including pleraplysillin-1 (**6**),[4] a unique sesquiterpene which is recognized synthetically as the homologated ochtodane at the C(1)-position with furfuryl moiety. A successful application of the ochtodane derivative (**3**) obtained in this work to the synthesis of the sesquiterpene (**6**) will be reported in the following paper.[18]

Experimental

General. IR spectra were taken on a JASCO IRA-1 spectrometer in $CHCl_3$ solution and the absorption bands (ν_{max}) are reported in cm^{-1}. Mass spectra (MS) were obtained on a JMS-D300 instrument at an ionizing potential of 70eV and peaks are reported in *m/z* values with relative intensities (%) in parenthesis. ^{1}H-NMR spectra were recorded on a Hitachi R-20B spectrometer (60MHz) in CCl_4 solution, unless otherwise noted, with tetramethylsilane (TMS) as an internal standard and chemical shifts are reported in δ (ppm) relative to TMS and coupling constants (*J*) in hertz (Hz). All the solvents used in reactions were freshly distilled to remove moisture. Reactions were carried out usually under nitrogen unless otherwise noted. Reaction mixtures were usually worked up as follows: A mixture was extracted with Et_2O, washed with water or saturated brine and saturated aqueous $NaHCO_3$, if necessary, dried over anhydrous $MgSO_4$, concentrated *in vacuo* using a rotary evaporator at water aspirator pressure below room temperature, to give a crude product which was purified by column chromatography. Silica gel (Wakogel B-5F) and Wakogel C-200 were employed respectively for analytical thin-layer (TLC) and column chromatography using hexane-Et_2O solvent system.

Materials. Myrcene (**5**) was purchased from Tokyo Kasei (TCI). Benzenesulfenyl chloride (PhSCl) was freshly prepared according to the literature.[19] Myrcene 6,7-epoxide (**10**) was obtained by the reported method.[20] The terminal methallylic sulfide (**9**) was prepared according to our reported method.[11] The β-hydroxy sulfide, 2-methyl-6-methylene-3-phenylthio-7-octen-2-ol (**8**) was prepared as follows: To a solution of myrcene (**5**) (680mg, 5.0mmol) in CH_2Cl_2 (10ml) was added dropwise a solution of PhSCl (725mg, 5.0mmol) in CH_2Cl_2 (3.0ml) at −20°C. After being stirred for 10min, the mixture was concentrated *in vacuo* to give the crude adduct (**7**) (1.4g).[11] The adduct was dissolved in aq CH_3CN ($CH_3CN:H_2O$=5:1)(20ml) and stirred at room temperature for 20h.[11a] The mixture was worked up by the usual manner to give **8** (720mg, 55) as oil. Date for **8** follow: IR 3400, 1595, 1590; MS 262 (M^+, 71), 204 (43), 137 (40), 136 (100), 135 (74), 123 (93), 110 (57); NMR 1.16, 1.23 (each 3H, $(C\underline{H}_3)_2C(OH)$, 2.31 (1H, s, OH), 2.98 (1H, dd, *J*=11.0 and 3.0, CH(SPh)), 4.80—5.30 (4H, m, $2X=CH_2$), 6.03—6.54 (1H, dd, *J*=18.0 and 11.0, $C\underline{H}=CH_2$). The compound **8** was also obtained alternatively as follows: The crude adduct (**7**) prepared from **5** (5mmol) was stirred with AcONa (1.23g, 15mmol) in AcOH (20ml) at 20°C for 1h. Usual work-up of the mixture gave the corresponding acetate of the β-hydroxy sulfide (**8**) (990mg, 65%),[11b] which was hydrolyzed in EtOH (15ml) with 3% NaOH (15ml) at room temperature for 2h to give **8** (690 mg, 81%).

Acid-catalyzed Cyclization of the Terminally Sulfur-Functionalized Myrcence Derivatives (7) and (8). Cyclization of the Benzenesulfenyl Chloride-Myrcene Adduct (7) Catalyzed by $SnCl_4$. To a solution of the adduct (**7**) prepared from myrcene (**5**) (550mg, 4.0mmol) and PhSCl (600mg, 4.1mmol) in CH_2Cl_2 (12ml) at −20°C, was added dropwise over 5 min a solution of $SnCl_4$ (100μl, 0.85mmol) in CH_2Cl_2 (2.0ml) at −20°C. After being stirred for 30min at −20°C, the mixture was diluted with CH_2Cl_2, washed with successively with saturated $NaHCO_3$ and water, dried, and concentrated to give the crude 1-chloro-6-phenylthio-2-ochtodene (**11**) (1.09g) as oil: MS 282 ($(M+2)^+$, 30), 280 (M^+, 72), 245 (75), 170 (33), 135 (63), 110 (100); NMR 0.96 (3H, s, one of the CH_3 of $C(7)(CH_3)_2$),
1.16 (major) and 1.19 (minor) (overall 3H, singlets (75:25), the other one of $C(7)(CH_3)_2$), 3.95 (2H, d, *J*=8.0, $=CHC\underline{H}_2Cl$), 5.31 (1H, bt, *J*=8.0, $=C\underline{H}CH_2Cl$). The crude chloride (**11**), without further purification, was warmed with AcONa (550mg, 6.7mmol) in DMF (12ml) at 60°C for 16h. The reaction mixture was worked up by the usual manner to leave an oily product (1.02g). Purification of the product by column chromatography afforded the oily acetate, 1-acetoxy-6-phenylthio-2-ochtodene (**12**) (705mg, 58% from **5**). Data for **12** follow: IR 1720, 1580; MS 304 (M^+, 7), 244 (30), 135 (100), 134 (66); NMR 0.92 (3H, s, one of the CH_3 of $C(7)(CH_3)_2$), 1.14 (major) and 1.18 (minor) (overall 3H, singlets (75:25), the other one of $C(7)(CH_3)_2$), 1.95 (3H, s, CH_3CO_2), 2.83—3.10 (1H, dd, *J*=10.0 and 4.5, CH(SPh)), 4.46 (2H, d, *J*=7.5, $=CHC\underline{H}_2OAc$), 5.21 (1H, bt, *J*=7.5, $=C\underline{H}CH_2OAc$); Found: C, 70.75; H, 7.83%. Calcd for $C_{18}H_{24}O_2S$: C, 71.10; H, 7.95%. Cyclizations of **7** at 0°C and −78°C were

examined and the results are listed in Table 1.

Cyclization of 7 Catalyzed by $TiCl_4$. Cyclization of **7** was carried out at −20 °C in CH_2Cl_2 using 0.3 equiv of $TiCl_4$ by the same procedure as described above and the crude product was directly converted into the acetate (**12**) (28%, *E*:*Z*=77:23).

Cyclization of 7 Using CF_3CO_2H. A solution of the crude adduct (**7**) (140 mg) in CH_2Cl_2 (0.5 ml) was added dropwise over 5 min at −20 °C into a mixture of CH_2Cl_2 (3.0 ml) and CF_3CO_2H (0.5 ml, 6.5 mmol). After being stirred for 80 min, the mixture was poured into water and the product was extracted with CH_2Cl_2, washed successively with saturated $NaHCO_3$ and brine, dried, and concentrated. The crude product (137 mg) was purified by column chromatography to give the chloride (**11**) (35 mg, 25%) as the less polar fraction and the trifluoroacetate, 6-phenylthio-1-trifluoroacetoxy-2-ochtodene (**14**) (45 mg, 25%) as the more polar one, spectral data of which follow: IR 1780, 1660, 1580; MS 358 (M^+, 37), 248 (26), 135 (100), 134 (41); NMR 0.93 (3H, s, one of the CH_3 of $C(7)(CH_3)_2$), 1.16 (major) and 1.20 (minor) (overall 3H, s, the other one of $C(7)(CH_3)_2$), 2.87—3.10 (1H, dd, *J*=10.0 and 4.0, CH(SPh)), 4.77 (2H, d, *J*=7.5, $=CHCH_2OTfa$), 5.32 (1H, bt, *J*=7.5, $=CHCH_2OTfa$).

Acid-catalyzed Cyclization of the β-Hydroxy Sulfide (8) Using $SnCl_4$. To an ice-cold solution of **8** (260 mg, 1.0 mmol) in CH_2Cl_2 (5.0 ml), $SnCl_4$ (110 μl, 1.0 mmol) was added dropwise. Stirring was continued for 30 min at the temperature and the reaction was quenched by addition of water. The mixture was extracted with Et_2O and worked up by the usual manner providing the crude chloride (**11**) which was converted into the corresponding acetate (**12**) (164 mg, 54%). The *E*:*Z*-ratio (*ca.* 50:50) was determined by ^{1}H-NMR analysis of the diagnostic methyl signal at δ 1.14 and 1.18.

Cyclization of 8 Using CF_3CO_2H. To an ice-cold solution of **8** (130 mg, 0.5 mmol) in CH_2Cl_2 (10 ml), CF_3CO_2H (4.0 ml) was added dropwise over 25 min and stirring was continued for 15 min at 0 °C. The mixture was poured into water and the product was extracted with CH_2Cl_2. The organic layer was worked up by the usual manner to give the trifluoroacetate (**14**) (114 mg, 64%) as oil. The *E*:*Z*-ratio was determined as 64:36 by ^{1}H-NMR analysis of the diagnostic methyl signal at δ 1.16 and 1.20. Results of the reaction of **8** with CF_3CO_2H at −20 °C in CH_2Cl_2 are listed in Table 1.

Cyclization of 8 Using H_2SO_4. To a solution of **8** (2.62 g, 10 mmol) in Et_2O (110 ml) was added dropwise over 10 min a mixture of concd H_2SO_4 (3.7 ml) and Et_2O (25 ml) at room temperature and the mixture was stirred for 4 h. The usual work-up of the mixture followed by the isolation of the product afforded the isomeric mixture of diene (**15**) (1.95 g, 80%) as oil. Data for **15** follow: MS 244 (M^+, 56), 164 (45), 136 (59), 135 (100), 134 (95), 119 (57); NMR 1.02 and 1.16 (major pair of singlets of 60 intensity), 1.10 and 1.27 (minor pair of singlets of 40 intensity) (overall 6H, $C(CH_3)_2$), 3.00—3.23 (1H, dd, *J*=9.0 and 5.5, CH(SPh)), 4.75—5.65 (3H, m, $C(1)H_2$ and C(4)H or C(8)H), 6.02—6.50 (1H, dd, *J*=18.0 and 11.0, C(2)H); Found: C, 78.36; H, 8.41%. Calcd for $C_{16}H_{20}S$: C, 78.63; H, 8.25%.

6-Phenylthio-2-ochtoden-1-ol (13): A mixture of the acetate (**12**) (360 mg, 1.18 mmol), EtOH (5.0 ml), and 3% NaOH (5.0 ml) was stirred for 20 h at room temperature. After evaporation of EtOH, the residue was worked up by the usual manner to give a crude product (310 mg), which was purified by column chromatography yielding the alcohol (**13**) (276 mg, 89%) as oil. Data for **13** follow: IR 3320, 1660, 1580; MS 262 (M^+, 28), 244 (15), 152 (22), 135 (100), 134 (72); NMR 0.92 (3H, s, one of the CH_3 of $C(7)(CH_3)_2$), 1.14 (major) and 1.18 (minor) (overall 3H, s, the other one of $C(7)(CH_3)_2$), 1.62 (1H, s, OH), 2.00 (2H, s, $C(8)H_2$), 2.84—3.10 (1H, dd, *J*=10.5 and 4.5, CH(SPh)), 4.01 (2H, d, *J*=7.0, $=CHCH_2OH$), 5.28 (1H, bt, *J*=7.0, $=CHCH_2OH$); Found: C, 72.98; H, 8.45%. Calcd for $C_{16}H_{22}OS$: C, 73.23; H, 8.45%.

2-Ochtoden-1-ol (3): A solution of the alcohol (**13**) (102 mg, 0.4 mmol) in THF (0.5 ml) was added dropwise into a chilled (−78 °C) blue solution of Li (50 mg, 7 mgatm) in liq. NH_3 (*ca.* 10 ml) and the mixture was stirred for 30 min at the temperature. Then, reaction was quenched by introduction of gaseous butadiene followed by addition of MeOH (1.0 ml) to destroy the excess Li and the cold bath was removed to evaporate NH_3. The residue was worked up by the usual manner and the crude product was purified by column chromatography to give the alcohol (**3**) (44 mg, 73%) as oil. Data for **3** follow: IR 3400, 1660; MS 154 (M^+, 16%), 136 (58), 121 (45), 95 (57), 93 (100); NMR 0.87 (6H, s, $C(CH_3)_2$), 1.85 (major) and 1.92 (minor) (overall 2H, s, $C(8)H_2$), 2.43 (1H, s, OH), 3.97 (minor) and 4.02 (major) (overall 2H, d, *J*=7.0, $=CHCH_2OH$), 5.24 (1H, d, *J*=7.0, $=CHCH_2OH$).

2-Ochtoden-1-al (4): The aldehyde (**4**) was obtained in 85% yield from the alcohol (**3**) by oxidation with active MnO_2 in pentane according to the literature.[2] Data for **4** follow: IR 1680, 1640; NMR 0.93 (major) and 0.97 (minor) (overall 6H, s, $C(CH_3)_2$), 2.05 (major) and 2.47 (minor) (overall 2H, s, $C(8)H_2$), 2.65 (2H, bt, *J*=6.0, $C(4)H_2$), 5.67 (major) and 5.81 (minor) (overall 1H, d, *J*=8.5, $=CHCHO$), 9.88 (minor) and 9.93 (major) (overall 1H, d, *J*=8.5, $=CHCHO$).

Transformation of the Diene Mixture (15) to the Regioisomeric Mixture of Esters (16). To an ice-cold solution of **15** (245 mg, 1.0 mmol) in THF (5.0 ml), a 1/3 M (1 M=1 mol dm^{-3}) solution of BH_3–THF (3.0 ml) was added dropwise over 30 min and the mixture was stirred for 30 min at 0 °C. To the mixture was added dropwise 3 M NaOH (0.8 ml) and 30% H_2O_2 (0.8 ml) at 0 °C successively. After being stirred for 2 h at room temperature, the mixture was worked up to give the dihydro alcohol, 6-phenylthio-3-ochtoden-1-ol (140 mg, 62%) with a recovery of **15** (36 mg). Data for the dihydro alcohol follow: IR 3560, 3400, 1580; MS 262 (M^+, 61), 153 (100), 136 (70); NMR 0.98, 1.07 (major pair of singlets) and 1.03, 1.20 (minor pair of singlets) (overall 6H, $C(CH_3)_2$), 2.50 (1H, s, OH), 2.90—3.20 (1H, m, CH(SPh)), 3.53 (2H, t, *J*=7.0, CH_2OH), 5.20 (minor singlet of C(8)-olefinic H) and 5.34 (major broad singlet of C(4)-olefinic H); Found: C, 73.18; H, 8.57%. Calcd for $C_{16}H_{22}OS$: C, 73.23; H, 8.45%. The 6-phenylthio alcohol obtained was desulfurized to 3-ochtoden-1-ol in 81% yield by the same procedure described for **3**. Data for the alcohol follow: MS 154 (M^+, 96), 139 (99), 121 (98), 109 (100), 107 (70); NMR 0.89 (major) and 0.95 (minor) (overall 6H, s, $C(CH_3)_2$), 2.57 (1H, s, OH), 3.53 (2H, t, *J*=7.0, CH_2OH), 5.15 (minor singlet of C(8)-olefinic H) and 5.39 (major broad singlet of C(4)-olefinic H). The alcohol (55 mg, 0.35 mmol) was dissolved in acetone (3.5 ml) and 15 drops of the Jones reagent prepared from CrO_3 (14 g), H_2O (100 ml), and concd H_2SO_4 (12 ml), was added to the ice-cold solution. The mixture was stirred for 2.5 h at 0 °C and then for 1 h at room temperature. Usual work-up of the mixture gave the crude carboxylic acid (55 mg) which was esterified with an ethereal solution of CH_2N_2 by the usual manner. Purification of the crude product by column chromatography provided the ester,

methyl 3-ochtoden-1-oate (**16**) (40mg, 62%). Spectral data of the ester were consistent with those reported by Wolinsky:[6a] IR 1740; NMR 0.91 (major) and 0.96 (minor) (overall 6H, s, $C(CH_3)_2$), 2.92 (2H, s, $=CCH_2CO_2$), 3.65 (3H, s, CO_2CH_3), 5.27 (minor singlet of C(8)-olefinic H) and 5.52 (major broad singlet of C(4)-olefinic H).

Cyclization of Myrcene 6,7-Epoxide (10). A solution of the epoxide (**10**) (300mg, 2.0mmol) in CH_2Cl_2 (1.0ml) was added dropwise into a mixture of CF_3CO_2H (0.8ml, 10mmol) and CH_2Cl_2 (8.0ml) at −20°C. The mixture was stirred for 20min at −20°C and then poured into water. Extraction of the mixture with CH_2Cl_2 followed by the usual work-up gave a crude product (427mg), which was purified by column chromatography to yield the hydroxy ester, 6-hydroxy-2-ochtodene-1-yl trifluoroacetate (**17**) (284mg, 54%). Data for **17** follow: IR 3400, 1780, 1660; MS 266 (M^+, 7), 248 (44), 152 (92), 135 (100), 134 (98), 119 (96); NMR 0.81, 0.91 (each 3H, s, $C(CH_3)_2$), 1.89 (1H, s, OH), 3.40 (1H, dd, J=8.0 and 4.0, $C\underline{H}(OH)$), 4.79 (2H, d, J=7.5, $=CHC\underline{H}_2OTfa$), 5.28 (1H, bt, J=7.5, $=C\underline{H}CH_2OTfa$); Found: C, 54.28; H, 6.53%. Calcd for $C_{12}H_{17}O_3F_3$: C, 54.13; H, 6.44%. Cyclization of **10** at −5°C and at −78°C was examined and the results are listed in Table 2, in which the E:Z-ratio was determined by ^{1}H-NMR analysis of the corresponding ketone (**18**) derived from **17**, *vide infra*.

6-Oxo-2-ochtoden-1-yl Trifluoroacetate (18): A solution of the alcohol (**17**) (80mg, 0.3mmol) in CH_2Cl_2 (0.5ml) was added dropwise into a solution of pyridinium chlorochromate (97mg) in CH_2Cl_2 (1.0ml) at room temperature and stirring was continued for 2h. To the mixture, Et_2O (5.0ml) was added and the insoluble materials were removed by filtration. The filtrate was concentrated and the residue was chromatographed to give the ketone (**18**) (69mg, 87%). Data for **18** follow: IR 1780, 1705; NMR 1.04 (major) and 1.07 (minor) (overall 6H, $C(CH_3)_2$), 2.33 (2H, s, $C(8)H_2$), 2.30—2.85 (4H, m, $COCH_2CH_2C=$), 4.89 (2H, d, J=7.5, $=CHC\underline{H}_2OTfa$), 5.53 (1H, bt, J=7.5, $=C\underline{H}CH_2OTfa$); Found: C, 54.82; H, 5.95%. Calcd for $C_{12}H_{15}O_3F_3$: C, 54.55; H, 5.72%.

1-Hydroxy-2-ochtoden-6-one (19): The trifluoroacetate (**18**) was hydrolyzed by treatment with a mixture of EtOH and 3% NaOH (1:1) at room temperature for 10min to give the oily keto alcohol (**19**) in 92% yield. Data for **19** follow: IR 3550, 3400, 1695; MS 168 (M^+, 15), 150 (100), 135 (17), 123 (32), 107 (72); NMR 1.03 (6H, s, $C(CH_3)_2$), 2.26 (2H, s, $C(8)H_2$), 2.35—2.80 (4H, m, $COCH_2CH_2C=$), 2.96 (1h, s, OH), 4.09 (2H, d, J=7.0, $=CHC\underline{H}_2OH$), 5.49 (1H, bt, J=7.0, $=C\underline{H}CH_2OH$); Found: C, 71.54; H, 9.85%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%.

5,5-Dideuterio-1-hydroxy-2-ochtoden-6-one (21): A solution of the keto alcohol (**19**) (30mg, 0.2mmol) in MeOD (0.5ml) was added into a solution of NaOMe in MeOD, prepared from Na (3mg) and MeOD (0.5ml), at room temperature and the mixture was stirred for 20h. After addition of D_2O (1.0ml), the mixture was extracted with Et_2O and worked up by the usual manner to give the 5,5-dideuterio keto alcohol (**21**) (21mg). Data for **21** follow: IR 3480, 1690; MS 170 (M^+, 15), 152 (100), 137 (26), 125 (40), 109 (98); NMR 1.03 (6H, s, $C(CH_3)_2$), 2.25 (2H, s, $C(8)H_2$), 2.50 (2H, s, $C(4)H_2$), 2.58 (1H, s, OH), 4.09 (2H, d, J=7.0, $=CHC\underline{H}_2OH$), 5.49 (1H, bt, J=7.0, $=C\underline{H}CH_2OH$).

6-Oxo-2-ochtodene-1-al (20): Active MnO_2 (1.0g) was added at 0°C into a stirred solution of the keto alcohol (**19**) (30mg, 0.2mmol) in $CHCl_3$ (10ml) and stirring was continued for 30min at the temperature. The mixture was filtered and the filtrate was purified by column chromatography to give the keto aldehyde (**20**) (28mg, 94%) as oil. Data for **20** follow: IR 1690, 1660; NMR 1.10 (major) and 1.13 (minor) (overall 6H, s, $C(CH_3)_2$), 2.39—2.70 (2H, m, $COC\underline{H}_2CH_2C=$), 2.48 (2H, d, J=2.0, $C(8)H_2$), 2.85—3.26 (2H, m, $C(4)H_2$), 5.89 (1H, dt, J=7.5 and 2.0, $=C\underline{H}CHO$), 9.93 (1H, d, J=7.5, $=CHC\underline{H}O$).

5,5-Dideuterio-6-oxo-2-ochtodene-1-al (22): The dideuterio keto aldehyde (**22**) was prepared from the dideuterio keto alcohol (**21**) by the same procedure described for **20**. Data for **22** follow: IR 1690, 1660; MS 168 (M^+, 56), 139 (97), 125 (100); NMR 1.10 (major) and 1.13 (minor) (overall 6H, s, $C(CH_3)_2$), 2.48 (major doublet (J=2.0)) and 2.67 (minor broad singlet) (overall 2H, $C(8)H_2$), 2.89 (minor) and 3.09 (major) (overall 2H, s, $C(4)H_2$), 5.89 (1H, dt, J=7.5 and 2.0, $=C\underline{H}CHO$), 9.93 (1H, d, J=7.5, $=CHC\underline{H}O$).

Deoxygenation of the Keto Alcohol (19) Providing the Alcohol (3). A mixture of the keto alcohol (**19**) (72mg, 0.4mmol) and *p*-toluenesulfonyl hydrazide (80mg, 0.4mmol) in MeOH (5.0ml) was heated under reflux for 4h. After cooling and addition of MeOH (4.0ml), $NaBH_4$ (325mg, 8.5mmol) was added portions to the mixture at 0°C, and the mixture was heated under reflux for 2h. The reaction mixture was concentrated and the residue was worked up by the usual manner to give a crude product (68mg). Purification of the product by column chromatography yielded the alcohol (**3**) (43mg, 65%). The alcohol exhibited identical spectra with those obtained from **13**.

Synthesis of (±)-(2Z)-2,4-Ochtodadiene-1,6-diol (26) Starting from the 6-Phenylthio Acetate (12). 1-Acetoxy-2,5-ochtodadiene (**23**): A mixture of the acetate (**12** E:Z=85:15) (1.3g, 4.3mmol), AcOH (15ml), and 30% H_2O_2 (460μl) was stirred for 20h at room temperature. The reaction mixture was poured into water and the mixture was extracted with CH_2Cl_2. The organic layer was worked up by the usual manner to give the crude sulfoxide (1.37g), which was, without further purification, heated under reflux with $NaHCO_3$ (720mg, 8.5mmol) in xylene (40ml) for 4h. The reaction mixture was diluted with Et_2O and worked up by the usual manner to give the oily diene acetate (**23**) (655mg, 79%). Data for **23** follow: IR 1725; MS 194 (M^+, 2), 134 (72), 119 (100); NMR 0.94 (major) and 0.98 (minor) (overall 6H, s, $C(CH_3)_2$), 1.95 (3H, s, CH_3CO_2), 2.08 (major) and 2.20 (minor) (overall 2H, s, $C(8)H_2$), 2.70 (minor) and 2.78 (major) (overall 2H, bs, $C(4)H_2$), 4.53 (2H, d, J=7.5, $=CHC\underline{H}_2OAc$), 5.33 (1H, bt, J=7.5, $=C\underline{H}CH_2OAc$), 5.40—5.60 (2H, m, CH=CH).

1-Acetoxy-5,6-epoxy-2-ochtodene (24): A solution of *m*-chloroperbenzoic acid (net 80%) (305mg, 1.4mmol) in CH_2Cl_2 (4.0ml) was added dropwise into a cold (−20°C) mixture of the diene acetate (**23** E:Z=85:15) (230mg, 1.2mmol) and $NaHCO_3$ (100mg, 1.2mmol) in CH_2Cl_2 (12ml) and the mixture was stirred for 3h at −20°C and then for 3.5h at 0°C. The reaction mixture was diluted with CH_2Cl_2 and worked up by the usual manner to give a crude product (260mg), which was purified by column chromatography to afford the oily epoxide (**24**) (135mg, 59%) with a small amount of the isomeric 1-acetoxy-2,3-epoxy-5-ochtodene (28mg). By careful column chromatography of the epoxide (**24**) on silica gel, the E- and Z-component were separable. The less polar and minor E-**24**: NMR ($CDCl_3$) 0.96, 1.12 (each 3H, s, $C(CH_3)_2$), 1.98 (2H, bs, $C(8)H_2$), 2.04 (3H, s, CH_3CO_2), 2.60 (2H, bd, J=3.0, $C(4)H_2$), 2.80 (1H, d, J=4.0, C(6)H), 3.23 (1H, m,

C(7)H), 4.54 (2H, d, J=7.0, =CHC$\underline{H}_2$OAc), 5.45 (1H, bt, J=7.0, =C$\underline{H}$CH$_2$OAc). The more polar and major *Z*-**24**: NMR ($CDCl_3$) 0.93, 1.10 (each 3H, s, C(CH_3)$_2$), 2.04 (3H, s, CH_3CO_2), 1.59, 2.25 (each 1H, d, J=13.0, C(8)H$_2$), 2.68 (2H, bs, C(4)H$_2$), 2.83 (1H, d, J=4.0, C(6)H), 3.23 (1H, br, C(5)H), 4.55 (2H, d, J=7.5, =CHC$\underline{H}_2$OAc), 5.28 (1H, bt, J=7.5, =C$\underline{H}$CH$_2$OAc); IR 1720; MS 210 (M^+, 2), 156 (76), 150 (100), 139 (91), 135 (92).

5,6-Epoxy-2-ochtoden-1-ol (25): A mixture of the epoxy acetate (**24**) (105mg) and 3% NaOH (4.0ml) in EtOH (4.0ml) was stirred for 1.5h at room temperature and the mixture was worked up by the usual manner to give the epoxy alcohol (**25**) (77mg, 92%). (*Z*)-**25**: IR 3560, 3400; MS 150 ($(M-18)^+$, 16), 135 (47), 121 (100), 107 (81); NMR ($CDCl_3$) 0.92, 1.06 (each 3H, s, C(CH_3)$_2$), 1.60, 2.21 (each 1H, d, J=14.0, C(8)H$_2$), 2.50 (1H, s, OH), 2.63 (2H, bs, C(4)H$_2$), 2.83 (1H, d, J=4.0, C(6)H), 3.21 (1H, m, C(5)H), 4.10 (2H, d, J=7.0, =CHC$\underline{H}_2$OH), 5.33 (1H, bt, J=7.0, =C$\underline{H}$CH$_2$OH). (*E*)-**25**: NMR ($CDCl_3$) 0.95, 1.10 (each 3H, s, C(CH_3)$_2$), 1.92 (2H, s, C(8)H$_2$), 2.42 (1H, s, OH), 2.54 (2H, bd, J=3.0, C(4)H$_2$), 2.78 (1H, d, J=4.0, C(6)H), 3.23 (1H, m, C(5)H), 4.08 (2H, d, J=7.0, =CHC$\underline{H}_2$OH), 5.48 (1H, bt, J=7.0, =C$\underline{H}$CH$_2$OH).

(±)-(2Z)-2,4-Ochtodadiene-1,6-diol (26): To a solution of lithium diisopropylamide (LDA) in THF, prepared from diisopropylamine (110μl), 1.6M solution of *n*-BuLi-hexane (0.53ml) in THF (1.5ml) at −20°C, was added dropwise a solution of the epoxy alcohol (**25** *E*:*Z*=15:85) (50mg, 0.3mmol) in THF (0.5ml) at −78°C under argon. The mixture was stirred for 40min under gradual warming up to −20°C, and then for 1h at −20°C. Reaction was quenched by addition of water and the mixture was worked up by the usual manner. Purification of the crude product by column chromatography afforded the oily diene diol (**26**) (38mg, 73%) with a small amount of recovery of starting material (**25**) (8mg) which proved to change in the *E*:*Z*-proportion to the ratio *E*:*Z*=70:30 from ^{1}H-NMR analysis. Spectral data of **26** obtained were consistent with those reported for the natural one:[1b] IR 3500, 3300, 1650, 1600; MS 168 (M^+, 15), 150 (45), 135 (68), 107 (100); NMR ($CDCl_3$) 0.87, 0.97 (each 3H, s, C(CH_3)$_2$), 1.73 (2H, s, 2×OH), 2.13 (2H, s, C(8)H$_2$), 3.95 (2H, d, J=3.0, C$\underline{H}$(OH)), 4.25 (2H, d, J=7.0, =CHC$\underline{H}_2$OH), 5.47 (1H, bt, J=7.0, =C$\underline{H}$CH$_2$OH), 5.75 (1H, dd, J=10.0 and 3.0, C(5)H), 6.43 (1H, d, J=10.0, C(4)H).

*Synthesis of **26** Starting from the Keto Alcohol (**19**). 1-Hydroxy-5-Phenylseleno-2-ochtoden-6-one (**27**)*: To a solution of LDA in THF, prepared from diisopropylamine (170μl) and 1.6M solution of *n*-BuLi-hexane (0.75ml) in THF (1.5ml), was added dropwise a solution of the keto alcohol (**19**) (84mg, 0.5mmol) in THF (0.5ml) at −78°C under argon and the mixture was stirred for 15min at −78°C and then for 45min at −20°C. After warming up of the mixture to 0°C, a solution of diphenyl diselenide (156mg, 0.5mmol) in THF (0.5ml) was added rapidly into the mixture. Stirring was continued for 1h at room temperature and the mixture was poured into water. The mixture was extracted with Et_2O and worked up by the usual manner to give a crude product (229mg). Purification of the product by column chromatography afforded the oily seleno keto alcohol (**27**) (89mg, 70%) and a recovery of the strating material **19** (18mg). Data for **27** follow: IR 3560, 3400, 1690, 1580; MS 324 (M^+, 28), 167 (100), 149 (65); NMR 1.08, 1.16 (each 3H, s, C(CH_3)$_2$), 2.30 (1H, s, OH), 2.10—3.20 (4H, m, C(4)H$_2$ and C(8)H$_2$), 3.97 (2H, d, J=7.0, =CHC$\underline{H}_2$-OH), 3.90—4.15 (1H, m, CH(SePh)), 5.52 (1H, bt, J=7.0, =C$\underline{H}$CH$_2$OH); Found: C, 59.32; H, 6.37%. Calcd for $C_{16}H_{20}O_2Se$: C, 59.44; H, 6.24%.

5-Phenylseleno-2-ochtodene-1,6-diol (28): A solution of the seleno keto alcohol (**27**) (90mg, 0.3mmol) in Et_2O (2.0ml) was added dropwise into a chilled auspension of $LiAlH_4$ (22mg, 0.6mmol) in Et_2O (1.0ml) at −20°C and the mixture was stirred for 2h at −20°C and then for 1h at room temperature. Reaction was quenched by addition of wet Et_2O and the mixture was decanted to remove inorganic substances. The organic layer was worked up by the usual manner. Purification of the product by column chromatography provide the oily seleno diol (**28**) (76mg, 84%) as a diastereoisomeric mixture. Data for **28** follow: IR 3560, 3450, 1660, 1580; NMR 0.78, 0.80, 0.98, 1.02 (each 3/2H, s, C(CH_3)$_2$), 1.30—3.80 (8H, m, 2×OH, C$\underline{H}$(OH), CH(SePh), C(4)H$_2$, and C(8)H$_2$), 4.02 (2H, bd, J=7.0, =CHC$\underline{H}_2$OH), 5.30 (1H, bt, J=7.0, =C$\underline{H}$CH$_2$OH).

(±)-(2Z)-2,4-Ochtodadiene-1,6-diol (26): To a solution of the seleno diol (**28**) (50mg, 0.15mmol) in MeOH (2.0ml) and water (0.75ml) was added $NaIO_4$ (65mg, 0.3mmol) in portions at 0°C. The mixture was stirred for 15min at 0°C and then for 7h at room temperature. After addition of 5% $NaHCO_3$ (5.0ml), the mixture was extracted with CH_2Cl_2 and worked up by the usual manner. Purification of the product by column chromatography gave the oily diene diol (**26**) (16mg, 61%), which showed identical apectral data with those obtained from **25**.

We thank Professor W. Fenical and Dr. V. Paul, Scripps Institution of Oceanography, University of California, for providing the spectral data of natural both stereoisomers of 2,4-ochtodadien-1,6-diol (**26**).

Synthetic Studies on the Ochtodane Type Terpenes II.[1] Synthesis of Pleraplysillin-1

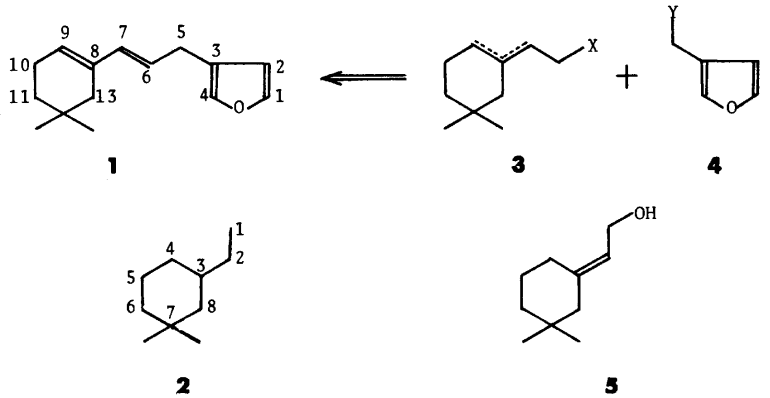
Yukio MASAKI,* Kinji HASHIMOTO, Yuzuru SERIZAWA, and Kenji KAJI
Gifu Pharmaceutical University, 5-6-1 Mitahora Higashi, Gifu 502
(Received May 4, 1984)

A furyl sesquiterpene pleraplysillin-1 (**1**), which possesses the ochtodane skeleton (**2**) in the molecule, was synthesized regio- and stereoselectively starting from the ochtodane type monoterpene (**5**). Two approaches were investigated: One is the route by way of the benzenesulfenyl chloride addition to a sesquiterpene (**9**) or (**13**) which involve the whole carbon framework of **1** and the exocyclic *E*- or *Z*-double bond, and the other involves the regioselective formation of the endocyclic double bond of the ochtodane synthon (**15**) utilizing the hydroxyl-assisted epoxide opening reaction followed by homologation with the 3-furylmethyl moiety. In both of the routes the geometry of the exocyclic double bond of the ochtodane synthon played an important role in the regioselective formation of the endocyclic double bond in **1**.

The explosive growth of marine natural product chemistry during the last decade has given rise to the discovery of a vast array of compounds which have polyhalogenated and/or oxygenated, and unique carbon frameworks never found in the terrestrial organisms.[2] In 1972, a furyl sesquiterpene pleraplysillin-1 (**1**) was isolated from a marine sponge, *Pleraplysilla spinifera*, by Cimino and coworkers.[3] The terpene (**1**) possesses a unique carbon skeleton which is postulated to arise by enzymic carbocyclization involving a lateral methyl group of the presumed farnesyl precursor and the terminal oxidation forming the furan portion. The structural elucidation of **1** has been done by spectral analyses of itself and the hydrogenated product.[3] Recently, two groups, Moore *et al.*[4a] and Fenical *et al.*,[4b] have isolated variously functionalized monoterpenes with the 3,3-dimethyl-1-ethylcyclohexane carbon skeleton (**2**), which was suggested to name "ochtodane."

The carbon framework of pleraplysillin-1 (**1**) is analyzed retro-synthetically as the assembly of an ochtodane (**3**) and 3-furylmethyl (**4**) derivatives. In the preceding paper, we have introduced a facile method for the stereoselective construction of the ochtodane skeleton (**2**) starting from myrcene.[1] Here we report the first regio- and stereoselective synthesis of the sesquiterpene (**1**).[5] The major synthetic efforts focused on the regio- and stereoselective construction of the conjugated diene system in the molecule (**1**). We have investigated two approaches. One of them involves the benzenesulfenyl chloride addition to the trisubstituted and exocyclic C(7)-olefin in the sesquiterpene (**9**) or (**13**) which contain the whole carbons of **1**, followed by formation of the requisite conjugated diene system. The other involves the regioselective formation of the requisite endocyclic C(3)-olefin of the ochtodane moiety followed by the homologation with 3-furylmethyl synthon and latent formation of the other acyclic C(6)-olefinic portion of the conjugated diene system. By the latter method the successful synthesis of **1** was achieved.

1) Approach by Way of the Benzenesulfenyl Chloride Addition (Scheme 1). In order to obtain the sesquiterpene (**9**), the key compound for the olefinic elaboration aiming at the requisite conjugated diene system, the ochtodane type compound with the sulfur-containing auxiliary activator for C–C bond formation at the C(1)-position was prepared from the (*E*)-alcohol (**5**) which was obtained highly stereoselectively by the reported method.[1] Thus, bromination of **5** with PBr_3 followed by treatment of the bromide (**6**) with *p*-Tol-SO_2Na in DMF afforded the crystaline sulfone (**7**), which was purified by recrystallization to remove the (*Z*)-isomer arising from the (*Z*)-alcohol which existed in the starting alcohol (**5**) as impurity.[1] The carbon–carbon bond formation between the allylic sulfone (**7**) and 3-furylmethyl bromide (**4** Y=Br) was performed smoothly in 76% yield with *n*-BuLi in THF at −78—



1 **3** **4**

2 **5**

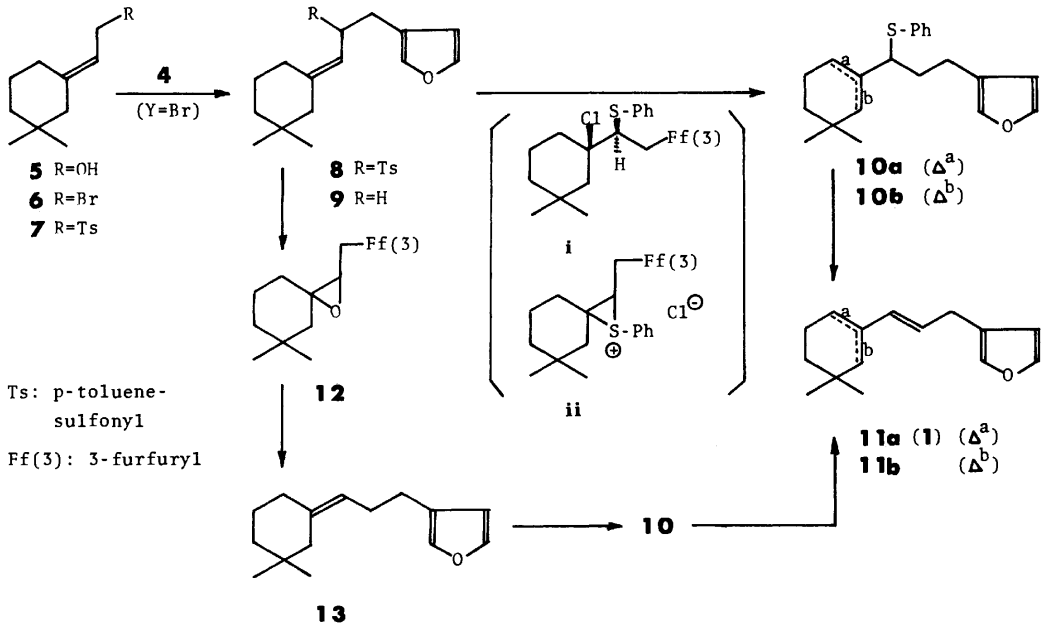
Chart 1.

0°C providing the sesquiterpenoid (**8**). Reductive desulfurization of this compound leading to the sulfur-free compound (**9**) was carried out by the Birch reduction with Li in liq. NH_3 in 74% yield. Treatment of the furyl terpene (**9**), which possesses the pure exocyclic *E*-double bond, with an equimolar amount of PhSCl in CH_2Cl_2 at −78°C for 10 min followed by evaporation of the solvent at room temperature gave the regioisomeric mixture of allylic sulfides (**10**) (79%) instead of the expected adduct (**i**). The structure and regioisomeric proportion were determined by spectral analysis: Mass spectrum showed the M^+ ion at 326, and ^{1}H-NMR exhibited signals for the olefinic protons at δ 4.85 as the major singlet and 5.23 as the minor broad singlet in a ratio 77:23 and those of the geminal dimethyl groups at δ 0.65, 0.86, and at δ 0.80, 0.92 in the same ratio of intensity. The major component was assigned to the undesirable isomer (**10b**) on the basis of the shape of the signal at δ 4.85 for the isolated C(13)-olefinic proton in ^{1}H-NMR. The allylic sulfide (**10**) obtained was converted into the final conjugated diene (**11**) in 83% yield by the sequential treatment of **10** with 30% H_2O_2 in AcOH followed by heating the corresponding sulfoxide in refluxing toluene. Comparison of ^{1}H-NMR of the resultant diene (**11**) with the reported data of natural pleraplysillin-1 (**1**)[3] indicated that the product contains the desired **1** (**11a**) in a minor proportion (*ca.* 23%) and the regioisomer (**11b**) as the major component (*ca.* 77%). Characteristic signals of these regioisomers **1** and **11b** were detected at δ 0.92 (s) and 0.97 (s) assignable respectively to the geminal methyl groups of **1** and **11b**, at δ 1.68 (s) to the C(13)-methylene of **1**, and at δ 5.30 (s) to the C(13)-olefinic proton of **11b**.

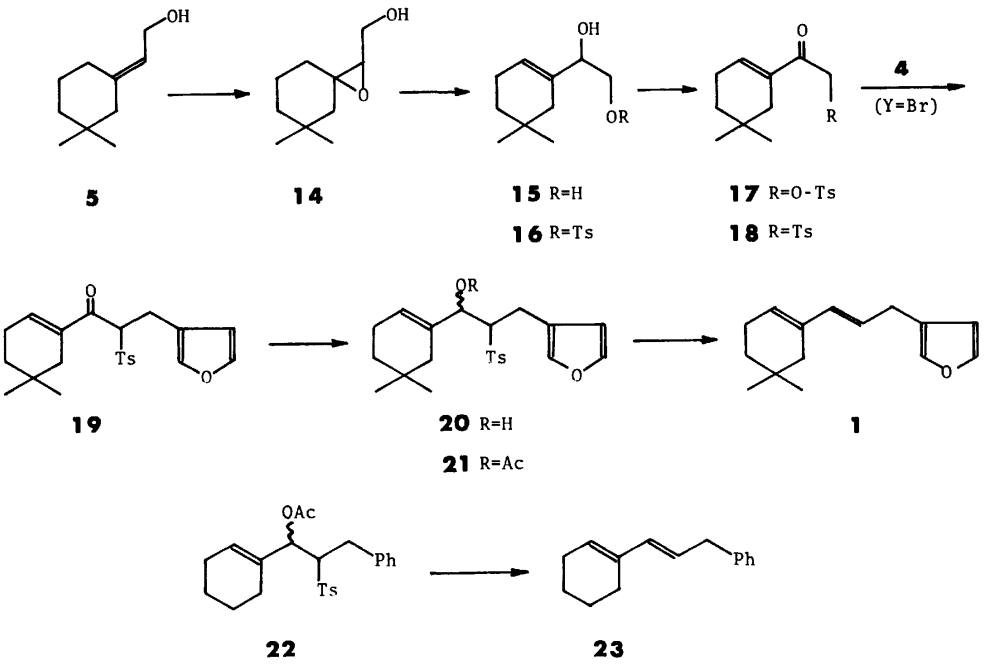
Although the stereo-electronic mechanisms in the dehydrochlorination of the intermediary adduct (**i**) or the episulfonium ion (**ii**) are not clear, the stereochemistry of the exocyclic C(7)-double bond of **9** seemed to affect the regioselectivity in the formation of the allylic sulfide (**10**). Thus, we tried the same procedure on the (*Z*)-olefin (**13**) (*E*:*Z*=20:80), which was prepared from the (*E*)-olefin (**9**) (*E*:*Z*=85:15) *via* the epoxide (**12**) according to the method for geometric inversion of olefins developed by Vedejs.[6] Addition of PhSCl to the (*Z*)-olefin (**13**) gave the anticipated result that the product contained the desired allylic sulfide (**10a**) as the major component (60%) and the undesirable one (**10b**) as the minor (40%). The identical product ratio (**1**:**11b**=60:40) was observed in the final diene (**11**) derived analogously. The above results implied that the desired natural **1** would be obtained in less than *ca.* 77% regioselectivity concerning the C(8)-double bond so far as use of this sequence of procedures even if the pure (*Z*)-olefin (**13**) would be used. Attempted separation of each component of the regioisomers of allylic sulfides (**10**) and the final diene (**11**) was unsuccessful. So, we searched for the more regio- and stereoselective route.

II) Approach by Way of the Regioselective Epoxide-ring Opening (Scheme 2). Considering the above results, we investigated another route in which the endocyclic double bond in the ochtodane moiety of **1** is formed regioselectively in the early stage of the synthesis. Application of the regioselective epoxide-ring opening method developed by Sharpless[7] to the β,γ-epoxy alcohol (**14**) prepared from (*E*)-alcohol (**5**) seemed to be the method of choice for this purpose.

Epoxidation of the alcohol (**5**) with *m*-chloroperbenzoic acid providing the epoxide (**14**) (91%) and subsequent treatment of **14** with 1.2 equiv of $Ti(OPr^i)_4$ in CH_2Cl_2 at 15°C for 20 h afforded regioselectively the enediol (**15**) in 77% yield. ^{1}H-NMR spectrum of the product showed a little contamination of the undesirable regioisomer which would be ascribed to the



Scheme 1.



Scheme 2.

presence of the (*Z*)-isomer (*ca.* 6%) in the starting material (**5**),[1] and to the undesirable olefination which might take place slightly in the epoxide-ring opening reaction (**14**→**15**). Selective tosylation of the primary alcohol in **15** was carried out on treatment of **15** with 1.3 equiv of *p*-TsCl in pyridine to give the mono tosylate (**16**) in 76% yield. Oxidation of the allylic alcohol (**16**) with active MnO_2 gave the keto tosylate (**17**) which was converted to the crystalline keto sulfone (**18**) (70% overall yield from **16**) by treatment with *p*-Tol-SO_2Na in DMF. Purification of the compound **18** by recrystallization removed the undesirable olefinic regioisomer with 3(8)-double bond and furnished the regiochemically homogeneous sulfone (**18**) (mp 111—113°C). The structure of **18** was characterized by spectral and elemental analyses: Signals for the two allylic methylene at δ 1.96 (bs, C(8)-methylene) and 2.10—2.50 (m, C(5)-methylene) and for the C(4)-olefinic proton at δ 6.95 as broad singlet appeared in ^{1}H-NMR. The carbon-carbon bond formation between **18** and 3-furylmethyl bromide (**4** Y=Br) proceeded smoothly in the presence of 1.2 equiv of NaH DMF-THF (1:1) at 15°C to give the crystalline sulfone (**19**) (mp 136—140°C) in high (92%) yield. Attention was focused on the next step for the stereoselective formation of the other C(6)-olefinic bond of the conjugated diene system in **1**. Kocienski reported that treatment either of *erythro*- or *threo*-β-acetoxy sulfones with sodium amalgam (Na-Hg) effected reductive elimination to afford exclusively (*E*)-olefins.[8] We tried to apply this condition to our system. Reduction of the keto sulfone (**19**) with $NaBH_4$ in EtOH at 0°C afforded the crystalline alcohol (**20**), which was, without further separation of the diastereoisomers, acetylated to give the β-acetoxy sulfone (**21**) in nearly quantitative yield. Unfortunately, application of Kociensky's condition using 5% Na-Hg with MeOH in AcOEt at −20°C to **21** resulted in the preponderant formation of the methanolysis product (**20**) with a small amount of the conjugated diene (**1**) (7%) which proved to be contaminated with the undesirable (6*Z*)-olefinic isomer to some extent (*ca.* 20%) in high performance liquid chromatography (HPLC) using 5% $AgNO_3$-imprgnated silica gel (see the experimental section) and ^{1}H-NMR analyses. The desired reductive elimination producing **1**, in turn, was accomplished by treatment of **21** with Na and EtOH in THF at −78°C (modified Bouvault-Blanc conditions)[9] in 65% yield. Analyses by HPLC and ^{1}H-NMR proved the product containing *ca.* 11% of the (6*Z*)-isomer. This stereoselectivity observed in the reductive elimination was constant regardless of the stereochemistry of the β-acetoxy sulfone (**21**) because the stereochemically pure **21** prepared from the recrystallized β-hydroxy sulfone (**20**), although not characterized stereochemically, afforded the diene (**1**) with the identical isomeric ratio (**1**:(6*Z*)-isomer=89:11). The analogous results were obtained in the model compound (**22**). Thus, the compound **22** which possesses the same functionality as **21**, produced the conjugated diene (**23**) of the ratio *E*:*Z*=86:14. The desired diene (**1**) was separated by careful column chromatography on 5% $AgNO_3$-impregnated silica gel and identified with natural pleraplysilin-1 (**1**) by spectral comparison.[3]

Experimental

General. IR spectra were recorded on a JASCO IRA-1 spectrometer in $CHCl_3$ solution and the absorption bands (ν_{max}) are reported in cm^{-1}. Mass spectra (MS) were taken on a

JMS-D300 instrument at an ionizing potential of 70 eV and peaks are given in *m/z* values with relative intensities (%) in parenthesis. ^{1}H-NMR spectra were run on a Hitachi R-20B spectrometer (60 MHz)in CCl_4 solution, unless otherwise noted, with tetramethylsilane (TMS) as an internal standard and chemical shifts are reported in δ (ppm) relative to TMS and coupling constants (J) in hertz (Hz). The numbering of pleraplysillin-1 (**1**) was adopted in the description of the synthetic intermediates with sesquiterpene skeleton in ^{1}H-NMR data. All the solvents used in reactions were freshly distilled to remove moisture. Reactions were carried out under nitrogen unless otherwise noted. Reaction mixtures were usually worked up as follows: A mixture was extracted with Et_2O or CH_2Cl_2, washed with water or saturated brine and saturated $NaHCO_3$, if necessary, dried over anhydrous $MgSO_4$, concentrated *in vacuo* below room temperature to give a crude product which was purified by column chromatography. Silica gel (Wakogel B-5F) and Wokogel C-200 were employed respectively for analytical thin-layer (TLC) and column chromatography using hexane–Et_2O solvent system as eluent. High performance liquid chromatography (HPLC) was carried out by using a column (4.0 mm×25cm) packed with 5% $AgNO_3$-impregnated silica gel, which was prepared by drying the slurry of LiChrosorb Si 60 (MERCK) (10 g) and $AgNO_3$ (0.5 g) in water (40 ml) at 100—110 °C for 20 h, and by elution with hexane.

Materials. The starting material in the present synthesis, (*E*)-2-ochtodene-1-ol (**5**) was prepared in 85—94% of *E*-stereoselectivity from myrcene *via* the benzensulfenyl chloride adduct or the 6,7-epoxide according to the method described in the preceding parer.[1]

Synthetic Approach to Pleraplysillin-1 (1) by Way of the Benzenesulfenyl Chloride Addition. (E)-1-(p-Tolylsulfonyl) 2-ochtodene (7): PBr_3 (95 μl, 1.0 mmol) was added dropwise into an ice-cold solution of the alcohol (**5**) (376 mg, 2.4 mmol) in Et_2O (4.0 ml) and the mixture was stirred for 30 min at 0 °C and then kept in refrigerator 16 h. The mixture was diluted with Et_2O, washed successively with saturated $NaHCO_3$ and brine, dried, and concentrated to give the crude oily bromide (**6**) (420 mg, 80%): NMR 0.90 (6H, s, $C(CH_3)_2$), 1.20—1.90 (4H, m, $C(5)H_2C(6)H_2$), 1.93 (2H, s, $C(8)H_2$), 2.22 (2H, bt, J=5.5, $C(4)H_2$), 3.98 (2H, d, J=9.0, $=CHC\underline{H}_2Br$), 5.48 (1H, bt. J=9.0, $=CHC\underline{H}_2Br$). To a solution of the bromide in DMF (4.5 ml) was added in portions sodium *p*-toluenesulfinate (*p*-TsNa) (690 mg, 3.8 mmol) at room temperature and the mixture was stirred for 16 h. The reaction mixture was worked up by the usual manner to give a crude product (540 mg), which was purified by column chromatography providing the crystalline sulfone (**7**) (480 mg, 87%). Recrystallization from Et_2O–hexane gave pure (*E*)-sulfone (**7**), mp 65—66 °C. Data for **7** follow: IR 1650, 1595; MS 292 (M^+, 2), 157 (8), 137 (100), 136 (44), 121 (18); NMR ($CDCl_3$) 0.80 (6H, s, $C(CH_3)_2$), 1.20—1.40 (4H, br, $C(4)H_2$), 1.85 (2H, s, $C(8)H_2$), 2.43 (3H, s, CH_3Ph), 3.82 (2H, d, J=8.5, $=CC\underline{H}_2Ts$), 5.02 (1H, bt, J=8.5, $=C\underline{H}$-$C\underline{H}_2Ts$), 7.27—7.81 (4H, A_2B_2q, J=9.0, arom-H); Found: C, 69.75; H, 8.38%. Calcd for $C_{17}H_{24}O_2S$: C, 69.83; H, 8.27%.

(E)-3-[3-(3-Furyl)-2-(p-tolylsulfonyl)-propylidene]-1,1-dimethylcyclohexane (8): 1.6 M (1M=1 mol dm^{-3}) solution of *n*-BuLi–hexane (0.75 ml) was added dropwise over 5 min into a solution of the sulfone (**7**) (290 mg, 1.0 mmol) and hexamethylphosphoric triamide (HMPA) (250 μl) in THF (2.5 ml) at −78 °C under argon. After stirring the mixture for 20 min at the temperature, a solution of 3-furylmethyl bromide (**4** Y=Br) (170 mg, 1.1 mmol), freshly prepared from 3-furylmethanol, in THF (0.5 ml) was added into the mixture. The mixture was stirred for 1.5 h under gradual warming up to 0 °C and worked up by the usual manner to give a crude product (380 mg). Purification by column chromatography afforded the oily coupled sulfone (**8**) (282 mg, 76%). Data for **8** follow: NMR 0.63, 0.72 (each 3H, s, $C(CH_3)_2$), 1.73 (2H, s, $C(13)H_2$), 2.40 (3H, s, CH_3Ph), 2.59 (1H, dd, J=14.5 and 11.5, one of $C(5)H_2$), 3.28 (1H, dd, J=14.5 and 3.0, the other one of $C(5)H_2$), 3.92 (1H, m, J=11.5, 10.0, and 3.0, CH(Ts)), 4.78 (1H, d, J=10.0, C(7)H), 6.18, 7.15, 7.20 (each 1H, s, C(2)H, C(1)H, and C(4)H), 7.15—7.72 (4H, A_2B_2q, J=8.5, arom-H (Ts)); Found: C, 71.08; H, 7.51%. Calcd for $C_{22}H_{28}O_3S$: C, 70.94; H, 7.58%.

(E)-3-[3-(3-Furyl)propylidene]-1,1-dimethylcyclohexane (9): To a chilled blue solution of Li (70 mg, 10 mg atm) in liq. NH_3 (*ca.* 10 ml) was added dropwise a solution of the sulfone (**8**) (270 mg, 0.7 mmol) in THF (1.0 ml) at −78 °C under argon. Stirring was continued for 40 min at the temperature and then reaction was quenched by introduction of gaseous butadiene followed by addition of MeOH (1.0 ml). After the cold bath was removed to evaporate NH_3, the residue was extracted with Et_2O, washed with water, dried, and concentrated to give a crude oil (135 mg). Purification of the product by column chromatography yielded the sesquiterpene (**9**) (100 mg, 74%) as oil: NMR 0.82 (6H, s, $C(CH_3)_2$), 1.20—1.60 (4H, m, $C(10)H_2C(11)H_2$), 1.79 (2H, s, $C(13)H_2$), 1.85—2.50 (6H, m, $C(5)H_2C(6)H_2$ and $C(9)H_2$), 4.97 (1H, bt, J=6.0, C(7)H), 6.15, 7.08, 7.21 (each 1H, s, C(2)H, C(1)H and C(4)H).

Reaction of the (E)-Furyl Sesquiterpene (9) with Benzenesulfenyl Chloride (PhSCl). A solution of PhSCl (75 mg, 0.5 mmol) in CH_2Cl_2 (0.5 ml) was added dropwise into a cold mixture of the terpene (**9**) (110 mg, 0.5 mmol) in CH_2Cl_2 (3.0 ml) at −78 °C and the mixture was stirred for 10 min at the temperature. Evaporation of the solvent at room temperature gave a crude product (170 mg). Purification by column chromatography afforded the oily sulfide, 1-[3-(3-furyl)-1-(phenylthio)propyl]-5,5-dimethylcyclohexene and -3,3-dimethylcyclohexene (**10**) (130 mg, 79%). Data for **10** follow: IR 1580; MS 326 (M^+, 9), 217 (100), 135 (42); NMR 0.65, 0.86 (major pair of singlets of 77% intensity) and 0.80, 0.92 (minor pair of singlets of 23% intensity) (overall 6H, $C(CH_3)_2$), 3.25—3.65 (1H, m, CH(SPh)), 4.85 (major singlet assignable to C(13)H of **10b**) and 5.23 (minor broad singlet to C(9)H of **10a**) (overall 1H), 6.14 (1H, s, C(2)H), 7.00—7.35 (7H, m, arom-H); Found: C, 77.43; H, 7.89%. Calcd for $C_{21}H_{26}OS$: C, 77.27; H, 8.03%.

Oxidative Elimination of the Thiophenol from the Sulfide (10) Providing the Diene, (E)-1-[3-(3-Furyl)-1-propenyl]-5,5-dimethyl and 3,3-dimethylcyclohexene (11). A mixture of the sulfide (**10**) (100 mg, 0.3 mmol), 30% H_2O_2 (40 μl), and AcOH (2.0 ml stirred for 16 h at room temperature. The mixture was diluted with Et_2O, washed successively with water, saturated $NaHCO_3$, and brine, dried, and concentrated to give the crude sulfoxide (105 mg), which was, without further purification, heated with $NaHCO_3$ (50 mg) in toluene (6.0 ml) under reflux for 3 h. The mixture was worked up by the usual manner and purification of the product by column chromatography gave the oily diene (**11**) (55 mg, 83%). Data for **11** follow: IR 1560, 1500; MS 216 (M^+, 100), 201 (25), 160 (31), 135 (18), 107 (18); NMR 0.92 (minor) and 0.97 (major) (overall 6H, s (23:77), $C(CH_3)_2$), 1.20—2.20 (6H, m, $C(10)H_2C(11)H_2$ and $C(9)H_2$ or $C(13)H_2$), 3.16 (2H, d, J=6.0, $C(5)H_2$), 5.20—5.95 (3H, m, 3 =CH containing C(13)H of **11b** as singlet), 6.15, 7.10, 7.23

(each 1H, s, C(2)H, C(1)H, and C(4)H).

Olefinic Inversion of the (E)-Furyl terpene (9) via the Epoxide (12) Providing the (Z)-Furyl Terpene (13) by the Vedejs' Method.[8] *m*-Chloroperbenzoic acid (MCPBA) (net 80%) (202 mg, 0.9 mmol) was added in portions into a solution of the (*E*)-furyl terpene (**9** *E*:*Z*=85:15) (186 mg, 0.8 mmol), prepared from the alcohol (**5** *E*:*Z*=85:15) by the same procedure described above without recrystallization of the sulfone (**7**), in CH_2Cl_2 (10 ml) at 0 °C. The mixture was diluted with CH_2Cl_2, washed successively with 3% NaOH and water, dried, and concentrated to give a crude product (190 mg). Purification by column chromatography gave the epoxide (**12**) (152 mg, 76%) as oil: NMR 0.86, 0.95 (each 3H, s, $C(CH_3)_2$), 1.51—1.90 (10 H, m), 2.35—2.70 (3H, m, C(5)H_2 and C(7)H), 6.18, 7.13, 7.23 (each 1H, s, C(2)H, C(1)H, and C(4)H). To a solution of $LiP(Ph)_2$ in THF, prepared from $ClP(Ph)_2$ (120 mg, 0.5 mmol) and Li (7 mg, 1.0 mg atm) in THF (1.5 ml) under ultrasonic irradiation at 15 °C for 2 h, was added dropwise a solution of the epoxide (**12**) (100 mg, 0.4 mmol) in THF (0.5 ml) at room temperature under argon. After stirring the mixture for 1 h, MeI (50 μl) was added into the mixture at room temperature. Stirring was continued for 45 min and the mixture was worked up by the usual manner. Purification of the product by column chromatography provided the inverted olefin (**13**) (58 mg, 65%) as oil: NMR 0.82 (minor) and 0.86 (major) (overall 6H, s (20:80), $C(CH_3)_2$), 1.20—1.70 (4H, m, C(10)H_2C(11)H_2), 1.79 (minor) and 1.87 (major) (overall 2H, s, C(13)H_2), 1.80—2.50 (6H, m, C(5)H_2C(6)H_2 and C(9)H_2), 4.97 (minor) and 5.12 (major) (overall 1H, bt, *J*=6.0, C(7)H), 6.15, 7.08, 7.21 (each 1H, s, C(2)H, C(1)H, and C(4)H).

Synthesis of Pleraplysillin-1 (1) from (Z)-Furyl Sesquiterpene (13). The PhSCl addition of the (*Z*)-olefin (**13** *E*:*Z*=20:80) was carried out by the identical conditions described for the (*E*)-olefin (**9**) to give the allylic sulfide (**10**) in 77% yield. ^{1}H-NMR analysis indicated the isomeric ratio of **10** to be **10a**:**10b**=60:40 as follows: NMR 0.65, 0.86 (minor pair of singlets 40% intensity) and 0.80, 0.92 (major pair of singlets of 60% intensity) (overall 6H, $C(CH_3)_2$), 4.85 (minor singlet assignable to C(13)H of **10b**) and 5.23 (major broad singlet assignable to C(9)H of **10a**) (overall 1H, 40:60). Oxidative elimination of thiophenol from the sulfide (**10**) obtained was achieved analogously by oxidation with H_2O_2 in AcOH followed by heating in toluene as described above for **10** (**10a**:**10b**=23:77). The diene, thus obtained in 80% yield, contained desired pleraplysillin-1 (**1**) as the major component: IR 1560, 1500; MS 216 (M^+, 100), 201 (20), 160 (32), 135 (21), 107 (28); NMR 0.92 (major) and 0.97 (minor) (overall 6H, s (60:40), $C(CH_3)_2$), 1.34 (major triplet assignable to C(11)H_2 of **1**), 1.85 (major singlet assignable to C(13)H_2), 3.15 (2H, d, *J*=6.0, C(5)H_2), 5.20—6.10 (3H, m, 3 =CH), 6.15, 7.10, 7.23 (each 1H, s, C(2)H, C(1)H, and C(4)H). The major signals in ^{1}H-NMR were identical with those observed for the pure **1** synthesized by the alternative route, *vide infra*. The diene obtained showed a single peak in HPLC analysis and all the efforts for separation of each regioisomer were unsuccessful.

Synthetic Approach to Pleraplysillin-1 (1) by Way of Regioselective Epoxide-Ring Opening of the β,γ-Epoxy Alcohol (14). *2,3-Epoxyochtodane-1-ol (14)*: A solution of MCPBA net 80%) (920 mg, 4.3 mmol) in CH_2Cl_2 (10 ml) was added dropwise into an ice-cold solution of the alcohol (**5**) (600 mg, 3.9 mmol) in CH_2Cl_2 (20 ml) and the mixture was stirred for 45 min at 0 °C. The mixture was worked up analogously as described for **12** gave the epoxide (**14**) (605 mg, 91%): NMR 0.93, 0.98 (each 3H, s, $C(CH_3)_2$), 1.15—1.90 (8H, br), 2.77 (1H, t, *J*=6.0, C(O)HCH_2OH), 3.64 (2H, d, *J*=6.0, C(O)HCH_2OH), 3.92 (1H, bs, OH).

3-Ochtodene-1,2-diol (15): The epoxide-ring opening was achieved according to the procedure developed by Sharpless.[7] To a solution of the epoxy alcohol (**14**) (650 mg, 3.8 mmol) in CH_2Cl_2 (20 ml) was added dropwise a solution of $Ti(OPr^i)_4$ (1.3 g, 4.5 mmol) in CH_2Cl_2 (5.0 ml) at 0 °C. The mixture was stirred for 30 min at 0 °C and then for 15 h at room temperature. After evaporation of the solvent *in vacuo*, Et_2O (20 ml) and 5% H_2SO_4 (15 ml) was added to the residue and the mixture was stirred for 30 min at room temperature. The reaction mixture was worked up by the usual manner to give a crude product (630 mg), which was purified by column chromatography to afford the diol (**15**) (500 mg, 77%) as oil: IR 3520, 3380; NMR 0.88 (major) and 0.97 (minor) (overall 6H, s (94:6), $C(CH_3)_2$), 1.31 (2H, t, *J*=6.5, C(6)H_2), 1.73 (2H, s, C(8)H_2), 1.85—2.20 (2H, m, C(5)H_2), 3.35—4.10 (2H, m, C(OH)HCH_2OH), 3.85—4.13 (1H, m, C(OH)HCH_2OH), 4.46 (2H, bs, 2×OH), 5.40 (minor) and 5.65 (major) (overall 1H, bs (94:6), =CH).

2-Hydroxy-3-ochtodene-1-yl Tosylate (16): A mixture of the diol (**15**) (430 mg, 2.5 mmol) and *p*-TsCl (570 mg, 3.0 mmol) in pyridine (8.0 ml) was stirred for 16 h at room temperature. The reaction mixture was extracted with Et_2O, washed successively with 3% HCl, 5% $NaHCO_3$, and brine, dried, and concentrated to give a crude product (770 mg). Purification of the product by column chromatography afforded the mono tosylate (**16**) (620 mg, 76%) as oil: NMR 0.82 (major) and 0.91 (minor) (overall 6H, s, $C(CH_3)_2$), 1.23 (2H, t, *J*=7.0, C(6)H_2), 1.62 (2H, bs, C(8)H_2), 1.77—2.20 (2H, m, C(5)H_2), 2.39 (3H, s, CH_3Ph), 3.07 (1H, s, OH), 3.75—4.25 (3H, m, C(OH)HCH_2OTs), 5.38 (minor) and 5.60 (major) (overall 1H, bs, =CH), 7.20—7.80 (4H, A_2B_2q, *J*=8.5, arom-H).

2-Oxo-3-ochtodene-1-yl Tosylate (17): Active MnO_2 (2.5 g) was added into a solution of the alcohol (**16**) (440 mg, 1.3 mmol) in CH_2Cl_2 (20 ml) at room temperature and the mixture was stirred for 3.5 h. The reaction mixture was filtered and the filtrate was purified by column chromatography to give the keto tosylate (**17**) (390 mg, 89%) as oil: IR 1650, 1620, 1590; NMR 0.85 (major) and 1.02 (minor) (overall 6H, s, $C(CH_3)_2$), 1.30 (2H, t, *J*=6.5, C(6)H_2), 1.90 (2H, bs, C(8)H_2), 2.00—2.40 (2H, m, C(5)H_2), 2.40 (3H, s, CH_3Ph), 4.88 (2H, C(O)CH_2OTs), 6.46 (minor) and 6.77 (major) (overall 1H, bs, =CH), 7.20—7.83 (4H, A_2B_2q, *J*=8.5, arom-H).

1-Tosyl-3-ochtodene-2-one (18): A mixture of the keto tosylate (**17**) (370 mg, 1.15 mmol) and *p*-TsNa (574 mg, 2.2 mmol) in DMF (8.0 ml) was stirred for 16 h at room temperature. The reaction mixture was worked up by the usual manner to give a crude product (345 mg). Purification by column chromatography gave the crystalline keto sulfone (**18**) (286 mg, 82%). Recrystallization from Et_2O–hexane yielded the pure regio isomer (**18**), mp 110—113 °C. Data for **18** follow: IR 1650, 1625, 1595; NMR ($CDCl_3$) 0.89 (6H, s, $C(CH_3)_2$), 1.34 (2H, t, *J*=6.5, C(6)H_2), 1.96 (2H, bs, C(8)H_2), 2.10—2.50 (2H, m, C(5)H_2), 2.45 (3H, s, CH_3Ph), 4.44 (2H, s, C(O)CH_2Ts), 6.95 (1H, bs, =CH), 7.25—7.83 (4H, A_2B_2q, *J*=8.5, arom-H); Found: C, 66.53; H, 7.29%. Calcd for $C_{17}H_{22}O_3S$: C, 66.64; H, 7.24%.

1-[3-(3-Furyl)-2-tosylpropionyl]-5,5-dimethylcyclohexene (19): A solution of the keto sulfone (**18**) (140 mg, 0.45 mmol) in THF (0.5 ml) was added into an ice-cold mixture of NaH (13 mg, 0.55 mmol), THF (1.5 ml), and DMF (2.0 ml) and stirring was continued for 10 min at 0 °C. Then, a solution of 3-

furylmethyl bromide (**4** Y=Br) (82 mg, 0.5 mmol) in THF (0.5 ml) was added into the mixture at room temperature. The mixture was stirred for 16 h at room temperature and worked up by the usual manner. Purification of the crude product (172 mg) by column chromatography afforded the crystalline coupled keto sulfone (**19**) (164 mg, 92%), mp 136—140 °C (Et_2O-hexane). Data for **19** follow: IR 1650, 1630, 1600; NMR ($CDCl_3$) 0.77, 0.82 (each 3H, s, $C(CH_3)_2$), 1.25 (2H, t, J=6.5, $C(11)H_2$), 1.88 (2H, bs, $C(13)H_2$), 2.00—2.30 (2H, m, $C(10)H_2$), 2.42 (3H, s, CH_3Ph), 3.11, 3.12 (each 1H, d, J=8.5 and 6.0, C(Ts)HC$\underline{H}_2$-furyl), 4.93 (1H, dd, J=8.5 and 6.0, C(Ts)$\underline{H}CH_2$-furyl), 6.08 (1H, s, C(2)H), 6.73 (1H), bs, C(9)H), 7.07, 7.22 (each 1H, s, C(1)H and C(4)H), 7.20—7.72 (4H, A_2B_2q, J=8.5, arom-H); Found: C, 68.30; H, 6.86%. Calcd for $C_{22}H_{26}O_4S$: C, 68.37; H, 6.78%.

*3-(3-Furyl)-1-(5,5-dimethyl-1-hexenyl)-2-tosyl-1-propanol (**20**)*: $NaBH_4$ (24 mg, 0.63 mmol) was added in portions into a solution of the keto sulfone (**19**) (124 mg, 0.32 mmol) in EtOH (5.0 ml) at 0 °C and stirring was continued for 30 min at 0 °C. Extraction of the mixture with Et_2O followed by the usual work-up gave the crystalline hydroxy sulfone (**20**) (125 mg, 100%), mp 130—135 °C (Et_2O-hexane). Data for 20 follow: IR 3440, 1590; MS 388 (M^+, 2), 307 (19), 233 (85), 215 (100), 165 (47); NMR 0.79, 0.82 (each 3H, s, $C(CH_3)_2$), 1.15 (2H, t, J=6.5, $C(11)H_2$), 1.69 (1H, bs, $C(13)H_2$), 1.90—2.20 (2H, m, $C(10)H_2$), 2.42 (3H, s, CH_3Ph), 2.78, 2.85 (each 1H, d, J=6.0 and 5.0, C(Ts)HC$\underline{H}_2$-furyl), 3.15—3.57 (1H, m, C(OH)HC(Ts)$\underline{H}CH_2$-furyl), 4.00 (1H, d, J=4.0, OH), 4.32 (1H, dd, J=7.5 and 4.0, C(OH)$\underline{H}$C(Ts)H), 5.70 (1H, bs, C(9)H), 6.07, 7.06, 7.20 (each 1H, s, C(2)H, C(1)H, and C(4)H), 7.15—7.75 (4H, A_2B_2q, J=8.5, arom-H); Found: C, 68.04; H, 7.24%. Calcd for $C_{22}H_{28}O_4S$: C, 68.01; H, 7.26%.

*1-[1-Acetoxy-3-(3-furyl)-2-tosylpropyl]-5,5-dimethylcyclohexene (**21**)*: A mixture of the alcohol (**20**) (100 mg, 0.26 mmol), Ac_2O (0.5 ml), and pyridine (0.5 ml) was stirred for 16 h at room temperature. The reaction mixture was worked up by the usual manner to give the acetoxy sulfone (**21**) (105 mg, 95%) as oil. Data for **21** follow: IR 1740, 1595; MS 370 [$(M-60)^+$, 2], 275 (7), 232 (12), 215 (100); NMR 0.79, 0.83 (each 3H, s, $C(CH_3)_2$), 1.25 (2H, t, J=6.5, $C(11)H_2$), 1.55 (2H, bs, $C(13)H_2$), 1.67 (3H, s, CH_3CO_2), 1.83—2.20 (2H, m, $C(10)H_2$), 2.42 (3H, s, CH_3Ph), 2.76, 2.90 (each 1H, d, J=6.0 and 5.5, C(Ts)HC$\underline{H}_2$-furyl), 3.10—3.60 (1H, m, C(OAc)HC(Ts)$\underline{H}CH_2$-furyl), 5.36 (1H, d, J=8.0, C(OAc)$\underline{H}$C(Ts)H), 5.65 (1H, bs, C(9)H), 6.24, 7.17, 7.23 (each 1H, s, C(2)H, C(1)H, and C(4)H), 7.20—7.72 (4H, A_2B_2q, J=8.5, arom-H).

*Synthesis of Pleraplysillin-1 (1) by Reductive Elimination of the Acetoxy Sulfone (**21**). Method A Using Sodium Amalgam.*[8] 5% Na-Hg (2.0 g) was added at once into a cold solution of the acetoxy sulfone (**21**) (150 mg, 0.35 mmol) in a mixed solvent of MeOH (1.5 ml) and AcOEt (0.7 ml) at −20 °C and stirred was continued for 2.5 h at the temperature. The mixture was worked up by the usual manner. Purification of the product by column chromatography gave mainly the hydroxy sulfone (**20**) (96 mg, 71%) and a small amount of the sulfur-free diene (**1**) (5 mg, 7%), which appeared homogeneous in the ordinary TLC but proved to contain two compounds in a ratio *ca.* 80:20 by HPLC analysis using 5% $AgNO_3$-impregnated silica gel. The major less polar component was identified with pleraplysillin-1 (**1**) by coinjection of pure **1** prepared by the alternative conditions (Method B), *vide infra*. Spectral data for the diene were almost identical with those of pure **1** obtained by the modified Bouvault-Blanc conditions (Method B) except for the ratio (*ca.* 80:20) of intensity of the doublet signals at δ 3.15 and 3.26 (J=6.5 Hz) respectively assignable to the $C(5)H_2$ of **1** and the corresponding (6*Z*)-isomer in ^{1}H-NMR.

Method B Utilizing the Modified Bouvalut-Blanc Conditions.[9] Pieces of Na (70 mg, 3.0 mgatm) were added into a cold solution of the acetoxy sulfone (**21**) (150 mg, 0.35 mmol) and EtOH (0.3 ml) in THF (2.0 ml) at −78 °C and the mixture was stirred for 1 h at the temperature. The mixture was extracted with hexane, washed with water, dried, and concentrated. Purification of the product by column chromatography gave the diene (**1**) (49 mg, 65%) as oil. Spectral properties of the diene were consistent with those of the isolated pure **1**, described below, except for the appearance of minor doublet (*ca.* 11%) at 3.26 assignable to the $C(5)H_2$ of the corresponding (6*Z*)-isomer of **1** in ^{1}H-NMR. HPLC analysis also showed that the product contains a minor amount (*ca.* 11%) of the isomer as the more polar component. Careful column chromatography of the diene on 5% $AgNO_3$-impregnated silica gel by elution with hexane gave pure pleraplysillin-1 (**1**). Spectral data for the synthetic compound were consistent with those reported for the natural **1**:[3] IR 1560, 1500, 1445, 1425, 1380, 1360, 1050, 1010, 960, 865; MS 216 (M^+, 100), 201 (25), 160 (40), 145 (30), 135 (27), 131 (37), 118 (29), 107 (37), 91 (50), 81 (49); NMR 0.92 (6H, s, $C(CH_3)_2$), 1.34 (2H, t, J=6.0, $C(11)H_2$), 1.85 (2H, s, $C(13)H_2$), 2.00—2.25 (2H, m, $C(10)H_2$), 3.15 (2H, d, J=6.5, $C(5)H_2$), 5.20—5.70 (2H, m C(6)H and C(9)H), 6.03 (1H, d, J=15.0, C(7)H), 6.15, 7.10, 7.23 (each 1H, s, C(2)H, C(1)H, and C(4)H).

*Synthesis of the Model Compound, 1-(1-Acetoxy-3-phenyl-2-tosylpropyl)cyclohexene (**22**).* 1.6 M solution of *n*-BuLi-hexane (3.1 ml) was added dropwise into a solution of phenethyl *p*-tolyl sulfone (1.17 g, 4.5 mmol), prepared from phenethyl bromide, in THF (8.0 ml) at −78 °C under argon. After stirring of the mixture for 30 min at −78 °C, a solution of 1-cyclohexenecarbaldehyde (550 mg, 5.0 mmol), prepared from cyclohexanone *p*-tosylhydrazone,[10] in THF (1.0 ml) was added into the mixture. The mixture was stirred for 30 min at the temperature and worked up by the usual manner. Product isolation gave 1-(1-cyclohexenyl)-3-phenyl-2-tosyl-1-propanol (1.42 g, 85%) as a diasteroisomeric mixture: NMR 0.85—1.50 (6H, br, $C\underline{H}_2C\underline{H}_2C\underline{H}_2CH$=), 1.65—2.10 (2H, br, $C\underline{H}_2CH$=), 2.41 (3H, s, CH_3Ph), 2.40—3.60 (3H, m, C(OH)HC(Ts)$\underline{H}C\underline{H}_2Ph$), 4.03 (1H, s, OH), 3.92 (major doublet (J=15.0)) and 4.30 (minor doublet (J=12.0)) (overall 1H, C(OH)$\underline{H}$C(Ts)H), 5.62 (major) and 5.86 (minor) (overall 1H, bs, =C$\underline{H}CH_2$), 6.80—7.87 (9H, m, arom-H). Careful column chromatography of the diasteroisomeric mixture gave one of the stereoisomer as a TLC-homogeneous oil: IR 3450, 1595; MS 370 (M^+, 3), 352 (4), 260 (31), 214 (81), 197 (98), 196 (100); NMR showed almost identical spectrum with that of the stereoisomeic mixture except for absence of the minor doublet at δ 4.30 and of the minor broad singlet at δ 5.86. The hydroxy sulfone (diastereoisomeric mixture) was acetylated analogously as described for **20** to give the crystalline acetoxy sulfone (**22**) in 88% yield as a diastereoisomeric mixture. Data for **22** follow: IR 1740, 1590; NMR 1.10—1.55 (6H, br, $C\underline{H}_2C\underline{H}_2C\underline{H}_2CH$=), 1.66 (major) and 1.92 (minor) (overall 3H, s, CH_3CO_2), 1.70—2.05 (2H, br, $C\underline{H}_2CH$=), 2.38 (3H, s, CH_3Ph), 2.40—3.80 (3H, m, C(OAc)HC(Ts)$\underline{H}C\underline{H}_2$-Ph), 5.33 (1H, d, J=8.0, C(OAc)$\underline{H}$C(Ts)H), 5.40 (minor) and 5.60 (major) (overall 1H, bs, C$\underline{H}CH_2$), 7.09 (5H, s, arom-H (Ph)), 7.15—7.73 (4H, A_2B_2q, J=8.5, arom-H (Ts)). From the

purified stereoisomer of hydroxysulfone was obtained the stereochemically pure one of acetoxy sulfone (**22**); mp 81—83 °C (Et_2O–hexane). Spectral properties were identical with the corresponding diastereoisomeric mixture except for absence of the minor singlet at δ 1.92 and broad singlet at δ 5.40 in ^{1}H-NMR. Found: C, 69.72; H, 6.93%. Calcd for $C_{24}H_{28}O_4S$: C, 69.88; H, 6.84%.

*Reductive Elimination of the Acetoxy Sulfone (**22**) Providing the Diene, 1-(3-Phenyl-1-propenyl)cyclohexene (**23**).* Treatment of the acetoxy sulfone (**22**) with Na and EtOH in THF by the same procedure (Method B) as described for **21** gave the diene (**23**) in 76% yield as oil. HPLC analysis of the diene (**23**) obtained either from the diastereoisomeric mixture of **22** or from the stereochemically pure **22** showed the identical chromatogram of a mixture of the geometric isomers (86:14) concerning the disubstituted olefinic bond. Data for **23** follow: IR 1600, 1490, 1445, 1430; MS 198 (M^+, 100), 169 (24), 155 (34), 141 (34), 129 (45), 117 (33), 107 (63), 91 (90), 97 (84); NMR 1.40—1.77 (4H, br, CH_2CH_2), 1.88—2.27 (4H, br, 2×=CHC<u>H</u>$_2$), 3.35 (major) and 3.54 (minor) (overall 2H, d (*E*:*Z*=86:14) *J*=6.0, CHC<u>H</u>$_2$Ph), 5.21—5.70 (2H, m, 2×=C<u>H</u>CH_2), 5.94 (1H, d, *J*=15.0, =CC<u>H</u>=CHCH$_2$Ph).

(Received April 5, 1984)

Cycloadditions of 1-ethoxycarbonyl-1*H*-azepine with 5-methoxycarbonyl-2-pyrone gave [4+2] and [4+6] type adducts and a benzazepine derivative, while the reaction of the azepine derivative with 3-methoxycarbonyl-2-pyrone afforded only a [4+2] type adduct. Similarly, an addition of 1-ethoxycarbonyl-1*H*-1,2-diazepine with 5-methoxycarbonyl-2-pyrone gave a benzodiazepine derivative. Reactions of the azepine and the diazepine derivatives with tetrachlorocyclopentadienone dimethyl acetal afforded [4+2] type adducts.

Azepine and diazepine derivatives are known to be nonplaner compounds and to behave as olefinic compounds rather than aromatic materials.[1-4] The addition reactions of azepines and diazepines have received considerable attention from the viewpoint of a synthetic utility and an elucidation of the chemical reactivity. Azepines and diazepines are known to give [4+2] type adducts when allowed to react with dienophiles and afford [4+2] and [4+6] type adducts in reactions with enophiles.[2]

As a part of our research effort concerning the addition reactions of the heterocyclic compounds,[3] we have studied the cycloaddition reactions of azepine and diazepine derivatives with 2-pyrone derivatives and cyclopentadiene derivatives. We wish to report the results of these reactions.

Results

1-Ethoxycarbonyl-1*H*-azepine (**1a**) was allowed to react with 5-methoxycarbonyl-2-pyrone (**3**) in benzene at 80 °C for 57 h to give adducts **6** and **7** in yields of 25 and 20%, respectively. The same reaction under more drastic conditions (in toluene, 140 °C for 10 d) afforded the benzazepine derivative **8** and the [6+6] type dimer **9**[4] of **1a** in 5 and 36% yields, respectively. The reaction of 1-methoxycarbonyl-1*H*-azepine (**1b**) with 3-methoxycarbonyl-2-pyrone (**4**) at 80 °C for 68 h afforded adduct **10** and the [6+4] type dimer **11**[5] of **1b** in yields of 5 and 11%, respectively. The reaction of 1-ethoxycarbonyl-1*H*-1,2-diazepine (**2**) and **3** in benzene at 80 °C for 10 d gave no adduct but the reaction at 110 °C in toluene for 10 d gave a benzodiazepine derivative **12** in 12% yield. The reaction of **2** with **4** gave no adduct. Under conditions analogous to the above, **1** and **2** were allowed to react with 2-pyrone (**5**), but no adduct was obtained.

Upon heating in xylene at 140 °C for 50 min adduct **6** gave the benzazepine derivative **8** in 5% yield, which was obtained in better yield (17%) by a reaction of **6** with o-chloranil in anisole at 140 °C for 45 min. After heating, adduct 7 underwent a retro-Diels-Alder reaction to yield **1a** and **3**. The adduct **10** gave a resinous material upon heating, which was not further characterized.

The reaction of **1a** with tetrachlorocyclopentadienone dimethyl acetal (**13**) at 100 °C for 5 h afforded adduct **14** as crystalline material of mp 68—70 °C in yield of 48%.[5] The diazepine derivative **2** was also allowed to react with **13** at 100 °C for 15 h to give the adduct **15** in 39% yield. Under conditions analogous to the above **1** and **2** were allowed to react with cyclopentadienone diethyl acetal, however, no adduct was obtained. All attempts to hydrolyze the acetal components of **14** and **15** to the corresponding ketones and to substitute the chlorine atoms with hydrogen atoms were unsuccessful.

Elemental analyses and/or the molecular ion peaks in the mass spectra revealed that products **6**, **7**, and **10** are the 1:1 adducts of **1a** and **3**, and **1b** and **4**, respectively. The existence of lactone rings in these products is shown by the IR spectra (**6**; 1780, **7**; 1760, and **10**; 1775 cm^{-1}). The structures of the [4+2] type adducts **6** and **10** were determined on the basis of NMR spectral properties, employing the double- and triple-resonance technique. The small coupling constants between the bridgehead protons (**6**; $J_{1,2}$=3.0, $J_{2,3}$=$J_{7,8}$=4.3, and $J_{8,9}$=2.3 Hz, **10**; $J_{1,2}$=2.2 and $J_{2,3}$=$J_{7,8}$=4.0 Hz) indicate the endo structures of **6** and **10**.[6] These structures were further substantiated by the similarity of their NMR spectra to those of the [4+2] type adduct **14**.[5]

The IR absorption due to the urethane group of **7** appears at 1705 cm^{-1}, indicating that this urethane group is not conjugated with any unsaturated group. The [6+6] type dimer **9** also shows an absorption due to the urethane group at almost the same wave length (1700 cm^{-1}) in its IR spectrum.[4] The structure of **7** was determined mainly on the basis of NMR spectral properties and was confirmed by a comparison of its NMR spectrum to that of an analogous compound **16**.[7]

The signals due to the bridgehead protons, H_2 and H_7 (5.06—5.43 ppm) of **7** were observed at rather low field. The same tendency was observed with the [6+6] type dimer **9** (4.95 ppm)[4] substantiating the structure of 7. Each signal due to H_1, H_8, and the protons of ethoxycarbonyl group appears as a pair of signals at a slightly different chemical shift in the NMR spectrum at room temperature. At 70 °C, these three pairs coalesced to three independent signals. This phenom-

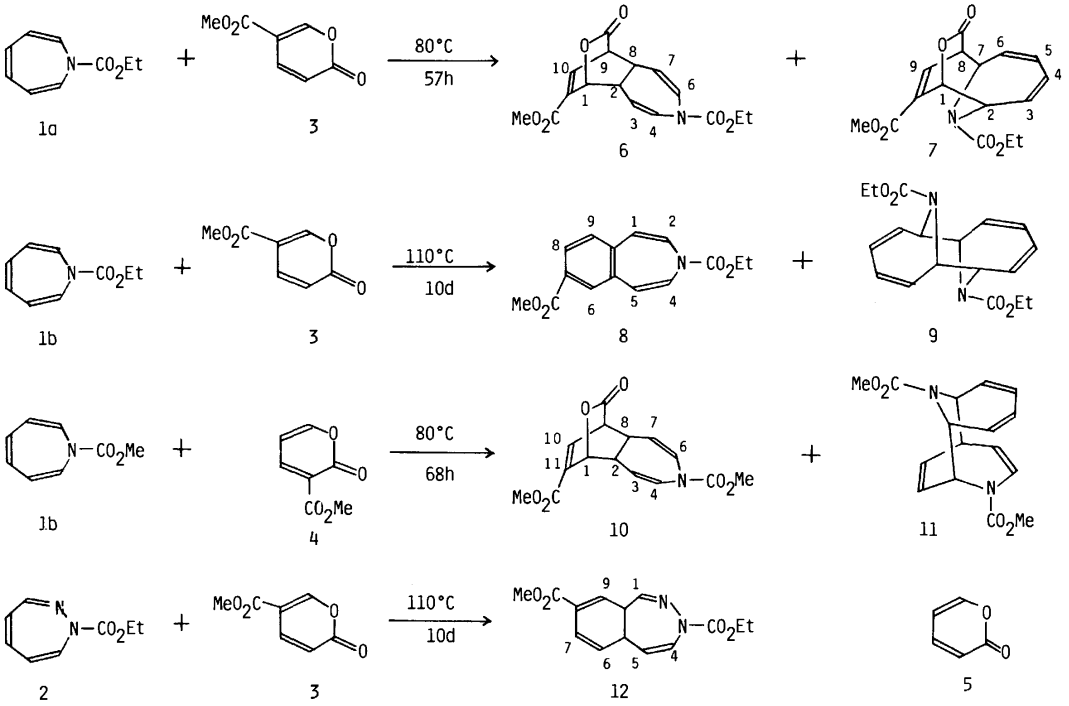

Fig. 1

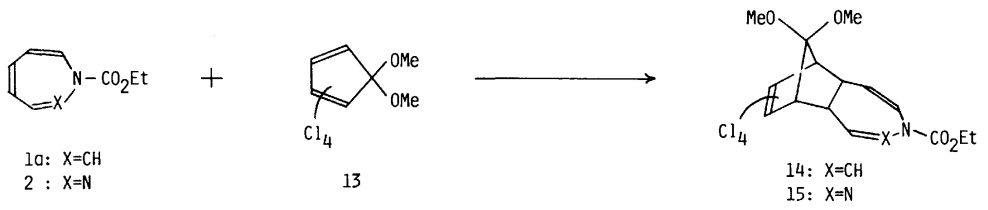

Fig. 2.

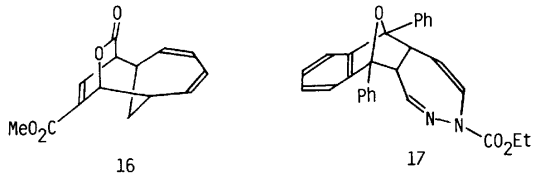

Fig. 3.

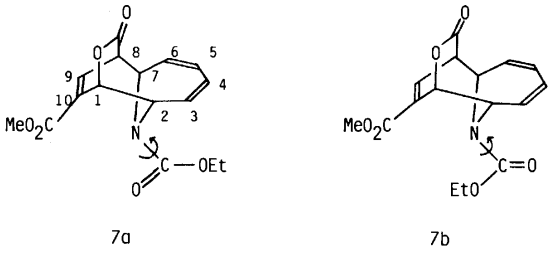

Fig. 4.

enon can be explained in terms of the existence of two rotamers (**7a** and **7b**) resulting from the rotation of the ethoxycarbonyl group as shown in Fig. 4.[3b,3d,8]

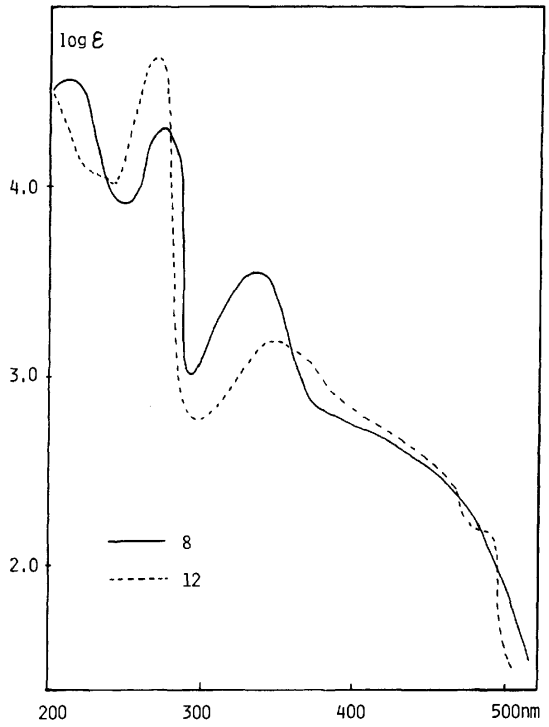
Elemental analyses and the molecular-ion peaks in the mass spectra indicate that **8** and **12** are the products of decarboxylations of the 1:1 adducts of **3** with **1a** and **2**, respectively. The UV spectra reveal that these products are the azepine and the diazepine derivatives.[9] The structure of **8** was determined on the basis of the NMR spectrum as well as the independent synthesis of **8** by the thermolysis of **6**. The NMR signals due to the protons on the seven-membered ring appear as two pairs of signals with slight differencies in chemical shift, showing **8** to be an almost symmetric compound.

In the NMR spectrum of **12**, the chemical shifts of H_1 (7.31 ppm), H_4 (6.47 ppm), and H_5 (5.55 ppm) closely resemble those of the corresponding protons (7.31, 6.22, and 5.67 ppm) of **2**, suggesting the presence of the 3*H*-2,3-benzodiazepine skeleton. The position of the methoxycarbonyl group on the benzene ring was determined by the appearance of the NOE between H_5 and H_6, and H_1 and H_9 with 15 and 17%, respectively.

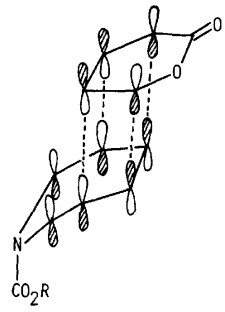
The structure of **14** was confirmed by a comparison of the physical properties with values found in the literature.[5] The Structure of **15** was elucidated on the basis of its NMR spectrum and was confirmed by a comparison of its NMR spectrum to that of an analogous compound **17**.[3]

Discussion

Though the yields of the products mentioned above

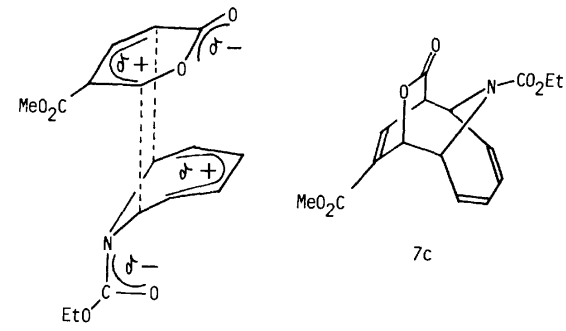


UV Spectra of 8 and 12 in Cyclohexane
Fig. 5.



18
Fig. 6.

are not high, it is significant that 2-pyrone derivatives reacted with azepine and diazepine derivatives since it has been previously reported by Anastassiou *et al.* that 2-pyrone is inert toward heterocyclic compounds such as **1** and **2**.[10] The experimental results obtained in our laboratory seem to suggest that the introduction of electron-withdrawing groups such as the methoxycarbonyl group increased the reactivity of the 2-pyrones with azepine and diazepine derivatives. This phenomenon can be rationalized by visualizing the reaction as an inverse electron-demanding Diels-Alder reaction in which the HOMO of the heterocyclic compounds interact with the LUMO of the 2-pyrones.[2c,11] In such cases, a lowering of the LUMO of the 2-pyrones or an elevation of the HOMO of the heterocyclic compounds are thought to promote the interaction of the transition state which allows the chemical reaction to proceed. Thus, the introduction of a methoxycarbouyl group,



19

7c

Fig. 7.

which is known to lower the orbital energies of the system,[2c,12] is thought to be responsible for the success of the reaction.

The steric repulsion between the heterocyclic compounds and the methoxycarbonyl group at the reaction site of **4** may explain the lower yield of the reaction with **4** than with **3**. The endo mode of the reactions to form **6** and **10** is explained by the secondary orbital interaction in the transition state of **18**.

The preferential formation of **7**, and not **7c**, can be rationalized by the dipole-dipole interaction between the reactants in the transition state **19** as shown in Fig. 7.[2c,3c,13] The formation of **8** is a result of the decarboxylation reaction of **6** as shown by the experiment mentioned above. The benzodiazepine derivative **12** is also thought to be obtained through the decarboxylation reaction of the 1:1 adduct of **2** and **3**, corresponding to **6**.

The inactivity of cyclopentadienone diethyl acetal and the activity of **13** in the reactions with **1** and **2** can be explained by the following argument. Cyclopentadienone diethyl acetal contains an electron-rich conjugated double bond which is not suitable as an enophile in the inverse electron-demanding Diels-Alder reaction previously described.[2c] In fact, **13**, has an electron-defficient conjugated double bond substituted by chlorine atoms.

Experimental

All the reactions were carried out under a nitrogen stream. All melting and boiling points were uncorrected. NMR spectra were measured with a Varian HA-100 or Hitachi R-20B spectrometer with deuteriochloroform or carbon tetrachloride as solvents and tetramethylsilane as an internal standard. The IR spectra were measured in carbon tetrachloride solutions or potassium bromide disks and the UV spectra were measured in cyclohexane solutions. The mass spectra were measured with a Hitachi RMU 6D spectrometer at 70eV.

Reaction of **1a** *with* **3** *at 80°C.* A mixture of **1a** (1.52g, 9.2mmol) and **3** (7.10g, 46mmol) in benzene (20ml) was kept at 80°C for 57h. After evaporation of the solvent on a rotary evaporator, colorless crystals of recovered **3** were collected by filtration (4.67g, 66%). The filtrate was chromatographed on silica gel to give a red oil **1a** (120mg, 8%, pet ether-benzene 4:1 as an eluent), crystals **3** (1.19g, 17%, pet ether-benzene

1:1 as an eluent), a colorless viscous oil **6** (820mg, 25%, pet ether-benzene 1:2 as an eluent), and colorless crystals **7** (610 mg, 20%, ether as an eluent). The oil **6** and the crystals **7** were further purified by repeated chromatography on silica gel using benzene as an eluent and recrystallization from ethanol, respectively. **6**: Found: C, 60.19; H, 5.43; N, 4.14%. Calcd for $C_{16}H_{17}O_6N$: C, 60.18; H, 5.37; N, 4.39%. Ms *m/z* (rel intensity) 319 (M^+, 1), 165 (100), 127 (20), and 92 (54). IR (oil) 3050, 2950, 1780, and 1735cm^{-1}. NMR (CCl_4) δ=1.31 (t, CH_3, J=7.0Hz), 3.11 (ddd, H_8), 3.30 (ddd, H_2), 3.62 (dd, H_9), 3.70 (s, OCH_3), 4.20 (q, CH_2, J=7.0Hz), 4.77 (dd, H_3 or H_7), 4.82 (dd, H_7 or H_3), 5.46 (dd, H_1), 6.81 (d, 2H, H_4 and H_6), and 7.10 (dd, H_{10}). IR (KBr) 3030, 2950, 1760, and 1705cm^{-1}. NMR ($CDCl_3$) δ=1.20 and 1.28 (t,CH_3, J=7.0Hz), 3.79 and 3.82 (dd, H_8), 3.83 (s, OCH_3), 4.06 (q, CH_2, J=7.0Hz), 5.06—5.43 (m, 2H, H_2 and H_7), 5.54 and 5.62 (dd, H_1), 6.07 (bs, 4H, H_3-H_6), and 7.23 (dd, H_9). Coupling constants in Hz, $J_{1,2}$=4.8, $J_{1,9}$=1.4, $J_{2,3}$=4.7, $J_{7,8}$=4.0, and $J_{8,9}$=6.9.

Reaction of ***1a*** *with* ***3*** *at 110°C.* A mixture of **1a** (4.13g, 25mmol) and 3 (4.50g, 29mmol) in toluene (50ml) were kept at 110°C for 10d. After evaporation of the solvent on a rotary evaporator, the residue was chromatographed on silica gel to afford a red oil of recovered **1a** (420mg, 10%, pet ether-ether 1:1 as an eluent), red crystals **8** (300mg, 5%, pet ether-ether 4:6 as an eluent), and colorless crystals **9** (1.46g, 35%, pet ether-ether 3:7 as an eluent). Recrystallization of **8** from ethanol gave pure crystals, mp 82—84°C. Found: C, 65.61; H, 5.33; N, 5.10%. Calcd for $C_{15}H_{15}O_4N$: C, 65.92; H, 5.33; N, 5.13%. MS *m/z* (rel intensity) 273 (M^+, 83), 201 (39), 200 (100), 173 (22), 142 (16), and 115 (9). IR (KBr) 3030, 2960, and 1720cm^{-1}. NMR (CCl_4) δ=1.30 (t, CH_3, J=7.0Hz), 3.78 (s, OCH_3), 4.17 (q, CH_2, J=7.0Hz), 5.14 (d, H_1 or H_5), 5.19 (H_5 or H_1), 6.09 (d, H_2 or H_4), 6.15 (d, H_4 or H_2), 6.57 (d, H_9), 7.20 (d, H_6), and 7.48 (dd, H_8). Coupling constants in Hz, $J_{1,2}$=$J_{4,5}$=10.3, $J_{6,8}$=1.8, and $J_{8,9}$=8.0.

Reaction of ***1b*** *with* ***4***. A mixture of **1b** (900mg, 6.0 mmol) and **4** (4.62g, 30.0mmol) in benzene (10ml) was kept at 80°C for 68h. After evaporation of the solvent on a rotary evaporator, the residue was chromatographed on silica gel to yield a red oil of recovered **1b** (300mg, 33%, benzene-ether 19:1 as an eluent) and a colorless resinous oil (220mg, benzene-ether 9:1 as an eluent), which was thin-layer chromatographed on alumina using pet ether-ether 1:4 as a developing solvent to give colorless crystals **11** (100 mg, 11%, R_f=0.7) and a colorless resinous oil **10** (95mg, 5%, R_f=0.6). The oil **10** was unstable toward distillation (0.05Torr, bath temperature 135°C) and was purified by repeated thin-layer chromatography on alumina using pet ether-ether 1:4 as a developing solvent; however, an analytically pure sample could not be obtained. MS *m/z* (rel intensity) 305 (M^+, 1), 151 (100), 123 (6), and 92 (46). IR (oil) 3030, 2980, 1775, and 1740cm^{-1}. NMR (CCl_4) δ=3.33 (m, 2H, H_2 and H_8), 3.80 (s, OCH_3), 3.90 (s. OCH_3), 4.67 (m, 2H, H_3 and H_7), 5.00 (ddd, H_1), 6.36 (dd, H_{11}), 6.70 (dd, H_{10}), and 6.82 (d, H_4 and H_6). Coupling constatnts in Hz, $J_{1,2}$=2.2, $J_{1,10}$=2.0, $J_{1,11}$=4.7, $J_{2,3}$=$J_{7,8}$=4.0, $J_{3,4}$=$J_{6,7}$=10.0, and $J_{10,11}$=8.0.

Reaction of ***2*** *with* ***3***. A mixture of 2 (245mg, 1.5mmol) and **3** (350mg, 2.3mmol) in toluene (10ml) was kept at 110°C for 10d. After evaporation of the solvent on a rotary evaporator, the residue was chromatographed on silica gel to afford orange crystals **12** (48mg, 12%, pet ether-ether 1:2 as an eluent), which were purified by recrystallization from ethanol. However, an analytically pure sample was not obtained because of a tendency to decompose to a resinous material. **12**: MS *m/z* (rel intensity) 274 (M^+, 100), 243 (12), 215 (34), 202 (96), 174 (28), 144 (42), and 116 (26). IR (KBr), 3030, 2960, 1730, and 1710cm^{-1}. NMR (CCl_4) δ=1.34 (t, CH_3, J=7.0Hz), 3.84 (s, OCH_3), 4.22 (q, CH_2), 5.55 (d, H_5), 6.47 (d, H_4), 6.86 (d, H_6), 7.31 (s, H_1), 7.61 (d, H_9), and 7.77 (dd, H_7). Coupling constants in Hz, $J_{4,5}$=9.0, $J_{6,7}$=8.0, $J_{7,9}$=1.8.

Thermal Reaction of ***6***. A solution of **6** (55mg, 0.17mmol) in xylene (2ml) was kept at 140°C for 50min. After evaporation of the solvent on a rotary evaporator, the residue was thin-layer chromatographed on silica gel using pet ether-ether 1:1 as a developing solvent to give **8** (2mg, 4%, R_f=0.7) and the recovered **6** (27mg, 49%, R_f=0.5).

Reaction of ***6*** *with o-Chloranil.* A mixture of **6** (81mg, 0.25mmol) and *o*-chloranil (69mg, 0.28mmol) in anisole (5ml) was kept at 140°C for 45min. The reaction mixture was chromatographed on alumina to yield an oil (150mg) using ether as an eluent. The oil was thin-layer chromatographed on silica gel using pet ether-ether 1:1 as a developing solvent to give **8** (12mg, 17%, R_f=0.7).

Reaction of ***2*** *with* ***13***. A mixture of **2** (1.00g, 6.0mmol) and **13** (3.20g, 12.1mmol) in benzene (3ml) was kept at 100°C for 15h in a sealed ampoule. The reaction mixture was chromatographed on silica gel to give recovered **13** (2.46g, 77%, benzene as an eluent) and colorless crystals **15** (1.03g, 39%, benzene-ether 1:1 as an eluent), which were recrystallized from ether to give pure **15**; mp 77—77.5°C. Found: C, 41.84; H, 3.64; N, 6.38%. Calcd for $C_{15}H_{16}O_4N_2Cl_4$: C, 41.88; H, 3.75; N, 6.51%. MS *m/z* (rel intensity) 430 (M^+, 1) and 165 (100). IR (KBr) 3030, 2970, and 1720cm^{-1}. NMR ($CDCl_3$) δ=1.35 (t, CH_3, J=7.0Hz), 3.48 (m, 2H, H_2 and H_8), 3.53 (s, OCH_3), 3.60 (s, OCH_3), 4.23 (q, CH_2, J=7.0Hz), 4.95 (m, H_7), 6.93 (d, H_3), and 7.15 (d, H_6). Coupling constants, $J_{2,3}$=1.5, $J_{6,7}$=10.0, and $J_{7,8}$=2.5.

The authors are indebted to Professor Sho Ito of Tohoku University for his fruitfull suggestions.

Oxidative Coupling of 1-(2,6-Dichlorobenzoyl)pyrroles and -pyrazoles and Alkyl Acrylates by Palladium(II) Acetate

Toshio ITAHARA,* Kazukuni KAWASAKI, and Fumio OUSETO
Institute of Chemistry, College of Liberal Arts, Kagoshima University, Korimoto, Kagoshima 890
(Received April 21, 1984)

Treatments of 1-(2,6-dichlorobenzoyl)-, 3-acetyl-1-(2,6-dichlorobenzoyl)-, 1-(2,6-dichlorobenzoyl)-2-formyl-, and 1-(phenylsulfonyl)pyrroles with palladium acetate and alkyl acrylates gave the corresponding α-alkenyl-substituted pyrroles in good yields, while the reaction of 1-(2,6-dichlorobenzoyl)-2,5-dimethylpyrrole gave small amounts of β-alkenyl-substituted pyrroles. Under similar conditions, 1-(2,6-dichlorobenzoyl)pyrazole and 1-(2,6-dichlorobenzoyl)-3,5-dimethylpyrazole reacted with palladium acetate and alkyl acrylates to give the corresponding 4-alkenyl-substituted pyrazoles. The reaction of 1-(2,6-dichlorobenzoyl)-4-methylpyrazole gave 5-alkenyl-substituted pyrazole.

Palladium(II) salts-assisted alkenylation of arenes is a useful method for the direct synthesis of aromatic-substitued olefins.[1] Fujiwara *et al.* reported the alkenylation of heteroarenes with palladium acetate and olefins.[2,3] We reported that 2,6-dichlorobenzoyl group was an effective protecting substituent for the alkenylation of 1-acylindoles[4] and the arylation of 1-acylpyrroles with arenes.[5] Pyrrolyl-, pyrazolyl-, and imidazolyl-acrylic acids and their esters are important precursors for the synthesis of physiologically active compounds. These observations led us to examine reactions of 1-(2,6-dichlorobenzoyl)pyrroles, -pyrazoles, and -imidazoles with palladium acetate and alkyl acrylates. The treatment of 1-(2,6-dichlorobenzoyl)pyrroles with palladium acetate and alkyl acrylates gave alkyl 3-(2-pyrrolyl)acrylates in high yields. The reaction of 1-(phenylsulfonyl)pyrrole (**10**) also gave alkenyl-substituted pyrroles. Furthermore, 1-(2,6-dichlorobenzoyl)pyrazoles reacted with palladium acetate and alkyl acrylates to give alkyl 3-(4-pyrazolyl)acrylates, while an attempted oxidative coupling of 1-(2,6-dichlorobenzoyl)imidazoles and methyl acrylate failed under our experimental conditions.

Results and Discussion

Although it was reported that the treatment of 1-methylpyrrole with styrene in the presence of palladium acetate gave small amounts of 2- and 3-styryl-1-methylpyrroles,[2] the reaction of 1-methyl- and 1-benzoylpyrroles with palladium acetate and methyl acrylate in acetic acid at reflux temperature gave complex

a) The reaction was performed by heating an acetic acid solution (40 ml) of substrate (1 mmol), $Pd(OAc)_2$ (1 mmol), and alkyl acrylate (3 mmol) in air at reflux temperature. b) Yield based on the substrate consumed.

reaction mixtures. On the other hand, the treatment of 1-(2,6-dichlorobenzoyl)pyrrole (**1**) with methyl acrylate gave the expected coupling products (**2a**) and (**3a**) in almost quantitative yields based on palladium acetate used. Furthermore, the reaction of **2a** with methyl acrylate and palladium acetate gave **3a**, suggesting that **2a** is the intermediate in the formation of **3a** from **1**. The treatment of **1** with ethyl acrylate also gave the coupling products (**2b**) and (**3b**).

Substituent effects on the oxidative coupling of the pyrroles and alkyl acrylates were further investigated. The treatment of 3-acetyl-1-(2,6-dichlorobenzoyl)-2,4-dimethylpyrrole (**4**) with methyl acrylate and ethyl acrylate gave (**5a**) and (**5b**), respectively. Under similar conditions, 1-(2,6-dichlorobenzoyl)-2-formylpyrrole (**6**) gave (**7a**) and (**7b**), when treated with methyl acrylate and ethyl acrylate, respectively. The fact that the formyl group was transferred intact through the oxidation with palladium acetate was already reported in the case of dimerization[6)] and alkenylation with methyl acrylate[7)] of furfural and of 2-formylthiophenes. When the substrate was 2,5-disubstituted pyrrole such as 1-(2,6-dichlorobenzoyl)-2,5-dimethylpyrrole (**8**) β-alkenyl substituted products were obtained; the treatment of **8** with methyl acrylate and ethyl acrylate in the presence of palladium acetate gave (**9a**) and (**9b**), respectively, although the yields of **9a** and **9b** were not good.

Recently we reported the oxidative coupling of 1-(phenylsulfonyl)indole and olefins bearing electron-withdrawing groups by palladium acetate.[8)] Since the acylation of 1-(phenylsulfonyl)pyrrole (**10**) with acyl halides and Lewis acids has been reported,[9)] we carried out experiments on the oxidative coupling of **10** and ethyl acrylate. The reaction gave the expected coupling products (**11b**) and (**12b**).

In an effort to elucidate the scope of the oxidative coupling of aromatic heterocyles containing nitrogen atom and alkyl acrylates, the reactions of 1-(2,6-dichlorobenzoyl)pyrazoles and -imidazoles were investigated. The treatment of 1-(2,6-dichlorobenzoyl)pyrazole (**13**) with methyl acrylate and ethyl acrylate in the presence of palladium acetate gave 4-alkenyl-substituted pyrazoles (**14a**) and (**14b**), respectively. Similarly 1-(2,6-dichlorobenzoyl)-3,5-dimethylpyrazole (**15**) reacted with methyl acrylate and ethyl acrylate giving (**16a**) and (**16b**), respectively. On the other hand, the treatment of 1-(2,6-dichlorobenzoyl)-4-methylpyrazole (**17**) with methyl acrylate and palladium acetate gave a 5-alkenyl-substituted pyrazole (**18a**). These results are summarized in Table 1. However, no reaction occurred when the substrate was 1-(2,6-dichlorobenzoyl)-1*H*-indazole (**19**). The attempted oxidative coupling of the imidazoles such as 1-(2,6-dichlorobenzoyl)imidazole (**20**), 1-(2,6-dichlorobenzoyl)-2-methylimidazole (**21**), and 1-(2,6-dichlorobenzoyl)-2-phenyl-imidazole (**22**) and methyl acrylate failed either under our reaction conditions.

The structures of **1**—**22** except for the known compound (**10**)[10)] were determined on the basis of elemental analyses and spectral data. Furthermore, proton NMR spectra showed that all the coupling products have the E stereochemistry.

Table 1 shows an interesting fact that the presence of two methyl groups at the 3- and 5-positions of **15** decreased the conversions and yields of the alkenylation at the 4-position of the pyrazole, although methyl group is an electron-donating substituent. This fact may be interepreted in terms of steric effects. In order to elucidate the steric effects on the alkenylation with methyl acrylate, carboxylation reactions with carbon monoxide of methylbenzenes were also undertaken.

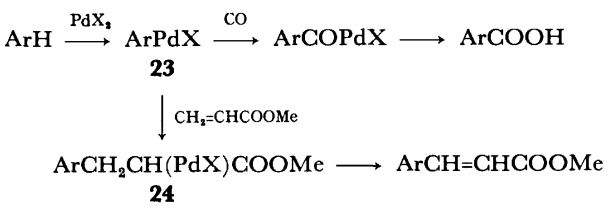
The treatment of *p*-xylene (**25**) under carbon mon-

oxide gave 2,5-dimethylbenzoic acid (**26**) and with methyl acrylate gave methyl 2,5-dimethylcinnamate (**27**). Hydrolysis of **27** gave 2,5-dimethylcinnamic acid (**28**), providing an evidence for the structure of **27**. Mesityrene (**29**) and pentamethylbenzene (**31**) also reacted with carbon monoxide to give 2,4,6-trimethylbenzoic acid (**30**) and pentamethylbenzoic acid (**32**), respectively. However, the reactions of **29** and **31** with methyl acrylate gave complex reaction mixtures under our reaction conditions, and no alkenyl-substituted benzenes such as methyl 2,4,6-trimethylcinnamate and methyl pentamethylcinnamate were obtained, although the oxidative coupling of **29** with styrene had been reported to proceed.[11]

The previous studies concerning the oxidative coupling of arenes and olefins[1] and the carboxylation of arenes with carbon monoxide[12,13] showed that the both reactions proceeded *via* the same intermediate, arylpalladium complex (**23**), as shown in Scheme 1. Therefore, the above results suggest that the formation of the intermediate **24** from **23** is affected by the steric effects of the two methyl groups at 2- and 6-positions of the benzene nucleus or at 3- and 5-positions of **15**, since Watanabe *et al.*[11] have reported that there is a steric hindrance in the transition state involving the palladium–carbon σ-bond on the coupling of styrene and alkylbenzene such as toluene, **25**, and **29**.

Palladium acetate-catalyzed reactions of **1** and **13** with methyl acrylate were carried out using AgOAc,[1] $Cu(OAc)_2$,[1] $Na_2S_2O_8$,[13] and $NaNO_2$[14] as re-oxidants. These results are summarized in Table 2.

It is known that the treatment of 1-substituted pyrazoles and 1-substituted pyrroles with butyllithium gives 1-substituted 5-lithiopyrazoles[15] and 1-substituted α-lithiopyrroles,[16] respectively. On the other hand, it was found that palladium acetate preferentially attacked the 4-position of the pyrazole nucleus, although the palladation of pyrroles occured at α-position of the pyrrole nucleus. The difference between lithiation and palladation of 1-substituted pyrazoles is of interest from the view point of synthetic chemistry utilizing metals.



Scheme 1

Experimental

General. All the melting points are uncorrected. The elemental analyses were performed by the Analytical Center of Kyoto University. The infrared spectra were recorded with a JASCO IRA-1 spectrometer. The proton magnetic resonance spectra were recorded with a JEOL PMX60A spectrometer, using Me_4Si as the internal reference.

*Preparation of the Starting 1-(2,6-Dichlorobenzoyl)-Substituted Aromatic Heterocycles (**1**), (**4**), (**6**), (**8**), (**13**), (**15**), (**17**), (**19**), (**20**), (**21**), and (**22**).* To a stirred solution of 1*H*-aromatic heterocycle and sodium hydride in *N*,*N*-dimethylformamide (DMF), 2,6-dichlorobenzoyl chloride was added dropwise under nitrogen at 0 °C. Then the mixture was stirred at room temperature for 16 h and poured into an excess of ice-cooled water to give 1-(2,6-dichlorobenzoyl)-substituted aromatic heterocycle as a crystalline product, which was collected by suction and recrystallized from ether–hexane. These results are summarized in Table 3. The spectral and analytical data are given below.

*1-(2,6-Dichlorobenzoyl)pyrrole (**1**)*: Mp 121.5—122.5 °C; IR (Nujol) 1710 cm^{-1}; NMR ($CDCl_3$) δ=6.29 (t, 2H, J=3 Hz), 6.8—7.4 (broad, 2H), 7.33 (s, 3H). Found: C, 55.06; H, 2.91; N, 5.83%. Calcd for $C_{11}H_7NOCl_2$: C, 55.03; H, 2.94; N, 5.83%.

*3-Acetyl-1-(2,6-dichlorobenzoyl)-2,4-dimethylpyrrole (**4**)*: Mp 127.5—128.5 °C; IR (Nujol) 1720, 1675 cm^{-1}; NMR ($CDCl_3$) δ=2.11 (s, 3H), 2.44 (s, 3H), 2.80 (s, broad, 3H), 6.20 (s, broad, 1H), 7.30 (s, 3H); Mass: *m/z* (rel. intensity) 311 (12), 309 (19), 175 (61), 173 (100). Found: C, 57.94; H, 4.26; N, 4.43%. Calcd for $C_{15}H_{13}NO_2Cl_2$: C, 58.08; H, 4.22; N, 4.52%.

*1-(2,6-Dichlorobenzoyl)-2-formylpyrrole (**6**)*: Mp 125—126 °C; IR (Nujol) 1720, 1660 cm^{-1}; NMR ($CDCl_3$) δ=6.23 (t, 1H, J=3.5 Hz), 6.63—6.78 (m, 1H), 7.13—7.30 (m, 1H), 7.31 (s, 3H), 10.30 (s, 1H). Found: C, 53.56; H, 2.69; N, 5.21%. Calcd for $C_{12}H_7NO_2Cl_2$: C, 53.76; H, 2.63; N, 5.22%.

*1-(2,6-Dichlorobenzoyl)-2,5-dimethylpyrrole (**8**)*: Mp 102.5—104.0 °C; IR (Nujol) 1690 cm^{-1}; NMR ($CDCl_3$) δ=2.10 (s, broad, 6H), 6.83 (s, 2H), 7.30 (s, 3H); Mass: *m/z* (rel. intensity) 269 (16), 267 (25), 175 (64), 173 (100). Found: C, 58.19; H, 3.99; N,

Table 2. Palladium acetate-catalyzed alkenylation of **1** and of **13** with methyl acrylate and re-oxidants[a]

Substrate	Re-oxidant (mmol)	Products Yield/%[b]; Yield/%[c] (Conversion/%)
1	AgOAc (2)	**2a**: 534; 68(78), **3a**: 446; 29(78)
1	$Cu(OAc)_2$ (1)	**2a**: 444; 54(83), **3a**: 480; 29(83)
1	$Na_2S_2O_8$ (1)	**2a**: 586; 64(91), **3a**: 470; 26(91)
1	$NaNO_2$ (2)	**2a**: 386; 42(92), **3a**: 353; 19(92)
13	AgOAc (2)	**14a**: 93; 78(12)
13	$Cu(OAc)_2$ (1)	**14a**: 91; 88(11)
13	$Na_2S_2O_8$ (1)	**14a**: 98; 65(15)
13	$NaNO_2$ (1)	**14a**: 89; 71(13)

a) Reaction conditions used in all experiments: substrate (1 mmol), $Pd(OAc)_2$ (0.1 mmol), methyl acrylate (3 mmol), re-oxidant, acetic acid (40 ml), at reflux temperature in air, 16 h reaction. b) Yield based on $Pd(OAc)_2$ used. c) Yield based on the substrate consumed.

TABLE 3. SYNTHESIS OF 1-(2,6-DICHLOROBENZOYL)-SUBSTITUTED AROMATIC HETEROCYCLES FROM 1*H*-AROMATIC HETEROCYCLES

1*H*-Aromatic heterocycles (mmol)	NaH (mmol)	2,6-$Cl_2C_6H_3COCl$ (mmol)	DMF (ml)	Products (mmol; Yield/%[a])
Pyrrole (48)	48	48	200	**1** (37 mmol; 76%)
3-Acetyl-2,4-dimethylpyrrole (29)	29	29	150	**4** (23 mmol; 78%)
2-Formylpyrrole (52)	52	48	200	**6** (37 mmol; 71%)
2,5-Dimethylpyrrole (53)	53	48	200	**8** (10 mmol; 19%)
Pyrazole (59)	59	48	200	**13** (47 mmol; 79%)
3,5-Dimethylpyrazole (37)	37	37	150	**15** (29 mmol; 78%)
4-Methylpyrazole (18.3)	18.3	18.3	100	**17** (15 mmol; 81%)
Indazole (16.9)	16.9	14.6	100	**19** (15 mmol; 89%)
Imidazole (50)	50	48	200	**20** (28 mmol; 56%)
2-Methylimidazole (59.8)	58.8	47.8	200	**21** (36 mmol; 61%)
2-Phenylimidazole (31)	31	30.1	150	**22** (19 mmol; 62%)

a. Yields based on the 1H-aromatic heterocycles used.

5.05%. Calcd for $C_{13}H_{11}NOCl_2$: C, 58.23; H, 4.14; N, 5.22%.

*1-(2,6-Dichlorobenzoyl)pyrazole (**13**)*: Mp 118.5—119.5 °C; IR (Nujol) 1730 cm^{-1}; NMR ($CDCl_3$) δ=6.46 (d.d, 1H, J= 1 Hz, J=3 Hz), 7.29 (s, 3H), 7.66 (d, 1H, J=1 Hz), 8.30 (d, 1H, J=3 Hz), Found: C, 50.09; H, 2.41; N, 11.74%. Calcd for $C_{10}H_6N_2OCl_2$: C, 49.82; H, 2.51; N, 11.62%.

*1-(2,6-Dichlorobenzoyl)-3,5-dimethylpyrazole (**15**)*: Mp 169.5—170.0 °C; IR (Nujol) 1710—1700 (broad) cm^{-1}; NMR ($CDCl_3$) 2.14 (s, 3H), 2.68 (s, broad, 3H), 6.05 (s, broad, 1H), 7.33 (s, 3H). Found: C, 53.49; H, 3.65; N, 10.37%. Calcd for $C_{12}H_{10}N_2OCl_2$: C, 53.55; H, 3.75; N, 10.41%.

*1-(2,6-Dichlorobenzoyl)-4-methylpyrazole (**17**)*: Mp 165—166 °C; IR (Nujol) 1715—1700 (broad) cm^{-1}; NMR ($CDCl_3$) δ= 2.14 (d, 3H, J=1 Hz), 7.35 (s, 3H), 7.52 (s, 1H), 8.09 (q, 1H, J= 1 Hz). Found: C, 51.97; H, 3.09; N, 11.27%. Calcd for $C_{11}H_8N_2OCl_2$: C, 51.79; H, 3.16; N, 10.98%.

*1-(2,6-Dichlorobenzoyl)indazole (**19**)*: Mp 151.5—152.5 °C; IR (Nujol) 1690 cm^{-1}; NMR($CDCl_3$) δ=7.32 (s, 3H), 7.2—7.8 (m, 3H), 8.07 (s, 1H), 8.55 (broad, d, 1H, J=8 Hz). Found: C, 57.81; H, 2.67; N, 9.61%. Calcd for $C_{14}H_8N_2OCl_2$: C, 57.76; H, 2.77; N, 9.62%.

*1-(2,6-Dichlorobenzoyl)imidazole (**20**)*: Mp 60.5—61.5 °C; IR (KBr) 1730 cm^{-1}; NMR ($CDCl_3$) δ=7.06—7.20 (broad, 1H), 7.3—7.5 (broad, 4H), 7.76—7.9 (broad, 1H). Found: C, 49.73; H, 2.43; N, 11.65%. Calcd for $C_{10}H_6N_2OCl_2$: C, 49.82; H, 2.51; N, 11.62%.

*1-(2,6-Dichlorobenzoyl)-2-methylimidazole (**21**)*: Mp 120.5—121.0 °C; IR (Nujol) 1730 cm^{-1}; NMR ($CDCl_3$) δ=2.68 (s, 3H), 6.64—6.90 (m, 2H), 7.32(s, 3H). Found: C, 51.51; H, 3.32; N, 10.99%. Calcd for $C_{11}H_8N_2OCl_2$: C, 51.79; H, 3.16; N, 10.98%.

*1-(2,6-Dichlorobenzoyl)-2-phenylimidazole (**22**)*: Mp 102.5—104.0 °C; IR (Nujol) 1710 cm^{-1}; NMR ($CDCl_3$) δ=7.10—7.63 (m, 10H). Found: C, 60.39; H, 3.10; N, 8.73%. Calcd for $C_{16}H_{10}N_2OCl_2$: C, 60.59; H, 3.18; N, 8.83%.

*1-(Phenylsulfonyl)pyrrole (**10**).* To a stirred solution of pyrrole (149 mmol) and sodium hydride (149 mmol) in *N,N*-dimethylformamide (200 ml), benzenesulfonyl chloride (149 mmol) was added dropwise under nitrogen at 0 °C. Then the mixture was stirred at room temperature for 3 h and poured into an excess of ice-cooled water to give **10** (80.5 mmol; 54% yield based on pyrrole used): Mp 88—89 °C (lit,[8] 89.0—89.5 °C).

*General Procedure for the Stoichiometric Alkenylation of Pyrroles (**1**), (**2a**), (**4**), (**6**), (**8**), and (**10**), and Pyrazoles (**13**), (**15**), and (**17**) with palladium Acetate and Alkyl Acrylates.* A solution of the pyrroles or the pyrazoles (1 mmol), alkyl acrylates (3 mmol), and palladium acetate (1 mmol) in acetic acid (40 ml) was heated at reflux temperature in air. The reaction mixture was evaporated to give a brown residue which was then chromatographed on a silica-gel plate, developed by benzene or chloroform, to give alkyl 3-(2-pyrrolyl)- or 3-(4-pyrazolyl)acrylates. The results are summarized in Table 1. The spectral and analytical data are given below.

*Methyl (E)-3-[1-(2,6-Dichlorobenzoyl)-2-pyrrolyl]acrylate (**2a**)*: Mp 110.5—111.5 °C; IR (Nujol) 1720, 1700, 1630 cm^{-1}; NMR ($CDCl_3$) δ=3.79 (s, 3H), 6.23 (t, 1H, J=3.5 Hz), 6.27 (d, 1H, J=16 Hz), 6.5—6.9 (m, 2H), 7.35 (s, 3H), 8.45 (d, broad, 1H, J=16 Hz); Mass: *m/z* (rel. intensity) 325 (13), 323 (19), 175 (65), 173 (100). Found: C, 55.62; H, 3.46; N, 4.56%. Calcd for $C_{15}H_{11}NO_3Cl_2$: C, 55.58; H, 3.42; N, 4.32%.

*(E)-Ethyl 3-[1-(2,6-Dichlorobenzoyl)pyrrol-2-yl]acrylate (**2b**)*: Mp 133—134 °C; IR (Nujol) 1710, 1705, 1620 cm^{-1}; NMR ($CDCl_3$) δ=1.31 (t, 3H, J=7 Hz), 4.22 (q, 2H, J=7 Hz), 6.23 (t, 1H, J=3.5 Hz), 6.26 (d, 1H, J=16 Hz), 6.5—6.9 (m, 2H), 7.34 (s, 3H), 8.4 (d, broad, 1H, J=16 Hz); Mass: *m/z* (rel. intensity) 339 (7), 337 (11), 175 (65), 173 (100). Found: C, 56.74; H, 3.93; N, 4.19%. Calcd for $C_{16}H_{13}NO_3Cl_2$: C, 56.82; H, 3.87; N, 4.14%.

*Dimethyl (E,E)-3,3'-[1-(2,6-Dichlorobenzoyl)pyrrole-2,5-diyl]diacrylate (**3a**)*: Mp 166—168 °C; IR (Nujol) 1710 (broad), 1615 cm^{-1}; NMR ($CDCl_3$) δ=3.67 (s, 6H), 6.08 (d, 2H, J= 16 Hz), 6.63 (s, 2H), 7.30 (s, 3H), 7.50 (d, 2H, J=16 Hz). Mass: *m/z* (rel. intensity) 409 (8), 407 (12), 175 (65), 173 (100). Found: C, 56.15; H, 3.65; N, 3.42%. Calcd for $C_{19}H_{15}NO_5Cl_2$: C, 55.90; H, 3.70; N, 3.43%.

*Diethyl (E,E)-3,3'-[1-(2,6-Dichlorobenzoyl)pyrrole-2,5-diyl]diacrylate (**3b**)*: Mp 153—154 °C; IR (Nujol) 1710 (broad), 1615 cm^{-1}; NMR ($CDCl_3$) δ=1.28 (t, 6H, J=7 Hz), 4.14 (q, 4H, J=7 Hz), 6.13 (d, 2H, J=16 Hz), 6.68 (s, 2H), 7.37 (s, 3H), 7.53 (d, 2H, J=16 Hz); Mass: 437 (5), 435 (7), 175 (63), 173 (100). Found: C, 58.07; H, 4.47; N, 3.41%. Calcd for $C_{21}H_{19}NO_5Cl_2$: C, 57.81; H, 4.39; N, 3.21%.

*Methyl (E)-3-[4-Acetyl-1-(2,6-dichlorobenzoyl)-3,5-dimethyl-2-pyrrolyl]acrylate (**5a**)*: Mp 121—123 °C; IR (Nujol) 1720, 1660 1625 cm^{-1}; NMR ($CDCl_3$) δ=2.21 (s, 3H), 2.48 (s, 3H), 2.53 (s, 3H), 3.65 (s, 3H), 5.68 (d, 1H, J=16 Hz), 7.18 (d, 1H, J= 16 Hz), 7.30 (s, 3H); Mass: *m/z* (rel. intensity) 395 (9), 393 (14), 175 (63), 173 (100). Found: C, 57.59; H, 4.63; 3.70%. Calcd for $C_{19}H_{17}NO_4Cl_2$: C, 57.88; H, 4.35; N, 3.55%.

*Ethyl (E)-3-[4-Acetyl-1-(2,6-dichlorobenzoyl)-3,5-dimethyl-2-pyrrolyl]acrylate (**5b**)*: Mp 114—116 °C; IR (Nujol) 1710 (broad),

1660, 1625 cm^{-1}; NMR ($CDCl_3$) δ=1.26 (t, 3H, J=7 Hz), 2.22 (s, 3H), 2.50 (s, 3H), 2.56 (s, 3H), 4.12 (q, 2H, J=7 Hz), 5.68 (d, 1H, J=16 Hz), 7.16 (d, 1H, J=16 Hz), 7.33 (s, 3H); Mass: m/z (rel. intensity) 409 (8), 407 (13), 175 (63), 173 (100). Found: C, 58.65; H, 4.71; N, 3.20%. Calcd for $C_{20}H_{19}NO_4Cl_2$: C, 58.84; H, 4.69; N, 3.43%.

*Methyl (E)-3-[1-(2,6-Dichlorobenzoyl)-5-formyl-2-pyrrolyl]acrylate (**7a**)*: Mp 182.0—183.5 °C; IR (Nujol) 1720, 1705, 1675, 1630 cm^{-1}; NMR ($CDCl_3$) δ=3.70 (s, 3H), 6.19 (d, 1H, J=16 Hz), 6.65 (d, 1H, J=3.5 Hz), 7.10—7.55 (m, 2H), 7.33 (s, 3H), 9.72 (s, 1H); Mass: m/z (rel. intensity) 353 (4), 351 (6), 175 (62), 173 (100). Found: C, 54.67; H, 3.06; N, 4.12%. Calcd for $C_{16}H_{11}NO_4Cl_2$: C, 54.41; H, 3.14; N, 3.97%.

*Ethyl (E)-3-[1-(2,6-Dichlorobenzoyl)-5-formyl-2-pyrrolyl]acrylate (**7b**)*: Mp 145—147 °C; IR (Nujol) 1710 (broad), 1675, 1630 cm^{-1}; NMR ($CDCl_3$) δ=1.26 (t, 3H, J=7 Hz), 4.13 (q, 2H, J=7 Hz), 6.20 (d, 1H, J=16 Hz), 6.63 (d, 1H, J=3.5 Hz), 7.06—7.53 (m, 2H), 7.33 (s, 3H), 9.73(s, 1H); Mass: m/z (rel. intensity) 367 (4), 365 (6), 175 (64), 173 (100). Found: C, 55.56; H, 3.50; N, 3.89%. Calcd for $C_{17}H_{13}NO_4Cl_2$: C, 55.61; H, 3.57; N, 3.81%.

*Methyl (E)-3-[1-(2,6-Dichlorobenzoyl)-2,5-dimethyl-3-pyrrolyl]acrylate (**9a**)*: Mp 117—118 °C; IR (Nujol) 1725, 1700, 1635 cm^{-1}; NMR ($CDCl_3$) δ=2.07 (s, broad, 3H), 2.26 (s, broad, 3H), 3.76 (s, 3H), 6.05 (d, 1H, J=16 Hz), 6.14 (s, 1H), 7.33 (s, 3H), 7.60 (d, 1H, J=16 Hz); Mass: m/z (rel. intensity) 353 (11), 351 (17), 175 (65), 173 (100). Found: C, 58.14; H, 4.43; N, 3.96%. Calcd for $C_{17}H_{15}NO_3Cl_2$: C, 57.92; H, 4.29; N, 3.98%.

*Ethyl (E)-3-[1-(2,6-Dichlorobenzoyl)-2,5-dimethyl-3-pyrrolyl]acrylate (**9b**)*: Mp 126.5—127.5 °C; IR (Nujol) 1715, 1635 cm^{-1}; NMR ($CDCl_3$) δ=1.30 (t, 3H, J=7 Hz), 2.07 (s, broad, 3H), 2.25 (s, broad, 3H), 4.23 (q, 2H, J=7 Hz), 6.05 (d, 1H, J=16 Hz), 6.14 (s, 1H), 7.35 (s, 3H), 7.58 (d, 1H, J=16 Hz); Mass: m/z (rel. intensity) 367 (12), 365 (17), 175 (65), 173 (100). Found: C, 58.77; H, 4.73; N, 3.76%. Calcd for $C_{18}H_{17}NO_3Cl_2$: C, 59.03; H, 4.68; N, 3.82%.

*Ethyl (E)-3-[1-(Phenylsulfonyl)-2-pyrrolyl]acrylate (**11b**)*: Mp 78—79 °C; IR (Nujol) 1705, 1625, 1370, 1185 (broad) cm^{-1}; NMR ($CDCl_3$) δ=1.32 (t, 3H, J=7 Hz), 4.24 (q, 2H, J=7 Hz), 6.12 (d, 1H, J=16 Hz), 6.35 (t, 1H, J=3.5 Hz), 6.4—6.8 (m, 1H), 7.2—7.9 (m, 6H), 8.07 (d, 1H, J=16 Hz); Mass: m/z (rel. intensity) 305 (33), 141 (25), 136 (26), 119 (47), 77 (100). Found: C, 58.90; H, 4.83; N, 4.59%. Calcd for $C_{15}H_{15}NO_4S$: C, 59.00; H, 4.95; N, 4.89%.

*Diethyl (E,E)-3,3'-[1-(Phenylsulfonyl)pyrrole-2,5-diyl]diacrylate (**12b**)*: Mp 85—86 °C; IR (Nujol) 1705, 1620, 1380, 1370, 1175 (broad) cm^{-1}; NMR ($CDCl_3$) δ=1.32 (t, 6H, J=7 Hz), 4.25 (q, 4H, J=7 Hz), 6.16 (d, 2H, J=16 Hz), 6.64 (s, 2H), 7.2—8.0 (m, 5H), 8.24 (d, 2H, J=16 Hz); Mass: m/z (rel. intensity) 404 (25), 403 (100), 262 (63). Found: C, 59.54; H, 5.25; N, 3.56%. Calcd for $C_{20}H_{21}NO_6S$: C, 59.57; H, 5.25; N, 3.47%.

*Methyl (E)-3-[1-(2,6-Dichlorobenzoyl)-4-pyrazolyl]acrylate (**14a**)*: Mp 164—166 °C; IR (Nujol) 1730, 1700, 1660 cm^{-1}; NMR ($CDCl_3$) δ=3.75 (s, 3H), 6.27 (d, 1H, J=16 Hz), 7.32 (s, 3H), 7.52 (d, 1H, J=16 Hz), 7.82 (s, 1H), 8.42 (s, 1H); Mass: m/z (rel. intensity) 326 (6), 324 (8), 291 (10), 289 (28), 175 (66), 173 (100). Found: C, 51.85; H, 2.91; N, 8.56%. Calcd for $C_{14}H_{10}N_2O_3Cl_2$: C, 51.72; H, 3.10; N, 8.62%.

*Ethyl (E)-3-[1-(2,6-Dichlorobenzoyl)-4-pyrazolyl]acrylate (**14b**)*: Mp 133—134 °C; IR (KBr) 1725, 1695, 1660, 1620 cm^{-1}; NMR ($CDCl_3$) δ=1.33 (t, 3H, J=7 Hz), 4.27 (q, 2H, J=7 Hz), 6.32 (d, 1H, J=16 Hz), 7.38 (s, 3H), 7.58 (d, 1H, J=16 Hz), 7.89 (s, 1H), 8.49 (s, 1H); Mass: m/z (rel. intensity) 340 (6), 338 (9), 305 (11), 303 (32), 175 (63), 173 (100). Found: C, 53.32; H, 3.49; N, 8.14%. Calcd for $C_{15}H_{12}N_2O_3Cl_2$: C, 53.12; H, 3.57; N, 8.26%.

*Methyl (E)-3-[1-(2,6-Dichlorobenzoyl)-3,5-dimethyl-4-pyrazolyl]acrylate (**16a**)*: Mp 176—178 °C; IR (KBr) 1725, 1705, 1660, 1620 cm^{-1}; NMR ($CDCl_3$) δ=2.28 (s, 3H), 2.80 (s, 3H), 3.79 (s, 3H), 6.20 (d, 1H, J=16 Hz), 7.32 (s, 3H), 7.62 (d, 1H, J=16 Hz); Mass: m/z (rel. intensity) 354 (7), 352 (10), 319 (17), 317 (49), 175 (65), 173 (100). Found: C, 54.33; H, 3.89; N, 7.80%. Calcd for $C_{16}H_{14}N_2O_3Cl_2$: C, 54.40; H, 4.00; N, 7.93%.

*Ethyl (E)-3-[1-(2,6-Dichlorobenzoyl)-3,5-dimethyl-4-pyrazolyl]acrylate (**16b**)*: Mp 161—163 °C; IR (KBr) 1725, 1710, 1660, 1620 cm^{-1}; NMR ($CDCl_3$) δ=1.32 (t, 3H, J=7 Hz), 2.27 (s, 3H), 2.81 (s, 3H), 4.27 (q, 2H, J=7 Hz), 6.21 (d, 1H, J=16 Hz), 7.33 (s, 3H), 7.62 (d, 1H, J=16 Hz); Mass: m/z (rel. intensity) 368 (10), 366 (14), 333 (25), 331 (69), 175 (65), 173 (100). Found: C, 55.77; H, 4.37; N, 7.52%. Calcd for $C_{17}H_{16}N_2O_3Cl_2$: C, 55.60; H, 4.39; N, 7.63%.

*Methyl (E)-3-[2-(2,6-Dichlorobenzoyl)-4-methyl-2H-pyrazol-3-yl]acrylate (**18a**)*: Mp 161—162 °C; IR (Nujol) 1730—1710 (broad), 1660 cm^{-1}; NMR($CDCl_3$) δ=2.24 (s,3H), 3.83 (s, 3H), 6.30 (d, 1H, J=16 Hz), 7.33 (s, 3H), 7.52 (s, 1H), 8.40 (d, 1H, J=16 Hz); Mass: m/z (rel. intensity) 340 (10), 338 (14), 305 (9), 303(25), 175 (64), 173 (100); High-resolution Mass: m/z 338.0206 (M^+). Found: C, 52.62; H, 3.46; N, 8.21%. Calcd for $C_{15}H_{12}N_2O_3Cl_2$: C, 53.12; H, 3.57; N, 8.26%.

*Palladium Acetate-catalyzed Alkenylation of **1** and of **13** with Methyl Acrylate.* A solution of **1** or **13** (1 mmol), methyl acrylate (3 mmol), re-oxidants (listed in Table 2), and palladium acetate (0.1 mmol) in acetic acid (40 ml) was heated at reflux temperature in air for 16 h. The reaction mixture was evaporated to give a brown residue which was chromatographed on a silica-gel plate, developed by benzene or chloroform, to give alkenyl-substituted pyrroles (**2a**) and (**3a**) and pyrazole (**14a**). The results are summarized in Table 2.

Carboxylation of Methylbenzenes with Carbon Monoxide and Palladium Acetate. Carbon monoxide was bubbled through the stirred solution of methylbenzenes (10 mmol) in acetic acid (40 ml) containing palladium acetate (1 mmol) at reflux temperature for 7 h. The reaction mixture was evaporated and chromatorgaphed on a silica-gel column with benzene/ether to give methylbenzoic acids: 2,5-dimethylbenzoic acid (**26**) (0.16 mmol, 16% yield based on palladium acetate used); 2,4,6-trimethylbenzoic acid (**30**) (0.43 mmol, 43% yield); pentamethylbenzoic acid (**32**) (0.21 mmol, 21% yield): Mp 207—210 °C (lit,[17] 211 °C); IR (Nujol) 3300—2300, 1700 cm^{-1}; NMR ($CDCl_3$) δ=2.19 (s, broad, 9H), 2.27 (s, broad, 6H), 10.0 (s, broad, 1H). The structures of **26** and **30** were confirmed by comparing the IR spectra with those of the commercially available samples.

*Methyl (E)-2,5-Dimethylcinnamate (**27**).* A solution of *p*-xylene (**25**) (10 mmol), methyl acrylate (3 mmol), and palladium acetate (1 mmol) in acetic acid (40 ml) was stirred at reflux temperature in air for 7 h. The mixture was evaporated to give a brown residue which was chromatographed on a silica-gel plate, developed by a mixture of hexane and ether (1:1) to give **27** (0.50 mmol, 50% yield based on palladium acetate used): Bp 100 °C/10 Torr. (1 Torr=133.322 Pa); IR (Nujol) 1745, 1725, 1640 cm^{-1}; NMR($CDCl_3$) δ=2.32 (s, 3H), 2.36 (s, 3H), 3.78 (s, 3H), 6.29 (d, 1H, J=16 Hz), 7.00—7.35 (m, 3H), 3H), 7.91 (d, 1H, J=16 Hz). Found: C, 75.53; H, 7.63%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

(E)-2,5-Dimethylcinnamic Acid (28). A solution of **27** (1.85 mmol) and sodium hydroxide (52.5 mmol) in a mixture of methanol (50 ml) and water (50 ml) was heated at reflux temperature in air for 7 h. The mixture was poured into an excess of ice-cooled water and neutralized with dilute hydrochloric acid to give **28** as a crystalline product (1.70 mmol, 92% yield): Mp 130—132°C; IR (Nujol) 1690, 1620, 1610 cm^{-1}; NMR ($CDCl_3$) δ=2.32 (s, 3H), 2.39 (s, 3H), 6.32 (d, 1H, J=16 Hz), 7.06 (s, broad, 2H), 7.35 (s, broad, 1H), 8.03 (d, 1H, J=16 Hz), 10.14 (s, broad, 1H). Found: C, 74.97; H, 6.86%. Calcd for $C_{11}H_{12}O_2$: C, 74.72; H, 6.87%.

The authors wish to thank Professors Tsunao Hase and Tsutomu Sakakibara of Kagoshima University for their support throughout the study, and Dr. Tetsuo Iwagawa for his mass-spectrometric analyses.

Syntheses and Physical Properties of Several Polyphenylenes Containing Mixed Linkages[1)]

Yasuhiro FUJIOKA
Kyoto Pharmaceutical University, Misasagi-nakauchi-cho, Yamashina-ku, Kyoto 607
(Received May 12, 1984)

Fourteen macrocyclic polyphenylenes, including the following ten new compounds, were synthesized by intra- or intermolecular homo-coupling of di-Grignard compound and by cross-coupling of two kinds of di-Grignard compounds with copper(II) chloride: *m,m,o,p,o*-pentaphenylene; *o,o,p,o,o,p*-, *m,o,p,m,o,p*-, *o,p,o,p,o,p*-, *m,o,p,o,p,o*-, *m,o,m,o,m,o*-, and *m,m,m,o,m,o*-hexaphenylene; *m,o,p,p,o,m,p*-, and *m,m,m,m,p,o,p*-heptaphenylene; and *m,o,o,m,o,o,m,o,o,m,o,o*-dodecaphenylene. ^{1}H NMR spectra of the polyphenylenes, compared with those of open-chain analogues, provide valuable information on the nonplanar spacial relationship of constituting phenylene rings. UV spectra of the compounds containing *p*-phenylene ring(s) suggest that the lack or decrease in intensity of K-band above *ca.* 260 nm or a marked shift of that band provides useful conformational information. Empirical Hückel molecular orbital calculations of longest-wavelength absorption bands of twelve polyphenylenes were also carried out. The calculations furnish additional bases for their conformational aspects deduced from their spectral data and Dreiding stereomodels. IR spectra indicate that lack of intense band(s) near 700 cm^{-1} may generally be regarded as a piece of plausible evidence for the macrocyclic structure containing no *m*-phenylene ring. Stabilities of the polyphenylenes to electron bombardment are also discussed.

In our previous studies[2)] a series of closely related linear and branched polyphenyls was synthesized and the relationship was discussed between the number and arrangement of benzene rings and physical properties including IR, UV, and ^{1}H NMR spectral characteristics. In addition, empirical Hückel molecular orbital (HMO) calculations were performed of longest-wavelength absorption bands of forty-two linear polyphenyls. The results indicated that the common parameters (cos θ and β) used might successfully apply to linear polyphenyls. In connection with these works on polyphenyls, I was much interested in studying syntheses of macrocyclic polyphenylenes in which both terminal rings of polyphenyls are linked to each other so that the rotation of pivot bonds is restricted significantly because of their rigid geometry.

Previously, syntheses and properties of several polyphenylenes have been reported by Rapson *et al.*[3)] and Wittig *et al.*[4)] for the *o*-series and by Staab *et al.*[5)] for the *m*-series from the viewpoint of transannular π-electronic interactions in macrocyclic systems. Recently, some of their heterocyclic analogues have also been prepared by Kauffmann.[6)] In addition, Vögtle *et al.*[7)] have synthesized helical compounds which are clamped by methylenes or other bridges at the ends of a linear polyphenyl chain. Nevertheless, only a few polyphenylenes consisting of mixed phenylene linkages have so far been reported.[8)]

The present study was undertaken to synthesize hitherto unknown polyphenylenes consisting of all of three or two kinds of phenylene linkages, and to investigate their spectral characteristics attributable to their macrocyclic structures. Their IR, UV, ^{1}H NMR, and mass (MS) spectra have been measured. By comparing data with those of open-chain analogues, restricted rotation of pivot bonds caused by the rigid geometry, π-electronic interactions, and other conformational problems have been discussed. Further, HMO calculations of longest-wavelength absorption bands of polyphenylenes have been performed to obtain additional valuable information about their conformational aspects.

Results and Discussion

Syntheses. The earlier reactions used for the preparation of polyphenylenes are based mainly on the following reactions: 1) Homo-coupling of di-Grignard compounds with copper(II) or cobalt(II) chloride,[3a,5)] 2) homo-coupling of dilithium aromatics with transition metal halides,[4,9)] and 3) Ullmann homo-coupling of appropriate diiodo compounds.[8b,10)] In the present work, reaction 1 has been adopted because of the facile preparation of the starting and intermediate materials, as well as of the facile isolation of polyphenylenes from several by-products. Thus eleven polyphenylenes (**1**—**11**) (Chart 1), including nine hitherto unknown compounds, were synthesized by the intra- or intermolecular homo-coupling of di-Grignard compound or by cross-coupling of two kinds of di-Grignard compounds, with copper(II) chloride.

The key intermediate dibromo compounds were prepared as follows: First, the following six intermediate dinitroterphenyls were prepared by the Ullmann cross-coupling of *o*- or *m*-diiodobenzene (**15** or **16**) and 2-chloro- or 3-iodonitrobenzene (**17** or **18**), and of 4-iodo-2′- or 4-iodo-3′-nitrobiphenyl (**19** or **20**) and **17** or **18**: 3,3″-dinitro-*o*-(**21a**), 2,2″-dinitro-*m*-(**22a**), and 3,3″-dinitro-*m*-terphenyl (**23a**), and 2,2″-(**24a**), 2,3″-(**25a**), and 3,3″-dinitro-*p*-terphenyl (**26a**). The dinitro compounds (**21a**—**26a**) thus obtained were reduced to the corresponding diamino compounds (**21b**—**26b**) with activated iron in hot benzene, and then converted into dibromoterphenyls (**21c**—**26c**) by the Sandmeyer

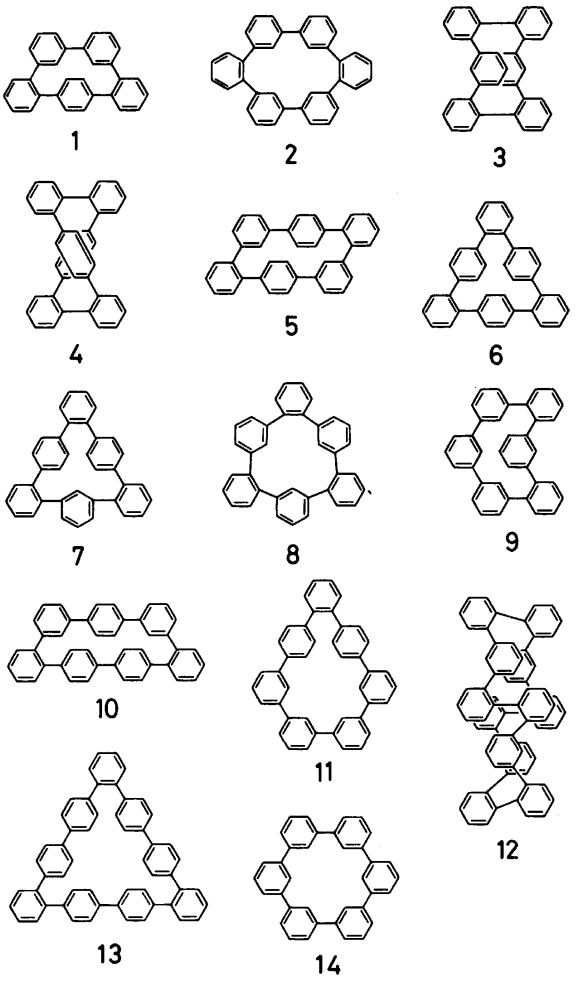

Chart 1.

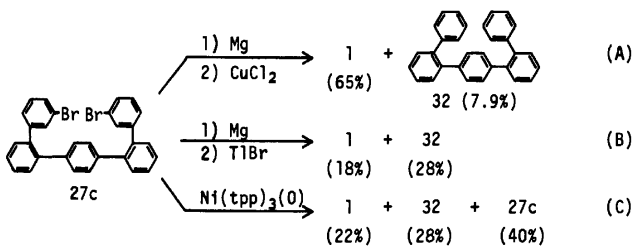
reaction. Similarly, the dinitroquinquephenyls (2,2″-bis(3-nitrophenyl)-*p*-(**27a**) and 4,4″-bis(3-nitrophenyl)-*o*-terphenyl (**28a**)), obtained by the Ullmann cross-coupling of **18** and 2,2″-diiodo-*p*-(**24d**) or 4,4″-diiodo-*o*-terphenyl, were converted into the dibromo compounds (**27c** and **28c**) *via* the corresponding diamines (**27b** and **28b**). Analogously, 2,2‴-dibromo-*p*-quaterphenyl (**29c**) and 3,3′-dibromobiphenyl (**30c**) were prepared by the Sandmeyer reaction of the corresponding diamines, whereas only 4,4″-dibromo-*o*-terphenyl (**31c**) was obtained by direct bromination of *o*-terphenyl.

For the synthesis of polyphenylene **1**, three methods have primarily been applied (Scheme 1). Thus, the intramolecular homo-coupling of the di-Grignard compound derived from **27c** with anhydrous copper(II) chloride in a tetrahydrofuran (THF)–benzene (1 : 1, v/v) mixture (method A), gave macrocyclic pentaphenylene



Scheme 1.

(**1**) in a fairly good yield (65%) with its open-chain analogue (2,2″-diphenyl-*p*-terphenyl (**32**), 7.9%). The coupling of the same di-Grignard compound with thallium(I) bromide (method B)[11] and that of **27c** with tris(triphenylphosphine)nickel(0)[12] (method C) afforded **1** only in low yields (18 and 22%, respectively), with predominant formation of **32** accompanied.

On the basis of these results, method A was adopted for the preparation of the remaining ten polyphenylenes (**2**—**11**). Thus, each of **2**—**5** was prepared by the intermolecular homo-coupling reaction of the di-Grignard compound derived from each of dibromides (**21c**, **22c**, **24c**, and **25c**) with anhydrous copper(II) chloride according to the reaction

while each of **6**—**11** was obtained by the intermolecular cross-coupling of two kinds of di-Grignard compounds derived from each of dibromides (**21c**—**24c**, **26c**, and **28c**—**31c**) according to the reaction

The yields of desired polyphenylenes and of other macrocyclic compounds, obtained as by-products, are given in Table 1.

The polyphenylenes **1**—**14**, thus prepared, gave satisfactory analytical results and spectral (IR and MS) data consistent with their proposed structures. Of these polyphenylenes, alternative syntheses of four species have been reported earlier by other workers (**2**,[8c] **3**,[8b] **13**,[8a] and **14**[5b]). The melting points and spectral data of these compounds except **2**[13] are practically consistent with those of previous authors.

In contrast to the yield of **1** (65%), those of the intermolecular homo-coupling products **2**—**5** were rather low (14—16%). Furthermore, the yields of the intermolecular cross-coupling products, except that of **6** (16%), were low (2.3—5.1%) as expected, presumably due to the competitive homo-coupling of each of the reactants and to more or less hindered conformations of the polyphenylenes. Indeed, in the preparations of **6**—**9** and **11**, one or two reasonable homo-coupled

Table 1. Syntheses of polyphenylenes

Reactants	Polyphenylene (Yield/%)	Other polyphenylenes (Yield/%)
27c	**1** (65)	—
21c	**2** (16)	—
22c	**3** (14)	**12** (1.3)
24c	**4** (13)	—
25c	**5** (14)	—
24c+**31c**	**6** (16)	**13** (4.5)
22c+**31c**	**7** (4.5)	**3** (6.5), **13** (2.6)
21c+**22c**	**8** (2.3)	**2** (3.3), **3** (4.4)
22c+**23c**	**9** (3.3)	**3** (4.9), **14** (4.1)
26c+**29c**	**10** (5.0)	—
28c+**30c**	**11** (5.1)	**14** (2.9)

polyphenylenes (**2**, **3**, **13**, and **14**) were isolated in yields of 2.6—6.5%. Beside these, macrocyclic dodecaphenylene (**12**), a tetramer of the reactant, was obtained. In spite of the low yields of the polyphenylenes, most of them were isolated rather with ease from a complex mixture of by-products[14] because of their sparing solubilities and distinguishable crystal forms.

Most of the polyphenylenes melt at much higher temperatures than the open-chain analogues,[15] and the rise in their melting points may be ascribed to the rigid geometry caused by their endless macrocyclic structures.

In the preparations of **3** and **8**, formation of two atropisomers were expected. However, only one compound in each, presumably having a centro-symmetrical conformation on the basis of spectral data to be described later, was isolated. Although the polyphenylene **4** would be a racemate, no identification of antipodes by resolution was attempted.

Physical Properties. *IR Spectra*: The IR spectra of the polyphenylenes **1**—**14** were measured by the KBr-disk method. All the polyphenylenes commonly give the following absorptions: A group of prominent bands due to C–H out-of-plane deformation vibrations in the 675—920 cm^{-1} region; intense bands due to C–C out-of-plane deformation vibrations in the fairly narrow region of 685—715 cm^{-1} (except for **4**, **6**, and **13**); medium bands due to C–C in-plane deformation vibrations near 1000 cm^{-1}; and weak bands due to C–H in-plane deformation vibrations in the 975—1350 cm^{-1} region. In addition, groups of medium bands due to C–C stretching vibrations and weak bands due to aromatic C–H stretching vibrations in the 1350—1600 and 3000—3100 cm^{-1} regions, respectively, are observed.

It has already been known that the prominent bands in the 675—920 cm^{-1} region of the linear polyphenyls are correlated closely to the substitution patterns of the benzene rings comprising each of the compounds.[2,16] A precise examination of the characteristic bands of the polyphenylenes in the same region, has proved that the assignments of the bands generalized for the polyphenyls may also apply to the macrocyclic polyphenylenes. Thus, the prominent bands of the polyphenylenes in the 675—920 cm^{-1} region correspond to the kinds of phenylene rings constituting each of the polyphenylenes as shown in Table 2.

Of the spectra of the fourteen polyphenylenes, those of **1**—**3**, **5**, **7**—**12**, and **14**, which contain *m*-phenylene ring(s), show without exception the strong C–C out-of-plane deformation vibration bands due to *m*-phenylene ring in the narrow range of 704—713 cm^{-1}, whereas those of remaining **4**, **6**, and **13**, which have no *m*-phenylene ring, do not show any analogous intense bands. Concerning these bands of polyphenyls, Stewart and Hellmann[16a] have pointed out that the strong bands due to the C–C out-of-plane bending vibrations near 700 cm^{-1} are characteristic of phenyl and *m*-phenylene rings, whereas the bands corresponding to the *o*- and *p*-phenylene rings are forbidden in IR. The above results, therefore, suggest that the lack of intense bands near 700 cm^{-1} with macrocyclic polyphenylenes may generally be regarded as a piece of plausible evidence for the macrocyclic structure containing no *m*-phenylene ring.

^1H NMR Spectra: The ^1H NMR spectra of the polyphenylenes **1**—**13** were measured at 200 and 80 MHz in $CDCl_3$ solution, and the chemical shifts from tetramethylsilane are summarized in Table 3.

The isolated *m*-phenylene proton signals of **1**, **5**, and **10** (δ=6.61—6.63, 6.23—6.26, and 6.50—6.53, respectively) are observed at much higher fields (by *ca.* 1.18, 1.56, and 1.29 ppm) than that of *m*-terphenyl (δ=7.78—7.83, m).[2e] The remarkable high-field shifts may reflect the anisotropic effects caused by the *p*-phenylene ring on which the isolated *m*-phenylene protons are located. On the other hand, the *p*-phenylene proton signals are found at higher field in **1** (0.43 ppm) and at much higher field in **5** (0.70 ppm) than that of *p*-terphenyl (δ=7.68, s),[2a,e] owing to the anisotropic effect of the inclined *m*-phenylene rings in **1** and **5** and an additional effect of the parallel *p*-phenylene rings in **5**. The analogous high-field shifts of the *p*-phenylene proton signals of **10** can also be explained in terms of the anisotropic effect similar to that described above. The foregoing considerations are fully substantiated by inspection of the Dreiding stereomodels.

The two *p*-phenylene rings of **4** are forced to face-to-face arrangement,[17] analogously to the *m*-phenylene rings of **3**.[8b] The *p*-phenylene proton signals (δ=6.68 and 6.90) of **4** are remarkably shifted toward high field (by *ca.* 1.00 and 0.78 ppm) relative to that of *p*-terphenyl (δ=7.68). This corresponds to the behavior of phenylene protons observed in [2.2]paracyclophane,[18] 4,4‴-dimethylene-*o*-quaterphenylophane,[7a] and a cyclic pyrazole analogue of **4**,[17b] and the marked high-field shift of **4** undoubtedly reflects the anisotropic effect of the faced *p*-phenylene rings. Analogous but more significant high-field shifts over 1 ppm are also observed in the *m*-phenylene proton signals of **3**. Furthermore, the spectrum of **3** is superimposable with that of the compound prepared alternatively by Wittig *et al.*[8b] Therefore, the macrocycle **3** obtained in the present work is evidently a "crosslike" conformer[8b] in the two possible atropisomers.

In the spectrum of **6**, consisting of two equivalent singlets (δ=6.97 and 7.41), the low-field one is assigned to the protons of the three *o*-phenylene rings by comparison with the *o*-phenylene proton signal of *o*-terphenyl (δ=7.41, s)[2a,e] and of **13** (δ=7.40—7.50), and therefore the high-field one is assignable to those of the three *p*-phenylene rings without any contradiction. The high-field shifts (by 0.71 and 0.20 ppm) of the singlet (δ=6.97), relative to the signal of the *p*-phenylene protons of *p*-terphenyl (δ=7.68) and that of the phenyl protons of *o*-terphenyl (δ=7.17),[2a,e] may be

a) v, very; s, strong; m, medium; w, weak; sh, shoulder. γ_{C-C} and γ_{C-H} refer to the vibrations which are primarily the out-of-plane C-C and out-of-plane C-H bending motions, respectively. *o*, *m*, and *p* in parentheses refer to *ortho*-, *meta*-, and *para*-substituted rings, respectively.

ascribed to the mutual anisotropic effect of *p*-phenylene rings situated oppositely.

Furthermore, in the case of **7**, one of *m*-phenylene analogues of **6**, the isolated proton signal (δ=6.40—6.42) and the *p*-phenylene proton signals (δ=6.68 and 6.73, and 6.95 and 7.15) are observed in the high-field regions as compared with that of *m*-terphenyl (δ=7.78—7.83) and with those of *p*-terphenyl (δ=7.68) and **6** (δ=6.97), respectively. The significant high-field shifts reasonably reflect the conformation in which the *m*-phenylene ring is situated oppositely to two angular *p*-phenylene rings.

Finally, in the spectra of **2**, **8**, **9**, and **11**, a comparison of the characteristic features in phenylene proton signals with those of open-chain analogues[2)] is in full support of the validity of the conformational considerations developed based on the Dreiding stereomodels.

The foregoing results suggest that the prominent

a) δ (ppm) from the internal standard TMS.

high-field shift found for the phenylene proton signals of macrocyclic polyphenylenes, as compared with those of open-chain analogues, may reflect the anisotropic effect of the neighboring phenylene rings, which, originating from the rigid geometry of the macrocyclic structures, may result in a restricted rotation of pivot bonds and an overcrowded conformation. Consequently, the ^{1}H NMR spectra of macrocyclic polyphenylenes, when compared with those of open-chain analogues, may provide useful information for the nonplanar spacial relationship of constituting phenylene rings in solution.

UV Spectra: The UV spectra of the polyphenylenes **1**—**14** were measured in cyclohexane solution. The absorption curves are shown in Figs. 1—6. The absorption maxima above 220 nm for **3**, **13**, and **14** coincide within 3 nm with those of other workers.[5b,8a,b)] All of the polyphenylenes, similarly to the open-chain analogues,[2,19)] display the E-band in the fairly narrow region of 190—210 nm and the K-band in the broad region of 230—320 nm with high intensity.

Previous studies on the UV spectra of the polyphenyls[2)] have indicated that a twist of the pivot bond in the conjugated system influences the interaction of π-electrons across the pivot bond as well as the conjugation of the system, and that the arrangement of the p-phenylene unit(s) in the molecule, even in the presence of o- or m-phenylene units, has a tendency to maintain the coplanarity of the benzene rings. In the case of the polyphenylenes, their overcrowded spacial relationship due to the rigid geometry may cause an enhanced restricted rotation of the pivot bonds, and consequently affects inevitably the spectral feature of K-band.

The spectrum of **1**, containing one *p*-phenylene ring, displays none of bands near 280 nm, which have been found characteristic of the *p*-phenylene unit in the spectrum of the open-chain analogue (**32**: 242 and 280 nm),[2a] but rather intense K-bands (237 and 256 (sh), ε=53700 and 36600), which are related closely to the K-bands of the open-chain compound (ϕommoϕ:[20] 237 and 252 (sh), 74100 and 45400) containing no *p*-phenylene rings.[2b,g] The lack of K-band near 280 nm provides conclusive evidence for the conformation, in which *o*- and *p*-phenylene rings should be highly twisted to one another owing to the steric repulsion of both the isolated hydrogen atoms (*m*-phenylene rings) and the π-electron cloud (*p*-phenylene ring) (Fig. 1). An analogous lack of K-band was also observed in the case of **7** (Fig. 2).

Similarly, an analogous spacial situation of *p*-phenylene ring may result in decrease of π-π interaction across the pivot bonds. Indeed, the spectrum of **5** (246 and 264 (sh)) shows a remarkable hypsochromic shift of the characteristic band for *p*-linkage, compared with those of the corresponding open-chain analogues (ϕmpoϕ: 250 and 275 (sh);[2a] ϕmopmϕ: 249 and 276 (sh)[2f]) (Fig. 3). Also, the spectrum of **6**, which has an alternate arrangement of *o*- and *p*-phenylene rings, has a K-band (276 (sh), 13500) similar in loca-

tion to, but much weaker in intensity than, those of the open-chain reference compounds (*cf.* **32**: 280, 18500; *φpopφ*: 284 (sh), 30600).[2a] In the case of **11**, beside an analogous decrease in intensity of K-bands near 280nm, a significant K-band (256 and 284 (infl), 107700 and 24100) similar to that of *m*-sexiphenyl (249, 101700)[2g] is reasonably observed (Fig. 2). The marked shift or decrease in intensity of the K-band near 280 nm surely reflects the reduced π-π interaction across the pivot bonds of *p*-phenylene ring because of an enhanced twisting of the bonds. In the spectrum of **10**, however, the weak shoulder (312, 16800) found at rather a long wavelength as compared with those of the reference compound (*φoppoφ*: 297, 38900),[2a] seems to be associated with the reduced twisting of *o*-phenylene linkages, caused by the relaxation of steric repulsion of the molecule, in contrast to the cases of **1** and **5** (Fig. 4).

On the other hand, in the spectrum of **4** (236, 286, and 288 (sh); 42300, 34000, and 33600), which has parallel *p*-phenylene rings, longer-wavelength bands are observed at rather red in comparison with those of the open-chain analogues (*cf.* **32**: 242 and 280, 43200 and 18500;[2a] *φpoopφ*: 240 (sh) and 272, 28100 and 51200[2b,g]). The marked shift corresponds to the behavior of [2.2]paracyclophane and other strained compounds[17a] and can be explained on the basis of transannular π-electronic interaction of the two chromophores lying face-to-face (Fig. 5).

The spectra of **2**, **3**, **8**, **9**, and **12**, all of which consist of *o*- and *m*-phenylene rings without any *p*-phenylene rings, show similar characteristic K-bands (near 235 and near 250 (sh)) related closely to those of the reference open-chain analogues (*cf.* *φommoφ*: 237 and 252 (sh); *φmoomφ*: 236 and 245;[2b] *φomooφ*: 232 and 250 (sh);[2f] *φmomφ*: 237 and 249 (sh); *φomoφ*: 234 and 250 (sh);[2a] *φmmomφ*: 239 and 250 (sh)).[2f] From these observations it may be deducible that the restricted rotation of pivot bonds caused by the macroring formation of such open-chain analogues will give no appreciable influence on the spectral feature of K-band (Fig. 6).

The foregoing results on the spectra of polyphenylenes containing *p*-phenylene ring(s) suggest the following aspect: The lack or decrease in intensity of K-band above *ca.* 260nm, or a marked shift of the band, reflects the enhanced restricted rotation of the pivot bonds of *p*-phenylene ring(s), and consequently provides useful conformational information. The proposed conformations of the polyphenylenes based on the UV spectral data have been confirmed to agree qualitatively with those obtained from the ^{1}H NMR spectral data.

HMO Calculations: Previously HMO calculations of longest-wavelength absorption bands of forty-two linear polyphenyls up to octiphenyls were performed by assuming dihedral angles of pivot bonds to be as follows: 50° for the phenyl—*o*- and *o*-—*o*-phenylene linkages, 35° for the *o*-—*p*- and *m*-—*o*-phenylene linkages, and 20° for the other linkages.[2a,c,d] Resonance integrals (π-π) were used with the values of cos θ of these dihedral angles. The results indicated that the parameters (cos θ and β) used successfully applied to many such linear polyphenyls.

In the present study, two sets of HMO calculations (A and B) of longest-wavelength absorption bands of

a) For β, −3.70 eV was used as a mean value calculated from the absorption bands of biphenyl and the first four *p*-polyphenyls (Refs. 2a, 2c, and 2d). b) m, o, and p refer to *m*-, *o*-, and *p*-phenylene rings. The figures in parentheses refer to the dihedral angle of the pivot bond. Both terminal phenylene rings are duplicated.

the polyphenylenes were carried out by assuming the dihedral angles of the pivot bonds as those 1) previously used for the linear polyphenyls (for A) and 2) obtained by an apparent inspection of the Dreiding stereomodels (for B). The results obtained are summarized in Table 4.

The calculated and observed longest wavelengths of the polyphenylenes show a poor agreement for the values by calculation A, except in the cases of **6** and **10**, but a fairly good agreement within 5 nm for those by calculation B. Evidently the above poor agreement is due to unsuitable parameters (cos θ) derived from the impractically small dihedral angles of the pivot bonds instead of relatively large ones caused by the rigid geometry of macrocyclic structure. The above favorable agreement presumably justifies the estimates of their dihedral angles, and supports the proposed conformations of the polyphenylenes based on the UV and ^{1}H NMR spectral data.

The foregoing results indicate that prediction of the longest-wavelength absorption bands of the polyphenylenes by HMO calculations is possible with a fairly good precision by use of the dihedral angles of the pivot bonds as estimated by inspection of the Dreiding stereomodels. The calculations gave also additional bases for their conformational aspects deduced from their spectral data and stereomodels.

MS Spectra: Only a few studies have been reported on MS spectra of polyphenylenes and related polyphenyls consisting of three or more benzene rings.[2e,5e,21] The MS spectra of the polyphenylenes **1—13** containing mixed linkages and of **14** were measured at 70 eV. The spectral data are briefed in Tables 5 and 6.

All of the spectra commonly display the molecular ion (M^+) as the most abundant ion. As fragment ions, $(M-Hy)^+$ and $(M-CxHy)^+$ are found in appreciable amounts. The spectra show also considerable amounts of doubly charged ions M^{2+}, $(M-Hy)^{2+}$, and $(M-CxHy)^{2+}$ together with small amounts of corresponding triply charged ions.

An inspection of each spectrum discloses the following facts: Firstly, the second most abundant ion is M^{2+} or $(M-1)^+$. Secondly, the amount of singly to triply charged molecular ions (including isotope ions) of **1—13**, each of which contains one or more *o*-phenylene rings, seems to be low in comparison with that of **14**, which consists of only *m*-phenylene rings. Furthermore, the values $(M^{2+}+M^{3+})/M^+$ of **1—13** increase approximately with increasing number of phenylene rings. The highest value of **14** obviously correlates to the absence of *o*-phenylene ring, which markedly reduces the stability of molecular ions as a result of lowered resonance stabilization. Thirdly, the value of $(M-Hy)^+/(M-Hy)^{2+}$ is rather high in the spectra of **1** and **11** and slightly high in those of **5—7**.

Previous electron-impact studies have shown that stabilities of *o*-polyphenylenes are less than those of *m*-polyphenylenes,[5e] and that those of polyphenyls decrease in the order of *p*->*m*->*o*-series.[2e,21] These results lead to a conclusion that the stabilities to electron bombardment of polyphenylenes containing *o*-phenylene rings, regardless of the presence of *m*- or *p*-phenylene ring(s), are substantially less than those of *m*-polyphenylenes.

Experimental

Melting points were determined with a Mettler FP-51 apparatus, except for those above 300 °C, which were determined with a Shimadzu DSC-30M differential scanning calorimeter. UV spectra were measured on a Shimadzu UV-360 spectrophotometer, IR spectra on a Leitz III-G spectrophotometer, and ^{1}H NMR spectra on Varian XL-200 (200 MHz) and CFT-20 (80 MHz) spectrometers with tetramethylsilane as an internal standard. MS spectra were recorded on a Hitachi RMU-6MG mass spectrometer. HMO

a)—c) The generic ions $(M-Hy)^+$, *etc.* refer to the sums of fragment ions corresponding to the loss of one to ten H atoms, to the loss of one to six carbon units, and to the loss of seven to twelve carbon units, respectively, from the molecular ions.

calculations were carried out on a Hewlett-Packard HP-85 personal computer with a 16K RAM attached.[22]

Commercially available *o*- (**15**) and *m*-diiodobenzene (**16**) and *o*-chloro- (**17**) and *m*-iodonitrobenzene (**18**) were purified before use. 4-Iodo-2′- (**19**) and 4-iodo-3′-nitrobiphenyl (**20**), 2,2‴-diamino-*p*-quaterphenyl,[2d] and 3,3′-diaminobiphenyl[2f] were prepared by the methods previously reported.

2,2″-Diiodo-*p*-terphenyl (**24d**) was prepared from the corresponding diamine (**24b**, described below) by a method similar to that of Cade and Pilbeam.[23] Colorless needles from ethanol: Mp 158.9°C; yield 50%. Found: C, 44.84; H, 2.42%. Calcd for $C_{18}H_{12}I_2$: C, 44.84; H, 2.51%.

4,4″-Dibromo-*o*-terphenyl (**31c**) was prepared by direct bromination[8a] of commercially available *o*-terphenyl. Colorless plates from ethanol: Mp 170.5°C (lit,[8a] 170°C); yield 61%. (Found: C, 55.55; H, 2.93%).

Preparation of Dinitropolyphenyls (21a—28a). Procedure A: A solution of two kinds of iodides in dimethylformamide (DMF) was brought to reflux. Copper powder was added in three portions at intervals of 2h with stirring, and the mixture was refluxed for an additional 16h. The hot reaction mixture was filtered, and the solid material was washed several times with hot DMF and benzene. The filtrates were combined and then cooled, and the resulting solid was removed by filtration.[24] After removal of the solvents *in vacuo*, the residue (after distillation *in vacuo* for the preparation of **23a**)[24] was subjected to a chromatography on alumina using a cyclohexane-benzene (3:7, v/v) mixture (C-B(3:7)) and benzene, or benzene as the eluents.[24]

3,3″-Dinitro-o-terphenyl (21a): A solution of **15** (26.4g) and **18** (159g) in DMF (600ml) was treated with copper powder (254g). The eluate with a C-B (3:7) mixture gave **21a** as pale yellow prisms from ethanol: Mp 142.0°C; yield 10.3g (40%). Found: C, 67.73; H, 3.65; N, 8.93%. Calcd for $C_{18}H_{12}N_2O_4$: C, 67.50; H, 3.78; N, 8.75%.

3,3″-Dinitro-m-terphenyl (23a): A solution of **16** (66.0g) and **18** (399g) in DMF (1300ml) was treated with copper powder (572g). A double crystallization of the eluate from benzene provided **23a** as pale yellow needles: Mp 142.1°C; 23.6g (37%). Found: C, 67.77; H, 4.08; N, 8.88%.

Procedure B: A mixture of two kinds of halides in a reaction tube (ϕ 4.5×20cm) was heated in an oil bath at 205—220°C (225—235°C for the preparation of **26a—28a**), copper powder was added in portions with stirring over a 2-h period, and then the mixture was heated at 215—230°C (230—240°C for the preparation of **26a—28a**) for an additional hour. After

cooling, the reaction product was extracted with hot benzene and then the solvent was distilled off. The remaining was distilled *in vacuo* to separate a distillate (bp 100—210 °C/667 Pa, 161—220 °C/667 Pa, 80—205 °C/933 Pa, and 150—240 °C/400 Pa in the preparation of **22a**, **24a**, **25a**, and **26a—28a**, respectively)[26] from a tarry or soild residue. The residue was recrystallized or chromatographed on alumina with benzene (C-B(1:1) in the preparation of **26a**).

2,2″-Dinitro-m-*terphenyl (22a)*: A mixture of **16** (8.25 g) and **17** (39.4 g) was treated with copper powder (95.3 g). Repeated crystallizations of the residue from benzene and then from ethanol afforded **22a** as pale yellow needles: Mp 163.4 °C; 2.5 g (31%). Found: C, 67.41; H, 3.93; N, 8.64%. Calcd for $C_{18}H_{12}N_2O_4$: C, 67.50; H, 3.78; N, 8.75%.

2,2″-Dinitro-p-*terphenyl (24a)*: A mixture of **19** (16.3 g) and **17** (39.4 g) was heated with copper powder (95.3 g). The eluate gave **24a** as pale yellow cubes from benzene: Mp 235.5 °C (lit,[27] 228—230.5 °C); 10.0 g (62%). (Found: C, 67.69; H, 4.02; N, 8.70%).

2,3″-Dinitro-p-*terphenyl (25a)*: A mixture of **20** (16.3 g) and **17** (39.4 g) was treated with copper powder (95.3 g). The eluate provided **25a** as pale yellow needles from benzene: Mp 145.4 °C; 4.9 g (31%). Found: C, 67.47; H, 3.75; N, 8.88%.

3,3″-Dinitro-p-*terphenyl (26a)*: A mixture of **20** (16.3 g) and **18** (49.8 g) was heated with copper powder (79.4 g). Several crystallizations of the eluate from benzene afforded **26a** as yellow needles: Mp 211.3 °C; 4.4 g (27%). Found: C, 67.78; H, 3.88; N, 8.90%.

2,2″-Bis(3-nitrophenyl)-p-*terphenyl (27a)*: A mixture of **24d** (9.64 g) and **18** (49.8 g) was treated with copper powder (76.3 g). Recrystallization of the eluate from benzene gave **27a** as pale yellow prisms: Mp 240.1 °C; 3.8 g (40%). Found: C, 76.52; H, 4.15; N, 5.97%. Calcd for $C_{30}H_{20}N_2O_4$: C, 76.26; H, 4.27; N, 5.93%.

4,4″-Bis(3-nitrophenyl)-o-*terphenyl (28a)*: A mixture of 4,4″-diiodo-*o*-terphenyl[2e] (12.1 g) and **18** (49.8 g) was treated with copper powder (79.4 g). Recrystallization of the eluate from benzene afforded **28a** as yellow needles: Mp 228.0 °C; 2.7 g (23%). Found: C, 76.42; H, 4.12; N, 5.68%.

Preparation of Diaminopolyphenyls (21b—28b). A solution of each of the dinitro compounds (**21a—26a**: 16.0 g, **27a** and **28a**: 14.2 g) in hot benzene (800—1200 ml) was treated with activated iron by a method similar to that of Hazlet and Dornfeld.[28] After filtration, hydrobromic acid (about 47%) was added in portions to the filtrate with stirring, and then the precipitate formed was collected, washed with benzene and small amount of water, and dried; yield 96—98%. A portion of the salt was treated in the usual manner with aqueous alkali into the free base, which crystallized from ethanol or benzene.

3,3″-Diamino-o-*terphenyl (21b)*: Brown oil. **21b**·2HBr: White powder. Found: C, 51.33; H, 4.22; N, 6.73%. Calcd for $C_{18}H_{18}Br_2N_2$: C, 51.21; H, 4.30; N, 6.64%.

2,2″-Diamino-m-*terphenyl (22b)*: Colorless prisms; mp 120.9 °C. Found: C, 83.12; H, 6.22; N, 10.54%. Calcd for $C_{18}H_{16}N_2$: C, 83.04; H, 6.19; N, 10.76%.

3,3″-Diamino-m-*terphenyl (23b)*: Colorless oil. Found: C, 83.23; H, 5.96; N, 10.70%.

2,2″-Diamino-p-*terphenyl (24b)*: Colorless needles; mp 212.0 °C (lit,[27] 204.5—205.5 °C). (Found: C, 82.99; H, 6.10; N, 10.86%).

2,3″-Diamino-p-*terphenyl (25b)*: Colorless needles; mp 180.0 °C. Found: C, 82.76; H, 6.08; N, 10.82%.

3,3″-Diamino-p-*terphenyl (26b)*: Colorless needles; mp 196.6 °C. Found: C, 83.24; H, 6.40; N, 10.66%.

2,2″-Bis(3-aminophenyl)-p-*terphenyl (27b)*: Colorless prisms; mp 229.1 °C. Found: C, 87.27; H, 5.64; N, 6.61%. Calcd for $C_{30}H_{24}N_2$: C, 87.35; H, 5.86; N, 6.79%.

4,4″-Bis(3-aminophenyl)-o-*terphenyl (28b)*: Colorless plates; mp 210.4 °C. Found: C, 87.64; H, 5.89; N, 6.70%.

Preparation of Dibromopolyphenyls (21c—30c). A suspension of bishydrobromide of each of the diamino compounds (50 mmol) in 47% hydrobromic acid (100 ml) and water (150 ml) was bis-diazotized with sodium nitrite (7.3 g, 106 mmol) in water (20 ml) at 0—5 °C with stirring for 2 h. The cold suspension of bis(diazonium) salt formed was added in portions to a solution of freshly prepared copper(I) bromide (15.8 g, 110 mmol) in 47% hydrobromic acid (70 ml) with stirring, and the mixture was heated slowly up to *ca.* 80 °C and then cooled. The benzene extract was washed successively with water, sodium thiosulfate solution, sodium hydroxide solution, and water. After removal of the solvent, the residue was chromatographed on alumina with cyclohexane and/or C-B (9:1, 4:1, and 1:1) mixtures as the eluent to give dibromo compounds.

3,3″-Dibromo-o-*terphenyl (21c)*: Colorless needles from ethanol; mp 90.9 °C; yield 42%. Found: C, 55.87; H, 3.01%. Calcd for $C_{18}H_{12}Br_2$: C, 55.71; H, 3.12%.

2,2″-Dibromo-m-*terphenyl (22c)*: Colorless cubes from benzene; mp 76.3 °C; 64%. Found: C, 55.88; H, 3.28%.

3,3″-Dibromo-m-*terphenyl (23c)*: Colorless oil (lit,[5c] colorless viscous oil); 47%. (Found: C, 55.95; H, 3.04%).

2,2″-Dibromo-p-*terphenyl (24c)*: Colorless needles from ethanol; mp 137.4 °C; 58%. Found: C, 55.92; H, 3.14%.

2,3″-Dibromo-p-*terphenyl (25c)*: Colorless plates from ethanol; mp 114.9 °C; 63%. Found: C, 55.98; H, 2.94%.

3,3″-Dibromo-p-*terphenyl (26c)*: Colorless plates from benzene; mp 149.8 °C; 45%. Found: C, 55.83; H, 2.99%.

2,2″-Bis(3-bromophenyl)-p-*terphenyl (27c)*: Colorless prisms from benzene-cyclohexane; mp 190.1 °C; 64%. Found: C, 66.94; H, 3.67%. Calcd for $C_{30}H_{20}Br_2$: C, 66.69; H, 3.73%.

4,4″-Bis(3-bromophenyl)-o-*terphenyl (28c)*: Colorless needles from ethanol-benzene; mp 142.3 °C; 53%. Found: C, 66.89; H, 3.76%.

2,2‴-Dibromo-p-*quaterphenyl (29c)*: Colorless needles from benzene-ethanol; mp 174.8 °C; 30%. Found: C, 61.86; H, 3.32%. Calcd for $C_{24}H_{16}Br_2$: C, 62.10; H, 3.47%.

3,3′-Dibromobiphenyl (30c): Colorless needles from ethanol; mp 54.6 °C (lit,[5c] 53 °C); 55%. (Found: C, 46.31; H, 2.59%).

Preparation of m,m,o,p,o-*Pentaphenylene (1). Procedure A*: A solution of di-Grignard compound was prepared from **27c** (2.70 g, 5.9 mmol), magnesium turnings (0.25 g, 10 mmol), and a THF-benzene (1:1, v/v) mixture (T-B(1:1)) (40 ml) under nitrogen in the usual manner. To the Grignard reagent thus prepared, after dilution with T-B (1:1) (60 ml), anhydrous copper(II) chloride (1.74 g, 13 mmol) was added. The mixture was refluxed with stirring for 4 h and then hydrolyzed with ammonium chloride (2 g) and concentrated hydrochloric acid (4 ml) in water (40 ml). The product was extracted with benzene. The organic layer was separated, washed with water, and then dried. After removal of the solvent, the residue was chromatographed on alumina with C-B (9:1) to give 2,2″-diphenyl-*p*-terphenyl (**32**) as colorless needles from ethanol: Mp 185.7 °C (lit,[2a] 185.8 °C); yield 151 mg (7.9%). Subsequent elutions with C-B (9:1), C-B

(4:1), and C-B (3:1) provided **1**.

1: Colorless cubes from hexane; mp 188.6°C; yield 1233 mg (65%); UV λ_{max} (ε) 190 (66300), 211 (76900), 237 (53700), and 256 nm (sh) (36600). Found: C, 94.97; H, 5.29%; M^+, 380. Calcd for $C_{30}H_{20}$: C, 94.70; H, 5.30%; M^+, 380.

Procedure B: A mixture of the di-Grignard reagent, prepared from **27c** (540 mg, 1.0 mmol) and magnesium turnings (50 mg, 2 mmol) in T-B (1:1) (20 ml), and thallium(I) bromide (569 mg, 2.0 mmol) was stirred and refluxed under nitrogen for 5 h, and then hydrolyzed with dilute hydrochloric acid.[11] The benzene extract of the product was worked up as described for procedure A to afford **32** (105 mg, 28%) and **1** (68 mg, 18%).

Procedure C: A solution of tris(triphenylphosphine)nickel(0) [Ni(tpp)$_3$] was prepared from bis(triphenylphosphine)nickel(II) dichloride[29] (635 mg, 1.0 mmol), triphenylphosphine (524 mg, 2.0 mmol), and zinc powder (66 mg, 1.0 mmol) in dry, O_2-free DMF (5 ml) under nitrogen at 50°C for 1 h, by a method similar to that of Kende *et al.*[12] To the red-brown slurry of Ni(tpp)$_3$ thus prepared, **27c** (540 mg, 1.0 mmol) in dry, O_2-free DMF (2 ml) was added and the reaction mixture was stirred under nitrogen at 50°C for 24 h. It was then cooled, poured into 2% hydrochloric acid (20 ml), extracted into benzene, and washed well with water, and the solvent was distilled off. The products were analyzed by quantitative GLPC, using *p*-terphenyl as an internal standard calibrated against the pure samples, to give **32** (28%), **1** (22%), and starting material **27c** (40%).

Preparation of m,m,o,m,m,o-*Hexaphenylene (2)*. To the solution of di-Grignard compound prepared from **21c** (3.88 g, 10 mmol) and magnesium turnings (0.49 g, 20 mmol) in THF (20 ml), after dilution with THF (80 ml), anhydrous copper(II) chloride (3.40 g, 25 mmol) was added. The mixture was worked up as described for **1**. The benzene extract was chromatographed on alumina, with cyclohexane and then with C-B (9:1) as the eluents, to provide **2** and a bromosexiphenyl: Colorless needles from benzene-ethanol; mp 150.0°C; 39 mg. Found: C, 80.52; H, 4.61%; M^+, 537. Calcd for $C_{36}H_{25}Br$: C, 80.45; H, 4.69%; M^+, 537.

2: Colorless prisms from benzene-ethanol; mp 292.0°C; 363 mg (16%); UV λ_{max} (ε) 188 (75500), 207 (68600), 236 (92800), and 248 nm (sh) (58700). Found: C, 94.86; H, 5.45%; M^+, 456. Calcd for $C_{36}H_{24}$: C, 94.70; H, 5.30%; M^+, 456.

Preparation of m,o,o,m,o,o-*Hexaphenylene (3)*. The Grignard reagent prepared from **22c** (9.70 g), magnesium turnings (1.22 g), and THF (50 ml), after dilution with THF (200 ml) followed by addition of anhydrous copper(II) chloride (8.60 g), was treated as described for the preparation of **1**. The benzene extract was dissolved in benzene and then allowed to stand overnight to separate out colorless, transparent plates and an amorphous precipitate. The plates and liquid part containing the amorphous precipitate were separated by decantation. Recrystallization of the former from benzene gave **3** (425 mg). The latter together with filtrates, after removal of the solvent, was chromatographed on alumina with C-B (4:1) to afford an additional **3** (650 mg) and *m,o,o,m,o,o,m,o,o,m,o,o*-dodecaphenylene (**12**).

3: Colorless plates from benzene; mp 403°C (lit,[8b] 382°C); 799 mg (14%); UV λ_{max} (ε) 235 (95700) and 242 nm (sh) (87300) (lit,[8b] λ_{max} (log ε) 235 (4.98)). (Found: C, 94.62; H, 5.28%; M^+, 456).

12: Colorless needles from benzene; mp 444°C; 73 mg (1.3%); UV λ_{max} (ε) 195 (136400), 230 (121600), and 252 nm (sh) (79200). Found: C, 94.78; H, 5.25%; M^+, 912. Calcd for $C_{72}H_{48}$: C, 94.70; H, 5.30%; M^+, 912.

Preparation of o,o,p,o,o,p-*Hexaphenylene (4)*. The Grignard reagent prepared from **24c** (9.70 g) and magnesium turnings (1.22 g) in T-B (1:1) (80 ml),[30] after dilution with T-B (1:1) (120 ml) followed by addition of anhydrous copper(II) chloride (8.60 g), was worked up as described for **1**. The benzene extract was dissolved in benzene, and then allowed to stand overnight. The precipitate formed was collected and recrystallized from benzene to afford **4** (540 mg). The filtrates, after removal of the solvent, were subjected to a chromatography on alumina with C-B (4:1) to give *p*-terphenyl (**33**) (105 mg). Subsequent elutions with C-B (4:1) and C-B (2:1) provided an additional **4** (230 mg).

4: Colorless cubes from benzene; mp 446°C; 770 mg (14%); UV λ_{max} (ε) 198 (69300), 203 (sh) (66000), 236 (42300), 284 (34000), and 288 nm (sh) (33600). Found: C, 94.98; H, 5.13%; M^+, 456. Calcd for $C_{36}H_{24}$: C, 94.70; H, 5.30%; M^+, 456.

Preparation of m,o,p,m,o,p-*Hexaphenylene (5)*. The Grignard reagent prepared from **25c** (7.76 g) and magnesium turnings (0.98 g) in T-B (2:1) (90 ml), after dilution with T-B (2:1) (110 ml), was treated with anhydrous copper(II) chloride (6.80 g) as described for **1**. The benzene extract was chromatographed on alumina with C-B (4:1). The repeated fractional crystallizations of the eluate from hexane-benzene afforded **33** (125 mg) and **5**.

5: Colorless needles from hexane-benzene; mp 292.2°C; 630 mg (14%); UV λ_{max} (ε) 195 (76800), 206 (77800), 246 (80300), and 264 nm (sh) (43600). Found: C, 94.63; H, 5.04%; M^+, 456. Calcd for $C_{36}H_{24}$: C, 94.70; H, 5.30%; M^+, 456.

Preparation of o,p,o,p,o,p-*Hexaphenylene (6)*. To a mixture of two kinds of di-Grignard reagents prepared from **24c** (3.88 g, 10 mmol) and **31c** (19.41 g, 50 mmol), magnesium turnings (2.92 g, 120 mmol), and T-B (2:1) (150 ml), after dilution with T-B (1:2) (150 ml), anhydrous copper(II) chloride (20.4 g, 150 mmol) was added. The mixture was refluxed with stirring for 5 h, and hydrolyzed with a mixture of ammonium chloride (24 g), concentrated hydrochloric acid (48 ml), and water (480 ml), and then the precipitate formed was filtered. The benzene extract of the filtrate was washed with water and then dried. The precipitate was extracted with hot benzene. The combined benzene extract, after removal of the solvent, was treated with 800 ml of hot C-B (4:1) to be separated into soluble and insoluble parts. The benzene solution of the latter was allowed to stand for 2 d to separate out colorless, transparent cubes and an amorphous precipitate. The cubes were separated by decantation followed by several crystallizations from benzene to give *o,p,p,o,p,p,o,p,p*-nonaphenylene (**13**) (350 mg). The former was subjected to a chromatography on alumina with C-B (4:1) and C-B (2:1) to provide **6** and an additional **13** (163 mg).

6: Colorless needles from hexane; mp 312°C; 734 mg (16%); UV λ_{max} (ε) 188 (sh) (91500), 200 (96500), 245 (43700), and 276 nm (sh) (13500). Found: C, 94.95; H, 5.11%; M^+, 456. Calcd for $C_{36}H_{24}$: C, 94.70; H, 5.30%; M^+, 456.

13: Colorless cubes from benzene; mp 488°C (lit,[8a] 492°C); 513 mg (4.5%); UV λ_{max} (ε) 203 (133500), 279 (89100), and 320 nm (sh) (21900) (lit,[8a] 282.5 nm (82300) in $CHCl_3$). (Found: C, 94.69; H, 5.23%; M^+, 684).

Preparation of m,o,p,o,p,o-*Hexaphenylene (7)*. To a solution of two kinds of di-Grignard compounds prepared from **22c** (3.88 g) and **31c** (19.41 g), magnesium turnings (2.92 g), and T-B (1:1) (150 ml), after dilution with T-B (1:1) (150 ml), anhydrous copper(II) chloride (20.4 g) was added,

and then the mixture was worked up as described for **6**. The benzene extract, after removal of the solvent, was treated with hot C-B (4:1) (1000ml) to be separated into soluble and insoluble parts. Several crystallizations of the latter from benzene afforded **13** (180mg). The former was chromatographed on alumina with C-B (4:1) and C-B (1:1) to give two fractions. The repeated fractional crystallizations of the first from C-B (1:1) afforded **3** (148mg, 6.5%) and **7**. The second, upon recrystallization from benzene, provided an additional **13** (116mg; total yield 2.6%).

7: Colorless cubes from benzene; mp 308°C; 205mg (4.5%); UV λ_{max} (ε) 198 (86600), 205 (sh) (84900), and 237nm (46600). Found: C, 94.67; H, 5.28%; M^+, 456. Calcd for $C_{36}H_{24}$: C, 94.70; H, 5.30%; M^+, 456.

Preparation of m,o,m,o,m,o-*Hexaphenylene (8).* A mixture of two kinds of di-Grignard reagents prepared from **21c** (3.88g) and **22c** (3.88g), magnesium turnings (980mg), and T-B (2:1) (75ml), after dilution with T-B (2:1) (75ml), was terated with anhydrous copper(II) chloride (6.88g) as described for **6**. The benzene extract was chromatographed on alumina with C-B (9:1) and C-B (5:1) to give **3** (100mg, 4.4%), **2** (75mg, 3.3%), and **8**.

8: Colorless needles from hexane; mp 270.8°C; 105mg (2.3%); UV λ_{max} (ε) 189 (85600), 207 (73200), 233 (81800), and 254nm (sh) (36000). Found: C, 94.80; H, 5.35%; M^+, 456. Calcd for $C_{36}H_{24}$: C, 94.70; H, 5.30%; M^+, 456.

Preparation of m,m,m,o,m,o-*Hexaphenylene (9).* A mixture of two kinds of di-Grignard reagents prepared from **22c** (5.82g), **23c** (3.88g), and magnesium turnings (1.22g) in T-B (1:1) (60ml), after dilution with T-B (1:1) (80ml) followed by addition of anhydrous copper(II) chloride (8.60g), was worked up as described for **6**. After hydrolysis of the reaction mixture, the precipitate formed was filtered off. Recrystallization of the precipitate from xylene gave *m*-hexaphenylene (**14**). The benzene extract of the filtrate, after removal of the solvent, was chromatographed on alumina with C-B (4:1) and C-B (1:1). The repeated fractional crystallizations of the eluate from benzene-hexane provided **9** and **3** (168mg, 4.9%).

9: Colorless prisms from hexane; mp 315°C; 150mg (3.3%); UV λ_{max} (ε) 190 (87500), 240 (107300), and 252nm (sh) (65700). Found: C, 94.82; H, 5.40%; M^+, 456. Calcd for $C_{36}H_{24}$: C, 94.70; H, 5.30%; M^+, 456.

14: Colorless needles from xylene; mp 505°C (lit,[5b] 507—508°C); 94mg (4.1%); UV λ_{max} (ε) 191 (99800), 198 (sh) (88100), and 247nm (118900) (lit,[5b] 251 (119000) in THF). (Found: C, 94.42; H, 5.59%; M^+, 456).

Preparation of m,o,p,p,o,m,p-*Heptaphenylene (10).* A mixture of two kinds of di-Grignard reagents prepared from **26c** (3.88g), **29c** (4.64g), and magnesium turnings (980mg) in T-B (1:1) (150ml), after dilution with T-B (1:1) (150ml), was treated with anhydrous copper(II) chloride (6.88g) as described for the preparation of **6**. The soluble part of the benzene extract in C-B (4:1) (500ml) was chromatographed on alumina with C-B(4:1) and C-B (1:1) to afford **10**.

10: Colorless needles from benzene; mp 341°C; 266mg (5.0%); UV λ_{max} (ε) 198 (87200), 205 (sh) (84600), 267 (71400), and 312nm (sh) (16800). Found: C, 94.59; H, 5.47%; M^+, 532. Calcd for $C_{42}H_{28}$: C, 94.70; H, 5.30%; M^+, 532.

Preparation of m,m,m,m,p,o,p-*Heptaphenylene (11).* To a solution of two kinds of di-Grignard compounds prepared from **28c** (5.4g), **30c** (15.6g), and magnesium turnings (2.93g) in T-B (2:1) (200ml), after dilution with T-B (2:1) (200ml), anhydrous copper(II) chloride (20.6g) was added, and then the mixture was worked up as described for **6**. The reaction mixture was treated with benzene to be separated into soluble and insoluble parts. Recrystallization of the latter from xylene gave **14** (185mg). The former was subjected to a chromatography on alumina progressively with C-B (4:1) and with C-B (1:1) to provide an additional **14** (38mg, total yield 2.9%) and **11**, respectively.

11: Colorless needles from benzene; mp 378°C; 273mg (5.1%); UV λ_{max} (ε) 202 (38700), 256 (107700), and 284nm (infl) (24100). Found: C, 94.68; H, 5.41%; M^+, 532. Calcd for $C_{42}H_{28}$: C, 94.70; H, 5.30%; M^+, 532.

The author wishes to thank Professor Aritsune Kaji of Kyoto University for his valuable discussions and suggestions. Thanks are due to Nippon Shinyaku Co., Ltd. and Mr. Yasuhiro Fujiwara of this university for the measurements of ^1H NMR spectra.

Preparation and ESR Studies of New Stable Tocopheroxyl Model Radicals

Kazuo MUKAI,* Kimiko TAKAMATSU, and Kazuhiko ISHIZU
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790
(Received May 24, 1984)

New tocopherol (vitamin E) model compounds (tocopherol **1**; 7-*t*-butyl-2,2-dimethyl-6-chromanol, tocopherol **2**; 7-*t*-butyl-2,2,5-trimethyl-6-chromanol, and tocopherol **3**; 5,7-diisopropyl-2,2-dimethyl-6-chromanol) have been synthesized by condensation of 2-methyl-3-buten-2-ol to the corresponding alkylhydroquinone. Electron spin resonance measurements were performed for the tocopheroxyl radicals obtained from the above tocopherol model compounds by oxidizing the phenol precursors with PbO_2 in toluene. The proton hyperfine coupling constants and g_{iso}-values were determined. The tocopheroxyl radicals **2** and **3** having large alkyl substituents at both ortho positions (C-5 and C-7) are fairly stable, and the radical stability, as measured by the intensities of the ESR signals, increases in the order tocopheroxyl **1**<α-tocopheroxyl model<tocopheroxyl **2**<tocopheroxyl **3**. The result suggests that the *in vitro* antioxidant activities of tocopherols **2** and **3** are higher than that of α-tocopherol model.

It has been well recognized that tocopherols (vitamin E) function as natural antioxidants, particularly in biomembranes by protecting unsaturated lipids from peroxidation.[1-3] The ESR study of the tocopheroxyl radicals obtained by the oxidation of tocopherols is of biological interest since they are involved in vitamin E reactions. Therefore, recently, some workers have reported the ESR spectra of α-, β-, γ-, and δ-tocopheroxyl radicals and their model compounds, and determined the proton hyperfine splittings exactly.[4-10]

Generally, in these tocopheroxyl radicals, replacement of ortho methyl groups at C-5 and C-7 positions with protons lowers the concentration of the tocopheroxyl radicals in solution, as well as the longevity of the radicals. The approximate order of stability, as measured by the intensities of the ESR signals, was: α-, β-, γ-, and δ-tocopheroxyl.[8] The above relative stabilities of the tocopheroxyl radicals correlate well with their biological activities[11] which yield: α->β->γ->δ-tocopherol, and with *in vitro* tests of their relative reactivities toward peroxide radical[12] and singlet oxygen[13] which yield the same order. Further, α-tocopherol and α-tocopherol model, where the isoprenoid side chain is replaced by a methyl group, have similar *in vitro* antioxidant activity,[12] although the latter compound generally shows little or no vitamin E activity *in vivo*.[14,15] These findings suggest that the presence of methyl groups at C-5 and C-7 positions in tocopherols and their model compounds is of great importance to their antioxidant action.

In the present work, in order to obtain further information on such antioxidant action, we have prepared three kinds of new tocopherol model compounds (tocopherol **1**; 7-*t*-butyl-2,2-dimethyl-6-chromanol, tocopherol **2**; 7-*t*-butyl-2,2,5-trimethyl-6-chromanol, and tocopherol **3**; 5,7-diisopropyl-2,2-dimethyl-6-chromanol) (see Fig. 1), and have succeeded in measuring well-resolved ESR spectra of tocopheroxyl-type radicals obtained by the PbO_2 oxidation of the above tocopherol model compounds in toluene at room temperature. The proton hyperfine coupling constants and g_{iso}-values were correctly determined for each radical. From the results, the electronic structure of the tocopheroxyl radicals has been discussed. Especially, the tocopheroxyls **2** and **3** having large alkyl groups at both ortho positions (C-5 and C-7) showed higher radical stability than that of α-tocopheroxyl model, as measured by the ESR intensity change. The result suggests that tocopherols **2** and **3** have higher *in vitro* antioxidant activity than that of α-tocopherol model.

Experimental

Measurements. The ESR measurements were carried out using a JES-FE-2XG spectrometer equipped with a Takeda-Riken microwave frequency counter. The g-values were measured relative to the value of Li-TCNQ powder, calibrated with $(KSO_3)_2NO$ (g=2.0054).[16] All the ESR spectra have been measured in a sealed, degassed system. In all the cases, we made careful measurements of the decay of the ESR signal intensity for the tocopheroxyl radicals obtained by oxidizing the toluene solution of tocopherol precursors (1.0 ml, 5.0×10^{-3} M (1 M=1 mol dm^{-3})) with PbO_2 (0.7 g).

Preparation of Specimens. 2-*t*-Butyl-6-methylhydroquinone (mp 98.5—100.5 °C) (lit, 97—98 °C)[17] and 2,6-diisopropylhydroquinone (mp 108.5—110.0 °C) (lit, 105.5—106.0 °C)[17]

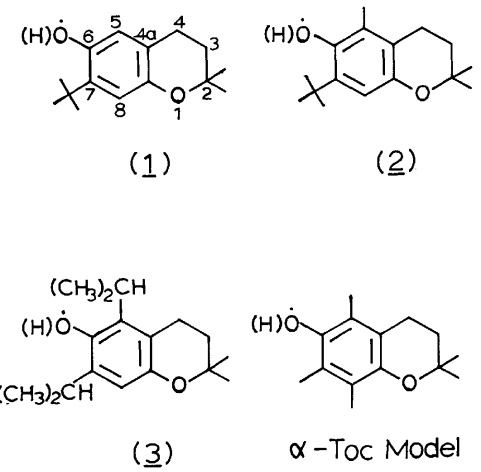

Fig. 1. Molecular structures of tocopherols and tocopheroxyls (**1**, **2**, **3**, and α-model), and the atomic numbering system.

were prepared from 2-*t*-butyl-6-methylphenol and 2,6-diisopropylphenol respectively by the standard procedure, as reported for the syntheses of the 2,3-, 2,5-, and 2,6-dimethylhydroquinone.[18]

2,2,5,7,8-Pentamethyl-6-chromanol (α-tocopherol model) and 2,2-dimethyl-6-chromanol (tocol model) were prepared according to the method of Nilsson *et al.*[19] Tocopherols **1**, **2**, and **3** were synthesized by condensation of 2-methyl-3-buten-2-ol to the corresponding alkylhydroquinone, according to a procedure similar to that used by Nilsson *et al.* to prepare α-, β-, γ-, and δ- tocopherol models.[19] Tocopherol **1** was also prepared by the reaction of 2,2-dimethyl-6-chromanol (tocol model) with isobutene in benzene in the presence of H_2SO_4.[20]

7-t-Butyl-2,2,5-trimethyl-6-chromanol (Tocopherol 2). 2-*t*-Butyl-6-methylhydroquinone (4.0 g, 22 mmol) was dissolved in formic acid (99%) (50 ml) and THF (tetrahydrofuran) (5 ml), and the solution was heated to reflux. A THF (2 ml) solution of 2-methyl-3-buten-2-ol (1.9 g, 22 mmol) was added dropwise slowly during 1 h, and the refluxing was continued for an additional 3 h with stirring. The reaction mixture was poured onto crushed ice (150 g), and extracted with diethyl ether (5×25 ml). Petroleum ether (bp 40—50 °C) (25 ml) was added to the combined diethyl ether extracts and the mixture was washed with water (5×25 ml). After removal of the solvent, the residue was dissolved in methanol (75 ml), 1 ml of concd HCl was added, and the solution was refluxed for 20 min to hydrolyze formate of **2** produced. The methanol was then evaporated, and the residue was taken up in diethyl ether (100 ml), washed with $NaHCO_3$ solution and with water, and the solution was dried over anhydrous sodium sulfate. The solvent was evaporated, and the residual oil was extracted three times with hot petroleum ether (bp 50—60 °C) (3×100 ml). After removal of the solvent, the oily solids obtained were recrystallized twice from benzene, giving white crystals (1.5 g). Mp 145.0—147.0 °C. Found: C, 77.39; H, 9.93%. Calcd for $C_{16}H_{24}O_2$: C, 77.38; H, 9.74%. UV spectrum (ethanol) λ_{max}=292 nm, log ε=3.55. NMR spectrum δ=1.29 ppm (6H, s, 2-CH_3), 1.37 (9H, s, 7-*t*-Bu), 1.77 (2H, t, 3-CH_2, *J*=6.7 Hz), 2.10 (3H, s, 5-CH_3), 2.60 (2H, t, 4-CH_2, *J*=6.7 Hz), 4.27 (1H, s, 6-OH), 6.54 (1H, s, 8-H); δ in $CDCl_3$ with TMS as an internal standard.

5,7-Diisopropyl-2,2-dimethyl-6-chromanol (Tocopherol 3). Tocopherol **3** was prepared from 2,6-diisopropylhydroquinone (4.0 g, 21 mmol) and 2-methyl-3-buten-2-ol (1.8 g, 21 mmol) in 50 ml of formic acid (99%) and 7 ml of THF, following a method similar to that used with tocopherol **2**. After hydrolysis of the formate of **3** and diethyl ether extraction, the diethyl ether was evaporated and the crude product was extracted several times with petroleum ether to remove the unreacted 2,6-diisopropylhydroquinone. After removal of the petroleum ether, a viscous oil remained. The residue was twice chromatographed on 50 g of silica gel with benzene as the eluting agent. The subsequent removal of the benzene from **3** solution left a slightly brownish oil; this was dissolved in diethyl ether (5 ml) and heated at 60 °C for 2 h under a vacuum (5×10^{-3} Torr (1 Torr≈133.322 Pa)) in order to completely remove the benzene solvent included in the crystal. Viscous oil (2.2 g). Found: C, 77.67; H, 10.26%. Calcd for $C_{17}H_{26}O_2$: C, 77.82; H, 9.99%. UV spectrum (ethanol) λ_{max}=295 nm, log ε=3.57. NMR spectrum δ=1.20 (6H, d, 5- or 7-$CH(CH_3)_2$, *J*=7.0 Hz), 1.28 (6H, s, 2-CH_3), 1.34 (6H, d, 5- or 7-$CH(CH_3)_2$, *J*=7.0 Hz), 1.73 (2H, t, 3-CH_2, *J*=6.6 Hz), 2.68 (2H, t, 4-CH_2 *J*=6.6 Hz), 2.64—3.46 (2H, m, 5- and 7-$CH(CH_3)_2$), 4.28 (1H, s, 6-OH), 6.48 (1H, s, 8-H); δ in $CDCl_3$ with TMS as an internal standard).

7-t-Butyl-2,2-dimethyl-6-chromanol (Tocopherol 1). Method A: To 1.0 g (5.6 mmol) of 2,2-dimethyl-6-chromanol (tocol model) in 13 ml of benzene, 5 drops of concd H_2SO_4 were added, and isobutene (6.0 g, 0.107 mol) was introduced for 3 h under stirring at 50 °C.[20] The reaction mixture was washed with water, and dried over anhydrous sodium sulfate. After removal of the benzene, the solids remained were recrystallized first from ligroin (bp 75—90 °C), and then from ethanol, giving white crystals (0.3 g). Mp 184.0—185.0 °C. Found: C, 76.70; H, 9.49%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%. UV spectrum (ethanol) λ_{max}=226 nm, log ε=3.63, λ_{sh}=230 nm, log ε=3.59, λ_{max}=298 nm, log ε=3.65. NMR spectrum δ=1.25 (6H, s, 2-CH_3), 1.29 (9H, s, 7-*t*-Bu), 1.74 (2H, t, 3-CH_2, *J*=6.7 Hz), 2.65 (2H, t,4-CH_2, *J*=6.7 Hz), 4.48 (1H, s, 6-OH), 6.38 (1H, s, 5- or 8-H), 6.70 (1H, s, 5- or 8-H); δ in $CDCl_3$ with TMS as an internal standard.

7-t-Butyl-2,2-dimethyl-6-chromanol (Tocopherol 1). Method B: Tocopherol **1** was prepared from 2-*t*-butylhydroquinone (3.7 g, 22 mmol) and 2-methyl-3-buten-2-ol (1.9 g, 22 mmol) in 50 ml of formic acid (99%) and 7 ml of THF, following a method similar to that used with **2**. The product was extracted and the formates were hydrolyzed as before. The oily residue obtained was chromatographed on 50 g of silica-gel with ether–petroleum ether (1:5) as the eluting agent. After removal of the solvent, the oily crystals remained were washed with petroleum ether, and recrystallized from ligroin, giving white crystals (0.5 g). Mp 183.0—185.0 °C. The ultraviolet and NMR spectra of the compound were shown to be identical with the material prepared by method A.

Results and Discussion

As has been described in our previous paper, the oxidation product of the α-, β-, γ-, δ-tocopherols, tocol and their model compounds with PbO_2 in toluene gives well-resolved hyperfine patterns, and the spectra were assigned to the primary tocopheroxyl-type radicals formed from the parent tocopherols by abstraction of a phenolic hydrogen atom.[8]

The tocopherol **1** was similarly oxidized with PbO_2 in toluene under vacuum. The ESR spectrum of this solution at room temperature is shown in Fig. 2a. The spectrum can be reconstracted with three groups of 1, 2 and 1 equivalent protons, showing three different hyperfine couplings 5.91, 1.22, and 1.04 G (1 G=10^{-4} T), respectively. These couplings will be assigned to a ring proton at C-5 (a_5^H=5.91 G), two equivalently interacting methylene protons at C-4 ($a_4^{CH_2}$=1.22 G), and a ring proton at C-8 (a_8^H=1.04 G), taking the analysis of α-, β-, γ-, and δ-tocopheroxyls into account. No interaction was observed for the methylene protons at C-3 and the *t*-butyl protons at C-7.

Similarly, the toluene solution ESR spectrum of the tocopheroxyl **2** radical has been measured (see Fig. 2b). The spectrum at 20 °C can be easily analyzed, giving three different hyperfine couplings, $a_5^{CH_3}$= 6.05 G, $a_4^{CH_2}$=1.55 G, and a_8^H=0.72 G.

The ESR spectrum of the tocopheroxyl **3** measured at 20°C is given in Fig. 2c. The spectrum can be reconstructed with four groups of 1, 2, 1, and 1 equivalent protons, showing four different hyperfine splittings (2.72, 1.39, 0.75, and 0.65 G), respectively. The assignment of the hyperfine splittings has been performed by a comparison of experimentally obtained hyperfine couplings with reported ones for α-, β-, γ-, and δ-tocopheroxyls[8] and 2,6-diisopropyl-4-methoxyphenoxyl radical.[17] The tentative assignments are as follows: a_7^{CH}=2.72 G, $a_4^{CH_2}$=1.39 G, a_8^{H}=0.75 G, and a_5^{CH}=0.65 G.

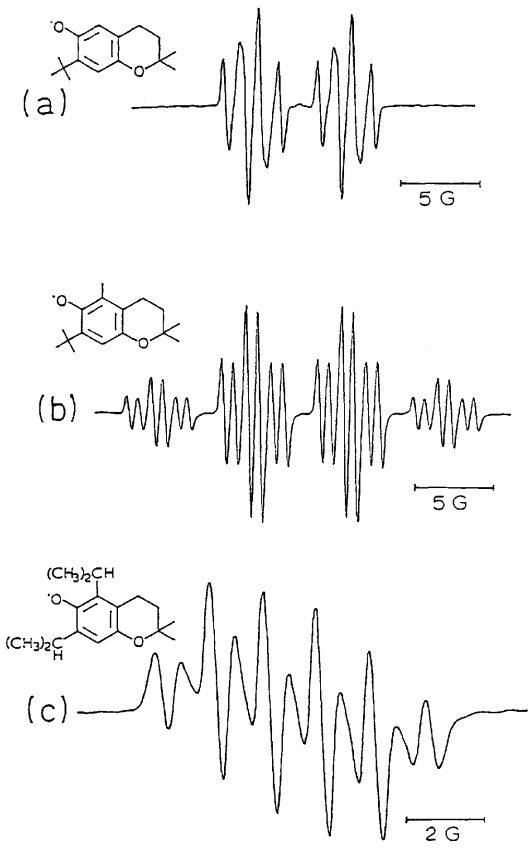

Fig. 2. ESR spectra of (a) tocopheroxyl **1**, (b) tocopheroxyl **2**, and (c) tocopheroxyl **3** in toluene at 20°C.

All the hyperfine couplings and g_{iso}-values obtained for these new tocopheroxyl model radicals are summarized in Table 1, together with those of α-tocopheroxyl model.[7]

The experimental values of spin densities (ρ_i^π) were estimated using the relations, $a_i^H=27\rho_i^\pi$, $a_i^{CH_3}=27\rho_i^\pi$, and $a_4^{CH_2}=54\cos^2 30°\times\rho_{4a}^\pi$, as performed for α-, β-, γ-, and δ-tocopheroxyl radicals.[7,8] All the experimental spin densities (ρ_i^π) calculated from the ESR hyperfine couplings are summarized in Table 1.

As is clear from the results listed in Table 1, unpaired spin density at C-5 position is similar to each other in these tocopheroxyl radicals. On the other hand, unpaired spin densities at C-8 position in **1**, **2**, and **3** are 8% higher, 25% lower, and 22% lower than that at C-8 position in α-tocopheroxyl model, respectively. Similarly, the unpaired spin densities at C-4a position are different each other in these tocopheroxyls. The result suggests that alkyl-substitution effect is considerable for the unpaired spin density at meta carbon atoms (C-4a and C-8 positions) with small negative spin densities. However, it is not clear at present how the above differences in the electronic structure of these tocopheroxyls relate to the antioxidant activity of tocopherols.

In order to obtain the information on the radical stability of these tocopheroxyls, radical decay measurements were performed on tocopheroxyls **1**, **2**, **3**, and α-tocopheroxyl model in toluene. Shown in Fig. 3 are typical plots of the ESR signal intensity as a function of time for the tocopheroxyls at 20°C. As it is clear from the results shown in Fig. 3, the order of stability, as measured by the intensities of the ESR signals, was tocopheroxyl **3**, **2**, and α-tocopheroxyl model. Especially, tocopheroxyl **3** is very stable and the ESR signal

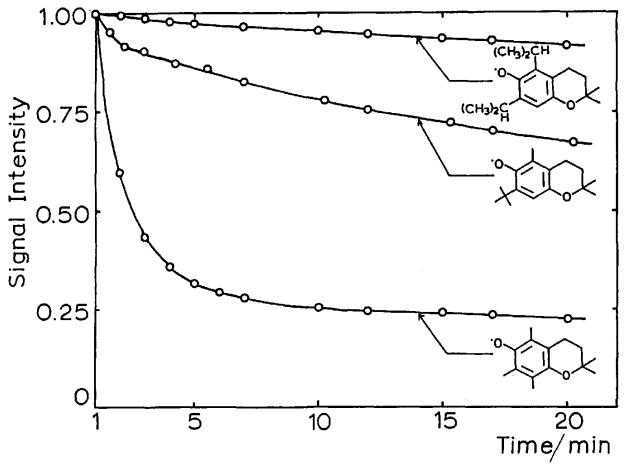

Fig. 3. Plots of the ESR signal intensity of tocopheroxyl **2**, tocopheroxyl **3**, and α-tocopheroxyl model at 20°C as a function of time.

intensity decreased to about half of the initial intensity after 20 h, because **3** has large isopropyl groups at both C-5 and C-7 positions. On the other hand, tocopheroxyl **1** has no alkyl substituent at C-5 position which is the most reactive site of the tocopheroxyl, and thus showed fast radical decay.

As described in a previous section, the relative radical stability of α-, β-, γ-, and δ-tocopheroxyls[8] is in agreement with *in vivo* and *in vitro* tests of their relative antioxidant activities which yield: α->β->γ->δ-tocopherol.[3,11-13] The result of the present radical decay measurement shows that tocopheroxyls **2** and **3** are more stable than α-tocopheroxyl. Therefore, we can expect that tocopherols **2** and **3** have higher antioxidant activity than α-tocopherol. Measurements of *in vitro* antioxidant activity of these tocopherols are now in progress.

We are very grateful to Professor Kenji Fukuzawa for his valuable discussions and suggestions. We also wish to thank Mr. Nobuyuki Kuwano and Miss Chie Morimoto for their help in the preparation of tocopherol **1**.

Copper(II)-Poly(L-histidine) as an Enzyme Model for L-Ascorbate Oxidase

Jun-ichi UEDA and Akira HANAKI*
National Institute of Radiological Sciences, 4-9-1 Anagawa, Chiba 260
(Received June 13, 1984)

The autoxidation catalyzed by copper(II)-poly(L-histidine) was studied by a rapid-mixing spectrophotometric method. The reaction obeys Michaelis-Menten kinetics. The double reciprocal plots of the velocity against the concentrations, *i.e.* the Lineweaver-Burk plots, of ascorbate and of oxygen gave a straight line. A kinetic analysis of the Lineweaver-Burk plot of the reaction reveals that the autoxidation of ascorbate by Cu(II)-PLH proceeds a so-called Ping-Pong mechanism. Copper(II) ion associates with PLH. The rate of ascorbate autoxidation appeared to depend on the concentration of copper(II) ion in the PLH phase, which is designated as the average binding number. The copper(II) ion concentrated in the PLH phase is highly reactive and is likely to be perturbed by the addition of inert electrolytes. The labile copper(II) ion, which is concentrated in the polymer phase, may be the catalytically active species.

The copper-catalyzed autoxidation of ascorbate has been widely studied as a model of the enzyme reaction.[1,2] The catalytic activity of copper(II) ion is substantially dependent on the nature of the ligand and the coordination environment around the metal ion. Chloride ion was found to induce an increase in the catalytic activity of the copper(II) ion,[3] while ethylenediaminetetraacetic acid[4] or 1,10-phenanthroline[5] inhibited the oxidation. Of much interest is that the copper(II) complex of poly(L-histidine) (Cu(II)-PLH) shows a higher catalytic activity than copper(II) ions in their aqua or amino acidato complexes.[6] On the other hand, other cationic poly(amino acid)s, such as poly(L-lysine) and poly(L-arginine), exhibited little effect on the acceleration of the reaction.[4] The specific effect of PLH on the reaction, which is abolished in the presence of moderate concentration of inert electrolyte, is interpreted by the electrostatic effect of the polyelectrolyte on the concentration of the substrate involved in the close vicinity of the bound copper(II) ion.[6]

We consider that PLH participates not only in the concentration of the substrate by the electrostatic effect in the vicinity of the catalytically active site, but also in the modification of catalytic activity of copper(II) ion by the Cu(II)-PLH interaction. The purpose of this study is to examine how the reaction mechanism of autoxidation and the catalytic activity of copper(II) ions are altered in the presence of PLH.

Experimental

Materials. PLH was a product of Sigma Chemical Co. (lot 98c-5026, degree of polymerization 58, approximate molecular weight based on viscosity measurement 8000). The polymer dissolved in 0.01 mol dm^{-3} acetic acid was dialyzed against doubly distilled water and then lyophylized. L-Ascorbic acid, copper(II) perchlorate, and acetic acid were reagent grade chemicals, which were commercially available, and used without further purification. A stock solution of copper(II) perchlorate dissolved in doubly distilled water was standardized by the conventional complexometric titration with EDTA. The copper(II) solution was diluted by acetate buffer to an appropriate concentration. The ascorbic acid solution was freshly prepared just before kinetic runs.

Kinetic Procedure. The oxidation of ascorbate was conducted at 25 °C in a quartz flow-cell by using a rapid-mixing technique with a Union MX-7 mixing apparatus. Routinely, the reaction was carried out in 0.02 mol dm^{-3} acetate buffer and under 100% oxygen. The solutions of copper(II) ion and ascorbate were saturated with pure oxygen or nitrogen-oxygen mixture by bubbling prior to the kinetic run. The concentration of oxygen dissolved in the medium was determined electrometrically with a Beckman Fieldlab oxygen analyzer, which had been calibrated against air-saturated water. The reaction was started by mixing rapidly both the reactants. After the start of the reaction, the decrease of ascorbate concentration was recorded spectrophotometrically at 260nm with a Union 401 spectrophotometer. In the kinetic experiment, initial rates were determined at pH 3.6, 4.0, and 4.4 by a graphical method. The pH value of the solution was measured on a TOA DENPA HM-5A pH meter.

Equilibrium Dialysis. Equilibrium dialysis was performed according to the method of Yamaoka *et al.*[7] A 4ml plastic dialysis cell which was seperated to two chambers by a Visking cellulose membrane was used. In one chamber(A) was contained 2ml of copper(II) solution containing various amounts of PLH, and in another (B) 2ml of copper(II) solution. The initial concentrations of copper(II) in both chambers are set to be equal. The dialysis cell was shaken at room temperature for 18h to reach an equilibrium and then the concentration of copper(II) in the chamber(B) was determined by atomic absorption spectrophotometry with a HITACHI 170-70 Zeeman spectrometer. Since copper(II) adsorbed on the cellulose membrane is very small, total amount of copper(II) in the cell is considered to be constant. If PLH has an ability to bind with copper(II) ion, the copper(II) ion in the chamber (B) diffuses across the chamber (A). Then, the concentration of copper(II) increases in the chamber (A), in which both free and PLH-bound copper(II) ions are contained. Under the equilibrium condition, the concentration of free copper(II) ion, $[Cu^{2+}]$, is equal in both chambers. The difference of the copper(II) concentration between the initial and equilibrated states corresponds to the quantity of the PLH-bound copper(II). The equation describing those relations is shown in Eq. 1.

$$[Cu^{2+}]_{bound} = \{[Cu^{2+}]_o - [Cu^{2+}]\} \times \{(V_1+V_2)/V_1\}, \quad (1)$$

where $[Cu^{2+}]_{bound}$ and $[Cu^{2+}]_o$ represent the concentration of

PLH-bound copper(II) ion in the chamber(A) and the initial concentration of copper(II) ion, and V_1 and V_2 are the volumes of the solutions in the chambers(A) and (B), respectively. The concentration of bound copper(II) ion in the polymer phase constructing by PLH, which is usually termed as the average binding number, $\bar{\nu}$, is given by Eq. 2.

$$\bar{\nu} = [Cu^{2+}]_{bound}/[PLH]_{total} \quad (2)$$

Results

1) Effect of PLH. The copper-catalyzed autoxidation of ascorbate was enhanced by the addition of PLH. In Table 1 is summarized the rate of oxidation at various concentrations of ascorbate. Obviously, the rate was observed to increase at least fivefold by the addition of 5 mg dm^{-3} PLH over the range of 0.5—10×10^{-5} mol dm^{-3} ascorbate. The reaction obeys the Michaelis-Menten mechanism. In the absence of PLH, the rate increased linearly with an increase of the ascorbate concentration.

The catalytic activity of copper(II) ion depends closely on the concentration of PLH added. Though PLH itself does not possess the catalytic activity, it enhances the autoxidation of ascorbate probably by complexing with copper(II) ion. When the rate is plotted against the amounts of PLH added, the rate profile displays a bell-shaped curve with the maximum varied depending on the pH of the medium. Some examples are shown in Fig. 1, where the total concentration of copper(II) ion is fixed at constant.

2) Effect of pH. The rate of the autoxidation varied depending on pH as shown in Fig. 2. The rate of oxidation catalyzed by free copper(II) ion increased with pH throughout the range measured, whereas the Cu(II)-PLH-catalyzed oxidation showed a different behavior. The pH-rate profile displayed a bell-shaped curve with a maximum at pH 4.3.

3) Effect of Varying Concentrations of Ascorbate. In the copper-catalyzed autoxidation, the double reciprocal plot of the rate against the ascorbate concentration, *i.e.* Lineweaver-Burk plot, gives a straight line. The

families of straight lines of those double reciprocal plots obtained by changing the concentrations of oxygen intersect at a point on the abscissa as shown in Fig. 3A. The intercepts at the ordinate and at the abscissa correspond respectively to the reciprocals of the apparent maximal velocity, V'_{max}, and of the half saturation concentration of ascorbate, $K_{0.5}$, for the reaction. The value of V'_{max} and $K_{0.5}$ at 5×10^{-5} mol dm^{-3} ascorbic acid are shown in Table 2. On the other hand, in the Cu(II)-PLH-catalyzed oxidation, the double reciprocal plot of the rate against the ascorbate concentration at a fixed oxygen concentration gives straight line as shown in Fig. 3B. A series of the double reciprocal plots for the various concentrations of oxygen appears to be parallel. V'_{max} and $K_{0.5}$ at 5×10^{-5} mol dm^{-3} ascorbic acid are given in Table 2.

4) Effect of Varying Concentrations of Oxygen. Both the rates of the copper(II)- and Cu(II)-PLH-

Oxygen	12.0	5.3	3.2	0.4

[Ascorbate]=5×10^{-5} mol dm^{-3}, [Oxygen]=1.3×10^{-3} mol dm^{-3}, $[Cu^{2+}]=6\times10^{-6}$ mol dm^{-3}, [PLH]=5 mg dm^{-3}, pH 4.0 (0.02 mol dm^{-3} acetate buffer).

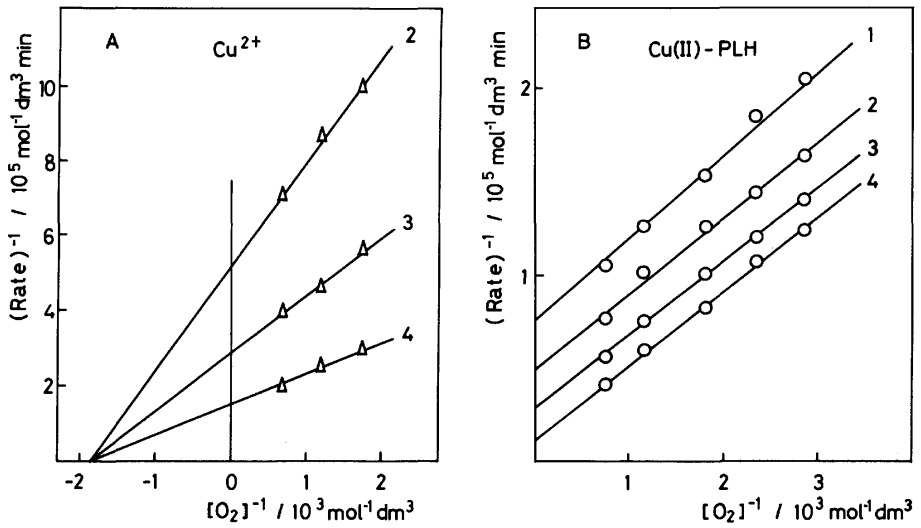

Fig. 4. Double reciprocal plot of the rate against the concentration of oxygen.
$[Cu^{2+}]_0=6.0\times10^{-6}$ mol dm^{-3}, [PLH]=5 mg dm^{-3}, [Ascorbate]=(1) 1.5, (2) 2.5, (3) 5.0, and (4) 10×10^{-4} mol dm^{-3}, pH 4.0.

catalyzed oxidation depended on the concentration of oxygen. In the copper(II)-catalyzed autoxidation, the families of the double reciprocal plots obtained by changing the concentrations of ascorbate intersect at a point on the abscissa as shown in Fig. 4A. The value of V'_{max} and $K_{0.5}$ at 1.3×10^{-3} mol dm^{-3} oxygen are shown in Table 2. In the Cu(II)-PLH-catalyzed reaction, a series of the double reciprocal plots for the various concentrations of ascorbate appears to be parallel as shown in Fig. 4B. V'_{max} and $K_{0.5}$ at 1.3×10^{-3} mol dm^{-3} oxygen are shown in Table 2. The presence of parallel Lineweaver-Burk plots for various concentrations of another reactant indicates a possibility that the reaction proceeds by a Ping-Pong mechanism[8] as discussed later.

5) Effect of Anion. Inert electrolyte such as acetate ion modified the catalytic activity. The effect of anion at various concentrations on the rate is shown in Fig. 5. The effect of anion is shown to vary depending on the concentration of PLH-bound copper(II) and pH. At pH 4.4, the addition of increasing amounts of acetate ion brings a rapid reduction in the rate at 1.1 mmol Cu/g PLH, while a slow reduction at 0.97 mmol Cu/g PLH. These results indicate that the highly active Cu(II)-PLH complex which contains more than 1.0 mmol Cu/g PLH is apt to undergo strucural perturbation by inert electrolyte. At pH 4.0, such distinct effect by anion was not shown.

Discussion

1) Reaction Mechanism. The presence of PLH enhances remarkably the catalytic activity of copper(II) ion and alters the mechanism of the reaction. In the copper(II)-catalyzed autoxidation, a series of the Lineweaver-Burk plots for the various concentrations of ascorbate or oxygen intersect on the abscissa as shown in Figs. 3A and 4A. In the autoxidation catalyzed by Cu(II)-PLH, on the contrary, a series of the Lineweaver-Burk plots was parallel. Parallel Lineweaver-Burk plots observed for various concentrations of another reactant, which are obtained in the reaction by several oxidase such as ascorbate oxidase,[9] are explained by the Ping-Pong mechanism. In the Ping-Pong mechanism, the oxidation of the substrate by the catalyst (Eq. 3) and the reoxidation of the catalyst (Eq. 4) proceed alternatively.

$$S + Cu(II)^* \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Cu(II)^*\text{-}S \xrightarrow{k_2} Cu(I)^* + P, \quad (3)$$

$$Cu(I)^* + O_2 \xrightarrow{k_3} Cu(II)^* + O_2^-, \quad (4)$$

where Cu(II)* and Cu(I)* stand for the oxidized and reduced forms of the catalyst, respectively. S and P stand for the substrate and the product, respectively. The values of k are rate constants. O_2^- produced is probably either dismuted to O_2 and H_2O_2 or reduced to H_2O_2. The mechanism for Cu(II)-PLH-catalyzed oxidation resembles kinetically that of the enzyme reaction.

The steady state rate equation for this mechanism is

$$V_{max}/v = 1 + K_{0.5}/[S] + k_2/k_3 \times 1/[O_2], \quad (5)$$

where $K_{0.5}$ represents the Michaelis constant, *i.e.* the half saturation concentration of ascorbate, of Eq. 3. From the plot of $1/v$, where v represents the apparent maximal velocity of ascorbate oxidation at various oxygen concentrations, against $1/[O_2]$, it is possible to obtain the true maximal velocity (V_{max}) at infinite concentrations of ascorbate and oxygen; V_{max} was obtained as 1.7×10^{-4} mol dm^{-3}min^{-1}.

2) Cu(II)-PLH Binding and the Catalytic Activity. Cu(II)-PLH appears to be an excellent reaction model

for ascorbate oxidase. The binding of copper(II) ion to PLH, which is confirmed by the equilibrium dialysis experiment, seems necessary for the enhancement of the reaction. PLH is shown to bind copper(II) ion at low pH, starting at pH 3, with a maximum binding constant at pH 5.[10] The catalytically inactive poly-(amino acid)s do not associate with copper(II) ion. Therefore, the catalytic activity is expected to be related to the amount of the PLH-bound copper(II) ion, which locates in the polymer phase and is evaluated by the average binding number ($\bar{\nu}$) given by Eq. 2.

The quantity of PLH-bound copper(II), $[Cu^{2+}]_{bound}$, was obtainable from the equilibrium dialysis experiment under the same experimental conditions. The values of $\bar{\nu}$ under the same conditions as the kinetic run are shown in Table 3 along with the rate observed. In the Cu(II)-PLH system, both PLH-bound and free copper(II) ion always exist in the medium and both possess the catalytic activity. Then, the observed rate of the oxidation, V_{obsd}, may be expressed as the sum of the rates due to PLH-bound copper(II) ion, $V_{bound\,Cu}$ and due to free copper(II) ion, V_{Cu}.

$$V_{obsd} = V_{bound\,Cu} + V_{Cu}. \quad (6)$$

Since the value of V_{Cu} is linearly proportional to the concentration of free copper(II) ion, which had been examined by a separate experiment. V_{Cu} can be estimated in each kinetic run. Accordingly, the rate of oxidation by Cu(II)-PLH, $V_{bound\,Cu}$, is obtainable by Eq. 6. Under the experimental conditions, the total concentration of copper(II) ion is kept at constant. But, since the amounts of PLH are variable, the concentration of copper(II) ion in the polymer phase, which corresponds to $\bar{\nu}$, is variable. Therefore, the rate per the PLH-bound copper(II) ion, which is designated as k_{sp}, should be expressed by $V_{bound\,Cu}/[Cu^{2+}]_{bound}$. We tried to obtain a correlation between k_{sp} and $\bar{\nu}$. If PLH acts merely as chelating agent for copper(II) ion, k_{sp} is expected to be a constant irrespective of the variation of $\bar{\nu}$. However, as shown in Fig. 6, the plots of k_{sp} against $\bar{\nu}$ at pH 4.0 and 4.4 indicate that the specific rate, k_{sp}, increases with $\bar{\nu}$, but not proportional to $\bar{\nu}$. As shown above, the binding number of copper(II) ion per PLH corresponds to the concentration of copper(II) ion located in the polymer matrix of PLH. Ascorbate is also suggested to be concentrated in the polymer phase.[6] Then, the encounter of the copper(II) ion in PLH phase with ascorbate anion may increase with an increase of $\bar{\nu}$. Under the conditions at $\bar{\nu}<1.0$ mmol Cu(II)/g PLH, k_{sp} is larger at pH 4.0 than at pH 4.4. This may be explained by the pH dependence of the ligand exchange rate between copper(II) ion and PLH. A ^{1}H NMR study of the Cu(II)-PLH interaction indicates that the ligand exchange of copper(II) ion in the PLH matrix occurs rapidly under weakly acidic conditions, reducing with increase of pH over pH 3.5.[11] It is suggested that the Cu(II)-PLH binding is rather labile at pH 4.0 and rather tight at pH 4.4. Hence, labile copper(II) ion in PLH phase is assumed

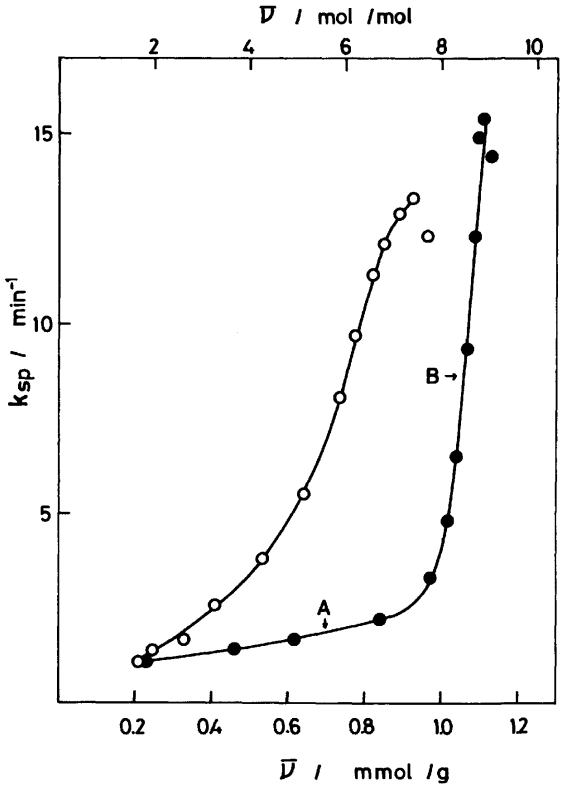

Fig. 6. Relation of Cu(II)-PLH binding and catalytic activity.
pH=4.0(○) and 4.4(●).

to be catalytically active. Of much interest is that the plot at pH 4.4 appears to be composed of two phases, which can be distinguished clearly and is designated A and B, respectively. k_{sp} begins to increase drastically from $\bar{\nu}$=1.0 mmol Cu/g PLH. Provided that the apparent molecular weight of the PLH used is 8000, 1.0 mmol Cu/g PLH corresponds to 8 mol Cu/mol PLH. The PLH used can bind maximally with 9 molar copper(II) at pH 4.4. The mode of interaction of copper(II) ion with PLH also changes dramatically from $\bar{\nu}$=1.0 mmol Cu/g PLH, which is deduced from the effect of electrolytes on the rate of oxidation. As shown in Fig. 5, at $\bar{\nu}$=1.1 mmol Cu/g PLH, where the bound copper(II) ion is in the phase (B), the rate decreased rapidly by the addition of acetate anion. In the phase (A) where $\bar{\nu}$ is 0.97 mmol Cu/g PLH, on the contrary, the rate decreased a little by the addition of the electrolyte. The copper(II) ion in the phase (B) interacts very weakly with PLH, being easily perturbed by electrolyte as compared with the copper(II) ion in the phase (A). These findings support that the bound copper(II) ion which is labile in the matrix of PLH, is a highly catalytic active species.

In conclusion, we suggest that specific effect of PLH on the ascorbate oxidation is not only the concentration of the copper(II) ion and/or ascorbate in the matrix of PLH, but also the formation of a labile and catalytically active copper(II) ion.

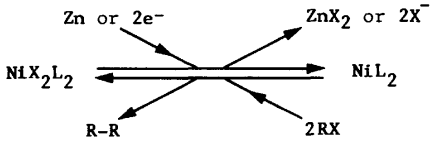
(Received June 13, 1984)

The catalytic activity of nickel(0) generated *in situ* from nickel(II) salt was examined in a dehalogenative coupling of alkenyl halides with zinc powder. The reaction of alkenyl bromides took place provided that potassium iodide was present to assist the reduction of nickel(II) with zinc powder, and also to convert the alkenyl bromides to the corresponding alkenyl iodides. A speculative view concerning the disproportionation step is advanced in an attempt to explain the unique stereochemistry observed.

It is well known that a variety of transition-metal complexes react readily with such organic halides as aryl halides and alkenyl halides to afford dehalogenative coupling products, biaryls, and conjugated alkadienes.[1] The excellent reactivities of nickel(0) complexes to the Ullmann-type coupling have previously been proved, but the synthetic usefulness of the nickel-assisted reaction has been limited since stoichiometric amounts of unstable complexes are required to perform the reaction.[2] Recently, however, a catalytic procedure has been devised in which the dehalogenative coupling of aryl halides proceeds by the utilization of chemical reducing agents like zinc powder or electrochemically in the presence of a small amount of a stable nickel(II)-phosphine complex as a catalyst.[3]



L=PPh_3,[3] PR_3,[5] none[4]

R=Aryl, Alkenyl, Heteroaromatic

In a previous paper, we reported that a simple, phosphine-free nickel(II) compound like nickel(II) chloride or bromide is more effective for the dehalogenative coupling of aryl halides with zinc powder than the nickel(II)-phosphine complex.[4] In this paper, the simple nickel(II) catalyst is applied to a dehalogenative coupling of alkenyl halides with zinc powder hoping thus to achieve a convenient method of synthesizing conjugated dienes from alkenyl halides, but also to obtain insight into the mechanism of this kind of coupling reaction through the product analysis.[6]

Results and Discussion

Reaction Conditions. The reaction of 2-bromo-1,1-diphenylethene (**1**) with zinc powder in the presence of nickel(II) salt was examined under various conditions (Eq. 1). The results are listed in Table 1. It is noteworthy that the coupling product, 1,1,4,4-tetraphen-

$$\underset{\mathbf{1}}{2\,Ph_2C{=}CHBr} + Zn \xrightarrow{NiX_2} \underset{\mathbf{2}}{Ph_2C{=}CH{-}CH{=}CPh_2} + ZnX_2 \quad (1)$$

a) In the presence of 0.25 mmol of **1** and 0.25 mmol of Zn in 0.5 cm^3 of the solvent at 40 °C under nitrogen. b) Crystalline $NiCl_2$ (0.10 mmol) or 0.17 mol dm^{-3}-DMF solution of $NiBr_2$ (0.01 mmol) was used. c) Yields based on using **1** were determined by GLC using internal standards. d) Molar ratio. e) *N,N*-Dimethylformamide. f) Tetrahydrofuran. g) Run at 20 °C. h) Run using 0.15 mmol of Zn.

yl-1,3-butadiene (**2**), was obtained only in the runs where potassium iodide was present in the reaction mixture (Runs 1 and 9). This fact probably suggests that the metallic nickel generated *in situ* acted as an active catalyst, since the presence of potassium iodide is critical to reduce a nickel(II) salt with zinc powder under the conditions examined.[4] Thus, in the presence of catalytic amounts (0.04—0.4 molar equivalents to **1**) of nickel(II) salt and potassium iodide (2.0 molar equivalents to **1**), the coupling reaction proceeded smoothly using a stoichiometric amount of or a little more (0.6—1.0 molar equivalents to **1**) of zinc powder in such a solvent as hexamethylphosphoric triamide (HMPA), *N*-methyl-2-pyrrolidone (NMP) or 1,1,3,3-tetramethylurea (TMU) under mild conditions (20—40 °C) to afford **2** in a high yield. Thiourea (TU) or 1,1,3,3-tetramethylthiourea (TMTU), which assists the reduction of nickel(II) salt with zinc powder in the same manner as potassium iodide,[7] accelerated the reaction (Runs 1 and 11—13 and Table 2).

The results from various alkenyl halides are listed in Table 2. All the alkenyl bromides and iodides examined gave coupling products in fair to excellent yields, whereas alkenyl chlorides gave such products in extremely poor yields (Runs 16 and 17). No substitution pattern (α-, or β-substitution, α,β-, or β,β'-disubstitution, or functional group) significantly influenced the total reactivities. Unfortunately, the coupling products from β-substituted alkenyl halides always consisted of geometrical isomers (Runs 22—29). However, the major products were the desired ones, which were, in certain cases, obtained in geometrically pure forms from such mixtures after a simple procedure of purification (Runs 25, 26, and 28).[8]

Although readily available alkenyl bromides were the substrates of choice in most experiments, they might not afford coupling products directly. That is, under the present conditions, alkenyl bromides are known to react readily with iodide ions to yield the corresponding alkenyl iodides,[9] and, in fact, interrupted experiments showed that alkenyl bromides turned rapidly to alkenyl iodides (Run 35 in Table 3), and subsequently to coupling products at diminished rates (Runs 34 and 1). Furthermore, the reactions of alkenyl iodides did not necessarily need the presence of potsssium iodide in the reaction mixture if TU or TMTU was present in the place of potassium iodide (Runs 39 and 43).

a) In the presence of 0.25 mmol of alkenyl halide in 0.5 cm^3 of HMPA at 40 °C (Runs 34—42) or at 25 °C (Run 43) under nitrogen. The molar ratios of the components were as follows: RX/$NiCl_2$/Zn/KI(when used)/TMTU(Runs 36, 38, and 39) or TU(Runs 41 and 43)=1.0/0.4/1.0/2.0/0.04. b) Yields were determined by GLC using internal standards. c) The conversion was 96%. The yield of 2-iodo-1,1-diphenylethene was 62%. d) The conversion was 78%. The yield of 2-iodo-1,1-diphenylethene was 76%. e) The conversion was 6%. f) The conversion was 3%. g) Mixture of geometrical isomers.

This result is in marked contrast with that of the reaction of alkenyl bromides, where potassium iodide could not be replaced by TU or TMTU (Runs 36 and 41). These facts probably suggest that alkenyl iodides are reactive toward the coupling reaction, while alkenyl bromides are essentially not reactive under the conditions examined.

Stereochemistry. As is shown in Table 2, the reaction took place with some isomerization at the double bond. Although the low stereoselectivity considerably restricted the synthetic utility, the unique stereochemistry observed obviously ruled out the random scrambling of the configuration at sp^2-carbon; one of the two double bonds in a produced diene invariably retained the original geometry at the double bond except for the methyl 3-haloacrylates. For example, (*Z*)-1-bromopropene afforded (*Z,Z*)-2,4-hexadiene mainly, plus (*E,Z*)-isomer as a minor product, but little of the (*E,E*)-isomer (Run 22). It is apparent that the extent of concomitant isomerization ((*E,Z*)/(*E,E*) from (*E*)-alkenyl halide or (*E,Z*)/(*Z,Z*) from (*Z*)-alkenyl halide) was affected by both the steric and electronic effects of substituents bonded to the β positions. Then, the reaction of *p*-substituted β-bromostyrene was undertaken in order to examine the electronic effect on the composition of geometrical isomers exactly. Since the (*E,Z*)-isomer tended to isomerize to the (*E,E*)-isomer under the present reaction conditions, the composition at zero conversion had been determined (see Experimental). The results clearly showed that the extent of the concomitant isomerization increased with the increase in the electron-withdrawing ability of the substituents (Runs 30—32).

Reaction Path. For a nickel(0) or palladium(0)-assisted dehalogenative coupling of aryl halides or alkenyl halides, sequential steps of oxidative addition (Eq. 2), disproportionation (Eq. 3), and reductive elimination (Eq. 4) had been proposed as a reaction path:[4,10,11]

$$\mathrm{Ni(0)} + \mathrm{RX} \rightleftharpoons \mathrm{R\text{-}Ni\text{-}X}, \quad (2)$$

$$\mathrm{R\text{-}Ni\text{-}X} \longrightarrow 1/2\ \mathrm{R\text{-}Ni\text{-}R} + 1/2\ \mathrm{NiX_2}, \quad (3)$$

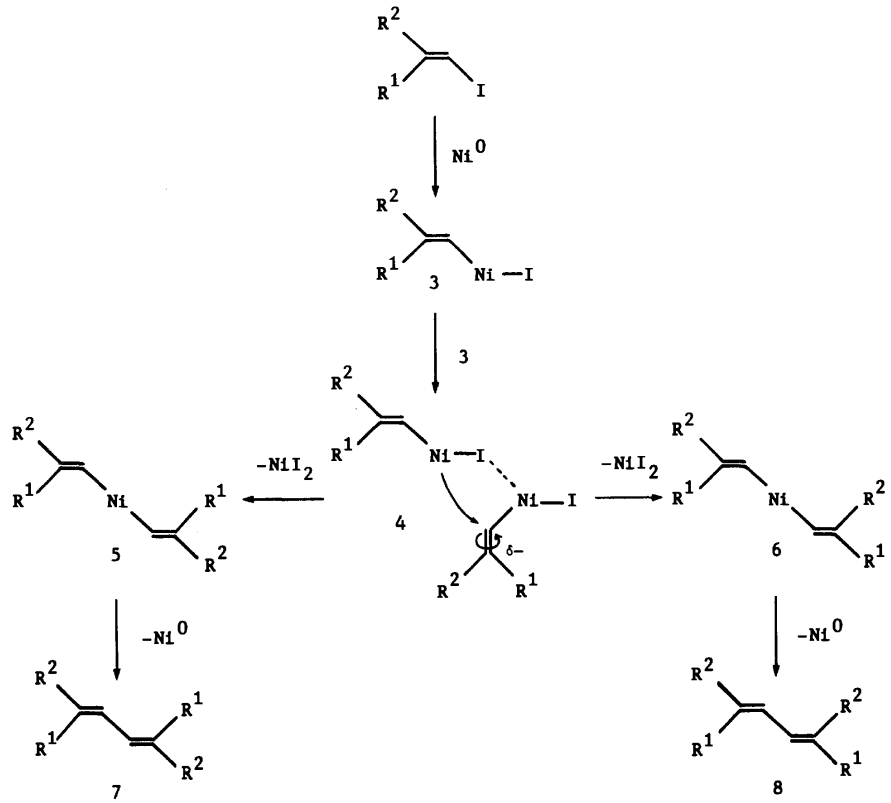
$$\mathrm{R\text{-}Ni\text{-}R} \longrightarrow 1/2\ \mathrm{R\text{-}R} + 1/2\ \mathrm{Ni(0)}. \quad (4)$$

Each step is well-known and is frequently encountered in organotransition-metal chemistry. In our reaction, RX represents alkenyl iodides, and the nickel(II) generated in Eq. 3 may react further with excess zinc powder in the presence of potassium iodide, TU, or TMTU to regenerate the nickel(0) to ensure the catalytic cycle (Eq. 5). Some comments can be

$$\mathrm{NiX_2} + \mathrm{Zn} \xrightarrow{\text{KI or TU}} \mathrm{Ni(0)} + \mathrm{ZnX_2} \quad (5)$$

made based on the obtained results.

The observed difference in reactivities between alkenyl bromides and alkenyl iodides may partly come from the difference in the bridging efficiencies of the halogen atoms. It is known that an iodide ligand can bridge two metal species far more effectively than a bromide ligand.[12] Therefore, an iodide ligand in an oxidative adduct (**3**) may bring two nickel atoms close to (**4**), and such an association should be favorable for the succeeding disproportionation.



It has been established that the oxidative addition of alkenyl halides to low-valent transition-metal complexes proceeds with a retention of the configuration of the alkenyl groups,[13] and it is also believed that reductive elimination proceeds with the retention of the configuration of alkenyl ligands.[14] Therefore, the observed specific geometrical isomerization possibly took place at a stage of disproportionation; the double-bond character of the transferred alkenyl ligand might be partly released at the same stage, and, consequently, two kinds of dialkenylnickel complexes (**5** and **6**) may be produced from **3**. Another observation, that electron-withdrawing groups attached to the double bond tended to increase the ratio of isomerized diene (**8**), possibly suggests that an anionic character appeared synchronously on the transferred alkenyl ligand as the weakening of the double bond progressed.[15] Further investigations are, however, necessary to clarify the mechanistic details of this disproportionation step.

Experimental

All the reagents were used directly as obtained commercially, unless otherwise noted. The solvents were distilled and were dried over Molecular Sieve (3A). The 2-bromo-1,1-diphenylethene,[17] 2-iodo-1,1-diphenylethene,[18] 1-bromo-2-methyl-1-propene,[19] 1-bromo-1-cycloheptene,[20] 1-bromo-1-cyclooctene,[20] 1-bromomethylenecyclohexane,[21] (*E*)-β-bromostyrene (*Z*/*E*<1/99),[22] (*Z*)-β-bromostyrene (*Z*/*E*=98/2),[23] (*E*)-*p*-methyl-β-bromostyrene (*Z*/*E*<1/99),[24] (*E*)-*p*-chloro-β-bromostyrene (*Z*/*E*<1/99),[24] methyl (*Z*)-3-bromoacrylate (*Z*/*E*>99/1),[25] and methyl (*Z*)-3-iodoacrylate (*Z*/*E*>99/1),[25] were prepared according to the procedures in the literature. A Hitachi 160 gas chromatograph was used for the GLC analysis. The peak areas were determined with a Shimadzu Chromatopac 1A. The ^{1}H NMR spectra were obtained on a JOEL PMX 60 spectrometer, using Me_4Si as the internal standard. The IR spectra were recorded on a Hitachi 260-10 spectrometer. Photoisomerizations were carried out using a Rayonet Photochemical Reactor (Soutbern New England Ultraviolet Company).

General Procedure for Homo-coupling. Preparation of 1,1,4,4-Tetraphenyl-1,3-butadiene: A mixture of 2-bromo-1,1-diphenylethene (260 mg, 1.0 mmol), nickel(II) chloride (52 mg, 0.40 mmol), zinc powder (65 mg, 1.0 mmol), potassium iodide (332 mg, 2.0 mmol), and HMPA (2 cm^3) was evacuated, flushed with nitrogen, and kept at 40 °C with stirring for 7 h. To the mixture, dilute hydrochloric acid (1 mol dm^{-3}, 6 cm^3) was then added and the organic materials were extracted with a mixture of ether (10 cm^3) and chloroform (4 cm^3), washed with two portions of aqueous sodium chloride (4 cm^3), and dried over anhydrous magnesium sulfate. The subsequent evaporation of the solvents gave a pale yellow solid, which was triturated with a small amount of hexane to leave 143 mg of 1,1,4,4-tetraphenyl-1,3-butadiene (78%). Both the NMR and IR spectra were consistent with those of an authentic sample. Mp 193—196 °C (lit,[26] 207—210 °C). Found: C, 94.00; H, 6.07%. Calcd for $C_{28}H_{22}$: C, 93.81; H, 6.19%.

2,5-Dimethyl-2,4-hexadiene: Mp 13—15 °C (lit,[27] 14.5 °C). Found: C, 86.68; H, 12.67%. Calcd for 0.9935 C_8H_{14}: C, 86.62; H, 12.73%.

1,1'-(1,2-Ethanediylidene)biscyclohexane: Mp 42—44 °C (lit,[28] 45—47 °C). Found: C, 88.47; H, 11.60%. Calcd for $C_{14}H_{22}$: C, 88.35; H, 11.65%.

1,1'-Bi(1-cycloheptenyl): Bp 110—113 °C/1.5 mmHg (1 mmHg=133.322 Pa) (lit,[29] 133 °C/10 mmHg). Found: C,

88.57; H, 11.56%. Calcd for $C_{14}H_{22}$: C, 88.35; H, 11.65%.

1,1'-Bi(1-cyclooctenyl): Mp 38 °C (lit,[30] 43 °C). Found: C, 87.73; H, 11.93%. Calcd for $C_{16}H_{26}$: C, 88.00; H, 12.00%.

Preparation of (E,E)-1,4-Bis(4-methylphenyl)-1,3-butadiene: A mixture of (*E*)-*p*-methyl-β-bromostyrene (493 mg, 2.5 mmol), nickel(II) chloride (130 mg, 1.0 mmol), zinc powder (163 mg, 2.5 mmol), potassium iodide (880 mg, 5.0 mmol), and HMPA (2.5 cm^3) was kept at 40 °C for 6 h with stirring under nitrogen. Subsequent treatment similar to that described above gave 290 mg of 1,4-bis(4-methylphenyl)-1,3-butadiene (1:5 mixture of (*E,Z*)- and (*E,E*)-isomers). Recrystallization from ethanol gave 168 mg of pure (*E,E*)-diene (57%). The absence of (*E,Z*)-diene was ascertained by means of GLC. The NMR spectrum was consistent with the previously reported one.[31] Mp 210—211 °C (lit,[32] 198 °C). IR (KBr) 994, 852, and 796 cm^{-1}. Found: C, 92.88; H, 7.45%. Calcd for $C_{14}H_{10}$: C, 92.26; H, 7.74%.

(E,E)-1,4-Bis(4-chlorophenyl)-1,3-butadiene:[33] Mp 214—215 °C. IR (KBr) 1093, 997, 855, and 801 cm^{-1}. ^1H NMR (THF-d_8) δ=6.2—7.1 (m, 4H, olefinic H), and 7.4 (s, 8H, aromatic H). Found: C, 69.89; H, 4.63%. Calcd for $C_{16}H_{12}Cl_2$: C, 69.84; H, 4.40%.

Dimethyl (Z,Z)-2,4-Hexadienedioate: Mp 70.5—72 °C (lit,[34] 73 °C). Found: C, 56.42; H, 5.87%. Calcd for $C_8H_{10}O_4$: C, 56.47; H, 5.92%.

Composition of Geometrical Isomers at Zero Conversion. The Reaction of (E)-p-Methyl-β-bromostyrene: A mixture of (*E*)-*p*-methyl-β-bromostyrene (49 mg, 0.25 mmol), nickel(II) bromide (0.059 cm^3 of 0.17 mol dm^{-3}-DMF solution, 0.01 mmol), potassium iodide (83 mg, 0.50 mmol), zinc powder (16 mg, 0.25 mmol), and HMPA (0.5 cm^3) was heated at 40 °C for 20 min. To the mixture, ether (8 cm^3) and dibenzyl ether (10 mg, internal standard) were then added. GLC analysis of the mixture showed that 0.9% of (*E,Z*)-diene and 4.5% of (*E,E*)-diene were produced. (Authentic samples of (*E,Z*)-dienes were prepared following the previously reported methods.[31,35]) In a similar mixture which had been heated for 35 min or 45 min, 3% or 5% of (*E,Z*)-diene and 16% or 28% of (*E,E*)-diene were produced. From the plot of the molar ratio of the two isomers *vs.* the total yield ((*E,Z*)/(*E,E*):yield=4.8:5.4%, 5.1:19%, 5.4:33%), the molar ratio of the two isomers at 0% was estimated to be 4.6.

Convenient Syntheses of Vitamin K and Coenzyme Q by the Coupling of Grignard Reagents with Allylic Phosphate

Shuki ARAKI, Takashi SATO, Hiroyuki MIYAGAWA, and Yasuo BUTSUGAN*
Department of Synthetic Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received July 6, 1984)

Convenient syntheses of vitamin K and coenzyme Q are described. Grignard coupling of polyprenyl diethyl phosphates with 1,4-dimethoxy-3-methyl-2-naphthylmagnesium bromide gave high yields of the polyprenylated hydroquinone dimethyl ethers regioselectively with the preservation of the stereochemistry. The precursors of coenzyme Q were similarly obtained by the coupling of 2,3,4,5-tetramethoxy-6-methylphenylmagnesium bromide and the polyprenyl phosphates. The synthesized (polyprenyl)hydroquinone dimethyl ethers are known to be oxidized to the biologically active quinones.

Regio- and stereoselective carbon–carbon bond formation at either the α- or γ-position of an allylic system is a fundamental subject in synthetic organic chemistry. A number of methods with satisfactory selectivity have been developed, some of which involve the coupling of allylic species and organometallics.[1] Recently we have reported that phosphate esters of primary allylic alcohols such as geraniol and nerol allylate a variety of Grignard reagents at the α-position with the preservation of the stereochemistry of the allylic double bond.[2] As an application of this coupling reaction, the syntheses of the biologically active quinones, vitamin K and coenzyme Q, are described in the present paper.

Vitamin K and coenzyme Q are composed of a polyprenyl chain and a naphthoquinone or a benzoquinone nucleus.[3] The synthetic methods of these quinones hitherto reported can be classified into four groups in regard to the fashion of the coupling between the nucleus and the side chain: (a) Friedel-Crafts type coupling,[4] (b) reaction of π-allylnickel complex with halohydroquinone,[5] (c) Lewis acid catalyzed coupling of (polyprenyl)stannane with quinone,[6] and (d) reaction of aryl Grignard reagent or arylcuprate(I) with polyprenyl halide.[7] The method reported in this paper is a modification of the last group, which involves the reaction of polyprenyl phosphates with the Grignard reagents of hydroquinone dimethyl ethers. The coupling proceeded regioselectively in excellent yields without loss of the stereochemistry.

Results and Discussion

To a stirred solution of 1,4-dimethoxy-3-methyl-2-naphthylmagnesium bromide (**1**) in tetrahydrofuran (THF) was added prenyl diethyl phosphate (**2a**) and the mixture was stirred overnight at room temperature. After hydrolysis and vacuum distillation, the coupling product, 1,4-dimethoxy-3-methyl-2-prenylnaphthalene (**3a**), was isolated in high yield (93%) (Table 1). As expected,[2] the coupling occurred exclusively at the α-position of the prenyl phosphate (**2a**), and the formation of the γ-attack product [1,4-dimethoxy-3-methyl-2-(1,1-dimethyl-2-propenyl)naphthalene] was not observed by glc and ^{1}H NMR analyses. In a similar way, geranyl (**2b**) and neryl diethyl phosphates (**2c**) gave the respective coupling products (**3b** and **3c**) in 80 and 86% yields, respectively. Glc showed that no *E*-*Z* isomerization occurred during the coupling. Snyder reported[7a] that the reaction of the Grignard reagent (**1**) and geranyl and neryl bromides gave **3b** and **3c**, however the yield of the *Z*-isomer (**3c**) was relatively lower (62%) than that of the *E*-isomer (**3b**) (92%). The present coupling using allylic phosphates did not show such suppression of the yield even in the reaction of the neryl phosphate (**2c**). (2*E*)- and (2*Z*)-Farnesyl derivatives were also obtained regioselectively with the preservation of the stereochemistry of the farnesyl group (confirmed by HPLC). The precursor (**3f**) of vitamin K_1 was similarly prepared from phytyl diethyl phosphate (**2f**) in 87% yield. The synthesized (polyprenyl)hydroquinone dimethyl ethers (**3a—f**) are known[7a,7c] to be demethylatively oxidized by silver(II) oxide or cerium(IV) diammonium nitrate to the respective vitamin K_2 (**4a—e**) and vitamin K_1 (**4f**).

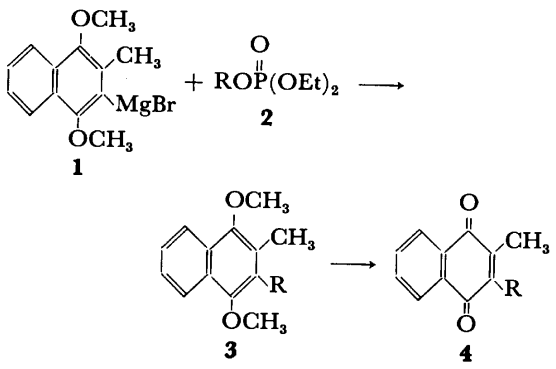

TABLE 1. YIELDS AND STEREOCHEMISTRY OF 1,4-DIMETHOXY-2-METHYL-3-POLYPRENYLNAPHTHALENES (**3a—f**)

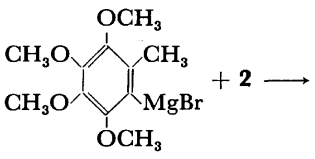
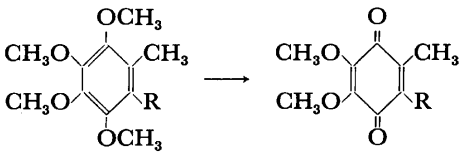
R	Yield/%	Stereochemistry at Δ^2 (*E*/*Z*)
Prenyl (**3a**)	93	—
Geranyl (**3b**)	80	10/0[a]
Neryl (**3c**)	86	0/10[a]
(2*E*)-Farnesyl (**3d**)	76	10/0[b]
(2*Z*)-Farnesyl (**3e**)	87	2/8[b,c]
Phytyl (**3f**)	87	10/0[d]

a) Determined by glc. b) Determined by HPLC. c) Due to (2*E*)-farnesol mixed in the (2*Z*)-farnesol used (*E*/*Z*=2/8). d) Determined by ^{1}H NMR (200 MHz).

The precursors (**6a—e**) of coenzyme Q were analogously prepared from 2,3,4,5-tetramethoxy-6-methylphenylmagnesium bromide (**5**) and polyprenyl diethyl phosphates (**2a—e**). The yields are listed in Table 2. Again, no detectable amounts of γ-coupling nor *E-Z* isomerization were observed. The dimethyl ethers (**6a—e**) can be demethylatively oxidized to coenzyme Q (**7a—e**).[7a,7c]



5



6 **7**

In summary, several examples of vitamin K and coenzyme Q precursors bearing a polyprenyl chain of different length and stereochemistry were synthesized. The advantages of the present method are (1) regioselectivity is very high and the isomerization of the allylic double bond is negligible, (2) the yields are excellent, (3) reaction conditions are mild, and (4) experimental operations are simple. Therefore, this method provides a convenient route for the syntheses of vitamin K and coenzyme Q.

Experimental

General. Infrared spectra were recorded on a JASCO IRA-1 spectrophotometer. ^{1}H NMR spectra were determined with a Hitachi R-24A (60 MHz) spectrometer, or with a Varian XL-200 (200 MHz) spectrometer in CCl_4 or $CDCl_3$. Chemical shifts (δ) are recorded in ppm downfield from Me_4Si. Mass spectra were measured on a Hitachi M-52 mass spectrometer, operating with an ionization energy of 20 eV. HPLC analysis was performed by using a JASCO TRI ROTAR-II with a silica-gel column (Fine Sil 20, 4.6 mm× 25 cm) eluting with hexane–chloroform (100 : 1). Glc analysis was done on a Yanaco G1800 gas chromatograph, equipped with a column packed with Apiezon Grease L on Uniport B. Elemental analysis was performed at the Elemental Analysis Center of Kyoto University. Polyprenyl diethyl phosphates (**2a—f**) were prepared from polyprenyl alcohols and diethyl phosphorochloridate according to the method for the corresponding diphenyl phosphates.[8] (2*Z*)-Farnesol (2*Z*/2*E*=8/2) was prepared by the diisobutylaluminum hydride reduction of ethyl (2*Z*)-farnesoate (2*Z*/2*E*=8/2) which was obtained by the fractional distillation of a mixture of the (2*Z*)- and (2*E*)-isomers (2*Z*/2*E*=2/8) synthesized by the Wittig-Horner reaction of geranylacetone.[9]

Grignard Coupling of 1,4-Dimethoxy-3-methyl-2-naphthylmagnesium Bromide (1) with Polyprenyl Diethyl Phosphates (2a—f). The following preparation of **3a** is a representative. The Grignard reagent, 1,4-dimethoxy-3-methyl-2-naphthylmagnesium bromide (**1**), was prepared in a conventional manner using tetrahydrofuran (THF) as a solvent. To a stirred solution of **1** (2.28 mmol) in 3 ml of THF was added a solution of prenyl diethyl phosphate (**2a**) (297 mg, 1.34 mmol) in 3 ml of THF at 0 °C. The reaction mixture was stirred overnight at room temperature and then quenched by the addition of water. The product was extracted with ether and the extracts were dried over anhydrous sodium sulfate and then concentrated. The residue was distilled (Kugelrohr) to give 1,4-dimethoxy-2-methylnaphthalene [bp 130 °C/5 Torr (1 Torr≈133.322 Pa), 177 mg] and **3a** (bp 150 °C/5 Torr, 335 mg, 93%). Higher analogs of the polyprenylated compounds (**3b—f**) were similarly prepared and purified by column chromatography on silica-gel (benzene–ether gradient).

Table 2. Yields and stereochemistry of 1,2,3,4-tetramethoxy-5-methyl-6-polyprenylbenzenes (**6a—e**)

R	Yield/%	Stereochemistry at Δ^2 (*E*/*Z*)
Prenyl (**6a**)	85	—
Geranyl (**6b**)	82	10/0[a]
Neryl (**6c**)	84	0/10[a]
(2*E*)-Farnesyl (**6d**)	70	10/0[b]
(2*Z*)-Farnesyl (**6e**)	75	2/8[b,c]

a) Determined by glc. b) Determined by ^{1}H NMR (200 MHz). c) Due to (2*E*)-farnesol mixed in the (2*Z*)-farnesol used (*E*/*Z*=2/8).

1,4-Dimethoxy-2-methyl-3-prenylnaphthalene (3a):[7c] IR (neat) 2950, 1594, 1452, 1355, 1266, 1195, 1065, 1018, 975, 775, and 712 cm^{-1}: ^{1}H NMR (CCl_4) 7.16—8.01 (m, 4H, aromatic), 5.07 (t, *J*=6 Hz, 1H, olefin), 3.81 (s, 3H, OCH_3), 3.78 (s, 3H, CH_3), 3.47 (d, *J*=6 Hz, 2H, CH_2), 2.33 (s, 3H, CH_3), 1.81 (s, 3H, CH_3), 1.70 (s, 3H, CH_3); Mass *m*/*z* 270 (M^+).

1,4-Dimethoxy-2-methyl-3-geranylnaphthalene (3b):[7a] IR (neat) 2950, 1590, 1450, 1355, 1265, 1190, 1060, 830, and 770 cm^{-1}; ^{1}H NMR (CCl_4) 7.16—8.05 (m, 4H, aromatic), 4.81—5.24 (m, 2H, olefin), 3.75 (s, 3H, OCH_3), 3.44 (d, *J*=6 Hz, 2H, CH_2), 2.26 (s, 3H, CH_3), 1.94 (m, 4H, CH_2×2), 1.75 (s, 3H, CH_3), 1.56 (s, 3H, CH_3), 1.50 (s, 3H, CH_3); Mass *m*/*z* 338 (M^+).

1,4-Dimethoxy-2-methyl-3-nerylnaphthalene (3c):[7a] IR (neat) 2950, 1600, 1460, 1360, 1270, 1200, 1070, 830, and 780 cm^{-1}; ^{1}H NMR (CCl_4) 7.12—8.04 (m, 4H, aromatic), 4.86—5.22 (m, 2H, olefin), 3.73 (s×2, 6H, OCH_3), 3.43 (d, *J*=7 Hz, 2H, CH_2), 2.26 (s, 3H, CH_3), 2.17 (m, 4H, CH_2×2), 1.58—1.71 (m, 9H, CH_3×3); Mass *m*/*z* 338 (M^+).

1,4-Dimethoxy-2-methyl-3-[(2E)-farnesyl]naphthalene (3d): IR (neat) 2945, 1592, 1456, 1355, 1268, 1066, and 770 cm^{-1}; ^{1}H NMR ($CDCl_3$) 8.10 (m, 2H, aromatic), 7.50 (m, 2H, aromatic), 5.11 (m, 3H, olefin), 3.89 (s, 3H, OCH_3), 3.87 (s, 3H, OCH_3), 3.59 (d, *J*=6 Hz, 2H, CH_2), 2.39 (s, 3H, CH_3), 2.06 (m, 8H, CH_2×4), 1.84 (s, 3H, CH_3), 1.66 (s, 3H, CH_3), 1.60 (s, 6H, CH_3×2); Mass *m*/*z* 406 (M^+). Found: C, 82.44; H, 9.17%. Calcd for $C_{28}H_{38}O_2$: C, 82.71; H, 9.42%.

1,4-Dimethoxy-2-methyl-3-[(2Z)-farnesyl]naphthalene (3e): IR (neat) 2950, 1596, 1456, 1356, 1269, 1068, and 774 cm^{-1}; ^{1}H NMR ($CDCl_3$) 8.10 (m, 2H, aromatic), 7.50 (m, 2H, aromatic), 5.27 (m, 1H, olefin), 5.16 (m, 2H, olefin), 3.88 (s, 3H, OCH_3), 3.86 (s, 3H, OCH_3), 3.59 (d, *J*=6 Hz, 2H, CH_2), 2.40 (s, 3H, CH_3), 2.35—1.90 (m, 8H, CH_2×4), 1.73 (m, 3H, CH_3), 1.70 (s, 3H, CH_3), 1.68 (s, 3H, CH_3), 1.63 (s, 3H, CH_3); Mass *m*/*z* 406 (M^+). Found: C, 82.63; H, 9.52%. Calcd for $C_{28}H_{38}O_2$:

C, 82.71; H, 9.42%.

*1,4-Dimethoxy-2-methyl-3-phytylnaphthalene (**3f**)*: IR (neat) 2940, 1592, 1455, 1355, 1265, 1192, 1098, 1065, 1014, 970, and 770 cm^{-1}; ^1H NMR (CCl_4) 7.03—8.01 (m, 4H, aromatic), 5.03 (t, J=6 Hz, 1H, olefin), 3.81 (s, 3H, OCH_3), 3.78 (s, 3H, OCH_3), 3.41 (d, J=6 Hz, 2H, CH_2), 2.25 (s, 3H, CH_3), 2.20—1.50 (m, 5H, CH_2 and CHX3), 1.73 (s, 3H, CH_3), 1.12 (br, 16H, CH_2X8), 0.81 (d, J=7 Hz, 12H, CH_3X4); Mass m/z 480 (M^+). Found: C, 82.30; H, 11.17%. Calcd for $C_{33}H_{52}O_2$: C, 82.44; H, 10.90%.

Precursors (**6a—e**) of coenzyme Q were analogously obtained by the Grignard reactions of 2,3,4,5-tetramethoxy-6-methylphenylmagnesium bromide and the polyprenyl phosphates (**2a—e**), and characterized by IR, ^1H NMR, and Mass spectra.

*1,2,3,4-Tetramethoxy-5-methyl-6-prenylbenzene (**6a**)*: IR (neat) 2950, 1468, 1408, 1355, 1260, 1196,, 1100, 1070, 1042, and 980 cm^{-1}; ^1H NMR (CCl_4) 4.96 (t, J=6 Hz, 1H, olefin), 3.82 (s, 6H, OCH_3X2), 3.73 (s, 6H, OCH_3X2), 3.22 (d, J=6 Hz, 2H, CH_2), 2.09 (s, 3H, CH_3), 1.75 (s, 3H, CH_3), 1.67 (s, 3H, CH_3); Mass m/z 280 (M^+). Found: C, 68.05; H, 8.78%. Cacld for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63%.

*1,2,3,4-Tetramethoxy-5-methyl-6-geranylbenzene (**6b**)*:[7c] IR (neat) 2950, 1470, 1410, 1350, 1260, 1200, 1100, 1040, and 980 cm^{-1}; ^1H NMR (CCl_4) 4.79—5.09 (m, 2H, olefin), 3.76 (s, 6H, OCH_3X2), 3.67 (s, 6H, OCH_3X2), 3.21 (d, J=7 Hz, 2H, CH_2), 2.11 (s, 3H, CH_3), 1.92 (m, 4H, CH_2X2), 1.68 (s, 3H, CH_3), 1.57 (s, 3H, CH_3), 1.51 (s, 3H, CH_3); Mass m/z 338 (M^+).

*1,2,3,4-Tetramethoxy-5-methyl-6-nerylbenzene (**6c**)*: IR (neat) 2950, 1470, 1410, 1350, 1260, 1200, 1100, 1040, and 980 cm^{-1}; ^1H NMR (CCl_4) 4.78—5.16 (m, 2H, olefin), 3.76 (s, 6H, OCH_3X2), 3.67 (s, 6H, OCH_3X2), 3.17 (d, J=7 Hz, 2H, CH_2), 2.10 (m, 4H, CH_2X2), 2.02 (s, 3H, CH_2), 1.62 (m, 9H, CH_3X3); Mass m/z 338 (M^+). Found: C, 72.09; H, 9.26%. Calcd for $C_{21}H_{32}O_4$: C, 72.38; H, 9.26%.

*1,2,3,4-Tetramethoxy-5-methyl-6-[(2E)-farnesyl]benzene (**6d**)*: IR (neat) 2950, 1465, 1408, 1355, 1108, 1042, and 980 cm^{-1}; ^1H NMR ($CDCl_3$) 5.08 (m, 3H, olefin), 3.92 (s, 6H, OCH_3X2), 3.80 (s, 6H, OCH_3X2), 3.33 (d, J=7 Hz, 2H, CH_2), 2.17 (s, 3H, CH_3), 2.04 (m, 8H, CH_2X4), 1.78 (s, 3H, CH_3), 1.67 (s, 3H, CH_3), 1.59 (s, 3H, CH_3); Mass m/z 406 (M^+). Found: C, 74.87; H, 9.72%. Calcd for $C_{26}H_{40}O_4$: C, 74.96; H, 9.68%.

*1,2,3,4-Tetramethoxy-5-methyl-6-[(2Z)-farnesyl]benzene (**6e**)*: IR (neat) 2930, 1465, 1406, 1352, 1103, 1041, and 978 cm^{-1}: ^1H NMR ($CDCl_3$) 5.24 (m, 1H, olefin), 5.07 (m, 2H, olefin), 3.92 (s, 6H, OCH_3X2), 3.80 (s, 6H, OCH_3), 3.36 (d, J=7 Hz, 2H, CH_2), 2.40—1.90 (m, 4H, CH_2X2), 2.16 (s, 3H, CH_3), 1.70 (s, 6H, CH_3X2), 1.66 (s, 3H, CH_3), 1.63 (s, 3H, CH_3); Mass m/z 406 (M^+). Found: C, 75.14; H, 9.74%. Calcd for $C_{26}H_{40}O_4$: C, 74.96; H, 9.68%.

We are grateful to Kuraray Co., Ltd., for a generous gift of some starting compounds. This work was supported by a Grant-in-Aid for Scientific Research (No. 58550562) from the Ministry of Education, Science, and Culture of Japan.

7-Diazo-7*H*-benz[*de*]anthracene and 7*H*-Benz[*de*]anthracen-7-ylidene

Akira IZUOKA, Shigeru MURATA, and Hiizu IWAMURA*
Department of Applied Molecular Science, The Institute for Molecular Science, Myodaiji, Okazaki 444
(Received April 14, 1984)

7-Diazo-7*H*-benz[*de*]anthracene has been prepared by the HgO oxidation of the corresponding hydrazone in ether. The yellow-green diazo compound in a 2-methyltetrahydrofuran matrix has been photolyzed with a high-pressure mercury lamp in an ESR cavity at 14 K. From the *X*, *Y*, and *Z* transitions due to the unoriented triplet species, the zero-field splitting parameters of 7*H*-benz[*de*]anthracen-7-ylidene have been determined: $|D|=0.2662$ and $|E|=0.0175\,cm^{-1}$. A temperature dependence experiment showed linear signal intensities *vs.* $1/T$ plots, indicating that the carbene is in the ground triplet state. The zero-field splitting parameters have been theoretically calculated by assuming the dipolar interaction of the electron spins one on the n-orbital at the 7-position and the other delocalized on the Hückel π-framework.

High-spin organic molecules are of recent interest as a model for organic ferromagnets.[1] Special attention has been devoted to antiaromatic annulenes[2] and polyradicals.[3] Our approach to the subject is characterized by the construction of polycarbenes by taking advantage of triplet diphenylcarbene as an appropriate building block.[4] Thus the nonet ground state of a tetracarbene, *m*-phenylenebis((diphenylmethylen-3-yl)methylene), has been generated and characterized by ESR spectroscopy.[5] In order to develop magnetic organic materials of interest, there remain several difficulties to overcome. The increase of the spin multiplicity and the thermal stability of the polycarbenes is one of the few important factors. As a part of these efforts, we have scrutinized several new carbenes to be used as a unit. In this paper, we report the preparation of the diazo compound and generation of the triplet carbene derived from 7*H*-benz[*de*]-anthracen-7-one. The ESR spectra of the carbene have also been fully analyzed.

Results and Discussion

Preparation of 7-Diazo-7H-benz[de]anthracene. The diazo compound was prepared by typical mercury(II) oxide oxidation of the corresponding hydrazone which in turn was obtained by sluggish reaction of 7*H*-benz[*de*]-anthracen-7-one with hydrazine hydrate. The yellow-green diazo compound crystallized in fine prisms. A characteristic IR band was observed at $2030\,cm^{-1}$. UV absorptions due to the π-π^* and n-π^* transitions were observed at 407 (log ε=4.14), 425 (4.10) and 600 nm (2.42), respectively. The 400 MHz ^{1}H NMR spectrum exhibited first-order multiplets (Fig. 1) which were analyzed by the standard decoupling technique. The upfield shifts of the hydrogens peri to the diazo group are noted. The corresponding hydrogens of the precursor ketone appear in the lowest field.

Photochemical Generation and ESR Characterization of 7H-Benz[de]anthracen-7-ylidene. 7-Diazo-7*H*-benz-[*de*]anthracene in 2-methyltetrahydrofuran matrices was irradiated with a high-pressure mercury lamp in an ESR cavity at 14K. The resulting ESR spectrum obtained at 9.332GHz is reproduced in Fig. 2. The signals are typical fine structure patterns for unoriented triplet species. Signals at 420.9, 485.5, and 617.5 mT are assigned to a set of the high-field *X*, *Y*, and *Z* transitions from which the zero-field splitting parameters were obtained as $|D|=0.2662$ and $|E|=0.0175\,cm^{-1}$ by solving Eqs:[6a]

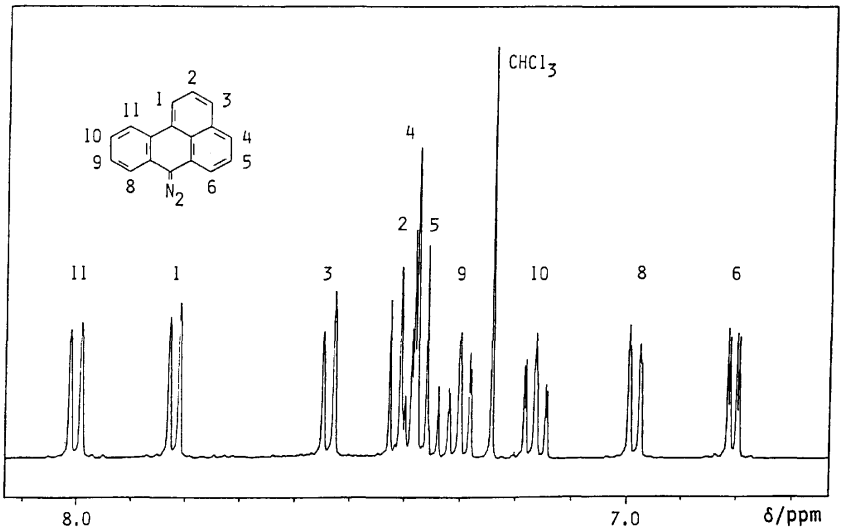

Fig. 1. ^{1}H NMR spectrum (400 MHz) of 7-diazo-7*H*-benz[*de*]anthracene.

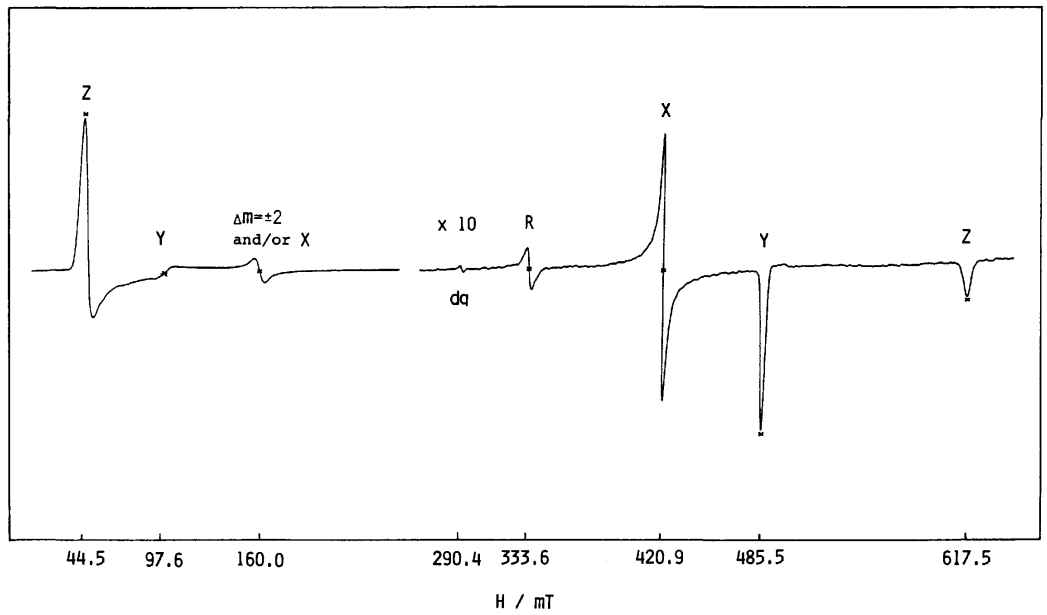

Fig. 2. ESR spectrum (9.332 GHz) obtained by photolysis of 7-diazo-7H-benz[de]-anthracene in 2-methyltetrahydrofuran glass at 14 K.

$$(g\beta H_X)^2 = (g_e/g_{XX})^2[(g\beta H_0 \pm D \mp E)(g\beta H_0 \mp 2E)]$$
$$(g\beta H_Y)^2 = (g_e/g_{YY})^2[(g\beta H_0 \pm D \pm E)(g\beta H_0 \pm 2E)] \quad (1)$$
$$(g\beta H_Z)^2 = (g_e/g_{ZZ})^2[(g\beta H_0 \pm D)^2 \mp E^2].$$

The corresponding low-field X, Y, and Z transitions were calculated from these zero-field parameters using Eqs. 1 to give the resonance fields 157.4, 93.5, and 44.5 mT, respectively. These values agree reasonably well with the observed low-field transitions as shown in Fig. 2. The resonance at 160 mT which was assigned to the X transition may contain the signal due to $\Delta m = \pm 2$ transition. Other signals at 290.4 and 333.6 mT are assigned to the double quantum transition of the carbene and a normal resonance due to fortuitous doublet species, respectively.

The D values of typical diarylcarbenes are in the range 0.41—0.37 cm^{-1}. With the exception of di(9-anthryl)methylene (D=0.113 cm^{-1} at 4 K),[6b] the D parameter of 7H-benz[de]anthracen-7-ylidene obtained in this study is the smallest ever reported, showing extensive delocalization of the odd electron in the π-framework of the molecule.

The temperature dependence of the ESR signal intensity of the low-field Z transition in the range 15—77 K obeyed the Curie-Weiss linear plot (Fig. 3). The triplet carbene is concluded not to be thermally populated from the ground state singlet. In 2-methyltetrahydrofuran matrices, the ESR signals started to disappear at 85 K. In powdered crystals which gave birth to 7H-benz[de]anthracen-7-ylidene on irradiation ($|D|$=0.2608 and $|E|$=0.0181 cm^{-1}), it was stable up until 205 K. The thermal stability of the carbene due to delocalization of the odd electron in the π-orbital was not so satisfactory as it was expected.

Calculation of the Zero-field Splitting Parameters. The zero-field splitting parameters D and E have been calculated theoretically by the point dipole approximation; only the two-center Coulomb term in the single configuration approximation was considered. The sites of the point electron spins were empirically fixed according to the method of Hutton and Roth[7] for the reason of simplicity and empirical reproducibility. Thus the electron spin in the π-orbitals was simulated by two point spins in the π-

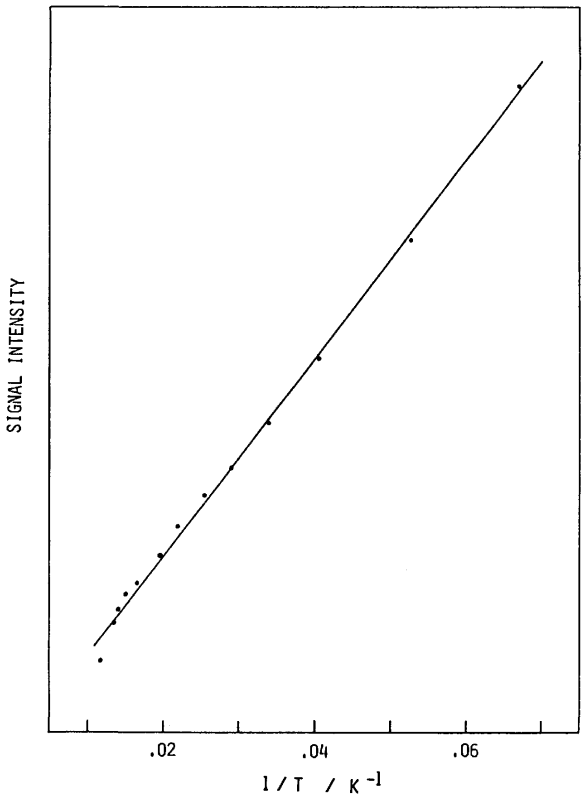

Fig. 3. Plots of signal intensity of the lowfield Z line of 7H-benz[de]anthracen-7-ylidene *vs.* $1/T$.

lobes located 0.821 Å above and below and molecular plane, each with a half of the spin density on the atom. The σ-electron spin was assumed to be localized on the divalent carbon and expressed by two point spins in the sp^2-orbital placed at ±0.876 Å from the carbon atom with the spin density of 0.7 in the negative lobe and 0.3 in the positive lobe.[7] The molecular geometry used in the calculation was constructed by the C-C bond distance of 1.40 Å and the bond angles of 120°.

Since the spin-orbit coupling of the two electrons is considered not to contribute to the zero-field parameters in carbenes containing only first-row atoms,[8] only the dipolar spin-spin interaction was taken into consideration. The spin-spin Hamiltonian is described by Eq. 2:

$$H_{ss} = S\mathbf{D}S, \tag{2}$$

where S is the total spin operator and $\mathbf{D}$ is the dipolar coupling tensor, the elements of which are obtained by the summation of the interactions of each σ spin with each π spin. When the matrix is diagonalized, the zero-field splitting parameters D and E are calculated as Eqs. 3:

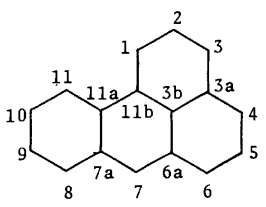
$$D = -\frac{3}{2}Z, \qquad E = -\frac{1}{2}(X-Y), \tag{3}$$

where $-X$, $-Y$, and $-Z$ are the components of the diagonalized matrix.

As in the calculation by Hutton and Roth,[7] it was assumed that the π spin density distribution was equal to that in the corresponding radical 7*H*-benz[*de*]anthracen-7-yl. We obtained the spin densities of the radical by the McLachlan method with the use of the zero-order spin densities derived from the Hückel molecular orbital (HMO) theory; the usual HMO parameters α_o and β_o were employed in all the carbon atoms and C-C bonds, respectively.

Table 1. The π spin densities of 7*H*-benz[*de*]anthracen-7-yl used for calculation of the π spin distribution in 7*H*-benz[*de*]anthracen-7-ylidene

Atom	Spin density	Atom	Spin density
1	0.1456	7	0.3567
2	−0.0512	7a	−0.0478
3	0.1502	8	0.0901
3a	−0.0459	9	−0.0362
3b	0.0149	10	0.0798
4	0.2385	11	−0.0370
5	−0.0745	11a	0.0792
6	0.2441	11b	−0.0433
6a	−0.0632		



The π spin density distribution calculated by the above method is shown in Table 1. The spin density is found to be delocalized mostly in the naphthalene moiety. With the use of the values in Table 1, the dipolar interaction matrix $\mathbf{D}$ was calculated and diagonalized.[9] The zero-field splitting parameters were obtained according to Eqs. 3: D=0.2486 and E=0.0130 cm^{-1}. The agreement with the experimental values is commendable.

The spin delocalization in the π system and consequent low density at C-7 (0.357) account for the low D value. The spin distribution in the naphthalene ring of 7*H*-benz[*de*]anthracen-7-ylidene carries an interesting implication as regards the magnetic interaction between the molecules in crystal packing. It is usually the case for organic molecules in the crystal field to have the intermolecular distances governed by the van der Waals interaction. At these distances (~4 Å), the exchange interaction between the electron spins on the neighboring molecules tends to be negative. The more stable Coulomb interaction under these conditions is the α spins of one molecule facing the β spins of the other. Therefore, if the molecules of 7*H*-benz[*de*]anthracen-7-ylidene take the superimposable stacking has the crystals, the different spins (α and β) will develop between the two neighboring triplet molecules and the intermolecular interaction should become antiferromagnetic. On the other hand, if the parallel stacking has the phase shift or inversion as shown in Fig. 4, the α *vs.* β relationship holds in the overlapping naphthalene moieties with the high σ and π spin densities at the 7-position having the same sign of spins. The interaction could now become ferromagnetic. Thus the crystal structure of these and other aromatic diazo compounds is of interest and under current study in these laboratories.

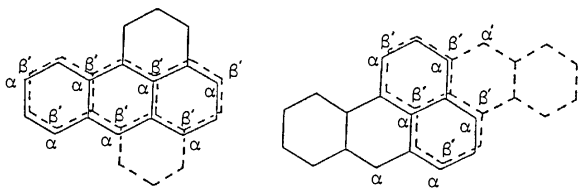


Fig. 4. Some molecular stacking models for potentially ferromagnetic molecular interaction.

Experimental

7H-Benz[de]anthracen-7-one Hydrazone. A mixture of 7*H*-benz[*de*]anthracen-7-one (2.00 g, 8.70 mmol), zinc chloride (3.60 g, 26.5 mmol) and 30 cm^3 of hydrazine hydrate in 60 cm^3 of ethylene glycol was refluxed with stirring for 12 h, poured into 200 cm^3 of water, and extracted with dichloromethane. The organic layer was washed with water, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The residue was chromatographed on alumina and eluted with dichloromethane. Recrystallization from hexane gave 1.16 g (55%) of yellow microcrystalline needles; mp 126—127 °C; IR (KBr) 1630 (C=N), 3180, 3320

(NH_2) cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.41 (t, J=7.0 Hz, 1H), 7.44 (t, J=7.0 Hz, 1H), 7.62 (dd, J=7.3, 8.2 Hz, 1H), 7.63 (dd, J=7.3, 8.2 Hz, 1H), 7.82 (d, J=8.2 Hz, 1H), 7.88 (d, J=8.2 Hz, 1H), 8.08 (d, J=7.0 Hz, 1H), 8.17 (d, J=7.0 Hz, 1H), 8.22 (d, J=7.3 Hz, 1H) and 8.41 (d, J=7.3 Hz, 1H).

Found: C, 83.88; H, 4.87; N, 11.41%. Calcd for $C_{17}H_{12}N_2$: C, 83.58; H, 4.95; N, 11.47%.

7-Diazo-7H-benz[de]anthracene. Yellow mercury(II) oxide (1.8 g, 8.3 mmol), anhydrous sodium sulfate (2.0 g) and five drops of a freshly prepared saturated solution of potassium hydroxide in absolute ethanol were added to a solution of 0.20 g (0.82 mmol) of 7*H*-benz[*de*]anthracen-7-one hydrazone in 20 cm^3 of dry tetrahydrofuran at room temperature. The mixture was stirred for 1.5 h in the dark. Inorganic salts were removed by filtration and the solution was concentrated under reduced pressure at room temperature to give 0.2 g (quantitative yield) of yellow-green powder. The product was already spectroscopically pure. The analytical sample was prepared by recrystallization from ether; mp 98—100 °C (decomp); IR (KBr) 2030 cm^{-1}; UV (ether) 269 (log ε 4.53), 285 (4.37), 327 (3.93), 407 (4.14), 425 (4.10), and 600 nm (2.42); ^1H NMR ($CDCl_3$) δ=6.81 (d, J=6.7 Hz, 1H), 6.97 (d, J=7.9 Hz, 1H), 7.16 (dd, J=7.6, 8.3 Hz, 1H), 7.30 (dd, J=7.9, 8.3 Hz, 1H), 7.36 (dd, J=6.7, 8.8 Hz, 1H), 7.39 (d, J=8.8 Hz, 1H), 7.41 (dd, J=7.3, 8.2 Hz, 1H), 7.54 (d, J=8.2 Hz, 1H), 7.82 (d, J=7.3 Hz, 1H), and 8.00 (d, J=7.6 Hz, 1H).

Found: C, 84.22; H, 4.45; N, 11.58%. Calcd for $C_{17}H_{10}N_2$: C, 84.27; H, 4.16; N, 11.57%.

Spectral Measurements. IR spectra were recorded on a JASCO IR-810 spectrometer. NMR spectra were obtained on a JNM GX-400 spectrometer (400 MHz for ^1H) using tetramethylsilane as an internal standard. UV spectra were measured on a HITACHI 340 spectrometer.

ESR spectra were measured on a Varian E-112 spectrometer (X-band microwave unit, 100 kHz field modulation) equipped with an Air Products LTD-3-110 liquid helium transfer system. The diazo compound (*ca.* 2 mg) was dissolved in 2-methyltetrahydrofuran (0.5 cm^3) and the solution was degassed in a quartz cell by three freeze-thaw cycles. The sample was rapidly cooled in a pre-cooled ESR cavity and irradiated with a high-pressure mercury lamp (500 W) at 14 K. The signals due to the triplet carbene appeared immediately after the start of irradiation. The resonance magnetic field values of the signals were measured with the aid of a Varian E500 NMR gauss meter. The dependence of the signal intensities on temperatures was measured by the use of a temperature controlling accessory. The low-field Z line (at 44.5 mT at 14 K) was scanned repeatedly at several temperatures and the peak heights were plotted against $1/T$. In a separate run, the diazo compound (5 mg) was mixed with 7*H*-benz[*de*]anthracen-7-one (100 mg) in a mortar with a pestle made of agate, and the mixture was placed in a quartz sample tube (5 mm o.d.) 2 cm in height from the bottom. The sample was irradiated in an ESR cavity to obtain the spectrum of the triplet species.

Theoretical Calculations. Calculations were carried out on a Hitachi M-200H computer, using the program named "Huckel Molecular Orbirtal Calculation" programmed by Dr. H. Kihara and filed in the Program Library of the Computer Center of the Institute for Molecular Science. The McLachlan correction parameter λ was set at 1.2 in the program.

We wish to thank Dr. T. Sugawara of these laboratories for his helpful comments during this work. A collaboration of Prof. R. D. McKelvey in the preliminary preparation of the hydrazone is acknowledged.

7) R. S. Hutton and H. D. Roth, *J. Am. Chem. Soc.*, **104**, 7395 (1982). These approximations were first employed to assign the spin density distributions obtained for fluorenylidene by the ENDOR method.[8] Later the empirical values were modified by Hutton and Roth to reproduce the zero-field splitting parameters of methylene. The latter values were used in this study. Since the triplet carbene discussed here is considered to have a smaller bond angle at the divalent carbon owing to the constraint of the ring, a new set of parameters should have been introduced to obtain better agreement with the experimental D and E values.

8) See for example: C. A. Hutchison, Jr. and G. A. Pearson, *J. Chem. Phys.*, **47**, 520 (1967).

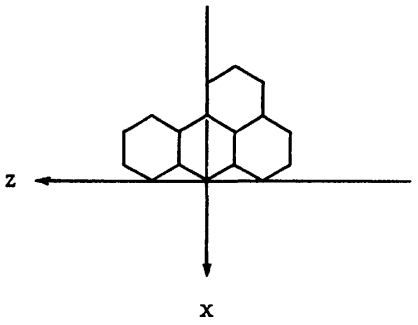
9) In the concrete, the dipolar interaction matrix in Eq. 2 for 7*H*-benz[*de*]anthracen-7-ylidene was given by Eq.:

$$\boldsymbol{D} = \frac{(g\beta)^2}{2}\begin{bmatrix} \frac{r^2-3x^2}{r^5} & \frac{-3xy}{r^5} & \frac{-3xz}{r^5} \\ \frac{-3xy}{r^5} & \frac{r^2-3y^2}{r^5} & \frac{-3yz}{r^5} \\ \frac{-3xz}{r^5} & \frac{-3yz}{r^5} & \frac{r^2-3z^2}{r^5} \end{bmatrix}$$

$$= \begin{bmatrix} -0.0699 & 0.0 & -0.0029 \\ 0.0 & -0.0958 & 0.0 \\ -0.0029 & 0.0 & 0.1657 \end{bmatrix}$$

The calculation was made on the assumption that the molecular plane makes the xz plane and the origin of the coordinates is at the atom 7 (*i.e.* divalent carbon). The off-

diagonal elements in the above matrix are so small that, after diagonalization, the values of the diagonal elements are little changed.



The coordinate systm given here was arbitrarily taken for convenience of calculations and different from the principal axes *X*, *Y*, and *Z* of the carbene molecule. Conventionally used **H** was employed in a unit of mT throughout this paper to represent magnetic fux density **B**.

The Mechanism and Stereochemistry of Asymmetric Transformation *via* Chiral Oxazolines

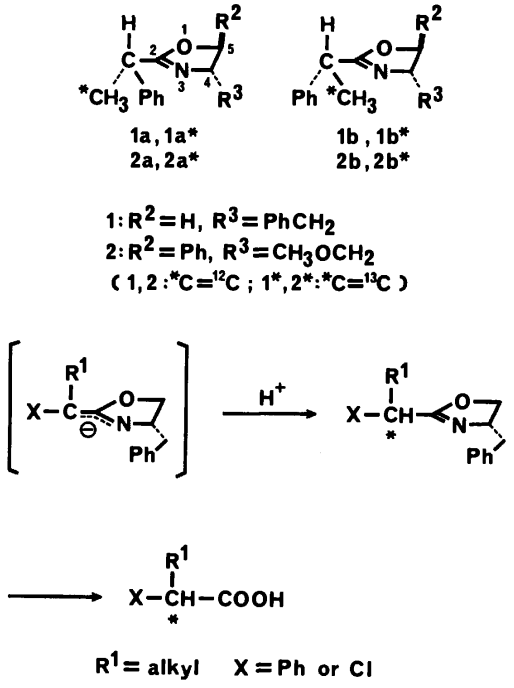
(Received June 9, 1984)

The stereoselectivity of asymmetric transformation of 2-substituted alkanoic acids *via* oxazolines was clarified by measuring the isomeric ratio of ^{13}C-labeled lithio oxazolines by ^{13}C NMR. The mechanism of the process was discussed from substituent effects of the oxazoline ring and solvent effects on the transformation.

Theoretically, asymmetric transformation of racemic compounds into a single optically active form is one of the best methods to obtain chiral substances.[1,2] However, suitable substances for the transformation have been practically limited to optically labile compounds such as atropisomers.[3]

In a previous paper,[4] we reported the asymmetric transformation of optically stable alkanoic acids into optically active form *via* chiral oxazolines. In the transformation, optically active alkanoic acids were obtained by metalation of oxazolines with butyllithium followed by quenching the lithio oxazolines by addition of water, and subsequent hydrolysis (Scheme 1). In this paper the mechanism and stereochemistry of the process will be discussed.

Oxazolines **1**, **2**, and ^{13}C-labeled **1**, **2** (**1***, **2***) were prepared according to the methods described previously,[4] and the epimers (**1a**, **1b**, **1a***, **1b***, **2a**, **2b**, **2a***, **2b***) were separated by silica-gel chromatography. Each epimer was submitted to the transformation separately. Deuterium oxide was used instead of water to quench the carbanions to assure the quantitative formation of carbanions (**I** and **II**). Thus, **1** and **2** were converted to the deuterated epimers (**1-d** and **2-d**) as shown in Scheme 2. The extent of asymmetric induction through the metallation and protonation process was monitored by GLPC analysis. The isomeric ratios of the intermediate lithio oxazolines were measured by ^{13}C NMR.



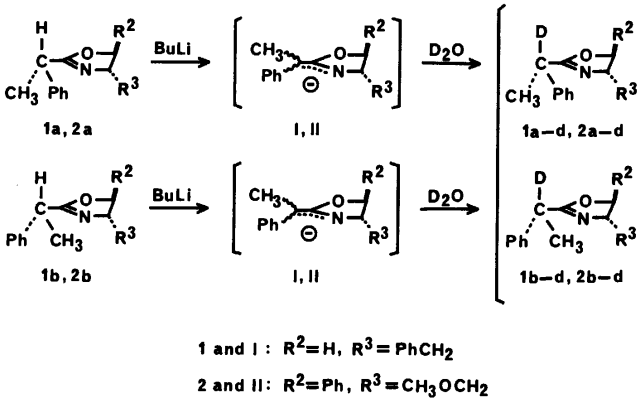
Scheme 1.

Experimental

IR spectra were measured with a JASCO A-3 spectrometer, mass spectra were recorded with a Hitachi M-80 mass spectrometer, optical rotations were measured with a JASCO Digital Automatic Polarimeter Model DIP-181. ^1H NMR spectra were obtained with a JNM-PS-100 spectrometer (100 MHz), and chemical shifts are expressed in δ downfield from TMS as an internal standard. ^{13}C NMR spectra were obtained with a JNM-FX-100 (25 MHz), and chemical shifts are reported in δ values relative to the β-THF signal which we defined as δ 25.0. GLPC analysis was carried out on a Shimadzu Gas Chromatograph GC-4CM equipped with a hydrogen flame ionization detector (column: OV-1 0.3 mm×50 m).

(4S)-2-(1-Phenylethyl)-4-benzyl-2-oxazoline (1a and 1b). A mixture of two epimers (**1a** and **1b**) was prepared from (4*S*)-(−)-2,4-dibenzyl-2-oxazoline and iodomethane according to the method described previously.[4] The two epimers were separated by silica-gel chromatography [silica gel 60 prepacked column (Merck), 40% ether–hexane].

1a: ^1H NMR ($CDCl_3$) δ=1.54 (3H, d, J=7 Hz, $\underline{CH_3}CH$),



Scheme 2.

2.66 (1H, dd, J=14 and 8Hz, PhC$\underline{H}_2$), 3.11 (1H, dd, J=14 and 5Hz, PhC$\underline{H}_2$), 3.71 (1H, q, J=7Hz, $CH_3C\underline{H}$, 3.9—4.6 (3H, m), and 7.2—7.5 (10H, m).

1b: ^{1}H NMR ($CDCl_3$) δ=1.52 (3H, d, J=7Hz, C$\underline{H}_3$CH), 2.66 (1H, dd, J=14 and 8Hz, PhC$\underline{H}_2$), 3.13 (1H, dd, J=14 and 5Hz, PhC$\underline{H}_2$), 3.72 (1H, q, J=7Hz, $CH_3C\underline{H}$), 3.9—4.6 (3H, m) and 7.1—7.5 (10H, m).

Absolute Configuration of 1a and 1b. To determine the absolute configuration at C-2 *exo* methine of **1a** and **1b**, the mixture of **1a** and **1b** (**1a**:**1b**=10:90, 133mg) was hydrolyzed in 3M sulfuric acid (1M=1 mol dm^{-3}). The configuration of the resulting 2-phenylpropionic acid [yield 88%; $[\alpha]_D^{25}$ −54.8° (c 1.6, $CHCl_3$) o.p. 72%] was the *R*-configuration.[5]

(4S)-2-(1-Phenyl[2-^{13}C]ethyl)-4-benzyl-2-oxazoline (1a and 1b*).* A mixture of ^{13}C-enriched **1a** and **1b** (**1a*** and **1b***) was prepared using *ca.* 50% enriched [^{13}C]-iodomethane by the method described previously.[4] The two epimers were separated by silica-gel chromatography as described above.

(4S,5S)-2-(1-Phenylethyl)-4-methoxymethyl-5-phenyl-2-oxazoline (2a and 2b). A mixture of two epimers (**2a** and **2b**) was prepared according to the method described by Meyers *et al.*[6] The two epimers were separated by silica-gel chromatography [C.I.G. prepacked column (Kusano Kagakukikai Co.), 1% ethanol-hexane].

2a: ^{1}H NMR ($CDCl_3$) δ=1.62 (3H, d, J=7Hz, C$\underline{H}_3$CH), 3.40 (3H, s, C$\underline{H}_3$O), 3.6 (2H, m) 3.87 (1H, q, J=7Hz, $CH_3C\underline{H}$), 4.1 (1H, m), 5.28 (1H, d, J=6Hz, PhC$\underline{H}$O), and 7.1—7.5 (10H, m).

2b: ^{1}H NMR ($CDCl_3$) δ=1.60 (3H, d, J=7Hz, C$\underline{H}_3$CH), 3.40 (3H, s, C$\underline{H}_3$O), 3.6 (2H, m), 3.87 (1H, q, J=7Hz, $CH_3C\underline{H}$), 4.1 (1H, m), 5.25 (1H, d, J=6Hz, PhC$\underline{H}$O), and 7.1—7.5 (10H, m).

Absolute Configuration of 2a and 2b. To determine the absolute configuration at C-2 *exo* methine of **2a** and **2b**, the mixture of **2a** and **2b** (6:94, 148mg) was hydrolyzed in 6M sulfuric acid. The configuration of the resulting 2-phenylpropionic acid [yield 85%; $[\alpha]_D^{34}$ −53.8° (c 1.6, $CHCl_3$) o.p. 70%] was the *R*-configuration.[5]

(4S,5S)-2-(1-Phenyl[2-^{13}C]ethyl)-4-methoxymethyl-5-phenyl-2-oxazoline (2a and 2b*).* A mixture of ^{13}C-enriched **2a** and **2b** (**2a*** and **2b***) was prepared using *ca.* 90% enriched [^{13}C]-iodomethane by the method described previously.[6]

4:96	41:59	94

a) Post metalation period was 45 min.

The two epimers were separated by silica-gel chromatography as described above.

Asymmetric Transformation of 1 in Tetrahydrofuran. The three mixtures of **1a** and **1b** [13.3mg (0.05mmol); **1a**:**1b**= 98:2, 49:51, 4:96] were prepared, and each mixture was dissolved in 1ml of dry tetrahydrofuran under nitrogen atmosphere. Each solution thus prepared was cooled to −78 °C, and a solution of butyllithium (0.16ml, 0.2mmol) in hexane was added dropwise to the solution under stirring at −78°C.[7] The reaction mixture was stirred for a given period (5, 45, and 300min; the post metalation period) at −78 °C, and then 1ml of 25% deuterium oxide-tetrahydrofuran solution was added and allowed to warm to room temperature. The mixture was extracted with ether, and the organic layer was washed with brine, dried over sodium sulfate, and concentrated under reduced pressure. The ratio of deuterated epimers (**1a-d** and **1b-d**) in this residue was determined by GLPC (170°C), and deuterium incorporation was detected by Mass and ^{1}H NMR spectra. The results are shown in Table 1.

Asymmetric Transformation of 1 in 25% Hexamethlphosphoric Triamide-Tetrahydrofuran. The three mixtures of **1a** and **1b** [13.3mg (0.05mmol); **1a**:**1b**=98:2, 49:51, 4:96] were prepared, and each mixture was dissolved in 1ml of dry 25% hexamethylphosphoric triamide-tetrahydrofuran under nitrogen atmosphere. The samples were treated as the method described for the asymmetric transformaiton of **1** in tetrahydrofuran, and in these reactions the post metalation period was 45min. The results are shown in Table 2.

^{13}C NMR Measurements of Lithio Oxazolines of ^{13}C-Labeled 1. Five mixtures of ^{13}C-labeled epimers of **1** (**1a***:**1b***= 99:1, 74:26, 49:51, 26:74, 3:97) were prepared. Each mixture (26.6mg, 0.1mmol) was dissolved in 0.2ml of dry tetrahydrofuran under nitrogen atmosphere, and 0.17ml of butyllithium in hexane (1.2M, 0.2mmol) was added to the solution with stirring at −78°C.[7] The ^{13}C NMR spectrum of each solution was recorded at −78°C under quantitative conditions,[8,9] and showed a major peak at δ 16.1 (lithio oxazoline **IA***) and a minor peak at δ 18.1 (lithio oxazoline **IB***). After the measurment of the spectrum, 0.2ml of 25% deuterium oxide-tertrahydrofuran solution was added to the sample at −78°C. The ratio of the deuterated epimers (**1a***-**d** and **1b***-**d**) in the resulting mixture was determined by GLPC analysis as described before. The results are shown in Table 3.

^{13}C NMR Measurements of Lithio Oxazolines of ^{13}C-Labeled 2. Five mixtures of ^{13}C-labeled epimers of **2** (**2a***:**2b***= 95:5, 73:27, 54:46, 30:70, 2:98) were prepared. Each mixture (14.8mg, 0.05mol) was dissolved in 0.3ml of dry tetrahydrofuran under nitrogen atmosphere, and 0.071ml of butyllithium in hexane (1.4M, 0.1mmol) was added to the solution with stirring at −78°C.[7] The ^{13}C NMR spectrum of each solution was recorded as described above, and showed two peaks at δ 15.8 (lithio oxazoline **IIA***) and δ 18.0 (lithio

oxazoline **IIB***). After the measurment of the spectrum, 0.1 ml of 25% deuterium oxide–tetrahydrofuran was added to the sample at −78°C. The ratio of the deuterated epimers (**2a*-d** and **2b*-d**) in the resulting mixture was determined by GLPC analysis as described before. The results are shown in Table 4.

(4R,5R)-2-(1-Phenylethyl)-4-methyl-5-phenyl-2-oxazoline (4). (4*R*,5*R*)-2-Benzyl-4-methyl-5-phenyl-2-oxazoline was prepared from (−)-norpseudoephedrine and ethyl 2-phenylacetimidate by the method described previously.[4] The obtained oxazoline was alkylated by iodomethane according to the method described by Meyers *et al.* to give **4**:[6] IR (neat 1670cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.35 (3H, d), 1.60 (3h, d), 3.8 (2H, m), 4.77 (1H, d), and 6.8—7.5 (10H, m); MS (70eV) *m/z* (rel intensity) 265 (M^+; 2), 160 (19), 159 (86), 144 (23), 106 (5), 105 (100), and 77 (16).

(4R,5S)-2-(1-Phenylethyl)-4-methyl-5-phenyl-2-oxazoline (5). (4*R*,5*S*)-2-Benzyl-4-methyl-5-phenyl-2-oxazoline was prepared from (+)-norephedrine, and this oxazoline was alkylated to give **5** by the same method as described above: IR (neat) 1670cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.74 (3H, d), 1.59 (3H, d), 3.8 (1H, m), 4.3 (1H, m), 5.37 (1H, d), and 6.8—7.4 (10H, m); *m/z* (rel intensity) 265 (M^+; 4), 160 (28), 159 (79), 144 (34), 105 (100), 79 (28), and 77 (33).

Hydrolysis of 4 and 5 before and after the Asymmetric Transformation. **4** and **5** were hydrolyzed before and after the asymmetric transformation as described previously to give chiral 2-phenylpropionic acid,[4] and the results are shown in Table 5.

Results and Discussion

Asymmetric Transformation of 1. After the asymmetric transformation of **1** in tetrahydrofuran, **1a** (98%) gave a deuterated mixture of **1a-d** and **1b-d** in a ratio of 8:2, and **1b** (96%) gave it in a ratio of 6:4 as shown in Table 1. In this transformation the configuration at C-2 *exo* methine of **1a** was retained *ca.* 80%, whereas in the case of **1b** inversion of the configuration predominated over retention of the configuration. This difference is not due to insufficient deprotonation from **1a** or **1b** because deuterium incorporation was above 90% in both cases. The post metalation period (stirring period of the reaction mixture after the addition of butyllithium) was varied in the range of 5min, 45min, and 300min to examine the effect on the transformation. As shown in Table 1, ratios of the resulting epimers were practically independent on the post metalation period.

To clarify solvent effects, the transformation was performed in 25% hexamethylphosphoric triamide–tetrahydrofuran solution. The results are shown in Table 2. In this case, both **1a** (98%) and **1b** (96%) gave **1a-d** and **1b-d** in a ratio of 4:6 with deuterium incorporation above 90% in contrast with the results obtained in tetrahydrofuran.

These results indicate that the ratio of intermediate lithio oxazolines fomed in 25% hexamethylphosphoric triamide–tetrahydrofuran solution did not depend on that of **1a** and **1b**. On the other hand the ratio of the lithio oxazolines formed in tetrahydrofuran solution depended on that of starting epimers, and once they were formed the ratio did not change under the experimental conditions.

^{13}C NMR Measurment of Intermediate Lithio Oxazolines. This asymmetric transformation consists of the formation of lithio carbanions and successive protonation to them. To elucidate the mechanism of the process in tetrahydrofuran, the ratio of the lithio oxazolines was measured by ^{13}C NMR. In order to facilitate the ^{13}C NMR measurement, ^{13}C-enriched oxazolines (**1a*** and **1b***) were synthesized. The mixtures of **1a*** and **1b*** were prepared in various epimeric ratios and dissolved in tetrahydrofuran. Yellow solutions of lithio oxazolines were obtained by adding butyllithium. Two signals due to ^{13}C-enriched methyl carbon were observed at δ 16.1 (**IA***) and δ 18.1 (**IB***). After integration of these two signals (Table 3), the lithio oxazolines were quenched by deuterium oxide. ^{1}H NMR spectra showed that deuterium was incorporated to the *exo* methine carbon, α to the oxazoline ring. The ratios of the resulting deuterated **1a*-d** and **1b*-d** are summarized in Table 3.

The relationships between the ratio of **1a***:**1b*** and that of lithio oxazolines (**IA***:**IB***), and the ratio of lithio oxazolines and that of **1a*-d**:**1b*-d** are shown in Figs. 1 and 2, respectively.

Previously, the stereochemistry of the lithio carban-

ions of (4*S*,5*S*)-2-[2-^{13}C]ethyl-4-methoxymethyl-5-phenyl-2-oxazoline (**3***) were established by Meyers *et al.*[9] and Newcomb *et al.*[10] Therefore, (4*S*,5*S*)-2-(1-phenyl[2-^{13}C]ethyl)-4-methoxymethyl-5-phenyl-2-oxazoline (**2***), which has an analogous structure to **3*** and also to **1***, was prepared and treated in the same manner as described for **1*** to clarify the stereochemistry of the intermediate lithio oxazolines. Two signals due to ^{13}C-enriched methyl carbon of the lithio oxazoline were observed at δ 15.8 (**IIA***) and δ 18.0 (**IIB***). The results for the stereoselective transformation are summarized in Table 4, Fig. 3, and Fig. 4.

Stereochemistry of Intermediate Lithio Oxazolines. In the case of **1*** and **2***, ^{1}H NMR spectra showed that deuterium was incorporated to the *exo* methine carbon, α to the oxazoline ring. Two signals due to ^{13}C-enriched methyl carbon were observed for **1*** and **2***, respectively, in ^{13}C NMR spectra. These spectral data indicate that intermediate lithio oxazolines (**I**, **II**) exist as mixtures of *E*- and *Z*-isomers.

The relationship between the structure of lithio oxazoline of **3*** and the chemical shift of its ^{13}C-enriched methyl carbon was established by Meyers *et al.*[9] and Newcomb *et al.*[10] They assinged, in tetrahydrofuran solutions, a high field peak to **IIIA*** and a low field one to **IIIB***, respectively (Fig. 5).

According to the above structual assignment, in the

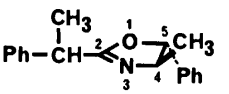
case of **1*** and **2***, lithio oxazolines **IA***, **IB***, **IIA***, and **IIB*** are assigned to the structures illustrated in Fig. 6 from their chemical shifts. Chemical sifts of ^{13}C-enriched methyl signals of **I***—**III*** are summarized in Table 6.

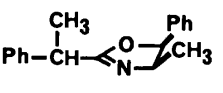
Stereoselectivity of Asymmetric Transformation. The selectivities of the formation of the lithio oxazolines from **1*** and **2***, and that of deuterated epimers from the lithio oxazolines were calculated from the slopes of the straight lines in Figs. 1—4. Since the structures of lithio oxazolines were assigned as described above, the selectivities of the asymmetric transformation are illustrated in Schemes 3 and 4.

In the case of **1***, retention of the stereochemistry of **1a*** was explained by the selective formation of **IA*** from **1a*** and that of **1a*-d** from **IA***. Inversion of the stereochemstry of **1b*** was accounted for by the preferential formation of **IA*** from **1b*** and by the partial formation of **1a*-d** from **IB***. **2*** also showed the same trend of stereoselectivity to **1***. However in the case of **2***, the stereoselectivity of deuterium incorporation was slightly lower than that of **1***. This fact can be explained by the steric effect of substituents at oxazoline ring of **2*** which has a phenyl group on the oppsite side of a methoxymethyl group. The deuterium approach from the top side of the ring may be interfered to some extent by the phenyl group.

In both cases of **1*** and **2***, deuterium was incorporated from the top side of the oxazoline ring, and this stereoselectivity is seemed to be determined by steric effects at 4 position of the oxazoline ring. To elucidate the steric effects of substituents at 4 and 5 positions, asymmetric transformation of oxazolines **4** and **5** was examined. Configurations of the acids ob-



4



5

tained by hydrolysis of **4** and **5** after the asymmetric transformation were both *R*-configuration as shown in Table 5. Because the configuration of the resulting acids was not affected by the C-5 configuration, steric effects of a 5 positioned substituent was accounted to be smaller than that of a 4 positioned substituent.

From above results, at first deuterium is considered to approach stereoselectively to the nitrogen of the oxazoline ring, and in this approach the selectivity would be substantially affected by the 4 positioned substituents.

This stereoselective deuterium approach and the subsequent stereoselective deuterium transfer to the α carbon would result in the deuterium incorporation to the oxazoline anions (**I** and **II**) from the top side of the ring. This stereoselective process is well correspond to that observed in the asymmetric transformation of carbonyl compounds *via* enamines.[11]

Syntheses of 23-Dialkylamino-23-deoxydemycinosyltylosins and Conformational Study of Mycaminosyl Tylonolide by Nuclear Overhauser Difference Spectroscopy

Shuichi SAKAMOTO, Tsutomu TSUCHIYA,* Toshiaki MIYAKE, Akihiro TANAKA, and Sumio UMEZAWA

Institute of Bioorganic Chemistry, 1614 Ida, Nakahara-ku, Kawasaki 211

(Received July 6, 1984)

23-Dialkylamino-23-deoxydemycinosyltylosins have been prepared by treating 23-deoxy-23-iododemycinosyltylosin (**2**) with a series of amines including dimethylamine, diethylamine, and piperidine. 14(23)-Unsaturated derivatives, 23-deoxy-14(23)-enomycaminosyl tylonolide (**17**) and 23-deoxy-14(23)-enodemycinosyltylosin (**4**) have also been prepared. The conformation of mycaminosyl tylonolide dissolved in chloroform-*d* was determined by nuclear Overhauser difference spectroscopy, revealing that the two three-member groups of H(10), Me(22), and H(14) and of H(11), H(13), and H(15) stood, respectively, in a line in this order.

Demycinosyltylosin (DMT), which cannot be prepared practically by acidic hydrolysis of tylosin on account of the preferential removal of mycarose moiety from tylosin, was isolated from a culture of a blocked mutant[1] of tylosin-producing strain, *Streptomyces fradiae*. Okamoto *et al.*[2] also prepared the same compound in large amounts by fermentation of a blocked mutant (YO-9010) of *Streptomyces fradiae* NRRL 2702. Tatsuta *et al.*[3] synthesized the compound in the course of the total synthesis of tylosin. The compound has a reactive primary hydroxyl group at C-23, and this stimulated us to prepare derivatives having functional groups other than the hydroxyl at the C-23.

Recently we prepared 23-dialkylamino derivatives[4] of mycaminosyl tylonolide (MT) and 4′-deoxymycaminosyl tylonolide[5] (DT) by converting their hydroxyls at C-23 to dialkylamino groups *via* the corresponding iodo derivatives and found that the dialkylamino derivatives showed strong antibacterial activities against Gram-negative bacteria. Since DMT (**1**) includes MT-mycarose (1″→4′) structure, the C-23-dialkylamino derivatives of **1** were expected to have similar antibacterial activities as well.

Results and Discussion

Treatment of DMT (**1**) with iodine and triphenylphosphine according to Matsubara *et al.*[6] but changing the solvent to pyridine,[7] without protection of the formyl group, gave readily 23-deoxy-23-iododemycinosyltylosin (**2**). The structure was confirmed by the ^{1}H-NMR spectrum. Treatment of the iodo derivative (**2**) with dimethylamine in hot acetonitrile according to Tanaka *et al.*[4] gave the 23-deoxy-23-dimethylamino derivative (**3**) in a short period in high yield (83%) with slight 14(23)-ene product (**4**) accompanied. If, in this reaction, excess dimethylamine was used, proportion of **4** increased. In a similar fashion, other 23-deoxy-23-dialkylamino derivatives of **1** were prepared from **2** and a series of dialkylamines, namely, diethylamine, *N*-methyl-2-hydroxyethylamine, pyrrolidine, piperidine, hexahydroazepine, and octahydroazocine (giving **9**—**14**, respectively). Reaction conditions and analytical data of these products are shown in Table 1.

4″-*O*-Acetyl derivative (**7**) of **3** was next prepared. Treatment of **3** with acetic anhydride in acetonitrile in the presence of sodium hydrogencarbonate at room temperature gave almost quantitatively the 2′-*O*-acetyl derivative (**5**), which was then acetylated with acetic anhydride in pyridine under conditions to avoid the acetylation of HO-3. After a week at 0°C, 2′,4″-di-*O*-acetyl derivative (**6**) was obtained in a moderate yield (52%) with the starting material (**5**) and 2′,3,4″-tri-*O*-acetyl compound (**8**). Compound **8** was prepared, in a separate experiment, by per-*O*-acetylation of **3** (see Experimental). Heating **6** in methanol selectively cleaved the 2′-*O*-acetyl group to give the 4″-*O*-acetyl derivative (**7**) in high yield. Possibly, the selective deacetylation at C-2′ may be due to the presence of the dimethylamino group at C-3′ which attracts a proton

I

^{1}H-NMR Spectral Studies. Chemical structures of **2**, **3**, **5**, **6**, **7**, and **8** were confirmed by their ^{1}H-NMR spectra. The proton chemical shifts of these compounds, MT, and DMT (**1**) are shown in Table 2, and the spectrum of MT, in Fig. 1. In MT and DMT, no substantial differences in shift values between the corresponding protons of both compounds were observed, although slight differences being observed in H-1′, 2′, 3′, 4′, and *N*-methyls at C-3′. In the 23-iodo compound (**2**), pronounced up-field shifts of methylene protons at C-23 were observed, in comparison to **1**, and moderate shift changes in H-13, 14, and 15, all of these hydrogen atoms locating in the vicinity of C-23. In the 23-dimethylamino derivative (**3**), pronounced up-field shifts of the methylene protons at C-23 were observed, in comparison to the iodo derivative (**2**), and moderate to slight shift changes in H-10, 13, 14, and 15. These

TABLE 2. PROTON CHEMICAL SHIFT DATA[a] OF MT, DMT(**1**), **2**, **3**, **4**, **5**, **6**, **7**, AND **8** (in $CDCl_3$ at 50°[b] for MT and DMT, and 24° for other compounds)

a) After the shift values (δ), multiplicity of the signals is cited, that is omitted if the multiplicity is the same with that of the left-handed compound. Asterisk, *, **, and *** mean that the $\Delta\delta$ between the figures of the right and the left are 0.04—0.09, 0.1—0.2, and >0.2ppm, respectively, except for **4** and **8**. b) Signals of MT and DMT were not sharp at 24°. c) Slightly broadened, d) Broadened, e) $J \leq 1$ Hz, f) Signal height is 60—70% of that of H-6″.

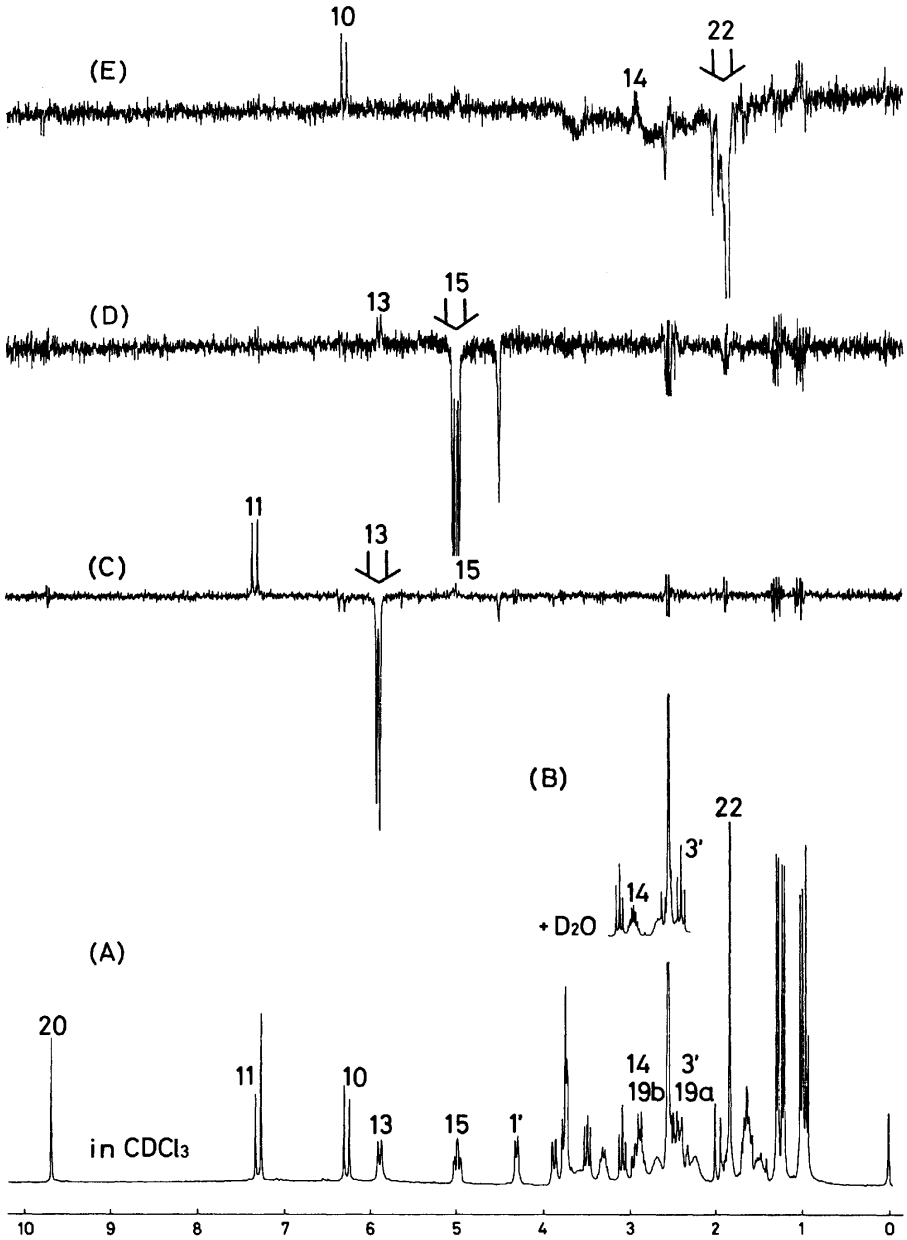

Fig. 1. ^{1}H-NMR spectra of MT. (A) Normal spectrum, (B) measured after addition of D_2O followed by standing for 5d with occasional shaking (indicating that H-19a, b were deuterated), (C–E) NOE difference spectrum; arrows mean the positions irradiated.

results indicate that functional group changes occur at the C-23. The momo-*O*-acetyl derivative (**5**) of **3** showed pronounced down-field shift of H-2′, and moderate shift changes of *N*-methyls at C-3′, H-4′, and 5′, in comparison to the corresponding chemical shifts of **3**, indicating that HO-2′ was acetylated. The di-*O*-acetyl derivative (**6**) showed pronounced down-field shifts of H-2′ and 4″ in comparison to the corresponding shifts of **3**, indicating that HO-4″ (and not HO-3) was acetylated in addition to HO-2′. Selective deacetylation of **6** gave monoacetyl derivative (**7**), that showed up-field shift of H-2′, indicating that 2′-*O*-acetyl group was removed. It is worthy to mention that *O*-acetyl methyl protons at C-2′, 3, and 4″ resonated invariably at δ 2.08, 2.11, and 2.16, respectively in the four compounds (**5**, **6**, **7**, **8**) usable for diagnosis of the acetyl positions.

Decoupling results obtained in MT are shown in Table 3, with the general coupling constants relating to **2**, **3**, **5**, **6**, **7**, **8**, MT, and DMT. As was cited in the Table, substantially the same J values were observed in the corresponding protons in all compounds described above, with slight exceptions, and the values showed good accordance with those of rosaramicin reported.[8]

Some stereochemical problems between the range of C-10 and C-15 are next described. The large coupling constants of $J_{10,11}$ in the compounds described above indicate that H-10 and 11 are in trans relationship, as repeatedly reported in similar compounds. However, ^{1}H-NMR spectral study in a solution describing the

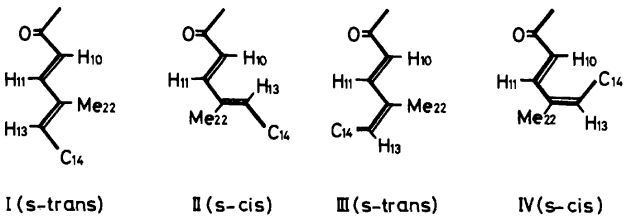

Chart 1.

spacial situation related to H-11, Me-22, and H-13 has not been reported yet. Theoretically, the following four structures (I, II, III, and IV) should be considered. Omura *et al.*[9] reported, by the X-ray crystallographic study of protylonolide, that Me-22 and H-13 are trans, and that Me-22 and H-11 are also trans. From the former result, structures III and IV should be abandoned. However, in the latter relationship, possibility of structure II should be considered, because, in a solution, rotational energy around the axis of C(11)—C(12), is thought to be not so high as to prevent the debate. To clarify the problem, nuclear Overhauser effects (NOE) between some important hydrogen atoms were measured using the NOE difference spectroscopy[10] (Fig. 1). Irradiation at δ 1.83 (Me-22) of MT caused pronounced positive enhancement (≈15%) of each of the resonances of H-10* and 14, but not other resonances including H-11* and 13. On this experiment, if strongly irradiated, slight enhancement of H-15 was observed. This may be caused by the simultaneous irradiation of H-16b (δ ≈1.86) as well as

*Resonances at δ 6.3 and 7.3, both appeared as a doublet, were assigned to H-10 and 11, respectively. These assignments will be reasonable from the point of view of mesomeric effect[11a] and the comparison of the chemical shifts of the corresponding protons of, for example, mycinamicins,[12] which have a similar α,β,γ,δ-unsaturated carbonyl fragments lacking the methyl group at C-12.

Me-22, and H-15 may be enhanced through space or through bond interaction. Irradiation of H-11 and H-13 also caused pronounced positive enhancements (20—22%) of H-13 and H-11, respectively, with small signal increase (5—6%) of H-15 in the latter case. Irradiation of H-15 also caused enhancement (≈5%) of H-13. In conclusion, these results show that Me-22 is located in close proximity with both H-10 and 14, that is, between H-10 and 14, and H-13 is located be-

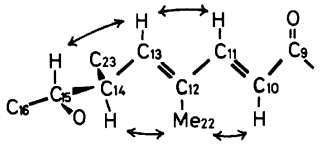

Chart 2.

tween H-11 and 15, as depicted above. The conclusion clearly supported the structure of I having *s*-trans[13] structure, and also confirmed the absolute configuration at C-15 to be *R*.

The structure of **4** was confirmed by the ^{1}H-NMR spectrum (Table 2). In the spectrum, H-13 appeared as a singlet suggesting the absence of H-14. Resonances of methylene protons at C-23, which appeared at $\delta \approx 3.7$ in MT, appeared as two singlets at δ 5.09 and 5.33. The chemical shifts and zero coupling suggest[11b] the presence of a terminal double bond.

To confirm the structure of **4** further, 23-deoxy-14(23)-enomycaminosyl tylonolide (**17**), a simpler analog, was prepared starting from 23-bromo-23-deoxymycaminosyl tylonolide diethyl acetal[7] (**15**) with silver fluoride *via* the corresponding 14(23)-ene compound (**16**). The ^{1}H-NMR spectra of the macrolactone portions of **17** and **4** showed good accordance.

Antibacterial spectra (Table 4) of the new derivatives showed that introduction of a dialkylamino group at C-23 of DMT (**1**) gave activities, comparable to that of parent DMT. Among the compounds, the 4″-*O*-acetyl derivative (**7**), 23-deoxy-23-piperidino and hexahydroazepine-1-yl derivatives (**12**, **13**) were most active against both Gram-positive and-negative bacteria.

Experimental

General. Optical rotations were measured with a Perkin-Elmer 241 polarimeter. Thin-layer chromatography (TLC) was carried out on Kieselgel 60 F-254 (E. Merck) silica

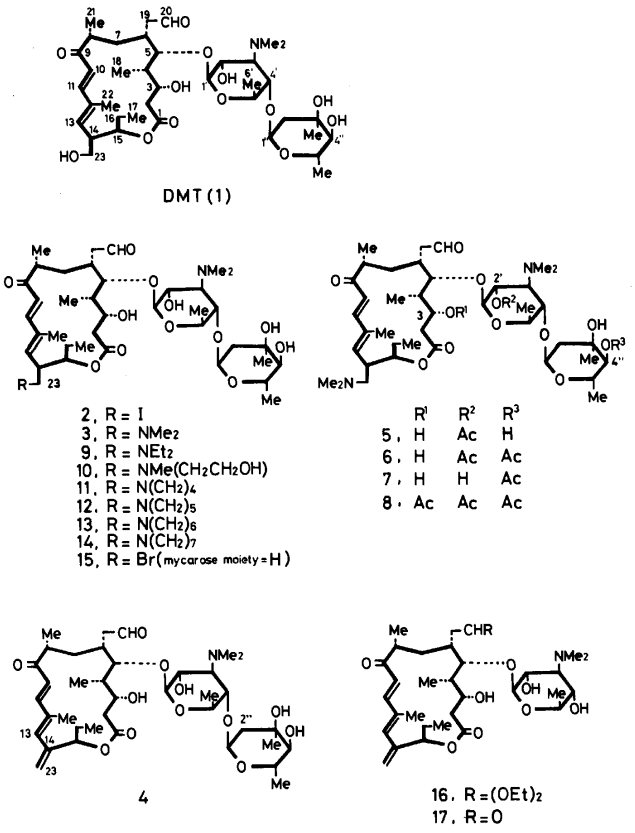

Chart 3.

gel with detection by spraying with sulfuric acid, followed by slight heating. Column chromatography was performed on Wakogel C-200, or Kieselgel 60, 230—400 mesh (E. Merck). UV spectrum was recorded with a Hitachi 200-10 spectrometer. ^{1}H-NMR spectra were recorded at 90 MHz with a Varian EM-390 spectrometer, or at 250 MHz in the FT mode with a Bruker WM 250 spectrometer at 24°C unless otherwise stated.

23-Deoxy-23-iododemycinosyltylosin (2). A mixture of crude demycinosyltylosin (**1**, 1.06 g) obtained from a culture, triphenylphosphine (0.93 g), and iodine (0.4 g) in dry pyridine (52 ml) was stirred under nitrogen at 0°C for 3.5 h. After addition of 0.1 M aqueous sodium thiosulfate (3 ml) to decompose the excess iodine, the mixture was evaporated. The chloroform solution of the residue was washed with saturated aqueous sodium hydrogencarbonate, saturated aqueous sodium sulfate, dried (Na_2SO_4), and evaporated. Silica-gel column chromatography of the residue with chloroform–methanol–28% aqueous ammonia (50:1:0.1) as the eluant gave a solid of **2**, 930 mg. It showed, on TLC with chloroform–methanol–28% aqueous ammonia (10:1:0.1), a single

spot of R_f 0.47 (*cf* **1**, 0.32), $[\alpha]_D^{22}$+4° (*c* 1, chloroform). ^{1}H-NMR ($CDCl_3$): $J_{14,23a}$ 9, $J_{14,23b}$≈3, $J_{23a,23b}$ 10 Hz. Irradiation of H-14 collapsed the signals of H-15, H-23a, 23b, and H-13 to double doublets, a doublet, a doublet, and a singlet, respectively. Irradiation at δ 3.3 (H-23b), or of H-13 collapsed the signals of H-14 to a quartet, and double triplets, respectively. Irradiation of H-1″ collapsed the double doublets of H-2″a to a doublet.

Found: C, 52.76; H, 7.05; N, 1.36; I, 14.52%. Calcd for $C_{38}H_{62}INO_{12}\cdot H_2O$: C, 52.47; H, 7.36; N, 1.61; I, 14.61%.

23-Deoxy-23-dimethylaminodemycinosyltylosin (3) and 23-Deoxy-14(23)-enodemycinosyltylosin (4). A solution of **2** (750mg) and dimethylamine (0.88ml of 5M solution in acetonitrile (1M=1 moldm^{-3}); 5mol equivalents for **2**) in acetonitrile (15ml) was heated at 80°C for 30min. The same amount of dimethylamine was added, and the reaction was continued for further 30min. On TLC with chloroform–methanol–28% aqueous ammonia (10:1:0.1), the solution showed spots of R_f 0.35 (**3**) and 0.47 (slight, **4**, the R_f value being the same with that of **2**). Evaporation gave a residue, which was extracted with chloroform. The organic layer was washed with saturated aqueous sodium hydrogencarbonate and saturated aqueous sodium sulfate, dried (Na_2SO_4), and evaporated to give a solid (718mg). Purification by silica-gel column chromatography with chloroform–methanol–28% aqueous ammonia (40:1:0.1) gave solids of **3**, 564mg (83%) and **4**, 71mg (11%).

Compound **4**: $[\alpha]_D^{20}$+11° (*c* 1, chloroform); ^{1}H-NMR ($CDCl_3$): $J_{2b,3}$ 10, $J_{4,5}$ 7, $J_{10,11}$ 16, $J_{13,22}$ 1, $J_{15,16a}$=$J_{15,16b}$ ≈6.5, $J_{23a,23b}$ 0, $J_{1',2'}$ 7.5, $J_{2',3'}$ 10, $J_{1'',2''a}$ 3.7, $J_{1'',2''b}$ 0, $J_{2''a,2''b}$ 15 Hz.

Irradiation at δ 1.83 (H-16a,b) collapsed the triplet of H-15 and H-17 to a singlet, respectively. Irradiation of H-13 collapsed the small doublet of H-22 to a singlet. Irradiation of H-1″ collapsed the double doublets of H-2″a to a doublet.

Found: C, 59.74; H, 7.91; N, 1.78%. Calcd for $C_{38}H_{61}NO_{12}\cdot H_2CO_3$: C, 59.62; H, 8.03; N, 1.78%.

2′-O-Acetyl-23-deoxy-23-dimethylaminodemycinosyltylosin (5). To a solution of **3** (564mg) in acetonitrile (11ml) were added acetic anhydride (0.37ml) and powdered sodium hydrogencarbonate (0.6g) and the mixture was stirred at room temperature for 4h. Evaporation gave a residue, which was treated with ice-cold aqueous half-saturated sodium hydrogencarbonate under stirring for 30min. Extraction of the mixture with chloroform, washing the organic layer with a saturated aqueous sodium sulfate, drying over sodium sulfate, and evaporation gave a solid of **5**, 568mg (95%), $[\alpha]_D^{20}$−37° (*c* 1, chloroform).

Found: C, 62.05; H, 8.58; N, 3.36%. Calcd for $C_{42}H_{70}N_2O_{13}$; C, 62.22; H, 8.64; H, 3.46%.

2′,4″-Di-O-acetyl-23-deoxy-23-dimethylaminodemycinosyltylosin (6). A mixture of **5** (43.6mg) and acetic anhydride (8.2μl) in pyridine (0.22ml) was kept at 0°C for 7d. After addition of water (0.05ml), followed by standing for a few min, the mixture was poured into saturated aqueous sodium hydrogencarbonate (2ml). Extraction of the mixture with chloroform, washing the organic layer with saturated aqueous sodium hydrogencarbonate and then saturated aqueous sodium sulfate, drying over sodium sulfate, and evaporation gave a residue. Silica-gel column chromatography of the residue with toluene–acetone (2:1) as the developer gave **6**, 24mg (52%) and a mixture of **5** recovered and tri-*O*-acetyl compound, 19.7mg. **6**: $[\alpha]_D^{20}$−47° (*c* 1, chloroform).

Found: C, 61.68; H, 8.38; N, 3.12%. Calcd for $C_{44}H_{72}N_2O_{14}$: C, 61.97; H, 8.45; N, 3.29%.

4″-O-Acetyl-23-deoxy-23-dimethylaminodemycinosyltylosin (7). A solution of **6** (24mg) in methanol (0.24ml) was heated at 60°C overnight. Evaporation gave a solid, that was chromatographed on a silica-gel column with chloroform–methanol–28% aqueous ammonia (50:1:0.1) to give a solid of **7**, 20.9mg (91.5%), $[\alpha]_D^{22}$−28° (*c* 1, chloroform).

Found: C, 60.56; H, 8.17; N, 3.26%. Calcd for $C_{42}H_{70}N_2O_{13}\cdot 1/2H_2CO_3$: C, 60.64; H, 8.44; N, 3.33%.

2′,3,4″-Tri-O-acetyl-23-deoxy-23-dimethylaminodemycinosyltylosin (8). A mixture of **3** (21mg) and acetic anhydride (42μl) in pyridine (0.1ml) was kept at 0°C for 2d. After addition of water (20μl) the solution was concentrated. The chloroform solution of the residue was treated as usual to give, after chromatography, a solid of **8**, 15mg (63%), $[\alpha]_D^{20}$−35° (*c* 1, chloroform).

^{1}H-NMR ($CDCl_3$): Irradiation of H-2b collapsed the doublet of H-2a and the broad doublet of H-3 to a singlet, respectively. Irradiation at δ 1.80 (H-2″a) collapsed the doublet of H-1″ to a singlet.

Found: C, 60.95; H, 8.07; N, 3.06%. Calcd for $C_{46}H_{74}N_2O_{15}\cdot 1/2H_2O$: C, 61.13; H, 8.31; N, 3.10%.

Preparation of 9, 10, 11, 12, 13, and 14. To a solution of **2** (≈100mg) in acetonitrile (2ml) was added the corresponding amine (5 equivalents for **2**), that is, diethylamine (for the preparation of **9**), *N*-methyl-2-hydroxyethylamine (for **10**), pyrrolidine (for **11**), piperidine (for **12**), hexahydroazepine (for **13**), and octahydroazocine (for **14**), and the solution was heated at 80°C for the period cited in Table 1. Work-up as described for **3** gave the desired 23-dialkylamino derivatives.

^{1}H-NMR spectra of **9**, **10**, **11**, **12**, **13**, and **14** in $CDCl_3$. Compound **9**: H-23a signals did not appear near δ 2.3, and were hardly discernible by overlapping by other signals. Some other signals were: δ 4.75 (1H, dt, H-15), 5.76 (1H, d, H-13), 6.25 (1H, d, H-10).

Compound **10**: δ 1.83 (1H, d, H-22), 2.24 (3H, s, NMe), 4.76 (1H, dt, H-15), 5.74 (1H, d, H-13), 6.28 (1H, d, H-10).

Compound **11**: δ 2.54 (1H, dd, *J* 4.5 and 12Hz, H-23b), 2.63 (1H, dd, *J* 10 and 12Hz, H-23a), 4.77 (1H, dt, H-15), 5.80 (1H, d, H-13), 6.26 (1H, d, H-10).

Compound **12**: δ 4.75 (H-15), 5.76 (H-13), 6.26 (H-10).

Compound **13**: δ ≈2.57 (H-23a) 2.66 (1H, dd, *J* 4.5 and 12Hz, H-23b), 4.77 (H-15), 5.79 (H-13), 6.26 (H-10).

Compound **14**: δ 4.75 (H-15), 5.81 (H-13), 6.26 (H-10).

23-Deoxy-14(23)-enomycaminosyl Tylonolide Diethyl Acetal (16). To a solution of **15**[7] (55mg) in pyridine (0.55ml) was added silver fluoride (30mg) and the mixture was stirred at room temperature overnight. The solution showed, on TLC with chloroform–methanol (6:1), a single spot having the same R_f value with that of **15**. Concentration gave a residue, which was extracted with dichloromethane. Evaporation with several additions of toluene gave a solid, which was purified by column chromatography with chloroform–methanol (6:1) to give a solid, 47.1mg (96%), $[\alpha]_D^{25}$+19° (*c* 1, chloroform) ^{1}H-NMR ($CDCl_3$): δ 1.90 (3H, d, H-22), 2.55 (6H, s, NMe_2), 4.35 (1H, d, $J_{1',2'}$ 7.5Hz, H-1′), 5.12 (1H, s, H-23a), 5.35 (1H, s, H-23b), ≈5.3 (1H, H-15), 6.22 (1H, s, H-13), 6.42 (1H, d, $J_{10,11}$ 16Hz, H-10), 7.22 (1H, d, H-11).

Found: C, 64.24; H, 8.93; N, 2.13%. Calcd for $C_{35}H_{59}NO_{10}$: C, 64.29; H, 9.10; N, 2.14%.

23-Deoxy-14(23)enomycaminosyl Tylonolide (17). A solution of **16** (30mg) in a mixture of acetonitrile (0.6ml) and 0.1M aqueous hydrochloric acid (0.92ml) was kept at

room temperature for 1 h. The solution showed, on TLC with chloroform–methanol (6:1), a spot at R_f 0.23 (*cf* **16**: R_f 0.32). Neutralization with sodium hydrogencarbonate followed by usual work-up gave a solid, which was purified by column chromatography with chloroform–methanol–28% aqueous ammonia (13:1:0.1) to give a solid, 21.4 mg (88%), $[\alpha]_D^{25}$+59° (*c* 1, chloroform), λ_{max}^{MeOH} 292 (ε 23000). This value was in good agreement with the calculated value (293) by Woodward generalization[14], treating the unsaturated ketone as an acylic system.

^{1}H-NMR ($CDCl_3$): δ 1.90 (3H, d, H-22), 2.53 (6H, s, NMe_2), 4.33 (1H, d, $J_{1',2'}$ 7.5 Hz), 5.13 (1H, s, H-23a), 5.37 (1H, s, H-23b), 6.26 (1H, s, H-13), 6.38 (1H, d, $J_{10,11}$ 16 Hz, H-16), 7.28 (1H, d, H-11), 9.88 (1H, s, H-20).

Found: C, 64.49; H, 8.68; N, 2.34%. Calcd for $C_{31}H_{49}NO_9$: C, 64.23; H, 8.52; N, 2.42%.

We are grateful to Professor Hamao Umezawa of Institute of Microbial Chemistry for the support and encouragements thoroughout the studies. Starting material, demycinosyltylosin was kindly supplied by Dr. Tomio Takeuchi of the Institute. We are also grateful to Dr. Masa Hamada of the Institute for bioassay, to Mrs. Yukiko Otsuka, and Miss Ikuko Inoue of our Institute for measurements of the ^{1}H-NMR spectra, to Mr. Saburo Nakada of Keio University for elemental analysis, and to Miss Sachiko Yanagida for preparation of the manuscript.

Photoelectron Angular Distribution for Jahn-Teller Split Bands of Some Molecules in VUV Photoelectron Spectroscopy

Haruo SHIROMARU and Shunji KATSUMATA*
Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo 060
(Received June 28, 1984)

Measurements of photoelectron angular distribution were carried out with NeI and HeI resonance lines for Jahn-Teller split bands of methane, ethane, cyclopropane, neopentane, tetramethylsilane, carbon tetrachloride, and ammonia. The variation of an asymmetry parameter β across the band is presented. Significant β variations across the Jahn-Teller split bands due to the 1^2T_2 states of $C(CH_3)_4^+$ and CCl_4^+ could not be explained in terms of photoelectron energy dependence of β. These abnormal variations will be discussed on the basis of characteristics of the degenerate molecular orbitals split by the Jahn-Teller effect.

Ejection of an electron from a fully occupied degenerate orbital in a molecule induces an orbitally degenerate doublet state of the corresponding ion. The degeneracy of such a state can be removed by a spin-orbit coupling and/or the Jahn-Teller (J-T) effect. The Jahn-Teller effect means that a molecule in a degenerate electronic state is unstable toward distortions that lower the molecular symmetry, thereby removing the electronic degeneracy. The J-T split bands in molecular photoelectron spectroscopy are well known and we can see some typical examples in fundamental molecules as summarized by Rabalais.[1] Interestingly two evidences called the static and dynamic Jahn-Teller effects are distinguished for convenience. The static Jahn-Teller effect means that the distorted molecule has a permanent distortion that lowers its symmetry and that the interaction between the electronic and vibrational motions may be very small. The dynamic Jahn-Teller effect refers to the coupling of the electronic and vibrational motions. The difference between these Jahn-Teller effects should be discriminated by analyzing the appearance of the J-T active vibrational modes and the magnitude of the J-T energy splitting.

On the other hand, measurement of photoelectron angular distribution gives important and valuable information on the electronic structure of a molecule and on the coupling between electronic and vibrational motions. The former information gives correlation between the nature (σ or π types) of ionized molecular orbital and the value of β, an asymmetry parameter,[2-10] and has so far been used to confirm the orbital assignments of photoelectron (PE) spectra for many large molecules by several workers.[11-25] The latter information mainly associated with shape resonances has demonstrated several aspects of photoionization processes.[26-29] Photoelectron vibrational structures obtained with line sources such as NeI and HeI resonance lines are typically well represented by the Franck-Condon (F-C) factors between vibrational wavefunctions of the ground and ionic states, and generally give the same photoelectron angular distribution. Deviations are the exception and are usually attributed to many-electron interactions with an intermediate and autoionizing state. However shape resonances which lead to the temporary trapping of photoelectrons by a centrifugal barrier enhance the coupling between electronic and nuclear motions and the effects are large in both vibrational intensities and angular distributions. Therefore, when there is no autoionization process in the vicinity of shape resonances, the effects of shape resonance on PE bands induce non-Franck-Condon vibrational intensity distribution and the vibration-dependent angular distribution. Experimental confirmation of non-F-C intensity distribution was reported for the 5σ levels of CO[26] and for the $3\sigma_g$ level of N_2.[28] Experimental confirmation of the v-dependent angular distribution has also been reported for N_2,[27,30,31,33,35-38] CO,[29,34-37,39] O_2[31,35,37] and CO_2.[32,35,36,40] Most measurements of vibrationally resolved angular distributions have been restricted to the single HeI wavelength,[30-36] so that energy-dependence effects could not be confirmed.

In relation to the dependence of β on vibrational structures, it is of interest to know how β values for J-T split bands depend on geometrical distortions of individual components of the final state. Photoelectron angular distribution measurements have been so far reported for J-T split bands of some molecules.[11,12,18,19,41] Carlson and White reported for the first time that the HeI β values of components for each of J-T split bands in halomethanes are essentially equal to one another.[11] Leng and Nyberg pointed out that this fact is also true in cases of cyclopropane and allene.[18,19] Sell and Kuppermann have found the monotonic change of β across band II in SF_6[41] but concluded that the β variation is typical of general photoelectron energy dependence.[7]

Focusing on the problem about the β variation across the J-T split band, we carefully measured photoelectron angular distributions for various J-T split bands of several molecules.

Experimental

The photoelectron angular distribution of free molecules for unpolarized radiation is given by

$$J(\theta) \propto 1 + \frac{1}{2}\beta\left(\frac{3}{2}\sin^2\theta - 1\right), \quad (1)$$

where $J(\theta)$ is the photoelectron intensity, θ is the angle between the incoming photons and the outgoing photoelectrons, and β is the asymmetry parameter ranging between -1 and 2. Therefore, the β values of individual bands were calculated from PE spectral data obtained at two angles of 90° and 135° with the following expression derived from Eq. 1

$$\beta = 8(R-1)/(R+2) \quad (2)$$

where $R=J\,(90°)/J\,(135°)$.

Measurements of photoelectron angular distribution were carried out with a photoelectron spectrometer (VG Scientific Ltd., model ADES-400), as previously described elsewhere.[24] The PE spectrometer was connected to a microcomputer (NEC COMPO BS/80) system, in order to automatically control a scan voltage, a sample pressure and rotation of a turn table putting an analyzer. The PE spectra obtained were stored temporarily in a multichannel scaler (16bits×4K channels) and preserved in a floppy disk for calculating β values later. The multichannel scaler and controllers were home-made. Each β value of the spectral data was evaluated with Eq. 2 after subtracting the background and correcting the energy shift between the data obtained at 90° and 135°.

Since the β values obtained by an angular-dispersive PE spectrometer often contain a systematic error because of the various experimental problems, the systematic error must always be assessed in order to determine the most accurate values. Therefore we measured the β values for the PE bands of Ar, Xe, N_2, O_2, and CO_2 as a check on a calibration before and after measurements of samples in question. For these calibration gases, plots of our experimental raw β values against the corresponding ones taken from Ref. 36 exhibit a linear relationship in the range between -1 and 2, as shown in Fig. 1. Therefore all β values presented in this work were corrected by using such linear relationship. Furtheremore, standard deviations of the β values were found to be less than 0.03 under our experimental conditions. Energy resolutions used here were about 55 and 120meV in a full width at half maximum of the peak ($^2P_{3/2}$) of Ar.

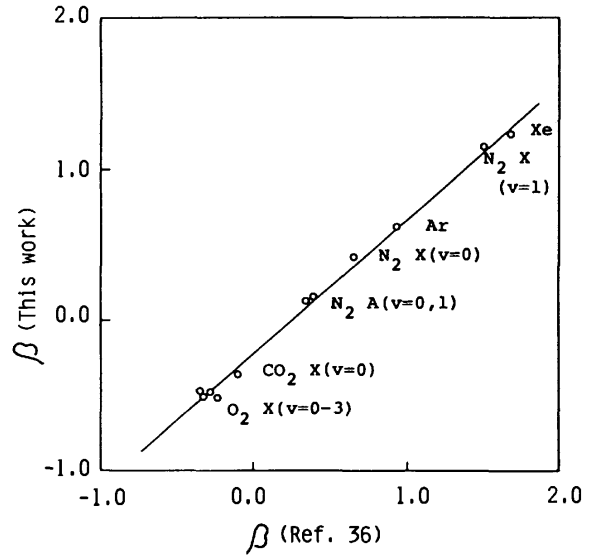

Fig. 1. Plot of our experimental raw β values of PE bands for calibration gases against those taken from Ref. 36.

The samples used here are methane, ethane, cyclopropane, neopentane, tetramethylsilane, carbon tetrachloride and ammonia. Methane and ethane were purchased from Gascro Kogyo K. K., neopentane and tetramethylsilane from Tokyo Kasei K. K., and cyclopropane from Takachiho Kagaku Cogyo K. K. All gaseous chemicals were about 99.5% pure. Ammonia was dehydrated by use of the drying agent of CaO, and the others were used without further purification.

Results

Plots of β values against ionization energies are shown in Figs. 2—8 for the PE spectra of the molecules mentioned above, together with the HeI spectra obtained at θ=90°. Each value of β is the mean value for eleven channels' and the error bar indicates the standard deviation. The experimental NeI and HeI β values for various bands are summarized in Table 1, together with assignments of the ionic states and the available data.

The PE spectrum of methane (Fig. 2) consists of three components of the 1^2T_2 state split by the J-T effect.[42] The HeI β value for each of the components is found to be almost the same. On the other hand, the NeI β values decreases monotonically above 15eV. However, considering the vicinity to the threshold and the background of slow electrons, this variation of the NeI β value cannot be verified definitely. Our NeI and HeI β values are slightly larger than those of Carlson *et al.*[43] and Marr and Holmes.[44] However, it may be concluded that no significant variation of the HeI β across the J-T split band was observed in agreement with the result of Carlson *et al.*[43]

The PE spectrum of ethane (Fig. 3) consists of the 1^2E_g, 1^2A_{1g}, and 1^2E_u ionic states.[42] There are three band maxima in the 11.5—14.5eV region which were assigned to the 1^2E_g and 1^2A_{1g} states although the order of their states has been controversial. To our knowledge, no data of β values for these bands have ever been published. It has been expected that the order of the 1^2A_g and 1^2E_g states might be determined from photoelectron angular distribution measurements. However, the order could not be identified clearly since, as can be seen from Fig. 3, no definite difference among β values for these maxima was observed at both NeI and HeI radiations. Nevertheless it may be concluded that there is no variation of β across the J-T split band of the 1^2E_g state. The PE band assigned to the 1^2E_u state in the region of 14.5 to 16.5eV exhibits two maxima due to the J-T splitting. The HeI β variation across the band seems to slightly decrease toward higher ionization energy (*ca.* 0.05/eV) while the NeI β variation is steep but it is not certain owing to the vicinity to the threshold.

The PE spectrum of neopentane (Fig. 4) in the 10-17eV region consists of four bands due to ionization from the $4t_2$, $1t_1$, 1e, and $3t_2$ orbital.[42] All these bands display the J-T splittings as discussed by Jonas *et al.*[12] Concerning the β variation across each of the

a) Taken from Ref. 42 unless other comments are made. I_v indicates the ionization energy for each peak in the band. b) E_e is the photoelectron kinetic energy. NeI and HeI photon energies are 16.85 and 21.22 eV, respectively. c) Ref. 48. d) Ref. 43. e) Ref. 19. f) Ref. 12. g) Ref. 49. h) Ref. 45. i) Ref. 35.

four bands, significant variations were observed for the first and fourth bands but no variations for the second and third bands, as can be seen in Fig. 4. The HeI β variation across the first band (1^2T_2) (Fig. 5) was found to increase monotonically toward higher ionization energy (*ca.* 0.15/eV). This variation seems to be also realized even in the NeI β variation. In Fig. 4, NeI β plots for the first and second components for the 1^2T_2 band split by the J-T effect increase gradually, but that for the third component decreases suddenly by the overlap effect of the small β value of the second band (1^2T_1). The HeI β variation across the fourth band (2^2T_2) is seen to decrease in contrast with that for the first band. The NeI β variation across the 2^2T_2 band is uncertain as well as that of the third band (1^2E) owing to the vicinity of the threshold and the background of slow electrons. Our HeI β values obtained here are considerably small in comparison with those of Jonas *et al.*[12] It may be concluded that the first and fourth bands show the significant β variations.

Figure 6 shows the PE spectrum of $Si(CH_3)_4$ and NeI and HeI β plots for PE bands in the region of 10 to 16eV. The HeI β values are in good agreement with those reported by Jonas *et al.*[12] This molecule is interesting by virtue of the similarity to $C(CH_3)_4$. Concerning the variation of β across the first band due

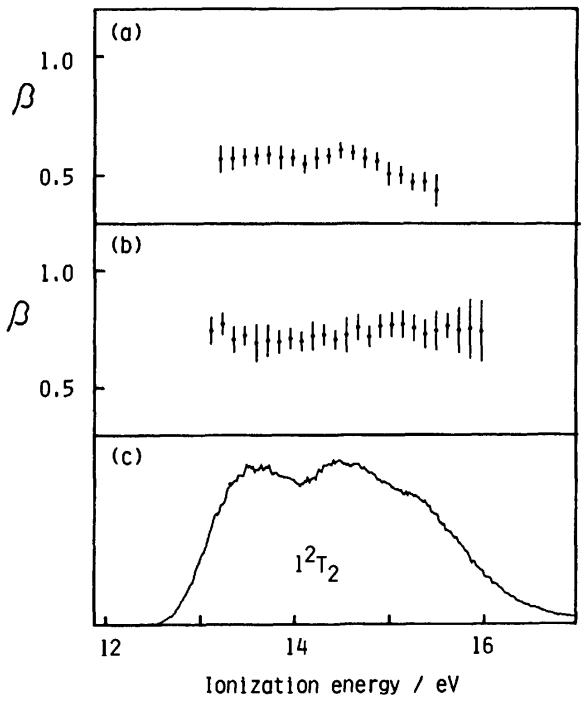

Fig. 2. Plots of β values of methane obtained with (a) NeI and (b) HeI photons and (c) HeI PE spectrum at θ=90°.

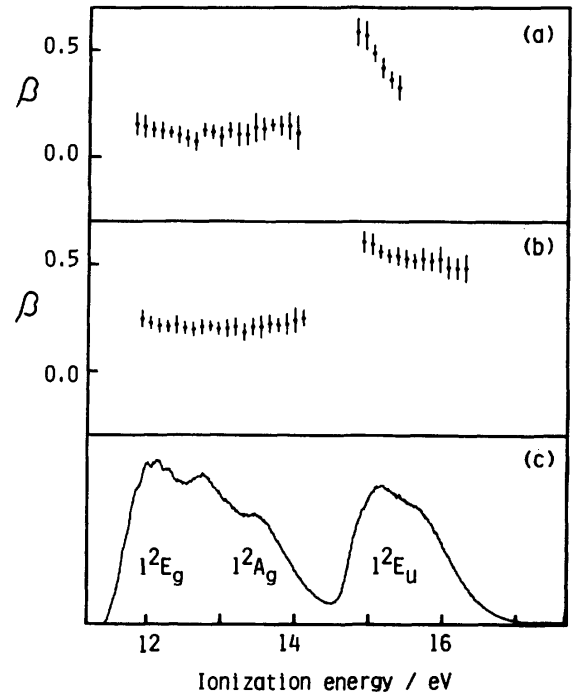

Fig. 3. Plots of β values of ethane obtained with (a) NeI and (b) HeI photons and (c) HeI PE spectrum at θ=90°.

to the 1^2T_2 state, the HeI β plot shows no variation but the NeI β plot a significant variation. Variations of β for the other bands were uncertain because the PE bands are heavily overlapped with each other.

Carbon tetrachloride has the same valence electronic structure as neopentane. Orbital assignments of the PE spectra (Figs. 7A and 7B) are well known and the first

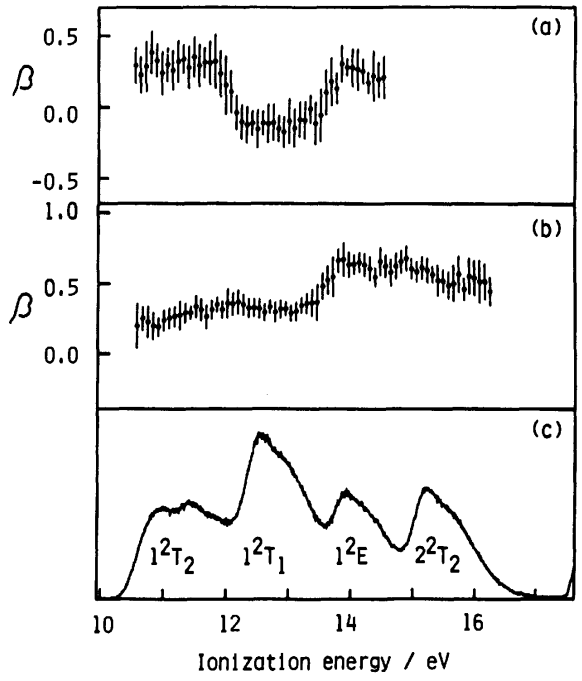

Fig. 4. Plots of β values of neopentane obtained with (a) NeI and (b) HeI photons and (c) HeI PE spectrum at θ=90°.

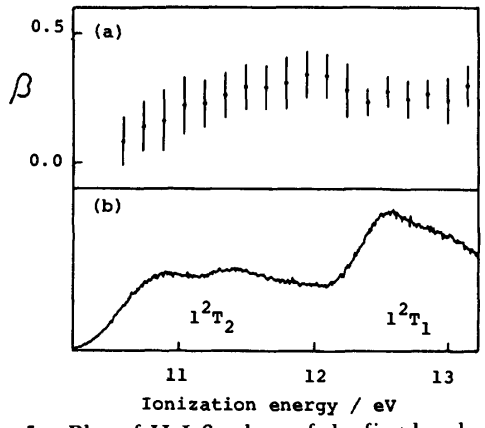

Fig. 5. Plot of HeI β values of the first band of neopentane and HeI PE spectrum obtained at θ=90°.

four bands are assigned to the 1^2T_1, 1^2T_2, 1^2E, and 2^2T_2 states, respectively.[42] The second (1^2T_2) and third (1^2E) bands show the J-T splittings. The HeI β values for these four bands have so far been reported by Carlson and White[11] and Carlson *et al.*[45] who have not taken account of β variation across each of the bands. Our HeI β values for the four bands are in good agreement with those of Carlson *et al.*[45] It is found from Figs. 7A and 7B that the β variations exist definitely for the 1^2T_2 and 2^2T_2 bands but no significant variation for the other bands. Carbon dioxide and argon shown in Figs. 7A and 7B, respectively, were used as an internal standard to check and correct energy shifts between the spectra obtained at 90° and 135°. The correction was performed by making the β values for the peak of the the internal standard flat.

For the PE spectrum of ammonia, the second band assigned to the $1^2E'$ ionic state exhibits the J-T splitting

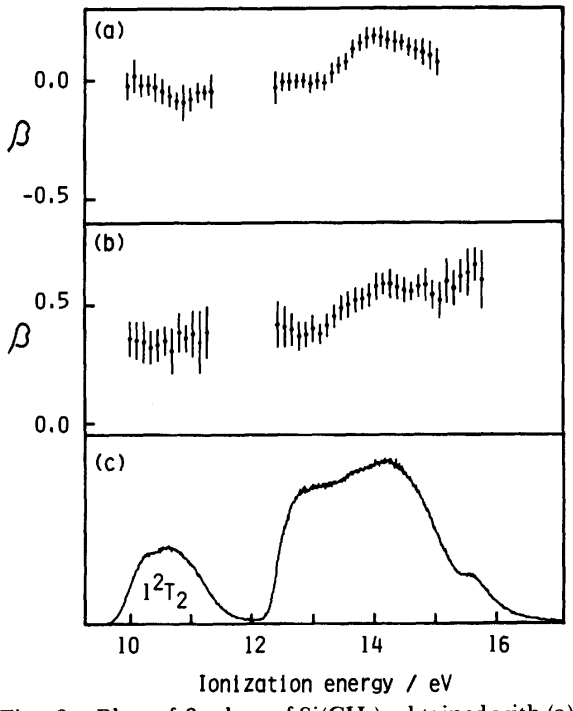

Fig. 6. Plots of β values of $Si(CH_3)_4$ obtained with (a) NeI and (b) HeI photons and (c) HeI PE spectrum at θ=90°.

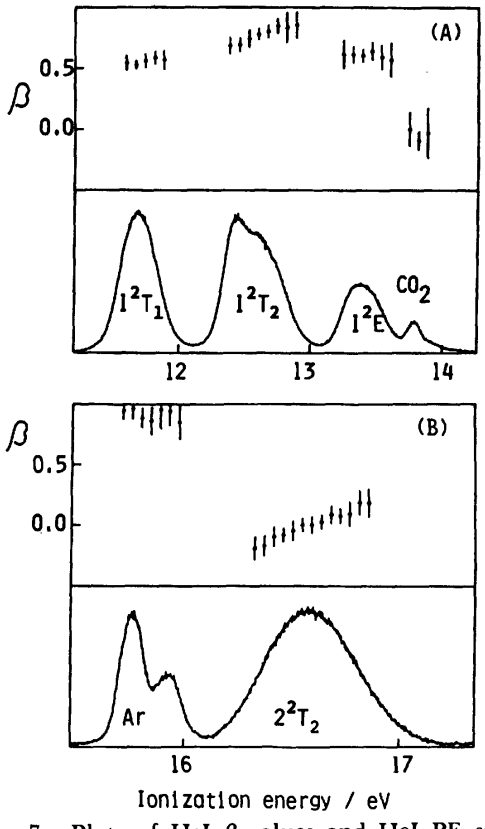

Fig. 7. Plots of HeI β values and HeI PE spectra obtained at θ=90° for (A) the first three bands of CCl_4 and (B) the fourth band of CCl_4.

of about 0.7eV.[42] The HeI β variation across the band is flat as shown in Fig. 8A. Our HeI β values obtained here are higher by about 0.3 than those of Hancock and Samson.[35]

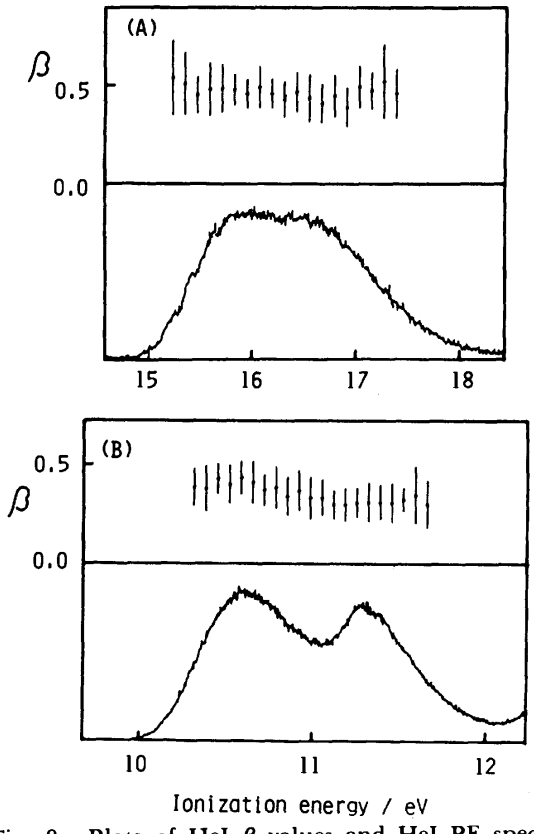

Fig. 8. Plots of HeI β values and HeI PE spectra obtained at θ=90° for (A) the second band of ammonia and (B) the first band of cyclopropane.

For the PE spectrum of cyclopropane (Fig. 8B), the first band ($1^2E'$) having two peaks shows the relatively large splitting (0.7eV) by the J-T effect.[42] Leng and Nyberg[19] have reported a significant variation of β across the band. We also confirmed the same variation although our HeI β values obtained here are slightly lower than those of Leng and Nyberg, as listed in Table 1.

Discussion

The asymmetry parameter basically depends on two factors; the kinetic energy of the photoelectron and the nature of the molecular orbital from which the photoelectron is ejected. When considering variation of β across a band, it must be checked whether the variation is analogous to the photoelectron energy dependence. The energy dependence of β for various bands is shown in Fig. 9 by using the experimental NeI and HeI β values. Here, the energy dependence was assumed to be linear in the region of NeI to HeI photon energies. This assumption seems to be valid from the fact that the energy separation between the two photon energies is relatively small. For example, the energy dependence of β obtained with synchrotron radiation[45] is nearly linear for each of the four bands of CCl_4, as shown in Fig. 9. Consequently it may be noted from Fig. 9 that the energy dependence of β for

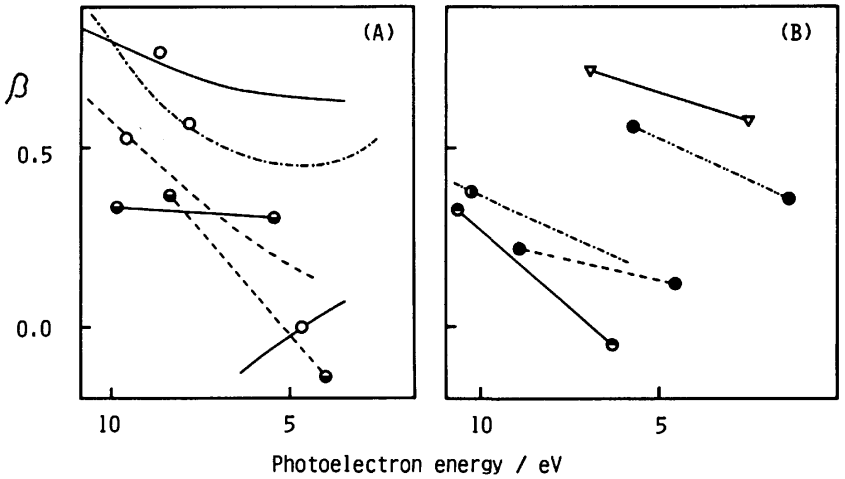

Fig. 9. Photoelectron energy dependence of β in the region of NeI and HeI photons for (A) CCl_4 (○) and neopentane (◒); $^2T_2$ (——), $^2T_1$ (----), and ^2E (-·-·-), and (B) 1^2T_2 (—▽—) of methane, $1^2E'$ (-·-◑-·-) of cyclopropane 1^2E_{1g} (--●--) and 1^2E_{1u} (-··-●-··-) of ethane, and 1^2T_2 (—◒—) of TMS.

each of the bands discussed in this work decreases commonly toward lower photoelectron energy, except for that of the 2^2T_2 band of CCl_4.

Figure 10 shows the degree of variation of HeI β with the J-T splitting for each of the J-T split bands in question. Then, it is found that the trend of β variations for the 1^2T_2 band of CCl_4 and the 1^2T_2 band of $C(CH_3)_4$ is certainly different from the energy dependence of β as shown in Fig. 9. The β variations for the other bands are very small or similar to the tendency of the energy dependence. The variations of β across the vibrational envelopes of π bands for various unsaturated hydrocarbons[2,7,8] and across the J-T split bands of some molecules[11,19,41] have been so far reported. Most of the β variations were interpreted in terms of the photoelectron energy dependence. In this sense, β variations for the 1^2T_2 bands of CCl_4 and $C(CH_3)_4$ cannot be explained in terms of the energy dependence. Here we tried to consider the abnormal β variation on the basis of characteristics of the ionized molecular orbitals.

The asymmetry parameter for an atom is given as a function of the quantum number (l) of an orbital angular momentum of an ionized orbital,[46] and it may be generally recognized that the larger the value of l is, the lower the β value. For molecular orbitals (MOs), the value of l is usually a poor quantum number. An MO (ψ_j) is expanded in terms of the spherical harmonics $Y_{lm}(\theta,\phi)$,[13,47]

$$\Psi_j(r,\theta,\phi) = \sum_{l=0}^{\infty}\sum_{m=-l}^{l} C_{lm}(r)Y_{lm}(\theta,\phi), \quad (3)$$

$$C_{lm}(r) = \iint Y^*_{lm}(\theta,\phi)\Psi_j(r,\theta,\phi)\sin\theta\,d\theta\,d\phi, \quad (4)$$

where $C_{lm}(r)$ is the expansion coefficient, depending on the character of the MO and on a position of the origin of the one-center expansion. If the molecule has a center of symmetry, it is reasonable to select the center as the origin. The most probable value of l is that one corresponding to the maximum value of $|C_{lm}|^2$ integrated over r. We abbreviate $|C_{lm}|^2$ to C^2_{lm} hereafter. The C^2_{lm} value for each component of the degenerate MO in the ionic state is the same but the values for the individual MOs lifted by the J-T effect should be different from each other. A significant variation of β across the J-T split band should be attributed to the value of l or the value of C^2_{lm} for the corresponding MO.

In this sense, we calculated the values of C^2_{lm} integrated over r to determine the most probable values

	I_2	16.58	0.469	0.261	0.106		
	I_3		0.468	0.272	0.108		

a) The values are the experimental ionization energies.

of l for the MOs corresponding to the J-T split components in the $^2T_2$ state of CH_4^+. The values of l and m used for this expansion were from 0 to 6 and 0 to 4, respectively. The normalized condition was completely satisfied within these limitations of l and m. The calculated results are listed in Table 2. We used the MOs obtained in Types I, I′, and IV described in Ref. 48 as the J-T distorted geometries of CH_4^+. It is found from Table 2 that the most probable l value for each of the MOs is 1. Concerning the values of C_{lm}^2 for l=1, those of the degenerate MOs (Td) are equal to one another whereas each of the split MOs' is not the same and increases with increase of the ionization energy. The variation of β may be attributed to this slight variation of C_{lm}^2 (about 0.03).

The calculation of the MO expansion for CCl_4^+ was also carried out. The molecular orbitals obtained in Type I were used for CCl_4^+.[50] The calculated results are listed in Table 3. The normalized condition was almost completely (90%) satisfied. It is found that the most probable l values for the 1^2T_1, 1^2E, and 2^2T_2 states are 3, 2, and 1, respectively. However, the most probable value for the second state (1^2T_2) cannot be determined because the C_{lm}^2 values for l=1, 2, and 4 are close to one another. The difference of the C_{lm}^2 values among the J-T split MOs in the individual ionic states is commonly slight (0.03) as shown in Table 3. If experimental β values can be estimated on the basis of the weighted average on the theoretical β values for the quantum numbers (ls) obtained from the one-center expansion method, it may be noted that the more the number of ls inducing significant variations of the C_{lm}^2 values is, the larger the variation of β. Considering that the abnormal variation of β appears only in the second PE band of CCl_4, the interpretation in terms of the variation of the C_{lm}^2 value seems to be consistent with the experimental results.

As another approarch, we calculated radial distributions ($4\pi r^2\psi^2$) of the degenerate MOs of neutral molecules to predict the β variations in the approximation of Koopmans' theorem. This is to compare distribution patterns of the MOs for the bands showing β variations with those of the MOs for the bands showing no β variation. This comparison is more useful for the intramolecular bands than the intermolecular bands. Figure 11 shows the radial distributions of the degenerate orbitals for CH_4, NH_3, and $C(CH_3)_4$, the centers of the molecules being taken at C and N atoms. The β variations for the 1^2T_2 state of CH_4^+ and for the $1^2E'$ state of NH_3^+ are very small although the magnitude of the J-T splittings are considerably large. The β variations for the 1^2T_1 and 1^2E states for $C(CH_3)_4^+$ are also very small. The radial distributions for these states exhibit the pattern which consists of a single peak. On the other hand, the β variation for the 1^2T_2 state of $C(CH_3)_4^+$ is abnormal, and the radial distribution for this state shows the pattern which consists of two peaks. This pattern is quite different from those for the $^2T_1$ and ^2E states of this molecule. The radial distribution pattern for the 2^2T_2 state, which consists of one shoulder and one peak, is closer to that for the 1^2T_2 rather than those for the $^2T_1$ and ^2E states although the variation of β for the 2^2T_2 band is not so remarkable.

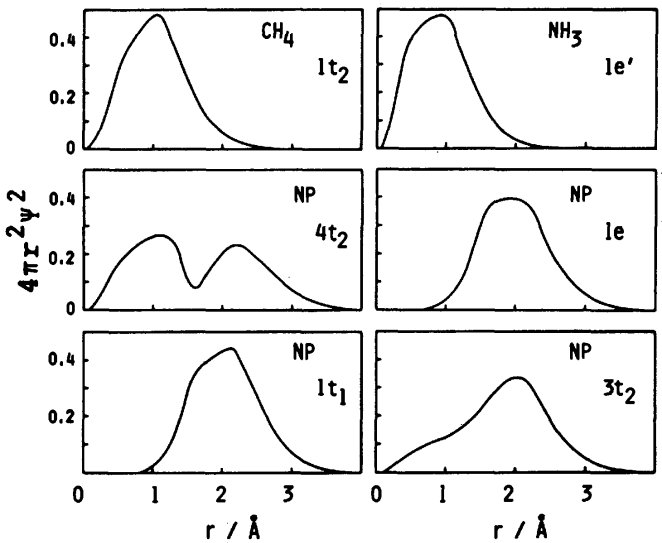

Fig. 11. Radial distributions of various MOs for methane, ammonia and neopentane (NP).

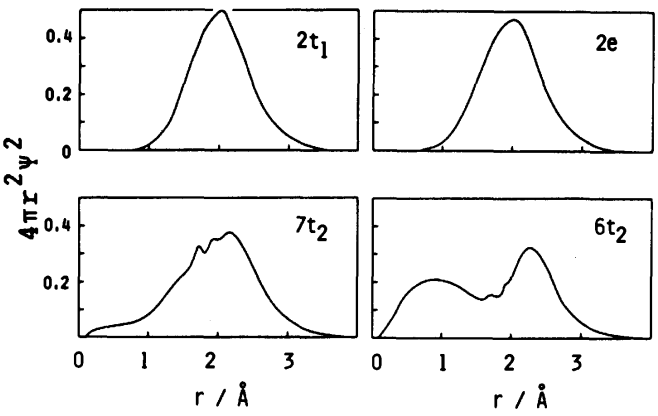

Fig. 12. Radial distributions of various MOs for CCl_4.

Concerning the radial distributions in CCl_4 shown in Fig. 12, the distribution patterns for the 1^2T_2 and 2^2T_2 states in CCl_4^+ are very similar to those for the 2^2T_2 and 1^2T_2 states in $C(CH_3)_4^+$, respectively. For CCl_4, the β variation for the 1^2T_2 state is abnormal. The β variation for the 2^2T_2 state shows the change of about 0.7 per 1 eV (Fig. 7B) which is quite large in comparison with the energy dependence of β (about 0.06 per 1 eV).[44]

In addition to the above considerations, we suggest that the effects of the shape resonance and the vibronic interaction on the β variation across the J-T split band should be investigated for these molecules.

The *ab initio* SCF MO calculations and the calculations of the one-center expansion of the MOs and the radial distributions of the MOs were carried out at the Hokkaido University Computing Center. The *ab initio* SCF MO calculations were performed with IMS version of GAUSSIAN 70 using 4-31 G basis set.

Molecular Structure of [2]Paracyclo[2](2,5)furanophane†

Fumio HAMA,†† Yasushi KAI, Noritake YASUOKA,††† and Nobutami KASAI*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565
(Received June 30,1984)

The molecular structures of [2]paracyclo[2](2,5)furanophane (**1**) at 20 °C and −150 °C have been determined by means of X-ray diffraction. The crystal is tetragonal, with a=15.996(1), c=8.374(1)Å (at 20 °C), and a=15.823(3), c=8.330(3)Å (at −150 °C), space group $P\bar{4}2_1c$, and Z=8. The structures were solved by the direct method, and refined anisotropically by the block-diagonal least-squares procedure: R=0.069 and 0.075 for the structures at 20 °C and −150 °C, respectively. The furan ring has an envelope form, and the benzene ring boat-shape.

Many multi-layered paracyclofuranophanes have been synthesized by Misumi and his co-workers[1] in order to investigate the trans-annular π-electron interaction between benzene and heteroaromatic rings. They observed the ring inversion phenomena of furan rings in double-, triple-, and quadruple-layered paracyclofuranophanes by variable temperature NMR spectroscopy. The flipping of furan ring in triple- and quadruple-layered paracyclofuranophanes were found to be easier than that in double-layered one. On the other hand, no ring inversion of the thiophene ring was observed in the multi-layered paracyclothiophenophanes.

In a series of structural studies on layered cyclophanes, the molecular sturctures of double- and triple-layered paracycloheterophane containing furan and thiophene rings have been determined by means of X-ray diffraction in order to obtain structural informations about the ring inversion. The molecular structures of triple-layered paracyclofuranophane (**3**) and dimethyl triple-layered paracyclothiopheneophane (**4**) have been reported.[2] This paper deals with the molecular structure of double-layered paracyclofuranophane (**1**) ([2]paracyclo[2](2,5)furanophane) at 20 °C and −150 °C, temperatures above and below the coalescence (−39 °C) of NMR signals of aromatic protons of benzene ring faced to the furan ring.[1]

The structure analysis of double-layered paracyclothiophenophane ([2]paracyclo[2](2,5)thiophenophane) was also tried; however, due to the reason mentioned later the intensity data collection has been discontinued.

4: Dimethyl triple-layered paracyclothiophenophane

Experimental

[2]Paracyclo[2](2,5)furanophane (1). Crystals of double-layered paracyclofuranophane are colorless tetragonal prisms. Preliminary oscillation and Weissenberg photographs showed that the crystal belongs to the tetragonal system, and the systematic absence of reflections (hhl; l=2n+1 and $h00$; h=2n+1) determined the space group as $P\bar{4}2_1c$.

For the measurements of the unit-cell dimensions and integrated intensities, a Rigaku automated, four-circle diffractometer was used. A crystal with approximate dimensions of 0.2×0.2×0.2mm was selected for the X-ray work. The unit-cell parameters were precisely determied by the least-squares fit of 2θ values of high angle reflections.

Crystal Data. $C_{14}H_{14}O$, M 198.3, tetragonal, space group $P\bar{4}2_1c$, (20 °C) a=15.996(1), c=8.374(1)Å, V=2142.5(4)Å^3, Z=8, D_m=1.23 g cm^{-3}, D_c=1.229 g cm^{-3}, μ(Cu$K\alpha$)=5.97 cm^{-1}; (−150 °C) a=15.823(3), c=8.330(3)Å, V=2085.4(10)Å^3, Z=8, D_c=1.263 g cm^{-3}, μ(Mo$K\alpha$)=0.84 cm^{-1}.

Intensity measurements were carried out by the θ−2θ scan technique at a 2θ scan rate of 4 ° min^{-1}. For the room temperature (20 °C) experiment nickel-filtered Cu$K\alpha$ radiation was used. The scan width was $\Delta 2\theta=(2.0+0.3\tan\theta)°$. The backgrounds were counted for 7.5 s at both ends of a scan. For the low temperature experiment the crystal was kept at −150 °C with the liquid nitrogen gas flow method. Graphite monochromatized Mo$K\alpha$ radiation was used. The scan width was $\Delta 2\theta=(2.0+0.7\tan\theta)°$. The backgrounds were counted for 5 s. The scans were repeated up to three times when the structure factor magnitude $|F_o|$ was less than $3\sigma(F_o)$, where $\sigma(F_o)$ is the standard deviation estimated from the counting statistics. Totals of 922 (at 20 °C; Cu$K\alpha$, $2\theta \leqq 120°$) and 1728 (at −150 °C; Mo$K\alpha$, $2\theta \leqq 60°$) reflections were collected, among which 106 and 267 reflections less than $3\sigma(F_o)$ were considered as unobserved. No intensity decrease of standard reflections was observed during the experiment. Corrections for the usual Lorentz and polarization effects were carried out, but no absorption correction was made [μ(Cu$K\alpha$)=5.97 and μ(Mo$K\alpha$)=0.84 cm^{-1}].

[2]Paracyclo[2](2,5)thiophenophane (2). *Crystal Data.* $C_{14}H_{14}S$, M 214.3, tetragonal, space group $P4_2nm$, $P\bar{4}n2$, or $P4_2/mnm$, a=7.762, c=9.159Å, V=551.9Å^3, Z=2, D_m=1.27 g cm^{-3}, D_c=1.29 g cm^{-3}.

The systematic absence of reflections showed the space group to be $P4_2nm$ (No. 102), $P\bar{4}n2$ (No. 118), or $P4_2/mnm$ (No. 136). Since two molecules are contained per unit-cell, the molecular symmetry in the crystal should be mm for the

††† Present address: Institute for Protein Research, Osaka University, Yamadaoka, Suita, Osaka 565.

space group $P4_2nm$, 222 or $\bar{4}$ for $P\bar{4}n2$, or mmm for $P4_2/mnm$. However, the possible highest symmetry of the present molecule is m, the crystal may include some disordered structure. For this reason the further X-ray experiment was given up.

Structure Solution and Refinement

The room temperautre structure was first solved by the direct method (*MULTAN* 74).[3] 18 peaks on the E map, synthesized with the set of phases with the highest figure of merit, gave an approximate structure of the molecule, but three peaks among them were later excluded as spurious. The refinement was carried out by the block-diagonal least-squares procedure with unit weight (*HBLS* V).[4] Six cycles of isotropic refinement gave the R index of 0.123. After an anisotropic refinement of non-hydrogen atoms (4 cycles, R=0.105) hydrogen atoms located on their calculated positions with isotropic temperature factors were included in the refinement. The final R value was 0.069 for the observed reflections. Atomic paramters are given in Table 1.*

The refinement of the low temperature structure started from the positional paramters for the 15 non-hydrogen atoms determined with the room temperature data: the isotropic temperature factor of B=2.0 Å^2 being assumed for each atom. Successive anisotropic refinement (four cycles) gave the R value of 0.105. Hydrogen atoms were located at the calculated positions and refined isotropically. The weighting scheme used was $w=\{\sigma^2(F_o)+a|F_o|+b|F_o|^2\}^{-1}$ for $|F_o|>0$ and w=c for $|F_o|=0$. The final R value was 0.076 (R_w=0.078) with a=−0.0893, b=0.0018, and c=0. The final atomic parameters with equivalent temperature facors are given in Table 1.*

The atomic scattering factors for non-hydrogen atoms were taken from International Tables for X-ray Crystallography, Vol. IV[5] and those for hydrogen atoms from Stewart, Davidson, and Simpson.[6] Computations were done on an ACOS 700S computer at the Crystallographic Research Center, Institute for Protein Reserach, Osaka University.

Results and Discussion

Molecular Structure. A perspective view of the molecular structure of double-layered paracyclofuranophane at −150 °C is drawn (ORTEP II)[7] in Fig. 1, with the atomic labelling. The molecular structure projected onto the plane defined by the C(10), C(11), C(13), and C(14) atoms is shown in Fig. 2(a), that onto the plane formed by the C(1), C(2), C(7), and C(8) in Fig. 2(b), and that along the plane made by the C(10), C(11), C(13), and C(14) in Fig. 2(c). Interatomic bond distances and bond angles at −150 °C are also given in Fig. 2 with estimated standard deviations, together with the parameters to describe the out-of-plane deformation of the benzene ring. No essential difference has been observed between the structures at 20 °C and −150 °C; therefore, the discussion will be limited hereafter on the low temperature structure otherwise stated.

The coincidence of structural parameters of chemically equivalent parts of the molecule is good: the molecule has an approximate mirror symmetry. The furan ring takes an envelope form with the oxygen atom away from the benzene ring: the dihedral angle between the planes made by the O, C(3), and C(6) atoms and the C(3), C(4), C(5), and C(6) being 3.3°. This is similar to the corresponding angle in the triple-layered paracyclofuranophane[3.8°].

Two CH_2–CH_2 bridge bonds also have a similar structure as those in the triple-layered paracyclophane: C–C distances being 1.589(6) and 1.582(6) Å, and the torsion angles around the C–C bond 34.8 and 30.3°. The C(1)–C(2)–C(3) and C(6)–C(7)–C(8) angles are 113.4(3) and 114.6(3)°, respectively, which are larger than the C(2)–C(1)–C(12) [108.3(3)°] and C(7)–C(8)–C(9) [108.3(3)°] angles.

The benzene ring adopts a symmetrical boat form as in the case of many other cyclophanes. The C(9) and C(12) atoms deviate from the plane defined by the C(10), C(11), C(13), and C(14) atoms by 13.8 and 14.2°, respectively. The C(1)–C(12) vector makes an anlge of 15.6° to the plane made by the C(11), C(12), and C(13), and the corresponding angle of the C(8)–C(9) vector is 15.1°. The C(1)–C(12)–C(13) and C(8)–C(9)–C(14) angles [117.8(3) and 117.7(3)°, respectively] are smaller than the C(1)–C(12)–C(11) and C(8)–C(9)–C(10) [122.3(4) and 122.0(4)°, respectively], which are also smaller than the corresponding angles in the triple-layered paracyclofuranophane. These facts may be explained by the fact that the C(1) and C(8) atoms are shifted back to the C(13) and C(14) atoms, respectively, so that the nonbonded atomic interactions between the furan and benzene rings is minimized.

Table 2 summarizes the structural parameters to

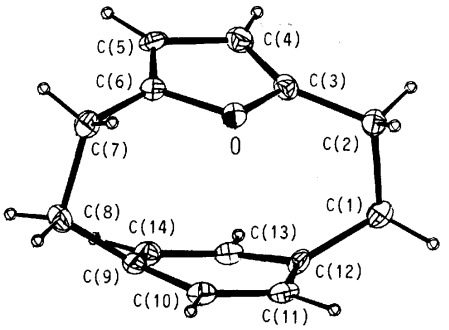

Fig. 1. A perspective view (*ORTEP* drawing)[7] of the double-layered paracyclofuranophane molecule (−150°C) with the atom labelling.
Non-hydrogen atoms are represented by thermal ellipsoids with 50% probability level, hydrogen atoms as spheres with B=0.5 Å^2.

*Tables of observed and calculated structure factors and anisotropic temperature factors of both structures 20 °C and −150 °C are kept at the Chemical Society of Japan, Document No. 8433.

show the out-of-plane deformation of heteroaromatic ring (θ_1), relative position of the heteroaromatic ring to the benzene ring next to it(θ_2), and nonbonded distances between the heteroatom and benzene carbon atoms (*a* to *f*) in double- and triple-layered paracyclofuranophane and triple-layered paracyclothiophenophane molecules.

The marked difference between the molecular structures of double- and triple-layered paracyclofuranophanes is that *c* and *f* distances in the triple-layered one are much longer than those in the double-layered one. On the other hand, *a*, *b*, *d*, and *e* distances in these two molecules have respectively similar values. This feature is due to the structural difference of the benzene ring next to the furan ring in these molecules; boat form in the double-layered one and twisted form in the triple-layered one. This is probably the most important structural factor to lower the energy barrier of the ring inversion of the furan in triple- and quadruple-layered paracyclofuranophane compared with the double-layered one.

Crystal Structure. Figure 3 shows the crystal structure of double-layered paracyclofuranophane. Molecules are loosely packed in the crystal. Only one or two intermolecular atomic contacts are less than 3.8 Å: the closest one being C(5)(x,y,z)····C(4) (−0.5+y, 0.5+x, 0.5+z)[3.727(9)(20°C) and 3.667(6)Å (−150°C)].

The authors wish to express their deep thanks to Professor Soichi Misumi and co-workers, Institute for Scientific and Industrial Research, Osaka University for crystals and helpfull discussions.

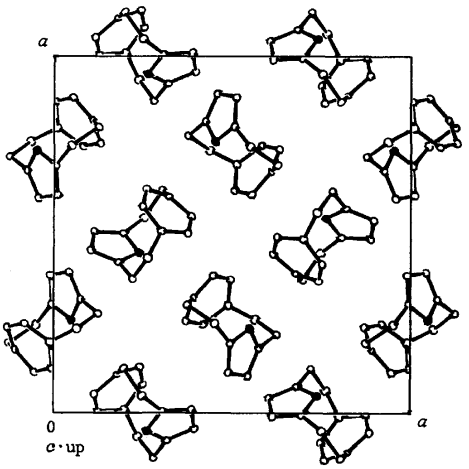

Fig. 3. Crystal structure viewed down along the c axis (*ORTEP* drawing).[7]
Carbon and oxygen atoms are respectively represented by white and black ellipsoids. Hydrogen atoms omitted.

Coexistence of Hydrogen Atom Transfer Reactions through and not through Triplet Ion Pair between *p*-Chloranil and Durene

Harumichi KOBASHI,* Masa-aki FUNABASHI, Tomoyuki KONDO, Toshifumi MORITA, Tadashi OKADA,† and Noboru MATAGA†

(Received, July 13, 1984)

Mechanisms of hydrogen atom abstraction reactions by triplet state *p*-chloranil (^{3}CA) from durene (DH) were studied by picosecond and nanosecond laser photolysis and transient photoconductivity measurements. ^{3}CA was quenched by DH through diffusional encounter to form a triplet ion pair (IP) between CA and DH, *p*-chloranil semiquinone radical (CAH·), and 2,4,5-trimethylbenzyl radical (D·). Ionic dissociation of IP was observed in 1,2-dichloroethane (DCE) as well as in acetonitrile. However, no transient species was observed by direct excitation of a charge-transfer (CT) band of the electron donor-acceptor (EDA) complex between CA and DH. The H-atom transfer leading to production of CAH· was found to proceed through two distinct mechanisms; H-atom transfer *via* IP (Mechanism I) and a more rapid transfer competing with IP formation (Mechanism II). The quantum yields of CAH· produced by Mechanisms I and II and the first-order rate constants for proton transfer, ionic dissociation, and intersystem crossing competing with one another in the IP state were estimated to be (0.1 and 0.2) and (2, 5, and 13)$\times 10^6$ s^{-1}, respectively, in DCE at room temperature.

In the case of the photochemical hydrogen abstraction reaction of triplet ketones or quinones, two different and noteworthy mechanisms have been reported. One is the two-step mechanism of electron transfer followed by proton transfer *via* ion-pair (IP) state (Mechanism I). This is the case of triplet benzophenone and several amines in high-polarity solvents[1] as well as the case of the excited singlet pyrene–aromatic amines.[2] Another is the rapid H-atom transfer in nonrelaxed encounter complex competing with IP formation (Mechanism II) as observed in the system of triplet state 2,6-diphenyl-*p*-benzoquinone and aromatic amines.[3] Since most of the triplet state quinones are strong electron and hydrogen acceptors, it is not easy to determine which mechanism is predominant in their H abstraction reactions. Very careful examinations based on direct observation of short-lived transient species are neccesary to elucidate the reaction mechanism.

In the course of our investigations concerning photo-reduction of ^{3}CA by several electron and hydrogen donors,[4] we observed in the CA–DH system that CAH· radicals were produced simultaneously with the formation of IP between CA and DH and also grew up concomitantly with the decay of IP. We have examined the mechanism of this reaction mainly in DCE solution by means of picosecond (ps) and nanosecond (ns) laser photolysis and transient absorption measurements as well as transient photoconductivity studies in the ns time region. Results show coexistence of Mechanisms I and II.

Experimental

Transient absorption spectra in the ps and ns region were measured using a mode-locked ruby laser system (λ 347 nm, FWHM ≈30 ps, energy ≈10 mJ)[5] at 25 °C and a conventional ns ruby laser system[4] at 20±1 °C unless otherwise stated. Photolysis at 502 as well as 532 nm was also performed by using a flash-lamp pumped dye laser (dye: Green-4 of Phase-R Co., pulse width ≈250 ns, energy ≈110 mJ)[6] and a ps Nd^{3+}: YAG laser system,[7] respectively. Transient photocurrents were measured using the same type of quartz cuvette with two Ni- or Pt-plate electrodes as utilized previously.[8] The DC voltage (90—540 V) was supplied between the electrodes from a bank of dry batteries. The output signal across a 50 Ω load resister was fed into a 200 MHz oscilloscope (Iwatsu, SS-6200) through AC coupling. The ground state absorption spectra were recorded on a Hitachi Model 200 spectrophotometer. All solutions were carefully degassed by freeze-pump-thaw cycles.

p-Chloranil (CA: tetrachloro-*p*-benzoquinone) was purified by the same method as described elsewhere.[4a] The GR grade durene (DH: 1,2,4,5-tetramethylbenzene) was recrystallized twice from cyclohexane and sublimed *in vacuo*. Solvents: 1,2-dichloroethane, acetonitrile, and ethyl acetate were purified by the usual methods.

Results and Discussion

EDA Complex Formation in the Ground State. The DCE solutions of CA (0.001—0.002 mol dm^{-3}) and DH (0.075—0.40 mol dm^{-3}) showed a CT band (λ_{max} 480 nm; ε 2650±100 dm^3 mol^{-1} cm^{-1}) due to the EDA complex (CA···DH) with the formation constant K=0.89±0.03 dm^3 mol^{-1} (at 20 °C) which was determined using the Benesi-Hildebrand method. The thermodynamic quantities, ΔH (−18.1±1.2 kJ mol^{-1}) and ΔS (−63±4 J mol^{-1} K^{-1}), were obtained by the measurement of the temperature dependence of K in the range 4—57 °C. These values are comparable with those for the same complex in carbon tetrachloride reported previously.[9] The absorption spectra of the complex and uncomplexed CA involved in the DCE solution are illustrated in Fig. 1.

Picosecond and Nanosecond Laser Photolysis. The laser photolysis at 502 as well as 532 nm, where exclusive-

ly the CT band was excited (indicated by arrows in Fig. 1), did not give any transient absorption over the time range from picosecond to several microseconds. No permanent change of the ground state absorption spectrum was recognized after several laser shots. These findings suggest that the S_1 state of the complex decays so rapidly through internal conversion that its detection is not possible even by means of the ps laser photo-

lysis method. Some discussions will be given later concerning this result.

In the following we show results of the photolysis at 347 nm where excitation of uncomplexed CA is possible. Figure 2 presents time-resolved absorption spectra for the solution containing CA (3.0×10^{-3} mol dm^{-3}) and DH (0.20 mol dm^{-3}) observed by the ps ruby laser photolysis. Figure 3a shows transient absorption spectra measured by the ns flash photolysis and Fig. 3b gives reference spectra of ^{3}CA,[4a] CAH·,[4b] and *p*-chloranil radical anion (CA$^-$).[10]

The absorption band around 510 nm in the spectrum observed at 0 ps (Fig. 2a) resembles that of ^{3}CA. After reaching the maximum intensity, the absorbance around 510 nm decreases while a new band around 450 nm grows up. The latter absorption band is similar to that of CA$^-$. The spectra observed at several delay times from 100 ps to 1.5 ns could be reproduced by the superposition of the spectra at 0 ps (**A**) and 3 ns (**B**), which has been performed by a microcomputer using the least-square method. An example for the spectrum at 500 ps is given in Fig. 4, where the agreement between the calculated spectrum (b(1)) composed of **A** and **B** and the observed one (a) is satisfactory. The time dependence of each component obtained by such procedure is indicated in Fig. 5. The decay time of **A** and the rise time of **B** are estimated respectively to be about 0.7 and 0.6 ns, being in agreement with each other. This indicates that the species responsible for the spectrum **B** is produced from the transient which

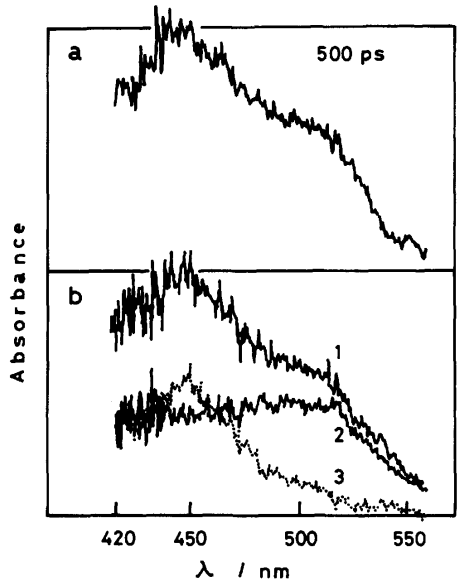

Fig. 4. Comparison of the spectrum observed at 500 ps with the spectrum obtained by superposition of **A** and **B**.
a): observed spectrum, b): (1) calculated spectrum (**A**+**B**), (2) component spectrum **A**, (3) component specturm **B**.

shows the spectrum **A**.

As can be seen from Fig. 3, no absorption band around 510nm corresponding to **A** was observed by the ns laser photolysis since the transient species responsible for **A** was quenched by DH of high concentration (0.20 moldm^{-3}) very rapidly. The spectrum (**C**) observed immediately after excitation by the ns pulse (Fig. 3a(1)) is quite similar, in the 420—500nm region, to the spectrum **B**. Therefore, it is plausible that **C** is substantially the same as **B**. Comparison of **C** with **B** in the wavelength region less than 420nm was not possible because of the absence of observed band in the case of **B** owing to the low intensity of the ps probe pulse.

The spectrum **C** is replaced completely by the spectrum (**D**) with definite absorption maxima at 435 and 365nm and a shoulder around 448nm at the delay time of 335ns. The decay profile of the absorbance at 448nm is shown in Fig. 6, which indicates the existence of two components. Since the long-lived component did not show decay in 100ns domain, we subtracted its absorbance (D_∞) from the observed total absorbance D. A straight line (b) obtained by plotting log (D—D_∞) against time yields the decay time (τ_d) of 49±2ns at 20°C of the transient species responsible for the band at 448nm. The τ_d values were independent on [CA] in the (0.81—3.65)×10^{-3}moldm^{-3} range, [DH] in the 0.05—0.20 moldm^{-3} range, and on monitoring wavelength in the 448—480nm region, within experimental accuracy.

Assignment of Transient Spectra and Reaction Mechanism. Since no transient absorption was observed by direct excitation of the EDA complex, only free CA present

in the solution seems to contribute to the appearance of **A**. Excited CA is known to cause rapid intersystem crossing (ISC, $k_{ISC} \approx 3\times10^{10}s^{-1}$, $\Phi_{ISC}=1$) from S_1 to T_1 in acetonitrile.[11] We have also confirmed that ISC is also rapid ($>3\times10^{10}s^{-1}$) in the DCE solution of CA (0.003 moldm^{-3})-diphenylamine (0.1 moldm^{-3}) system in a separate experiment performed by means of the Nd^{3+}: YAG laser photolysis.[12] Therefore, the spectrum **A** can be assigned to that of ^{3}CA.[13]

As shown in Fig. 3b, CA$^{\cdot-}$ shows a strong band with maximum at 448nm where CAH· shows only a negligibly weak absorption. Therefore, the absorption band at 448nm in **B**, **C**, and **D** can be attributed to CA$^{\cdot-}$. Figure 5 shows that CA$^{\cdot-}$ in question is produced in the course of the collisional quenching of ^{3}CA by DH, since ^{3}CA is quenched by DH with nearly diffusion-controlled rate.[14] However, the transient species showing the 448nm absorption in **C** (*i.e.*, **B**) is not free CA$^{\cdot-}$ because its decay obeys the first-order kinetics (Fig. 6b). Accordingly, this absorption band at 448nm can be assigned to CA$^{\cdot-}$ of the triplet ion pair ^{3}(CA$^{\cdot-}$··· DH$^+$). The spin state should be assigned to the triplet state because the observed species with a fairly long life was produced from the triplet state precursor while no

CT singlet state $^1(CA^{\overline{\cdot}}\cdots DH^+)$, which should be produced by the direct excitation of the CT band, was observed. That no absorption band due to the counter ion DH^+ was detected is probably due to its low intensity in the visible region.[15] The ion-pair formation may be rationalized also from the following estimations concerning the free energy change ΔG of the reaction $^3CA+DH\rightarrow{}^3(CA_s^{\overline{\cdot}}\cdots DH_s^+)$ or $^3(CA^{\overline{\cdot}}\cdots DH^+)_s$, where $^3(CA_s^{\overline{\cdot}}\cdots DH_s^+)$ represents the solvent-separated ion pair and $^3(CA^{\overline{\cdot}}\cdots DH^+)_s$ refers to the contact ion pair or the triplet exciplex with nearly complete CT character. The quenching of ^3CA is not attributable to the T-T energy transfer, $^3CA+DH\rightarrow CA+{}^3DH$, in view of the fact that the energy of ^3CA above the ground state ($E_T(^3CA)\approx 2.13$ eV[16]) is much lower than that of ^3DH ($E_T(^3DH)=3.37$ eV).[17] The ΔG values of the ion-pair formation in DCE are estimated approximately to be -0.43 eV for $^3(CA_s^{\overline{\cdot}}\cdots DH_s^+)$ by the equation:[18]

$$\Delta G(CA_s^{\overline{\cdot}}\cdots DH_s^+) = E(DH/DH^+) - E(CA^{\overline{\cdot}}/CA) - E_T(^3CA) - e^2/\varepsilon R + (e^2/2)(1/R_+ + 1/R_-)(1/\varepsilon - 1/37.5), \quad (1)$$

and -0.73 eV for $^3(CA^{\overline{\cdot}}\cdots DH^+)_s$ by[19]

$$\Delta G(CA^{\overline{\cdot}}\cdots DH^+)_s = E(DH/DH^+) - E(CA^{\overline{\cdot}}/CA) - E_T(^3CA) + 0.32 - 0.7[f(\varepsilon) - 0.5f(n^2)] \quad (2)$$

in eV unit, where $E(DH/DH^+)$ and $E(CA^{\overline{\cdot}}/CA)$ are the polarographic oxidation potential of DH (1.59 V)[20] and the reduction potential of CA (0.01 V)[21] respectively, ε and n are the dielectric constant and refractive index of solvent respectively, $f(x)=2(x-1)/(2x+1)$, and other symbols and parameter values are the same as used in the references. Since both values of ΔG are negatively large, the electron transfer would occur to form the ion pairs. Contact and solvent-separated ion pairs have been discriminated in some EDA systems.[1c,3b,22,23] However, the discrimination between them was not possible for the present system in DCE solution. Therefore, we use throughout this paper the term "triplet ion pair (IP)," without discrimination between contact and solvent-separated ion pairs, for the species exhibiting the 448 nm band in the spectrum **C** (and **B**) with the lifetime of 49 ns.

The spectra **C** and **D** in Fig. 3a appear at first glance to resemble the reference spectra of $CA^{\overline{\cdot}}$ and CAH· respectively but close inspection makes clear the differences between them. The ratio of 435 to 448 nm absorbance in **C** is significantly higher than the corresponding ratio in the reference spectrum of $CA^{\overline{\cdot}}$ and additionally **C** involves the band at 365 nm which is characteristic of CAH·. In the spectrum **D**, the intensity ratio of 365 to 435 nm band is small compared with that of CAH· and the shoulder around 448 nm which is characteristic of $CA^{\overline{\cdot}}$ is observed. It is, therefore, suggested that both spectra **C** and **D** involve the absorption bands of the two species CAH· and $CA^{\overline{\cdot}}$. The decomposition of the spectrum into CAH· and $CA^{\overline{\cdot}}$ was then performed very carefully and the result is given in Fig. 7. The procedure for decomposition was made by normalizing the reference spectrum of $CA^{\overline{\cdot}}$ to the observed one at 448 nm and then subtracting the former from the latter. The obtained spectrum (Fig. 7a (3)) agrees with the spectrum of CAH·. A small difference between the spectrum of $CA^{\overline{\cdot}}$ and the observed one (**C**) in the wavelength region longer than 448 nm seems attributable to a small difference in the spectra between IP and free $CA^{\overline{\cdot}}$. The spectrum **D** can be reproduced quite well by superposing spectra of CAH· and $CA^{\overline{\cdot}}$ (Fig. 7b). Since, as is shown in Fig. 8, the 448 nm absorbance in **D** shows the second order decay, this absorption band may be assigned to free $CA^{\overline{\cdot}}$. From the results of the analysis indicated in Fig. 7, it can be concluded that CAH· radicals are rapidly produced in part competitively with IP formation and further increase in accordance with decrease of IP.

(a) log D *vs.* t and (b) log $(D-D_\infty)$ *vs.* t measured at 448 nm, (c) log D *vs.* t and (d) log $(D_\infty-D)$ *vs.* t measured at 365 nm.

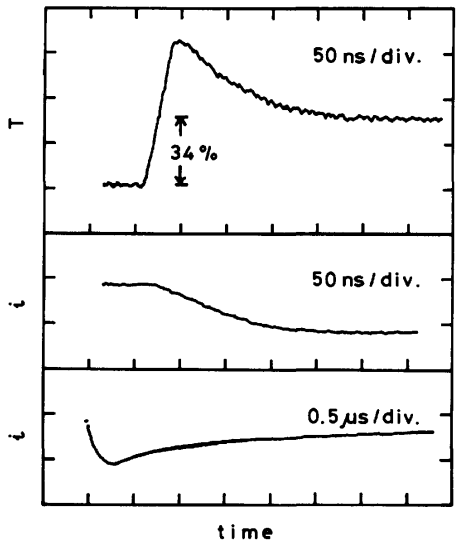

Fig. 10. Oscilloscope traces for transient absorption (T: transmittance) monitored at 448 nm (a) and transient photocurrents ($i\approx0.1$ mA/div), (b) and (c), in DCE solution:
[CA]=0.0025 mol dm^{-3}, [DH]=0.20 mol dm^{-3}.

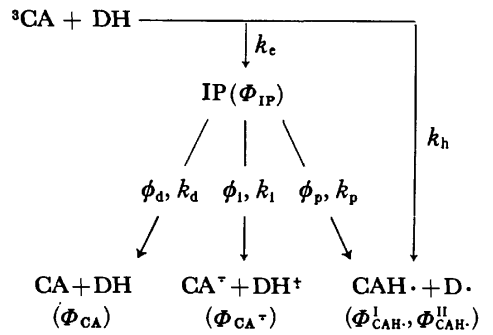
Therefore, it is confirmed that the H-atom transfer in problem proceeds through both Mechanisms I and II.

Although in DCE solution the slow rise of CAH· was established on the basis of the result of spectrum decomposition, the rise was observed directly by monitoring the characteristic absorption band of CAH· at 365 or 435 nm in other less polar solvents. Figure 9 shows time dependence of 365 nm absorbance, D^{365}, (line c) together with that of 448 nm absorbance, D^{448}, (line a) observed in ethyl acetate solution. The line b is the plot of $D^{448}-D_\infty^{448}$ against t yielding the decay time (τ_d) of IP. The line d is the plot of $D_\infty^{365}-D^{365}$, yielding the rise time (τ_r) of CAH·. Here, D_∞^{448} and D_∞^{365} are the absorbances in the plateau region observed at 448 and 365 nm, respectively. It is clear that CAH· grows up concomitantly with decay of IP because τ_r value (51 ns) agrees with τ_d value (47 ns) within experimental accuracy.

The formation of free ions as noted in the discussion of the spectrum **D** was examined by transient photoconductivity measurement. Figure 10 demonstrates the oscillograms of photocurrent together with the temporal behavior of transient absorption. The rise time (50±3 ns from 5 runs) of the photocurrent was in good agreement with the decay time of IP and the decay of the current followed exactly the second-order kinetics. It is therefore confirmed that the ionic dissociation producing free CA^- occurs subsequent to the IP formation.

In addition to these measurements, we have observed a fairly sharp absorption band around 330 nm simultaneously with the bands of CAH·. This observation suggests strongly the pair production of CAH· and 2,4,5-trimethylbenzyl radical (D·), because D· has a sharp band at 330 nm.[24]

From the above described results, the deactivation processes of ^{3}CA by the interaction with DH may be schematically represented as follows:



(3)

Here, the letters Φ, ϕ, and k represent the quantum yield of transient species from ^{3}CA, the fractional efficiency of each reaction from IP, and the rate constant of each reaction process, respectively. The subscripts e, h, p, i, and d refer in turn to the processes of electron transfer, hydrogen transfer, proton transfer, ionic dissociation, and degradation through ISC of IP returning back to the ground state. $\Phi^I_{CAH\cdot}$ and $\Phi^{II}_{CAH\cdot}$ denote the quantum yields of CAH· formation by the mechanism I and II, respectively. Estimation for these values measured in DCE solution will be given in the later section.

No Transient Formation by Direct Excitation of the EDA Complex. We examine here the mechanism for the result that direct photoexcitation into the CT band of the complex affords no transient absorption. The energy levels of locally excited (LE) singlet ^{1}(CA*···

DH) and triplet ^{3}(CA*···DH) states may be approximately the same as those of ^{1}CA*+DH and ^{3}CA*+DH states which lie in 2.63[25] and 2.31 eV[16] above the CA+DH state, respectively. The energies of CT singlet ^{1}($CA^{\cdot-}$···DH^+) and triplet ^{3}($CA^{\cdot-}$···DH^+) states may be given approximately as 1.7 and 1.3 eV, respectively, from the position of onset of the CT band and from the energy of ^{3}($CA^{\cdot-}$···D^+)$_s$ state estimated by using Eq. 2. Since the energy gap between zero-order ^{1}CT and ^{1}LE states is large, their mixing will be small. This condition results in small splitting betwecn ^{1}CT and ^{3}CT states. In practice, ^{1}($CA^{\cdot-}$···DH^+) and ^{3}($CA^{\cdot-}$···DH^+) states will lie closer to each other than the expectation from the above estimation owing to the intra-complex as well as stabilization induced by solvent reorientation in ^{1}($CA^{\cdot-}$···DH^+). In any way, these ^{1}($CA^{\cdot-}$···DH^+) and ^{3}($CA^{\cdot-}$···DH^+) states will be the lowest excited singlet and triplet states, respectively, and ^{3}(CA*···DH) state will locate higher than ^{1}($CA^{\cdot-}$···DH^+) state.

The fact that no transient formation was observed in the case of direct excitation of EDA complex means that ISC does not take place effectively in the complex from the ^{1}CT state to the ^{3}CT state. This is also supported by the fact that no CT phosphorescence could be observed at low temperature. ISC between the CT states is forbidden since the matrix element of spin-orbit interaction, $<^1\mathrm{CT}|H_{SO}|^3\mathrm{CT}>$ which governs the ISC rate, becomes null in the usual one-electron approximation. Therefore, ISC may be unfavorable to take place competing with the allowed internal conversion from the ^{1}CT state to the ground state. Since no LE state lies between the ^{1}CT and ^{3}CT states, the conclusion inferred above is in harmony with the selection rule proposed by Lim *et al.* for the systems of tetracyanoethylene-methylated benzenes and 1,2,4,5-tetracyanobenzene-methylated benzenes.[26] The internal conversion would be so rapid that no transient species was observed even by the present ps time resolution. Similar results of ps laser photolysis studies have been reported also for the duroquinone-triethylamine,[27a] porphyrin-quinone,[27b] and pyrene-pyromellitic dianhydride[27c] systems.

Yields of IP, CAH·, and $CA^{\cdot-}$ and Rate Constants for Decay Processes of IP. Estimation of Φ_{IP}, $\Phi^{II}_{CAH\cdot}$, k_e, *and* k_h: Since the triplet yield of CA has been known to be unity,[4a,11b] Φ_{IP} can be estimated from Fig. 5 using Eq. 4:

$$\Phi_{IP} = \frac{D_{IP}(3)/\varepsilon_{IP}}{D_{3CA}(0)/\varepsilon_{3CA}}, \quad (4)$$

where $D_{IP}(3)$ is the 448 nm absorbance due to IP at 3 ns, D_{3CA} (0) is the 510 nm absorbance of ^{3}CA at 0 ps, ε_{IP} is the molar absorption coefficient of IP at 448 nm (9.0×10^3 $dm^3mol^{-1}cm^{-1}$)[28] and ε_{3CA} is that of ^{3}CA in DCE at 510 nm, $(7.3\pm0.3)\times10^3$ $dm^3mol^{-1}cm^{-1}$.[29] The Φ_{IP} value obtained is 0.81 within the error of about 10%. $\Phi^{II}_{CAH\cdot}$ value is obtained to be 0.19 by the relation $\Phi^{II}_{CAH\cdot}=1-\Phi_{IP}$ according to (3). By using the quenching rate constant of ^{3}CA by DH measured at 15 °C,[14] approximate values of second-order rate constants, k_e and k_h, are estimated to be 2.5×10^9 $dm^3mol^{-1}s^{-1}$ and 0.6×10^9 $dm^3mol^{-1}s^{-1}$, respectively.

Determination of $\Phi^{total}_{CAH\cdot}$, $\Phi_{CA^{\cdot-}}$, $\Phi^{I}_{CAH\cdot}$ *and* Φ_{CA}: For the pupose of obtaining the total yields of CAH· ($\Phi^{total}_{CAH\cdot}\equiv\Phi^{I}_{CAH\cdot}+\Phi^{II}_{CAH\cdot}$) and $\Phi_{CA^{\cdot-}}$ values, the ns laser photolysis was carried out, under the same laser intensity, for solutions of CA in the presence and absence of DH. The absorbances at 347 nm of the solutions were adjusted equal to each other. The solutions containing CA alone were used as references for the yield of ^{3}CA. Then, $\Phi^{total}_{CAH\cdot}$ and $\Phi_{CA^{\cdot-}}$ can be expressed by Eqs. 5 and 6 respectively using transient absorbances measured at 300 ns after the laser excitation.

$$\Phi^{total}_{CAH\cdot} = \frac{D_{CAH\cdot}/\varepsilon_{CAH\cdot}}{D^{calc}_{3CA}/\varepsilon_{3CA}}, \quad (5)$$

$$\Phi_{CA^{\cdot-}} = \frac{D_{CA^{\cdot-}}/\varepsilon_{CA^{\cdot-}}}{D^{calc}_{3CA}/\varepsilon_{3CA}}, \quad (6)$$

where $D_{CAH\cdot}$ and $D_{CA^{\cdot-}}$ are the absorbances of CAH· at 435 nm and $CA^{\cdot-}$ at 448 nm after the spectrum decomposition, respectively, and $D^{calc}_{3CA}\equiv D_{3CA}\cdot D^0_{CA}/(D^0_{CA}+D^0_C)$ is the calculated absorbance of ^{3}CA which should be produced in the mixed solution of CA and DH immediately after the excitation. D_{3CA} is the 510 nm absorbance of ^{3}CA observed in the reference solution of CA. D^0_{CA} and D^0_C are the 347 nm absorbances of uncomplexed CA and complex CA···DH respectively and hence $D^0_{CA}/(D^0_{CA}+D^0_C)$ means the fraction of absorbance due to free CA present in the mixed solution to the total absorbance at 347 nm. $\varepsilon_{CAH\cdot}$ is the molar absorption coefficient of CAH· in DCE (1.0×10^4 $dm^3mol^{-1}cm^{-1}$ at 435 nm)[30] and $\varepsilon_{CA^{\cdot-}}$ is that of $CA^{\cdot-}$ (9.0×10^3 $dm^3mol^{-1}cm^{-1}$ at 448 nm).[28b,31] Table 1 shows results obtained. Although rather large error (about 20%) was presumed for each Φ value, the agreement among several measurements for each pair of solutions was good (within 10%). Both values of $\Phi^{total}_{CAH\cdot}$ and $\Phi_{CA^{\cdot-}}$ are independent on [CA] as well as [DH]. $\Phi^{I}_{CAH\cdot}$ was evaluated to be 0.10 by using the relation $\Phi^{I}_{CAH\cdot}=\Phi^{total}_{CAH\cdot}-\Phi^{II}_{CAH\cdot}$ with the value of $\Phi^{II}_{CAH\cdot}=0.19$. The Φ_{CA} value was calculated to be 0.52 by $\Phi_{CA}=1-\Phi^{total}_{CAH\cdot}-\Phi_{CA^{\cdot-}}$. If the quenching of ^{3}CA yielding no transient species is competing with IP formation in

TABLE 1. YIELDS OF CAH· AND $CA^{\cdot-}$ IN DCE AT 20 °C

[CA] /10^{-3}mol dm^{-3}	[DH] /10^{-1}mol dm^{-3}	$\Phi^{total}_{CAH\cdot}$	$\Phi_{CA^{\cdot-}}$
2.0	0.1	0.29	0.18
2.0	1.0	0.29	0.17
2.0	1.5	0.28	0.19
2.0	2.0	0.28	0.21
2.0	2.5	0.29	0.21
2.5	1.0	0.29	0.20
2.0	1.0	0.30	0.19

		av. 0.29	0.19

the encounter complex, Φ_{CA} must satisfy the relation $\Phi_{CA}=1-\Phi_{IP}-\Phi^{II}_{CAH\cdot}<1-\Phi_{IP}=0.19$. This relation contradicts the experimental result ($\Phi_{CA}=0.52$), so that the deactivation to the ground state competing with IP formation may be neglected in (3).

Determination of ϕ_p, ϕ_i, ϕ_d, k_p, k_i, *and* k_d: Using the Φ values together with the τ_d value the efficiencies (ϕ) for decay channels of IP and the first-order rate constants (k) for the corresponding processes could be estimated as follows:

$$\begin{aligned} \phi_p &= 0.1_2, \; k_p = 2\times10^6\ s^{-1}, \\ \phi_i &= 0.2_3, \; k_i = 5\times10^6\ s^{-1}, \\ \phi_d &= 0.6_5, \; k_d = 13\times10^6\ s^{-1}. \end{aligned} \tag{7}$$

On the other hand, from the time dependence of absorbances obtained by the ns laser photolysis alone, we could also estimate $\phi_p=0.1_4$ by Eq. 8,

$$\phi_p = \frac{\{D_{CAH\cdot}(300)-D_{CAH\cdot}(50)\}/\varepsilon_{CAH\cdot}}{D_{448}(50)/\varepsilon_{IP}} \tag{8}$$

assuming that D_{448} (50), the 448nm absorbance observed at 50ns, is due to IP. In Eq. 8, $D_{CAH\cdot}$ (50) and $D_{CAH\cdot}$ (300) are the absorbances of CAH· at 435nm (after the spectrum decomposition) measured at 50 and 300ns, respectively, and $\varepsilon_{CAH\cdot}$ and ε_{IP} are the same as in Eqs. 5 and 6.

For the purpose of comparison we present here briefly some results obtained in the CA-diphenylamine (DPA)-DCE system.[12] We have found the triplet IP, $^3(CA^{\overline{\cdot}}\cdots DPA^+)$, with a lifetime of *ca.* 8ns, $k_i\approx1\times10^7\ s^{-1}$, and $k_d\approx1.1\times10^8\ s^{-1}$, whereas no proton transfer in $^3(CA^{\overline{\cdot}}\cdots DPA^+)$ has been detected. The k_p value given in Eq. 7 is much less than the corresponding values for benzophenone (BP)-*N*,*N*-dimethylaniline (DMA) system ($k_p=2.0\times10^9 s^{-1}$ in acetonitrile)[1] and pyrene (P)-primary or secondary aromatic amine system (*e.g.*, ($k_p=5\times10^9 s^{-1}$ for P-DPA system in toluene).[2] Although the number of data of k_p value in Mechanism I is still scarce for any detailed discussion, these data appear to indicate that the rate of proton transfer in IP decreases with increase of the free energy change of this reaction.[32] In Eq. 7, the k_i value is larger than the k_p value by a factor of about 2.5. However, the rate of ionic dissociation in DCE is much slower than that in acetonitrile, where the photocurrent has been found to reach its maximum intensity immediately after the pulsing (Fig. 11). Therefore, the slow dissociation in DCE

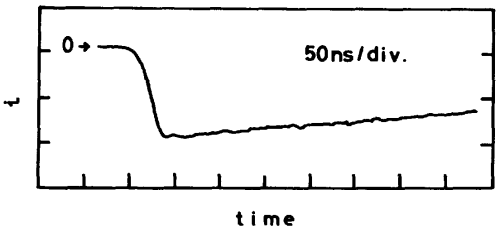

Fig. 11. Transient photocurrent measured in acetonitrile.

may be largely dependent on a fairly strong binding by Coulomb force between the ions in IP, which does not contradict the fact that both k_i values for $^3(CA^{\overline{\cdot}}\cdots DH^+)$ and $^3(CA^{\overline{\cdot}}\cdots DPA^+)$ are close to each other. It is known that the ionic dissociation to free ions occurs from solvent-separated ion pair (SSIP)[22] while the proton transfer takes place from contact ion pair (CIP).[1] From the fact that the rise time of photocurrent is equal to the decay time of IP, it may be inferred that IP observed here in DCE comprises both CIP and SSIP in equilibrium with each other. It is often used that because of spin-forbidden nature a back electron-transfer in triplet IP leading to the ground state cannot compete with ionic dissociation. However, in DCE of moderately polar solvent the back electron-transfer (k_d) can take place effectively rather than the ionic dissociation (k_i). Similar observation about the competition between k_d and k_i processes has been reported for various quinone-aromatic amine systems.[33] Moreover, the k_d value ($\approx1.1\times10^8 s^{-1}$) for $^3(CA^{\overline{\cdot}}\cdots DPA^+)$ obtained by us in DCE agrees well with $k_d=1.1\times10^8\ s^{-1}$ obtained by a different procedure in benzene-benzonitrile mixture.[3c] The k_d value in $^3(CA^{\overline{\cdot}}\cdots DH^+)$ is of one order of magnitude smaller than that in $^3(CA^{\overline{\cdot}}\cdots DPA^+)$. This tendency is parallel to the linear relation between log k_d and the energy level of IP above the ground state,[33] since the energy of $^3(CA^{\overline{\cdot}}\cdots DPA^+)$ is estimated by Eq. 2 to be lower by 0.81eV than that of $^3(CA^{\overline{\cdot}}\cdots DH^+)$. Hence, it seems to indicate that ISC of IP obeys the energy gap law of radiationless transition.

Competition of Mechanisms I and II. Finally we consider the mechanism of competition of I and II. A key point determining the mechanism must be involved in a collision complex between ^{3}CA and DH. Since in the present case DH approaches by diffusion to ^{3}CA from random directions, the collision complex with various donor-acceptor configurations might be produced. It may be true that an electron transfer occurs depending principally on the separation distance but not so severely on the mutual orientation between donor and acceptor. On the other hand, H-atom transfer will depend strongly on the local disposition of the transfer sites in the collision complex. Therefore, difference in conformations of the collision complexes seems to reflect the difference in the mechanisms of H-atom transfer. In the present case, it is supposed that a large part (about 80%) of the collision complexes can take conformations favorable to cause the electron transfer followed by immediate relaxation to the IP state; *e.g.*, a conformation with face to face approach between the donor and the acceptor. The other collision complexes of about 20% would take some special conformations favorable to undergo the rapid H-atom transfer; *e.g.*, a conformation with the transfer sites very close to each other like a hydrogen bonding bridge between O-atom of the acceptor and H-atom of methyl groups on the donor. Such a rapid H-atom transfer in the collision complex has been suggested for the dynamic quench-

ing in the hydrogen bonding interaction systems such as 2-naphthol-pyridine-cyclohexane system[34] as well as the quenching of triplet quinones by aromatic amines.[3] Recently, very fast H-atom transfer by a two-step mechanism of electron transfer followed by proton transfer has been verified both in EDA systems[1,2] and in hydrogen bonding interaction systems.[18,35] Taking these facts into account, it seems that the rapid H-atom transfer observed here also proceeds through the mechanism by transitory electron transfer preceding proton transfer.[36] Therefore, it may be interpreted that the first event of the quenching is an electron transfer from DH to ^{3}CA and succesively, in the collision complex, a rapid proton transfer and relaxation to the IP state compete with each other. The net H-atom transfer by Mechanism I occurs relatively slowly depending on the rate of proton transfer in IP. This suggests that a fairly high potential barrier is necessary to take a conformation favorable for causing the proton transfer from the relaxed state IP. A detailed study of the temperature dependence of this process will be published in a separate paper.

28) An ε_{IP} value may be approximated by the molar absorption coefficient of CA$^-$ (ε_{CA^-}). The ε_{CA^-} values reported previously are: a) 9.7×10^3 dm^{3}mol^{-1}cm^{-1} in acetonitrile at 448 nm,[10] b) 9.0×10^3 dm^{3}mol^{-1}cm^{-1} in acetone at 450 nm (Y. Iida, *Bull. Chem. Soc. Jpn.*, **43**, 2772 (1970)), and c) 7.7×10^3 dm^{3}mol^{-1}cm^{-1} in ethanol at 454.5 nm (N. Sakai, I. Shirotani, and S. Minomura, *Bull. Chem. Soc. Jpn.*, **44**, 675 (1971)). The ε_{CA^-} values fairly depend on solvent properties such as protic or aprotic solvent or solvent polarity. As the ε_{IP} value, we here employed the ε_{CA^-} value in acetone which is aprotic solvent with a dielectric constant (21.5) rather close to that of aprotic DCE (10.7).

29) This value which was estimated again by the same method as used in Ref. 4a is in good agreement with the previously reported value: $(7.2\pm1.3)\times10^3$ dm^{3}mol^{-1}cm^{-1}.[4a]

30) This $\varepsilon_{CAH\cdot}$ value in DCE was determined by comparison with the known value: 7.7×10^3 dm^{-1}cm^{-1} (S. K. Wong, L. Fabes, W. J. Green, and J. K. S. Wan, *J. Chem. Soc. Faraday Trans. 1*, **68**, 211 (1972)) in 1,4-dioxane at 435 nm as a reference, assuming that the integrated intensity of CAH· absorption around 435 nm is independent on solvent.

31) Since the spectrum of $CA^{\cdot-}$ in CH_3CN was used as a reference of free $CA^{\cdot-}$ in the spectrum decomposition (Fig. 7), the value of $\varepsilon_{CA^{\cdot-}}$ in CH_3CN might be also employed. However, the use of it did not alter the results in Table 1.

32) For example, the energy separations (E_R) between the ground CA+DH and radical pair states in the CA-DH and BP-DMA systems are estimated nearly equal, because the H-atom transfer sites of both systems, >C=O and $-CH_3$, are very similar to each other. If the entropy changes for proton transfer in contact ion-pair (CIP) states, $(CA^{\cdot-}\cdots DH^+)_s$ and $(BP^{\cdot-}\cdots DMA^+)_s$, leading to the formation of neutral radicals are approximately equal, the free energy change (ΔG) accompaning this reaction depends on the energy of CIP above the gorund state (E_{CIP}). The E_{CIP} values for $(CA^{\cdot-}\cdots DH^+)_s$ in DCE and $(BP^{\cdot-}\cdots DMA^+)_s$ in CH_3CN are estimated to be 134 and 305 kJmol^{-1}, respectively, and hence ΔG value is larger for the CA-DH system than for the BP-DMA system. It has been measured that the energy of radical pair state produced in BP-aniline system in ethanol is 188 kJmol^{-1} above the ground state (L. J. Rothberg, J. D. Simon, M. Bernstein, and K. S. Peters, *J. Am. Chem. Soc.*, **105**, 3464 (1983)). Assuming that this value is approximately equal to the E_R value since the bond energies of C-H and N-H are also approximately equal to each other, the proton transfer from CIP is endothermic for the CA-DH system and exothermic for the BP-DMA system. The marked difference in k_p values for the two systems may be attributed to these conditions.

(Received April 7, 1984)

Mössbauer study of potassium germanate glasses containing a small amount of Sn^{4+} has been performed to know the relationship between the abnormal composition dependence of physical properties, so-called germanate anomaly, and the local structural change of the glasses. Distinct increases in isomer shift and linewidth and a distinct decrease in quadrupole splitting are observed when the concentration of alkali oxide exceeds about 16 mol%. These changes are ascribed to the formation of nonbridging oxygen atoms in GeO_4 units. This is also supported by a drastic decrease in a parameter of intermolecular force constant obtained from the temperature dependence of Mössbauer absorption area. The composition dependence of the parameter is well consistent with that of glass transition temperature (T_g) of the same samples. Transformation of GeO_4 tetrahedra into GeO_6 octahedra is also confirmed by increases in the parameter of intermolecular force constant and in T_g in the alkali content region lower than 16 mol%. The role of Sn^{4+} is concluded to be a network modifier which is present at an interstitial site of three-dimensional network composed of GeO_4 and GeO_6 units.

Abnormal change in the physical properties of germanate glasses, so-called germanate anomaly, was first reported by Ivanov and Evstroviev.[1] They found maxima in the density- and refractive index-composition curves at the alkali oxide concentration of 10—15 mol%. Similar results were also obtained by Murthy and Ip,[2] and by Murthy and Scroggie[3] in germanate and aluminogermanate glasses, respectively. The germanate anomaly was also observed on viscosity[4] and glass transition temperature,[4,5] and in these physical properties-composition curves, the maxima were observed at the alkali contents of about 17[4] and 15—16[5] mol%, respectively. The decreases in viscosity and glass transition temperature at the alkali content region higher than the critical concentration (17 and 15—16 mol%) were tentatively attributed to the formation of nonbridging oxygen (NBO), because the decreases were thought to be due to the decrease in the cohesiveness of the glasses,[4] and to the depolymerization of the glass network.[5]

Structural study of germanate glasses was first carried out by Murthy and Kirby,[6] and a change in the coordination number of germanium(IV) from 4 to 6 was concluded from a red shift of IR absorption band due to Ge–O–Ge stretching vibration. Fraction of GeO_6 units was first estimated by Sakka *et al.*[7] based on the difference in the IR peak position of the Ge–O–Ge stretching vibration between hexagonal GeO_2 composed of GeO_4 units (875 cm^{-1}) and tetragonal GeO_2 composed of GeO_6 units (700 cm^{-1}). As the result, a maximum fraction of GeO_6 units (28%) was observed at a composition of about 15—20 mol% alkali oxide. The same idea as that in the IR study[7] was applied to X-ray diffraction study[8] and a maximum fraction of GeO_6 units (10—35%) was obtained at a composition region of 20—30 mol% alkali oxide. EXAFS study was also utilized by Sakka *et al.*[9] to know the fraction of GeO_6 units in germanate glasses, and a maximum was observed at an alkali oxide concentration of 15—16 mol%. Raman study by Verweij and Buster[10] revealed the presence of NBO in germanate glasses, in which stretching vibration band due to $Ge-O^-$ was observed at 850—880 cm^{-1}. The Raman study led to a conclusion that the fraction of GeO_6 units increases in the alkali content region ranging from 0 to 18 mol% and then decreases in the region from 18 to 33 mol% with the formation of NBO in GeO_4 units. Smets and Lommen[11] estimated the fraction of NBO in germanate and silicate glasses using X-ray photoelectron spectroscopy (XPS), and the formation of NBO was concluded to start at an alkali oxide concentration of 18 mol% in the case of germanate glasses.

Mössbauer spectroscopy of ^{57}Fe has been successfully used by the present authors for the structural studies of borate,[12–17] borosilicate,[18–19] phosphate,[20,21] and borophosphate[22] glasses to estimate the formation of NBO[12–14,18–22] and, furthermore, the fraction of NBO.[13,14,19] Mössbauer spectroscopy has also been used to examine the steric configuration of halide ions[15,16] in borate glasses as well as a chemical effect of $^{10}B(n,\alpha)^7Li$ nuclear reaction.[17] Kinetic study of the crystallization of borosilicate glasses has also been performed by means of Mössbauer spectroscopy.[23,24] Mössbauer spectroscopy of ^{119}Sn has been utilized to know the structures of borate[25–28] and silicate[25,29,30] glasses. The studies clarified that most Sn^{4+} species are present in octahedral environment and also that stannous ions in borate[27,28] and silicate[30] glasses play a role of network modifier when the SnO content is not so high. It is also noteworthy that the formation of NBO in borate glasses is observed in an alkali content region $\geq$20 mol%, which is consistent with our previous results[12–14,17] obtained from ^{57}Fe Mössbauer studies. These Mössbauer results are reproduced in a review article[31] by Müller-Warmuth and Eckert together with the NMR results of several kinds of glasses.

The present study was carried out to elucidate the local structure of germanate glasses, because most results on the structure and physical properties of the

glasses obtained so far are contradictory and also the germanate anomaly is assumed to be closely correlated with the presence of NBO.

Experimental

All glass samples, denoted by a formula $x\mathrm{K_2O}\cdot(100-x)\mathrm{GeO_2}\cdot 2\mathrm{SnO_2}$, were prepared by fusing mixtures of weighed quantities of guaranteed reagent grade $\mathrm{K_2CO_3}$, $\mathrm{GeO_2}$, and $\mathrm{SnO_2}$ at 1200 °C for 2h in an electric muffle furnace. The $\mathrm{K_2O}$ content, x, was changed from 10 to 30 at 5 intervals. Transparent and colorless glasses were prepared by quenching the melts in platinum crucibles with cold water. All the glass samples prepared in this way were confirmed to be amorphous by X-ray diffraction. Mössbauer measurements were performed by a constant acceleration method at various temperatures using a source of $\mathrm{Ca^{119m}SnO_3}$. Barium stannate ($\mathrm{BaSnO_3}$) was used as a reference for isomer shift. The velocity of spectrometer was calibrated with a metallic iron enriched with $^{57}\mathrm{Fe}$. All the Mössbauer spectra were fitted to Lorenzian lineshapes by computer calculations. DTA measurements of the glasses (10mg) were performed with a heating rate of 5 °C $\mathrm{min^{-1}}$ ranging from room temperature to 700 °C.

Results and Discussion

Mössbauer spectra for the germanate glasses containing tin proved to consist apparently of a single absorption peak, as shown in Fig. 1. The isomer shift suggests that tin is present as tetravalent ionic species ($\mathrm{Sn^{4+}}$) with octahedral symmetry[32] because the value is close to, and also smaller than zero velocity. Each

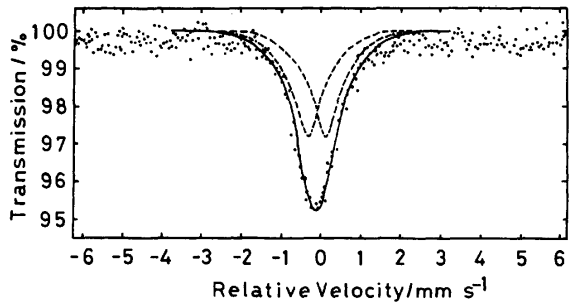

Fig. 1. Mössbauer spectrum of $10\mathrm{K_2O}\cdot 90\mathrm{GeO_2}\cdot 2\mathrm{SnO_2}$ glass.

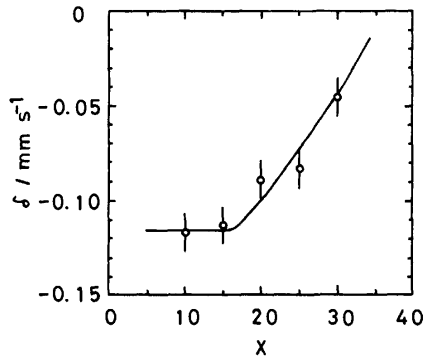

Fig. 2. Variation of the isomer shift of $\mathrm{Sn^{4+}}$ with $\mathrm{K_2O}$ content.

Mössbauer spectrum was analyzed into a kind of doublet, as shown by broken lines in Fig. 1, and also as a single peak shown by a solid line. The doublet analysis was performed because it was expected that some information on the electric field gradient at tin nucleus or symmetry around $\mathrm{Sn^{4+}}$, if present, could be obtained from the quadrupole splitting. The change in the isomer shift of the $\mathrm{Sn^{4+}}$ absorption peak is shown in Fig. 2 as a function of the $\mathrm{K_2O}$ content. (Each isomer shift value plotted in Fig. 2 is also consistent with the corresponding value obtained from a single peak analysis, within the experimental error.) It is seen from Fig. 2 that the isomer shift of $\mathrm{Sn^{4+}}$ increases almost linearly in the alkali content region higher than $x=$ 16—17. The increase in the isomer shift means the increased s-electron density at tin nucleus.[32] This is consistent with our previous results obtained in the case of borate[12] and borosilicate[18] glasses containing iron, where a continuous decrease in the isomer shift of $\mathrm{Fe^{3+}}$ was attributed to an increased s-electron density at the iron nucleus owing to the formation of NBO. (The decrease in the isomer shifts of $\mathrm{Fe^{2+}}$ and $\mathrm{Fe^{3+}}$ corresponds to the increase in the s-electron density at the iron nucleus because the radius of iron nucleus at the excited state is smaller than that at the ground state). The increase in the isomer shift of $\mathrm{Sn^{4+}}$, *i.e.*, the increase in the s-electron density at tin nucleus, is then assumed to be related in anyway with the formation of NBO in germanate glasses. In the case of $\mathrm{Sn^{4+}}$ the increase in isomer shift is known to be related to the increase in covalency.[27,32] The increase in the covalency with the formation of NBO is also observed in the case of borate glasses[28,28] containing $\mathrm{Sn^{2+}}$, although the apparent phenomenon is contrary to the present result. Mössbauer measurements at lower temperatures also gave a result similar to that shown in Fig. 2, and the individual isomer shift values slightly increased as a whole because of the reduced second order Doppler effect (*ca.* 0.04—0.05 $\mathrm{mm\,s^{-1}}$ in the temperature range from 78 to 298K). The second order Doppler effect shifts the peak position in the direction of negative velocity, in proportion to the vibration frequency of solid or measuring temperature.[33] The increase in the isomer shift of $\mathrm{Sn^{4+}}$ shown in Fig. 2 is therefore concluded to be due not to the second order Doppler shift, but to the increased s-electron density at tin nucleus and the increased covalency in the chemical bond between tin and oxygen, as described above.

Change in the quadrupole splitting of $\mathrm{Sn^{4+}}$ is shown in Fig. 3. The quadrupole splitting decreases linearly with alkali oxide content in the alkali content region higher than $x\simeq 17$. This is compatible with the result of isomer shift shown in Fig. 2. The decrease in the quadrupole splitting of $\mathrm{Sn^{4+}}$ suggests the increase in the symmetry around tin nucleus because the contribution of valence electrons (q_{val}) to the electric field gradient is negligible in the case of $\mathrm{Sn^{4+}}$ with an electron configuration of $4d^{10}$. This is also the case for

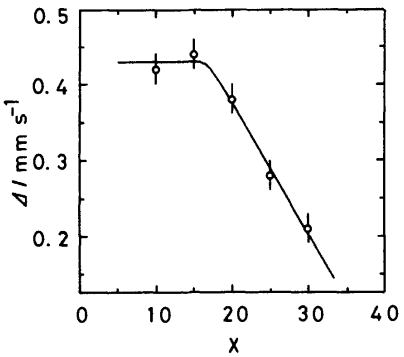

Fig. 3. Variation of the quadrupole splitting of Sn^{4+} with K_2O content.

Fe^{3+} with the $3d^5$ configuration, where a decrease in quadrupole splitting due to the formation of NBO has been observed in borate,[12] borosilicate,[18] phosphate,[20] and borophosphate[22] glasses. The continuous decrease in the quadrupole splitting shown in Fig. 3 is therefore ascribed to the increased symmetry around Sn^{4+} surrounded by six oxygen atoms, owing to the formation of NBO.

Change in the linewidth (FWHM) of the double peak is shown in Fig. 4. In general linewidths of absorption lines for amorphous materials are known to be greater than those for the corresponding crystalline materials. The linewidth ranges from 0.8 to 1.44 $mm\,s^{-1}$ in the case of Sn^{4+} in glasses.[25,26,29,34] The present result is also consistent with those results. The most remarkable feature of Fig. 4 is that the linewidth shows a drastic increase in the alkali content region higher than x=17—18, suggesting an increased irregularity of the steric configuration of glass forming atoms such as oxygen and germanium. This is a quite reverse phenomenon as compared with the earlier results of borate[12] or borosilicate[18] glasses containing Fe^{3+} ions where a continuous decrease in linewidth was observed with the formation of NBO. This will probably be explained by the difference in the structural roles of Fe^{3+} and Sn^{4+}, *i.e.*, the former ion plays a role of network former at the substitutional site of B and Si constituting BO_4 and SiO_4 tetrahedral units, respectively, and the latter is assumed to be present as a network modifier with octahedral symmetry at interstitial sites in a three-dimensional network composed of GeO_4 and GeO_6 units. In contrast with the well-studied role of iron in glasses, the role of tin has not been well understood and the results so far published are contradictory each other.[31] Dannheim *et al.*[30] suggested that both Sn^{4+} and Sn^{2+} in silicate glasses occupy the position of network modifier when the alkali concentration is not so high. This is consistent with the present result. In view of the distinct changes in the isomer shift (Fig. 2) and quadrupole splitting (Fig. 3), from which a formation of NBO could be deduced, the increase in the linewidth of Sn^{4+} is ascribed to the increased disorder brought about by the formation of NBO at the neighboring site of Sn^{4+}.

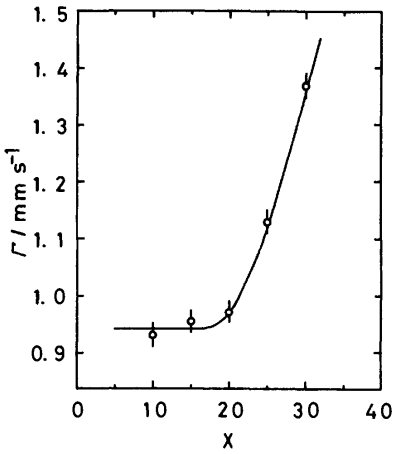

Fig. 4. Variation of the linewidth of Sn^{4+} with K_2O content.

Lattice dynamic study was then performed to confirm the conclusion obtained from the results of isomer shift, quadrupole splitting, and linewidth because it was expected that lattice vibration would be changed with the formation of NBO, *i.e.*, with the depolymerization of three-dimensional network. The correlation between the lattice vibration and the Mössbauer recoil-free fraction f has already been reported by using a Debye approximation.[32,33] In the high temperature limit

$$f = \exp(-6E_R T/k\theta^2), \tag{1}$$

where E_R and k are recoil energy and Boltzmann constant, respectively, and θ is the Debye temperature denoted as $k\theta=h\nu_{max}$ where h is Planck constant and ν_{max} is the maximum lattice vibration frequency. The correlation between E_R and Mössbauer transition energy E (23.9keV in the present study) is given by

$$E_R = E^2/2Mc^2, \tag{2}$$

where M is the mass of Mössbauer nucleus and c is the velocity of light. Combining the two equations, we obtain

$$f = \exp(-3E^2T/Mc^2k\theta^2). \tag{3}$$

Equation 3 is further modificated by differentiating the natural logarithm of f with T:

$$\theta^2M = \frac{3E^2}{kc^2}\left(\frac{-\mathrm{d}\ln f}{\mathrm{d}T}\right)^{-1}. \tag{4}$$

Matsubara *et al.*[34] showed the proportionality of θ^2M to the intermolecular force constant α and termed θ^2M "parameter of intermolecular force constant." They also showed the relationship between θ^2M and the degree of polymerization in a number of organotin compounds. As the result, the parameter was proved to be very useful for the determination of the degree of polymerization and molecular association. In the present study $\mathrm{d}\ln A/\mathrm{d}T$ was utilized instead of $\mathrm{d}\ln f/\mathrm{d}T$ because the latter can be approximated by the former

when a very thin sample is measured and the absorption area (A) is not saturated. In Fig. 5 the individual absorption areas are normalized by the area at 78K. It is seen from Fig. 5 that there is a linear relationship between $\ln A$ and T. Therefore θ^2M is obtained by dividing $3E^2/kc^2$, *i.e.*, 2.13×10^4 in the case of 23.9keV ^{119}Sn, with the slope of the individual straight line. The values of θ^2M are plotted in Fig. 6, together with the Debye temperature calculated by substituting the formula weight in M. Considering the Mössbauer and Raman study by Herber *et al.*,[35] where M is consistent with the molecular weight of organotin compound, the Debye temperatures shown in Fig. 6 are assumed to be rather reasonable ones. The values of θ^2M (All the values in the present paper must be multiplicated by a factor of 10^6) are reported to be about unity for monomer and to be 1.3 and 1.7 for one- and two- dimensional polymers, respectively.[34] It is also reported that the θ^2M values are 2.1 and 3.2 for two three-dimensional polymer compounds.[34] These are the values reported for the organotin compounds in which the chemical bonds between tin and the neighboring atoms are essentially covalent. The parameter (θ^2M) for ionic compound can also be obtained if the Debye temperature or the recoil-free fraction at different temperatures is known. The values of θ^2M calculated for the representative ionic compounds $BaSnO_3$[36] and SnO_2[37] are 22.4 and 8.9 (amorphous) —14.8 (crystalline), respectively, being larger than those for the covalent compounds. From the difference in the Debye temperature of SnO_2,[37] θ^2M is expected to be larger for the crystalline material than for the corresponding amorphous material. Comparing the magnitude of θ^2M obtained in the present study with those for the covalent and ionic compounds described above, the chemical bond between Sn^{4+} and oxygen seems to be essentially ionic. It is generally known that the chemical bonds between network modifier and the neighboring atoms, *i.e.*, oxygen in the case of oxide glasses, are essentially ionic. The present result therefore leads to a conclusion that the role of Sn^{4+} in germanate glasses is a network modifier which is present at an interstitial site of three-dimensional network composed of GeO_4 and GeO_6 units. It is expected that the intermolecular force for a Mössbauer nucleus at an interstitial site becomes less intense than that at a substitutional site. In fact, the θ^2M values obtained in the present study (6.2—8.7) are smaller than that for the amorphous SnO_2 (8.9). The role of Sn^{4+} in germanate glasses is therefore concluded to be similar to that of alkali metal ions like Na^+ and K^+.

Another important feature of Fig. 6 is the distinct composition dependence of θ^2M (and also θ) with a maximum at the K_2O concentration of about x=16. The increase in θ^2M with increasing alkali content of the germanate glasses is reasonably explained by an increase in the number of bridging oxygen atoms owing to the formation of GeO_6 units instead of GeO_4

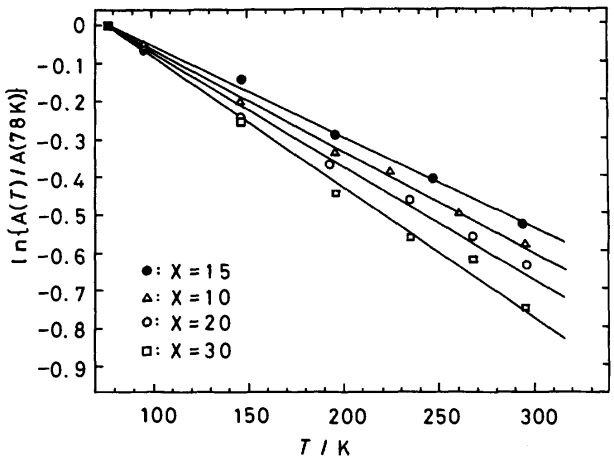

Fig. 5. Plots of the absorption area against temperature.

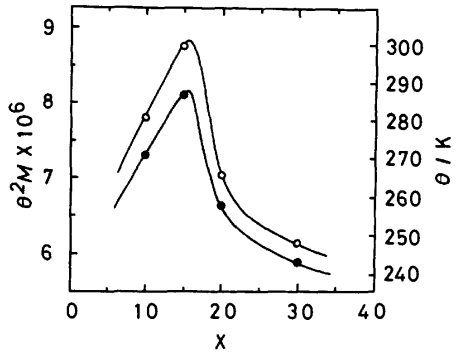

Fig. 6. Variations of the parameter of intermolecular force constant (○) and the Debye temperature (●) with K_2O content.

units. The decrease in θ^2M at the alkali content region higher than x=16 is well explained by the formation of NBO which is expected to bring about a drastic decrease in the intermolecular force because of the destruction of network structure. The structural change will result in some physical properties such as glass transition temperature (T_g) and viscosity. Figure 7 shows the result of DTA measurement, which is well consistent with the result of θ^2M. A maximum is observed at almost the same alkali concentration as does that in the θ^2M plot. It is interesting to note that the decrease in T_g is not so rapid as that of θ^2M at the higher alkali content region. This may be due to the different characteristics of the two methods, *i.e.*, T_g corresponds to the mean transition energy for the glass matrix, while θ^2M is closely concerned with the local vibrational energy in the neighborhood of ^{119}Sn. It is therefore, concluded that the parameter of intermolecular force constant, as well as the Mössbauer parameters like isomer shift and quadrupole splitting, is exceedingly sensitive to the structural change of glasses.

All the experimental results obtained in the present study are as follows. In potassium germanate glasses of which the alkali oxide contents are lower than about 16mol%, the increase of the alkali contents results in the increase in the fraction of GeO_6 units. In the alkali

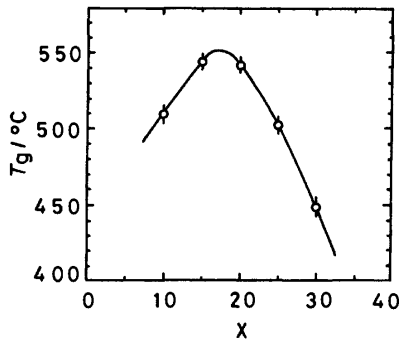

Fig. 7. Variation of the glass transition temperature with K_2O content.

content region higher than about 16mol% the increase in the alkali contents results in the formation of NBO in GeO_4 units in competition with the formation of GeO_6 units, and the former reaction will be predominant with increasing alkali contents. Stannic ion would be present at a site similar to that of K^+, *i.e.*, at an interstitial site in the network composed of GeO_4 and GeO_6 units, as a network modifier with octahedral symmetry.

The authors are indebted to Prof. Sumio Sakka of Kyoto university for his useful suggestion on the structure of germanate glasses. They are also grateful to Prof. Hirotoshi Sano of Tokyo Metropolitan University for his useful discussion.

Determination of Trace Amounts of Copper as the Complex with Bathocuproinedisulfonate after Enrichment in the Thin Layer of Anion-exchange Resin

Masaaki OHTA and Kunio OHZEKI*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 21, 1984)

A simple and selective method for the determination of trace amounts of copper is developed. The method is based on the concentration of copper as the complex with bathocuproinedisulfonate (BCS) with the use of finely divided anion-exchange resin, collection of the resin on a membrane filter as the disk of thin layer, and determination of the colored complex in the resin phase by densitometry. The copper(I)-BCS complex in sample volumes ranging from 50—200 cm^3 was effectively concentrated by factors ranging from 2500—10000. The method was applied to tap water. Copper at ppb ($\mu g\ dm^{-3}$) level was successfully determined.

As well known, cuproine and its derivatives are highly selective color-developing reagents for copper.[1] Among them, bathocuproinedisulfonate has been used for the direct determination of copper in the aqueous solutions.[2]

Fugimoto *et al.*[3] studied the resin spot test of copper and reported that copper(I) bathocuproinedisulfonate was extremely strongly fixed on the beads of anion-exchange resin. The idea of resin spot test was further extended to ion-exchanger colorimetry,[4] in which the resin phase absorbance was measured directly in a 1-mm cell. Nigo *et al.*[5] applied the method to the trace determination of copper as the porphyrin complex. The method of combined use of finely divided anion- and cation-exchange resins was also reported.[6,7] The colored species collected in the thin layer of mixed resins were determined spectrophotometrically[6] or densitometrically.[7]

In the present paper, the extraction of trace amounts of copper as bathocuproinedisulfonate is studied by the use of finely divided anion-exchange resin. The determination is carried out by using densitometer and the results are compared with those obtained by the combined use of anion- and cation-exchange resins.

Experimental

Reagents. Hydrochloric acid used was of super special grade (SSG reagent, Wako). All other chemicals used were of analytical reagent grade. A stock copper(II) solution (1000 $\mu g\ Cu\ cm^{-3}$) was prepared by dissolving copper(II) sulfate pentahydrate in deionized water containing hydrochloric acid (pH *ca.* 1). The working solution (10 $\mu g\ Cu\ cm^{-3}$) was prepared by appropriate dilution. The reagents, 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (Bathocuproine, abbreviated as BC) and disodium salt of 2,9-dimethyl-1,10-phenanthrolyl-4,7-dibenzene-*p,p'*-disulfonic acid (Bathocuproinedisulfonic acid, disodium salt, abbreviated as BCS) were obtained from Dojindo Lab., and used without further purification. A 1 $mmol\ dm^{-3}$ ethanolic solution of BC and 0.67 $mmol\ dm^{-3}$ aqueous solution of BCS were prepared. The purity of BCS, which was estimated from absorbance-mole ratio (BCS/Cu) plots, was 78%. An aqueous 10% W/V solution of hydroxylammonium chloride and 30% W/V sodium acetate solution were purified by extracting the impurity due to copper ion as the BC complex into chloroform.

Ion-exchange Resin Suspension. The macroreticular type ion exchangers, Amberlyst 15 and A-27 (Rhom and Haas Co.) were used in RSO_3H and $RN(CH_3)_3Cl$ forms, respectively. The cation-exchange resin suspension (CRS) and the anion-exchange resin suspension (ARS) were prepared according to the reported method,[8] that is, the wet resin was crashed in the slurry and sieved through 3G3 glass filter. The ion-exchange capacities of CRS and ARS were determined by the conductometric titration with standard solutions of sodium hydroxide and silver nitrate. The capacities of CRS and ARS were found to be 6.72 $\mu eq\ cm^{-3}$ and 5.11 $\mu eq\ cm^{-3}$, respectively. When 2 cm^3 of CRS was mixed with 3 cm^3 of ARS, both resins were almost completely coagulated and quantitatively collected on a filter paper.

Apparatus. The densitometer used was a Shimadzu Chromatoscanner CS-920 equipped with linearizer. A Shimadzu UV-visible recording spectrophotometer, type UV-240, was used for measuring absorption spectra. A Toyo KG-25 filter holder was used. The filters used were TM-1 (0.65 μm pore size, 47 mm in diameter, Toyo) or No. 5B filter paper. Micropipets were used.

General Procedure. A 50-cm^3 aliquot of sample solution containing less than 1 μg of copper was placed in a 100-cm^3 beaker. A 1-cm^3 portion of 10% hydroxylammonium chloride, 0.5 cm^3 of 0.67 $mmol\ dm^{-3}$ BCS, and 1 cm^3 of 30% sodium acetate solution were added successively. The pH of final solution was about 6. The solution was stirred by means of a magnetic stirrer for 2 min and then 1.0 cm^3 of ARS was added. The mixture was further stirred for 10 min. The anion-exchange resin was then collected by filtration with suction on a membrane filter (TM-1). The copper(I)-BCS complex was thus concentrated in a disk of the thin layer with 17 mm in diameter and about 0.1 mm in thickness. The wet membrane filter was placed on a white plastic plate fixed on a scanning board in the densitometer. The absorbance was measured with or without linearizer at 485 nm by scanning the light beam in a range of 24 mm wide and 30 mm long. In the case of the mixed resin method, the combination of 2.0 cm^3 CRS and 3.0 cm^3 ARS was used and the mixed resins were collected on a filter paper of No. 5B.

Results and Discussion

Copper(I)-BCS Complex in the Resin Phase. A

trace amount of copper was quantitatively extracted to the resin phase when the amount of BCS was in excess of the stoichiometric value (Fig. 1). A constant coloration was obtained at pH above 3. Figure 2 shows the absorption spectrum of the complex in the resin phase. Although there is a general similarity between the absorption spectra of the complex in the solution and in the resin phase, but a small shift of the maximum wavelength was observed from 480 nm in the solution to 485 nm in the resin phase. The coloration was stable for at least 2 h, when the resin thin layer was kept wet with water.

The maximum fixable amounts of copper(I)-BCS complex and BCS on the resin in 1.0 cm^3 of ARS were found to be 0.16 μmol and 0.57 μmol, respectively. These values were much smaller than the total exchange capacity (5.11 μeq) of the resin. The bulky ions might be fixed only on the surface of the resin particles. Since the recovery of the complex corresponding to 0.5 μg of copper was quantitative in the presence of 10 μmol of BCS, it was indicated that the copper(I)-BCS complex was much more strongly fixed on the resin than the reagent.

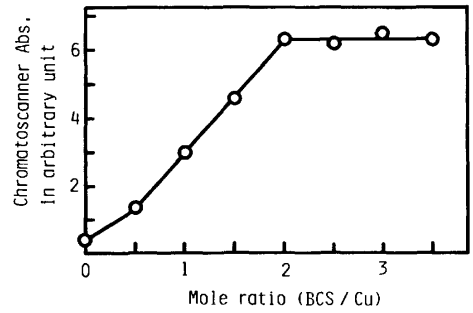

Fig. 1. Effect of BCS amount on the fixation of copper as the BCS complex to the anion-exchange resin.
Copper: 1.0 μg, sample volume: 50 cm^3, pH: 6, ARS: 1.0 cm^3 (5.11 μeq).

Effect of Sample Volume. The effect of sample volume was examined by the use of 1.0 cm^3 of ARS. A 1.0-μg portion of copper was effectively recovered from different sample volumes ranging from 50—200 cm^3. The rate of filtration was about 10 $cm^3 min^{-1}$. The volume of resin phase was estimated to be about 0.02 cm^3, and so the concentration factors were in the range of 2500—10000.

Effect of Foreign Ions. The effect of foreign ions on the determination of copper(II) was examined (Table 1). Except for iron(III), other cations and anions studied did not affect the determination of copper. Iron(III) gave a positive error, which was due to the formation of colored hydroxide. The interference by

a) 95% confidence limits

iron was eliminated by the addition of sodium fluoride. It was found that the copper(I)-BCS complex was quantitatively recovered even in the presence of 4 mol dm^{-3} sodium chloride.

Calibration Curve. The calibration curves obtained by the single resin method and the mixed resin method showed good linearity when the linearizer was applied. The slope of calibration curve obtained by the single resin method was about two times greater than that obtained by the mixed resin method. The results were summarized in Table 2, in which the limit of detection of copper was calculated as three times the standard deviation of the blank value.[9]

Determination of Total Copper in Tap Water. The single resin method and the mixed resin method were applied to the determination of total copper in the tap water supplied to our laboratory from a well in the University campus. After running the water for more than 20 min, the sample water was taken and acidified to pH 1. The results were summarized in Table 3. No significant difference was found between the variables (F-test) as well as between the mean values (t-test).

Comparison of the Methods. Generally, the concentration factor and thus the sensitivity of the single resin method is superior to those of the mixed resin method. However, as the mixed resins coagulate tightly with each other, the resulting thin layer is much more sturdy than that obtained by a single resin method. Therefore, it is possible to immerse the thin layer of mixed resins in the solution for making additional coloration, as successfully indicated in the determination of hexacyanoferrate(III) as Turnbull's Blue[10] and cobalt as the thiocyanate complex.[11]

Preparation and Spectroscopic Studies of the Stereoisomers of $[Co(acac)_2(R^1R^2NCH_2CH_2NR^3R^4$ or *o*-Phenylenediamine)]$^+$ (R^1—R^4= H, CH_3, or C_6H_5; acac=2,4-Pentanedionate ion) and Isomer Distribution at Equilibrium

Yue OUYANG,† Masaaki KOJIMA, and Junnosuke FUJITA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received July 11, 1984)

A series of complexes of the type, $[Co(acac)_2L]^+$, where acac=2,4-pentanedionate ion and L denotes $R^1R^2NCH_2CH_2NR^3R^4$ (R^1—R^4=H or CH_3), *N*-phenylethylenediamine, *N*,*N*′-diphenylethylenediamine, and *o*-phenylenediamine were prepared and the isomers separated. The absorption spectra and the distributions of the isomers at equilibrium were determined and the results are discussed.

York *et al.*[1] reported that the *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (Me_4en) ligand in $[Co(acac)_2(Me_4en)]^+$ (acac=2,4-pentanedionate ion) has a very low ligand field strength comparable to that of the oxygen donors of acac. Akamatsu and Shimura[2] showed that the ligand field strength of the tertiary amine end of *N*,*N*-dimethylethylenediamine (*N*,*N*-Me_2en) is weaker than those of oxalato and carbonato ligands. Thus the ligand field strength of ethylenediamine (en) is considerably reduced by the introduction of methyl groups on the nitrogen. In this paper, we report the preparation of $[Co(acac)_2(R^1R^2NCH_2CH_2NR^3R^4)]^+$ (R^1—R^4=H or CH_3), the separation of the isomers, the distributions of the isomers at equilibrium, and the absorption spectra of the isomers. Very recently Ito[3] reported the absorption spectra of bis(acac)-cobalt(III) complexes with *N*-methylated ethylenediamine, however, the complexes were not separated into the isomers.

A cobalt(III) complex with an *N*-phenyl-substituted ethylenediamine ligand will be less stable than the corresponding en complex for both steric and electronic reasons.[4] The two acac ligands seem to stabilize the *N*-phenyl-substituted amine-cobalt(III) system; we have obtained $[Co(acac)_2$(Ph-en, *N*,*N*′-Ph_2en, or opd)$]^+$ (Ph-en=*N*-phenylethylenediamine, *N*,*N*′-Ph_2en=*N*,*N*′-diphenylethylenediamine, opd=*o*-phenylenediamine).

Experimental

Λ(R),Δ(S)-[Co(acac)$_2$(Me-en)]ClO$_4$·0.5H$_2$O and Λ(S),Δ(R)-[Co(acac)$_2$(Me-en)]ClO$_4$(Me-en=N-*Methylethylenediamine).* To a solution of $[Co(acac)_3]$ (3.0 g, 8.4 mmol) in methanol (300 cm^3) were added Me-en (0.69 g, 9.3 mmol) and active charcoal (0.5 g). The mixture was stirred for 30 min and then filtered. The purple filtrate was diluted with water (3 dm^3), and applied on a column (ϕ4.5 cm×20 cm) of SP-Sephadex C-25. By elution with 0.05 mol dm^{-3} NaCl, a purple and a red band developed in this order. The eluate containing the purple band was collected and evaporated to a small volume. To the concentrate sodium perchlorate was added to yield purple crystals, which were recrystallized from water (50 °C). Yield: 1.5 g. The crystals were a mixture of the two racemic pairs of diastereomers, and they were separated by a column chromatographic method. About 0.3 g of the mixture was dissolved in a small amount of water and the solution was applied on a column (ϕ2.2 cm×50 cm) of SE-Toyopearl[5] HW-40 (fine; eluent: 0.05 mol dm^{-3} NaCl). A recycling-chromatographic technique was employed. After three times of recycling, the column showed two purple bands, M-I (*Λ*(*R*), *Δ*(*S*)) and M-II (*Λ*(*S*), *Δ*(*R*)), in the order of elution with the ratio of 1:3. From each eluate the perchlorate of the diastereomer was obtained by the same method as that described above. Anal. (*Λ*(*R*), *Δ*(*S*), $C_{13}H_{25}N_2ClCoO_{8.5}$) C, H, N. Anal. (*Λ*(*S*), *Δ*(*R*), $C_{13}H_{24}N_2ClCoO_8$) C, H, N.

(−)$_{589}$-Λ(S)- and (−)$_{589}$-Λ(R)-[Co(acac)$_2$(Me-en)]ClO$_4$. A suspension of *Λ*(*S*), *Δ*(*R*)-$[Co(acac)_2(Me\text{-}en)]ClO_4$ (0.866 g, 2.0 mmol) and Dowex 1×8 (Cl^- form, *ca.* 3 g) in 30 cm^3 of water was stirred for 20 min, filtered, and the exchanger washed with water (5 cm^3×2). To the combined filtrate and washings was added a hot (*ca.* 70 °C) solution containing sodium di-*O*-benzoyl-*d*-tartrate (0.402 g, 1.0 mmol) and di-*O*-benzoyl-*d*-tartaric acid monohydrate (0.376 g, 1.0 mmol) in 100 cm^3 of water. The mixture was allowed to stand overnight at room temperature and recrystallized from hot water (70 cm^3). Yield: 0.30 g. The diastereomer was dissolved in water and applied on a column (ϕ2 cm×5 cm) of SP-Sephadex C-25. The column was washed with water, and the complex (*Λ*(*S*)-isomer) was eluted with 0.2 mol dm^{-3} NaCl. The complex was isolated as the perchlorate and recrystallized in the same way as for the racemate. Yield: 80 mg. Anal. ($C_{13}H_{24}N_2ClCoO_8$) C, H, N.

The *Λ*(*S*)-isomer (60 mg) was epimerized in 0.1 mol dm^{-3} NaOH (20 cm^3, pH *ca.* 13) at room temperature. After 1 h, the reaction mixture was applied on a column (ϕ2.2 cm×50 cm) of SE-Toyopearl HW-40 (fine). By elution with 0.05 mol dm^{-3} NaCl, two purple bands developed. From the eluate containing the faster-moving band the perchlorate of the *Λ*(*R*)-isomer was obtained as described for the racemate. Yield: 20 mg. Anal. ($C_{13}H_{24}N_2ClCoO_8$) C, H, N. The *Λ*(*S*)-isomer was recovered from the slower-moving band.

[Co(acac)$_2$(N,N-Me$_2$en)]ClO$_4$. This complex was prepared by a method analogous to that described for the corresponding Me-en complexes. Column chromatography on SP-Sephadex C-25 (eluent: 0.05 mol dm^{-3} NaCl) showed two purple bands. From the eluate containing the faster-moving band the complex was isolated as the perchlorate by the same method as for the Me-en complex, and recrystallized from chloroform by the addition of diethyl ether. Yield: 60%.

†Pressent address: Department of Chemistry, Unversity of Hainan, Hainan Island, Kwantung Province, People's Republic of China.

Anal. ($C_{14}H_{26}N_2ClCoO_8$) C, H, N. The slower-moving band seemed to contain $[Co(acac)(N,N\text{-}Me_2en)_2]^{2+}$ but this complex was not isolated.

Λ(RR),Δ(SS)- and Λ(SR),Δ(RS)-[Co(acac)$_2$(N,N′-Me$_2$en)]ClO$_4$, and Λ(SS),Δ(RR)-[Co(acac)$_2$(N,N′-Me$_2$en)]ClO$_4$·H$_2$O (N,N′-Me$_2$*en*=N,N′-*Dimethylethylenediamine).* These complexes were prepared in the same way as that for the Me-en complexes in a 48% yield and separated into the three racemic pairs of diastereomers, *Λ(RR),Δ(SS)*, *Λ(SR),Δ(RS)*, and *Λ(SS), Δ(RR)* in the ratio of 5:1:3 by the same chromatographic method as used for the Me-en complex. Anal. (*Λ(RR), Δ(SS)*, and *Λ(SR), Δ(RS)*, $C_{14}H_{26}N_2ClCoO_8$) C, H, N. Anal. (*Λ(SS), Δ(RR)*, $C_{14}H_{28}N_2ClCoO_9$) C, H, N.

Λ(R),Δ(S)- and Λ(S), Δ(R)-[Co(acac)$_2$(Me$_3$en)]ClO$_4$(Me$_3$en=N,N,N′-*Trimethylethylenediamine).* These complexes were prepared by the same method as that described for the Me-en complexes in a total yield of 78%. The two racemic pairs of diastereomers, *Λ(R), Δ(S)* and *Λ(S), Δ(R)* were obtained as the perchlorate salts in the ratio 10:1 from the mixture of the isomers. Anal. (*Λ(R), Δ(S)*, and *Λ(S), Δ(R)*, $C_{15}H_{28}N_2ClCoO_8$) C, H, N.

[Co(acac)$_2$(Me$_4$en)]ClO$_4$. This complex was prepared analogous to the Me-en complex. Column chromatography of the reaction mixture on SP-Sephadex C-25 (eluent: 0.05 mol dm^{-3} NaCl) developed three bands; brown, pink, and green in the order of elution. From the green eluate the complex was isolated as the perchlorate. Yield: 20%. Anal. ($C_{16}H_{30}N_2ClCoO_8$) C, H, N. York *et al.*[1] prepared this complex by the reaction of *trans*-Na[Co(NO$_2$)$_2$(acac)$_2$] with Me$_4$en in the presence of active charcoal.

Λ(R),Δ(S)- and Λ(S),Δ(R)-[Co(acac)$_2$(Ph-en)]ClO$_4$. To a solution of [Co(acac)$_3$] (3 g, 8.4 mmol) in methanol (100 cm^3) were added a solution of Ph-en (1.27 g, 9.3 mmol) in methanol (50 cm^3), active charcoal (0.5 g), and acetic acid (2 cm^3). The mixture was stirred for 3 h and then filtered. The filtrate diluted with water (3 dm^3) was applied on a column of SP-Sephadex C-25 by the same procedure as for the Me-en complex to give a single band. From the purple eluate the complex was isolated as the perchlorate. Yield: 75%. By fractional crystallization from chloroform, the complex was separated into the two racemic pairs of diastereomers, *Λ(S), Δ(R)* and *Λ(R), Δ(S)*. The *Λ(S), Δ(R)*-pair is less soluble and the more soluble *Λ(R), Δ(S)*-pair was obtained from the mother liquor by the addition of diethyl ether, the ratio of the former to the latter being *ca.* 1:7. Both pairs were recrystallized from acetonitrile by the addition of diethyl ether. Found for the *Λ(S), Δ(R)*-pair: C, 43.49; H, 5.72; N, 5.58%. Found for the *Λ(R), Δ(S)*-pair: C, 43.74; H, 5.28; N, 5.69%. Calcd for $C_{18}H_{26}N_2ClCoO_8$: C, 43.87; H, 5.32; N, 5.68%. The complexes were converted into the more soluble chlorides by means of Dowex 1×8 (Cl^- form) before the determination of the isomer distribution.

Λ(RR),Δ(SS)-[Co(acac)$_2$(N,N′-Ph$_2$en)]ClO$_4$·0.5H$_2$O. This complex was prepared analogous to the Ph-en complexes except that the reaction mixture was stirred for a longer time (60 h). Column chromatography on SP-Sephadex C-25 (eluent: 0.05 mol dm^{-3} NaCl) resulted in three bands, green, violet, and red in the order of elution. From the green band, the complex was isolated as the perchlorate in the same way as for the Me-en complexes. Yield: 85%. When the preparation was carried out without the addition of acetic acid, the reaction proceeded slowly; about half of the starting complex remained unreacted after 60 h. The complex isolated was the *Λ(RR), Δ(SS)*-pair as confirmed by the ^{1}H NMR spectrum (*vide infra*). Anal. ($C_{24}H_{30}N_2ClCoO_8$) C, H, N. No fraction indicative of other isomers was obtained in column chromatography. The violet and the red band do not contain the desired complex.

[Co(acac)$_2$(opd)]ClO$_4$. To a solution of [Co(acac)$_3$] (1 g, 2.8 mmol) in methanol (50 cm^3) was added active charcoal (0.5 g). The mixture was deoxygenated with nitrogen, and then mixed with a deoxygenated solution of opd (0.33 g, 3.1 mmol) in methanol (20 cm^3). The mixture was stirred for 1 h and filtered. The purple filtrate was diluted with 0.01 mol dm^{-3} HCl (1 dm^3) and applied on a column (ϕ4.5 cm×30 cm) of SP-Sephadex C-25. By elution with 0.05 mol dm^{-3} NaCl-0.01 mol dm^{-3} HCl, two bands, purplish red and violet appeared in this order. The eluate containing the purplish red band was collected and evaporated to a small volume, and to the concentrate was added an excess of $NaClO_4$ to yield the perchlorate of the complex. It was recrystallized from 0.02 mol dm^{-3} $HClO_4$ (50 °C). Yield: 35%. Anal. ($C_{16}H_{22}N_2ClCoO_8$) C, H, N. This complex is unstable in neutral or alkaline solution.

Isomer Distribution at Equilibrium. A racemic pair of diastereomers of Me-en, *N,N′*-Me$_2$en, or Me$_3$en complex (*ca.* 1 mg) was epimerized in 0.1 mol dm^{-3} Na_3PO_4 (pH 12.1, 2 cm^3) at 25 °C. Portions (0.2 cm^3) of the reaction mixture were withdrawn at timed intervals, neutralized with dilute acetic acid, and chromatographed (sample volume: 4×10^{-3} cm^3) on a JASCO FINE SIL C_{18} column (ϕ4.6 mm×30 cm) with 0.01 mol dm^{-3} sodium 1-heptanesulfonate in 97.5% MeOH–2.5% H_2O as the eluent (flow rate: 0.5 cm^3 min^{-1}). The chromatographic procedures were carried out with a JASCO TRI ROTAR HPLC system, and the complexes were detected by a JASCO UVIDEC 100-IV spectrophotometric detector at 240 nm. The areas of the bands on the chromatograms were determined by weighing paper cutouts matching the bands. The experiments were carried out until the mixture attained equilibrium and no change in the elution curve was observed.

The isomer distribution of the Ph-en complex was determined by a ^{1}H NMR method. The chloride of the *Λ(S), Δ(R)* (or *Λ(R), Δ(S)*) pair (*ca.* 0.2 g) was dissolved in 0.1 mol dm^{-3} Na_3PO_4 (20 cm^3, pH 12.1) at 25 °C. Portions (4 cm^3) of the reaction mixture were withdrawn every 2 h and mixed with a solution of $NaClO_4$ (*ca.* 2 mol dm^{-3}) in 0.1 mol dm^{-3} $HClO_4$. The perchlorate of the complex which precipitated was collected by filtration, air dried, and the ^{1}H NMR spectrum was measured in CD_3CN. The distribution of the isomers was determined by measuring the intensities of the methine proton signals of the acac chelate rings (*vide infra*).

Measurements. Absorption and circular dichroism (CD) spectra were recorded on a Hitachi 323 spectrophotometer and a JASCO J-40CS spectropolarimeter, respectively. ^{1}H NMR spectra were measured with a JEOL PMX-60 spectrometer. Optical rotations at 589 nm were measured with a JASCO DIP-4 polarimeter.

Results and Discussion

Preparation and Characterization of the Isomers. All the complexes, $[Co(acac)_2(diamine)]^+$ were prepared from [Co(acac)$_3$] and the diamine ligand in methanol in the presence of active charcoal. The opd complex was prepared under a nitrogen atmosphere.

By the preparations of the Ph-en and *N,N'*-Ph_2en complexes, acetic acid was added to promote the reaction (Experimental). The two acac ligands seem to stabilize the *N*-phenyl-substituted amine–cobalt(III) system. A cobalt(III) complex with an *N*-phenyl-substituted amine ligand is usually unstable and difficult to prepare. For example, although the preparation of $[Co(opd)_3]^{3+}$ has been reported,[6] we could not repeat the results in spite of many attempts. Redox reaction between the phenyl group and the cobalt(III) ion seems to be related to the instability. All the complexes prepared in the present study were purified by column chromatography on SP-Sephadex C-25, and isolated as the perchlorates. The complexes containing a chiral nitrogen atom were separated into the racemic pairs of diastereomers by SE-Toyopearl column chromatography. It has been found that this exchanger is more effective than SP-Sephadex in the separation of diastereomers of uni- and dipositive cobalt(III) complexes.[7,8] However, the separation of the pairs *Λ*(*R*), *Δ*(*S*) and *Λ*(*S*), *Δ*(*R*) of $[Co(acac)_2(Ph\text{-}en)]^+$ was not achieved by the chromatographic method, but by fractional crystallization of their perchlorates. The *Λ*(*S*), *Δ*(*R*)-$[Co(acac)_2(Me\text{-}en)]^+$ pair was resolved by the chemical method with hydrogen di-*O*-benzoyl-*d*-tartrate. The *Λ*(*S*)-isomer formed the less soluble diastereomeric salt which was converted into the perchlorate. The *Λ*(*S*)-isomer was epimerized to give a mixture of the *Λ*(*S*)- and *Λ*(*R*)-isomers which were separated by column chromatography on SE-Toyopearl.

The structures of the isomers were assigned on the basis of the ^1H NMR and CD spectra. Four isomers, *Λ*(*R*), *Λ*(*S*), *Δ*(*R*), and *Δ*(*S*) are possible for $[Co(acac)_2(Me\text{-}en)]^+$ (Fig. 1). In the *Δ*(*R*) and *Λ*(*S*) configurations, the *N*-methyl group is placed over one of the two acac chelate rings and the methyl protons will be shielded by the acac ring. Thus, pair M-I (Experimental) which shows a doublet assignable to the *N*-methyl protons at a higher magnetic field (1.80, Table 1) is assigned to the racemic pair of diastereomers, *Δ*(*R*) and *Λ*(*S*). The structures of the complexes with *N,N'*-Me_2en and Me_3en were assigned in the same way (Table 1). Examination of molecular models indicates that in *Λ*(*S*)- and *Λ*(*R*)-$[Co(acac)_2(Ph\text{-}en)]^+$, the phenyl group strongly shields the methine proton of one of the two acac chelate rings. The resonance at δ 4.88 of the more soluble racemic pair can safely be attributed to the shielded methine proton, and thus the pair is assigned to the racemic pair of diastereomers, *Δ*(*S*) and *Λ*(*R*). The *N,N'*-Ph_2en complex which shows a singlet (2H, 4.86 ppm) attributable to the shielded methine protons is assigned to the racemic pair of the *Δ*(*SS*) and *Λ*(*RR*) isomers.

The absolute configurations, *Λ* or *Δ*, of the optically active Me-en complexes were assigned on the basis of the CD spectra (Fig. 2). In general, the optical activity of a metal complex is explained as a superposition of the configurational and the vicinal effects, the former being usually larger than the latter.[9,10] The two isomers in Fig. 2 show a similar CD pattern and exhibit a main positive CD band in the region of the first absorption band. Thus both isomers are assigned to the *Λ* configuration. Half the sum of the two CD spectra should give the *Λ* configurational effect. In fact, the calculated CD curve is quite similar to the reported CD spectrum of *Λ*-$[Co(acac)_2(en)]^+$[11] where no vicinal effect exists. This result shows that the additivity between the two effects holds for the two isomers, and confirms the above assignments.

Absorption Spectra. The absorption data for the complexes are listed in Table 2, and the representative spectra are shown in Figs. 3 and 4. All the complexes show the first absorption band, $^1A_{1g} \rightarrow {}^1T_{1g}$ (O_h) in the

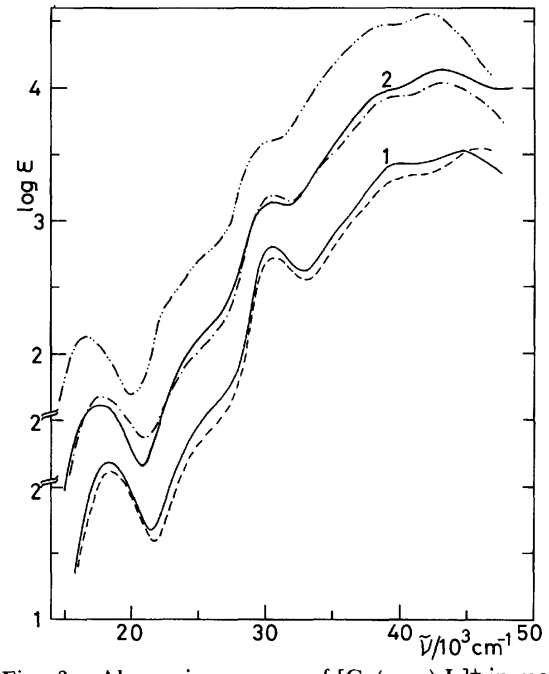

Fig. 3. Absorption spectra of [Co(acac)$_2$L]$^+$ in methanol. L=en (----), Me-en (Λ(S),Δ(R)-pair, ——1), N,N-Me$_2$en (-·-·-), Me$_3$en (Λ(S),Δ(R)-pair, ——2), and Me$_4$en (-···-).

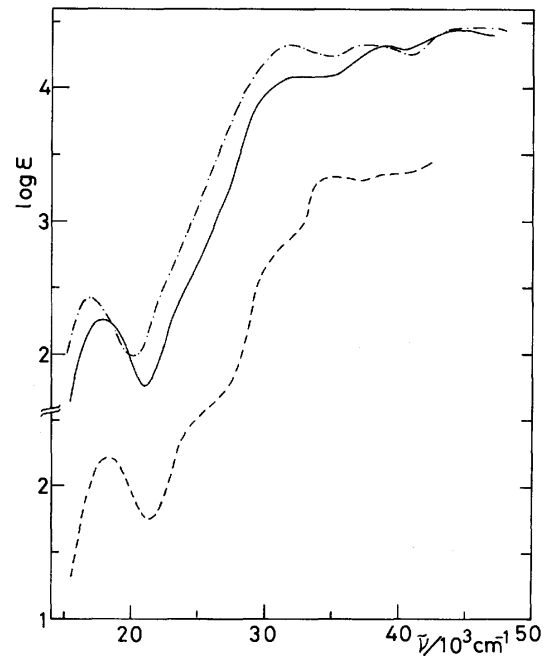

Fig. 4. Absorption spectra of [Co(acac)$_2$L]$^+$ in methanol. L=Ph-en (Λ(S),Δ(R)-pair, ——), N,N'-Ph$_2$en (-·-·-), and opd (---).

region of 16600 to 18300 cm^{-1}. Most of the spectra show a weak shoulder around 25000 cm^{-1}. The corresponding en complex shows a shoulder at *ca.* 24000 cm^{-1} and the transition has been assigned by Boucher to the second d-d absorption band, $^1A_{1g}\rightarrow{}^1T_{2g}$ (O_h)[11]. As seen in Fig. 5 the first absorption band shifts to lower energy as the number of the substituents (CH_3 or C_6H_5) on the nitrogen atom increases. York *et al.*[1] pointed out that the Me$_4$en ligand in [Co(acac)$_2$(Me$_4$en)]$^+$ has a ligand field strength comparable to that of the oxygen donors of acac; the complex shows the first absorption band (16640 cm^{-1}) at nearly the same position as that of [Co(acac)$_3$] (16750 cm^{-1}). The low ligand field strength of the Me$_4$en ligand was ascribed to the steric repulsions which occur in the complex.[1] The [Co(acac)$_2$(N,N-Me$_2$en)]$^+$ complex exhibits the first absorption band at lower energy than those of any of the isomers of the corresponding N,N'-Me$_2$en complex. When the methyl group attached to the nitrogen atom is replaced by a phenyl group, the d-d absorption band shifts to lower energy. Thus the ligand field strengths of the diamines studied here decrease in the order of en>Me-en>N,N'-Me$_2$en>N,N-Me$_2$en~Ph-en>Me$_3$en>N,N'-Ph$_2$en>Me$_4$en. The first absorption band of the opd complex (18250 cm^{-1}) is at nearly the same position as those of the Me-en complexes (18250 and 18300 cm^{-1}, respectively). Except for the Me$_3$en complex, the isomer in which the substituent attached to the nitrogen atom is placed over an acac chelate ring exhibits the first absorption band at lower energy than the other isomers.

The complexes containing an N-methyl-substituted ethylenediamine show a band assignable to a Co^{III}-to-acac d$\pi\rightarrow\pi^*$ transition[12] at 30600—30300 cm^{-1}. For the en complex the corresponding transition occurs at 30700 cm^{-1}. The position shifts slightly to lower energy with an increasing number of methyl groups. On the other hand, the positions of a shoulder (38500—39500 cm^{-1}) which is assigned to another d$\pi\rightarrow\pi^*$ transition,[12] and the $\pi\rightarrow\pi^*$ transition of acac[12]

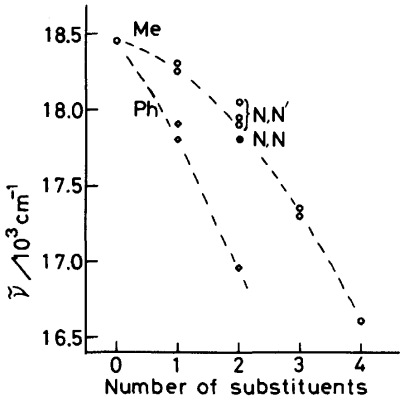

Fig. 5. Correlation between the positions of the first absorption band of $[Co(acac)_2(R^1R^2NCH_2CH_2NR^3R^4)]^+$ (R^1—R^4=H, CH_3, or C_6H_5) and the number of substituents on the nitrogen atoms.

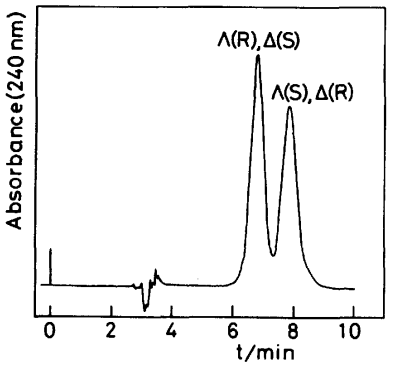

Fig. 6. Elution curve of $[Co(acac)_2(Me\text{-}en)]^+$ equilibrated at pH 12.1 and 25 °C. Chromatographic conditions: column, JASCO FINE SIL C_{18} (ϕ4.6 mm×30 cm); eluent, 0.01 mol dm^{-3} sodium 1-heptanesulfonate in 97.5% MeOH-2.5% H_2O; flow rate, 1 cm^3 min^{-1}; sample volume, 4×10^{-3} cm^{-3} containing *ca.* 4×10^{-9} mol complex.

(42400—44400 cm^{-1}) shift to lower energy to a larger extent as the number of the *N*-methyl groups increases.

Equilibrium Isomer Distribution. The isomers of Me-en, *N,N'*-Me_2en, and Me_3en complexes were equilibrated at pH 12.1 and 25 °C, and the distributions were analyzed by the reversed-phase high performance liquid chromatographic technique.[13] This method has the great advantages of short elution time and micro quantities of samples.[8,14] All the complexes attained equilibrium within one day. Figure 6 shows an example of the Me-en complex and the results are given in Table 1. No decomposition product was observed in column chromatography. The runs starting from any isomer gave the same result within the experimental error (*ca.* ±3%). In general, the more crowded or strained isomer of a metal complex exhibits the d-d absorption bands at lower energy and the abundance is smaller than that of the other isomer.[15] There is, however, no clear relationship between the distribution of the isomers and positions of the absorption bands (Tables 1 and 2).

It was difficult to separate the isomers of the Ph-en complex by HPLC technique, and thus the isomer distribution was determined by the ^1H NMR method. The epimerization was accompanied by a slight decomposition of the complex to cobalt(II), which resulted in a broadening of the ^1H NMR signals. Thus, it was necessary to isolate the cobalt(III) complex after the reaction in order to obtain a well-resolved spectrum. The complex attained equilibrium in 5h at pH 12.1 and 25 °C. The rate of epimerization seems to be similar to those of the *N*-methyl-substituted diamine complexes. A detailed account of kinetic studies will be reported subsequently.

Steric and Electronic Effects of Unidentate Tertiary Phosphine Ligands on Chemical and Absorption Spectral Properties of Their Mixed Cobalt(III) Complexes with Acetylacetonate Ions

Katsuaki KATOH, Hirofumi SUGIURA, Kazuo KASHIWABARA, and Junnosuke FUJITA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received July 14, 1984)

A large number of new unidentate tertiary phosphine-cobalt(III) complexes containing acetylacetonate ions were prepared. The complexes are grouped into four types; (A) *cis*- and *trans*-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$, (B) *trans*-$[Co(acac)_2(H_2O)(PR_nPh_{3-n})]^+$, (C) *trans*-$[Co(acac)_2(L)(PMe_2Ph)]^{n+}$, and (D) *trans*-(P,P)-$[Co(acac)(CN)_2(PR_nPh_{3-n})_2]$ (acac: acetylacetonate ion, R: CH_3(Me), C_2H_5(Et), *n*-C_3H_7(Pr), *i*-C_3H_7(Pr^i), *n*-C_4H_9(Bu), *i*-C_4H_9(Bu^i), *c*-C_6H_{11} (Cy), Ph: C_6H_5, L: NH_3, CH_3NH_2, C_5H_5N(py), NCS^-). The complexes of type A form cis and trans isomers in a different ratio depending upon the bulkiness and basicity of a phosphine ligand, and the ratios for the complexes with R=Me and Et were examined in some detail. The trans isomers of type A show a strong absorption band in the d-d transition region, which is assumed to involve charge transfer transitions between the cobalt(III) ion and a phosphine ligand, while the cis isomers exhibit the first d-d band split into two components with medium intensity. The complexes of type B show a distinct peak of the first d-d band, the energy shifts of which were discussed in terms of the bulkiness and basicity of phosphine ligands. The complexes of types C and D were prepared to compare the chemical and absorption spectral properties with those of complexes of types A and B.

It is well known that changing substituents on a phosphorus donor atom has a marked influence on physical and chemical properties of metal phosphine complexes.[1] To our knowledge, however, little work has been reported on Co^{III} complexes probably because of the lack of suitable complexes. In a previous paper,[2] we reported that a series of unidentate phosphine ligands, $P(CH_3)_n(C_6H_5)_{3-n}$ (n=1,2,3) forms mixed Co^{III} complexes of the type, $[Co(acac)_2(phosphine)_2]^+$ (acac= acetylacetonate ion). The complexes yielded cis and/or trans isomers depending on the kind of phosphines, and large differences in electronic spectra were observed among the complexes. In order to examine more thoroughly such chemical and spectroscopic properties of Co^{III}-phosphine complexes, we have prepared a large number of Co^{III} complexes containing many kinds of unidentate phosphine ligands. The phosphines used in this study are PR_nPh_{3-n}(***P***) (R= CH_3(Me), C_2H_5(Et), *n*-C_3H_7(Pr), *i*-C_3H_7(Pr^i), *n*-C_4H_9(Bu), *i*-C_4H_9(Bu^i), *c*-C_6H_{11}(Cy), Ph=C_6H_5), and the new (55) and known (10)[2] complexes examined are grouped into the following four types; *cis*- and/or *trans*-$[Co(acac)_2(\boldsymbol{P})_2]^+$(26 complexes), *trans*-$[Co(acac)_2(H_2O)(\boldsymbol{P})]^+$ (18 complexes), *trans*-$[Co(acac)_2(L)(PMe_2Ph)]^{n+}$ (4 complexes with L=NH_3, CH_3NH_2, C_5H_5N(py), or NCS^-), and *trans*(P,P)-$[Co(acac)(CN)_2(\boldsymbol{P})_2]$ (17 complexes).

Experimental

The phosphine ligands were prepared according to the literature methods,[3] and handled under an atmosphere of nitrogen until they formed Co^{III} complexes. Absorption and ^1H NMR spectra were recorded on a Hitachi 323 spectrophotometer, and a Jeol JNM-PMX 60 spectrometer, respectively.

Preparation of Complexes. *1) cis-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$ and trans-$[Co(acac)_2(H_2O)(PR_nPh_{3-n})]^+$ (R=Et, Pr, Bu; n=1, 2, 3).* These complexes were prepared by two methods a) and b). a) A mixture of $[Co(acac)_3]$[4] (2mmol), the phosphine ligand (4mmol), and active charcoal (*ca.* 0.1g) in ethanol-acetic acid (10:1, 60cm^3) was stirred at room temperature for 10h, and then filtered. The filtrate was diluted with water-methanol (2:1, 3dm^3), and the solution was applied on a small column (ϕ2.7cm×3cm) of SP-Sephadex C-25. The Sephadex charged with the product was placed on the top of a column (ϕ2.7cm×130cm) of SP-Sephadex C-25. By elution with 0.02mol/dm^3 NaCl the band separated into two bands. The fraction of the first band, the color of which changing from blue-violet to green during the elution, was collected and concentrated to a small volume under reduced pressure. To the concentrate was added $NaPF_6$ (or $NaClO_4$). The resulting green precipitate was filtered and dissolved in the minimum amount of methanol-water (5:1). The solution was filtered and allowed to stand at room temperature. Green crystals of *trans*-$[Co(acac)_2(H_2O)(PR_nPh_{3-n})]PF_6$ (or ClO_4) were slowly deposited with evaporation of the solvent, filtered, and air dried. From the second red-brown band were obtained red-brown crystals of *cis*-$[Co(acac)_2(PR_nPh_{3-n})_2]PF_6$ (or ClO_4) by the same procedure as that for the first band. In cases of the PPr_3 and PPr_2Ph complexes, *cis*-$[Co(acac)_2(\boldsymbol{P})_2]^+$ was eluted faster than *trans*-$[Co(acac)_2(H_2O)(\boldsymbol{P})]^+$ was. The combined yield of *trans*-$[Co(acac)_2(H_2O)(PR_nPh_{3-n})]^+$ and *cis*-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$ was 30—60%, and the ratio of the former to the latter increased as the number of phenyl groups of the phosphine ligand increases.

b) $[Co(acac)_2(H_2O)_2]$[5] (2mmol) and the phosphine ligand (4.1mmol) were dissolved in a mixture of ethanol (80cm^3) and acetic acid (1cm^3), and then PbO_2 (2.1mmol) was added to the solution. The mixture was stirred for 2h, and then active charcoal (*ca.* 0.1g) was added. Stirring was continued for 10h. The resulting solution was filtered, and the filtrate was diluted with water-methanol (2:1, 2dm^3). The solution was subjected to column chromatography and the complexes were isolated by the same way as that described in a). The yield was 60—80% and better than that by method a). In particular, the yields of the $PRPh_2$ complexes increased markedly.

2) trans-*[Co(acac)$_2$(H$_2$O)(PR$_n$Ph$_{3-n}$)]$^+$ (PR$_n$Ph$_{3-n}$=PPh$_3$, PPr^{i}Ph$_2$, PPr$^i_2$Ph, PBu^{i}Ph$_2$, PBu$^i_2$Ph, PBu$^i_3$, and PCy$_3$).* These complexes were prepared by a method similar to method b). [Co(acac)$_2$(H$_2$O)$_2$] (2 mmol) and the phosphine ligand (2 mmol) were dissolved in a mixture of ethanol (60 cm^3) and acetic acid (1 cm^3). To the solution was added PbO_2 (2.1 mmol), and the mixture was stirred for 2 h, and then filtered. The filtrate was diluted with water (1 dm^3), and the solution was applied on a column (ϕ3 cm×30 cm) of SP-Sephadex C-25. The column was eluted with 0.05 mol/dm^3 NaCl, and a green fraction was collected. To the fraction was added $NaPF_6$ or $NaClO_4$ until a precipitate appears, and then the solution was allowed to stand at room temperature. Green crystals of *trans*-[Co(acac)$_2$(H$_2$O)(PR$_n$Ph$_{3-n}$)]PF$_6$ or ClO$_4$ were filtered, washed with a small amount of cold water, and air dried. The yield was 50—80%. The complexes decompose slowly in aqueous solution. No *cis*-[Co(acac)$_2$(PR$_n$Ph$_{3-n}$)$_2$]$^+$ was formed even though the reaction was carried out in the presence of two molar quantity of the phosphine and active charcoal.

3) trans-*[Co(acac)$_2$(PR$_n$Ph$_{3-n}$)$_2$]$^+$ (R=Et, Pr, Bu; n=0, 1, 2, 3) and* trans-*[Co(acac)$_2$(PRPh$_2$)$_2$]$^+$ (R=Pr^i, Bu^i).* These complexes can be prepared by two methods a) and b). a) An ethanol solution (30 cm^3) containing *trans*-[Co(acac)$_2$(H$_2$O)(PR$_n$Ph$_{3-n}$)]PF$_6$ or ClO$_4$ (0.3 mmol) and the phosphine ligand (1 mmol) was stirred for 30 min. To the resulting solution was added hexane until a red-brown precipitate was no longer formed. The precipitate was filtered and recrystallized from dichloromethane by adding hexane. The yield was *ca.* 80%.

b) [Co(acac)$_2$(H$_2$O)$_2$] (2 mmol) and the phosphine ligand (4 mmol) were dissolved in a mixture of ethanol (40 cm^3) and acetic acid (1 cm^3) with stirring, and then PbO_2 (2.1 mmol) was added. After stirring for 2 h the mixture was filtered, and excess $NaPF_6$ or $NaClO_4$ was added to the filtrate. The resulting precipitate was filtered and recrystallized from dichloromethane by adding hexane. The yield was *ca.* 80%. The bis(phosphine) complexes of PBu$^i_3$, PBu$^i_2$Ph, and PPr$^i_2$Ph seem to be formed in solution since the solution is intensely colored, but the complexes could not be isolated. The bis(PCy$_3$) complex seems to be very unstable, since a green ethanol solution of *trans*-[Co(acac)$_2$(H$_2$O)(PCy$_3$)]$^+$ turns intense red-brown on addition of excess PCy$_3$, but rapidly changes to a pale pink solution indicating the reduction of Co^{III} to Co^{II}.

4) trans-*[Co(acac)$_2$(L)(PMe$_2$Ph)]$^{n+}$ (L=NH$_3$, CH$_3$NH$_2$, py, NCS$^-$).* A methanol solution (20 cm^3) containing [Co(acac)$_2$(H$_2$O)(PMe$_2$Ph)]PF$_6$[2] (0.5 mmol) and ligand L (5 mmol) was stirred for 30 min at room temperature, and then water (10 cm^3) was added. The solution was allowed to stand at room temperature. The crystals which were slowly deposited with evaporation of the solvent were filtered and recrystallized from ethanol by adding an aqueous solution of ligand L. Yields: 40% (NH_3), 50% (CH_3NH_2), 75% (py), and 90% (NCS^-).

5) trans*(P,P)-[Co(acac)(CN)$_2$(PR$_n$Ph$_{3-n}$)$_2$] (R=Et, Pr, Bu, Bu^i; n=1, 2, 3. R=Pr^i; n=1).* These complexes were prepared by a method similar to that for the corresponding PMePh$_2$ complex.[2] A mixture of K[Co(acac)$_2$(CN)$_2$] (2 mmol) and the phosphine ligand (4 mmol) in ethanol (60 cm^3) was stirred at 30—40 °C for 10 h for the complexes of R=Et, Pr, and Bu, and at 40—50 °C for 24 h for the complexes of R=Bu^i and Pr^i. The resulting orange yellow solution was evaporated to dryness under reduced pressure, and the residue was extracted with a small amount of chloroform. The extract was chromatographed by use of an alumina column (ϕ3 cm×5 cm)

and a mixture of hexane and ethanol (1:10). The eluate was concentrated to a small volume, and the concentrate was rechromatographed by use of a column (ϕ3 cm×60 cm) of SP-Sephadex LH-20 and a mixture of hexane and ethanol (5:1). The orange yellow eluate was evaporated to a small volume, and then water was added until a precipitate began to appear. The crystals which were deposited on standing at room temperature were filtered and air-dried. Yields: 45—70% (R=Et, Pr), 20—50% (R=Bu), 10% (R=Pr^i, Bu^i). The yield tends to decrease with the increasing bulkiness of R and the increasing number of phenyl groups of the ligand.

Analytical data of the new complexes are given in Tables 1—3.

Isomer Distribution of [Co(acac)$_2$(PR$_n$Ph$_{3-n}$)$_2$]$^+$ (R=Me, Et; n=0, 1, 2, 3) at Equilibrium. a) A mixture of *cis*- or *trans*-[Co(acac)$_2$(PR$_n$Ph$_{3-n}$)$_2$]PF$_6$ (*ca.* 0.1 mmol), the corresponding phosphine ligand (*ca.* 0.01 mmol), and a small amount of active charcoal in ethanol-dichloromethane (1:1, 20 cm^3) was stirred at 20±0.5 °C for 24 h. The mixture was filtered, and the filtrate was evaporated to dryness under reduced pressure. The residue was stored in a vacuum dessicator overnight for complete elimination of the solvent and moisture. The sample thus obtained was dissolved in CD_2Cl_2, and the ^{1}H NMR spectrum was recorded. The formation ratio of the cis to trans isomers was determined from the intensity ratio of methine signals of acac in these isomers.

b) [Co(acac)$_2$(H$_2$O)$_2$] (2 mmol) and the phosphine ligand (4.5 mmol) were dissolved in a mixture of ethanol (60 cm^3) and acetic acid (1 cm^3), and then PbO_2 (2.1 mmol) was added. The mixture was stirred for 2 h, and then active charcoal (*ca.* 0.1 g) was added. The whole was kept at 20±0.5 °C with stirring for 24 h. The resulting mixture was filtered, and the filtrate was chromatographed by the same method as that described in 1) method b) in order to separate the two isomers. The trans isomer completely changed into *trans*-[Co(acac)$_2$(H$_2$O)(PR$_n$-Ph$_{3-n}$)]$^+$ during the elution. The abundance of the complex

in each fraction was determined by measuring the optical density. The values of formation ratio of the *cis*-bis(phosphine) complex to the *trans*-(aqua)(phosphine) complex thus obtained were almost the same as those determined by the above ^1H NMR method.

Results and Discussion

Preparation and Chemical Properties of the Complexes. In a previous paper,[2] we reported that trimethylphosphine and its phenyl analogs, PMe_nPh_{3-n} (n=1, 2, 3) react with [Co(acac)$_3$] in ethanol in the presence of active charcoal to yield $[Co(acac)_2(PMe_nPh_{3-n})_2]^+$, but the reaction with bulky PPh_3 does not take place under similar conditions. Bulky alkylphosphines such as PBu^i_3, PPr^i_2Ph, and PCy_3 used in this study do not react with [Co(acac)$_3$] either. Thus reactivity of unidentate phosphine ligands toward [Co(acac)$_3$] seems to depend on their bulkiness. In this study, however, we have prepared such bulky phosphine complexes of the $[Co(acac)_2(\boldsymbol{P})_2]^+$ type in good yields by oxidizing a mixture of $[Co(acac)_2(H_2O)_2]$ and the phosphine ligand in ethanol with PbO_2. The less bulky phosphine complexes can also be prepared by this method in good yield.

The new preparative method affords only the trans isomer of $[Co(acac)_2(\boldsymbol{P})_2]^+$ when active charcoal is not added to the reaction mixture. In the presence of active charcoal, however, both trans and cis isomers are formed if the complex can exist in the cis isomer. The structure of the complex can be easily assigned from NMR and absorption spectra as reported for the PMe_nPh_{3-n} complexes.[2] The cis isomers, the formation of which was confirmed by column chromatography, are those with PR_nPh_{3-n} (R=Me, Et, Pr, Bu; n= 1, 2, 3). For the most bulky PCy_3 ligand, only *trans*-$[Co(acac)_2(H_2O)(PCy_3)]^+$ is isolated, no bis(PCy_3) complex being formed under the given experimental conditions (see Experimental). The Co^{III}–P bond would lengthen and weaken with increasing bulkiness of the phosphine ligand. The bulkiness of phosphine ligands can be estimated in terms of the cone angle(θ°) defined by Tolman.[1] In a series of $[Co(DH)_2(Cl)(\boldsymbol{P})]$ ($\boldsymbol{P}$=PBu_3, PPh_3, PCy_3; DH=dimethylglyoximate ion), the Co^{III}–P bond lengthens in the order of the PBu_3(2.271 Å)[6] <PPh_3(2.327 Å)[7] <PCy_3(2.369 Å)[8] complexes, with the increasing cone angle of the phosphine ligands, PBu_3(132°)<PPh_3(145°)<PCy_3(170°).

Both trans and cis isomers of $[Co(acac)_2(PR_nPh_{3-n})_2]^+$ (R=Me, n=2; R=Et, Pr, Bu, n=1, 2, 3) isomerize to each other in ethanol in the presence of active charcoal, and the isomerization attains equilibrium fairly rapidly. Distributions of the two isomers at 25 °C were examined for the complexes with R=Me and Et. The proportions (%) of the trans isomers are plotted against the cone angles (θ°) of phosphine ligands in Fig. 1. With the increasing cone angle, the proportion of the trans isomer increases, and almost linear relationships are seen among the complexes with PR_nPh_{3-n} (n=2,3) and among those with PR_nPh_{3-n} (n=0, 1). The smallest PMe_3 complex affords only the cis isomer, while the largest PPh_3 complex only the trans one. The $PMePh_2$ and PEt_2Ph ligands have the same cone angle (136°), but form the trans isomer in a remarkably different proportion. The difference might come from the difference in electronic effect of the phosphine ligands. According to the parameter($\sum\chi i/cm^{-1}$) given by Tolman[1] for the electronic effect of phosphines, PEt_2Ph (7.9) is more basic than $PMePh_2$ (11.2). Thus it is seen that when two kinds of phosphine ligands have a similar steric effect, the complex with the more basic phosphine ligand yields the cis isomer in a larger amount. Cotton *et al.*[9] reported a tendency to isomerize to the trans isomer in $[Mo(CO)_4(PR_3)_2]$ (R=Me, Et, Bu) with an increasing bulkiness of PR_3. Ounapu *et al.*[10] observed also a similar trend in $[W(CO)_4(PRPh_2)_2]$ (R=Me, Et, Pr^i, Bu^t, Ph); the value of the trans/cis ratio increases with an increase in bulkiness of R.

All of *trans*-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$ rapidly hydrolyze when dissolved in ethanol (not anhydrous) to afford *trans*-$[Co(acac)_2(H_2O)(PR_nPh_{3-n})]^+$. The hydrolysis is depressed by addition of the free phosphine ligand, and hence the complex in solution will exist in the following equilibrium;

$$\textit{trans}\text{-}[Co(acac)_2(PR_nPh_{3-n})_2]^+ \underset{PR_nPh_{3-n}}{\overset{H_2O}{\rightleftharpoons}} \textit{trans}\text{-}[Co(acac)_2(H_2O)(PR_nPh_{3-n})]^+$$

The rapid hydrolysis can be attributed to a strong trans effect of PR_nPh_{3-n}. Similar solvolyses were reported for *trans*-$[Co(acac)_2(NO_2)_2]^-$ in water[11] and *trans*-[Co(acac)$_2$(CN)(py)] in dimethyl sulfoxide(DMSO),[12] which rapidly yield *trans*-$[Co(acac)_2(NO_2)(H_2O)]$ and *trans*-[Co(acac)$_2$(CN)(DMSO)], respectively. The resulting *trans*-$[Co(acac)_2(H_2O)(PR_nPh_{3-n})]^+$ complexes are stable to further hydrolysis, although those with bulky PCy_3, PPr^i_2Ph and PPh_3 decompose slowly to

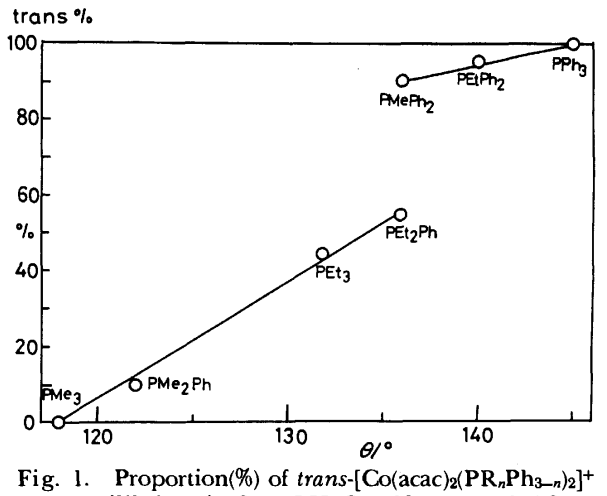

Fig. 1. Proportion(%) of *trans*-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$ at equilibrium in C_2H_5OH–CH_2Cl_2 (1:1) at 25 °C *vs.* Tolman's cone angle (θ°) of the phosphine ligand.

give Co^{II} species. The aqua ligand in *trans*-$[Co(acac)_2(H_2O)(PR_nPh_{3-n})]^+$ is readily replaced by various bases (L) to afford *trans*-$[Co(acac)_2(L)(PR_nPh_{3-n})]^{n+}$. We have isolated complexes of this type for PMe_2Ph and L=NH_3, CH_3NH_2, py, or NCS^-. All of these complexes immediately lose L to give original *trans*-$[Co(acac)_2(H_2O)(PMe_2Ph)]^+$ when dissolved in methanol or ethanol (not anhydrous). This is in marked contrast to the inertness of *trans*-$[Co(acac)_2(NO_2)(NH_3$ or py$)]$ in solvolysis.[13] The trans effects of cyanide and phosphine ligands should be much greater than that of NO_2^-.[14] When $PMePh_2$ for L is added to a methanol solution of *trans*-$[Co(acac)_2(H_2O)(PMe_2Ph)]^+$, a disproportionation reaction takes place to yield *trans*-$[Co(acac)_2(PMe_2Ph)_2]^+$ and *trans*-$[Co(acac)_2(PMePh_2)_2]^+$ in addition to *trans*-$[Co(acac)_2(PMe_2Ph)(PMePh_2)]^+$. The reaction of CN^- with $[Co(acac)_2(H_2O)(PMe_2Ph)]^+$ affords *cis*-$[Co(acac)_2(CN)(PMe_2Ph)]$, no trans isomer being formed. Since CN^- has strong ability of trans influence as a phosphine and is much smaller in size, the complex would be greatly stabilized in the cis isomer.

The $[Co(acac)(CN)_2(PR_nPh_{3-n})_2]$-type complexes have been prepared from *cis*-$[Co(acac)_2(CN)_2]^-$ and PR_nPh_{3-n} by a method similar to that for the corresponding PMe_nPh_{3-n} complexes.[2] All the complexes yield only the trans (P,P) isomer of three possible geometrical isomers. The assignment of the trans (P,P) isomer can be made easily from NMR spectra as reported for the PMe_nPh_{3-n} complexes.[2] The stereoselective formation of the trans (P,P) isomer over various kinds of phosphines might result from stronger trans influence of CN^- than that of a phosphine ligand. Furthermore, the steric effect of bulky phosphine ligands would facilitate formation of the trans (P,P) isomer. The yield of the complex decreases with increasing bulkiness of phosphines, and extremely bulky phosphines such as PPr_2^iPh and PCy_3 do not react with *cis*-$[Co(acac)_2(CN)_2]^-$. All the complexes obtained are stable in methanol or ethanol, and show no solvolysis in contrast to trans-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$ stated previously. The reason for this remains unknown. Since the *trans*-$[Co(CN)_4(PMe_nPh_{3-n})_2]^-$ (n=0, 1, 2) complexes are also inert to solvolysis,[2] strong and soft cyanide ions in such trans (P,P) complexes might play an important role in strengthening the Co^{III}–P bond.

^1H NMR Spectra. In Tables 1—3 are listed data of the methine and methyl signals of acac in ^1H NMR spectra of the complexes. General features in chemical shift of these signals are similar to those reported for the complexes of PMe_nPh_{3-n}.[2] For *trans*-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$ the methine signal of acac shows a remarkable high field shift as the number of phenyl groups on the phosphorus atom increases. The methyl signal also shows the same high field shift, but the extent of shift is not so large as that of the methine signal. As suggested in our previous papers,[2,15] the high field shift of these protons can be attributed to a shielding effect by the ring current of phenyl groups of the phosphine ligand located over the acac ring. No such remarkable high field shifts are observed for *cis*-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$ (n=1, 2). In a previous paper, we examined the crowded structure of *cis*-$[Co(acac)_2(PMe_2Ph)_2]^+$ with molecular models, and suggested a structure where the methyl proton (s) of PMe_2Ph is placed over the acac ring. This structure is supported by the fact that the chemical shift of the methine proton is very similar to that in *cis*-$[Co(acac)_2(PMe_3)_2]^+$. A similar structure can be assigned to other PR_2Ph complexes of this type (R= Et, Pr, Bu), since all methine proton signals of these complexes and *cis*-$[Co(acac)_2(PR_3)_2]^+$ (R=Et, Pr, Bu) are observed at nearly the same position. The methine signals of *cis*-$[Co(acac)_2(PRPh_2)_2]^+$ shift to a high field compared with those of the PR_3 and PR_2Ph complexes, but the magnitudes of shift are much smaller than those observed in the corresponding trans isomers. Thus the $PRPh_2$ complexes would also have a structure similar to that of the PR_2Ph complexes; the R group is located over the acac ring.

In contrast to *trans*-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$ (n= 0, 1, 2), *trans*-$[Co(acac)_2(H_2O)(PR_nPh_{3-n})]^+$ (n=0, 1, 2) show a very small high field shift in the methine signals, although both types of complex are similar and have the phosphine ligand at the apical site to the plane formed by two acac ligands. In these aqua complexes, the two acac chelate rings might not be planar, but bent toward the small aqua ligand to release the crowding with the bulky phosphine ligand as have been observed for *trans*-$[Co(DH)_2(Cl)(\boldsymbol{P})]$ ($\boldsymbol{P}$= PBu_3[6], PPh_3[7], PCy_3[8]). Accordingly, the methine proton would not be effectively shielded by the phenyl group to give a very small high field shift. The same explanation can be offered for the small high field shift of the methine signals in *trans*-$[Co(acac)_2(L)(PMe_2Ph)]^{n+}$ (L=NH_3, CH_3NH_2,py, NCS^-). Both methine and methyl signals of *trans*(P,P)-$[Co(acac)(CN)_2(PR_nPh_{3-n})_2]$ (n=0, 1, 2) are observed at a remarkably high field compared with those of the corresponding PR_3 complexes. The magnitudes of shift, in particular those in the PR_2Ph complexes are even larger than those observed in *trans*-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$ (n=0, 1, 2). As stated previously, these dicyano complexes are quite stable to solvolysis, and hence the Co^{III}–P bonds would be stronger and shorter than those in *trans*-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$ which rapidly undergo solvolysis. The large high field shift might be caused by such strong coordination of the PR_nPh_{3-n} (n=0, 1, 2) ligands at the apical position.

Absorption Spectra. In Fig. 2 are shown absorption spectra of PPr_nPh_{3-n} complexes of the types, *trans*- and *cis*-$[Co(acac)_2(\boldsymbol{P})_2]^+$, *trans*-$[Co(acac)_2(H_2O)(\boldsymbol{P})]^+$, and *trans*(P,P)-$[Co(acac)(CN)_2(\boldsymbol{P})_2]$. The spectral patterns remain almost unchanged by changing the kind of alkyl groups. Tables 1—3 list the data of absorption bands observed in the low energy region.

All of *trans*-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$ show a very

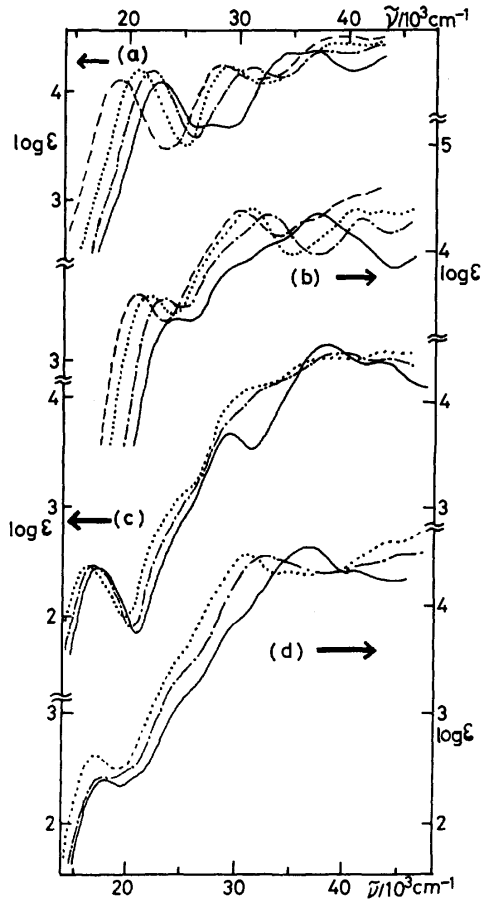

Fig. 2. Absorption spectra of a) *trans*-$[Co(acac)_2(\boldsymbol{P})_2]^+$ b) *trans*(P,P)-$[Co(acac)(CN)_2(\boldsymbol{P})_2]$, c) *trans*-$[Co(acac)_2(H_2O)(\boldsymbol{P})]^+$, d) *cis*-$[Co(acac)_2(\boldsymbol{P})_2]^+$ where denote PPr_3 (——), PPr_2Ph (-·-·-), $PPrPh_2$ (·····), and PPh_3 (----).

strong band in the 19000—23000 cm^{-1} region. Because of the strong intensity, these bands may be assigned to a charge transfer transition. However, no such low energy, strong bands are observed in the phosphine complexes of other types studied here. The bands shift largely to the low energy side as the number of phenyl groups in PR_nPh_{3-n} increases. The first absorption band of the complexes is almost hidden by this strong band, but the shoulders in the lowest energy region observed in the PR_3 and PR_2Ph complexes can be assigned to a part of the first absorption band. The spectra of a series of *trans*-$[Co(acac)_2(CH_3NH_2)_n(PMe_2Ph)_{2-n}]^+$ (n=0, 1, 2) given in Fig. 3 show more clearly that *trans*-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$ has the first absorption band on the low energy side of the strong band. Neither *cis*-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$ nor *trans*-$[Co(acac)_2(H_2O)(PR_nPh_{3-n})]^+$ exhibit such a strong band in the low energy region. The complexes show a band of medium intensity in this region, which can be assigned to the first absorption band from a comparison with the spectra shown in Fig. 3 and those of *cis*-$[Co(acac)_2(CN)_n(PMe_3)_{2-n}]^{(1-n)+}$ (n=0, 1, 2).[2] The *trans*-(P,P)-$[Co(acac)(CN)_2(PR_nPh_{3-n})_2]$ complexes give a fairly strong band in the 21000—24000 cm^{-1} region.

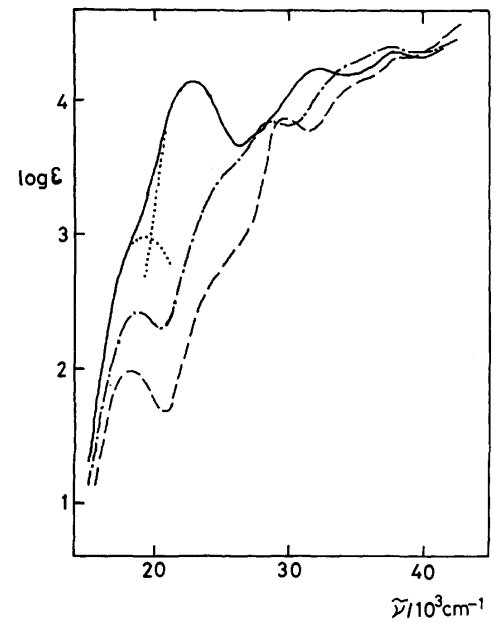

Fig. 3. Absorption spectra of *trans*-$[Co(acac)_2(PMe_2Ph)_2]^+$ (——), *trans*-$[Co(acac)_2(CH_3NH_2)(PMe_2Ph)]^+$ (-·-·-), and *trans*-$[Co(acac)_2(CH_3NH_2)_2]^+$ (-----).

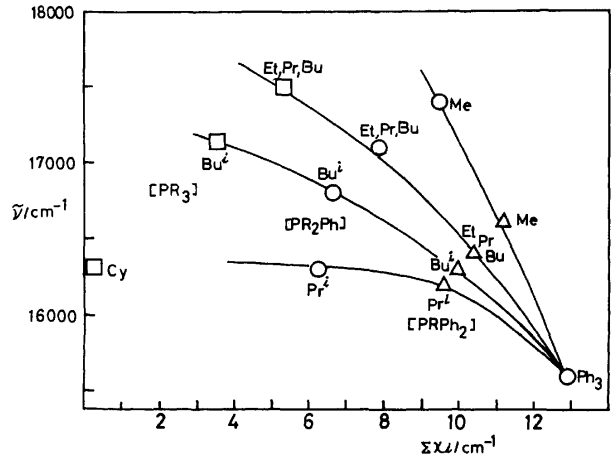

Fig. 4. Plots of the first absorption band(cm^{-1}) of *trans*-$[Co(acac)_2(H_2O)(\boldsymbol{P})]^+$ *vs.* Tolman's substituent additivity value, $\sum\chi i(cm^{-1})$ of the phosphine ligand.

These bands may be assigned to the first absorption band, since the $Ph_2PCH_2CH_2PPh_2$ and $Ph_2PCH_2CH_2CH_2PPh_2$ complexes of the *cis*-[Co(acac)(CN)$_2$(diphosphine)] type also show a similar band in this region with a little smaller intensity of $\log\varepsilon$=3.03 and 3.12, respectively. It has been reported that the first absorption band of *trans*(P,P)-phosphine complexes is always stronger than that of the corresponding cis(P,P) isomers.[2] The same relation is seen between the first absorption bands of *trans*- and *cis*-$[Co(acac)_2(PR_nPh_{3-n})_2]^+$ shown in Fig. 2a and 2d. In the higher energy region, all of the complexes show complicated spectra, and no clear assignment can be made at present.

In Fig. 4 are plotted the absorption maxima of the first bands of *trans*-$[Co(acac)_2(H_2O)(PR_nPh_{3-n})]^+$ *vs.* Tolman's parameters, $\sum\chi i$ (electronic effect) for the

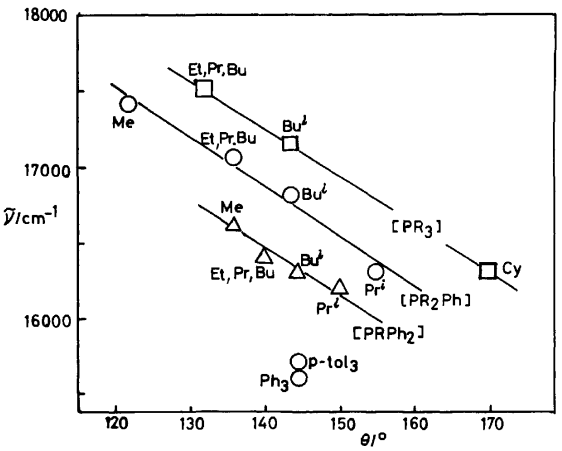

Fig. 5. Plots of the first absorption band(cm^{-1}) of *trans*-[Co(acac)$_2$(H$_2$O)(***P***)]$^+$ *vs.* Tolman's cone angle (θ°) of the phosphine ligand.

phosphine ligands. In general, the absorption maxima shift to high energy with decreasing the value of $\sum\chi i$ (increasing basicity). However, the extent of shift depends clearly on the kind of R on PR$_n$Ph$_{3-n}$; the more bulky the R group becomes, the smaller the extent of shift arises. The PCy$_3$ ligand is much more basic than PPr$^i_2$Ph, but the former is more bulky (Tolman's cone angle: 170°) than the latter (155°), and consequently the complexes of these two phosphines show the first absorption band at nearly the same position. Of the phosphines, four PBu^i_nPh$_{3-n}$ (n=0, 1, 2, 3) have a similar cone angle (*ca.* 145°). Hence the line connecting the points of these phosphines in Fig. 4 would show the electronic effect of phosphines with a constant cone angle (*ca.* 145°) on the first absorption bands of *trans*-[Co(acac)$_2$(H$_2$O)(PR$_n$Ph$_{3-n}$)]$^+$. The complexes with a less bulky phosphine and those with a more bulky one than PB^i_nPh$_{3-n}$ give the first absorption band at higher and lower energy, respectively, than values on the line, when the phosphine has the same $\sum\chi i$ value as that of PBu^i_nPh$_{3-n}$.

Figure 5 shows a plot of the first absorption maxima *vs.* Tolman's cone angles(θ°) (steric effect) for phosphine ligands in the same *trans*-[Co(acac)$_2$(H$_2$O)-(PR$_n$Ph$_{3-n}$)]$^+$ complexes. Good linear relations are seen between the absorption maxima and each group of phosphines, PR$_3$, PR$_2$Ph, and PRPh$_2$, *i.e.*, for each group of phosphines, the absorption maxima shift linearly to lower energy with an increase in cone angle of the phosphine ligand. As stated previously, four PBu^i_nPh$_{3-n}$ have a similar cone angle. The energy difference in absorption maxima of these phosphine complexes should come from the difference in basicity of the phosphines. Thus Figs. 4 and 5 clearly demonstrate that the ligand field strength of phosphines to the Co^{III} ion is dependent not only on the basicity but also on the bulkiness strongly. Similar dependence is seen for the lowest energy bands of the *trans*(P,P)-[Co(acac)(CN)$_2$(PR$_n$Ph$_{3-n}$)$_2$] complexes.

(Received December 24, 1983)

Synopsis. A new surface-active porphyrin, 1-dodecyl-4-(10,15,20-triphenyl-5-porphinyl)pyridinium bromide, and its copper complex (Cu(II)DPyTPP) were synthesized. In toluene, chloroform and ethanol, a typical ESR hyperfine structure (hfs) ascribable to monomeric Cu(II) porphyrin was observed. In ethanol containing a buffer of pH=7.4, a reversible formation of the micellar colloid which is strongly dependent on the water/ethanol mixing ratio, was confirmed based on mearsurements of ESR line broadening and the splitting of the Soret band.

As a simple model for naturally occuring Hemeproteins, micellar vesicles which contain surface-active porphyrins have already been reported.[1,2] Yamamura synthesized Cu(II)-4,4′,4″,4‴-(5,10,15,20-porphyneteayl)-tetrakis{1-octadecylpyridinium}tetraiodide, whose ESR spectra revealed a broadened ESR line width, related to strong paramagnetic interactions between the metal active sites in the reversed micellar visicles.[3] On the other hand, Katagi *et al,* found that the Soret band (426nm) of magnesium porphyrins showed a red shift when it was incorporated into liposome vesicles.[4] A concomitant decrease of the absorption intensity was also observed.

To our present knowledge, there have been a few investigations of the Cu(II) porphyrin systems incorporated in the micellar vesicles, in which the ESR and optical spectrographic data were combined in order to understand the physicochemical properties of the metallo-porphyrins systems. We now report on the preparation of a new surface active porphyrin copper complex, Cu(II)DPyTPP, which bears both the hydrophilic pyridinium group and the hydrophobic alkyl group (Fig. 1). At a critical value in the water-ethanol mixing ratio, a reversible formation of micelles was clearly demonstrated based on measurements of the line broadening of the ESR hfs and the anomalous splitting in the Soret band of the Cu(II)-DPyTPP complex.

Experimental

Preparation: $DPyTPPH_2$ was prepared by the N-alkylation of the free base, $PyTPPH_2$, which was obtained from the usual mixed aldehyde method.[5] The N-alkylation of $PyTPPH_2$ was carried out in a refluxing DMF[6] in the presence of a 50-fold excess of dodecyl bromide; yield 70 (%).

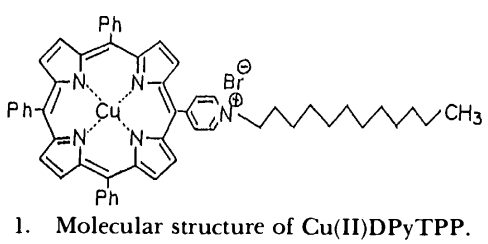

Fig. 1. Molecular structure of Cu(II)DPyTPP.

Found (%): C, 76.37; H, 6.29; N, 8.10; Br, 9.24. Calcd (%) for $C_{55}H_{54}N_5Br$: C, 76.38; H, 6.41; N, 8.03; Br, 9.34. Cu(II)-DPyTPP was prepared by the ordinary method; the 40% excess of dry $CuBr_2$ and $DPyTPPH_2$ were treated in refluxing ethanol for 1 hour under a nitrogen atomsphere.

Found (%): C, 70.84; H, 5.86; N, 7.76; Br, 8.82. Calcd (%) for $C_{55}H_{52}N_5BrCu$: C, 71.13; H, 5.87; N, 7.54; Br, 8.69.

Measurments: ESR measurments were carried out while changing the solvent mixing ratio, r=water/ethanol, 0/10 to 9/1. The final concentration of the copper complex kept in 2×10^{-5}M (1M=1 mol dm^{-3}), and the pH was adjusted to 7.4 with 2×10^{-3}M Tris-Cl. ESR spectra at 77K were recorded with a JEOL-FE-2XG X-band spectrometer with a 100KHz modulation. The magnetic field was calibrated by the splitting of Mn(II) in MgO (A_{3-4}=8.69mT) and the g-values were standardized using Li-TCNQ (g=2.00252) as a reference. The optical spectra were recorded with a JASCO UVDEC-1 spectrometer at room temperature. All the measurements were performed at the Advanced Instrumental Center for Chemical Analysis, Ehime University.

Results and Discussion

The optical spectrum of Cu(II)DPyTPP measured in ethanol was identical with that reported previously (Soret band λ_{max}=426nm, $\varepsilon=2.31\times10^5$, α-band; λ_{max}=548nm, $\varepsilon=22\times10^3$, β-band; λ_{max}=578nm, $\varepsilon=3\times10^3$).[7] When the buffer solution was added to the ethanol solution, the intensity of the Soret band decreased depending on the solvent composition, but no significant shift of λ_{max} was observed in both the Soret band and α-band until r=4/6, as shown in Fig. 2. When the r-value became about 7/3, a drastic spectral change was observed involving an abrupt decrease of the Soret band and a splitting of the Soret band into two different absorption maxima, (λ_{max}=440nm, $\varepsilon=4.96\times10^4$ and λ_{max}=392nm, $\varepsilon=2.6\times10^4$) (Fig. 2). A concomitant red shift was also noted in the α-band from 540nm to 553nm. With higher r-values than 7/3, the sparated maxima in the Soret band began to merge into a single peak with an increased ε-value and the α-band blue shifted, (Fig. 2). The observed trend in the visible absorption spectra is consistent with a spectral change reported for a surfactant Mg(II) porphyrin incorporated into liposome vesicles.[4] The formation of micelles with our surfactant Cu(II)porphyrin, therefore, was suggested. In order to understand the mechanism of this surfactant porphyrin in detail, studies were made with the aid of ESR spectrometry. As shown in Fig. 3-a, a well resolved hfs of the monomeric Cu(II)DPyTPP was ovserved in ethanol. The observed ESR parameters were actually identical with those measured in toluene and chloroform, ($g_{//}$=2.196, $g_{\perp}$=2.067, $A_{\perp}=203.8\times10^{-4}$cm^{-1}).[8] When a buffer solution was added to the ethanol, a slight decrease in the ESR line intensity ascribed to the ligand N hyperfine was ob-

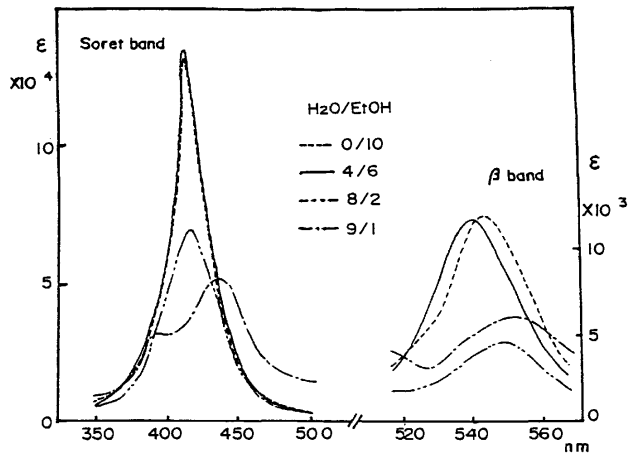

Fig. 2. Absorption spectra of Cu(II)DPyTPP (2×10^{-5} M), with various mixing ratio of ethanol and water, where the pH was adjusted to 7.4 by Tris-Cl (2×10^{-3}M).

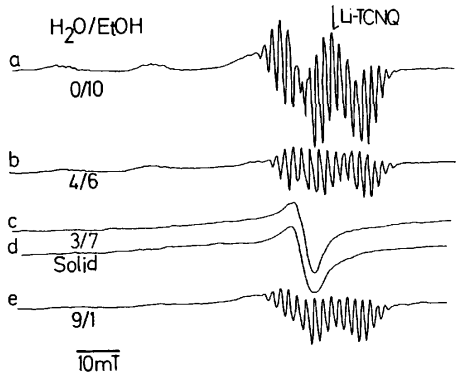

Fig. 3. ESR spectra of Cu(II)DPyTPP (2×10^{-5}M) at 77K, with various mixing ratio of ethanol and water, where the pH adjusted to 7.4 by Tris-Cl (2×10^{-3}M).

served. However, the mangitude of the hfs for both copper and the ligand N atoms showed no significant changes unitil $r=4/6$, as shown in Fig. 3-b. An abrupt decrease in the net ESR line intensity and anomalous line broadening occures at the r-value 7/3, where hyperfine splittings for ligand N and copper atoms were smeared out except for the hfs due to the g-anisotropy. It is notewothy that the ESR line shape of Fig. 3-c was analogous to that measuerd for a powdered Cu(II)DPyTPP complex, Fig. 3-d. A similar line broadening due to a clustering of the copper tetra-alyl porphyrin has been described for copper complexes involving the surfactant active porphyrins upon the micellar formation.[3] The central copper ions interact magnetically in such a way as to smear out the copper nuclear hyperfine interaction. The ESR spectra of the dimer Cu(II) obtained from the proto-porphyrin derivatives have already been reported, and the internuclear distance between the copper ions were found to lie in a range from 3.5 to 4 Å.[9] Many trials were made to detect the formation of the triplet species in the ESR spectra. In the persent case, however, positive evidence for the dimer formation was hardly obtained everywhere. With a further addition of the buffer solution, 9/1, the ESR signal again revealed a well resolved hfs due to the monomeric Cu(II) and ligand N was clearly detected as shown in Fig. 3-e, ($g_{//}=2.202$, $g_{\perp}=2.064$, $A_{//}=195\times10^{-4}\,cm^{-1}$). In comparision with the values measured in a weak polar solvent, such as chloroform and toluene, the observed $g_{//}$-value was slightly higher and the $A_{//}$-value was, conversely, reduced. On the bases of the observation of the optical and ESR spectra, some important notions on micelle formation with a surfactant metallo-porphyrin can be deduced. For lower contents of water (0/10 to 4/6) the spectroscopic data suggest that a relatively small intermolecular interaction exists between each chromophore. The decrease in the magnitude of the ESR line intensity and the disappearance of the ligand N hyperfine observed in the medium water content, 4/6 to 7/3, might be attributed to an electron spin-spin interaction among the metal sites, which can be accessible together by the hydrophobic interaction between the long alkyl chains. The splittings of the Soret band supported the evidence that the metalloporphyrin actually formed the micellar vesicles. For r-values greater than 9/1, the reappearance of a well resolved ESR hfs and the collapes of the splittings in the Soret band were observed. These findings suggest that a molecular rearrangement on metalloporphyrin array occurs in the micell vesicles, in which the interaction between the active sites is reduced. Such a rearrangement of metallo-porphyrin is probably due to the hydration of the metal chrmophore, where the hydration would be greatly accelerated by the hydrophilic pyridinium group involved in the surfactant porphyrin. In this situation, the solvation of the water molecule causes a distortion of the copper porphyrin, as judged from the trend in the observed ESR parameter. This trend indicates that the $g_{//}$-value shows a slight increase while the $A_{//}$- value is reduced.[10] The results herein may provide not only a model for metalloporphyrin containing proteins but also a useful tool for understanding the orientation of the metalloporphyrin moiety in proteins.

Ab Initio Gradient Calculation of the Molecular Structures of Dimethyl Ether and Dimethyl Sulfide

Akira TSUBOYAMA, Kouichi TAKESHITA, Shigehiro KONAKA, and Masao KIMURA*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received June 28, 1984)

Synopsis. The molecular structures and torsional potentials of $(CH_3)_2O$ and $(CH_3)_2S$ have been calculated by the *ab initio* gradient method using a MIDI-4 basis set augumented with polarization functions. The calculations have confirmed that the molecules take the staggered-staggered conformation with C_{2v} symmetry.

According to microwave spectroscopic studies, dimethyl ether[1] and dimethyl sulfide[2] molecules have C_{2v} symmetry in the equilibrium state and each methyl group is staggered against the opposite C–O or C–S bond. However, there remains a possibility of a near staggered-staggered conformation with C_2 symmetry. Actually, the torsional angle, τ, for dimethyl ether was calculated to be 4° from the r_s-structure (as for the definition of τ, see Fig. 1), although Blukis *et al.* ascribed it to the zero-point torsional effect because such a small separation of the two potential minima requires an unreasonably high and sharp potential hump between them.[1] Recently Tamagawa *et al.*[3] have studied the structure of dimethyl ether by a joint analysis of the electron-diffraction and microwave spectroscopic data and determined τ to be 2(11)°. The possibility of C_2 symmetry has thus not been excluded.

Lombardi *et al.* performed a conformational analysis of dimethyl ether based on a model where the barrier to internal rotation was assumed to arise only as a result of exchange interactions among electrons on nonbonded atoms and lone-pair electrons on the oxygen.[4] According to their calculation, the torsional potential of dimethyl ether has two separate minima at $\tau=\pm17.5°$ and the height of the barrier between them is 0.52 kcal/mol.† It may be noted that their exchange perturbation theory was successfully applied to the calculation of the rotational barriers of more than thirty molecules.[5]

A recent electron-diffraction study[6] has revealed that the di-*t*-butyl sulfide molecule takes only one stable conformation of C_2 symmetry with the *t*-butyl groups rotated by 12(8)° from the staggered conformation. Although no question has so far been raised on the molecular symmetry of dimethyl sulfide, it is worthwhile to investigate it theoretically in connection with dimethyl ether and di-*t*-butyl sulfide.

A number of *ab initio* MO calculations have been reported for dimethyl ether and dimethyl sulfide. The barriers to internal rotation have been studied with the STO-3G basis set,[7,8] but the possibility of a near staggered-staggered conformation has not been examined. The bond lengths and angles of dimethyl ether for the staggered model have been calculated by several authors,[9–11] but no *ab initio* calculation has been reported for the structural parameters of dimethyl sulfide. The purpose of the present work is to study the torsional potentials and structures of these molecules by *ab initio* calculations using Pulay's gradient method.[12] The JAMOL3 program[13] and the MIDI-4 basis set,[14] augumented with d polarization functions for the C, O, and S atoms, were used for the SCF-LCAO-MO calculations, while geometry optimizations were performed with the GRAMOL program[15] by assuming C_2 symmetry. Optimizations were repeated until the largest atomic forces were of the order of 2×10^{-2} mdyn.††

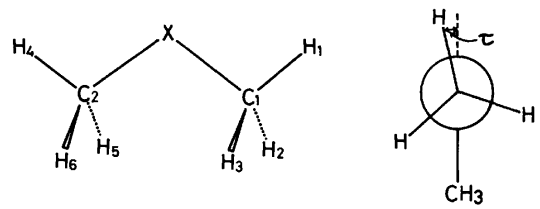

Fig. 1. Numbering of atoms and definition of the torsional angle, τ. X represents O or S.

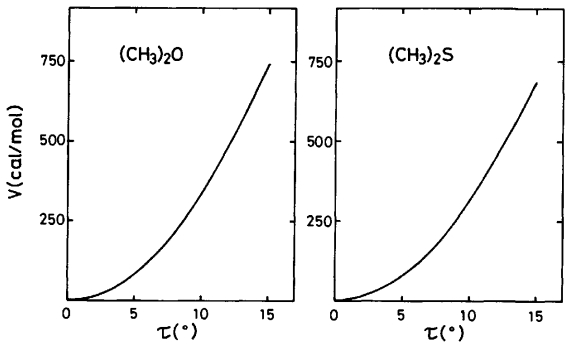

Fig. 2. Torsional potentials for dimethylether and dimethylsulfide.

The calculated torsional potentials are displayed in Fig. 2. The minima of the potentials are at $\tau=0$. The calculated potentials cover only a limited range of τ-values, but they fit well into a simple analytical expression for the torsional potentials with threefold symmetry, *i.e.*, $V_3(1-\cos3\tau)$. The values of the potential barrier, V_3, were thus estimated to be 2.5 and 2.3 kcal/mol for dimethyl ether and dimethyl sulfide respectively. The experimental values of V_3 are 2.72[1] and 2.70 kcal/mol[16] for dimethyl ether and 2.1 kcal/mol[2] for dimethyl sulfide. The present calculations give potential barriers close to the experimental data.

The calculated geometrical parameters are compared with the observed ones in Table 1. The agreement between the calculated and experimental geometries is

†1 cal/mol=4.184 J/mol.

††1 mdyn=10^{-8} N.

Vibronic-Level Dependence of the Radiative Decay Rate in Pyrazine and Pyrimidine Vapors: Re-examination under High Spectral Resolution

Osamu SEKIGUCHI, Nobuhiro OHTA, and Hiroaki BABA*

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received July 16, 1984)

Synopsis. The radiative decay rate constants (k_F) for vibronic levels in S_1 of pyrazine and pyrimidine were derived by using the quantum yields measured under the conditions of SVL excitation. The vibronic level dependence of k_F in pyrazine can be explained by the Herzberg-Teller theory.

Pyrazine and pyrimidine are prototypes of intermediate-case molecules and their fluorescence emissions consist of two components, fast and slow fluorescence, in the vapor phase at low pressure. The vibronic coupling through the ν_{10a} vibration in the S_1 state of pyrazine was studied by Yamazaki *et al.*[1,2] From quantum yields and lifetimes measured for the fast fluorescence, they derived the radiative decay rate constants for individual vibronic levels, and compared these experimental decay constants with theoretical ones obtained on the basis of the Herzberg-Teller theory. They concluded that the theory overestimates the rate constants for levels involving the ν_{10a} vibration. However, their quantum yields were obtained with the spectral resolution ($\approx 20\,cm^{-1}$) insufficient for exciting single vibronic levels (SVL) separately,[1] while their lifetimes were obtained with significantly higher resolution.[2] We have newly measured the SVL fluorescence quantum yields for pyrazine and pyrimidine in the vapor phase with narrow-band excitation ($\approx 0.5\,cm^{-1}$) and re-examined the magnitude of the vibronic coupling in pyrazine. In this study we are solely concerned with the fast fluorescence; hereafter it will be simply called fluorescence.

Experimental

The apparatus and the method for optical measurements were the same as described previously;[3,4] the exciting laser pulse has a bandwidth of $\approx 0.5\,cm^{-1}$. The sample vapors were at moderately high pressures (17.0 mTorr† pyrazine +12.2 Torr SF_6, and 156 mTorr pyrimidine+36 Torr SF_6), where the slow component is quenched completely and the fast is free from collision.[3] Since the excitation spectra were obtained by monitoring a part of the total fluorescence intensity, a correction was made so that the ratio of the actually monitored intensity to the total might be constant for all the bands studied.

Results and Discussion

Figure 1 shows absorption and fluorescence-excitation spectra for pyrazine. Owing to the high resolution, vibronic bands (*e.g.*, $10a_0^1$ and $6a_0^1 16b_1^1$) are well separated from one another and even their band contours are discernible to a certain extent. The relative fluorescence quantum yield for each SVL was obtained by comparing the integrated intensity of the band, related to the SVL, in the excitation spectrum with that of the corresponding absorption band. In either case the contribution of the underlying continuum due to the overlapping of the other bands was subtracted from the integrated intensity.

The SVL fluorescence quantum yields (Φ_F) of pyr-

†1 Torr≈133.322 Pa.

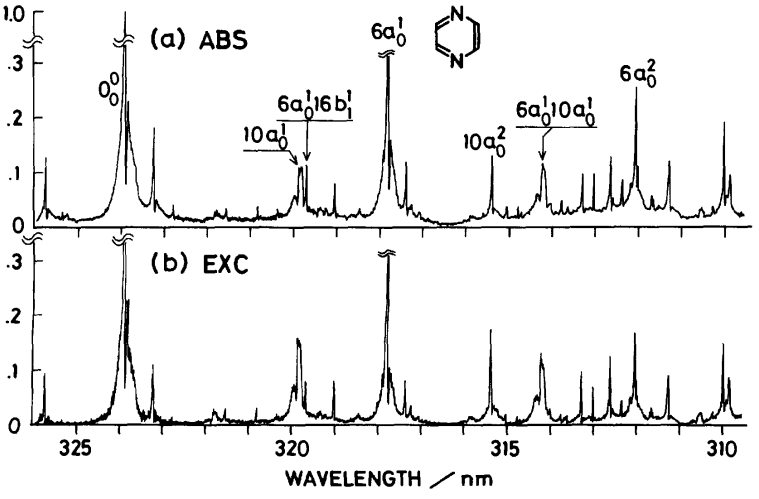

Fig. 1. Absorption spectrum (a) and fluorescence excitation spectrum (b) for pyrazine. In each spectrum, the peak height of the 0_0^0 band is normalized to unity. The peak heights of the $6a_0^1$ band in the absorption and excitation spectra are 0.74 and 0.50, respectively. The excitation spectrum has been corrected for the variation of the exciting laser intensity, but in this spectrum the correction described in the text has not been made.

TABLE 1. QUANTUM YIELDS, LIFETIMES AND RADIATIVE RATE CONSTANTS

	Level	Φ_F	τ_F[b]	k_F^{exp}[c]	k_F^{theor}[d]
		10^{-4}	ns	$10^6 s^{-1}$	$10^6 s^{-1}$

	12^2	7.8	1.4	0.56	
	$6a^212^1$	9.1	1.4	0.65	

a) The absolute Φ_F value for the 0^0 level was determined by reference to the data in Ref. 3. b) The lifetimes for pyrazine were taken from Ref. 2, and those for pyrimidine were newly measured in this study with an excitation bandwidth of $\approx 0.5\,cm^{-1}$. c) Experimentally obtained k_F. d) Theoretically obtained k_F; the relative values of k_F originally obtained from the theory were placed on an absolute scale by fitting $k_F^{theor}(0^0)$ to $k_F^{exp}(0^0)$.

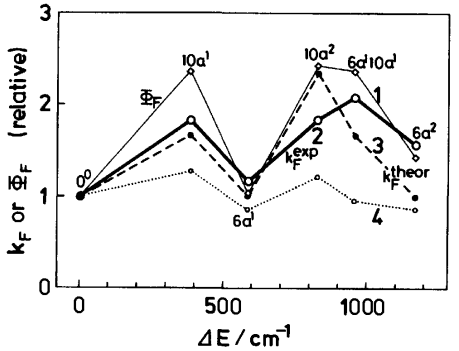

Fig. 2. Relative values for Φ_F and k_F plotted against ΔE for pyrazine: (1) Φ_F; (2) k_F^{exp}; (3) k_F^{theor}; (4) k_F, obtained in a low resolution experiment. Values in (1)—(3) were obtained in this study and those in (4) were taken from Ref. 2.

azine are given in Table 1, and a plot of Φ_F against the excess vibrational energy (ΔE) is shown in Fig. 2 by a lean solid line. The values of Φ_F for the levels involving $10a^j$ (Φ_F^j) are significantly larger than that for the 0^0 level (Φ_F^0), *i.e.*, $\Phi_F^j/\Phi_F^0 \gtrsim 2$ for $j \geq 1$. The ν_{10a} (b_{1g}) vibration can induce vibronic coupling between $S_1(^1B_{3u})$ and $S_2(^1B_{2u})$. Since the transition from S_0 to S_2 has a much larger oscillator strength, levels involving $10a^j$ will show larger radiative decay rate constants (k_F), and hence larger Φ_F values, than do the other vibronic levels. It is to be noted, however, that large Φ_F values may result not only from large k_F values but also from small total decay constants, as pointed out by Yamazaki *et al.*[2]

The values of k_F were obtained by combining the values of Φ_F measured in the present study with the lifetimes (τ_F) reported by Yamazaki *et al.*[2] (Table 1). As is shown in Fig. 2 with a thick solid line, the resulting k_F values vary with ΔE more widely than those obtained from the low resolution study[2] (shown by a dotted line). The values of k_F, like those of Φ_F, are obviously large for the levels involving $10a^j$, *i.e.*, $k_F^j/k_F^0 \gtrsim 2$ for $j \geq 1$. This is a direct manifestation of the vibronic coupling through the ν_{10a} vibration.

We treat the vibronic-level dependence of k_F in pyrazine by means of the Herzberg-Teller theory[5] assuming the harmonic oscillator approximation for the ν_{10a} vibration. Although ν_{10a} is known to be anharmonic,[6] the anharmonicity is not large enough to produce a significant effect on the following discussion.[1] The radiative decay rate constant for the $10a^j$ level relative to that for the zero-point level is given by[1]

$$\frac{k_F^j}{k_F^0} = \frac{1+(\zeta/u)(2j+1)}{1+\zeta/u}, \qquad (1)$$

where j is the quantum number of ν_{10a}, ζ the intensity ratio of the $10a_0^1$ absorption band to the 0_0^0, and u is a numerical factor equal to 0.346 in this case. Yamazaki *et al.*[1] derived $\zeta=0.23$ for pyrazine from a high resolution spectrum. We obtained $\zeta=0.18$ by excluding the underlying continuum, although 0.23 was obtained by including it. The value of k_F calculated theoretically by using $\zeta=0.18$ is plotted against ΔE, with the result shown in Fig. 2 by a broken line (see also Table 1). It is seen that with respect to k_F the present experimental result agrees fairly well with what is predicted by the simple Herzberg-Teller theory.

For pyrimidine, the experimental k_F value, obtained in the same manner as k_F of pyrazine, was found to decrease roughly monotonically up to $\Delta E \approx 2500\,cm^{-1}$ (Table 1), as in the case of the low resolution study, indicating that the vibronic levels in S_1 pyrimidine are not appreciably perturbed by vibronic coupling.

Solvent Extraction of Copper(II) with 2-(*o*-Hydroxyphenyl)benzothiazole

Kenji SHIMIZU and Akiko FURUHASHI*
Department of Chemistry, Aoyama Gakuin University, 1626 Ono, Atsugi 243-01
(Received January 10, 1984)

Synopsis. Equilibrium and kinetic aspects of the solvent extraction of Cu(II) with 2-(*o*-hydroxyphenyl)benzothiazole have been carried out using a water–chloroform system. The complex extracted into chloroform was greenish-brown in color and the absorbance at 490.0 nm obeyed Beer's law up to 2×10^{-4} mol/dm^3. The complex was 1:2 (Cu^{2+}:ligand) type and the over-all stability constant, β_2, was 1.3×10^{17} at an ionic strength of 0.3. The extraction constant, K_{ex}, was 2.5×10^{-8}. The extraction kinetics were first order with Cu(II) ions and the reagent anions. The rate constant for the reaction was found to be 5.0×10^{9} mol^{-1} min^{-1}.

Solvent extraction (liquid-liquid extraction) of metal chelate complexes has been used as a separation method for a long time. For extraction of metal ions, it is preferable that the chelating reagent used has a high distribution coefficient (K_{DR}) and pH dependence in the system chosen. Thus, dithizone,[1] 8-quinolinol, cupferron and others have been used widely.[2] In this study, extraction of copper(II) with 2-(*o*-hydroxyphenyl)benzothiazole was investigated. It could have been expected that this reagent would be effective for extraction of certain metal ions because of its high molecular weight and low solubility in water. The reagent forms complex compounds with certain metal ions such as Co(II), Pb(II), and Ni(II).[3] However, there is no report of solvent extraction being attempted with this reagent. On the other hand, its luminescence properties have been studied.[4] In this paper, equilibrium and kinetic studies with this reagent of copper(II) in a water–chloroform system are reported.

Experimental

Reagents. 2-(*o*-hydroxyphenyl)benzothiazole(HPBT) was obtained from INC Pharmaceuticals Inc. All reagents for this study were of reagent grade from Wako Chemical Co. Ltd.

Instrumentation. The atomic absorption spectra were obtained using a Nippon Jarrel Ash AA-1 Mark-II Atomic Absorption Spectrophotometer by the use of air and acetylene flame. The electronic spectra were obtained with a Shimazu UV-240 Spectrophotometer.

All equilibrium extraction were performed by agitating the samples in 25 dm^3 vials for 30 min (120 strokes/min) at 25±1 °C. After agitation, the solutions were allowed to stand for 10 min before further operations were carried out.†

The kinetic study was carried out in the same manner as the equilibrium investigation, and only the agitating time was changed.

Measurement of Reagent Distribution Constant (K_{DR}). Equal volumes (6 dm^3) of 0.1 mol/dm^3 solution of HPBT in chloroform and the appropriate buffer solution were shaken and the aqueous phase was pipetted into a glass tube and centrifuged. The pH was adjusted to the first measured pH. Then 4.5 dm^3 each of the aqueous phase and chloroform were shaken together. The absorbance of the organic phase at 334.7 nm was measured. The distribution ratio D was obtained by the $D=(\varepsilon C_o-A_f)/A_f$, where ε is the molar absorptivity, C_o is original concentration of HPBT in chloroform and A_f is final absorbance of the chloroform layer.

Distribution Measurement of Copper(II). A 5-dm^3 chloroform solution of HPBT (0.01—0.03 mol/dm^3) and an equal volume of a buffer solution (pH, 1—13) containing Cu(II) ion*1 of 2×10^{-4} mol/dm^3 were agitated. The copper content in the chloroform layer was determined by atomic absorption spectra using the 324.8-nm line.

The absorption spectra of the chloroform layer were determined over the range 350—700 nm. At 490.0 nm the absorbance obeyed Beer's law up to 2×10^{-4} mol/dm^3 of Cu(II). Consequently, the determination of copper extracted into chloroform was carried out by the spectrophotometric method.

The extractability (E%) and distribution ratio (D) are obtained by the equations $E\%=A_2/A_1\times100$ and $D=E/(100-E)$, where A_1, is the copper concentration in the initial aqueous phase and A_2 is the copper concentration in the chloroform at extraction equilibrium.

Measurement of Distribution Coefficient of Copper Complex (K_{DC}). 5 dm^3 each of 2×10^{-1} mol/dm^3 of HPBT solution in chloroform and 2×10^{-3} mol/dm^3 of copper ion*2 in buffer solution (pH=9.0) were agitated. Then 4.5 dm^3 each of the aqueous layer and chloroform were shaken and the absorbance of the chloroform layer was measured at 490.0 nm. K_{DC} can be obtained as the equation $K_{DC}=A_1/A_2$, where A_1 and A_2 are absorbance of the chloroform layers first and second extracted, respectively.

Results and Discussion

The theoretical basis for the determination of the several constants will not be discussed here in detail. They are not special and a number of references are available.[5–7]

Distribution of Reagent. Experimental results were shown in Fig. 1. The constants for HPBT are tabulated in Table 1.

Extraction of Copper. Extractability of copper changes according to pH as was showm in Fig. 2. The plots of log D against pH (fixed concentration of HPBT) or log [HPBT] (fixed pH) showed linear relations and their slopes were all 2. The results indicate the extracted complex has 1:2 (Cu^{2+}:HPBT) composition.[8] The results for the complex were summarized in Table 2. The over-all stability constant (β_2) is smaller than that of the 8-quinolinol complex (23.4)[9] although the molecular weight of HPBT is larger and pK_{a2} is higher as compared with the respective values for 8-quinolinol. It can be presumed that HPBT forms a six-membered chelate ring with the metal ion but 8-quinolinol forms a five-membered chelate ring. Free rotation of the hydroxyphenyl group and the bonding distance with copper(II) may influence the result.

Kinetic of Extraction of Copper(II) Ion. The reaction with the metal ion was taken to obey a first order reaction by analogy with other work.[10] The

†The condition was investigated previously.

*1, *2, Copper (II) acetate was used. The results when copper (II) nitrate was used did not change.

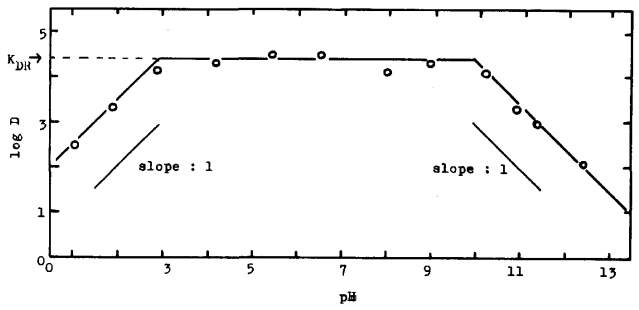

Fig. 1. Distribution ratio change of HPBT with pH in water-chloroform system.

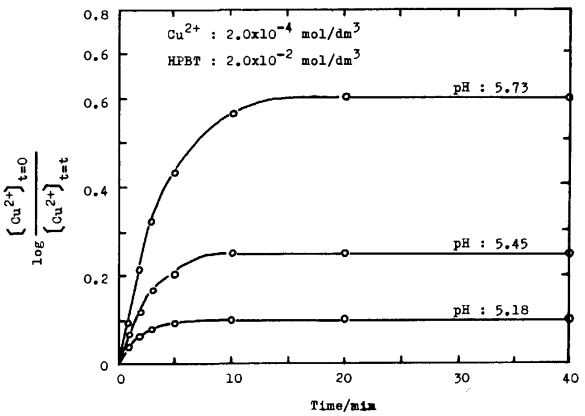

Fig. 3. Relationship between $\log[Cu^{2+}]_{t=0}/[Cu^{2+}]_{t=t}$ and extraction time.

reaction rate should be given by

$$-d[Cu^{2+}]/dt = k[Cu^{2+}][PBT^-] \quad (1)$$

for the slowest reaction $Cu^{2+}+PBT^- \rightarrow [Cu\cdot PBT]^+$. For this reaction, the rate constant, k, is presented. An equation

$$\log(\log[Cu^{2+}]_{t=0}/[Cu^{2+}]_{t=t}) = \log(kK_{a2}/2.303K_{DR}) + \log[HPBT]_o + pH + \log t$$

can be obtained by substituting $K_{a2}=[H^+][PBT^-]/[HPBT]$ and $K_{DR}=[HPBT]_{org}/[HPBT]_w$ into the Eq. 1 and integration. The plots of $\log(\log[Cu^{2+}]_{t=0}/[Cu^{2+}]_{t=t})$ *vs.* pH and $\log[HPBT]_0$ showed linear relations with all slopes equal to unity, indicating that the rate-determining step was controlled by the formation of the 1 : 1 complex. The initial slopes were changed in the plots of $\log[Cu^{2+}]_{t=0}/[Cu^{2+}]_{t=t}$ *vs.* time as were shown in Fig. 3. The kinetic data are shown in Table 3. From this the rate constant, k, can be calculated by the relation $k=k'\times K_{DR}/K_{a2}$, where k'=slope$\times$2.303$[H^+]$/ $[HPBT]_0$.

The value of k thus obtained was 5.0×10^9 mol^{-1} min^{-1}. The value is relatively large compared with the case of the extraction of Co^{2+} and Ni^{2+} with dithizone. It is assumed that this is due to the Jahn-Teller effect. Namely, water molecules on the z axis are liberated easily.[7] For Co^{2+} extraction with HPBT, we obtained $k=4.2\times10^5$ mol^{-1} min^{-1}.

The Phosphorus-31 Nuclear Magnetic Resonance Spectra of Bis(acetylacetonato)cobalt(III) Complexes Containing Bidentate Diphosphines

Yoshio KOIKE, Toshio TAKAYAMA, and Masatoshi WATABE*,†
Department of Chemistry, Kanagawa University, Yokohama 221
†*General Education Department, Kogakuin University, Hachioji 192*
(Received April 26, 1984)

Synopsis. The phosphorus-31 nuclear magnetic resonance spectra of $[Co(acac)_2(P\text{-}P)]^+$(P-P=diphosphine ligand) of the Werner type were measured, and the coordination chemical shifts were compared with those of complexes studied before. The coordination chemical shifts of the five-membered chelate ring were twice as much as those of the six-membered ring.

The nuclear magnetic resonance spectoroscopy of phosphines in coordination compounds is an area of considerable potential interest and a great deal of ^{31}P NMR data of transition metal phosphine complexes have been reported. However, all the metals dealt with thus far have been soft, such as the Pt, Rh, Hg, and Ag atoms and Ni, Mn, Co, Cr, Mo, and W in their lower-valence states.[1,2] Though recently several cobalt(III) phosphine complexes of the Werner type have been prepared, no ^{31}P-NMR data of these complexes have been reported.[3] The paper deals with the ^{31}P NMR spectra of bis(acetylacetonato)cobalt(III) complexes with a bidentate diphosphine. Some complexes were newly prepared.

Experimental

The diphosphine ligands and their abbreviations are as follows;

(a) $Ph_2PCH_2CH_2PPh_2$ (dppe)
(b) $Ph_2PCH(CH_3)CH_2PPh_2$ (mdppe)
(c) $Ph_2PCH_2CH_2CH_2PPh_2$ (dppp)
(d) $Ph_2PCH(CH_3)CH_2CH_2PPh_2$ (mdppp)
(e) $Ph_2PCH{=}CHPPh_2$ (dpp)

The dppe, dppp, and dpp ligands were prepared by the method of Hewertson and Watson,[4] while the mdppe and mdppp ligands were prepared by the method of Fryzuk.[5] All the complexes were prepared by a method similar to that of Kashiwabara *et al.*[3] from tris(acetylacetonato)cobalt(III) and the corresponding diphosphine. The analytical data of the new complexes are as follows; Calcd for $[Co(acac)_2mdppe]BF_4 \cdot H_2O$ C, 57.39; H, 5.47; N, 0.00%. Found: C, 57.21; H, 5.08; N, 0.02%. The ^{31}P NMR spectra were obtained in the Fourier transform mode with a Varian FT-80A spectrometer. The chemical shifts at 32.206 MHz were determined by the use of a 4 kHz range and a 16 K memory and were measured with respect to an external 85% H_3PO_4. The pulse width was 15 μs, and the pulse delay, 4s. About 200 mg of the complex was dissolved in 1.5 cm^3 of $CDCl_3$ in a 10 mm tube, and the spectra were accumulated 1000 times for free ligands and 15000 times for the complexes at 37 °C.

Results and Discussion

The ^{31}P NMR spectra of the ligands are shown in Fig. 1 (upper). Symmetrical ligands have one peak (ligands (a), (c), (e)), while unsymmetrical ones have more than one peak (ligands (b), (d)). The chemical shifts of the ligands can reasonably be predicted from the group contributions in terms of the α, β, and γ substituent effects at the α, β, and γ positions (P_α-C_β-C_γ-C_δ; P=phosphorus, C=carbon). The effect of substituting a methyl group for a hydrogen atom at C_β is deshielding, while an upfield shift is observed when a methyl group replaces a hydrogen atom at C_γ. The splitting of the two peeks for Ligand (b) is due to the ^{31}P-^{31}P coupling (24.6 Hz).

The ^{31}P NMR spectra of bis(acetylacetonato)cobalt(III) complexes with a bidentate diphosphine are shown in Fig. 1 (lower). The chemical shift data are listed in Table 1. When the saturated 5-membered chelate ligands (a) and (b) coordinate to the cobalt(III) ion, the coordination chemical shifts, $\Delta(=\delta(\text{coordinated}) - \delta(\text{free}))$, are about 56—62 ppm for Ligands (a) and (b), whereas the values for the saturated 6-membered chelate ligands (c) and (d) are 26—28 ppm, much smaller than those for Ligands (a), (b). Several authors have found a trend of ^{31}P NMR chemical shifts in relation to the chelate effect of diphosphins in organometallic complexes. The coordination chemical shifts always show a low-field shift for four-, five-, and six-membered

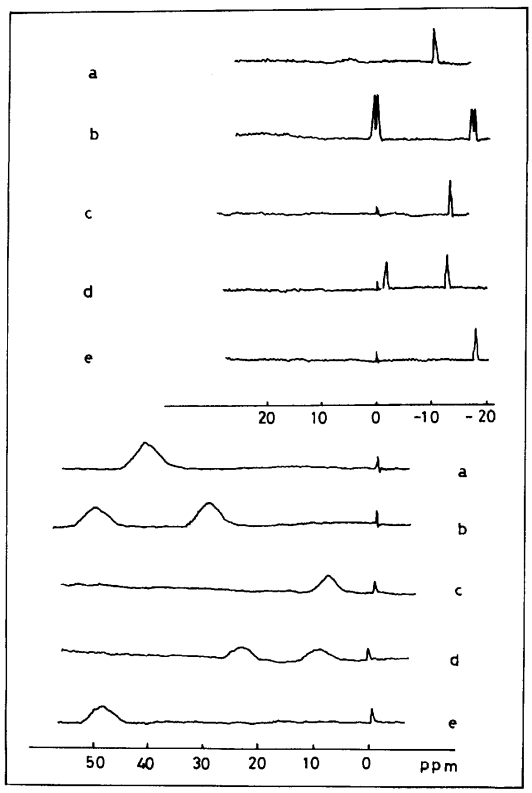

Fig. 1. ^{31}P NMR spectra of ligands(upper) and the complexes(lower).

TABLE 1. ^{31}P CHEMICAL SHIFTS OF THE FREE LIGANDS AND THEIR COMPLEXES

Ligand	Free	Complex	Δ
(a) $Ph_2PCH_2CH_2PPh_2$	−12.42	49.68	62.10
(b) $Ph_2PCH(CH_3)CH_2PPh_2$	−20.80	36.02	56.82
	0.93	60.24	59.31
(c) $Ph_2PCH_2CH_2CH_2PPh_2$	−17.17	9.32	26.49
(d) $Ph_2PCH(CH_3)CH_2CH_2PPh_2$	−16.77	9.33	26.10
	−2.64	24.84	27.48
(e) $Ph_2PCH=CHPPh_2$	−19.87	57.13	77.00

*δ ppm from H_3PO_4. $\Delta=\delta_{complex}-\delta_{free}$.

diphosphine chelate-ring complexes,[1,2] the Δ values of five-membered chelate rings are about two or three times as much as those of six-membered chelate rings. For example, the values of Δ for $[Pt(CH_3)_2dppe]$ and $[Pt(CH_3)_2dppp]$ are 67.7 and 20.5 ppm respectively. As is shown in Table 1, the coordination chemical shifts of the five-membered chelate rings obtained are twice as large as those of the six-membered chelate rings.

The coordination chemical shift of $[Co(acac)_2dpp]$ is 77 ppm, the largest of all the complexes studied here. It shoud be compared with the datum that the Δ value of +120 ppm for $[CpV(CO)_2(dpp)]$ (Cp=cyclopentadienyl) is slightly larger than that of +112 ppm for $[CpV(CO)_2(dppe)]$.[6]

Organometallic phosphine complexes have been reported to show relatively sharp signals, with couplings of the phosphorus atom to other nuclei of spin 1/2, while all the peaks studied here show broadening (half-width, *ca.* 100 Hz). Though the complexes containing the (b) and (d) ligands must have diastereomers, it is of no use to ascertain their geometries because the broad peaks were obtained. Several possible origins may be considered the broadening of the ^{31}P NMR peaks of cobalt(III) complexes: (a) a configurational change between Δ and Λ (b) a coupling between cobalt-59 and phosphorus atom, and (c) the paramagnetic effect. The (a) factor can easily be eliminated because $[Co(acac)_2(S\text{-}mdppe)]$ could be resolved to Δ and Λ isomers with Sephadex A-25 chromatography. No datum has been reported concerning any coupling between the cobalt-59 and phosphorus-31 atoms. The paramagnetic effect may broaden the ^{31}P signals, this parhaps because of cobalt(II) ion yielded by the following redox reaction.

$$2Co^{3+} + \gtrdot P + H_2O \longrightarrow 2Co^{2+} + \gtrdot P{=}O + 2H^+$$

However the ^1H NMR spectra of these complexes show sharp signals for all complexes. We can not explain this broadening well.

A Facile Method for Activation of Carboxylic Acids

Shizuaki MURATA

Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464

(Received March 13, 1984)

Synopsis. 1,1′-Oxalyldiimidazole, -1,2,4-triazole, and -1,2,3,4-tetrazole were prepared *in situ* from oxalyl dichloride and corresponding 1*H*-azoles. The 1,1′-oxalyldiazoles converted carboxylic acids and their salts into 1-acylazoles.

1-Acylazoles have been widely used as activated acyl species.[1] It was reported in a previous paper that 1,1′-oxalyldiimidazole[2] is a suitable reagent for the preparation of 1-acylimidazoles.[3] There remained, however, two problems worthy of further investigation; *i.e.* the isolation of the 1-acylazoles and the application to a variety of 1-acylazoles. In the present paper, these problems are examined and an effective method for the preparation of various 1-acylazoles is described.

1,1′-Oxalyldiimidazole (**1**) was reported to be prepared by the reaction of 1*H*-imidazole and oxalyl dichloride in the presence of a tertiary amine.[3] This procedure was found to also be applicable for the synthesis of other 1,1′-oxalyldiazoles. 1,1′-Oxalyldi-1,2,4-triazole (**2**) and -1,2,3,4-tetrazole (**3**) were formed in a reaction involving the corresponding 1*H*-azole and oxalyl dichloride in the presence of *N,N*-diisopropylethylamine at 0—30°C. *N,N*-Dicyclohexylmethylamine and 2,6-di-*t*-butylpyridine, as well as the 1*H*-azoles themselves, could be used for the hydrogen chloride acceptor. The resulting mixtures involving **2** and **3** were used in a follow-up reaction to prepare 1-acylazoles.

Now, the reaction of **2** or **3** with a carboxylic acid, such as linoleic acid (C 18, Δ=2), linolenic acid (C 18, Δ=3), and arachidonic acid (C 20, Δ=4), in chloroform proceeded with CO and CO_2 evolution to give the corresponding 1-acyl-1,2,4-triazole (**5**) or -1,2,3,4-tetrazole (**6**) in high yields. In DMF, **2** and **3** converted the lithium and sodium salts of those fatty acids into **5** and **6**. The isolation and purification of produced 1-linoleoylimidazole (**4a**), -1,2,4-triazole (**5a**), and -1,2,3,4-tetrazole (**6a**) were performed successfully by extraction with a light petroleum followed by distillation.

1-Linoleoylimidazole (**4a**) was converted into methyl linoleate (**7a**) by its treatment with methanol in the presence of potassium *t*-butoxide. It is known that the condensation of 1-acylimidazole **4** with an alcohol requires a basic catalyst.[1] Since the reaction of **5a** or **6a** with methanol proceeded smoothly in the absence of a basic catalyst, it may be concluded that **5** and **6** are more reactive than **4**. 1-Linolenoylimidazole (**4b**) and 1-arachidonoyltetrazole (**6c**) were converted into the methyl esters **7b** and **7c** by the same treatment. The results are summerized in Table 1.

carboxylic acids. Since 1,1'-oxalyldiazoles **1**—**3** can be prepared safely from easily available reagents and work in the mild conditions almost same as 1,1-carbonyldiimidazole, the utilization of **1**—**3** is suggested to be more suitable for a large-scale experiment.

Experimental

General. IR spectra were recorded on a JASCO IR A-102 spectrometer. ^{1}H NMR spectra were measured on JEOL PMX-60Si and Fx-90Q instruments. GLC analyses were done on a Gasukuro Kogyo Model 370 instrument using a capillary column of PEG 20 M (0.25 mm×25 m). Elemental analyses were performed at the Analytical Center of Faculty of Agriculture in Nagoya University. 1*H*-Azoles were dried over P_2O_5 *in vacuo*.

A General Procedure for 1-Acylazoles **4**—**6**. To a 1:1 mixture of a 1*H*-azole and *N,N'*-diisopropylethylamine in dry $CHCl_3$ or DMF (2—2.5 ml for 1 mmol) was added oxalyl dichloride (0.5 equiv), drop-by-drop, at −30—−10 °C. After 1—2h stirring, a fatty acid (or its salt) was added to the resulting mixture containing **1**, **2**, or **3**. This was stirred for 1 h at 0 °C, then warmed and maintained at an appropriate temperature for several hours. Three times the volume of petroleum ether or pentane was added to the solutions. A yellow-brown emulsion was separated into a colorless-yellow clear solution and a dark oil by centrifuge. Then, the oil was rinsed twice with the light petroleum. Concentration (40 °C, 6500 Pa) of the combined petroleum solutions yielded **4**—**6** as colorless-yellow oils. Bulb-to-bulb distillation of the oil gave an analytically pure sample.

1-Linoleoylimidazole[5] *(4a).* **4a** (89% (2.92 g) from linoleic acid, 88% (3.03 g) from sodium linoleate, 74% (0.28 g) from lithium linoleate): bp 230 °C (bath)/130 Pa; IR (neat) 1745 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) 8.15 (1H, brs, H(C5) of imidazole), 7.43 (1H, dd, J=1.3 Hz, H(C2)), 7.08 (1H, m, H(C3)), 5.37 (4H, m, CH=CH), 2.82 (2H, m, =CCH_2C=), 2.05 (6H, m, CH_2C= and CH_2CO), 1.37 (16H, br, CH_2), 0.89 (3H, brt, CH_3).

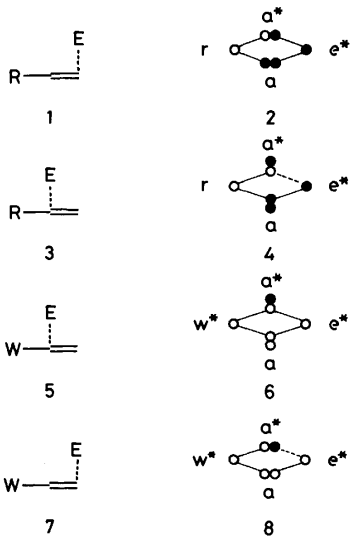
Orbital Phase Explanation of Regioselectivity of Organic Reactions

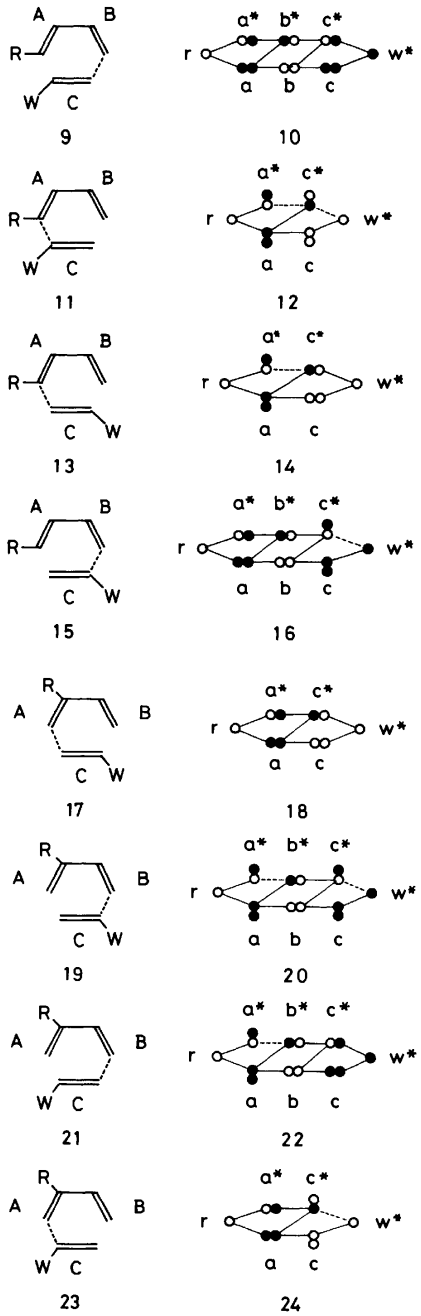
Satoshi INAGAKI
Department of Chemistry, Faculty of Engineering, Gifu University, Yanagido, Gifu 501-11
(Received May 7, 1984)

Synopsis. The regioselectivity of such fundamental organic reactions as electrophilic addition to olefins, Diels-Alder cycloaddition, and electrophilic aromatic substitution, can be explained by the phase continuity-discontinuity properties of orbitals involved in cyclic interaction for acyclic delocalization of electrons.

Electron delocalization in acyclic conjugated systems was recently found to involve cyclic interaction of orbitals of subsystems.[1] The acyclic delocalization is under control of the continuity-discontinuity property of orbital phase. The phase continuity requirement is simultaneous satisfaction of the following conditions: (i) the occupied orbitals out of phase; (ii) the vacant orbitals in phase; (iii) the occupied and vacant orbitals in phase. The concept of cyclic orbital interaction in acyclic conjugation has been applied[1-2] to explaining why cross-conjugation is thermodynamically more favorable than linear conjugation in polyanions while the thermodynamic preference is opposite for polyenes. The phase continuity-discontinuity properties of orbitals involved in acyclic delocalization have been employed to design a variety of interesting electron-localizing and delocalizing conjugated systems.[3] We show that acyclic delocalization under control of orbital phase covers the regioselectivity of fundamental organic reactions.

Addition of electrophile (E) to C=C bond (A) with electron-releasing (R) and -withdrawing (W) substituents selectively occurs at the β- and α-carbon, respectively. The transition state is considered as a system where three subsystems, R or W, A, and E interact in an acyclic manner. The electron delocalization from R to E *via* A can be expected to control the regioselectivity of the reactions. The orbitals involved in the delocalization are the occupied orbital (r) of R, the vacant orbital (e*) of E, and the bonding (a) and antibonding (a*) orbital of A. For the β- addition (**1**) the delocalization is favored by the orbital phase continuity (**2**), whereas the phase is discontinuous (**4**) for the α addition (**3**).[4] Similarly, the transition state of the electrophilic addition to W-substituted olefins is considered to be an interacting system composed of W, A, and E. The acyclic delocalization from A to W and E can be expected to



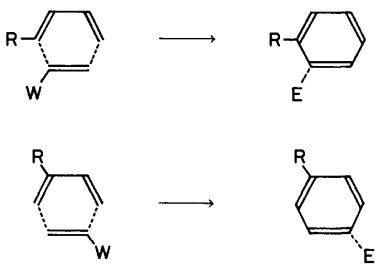


control the regioselectivity. The cyclic orbital interaction involves, a, a*, e*, and w*. The α-addition (**5**) is favored by the orbital phase continuity (**6**), the β-addition (**7**) being disfavored by the phase property (**8**).

A diene with R at a terminal carbon reacts with a W-substituted dienophile to preferentially give an "ortho"-cycloadduct. An R-substituent on an inner carbon leads to a "para"-cycloadduct. There are two pathways for the delocalization from R to W at cyclic transition state. The delocalization occurs through a long path *via* the substituted (A) and unsubstituted (B) double bonds in the diene and that (C) in the dienophile and through a short path *via* A and C. The delocalization along the long R-A-B-C-W path contains cyclic interaction among the occupied orbital (r) of R, the vacant orbital (w*) of W, the bonding (a, b, c) and antibonding (a*, b*, c*) orbitals of A, B, and C. The delocalization along the short R-A-C-W path involves the interaction among r, a, c, w*, c*, and a* orbitals. For the ortho-adduct formation from 1-R-diene the R-A-B-C-W delocalization (**9**) is favored by the orbital phase continuity (**10**), the R-A-C-W delocalization (**11**) being disfavored by the phase property (**12**). Neither is favored by phase property (**14**, **16**) for the meta-adduct formation (**13** and **15**). As a result, the orbital phase favors an acyclic delocalization path (**9**) at the transition state to the ortho-adduct.

A similar argument holds for the Diels-Alder reaction involving 2-R-diene. At the transition state to the para-product the delocalization along the R-A-C-W path (**17**) is favored by the orbital phase continuity (**18**), that along the R-A-B-C-W path (**19**) disfavored (**20**). The acyclic delocalization is disfavored (**22**, **24**) for both paths (**21** and **23**) at the transition state to the meta-cycloadduct.

The transition state model for the aromatic substitution can be formally generated from that for the Diels-Alder reactions as illustrated in Scheme. The



Scheme

incipient σ-bonds between diene and dienophile and π-type interaction between dienophile and W are replaced by π-type interactions in benzene and an incipient σ-bond between benzene and E. The preferential formation of ortho- and para-adducts in Diels-Alder reactions has been shown to be controlled by the acyclic delocalization. At the same qualitative level we can say that the ortho/para-orientation arises from the orbital phase properties for acyclic delocalization.

We gratefully acknowledge support of this work by a grant from the Ministry of Education, Science, and Culture.

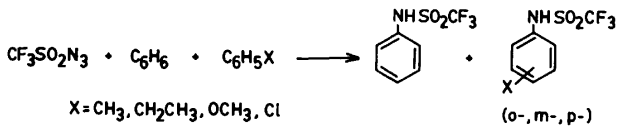
(Received June 7, 1984)

Synopsis. Thermolysis of trifluoromethanesulfonyl azide in solvents composed of 1:1 mixtures of benzene and substituted benzenes gives trifluoromethanesulfonanilide and substituted trifluoromethanesulfonanilides. The isomer ratios, the total rate ratios, and the partial rate factors for the sulfonamidation have been determined. By the intramolecular and intermolecular selectivities, the reaction mechanism involving trifluoromethanesulfonyl nitrene intermediate is discussed.

The thermal decomposition of sulfonyl azides in aromatic solvents was first reported by Curtius and Schmidt.[1] Abramovitch *et al.* studied the thermal reactions of methanesulfonyl azide with substituted benzenes and determined the isomer ratios, total rate ratios, and partial rate factors for the sulfonamidation.[2] We have studied the thermal reaction of trifluoromethanesulfonyl azide with monosubstituted benzenes since we have interest in the reactivities and selectivities of sulfonyl nitrenes possessing a strong electron-withdrawing group.

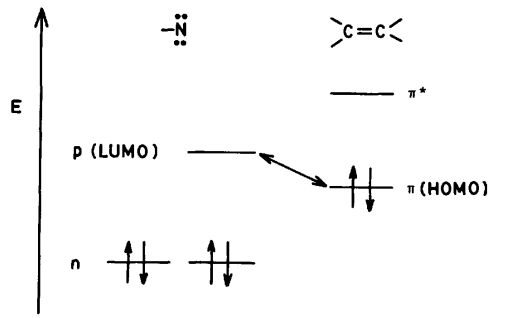
Thermal reactions of trifluoromethanesulfonyl azide in an equimolar mixture of benzene and substituted benzenes at 120 °C in a degassed sealed tube were carried out. The reaction products were trifluoromethanesulfonanilide and substituted trifluoromethanesulfonanilides which were analyzed on a silica-gel-column-packed HPLC using chloroform–ethanol as an eluent. The isomer ratio, the total rate ratios, and the partial rate factors for the trifluoromethanesulfonamidation were determined and the results are summarized in the Table together with those for sulfonamidation with methanesulfonyl azide.[2]



As shown in the Table, the partial rate factors for the trifluoromethanesulfonamidation of anisol are smaller than those for the methanesulfonamidation. Similar results were obtained in the sulfonamidation of toluene. Unfortunately, in the case of the sulfonamidation of toluene or ethylbenzene, ortho and meta or meta and para isomers of trifluoromethanesulfonanilides, respectively, could not be separated under various HPLC separating conditions. This implies that trifluoromethanesulfonyl nitrene intermediate formed by the thermolysis is more reactive and less selective than a methanesulfonyl nitrene. The fact that the total rate ratios for the trifluoromethanesulfonamidation of any substituted benzenes (especially that of chlorobenzene) are close to unity compared with methanesulfonamidation supports this interpretation. The trifluoromethanesulfonamidation has electrophilic nature since the total rate ratios are larger value in the electron-donating group (k_{OMe}/k, k_{Me}/k, and k_{Et}/k were 1.53, 1.12, and 1.10, respectively) and smaller value in the electron-withdrawing group (k_{Cl}/k=0.64). And also, no trifluoromethanesulfonamidation was observed in the reaction of triflazide with nitrobenzene. The ionic character indicates the trifluoromethanesulfonyl nitrene reacts in a singlet state.

$$CF_3SO_2N_3 \xrightarrow[-N_2]{} CF_3SO_2\ddot{N}$$

According to the frontier molecular orbital theory, the electrophilic reactions of a singlet carbene with olefins are directed by the interaction with lowest unoccupied molecular orbital (LUMO) of the carbene and highest occupied molecular orbital (HOMO) of the olefin.[3] This conception could be applied in the reaction of electrophilic nitrene with olefins as shown below. Trifluoromethyl group should decrease the



energy level of the LUMO (vacant p orbital) of the trifluoromethanesulfonyl nitrene in the singlet state compared with that of methanesulfonyl nitrene, thus the interaction of LUMO of trifluoromethanesulfonyl nitrene and HOMO of benzene becomes easier. Consequently, the trifluoromethanesulfonyl nitrene intermediate showed higher reactivities and lower selectivities (partial rate factors and total rate ratios are closer to unity) in the sulfonamidation of arenes compared with methanesulfonamidation.

The isomer ratios of the trifluoromethanesulfonamidation were similar to those for the methanesulfonamidation. According to the mechanism for the methanesulfonamidation of arenes proposed by Abramovitch *et al.*,[2] a singlet sulfonyl nitrene adds to the aromatic ring giving aziridine, followed by opening of the three membered ring affording the final product *via* a carbonium ion intermediate. If we assume a similar mechanism for the trifluoromethanesulfonamidation as shown below, the ring opening will be directed by the stability of carbonium ion which is effected by the substituent X in the aromatic ring and does not depend on the group attached on the sulfonyl group (methyl or trifluoromethyl). Therefore, intramolecular selectivities (isomer ratios) of sulfonamidation of monosubstituted benzenes are quite similar in the cases of trifluoro-

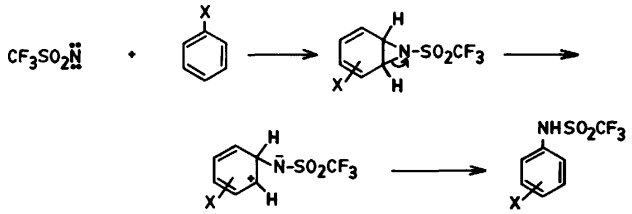
methanesulfonamidation and methanesulfonamidation.



Experimental

Materials. Trifluoromethanesulfonyl chloride was prepared from 25.0 g of trifluoromethanesulfonic acid treated with 50.0 g of phosphorus pentachloride at 100°C. The volatile component was trapped by an ice-bath and distilled to give 24.0 g (85%) of trifluoromethanesulfonyl chloride: bp 33°C. Trifluoromethanesulfonyl azide was prepared by dropping 8.4 g of trifluoromethanesulfonyl chloride into a slurry of 4.2 g of sodium azide in 60 cm^3 of acetonitrile with stirring at 0°C and the mixture was stirred for additional 3 h. The organic layer was extracted with decalin, the extract washed with water and dried over anhydrous magnesium sulfate. Careful distillation of the extract gave 6.8 g (78%) of trifluoromethanesulfonyl azide: bp 45°C/350 Torr (52.2°C/444 Torr:[4] 1 Torr=133.322 Pa); IR (neat) 1130, 1160, 1220, 1420, and 2150 cm^{-1}; Mass *m/z* 175 (M^+).

Preparation of Authentic Trifluoromethanesulfonimides. The general procedure described by Marvel *et al.* was used.[5] To a dichloromethane solution of 2 molar equiv of the amine was added 1 equiv of trifluoromethanesulfonyl chloride in dichloromethane at 0°C. The solution was stirred at room temperature for 3 h, and refluxed for 5 h. The reaction mixture was washed with 5% hydrochloric acid and water, then the organic layer was dried with anhydrous magnesium sulfate. Evaporation of the solvent left a residue which was subjected to Florisil column chromatography using benzene as eluent. The amide isolated was recrystallized from hexane.

Trifluoromethanesulfonanilide. Mp 65.5—66.0°C (66—67°C[6]); IR (KBr) 1140, 1200, 1360, and 3300 cm^{-1}; NMR ($CDCl_3$) δ=6.52 (1H, s) and 7.37 (5H, s); Mass *m/z* 226 (M^++1).

The Reaction of Trifluoromethanesulfonyl Azide with Substituted Benzenes. A solution of trifluoromethanesulfonyl azide (105 mg, 0.6 mmol) in benzene (2.34 g, 30 mmol) and monosubstituted benzene (30 mmol) was heated at 120°C in a degassed sealed tube for 24 h. The reaction mixture was subjected to Florisil column chromatography using hexane-ethyl acetate as eluent to remove the resinous by-product. The trifluoromethanesulfonanilide and substituted trifluoromethanesulfonanilides formed were analyzed by HPLC using silica-gel column and chloroform-ethanol as eluent. The isomer ratios and partial rate factors for the trifluoromethanesulfonamidation were determined. The overall yield of the amidation based on the trifluoromethanesulfonyl azide used was 50—80%. The results are summarized in Table 1.

A Simple Synthesis of Methyl 2,3,6- and 2,4,6-Tri-*O*-benzyl-α-D-mannosides

Shinkiti KOTO,* Kazuhiro TAKENAKA, Naohiko MORISHIMA, Akiko SUGIMOTO, and Shonosuke ZEN
School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108
(Received June 12, 1984)

Synopsis. Cotrolled benzylation of methyl α-D-mannopyranoside with benzyl chloride and LiOH selectively gave the 2,3,6-tribenzyl ether in a 53% yield. Such a reaction using benzyl chloride and KOH afforded mainly the 2,4,6-tribenzyl ether in a 41% yield. The products were allylated and then hydrolyzed to give the corresponding 1-OH derivatives.

Various methods for the synthesis of partially benzylated carbohydrates have been proposed.[1] This kind of compound, however, has often been prepared through direct benzylation[2] of readily available methyl glycosides.[3-5]

Benzylation of methyl α-D-mannopyranoside (**1**) in benzyl chloride (BnCl) and LiOH (8 equiv) at 140 °C for 9 h selectively gave the 2,3,6-tribenzyl ether **2** in a 53% yield. Benzylation of **1** in BnCl and KOH (4.5 equiv) at 140 °C for 3 h mainly furnished the 2,4,6-tribenzyl ether **3**[6] in a 41% yield.

A trace (<1%) of the 3,4,6-tribenzyl ether **4**[7] and an appreciable quantity (3—8%) of the 2,3,4-tribenzyl ether **5**[8] were always isolated from the reaction mixture. Controlled benzylation of the 3,4-dibenzyl ether **7**[9] also gave **5** as the main product. These show that the 2-OH group, rather than the 6-OH group, of **1** has an unusual susceptibility to benzylation.

Other mannosides, benzyl,[10] allyl,[11] and phenyl α-D-mannopyranosides[12] (**8**, **12**, and **16**) afforded preferentially the corresponding 2,3,6-tribenzyl ethers *via* the benzylation with LiOH.

The tribenzyl ethers, **2** and **3**, were allylated and hydrolyzed to the respective 1-OH derivatives, **20** and **21**.[6c]

Experimental[3-5]

4-O-Allyl-2,3,6-tri-O-benzyl-D-mannopyranose (20). Compound **2** (157.7 mg, 0.34 mmol) was allylated in allyl bromide (Wako, 3 ml) in the presence of NaH (Wako, 60%, 95 mg) at 70 °C for 2 h. The allyl ether was hydrolyzed in a mixture of AcOH (5.4 ml) containing aq H_2SO_4 (3M, 0.75 ml (1 M=1 mol dm^{-3})) at 100 °C for 1.3 h to gave **20** (70.0 mg, 42%).

3-O-Allyl-2,4,6-tri-O-benzyl-D-mannopyranose (21). Compound **3** (145.9 mg) was converted into **21** (50.8 mg, 33%).

Methyl 2-O-Acetyl-3,4,6-tri-O-benzyl-α-D-mannopyranoside. 1,2,3,4,6-Penta-*O*-acetyl-α-D-mannopyranose (Kyowa, 250 mg, 0.64 mmol) was stirred in CH_2Cl_2 (0.65 ml) containing

AcBr (Wako, 0.55 ml) and H_2O (0.11 ml).[14] After stirring for 3 h at room temperature, evaporation and co-evaporation with toluene gave a syrup, which was treated in $MeNO_2$ (0.64 ml) with 2,6-dimethylpyridine (0.24 ml) and MeOH (0.20 ml) at room temperature overnight. The mixture was diluted with $CHCl_3$, washed with aq $NaHCO_3$ (5%) and the organic layer evaporated to give a syrup, which was stirred in BnCl (4 ml) containing crushed KOH (1.0 g) at 110—120 °C for 2 h. After filtration and evaporation, the mixture was chromatographed on alumina (Woelm, 02084) just with hexane–toluene and subsequently with diisopropyl ether–2-butanone systems to give a syrup (294.2 mg). This was treated in CH_2Cl_2 (4 ml) with $BF_3 \cdot Et_2O$ (5 μl) at room temperature for 5 min, followed by chromatography, to give the titled compound (232.3 mg, 72%, $[\alpha]_D^{20}$ +26 °(*c* 6, $CHCl_3$), lit,[7a] $[\alpha]_D^{27}$ +27.9 ° (*c* 2.24, CH_2Cl_2). Found: C, 71.42; H, 6.80%. Calcd for $C_{30}H_{34}O_7$: C, 71.13; H, 6.77%).

This was quantitatively deacetylated with dil methanolic NaOMe to give **4**.

Benzylation of Methyl 3,4-Di-O-benzyl-α-D-mannopyranoside (7). The dibenzyl ether **7**[9] (63.5 mg, 0.17 mmol) was stirred in BnCl (1.2 ml) containing LiOH (12.2 mg at 140 °C for 9 h. Chromatography gave a trace of **6**,[13] **5** (21.7 mg, 28%), **4** (4.1 mg, 5%), and unchanged **7**.

When **7** (63.2 mg), KOH (14.3 mg) and BnCl (1.2 ml) was stirred at 140 °C for 3 h, **5** (15.6 mg, 20%) and **4** (12%) were obtained after chromatography.

Studies of Unusual Amino Acids and Their Peptides. XV. The Chemistry of *N*-Carboxymethyl Amino Acids. III. The Synthesis of *N*-Tosyl-*N*-carboxymethyl Amino Acid Derivatives by *N*-Alkoxycarbonylmethylation

Toshifumi MIYAZAWA,* Takashi YAMADA, and Shigeru KUWATA
Department of Chemistry, Faculty of Science, Konan University, Okamoto, Higashinada-ku, Kobe 658
(Received June 22, 1984)

Synopsis. The alkoxycarbonylmethylation of the amide nitrogen of *N*-tosyl amino acid esters with iodoacetic acid esters in the presence of silver(I) oxide in *N*,*N*-dimethylformamide afforded the corresponding *N*-tosyl-*N*-carboxymethyl amino acid esters in good yields without racemization of the amino acids.

Previous publications[1,2] from this laboratory have dealt with the first systematic investigation regarding the preparation and properties of *N*-carboxymethyl (Cm-) amino acids and their derivatives, especially their peptides. On the synthetic routes adopted, a Cm-amino acid[3] (or its ester) was at first prepared from the corresponding parent amino acid, and then converted to an appropriate *N*-protected intermediate for further derivation. As a possible alternative, we examined the carboxymethylation of the amide nitrogen of *N*-protected amino acid derivatives for preparing Cm-amino acid derivatives.

The *N*-alkylation of tosylamides, which has often been used as a preparative reaction, may also be applicable to *N*-alkoxycarbonylmethylation. Attempts to react *N*-tosyl amino acids with methyl iodoacetate in aqueous alkaline solutions,[4] however, were unsuccessful. On the other hand, the *N*-alkoxycarbonylmethylation of an *N*-tosyl amino acid ester (**1**) with an iodoacetic acid ester (**2**) in the presence of silver(I) oxide[5] yielded an *N*-tosyl Cm-amino acid derivative (**3**).

a) Isolated yield. b) Benzene–EtOAc (3:1). c) Obtained as crystals: **3d**, mp 100—101 °C ($CHCl_3$–hexane); **3e**, mp 47—49 °C (cyclohexane); **3f**, mp 60—61 °C (cyclohexane).

An investigation of the conditions for this reaction employing methyl *N*-tosylalaninate and methyl iodoacetate revealed that the best yield was obtained using the reactants in an 8:2:1 molar ratio (ICH_2CO_2-Me/Ag_2O/Tos-Ala-OMe) in *N*,*N*-dimethylformamide (DMF) after 24 h at room temperature. As can be seen from Table 1, several *N*-tosyl Cm-amino acid methyl esters (**3a—h**) were thus prepared from the methyl esters of *N*-tosyl monoamino mono- and dicarboxylic acids as substrates in a 70—80% isolated yield under the above reaction conditions. All the compounds, except **3d**, **3e**, and **3f**, were obtained as oils. Their homogeneity was demonstrated by elemental analyses, TLC on silica gel, and ^1H NMR spectral data. In the NMR spectra the absorption attributable to the methylene protons in the *N*-alkoxycarbonylmethyl group appeared at δ=3.8—4.4, in many cases as an AB quartet with J=18—19 Hz.

The above reaction conditions were also applicable to cases where R^1 on **1** and/or R^2 on **2** were groups other than the methyl group (**3i—n**). The Cm-amino acid derivatives carrying two different ester groups, such as **3l—n**, are practically useful intermediates for further derivation. When an *N*-tosyl amino acid itself was used as a substrate instead of its ester, *O*-alkoxycarbonylmethylation occurred simultaneously with the *N*-alkoxycarbonylmethylation. The analytical and spectral data were compatible with the assigned structures (**4**) of the products (Table 2, **4a—c**).

$$\text{Tos-}\overset{\text{OMe}}{\overset{|}{\text{C}}}\text{mAA-OCH}_2\text{CO}_2\text{Me}$$
4

The specific rotation of the *N*-tosyl Cm-amino acid dimethyl ester (**3a**, **3g**, or **3h**) prepared by the present method was in good accordance with that of a sample prepared by esterification with diazomethane of the corresponding *N*-tosyl Cm-amino acid synthesized previously.[2] Furthermore, the *N*-tosyl Cm-amino acid prepared by the catalytic hydrogenation of its dibenzyl ester (**3i** or **3k**) was identical in its specific rotation

TABLE 2. METHOXYCARBONYLMETHYLATION OF *N*-TOSYL AMINO ACIDS

Product **4**		Yield[a]	$[\alpha]_D^{25}$	TLC,
	AA	%	(MeOH)	R_f[b]

4b	Phe	73	−9.0° (*c* 1.6)	0.48
4c	Val	72	−68.4° (*c* 1.4)	0.49

a) Isolated yield. b) Benzene–EtOAc (3:1).

with an authentic sample.[2] These results indicate that no appreciable racemization occurred during *N*-alkoxycarbonylmethylation. In addition, since the yields for *N*-tosylation of free Cm-amino acids were rather low,[2] the present route to *N*-tosyl Cm-amino acid derivatives is a convenient alternative for preparing compounds containing Cm-amino acids.

The *N*-alkoxycarbonylmethylation of *N*-benzyloxycarbonyl amino acid esters would not proceed smoothly under the above conditions, nor even at an elevated temperature, in contrast to the corresponding *N*-methylation.[5]

Experimental

Optical rotations were measured with a JASCO DIP-4 polarimeter. Melting points are uncorrected. ^{1}H NMR spectra were recorded on a Hitachi R-24B spectrometer. TLC and preparative TLC were performed on Merck Kieselgel 60 F_{254} and Kieselgel GF_{254} (Type 60), respectively. All new compounds (**3a—n** and **4a—c**) gave satisfactory microanalysis (C, H, N ±0.3%).

General Procedure for the N-*Alkoxycarbonylmethylation of* N-*Tosyl Amino Acids and Their Esters.* *Methyl* N-*Tosyl*-N-*(methoxycarbonylmethyl)alaninate (**3a**)*: A solution of Tos-Ala-OMe (130 mg, 0.5 mmol) and ICH_2CO_2Me (800 mg, 4 mmol) in DMF (4 ml) was stirred at room temperature with Ag_2O (232 mg, 1 mmol) in the dark for 24 h. The reaction mixture was filtered, and the filtrate was mixed with $CHCl_3$, washed with 5% $Na_2S_2O_3$ and water, and dried over Na_2SO_4. Evaporation of the solvent *in vacuo* afforded a syrup, which was chromatographed on preparative layers of silica gel with benzene–EtOAc (49:1); yield, 125 mg (76%); syrup, $[\alpha]_D^{25}$ −54.7° (*c* 0.79, MeOH).

Methoxycarbonylmethyl N-*Tosyl*-N-*(methoxycarbonylmethyl)alaninate (**4a**)*: Tos-Ala (130 mg, 0.5 mmol) was reacted with ICH_2CO_2Me (800 mg, 4 mmol) in the presence of Ag_2O (464 mg, 2 mmol) in DMF (4 ml) for 36 h. After a work-up similar to the above, the final purification was performed by preparative TLC with benzene–EtOAc (9:1); yield, 130 mg (66%); syrup, $[\alpha]_D^{25}$ −37.3° (*c* 0.67, MeOH).

Preparation of the Dimethyl Esters from N-*Tosyl Cm-amino Acids by Treatment with Diazomethane.* *Tos-CmAla-OMe*: Tos-CmAla[2] (215 mg) was dissolved in EtOAc and treated with an ethereal solution of CH_2N_2 as usual. Purification by preparative TLC with benzene–EtOAc (49:1) afforded a syrup; yield, 219 mg (93%); $[\alpha]_D^{25}$ −55.2° (*c* 1.0, MeOH).

Tos-CmPhe-OMe ($[\alpha]_D^{25}$ −13.2° (*c* 0.66, MeOH)) and Tos-CmVal-OMe ($[\alpha]_D^{25}$ −70.8° (*c* 0.96, MeOH)) were prepared from Tos-CmPhe[2] and Tos-CmVal,[2] respectively, in the same manner as above.

N-*Tosyl Cm-amino Acids Prepared by Catalytic Hydrogenation of Their Dibenzyl Esters.* *Tos-CmVal*: **3k** (285 mg) was hydrogenated in dioxane (15 ml) in the presence of 5% Pd-C (140 mg). After the absorption of hydrogen had ceased, the catalyst was filtered off and the filtrate evaporated *in vacuo*. The residue was dissolved in ether and extracted with 5% $NaHCO_3$. The extracts were combined, washed with ether, and acidified with 4 M HCl (1 M=1 mol dm^{-3}) to pH 2. The turbid mixture was extracted with EtOAc. The extracts were combined, washed with water, and dried over Na_2SO_4. Evaporation of the solvent afforded crystals; yield, 140 mg (76%); mp 179.5—181 °C (EtOAc–hexane), $[\alpha]_D^{25}$ −55.4° (*c* 0.70, MeOH). Lit,[2] mp 179.5—181 °C, $[\alpha]_D^{25}$ −55.6° (*c* 1.0, MeOH).

Tos-CmAla was prepared from **3i** in the same manner as above; $[\alpha]_D^{25}$ −33.2° (*c* 0.62, MeOH). Lit,[2] $[\alpha]_D^{25}$ −33.7° (*c* 0.82, MeOH).

^{1}H NMR Spectra (CDCl$_3$) of Products, 3 and 4. **3a**: δ=1.31 (3H, d), 2.39 (3H, s), 3.47 (3H, s), 3.62 (3H, s), 3.95 and 4.12 (2H, ABq), 4.36 (1H, q), 7.19 and 7.65 (4H, ABq).

3b: δ=2.40 (3H, s), 2.7—3.0 (2H, 4 peaks), 3.50 (3H, s), 3.55 (3H, s), 3.59 (3H, s), 4.02 (2H, s), 4.68 (1H, *t*-like), 7.21 and 7.65 (4H, ABq).

3c: δ=1.6—2.8 (4H, m), 2.40 (3H, s), 3.47 (3H, s), 3.61 (3H, s), 3.69 (3H, s), 3.92 and 4.19 (2H, ABq), 4.46 (1H, q), 7.25 and 7.69 (4H, ABq).

3d: δ=2.40 (3H, s), 3.61 (6H, s), 4.16 (4H, s), 7.25 and 7.65 (4H, ABq).

3e: δ=0.7—1.0 (6H, m), 1.1—2.0 (3H, m), 2.39 (3H, s), 3.41 (3H, s), 3.64 (3H, s), 3.86 (1H, d), 4.00 and 4.30 (2H, ABq), 7.22 and 7.70 (4H, ABq).

3f: δ=0.83 and 0.86 (6H, 2× d), 1.1—2.0 (3H, m), 2.40 (3H, s), 3.47 (3H, s), 3.69 (3H, s), 4.11 (2H, s), 4.38 (1H, *t*-like), 7.26 and 7.72 (4H, ABq).

3g: δ=2.36 (3H, s), 2.86 and 2.99 (2H, *d*-like), 3.30 (3H, s), 3.59 (3H, s), 4.11 and 4.13 (2H, 2× *s*-like), 4.42 (1H, *t*-like), 7.04 (5H, s), 7.12 and 7.61 (4H, ABq).

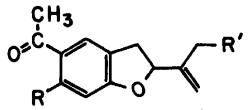
(Received June 23, 1984)

Synopsis. 2-Isopropenyl-6-methoxy-2,3-dihydrobenzofuran, prepared from *m*-methoxyphenol and 1,4-dibromo-2-methyl-2-butene, was converted to racemic dihydroageratone *via* oxidation with selenium dioxide, the acetylation with acetic acid–trifluoroacetic anhydride, and the demethylation with magnesium iodide etherate.

Some syntheses of 2-isopropenyl-2,3-dihydrobenzofuran derivatives were reported. They mainly consisted of two methods; one was the dehydration of 2-(1-hydroxy-1-methylethyl)-2,3-dihydrobenzofurans and the other was our one-step cyclization of the phenols and 1,4-dibromo-2-methyl-2-butene.[1] We have already reported the synthesis of 5-acetyl-2-[1-(hydroxymethyl)-vinyl]-2,3-dihydrobenzofuran (**1**) having an oxidized isopropenyl group.[2] Dihydroageratone (**2**), isolated from *Ageratum houstnianum* by Anthonsen and Chanthrasakul, also exhibited an oxidized side chain.[3] Here, we describe the synthesis of the dihydroageratone (**2**) having an oxidized isopropenyl and a phenolic hydroxyl group.



1 R=H, R′=OAc
2 R=OH, R′=OAc
3 R=OH, R′=H

Chart 1.

For the synthesis of **2**, a key step was to remove the protection of the phenolic hydroxyl group. In the syntheses of hydroxytremetone (**3**), Oda *et al.* used alkaline hydrolysis for the removal of the acetyl group[4] and Harada *et al.* used hydrogenolysis for the removal of the benzyl group.[5] However, in our one-step cyclization using sodium metal, the protection by *O*-acetylation was unsuitable, and the deprotection of a benzyl group by hydrogenolysis or acidic cleavage might have caused a hydrogenation or an isomerization on the isopropenyl side chain. However, we were able to remove the protection by demethylation with magnesium iodide etherate without affecting the isopropenyl group.

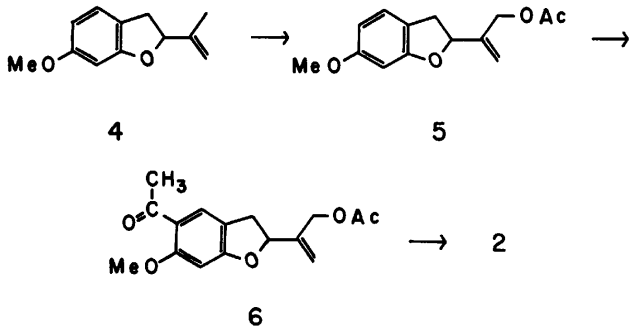


Chart 2.

We have already described the preparation of 2-isopropenyl-6-methoxy-2,3-dihydrobenzofuran (**4**) from *m*-methoxyphenol and 1,4-dibromo-2-methyl-2-butene.[1] When the dihydrobenzofuran **4** was heated with selenium dioxide in refluxing acetic anhydride for 7 h, 2-[1-(acetoxymethyl)vinyl]-6-methoxy-2,3-dihydrobenzofuran (**5**) was obtained in 7.1% yield. A carbonyl absorption at 1740 cm^{-1} in the IR spectrum and a methyl signal at δ 1.9 in the ^1H NMR spectrum showed the exsistence of an acetoxyl group. Further, a methylene signal at δ 4.6 showed that the acetoxyl group was on the methyl carbon in the isopropenyl group. Acylation of the acetate **5** with acetic acid–trifluoroacetic anhydride at room temperature for 3 h gave 2-[1-(acetoxymethyl)vinyl]-5-acetyl-6-methoxy-2,3-dihydrobenzofuran (**6**) in 48.3% yield. A new carbonyl absorption in the IR spectrum and two singlets at δ 6.5 and 7.7 in the ^1H NMR specturm indicated that the acetylation was at position 5. Refluxing the keto-acetate **6** with magnesium iodide etherate in dry benzene for 3 h gave the corresponding demethylated product **3** in 20.5% yield without any isomerization. Carbonyl absorption at 1635 cm^{-1} in the IR specturum and a signal at δ 13.0 in the ^1H NMR indicated the formation of intramolecular hydrogen bonding. This reagent was very useful for the demethylation of a methoxyl group in the ortho position of an acyl group in mild conditions. The spectral data of this demethylated product **3** were identical with reported data of natural dihydroageratone.[3]

Two methoxy ketones, 5-acetyl-2-isopropenyl-4-methoxy- and -6-methoxy-2,3-dihydrobenzofuran (**7** and **8**) have already been reported.[1] They were similarly demethylated with magnesium iodide etherate to give corresponding hydroxy ketones, **9** and **3**. The spectral data of the hydroxyketone **3** were identical with those of natural hydroxytremetone.[6] However, the other hydroxy ketone, 5-acetyl-6-hydroxy-2-isopropenyl-2,3-dihydrobenzofuran (**9**), did not agree with the natural compound[7] in the spectral data. Both samples showed intramolecular hydrogen bonding in their IR and ^1H NMR spectra. However, in the ^1H NMR spectra, our synthetic sample showed aromatic signals at δ 6.3 and 7.5, while the natural sample showed them at δ 6.81 and 6.99. This indicated that the natural compound had another structure, 4-acetyl-5-hydroxy-2-isopropenyl-2,3-dihydrobenzofuran or 7-acetyl-6-hydroxy-2-isopropenyl-2,3-dihydrobenzofuran, having a hydrogen-bonding between a phenolic hydroxyl group and an acetyl group and no aromatic proton in ortho position of an acetyl group.[8]

Experimental

The boiling points were uncorrected (in boiling points:

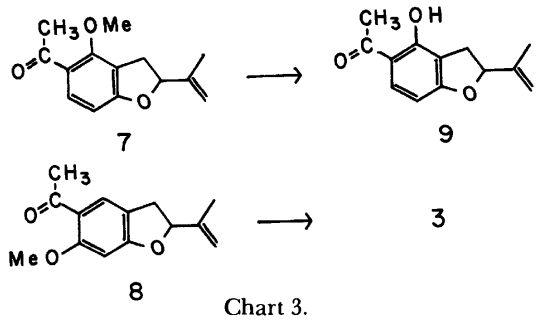

Chart 3.

1 mmHg=133.322 Pa). The IR spectra were measured on a Hitachi EPI-S2 spectrophotometer in a liquid film and the UV spectra were taken on a Hitachi 220 A spectrophotometer in an ethanolic solution. The ^{1}H NMR spectra were recorded on a JEOL JNM-MH-60 NMR spectrometer and the mass spectra were recorded on a JEOL JMS-OISG-2 mass spectrometer.

2-[1-(Acetoxymethyl)vinyl]-6-methoxy-2,3-dihydrobenzofuran (5). To a solution of 2-isopropenyl-6-methoxy-2,3-dihydrobenzofuran (**4**)[1] (1.08 g, 5.68 mmol) in acetic anhydride (15 ml), powdered selenium dioxide (578 mg, 5.21 mmol) was added, and the mixture was refluxed for 7 h. After cooling, the mixture was diluted with ether and filtered. The ether and the excess acetic anhydride was removed from the filtrate under reduced pressure. The residue was dissolved in ether and the ethereal solution was washed with saturated sodium hydrogencarbonate solution and then with saturated sodium chloride solution, and dried over anhydrous sodium sulfate. After the removal of the ether, the residual oil was purified on a silica-gel column. Fractions eluted with benzene gave pure 2-[1-(acetoxymethyl)vinyl]-6-methoxy-2,3-dihydrobenzofuran (**5**) (100 mg, 7.1%) as an oil; IR (neat) 1740 cm^{-1}. ^{1}H NMR (CCl_4) δ=2.0 (3H s), 3.0 (1H, dd, J=16 and 9 Hz), 3.3 (1H, dd, J=16 and 9 Hz), 3.7 (3H, s), 4.6 (2H, broad s), 5.1 (1H, broad s), 5.2 (1H, t, J=9 Hz), 5.3 (1H, broad s), 6.3 (2H, m), and 6.9 (1H, d, J=9 Hz).

Found: C, 67.57; H, 6.73%; M$^+$ 248. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%; M$^+$ 248.

2-[1-(Acetoxymethyl)vinyl]-5-acetyl-6-methoxy-2,3-dihydrobenzofuran (6). By a method similar to one described in our previous parer,[1] 2-[1-(acetoxymethyl)vinyl]-6-methoxy-2,3-dihydrobenzofuran (**5**)(200 mg, 0.806 mmol) was acetylated with acetic acid (97 mg, 1.6 mmol) and trifluoroacetic anhydride (500 mg, 2.38 mmol) at room temperature for 3 h, and gave a crude oil (229 mg). The crude oil was purified on a silica-gel column. Fractions eluted with chloroform gave pure 2-[1-(acetoxymethyl)vinyl]-5-acetyl-6-methoxy-2,3-dihydrobenzofuran (**6**) (113 mg, 48.3%) as an oil; bp 230—250 °C/15 mmHg (bath temp). IR (neat) 1740 and 1660 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.1 (3H, s), 2.6 (3H, s), 3.2 (1H, dd, J=16 and 9 Hz), 3.4 (1H, dd, J=16 and 9 Hz), 3.9 (3H, s), 4.7 (2H, s), 5.3 (1H, broad s), 5.4 (1H, broad s), 5.4 (1H, t, J=9 Hz), 6.5 (1H, s), and 7.7 (1H, s).

Found: C, 66.42; H, 6.31%; M$^+$ 290. Calcd for $C_{16}H_{18}O_5$: C, 66.19; H, 6.25%; M$^+$ 290.

2-[1-(Acetoxymethyl)vinyl]-5-acetyl-6-hydroxy-2,3-dihydrobenzofuran (Racemic Dihydroageratone) (2). To magnesium metal (21 mg, 0.80 mmol) in dry ether (0.24 ml) and dry benzene (0.5 ml), iodine crystals (108 mg, 0.850 mmol) were added in small portions. The mixture was stirred until the iodine color disappeared (*ca.* 3 h). A solution of 2-[1-(acetoxymethyl)-vinyl]-5-acetyl-6-methoxy-2,3-dihydrobenzofuran (**6**) (165 mg, 0.638 mmol) in dry benzene was added to the benzene solution of magnesium iodide etherate prepared previously. The mixture was then refluxed for 3 h. After cooling, the mixture was poured onto 10% hydrochloric acid and extracted with ether. The ethereal solution was washed with a saturated sodium hydrogencarbonate solution and dried over anhydrous sodium sulfate. After the removal of the ether and benzene, the residual oil was purified on a silica-gel column. Fractions eluted with chloroform gave pure 2-[1-(acetoxymethyl)vinyl]-5-acetyl-6-hydroxy-2,3-dihydrobenzofuran (**2**) as an oil; bp 247—255 °C/15 mmHg. IR (neat) 1740 and 1635 cm^{-1}. UV (EtOH) 238 (log ε 4.47), 277 (4.29), and 325 nm 4.11). ^{1}H NMR (CCl_4) δ=2.0 (3H, s), 2.5 (3H, s), 3.1 (1H, dd, J=16 and 9 Hz), 3.4 (1H, dd, J=16 and 9 Hz), 4.5 (2H, s), 5.4 (2H, broad s), 5.4 (1H, t, J=9 Hz), 6.5 (1H, s), 7.5 (1H, s), and 13.0 (1H, s). Mass m/z 276 (M$^+$), 216 (M$^+$—$C_2H_4O_2$), and 176 (M$^+$—$C_5H_8O_2$).

Found: C, 65.29; H, 6.06%; M$^+$ 276. Calcd for $C_{15}H_{16}O_5$: C, 65.21; H, 5.84%; M$^+$ 276.

Those spectral data agreed with the reported data of natural dihydroageratone.[3]

Demethylation of 5-Acetyl-2-isopropenyl-4-methoxy- and -6-methoxy-2,3-dihydrobenzofuran (7 and 8). By a method similar to that described for the preparation of **2**, 5-acetyl-2-isopropenyl-4-methoxy- or -6-methoxy-2,3-dihydrobenzofuran (**7** or **8**) was demethylated with magnesium iodide etherate to give 5-acetyl-4-hydroxy-2-isopropenyl-2,3-dihydrobenzofuran (**9**); yield 42.1%; bp 190—215 °C/15 mmHg (bath temp); IR (neat) 1645 cm^{-1}; UV (EtOH) 234 (logε 3.94), 241 (3.94), and 288 nm (4.19); ^{1}H NMR (CCl_4) δ=1.8 (3H, broad s), 2.5 (3H, s), 3.0 (1H, dd, J=16 and 10 Hz), 3.3 (1H, dd, J=16 and 10 Hz), 4.9 (1H, broad s), 5.1 (1H, broad s), 5.3 (1H, t, J=10 Hz), 6.3 (1H, d, J=10 Hz), 7.5 (1H, d, J=10 Hz), and 12.7 (1H, s); Mass m/z 218 (M$^+$) and 203 (M$^+$ —CH_3). Found: C, 71.35; H, 6.38%; M$^+$ 218. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%; M$^+$ 218; and 5-acetyl-6-hydroxy-2-isopropenyl-2,3-dihydrobenzofuran (**3**); yield 44.7%; IR (neat) 1640 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.7 (3H, broad s), 2.4 (3H, s), 2.9 (1H, dd, J=16 and 9 Hz), 3.2 (1H, dd, J=16 and 9 Hz), 4.9 (1H, broad s), 5.0 (1H, broad s), 5.2 (1H, t, J=9 Hz), 6.2 (1H, s), 7.4 (1H, s), and 12.7 (1H, s).

The hydroxy ketone **3** was identical to natural hydroxytremetone[6] in their IR and ^{1}H NMR spectra, but the other hydroxy ketone **9** did not agreed with that of the natural compound (reported by Bohlmann *et al.*).[7,8]

We wish to thank Professer Dr. Ferdinand Bohlmann for providing copies of the IR and ^{1}H NMR spectra of natural compound.

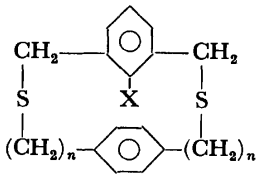
^{1}H-NMR Study of the Aromatic-ring Motion in 3,12-Dithia-[4.4]metaparacyclophanes

Kazuhiko TSUCHIYA, Tetsuo TAKEMURA, and Nobuo MORI*
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received June 27, 1984)

Synopsis. In 10-substituted 3,12-dithia[4.4]metaparacyclophanes, the free energy barrier to the rotation of the para-bridged ring increases with the substituent in the order: H<F<CH_3O<Cl, whereas for the flipping of the meta-bridged ring, the order of CH_3O and Cl is reversed. This is discussed in terms of the steric-size anisotropy of the CH_3O group.

There have been several ^{1}H-NMR and stereochemical studies of the aromatic-ring motion in [2.2]- and 2,11-dithia[3.3]metaparacyclophanes. In [2.2]metaparacyclophane itself, the meta-ring can flip[1] even with a sizable energy barrier to flipping,[1-4] but the para-ring can not rotate because of the severe nonbonded interaction between the para-ring and the 8-hydrogen atom.[1,3,4] In the dithia[3.3]phanes,[4,5] where there is a much weaker interaction between the para-ring and a substituent at the 9-position, it becomes easier for both rings to move, the facility being dependent on the steric size of the 9-substituent.[5]

In the present work, we have investigated the relative motility of the two benzene rings in 3,12-dithia-[4.4]- and 4,13-dithia[5.5]metaparacyclophanes, **1—5**, by means of ^{1}H-NMR spectroscopy.



Compound	n	X
1	2	H
2	2	F
3	2	Cl
4	2	CH_3O
5	3	CH_3O

In **1—5**, the rotation of the para-ring and the flipping of the meta-ring were followed separately, as was done in the dithia[3.3]phanes,[5] by variable-temperature measurements of the 100-MHz spectra of the para-ring protons and of the meta-bridged benzylic methylene protons.

In **1**, the para-ring and the 4,11-methylene protons showed sharp, temperature-independent singlets at δ 6.83 and 3.45 respectively down to −51 °C, indicating a rapid rotation of the para-ring and a rapid flipping of the meta-ring in the temperature range examined. The bridging ethylene protons also showed a temperature-independent AA'BB' multiplet down to −51 °C.

In **2**, the para-ring and the methylene protons showed sharp singlets at δ 6.70 and 3.44 respectively at room temperature; each of them became broader as the temperature dropped down to −51 °C. The ethylene protons showed an AA'BB' multiplet at room temperature; this multiplet approached an ABCD system with the drop in the temperature.

In **3**, the para-ring protons showed two narrow AA'XX' multiplets centered at δ 6.44 and 6.87 at room temperature; they coalesced to a broad singlet at 88 °C and became a sharp singlet at 120 °C. On the other hand, at room temperature the 4,11-methylene protons showed an AB quartet (δ 3.35, 3.69; J=15 Hz) which coalesced at 133 °C. The ethylene protons showed a very wide, unsymmetrical, finely split ABCD multiplet at low temperature; this multiplet approached an AA'BB' multiplet with the rise in the temperature.

The low-temperature spectrum of **4** was very similar to that of **3**. The two multiplets due to the para-ring protons (δ 6.48, 6.80) coalesced at 54 °C, whereas the AB quartet due to the two-methylene protons (δ 3.29, 3.64; J=15 Hz) was temperature-independent up to 162 °C. The ethylene protons gave an ABCD multiplet at low temperatures; this multiplet approached an AA'BB' system with the rise in the temperature.

In **5**, the para-ring protons showed a temperature-independent sharp singlet down to −51 °C, whereas the 5,12-methylene protons gave, at −40 °C, an AB quartet (δ 3.38, 3.84; J=15 Hz) which coalesced at 15 °C.

The table gives the free-energy barriers to ring motion (ΔG^*), estimated using the chemical-shift difference at a low temperature ($\Delta\nu$) and the coalescence temperature (T_c).[6] It can be noticed that, in **1—4**, the free-energy barrier to rotation of the para-ring increases with X in the order: H<F<CH_3O<Cl, whereas for the flipping of the meta-ring the order of CH_3O and Cl

TABLE 1. ^{1}H-NMR DATA FOR COMPOUNDS **1—5**

Compound	X	Solvent	Protons concerned	$\Delta\nu$/Hz	T_c/°C	ΔG^*/kcal mol^{-1}[b]
1	H	$CDCl_3$	*p*-ArH	—	$\ll -51$	—[c]
			m-$ArCH_2$	—	$\ll -51$	—[c]
2	F	$CDCl_3$	*p*-ArH	—	< -51	—[c]
			m-$ArCH_2$	—	< -51	—[c]
3	Cl	DMSO-d_6	*p*-ArH	43.0[a]	88	18
			m-$ArCH_2$	33.8[a]	133	21
4	CH_3O	DMSO-d_6	*p*-ArH	32.0	54	16
			m-$ArCH_2$	34.9	$\gg 162$	>22
5	CH_3O	$CDCl_3$	*p*-ArH	—	$\ll -51$	—
			m-$ArCH_2$	46.3	15	14

a) Values in $CDCl_3$. b) 1 cal=4.184 J. c) Since the spectrum of **2** was temperature-dependent but that of **1** was temperature-independent, ΔG^* for **2** can be expected to be larger than that for **1**.

is reversed.[7] This may be explained in terms of the anisotropy of the steric size of the methoxyl group. If the para-ring rotation is influenced dominantly by the nonbonded interaction of X with the para-ring, the free-energy barrier should correlate with the net size of the C-X moiety, which can be approximately estimated as the sum of the bond length of C_{sp^2}–X and the steric size (or the van der Waals radius) of X. This is the case only, however, when X is a single atom: the order of the net size is 2.2 for H<2.7 for F<3.5 Å for Cl. For CH_3O, the net size is estimated to be *ca.* 4.0 Å in the direction along the C–OCH_3 bond axis, but this is too large. Molecular models suggest that, in **4**, the CH_3 moiety of the CH_3O group is not a severe obstacle to the rotating of the para-ring when it is not very much distorted out of the plane of the attached meta-ring. Neglecting the steric size of the CH_3 moiety, the size estimation leads to a net size of *ca.* 2.8 Å (the sum of the bond length of C_{sp^2}–O and the van der Waals radius of O), a value between those for F and Cl. Thus, this or a somewhat larger size seems rather reasonable.

On the other hand, the meta-ring flipping may be influenced not only by the above X···para-ring interaction, but also by the nonbonded interaction of X with the bridging chains. This interaction should be dependent on the van der Waals radius of X, if X is a single atom. Of importance for CH_3O is the net size in the direction along the O–CH_3 bond axis, when the CH_3 moiety is substantially coplanar with the attached meta-ring. The order of the size of X estimated in this way is 1.2 for H<1.35 for F<1.8 for Cl<3.4 Å for CH_3O, in agreement with the order of $\Delta G^{\neq}$.

The lower $\Delta G^{\neq}$ values for **5** give further evidence for the dependence of the ring motions on the length of the bridging chains or on the nonbonded interaction between X and the para-ring.

Experimental

Samples. **1** was prepared by the literature method:[8] Mp 81.0°C. **2**—**5** are unknown and were similarly prepared using the corresponding 2-substituted *m*-xylenes.

2: Mp 113.3—113.8°C; Found: C, 67.78; H, 6.02; S, 19.51%; M^+, 318. Calcd for $C_{18}H_{19}S_2F$: C, 67.89; H, 6.01; S, 20.13%; M^+, 318.

3: Mp 132.1—132.4°C; Found: C, 64.70; H, 5.73; S 19.05%; M^+, 334. Calcd for $C_{18}H_{19}S_2Cl$: C, 64.55; H, 5.72; S, 19.15%; M^+, 334.

4: Mp 93.4—94.2°C; Found: C, 69.00; H, 6.79; S, 19.08%; M^+, 330. Calcd for $C_{19}H_{22}S_2O$: C, 69.05; H, 6.71; S, 19.40%; M^+, 330.

5: Mp 80.2—81.3°C; Found: C, 70.75; H, 7.35; S, 17.90%; M^+, 358. Calcd for $C_{21}H_{26}S_2O$: C, 70.34, H, 7.31; S, 17.89%; M^+, 358.

^{1}H-NMR spectra were recorded on a JEOL JNM-FX 100 spectrometer (100 MHz) for solutions of *ca.* 10 w/v% in dimethyl-d_6 sulfoxide or chloroform-*d*; the measurement temperature was that in the probe. Mass spectra were recorded on a HITACHI M-80 spectrometer.
