
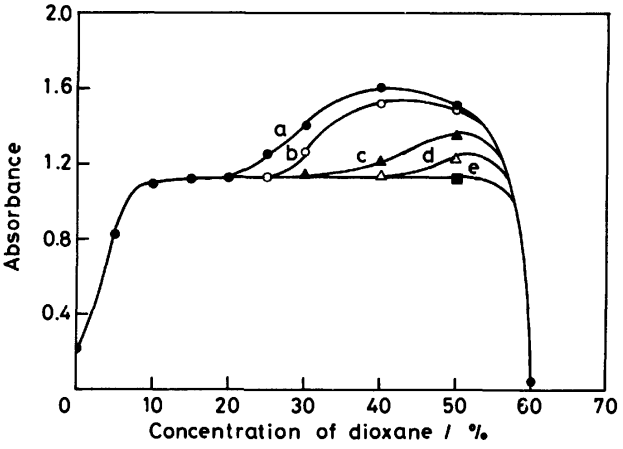

Fig. 4. Profile for the formation and survival of β-molybdophosphate in aqueous dioxane media at the time: (a) 6 min, (b) 20 min, (c) 2 h, (d) 5 h, and (e) 14 h.

† Let $C_{\alpha,t}$ and $C_{\beta,t}$ be the respective concentrations of α and β-molybdophosphate at time t during the conversion. The values of $C_{\alpha,t}$ (or those of $C_{\beta,t}$) were calculated by solving the following equations: $E_t=\varepsilon_\alpha \cdot C_{\alpha,t}+\varepsilon_\beta \cdot C_{\beta,t}$ and $C=C_{\alpha,t}+C_{\beta,t}$, where ε_α and ε_β denote the molar absorption coefficients of α- and β-molybdophosphate at 420 nm (being calculated from the final and the initial absorbances in Fig. 1 as 1.60×10^3 and 9.70×10^2 l mol^{-1} cm^{-1}, respectively), C is the total concentration of molybdophosphate and is known as 1×10^{-3} M in this experiment. The plot of log $C_{\beta,t}$ against time gave a straight line and the first-order rate constant for the conversion reaction was evaluated from the slope of the line.

observed at all. Only at elevated temperatures above 30 °C, extraordinary absorbances could be observed,[7] although they decreased to the ordinary values within several seconds. In consequence, it can be said that at these lower acetonitrile concentrations, β-molybdophosphate scarecely exists because of a rapid conversion to α-molybdophosphate.

β-Molybdophosphate can similarly be stabilized by virtue of acetone or dioxane in the reaction medium. The formation and the conversion of the complex in these media are illustrated in Figs. 3 and 4. By comparing Figs. 2—4, it is shown that any of the organic solvents employed here have essentially the same effect on the formation of β-molybdophosphate but the largest effect is attained by acetone, the complex being stabilized to exist even after 5 h in 60% acetone medium (curve d in Fig. 3, for example).

Preparation of α- and β-Molybdophosphate. As the most convenient method for preparing α-and β-molybdophosphate individually, the following procedures and conditions are recommended.

To obtain a 10-cm³ solution of either α- or β-molybdophosphate add a desired amount (should be less than 200 mm³, however) of 0.1 M phosphate standard solution into a 10-cm³ aliquot of the mixed molybdate reagent composed of 0.05 M Mo(VI)/1.2 M HCl/40% acetonitrile (being equilibrated at 25 °C) and shake the mixture well.. Thus, β-molybdophosphate will be formed instantaneously and will survive almost entirely through the following 20 min (during which, the degree of the conversion can be practically neglected). To obtain α-molybdophosphate, stand the same solution for more than 6 h. It is quite possible, of course, to prepare the complexes in an aqueous acetone medium. But, note that when acetone is used instead of acetonitrile β-molybdophosphate takes several minutes to form and takes a few days to convert to α completely. Also note, when dioxane is used, the complex forms in 2 min and converts to the other complex in *ca.* 6 h.

From the foregoing examinations, it is obvious that β-molybdophosphate should be prepared freshly for every use and exercised out within 20 min after preparation. However, α-molybdophosphate is stable enough to be stored for at least one month.

Chemical Reduction of α- and β-Molybdophosphate to the Respective Blue Species. In order to obtain a pure blue species of β-molybdophosphate by retaining a critical concentration of acetonitrile in the medium, several kinds of metals were tested as the dry reductants.

For the test, a series of 10-cm³ solutions of 5×10^{-5} M β-molybdophosphate were prepared in the 40% acetonitrile medium and shaken vigorously with a 60-mg dose of each metal such as nickel, iron, cobalt, lead, and copper. The formation of the blue species was monitored by measuring the absorbance at 788 nm. The results obtained with nickel are represented in Fig. 5A as a function of the shaking time with the metal and the standing time thenafter. As indicated by curve a in the Figure, when the reduction was initiated by shaking for several seconds, the solution slowly turned to blue and the absorbance reached a constant value on standing. Curves b and c show that the longer the shaking time is prolonged, the more rapidly the reduction proceeds. It is also shown by d and e, however, that the longer-shaking exceeding over 1 min is not profitable for the reduction, since other unstable blue species are produced (which give more deeply blue color but decay slowly on standing). The absorption spectrum of the most stable blue species of β-molybdophosphate is shown in Fig. 6 as curve a.

Quite similarly, α-molybdophosphate was reduced

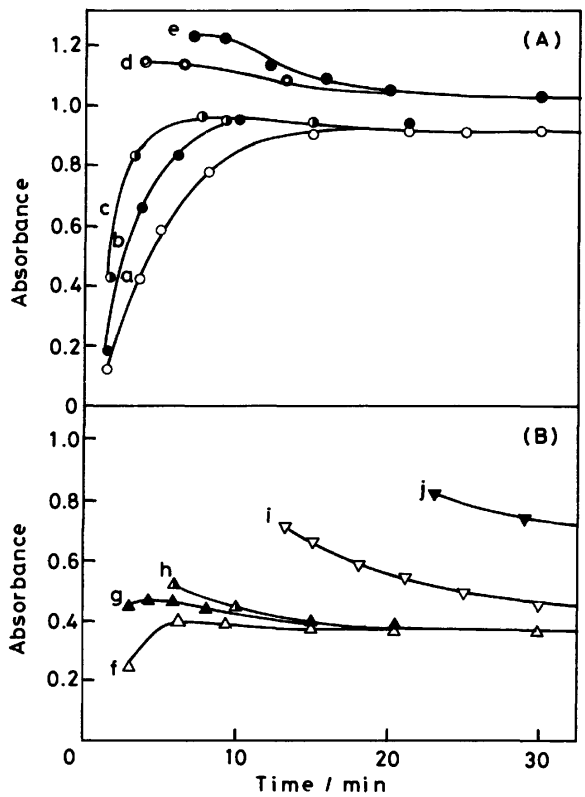

Fig. 5. The shaking time with nickel reductant and the standing time needed for the reduction of α- or/and β-molybdophosphate to the respective blue species. A 10 cm³ of 5×10^{-5} M solution of either α- or/and β-molybdophosphate prepared in the 40 % aqueous acetonitrile medium, was shaken with a 60 mg dose of nickel. For β (in the upper part of the Figure), the shaking time was varied as: (a) 6 s, (b) 10 s, (c) 30 s, (d) 1 min, and (e) 15 min and the formation of the blue species was monitored as a function of the standing time thenafter. For α (in the lower part of the Figure), the shaking time was as: (f) 30 s, (g) 1 min, (h) 4 min, (i) 10 min, and (j) 20 min.

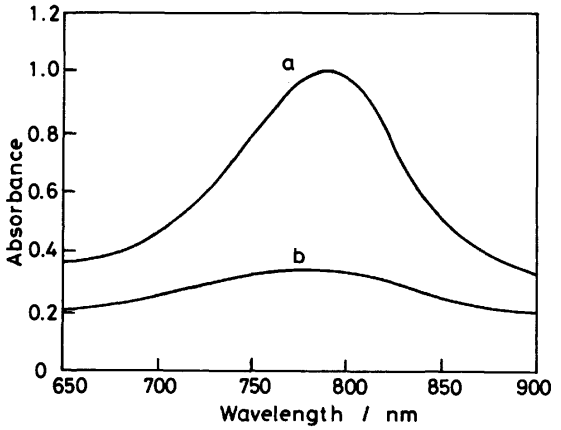

Fig. 6. Absorption spectra of the blue species of α- or/and β-molybdophosphate in the 40 % aqueous acetonitrile medium.
Curve a is for 5×10^{-5} M β-molybdophosphate, reduced with a 60 mg dose of nickel by shaking for several seconds and standing it for 15 min, and curve b for 5×10^{-5} M α-molybdophosphate reduced by shaking for 30 s and standing for 15 min.

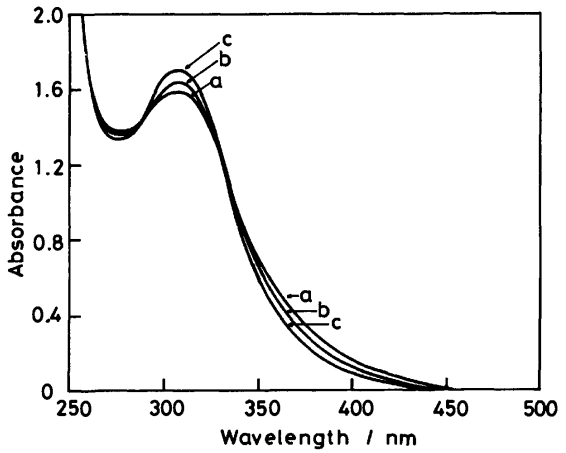

Fig. 7. Absorption spectra inherent to the respective α- or/and β-molybdophosphate.
Curve a is for β extracted at $t=10$ min and curve c is for α at $t=8$ h, during the conversion of β to α(see the text for the detailed extraction procedure). Thence, curve b for the mixture of α and β extracted at $t=1$ h. The initial concentration of the complexes in the 40 % aqueous acetonitrile medium, 4.5×10^{-5} M, was finally concentrated up to 7.5×10^{-5} M through this extraction.

to the corresponding blue species by using nickel. The shaking time and the standing time required for the reduction are shown in Fig. 5B. As shown by curve f, one of the most stable blue species was attained by shaking for 30 s and standing for 15 min. The absorption spectrum is given in Fig. 6 as curve b and compared with that of the reduced β-molybdophosphate (curve a). α- and β-molybdophosphate can be characterized even in their reduced forms; the former showing an absorption maximum at 770 nm with $\varepsilon=(6.43\pm0.15)\times10^3$ and the latter at 788 nm with $\varepsilon=(1.99\pm0.06)\times10^4$ l mol^{-1} cm^{-1}, respectively.

Similar to nickel, iron and lead also reduced the complexes although, the reduction with these metals proceeded rather faster than with nickel. Moreover, with these metals it was seen by visual observation that the solutions of the molybdophosphate complexes turned to a greenish blue. This was solely because the background color (reddish yellow) due to the reduction of the reagent molybdate covered the blue color of the reduced complexes. In fact, in the absorption spectrum being measured using a spectrophotometer, the inherent absorption maxima of the blue species were clearly revealed since the background color only occurred in a spectral region shorter than 500 nm.

Copper was less reactive compared with the three metals mentioned above and the reduction remained incomplete. Cobalt was even less reactive, the molybdophosphate complexes being slightly blue.

Extraction Isolation of α- and β-Molybdophosphate. For either α- or/and β-molybdophosphate formed in the 40% acetonitrile medium, an addition of the proper amount of chloroform was quite effective to extract the complex. Such an extra addition of chloroform served to extract a sufficient amount of acetonitrile from the medium into an organic phase, to which molybdophosphate was quantitatively extracted, the reagent molybdate being left in the aqueous phase. As to our examination performed here, chloroform was one of the unique solvents and the most excellent for such extraction isolation.

In practice, at appropriate intervals during the conversion of β to α, 3.0-cm^3 of chloroform was added to a 10-cm^3 solution of 4.5×10^{-5} M molybdophosphate, and either α- or/and β-molybdophosphate or their mixture was extracted. At every extraction an approximate 6 cm^3 of organic phase was recovered at the lower layer. The absorption spectra of these organic extracts were measured as superimposed in Fig. 7: Curve a was for β-molybdophosphate (which was attained by the extraction at $t=10$ min), curve b for the mixture of α and β (at $t=1$ h), and curve c for α (at $t=8$ h). According to the conversion reaction, the absorption spectrum changed from that of β to that of α, keeping isosbestic points at around 285 nm and 335 nm.

In paralell to these spectral measurements, the organic extracts were analyzed with respect to the contents of molybdenum and phosphorus, and the Mo/P ratios were determined. As the result, it was confirmed that, irrespective of the differences among the absorption spectra of a, b, and c in Fig. 7, the Mo/P ratios in the organic extracts remained unchanged and equally fell into a value of 12.1±0.3. That is, α- and β-molybdophosphate are quite identi-

cal in their compositions but possibly different in their structures. The detailed structure of β-molybdophosphate has not been analyzed yet because of the difficulty in crystallization, but it would be successfully deduced by Chalmers[2] from the Keggin structure.

It was also possible to extract the blue species of α- and β-molybdophosphate by the similar addition of chloroform. It is recommended to add 0.3 cm^3 of the solvent into a 10-cm^3 solution where the molybdophosphate complex is in a reduced form. Usually, an approximate 1.56 cm^3 of the organic phase is recovered at the upper layer, and the reduced complexes are effectively concentrated into the phase.[††] Although the blue color was highly increased in the organic phase, the characteristic absorption maxima of α- and β-molybdophosphate were retained unchanged even after the extraction.

Extraction isolation of the molybdophosphate complexes was unsuccessful in aqueous acetone and aqueous dioxane media because suitable solvents were not yet found for the phase separations of the mixed solvents.

Analytical Consideration. A variety of sensitive methods for phosphate determination have been reported by using water-miscible organic solvents such as acetone. Among these methods, however, the recommended procedures or the optimum conditions are widely different or even contradictory to each other. Now, it can be obviously said that in these methods two different effects by the organic solvent are involved, and either one of the effects has been overlooked. As confirmed in this paper, one of the solvent effect is due to the stabilization of α-molybdophosphate, where the organic solvent serves to shift the *reversible* formation equilibrium of the complex to the completion, and the other is due to the kinetic stabilization of β-molybdophosphate, where the *irreversible* conversion of the complex is retarded by the solvent.

For the same reason as above, one could not obtain β-molybdophosphate even by treating with organic solvents the crystallized molybdophosphate, *e.g.*, $24MoO_3 \cdot P_2O_5 \cdot 3H_2O$, or by extracting molybdophosphate from its aqueous solutions into various organic solvents. In either case, the conversion of β to α had already been completed. In consequence, an aqueous medium (including certain organic solvents) is indispensably needed for preparing β-molybdophosphate.

It was made evident that β-molybdophosphate shows higher absorbances than α-molybdophosphate in both forms of the reduced blue (Fig. 6) and the oxidized yellow (Fig. 7). This spectroscopic nature is capable of more sensitive determination of phosphate ion by utilizing the formation of β-molybdophosphate rather than that of α-molybdophosphate, especially in its reduced blue form. In addition to this, the extraction of the blue complex may further sensitize the phosphate determination by concentrating it into a small volume of the organic phase by the aid of auxiliary solvent of chloroform.

[††] At this extraction using a relatively small amount of chloroform (0.3 cm^3), approximately 1.4% of reagent molybdate is extracted along with the molybdophosphate complexes. However, the reagent molybdate is colorless and causes no practical interference with the spectral measurements in the visible region of the reduced blue complexes.

Kinetics of the Ligand-exchange Reactions in Th(tta)$_4$ and Th(tta)$_4$dmso in Organic Solvents

Naoshi FUJIWARA, Hiroshi TOMIYASU, and Hiroshi FUKUTOMI*
Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152
(Received October 16, 1984)

The exchange reactions of 2-thenoyltrifluoroacetonate (tta) in Th(tta)$_4$ and of dimethyl sulfoxide (dmso) in Th(tta)$_4$dmso have been studied by the NMR method. It was found that the first-order rate constant of tta exchange in acetonitrile-d_3 depended linearly on the concentrations of Htta in the enol form, Htta$_{enol}$, and that the rate was retarded markedly by the addition of DMSO. The activation parameters ΔH^* (kJ mol^{-1}) and ΔS^* (JK^{-1} mol^{-1}) were determined to be 43.9±0.5 and −58.4±1.5, respectively and the mechanism including the formation of a nine-coordinate intermediate was proposed. For Th(tta)$_4$dmso, the rate of dmso exchange in acetone-d_6 was much faster than that of β-diketonate exchange, and an interchange mechanism was proposed on the basis of a nonlinear dependency of the first-order rate constant on the free DMSO concentration.

In previous papers,[1,2] we reported the kinetics of the ligand exchange reaction in tetrakis(acetylacetonato)thorium(IV), Th(acac)$_4$, and proposed that the reaction proceeded *via* a nine-coordinate intermediate for the acac exchange. It has been known that thorium(IV) forms an eight-coordinate complex[3] with 4,4,4-trifluoro-1-(2-thienyl)-1,3-butanedione, whose common name is 2-thenoyltrifluoroacetone (Htta). On extraction of Th(IV) by Htta, a marked synergic effect was observed in the presence of unidentate donor bases, *e.g.* tributyl phosphate and trioctylphosphine oxide.[4,5,6] This synergic effect suggests that Th(tta)$_4$ may form nine-coordinate complexes with unidentate bases. In fact, several nine-coordinate adducts between Th(tta)$_4$ and bases were isolated.[7,8] From these facts, it is expected that some nine-coordinate intermediate probably plays an important role in the ligand-exchange reaction between Th(tta)$_4$ and Htta. In this paper, we report the formation of nine-coordinate Th(tta)$_4$L(L: unidentate ligand), and the kinetic results of the exchange reaction of tta and dmso in Th(tta)$_4$ and Th(tta)$_4$dmso, respectively.

Experimental

Materials. The Th(tta)$_4$ complex was prepared as follows. An aqueous solution (40 cm^3) containing thorium tetrachloride (0.01 mol) was stirred with the same volume of a benzene solution which contained a large excess amount of Htta. Aqueous ammonia was added to the mixture until the pH of the solution became 5. The brownish yellow benzene phase was separated and a yellow precipitate was obtained by evaporation of benzene under reduced pressure. The precipitate was washed with hexane and recrystallized from hot benzene, and then from 1,2-dichloroethane. Found: C, 34.5; H, 1.4%. Calcd for $C_{32}H_{16}O_8F_{12}S_4Th$: C, 34.4, H, 1.1%.

Purification of 2-thenoyltrifluoroacetone was carried out by recrystallization from hexane. Dimethyl sulfoxide and hexamethyl phosphoric triamide (HMPT) were distilled under reduced pressure. Acetonitrile was dried over phosphorus pentaoxide and distilled. Acetone-d_6 and acetonitrile-d_3 were dried over molecular sieve 4A.

Measurements of UV and NMR Spectra. UV spectra were measured by using Shimadzu 210A and UV-365 spectrophotometers with 0.1 mm and 1.0 mm quartz cells. A JEOL JNM-FX 100 FT-NMR equipped with a JNM-VT-3B temperature controller was used for NMR measurements.

Determination of the Fraction of Keto- and Enol-forms in Htta. The concentration ratio, [enol]/[keto], was determined by area measurements of methine and methylene proton signals for enol- and keto-isomers, respectively. In order to obtain the temperature dependence of the ratio, the area measurements were performed in the temperature range from 30 to 70 °C. The values of enthalpy and entropy were ΔH=−15.5±0.8 kJ mol^{-1} and ΔS=−24.3±2.4 J K^{-1} mol^{-1} in CD_3CN. The fractions of the enol isomer at each temperature were calculated by using these values.

Rate Analysis. The first-order rate constants of ligand-exchange reactions were determined from the line shape analysis of NMR signals by using the two-site model.[2,9] A Sord M-232 microcomputer system was used for the calculation.

Results

Ligand-exchange between Th(tta)$_4$ and Htta. The absorption spectrum of Th(tta)$_4$ shows a peak at 350 nm with the molar extinction coefficient of 8.3×10^4 M^{-1} cm^{-1} (1 M=1 mol dm^{-3}) in acetonitrile. The spectrum of the mixture of Th(tta)$_4$ and Htta coincided with the sum of those of each component in acetonitrile, and remained unchanged for several hours. As is shown in Fig. 1, the ^{1}H NMR spectra of the mixture of Th(tta)$_4$ and Htta in CD_3CN and CD_3COCD_3 gave two methine proton signals at room temperature, and the signal in the higher magnetic field was assigned to coordinated tta and that in the lower field to free Htta in the enol-form. The ^{19}F NMR spectra of the reaction mixture in CD_3CN showed also two ^{19}F signals of trifluoromethyl at room temperature, where the one in the higher field was assigned to Htta and the other to Th(tta)$_4$. In both the ^{1}H and ^{19}F spectra

[Th(tta)$_4$]=0.0357−0.0363 mol kg^{-1}.

in CD_3CN, the ≥CH and -CF_3 signals coalesced as the temperature was raised (Fig. 1). These changes in NMR spectra can be attributed to the ligand exchange between Th(tta)$_4$ and Htta in the enol-form. No change was observed in methylene proton signals of Htta in the keto-form. Therefore, the ligand-exchange reaction between Th(tta)$_4$ and Htta in the enol-form can be described as follows.

$$Th(tta)_4 + Htta^*_{enol} \rightleftharpoons Th(tta)_3tta^* + Htta_{enol}, \quad (1)$$

where the asterisk denotes the exchanging species.

The observed first-order rate constant, k^{tta}_{obsd}, for the tta exchange reaction is given by

$$k^{tta}_{obsd} = 4\tau_c^{-1}, \quad (2)$$

where τ_c is the life time of tta in the coordination site. Plots of k^{tta}_{obsd} against the concentrations of Th(tta)$_4$ and Htta$_{enol}$ are shown in Figs. 2 and 3, respectively. The first-order rate constant was independent of [Th(tta)$_4$] though the data at 52 and 60 °C deviated from straight lines and linearly depended on [Htta]$_{enol}$. The intercepts in Fig. 3 might be regarded to be zero within experimental errors. These results lead to the following relationship between k^{tta}_{obsd} and [Htta]$_{enol}$,

$$k^{tta}_{obsd} = k[Htta]_{enol} \quad (3)$$

where k refers to the second order rate constant, and the values of k are listed in Table 1. The rate of tta

14	0.366

a) $[Th(tta)_4]=4.58\times10^{-5}$ mol dm^{-3}.

exchange was retarded in the presence of free DMSO. Under the conditions that $[Th(tta)_4]$=0.0443 mol kg^{-1}, $[Htta]_{total}$=0.181 mol kg^{-1} and [DMSO]=0.197 mol kg^{-1} in CD_3CN, the methine proton signals of $Th(tta)_4$ and $Htta_{enol}$ were separated even at 70 °C, and their line widths were slightly broader than those at 20 °C.

Formation of $Th(tta)_4L$ Complexes and the dmso Exchange in $Th(tta)_4$dmso. The molar extinction coefficient of $Th(tta)_4$ in acetonitrile was measured in the presence of DMSO or HMPT. Slight changes in absorption spectra with an isosbestic point at 340 nm were observed by the addition of DMSO, and the results are shown in Table 2. Similar spectral changes were also observed in the presence of HMPT. These changes in spectra suggest the formation of adduct complexes between $Th(tta)_4$ and DMSO or HMPT. In addition, the ^1H NMR spectra of mixtures of $Th(tta)_4$ and DMSO or HMPT in acetone-d_6 may give additional evidence for 1:1 adduct complex formation. As seen in Fig. 4, the ^1H NMR spectra of the solution containing $Th(tta)_4$ and DMSO gave a sharp signal of methyl protons at −20 °C. As the temperature of the solution was lowered, this signal broadened and then split into two peaks, in which the peak in the higher field was assigned to the methyl protons of free DMSO, while the solution containing $Th(tta)_4$ (0.0662 mol kg^{-1})

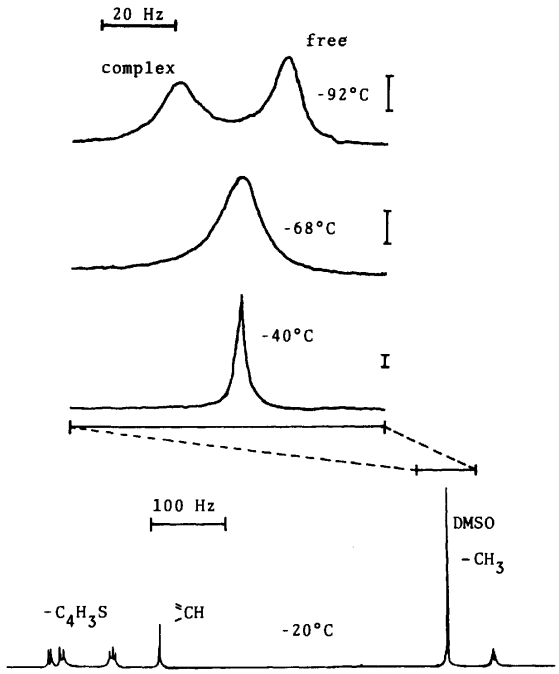

Fig. 4. ^1H NMR spectrum of the mixture of $Th(tta)_4$ and DMSO, and a change in methyl proton signals in CD_3COCD_3 with temperature.
$[Th(tta)_4]=0.0508$ mol kg^{-1}, [DMSO]=0.103 mol kg^{-1}.

and DMSO (0.0270 mol kg^{-1}) whose concentration was less than equivalent showed a single methyl proton signal, and no methyl proton signal of free DMSO was observed at any temperature. The chemical shift of this single methyl proton signal coincided with that of the peak in the lower field in Fig. 4. This fact also suggests that DMSO in the mixture forms a 1:1 adduct complex with $Th(tta)_4$, and the left-hand peak in Fig. 4 can be assigned to the methyl protons of the adduct complex, $Th(tta)_4$dmso. Similar changes in NMR spectra were observed for the mixture of $Th(tta)_4$ and HMPT as is shown in Fig. 5, in which two signals of methyl protons of HMPT were observed at 10 °C and each signal split into two peaks at −40 °C. Left-hand peaks (C) of each signal can be assigned to the methyl protons of the complex, $Th(tta)_4$hmpt. Attempts to determine accurate values of formation constants of 1:1 adduct complexes between $Th(tta)_4$ and DMSO or HMPT in acetonitrile and acetone were unsuccessful because of very large values of molar extinction coefficients for complexes and of rather small changes in absorbance on adduct formation. The value for $Th(tta)_4$dmso is estimated to be some value between 10^4 and 10^5 $mol^{-1}\,kg$. A simulated line shape of NMR spectrum, which is obtained from the two-site model by assuming that the left-hand peak in Fig. 4 is the methyl protons of $Th(tta)_4$dmso, and that the dmso exchange reaction takes place between $Th(tta)_4$dmso and free DMSO, shows satisfactory agreement with the observed

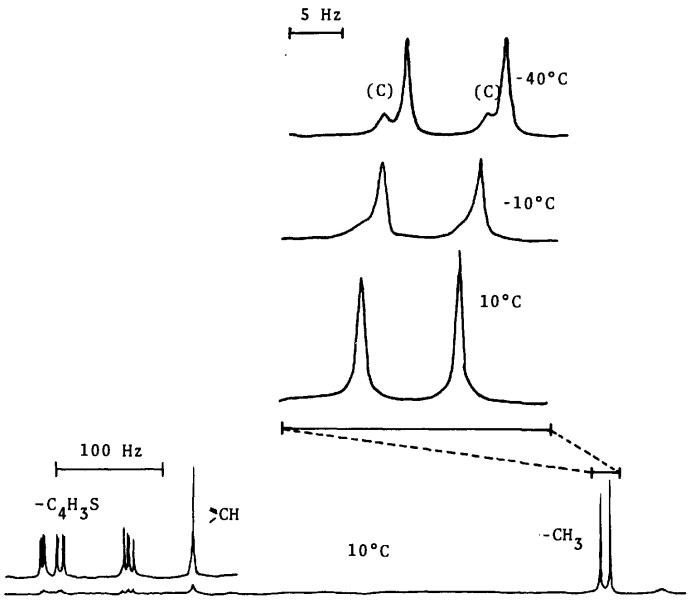

Fig. 5. ^{1}H NMR spectrum of the mixture of Th(tta)$_4$ and HMPT, and a change in methyl proton signals in CD_3COCD_3 with temperature.
[Th(tta)$_4$] = 0.048 mol kg^{-1}, [HMPT] = 0.210 mol kg^{-1}.

signals.

All these results indicate that Th(tta)$_4$ and L (L=dmso or hmpt) form the nine-coordinate complex, Th(tta)$_4$L, and the change in ^{1}H NMR spectra in Fig. 4 can be attributed to the dmso exchange reaction in Th(tta)$_4$dmso as written by Eq. 4.[10]

$$\text{Th(tta)}_4\text{dmso} + \text{DMSO}^* \rightleftharpoons \text{Th(tta)}_4\text{dmso}^* + \text{DMSO} \quad (4)$$

The observed first-order rate constant of the dmso exchange in Th(tta)$_4$dmso, k_{obsd}^{dmso}, does not depend linearly on the concentration of DMSO as shown in Fig. 6. Plots of $k_{obsd}^{dmso^{-1}}$ *vs.* [DMSO]$^{-1}$ give straight lines with intercepts and yield

$$k_{obsd}^{dmso^{-1}} = p + q[\text{DMSO}]^{-1}, \quad (5)$$

where p and q are constants.

Discussion

A pathway which is similar to the mechanism proposed for the acac exchange in Th(acac)$_4$[2] is proposed for the mechanism of the tta exchange reaction in Th(tta)$_4$. As shown in Fig. 7, Th(tta)$_4$ forms a nine-coordinate intermediate, Th(tta)$_4$Htta*, with Htta$^*_{enol}$, and the proton of Htta$^*_{enol}$, is transferred to one of the coordinated tta (II→II′), followed by rapid dissociation of Htta$_{enol}$ from the coordination sphere (II′→I′). If complexes I and II are in fast equilibrium, and [II] is much smaller than [I], the first-order rate constant, k_{ex}, can be written by

$$k_{ex} = k_2K_1[\text{Htta}]_{enol}, \quad (6)$$

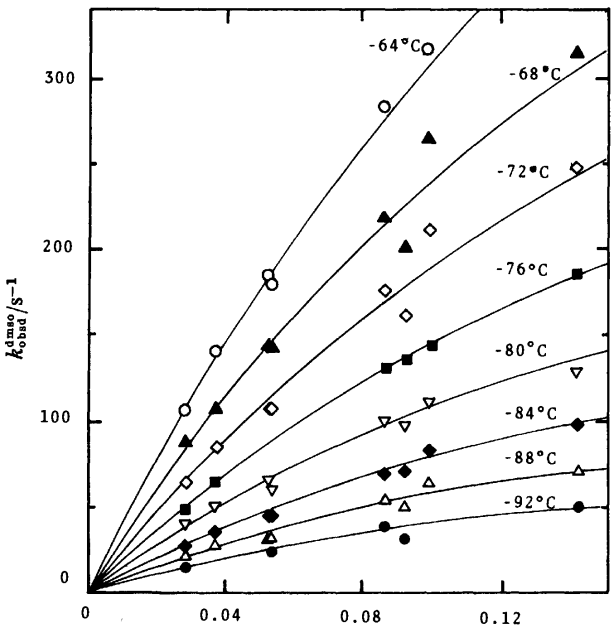

Fig. 6. Plots of k_{obsd}^{dmso} *vs.* [DMSO] in CD_3COCD_3.
[Th(tta)$_4$dmso] = 0.0227 − 0.0672 mol kg^{-1}.

where K_1 is the formation constant of complex II, and k_2 is the rate constant for the proton transfer reaction. Equation 6 is the same as Eq. 3 obtained experimentally, where k corresponds to k_2K_1.

The retardation effect by the addition of DMSO can be interpreted by the formation of nine-coordinate adduct complex (III). It seems reasonable to assume that the formation of Th(tta)$_4$Htta is hindered by DMSO. The rate of the tta exchange reaction in

$Hf(acac)_4$	C_6H_6	74.0	26	12

a) 1,2-Dichloroethane. b) 1,1,1-Trifluoroacetylacetonate. c) 6,6,7,7,8,8,8-Heptafluoro-2,2-dimethyl-3,5-octanedionate. d) Acetonitrile. e) Tetrahydrofuran.

$Th(tta)_4$ was slower than that of the acac exchange reaction in $Th(acac)_4$. According to the proposed mechanism (Fig. 7), the difference in reaction rate might be ascribed to the following causes: (1) The formation constant of $Th(tta)_4Htta$ is smaller than that of $Th(acac)_4Hacac$. (2) Replacement of coordinated tta by incoming $Htta_{enol}$ is slower than the acac replacement in $Th(acac)_4Hacac$. However, it is difficult at present to determine which causes to be predominant.

The values of activation parameters for the second-order rate constant of ligand-exchange reactions in β-diketonato complexes are listed in Table 3. In spite of a variety of ligands and solvents, it seems that there is a linear relationship between the values of ΔH^* and ΔS^* for the ligand-exchange reactions in $Th(acac)_4$, $Th(tta)_4$, $U(fod)_4$, $Zr(tfac)_4$, $Hf(tfac)_4$, and $VO(acac)_2$.[2,11-13] Although it is hardly discernible whether this relationship is held by accident or implies a mechanistic similarlity, almost the same mechanism has been proposed for the ligand-exchange reactions in $Th(acac)_4$, $Th(tta)_4$ and $U(fod)_4$, while different reaction mechanisms are proposed for $V(acac)_3$[14] and $Ga(acac)_3$.[15]

As described above, k_{obsd}^{dmso} does not follow the linear relationship with respect to free DMSO concentration. This fact suggests that neither the dissociative mechanism (D) nor the associative mechanism (A) fits the dmso exchange mechanism in $Th(tta)_4dmso$. On

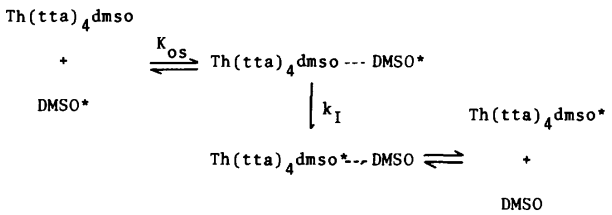

Fig. 8. Mechanism of the dmso exchange in $Th(tta)_4dmso$ in CD_3COCD_3.

the other hand, the interchange mechanism (I)[16] seems to be probable as seen in Fig. 8, where free DMSO and $Th(tta)_4dmso$ form an outer-sphere complex, and the interchange process between the coordinated dmso and DMSO in the outer-sphere is the rate-determining step. On the basis of the I mechanism, the first-order rate constant of dmso exchange, k_{ex}^{dmso}, is expressed by

$$k_{ex}^{dmso} = \frac{k_I K_{os}[DMSO]}{1+K_{os}[DMSO]}, \quad (7a)$$

or

$$k_{ex}^{dmso^{-1}} = \frac{1}{k_I} + \frac{1}{k_I K_{os}}[DMSO]^{-1}, \quad (7b)$$

where k_I is the rate constant of the interchange process and K_{os} is the formation constant of the outer-sphere complex. Equation 7b is identical with Eq. 5, which was determined experimentally. Hence, the proposed I mechanism can interprete well the dmso exchange reaction in $Th(tta)_4dmso$ in acetone-d_6. Values of k_I and K_{os}, which were obtained from $k_I=1/p$ and $K_{os}=1/qk_I$, are listed in Table 4. The rate of the dmso exchange in $Th(tta)_4dmso$ is much faster than that of the tta exchange in $Th(tta)_4$. This fact supports the assumption that $Th(tta)_4$ and $Th(tta)_4Htta$ are in a fast equilibrium as shown in Fig. 7.

The *N,N*-dimethylformamide (dmf) exchange in eight-coordinate complexes, $[Tb(dmf)_8]^{3+}$, $[Er(dmf)_8]^{3+}$, and $[Tm(dmf)_8]^{3+}$, were studied by Merbach *et al.*[17-18] and they reported that the smaller the size of the central metal ion was, the more dissociative the character of the exchange mechanism was. In spite of the large negative value of ΔS^*, the I_d mechanism was proposed for $[Tb(dmf)_8]^{3+}$, where Tb(III) has a large ionic radius, and the D mechanism was proposed for $[Tm(dmf)_8]^{3+}$. Based on these facts, we

Table 4. Kinetic parameters of dmso exchange in $Th(tta)_4dmso$ in CD_3COCD_3

T / °C	k_I / $10^2\ s^{-1}$	K_{os} / $mol^{-1}\ kg$
−64	11.8±4.1	3.5
−68	7.4±1.9	4.7
−72	7.9±3.1	3.2
−76	5.8±0.2	3.3
−80	3.0±1.6	5.3
−84	3.2±1.2	3.2
−88	1.6±0.8	4.9
−92	1.0±0.3	6.1
	$\Delta H^* = 25.1 \pm 2.5$ kJ mol^{-1}	
	$\Delta S^* = -65 \pm 13$ J K^{-1} mol^{-1}	

can not rule out the possibility of the I_d mechanism in the dmso exchange in $Th(tta)_4dmso$, though the I_a mechanism seems to be more likely by considering a large ionic radius of Th(IV) and the negative ΔS^* value.

The authors wish to thank Professor James H. Espenson of Iowa State University for helpful discussions. The present work was partly supported by a Grant-in-Aid for Scientific Research No. 57470035 from the Ministry of Education, Science and Culture.

(Received November 13, 1984)

(−)$_{546}$-*trans*-[$Co(NO_2)_2$(*R*,*R*-dmchxn)$_2$]$^+$ and (+)$_{546}$-*Λ*-[$Co(CO_3)$(*R*,*R*-dmchxn)$_2$]$^+$, which had been newly prepared, reacted with concentrated HCl to give, respectively, (−)$_{435}$-*trans*-(*SSSS*)-[$CoCl_2$(*R*,*R*-dmchxn)$_2$]$^+$ and (+)$_{435}$-*trans*-(*SRRS*)-[$CoCl_2$(*R*,*R*-dmchxn)$_2$]$^+$ stereospecifically, where *R*,*R*-dmchxn=(1*R*,2*R*)-*N*,*N*′-dimethyl-1,2-cyclohexanediamine. The stereospecific formation of (+)$_{546}$-*Λ*-[$Co(CO_3)$(*R*,*R*-dmchxn)$_2$]$^+$ has been observed. The *trans*-dichloro complexes and their precursors have been characterized by elemental analysis and by electronic absorption, circular dichroism, ^{1}H NMR, and ^{13}C NMR spectroscopies. An X-ray crystal-structure determination was undertaken on one of the *trans*-dichloro isomers, (+)$_{435}$-[$CoCl_2$(*R*,*R*-dmchxn)$_2$]Cl·HCl·$2H_2O$, whose structure could not be characterized by usual spectroscopies. This complex forms triclinic crystals with a=11.395(10) Å, b=11.674(8) Å, c=11.031(8) Å, α=98.62(6)°, β=102.48(8)°, γ=118.24(5)°, and Z=2, in the space group P1. Least-squares refinements converged at an R value of 0.041 for 4870 independent reflections with $F_o > 3[\sigma(F_o)]$. The complex cation has an approximately twofold symmetry. The conformations of the two five-membered chelate rings are both *λ*. The arrangements of the groups around the two secondary nitrogen atoms are *R* and *S* in each diamine. The isomerization from the (+)$_{435}$-*trans*-dichloro complex to the (−)$_{435}$ isomer has been observed under mild basic conditions.

It is an interesting subject to design ligands suitable for metal-assisted asymmetric synthesis where the orientation of the donor substituents can play a major role in the diastereotopic discrimination of the substrate. To examine the coordination behavior of the *N*-substituted polyamine from this point of view is an interesting subject, since the *N*-alkyl groups in the polyamines or diamines significantly affect the structures of metal complexes.[1,2]

As a part of a study to develop useful optical-active ligands for asymmetric synthesis, we have been investigated cobalt(III) complexes of the *N*-alkylated diamines. During this investigation, we have obtained two isomers of the *trans*-dichlorobis(diamine)cobalt(III) complex, where the diamine is (1*R*,2*R*)-*N*,*N*′-dimethyl-1,2-cyclohexanediamine (*R*,*R*-dmchxn), whose chelate ring would be fixed in the *λ* gauche conformation with its rigid cyclohexane-ring skeleton. These *trans*-dichloro isomers, which are important precursors of the corresponding amino acidato complexes, (−)$_{435}$-*trans*-[$CoCl_2$(*R*,*R*-dmchxn)$_2$]$^+$ and (+)$_{435}$-*trans*-[$CoCl_2$(*R*,*R*-dmchxn)$_2$]$^+$, were derived from (−)$_{546}$-*trans*-[$Co(NO_2)_2$(*R*,*R*-dmchxn)$_2$]$^+$ and (+)$_{546}$-[$Co(CO_3)$(*R*,*R*-dmchxn)$_2$]$^+$ respectively.

In this paper we wish to report the syntheses and characterization of these four cobalt(III) complexes containing *R*,*R*-dmchxn, including an X-ray crystal-strauctured determination of one of the *trans*-dichloro isomers, (+)$_{435}$-*trans*-[$CoCl_2$(*R*,*R*-dmchxn)$_2$]Cl·HCl·$2H_2O$, whose structure could not be characterized by usual spectroscopies. In addition, the conversion reaction between the two *trans*-dichloro complexes has been investigated in order to elucidate the relationship between the two isomers.

† Present address: Department of Engineering, National Science Museum, Ueno Park, Taito-ku, Tokyo 110.

Experimental

Measurement. The visible absorption spectra were recorded on a Shimadzu UV-210 spectrophotometer. The circular dichroism spectra were measured with a JASCO J-500A recording spectropolarimeter. The spectra were obtained in methanol for the *trans*-dichloro complexes and in water for the dinitro and carbonato complexes. The ^{1}H NMR spectra were measured on a HITACHI R-40 (90 MHz) spectrometer, with tetramethylsilane or sodium 3-trimethylsilyl-1-propanesulfonate as an internal standard. The ^{13}C NMR spectra were obtained on a JEOL PS-100 (100 MHz) spectrometer, with tetramethylsilane as the external standard. Elemental analyses were performed by Shounan Bunseki Center Co., Ltd.

Materials. All the reagents were of the best commercial grade and were used without further purification. (1*R*,2*R*)-*N*,*N*′-Dimethyl-1,2-clohexanediamine (*R*,*R*-dmchxn) was prepared by the method of Kashiwabara *et al.*[3]

Preparation of (−)$_{546}$-trans-[Co(NO$_2$)$_2$(R,R-dmchxn)$_2$]ClO$_4$·H$_2$O (1a). A solution of *R*,*R*-dmchxn (4.4 g) in water (30 mL) was added, drop by drop, to an aqueous solution containing sodium hexanitrocobaltate(III) (7.7 g), after which the solution was heated at 70 °C for 1 h while being stirred. After cooling to room temperature, a solution of sodium perchlorate (2.5 g) in water (10 mL) was added to the reacted solution with stirring, and the solution was left to stand overnight at room temperature. The resulting yellow crystals were filtered, washed with

ice-cold water, and air-dried. Recrystallization was performed from a minimum amount of water at 55 °C; yield, 6.5 g. Anal. Calcd for $C_{16}H_{38}N_6O_9ClCo$: C, 34.76; H, 6.93; N, 15.20. Found: C, 34.55; H, 6.87; N, 15.15. ^1H NMR (D_2O) δ=2.10 (*s*, N-CH_3). ^{13}C NMR (D_2O) δ= 25.5, 31.2, 38.2, and 69.3.

Preparation of $(-)_{435}$-trans-*[$CoCl_2$(R,R-dmchxn)$_2$]Cl·HCl·$2H_2O$ (**1b**).* Slightly soluble perchlorate salt, $(-)_{546}$-*trans* $[Co(NO_2)_2(R,R\text{-dmchxn})_2]ClO_4\cdot H_2O$ (**1a**) (3.5 g) was converted to more soluble chloride salt by the vigorous stirring of the perchlorate salt with an anion-exchange resin (QAE-Sephadex, 100—200 mesh, 2 g) in the Cl^- form for 6 h. Concentrated hydrochloric acid (50 mL) was then poured onto the chloride salt of the *trans*-$[Co(NO_2)_2(R,R\text{-dmchxn})_2]^+$, which had been obtained by the evaporation of the aqueous solution after the removal of the resin. The solution was heated on a water bath at 90 °C and concentrated at that temperature continuously. The original violet color turned to green, and green crystals gradually formed in the solution. Then the solution was cooled to room temperature and allowed to stand overnight. The resulting green crystals were filtered, washed with a small amount of hydrochloric acid (1 M (1 M=1 mol dm^{-3})), and air-dried; yield, 2.1 g. Anal. Calcd for $C_{16}H_{41}N_4O_2Cl_4Co$: C, 36.84; H, 8.60; N, 10.62. Found: C, 37.18; H, 8.68; N, 10.38. ^1H NMR (CD_3OD) δ=2.43 (*d*, N-CH_3). ^{13}C NMR (D_2O-DCl) δ=24.4, 29.8, 37.8, and 69.5.

Preparation of $(+)_{546}$-*[$Co(CO_3)$(R,R-dmchxn)$_2$]Cl·$2H_2O$ (**2a**).* *R,R*-Dmchxn (2.8 g) was added to a fresh solution (30 mL) containing sodium tricarbonatocobaltate(III) trihydrate (3.6 g). The solution was warmed on a water bath for 1 h at 50 °C. The original green color gradually turned to a reddish purple. After cooling to room temperature, an aqueous solution (30 mL) of sodium chloride (2.5 g) was stirred into the solution. Then, the solution was allowed to stand overnight. The resulting crystals were recrystallized from water at 60 °C. The reddish purple crystals which separated were filtered, washed with ethanol and ether, and air-dried; yield, 4.0 g. The formation of only one isomer has been observed. Anal. Calcd for $C_{17}H_{40}N_4O_5ClCo$: C, 42.99; H, 8.48; N, 11.80. Found: C, 43.01; H, 8.73; N, 11.89. ^1H NMR (D_2O) δ=2.02 and 2.05 (*s*, N-CH_3). ^{13}C NMR (D_2O) δ=24.6, 25.2, 29.2, 30.8, 31.4, 32.7, 63.3, 65.9, and 168.6.

Preparation of $(+)_{435}$-trans-*[$CoCl_2$(R,R-dmchxn)$_2$]Cl·HCl·$2H_2O$ (**2b**).* 2.0 g of the $(+)_{546}$-$[Co(CO_3)(R,R\text{-dmchxn})_2]$-$Cl\cdot 2H_2O$ (**2a**) obtained above was dissolved in a minimum volume of water. The solution was acidified with concentrated hydrochloric acid (50 mL), followed by foaming. The solution was heated on a water bath at 90 °C and then concentrated. The green crystals which separated were filtered, washed with ice-cold hydrochloric acid (1 M), and air-dried. Recrystallization was performed from 6 M hydrochloric acid; yield, 2.0 g. Anal. Calcd for $C_{16}H_{41}N_4O_2Cl_4Co$: C, 36.84; H, 8.60; N,10.62. Found: C, 36.80; H, 8.91; N, 10.73. ^1H NMR (CD_3OD) δ=2.25 and 2.34 (*d*, N-CH_3). ^{13}C NMR (D_2O-DCl) δ=25.1, 25.6, 29.6, 37.8, 38.2, 64.7, 65.2, and 68.0.

Conversion Reaction from $(+)_{435}$-trans-*[$CoCl_2$(R,R-dmchxn)$_2$]$^+$ Ion to* $(-)_{435}$-trans *Isomer.* A sample (100 mg) of either the $(+)_{435}$-*trans* or $(-)_{435}$-*trans* isomer was dissolved in methanol (60 mL). To the solutions we then added 1 mL of a methanol solution containing 2,6-lutidine (40 mg), after which the solutions were stored at 45 °C. The CD spectra were recorded every 30 min. After 1 d, the CD spectra of the $(+)_{435}$-*trans* isomer became identical with that of the $(-)_{435}$-*trans* isomer, which did not change under the same conditions. The same reaction was also followed by ^1H NMR measurements. The results obtained by these two ways agreed with each other.

X-Ray Analysis. The crystal used in the data collection was a green prism with the approximate dimensions of 0.51×0.24×0.43 mm^3. The diffraction data were measured on a Rigaku AFC-5 diffractometer with graphite monochromatized Mo $K\alpha$ radiation. Within the range of $2\theta<65°$, 4870 independent reflections with $F_o>3[\sigma(F_o)]$ were obtained. The intensities were corrected for Lorentz and polarization factors and for absorption (μ=11.7 cm^{-1}).

Crystal data are: Triclinic, P1, a=11.395(10), b=11.674 (8), c=11.031(8) Å, α=98.62(6), β=102.48(8), γ=118.24(5)°, Z=2, D_m=1.435, D_x=1.438 gcm^{-3}.

The structure was solved by the heavy-atom method and refined by a block-diagonal least-squares method. A unit-weight weighting scheme was employed. All the hydrogen atoms except for those of the water and hydrochloride of crystallization were located by assuming a tetrahedral coordination; they are all included in the final refinement with the isotropic temperature factors. The atomic-scattering factors and values of f' and f'' for Co, Cl, O, and C were taken from Ref 4. The final indicies were R=0.041 and R'=0.044.

All the calculations were performed on a FACOM M-380 computer at the Institute of Physical and Chemical Research with Universal Program System UNICS III.[5]

Results and Discussion

Preparations. Two types of procedures were used for the preparation of *trans*-$[CoCl_2(R,R\text{-dmchxn})_2]^+$-type complexes. In the methods, the resulting *trans*-dichloro complexes, **1b** and **2b**, were obtained from **1a** and **2a** respectively by treatment with concentrated hydrochloric acid.

Method 1. The $(-)_{546}$-*trans*-$[CoCl_2(R,R\text{-dmchxn})_2]^+$ complex (**1b**) was obtained by the usual substitution reaction, using hexanitrocobaltate(III) as the starting material.[6] The reaction scheme is:

$$[Co(NO_2)_6]^{3-} + 2R,R\text{-dmchxn} \longrightarrow trans\text{-}[Co(NO_2)_2(R,R\text{-dmchxn})_2]^+ \quad (\mathbf{1a}).$$

$$(\mathbf{1a}) + \text{concd HCl} \longrightarrow trans\text{-}[CoCl_2(R,R\text{-dmchxn})_2]^+ \quad (\mathbf{1b}).$$

Method 2. The $(+)_{435}$-*trans*-$[CoCl_2(R,R\text{-dmchxn})_2]^+$ complex (**2b**) was also obtained by the usual substitution reaction, using tricarbonatocobaltate(III) as the starting material.[7] The reaction scheme is:

$$[Co(CO_3)_3]^{3-} + 2R,R\text{-dmchxn} \longrightarrow \Lambda\text{-}[Co(CO_3)(R,R\text{-dmchxn})_2]^+ \quad (\mathbf{2a}).$$

$$(\mathbf{2a}) + \text{concd HCl} \longrightarrow trans\text{-}[CoCl_2(R,R\text{-dmchxn})_2]^+ \quad (\mathbf{2b}).$$

For each complex, **1a**, **1b**, **2a**, or **2b**, only one isomer was obtained stereospecifically. The structural assignments of the geometries of the present complexes are based on (a) the ^{1}H NMR signals of the *N*-methyl groups, (b) the ^{13}C NMR signals of the complexes, and (c) the electronic absorption and the circular dichroism spectra. The data on the electronic spectra and circular dichroism curves for the dinitro, carbonato, and the dichloro complexes are given in Fig. 1 and Table 1. The results of the ^{1}H and ^{13}C NMR spectra of the four complexes are presented in the Experimental section.

Structures of Two trans*-Dichloro Complexes.* The dichloro complexes **1b** and **2b** obtained are green, which is characteristic of the *trans*-$[CoCl_2N_4]^+$ type. The visible absorption spectra of **1b** and **2b** are very similar to each other and give typical *trans*-$[CoCl_2N_4]^+$ absorptions (Fig. 1b). On the other hand, the CD spectra of **1b** and **2b** are significantly different from each other. The changes in the CD spectrum of $(+)_{435}$-*trans*-$[CoCl_2(R,R\text{-dmchxn})_2]^+$ during the conversion reaction are shown in Fig. 2. In the CD spectra of the $(-)_{435}$-*trans*-dichloro complex **1b**, no change has been observed during the same treatment. The reaction scheme is:

$$(+)_{435}\text{-}trans\text{-}[CoCl_2(R,R\text{-dmchxn})_2]^+ \ (\mathbf{2b}) \xrightarrow{\text{2,6-lutidine}} (-)_{435}\text{-}trans\text{-}[CoCl_2(R,R\text{-dmchxn})_2]^+ \ (\mathbf{1b}).$$

It is generally accepted that the absolute configuration of the asymmetric nitrogen atoms coor-

a) Ref. 27).

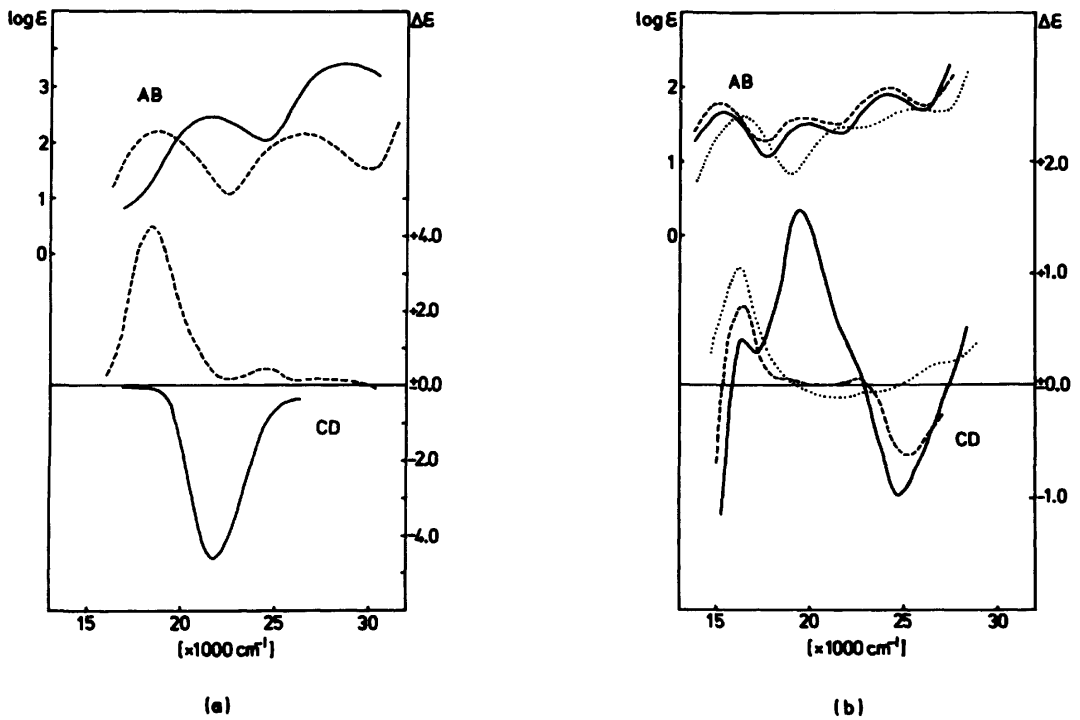

Fig. 1. (a) The AB and CD spectra of $(-)_{546}$-*trans*-$[Co(NO_2)_2(R,R\text{-dmchxn})_2]^+$ (**1a**) and $(+)_{546}$-Λ-$[Co(CO_3)(R,R\text{-dmchxn})_2]^+$ (**2a**) complexes. The solid line indicates the former complex ion. (b) The AB and CD spectra of *trans*-$[CoCl_2(R,R\text{-dmchxn})_2]^+$ complexes in methanol. The solid line and the broken line indicate the $(-)_{435}$-isomer (**1b**) and the $(+)_{435}$-isomer (**2b**), respectively. The AB and CD spectra of *trans*-$[CoCl_2(R,R\text{-chxn})_2]^+$ in methanol is presented by the dotted line.

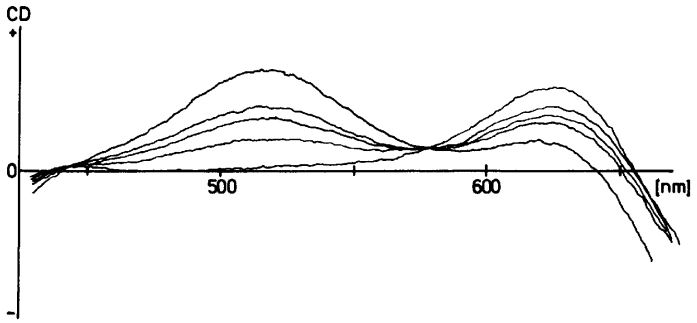

Fig. 2. The changes in the CD spectrum of $(-)_{435}$-*trans*-$[CoCl_2(R,R\text{-dmchxn})_2]^+$ during the conversion reaction.

dinated to a Co(III) can be changed under mild basic conditions without any change in the absorption spectrum, which is generally sensitive to any change in the structure of the complex.[8] The present conversion reaction using 2,6-lutidine proceeded from **2b** to **1b** without any color change, and the CD curves of **2b** during the reaction passed through the isodichroic points (439 and 578 nm, Fig. 2). Accordingly, these results indicate that the two dichloro complexes obtained differ in the absolute configurations of the coordinated secondary nitrogen centers, and that the isomeric mixtures produced during the reaction are composed of **2b** and **1b**.

The ^1H NMR spectrum of **1b** shows and *N*-methyl doublet at δ 2.43. The ^{13}C NMR spectrum of **1b** gives only four signals, though this complex contains 16 carbon atoms as its components. These NMR results prove that the four methyl groups on the nitrogen atoms are in the same chemical environment.

The X-ray structure analysis and circular dichroism studies of *trans*-[$CoCl_2$(*N*-methyl-substituted diamine)$_2$]$^+$ suggest the following empirical rule: the sign of the CD band near 22000 cm^{-1} ($A_{1g} \rightarrow A_{2g}$-($D_{4h}$) CD band) can be closely related to the configuration of the asymmetric nitrogen centers, as has been shown for *trans*-dichlorobis(diamine)-cobalt(III) complexes of *N*-methyl and *C*-methylethylenediamine.[9-11] When a complex involving five-membered chelate rings of λ-gauche conformations gives a positive Cotton effect in this region, it should be assigned to the *S* configuration around the asymmetric nitrogen center. According to this rule and the NMR results of **1b**, the absolute configurations around the four asymmetric nitrogen centers of the $(-)_{435}$-*trans*-dichloro complex **1b** might be concluded to be all *S*, since a large positive Cotton effect has been observed in the corresponding region (Fig. 1b) and since (1*R*,2*R*)-1,2-cyclohexanediamine adopts the λ-gauche conformation toward the Co(III) ion. Consequently, the structure of the $(-)_{435}$-isomer **1b** can be identified as the

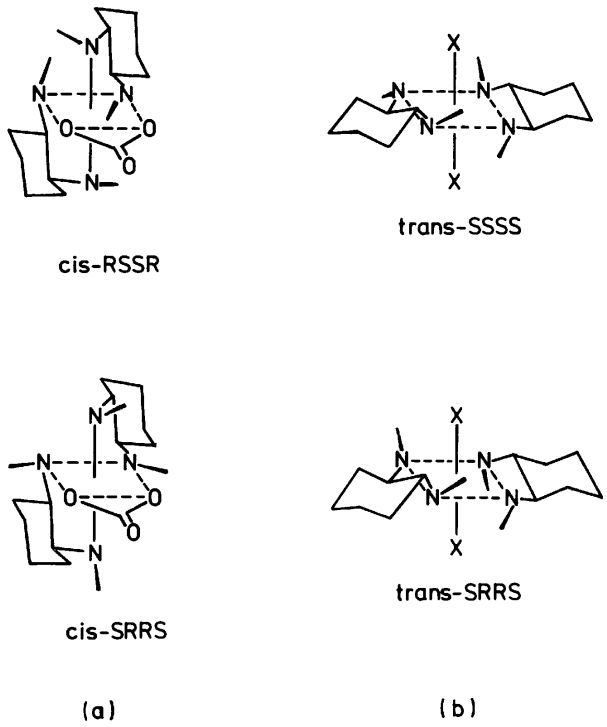

Fig. 3. (a) Two possible isomers of Λ-$[Co(CO_3)(R,R\text{-dmchxn})_2]^+$, and (b) structures of *trans*-type complexes, *trans*-$[CoX_2(R,R\text{-dmchxn})_2]^+$ ($X=NO_2^-$ or Cl^-).

trans-SSSS structure (Fig. 3b, $X=Cl^-$), which is thought to be most stable of the combinations of asymmetric nitrogen atoms.

On the other hand, the ^1H NMR spectrum of **2b** gives two kinds of *N*-methyl doublets, showing the presence of two pairs of *N*-methyl groups in different chemical environments. The ^{13}C NMR spectrum of **2b**, moreover, suggests that one twofold axis through the Co(III) ion exists, as eight signals were observed. The CD spectrum of the complex **2b** is very similar to that of the complex *trans*-$[CoCl_2(1R,2R)\text{-chxn})_2]^+$[12], which has four coordinated primary nitrogen atoms and no asymmetric center except for the asymmetric carbon atoms belonging to the (1*R*,2*R*)-1,2-cyclohexanediamine. Since no contribution from the asymmetric nitrogen centers appears in the CD spectrum,

a) Positional parameters are multiplied by 10^4.

the complex **2b** may have the same numbers of secondary nitrogen centers in opposite configurations, two *R* and two *S*. From these spectral results, three geometrical isomers (*trans-SRRS*, *trans-RSSR*, and *trans-SSRR*) are possible for the *trans*-dichloro complex with one C_2 symmetry. Accordingly, it is difficult to assign the geometry of **2b** by means of the AB, CD, and NMR spectroscopies. The following section will deal with the detailed structural results concerning the **2b** complex obtained from X-ray diffraction.

Crystal and Molecular Structure of 2b. The final atomic coordinates of non-hydrogen atoms are listed in Table 2. The thermal parameters, the parameters for the hydrogen atoms, and the lists of structure factor amplitudes are available as supplementary material.[13)] Selected bond lengths and angles are presented in Tables 3 and 4. Perspective drawings of the complex cations showing ellipsoids of thermal

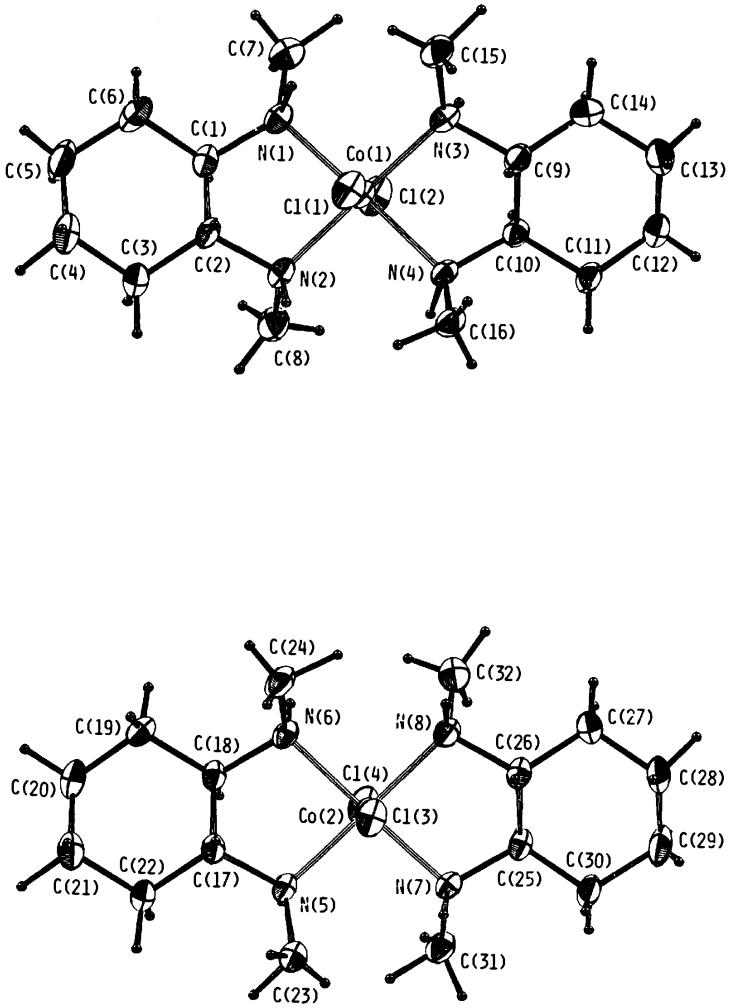

Fig. 4. Perspective drawings of the complex cations $(-)_{435}$-*trans*-$[CoCl_2(R,R\text{-dmchxn})_2]^+$ and the numbering scheme for the atoms.

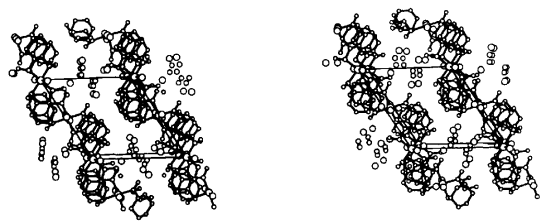

Fig. 5. A stereoscopic illustration of one unit cell, viewed down the c axis with the a axis vertical.

motion are given in Fig. 4. A stereoview of the contents of one unit cell and each conformation of the diamine-chelate rings are shown in Fig. 5 and 6 respectively.

The unit cell consists of 2 complex cations, chloride counterions, hydrochloride molecules, and the 4 waters of crystallization. The two complex cations in one unit cell have almost identical structures. The complex cations have an approximately C_2 symmetry. Each cobalt atom is surrounded by four nitrogen atoms and two chlorine atoms at the apices of a slightly distorted octahedron. The chloro groups are in the trans positions. The absolute configurations around the asymmetric carbon centers are both *R* for each cyclohexanediamine. The conformations of the two five-membered chelate rings are both λ in each complex ion. The four cyclohexane rings adopt the chair conformation, and all the *C*-methylene groups have equatorial orientation with respect to the chelate rings. The structure of (1*R*,2*R*)-1,2-cyclohexanediamine, used in the syntheses, agrees with the known absolute configurations.[14,15] The arrangements around the secondary nitrogen atoms are the pair of the *R* and *S* configurations in the notation of Cahn, Ingold, and Prelog.[16] In each complex ion, two *N*-methyl groups have equatorial orientations, while the other groups have axial orientations, with respect to the chelate rings. The *N*-methyl group bonded to the nitrogen atom of the *R* or *S* configuration in each diamine is neighboring with the group linked to that of the same configuration of the other respective diamine. This findings as to the structure around the asymmetric nitrogen centers, which involves the asymmetric nitrogen atoms of two *R* and two *S* configurations in each complex ion, agrees with the spectral assignment of **2b** (*vide supra*).

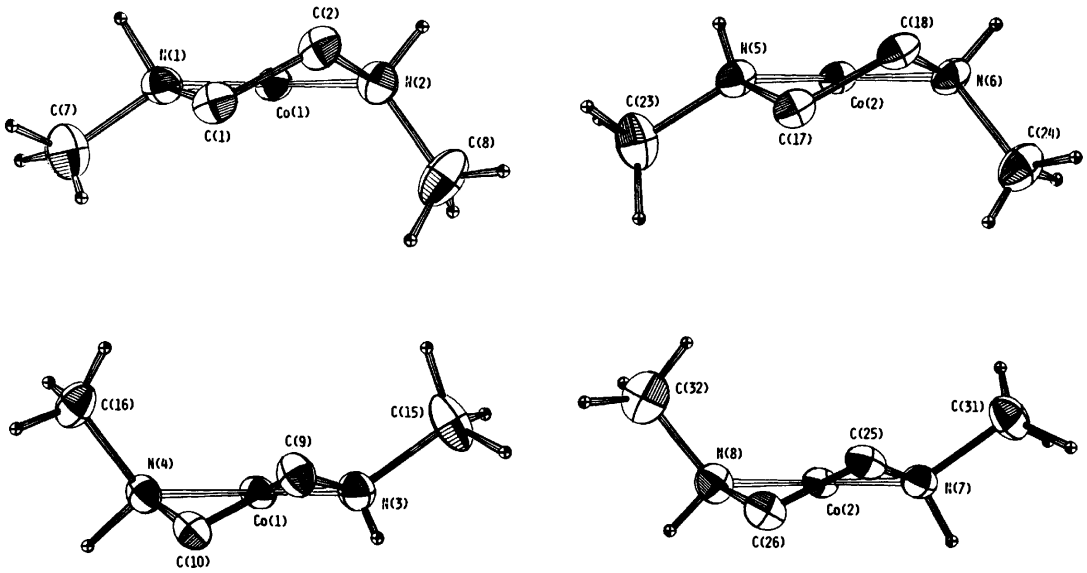

Fig. 6. Each conformation of the four diamine-chelate rings.

The average Co–N bond distance is 1.998(6) Å, slightly longer than the recent values reported for *trans*-$[CoCl_2(en)_2]^+$; the average Co–N(ethylenediamine) lengths are 1.960(5), 1.960(10), and 1.950(3) Å.[17] Moreover, the present Co–N value is slightly long as compared with the average distances reported for the Co–N bond in *tris*-type complexes involving *trans*-1,2-cyclohexanediamine, 1.972(5) and 1.984(4) Å for $(-)_{589}$-$[Co((+)\text{-chxn})_2((-)\text{-chxn})]^{3+}$ and $(-)_{589}$-$[Co((-)\text{-chxn})_3]^{3+}$ respectively.[14,15] Such as elongation of the chelate bond Co–N is also occasionally observed in the complexes involving *N*-alkylated diamines, for example, $(-)_{546}$-*trans*-$[Co(NO_2)_2((-)_{589}\text{-}2,2'\text{-bpp})_2]^+$,[18] *trans*-$[Co(pip)_2(tpp)]^+$,[19] and $(-)_{589}$-*cis*-$[Co(NO_2)_2(N^1\text{-me-}(S)\text{-pn})_2]^+$,[20] where 2,2′-bpp, pip, tpp, and N^1-me-(*S*)-pn represent 2,2′-bipiperidine, piperidine, the 5,10,15,20-tetraphenylporphinate anion, and (2*S*)-N^1-methyl-1,2-propanediamine respectively, the average Co–N(2,2′-bpp), Co–N(pip), and Co–N(N^1-me-(*S*)-pn) distances being 2.004(5), 2.060(3), and 2.015(5) Å respectively. The ring angles at the cobalt atom for the five-membered chelate rings, N(1)–Co(1)–N(2), N(3)–Co(1)–N(4), N(5)–Co(2)–N(6), and N(7)–Co(2)–N(8), are 86.3(2), 86.2(2), 86.7(2), and 86.4(2)° respectively, the average being 86.4(2)°. These angles appear normal for Co(III) five-membered chelate rings, which are usually less than 90°, though the angles of the present complex are slightly larger than those observed in the complexes coordinating the bidentate ligands *trans*-1,2-cyclohexanediamine and 2,2′-bipiperidine described above, which range from 84.1(2) to 84.7(2)°. The Co–Cl bond lengths of Co(1)–Cl(1) and Co(2)–Cl(4) are 2.261(3) and 2.264(3) Å, which can be compared with the mean values of 2.253(2), 2.254(3), 2.244(1), and 2.26 Å in *trans*-$[CoCl_2(en)_2]^+$,[17] 2.26 Å in *trans*-$[CoCl_2(1,3\text{-propanediamine}_2]^+$,[21] and 2.257(2) Å in *trans*-$[CoCl_2((-)\text{-}1,2\text{-cyclopentanediamine})_2]^+$,[22] where as the bond lengths of Co(1)–Cl(2) and Co(2)–Cl(3) are 2.217(3) and 2.236(3) Å respectively, slightly shorter than the other values. The average N–C and C–C distances, 1.491(11) and 1.518(12) Å respectively, are comparable with the reported values in $(-)_{589}$-$[Co((+)\text{-chxn})_2((-)\text{-chxn})]^{3+}$ (1.486(7) and 1.498(8) Å) and $(-)_{589}$-$[Co((-)\text{-chxn})_3]^{3+}$ (1.494(7) and 1.516(8) Å), for the mean N–C and C–C distances respectively of the cyclohexanediamine. The average C–C bond distance of the chelate-ring carbon atoms is 1.509(11) Å, which is quite normal for Co(III) five-membered chelate rings. The average bond angle at the carbon and nitrogen atoms for the (1*R*,2*R*)-*N*,*N*′-dimethyl-1,2-cyclohexanediamine is 111.6°, which is slightly large as compared with the idealized tetrahedral values of 109.5°. This enlargement of the average bond angle of the ligand is mainly due to the larger angles at the carbon and nitrogen atoms belonging to the asymmetric nitrogen atoms whose absolute configurations are *R* around them; for example, the bond angles of N(2)–C(2)–C(3), N(4)–C(10)–C(11), N(6)–C(18)–C(19), and N(8)–C(26)–C(27) are 114.5(7), 116.5(6), 116.9(7), and 115.8(5)° respectively.

Thus, the exact structure of the $(+)_{435}$-*trans*-dichloro complex **2b**, which could not be determined by usual spectroscopy, has been elucidated as the isomer *trans*-*SRRS* (Fig. 3b, X=Cl^-). On the basis of the spectral evidence and the crystal structure of these two *trans*-dichloro complexes **1b** and **2b**, the structures of their precursors, **1a** and **2a**, will be discussed in the following section.

Structural Assignment of the Precursors. It is generally acknowledged that the AB spectral patterns of Co(III) diacidobis(diamine) complexes are characteristic of their geometry.[23] It is recognized that *cis*- and *trans*-dinitro complexes of Co(III) show

λ_{max} at ≈330 nm and ≈350 nm respectively. The present dinitro complex **1a** shows λ_{max} at 351 nm (Fig. 1a), showing that it has the *trans* configuration with respect to the two nitro groups. The ^1H NMR spectrum of Ia shows an *N*-methyl signal at δ 2.10, indicating that the four methyl groups in the complex ion are in the same chemical environment. In the ^{13}C NMR spectrum of **1a**, moreover, four signals were observed when irradiating all of the hydrogen nuclei. Because the dinitro complex **1a** contains 16 carbon atoms, this result means that **1a** has a triple twofold symmetry, like the derived dichloro complex **1b**. Generally, the absolute configuration of the coordinated asymmetric nitrogen centers can be effected to fit in with *S* arrangements when the five-membered chelates adopt the λ-gauche conformations, as has been indicated in the case of the Co(III) complex containing *N*-methylethylenediamine.[24] The absolute configurations around the four asymmetric nitrogen atoms of **1a**, therefore, can be concluded to all be *S*, and the four methyl groups can be concluded to have an equatorial orientation with respect to the chelate rings (Fig. 3b, *trans-SSSS*, X=NO_2^-).

The visible absorption spectrum of **2a** is very similar to that of *cis*-$[Co(CO_3)(en)_2]^+$,[25] and it gives the typical *cis*-$[CoN_4O_2]^+$ absorption (Fig. 1a). In the CD spectrum of **2a**, a large positive Cotton effect has been observed in the first absorption region, comparable with that of Λ-$[Co(CO_3)((2R)\text{-1,2-propanediamine})_2]^+$.[26] The absolute configuration around Co(III) can be assigned to Λ on the basis of this observaton. The ^1H NMR spectrum of **2a** shows two kinds of *N*-methyl signals, like the derived dichloro complex **2b**. Moreover, nine signals were observed in the ^{13}C NMR spectrum of **2a**, though the carbonato complex contains 17 carbon atoms. It has been elucidated by the present X-ray study that the *trans*-dichloro complex **2b** derived from this carbonato complex **2a** has two secondary nitrogen atoms of the *R* configuration and two of those of the *S* arrangement in each diamine. It can be expected that the carbonato complex reacts with hydrochloric acid to yield the *trans*-dichloro complex, with a retention of the absolute configuration of the asymmetric nitrogen centers. From these considerations, the structure of the carbonato complex **2a** may be restricted to either the *cis-SRRS* or *cis-RSSR* isomer (Fig. 3a), though ten structures are theoretically possible. According to the molecular model study, the *cis-SRRS* isomer seems to be more stable than the latter, since the *N*-methyl groups bonded to the asymmetric nitrogen atom of the *R* configuration in the isomer is distant from the neighboring diamine chelate ring, while those of the *S* configuration in the *cis-RSSR* are close to the corresponding chelate ring. Thus, the present carbonato complex **2a** can be tentatively assigned to the *cis-SRRS* isomer.

Thus, the new complexes, $(-)_{546}$-*trans*-(*SSSS*)-$[Co(NO_2)_2(R,R\text{-dmchxn})_2]^+$, $(+)_{546}$-Λ-$[Co(CO_3)(R,R\text{-dmchxn})_2]^+$, $(-)_{435}$-*trans*-(*SSSS*)-$[CoCl_2(R,R\text{-dmchxn})_2]^+$, and $(+)_{435}$-*trans*-(*SRRS*)-$[CoCl_2(R,R\text{-dmchxn})_2]^+$, were prepared and characterized. It is evident that $(+)_{546}$-Λ-$[Co(CO_3)(R,R\text{-dmchxn})_2]^+$ was converted by concentrated HCl to $(+)_{435}$-*trans*-(*SRRS*)-$[CoCl_2(R,R\text{-dmchxn})_2]^+$, with a retention of the configuration of the secondary nitrogen atoms. This observation will be very important in discussing the mechanism of the *cis-trans* conversion reaction when the exact structure of the starting carbonato complex can be determined by means of X-ray crystallography.

For all four complexes investigated in this study, the stereospecific formation has been observed. For the $[Co(CO_3)(R,R\text{-dmchxn})_2]^+$ complex, only the Λ isomer has been detected. This result indicates that suitably designed diamines could govern the overall geometry of the complexes and afford useful coordination sites for the asymmetric reactions, as is observed in the case of the linear tetradentate tetraamines.[1,2,27]

Studies are now in progress to establish the stereochemistry of this system in hoping to clarify the mechanism for the *cis-trans* conversion reaction and to develop suitable ligands for metal-assisted asymmetric reactions.

New Type of Aldol Condensations Catalyzed by Metal(II) Complexes of α-Amino Acid Esters and that with Cyclodextrin System

Ken-ichi WATANABE,* Yoichi YAMADA, and Katsuhisa GOTO
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagayaku, Tokyo 158
(Received May 18, 1984)

The aldol condensations of *p*-nitrobenzaldehyde with acetone catalyzed by metal complexes of α-amino acid esters proceeded under mild and neutral conditions to afford an enantiomeric excess aldol-type product, 4-hydroxy-4-(4-nitrophenyl)-2-butanone, along with some dehydrated products without any by-product. The most effective catalyst system was a zinc(II) complex of the tyrosine ethyl ester, Zn^{II}–$(TyrOEt)_2$ in MeOH. Complexes of the second-row transition metals were inadequate for the reactions. Reactions at 30—40 °C for 24 h were favorable regarding the asymmetric induction. An H_2O solvent was the best for aldol-type product formations without asymmetric induction. An assistant effect of cyclodextrins(especially, β-CD) on the catalysis of the Zn^{II}–TyrOEt complex were thought to be observed.

Aldol-condensation reactions are generally catalyzed using bases and acids. Accordingly, some side reactions are apt to occur, and it is not always easy to get only cross-aldol-reaction products. Recently, we found that the reactions are generelly catalyzed under neutral conditions by 2,2′-bipyridine complexes of the first-row transition metals[1] and also by cobalt(II) complexes of pyridine-containing copolymers.[2] The reactions of various aldehydes with ketones in the presence of these metal complex catalysts afford liberated condensation products in satisfactory yields without any by-products. However, the reaction products are always α,β-unsaturated ketones(2) derived through the dehydration of the aldol-type products, β-hydroxy ketones(1).

$$\mathrm{RCH(=O) + CH_3C(=O)R' \xrightarrow[\text{DMF., 80 °C}]{\text{M(II)-L}_n} \underset{\text{aldol-type product (1)}}{\mathrm{RCH(OH)CH_2C(=O)R'}}}$$

$$\xrightarrow{-H_2O} \underset{\text{dehydrated product (2)}}{\mathrm{RCH{=}CHC(=O)R'}}$$

We have developed a new investigative technique for the following three objectives regarding these complex-catalyzed aldol reactions:

1) To produce the aldol-type product(1) without the dehydrated product(2), or to depress any dehydration if it occurs.

2) To get an optically active aldol-type product(1) by use of a chiral metal-complex catalysts with optically active ligands.

3) To apply the inclusion effects of cyclodextrins to enhance the catalytic activity of the metal-complex system.

In order to realize these objectives, reactions of *p*-nitrobenzaldehyde with acetone were adopted as the standards due to their high reactivity and of a relative difficulty regarding the dehydration of the aldol-type product. Metal species of the employed complexes were the first- and second-row transition metal salts. The first-row efficiencies were investigated in one of our previous studies[1,2] and it was of interest to examine the second-row for the first time. As a result of various examinations involving chiral ligands of the complexes, we have found that esters of α-amino acids are fairly effective for the purpose of obtaining the aldol reactions with asymmetric induction. Among esters of the α-amino acids easily prepared, L-tyrosine ethyl ester (L-TyrOEt, mp 108 °C) and L-histidine methyl ester (L-HisOMe, mp 61 °C) were used, since they are crystals and can be easily handled and purified. Quinine and quinidine as ligands were also examined because pyridine and bipyridine *etc.* were the most effective ligands of the complex catalysts for the aldol condensations.[1,2]

Since the 1970's, many studies have been reported in regard to the aldol reactions utilizing organometallic compounds as an auxiliary reagent for diasteroselective additions through metal enolate intermediates.[3] Our studies since 1978 have been essentially different in that metal complexes were used as catalysts. Such studies as the asymmetric aldol reactions catalyzed by chiral metal complexes of an α-amino acid system under neutral conditions have not been reported yet.

Cyclodextrins(CD) possess hydrophobic cavities in which hydrophobic molecules are able to be selectively included. For this reason, many studies on the effect of the inclusion behavior on catalytic, regioselective, and enantioselective reactions by use of CDs have been reported.[4] Such inclusion effects are sometimes used to simulate an enzyme action. We have investigated assistant effects of CDs on complex-catalyzed aldol reactions. In this paper, the scope and limitations of these complex-catalyzed aldol reactions are reported in detail.

Results and Discussion

Effects of Metal Species and Ligands of the Complex Catalysts. Effects of metal species and ligands of

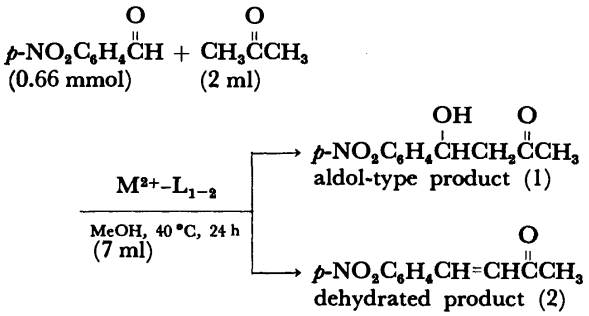
a) Reaction conditions: aldehyde 0.66 mmol, acetone 2 ml(excess), catalyst 16 mol% of the aldehyde, solvent MeOH 7 ml, at 40 °C for 24 h. b) Aldol-type product. c) Dehydrated product, by NMR. d) Reaction for 48 h. e) $Zn(OAc)_2$ complex was used for 48 h. f) Quinine. g) Quinidine. h) Reaction at 30 °C. i) 100% by NMR. j) Imidazol.

complex catalysts on the reactions of *p*-nitrobenzaldehyde with acetone were examined for the first time. Tables 1 and 2 show that among the metal ions and ligands examined, an Zn^{2+}–L-TyrOEt system was the most adequate catalyst.



In order to prepare the complex catalysts, the metal salt and the ligand compound were mixed with dry methanol and stirred for a while; and, the complex solution was subsequently used without the isolation of the complex in its crystal form. The homogeneous reaction proceeded smoothly at 40 °C for 24 h and the aldol-type product(1), 4-hydroxy-4-(4-nitrophenyl)-2-butanone, was obtained from the reaction mixture by means of column chromatography with silica-gel. The reaction did not proceed without the catalyst and was extremely slow when only the metal salts were used without the ligand. As was expected, the reactions with an L-TyrOEt complex afforded an enantiomeric excess product(1) having a minus sign $[\alpha]_D$. A plus sign in the reaction with the D-TyrOEt complex, indicated that an asymmetric regulation occurred (Table 1). The Zn^{II}–$(TyrOEt)_2$ (1:2) complex was superior to the 1:1 complex with respect to the product yield and the asymmetric induction.

TABLE 2. ALDOL CONDENSATIONS OF *p*-NITROBENZALDEHYDE WITH ACETONE (2) (EFFECTS OF METAL SPECIES OF L-TyrOEt COMPLEXES(M : L = 1 : 2)[a])

Metal salts	Yield of (1)/%[b] (isolated)	$[\alpha]_D$ (in EtOH)	Yield of (2)/%[c] (NMR)
$Co(OAc)_2 \cdot 4H_2O$	33	−5.7	13
$Ni(OAc)_2 \cdot 4H_2O$	26	−8.2	11
$Ni(NO_3)_2 \cdot 6H_2O$[d]	63	−3.0	+
$Cu(OAc)_2 \cdot H_2O$	9	−2.7	4
$Zn(OAc)_2 \cdot 2H_2O$	22	−6.2	30
$Zn(NO_3)_2 \cdot 6H_2O$	40	−11.2	42
$ZnCl_2$	19	−4.9	48
$RuCl_3 \cdot 3H_2O$[e]	0		0
$RuCl_3 \cdot 3H_2O$[f]	14	+2.5	8
$Pd(OAc)_2$[g]	0		0
$RhCl_3 \cdot 3H_2O$	0		0

a) Reaction conditions were similar to those shown in Table 1. b) Aldol-type product. c) Dehydrated product. d) Reaction for 48 h. e) Formation of acetal (62%) with MeOH without any aldol condensation products. f) Reaction in 9 ml. acetone without MeOH. g) Deposition of Pd° during the reaction.

The reactions with quinine(Q) and quinidine(Q') complexes showed no asymmetric induction at all. Examinations with other Q-complexes were further

carried out using Co, Ni, and $Cu(OAc)_2$, $RuCl_3$, and $Pd(OAc, NO_3$, and $Cl)_2$ *etc.*; but, almost no reaction took place. It was found that mixed ligand complexes of Zn^{II}–Q (or Q′)-bpy (1:1:1) showed a high catalytic activity to give only product(1) quantitatively even at 30 °C (100%, by NMR) but without any asymmetric induction. The reaction with a $Zn(NO_3)_2$–bpy_2 complex gave product(1) (40 °C, 24 h, racemate) in a 60% yield (by NMR).

From the results in Table 2, it is evident that $Zn(NO_3)_2$ is a very effective metal species. On the contrary, the second-row transition metal salts were all inadequate for the reactions. Besides $Pd(OAc)_2$, $Pd(NO_3)_2$, and $PdCl_2$ were also examined but none of them showed any catalytic activity at all. In the presence of the $RuCl_3$–(L-TyrOEt)$_2$ complex, an acetal of the aldehyde with a MeOH solvent was formed in a 62% yield(NMR) and no aldol reaction took place at all (see experimental). Then, the reaction was carried out in acetone without MeOH, no notable result was obtained (product(1), 14%).

Now, the optical purity of the aldol-type product obtained in the reactions is still unknown since the specific rotation of the pure enantiomer is unknown. We tried to determine the enantiomeric excess of the aldol-type product(1) by means of ^{1}H-NMR spectroscopy with shift reagents (Eu(tbc)$_3$ and Eu(tfc)$_3$) or by some other methods. However, definite values were not obtained.

Examination of the Complex Formation. When the metal salts and the ligand compounds were added together in methanol, a color change was observed, indicating a complex formation. In order to further understand this formation, UV spectra of $Ni(OAc)_2 \cdot 4H_2O$, L-TyrOEt, and $Ni(OAc)_2$–(L-TyrOEt)$_{1-2}$ complexes were measured. Also, the pH of the solution (MeOH+H_2O) and their optical rotation (in EtOH) were measured (Table 3). The absorption maximum of the Ni^{2+} (670 nm) showed a blue shift after the addition of L-TyrOEt. The hyperchromic effect was observed, indicating a change of the electronic state of the Ni^{2+} ion by the coordination of the ligand. On the other hand, the pH of a TyrOEt solution itself (7.8) turned almost neutral (7.0—7.2) in a Ni^{II}–TyrOEt complex solution (M:L=1:1, 1:2) which was similar in pH to a $Ni(OAc)_2$ solution. This means that the NH_2 group of the ligand was masked by the coordination. With regard to the specific rotation, $[\alpha]_D$=+19.8° of the TyrOEt turned into −2.5°—−3.3°, indicating a chiral complex formation.

Examination of Catalysis of $Zn(NO_3)_2$-(L-TyrOEt)$_2$ Complex System. On the basis of the above examinations, the effects of the solvent, temperature, reaction time, and the amount of the catalyst were widly studied with regard to catalysis of the $Zn(NO_3)_2$–(TyrOEt)$_2$ complex. The results of reactions in various solvents are shown in Table 4. DMF, THF, and HMPA as solvents were also examined, but the reactions did not proceed well and isolation of the products was difficult. According to Table 4, a H_2O solvent was the best in view of the aldol-type product formation (100%, by NMR). However, almost no asymmetric induction was observed. On the other hand, MeOH was the best regarding asymmetric induction. Acetone might represent a special case, as it is the substrate for the reactions and the reactions were completed within 8 h.

It may be presumed that the aldol-type(1) and the dehydrated-type(2) were in equilibrium; hence, the reaction in pure H_2O did not afford (2) at all. The

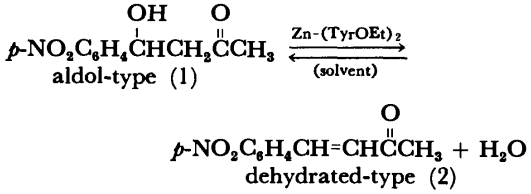


Table 3. Physical properties of Ni^{II}-L-TyrOEt complexes and the components

Compound[a]	pH	$[\alpha]_D$ (in EtOH)	UV λ_{max}	UV A

5 2	45	−9.7	+
3 4	77	−3.2	+
1 6	81	−2.2	0

a) Reactions and the reaction conditions are similar to those shown in Table 2(40 °C, 24 h, catalyst: 16 mol% of the aldehyde). b) Aldol-type product. c) Dehydrated product. d) Acetone 9 ml. e) pH 7. f) 100% by ^{1}H-NMR, the reaction was completed within 20 h.

results of the reactions in MeOH–H_2O mixed solvents at various ratios support the above equilibrization. The low $[\alpha]_D$ value of the product(1) may be due to the reversible dehydration-hydration reactions which cause the racemization of (1). In order to ascertain this assumption, the aldol-type(1) showing $[\alpha]_D=-12°$ was treated with a catalyst in H_2O or MeOH under similar conditions to those shown in Table 4. Treating in H_2O (addition of a small amount of MeOH to make the system homogeneous), the racemization occurred ($[\alpha]_D$ decreased to $-5°$), but no racemization occurred in the MeOH solvent (Eq. 1).

$$\text{(1) } ([\alpha]_D=-12°) \xrightarrow{\text{cat}} \begin{cases} \xrightarrow{H_2O} \text{(2) } 11\%\cdots[\alpha]_D \rightarrow -5° \\ \xrightarrow{\text{MeOH}} \text{(2) } 38\%\cdots[\alpha]_D \rightarrow -12° \end{cases} \quad (1)$$

$$\text{(2)} \xrightarrow{\text{cat., } H_2O} \text{(1) } 18\% \quad (2)$$

On the other hand, the hydration of (2) in H_2O occurred in a 18% yield (Eq. 2). Thus, an equilibrium between (1) and (2) in connection with the racemization was confirmed.

The effects of the reaction temperature, time, and the amount of the catalyst are summarized in Table 5. Comparing Entries 1(20 °C), 2(30 °C), 6(40 °C), and 8(50 °C) with each other, the elevation of the temperature seems to affect the dehydration and racemization. In Entry 3(48 h), $[\alpha]_D$ value of (1) is low compared with 2(24 h) and the prolonged reaction time seems to unfavorably affect the results accompanying racemization and dehydration, even in the MeOH solvent.

When twice the amount of the catalyst was employed (Entry 4, 32 mol% of the aldehyde), the reaction proceeded quickly (conversion 100%, by NMR, 24 h), but the dehydration increased up to 52% (NMR). On the contrary, when half the amount of catalyst was used (Entry 5, 8 mol% of the aldehyde), the reaction was very slow (conversion 30%, by NMR, 24 h) and gave a small amount of (2). Thus, an amount of the catalyst affected both the reaction velocity and the dehydration rate, but not to the degree of the racemization in the MeOH solvent. Benzaldehyde and *p*-chlorobenzaldehyde were also reactive with this catalyst system, but a high degree of the dehydration was notable under these conditions. As a general conclusion, the factors controlling the reactions are solvent, reaction temperature, time, and the amount of the catalyst. The effect of the reaction temperature seems to be most serious for asymmetric induction.

Assistant Effects of Cyclodextrins on the Catalysis of Zn^{II}-L-TyrOEt Complex. It has been known that aromatic aldehydes such as *p*-nitrobenzaldehyde are included well in the cavity of the CD.[4,5] In this system, the coordination of the *sec.* hydroxyl group located on the edge of the CD to the Zn^{2+} ion of the complex coexisted will occur. Then, the coordination of the formyl group to the Zn^{2+} ion may be accelerated. As a result, an increase in the reactivity may be expected. Since the CDs were soluble in H_2O but not in MeOH, reactions with a CD–Zn^{II}–TyrOEt system (1:1:1) were carried out in H_2O (pH 6 and 7). The pH of the reaction mixture with CD–Zn^{II}–TyrOEt was 6, and a buffer KH_2PO_4/NaOH was employed to adjust the pH to 7. The results of the experiments are shown in Table 6.

The sole α- or β-CD did not show any catalytic activity under these conditions. Entry 1 gave the aldol-type product in not very high yield in contrast with the reaction with the 1:2 complex (Table 4, 83%[f]). Whereas, in Entry 2, the catalytic activity increased much (100% yield, by NMR) without any

9	β-CD+Zn^{II}+TyrOEt	18		With p-ClC_6H_4CHO

a) Reactions of p-nitrobenzaldehyde with acetone, conditions: catalyst, 16 mol% of the aldehyde, 40 °C, 24 h in H_2O. b) By ^1H-NMR. c) Buffer, KH_2PO_4/NaOH, was used.

dehydration. The assistant effect of the CD was more remarkable with the β-CD, as shown in Entry 3. The yield of (1) increased up to 100% even in the pH 6 solution.

The retio of the added CD seemed to be adequate in CD-Zn^{II}-TyrOEt=1:1:1. When three times the amount of α-CD was used (Entry 6, 3:1:1), the yield of (1) decreased to 55%, even in the pH 7 solution (unreacted aldehyde 45%). This was lower than that for a reaction without the CD (Entry 1). In Entry 7, the yield of (1) was lower than that for reactions with the $Zn(NO_3)_2$ complex system. All the reactions in Table 6 were carried out in an H_2O solvent; therefore, it could be infered that almost no asymmetric induction was observed in the reactions. When mixed solvents were used (MeOH 4 ml+H_2O 3 ml) under similar conditions to those in Entry 2(pH 7), the yield of (1) was only 20% in contrast with 100% in Entry 2. Accordingly, it may be necessary to find an adequate solvent system or some other reaction methods for asymmetric induction.

Conclusion. An original and preliminary survey on the aldol reactions catalyzed by metal complexes bearing ligands of the α-amino acid ester have been achieved. The most adequate catalytic system to afford an enantiomeric excess of the aldol-type product was the $Zn(NO_3)_2$-(L-TyrOEt)$_2$ in MeOH. The assistant effects of α- and β-cyclodextrins, especially of the β-CD, on the catalysis of the Zn^{II}-TyrOEt complex in the aldol reactions were observed evidently.

Aldol reactions in biological systems have been known to be catalyzed by aldolase enzymes, Class-I and -II.[6] The latter is a metalloenzyme containing a Zn^{2+} ion at the active sites. However, the catalysis of the Class-II aldolase has not been sufficiently elucidated. Therefore, our reaction systems with Zn^{II}-L-TyrOEt and CD-Zn^{II}-L-TyrOEt may present novel possibilities for understanding a Zn^{2+} ion catalysis from the point of view of organic catalytic reactions.

Experimental

Instruments. The ^1H-NMR spectra were taken with a Hitachi Perkin-Elmer R-20A spectrophotometer (60 MHz). The UV and IR spectra were taken with a Hitachi 220A double-beam spectrophotometer and a Hitachi 260-10 Infrared spectrophotometer, respectively. The optical rotations were measured with a JASCO DIP-140 digital polarimeter (Nippon Bunko).

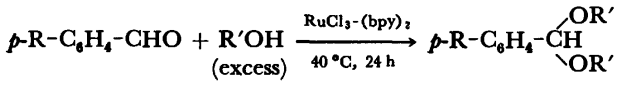
Materials. L-, D-, and DL-Tyrosine ethyl esters and the L-tyrosine methyl ester were prepared from their original amino acids with alcohols in the presence of small quantities of concd sulfuric acid, L-TyrOEt: mp 105 °C, $[\alpha]_D$=+19.5° (EtOH), (lit,[7] 108 °C, +20°), DL-TyrOEt: mp 99—102 °, L-TyrOMe: mp 128—131 °C, $[\alpha]_D$=+28.0° (EtOH) (lit,[8] 135 °C, +25.7°). L-Histidine methyl ester was obtained from L-HisOMe·2HCl, mp 60—61 °C, $[\alpha]_D$=+11.2° (MeOH), Anal ($C_7H_{11}O_2N_3$) C,H,N. Other ligand compounds were commercially available, quinine: mp 177 °C, $[\alpha]_D$=−117° (in $CHCl_3$), qunidine: mp 175 °C, $[\alpha]_D$=−230° (in $CHCl_3$), 2,2′-bipyridine: mp 69.7 °C (recrystallyzed from EtOH-H_2O). The solvents used were distilled before use, and the dry methanol was preserved with molecular sieves. α- and β-cyclodextrins were commercially available, α-CD: $[\alpha]_D$=+133°, β-CD: $[\alpha]_D$=+154° (in H_2O).

The Aldol Reactions with Chiral Metal Complexes. As a representative example, the reaction of p-nitrobenzaldehyde with acetone in the presence of $Zn(NO_3)_2$-(TyrOEt)$_2$ in MeOH is described. To a solution of $Zn(NO_3)_2 \cdot 6H_2O$ (33 mg, 0.11 mmol) in MeOH (3.5 ml), L-TyrOEt (46.mg, 0.22 mmol) in MeOH (3.5 ml) was added and the mixed solution was well stirred (M:L=1:2). A solution of the complex catalyst was added to a solution of p-nitrobenzaldehyde (100 mg, 0.66 mmol) in 2 ml of acetone in a 20-ml flask. The flask was plugged and the reaction mixture was stirred with a magnetic stirrer for 24 h at 40 °C. After the reaction, the reaction mixture was diluted with water and extracted with ethyl acetate. The organic layer separated was dried over anhydrous magnesium sulfate and then evaporated under a reduced pressure at room temperature to give an oily mixture of unreacted aldehyde, aldol

type product, and its dehydrated product. The oily mixture was submitted to column chromatography on silica-gel (eluent: hexane and ethyl acetate, 1:1) to give the aldol-type product which was monitored by TLC on silica gel (R_f value: aldol-type 0.32, dehydrated-type 0.53, aldehyde 0.67). In the case of the determination of the ratio of these components, the ^{1}H-MNR spectra of the oily mixture was measured ($CDCl_3$, TMS 1%) before the chromatographic separation, and each percentage was calculated. The fractions of the aldol-type product were collected together and evaporated under reduced pressure. Thus, the aldol-type product, 4-hydroxy-4-(4-nitrophenyl)-2-butanone, was obtained. The enantimeric excess one was oily but the racemate was light-yellowish crystals of mp 63 °C.[9] Its optical rotation was measured in EtOH with D-line and the specific rotation was calculated.

The Aldol Reactions with Cyclodextrin(CD)-Zn^{II}-L-TyrOEt System. $Zn(NO_3)_2 \cdot 6H_2O$ (33 mg, 0.11 mmol) and β-CD (124 mg, 0.11 mmol) were dissolved together in H_2O (7 ml). To this solution, a solution of L-TyrOEt (23 mg, 0.11 mmol) in acetone (1 ml) was added and stirred. This was a water solution of the CD-Zn^{II}-L-TyrOEt (1:1:1) catalyst system. Then, a solution of *p*-nitrobenzaldehyde (100 mg, 0.66 mmol) in acetone (1 ml) was added to the catalyst solution and the pH of the reaction mixture was adjusted to 6 or 7. The amount of the catalyst system was 16 mol% of the aldehyde used. The flask was plugged and kept at 40 °C for 24 h (magnetic stirring). The procedures after the reaction were similar to that of the reactions without the CD. An extraction with ethyl acetate was also carried out.

The Acetal Formation with $RuCl_3$ Complexes. In a reaction with $RuCl_3$-$(TyrOEt)_2$ in MeOH (Table 2), only the *p*-nitrobenzaldehyde dimethyl acetal was obtained in a 62% yield without any aldol reaction product at all. The acetal was isolated by means of column chromatography as well as the aldol-type product. Thereupon, it was prepared separately from the aldehyde and methanol by the conventional method (HCl catalyst) for further identification. R_f value: 0.54 by silica-gel TLC, bp 64.7 °C ^{1}H-NMR ($CDCl_3$): δ=3.39 (3H, s, CH_3), 5.51 (1H, s, CH), 7.59—8.34 (q, aromatic proton). It was found that acetals were also formed with the $RuCl_3$-$(bpy)_2$ complex as follows.



R	R'OH	Catalyst (mol% of CHO)	Yield/% (NMR)
NO_2	MeOH	16	100
		1	100
	EtOH	1	80
	i-PrOH	1	41
H	MeOH	2	100
OMe		2	54

Reaction Products. 4-Hydroxy-4-(4-nitrophenyl)-2-butanone (racemate),[9] mp 63 °C, Found: C, 57.44; H, 5.30; N, 6.61%. Calcd for $C_{10}H_{11}O_4N$: C, 57.41; H, 5.30; N, 6.70%. IR (cm^{-1}): 3400 (OH), 1710 (C=O), 1510, 1440 (NO_2). ^{1}H-NMR ($CDCl_3$): δ=2.19 (s, 3H), 2.88 (d, 2H), 4.10 (br.s, OH), 5.18 (t, 1H), 7.56—8.15 (q, aromatic proton). 4-(4-nitrophenyl)-3-buten-2-one(dehydrated product),[9] mp 114—116 °C, ^{1}H-NMR ($CDCl_3$): δ=2.42 (s, 3H), 6.68—6.96 (d, 1H), 7.30—7.46 (d, 1H), 7.64—8.37 (q, aromatic proton). 4-hydroxy-4-phenyl-2-butanone, oil, ^{1}H-NMR ($CDCl_3$): δ=2.14 (s, 3H), 2.73 (d, 2H), 5.19 (t, 1H), 7.36-8.03 (m, aromatic proton). 4-hydroxy-4-(4-chlorophenyl)-2-butanone, oil, ^{1}H-NMR ($CDCl_3$): δ=2.14 (s, 3H), 2.73 (d, 2H), 5.10 (t, 1H), 7.32—7.82 (q, aromatic proton).

Preparation and Chiroptical Properties of Optically Active Tetracyclic Cage-shaped Hydrocarbons; [*m*.0]Triblattanes and [*m*.1]Triblattanes

Koichiro NAEMURA,* Tohru KATOH, Rinkō FUKUNAGA, Hiroaki CHIKAMATSU, and Masao NAKAZAKI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received November 13, 1984)

Horse liver alcohol dehydrogenase mediated reduction of tetracyclo[4.3.0.$0^{2,5}$.$0^{3,8}$]nonan-9-one ([1.0]triblattan-9-one) (**17**) gave (+)-**17** and (−)-tetracyclo[4.3.0.$0^{2,5}$.$0^{3,8}$]nonan-9-ol (**18**). Hydrogenolysis of (+)-**17** with 5% rhodium-alumina to (+)-(1*R*,3*R*,6R8*R*)-twist-brendan-9-ol with known absolute rotation allowed us to assign the 1*S*,2*S*,3*R*,5*R*,6*R*,8*R* absolute configuration to (+)-**17** and to calculate the absolute rotation of (+)**17**. Wolff-Kishner reduction of (+)-**17** gave (+)-[1.0]triblattane. BF_3-Catalyzed diazomethane ring expansion of (+)-**17** was followed by Wolff-Kishner reduction to afford optically active [*m*.0]triblattanes. (+)-Tetracyclo-[5.2.1^{2,6}.$0^{4,8}$]decan-5-one ([1.1]triblattan-5-one) with known absolute configuration and absolute rotation was transformed to optically active [*m*.1]triblattanes by diazomethane ring expansion with BF_3 etherate followed by Wolff-Kishner reduction. The known optical purities of our starting materials permitted calculation of the absolute molecular rotations of [*m*.0]triblattanes and [*m*.1]triblattanes. The chiroptical properties of triblattanes are discussed.

The C2–C8 diagonal bridging of D_3-twisted bicyclo[2.2.2]octane (**1**) with a polymethylene bridge provides a tricyclic cage-shaped hydrocarbon **2**, and further C3–C6 diagonal bridging of the chiral molecule with a polymethylene bridge gives a tetracyclic hydrocarbon **3**. Final C5–C7 diagonal bridging furnishes a pentacyclic hydrocarbon **4**.

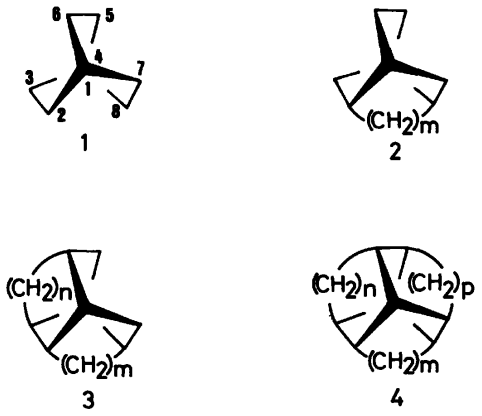

Chart 1.

We have coined for these hydrocarbons **2**, **3**, and **4** the generic names [*m*], [*m*.*n*], and [*m*.*n*.*p*]triblattane, respectively. Since our first preparation of twistane ([2]triblattane) in an optically active form,[1] we have been interested in the preparation, stereochemistry, and biological transformation of triblattanes.

Figure 1 shows the correlation between bridge span (*m*) and absolute molecular rotation ($[M]_{D\ abs.}$) in triblattanes[2,3] which have been prepared in optically active modification in our laboratory, except for [0]triblattane.[4] Inspection of the Fig. 1 reveals the interesting chiroptical features, (a) all dextrorotatory enantiomers possess a central core, D_3-twisted bicyclo[2.2.2]octane framework, fixed in a P-helical conformation, (b) however, triblattanes having two long diagonal bridges are levorotatory in spite of possessing the central core with P-helicity as shown in a se-

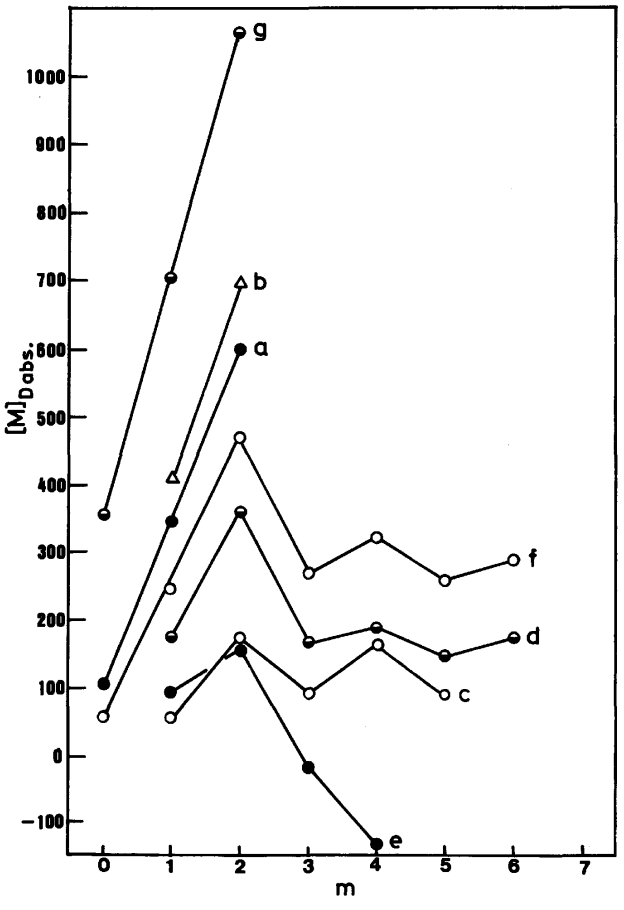

Fig. 1. Correlation between bridge span (*m*) and absolute molecular rotation ($[M]_{D\ abs.}$); a: [*m*]triblattane (**2**), b: [*m*.1]triblattane (**3**, $n=1$), c: [*m*.1.0]triblattane (**4**, $n=1$ $p=0$), d: [*m*.2.0]triblattane (**4**, $n=2$ $p=0$), e: [*m*.3.0]triblattane (**4**, $n=3$ $p=0$), f: [*m*.1.1]triblattane (**4**, $n=p=1$), g: [*m*.2.2]triblattane (**4**, $n=p=2$).

ries of [*m*.3.0]triblattanes ($m \geqq 3$), (c) for all series of triblattanes, the values of molecular rotations increase linearly with bridge span (*m*) to $m=2$, (d) the values drop abruptly on going from $m=2$ to $m=3$ and then remain almost constant.

Natural extension of these studies led us to investigate chiroptical properties of series of tetracyclic triblattanes. In this paper, we wish to report the preparation of series of optically active [*m*.0]triblattanes (**5**—**8**) and [*m*.1]triblattanes (**9**—**15**) with known absolute configuration and discuss their chiroptical properties.

Results and Discussion

Optical Resolution of [1.0]Triblattan-9-one. The diagonal bridging between C3 and C6 positions of [0]triblattane (**2**, $m=0$), being the smallest triblattane, furnishes a series of [*m*.0]triblattanes (**3**, $n=0$). The first task is optical resolution of (±)-[1.0]triblattan-9-one (**17**), being the starting material for the preparation of [*m*.0]triblattanes. Acid hydrolysis of 9,9-ethylenedioxytetracyclo[4.3.0.$0^{2,5}$.$0^{3,8}$]nonane (**16**), prepared according to Toyne's procedure,[5] gave (±)-**17** which was resolved by horse liver alcohol dehydrogenase (HLADH) mediated reduction. The ketone (±)-**17** was incubated for 5 min at 25 °C with NAD^+ and HLADH in 1/15 M (1 M=1 mol dm^{-3}) Sørensen phosphate buffer solution (pH 7.0). GLC analysis of the ether-extracted metabolite revealed the presence of the recovered ketone **17** (51%) and a 4:

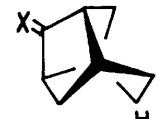
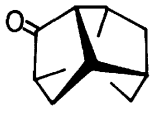
(−)-18



(+)-19 X=<H OH>
20 X=<O O>

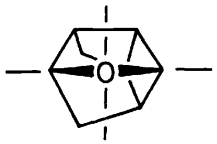


(+)-21

Chart 3.

1 mixture of diastereomeric alcohols (49%). Column chromatography of the metabolite on alumina furnished (+)-**17**, mp 96—98 °C (in a sealed tube) $[\alpha]_D$ +46.3°, and the major alcohol (−)-**18**, mp 118—120 °C (in a sealed tube) $[\alpha]_D$ −67.7°, but attempts to purify the minor alcohol were unsuccessful. The mixture of metabolite alcohols was oxidized with chromium trioxide in acetone gave (−)-**17**, $[\alpha]_D$ −33.0°, as a sole product.

Our next task is determination of the absolute configuration of (+)-**17** and (−)-**18**. Circular dichroism (CD) spectra of cage-shaped ketones,[2] prepared from intermediates of known absolute configuration, indicate that the sign of CD curve due to n-π^* transition can be predicted by applying the octant rule to the "outer ring"[6] in the projection formula which holds the carbonyl group at the "point of twist".[7] Applying this generalization to the projection formula **22** of the ketone (+)-**17** with negative Cotton effect, we obtain the 1*S*,2*S*,3*R*,5*R*,6*S*,8*R* absolute configuration for (+)-**17**. In other words, (+)-**17** possess the D_3-twisted bicyclo[2.2.2]octane framework fixed in a P-helical conformation.



22

Chart 4.

This conclusion was unambiguously confirmed by the chemical conversion of (+)-**17** to (+)-twistbrendan-9-ol (**19**), whose absolute configuration and absolute rotation have been determined in our laboratory.[8] Hydrogenolysis of 9,9-ethylenedioxytetracyclo[4.3.0.$0^{2,5}$.$0^{3,8}$]nonane (**16**) with 5% rhodium-alumina to 9,9-ethylenedioxytwistbrendane (**20**) has been reported by Toyne.[5] The ketone (+)-**17**, $[\alpha]_D$ +46.3°, was hydrogenolyzed with 5% rhodium-alumina in cyclohexane to yield (+)-(1*R*,3*R*,6*R*,8*R*)-twistbrendan-9-ol (**19**), $[\alpha]_D$ +122° (46.5% optical purity).[8] The result permitted us to confirm the absolute configuration and calculate the absolute rotation of (+)-**17** ($[\alpha]_{D\,abs.}$ +99.6°). Jones oxidation of the major alcohol (−)-**18**, $[\alpha]_D$ −67.7°, to (−)-**17**, $[\alpha]_D$ −55.7° (55.9% o.p.), possessing the central core of M-helicity, allowed us to calculate the optical purity of the metabolite alcohol (−)-**18** and to prove the central core of (−)-**18** to be fixed in a M-helical conformation. However, the configuration of the hydroxyl group is unknown.

Preparation of [m.0]Triblattanes. The ketone (+)-**17**, $[\alpha]_D$ +46.3°, was reduced by Wolff-Kishner reduction and the product was chromatographed on alumina to give [1.0]triblattane (**5**), mp 103—105 °C (in a sealed tube) $[\alpha]_D$ +48.9°. In a previous paper,[3,9]

we reported our successful preparation of series of pentacyclic triblattanes by diazomethane ring expansion of cage-shaped ketones. Our preliminary experiment utilizing (±)-**17** indicated that when kept at 0 °C for 6 d an ethereal solution of (±)-**17** containing 10 equiv of diazomethane gave a mixture of [1.0]triblattanone and [2.0]triblattanones with unknown location of the carbonyl group in the expanded bridge. The mixture was directly reduced by Wolff-Kishner reduction to yield a 6:4 mixture of [1.0]triblattane (**5**) and [2.0]triblattane (**6**).

Addition of boron trifluoride was found to push the ring expansion further furnishing a product consisting of higher homologs. An ethereal solution of (+)-**17** containing diazomethane and 1 equiv of BF_3 etherate was kept at 0 °C for 30 min. To reveal composition of the ring-expanded product, the product was directly converted to a mixture of hydrocarbons by Wolff-Kishner reduction and the product was analyzed by GLC. The results are given in Table 1.

After these preliminary experiments utilizing (±)-**17**, we carried out the preparative experiment with (+)-**17**. An ethereal solution of (+)-**17**, $[\alpha]_D$ +46.3°, containing of 4 equiv of diazomethane and 1 equiv of BF_3 etherate was kept at 0 °C for 1 h. The mixture of ring-expanded ketones was directly transformed to a mixture of [*m*.0]triblattanes by Wolff-Kishner reduction. After being analyzed by GLC, the product was separated by preparative GLC to furnish (+)-**6**, (+)-**7**, and (−)-**8**. The structures of these hydrocarbons were confirmed on the basis of their mass spectra and elemental analyses.

*Preparation of [*m.1*]Triblattanes.* The synthesis of a series of [*m*.1]triblattanes (**3**, n=1) began with tetracyclo[5.2.1.$0^{2,6}$.$0^{4,8}$]decan-5-one ([1.1]triblattan-5-one) (**21**) which has been prepared in an optically active form with known absolute configuration and absolute rotation in our laboratory.[10] Diazomethane ring expansion of (±)-**21** without catalyst gave no ring-expanded product. Treatment of (±)-**21** with excess of diazomethane and 1 equiv of BF_3 etherate followed by Wolff-Kishner reduction yielded a mixture of ring-expanded hydrocarbons. The results are given in Table 2.

We carried out the preparative experiment with (+)-**21**, $[\alpha]_D$ +145° (59.6% o.p.), which was dissolved in an ethereal solution containing of 15 equiv of diazomethane and 1 equiv of BF_3 etherate. After the mixture was kept at 0 °C for 1 h, the resulting mixture of ring-expanded ketones was reduced by Wolff-Kishner reduction to yield a mixture of [*m*.1]triblattanes which was analyzed by GLC. Preparative GLC separated and purified these hydrocarbons **9**—**15**.

*Chiroptical Properties of [*m.0*]Triblattanes and [*m.1*]-Triblattanes.* The known optical purities of our starting materials (+)-**17** and (+)-**21** permitted us to calculate the absolute molecular rotations of these new triblattanes (Table 3).

These values are plotted in Fig. 2 together with that of [2.2]-triblattane.[11] A few conspicuous features are worth noting, (a) all [*m*.1]triblattanes having the central core of P-helicity are dextrorotatory, (b) [*m*.0]triblattanes possessing a short diagonal bridge (m<4) as well as the central core of P-helicity are dextrorotatory, but [4.0]triblattane, like [*m*.3.0]triblattanes (m=3,4), is levorotatory in spite of having the central core fixed in a P-helical conformation, (c) the presence of a zero bridge in [*m*.0]triblattanes is reflected in a markedly decreased molecular rotation relative to [*m*.1]triblattanes and [*m*.2]triblattanes.

Experimental

Infrared spectral data were obtained from a Hitachi 260-10 spectrophotometer. Optical rotations were measured with a JASCO-DIP-140 automatic polarimeter. Circular dichroism data were collected with a JASCO J-40 spectropolarimeter. Mass spectra were taken with a Hitachi RMS-4 spectrometer. Elemental analyses were performed on a

Yanagimoto CHN-Corder, Type II. GLC analyses were performed on a JGC-20 K equipped with a FID and using a 1 m×3 mm column of 10% PEG 20 M on UniportHP. Preparative GLC were done on a JGC-20 K equipped with a TCD and using a 2 m×3 mm column of 10% PEG 20 M on UniportHP. HLADH was purchased from Boehringer (Mannheim) as a crystalline suspension in phosphate buffer containing 10% ethanol.

(±)-Tetracyclo[4.3.0.0^{2,5}.0^{3,8}]nonan-9-one (17). 9,9-Ethylenedioxytetracyclo[4.3.0.0^{2,5}.0^{3,8}]nonane (**16**) (670 mg, 3.76 mmol), prepared according to Toyne's procedure,[5] was mixed with 5% sulfuric acid (20 mL) and the mixture was stirred for 2 d at room temperature. After the reaction mixture was extracted with ether, the extract was worked up as usual. The product was chromatographed on alumina and elution with pentane gave a solid which was sublimed at 50—60 °C (20 mmHg (1 mmHg=133.322 Pa)) to yield 216 mg of **17** (43% yield); mp 100—101 °C (in a sealed tube); IR (KBr) 1760 cm^{-1}; Found: C, 80.41; H, 7.53%. Calcd for $C_9H_{10}O$: C, 80.56; H, 7.51%.

HLADH-mediated Reduction of (±)-Tetracyclo[4.3.0.0^{2,5}.0^{3,8}]nonan-9-one (17). The ketone (±)-**17** (92.3 mg, 0.690 mmol) was dissolved in 1 L of 1/15 M Sφrensen phosphate buffer solution (pH 7.0) and then to the solution was added NAD^+ (42.6 mg, 0.0594 mmol), ethanol (1 mL), and HLADH (4 mg). After being incubated at 25 °C for 5 min, the mixture was extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated to give a metabolite mixture (81 mg). GLC analysis of the metabolite revealed the presence of **17** (51%) and a 4:1 mixture of diastereomeric alcohols (49%). The product was chromatographed on alumina, and elution with pentane afforded 37 mg of **17**; mp 98—100 °C (in a sealed tube); $[\alpha]_D^{22}$ +46.3° (*c* 0.220, $CHCl_3$); C.D. (*c* 4.43×10^{-2} mol dm^{-3}, 2,2,4-trimethylpentane) $[\theta]_{291}$ −3.92×10^2 (sh), $[\theta]_{296}$ −5.59×10^2 (sh), $[\theta]_{300}$ −6.35×10^2, $[\theta]_{303}$ −6.18×10^2 (sh); Found: C, 80.43; H, 7.52%. Calcd for $C_9H_{10}O$: C, 80.56; H, 7.51%. Elution with pentane–ether (95:5. v:v) gave 22 mg of **18**; 118—120 °C (in a sealed tube); $[\alpha]_D^{24}$ −67.7° (*c* 0.200, $CHCl_3$); Found: C, 79.18; H, 8.85%. Calcd for $C_9H_{12}O$: C, 79.37; H, 8.88%. Further elution with the same solvent gave 13 mg of a mixture of diastereomeric alcohols.

Oxidation of the Mixture of Diastereomeric Alcohols. To a solution of the 4:1 mixture of alcohols (140 mg, 1.03 mmol) in acetone (2 mL) was added excess of 8 N Jones' reagent.[14] After being stirred for 3 h at room temperature, the reaction mixture was diluted with water (10 mL) and extracted with ether. After a usual workup, the extract was concentrated to give a solid which was chromatographed on alumina (pentane eluent) to furnish 119 mg of (−)-**17** (86% yield); mp 99—101 °C (in a sealed tube); $[\alpha]_D^{23}$ −33.0° (*c* 0.372, $CHCl_3$); Found: C, 80.39; H, 7.51%. Calcd for $C_9H_{10}O$: C, 80.56; H, 7.51%.

Oxidation of the Major Alcohol 18. Oxidation of (−)-**18** (50 mg, 0.37 mmol), $[\alpha]_D$ −67.7°, which 8N Jones' reagent in acetone was carried out by the same procedure described above. Chromatography of the product on alumina followed by sublimation furnished 42 mg of (−)-**17** (85% yield); mp 98—99 °C (in a sealed tube); $[\alpha]_D^{22}$ −55.7° (*c* 0.250, $CHCl_3$); Found: C, 80.44; H, 7.53%. Calcd for $C_6H_{10}O$: C, 80.56; H, 7.51%.

Hydrogenolysis of (+)-Tetracyclo[4.3.0.0^{2,5}.0^{3,8}]nonan-9-one (17). A mixture of (+)-**17** (79 mg, 0.59 mmol), $[\alpha]_D$ +46.3°, rhodium–alumina (50 mg), and cyclohexane (20 mL) was shaken at room temperature in a hydrogenation flask at 1 atm of hydrogen. After the hydrogen absorption had ceased, the catalyst was filtered off. The filtrate was concentrated to give a solid which was purified by preparative GLC to furnish 42 mg of (+)-**19**; mp 162—164 °C (in a sealed tube) (lit,[8] mp 162—165 °C); $[\alpha]_D^{24}$ +122° (*c* 0.115, MeOH) (lit,[8] $[\alpha]_D^{23}$ +164° (MeOH)). Spectral comparison with an authentic specimen confirmed its identity.

(+)-Tetracyclo[4.3.0.0^{2,5}.0^{3,8}]nonane (5). A mixture of (+)-**17** (80 mg, 0.60 mmol), $[\alpha]_D$ +46.3°, 100% hydrazine hydrate (0.1 mL), potassium hydroxide (53 mg), and triethylene glycol (2 mL) was heated for 1 h at 110—120 °C and then for an additional 3 h at 190—200 °C. After cooling to room temperature, the reaction mixture was diluted with water and extracted with pentane. The extract was washed with water, dried ($MgSO_4$), and concentrated. The product was chromatographed on alumina (pentane eluent) to give a solid which was sublimed at 50—60 °C (760 mmHg) to yield 27 mg of (+)-**5** (38% yield); mp 103—105 °C (in a sealed tube); $[\alpha]_D^{25}$ +48.9° (*c* 0.180, $CHCl_3$); MS, *m/z* 120 (M^+); Found: C, 89.84; H, 10.01%. Calcd for C_9H_{12}: C,

89.94; H, 10.06%.

Product Distribution in the Diazomethane Ring Expansion of (±)-Tetracyclo[4.3.0.0^{2,5}.0^{3,8}]nonan-9-one (17). Without Catalyst: An ethereal solution of diazomethane (630 mg, 14.9 mmol) was added to an ice cooled solution of (±)-**17** (200 mg, 1.49 mmol) in dry ether (20 mL). The reaction mixture was allowed to stand at 0 °C for 6 d. The product was analyzed by GLC.

With BF_3 etherate Catalyst: The following experimental procedure is typical. An ethereal solution of diazomethane (63 mg, 1.5 mmol) was added to a stirred and chilled (0 °C) solution of (±)-**17** (200 mg, 1.49 mmol) and BF_3 etherate (0.19 mL, 1.5 mmol) in dry ether (20 mL). After the mixture was kept at 0 °C for 30 min, a deposited solid was removed by filtration and the filtrate was washed with aq $NaHCO_3$ solution and water, dried ($MgSO_4$), and concentrated to give an oily product (190 mg). The product was mixed with 100% hydrazine hydrate (0.24 mL), potassium hydroxide (130 mg), and triethylene glycol (2 mL) and then the mixture was heated for 1 h at 110—120 °C and for an additional 4 h at 190—200 °C. After a workup described for the preparation of (+)-**5**, the product (110 mg) was analyzed by GLC.

Preparation of (+)-[2.0]Triblattane (6), (+)-[3.0]Triblattane (7), and (−)-[4.0]Triblattane (8). An ethereal solution of diazomethane (188 mg, 4.47 mmol) was added to a stirred solution of (+)-**17** (150 mg, 1.12 mmol), $[\alpha]_D$ +46.3°, and BF_3 etherate (0.14 mL, 1.1 mmol) in dry ether (15 mL) with ice-cooling. After being stirred for 1 h at 0 °C, the reaction mixture was worked up as described for the reaction of (±)-**17** to yield 145 mg of a mixture of ring expanded ketones, which was without purification used in the next reaction. Wolff-Kishner reduction of the crude product with 100% hydrazine hydrate (0.18 mL), potassium hydroxide (95 mg), and triethylene glycol (2 mL) was carried out by the same procedure as described for the preparation of (+)-**5**. GLC analysis of the product (120 mg) revealed the presence of **5** (3%), **6** (57%), **7** (25%), and **8** (15%). Preparative GLC (at 120 °C) provided specimens of **6** (42 mg); R_t. 2′48″, **7** (18 mg); R_t. 5′48″, and **8** (13 mg); R_t. 11′54″. (+)-[2.0]Triblattane (**6**); mp 123—124 °C (in a sealed tube); $[\alpha]_D^{22}$ +76.1° (*c* 0.325, $CHCl_3$); MS *m/z* 134 (M^+); Found: C, 89.42; H, 10.47%. Calcd for $C_{10}H_{14}$: C, 89.49; H, 10.51%. (+)-[3.0]Triblattane (**7**); semisolid; $[\alpha]_D^{22}$ +2.60° (*c* 0.153, $CHCl_3$); MS *m/z* 148 (M^+); Found: C, 89.17; H, 10.81%. Calcd for $C_{11}H_{16}$: C, 89.12; H, 10.88%. (−)-[4.0]Triblattane (**8**); oil; $[\alpha]_D^{22}$ −19.3° (*c* 0.127, $CHCl_3$); MS *m/z* 162 (M^+); Found: C, 88.78; H, 11.15%. Calcd for $C_{12}H_{18}$: C, 88.82; H, 11.18%.

Product Distribution in the Diazomethane Ring-expansion of (±)-Tetracyclo [5.2.1.0^{2,6}.0^{4,8}]decan-5-one (21). The following experimental procedure is typical. To a chilled (0 °C) solution of (±)-**21** (100 mg, 0.675 mmol) in dry ether (10 mL) was added BF_3 etherate (0.085 mL, 0.68 mmol) and then to the mixture was added an ethereal solution of diazomethane (28 mg, 0.68 mmol). After being stirred for 1 h at 0 °C, the mixture was worked up as described for the reaction of (±)-**17**. Wolff-Kishner reduction of the crude mixture of ring-expanded ketones was carried out by the same procedure as described for the preparation of (+)-**5** and the product was analyzed by GLC.

Preparation of Optically Active [m.1]Triblattanes (9—15). A solution of (+)-**21** (500 mg, 3.37 mmol), $[\alpha]_D^{23}$ +145° ($CHCl_3$) (59.6% o.p.)[10], in dry ether (50 mL) was cooled in an ice bath. To the chilled solution was successively added BF_3 etherate (0.425 mL, 3.37 mmol) and an ethereal solution of diazomethane (2.10 g, 50.0 mmol). After being stirred for 30 min at 0 °C, the reaction mixture was worked up as described for the reaction of (±)-**17** to give 480 mg of a mixture of ketones, which was without purification used in the next reaction. Wolff-Kishner reduction of the crude product was carried out with 100% hydrazine hydrate (0.55 mL), potassium hydroxide (300 mg), and triethylene glycol (10 mL) by the same manner described for the preparation of (+)-**5**. GLC analysis of the product (450 mg) revealed the presence of **9** (9%), **10** (15%), **11** (14%), **12** (25%), **13** (4%), **14** (19%), and **15** (14%). Preparative GLC (at 150 °C) provided specimens of **9** (40 mg); *R*. 2′10″, **10** 56 mg); R_t. 2′55″, **11** (55 mg); R_t. 3′48″, **12** (85 mg); R_t. 8′36″, **13** (20 mg); R_t. 17′00″, **14** (50 mg), R_t. 29′06″, and **15** (25 mg), R_t. 42′06″. (+)-[1.1]Triblattane (**9**); mp 163—164 °C (in a sealed tube) (lit,[10] mp 164.5—165.5 °C); $[\alpha]_D^{23}$ +234° (*c* 0.360, $CHCl_3$); the identity was established by the comparison of its GLC retention time with that of an authentic sample. (+)-[2.1]Triblattane (**10**); mp 138—140 °C (in a sealed tube) (lit,[11] mp 140—141 °C); $[\alpha]_D^{23}$ +276° (*c* 0.330, $CHCl_3$); the identity was established by the comparison of its GLC retention time with that of an authentic sample. (+)-[3.1]Triblattane (**11**); oil; $[\alpha]_D^{23}$ +138° (*c* 0.532, $CHCl_3$); MS *m/z* 162 (M^+); Found: C, 88.58; H, 11.28%. Calcd for $C_{12}H_{18}$: C, 88.82; H, 11.18%. (+)-[4.1]Triblattane (**12**); oil; $[\alpha]_D^{24}$ +129° (*c* 0.833, $CHCl_3$); MS *m/z* 176 (M^+); Found: C, 88.31; H, 11.46%. Calcd for $C_{13}H_{20}$: C, 88.56, H, 11.44%. (+)-[5.1]Triblattane (**13**); oil; $[\alpha]_D^{24}$ +92.4° (*c* 0.208, $CHCl_3$); MS *m/z* 190 (M^+); Found: C, 88.55; H, 11.54%. Calcd for $C_{14}H_{22}$: C, 88.35; H, 11.65%. (+)-[6.1]Triblattane (**14**); oil; $[\alpha]_D^{25}$ +111° (*c* 0.485, $CHCl_3$); MS *m/z* 204 (M^+); Found: C, 87.93; H, 11.80%. Calcd for $C_{15}H_{24}$: C, 88.16; H, 11.84%. (+)-[7.1]-Triblattane (**15**); oil; $[\alpha]_D^{25}$ +80.0° (*c* 0.254, $CHCl_3$); MS *m/z* 218 (M^+); Found: C, 87.84; H, 11.88%. Calcd for $C_{16}H_{26}$: C, 88.00; H, 12.00%.

(Received November 15, 1984)

It was shown that *N*-(4-methoxybenzyl) group on 2,5-piperazinediones can be oxidatively removed with cerium(IV) diammonium nitrate under mild conditions, and the oxidative removal was performed in some model compounds which have several functional groups.

For syntheses of biologically active 2,5-piperazinediones (PDO) having complicated structures such as bicyclomycin,[1] antibiotic 593A,[2] sirodesmin,[3] aspirochlorine[4] *etc.*, the selection of a suitable *N*-protecting group is an important problem. The protecting group should be easily introducible, improvable the solubility of this class of polar compounds, stable under various reaction conditions for conversions, and selectively removable under mild conditions. Up to the present, methylthiomethyl,[5] methoxymethyl,[5,6] and acyl[5,7] groups have been used, but, there are still remaining some problems in stability or conditions for deprotection. In a previous communication,[8] we reported that *N*-(4-methoxybenzyl) group on PDO can be removed by cerium(IV) diammonium nitrate (CAN), and satisfied the aforementioned conditions. This paper describes detailed data of the communication.

The oxidative removal of *O*-benzyl and *O*-(4-methoxybenzyl) groups has been done by the use of DDQ,[9] triphenylmethyl tetrafluoroborate,[10] chromium trioxide[11] and electrolytic oxidation[12] *etc.* For *N*-protecting group of β-lactams, oxidative removal of 2,4-dimethoxybenzyl[13] and 3,4-dimethoxybenzyl[14] groups with potassium peroxodisulfate and of 4-(methoxymethyloxy)phenyl[15] and 4-methoxyphenyl groups[16] with CAN have been reported, but, the introduction of these protecting groups is more or less tedious. Autoxidative removal of *N*-benzyl group in an amino sugar with potassium *t*-butoxide–dimethyl sulfoxide[17] is known, but the strongly alkaline conditions are unsuitable for PDO derivatives. Recently, 4-methoxybenzyl group was actually utilized for the synthesis of bicyclomycin.[18]

Results and Discussion

Model compounds (**1i**, **3e—i**, **5a—c**, **6a**) for the examination of oxidative deprotection were synthesized as follows. Condensation of *N*,*N*′-diacetylanhydroglycine with *p*-tolualdehyde in the presence of potassium *t*-butoxide[19] gave the corresponding (*Z*)-1-acetyl-3-(4-methylbenzylidene)-PDO (**1a**) in 87% yield. *N*-Benzylation of the corresponding 3-isobutylidene derivative[19] in *N*,*N*-dimethylformamide (DMF) with sodium hydride and benzyl bromide gave the *N*-benzyl derivative (**1b**) in 73% yield. When benzyl chloride instead of the bromide was used, a 1:1 mixture of **1b** and the corresponding *O*-benzyl derivative (**2**) of the enolate was produced, but the formation of **2** was generally less than 5% in the reaction with the bromide. In a similar way, 3-benzylidene (**1c**) and 3-(4-methylbenzylidene) (**1d**) derivatives were obtained. The formation of **2** may be attributed to the steric hindrance and conjugation of 3-alkylidene group, and also to the soft-hard interrelation between reagents and atoms of the reaction center. A similar reaction of (*Z*)-1-acetyl-3-isobutylidene-PDO[19] with 4-methoxybenzyl bromide gave **1e** in 93% yield. Treatment of **1b—d** with hydrazine gave quantitatively the corresponding *N*-deacetylated derivatives (**1f—h**). Hydrogenation of **1f,g** and the corresponding 6-benzylidene-1-methyl-[20] and 1-benzyl-6-[(ethoxycarbonyl)ethylidene]-PDO[21] in the presence of 10% palladium–carbon gave the corresponding saturated compounds (**3a—d**) in good yields, respectively. *N*-(4-Methoxybenzyl)ation in nonhindered site of **3a—c** proceeded smoothly with sodium hydride and the chloride to give the corresponding 4-(4-methoxybenzyl)-PDO (**3e—g**) in good yields. A similar reaction of **1f—h** and **3d** gave also **1i—k** and **3h**, respectively. Treatment of **1i—k** in methanol with *N*-bromosuccinimide gave the corresponding 6-(1-bromoalkyl)-6-methoxy-PDO (**4a—c**) in good yields. Hydrogenation of **4a—c** in the presence of palladium–carbon gave the corresponding debrominated PDO (**5a—c**) in 47—60% yields.

While, catalytic hydrogenation of **1e** gave 1-acetyl-3-isobutyl-4-(4-methoxybenzyl)-PDO (**3i**) in 94% yield, and a successive treatment of **3e** in tetrahydrofuran with lithium 2,2,6,6-tetramethylpiperidide and allyl bromide at −78 °C gave crystalline 3-allyl-1-benzyl-

6-isobutyl-4-(4-methoxybenzyl)-PDO (**6a**) of *cis*-configuration in 46% yield. Thus, various PDO having different *N*-protecting groups and unsaturated bonds were synthesized.

An attempted oxidation of **3e** with DDQ under various conditions did not proceed, and oxidation with 5 equiv of 0.1 M (1 M=1 mol dm^{-3}) chromium trioxide in acetic acid at room temperature for 1 day gave *N*-de(4-methoxybenzyl)ated product, **3a**, in 41% yield. The results in the similar oxidation with CAN are summarized in Table 1.

The oxidation of **3e** in aqueous acetonitrile with a low concentration of CAN (Run 1) did not proceed even for a longer reaction time, but with 0.17 M solution (Run 2) gave **3a** in 55% yield, indicating the existence of concentration-dependency in this reaction. Thus, the reaction with 0.25 M CAN (Run 3) gave **3e** in quantitative yield. The reaction proceeded smoothly, even in the presence of only small amount of water (Run 4) and also at a lower temperature (Runs 5—6), if a proper concentration of excess CAN is maintained. Methanol can also be used as a solvent (Runs 7—8), but, 1-benzyl-6-isobutyl-4-(α,4-dimethoxybenzyl)-PDO (**7**) was produced as the major product, when absolute methanol was used (Run 9). The formation of **7** indicates that methoxide anion attacks the intermediate iminium cation [$>\overset{+}{N}=$CH-C_6H_4-OMe], which was produced by the direct electron transfer from alkylbenzene moiety to cerium(IV) ion or *via* a benzylic hydrogen abstraction by the metal ligands,[22] in methanol solution. In the presence of water, the attack of hydroxide anion gave the *N*-free PDO and *p*-anisaldehyde, and the latter was actually isolated in the corresponding yield.

As shown in Table 2, a similar oxidation of **3f—h** (Runs 1—3) gave **3b—d**, respectively. No oxidation of *N*-benzyl and terminal alkylbenzene moiety was observed, and an ester function was not affected under the reaction conditions. A lower yield of **3c** may be attributed to its low solubility in ethyl acetate for extraction. Oxidation of **5a—c** and **3i** (Runs 4—7) proceeded smoothly to give **5d—f** and **3j**, respectively. In these cases, 6-*O*-methoxyl and *N*-acetyl groups were not affected. The oxidation of **1i** with 0.5 M CAN (Run 8) was unexpectedly accompanied with an oxidative addition reaction to give 1-benzyl-

6-hydroxy-6-[2-methyl-1-(nitrooxy)propyl]-PDO (**8a**), whereas only oxidative addition product (**8b**) was obtained by the reaction with 0.05 M CAN (Run 9). These results indicate that CAN can not be applied for the selective removal of *N*-(4-methoxybenzyl) group in alkylidene-PDO. However, oxidation of **6a** having an isolated methylene function (Run 10) gave successfully the expected product (**6b**), without accompanying with the addition reaction.

Structures of new compounds were ascertained by ^{1}H NMR spectra (see Experimental). It is characteristic that the H-6 protons of (*Z*)-alkylidene-PDO commonly appeared as a singlet, whereas those of alkyl-PDO as nonequivalent multiplets. The lower chemical shift of methylene protons (δ=5.29s) of *O*-benzyl group of **2** compared with those (δ=4.63s—4.96s) of *N*-benzyl groups of alkylidene-PDO supported its enol ether structure. The α-methoxyl signals of **7** indicated that it is composed of two epimers at the benzylic position. In addition, the chemical shift of H-1′ of **8a** (δ=5.05d) and **8b** (δ=5.00d) supported the assignment of the position of nitrate. This assignment was further confirmed from the δ value of C-1″ of **8b** in ^{13}C NMR (Table 3). Comparison of data for **6a** and **6b** proved the lack of *N*-(4-methoxybenzyl) group in **6b** and its effect was observed in the chemical shifts of C-3, C-6, C-1′, C-2′, and may be C-5.

In conclusion, it was shown that 4-methoxybenzyl group can be easily introduced to PDO skeleton as a suitable *N*-protecting group and also smoothly removed by CAN oxidation under mild conditions, except for alkylidene-PDO.

Experimental

General. Melting points were determined with a Mel-temp apparatus or with a Yanagimoto micro melting-point apparatus, and were not corrected. IR spectra were recorded with a Hitachi EPI-G2 grating spectrometer. ^{1}H and ^{13}C NMR spectra were recorded with a JEOL JMN PS-100 and a JEOL FX-90Q spectrometers, respectively, in $CDCl_3$ solution with tetramethylsilane as the internal standard. Column chromatography was performed on Wakogel C-200 or C-300 (Wako Pure Chemical Industries. Ltd.).

*(Z)-1-Acetyl-3-(4-methylbenzylidene)-2,5-piperazinedione (**1a**).* To a solution of *N,N′*-diacetylanhydroglycine (4.00 g, 20.6 mmol) and *p*-tolualdehyde (3.71 g, 30.9 mmol) in *N,N*-dimethylformamide (DMF, 54 cm^3) was added dropwise 0.5 M potassium *t*-butoxide in *t*-butyl alcohol (43.3 cm^3, 21.6 mmol) with stirring at 0 °C. The resulting solution was kept for 1 h at 0 °C and then overnight at room temperature, neutralized with acetic acid, and poured into ice-water. The precipitate formed was filtered, and recrystallized from methanol to give **1a** (4.63 g) as colorless needles in 87% yield. Mp 153—154 °C, ν_{max}^{KBr} (cm^{-1}): 3260 (NH), 1700 (C=O), ^1H NMR δ=8.0 (bs, 1H, NH), 7.28 (s, 4H, Ph), 7.16 (s, 1H, H-1′), 4.49 (s, 2H, H-6), 2.64 (s, 3H, Me), 2.40 (s, 3H, NAc).

Found: C, 65.03; H, 5.51; N, 10.62%. Calcd for $C_{14}H_{14}N_2O_3$: C, 65.10; H, 5.46; N, 10.85%.

N-Benzylation of (Z)-1-Acetyl-3-alkylidene-2,5-piperazinediones. (*Z*)-1-Acetyl-4-benzyl-3-isobutylidene-2,5-piperazinedione (**1b**) was typically prepared as follows. To a suspension of 50% sodium hydride (2.52 g, 52.5 mmol) in dry DMF (250 cm^3) was added a solution of (*Z*)-1-acetyl-3-isobutylidene-2,5-piperazinedione (10.5 g, 50.0 mmol) in dry DMF (50 cm^3) with stirring at 0 °C, and after keeping the conditions for 30 min benzyl bromide (9.0 g, 52.5 mmol) was further added dropwise, and stirred for 2 h at 0 °C. The resulting solution was kept at room temperature overnight, neutralized with acetic acid, poured into ice-water, and then extracted with ether. The usual work-up of the extract gave a crude syrup, which was purified on a column of silica gel (hexane–ethyl acetate 7:3) to give colorless syrupy **1b** (10.9 g, 73%) and syrupy (*Z*)-1-acetyl-5-benzyloxy-3-isobutylidene-3,6-dihydro-2(1*H*)-pyrazinone (**2**: 0.75 g, 5.0%).

N-(4-Methoxybenzyl)ation of 2,5-Piperazinediones. 4-Methoxybenzyl bromide was prepared by an improved method of that for 4-methoxybenzyl chloride[23] as follows. A mixture of 4-methoxybenzyl alcohol (1.00 g, 7.25 mmol) and conc hydrobromic acid (2.0 cm^3) was vigorously stirred at room temperature for 15 min and then extracted with ether (50 cm^3). The extract was washed with saturated sodium hydrogencarbonate and then water, dried over calcium chloride, and then evaporated to give unstable 4-methoxybenzyl bromide (1.45 g) quantitatively as a liquid, which can be used for the next reaction without purification.

The reaction procedure is exemplified by the preparation of (*Z*)-1-benzyl-6-isobutylidene-4-(4-methoxybenzyl)-2,5-piperazinedione (**1i**). To a suspension of 50% sodium hydride (337 mg, 7.01 mmol) in dry DMF (35 cm^3) was added with stirring a solution of **1f** (1.73 g, 6.68 mmol) in dry DMF (5 cm^3) at 0 °C. After keeping the conditions for 30 min, 4-methoxybenzyl bromide (1.61 g, 8.02 mmol) was further added dropwise at 0 °C. The resulting solution was kept at 0 °C for 2 h and then overnight at room temperature, neutralized with acetic acid, poured into ice-water, and then extracted with ethyl acetate. The usual processing of the extract gave a crude syrup which was purified on a column of silica gel (hexane–ethyl acetate 7:3) to give colorless syrup. The syrup was crystallized from ethanol–ether to give **1i** (2.01 g) as colorless prisms in 80% yield. Mp 98.5 °C, ν_{max}^{KBr} (cm^{-1}): 1695, 1675 sh (C=O), 1635 (C=C), ^1H NMR δ=7.4—7.05 (m, 5H, Ph), 7.15 and 6.83 (each d, 4H, J_{ortho}=8.0 Hz, MBn), 6.11 (d, 1H, $J_{1',2'}$=11.0 Hz, H-1′), 4.91 (s, 2H, CH_2 in Bn), 4.56 (s, 2H, CH_2 in MBn), 3.88 (s, 2H, H-3), 3.80 (s, 3H, OMe), 2.67 (dq, 1H, H-2′), 1.02 (d, 6H, $J_{2',3'}$=6.0 Hz, H-3′).

Found: C, 67.87; H, 6.71; N, 6.34%. Calcd for $C_{24}H_{28}N_2O_5$: C, 67.90; H, 6.65; N, 6.60%.

*6-Alkyl-1-benzyl-6-methoxy-4-(4-methoxybenzyl)-2,5-piperazinediones (**5a—c**).* Compounds **5a—c** were obtained from **1i—k** by successive reactions of NBS and reduction. The procedure is exemplified by the conversion of **1i** into **5a** as follows. To a solution of **1i** (1.90 g, 5.02 mmol) in methanol (80 cm^3) was added NBS (938 mg, 5.27 mmol), and the mixture was stirred at room temperature for 30 min, evaporated, and the residue was extracted with ethyl acetate. The usual processing of the extract gave a crude syrup which was purified on a column of silica gel (hexane–ethyl acetate 7:3) to give 1-benzyl-6-(1-bromo-2-methylpropyl)-6-methoxy-4-(4-methoxybenzyl)-2,5-piperazinedione (**4a**: 2.48 g, 98%) as a colorless syrup. ^{1}H NMR δ=7.5—7.1 (m, 7H, Ph and 1/2×MBn), 6.82 (d, 2H, J_{ortho}=8.0 Hz, 1/2×MBn), 4.65 (s, 2H, CH_2 in Bn), 4.59 (s, 2H, CH_2 in MBn), 4.17 and 3.88 (ABq, 2H, J=16.0 Hz, H-3), 4.08 (d, 1H, $J_{1',2'}$=3.0 Hz, H-1'), 3.79 (s, 3H, OMe), 3.05 (s, 3H, 3-OMe), 2.58 (dqq, 1H, H-2'), 1.01 (d, 6H, $J_{2',3'}$=7.0 Hz, H-3').

Found: C, 56.88; H, 5.66; N, 5.53; Br, 15.60%. Calcd for $C_{24}H_{29}N_2O_5Br$: C, 57.03; H, 5.78; N, 5.54; Br, 15.81%.

The same compound was obtained in 96% yield by treatment of **1i** with a mixture of equimolar bromine and excess methanol.

A solution of **4a** (450 mg, 0.890 mmol) in methanol (50 cm^3) was catalytically hydrogenolyzed in the presence of 10% palladium–carbon (200 mg) and ammonium acetate (343 mg, 4.45 mmol) at room temperature for 24 h. The usual processing of the reaction mixture gave the crude product which was purified on a silica gel column (hexane–ethyl acetate 7:3) to give 1-benzyl-6-methoxy-4-(4-methoxybenzyl)-6-(2-methylpropyl)-2,5-piperazinedione (**5a**: 237 mg, 62%) as a colorless syrup. ^{1}H NMR δ=7.5—7.1 (m, 7H, Ph and 1/2×MBn), 6.83 (d, 2H, J_{ortho}=8.0 Hz, 1/2×MBn), 4.77 and 4.33 (ABq, 2H, J=14.0 Hz, CH_2 in Bn), 4.73 and 4.53 (ABq, 2H, J=14.5 Hz, CH_2 in MBn), 3.99 (s, 2H, H-3), 3.79 (s, 3H, OMe), 2.87 (s, 3H, 3-OMe), 2.13 and 1.86 (dABq, 2H, $J_{1',2'}$=8.0 and 4.5, $J_{A,B}$=15.0 Hz, H-1').

Found: C, 67.38; H, 7.21; N, 6.46%. Calcd for $C_{24}H_{30}N_2O_5$: C, 67.58; H, 7.09; N, 6.57%.

Compounds **5b,c** were obtained without characterization of the intermediates, **4b,c**.

1,6-Dibenzyl-6-methoxy-4-(4-methoxybenzyl)-2,5-piperazinedione (**5b**): yield 48% from **1j**, mp 115 °C (prisms from cyclohexane), ^{1}H NMR δ=7.6—6.7 (m, 14H, 2×Ph and MBn), 5.13 and 4.08 (ABq, 2H, J=13.5 Hz, CH_2 in Bn), 4.52 and 4.42 (ABq, 2H, J=14.0 Hz, CH_2 in MBn), 3.74 (s, 3H, OMe), 3.37 and 3.27 (ABq, 2H, J=13.5 Hz, H-1'), 3.28 and 2.36 (ABq, 2H, J=17.5 Hz, H-3), 2.84 (s, 3H, 3-OMe).

Found: C, 72.92; H, 6.29; N, 6.31%. Calcd for $C_{27}H_{28}N_2O_4$: C, 72.95; H, 6.35; N, 6.30%.

1-Benzyl-6-methoxy-4-(4-methoxybenzyl)-6-(4-methylbenzyl)-2,5-piperazinedione (**5c**): yield 56% from **1k**, syrup, ^{1}H NMR δ=7.5—6.6 (m, 13H, Ph, Tol and MBn), 5.10 and 5.37 (ABq, 2H, J=14.0 Hz, CH_2 in Bn), 4.42 and 4.13 (ABq, 2H, J=14.0 Hz, CH_2 in MBn), 3.70 (s, 3H, OMe), 3.42 and 2.41 (ABq, 2H, J=13.5 Hz, H-1'), 2.79 (s, 3H, 3-OMe), 2.19 (s, 3H, Me).

Found: C, 73.26; H, 6.61; N, 6.03%. Calcd for $C_{28}H_{30}N_2O_4$: C, 73.34; H, 6.59; N, 6.11%.

*3-Allyl-1-benzyl-6-isobutyl-4-(4-methoxybenzyl)-2,5-piperazinedione (**6a**).* To a solution of 2,2,6,6-tetramethylpiperazine (508 mg, 3.60 mmol) in tetrahydrofuran (12 cm^3) was successively added dropwise with stirring butyllithium (1.6 M hexane solution, 604 cm^{-3}, 3.60 mmol) and a solution of **3e** (1.14 g, 3.00 mmol) in tetrahydrofuran (7 cm^3) at −78 °C. After keeping the conditions for 15 min, allyl bromide (436 mg, 3.60 mmol) was further added and stirred for 1 h at −78 °C. The temperature of the reaction mixture was raised slowly to room temperature, poured into saturated ammonium chloride solution, and extracted with dichloromethane. The usual processing of the extract gave a crude syrup which was purified on a column of silica gel (hexane–ethyl acetate 7:3) to give a colorless syrup. The syrup was crystallized from ethanol–ether to give **6a** (695 mg, 46%). Mp 123—124 °C, ν_{max}^{KBr} (cm^{-1}): 1650 (C=O), ^{1}H NMR δ=7.22 (s, 5H, Ph), 7.13 and 6.81 (each d, 4H, J_{ortho}=9.0 Hz, MBn), 5.8—5.25 (m, 1H, H-2'), 5.47 and 3.83 (ABq, 2H, J=15.0 Hz, CH_2 in Bn), 5.47 and 3.79 (ABq, 2H, J=15.0 Hz, CH_2 in MBn), 5.40 (dd, 1H, $J_{3'a,3'b}$=2.0, $J_{3'a,2'}$=1.5 Hz, H-3'a), 5.17 (dd, 1H, $J_{3'b,2'}$=8.0 Hz, H-3'b), 4.05—3.6 (m, 2H, H-3 and 6), 3.80 (s, 3H, OMe), 3.1—2.5 (m, 2H, H-1'), 1.9—1.45 (m, 3H, H-1'' and 2''), 0.95 and 0.87 (each d, 6H, $J_{2',3'}$=5.5 Hz, H-3'').

Found: C, 73.96; H, 7.72; N, 6.48%. Calcd for $C_{26}H_{32}N_2O_5$: C, 74.25; H, 7.67; N, 6.66%.

*Oxidation of **3e** with Chromium Trioxide.* A mixture of a solution of **3e** (200 mg, 0.526 mmol) and chromium trioxide (263 mg, 1.58 mmol) in glacial acetic acid (25 cm^3) was stirred for 24 h at room temperature, poured into ice-water, and extracted with ethyl acetate. The usual process-

ing of the extract gave a crude syrup which was purified on a column of silica gel to give **3a** (56 mg) in 41% yield.

Oxidative Removal of N-(4-Methoxybenzyl) Group of 3e—i,1i,5a—c, and 6a with Cerium(IV) Diammonium Nitrate. The general procedure is exemplified by the conversion of **3e** into **3a**. A solution of **3e** (95.1 mg, 0.25 mmol) and CAN (548 mg, 1.00 mmol) in acetonitrile (3.0 cm^3) and water (1.0 cm^3) was stirred at room temperature for 2 h, poured into water, and then extracted with ethyl acetate. The extract was successively washed with saturated sodium hydrogencarbonate and water, dried over anhydrous magnesium sulfate, and then evaporated to give crude product, which was purified on a flash column of silica gel (hexane–ethyl acetate 7:3) to give **3a** (62.7 mg) in 96% yield.

A similar oxidation of **3f—h** gave **3b—d**, respectively. Compounds **5a—c**, **3i**, and **6a** were also successfully converted into **5d—f**, **3j**, and **6b**, respectively.

1-Benzyl-6-isobutyl-6-methoxy-2,5-piperazinedione (**5d**): syrup, ν_{max}^{KBr} (cm^{-1}): 3250 (NH), 1680, 1660 (C=O), ^1H NMR δ=8.24 (bs, 1H, NH), 7.5—7.1 (m, 5H, Ph), 4.66 (s, 2H, CH_2 in Bn), 4.24 and 4.08 (ABq, 2H, J=17.5 Hz, H-3), 2.92 (s, 3H, 3-OMe), 2.1—1.5 (m, 3H, H-1′ and 2′), 0.81 and 0.53 (each d, 6H, $J_{2',3'}$=7.0 Hz, H-3′).

Found: C, 66.03; H, 7.47; N, 9.51%. Calcd for $C_{16}H_{22}N_2O_3$: C, 66.18; H, 7.64; N, 9.65%.

1,6-Dibenzyl-6-methoxy-2,5-piperazinedione (**5e**): mp 157 °C (prisms from ethanol–ether), ν_{max}^{KBr} (cm^{-1}): 3320 (NH), 1710 (C=O), ^1H NMR δ=7.72 (bd, 1H, NH), 7.6—6.9 (m, 10H, 2×Ph), 5.18 and 4.35 (ABq, 2H, J=14.0 Hz, CH_2 in Bn), 3.62 (dd, 1H, $J_{3a,NH}$=2.5 Hz, H-3a), 3.29 (s, 2H, H-1′), 2.81 (s, 3H, 3-OMe), 2.48 (d, 1H, $J_{3a,3b}$=17.0 Hz, H-3b).

N-Hydroxy Amides. III.[1] Active Esters of Polystyrene-bound 1-Hydroxy-2-pyrrolidinone and Their Use in Peptide Synthesis

Masayasu AKIYAMA,* Kazuyuki SHIMIZU, Seiichi AIBA, and Hiroaki KATOH
Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received November 20, 1984)

A polymer-bond cyclic *N*-hydroxy amide has been prepared by reaction of aminomethylated copoly(styrene–2% divinylbenzene) with 1-hydroxy-5-oxo-3-pyrrolidinecarboxylic acid using dicyclohexylcarbodiimide (DCC) as a condensing agent. Several *N*-blocked α-amino acids have been loaded on this resin by use of DCC. The amino acid resin can be utilized for peptide synthesis. Repetitive usage of the resin in the form of esters and facile synthesis of a biologically active pentapeptide, Leu[5]-enkephalin, show the usefulness of the polymer-bound 1-hydroxy-2-pyrrolidinone.

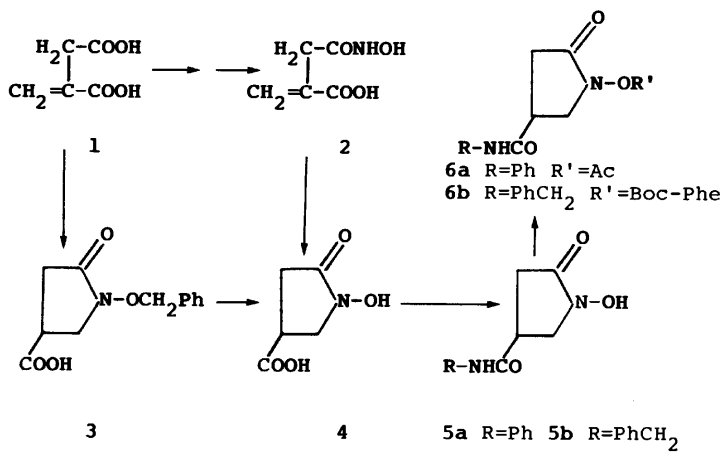
It is well documented that polymer-bound reagents are useful and economical in syntheses where repetitive procedures are required.[2–5] Thus a number of polymeric active esters have been prepared, including recent examples, and used in peptide synthesis.[6–11] *N*-Hydroxy ester-type polymers are prefered to a phenolic ester type to suppress racemization.[12] For recycling, however, *N*-hydroxysuccinimide polymers[7] are of limited utility because of a side reaction between *N*-hydroxysuccinimide (HOSu) and dicyclohexylcarbodiimide (DCC).[13] Polymers of highly active 1-hydroxybenzotriazole esters[8] are recognized to be sensitive to moisture and alcohols.[10]

In the course of our study,[14] it was found that 1-hydroxy-5-oxo-3-pyrrolidinecarboxylic acid (**4**) is readily obtainable from 2-methylenesuccinic acid. A pyrrolidinone ring is more stable than a HOSu ring due to the lack of one of the two carbonyl groups; yet esters of the *N*-hydroxypyrrolidinone are expected to retain a high reactivity, as many hydroxamate esters have been used as an acylating agent.[15,16] It is necessary to explore various functional groups in order to provide practical polymers. No polymer having a cyclic hydroxamic moiety has been tested so far. This paper describes the preparation and use of polymer-bound 1-hydroxy-2-pyrrolidinone as a recyclable polymeric hydroxy component together with synthesis of a biologically active peptide, Leu[5]-enkephalin[17].

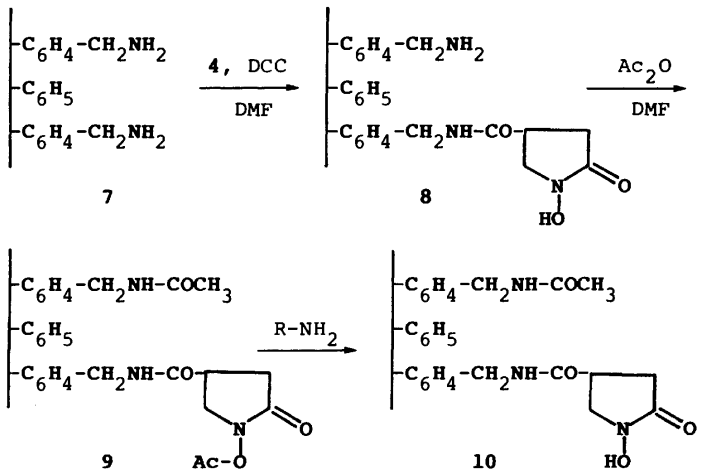
Results and Discussion

1-Hydroxy-2-pyrrolidinone Derivatives. Mild heating of *N*-hydroxy-3-carboxy-3-butenamide (**2**) gave 1-hydrpxy-5-oxo-3-pyrrolidinecarboxylic acid (**4**). The compound was also obtained *via* a reaction of 2-methylenesuccinic acid with *O*-benzylhydroxylamine. Scheme 1 shows these transformations. Reaction of **4** with aniline or benzylamine in the presence of DCC yielded the corresponding amides **5a** and **5b**. Acetic anhydride converted the amide **5a** to the acetoxy pyrrolidinone **6a** whose characteristic ester absorption is observed at 1800 cm^{-1}. The acetoxy amide **6a** reacted with cyclohexylamine to give *N*-cyclohexylacetamide. An amino acid ester **6b** can be obtained and used as an active ester. However, compound **4** is more suitable as a polymeric ligand, since problems such as solubility and crystallinity encountered with monomeric derivatives can be avoided through attachment to a polymer.

Polymer-bound 1-Hydroxy-2-pyrrolidinone and Its



Scheme 1.



Scheme 2.

Amino Acid Esters. Commercial beads of styrene–2% divinylbenzene (DVB) copolymer were used as the starting material. A 2% content of DVB is adequate for a base polymer in several respects.[5] Aminomethyl resin **7** (1.41—3.73 mmol/g) was prepared by phthalimidomethylation of the starting polymer beads.[18] The key step in the resin preparation was introduction of the hydroxy pyrrolidinone unit to the polymer **7** (Scheme 2). The aminomethyl resin **7** reacted with **4** in *N,N*-dimethylformamide (DMF) in the presence of DCC, without any protection of the hydroxamic acid moiety. The extent of the reaction was in the range of 60—80%, and complete removal of unchanged **4** was difficult at this stage. Exhaustive acetylation of the resin blocked the *N*-hydroxy group and any remaining free amino groups of polymer **8**. The *O*-acetyl group of polymer **9** is readily removed by aminolysis, affording the desired *N*-hydroxypyrrolidinone resin **10** (0.85—3.17 mmol/g). The resin **7** similarly reacted with 1-benzyloxy-5-oxo-3-pyrrolidinecarboxylic acid (**3**), but subsequent debenzylation was difficult to perform. The content of the *N*-hydroxypyrrolidinone unit was estimated by aminolysis of the *O*-acetyl group.[8,19]

The pyrrolidinone resin has the good mechanical property of the starting beads and swells well in DMF, THF, $CHCl_3$, CH_2Cl_2, and benzene. The bead-type resin can be easily filtered and washed with these and alcoholic solvents.

Molecular models suggest that the *N*-hydroxy amide moiety of the pyrrolidinone ring extends from the polymer backbone due to the trans configuration of the linking amide linkage.

Preparation of polymer-bound active esters was performed by reaction of appropriate *N*-protected amino acids with resin **10** in DMF in the presence of DCC. The esterified resin showed a characteristic peak at 1800 cm^{-1}. The amino acid content was determined by titration.[8,19] Figure 1 shows the progress of a loading reaction of Boc-Phe-OH, chosen as an example. It takes 40 h with DCC alone, but addition of 1-hydroxybenzotriazole accelerates the reaction. The symmetric anhydride technique is effective in shortening the reaction time. Table 1 shows typical results obtained with DCC alone. The polymers are stable for months when stored in a desiccator.

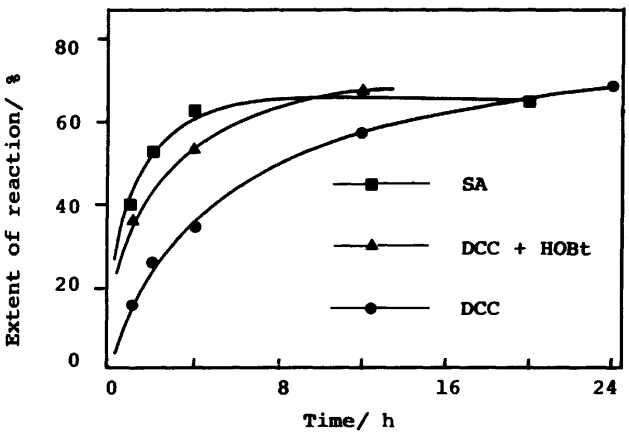


Fig. 1. Progress of the loading reaction of Boc-Phe-OH on the *N*-OH resin (**10**); 2 mol reagents were used for 1 mol *N*-OH unit, in DMF at room temperature; SA, symmetric anhydride method; HOBt, 1-hydroxybenzotriazole. The extent of the reaction was followed by aminolysis.

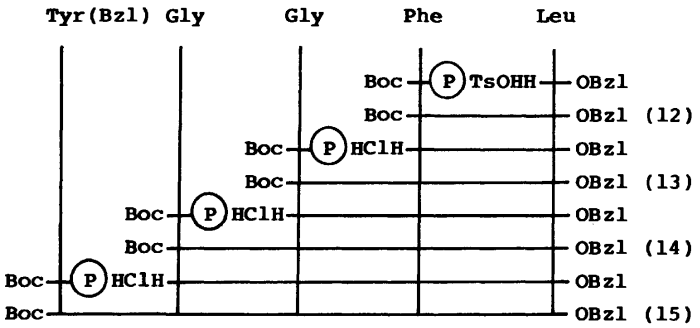
Peptide Synthesis by Use of Polymer Reagents. The coupling procedure to form a peptide bond is simple; addition of an amino component to an appropriate resin suspension and removal of a wasted polymer after a suitable reaction time. The usual work-up gives a peptide. In a coupling between Boc-Phe resin and H-Leu-OBzl, a rather prolonged time (48 h) for completion was observed in contrast to



Scheme 3.

the case of HOSu esters, where the coupling usually completes within 20 h at room temperature.[7] Nevertheless, a routine coupling was carried out in DMF at 35 °C for 24 h to give a practical yield.

Repetitive usage is an important factor for polymer reagents. This was examined using the same resin repeatedly. Good reproducible results in the peptide formation are notable (Table 2). Further use was not attempted since some of the polymer beads became powdered.

Table 1. Polymer-bound active esters of *N*-blocked amino acids[a]

N-Blocked amino acid bound to polymer	Content of ester mmol/g
Boc-Ala	0.93
Boc-Gly	1.05
Boc-Phe	0.88
Boc-Pro	0.56
Boc-Val	0.64
Cbz-Ala[b]	0.70
Cbz-Gly[b]	0.55
Cbz-Leu[b]	0.65
Cbz-Tyr(Bzl)	0.97

a) Polymer-bound 1-hydroxy-2-pyrrolidinone having an *N*-OH content = 1.27 mmol/g was used; the content of ester was assayed by the titration method. b) Polymer of an *N*-OH content = 1.04 mmol/g was used; the ester content was estimated from weight gain.

Table 2. Results of repetitive use of a single polymer

Peptide formed	Recycle run[a]	Yield/%
Boc-Phe-Leu-OBzl[b]	1	94
	2	87
	3	94
Boc-Gly-Phe-Leu-OBzl[c]	4	69
	5	71
	6	68

a) Boc-Phe resin (*ca.* 4 g) was used as a starting polymer. b) Reaction of the Boc-Phe resin with H-Leu-OBzl gave *ca.* 1.5 g of the peptide. c) After complete detachment of Boc-Phe residue with cyclohexylamine, the resin was loaded with Boc-Gly and subjected to aminolysis with H-Phe-Leu-OBzl to give *ca.* 1.0 g of the peptide.

Leu^5*-Enkephalin.* In an extension of these couplings, synthesis of the protected peptide of Leu^5-enkephalin was carried out as depicted in Scheme 3. This coupling order of amino acids is rather few, since the Gly^2-Gly^3 sequence is usually prepared separately.[17] Removal of the protective groups, followed by column chromatography, gave the free petide (**16**), Leu^5-enkephalin. The peptide was digested almost completely by an aminopeptidase and was physiologically effective.

The present results show that the 1-hydroxy-2-pyrrolidinone unit is a useful functional moiety when utilized as a polymeric ligand, although aminolysis of its esters is rather slow.

Experimental

All the melting points are uncorrected. IR spectra were obtained with a JASCO 403G spectrophotometer and ^{1}H NMR spectra were recorded on a JEOL C-60HL spectrometer with TMS as internal standard. Optical rotations were measured with a JASCO ORD/UV-5 spectrometer. HPLC was carried out with a JASCO model twincle apparatus using a column packed with Finepak SIL C_{18}. Microanalysis was performed by the Analytical Section, Institute of Physical and Chemical Research, Saitama. TLC was carried out using Merck precoated silica gel $60F_{254}$ plates: R_f^1, EtOAc; R_f^2, $CHCl_3$-MeOH-C_6H_6 (6:1:3); R_f^3, THF-hexane (1:1); R_f^4, $CHCl_3$-MeOH-AcOH-H_2O (30:20:4:6). Aminopeptidase M (Sigma) was used as received. 1 M = 1 mol dm^{-3}.

1-Benzyloxy-5-oxo-3-pyrrolidinecarboxylic Acid (3). A mixture of 2-methylenesuccinic acid (30 g, 0.24 mol), *O*-benzylhydroxylamine (25.6 g, 0.24 mol) and water (240 mL) was refluxed for 1 h, and the hot, aqueous layer removed by decantation. The residue was recrystallized from water to give 43 g (78%) of **3**, 151—152 °C; IR, 1725 (-CO_2H) and 1635 (-CO-N-) cm^{-1}. Found: C, 61.19; H, 5.55; N, 5.94%. Calcd for $C_{12}H_{13}NO_4$: C, 61.27; H, 5.57; N, 5.96%.

1-Hydroxy-5-oxo-3-pyrrolidinecarboxylic Acid (4). (A): *N*-Hydroxy-3-carboxy-3-butenamide (**2**)[14] (0.50 g, 3.4 mmol) in 1-butanol (30 mL) was refluxed for 0.5 h and evaporated

to give an oil which crystallized on cooling (0.30 g, 60%). Recrystallization from acetone–hexane gave a sample, mp 145—146 °C; IR, 1700 (-CO_2H) and 1630 (-CO-N) cm^{-1}; ^1H NMR (DMSO-d_6) δ=3.62 (2H, m, -CH_2-N), 3.20 (1H, m, -CH-COO) and 2.44 (2H, d, -CH_2-CO-N, J=7.2 Hz). Found: C, 40.99; H, 4.84; N, 9.60%. Calcd for $C_5H_7NO_4$: C, 41.38; H, 4.84; N, 9.60%.

(*B*): A solution of **3** (6.0 g, 25 mmol) in MeOH (160 mL) was hydrogenated with H_2 in the presence of 10% Pd/C (0.20 g) under the atmospheric pressure for 2 d to give, after recrystallization, 2.8 g (88%) of **4**, mp 150—151 °C.

*1-Hydroxy-4-phenylcarbamoyl-2-pyrrolidinone (**5a**).* To a chilled solution of **4** (1.00 g, 6.9 mmol) and aniline (0.96 g, 10 mmol) in DMF (20 mL) was added a solution of dicyclohexylcarbodiimide (DCC) (1.42 g, 7 mmol) in DMF (3 mL); the mixture was stirred overnight at room temperature. *N,N'*-Dicyclohexylurea (DCU) was filtered off and the solvent evaporated. The residue was recrystallized from acetone–hexane to yield 1.06 g (70%) of **5a**, mp 183—184 °C (decomp); IR, 1685 (-CO-N(OH)-) and 1665 (-CONH-) cm^{-1}. Found: C, 59.93; H, 5.69; N, 12.92%. Calcd for $C_{11}H_{12}N_2O_3$: C, 59.99; H, 5.49; N, 12.72%.

*1-Hydroxy-4-benzylcarbamoyl-2-pyrrolidinone (**5b**).* *N*-Ethyl-*N'*-(3-dimethylaminopropyl)carbodiimide (WSC) (1.60 g, 8.5 mmol) was added to a solution containing **4** (1.0 g, 6.9 mmol) and benzylamine (0.84 g, 7.8 mmol) in DMF (15 mL), and the mixture stirred for 24 h at room temperature. The usual work-up gave 0.25 g (15%) of **5b**, mp 185—186 °C. Found: C, 61.78; H, 6.10; N, 11.75%. Calcd for $C_{12}H_{14}N_2O_3$: C,61.52; H, 6.02; N, 11.96%.

*1-Acetoxy-4-phenylcarbamoyl-2-pyrrolidinone (**6a**).* A suspension mixture of **4** (0.50 g, 2.3 mmol) and acetic anhydride (0.35 g, 3.4 mmol) in THF (7 mL) was stirred for 5 h at room temperature, the mixture evaporated. The residue was recrystallized from THF–hexane to give 0.38 g (68%) of **6a**, mp 111—112 °C; IR, 1795 (CH_3CO), 1715 (-CO-N) and 1665 (-CONH-) cm^{-1}. Found: C, 59.59; H, 5.41; N, 10.69%. Calcd for $C_{13}H_{14}N_2O_4$: C, 59.53; H, 5.38; N, 10.68%.

*Acetylation with **6a**:* A mixture of **6a** (0.26 g, 1 mmol) and cyclohexylamine (0.10 g, 1 mmol) in THF (3 mL) was stirred for 2 h at room temperature to give *N*-cyclohexylacetamide (0.70 g, 50%), mp 99—100 °C (104 °C for a pure sample).

*1-[N-(t-Butoxycarbonyl)phenylalanyloxy]-4-benzylcarbamoyl-2-pyrrolidinone (**6b**).* To a chilled solution containing **5b** (0.18 g, 0.75 mmol) and Boc-Phe-OH (0.20 g, 0.76 mmol) in DMF (9 mL) was added WSC (0.20 g, 1.0 mmol). The mixture was stirred for 18 h at room temperature and evaporated. Work-up and recrystallization from THF–hexane gave 0.18 g (45%) of **6b**, mp 103—106 °C. Found: C, 64.69; H, 6.40; N, 8.65%. Calcd for $C_{26}H_{31}N_3O_6$: C, 64.85; H, 6.49; N. 8.73%.

*Aminomethylated Polystyrene (**7**).* Commercial copoly(styrene-2% divinylbenzene) beads (100—200 mesh) were washed and subjected to phthalimidomethylation.[18] The following is as example: Resin beads (15.6 g) and *N*-(chloromethyl)phthalimide (15.3 g, 78 mmol) in CH_2Cl_2 (140 mL) containing $SnCl_4$ (9.45 g, 36 mmol) were stirred for 15 h at room temperature. The resin was washed with CH_2Cl_2, EtOH, MeOH, and Et_2O, and dried, yielding 27.2 g. The content of phthalimido group (IR 1775 and 1715 cm^{-1}) was 2.51 mmol/g from microanalysis; 2.66 mmol/g from weight gain.

The resulting phthalimidomethyl resin (26.9 g) was hydrolyzed in aqueous methylamine solution (60 mL; 40%) at first for 100 h and additionally for 20 h at room temperature, to give 19.6 g of **7** (aminomethyl content, 3.73 mmol/g; no peak at 1775 and 1715 cm^{-1}). By a similar procedure polymers (**7**) having different aminomethyl contents (1.41—3.73 mmol/g) were obtained.

*Preparation of Polymer-bound 1-Hydroxy-2-pyrrolidinone (**10**).* A mixture of aminomethyl polystyrene (**7**) (5.00 g; 3.73 mmol/g) and the pyrrolidinone **4** (3.00 g, 21 mmol) in DMF (50 mL) was kept for 2 h at room temperature with stirring and chilled. To this was added DCC (4.25 g, 21 mmol) in DMF (20 mL), and the suspension kept at 0 °C for 2 h and at room temperature for 18 h. The resin was filtered off, washed with DMF and hot MeOH alternatively 3 times, then with ether, and dried under vacuum.

The dried resin was allowed to react with acetic anhydride (16.3 g, 160 mmol) in DMF (50 mL) for 40 h at room temperature. The resin was filtered, washed with CH_2Cl_2 and MeOH alternatively 4 times, then with ether, and dried under vacuum.

The dried acetylated resin (**9**) was swollen in AcOEt–CH_2Cl_2 solution (60 mL; 5:7 v/v). To this was added cyclohexylamine (2.60, 26 mmol) and stirred for 45 h at room temperature. The resin was filtered off, washed with DMF, MeOH, CH_2Cl_2, and ether, and dried under vacuum, affording the *N*-hydroxypyrrolidinone resin (**10**) (6.67 g; 3.17 mmol/g).

The Acyl Group Content of the Polymers. Titration: *O*-Acyl resin (*ca.* 35 mg) was heated with benzylamine in toluene (1 mL; 0.30 M) at 80 °C for 1 h. After cooling the mixture was titrated with $HClO_4$ in AcOH (0.01 M) using Methylene Blue as an indicator.

HPLC Procedure: Excess benzylamine unconsumed in the aminolysis was analyzed by HPLC. The column was eluted with MeOH–0.1% phosphate buffer (65:35 v/v).

*Preparation of Polymer-bound Amino Acid Esters (**11**).* A mixture of polymer-bound pyrrolidinone (**10**) (3.47 g; 1.27 mmol/g) and an *N*-protected amino acid (8.81 mmol) in DMF (30 mL) was stirred for 2 h at room temperature and chilled. To this was added DCC (8.8 mmol) in DMF (10 mL) at 0 °C; the suspension was stirred for 2 h at 0 °C and for 22 h at room temperature. The resin was filtered off and washed with DMF (2×20 mL), MeOH–$CHCl_3$ (2×20 mL, 1:1 v/v), and Et_2O, and then dried under vacuum. The content of the resin was determined by titration using a part of the resin. Typical data were summarized in Table 1. 1-Hydroxybenzotriazole-DCC procedure was similarly carried out as above. In a symmetric anhydride procedure, an anhydride derived from Boc-Phe-OH (2 equiv) and DCC (1 equiv) in DMF was added *in situ* to a resin suspension at room temperature.

Synthesis of Protected Peptides with Polymer-bound Reagents. General Procedure: Boc-amino acid resin (3.6 mmol) was swollen in DMF (30 mL) for 1 h. A mixture of a hydrochloride or tosylate of an amino component (3.0 mmol) and Et_3N (0.303 g, 3.0 mmol) in DMF (10 mL) was added to the swollen suspension and stirred for 30 h at 35 °C. The resin was filtered off and washed with DMF (3×20 mL). The combined filtrate and washings were evaporated to give a residue which was diluted with EtOAc (60 mL). The EtOAc layer was washed with 5% $NaHCO_3$

(3×20 mL), water, 5% citric acid (3×20 mL) and water, and dried (Na_2SO_4). Evaporation of the solvent gave a product.

Boc-Phe resin and TsOH·H-Leu-OBzl gave *Boc-Phe-Leu-OBzl* (**12**), 1.32 g (94%); mp 84—85 °C. Recrystallization from Et_2O-petroleum ether, mp 85—86 °C (lit, [17a] 85.5—86.5 °C); $[\alpha]_D$ −16.3° (THF); R_f^1=0.86, R_f^2=0.91, R_f^3=0.90.

Boc-Gly resin (3.15 g; 1.17 mmol/g) and HCl·H-Phe-Leu-OBzl (1.34 g, 3.31 mmol) produced *Boc-Gly-Phe-Leu-OBzl* (**13**) as an oil; 1.16 g (68%); R_f^1=0.80, R_f^2=0.67, R_f^3=0.75. The peptide **13** gave HCl·H-Gly-Phe-Leu-OBzl by treatment with HCl-dioxane. Neutralization of the hydrochloride and recrystallization from Et_2O gave the free peptide, mp 103—104 °C; $[\alpha]_D$ −16° (THF). Found: C, 67.68; H, 7.38; N, 9.85%. Calcd for $C_{24}H_{31}N_3O_4$: C, 67.74; H, 7.34; N, 9.88%.

Boc-Gly resin (4.82 g; 1.10 mmol/g) and HCl·H-Gly-Phe-Leu-OBzl (2.20 g, 4.76 mmol) gave *Boc-Gly-Gly-Phe-Leu-OBzl* (**14**), 2.20 g (79%). Recrystallization from THF-petroleum ether gave mp 160—161.5 °C (lit,[17d] mp 162.5—163.5 °C); $[\alpha]_D$ −16.7° (THF); R_f^1=0.27, R_f^2=0.56, R_f^3=0.41.

Boc-Try(Bzl)-Gly-Gly-Phe-Leu-OBzl (**15**) was produced from Boc-Tyr(Bzl) resin (2.26 g; 0.62 mmol/g) and HCl·H-Gly-Gly-Phe-Leu-OBzl (0.648 g, 1.25 mmol); 0.853 g (81%), mp 181—182 °C. Recrystallization from MeOH-petroleum ether gave a sample of mp 187—188 °C; $[\alpha]_D$ −17.4° (DMF); R_f^2=0.52, R_f^3=0.17. Found: C, 66.87; H, 6.83; N, 8.26%. Calcd for $C_{47}H_{57}N_5O_9 \cdot 1/2H_2O$: C, 66.80; H, 6.92; N, 8.29%.

Leu^5-Enkephalin. The protective groups of **15** were removed by hydrogenation and then by treatment with HCl-dioxane, followed by column chromatography,[17b] to give H-Tyr-Gly-Gly-Phe-Leu-OH (**16**); 0.29 g (42%) from 0.76 g of **15**, mp 200—201 °C (lit,[17b-d] mp 206—208 °C); $[\alpha]_D$ −22.5° (DMF) (lit, [17b,d] $[\alpha]_D$ −23.4°); R_f^4=0.76.

Biological Assay: The peptide (**16**) (3 mg) was incubated with aminopeptidase M (0.016 mg) in phospate buffer (1 mL; pH=7.2) at 36 °C; 8 μL aliquots of the mixture were analyzed for the peptide using HPLC at appropriate time intervals. The peptide was virtually digested with the pseudo-first-oder rate within 1.5 h. *In vivo* analgesic activity was observed for 5-week-old male mice with the peptide in dimethyl sulfoxide solution (16.7 mg/mL). 10 μL (300 nmol) of the solution was injected intracerebroventricularly and, in a few minutes, the analgesic state was carefully watched for the mouse. The state lasted for *ca.* 15 min.

We thank Messrs. Masashi Maruyama, Masahisa Yoshimi, and Toshikazu Nagura for performing some of the experiments.

Bilirubin in Aqueous Solution. Absorption Spectrum, Aqueous Solubility, and Dissociation Constants

Yoshikiyo MOROI,* Ryohei MATUURA, and Tetsuo HISADOME†

Department of Chemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812

†*Department of Surgery 1, Faculty of Medicine, Kyushu University 60, Higashi-ku, Fukuoka 812*

(Received November 28, 1984)

This report analyzes the change of both spectrum and solubility of bilirubin with pH in buffer solutions. Bilirubin (AH_2) is a dibasic acid which dissociates by two steps ($AH_2 \overset{K_1}{\rightleftharpoons} AH_1 \overset{K_2}{\rightleftharpoons} A$) with increasing pH; the wavelengths at the resulting three isosbestic points are 457 nm (AH_2 and AH_1), 485 nm (AH_1 and A), and 472 nm (A and AH_2). The solubility increases with increasing pH, where the total concentration ($[AH_2]+[AH_1]+[A]$) changes subject to a second-order curve of $1/a_{H^+}$. From the spectral change and the three coefficients of the solubility curve, K_1 and K_2 values were estimated to be $(6.7\pm2.6)\times10^{-7}$ and $(3.4\pm1.0)\times10^{-8}$, respectively. These dissociation constants are much smaller than those of aliphatic carboxylic groups, and the reason for it was discussed together with the values already reported and their reliability.

Bilirubin is one of the major components of gallstone[1,2] and is solubilized together with cholesterol in the mixed micelle of bile salts and lecithin in human bile.[3-6] Indeed, gallstone formation has been much investigated for twenty years from the view point of solubilization,[4-7] but the mechanism of the formation has not been made clear yet. Through these studies, the aqueous solubility of free bilirubin has been found to play a very important role in an elucidation of gallstone formation, and hence the two dissociation constants of bilirubin which are closely related to its solubility have been tried to be speculated or determined by several investigators.[8,9] Nevertheless, the correct values have not been determined yet because of the extremely small solubility of bilirubin even at neutral pH.

Bilirubin decomposes easily under oxygen, and its photooxidation has been extensively studied.[10-12] So, its purification is an important requirement to have reliable experimental results, and several purification methods have been proposed.[13-15] In this report, the authors have examined the solution properties of purified bilirubin in buffer solutions from the spectrum and solubility changes with pH. In the preceding paper,[16] the solubility change with pH was found to be very useful to determine acidity constants of acids which are sparingly soluble in aqueous solution. The solubility method is a modification of the isoextraction method for determination of dissociation constants.[17]

Accordingly, the main attention has been paid only to the determination of the two dissociation constants of bilirubin using two methods, a spectrophotometric and a solubility method. In this paper, therefore, the authors do not relate the constants to bilirubin metabolism or other biochemical events but make clear the physicochemical properties of aqueous bilirubin in solution.

The constants obtained independently by the two methods were in reasonable agreement. In any event, it is the first time that the two constants have been determined reliably. Therefore, they will become invaluable for future study on gallstone formation and on the pathological influence of bilirubin upon the human body.

Experimental

Materials. Chloroform of guaranteed reagent grade was further purified by alternate washing with dilute acid and alkali three times each followed by distilled water several times and then stored under distrilled water in the dark. Bilirubin from Sigma Chem. Corp. was purified as described previously[13] in the most respects. The different repect is the following; the bilirubin was dissolved first in the chloroform which had been beforehand passed through the column of anhydrous sodium sulfate heated at 300 °C for three hours, and then the chloroform solution of bilirubin was run down the column again shielded from light. Other reagents were of analytical reagent grade and used without further purification. Water used was distilled twice from alkaline permanganate.

Rate of Decomposition. Immediately after dissolution of bilirubin in 0.05 mol dm^{-3} NaOH solution, an aliquot of the solution was transfered into a photometric cell containing buffer solution whose ionic strength was 0.05, and then the change of the optical density of the solution with time was followed for more than two hours by spectrophotometer (Hitachi 100-50), where the bilirubin concentration is 2.5×10^{-6} mol dm^{-3} and the temperature is at 25 °C.

Spectrum. The absorption spectra of bilirubin in buffer solution (H_3PO_4-NaH_2PO_4-Na_2HPO_4 for pH≤8 and H_3BO_3-NaH_2BO_3 for pH>8) whose ionic strength(I) is 0.05 were obtained at 25 °C; immediately after the bilirubin had dissolved in alkaline solution (I=0.05), an aliquot of the solution was introduced into the buffer solutions, where the bilirubin concentration was 1.39×10^{-6} mol dm^{-3}. It took less than five minutes to finish recording the absorption spectra after the bilirubin dissolution. Almost no change in pH of the solutions were observed before and after the spectrum measurement.

Solubility. The apparatus and procedure are the same as those in the previous paper.[16] In preparing buffer solutions, ionic strength and temperature were made to resemble human bile (I=0.15 and 37 °C) and the reagents

used were the same as in the spectrum section. As bilirubin is not only chemically unstable but also photosensitive, the solubility measurement was carried out in a dark room and under the conditions of short dissolution time. First of all, the amount of bilirubin powder to be suspended in the buffer solution (3 ml) which is necessary to reach dissolution equilibrium within one hour was first examined and was found to be about 30 mg. Then, the solubility was determined spectrophotometrically at 37 °C against $1/a_{H^+}$ of each buffer solution under the above conditions.

Results and Discussion

Purity. Elemental analysis of purified bilirubin was 67.71 (67.79)% for C, 6.28 (6.21)% for H, and 9.49 (9.58)% for N, where the values in parentheses are calculated ones. The absorption spectra of original and purified bilirubin in chloroform are shown in Fig. 1. Impurities absorbing below 350 nm in chloroform solution were almost completely removed by the above purification process. The molar absorption coefficients in chloroform and in aqueous alkali solution are 5.67×10^4 mol^{-1} dm^3 cm^{-1} at 455 nm and 5.45×10^4 mol^{-1} dm^3 cm^{-1} at 438 nm,

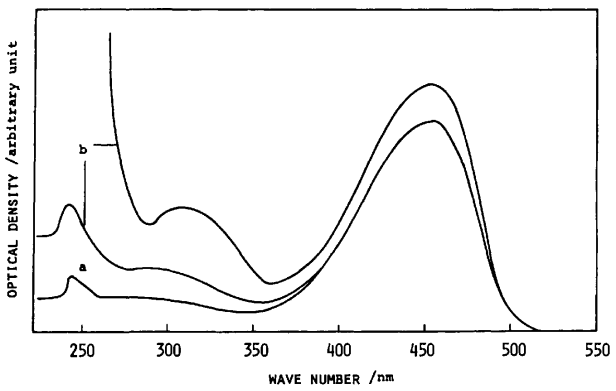

Fig. 1. Absorption spectra of purified(a) and unpurified bilirubin(b) in chloroform solution.

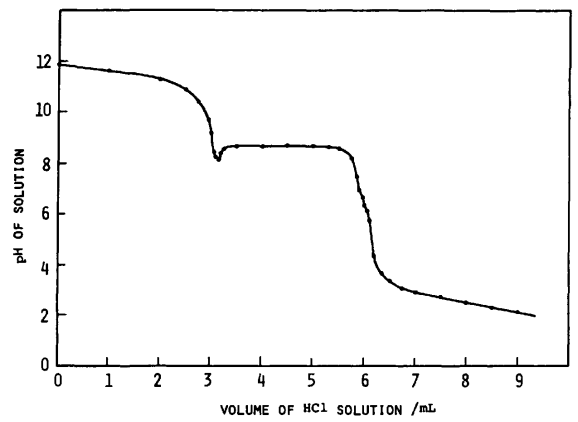

Fig. 2. Back-titration curve of bilirubin in alkali solution by HCl solution; 42.25 mg bilirubin dissolved in 10 ml of 3.018×10^{-2} mol dm^{-3} NaOH solution was titrated with 4.994×10^{-2} mol dm^{-3} HCl solution.

respectively. The former value can be compared with the literature value 6.07×10^4.[13] The titration curve is illustrated in Fig. 2. The result is appreciably different from that reported before.[9] The purity was found to go up to 99.8% with respect to two carboxyl groups from 90.4% of unpurified bilirubin. It is quite clear from this titration curve that bilirubin is dibasic acid in the pH region below 10 and that there exist two steps on pH decrease around the endpoint of titration due to different dissociation constants. The titration curve is quite similar to that of bile acids[18] which start micelle formation above their cmc,[19] but their physicochemical meaning is much different as will be clear later. The almost flat initial part of the curve represents the titration of excess NaOH. After neutralization of excess NaOH, the pH continues to decrease steeply with a small amount of HCl and then rises sharply again. With each successive addition of HCl, an almost equivalent amount of bilirubin is precipitated, where the pH of titration solution with bilirubin solid suspension hardly decreases keeping the value of 8.5 to the endpoint of the neutralization. The sharp rise of pH is accompanied by the precipitation of bilirubin. This indicates that supersaturation of bilirubin is broken at pH 8.15. The extent of the supersaturation can be estimated to be more than 10^{-4} mol dm^{-3} from the titration curve. Other acidic groups with $pK>10$ are out of the present discussion.[20]

Decomposition of Bilirubin in Buffer Solutions. Biomolecules are very easy to decompose, once they are taken out from their mother tissue. Thus, it is very important for the present investigation to know how easily bilirubin degrades in buffer solutions. As the decay kinetics of bilirubin is not the main purpose, very simple first-order kinetics is adopted, neglecting the effect of H^+ or OH^- ions;

$$OD = OD_0 \exp(-k^{app}t). \quad (1)$$

where an optical density(OD) is used in place of concentration, k^{app} is an apparent first-order rate constant, and t is time in unit of hour. The decay curves turned out to be approximately expressed by Eq. 1. The k^{app} values and the wavelength pursued are given in Table 1. From the results, more than 90% of birirubin can remain unchanged for one hour.

Spectrum Change with pH. It has become clear from the titration curve that bilirubin is a dibasic acid. Therefore, it dissociates stepwise from acidic to basic form with increasing pH;

$$\underset{1}{AH_2} \overset{K_1}{\rightleftharpoons} \underset{2}{AH_1^-} \overset{K_2}{\rightleftharpoons} \underset{3}{A^{2-}}. \quad (2)$$

Figure 3 shows the absorption spectra in several buffer solutions. As is expected, the spectrum

Table 1. Apparent rate constant (k^{app}) of decomposition of bilirubin in buffer solutions of different pH at 25 °C

pH	λ^{obsd}/nm	$10^2\,k^{app}/k^{-1}$

7.96	440	7.3
7.37	450	9.0
7.07	450	11.5
6.38	453	10.1
6.09	440	5.1
4.41	440	7.8

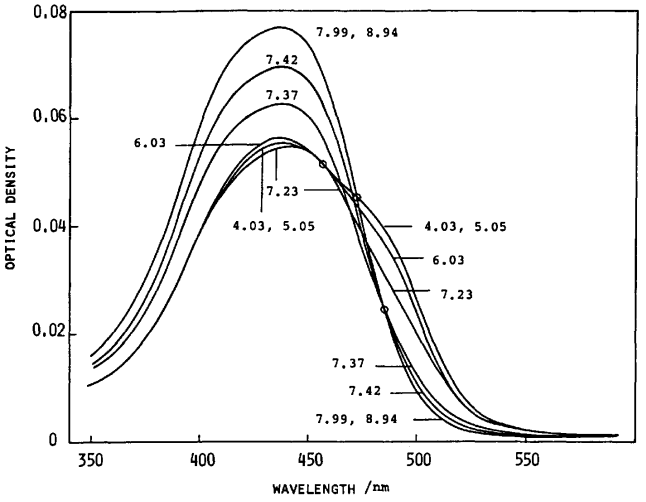

Fig. 3. Absorption spectra of bilirubin in buffer solutions with different pH and three isosbestic points(o): the number in the figure is pH of buffer solution and the bilirubin concentration is 1.39×10^{-6} mol dm^{-3}.

changes with pH of the solution. The concentration of each solution is 1.39×10^{-6} mol dm^{-3} which is higher than the solubility at pH 8, 1.0×10^{-6} mol dm^{-3} (Fig. 4). However, any precipitation has not been observed, because the concentration is so small that the supersaturation is easy to stand far up to 10^{-4} mol dm^{-3} as can be seen from the titration curve. The spectra of A^{2-} above pH 8 remain the same and has the absorption maximum at 438 nm with the molar absorption coefficient of 5.45×10^4 mol^{-1} dm^3 cm^{-1}. On the other hand, the spectra of AH_2 below pH 5 also remain unchanged, where the wavelength of the absorption maximum is 437 nm with the molar absorption coefficient of 3.92×10^4 mol^{-1} dm^3 cm^{-1}. The wavelength of three isosbestic points obtained from many spectra of different pH are 457 nm for AH_2 and AH_1^-, 485 nm for AH_1^- and A^{2-}, and 472 nm for A^{2-} and AH_2.

Solubility. The solubilities determined spectrophotometrically at 37 °C against $1/a_{H^+}$ of each buffer solution are shown in Fig. 4. Bilirubin which

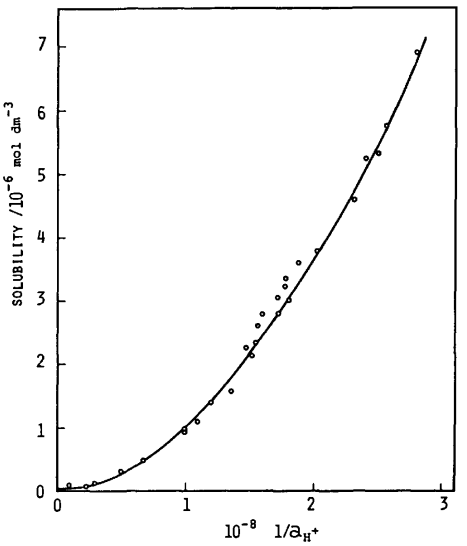

Fig. 4. Solubility of bilirubin in buffer solution as a function of $1/a_{H^+}$: ionic strength=0.15 and temperature=37 °C.

is a dibasic acid dissociates by two steps, and the total analytical concentration then becomes[16]

$$C_t = [AH_2] + [AH_1] + [A] = [AH_2]\left\{1+\frac{K_1}{\gamma_2}\frac{1}{a_{H^+}}+\frac{K_1K_2}{\gamma_3}\left(\frac{1}{a_{H^+}}\right)^2\right\}. \quad (3)$$

The concentration $[AH_2]$ should remain constant at constant temperature and ionic strength as far as AH_2 solid coexists in the solution, because AH_2 in the solution is in chemical equilibrium with solid AH_2. Since every parameter except $1/a_{H^+}$ of the right side of Eq. 3 is constant based on the above reasons, the total concentration C_t changes with the second-power curve of $1/a_{H^+}$. Three coefficients of the curve $(A+B(1/a_{H^+})+C(1/a_{H^+})^2)$ were estimated by applying the second-power curve to the solubility data where the method of least square was employed for the best fit between them, and they were found to be

$$A = 1.132\times10^{-9},\ B = 1.728\times10^{-15},$$

and

$$C = 8.176\times10^{-23}\ \text{mol dm}^{-3}.$$

Now it became clear that the total analytical concentration increases with increasing pH by being subject to the second-power curve of $1/a_{H^+}$ in this case, too. This means that dimerization or polymerization of bilirubin does not take place in these buffer solutions. It is incorrect that the logarithm of the solubility varies linearly with pH.[21]

Evaluation of Dissociation Constants

Spectrophotometric Method. Spectrum of bilirubin depends on the pH of its solution as seen

above. At any wavelength except that of the isosbestic point, the optical density can be expressed as

$$OD = \varepsilon_1 C_1 + \varepsilon_2 C_2 + \varepsilon_3 C_3 \quad (4)$$

where ε_i is molar absorption coefficient and C_i is molar concentration of species i. On the other hand, the total concentration is

$$C_t = C_1 + C_2 + C_3 \quad (5)$$

and they can be related with one another by the dissociation constants as

$$K_1 = \frac{C_2 \gamma_2 a_{H^+}}{C_1 \gamma_1} \quad (6)$$

and

$$K_2 = \frac{C_3 \gamma_3 a_{H^+}}{C_2 \gamma_2}, \quad (7)$$

where γ_i is the activity coefficient of i. By combining the above four equations, there results

$$\frac{\gamma_3 a_{H^+}^2}{K_1 K_2}\varepsilon_1 + \frac{\gamma_3 a_{H^+}}{\gamma_2 K_2}\varepsilon_2 + \varepsilon_3 = \frac{OD}{C_t}\left(\frac{\gamma_3 a_{H^+}^2}{K_1 K_2} + \frac{\gamma_3 a_{H^+}}{\gamma_2 K_2} + 1\right) \quad (8)$$

where γ_1 is assumed to be unity because of uncharged species of **1**. ε_1 and ε_3 are easily determined from the spectrum of low and high pH solutions of bilirubin, respectively, and their activity coefficients can be estimated at the ionic strength(I) of 0.05 and 25 °C from the equation suggested by Bates[22]

$$\log \gamma_i = -\frac{0.5|z_i|^2\sqrt{I}}{1+1.5\sqrt{I}} \quad (9)$$

where z_i is a valency of i. Now, it is theoretically possible to determine K_1, K_2, and ε_2 values from three different OD values of different pH solution at fixed wavelength and at known total concentration. Practically, however, the spectrum whose variation with pH is large can be used for the present purpose; only K_i which brings about larger spectrum change with small pH change can be determined with high accuracy. Two wavelengths, 490 and 438 nm, were used for the determination of K_1 and K_2 values, respectively. The molar absorption coefficients used are

$$\varepsilon_1 = 2.46 \times 10^4,$$
$$\varepsilon_3 = 1.24 \times 10^4 \text{ mol}^{-1}\text{ dm}^3\text{ cm}^{-1} \text{ at } 490 \text{ nm}$$

and

$$\varepsilon_1 = 3.88 \times 10^4,$$
$$\varepsilon_3 = 5.45 \times 10^4 \text{ mol}^{-1}\text{ dm}^3\text{ cm}^{-1} \text{ at } 438 \text{ nm}.$$

The K_i values thus obtained are

$$K_1 = (3.1\text{—}8.7) \times 10^{-7},$$
$$K_2 = (2.5\text{—}5.1) \times 10^{-8} \text{ at } 25\,^\circ\text{C}.$$

Solubility Method. As is clear from Eq. 3, the values of K_1 and K_2 can be obtained from the three coefficients of the second-power curve $(A+B(1/a_{H^+})+C(1/a_{H^+})^2)$ as

$$K_1 = \gamma_2 B/A, \quad (10)$$
$$K_2 = \gamma_3 C/\gamma_2 B, \quad (11)$$

From the three coefficients given above, K_1 and K_2 values become

$$K_1 = 9.7 \times 10^{-7} \text{ and } K_2 = 2.4 \times 10^{-8} \text{ at } 37\,^\circ\text{C}.$$

Although the A value cannot be precisely determined for a scarcely soluble acid like the present, B and C values are rather easy and more accurate to determine. Therefore, K_2 value is more reliable than K_1 value. In our preceding paper[16] the authors reported the method to determine K_1 value of dibasic acid by employing $[AH_2]$ as a parameter. However, this method can be used only when the two coefficients, B and C, are very accurate. In the present case, on the other hand, bilirubin is not so stable and these coefficients cannot be accurately determined, as is obvious from the plots in Fig. 4.[23] The feasible concentration range of AH_2 based on the range of K_1 values obtained above is shown in Fig. 5, supposing B value to be fairly accurate. Indeed there results some difference in value between the two dissociation constants depending on the methods employed, but the diminution of the difference is quite difficult in this case judging from the instability of bilirubin as is obvious in the section of its decomposition.

Now it can be said that K_1 value ranges from 3×10^{-7} to 1×10^{-6}, while K_2 value is between 2×10^{-8} and 5×10^{-8}, although the values obtained from the two methods are not coincident each other. The dissociation constants of aliphatic monocarboxylic acids as in bilirubin usually range from 10^{-5} to 10^{-3} and the second dissociation constants of corresponding dicarboxylic acids are between 10^{-8} and 10^{-5}.[24] The

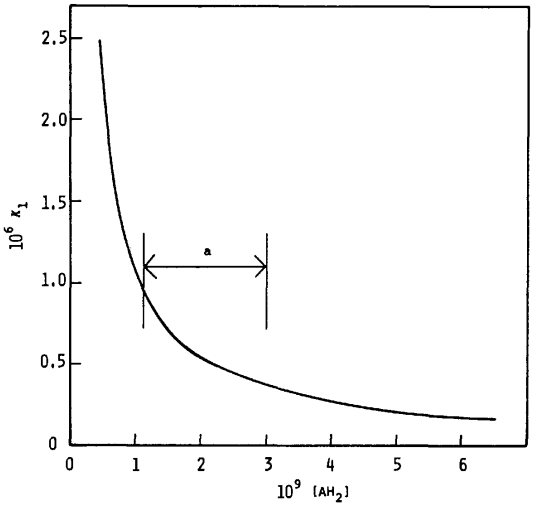

Fig. 5. Variation of K_1 value as a function of concentration of AH_2 and its feasible concentration range(a).

extreme small second dissociation constant of bilirubin can be ascribed partly to a free energy increase by electrostatic repulsion between two carboxylato groups[25] when the second dissociation takes place, as has been done in most cases. The distance between the two groups can range from 0 to 10 Å by CPK molecular model. This range can become the factor somehow to explain the difference between the obtained K_1 and K_2 values. The K_1 value of 10^{-6} at maximum also seems too small for the carboxyl group judging from dissociation constants of most aliphatic monocarboxylic acids. It is then highly possible that the smaller values of K_1 and K_2 are due to stabilization of the carboxyl groups by intramolecular hydrogen bond formation.

Finally, a few remarks on previous works by other investigators on the solubility, the absorption spectra, and the dissociation constants will be made. Overbeek *et al.* expected the dissociation constants for the two carboxyl groups, $K_1=4\times10^{-5}$ and $K_2=1\times10^{-5}$, and estimated the total solubility of 2×10^{-4} mol dm^{-3} at pH=8.[8] It is two hundred times higher than that of present case at the same pH, which indicates that their expected dissociation constants might be totally incorrect. On the other hand, the solubility determined by Brodersen, 9×10^{-8} mol dm^{-3} at pH=8,[21] is one tenth of the solubility determined by us because of extremely scanty solubility of solid bilirubin; 2.5 mg of solid bilirubin in 25 ml buffer solution was too small to reach the solubility equilibrium within one hour in our preliminary experiment. In addition, they attributed the spectrum change with time to bilirubin aggregation.[21] Even if it were true that the bilirubin aggregation took place during the process of spectral measurement in lower pH buffer solutions, the spectrum in Fig. 3 would be trustworthy with more than 98% confidence judging from k^{app} values in Table 1 obtained from higher bilirubin concentration than that for spectral measurement and from the time required for the measurement. Hansen *et al.* insisted that the dissociation constants(pK) of the two carboxyl groups should be well below 7 and obtained the calculated value of pK=4.4.[20] As mentioned above, the pH value with pH titration for the suspended neutralized precipitate bilirubin is around 8.5. If pK=4.4 is correct, $[A^{2-}]/[AH^-]$ must be larger than 10^4 at pH=8.5 and the total solubility becomes more than 10^{-1} mol dm^{-3}, $[AH_2]$ being assumed to be 10^{-9} mol dm^{-3}. Such a high solubility should not bring about the bilirubin precipitation during the back titration. On the other hand, Krasner and Yaffe concluded that both carboxyls have pK=7.55 at 26 °C from the titration curve.[9] The values are almost equal to the present K_2 value.

The strong dependence of the solubility of bilirubin on solution pH must have great importance for gallstone formation. The rapid decrease of solubility of bilirubin below pH 8 suggests that gallstone formation might be due to a lowering of pH in gall bladder. The solubility of bilirubin in buffer solutions has been extensively measured by several investigators. Nevertheless, the reported values have shown a wide variety depending on methods and conditions employed. However, the solubilities obtained here are rather accurate, and therefore we believe that they will become very useful for future study of the pathological function of bilirubin in the human body.

We wish to thank Dr. T. Furusawa of Koga surgery hospital for discussion of bilirubin properties in aqueous solutions from the viewpoint of gallstone formation. Thanks are also due to the Ito Science Foundation for financial support. Technical help of Mr. H. Noma is greatly acknowledged.

Preparation of New Nitrogen-bridged Heterocycles. 11.[1] A New Synthetic Method of Pyrazolo[1,5-*a*]pyridines from the Alkaline Treatment of 1-[(Acylmethylthio)-methyleneamino]pyridinium Salts

Akikazu KAKEHI,* Suketaka ITO, Masayoshi ITO, Toshiaki YOTSUYA, and Kenji NAGATA
Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380
(Received November 29, 1984)

Alkaline treatment of 1-[(acylmethylthio)methyleneamino]pyridinium halides gave unexpectedly 3-acyl- or 3-(acylthio)pyrazolo[1,5-*a*]pyridine derivatives in 35—87% yields. Some 4,4a-dihydropyrido[1,2-*d*][1,3,4]thiadiazine intermediates involved in these reactions could be detected by their nmr follows and three related 4a,8-dimethyl derivatives were isolated. Substituent effect and possible mechanisms are also discussed.

In our previous communication[2] we have reported abnormal syntheses of 2-alkylthio-3-acyl- and 2-alkylthio3-(acylthio)pyrazolo[1,5-*a*]pyridine derivatives by the reactions of 1-[(acylmethlthio)methyleneamino]pyridinium salts with base, and assumed that these reactions must proceed *via* the desulfurization and the rearrangement of transient pyrido[1,2-*d*][1,3,4]-thiadiazine intermediates. Recently, Schmidt[3] has descrirbed that the 1,3,4-thiadiazinyl anions generated from the deprotonation of 6*H*-thiadiazines are thermally labile and are converted smoothly to desulfurized pyrazoles and the rearranged 4-mercaptopyrazoles. Our intermediates stated above are isoelectronic with such anions and are very intriguing molecules which have an antiaromatic (or a nonaromatic) 12-pi electron system. In this paper we wish to report a new synthetic method for 2-alkylthio-3-acyl- and 3-(acylthio)pyrazolo[1,5-*a*]pyridine derivatives and our attemps to detect the intermediates involved in the synthetic reactions of these compounds.

Result and Discussion

Reactions of Pyridinium Salts with Base. Treatment of 1-[(ethoxycarbonylmethylthio)methyleneamino]pyridinium bromides **11—19**. Obtainable by the alkylations of the corresponding pyridinium *N*-ylides **1—9** with ethyl bromoacetate **10** in quantitatively yields, with excess potassium carbonate in chloroform at room temperature afforded ethyl pyrazolo-[1,5-*a*]pyridine-3-carboxylate **20—28** in 35—82% yields along with the release of sulfur. (Scheme 1) The same pyrazolopyridines **20—22** could be aslo obtained from similar reactions of pyridinium iodides **30—32** which were prepared from the *N*-ylides **7—9** and methyl iodide **29**. The reaction of unsymmetrically substituted 3-methylpyridinium salt **34** with base gave a *ca.* 2:1 mixure of the corresponding 4-methyl- **35** and 6-methylpyrazolopyridine derivative **36** in 83% yield. (Scheme 2) On the other hand, the alkaline treatment of 1-[(phenacylthio)methyleneamino]pyridinium bromides **42—62** prepared from *N*-ylides **1—6** and phenacyl bromides **37—41** did not yield the initially expected 3-aroylpyrazolo[1,5-*a*]pyridines such as **63** at all, but, instead of them, afforded 3-(aroylthio)pyrazolo[1,5-*a*]pyridine derivatives in good yields, respectively. (Scheme 3) Similarly, unsymmetrical 3-methylpyridinium bromides **85** and **86** provided the corresponding isomeric mixtures **87** and **88** (its ratio was *ca.* 9:7), and **89** and **90** (its ratio was *ca.*

4:3) in 69 and 86% yields. (Scheme 4)

In order to investigate further the substituent effect in these reactions, we examined the reactions of pyridinium salts having an acetyl and a cyano group. The reactions of salts **93** and **95** synthesized from *N*-ylides **1** and **3** and bromoacetone **91** with base afforded only 3-(acetylthio)pyrazolopyridines **99** and **101**, but similar reactions of iodides **96** and **98** prepared from the same *N*-ylides and chloroacetone **92** in the presence of sodium iodide gave 3-acetyl derivatives **102** and **104** as major products together with the formation of a small amount of 3-acetylthio compound **101**. However, no 7-methylpyrazolopyridine derivatives such as **100** and **103** could be obtained from the reactions of 2-methylpyridinium bromide **94** and iodide **97**. (Scheme 5) On the other

hand, the reactions of 1-[(cyanomethylthio)methyleneamino]pyridinium salts **107—112** with base gave only 3-cyano derivatives **113—115** in 32—55% yield but not 3-(thiocyanato)pyrazolopyridines at all. (Scheme 6)

The structures of 3-ethoxycarbonyl- **20—28**, **35**, and **36**, 3-acetyl- **102** and **104**, and 3-cyanopyrazolo[1,5-*a*]-pyridines **113—115** were decided by their physical and spectral inspections and partly by the comparisons of **20—22** with authentic samples prepared independently.[4] In particular, the chemical shifts and the signal patterns attributable to the skeletal protons in their NMR spectra (See Table 1) were quite similar to those of known pyrazolo[1,5-*a*]-pyridine-3-carboxylate[5] and 3-vinylpyrazolo[1,5-*a*]-pyridines.[6] Their microanalyses and mass spectra were in good accord with the molecular compositions involving only one sulfur atom, and the detection of the sulfur from the reaction mixtures also supported our proposed structures. On the other hand, their analyses and some mass spectra of products **64—84** and **87—90** obtained from 1-[(phenacylthio)methyleneamino]pyridinium bromides **42—62**, **85** and **86**, showed results different apparently from those of 3-aroylpyrazolo[1,5-*a*]pyridine derivatives such as **63** expected initially, that is, they suggested the molecular compositions having two sulfur atoms. In order to obtain further information about these structures, we attempted the syntheses of some 3-benzoylpyrazolopyridines and the comparisons of the resulting products with 3-aroylthio derivatives. As might be expected, 3-benzoyl-2-(methylthio)pyrazolo-[1,5-*a*]pyridines **120—122** were synthesized in very good yields by the reactions of 1-aminopyridinium iodides **116—118** with 2-benzoyl-1,1-bis(methylthio)-ethylene **119** in the presence of excess potassium carbonate in chloroform. (Scheme 7) There was little difference between both NMR spectra (See Table 1) of these 3-benzoylthio-3-(methylthio)pyrazolopyridines **64**, **69**, and **74** and 3-benzoyl compounds **120—122**, but, in their IR spectra, the large differences between their carbonyl absorptions were observed: Each band of **64**, **69**, and **74** appeared at much

higher region (1665—1675 cm^{-1}) than those (1600—1610 cm^{-1}) of **120—122**, indicative of the absence of the conjugation between the benzoyl and the aromatic pyrazolopyridine ring. Further structural support for compounds **64—84**, **87—90**, **99**, and **101** was provided by their acid hydrolyses. Disulfides **123—125** could be obtained easily by heating 3-(benzoylthio)pyrazolopyridines **64**, **69**, and **74** with concentrated hydrochloric acid. (scheme 8) Compound **123** was also obtained by only heating 3-(acetylthio)pyrazolopyridine **99** with ethanol. The structures of **123—125** were assigned to be bis[2-(methylthio)pyrazolo-[1,5-*a*]pyridine-3-yl] disulfides, because their NMR spectra showed both presences of a methylthio group and a pyrazolopyridine skeleton and their Mass spectra exhibited the molecular weights bearing four sulfur atoms in each molecule.

The X-ray analysis of 3-(*p*-chlorobenzoylthio)-7-methyl-2-(methylthio)pyrazolo[1,5-*a*]pyridine **70** was carried out (See Fig. 1), and the structures of other rearranged products **64—69**, **71—84**, **87—90**, **99**, and **101** were finally concluded by the physical and spectral analogies with **70**.

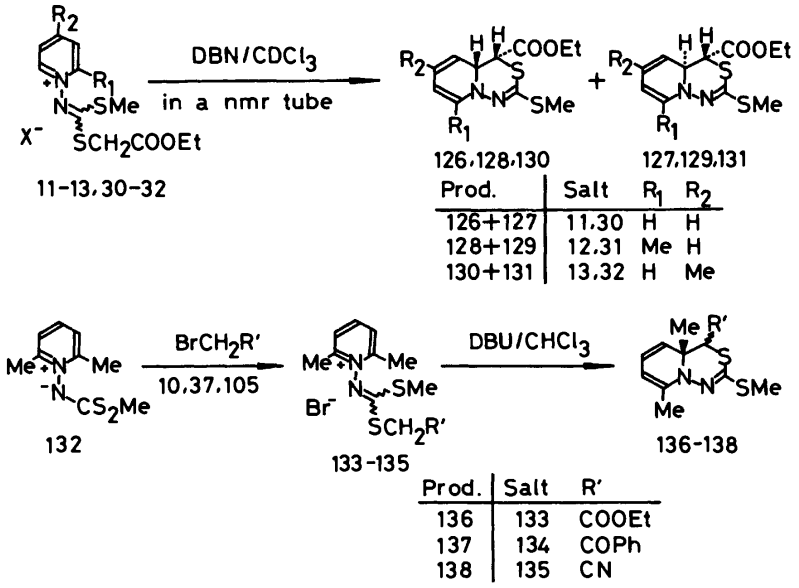
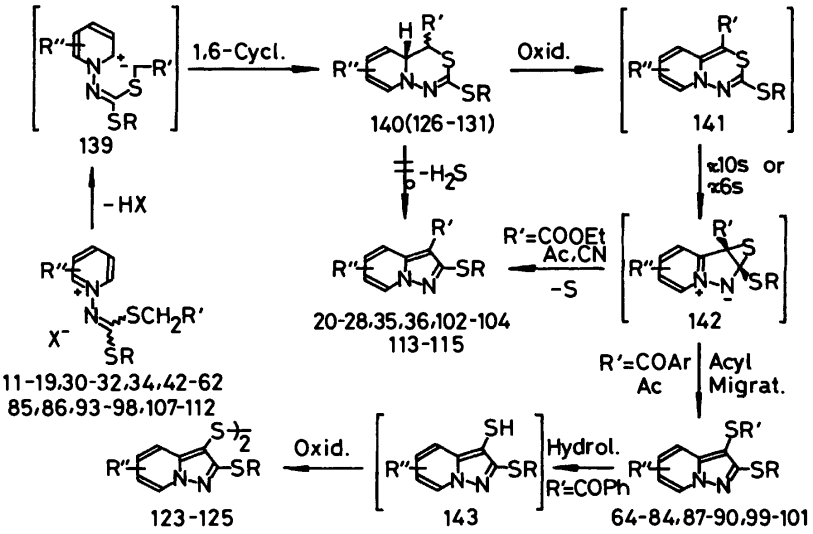
Detection and Isolation of Pyrido[1,2-d][1,3,4]thiadiazine Derivatives. On the TLC of the mixtures at the early reaction stage, we often observed certain significant spots different clearly from those of products described above. Our attempts to isolate these substances were unuccessful because of their thermal instability, but some of them could be detected by the NMR follows of the reactions of pyridinium salts with base. For example, treatment of pyridinium bromides **11—13** with DBN in deuteriochloroform in a NMR tube caused instantly the disappearance of the salts and the generations of new nonaromatic compounds **126—131**. The same products **126—131** were also observed in the reactions of pyridinium iodides **30—32** with DBN. In the NMR spectra of **126—131** (See Table 2), the signals due to all skeletal protons appeared in an olefinic region of δ 3.4—6.5 and not in an aromatic region as shown in those of pyrazolo[1,5-*a*]pyridine derivatives (Table 1). These values of **126—131** were considerably similar to those of 3,3a-dihydropyrazolo-[1,5-*a*]pyridines[7] and 1,9a-dihydropyrido[1,2-*b*][1,2,4]-triazines,[8] and this fact suggested strongly the presence of a 1,2-dihydropyridine moiety in these molecules. We next examined the syntheses of isolable pyridothiadiazines possessing a methyl group at the 4a-position, since the instability of these molecules might be caused by the susceptibility to the oxidation of the 4- and 4a-protons. The treatment of 2,6-dimethylpyridinium bromides **133—135** with DBU in chloroform gave considerably stable 4a,8-dimethyl-4,4a-dihydropyrido[1,2-*d*][1,3,4]thiadiazines **136—138** in 81, 43, and 78% yields, respectively. (Scheme 9) In contrast with the above reactions of **11—13** and **30—32**, compounds **136—138** were not *cis-trans* mixtures (See Table 2) but their configurations could not be decided because of the absence of the coupling constants between the 4- and the 4a-substituents.

Reaction Mechanisms. Possible mechanisms for these reactions are shown in Scheme 10. The reactions must be initiated by the dehydrohalogenation of pyridinium salts, and undergo the 1,6-cyclization of the resulting ionic intermediates **139** to give 4,4a-dihydropyridothiadiazines **140** as detected partly by their NMR spectrometry. The oxidation of **140** may afford antiaromatic (or nonaromatic) 12-pi pyridothiadiazines **141**, and their symmetry-allowed disrotatory cyclizations may give rise to tricyclic thiiranes **142**. The desulfurization of the reactive species **142** should provide 3-acyl- **20—28**, **35**, **36**, and **102—104** and 3-cyanopyrazolopyridines **113—115**, while the opening of the thiirane ring with the acyl migration



Scheme 9.



Scheme 10.

should lead to 3-(acylthio)pyrazolopyridines **64—84**, **87—90**, and **99—101**. An alternative route from dihydropyridothiadiazines **140** to 3-acyl- or 3-cyanopyrazolopyridines *via* the elimination of hydrogen sulfide is negligible, since no evolution of gaseous hydrogen sulfide could be observed. Of the reaction sequence the routes from pyridothiadiazines **141** to two types of pyrazolopyridines are the same with those described for the thiadiazinyl anion-pyrazoles transformation by Schmidt,[3] except the acyl migration in place of the proton transfer. The substituent effect which influences the desulfurization and the rearrangement in these reactions is still uncertain, but it may be related to the migrating or eliminating ability of these substituents. The formation of disulfides **123—125** can be interpreted reasonably by the acid hydrolyses of 3-(benzoylthio)pyrazolo[1,5-*a*]-pyridines **64**, **69**, and **74** followed by the air oxidation of the resulting thiols **143** to the disulfides.

Experimental

Melting points were measured with a Yanagimoto micromelting point apparatus and are uncorrected. Microanalyses were carried out on a perkin-Elmer 240 Elemental Analyzer. The NMR spectra were determined with a Varian EM360A Spectrometer in deuteriochloroform with tetramethylsilane as an internal standard. The chemical shifts are expressed in δ values. The IR spectra were taken with a Hitachi 260-10 Infrared Spectrophotometer. The Mass spectra were obtained with a JEOL JMS-01SG-2 Mass Spectrometer attached with a JEC-6 Spectrocomputer.

Preparations of Pyridinium N-Ylides. These pyridinium *N*-ylides **1—9**, **33**, and **132** were synthesized ac-

Preparations of Pyrazolo[1,5-a]pyridine Derivatives. *General Method A*: A chloroform solution (20 ml) of pyridinium *N*-ylide (2 mmol) was allowed to react overnight with a small excess of an alkylating agent (2.4 mmol) at room temperature. The resulting solution was then concentrated at reduced pressure and the residue was washed three times with ether to remove the remaining alkylating agent. The

almost pure pyridinium salt was dissolved again in chloroform (30 ml) and treated with potassium carbonate (5 g) at room temperature until the salt was completely consumed. (about 1 or 2 d) The reaction mixture was filtered to remove insoluble inorganic substances and the filtrate was concentrated at reduced pressure. The residue was separated by column chromatography on alumina using hexane, ether, and chloroform as eluents. Evaporation of the chloroform layer and recrystallzation of the resulting crude product from ethanol afforded pure pyrazolopyridine derivative.

B: Pyridinium iodides **96—98** and **110—112** were prepared by the reactions of pyridinium *N*-ylides **1—3** (4 mmol) with a large excess of chloride **92** or **106** (5 g) in the presence of sodium iodide (5 g) in acetone (60 ml) at room temperature for 2 d. After the evaporation of acetone and the removal of excess chloride by repeated washings with ether, the resulting salts were dissolved in chloroform (60 ml) and allowed to react with potassium carbonate (10 g) at room temperature for 3 d. Similar work-ups of the reaction mixtures provided the corresponding pyrazolopyridine derivatives.

In the reactions of pyridinium salts **11—19**, **30—32**, and **34** with base the elimination of sulfur was observed, though its quantity could not be decided because of the heterogeneous reactions. On the other hand, no evolution of hydrogen sulfide from these reaction systems could be detected. Compound **99** was converted easily to disulfide **120** by the recrystallization from ethanol. The Mass spectra of **20—22**, **26—28**, **64—68**, and **113—115** gave satisfactory values 236, 250, 250, 308, 322, 322, 300, 336, 380, 314, 376, 189, 203, and 203, for each molecular ion, respectively. These results and some properties are listed in Tables 1 and 3.

Preparations of 3-Benzoylpyrazolo[1,5-a]pyridines 120—122. General Method: A mixture of 1-aminopyridinium iodide (2 mmol) and 2-benzoyl-1,1-bis(methylthio)ethylene **119** (2 mmol) was stirred with potassium carbonate (5 g) in chloroform (30 ml) at room temperature for 2 d. The reaction mixture was then filtered to remove inorganic substances and the filtrate was concentrated at reduced pressure. The residue was separated by column chromatography (alumina) using hexane, ether, and chloroform as eluents. After the evaporation of the solvent, recrystallization of the residue from ethanol afforded 3-benzoyl-2-(methylthio)-pyrazolo[1,5-*a*]pyridine derivative. Some data except their NMR spectra (see Table 1) of these products are as follows: **120**, 93%, colorless needles, mp 104—105 °C, ν (KBr) 1605 cm^{-1} (CO). Found: C, 67.22; H, 4.48; N, 10.43%. Calcd for $C_{15}H_{12}N_2OS$: C, 67.14; H, 4.51; N, 10.44%. **121**, 91%, colorless needles, mp 126—128 °C, ν (KBr) 1605 cm^{-1} (CO). Found: C, 68.01: H, 4.90; N, 10.09%. Calcd for $C_{16}H_{14}N_2OS$: C, 68.06; H, 5.00 N, 10.09%. **122**, 93%, colorless needles, mp 161—162 °C, ν (KBr) 1601 cm^{-1} (CO). Found: C, 67.98; H, 4.98; N, 9.85%. Calcd for $C_{16}H_{14}N_2OS$: C, 68.06; H, 5.00; N,9.92%.

Acid Hydrolyses of 3-(Benzoylthio)pyrazolo[1,5-a]pyridines 64, 69, and 74. General Method: A mixture of 3-benzoylthio derivative (1 mmol) and a concentrated hydrochloric acid (10 ml) was heated at 60—80 °C in a water bath for 30 min. After cooling to room temperature, the reaction mixture was neutralized carefully with an aqueous potassium carbonate and then extracted twice with 100 ml portion of chloroform. The combined extracts were filtered through phase-separating filter paper and the resulting solution was then concentrated at reduced pressure. The residue was separated by column chromatography on alumina using hexane and ether as eluents. The evaporation of the ether layer and recrystallization of the crude crystals from a mixture of ether—hexane gave the disulfide.

These disulfides **123—125** were also formed by refluxing

Calcd for $C_{18}H_{18}N_4S_4$: C, 51.64; H, 4.33; N, 13.38%. **125**, 45%, pale yellow needles, mp 177—178 °C, ν (KBr) 783, 1356, and 1639 cm^{-1}, Found: C, 51.82; H, 4.39; N, 13.14%; M$^+$, 418. Calcd for $C_{18}H_{18}N_4S_4$: C, 51.64; H, 4.33; N, 13.38%.

X-Ray Crystallography. The crystal of 3-(*p*-chlorobenzoylthio)-7-methyl-2-(methylthio)pyrazolo[1,5-*a*]pyridine **70** was grown from ethanol. A suitable crystal was mounted on a Rigaku AFC-6B diffractometer and the intensity data of $|F_o|>3\sigma|F_o|$ were colleted using Mo($K\alpha$) radiation of 0.71070 Å wave length within the range of $2\theta<55°$. Total reflections usd for the analysis were 1617. The structure was solved by the MULTAN method and the final R values was 9.1%.

The crystal data are as follows (see Fig. 2 for the bond lengths and the bond angles of this molecule): **70**, $C_{16}H_{13}N_2OS_2Cl$, F.W.=348.9, monoclinic, space group $P2_1/C$, a=16.816(6) Å, b=6.331(1) Å, c=17.026(5) Å, β=116.21(2)°, z=4, Dc=1.42 g/cm^3.

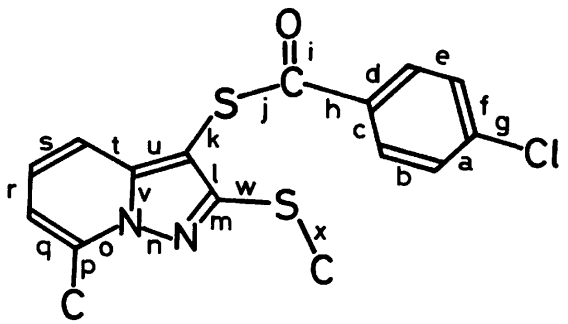

Fig. 2.

Bond lengths (Å): a=1.364(20), b=1.410(21), c=1.381(15), d=1.410(20), e=1.421(22), f=1.365(19), g=1.750(23), h=1.482(20), i=1.205(13), j=1.784(19), k=1.741(17), l=1.369(16), m=1.337(19), n=1.374(13), o=1.373(21), p=1.489(16), q=1.360(17), r=1.424(17), s=1.384(23), t=1.412(17), u=1.414(19), v=1.385(13). w=1.747(13), x=1.824(14).

Bond angles (°): ab=117.7(13), af=124.0(10), ag=117.8(12), bc=120.2(10), cd=121.3(10), ch=122.8(9), de=117.6(14), dh=115.9(13), ef=19.2(11), fg=118.2(9), hi=124.0(9), hj=114.0(11), ij=122.0(8), jk=102.9(10), kl=129.2(8), ku=124.0(10), lm=113.7(9), lu=106.1(10), lw=124.7(10), mn=103.3(9), mw=121.6(10), no=123.5(8), nv=113.0(11), op=118.0(11), oq=116.3(9), ov=123.4(11), pq=125.7(11), qr=123.2(12), rs=119.5(13) st=117.5(10), tu=136.0(9), tv=120.1(11), uv=103.9(12), wx=101.9(11).

Detections of 4,4a-Dihydropyrido[1,2-d][1,3,4]thiadiazines ***126—131.*** *General Method*: A deuteriochloroform solution (0.5 ml) of pyridinium halide (0.1 mmol) which was placed in a NMR tube was treated with two drops of DBN (about 40 mg, 0.26 mmol). The NMR spec-

trum of resulting solution which was turned instantly red was measured. However, our attempts to isolate these intermediates **126—131** from the reaction mixtures were unsuccessful because their column separations did not afford them at all but gave always only ethyl 2-(methylthio)pyrazolo[1,5-*a*]pyridine-3-carboxylates **20—22**. In addition, compounds **126—131** were completely decomposed by heating them at **50—60** °C for only a few minutes. The NMR spectral data of **126—131** are shown in Table 2.

Isolations of 4a,8-Dimethyl-4,4a-dihydropyrido[1,2-d][1,3,4]-thiadiazines 136—138. General Method: 2,6-Dimethylpyrildinium *N*-ylide **132** (424 mg, 2 mmol) was treated with bromide (3 mmol) in chloroform (20 ml) at room temperature for 1 d. The reaction mixture was then concentrated at reduced pressure and the residue was washed three times with ether to remove excess alkylating agent. The pyridinium salt was again dissolved in chloroform (15 ml) and the resulting solution was cooled to 0 °C in an ice bath. DBU (453 mg,3 mmol) was added dropwise into the solution under stirring at 0 °C and the reddish solution was immediately separated by column chromatography (two times) on alumina using chloroform as an eluent. The removal of chloroform at reduced pressure at below 40 °C afforded oils of **136—138**. However, the preparations of pure samples for the analyses were unsuccessful because of their thermal instability and the failure to their crystallization. These compounds **136—138** could be stored for about a week in the freezer but decomposed completely at room temperature for about 1 d. Some data except their NMR spectra (see Table 2) are as follow: **136**, 81%, orange oil, ν (Neat) 1738 (CO), 1630, 1368, 1150, 711 cm^{-1}. **137**, 43%, yellow oil, ν (Neat) 1681 (CO), 1491, 1370, 1210, 981 cm^{-1}. **138**, 78%, Orenge oil, ν (Neat) 2245 (CN),1648,1586,1370,1138,715 cm^{-1}.

The authors wish to thank Dr. Yoshinori Tominaga (Nagasaki University) for the offer of authentic samples of pyrazolo[1,5-*a*]pyridines and Mr. Toshihiko Hori (Rigaku Denki Co. Ltd) for the X-ray analysis of 3-(*p*-chlorobenzoylthio)pyrazolo-[1,5-*a*]pyridine.

Preparation and Some Reactions of Diarylgermylenedialkali Metals

Kunio MOCHIDA,* Naoki MATSUSHIGE, and Mari HAMASHIMA
Department of Chemistry, Faculty of Sciences, Gakushuin University, 1-5-1 Mejiro, Toshima-ku, Tokyo 171
(Received November 7, 1984)

The reactions of diarylgermanes with alkali metals in HMPA/THF or THF were found to give the corresponding diarylgermylenedialkali metals in high yields. Diphenylgermylenedipotassium reacted with aryl halides or carbonyl compounds to give reduction products predominantly. With alkyl halides, diphenylgermylenedipotassium gave mainly substitution products.

The reactions of organogermylalkali metals with organic halides or carbonyl compounds are useful for the formation of carbon-germanium bonds.[1-10] Because of its importance, the study of organogermylalkali metals has been reviewed.[1] Among them, however, there are only a few reports regarding organogermylenedialkali metals (probably due to the lack of a useful preparative method). For example, Krause and Carney examined the reaction of germane (GeH_4) with sodium in liquid ammonia but only suggested the probable existence of germylenedisodium (GeH_2Na_2).[11] Cross and Glockling found the reaction of tetrabenzylgermane with lithium in ethylene glycol dimethyl ether or butyllithium to yield dibenzylgermylenedilithium in 7.8% or 2% yields, respectively.[12] Recently, Bulten and Noltes have reported briefly on the reaction of dibutyldichlorogermane with potassium in HMPA to give dibutylgermylenedipotassium in 22% yield.[13] Yields of organogermylenedialkali metals reported are low and the reactions of organogermylenedialkali metals with organic substrates remain to be disclosed.

In this paper, we present the preparation of diarylgermylenedialkali metals from diarylgermanes and alkali metals in HMPA/THF or THF in high yields and then the reactions of diphenylgermylenedipotassium with organic halides and carbonyl compounds.

Results and Discussion

Preparation of Diarylgermylenedialkali Metals. Diarylgermylenedialkali metals (Ar_2GeM_2, **1**, Ar= C_6H_5, p-$CH_3C_6H_4$, M=Li, Na, K) were prepared from the corresponding diarylgermanes (Ar_2GeH_2) and alkali metals in HMPA/THF or THF. The color of **1** was reddish brown (λ_{max} 320 nm in case of diphenylgermylenedipotassium).

I, thus prepared, was characterized by the following experiments: (1) ^1H and ^{13}C NMR of **1**, and (2) the formation of diarylgermanes-d_2 by hydrolysis of **1** with D_2O.

$$Ar_2GeH_2 + 4M \xrightarrow[\text{or THF}]{\text{HMPA/THF}} Ar_2GeM_2 + 2MH \quad (1)$$
$$Ar = C_6H_5,\ p\text{-}CH_3C_6H_4,\ M = Li,\ Na,\ K$$

$$Ar_2GeM_2 \xrightarrow{D_2O} Ar_2GeD_2 \quad (2)$$

(1) ^1H and ^{13}C NMR parameters of diphenylgermylenedipotassium (Ph_2GeK_2, **1a**) and di (p-tolyl)germylenedipotassium ((p-$CH_3C_6H_4)_2GeK_2$, **1b**) are summarized in Table 1, together with those of the starting materials. The chemical shifts of aromatic protons in **1a** and **1b** in comparison with those of the corresponding diarylgermanes are shifted slightly to a higher field, while those of C-1 carbon drastically to a lower field. The observed shifts may be due to the unusual charge distribution; $Ar_2Ge^{\delta-}K_2^{\delta+}$ in comparison with $Ar_2Ge^{\delta+}H_2^{\delta-}$. Thus, negative charge on the aromatic ring may produce an upfield shift of aromatic protons and downfield shift of C-1 carbon. Such phenomena for NMR spectra of organometallic compounds have been reported.[14-18]

(2) It is well known that organogermanium hydrides are formed quantitatively by hydrolysis of

Table 1. ^1H and ^{13}C NMR data of diarylgermylenedipotassium and diarylgermanes in THF-d_8

Compound	^1H NMR			^{13}C NMR				
	Ge-Ph	Ge-H	Me	C-1	C-2	C-3	C-4	Me

organogermylalkali metals.[1] Therefore, the formation and yield of organogermanium hydrides after hydrolysis can be regarded as those of organogermylalkali metals. The yields of **1** were estimated to be 83—96% on the basis of those of diarylgermanes-d_2 formed by hydrolysis of **1** with D_2O.

Reactions of Diphenylgermylenedipotassium, 1a. Reactions of **1a** with organic halides and carbonyl compounds were examined at room temperature for 30 min. Hydrolysis of the reaction mixtures led to reduction products, substitution products, digermanes, and polymers containing germanium. Products were isolated by preparative GLC and TLC, and identified by comparing their IR, NMR, and retention times on GLC with those authentic samples.

Reactions of **1a** with halotoluenes (halogen=Br, Cl, and F) were examined. Reactions of **1a** with bromotoluene gave toluene in 127.7% yield. Digermanes and polymers were also formed. However, no substitution products, diphenylditolylgermane or diphenyltolylgermane, were detected. Reaction of **1a** with chlorotoluene gave toluene in 3.6% yield. No tolylgermanes were formed. Diphenylgermane obtained by hydrolysis of **1a** was recovered in 45.9% yield, and digermanes and polymers were observed. With fluorotoluene, **1a** gave neither toluene nor tolylgermanes. Diphenylgermane was found in 47.1% yield. Digermanes and polymers were formed. The yield of toluene in the reactions of **1a** with halotoluenes increased in the order Br>Cl>F.

In contrast, reactions of **1a** with alkyl halides or benzyl chloride gave predominantly substitution products. Reduction products were also formed as minor products. Reactions of **1a** with alkyl bromides or iodides gave predominantly dialkyldiphenylgermanes. Alkyldiphenylgermanes were minor products. Similarly, dibenzyldiphenylgermane was formed in the reaction of **1a** with benzyl chloride mainly. On the other hand, **1a** reacted with alkyl chlorides to give alkyldiphenylgermanes predominantly. However, **1a** reacted with *t*-butyl chloride to give no *t*-butylgermanes. No diphenylgermane was recovered. Digermanes and polymers were formed. Furthermore, **1a** reacted with 1,4-dibromobutane or 1,5-dibromopentane to give 1,1-diphenylgermacyclopentane or 1,1-diphenylgermacyclohexane, respectively. These results are summarized in Table 2. In a separate experiment, reactions of KH which can be produced in the preparation of **1a** from diphenylgermane and potassium with organic halides were also examined under similar conditions. KH reacted with bromotoluene to give toluene in 10—15% yield. With chlorotoluene, benzyl chloride, or alkyl halides, no reduction products were formed.

With carbonyl compounds, **1a** gave reduction products and aldol condensation products as the main products. Unidentified substitution products were also formed as minor products. Digermanes and polymers were again observed. In a separate experiment, KH was found to react with carbonyl compounds to give aldol condensation products under similar conditions, but no reduction products. There-

a) The reactions were carried out at room temperature for 30 min. The yields of products were based on the concentrations of consumed Ph_2GeK_2 and KH. b) Digermanes, polymers, and other unidentified products were also formed. c) The concentration of Ph_2GeK_2 was determined by that of Ph_2GeD_2 by hydrolysis with D_2O.

fore, the reduction products should have arisen from the reaction of **1a** with carbonyl compounds. The results in the reactions of **1a** with carbonyl compounds and KH with carbonyl compounds are summarized in Table 3. The yields of reduction products shown in Table 3 increased in the order benzophenone>acetophenone>acetone.

The results of the reactions of **1a** with organic halides and carbonyl compounds shown in Tables 2 and 3 are different from those of organogermylalkali metals.[1] It has been reported that organogermylalkali metals react with halotoluenes or carbonyl compounds to give tolylgermanes or organogermylcarbinols as main products, respectively.

The mechanism for the reactions of **1a** with organic halides or carbonyl compounds are not clear. However, taking the formation of reduction products shown in Tables 2 and 3 into consideration, electron transfer between **1a** and organic substrates might be important.

Experimental

Materials. Ph_2GeH_2,[19] Ph_2GeD_2,[20] bp 140—143 °C/0.7 mmHg (1 mmHg≈133.322 Pa), Ph_2GeBr_2, bp 115—120 °C/0.15 mmHg,[21] Ph_2GeEt_2, bp 100—108 °C/0.3 mmHg,[22] $Ph_2Ge(H)Et$, bp 110—115 °C/0.8 mmHg,[23] Ph_2GeBu_2, bp 125 °C/0.4 mmHg,[22] $Ph_2Ge(H)Bu$, bp 107—109 °C/0.08 mmHg,[23] $Ph_2Ge(C_8H_{17})_2$, bp 195—198 °C/0.3 mmHg,[24] $(p\text{-}CH_3C_6H_4)_2GeBr_2$, bp 230—233 °C/13 mmHg,[25] $Ph_3Ge(C_8H_{17})$, mp 72—73 °C,[26] 1,1-diphenylgermacyclopentane, bp 118—122 °C/0.15 mmHg,[27] and 1,1-diphenylgermacyclohexane, bp 118 °C/0.16 mmHg[27] were prepared as described in the cited references. KH is commercially available.

Preparation of Di(p-tolyl)germane. A mixture of di(*p*-tolyl)dibromogermane (4.1 g, 0.01 mol) and lithium aluminum hydride (1.0 g, 0.025 mol) in ether (100 cm³) was stirred with reflux for 3 h. After hydrolysis, the organic layer was dried over calcium chloride. The solvent was removed and then fractional distillation gave di(*p*-tolyl)germane (1.9 g, 7.5 mmol, 75.0%), bp 115 °C/2.0 mmHg; n^{20} 1.5839; IR (neat, cm^{-1}) 2050 (Ge-H). Found: C, 65.72: H, 6.46%, Calcd. for $C_{14}H_{16}Ge$: C, 65.46: H, 6.28%.

Preparation of Diphenyloctylbromogermane. Diphenyloctylbromogermane was prepared by bromination of triphenyloctylgermane (8.3 g, 0.02 mol) with an equivalent of bromine (3.2 g, 0.02 mol) in refluxing 1,2-dibromoethane (50 cm³) for 2 h. The solvent was removed under reduced pressure, leaving about 10 cm³ of residue. Fractional distillation gave crude diphenyloctylbromogermane (5.8 g, 14 mmol, 69.1%), bp 136—150 °C/0.05 mmHg; NMR (δ in $CDCl_3$) 0.52—1.88 (m, 17H), 6.88—7.78 (m, 10H).

Preparation of Diphenyloctylgermane. A mixture of diphenyloctylbromogermane (5.8 g, 14 mmol) and lithium aluminum hydride (1.0 g, 25 mmol) in ether (100 cm³) was stirred with reflux for 3h. After hydrolysis, the organic layer was dried over calcium chloride. The solvent was removed and then fractional distillation gave diphenyloctylgermane (1.3 g, 3.8 mmol, 38.1%), bp 150—158 °C/0.7 mmHg; n^{20} 1.5429; IR (neat, cm^{-1}) 2030 (Ge-H); NMR (δ in $CDCl_3$) 0.35—1.95 (m, 17H), 4.90—5.10 (m, 1H), 6.85—7.95 (m, 10H). Found: C, 70.39; H, 8.35%, Calcd. for $C_{20}H_{28}Ge$: C, 70.44: H, 8.26%.

Preparation of Isopropyldiphenylgermane. Isopropylmagnesium chloride was prepared from isopropyl chloride (9.0 g, 0.12 mol) and magnesium (4.0 g, 0.12 g atom) in ether (50 cm³) and benzene (20 cm³). To this Grignard reagent, diphenyldibromogermane (3.9 g, 0.01 mol) dis-

solved in ether (2 cm^3) was added. Toluene (50 cm^3) was added dropwise to this reaction mixture, and the ether was replaced immediately by toluene through distillation. The reaction mixture was stirred with reflux for 7 h. After hydrolysis, the organic layer was dried over calcium chloride. The solvent was removed and then fractional distillation gave isopropyldiphenylgermane (1.1 g, 4.06 mmol, 40.6%), bp 100—104 °C/0.4 mmHg; n^{20} 1.5718; IR (neat, cm^{-1}) 2025 (Ge-H); NMR (δ in $CDCl_3$) 0.91—1.40 (d, J=6.8 Hz, 6H), 0.65—2.10 (m, 1H), 4.80—5.00 (d, J=4.0 Hz, 1H), 6.85—7.75 (m, 10H). Found: C, 66.64: H, 6.79%, Calcd. for $C_{15}H_{18}Ge$: C, 66.51: H, 6.70%.

Preparation of Dibenzyldiphenylgermane. Benzylmagnesium chloride was prepared from benzyl chloride (12.7 g, 0.10 mol) and magnesium (2.3 g, 0.1 g atom) in ether (100 cm^3). To this Grignard reagent, diphenyldibromogermane (3.9 g, 0.01 mol) dissolved in ether (5 cm^3) was added. The reaction mixture was stirred with reflux for 5 h. After hydrolysis, the organic layer was dried over calcium chloride. The solvent was removed and then fractional distillation gave dibenzyldiphenylgermane (0.8 g, 2.0 mmol, 19.6%), bp 156 °C/0.08 mmHg; n^{20} 1.6321; NMR (δ in $CDCl_3$) 2.61 (s, 1H), 6.54—7.33 (m, 5H). Found: C, 76.46: H, 6.02%, Calcd. for $C_{26}H_{24}Ge$: C, 76.34: H, 5.91%.

Preparation of Diphenylgermylenedipotassium. Potassium (1.8 g, 0.046 g atom) was cut into small pieces and placed in the reaction vessel containing anhydrous HMPA (7.5 cm^3, 0.045 mol) and THF (11.0 cm^3) under argon. The vessel (50 cm^3 two-necked flask) was fitted with a condenser, drying tube argon inlet, and pressure equalizing dropping funnel. Diphenylgermane (1.20 g, 5.0 mmol) dissolved in THF (1.0 cm^3) was placed in the dropping funnel. The reaction vessel was blanketed with argon and K/HMPA/THF was stirred vigorously. The color of the solution changed to blue. The diphenylgermane solution was added dropwise and the change from blue to reddish brown usually appeared after about 40 min. The yield of diphenylgermylenedipotassium was determined from the concentration of diphenylgermane-d_2 after hydrolysis with D_2O (84—96%).

Preparation of Diphenylgermylenedilithium or Diphenylgermylenedisodium. Diphenylgermylenedilithium or diphenylgermylenedisodium was prepared as described above diphenylgermylenedipotassium.

*Reaction of Diphenylgermylenedipotassium, **1a**, with Ethyl Bromide.* A typical example for the reactions of **1a** with organic halides was described. A solution of **1a** (0.534 mmol) in HMPA/THF was added to ethyl bromide (7.40 mmol) dissolved in THF (1.0 cm^3) and stirred for 30 min. The reaction vessel was cooled with water bath. After hydrolysis, the reaction mixture was extracted with ether. The organic layer was dried over anhydrous sodium sulfate.

*Reaction of **1a** with Acetophenone.* A typical example for the reactions of **1a** with carbonyl compounds was described. A solution of **1a** (0.527 mmol) in HMPA/THF was added to acetophenone (2.11 mmol) dissolved in THF (1.0 cm^3) and stirred for 30 min. The reaction vessel was cooled with water bath. After hydrolysis, the reaction mixture was extracted with ether. The organic layer was dried over anhydrous sodium sulfate.

Reaction of KH with p-Bromotoluene. A typical example for the reactions of KH with organic halides was described. KH(1.0 g, 24.9 mmol) was placed in the reaction vessel containing anhydrous HMPA (8.0 cm^3) and THF (16.0 cm^3) under argon. To this solution, *p*-bromotoluene (1.7 g, 10.0 mmol) was added and stirred for 30 min. The reaction vessel was cooled with water bath. After hydrolysis, the reaction mixture was extracted with ether. The organic layer was dried over anhydrous sodium sulfate.

Reaction of KH with Acetone. A typical example for the reactions of KH with carbonyl compounds was described. KH (1.0 g, 24.9 mmol) was placed in the reaction vessel containing anhydrous HMPA (8 cm^3) and THF (16 cm^3) under argon. To this solution, acetone (5.8 g, 0.10 mol) was added and stirred for 30 min. The reaction vessel was cooled with water bath. After hydrolysis, the organic layer was dried over anhydrous sodium sulfate.

The authors are grateful to Professor Hideki Sakurai and Dr. Mitsuo Kira of Tohoku University for elementary analysis and GC-Mass measurements. We also thank Mr. Takeyoshi Kondo of Tohoku University for ^{13}C NMR measurements.

Synthesis Utilizing Reducing Ability of Carbon Monoxide. New Methods for Synthesis of *N*-Substituted Selenoamides

Akiya OGAWA, Jun-ichi MIYAKE, Nobuaki KAMBE, Shinji MURAI, and Noboru SONODA*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received November 12, 1984)

Convenient one-pot syntheses of *N*-substituted selenoamides (**2**) from nitriles, metallic selenium, carbon monoxide, water, and amines have been developed on the basis of an amino-group-exchange reaction of *in situ* formed *N*-unsubstituted selenoamides (**1**) with primary or secondary amines. The reactions consist of two processes, *i.e.*, the formation of selenoamides **1** by the reaction of nitriles and H_2Se formed from selenium, carbon monoxide and water, and the subsequent amino-group-exchange reaction of **1** with aliphatic amines. The obtained **2** are generally stable enough to be kept for several weeks under the atmosphere of nitrogen at 0 °C without any appreciable degradation. In the cases of primary amines, the corresponding selenoamides were also obtained from nitriles, selenium, carbon monoxide, and primary amines by a single-step mixing at the beginning of the reaction.

The development of new synthetic reactions using carbon monoxide has been the subject of continuing interest.[1] One of the fascinating applications of carbon monoxide to organic synthesis is as reducing agent.[2] Recently, we reported that elemental selenium is readily reduced to hydrogen selenide by carbon monoxide and water under mild conditions,[3] and that a variety of *N*-unsubstituted selenoamides (**1**) can be synthesized in high yields from the corresponding nitriles by use of this reaction system (Eq. 1).[4]

$$RCN + Se + CO + H_2O \xrightarrow{base} \underset{\mathbf{1}}{R\text{-}\overset{\overset{Se}{\|}}{C}\text{-}NH_2} + CO_2 \qquad (1)$$

Selenoamides are not only useful for the synthesis of selenium–nitrogen heterocycles such as 1,3-selenazoles,[5] but also synthetically promising because they can be expected to react with various organic or inorganic reagents owing to the high reactivity of their carbon–selenium double bond. But the development of their chemistry has been greatly restricted by the lack of general procedures for the formation of selenoamides. The hitherto known procedures for synthesis of *N*-substituted selenoamides (**2**) were limited to the following three methods: (i) The reaction of amides with phosphorus selenide,[6] (ii) the substitution reaction of selenoesters with amines,[7] and (iii) the addition of secondary amines to alkyneselenols.[8] However, these methods are not general, and in some cases the yields are very low.

Now we wish to describe new efficient methods for the synthesis of selenoamides **2**, which were developed by the modification of the reaction system of Eq. 1.

Results and Discussion

Our strategy for the synthesis of **2** is the amino-group-exchange reaction of **1** formed *in situ* from the reaction of Eq. 1 with primary or secondary amines (Eq. 2).

$$RCN + Se + CO + H_2O \xrightarrow[-CO_2]{base} [\mathbf{1}] \xrightarrow[-NH_3]{R^1NH_2} \underset{\mathbf{2}}{R\text{-}\overset{\overset{Se}{\|}}{C}\text{-}NHR^1} \qquad (2)$$

The reaction of benzonitrile with selenium, carbon monoxide, and water in the presence of triethylamine in THF at 100 °C for 5 h, followed by treatment of the resulting mixture with butylamine at 100 °C for 3 h successfully afforded *N*-butylbenzenecarboselenoamide (**2b**) (81%) [Method A].

The representative results are shown in Table 1. The reaction appears general with respect to the substituents of selenoamides: Both aromatic and aliphatic, and both *N*-mono- and *N*,*N*-disubstituted selenoamides were all easily synthesized in moderate to high yields. But the yields of aromatic selenoamides (**2a—2g**) differed depending on the bulkiness of the alkyl groups of amines (R=primary alkyl group: >80%; secondary: 30—50%; tertiary: 0%). In the cases of *N*-(*s*-alkyl) derivatives (**2a**, **2c**, and **2f**), better yields were obtained when the amino-group-exchange reaction was conducted for a longer reaction time (20h). On the other hand, the amino-group-exchange reaction with aromatic amines did not take place under these reaction conditions.

Structural assignments of selenoamides were based on spectral analyses (IR, ^{1}H-NMR, and Mass spectrum: see Table 1) and elemental analyses after purification of the products by column chromatography on silica gel.

N-Substituted selenoamides are yellow crystalline or red oil, and are generally stable enough to be kept for several weeks under an atmosphere of nitrogen at about 0 °C without degradation. Upon exposure to air, however, they gradually decomposed along with the deposition of elemental selenium.

In addition to Method A, a more facile procedure (Method B) became available for the preparation of

Table 1. Synthesis of *N*-substituted Selenoamides[a)]

a) All reactions were performed on 5 mmol scale according to the procedures described in the text. b) Isolated yield. c) The yields in the parentheses refer to that obtained by the reaction conducted for prolonged reaction periods in the amino-group-exchange reaction (20 h).

N-monosubstituted selenoamides (Eq. 3). For example, *N*-benzylbenzenecarboselenoamide (**2e**) was obtained in 94% yield by heating the mixture of benzonitrile, selenium, and benzylamine under CO pressure in THF.

$$RCN + Se + CO + 3R^1NH_2 \longrightarrow \mathbf{2} + (R^1NH)_2C{=}O + NH_3 \quad (3)$$

As shown in Eq. 3, Method B affords the corresponding urea derivative as a by-product concomitantly, which is easily separable from **2**. A suggested reaction path is illustrated in Eq. 4.

$$2R^1NH_2 + Se + CO \xrightarrow[-(R^1NH)_2C{=}O]{} H_2Se \xrightarrow{RCN} \mathbf{1} \xrightarrow[-NH_3]{R^1NH_2} \mathbf{2} \quad (4)$$

This method is inapplicable to synthesis of *N,N*-disubstituted selenoamides probably because the reaction of secondary amines with carbon monoxide and selenium does not give hydrogen selenide but the ammonium salts of selenocarbamic *Se*-acids.[9)]

In summary, general and convenient methods for the synthesis of selenoamides using carbon monoxide and selenium have been developed. The present

methods offer several advantages against hitherto known methods: (i) A wide range of applicability to a variety of selenoamides (aromatic and aliphatic; *N*-monosubstituted, and *N,N*-disubstituted); (ii) satisfactory yields of a variety of selenoamides; (iii) one-pot syntheses with simple operations without troublesome handling of hydrogen selenide.

Experimental

General. The instruments used were as follows: Melting points, Yanagimoto micro melting point apparatus; ^{1}H-NMR, Hitachi R-24B; IR, Shimadzu IR-400; MS, Hitachi RMU-6A.

All reactions were carried out using a 50-mL stainless-steel autoclave (SUS-304) purchased from Taiatsu Scientific Glass Co., Ltd.

Metallic selenium (99.99%) from Nakarai Chem. Co., Ltd. and carbon monoxide (99.99%) from Neriki Gas Co. Ltd. were used as purchased. Nitriles (benzonitrile, butyronitrile, acetonitrile, and phenylacetonitrile), amines (isopropylamine, butylamine, *s*-butylamine, *t*-butylamine, benzylamine, cyclohexylamine, octylamine, dimethylamine, piperidine, and triethylamine), and solvent (tetrahydrofuran) were all purchased from commercial sources, and purified by distillation or recrystallization. CO pressures mentioned in the paper refer to those at 25 °C.

General Experimental Procedure for Synthesis of 2 (Method A). In an autoclave were placed benzonitrile (0.52 g, 5 mmol), selenium (0.43 g, 5.5 mmol), water (1 mL, 56 mmol), triethylamine (1 mL), THF (5 mL), and a magnetic stirring bar. The autoclave was flushed with carbon monoxide three times, charged at 5 kg/cm^2, and set in an oil bath maintained at 100 °C. The reaction was carried out for 5 h with magnetic stirring. Then the autoclave was cooled to room temperature, and the carbon monoxide was purged in a well-ventilated hood. Butylamine (1.0 mL, 10 mmol) was immediately added to the reaction mixture under an atmosphere of nitrogen, and the reaction was continued at 100 °C for 3 h under nitrogen. After the reaction was complete, the resulting mixture was transferred to a 100 mL flask, dried overnight ($MgSO_4$), and then filtered. Evaporation of the filtrate, followed by purification by the column chromatography on silica gel (hexane–Et_2O) gave 0.97 g (4.0 mmol, 81%) of **2b**: Found: C, 55.39; H, 6.58; N, 5.85. Calcd for $C_{11}H_{15}NSe$: C, 55.00; H, 6.29; N, 5.83.

Similarly prepared were the followings.

2g: Found: C, 60.97; H, 8.05; N, 4.87. Calcd for $C_{15}H_{23}NSe$: C, 60.80; H, 7.82; N, 4.73.

2h: Found: C, 50.98; H, 5.34; N, 6.57. Calcd for $C_9H_{11}NSe$: C, 50.95; H, 5.23; N, 6.60.

2i: Found: C, 57.21; H, 6.08; N, 5.50. Calcd for $C_{12}H_{15}NSe$: C, 57.15; H, 5.99; N, 5.55.

2j: Found: C, 47.09; H, 8.71; N, 6.81. Calcd for $C_8H_{17}NSe$: C, 46.60; H, 8.31; N, 6.79.

2k: Found: C, 55.13; H, 6.34; N, 5.72. Calcd for $C_{11}H_{15}NSe$: C, 55.00; H, 6.29; N, 5.83.

2l: Found: C, 51.18; H, 5.18; N, 6.55. Calcd for $C_9H_{11}NSe$: C, 50.95; H, 5.23; N, 6.60.

2m: Found: C, 62.60; H, 5.24; N, 4.82. Calcd for $C_{15}H_{15}NSe$: C, 62.50; H, 5.25; N, 4.86.

(Method B). Benzonitrile (0.52 g, 5 mmol), selenium (0.43 g, 5.5 mmol), butylamine (2.0 mL, 20 mmol), and THF (5 mL) were placed in an autoclave with a magnetic stirring bar. The reaction was carried out under the pressure of CO (5 kg/cm^2) at 80 °C for 5 h in a similar manner to that described in Method A. After the reaction was complete, the autoclave was cooled to room temperature and the carbon monoxide was purged. The reaction mixture was trasferred to a 100 mL flask and left overnight under the atmosphere of air in order to decompose benzenecarboselenoamide (**1**) and the remaining hydrogen selenide. The depositing metallic selenium was filtered off, and the solvent was removed from the filtrate under reduced pressure. The resulting residue was chromatographed on silica gel to give 1.12 g (4.7 mmol, 93%) of **2b** and 0.86 g (5.0 mmol) of *N,N'*-dibutylurea.

This work was supported in part by a Grant-in-Aid for Scientific Research No. 57470061 from the Ministry of Education, Science, and Culture of Japan.

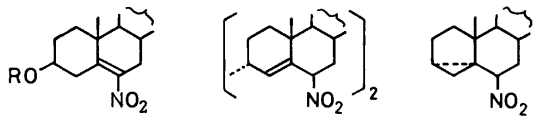
Stereochemical Control in Electron-transfer Induced Reactions. Cyclic Voltammetry and Cathodic Reduction of Epimeric 3-Halogeno-6-nitro-5-cholestenes[1)]

Takeo SATO,* Takahiro WADA, Yoshihisa KOMEICHI, and Masatsune KAINOSHO
Department of Chemistry, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158
(Received November 21, 1984)

The cathodic electrolyses and cyclic voltammetric measurements were carried out for epimeric 3-halogeno-6-nitro-5-cholestenes. The stability and the fate of anion radicals were found to be highly dependent on the stereochemistry of homoallylic halogen groups. Half-lives of the anion radical from 3α-chloro- and 3α-bromo derivatives were found to be 12.5 and 1.6 s, respectively, while those of 3β-halogeno derivatives were much shorter. On cathodic reduction 3β-derivatives gave a cyclosteroid, 6β-nitro-3α,5α-cyclo-5α-cholestane in a two-electron process, whereas 3α-derivatives gave a dimer, 6β,6′β-dinitro-3α,3′α-cholesta-4,4′-diene, as the major product *via* a one-electron process. Detailed CV studies were carried out for 6-nitro-5-cholestene as a model. The stereochemistry of 3,3′-dimer was established by the ^{1}H NMR measurements.

In a previous paper of this series[2)] we have shown that the cathodic reduction of nitro olefinic esters **1** in *N,N*-dimethylformamide (DMF) gives two types of products, namely, a 3,3′-dimer, 6β,6′β-dinitro-3α,3′α-cholesta-4,4′-diene (**2**), and a cyclosteroid, 6β-nitro-3α,5α-cyclo-5α-cholestane (**3**), depending on a leaving-group ability of an equatorial ester group at C-3. For example, tosylate **1a** gave **3** as the major product while acetate **1b** gave only the dimer **2**. Trifluoroacetate **1c** showed an intermediate behavior and gave equimolar amounts of **2** and **3**. In these reactions a nitro olefinic moiety served as an electron inlet and no reduction of the nitro group itself occurred.



R
1a p-Ts
1b CH_3CO
1c CF_3CO

2 3

Recently, Yates and coworker[3)] reported that the reaction of **1b** with lithium dimethylcuprate(I) in ether gave 3α,5α-cyclooxime but no dimeric product. The reaction was assumed to occur *via* a one-electron reduction mechanism.

We have shown[1,2)] that the cyclic voltammogram (CV) is highly dependent on the C-3 ester groups. Indeed the CV method has been shown to be used effectively to predict the reaction course which was dependent on the stability of an initially-formed anion radicals.

In this paper we describe further substituent effects on the CV behavior and cathodic reactions using epimeric 3α- and 3β-halogeno-6-nitro-5-cholestenes (**4a**), (**4b**), (**5a**), and (**5b**). We also describe the stereochemistry of dimer **2** studied by using proton NMR.

Preparation. 3β-Chloro- and 3β-bromo-6-nitro-5-cholestenes (**4a**) and (**4b**) were prepared from

4a X=Cl
4b X=Br

5a X=Cl
5b X=Br

cholesterol by halogenation followed by nitration according to the literature.[4a,b)] We found 3α derivatives **5a** and **5b** could be prepared simply by reversing the reaction order. Namely, **5a** and **5b** were obtained by the halogenation of 6-nitrocholesterol with phosphorus pentachloride or phosphorus tribromide which gave the corresponding halogeno products with inversion of stereochemistry at C-3 in 38 and 20% yields respectively. Low yields were outweighed by shorter reaction steps. The conventional route for 3α derivatives required lengthy steps involving halogenation with inversion at C-3 of 3β-hydroxy-5α-cholestan-6-one followed by lithium aluminum hydride reduction, dehydration, and nitration.

The stereochemistry of substitution at C-3 has been known to be controlled by the π electron density at C-5.[4c)] In the present case, low-electron density at C-5 in nitro-olefinic group directed the reaction course toward inversion which was common both for halogenation of cholestanol[4c)] and also for acetoxylation of 3-chlorocholest-5-en-7-one.[5)]

Cyclic Voltammetry. The CV measurements were carried out in DMF containing 0.1 mol dm^{-3} of tetrabutylammonium perchlorate (TBAP) for solutions with concn 10^{-3}—10^{-4} mol dm^{-3}. For a reversible wave $E=E_{pc}-(E_{pc}-E_{pa})/2$ was calculated. When no anodic peak was recorded E was approximated by the potential at which $i=0.85\ i_{pc}$.[6)] The results are summarized in Tables 1 and 2. Table 1 shows data for compound **6** in detail together with those for **1a**, **1b**, and **1c** for comparison purpose.[2)] Table 2 summarizes the data for **4a**, **4b**, **5a**, and **5b**. With compounds **6**, **4b**, and **5b** a series of measurements

a) The measurements were carried out similarly as those in Table 1. b) The potential at which $i=0.85\ i_{pc}$ is shown. c) The concentration of solution, 6.7×10^{-4} mol dm^{-3}.

were conducted using a single solution and the peak current data are tabulated together with the other parameters.

In order to examine the effect of C-3 substituents and its stereochemistry on the electron-transfer process we first investigated the CV of 6-nitro-5-cholestene (**6**) in detail as the model (Table 1, Figs. 1 and 2).

Compound **6** showed a reversible wave for varied scan rates indicating reversible electron-transfer between **6** and its anion radical **7**. The CV curves for 50 and 250 mV s^{-1} are shown in Fig. 1. The cathodic potential E was found to be −1.5 V. The anion radical is fairly stable and assumed to be composed of a resonance hybrid between **8** and **9**. At lower scan rates the current ratio i_{pa}/i_{pc} became almost unity. The peak potential difference, $E_{pa}-E_{pc}$, was 70 mV at the scan rate of 5 mV s^{-1}, the value of which was close to 56 mV required for an ideal one-electron transfer process.[6]

When higher scan rates were used, however, the peak potential difference showed a steady increase, reflecting limited electron-transfer rate. At the scan rate of 7V s^{-1} recorded using a wave-memory technique, the peak potential difference reached 840 mV, while the peak current ratio decreased to 0.65.

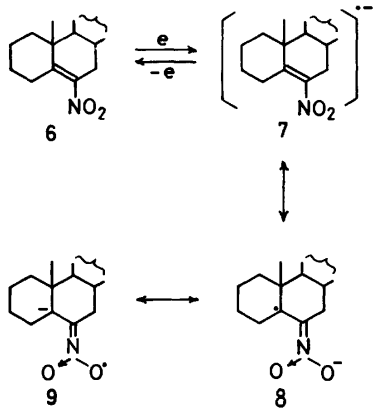

Figure 2 shows the dependence of the cathodic current i_{pc} on the square root of the scan rate. A good linear relation was obtained as expected from the Randles-Sevcik equation,[6]

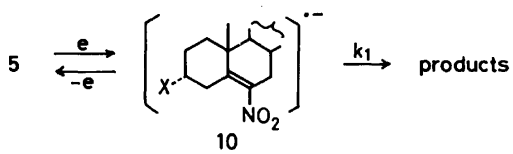
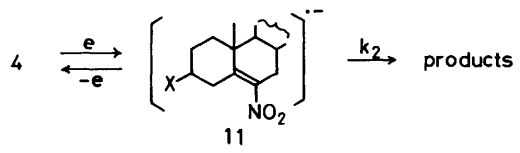
$$i_p = 2.687\times10^5 n^{3/2} A D^{1/2} C v^{1/2}$$

The effect of a homoallylic substituent at C-3 was then investigated using substrates **4** and **5** (Table 2, Fig. 1). The CV curves for 3-axial halogeno derivatives **5a** and **5b** recorded in two speeds, 50 and 250 mV s^{-1}, are shown in Fig. 1. 3-Axial chloro derivative **5a** showed a reversible wave for both scan rates. The corresponding bromo derivative **5b**, however, showed no anodic peak at the scan rate of 50 mV s^{-1} but it appeared as a small peak at −1.42 V on increasing the scan rate fivefold indicating the presence of coupled chemical reactions. Reversibility was increased markedly by employing higher scan rates. The plot between i_{pc} and $v^{1/2}$ for 3α-bromo derivative **5b** results in a nonlinear correlation unlike the case of compound **6** (Fig. 2).

In 3α-derivatives a reversible electron-transfer process is assumed to be coupled with chemical reactions with the rate of k_1. The CV behavior indicated that k_1 was larger for bromo derivative than for chloro derivative. These results indicate the anion radical formed from **5a** and **5b** have a limited stability.



For 3β-chloro and 3β-bromo derivatives, **4a** and **4b**, no anodic peak was recorded even when high speed CV determination was carried out. This indicates a higher reactivity of the 3β-halogeno anion radical **11** compared with the 3α-halogeno anion radical **10** ($k_2 > k_1$). The CV behavior of **4** resembles to that of 3β-tosylate **1a**.[2] Figure 1 shows voltammograms at two speeds of **4b**. Compound **4a** also showed similar voltammograms.



Whereas halogeno substituents at C-3 and its stereochemistry were found to affect the voltammograms in various ways, the cathodic potentials for these compounds were found to fall within a narrow range of −1.4—−1.5 V.

Half lives for these anion radical can be estimated by using the House method.[7] One assumes a simple EC reaction composed of a reversible electron transfer coupled with an irreversible chemical reaction. By carrying out the CV determination at various speeds one can obtain a voltammogram with i_{pa} just half of i_{pc}. The half-life of an anion radical can be regarded as the elapsed time between the cathodic peak and the anodic peak on potential reversal.

Compound **6** showed a good reversible wave throughout the scan ranges used even when a very slow sweep rate was employed. By contrast, equatorial halogeno derivatives **4a** and **4b** showed no anodic peak even when higher scan rates were employed, the situation is similar to tosylate **1a**, indicative of short life of the corresponding anion radicals. Axial isomers **5a** and **5b** showed an intermediate behavior and half-lives for anion radicals **10** were estimated to be 12.5 s for chloro derivative **5a** and 1.6 s for bromo derivative **5b**. Thus the stability of the anion radicals from the following compounds decreases in the order;

6>5a>5b>4a, 4b, 1a

Cathodic Reaction. The cathodic reduction was carried out in DMF containing 0.1 mol dm^{-3} of tetrabutylammonium perchlorate (TBAP) as a supporting electrolyte using a divided cell under nitrogen. Constant current conditions (0.45 mA cm^{-2}) were employed to compare with the results for esters **1** which were electrolyzed similarly. The results are summarized in Table 3.

When 1 F mol^{-1} of electricity had been consumed the reaction was stopped: Both equatorial compounds **4a** and **4b** gave cyclosteroid **3** in 40 and 43% yields, respectively. On further electrolysis **4a** gave 61% yield of **3** when 1.8 F mol^{-1} of electricity was passed. The yield of **3** from **4b** reached 70% when 1.9 F mol^{-1} was consumed. Apparently the reaction proceeds in a two-electron scheme involving an anion radical **12** to give **13** followed by further electron transfer and protonation as proposed before.[2]

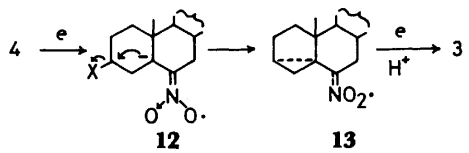


TABLE 3. CONTROLLED-CURRENT ELECTROLYSES OF NITRO ESTERS **4a**,**4b**,**5a**, AND **5b**[a)]

Compound	Concn/mmol dm^{-3}	Electricity / F mol^{-1}	Yield/%		Recovery/%
			2	**3**	
4a	22.2	1.0	5	40	45
	22.2	1.8	8	61	0
	25.6[b)]	1.3	4	52	0
4b	20.2	1.0	Trace	43	49
	20.2	1.9	Trace	70	Trace
5a	20.0	1.0	37	0	0
5b	20.2	1.0	35	0	0

a) The electrolysis reactions were carried out at constant-current conditions in DMF–TBAP (0.1 mol dm^{-3}) using platinum electrodes. SCE was used as a reference. Current density was 0.45 mA cm^{-2} except for b) for which 0.85 mA cm^{-2} was used.

Similarly, axial isomers **5a** and **5b** were electrolyzed cathodically under conditions shown in Table 3. These gave dimer **2** in 37 and 35% yields, respectively possibly *via* a radical species as depicted in a previous paper.[2)]

Epimeric compounds were found to behave differently and the two competing reactions leading to **2** and **3** were dependent not only on the leaving group ability but also on the stereochemistry. The equatorial chloro and bromo derivatives behaved similarly to tosylate **1a** indicating the importance of leaving group ability on cyclosteroid formation. By contrast, the axial halogeno derivatives underwent dimerization reaction typical to acetate **1b**. The results can be rationalized by assuming that a favorite geometry for concerted elimination to form the cyclosteroid is possible only for an equatorial leaving group as in **12**.

The CV results again were found to be instructive: Those with reversible wave tend to give the dimer whereas those with irreversible wave the cyclosteroid. In other words those compounds forming short-lived anion radicals such as tosylate **1a** and equatorial halogeno derivatives **4a** and **4b** were lost rapidly in an intramolecular cyclosteroid formation, whereas those with long-lived anion radicals such as acetate **1b**, **5a**, and **5b** underwent an intermolecular coupling.

The Stereochemistry of 6β,6′β-Dinitro-3α,3′α-cholesta-4,4′-diene (2). Although the orientation of the 6-nitro group in compound **2** was established to be axial based on the NMR evidence the stereochemistry of ring junction between C-3 and C-3′ has remained unsettled.[2)]

There are several reports on the formation of dimeric steroids. Fried and Abraham[8)] reported the formation of a pinacol by the modified Birch reduction of estrone methyl ether. The stereochmistry at the ring juncture was deduced to be 3α,3′α by comparing the NMR spectra with those of monomeric compounds. Other examples of reductive coupling in steroidal ketones include dehydroepiandrosterone[9)] and some α,β-unsaturated ketones.[10)]

TABLE 4. THE 360 MHz ^{1}H NMR SPECTRAL DATA FOR DIMER **2**

Proton	Chemical shift/δ	Coupling constant/Hz	
C-2H$_{eq}$	2.020		
		$J_{2a,3e}$	3
C-3H$_{eq}$	2.175		
		$J_{3e,4}$	3
C-4H	5.905		
C-6H$_{eq}$	4.678		
		$J_{6e,7a}$	5.3
C-7H$_{eq}$	2.635		

Grignard reaction of 3-chlorocholestane[11)] or 3-chloro-5-cholestene[12)] produced a dimeric product, which was structually closely related to our dimer **2**, in a low yield but the configuration at C-3 and C-3′ remained unsettled.

The cathodic reaction of nitro olefin **1b** produced[2)] dimer **2** in a 54% yield, which separated out from the solution during the electrolysis. The examination of crude material by using NMR spectroscopy revealed that the material was a single compound although three stereoisomers, 3α,3′α-, 3α,3′β-, and 3β,3′β-types, were possible.

The proton NMR spectra of **2** were determined in $CDCl_3$ at the frequency of 360 MHz where nearly all proton signals in rings A and B were observed as separate signals. Five one-proton signals, C-2, 3, 4, 6, and 7H, were assigned by the first order analysis as shown in Table 4. The absorption due to C-3H appeared as a narrow peak at δ 2.175. The expanded spectrum clearly showed that it consisted of a double-doublet with J=3 Hz. The configuration of C-3H was deduced to be equatorial since $J_{2a,3e}=J^3_{e,4}=3$ Hz. Accordingly the stereochemistry of bonding between C-3 and C-3′ was established as α,α′-type.

Experimental

3β-Halogeno-6-nitro-5-cholestene (4a and 4b). 3β-Chloro-6-nitro-5-cholestene (**4a**) was prepared by the

nitration of 3β-chloro-5-cholestene,[4a] recrystallized from acetone, colorless needles, mp 153.5—154.5 °C. Similarly, 3β-bromo-6-nitro-5-cholestene (**4b**) was prepared,[4b] colorless needles from acetone, mp 158—159 °C.

3α-Chloro-6-nitro-5-cholestene (5a). To a stirred chloroform suspension (750 cm^3) containing 6-nitrocholestrol (20 g, 46 mmol) and barium carbonate (40 g), phosphorus pentachloride (37 g, 0.18 mol) was added under cooling in an ice bath. After 1.5 h stirring, water (400 cm^3) was added and the chloroform layer was washed with water, aq sodium carbonate, and water. Evaporation of chloroform, after being dried over calcium chloride, gave a solid which was purified by passing through a silica-gel column using hexane-benzene (4:1) as an eluent. Recrystallization from acetone gave **5a** (7.9 g, 38% yield) as colorless plates, mp 163—164 °C; IR (nujol) 1660 (C=C) and 1515 cm^{-1} (conj NO_2); ^1H NMR ($CDCl_3$) δ=0.72 (3H, s, C-18H), 1.15 (3H, s, C-19H), and 4.51 (1H, m, $w_{1/2}$=8.0 Hz, C-3H_{eq}).

Found: C, 72.13; H, 9.83; N, 3.20%. Calcd for $C_{27}H_{44}NO_2Cl$: C, 72.05; H, 9.85; N, 3.11%.

3α-Bromo-6-nitro-5-cholestene (5b). To a refluxing benzene solution (70 cm^3) of 6-nitrocholesterol (25 g, 58 mmol) was added phosphorus tribromide (7.5 cm^3, 79 mmol) in benzene (10 cm^3). After 2 h refluxing benzene was removed by evaporation and the residue was taken up in ether. The ethereal layer was washed with aq sodium hydroxide and water, and dried over magnesium sulfate. The product was purified by passing through a silica-gel column using hexane-benzene (2:1) as an eluent to give **5b** (5.7 g, 20%) after recrystallization from acetone, mp 154—155 °C; IR (nujol) 1660 (C=C) and 1515 cm^{-1} (conj NO_2); ^1H NMR ($CDCl_3$) δ=0.72 (3H, s, C-18H), 1.14 (3H, s, C-19H), and 4.65 (1H, m, $w_{1/2}$=8.0 Hz, C-3H_{eq})

Found: C, 65.53; H, 8.83; N, 2.85%. Calcd for $C_{27}H_{44}NO_2Br$: C, 65.57; H, 8.97; N, 2.83%.

Electrolyses. The controlled current electrolysis, using either 0.45 mA/cm^2 or 0.85 mA/cm^2, was carried out for **4a**, **4b**, **5a**, and **5b**. A Hokuto potentiostat/galvanostat HA-101 apparatus with max. output 30 V (1 A) was used. The cylindrical cell used previously[2] was equipped with a side arm for connecting the reference electrode, SCE, with the aid of two junction bridges, filled with satd KCl and DMF-TBAP (0.1 mol dm^{-3}) solutions. A ceramic thimble was used as a divider and was placed over a glass spacer to allow efficient stirring by a magnetic stirrer. A punched platinum electrode with an area of 118 cm^2 was used as the cathode together with a platinum wire anode placed in the above thimble. Representative examples are summarised in Table 3.

As an example the cathodic reduction of 3β-chloro-6-nitro-5-cholestene (**4a**) is described.

a) Electricity; 1 F mol^{-1}. After passing purified nitrogen for 20 m, a solution of **4a** (0.5 g, 1.1 mmol) in DMF (50 cm^3) containing 0.1 mol dm^{-3} of TBAP was electrolyzed at the current density of 0.42 mA cm^{-2} until 1 F mol^{-1} of electricity was consumed. DMF was evaporated *in vacuo* and the residue was extracted with ether. When the etherial solution was washed with water a part of TBAP was separated out, which was filtered off. The ethereal solution was washed with water again and dried. The ether extract contained **4a** (R_f=0.38) and a cyclosteroid **3** (R_f=0.35) together with dimer **6** as a slow moving fraction on examination by TLC. The mixture **4a** and **3** was separated on a Merck Lobar column using hexane-benzene (4:1) as an eluent. Recovery of **4a** was 45% while compounds **2**[2] and **3**[2] were obtained in 5 and 40% yields respectively.

b) Electricity; 1.8 F mol^{-1}. When the electrolysis was further continued, the voltage between the working and the reference electrodes was raised steadily. The electrolysis was switched to a controlled potential mode when the voltage reached −1.55 V. Current stopped essentially when 1.8F mol^{-1} of electricity had been consumed. The reaction mixture contained **2** (8%) and **3** (61%), no starting material being left.

Cyclic Voltammetry. The cyclic voltammetry measurements were carried out using the combination of a function generator, Hokuto HB-107A, and a potantiostat, Hokuto HA-101. For high-speed record, the output was stored in a wave-memory device, NF Circuit Block WM-812A. A modified H-type cell, separated by a sintered glass divider, is equipped with two side arms for connecting a nitrogen bubbler and a reference electrode, SCE, which is connected using two junction bridges filled with KCl and DMF-TBAP solutions. Molecular sieve 1A (Wako chemicals) was added to the bridge directly immersed in the cell to avoid contamination by water. Results are summarized in Tables 1 and 2. Representative CV curves are shown in Figure 1.

NMR Spectra. The ^1H NMR spectra were recorded with a Bruker WM-360 spectrometer.

We thank Professor Y. Kyogoku, The Protein Research Institute of Osaka University, for the NMR measurements.

Amide Ion Formation and *N*-Alkylation of Aminoanthraquinones in the Presence of Potassium Hydroxide in Dimethyl Sulfoxide[1)]

Sadao Arai, Seijiro Kato, and Mitsuhiko Hida*
Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Recieved November 21, 1984)

Amide ions were formed by the deprotonation of the amino group of amino- and (monoalkylamino)-anthraquinones in the presence of powdered potassium hydroxide in dimethyl sulfoxide (DMSO). Under a nitrogen atmosphere these amide ions changed to their radical anions. The amide ions of 1-amino-anthraquinones reacted with excess alkyl halides to yield 1-alkylaminoanthraquinones, while the *N*-alkylation of 2-aminoanthraquinones afforded 2-dialkylaminoanthraquinones in good yields. 2-Aminobenzophenone underwent mono-*N*-alkylation, while 4-aminoazobenzene and p-nitroaniline underwent di-*N*-alkylation. It was also found that the carbanion of DMSO easily attacked the carbonyl group of the (dialkylamino)-anthraquinones.

During the course of our studies on the photonucleophilic reactions[2)] we examined a reaction between an hydroxide ion and aminoanthraquinones. We found that the color of the aminoanthraquinones rapidly changed from red or orange to green upon being mixed with powdered potassium hydroxide (KOH) in dipolar aprotic solvents such as dimethyl sulfoxide (DMSO), *N*,*N*-dimethylformamide (DMF), and pyridine. The color changes of aminoanthraquinones caused by the action of alkali hydroxide have attracted attention for a long time in relation to the mechanism of indanthrone formation by the fusion of 2-aminoanthraquinone with KOH.[3-5)] However, no decisive evidence regarding the mechanism of the color reactions has been presented, and the behavior of aminoanthraquinones in an alkaline media still remains obscure.

In this paper we describe in detail the behavior of aminoanthraquinones in an KOH–DMSO system under air and nitrogen atmosphere. It also describes how aminoanthraquinones and some aromatic amines having an electron-withdrawing group are easily *N*-alkylated by alkyl halides *via* their amide ions in the presence of powdered KOH in DMSO.

Results and Discussion

The Formation of Amide Ion. When 1-aminoanthraquinone(**1**) was mixed with powdered KOH[6)] in DMSO at room temperature, the solution turned from orange to green. The visible absorption spectra of a **1**–KOH–DMSO system are shown in Fig. 1. Although a green solution also formed in dipolar aprotic solvents such as DMF and pyridine, DMSO was the most effective solvent among them, because of the good solubility of KOH. The color of the solution immediately turned from green to orange, the original color, after the addition of water, and **1** was nearly quantitatively recovered (Table 3, Entry 1). Although Shah reported the formation of indanthrone from **1** and KOH in DMSO at 60 °C[4,5)], no

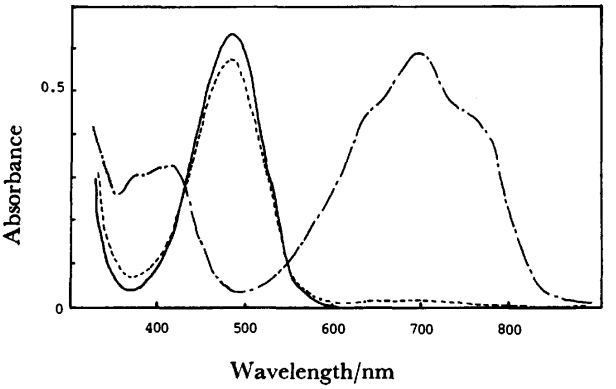

Fig. 1. Absorption spectra of **1** in DMSO.
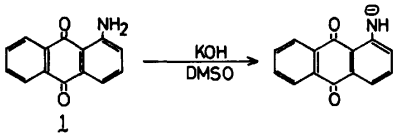
[**1**]=*ca.* 1×10^{-4} mol·dm^{-3}. KOH free (——), in the presence of KOH(– – –), addition of H_2O into KOH–DMSO system(----).

indanthrone was observed in our system. In the green solution no paramagnetic species was detected by an ESR measurement. These results ruled out Brunner and Deffner's proposal[7] that the color change was caused by the formation of a charge-transfer complex between **1** and the carbanion of DMSO ($CH_3SO\overset{\ominus}{C}H_2$). Further, after the addition of alkyl halide to the green solution, it became red and an *N*-alkylated product was obtained in good yield at room temperature (*vide infra*). Consequently, we concluded that the color change of **1** in an KOH-DMSO solution was undoubtedly caused by the loss of a proton from the amino group to afford the amide ion:



(1)

1

Similar results were also obtained in the case of 2-aminoanthraquinone(**5**); that is, the new absorption band appeared in the region of 550—850 nm (Table 1) and disappeared after the addition of water. The resulting green solution also afforded an *N*-alkylated product after the addition of an alkyl halide. Although Bradley reported that **5** exhibited no alkali color reaction in a pyridine containing methanolic KOH,[8] our results indicated that the amino group of **5** was easily deprotonated in an KOH-DMSO solution to give the amide ion.

Monoalkylaminoanthraquinones(**2** and **6**) also gave green solution on being mixed with powdered KOH in DMSO. Although the color returned to the original one after the addition of water, a TLC examination showed both the recovered one and the dealkylated product(**1** or **5**). These results show that the dealkylation occurs under basic conditions, although (monoalkylamino)anthraquinones have been known to give the dealkylated products under acidic conditions.[9]

The color of 1-dimethylaminoanthraquinone(**3**), having no N-H bond, was little affected by the addition of powdered KOH in DMSO. This result also supports the idea that the color changes of aminoanthraquinones were caused by the loss of a proton from the amino group to afford the amide ion.

Table 1. Absorption spectra of aminoanthraquinones in the presence of powdered KOH in DMSO

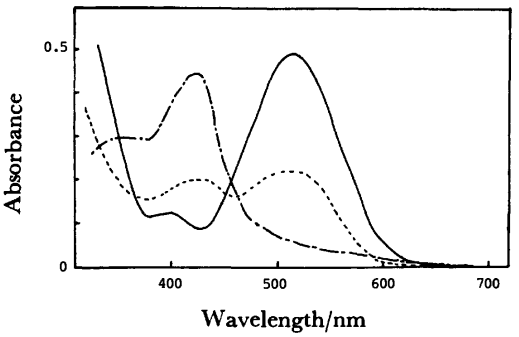

Fig. 2. Absorption spectra of **3** in DMSO. [**3**]=*ca.* 1×10^{-4} mol·dm^{-3}. KOH free(——), in the presence of KOH pretreated with methanol(———), addition of H_2O into KOH-DMSO system(----).

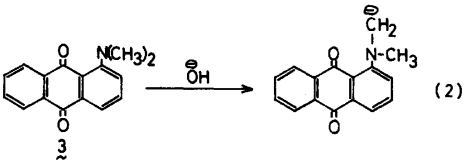
The Reaction of (Dialkylamino)anthraquinones with DMSO. In order to prepare a fine KOH powder, KOH was dissolved in anhydrous methanol and then methanol was evaporated *in vacuo*. When **3** was mixed with the resulting fine, white KOH powder in DMSO, the color immediately changed from red to yellow. Figure 2 shows that the absorption band (510 nm) of **3** disappeared and a new band appeared at 420 nm. The color change was hypsochromic, contrary to the formation of amide ion. Since no radicals were detected in the yellow solution during ESR measurements, the yellow species could not be the radical anion.

After the addition of D_2O to the yellow solution of **3**, the absorption spectra did not return to the original state and a TLC examination indicated two spots, red and yellow. It was found that the mass spectrum of the red component was identical with that of **3** and no deuteration took place. This result showed that the hypsochromic change was not attributed to the formation of the carbanion of aminomethyl group of **3**:

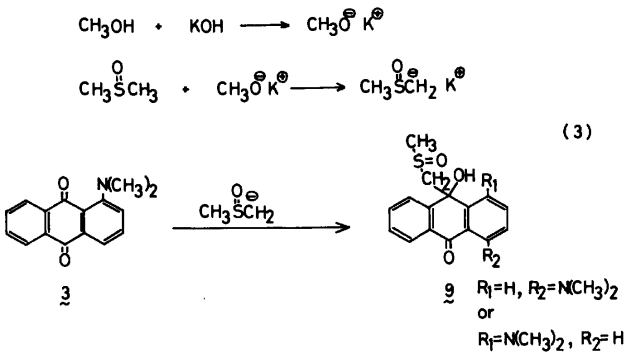


(2)

3

These color changes were not observed in a DMF solution. This result indicated that DMSO was responsible for the hypsochromic changes. The mass spectra[*m/z* 329(M+), 251, 78] clearly indicated that the yellow hygroscopic compound was an 1:1 adduct of **3** and DMSO. Actually, sulfur atoms were detected using the standard method with lead acetate. The IR spectrum showed the appearances of a hydroxyl group (3250 cm^{-1}) and a sulfinyl group (1015 cm^{-1}). ^{1}H NMR analysis also supported the idea that the new yellow compound was a DMSO addition com-

pound(**9**). However, the definitive evidences whether the addition occurred at 9- or 10-carbonyl group of **3** could not be obtained. These results indicated that potassium methylsulfinylmethanide (CH_3SOCH_2K) was formed by the reaction of DMSO with KOH pretreated with methanol (probably potassium methoxide[10]) and reacted with **3** to yield DMSO addition compound(**9**) as shown in Eq. 3.

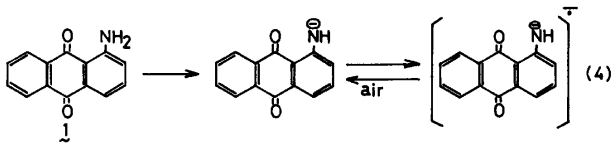


It has been reported that methylsulfinylmethanide, formed by the reaction of DMSO with potassium *t*-butoxide or sodium hydride, reacted quantitatively with benzophenone to yield the β-hydroxy sulfoxide.[11]

A similar hypsochromic change was also observed in the case of (dialkylamino)anthraquinones(**4**, **7**, and **8**)(Table 2). However, the color changes of aminoanthraquinones(**1**, **2**, **5**, and **6**), which were caused by the KOH pretreated with methanol, were the same as those treated with powdered KOH. These results indicate that methylsulfinylmethanide does not attack the amide ions.

The Formation of Radical Species under a Nitrogen Atmosphere. When anthraquinone was mixed with powdered KOH in DMSO under a nitrogen atmosphere, a red solution immediately resulted. The red solution showed a well-resolved ESR spectrum: The hyperfine coupling constants were a_{H_1}=0.94 G(1 G=10^{-4} T) and a_{H_2}=0.29 G. These values almost agreed with those of anthraquinone radical anion generated by electrochemical reduction.[12] These results suggest that aminoanthraquinones may be reduced to the radical anion in KOH–DMSO solution under a nitrogen atmosphere.

Under a N_2 atmosphere the color of **1** rapidly changed from orange to green similar to a system under air when mixed with powdered KOH in DMSO. This green solution, however, slowly turned to violet. The spectral changes are shown in Fig. 3. The violet solution was paramagnetic(g=2.003) and showed well-resolved ESR spectrum (Fig. 4). When air was bubbled through the violet solution, it became green and no radical species were detected. Further the addition of water caused this aerated solution to change from green to orange. These results revealed that the radical species was not a radical anion of **1**, but one of the amide ions:



A radical anion would be formed by an electron transfer from a naked hydroxide ion to the amide ion.

The (monoalkylamino)anthraquinones(**2** and **6**)

changed to the radical anions of their amide ions more rapidly than **1** and **5**. The spectral data are shown in Table 1. The colors of (dialkylamino)anthraquinones(**3**, **4**, **7**, and **8**) did not change in powdered KOH–DMSO system, while those in the presence of KOH pretreated with methanol in DMSO rapidly changed from red to yellow and then to violet. By the introduction of air into violet solution, a yellow solution was reproduced. The radical species would be the radical anion of the yellow DMSO addition compound.

The N-Alkylation of Aminoanthraquinones via their Amide Ions. The amide ions formed in an KOH–DMSO system would be easily *N*-alkylated by alkyl halides. The compound(**1** or **5**) was first converted to its amide ion by treating it with powdered KOH in DMSO under air. Then, excess alkyl halide was added at 30 °C. Table 3 lists the results of *N*-alkylation. In KOH-free systems the yields were negligibly small. However, the yields dramatically increased after the addition of powdered KOH. This result confirmed that the amino group of **1** and **5** was deprotonated in the KOH–DMSO system.

Table 3 shows that **1** was converted to its monoalkylamino derivatives while **5** gave the (dialkylamino)anthraquinones in high yields. The different reactivities between **1** and **5** toward alkyl halides may be explained as follows. 1-Alkylaminoanthraquinone was also deprotonated to give its amide ion, but the attack of alkyl halide to the amide ion may be

 (**12**)	30	 (**23**): 69 +  (**24**): 14
 (**13**)	60	 (**25**): 84
 (**14**)	60	 (**26**): 79
 (**15**)	60	 (**27**): 81

a) Substrate=1 mmol, *n*-C_4H_9I=10 mmol, KOH=10 mmol, DMSO=30 ml, at 30 °C. b) Several unidentified products were obtained.

sterically hindered by the adjacent carbonyl group. On the other hand, the alkylation of the amide ion of **5** is insensitive to such a steric factor. Consequently, **5** was easily converted into its dialkylamino derivatives, while the *N*-alkylation of **1** stopped at the stage of monoalkylation. When the reaction of **5** with butyl iodide was quenched with water after 5 min, 2-butylaminoanthraquinone was also obtained together with 2-dibutylaminoanthraquinone (Table 3, Entry 9). Table 3 also shows that the yield of *N*-alkylation of **1** decreased with the increase of the reaction time, contrary to the reaction of **5**.

The *N*-alkylation of diaminoanthraquinones also took place under similar conditions. 1,4-Diaminoanthraquinone(**10**) changed from violet to marine blue, 1,5-diaminoanthraquinone(**11**) from red to cobalt blue, and 2,6-diaminoanthraquinone(**12**) from orange to dark green in KOH–DMSO solution. By the addition of butyl iodide, **11** and **12** were easily *N*-alkylated, but in the reaction of **10** several unidentified products were formed. Table 4 shows that 1-amino group suffered monoalkylation and 2-amino group suffered dialkylation in analogy with monoaminoanthraquinone(**1** and **5**).

N-Alkylation of Aromatic Amines with Electron-withdrawing Group. The *N*-alkylation of aromatic amines activated by the electron-withdrawing group would also be expected by using an KOH–DMSO system. The color of 2-aminobenzophenone(**13**) was changed from yellow to red, *p*-aminoazobenzene(**14**) from orange to deep red, and *p*-nitroaniline(**15**) from yellow to orange when treated with powdered KOH in DMSO. The results of *N*-alkylation of these amines are shown in Table 4. Table 4 shows the very similar results to the case of aminoanthraquinones, that is, **13** underwent mono-*N*-alkylation, while **14** and **15** underwent di-*N*-alkylation.

a) NMR data in CCl_4. b) The NMR spectra could not be measured because of low solubility.

Although the *N*-alkylation of nitrogen heterocyclic compounds and aromatic amines by the use of various bases has been reported,[13] these results indicate that the reaction using an KOH–DMSO system affords a rapid, simple, and mild method of *N*-alkylation of aromatic amines.

Experimental

Materials. Commercial reagent-grade chemicals were used without further purification. Dimethyl sulfoxide was distilled twice under reduced pressure and stored under a nitrogen atmosphere. Aminoanthraquinones (Sumitomo Chemical Co.) were purified as follows: **1** and **2** were purified by alumina column chromatography and recrystallized from benzene. The compounds **10** and **11** were purified by recrystallization from toluene. The purification of **5** and **12** were performed by Maki's method.[14] Compound **3** was prepared by the condensation of 1-chloroanthraquinone and dimethylamine in ethanol and purified by column chromatography on silica gel with benzene as eluent and recrystallized from ethanol (Found: C, 76.53; H, 5.16; N, 5.50%). The Preparation of **4** and **8** were performed by the reaction of 1- and 2-chloroanthraquinone with piperidine and purified by column chromatography on silica gel and recrystallized from ethanol (Found: **4**; C, 78.24; H, 5.88; N, 4.86%. **8**; C, 78.13; H, 5.71; N, 4.63%). The compound **13** was prepared according to the literature[15].

Instruments. Visible spectra were recorded with a Shimadzu UV-210 spectrometer. ^{1}H NMR spectra were measured with a Hitachi R-24 spectrometer in $CDCl_3$ and CCl_4 with tetramethylsilane and in D_2O with sodium 3-trimethylsilyl-1-propanesulfonate as an internal standard. IR spectra were recorded on a JASCO IRA-1 spectrophotometer. Mass spectra were recorded with a JEOL JMS-D 100 mass spectrometer by direct insertion. The ESR spectra were taken on a JEOL-PE-3X instrument, equipped with a 100 KHz field modulation unit. Elementary analyses were performed on a Yanaco MT2 CHN corder.

Reaction of 1-Dimethylaminoanthraquinone. Powdered KOH 560 mg (10 mmol) was dissolved in anhydrous methanol (20 ml) and then solvent was evaporated under reduced pressure. The fine, powdered KOH was dissolved in 100 ml of DMSO. 251 mg (1 mmol) of **3** was added to the solution and stirred for 10 min at room temperature. The resulting orange mixture was poured into water (700 ml), followed by extraction with benzene several times. After the benzene was evaporated, the residue was chromatographed on a silica gel by employing first benzene and then benzene–ethanol(20+1) as eluents. The early red fractions contained 28 mg of the starting material **3** (11%). The later yellow fractions contained 279 mg of DMSO addition compound(**9**)(85%). The spectral properties of **9** are as follows: ^{1}H NMR(D_2O) 2.34 (s, 3H), 2.84 (s, 6H), 3.36 (s, 2H), 6.9—8.1 (m, 7H). IR(KBr) 3250, 1640, 1268, 1015, 785, 695 cm^{-1}. MS(*m/z*) 329(M+), 312, 251, 248, 78. UV(C_2H_5OH) 424 nm.

Procedure for N-Alkylation. A typical procedure is described for the reaction of **1** with butyl iodide. The compound **1** (1 mmol) was stirred with powdered KOH (10 mmol) in DMSO (30 ml) for 30 min at 30 °C. The color of the mixture changed rapidly from red to green. Then, butyl iodide (10 mmol) was added to the mixture and the solution was stirred for 5 min at 30 °C. By the addition of butyl iodide, the color of the solution turned to dark red and the reaction was quenched with water (700 ml). The mixture was then extracted with benzene several times, washed with water and evaporated. Then the residue was submitted to column chromatography on silica gel using benzene as the eluent. The physical properties and analytical data for the *N*-alkylated products are given in Table 5.

We wish to express their thanks to Dr. Kinji Anda and his colleagues of Tokyo Metropolitan Industrial Technology Center for mass spectral measurements.

Pentoside Synthesis by Dehydrative Glycosylation. Synthesis of *O*-α-L-Arabinofuranosyl-(1→3)-*O*-β-D-xylopyranosyl-(1→4)-D-xylopyranose

Shinkiti KOTO,* Naohiko MORISHIMA, Kazuhiro TAKENAKA, Chisa UCHIDA, and Shonosuke ZEN
School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108
(Received December 5, 1984)

O-α-L-Arabinofuranosyl-(1→3)-*O*-β-D-xylopyranosyl-(1→4)-D-xylopyranose isolated from the hydrolyzate of corncobs arabinoxylan was synthesized by way of dehydrative glycosylation.

Dehydrative glycosylation has been used in the synthesis of several trisaccharides.[1] This report deals with the synthesis of the trisaccharide, *O*-α-D-arabinofuranosyl-(1→3)-*O*-β-D-xylopyranosyl-(1→4)-D-xylopyranose (**25**), isolated from the hydrolytic products of corncobs arabinoxylan by a xylanase from *Streptomyces* sp. E-86[2], using dehydrative glycosylation.[3]

Direct benzylation of methyl β-D-xylopyranoside (**1**) in benzyl chloride in the presence of lithium hydroxide and dimethyl sulfoxide afforded the 2,4-dibenzyl ether **2** in a practical yield. Benzylation of the acetate **5** in benzyl chloride with potassium hydroxide gave mainly the 2,4-dibenzyl ether **6**. On the other hand, cyclohexylidenation of benzyl α-D-xylopyranoside (**4**) gave the 2,3-acetal **7** preferentially. This was derived into the 2,3-dibenzyl ether **9** *via* a sequence of reactions: allylation, decyclohexylidenation, benzylation and deallylation. The location of the unprotected hydroxyl group of these partially benzylated xylosides was determined by observing H-1 NMR spectra of their acetates (Table 1).

Methyl 2,4-di-*O*-benzyl-α-D-xylopyranoside (**10**)[4] was allylated and then hydrolyzed into the protected xylose **11**. The 2,4-dibenzyl ether **6** was acetylated and then treated with titanium tetrachloride, followed by hydrolysis on moist silica gel, to furnish the protected xylose **12**.[5] The corresponding benzoate **13** was also obtained similarly from **6** *via* benzoylation.

Using these donors and acceptors, a stepwise synthesis of **25** was then attempted as shown in Fig. 1. The first β-xylosylation was carried out using only the allylated donor **11** for the acceptor **9** and the NSD mixture composed of *p*-nitrobenzenesulfonyl chloride (NsCl), silver trifluoromethanesulfonate (AgOTf), and 1,8-diazabicyclo [5.4.0] undec-7-ene (DBU). reaction proceeded with a poor selectivity. Similar xylosylation using the acylated donors, **12** and **13**, gave the α-anomer selectively. The acyloxyl group at the C-3 position appears to effect for the formation of the α-anomer in this dehydrative xylosylation. The second glycosylation of the xylobiose derivarive **20** was performed using the arabinofuranosyl donor **14**

and the NSD mixture. The condensation gave the desired α-anomer selectively. The acceptor **2** was also α-arabinosylated. Deprotection of the fully benzylated trisaccharide **24** gave the trisaccharide **25**, of which C-13 NMR spectrum was consistent with the proposed structure as shown in Table 3. The optical rotation value of **25** agreed well with the expected value based on the data of the relevant compounds (Table 4). Therefore, these results indicate that the trisaccharide from corncobs arabinoxylan has the structure that has been proposed.[2]

Experimental

The instruments used for determining the physical characters of the compounds and chromatography have been described in previous reports.[1] The evaporation of the solvent was carried out under reduced pressure at 35—45 °C unless otherwise stated. Data regarding the chemical shifts of the anomeric carbon are in Table 2. Analytical and physical data of the compounds are summarized in Table 5.

Methyl 2,4-Di-O-benzyl-β-D-xylopyranoside (2). A mixture of methyl β-D-xylopyranoside (**1**, Pfanstiehl, 100 mg, 0.61 mmol), lithium hydroxide (88 mg)[6], dimethyl sulfoxide (0.35 ml) and benzyl chloride (2.0 ml) was vigorously stirred at 130 °C for 0.5 h. After the usual work-up, the mixture was chromatographed (gradient, toluene 2-butanone=100/1→1/1) to give the tribenzyl ether (33 mg, 2%. Found: C, 74.56; H, 6.97%), **2** (111 mg, 53%) and then a mixture of the 2,3- and the 3,4-dibenzyl ethers (78 mg, 37%. Found: C, 69,82; H, 6.95%).

Benzyl α-D-xylopyranoside (4). A mixture of D-xylose **3**, Wako, 15 g, 100 mmol), benzyl alcohol (15 ml) and *p*-toluenesulfonic acid monohydrate (4.4 g) was stirred at 75 °C for 1.5 h. After the addition of chloroform (30 ml) and triethylamine (3.6 ml), the mixture was directly chromatographed (chloroform/methanol=100/1→1/1). The obtained crude solid (6.2 g) was recrystallyzed from ethyl acetate containing 2-butanone to give pure **4** (4.5 g, 19%).

2-Methoxylethyl 2,3,4-tri-O-benzyl-β-D-xylopyranoside (5). Acetic acid (4.0 ml) was added into a stirred suspension of **3** (3.0 g, 20 mmol) in acetyl bromide (7.0 m) at 0 °C.[7]

XX=4-*O*-(β-D-xylopyranosyl)-D-xylose, MXX=methyl 4-*O*-(β-D-xylopyranosyl)-β-D-xylopyranoside.

After being stirred at room temperature for 2 h, evaporation and co-evaporation with toluene gave a syrup. This was stirred in nitromethane (9 ml) containing 2-methoxyethanol (4.6 ml) and mercury(II) cyanide (8.6 mg). After the usual processing, the chromatography (toluene/2-butanone= 100/1→1/1) of the mixture gave crude solid (5.1 g), which was crystallized with hexane containing diisopropyl ether to give **5** (1.7 g, 26%).

2-Methoxyethyl 2,4-Di-O-benzyl-β-D-xylopyranoside (6). A mixture of **5** (1.0 g, 3.0 mmol), potassium hydroxide

(1.5 g), and benzyl chloride (20 ml) was vigorously stirred at 120 °C for 16 h, followed by chromatography (toluene/2-butanone=100/1→1/1), to afford the tribenzyl ether (0.26 g, 18%), **6** (0.64 g, 55%), and then a mixture of the other dibenzyl ethers (0.32 g, 28%).

Benzyl 2,3- and 3,4-O-Cyclohexylidene-α-D-xylopyranosides (7 and 8). A mixture of **4** (800 mg, 3.3 mmol), 1,1-dimethoxycyclohexane (2 ml), *p*-toluenesulfonic acid monohydrate (10 mg), and *N,N*-dimethylformamide (5 ml) was heated at 120 °C for 4 h. After the addition of triethylamine (0.1 ml), the solution was evaporated at 70 °C and the obtained residue was chromatographed (toluene/2-butanone=100/1→1/1) to give **8** (117 mg, 11%) and then **7** (451 mg, 42%).

Benzyl 2,3-Di-O-benzyl-α-D-xylopyranoside (9). A mixture of **7** (0.41 g, 1.3 mmol), sodium hydride (≈60%, 0.2 g) and allyl bromide (4 ml) was stirred at 80 °C for 1 h. The mixture was filtered and the filtrate was concentrated to give a syrup which was dissolved in aq acetic acid (80%, 6 ml) containing acetone (1 ml). After kept standing for 1 h at room temperature, the solution was evaporated and co-evaporated with toluene. The obtained syrup was heated in benzyl chloride (4.5 ml) containing crushed potassium hydroxide (1.5 g) at 120 °C for 2 h. After the usual work-up, the mixture was chromatographed (toluene/2-butanone=100/1→1/1). The fully benzylated derivative thus obtained (0.54 g, 92% from **7**) was heated in dimethyl sulfoxide (2 ml) containing potassium *t*-butoxide (0.4 g) under a stream of nitrogen at 115 °C for 1 h. After dilution with toluene, the solution was washed with water and evaporated. The obtained residue was treated with acetone (10 ml) containing aq hydrochloric acid (2 M†, 0.5 ml) at room temperature for 0.5 h. After the addition of sodium hydrogencarbonate, the mixture was evaporated and chromatographed (toluene/2-butanone=100/1→1/1) to afford **9** (204 mg, 48% from **7**).

3-O-Allyl-2,4-di-O-benzyl-D-xylopyranose (11). Methyl 2,4-di-*O*-benzyl-α-D-xylopyranoside (**10**) (680 mg, 2.0 mmol) was heated in allyl bromide (7 ml) containing sodium hydride (≈60%, 168 mg) at 80 °C for 0.5 h. After filtration and evaporation, the residue was heated in aq acetic acid (80%, 5 ml) containing aq sulfuric acid (3 M, 0.8 ml) at 90 °C for 0.5 h. After the addition of sodium hydrogencarbonate (0.6 g), evaporation and chromatography (toluene/2-butanone=100/1→1/1), gave **11** (380 mg, 52%).

3-O-Acetyl-2,4-di-O-benzyl-D-xylopyranose (12). Compound **6** (245.9 mg, 0.63 mmol) was treated with acetic anhydride (2 ml) and pyridine (2 ml) overnight. The pure acetate (278.2 mg, $[\alpha]_D^{20}$ +5° (*c* 0.8, $CHCl_3$). Found: C, 67.67; H, 6.94%) obtained after a brief chromatography (toluene/2-butanone=10/1) was dissolved in dichloromethane (4.5 ml) and then treated with titanium tetrachloride (41 μl) for 15 min at room temperature. After the usual work-up, the mixture was adsorbed on a silica-gel column and chromatographed (toluene/2-butanone=100/1→1/1) to afford **12** (164.1 mg, 67%).

3-O-Benzoyl-2,4-di-O-benzyl-D-xylopyranose (13). Compound **6** (317.7 mg, 0.82 mmol) was benzoylated with benzoyl chloride (0.2 ml) and pyridine (2 ml) overnight. After the usual processing the mixture was chromatographed (toluene/2-butanone=20/1) to give pure benzoate ($[\alpha]_D^{20}$ +24° (*c* 0.8, $CHCl_3$). Found: C, 70.26, H; 6.46%). This was treated with titanium tetrachloride (57 μl) in dichloromethane (7.2 ml), followed by work-up as described for **12**, to afford **13** (234.2 mg, 73%).

Methyl 3-O-(2,3,4-Tri-O-benzyl-α-L-arabinofuranosyl)-β-D-xylopyranoside (15). DBU (45.5 μl) was added into a stirred mixture of 2,3,4-tri-*O*-benzyl-L-arabinofuranose (**14**, Pfanstiehl, 57.3 mg, 0.14 mmol), **2** (36.1 mg, 0.10 mmol), NsCl (67.5 mg), and AgOTf (78.3 mg) in dichloromethane (0.96 ml) at −55 °C. The bath temperature was rised to 0 °C at which temperature the mixture was stirred overnight. The mixture was chromatographed (toluene/2-butanone=100/1→1/1) to give the self-condensation product **16** (15.8 mg, 14%; δ_C ($CDCl_3$, TMS) 102.5 (C-1), 88.3, 84.1, 81.5, 73.6, 72.4, 72.1, 70.1) and **15** (57 mg, 73%).

Methyl 3-O-(α-L-Arabinofuranosyl)-β-D-xylopyranoside (17). The hydrogenolysis of **15** (50 mg, 0.067 mmol) over palladium on carbon (10%, 40 mg) in acetic acid (6 ml) under 340 kPa of hydrogen at room temperature overnight, followed by chromatography (chloroform/methanol=10/1=1/1), affofded **17** (15.9 mg, 80%).

Benzyl 4-O-(3-O-Allyl-2,4-di-O-benzyl-α- and -β-D-xylopyranosyl)-2,3-di-O-benzyl-α-D-xylopyranoside (18 and 19). DBU (53 μl) was added into a stirred mixture of **11** (100 mg, 0.27 mmol), **9** (87.3 mg, 0.21 mmol), NsCl (78.2 mg), and AgOTf (90.9 mg) in dichloromethane (1.0 ml) at −55 °C. The bath temperature was rised to 0 °C and then the mixture was stirred overnight. The chromatography of the reaction mixture (toluene/2-butanone=100/1→1/1) furnished **18** (27.6 mg, 17%) and then **19** (76.2 mg, 47%).

Benzyl 4-O-(2,4-Di-O-benzyl-β-D-xylopyranosyl)-2,3-di-O-benzyl-α-D-xylopyranoside (20). A mixture of **19** (93.1 mg, 0.12 mmol) and potassium *t*-butoxide (77 mg) in dimethylsulfoxide (0.4 ml) was heated at 120 °C for 6 h under a stream of nitrogen. Toluene and water were added to the solution and the organic layer was evaporated and then hydrolyzed in acetone (4 ml) containing aq hydrochloric acid (2 M, 0.1 ml) at room temperature. After addition of sodium hydrogencarbonate and concentration, chromatography (toluene/2-butanone=100/1→1/1) of the residue gave **20** (20.7 mg, 53%).

Benzyl 4-O-(2,4-Di-O-benzyl-α-D-xylopyranosyl)-2,3-di-O-benzyl-β-D-xylopyranoside (21). A mixture of **18** (27.6 mg, 0.036 mmol), tris(triphenylphosphine)rhodium(I) chloride (10 mg), ethanol (0.7 ml), benzene (0.3 ml) and water (0.1 ml) was refluxed for 5.5 h. Evaporation and treatment with aq hydrochloric acid (1 M, 0.04 ml) in acetone (1.5 ml), followed by chromatography (toluene/2-butanone=10/1), gave **21** (20.7 mg, 79%).

Benzyl 4-O-(3-O-Acetyl-2,4-di-O-benzyl-α-D-xylopyranosyl)-2,3-di-O-benzyl-α-D-xylopyranoside (22). The condensation of **12** (129.4 mg, 0.35 mmol) and **9** (112.4 mg, 0.27 mmol) was carried out using NsCl (101 mg), AgOTf (117 mg), and DBU (63.5 μl) in dichloromethane (1.42 ml) in the manner described for the synthesis of **18** and **19**. Chromatography gave **22** (45 mg, 22%). This was deacetylated in methanolic sodium methoxide (0.075 M, 2 ml) containing acetone (0.5 ml) at room temperature, followed by chromatography, to give **21**.

Benzyl 4-O-(3-O-Benzoyl-2,4-di-O-benzyl-α-D-xylopyranosyl)-2,3-di-O-benzyl-α-D-xylopyranoside (23). A similar condensation of **13** (146.6 mg, 0.34 mmol) and **9** (108.4 mg,

† 1 M=1 mol dm^{-3}.

0.26 mmol) by use of NsCl (97.3 mg), AgOTf (112.8 mg), and DBU (61.2 μl) in dichloromethane (1.39 ml) gave **23** (49.2 mg, 23%). This was treated with methanolic sodium methoxide (0.15 M, 2 ml) containing acetone (0.5 ml) at room temperature, followed by chromatography, gave **21**.

Benzyl O-(2,3,4-Tri-O-benzyl-α-L-arabinofuranosyl)-(1→3)-O-(2,4-di-O-benzyl-β-D-xylopyranosyl)-(1→4)-2,3-di-O-benzyl-α-D-xylopyranoside (24). Condensation of **14** (34.7 mg, 0.083 mmol) and **19** (46.5 mg, 0.064 mmol) was carried out using NsCl (40.9 mg), AgOTf (47.4 mg), and DBU (27.5 μl) in dichloromethane (0.58 ml) in the same manner as described above. Chromatography (toluene/2-butanone=100/1→1/1) gave **24** (54.8 mg, 76%).

O-α-L-Arabinofuranosyl-(1→3)-O-β-D-xylopyranosyl-(1→4)-D-xylopyranose (25). Hydrogenolysis of **24** (30 mg, 0.026 mmol) over palladium on carbon (10%, 30 mg) in acetic acid (6 ml) under 340 kPa of hydrogen at 25 °C overnight. Chromatography (chloroform/methanol=10/1→1/1) gave **25** (5.6 mg, 51%).

Synthesis and Properties of Gramicidin S Analogs Containing Pro-D-Phe Sequence in Place of D-Phe-Pro Sequence in the β-Turn Part of the Antibiotic

Makoto TAMAKI,* Michiaki TAKIMOTO, and Ichiro MURAMATSU†
Department of Chemistry, Faculty of Science, Toho University, Miyama, Funabashi-shi, Chiba 274
†*Department of Chemistry, College of Science, Rikkyo University, Nishi-ikebukuro, Tokyo 171*
(Received December 10, 1984)

Two analogs of gramicidin S, [L-Pro⁴, D-Phe⁵]-gramicidin S and [L-Pro⁴·⁴′, D-Phe⁵·⁵′]-gramicidin S, were synthesized in order to investigate the relationships among positions of Pro residues, antibiotic activity and CD spectra. [L-Pro⁴·⁴′, D-Phe⁵·⁵′]-gramicidin S showed little activity. On the other hand, the activity of [L-Pro⁴, D-Phe⁵]-gramicidin S against *Bacillus subtilis* and *Micrococcus flavus* was the same as that of gramicidin S, and its activity toward other microorganisms tested was 1/2 that of gramicidin S. The CD spectra of these analogs and gramicidin S in an aqueous solution differ from each other, indicating that these peptides have different conformations in aqueous solutions. The CD spectrum of [L-Pro⁴, D-Phe⁵]-gramicidin S resembles a graphical average of the CD spectra of gramicidin S and [L-Pro⁴·⁴′, D-Phe⁵·⁵′]-gramicidin S.

The secondary structure of gramicidin S (GS)[1] (Fig. 1) is established as an antiparallel β-sheet conformation containing two type-II′ β-turns derived from a D-Phe-Pro sequence.[2] In studies regarding the structure-activity relationship of GS, it has been proposed that a specific conformation is necessary in order to exhibit any antibiotic activity.[3,4] Recently, we synthesized two GS analogs containing D-Phe-Pro-D-Val or Phe-Pro-D-Val sequences in place of the D-Phe-Pro-Val sequence in the β-turn part of this antibiotic and discussed the role of the D-Phe-Pro-Val sequence for exhibiting the activity.[5] We also reported that during studies of an antibiotic cyclododecapeptide, gratisin, *cyclo*(-Val[1]-Orn[2]-Leu[3]-D-Phe[4]-Pro[5]-D-Tyr[6]-)₂, *cyclo*(-Val-Orn-Leu-D-Phe-D-Tyr-Pro-)₂ and *cyclo*(-Val-Orn-Leu-Pro-D-Phe-D-Phe-)₂ (in which the Pro residues ocuppy positions different from each other) possessed a strong activity.[6] In connection with these results, it is of interest to study the relationship among positions of Pro residues, secondary structures, and the antibiotic activity of GS.

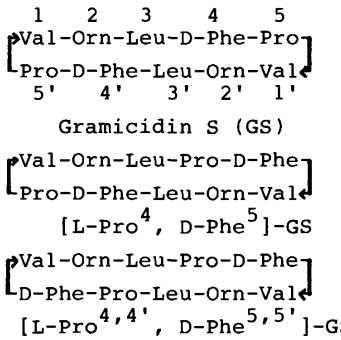

Fig. 1. Primary structure of gramicidin S and its analogs.

In the present paper, we wish to describe the synthesis, antibiotic activity and CD spectra of [L-Pro⁴, D-Phe⁵]- and [L-Pro⁴·⁴′, D-Phe⁵·⁵′]-GS (Fig. 1), in which one or two of D-Phe-Pro sequences in GS is replaced with a Pro-D-Phe sequence.

The synthetic routes of [L-Pro⁴, D-Phe⁵]- and [L-Pro⁴·⁴′, D-Phe⁵·⁵′]-GS are shown in Schemes 1 and 2. The synthetic methods are similar to those discussed in a previous paper of this series.[5] The yields, physical properties and analytical data of the intermediary products are summerized in Table 1. The homoge-

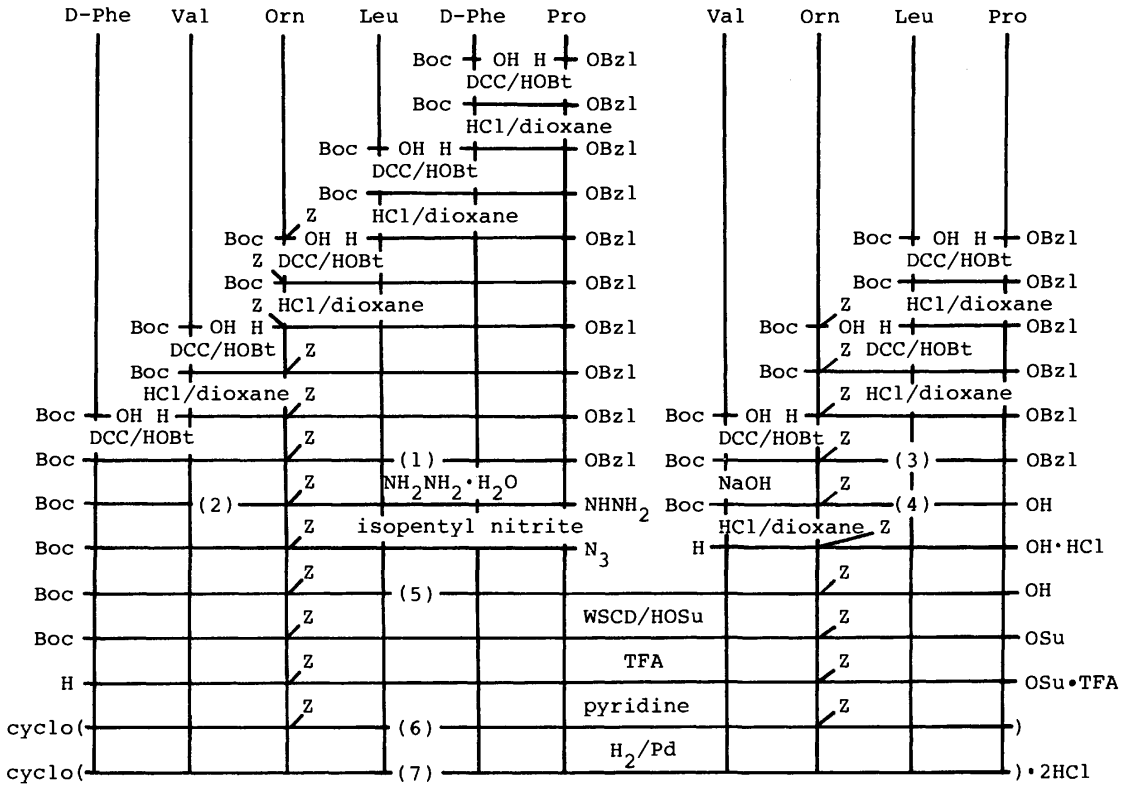
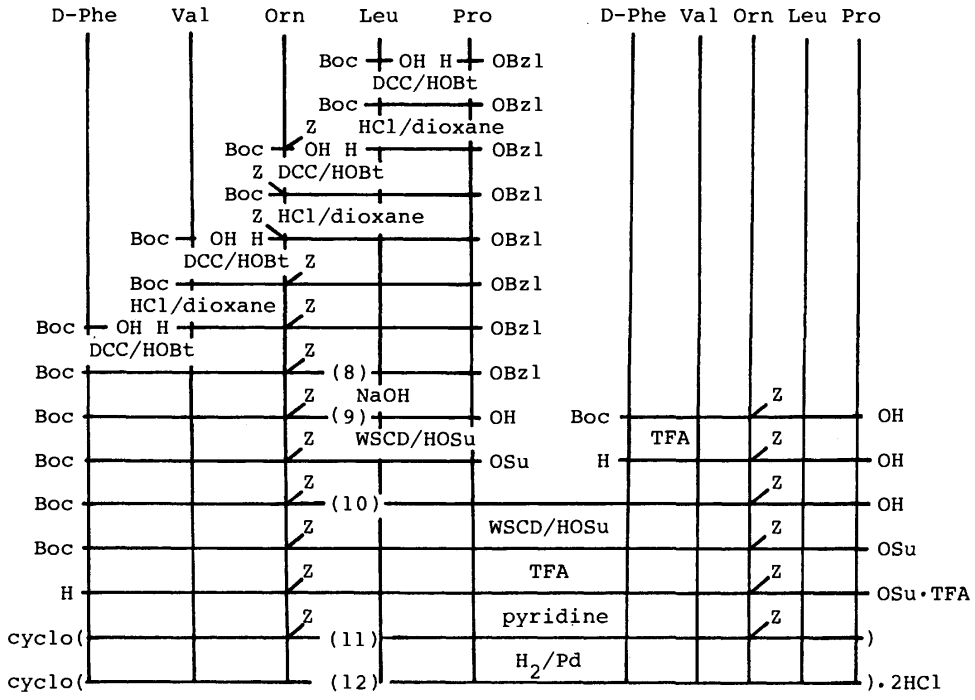
neity of the analogs was confirmed by thin-layer chromatography, cellulose plate electrophoresis, elemental analysis, amino acid analysis and fast-atom-bomberdment (FAB) mass spectrometry (Table 2).

The CD spectra of [L-Pro^{4}, D-Phe^{5}]-GS, [L-Pro$^{4,4'}$, D-Phe$^{5,5'}$]-GS and GS in aqueous solutions are shown in Fig. 2. The shapes of [L-Pro$^{4,4'}$, D-Phe$^{5,5'}$]-GS and GS differ from each other, indicating that these peptides have different conformations in aqueous solutions. On the other hand, the feature of the CD spectrum of



Scheme 1. Synthesis of [L-Pro^{4}, D-Phe^{5}]-GS.



Scheme 2. Synthesis of [L-Pro$^{4,4'}$, D-Phe$^{5,5'}$]-GS.

[L-Pro⁴, D-Phe⁵]-GS resembles the graphical average of the spectra of GS and [L-Pro⁴,⁴′, D-Phe⁵,⁵′]-GS. The latter was also very similar to the spectrum of an equimolar mixture of both peptides. The difference found in the ellipticities of these compounds seems to reflect the difference of the stability of their structures in aqueous solutions. The existence of the additivity in a CD spectra of these analogs and GS suggests that D-Phe–Pro and Pro–D-Phe sequences of each β-turn part contribute separately to their spectra of these peptides.

The antibiotic activity of GS and these two analogs

a) Minimum inhibitory concentration in μg/ml: The minimum amount of the compounds necessary for the complete inhibition of growth was determined by a agar dilution method with 10^6 organisms per milliter.

toward several microorganisms are summerized in Table 3. [L-Pro$^{4,4'}$, D-Phe$^{5,5'}$]-GS showed little activity. This indicates that the positions of the two Pro residues of GS can not be transposed without a loss of activity. Several gratisin isomers, in which Pro residues occupy positions different from esch other, showed strong activity.[6] The significant difference in this regard may result from the distinction of their rings.

The activity of [L-Pro^4, D-Phe^5]-GS against *Bacillus subtilis* and *Micrococcus flavus* was the same as that of GS, and the activity toward other organisms tested was a little less compared to GS. This shows that a single D-Phe-Pro sequence in the β-turn part of GS can be inverted without affecting the activity. Similar results have been reported by Sofuku *et al.* for [δ-Ava$^{4-5}$]- and [δ-Ava$^{4-5,4'-5'}$]-GS, in which D-Phe-Pro sequences of GS are replaced, singly or together, with a δ-Ava residue.[7] That is, [δ-Ava$^{4-5}$]-GS showed antibiotic activity, but [δ-Ava$^{4-5,4'-5'}$]-GS not active. Recently, in studies on [L-Pro$^{4,4'}$, D-Ala$^{5,5'}$]-GS, in which D-Phe-Pro sequences in GS were replaced with Pro-D-Ala sequence, it was reported that this analog showed no activity,[8] and that it could take a GS-like conformation in an aqueous solution, but its population decreased in a less-polar environment.[9] In the present studies, it is likely that when the synthetic analogs interact with a cell membrane of target microorganisms, the presence of a D-Phe-Pro sequence in [L-Pro^4, D-Phe^5]-GS makes this analog feasible to adopt the GS-like conformation, while [L-Pro$^{4,4'}$, D-Phe$^{5,5'}$]-GS cannot take the GS-like conformation.

Experimental

The synthetic manners of the analogs are similar to those reported in a previous paper of this series.[5] The yields, physical properties and analytical data of the intermediary and final products are summerized in Tables 1 and 2. All melting points are uncorrected. The molecular weights of GS analogs were determined by fast-atom-bomberdment (FAB) mass spectrometry using a JMS D-300 mass spectrometer. Amino acid analyses were carried out using a Hitachi 835 amino acid analyzer, after the hydrolysis of peptides in 6 M† HCl at 110 °C for 24 h. Thin-layer chromatography was performed on Merck silica-gel F_{254} plates with the following solvent systems (v/v): R_f^1, $CHCl_3$-MeOH (9:1); R_f^2, $CHCl_3$-MeOH-AcOH (95:5:3); R_f^3, *n*-BuOH-AcOH-H_2O (4:1:1); R_f^4, *n*-BuOH-pyridine-AcOH-H_2O (4:1:1:2). The yields of peptides **3** and **8** were calculated on the basis of the amount of Pro-OBzl as a starting material. The CD spectra shown in Fig. 2 were obtained using a JASCO spectropolarimeter (model J-500). The CD spectroscopy of GS and the analogs was carried out with an aqueous solution of their dihydrochlorides. Cellulose plate electrophoresis was carried out with a cellulose (Avicel) plate and with a solvent system of HCOOH-AcOH-MeOH-H_2O (1:3:6:10 v/v, PH 1.4) for 2 h at 500 V/20 cm. Each of the analogs revealed a single spot, the mobility being the same as that of GS.

† 1 M=1 mol dm^{-3}.

We are grateful to the staff of the Research Laboratories of Toyo Jozo Co. for elemental analyses, microbiological assays and the measurements of FAB Mass.

Syntheses and Properties of Oligo-L-leucines Containing α-Aminoisobutyric Acid Residues. The Novel Strategy for Solubility Improvement in Helical Oligopeptides Based on the Restriction of the Values of the Backbone Dihedral Angles φ and ψ of α-Aminoisobutyric Acid Residues[1]

Mitsuaki NARITA,* Masamitsu DOI, Hiroki SUGASAWA, and Kazunori ISHIKAWA

(Received December 12, 1984)

In order to provide a succinct demonstration of the usefulness of a new strategy for solubility improvement in protected peptide fragments included in α-helical regions of proteins, model oligo(Leu)s containing Aib or Ala residues were prepared by stepwise elongation and fragment condensation methods. The peptides prepared were the following: Boc-(Leu$_3$-Aib)$_n$-OBzl, Boc-(Leu$_4$-Aib)$_n$-OBzl, and Boc-(leu$_3$-Ala)$_n$OBzl (n=1—3). Carboxyl component peptides having Aib residues at the C-terminals smoothly reacted with amino component peptides in high yields with no care of racemization due to the absence of chiral centers in Aib residues. As expected, peptides containing Aib residues have high solubility in moderate- and high-polar organic solvents and are easily purified by recrystallization from aqueous ethanol. This is in remarkable contrast with the result that the octa- and dodecapeptides containing Ala residues are barely soluble or insoluble in these solvents. Conformational analyses by IR spectroscopies indicated that Boc-(Leu$_3$-Aib)$_n$-OBzl and Boc-(Leu$_4$-Aib)$_n$-OBzl (n=2 and 3) had helical conformations (3_{10}- or α-helices) in dichloromethane, whereas Boc-(Leu$_3$-Ala)$_n$-OBzl (n=2 and 3) had fully developed β-sheet structures in the solid state. The high solubility of the peptides containing Aib residues is explained by the observation that replacement of C$^\alpha$ hydrogen atoms with methyl groups greatly disturbs β-sheet structures, promoting helical folding in peptides. The implications of the new findings for the chemistry of peptides and proteins containing α,α-disubstituted α-amino acid residues is also discussed by building up a CPK model of an α-helical structure.

In our recent papers,[2-8] we have demonstrated that a β-sheet aggregation plays an important role in the insolubility of oligopeptides larger than octa- or nonapeptide levels, and that the temporary protection of a NH peptide bond in a central position of a peptide chain helps improve solubility to a remarkable extent. The solubility improvement is attributed to the existence of tertiary peptide bonds of X-(Z)Y bonds, where X and Y are arbitrary amino acid residues and Z is a temporary protecting group for the X-Y peptide bond. The tertiary peptide bond causes disturbance of the β-sheet structure by the rotation of the tertiary peptide bond plane, and we called this segmentation of structures the "peptide segment separation."[2] On the basis of these results, solubility prediction of protected polypeptides was also successfully performed by making use of both the randomness of peptide structures in the solid state and the existence of tertiary peptide bonds.[6]

At this juncture, we would like to propose a novel strategy for improving solubility of protected oligo- and polypeptide fragments included in α-helical regions of proteins. The protected peptide fragments ranging from octa- to around pentadecapeptides have, in general, β-sheet structures and are less soluble in organic solvents.[2,6,9,10] Insolubility of protected peptide fragments is one of serious problems in the efforts of protein syntheses, and it has been found very difficult to achieve further elongation of these peptide chains.[11-16] Thus, solubility improvement in the peptides is one of the upmost important problems to be solved in protein syntheses. The strategy for solubility improvement as proposed in this paper is based on the restriction of the values around the helical regions of the backbone dihedral angles φ and ψ of Aib residues in partial replacement of Ala residues with Aib residues. The conformational space of an Aib residue is sterically severely restricted, and, φ,ψ torsional angles of the Aib residue in a linear polypeptide are mainly found in the region of conformational map which includes both the α-helix (φ=±57°, ψ=±47°) and 3_{10}-helix (φ=±60°, ψ=±30°).[17] The conformational preferences of linear peptides containing α,α-disubstituted α-amino acids have recently been reviewed, and the ability of Aib residues to promote helical folding in peptides is well documented in the conformational analyses of membrane-channel-forming polypeptides like alamethicin and suzukacillin.[18] Thus, partial replacement of Ala residues with Aib residues in protected polypeptide fragments included in α-helical regions of proteins is expected to disturb β-sheet structures, which are general conformations of the protected polypeptide fragments ranging from octa- to around pentadecapeptides included in α-helical regions of proteins, and to promote helical folding in peptides, providing solubility improvement in the peptide fragments (Fig. 1). In this connection, it is well recognized that the β→helical conformational transformation results in remarkable solubil-

ity improvement. Furthermore, CPK models of α-helical structures suggest to us that the replacement takes place without difficulty keeping the nature of proteins intact. Therefore, replacement of a few Ala residues with Aib residues in proteins offers the prospect for creating novel proteins not found in nature.

In this paper, we report syntheses of oligo(Leu)s containing Aib or Ala residues and demonstrate the effect of the replacement of Ala residues with Aib residues on solubility and conformations of the oligo(Leu)s.

Results

Syntheses and Solubilities of Oligo(Leu)s Containing Aib or Ala Residues. In order to demonstrate the usefulness of the strategy for solubility improvement in helical oligopeptides, model oligo(Leu)s containing Aib or Ala residues were prepared by stepwise elongation and fragment condensation methods. The synthetic scheme is shown below. Boc-Leu_3-Aib-OBzl (**1**), Boc-Leu_4-Aib-OBzl (**4**), and Boc-Leu_3-Ala-OBzl (**7**) were prepared by a stepwise elongation, starting with H-Aib-OBzl and H-Ala-OBzl as amino components. The stepwise elongation was performed in dichloromethane using DCC activation. The liberation of the amino group from Boc-peptide Bzl esters in the stepwise elongation was carried out by treatment with 3 M HCl/AcOEt (1 M=1 mol dm^{-3}) followed by treatment with NMM. Removal of the

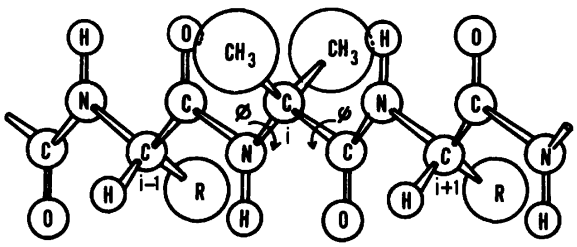

Fig. 1. Disturbance of a β-sheet structure by the restriction of the values of the backbone dihedral angles ϕ and Ψ of an Aib residue.

Scheme

Bzl group from the peptides **1**, **4**, and **7** was performed by hydrogenolysis using Pd/C as a catalyst and the products **1'**, **4'**, and **7'** were used as carboxyl components in a subsequent fragment condensation. Boc-(Leu$_3$-Aib)$_n$-OBzl (n=2, **2**; n=3, **3**), Boc-(Leu$_4$-Aib)$_n$-OBzl (n=2, **5**; n=3, **6**), and Boc-(Leu$_3$-Ala)$_n$-OBzl (n=2, **8**; n=3, **9**) were prepared in dichloromethane, DMF, or HMPA by a fragment condensation method using DCC activation in the presence of HOBt. Removal of the Boc group from the peptides **1**, **2**, **4**, **5**, **7**, and **8** was carried out by treatment with 3 M HCl/AcOEt or TFA/CH_2Cl_2 (1/2, v/v). The coupling reactions were monitored by HPLC on a gel filtration column and a representative result was shown in Fig. 2. Boc-Leu$_3$-Aib-OH and Boc-Leu$_4$-Aib-OH were easily coupled with H-(Leu$_3$-Aib)$_n$-OBzl and H-(Leu$_4$-Aib)$_n$-OBzl (n= 1 and 2) in high yields, respectively, and the reactions could be performed with no care of racemization since Aib residues had no asymmetric carbon.

All the peptides containing Aib residues have high solubility in moderate- and high-polar organic solvents such as dichloromethane, chloroform, acetone, EtOH, MeOH, DMF, DMA, NMP, and HMPA (Table 1), and are easily purified by recrystallizations from aqueous ethanol. This is in remarkable contrast with the result that the peptides **8** and **9** are barely soluble or insoluble in these solvents except HMPA and are purified by washing with hot methanol. Homogeneity of the peptides except **8** and **9** was easily ascertained as the peptides had a single peak on HPLC. The synthetic results and physical properties of the peptides are assembled in Table 2. Elemental and amino acid analyses of the peptides shown in Table 3 are in good agreement with the calculated values.

IR Absorption Studies of Oligo(Leu)s Containing Aib or Ala Residues. Conformational analyses of the peptides **1**—**6** by IR absorption measurements were first carried out in dichloromethane. Figure 3 shows the most significant spectral regions for the conformational assignments (3600—3200 cm^{-1}, amide A; 1750—1600 cm^{-1}, amide I; 500—400 cm^{-1}, far-IR). As expected from solubility data and the nature of Aib residues, no band at around 3280 cm^{-1} and 1630 cm^{-1} is observed in all of the peptides **1**—**6**, indicating

a) Leu/Ala.

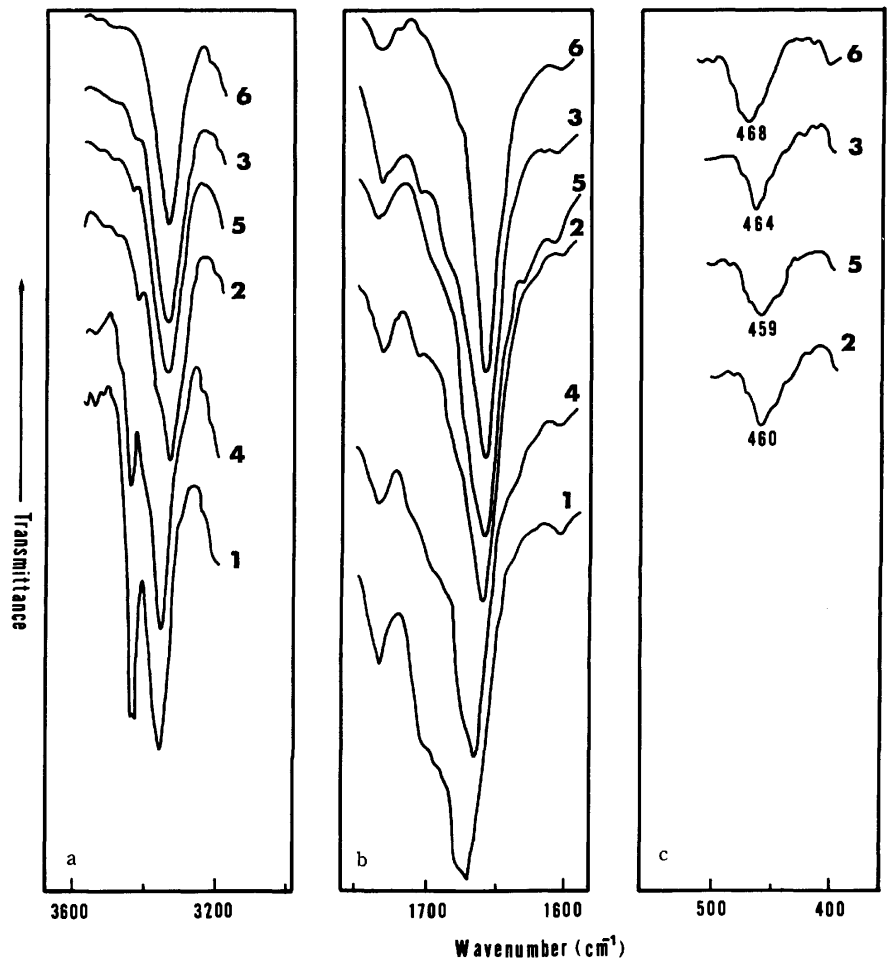

Fig. 3. IR absorption spectra of the peptides **1**—**6**. a: The amide A region, in methylene chloride; b: the amide I region, in methylene chloride; c: the far-IR, in a solid state.

conformation (3_{10}- or α-helix), the peptides **2**—**6** show strong intensity bands at 3340—3320 cm^{-1} and 1665—1659 cm^{-1}, indicating a helical structure (3_{10}- or α-helix), although the frequencies of the amide I region are rather high.[21] Weak or medium-intensity bands at 3430—3420 cm^{-1} of the peptides **2**—**6** are also assigned to the nonhydrogen bonding NH bonds, which are attributed to the NH bonds of two or three Leu residues at the N-terminal portions. The helical structure in the solid state also seems to be evidenced by a far-IR band at 468-459 cm^{-1} (Fig. 3c), which is characteristic of Leu residues with an α-helical conformation.[22] Figure 4 shows IR spectra of the peptides **8** and **9** in the solid state. Both peptides are barely soluble or insoluble in dichloromethane, and their IR measurement can not be performed in dichloromethane. In contrast with the peptides containing Aib residues, the peptides containing Ala residues (**8** and **9**) show strong bands at 3270 cm^{-1} and 1628 cm^{-1} and a weak band at 1693 cm^{-1}, assigned to antiparallel β-sheet structures.[21]

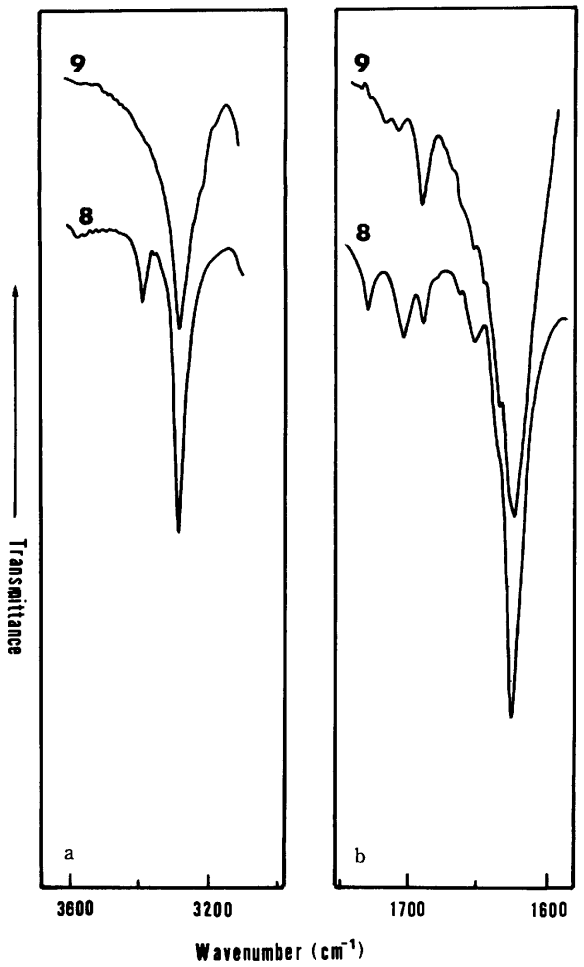

Fig. 4. IR absorption spectra of the peptides **8** and **9** in a solid state. a: The amide A region; b: the amide I region.

Discussion

As shown in Fig. 2, the carboxyl component peptides having Aib residues at the C-terminals react smoothly with amino component peptides in high yields, although the C-terminal Aib residues are sterically hindered.[23] The reaction of H-Aib-OBzl with Boc-Leu-OH is also performed by the usual stepwise method. Extreme difference in solubility between the peptides containing Ala residues and those containing Aib residues is readily explained by the conformational transformation of the peptides from β-sheet to helical structures. The ability of Aib residues to promote helical folding in peptides is outstanding in this study. The replacement of two Ala residues in the peptide **8** with two Aib residues constrains helical folding in the peptide **2**, and dramatic change takes place in solubility. Helical folding in the peptide **4** having the only one Aib residue at the C-terminal is also remarkable. Details of IR absorption conformational analyses of the peptides **1** and **4** will be presented in the following paper.[20] In the relation with this structure, the structures of the pentapeptides of Boc-Leu-Aib-Pro-Val-Aib-OMe and Boc-Ala-Aib-Ala-Aib-Aib-OMe, which were fragments of alamethicin and suzukacillin, were determined in the solid state, by X-ray diffraction analyses, to be a 3_{10}-helix.[24,25] The conformational-energy calculations for an Aib residue have demonstrated that only two small regions of the Ramachandran map are available.[26,27] The regions correspond to less than 1.0% of the total surface, where the right- and left-handed α-helices ($\phi=\pm57°$, $\psi=\pm47°$) and 3_{10}-helices ($\phi=\pm60°$, $\psi=\pm30°$) are found. 3_{10}- and α-helical conformations, however, could not be distinguished by the present IR analyses. Therefore, ^1H NMR analyses of the peptides are necessary to characterize their intramolecular hydrogen bonding patterns (3_{10}-helix, 4→1; α-helix, 5→1).[28]

In order to evaluate the influence on the nature of proteins of the replacement of a few Ala residues with Aib residues, a CPK model of the α-helical structure of Boc-$(Leu_3$-Aib$)_3$-OBzl is shown in Fig. 5. Figure 5 indicates that the replacement of C^α hydrogen atoms of Ala residues with methyl groups would have no or a little influence on the total feature of the α-helical regions of proteins and that the nature of proteins would be kept intact. The C^β_D methyl groups are identified by arrows in the model, where the C^β_D carbon atom that substitutes for the C^α hydrogen atom in Ala is designated as C^β_D. Figure 5 also indicates that the replacement of C^α hydrogen atoms of Leu residues with methyl groups is sterically permitted. The C^α hydrogen atoms are also identified by H^α in the model.

Based on the above discussion,[29] the perspective in

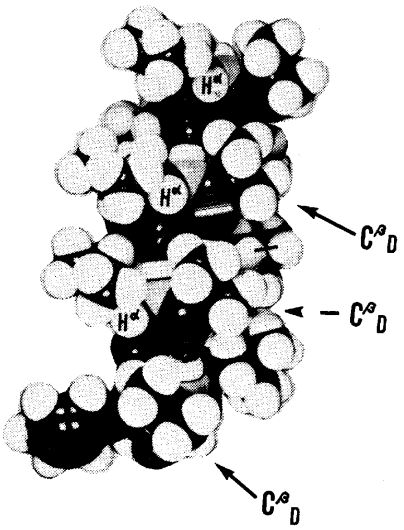

Fig. 5. The CPK model of the α-helical structure of the peptide 3. The arrows in the model indicate C^{β}_{D} methyl groups of Aib residues. The H^{α} atoms in the model indicate C hydrogen atoms of Leu residues.

the chemistry of peptides and proteins containing α,α-disubstituted α-amino acid residues gets into shape as follows: (1) Carboxyl component peptides having Aib residues at the C-terminals react with amino component peptides with no care of racemization due to the absence of chiral centers in Aib residues, and the reaction is carried out in high yields in common organic solvents using usual coupling reagents, (2) partial replacement of C^{α} hydrogen atoms with methyl groups remarkably helps improve solubility of intermediate peptide fragments included in α-helical regions of natural proteins and make further chain elongation easy in the modified protein syntheses, and (3) the replacement in α-helical regions of natural proteins keeps the nature of proteins intact.

Conclusion

The novel strategy for solubility improvement based on the restricted values of the backbone dihedral angles ϕ and ψ of Aib residues was successfully applied to model oligo(Leu)s. Partial replacement of C^{α} hydrogen atoms with methyl groups in α-helical regions of proteins is estimated, by building up the CPK model of the α-helical structure, to give no or a little influence on the nature of proteins. Thus, this strategy opens up a new breakthrough in creating proteins with novel properties which can not be achieved by genetic engineering technology.

Experimental

General. The uncorrected capillary melting points were reported. The optical rotations were taken in a 1 cm cell on a JASCO model ORD/UV-5 optical rotatory dispersion recorder. The amino acid compositions of acid hydrolysates were determined with a Shimadzu HPLC LC-3A all amino acid analysis system. The acid hydrolyses of the peptides were carried out with propionic acid/12 M HCl (2/1, v/v) for 2 d at 115 °C in sealed tubes. Analytical HPLC of the peptides was performed on a column packed with an acrylonitrile-divinylbenzene-styrene copolymer (7.5×500 mm)[30] using a mini micro pump NSP-800-5DX (Nihon Seimitsu Kagaku) and a refractive index detector model RI-3H (Japan Analytical Industry). The operating conditions of HPLC were the following: Column with exclusion limit of 5000; solvent, DMF; flow rate, 1 ml/min; chart speed, 0.5 cm/min; temperature, room temperature. The IR spectra in the solid state were recorded for nujor mulls with a JASCO model DS-701G spectrometer. Those in solution were recorded employing 0.025 mm pathlength cells with potassium bromide windows. The concentration of the solution was kept near 3.0 g/dl.

Preparation of the Peptides 1 and 4. DCC (11.3 g, 1.0 equiv) was added to an ice-chilled, stirred mixture of Boc-Leu-OH·H_2O (13.7 g, 1.0 equiv), H-Aib-OBzl·TsOH (20.0 g, 54.8 mmol), and NMM (5.6 g, 1.0 equiv) in dichloromethane (500 ml). The reaction mixture was stirred in an ice-chilled bath for 3 h, at room temperature overnight, and then filtered. The filtrate was washed with water, 10% citric acid, and 5% sodium hydrogencarbonate, dried over sodium sulfate, using charcol for decolorization, filtered, and concentrated *in vacuo*. The residue was used for the subsequent coupling reaction as an amino component after removal of the Boc group by treatment with 3 M HCl/AcOEt. The preparative procedure of Boc-Leu_2-Aib-OBzl, Boc-Leu_3-Aib-OBzl, and Boc-Leu_4-Aib-OBzl were essentially the same with that of Boc-Leu-Aib-OBzl. The peptides **1** and **4** were purified by recrystallization from aqueous ethanol.

Preparation of the Peptide 7. Preparation of the peptide **7** was carried out in dichloromethane (200 ml) in the same manner described above, using Boc-Leu-OH·H_2O (6.4 g, 1.1 equiv), H-Leu_2-Ala_2-OBzl·HCl (11.7 g, 23 mmol), and NMM (2.3 g, 1.0 equiv). The peptide **7** was purified by recrystallization from AcOEt.

General Procedure for Hydrogenolyses of the Peptides 1, 4, and 7. Hydrogenolyses of the peptides **1**, **4**, and **7** were performed in a mixture of acetic acid and methanol (1/5, v/v) at atmospheric pressure overnight using 10% Pd/C (10 wt.%) as a catalyst. After removal of Pd/C by filtration, the filtrate was concentrated *in vacuo*, and the residue was triturated with water. After filtration and drying, the products were purified by recrystallization from aqueous ethanol.

General Procedure for Removal of the Boc Group from the Peptides 1, 2, 4, 5, and 7. Each peptide (5 mmol) in 3 M HCl/AcOEt (30 ml) was stirred in an ice-chilled bath for 1.5 h. The mixture was concentrated *in vacuo*, followed by repetition of addition and removal, *in vacuo*, of dichloromethane. The residue was used with NMM (5 mmol) as an amino component for the subsequent coupling.

Removal of the Boc Group from the Peptide 8. The peptide **8** (5 mmol) in TFA/dichloromethane (1/2, v/v) (70 ml) was stirred at room temperature for 1 h. The solution was concentrated *in vacuo*, and the residue was dis-

solved in methanol containing an excess of NMM. The solution was poured into water to precipitate crystalline materials, which were used as an amino component for the subsequent coupling reaction.

Preparation of the Peptides 2, 3, 5, 6, 8, and 9. DCC (1.1 equiv) and HOBt (1.1 equiv) were added to an ice-chilled, stirred mixture of a carboxyl component (1.1 equiv), NMM (1.0 equiv), and an amino component. In the preparation of the peptides **2**, **3**, **5**, and **6**, the coupling reactions were carried out in dichloromethane. The reaction mixture was stirred in an ice-chilled bath for 3 h, at room temperature overnight, and then filtered. The filtrate was subjected to the same work-up procedure described above. The products were purified by recrystallization from aqueous ethanol. In the preparation of the peptides **8** and **9**, the coupling reaction was carried out in DMF and HMPA, respectively. The reaction mixture was stirred in an ice-chilled bath for 3 h, at room temperature for 2 d, and filtered. The filtrate was concentrated *in vacuo*, and the crystalline residue was purified by washing with hot methanol. The synthetic results and analytical data were shown in Tables 2 and 3.

(Received December 24, 1984)

Reaction of epoxides with [*n*-$Bu_3SnAlMe_3$]$^-Li^+$ affords β-oxido stannanes which collapse to alkene with overall retention of stereochemistry. The S_N2 type ring opening of epoxides by tributylstannyl anion followed by anti elimination of Bu_3Sn and OAl^-Me_3 groups explains the stereochemical results. The method can be successfully applied to hydroxy epoxides derived from (*E*)-2-nonen-1-ol. The deoxygenation of epoxides with $PhMe_2SiAlEt_2$ also provides olefins of the same geometry as epoxides.

Reagents believed to contain Si–Mg, Si–Al, Sn–Mg, and Sn–Al linkage are obviously reductants in which a Lewis acid center is incorporated. The single bond is weak and the previously reported reaction[1,2] with an acetylenic linkage affords simple and general access to the cis-addition products of the component atoms. In order to examine the nature of these reagents more precisely, we have studied the deoxygenation of epoxides by means of Sn–Al or Si–Al reagents.

The deoxygenation of epoxides to olefins has been widely studied and numerous reagents have been developed. The reduction with strongly reductive metals or metal salts such as chromium(II) ion,[3] tungsten complexes,[4] $TiCl_3/LiAlH_4$,[5] $NbCl_5/NaAlH_4$,[6] and $FeCl_3/n$-BuLi[7] produces olefins non-stereospecifically through a radical intermediate. For instance, treatment of *cis*- or *trans*-5,6-epoxydecane with $TiCl_3/LiAlH_4$ has provided a mixture of (*Z*)- and (*E*)-5-decene in a 21/79 or 18/82 ratio,[5] respectively. In contrast, the reaction with Me_3SiK[8] or $PhMe_2SiLi$[9] has proceeded stereospecifically to give the olefin of geometry opposite to that of the starting epoxide.[10] Here we wish to report that [*n*-$Bu_3SnAlMe_3$]$^-Li^+$ (**1**) is effective for the deoxygenation of epoxides to provide olefins of the same geometry as epoxides (Scheme 1).[11]

Treatment of (*E*)-5-decene oxide with the reagent **1** derived from *n*-Bu_3SnLi[12] and Me_3Al at 25 °C gave (*E*)-5-decene exclusively, while (*Z*)-5-decene oxide provided (*Z*)-5-decene as a single product. The results are summarized in Table 1. With some exceptions,[13] the deoxygenation reactions proceeded mostly with high stereospecificities. The deoxygenated product of (*Z*)-stilbene oxide, (*Z*)-stilbene, proved to isomerize partially under the reaction conditions, since treatment of (*Z*)-stilbene with the reagent **1** at 25 °C for 24 h gave a mixture of (*E*)-stilbene and (*Z*)-isomer (*E*/*Z*=40/60).

A priori, the overall retention of configuration can

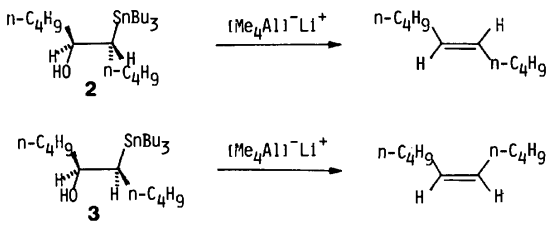
be explained by two ways: (1) S_N2 attack of *n*-Bu_3Sn anion followed by anti-elimination of Bu_3Sn and OAl^-Me_3 groups, or alternatively (2) retentive C–Sn bond formation under the epoxide ring opening and successive syn elimination of above groups. The stereochemistry of the elimination reaction was studied on the reaction of *erythro*- and *threo*-6-(tributylstannyl)-5-decanols (**2** and **3**) with organoaluminum reagent. Reaction of (*E*)- or (*Z*)-5-decene oxide with tributyltin sodium[14] in 1,2-dimethoxyethane gave the desired erythro- or threo isomer (**2** or **3**), respectively. Exposure of *erythro*-6-(tributylstannyl)-5-decanol **2** to [Me_4Al]$^-Li^+$ derived from Me_3Al and MeLi, yielded (*E*)-5-decene exclusively, whereas the threo isomer **3** gave (*Z*)-5-decene with high stereoselectivity (Scheme 2).[15] These results proved that the elimination proceeded in anti fashion[16] and therefore



Scheme 2.

the epoxide ring opening must have proceeded with inversion of its stereochemistry at the carbon bearing oxygen. Moreover, both processes are stereospecific.

The intermediate alkoxy stannanes have not been characterized in the deoxygenation reaction with the reagent **1** and we assume that two positional isomers are present, derived from either mode of S_N2 epoxide opening in the case of unsymmetrical epoxides such as **4**, **5**, **6**, and **7**. This complication in no way impairs conversion to olefins in the case of **4** and **5**, since elimination of *n*-Bu_3Sn and oxide group from each pair of intermediates provides the same (*Z*)-alkene **8** (Scheme 3). Situation is more complicated in the case of epoxides **6** and **7** derived from (*E*)- and (*Z*)-2-nonen-1-ol. The S_N2 type ring opening of the (*E*)-epoxide **6** could afford two isomeric β-oxido stannanes **9** and **10**. The former β-oxido stannane **9** would provide (*E*)-2-nonen-1-ol **11** by anti elimination, whereas the latter isomer **10** would produce 1-nonen-3-ol (**12**) in addition to starting allylic alcohol **11**. The absence of the compound **12** in the reaction mixture implies that a single isomer **9** is produced by epoxide ring opening. We are tempted to assume the following reaction scheme. The hydroxyl group is converted into aluminum alkoxide with the first stannyl reagent. The epoxide-oxygen coordinates to the aluminum and this coordination plays the important role in the product determining ring opening step. The epoxide carbon

(C_3)-oxygen bond is cleaved by the attack of the stannyl anion liberated from the second molecule **1** (Scheme 4)[17]

Another stannylalanate reagent, [*n*-$Bu_3SnAlEt_3$]$^-$-Li^+ derived from *n*-Bu_3SnLi and Et_3Al was as effective as the reagent **1** for the reduction of epoxides, although the prolonged reaction time was needed for the completion (run 5 and 6 in Table 1). A stannylaluminum, *n*-$Bu_3SnAlEt_2$ prepared from *n*-Bu_3SnLi and Et_2AlCl was not effective for the transformation. The starting epoxides were recovered unchanged after heating the reaction mixture in CH_2ClCH_2Cl or THF. High nucleophilicity of tributylstannyl anion of the ate complex **1** could explain the facile epoxide ring opening in S_N2 fashion.

Finally, the reaction of epoxides with silyl-metal reagents such as $[PhMe_2SiAlMe_3]^-Li^+$ and $PhMe_2SiAlEt_2$ were examined. These reagents have proven to be less reactive for the deoxygenation of epoxides than the above mentioned stannyl reagents. Highly reactive epoxides bearing a phenyl substituent only gave the corresponding olefins in moderate yields (Table 2). Other purely aliphatic epoxides such as 5-decene oxide and 1-dodecene oxide gave the complex mixture containing the desired olefins as a minor component (<20%) after prolonged heating in CH_2ClCH_2Cl or benzene.

Experimental

The IR spectra were determined on a Shimadzu IR-27-G spectrometer, the mass spectra on a Hitachi M-80 machine, and the proton NMR spectra on a Varian EM-390 spectrometer, and the ^{119}Sn NMR spectra on a JEOL JNM-FX 90Q spectrometer. The chemical shifts of the proton NMR are given in δ with TMS as an internal standard, and those of the ^{119}Sn NMR are given in δ with tetramethylstannane as an internal standard. The analyses were carried out by the

staff at the Elemental Analyses Center of Kyoto University. Tetrahydrofuran was freshly distilled from sodium benzophenone ketyl. Purificaton of products was performed by column chromatography on silica-gel (Wakogel C-100) or preparative thin-layer chromatography (TLC). Analytical GLPC was performed with a Yanagimoto GCG-550-F and a Shimadzu GC-4CPT.

General Procedure for the Deoxygenation of Epoxide with [n-Bu$_3$SnAlMe$_3$]$^-$Li$^+$. Transformation of (*E*)-5-decene oxide into (*E*)-5-decene is representative. Butyllithium (1.7 M* hexane solution, 3.5 ml, 6.0 mmol) was added dropwise to a suspension of anhydrous $SnCl_2$ (0.38 g, 2.0 mmol) in THF (5.0 ml) at 0 °C under an argon atmosphere. The solution turned to reddish brown immediately. After stirring for 10 min, a hexane solution of Me_3Al (1.0 M, 2.0 ml, 2.0 mmol) was added. The resulting mixture was stirred for another 10 min, then a solution of epoxide (0.16 g, 1.0 mmol) in THF (2.0 ml) was added. The whole was stirred for 24 h at 25 °C and the reaction mixture was poured into 1 M HCl and extracted with ether. The organic layer was dried (Na_2SO_4) and concentrated *in vacuo* to give 5-decene which was purified by silica-gel column chromatography. In order to check the *cis:trans* ratio of the product, the olefin was transformed into epoxide upon treatment with 86% *m*-chloroperbenzoic acid (0.60 g, 3.0 mmol) in CH_2Cl_2. Workup and purification by silica-gel column chromatography gave (*E*)-5-decene oxide exclusively (0.12 g, 80% overall yield): bp 95 °C/15 Torr** (bath temp); NMR (CCl_4) δ=1.83 (t, J=6 Hz, 6H), 1.16—1.46 (m, 12H), 2.30—2.55 (m, 2H). GLPC examination of the epoxide showed only one peak at t_r=4.0 min (Silicone OV-17 3% on Uniport HP, 2 m, 100 °C). The peak at t_r=4.6 min corresponding to (*Z*)-5-decene oxide (NMR (CCl_4) δ 1.83 (t, J=6 Hz, 6H), 1.10—1.46 (m, 12H), 2.30—2.55 (m, 2H)) was not observed.

erythro-*6-(Tributylstannyl)-5-decanol (2).* The title compound was obtained according to the reported procedure[14] using *n*-Bu_3SnCl instead of Ph_3SnCl. A solution of tributyltin chloride (4.1 g, 12.5 mmol) in DME (4.0 ml) was added slowly to a DME solution (10 ml) of sodium naphthalene prepared from sodium metal (0.58 g, 0.025 g-atom) and naphthalene (0.26 g, 21 mmol) to maintain a green color at all times. After complete addition, the solution was stirred for 2 h and then cooled in an ice bath and a solution of *trans*-5-decene epoxide (0.78 g, 5.0 mmol) in DME (2.0 ml) was added dropwise. The resulting solution was stirred for another 1.5 h. Workup and purification by silica-gel column chromatography gave stannyl compound **2** as a colorless oil: bp 140 °C (dec. 0.1 Torr, bath temp); IR (neat) 3350, 2900, 1460, 1385, 1060, 1000 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=0.71—1.05 (m, 21H), 1.10—1.75 (m, 26H), 3.73—3.95 (m, 1H), ^{119}Sn-NMR ($CDCl_3$) δ=−15.7. Found: *m/z* 389.2045. $C_{18}H_{39}O^{119}Sn$: M−C_4H_9 389.2019.

threo-*6-(Tributylstannyl)-5-decanol (3)*: Bp 140 °C (dec. 0.1 Torr, bath temp); IR (neat) 3400, 2900, 1460, 1378, 1070, 1000 cm^{-1}; ^{1}H-NMR ($CDCl_3$) 0.75—1.10 (m, 21H), 1.15—1.75 (m, 26H), 3.70—3.95 (m, 1H), ^{119}Sn-NMR ($CDCl_3$) δ=−19.3. Found: *m/z* 389.1997. Calcd for $C_{18}H_{39}O^{119}Sn$: M−C_4H_9 389.2019.

Elimination of erythro- *and* threo-*6-(Tributylstannyl)-5-decanol to (E)- and (Z)-5-decene.* A solution of *erythro* β-hydroxy stannane **2** (0.67 g, 1.5 mmol) in THF (3.0 ml) was added to a solution of [Me_4Al]$^-$Li$^+$ derived from Me_3Al (1.0 M hexane solution, 3.0 ml, 3.0 mmol) and MeLi (1.5 M ether solution, 2.0 ml, 3.0 mmol) at 0 °C. The mixture was stirred for 40 h at 25 °C. Workup (1 M HCl, ether) and purification by silica-gel column chromatography gave (*E*)-5-decene (0.14 g, 65% yield) which was oxidized into 5-decene oxide upon treatment with *m*CPBA. The purity of the resulting epoxide was found to be >99% (*E*) by the GLPC examination. Starting from *threo* isomer **3** (0.67 g, 1.5 mmol), (*Z*)-5-decene (0.12 g, 57% yield) was obtained as a single isomer (>99% (*Z*)).

Conversion of trans-*2,3-epoxy-1-nonanol (6) into (E)-2-nonen-1-ol.* A solution of [*n*-Bu$_3$SnAlMe$_3$]$^-$Li$^+$ (5.08 mmol) was prepared from *n*-Bu_3SnLi[18] and Me_3Al according to the procedure described above. A THF solution of epoxide **6** (0.20 g, 1.27 mmol) was added and the whole was stirred for 18 h at 25 °C. Extractive workup (1 M HCl, ether) and purification by preparative thin-layer chromatography on silica-gel gave (*E*)-allylic alcohol (0.11 g, 75% yield) as a colorless oil. The alcohol was treated with *m*CPBA to give epoxy alcohol whose purity (>99% (*E*)) was determined by GLPC (t_r=6.0 min, Silicone OV-17 3% on Uniport HP, 2 m, 120 °C). The epoxy alcohol derived from (*Z*)-2-nonen-1-ol had a longer retention time (t_r=7.0 min).

General Procedure for the Deoxygenation of Epoxides by Means of PhMe$_2$SiAlEt$_2$. Reduction of (*E*)-stilbene oxide to (*E*)-stilbene is representative. A THF solution of $PhMe_2SiLi$[19] (0.65 M, 3.0 ml, 2.0 mmol) was added to a hexane solution of diethylaluminium chloride (1.0 M, 2.0 ml, 2.0 mmol) at 0 °C under an argon atmosphere. After stirring for 20 min at 25 °C, the solvent was evaporated *in vacuo* and hexane (8 ml) was introduced to the residue. Then a hexane solution of (*E*)-stilbene oxide (0.20 g, 1.0 mmol) was added and the resulting mixture was stirred at 25 °C for 4 h. The mixture was diluted with AcOEt and poured into 1 M HCl. Organic layer was dried (Na_2SO_4) and concentrated *in vacuo*. The remaining semisolid was submitted to preparative thin-layer chromatography on silica-gel to give (*E*)-stilbene (0.13 g, 71% yield) as crystals which was identical with an authentic sample. The purity of the compound was checked by NMR and GLPC (t_r=8.0 min, Silicone OV-17 3% on Uniport HP, 2 m, 140 °C). (*Z*)-stilbene had a longer retention time (t_r=11.0 min).

Deoxygenation of Epoxide derived from Cinnamyl Alcohol Benzyl Ether by Means of [PhMe$_2$SiAlMe$_3$]$^-$Li$^+$. A hexane solution of Me_3Al (1.0 M, 2.0 ml, 2.0 mmol) was added dropwise to a THF solution of $PhMe_2SiLi$ (0.3 M, 6.5 ml, 2.0 mmol) at 0 °C. After stirring for 10 min, a THF solution of epoxide (0.24 g, 1.0 mmol) was added and the reaction mixture was warmed to room temperature, the whole was stirred for 18 h. The mixture was poured into water and extracted with ether. Purification by silica-gel column chromatography gave cinnamyl alcohol as a colorless oil. GLPC analysis proved that the purity of the alcohol was >97% (*Z*) (t_r=11.5 min, Silicone OV-17 3% on Uniport HP, 2 m, 180 °C). Retention time of (*E*)-isomer was 18.0 min.

Financial support by the Ministry of Education, Science, and Culture (Grant-in-Aid for Special Project Research #59104005) is acknowledged.

Brillouin Scattering of Supercooled Liquids. I. *Tri-o*-tolyl Phosphate

Shinobu KODA, Hiroyasu NOMURA,* Masayuki NAKAMURA, and Yutaka MIYAHARA
Department of Chemical Engineering, School of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
(Received August 6, 1984)

The sound velocities of *tri-o*-tolyl phosphate in the GHz region were measured by means of the Brillouin scattering method over a wide range of temperatures. In the temperature range from 283 to 313 K, the sound velocity dispersion was observed directly. The relaxation curves of the longitudinal modulus could be analyzed using a B.E.L. model with a parameter of K=0.5. With a rising temperature, a deviation from the B.E.L. model appeared. We considered that the deviation was attributed to the rotational molecular motion of *tri-o*-tolyl phosphate.

Supercooled liquids or glassy materials have abnormally large viscosities compared with those of ordinary liquids. The relaxation times of dynamic shear and bulk viscosities of supercooled liquids are so long that they are within the measurable frequency range. Therefore, the supercooled liquids have been accepted as to be pertinent in clarifying the structure and dynamic properties of liquids.

Earlier investigations of the viscoelastic properties of supercooled liquids have been surveyed by Harrison.[1] Most investigations described were those carried out in the MHz region using ultrasonic and dielectric methods.

Barlow, Lamb and their coworkers[2-6] have extensively studied the viscoelastic properties of many supercooled liquids by means of transverse and longitudinal ultrasonic methods. They showed that the shear modulus of supercooled liquids displays a relaxation phenomena and the distribution of the relaxation times was considerably broader than that predicted from the single Maxwellian relaxation model. It was concluded that the relaxation behavior observed in most supercooled liquids can be described in terms of the generalized B. E. L. (Barlow-Erginsav-Lamb) model.[3]

On the other hand, Litovitz and his coworkers[7-11] have given another description of the relaxation phenomena of supercooled liquids. They indicated that the relaxation behavior of supercooled liquids can be explained by taking account of the distribution of the relaxation times of the cooperative motion of the molecules.[11] Moreover, they measured the relaxation times of the shear and bulk moduli of molten salt, B_2O_3, from 650 to 1000 °C and showed that the shear relaxation process can be represented by a single relaxation time in the temperature range above 800 °C where the shear viscosity is of the Arrhenius type. On the other hand, the shear and bulk relaxation processes exhibit an increasingly broad distribution of relaxation times in the non-Arrhenius region of the lower temperatures.[11] They also found that the master curve of the reduced longitudinal modulus of glycerol in the GHz region is not consitent with the corresponding master curve in the MHz region.[9]

In studying the relaxation phenomena of supercooled liquids, it is necessary to perform experiments over wider temperature and frequency ranges. In order to obtain the longitudinal modulus in the GHz region, the Brillouin scattering method is very useful. Recently, several experimental results regarding supercooled liquids investigated by the Brillouin scattering method have been reported.[12-18] In these works, much attention was given to the Rayleigh dip due to the shear mode of the thermal motion of the molecules in liquids. Scant attention was attracted to the longitudinal mode.

The purpose of this study was to obtain the longitudinal sound velocity in the GHz region for *tri-o*-tolyl phosphate using the Brillouin scattering method as a function of temperature and scattering angle. The sample, *tri-o*-tolyl phosphate, was chosen since its longitudinal and shear moduli in the MHz region have been well investigated by the present authors[19] and Barlow *et al.*[2-6] The longitudinal modulus of *tri-o*-tolyl phosphate in the GHz region is compared with those in the MHz region and a discussion is given regarding the basis of the B. E. L. model. The molecular dynamical investigations of the sample were carried out by means of Raman and depolarized Rayleigh scattering methods.

Experimental

Sample. *Tri-o*-tolyl Phosphate, *tris*(2-methylphenyl) phosphate (practical grade) was obtained from Eastman Organic Chemicals. *Tri-o*-tolyl Phosphate is hereafter abbreviated as TOTP. The sample was purified by fractional distillation under reduced pressure and was checked by Raman spectroscopy.

Brillouin Spectra. The Brillouin spectra were measured using a pressure-scanning Fabry-Perot interferometer. The light source was a He-Ne laser (NEC, GLG 5800) with an output of 50 mw. A detailed description of the apparatus and procedure is found in a previous paper.[20]

In order to obtain the Brillouin spectra over wider temperature ranges, a sample cell (as shown in Fig. 1) was used. This cell was made of Pyrex glass and the diameter of

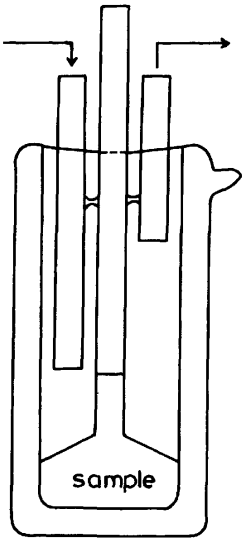

Fig. 1. Brillouin cell. The temperature is regulated by flowing the heated air or cooled air by liquid nitrogen.

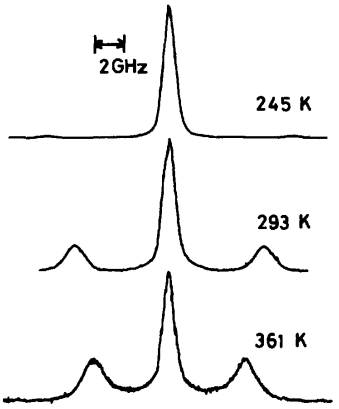

Fig. 2. Representative Brillouin spectra. ($\theta=90°$)

the inner cylinder containing the samle was 5 cm and that of the outer cylinder was 7 cm. The temperature of the sample was regulated by flowing heated and/or cooled air with liquid nitrogen around the inner glass cylinder. The attainable temperature ranges within this cell are from 210 to 350 K with an accuracy of ±1 K. The measured scattering angles were from 20 to 160° for each temerature. The Brillouin spectrum was recorded using an X-Y recorder. At the same time, the spectral intensity and the pressure were punched out on tape as digital data. These data were analyzed to determined the Brillouin frequency shift using a computer.[20] For illustration, the typical Brillouin spectra of TOTP are shown in Fig. 2.

The refractive indexes necessary for the analysis of a sample were measured by means of an Abbe refractometer (Atago) in the temperature range 278 to 337 K.

Raman Spectra. The Raman spectra were measured using a laser Raman Spectrometer JEOL-Ul (Japan Electron Optical Laboratory Co., Ltd.) and an argon ion laser (Coherent Radiation Co., Ltd.), operating at 488 nm (800 mw). The temperature dependence of the Raman spectra was measured with a variable-temperature Raman cell of the Harney-Miller type. The 1047 cm^{-1} band, P-O stretching vibrational mode, of TOTP was measured by using polarizing scattered beam parallel, $I_{\parallel}(\omega)$ and perpendicular, $I_{\perp}(\omega)$ to the electric field vector $\vec{E}$ of the incident light.

Deplorarized Rayleigh Scattering Spectra. The light scattering spectrometer used was consisted of a He-Ne laser (NEC, GLG 5800, 50 mw) and a piezoelectrically driven Fabry Perot interferometer (Burleigh RC 11) with a stabilization system (Burleigh DAS 10, RC 43). The laser beam was irradiated on a sample cell made of quartz. The scattered light at 90° was collimated by a lens through a Glan Thomson prism and the observed spectra were stored in a multichannel analyzer (Anberra Series 30). These spectra could be transfered in a digital form to a microcomputer (Sharp Mz-80c) for further processing. The exeprimental procedures and the correction of instrumental width have been reported elsewhere in details.[21,22] The measuring temperature ranged from 263 to 373 K with an accuracy of±0.5 K.

Results

The sound velocity, V, was calculated from the equation[23]

$$V=\left(\frac{\Delta\omega}{\omega_0}\right)\frac{c}{2n\sin(\theta/2)}, \quad (1)$$

where $\Delta\omega$ is the Brillouin frequency shift, ω_0 the frequency of the incident light, c the velocity of light, n the refractive index of a liquid sample, and θ the scattering angle. The temperature dependence of sound velocities measured at various scattering angles are shown in Fig. 3. It is noted that the constancy of the scattering angle does not always correspond to the constancy of the frequency, because of the temperature dependence of refractive index of a sample. However, as is shown in Fig. 3, at larger scattering angles and lower temperatures, the sound velocity was independent of the scattering angle. This sound velocity can be treated as the sound velocity at the high frequency limit for each temperature. Upon increasing the temperature, the dispersion of sound

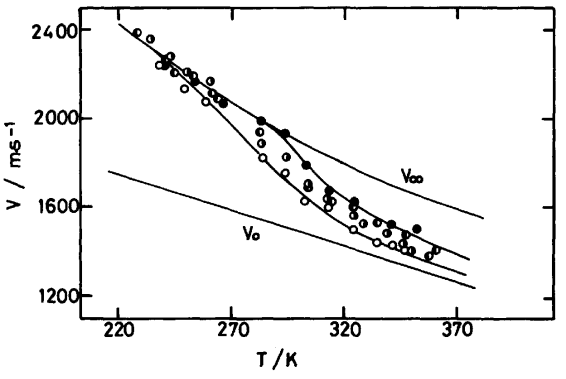

Fig. 3. Temperature dependence of the sound velocity. (●); $\theta=133°$, (◐); $\theta=90°$, (◑); $\theta=60°$, (○); $\theta=35°$.

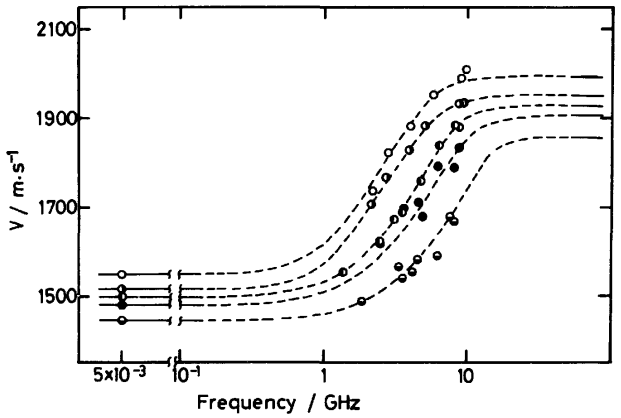

Fig. 4. Frequency dependence of the sound velocity. (○); $T=283$ K, (◑); $T=293$ K, (◐); $T=298$ K, (●); $T=303$ K, (◒); $T=313$ K.

velocity was observed as shown in Fig. 3. On the other hand, Fig. 4 shows the frequency dependence of sound velocity at a constant temperature between 283 and 313 K. The curves clearly show the sound velocity dispersion and the dispersion strength decreases with increasing temperature. In Figs. 3 and 4, the sound velocity at the high frequency limit, V_∞ for each temperature was estimated by extrapolating the V_∞ below 270 K, which were observed directly as shown in Fig. 3. The sound velocity at low frequency limit, V_0, was sometimes measured using by an ultrasonic interferometer working at 4.0 MHz. In wider temperature ranges, the empirical equation proposed by Barlow *et al.*[6] was used.

The Brillouin scattering data also give the Landau-Placzek ratio, $I_R/2I_B$, where I_R and I_B are the intensities of the Rayleigh and Brillouin lines, respectively. However, in this experiment, the accurate intensities of the Rayleigh and Brillouin lines could not be obtained because of the following factors; the diffuse reflection of the cell, a correction of instrumental broadening, the extremely low intensity of Brillouin lines at low temperatures (see Fig. 2) and so on. Therefore, our attention was concentrated upon the Brillouin frequency shift, that is, the sound velocity.

Information regarding the reorientational motion of TOTP can be obtained from an analysis of the Raman line shape[24-26] and/or the depolarized Rayleigh line shape.[27] The half-width refers to the reorientational motion of a molecule, ω_{or}, and can be estimated from the difference between the half-widths of the anisotropic and isotropic Raman lines, $\omega_{anis}(1/2)$ and ω_{isot} (1/2). Details regarding data analysis are presented elsewhere.[28] Figure 5 shows the temperature dependences of $\omega_{isot}(1/2)$ and $\omega_{anis}(1/2)$ after a correction for the broadening effect due to the slit width. As shown in Fig. 5, ω_{or}-

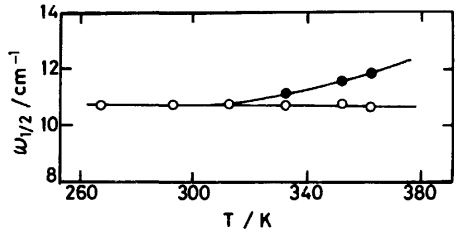

Fig. 5. Temperature dependences of $\omega_{isot}(1/2)$ (○) and $\omega_{anis}(1/2)$ (●).

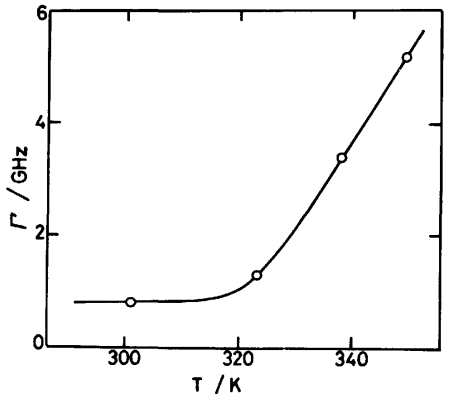

Fig. 6. Temperature dependence of the half-width, Γ, obtained from the depolarized Rayleigh spectrum.

$(=\omega_{anis}(1/2)-\omega_{isot}(1/2))$ was nearly equal to zero at lower temperatures within experimental error, but at a temperature above about 310 K, ω_{or} increased with increasing temperature.

The reorientational correlation times of TOTP can also be obtained from the half-width, Γ, at the half-peak height of the depolarized Rayleigh spectrum.[27] The temperature dependence of Γ after the correction of the instrumental slit width is shown in Fig. 6. In the lower temperature region, the values of Γ do not depend on temperature but at a temperature above 310 K, they increase with increasing temperature.

In the case of a simple molecule, such as a symmetric top, the reorientational correlation time of molecules at a particular molecular axis can be estimated from data of ω_{or} of Raman lines and/or Γ of depolarized Rayleigh lines. However, the molecules such as TOTP are not so simple as to give well defined reorientational correlation times. Therefore, we can not estimate the reorientational correlation time of TOTP from the data of ω_{or} and/or Γ. At least in our opinion, however, ω_{or} and/or Γ can be a measure of the reorientational motion of a molecule in liquids.

Discussion

Generally, there are two mechanisms which give rise to the dispersion of the sound velocity in the GHz region; one is vibrational relaxation due

to an energy transfer from the vibrational mode to the translational motion and the other is the structural relaxation.

The relaxation strength, ε, defined as[29]

$$\varepsilon = \frac{(V_\infty^2 - V_0^2)}{V_0^2}, \tag{2}$$

is shown in Fig. 7 as a function of temperature. The ε, ranging from 220 to 280 K, decreases with increasing temperature. This result indicates that the observed relaxation in this temperature range is not the vibrational relaxation, since the relaxation strength of the vibrational one should increase with temperature.[30] Besides, the value of ε which was estimated theoretically by Planck-Einstein relation was one order of magnitude smaller than those obtained experimentally.[31]

Barlow *et al.* indicated that the relaxation process observed for TOTP in the MHz region can be interpreted as the structural relaxation.[2-6] Figure 8 shows a plot of the longitudinal modulus ($M=1/\rho V^2$) reduced by the shear modulus of the high-frequency limit against the normalized freguency, $\eta\omega/G_\infty$, where η is the viscosity. The values of G_∞ at each temperaure used were those reported previously.[19] The reduced longitudinal moduli result in a master curve within experimental errors. The same quantity

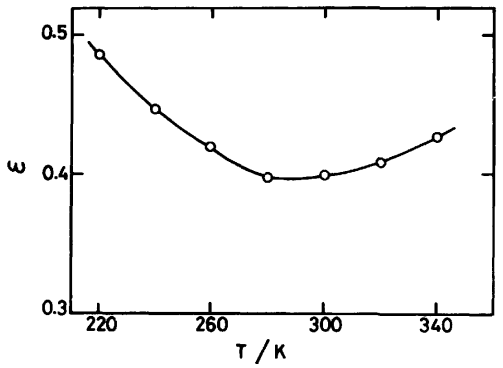

Fig. 7. Temperature dependence of the relaxation strength, ε.

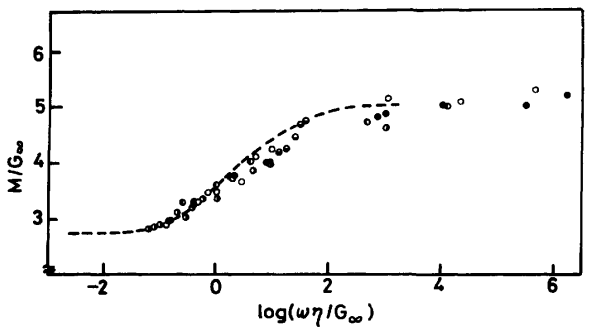

Fig. 8. Values of the reduced longitudinal modulus, M/G_∞, plotted as a function of $\log(\omega\eta/G_\infty)$. The broken line represents the data obtained by Barlow *et al.*[6]

in the MHz region, which was obtained by Barlow *et al.*[6], was compared as in Fig. 8. It seems that the values of M/G_∞ in the GHz region deviate slightly from those in the MHz region.

Various expressions have been used to describe the structural relaxation of supercooled liquids.[1] Such expressions can be classified into two types; one refers to the distribution of the relaxation and the other to the phenomenological parameters. At this stage, it is difficult to determine the distribution function of the relaxation times explicitly and sometimes, a distribution function is assumed. On the other hand, the relaxation behavior of a supercooled liquid in the MHz region is reduced to the normalized curve which is represented by the B. E. L. equation.[3] Moreover, the B. E. L. equation has also been described by a defect-diffusion model at the molecular level.,[32,33] It is worth comparing the applicability of the B. E. L. model to the experimental result in the GHz region.

According to the generalized B. E. L. model,[1,3] the complex compliance $J^*(i\omega)$, is represented by

$$\frac{J^*(i\omega)}{J_\infty^*} = 1 + \frac{G_\infty}{i\eta\omega} + 2K\left(\frac{G_\infty}{i\eta\omega}\right)^{1/2} \tag{3}$$

where J_∞^* is the compliance of the high-frequency limit and K the parameter where $K=0$ corresponds to the single relaxation process of the Mexwellian. Starting from Eq.3, the real parts of the shear, bulk and longitudinal moduli can be estimated. In Figs. 9 and 10, the normalized longitudinal modulus obtained in this experiment is compared with the value estimated from the generalized B. E. L. model. As is seen in Fig. 9, the experimental results are fitted to the generalized B. E. L. model equation, with the value of K being between 0.5 and 1.0. In Fig. 10, the experimental results above $\log(\eta\omega/G_\infty)\geqq 0$ are also reproduced with the generalized B. E. L. equation within experimental errors. The temperature corres-

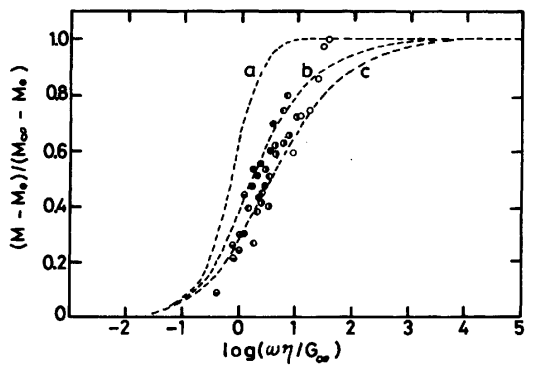

Fig. 9. Values of the normalized longitudinal modulus, $(M-M_0)/(M_\infty-M_0)$ plotted as a function of $\log(\omega\eta/G_\infty)$. The broken lines are calculated for $K=$ 0 (a), 0.5 (b) and 1.0 (c). The symbols are the same in Fig. 4.

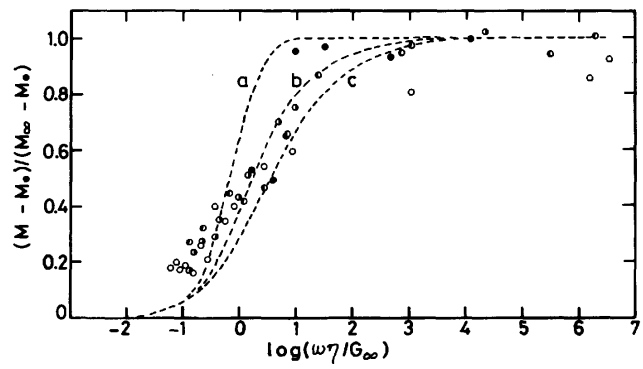

Fig. 10. Values of the normalized longitudinal modulus, $(M-M_0)/(M_\infty-M_0)$ plotted as a function of log $(\omega\eta/G_\infty)$. The broken lines are calculated for K = 0 (a), 0.5 (b) and 1.0 (c). The symbols are the same in Fig. 3.

ponding to $\log(\eta\omega/G_\infty)\simeq 0$ in the GHz region is about 310 K. Therefore,the relaxation of the longitudinal modulus below 310 K is described by the B. E. L. model. Above 310 K, the deviation from the B. E. L. model is appreciable, as can be seen in Fig. 10.

The deviation may be attributed to the following; above 310 K, the dynamic state of TOTP changes and this affects the structural relaxation due to the collective motion of the TOTP molecules. This consideration is supported by the molecular dynamical results of the Raman and depolarized Rayleigh scattering.

The ω_{or} and Γ give information about the molecular motion as described in the previous section. As can be seen in Figs. 6 and 7, the values of ω_{or} and Γ increase with temperature above 310 K. Below that temperature, the value of ω_{or} is nearly equal to zero and that of Γ levels off. These facts indicate that the reorientational motion of TOTP below 310 K is very slow or is almost frozen. Above this temperature, however, reorientational motion will occur. At the same temperature, the temperature dependence of the relaxation strength of sound dispersion of TOTP changed to positive. This asserts that at higher temperatures, the relaxation process may involve the rotational motion of TOTP molecules.

It is a very interesting point how the distribution of relaxation times of the longitudinal modulus relate to the liquid structure and molecular motion. This distribution of relaxation times somewhat depends on the temperature, that is measured frequency ranges (see Fig. 8). At least, we conclude that the deviation from the B. E. L. model at higher temperatures is attributed to the changes of liquid structure of TOTP, especially the changes regarding its dynamical state.

The authors would like to express their appreciation to Dr. T. Kato of Institute of Molecular Science for permission to use the light-scattering spectrometer of depolarized Rayleigh scattering spectra, and also to Mr. T. Watanabe, Glass-technician of Work Shop for Experimentation and Practice, School of Engineering, Nagoya University for making the low temperature cell (see Fig. 1). This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Japan (No. 58540255).

Effects of Addition of Vanadium to Alumina-supported Ruthenium Catalyst on Adsorption and Hydrogenation of Carbon Monoxide

Toshiyuki ENOMOTO, Toshio OKUHARA,* and Makoto MISONO
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Recieved September 29, 1984)

The hydrogenation of carbon monoxide to hydrocarbons (Fischer-Tropsch synthesis) was studied over Ru/Al_2O_3 catalysts to which transition metals such as V, Cr, Mn, and Ag were added. Among these additives, V was most effective for the suppression of methane formation, without changing the olefin/paraffin ratio and the propagation probability. The catalytic activity decreased and the infrared band of adsorbed carbon monoxide shifted only slightly upon the V addition, showing little change in the electronic state of Ru. The particle size of the Ru remained almost unchanged, although the degree of hydrogen adsorption decreased to half. This indicates that Ru particles were partially covered by V (or an oxide of V). The effect on the turnover frequency of hydrogenation of CO was compared with those for the hydrogenation of benzene, and the hydrogenolysis of ethane. These effects were found to be very similar to an ensemble effect reported for $Ru-Cu/SiO_2$ catalysts. On the basis of these results, it is concluded that the addition of V brought about an effect similar to the ensemble effect.

In Fischer-Tropsch synthesis, it has been reported that the addition of some transition metal elements sharply changed the activity and selectivity. A Co catalyst containing a Mn oxide showed a high selectivity to ethylene.[1] Mn and V oxides were also important components for producing lower olefins in composite catalysts based on Fe.[2] In the synthesis of C_2-oxygenated compounds over Rh catalysts, transition-metal elements such as Mn, Fe, Zr, and Ti were also effective additives.[3-5] Although little is known about the structure of these catalysts, bimetallic catalysts composed of group-VIII metals and early transition metals are becoming important in CO hydrogenation.[4]

Ru is the most active catalyst among group-VIII metals for Fischer-Tropsch synthesis,[6] but there is now only a little basic research being conducted regarding the role of additives to it.[7] Mori *et al.* reported that the addition of V or Mo to Ru/Al_2O_3 increased the rate of CO dissociation.[8] We observed that the addition of V to Ru/Al_2O_3 suppressed the formation of methane.[9] In addition, Kikuchi *et al.* have reported that V_2O_3 was an effective support for Ru in the formation of lower olefins.[10]

In the present work, the effects of transition metals added to Ru/Al_2O_3 on both the hydrogenation and the adsorption of CO were studied concurrently. Catalysts were characterized by hydrogen adsorption and electron microscopy (EM), and by comparing the effect of these additives on other reactions.

Experimental

Catalysts. A Ru/Al_2O_3 catalyst was prepared by incipient-wetness impregnation of γ-Al_2O_3 with an aqueous solution of $RuCl_3$.[11] The catalysts containing other transition metals were prepared by the co-impregnation of mixed aqueous solutions of $RuCl_3$ and VCl_3, $Co(OCOCH_3)_2$, $Cr(OCOCH_3)_3$, or $Mn(OCOCH_3)_2$ onto Al_2O_3. The catalyst containing Ag was prepared by the impregnation of an aqueous solution of $AgNO_3$ with the Ru/Al_2O_3 dried at 100 °C. After the impregnation, these catalysts were dried at 100 °C for 10 h. They contained 1.6% Ru, and the atomic ratio of additive-metals to Ru was 1. In the case of V and Cr, the amounts added were varied while keeping the amount of Ru constant. Hereafter, these catalysts will be designated *e.g.*, as $Ru-V(1:5)/Al_2O_3$ and $Ru-Cr(1:1)/Al_2O_3$, where the ratio is the atomic ratio of Ru to the additive metals.

Procedure. The hydrogenation of CO was examined in a closed circulation system (200 cm^3) at 220 °C using a 1:2 mixture of CO and H_2 under a total pressure of 500 Torr (1 Torr=133.3 Pa) with a trap kept at liquid-nitrogen temperature in order to suppress any secondary reactions of products. The activities and selectivities were determined in the second run in which the reaction proceeded at a steady rate.[11] The reaction was also performed in a conventional flow reactor at 260 °C under an atmospheric pressure ($H_2/CO=2$) using 0.6—1.2 g of catalysts.[12] The products were analyzed using gas chromatography. CO and methane were analyzed using a Molecular Sieve 5A column at 25 °C. C_1-C_{12} hydrocarbons were analyzed using an FID gas chromatograph (Yanagimoto GC 2800) equipped with a VZ-10 column and a Silicone SE-30 column. The formation of methanol, ethanol, and acetaldehyde was checked using a Porapak R column and was found to be negligible.

The hydrogenolysis of ethane was carried out in the circulation system at 150 °C under 150 Torr of a 1:2 mixture of ethane and H_2. The hydrogenation of benzene was performed using a pulse method at 120 °C. 50 mg of the catalyst was loaded in a glass tubular reactor (8 mm diameter) and benzene (1 μl) was injected into H_2 stream (25 ml/min) at the inlet of the reactor. All these reactions were carried out after the catalysts were pretreated with H_2 at 450 °C for 2 h.

Other Measurements. The adsorption of CO and H_2 was measured at room temperature with a high-vacuum static system after a reduction by H_2 at 450 °C for 2 h.[11] The infrared spectra of the adsorbed CO were recorded

using an FT-IR (JEOL IR-10) after the same procedure as described previously.[11] Transmission electron micrographs were obtained with a JEOL JEM 1250 electron microscope (1000 keV, final magnification: ×150000). Particles of the catalysts reduced at 450 °C were suspended in water and collected on a microgrid. More than ten micrographs of each catalyst were taken and the particle-size distributions were estimated from a total of 60—90 particles of Ru.

Results

Hydrogenation of CO. Table 1 summarizes the effects of the addition of various metals to Ru/Al_2O_3 regarding the hydrogenation of CO which was carried out in the closed-circulation system. As for the catalytic activity, no remarkable change was observed, except for the Ag which appreciably lowered the activity. The addition of V suppressed the formation of methane and enhanced the selectivity to C_2–C_4 olefins (suppression of methane formation was also found for Mn to some extent). Then, the effect of the content of V was examined in the same system, and compared with the effect of Cr. When the atomic ratio of Cr to Ru increased from 0.1 to 2, both the activity and selectivity remained almost unchanged. On the other hand, upon the addition of V (V/Ru=5 in atomic ratio), the activity decreased to about 1/5 and the selectivity of C_2–C_4 olefins increased from 42 to 64%, and methane decreased from 28 to 22% in weight. To examine the effect of the addition of V in greater detail, the reaction was carried out in the flow system at 260 °C.

Table 1. Effect of the addition of transition metals to Ru/Al_2O_3 on the hydrogenation of CO[a]

Additives[b]	none	V	Ag	Co	Cr	Mn

C_2–C_4 olefins	42	52	46	45	41	38
C_2–C_4 paraffins	7	7	6	11	11	12
$C_{5(+)}$	23	18	11	17	21	27

a) Circulation system, 220 °C, 500 Torr ($H_2/CO=2$). b) Ru : additives = 1 : 1 in atomic ratio. c) 10^2 ml (STP)g-Ru^{-1} h^{-1}. d) Weight percentage.

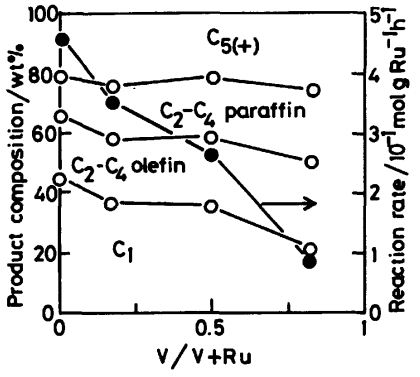

Fig. 1. Effects of the content of V in Ru–V/Al_2O_3 on catalytic activity and selectivity in the CO hydrogenation (flow system, $T=260$ °C, $P=1$ atm, $H_2/CO=2$). The conversion (based on CO) was adjusted in the range of 5—11%.

Figure 1 shows the changes of the reaction rate and selectivity as a function of the V content. The rate decreased monotonously as the V/(V+Ru) ratio increased from 0 to 0.83 (from 0 to 5 in V/Ru ratio). As for the selectivity, the fraction of methane decreased with the increase of the V content; methane was 25% in weight at V/(V+Ru)=0.83, while it was 45% over Ru/Al_2O_3. Due to the difference of the reaction conditions, the selectivity change observed here did not agree quantitatively with that obtained in the circulation system. However, the trend was similar.

The distributions of product hydrocarbons followed the Schultz-Flory plot, as shown in Fig. 2. The propagation probabilities (α) obtained from the slopes were 0.53, 0.53, and 0.57 for Ru/Al_2O_3, Ru–V(1:1)/Al_2O_3 and Ru–V(1:5)/Al_2O_3, respectively. The α values obtained from the intercepts were nearly equal to the α values from the slopes.

Figure 3 shows plots of the distribution of carbon number *vs.* the conversion for Ru/Al_2O_3 and Ru–V(1:5)/Al_2O_3. Over both catalysts, the product distribution was almost independent of the conversion up to about 30%. That is, the lower selectivity to methane observed over Ru–V(1:5)/Al_2O_3 was retained at high conversions.

In Fig. 4, the propene/propane ratio in the product is plotted against the conversion. For comparison, the results for Ru/Al_2O_3 treated with K or P are included in the figure.[9,12] Over these catalysts

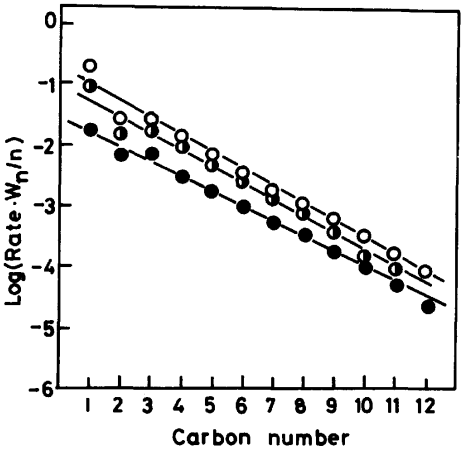

Fig. 2. Schultz-Flory plot (logarithm of $(Rate \cdot W_n/n)$, where W_n is weight percentage, and n is carbon number). The conversion was adjusted in the range of 5—11 %.

except for Ru/Al_2O_3 treated with K, the ratio greatly decreased as the conversion increased. The change in the ratio over $Ru-V(1:5)Al_2O_3$ was not very different from that over Ru/Al_2O_3, while the addition of K and P had great effects on the change in the ratio.[12]

Chemisorption of H_2 and CO. Chemisorption data of H_2 and CO are summarized in Table 2, where H/Ru and CO/Ru are respectively the number of hydrogen atoms or CO molecules adsorbed divided by the number of Ru atoms in the catalysts. The H/Ru decreased monotonously from 0.2 to 0.1 as the ratio of V/Ru increased from 0 to 5. Hereafter, the dispersion will be defined as H/Ru, by assuming that a hydrogen atom is adsorbed on a surface Ru atom at 1:1 stoichiometry.[13] The CO/Ru ratio was always greater than H/Ru, and also decreased as the amount of V increased.

Figure 5 shows the infrared spectra of CO adsorbed on Ru/Al_2O_3 and $Ru-V(1:5)/Al_2O_3$. The spectra were recorded at 25 °C after evacuation at several temperatures. In addition to the high frequency band at 2144 cm^{-1}, broad bands at about 1900—2100 cm^{-1}

Table 2. Adsorption of CO and H_2 on $Ru-V/Al_2O_3$

V/Ru[a]	0	0.2	1.0	5.0
CO/Ru[b]	0.63	0.54	0.59	0.34
H/Ru[c]	0.20	0.16	0.16	0.10

a) Atomic ratio. b) Irreversible adsorption at 25 °C. c) Total adsorption at 25 °C.

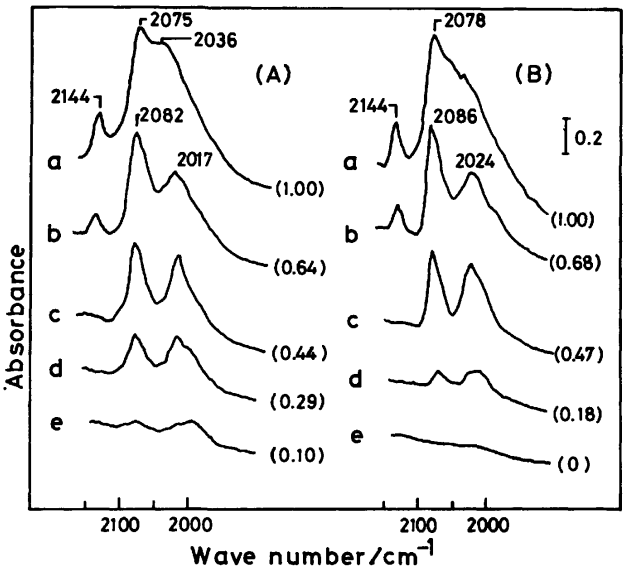

Fig. 5. Infrared spectral changes of adsorbed CO during stepwise thermal desorption on (A) Ru/Al_2O_3 and (B) $Ru-V(1:5)/Al_2O_3$. The spectra of CO were taken at 25 °C after evacuation at (a) 25 °C, (b) 100 °C, (c) 200 °C, (d) 250 °C, and (e) 300 °C. The figures in parentheses are the integrated absorbance relative to that obtained after the evacuation at 25 °C.

were observed over both catalysts. After an evacuation at above 100 °C, three resolved bands appeared at 2144, 2082, and 2017 cm^{-1} over Ru/Al_2O_3, and were quite similar to that on $Ru-V(1:5)/Al_2O_3$. The difference in the band position was less than about 8 cm^{-1}. The figures in parentheses indicate the integrated intensity of the infrared bands of adsorbed CO. The CO bands of the two catalysts decreased very similarly when the evacuation temperature was raised.

Figure 6 shows the particle size distributions of Ru measured by EM after the catalysts were reduced. The distribution pattern on $Ru-V(1:5)/Al_2O_3$ was almost similar to that of Ru/Al_2O_3. The average particle sizes were estimated to be 106 and 104 Å for Ru/Al_2O_3 and $Ru-V(1:5)/Al_2O_3$, respectively.

Effect of V Content on Turnover Frequency. Figure 7 shows the changes in the turnover frequencies (designated as TOF; relative to those over Ru/Al_2O_3) of hydrogenation of CO and benzene, and of hydrogenolysis of ethane as a function of the V content. The TOF values of these reactions all decreased, but the extent of the decrease was greatly

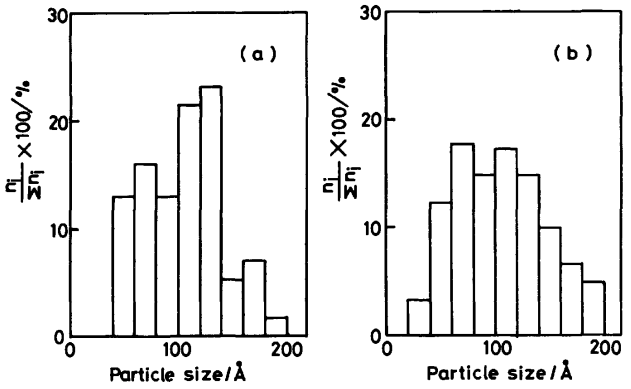

Fig. 6. Distribution of particle size of Ru on (a) Ru/Al_2O_3 and (b) $Ru–V(1:5)/Al_2O_3$. n_i is number of particles having i Å of diameter.

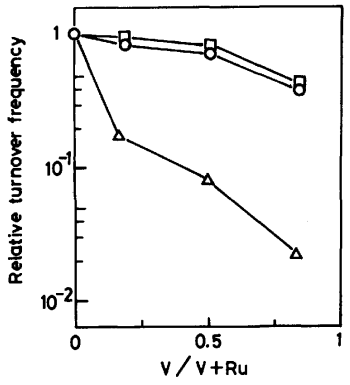

Fig. 7. Changes in TOF of various reactions over $Ru–V/Al_2O_3$ as a function of V content.
○: Hydrogenation of CO (260 °C, 1 atm, $H_2/CO=2$). □: Hydrogenation of benzene (120 °C, 1 atm, in a flowing H_2). △: Hydrogenolysis of ethane (150 °C, ethane; 50 Torr, H_2; 100 Torr).

different depending on the kind of reaction. When V/(Ru+V) was 0.83, the TOF for the hydrogenolysis of ethane lowered to 1/50, while the TOF of the other two reactions decreased only to 1/2.5. It was observed that the addition of Cr (Cr/(Cr+Ru)= 0—0.5) decreased only slightly the TOF for the hydrogenolysis of ethane.

Discussion

Effects of Dispersion caused by the V-addition. As shown in Fig. 6, the particle-size distribution of Ru changed only slightly upon the addition of V, while H/Ru decreased considerably (Table 2). Therefore, the reason for the decrease in H/Ru is probably that the surfaces of Ru particles (≈100 Å) were partially covered with V, and H or CO could not be adsorbed on the V-covered surface. The chemical state of V is not clear at present, but the V is probably present in a form of an oxide.

Several reports[11,14,15] have shown that the dispersion of Ru on Ru/Al_2O_3 greatly affects the TOF of the hydrogenation of CO. When the dispersion of Ru was controlled by altering the amount of loaded Ru, the TOF of the CO hydrogenation increased monotonously from 28×10^{-3} s^{-1} to 117×10^{-3} s^{-1} at 250 °C as the dispersion decreased from 0.60 to 0.23.[14] However, in the present case, when the dispersion (H/Ru) was lowered by the addition of V (V/Ru = 5) from 0.2 to 0.1, the TOF of the CO hydrogenation decreased (Fig. 7). Thus, the decrease in the TOF after the addition of V cannot be explained by any changes in the dispersion. As for the selectivity *vs.* conversion, it was reported that the product distribution was almost independent of the dispersion of Ru in this dispersion range.[11,14,15] Therefore, a considerable decrease in the fraction of methane caused by V (Fig. 1) also indicates that the effects of V are different from the dispersion effect reported.

Amount	−	−	−
Frequency of ir band	+	−	no

+: Increase, −: Decrease, (−): Slight decrease, no: No effect. a) Olefin/paraffin ratio. b) Propagation probability.

Electronic Effects. It is known that the addition of electron-donating additives like alkali metals and electron-withdrawing additives like P changed the electronic state of catalytically active metals. By this effect, the activity and selectivity varied greatly,[16–18] and those changes in the electronic state are reflected in the shift of the infrared bands of adsorbed CO.[12] The effects are summarized in Table 3, in which the effects of V found in the present work are also included. Since no significant shift of the infrared band of adsorbed CO was observed upon the addition of V (Fig. 5), it may be concluded that the change in the electronic state of Ru was small in the case of V-addition.[19] Mori *et al.* also reported that the infrared band position of CO was unchanged upon the addition of V to Ru/Al_2O_3.[20] Furthermore, in contrast to K and P-addition (electronic effect), the olefin/paraffin ratio and the propagation probability little varied upon the addition of V, supporting a small electronic effect for V.

It was reported by Kikuchi *et al.* that when V_2O_3 was used as a suppurt for Ru, the activity was

enhanced and the products shifted to higher hydrocarbons.[10] They assumed that the effect of V_2O_3-support was ascribed to an electron transfer from V_2O_3 to Ru (SMSI effect). This effect of V_2O_3-support on both the activity and selectivity is quite different from that of the addition of V to Ru/Al_2O_3 observed in the present study. Although the details are not clear, the difference in the from of V is a possible reason; for example, Ru is partially covered by V in the present study, while it is not covered in the case of V_2O_3-support.

Ensemble Effects. Considering a model of $Ru-V(1:5)/Al_2O_3$, in which part of Ru surface is covered by V, the changes in the surface structure of Ru seem to have affected the catalytic reactions. It is well known that the addition of an inert group-IB metal to group-VIII metals greatly changes the catalytic activities for hydrogenolysis of hydrocarbons and hydrogenation of CO.[21-23] These changes have usually been ascribed to a geometric effect due to the changes in the size of the surface metal ensemble (ensemble effect), and these reactions are regarded as structure-sensitive reactions.[21,22,23] In the case of bimetallic $Ru-Cu/SiO_2$, the addition of Cu to Ru at 1:1 atomic ratio decreased the amount of hydrogen adsorption to about half and decreased the catalytic activity.[23] But the structure-sensitivity varied depending upon the kind of reactions. The TOF of the hydrogenolysis of ethane decreased to about 1/1000, while that of the hydrogenation of CO decreased 1/50, when Cu was added to Ru at 1:1 atomic ratio, though both were reported to be structure-sensitive.[22,23] This difference in the extent of the decrease of the TOF between the two reactions was quite similar to that observed in the present work (Fig. 7). The TOF decreased to about 1/50 and 1/2.5 for the hydrogenolysis of ethane and the hydrogenation of CO by the addition of V (V/Ru= 5). Therefore, the changes of the activity and selectivity with the addition of V is presumably due to an effect similar to the ensemble effect. As shown in Fig. 2, there was no effect due to the addition of V on the propagation probability. This is in contrast to the case of K and P[12] and is consistent with the fact that the propagation probability is almost independent of the particle size of Ru.[11,14]

A notable change in the selectivity caused by V was a decrease in methane formation (Fig. 1). There is a possibility that methane was produced mainly by the hydrogenolysis of higher hydrocarbons and the addition of V suppressed the hydrogenolysis, since the rate of hydrogenolysis of ethane was greatly decreased by the addition of V, as shown in Fig. 7. However, most of methane was not a secondary product, since the fraction of methane was independent of the conversion (Fig. 3). The suppression of methane formation by the addition of V is probably due to the ensemble effect, since a decrease in the methane selectivity due to the effect has also been observed for Ru-Cu/zeolite.[24] The lower methane formation reported for Fe and Co catalysts containing V or Mn,[1,2] also seems to be brought about by an effect similar to the ensemble effect.

The present work was supported in part by a Grant-in-Aid for Scientific Research No. 58045027 from the Ministry of Education, Science and Culture. We gratefully acknowledge Mr. Hideo Tsunakawa, Engineering Research Institute, for measurement of electron micrograph.

Raman Spectra of Compounds under Inversion Motions. IV. *N*-Methyl-2-pyrrolidone

Kunio FUKUSHIMA* and Masahiro YAMAJI
Department of Chemistry, Faculty of Science, Shizuoka University, 836, Oya, Shizuoka 422
(Received December 8, 1984)

The Raman spectra of *N*-methyl-2-pyrrolidone in various states were measured. Remarkable changes in the spectrum of CH_2 bending vibrations were found besides a spectrum change of the skeletal vibrations. Normal vibration calculations and measurements regarding band-intensity changes associated with temperature changes suggest that a change of the ring conformation takes place in this molecule by hydrogen bonding to a nitrogen atom.

Former studies[1] made it clear that hydrogen bonding to some kind of nitrogen atom causes the frequencies of the Raman bands of the skeltal-deformation vibrations to change remarkably, and the phenomenon was interpreted to be associated with an inversion at the nitrogen. In the present study, *N*-methyl-2-pyrrolidone was investigated from the point of view that the molecule may have a lower potential barrier for inversion at the nitrogen because of a tendency of the CONCC skeleton to form a plane by resonance and, therefore, might show a specific spectrum change due to hydrogen bonding to the nitrogen.

Experimental

Sample *N*-methyl-2-pyrrolidone was a commercial product from Tokyo Kasei Co. (grade GR). The Raman spectra were recorded on a Model R-800T Raman spectrometer (Japan Spectroscopic Co.) with an excitation effected by a Spectra Physics argon ion laser (Model 165) at 514.5 nm (300 mW). The depolarization ratio was measured with a system consisting of a half-wave plate, a lens, and a polarizer. Liquid samples at room temperature were measured with 0.3 ml Raman cells, while crystals, solutions, and pure liquids at lower temperatures were measured with an Oxford-type cryostat and liquid nitrogen. Experimental results are shown in Tables 1 and 2 and Figs. 1—3.

Normal Coordinate Treatment

Normal vibration calculations regarding the axial and equatorial conformers of *N*-methyl-2-pyrrolidone were carried out according to Wilson's GF matrix method[2] by use of the Computation Center, University of Tokyo and the library programs BGLZ and LSMB. The molecular parameters used are: bond

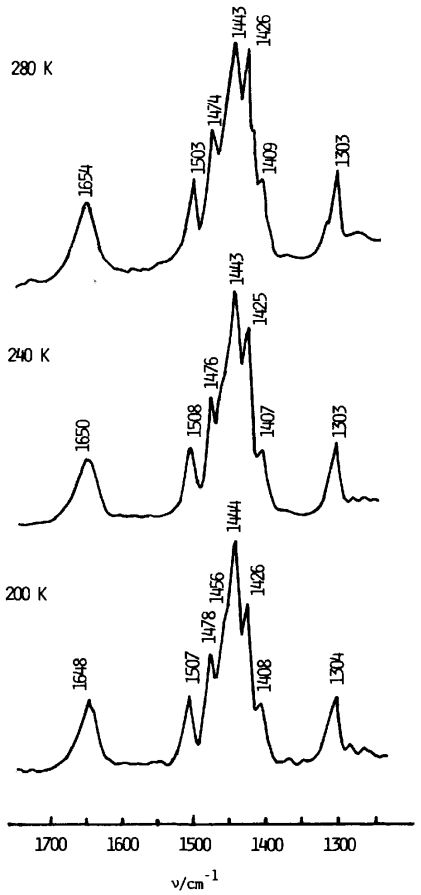

Fig. 2. Temperature dependence of spectra of *N*-methyl-2-pyrrolidone in an aqueous solution (mol fraction of *N*-methyl-2-pyrrolidone : 0.406).

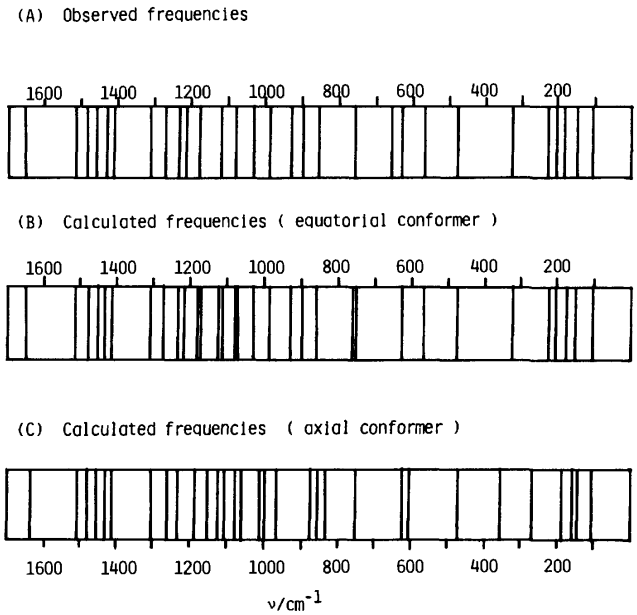

Fig. 3. Calculated frequencies of conformers of *N*-methyl-2-pyrrolidone compared with observed frequencies of pure liquid.

lengths, r(N-CO)=1.48 Å, r(CH_2-CO)=1.53 Å, r(CH_2-CH_2)=1.54 Å, r(CH_2-CN)=1.53 Å, r(CH_2-N)=1.48 Å, r(C=O)=1.24 Å, r(N-CH_3)=1.49 Å, r(C-H)=1.09 Å; bond angles, (CH_2-N-CO)=100.8°, (CH_3-N-CO)=(CH_2-N-CH_3)=111.6°, (CH_2-CO-N)=(CH_2-CH_2-N)=105°, (CH_2-CH_2-CO)=(CH_2-CH_2-CH_2)=104°, (N-C=O)=(CH_2-C=O)=127.5°, and bond angles of CH_3 group=tetrahedral angles.[3,4] For the molecular models, an envelope structure for the five membered ring was used as in the case of *N*-methylpyrrolidine.[5] Most of the force constants used are those of *N*-methylpyrrolidine.[5] The result of the calculation is shown in Fig. 3.

Results and Discussion

Spectrum Change Associated with the State Change from Liquid to Solid. As shown in Table 1, no appreciable spectrum change was observed except for the change in the region, 100 cm^{-1}—250 cm^{-1} where several new bands of lattice vibrations appear in the spectrum of the solid, and also the appearance of some bands in the spectra of the solid, which were not clearly observed in the spectra of the pure liquid because of weakness and broadness. This shows that one kind of conformer exists both in the solid and liquid states.

Spectra of Solutions for Non Hydrogen Bonding Solvents. The spectra of *N*-methyl-2-pyrrolidone in benzene, carbon tetrachloride, acetone, acetonitrile, and pyridine are almost the same as that of a pure liquid. Therefore, the conformer in these solutions is the same as that of a pure liquid. In Table 2, as a representative, the Raman bands of benzene solution are shown.

Spectrum Change Associated with Solution into Hydrogen Bonding Solvents. Change of Raman bands of skeletal deformation vibrations: The Raman bands at 310 cm^{-1} and 170 cm^{-1} in the spectra of a pure liquid shift to 325 cm^{-1} and 225 cm^{-1}, respectively, in spectra of solutions (refer to Table 1). A normal vibration calculation shows that these frequency shifts are not caused by a conformational change, equatorial conformer to axial conformer (refer to Fig. 3) and also that the former band is due to the vibrational mode of the C-N-C skeleton. These shifts, along with temperature dependence of intensities of these bands, suggest that the same kind of change of valence state of nitrogen atom (as described in former studies[1]) also takes place in this molecule. Corresponding frequencies for solutions of formic acid, acetic acid or aqueous hydrochloric acid (refer to Table 2) confirm that the frequency change in aqueous solutions is due to conformational change arising from the change of valence state of nitrogen atom.

The band of pure liquid at 170 cm^{-1}, which is

ν: Raman shift frequency. I: relative intensity. ρ: depolarization ratio. *: solvent band.

assigned to C-C, C-N torsional modes by normal vibration calculation and, therefore, is caused by ring vibration, shifts by 55 cm^{-1} on hydrogen bond formation to nitrogen atom. This change of ring vibration associated with hydrogen bond formation is a discovery in the present study along with the following remarkable change of CH_2 bending vibrations.

Remarkable Change of Raman Bands of CH_2 Bending Vibration: As shown in Table 1 and Fig. 1, a remarkable spectrum change was observed for aqueous solutions in the region of 1400—1550 cm^{-1}. With a decreasing concentration of *N*-methyl-2-pyrrolidone, intensities of the bands at 1401 cm^{-1}, 1431 cm^{-1}, 1503 cm^{-1} decrease, while those of the newly observed bands at 1410 cm^{-1}, 1450 cm^{-1}, 1510 cm^{-1} increase, The band at 1458 cm^{-1}, 1473 cm^{-1} also increase their intensities. These bands are clearly assigned to the CH_2 bending vibrations. Usually, the CH_2 bending vibrations do not show any great changes, and such a change has not been reported so far. It is amazing that the CH_2 bending bands of the

molecule change so much. The band at 1426 cm^{-1} decreases in intensity as the temperature decrease, while the band at 1443 cm^{-1} increases its intensity (refer to Fig. 2).

From the measurement of the intensity change, an enthalpy change of −2.0 kJ/mol was obtained, showing that the latter band is assigned to the conformer having a smaller enthalpy value and therefore, it is due to the hydrogen-bonded conformer. Considering the change of the band at 170 cm^{-1}, which shows a change in ring conformation by hydrogen bonding, the above change of the CH_2 vibration bands suggests that the shape of the ring in the molecule changes by hydrogen bonding to a nitrogen atom, and the electronic state of the carbon atom of the CH_2 groups changes to cause a remarkable change in the CH_2 vibrations. As the skeleton of 2-pyrrolidone was reported to take a planar conformation,[3] the real molecular ring of *N*-methyl-2-pyrrolidone might be also an almost planar ring a little different from the envelope model, which is commonly approved for five-membered ring and used in the present calculation, and nitrogen atom might be nearly in sp^2 state. The above spectrum change may be caused by the change of the sp^2 state of nitrogen into an sp^3 state by hydrogen bond formation.

For solutions for formic acid, acetic acid, aqueous hydrochloric acid, where a proton is attached to the nitrogen atom to form an sp^3 state nitrogen atom, only three bands appear at ≈1415 cm^{-1}, ≈1453 cm^{-1} and ≈1474 cm^{-1}, which correspond to the bands at ≈1410 cm^{-1}, ≈1450 cm^{-1}, and ≈1477 cm^{-1} increasing intensities in aqueous solutions. This is more evidence that the change in aqueous solutions may be a state change of the nitrogen atom from sp^2 to sp^3.

Role of the Intermediate Layer and Factors Determining Chemical Composition of the Film in the Electroless Ferrite-plating

Yutaka TAMAURA,* Yukitoshi TANNO,† and Masanori ABE†

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

†*Department of Physical Electronics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152*

(Received August 21, 1984)

This paper describes electroless ferrite-plating on a Cu substrate whose surface is oxidized (the Cu-oxide layer works as an intermediate layer for the plating). Electron-diffraction and cathodic-reduction analyses showed that a Fe_3O_4 thin layer is formed on the intermediate layer during the initial reaction of the plating. This thin layer grows by the repetition of the adsorption of metal ions to the surface of the layer and the oxidation of the adsorbed Fe^{II} ions. Based on the adsorption-equilibrium of the metal ions on the surface of the film, the relationship between the composition of the metal ions adsorbed and that of the metal ions incorporated into the Co-ferrite film was formulated in terms of the concentrations of the metal ions in the reaction solution and the reaction pH. The analysis of the experimental data with this equation showed that the Co^{II} ions are more readily incorporated into the ferrite layer, as the mol ratio of the adsorbed Co^{II} ions to adsorbed iron ions ($R_{ads.}$) increases, but that a higher $R_{ads.}$ becomes unfavorable for the incorporation.

Recently, we reported a new method which enables the formation of crystalline-spinel film in an aqueous solution at low temperatures (below 80 °C).[1,2] Ferrite films are formed on the substrates by the oxidation of a mixed suspension of Fe^{II} and other metal ions (M^{n+}) in which the substrates are soaked. We can use various oxidizing agents such as air ("the air-bubbling method"), nitrate ion, hydrogen peroxide *etc.*, and anodic current. Thus, our method is a kind of electroless (chemical) plating or electro-plating. In the electroless ferrite plating on the poly(ethylene terephthalate)(PET) and stainless-steel substrates, an intermediate layer (an oxide layer of chemically plated copper or electro-plated Fe_3O_4) is required.[1,2]

The purposes of the present paper are 1) to clarify the initial reaction occurring on the intermediate layer of copper oxide in the electroless ferrite plating, and 2) to study the relationship between the adsorption behavior of the metal ions and the composition of the ferrite films formed during the electroless plating. For the performance of the study on the latter subject, we have devised a specially designed apparatus. We call the method using this apparatus, "the rotating-disc method."

Experimental

Chemicals and Substrates. Chemical reagents of analytical grade were used. NaOH solutions were prepared by dissolving NaOH in distilled water free from CO_2 and O_2. Copper sheets (30 μm×10×20 mm) whose surface had been oxidized in air at 160 °C for 30 min, were used as substrates.

Experiment of the Initial Reaction. After passing nitrogen gas into the solution containing Fe^{II} ions (17 mmol dm^{-3}, pH 7.0, T=70 °C) for 2 h, the Cu-substrate was dipped in the solution for 30 s—2h under a nitrogen atmosphere. The electron-diffraction pattern and cathodic-reduction curves of the oxides formed on the substrate were taken. The cathodic-reduction curves were taken using a Beckman Electroscan Model 30, applying a DC current at 10 A cm^{-1} in a stagnant borate buffer solution (pH 8.4, consisting of equal volumes of 0.075 mol dm^{-3} $Na_2B_4O_7 \cdot 10H_2O$ and 0.075 mol dm^{-3} H_3BO_3 solutions) at 25 °C under a slow nitrogen gas stream. The borate buffer solution was deaerated before the measurement by passing nitrogen gas for several hours.

The Rotating-disc Method. A specially designed

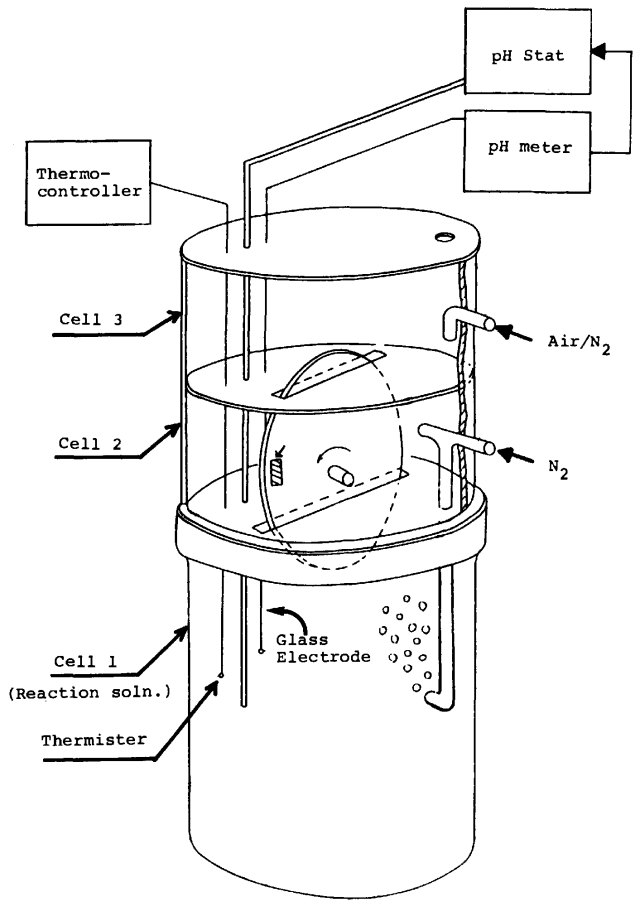

Fig. 1. The improved apparatus used for the chemical ferrite-plating.

apparatus (as illustrated in Fig. 1) was used. It is composed of three separated cells of a reaction solution (cell-1), an N_2 ambient to screen the reaction solution from oxygen (cell-2), and an air/N_2 (1:50) ambient (cell-3).

The Cu-substrates were mounted on the disc, and Cell number 1 was filled with about 1 dm^3 of distilled water through which nitrogen gas had been passed for 1 h to remove any dissolved oxygen. Nitrogen gas was passed through all the cells. After raising the temperature of the water in cell 1 to 70 °C, $FeCl_2 \cdot 3.5H_2O$ and $CoCl_2 \cdot 6H_2O$ were dissolved (Fe^{II}; 5.2 mmol dm^{-3}, Co^{II}; 0—15 mmol dm^{-3}). The pH was adjusted to a desired value (6.0—7.5) by adding an NaOH solution, and then the disc was rotated at 50—60 min^{-1}. After 5 min, the air/N_2 gas (1:50) was passed through cell 3 in place of nitrogen gas. After 2 h, the rotation of the disc was stopped, and the substrates were removed from the disc. The phase of the film was examined by electron and X-ray diffraction methods.

In "the rotating-disc method", the oxidation reaction takes place only on the surface of the substrate in cell 3, and a little amount of the metal ions are consumed during the formation of the ferrite film. Therefore, the concentrations of the metal ions in the reaction solution can be kept constant during the reaction. The thickness of the film was estimated by the chemical analysis of the film, assuming the chemical formula of $(Fe, Co)_{3.00}O_{4.00}$ and the density equal to that for $CoFe_2O_4$.

Chemical Anaylsis. Iron and cobalt contents in the ferrite films were determined by the atomic absorption method after dissolving the films in an HCl solution (1:1).

Results and Discussion

Formation of a Thin Fe_3O_4 Layer on the Cu-substrate in the Initial Reaction. The electron-diffraction

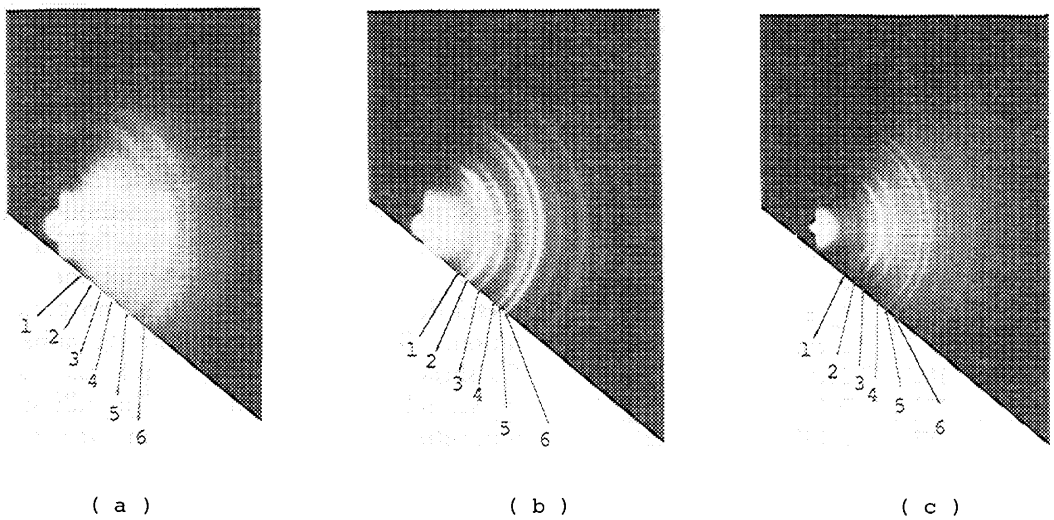

Fig. 2. Electron diffraction photographs for (a) the surface coating as formed on the Cu-sheet, (b) the Fe_3O_4 layer top coating formed on the Cu-oxide coating, and (c) a Co-ferrite film ($Co_{0.3}Fe_{2.7}O_4$) prepared by the rotating-disc method.

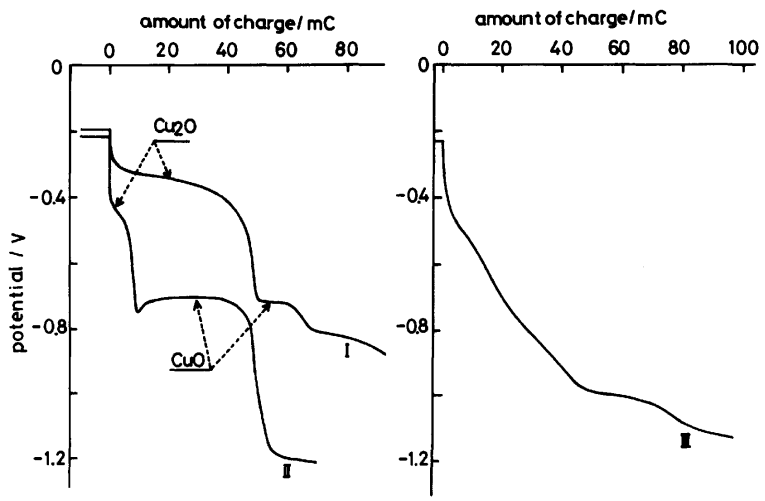

Fig. 3. Cathodic reduction curves for (a) the surface coating as formed on the Cu-sheet by heating in air at 160 °C for 10 min.(curve I) and 30 min.(curveII), and (b) the Fe_3O_4 top coating formed on the Cu-oxide coating.

pattern (Fig. 2a) and the *d* values (Table 1a) showed that the surface of the Cu-substrate was covered with oxide layers of Cu_2O and CuO. Curves I and II in Fig. 3a show the cathodic-reduction curves of the coatings formed on the Cu-substrate by heating in air at 160 °C for 10 and 30 min, respectively. They show two plateaus at the potential characteristic of CuO and Cu_2O, respectively. The ratio of CuO/Cu_2O increases as the heating time increases from 10 to 30 min. When the Cu-substrate with the Cu-oxide coating (30 min oxidation) was soaked in the reaction solution containing Fe^{II} ion (17 mmol dm^{-3}) at pH 7.0 and 70 °C under a nitrogen atmosphere for 30 s, a thin Fe_3O_4 layer was formed on the Cu-sheet substrate, as shown by the electron diffraction data and the cathodic-reduction measurement of Fig. 2b, Table 1b, and Fig. 3b. The layer was very thin; strong metallic copper color appeared through the film (its thickness could not be measured). This reaction was completed almost instantly; the thin Fe_3O_4 layer did not grow any more, even though the dipping time was extended to 2 h. It is assumed that the Fe^{II} ions are oxidized on the surface of the Cu-oxide layer, and that the thin Fe_3O_4 layer is deposited on its surface. This reaction will stop when the surface of the Cu-sheet substrate is completely covered with the thin Fe_3O_4 layer. This would be the cause for the formation of the thin layer. The formation of ferrite films (or particles) in the aqueous solution proceeds in two stages;[1-4] 1) the adsorption of the metal ions to the solid surface, and 2) the ferrite-formation with the oxidation of Fe^{II} ions to Fe^{III}. The Cu-oxide coating on the Cu-sheet substrate exhibits the activity of not only adsorbing the ions but also oxidizing Fe^{II} into Fe^{III}, thus forming the thin Fe_3O_4 layer.

Table 1. The "*d*"-values observed in the electron diffraction patterns of Figs. 1(a), (b), and (c), which are compared to literature values obtained by X-ray diffractometry for Cu-oxides, Fe_3O_4, and $CoFe_2O_4$, respectively

Formation of Co-ferrite Films on the Cu-substrate by "the Rotating-disc Method." Figure 2c and Table 1c show the results of the electron diffractometry on the Co-ferrite film ($Co_{0.3}Fe_{2.7}O_4$, 370 nm thickness) deposited by "the rotating-disc method" (the mol ratio of $Co^{II}/Fe^{II}=0.50$ in the reaction solution, pH 7.0). X-ray diffractometry showed that the film has the crystallized spinel structure with no preferred orientation. This film showed strong adhesion to the Cu-sheet substrate, and could not be detached by scratching with a nail. The adhesion and the magnetic property of the film will be published elsewhere.[5] Co-ferrite films with various compositions ($Co_xFe_{3-x}O_4$, $x=0.10$—0.52; the oxidation state of the Co-ferrite film is not unequivocal) were plated on the Cu-substrate in the pH range of 6.5—7.5 and at the mol ratios of $[Co^{II}]/[Fe^{II}]=0.5$—3.0 in the reaction solution. At pH 5.5, where little amount of the metal ions of Fe^{II} and Co^{II} are adsorbed,[3] no Co-ferrite films were deposited, although we used the substrate whose surface had been oxidized.

The reaction mechanism of the formation of the Co-ferrite film is considered as follows: When the substrate is dipped into the reaction solution (pH 7.0), Fe^{II} and Co^{II} ions are adsorbed on the surface of the Cu-oxide coating. When some of the adsorbed Fe^{II} ions are oxidized by Cu-oxide, the metal ions (Fe^{II}, Fe^{III}, Co^{II}) on the surface are transformed into a Co-ferrite, forming a thin ferrite layer on the surface. The ferrite layer, thus formed, can adsorb the Co^{II} and Fe^{II} ions. Some of the adsorbed Fe^{II} ions are oxidized by oxygen in cell 3, and a new Co-ferrite layer is formed. These adsorption-oxidation reactions are repeated by rotating the disc, which results in the growth of the ferrite layer.

The adsorption reaction occurs at a higher rate than

that of the ferrite-formation reaction;[3] the adsorption reaction is the rate-determining step. Furthermore, in "the rotating-disc method", the concentrations of the metal ions in the reaction solution (cell-1) are kept constant. This means that, in "the rotating-disc method", the chemical composition of the ferrite film can be discussed based on the adsorption-equilibrium of the metal ions in terms of the concentrations of the metal ions and the reaction pH.

Effect of Concentrations of Metal ions in the Reaction Solution and the Reaction pH on the Composition of the Co-ferrite Films. We assume here that a layer of ferrite, say Fe_3O_4, has been already formed on the oxide coating of the substrate. The OH group at the solid/liquid interface exhibits an amphoteric property, as

$$\begin{matrix} Fe^{3+} \\ >O^- \\ Fe^{2+} \end{matrix} \overset{H^+}{\rightleftharpoons} \begin{matrix} Fe^{3+} \\ >OH \\ Fe^{2+} \end{matrix} \overset{H^+}{\rightleftharpoons} \begin{matrix} Fe^{3+} \\ >OH^{2+}. \\ Fe^{2+} \end{matrix} \quad (1)$$

The OH group works as the adsorption site for the metal ions. In general, there are two types of adsorption, *i.e.*, those unaccompanied and accompanied by hydrolysis: For the Fe^{2+} ions

$$\begin{matrix} Fe^{3+} \\ >OH \\ Fe^{2+} \end{matrix} + Fe^{2+} \overset{K_1^{Fe}}{\rightleftharpoons} \begin{matrix} Fe^{3+} \\ >O^-\text{-}Fe^{2} \\ Fe^{2+} \end{matrix} + H^+ \quad (2a)$$

and

$$\begin{matrix} Fe^{3+} \\ >OH \\ Fe^{2+} \end{matrix} + Fe^{2+} + H_2O \overset{K_2^{Fe}}{\rightleftharpoons} \begin{matrix} Fe^{3+} \\ >O^-\text{-}Fe^{2+}\text{-}OH^- \\ Fe^{2+} \end{matrix} + 2H^+, \quad (2b)$$

and for the Co^{2+} ions,

$$\begin{matrix} Fe^{3+} \\ >OH \\ Fe^{2+} \end{matrix} + Co^{2+} \overset{K_1^{Co}}{\rightleftharpoons} \begin{matrix} Fe^{3+} \\ >O^-\text{-}Co^{2+} \\ Fe^{2+} \end{matrix} + H^+, \quad (2a')$$

and,

$$\begin{matrix} Fe^{3+} \\ >OH \\ Fe^{2+} \end{matrix} + Co^{2+} + H_2O \overset{K_2^{Co}}{\rightleftharpoons} \begin{matrix} Fe^{3+} \\ >O^-\text{-}Co^{2+}\text{-}OH^- \\ Fe^{2+} \end{matrix} + 2H^+. \quad (2b')$$

Here, K_1^{Fe} and K_2^{Fe} (K_1^{Co} and K_2^{Co}) are the equilibrium constants for the adsorption of the Fe^{2+} (Co^{2+}) ions. The adsorption unaccompanied by the hydrolysis (Eqs. 2a and 2a') dominates when the pH of the solution is low, while that accompanied by the hydrolysis (Eqs. 2b and 2b') dominates when the pH is high.[6] When some of the Fe^{II} ions [adsorbed following Eqs. 2a and 2b] are oxidized, the ions on the surface (Fe^{II}, Fe^{III}, and Co^{II}), both hydrolyzed and unhydrolyzed, are transformed into spinel ferrite.

In the rotating-disc method, the concentrations of the Fe^{II} and Co^{II} ions in the solution are kept constant. In the pH range studied here (6—7.5), almost all of the Fe^{II} and Co^{II} ions in the solution are Fe^{2+} and Co^{2+}. Therefore, the equilibrium constants for the adsorption of the ions are expressed in terms of the concentrations in the reaction solution of cell-1 (Fig. 1) as follows:

For Eqs. 2a and 2b,

$$K_1^{Fe} = [>O^-\text{-}Fe^{2+}][H^+]/([Fe^{2+}][>OH]), \quad (3a)$$

$$K_2^{Fe} = [>O^-\text{-}Fe^{2+}\text{-}OH^-][H^+]^2/([Fe^{2+}][>OH]), \quad (3b)$$

and for Eqs. 2a′ and 2b′,

$$K_1^{Co} = [>O^-\text{-}Co^{2+}][H^+]/([Co^{2+}][>OH]), \quad (3a')$$

$$K_2^{Co} = [>O^-\text{-}Co^{2+}\text{-}OH^-][H^+]^2/([Co^{2+}][>OH]). \quad (3b')$$

Here, $[H^+]$, $[Fe^{2+}]$, and $[Co^{2+}]$ are the concentrations of the respective ions in the solution, [>OH] is that of the adsorption site, and $[>O^-\text{-}Fe^{2+}]$,$[>O^-\text{-}Fe^{2+}\text{-}OH^-]$, $[>O^-\text{-}Co^{2+}]$, and $[>O^-\text{-}Co^{2+}\text{-}OH^-]$ are those of the Fe^{II} and Co^{II} ions adsorbed without and with the hydrolysis*, respectively.

The ratio of the adsorbed Co^{II} ions to the adsorbed Fe^{II} ions is given by

$$\begin{aligned} R_{ads.} &= (Co/Fe)_{ads.} \\ &= ([>O^-\text{-}Co^{2+}] + [>O^-\text{-}Co^{2+}\text{-}OH^-])/ \\ &\quad ([>O^-\text{-}Fe^{2+}] + [>O^-\text{-}Fe^{2+}\text{-}OH^-]) \end{aligned} \quad (4)$$

Using Eqs. 3a—3b′, we can substitute the adsorbed-ion concentrations in Eq. 4 with the ion concentrations in the reaction solution as

$$R_{ads.} = ([Co^{2+}]/[Fe^{2+}])(K_1^{Co}[H^+] + K_2^{Co})/(K_1^{Fe}[H^+] + K_2^{Fe}). \quad (5)$$

Now, we introduce a ratio, t, as

$$t = R_{film}/R_{ads.}, \quad (6)$$

where R_{film} is the mol ratio of Co^{II} to Fe_{total} in the ferrite film. From Eqs. 5 and 6, we obtain

$$\log R_{film} = \log \frac{[Co^{2+}]}{[Fe^{2+}]} + \log\left(t\frac{K_1^{Co}[H^+] + K_2^{Co}}{K_1^{Fe}[H^+] + K_2^{Fe}}\right) \quad (7)$$

which expresses R_{film} as a function of $[Co^{2+}]/[Fe^{2+}]$, t, and the pH. Figure 4 shows the relationship between log R_{film} and pH at $[Co^{2+}]/[Fe^{2+}]$=0.50, 0.75, and 3.0. The composition of the ferrite film (R_{film}) increases linearly with an increase in the reaction pH at a given mol ratio of $[Co^{2+}]/[Fe^{2+}]$. Thus, the second term of the right side in Eq. 7 varies linearly with the reaction pH (the 1st term is constant for each curve.)

Here, we discuss the ratio t. Assuming that t at $[Co^{2+}]/[Fe^{2+}]$=3.0 (Curve A in Fig. 4) as t_o, and those for 0.75 and 0.5 (Curves B and C in Fig. 4) as t_n, we can calculate t_n/t_o for various pH values

* The concentrations of the ions, *i.e.*, $[H^+]$, $[Fe^{2+}]$, and $[Co^{2+}]$, are expressed in the unit of mol/volume, while those of the adsorption sites and the adsorbed ions, *i.e.*, [>OH], $[>O^-\text{-}Fe^{2+}\text{-}OH^-]$, $[>O^-\text{-}Co^{2+}]$, *etc.*, are in number/area.

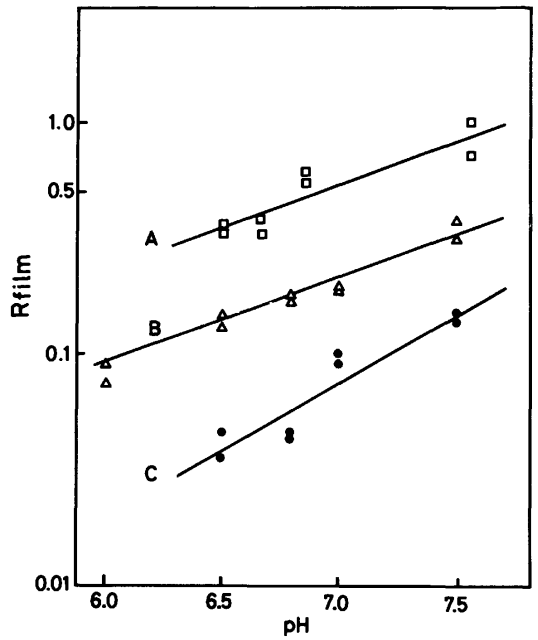

Fig. 4. The pH dependence of the atomic ratio (R_{film} =Co/Fe) of the films prepared by the rotaing-disc method using the solutions with the ion ratios of [Co^{II}]/[Fe^{II}]=3.0 (Curve A), 0.75 (B), and 0.50 (C).

using Eq. 7. When the t_n/t_o is k_n, Eq. 6 is rewritten as

$$\log R_{film}/k_n = \log R_{ads.} + \log t_0. \quad (8)$$

Since t_o is constant for a given pH value, Eq. 8 shows that the change in the value of log R_{film}/k_n at constant pH value is that in the value of $R_{ads.}$ Thus, for a given reaction pH, the relationship between k_n and R_{film}/k_n will give how the $R_{ads.}$ affects the incorporatation of the Co^{II} ions into the ferrite layer. This is given by Fig. 5. As can be seen here, the Co^{II} ions are more readily incorporated into the ferrite layer, as the mol ratio of the adsorbed Co^{II} ions to the adsorbed iron ions ($R_{ads.}$) increases. However, a higher $R_{ads.}$ becomes unfavorable for the incorporation.

Conclusion

(1) In the initial reaction of the electroless ferrite-plating, the intermediate layer of the Cu-oxide adsorbs the metal ions and oxidizes the adsorbed Fe^{II} ions, and a thin ferrite-layer is formed on the surface.

(2) Co-ferrite films ($Co_xFe_{3-x}O_4$, x=0.10—0.52) were plated on the Cu-substrate with the intermediate layer of the Cu-oxides by "the rotating-disc method" in the pH range 6.5—7.5 and at the mol ratios of [Co^{II}]/[Fe^{II}]=0.5—3.0 in the reaction solution (T=70 °C).

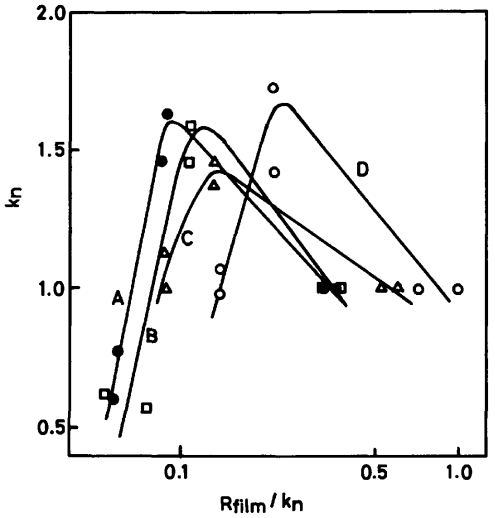

Fig. 5. The relationship between k_n and R_{film}/k_n at pH 6.5 (Curve A), 6.8(B), 7.0(C), and 7.5(D).

(3) Based on the adsorption-equilibrium of the metal ions on the surface of the film, the relationship between the composition of the metal ions adsorbed and that of the metal ions incorporated into the Co-ferrite film was formulated in terms of the concentrations of the metal ions in the reaction solution and the reaction pH. The analysis of the experimental data with this equation showed that the Co^{II} ions are more readily incorporated into the ferrite layer, as the mol ratio of the adsorbed Co^{II} ions to adsorbed iron ions ($R_{ads.}$) increases, but that a higher $R_{ads.}$ becomes unfavorable for the incorporation.

Solubility of Tris(acetylacetonato)chromium(III) in Aqueous Alcohol Mixtures

Manabu YAMAMOTO
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda, Nakaku, Hiroshima, 730
(Received December 10, 1984)

From the temperature dependence of the solubility of tris(acetylacetonato)chromium(III) in aqueous *t*-butyl alcohol mixtures and in aqueous methanol mixtures, thermodynamic parameters of the solution were calculated. The solubility and these parameters in aqueous *t*-butyl alcohol mixtures could be explained qualitatively by the cavity formation terms of the scaled particle theory. It was suggested that tris(acetylacetonato)chromium(III) is in water microphases at $X_{BuOH} \leqq 0.04$ and in *t*-butyl alcohol microphases over this region.

2,4-Pentanedione(acetylacetone) is one of the most useful reagents in analytical chemistry to separate a particular metal ion from various matrixes. Besides the analytical purpose, acetylacetonato complexes such as tris(acetylacetonato)chromium(III) ($Cr(acac)_3$), and tris(acetylacetonato)cobalt(III) ($Co(acac)_3$) seem to be useful model compounds in solution chemistry to clarify solute-solvent interactions of metal chelates as they are stable, large, spherical and rigid solutes.[1,2]

In a previous study,[1] the solubility of $Cr(acac)_3$ was measured from 5 to 75 °C in water, which shows a characteristic feature of a hydrophobic solute with a solubility minimum at 45 °C. With a hard sphere diameter of 8.97 Å for $Cr(acac)_3$, a cavity formation term was calculated by the scaled particle theory (SPT),[3,4] and it was shown that the aqueous solubility of $Cr(acac)_3$ could be explained qualitatively by the cavity formation term.

In the present study, the solubility of $Cr(acac)_3$ was measured in aqueous *t*-butyl alcohol and a few of aqueous methanol mixtures, and the dependences of the solubility on the temperature and concentrations of alcohols were examined in connection with the structural properties of the solvents.

Experimental

A preparation of $Cr(acac)_3$ was given in the previous paper.[1] *t*-Butyl alcohol (*t*-BuOH) was a special grade and methanol (MeOH) was a liquid chromatography grade. The procedure for the solubility measurement followed that of the previous study.[1] Solubility measurements were performed from 5 to 60 °C for X_{BuOH} of 0.005 to 0.015 and X_{MeOH} of 0.025 to 0.05, and from 5 to 45 °C for the other mixtures. The solubility was determined spectrophotometrically by the following equation,

$$\varepsilon = am + bm^2, \tag{1}$$

where ε is the absorbance at 380 nm at 25±1 °C, m is the concentration in mol/kg. Parameters a and b for each solvent were given in Table 1. Solubility measurements were repeated at appropriate intervals until the concentrations agreed within ±1%.

Results and Discussion

Solubility curves of $Cr(acac)_3$ in aqueous *t*-butyl alcohol are shown in Fig. 1. For the region $X_{BuOH} < 0.04$, the solubility minimum is observed as in water, but when X_{BuOH} becomes higher than 0.04, the solubility increases monotonically with increasing temperature. A similar trend was observed for the solubility in aqueous methanol, where the solubility curves are like that in water at $X_{MeOH} \leqq 0.11$.

On the calculation of the thermodynamic parameters of the solution from the temperature dependence of solubility, several equations were examined to represent the solubility curves and equations with three or four parameters were confirmed to be sufficient as found in the previous study for water.[1] In this study the simplest of the following equations were used,

$$\Delta C_p = A, \tag{2}$$

$$\Delta H_{soln} = \Delta H_0 + AT, \tag{3}$$

$$\ln m = -\Delta H_0/RT + (A/R) \ln T + B/R. \tag{4}$$

The parameters of these equations are given in Table 2. Solubilities calculated by Eq. 4 agreed with experimental ones within the error of less than ±1%. Thermodynamic parameters at 25 °C are

given in Table 3. ΔH_{soln} changes from exothermic to endothermic with increasing the mole fraction of alcohols, which was accompanied by the change of ΔS_{soln} from negative to positive values.

$\Delta H-\Delta S$ compensation plots for these two aqueous alcohol mixtures seems to consist of nearly the same line as shown in Fig. 2. The compensation temperature is almost the same, that is, 291±1 *K* for $0 \leq X_{BuOH} \leq 0.04$, and 286±1 *K* for $0 \leq X_{MeOH} \leq 0.11$. Compensation temperatures become higher for both of the mixtures over these regions.

These facts show that the solution process in highly aqueous regions is strongly dependent on the water structure, and then the structural change of water around $Cr(acac)_3$ is reflected on the thermodynamic parameters of the solution of $Cr(acac)_3$ in these solvents.

The deviation of plots from this compensation line with increasing the concentration of alcohols is due to the fact that the structure of the medium changes from water like to organic, and $Cr(acac)_3$ may become to be solvated selectively by alcohols.

In an SPT flame, the free energy of solvation of a gaseous solute (ΔG_{solv}) can be separated into a cavity

formation term (G_{cav}) and an interaction term (ΔG_{int}) as Eq. 5,[4]

$$\Delta G_{solv} = G_{cav} + \Delta G_{int} + RT\ln(RT/V), \quad (5)$$

where V is the apparent molar volume of the mixed solvent. The free energy of the solution of a solid solute (ΔG_{soln}) used in the present study could be obtained after a correction of the sublimation energy.[1] The free energy of transfer from water to an aqueous mixture (shown in Fig. 3) does not necessitate such a correction. G_{cav} of Cr(acac)3 in aqueous t-butyl alcohol mixtures were calculated by Eq. 6,[4-6]

$$G_{cav} = -RT\ln(1-y_3) + RT[3y_2/(1-y_3)]a_2 + RT[3y_1/(1-y_3) + 4.5y_2^2/(1-y_3)^2]a_2^2 - (1/6)\pi NPa_2^3, \quad (6)$$

where a_2 is the diameter of the solute molecule, $y_i=(\pi/6)\sum_j \rho_j \sigma_j^i$, $i=1-3$, ρ_j and σ_j are the number density and the hard-sphere diameter of the jth component, and P is the pressure. In the following calculation, 9.87 Å,[1] 2.77 Å,[4] and 5.29 Å[6] were used as hard sphere diameters of Cr(acac)3, water and t-butyl alcohol, respectively. Densities of aqueous t-butyl alcohol mixtures were from Desnoyers *et al.*[7]

A free energy of transfer (ΔG_{tr}) and a free enrgy of transfer of cavity formation ($\Delta G_{cav,tr}$) are given in Fig. 3. Corresponding to the ΔH-ΔS compensation, ΔG_{tr} is only a little negative or positive in a highly aqueous region. Upon increasing the temperature, and upon increasing X_{BuOH}, ΔG_{tr} becomes negatively large.

As an example of the dependences of G_{cav} on the hard sphere diameter of t-butyl alcohol, $\Delta G_{cav,tr}$ at 25 °C were calculated with different hard sphere diameters of t-butyl alcohol. As shown in Fig. 3, the hard sphere diameter of t-butyl alcohol is a very important parameter for estimating G_{cav} quantitatively. But these curves indicate that the trend of the transfer function, and therefore the dependence of solubility on the solvent compositions can be represented only by the G_{cav} terms qualitatively.

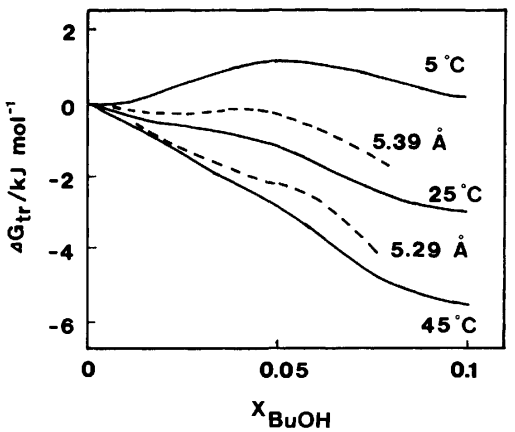

Fig. 3. Free energy of transfer of Cr(acac)3 from water to aqueous t-butyl alcohol mixtures.
----: $\Delta G_{cav,tr}$ calculated by SPT for the hard sphere diameter of t-butyl alcohol as 5.39 Å and 5.29 Å at 25 °C.

Assuming an interaction term of ΔG_{int} to be constant in the present range and estimating ΔG_{int} from ΔG_{soln} an G_{cav} in water, ΔG_{soln} in aqueous t-butyl alcohol mixtures were calculated and solubilities corresponding to these ΔG_{soln} are plotted in Fig. 1. The calculated solubilities for aqueous t-butyl alcohol mixtures were lower than the observed ones, though these solubility curves reproduce the presence of the temperature at which solubilities are approximately equal at $X_{BuOH} \leq 0.04$ as observed in the experimental solubility curves. That the cavity formation terms can reproduce such a phenomena means that G_{cav} changes in a similar way. Such a change of G_{cav} may be due to a change in the solvent structure, caused by an equilibrium of the two phases in these solvent mixtures.

For the structure of the aqueous t-butyl alcohol mixture, it was proposed that when $X_{BuOH} \leq 0.045$, a clathrate-like species of t-BuOH$(H_2O)_{21}$ is dispersed in the water and at $X_{BuOH} > 0.045$, (t-BuOH$(H_2O)_{21})_5$ is dispersed in t-butyl alcohol.[8] Therefore a fraction of free water available for the hydration of Cr(acac)3 decreases with an increase in the mole fraction of t-butyl alcohol at $X_{BuOH} \leq 0.045$. If Cr(acac)3 is considered to dissolve in the aqueous microphase at $X_{BuOH} \leq 0.045$, it is reasonable that the solubility curves in this mole fraction range are like that in water. In this case, it is also expected that the solubility decreases with increasing the concentration of t-butyl alcohol at lower temperatures, where the clathrate hydrate is stable. On the other hand, by assuming that Cr(acac)3 dissolves mainly in microphase of t-butyl alcohol at $X_{BuOH} > 0.045$, the solubility is also expected to increase monotonically with increasing temperature, observed usually on the solubility in organic solvents. The breakdown of the clathrate hydrate-like structure with increasing temperature at $X_{BuOH} > 0.045$[8] brings about an increase of the t-butyl alcohol available for Cr(acac)3 and then the solubility begins to increase steeply with temperature.

The fact that the ΔH-ΔS compensation curves for propanol mixture was explained in a similar way, that is, benzene is in an aqueous medium when $X_{PrOH} \leq 0.1$, but beyond this region dissolves in the 2-propanol microphases and benzene enhances the formation of 2-propanol microphases.[9]

The fact that the ΔH-ΔS compensation curves for aqueous t-butyl alcohol mixtures and aqueous methanol mixtures almost coincide in the highly aqueous region means that regarding the solubility of Cr(acac)3, the difference of chemical interactions of methanol and t-butyl alcohol with Cr(acac)3 is only a

minor importance compared with the difference of hydrophobicities, or the difference of abilities of these two alcohols to modify the water structure.

The large negative entropy in water, most of which is evaluated as S_{cav},[1] changes from a large negative value to a positive value at $X_{BuOH}=0.04$ at 25 °C. Corresponding to this entropy change, a large ΔC_p in water, most of which is also due to the large C_{cav},[1] decreases only a little in the mole fraction range of 0 to 0.04, and after that it changes suddenly to a very small value (Table 2). Values of ΔC_p include ambiguity when they were obtained as second delivatives of solubility curves. Though it was claimed that ΔC_p is rather independent of temperature for a process where $\Delta H-\Delta S$ compensation occurs due to the structural change of water.[10] Therefore ΔC_p obtained by Eq. 2 (assuming ΔC_p=constant) may be reliable as a measure of the change of the local structure on the solution of $Cr(acac)_3$ for the highly aqueous region. The dependences of ΔS_{soln} and ΔC_p on the mole fraction of *t*-butyl alcohol also suggest a change in the solvation of $Cr(acac)_3$ from the hydrophobic hydration in a highly aqueous region to selective solvation by *t*-butyl alcohol at $X_{BuOH}>0.04$, by dissolving in *t*-butyl alcohol microphase. The stabilization of $Cr(acac)_3$ observed in ΔG_{tr} at temperatures higher than 25 °C at $X_{BuOH}>0.04$ can also be understood by assuming such a change of solvation.

The difference in the solubilities between the observed and the calculated values may be mainly due to the ambiguity of cavity formation terms by SPT, and also due to the uncertainly of the hard sphere diameter of *t*-butyl alcohol. The solvation schema discussed above tends to change the solubility of $Cr(acac)_3$ in a similar way as expected from the cavity formation terms by SPT. Therefore, the overlap of these two factors, especially selective solvation by *t*-butyl alcohol in the alcohol rich region, may be relevant to the higher solubility compared to the calculated one.

The author is grateful to Professor Yuroku Yamamoto of Hiroshima University for his valuable discussion throughout the work. He also express his thanks to Mr. Hiroshi Tamai for assistance with the experiments.

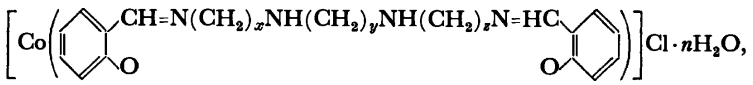
Cobalt(III) Complexes with [N6−nXn]-type Ligands. V.[1] The Preparation and Properties of *N,N'*-Disalicylidene-substituted Quadridentate Amine Cobalt(III) Complexes

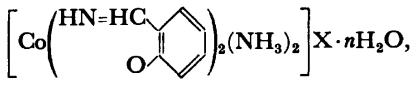
Yoshihisa YAMAMOTO* and Shoko TSUKUDA
Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02
(Received August 4, 1984)

(1,8-*N*-Disalicylidene-3,6-diazaoctane-1,8-diamine)cobalt(III) chloride hydrate (**1a**; *x,y,z*: 2,2,2),



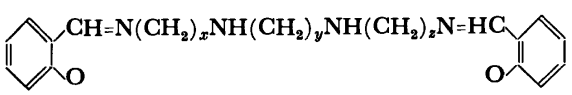
(1,9-*N*-disalicylidene-3,7-diazanonane-1,9-diamine)cobalt(III) chloride (**2a**; *x,y,z*: 2,3,2), (1,10-*N*-disalicylidene-4,7-diazadecane-1,10-diamine)cobalt(III) chloride (**3a**; *x,y,z*: 3,2,3), and (1,11-*N*-disalicylidene-4,8-diazaundecane-1,11-diamine)cobalt(III) chloride hydrate (**4a**; *x,y,z*: 3,3,3) have been isolated from a reaction mixture of $[CoCl_2L]Cl\cdot nH_2O$ (L: quadridentate amine), AgOH, and salicylaldehyde or from one of quadridentate amine, salicylaldehyde, $CoCl_2\cdot 6H_2O$ and air, and characterized. The ^1H and ^{13}C chemical shifts of their amine protons, methylene protons, and methylene carbons have been assigned. The configurations of **1a** and **2a** are the *trans,cis(mf2m)* configuration for the two CH=N− and two phenoxyl groups of the coordinated *N,N'*-disalicylidene-substituted quadridentate amine ligands. On the other hand, complexes **3a** and **4a** have the *cis,trans(fm2f)* configuration.

Previously, we have been concerned with the preparation and properties of isomers of the mixed ligand complexes of the $[CoN_{6-n}O_n]$ type, *e.g.*, the diamminebis(salicylideneaminato)cobalt(III) complexes,[1]



and salicylato(quadridentate amine)cobalt(III) complexes,[2-5] $[Co(sal\text{-}R)L]X\cdot nH_2O$ (R: H, Me; L: 2,2,2-tet, 2,3,2-tet, 3,2,3-tet, and 3,3,3-tet). Three isomers of the former complexes have been isolated; their configurations are the *trans,trans,trans-*, *trans,cis,cis-*, and *cis,trans,cis*-positions for the two ammine ligands, two CH=NH, and two phenoxyl groups of the coordinated salicylideneaminato ligands respectively. In the latter complexes, the *cis*-β_1 and β_2 isomers have been isolated, and the ^1H and ^{13}C chemical shifts of their amine protons,[3] center methylene, and NH_2- and NH-side methylene protons and carbons[5] have previously been assigned. The assignments of the =N-side methylene protons and carbons have, however, so far remained unsolved.

Many investigations of metal complexes (metal: Cu^{II}, Co^{II}, Ni^{II}, Al^{III}, Ga^{III}, Mn^{III}, Fe^{III}, Co^{III}) with the *N,N'*-disalicylidene-substituted quadridentate amine ligand,



(*x,y,z*: 2,2,2), have been reported, especially with regard to their preparation,[6-8] IR spectra,[6-8] magnetic susceptibility,[8,9] and geometrical isomerism,[9] but the NMR spectra have never been reported. These metal complexes have a *trans,cis(mf2m)*[10,11] configuration for the two CH=N and two phenoxyl groups, but complexes with a *trans,cis(f4)*, *cis,trans(fm2f)* or *cis,cis-(f2mf* or *fmf2)*[10,11] configuration have never been described except for iron complexes[12] with the *N,N'*-disalicylidene-substituted quadridentate amine ligand (*x,y,z*: 3,2,3 and 3,3,3), which has the *cis,-trans(fm2f)* configuration. Even now, the metal complexes with the *N,N'*-disalicylidene-substituted quadridentate amine ligand (*x,y,z*: 2,3,2) have not yet been reported. In addition, very little is known of the properties and general chemistry of the metal complexes with the ligands of *x,y,z*: 2,3,2; 3,2,3 and 3,3,3, in contrast with the large amount of information available on the complexes with the ligand of *x,y,z*: 2,2,2. The present paper deals with the preparation and properties of the cobalt(III) complexes with the *N,N'*-disalicylidene-substituted quadridentate amine ligand (*x,y,z*: 2,2,2; 2,3,2; 3,2,3 and 3,3,3); it also deals with the assignments of the configurations of the isomers and of the ^1H and ^{13}C chemical shifts of the =N-side methylene protons and carbons.

Results and Discussion

The (*N,N'*-disalicylidene-substituted quadridentate amine)cobalt(III) chloride hydrates, **1a**, **2a**, **3a**, and **4a** (Scheme 1), have been isolated from a reaction mixture of $[CoCl_2L]Cl\cdot nH_2O$ (L: quadridentate amine),

	x, y, z			x, y, z	
1a	2	2	2	**3a**	3	2	3
2a	2	3	2	**4a**	3	3	3

Scheme 1.

AgOH, and salicylaldehyde or from one of quadridentate amine, salicylaldehyde, $CoCl_2 \cdot 6H_2O$, and air. The corresponding nitrates (**1b**, **2b**, **3b**, **4b**) and picrates (**1c**, **2c**, **3c**, **4c**) have been prepared from a reaction mixture of silver nitrate or picric acid and **1a**, **2a**, **3a**, or **4a**, respectively.

The electric conductivities of **1a**, **2a**, **3a**, and **4a** in aqueous solutions were 97—103 S cm^2 equiv^{-1}. The IR spectra of these complexes showed a strong peak for CH=N stretching[6,7] at *ca.* 1620 or *ca.* 1640 cm^{-1} and three strong peaks for C-N stretching[6,7] in the 1126—1208 cm^{-1} region. The absorption spectra of **1a** and **3a** are closely similar to those of **2a** and **4a** respectively, as is shown in Fig. 1 and Table 1. The absorption bands at 388—403 nm and at about 590 nm or 628 nm are assigned to the charge-transfer band[13-15] and the first absorption band ($^1T_{1g} \leftarrow {}^1A_{1g}$ in an O_h approximation) respectively.

The ^{1}H NMR spectra of all the complexes were measured in dimethyl sulfoxide (DMSO-d_6) or MeOH-d_4, while the ^{13}C NMR spectra of **1a**, **2a**, **3a**, and **4a** were measured in D_2O. Their spectra suggested a C_2 symmetry, as is shown in Fig. 2. The ^{1}H NMR spectra of **1c** and **3c** are similar to those of **2c** and **4c** respectively. The signals at δ 1.3—4.3 are assigned to the methylene protons of the coordinated *N,N'*-disalicylidene-substituted quadridentate amine ligand (abbreviation: sexidentate ligand). The signals at δ 4.6—6.0 are assigned to the NH protons. The multiplet signals at δ 6.2—7.4 are assigned to the ring protons. The signals at δ 7.6—8.4 are assigned to the CH=N protons. The lowest signals are assigned to the picrate protons. The methylene-proton signals of **1c** and **2c** can be divided into three or four groups at the δ 1.7—2.1, 2.2—2.8, 2.8—3.1, and 4.2—4.3 regions. The signal at δ 1.7—2.1 of **2c** is assigned to the center methylene protons ($NHCH_2C\underline{H}_2CH_2NH$), while the signals at δ 2.2—2.8 and 2.8—3.1 of **1c** and **2c** are assigned to the NH-side methylene protons ($=NCH_2C\underline{H}_2NHC\underline{H}_2-$) of the coordinated sexidentate ligands by comparison with those of salicylato(quadridentate amine)cobalt(III) chloride hydrate, $[Co(sal)L]Cl \cdot nH_2O$ (**5**), (L: 2,2,2-tet; 2,3,2-tet; 3,2,3-tet and 3,3,3-tet), previously reported.[5] Thus, the signals at δ 4.2—4.3 of **1c** and **2c** have been assigned to the =N-side methylene protons ($=NC\underline{H}_2CH_2NH$) of the coordinated sexidentate ligands. In the NH-side methylene-proton signals of **2c**, the intensity ratio of two methylene-proton signals at δ 2.35 and 2.86 is 6:2; *i.e.*, the two methylene protons at δ 2.86 are overlapped with those at δ 2.35 because of the influence of C-5 center methylene. Therefore, the signals at δ 2.35 and 2.86 of **2c** can be assigned to the C-3, C-7 methylene protons (*cf.* Table 2) and the C-4, C-6 methylene protons respectively. The signals at δ 2.3—3.6 of **3c** and 1.4—3.9 of **4c** are difficult to assign to the individual methylene protons. The ^{13}C NMR spectra of **1a**, **2a**, **3a**, and **4a** showed 3—5 signals for the quadridentate amine carbons at δ 20—60 and 7 signals at δ 117—170 for the salicylidene carbons, as is shown in Fig. 2. The chemical shifts of the center methylene carbons at δ 20—31, the NH-side methylene carbons at 45—54, and the ring

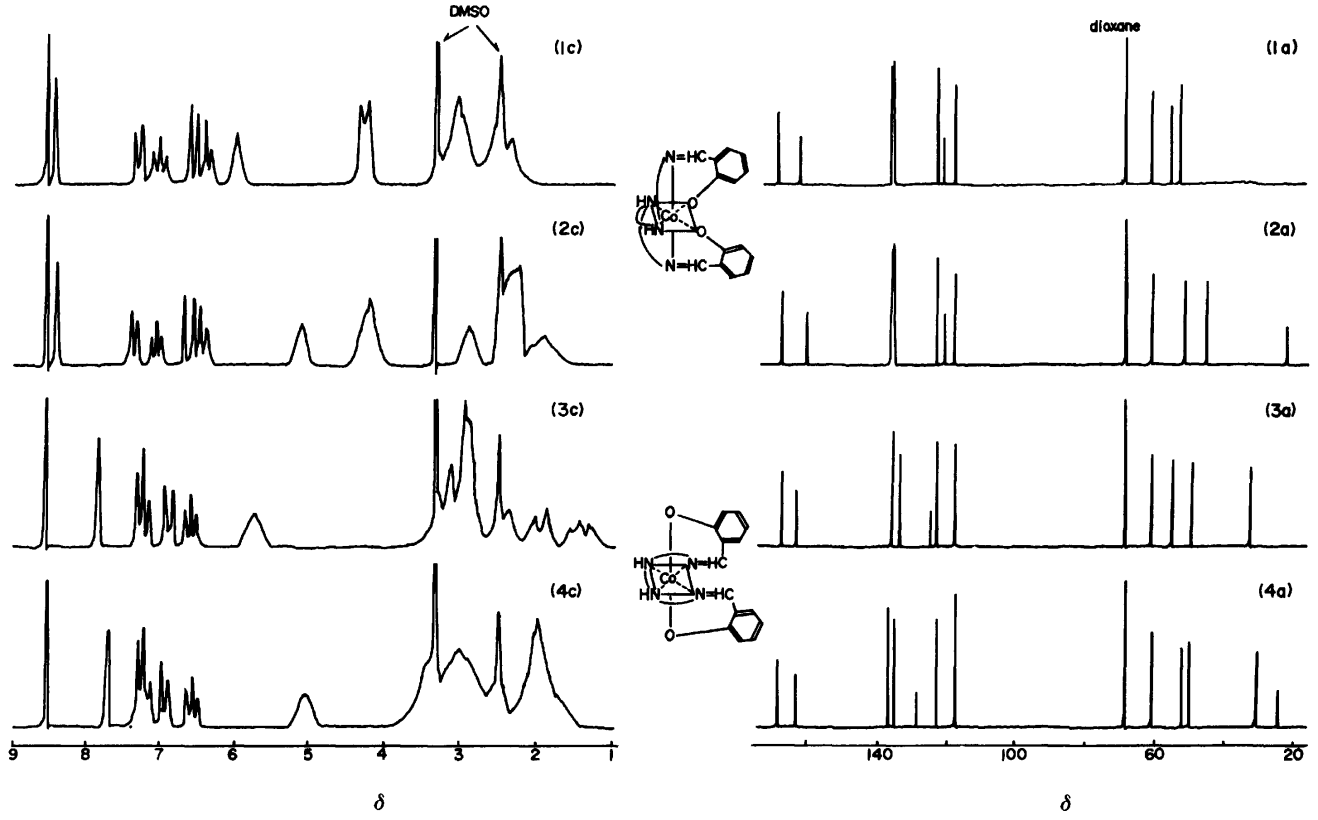

Fig. 2. The ^1H and ^{13}C NMR spectra of complexes.
1a: [Co($sal_2$2,2,2-tet)]Cl·H_2O, **1c**: [Co($sal_2$2,2,2-tet)]pic, **2a**: [Co($sal_2$2,3,2-tet)]Cl **2c**: [Co($sal_2$2,3,2-tet)]pic, **3a**: [Co($sal_2$3,2,3-tet)]Cl, **3c**: [Co($sal_2$3,2,3-tet)]pic, **4a**: [Co($sal_2$3,3,3-tet)]Cl·H_2O, **4c**: [Co($sal_2$3,3,3-tet)]pic.

carbons were assigned on the basis of the results of **5**[5] and salicylato(tetraammine)cobalt(III) chloride monohydrate,[16] [Co(sal)(NH_3)$_4$]Cl·H_2O (**6**), as is shown in Table 2. Thus, the signals at *ca.* δ 60 have been assigned to the =N-side methylene carbons of the coordinated sexidentate ligands. The chemical shifts of the =N-side methylene protons and carbons are lower than those of the NH-side methylene protons and carbons respectively. Therefore, the order of the ^1H and ^{13}C chemical shifts of the center, NH_2–,[5] NH–, and =N-side methylene protons or carbons is as is shown in Scheme 2;

Scheme 2.

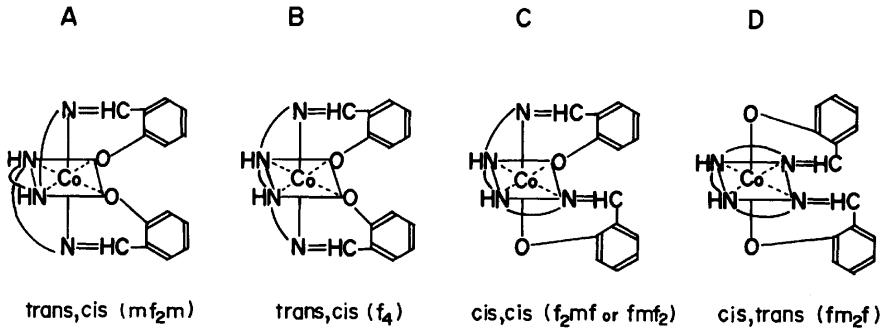

Fig. 3. The configurations of (*N,N'*-disalicylidene-substituted quadridentate amine)cobalt(III) complexes.

Complexes **1a**, **2a**, **3a**, and **4a** have four isomers of **A**, **B**, **C**, and **D**, as is shown in Fig. 3. The configurations of **A**, **B**, and **D** have a C_2 symmetry, while the configuration of **C** has a C_1 symmetry. The IR, ^1H, and ^{13}C NMR spectra of Complexes **1a**, **2a**, **3a**, and **4a** are suggestive of a C_2 symmetry;[13,15,17,18] *i.e.*, the isomers of these complexes can be assigned to the **A**, **B**, or **D** configurations. A clear distinction between one group of **1a**, **2a** complexes and the other group of **3a**, **4a** complexes was found in the color, solubility, IR, electronic absorption, NMR spectra, and the Dreiding stereo model. **1a** and **2a** are brown, while **3a** and **4a** are green. Complexes **1a** and **2a** are very soluble in DMSO, though **3a** and **4a** are only slightly soluble. The C=N stretching signals (at 1642 cm^{-1} for **1a** and at 1620 cm^{-1} for **3a**) in the IR spectra, the electronic absorption bands (at 388, 470, and 590 nm for **1a** and at 398, 430, and 628 nm for **3a**), and the methylene-proton signals, the CH=N proton signals (at δ 8.4 for **1a** and at δ 7.6 for **3a**), and the ring-proton signals (multiplet, triplet, and doublet signals for **1a** and triplet, doublet, and multiplet signals for **3a**) of the ^1H NMR spectra of **1a** and **3a** are closely similar to those of **2a** and **4a** respectively, as is shown in Tables 1 and 2. In the Dreiding stereo model, the methylene-loop rings of the coordinated sexidentate ligands of former complexes show that the **A** isomer[6] is not strained, though the other isomers, **B** and **D**, are greatly strained. Thus, the complexes of the former group are assigned to the **A** isomer, which has a *trans,cis*(mf_2m)[10,11] configuration[6] for the two CH=N and two phenoxyl groups. On the other hand, in the methylene-loop rings of the latter complexes, the **A**, **B**, and **D** isomers are not strained, though the methylene protons of the methylene-loop ring of the **A** and **B** isomers have a steric repulsion because of the non-planar structure. It has been established that, in iron[8,9,12] and cobalt[19] complexes of [$Fe^{III}Sal_2$3,2,3-tet]$^+$, and [$Fe^{III}Sal_2$2,2,2-tet]$^+$ and of [$Co^{III}Cl_2$3,2,3-tet]$^+$, [$Co^{III}Cl_2$2,2,2-tet]$^+$, the 3,2,3-tet ligand takes a structure with four nitrogens in plane, while the 2,2,2-tet ligand usually adopts a non-planar structure. Thus, the complexes of the latter group are assigned to the **D** isomer, which has a *cis,trans* (fm_2f)[10,11] configuration for the two CH=N and two phenoxyl groups. The color, solubility, IR, electronic absorption, and NMR spectra of the latter complexes are very different from those of the former complexes. These differences are due to the configuration of the complexes.

Experimental

Measurements. The NMR spectra were recorded with an FX-60 spectrometer (JEOL) for ^{13}C NMR and with an R-40 apparatus (Hitachi) for ^1H NMR. The IR spectra were recorded over potassium bromide disks with an IR-27G spectrophotometer (Shimadzu). The visible absorption spectra were recorded with a Shimadzu MPS-5000 recording spectrophotometer. The electric conductivities of the aqueous solution were determined by the use of a conductometric meter, CM-30 (Shimadzu), at room temperature.

Preparation of Complexes. (1,8-N-Disalicylidene-3,6-diazaoctane-1,8-diamine)cobalt(III) Chloride (1a): *Method A*: *cis*-α or β-Dichloro(3,6-diazaoctane-1,8-diamine(trien))cobalt(III) chloride[20,21] (3.0 g, 9.63 mmol) was added to moistened fresh AgOH, which has been made from silver nitrate (3.27 g, 19.25 mmol) and potassium hydroxide (1.08 g, 19.25

mmol). The mixture was stirred for several minutes at room temperature and then stirred for about 40 min at 60 °C. The silver chloride thus precipitated was filtered off. A methanol solution (20 cm^3) of salicylaldehyde (2.36 g, 19.33 mmol) was then added, drop by drop, to the reddish violet filtrate. The solution was stirred at 50 °C for 24 h. The solution was concentrated on a rotary evaporator, and the reaction mixture was dried over silica gel. Complex **1a** was extracted with dry methanol or dry ethanol from the dried reaction mixture. The purification of the complexes was achieved by column chromatography on alumina. When the solvent was then eluted with methanol or ethanol, the effluent of the first brown band of Complex **1a** was collected and the solution was concentrated. Then, the precipitated complex was recrystallized twice from ethanol–ether (3:2). Yield: 2.41 g (53.8%).

No other isomer was isolated from the second red band and third pink bands, which perhaps $[CoCl(OH)trien]^+$ or $[Co(OH)_2trien]^+$.[22]

Method B: A methanol solution (10 cm^3) of trien (1.46 g, 9.98 mmol) was added to a methanol solution (40 cm^3) of salicylaldehyde (2.44 g, 19.98 mmol), and the mixture was stirred 10 min at room temperature. Then, the solution was added to a methanol solution (50 cm^3) of $CoCl_2 \cdot 6H_2O$ (2.38 g, 10.0 mmol). Air was bubbled into the solution for 7 h, and the solution was concentrated on a rotary evaporator. The complex thus precipitated was recrystallized twice from water–acetone or ethanol–ether. Yield: 2.34 g (50.4%). Found: C, 51.41; H, 6.00; N, 12.04; Cl, 8.02%. Calcd for $CoC_{20}H_{26}N_4O_3Cl$ (MW 464.84) C, 51.68; H, 5.64; N, 12.05; Cl, 7.63%. Color: brownish black.

*(1,8-*N*-Disalicylidene-3,6-diazaoctane-1,8-diamine)cobalt(III) Nitrate Hydrate (**1b**)*: An aqueous solution of silver nitrate (0.18 g, 1.06 mmol) was added to an aqueous solution of **1a** (0.48 g, 1.03 mmol). The mixture was stirred, and the silver chloride thus precipitated was filtered. The filtrate was concentrated on a rotary evaporator. Then, the precipitated complex was recrystallized twice from methanol–ether. Yield: 0.22 g (43.4%). Found: C, 48.56; H, 5.69; N, 14.22%. Calcd for $CoC_{20}H_{26}N_5O_6$ (MW 491.39) C, 48.89; H, 5.33; N, 14.25%. Color: brown.

*(1,8-*N*-Disalicylidene-3,6-diazaoctane-1,8-diamine)cobalt(III) Picrate (**1c**)*: An aqueous solution of picric acid (0.10 g, 0.436 mmol) was added to an aqueous solution of **1a** (0.20 g, 0.430 mmol). The mixture was stirred, and then the precipitated complex was filtered, washed with water, and dried. Yield: 0.26 g (94.5%). Found: C, 48.80; H, 4.28; N, 15.89%. Calcd for $CoC_{26}H_{26}N_7O_9$ (MW 639.47) C, 48.84; H, 4.10; N, 15.33%. Color: yellowish brown.

*(1,9-*N*-Disalicylidene-3,7-diazanonane-1,9-diamine)cobalt(III) Chloride (**2a**)*: A methanol solution (10 cm^3) of 3,7-diazanonane-1,9-diamine (2,3,2-tet) (1.60 g, 9.98 mmol) was added to a methanol solution (40 cm^3) of salicylaldehyde (2.44 g, 19.98 mmol), after which the mixture was stirred 10 min at room temperature. Then the solution was added to a methanol solution (50 cm^3) of $CoCl_2 \cdot 6H_2O$ (2.38 g, 10.0 mmol). Air was bubbled into the solution for 7 h, the solution was concentrated in a rotary evaporator, and the reaction mixture was dried over silica gel. Complex **2a** was extracted with dry methanol from the dried mixture. The purification of the complexes was achieved by column chromatography on alumina. When the solvent was eluted with methanol, the effluent of the first brown band of Complex **2a** was collected and the solution was concentrated. Then, the precipitated complex was recrystallized twice from methanol–acetone–ether. Yield: 1.20 g (26.1%). Found: C, 54.51; H, 6.01; N, 12.07; Cl, 7.93%. Calcd for $CoC_{21}H_{26}N_4O_2Cl$ (MW 460.85) C, 54.73; H, 5.69; N, 12.16; Cl, 7.69%. Color: brownish black.

*(1,9-*N*-Disalicylidene-3,7-diazanonane-1,9-diamine)cobalt(III) Nitrate (**2b**)*: Complex **2b** has been prepared from the reaction mixture of silver nitrate (0.18 g, 1.06 mmol) and Complex **2a** (0.46 g, 0.998 mmol) according to the method used for **1b**. Yield: 0.16 g (32.9%). Found: C, 51.11; H, 5.08; N, 14.60%. Calcd for $CoC_{21}H_{26}N_5O_5$ (MW 487.40) C, 51.75; H, 5.38; N, 14.37%. Color: brown.

*(1,9-*N*-Disalicylidene-3,7-diazanonane-1,9-diamine)cobalt(III) Picrate (**2c**)*: Complex **2c** has been prepared from the reaction mixture of **2a** (0.2 g, 0.434 mmol) and picric acid (0.1 g, 0.436 mmol) according to the method used for **1c**. Yield: 0.16 g (56.4%). Found: C, 49.28; H, 4.49; N, 15.04%. Calcd for $CoC_{27}H_{28}N_7O_9$ (MW 653.49) C, 49.62; H, 4.32; N, 15.00%. Color: yellowish brown.

*(1,10-*N*-Disalicylidene-4,7-diazadecane-1,10-diamine)cobalt(III) Chloride (**3a**)*: Complex **3a** has been prepared from a reaction mixture of *trans*-dichloro(4,7-diazadecane-1,10-diamine)cobalt(III) chloride hydrate[23] (3.0 g, 8.39 mmol), AgOH (2.09 g, 16.74 mmol) which had been obtained from silver nitrate, and potassium hydroxide and salicylaldehyde (2.05 g, 16.79 mmol) according to the method used for **A** of **1a**. The green complex of **3a** was recrystallized twice from methanol–ether. Yield: 0.75 g (18.8%). Found: C, 55.49; H, 5.72; N, 12.09; Cl, 8.02%. Calcd for $CoC_{22}H_{28}N_4O_2Cl$ (MW 474.88) C, 55.64; H, 5.94; N, 11.80; Cl, 7.47%. Color: green.

*(1,10-*N*-Disalicylidene-4,7-diazadecane-1,10-diamine)cobalt(III) Nitrate (**3b**)*: Complex **3b** was prepared from the reaction mixture of Complex **3a** (0.47 g, 0.99 mmol) and silver nitrate (0.17 g, 1.00 mmol) according to the method used for **1b**. Yield: 0.22 g (44.3%). Found: C, 52.70; H, 5.78; N, 14.01%. Calcd for $CoC_{22}H_{28}N_5O_5$ (MW 501.43) C, 52.70; H, 5.63; N, 13.97%. Color: green.

*(1,10-*N*-Disalicylidene-4,7-diazadecane-1,10-diamine)cobalt(III) Picrate (**3c**)*: This complex was prepared from the reaction mixture of Complex **3a** (0.16 g, 0.337 mmol) and picric acid (0.08 g, 0.349 mmol) according to the method used for **1c**. Yield: 0.18 g (80.0%). Found: C, 50.64; H, 4.51; N, 15.09%. Calcd for $CoC_{28}H_{30}N_7O_9$ (MW 667.52) C, 50.38; H, 4.53; N, 14.69%. Color: yellowish green.

*(1,11-*N*-Disalicylidene-4,8-diazaundecane-1,11-diamine)cobalt(III) Chloride Hydrate (**4a**)*: A methanol solution (10 cm^3) of 4,8-diazaundecane-1,11-diamine (3,3,3-tet) (1.88 g, 9.98 mmol) was added to a methanol solution (40 cm^3) of salicylaldehyde (2.44 g, 19.98 mmol), and the mixture was stirred 10 min at room temperature. Then, the solution was added to a methanol solution (50 cm^3) of $CoCl_2 \cdot 6H_2O$ (2.38 g, 10.0 mmol). Air was bubbled into the solution for 7 h, and the solution was concentrated on a rotary evaporator. The concentrated solution was submitted to a column chromatography on alumina. On eluting the solvent with methanol, the eluent of the first brown band was collected and concentrated. The purification of the complex was achieved by the use of a column of ion-exchange resin (SP-Sephadex C-25 Na^+ form). After the mixture had been

eluted with 0.2 mol dm^{-3} of NaCl the fourth green band of Complex **4a** was collected and concentrated on a rotary evaporator, and the precipitated NaCl was removed by filtration. The green complex was recrystallized twice from methanol–ether. Yield: 0.43 g (8.5%). Found: C, 54.92; H, 6.55; N, 10.72; Cl, 7.31%. Calcd for $CoC_{23}H_{32}N_4O_3Cl$ (MW 506.92) C, 54.50; H, 6.36; N, 11.05; Cl, 6.99%. Color: green.

Attempts to isolate another isomer from this reaction mixture were unsuccessful, because the other bands in the column of the ion-exchange resin were small.

*(1,11-*N*-Disalicylidene-4,8-diazaundecane-1,11-diamine)cobalt(III) Nitrate (4b)*: This complex was prepared from the reaction mixture of Complex **4a** (0.50 g, 0.986 mmol) and silver nitrate (0.17 g, 1.00 mmol) according to the method used for **1b**. Yield: 0.26 g (51.1%). Found: C, 53.51; H, 5.59; N, 13.28%. Calcd for $CoC_{23}H_{30}N_5O_5$ (MW 515.45) C, 53.59; H, 5.87; N, 13.59%. Color: green.

*(1,11-*N*-Disalicylidene-4,8-diazaundecane-1,11-diamine)cobalt(III) Picrate (4c)*: This complex was prepared from the reaction mixture of Complex **4a** (0.19 g, 0.375 mmol) and picric acid (0.09 g, 0.393 mmol) according to the method used for **1c**. Yield: 0.23 g (90.0%). Found: C, 51.29; H, 5.04; N, 14.24%. Calcd for $CoC_{29}H_{32}N_7O_9$ (MW 681.55) C, 51.11; H, 4.73; N, 14.39%. Color: yellowish green.

Solubility: Complexes **1a—c** and **2a—c** are very soluble in DMSO, DMF, and methanol and are soluble in ethanol. Complexes **1a—b** and **2a—b** are very soluble in water, though **1c** and **2c** are insoluble in water. Complexes **3a** and **4a** are soluble in methanol, though they are only slightly soluble in water, DMSO, and DMF. Complexes **3b—c** and **4b—c** are soluble in DMSO, DMF and methanol, though they are insoluble in water.

The Identification of the Compositions of the Compounds Formed in an Addition Reaction Involving Insoluble Substances

Goro HIHARA,* Tadashi SHIMIZU,† Hiroshi MIYAMAE, and Miharu NAGATA
Department of Chemistry, Faculty of Science, Josai University, Sakado, Saitama 350-02
(Received August 7, 1984)

A method has been developed for the identification of the compositions of all the insoluble compounds which are formed in the reaction of an insoluble substance (A) with a soluble one (B). It consists of allowing a fixed amount of A to react with various amounts of B in a fixed volume of a solution, determining the concentrations of B(=[B]) remaining unreacted after the equilibrium is reached, and then finding the number of the formed compounds and their compositions from the variations in [B] on the basis of the phase rule. This method was applied to the reactions of PbI_2 with diethylenetriamine (dien) and with 1,3-propanediamine (pren); the presence of the following addition compounds was found: $PbI_2 \cdot Y$(dien) (Y=1/2 and 1) and $PbI_2 \cdot Y$(pren) (Y=4/5, 1, and 2).

In studying coordination compounds, the first step is to determine the compositions of the complexes formed in the reaction. When all of the species involved are soluble in a common solvent, there have already been developed several useful methods, such as the continuous variation[1-3] and the mole ratio methods.[4] However, they can not be used when some of the species concerned are insoluble. A method which is applicable to such a case was reported in a previous paper.[5] It consists, essentially, in pursuing the variations in the concentrations of a soluble substance [B] in equilibrium with the insoluble ones.

In the present study, this method was applied to the reactions of PbI_2 with diethylenetriamine and with 1, 3-propanediamine; it will be pointed out that the examination of the powder X-ray diffraction patterns of the insoluble compounds is very helpful in confirming the presence of complexes formed in the reaction, especially when such complexes are otherwise apt to be overlooked.

Theoretical

Let us assume that an insoluble substance, A, reacts with a soluble one, B, in a solution according to Eqs. 1 and 2 to yield two insoluble addition compounds;

$$\text{A(solid)} + m\text{B(soln.)} = \text{A}\cdot m\text{B(solid)} \quad (1)$$

$$\text{A}\cdot m\text{B(solid)} + n\text{B(soln.)} = \text{A}\cdot(m+n)\text{B(solid)}. \quad (2)$$

The degree of freedom of this system, f, is given on the basis of the phase rule by:

$$f = c + 2 - p, \quad (3)$$

in which c is the number of the components, and p, the number of phases. Since the system is composed of A, B, and a solvent, c equals 3. Therefore,

$$f = 5 - p. \quad (4)$$

Under a constant temperature and pressure, f becomes $(3-p)$:

$$f = 3 - p. \quad (5)$$

When the equilibrium is established between the solution and one of three solid phases, A, A·mB, or A·$(m+n)$B, the system becomes univariant and the concentration of B in the solution is capable of variation within a definite range. On the other hand, when two solid phases and the solution are in equilibrium, there appears an invariant state and the concentrations of B remain fixed, as long as either A and A·mB or A·mB and A·$(m+n)$B coexist in the solid.

When a fixed amount of A is put in a fixed volume of a solution containing various quantities of B and each mixture is allowed to stand until an equilibrium is established, the concentration of B remaining in each solution is determined in some way. The relations between the amounts of B taken at the beginning and the concentrations of B remaining at the end of the reaction are depicted by the solid curve in Fig. 1, which is tentatively termed a "concentration curve."

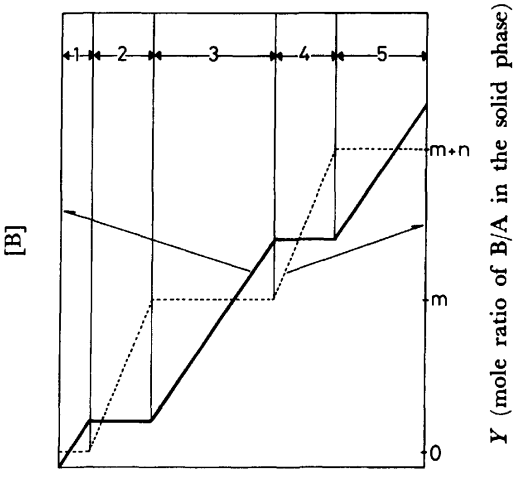

Fig. 1. A typical phase diagram for a ternary system where two insoluble addition compounds, A·mB and A·$(m+n)$B form.

† Present address: Colcoat Co., Ltd.,Gyoda, Saitama 361.

The two plateaus on the concentration curve represent two invariant states, one of which corresponds to the coexistence of A and A·mB, and the other, A·mB and A·$(m+n)$B. Each incline on the curve is related to each univariant state.

The composition of each sediment which is equilibrated with the solution can be calculated from Eq. 6;

$$Y = (X - V[\mathrm{B}])/Z, \quad (6)$$

where Y is the mole ratio of B/A in the sediment; X, the amount of B in mol taken at the beginning; [B], the concentration of B in mol/dm^3 in the final solution; V, the volume of the solution in dm^3, and Z, the total amount of A in mol taken at the beginning. The composition of each sediment calculated is also plotted by the dashed curve in Fig. 1, which is tentatively termed a "composition curve." The curve should reveal three plateaus, which correspond to the compositions of A, A·mB, and A·$(m+n)$B in the solid phase.

Experimental

Apparatus. A Toa Denpa HM-5H pH meter was used to determine the concentration of amines in the solution and the content of amines in the sediments. When it was necessary to characterize the sediments, use was made of powder X-ray diffractometry with a Rigaku Denki Geigerflex Diffractometer.

Reagents. PbI_2 was prepared by mixing a solution of KI with that of $Pb(NO_3)_2$ in a stoichiometric ratio. The diethylenetriamine (dien) (99.0% pure) was obtained from Wako Pure Chemical Industries, Ltd. The 1, 3-propanediamine (pren) (99.0% pure) was obtained from Tokyo Kasei Co., Ltd. These amines were used without any further purification. The ethanol was dehydrated with molecular sieves (4Al/16) and then distilled.

The Addition Reaction of PbI_2 with dien. One g (2.17 mmol) of finely powdered PbI_2 was suspended in an ampoule with 10.0 ml of an ethanol solution containing the desired amount of dien. The mole ratio of dien/PbI_2 was varied in the range of 0.3—3.0. Then each ampoule was sealed and kept at 20.0±0.2 °C for about two months. For the smooth progress of the reaction, each ampoule was shaken violently for 10 min twice 1 d. The sediments were separated from the solutions and then subjected to chemical analysis and powder X-ray diffractometry. The concentration of dien in each solution was also determined. A similar treatment was done in the case of the reaction of PbI_2 with pren.

Analysis of the Solutions and the Sediments. Five ml of each solution separated from the sediment was diluted with about 35 ml of water, and the amine was potentiometrically titrated with 0.1 M (1 M=1 mol dm^{-3}) HCl. The content of Pb^{2+} in the solution was determined by titrating with 0.01 M EDTA, using xyrenol orange as an indicator.[6] For the determination of the amine content in the sediments, about 10—20 mg of the sediment was dissolved in 10.00 ml of 0.1 M HCl. After 30 ml of water had been added, the excess of HCl back-titrated potentiometrically by 0.1 M NaOH. The Pb content of the sediments was determined by the complexometric titration described above after about 10—20 mg of each sediment had been dissolved into 40 ml of water containing 0.5 ml of 1 M HNO_3.

Results and Discussion

Preliminary experiments confirmed that PbI_2 does not react with ethanol and is scarcely soluble in it, even in the presence of pren or dien. The direct reactions of PbI_2 with dien were made in various mole ratios of dien/PbI_2, 0.5, 1, 2, and 3. The unreacted dien was removed by pressing the products with a filter paper. The diffraction patterns of the products were similar to those of the products formed in the ethanolic solution containing the amine. These facts show that the net reactions in the ethanolic solutions are the addition reactions of PbI_2 with the amines and that ethanol acts merely as a diluent.

The findings on the reaction of PbI_2 with pren are shown in Fig.2 in the same manner as in Fig. 1. The concentration curve ascends from about 0.8 of X/Z(=pren/PbI_2) on the abscissa, and the composition curve becomes flat at Y=0.8 in the range of about 0.75—1.35 of X/Z. This shows the presence of an addition compound, PbI_2·4/5(pren). The occurrence of two other compounds, PbI_2·pren and PbI_2·2pren, can be pointed out in a similar way.

Figure 3 represents the findings on the reaction of

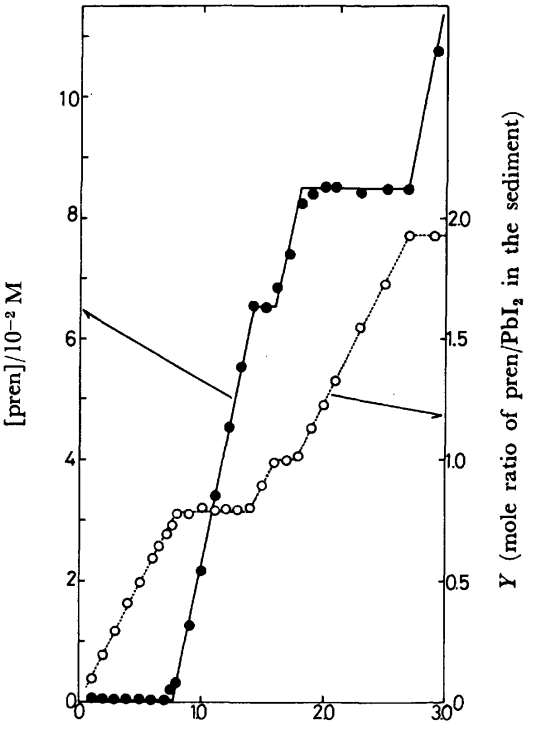

Fig. 2. The relation between the concentration of 1,3-propanediamine (pren) remaining in the solution and the composition of the sediments at 20 °C.

PbI_2 with dien. The concentration curve ascends from 0.5 and becomes flat at 0.55 of X/Z (=dien/PbI_2). The value of Y in the region of 0.5—0.55 of X/Z can be read as 0.5 from the composition curve, although it does not seem to have the corresponding plateau because of the narrow range. This is considered to imply the presence of $PbI_2 \cdot 1/2$(dien) according to the phase rule. The presence of $PbI_2 \cdot 1/2$(dien) can be confirmed from the powder X-ray diffraction patterns of the sediments, which are shown in Fig. 4. When the patterns are examined, it can be seen that the characteristic peak of 9.4°(=2θ) has a maximum intensity at Y=0.5 and that it disappears at Y=0.0 and 1.0. This fact indicates the presence of $PbI_2 \cdot 1/2$(dien). The presence of one more compound, PbI_2·dien, can be pointed out, since the concentration curve ascends from about 1.1 of X/Z(=dien/PbI_2) and the composition curve becomes flat at Y=1.0 in the range of 1.1—2.3 of X/Z in Fig. 3. Table 1 lists the data on the compositions of some sediments found by chemical analysis. The values of Y of $PbI_2 \cdot Y$(dien) obtained by substituting the equilibrated concentrations of dien for [B] in Eq. 6 agree very closely with those found by chemical analysis.

If a compound forms over a wide range of X/Z (=B/A), its presence can be confirmed on the basis of the resulting slope of the concentration curve and the corresponding plateau of the composition curve. This is the case with such compounds as $PbI_2 \cdot 4/5$ (pren) and $[Ag(thiopyrine)_3]ClO_4$.[8] However, if a compound forms in a narrow range of X/Z, its presence is liable to be overlooked because the corre-

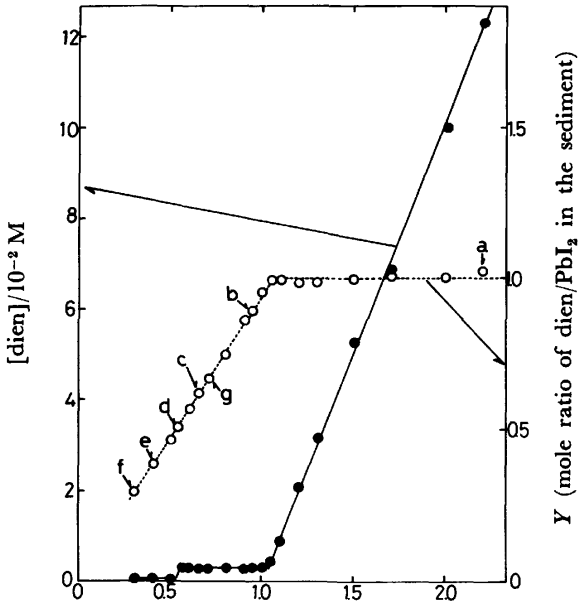

Fig. 3. The relation between the concentration of dien remaining in the solution and the composition of the sediments at 20 °C. The range of the mole ratio over 2.3 was omitted since the concentrations increased monotonously and the mole ratio of the sediments was equal to nearly 1.

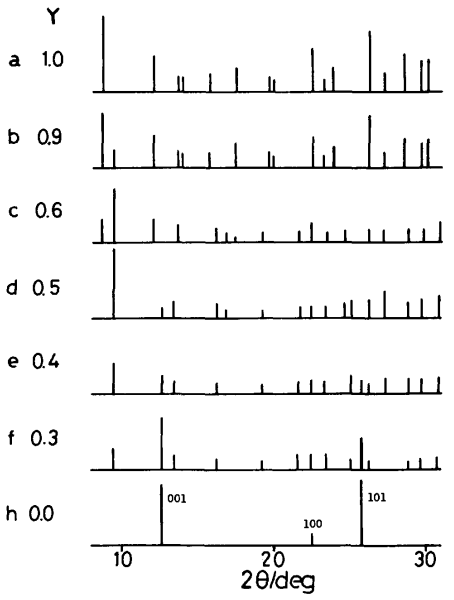

Fig. 4. The powder X-ray diffraction patterns of $PbI_2 \cdot Y$ (dien) where Y represents the mole ratio of dien/PbI_2 found by chemical analysis. The marks a—f are shown in Fig. 3 and h is the pattern of the sediment obtained by immersing PbI_2 in ethanol. Its peaks are the same as those of PbI_2 and are indexed.[9]

Table 1. The composition of some sediments grown in the PbI_2-dien-ethanol system

Sediment[a]	Found by chemical analysis				Determined from dien concn.[c]	
	Pb %	PbI_2[b] %	dien %	Recovery %	Y(mole ratio of dien/PbI_2)	
a	37.3	83.0	18.7	102	1.01	1.03
f	42.9	95.5	6.7	102	0.31	0.30
g	39.0	86.8	14.2	101	0.73	0.67

a) The sediments analyzed are shown in Fig. 3. b) The weight percentage of PbI_2 was calculated from the content of lead. c) These mole ratios were evaluated from Eq. 6, using the concentration of dien in the solution after the equilibration.

sponding plateau does not always appear in the composition curve, even though the concentration curve ascends. This is the case with such compounds as $PbI_2 \cdot 1/2$(dien) and $PbI_2 \cdot 2/3$(en) (en=ethylenediamine). In a previous paper[5] on the reaction of PbI_2 with en, spectrophotometry[7] could follow the minute variations in the concentrations of en in the vicinity of the range where $PbI_2 \cdot 2/3$(en) formed, and its presence was pointed out clearly, although the plateau did not appear in the composition curve. Since the minute variations in the concentrations of dien could not be followed accurately in the range where $PbI_2 \cdot 1/2$(dien) formed, X-ray powder diffractometry was used instead of spectrophotometry in order to confirm its presence. X-Ray powder diffractometry as well as spectrophotometry was found to be helpful in confirming the presence of the compounds which formed in a narrow range of X/Z.

When the present method is compared with the mole ratio and continuous variation methods, it is found to be more similar to the former than to the latter, since a fixed amount of one of two substances is allowed to react with various amounts of the other. The present method is applied to a heterogeneous system, while the mole ratio method is applied to a homogeneous system. Therefore, the method described here may be taken as a substitute for the mole ratio method in a heterogeneous system.

The method for the identification of the insoluble addition compounds was found to be applicable to the reactions of PbI_2 with pren and dien. The following addition compounds were confirmed: $PbI_2 \cdot Y$(pren) (Y=4/5, 1, and 2) and $PbI_2 \cdot Y$(dien) (Y=1/2 and 1). Many compounds have been reported of PbI_2 with Lewis bases, such as aniline,[10] thiourea,[11] and *N*,*N*-dimethylformamide.[12] Since most of them have the composition of 1:1 or 1:2 (=PbI_2:base), $PbI_2 \cdot 4/5$(pren) and $PbI_2 \cdot 1/2$(dien) have unusual compositions. On the other hand, there have been few reports on crystal structures of compounds of PbI_2 with Lewis bases: $PbI_2 \cdot 2$(dimethylsuloxide),[13] $PbI_2 \cdot 2$(pyridine),[14] and $PbI_2 \cdot 2$(en).[15] An X-ray study of $PbI_2 \cdot 2$(pren) and $PbI_2 \cdot$dien is now in progress in our laboratory.

We are grateful to Professor Hiroshi Suguro of this University for his helpful discussions.

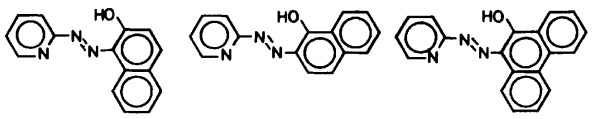
Bivalent Cobalt Complexes with 1-(2-Pyridylazo)-2-naphthol and Analogous Ligands

Katsura MOCHIZUKI* and Masatoshi FUJIMOTO*,†
Department of Chemistry, Yokohama City University, Yokohama 236
†*Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060*
(Received September 25, 1984)

Bivalent cobalt complexes with the title ligands were synthesized, isolated, and characterized by absorption spectra and magnetic moments. It has been suggested that the cobalt(II) complexes have more flexible structures than the corresponding cobalt(III) complexes. The cobalt(II) complexes were found to be oxidized to the cobalt(III) complexes in DMSO in the presence of copper(II) ions. Cyclic voltammetry elucidated the reversible Co^{II}/Co^{III} couples of the cobalt complexes in acetonitrile. The values of $E_{1/2}$ for the Co^{II}/Co^{III} couples were found to depend on the coordinating ligands. The relation between $E_{1/2}$ and pK_a of the *ortho*-hydroxyl group in the ligands was discussed.

Some *o*-hydroxy azo compounds in the following structural formula[1] are well known to behave as terdentate ligands,[2,3] which form colored chelates with many metal ions.[4] They have been used as sensitive analytical reagents for the spectrophotometric determination of cobalt,[5,6] because they form very stable cobalt(III) complexes.[7]



In the reactions between cobalt(II) ion and the title ligands in aqueous media, the cobalt(II) complexes formed are immediately oxidized by dissolved oxygen to the corresponding cobalt(III) complexes.[7] Therefore it is difficult to isolate the cobalt(II) complexes and to investigate their characters, whereas the formation[7] and the structures[8,9] of the cobalt(III) complexes have been well characterized. In addition, some information about redox behavior of such cobalt complexes has been obtained: (1) The cobalt(II) complexes are easily oxidized in aqueous solution, but they are considerably stable in organic solvents,[5,10] and (2) the cobalt(III) complex with β-PAN are reduced to the cobalt(II) complex by hyperoxide in dimethyl sulfoxide, DMSO,[11] though details of the electrochemical data about the Co^{II}/Co^{III} couples, which enable us to predict what complex prefers the cobalt(III) state, have not been reported so far.

In the present paper,[10] we report the synthesis, isolation, and characterization of the cobalt(II) complexes with the title ligands, as well as the electrochemical study of their cobalt complexes in acetonitrile solution by cyclic voltammetry.

Experimental

Measurements. Absorption spectra were recorded on Hitachi EPS-3T and 340 spectrophotometers. Magnetic susceptibilities were measured by Gouy method. The pH was measured with a TOA HM-20E pH-meter equipped with a composite electrode, type GST-155C.

Cyclic voltammograms were recorded at 25±0.3 °C with a Yanagimoto Polarographic Analyzer P-1100. The three-electrode system, consisting of a glassy carbon indicator electrode, GCE, (surface area: 7.1×10^{-2} cm^2), a platinum-wire auxiliary electrode, and a reference electrode, was employed. The reference electrode systems were as follows: (A) sample || salt bridge with saturated Et_4NClO_4 || saturated KCl || agar bridge of saturated KCl || SCE, and (B) sample || CH_3CN salt bridge containing 0.1 mol dm^{-3} Et_4NClO_4 || Ag–Ag^+(0.01 mol dm^{-3} $AgNO_3$) in acetonitrile. G4-sintered glasses were set between bridges and samples or reference electrodes. The difference in potentials observed for the above two systems, $E(Ag/Ag^+)-E(SCE)$, was always constant, −0.315 V, in all our measurements.[12] The potentials measured in (A) are listed in the text and tables. A glassy carbon electrode was polished up with diamond powder (Royal Diamond Compound 1-W-47) until the surface became a mirror before each run, so that sufficient reproducibilities could be obtained. Et_4NClO_4 was used as a supporting electrolyte.

Materials. Commercial grade acetonitrile dried over CaH_2 was twice distilled under nitrogen atmosphere. The purified solvent was stored under nitrogen atmosphere.

The cobalt complexes, $[Co^{III}(\beta\text{-pan})_2]Cl$[11] and $[Co^{III}(\beta\text{-pan})(dien)](ClO_4)_2$,[9] were reported previously.

The bivalent cobalt complex, $[Co^{II}(\beta\text{-tan})_2]$ was prepared from the stoichiometric amount of $Co(ClO_4)_2\cdot6H_2O$ and β-TAN in a similar way to $[Co^{III}(\beta\text{-pan})_2]Cl$, and easily isolated. The composition (metal to ligand ratio=1:2) and the oxidation state of the cobalt were confirmed by UV spectra[15] and elemental analysis. On the other hand, the bivalent cobalt complexes with β-PAN, α-PAN, and PAPhen could not be obtained by mixing the components. The syntheses of the cobalt(II) complexes were as follows:

1) Free acid form of β-PAN (1.0 g) and ascorbic acid (1.0 g) were completely dissolved in ethanol (500 cm^3) by heating under nitrogen atmosphere. To the solution, $CoCl_2$ (0.26 g) dissolved in a small amount of ethanol was added. The mixture was stirred and kept at 50 °C for 1.5 h. The green product formed was filtered, washed with ethanol, and dried *in vacuo* (yield 1.25 g). The green complex of a definite composition was always obtained

under the above conditions. Found: C, 54.51; H, 3.74; N, 10.86; Cl, 6.62%. Calcd for $C_{30}H_{20}N_6O_2Co \cdot C_6H_8O_6 \cdot (3/2)HCl$: C, 54.99; H, 3.78; N, 10.69, Cl, 6.76%. An analogous product was obtained for α-PAN. IR spectrum of the green complex shows the bands corresponding to ascorbic acid at around 1753 and 1650—1680 cm^{-1}. The magnetic moment μ_{eff} at 300 K is 1.94 BM. ESR spectra show no signals of organic radicals. Above data suggest that the green complex is a bivalent cobalt complex, though the state of ascorbic acid in the green complex and the structure of the green complex are not clear. A similar product was obtained for PAPhen by the analogous method. Found: C, 58.78; H, 3.87; N, 9.77%. Calcd for $C_{38}H_{24}N_6O_2Co \cdot C_6H_8O_6 \cdot 2HCl$: C, 57.29; H, 3.89; N, 9.54%.

2) To an ethanol solution (500 cm^3) of the green complex (1.0 g) with β-PAN, sodium metal (0.1 g) dissolved in ethanol (5 cm^3) was added. The solution turned red immediately. The red complex precipitated by evaporation was filtered, washed with ethanol thoroughly, recrystallized from ethanol-chloroform (1:1 v/v) several times, and dried *in vacuo* (yield *ca.* 60%). The red complex is more soluble in nonpolar solvents such as chloroform than in ethanol and insoluble in water, indicating itself acting as a noncharged complex. ESR spectra at 77 K showed the signal of cobalt(II) ion for the red complex, whereas no signal appeared for $[Co^{III}(\beta\text{-pan})_2]Cl$. The red complexes, $[Co^{II}(\alpha\text{-pan})_2]$ and $[Co^{II}(paphen)_2]$, were also synthesized by the analogous method. $[Co^{II}(\beta\text{-pan})_2]$: Color: deep reddish purple. Crystal form: too fine to be identified. Found: C, 63.52; H, 3.65; N, 14.39; Cl, 1.27%. Calcd for $C_{30}H_{20}N_6O_2Co \cdot (1/4)NaCl$: C, 63.21; H, 3.54; N, 14.74; Cl, 1.55%. $[Co^{II}(\alpha\text{-pan})_2]$: Color: dark purple. Tabular crystals. Found: C, 63.17; H, 3.65; N, 14.83%. Calcd for $C_{30}H_{20}N_6O_2Co \cdot (1/4)NaCl$: C, 63.21; H, 3.54; N, 14.74%. $[Co^{II}(paphen)_2]$: Color: deep red purple. Tabular crystals. Found: C, 68.04; H, 3.59; N, 12.87%. Calcd for $C_{38}H_{24}N_6O_2Co$: C, 69.62; H, 3.69; N, 12.82%.

Results and Discussion

Characterization of the Red Cobalt(II) Complexes. The data of absorption spectra in $CHCl_3$ and magnetic moments (solid) at room temperature for the red complexes are listed in Table 1. The absorption spectrum of $[Co^{II}(\beta\text{-pan})_2]$ is the same as that of the cobalt(II) complex observed in the rapid-scan spectral study of the reaction between Co^{2+} ion and β-PAN[7] and in the reduction product of $[Co^{III}(\beta\text{-pan})_2]Cl$ by O_2^- ion.[11] The data of elemental analysis and the absence of absorption bands assignable to cobalt(III) in the spectra measured in $CHCl_3$ indicate that the complexes do not contain cobalt(III) complexes. Though the absorption spectra of these complexes did not change in an aprotic solvent, DMSO, even bubbled with O_2 for *ca.* 30 min, the absorption spectra changed immediately to those corresponding to the cobalt(III) complexes, when a small amount of water (0.5 cm^3 H_2O to 3.5 cm^3 DMSO) was added.

Table 1. Data of absorption spectra and magnetic moments

Complex	λ_{max}/nm	$\varepsilon/10^4$ mol^{-1} dm^3 cm^{-1}	μ_{eff}/BM at 297 K
$[Co^{II}(\beta\text{-pan})_2]$	522	2.83	2.31
$[Co^{II}(\alpha\text{-pan})_2]$	322	2.80	2.16
	545	3.44	
$[Co^{II}(paphen)_2]$	310	3.38	2.52
	520	3.74	

Magnetic moments of the red complexes also show that these complexes are not cobalt(III) complexes but cobalt(II) complexes with more than one spin. It is well known that μ_{eff} of a cobalt(II) complex is variable depending on its spin-state, coordination number and geometry.[16] For example, the μ_{eff} values are expected to be 5.0—5.8, 1.80—1.85, and 2.2—2.9 BM, for octahedral high-spin, octahedral low-spin, and four-coordinated low-spin cobalt(II) complexes, respectively.[16] The μ_{eff} values listed in Table 1 are smaller than those for octahedral high-spin complexes and larger than those for octahedral low-spin complexes. The reason for this anomalous magnetic moment is interpreted as follows: 1) A mixture of high-spin cobalt(II) complexes and diamagnetic cobalt(III) complexes, 2) four-coordinated low-spin complexes, or 3) spin-state equilibrium between ^2E_g and $^4T_{1g}$ states. The possibility for 1) is excluded from results of absorption spectra and elemental analyses as mentioned above. From the results of temperature-dependence of the magnetic moment for $Co^{II}(paphen)_2 \cdot 4EtOH \cdot (1/3)CHCl_3$ (pink complex), Pandeya *et al.* took the spin-state equilibrium between ^2E_g and $^4T_{1g}$ into account.[17] Though the composition of their complex is different from that synthesized in the present study, the similarity of our data to theirs suggests that the case 3) is more probable for the other red complexes, $[Co^{II}(\beta\text{-pan})_2]$ and $[Co^{II}(\alpha\text{-pan})_2]$. Therefore, the structures of the cobalt(II) complexes are expected to be considerably flexible, whereas cobalt(III) complexes have rigid structures.[9]

These cobalt(II) complexes were found to react with copper(II) ions in DMSO. The red solutions of the cobalt(II) complexes in DMSO changed to green by the addition of copper(II) perchlorate; the same changes were observed for other copper(II) salts as well. The spectra of the final products corresponded to those for the cobalt(III) complexes. The effect of perchlorate ions was neglected, since no changes in the spectra of the cobalt(II) complexes were observed by the addition of perchlorates of other metals such as zinc(II). The oxidation by copper(II) ions should form copper(I) ions. The difference between the spectra of the final products with and without addition of 2,2′-biquinoline gave the spectrum of

copper(I)-2,2′-biquinoline complex, indicating the presence of copper(I) ions in the solutions of final products. These observations reveal the oxidation of the cobalt(II) complexes to the corresponding cobalt(III) complexes by copper(II) ions in DMSO.

Cyclic Voltammetry on the Cobalt Complexes. Cyclic voltammetry was carried out between −0.5 and +0.7 V *vs.* SCE in the scan-speed range from 10 to 500 m V s^{-1}. $[Co^{III}(\beta\text{-pan})_2]Cl$ showed one peak in both cathodic and anodic runs in this potential range. The other cobalt complexes with analogous ligands also showed similar cyclic voltammograms in the same potential range. Figure 1 shows the typical cyclic voltammogram of $[Co^{III}(\beta\text{-pan})_2]Cl$ in acetonitrile.[18] The cyclic voltammograms observed on $[Co^{II}(\beta\text{-pan})_2]$ and $[Co^{III}(\beta\text{-pan})_2]ClO_4$ were essentially the same to that of $[Co^{III}(\beta\text{-pan})_2]Cl$. The data for $[Co^{III}(\beta\text{-pan})_2]^+$ are listed in Table 2. It was found that (1) the cathodic and anodic peak currents of the observed wave, $(i_p)_c$ and $(i_p)_a$, measured at various sweep rates, v, were propotional to $v^{1/2}$, (2) the difference between cathodic ($(E_p)_c$) and anodic ($(E_p)_a$) peak potentials, $\Delta E=(E_p)_c-(E_p)_a$ was always *ca.* 60 mV, (3) the values of $(E_p)_c$ and $(E_p)_a$ were independent of v, (4) $(i_p)_a/(i_p)_c=1$ for all v, and (5) the peak potentials were independent of the kinds of indicator electrodes: A very similar wave was obtained when a GCE was changed to a Pt-electrode. On the basis of these results, the wave observed can be regarded as a simple one-electron transfer reversible system, $A+e \rightleftharpoons B$.[19]

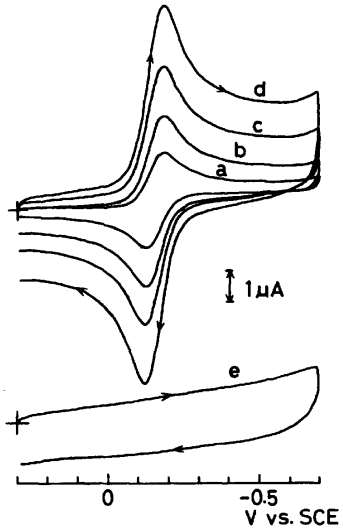


Fig. 1. Cyclic voltamograms of 2.0×10^{-4} mol dm^{-3} $[Co^{III}(\beta\text{-pan})_2]^+$ in acetonitrile solution cotaining 0.1 mol dm^{-3} Et_4NClO_4 at 25 °C. Sweep rate: **a**, 20; **b**, 50; **c**, 100; **d**, 200 mV s^{-1}. **e** is blank at sweep rate = 100 mV s^{-1}.

In order to elucidate the products of one-electron reduction of $[Co^{III}(\beta\text{-pan})_2]^+$, the constant potential electrolysis of the cobalt(III) complex at −1.0 V *vs.* Ag/Ag^+ (−0.68 V *vs.* SCE) was performed under the same conditions as in the measurement of the cyclic voltammogram. The absorption spectrum of the solution was observed during the electrolysis. As the absorption at 600 nm due to the cobalt(III) complex decreased gradually, a new band at about 520 nm due to the cobalt(II) complex appeared. Finally, the absorption spectrum almost coincided with that of $[Co^{II}(\beta\text{-pan})_2]$. Therefore, the above mentioned one-electron reversible process can be assigned

to the electron transfer, $[Co^{III}(\beta\text{-pan})_2]^+ + e \rightleftharpoons [Co^{II}(\beta\text{-pan})_2]$. The waves observed for the other cobalt complexes were also assignable to that for the Co^{II}/Co^{III} couples.

The data for the cobalt complexes with β-PAN and analogous ligands in acetonitrile are listed in Table 3 with the values of pK_a for the *ortho*-hydroxyl groups in the ligands. It is obvious that $E_{1/2}$ of the Co^{II}/Co^{III} couple is dependent on the coordinating ligands. Some features are as follows: $E_{1/2}$ of the Co^{II}/Co^{III} couple shifts to the more negative side in $[Co^{III}(\beta\text{-pan})(dien)]^{2+}$ which has one β-PAN, than in $[Co^{III}(\beta\text{-pan})_2]^+$. The value of $E_{1/2}$ of $[Co^{II}(\beta\text{-pan})_2]$ is more negative than that of $[Co^{II}(\alpha\text{-pan})_2]$ where α-PAN is different from β-PAN in the position of the azo and *ortho*-hydroxyl groups attached to the naphthol moiety. From the comparison between $[Co^{II}(\beta\text{-pan})_2]$ and $[Co^{II}(\beta\text{-tan})_2]$, in which the ligands have the same moieties, 2-naphthols, $E_{1/2}$ of the complex with thiazolyl group is more positive than that of the complex with pyridyl group. Therefore, $[Co^{II}(\beta\text{-tan})_2]$ is expected to be more stable than $[Co^{II}(\beta\text{-pan})_2]$ against the oxidation by dissolved oxygen in aqueous solution (the half-wave potential for $O_2 \rightarrow O_2^-$, $E_{1/2} = -0.05$ V *vs.* SCE in aqueous neutral solution[20]). Indeed, the observations such as, the easy extraction of $[Co^{II}(\beta\text{-tan})_2]$ into organic phase[15] and the considerably easy isolation of the complex, support the above idea. For the cobalt complexes with these analogous ligands, there is a remarkable feature of the relation between $E_{1/2}$ and pK_a of the ligands. It can be seen that as the pK_a value of the *ortho*-hydroxyl group in the coordinating ligand increases, $E_{1/2}$ shifts to the more negative direction. This suggests that cobalt(III) state is more stabilized as the basicity of the coordinating ligand increases, *i.e.*, as the ligand can coordinate strongly to the cobalt ion.

The authors thank Professor Akira Yamada, Yokohama City University for the kind advices in the measurements of cyclic voltammograms and Professor Yoshio Matsunaga, Hokkaido University for the kindness in the measurements of magnetic susceptibilities.

Recovery of Heavy Metals with Calcium Silicon Alloy. IV. Stoichiometric Discussion of the Reduction of Lead(II), Nickel(II), Iron(III), and Mercury(II) Ions

Shuzo TOKUNAGA
National Chemical Laboratory for Industry, Yatabe, Ibaraki 305
(Received September 25, 1984)

The reduction of Pb^{2+} and Ni^{2+} ions to the metallic state with the Ca–Si alloy powder can be stoichiometrically interpreted by the following elementary reactions 1—4 including the decomposition of water, a side reaction:

$$Ca^0 + Me^{z+} = Ca^{2+} + Me^0 \quad (1)$$

$$(Ca^0 + 2Me^{z+} = Ca^{2+} + 2Me^{z-1}) \quad (1')$$

$$Si^0 + 2Me^{z+} + 3H_2O = H_2SiO_3 + 2Me^0 + 4H^+ \quad (2)$$

$$(Si^0 + 4Me^{z+} + 3H_2O = H_2SiO_3 + 4Me^{z-1} + 4H^+) \quad (2')$$

$$Ca^0 + 2H_2O = Ca^{2+} + H_2 + 2OH^- \quad (3)$$

$$Si^0 + 3H_2O = H_2SiO_3 + 2H_2 \quad (4)$$

The occurrence of a reaction other than the above ones was suggested for the reduction of Fe^{3+} to Fe^{2+} ion under strongly acidic conditions. The reduction of Pb^{2+} and Ni^{2+} ions proceeded very slowly. On viewing the equivalents oxidized, the contribution of Ca in the alloy to the overall reaction was greater than that of Si; Si scarcely participated at all in the reduction of Fe^{3+} ion. Based on the above elementary reactions, the reduction of Hg^{2+} ion was discussed stoichiometrically. Almost the same equivalents of Hg^0 and Hg^I species formed in a 20-matom dm^{-3} Hg^{2+} solution, with an initial pH of 4.0. The contribution of Si to the reaction was greater than that of Ca.

Cu^{2+}, Hg^{2+}, Fe^{3+}, Pb^{2+}, Cr^{6+}, Cd^{2+}, and Zn^{2+} ions can be effectively removed from aqueous solutions with some silicon alloy powders containing Ca or Mg.[1-4] It has been considered that the removal of these metal ions is mainly due to their reduction to the insoluble species in the lower oxidation states and to their hydrolysis by OH^- ion formed by the decomposition of water, a side reaction. However, the mechanisms of these reactions have not been well elucidated. Of these reactions, the reduction of Cu^{2+} ion with the Ca–Si alloy was, in Part III, investigated stoichiometrically under weakly acidic conditions in order to prevent the hydrolysis of metal ions.[5] It has proved that the overall reaction can be substantially represented by the following four elementary reactions:

$$Ca^0 + Cu^{2+} = Ca^{2+} + Cu^0 \quad (5)$$

$$Si^0 + 2Cu^{2+} + 3H_2O = H_2SiO_3 + 2Cu^0 + 4H^+ \quad (6)$$

$$Ca^0 + 2H_2O = Ca^{2+} + H_2 + 2OH^- \quad (7)$$

$$Si^0 + 3H_2O = H_2SiO_3 + 2H_2 \quad (8)$$

The reduction of metal ions had been thought to take place mainly by Ca in the alloy, which, in the elementary state, has an extremely low standard-electrode potential, E^0=−2.866 V.[6] However, the above mechanism has shown that Si (E^0=−0.857 V)[6] in the alloy, a practically nonreactive element in aqueous solutions, mainly because of the effect of passivation, also exhibits great reducing power. Especially in solutions with Cu^{2+} concentrations higher than *ca.* 10 matom dm^{-3}, the equivalents of Si oxidized were greater than those of Ca.

The objectives of the present study are to elucidate the reaction mechanism of the reduction of metal ions other than Cu^{2+} ion with the Ca–Si alloy powder and to investigate the behavior of the reaction products, which has been obscure in the previous studies. By applying the method used for the reduction of Cu^{2+} ion, stoichiometric discussions will be made of all the reaction products of the reduction of Pb^{2+}, Ni^{2+}, Fe^{3+}, and Hg^{2+} ions, which differ in standard electrode potential and in the variation of the pH and the oxidation state. In Part I, the reducing effects of the alloy on various metal ions were examined by determining the dissolved components after a 24-h reaction period under the reaction conditions of *ca.* 0.2- to 18-matom dm^{-3} metal-ion concentrations and acidities of pH *ca.* 4 to 1-mol dm^{-3} HCl.[3] Subsequent studies by the author have revealed the following facts: The reducing effects on Ni^{2+} and Co^{2+} ions become appreciable only at neutral conditions, oxidation products of Si exist in the solid phase as well as in the solution, and the reaction rates greatly vary with the metal ions, resulting in different degrees of the side reaction. Therefore, in the present study, reactions were carried out under conditions agreeing with the respective metal ions. Concentration changes of the reaction products with the passage of time were determined in order to discuss their behavior and the relation between the metal-ion reduction and the side reaction.

Experimental

Metal-ion Solutions. Sample solutions were prepared by dissolving lead(II), nickel(II), iron(III), and mercury(II) chlorides of a reagent grade in distilled water.

Experimental Procedure. The procedure used was that reported in Part III.[5]

Results and Discussion

Outline of the Overall Reaction. In weakly acidic aqueous solutions, Cu^{2+}, Pb^{2+}, and Ni^{2+} ions are reduced by the Ca-Si alloy to form Cu^0, Pb^0, and Ni^0, respectively, in the solid phase. In the reduction of Hg^{2+} ion, insoluble Hg^0 and Hg^I species form simultaneously. A decrease in the pH is observed in these metal-ion solutions at high concentrations. Fe^{3+} ion is reduced to Fe^{2+} ion, and no solid product of iron, except hydroxide, forms. At that time, the pH tends to increase independently of the Fe^{3+} concentration.

The alloy, on the other hand, is oxidized concurrently with the metal-ion reduction to form Ca^{II} and Si^{IV} species. In addition to these reactions, there occurs a decomposition of water by the alloy as a side reaction. As has been reported previously, the alloy is practically stable and scarcely causes decomposition of water in metal-ion-free aqueous solutions above pH *ca.* 3.[3] It can, therefore, be said that the reaction with metal ions increases the active surface of the alloy, consequently causing such an appreciable side reaction.

Method of Stoichiometric Discussion. From the phenomena accompanying the reduction of metal ions by the alloy, the overall reaction is considered to be composed of the following elementary reactions, similarly to the case of the Cu^{2+} reduction:

$$Ca^0 + Me^{z+} = Ca^{2+} + Me^0 \quad (1)$$

$$(Ca^0 + 2Me^{z+} = Ca^{2+} + 2Me^{z-1}) \quad (1')$$

$$Si^0 + 2Me^{z+} + 3H_2O = H_2SiO_3 + 2Me^0 + 4H^+ \quad (2)$$

$$(Si^0 + 4Me^{z+} + 3H_2O = H_2SiO_3 + 4Me^{z-1} + 4H^+) \quad (2')$$

$$Ca^0 + 2H_2O = Ca^{2+} + H_2 + 2OH^- \quad (3)$$

$$Si^0 + 3H_2O = H_2SiO_3 + 2H_2 \quad (4)$$

Reactions 1 and 2 are for a reduction of divalent metal ions to the metallic state, such as those of Pb^{2+} and Ni^{2+} ions. Reactions 1′ and 2′ are for a one-electron reduction, such as those of Fe^{3+} and Hg^{2+} ions. Whether or not the above reactions are valid can be decided by ascertaining the equality between the total equivalents of the reduction and the oxidation products. The total-reduction equivalent is expressed by the sum of the equivalents of metal ions reduced and hydrogen produced. Both of them can be determined except in the reaction of Hg^{2+} ion, where Hg^0 and Hg^I species form in the solid phase and where, consequently, their separate determination is difficult. On the other hand, the total-oxidation equivalent is expressed by the sum of the equivalents of Ca^{II} and Si^{IV} species. Ca^{II} species is considered to be present in acidic solutions entirely in the form of Ca^{2+} ion, consequently it can readily be determined. However, the determination of Si^{IV} species is very difficult, since they exist not only in the dissolved form, but also in amorphous silica in the solid phase, together with the unreacted alloy. If the above elementary reactions are valid, the amounts of Si^{IV} species must be equal to either $(H_2+\Delta H^+)$ in equivalent when the pH decreases in the course of the reaction or to $(H_2-\Delta OH^-)$ when the pH increases. Therefore, the validity of the above reactions was evaluated by using the values of Si^{IV} calculated in such a way, while those of the other products were determined directly. For this purpose, stoichiometric discussions were made of the reactions of Pb^{2+}, Ni^{2+}, and Fe^{3+} ions, where only a single species of the metal product forms, and where, consequently, the equivalents of the metal ion reduced can readily be determined.

Reduction of Pb^{2+} Ion. The equality of the total equivalents between the oxidation products $(Ca^{2+}+Si^{IV})$ and the reduction products (Pb^0+H_2) was examined with 10.0-, 20.0-, and 30.0-matom dm^{-3} Pb^{2+} solutions, all with an initial pH of 4.0. The standard electrode potential for the reduction of Pb^{2+} ion to Pb^0 is not very high: $E^0=-0.126$ V.[6] The reaction proceeded slowly, and only 61, 52, and 44% of the Pb^{2+} ions were reduced in 60 min in the 10.0-, 20.0-, and 30.0-matom dm^{-3} solutions, respectively. All the Pb^{2+} ions was not reduced even in 3 h. However, separate experiments showed that all the Pb^{2+} ions was reduced at Pb^{2+} concentrations lower than *ca.* 1 matom dm^{-3} in 1 h. The pH decreased to *ca.* 3.6, 3.0, and 2.7 after 60 min in the 10.0-, 20.0-, and 30.0-matom dm^{-3} solutions, respectively, because of the formation of H^+ ion in the reduction of Pb^{2+} ion by Si. Equivalents of the reaction products in a 60-min reaction period for each sample solution are collectively illustrated in Fig. 1.

The total-oxidation equivalents $(Ca^{2+}+Si^{IV})$ showed good agreement with the total-reduction equivalents (Pb^0+H_2) through the 60-min reaction period in each solution. This fact indicates that the above elementary reactions 1—4, just as in the reduction of Cu^{2+} ion, are also valid for the reduction of Pb^{2+} ions. Consequently, the estimation of the equivalents of Si^{IV} oxidized is also appropriate.

In each solution, the equivalents of Ca oxidized showed a small increase in the vicinity of 60 min. On the other hand, that of Si showed a tendency to increase. This seemed related to the relative amounts

of Ca and Si remaining unreacted. The equivalents of Ca oxidized were greater than those of Si, indicating the greater contribution of Ca to the reaction. It was more significant at higher Pb^{2+} concentrations. The proportion of the equivalents of H_2 to the total-reduction values became smaller at higher Pb^{2+} concentrations. Thus, the alloy acted more effectively on the reduction of Pb^{2+} ion.

Reduction of Ni^{2+} Ion. The results regarding a 5.0-matom dm^{-3} Ni^{2+} solution are shown in Fig. 2. The initial pH was adjusted at *ca.* 6 since, at pH's lower than *ca.* 5, Ni^0 forming in the reaction readily dissolves and does not deposit in the solid phase. The reaction rate was very small since the reaction was carried out at pH's around neutrality and since, in addition, the standard electrode potential for the reduction of Ni^{2+} to Ni^0 is very low: $E^0=-0.250$ V.[6] About 17% of the Ni^{2+} ions were reduced in *ca.* 1 h; thereafter, the reaction became inappreciable. The pH rose to 7.2 after 5 min, but thereafter tended to decrease slowly, indicating the reduction of Ni^{2+} ion by Si. A satisfactory equivalence was established between the total equivalents of the reduction products and those of the oxidation products. Therefore, the redution of Ni^{2+} ion with a low standard-electrode potential can also be interpreted by the same elementary reactions as those for Cu^{2+} and Pb^{2+} ions. The reaction under neutral conditions (pH 6—7) is one of the causes of the slight extent of water decomposition. The equivalents of Ca oxidized were about twice those of Si, indicating that Ca contributes more greatly to the overall reaction, such as in the case of the Pb^{2+}-ion reduction.

Reduction of Fe^{3+} Ion. Fe^{3+} ion can readily be hydrolyzed and so become little subject to reduction by the alloy. The initial pH of the sample solution was adjusted at 2.0 to prevent the hydrolysis. It proved improper to use Fe^{3+} solutions of concentrations lower than *ca.* 10 matom dm^{-3} under such strongly acidic conditions, since the decomposition of water was dominant over the metal-ion reduction. Then a stoichiometric discussion was made of a 20-matom dm^{-3} Fe^{3+} solution where the reduction of Fe^{3+} ion was predominant. The results are shown

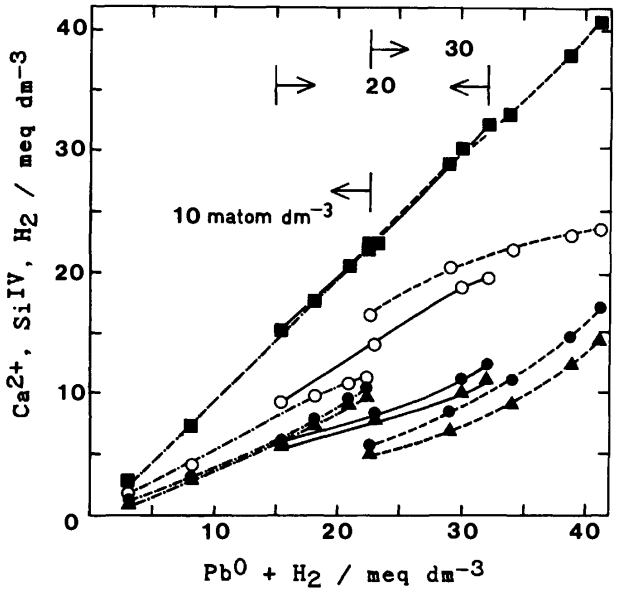

Fig. 1. Relation between equivalents of reduction products (Pb^0 and H_2) and oxidation products (Ca^{2+} and Si^{IV}).

■: Fe^{2+}, ▲: H_2, ○: Ca^{2+}, ●: Si^{IV}, △: ΔOH^-, ⊠: $Fe^{2+}+H_2$, ⊕: $Ca^{2+}+Si^{IV}$.

in Fig. 3. The standard electrode potential for the reduction of Fe^{3+} ion to Fe^{2+} ion is very high: E^0=0.771 V.[6] Fe^{3+} ion was entirely reduced in 15 min. Equivalence was not established between the total-oxidation equivalents and the total-reduction equivalents, the former being *ca.* 0.8—0.9 times the latter. Such a disagreement in equivalent has also been observed in the reduction of Cu^{2+} ion at an initial pH of 2.0, though the runs at an initial pH of 4.0 show complete agreement. This disagreement can principally be attributed to the existence of elementary reactions other than 1′, 2′, 3, and 4, for example, the formation of insoluble Ca^{II} species in the solid phase under such strongly acidic conditions.

The equivalents of Ca oxidized were much greater than those of Si. No decrease in pH at all was observed in the Fe^{3+} reduction, but a pH decrease was noticed in the Cu^{2+} run, even at an initial pH of 2.0. These facts indicate that Fe^{3+} ion is reduced mainly by Ca and that Si is consumed in the decomposition of water. It is a remarkable feature of the Fe^{3+} reduction that Si scarcely participates in the reduction reaction of a high standard-electrode potential. The cause of this has not yet been ascertained.

Reduction of Hg^{2+} Ion. Hg^{2+} ion is reduced by the alloy to form Hg^0 and Hg^I species (Hg_2Cl_2 in the present case, where chloride ion solely exists as an anion) simultaneously in the solid phase. Because of the difficulty of the separate determination of the two solid mercury species, different in the oxidation state, no detailed stoichiometric discussions have been made.[7] The above results in the present study indicate that the elementary reactions 1—4, 1′, and 2′ can also be applied as the reaction mechanism to the reduction of Hg^{2+} ion in weakly acidic solutions.

Based on these elementary reactions, the following two equations hold in equivalent: $Hg^0+Hg^I+H_2=Ca^{2+}+Si^{IV}$ and $Si^{IV}=H_2+\Delta H^+$. The amounts of Hg^0 and Hg^I can be estimated as follows:
Let x and y be the numbers of Hg^0 and Hg^I atoms formed, respectively, and let a and b be those of the removed Hg^{2+} and the total equivalent of the reduced Hg^{2+}, respectively. Then we obtain:

$$a = x + y \quad \text{and}$$
$$b = 2x + y.$$

By solving these equations, we get:

$$x = b - a \quad \text{and}$$
$$y = 2a - b.$$

In this way, the behavior of the reaction products in a 20-matom dm^{-3} Hg^{2+} solution with an initial pH of 4.0 was discussed. The results are shown in Fig. 4. Almost all the Hg^{2+} ions were removed in *ca.* 5 min. At that time, nearly equal equivalents of Hg^0 and Hg_2Cl_2 were formed in the solid phase,

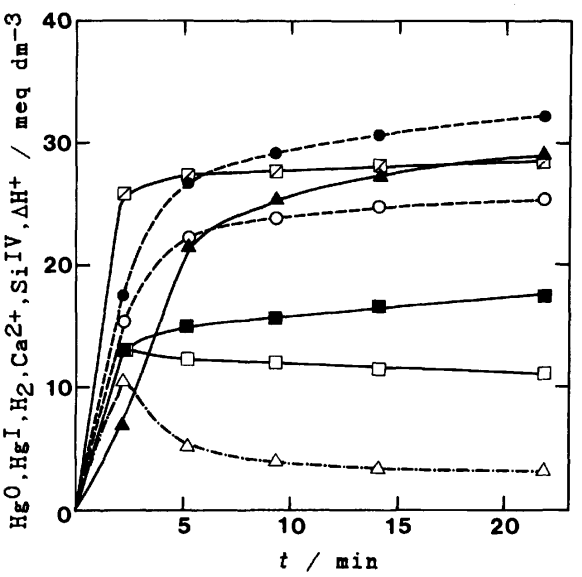

Fig. 4. Behavior of the reaction products in the reduction of 20.0-matom dm^{-3} Hg^{2+} solution.
▨: Hg^0+Hg^I, ■: Hg^0, □: Hg^I, ▲: H_2, ○: Ca^{2+}, ●: Si^{IV}, △: ΔH^+.

indicating that only one-third the initial amounts of Hg^{2+} ions were reduced to Hg^0, since the equivalent of Hg^0 is twice that of Hg^I. The standard electrode potentials for the reduction of Hg^{2+} to Hg^I and that of Hg^I to Hg^0 are 0.920 and 0.788 V, respectively.[8] These values are much higher than that of Cu^{2+} ion (E^0=0.337 V), which proceeds very efficiently to form the metallic species. In this system, the presence of Cl^- ion resulted in the formation of very stable Hg_2Cl_2, which made the reduction of Hg^{2+} ion incomplete. From *ca.* 5 min, Hg_2Cl_2 tended to decrease, while, in turn, Hg^0 increased. The rate of the reduction was small because of the very low solubility of Hg_2Cl_2. The covering of the alloy particles by the reaction products was not significant, just as in the other metal-ion runs.

The equivalents of Si oxidized were greater than those of Ca, indicating the greater contribution of Si to the overall reaction, such as in the case of the Cu^{2+} reduction. At the initial stage of the reaction, the pH decreased to *ca.* 2 because of the formation of H^+ ion in the reduction of Hg^{2+} ion by Si. In Hg^{2+} solutions of 5 matom dm^{-3} or lower, the equivalents of Si oxidized were smaller than those of Ca. The decomposition of water occurred subsequently to the Hg^{2+} reduction and exceeded the latter after *ca.* 20 min. After the greater part of the Hg^{2+} ions had been removed, the values of ΔH^+ decreased because of the formation of OH^- ion in the decomposition of water by Ca.

Regarding the contribution of Ca and Si in the alloy to the reaction, the following conclusions can generally be reached. The reduction of metal ions with low standard-electrode potentials, such as those

of Ni^{2+} and Pb^{2+} ions, proceeds mainly by Ca. Ca in the alloy seems to have a still lower electrode potential than Si. In the reduction of high electrode potentials, such as those of Cu^{2+} and Hg^{2+} ions, the reduction of metal ions by Si becomes significant, as does that by Ca. The oxidation rates of Ca and Si increase as the electrode potential of the reduction of a metal ion and the metal-ion concentration increase. At the beginning of the reaction, the oxidation rate of Ca seems greater than that of Si because of its higher electrode potential. However, the oxidation rate of Ca tends to decrease greatly when the reaction has proceeded to some extent and, consequently, the amount of unreacted Ca has become relatively small. On the other hand, the oxidation rate of Si does not decrease so much because of its large equivalent, twice that of Ca, and its large content in the alloy.

Chromatographic Study of Optical Resolution. XII. Optical Resolution of Bis(oxalato)(1,10-phenanthroline)cobaltate(III) and Its Related Anion Complexes with Cinchona Alkaloid Cations as Eluent

Katsuhiko MIYOSHI, Masahiko NATSUBORI, Naoko DOHMOTO, Shinji IZUMOTO, and Hayami YONEDA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-senda-machi, Naka-ku, Hiroshima 730

(Received November 29, 1984)

Ion-exchange chromatography was applied to the optical resolution of three anion complexes, $[Co(ox)_2(phen)]^-$, $[Co(ox)_2(bpy)]^-$, and $[Co(ox)_2(en)]^-$ (ox=oxalate anion, phen=1,10-phenanthroline, bpy=2,2′-bipyridine, and en=ethylenediamine) using as a chiral eluent aqueous solutions of various cinchona alkaloid cations, *i.e.*, cinchoninium, cinchonidinium, quinidinium, and quininium ions, and their 9-acetoxy and N^1-methyl derivatives. Fairly good resolution was achieved for the first two complexes with the 9-acetoxy derivatives as eluent, but no practical resolution was attained for $[Co(ox)_2(en)]^-$. Retention volumes V_R determined and separation factors α estimated from V_R revealed that both of the HO-C(9) and H-N(1)$^+$ groups of each alkaloid participate in the interaction with the complex, and that the α value is increased upon acetylation of the OH group with the elution order reversed. These observations were interpreted in terms of two concomitant interaction modes in which the HO-C(9) and H-N(1)$^+$ groups are hydrogen-bonded to the ox ligand(s) and the quinoline ring is stacked with the phen or bpy ligand of the anion complex.

Many examples of successful optical resolution by chromatography have been reported for cationic metal complexes, and the mechanism by which chiral discrimination is effected there have been discussed in detail.[1,2] On the other hand, only few anionic metal complexes have been subjected to chromatographic resolution simply because suitable cationic resolving agents are not available. Cinchona alkaloids, *i.e.*, (8*R*,9*S*)-cinchonine, (8*S*,9*R*)-cinchonidine, (8*R*,9*S*)-quinidine, and (8*S*,9*R*)-quinine, have long been used as resolving agents in optical resolution of several anionic complexes *via* diastereomer formation. Thus, these chiral alkaloid cations may potentially serve as eluent in chromatographic resolution of anionic complexes. In fact, Yamazaki[3] succeeded in complete resolution of $[Co(edta)]^-$ and *cis*-$[Co(ida)_2]^-$ (edta and ida=ethylenediaminetetraacetate and iminodiacetate anions, respectively) using quininium ion as an ion-pairing reagent in reversed-phase chromatography, and Izumoto *et al.*[4] extended this technique to the optical resolution of several anion complexes of the type *cis*-$[Co(O)_4(N)_2]^-$. However, these anion complexes are not easily resolved by normal-phase ion-exchange chromatography even with cinchona alkaloid cations used as eluent. This is probably because these alkaloids exhibit no strong tendency to associate with common anionic complexes unless they are introduced into some special environment, *e.g.*, hydrophobic environment as in reversed-phase chromatography.

In our previous paper,[5] it was reported that monoprotonated species of cinchona alkaloids bear a strong ability to displace the chiral equilibrium between two enantiomers of a labile metal complex, $[Cr(ox)_2(phen)]^-$ (ox=oxalate anion and phen=1,10-phenanthroline) in aqueous solution. This observation suggests that cinchona alkaloid cations associate appreciably with $[Cr(ox)_2(phen)]^-$ and impose their spacial demands on the two enantiomers differently. Therefore, the corresponding inert cobalt(III) complex is expected to be resolved by usual ion-exchange chromatography if these alkaloids are used as eluent. With this expectation in mind, an attempt was made to resolve the three anion complexes, $[Co(ox)_2(phen)]^-$, $[Co(ox)_2(bpy)]^-$, and $[Co(ox)_2(en)]^-$, (bpy=bipyridine and en=ethylenediamine) with various cinchona alkaloid cations employed as a chiral eluent, and their stereoselective interactions are discussed in detail.

Experimental

Materials. $Na[Co(ox)_2(en)]\cdot H_2O$[6] and $K[Co(ox)_2(bpy)]\cdot 3H_2O$[7] were prepared as described in the literature. $K[Co(ox)_2(phen)]\cdot 4H_2O$ was derived from $[Co(ox)(phen)_2]\cdot[Co(ox)_2(phen)]\cdot 3H_2O$[7] at room temperature according to the procedures applied to the corresponding bpy complex.[7,8] Absolute configurations of these complexes were assigned previously. 9-Acetoxy and N^1-methyl derivatives of various cinchona alkaloids used as eluent were obtained as monohydrochlorides and monochlorides, respectively, according to the procedures presented earlier.[4,8] They were found to be satisfactorily pure by elemental analysis. Unmodified cinchona alkaloids commercially available were also converted to monohydrochlorides to prepare their aqueous solutions. The anion-exchange resin used was IEX-520 QAE-SIL (Toyo Soda Manufacturing Co. Ltd.), which carries quaternary ammonium groups covalently bonded to the surface of silica gel.

Chromatography. Columns (4×150 mm) were packed with IEX-520 QAE-SIL and each was equilibrated with an aqueous eluent containing one of various cinchona alkaloids as monohydrochloride or monochloride salt at a concentration of 0.01 mol/dm^3. Each eluent with pH adjusted to 4.0 with acetic acid, was degassed by an

aspirator before use. An aqueous solution (20 μl) of a racemic complex (0.1 mol/dm³) containing bis(ethylenediamine)copper(II) chloride (0.05 mol/dm³) as a marker for void volume measurement, was injected by a syringe on the top of the column and was eluted at an elution rate of 1.0 cm³/min. The eluate was guided to a flow cell to detect the complex at 535 nm with a Shimadzu UV-140 spectrophotometer. The adjusted retention volumes V_R of both enantiomers were estimated from the elution curves thus recorded and were found to be reproducible to within at least ±0.2 cm³ for $[Co(ox)_2(phen)]^-$ and $[Co(ox)_2(bpy)]^-$ and ±0.1 cm³ for $[Co(ox)_2(en)]^-$. The elution order was determined by the CD spectra of fractionally collected eluates. Each complex was also eluted with an aqueous NaCl solution (0.01 mol/dm³) to estimate its intrinsic affinity for the resin. The chromatographic apparatus used in this study was the same as in our previous works[9] except that a Jasco BIP-1 pump for HPLC was newly employed. The CD spectra were recorded on a Jasco J-40CS spectropolarimeter at ambient temperature.

Results and Discussion

Elution Curves. Figure 1 shows the structures of the cinchona alkaloids used as eluents in the present study. In addition to these naturally occurring alkaloids, their 9-acetoxy (9-AcO) and N^1-methyl (N^1-Me) derivatives were used. The three racemic complexes $[Co(ox)_2(phen)]^-$, $[Co(ox)_2(bpy)]^-$, and $[Co(ox)_2(en)]^-$ were at first eluted with a neutral eluent in which each alkaloid exists predominantly as a monoprotonated species. The adjusted retention volumes V_R, however, showed no satisfactory reproducibility. This implies that protonation and deprotonation take place on the N(1) and N(1′) atoms of the alkaloid as well as on the incompletely alkylated amine groups present in the resin. On the other hand, the separation factor α, the ratio of V_R for the late-eluted enantiomer to V_R for the other, was found to be higher than that obtained with a slightly acidified eluent (pH=4.0 with acetic acid) used in the later runs. For example, α values of 1.10 and 1.05 were derived for the phen and bpy complexes, respectively, with a neutral (8*S*,9*R*)-9-acetoxycinchonidinium (9-AcO-CD) chloride solution, whereas 1.08 and 1.03 were obtained respectively with an acidified 9-AcO-CD chloride solution. The present study was undertaken to elucidate the mechanisms of chromatographic resolution of the anion complexes rather than to search for the optimum conditions for the resolution. Accordingly, acidified eluents were used throughout the following chromatographic runs at the expense of discrimination efficiency. Under these conditions, each alkaloid exists predominantly as a diprotonated species, and protonation is complete on the incompletely alkylated amine groups partly present in the resin.

In Figs. 2 and 3 are shown typical elution curves of the three anion complexes recorded with (8*R*,9*S*)-quinidinium (QD) chloride and (8*R*,9*S*)-9-acetoxyquinidinium (9-AcO-QD) chloride as eluent, respectively. Fairly good resolution is achieved for $[Co(ox)_2(phen)]^-$ with QD (separation factor α=1.09) and for $[Co(ox)_2(bpy)]^-$ and $[Co(ox)_2(phen)]^-$ with 9-AcO-QD (α=1.10 and 1.16, respectively), but no practical resolution is accomplished for $[Co(ox)_2$-

(en)]$^-$ with any of the two eluents, as seen in Figs. 2 and 3. It is also notable that the elution order is reversed for the phen and bpy complexes when the HO-C(9) group of QD is acetylated. The reversal in the elution order is also observed for the two complexes with other alkaloids, as seen later (Table 1).

Retention Volumes V_R *and Separation Factors* α. In Table 1 are summarized the fast-eluted enantiomers (Λ or Δ), average retention volumes V_R, and separation factors α obtained for the three complexes with various cinchona alkaloid cations as eluents. Several important observations are noted here. (1) Better resolution is attained for the phen complex with a particular eluent than for the bpy complex, while no practical resolution is possible for $[Co(ox)_2(en)]^-$ with any of the eluents examined. (2) Except for $[Co(ox)_2(en)]^-$, the Δ enantiomer is generally eluted faster with the unmodified and N^1-methylated alkaloids having an (8*R*,9*S*) configuration, and the Λ enantiomer is eluted faster with those having an (8*S*,9*R*) configuration. The elution order is completely reversed upon acetylation of the HO-C(9) group on each alkaloid. (3) The elution ability of each alkaloid is diminished upon acetylation of the HO-C(9) group and N^1-methylation for all three complexes, while the former modification leads not only to the reversal in the elution order but also to the increased separation factor α for the phen and bpy complexes. (4) The alkaloids with an (8*R*,9*S*) configuration bear a stronger elution ability for each complex than those with an (8*S*,9*R*) configuration. (5) For the unmodified and N^1-methylated alkaloids, the (8*S*,9*R*) isomers afford higher α values than the (8*R*,9*S*) isomers, whereas higher α values are obtained with the (8*R*,9*S*) isomers for the 9-AcO derivatives. It is not obvious from the data in Table 1 whether α values of the en complex also depend on the configurations of the C(8) and C(9) atoms of the eluent alkaloids. (6) The alkaloids carrying a methoxy (MeO) group at the 6′ position on the quinoline ring, *i.e.*, quinidine (QD) and quinine (QN) and their derivatives afford lower V_R values for each complex, *i.e.*, they bear a greater elution ability for it, than cinchonine (CN) and cinchonidine (CD) and their derivatives, respectively. This does not hold for the en complex.

The first observation suggests that the aromatic phen or bpy ligand plays an essential role in the interaction with the eluent cation. In fact, the pmr measurements reported previously[8] indicate that the quinoline ring of QN or 9-AcO-QN is stacked with the phen ligand of $[Co(ox)_2(phen)]^-$ in D_2O. Since the stacking is expected to be more extensive with the phen ligand, observation (1) is consistent with the pmr measurements. If the MeO group on the quinoline ring works to strengthen the stacking between the two aromatic rings, for example by its π electron-releasing effect,[10] observation (6) also supports the view that the stacking leads to an appreciable association between the eluent cation and the phen or bpy complex in water. For the en complex, no such stacking is possible, so that no practical resolution is achieved with any of the cinchona alkaloids and the presence of the MeO group should have no effect on the elution ability of any alkaloid for this complex, as is actually the case.

Observation (3) is interpreted to mean that both of

a) V_R for the late-eluted enantiomer. b) V_R for the fast-eluted enantiomer. c) Partial resolution. d) No practical resolution. e) Type 2 mode predominates over the type 1 mode (see the text).

the HO-C(9) and H-N(1)$^+$ groups of each alkaloid participate in the interaction with the anion complexes. These acidic groups are likely to form hydrogen bonds to the basic ox ligand(s) of the complex. Then, acetylation and N^1-methylation of each alkaloid naturally prohibit these hydrogen-bonding interaction, its elution ability being thereby lowered. It is also probable from observation (3) that acetylation of each alkaloid leads to a drastic change in the interaction mode with the phen and bpy complexes. On the other hand, N^1-methylation leads only to diminished elution ability of each alkaloid for the respective complexes. The elution ability is similarly lowered for the 9-AcO derivatives upon N^1-methylation with the elution order unaltered.

Observation (4) implies that each complex interacts with the eluents by responding differently to their (8*R*,9*S*) and (8*S*,9*R*) isomers. Since these isomers are not enantiomeric owing to the presence of other two asymmetric carbon atoms (3*R*,4*S*) in common, the vinyl group at the C(3) atom must have some influence on the interaction with the complex.

Association Models. All the implications drawn from the experimental data given in Table 1 are interpreted reasonably within the framework of the association models advanced previously to account for the stereochemical aspects of the Pfeiffer effect of [Cr(ox)$_2$(phen)]$^-$.[8] The model called the type 1 is reproduced in Figs. 4 and 5 for the phen complex with (8*S*,9*R*)-QN and (8*R*,9*S*)-QD, respectively. In this model, two interaction modes are involved; the stacking between the phen and quinoline rings, and the hydrogen bonds of the H-N(1)$^+$ and HO-C(9) groups to the ox ligand(s). The simultaneous hydrogen bonds of the two groups to the complex are possible only when the complex approaches the alkaloid from above, as seen in Figs. 4 and 5. That is, type 1 model is valid only for the alkaloids having the OH group available for the hydrogen-bonding interaction.

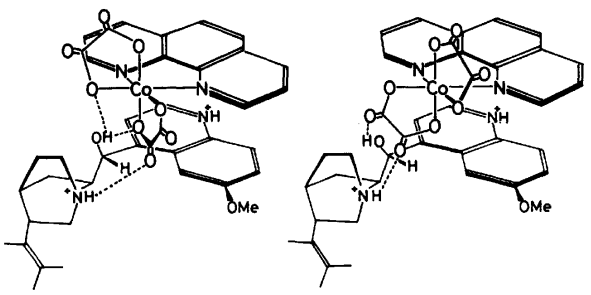

Fig. 4. Type 1 association models for (8*S*,9*R*)-quininium (QN) ion with *Λ*-[Co(ox)$_2$(phen)]$^-$ (left) and with *Δ*-[Co(ox)$_2$(phen)]$^-$ (right).

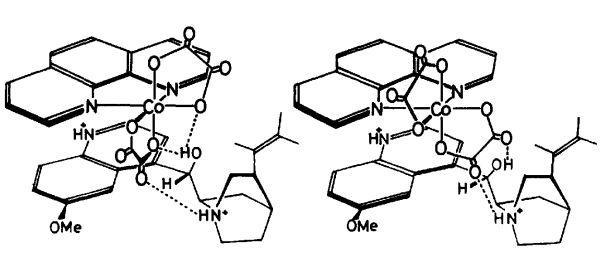

Fig. 5. Type 1 association models for (8*R*,9*S*)-quinidinium (QD) ion with *Δ*-[Co(ox)$_2$(phen)]$^-$ (left) and with *Λ*-[Co(ox)$_2$(phen)]$^-$ (right).

When the complex has a *Λ* configuration, the HO-C(9) group of (8*S*,9*R*)-QN can be nicely located to form hydrogen bonds to both ox ligands, and the H-N(1)$^+$ group is also hydrogen-bonded to the carbonyl group on one of the ox ligands (left model in Fig. 4). On the other hand, when the complex has a *Δ* configuration, only one ox ligand can participate in the hydrogen-bonding interaction with (8*S*,9*R*)-QN (right model in Fig. 4). In this way, chiral discrimination between the two enantiomers is effected for [Co(ox)$_2$(phen)]$^-$, and [Co(ox)$_2$(bpy)]$^-$ is similarly discriminated, though to a lesser extent owing to the reduced aromaticity of the ligand.

With (8*R*,9*S*)-QD, the *Δ* complex can interact more favorably, as seen in Fig. 5, in keeping with the elution orders listed in Table 1. When a comparison is made between (8*S*,9*R*)-QN and (8*R*,9*S*)-QD with respect to type 1 interaction, they behave evidently in an enantiomeric fashion; no definite difference is discernible between them. Then, it follows that the dependence of V_R and α on the configurations around the C(8) and C(9) atoms is not accounted for by the type 1 model alone. Further discussions are needed to interpret observations (4) and (5) reasonably (see later).

If the H-N(1)$^+$ group of each alkaloid is methylated, it ceases to hydrogen bond to the C=O group on the ox ligand. Then, it is natural for the elution ability to be lowered upon N^1-methylation in the type 1 model. Since the elution ability is similarly lowered for the en complex, the hydrogen-bonding interaction of the H-N(1)$^+$ group certainly prevails also for the en complex.

The chromatographic behavior exhibited by the 9-AcO derivatives is now examined in detail. It is evident that the 9-AcO-derivatives cannot adopt the type 1 mode in which the hydrogen-bonding interaction of the HO-C(9) group is indispensable. Then, an alternative association model (called type 2) is proposed in which the complex approaches the alkaloid from below to gain the stacking between the phen and quinoline rings as before (Figs. 6 and 7). In this model, the AcO group is not involved in the interaction with the complex, but it blocks access of the complex from above. Hence, the *Δ* complex can associate more favorably through dual hydrogen bonds with (8*S*,9*R*)-9-AcO-QN (left model in Fig. 6), the parent alkaloid of which (*i.e.*, (8*S*,9*R*)-QN) favors

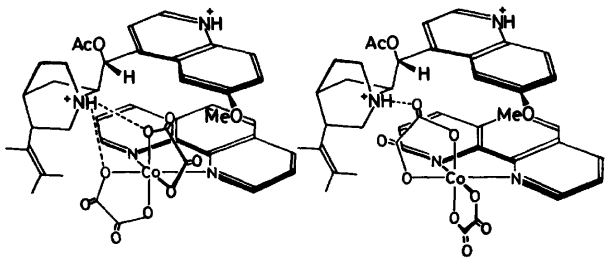

Fig. 6. Type 2 association models for (8*S*,9*R*)-9-acetoxyquininium (9-AcO-QN) ion with *Δ*-$[Co(ox)_2(phen)]^-$ (left) and with *Λ*-$[Co(ox)_2(phen)]^-$ (right).

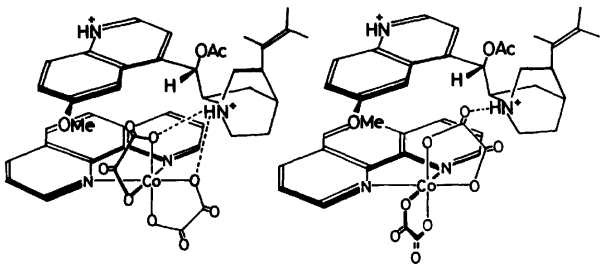

Fig. 7. Type 2 association models for (8*R*,9*S*)-9-acetoxyquinidinium (9-AcO-QD) ion with *Λ*-$[Co(ox)_2(phen)]^-$ (left) and with *Δ*-$[Co(ox)_2(phen)]^-$ (right).

the opposite enantiomer in the type 1 model (Fig. 4). By contrast, the *Λ* complex interacts with (8*S*,9*R*)-9-AcO-QN only through a single hydrogen bond (right model in Fig. 6). The reversal in the elution order upon acetylation is rationalized in this way. Furthermore, it is to be expected from a consideration of Figs. 6 and 7 that the elution ability of each alkaloid will be lowered upon acetylation, because only the H–N(1)$^+$ group is involved in the hydrogen bond to the complex in the type 2 mode, and that N^1-methylation of the 9-AcO derivatives will lead to their further diminished elution ability.

Figure 7 shows how (8*R*,9*S*)-9-AcO-QD interacts more favorably with the *Λ* complex than with the *Δ* complex *via* the type 2 mode, in accordance with the elution orders of the phen and bpy complexes. However, a close comparison between (8*R*,9*S*)-9-AcO-QD and (8*S*,9*R*)-9-AcO-QN with respect to the type 2 interaction reveals that steric hindrance is anticipated between the vinyl group at the C(3) atom and one ox ligand when the interacting alkaloid has an (8*S*,9*R*) configuration like QN and CD (Fig. 6). On the contrary, the vinyl group is far from any part of the complex when the alkaloid has an (8*R*,9*S*) configuration like QD and CN (Fig. 7). In other words, the type 2 model predicts that (8*R*,9*S*)-CN and (8*R*,9*S*)-QD associate with the complex more smoothly than (8*S*,9*R*)-CD and (8*S*,9*R*)-QN, respectively, in the type 2 mode. This prediction is fulfilled by the V_R and α values obtained with their 9-AcO derivatives which adopt the type 2 mode exclusively; (8*R*,9*S*)-9-AcO-CN and (8*R*,9*S*)-9-AcO-QD afford smaller V_R values and higher α values than (8*S*,9*R*)-9-AcO-CD and (8*S*,9*R*)-9-AcO-QN, respectively, for both phen and bpy complexes.

It is easily accepted that the unmodified and N^1-methylated alkaloids having the HO–C(9) group can also adopt the type 2 mode in which the OH group is not involved. Then, it follows that the (8*R*,9*S*)-alkaloids, for example, favor the *Δ* complex in the type 1 mode, but they favor the *Λ* complex in the type 2 mode. The overall elution order is of course governed by the type 1 mode, since the type 1 mode predominates over the type 2 mode (with three exceptions, see below.) owing to the presence of the hydrogen-bonding interaction of the HO–C(9) group in the former mode. Then, lower α values are naturally obtained with the unmodified and N^1-methylated alkaloids which adopt the two modes simultaneously than with their 9-AcO derivatives which are forced to adopt the type 2 mode only. Furthermore, the unmodified and N^1-methylated alkaloids with an (8*R*,9*S*) configuration should exhibit much lower α values and stronger elution ability, since they interact with the complex more intimately in the type 2 mode than do those with an (8*S*,9*R*) configuration. In this way, the dependence of V_R and α values on the configurations around the C(8) and C(9) atoms is explained for these unmodified and N^1-methylated alkaloids in terms of the two concomitant interaction modes (type 1 and type 2) which favor opposite enantiomers of each complex with a particular alkaloid.

It is evident from Table 1 that (8*R*,9*S*)-CN and (8*R*,9*S*)-N^1-Me-CN afford very low α values, as expected, while α values obtained with (8*R*,9*S*)-QD and (8*R*,9*S*)-N^1-Me-QD carrying a MeO group are not so low as compared with those obtained with (8*S*,9*R*)-QN and (8*S*,9*R*)-N^1-Me-QN. This suggests that the MeO group works to strengthen the stacking in the type 1 mode to a greater extent than in the type 2 mode. In fact, if the (8*R*,9*S*)-alkaloids having no MeO group like CN and N^1-Me-CN are used as eluent, the resulting elution order is reverse to that predicted by the type 1 model. Thus, it is fairly likely that the type 2 mode predominates over the type 1 mode for these alkaloids. In this way, the three exceptional elution orders are rationalized. The above discussions lead us to conclude that the 9-AcO derivatives, particularly those with an (8*R*,9*S*) configuration, are effective as eluents in the chromatographic resolution of $[Co(ox)_2(phen)]^-$ and $[Co(ox)_2(bpy)]^-$, since these eluents adopt the type 2 mode exclusively and interact with the complex smoothly in the type 2 mode. N^1-Methylation of these 9-AcO derivatives tends to give rise to further improved discrimination efficiency.

Resolution of $[Co(ox)_2(en)]^-$. The above discussions apply to the phen and bpy complexes only. For the en complex, no practical resolution is achieved by usual ion-exchange chromatography with any alkaloids as eluent probably owing to the absence of the stacking interaction mentioned earlier. Izumoto *et al.*,[4] on the other hand, resolved this complex successfully by reversed-phase chromatography using (8*S*,9*R*)-QN as an ion-pairing reagent (α=1.14 at pH=4.9), and they proposed a mode of chiral discrimination in which the hydrogen bond of the H-N(1)$^+$ group to the ox ligands served as a dominant interaction, but the HO-C(9) group was not involved at all. The discrimination mechanism they proposed, however, fails to accommodate our present experimental results that V_R of the en complex also depends on the configurations around the C(8) and C(9) atoms of the eluent alkaloid and it is increased upon acetylation. As judged from the elution orders of the en complex obtained in the present study, this complex is likely to interact with each alkaloid dominantly *via* the type 2 mode. If the type 1 and 2 modes are compared from the electrostatic point of view, the negative charge on the ox ligands is more effectively neutralized in the latter mode by the positively charged H-N(1)$^+$ group. Since the en complex has no aromatic ligand leading to an appreciable association with the eluent alkaloid, electrostatic and hydrogen-bonding interactions are expected to serve as the main driving forces for the en complex to interact with the eluent. As a result, it is not unreasonable to suppose that the en complex adopts the type 2 mode predominantly in which the electrostatic interaction prevails to a greater extent than in the type 1 mode. Then, it is exactly what is predicted in the type 2 mode that the (8*R*,9*S*)-alkaloids elute this complex faster than the (8*S*,9*R*)-alkaloids. In addition, the elution order of the en complex is naturally unaltered upon acetylation. The contribution of the type 1 mode is, of course, not ruled out, since the lowered elution ability for this complex upon acetylation of each eluent could not otherwise be explained.

The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 59540392) from the Ministry of Education, Science and Culture.

Hexaamminecobalt(III)-Hydrogen Ion Exchange in α- and θ-Zirconium Phosphates with Various Particle-size Distribution[1)]

Yoshitsugu HASEGAWA* and Kunio FUJITA
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Nakamachi, Koganei, Tokyo 184
(Received December 17, 1984)

The hexaamminecobalt(III)-hydrogen ion exchange in zirconium phosphates was studied by means of the batch method, mainly with regard to the particle-size distribution of zirconium phosphates. α-Zirconium phosphates were prepared by the direct-precipitation method. The degree of ion exchange increased with the fineness of the zirconium phosphates used. The ion exchange proceeded to a lesser extent in highly crystalline α-zirconium phosphate. θ-Zirconium phosphate with the interlayer distance of 10.4 Å took up the complex cation selectively and easily. Fifty percent of the protons in the θ-zirconium phosphate were thus replaced with hexaamminecobalt(III), and the interlayer distance was expanded to 11.2 Å.

An inorganic ion exchanger, α-zirconium phosphate, $Zr(HPO_4)_2 \cdot H_2O$, has been investigated by many workers. Its crystal structure is known precisely, and the ion-exchange behavior toward many cations has been discussed with regard to the structure.[2,3)] α-Zirconium phosphate acts as an ion-sieve due to its structural restriction. However, α-zirconium phosphate can also be used as an ion-exchanger with large cations, such as cobaltcene, hexaamminecobalt(III), and tetraammineplatinum(II) ions, in spite of probable steric hindrance.[4—6)]

The ion-exchange properties of α-zirconium phosphate have been influenced by the method of preparation, since the method has much effect on the crystallinity and particle-size distribution.[7)] Although the effect of crystallinity has been studied extensively, that of particle size has been investigated only for the potassium-hydrogen ion exchange by means of α-zirconium phosphate, which has the same crystallinity.[8)]

α-Zirconium phosphate also has a possibility of use as a catalyst or catalytic support.[3)] When α-zirconium phosphate is applied to a catalytic support, a complex cation which has an ionic radius larger than 1.3 Å may be used. Hexaamminecobalt(III) was selected as a model of the complex cation, and the ion exchange was studied previously. In this case, not all the protons in α-zirconium phosphate involved in the ion exchange, and the unreacted α-zirconium phosphate coexisted with the hexaamminecobalt(III) form of α-zirconium phosphate.[5)] During the course of these experiments, our attention was called to a subtle difference in the ion-exchange behavior among α-zirconium phosphates toward the complex cation.

According to Haynes, Jr., the particle-size distribution should be considered in some cases in estimating catalytic effectiveness in a heterogeneous catalyst.[9)] Synthetic zeolite catalysts are typical examples of this case. Hence, it is of interest to study the hexaamminecobalt(III)-hydrogen ion exchange with regard to the particle-size distribution of α-zirconium phosphate.

Alberti *et al.* pointed out that a highly hydrated zirconium phosphate, for example, θ-zirconium phosphate, can easily exchange several cations with large ionic radii.[10)] However, their method of preparation was complex in procedure, and severe conditions were required for the starting material. Since Kijima recently reported a simple method of preparation,[11)] the same ion exchange has now been studied with θ-zirconium phosphate.

Experimental

Preparation of α- and θ-Zirconium Phosphates and Hexaamminecobalt(III) Trichloride. α-Zirconium phosphates were prepared by two direct-precipitation methods. One of the methods was previously reported, and Samples A and B were obtained.[12)] When Sample A was prepared, the zirconium dichloride oxide octahydrate used as a starting material was purified to remove the free hydrochloric acid; Sample B was prepared without the purification. The Inoue and Yamada method was modified to prepare Sample C.[13)] The following conditions were employed: $ZrOCl_2 \cdot 8H_2O$ 0.26 mol dm^{-3}, HF 1.7 mol dm^{-3}, H_3PO_4 6.2 mol dm^{-3}; reaction temperature, 50 °C, and reaction time, 120 h. Since large crystallites were obtained, the products were sieved and the fraction under 400-mesh was used. Sample D was prepared from the large crystallites obtained in the preparation of Sample C. They were ground and sieved under a 400 mesh.

θ-Zirconium phosphate, $Zr(HPO_4)_2 \cdot 6H_2O$, was prepared according to the literature.[11)] The exchanger thus obtained will herein be referred to as Sample E. Identification was made by means of X-ray diffractometry.

Hexaamminecobalt(III) trichloride, $[Co(NH_3)_6]Cl_3$, was prepared according to the literature.[14)]

Ion Exchange. The ion exchange was carried out by the batch method. In view of the rate of the reaction and the stability of hexaamminecobalt(III) ions in the solution, the experimental conditions were determined as follows; the concentration of the complex cation, 0.02 mol dm^{-3}, reaction temperature, 90 °C, and reaction time, 30 min. After the end of the reaction, the exchanger was separated by centrifugation. The

pH value of the supernatant was determined with a pH meter. The exchanger was again added to a new complex solution, and the ion exchange was carried out. This procedure was repeated until the pH value of the supernatant was over 5.

Particle-size Distribution and Structural Study. The particle-size distribution was measured with a Shimadzu centrifugal particle-size analyzer SA-CP2 for Samples A, B, and C and with a Seishin Kogyo microphotosizer SKA-5000 for Sample D. Distilled water or a sucrose solution was used as the dispersion medium.

The crystallite size of zirconium phosphates was estimated from the Scherrer equation: $D=K\lambda/\beta\cos\theta$, where K=constant(0.9), β=corrected breadth at half-height, λ=wave length(1.542 Å), and θ=Bragg angle.[15]

The change in the interlayer distance was observed by means of X-ray diffractometry. The powder patterns were recorded with a Rigaku Denki Geigerflex diffractometer, using Ni-filtered Cu $K\alpha$ radiation(λ=1.542 Å).

Results and Discussion

Particle-size Distribution. Since α-zirconium phosphate has a layered structure and has been obtained as thin hexagonal or triangular platelets,[2] the apparent Stokes radius should be considered as an approximate index. The particle-size distribution curves are shown in Fig.1. Sample A had the $D50$ of 3 μm, where $D50$ means 50% diameter(median size); most of the fraction of the particles was present under 2 μm. The $D50$ of Sample B was 2 μm, and 32% of the particles were present between 2—1 μm. The particles of Sample C were coarse. The $D50$ was equal to 30 μm, and 50% of the sample had a diameter of 20—30 μm. Two percent of the sample were present under 5 μm. Sample D was more coarse than Sample C and had a $D50$ of 50 μm. Both Samples C and D had much the same high crystallinity.

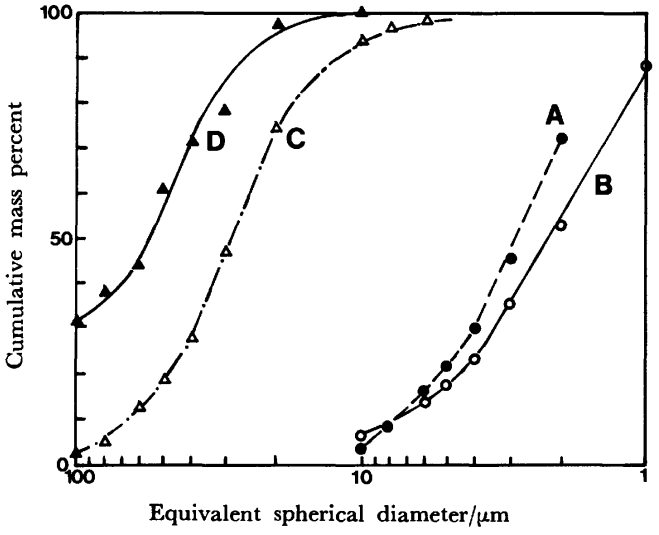

Fig. 1. Particle size distribution of Samples A,B,C, and D.

Since Sample E (θ-zirconium phosphate) was very fine, the crystallite size was measured by means of X-ray diffractometry. Sample E had an average thickness of 0.06 μm in the direction of (002). Another sample of α-zirconium phosphate (Sample F) was obtained by drying θ-zirconium phosphate in air at room temperature. The particle size of Sample F in the direction of (002) was almost equal to 0.04 μm. The estimated size is compatible with the predicted value of 0.043 μm. Since the interlayer distance of θ-zirconium phosphate decreases upon drying from 10.4 to 7.6 Å, it is possible to predict the crystallite size of Sample F. The crystallinities of Sample E and F can be considered to be much the same. The order of particle sizes was as follows: Sample F<Sample E<Sample B<Sample A<Sample C<Sample D.

Ion Exchange. The pH value of the supernatant solution was employed as an index to estimate the degree of the ion-exchange reaction.

Figure 2 shows the pH change in the supernatant. Sample A and B behaved similarly. Here, the reaction proceeded considerably at the early runs of the ion exchange. The pH change was moderate through the whole ion-exchange runs in Sample C. The degree of ion exchange per run was smaller in Sample C than in Samples A and B. In contrast to Sample C, the pH values increased rapidly in Sample D.

The above fact indicate that the particle-size distribution of the exchanger was related to the ion-exchange behavior and the degree of ion exchange. The smaller the particles were, the more easily could the reaction take place. When the pH change in Sample C is compared with that of Sample D, it can be stated that, even though the exchangers have the same crystallinity, the ion-exchange behavior differs significantly. The difference between Samples

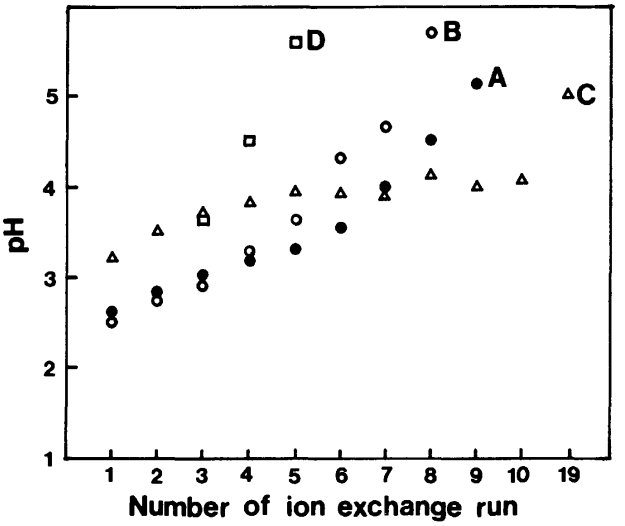

Fig. 2. pH change in the supernatant with the ion-exchange run for Samples A,B,C, and D.
In Sample C pH values of the first two runs overlapped with those of Sample A.

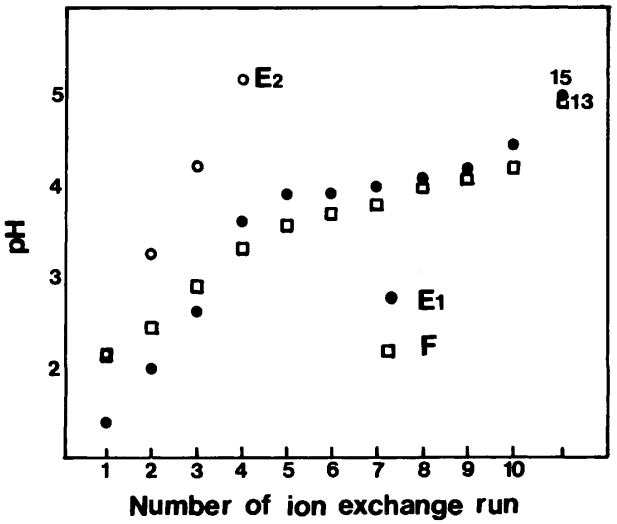

Fig. 3. pH change in the supernatant with the ion-exchange run for Samples E and F.

A and B and Sample D is probably caused by the nature of the surfaces. Since the cleavage of α-zirconium phosphate by grinding will take place mainly at the (002) plane, it is probable that the ratio of the protons on the surface to those in the crystallite increases and that the ion exchange accelerates at early runs.

The pH change in Samples E and F is shown in Fig. 3. Since θ-zirconium phosphate easily lost hydrated waters and changed to α-form in air, it must be stored in distilled water. Therefore, it is unable to weigh the exchanger to be used. In this figure, two typical pH changes are shown. The ratio of the amounts of exchanger to the volume of the complex solution was larger for E1 than for E2. The two curves appear quite different. The curves show that the pH value of the supernatant was lower for E1 than for E2 and that E1 needed more ion-exchange runs to the end of the reaction. For this difference, there are two possible explanations. One is that more complex cations must be used to replace more protons. Another is that, because the complex cation is more stable in an acidic solution than in a neutral or alkaline solution, the ion-exchange reaction proceeded more for E1.

The ion-exchange reaction proceeded extensively, especially when the ratio was high. When the complex solution was added to Sample E, the color of the exchanger surface turned orange, the same as the complex cation. These facts indicate that the ion exchange occurred fast, even at room temperature. The pH value of the supernatant for E1 was significantly low in the first run. This means that θ-zirconium phosphate took up selectively the complex cation and that the degree of the reaction was high.

In Sample F the ion exchange proceeded similarly to Samples A and B, though the pH values were lower in the first two ion-exchange runs. This is probably because the particle size of Sample F was smaller than that of Samples A and B.

Table 1. Content of nitrogen, hydrogen, and ignition loss

Sample	N(%)	H(%)	Ig. loss (%)	(H/N) molar ratio
Sample A	5.48	2.45	19.99	6.19
Sample B	6.93	2.75	21.51	5.57
Sample C	3.03	1.97	16.81	9.02
Sample D	3.02	1.95	17.14	8.98
Sample E	7.25	2.81	24.46	5.38
Sample F	4.70	2.26	19.12	6.69

Table 1 shows the contents of nitrogen and hydrogen and the ignition loss of the sample. It is possible for the molecular formula of the exchanger at the final ion-exchange run to be represented as $Zr[Co(NH_3)_6]_x(H)_{2-3x}(PO_4)_2 \cdot 2H_2O (x=0—2/3)$ (see below for Sample E (θ-zirconium phosphate)).[5,16] The amount of nitrogen is $6x$, and that of hydrogen, $18x+(2-3x)+4=15x+6$. Thus, the following relationship is derived: molar ratio of hydrogen to nitrogen, $r=H/N=(15x+6)/6x=2.5+1/x$. When x is equal to 1/3, r becomes 5.5. This is the case for Sample E. Consequently, the larger the ratio r, the lower the degree of the ion-exchange. The degree almost corresponded to that predicted from Figs. 2 and 3 and to the order of particle size except for Sample F. For this anomalous behavior of Sample F, no adequate explanation can be given.

For θ-zirconium phosphate the compound obtained on the final ion-exchange run, referred to as θ-ZPCo, was analyzed chemically. Found; Zr, 23.9 (1.00): PO_4, 48.9 (2.02): Co, 5.15 (0.33): N, 7.25 (1.98): H, 2.81% (10.6). In parentheses are given the molar ratio of each element to zirconium. Calcd for $Zr[Co(NH_3)_6]_{0.33}H(PO_4)_2 \cdot 2H_2O$; Zr, 24.5: PO_4, 51.5: Co, 5.28: N, 7.53: H, 2.99%. It should be noted that the ratio of nitrogen to cobalt was equal to 5.9. It can be stated that fifty percent of the protons in θ-zirconium phosphate were exchanged with the hexaamminecobalt(III) ion.

Structural Study. It is well known that the interlayer distance of zirconium phosphate is dependent on an existing cation between layers. In general, two peaks due to the original zirconium phosphate and its salt form appear in the lowest-angle region of an X-ray diffractogram.[5,6] Hence, the approximate degree of the ion exchange can be estimated by comparing the intensity of the two peaks. After the final ion-exchange run, an X-ray diffractogram of each sample was recorded. As is shown in Figs. 4 and 5, the interlayer distance of α-zirconium phosphates expanded from 7.6 Å(2θ=11.7°) to 11.2 Å(2θ=7.7°).

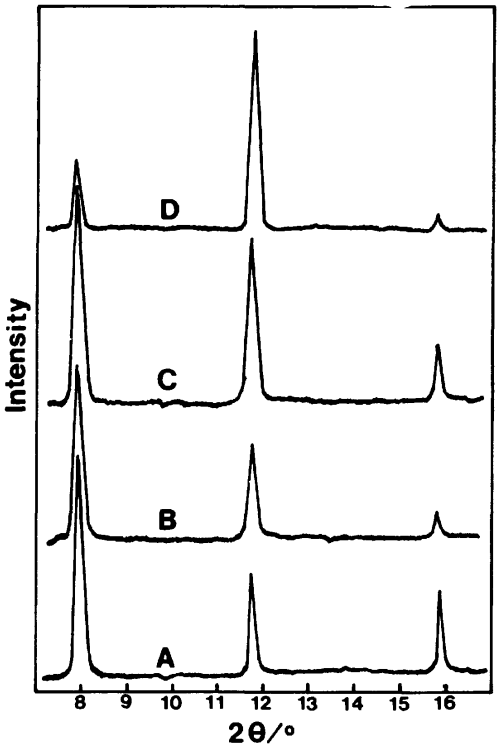

Fig. 4. Schematic diagram of X-ray powder diffraction at the lowest angle region for Samples A,B,C, and D.

The X-ray diffractograms of Samples A and B were similar, but that of Sample C was different. The diffractogram of Sample D showed that most of the α-zirconium phosphates were present unreacted. These facts agreed with what would be expected from Table 1.

An interlayer distance of 11.2 Å was observed, and the peak of 10.4 Å corresponding to the interlayer distance of θ-zirconium phosphate disappeared in the first ion exchange of Sample El. Since the difference between the two distances was small, and since θ-zirconium phosphate took up considerable amounts of the complex cation, the interlayer distance could expand easily.

In the case of Sample F, only the peak of 11.2 Å was present in the diffractogram. This differed distinctly from the cases of other α-zirconium phosphates and suggests that hydrogen-hexaamminecobalt(III) ion-exchange can be affected by factors other than those discussed in this work.

We are grateful to Mr. Seiichiro Iwafune for his measurements of the particle-size distribution.

The Polarographic Behavior of Tl(I) and Na(I) Ions and Bis(*o*-phenylenediamine)nickel(II) in *N,N*-Dimethylformamide-Dimethyl Sulfoxide Mixtures

Shigeo SAWADA
Department of Chemistry, Faculty of Science and Technology, Kinki University, Kowakae, Higashi-Osaka 577
(Received July 24, 1984)

The polarographic behavior of Tl(I) and Na(I) ions and the bis(*o*-phenylenediamine)nickel(II) [Ni(opd)$_2$] complex were studied using *N,N*-dimethylformamide (DMF)–dimethyl sulfoxide (DMSO) mixed solvents of various compositions. The diffusion currents of the Tl(I) and Na(I) ions and [Ni(opd)$_2$] complex decreased linearly with an increase in the concentration of the supporting electrolyte in DMF–DMSO solvent mixtures. The ratio of the slope to the intercept is related to the D coefficient in the revised Jones-Dole equation of viscosity. Ion-solvent interaction was considered from the Stokes radius, calculated from the diffusion current at an infinite dilution of the supporting electrolyte. The half-wave potentials of both the Tl(I) ion and the [Ni(opd)$_2$] complex shifted to a negative direction with an increase in the concentration of the supporting electrolyte. Although the half-wave potential of the [Ni(opd)$_2$] complex shifted to a slightly positive potential, that of the Tl(I) ion shifted to a negative potential with an increase in the content of DMSO.

It has been reported that, in water-organic mixed solvent systems, the observed diffusion current (i_d) becomes lower than that calculated from the solution viscosity (η) by means of this equation: $i_d = i_{d,aq}\,\eta_{aq}^{1/2}/\eta^{1/2}$ (aq=aqueous solution) with an increase in the organic solvent contents for metal ions and ionic organic compounds, but the reverse tendency is found for neutral organic compounds.[1] In such systems, the phenomena may be due to the characteristics of water as a solvent, that is, its strong capacities of hydrogen-bonding and dissociation. DMF–DMSO mixed solvents in which both components have similar dielectric constants and dipole moments, but different viscosities, were chosen in order to clarify the above points. The present paper aims to examine the change in polarographic behavior between ionic and neutral depolarizers with the change in the composition of DMF–DMSO mixed solvents by using the Tl(I) ion and the [Ni(opd)$_2$] complex.

Experimental

DMF and DMSO were used as the solvents. The solvents were purified by distillation under reduced pressure, adding Wako 5A molecular sieves. The water contents, as determined by the Karl-Fischer method, were less than 0.01%. The mixed solvents were represented in volume %. The $TlClO_4$ was recrystallized once from distilled water. The tetraethylammonium perchlorate (TEAP), after having been prepared in the usual manner, was recrystallized at least eight times from distilled water.[2] The tetrapropylammonium perchlorate (TPAP) was prepared in the usual manner and recrystallized from distilled water. The tetrabutylammonium perchlorate (TBAP) was prepared by ion-exchange methods[3] and purified by recrystallization from acetone–water and ethanol–water. These crystals were dried under reduced pressure at 60 °C. The [Ni(opd)$_2$] was prepared by air-oxidizing, for over 24 h, nickel(II) chloride hexahydrate and *o*-phenylenediamine; it was purified by using Soxlet's extractor with acetone.[4]

The polarographic diffusion current was measured by means of a Yanagimoto Type P-8 polarograph. An aqueous saturated calomel electrode was used as the reference electrode. The characteristics of the dropping mercury electrode used were m=1.710 mg s^{-1} and t=4.1 s at h=50 cm. The counter electrode was 0.5 mm ϕ platinum wire. The electrolytic cell was an H-shaped cell separated by a diaphragm; contact between the electrolytic cell and the reference electrode was made by means of an agar bridge containing saturated NaCl and a 1500-cps methylcellulose bridge containing 1 M (1 M=1 mol dm^{-3}) $NaClO_4$ in the same solvent composition as the test solution.[5] These bridge were renewed for each experiment. The viscosity and density were measured with, respectively, an Ostwald viscometer and a Weld-type picnometer at 25 °C.

Results and Discussion

The wave heights of the Tl(I) ion at various concentrations of TBAP were measured in DMF–DMSO mixed solvents. The results are shown in Fig. 1. Since the concentration (c) of the supporting electrolyte is

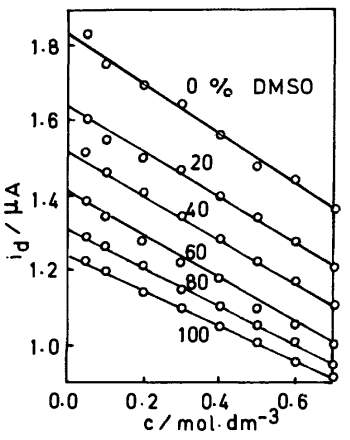

Fig. 1. Variation of i_d of Tl(I) with concentration of TBAP in DMF–DMSO.

sufficiently higher relative to the depolarizer, there was no influence of the migration current. The diffusion current of the Tl(I) ion varies little with the c of the supporting electrolyte in an aqueous solution, but it varies significantly in DMF–DMSO mixed solvents. According to the tracer-diffusion theory, the diffusion coefficient, D, decreases linearly with the $c^{1/2}$ of the supporting electrolyte; also, the diffusion current must decrease linearly with the $c^{1/2}$ of the supporting electrolyte. In the present work, however, the diffusion current decreased linearly with the c of the supporting electrolyte at higher concentrations of the supporting electrolyte. This might be attributed to a depreciation of solvent activity due to the solvation of the ion. The measurements were also carried out by exchanging the supporting electrolyte with $NaClO_4$, TEAP, and TPAP. Furthermore, the measurements were also carried out on the Na(I) ion and $[Ni(opd)_2]$, depolarizers other than the Tl(I) ion. In order to facilitate the comparison of the slope of the plot of i_d *vs.* the c of the supporting electrolyte, the following equation was used:

$$i_{d,r} = i_d/i_{d,0} = 1 - \alpha c \qquad (1)$$

where i_d is the diffusion current at the c of the supporting electrolyte; $i_{d,0}$, that at an infinite dilution of the supporting electrolyte, and α, the slope. Table 1 represents the α values for Tl(I) and Na(I) ions and for $[Ni(opd)_2]$ in DMF–DMSO mixed solvents containing each supporting electrolyte. It may be seen from Table 1 that the α values become larger in this order: TEAP, $NaClO_4$, and TBAP. However, since the effect of the c of the supporting electrolyte on the viscosity of the solution is contained in the magnitude of the value of α, the concentration dependence of the viscosity must also be examined.

The viscosity of the solution at various concentra-

tions of TBAP were measured in DMF–DMSO mixed solvents. Fig. 2 shows the results. The viscosity of the solution increased quadratically with the concentration of the electrolyte, and the relative viscosity obeyed the following revised Jones-Dole equation[6]:

$$\eta_r = \eta/\eta_0 = 1 + Ac^{1/2} + Bc + Dc^2 \quad (2)$$

where η is the viscosity at the c of the electrolyte, where η_0 is that at zero of c, and where A, B, and D are constants. The experiment was carried out by exchanging the electrolyte with $NaClO_4$, TEAP, and TBAP. The values of the constants were evaluated by the least-squares method. Table 2 shows the results. It may be seen from Table 2 that the magnitudes of both A and B for the four electrolytes are nearly equal, but that of D becomes larger in this order: TEAP, $NaClO_4$, and TBAP, as in the case of the α values. Hence, the D coefficient and the α values may have the same cause.

If the cause of the i_d depression with the increase in the concentration of the supporting electrolyte were only the increase in the viscosity, then $i_{d,r}\eta_r^{1/2}$ would remain at unity. However, as influences other than the viscosity act on it, $i_{d,r}\eta_r^{1/2}$ varies from unity with the c of the supporting electrolyte as follows:

$$i_{d,r}\eta_r^{1/2} = 1 + Kc \quad (3)$$

where K is the coefficient representing the deviation from the Stokes equation. The above equation holds within about 0.5 M only. The values of K was evaluated in each case. Table 3 shows the results. In the cases in which the supporting electrolyte is TEAP or TBAP without the Na(I) ion, the value of K gradually decreases with the increase in the DMSO content. In the cases in which the depolarizer is the Tl(I) ion, the value of K for TBAP as the supporting electrolyte is smaller than TEAP. On the other hand, in the cases in which the depolarizer is [Ni(opd)$_2$], there is no difference between the values of K for TEAP and TBAP. The results show that the extent of the solvation of the depolarizer varies with the c of the electrolyte and that tendency differs with the kind of electrolyte and the kind of depolarizer[7].

The interaction between the supporting electrolyte and the solvent or the interaction between the solvents appears in the supporting-electrolyte-concentration-dependence of the polarographic diffusion current, but the interaction between the depolarizer and the solvent appears in the diffusion current at an infinite

dilution of the supporting electrolyte. The diffusion current extrapolated to the concentration zero of the supporting electrolyte is independent of the kind of supporting electrolyte and is the same if the depolarizer and the solvent are the same. The diffusion coefficient D was evaluated from the diffusion current at an infinite dilution by means of the Ilkovic equation. The viscosity of the solvent in DMF-DMSO mixtures varied, as Fig. 3 shows. The Stokes radius was calculated by means of the following Stokes-Einstein equation:

$$r_s = kT/(6\pi\eta_0 D) \quad (4)$$

where k is the Boltzmann constant and η_0, the viscosity of the solvent. Table 4 shows the results. It may be seen that the Stokes radius becomes smaller with an increase in the DMSO content. Since DMSO is easier to solvate than DMF, the size of the diffusing particle in DMSO should become larger. However, the greater the DMSO content, the smaller the size of the observed Stokes radius. This might be ascribed to the presence of the association of DMSO.[8]

Table 5 shows the half-wave potentials of the Tl(I) ion and the [Ni(opd)$_2$] complex in DMF-DMSO mixed solvents containing 0.1 or 0.7 M TPAP and TBAP. The half-wave potentials of the Tl(I) ion and the [Ni(opd)$_2$] complex shifted to positive potentials with an increase in the concentrations of TPAP and TBAP in every solvent composition. This is attributable to the shift to the positive potential of the liquid-junction potential with an increase in the concentration of the supporting electrolyte. The half-wave potentials shifted to slightly negative potentials with an increase in the numbers of carbon atoms in the alkyl group of the tetraalkylammonium ion. While the half-wave potential of [Ni (opd)$_2$] shifted by about 0.03 V to a positive potential with an increase in the content of DMSO, the half-wave potential of the Tl(I) ion shifted by about 0.10 V to a negative potential. This is attributable to the stronger solvation of the Tl(I) ion by DMSO than by DMF, while [Ni(opd)$_2$], having a large size and a zero charge, is solvated only weakly in both solvents.

(Received September 3, 1984)

The Fe K-edge spectra were measured on $FeCl_3$ aqueous solutions by use of synchrotron radiation to reveal the solute structure from the analysis of Fe K-edge EXAFS and XANES. It is concluded that the solute exists mainly as $[Fe(H_2O)_6]^{3+}$ but partially as $[FeCl(H_2O)_5]^{3+}$ at $FeCl_3$ concentration of 0.1—1 mol dm^{-3}, and it exsits mainly as $[FeCl_2(H_2O)_4]^+$ at the concentration of 3—4 mol dm^{-3}. In the diliquescent product of $FeCl_3$, about a half of the solute is in the state of $[FeCl_4]^-$ and the remaining half is likely to be in the state of $[FeCl_2(H_2O)_4]^+$. No indication was found for the dimer formation of $FeCl_3$ even in the deliquescent product.

The structures of the iron(III) chloro complexes which are formed in the aqueous solution of $FeCl_3$, have been extensively investigated by means of X-ray diffraction.[1—10] But the conclusions given by different authors are still mutually conflicting in several respects. Recently, Magini *et al.* concluded that the dominant solute species existing in an aqueous solution of $FeCl_3$ at the concentration of about 4 mol dm^{-3} was octahedral chloro complexes.[5,10] On the other hand, Wertz *et al.* reported that the octahedral aqua complex $[Fe(H_2O)_6]^{3+}$ was dominant in the solution of the same concentration, which was freshly prepared from $FeCl_3 \cdot 6H_2O$, but octahedral chloro complexes $[FeCl_x(H_2O)_{6-x}]$ were gradually formed to have an average composition $[FeCl_{1.4}(H_2O)_{4.6}]$ after aging the solution for 14 months, whereas the tetrahedral chloro complexes were dominant when the solution was prepared from anhydrous $FeCl_3$.[7,8] From the examination of the X-ray diffraction pattern of the melt of $FeCl_3 \cdot 6H_2O$, Magini *et al.* claimed that the dimer of $FeCl_3$ was partially formed in this melt.[6] Wertz *et al.* also assumed without any direct experimental evidence, that the dimeric species Fe_2Cl_6 should exist also in a concentrated aqueous solution of about 4 mol dm^{-3} prepared from anhydrous $FeCl_3$.[7]

There could be several different kinds of the chloro complex coexisting in the $FeCl_3$ solution and the dominant species should vary depending on the solute concentration, but little is known about their equilibrium.[5] It is desirable to study over a wide range of the solute concentration from this point of view. But the X-ray diffraction studies hitherto reported were done only on the $FeCl_3$ solutions of a relatively high concentration, mostly above 1 mol dm^{-3}, because X-ray diffraction data inevitably contain a large contribution of the diffraction by the solvent. In this respect, it is of great interest to use extended X-ray absorption fine structure (EXAFS) and X-ray absorption near edge structure (XANES), since one can obtain from the analysis of EXAFS and XANES of Fe K-edge spectrum the information on the local structure surrounding Fe atom without being greatly disturbed by the presence of solvent even in the case of a considerably dilute solution.[11] We have already used this technique successfully in the structural studies on the systems involving Fe–Cl bond such as anhydrous $FeCl_3$[12] and $FeCl_3$-doped polyacetylene.[13]

In the present study, we measured Fe K-edge EXAFS and XANES in the X-ray absorption spectra of $FeCl_3$ aqueous solutions to derive the structural information on the solute.

Experimental

Preliminary experiments of X-ray absorption spectra (XAS) were carried out by use of the in-laboratory EXAFS spectrometer which was described elsewhere,[14] but final XAS data were obtained by use of synchrotron radiation employing the EXAFS facilities at BL-10B of the Photon Factory in the National Laboratory for High-Energy Physics (KEK-PF). The details of this experimental setup have been described elsewhere.[15] In the present study, a Si(311) channel-cut crystal was used to monochromatize X-rays from 2.5 GeV electron storage ring. The sample cell used in the XAS measurement of a liquid sample had two hard polypropylene windows to pass X-rays. The separation between the two windows was variable by changing the spacer between the windows. We set the sample thickness so as to keep the absolute absorbance at Fe K-edge below 3.0 in all cases. All XAS measurements were carried out at room temperature.

The sample solutions investigated in the present study are listed in Table 1, together with their abbreviated symbols, where the number stands for the concentration in mol dm^{-3} and the characters N and A stand for the neutral and acidified cases, respectively. Each solution was prepared by dissolving an appropriate amount of $FeCl_3 \cdot 6H_2O$ (reagent grade) into distilled water. We used nitric acid to acidify the solution except in the sample which is

denoted as Cl3A where HCl was used to see the effect of Cl^- ion, the ratio [acid]/[$FeCl_3$] being unity in all acidified samples. The deliquescent product of anhydrous $FeCl_3$(DP in Table 1) was taken up as the most concentrated non-acidified solution of $FeCl_3$.

We also measured the UV-visible absorption spectra of the sample solutions in order to characterize the solute state by comparing them with the reported data.[16-18] In the measurement of UV-visible absorption spectrum, perchloric acid was used to acidify the solutions instead of nitric acid, because NO_3^- has a strong absorption band at 220 nm.

Results

UV-visible absorption spectrum is known to be useful to characterize the coordination state of iron(III) complex. The absorption spectrum of a nitromethane solution of $[N(C_2H_5)_4][FeCl_4]$ and that of an aqueous solution of $Fe(ClO_4)_3 \cdot 6H_2O$ are shown in Fig. 1. The former is a typical case where the solute exists exclusively in the form of $[FeCl_4]^-$. The strong peaks at 317 and 365 nm and the weak peaks at 446, 532, 606, 685, and 728 nm in its absorption spectrum are the ones characteristic of $[FeCl_4]^-$.[19] In the aqueous solution of $Fe(ClO_4)_3 \cdot 6H_2O$, the peaks at 240 and 330 nm and the shoulder at 440 nm are the structure characteristic of $[Fe(H_2O)_6]^{3+}$ and its hydrolysis products.[20] We denote the species existing in this case as $[Fe(H_2O)_6]^{3+}$ for convenience, although it could be partially in the state of the hydrolysis product. The UV-visible absorption spectra of non-acidified aqueous solutions of $FeCl_3$ are shown in Fig. 2. According to the general features of the observed spectra, we can classify the solutions into the following three groups; the solutions where $FeCl_3$ concentration is less than 1 mol dm^{-3} (Group 1), the solutions with the concentration of 3—4 mol dm^{-3} (Group 2) and the very concentrated solutions such as DP (Group 3). The absorption spectra of the solutions of Group 1 exhibit strong peaks at 220 and 335 nm, and resemble the spectrum of $[Fe(H_2O)_6]^{3+}$ except for a small difference as regards the positions and relative intensities of absorption maxima. This type of spectrum has been attributed to the octahedral chloro complexes such as $[FeCl(H_2O)_5]^{2+}$ and/or $[FeCl_2(H_2O)_4]^+$.[16-18] On the other hand, the absorption spectrum of DP (a solution of Group 3) exhibits the features characteristic of $[FeCl_4]^-$, suggesting that $[FeCl_4]^-$ is the dominant species in this case. The spectra of

the solutions of Group 2 show the features in-between the above-mentioned two cases. This seems to be due to the co-existence of the octahedral and tetrahedral complexes. Figure 3 shows the spectra of the solutions acidified with perchloric acid. No remarkable change can be found in the spectrum on acidifying the solution.

Figure 4 shows the Fe K-edge region of the X-ray absorption spectra of the crystalline powders of $Fe(NO_3)_3 \cdot 9H_2O$, $FeCl_3 \cdot 6H_2O$, and $[N(C_2H_5)_4][FeCl_4]$. In these compounds, the local structure around Fe atom can be described as $[Fe(H_2O)_6]^{3+}$, *trans*-$[FeCl_2(H_2O)_4]^+$, and $[FeCl_4]^-$, respectively. Since XANES is determined by the local structure surrounding the X-ray absorbing atom, the spectra shown here can be taken respectively as those characteristic of the above-mentioned three kinds of iron(III) complex. All three spectra show a pre-edge structure which is attributable to the 1s-3d transition, but its shape and intensity are different between octahedral complexes and a tetrahedral one. In the cases of $[Fe(H_2O)_6]^{3+}$ and $[FeCl_2(H_2O)_4]^+$, both of which are octahedral complexes, the 1s-3d transition splits into two weak peaks, whereas it gives a relatively strong sharp peak in the case of the tetrahedral complex $[FeCl_4]^-$. Difference can be found also in the region above the absorption edge. The spectrum of $[Fe(H_2O)_6]^{3+}$ exhibits a considerably sharp peak just above the absorption edge, which is accompanied by a weak shoulder structure, the spectrum of $[FeCl_2(H_2O)_4]^+$ shows two broad absorption maxima around the absorption edge, and the spectrum of $[FeCl_4]^-$ exhibits three relatively sharp peaks followed by a broad structure.

XANES regions of the X-ray absorption spectra of the non-acidified solutions are shown in Fig. 5. The spectra shown here can be classified into three types. The first is the case observed for relatively dilute solutions where $FeCl_3$ concentration is less than 1 mol dm^{-3}. In this case, the spectrum exhibits weak 1s-3d double peaks in the pre-edge region and a relatively sharp peak just above the absorption edge. The second is the case observed for the solutions of the concentration range of 3—4 mol dm^{-3}, where the spectra again show weak double pre-edge peaks like in the first case, but the maximum just above the absorption edge splits into two peaks. The third is the case observed for a very concentrated solution like DP. In this case, the spectrum shows a sharp pre-edge 1s-3d peak and a shoulder structure and two peaks around the absorption edge. This classification of non-acidified solutions from XANES corresponds to the one which we have done from UV-visible absorption spectroscopy. The appearance of weak double pre-edge peaks associated with 1s-3d transition is characteristic of iron(III) octahedral complex as we have mentioned. The spectrum of the first type,observed for the relatively dilute solutions (the solutions of Group 1), resembles the spectrum of $[Fe(H_2O)_6]^{3+}$, but the spectral shape above the absorption edge is a little different from the latter. Seemingly the difference is due to the coexistence of the octahedral chloro complex. The general shape of the

spectrum of the second type, observed for the 3—4 mol dm^{-3} solutions (the solutions of Group 2), corresponds to the spectrum of $[FeCl_2(H_2O)_4]^+$, indicating that the solute exists predominantly in the state of the octahedral chloro complex, but there are relatively sharp structrures above the absorption edge, which look like the structures due to $[FeCl_4]^-$ coexisting in the solution. The spectrum of DP exhibits a sharp single pre-edge 1s–3d peak and relatively sharp structures above the absorption edge, both of which are characteristic of the tetrahedral complex $[FeCl_4]^-$. However, the intensity of the pre-edge peak relative to the Fe K-edge jump is significantly smaller as compared with the spectrum of $[N(C_2H_5)_4]$ $[FeCl_4]$. This fact indicates that the solution contains not only $[FeCl_4]^-$, but also octahedral complexes. The above-mentioned conclusions derived from XANES are consistent with those from UV-visible absorption spectroscopy. From the intensity of the pre-edge peak relative to the edge-jump, we approximately estimate the fraction of $[FeCl_4]^-$ ion among the total amount of the solute to be about 50%.[21]

Figure 6 shows the XANES spectra of the acidified solutions. Their spectral shapes are almost the same as those of the non-acidified solutions. Wertz *et al.* suggested that $[FeCl_4]^-$ comes to be the prominent species when the solution is acidified with hydrochloric acid.[9] However, little difference was observed among the spectra of C13A, 3A, and 3N. This means that the main species are not significantly different among these solutions and that $[FeCl_4]^-$ is not predominant in C13A.

The EXAFS oscillation $\chi(k)$ was extracted from an observed XAS spectrum by the following way. The smoothly varying component $\mu_s(\lambda)$ was estimated by fitting the observed spectrum using the cubic spline technique.[11] We estimated the absorbance for the free atom, $\mu_o(\lambda)$, in the region of 50—60eV from the edge by subtracting the background μ_b from μ_s. The background μ_b was determined by a smooth extrapolation from the pre-edge region by use of Victoreen's equation.

$$\mu_b(\lambda) = C\lambda^3 + D\lambda^4 \quad (1)$$

The μ_o value in other region was estimated by assuming that its wavelength dependence was describable with the Victreen's equation, the parameters of which were taken from the literature.[22] The photon energy E was converted to the photoelectron wave number k by Eq. 2.

$$k = \sqrt{2m(E-E_0)}/\hbar \quad (2)$$

where E_o is the ionization threshold. Then the EXAFS oscillation $\chi(k)$ was calculated by using Eq. 3.

$$\chi(k) = (\mu-\mu_s)/\mu_0 \quad (3)$$

The Fourier transforms of $k^3\cdot\chi(k)$ over the region of k=4.0—12.0 Å^{-1} are shown in Figs. 7—9. Both for non-acidified and acidified cases, the main peak of Fourier transform is at 1.60—1.61 Å when the solute concentration is less than 1 mol dm^{-3} (the

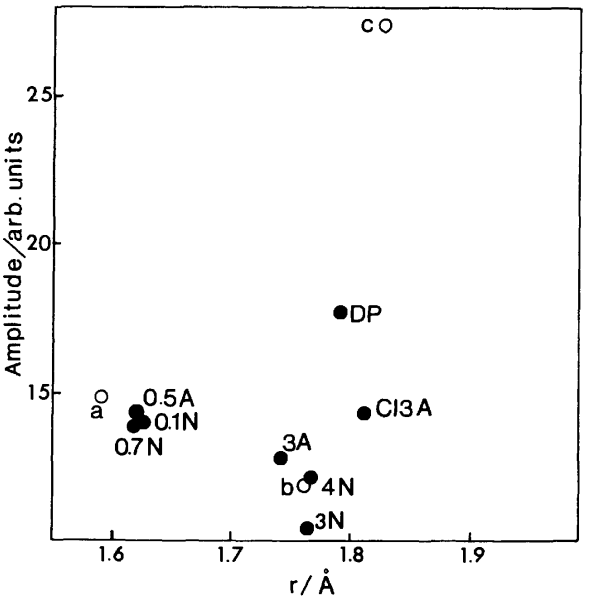

Fig. 10. Plots of the amplitude of the main peak of Fourier transform against the peak position. (a): $Fe(NO_3)_3 \cdot 9H_2O$, (b): $FeCl_3 \cdot 6H_2O$, (c): $[N(C_2H_5)_4][FeCl_4]$. Refer to Table 1 for abbreviated symbols of the solutions.

solutions of Group 1), but the corresponding peak shifts to 1.76 Å in the case of DP. The solutions of the Group 2 show the corresponding peak at a position in-between these two cases. The above-mentioned main peak of Fourier transform is attributable to Fe-Cl and/or Fe-O(H_2O). Since Fe-Cl distance is longer than Fe-O distance, the shift of the main peak is associated with the increase of the number of Cl atoms coordinating to Fe atom. The peak amplitude should be also dependent on the Cl/O ratio surrounding Fe atom. In Fig.10, we plotted the amplitude of the main peak of Fourier transform against the peak position. The position of the point in this plot could be a good criterion of the average state of the solute.[23] Note that the points for the solutions 0.1N, 0.7N, and 0.5A (Group 1) are nearly at the same position, whereas the points for much concentrated solutions fall in a quite different area. We have also shown the points obtained for the reference materials in which the local structures surrounding Fe atom are $[Fe(H_2O)_6]^{3+}$, $[FeCl_2(H_2O)_4]^+$ and $[FeCl_4]^-$, respectively. We can see that the point for $[Fe(H_2O)_6]^{3+}$ is located at the position shifted a little to the left from the points for the $FeCl_3$ solutions of Group 1, and the point for $[FeCl_2(H_2O)_4]^+$ is in the area where the points for much concentrated $FeCl_3$ solutions are located. This fact again indicates that the solute is in the state of $[Fe(H_2O)_6]^{3+}$ along with chloro complexes in the solutions of Group 1, while it is mainly in the states of $[FeCl_2(H_2O)_4]^+$ and other chloro complexes in much concentrated solutions. Note that the point for DP is significantly separated from the point for $[FeCl_4]^-$. This fact again indicates that the solute is not entirely in the state of $[FeCl_4]^-$ in DP as we have concluded from XANES.

Performing the inverse Fourier transformation over the region of the main peak (r=1.0–2.2 Å) of each Fourier transform, we carried out further analysis of EXAFS oscillation by means of the nonlinear least square curve-fitting method, using the Eq.4.

$$k^3 \cdot \chi(k) = \sum_j k^2 S_j(k)(N_j/r_j^2)F_j(k) \times \exp(-2\sigma_j^2 k^2) \sin(2kr_j + \phi_j(k)) \quad (4)$$

* The interatomic distances determined by crystal structure analysis are given in brackets; (a) from Ref. 30, (b) from Ref. 31, (c) from Ref. 32, (d) from Ref. 33, (e) from Ref. 34. ** The inaccuracy of these S values was found to be 20—30%.

where N_j is the coordination number of the j-th shell at the distance r_j from the X-ray absorbing atom, $F_j(k)$ the back-scattering amplitude for the photoelectron wave number k, $\phi_j(k)$ the phase shift, σ_j the Debye-Waller factor of the atoms in the j-th shell. $S_j(k)$ is the amplitude reduction factor, which was assumed to be independent of k in the present study.[24]

The theoretical functions given in the literature were used for $F_j(k)$ and $\phi_j(k)$ in Eq. 4.[25] The validity of the assumed back-scattering amplitude and phase shift founctions were checked by carrying out the analysis of the EXAFS of the reference samples. As shown in Table 2, the results from EXAFS showed a satisfactory agreement with the crystallographic data.

In general, the amplitude reduction factor S_j should be different for different kinds of atom. But we assumed it to be the same value for the nearest neighbor Cl and O atoms.[26] We took this approximation in order to avoid the nonlinear least square analysis converging to the odd minimum points.

In the final refinement stage, we assumed the sum of the coordination numbers of Cl and O to be 6 for all solutions except for DP, where the best fit between the observed and calculated EXAFS oscillations was attained when the coordination numbers of Cl and O were assumed to be 3 and 2, respectively. The above-mentioned assumption is based on the conclusions derived from XANES and UV-visible absorption spectra, which show that the main species are octahedral complexes in all solutions except DP. The final results of curve-fitting analysis are summarized in Table 3. The average Fe-O distance obtained in the present study was 2.0 Å, which is close to the value reported by Magini *et al.*[6] The Fe-Cl distances were found to be 2.26—2.35 Å for the solutions of Group 1 and Group 2. This value corresponds to the distance which is usually found for the octahedral chloro complexes in the crystals of iron(III) compounds: The distance is known to be 2.30 Å in $FeCl_3 \cdot 6H_2O$,[27] 2.36 Å in $FeSbCl_8 \cdot 8H_2O$[28] and 2.368 Å in FeOCl.[29] In the solutions of Group 1, the best result in the curve-fitting analysis was attained only when the contribution of Cl atoms was taken into account. Probably this means that a fraction of the solute is in the form of octahedral chloro complexes even in the relatively dilute solutions. The coordination numbers obtained for the solutions of Group 2, well correspond to $[FeCl_2(H_2O)_4]^+$. Possibly this is the main solute species in these solutions. The Fe-Cl distance found for DP is 2.22 Å, which is shorter than the Fe-Cl distances found for more dilute solutions. This Fe-Cl distance is close to the value expected for the tetrahedral complex $[FeCl_4]^-$, but the best fit was not attainable between the calculated and observed EXAFS oscillations when the contribution of O atoms was neglected. As we have already mentioned, the coordination numbers for the best fit are 3 and 2 for Cl and O, respectively. These average coordination numbers imply that the octahedral chloro complexes of the type $[FeCl_x(H_2O)_{6-x}]$ are coexisting with $[FeCl_4]^-$ in DP. Another point that we noted in the analysis of the Fe K-edge EXAFS of DP, is that no peak attributable to Fe-Fe could be found in the Fourier transform (see Fig. 9). Thus the dimeric species Fe_2Cl_6 is unlikely to exist, at least as one of the main solute species, in DP and in a concentrated solution of $FeCl_3$.

TABLE 3. RESULTS OF THE CURVE-FITTING ANALYSIS OF THE EXAFS DATA OF $FeCl_3$ SOLUTIONS

* The inaccuracy of these S values was found to be 20—30%.

Discussion

Summarizing the experimental results concerned with Fe K-edge EXAFS and XANES together with those of UV-visible absorption spectroscopy, we can derive the following conclusion for the solute state in the $FeCl_3$ aqueous solution. In the solutions of $FeCl_3$ concentration of 0.1—1 mol dm^{-3}, the solute is mainly in the state of $[Fe(H_2O)_6]^{3+}$ but partially in the state of other complexes, such as $[FeCl(H_2O)_5]^{2+}$. The average Cl coordination number increases with the increase of $FeCl_3$ concentration, and $[FeCl_2(H_2O)_4]^+$ becomes the main solute species in the solutions of the concentration of 3—4 mol dm^{-3}. Although the coexistence of $[FeCl_4]^-$ is expected from the results of UV-visible absorption spectroscopy, its amount is likely to be very small as far as we judge from the results of X-ray absorption spectroscopy. In the discussion given in the present paper, we have not explicitly taken up the hydrolysis products of the type $[FeCl_x(H_2O)_{6-x-y}(OH)_y]$ derivable from $[FeCl_x(H_2O)_{6-x}]$, which are reported to be formed in a non-acidified solution. Unfortunately, it is hard to distinguish the formers from the latters in the analysis of the EXAFS data. Therefore, whenever we say $[FeCl_x(H_2O)_{6-x}]$, it should be taken to include also the corresponding hydrolysis products.

Magini and Radnai considered that the main species in the solution of $FeCl_3$ concentration of about 4 mol dm^{-3} is $[FeCl_3(H_2O)_3]$.[5] But this kind of octahedral chloro complex has never been found among the crystals of iron(III) compounds, and the results of the present study have shown that the solute mainly exists in the state of $[FeCl_2(H_2O)_4]^+$ in the solution of the $FeCl_3$ concentration of 3—4 mol dm^{-3}, in disagreement with the conclusion by Magini and Radnai. There seems to be no indication for the existence of $[FeCl_3(H_2O)_3]$. Seemingly in an aqueous solution of $FeCl_3$, an octahedral complex becomes less stable than a tetrahedral complex as the Cl coordination number exceeds 2 probably because of the increase of the repulsive cis-cis interaction between Cl^- ions.

In the case of DP, the EXAFS data indicate that the solute is partly in the state of $[FeCl_4]^-$ and partly in the state of the octahedral chloro complexes. We estimated the fraction of $[FeCl_4]^-$ to be about 50% from the height of the pre-edge peak associated with 1s-3d transition. The remaining part is most likely to be in the state of $[FeCl_2(H_2O)_4]^+$. The Cl/Fe ratio derived from the analysis of the EXAFS data can be satisfactorily understood with this model. From the present study of XANES and UV-visible absorption spectra we can conclude that $[FeCl_4]^-$ starts to be formed at the $FeCl_3$ concentration of about 4 mol dm^{-3}, though the amount may not be so large at this concentration. Inoue *et al.* reported that the physical properties of the $FeCl_3$ aqueous solution abruptly change at the $FeCl_3$ concentration of about 4 mol dm^{-3}, and attributed this behavior to the formation of $[FeCl_4]^-$.[30] This is consistent with our conclusions.

It has been often assumed that the $FeCl_3$ dimer, Fe_2Cl_6, is formed in a concentrated $FeCl_3$ solution.[5,6,8] However, no peak corresponding to Fe-Fe distance of Fe_2Cl_6, which is reported to be 2.75—2.80 Å by Magini,[6] can be found in the Fourier transform of the EXAFS data of DP. Thus we conclude that Fe_2Cl_6 is unlikely to exist, at least as one of the dominant species, in a concentrated $FeCl_3$ solution.

The authours are grateful to Dr. T. Matsushita and Dr. H. Oyanagi for their helpful advice for the XAS measurement at the Photon Factory. The authors also thank to Dr. I. Ikemoto and Dr. N. Kosugi for their discussions and helps in the XAS experiments.

The Co-amination of Phenol and Cyclohexanol with Palladium-on-carbon Catalyst in the Liquid Phase. An Application of a Hydrogen-transfer Reaction

Hideaki HAMADA, Makoto YAMAMOTO,† Yasushi KUWAHARA, Takehiko MATSUZAKI, and Katsuhiko WAKABAYASHI*

National Chemical Laboratory for Industry, Yatabe, Tsukuba, Ibaraki 305

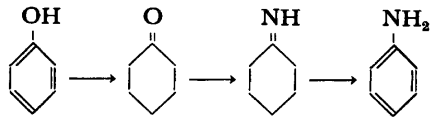
(Received September 19, 1984)

Phenol and Cyclohexanol are simultaneously aminated to aniline and cyclohexylamine by ammonolysis with the palladium-on-carbon catalyst in the liquid phase, although the amination of either phenol or cyclohexanol hardly occurs without the other. In contrast, carbon-supported ruthenium, rhodium, and platinum catalysts are ineffective for this co-amination; they are active only for the amination of cyclohexanol to cyclohexylamine. These results are explained by the specific activity of palladium for hydrogen transfer between phenol and cyclohexanol.

It is well known that the amination of phenol to aniline by ammonolysis catalyzed by acidic catalysts, such as silica-alumina,[1,2] zeolites,[3] and metal chlorides.[4] Supported metal catalysts are known to be effective for the amination of cyclohexanol to cyclohexylamine, the hydroamination of phenol to cyclohexylamine, and the dehydroamination of cyclohexanol to aniline. For example, Richardson and Lu[5] reported that the vapor-phase dehydroamination of cyclohexanol to aniline took place over supported platinum catalysts. Recently, it has been found that these supported metal catalysts, in cooperation with hydrogen or hydrogen-transfer agents, are also effective for the amination of phenol to aniline. Ono and Ishida[6] reported that phenol was successfully aminated to aniline with ammonia and hydrogen over palladium-on-alumina in the vapor phase. We previously reported[7] that phenol was aminated with ammonia with palladium-on-carbon in the presence of cyclohexanone, which is a hydrogen-transfer agent.

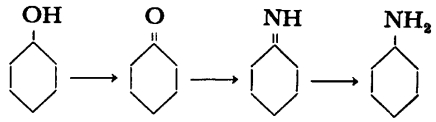
The following reaction pathway has been proposed for the amination of phenol over supported metal catalysts:[7]



(1)

The first step of this scheme is the formation of cyclohexanone due to the hydrogenation of phenol, which means that hydrogen or hydrogen-transfer agents are needed.

On the other hand, the amination of cyclohexanol to cyclohexylamine with ammonia over supported metal catalysts has been considered to proceed through the pathway indicated below.[8] In this case, the first step is the dehydrogenation of cyclohexanol to cyclohexanone.



(2)

Taking these two reaction schemes into consideration, we investigated the possibility of the liquid-phase co-ammonolysis of phenol and cyclohexanol; we have found that phenol and cyclohexanol can be simultaneously aminated with the palladium-on-carbon catalyst.

We have already reported a part of our results in a letter.[9] This paper is a detailed report of this co-amination reaction. The specific catalytic activity of palladium and the reaction scheme are also discussed.

Experimental

Catalysts and Reagents. The 5 wt% metal-on-carbon catalysts were of commercial origin (Nippon Engelhard Co.). The reagents were of a guaranteed reagent grade and were used without further purification except in the case of *N*-cyclohexylaniline, which was prepared by the reaction of phenol and cyclohexylamine using palladium-on-carbon. The ammonia and hydrogen were supplied from gas cylinders.

Procedures. Each experiment was run in a 100-cm^3 stainless-steel autoclave. Unless otherwise specified, phenol, cyclohexanol, and the catalyst were put into the autoclave. The autoclave was sealed, purged with hydrogen, and evacuated successively, and then ammonia was introduced into the autoclave from a pressure-resistant gas-collecting tube. The autoclave thus prepared was set in an electric furnace and heated for the reaction. At the end of each reaction, the autoclave was cooled and the excess ammonia was released. The contents were filtered to remove the catalyst. 2-Propanol was used as a solvent to assist in removing the reaction mixture from the autoclave and in washing the filter cake. The filtered reaction mixture was analyzed by means of gas chromatography. A 5-m column of Silicon DC-550 (20 wt%) on Chromosorb W AW-DMCS, operating at 145 °C, was used to analyze phenol, aniline,

cyclohexylamine, and cyclohexanone. A 3-m column of PEG-20 M (20 wt%) on Chromosorb W AW-DMCS, operating from 130 °C to 220 °C, was used to analyze cyclohexanol, dicyclohexylamine, *N*-cyclohecylaniline, and diphenylamine.

Results and Discussion

Need of Coexistence of Phenol and Cyclohexanol for Co-amination. Mixtures of phenol and cyclohexanol in various compositions were allowed to react with ammonia in the presence of palladium-on-carbon at 250 °C for 3 h. Figure 1 shows the effect of the mixture composition. Aniline and cyclohexylamine were obtained in high yields when nearly equal amounts of phenol and cyclohexanol were used, but the amination of phenol or cyclohexanol alone hardly took place at all. The maximum aniline yield was obtained at a 50% phenol content, while the cyclohexylamine yield reached its maximum value at a 20% phenol content. From these results, it is concluded that the amination of phenol and cyclohexanol with the palladium-on-carbon catalyst is promoted by the coexistence of the two components. *N*-cyclohexylaniline and dicyclohexylamine were also obtained as by-products. These by-products are considered to be formed by means of condensation reactions.

Effect of Reaction Temperature. The effect of the reaction temperature of the co-ammonolysis of equal amounts of phenol and cyclohexanol was examined in the temperature range of 200—270 °C with the palladium-on-carbon catalyst. As is shown in Fig. 2, the product yields increased with the reaction temperature. It should be noted thet the aniline yield was always higher than the cyclohexylamine yield, and that a considerable amount of *N*-cyclohexylaniline was formed at higher temperatures.

Effect of Ammonia Amount. Figure 3 shows the effect of the amount of ammonia. As can be seen in this figure, the product distribution changed greatly with the amount of ammonia. When phenol and cyclohexanol were allowed to react in the absence of ammonia, cyclohexanone was formed as the only product because of the hydrogen-transfer from cyclohexanol to phenol.

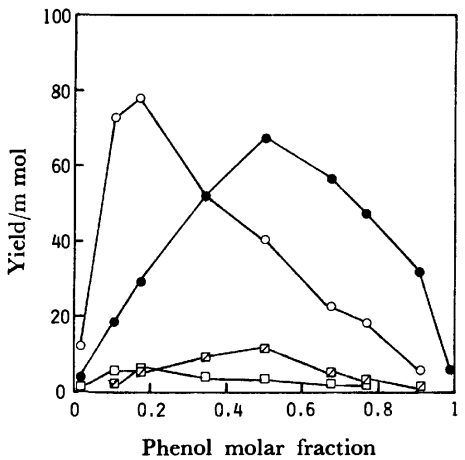


Fig. 1. Ammonolysis of phenol and cyclohexanol with various composition. Phenol and cyclohexanol (total 0.2 mol) are allowed to react with ammonia (1 mol) at 250 °C for 3 h over Pd/C (1 g).

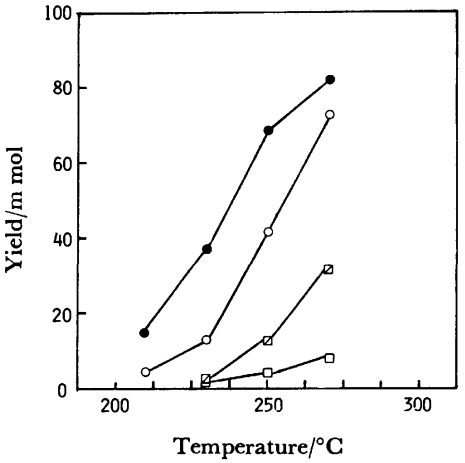

Fig. 2. Effect of reaction temperature on the co-amination. Phenol (0.1 mol) and cyclohexanol (0.1 mol) are allowed to react with ammonia (1 mol) for 3 h over Pd/C (1 g).
●: Aniline yield, ○: cyclohexylamine yield, ⊠: *N*-cyclohexylaniline yield ×2, □: dicyclohexylamine yield ×2.

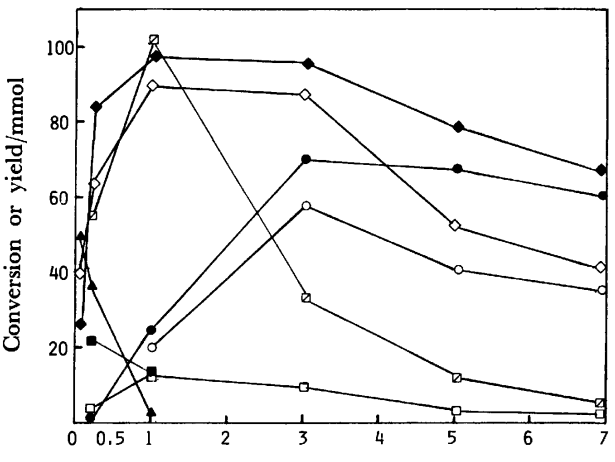

Fig. 3. Effect of ammonia amount on the co-amination. Phenol (0.1 mol) and cyclohexanol (0.1 mol) are allowed to react with ammonia at 250 °C for 3 h over Pd/C (1 g).
◆: Phenol conversion, ◇: cyclohexanol conversion, ●: aniline yield, ○: cyclohexylamine yield, ▲: cyclohexanone yield, ■: diphenylamine yield ×2, ⊠: *N*-cyclohexylaniline yield ×2, □: dicyclohexylamine yield ×2.

When the amount of ammonia increased to 0.2 mol, which was equivalent to the molar quantities of phenol plus cyclohexanol, the cyclohexanone yield decreased rapidly, while amination products composed mainly of *N*-cyclohexylaniline were observed to increase in yield. In this case, there was also a little formation of dicyclohexylamine, diphenylamine, aniline, and cyclohexylamine.

When the amount of ammonia increased in the ranges beyond 0.2 mol, the conversions of phenol and cyclohexanol gradually decreased again; the yields of *N*-cyclohexylaniline and dicyclohexylamine also decreased. Therefore, the selectivities to aniline and cyclohexylamine increased. In the presence of excess ammonia, the main products shifted to aniline and cyclohexylamine.

Effect of Reaction Time. The effect of the reaction time is shown in Fig. 4. The conversions and yields increased with the reaction time. It is noteworthy that the formation of aniline from phenol prevailed over that of cyclohexylamine from cyclohexanol at the initial stage of reaction.

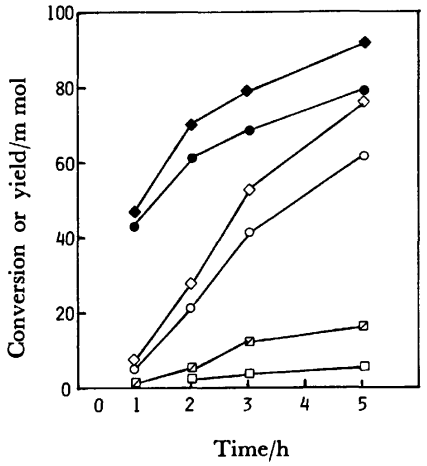

Fig. 4. Effect of reaction time on the co-amination. Phenol (0.1 mol) and cyclohexanol (0.1 mol) are allowed to react with ammonia (1 mol) at 250 °C over Pd/C (1 g).

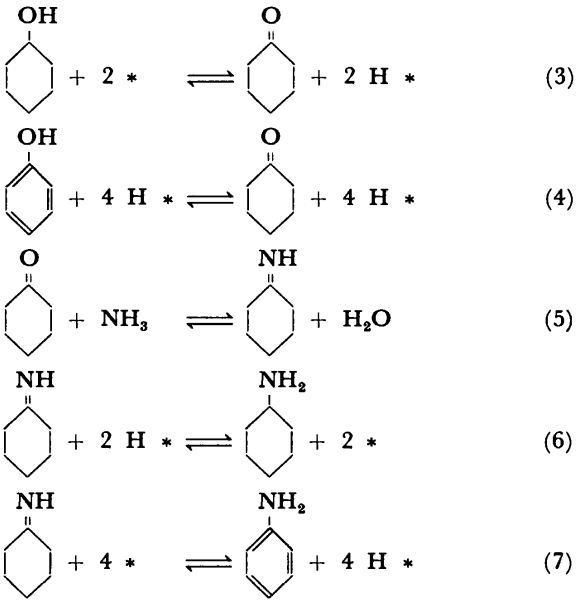
Cataltic Activities of Carbon-supported Platinum-group Metals. The catalytic activities of various carbon-supported platinum-group metals are compared in Table 1. As may be seen in this table, palladium was the only effective catalyst for the co-amination. Ruthenium, rhodium, and platinum were ineffective for the co-amination, and aniline was not formed from phenol, though the amination of cyclohexanol to cyclohexylamine did occur.

Reaction Scheme of Co-amination. The co-amination of phenol and cyclohexanol with the palladium-on-carbon catalyst is considered to proceed through the following reaction steps:



In these equations, * and H* represent an empty catalytic site and an adsorbed hydrogen atom respectively.

In the absence of cyclohexanol, the amination of phenol cannot occur because there is no adsorbed hydrogen, which is necessary for Eq. 4. Howerver, in the co-existence of phenol and cyclohexanol, they are effectively converted into cyclohexanone through hydrogen-transfer by Eqs. 3 and 4. In fact, the formation of a large amount of cyclohexanone by the reaction of phenol and cyclohexanol was observed in the absence of ammonia (Fig. 3). The resulting cyclohexanone reacts easily with ammonia to be converted into cyclohexanimin (Eq. 5), which is either hydrogenated

Table 1. Activities of carbon-supported platinum-group metal catalysts

	Aniline	Cyclohexylamine	*N*-Cyclohexylaniline	Dicyclohexylamine
Pd/C	68	41	6.0	1.9
Ru/C	0	71	0	0
Rh/C	4.0	44	0	0
Pt/C	1.9	74	0	0

Phenol (0.1 mol) and cyclohexanol (0.1 mol) are allowed to react with ammonia (1 mol) in the presence of a catalyst (1 g) at 250 °C for 3 h.

TABLE 2. AMMONOLYSIS OF PHENOL-CYCLOHEXYLAMINE OR ANILINE-CYCLOHEXANOL MIXTURES

Reactant	Product (Yield/m mol)					
	Phenol	Cyclohexanol	Aniline	Cyclohexylamine	*N*-Cyclohexylaniline	Dicyclohexylamine
Phenol-cyclohexylamine	9.3	0.7	68	77	18	3.8
Aniline-cyclohexanol	0	63	98	32	3.2	1.4

The reactant mixtures (0.1 mol+0.1 mol) are allowed to react with ammonia (1 mol) in the presence of Pd/C (1 g) at 250 °C for 3 h.

to cyclohexylamine (Eq. 6) or dehydrogenated to aniline (Eq. 7).

Figures 2 and 4 suggest that the amination of phenol to aniline (Steps 4, 5, and 7) prevails over that of cyclohexanol to cyclohexylamine (Steps 3, 5, and 6) in the early stages of the reaction. The factor which determines the ratio of these two reaction rates is not clear, but the concentration of adsorbed hydrogen may play an important role.

Taking the above reaction schemes into consideration,it is conceivable that the amination rate of phenol to aniline is accelerated in the presence of cyclohexylamine, because hydrogen-transfer can take place between phenol and cyclohexylamine. Also, the amination rate of cyclohexanol to cyclohexylamine may be accelerated in the presence of aniline. In order to examine the probable validity of these assumptions, phenol–cyclohexylamine and cyclohexanol–aniline mixtures were allowed to react with ammonia in the presence of the palladium-on-carbon catalyst. The results, shown in Table 2, support these assumptions.

Specificity of Palladium. As has been mentioned above, palladium-on-carbon was the only effective catalyst for the co-amination of phenol and cyclohexanol among the carbon-supported platinum-group metal catalysts. This specificity could be interpreted in terms of its specific catalytic activity for hydrogen-transfer reactions.

To get further insights into the specificity of palladium, the hydroamination of phenol was studied. Figure 5 shows the effect of the initial hydrogen pressure on the hydroamination of phenol with carbon-supported palladium. The yields of cyclohexylamine and dicyclohexylamine as well as the phenol conversion increased with an increase in the hydrogen pressure. It should be noted that considerable amounts of aniline were formed, along with *N*-cyclohexylaniline, at low hydrogen pressures. Figure 6 shows the effect of the reaction time. It is also worth noting that cyclohexylamine and dicyclohexylamine were formed at an early stage of the reaction, and that aniline and *N*-cyclohexylaniline increased in their yields with the reaction time. The latter result is consistent with the results in Table 2.

In order to compare the ruthenium catalyst with palladium, the hydroamination of phenol with

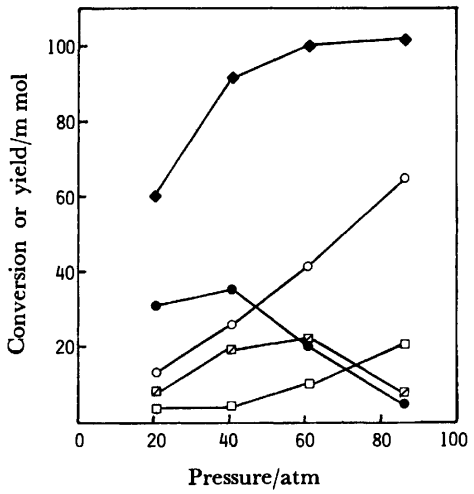

Fig. 5. Effect of initial hydrogen pressure on the hydroamination of phenol over Pd/C. Phenol (0.1 mol) is allowed to react with ammonia (0.6 mol) and hydrogen at 250 °C for 3 h over Pd/C (0.5 g).
◆: Phenol conversion, ●: aniline yield, ○: cyclohexylamine yield, ⊠: *N*-cyclohexylaniline yield ×2, □: dicyclohexylamine yield ×2.

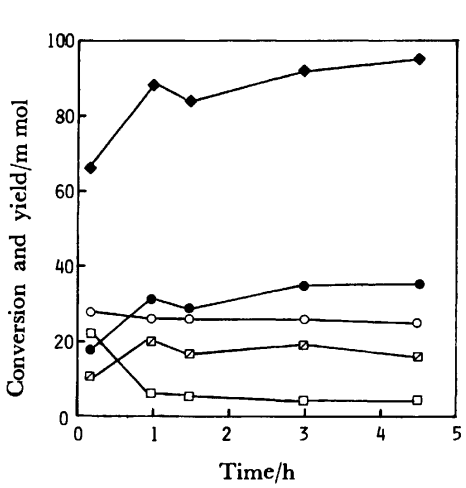

Fig. 6. Effect of reaction time on the hydroamination of phenol over Pd/C. Phenol (0.1 mol) is allowed to react with ammonia (0.6 mol) and hydrogen (40 atm) at 250 °C over Pd/C (0.5 g).
◆: Phenol conversion, ●: aniline yield, ○: cyclohexylamine yield, ⊠: *N*-cyclohexylaniline yield ×2, □: dicyclohexylamine yield ×2.

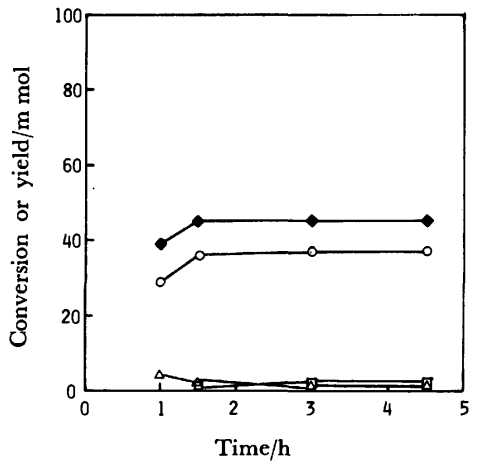

Fig. 7. Effect of reaction time on the hydroamination of phenol over Ru/C. Phenol (0.1 mol) is allowed to react with ammonia (0.6 mol) and hydrogen (40 atm) at 250 °C over Ru/C (0.5 g).
◆: Phenol conversion, ○: cyclohexylamine yield, △: cyclohexanol yield, □: dicyclohexylamine yield ×2.

ruthenium-on-carbon was studied. The effect of the reaction time is shown in Fig. 7. In this case, aniline was not formed, although the hydroamination of phenol to cyclohexylamine did take place. Therefore, it is concluded that ruthenium cannot catalyze hydrogen-transfer reactions. This conclusion might also apply to the cases of rhodium and platinum.

From these results, it is clear that the specificity of palladium is due to its unique catalytic activity for hydrogen-transfer reactions. Further work is necessary to elucidate the reason for this specificity of palladium.

Lumiflavin-sensitized Photooxygenation Accelerated by Adenine. III. Flash Photolytic Studies

Akio YOSHIMURA* and Shunji KATO†
Chemistry Department, College of General Education, Osaka University, Toyonaka, Osaka 560
(Received November 20, 1984)

Flash photolytic studies have been made of aqueous systems of lumiflavin-adenine-tryptophan, where the accelerating effect of adenine is observed on the lumiflavin-sensitized photooxygenation of tryptophan. The electron transfer occurs first from adenine to the triplet state of lumiflavin. When a little tryptophan is present in the aerated solutions, the tryptophan is oxidized by the successive electron-transfer reactions and the tryptophan decomposes instead of adenine. The rate parameter for each process has been determined.

The present authors showed previously that the lumiflavin-sensitized photooxygenation of tryptophan is accelerated by the addition of adenine when the concentration of tryptophan is low.[1] The singlet oxygen can be excluded from the intermediates on the basis of the following results: This effect is specific for flavin dyes (containing FAD), and the quantum yield using flavin dyes, which is higher than that using other dyes, increases with the oxygen concentration at very low oxygen concentrations, but decreases at higher concentrations. The addition of adenine accelerates the flavin-sensitized photooxygenation not only of tryptophan, but also of many reactants (indole, 3-indoleacetic acid, histidine, methionine, guanine, *etc.*),[1,2] and it does not affect the reaction products.[2]

To make clear this accelerating effect of adenine, flash photolytic studies have been made of these systems. Several papers have been published on the flash photolysis of flavin dyes.[3-5] In the present study, the electron transfer from adenine to the triplet state of lumiflavin and the succeeding reactions, especially in the presence of oxygen, were investigated. On irradiation, riboflavin loses its 440 nm absorption (photofading), but in the case of lumiflavin which does not have a ribityl side-chain, photofading does not occur at all in air.

Experimental

Materials. The lumiflavin was synthesized by the method of Hemmerich *et al.*[7] The adenine was recrystalized from water. The other reagents used were of a G. R. Grade.

Apparatus and Procedure. The flash photolysis was carried out in a 10-cm cylindrical quartz cell thermostated (25±0.1 °C) with circulated water, with exciting light from two xenon flash lamps connected in series to a 0.3 μF condensor charged to a potential of 18 kV (FWHM: 2 μs) through blue glass filters (Toshiba V-42). The monitoring light from a xenon short-arc lamp (Canrad-Hanovia L5122) was passed through the reaction cell and a Nalumi RM-23 monochromator and was detected with a Hamamatsu R928 photomultiplier. The transient signals were stored in a transient memory (Kawasaki Electronica M-500T; 0.5 μs; 10 bits×1 k words) and then transferred to a 16-bit minicomputer made by Dr. Tatebe[8] (34 k-word memory; 32 commands; cycle time: 0.4 μs). The subtraction of the signal due to the scatter light or the fluorescence, the calculation of the transient-absorbance change (Δabsorbance)(which was accumulated several times in the case of a weak signal), and the first- and second-order decay analysis plotting ln(Δabsorbance) and 1/(Δabsorbance) were carried out by the use of the computer.

The photolysis by a steady light of 436 nm was performed as previously described[1] at 25±0.1 °C.

Unless otherwise noted, all the experiments were carried out in a 0.05 M†† phosphate buffer at pH 7.2. The solution with a reduced concentration of oxygen was prepared by bubbling it with a mixture of oxygen and nitrogen of a known composition.

Results and Discussion

The fluorescence of lumiflavin was little quenched by adenine, tryptophan, oxygen, and iodide ions at the concentrations studied in this paper; therefore, the reactions of irradiated lumiflavin with these substances can be restricted to the reactions through the triplet state of lumiflavin. The degree of the conversion of lumiflavin to the triplet state by a single flash excitation was estimated from the difference in transient fluorescence intensities with and without sufficient triplet quenchers; iodide ions.[9] By the use of a 50 J flash excitation of 5 μM lumiflavin in the deaerated solution, 56% of lumiflavin was accumulated in the triplet state during the flash pulse. Using this ratio, the molar (decadic) absorption coefficient of the triplet state of lumiflavin was estimated to be 4400±300 M^{-1} cm^{-1} at 700 nm.

It has been reported that the lumiflavin triplet state is reduced to its semiquinone radical by some reductants; the molar absorption coefficient of the radical at pH 7.2 was estimated to be 3400±200 M^{-1} cm^{-1} at 600 nm.[4] The reactions of the lumiflavin triplet state were followed in the solutions

† Present address: Kobegakuin University, Nishi-ku, Kobe, 673.

†† 1 M=1 mol dm^{-3}.

containing 5 μM lumiflavin and 20—60 μM of each reactant, such as the tryptophan, adenine, oxygen, and iodide ions, at 700 nm. The electron transfer to lumiflavin occurred in the quenching reactions of the lumiflavin triplet state by the tryptophan and adenine (the observed efficiencies were 70%), while the semiquinone of lumiflavin was not observed in the quenching by the oxygen and iodide ions. The quenching-rate parameters measured were as follows:

$$^3LF + Trp \xrightarrow{k_1} LF^{\cdot-} + Trp^{+} \quad (LF + Trp) \quad (3.7\pm0.2)\times10^9\ M^{-1}\ s^{-1}, \quad (1)$$

$$^3LF + Ade \xrightarrow{k_2} LF^{\cdot-} + Ade^{+} \quad (LF + Ade) \quad (1.6\pm0.2)\times10^9\ M^{-1}\ s^{-1}, \quad (2)$$

$$^3LF + O_2 \xrightarrow{k_3} LF + O_2 \quad (1.2\pm0.1)\times10^9\ M^{-1}\ s^{-1}, \quad (3)$$

$$^3LF + I^- \xrightarrow{k_4} LF + I^- \quad (5.8\pm0.3)\times10^9\ M^{-1}\ s^{-1}, \quad (4)$$

$$^3LF \xrightarrow{k_5} LF \quad (1.5\pm0.1)\times10^3\ s^{-1}, \quad (5)$$

$$^3LF + LF \xrightarrow{k_6} 2LF \quad (7\pm0.5)\times10^8\ M^{-1}\ s^{-1}, \quad (6)$$

where LF, ^{3}LF, $LF^{\cdot-}$, Trp^{+}, and Ade^{+} denote the ground state, the triplet state, and the semiquinone radical of lumiflavin, the half-oxidized tryptophan radical, and the half-oxidized adenine radical respectively. The triplet state of lumiflavin is also quenched by the triplet state of lumiflavin, but the triplet-triplet quenching is negligible under weak light. It is not necessary to distinguish between Reactions 5 and 6 in this work, and the sum total of k_5+k_6[LF] ($5000\pm300\ s^{-1}$ at 5 μM lumiflavin) was used for the analysis.

The lumiflavin semiquinone decayed by the second-order because of the back-electron-transfer reactions. In the flash photolysis of deaerated solutions of lumiflavin with adenine or tryptophan, the lumiflavin was almost completely recovered, with little permanent photobleaching. The disproportionation reaction of the lumiflavin semiquinone was negligible when the lumiflavin was reduced by tryptophan or adenine.

In the flash photolysis of aerated solutions of lumiflavin, the lumiflavin semiquinone was also observed in the presence of sufficient tryptophan or adenine, as is shown in Fig. 1. The decay of the semiquinone was apparently first- order and was faster than that in the deaerated solutions. It has been reported that the semiquinone reacts with oxygen in the anionic form, but not in the neutral form.[6] The pK_a value of the lumiflavin semiquinone has been reported to be 8.36 from this reactivity with oxygen. In the aerated conditions, the electron-transfer reaction from lumiflavin semiquinone to oxygen preceded the back-electron-transfer reactions, as has been described above. The

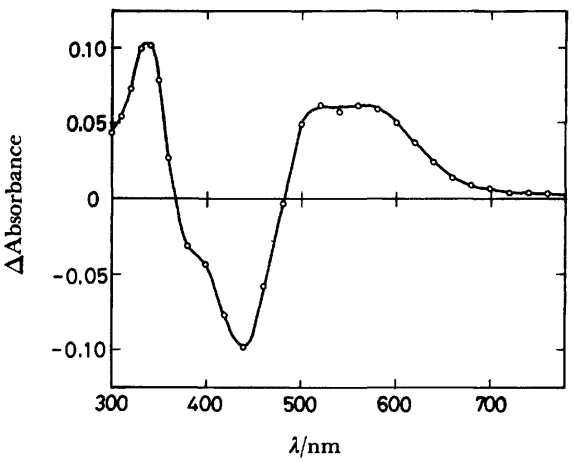

Fig. 1. The transient absorption spectrum at 40 μs after the flash excitation of 5 μM lumiflavin with 0.3 mM adenine in the aerated solutions at pH 7.2. (10-cm cell)

pseudo-first-order reaction of lumiflavin semiquinone with oxygen and the second-order recombination reactions are observed as follows:

$$LF^{\cdot-}(LFH\cdot) + O_2 \xrightarrow{k_7} LF + O_2^{\cdot-} \quad (3.7\pm0.2)\times10^7\ M^{-1}\ s^{-1}, \quad (7)$$

$$LF^{\cdot-}(LFH\cdot) + Trp^{+} \xrightarrow{k_8} LF + Trp \quad (2\pm0.4)\times10^9\ M^{-1}\ s^{-1}, \quad (8)$$

$$LF^{\cdot-}(LFH\cdot) + Ade^{+} \xrightarrow{k_9} LF + Ade \quad (2\pm0.4)\times10^9\ M^{-1}\ s^{-1}. \quad (9)$$

The rate parameter, k_7, is the apparent value at pH 7.2; it increases with the pH because of the increment in the ratio of $LF^{\cdot-}$/LFH·. Reaction 7 is the main reaction of the lumiflavin semiquinone in the steady-light photolysis of aerated solutions when the concentration of the intermediate is much lower than the concentration of oxygen.

When lumiflavin was irradiated in the presence of adenine and oxygen, a transient absorption was observed after the disappearance of semiquinone. This transient absorption at pH 7.2 was not appreciable enough for a quantitative analysis to be done because of the overlap of the absorbance change of lumiflavin semiquinone. On the other hand, at pH 8.5, the semiquinone disappeared very fast, reacting with oxygen, and a clear absorption spectrum of the long-lived species was obtained. The transient absorption spectrum after the lumiflavin semiquinone was completely disappeared is shown in Fig. 2-a. This species with a long lifetime was safely assigned to the half-oxidized adenine radical, because the addition of 10 μM tryptophan hastened the decay. This result is in accord with the previously reported results that the lumiflavin-sensitized photooxygena-

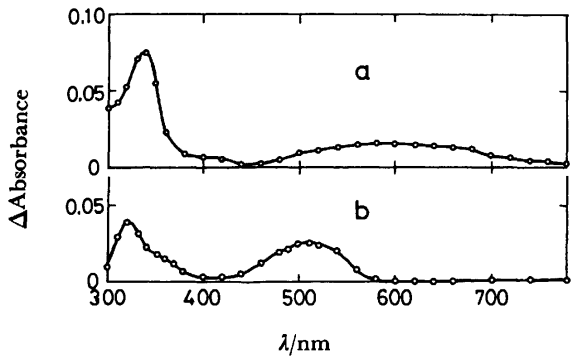

Fig. 2. The transient absorption spectra at 100 μs after the flash excitation of 5 μM lumiflavin with 0.3 mM adenine (a) and with 0.2 mM tryptophan (b) in the aerated solutions at pH 8.5. (10-cm cell)

tion of dilute tryptophan in a steady-light photolysis was accelerated by the addition of adenine.[1] The decomposition of tryptophan was observed also in this flash photolysis. The half-oxidized adenine radical decayed faster in the deaerated solutions than in the aerated solutions as a result of the electron-transfer reaction between Ade^{+} and LF^{-} in the deaerated solutions. The absorption coefficient of this half-oxidized adenine radical was estimated to be $5100\pm300\ M^{-1}\ cm^{-1}$ at 340 nm, assuming that the initial production of lumiflavin semiquinone is equal to that of the half-oxidized adenine radical in this aerated solution with sufficient adenine.

In the presence of tryptophan instead of adenine, the transient absorption spectrum obtained after the disappearance of lumiflavin semiquinone is shown in Fig. 2-b. This spectrum was assigned to the half-oxidized neutral radical of tryptophan (the pK_a of the radical is 4.3), as is shown in Ref. 10. The molar absorption coefficient at 510 nm was estimated in the above-mentioned manner to be $1700\pm100\ M^{-1}\ cm^{-1}$, which was in agreement with the reported value ($1800\pm50\ M^{-1}\ cm^{-1}$).[10] A similar transient spectrum was obtained with indole instead of tryptophan.

The transient absorption of the half-oxidized tryptophan radical was observed also by means of the flash-excitation lumiflavin with 0.3 mM adenine and 10 μM tryptophan, it was not observed without adenine because little redox reaction occurred in the aerated solution with such a little tryptophan.

The decay-rate parameter of the half-oxidized tryptophan radical in the aerated solutions (pH 8.5) was measured at 510 nm as follows:

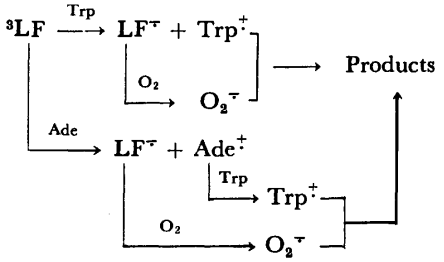
$$Trp^{+} + O_2^{-} \xrightarrow{k_{10}} \text{Products} \qquad (1.5\pm0.3)\times10^{9}\ M^{-1}\ s^{-1}, \quad (10)$$

while those of the half-oxidized adenine radical (pH 8.5) were observed at 340 nm as:

$$Ade^{+} + O_2^{-} \xrightarrow{k_{11}} Ade + O_2 \qquad (1.2\pm0.3)\times10^{9}\ M^{-1}\ s^{-1}, \quad (11)$$

$$Ade^{+} + Trp \xrightarrow{k_{12}} Ade + Trp^{+} \qquad (1.6\pm0.3)\times10^{8}\ M^{-1}\ s^{-1}. \quad (12)$$

A little decomposition of adenine was observed upon successive flashing on lumiflavin in the presence of oxygen (0.1 μM/flash), but the addition of a little tryptophan suppressed the decomposition of adenine (10 μM tryptophan is sufficient to suppress the adenine decomposition completely) and tryptophan decomposed as has been described above. This effect was continued after the complete decomposition of tryptophan; the photooxygenation products of tryptophan also suppressed the decomposition of adenine. The half-oxidized adenine radical with a long lifetime takes an electron from the substrates, and so the indirect sensitized photooxygenation of the substrates occurs. Now, the accelerating effect of adenine on the lumiflavin-sensitized photooxygenation at a low concentration of reactants can be clarified from the flash photolysis, shown schematically as follows:



It had been reported in the previous paper[1] that the effect of the addition of the iodide ion as a triplet-quencher for the lumiflavin-sensitized photooxygenation was independent of the presence or absence of adenine; this was regarded as the result of no direct reactivity of adenine with the triplet state of lumiflavin. However, the flash photolysis now shows that adenine reacts with the triplet state of lumiflavin. To resolve this conflict, the steady-light photolysis of the lumiflavin-sensitized photooxygenation of tryptophan has been reexamined over a wide range of concentrations of adenine and iodide ions.

The Stern-Volmer equation for the inhibition by iodide ions as against the lumiflavin-sensitized photooxygenation of tryptophan is written as:

$$\frac{\Phi_0}{\Phi_I} = 1 + \frac{k_4[I^-]}{k_1[Trp]+k_3[O_2]+k_5+k_6[LF]}, \quad (13)$$

where Φ_I and Φ_0 denote the quantum yield of the photooxygenation with and without iodide ions. The inverse of the slope of the Stern-Volmer plots, which were measured at various concentrations of tryptophan, were plotted against the concentration of tryp-

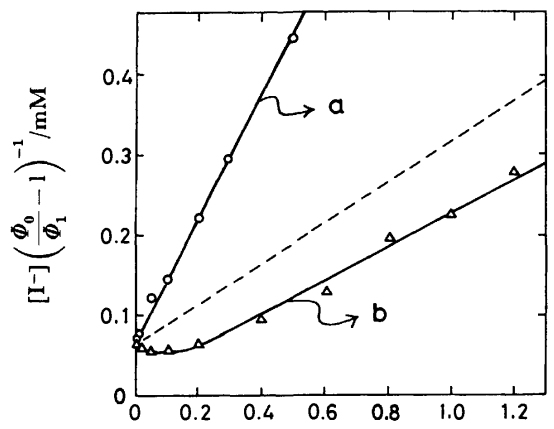


Fig. 3. The inhibition of iodide ion on the lumiflavin-sensitized photooxygenation of tryptophan in the presence and absence of adenine. Variation of the inverse of Stern-Volmer plots with the concentration of tryptophan (a) and adenine with 0.5 μM tryptophan (b).

tophan, as is shown in Fig. 3-a; the obtained linear relationship is written as:

$$[I^-]/\left(\frac{\Phi_0}{\Phi_I}-1\right)=\frac{k_1[\mathrm{Trp}]+k_3[O_2]+k_5+k_6[\mathrm{LF}]}{k_4}. \quad (14)$$

In the presence of adenine in various concentrations and a small amount of tryptophan (5 μM), the inhibiting effect of the iodide ion against the lumiflavin-sensitized photooxygenation of tryptophan was examined in the same manner. A linear relationship was also observed in the Stern-Volmer plot at every adenine concentration. In the presence of a large excess of adenine, the direct reaction between tryptophan and the triplet state of lumiflavin can be neglected; hence, the following simple relation between the inverse of the slope of the Stern-Volmer plots and the concentration of adenine can be expected by replacing the k_1[Trp] in Eq 14 with k_2[Ade]:

$$[I^-]/\left(\frac{\Phi_0}{\Phi_I}-1\right)=\frac{k_2[\mathrm{Ade}]+k_3[O_2]+k_5+k_6[\mathrm{LF}]}{k_4}. \quad (15)$$

The observed values are shown in Fig. 3-b; they deviate below from the broken line, which shows the values calculated from Eq. 15 using the rate parameter mentioned above. The inhibiting effect of the iodide ion is larger than that simply expected; the iodide ion quenches not only the triplet state of lumiflavin, but also any other intermediate. The slope of the Stern-Volmer plots in the presence of 0.2 mM adenine is, by chance, equal to that with dilute tryptophan and without adenine. In the previous work,[1] from this accidental coincidence of the effect of iodide ions, it was incorrectly inferred that adenine does not directly attack the triplet state of lumiflavin.

This additional inhibiting effect by iodide ions was also examined by means of flash photolysis. The decay of the half-oxidized adenine radical was examined in the presence of 0.05—0.2 mM of iodide ions at pH 8.5; the following reaction was thus observed:

$$\mathrm{Ade}^+ + I^- \longrightarrow \mathrm{Ade} + I\cdot \quad (4\pm1)\times10^7\ M^{-1}\ s^{-1}. \quad (16)$$

Although this rate parameter is small, the contribution was large even at low concentrations of iodide ions in the steady-light photolysis, because the rate of Reaction 10, in contrast with that of Reaction 16, depends on the light intensity. The slight decomposition of adenine by lumiflavin-sensitized steady-light photolysis in the aerated solutions was also suppressed by the addition of a small amount of iodide ions (50% by 5 μM iodide ions). The permanent oxidation of iodide ions was not observed in such a system by the starch-iodine complex method; the generated iodine should be reduced by O_2^-.

Now the conflict between the steady-light and flash photolyses is resolved. The previous explanation in Ref. 1 should be corrected.

Synthesis of Naphthalenoferrocenophanes

Akira KASAHARA,* Taeko IZUMI, Iwao SHIMIZU, Tadashi OIKAWA, Hiroshi UMEZAWA, Manabu MURAKAMI, and Osamu WATANABE

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received November 10, 1984)

Several naphthalenoferrocenophanes, in which the two cyclopentadienyl rings are linked by two naphthalene rings, were synthesized *via* intramolecular reductive coupling of the corresponding formyl compounds with a low valent titanium reagent. Their structures are deduced from IR, NMR, and UV spectra. Transannular π-electronic interaction between the two naphthalene rings is discussed on the basis of electronic spectra.

Recently a wide variety of cyclophanes with stacked aromatic nuclei have widely been studied as pertinent model compounds for π-electronic interactions.[1] From this point of view, we have previously reported of a synthesis of several ferrocenophanes containing aromatic nuclei: benzene[2] and biphenyl.[3] If one or two benzene rings are replaced by naphthalene ring, which has a larger molecular surface and a lower ionization potential than benzene, it is expected that such ferrocenophanes will show stronger transannular interactions. In this report, as a part of our studies on the metallocenophane chemistry, we describe of synthesis and properties of naphthalenoferrocenophanes **1a—d**, in which the two cyclopentadienyl rings are linked by one or two naphthalene rings.

Results and Discussion

Synthesis. Previous successful use of a reductive coupling reaction on appropriate carbonyl compounds for synthesis of [2.2.2] paracycloferrocenophanes[2] and biphenyloferrocenophanes[3] promoted us to attempt the synthesis of **1a—d** by this method. In connection with the synthesis of **1a—d**, it was desirable to synthesize in quantity intermediary compounds: 1,1′-bis(5-formyl-1-naphthyl)ferrocene (**2a**), 1,1′-bis(6-formyl-1-naphthyl)ferrocene (**2b**), 1,1′-bis(7-formyl-1-naphthyl)ferrocene (**2c**), and 1-(*p*-formylphenyl)-1′-(4-formyl-1-naphthyl)ferrocene (**2d**). The synthesis of intermediates **2a—c** was carried out by Gomberg's arylation of ferrocene with diazonium salts **3a—c** derived from 5-amino-naphthoic acid (**4a**), 5-amino-2-naphthoic acid (**4b**), and 8-amino-2-naphthoic acid (**4c**), followed by esterification, reduction with $LiAlH_4$, and oxidation with active MnO_2 in chloroform. On the other hand, the synthesis of the intermediate **2d** was carried out by Gomberg's arylation of (*p*-ethoxycarbonyl)ferrocene (**6**) with diazonium salts derived from 4-ethoxycarbonyl-1-naphthylamine (**7**), followed by reduction with $LiAlH_4$, and oxidation with active MnO_2 in chloroform.

The reductive coupling reactions of dialdehydes **2a—c** with low valent titanium reagents ($TiCl_4$–Zn[4]) using the high dilution method led to the formation of unsaturated naphthalenoferrocenophanes, [2](1,5)naphthaleno[0](1,1′)ferroceno[0](1,5)-naphthalenophan-1-ene (**5a**), [2](2,5)naphthaleno-[0](1,1′)ferroceno[0](1,6)naphthalenophan-1-ene (**5b**), and [2](2,8)naphthaleno[0](1,1′)ferroceno[0](1,7)-naphthalenophan-1-ene (**5c**), accompanied by the formation of reduction products of dialdehydes **2a—c**, respectively. The catalytic hydrogenation of the unsaturated ferrocenophane **5a—c** afforded the saturated naphthalenoferrocenophanes, [2](1,5)-naphthaleno[0](1,1′)ferroceno[0](1,5)naphthalenophane (**1a**), [2](2,5)naphthaleno[0](1,1′)ferroceno[0](1,6)-naphthalenophane (**1b**), and [2](2,8)naphthaleno-[0](1,1′)ferroceno[0](1,7)naphthalenophane (**1c**), respectively. However, the intramolecular reductive coupling of **2d**, for preparing the unsaturated ferrocenophane **5d**, was unsuccessful and led to the formation of reduction products of **9d**. Therefore, the saturated ferrocenophane, [2]paracyclo[0](1,1′)-ferroceno[0](1,4)naphthalenophane (**1d**), was prepared by ring closure of 1-[*p*-(bromomethyl)phenyl]-1′-[4-(bromomethyl)-1-naphthyl]ferrocene (**8**) with butyllithium.

Structures. The structures of the ferrocenophanes **1a—d** and **5a—d** were determined on the basis of IR, NMR, and mass spectra and elementary analyses. The ^1H NMR and IR spectral data of all the ferrocenophanes and the reference compounds are summarized in Tables 1 and 2, respectively. For the unsaturated ferrocenophane **5a**, the configuration of the olefinic bond has been confirmed to be cis because the IR spectrum of **5a** exhibits a band at 720 cm^{-1} chracteristic of *cis*-vinylene linkage and because the characteristic C–H out of deformation modes of *trans*-vinylene linkage around 960 cm^{-1} are absent. With the ^1H NMR spectrum of **5a**, it is noteworthy that the downfield shift of vinylene protons(δ=7.56) is observed, as with the case of [2.2.2](1,3,5)cyclophane-1,9,17-triene(vinylene protons, δ=7.37).[5] For both **1a** and **5a**, two possible conformations are considered from their ^1H NMR spectra, syn or skew. In addition, **1a** and **5a** have the same conformation so that **1a** could be synthesized from **5a** by catalytic hydrogenation, in which the

rotation of syn to skew at the 5-position of naphthalene ring is made impossible by bridging. The smaller upfield shift of protons Ha and Hd relative to protons Hb, Hc, He, and Hf in the naphthalene ring would be expected if **5a** had a skew form as with[2.2](1,5)naphthalenophane.[6] In the ^{1}H NMR spectra of **5a**, however, all the protons of naphthalene rings appear at higher fields than the corresponding protons of the reference compound, 1,1′-bis(5-methyl-1-naphthyl)ferrocene (**9a**), showing a shielding effect by the opposite naphthalene ring. This phenomenon suggests a *syn*-conformation for both **1a** and **5a** rather than a skewed one (**10**). In **1a** and **5a**, the molecule probably exists in such a conformation that the naphthalene rings approximately parallel to one another and approximately coplanar to the cyclopentadienyl ring. In ferrocene, the distance between the two cyclopentadienyl rings is 3.32 Å,[7] while the Van der Waals separation between parallel π-systems is 3.345 Å.[8] Thus, in **1a** and **5a**, a substantial repulsive interaction must exist between the two naphthalene rings which are bound together by ethylene or vinylene bridges at both the 5-positions. In the ^{1}H NMR spectra of both **1b** and **5b**, the aromatic protons He and Hf are shifted to higher field by about 0.9 ppm, compared with those of the reference compound, 1,1′-bis(6-methyl-1-naphthyl)ferrocene (**9b**). However, the signals of protons Ha, Hb, Hc, and Hd are observed at nearly the same positions as those of **9b**. These data support

1a	3100, 805 (1,1′-disubstituted ferrocene ring), 1600, 1580, 780, 770 (naphthalene ring), 715, and 685 (distorted naphthalene ring).
5a	3100, 805 (1,1′-disubstituted ferrocene ring), 1600, 1580, 785, 775 (naphthalene ring), 1620, 720 (cis -CH=CH-), 710, and 685 (distorted naphthalene ring).
9a	3100, 805 (1,1′-disubstituted ferrocene ring), 1590, and 770 (naphthalene ring).
1b	3100, 805 (1,1′-disubstituted ferrocene ring), 1590, 780, and 765 (naphthalene ring).
5b	3100, 805 (1,1′-disubstituted ferrocene ring), 1600, 1580, 775 (naphthalene ring), 1625, and 720 (cis -CH=CH-).
9b	3100, 810 (1,1′-disubstituted ferrocene ring), 1590, 785, and 770 (naphthalene ring).
1c	3100, 810 (1,1′-disubstituted ferrocene ring), 1600, and 830 (naphthalene ring).
5c	3100, 810 (1,1′-disubstituted ferrocene ring), 1590, 830 (naphthalene ring), 1620, and 735 (cis -CH=CH-).
9c	3100, 810 (1,1′-disubstituted ferrocene ring), 1600, and 830 (naphthalene ring).
1d	3100, 810 (1,1′-disubstituted ferrocene ring), 1600, 1580, 840, 820, 765 (naphthalene ring+*p*-disubstituted benzene ring), 725, and 695 (distorted aromatic ring).
9d	3100, 800 (1,1′-disubstituted ferrocene ring), 1600, 1580, 820, and 760 (naphthalene ring+*p*-disubstituted benzene ring).

the view that both **1b** and **5b** exist exclusively in the *anti*-conformation rather than in the *syn*-conformation owing to a π-π repulsive instabilization in the latter conformation. Furthermore, in **1b** and **5b**, the cyclopentadienyl protons Hα' are shifted to higher field by about 0.5 and 1.0 ppm, respectively, compared with those of **9b**. The remarkable upfield shifts of protons Hα' in **1b** and **5b** are probably due to a diamagnetic shielding effect on the opposed naphthalene ring and clearly indicate the *anti*-conformation rather than the vertically stacked conformation (**1b′**). In the ^{1}H NMR spectra of both **1c** and **5c**, the aromatic proton signals, except for Hf, are observed at nearly the same positions as those of the reference compound, 1,1′-bis(7-methyl-1-naphthyl)-ferrocene (**9c**). On the other hand, the aromatic protons Hf are shifted to higher fields by about 0.45 ppm, compared with those of the reference compound **9b**. These data suggest that, in both **1c** and **5c**, the two naphthalene rings are held not in a face to face conformation but in an *anti*-conformation. On the other hand, the ferrocenophane **1d** shows its signals of the bridge ethylene protons to be roughly divided into two groups of multiplets. Of these, the lower field multiplet is associated with the endo proton of methylenes attached to the condensed aromatic ring for the 1,4-bridged systems. The downfield shift of the proton is explained in terms of the large deshielding effect of the neighboring condensed aromatic ring. The phenyl protons show upfield shifts compared with those of the reference compound, 1-(*p*-tolyl)-1′-(4-methyl-1-naphthyl)-ferrocene (**9d**), and may reasonably be assigned by considering the diamagnetic anisotropy of the opposite aromatic ring. In the ferrocenophane **1d**, the upfield shifts (1.21 and 1.65 ppm) of the phenyl protons Ha′ and Hb′ are drastic as compared with those of protons Ha (0.47 ppm) and Hb (0.54 ppm), suggesting that protons Ha′ and Hb′ are situated above the center of the opposite naphthalene ring. The naphthalene protons Hc and Hd show reasonable upfield shifts. However, protons Hf and Hg show absorptions at a rather lower field and shifts of protons He and Hh are negligible. These data are best accounted for on the basis of the conformation **1d**, in which the benzene and naphthalene rings are approximately parallel to each other and are held face to face in close proximity by the ethylene bridges at both the 4-positions.

Electronic Spectra. Toluene and 1-methylnaphthalene show no absorption in the long wavelength region above 300 nm.[9] Figures 1,2,3, and 4 show the electronic spectra of naphthalenoferrocenophanes

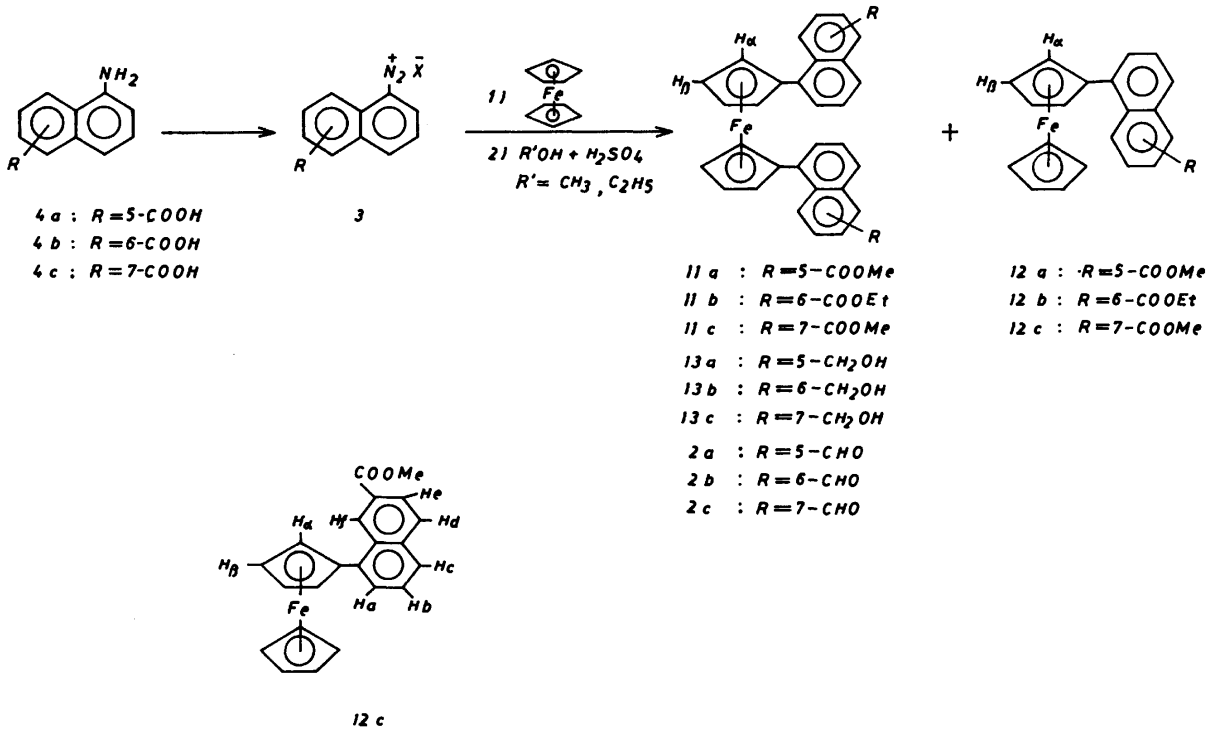
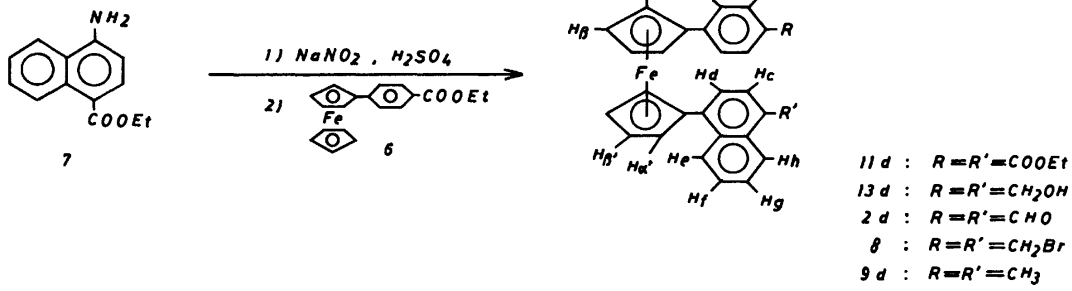
——: **1d**, ----: **9d**.

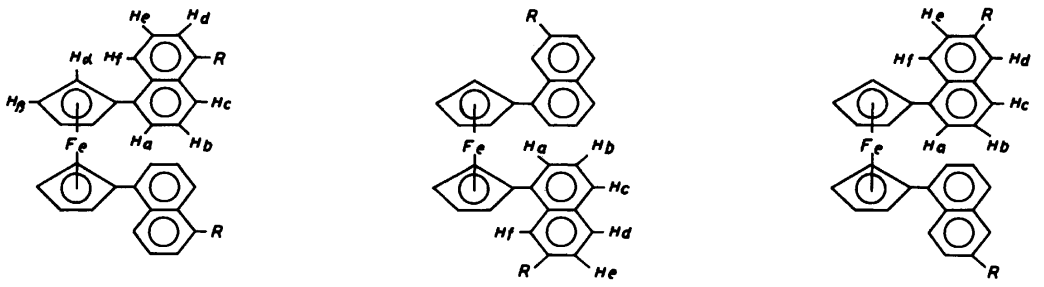
1a—d and **5a—c** together with those of the reference compounds **9a—d**. The electronic spectra of **1a**, **1b**, **5a**, and **5b** show somewhat bathochromic and hyperchromic shifts in the range 220—320 nm, compared with those of the reference compounds **9a** and **9b**, respectively. This may be due to transannular π-electronic interactions between the two naphthalene chromophores in **1a**, **1b**, **5a**, and **5b**. Furthermore, in **1a**, **1b**, **5a**, and **5b**, the bathochromic shifts of the unsaturated series are more significant than those of the saturated series, suggesting that the two naphthalene rings in the unsaturated ferrocenophanes **5a** and **5b** are closer in orientation to vertical stacking than those of the saturated ferrocenophanes **1a** and **1b**. On the other hand, in the 220—320 nm region, the electronic spectra of **1c** and **5c** are similar to the spectra of the reference compound 9c. This phenomenon and the small shielding effects on all the aromatic protons but proton Hf in the NMR spectra, indicate that the interactions between the two naphthalene rings in **1c** and **5c** are relatively weak. The electronic spectrum of ferrocene has two main absorptions at 325 and 440 nm. It has been shown that both the position and intensity of the 440 nm band are particularly sensitive to ferrocene ring-tilt distortion.[10] In the 330—500 nm region, the electronic spectra of the ferrocenophanes **1a—d** and **5a—c** show an increased intensity and a bathochromic shift to longer wavelengths, compared with those of the reference compounds **9a—d** bearing an untilted ferrocene ring. These phenomena suggest that, in all ferrocenophanes, ferrocene ring-tilt distortion will occur. In compounds **1a**, **5a**, and **1d**, the ferrocene ring-tilt distortion may be caused by the strong π-π repulsions between the two faced naphthalene rings or between the benzene and naphthalene rings. In **1b** and **5b**, the planes of the cyclopentadienyl and naphthalene rings probably have a nonplanar orientation owing to the short length of the side chain which is bridging at the 6-position of the naphthalene ring, and the ferrocene ring-tilt distortions may be caused by the repulsions between the B rings in the two naphthalene rings. On the other hand, in compounds **1c** and **5c**, the interactions between the two naphthalene rings are relatively weak, and accordingly the ferrocene ring-tilt distortions may be caused by the strain due to the short length of the side chain which is bridging at the 7-position in naphthalene rings.

Infrared Spectra. IR spectra of the [2.2]paracyclophane system are known to reveal obvious features. One is the increase in the intensity of a band in the 1580—1600 cm^{-1} region, which is related to the increased double-bond character due to the distortion of the benzene ring.[11] The other is the appearance of a strong new maximum in the 710 cm^{-1} region. Longone and Warren[11b] reported that the strong

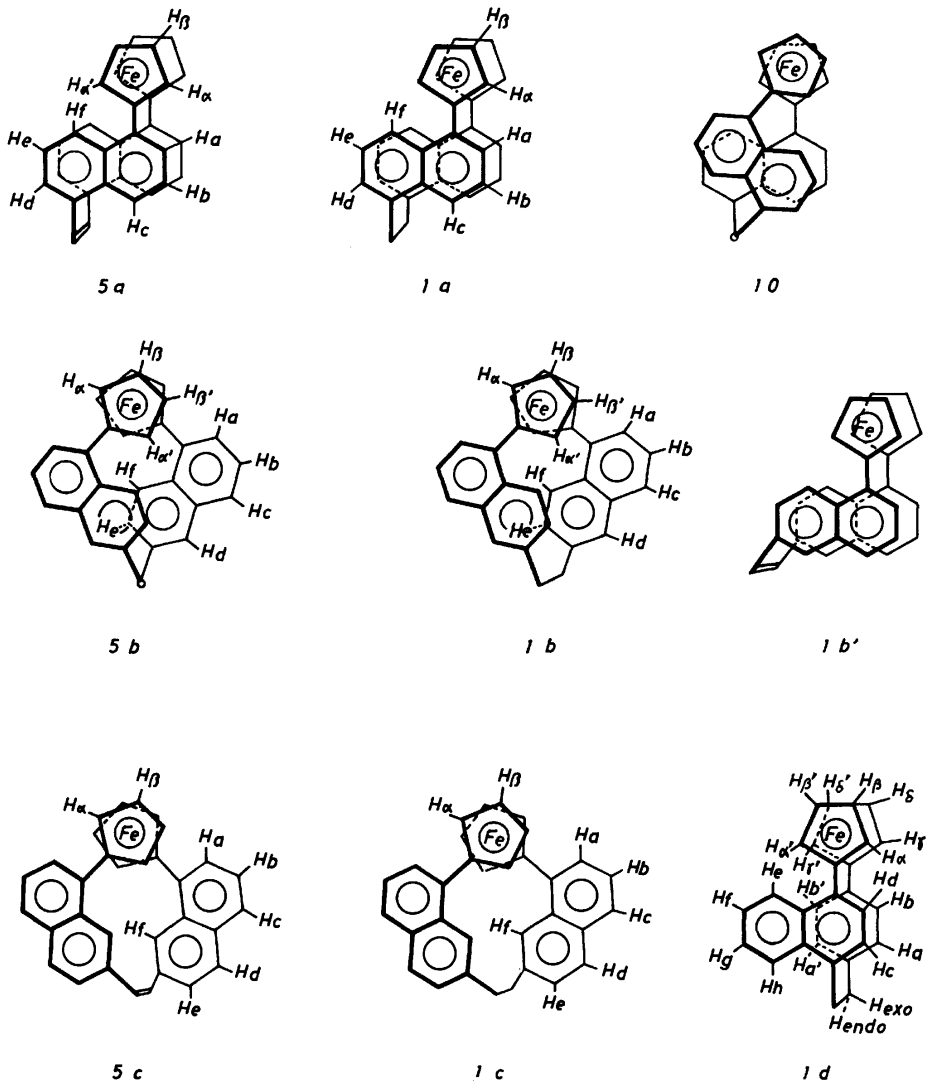
maxima at 725 cm^{-1} in [2.2]paracyclophane and 710 cm^{-1} in 4,7,12,15-tetramethyl[2.2]paracyclophane might be characteristic bands associated with the distorted benzene ring in the [2.2]paracyclophane system. We also reported of the same phenomenon in the [2]paracyclo[0](1,1')ferroceno[0]paracyclophane bearing the distorted benzene ring.[2] The naphthalenophanes **1a**, **5a**, and **1d** exhibit characteristic bands







Scheme 1.



Scheme 2.

around 700 cm^{-1}, whereas the reference compounds **9a** and **9d** bearing strain-free aromatic rings exhibit no bands in this region. This phenomenon may be due to the distortion of the aromatic rings in **1a**, **5a**, and **1d**. On the other hand, near 700 cm^{-1}, the IR spectra of **1b**, **5b**, **1c**, and **5c** are similar to those of the open-chain models **9b** and **9c**. This may be due to the lack of distortion of the aromatic rings in **1b**, **5b**, **1c**, and **5c** (see Table 2).

Experimental

Materials and Measurements. All melting points are uncorrected. 5-Amino-1-naphthoic acid (**4a**),[12] 5-amino-2-naphthoic acid (**4b**),[13] 8-amino-2-naphthoic acid (**4c**),[13] (*p*-ethoxycarbonylphenyl)ferrocene (**6**),[14] and 4-ethoxycarbonyl--1-naphthylamine (**7**)[15] were prepared by the methods described in the literature. IR, ^1H NMR, mass, and electronic spectra were recorded with Hitachi 260-10, Hitachi R-22, Hitachi RMU-6M, and Hitachi 200-10 spectrometers, respectively.

*1,1'-Bis[5-(methoxycarbonyl)-1-naphthyl]ferrocene (**11a**).* The amine **4a** (9.36 g, 50 mmol) was diazotized in 10% sulfuric acid at 0—5 °C with sodium nitrite (3.45 g, 50 mmol). After the diazotization the solution was added dropwise to a solution of ferrocene (3.72 g, 20 mmol) in acetic acid (150 cm^3) under a nitrogen atmosphere. The resulting dark brown solution was stirred overnight at room temperature and then poured into water. The precipitates formed were filtered off, washed with water, dried at room temperature, and then esterified in refluxing methanol (300 cm^3) containing 5 cm^3 of concd H_2SO_4 under a nitrogen atmosphere. After removal of the solvents *in vacuo*, the residue was extracted with chloroform and the chloroform extracts were washed with 5% sodium hydrogencarbonate solution and brine, dried over anhyd $MgSO_4$, filtered, and concentrated. The residue was purified by column chromatography (silica gel).

The first elution with benzene gave the starting material ferrocene (1.12 g, 30%), mp 173 °C.

The second elution with benzene afforded 1.17 g (15.9%

yield based on ferrocene) of (5-methoxycarbonyl-1-naphthyl)-ferrocene (**12a**): orange yellow crystal; mp 114—115 °C; IR (KBr) 3100, 1100, 1000, 805 (monosubstituted ferrocene ring), 1710 (-$COOCH_3$), 1600, 1500, 810, 790, and 770 cm^{-1} (naphthalene ring); ^1H NMR ($CDCl_3$) δ=3.96 (s, 3H, -CH_3), 4.13 (s, 5H, H_γ), 4.36 (t, 2H, H_β), 4.57 (t, 2H, H_α), and 7.31—8.80 (m, 6H, Ar-H). Found: C, 71.13; H, 4.81; M^+, 370. Calcd for $C_{22}H_{18}FeO_2$: C, 71.27; H, 4.89; M, 370.

The third elution with benzene gave 1.58 g (14.2% yield based on ferrocene) of reddish crystals, mp 156—158 °C, which were determined to be 1,1'-bis(5-methoxycarbonyl-1-naphthyl)ferrocene (**11a**): IR (KBr) 3100,805 (1,1'-disubstituted ferrocene ring), 1720 (-$COOCH_3$), 1600, 1500, 820, 790, and 770 cm^{-1} (naphthalene ring); ^1H NMR ($CDCl_3$) δ=3.91 (s, 6H, -CH_3), 4.42 (m, 4H, H_β), 4.58 (m, 4H, H_α), and 7.32—8.50 (m, 12H, Ar-H). Found: C, 73.53; H, 4.56; M^+, 554. Calcd for $C_{34}H_{26}FeO_4$: C, 73.65; H, 4.72; M, 554.

1,1'-Bis[6-(ethoxycarbonyl)-1-naphthyl]ferrocene (11b). Gomberg's arylation of ferrocene with diazonium salts derived from **4b**, followed by esterification in ethanol, was carried out in the same way as described above, and (6-ethoxycarbonyl-1-naphthyl)ferrocene (**12b**) (orange yellow crystals, mp 98—99 °C) and **11b** (reddish crystals, mp 130—132 °C) were obtained in 14 and 8% yields, respectively.

11b: IR (KBr) 3100, 810 (1,1'-disubstituted ferrocene ring), 1720 (-COOEt), 1600, 1500, 780, and 770 cm^{-1} (naphthalene ring); ^1H NMR ($CDCl_3$) δ=1.38 (t, 6H, -CH_3), 4.40 (t, 4H, H_β), 4.44 (q, 4H, -CH_2-), 4.61 (t, 4H, H_α), and 7.20—8.49 (m, 12H, naphthalene ring protons). Found: C, 74.39; H, 5.26; M^+, 582. Calcd for $C_{36}H_{30}FeO_4$: C, 74.23; H, 5.19; M, 582.

12b: IR (KBr) 3100, 1100, 1000, 805 (monosubstituted ferrocene ring), 1720 (-COOEt), 1600, 1500, 780, and 770 cm^{-1} (naphthalene ring); ^1H NMR ($CDCl_3$) δ=1.38 (t, 3H, -CH_3), 4.12 (s, 5H, H_γ), 4.37 (t, 2H, H_β), 4.41 (q, 2H, -CH_2), 4.60 (t, 2H, H_α), and 7.34—8.60 (m, 6H, naphthalene ring protons). Found: C, 71.75; H, 5.17; M^+, 384. Calcd for $C_{23}H_{20}FeO_2$: C, 71.88; H, 5.24; M, 384.

1,1'-Bis[7-(methoxycarbonyl)-1-naphthyl]ferrocene (11c). Gomberg's arylation of ferrocene with diazonium salts derived from **4c**, followed by esterification in methanol, was carried out in the same way as described for **11a**, and (7-methoxycarbonyl-1-naphthyl)ferrocene (**12c**) (orange yellow crystals, mp 90—92 °C) and **11c** (reddish orange crystals, mp 152—153 °C) were obtained in 12.5 and 6.2% yields, respectively.

11c: IR (KBr) 3100, 800 (1,1'-disubstituted ferrocene ring), 1720 (-$COOCH_3$), 1600, 1500, 835, and 740 cm^{-1} (naphthalene ring); ^1H NMR ($CDCl_3$) δ=3.96 (s, 6H, -CH_3), 4.50 (t, 4H, H_β), 4.90 (t, 4H, H_α), 7.11—7.93 (m, 10H, H_{a-e}), and 9.57 (br-s, 2H H_f). Found: C, 73.51; H, 4.58; M^+, 554. Calcd for $C_{34}H_{26}FeO_4$: C, 73.65; H, 4.72; M, 554.

12c: IR (KBr) 3100, 1100, 1000, 805 (monosubstituted ferrocene ring), 1720 (-$COOCH_3$), 1600, 1500, 835, and 740 cm^{-1} (naphthalene ring); ^1H NMR ($CDCl_3$) δ=3.92 (s, 3H, -CH_3), 4.19(s, 5H, H_γ), 4.42 (t, 2H, H_β), 4.66 (t, 2H, H_α), 7.29—8.11 (m, 5H, H_{a-e}), and 8.56 (br-s, 1H, H_f). Found: C, 71.22; H, 4.74; M^+, 370. Calcd for $C_{22}H_{18}FeO_2$: C, 71.37; H, 4.90; M, 370.

1-(p-Ethoxycarbonylphenyl)-1'-(4-ethoxycarbonyl-1-naphthyl)-ferrocene (11d). The amine **7** (3.01 g, 14 mmol) was diazotized in 5% sulfuric acid (830 cm^3) at 0—5 °C with sodium nitrite (1.0 g, 14.4 mmol). After the diazotization the diazotized salt solution was added rapidly to a solution of compound **6** (4.01 g, 12 mmol) in acetic acid (600 cm^3) in an atmosphere of nitrogen. The resulting dark brown solution was stirred overnight at room temperature and then poured into water. The reaction mixture was extracted with chloroform and the chloroform extracts were washed with 5% aqueous sodium hydrogencarbonate solution and with brine, dried over anhyd $MgSO_4$, filtered, and concentrated. The residue was purified by column chromatography with silica gel.

The first elution with hexane-diethyl ether (4:1) afforded the starting material **6** (0.78 g, 19.4%), mp 87—88 °C.

The second elution with hexane-diethyl ether (4:1) afforded 0.98 g (15.3% yield based on **6**) of **11d** in reddish oil: IR ($CHCl_3$) 3100, 805 (1,1'-disubstituted ferrocene ring), 1720 (-COOEt), 1600, 1500, 780, and 730 cm^{-1} (aromatic ring); 1H NMR ($CDCl_3$) δ=1.37 (t, 3H, -CH_3), 1.44 (t, 3H, -CH_3), 4.31(t, 2H, H_β), 4.38(t, 2H, $H_{\beta'}$), 4.41 (m, 4H, -CH_2-), 4.57 (t, 2H, H_α), 4.69 (t, 2H, $H_{\alpha'}$), and 7.34—8.94 (m, 10H, aromatic protons). Found: C, 72.06; H, 5.18; M^+, 532. Calcd for $C_{32}H_{28}FeO_4$: C, 72.18; H, 5.30; M, 532.

1,1'-Bis[5-(hydroxymethyl)-1-naphthyl]ferrocene (13a). To a suspension of $LiAlH_4$ (0.42 g, 11 mmol) in anhyd diethyl ether (50 cm^3) was added dropwise a solution of **11a** (2.21 g 4 mmol) in dry benzene (50 cm^3) at room temperature over 1 h, and the reaction mixture was then heated under reflux for an additional 4 h. After the mixture was decomposed with a amall amount of cold water, the organic layer was washed successively with 5% hydrochloric acid, 5% sodium hydrogencarbonate solution, and brine, and dried over anhyd $MgSO_4$. After removal of the solvents, the residue was purified by column chromatography on silica gel (benzene-diethyl ether, 1:1) to afford **13a** as orange yellow crystals, which were recrystallized from ethanol, mp 168—169 °C, in 72% yield: IR (KBr) 3100, 805 (1,1'-disubstituted ferrocene ring), 3400, 1020 (-OH), 1600, 820, 780, and 770 cm^{-1} (naphthalene ring); ^1H NMR ($CDCl_3$) δ=1.72 (br-s, 2H, -OH), 4.42 (t, 4H, H_β), 4.62 (t, 4H, H_α), 5.08 (s, 4H, -CH_2-), and 7.12—8.48 (m, 12H, naphthalene ring protons). Found: C, 77.28; H, 5.21; M^+, 498. Calcd for $C_{32}H_{26}FeO_2$: C, 77.12; H, 5.26; M, 498.

1,1'-Bis[6-(hydroxymethyl)-1-naphthyl]ferrocene (13b). A reduction of **11b** with $LiAlH_4$ was carried out in the same way as described above, and **13b** (orange yellow crystals, mp 163—164 °C) was obtained in 66% yield: IR (KBr) 3100, 805 (1,1'-disubstituted ferrocene ring), 3350, 1020 (-OH), 1590, 825, 780, and 760 cm^{-1} (naphthalene ring); ^1H NMR ($CDCl_3$) δ=1.72 (br-s 2H, -OH), 4.42 (t, 4H, H_β), 4.58 (t, 4H, H_α), 4.74 (s, 4H, -CH_2-), and 6.91—8.39 (m, 12H, naphthalene ring protons). Found: C, 77.21; H, 5.35; M^+ 498. Calcd for $C_{32}H_{26}FeO_2$: C, 77.12; H, 5.26; M, 498.

1,1'-Bis[7-(hydroxymethyl)-1-naphthyl]ferrocene (13c). A reduction of **11c** with $LiAlH_4$ was carried out in the same way as described for the ruduction of **11a** with $LiAlH_4$ and the product **13c** (orange yellow crystals, mp 136—137 °C) was obtained in 51% yield: IR (KBr) 3100, 810 (1,1'-disubstituted ferrocene ring), 3450, 1020 (-OH), 1590, 835, and 740 cm^{-1} (naphthalene ring); ^1H NMR ($CDCl_3$) δ=1.80 (br-s, 2H, -OH), 4.39 (t, 4H, H_β), 4.66 (s, 4H, -CH_2-), 4.78 (t, 4H, H_α), and 7.11—8.70 (m, 12H, naphthalene ring protons). Found: C, 69.96; H, 5.13; M^+, 498. Calcd for

$C_{32}H_{26}FeO_2$: C, 77.11; H, 5.25; M, 498.

1-[p-(Hydroxymethyl)phenyl]-1'-[4-(hydroxymethyl)-1-naphthyl]-ferrocene (13d). A reduction of **11d** with $LiAlH_4$ was carried out in the same way as described for the reduction of **11a** with $LiAlH_4$, and the product **13d** (orange yellow crystals, mp 60—62 °C) was obtained in 90% yield: IR (KBr) 3100,805 (1,1'-disubstited ferrocene ring), 3300, 1000 (-OH), 1600, 820, and 760 cm^{-1} (naphthalene ring); ^1H NMR ($CDCl_3$) δ=1.89 (s, 2H, -OH), 4.30 (t, 2H, Hβ), 4.34 (t, 2H, Hβ'), 4.57 (m, 4H, $-CH_2-$+Hα), 4.63 (t, 2H, Hα), 5.09 (s, 2H, $-CH_2-$), 7.06 (d, J=8 Hz, 2H, Ha), and 7.23—8.48 (m, 8H, Hb+naphthalene ring protons). Found: C, 76.46; H, 5.50; M^+, 448. Calcd for $C_{28}H_{24}FeO_2$: C, 76.37; H, 5.40; M, 448.

1,1'-Bis(5-formyl-1-naphthyl)ferrocene (2a). At room temperature, active manganese(IV) oxide (49 g) was added to a solution of **13a** (2.59 g, 5.2 mmol) in chloroform (150 cm^3) and the mixture was stirred in the dark for 12 h. After filtration to remove MnO_2, the reddish chloroform solution was evaporated to dryness and the residue was chromatographed by elution of chloroform on silica gel to afford reddish crystals **2a** (1.80 g, 70% yield): mp 175—176 °C; IR (KBr) 3100, 805 (1,1'-disubstituted ferrocene ring), 1680 (-CHO), 1590, 780, and 770 cm^{-1} (naphthalene ring); ^1H NMR ($CDCl_3$) δ=4.50 (t, 4H, Hβ), 4.59 (t, 4H, Hα), 7.24—8.73 (m, 10H, Ha, b, d, e, f), 9.14 (d, 2H, Hc), and 10.33 (s, 2H, -CHO). Found: C, 77.86; H, 4.55; M^+, 494. Calcd for $C_{32}H_{22}FeO_2$: C, 77.75; H, 4.49; M, 494.

1,1'-Bis(6-formyl-1-naphthyl)ferrocene (2b). An oxidation of **13b** with active manganese(IV) oxide was carried out in the same way as described above, and reddish crystals **2b** (mp 191—193 °C) were obtained in 81% yield: IR (KBr) 3100, 800 (1,1'-disubstituted ferrocene ring), 1690 (-CHO), 1590, 830, and 790 cm^{-1} (naphthalene ring); ^1H NMR ($CDCl_3$) δ=4.46 (t, 4H, Hβ), 4.63 (t, 4H, Hα), 7.20—8.52 (m, 12H, naphthalene ring protons), and 10.02 (s, 2H, -CHO). Found: C, 77.91; H, 4.58; M^+, 494. Calcd for $C_{32}H_{22}FeO_2$: C, 77.74; H, 4.48; M, 494.

1,1'-Bis(7-formyl-1-naphthyl)ferrocene (2c). An oxidation of **13c** with active manganese(IV) oxide was carried out in the same way as described for the oxidation of **13a** with active MnO_2, and reddish crystals **2c** (mp 204—205 °C) were obtained in 66% yield: IR (KBr) 3100, 800 (1,1'-disubstituted ferrocene ring), 1690 (-CHO), 1590, 830, and 760 cm^{-1} (naphthalene ring); ^1H NMR ($CDCl_3$) δ=4.51 (t, 4H, Hβ), 4.78 (t, 4H, Hα), 7.13—7.74 (m, 10H, Ha, b, c, d, e), 9.02 (s, 2H, Hf), and 9.81 (s, 2H, -CHO). Found: C, 77.62; H, 4.35; M^+, 494. Calcd for $C_{32}H_{22}FeO_2$: C, 77.75; H, 4.49; M, 494.

1-(p-Formylphenryl)-1'-(4-formyl-1-naphthyl)ferrocene (2d). An oxidation of **13d** with active manganese(IV) oxide was carried out in the same way as described for the oxidation of **13d** with active MnO_2, and reddish crystals **2d** (mp 168—170 °C) were obtained in 64% yield: IR (KBr) 3100, 805 (1,1'-disubstituted ferrocene ring), 1690 (-CHO), 1590, 830, 760, and 730 cm^{-1} (aromatic ring); ^1H NMR ($CDCl_3$) δ=4.46 (t, 2H, Hβ), 4.50 (t, 2H, Hβ'), 4.72 (T, 2H, Hα), 4.76 (t, 2H, Hα'), 7.23—8.92 (m, 10H, aromatic ring), 10.06 (s, 1H, -CHO), and 10.21 (s, 1H, -CHO). Found: C, 75.81; H, 4.59; M^+, 444. Calcd for $C_{28}H_{20}FeO_2$: C, 75.69; H, 4.54; M, 444.

1-[p-(Bromomethyl)phenyl]-1'-[4-(bromomethyl)-1-naphthyl]-ferrocene (8). In an atmosphere of nitrogen, chlorotrimethylsilane (8.47 g, 78 mmol) was added to a solution of anhyd lithium bromide (5.82 g, 67 mmol) in dry acetonitrile (210 cm) with stirring at room temperature. The alcohol **13d** (8.06 g, 18 mmol) was then added and the reaction mixture was heated under reflux for 0.5 h. After cooling, the mixture was extracted with diethyl ether (500 cm^3), and the extract was washed successively with water, 5% sodium hydrogencarbonate solution, and brine, and dried over anhyd $MgSO_4$. After removal of the solvents, the residue was purified by column chromatography on silica gel (dichloromethane) to afford **8** in reddish oil in 56% yield: IR ($CHCl_3$) 3100, 805 (1,1'-disubstituted ferrocene ring), 1600, 1500, 840, and 760 cm^{-1} (aromatic ring); ^1H NMR ($CDCl_3$) δ=4.28 (t, 2H, Hβ), 4.31 (t, 2H, Hβ), 4.38 (s, 4H, $-CH_2-$), 4.48 (t, 2H, Hα), 4.54 (t, 2H, Hα'), 7.18 (d, 2H, Ha), and 7.24—8.54 (m, 8H, Hb+naphthalene ring protons). Found: C, 58.46; H, 3.77; M^+ 574. Calcd for $C_{28}H_{22}Br_2Fe$: C, 58.57; H, 3.86; M, 574.

Intramolecular Reductive Coupling of 2a with $TiCl_4$-Zn. In an atmosphere of nitrogen, zinc dust (1.17 g, 18 mmol) was added in small portions to a stirred solution of $TiCl_4$ (1.80 g, 9 mmol) in dry THF (50 cm^3) at 0—5 °C. After the mixture was refluxed for 1.5 h, a solution of **2a** (0.89 g, 1.8 mmol) and dry pyridine (0.10 g) in dry THF (200 cm^3) was added over 14 h under reflux and the mixture was allowed to reflux for an additional 10 h and then quenched by addition of 50 cm^3 of saturated potassium carbonate solution. The mixture was stirred for 0.5 h, diluted with chloroform, and filtered through Celite. The chloroform layers were washed with brine and dried over anhyd $MgSO_4$. After removal of the solvents, the residue was dissolved in hexane and chromatographed on silica gel.

The first fraction, eluted with hexane–ether (5:1) and subjected to evaporation and recrystallization from ethanol, gave yellow orange crystals (0.09 g, 10.7%), mp 135—137 °C, which were determined to be 1,1'-bis(5-methyl-1-naphthyl)ferrocene(**9a**). Found: C, 82.56; H, 5.69; M^+, 466. Calcd for $C_{32}H_{26}Fe$: C, 82.41; H, 5.62; M, 466.

The second fraction, eluted with hexane–diethyl ether (5:1) and subjected to evaporation and recrystallization from benzene, gave reddish crystals (0.15 g, 18.0%), mp 241—242 °C, which were determined to be *syn*-[0](1,5)-naphthaleno[2](1,5)naphthaleno[0](1,1')ferrocenophan-9-ene (**5a**). Found: C, 83.21; H, 4.96; M^+, 462. Calcd for $C_{32}H_{22}Fe$: C, 83.13; H, 4.80; M, 462.

The third fraction, eluted with chloroform and subjected to evaporation and recrystallization from ethanol, gave orange yellow crystals (0.21 g, 23% yield), mp 168—169 °C, which were identified with 1,1'-bis(5-hydroxymethyl-1-naphthyl)ferrocene (**4a**) by comparison of IR, NMR, and mass spectra and a mixed-melting-point value with those of the authentic sample **4a**.

Reaction of 2b with $TiCl_4$-Zn. The reductive coupling of **2b** with $TiCl_4$–Zn was carried out in the same way as has been described above, and the products were separated by chromatography on silica gel.

The first fraction, eluted with benzene–hexane (1:1) and subjected to evaporation and recrystallization from ethanol, gave orange yellow crystals, mp 175—177 °C (8% yield), which were determined to be 1,1'-bis(6-methyl-1-naphthyl)-ferrocene (**9b**). Found: C, 82.55; H, 5.72; M^+, 466. Calcd for $C_{32}H_{26}Fe$: C, 82.41; H, 5.62; M, 466.

The second fraction, eluted with benzene and subjected

to evaporation and recrystallization from ethanol, gave deep reddish crystals, mp 224—226 °C (37.5% yield), which were determined to be *anti*-[0](1,6)naphthaleno[2](2,5)naphthaleno[0](1,1′)ferrocenophan-9-ene (**5b**). Found: C, 83.25; H, 4.93; M+, 462. Calcd for $C_{32}H_{22}Fe$: C, 83.13; H, 4.80; M, 462.

The third fraction, eluted with chloroform and subjected to evaporation and recrystallization from ethanol, gave yellowish crystals (mp 163—164 °C, 26% yield), which were identified with **4b** by comparison of IR, NMR, and mass spectra and a mixed-melting-point value with those of the authentic sample **4b**.

Reaction of 2c with $TiCl_4$–Zn. The reductive coupling of **2c** with $TiCl_4$–Zn was carried out in the same way as has been described for the reductive coupling of **2a** with $TiCl_4$–Zn, and the products were separated by chromatography on silica gel. The first fraction, eluted with hexane and subjected to recrystallization from ethanol, gave orange yellow crystals (mp 60—62 °C, 4.3% yield), which were determined to be 1,1′-bis(7-methyl-1-naphthyl)ferrocene (**9c**). Found: C, 82.28; H, 5.56; M+ 466. Calcd for $C_{32}H_{26}Fe$: C, 82.40; H, 5.61; M, 466.

The second fraction, eluted with hexane–THF (5:1) and subjected to evaporation and recrystallization from ethanol, gave deep reddish crystals (mp 246—247 °C, 20% yield), which were determined to be *anti*-[0](1,7)-naphthaleno[2](2,8)naphthaleno[0](1,1′)ferrocenophan-9-ene (**5c**). Found: C, 83.02; H, 4.67; M+, 462. Calcd for $C_{32}H_{22}Fe$: C, 83.13; H, 4.80; M, 462.

The third fraction, eluted with chloroform and subjected to evaporation and recrystallization from ethanol, gave yellowish crystals (mp 136—137 °C, 14% yield), which were identified with **4c** by comparison of IR, NMR, and mass spectra and a mixed-melting-point value with those of the authentic sample **4c**.

Reaction of 2d with $TiCl_4$–Zn. The reaction of **2d** with $TiCl_4$–Zn was carried out in the same way described for the reductive coupling of **2a** with $TiCl_4$–Zn, and the products were separated by chromatography on silica gel. The first fraction, eluted with hexane and subjected to evaporation and recrystallization from ethanol, gave reddish orange crystals (mp 51—52 °C, 32% yield), which were determined to be 1-(*p*-tolyl)-1′-(4-methyl-1-naphthyl)-ferrocene(**9d**). Found: C, 80.85; H, 5.94; M+, 416. Calcd for $C_{28}H_{24}Fe$: C, 80.78; H, 5.81; M, 416.

Catalytic Hydrogenation of 5a. In a mixture of dioxane (100 cm³) and ethanol (100 cm³), compound **5a** (0.50 g) was hydrogenated with PtO_2 (0.01 g) at room temperature under the ordinary pressure. The reaction mixture was filtered to remove the catalyst and the filtrate was evaporated to dryness *in vacuo*. The residue was chromatographed on silica gel with hexane to give reddish orange crystals (mp 182—184 °C, 82% yield), which were determined to be [0](1,5)naphthaleno[2](1,5)naphthaleno-[0](1,1′)ferrocenophane (**1a**). Found: C, 82.90; H, 5.35; M+, 464. Calcd for $C_{32}H_{24}Fe$: C, 82.77; H, 5.21; M, 464.

Catalytic Hydrogenation of 5b. The catalytic hydrogenation of **5b** was carried out in the same way as described above, and the product was purified by column chromatography on silica gel with benzene to give reddish orange crystals (mp 233—235 °C (dec), 80% yield), which were determined to be [0](1,6)naphthaleno[2](2,5)-naphthaleno[0](1,1′)ferrocenophane(**1b**). Found: C, 82.90; H, 5.35; M+, 464. Calcd for $C_{32}H_{24}Fe$: C, 82.77; H, 5.21; M, 464.

Catalytic Hydrogenation of 5c. The catalytic hydrogenation of **5c** was carried out in the same way as described for the catalytic hydrogenation of **5a**, and the product was purified by column chromatography on silica gel with benzene to give reddish crystals (mp 237—238 °C, 85% yield), which were determined to be [0](1,7)-naphthaleno[2](2,8)naphthaleno[0](1,1′)ferrocenophane(**1c**). Found: C, 82.70; H, 5.08 ; M+ 464. Calcd for $C_{32}H_{24}Fe$: C, 82.76; H, 5.20; M, 464.

Intramolecular Coupling of 8 with Butyllithium. In an atmosphere of nitrogen, a 15% solution of butyllithium in hexane (16 cm³) was added dropwise to a solution of **8** (4.50 g, 7.84 mmol) in dry THF (450 cm³) at −50 °C, and stirred at the same temperature for 2 h and then at 0 °C for 4 h. After a successive addition of water (50 cm³) and 1 M hydrochloric acid (70 cm³) (1 M=1 mol dm^{-3}), the mixture was extracted with chloroform. The chloroform extracts were washed successively with 1 M hydrochloric acid, brine, 5% sodium hydrogencarbonate solution, and brine, and dried over anhyd $MgSO_4$. After removal of the solvents, the residue was chromatographed on silica gel with hexane–diethyl ether (4:1) to give reddish crystals (mp 220 °C (dec), 20.5% yield), which were determined to be [2]paracyclo[0](1,1′)ferroceno[0](1,4)naphthalenophane(**1d**). Found: C, 81.25; H, 5.46; M+, 414. Calcd for $C_{28}H_{22}Fe$: C, 81.17; H, 5.35; M, 414.

(Received December 24, 1984)

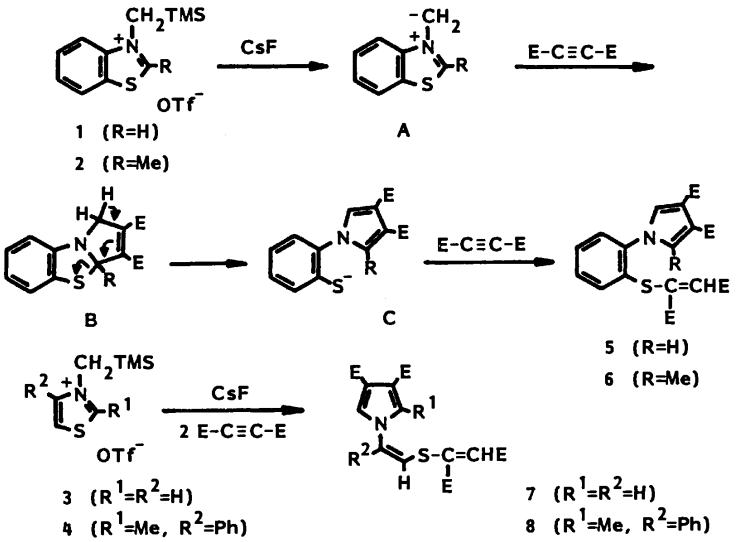
Desilylation of 3-(trimethylsilylmethyl)thiazolium triflates including 2-methyl derivatives with CsF generates the corresponding thiazolium methylides which are trapped with acetylenic and olefinic dipolarophiles. This paper presents the first example for the generation of nonstabilized thiazolium methylides including 2-methyl derivatives.

Thiazolium salts are versatile reagents in the filed of heterocyclic synthesis as their deprotonation leads to two sorts of reactive species. The deprotonation at the α-position of a highly acidic alkyl moiety on the nitrogen generates thiazolium methylides as 1,3-dipoles[1] and at the 2-alkyl substituent 2-methylenethiazolines as nucleophilic ketene acetals.[2] As shown with an example of 2-methyl-3-phenacylbenzothiazolium bromide,[3] however, even in the case of 2-methylthiazolium salts bearing a highly acidic alkyl moiety such as a phenacyl group on the nitrogen, the deprotonation occurs at the 2-methyl group leading to 2-methylenethiazolines. Thus, thiazolium methylides having 2-methyl group have not been reported up to date. In addition, nonstabilized methylides in thiazolium series, which carry no stabilizing substituents on the ylide carbon, have not been investigated, although increasing interest is recently being shown in nonstabilized nitrogen ylides.[4]

We have recently demonstrated that pyridinium triflates having a trimethylsilylmethyl group on the nitrogen generate nonstabilized pyridinium methylides when desilylated with a silylophile.[5] This method will be effectively applied to the generation of nonstabilized thiazolium methylides.

In the present paper we wish to report the generation of nonstabilized thiazolium methylides including 2-methyl derivatives from 3-(trimethylsilylmethyl)-thiazolium triflates.

When 3-(trimethylsilylmethyl)benzothiazolium triflate (**1**) and its 2-methyl derivative **2**, which were easily prepared from the corresponding thiazole and trimethylsilylmethyl triflate, were allowed to react with dimethyl acetylenedicarboxylate (DMAD, 2 equivalents) in the presence of cesium fluoride (1 equivalent) under reflux in 1,2-dimethoxyethane (DME) for 24 h, oily products **5** and **6** were obtained in 69 and 88% yields, respectively. On the basis of spectral data, the products **5** and **6**, in which two molecules of DMAD were incorporated, were assigned as a mixture of *N*-arylpyrrole compounds whose alkenylthio moieties on the phenyl group are in *E* and *Z* configurations. The NMR spectra were helpful for the structural determination since those



Scheme 1.

for the aryl moieties on the nitrogen were readily assigned by comparison with those of a model compound, a mixture of dimethyl phenylthiofumarate and -maleate obtainable from thiophenol and DMAD.[6]

As shown in Scheme 1, the formation of **5** and **6** strongly supports the intervention of a nonstabilized benzothiazolium methylide **A**. The methylide **A** is generated by the desilylation of the triflate **1** or **2**, and then **A** adds to DMAD forming a [3+2] cycloadduct **B**. The proton elimination in **B** opens the thiazoline ring to yield an anionic intermediate **C**, which is trapped with the second molecule of DMAD to give the final product **5** or **6**. The process from **B** to **C** is closely similar to that of rearrangement of intermediary [3+2] cycloadducts formed from stabilized thiazolium[1a,c] and imidazolium methylides[1a] and DMAD.

Even when an equivalent of DMAD was used in the above reaction a 1:1 adduct was not formed but instead **5** and **6** were obtained in low yields.

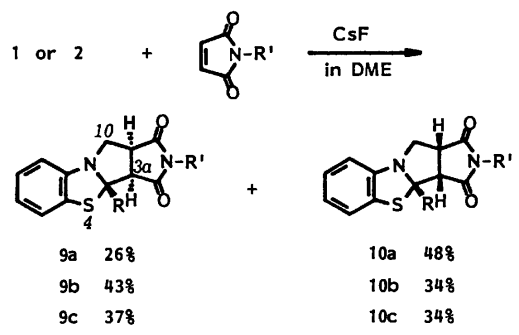
Under the same reaction conditions, the reaction of 3-(trimethylsilylmethyl)thiazolium triflate (**3**) and its 2-methyl-4-phenyl derivative **4** with DMAD in the presence of cesium fluoride proceeded through the same course to give the *N*-alkenylpyrroles **7** and **8** in 33 and 36% yields, respectively. In the compounds **7** and **8** the alkenylthio moieties originated from the second addition of DMAD are in *E* and *Z* forms.

Although stabilized thiazolium methylides reacted with DMAD to give rearranged products,[1a,c] they gave stable [3+2] cycloadducts in the reactions with olefinc dipolarophiles.[1d,f,h] Thus, we investigated the reaction with cyclic olefins, maleimides, in order to obtain the direct evidence for the generation of a nonstabilized thiazolium methylide through isolation of a [3+2] cycloadduct.

In fact, a nonstabilized thiazolium methylide such as **A** in the reaction with a maleimide was trapped as an isolabe [3+2] cycloadduct.

The reaction of the triflate **1** with *N*-(*p*-tolyl)maleimide or *N*-methylmaleimide (1 equivalent) in the presence of cesium fluoride (1 equivalent) in DME at room temperature for 24 h afforded a mixture of the corresponding *exo*-**9a** or **9b** and *endo*-cycloadduct **10a** or **10b**, together with recovery of the maleimide.

Under the same conditions, the triflate **2** reacted with *N*-(*p*-tolyl)maleimide in the presence of cesium fluoride to give a mixture of the *exo*- **9c** and *endo*-cycloadduct **10c** (Scheme 2). Owing to polymerization of the imide, however, [3+2] cycloadducts were not obtained in the reactions of triflates **3** and **4** under the same reaction conditions.



Scheme 2.

Structural elucidation of cycloadducts **9** and **10** was accomplished on the basis of spectral data. In the ^{1}H NMR spectra the 3a-H and 3b-H or 3b-Me in *exo*-cycloadducts **9** appeared downfield of those in *endo*-cycloadducts **10** owing to the anisotropy of 4-sulfur atom and 3-carbonyl group, respectively.

It should be emphasized that these cycloadducts are stable enough to be isolated,[7] and that these nonstereoselective cycloadditions are in contrast with the highly *endo*-selective cycloadditions of stabilized thiazolium methylides.[1d,f-h]

The present results provide the first example for the generation of nonstabilized thiazolium methylides as well as 2-methylthiazolium methylides.[8]

Experimental

General. IR spectra were obtained on a JASCO A-702 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-40 or a JEOL FX-100 instrument, and ^{13}C NMR spectra were measured on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane. Mass spectra were taken with a JEOL JMS-01SG-2 spectrometer at 75 eV ionization energy. Elemental analyses were performed on a Hitachi O26 CHN micro analyzer. All reactions were carried out under dry nitrogen.

Materials. Trimethylsilylmethyl triflate was prepared according to the reported method.[9] The following reagents were commercially available: benzothiazole, 2-methylbenzothiazole, thiazole, 2-methyl-4-phenylthiazole, dimethyl acetylenedicarboxylate and *N*-(*p*-tolyl)maleimide, and *N*-methylmaleimide.

General Procedure for the Preparation of Thiazolium Triflate. A solution of a thiazole (12.7 mmol) in dry CH_2Cl_2 (20 mL) was added dropwise to a solution of trimethylsilylmethyl triflate (3.0 g, 12.7 mmol) in dry CH_2Cl_2 (20 mL) at 0 °C. The reaction mixture was then allowed to warm to room temperature with stirring. After the mixture was stirred at room temperature for 1 h, the solvent was removed in vacuo to leave pure thiazolium triflate in good yield.

3-(Trimethylsilylmethyl)benzothiazolium Triflate (1): yield 100%; mp 110—111 °C; colorless needles; IR (KBr) 1250, 1150, 1030, 850 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=0.07 (s, 9H, $(CH_3)_3Si$), 4.64 (s, 2H, CH_2), 7.75—7.98 (m, 2H, 5- and 6-**H**), 8.34—8.54 (m, 2H, 4- and 7-**H**), 10.33 (s, 1H, 2-**H**); MS *m/z* 222 (M^+), 135 (M^+-CH_2TMS, base peak). Found:

C, 38.66; H, 4.48; N, 4.06%. Calcd for $C_{12}H_{16}NO_3S_2SiF_3$: C, 38.80; H, 4.34; N, 3.77%.

2-Methyl-3-(trimethylsilylmethyl)benzothiazolium Triflate (2): yield 100%; mp 119—120 °C; colorless prisms; IR (KBr) 1250, 1150, 1025, 850 cm^{-1}; ^1H NMR (DMSO-d_6) δ=0.13 (s, 9H, $(CH_3)_3Si$), 3.31 (s, 3H, 2-CH_3), 4.53 (s, 2H, CH_2), 7.68—7.95 (m, 2H, 5- and 6-**H**), 8.24—8.45 (m, 2H, 4- and 7-**H**); MS *m/z* 236 (M^+, base peak). Found: C, 40.29; H, 4.68; N, 3.84%. Calcd for $C_{13}H_{18}NO_3S_2SiF_3$: C, 40.50; H, 4.71; N, 3.63%.

3-(Trimethylsilylmethyl)thiazolium Triflate (3): yield 94%; mp 119—120 °C; colorless prisms; IR (KBr) 1250, 1140; 1020, 845 cm^{-1}; ^1H NMR (DMSO-d_6) δ=0.08 (s, 9H, $(CH_3)_3Si$), 4.19 (s, 2H, CH_2), 8.34 (t, 2H, *J*=1.0 Hz, 4- and 5-**H**), 9.92 (t, 1H, *J*=1.0 Hz, 2-**H**); MS *m/z* 172 (M^+, base peak). Found: C, 29.94; H, 4.35; N, 4.63%. Calcd for $C_8H_{14}NO_3S_2SiF_3$: C, 29.90; H, 4.39; N, 4.36%.

2-Methyl-4-phenyl-3-(trimethylsilylmethyl)thiazolium Triflate (4): Yield 83%; mp 130—132 °C; pale yellow prisms; IR (KBr) 1250, 1145, 1025, 850 cm^{-1}; ^1H NMR (DMSO-d_6) δ=−0.14 (s, 9H, $(CH_3)_3Si$), 2.95 (s, 3H, 2-CH_3), 4.23 (s, 2H, CH_2), 7.69 (s. 5H, Ar**H**), 8.18 (s, 1H, 5-**H**); MS *m/z* 262 (M^+), 135 (base peak). Found: C, 43.51; H, 4.70; N, 3.65%. Calcd for $C_{15}H_{20}NO_3S_2SiF_3$: C, 43.78; H, 4.90; N, 3.40%.

Reaction of Triflate 1 with DMAD in the Presence of Cesium Fluoride. A mixture of **1** (371 mg, 1 mmol), DMAD (284 mg, 2 mmol) and CsF (152 mg, 1 mmol) in dry DME (3 mL) was refluxed for 24 h. To the reaction mixture was added water (30 mL), and the resultant mixture was extracted with $CHCl_3$ (50 mL×2). The $CHCl_3$ extract was dried over $MgSO_4$, and concentrated *in vacuo*. The residue was chromatographed on silica gel using $CHCl_3$–Et_2O (9/1) as an eluent to give 300 mg (69%) of a mixture of *E* and *Z* forms of *N*-arylpyrrole **5** as brownish yellow viscous oil, which was thermally unstable: IR (neat) 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.48, 3.75 (each s, 3H×5/6, OCH_3 in *Z* form), 3.58, 3.68 (each s, 3H×1/6, OCH_3 in *E* form), 3.83 (s, 6H×5/6, OCH_3 in *Z* form), 3.85 (s, 6H×1/6, OCH_3 in *E* form), 5.75 (s, 1H×1/6, =C**H** in *E* form), 6.55 (s, 1H×5/6, =C**H** in *Z* form), 7.34—7.50 (m, 6H, Ar**H** and α-**H** of pyrrole ring); ^{13}C NMR ($CDCl_3$) of *Z* form δ=51.49, 52.02, 52.96 (each q), 116.48 (s, β-**C** of pyrrole ring), 123.17 (d, =**C**H), 127.28 (s), 129.40 (d, α-**C** of pyrrole ring), 129.75, 130.22, 134.68 (each d), 140.37 (s), 145.72 (s, =**C**^{S–}), 163.56, 163.85, 164.86 (each s, **C**=O); HRMS *m/z* 433.0841 ($C_{20}H_{19}NO_8S$ requires 433.0830).

Similarly, triflates **2**—**4** reacted with DMAD (2 equivalents) under the influence of CsF (1 equivalent) in dry DME under reflux for 24 h to give a mixture of *E* and *Z* forms of the corresponding pyrrole compounds **6**—**8**, respectively.

6: Yield 88%; red-colored viscous oil; IR (neat) 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.15 (s, 3H×1/11, C-CH_3 in *E* form), 2.20 (s, 3H×10/11, C-CH_3 in *Z* form), 3.48, 3.61, 3.68, 3.72 (each s, 3H×1/11, OCH_3 in *E* form), 3.52, 3.76, 3.80, 3.85 (each s, 3H×10/11, OCH_3 in *Z* form), 5.79 (s, 1H×1/11, =C**H** in *E* form), 6.65 (s, 1H×10/11, =C**H** in *Z* form), 7.17—7.50 (m, 5H, Ar**H**); MS *m/z* 447 (M^+), 356 (base peak). Found: C, 56.48; H, 4.85; N, 2.91%. Calcd for $C_{21}H_{21}NO_8S$: C, 56.37; H, 4.73; N, 3.13%.

7: Yield 33%; brownish yellow viscous oil; IR (neat) 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.75 (s, 3H×2/5, OCH_3 in *Z* form), 3.79 (s, 3H×3/5, OCH_3 in *E* form), 3.83 (s, 6H, OCH_3 in *E* and *Z* forms), 3.85 (s, 3H×3/5, OCH_3 in *E* form), 3.89 (s, 3H×2/5, OCH_3 in *Z* form), 5.95 (d, 1H×3/5, *J*=3.8 Hz, =C^{S–}**H** in *E* form), 6.04 (s, 1H×3/5, =C**H**E in *E* form), 6.05 (d, 1H×3/5, *J*=3.8 Hz, =C^{N<}**H** in *E* form), 6.69 (s, 1H×2/5, =C**H**E in *Z* form), 6.79 (d, 1H×2/5, *J*=8.6 Hz, =C^{S–}**H** in *Z* form) 6.95 (d, 1H×2/5, *J*=8.6 Hz, =C^{N<}**H** in *Z* form), 7.55 (s, 2H×2/5, α-**H** of pyrrole ring in *Z* form), 7.59 (s, 2H×3/5, α-H of pyrrole ring in *E* form); ^{13}C NMR ($CDCl_3$) of a mixture of *E* and *Z* forms δ=51.65, 52.19, 53.36, 53.51 (each q), 106.72, 111.54 (each d, =C**H**E), 116.81, 117.20 (each s, β-**C** of pyrrole ring), 117.23, 123.72 (each d, =**C**^{N<}**H**), 126.80, 129.52 (each d, =**C**^{S–}**H**), 127.87, 128.01 (each d, α-**C** of pyrrole ring), 143.31, 144.68 (each s, =**C**^{S–}**H**), 163.15, 163.29, 163.63, 163.83, 164.76 (each s, **C**=O); MS *m/z* 383 (M^+), 292 (base peak). Found: C, 49.88; H, 4.48; N, 3.79%. Calcd for $C_{16}H_{17}NO_8S$: C, 50.12; H, 4.47; N, 3.65%.

8: Yield 36%; brownish yellow viscous oil; IR (neat) 1715 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.16 (s, 3H×8/9, C-CH_3 in *E* form), 2.21 (s, 3H×1/9, C-CH_3 in *Z* form), 3.74 (s, 3H×8/9, OCH_3 in *E* form), 3.76 (s, 3H×1/9, OCH_3 in *Z* form), 3.81 (s, 3H, OCH_3 in *E* and *Z* forms), 3.86 (s, 3H×8/9, OCH_3 in *E* form), 3.89 (s, 3H×1/9, OCH_3 in *Z* form), 3.91 (s, 3H, OCH_3 in *E* and *Z* forms), 6.05 (s, 1H×8/9, =C**H**E in *E* form), 6.74 (s, 1H×1/9, =C**H**E in *Z* form), 7.00—7.37 (m, 7H, Ar**H** and α-**H** of pyrrole ring); MS *m/z* 473 (M^+), 382 (base peak). Found: C, 58.34; H, 4.99; N, 3.08%. Calcd for $C_{23}H_{23}NO_8S$: C, 58.34; H, 4.86; N, 2.96%.

Reaction of Triflate 1 with Maleimide in the Presence of Cesium Fluoride. A mixture of **1** (742 mg, 2 mmol), *N*-(*p*-tolyl)maleimide (374 mg, 2 mmol) and CsF (304 mg, 2 mmol) in dry DME (6 mL) was stirred at room temperature for 24 h. To the reaction mixture was added water (30 mL), and the resultant mixture was extracted with $CHCl_3$ (50 mL×2). The extract was dried over $MgSO_4$ and concentrated *in vacuo* to leave a residue. The residue was chromatographed on silica gel to give 177 mg (26%) of the *exo*-cycloadduct **9a** (from $CHCl_3$ elution) and 323 mg (48%) of the *endo*-cycloadduct **10a** (from $CHCl_3$–Et_2O (9/1) elution), together with recovery of 90 mg (24%) of the maleimide (from $CHCl_3$ elution).

9a: Pale yellow prisms; mp 153—154 °C; IR (KBr) 1765, 1695 cm^{-1}; ^1H NMR (benzene-d_6) δ=1.99 (s, 3H, CH_3), 2.66 (ddd, 1H, *J*=8.7, 8.0, 3.9 Hz, 10a-**H**), 3.03 (dd, 1H, *J*=8.7, 2.7 Hz, 3a-**H**), 3.13 (dd, 1H, *J*=10.1, 8.0 Hz, 10-**H**), 3.38 (dd, 1H, *J*=10.1, 3.9 Hz, 10-**H**), 5.52 (d, 1H, *J*=2.7 Hz, 3b-**H**), 6.44—7.23 (m, 8H, Ar**H**); MS *m/z* 336 (M^+), 150 (base peak). Found: C, 68.12; H, 4.75; N, 8.17%. Calcd for $C_{19}H_{16}N_2O_2S$: C, 67.84; H, 4.79; N, 8.33%.

10a: Colorless solid; mp 69—71 °C;[10] IR (KBr) 1770, 1690 cm^{-1}; ^1H NMR (benzene-d_6) δ=1.94 (s, 3H, CH_3), 2.44 (t, 1H, *J*=7.8 Hz, 10a-**H**), 2.61 (t, 1H, *J*=7.8 Hz, 3a-**H**), 2.67 (dd, 1H, *J*=12.0, 7.8 Hz, 3b-**H**), 6.38—7.50 (m, 8H, Ar**H**); MS *m/z* 336 (M^+), 107 (base peak).

Similarly, **1** reacted with *N*-methylmaleimide (1 equivalent) in the presence of CsF (1 equivalent) in dry DME at

room temperature for 24 h to give the *exo*-cycloadduct **9b** and *endo*-cycloadduct **10b** in 43 and 34% yields respectively, besides recovery of the maleimide (20%).

9b: Colorless needles; mp 134—135 °C; IR (KBr) 1775, 1700 cm^{-1}; ^1H NMR (benzene-d_6) δ=2.47 (s, 3H, NCH_3), 2.52 (dt, 1H, J=3.9, 7.8 Hz, 10a-**H**), 2.92 (dd, 1H, J=7.8, 2.6 Hz, 3a-**H**), 3.08 (dd, 1H, J=10.5, 7.8 Hz, 10-**H**), 3.28 (dd, 1H, J=10.5, 5.3 Hz, 10-**H**), 5.43 (d, 1H, J=2.6 Hz, 3b-**H**) 6.45—6.94 (m, 4H, Ar**H**); MS m/z 260 (M^+), 150 (base peak). Found: C, 59.80; H, 4.61; N, 10.63%. Calcd for $C_{13}H_{12}N_2O_2S$: C, 59.98; H, 4.65; N, 10.76%.

10b: Colorless solid; mp 116—120 °C;[10] IR (KBr) 1775, 1700 cm^{-1}; ^1H NMR (benzene-d_6) δ=2.25 (s, 3H, NCH_3), 2.32—2.62 (m, 3H, 3a-**H**, 10-**H**, and 10a-**H**), 3.87 (dd, 1H, J=12.7, 1.2 Hz, 10-**H**), 4.70 (d, 1H, J=7.7 Hz, 3b-**H**), 6.32—6.95 (m, 4H, Ar**H**); MS m/z 260 (M^+), 150 (base peak).

Reaction of Triflate **2** *with* N-(p-*Tolyl*)*maleimide in the Presence of Cesium Fluoride.* After the reaction of **2** (1.155 g, 3 mmol) with the maleimide (561 mg, 3 mmol) in the presence of CsF (456 mg, 3 mmol) in dry DME (9 mL) was performed at room temperature for 24 h, purification of the reaction mixture by chromatography (SiO_2) afforded the *exo*-cycloadduct **9c** (385 mg, 37%) and *endo*-cycloadduct **10c** (361 mg, 34%), together with recovery of the maleimide (60 mg, 11%).

9c: Colorless prisms; mp 140—141 °C; IR (KBr) 1770, 1695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.76 (s, 3H, 3b-CH_3), 2.39 (s, 3H, CH_3), 3.41 (dd, 1H, J=9.4, 7.9 Hz, 10-**H**), 3.64 (ddd, 1H, J=8.7, 7.9, 1.9 Hz, 10a-**H**), 3.87 (dd, 1H, J=7.9, 1.9 Hz, 10-**H**), 3.89 (d, 1H, J=8.7 Hz, 3a-**H**), 8.00—8.33 (m, 8H, Ar**H**); MS m/z 350 (M^+), 163 (base peak). Found: C, 68.30; H, 5.21; N, 7.81%. Calcd for $C_{20}H_{18}N_2O_2S$: C, 68.53; H, 5.18; N, 8.00%.

10c: Colorless solid; mp 67—70 °C;[10] IR (KBr) 1770, 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.88 (s, 3H, 3b-CH_3), 2.29 (s, 3H, CH_3), 3.31—3.76 (m, 3H, 3a-**H**, 10-**H**, and 10a-**H**), 4.25 (d, 1H, J=10.7 Hz, 10-**H**), 6.49—7.17 (m, 8H, Ar**H**); MS m/z 350 (M^+), 163 (base peak).

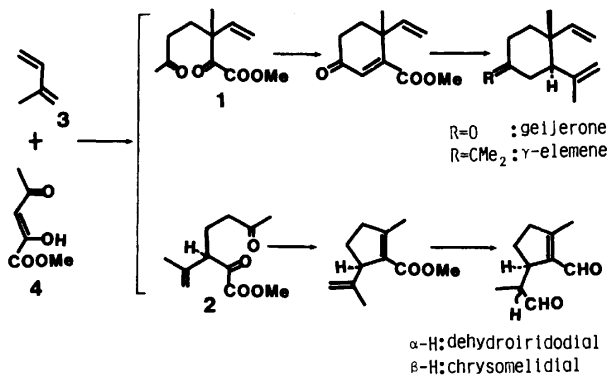
Synthetic Photochemistry. XXIX.[1] A Convenient Preparation of 1,2,3-Substituted Cyclopentenes from the Photoadducts of Methyl 2,4-Dioxopentanoate-Isoprene

Nobuo KATO and Hitoshi TAKESHITA*
Research Institute of Industrial Science, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816
(Received November 30, 1984)

Photoadducts obtained by cycloaddition of isoprene with methyl 2,4-dioxopentanoate were converted to cyclopentene derivatives. The stereochemistry of the intermediate glycols was estabilished by chemical correlations to each other; only the *cis*-glycols were convertible to the cyclopentenes under the conditions employed, suggesting a fore-going acetylation of the hindered glycol functions.

Previously, we have obtained two photocycloadducts (**1** and **2**) from isoprene (**3**) and methyl 2,4-dioxopentanoate (**4**),[2] and have utilized them for mono- and sesquiterpenoid syntheses; *i.e.*, **1** to geijerone and γ-elemene,[2] and **2** to dehydroiridodial and chrysomelidial.[3] It is noteworthy that the easy access of cyclopentane derivatives from **2** in the latter case provided a new method of C_5-homologation leading to the higher terpenic cyclopentanes having correct head-to-tail arrangement.[4] Since the photochemical addition proceeds in a highly regioselective manner,[5] and is effective even with the conjugated olefins,[1,6] fundamental understanding of this cyclopentane formation is important. We wish herein to present experimental details of the formation of 1,2,3-substituted cyclopentane derivatives from the photoadducts, **1** and **2**, by the Mukaiyama-McMurry reaction.[7]



Scheme 1.

The Reductive Cyclization of Methyl 3-Methyl-3-vinyl-2,6-dioxoheptanoate (1). When methyl 3-methyl-3-vinyl-2,6-dioxoheptanoate (**1**) was treated with titanium(II) chloride in tetrahydrofuran (THF), prepared *in situ* from titanium(IV) chloride and zinc, four isomeric reductive cyclisates, 1,2-dihydroxy-2-methoxycarbonyl-1,3-dimethyl-3-vinylcyclopentanes, **5** (45%), **6** (1%), **7** (2%), and **8** (37%), were obtained. Two major products (**5** and **8**) afforded 2,2-dimethyl-1,3-dioxolane derivatives (**9** and **10**) by treatment with 2,2-dimethoxypropane (DMP) and pyridinium *p*-toluenesulfonate (PPTS) in benzene, while the other two (**6** and **7**) were recovered unchanged. Based on these facts, **5** and **8** are deduced to be *cis*-glycol derivatives, and **6** and **7** are thus *trans*-glycols.

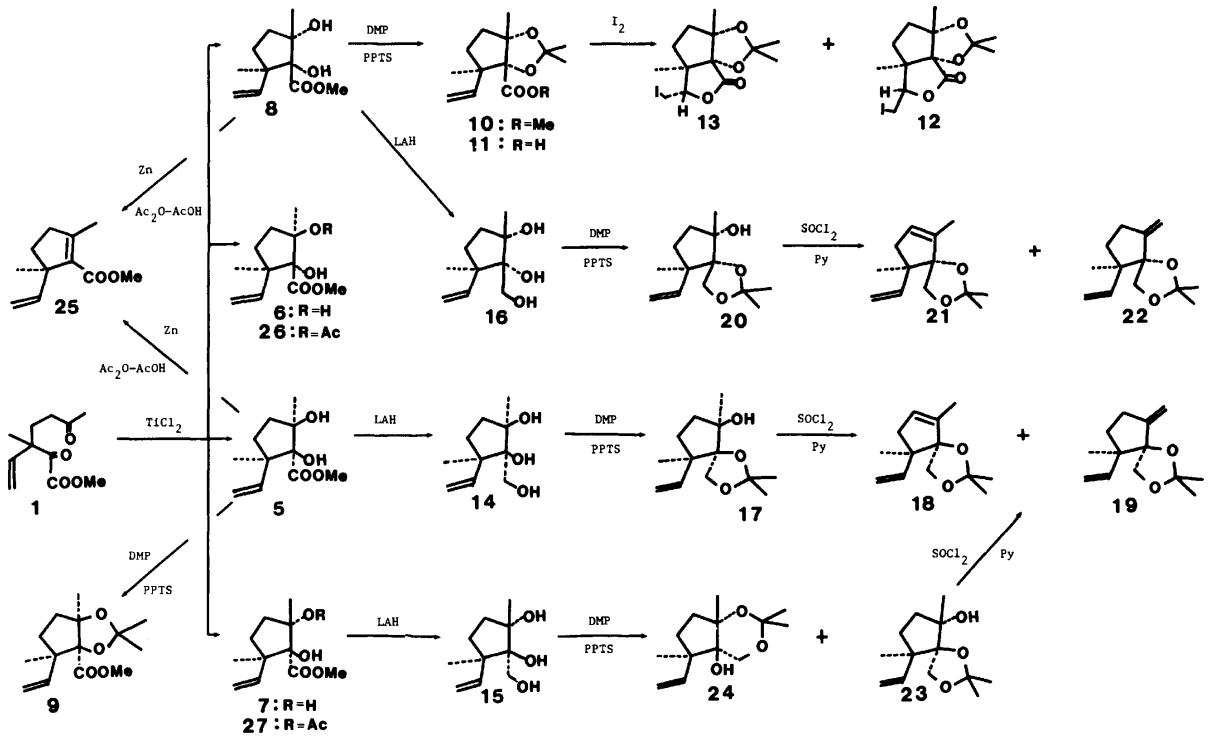
Consecutive treatments of **10** with sodium hydroxide in dimethyl sulfoxide (DMSO), and with iodine and sodium hydrogencarbonate in acetonitrile afforded, *via* the carboxylic acid (**11**), iodo γ-lactone derivatives (**12** and **13**), in 92 and 6% yields. Therefore, the ester and vinyl groups of **8** and **10** are in a *cis* relationship, and the full stereochemistry of **5** and **8** must be depicted as shown.

Moreover, the lithium aluminum hydride (LAH)-reduction of **5**, **7**, and **8** yielded the triol derivatives (**14**, **15**, and **16**) in good yields. Upon treatment of **14** with PPTS and DMP, the single dioxolane derivative (**17**) was obtained in 94% yield. Treatment of **17** with thionyl chloride in pyridine gave a 5:2-mixture of the unsaturated, anhydro 1,3-dioxolane derivatives (**18** and **19**), in 81% yield. On the other hand, the same treatment of **16** gave, *via* the 1,3-dioxolane (**20**), a 2:1-mixture of the unsaturated 1,3-dioxolane derivatives (**21** and **22**).

In the case of **15** (the triol derived from **7**), one of the *trans*-glycols, the DMP treatment afforded two acetals; one was the 1,3-dioxolane (**23**), and the other, a 1,3-dioxane (**24**). Treatment of **23** with thionyl chloride caused a facile dehydration to a mixture of unsaturated 1,3-dioxolanes, which consisted of **18** and **19** on the basis of NMR and gas-liquid chromatographic analyses. Therefore, the remaining products, **6** and **7**, must also have the configurations indicated.

Interestingly, the glycols, **5** and **8**, were reduced to the same cyclopentene derivative (**25**) by zinc in acetic acid and acetic anhydride, while the trans-isomers, **6** and **7**, merely formed monoacetates (**26** and **27**) under comparative conditions.

The Reductive Cyclization of Methyl 3-Isopropenyl-2,6-dioxoheptanoate (2). Methyl 3-isopropenyl-2,6-dioxoheptanoate (**2**) was treated with titanium(II) chloride to obtain three cyclopentanediols (**28**, **29**, and **30**) in a ratio of 1:1.5:9. By further reduction



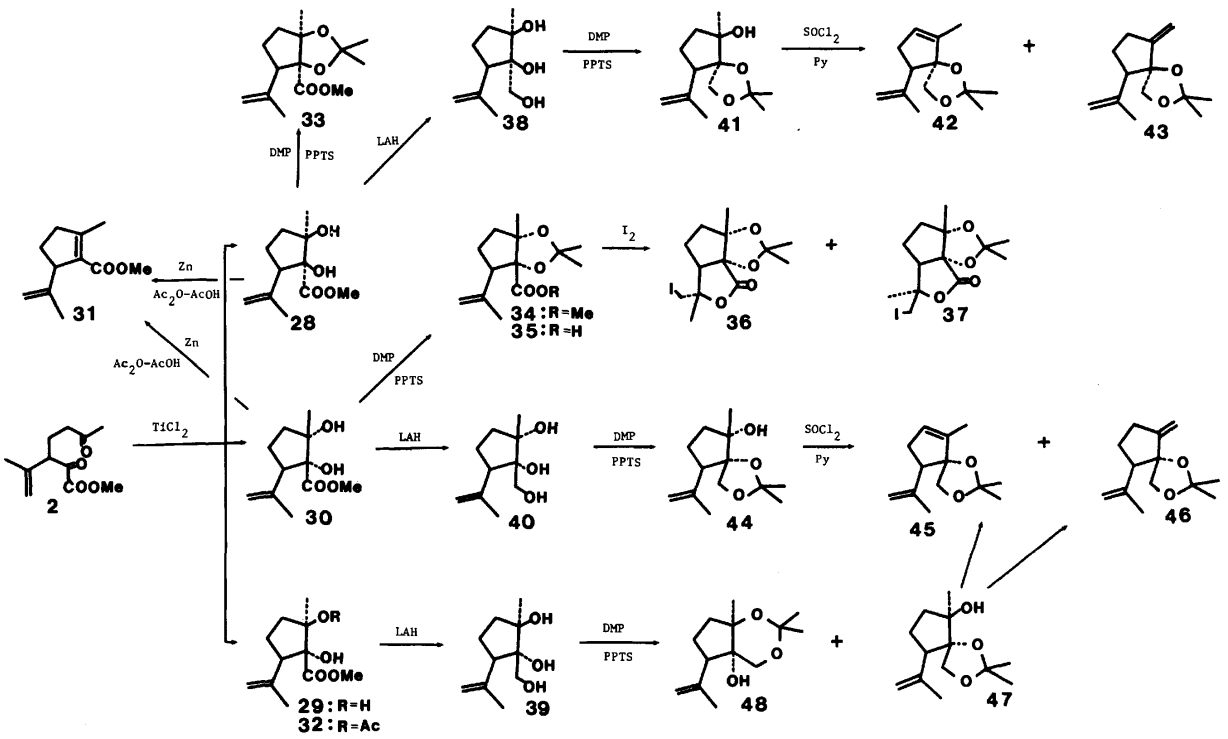
Scheme 2.

with zinc in acetic acid and acetic anhydride,[3] **28** and **30** yielded the same cyclopentene (**31**),[8] while the remaining **29** resulted in a monoacetylation to **32**, but not to **31**. By analogy with **6** and **7**, this might indicate the *trans* relationship for the glycol function of **29**. Indeed, **28** and **30** afforded the 2,2-dimethyl-1,3-dioxolane derivatives (**33** and **34**). The iodolactonization reaction of the acid (**35**) derived from **34** produced two iodo γ-lactones (**36** and **37**); the major product, **36**, colorless needles, showed an IR absorption due to $\nu_{C=O}$ at 1780 cm^{-1}. These two observations clarified the stereochemistry of **28** and **30** as depicted.

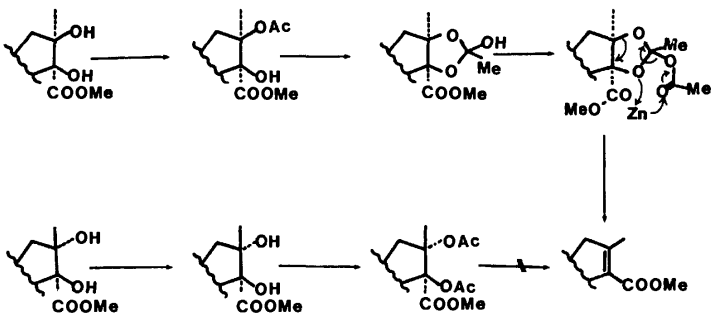
The stereochemistry of the minor product, **29**, was unambiguously elucidated by the following chemical correlations; the LAH-reduction of **28**, **29**, and **30** respectively afforded the triol derivatives (**38**, **39**, and **40**) in good yields. Treatment of **38** with DMP and PPTS in THF gave the 1,3-dioxolane (**41**), which upon treatment with thionyl chloride in pyridine afforded an isomeric pair of unsaturated 1,3-dioxolanes (**42** and **43**). Similarly, the DMP-treatment of **40** with PPTS afforded another 1,3-dioxolane (**44**), which was converted to a mixture of unsaturated 1,3-dioxolanes (**45** and **46**).

Subsequently, the DMP-treatment of the remaining triol (**39**) with PPTS was carried out to obtain two products, **47**, 40%, and **48**, 49%; the NMR analysis indicated that **47** was the expected 1,3-dioxolane, while **48** was the 1,3-dioxane. The similar dehydration of **47** as in the cases of **41** and **44**, afforded a mixture of the unsaturated 1,3-dioxolanes. This mixture was indeed identical with **45** and **46** in respect of NMR spectral and gas-liquid chromatographic analyses. Therefore, **39** and **40** mutually differ in the stereochemistry of the methyl and hydroxyl groups at C-1; the structure of **29** should be as shown.

In conclusion, it is particularly noteworthy that, for both series, the major cyclopentanediols were *cis*-derivatives. And the highly specific conversion to cyclopentene derivatives from only *cis*-glycols has supported the correctness of the orthoacetate mechanism already proposed.[9] Namely, the difference between the *cis*- and *trans*-glycols can be explained in of the structural difference of "diacetates"; it is well known that even hindered *cis*-glycols form diacetates by acetyl migration *via* bridged intermediates, while the *trans*-glycols can not make such an intermediate. It is true that in this case no *cis*-diacetate could be detected, and probably, they should have been rapidly reduced to olefins under the reaction conditions. On the other hand, the *trans*-diacetate, whose formation was in fact identified,[10] must suffer a severe steric hindrance. Should the reduction proceed *via* the *trans* elimination like ordinary debromination, the *trans*-isomers must be more favorable than the *cis*-isomers. But, this was not the case. Therefore, the reduction should occur from the orthoester acetates, 2-acetoxy-2-methyl-1,3-dioxolanes, which should be formed from the immediate precursors by the acid-catalyzed solvolysis.[11] Furthermore, this cyclopentene formation is to be expectable only with the photoadducts of **4** but not with those of acetylacetone, due to their readiness to give the cyclohexenones.[12] The relative unreactivity of the pho-



Scheme 3.



Scheme 4.

toadducts of **4** towards acid and base should have become favorable for this reductive cyclization.

Experimental

The mps were measured with Yanagimoto Micro-mp apparatus, and not corrected. The elemental analyses were performed by Miss S. Hirashima of this Institute. All the NMR spectra were taken on a JEOL FX 100 Model spectrometer in $CDCl_3$ solutions, and the chemical shifts expressed in δ unit were from the internal Me_4Si. Mass spectra were measured on a JEOL 01SG-2 Model apparatus. The IR spectra were measured on a Jasco IRA 102 Model spectrophotometer. The gas-liquid chromatographic analyses were performed on a JEOL JGC 20 K Model apparatus with a 200 cm column of 20% DOP on Uniport B (temperatures of column and injection chamber were 140 °C and 160 °C, and carrier gas (N_2) flow was 32 cm³/min), and the retention times measured under those conditions were designated by the term, *RT*.

$TiCl_2$-reduction of 1. To a THF-complex of $TiCl_4$ (prepared from 1.65 cm³) in anhydrous THF (200 cm³), Zn (2.0 g) was added at 0 °C under stirring. After a yellow coloration of the complex faded out completely, pyridine (1.2 cm³) was added. Then, into the resultant suspension, **1** (2.12 g) was added dropwise over a period of 30 min. After additional stirring for 1 h at 15—25 °C, the mixture was quenched with aqueous 30%-K_2CO_3, and fractionated with ether. After removing the precipitates through a short Celite column, the filtrate was evaporated, and chromatographed on a silica-gel (Wakogel C 300) column. From the least polar fractions from hexane–EtOAc (6:1), colorless granules, mp 59.5—60.5 °C, 960 mg (45%), **5** [Found: C, 61.47; H, 8.51%. Calcd for $C_{11}H_{18}O_4$: C, 61.66; H, 8.47%. ^{1}H-NMR δ=1.10 (3H, s), 1.28 (3H, s), 1.6—2.3 (4H, m), 2.90 (1H, br. s, OH), 3.71 (3H, s), 3.84 (1H, s, OH), 4.92 (1H, dd, J=10.3, 1.6 Hz), 4.98 (1H, dd, J=17.8, 1.6 Hz), and 5.78 (1H, dd, J=17.8, 10.3 Hz). ^{13}C-NMR δ=24.2, 24.9, 33.3, 35.7, 50.5, 52.4, 80.6, 88.8, 112.6, 144.0, and 175.3. ν: 3475, 3400, 2955, 1730, 1637, 1438, 1248, 1154, 1132, 1006, and 901 cm^{-1}. *m/z*: 214 (M^+)], was obtained. Subsequently, colorless

prisms, mp 66—66.5 °C, **6** [Found: C, 61.93; H, 8.50%. ^{1}H-NMR δ=1.26 (3H, s), 1.33 (3H, s), 1.7—2.1 (4H, m), 2.70 (1H, s, OH), 3.78 (3H, s), 3.94 (1H, br. s, OH), 5.17 (1H, dd, J=17.3, 1.6 Hz), 5.25 (1H, dd, J=10.9, 1.6 Hz), and 5.94 (1H, dd, J=17.3, 10.9 Hz). ^{13}C-NMR δ=23.5, 26.0, 34.2, 37.2, 51.7, 52.1, 84.0, 86.0, 115.8, 142.3, and 174.3. ν: 3500, 3400, 2965, 1706, 1640, 1451, 1383, 1252, 1198, 1042, 1029, and 906 cm^{-1}. m/z: 214 (M^+)], 19 mg (1%), and colorless needles, mp 105.5—106 °C, **7** [Found: C, 61.65; H, 8.52%. ^{1}H-NMR δ=1.20 (3H, s), 1.34 (3H, s), 1.4—2.3 (4H, m), 2.98 (1H, s, OH), 3.58 (1H, br. s, OH), 3.71 (3H, s), 4.87 (1H, dd, J=11, 1.4 Hz), 4.91 (1H, dd, J=17.4, 1.4 Hz), and 6.17 (1H, dd, J=17.4, 11 Hz). ^{13}C-NMR δ=20.5, 23.5, 36.8, 37.3, 51.2, 52.2, 83.9, 88.5, 111.3, 145.9, and 174.0. ν: 3470, 3340, 2975, 1712, 1634, 1390, 1251, 1068, 1036, 907, and 865 cm^{-1}. m/z: 214 (M^+)], 45 mg (2%), were obtained. The most polar fractions eluted with hexane-EtOAc (4:1) were colorless plates, mp 25 °C, **8** [Found: M^+, 214.1196. Calcd for $C_{11}H_{18}O_4$: 214.1204. ^{1}H-NMR δ=1.03 (3H, s), 1.13 (3H, s), 1.7—2.2 (4H, m), 2.64 (1H, br. s, OH), 3.64 (1H, s, OH), 3.80 (3H, s), 5.02 (1H, dd, J=11.1, 1.4 Hz), 5.04 (1H, dd, J=17.4, 1.4 Hz), and 6.33 (1H, dd, J=17.4, 11.1 Hz). ^{13}C-NMR δ=21.9, 24.2, 33.4, 36.2, 50.2, 52.4, 81.0, 89.2, 111.5, 144.3, and 174.5. ν: 3470, 3410, 2950, 1724, 1633, 1244, and 1138 cm^{-1}], 790 mg (37%).

DMP-acetalization of 5 to 9. A mixture of **5** (86 mg), DMP (1 cm^3), and PPTS (15 mg) in benzene (2 cm^3) was refluxed on an oil bath for 15 h. The mixture was then poured into $NaHCO_3$ solution, extracted with ether, and chromatographed on a silica-gel column with hexane-EtOAc (15:1) to give a colorless oil, 92 mg (90%), **9** [Found: M^+, 254.1512. Calcd for $C_{14}H_{22}O_4$: 254.1517. ^{1}H-NMR δ=1.21 (3H, s), 1.32 (3H, br. s), 1.50 (3H, br. s), 1.58 (3H, s), 1.6—2.0 (4H, m), 3.70 (3H, s), 5.00 (1H, dd, J=10.1, 1.3 Hz), 5.02 (1H, dd, J=18.0, 1.3 Hz), and 5.91 (1H, dd, J=18.0, 10.1 Hz). ν: 2990, 1738, 1637, 1460, 1380, 1267, 1086, 1058, 1043, 998, and 914 cm^{-1}].

DMP-acetalization of 8 to 10. Similarly, a benzene solution of **8** (67 mg) was refluxed for 15 h with DMP (1 cm^3) and PPTS (15 mg). Chromatographic purification of the product afforded a colorless oil, 77 mg (98%), **10** [Found: M^+, 254.1506. ^{1}H-NMR δ=1.01 (3H, br. s), 1.28 (3H, br. s), 1.47 (3H, br. s), 1.61 (3H, s), 1.7—2.4 (4H, m), 3.73 (3H, s), 4.99 (1H, dd, J=17.4, 1.4 Hz), 5.07 (1H, dd, J=10.9, 1.4 Hz), and 6.08 (1H, dd, J=17.4, 10.9 Hz). ν: 2990, 1738, 1637, 1454, 1380, 1265, 1088, 1046, 913, and 848 cm^{-1}].

Saponification and Iodolactonization of 10 to 12 and 13 via 11. To a DMSO solution (1 cm^3) of **10** (47 mg), an aqueous 20%-NaOH (0.6 cm^3) was added and refluxed for 2 h. The mixture was acidified with dil HCl, and extracted with ether to give colorless needles, mp 60.5—61.5 °C, **11**, 44 mg (100%) [Found: C, 64.78; H, 8.40%. Calcd for $C_{13}H_{20}O_4$: C, 64.98; H, 8.39%. ^{1}H-NMR δ=1.09 (3H, br. s), 1.37 (3H, br. s), 1.49 (3H, br. s), 1.60 (3H, s), 1.7—2.4 (4H, m), 5.06 (1H, dd, J=17.3, 1.3 Hz), 5.11 (1H, dd, J=11.0, 1.3 Hz), and 5.98 (1H, dd, J=17.3, 11.0 Hz). ν: 3500—2500, 2990, 1705, 1638, 1450, 1378, 1272, 1090, 1073, 1030, and 910 cm^{-1}. m/z: 240 (M^+)].

This acid, **11**, was then treated with I_2 (100 mg) in MeCN (2 cm^3) in the presence of $NaHCO_3$ (100 mg). After being stirred at 15—25 °C for 15 h, excess I_2 was decomposed with aqueous $NaHSO_3$, and extracted with ether. Silica-gel column chromatography (hexane-EtOAc=6:1) gave two epimeric iodo lactones, the major isomer, 62 mg (92%), colorless prisms, mp 84.5—85 °C, **12** [Found: C, 42.85; H, 5.34%. Calcd for $C_{13}H_{19}O_4I$: C, 42.64; H, 5.23%. ^{1}H-NMR δ=1.11 (3H, br. s), 1.41 (3H, br. s), 1.45 (3H, br. s), 1.62 (1H, m), 1.63 (3H, s), 2.1—2.3 (3H, m), 3.06 (1H, dd, J=11, 10 Hz), 3.38 (1H, dd, J=10, 5.5 Hz), and 5.01 (1H, dd, J=11, 5.5 Hz). ν: 2975, 1790, 1380, 1332, 1164, 1045, 1026, 915, 875, and 846 cm^{-1}. m/z: 366 (M^+)], and the minor, 4 mg (6%), a colorless oil, **13** [^{1}H-NMR δ=1.33 (3H, s), 1.42 (3H, br. s), 1.51 (3H, br. s), 1.61 (3H, s), 2.2—2.5 (4H, m), 3.59 (1H, dd, J=10, 6.5 Hz), 3.78 (1H, dd, J=10, 8.5 Hz), and 4.45 (1H, dd, J=8.5, 6.5 Hz)].

The LAH-reduction of 5 to 14. An anhydrous THF solution of **5** (214 mg) was treated with LAH (150 mg) at 15—25 °C for 1 h. The mixture was treated with EtOAc, diluted with aqueous NH_4Cl, and extracted with ether. Silica-gel column chromatography (hexane-EtOAc=1:1) of the extract gave colorless needles, mp 123—123.5 °C, 170 mg (91%), **14** [Found: C, 64.68; H, 9.57%. Calcd for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74%. ^{1}H-NMR δ=1.15 (3H, s), 1.39 (3H, s), 1.6—2.0 (4H, m), 2.21 (1H, dd, J=7.3, 6.2 Hz, OH), 2.60 (1H, s, OH), 3.61 (1H, dd, J=11.8, 6.2 Hz), 3.66 (1H, dd, J=11.8, 7.3 Hz), 3.77 (1H, s, OH), 5.01 (1H, dd, J=10.1, 1.3 Hz), 5.05 (1H, dd, J=17.8, 1.3 Hz), and 5.84 (1H, dd, J=17.8, 10.1 Hz). ν: 3440, 3380, 2980, 1657, 1373, 1042, 1004, and 927 cm^{-1}. m/z: 186 (M^+)].

The LAH-reduction of 7 to 15. An anhydrous THF solution (5 cm^3) of **7** (74 mg) was reduced similarly with LAH (60 mg) to give colorless prisms, mp 69—70 °C, 53 mg (82%) **15** [Found: C, 64.51; H, 9.70%. ^{1}H-NMR δ=1.12 (3H, s), 1.36 (3H, s), 1.6—2.1 (4H, m), 2.14 (1H, br. s, OH), 2.43 (1H, br. m, OH), 2.78 (1H, s, OH), 3.57 (1H, dd, J=11.5, 5 Hz), 3.88 (1H, dd, J=11.5, 4 Hz), 5.01 (1H, dd, J=10.5, 1.4 Hz), 5.07 (1H, dd, J=17.7, 1.4 Hz), and 6.13 (1H, dd, J=17.7, 10.5 Hz). ν: 3545, 3390, 2970, 2950, 1630, 1467, 1058, 1006, 994, and 902 cm^{-1}. m/z: 168 (M^+−18)].

The LAH-reduction of 8 to 16. Similarly, **8** (214 mg) was reduced with LAH (150 mg) to give colorless needles, mp 90—91 °C, 148 mg (80%) **16** [Found: C, 64.23; H, 9.69%. ^{1}H-NMR δ=1.08 (3H, s), 1.33 (1H, m), 1.44 (3H, s), 1.7—2.1 (3H, m), 2.10 (1H, dd, J=7.6, 5.5 Hz, OH), 2.82 (1H, s,, OH), 3.43 (1H, s, OH), 3.63 (1H, dd, J=11.0, 5.5 Hz), 3.69 (1H, dd, J=11.0, 7.6 Hz), 5.05 (1H, dd, J=17.3, 1.4 Hz), 5.11 (1H, dd, J=11.0, 1.4 Hz), and 6.15 (1H, dd, J=17.3, 11.0 Hz). ν: 3430, 3370, 2970, 1636, 1379, 1121, 1009, and 975 cm^{-1}. m/z: 168 (M^+−18)].

Reaction of 14 with DMP and PPTS. An anhydrous THF solution (5 cm^3) of **14** (170 mg) was treated with DMP (0.5 cm^3) and PPTS (30 mg), and kept at 15—25 °C for 3 h. The mixture was diluted with aqueous K_2CO_3 and extracted with ether. Silica-gel column chromatography (hexane-EtOAc=8:1) gave a colorless oil, **17**, 195 mg (94%) [Found: M^+, 226.1558. Calcd for $C_{13}H_{22}O_3$: 226.1568. ^{1}H-NMR δ=1.16 (3H, s), 1.25 (3H, s), 1.42 (3H, br. s), 1.46 (3H, br. s), 1.5—1.9 (4H, m), 3.13 (1H, br. s, OH), 3.88 (2H, s), 5.01 (1H, dd, J=10.6, 1.3 Hz), 5.03 (1H, dd, J=17.5, 1.3 Hz), and 5.83 (1H, dd, J=17.5, 10.6 Hz). ν: 3530, 2990, 1635, 1460, 1382, 1372, 1243, 1215, 1048, 914, 875, and 852 cm^{-1}].

Dehydration of 17 to 18 and 19. A pyridine solution (1 cm^3) of **17** (35 mg) was treated with $SOCl_2$ (30 mg) at 0 °C for 1 h. Then the mixture was poured into $NaHCO_3$ solu-

tion, and extracted with ether. The extract was rapidly passed through a silica-gel column with hexane-ether (15:1) to give a colorless oil, 26 mg (81%), whose gas-liquid chromatogram showed the presence of two compounds, **18** [Found: M^+, 208.1482. Calcd for $C_{13}H_{20}O_2$: 208.1462. *RT*=23.4 min], and **19** [Found: M^+, 208.1478. *RT*=23.9 min], in a ratio of 5:2. This was further confirmed by the ^{1}H-NMR spectral analysis of the mixture [δ=1.15 (3H, s), 1.42 (6H, s), 1.73 (3H, q, *J*=2 Hz), 2.0—2.4 (2H, m), 3.62 (1H, d, *J*=9 Hz), 3.87 (1H, d, *J*=9 Hz), 5.02 (1H, dd, *J*=11.0, 1.5 Hz), 5.05 (1H, dd, *J*=17.3, 1.5 Hz), 5.49 (1H, m), and 5.98 (1H, dd, *J*=17.3, 11.0 Hz) for **18**; δ=1.03 (3H, s), 1.44 (6H, s), 1.5—1.7 (2H, m), 2.3—2.5 (2H, m), 3.66 (1H, d, *J*=8.5 Hz), 3.96 (1H, d, *J*=8.5 Hz), 5.01 (1H, td, *J*=2.5, 0.8 Hz), 5.02 (1H, dd, *J*=17.2, 1.6 Hz), 5.05 (1H, dd, *J*=11.0, 1.6 Hz), 5.25 (1H, br. t, *J*=2.5 Hz), and 5.97 (1H, dd, *J*=17.2, 11.0 Hz) for **19**].

Acetal Formation of 16 with DMP. An anhydrous THF solution (5 cm^3) of **16** (148 mg) was treated with DMP (0.5 cm^3) and PPTS (30 mg) at 15—25 °C for 4 h. The extraction and silica-gel column chromatography of the mixture afforded a colorless oil, **20**, 166 mg (92%) [Found: M^+, 226.1578. ^{1}H-NMR δ=1.02 (3H, s), 1.33 (3H, s), 1.37 (3H, br. s), 1.44 (3H, br. s), 1.7—2.1 (4H, m), 3.41 (1H, s, OH), 3.85 (1H, d, *J*=9.5 Hz), 3.98 (1H, d, *J*=9.5 Hz), 4.97 (1H, dd, *J*=17.1, 1.4 Hz), 5.03 (1H, dd, *J*=11.2, 1.4 Hz), and 6.10 (1H, dd, *J*=17.1, 11.2 Hz). ν: 3510, 2990, 1638, 1460, 1382, 1372, 1243, 1050, 878, and 854 cm^{-1}].

Dehydration of 20 to 21 and 22. A pyridine solution (1 cm^3) of **20** (30 mg) was treated with $SOCl_2$ (30 mg) at 0 °C for 1 h. The mixture was poured into $NaHCO_3$ solution, extracted with ether, and passed through a silica-gel column to give colorless oils, **21**, 13 mg (46%) [Found: M^+, 208.1445. Calcd for $C_{13}H_{20}O_2$: 208.1462. *RT*=25.6 min. δ=1.08 (3H, s), 1.32 (3H, br. s), 1.43 (3H, br. s), 1.75 (3H, q, *J*=2 Hz), 1.93 (1H, d of quint, *J*=16, 2 Hz), 2.48 (1H, d of quint, *J*=16, 2 Hz), 3.78 (1H, d, *J*=9 Hz), 3.90 (1H, d, *J*=9 Hz), 5.03 (1H, dd, *J*=17.6, 1.6 Hz), 5.03 (1H, dd, *J*=10.7, 1.6 Hz), 5.52 (1H, m), and 6.18 (1H, dd, *J*=17.6, 10.7 Hz)], and **22**, 7 mg (24%) [Found: M^+, 208.1483. *RT*=22.5 min. δ=0.92 (3H, s), 1.35 (3H, br. s), 1.40 (3H, br. s), 1.40 (1H, m), 1.96 (1H, ddd, *J*=13, 10, 7 Hz), 2.2—2.7 (2H, m), 3.86 (1H, d, *J*=9 Hz), 3.90 (1H, d, *J*=9 Hz), 5.00 (1H, td, *J*=2.5, 0.8 Hz), 5.02 (1H, dd, *J*=17.2, 1.6 Hz), 5.09 (1H, dd, *J*=11.1, 1.6 Hz), 5.27 (1H, br. t, *J*=2.5 Hz), and 6.09 (1H, dd, *J*=17.2, 11.1 Hz)].

Acetal Formation of 15 with DMP. An anhydrous THF solution (2 cm^3) of **15** (49 mg) was treated with DMP (0.2 cm^3) and PPTS (20 mg) at 15—25 °C for 1 h. The mixture was diluted with aqueous $NaHCO_3$, ether extracted, and chromatographed on a silica-gel column to give a colorless oil, **24**, 17 mg (29%) [Found: M^+, 226.1557. ^{1}H-NMR δ=1.05 (3H, s), 1.25 (3H, br. s), 1.39 (3H, s), 1.43 (3H, br. s), 1.6—2.0 (4H, m), 2.28 (1H, br. s, OH), 3.18 (1H, d, *J*=12 Hz), 3.61 (1H, d, *J*=12 Hz), 5.01 (1H, dd, *J*=17.6, 1.4 Hz), 5.02 (1H, dd, *J*=10.5, 1.4 Hz), and 5.89 (1H, dd, *J*=17.6, 10.5 Hz). ν: 3485, 2980, 2950, 1640, 1467, 1448, 1376, 1225, 1052, 913, and 834 cm^{-1}], and a colorless oil, **23**, 35 mg (59%) [Found: M^+, 226.1557. ^{1}H-NMR δ=1.12 (3H, s), 1.31 (3H, s), 1.37 (3H, br. s), 1.44 (3H, br. s), 1.6—2.0 (4H, m), 1.80 (1H, s, OH), 3.86 (1H, d, *J*=10 Hz), 4.19 (1H, d, *J*=10 Hz), 5.01 (1H, dd, *J*=10.5, 1.4 Hz), 5.10 (1H, dd, *J*=17.7, 1.4 Hz), and 6.04 (1H, dd, *J*=17.7, 10.5 Hz). ν: 3500, 2990, 1634, 1454, 1381, 1372, 1209, 1049, 1021, 913, and 857 cm^{-1}].

Dehydration of 23 to 18 and 19. A pyridine solution of **23** (33 mg) was treated with $SOCl_2$ (30 mg) at 0 °C for 1 h. The mixture was washed with aqueous $NaHCO_3$, and extracted with ether to give a colorless oil, 25 mg (82%), whose NMR was identical with that of the products, a mixture of **18** and **19**, obtained from **17**, and the gas-liquid chromatograms from the both sources were mutually indistinguishable other than for a small difference in the ratio of **18** and **19**.

Reduction of 5 with Zn to 25. A mixed solution of AcOH (2 cm^3) and Ac_2O (1 cm^3) of **5** (21 mg) was refluxed with powdered Zn (300 mg) for 8 h. Zn was removed by filtration and the filtrate was poured into $NaHCO_3$, and extracted with benzene. The extract was rapidly passed through a silica-gel column to give a colorless liquid, 17 mg (95%), **25** [Found: M^+, 180.1155. Calcd for $C_{11}H_{16}O_2$: 180.1149. ^{1}H-NMR δ=1.31 (3H, s), 1.6—2.0 (2H, m), 2.05 (3H, br. s), 2.39 (2H, br. t, *J*=7 Hz), 3.67 (3H, s), 4.88 (1H, dd, *J*=10.8, 1.6 Hz), 4.90 (1H, dd, *J*=17.0, 1.6 Hz), and 5.96 (1H, dd, *J*=17.0, 10.8 Hz). ^{13}C-NMR δ=16.9, 24.4, 37.3, 38.0, 50.6, 52.4, 110.3, 133.6, 145.2, 155.0, and 166.4. ν: 2955, 1710, 1637, 1435, 1340, 1263, 1220, 1062, 908, and 788 cm^{-1}].

Reduction of 8 to 25. Similarly, **8** (21 mg) gave **25**, 16 mg (90%).

Attempted Reduction of 6 or 7. Mixed solutions of AcOH (1.3 cm^3) and Ac_2O (0.7 cm^3) respectively containing **6** (20 mg) and **7** (16 mg) were refluxed for 7 h with powdered Zn (200 mg); only the products isolated after the ordinary work-up and silica-gel column chromatography (hexane-EtOAc=8:1) were colorless oily monoacetates, **26**, 18 mg (77%) [Found: M^+, 256.1313. Calcd for $C_{13}H_{20}O_5$: 256.1310. ^{1}H-NMR δ=1.00 (3H, s), 1.49 (3H, s), 1.92 (3H, s), 2.0—2.5 (4H, m), 3.76 (3H, s), 4.01 (1H, s, OH), 5.05 (1H, dd, *J*=10.9, 1.2 Hz), 5.05 (1H, dd, *J*=17.7, 1.2 Hz), and 6.07 (1H, dd, *J*=17.7, 10.9 Hz). ν: 3500, 2955, 1740, 1730, 1638, 1439, 1371, 1256, 1212, 1143, 1020, and 908 cm^{-1}],[10] and **27**, 15 mg (78%) [Found: M^+, 256.1317. ^{1}H-NMR δ=1.16 (3H, s), 1.60 (3H, s), 1.91 (3H, s), 2.0—2.6 (4H, m), 3.67 (3H, s), 3.90 (1H, s, OH), 4.94 (1H, dd, *J*=10.3, 1.2 Hz), 4.98 (1H, dd, *J*=17.8, 1.2 Hz), and 5.83 (1H, dd, *J*=17.8, 10.3 Hz). ν: 3500, 2990, 2955, 1741, 1730, 1640, 1438, 1376, 1370, 1258, 1242, 1143, 1019, and 916 cm^{-1}].

$TiCl_2$-reduction of 2 to 28, 29, and 30. To an anhydrous THF suspension (300 cm^3) of pyridine complex of $TiCl_2$, prepared from $TiCl_4$ (3.3 cm^3), Zn (4 g), and pyridine (2.4 cm^3), a THF solution (20 cm^3) of **2** (4.25 g) was added dropwise over a period of 1 h under cooling with water. After continued stirring for 30 min at 15—25 °C, the mixture was treated with 30%-aqueous K_2CO_3 (300 cm^3), to which ether was added, and the precipitates were filtered off. The filtrate was extracted with ether and chromatographed on a silica-gel column. A colorless oil, 320 mg (8%), **28** [Found: C, 61.52; H, 8.51%. Calcd for $C_{11}H_{18}O_4$: C, 61.66; H, 8.47%. ^{1}H-NMR δ=1.08 (3H, s), 1.74 (3H, br. s), 1.9—2.0 (4H, m), 2.88 (1H, br. s, OH), 3.10 (1H, br. m), 3.75 (3H, s), 3.79 (1H, s, OH), and 4.79 (2H, m). ^{13}C-NMR δ=22.8, 23.1, 23.6, 34.9, 51.7, 52.3, 80.9, 88.5, 110.7, 143.9, and 174.5. ν: 3510, 2955, 1728, 1646, 1442, 1245, 1227, 1123,

1089, 951, and 890 cm^{-1}. *m/z*: 214 (M^+)], was eluted at first.

Subsequently, colorless needles, mp 57.5—58 °C, 470 mg (11%), **29** [Found: C, 61.54; H, 8.31%. ^{1}H-NMR δ=1.28 (3H, s), 1.69 (3H, br. s), 1.7—2.2 (4H, m), 2.83 (1H, s, OH), 3.28 (1H, br. s, OH), 3.43 (1H, m), 3.80 (3H, s), 4.89 (1H, br. s), and 5.00 (1H, m). ^{13}C-NMR δ=21.8, 23.5, 25.7, 37.5, 52.0, 52.6, 84.3, 85.1, 113.2, 140.9, and 175.4. *ν*: 3470, 3340, 2950, 1700, 1645, 1400, 1292, 1254, 1142, 1110, 1040, 928, and 893 cm^{-1}. *m/z*: 214 (M^+)], and a colorless oil, 2.91 g (68%), **30** [Found: C, 61.53; H, 8.50%. ^{1}H-NMR δ=1.26 (3H, s), 1.72 (3H, br. s), 1.7—2.1 (4H, m), 3.07 (1H, br. s, OH), 3.18 (1H, br. m), 3.61 (1H, s, OH), 3.80 (3H, s), 4.80 (1H, br. s), and 4.89 (1H, br. s). ^{13}C-NMR δ=22.5, 25.0, 25.1, 38.9, 51.0, 52.3, 81.6, 85.2, 112.9, 143.4, and 174.7. *ν*: 3490, 2950, 1725, 1641, 1440, 1376, 1257, 1121, 1047, and 892 cm^{-1}. *m/z*: 214 (M^+)], were obtained from the elutions with hexane–EtOAc (3:1).

*Reduction of **28** with Zn to **31**.* A mixture of AcOH (4 cm^3), Ac_2O (2 cm^3), and **28** (60 mg) was refluxed with powdered Zn (600 mg) for 8 h. The mixture was filtered to remove Zn, washed with $NaHCO_3$, and extracted with ether. Silica-gel column chromatography of the extract gave a colorless oil, **31**,[8] 22 mg (44%) [^{1}H-NMR δ=1.65 (1H, m), 1.68 (3H, dd, *J*=1.3, 1.0 Hz), 2.10 (1H, m), 2.11 (3H, q, *J*=1.2 Hz), 2.3—2.6 (2H, m), 3.56 (1H, br. m), 3.66 (3H, s), 4.61 (1H, m), and 4.64 (1H, m). ^{13}C-NMR δ=16.3, 20.6, 28.7, 39.2, 50.8, 53.2, 109.1, 129.5, 148.0, 156.4, and 166.5. *ν*: 2950, 1714, 1648, 1435, 1218, 1117, 1062, and 885 cm^{-1}].

*Reduction of **30** with Zn to **31**.* Similarly, **30** (150 mg) was reduced with Zn to **31**, 68 mg (54%), identical with the sample prepared from **28**.

*Attempted Reduction of **29**.* To a mixed solution of AcOH (1.3 cm^3) and Ac_2O (0.7 cm^3) of **29** (19 mg) was similarly refluxed with powdered Zn (200 mg) for 7 h. After the work-up the product isolated was **32**, 19 mg (83%) [Found: M^+, 256.1316. Calcd for $C_{13}H_{20}O_5$: 256.1310. ^{1}H-NMR δ=1.55 (3H, s), 1.74 (3H, br. s), 1.96 (3H, s), 1.8—2.4 (4H, m), 3.27 (1H, br. s, OH), 3.37 (1H, br. t, *J*=9 Hz), 3.79 (3H, s), 4.82 (1H, br. s), and 4.91 (1H, m). *ν*: 3510, 2955, 1742, 1730, 1642, 1439, 1370, 1246, 1116, 1022, and 892 cm^{-1}].

*DMP-treatment of **28**.* A mixture of **28** (45 mg), DMP (1 cm^3), and PPTS (10 mg) in benzene (1 cm^3) was refluxed for 25 h. The mixture was distilled *in vacuo*, and the residue was passed through a silica-gel column to give a colorless oil, **33**, 46 mg (86%) [Found: M^+ 254.1502. Calcd for $C_{14}H_{22}O_4$: 254.1517. ^{1}H-NMR δ=1.40 (3H, s), 1.45 (3H, br. s), 1.55 (3H, br. s), 1.75 (3H, br. s), 1.7—2.3 (4H, m), 2.90 (1H, br. m), 3.68 (3H, s), 5.71 (1H, br. s), and 5.79 (1H, m). *ν*: 2990, 1755, 1738, 1649, 1447, 1436, 1376, 1228, 1125, 1089, 1002, 887, and 870 cm^{-1}].

*DMP-treatment of **30**.* Similarly, a benzene solution (5 cm^3) of **30** (160 mg), DMP (2 cm^3), and PPTS (25 mg) was refluxed for 14 h to afford a colorless oil, **34**, 171 mg (90%) [Found: M^+, 254.1529. ^{1}H-NMR δ=1.38 (3H, s), 1.45 (6H, br. s), 1.71 (3H, br. s), 1.5—2.1 (4H, m), 3.03 (1H, br. m), 3.77 (3H, s), 4.72 (1H, br. s), and 4.82 (1H, m). *ν*: 2990, 1757, 1732, 1648, 1456, 1438, 1378, 1265, 1127, 1055, 1022, and 887 cm^{-1}].

*Saponification and Iodolactonization of **34** to **36** and **37** via **35**.* Into a DMSO solution (1 cm^3) of **34** (53 mg), 20%-NaOH solution (0.6 cm^3) was added and refluxed for 2 h. The mixture was then acidified with dil HCl, and extracted with ether to give 50 mg (100%), **35**, colorless granules, mp 86.5—87.5 °C [Found: C, 64.78; H, 8.37%. Calcd for $C_{13}H_{20}O_4$: C, 64.98; H, 8.39%. ^{1}H-NMR δ=1.48 (6H, s), 1.51 (3H, br. s), 1.73 (3H, br. s), 1.6—2.1 (4H, m), 3.06 (1H, br. m), 4.77 (1H, br. s), and 4.87 (1H, m). *ν*: 3400—2500, 2980, 1713, 1692, 1648, 1377, 1278, 1259, 1122, 1009, and 886 cm^{-1}. *m/z*: 240 (M^+)].

Then, **35** was treated with excess of I_2 (100 mg) in MeCN (2 cm^3) in the presence of $NaHCO_3$ (100 mg). After stirring at 15—25 °C for 15 h, I_2 was decomposed by $NaHSO_3$ solution, and extracted with ether. From the aqueous layer, starting **35** (25 mg) was recovered. Silica-gel column chromatography of the neutral extract afforded two isomeric iodo lactones, **36**, colorless prisms, mp 117.5—188 °C, 19 mg (50%) [Found: C, 42.76; H, 5.24%. Calcd for $C_{13}H_{19}O_4I$: C, 42.64; H, 5.23%. ^{1}H-NMR δ=1.48 (6H, s), 1.52 (3H, s), 1.77 (3H, s), 1.8—2.4 (5H, m), and 3.35 (2H, br. s). *ν*: 2990, 1780, 1371, 1285, 1185, and 1012 cm^{-1}. *m/z*: 366 (M^+)], and **37**, a colorless oil, 7 mg (18%) [^{1}H-NMR δ=1.48 (6H, s), 1.51 (3H, s), 1.69 (3H, s), 1.7—2.4 (5H, m), 3.63 (1H, d, *J*=11 Hz), and 3.76 (1H, d, *J*=11 Hz). *ν*: 2990, 1787, 1382, and 1000 cm^{-1}].

*LAH-reduction of **28** to **38**.* An anhydrous THF solution (7.5 cm^3) of **28** (118 mg) was treated with LAH (100 mg) at 15—25 °C for 1 h. Purification of the products by silica-gel column chromatography gave a colorless oil, 94 mg (92%) **38** [Found: C, 64.26; H, 9.78%. Calcd for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74%. ^{1}H-NMR δ=1.25 (3H, s), 1.6—1.9 (4H, m), 1.88 (3H, br. s), 2.41 (1H, br. m, OH), 2.79 (1H, br. s, OH), 2.90 (1H, br. t, *J*=9 Hz), 3.44 (1H, s, OH), 3.46 (1H, dd, *J*=12, 7 Hz), 3.64 (1H, dd, *J*=12, 5 Hz), 4.84 (1H, br. s), and 4.93 (1H, m). *ν*: 3400, 2790, 1642, 1450, 1380, 1120, 1045, 928, and 892 cm^{-1}. *m/z*: 168 (M^+−18)].

*LAH-reduction of **29** to **39**.* An anhydrous THF solution (5 cm^3) of **29** (70 mg) was treated with LAH (60 mg) at 15—25 °C for 1 h. From the mixture, a colorless oil, 47 mg (77%), **39** [Found: C, 64.27; H, 9.68%. ^{1}H-NMR δ=1.37 (3H, s), 1.5—2.1 (4H, m), 1.88 (3H, br. s), 1.99 (1H, s, OH), 2.15 (1H, br. s, OH), 2.83 (1H, dd, *J*=9, 3 Hz, OH), 3.09 (1H, br. t, *J*=9 Hz), 3.49 (1H, dd, *J*=11, 9 Hz), 3.74 (1H, dd, *J*=11, 3 Hz), 4.89 (1H, br. s), and 5.07 (1H, m). *ν*: 3400, 2975, 1638, 1375, 1106, 1032, 926, and 895 cm^{-1}. *m/z*: 168 (M^+−18)], was obtained.

*LAH-reduction of **30** to **40**.* Similarly, **30** (210 mg) in THF (10 cm^3) was reduced by LAH (150 mg) to colorless needles, mp 106.5—107 °C, 157 mg (86%), **40** [Found: C, 64.37; H, 9.95%. ^{1}H-NMR δ=1.35 (3H, s), 1.83 (3H, br. s), 1.5—2.1 (4H, m), 2.40 (1H, br. m, OH), 2.48 (1H, m), 2.75 (1H, br. s, OH), 3.17 (1H, br. s, OH), 3.65 (2H, br. d, *J*=4 Hz), 4.81 (1H, br. s), and 4.93 (1H, m). *ν*: 3445, 3400, 2955, 1633, 1377, 1343, 1120, 1097, 934, and 899 cm^{-1}. *m/z*: 168 (M^+−18)].

*DMP-treatment of **38** to **41**.* An anhydrous THF solution (2 cm^3) of **38** (53 mg) was treated with DMP (0.2 cm^3) and PPTS (20 mg) at 15—25 °C for 3 h. Extraction and silica-gel chromatographic purification afforded a colorless oil, 63 mg (98%), **41** [Found: M^+, 226.1569. Calcd for $C_{13}H_{22}O_3$: 226.1568. ^{1}H-NMR δ=1.23 (3H, s), 1.36 (3H, br. s), 1.46 (3H, br, s), 1.4—1.9 (4H, m), 1.82 (3H, br. s), 2.56 (1H, br. s, OH), 3.12 (1H, br. m), 3.76 (1H, d, *J*=9.5 Hz),

3.88 (1H, d, J=9.5 Hz), 4.77 (1H, br. s), and 5.03 (1H, m). ν: 3550, 2990, 1645, 1454, 1382, 1372, 1211, 1146, 1068, 888, 877, and 853 cm^{-1}].

*Dehydration of **41** to **42** and **43**.* A pyridine solution (1 cm^3) of **41** (27 mg) was treated with $SOCl_2$ (30 mg) at 0 °C for 1 h. The mixture was then quenched with $NaHCO_3$ solution and extracted with a 1:1-mixture of hexane–ether to give a colorless oil, 21 mg (85%), a 3:1-mixture of **42** [Found: M^+, 208.1465. Calcd for $C_{13}H_{20}O_2$: 208.1462. ^{1}H-NMR δ=1.37 (3H, br. s), 1.44 (3H, br. s), 1.55 (3H, dd, J=1.5, 0.8 Hz), 1.72 (3H, q, J=2 Hz), 2.08 (1H, dm, J=17 Hz), 2.64 (1H, dd of quint, J=17, 8, 2 Hz), 3.09 (1H, dd, J=8, 3.5 Hz), 3.81 (1H, d, J=9 Hz), 4.01 (1H, d, J=9 Hz), 4.81 (2H, m), and 5.57 (1H, m). RT= 30.4 min], and **43** [Found: M^+, 208.1477. ^{1}H-NMR δ= 1.40 (3H, br. s), 1.47 (3H, br. s), 1.78 (3H, dd, J= 1.5, 0.8 Hz), 1.5—2.1 (2H, m), 2.3—2.6 (2H, m), 2.69 (1H, dd, J=9.5, 7 Hz), 3.79 (1H, d, J=9 Hz), 4.06 (1H, d, J=9 Hz), 4.77 (1H, br. s), 4.91 (1H, m), 4.97 (1H, td, J=2.5, 0.8 Hz), and 5.22 (1H, br. t, J=2.5 Hz). RT=29.7 min].

*DMP-treatment of **40** to **44**.* An anhydrous THF solution (3 cm^3) of **40** (90 mg) was treated with DMP (0.3 cm^3) and PPTS (30 mg) at 15—25 °C for 3 h. The work-up gave a colorless oil, 105 mg (96%), **44** [Found: M^+, 226.1573. ^{1}H-NMR δ=1.24 (3H, s), 1.35 (3H, br. s), 1.4—2.1 (4H, m), 1.43 (3H, br. s), 1.82 (3H, br. s), 2.43 (1H, m), 2.87 (1H, br. s, OH), 3.84 (1H, d, J=9 Hz), 4.04 (1H, d, J=9 Hz), 4.76 (1H, br. s), and 4.87 (1H, m). ν: 3520, 2980, 1642, 1453, 1382, 1372, 1217, 1068, 890, and 860 cm^{-1}].

*Dehydration of **44** to **45** and **46**.* A pyridine solution (1.5 cm^3) of **44** (47 mg) was treated with $SOCl_2$ (45 mg) at 0 °C for 1 h. The reaction mixture was poured into aqueous $NaHCO_3$ and extracted with a 1:1-mixture of hexane–ether. The extract was passed through a silica-gel column with hexane–ether (15:1) to give a colorless oil, 36 mg (83%), a 3:1-mixture of **45** [Found: M^+, 208.1445. RT=23.9 min. ^{1}H-NMR δ=1.33 (3H, br. s), 1.42 (3H, br. s), 1.73 (3H, q, J=2 Hz), 1.75 (1H, dd, J=1.5, 0.8 Hz), 2.2—2.4 (2H, m), 2.74 (1H, dd, J=7.5, 5.5 Hz), 3.87 (2H, s), 4.78 (2H, m), and 5.52 (1H, m)] and **46** [Found: M^+, 208.1471. RT=26.9 min. ^{1}H-NMR δ=1.36 (3H, br. s), 1.45 (3H, br. s), 1.80 (3H, dd, J=1.5, 0.8 Hz), 1.6—2.0 (2H, m), 2.2—2.4 (3H, m), 3.85 (1H, d, J=8.5 Hz), 3.96 (1H, d, J=8.5 Hz), 4.71 (1H, br. s), 4.85 (1H, m), 5.01 (1H, td, J=2.5, 0.8 Hz), and 5.26 (1H, br. t, J=2.5 Hz)].

*DMP-treatment of **39** to **47** and **48**.* An anhydrous THF solution (1.5 cm^3) of **39** (37 mg) was treated with DMP (0.15 cm^3) and PPTS (15 mg^3) at 15—25 °C for 1 h, after which, the mixture was diluted with aqueous $NaHCO_3$, extracted with ether, and chromatographed on a silica-gel column. The fractions eluted from hexane–ether (4:1) were a colorless oil, 22 mg (49%), **48** [Found: C, 68.96; H, 9.88%. Calcd for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80%. ^{1}H-NMR δ=1.37 (3H, br. s), 1.41 (3H, s), 1.48 (3H, br. s), 1.84 (3H, br. s), 1.6—2.0 (5H, m), 3.18 (1H, br. m), 3.52 (1H, d, J=12 Hz), 3.73 (1H, d, J=12 Hz), 4.89 (1H, br. s), and 5.08 (1H, m). ν: 3530, 2995, 2950, 1638, 1453, 1379, 1191, 1075, and 891 cm^{-1}. m/z: 211 (M^+−15)]. Subsequently, a colorless oil, 18 mg (40%), **47** [Found: M^+, 226.1564. ^{1}H-NMR δ=1.28 (3H, br. s), 1.33 (3H, s), 1.41 (3H, br. s), 1.84 (3H, br. s), 1.5—2.1 (5H, m), 2.84 (1H, br. m), 3.88 (1H, d, J=9 Hz), 4.21 (1H, d, J=9 Hz), 4.78 (1H, br. s), and 4.93 (1H, m). ν: 3495, 2960, 1638, 1455, 1381, 1371, 1207, 1060, 880, and 851 cm^{-1}], was obtained.

*Dehydration of **47** to **45** and **46**.* A pyridine solution (0.5 cm^3) of **47** (16 mg) was treated with $SOCl_2$ (15 mg) at 0 °C for 1 h. The mixture was diluted with aqueous $NaHCO_3$, extracted with ether, and chromatographed on a silica-gel column to give a colorless oil, 12 mg (81%), which proved to be a 6:1-mixture of **45** and **46** from the NMR spectral and gas-liquid chromatographic analyses.

Synthetic Photochemistry. XXX.[1] The Addition Reactions of Cycloheptatriene with Some Aromatic *p*-Quinones[2]

Akira MORI and Hitoshi TAKESHITA*
Research Institute of Industrial Science, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816
(Received January 16, 1985)

The photochemical reactions of cycloheptatriene with *p*-benzoquinone and 1,4-naphthoquinone yielded the spirocyclic ethers, which had 7-oxabicyclo[4.2.1]nona-2,4-diene structures, by the characteristic (6+2)π cycloaddition process. The latter quinone further produced the carbocyclic (2+2)π and (6+2)π cycloadducts.

Previously, we have investigated the photoaddition reactions of cycloheptatriene (**1**) with methyl 2,4-dioxopentanoate, an enolized β-diketone,[3] and benzil and methyl pyruvate, α-dicarbonyl compounds,[4] to give the ene-reaction products in the major process; in the cases of the β-diketone, the (4+2)π and (6+2)π cycloadducts were also produced. From cyclic α-dicarbonyl compounds such as acenaphthenequinone and 1,2-naphthoquinone,[5] various kinds of cycloadducts were formed; the former gave the (2+2)π and (6+2)π cycloadducts along with the ene-reaction products, and the latter, the (6+2)π, (4+2)π, and (4+4)π cycloadducts. Thus, since **1** is remarkable in giving various *peri*-cycloadducts in the photoinduced reactions, we have been interested in *p*-quinones, the conjugated dicarbonyl compounds. Although the photochemical reactions of aromatic quinones with olefins have been widely studied,[6] studies of the reactions of **1** with *p*-quinones have been limited to those of 1,4-naphthoquinone (NQ) in benzene to give the so-called "1:1-spirooxetane adduct" (**2**),[7] which does, however, seem to lack a sound rationale for its structure deduction. Other than this, the recent photo-induced cycloaddition of duroquinone has been reported to form cage compounds (**3** and **4**).[8]

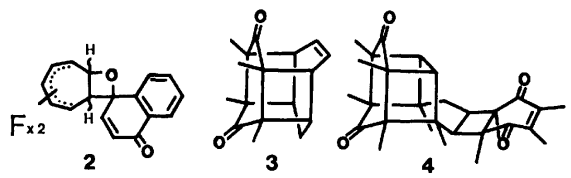

Chart 1.

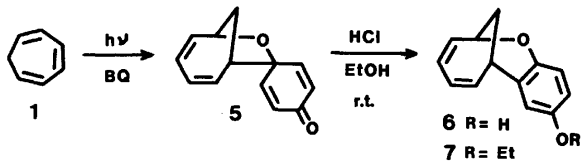
Results and Discussion

Upon the irradiation of a benzene solution of *p*-benzoquinone (BQ) and **1**, an oily 1:1-adduct (**5**) was obtained in 50—70% yields. Its structure was determined by the following spectroscopic data: the appearance of eight olefinic protons and four aliphatic protons in the ^{1}H NMR and only one carbonyl carbon at the ^{13}C NMR spectra indicated it to be a 1:1-adduct between the carbonyl part of BQ and the olefinic part of **1**. In order to determine the pericyclic mode of the addition, the decoupling experiments by double irradiation (NMDR) were performed in the presence of a lanthanoide-shift reagent. The irradiation of the doublet (J=13 Hz) at δ=3.21 (H-a) caused the doublet of triplets (J=13, 6.5 Hz) at 3.64 (H-b) to collapse to a triplet (J=6.5). The irradiation of H-b caused both the doublet of H-a and the triplet (J=6.5 Hz) at 5.48 (H-d), which was assigned to the proton at the ethereal carbon, to collapse to a singlet and a doublet (J=6.5 Hz) respectively. The irradiation of the triplet (J=6.5 Hz) at 4.00 (H-c) caused H-b to collapse to a doublet of doublets (J=13, 6.5 Hz). Therefore, the two allylic protons (H-d and H-c) did not spin-couple in each other. The observed magnitude (J=13 Hz) of the gem-coupling constant for the non-allylic methylene protons should be appropriate for that of a tetrahydrofuran. Consequently, **5** must be the (6+2)π cycloadduct.

The treatment of the adduct **5** with hydrogen chloride in ethanol resulted in its conversion to a phenol derivative (**6**) and its ethyl ether (**7**) *via* the dienone-phenol rearrangement.



Scheme 1.

Subsequently, the photoreaction of **1** with 1,4-naphthoquinone (NQ) was investigated. In the literature,[7] the formation of an oxetane derivative (**2**), as orange crystals, has been described, but this mode of the reaction was quite different from that in our present study. This might be also worth reinvestigating. Thus, when a benzene solution of NQ and **1** was exposed to a 400-W high-pressure mercury lamp, four 1:1-adducts (**8**, **9**, **10**, and **11**) were formed in a ratio of 58:4:17:21, in addition to a dehydro derivative (**12**) of **11**. The structures of these compounds were confirmed by the chemical and spectroscopic evidence. The ^{1}H NMR spectra of **8** and **9** closely resemble each other; when we compare

Table 1. The NMR data of 5 and the NMDR data of 5(31.4 mg) and $Eu(dpm)_3$(60.7 mg) in $CDCl_3$

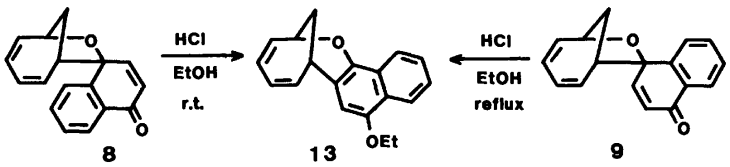
The symbols used here are defined as follows: o, changed; x, unchanged; —, unobserved. The values shown in parentheses are the coupling constants (J)/Hz.



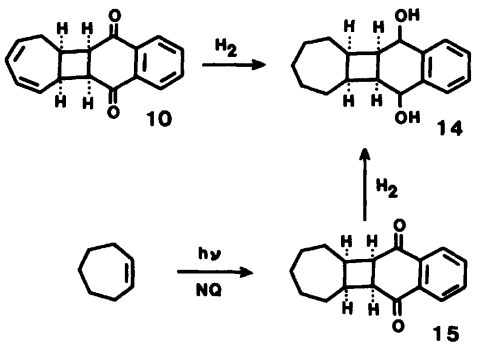
Scheme 2.

the chemical shifts of the corresponding pairs of hydrogens, one of the methylene protons of **9**, at 2.40, appeared in a higher field than that of **8**, at 2.68, and one of the four vinyl protons of **8**, at 5.10, caused a marked up-field shift, while all four vinyl protons of **9**, from 5.7 to 6.7, behaved normally. Therefore, the stereochemistries of **8** and **9** were deduced to be as depicted in Scheme 2. It is interesting that the sterically more crowded isomer, **8**, was predominant over the less crowded isomer, **9**.

The addition of hydrogen chloride in ethanol at room temperature also caused the dienone-phenol rearrangement of **8** to an aromatized ethyl ether (**13**), while it was necessary to reflux **9** to get the same product (**13**).

The third photoproduct (**10**) showed a rather poorly resolved ^1H NMR spectrum. However, since the methylene protons at 2.49 and 2.74 were proven to be allylic carbon by NMDR experiments, **10** can not be a (6+2)π cycloadduct. The catalytic reduction of **10** with platinum(IV) oxide gave an octahydro derivative (**14**), which was identical with the reduction product, a tetrahydro derivative, of one of the photoproducts (**15**) of NQ with cycloheptene. Therefore, **10** is a (2+2)π cycloadduct.

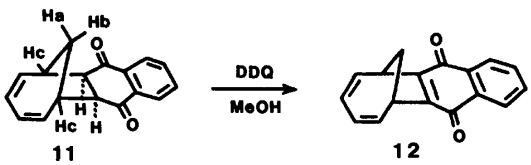
Next, the fourth product, **11**, was deduced from the NMDR experiments to be a symmetrical *exo*-(6+2)π cycloadduct. The irradiation of olefinic protons caused the broad doublet of doublets (J=7.5, 6 Hz) at 3.25 (H-c) to collapse to a broad doublet (J=6 Hz), but it did not affect the broad doublet signal (J=13 Hz) at 1.87 (H-a) or the doublet of triplets



Scheme 3.

(J=13, 6 Hz) at 2.04 (H-b). The coupling constant between H-c and H-d, being nearly zero, led us to conclude that the geometry of the ring juncture was that of the *exo*-adduct.

The remaining product, **12**, also exhibited a symmetrical ^1H NMR spectrum; the results of the elemental analysis suggested that it was a dehydrogenation product of **11**. Indeed, the DDQ (2,3-dichloro-5,6-dicyano-*p*-benzoquinone)-treatment of **11** afforded **12**.



Scheme 4.

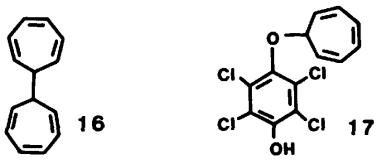


Chart 2.

The attempted photoreaction of **1** with 2,3,5,6-tetrachloro-*p*-benzoquinone (CB) gave no cycloadduct; the only products identified were the hydroquinone of CB and 1,1′-bicycloheptatrienyl (1,1′-bitropyl, **16**),[5,9] not the formerly reported monotropyl ether of tetrachlorohydroquinone (**17**).[10] Thus, CB behaved as an oxidizing agent rather than as a photocycloaddend toward **1**.

In conclusion, the photoreaction of **1** with BQ gave the single (6+2)π photoproduct, which coupled at the carbonyl group and the triene function of **1**, while the photoproducts of **1** with NQ, (6+2)π and (2+2)π cycloadducts, were derived from both the C=O group and the C=C group. This can be explained in terms of the nature of the excited species; that is, the lowest triplet of BQ is an n,π^* excited state, while that of NQ is thought to be considerably mixed with the n,π^* and π,π^* excited states.[11] The absence of any (4+2)π adduct in the photoproducts is consistent with the prediction based on the Woodward-Hoffmann rule,[12] but is in contrast to the reaction with a unique photocycloaddend, methyl 2,4-dioxopentanoate.[3]

Experimental

All the mps, which were measured by means of a Yanagimoto Micro-mp Apparatus, are uncorrected. The irradiations were performed by means of a 400-W high-pressure mercury lamp through a Pyrex glass filter, with running water-cooling under a nitrogen atmosphere. Elemental analyses were performed either at the Research Institute of Industrial Science or at the Analyses Center, Faculty of Science, Kyushu University. The NMR spectra were measured by the use of a JEOL FX 100 Spectrometer in a $CDCl_3$ solution, unless otherwise specified; the chemical shifts were expressed in δ unit from the internal Me_4Si. The mass spectra were measured by means of a JEOL 01SG-2 Spectrometer. The IR spectra were taken in either as KBr disks or as inserted liquid film between NaCl plates using a Jasco IR-A 102 spectrometer. All the UV spectra were taken by means of a Hitachi 124 Spectrophotometer in methanol.

Photoaddition of 1 with BQ. An anhydrous benzene solution (5 cm^3) of **1** (916 mg) and BQ (541 mg) was irradiated for 8.5 h. The mixture was filtered to remove the polymeric solid, and then, the filtrate was evaporated *in vacuo* to a give viscous syrup (1.2 g), which was chromatographed on a silica-gel column with benzene to yield a pale yellow oil; bp 115—118 °C (bath temp)/2 mm Hg, 681 mg (68%), **5** [Found: C, 77.72; H, 6.12%. Calcd for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04%. ^{13}C NMR δ=31.1, 47.3, 75.0, 89.1, 125.0, 126.8, 127.4, 127.8, 133.1, 133.6, 148.1, 149.9, and 184.6. λ_{max}: 228 nm (ε=15500), 264.5 (4400). *m/z*: 200 (M$^+$)].

Acid-catalyzed Rearrangement of 5. The photoadduct **5** (36.8 mg) was dissolved in EtOH (3 cm^3) containing concd HCl (0.03 cm^3), after which the mixture was kept at room temperature for 80 min with stirring. The mixture was then poured into water and extracted with ether. The extract was dried on $MgSO_4$ and chromatographed on a silica-gel column with benzene to yield a colorless oil; 23.2 mg (55%), **7** [Found: C, 79.07; H, 7.11%. Calcd for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%. ^{1}H NMR δ=1.33 (3H, t, *J*=7 Hz), 1.96 (1H, ddd, *J*=14, 2.5, 1 Hz), 2.58 (1H, ddd, *J*=14, 6, 4.5 Hz), 3.68 (1H, br. t, *J*=6 Hz), 3.93 (2H, q, *J*=7 Hz), 4.93 (1H, m), and 5.75—6.9 (7H, m). ^{13}C NMR δ=14.9, 28.9, 29.7, 33.5, 63.7, 114.0, 115.4, 117.9, 124.1, 125.0, 128.5, 131.9, 137.8, 146.2, and 152.6. λ_{max}: 222 nm (ε=12500), 249 (5000), 292 (2900). *m/z*: 228 (M$^+$)], and colorless crystals; mp 85—87 °C; 8.3 mg (23%); **6** [Found: 78.08; H, 6.02%. Calcd for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04%. ^{1}H NMR δ=1.98 (1H, ddd, *J*=14, 2, 1 Hz), 2.56 (1H, ddd, *J*=14, 6.5, 4 Hz), 3.68 (1H, dd, *J*=8.5, 6.5 Hz), 4.94 (1H, m), and 5.7—6.1 (3H, m). ^{13}C NMR δ=28.9, 33.3, 70.7, 114.8, 116.2, 118.1, 124.4, 125.1, 128.7, 131.8, 137.7, 146.1, and 149.0. ν: 3460, 3360 cm^{-1}. *m/z*: 200 (M$^+$)].

Photoaddition of 1 to NQ. An anhydrous benzene solution (10 cm^3) of **1** (920 mg) and NQ (790 mg) was irradiated for 1.5 h. The resultant mixture was chromatographed on a silica-gel column with hexane-benzene to afford a colorless oil; 292 mg (35%); **8** [Found: C, 81.37; H, 5.85%. Calcd for $C_{17}H_{14}O_2$: C, 81.58, H, 5.64%. ^{1}H NMR δ=2.68 (1H, d, *J*=12.5 Hz), 2.73 (1H, t, *J*=7 Hz), 3.00 (1H, td, *J*=12.5, 7 Hz), 4.76 (1H, t, *J*=7 Hz), 5.10 (1H, dd, *J*=11, 7 Hz), 5.6—6.2 (3H, m), 6.05 (1H, d, *J*=10.5 Hz), 7.18 (1H, d, *J*=10.5 Hz), and 7.2—8.0 (4H, m). ^{13}C NMR δ=32.4, 52.3, 74.6, 95.3, 125.8, 125.9, 127.2, 127.6, 128.2, 128.9, 130.9, 131.3, 133.0, 134.9, 141.0, 152.2, and 184.4. λ_{max}: 224 nm (ε=12500), 242.5 (9500), 253 (10200), 270 (sh., 7600). *m/z*: 250 (M$^+$)], a colorless oil; 20.5 mg (2.4%); **9** [Found: C, 81.49; H, 5.72%. ^{1}H NMR δ=2.40 (1H, d, *J*=12 Hz), 2.5—3.2 (2H, m), 4.85 (1H, br. t, *J*=6 Hz), 5.7—6.7 (4H, m), 6.17 (1H, d, *J*=10.5 Hz), 7.28 (1H, d, *J*=10.5 Hz), and 7.2—8.2 (4H, m). ν: 1680, 1607 cm^{-1}], colorless crystals; mp 103—104 °C; 108 mg (13%); **10** [Found: C, 81.37; H, 5.72%. ^{1}H NMR δ=2.49 (1H, ddd, *J*=13, 6.5, 4.5 Hz), 2.74 (1H, ddd, *J*=13, 9, 4 Hz), 3.0—3.6 (3H, m), 3.80 (1H, dd, *J*=9, 7.5 Hz), 5.95 (4H, m), and 7.6—8.2 (4H, m). ν: 1680, 1600 cm^{-1}], colorless crystals; mp 87—88 °C; 81.2 mg (10%); **11** [Found: C, 81.48; H, 5.67%. ^{1}H NMR δ=1.87 (1H, br. d, *J*=13 Hz), 2.04 (1H, dtm, *J*=13, 6 Hz), 3.25 (2H, dd, *J*=7.5, 6 Hz), 3.74 (2H, br. s), 5.84 (2H, dt, *J*=12, 3.5 Hz), 6.0—6.2 (2H, m), 7.6—7.9 (2H, m), and 8.0—8.2 (2H, m). ^{13}C NMR δ=31.3, 44.0, 62.1, 125.1, 126.7, 133.9, 134.9, 136.8, and 195.8. ν: 1673, 1588 cm^{-1}], and yellow crystals; mp 160—162 °C; 35 mg (8%); **12** [Found: C, 82.14; H, 4.83%. Calcd for $C_{17}H_{12}O_2$: C, 82.24; H, 4.87%. ^{1}H NMR δ=1.69 (1H, d, *J*=12 Hz), 2.36 (1H, dtt, *J*=12, 7, 1.5 Hz), 3.98 (1H, t, *J*=7 Hz), 5.8—6.3 (4H, m), 7.6 (2H, m), and 8.2 (2H, m). ν: 1645, 1590, 1583 cm^{-1}], and recovered NQ, 260 mg.

Acid-catalyzed Rearrangement of 8. The photoadduct **8** (65.7 mg) was dissolved in EtOH (5 cm^3) containing concd

HCl (0.03 cm^3), after which the mixture was kept at room temperature for 22 h. Then, the mixture was poured into water and extracted with ether. After drying on $MgSO_4$, the extract was chromatographed on a silica-gel column with benzene to yield colorless plates; mp 129—130 °C; 15.4 mg (21%); **13** [Found: C, 81.79; H, 6.52%. Calcd for $C_{19}H_{18}O_2$: C, 81.98; H, 6.52%. ^1H NMR δ=1.47 (3H, t, J=7 Hz), 2.04 (1H, ddd, J=14, 2.5, 1 Hz), 2.68 (1H, ddd, J=14, 5.5, 4 Hz), 3.68 (1H, dddd, J=8.5, 5.5, 2, 1 Hz), 4.08 (2H, q, J=7 Hz), 5.14 (1H, m), 5.7—6.5 (4H, m), 6.40 (1H, s), and 7.2—8.2 (4H, m). ν: 1628, 1595 cm^{-1}].

Acid-catalyzed Rearrangement of 9. Similarly, an EtOH solution (5 cm^3) of **9** (36.1 mg) and concd HCl (0.03 mg) was refluxed to yield colorless crystals (mp 129—130 °C; 17 mg (42%)), which were identical in every respect with the sample of **13** obtained from **8**.

Photoreaction of Cycloheptene with NQ. An anhydrous benzene solution (10 cm^3) of cycloheptene (1.95 g) and NQ (1.58 g) was irradiated for 22.5 h. Silica-gel column chromatography of the reaction mixture afforded colorless crystals; mp 71.5—72 °C; 140 mg (11%); **15** [Found: C, 80.08; H, 7.08%. Calcd for $C_{17}H_{18}O_2$: C, 80.28; H, 7.13%. ^1H NMR δ=1.0—2.2 (10H, m), 2.4—2.9 (2H, m), 3.0—3.2 (2H, m), and 7.6—8.1 (4H, m). ν: 1680, 1595, 1295, 1280 cm^{-1}], and recovered NQ, 786 mg (50%).

Catalytic Reduction of 10. An MeOH solution (4 cm^3) of **10** (46.1 mg) was hydrogenated with PtO_2. The subsequent removal of the solvent left the octahydro derivative (**14**) of **10**; 46.8 mg (100%); colorless crystals; mp 248—250 °C [Found: C, 78.69; H, 8.67%. Calcd for $C_{17}H_{22}O_2$: C, 79.03, H, 8.58%. ν: 3420, 2940, 1460, 1325, 1040, 750 cm^{-1}].

Catalytic Reduction of 15. An MeOH solution (2 cm^3) of **15** (23 mg) was similarly hydrogenated with PtO_2. The product isolated consisted of colorless crystals (mp 248—250 °C, 22.1 mg (95%)), which were identical in every respect with the authentic **14**.

Dehydrogenation of 11 with DDQ. An MeOH solution (2 cm^3) of **11** (51.7 mg) was refluxed with DDQ (50.2 mg) for 2 h. After the solvent had been removed *in vacuo*, the residue was chromatographed on a silica-gel column to give colorless crystals (mp 158—160 °C; 40.1 mg (78%)), which were identical in every respect with **12**.

Photoreaction of 1 with CB. An anhydrous benzene solution of **1** (2 g) and CB (1.22 g) was irradiated for 3 h. The reaction mixture was then filtered to remove an insoluble solid, which consisted of recovered CB and its hydroquinone (1.04 g (85%)); the filtrate was then chromatographed on a silica-gel column to give **16** (33 mg; colorless plates; mp 62.5—63.5 °C), whose identity with an authentic sample (lit,[5] mp 64—67 °) was confirmed by direct comparisons.

Photovoltaic Properties of Coumarin Dye Films

Sei-ichiro IIJIMA,* Fumio MIZUTANI, and Yoshio TANAKA
Research Institute for Polymers and Textiles, 1-1-4 Yatabe-Higashi, Tsukuba, Ibaraki 305
(Received August 24, 1984)

Synopsis. Al/vacuum-deposited dye/Ag(or Au) photocells prepared by using four kinds of coumarin dyes indicate that a Schottky barrier formed at an Al/dye interface is the origin of their photovoltaic effects. Quantum yields of the short-circuit photocurrent of 0.05—0.77% and the photovoltages of 0.30—0.95 V were obtained under 0.1 mW/cm² light.

Highly fluorescent coumarin dyes have been frequently used in the studies of the electronic-energy transfer between organic molecules.[1,2] In photoelectric energy-conversion systems, interesting applications can be expected for such coumarin dyes as "antenna pigments" by utilizing their high-emission intensities. For example, Fromherz and Arden have reported[3] a pH-modulated "molecular device" consistig of coumarin monolayer/cyanine monolayer/indium-tin oxide. The photoelectric properties of coumarin dyes themselves, however, have not been investigated so far, although studies of the properties are necessary for further applications of the dyes in photoenergy conversion. We wish to report in this article that some of the coumarin derivatives used in dye lasers act as p-type semiconductors in the photocells of the Al/dye/Ag(or Au) configuration.

$COCH_3$ 4

The coumarin dyes **1**—**4** were purchased from Eastman Kodak and were used without further purification. The photocells were formed in the sandwich-type configuration: Al/dye film/Ag(or Au). First, the semitransparent electrode of Al was vacuum-deposited onto a glass substrate, and then the dye was evaporated onto the Al-coated substrate in a vacuum below 5×10^{-4} Pa by heating up to 200 °C. Finally, Ag(or Au) was deposited onto the organic layer to form an effective area of 0.5 cm². A 300-W xenon arc lamp equipped with an interference filter was used as the monochromatic light source. The cells were usually illuminated from the Al side except in the illuminating-direction experiment on the Al/dye **1**/Au cell. The photovoltaic parameters were determined for the photocells with dye-layer thicknesses of 0.1—0.3 μm. Reproducible results, little affected by the film thickness, were obtained in this thickness range.

The current-voltage curves of Al/3-(2-benzothiazolyl)-7-diethylaminocoumarin (**1**)/Ag are shown in Fig. 1 as typical examples. For all the photocells in the present work, the Al electrode always became negative against the Ag (or Au) electrode on illumination, and the dark current-voltage curves showed rectification in such a way that negative bias of Al was in a forward direction. This behavior indicates that the coumarin dyes are char-

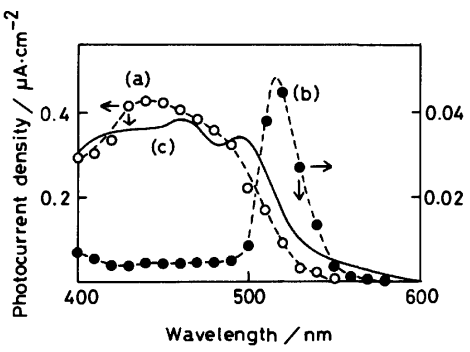

Fig. 2. Action spectra of short-circuit photocurrent for an Al/dye **1**/Ag cell and optical absorption spectrum of a dye **1** film. The values of photocurrent are corrected to the incident photon flux of 1×10^{15} photons/cm²·s.
(a) Action spectrum under the illumination from the Al side. (b) Action spectrum under the illumination from the Au side. (c) Absorption spectrum of a dye **1** film in an arbitrary unit.

acterized as p-type semiconductors forming a Schottky junction at the Al interface and an ohmic contact at the Ag(or Au) electrode. The existence of a photoactive region at the Al/dye interface was confirmed by an illuminating-direction experiment on an Al/dye **1**/Au cell (Fig. 2). The action spectrum of the short-circuit photocurrent obtained on illumination from the Al side resembled the optical-absorption spectrum of a vacuum-deposited **1** film (Fig. 2-(a)). On illumination from the Au side, on the other hand, an optical filtering effect of the dye phase[4] was observed (Fig. 2-(b)), indicating that the photons absorbed near the Al interface contribute mainly to the current generation.

The values of the open-circuit photovoltage (V_{oc}), the quantum yield of the short-circuit photocurrent (Φ_{sc}), and the photoenergy conversion efficiency (η) were determined under a monochromatic light at the peak-absorption wavelength of the dye film (Table 1). When measured, the fill factors were found to be around 0.25, almost independent of the dye structures. Among the four photocells of the Al/dye/Ag configuration, the cell using dye **2**, which has a carboxyl group at the 3-position of the coumarin ring, gave the best values of Φ_{sc} and η. This result is in accordance with the suggestion by Piechowski *et al.*[5] for merocyanine-based photocells that the strong adsorption of the electron-rich end of the dye molecule to Al_2O_3 layer forming over the Al surface is efficient in the cell performance. The comparison of the data for Al/dye **1**/Au with those for Al/dye **1**/Ag in Table 1, on the other hand, demonstrates that the cell performance is fairly much improved by the use of Au in place of Ag as the contact electrode. A tendency for a dye showing a higher fluorescence efficiency in solution to give a higher Φ_{sc} value has been pointed out for merocyanine-based photocells.[5] However, no such tendency was observed for the coumarin dyes.

Table 1. Photovoltaic parameters[a]

Photocell	V_{oc}/V	Φ_{sc}/%	η/%
Al/dye **1**/Ag	0.84	0.19	0.015
Al/dye **1**/Au	0.95	0.25	0.022
Al/dye **2**/Ag	0.49	0.77	0.033
Al/dye **3**/Ag	0.30	0.046	0.0012
Al/dye **4**/Ag	0.43	0.16	0.0058

a) Under a monochromatic light with an input intensity of 0.1 mW/cm^2. The wavelength of the light is 460 nm for Al/dye **1**/Ag and Al/dye **1**/Au, and 430 nm for the other photocells.

Studies of pH-modulated photoelectrodes utilizing the semiconductor characteristics of coumarin dyes themselves will be published elsewhere.[6]

(Received September 20, 1984)

Synopsis. Carbon-13 NMR data of 14 2-substituted thiophenes were obtained in $CDCl_3$. The correlation between the carbon chemical shifts and the Hammet constants was poor. The charge densities of typical compounds were calculated by the CNDO/2 method and they discussed in connection with the observed C-13 chemical shifts.

As an extension of our NMR studies of substituted thiophenes,[1-3] we have measured the C-13 NMR spectra of 14 2-substituted thiophenes and compared the data with those of the corresponding benzene derivatives.

Experimental

The C-13 NMR spectra were measured in a moderately concentrated solution (50 mg/0.8 ml) in $CDCl_3$ using a Varian XL-200 spectrometer with a frequency of 50.3 MHz. The chemical shifts were referred to an internal TMS signal. The compounds examined were prepared according to the methods previously reported in the literature. The chemical shifts and the coupling constants were obtained by the first-order analyses.

Results and Discussion

The C-13 chemical shifts and the one-bond carbon-proton coupling constants observed are tabulated in Tables 1 and 2, in which the values for monosubstituted benzenes, measured at a similar concentration (50 mg/0.8 ml) in $CDCl_3$, are also included for the sake of comparison. The values in Table 1 are almost entirely consistent with previously reported values in a pure liquid[1,2] and in an acetone solution.[4]

As may be seen in Table 1, the C_2 chemical-shift range (94 ppm) is rather wide as compared with those of the C_3 (34 ppm), the C_4 (5), and the C_5 (24). This indicates that, besides the inductive effect, the magnetic anisotropy effect of the substituent considerably affects the C_2 chemical shift, as has been pointed out previously for the monosubstituted benzenes.[5] The C_2, C_3, C_4, and C_5 shifts show parallel correlations with those of the C_{ipso}, C_o, C_m, and C_p of the corresponding monosubstituted benzenes respectively. The relation can be expressed by a simple equation as follows:

$$\delta(\mathrm{T}) = a \cdot \delta(\mathrm{B}) + b,$$

where δ(T) is a C-13 chemical shift of a thiophene derivative and δ(B) is that of the corresponding benzene. The correlation coefficients are 0.981, 0.871, and 0.935, and the proportional coefficients (a) are about 1.40, 1.62, and 1.42 for the C_2, C_3, and C_5 shifts respectively. Among the three, the C_3 shifts have the lowest correlation coefficient, because they suffer the so-called ortho-effect from their substituents. The C_5 shifts have a better correlation with the C_p shifts, for which the change was interpreted by the resonance effect of the substituents.[5] The C_4 shifts change little with the substituents and have no linear relation with the corresponding C_m shifts.

The electron densities of the carbons in the thiophenes have been calculated by the CNDO/2 method with or without d-orbitals.[6] The geometry of the thiophene skeleton was taken from a microwave geometry,[7] while those of the substituents were assumed to be the standard ones described previously.[8] Two planar geometries are considered in such

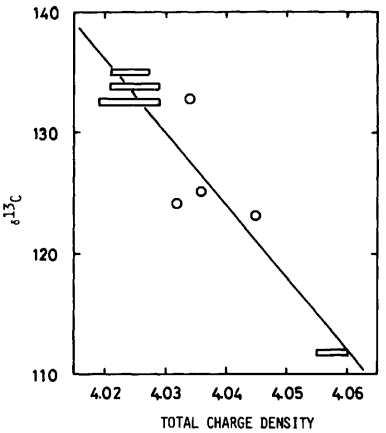

Fig. 1. Plot of C-13 chemical shifts in ppm (ordinate) *vs.* total charge densities (abscissa) for the C_5 of 2-substituted thiophenes.

cases as **2** where the orientation of the conjugated substituent can be in two ways on a molecular plane. Therefore, the results are shown by several sticks in Fig. 1 and are given in Table 3. The two ends of the stick in Fig. 1 correspond to the charge densities of the C_5 with two substituent orientations. Thus, the length of the stick shows the variation in the charge density dependent upon the conformation of the substituent. The proportionality coefficient of the C_5 shifts *vs.* their total charge densities is deduced to be −604 ppm/electron from Fig. 1 (r=0.93). As can be seen in Table 3, our calculation shows that the total charge densities increase at the C_α carbons and decrease at the C_β carbons when the d-orbitals are included in the calculation. Recently Osamura *et al.* pointed out the importance of the vacant d-orbitals of the sulfur atom.[9)]

As we have described before,[1)] the correlation between the C_5 shifts and the Hammet constants σ_p is not very good (r=0.85). The correlation with σ_p^+ seems to be better (r=0.90) than that with σ_p.[10)]

Influences of Supporting Silica Gel on the Catalytic Activity of B-18 Crown Ether-KCl Complex for the Selective Dehydrochlorination of 1,1,2-Trichloroethane

Hiroshi FUJITSU,* Takeshi TAKAGI,† and Isao MOCHIDA
Research Institute of Industrial Science
†*Department of Molecular Engineering, Graduate School of Engineering Sciences, Kyushu University, 86, Kasuga 816*
(Received November 10, 1984)

Synopsis. Catalytic dehydrochlorination of 1,1,2-trichloroethane into 1,1-dichloroethylene proceeded selectively around 200 °C over dibenzo-18-crown-6-KCl complex supported on silica gels. The reaction rate depended very much on the kinds of silica gel and impregnation levels of the complex, suggesting some roles of surface hydroxyl groups in this catalysis.

It has been established that basic substances promote the selective dehydrochlorination of 1,1,2-trichloroethane (TCE) into 1,1-dichloroethylene (1,1-DCE), whereas acidic ones promotes the formation of 1,2-dichloroethylene (1,2-DCE).[1] The selective synthesis of 1,1-DCE from TCE with recovery of dry hydrogen chloride is the most desirable process for the practical purpose; however, basic substances such as KOH react with hydrogen chloride eliminated to form the corresponding salts, proceeding the reaction stoichiometrically.

ICI patent claims the catalysis by CsCl on silica gel.[2] We reported previously some acid-proof basic catalysts,[3-5] such as hydrochlorinated 2-methylimidazole immobilized on silica gel. These catalysts exhibited high selectivity but low activity.

Naso and Ronzini,[6] and Viout[7] have reported the activity of crown ether-alkali halide complexes for the elimination and substitution reaction of alkyl and alkenyl halides. Mizuno *et al.*[8] reported the reactivity of alkyl halides over a complex (KCl-B18) supported on silica gel.

We report here the catalytic activity of the crown ether-potassium chloride complex supported on some silica gels. The liberation of hydrogen chloride can be expected rapid when a crown ether and a halide are properly selected. Nevertheless the elimination efficiency of the complex may also depend on the surface properties of silica gel, since hydrogen chloride produced inevitably interacts which the functional groups of the surface.

Experimental

Crown ether (dibenzo-18-crown-6:B-18) were purchased from Nippon Soda Co. Used silica gels were C-200 (650 m^2/g, Wako Junyaku Co.), MB-3A and MB-4A (500 and 260 m^2/g, respectively, Fuji-Davison Inc.). The catalyst was prepared by repeated impregnation (three times) of crown ether-KCl complex on to the silica gel from its methanol solution.

The dehydrochlorination of TCE was studied with a micro-catalytic gas chromatographic pulse technique.[9] The catalyst (1 g) was packed in a glass U tube and 2 μl of TCE was injected with a microsyringe after the hydrogen gas flow for 2 h at the reaction temperature.

Results

Catalytic activity of KCl-B18 supported on MB-3A (KCl-B18/MB-3A) in the successive pulses at several reaction temperatures is shown in Fig. 1. A very high conversion (94%) was observed in the first pulse at 250 °C, however the conversion decreased sharply with repeated pulses, reaching a constant value of conversion (25%) after the 7th pulse. Injection of 100 μl methanol after the 7th pulse recovered the conversion of 8th pulse to the level of 5th pulse, and its another injection maintained the conversion in the successive pulse. Lower reaction temperatures (200 or 220 °C) decreased the conversion in the first pulse (20 and 40%, respectively) as well as the extent of activity decrease with the repeated pulse. Remarkably high selectivities for 1,1-DCE formation over 90% were obtained at all reaction temperatures examined. Under the present reaction conditions, KCl supported alone on the silica gel (KCl 10%, 1 g) showed a very low activity (conversion in the first pulse: 9%), suggesting that KCl-B18 is the catalytic active species.

Catalytic activity of KCl-B18/MB-3A depended markedly on the loading levels of KCl-B18. The conversion in the first pulse increased considerably until

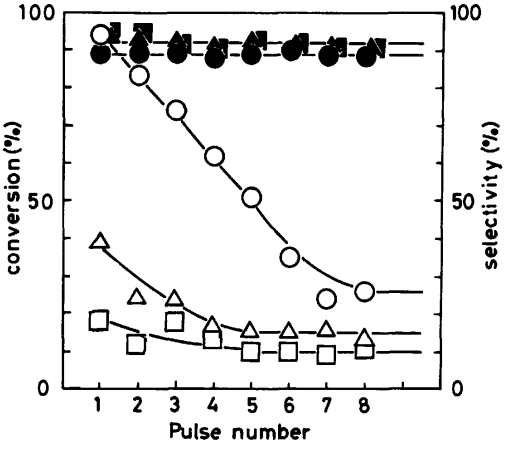

Fig. 1. Dehydrochlorination of TCE over KCl-B18/MB-3A cat. (loading level 19 wt%): 1 g, pulse size: 2 μl
○,●: React. temp: 250 °C, △,▲: react. temp: 220 °C, □,■: react. temp: 200 °C.
Open: conversion, closed: selectivity for 1,1-DCE formation, pulse interval was 1 h.

Table 1. Dehydrochlorination of TCE in the first pulse over KCl-B18 supported on several silica gels[a)]

Support	Conv./%	Selectivity/%	
		1,1-DCE	1,2-DCE
C-200	17	92	8
MB-3A	94	90	10
MB-4B	56	91	9

a) Catalyst (19 wt%): 1 g, react temp: 250 °C, pulse size: 2 μl.

the loading level reached 19 wt%, where the maximum value (94% conversion) was observed. More loading decreased the conversion which was as low as 43% at 37% loading. In contrast, the selectivity for 1,1-DCE formation was independent of the loading level.

Catalytic activities and selectivities of KCl-B18 supported on some silica gels in the first pulse are summarized in Table 1. Catalytic activity depended remarkably on the kind of supports, whereas selectivities were independently high. The activity order was as follows: MB-3A>MB-4B>C-200. The activity of MB-3A supporting catalyst was almost 5 times that of C-200 supporting one. Such a difference is much larger than that expected from their surface areas, suggesting positive roles of silica gels in this catalysis.

The amount of B-18 remaining on the gel after the 9th pulse determined by extracting the complex with methanol was 40% of originally supported one. Thermogravimetric measurements revealed that 78% of KCl-B18 remained on the silica surface at 250 °C without the dehydrochlorination reaction. These results suggest that the sublimation of B-18 accelerated by hydrogen chloride as well as the slow rate of hydrogen chloride release from the catalyst surface cause the significant decrease of activity in the repeated pulses.

Catalytic activity of KCl-B18/MB-3A was examined using a flow reactor (TCE: 3.5 kPa, catalysts (loading: 10%): 1 g, H_2 carrier: 60 $cm^3 \cdot min^{-1}$). The conversion of TCE was 13% at 250 °C in initial few minutes and then decreased very slowly to *ca.* 5% within 10 h. The total turnover number (reacted TCE/KCl-B18 in moles) reached more than 20 within 10 h at 250 °C. The selectivity for 1.1-DCE was constant to be *ca.* 90% throughout the reaction.

Discussion

Active species of KCl-crown ether complex supported on SiO_2 is assumed to its naked Cl^- ion,[6,8] which can abstract first the most acidic proton from TCE to be liberated as hydrogen chloride. The intermediate trichloroethanide anion is selectively converted into 1,1-DCE and may regenerate the active species by providing Cl^-.

According to the mechanism described, the stable activity may be expected, when no sublimation of the crown ether takes place. However, the activity decreased by the repeated pulses. Its recovery by methanol injection or lower activity in the flow reactor may suggest that the desorption of produced hydrogen chloride from the catalyst surface influences the activity. Marked variation of the activity in the first pulse due to silica gel supports also may indicate their significant roles in the elimination of hydrogen chloride as well as the better dispersion of KCl-crown ether complex on their surface. Such roles of silica gel support have been scarecely discussed.[10] The surface hydroxyl groups which can interact the chloride at the elimination stage may be the origin for these roles.

(Received July 31, 1984)

Synopsis. The title complex was prepared at pH 4.0. The crystal and molecular structures have been determined by X-ray diffraction. The crystals of $ZnCl_2(C_5H_9NO_2)_2$, F.W.=366.55, were orthorhombic: space group $P2_12_12_1$, a=13.527(3), b=16.263(3), c=6.598(1) Å, U=1451.4(5) Å^3, Z=4, D_m=1.67 g cm^{-3}, D_x=1.68 g cm^{-3}, and μ(Mo $K\alpha$)=21.2 cm^{-1}. The zinc atom is coordinated in a tetrahedral geometry to two chlorine atoms and the two carboxyl oxygen atoms of two L-proline ligands. Each L-proline is coordinated as a monodentate ligand.

The various coordination types of amino acid complexes are important for the discussion of the different metal-binding site models on proteins. Many complexes should be prepared under different conditions. However, most of the complexes with amino acids have been prepared under neutral or basic conditions. Therefore, we tried to prepare amino acid complexes at low pH, in order to study different coordination types from ones under neutral or basic conditions. In this work, as part of the program, a zinc complex of L-proline (Hpro) was prepared at low pH and the structure was determined in order to compare it with the cadmium complexes having analogous amino acid ligands.[1,2]

Experimental

Preparation of Dichlorobis(L-proline)zinc(II). To an aqueous solution of 4.61 g (0.04 mol) of Hpro, 2.73 g (0.02 mol) of $ZnCl_2$ was added. Then the solution (pH 4.0) was stirred for several hours on a water bath at 50—60 °C. Clear colorless prisms were obtained by standing at room temperature; they were air-dried. Found: C, 32.50; H, 4.90; N, 7.50; Zn, 17.7%. Calcd for $ZnCl_2(C_5H_9NO_2)_2$: C, 32.76; H, 4.96; N, 7.74; Zn, 17.84%. An almost quantitative yield of the complex was obtained.

X-Ray Measurements. The reflection intensities were collected by the θ—2θ scan technique ($2\theta \leqq 60°$) on a Philips PW1100 automated four-circle diffractometer. The intensities ($|F_o| \geqq 3\sigma(|F_o|)$) were corrected for Lorentz and polarization factors, but not for absorption, because of the low magnitude of μr (=0.25). All calculations were carried out on a HITAC M-280H computer at the Computer Center of The University of Tokyo, using the local version of UNICS.[3] The scattering factors were taken from tables.[4]

Structure Determination. The structure was solved by a heavy-atom method and refined by a block-diagonal least-squares method. The weighting scheme was $W=1/[\{\sigma(|F_o|)\}^2+(0.045\times|F_o|)^2)$. The final R value[5] was 0.035, with anisotropic temperature factors for all the non-hydrogen atoms.

Results and Discussion

The final atomic coordinates and the equivalent isotropic temperature factors, except for those of calculated hydrogen atoms, are shown in Table 1. The bond lengths and bond angles are in Table 2.[6]

C(A4)	4489(5)	740(4)	−438(8)	4.97
C(A5)	4664(4)	−49(3)	664(8)	4.19
O(B1)	1230(2)	2646(2)	−405(5)	3.47
O(B2)	1879(3)	1661(2)	−2338(6)	3.75
N(B)	2788(2)	2733(2)	−4826(6)	2.78
C(B1)	1772(3)	2377(3)	−4826(6)	2.69
C(B2)	2396(3)	3034(2)	−2825(7)	2.58
C(B3)	1895(4)	3842(2)	−3334(9)	3.75
C(B4)	2496(4)	4165(3)	−5103(11)	4.93
C(B5)	2703(4)	3415(3)	−6360(8)	4.40

a) The equivalent isotropic temperature factors were computed using the following expression: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2)$. The B_{ij}'s are defined by: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})]$.

A perspective drawing of the complex, with the numbering scheme, is shown in Fig. 1 and the crystal packing diagram in Fig. 2.

As shown in Fig. 1, the zinc atom is coordinated in a tetrahedral geometry to two chlorine atoms and two carboxyl oxygen atoms of two L-proline ligands: each of them is a zwitter ion. The angles around the zinc atom are not exactly tetrahedral angles, as shown in Table 2.

The nitrogen atom, N(A), is associated with two intermolecular hydrogen bonds, N(A)···O(A2)^{I} (2.856(6) Å) and N(A)···O(B2)^{I} (2.815(5) Å), as shown in Fig. 2. On the other hand, N(B) seems to connect only with Cl(2)^{II} *via* a hydrogen bond (N(B)···Cl(2)^{II}; 3.145(5) Å).[7] The difference of the intermolecular hydrogen bonds reflects the difference of the shapes of the two pyrrolidine rings. By these intermolecular hydrogen bonds, the complex molecules are connected to each other in three dimensions.

The system is different from those of $CdCl_2$(Hhpro) and $CdCl_2$(Hpro)·H_2O.[1,2] Both consist of one-dimensional polymers bridged by chlorine atoms and a carboxyl group, and the ligand 4-hydroxy-L-proline (Hhpro) or Hpro is coordinated to the metal with only carboxyl oxygen atoms as a zwitter ion. The polymers are aligned in parallel by hydrogen bonds or van der Waals' contacts in the crystals.

C(A3)-C(A4)-C(A5)	105.5(5)	C(B3)-C(B4)-C(B5)	104.1(4)
C(A4)-C(A5)-N(A)	104.3(4)	C(B4)-C(B5)-N(B)	104.0(4)

The difference of the crystal structures results from the halogeno zinc or cadmium complexes retaining the traces of the zinc or cadmium halide: zinc and cadmium chlorides consist of $ZnCl_4$ tetrahedra and $CdCl_6$ octahedra, respectively. In aqueous solutions of cadmium halides, there are significant amounts of the undissociated halides and polymeric species, as is well known.

The authors wish to express their thanks to Professor Yoichi Iitaka of The University of Tokyo for the collection of the intensity data. They would also like to thank Dr. F. S. Howell of Sophia University for correcting this manuscript.

(Received November 7, 1984)

Synopsis. The title complex has been synthesized, and its crystals and molecular structure has been determined by the use of the single-crystal X-ray-diffraction method. The crystal of $Nd_2C_{60}H_{138}O_{15}P_6S_{15}$, F. W.=2055.03, was monoclinic, with a space group of An; a=23.696(4), b=23.466(4), c=20.208(4) Å, β=111.22(2)°, Z=4, V=10475(4) Å^3, D_m=1.30(3), D_x=1.30 Mg m^{-3}, and μ(Mo $K\alpha$)=1.41 mm^{-1}. The complex consists of cationic and anionic species, as is shown in the title. The metal atom of the cationic complex is hepta-coordinated and is in a pentagonal-bipyramidal geometry, while the anionic one is octa-coordinated and is in a dodecahedral geometry.

In previous papers, we reported the syntheses and the structure determination of several *O,O'*-diisopropyl dithiophosphate (iPr_2dtp)—Lewis base mixed complexes.[1-4] One of them, $[Eu(iPr_2dtp)_2(dmso)_3][Eu(iPr_2dtp)_4]$ (**1**) (where dmso=dimethyl sulfoxide),[4] consists of a cationic complex and an anionic complex. We tried to obtain the same types of complexes from some other ligands, and found from its elemental analysis, that the title one could be expected to have that structure. However, as the ligand size of the title complex is much larger than that of **1**, it might have a structure different from that of **1**. Therefore, we determined its structure by the single-crystal X-ray-diffraction method.

Experimental

Synthesis of $[Nd(iPr_2dtp)_2(dbso)_3][Nd(iPr_2dtp)_4]$ (where dbso=Dibutyl Sulfoxide). Neodymium(III) chloride hexahydrate (0.59 g, 1.6 mmol) and $Na(iPr_2dtp)$ (1.7 g, 7.1 mmol) were added to 35 cm^3 of 2-propanol, and the mixture was refluxed for 20 min. After cooling, the residue was filtered off, and to the filtrate dbso (0.76 g, 5.0 mmol) was added. The solution was then refluxed for 10 min at about 65 °C and concentrated to about 7 cm^3 by the use of a vacuum rotary evaporator at about 60 °C, after which the solution was left standing in a refrigerator (about 5 °C) several days. Pure crystals appeared. Yield, 0.29 g (17%). The isomorphous europium(III) complex, $[Eu(iPr_2dtp)_2(dbso)_3][Eu(iPr_2dtp)_4]$ (**2**), was also obtained in the same way. Anal. ($M_2C_{60}H_{138}O_{15}P_6S_{15}$) M, C, H, S. (where M=Nd or Eu)

From lanthanum(III) chloride another type of complex, one with the formula of $La(iPr_2dtp)_3(dbso)_2$, was obtained. Anal. ($LaC_{34}H_{78}O_8P_3S_8$) La, C, H.

Single-crystal X-Ray Analysis. A crystal 0.3×0.3×0.25 mm^3 in size (all the edges were cut off, and it was shaped almost into a sphere) was used. The reflections within the range of 3°<2θ<55° were collected on a Rigaku AFC-6A four-circle automated X-ray diffractometer, with graphite-monochromated Mo $K\alpha$ radiation (scan speed, 4° min^{-1}) by means of the ω-scan technique. Of the 9536 reflections measured, 4674 reflections with $|F_o|>3\sigma(|F_o|)$ were used for the refinement. The intensities were corrected for the Lorentz and polarization factors, but no correction was made for the absorption and extinction. All the calculations were carried out on a HITAC M-280H computer at the Computer Center of The University of Tokyo, using the local version of the UNICS.[5] The scattering factors were taken from the tables.[6]

The structure was solved by the heavy-atom method. Although those of the central metal atoms and the neighboring atoms were exactly determined, those of the butyl and isopropyl carbon atoms were found to have relatively large standard deviations, even after repeated refinements, probably because they are not fixed tightly in the crystal, as in cases of the other adducts of the lanthanoid *O,O'*-dialkyl dithiophosphates.[1-4,7] The positions of six carbon atoms, C(9), C(11), C(103), C(123), C(124), and C(128), were fixed to the respective most probable positions. The position of a dbso sulfur atom, S(10), was divided into two; the occupancy factors of S(10A) and S(10B) are 53 and 47% respectively. The final R value was 0.055[8] reached by applying anisotropic temperature factors for all the atoms except the fixed ones.

The Measurement of the Visible Absorption Spectra. The visible absorption spectra were measured with a Hitachi 124 spectrophotometer, using an acetonitrile solution of the complexes (1.0×10^{-3}—10^{-2} mol dm^{-3} in concentration).

Results and Discussion

Selected bond lengths and bond angles are given in Table 1.[9] Perspective drawings of the cationic (**3**) and the anionic (**4**) complexes, along with the num-

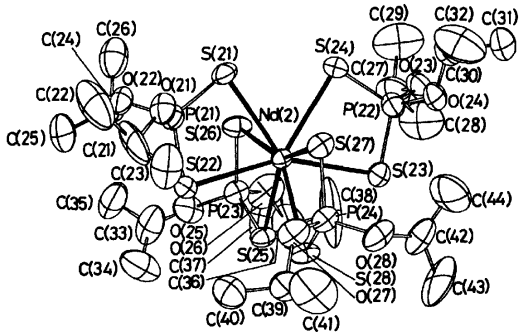

Fig. 2. A perspective drawing of $[Nd(iPr_2dtp)_4]^-$ and the numbering scheme.

bering scheme, are shown in Figs. 1 (for **3**) and 2 (for **4**),[9]

In **3**, $[Nd(iPr_2dtp)_2(dbso)_3]^+$, the neodymium(III) atom is hepta-coordinated and is in a pentagonal-bipyramidal configuration. Four sulfur atoms of two iPr_2dtp ligands, as well as one oxygen atom of a dbso ligand, bond equatorially, and two oxygen atoms of the dbso ligands are coordinated from the two ends of the axis. The average positional deviation of the central metal and the ligating four sulfur and one oxygen atoms from the average pentagon plane is 0.156 Å (the maximum deviation is 0.283 Å for S(14)). The angles between the average pentagon plane and the axis, O(101)-Nd(1) and O(102)-Nd(1), are 84.5 and 87.3 ° respectively.

In **4**, $[Nd(iPr_2dtp)_4]^-$, the central metal atom is octa-coordinated and is in a dodecahedral geometry. Each iPr_2dtp ligand spans an *m*-edge coordinated through both sulfur atoms.[9] The atomic positional deviations of the central metal and ligated sulfur atoms from their average trapezium plane are 0.055 Å on the average (0.097 Å at the maximum for S(28)). The dihedral angle between the two trapezia is 88.0 °.

Therefore, both **3** and **4** are in about the same type of configuration as those of **1**, although **3** and **4** are a little more deviated from the ideal forms than the respective ions of **1**.

The acetonitrile solution of **2** shows a charge-transfer band. The wavelength and the absorption coefficient of the absorption maximum are 410 nm and 1.8×10^2 dm^3 mol(Eu)$^{-1}$ cm^{-1}. These values are almost the same as those of **1**; the absorption coefficient is about one-half of the value of a neutral complex such as $Eu(iPr_2dtp)_3(bza)_2$ (bza=benzamide, $\varepsilon_{max}=4.2\times10^2$ dm^3 mol(Eu)$^{-1}$ cm^{-1}.[1])

The authors are greatly obliged to the Shin-Etsu Chemical Ind. Co., Ltd., for aiding this study by presenting highly pure lanthanoid oxides. The present work was supported partially by a Grant-in-Aid for Scientific Research (No. 57430011) from the Ministry of Education, Science, and Culture.

Cobalt(III) Complexes with Quadridentate Ligands. VI.[1] The Preparation and Properties of "*cis*-β_1 and β_2"-Isomers of the Salicylaldehydato(triethylenetetramine)-cobalt(III) Complex

Yoshihisa YAMAMOTO,* Eiko TOYOTA, and Shoko TSUKUDA
Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02
(Received November 13, 1984)

Synopsis *cis*-β_1 and β_2-Salicylaldehydato(triethylenetetramine)cobalt(III) chloride dihydrate have been isolated from a reaction mixture of salicylaldehyde, *cis*-α or β-dichloro(triethylenetetramine)cobalt(III) chloride and Ag_2O. The IR spectra of the complexes showed four strong absorption peaks in the 990—1100 cm^{-1} region. The complexes were assigned to the β-form. Their *cis*-β_1 and *cis*-β_2 configurations have been established by their ^1H NMR spectra.

Previously, we have been concerned with the preparation and properties of isomers of the mixed-ligand complexes of *cis*-β_1, β_2-salicylato(quadridentate amine)cobalt(III) chloride hydrates,[2,3] [Co(sal)L]Cl·$n$$H_2O$ (L: 2,2,2-tet; 2,3,2-tet; 3,2,3-tet; 3,3,3-tet. The abbreviation, tet, means tetramin; *e.g.*, triethylenetetramine is abbreviated to 2,2,2-tet). The preparation of the mixed-ligand metal complexes with salicylaldehydato and amine ligands had been very difficult, because the metal complexes with Schiff base ligands[4] had been obtained, such as (*N,N'*-disalicylidene-substituted triethylenetetramine)metal complexes in an octahedral configuration and (*N,N'*-disalicylidenepolymethylenediamine)metal complexes in a planar configuration. Thus, very little was known regarding the preparation and properties of aldehydato metal complexes with amine ligands in contrast with the large amount of information regarding salicylato metal complexes[1-3,5] with amine ligands. The present paper deals with the preparation and properties of the mixed-ligand cobalt(III) complexes with salicylaldehydato and triethylenetetramine ligands and deals with the assignments of the configuration of *cis*-β_1 and β_2 isomers.

Results and Discussion

A mixture of *cis*-β_1 and β_2-salicylaldehydato(triethylenetetramine)cobalt(III) chloride dihydrate has been isolated from a reaction mixture of *cis*-α or β-[$CoCl_2$trien]Cl, Ag_2O, and salicylaldehyde. The separation of the *cis*-β_1 isomer (complex **1**) and the *cis*-β_2 isomer (complex **2**, Fig. 1) was attempted using an ion-exchange resin. The *cis*-α isomer could not be obtained.

The electric conductivities of **1** and **2** in aqueous solutions were about 210 S cm^2 $equiv^{-1}$. The IR spectra of **1** and **2** showed four strong peaks in the 990—1100 cm^{-1} region (*cf.* Experimental section) and five peaks in the 3000—3300 cm^{-1} region. Thus, complexes **1** and **2** were assigned to the *cis*-β configuration.[6] The electronic absorption spectrum of **1** is very similar to that of **2**. The absorption bands at 420 and 510 nm were assigned to the charge-transfer band and the first d-d absorption band ($^1T_{1g} \leftarrow {}^1A_{1g}$), respectively. In the ^1H NMR spectra, the lowest field signals at δ 8.5—8.6 were assigned to the aldehyde group protons,[7] and the signals at δ 2.3—3.6 and 4.3—6.7 were assigned to the methylene protons[2] and the amine protons[2] of the coordinated triethylenetetramine ligand (abbreviation: trien ligand), respectively. The methylene proton signals at δ 2.4—2.8 and 2.8—3.6 of **2** were assigned to the NH_2-side and NH-side methylene protons,[3] respectively. The color, solubility, IR, ^{13}C and electronic absorption spectra of **1** were similar to those of **2**.

A clear distinction between **1** and **2** complexes was found in the ^1H NMR spectra. The chemical shift (δ=4.30) of the proton signal of the N(1)H_2 group of the coordinated trien of **2** was at a higher field than that (δ=4.40) of **1** as shown in Table 1.

Therefore, the N(1)H_2 group of **2** is considered to be at a position *trans*[2] to the phenoxyl oxygen of the salicylaldehydato ligand, which is more electronegative than the aldehyde group oxygen.

In addition, the methylene proton signal of **2** was separated to two group signals at δ 2.3—2.7 and 2.7—3.6, and their intensity ratio was 2:10, *i.e.*, two protons of the NH_2-side methylene protons at δ 2.4—

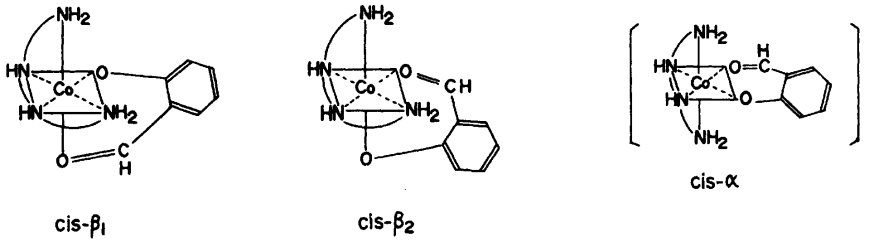

Fig. 1. The α, β_1, and β_2 configurations of salicylaldehydato(triethylenetetramine)cobalt(III) complex.

Table 1. ^1H, ^{13}C NMR and absorption spectra of complexes **1** and **2**.

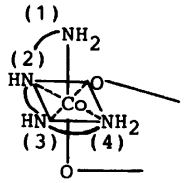
2[c]	42.4	47.6	48.7	50.2	52.2	53.0	120.1	170.0	118.1	141.2	124.4	137.4	196.2[b]



Solvent and Standard: a) 1.8 mol dm^{-3} D_2SO_4, internal DSS (δ=0), b) D_2O, internal dioxane (δ=67.4). c) *cf.* Ref. 3, 8 and 9.

2.8 overlap to the NH-side methylene protons at δ 2.8—3.6. While, the methylene proton signal of **1** was not separated to the two group signals. These properties are similar to those of the *cis*-β_2-salicylato-(quadridentate amine)cobalt(III) chloride hydrate,[2,3] *cis*-β_2-[Co(sal)L]Cl·nH_2O. Thus, the configurations of complexes **2** and **1** have been assigned to *cis*-β_2 and β_1, respectively.

Experimental

Measurements. The NMR spectra were recorded with an FX-60 spectrometer (JEOL) for ^{13}C NMR and with an R-40 apparatus (Hitachi) for ^1H NMR. The IR spectra were recorded over potassium bromide disks with a 270—30 spectrophotometer (Hitachi). The visible absorption spectra were recorded with a Shimadzu UV-210 recording spectrophotometer. The electric conductivities of an aqueous solution were determined by the use of a conductometric meter, CM-30 (Shimadzu), at room temperature.

Preparation of Complexes. Mixture of cis-β-*Salicylaldehydato(triethylenetetramine)cobalt(III) Chloride Dihydrate (1 and 2) and* cis-β-*Salicylato(triethylenetetramine)cobalt(III) Chloride Hydrate (3)*: *cis*-α or β-Dichloro(trien)cobalt(III) chloride (6.0 g, 19.26 mmol) was added to moistend fresh Ag_2O, which was made from silver nitrate (6.54 g, 38.50 mmol) and potassium hydroxide (2.16 g, 38.5 mmol). The mixture was stirred for several minutes at room temperature and then for about 40 min at 60 °C. The precipitated silver chloride was filtered off. The methanol solution (20 cm^3) of salicylaldehyde (2.36 g, 19.32 mmol) was added, drop by drop, to the reddish-violet filtrate. The solution was stirred at room temperature for 50 h and was then concentrated on a rotary evaporator. Then the concentrated solution was injected into a column chromatograph on alumina. On elution of methanol or ethanol, the eluent of the first red band was collected and concentrated. The purification was achieved by a column of ion-exchange resin (SP-Sephadex C-25, Na^+ form, 2.5×60 cm). On elution with 0.2 mol dm^{-3} NaCl, the first russet band was assigned to the *cis*-β-salicylato(trien)cobalt(III) chloride hydrate (**3**), and the second orange band (of complexes **1** and **2**) was collected and concentrated on a rotary evaporator. The precipitated NaCl was removed by filtration. Yields: Orange complexes **1** and **2**: 3.2 g (38.4%); russet complex **3**: 1.4 g (18.4%).

Separation of cis-β_1-*Salicylaldehydato(triethylenetetramine)-cobalt(III) Chloride Dihydrate (1) and* cis-β_2-*Salicylaldehydato-(triethylenetetramine)cobalt(III) Chloride Dihydrate (2)*: The separation of complexes **1** and **2** from the orange complex of 0.5 g was achieved by a column of ion-exchange resin (SP-Sephadex C-25, Na^+ form, 2.5×100 cm). On elution with 0.1 mol dm^{-3} NaCl, the effluent of the first orange band (complex **2**) and the second orange band (complex **1**) was collected and concentrated on a rotary evaporator, and the precipitated NaCl was removed by filtration. Yields: 0.13 g for **1**, 0.14 g for **2**. Found **1**: C, 35.90; H, 5.95; N, 12.68; Cl, 15.91%. **2**: C, 36.26; H, 6.52; N, 12.85; Cl, 16.01%. Calcd for $CoC_{13}H_{27}N_4O_4Cl_2$ (MW 433.22) C, 36.04; H, 6.28; N, 12.93; Cl, 16.37%. Dp: 187—189 °C for **1**; 184—185 °C for **2**. Λ=222 for **1**, 213 S cm^2 $equiv^{-1}$ for **2** in water. IR spectra **1**: 1002, 1032, 1059, and 1083 cm^{-1}; 3058, 3100, 3120, 3180, and 3210 cm^{-1}. **2**: 1002, 1035, 1059, and 1080 cm^{-1}; 3082, 3100, 3120, 3190, and 3200 cm^{-1}. Complexes **1** and **2** are very soluble in alcohols, dimethyl sulfoxide, and water, but insoluble in acetone and ether. Both complexes are highly hygroscopic.

Biaryl Formation in the Copper(I) Mediated Arylation of Stable Enolate Anions with *o*-Halogenonitrobenzenes

Singanallore V. THIRUVIKRAMAN and Hitomi SUZUKI*
Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790
(Received July 16, 1984)

Synopsis. *o*-Bromo- and *o*-iodonitrobenzenes react with stable enolate anions in hot DMF in the presence of copper(I) iodide, to afford not the expected arylation products but the coupling products, 2,2′-dinitrobiphenyls.

When heated in aprotic dipolar solvents such as DMF and HMPA in the presence of copper(I) iodide, nonactivated aromatic halides are activated to such an extent as to react with a variety of heteronucleophiles[1-7] and enolate anions,[8-11] giving the corresponding arylation products in good to moderate yields. However, moderately activated aryl halides such as halogenonitrobenzenes (**1**) behave differently from nonactivated ones to afford, in addition to the normal substitution product (**2**), significant amounts of *N*,*N*-dimethylanilines (**3**) and/or nitrobenzenes (**4**). Aryl-aryl coupling to form dinitrobiphenyls (**6**) is yet another unexpected pathway in the reaction of halogenonitrobenzenes, and is described herein.

Our attempts to prepare 2-(2-nitrophenyl)-3-oxobutanoate esters (**7**) as intermediates for the synthesis of heterocycles, by reacting *o*-bromo- or *o*-iodonitrobenzenes (**5**) with 3-oxobutanoate (acetoacetate) anion in the presence of copper(I) iodide in DMF at 100—120 °C, gave instead 2,2′-dinitrobiphenyls (**6a—6h**) as products. Table 1 lists several biphenyls obtained; in majority of cases their formation was achieved in good yields. The structures of all biphenyls were established by their elemental analyses, IR and ^{1}H NMR spectra, and agreement of their mps with those reported in literature. The effect of various enolate anions on the formation of dinitrobiphenyls is shown in Table 2. Also the role of enolate anion and copper(I) iodide is illustrated in Table 3.

Unlike the above cases, *m*-iodo- and *o*-chloronitrobenzenes suffered extensive reductive dehalogenation under similar conditions to give nitrobenzene as major product. Also *p*-iodonitrobenzene gave a mixture of ethyl 2-(4-nitrophenyl)-3-oxobutanoate and nitrobenzene accompained by a small amount of 4,4′-dinitrobiphenyl. Highly activated aromatic halides such as 2,4-dinitrochlorobenzene and 2,6- dinitroiodobenzene underwent normal S_NAr reaction without yielding any biphenyls.

As regards the mechanism which operates in the biphenyl formation, we withhold any comment at present, although it bears many features suggesting the involvement of electron transfer process.[12]

Experimental

*Reaction of o-Iodonitrobenzene (**5a**).* Sodium hydride (0.04 g, 1 mmol; 60% suspension in paraffin oil) was placed in a 25 ml flask and triturated with dry hexane. The oil-free grey solid was then covered with DMF (0.73 g, 10 mmol), and ethyl 3-oxobutanoate (0.065 g, 0.5 mmol) was added with stirring. After several minutes when hydrogen evolution ceased, copper(I) iodide (0.18 g, 1 mmol) was added to the resultant yellow solution. The solution

a) Reaction conditions: Substrate **5a** 1.0 mmol, NaH 1.0 mmol, and DMF 10 mmol; reaction time 5—6 h. Yields refer to the isolated ones.

changed to orange color, and later to brown when *o*-iodonitrobenzene (0.249 g, 1 mmol) was added. The mixture was heated gradually to 100 °C and the progress of reaction was monitored by TLC. After 4 h the mixture was allowed to cool, poured into water (10 ml), and acidified to pH 5—6, and extracted twice with ether (2×15 ml). The combined extracts were washed with water, dried, and evaporated to yield crude 2,2'-dinitrobiphenyl (**6a**) as a pasty solid. It was purified by column chromatography over silica gel, followed by recrystallization from benzene/hexane to give yellow crystals of the product. Yield, 0.09 g (75%). Mp 123—124 °C (lit,[13] mp 123.5—124.5 °C).

Reaction of p-*Iodonitrobenzene.* The reaction was carried out at 140 °C using the same ratio of substrate, nucleophile, catalyst and solvent, as described above. After 4 h, when the reaction was over, the mixture was worked up as usual. The oily product obtained after removal of solvent consisted of three components as revealed by TLC. They were separated by column chromatography over silica gel to give nitrobenzene (0.037 g, 30%); 4,4'-dinitrobiphenyl (0.005 g, 4%), white solid melting at 238 °C (lit,[14] 237 °C); and ethyl 2-(4-nitrophenyl)-3-oxobutanoate[15] (0.10 g, 40%), yellow oil.

Reaction of 2, 4-Dinitrochlorobenzene. The reaction was carried out by stirring a mixture of halide (0.20 g, 1 mmol), sodium hydride (0.04 g, 1 mmol), keto ester (0.13 g, 1 mmol), copper(I) iodide (0.19 g, 1 mmol), and DMF (0.73 g, 10 mmol) at 60 °C for 3 h, and the reaction mixture was worked up as usual. The crude product obtained was further purified by column chromatography over silica gel to give ethyl 2-(2,4-dinitrophenyl)-3-oxobutanoate as pale yellow crystals. Yield, 0.266 g (90%). Mp 93—94 °C (lit,[16] mp 93—94 °C).

Utilization of "2-Pyrrolidone Hydrotribromide" in the Synthesis of Flavones

Noboru TAKENO, Tohoru FUKUSHIMA, Shin-ichi TAKEDA,* and Kazuyasu KISHIMOTO†
Department of Industrial Chemistry, Muroran Institute of Technology, Muroran, Hokkaido 050
(Received October 13, 1984)

Synopsis. The reaction of flavanone with "2-pyrrolidone hydrotribromide" in tetrahydrofuran gave 3-bromoflavanone in a good yield. On the other hand, flavone was obtained in 97% yield when this reaction was carried out in dimethyl sulfoxide at 80 °C. Under the same conditions, most flavones were obtained from the corresponding flavanones in high purity and good yields.

The most commonly used methods for the synthesis of flavones are the acid-catalyzed cyclodehydration of 1-(*o*-hydroxyphenyl)-1,3-diketone derivatives[1] and the dehydrogenation of flavanones by selenium dioxide,[2] phosphorus pentachloride,[3] and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.[4] Flavanones also can be converted into the corresponding flavones by bromination at the C_3 position, followed by the base-catalyzed dehydrobromination.[5]

We now report that flavones can be easily obtained from the corresponding flavanones and "2-pyrrolidone hydrotribromide" (2-pyrrolidone-hydrogen bromide–bromine complex $(C_4H_7NO)_3 \cdot HBr \cdot Br_2$,[6] abbreviated to PHT) by a one-pot procedure.

The results obtained are summarized in Table 1. The reaction was followed by TLC and the reaction time was determined by the disappearance of the flavanones. The reaction of flavanone(**1**) with PHT in tetrahydrofuran(THF) gave 3-bromoflavanone(**2**) in excellent yield, although the product was a mixture of *cis*- and *trans*-isomers: The ratio of the former to the latter was determined on the basis of the ^1H NMR spectrum,[7] since the isomers cannot be separated. The ratio of the *cis*-isomer to the *trans*-isomer strongly depends on the reaction temperature used. An attempt to prepare flavone(**3**) by the above method was unsuccessful, although **2** was obtained in a good yield.

The reaction of **1** with PHT in dimethyl sulfoxide (DMSO) at room temperature gave a mixture of **2** and **3**: the ratio of the former to the latter was also determined on the basis of ^1H NMR spectrum, as shown in Table 1. On the other hand, when the reaction was caried out at 80 °C, **1** gave exclusively **3**, which was easily isolated from the reaction mixture (97%). Similarly, the other flavones were also obtained by this procedure in excellent yields except for 4′-methoxyflavanone(**4**) and 4′,7-dimethoxyflavanone(**5**) (see below). The key for direct formation of flavones from the corresponding flavanones involves the use of DMSO as a solvent. Since DMSO is an effective dehydrobromination agent,[8] the results indicates that the conversion of flavanones to the corresponding flavones proceed *via* 3-bromoflavanones. **4** and **5** gave the corresponding flavones in somewhat decreased yields, for it gave the corresponding 3-bromoflavones as by-product. The decreased yields of flavones may be due to the presence of an electron-releasing methoxyl group at the *p*-position in the phenyl group. In this case, it

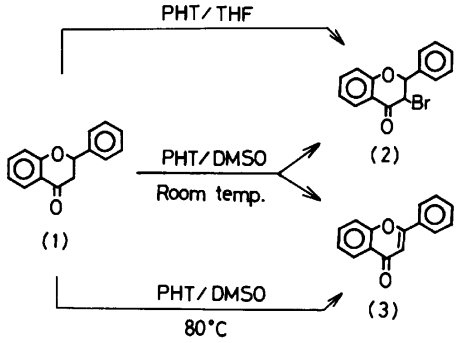
a) The ratio of *cis*-isomer to *trans*-isomer was determined on the basis of ^1H NMR spectrum.

† Present adress: Tomakomai Clinical Laboratory Co. Ltd., Hiyoshi, Tomakomai, Hokkaido 053.

is natural to suppose that 2,3-dibromoflavanones, obtained by the addition of Br_2 to the previously produced flavones, underwent dehydrobromination by DMSO to give the corresponding 3-bromoflavones.

In conclusion, most flavones were easily obtained from the corresponding flavanones and PHT in high purity and good yields.



Exprimental

^1H NMR spectra were obtained on a Hitachi R-22 with tetramethylsilane as internal reference. Mass spectra were measured with a JMS-D300 double-focusing mass spectrometer.

Materials. Flavanones were prepared according to a reported procedure.[9] Flavanones except for the new materials were identified by comparison with reported data.[10] *3'-Methoxyflavanone*: mp 76—77 °C. ^1H NMR (CCl_4) δ=2.62—3.10 (2H, m, C_3-H_{ax}, H_{eq}), 3.77 (3H, s, 3'-OCH_3), 5.34 (1H, dd, $J_{ax,ax}$=12.5 Hz, $J_{ax,eq}$=5.5 Hz, C_2-H_{ax}), 6.72—7.49 (7H, m, Aromatic), 7.86 (1H, dd, J_{ortho}=6.5 Hz, J_{meta}=1.5 Hz, C_5-H). Found: C, 75.78; H, 5.56. Calcd for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55. *3',7-Dimethoxyflavanone*: mp 101—102 °C. ^1H NMR ($CDCl_3$) δ=2.66—3.20 (2H, m, C_3-H), 3.83 (6H, s, 2×OCH_3), 5.43 (1H, dd, $J_{ax,ax}$=11 Hz, $J_{ax,eq}$=4 Hz, C_2-H), 6.49—7.42 (6H, m, Aromatic), 7.86 (1H, d, J_{ortho}=8 Hz, C_5-H). MS, Found: M^+=284. Calcd for $C_{17}H_{16}O_4$: M=284. *4'-Methoxyflavanone*: mp 87—88 °C [lit,[11] 96—97]. Though its melting point is different from the value in literature, we identified this material with 4'-methoxyflavanone from the following data. ^1H NMR (CCl_4) δ=2.58—3.13 (2H, m, C_3-H_{ax}, H_{eq}), 3.78 (3H, s, 4'-OCH_3), 5.33 (1H, dd, $J_{ax,ax}$=12 Hz, $J_{ax,eq}$=4.5 Hz, C_2-H_{ax}), 6.78—7.50 (7H, m, Aromatic), 7.83 (1H, dd, J_{ortho}=9 Hz, J_{meta}=2 Hz, C_5-H). Found: C, 75.60; H, 5.49. Calcd for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55.

Reaction Procedure. To a solution of flavanone (4.46 mmol) in the solvent (50 ml) was added a solution of PHT (4.84 mmol) in the solvent (50 ml). The mixture was stirred for a suitable time and temperature as indicated in Table 1. The reaction was followed by TLC (silica gel: benzene as sovent). Water was added to the cooled reaction mixture. The mixture was extracted with benzene and the organic extract was washed with brine, dried and evaporated.

Products of Reaction in THF. The residue was recrystallized from EtOH-H_2O: mp 85—105 °C. The product was a mixture of *cis*- and *trans*-3-bromoflavanone, indicated by integration of the ^1H NMR spectrum (see Table 1). ^1H NMR ($CDCl_3$) δ (ppm); *cis*-form: 4.54 (1H, d, J=2 Hz, β-H) [lit,[7] 4.53], 5.42 (1H, d, J=2 Hz, α-H) [lit,[7] 5.38], *trans*-form; 4.98(1H, d, J=8 Hz, β-H) [lit,[7] 4.98], 5.56 (1H, d, J=8 Hz, α-H) [lit,[7] 5.53].

Products of Reaction in DMSO. The product of reaction at room temperature was a mixture of 3-bromoflavanone and flavone as indicated by integration of ^1H NMR spectrum (see Table 1). Flavone: ^1H NMR ($CDCl_3$), δ=6.82 (1H, s, C_3-H), 7.31—7.99 (8H, m, Aromatic), 8.24 (1H, dd, J_{ortho}=8 Hz, J_{meta}=2 Hz, C_5-H). The residue of reaction at 80 °C was purified by silica-gel column chromatography (dichloromethane-diethyl ether, 5:1). Flavones and 3-bromo-4'-methoxyflavone, except for the new product, were identified by comparison with the reported data.[12] Satisfactory analysis was obtained for the new product, 3-bromo-4',7-dimethoxyflavone: mp 150—151 °C; ^1H NMR ($CDCl_3$) δ=3.91 (6H, s, 2×OCH_3), 6.85—7.90 (6H, m, Aromatic), 8.14 (1H, d, J_{ortho}=8 Hz, C_5-H); MS, Found: M^+=360, 362. Calcd for $C_{17}H_{13}O_4Br$: M=360, 362.

The authors wish to thank Dr. Tadashi Yoshida of Government Industrial Development Laboratory, Hokkaido, for his assistances in obtaining the mass spectra.

Stereoselectivity in the Reduction of Cyclic Ketones with Sodium Borohydride. Effect of the Ratio of the Components of a Mixed Solvent of Tetrahydrofuran and Methanol

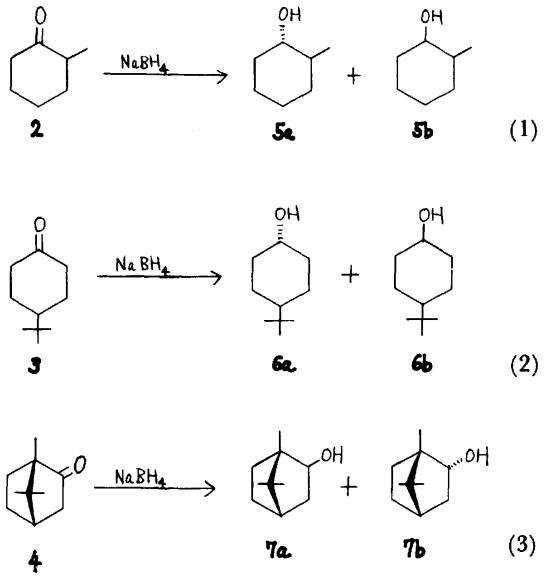
Kenso Soai* and Kazumi Ohi
Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo, 162
(Received November 19, 1984)

Synopsis. Reduction of relatively conformationally rigid cyclic ketones with sodium borohydride was examined in a mixed solvent of tetrahydrofuran(THF) and methanol(MeOH) with varying the ratio of the components. The highest stereoselectivities of the reductions were observed in the *mixed solvent*, and not in each *individual solvent*.

Sodium borohydride($NaBH_4$, **1**) has been used widely,[1] and its chemoselectivity is affected by the solvent.[2] Several reports have appeared on the stereoselectivity of the reduction of cyclic ketones with **1**.[3] However, nearly all the reductions have been carried out in a *single solvent*. To the best of our knowledge, the effect of *mixed solvents* on the stereoselectivity of **1** has not been closely examined.[4]

During our continuing study on asymmetric synthesis,[5] we reported that diastereoselectivity is higher in the reduction with **1** of chiral α-keto-amides in a mixed solvent of THF and MeOH than in either individual solvent.[6]

In the present paper, we describe the reduction of relatively conformationally rigid cyclic ketones with **1** in a mixed solvent of THF and MeOH. Cyclic ketones (**2**—**4**) were reduced with **1** at 0 °C in the mixed solvent of THF and MeOH with varying ratio of the components. Stereoselectivities were determined by GLC analyses of the isomeric alcohols formed. Predominant isomers from the reductions of 2-methylcyclohexanone(**2**), 4-*t*-butylcyclohexanone(**3**), and camphor(**4**) were *trans*-2-methylcyclohexanol (**5a**), *trans*-4-*t*-butylcyclohexanol(**6a**), and isoborneol (**7a**) respectively (Eq. 1—3. Only one enantiomer is shown in Eqs. 1 and 3. The actual products were racemic mixtures).



As shown in Figs. 1—3, in each case, stereoselectivities {shown as diastereomeric excesses (% d.e.)} of the product alcohols depended upon the volumetric ratio of THF and MeOH. The highest stereoselectivities in the reduction of cyclic ketones (**2**—**4**) were observed *in mixed solvent of THF and MeOH, and not in each individual solvent.* Diastereomeric excesses in the above mixed solvent of the appropriate ratio of components were higher than in the single solvent

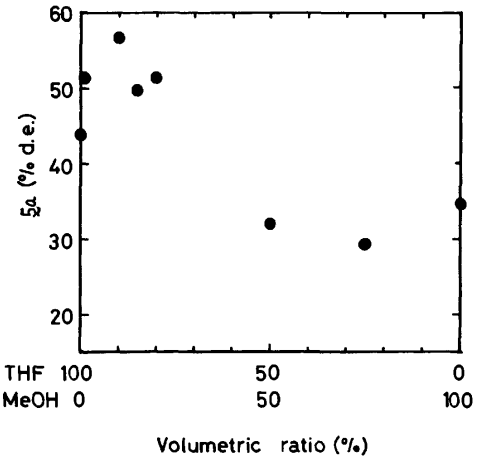


Fig. 1. Relation between Stereoselectivity of the Reduction of **2** and the Ratio of the Components of Mixed Solvent.

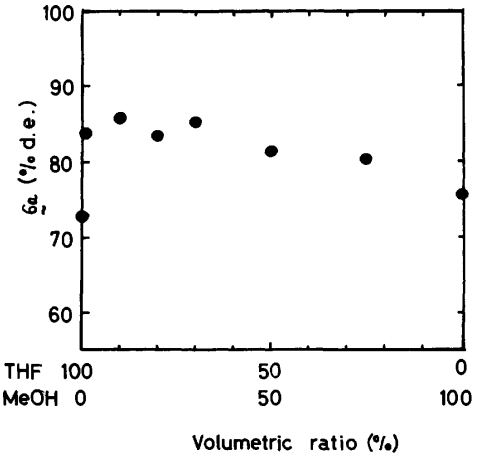

Fig. 2. Relation between Stereoselectivity of the Reduction of **3** and the Ratio of the Components of Mixed Solvent.

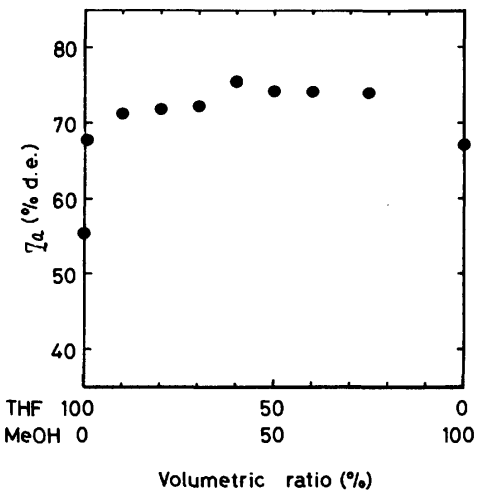

Fig. 3. Relation between Stereoselectivity of the Reduction of **4** and the Ratio of the Components of Mixed Solvent.

2-propanol. In the present mixed solvent of THF-MeOH, diastereomeric excesses of **5a**, **6a**, and **7a** reached 57, 86, and 75% d. e. respectively. On the other hand, reductions of **2**, **3**, and **4** with **1** in 2-propanol give **5a**, **6a**, and **7a** of 38, 66, and 72% d. e. respectively.[7,8] Therefore this mixed solvent may achieve higher stereoselectivities in the reduction of complicated cyclic ketones. Ketones **3** and **4** are conformationally rigid regardless of the ratio of the components of the mixed solvent.[9] Therefore the higher stereoselectivities in mixed solvent may be attributed, at least partly, to other than the ketones themselves, *i.e.* nature of the reducing species or mechanism of the reduction.

As described, mixed solvent of THF–MeOH is an influential factor on the stereoselective reduction of cyclic ketones with **1**.

Experimental

General Procedure for the Reduction of Ketones. Mixed solvent (1ml, THF–MeOH) was added to 1mmol of **1** with cooling in ice-bath, and was stirred for 5min. Ketone (1mmol) in 3ml of the above mixed solvent was added over a period of 15min. The mixture was stirred for 7—10h (ketones except camphor disappeared by TLC analysis). For the reduction of camphor, 3 molar amounts of **1** was used (reaction time 10 h). 1MHCl (1 M=1 mol dm^{-3}) was added to quench the reaction. Aqueous layers were extracted with ether and chloroform. The extracts were condensed, and were subjected to GLC analyses. In GLC analyses, all the products were identical with authentic samples purchased. GLC [poly(ethylene glycol)(PEG)-20 M or silicone SE-30, 25 m capillary column, flame ionization detector]. Column temp for 2-methylcyclohexanol; 65 °C, retention time, *cis*-**5b**; 21.1 min., *trans*-**5a**; 23.6 min., 4-*t*-butylcyclohexanol; 120 °C, *cis*-**6b**; 8.0 min., *trans*-**6a**; 9.2 min., isoborneol(**7a**); 5.9 min., borneol(**7b**); 6.1 min. 120 °C.

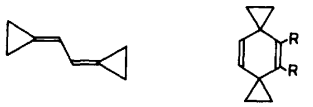
Synthesis of Dicyclopropylideneethane and Its Reaction with Some Dienophiles

Takashi Tsuji,* Ryo Kikuchi, and Shinya Nishida
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received November 22, 1984)

Synopsis. Preparation of dicyclopropylideneethane in three steps from 3-dimethylaminosulfolane and its reaction with some dienophiles are reported.

Dicyclopropylideneethane, **1**, a conjugated diene constituted of two highly strained, reactive methylenecyclopropanes, is of considerable interest in its physical as well as chemical properties. In particular, [4+2] cycloaddition products of **1** with acetylenic dienophiles, namely dispiro[2.2.2.2]deca-4,9-diene derivatives, **2**, will serve as the valuable substrate to synthesize variously-substituted [8]-paracycloph-4-enes and [4.2]paracyclophanes, as demonstrated previously in our laboratory.[1]

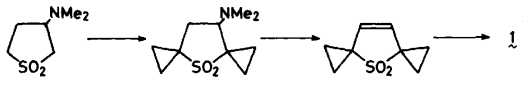


1 **2**

In 1972, Heinrich and Lüttke[2] have reported the formation of **1** as a minor component in the reaction of biallenyl with diazomethane. Since this approach will hold no preparative potential, it is desirable to explore proper synthetic routes for **1**. Paquette *et al.* have recently reported the synthesis of **1** from 1-trimethylsilylcyclopropanecarbaldehyde in several steps.[3] We independently prepared **1** from readily accessible 3-dimethylaminosulfolane[4] in three steps. By our hands, **1** reacted smoothly with some representative dienophiles and the yields of the adducts were substantially better than those reported by Paquette *et al.*[3]

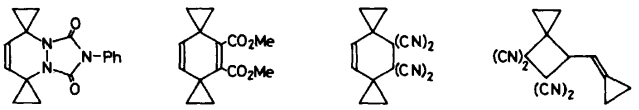
Results and Discussion

3-Dimethylaminosulfolane, **3**, was dicyclopropanated in one pot. Thus, the successive treatment of **3** in the presence of 2 equiv of oxirane with 2 equiv of *n*-BuLi, 2 equiv of benzenesulfonyl chloride, and 2 equiv of lithium diisopropylamide (LDA) afforded **4** in 40% yield. Oxidation of the amine, **4**, with 30% H_2O_2 followed by the thermal decomposition of the resulting *N*-oxide gave **5** in 80% yield.[5] Reduction of **5** with $LiAlH_4$ in refluxing THF afforded **1**[6] (50% yield by GLC; 28% yield by the isolation). The dicyclopropanated sulfolene, **5**, was thermally fairly stable and the attempted thermolysis (up to 250°C) failed to give appreciable amount of **1**.[7] Dicyclopropylideneethane, **1**, could be isolated as colorless crystals by preparative GLC, though **1** was liable to polymerize readily at room temperature.



3 **4** **5**

1,1,4,4-Tetrasubstituted butadienes are generally reluctant to undergo [4+2] cycloaddition because of the difficulty to attain *s-cis* conformation requisite for the reaction.[8] The diene, **1**, however, proved to be a fairly reactive one. Relief of the strain appears to contribute to the enhanced reactivity of **1**. The reaction of **1** with 4-phenyl-3*H*-1,2,4-triazole-3,5(4*H*)-dione (PTAD) was instantaneous at room temperature in benzene and the adduct, **6**, was obtained in 90% yield. The reaction with dimethyl acetylenedicarboxylate (DMAD) was much slower and required heating of a mixture of **1** and DMAD for 2 h at 80°C. Chromatographic purification of the product afforded **7** as colorless crystals in 35% yield. The addition of tetracyanoethylene (TCNE) to **1** smoothly proceeded at room temperature in dichloromethane. Chromatographic separation of the product mixture afforded **8** in 43% yield together with a 25% yield of **9**. It has recently been shown that some [2+2] adducts of TCNE to 1,3-butadienes relatively readily rearrange to the corresponding cyclohexene derivatives.[9] The latter product, **9**, however, showed no tendency to isomerize to **8** under the reaction conditions.



6 **7** **8** **9**

Therefore, the observed product distribution is a kinetically controlled result. The formation of [2+2] adduct, **9**, is at variance with the result of Paquette *et al.*, who carried out the reaction in carbon tetrachloride and isolated **8** in 27% yield, but none of **9**.[3] [2+2] Cycloaddition of TCNE to unsaturated compounds is generally accepted as a two-step process by way of zwitterion[9,10] and hence accelerated in polar solvents. The observed difference in the product compositions may be accounted for at least partly by the solvent polarity effect.

The preparation of **1** described above is simple and the reaction of **1** with dienophiles provides a convenient route to variously-substituted dispiro-[2.2.2.2]decene and -decadiene derivatives. The present methodology may also be extended to the preparation of related tetrasubstituted butadienes.

Experimental

Melting points are uncorrected. NMR spectra were

obtained at 100 MHz. Mass spectra were recorded at an ionizing voltage of 70 eV; ions of each spectrum were normalized to the spectrum's most intense ion set equal to 100.

Dicyclopropanation of 3. A solution of 3-dimethylaminosulfolane[4] (2.0 g, 12 mmol) and oxirane (1.5 ml, *ca.* 30 mmol) in 30 ml of THF was treated with 10 ml of 2.5 mol dm^{-3} hexane solution of *n*-BuLi (25 mmol) at 0—−10°C. After 20 min, a solution of benzenesulfonyl chloride (4.4 g, 24 mmol) in 10 ml of THF was added at −20—−30°C. The resulting mixture was stirred for 20 min at the above temperature, then treated with 25 mmol of LDA in 30 ml of THF below −40°C, and slowly warmed up to room temperature. After removal of solvent *in vacuo*, 9 ml of water was added and the product was extracted with five 50 ml portions of ether. The extracts were combined, dried with $MgSO_4$, and concentrated. The residual oil was distilled *in vacuo* to give 1.1 g of **4** (40%), bp 115—125 °C/10^{-3} mmHg (1 mmHg = 133.3 Pa), which solidified on standing and when crystallized from hexane had mp 71—72°C. NMR($CDCl_3$): δ=0.8—1.1 (m, 3H), 1.2—1.6 (m, 5H), 1.94 (dd, J=7.5 and 13.5 Hz, 1H), 2.29 (s, 6H), 2.48 (dd, J=7.5 and 13.5 Hz, 1H), 3.44 (t, J=7.5 Hz, 1H). IR (KBr): 1290, 1150, 1110, 1060, 1045, 1040, 690 cm^{-1}. MS *m/z*: 215 (M^+, 4), 136 (19), 110 (23), 96 (100), 82 (33), 71 (28), 44 (28), 42 (26). Found: C, 55.70; H, 7.99; N, 6.47; S, 14.95%. Calcd for $C_{10}H_{17}O_2NS$: C, 55.78; H, 7.96; N, 6.61 S, 14.89%.

Preparaion of 5. To a solution of 4 (4.35 g, 20.2 mmol) in 2.6 ml of methanol was added 2.2 ml of 30% aq H_2O_2. After 2 d at room temperature, a small amount of platinum black was added to destroy excess H_2O_2 and the mixture was stirred until evolution of gas had almost ceased. After removal of the catalyst, the solution was concentrated *in vacuo* and the residual oil was heated at 110°C/0.1 mmHg. Pungent gas evolution which ceased after 5 min was observed. The product sublimed and crystallized on the upper cold glass wall of the apparatus. The crude product was collected and sublimated at 110—120°C/14 mmHg giving 2.77 g of **5** (80%). Crystallization from methanol gave **5** melting at 123.5—124.5°C. NMR ($CDCl_3$): δ=1.1—1.8 (AA'XX' m, 8H), 5.67 (s, 2H). IR (KBr): 1290, 1135, 955, 730 cm^{-1}. UV(EtOH) max: 206.5 nm (ε, 10,600). Found: C, 56.45; H, 5.88; S, 18.93%. Calcd for $C_8H_{10}O_2S$: C, 56.45; H, 5.92; S, 18.83%.

Reductive Elimination of SO_2 from 5. To a suspension of 150 mg of $LiAlH_4$ (3.9 mmol) in 15 ml of THF was added 150 mg of **5** (0.88 mmol) and the mixture was refluxed. After 2 h, the sulfone had been consumed. The reaction mixture was cooled in an ice bath and treated successively with 150 µl of water, 150 µl of 15% NaOH, and 450 µl of water.[11] The resulting suspension to which a small amount of hydroquinone was added was filtered and the precipitate was washed well with pentane. The solvent was removed through a 15 cm packed column and the residue was subjected to preparative GLC (Apiezone Grease L 20% on Celite 545, 4 mm×2 m, 100 °C) giving 26 mg of **1** (28%) as colorless crystals melting at 39.5—42 °C. The yield of **1** determined by GLC with internal standard was 50%. The physical property of **1** agreed with that reported.[2,3]

Reaction of 1 with PTAD. To a solution of **1** (32 mg, 0.30 mmol) in 0.5 ml of benzene was added 50 mg of PTAD (0.29 mmol) in 0.5 ml of benzene under argon. The reaction was almost instantaneous and colorless crystals soon precipitated giving 72 mg of **6** (90%). Crystallization from benzene–hexane (1:1) gave analytically pure **6** melting at 149.5—150 °C. NMR($CDCl_3$): δ=0.7—1.3 (m, 4H), 1.9—2.5 (m, 4H), 5.25 (s, 2H), 7.47 (s, 5H). IR(KBr): 1760, 1695, 1505, 1420, 1330, 1150 cm^{-1}. MS *m/z*: 281 (M^+, 100), 254 (32), 147 (51), 135 (48), 134 (66), 119 (49), 126 (32), 91 (89), 79 (35). UV(EtOH) max: 220 (ε, 19,000), 250 nm (1200). Found: C, 68.43; H, 5.37; N, 15.02%. Calcd for $C_{16}H_{15}O_2N_3$: C, 68.31; H, 5.38; N, 14.94%.

Reaction of 1 with DMAD. A solution of **1** (24 mg, 0.23 mmol) in 150 µl of DMAD was heated at 80 °C for 2 h and then subjected to chromatography on SiO_2 with benzene elution. The fraction containing the product (R_f=0.22) was concentrated and the residue was crystallized from hexane to give 20 mg of **7** (35%) melting at 92—93 °C (lit,[3] 92.5—93 °C). UV(EtOH) max: 290 nm (ε, 6000). The NMR, IR, and MS spectra of **7** agreed with those reported.[3] Found: C, 67.92; H, 6.57%. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%.

Reaction of 1 with TCNE. A solution of 96 mg of **1** (0.87 mmol) and 145 mg of TCNE (1.13 mmol) in 30 ml of CH_2Cl_2 was stirred at room temperature for 4 d. Chromatography of the product mixture on SiO_2 with benzene elution afforded first 85 mg of **8** (43%, R_f=0.32), which showed a decomposition point of *ca.* 190 °C (lit,[3] 182 °C). Further elution with benzene produced 50 mg of **9** (25%, R_f=0.24) melting at 151.5—152.5 °C. The NMR and MS spectra of **8** agreed with those reported.[3] **8**: IR(KBr): 1640, 1440, 1410, 1270, 1035, 980, 955, 890, 760 cm^{-1}. Found: C, 71.70; H, 4.22; N, 23.89%. The Reaction of Cyclopentanone with Carbon Disulfide and Glycine Esters

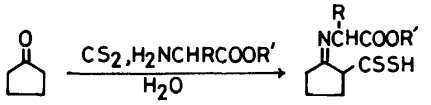
Naoaki FUKADA* and Kayoko YAMAMOTO
Department of Chemistry, Faculty of Science, Chiba University, Yayoicho, Chiba 260
(Received December 5, 1984)

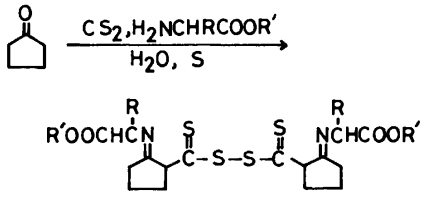
Synopsis. 2-(Methoxy- and ethoxycarbonylmethylimino)cyclopentanecarbodithioic acids were synthesized from cyclopentanone, carbon disulfide, and glycine esters. In the presence of sulfur, glycine, alanine, and phenylalanine esters reacted to give the corresponding oxidatively coupled products of dithiocarboxylic acid.

In the previous paper,[1] we have reported a convenient, one-step synthesis of 2-(alkylimino)-cyclopentanecarbodithioic acids by reaction of cyclopentanone with carbon disulfide in an aqueous amine medium. Earlier reports described the preparation of 2-imino-[2,3] and 2-(alkylimino)cycloalkanecarbodithioic acids.[4-6]

In this note, we wish to report the reaction of cyclopentanone with carbon disulfide in an aqueous solution of glycine esters. While the reaction of alkylamine was carried out below 10 °C for 0.5—2 h,[1] the present reaction required 6—8 h at room temperature. Although the yields were inferior, 2-(methoxy- and ethoxycarbonylmethylimino)cyclopentanecarbodithioic acids **1a** and **1b** were obtained from the corresponding glycine methyl and ethyl esters, respectively. In the case of alanine or phenylalanine ethyl ester, the reaction proceeded to give a crude unstable product in lower yield. However, it was difficult to isolate the corresponding pure dithiocarboxylic acid. The oxidatively coupled products **2a—d** were also directly obtained by the above reaction involving addition of sulfur to the starting materials.



1



2

The UV spectra of **1** and **2** as shown in Table 1 were similar to those of 2-(alkylimino)cyclopentanecarbodithioic acids (λ_{max} 304—306 and 393—398 nm in ethanol) and their oxidative dimers (λ_{max} 312—315 and 407—416 nm in chloroform).[1] Both the dithiocarboxylic acids **1a** and **1b** were exceedingly sensitive to Ni(II) ion, giving a pink red precipitate.[2,7]

Experimental

2-(Methoxycarbonylmethylimino)cyclopentanecarbodithioic Acid (1a). To a cooled mixture of cyclopentanone (5.7 g, 0.068 mol) and carbon disulfide (7.3 g, 0.096 mol) were added a solution of glycine methyl ester hydrochloride (9 g, 0.072 mol) in water (15 ml) and then a solution of sodium hydroxide (3 g, 0.075 mol) in water (15 ml). The mixture was shaken under nitrogen at room temperature for 6 h and allowed to stand overnight. The oily product was collected and washed with a small amount of ethanol. The yellow solid was purified by reprecipitation with acetone— a 2M HCl aqueous (1M=1 mol dm^{-3}) solution, IR (KBr), 2435 s (SH) 1740 *vs.* (C=O), and 1595 *vs.* cm^{-1} (C=N). Found: C, 46.87; H, 5.75; N, 6.00; S, 27.25%. Calcd for $C_9H_{13}NO_2S_2$: C, 46.73; H, 5.66; N, 6.05; S, 27.72%.

2-(Ethoxycarbonylmethylimino)cyclopentanecarbodithioic Acid (1b): Reprecipitated with acetone— a 2M HCl aqueous solution. IR (KBr), 2435 s (SH), 1740 *vs.* (C=O), and 1600 *vs.* cm^{-1} (C=N). Found: C, 48.99; H, 6.07; N, 5.74; S, 25.48%. Calcd for $C_{10}H_{15}NO_2S_2$: C, 48.95; H, 6.16; N, 5.71; S, 26.14%.

The Oxidatively Coupled Products of Dithiocarboxylic Acid (2). General Procedure. To a cooled mixture of cyclopentanone (1.5 g, 0.018 mol), carbon disulfide (2 g, 0.026 mol), and sulfur (0.1 g, 0.0031 mol) were added a solution of amino acid (glycine, alanine, or phenylalanine) ester hydrochloride (0.018 mol) in water (5 ml) and then a solution of sodium hydroxide (0.75 g, 0.019 mol) in water (4 ml). The mixture was shaken at room temperature for

Transition-metal-catalyzed Grignard Reaction of Isoprene Bromohydrin

Shuki ARAKI, Masayuki OHMURA, and Yasuo BUTSUGAN*
Department of Synthetic Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received December 10, 1984)

Synopsis. The coupling reaction of isoprene bromohydrin with aryl and alkyl Grignard reagents catalyzed by tetrakis(triphenylphosphine)palladium(0) selectively gave the vinyl-group-migrated products.

Isoprene bromohydrin (1-bromo-2-methyl-3-buten-2-ol) (**1**), easily obtainable from the reaction of *N*-bromosuccinimide and isoprene in tetrahydrofuran–water, is an interesting compound because of the unique behavior toward organometallic reagents. The reaction of **1** with allylic Grignard reagents in the presence of copper(I) iodide selectively gave vinyl-group-migrated products.[1] The copper(I)-catalyzed reaction of **1** with alkyllithium which has β-hydrogen yielded 2-alkyl-4-penten-2-ol, whereas with methyl-, phenyl-, or benzyllithium, 4-substituted 2-methyl-2-buten-1-ol was formed exclusively.[2] In order to examine further the transition-metal-catalyzed Grignard reaction of **1**, we tested various transition metal compounds and found that a palladium(0) complex was the most effective for the migration of the vinyl group of **1**.

Using phenylmagnesium bromide as a representative Grignard reagent, the product distribution under various catalysts was examined. The reactions were carried out in tetrahydrofuran using 5-fold excess of the Grignard reagent. In the absence of catalysts, a mixture of 2-methyl-4-phenyl-2-buten-1-ol (**4a**) and 2-methyl-1-phenyl-3-buten-1-ol (**5a**) was formed in the ratio of 37:63, together with trace amounts of 2-phenyl-4-penten-2-ol (**2a**) and 2-methyl-1-phenyl-3-buten-2-ol (**3a**). The alcohols (**4a** and **5a**) are considered to be produced *via* isoprene oxide.[2] Eight kinds of transition metal complexes, which are known as effective catalysts for the cross-coupling between Grignard reagents and organic halides,[3] were examined. Results are summarized in Table 1. Titanocene dichloride and cobalt(II) chloride did not show a significant catalytic effect. The reaction yields were poor in the cases of tris(1,3-diketonato)-iron(III) complexes and palladium(II) chloride. As reported,[1] copper(I) iodide-catalyzed reaction gave a 56:44 mixture of **2a** and **3a**. The selectivity (**2a** *vs.* **3a**) was improved by the use of bis(triphenylphosphine)-

a) Of the bromohydrin used. b) Tris(dibenzoylmethanato)iron(III).

nickel(II) chloride. Of the eight catalysts which are examined, tetrakis(triphenylphosphine)palladium(0) was found to be the most effective, leading exclusive formation of the vinyl-group-migrated product (**2a**) in 85% yield. *p*-Tolylmagnesium bromide also gave the migration product (**2b**) with high selectivity in the presence of a catalytic amount (0.5 mol%) of the palladium(0) complex. This catalyst is also effective for the reaction with alkyl Grignard reagents. Coupling reactions with butyl- and hexylmagnesium bromides exclusively gave the respective homoallylic alcohols (**2c** and **2d**) in 53 and 89% yields. However, the reactions of **1** with allyl and benzylmagnesium chlorides gave complex reaction mixtures even in the presence of the palladium(0) complex.

Experimental

General. Infrared spectra were recorded on a JASCO IRA-1 spectrophotometer. ^{1}H NMR spectra were recorded on a Hitachi R-24A spectrometer (60 MHz) or on a Varian XL-200 spectrometer (200 MHz) with Me_4Si as internal standard. Mass spectra were determined using a Hitachi M-52 instrument at 20 eV. Glc analyses and preparative glc were performed on a Yanaco G1800 gas chromatograph equipped with a column packed with 20% polyethylene glycol (PEG) 20M on Celite 545 (1 m×3 mm). Elemental analyses were performed at the Elemental Analysis Center of Kyoto University. For Kugelrohr distillation, a Shibata GTO-250R glass tube oven was used.

Preparation of 1. To a suspension of *N*-bromosuccinimide (12.3 g, 69 mmol) in a mixture of tetrahydrofuran (THF)–water (3:2) (120 cm^3) was added a solution of isoprene (7.0 g, 103 mmol) in THF (50 cm^3) at 0 °C. The reaction mixture was left at 0 °C for 3 h and then overnight at room temperature. The reaction mixture was poured into a saturated aqueous sodium chloride solution and the organic layer was separated. The aqueous layer was extracted with ether and the combined organic extracts were washed with brine and dried (Na_2SO_4). The solvent was evaporated and the residue was distilled under reduced pressure to give **1** as a colorless oil (6.9 g, 61%). **1**:[4] bp 69—70 °C/46 Torr (1 Torr≈133.322 Pa); IR (neat) 3430, 2990, 1412, 1372, 1239, 1056, and 930 cm^{-1}; ^{1}H NMR (CCl_4) 5.85 (dd, *J*=17, 10 Hz, 1H, olefin), 5.25 (dd, *J*=17, 2 Hz, 1H, olefin), 5.08 (dd, *J*=10, 2 Hz, 1H, olefin), 3.37 (s, 2H, CH_2), 2.02 (bs, 1H, OH), 1.33 (s, 3H, CH_3).

Transition-metal-catalyzed Grignard Reaction of Isoprene Bromohydrin (1). The following example represents the general procedure. To a solution of phenylmagnesium bromide, prepared from magnesium turnings (600 mg, 25 mg-atom) and bromobenzene (2.12 cm^3, 25 mmol) in THF (20 cm^3), was added tetrakis(triphenylphosphine)-palladium (29 mg, 0.025 mmol) and the mixture was stirred at 0 °C for 10 min. A solution of **1** (825 mg, 5 mmol) in THF (5 cm^3) was then added at 0 °C and the mixture was left overnight at room temperature. The reaction was quenched by the addition of water and the product was extracted with ether. The extracts were dried (Na_2SO_4) and the solvent was evaporated. In order to remove less polar impurities such as biphenyl, the residue was adsorbed on a silica-gel column and eluted first with benzene (50 cm^3) and then with ether (100 cm^3). The ether eluate was concentrated and distilled (Kugelrohr) (bp 100 °C/3 Torr) to produce a colorless oil (689 mg, 85%). Glc analysis revealed that this oil was pure **2a**.

In other experiments, the reaction mixture was treated in a similar manner and the product distribution was analyzed by glc. Results are summarized in Table 1. Pure samples of the products were obtained by preparative glc and the structures were deduced by their spectral and analytical data.

Oxidation of Anthracenols and Anthrone to Anthraquinones with Oxygen Mediated by Copper(II) Ion and Imidazole

Masaaki IWATA* and Hiroyoshi KUZUHARA
Riken (The Institute of Physical and Chemical Research), Wako, Saitama 351-01
(Received December 11, 1984)

Synopsis. The copper(II) chloride-imidazole-ethanol system turned out to oxidize 2-anthracenols to 1,2-anthraquinones and 2-methoxy-9-anthrone to 2-methoxy-9,10-anthraquinone in practical synthetic yield.

In the preliminary report,[1] copper(II) chloride and imidazole in the presence of oxygen in ethanol was found to be a tyrosinase mimic, which was exemplified by specific and enhanced oxidation of 2-anthracenol (**1**) to 1,2-anthraquinone (**2**) identified as the corresponding phenazine derivative (**3**). Simplicity and effectiveness of the method suggested that this could be applied for general practical synthesis of quinones.

To start with, 9-(2-*p*-cymenyl)-2-anthracenol (**4**) was stirred at ambient temperature with copper(II) chloride dihydrate and imidazole in ethanol for 22 h, resulting in 9-(2-*p*-cymenyl)-1,2-anthraquinone (**5**) in 86% yield. ^{1}H NMR spectrum of **5** supported the structure by appearance of doublet signals at δ 6.48 (C_3–H) and 7.60 (C_4–H), and a singlet signal at 7.81 (C_{10}–H).

Secondary, 2-methoxy-9-anthrone (**6**)[2] was treated at ambient temperature in the presence of copper(II) chloride dihydrate and imidazole in ethanol for 25 h, resulting in 2-methoxy-9,10-anthraquinone (**7**) in 81% yield, accompanied by 2,2′-dimethoxy-10,10′-bianthrone (**8**) in 6% yield. When an amount of imidazole was decreased, the reaction was retarded markedly.

These experiments imply that (a) in the presence of air, the mixture of copper(II) chloride and imidazole in ethanol works as effective oxidation catalysis for anthracenols and anthrone and (b) imidazole is indispensable for the oxidation reaction.

The practical synthetic method of 1,2-anthraquinones has been limited hitherto.[3] Fremy's salt is known to be only practical oxidant for the purpose.[4] The other methods[4] such as iron(III) chloride and chromium trioxide for 2-amino-1-anthracenol and chromium trioxide for 1,2-diacetoxyanthracene suffer from the moderate yields and the difficulty of the synthesis of the precursors. As for the synthesis of *o*-quinones, the morpholinocopper(II)–ethanol system[5] is unique and the first tyrosinase mimic. However, the system is far from the practical synthesis of *o*-quinones because it is only applicable to naphthols and phenols of the benzene series and always gives morpholine-substituted *o*-quinones.

9,10-Anthraquinones are of great importance for manufacture of dyes. The classical synthetic route through the cyclization of *o*-benzoylbenzoic acids is not always convenient because the position at which cyclization should take place is deactivated by the electron-withdrawing group at the ortho-position. Improvement has been made by the finding of the path through the cyclization of *o*-benzylbenzoic acids.[6] The resulting anthrones are, then, oxidized by chromium trioxide in refluxed acetic acid in "good" yield. The present system seems to afford advantage over the chromium trioxide method because of easy work-up and mild reaction conditions preventing from the formation of undesirable by-products.

The reaction mechanism of the present system is attractive especially in relation to copper-bound tyrosinase. The mechanism will be discussed elsewhere.

Experimental

The ^{1}H NMR spectra were recorded on JEOL JNM GX-400 instrument with Me_4Si as the internal standard. Electronic absorption spectra (UV) were recorded on a Hitachi 124 spectrophotometer. Infrared spectra (IR) were obtained on a Shimadzu IR-27 apparatus. Mass spectra (MS) were obtained with a Hitachi RMU 6-MG spectrometer by using a direct-inlet method, an ionizing potential at 20 eV. Merck silica gel 60 (Art 7734, 0.063—0.20) was used for column chromatography. Thin layer chromatography (tlc) was performed with precoated plates (Merck, Art. 5715, silica gel 60 F_{254}).

2-Anthracenol was prepared by demethylation of 2-methoxyanthracene by the method exemplified by that of 9-(2-*p*-cymenyl)-2-methoxyanthracene (*vide infra*), which was prepared by the Grignard reaction of 2-methoxy-9-

anthrone with 2-bromo-*p*-cymene.[2]

Oxidation of 2-Anthracenol (1). The mixture of **1** (0.516 mmol), copper(II) chloride dihydrate (0.347 mmol), and imidazole (0.347 mmol) in 20 ml of ethanol was shaken in oxygen atmosphere at ambient temperature. After the calculated amount of oxygen was uptaken, the mixture was filtered through Celite (No. 545) and washed several times with chloroform. The combined filtrate was evaporated. The residue was dissolved into acetic acid (5 ml) and 0.516 mmol of *o*-phenylenediamine was added. Dark red precipitate was collected in one day, and recrystallized from benzene to give the phenazine derivative of 1,2-anthraquinone (**3**): mp 220 °C (221—222 °C[7]; 185—190 °C[8]).

Demethylation of 9-(2-p-Cymenyl)-2-methoxyanthracene. According to the previous method,[9] the mixture of 1.43 g of 9-(2-*p*-cymenyl)-2-methoxyanthracene,[2] 20 ml of acetic acid, and 20 ml of 47% hydrobromic acid was refluxed for 3.5 h. Cooled reaction mixture was extracted with benzene and chromatographed on a silica-gel column eluted with benzene to give 0.85 g (62% yield) of 9-(2-*p*-cymenyl)-2-anthracenol (**4**) as viscous liquid; Calcd for $C_{24}H_{22}O$: C, 88.31; H, 6.79%. Found: C, 87.93; H, 6.51%. IR (neat): ν_{OH} 3500 and 3400 cm^{-1}.

Oxidation of 9-(2-p-Cymenyl)-2-anthracenol (4). **4** (0.613 mmol) was mixed in 20 ml of ethanol with copper(II) chloride dihydrate (0.3 mmol) and imidazole (0.3 mmol), and stirred at ambient temperature for 22 h. The reaction mixture was filtered through Celite (No. 545) and washed twice with chloroform. The filtrate was evaporated to dryness and the residue was chromatographed on a silica-gel column eluted with benzene–ethyl acetate (9:1 v/v) to give 9-(2-*p*-cymenyl)-1,2-anthraquinone (**5**) in 86% yield, which was recrystallized from benzene–petroleum ether; yellow red crystals, mp 170—172 °C. Calcd for $C_{24}H_{20}O_2$: C, 84.68; H, 5.92%. Found: C, 84.43; H, 5.92%. IR (KBr disk) $\nu_{C=O}$ 1660 cm^{-1}. UV (ethanol) λ_{max} 236.5, 298.5 and 444.5 nm. MS, a parent peak at *m/z* 340. ^1H NMR (CCl_4) δ=1.26 (6H, d, J=7.0, $-CH(C\underline{H}_3)_2$), 2.89 (1H, quin, J=7.0, $-C\underline{H}(CH_3)_2$), 1.86 (3H, s, Ar-$C\underline{H}_3$), 6.48 (1H, d, J=10.0, C_3-$\underline{H}$), 7.60 (1H, d, J=10.0, C_4-$\underline{H}$), and 7.81 (1H, s, C_{10}-$\underline{H}$).

Oxidation of 2-Methoxy-9-anthrone (6). The mixture of **6**[2] (1.12 g; 4.99 mmol), copper(II) chloride dihydrate (0.568 g; 3.33 mmol), and imidazole (0.573 g; 8.42 mmol) in 100 ml of ethanol was stirred at ambient temperature for 25 h. The reaction mixture was filtered through Celite (No. 545) and washed well with chloroform. The combined filtrate was evaporated and chromatographed on a silica-gel column eluted with benzene to give 0.96 g (81% yield) of 2-methoxy-9.10-anthraquinone (**7**) and 0.277 g (6% yield) of 2,2′-dimethoxy-10,10′-bianthrone (**8**).

7: IR (KBr) $\nu_{C=O}$ 1673 cm^{-1}; $\nu_{=C-O-C}$ 1305, 1290 cm^{-1}. ^1H NMR ($CDCl_3$) δ=3.99 (3H, s, O-$C\underline{H}_3$), 7.27 (1H, q, $J_{1,3}$=2.69, $J_{3,4}$=8.79, C_3-$\underline{H}$), 7.73 (1H, d, $J_{1,3}$=2.69, C_1-$\underline{H}$), and 8.26 (1H, d, $J_{3,4}$=8.79, C_4-$\underline{H}$).

8: IR (KBr) $\nu_{C=O}$ 1662 cm^{-1}; $\nu_{=C-O-C}$ 1320 cm^{-1}. ^1H NMR δ=3.85 (3H, s, O-$C\underline{H}_3$), 3.87 (3H, s, O-$C\underline{H}_3$), and 4.71 (2H, s, C_{10}- and $C_{10'}$-$\underline{H}$).

Iodination of Benzene with Iodine and Metal Salts in Acidic Solvents

Atsushi SHIMIZU,* Kazunori YAMATAKA,* and Toshiro ISOYA
Technical Development Department of Petrochemical Intermediates, Asahi Chemical Ind. Co., Ltd.
Nagahama-cho 4-3401, Nobeoka, Miyazaki 882
(Received December 12, 1984)

Synopsis. Iodobenzene was obtained by a reaction of benzene with molecular iodine in trifluoromethanesulfonic acid in oxygen atmosphere in the presence of vanadium salt as a catalyst. The method affords a new aromatic iodination process in which benzene is iodinated directly with molecular iodine.

Aromatic compounds can be brominated or chlorinated with bromine or chlorine in the presence of a catalyst, most often iron. On the other hand, iodine is the least reactive of the halogens in aromatic halogenation reactions where an oxidizing agent is normally required to oxidize iodine to a better electrophile, as opposed to the case of active substrates. Generally, iodination of benzene can be accomplished by iodine in the presence of nitric acid.[1] Recently several synthetic methods of iodoarens have been reported, which include (1) iodination of aromatics with molecular iodine in the presence of oxidizing agents,[2-4] (2) iodination of aromatics with a potent iodine donor[5,6] (3) decomposition of arylthallium compounds with potassium iodide or iodine,[7,8] and (4) electrochemical iodination of aromatics.[9,10] These procedures have some deficiencies. Metal salts are required as stoichiometric agents, iodine donors are hard to be prepared, or iodine is lost from the reaction as hydrogen iodide or metallic iodide.

Recently fluorine containing compounds such as trifluoromethanesulfonic acid or trifluoroacetic acid have been used as catalysts or solvents in various reactions to show remarkable effects. We have found that iodination of benzene with molecular iodine occurs in trifluoromethanesulfonic acid in the presence of sodium vanadate(V) and oxygen gas. The present paper will describe a new catalytic iodination of benzene.

Experimental

The Typical Procedures. In a 200-ml three-necked glass autoclave were placed 5.08 g (65.1 mmol) of benzene, 2.03 g (8.00 mmol) of iodine, 0.33 g (2.7 mmol) of sodium vanadate(V), and 12.5 g of trifluoromethanesulfonic acid. The mixture was magnetically stirred at 100 °C under 10 atm of air. When the colour of iodine was discharged and the solution became black after 1.5 h, the mixture was poured into 300 ml of ice-water containing 10% of sodium thiosulfate, and the products were extracted with 100 ml of hexane. Removal of hexane left 3.13 g of an oil which contained 2.99 g (14.7 mmol) of iodobenzene, 0.13 g (0.39 mmol) of *p*-diiodobenzene, and 0.01 g (0.04 mmol) of *o*-diiodobenzene. The yields based on iodine were 91.9, 2.5, and 0.2% respectively. All the products were characterized by comparison of NMR spectra, mass spectra, and GC retention times with those of authentic samples.

Results and Discussion

The results of the iodination in trifluoromethanesulfonic acid are shown in Table 1.

The reaction was performed as a two-layer system. The upper layer was benzene and the lower layer was trifluoromethanesulfonic acid. An increase in the quantity of trifluoromethanesulfonic acid was accompanied by an increase in the yield of iodobenzene. The presence of oxygen was essential in the reaction because iodobenzene was not obtainable without oxygen. Iodinations were examined in various combinations of solvents and metal salts, and the use of vanadium salt and trifluoromethanesulfonic acid gave an excellent yield of iodobenzene. The molar ratio of the iodobenzene to the metal salt reveals that the metal salt acts as a catalyst. Since the molar ratio

Other reaction conditions are as follows: Ag_2O, Fe_2O_3, V_2O_5=1.35 mmol; Co_3O_4=0.9 mmol; others=2.7 mmol; C_6H_6=5 g; CH_3SO_3H=12.5 g; O_2=5 kg/cm^2.

Table 3. Iodination of benzene in CF_3COOH

Run	C_6H_6	Iodine	Cat.		CF_3COOH	Press.		Temp	Time	C_6H_5I
	mmol	mmol	mmol		g	kg/cm^2		°C	h	mmol
1	65.3	15.2	V_2O_5	1.37	12.5	air	10	100	5.5	2.60
2	128.0	23.6	$FeCl_2 \cdot 4H_2O$	0.352	10.5	O_2	2	100	48.0	2.56

of consumed benzene to iodine was about 2:1, the overall reaction can be shown as follows:

$$2C_6H_6 + I_2 + 1/2O_2 \longrightarrow 2C_6H_5I + H_2O$$

The iodobenzene also gave diiodobenzene by a reaction with iodine.

Activities of various metal salts in the iodination were examined in methanesulfonic acid. All the results are summarized in Table 2.

Cu, Ti, Fe, and Mn salts were comparatively effective. Since the sorts of counter ions of metal ions do not seem to be important, we may describe that the metal salts were oxidizing catalysts, and not Lewis acids.

Trifluoroacetic acid could also be used as the solvent. Table 3 gives the results.

The iodination rate was dependent on the acidity of the solvent because the iodination rate decreased in the order $CF_3SO_3H > CH_3SO_3H > CF_3COOH$ and was nearly zero in CH_3COOH. The combination of acidic solvent, oxygen gas, and oxidizing catalyst are indispensable in the iodination reaction. We may describe the reaction pathways as follows:

$$CF_3SO_3H + I_2 \longrightarrow CF_3SO_3^- + HI_2^+$$

$$HI_2^+ \longrightarrow HI + I^+$$

$$I^+ + C_6H_6 \longrightarrow C_6H_5I + H^+$$

$$HI \longrightarrow H^+ + I^-$$

$$I^- + V^{5+} \longrightarrow 1/2I_2 + V^{4+}$$

$$V^{4+} + H^+ + 1/4O_2 \longrightarrow V^{5+} + 1/2H_2O$$

Although the reactive intermediate is represented as iodine ion in the pathways, possible intermediates other than iodine ion are HIO, CF_3SO_3I, CH_3SO_3I, or CF_3COOI.[3,4] It is not clear which is the true active intermediate.

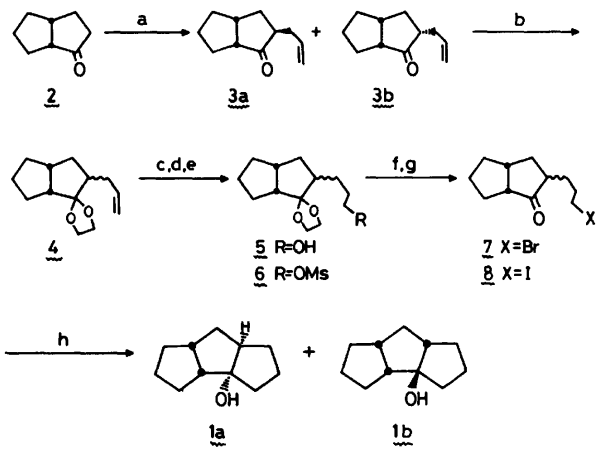
Synthesis of *cis-transoid-cis-* and *cis-cisoid-cis-* Tricyclo[6.3.0.0^{2,6}]undecan-1-ols

Kiyomi KAKIUCHI,* Hideyuki TAKEUCHI, Yoshito TOBE, and Yoshinobu ODAIRA
Department of Applied Fine Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received December 19, 1984)

Synopsis. Two isomeric linear triquinanes, *cis-transoid-cis-* and *cis-cisoid-cis*-tricyclo[6.3.0.0^{2,6}]undecan-1-ols, were effectively synthesized by means of the modified Barbier cyclization.

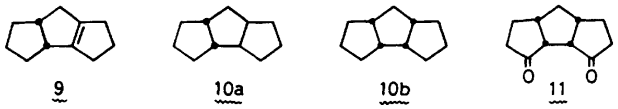
Recently, much attention has been focused on linearly fused triquinanes (tricyclo[6.3.0.0^{2,6}]undecanes), since a lot of natural products which possess this ring system have been found out and some of them, such as hirsutic acid and coriolin, display significant levels of biological activities.[1] In this connection, we wish to report here the facile synthesis of two isomeric linear triquinanes, *cis-transoid-cis-* and *cis-cisoid-cis*-tricyclo[6.3.0.0^{2,6}]undecan-1-ols (**1a**) and (**1b**) by means of a new cyclopentane annelation, that is, the modified Barbier cyclization.[2]



Scheme 1.

a) CH_2=$CHCH_2OH$, $CH_3C(OCH_3)_2CH_3$, TsOH, △; b) $HO(CH_2)_2OH$, TsOH; c) B_2H_6; d) H_2O_2; e) CH_3SO_2Cl (MsCl), Et_3N; f) LiBr; g) NaI; h) Mg, $HgCl_2$.

An ingenious adaptation of the Claisen rearrangement[3] of a diquinane, *cis*-bicyclo[3.3.0]octan-2-one (**2**),[4] gave the 3-allyl derivatives **3a** and **3b** (an approximate 1:1 ratio) in 73% yield. The mixture **3a** and **3b** was readily transformed to the 3-iodopropyl derivatives **8** as follows: i) acetalization, ii) hydroboration-oxidation of the acetals **4**, iii) mesylation of the alcohols **5**, iv) reaction of the mesylates **6** with lithium bromide,[5] and v) treatment of the bromides **7** with sodium iodide. Finally, reaction of **8** with magnesium activated by $HgCl_2$ afforded the desired alcohols **1a** and **1b** in 17% and 11% isolated yields from **3a** and **3b**, which were readily separated by column chromatography on silica gel.



Their structures were elucidated on the basis of spectroscopic data and the following chemical transformations. Elimination of the mesylates of **1a** and **1b** with $LiAlH_4$[6] gave the same olefin, *cis*-tricyclo[6.3.0.0^{2,6}]undec-1(8)-ene (**9**), in 65% and 67% yields, respectively. Hydrogenation of **9** with Pd on charcoal gave two hydrocarbons, tricyclo[6.3.0.0^{2,6}]-undecanes (**10a**) and (**10b**), in 43% and 35% yields. The hydrocarbon **10b** was also obtained in 45% yield by reductive deoxygenation[7] of the diethyl phosphate of **1b** with lithium in diethylamine. The *cis-cisoid-cis* stereochemistry of **10b** was determined by comparison with the authentic sample derived from *cis-cisoid-cis*-tricyclo[6.3.0.0^{2,6}]undecane-3,11-dione (**11**)[8] by Wolff-Kishner reduction. Consequently, **1b** was established to be the *cis-cisoid-cis*-isomer, and **1a** and **10a** were characterized to be *cis-transoid-cis*-isomers.

Experimental

All boiling points are uncorrected. Measurements of IR, MS, ^{1}H NMR, and ^{13}C NMR as well as analytical and preparative GLC were done on the same instruments as in the previous work.[6] Column chromatography was carried out with silica gel (Wakogel C-200). Yields were calculated from the isolated products based on the consumed starting materials.

exo- *and* endo-*3-(2-Propenyl)-*cis*-bicyclo[3.3.0]octan-2-ones (3a) and (3b).* A solution composed of **2** (10.0 g, 80.6 mmol), allyl alcohol (11.2 g, 193 mmol), 2,2-dimethoxypropane (10.0 g, 96.2 mmol), and *p*-toluenesulfonic acid monohydrate (TsOH·H_2O) (10 mg) and benzene (44 ml) was distilled through a spinning band column and operated at a reflux ratio of 10. After 19 ml of distillate had been collected at 55—60 °C, the distillation was continued with a reflux ratio of 3 until the overhead temperature reached 95 °C. Yellow residue was distilled *in vacuo* to give the recovered **2** (3.59 g; bp 51 °C/2 mmHg (mmHg=133.322 Pa)) and the allyl ketones **3a** and **3b** (6.21 g, 73%; bp 70 °C/1 mmHg) which were purified by column chromatography. Since **3a** and **3b** could not be separated by GLC or column chromatography, they were characterized as a mixture (an approximate 1:1 ratio calculated from ^{13}C NMR spectrum). **3a** and **3b**: IR 3080, 1740, 1640, 915 cm^{-1}; MS *m/z* 164 (M$^+$), 68 (base); ^{13}C NMR ($CDCl_3$) δ=223.4 (s), 220.9 (s), 136.1 (d), 135.9 (d), 116.2 (t), 115.9 (t), 52.2 (d), 51.3 (d), 49.8 (d), 46.6 (d), 38.5 (d), 37.8 (d), and ten triplets. Found: C, 80.56; H, 10.05%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.83%.

cis-transoid-cis- *and* cis-cisoid-cis-*Tricyclo[6.3.0.0^{2,6}]undecan-1-ols (1a) and (1b).* Reaction[9] of **3a** and **3b** (6.39 g, 39 mmol), ethylene glycol (12.2 g, 194 mmol), and TsOH·H_2O (194 mg) in toluene (220 ml) gave the acetals **4**: IR 3070, 1040, 915 cm^{-1}. Hydroboration[6] of the crude acetals **4** with diborane generated from $NaBH_4$ (2.94 g, 26.0 mmol) and BF_3·Et_2O (4.24 g, 31.2 mmol) in THF (170 ml), and the subsequent oxidation with H_2O_2 gave the alcohols **5**: IR 3400, 1040 cm^{-1}. Mesylation[9] of the crude alcohols **5** with methanesulfonyl chloride (9.1 ml, 116 mmol) and triethylamine (27.2 ml, 194 mmol) in dry ether (300 ml) gave the mesylates **6**: IR 1345, 1170 cm^{-1}. Reaction[9] of the crude mesylates **6** with lithium bromide (12.5 g, 119 mmol) in acetone (320 ml) gave the bromides **7**: 6.24 g, 65% from **3a** and **3b**; bp 120—122 °C/1.5 mmHg; IR 1735 cm^{-1}.

A suspension of **7** (25.5 mmol) and sodium iodide (7.65 g, 51.0 mmol) in acetone (93 ml) was stirred at room temperature for 2 h. The reaction mixture was concentrated *in vacuo* and ether was added. The organic layer was washed with 10% $NaHSO_3$ solution, water, and dried ($MgSO_4$). The solvent was removed *in vacuo* to give the crude iodides **8**: IR 1735 cm^{-1}.

A mixture of magnesium (1.7 g, 70.0 mmol) and $HgCl_2$ (0.4 g) in THF (90 ml) was heated to 45 °C. A solution of the above iodides **8** in THF (55 ml) was added over a period of *ca.* 30 min. During addition the temperature of the reaction mixture was maintained at 45—50 °C. After refluxing for 24 h, the mixture was hydrolyzed with water and decanted from the excess magnesium. The solution was extracted with ether and the organic layer was washed with water, dried ($MgSO_4$), and concentrated *in vacuo*. The residue was chromatographed to give the alcohols **1a** and **1b**. **1a**: 1.08 g, 26% from **8**; IR 3350 cm^{-1}; MS *m/z* 166 (M^+), 84 (base); ^1H NMR (CCl_4) δ=1.3—2.6 (m); ^{13}C NMR ($CDCl_3$) δ=92.0 (s), 53.1 (d), 50.4 (d), 42.9 (d), 41.5 (t), 37.7 (t), 34.1 (t), 30.8 (t), 28.1 (t), 26.6 (t), 23.7 (t). Found: C, 79.33; H, 11.21%. Calcd for $C_{11}H_{18}O$: C, 79.46; H, 10.92%. **1b**: 0.65 g, 17% from **8**; IR 3350 cm^{-1}; MS *m/z* 166 (M^+) 119 (base); ^1H NMR (CCl_4) δ=0.78 (q, 1H), 1.2—3.0 (m, 17H); ^{13}C NMR ($CDCl_3$) δ=93.6 (s), 55.4 (d), 55.0 (d), 44.8 (d), 39.6 (t), 35.9 (t), 31.8 (t), 29.6 (t), 28.0 (t), 26.6 (t), 25.4 (t). Found: C, 79.16; H, 11.19%. Calcd for $C_{11}H_{18}O$: C, 79.46; H, 10.92%.

cis-*Tricyclo[6.3.0.0^{2,6}]undec-1(8)-ene (9).* Mesylation of **1a** (50 mg, 0.30 mmol) as described above followed by treatment[6] of the crude mesylate with $LiAlH_4$ (23 mg, 0.60 mmol) gave the olefin **9**: 29 mg, 65% from **1a**; MS *m/z* 148 (M^+), 119 (base); ^1H NMR (CCl_4) δ=1.2—2.4 (m, 14H), 2.6—3.2 (m, 2H); ^{13}C NMR ($CDCl_3$) δ=148.2 (s), 144.4 (s), 47.6 (d), 46.8 (d), 37.4 (t), 35.7 (t), 30.3 (t), 29.4 (t), 28.2 (t), 27.9 (t), 26.0 (t). Found: C, 88.89; H, 11.14%. Calcd for $C_{11}H_{16}$: C, 89.12; H, 10.88%. The isomeric alcohol **1b** (50 mg, 0.30 mmol) was dehydrated as described for **1a** to give **9** (30 mg, 67%).

cis-transoid-cis- *and* cis-cisoid-cis-*Tricyclo[6.3.0.0^{2,6}]undecanes (10a) and (10b).* The olefin **9** (217 mg, 1.46 mmol) was hydrogenated as described previously[6] to give the two hydrocarbons **10a** and **10b**. **10a**: 95 mg, 43%; MS *m/z* 150 (M^+), 67 (base); ^{13}C NMR ($CDCl_3$) δ=52.3 (d, 2C), 44.8 (d, 2C), 40.1 (t), 33.9 (t, 2C), 32.9 (t, 2C), 26.1 (t, 2C). Found: C, 87.76; H, 12.32%. Calcd for $C_{11}H_{18}$: C, 87.92; H, 12.08%. **10b**: 78 mg, 35%; MS *m/z* 150 (M^+), 67 (base); ^{13}C NMR ($CDCl_3$) δ=47.3 (d, 2C), 47.2 (d, 2C), 40.2 (t), 31.5 (t, 2C), 28.4 (t, 2C), 27.2 (t, 2C). Found: C, 87.78; H, 12.36%. Calcd for $C_{11}H_{18}$: C, 87.92; H, 12.08%.

Synthesis of 10b by Reductive Deoxygenation from 1b. The reaction of the lithium alkoxide [derived from **1b** (486 mg, 2.93 mmol) and butyllithium (1.56 M hexane solution (1 M=1 mol dm^{-3}), 3.9 ml, 5.96 mmol)] with diethyl phosphorochloridate (506 mg, 2.93 mmol) gave the diethyl phosphate: IR 1250, 1010 cm^{-1}. Treatment of the crude phosphate with lithium (200 mg) in dry diethylamine (140 ml) followed by *t*-BuOH (1.5 ml) and THF (40 ml) gave 199 mg (45% from **1b**) of **10b** after usual workup.[7]

Synthesis of an Authentic Sample of 10b. Wolff-Kishner reduction of the diketone **11**[8] (500 mg, 2.81 mmol) as described previously[6] gave the hydrocarbon (165 mg, 39%) whose Mass and ^{13}C NMR spectra were identical with those of **10b**.

Syntheses of Diferrocenyl Trithiocarbonate and a Tetrathio-substituted Ethylene Derivatives of Ferrocene

Masaru SATO* and Sadatoshi AKABORI†
Chemical Analysis Center, Saitama University, Urawa, Saitama 338
†*Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274*
(Received December 14, 1984)

Synopsis. Diferrocenyl trithiocarbonate, 1,3-dithia-[3]ferrocenophane-2-thione, and 2,2′-bi(1,3-dithia[3]-ferrocenophan-2-ylidene) were prepared.

Electron-rich olefins,[1] in which all substituents are electron-donating groups, are interesting from the viewpoints of both their chemical reactivities and their physical properties. Tetrathio-substituted ethylene derivatives attract much attention in connection with tetrathiafulvalene which forms high-conducting complexes with DDQ,[2] but only a few derivatives have been prepared.[3] We now report the synthesis of tetrathio-substituted ethylene derivatives of ferrocene through 1,1′-ferrocenediyl trithiocarbonate.

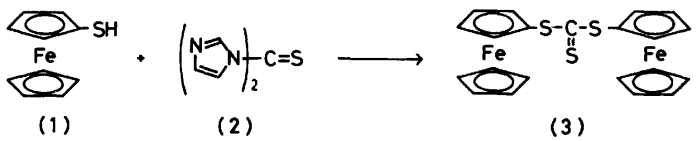
Ferrocenethiol (**1**) reacted with 1,1′-thiocarbonyldiimidazole (**2**) in tetrahydrofuran (THF) at room temperature to give diferrocenyl trithiocarbonate (**3**) in good yield. Similarly, the reaction of 1,1′-ferrocenedithiol (**4**) with **2** gave 1,3-dithia[3]ferrocenophane-2-thione (**5**) in a 78% yield. The structure of these compounds was confirmed by elemental analysis, mass- and ^{1}H-NMR spectra. For example, ^{1}H-NMR spectrum ($CDCl_3$) of **2** showed only two signals at δ 4.21 (s, 10H) and 4.43 (m, 8H), due to the cyclopentadienyl ring protons of a ferrocene nucleus. The comparison of the IR and electronic spectra of **5** and **3** is interesting. The stretching frequency of the thiocarbonyl group in **5** (975 cm^{-1}) appeared at lower frequency than that of **3** (1043 cm^{-1}). In the electronic spectrum, the absorption band of **5** (424 nm) showed a large bathochromic shift compared with that of **3** (406 nm). These results suggest that there is some interaction between the nonbonding d (e_{2g}) orbital of the ferrocene nucleus and the antibonding orbital of the thiocarbonyl double bond.

The compound **5** was refluxed for 24 h with triphenylphosphine to give 2,2′-bi(1,3-dithia[3]ferrocenophan-2-ylidene) (**6**) in good yield. A similar reaction of **5** with trimethyl phosphite gave **6** in a 44% yield. However, the reaction of **3** with triphenylphosphine or trimethyl phosphite affords no ethylenic compound. The compound **6** was insoluble in almost all common organic solvents, but slightly soluble in chloroform. The structure of **6** was determined by elemental analysis, mass (M^+ m/z 520) and ^{1}H-NMR spectra [δ 4.36 (t, 8H) and 4.19 (t, 8H)]. Attempt to prepare the charge-transfer complex with tetracyanoquinodimethane or tetracyanoethylene and oxidation with silver tetrafluoroborate in chloroform were unsuccessful.

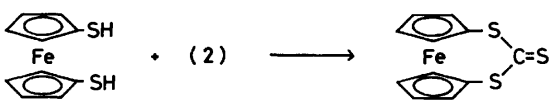
Experimental

Materials. Ferrocenethiol,[4] 1,1′-ferrocenedithiol,[5] and 1,1′-thiocarbonyldiimidazole[6] were prepared according to the literature.

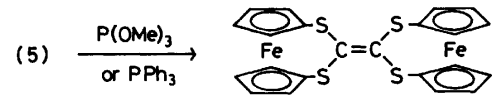
Diferrocenyl Trithiocarbonate (3). To a solution of ferrocenethiol (**1**) (0.40 g, 1.8 mmol) in N_2-saturated THF (10 cm^3) was added 1,1′-thiocarbonyldiimidazole (**2**) (0.19 g, 1.08 mmol). The solution was stirred for 2 h at room temperature. After evaporation, the residue was chromatographed on silica gel by elution with toluene to give diferrocenyl trithiocarbonate (**3**) (0.35 g, 81%) as orange crystals. Recrystallization from benzene–hexane gave an analytically pure sample as orange leaflets, mp 193—194 °C. Found: C, 52.90; H, 3.91%. Calcd for $C_{21}H_{18}S_3Fe_2$:



(1) (2) (3)



(4) (5)



(6)

C, 52.74; H, 3.79%. MS (75 eV): *m/z* 476 (M^+, 100%). IR (KBr): 1043 cm^{-1}. UV-VIS (EtOH): λ_{max} 406 nm (log ε 3.09). ^{1}H-NMR ($CDCl_3$): δ=4.43 (m, 8H) and 4.21 (s, 10H).

1,3-Dithia[3]ferrocenophane-2-thione (5). To a solution of 1,1′-ferrocenedithiol (**4**) (1.74 g, 7 mmol) in N_2-saturated THF (100 cm^3) was added **2** (1.46 g, 8.2 mmol). The solution was stirred for 1 h at room temperature. After evaporation, the residue was chromatographed on silica gel; elution with dichloromethane gave the title compound **5** (1.59 g, 78%) as red orange crystals. Recrystallization from benzene gave an analytically pure sample as red plates, mp 195 °C (dec). Found: C, 45.18; H, 2.79%. Calcd for $C_{11}H_8S_3Fe$: C, 45.21; H, 2.76%. MS (75 eV): *m/z* 292 (M^+, 100%). IR (KBr): 975 cm^{-1}. UV-VIS (EtOH): λ_{max} 424 nm (log ε 3.18). ^{1}H-NMR ($CDCl_3$): δ=4.54 (t, 4H, J=1.8 Hz) and 4.36 (t, 4HJ=1.8 Hz).

2,2′-bi(1,3-dithia[3]ferrocenophan-2-ylidene) (6). A solution of 1,3-dithia[3]ferrocenophane-2-thione (**5**) (0.20 g, 0.7 mmol) and triphenylphosphine (0.23 g, 0.88 mmol) in anhydrous toluene (5 cm^3) was refluxed for 24 h under nitrogen. After keeping at room temperature overnight, the resulting crystals (123 mg, 68%) were filtered. The yellow crystals were recrystallized from a large volume of chloroform. mp 250 °C. Found: C, 50.97; H, 3.28%. Calcd for $C_{22}H_{16}S_4Fe_2$: C, 50,79; H, 3.10%. IR (KBr): 3070, 1410, 1164, 1025, 895, and 815 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=4.36 (t, 8H, J=1.8 Hz) and 4.19 (t, 8H, J=1.8 Hz).

A solution of **5** (0.20 g, 0.7 mmol) and trimethyl phosphite (0.1 cm^3, 0.85 mmol) in anhydrous benzene (5 cm^3) was refluxed for 2 h. After a similar work-up described above, yellow crystals (80 mg, 44%) of **6** were obtained.

Response of Copper(II) and Cadmium(II) Ion-selective Electrodes in Some Nonaqueous Solvents

Makoto AIHARA,* Sachiko KANETAKE, and Yuka FUKUDA
Laboratory of Inorganic Chemistry, Faculty of Home Life Science, Fukuoka Women's University, Higashi-ku, Fukuoka 813
(Received October 2, 1984)

Synopsis. The response of cadmium(II) and copper(II) ion-selective electrodes was evaluated in methanol, ethanol, acetonitrile solutions and their mixtures with water. The electrodes showed an almost Nernstian behavior in nonaqueous solutions and their mixtures with water except in acetonitrile.

Application of ion-selective electrodes to nonaqueous solutions has been expanded by using solid membrane ion-selective electrode. Properties of the electrodes, *e.g.* their sensitivity, selectivity and response time are expected to be solvent dependent. Several authors reported the response of solid membrane electrode in a variety of organic solvents and their mixtures with water.[1-5] The response of solid membrane electrodes in different solvents is interesting but little is known about such solvent dependence.

This paper is concerned with the response of cadmium(II) and copper(II) ion-selective electrodes at direct potentiometry and potentiometric titrations in methanol, ethanol, acetonitrile and their mixtures with water.

Experimental

For the study, Ag_2S/MS (M=Cu or Cd) membrane disks were supplied by Denki Kagaku Keiki Co. LTD (Tokyo). A cross-section of the ion selective electrode made is shown in Fig. 1. Other apparatus were the same as in the previous report.[6]

Direct potentiometry and potentiometric titration in solution containing 0.1 M (1 M=1 mol dm^{-3}) sodium perchlorate were performed by the usual method. In every case, the electrode system was allowed to attain equilibrium (±0.1 mV) . Potentials at each titration became stable after a period of 5—30 min. All measurements were made at 25.0±0.1 °C.

Results and Discussion

Response of Cadmium(II) Ion-selective Electrode in Direct Potentiometry. Measurements by direct potentiometry of Cd (II) in methanol-water mixtures and pure methanol are shown in Fig. 2. Nernstian response in pure methanol was observed to 2×10^{-6} M at constant ionic strength of 0.1 M. The response becomes more ideal when some water is added.

In ethanol-water mixtures, the electrode responds similarly to the behavior in water-methanol mixtures.

In acetonitrile-water mixtures, the behavior of the electrode was different from the former cases. Approximate Nernstian response to cadmium concentration at constant ionic strength was observed from 10^{-3} M to 10^{-5} M at a solvent mixture containing 40 vol % acetonitrile and 60 vol % water (abbreviated as 40% acetonitrile solution). But intereference of an unknown nature gave very low readings in 80% acetonitrile solution.

Response of Copper(II) Ion-selective Electrode in Direct Potentiometry. In methanol-water mixture, the copper(II) electrode responds very well to copper concentration of 6×10^{-6} M and the Nernstian response was observed in the 80% methanol solution. But the electrode indicated the large shifts of the potential at the low concentration of copper(II) in 100% ethanol solution as shown in Fig. 3.

In ethanol-water mixtures, responses are linear in 20 and 40% ethanol solutions, but indicated the large

	80%	1.8	5.5
Acetonitrile	20%		5.3

shifts of potential at 80% ethanol and 100% ethanol concentration.

The results of these electrode responses are present in Table 1.

Evaluation of Selectivity Coefficients. The selectivity coefficients of these electrodes were determined by the mixed solution method. The values of the selectivity constants of the electrodes for two metals are given in Table 2. The selectivity coefficients in methanol-water and ethanol-water mixtures were somewhat larger than those in water.

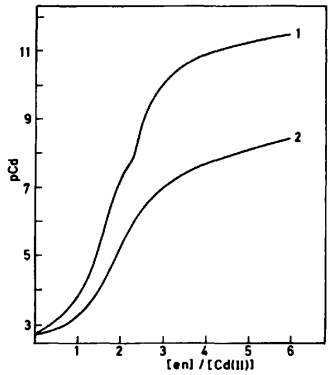

Fig. 4. Titration curves of 2×10^{-3} M $Cd(ClO_4)_2$ with 0.1 M en in 100 % methanol and ethanol solutions.
1; 100 % ethanol, 2; 100 % methanol.

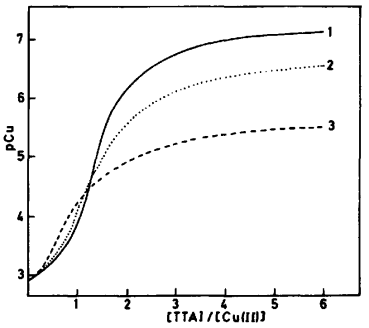

Fig. 5. Titration curves of 2×10^{-3} M $Cu(ClO_4)_2$ with 0.1 M TTA in 80 % ethanol solution.

Complex Formation Studies. In Figs. 4 and 5 are shown the potentiometric titration curves of cadmium(II) solution with ethylenediamine(en) in 100% methanol and ethanol solutions and copper(II) solution with thenoyltrifluoroacetone(TTA) in 80% ethanol solution. None of the titration curves showed any distinct break. The successive formation of complexes is proposed and more detail discussion is required for the determination of successive formation constants.

The authors wish to thank Denki Kagaku Keiki Co., LTD (Tokyo) for partial support of this work. We are grateful to Mr. Toru Ito for many helpful suggestions.

Effects of Uniaxial Pressure and Shear on the Electrical Conductivity of Solid. II. Electrical Conductivity in Some Amorphous Coordination Polymers[1)]

Seiichi KANDA,* Kuwako OHKAWA,† Kenichi YAMASHITA,††
Nobuo ODA,††† and Hideaki CHIHARA**
Department of Applied Chemistry, Faculty of Engineering, The University of Tokushima, Minamijosanjima, Tokushima 770
**Department of Chemistry, Faculty of Science, Osaka University, Toyonaka 560*
(Received April 27, 1984)

Three amorphous coordination polymers, R_2dtoaCu, where R=CH_3, $C_6H_5CH_2$, or cyclohexyl and dtoa= (*N,N'*-disubstituted dithiooxamidato), were prepared and the effect of uniaxial pressure on their electrical resistivities in the direction of the external pressure was measured. Application of the pressure up to 6×10^8 Pa caused an increase in the resistivity but, before reaching the equilibrium state, the resistivity exhibited a complicated time variation, which was not completely reversible upon pressure release as far as the measurement could trace. The results were explained on the basis of a model in which at least two competing processes occur. One of the processes is assumed to be reorientation of the two-dimensional network of molecules perpendicular to the applied pressure, which is a slow process and takes as long as hundreds of hours to reach the equilibrium. Activation energies of various processes were derived.

The three coordination polymers (R_2dtoaCu; R= CH_3, $C_6H_5CH_2$, and *cyclo*-C_6H_{11}) treated in this study are representatives of several *catena*-μ- (*N,N'*-disubstituted dithiooxamidato)-copper(II) coordination polymers, the resistivities of which range from 10^5 to 10^{10} Ωcm at 30°C.[2)] Although the technique of X-ray structural analysis[4)] is not applicable due to the amorphous structures, a two-dimensional network structure has been proposed on the basis of some evidence.[3)] An example of such a network model (Fig. 1) will be discussed later.

While numerous studies have been reported on the electrical properties of semiconductive polymers, there have been a few that dealt with the effect of pressure on the electrical properties, *e.g.* resistivity,[5-8)] dielectric constant,[5)] activation energy for conduction,[6)] electronic mobility,[7)] and superconducting transition;[8)] there have been no studies on the kinetic aspect of the pressure effect. Generally, the electrical resistivity of powder samples has been measured on compressed pellets or under pressure.[9)] The resistivity of semiconductive organic crystals usually decreases reversibly by several orders of magnitude with an increase of pressure up to 10^{10} Pa. Beyond 10^{10} Pa, irreversible chemical changes occur in some compounds, which result in irreversible changes in their resistivity.[10)] One exception was reported in the case of poly(phenylacetylene), where a large reversible increase in resistivity upon increasing the pressure was attributed to a large positive volume of activation.[11)]

In contrast to these cases, application of a uniaxial pressure less than 10^9 Pa on R_2dtoaCu coordination polymers results in an increase in resistivity and complicated hysteresis.[1)] Enhancement of this tendency with an application of shear stress substantiates the idea that the anomaly is attributed to the anisotropic structure of the macromolecule and its response to an external pressure.[12)] In the last report[1)] a semiquantitative study was presented on the hysteresis effect in the resistivity-pressure-temperature relationship. A model was then proposed which assumes molecular motions that depend on the temperature, the pressure, and the history of treatment. In this paper the phenomenon will be more quantitatively examined from standpoints of rate process and equilibrium properties.

Experimental

Materials. *N,N'*-dimethyldithiooxamide ($(CH_3)_2$dtoa-H_2), *N,N'*-dibenzyldithiooxamide ($(C_6H_5CH_2)_2$dtoaH_2), and *N,N'*-dicyclohexyldithiooxamide ($(C_6H_{11})_2$dtoaH_2), were kindly donated by Mallinckrodt Chemical Works, and were recrystallized from ethanol. The copper coordination polymers were prepared by mixing an aqueous solution of copper sulfate and a water-ethanol solution of the equivalent amounts of the ligands according to the reaction of the type:

$$Cu^{2+} + \begin{matrix} RHN & & S \\ \diagdown & & \diagup \\ & C-C & \\ \diagup & & \diagdown \\ S & & NHR \end{matrix} \longrightarrow 2H^+ + \text{the coordination polymer}$$

The structural model of the polymers is depicted in the Fig. 1. The amorphous precipitates were centrifuged and washed repeatedly with water and ethanol, successively.

Analyses of the Three Coordination Polymers. $(CH_3)_2$dtoa-Cu, Found: H, 2.83; C, 20.72; N, 11.22; Cu, 29.22%. Calcd for $C_4H_6N_2S_2Cu$: H, 2.89; C, 22.90; N, 13.35; Cu, 30.29%. $(C_6H_5CH_2)_2$dtoaCu, Found: H, 3.97; C, 53.27; N, 7.60; Cu, 16.70%. Calcd for $C_{16}H_{14}N_2S_2Cu$: H, 3.90; C, 53.10; N, 7.74; Cu, 17.47%. $(C_6H_{11})_2$dtoaCu, Found: H, 6.54; C, 48.4; N, 7.97; Cu, 18.41%. Calcd for $C_{14}H_{22}N_2S_2Cu$: H, 6.40; C, 48.6; N, 8.10; Cu, 18.36%. The slightly low values of nitrogen are frequently observed in coordination polymers containing copper(II) directly coordinated by nitrogen.[13)] The atomic ratios of the elements in the polymers were calculated from the analytical values by fixing the number of carbon atoms at the limiting value for infinite degree of polymerization.

a): Pellet of sample, b): pyrophyllite gasket, c): Teflon film for electrical insulation, d): polyethylene sheet, e): Teflon sheet, f): re-entrant well for thermocouple, g): O-ring for sealing, h): piston serving both as an electrode and a pressure transducer.

The reasonable agreements between the calculated and observed atomic ratios show that the polymers obtained have nearly stoichiometric composition, $(RNSC)_2Cu^{II}$. In fact, the polymers assume a two-dimensional network structure in which some vacancies of Cu sites are, in principle, possible. If it occurs, electroneutrality requires two additional hydrogen atoms to replace a copper atom. This is reflected in the low values of copper and the correspondingly high values of hydrogen in the elemental analyses.

Electrical Measurements. As a high pressure cell for the resistivity measurements, a pellet press was used with a steel piston having a diameter of 11.5 mm. The piston was used as an electrode with insulating Teflon film (0.2 mm thick) around it as shown in Fig. 2. By use of an oil pump and the above-mentioned cell, a maximum pressure of 9.0×10^8 Pa can be applied to the specimen. The temperature was controlled by a ribbon heater wound around the outside can, which is not shown in Fig. 2. A thermocouple for temperature measurements was inserted into the re-entrant well at the lower end. The vessel was not evacuated, but was sealed from the atmosphere with O-rings. The powder specimen was first premolded in 5 mm diameter at 1.8×10^8 Pa; the small pellet was mounted at the center of a pyrophyllite gasket which had been pretreated at 700 °C for 30 min; the assembly shown in Fig. 2 with a piece of thin Teflon ring, was pressed.

Electrical data under pressure were taken *in situ* a few minutes after the electrical field was applied. The electrical resistance was measured by means of a valve voltmeter with an applied electric field of 15 V cm^{-1}. The pellet assembly was replaced for each run at one temperature, which usually took as long as several hundred hours because of the long equilibration time under applied pressure. When, however, we measured the temperature dependence of the equilibrium resistivity values as shown later in Figs. 8 and 9, a single loading of the specimen was used. The effects of pressure were examined by using a uniaxial pressure of 6.0×10^8 Pa throughout this study. The same pressure value was used for determining the resistivity values of the specimens of the pellet form, which was applied only instantaneously and intermittently during the runs in which relaxation after pressure release was studied. Such instantaneous application of pressure would not affect the long-time response of the specimen. For the polymers under investigation there is a fast process which occurs upon compression or pressure release and which is followed by a very slow process as we will discuss in detail.

Results and Discussion

The Rate Process under a Uniaxial Pressure (6.0×10^8 Pa). Changes in the resistivity of $(CH_3)_2$dtoaCu, $(C_6H_5CH_2)_2$-dtoaCu, and $(C_6H_{11})_2$dtoaCu under a constant external pressure as the function of time are shown in Figs. 3, 4, and 5. The resistivities begin to change immediately after the external pressure was applied or released. These changes occur in a very short time and were not traced. However, such an initial stage of change was followed by a very gradual drift of the resistivity values extending up to several hundred hours. It is such a long-time behavior that we are interested in. In Figs. 3—5, $\rho_0^{\pm}$ is the initial resistivity value determined immediately after the fast process has been completed, the superscript $\pm$ meaning the compression or the pressure release operation.

The general feature of the time dependence as exemplified in Fig. 3a is that it is a kind of relaxation phenomenon. Ordinarily, such a relaxation process is characterized by a time constant which governs the first order rate process. In other words, the rate of change of resistivity, $d\rho^{\pm}/dt$, can be described by

$$d\rho^{\pm}/dt = -k^{\pm}(P, T)(\rho^{\pm} - \rho_{eq}^{\pm}) \quad (1)$$

Here, $\rho_{eq}^{\pm}$ is the asymptotic (equilibrium) value of the resistivity, k is the rate constant and equal to the reciprocal of the relaxation time.

The experimental values of resistivity were fitted to Eq. 1 in the integrated form and it was found that the equations can reproduce the observed results in certain ranges of time. The values of k thus derived are listed in Table 1 together with the activation energies derived from the Arrhenius equation

$$k^{\pm} = k_0^{\pm} \exp(-\Delta H_{\pm}^{\pm}/RT). \quad (2)$$

The plots of $k^{\pm}$ *vs.* T^{-1} are shown in Fig. 6.

The results of Figs. 3a and 3b fit Eq. 1 over the almost

entire range of time, whereas for the dibenzyl complex (Fig. 4b) and the dicyclohexyl complex (Fig. 5a), Eq. 1 can be applied only in the ranges in which $d\rho/dt<0$ in Fig. 4b and $d\rho/dt>0$ in Fig. 5a.

As shown by the insert of Fig. 4a, the resistivity of the dibenzyl complex does not show a monotonous change but has a small plateau. In the case of the dicyclohexyl complex (Fig. 5a), the initial change of the resistivity is opposite to the cases of the other two polymers, *i.e.* the resistivity decreases with time under a constant external pressure. After this initial process, the behavior (after 10 h. at 110°C) can be described by Eq. 1.

These additional features for which Eq. 1 does not apply strongly suggest that the time dependence of the resistivities, or the relaxation process, is not a simple process but there must be two or more mechanisms having different rate constants (or relaxation times) that proceed competitively.

A Structural Model. Application of uniaxial pressure usually decreases the resistivity of polycrystalline semiconductors parallel to the external stress. It is interpreted as due to improved contact between grains and decreased intermolecular distances. All the three substances examined in the present study, on the contrary, showed an increase in the resistivity under uniaxial pressure. However, the conditions of time and/or temperature were different from substance to substance, under which such an anomalous behavior was observed. This means that there must be some special cause that operates in these substances and opposes the ordinary compaction effects mentioned above. The special cause, which we will try to identify, will give rise to a complex overall behavior as seen in Fig. 5a in the case of the cyclohexyl complex.

Similarly, the release of the uniaxial pressure results in a decrease in the resistivity although here again there are differences in the overall behavior among the coordination polymers.

In order to find a mechanism by which such anomalous pressure dependence occurs, let us first consider about the structure of these polymers. The model of Fig. 1 is based on some evidence obtained from the composition, the X-ray diffraction pattern, and the magnetic data.[3] In this model, the polymer complex forms a two-dimensional network with the substituent, methyl, benzyl, or cyclohexyl group, attached at every N atom. The substituents will therefore protrude above and below the network plane but it is not easy to

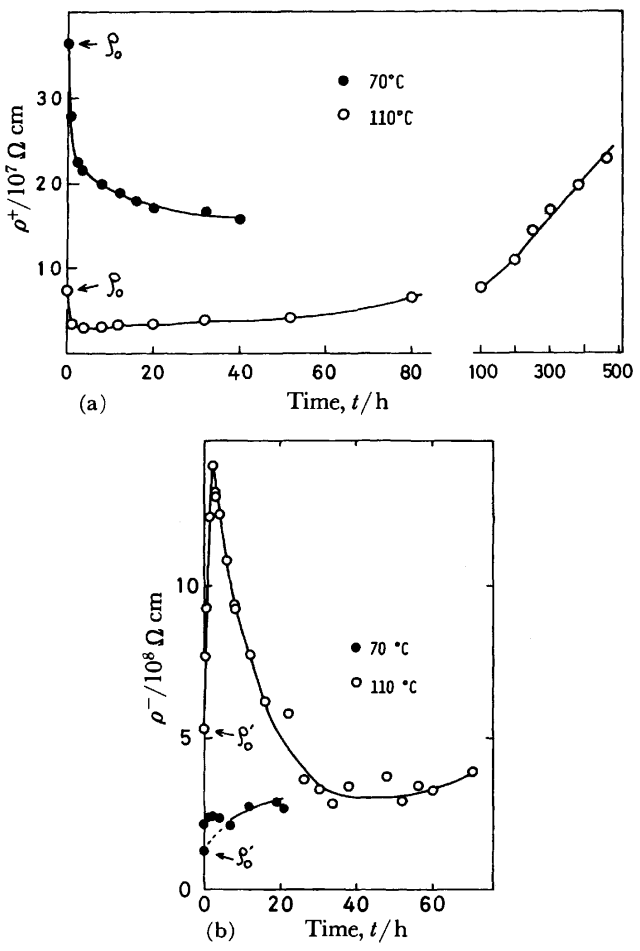

Fig. 5. Resistivity change of $(C_6H_{11})_2$dtoaCu.

(1): CH_3, $k^-(P=0)$, (2): CH_3, $k^+(P=6.0\times10^8$ Pa), (3): $C_6H_5CH_2$, $k^-(P=0)$, (4): $C_6H_5CH_2$, $k^+(P=6.0\times10^8$ Pa).

speculate about the conformation of the substituents. It is interesting in this connection to note that the measured bulk densities of the complexes under ordinary pressures were 1.55, 1.659, 1.76 g cm^{-3} for the methyl, benzyl, and cyclohexyl complexes, respectively; *i.e.* the methyl complex has the largest void space fraction and the cyclohexyl complex the smallest. In other words, the bulky substituents may lie more or less flat in parallel to the network plane. The electronic conduction will be very anisotropic because the electrons are likely to be delocalized whithin a network plane and only van der Waals interaction exists between the planes.

Now, the plausible explanation for the anomalous positive pressure coefficient of the electrical resistivity seems to be that there occurs some rearrangement of molecules as a result of compression. The increase in the resistivity in the direction of applied pressure will mean an increased contribution of the resistivity component perpendicular to the molecular plane. The polymer specimens as prepared have little preferred orientation but, as the uniaxial pressure is applied, the molecular plane will be gradually reoriented so that the plane tends to become perpendicular to the stress, thus increasing the resistivity in the direction of the stress. Such reorientation effect will, of course, be accompanied by deformation of grains. In quite general terms, the uniaxial stress causes randomly oriented molecular planes to be more or less ordered.

Change of Resistance with Time–An Interpretation. It should be noted that the pressure effects are not completely reversible. After a cycle of compression and pressure release, the resistivity does not completely return to its original value. This indicates that there are plastic parts in the deformation as well as elastic parts. Furthermore, if one compares Fig. 4a with Fig. 4b, the benzyl complex shows a smooth change of the resistivity upon compression, but, when the pressure is released, it shows a maximum in the resistance below 55 °C. Therefore, there are at least two competitive processes which give rise to a maximum in the resistivity; one is faster than the other. The faster process is not seen at or above 62 °C in Fig. 4b because the process becomes too rapid at higher temperature in the case of the benzyl complex. The fast process is the process by which the resistivity increases upon pressure release; this is the normal behavior in semiconductors and will be called the process N hereafter. The second process will be called the process A which shows an anomalous effect of decreasing resistivity upon pressure release (we assume that the processes N and A occur upon compression as well as upon pressure release).

The case of the cyclohexyl complex may be interpreted in an analogous way. Upon pressure release (Fig. 5b), there is a maximum in the resistivity which is seen at 110 °C. It is again the competitive effect of the processes N and A, only the process N being observed at 70 °C in a short time (less than 20 h). Upon

a) Omitted for the calculation of $\Delta H_-^{\neq}$.

compression (Fig. 5a), only the process N is seen in a short time particularly at a lower temperature. For this complex, the change of the resistivity was measured to 500 h (Fig. 5a) and the process A is seen to proceed slowly.

The case of the methyl complex looks simple, but it is probably because the process N finishes in a very short time. With regard to the process A, the value of $k^{\pm}$ (Table 1) is generally much larger for the methyl complex than for the other two complexes. This suggests a quicker response of the methyl complex with regard to the process N. The rate of the two processes depends strongly on temperature; at lower temperatures the process N can be so slow (as slow as the process A) that the two processes are not separable, causing a maximum in the resistivity to appear at a certain time as in the case of the dibenzyl and the dicyclohexyl complexes.

To rationalize the relationship between experimental observations on the processes N and A and the usual dynamics of the viscoelastic body, let us consider the Voigt model.[14]

Strain γ of polymer solids due to an external load is analyzed by use of a spring for elasticity and a dash-pot for plasticity. The two elements, the spring and the dash-pot, can be combined in parallel to build the Voigt element, which represents anelasticity *i.e.* time-dependent elastic deformation. The three macroscopic deformations (elastic, plastic and relaxationally elastic), γ_e, γ_p, and γ_r, are expressed schematically as a function of time in Fig. 7a. The elastic after-effect of anelasticity is given by

$$\gamma_r = \gamma_\infty[1 - \exp(-t/\tau)]. \quad (3)$$

The reciprocal of the relaxation time τ corresponds to $k^{\pm}$ in Eq. 1. The change in time of the resistivity of the three coordination polymers, $\Delta\rho$, generally have components, $(\Delta\rho)_e$, $(\Delta\rho)_p$, and $(\Delta\rho)_r$, in a manner similar to the case of the macroscopic deformation. While the sign of all the components of γ is the same, the sign of the $(\Delta\rho)_e$ is opposite to the sign of $(\Delta\rho)_r$ or $(\Delta\rho)_p$ in the compound studied (Fig. 7b). Typical examples of combination of these components are shown in Fig. 7c. It should be noticed that the apparent τ's (*i.e.* $1/k$) can be different during the compression and during release because of the relaxational components in the Voigt model.

If we associate the $(\Delta\rho)_e$ components mainly with the process N and $(\Delta\rho)_r$ and $(\Delta\rho)_p$ mainly with the process A, we obtain good correspondence between the behavior of the Voigt model and the time-dependence of the resistivities. Thus the elastic portion or the process N has a very fast response to external stimulations, whereas the process A is slower and causes an apparent hysteresis even if the molecular processes involved are the same upon compression and upon release.

What happens when the specimen is compressed will be viewed in the following way. The initial process will be deformation or collapse of grains to fill the void space between the grains (improved contact between grains), which is followed by a simple compression (time-dependent elastic deformation) which changes the intermolecular distances. This corresponds to the process N. The instantaneous elastic deformation will bring the molecular arrangement into an energetically unstable configuration which will then be relaxed by the time dependent elastic process and by the slow plastic deformation process (the process A). If we pursue our picture a little further, this relaxation will occur in such a way as to reorient the network planes so that the planes will become perpendicular to the direction of the stress. As the molecular arrangement is gradually relaxed, further elastic deformation will become possible at successively new molecular configuration and such secondary elastic deformation

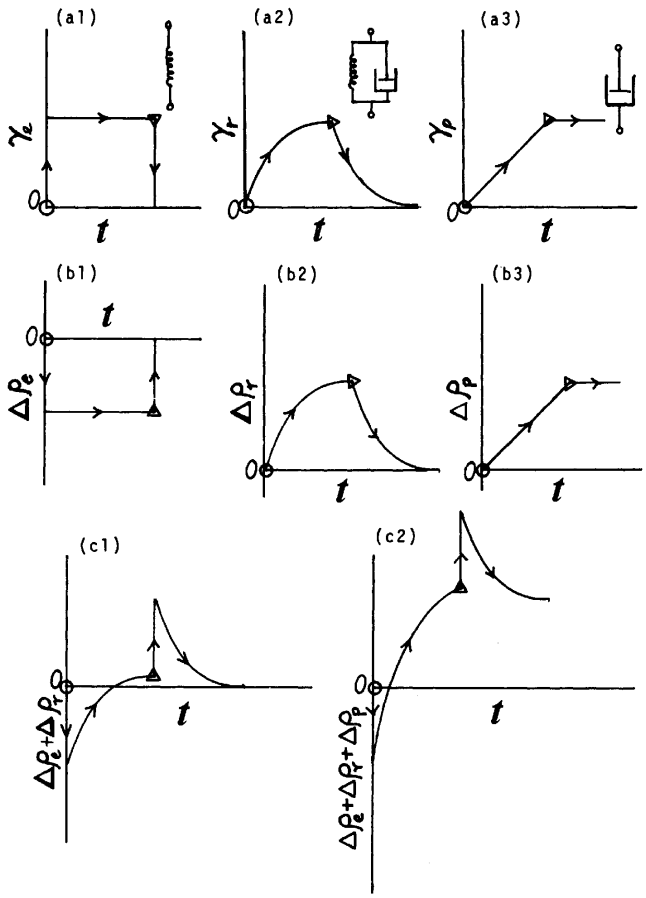

Fig. 7. Schematic representation of time evolution of the strain γ, and the electrical resistivity $\Delta\rho$ for elastic, Voigt, and plastic models: a1—a3 for the three models of γ respectively, b1—b3 for the three models of $\Delta\rho$, c1—c2 for combinations of the models of $\Delta\rho$.

will cause further relaxation due to plastic deformation. Therefore, the elastic and plastic processes mutually affect each other and so do the processes N and A. The values of $k^{\pm}$ in Table 1, in this vein, should be considered to correspond not to a well-defined single process but to a composite process.

Activation Energies for The Mechanical Process. From the plots of Fig. 6, the apparent activation energies of the relaxation process (the process A) were derived for the methyl and benzyl complexes as listed in Table 1. In both substances, the activation energy is larger upon compression than upon pressure release. The differences between the values for the two directions are almost the same in the two substances, 34 kJ mol^{-1} (57.2—23.0) and 35 kJ mol^{-1} (75.5—40.8) for the methyl and the benzyl complex, respectively. If the same activated state can be assumed in the two directions, the equality shows that the difference in energy between the initial state (random molecular arrangement) and the final state (oriented molecular arrangement) does not depend on whether the substituent is methyl or benzyl; the difference between the two substances lies in the height of the potential barrier hindering the relaxation.

Temperature Dependence of Equilibrium Resistivity. Because the long-time behavior was an extremely slow process, it was not easy to obtain the reliable equilibrium values of resistivity $\rho^{\pm}_{eq}(P,T)$ at a given temperature. The criterion for equilibrium and the method for determining the equilibrium values were as follows: (1) An attempt was first made to wait until a steady value was obtained under a constant external pressure at a temperature. (2) The temperature was then lowered under the same pressure and the specimen was brought to a state of equilibrium at that temperature. After a certain length of time, usually a few hours, the specimen was heated back to the original temperature where the resistivity approached the equilibrium value from the opposite side to the case (1). If the final value agreed with the value obtained in (1), it was taken as the equilibrium value. If it did not, the average value was adopted. This procedure was employed only at 70 °C.

Figures 8 and 9 will illustrate such sequence of changes. In Fig. 8, the point on the line 1 corresponds to the equilibrium state at the ambient pressure, which we call the random state. Suppose that the specimen (the dimethyl complex) which had been brought to equilibrium at 70 °C under the ambient pressure was pressed for 77 h; the final steady value was assumed to be the equilibrium state. The specimen was then cooled under pressure to a lower temperature where a new equilibrium was waited. Such a cooling was done usually in a short time and the change in the resistivity that occurred in this time is indicated by the broken lines in Figs. 8 and 9. After the equilibrium at 40 °C was obtained for the dimethyl complex (Fig. 8), it was heated back to 70 °C. This heating was done also in a short time and the change in resistivity followed the broken line. At 70 °C, the equilibrium state was approached from the opposite side this time, as explained in (2). Figure 9 shows similar results for the dibenzyl complex. It is interesting to note that the broken lines are more nearly parallel to the line 1 in Figs. 8 and 9 in comparison with the line 2 which connects the equilibrium values under pressure and has a larger slope than the line 1.

Now let us examine the activation energy for electronic conduction in the same direction as that of the external stress as obtained from Figs. 8 and 9. Under no uniaxial stress it was 0.34 eV (33 kJ mol^{-1}) and 0.29 eV (28 kJ mol^{-1}) for the methyl and benzyl complex, respectively. Under the stress of 6.0×10^8 Pa, the values are 0.45 eV (44 kJ mol^{-1}) and 0.43 eV (41 kJ mol^{-1}) corresponding to the state of oriented molecular arrangement. On the other hand, the non-equilibrium resistivity under the pressure gave the same activation energy as the equilibrium resistivity at the ambient pressure (dashed line and line 1 of Fig. 8). This fact

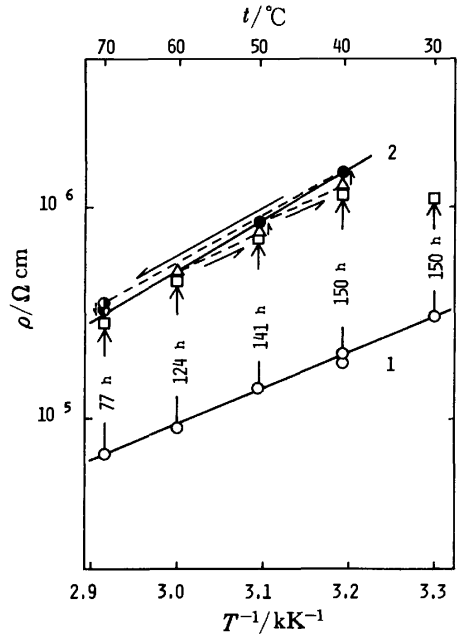

Fig. 8. Resistivity-temperature relation in the transient and the equilibrium states of $(CH_3)_2$dtoaCu. 1 and ○ correspond to the initial random state; 2 and ● the oriented equilibrium state, △ is the cooled state where a new equilibrium state ● is waited, ◑ is the heated-back state where the equilibrium is approached through ◐. □ is the values after the indicated elapse of time. See in the text.

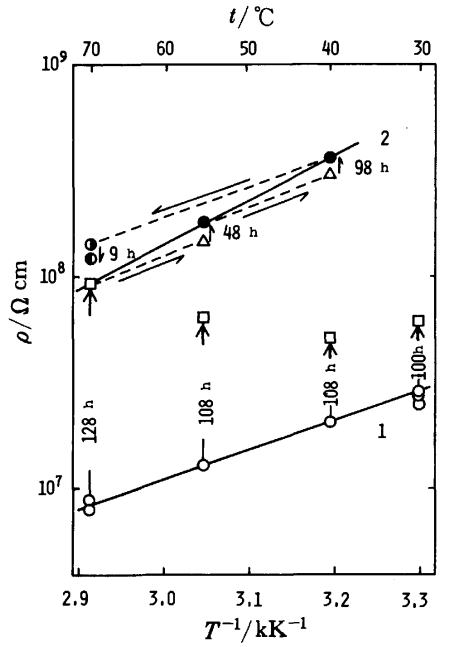

Fig. 9. Resistivity-temperature relation in the transient and the equilibrium states of $(C_6H_5CH_2)_2$dtoaCu. △, ●, ◑, ◐, and □ are essentially the same as in Fig. 8.

justifies our interpretation that the initial process that occurs when the specimen is compressed is the process N involving the improved contact between grains and the elastic deformation. The process A which follows brings the specimens to a state (the oriented state corresponding to the line 2) which requires higher activation energy of conduction (0.45 eV and 0.43 eV). The fact that the difference in the activation energy with or without the external stress is small indicates that reorientation of network planes is not complete under the stress of 6.0×10^8 Pa; the solid would become almost an insulator if the molecular reorientation were complete. Nevertheless the activation energy does increase rather than decrease upon compression and such an effect is also consistent with our picture about the nature of the process A by which the resistivity component increases in the direction perpendicular to the network plane.

Finally, it is very interesting to note that despite the close similarity in the response to uniaxial stress, the methyl and the benzyl complexes show very different equilibrium resistivity values, by a factor of about 10^2 both in the random and the oriented state. The methyl and benzyl complexes have very similar activation energy in their oriented state. Bulkiness and steric hindrance of the substituents are probably related to such a large difference in the resistivity through the deformation of the network structure.

The authors wish to express their thanks to Mr. Satoru Morinishi and Mr. Hideo Minami for their assistance in the measurment and the instrumentation. The present work was partially supported by Grant-in-Aid for Scientific Research No. 754123 from the Ministry of Education, Science and Culture.

Structural and Compositional Changes of Blue Orthorhombic Hydrogen Molybdenum Bronze, $H_{0.30}MoO_3$, by Vacuum Heating and Catalytic Activity for 1-Butene Isomerization

Noriyuki SOTANI,* Noritetsu YOSHIDA,† Yukio YOSHIOKA,† and Shozo KISHIMOTO†

College of Liberal Arts, Kobe University, Tsurukabuto, Nada, Kobe 657

†*Department of Chemistry, Faculty of Science, Kobe University, Rokkodai, Nada, Kobe 657*

(Received August 8, 1984)

Orthorhombic bronze, $H_{0.30}MoO_3$, was decomposed by vacuum heating to $MoO_{2.86}$ with a rhombic MoO_3 structure. The surface area increased slightly with the increase in the rhombic structure in which vacancies were produced. An approximate linear relationship was found between the catalytic activity of 1-butene isomerization and the hydrogen content(x) in the samples which were treated in air at 65 °C or *in vacuo* below 220 °C. On the other hand, the activity above 220 °C increased with the formation of vacancies.

Molybdenum bronzes (formulated as H_xMoO_3) are obtained from the reduction of MoO_3 by atomic hydrogen.[1-5] Four distinct phases are found in the range $0<x\leqq2.0$[4] and the homogenieties of these phases are as follows; (i) blue orthorhombic; $0.23<x<0.4$, (ii) blue monoclinic; $0.85<x<1.04$, (iii) monoclinic; $1.55<x<1.72$, and (iv) green monoclinic; $x=2.0$.

These bronzes were expected to be hydrogen reservoirs and interest, therefore, was centered on their catalytic properties. Sermon and Bond[6] have reported that hydrogen in 1% $Pt/H_{1.6}MoO_3$ was useful for 1-pentene hydrogenation. Marcq *et al.*[7] studied the catalytic hydrogenation reaction of ethylene on the red monoclinic bronze, $H_{1.6}MoO_3$, obtained from Pt-supported MoO_3 by hydrogen spillover and confirmed that the atomic hydrogen in the bronze was active for the catalytic hydrogenation of ethylene.

The authors studied the behavior of hydrogen in the blue orthorhombic bronze, $H_{0.30}MoO_3$, by thermogravimetry[8] and by the TPD method.[9] They confirmed that the bronze decomposed to $MoO_{2.86}$, a nonstoichiometric compound with the rhombic MoO_3 structure, in three steps when the bronze was heated under a vacuum of 10^{-4} Torr† and in a helium atomosphere.

Using proton NMR studies,[10] the authors found no difference in the behavior of the protons in the untreated and treated samples and indicated that the environments surrounding the protons did not change throught heat treatment.

In the present work, the catalytic activity for 1-butene isomerization over the bronzes was studied. The structural and compositional changes of the bronzes after these treatments were also studied. The authors tried to reveal the relationship between the catalytic activity and the hydrogen content(x) or between that and the structural and compositional changes of the samples.

Experimental

The preparation and identification of $H_{0.30}MoO_3$ used in the present experiments were described previously.[8-10] Samples, having various hydrogen contents, were prepared by heating the bronze *in vacuo* or in air. The structural and compositional changes of the samples were studied by X-ray powder diffractometry and infrared spectrophotometry.

1-Butene from Takachiho Kagaku Co. Ltd. was purified by repeated distillation *in vacuo*. The purity was confirmed by gaschromatography to be higher than 99%. A closed circulating system connected to a conventional vacuum line was used for isomerization of the 1-butene. The reaction mixtures were analyzed for each fixed time using the gaschromatograph with a coloum of 2,5-dimethylsulforan (DMS).

The surface area was determined by the BET method.

† 1 Torr≈133.322 Pa.

Results and Discussion

Structural and Compositional Changes of $H_{0.30}MoO_3$. Figure 1 shows the X-ray diffraction pattern of the samples heated at various temperatures *in vacuo* for 60 min. The sample heated at 238 °C showed an X-ray diffraction pattern due to the original orthorhombic structure. However, the pattern due to the rhombic structure appeared on samples treated at 297 and 349 °C. This result means that these samples consist of a mixture of the orthorhombic and rhombic structures. While the sample heated *in vacuo* at 398 °C showed only the X-ray patterns due to the rhombic structure,

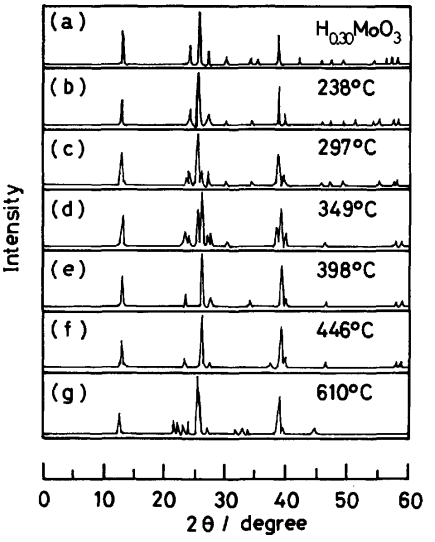

Fig. 1. X-ray diffraction patterns of the blue orthorhombic bronze, $H_{0.30}MoO_3$(a), and the samples treated at 238 °C(b), 297 °C(c), 349 °C(d), 398 °C(e), 446 °C(f), and 610 °C(g).

and the sample heated at 610 °C showed patterns due to mixture of the rhombic MoO_3 and Mo_4O_{11} structures.

As mentioned above, the samples treated at 297 and 349 °C were mixtures of orthorhombic and rhombic structures. The ratio of the orthorhombic to rhombic components was obtained to be 0.76/0.24 (297 °C) and 0.38/0.62 (349 °C), respectively. As the minimum phase limit of the orthorhombic structure was x=0.21 in the present work, the ratio can also be calculated from thermogravimetric data. The ratio was 0.80/0.20 (297 °C) and 0.35/0.65 (349 °C), respectively. These values are in very good agreement with each other. This suggests that the ratio obtained from the thermogravimetric data is easier to use than that obtained from the X-ray results. The sample in which the hydrogen content was x=0.06 showed only a pattern due to the rhombic structure. During vacuum heating, the only gas liberated from the sample was H_2O. No other gas was detected using a quadrupole gas analyzer. This result suggests that the hydrogen atoms in the samples reacted with lattice oxygen to produce H_2O. The bronze with the lowest hydrogen content (x=0.21) transformed to a compound with a hydrogen content of x= 0.06 and finally to a nonstoichiometric compound with a rhombic MoO_3 structure, which contains no hydrogen atoms. These results lead to the conclusion that vacancies should be produced in the samples during the evolution of H_2O under vacuum heating. These changes are formulated as follows;

$$H_{0.30}MoO_3 \xrightarrow{\approx 287^\circ C} H_{0.21}MoO_{2.95}{}^{*} \xrightarrow{\approx 390^\circ C} H_{0.06}MoO_{2.88}{}^{**} \xrightarrow{\approx 446^\circ C} MoO_{2.86}{}^{***} \xrightarrow{\approx 610^\circ C} MoO_3 + Mo_4O_{11}$$

*; Orthorhombic bronze with the lowest hydrogen content.

**; Isomorphous with rhombic MoO_3.

***; Nonstoichiometric compound with the rhombic MoO_3 structure.

Figure 2 shows the IR spectra of a sample treated at various temperatures for 60 min under a vacuum of 10^{-4} Torr. The orthorhombic bronze showed bands at 1004, 626, 569, and 355 cm^{-1}. These bands agree well with those reported by Schroder and Weizel.[3] The intensities of the bands at 1004, 626, and 428 cm^{-1} gradually decreased during vacuum heating. On the other hand, the bands at 986, 853, 819, 569, and 368 cm^{-1} appeared after heating at 297 °C and the intensities of these bands gradually increased by further heating. According to the X-ray results mentioned above, the samples treated at 297 and 398 °C were mixtures of orthorhombic and rhombic structures and the sample treated at 398 °C was a nonstoichiometric compound with a rhombic MoO_3 structure. These facts suggest

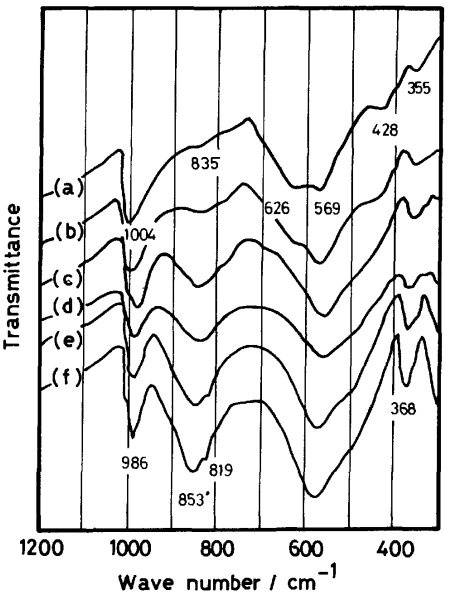

Fig. 2. IR spectra of the blue orthorhombic bronze, $H_{0.30}MoO_3$(a), and the samples treated at 238 °C(b), 297 °C(c), 349 °C(d), 398 °C(e) and 446 °C(f).

that a compound with a rhombic MoO_3 structure shows bands at 986, 853, and 819 cm^{-1}. These bands are a little lower than those at 998, 878, and 820 cm^{-1} in literatures.[11-13] This difference may be considered as a result of nonstoichometry. According to Nakamoto[12] and Feraro,[13] as shown in Fig. 3 (A1 and A2), the bands at 986, 853, and 819 cm^{-1} can be assigned to Mo=O(1), Mo-O(3,3')-Mo, and Mo-O(2,2')-Mo, respectively. Figure 3 also shows the coordination of the oxygen atoms arround the molybdenum atom in MoO_3 (B) and in the orthorhombic bronze(C). In MoO_3, the bond lengths of Mo-O(2'), Mo-O(3), and Mo-O(3') are 1.95, 2.25, and 1.73 Å, respectively. On the other hand, in orthorhombic bronze, that of Mo-O(2'), Mo-O(3), and Mo-O(3') is 1.96 Å. That is, by an insertion of atomic hydrogen into MoO_3, the bond length of Mo-O(3) in MoO_3 is shortened to 1.96 Å in the orthorhombic bronze and that of Mo-O(3'), longthened to 1.96 Å. However, that of Mo=O(1) showed no difference between the MoO_3 and the orthorhombic bronze. The band at 1004 cm^{-1} of the orthorhombic bronze is assumed to correspond to that at 998 cm^{-1} of the rhombic MoO_3. On the other hand, any band corresponding to the bands at 878 and 820 cm^{-1} due to MoO_3 was not observed in orthorhombic bronze. However, as atomic hydrogen was removed by vacuum heating, the bands at 986 and 819 cm^{-1} appeared and the intensities increased. These results suggest that, though small bands due to Mo-O(3,3')-Mo and Mo-O(2,2')-Mo in the orthorhombic bronze should be expected, they were not observed.

Changes in Surface Area. The changes in the surface areas of the samples treated under vacuum

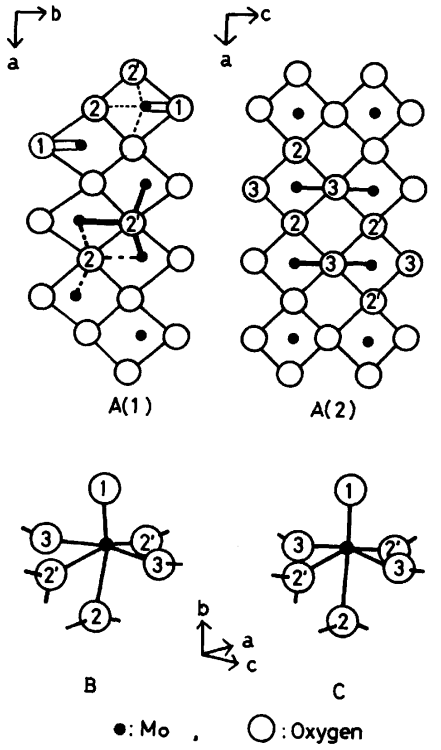

Fig. 3. Schematic model of MoO_3(A1,A2) and coordination of oxygen atoms around the molybdenum atoms in MoO_3(B) and in the bronze(C).

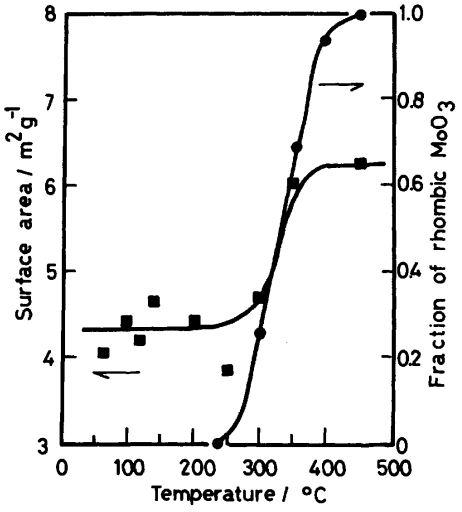

Fig. 4. Changes of the surface area and the fraction of the rhombic MoO_3 structure in the samples after vacuum heating.

heating at various temperatures are shown in Fig. 4. No large change was observed below 300°C, but the area increased slightly to a constant value at 360°C. The fraction of the rhombic structures in the samples is also shown in Fig. 4. The change in the fraction agrees well with that for the surface area. As mentioned above, isomorphous and nonstoichiometric compounds with rhombic structures have many vacancies produced by the reaction of lattice oxygen with hydrogen. Therefore, the increase in the surface area may be caused by an increase in the rhombic structure which has

vacancies.

Isomerization of 1-Butene. Catalytic isomerization of 1-butene was studied at 65°C over the bronzes treated at various temperatures in air and *in vacuo*. The activity was determined from the initial rate of decrease of 1-butene, which was divided by the surface area of the catalyst. The skeletal isomerization could not be observed. No other gasous hydrocarbons other than butenes were detected in the reaction mixtures under the present experimental conditions. Figure 5 shows typical changes of butenes with time over $H_{0.24}MoO_3$ at 65°C. The *cis*-2-butene is predominantly formed.

The samples with various hydrogen contents were obtained by heating the bronze in air at 65°C for various heating times. The activities of 1-butene isomerization were plotted against x, as shown in Fig. 6. A linear relationship exists between the activity and x. The activity of commercial MoO_3 was about 1/500 of the MoO_3 obtained from a bronze of which hydrogen was completely removed by heating in an oxygen

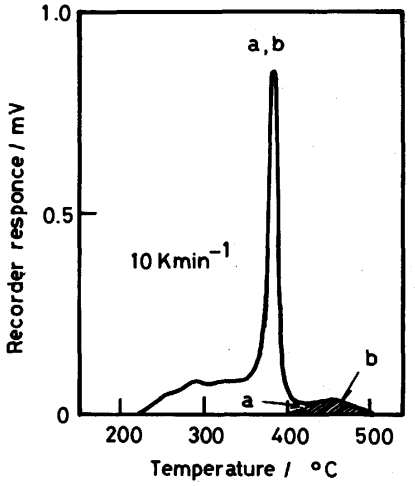

Fig. 7. TPD spectra of $H_{0.24}MoO_3$(a) and the sample after exposure to 1-butene.

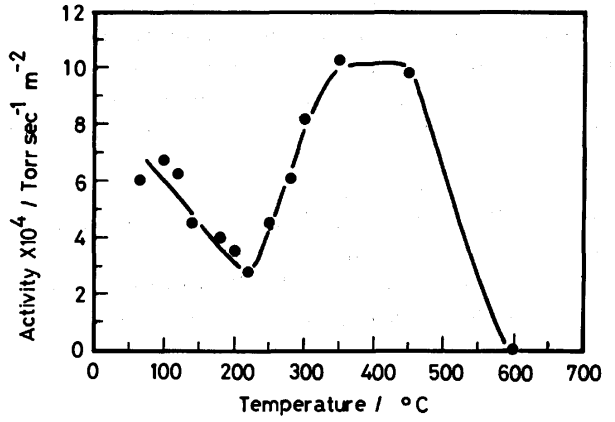

Fig. 8. Effect of evacuation temperature on catalytic activity of 1-butene isomerization.

atomosphere. Further, when the atomic hydrogen of the bronze was replaced by alkali metal ions, such as potassium ions, the activities of the alkali metal bronzes decreased markedly. As in the case of the hydrogenation of 1-pentene and ethylene over $H_{1.6}MoO_3$, the above results lead to the conclusion that hydrogen atoms in orthorhombic bronze, $H_{0.30}MoO_3$, are effective for the catalytic isomerization of 1-butene.

Figure 7 shows the TPD spectra of the orthorhombic bronze, $H_{0.24}MoO_3$(a), and the sample(b) after use as a catalyst for 1-butene isomerization. The shaded part is observed only in the spectrum of a used sample. The gas liberated as H_2O was trapped at −60—−63 °C. The value of the trapped gas obtained from the used sample was the same as that from the unused sample. This suggested that the area was equal to that of the unused sample. These results suggest that the bronze did not change at all throught the 1-butene isomerization. This leads to the conclusion that the hydrogen atoms in the bronze were effective for the catalytic isomerization of 1-butene. The shaded part is difficult to identify, but may be a strongly adsorbed species of hydrocarbons.

The cis/trans ratios of 1-butene isomerization over the samples were also plotted against x. As shown in Fig. 6, the ratio over MoO_3 obtained from the bronze is high. However, when small amounts of hydrogen is introduced, the ratio decreases steeply at first. Then, it decreased gradually to 1.6—1.7 with an increase in x. The cis/trans ratio at an equilibrium composition of butenes at 65 °C, as calculated from the thermodynamical data,[14] was 0.4. In the present work, therefore, the *cis*-2-butene was predominantly formed. It is well known[15] that when a solid acid catalyst is used for 1-butene isomerization, the cis/trans ratio is 1—2, while in the case of the solid base catalyst the ratio is more than 2. Considering the facts that the cis/trans ratios linearly decreased to 1.6—1.7 over the samples for which x increased, the bronze with small amounts of hydrogens was assumed to act as the solid acid catalyst. As hydrogen is involved with the bronze as atoms, it is reasonable that this atomic hydrogen acts as a solid acid catalyst.

Figure 8 shows the change in the activity of the samples which were treated *in vacuo* at various temperatures. The activity decreased linearly up to 220 °C, increased monotonously to a maximum value at 350 °C, and decreased sharply to nearly zero from 450 to 600 °C. The activity below 220 °C decreases linearly with a decrease in the hydrogen content of the samples without any structural change. In addition to the results mentioned above, this result suggests that the activity depends on the hydrogen atoms.

The activity increased from 220 to 350 °C and reached a constant value. In these temperature ranges, $H_{0.21}MoO_{2.95}$ decomposed rather rapidly to $H_{0.06}MoO_{2.88}$ with the rhombic MoO_3 structure with the formation of vacancies, which caused an increase in the surface area. The change from $H_{0.06}MoO_{2.88}$ to $MoO_{2.86}$ showed no significant change in the structure and in the surface area. Considering the above results, it is reasonable to conclude that the catalytic activity at this temperature range(220—350 °C) is attributed to the vacancies produced in the samples.

In this case, the cis/trans ratio on the samples treated below 220 °C varied with x, while the ratio above 220 °C was nearly constant at 1.4—1.7. As reported previously,[15] these ratios fell just in those ranges on the solid acid catalysts. As mentioned above, the activity for the isomerization of 1-butene above 220 °C is due to the vacancies produced in the bronze which show a reduced state. Considering the above results, it can be said that the activity above 220 °C results from the vacancies formed during treatment and that these vacancies act as a solid acid-like catalyst. A precise investigation is in progress.

The activity decreased markedly from 450 to 600 °C. From the X-ray and thermogravimetric results, the sample was confirmed to be a mixture of MoO_3 and Mo_4O_{11}. $MoO_{2.86}$, the nonstoichiometric compound with a rhombic structure, is converted to the stoichio-

metric MoO_3 and Mo_4O_{11}. The catalytic activity of 1-butene isomerization on MoO_3 and Mo_4O_{11} is very small. Therefore, these results lead to the conclusion that the decrease in the activity can be attributed to the existence of the stoichiometric MoO_3 and Mo_4O_{11}.

(Received October 25, 1984)

The molecular structure of an anhydrous zinc 8-quinolinolate obtained by sublimation has been determined by means of X-ray diffraction. The complex forms triclinic crystals; $a=11.858(1)$, $b=13.019(2)$, $c=10.834(1)$ Å, $\alpha=106.56(1)$, $\beta=109.00(1)$, and $\gamma=74.14(1)°$, space group $P\bar{1}$ (No. 2) with one $[Zn(C_9H_6NO)_2]_4$ molecule. The structure was solved by the heavy atom method and refined by the block-diagonal least-squares procedure to $R=0.043$ for 3320 non-zero reflections. The molecule is centrosymmetric and tetrameric; four $[Zn(C_9H_6NO)_2]$ units being connected by oxygen atoms of 8-quinolinolate ligands. Two types of bridging oxygen atoms were found. Two crystallographically independent zinc atoms take different geometries, hexa-, and penta-coordinations.

Many investigations have been carried out on the crystal structures of metal 8-quinolinolate complexes hitherto. Interesting weak intermolecular interactions have been found between metal and oxygen atoms of ligands in crystal structures of anhydrous copper 8-quinolinolates.[1-4]

The crystal structure of zinc 8-quinolinolate dihydrate has been determined by Merritt, Cady and Mundy,[5] redetermination of which has been carried out by Palenik.[6] Ogawa[7] reported a preliminary result of the X-ray studies on the solution-grown crystals of anhydrous zinc 8-quinolinolate; triclinic, $a=11.1$, $b=9.20$, $c=11.1$ Å, $\alpha=114.9$, $\beta=75.1$, $\gamma=90.8°$, and $Z=2$. This paper will deal with the crystal and molecular structure of an anhydrous zinc 8-quinolinolate recrystallized directly from the gas phase. Interestingly, 8-quinolinolate complexes of zinc were obtained by S. Ikeda and co-worker by the direct reaction of 8-quinolinol with zinc metal,[8] the study of which closely related to the dissolution of zinc and this fact promoted the present study.

Experimental

Anhydrous zinc 8-quinolinolate was prepared by drying the zinc 8-quinolinolate dihydrate above 130°C under vacuum. The complex was sublimed at about 400°C and recrystallized directly from the gas phase. Only few crystals with pale yellow color and small polyhedral shape were available for the X-ray experiment.

Crystal Data: $C_{72}H_{48}N_8O_8Zn_4$, M 1414.7, triclinic, space group $P\bar{1}$(No. 2), $a=11.858(1)$, $b=13.019(2)$, $c=10.834(1)$ Å, $\alpha=106.56(1)$, $\beta=109.00(1)$, and $\gamma=74.14(1)°$, $V=1485.3(3)$ Å^3, $D_c=1.581$ g cm^{-3} for $Z=1$.

Unit-cell dimensions were determined by the least-squares fit of 2θ values of higher order reflections using Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). The unit-cell was first taken as a base-centered lattice, $A\bar{1}$ and later transformed to the reduced standard cell, $P\bar{1}$. The measurement of the crystal density was omitted because no extra crystal was available but for the X-ray experiment.

A Rigaku automated, four-circle diffractometer was used for the intensity data collection. The integrated intensities were measured by the $\theta-2\theta$ scan technique using zirconium-filtered Mo $K\alpha$ radiation. The peak scan of each reflection was started at an angle of $(2\theta-1.0)°$ with the scan width of $(2.0+0.7\tan\theta)°$ and the scan rate in 2θ was 2° min^{-1}. Backgrounds were measured for 10 s at both ends of a scan. During the X-ray experiment the intensity fluctuations of four standard reflections measured after every 50 reflections were within the error of counting statistics. A total of 3659 independent reflections were measured. The intensities were corrected for usual Lorentz and polarization effects but not for the absorption [μ(Mo $K\alpha$)=17.1 cm^{-1}]. The crystal used had approximate dimensions of 0.1×0.1×0.2 mm.

Structure Solution and Refinement

The structure was solved by the heavy atom method. The initial coordinates of two crystallographically independent zinc atoms in an asymmetric unit were easily determined from the three-dimensional Patterson map. Non-hydrogen atoms could be located by the subsequent Fourier synthesis. The structure was refined by the block-diagonal least-squares procedure (*HBLS* V),[9] the function minimized being $\sum w(\Delta F)^2$. At the initial stage of the refinement, the intensity data used were limited within a sphere of $(\sin\theta)/\lambda \leqq 0.481$ (2743 out of 3659 total reflections) and $w=1$. Four cycles of isotropic refinement gave the R value of 0.076. Further refinement with anisotropic temperature factor for zinc atoms gave the R of 0.062. Anisotropic temperature factors were then introduced for the other non-hydrogen atoms. Hydrogen atoms were located on the calculated positions, almost all of which were confirmed by the difference Fourier synthesis, and they were also included in the structure factor calculation but their atomic coordinates were fixed with equal temperature factors ($B=3.0$ Å^2). Four cycles of the refinement improved the R to 0.051. At this stage, all of the reflection data were included in the least-squares calculation and the positional and thermal parameters of hydrogen atoms were also refined using small damping factors (one-tenth of those of the heavy atoms). After several cycles of the refinements the R index converged to 0.043 for non-zero (0.052 for all)

Results and Discussion

Molecular Structure. The molecular structure is shown in Fig. 1 with the numbering scheme of atoms in an asymmetric unit. The bond lengths and bond angles are listed in Table 2.

As seen in Fig. 1, two [$Zn(C_9H_6NO)_2$] units connected by two bridging oxygen atoms form an asymmetric unit. Two asymmetric units (x, y, z and $-x$, $1-y$, $-z$) related by a center of symmetry, connected by two bridging oxygen atoms, make the whole molecule tetrameric.

Geometry Around the Zinc Atoms. Two crystallographically independent zinc atoms have different coordination geometries. The Zn(1) atom takes a hexacoordination whereas the Zn(2) a penta-coordination.

The coordination geometry of the Zn(1) atom is octahedral but largely distorted. Bond lengths from the Zn(1) atom to the O(1), O(2), and O(2′) are equal [2.072(4), 2.075(4) and 2.053(4)Å]. These values are equal to the Zn–O bond length [2.066(15)Å] observed with the octahedrally coordinated zinc atom in the zinc 8-quinolinolate dihydrate.[6] But they are significantly shorter than the Zn(1)–O(3) length [2.163(4)Å]. Two Zn(1)–N bonds are equal in length [2.165(5) and 2.178(5) Å]. The O(1)–Zn(1)–O(2) angle is 174.5(2)°, which is close to 180°. But, the other two bond angles, N(1)–

(a) A perspective view.
Non-hydrogen atoms are drawn as thermal ellipsoids with 30% probability level and hydrogen atoms with $B=1.0$ Å^2.
(b) Numbering scheme of atoms in an asymmetric unit.

Zn(1)–O(3) [153.8(2)°] and N(2)–Zn(1)–O(2') [153.1(2)°] show large deviations from 180°. All of the other bond angles around the Zn(1) atom [between 77.0(2) and 107.6(2)°] deviate from 90°.

The geometry around the Zn(2) atom is distorted trigonal bipyramidal. The Zn(2) atom deviated by 0.20

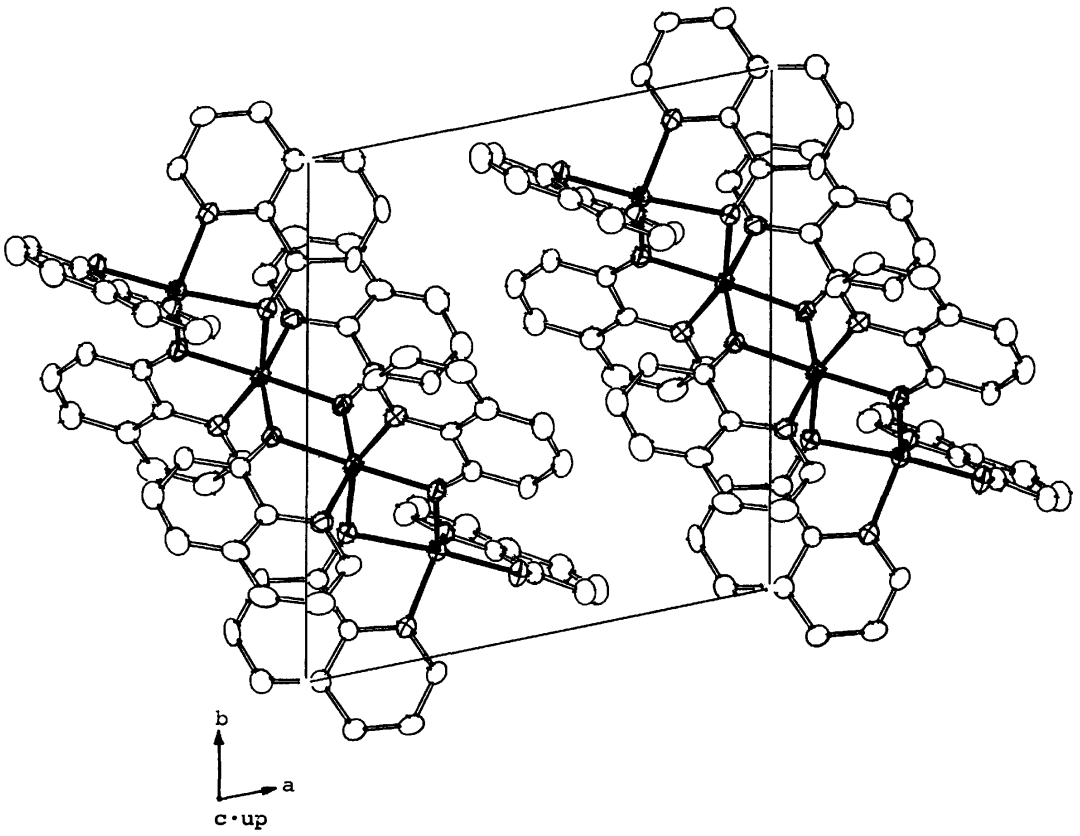

Fig. 2. Crystal structure[13] of $[Zn(C_9H_6NO)_2]_4$.
Non-hydrogen atoms are drawn as thermal ellipsoids with 30% probability level. Hydrogen atoms are omitted for clarity.

Å from the base plane defined by the O(1), N(3), and N(4) atoms. The O(3)-Zn(2)-O(4) angle is 173.9(2)°, three bond angles in the base plane are 116.6(2), 118.0(2), and 122.4(2)°, and the other angles are between 78.9(2) and 106.9(2)°. The Zn(2)-O(1) bond [1.965(4)Å] is the shortest among three Zn(2)-O bonds, and this is also the shortest Zn-O bond in the present complex. The Zn(2)-O(3) bond length [2.176(4)Å] is equal to the Zn(1)-O(3). These two are the longest Zn-O bonds and both involved with the O(3) atom. The sum of the three bond angles about the O(3) atom [329.6°] is largely deviated from 360°, whereas those about the O(1) [359.2°] and O(2) [358.0°] atoms are all equal to 360°. The Zn(2)-O(4) bond length is 2.020(4)Å, which is comparable to those of three Zn(1)-O bonds except the Zn(1)-O(3). The O(4) atom is the non-bridging oxygen atom at the apical position of the distorted trigonal bipyramid. Two Zn(2)-N bonds in the base plane [2.047(4) and 2.055(5)Å] are significantly shorter than the Zn(1)-N bonds which appeared in the geometry of the octahedrally coordinated Zn(1) atom.

Structure of the Quinolinolate Moieties. All of the corresponding bond lengths and bond angles in four quinolinolate moieties are equal within the limits of error.†††† The planarity of four quinolinolate moieties are slightly poor, they are planar within 0.08Å. These dimensions are similar to those of zinc 8-quinolinolate dihydrate[6] and β-copper 8-quinolinolate anhydride.[2]

†††† Bond lengths and bond angles in the quinolinolate moieties are also deposited at the Chemical Society of Japan, Document No. 8525.

C(19)·····C(43)[b]	3.436(9)		d,	$1-x$,	$-y$,	$-z$
C(44)·····C(44)[c]	3.399(14)					
C(44)·····C(45)[c]	3.480(10)					
C(45)·····C(49)[c]	3.538(10)					
O(4)·····C(31)[d]	3.378(7)					

Crystal Structure. Crystal structure projected along the c axis is depicted in Fig. 2. Several short interatomic contacts (less than 3.6Å) are observed (Table 3). Almost all of them are involved between carbon atoms of quinolinolate groups in adjacent molecules. The closest contact is observed between the O(4)(x, y, z) atom and C(31)($1-x$, $-y$, $-z$) [3.378(7)Å].

Calculations were mostly done on a NEAC 2200-700 computer at the Computation Center, Osaka University and at the final stage on an ACOS 850 computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University.

The authors wish to express their deep thanks to

Professor Shigero Ikeda, Faculty of Science, Osaka University for supply of crystals.

Tetraalkylammonium Ion-selective Electrodes with Supporting Electrolytes. An Experimental Test of the Theory of Liquid Ion-exchange Membrane Ion-selective Electrodes Based on the Concept of the Mixed Ion-transfer Potential

Takashi KAKIUCHI, Ichiro OBI, and Mitsugi SENDA*

(Received November 19, 1984)

Selectivity characteristics of liquid-membrane ion-selective electrodes for tetraethylammonium and triethylmethylammonium ion-selective electrodes in the presence of homologous tetraalkylammonium ions as interfering ions were studied with supporting electrolytes both in the liquid membrane and in the sample solution. The emf *vs.* logarithm of the concentration of the primary ion curves in the presence of interfering ion were well described by the theory of liquid-membrane ion-selective electrodes which is based on the concept of the mixed ion-transfer potential at the liquid-membrane/sample solution interface. The dependence of the selectivity coefficients on the concentrations of the primary ion in the liquid membrane and of the interfering ion in the sample solution agreed well with the theoretical prediction.

This paper reports a systematic study of the response of tetraethylammonium and triethylmethylammonium ion-selective liquid-membrane electrodes to the primary ion in the presence of interfering ions (a series of homologous tetraalkylammonium ions) in the sample solution and of the primary ion in the liquid membrane; the liquid membrane and the sample solution contained tetrapentylammonium tetraphenylborate (TPnATPB) and lithium sulfate, respectively, as the supporting electrolyte. In a previous paper,[1] we derived the theoretical equations for the response of ion-selective electrodes of liquid ion-exchange membrane type and presented the theory of the selectivity coefficient based on the concept of the mixed ion-transfer potential at the liquid-membrane/sample solution interface. The theory expresses the potential and the selectivity coefficient of the electrodes as functions of three factors: difference in the standard ion-transfer potential between the primary and interfering ions, the concentration ratios of the primary and interfering ions, and the mass-transfer coefficient ratios of these ions. The aim of this study is to verify experimentally these theoretical predictions by using the ion-selective electrodes which meet with the assumptions underlying the theory. The theory has assumed the presence of sufficient amounts of supporting electrolytes in both the liquid membrane and sample solution to ensure the absence of the migration of the relevant ions. This assumption is to simplify the treatment and to sculpture the fundamental characteristics of the ion-selective electrodes which are primarily determined by the ion-transfer processes at the liquid-membrane/sample solution interface. Such ion-transfer processes should also be essential in the liquid membrane ion-selective electrodes without having supporting electrolytes, like most of the ion-selective electrodes with liquid ion-exchangers hitherto studied.

Experimental

The electrochemical cells used in the present study are generally represented by:

I	II	III	IV	V	VI	VII	VIII
Ag	AgCl	2 mmol dm^{-3} R_1Cl (water)	*a* mmol dm^{-3} R_1TPB, 0.1 mol dm^{-3} TPnATPB (nitrobenzene)	*b* mmol dm^{-3} R_2Cl, *x* mmol dm^{-3} R_1Cl, 0.1 mol dm^{-3} Li_2SO_4 (water)	satd. KCl	AgCl	Ag

(I)

where phase III is the internal reference solution, phase IV is the liquid membrane, and phase V is the sample solution. R_1^+ and R_2^+ are the primary and the interfering ions, respectively, and TPB^- is tetraphenylborate ion. We used tetraethylammonium ion (TEA^+) for R_1^+ and trimethylethylammonium ion (Me_3EtN^+), trimethylpropylammonium ion (Me_3PrN^+), trimethylbutylammonium ion (Me_3BuN^+), and triethylmethylammonium ion (Et_3MeN^+) for R_2^+ in a series of experiments, and also Et_3MeN^+ for R_1^+ with TEA^+ for R_2^+ in the other series of experiments. Nitrobenzene was used as a solvent of the liquid membrane. In nitrobenzene, the tetraphenylborate salts of these alkylammonium ions are virtually completely dissociated as judged from the conductivity measurements.[2] The values of the standard ion-transfer potentials $\Delta^{W}_{NB}\varphi^{0}$ for the nitrobenzene–water system and of the diffusion coefficients of the relevant ions are given in Table 1, which shows that both $\Delta^{W}_{NB}\varphi^{0}_{R_1^+}$ and $\Delta^{W}_{NB}\varphi^{0}_{R_2^+}$ are much more negative than either of $\Delta^{W}_{NB}\varphi^{0}_{Li^+}$ and $\Delta^{W}_{NB}\varphi^{0}_{TPB^-}$ and, simultaneously, much more positive than either of $\Delta^{W}_{NB}\varphi^{0}_{TPnA^+}$ and $\Delta^{W}_{NB}\varphi^{0}_{SO_4^{2-}}$. Thus, the participation of the supporting electrolytes (TPnATPB in the liquid membrane and Li_2SO_4 in the sample solution) in the ion-transfer processes across the liquid-membrane/sample solution interface is very small[3] in the concentration ranges of R_1^+ and R_2^+ studied. The interference caused by supporting electrolytes becomes appreciable only when the ratio of the concentration of R_1^+ in the liquid membrane to that in the sample solution is very small.[1] In the following, the emf *vs.* logarithm of the concentration curves are analyzed in the lower concentration range of the primary ion in sample solution, where

1) Ref. 3. 2) Calculated from the data in Ref. 4. 3) Extrapolated from the data in Ref. 3. 4) Ref. 5. 5) Ref. 6.

the interference of the supporting electrolyte becomes negligible. $\Delta^{W}_{NB}\varphi^{0}_{Cl^-}$ is also much more negative than either of $\Delta^{W}_{NB}\varphi^{0}_{R_1^+}$ and $\Delta^{W}_{NB}\varphi^{0}_{R_2^+}$. Accordingly, R_1^+ and R_2^+ are practically the only ionic species which pertain to the ion-transfer processes across the interface in the concentration ranges we are concerned with. The potential difference between phases III and IV is solely determined by the distribution potential of a R_1^+ ion for the ions used in this study.[3] It is also unaffected by the composition of phase V, because the liquid membrane is sufficiently thick.[1] The change of the liquid junction potential between phases V and VI with the change of the electrolyte concentration in phase V is negligibly small because of the presence of supporting electrolytes. Therefore, the change of the electromotive force of the cell with the electrolyte concentration in phase V can be ascribed to the change of the potential difference between phases IV and V.

The electrochemical cell(I) was formed in a U-shaped poly(tetrafluoroethylene) tube 9 mm in inner diameter and 10 cm tall. About 8 ml of a nitrobenzene solution was first poured in the cell and then a reference solution and a sample solution were added to the nitrobenzene solution, one in each leg of the cell. A saturated potassium chloride solution saturated with silver chloride made contact with a sample solution *via* a glass frit. The cell was immersed into a water bath kept at 25.0±0.2 °C. The electromotive force (emf) of cell(I) was measured with a Keithley 616 electrometer. The emf was usually stable within 5 min after the formation of the liquid-membrane/sample solution contact, except at the lowest concentration of R_1^+, 0.1 mmol dm^{-3}, at which the emf values were less reproducible, probably due to impurities in the nitrobenzene solution.

Iodide salts of Me_3EtN^+, Me_3PrN^+, Me_3BuN^+, and Et_3MeN^+ were synthesized from trialkylamines and alkyl iodides[7] and then converted to the chloride salts.[8] These alkylammonium chloride and TEACl(Wako Pure Chem. Ind., Japan) were dried over P_2O_5 and used to prepare the stock solutions using thrice distilled water. The stock solutions were treated with silver chloride powder to remove trace iodide ions. TEATPB, Et_3MeTPB, and TPnATPB were prepared by precipitation from aqueous solution (for TEA^+ and Et_3MeN^+) or ethanol solution (for $TPnA^+$) of the iodide salts by adding an equimolar quantity of aqueous or ethanol solution of sodium tetraphenylborate (Dojin Lab., Japan) and were twice recrystallized from acetone. Reagent grade nitrobenzene was treated with active alumina and then equilibrated with thrice-distilled water. All other chemicals were of reagent grade.

Results

Tetraethylammonium Ion-selective Electrode. The electromotive force of the cell(I) was measured at a fixed concentration of TEATPB(R_1TPB) in the liquid membrane and of R_2Cl in the sample solution by varying the concentration of TEACl(R_1Cl) between 0.1 mmol dm^{-3} and 0.5 mol dm^{-3} in the sample solution. The interfering ions R_2^+ studied were Me_3EtN^+, Me_3PrN^+, Me_3BuN^+, and Et_3MeN^+, whose $\Delta^{W}_{NB}\varphi^{0}$'s are all more positive than that of TEA^+ ion. The measured sets of a and b values in the cell(I) are summarized in Table 2. The results for a=2 mmol dm^{-3} are shown in Figs. 1—4. In the absence of R_2^+ ion the emf showed a linear Nernstian response over the concentration range of TEACl studied, except at the highest concentrations (a=0.2 and 0.5 mol dm^{-3}) where interference by the supporting electrolyte occurs. The solid lines in these figures are the theoretical ones calculated from Eqs. 16—21 in Ref. 1 using the values in Table 1 for

coefficients in the liquid-membrane were taken as halves of those in the aqueous solution.[9] The ratios of the mass-transfer coefficients of the two ions were equated with the square root of the ratio of their diffusion coefficients; the mass-transfer was considered to occur primarily through diffusion in the present system.

Triethylmethylammonium Ion-selective Electrode. When the standard ion-transfer potential of an interfering ion is negative than that of the primary ion, the theory predicts that the degree of interference becomes more significant and the selectivity coefficient decreases with the decrease of the interfering ion concentration, in contrast to the cases where the standard ion transfer potential of an interfering ion is more positive than that of the primary ion. As an example of such a case, we studied the response of the Et_3MeN^+ ion-selective electrode in the presence of TEA^+ ion at $a=2$ mmol dm^{-3} and $b=0.2$, 1, 2, 5, 10, and 50 mmol dm^{-3}. The results are shown in Fig. 5. The solid lines are the theoretical curves calculated as described above.

Discussion

Figures 1—5 clearly show that for all the combinations of the primary and interfering ions studied the calculated curves agree well with the experimental points over wide ranges of the concentrations of the primary and interfering ions. This confirms that the theory of liquid ion-exchange membrane ion-selective electrodes previously derived by Kakiuchi and

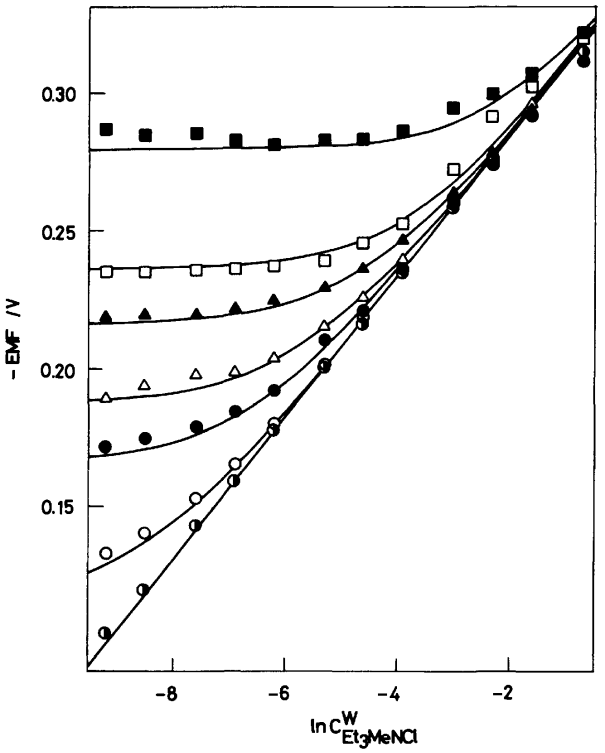

Fig. 5. Response of the Et_3MeN^+ ion-selective electrode in the presence of TEA^+ ion at $a=2$ mmol dm^{-3} and $b=0$(◑), 0.2(○), 1(●), 2(△), 5(▲), 10(□), and 50(■) mmol dm^{-3}.

Senda[1] satisfactorily describes the emf response of the ion-selective electrodes of the type represented by cell(I).

The selectivity characteristics of ion selective electrodes are usually evaluated by using the selectivity coefficient, $k_{i,j}^{pot}$, defined by the Nicolsky equation.[10] Although $k_{i,j}^{pot}$ is not a physical constant intrinsic to a given electrode system but depends on experimental conditions such as the concentrations of the relevant ions,[11] it has been widely used as a convenient measure of the selectivity of ion-selective electrodes.[12] Moreover, the manner of change of $k_{i,j}^{pot}$ with the concentration of primary ion has been sometimes used as a criterion for the validity of a theory of ion-selective electrodes.[13] We evaluated the selectivity coefficient of the ion-selective electrode(I) defined by a Nicolsky-type equation:[1]

$$E = E_{R_1}^0 - \frac{RT}{F} \ln \frac{c_{R_1}^W + k_{i,j}^{pot} c_{R_2}^W}{c_{R_1}^0} \qquad (1)$$

where E is the emf, $E_{R_1}^0$ is $\Delta_{NB}^W \varphi_{R_1}^0 + \Delta E_{ref}$, being the potential difference associated with the reference electrodes in the cell(I), and $c_{R_1}^W$, $c_{R_2}^W$, and $c_{R_1}^0$ are the concentrations of R_1^+ and R_2^+ ions in the sample solution and of R_1^+ ion in the liquid membrane, respectively. We used two methods to determine the $k_{i,j}^{pot}$ values: Method I using the intersection point of the two linear portions of the emf *vs.* $\log c_{R_1}^W$ curve and Method II using the concentration of a primary ion at which the emf *vs.* $\log c_{R_1}^W$ curve in the presence of an interfering ion deviates by $(RT/F)\ln 2 = 18$ mV from the curve without interfering ion. The former method gives the $k_{i,j}^{pot}$ value at the infinitely small $c_{R_1}^W$,[1] whereas the latter gives the one at the $c_{R_1}^W$ at which the curve deviates by 18 mV from the linear Nernstian response. Method I seems less sensitive to the scattering of the experimental emf values than Method II, since Method I necessarily averages out the scattering by using several points to draw a horizontal line at the lower values of $c_{R_1}^W$. However, Method I is not applicable to cases where such a horizontal part of the emf *vs.* $c_{R_1}^W$ curve is not attainable experimentally. The results are given in Tables 3—5 together with the theoretical values based on Eq. 24 in Ref. 1. For both methods, the calculated values of $k_{i,j}^{pot}$ agree well with the observed ones. Taking account of the fact that the observed $k_{i,j}^{pot}$ value is very sensitive to small scattering of emf values, this general agreement seems enough evidence of the validity of the theory for predicting the response of the ion-selective electrode of the type represented by the cell(I).

Table 3 shows that the $k_{i,j}^{pot}$ values decrease with the increase of the concentration of the interfering ions. This is what is theoretically expected for the case when the standard ion-transfer potential of the primary ion (TEA^+) is more negative than that of the interfering ion (Me_3EtN^+, Me_3PrN^+, Me_3BuN^+, and Et_3MeN^+). In the case of TEA^+ ion interference with respect to Et_3MeN^+ ion, the standard ion-transfer potential of the primary ion (Et_3MeN^+) is more positive than that of the interfering ion(TEA^+). The theory predicts in this case that the $k_{i,j}^{pot}$ value increases with increasing concentration of the interfering ion, which was confirmed experimentally as shown in Table 4. Such an inversion in the concentration dependence of $k_{i,j}^{pot}$ has been found also for a nitrate ion-selective electrode of liquid ion-exchange membrane type without supporting electrolytes.[15]

According to the theory, $k_{i,j}^{pot}$ depends not only on the concentration of the ions in sample solution but also on the concentration of the primary ion in liquid membrane. The $k_{i,j}^{pot}$ values for the TEA^+ ion-selective electrode at $a=0.5$, 1, 2, and 5 mmol dm^{-3} in the presence of Et_3MeN^+ in the sample solution at $b=10$ mmol dm^{-3} in cell(I) are given in Table 5. The $k_{i,j}^{pot}$ values determined by Method I clearly show the increasing tendency of $k_{i,j}^{pot}$ with the increase of the concentration of TEA^+ ion in the liquid membrane. Such a change of $k_{i,j}^{pot}$ was less conspicuous for the $k_{i,j}^{pot}$ estimated by Method II, probably because of the larger error inherent to this method.

The selectivity coefficients for a series of interfering ions for a given primary ion are usually discussed in terms of the difference in single ion partition coefficient defined by $K_i = c_i^W / c_i^O$ for i ion. By definition the difference in the single ion partition coefficient between two ions, i and j, is related to the difference in the standard ion-transfer potential between the two ions by

1) The concentration of Et_3MeN^+ ion in the sample solution was 10 mmol dm^{-3}.

$$\ln(K_i/K_j) = \frac{F}{RT}(z_j\Delta^W_0\varphi^0_j - z_i\Delta^W_0\varphi^0_i) \qquad (2)$$

where K_i and K_j are the single ion partition coefficients for the ions i and j, and z_k is the electric charge of the ion k(k=i or j). When the liquid-membrane contains lipophilic ligands, X, (usually belonging to the family of ionophores) which form complexes MX_n (n=1, 2, ···) with the ion M (M=i or j) transferred across the liquid-membrane/sample solution interface, the standard ion-transfer potential $\Delta^W_0\varphi^0_M$ (M=i or j) in Eq. 2 should be replaced by the apparent standard ion-transfer potential $\Delta^W_0\varphi^0_{M,app}$[16)] defined by

$$\Delta^W_0\varphi^0_{M,app} = \Delta^W_0\varphi^0_M - \frac{RT}{z_MF}\ln(\sum_n \beta_n c_X^n) \qquad (3)$$

where β_n is the over-all stability constant (β_0=1) of the complexes MX_n (n=0, 1, 2, ···), and c_X is the bulk concentration of X in the liquid membrane.

The experimental linear correlation between the logarithm of the selectivity coefficient and the logarithm of the single ion-partition coefficient have long been recognized for the liquid ion-exchange membrane ion-selective electrodes.[17)] The linear correlation is one of the important conclusions of Sandblom *et al.*'s theory[18)] for membrane electrode potential and hence the experimental linear correlation has been considered as demonstrating the essential validity of their theory. In our previous paper we have shown that the dependence of the logarithm of selectivity coefficient on the difference in the standard ion-transfer potential between the primary and interfering ions is approximately linear under certain conditions, but can be remarkably non-linear, depending on the mass-transfer coefficients of the ions. (See Fig. 4 in Ref. 1). Figure 6 shows a plot of the logarithm of the k^{pot}_{ij} by method I at a=2 mmol dm^{-3} and b=10 mmol dm^{-3} against the difference between the standard ion-transfer potentials of the primary and interfering ions. The upper four circles in Fig. 6 are for the TEA^+ ion-selective electrode with the interfering ions Me_3EtN^+, Me_3PrN^+, Et_3MeN^+, and Me_3BuN^+ and the lowest circle is for the Et_3MeN^+ ion-selective electrode with the interfering ion TEA^+. The selectivity coefficient increased with the increase

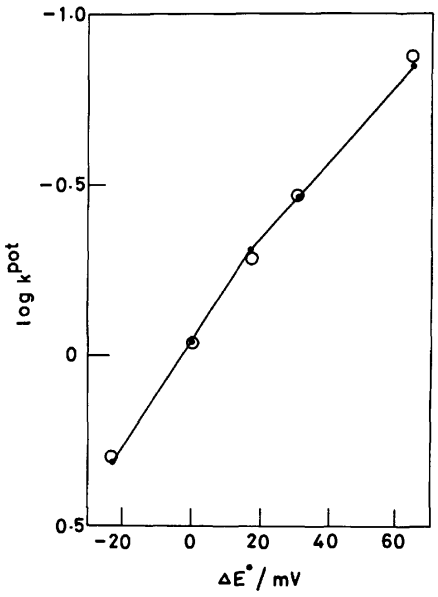

Fig. 6. Change of the logarithm of selectivity coefficient with the change of the difference between the standard ion-transfer potentials of the primary and interfering ions, ΔE. Upper four points are for the TEA^+ ion-selective electrode and the lowest point for the Et_3MeN^+ ion-selective electrode.

of the hydrophobicity of the interfering ions, *i.e.*, with the decrease of the standard ion-transfer potential. The solid line in Fig. 6 connects the theoretical points of $k_{i,j}^{pot}$ indicating a good agreement between the theory and the experimental results. The nonlinearity of the plot in Fig. 6 clearly demonstrates the validity of the theory in which the effect of the mass transfer coefficients of the ions is taken into account.

As demonstrated by this study, the emf response of the liquid ion exchange membrane ion-selective electrodes of the type represented by cell(I) is described well by the theory based on the concept of the mixed ion-transfer potential at the liquid-membrane/sample solution interface. This indicates that the ion-transfer processes at the interface between the liquid membrane and the sample solution has a general importance for the understanding of the basic properties of liquid ion-exchange membrane ion-selective electrodes.

The authors thank Mitsuru Shiomi for his assistance in emf measurements.

(Received November 30, 1984)

[$Co(4mqn)_2$]·$2H_2O$ (4mqn=4-methyl-8-quinolinolate ion) reacted with nitrogen monoxide in CH_2Cl_2 or in DMF at room temperature to give [$Co(4mqn)_2(NO)$] (**1**). [$Co(4mqn)_2$]·$2H_2O$ and **1** reacted with nitrogen monoxide in 10 vol% pyridine–DMF and in pyridine at *ca.* 283—288 K to precipitate [$Co(4mqn)_2(NO)(py)$] (**2**). When the reaction was carried out at *ca.* 293—303 K, [$Co(4mqn)_2(NO_2)(py)$] (**3**) instead of **2** was precipitated. From the filtrates, [$Co(4mqn)_2(NO_3)(py)$]·py·$2H_2O$ (**4**) was obtained. The gaseous product of the reactions giving **2** and **4**, and **3** and **4**, was dinitrogen oxide. The stoichiometries of the reactions in the pyridine–DMF and in pyridine were confirmed by mass analyses for the residual nitrogen monoxide and the produced dinitrogen oxide.

A number of studies of the reactions of transition-metal or transition-metal nitrosyl complexes with nitrogen monoxide, NO, have been reported.[1] However, there have been no careful examinations of the effects of the solvents used or those of the substituents of the ligands used on the reactions.

Bis(8-quinolinolato)cobalt(II) reacted with NO in CH_2Cl_2, which has a poor coordination ability, to give [$Co^{III}(qn)_2(NO)$] (qn=8-quinolinolate ion) with the NO^- group, and the nitrosyl reacted further with NO in CH_2Cl_2 to give [NO][$Co^{III}(qn)_2(NO_3)(NO_2)$], with the liberation of N_2O.[2] In this reaction, the nitrosyl group forms the NO_2^- with a retention of the original Co–NO bond. On the other hand, bis(2-methyl-8-quinolinolato)cobalt(II) reacted with NO in CH_2Cl_2 to give $[NO]_3[Co^I(2mqn)_2(NO_3)(NO_2)]$ and [$Co^0(2mqn)_2$-$(NO)_2$] (2mqn=2-methyl-8-quinolinolate ion), with the liberation of N_2O.[3] The difference in the reactions of NO with the corresponding cobalt ions seems to be due to the electron-donative power of the CH_3 group in the 2mqn.

In a solvent possessing a strong coordinating ability, such as pyridine, [$CoL_2(NO)$] with the NO^- group (L=5-chloro- or 5-nitro-8-quinolinolate ion) reacted with NO to give the nitrato complex, [$CoL_2(NO_3)(py)$], involving scrambling between the NO^- group and the NO.[4]

The present paper will describe the reactions of [$Co(4mqn)_2$]·$2H_2O$ or [$Co(4mqn)_2(NO)$] (4mqn=4-methyl-8-quinolinolate ion) with NO in CH_2Cl_2, DMF, 10 vol% pyridine–DMF, or pyridine; the effects of the solvents and the substituents in the quinoline ring on the reactions are also discussed. The stoichiometries of the reactions are also examined on the basis of the determination of the relative molar ratio of the residual NO to the N_2O produced.

Experimental

The JIS-GR CH_2Cl_2, DMF, and pyridine were dried over Zeorum A-4, stored under argon, and carefully degassed by three cycles of freeze-pump-thaw prior to use. The JIS-GR diethyl ether used as a precipitation reagent was deaerated with dinitrogen before use. The ^{15}NO was prepared by the reaction of $K^{15}NO_3$ (^{15}N atom%=99) with concd H_2SO_4 and mercury. The 4-methyl-8-quinolinol was prepared from *o*-aminophenol and methyl vinyl ketone.[5] The [$Co(4mqn)_2$]·$2H_2O$ was prepared by the ordinary method. Anal. ($CoC_{20}H_{20}O_4N_2$) Co, C, H, N.

The IR spectra of the solid products were measured on JASCO A-202 (400—4000 cm^{-1}) and JASCO IR-F (200—650 cm^{-1}) spectrometers. The isotopic shifts upon ^{15}N-substitution were carefully measured at 80 K. For identifying the gaseous products and examining the stoichiometry of the reaction in 10 vol% pyridine–DMF or in pyridine, a Hitachi M-80 double-focusing mass spectrometer equipped with a Hitachi data-processing system (M-003) was used; the IR bands of the gaseous materials and the ^{15}N-isotopic shifts[6] in the 1000—4000 cm^{-1} region were also measured. The magnetic susceptibilities of the solid products were measured by the Gouy method at room temperature.

All the reactions were treated in a vacuum line. The representative scale and the procedure were as follows: NO (5.0 mmol) was trapped in a reaction vessel (*ca.* 150 cm^3) containing [$Co(4mqn)_2$]·$2H_2O$ (0.5 mmol) suspended or dissolved in the organic solvents (10 cm^3) with the aid of liquid nitrogen. The reaction vessel was shaken under running water until the frozen solution thawed, and then the contents were stirred for 1—3 d to obtain the precipitate. By dropping the filtrate into deoxygenated diethyl ether, another product was precipitated. These products were washed with diethyl ether and dried under a vacuum. When [$Co(4mqn)_2(NO)$] was used as the starting material, the degassed pyridine–DMF or pyridine was poured into the reaction vessel containing the nitrosyl complex, which had been kept at the temperature of liquid nitrogen, and then NO was trapped. The contents were stirred after having been thawed under running water.

Results and Discussion

The elementary analyses, the chemical formulae, and the yields of the solid products are shown in Table 1. All the compounds were diamagnetic, indicating that they are low-spin type cobalt(III) compounds, since the formal oxidation number of the coordinating NO in the nitrosyl compounds is −I, as will be discussed later. The compounds are stable in the solid state under air, but the nitrosyl compounds are unstable in the

dissolved state.

Reaction of $[Co(4mqn)_2]\cdot 2H_2O$ with NO in CH_2Cl_2 or in DMF. $[Co(4mqn)_2]\cdot 2H_2O$ reacted with NO to precipitate $[Co(4mqn)_2(NO)]$ (**1**). No further reaction proceeded in CH_2Cl_2; however, in DMF **1** reacted further with NO to give a clear, reddish-brown solution, with the liberation of N_2O. However, the precipitate obtained by adding the solution to diethyl ether could not be characterized.

The IR bands at 1658(vs), 551(s), and 537(s) cm^{-1} for **1** shifted down by 31, 6, and 7 cm^{-1} respectively upon ^{15}N-substitution. The 1658 cm^{-1} band was assigned to the N-O stretching vibration, and the 551 and 537 cm^{-1} bands, to the skeletal vibrations between the cobalt and the NO group.[7] The wave numbers of the N-O stretching band and the electrophilic attack of NO on the NO group, as will be mentioned later, suggest that **1** is an NO^- complex.[4,7] The reaction giving **1** can be regarded as an oxidative addition of NO to cobalt(II).

Reaction of $[Co(4mqn)_2]\cdot 2H_2O$ or $[Co(4mqn)_2(NO)]$ with NO in 10vol% Pyridine-DMF or in Pyridine. The gaseous product was always only N_2O.

Reaction at ca. *283—288 K*: $[Co(4mqn)_2]\cdot 2H_2O$ reacted with NO to precipitate $[Co(4mqn)_2(NO)(py)]$ (**2**). The N-O stretching and the skeletal vibrations between the cobalt and the NO group were observed at 1616, 558, and 431 cm^{-1}. The wave numbers of the N-O stretching vibration for **1**, 1658 cm^{-1}, shifted down to 1616 cm^{-1} by the coordination of pyridine to the cobalt ion. The 321(s) cm^{-1} band of **2** could be assigned to the Co-N(pyridine) stretching vibration by a careful comparison of the IR spectrum for **2** with that for **1**.[8]

By adding the filtrate to deaerated diethyl ether, a brownish khaki product, **4**, was precipitated. This product was not clearly characterized. The IR band at 823(w) cm^{-1} shifted to 810 cm^{-1} upon ^{15}N-substitution, but no isotopic shifts for any other bands could be observed.[9]

The stoichiometries of the reactions to be discussed later can be reasonably explained on the assumption that **4** contains a nitrate ion. If so, the 823 cm^{-1} band can be assigned to the out-of-plane bending of NO_3^-.[4] The 321 cm^{-1} (s) band was assigned to the Co-N (pyridine) stretching vibration, as had been **2**. By the reactions of $[CoL_2]$ (L=5-chloro- or 5-nitro-8-quinolinolate ion) with NO in the same solvents, $[CoL_2(NO_3)(py)]$ was isolated.[4] **4** seems to be $[Co(4mqn)_2(NO_3)(py)]\cdot py\cdot 2H_2O$ considering the similarities of the reactions, the elementary analysis, the IR spectrum, and the stoichiometry of the reaction. The bands characteristic of a coordinating nitrate ion, with the exception of the 823 cm^{-1} band, seem to be hidden under the strong absorptions due to the 4mqn and pyridine. The water of crystallization in **4** may come from a small quantity of water contained in diethyl ether.

The reaction of $[Co(4mqn)_2]\cdot 2H_2O$ with NO consists of a nitrosylation reaction ($Co^{2+}+NO \rightarrow Co^{3+}+NO^-$) and the disproportionation of NO to NO_3^- and N_2O ($Co^{2+}+5NO \rightarrow Co^{3+}+NO_3^-+2N_2O$).

$[Co(4mqn)_2(NO)]$ reacted with NO to give the same products, **2** and **4**. The reaction can be described as $Co^{3+}+NO^-+4NO \rightarrow Co^{3+}+NO_3^-+2N_2O$.

Reaction at ca. *293—303 K*: Both $[Co(4mqn)_2]\cdot 2H_2O$ and **1** reacted with NO to precipitate $[Co(4mqn)_2(NO_2)(py)]$ (**3**). The terminal N-O stretching band of the nitrosyl complex could not be observed. The 1402(s) and 1314(s) cm^{-1} bands shifted to 1383 and 1291 cm^{-1} respectively upon ^{15}N-substitution (see Fig. 1). These bands can be assigned to the N-O stretching bands characteristic of the coordinating nitro ion.[4] The strong band at 320 cm^{-1} is the Co-N(pyridine) stretch-

* indicates the N–O stretching band characteristic of the coordinating nitro ion. The bands due to the nitro ion, and the bands due to the coordinating 4mqn and pyridine partially overlapped.
A region: poly(chlorotrifluoroethylene) oil mull, B region: Nujol mull.

ing vibration. The precipitate from the filtrate was **4**, like that prepared at a low temperature. The stoichiometry of the reaction reasonably explains that **3** and **4** contain a NO_2^- and a NO_3^- respectively, as will be discussed later.

The reaction of $[Co(4mqn)_2]\cdot 2H_2O$ with NO can be regarded as the disproportionations of NO to NO_2^- and N_2O ($Co^{2+}+3NO \rightarrow Co^{3+}+NO_2^-+N_2O$) and to NO_3^- and N_2O ($Co^{2+}+5NO \rightarrow Co^{3+}+NO_3^-+2N_2O$), involving the oxidation of Co^{2+} to Co^{3+}.

On the reaction of **1** with NO, the coordinating NO^- group was electrophilically attacked by NO to give NO_2^- and NO_3^-, with the liberation of N_2O: $Co^{3+}+NO^-+2NO \rightarrow Co^{3+}+NO_2^-+N_2O$ and $Co^{3+}+NO^-+4NO \rightarrow Co^{3+}+NO_3^-+2N_2O$.

Characterization of Reactions. The stoichiometries of the reactions in the pyridine-DMF and in pyridine were also examined. The relative molar ratios of the residual NO to the gaseous product, N_2O, were calculated from the reaction formulae, based on the yields of the solid products. The reaction formulae are shown in the last item. The observed ratios agreed with the calculated ones, shown in Table 2, indicating that the reactions shown in the last item proceed.

For examining the mechanism of the reaction of **1** with NO in the pyridine-DMF at *ca.* 288 K, the following isotopic combinations were used; *A*, (the ^{14}NO complex)-(^{15}NO gas) and *B*, (the ^{15}NO complex)-(^{14}NO gas). In the case of *A*, the molar ratio of ^{14}NO to ^{15}NO observed in the residual NO gas was almost equal to that of ^{14}NO to ^{15}NO contained in the reaction system. The same phenomenon was also observed for the case of *B*. Moreover, $[Co(4mqn)_2(^{14}NO)]$ reacted with ^{15}NO to give $[Co(4mqn)_2(^{14,15}NO)(py)]$, showing the ^{14}N–O and ^{15}N–O stretching bands. On a reaction at a higher temperature (*ca.* 298 K), the same ^{14}N–^{15}N scrambling as that at a lower temperature was observed.

These facts suggest that **1** decomposes perfectly to the cobalt(II) complex, $[Co(4mqn)_2]$, and NO, and that the resulting NO gas, together with NO gas, an original reactant, reacts again with $[Co(4mqn)_2]$ to give **1**. A part of the **1** is precipitated as **2** at a low temperature. On the other hand, at a high temperature, **1** reacts further with NO to give **3**. This reaction seems to proceed with a cleavage of the Co–NO bond, because the coordination of pyridine unstabilizes the Co–NO bond in the dissolved state.[4] The remaining part of **1** in the dissolved state reacts with NO to give **4**.

When a smaller amount of **1**, for example, 0.2 mmol, was used without changing the amounts of NO and the pyridine-DMF, only **4** was obtained. **2** reacted with NO in the pyridine-DMF on the same scale as has

Table 2. Stoichiometry of the reaction

Reactants		Solid products		NO/N_2O[c] Found	Calcd	Solvent

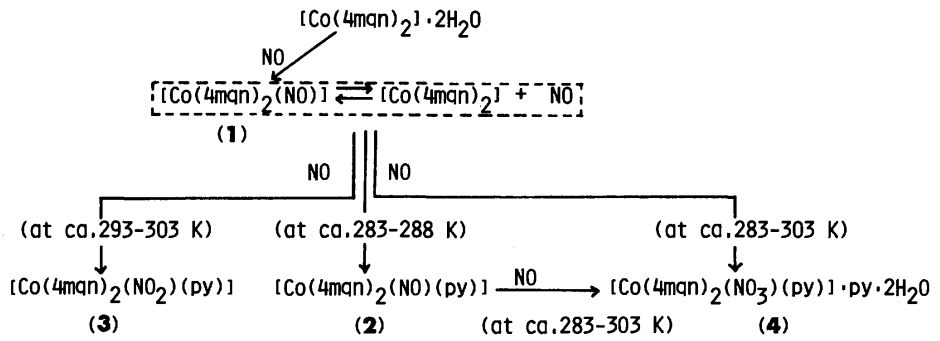
a) At *ca.* 283—288K. b) At *ca.* 293—303K. c) Relative molar ratio of the residual NO to the produced N_2O. d) mmol unit. **A**, $[Co(4mqn)_2]\cdot 2H_2O$. **1**, $[Co(4mqn)_2(NO)]$. **2**, $[Co(4mqn)_2(NO)(py)]$. **3**, $[Co(4mqn)_2(NO_2)(py)]$. **4**, $[Co(4mqn)_2(NO_3)(py)]\cdot py\cdot 2H_2O$. 4mqn=4-methyl-8-quinolinolate ion.



Scheme 1. Reaction of $[Co(4mqn)_2]\cdot 2H_2O$ or $[Co(4mqn)_2(NO)]$ with NO in 10 vol% py-DMF or in py.
(4mqn = 4-methyl-8-quinolinolate ion).

been described in the Experimental section to give only **4**, but to leave the unreacted **2** behind at both low and high temperatures. These facts suggest that **2** in the dissolved state reacts with NO to produce **4**, while **3** does not come from **2**. **3** hardly dissolved at all in the pyridine–DMF or in pyridine; hence, it did not react with NO to be recovered quantitatively. This indicates that **4** does not come from **3**. The reactions of $[Co(4mqn)_2]\cdot 2H_2O$ and $[Co(4mqn)_2(NO)]$ with NO are summarized in Scheme 1.

The critical temperature in the preparation of **2** or **3** was ambiguous. At 288—293 K, **2**, **3**, or their mixture was precipitated in subtly different conditions on that occasion.

In CH_2Cl_2, the reaction of $[Co(4mqn)_2]\cdot 2H_2O$ with NO was expected to be similar to that of $[Co(2mqn)_2]\cdot H_2O$ with NO because of the electron-donative power of the CH_3 group in the ligands.[3] However, the reaction gave only $[Co(4mqn)_2(NO)]$, and no further reaction with NO could be found such as was observed for the reactions of $[CoL_2]$ (L=5-chloro- or 5-nitro-8-quinolinolate ion) with NO.[4]

As for the reactions of $[Co(4mqn)_2]\cdot 2H_2O$ or $[Co(4mqn)_2(NO)]$ with NO in 10 vol% pyridine–DMF and in pyridine, $[Co(4mqn)_2(NO)(py)]$ and $[Co(4mqn)_2(NO_2)(py)]$ were prepared with $[Co(4mqn)_2(NO_3)(py)]\cdot py\cdot 2H_2O$ at low and high temperatures respectively, although $[CoL_2]$ and $[CoL_2(NO)]$ (L=8-quinolinolate, 5-chloro-, or 5-nitro-8-quinolinolate ion) reacted with NO in the same solvents to produce $[CoL_2(NO_3)(py)]$. No remarkable effects of the substituent in the quinoline ring on the reactions could be found except for the solubilities of the obtained compounds. The nitro complex, $[Co(4mqn)_2(NO_2)(py)]$, in the present study may be isolated because of its sparing solubility, since it is generally expected that, after $[CoL_2]$ has been nitrosylated, the NO^- group reacts with NO to give NO_3^- by way of NO_2^-.[4]

The present reaction in DMF could not be elucidated as observed for the reactions of $[CoL_2]$ (L=2-methyl- or 5-chloro-8-quinolinolate ion) with NO because the coordinating ability of DMF is not stronger than that of pyridine, and so complicated reactions may occur.

In the present study, the stoichiometries of the reactions in the pyridine–DMF and in pyridine were confirmed because all the products could be identified. It is very interesting that NO^- or NO_2^- is formed, together with NO_3^-, by the disproportionation of NO with a difference in the reaction temperature.

Partial Molal Volumes and Volume Changes for the Complex Formation of Metal Chelate Electrolytes, $Na_2[M(edta)]$ and $K[M(hedta)(H_2O)]$

Kouzou YOSHITANI
Faculty of General Education, Gifu University, Yanagido, Gifu 501-11
(Received December 1, 1984)

The partial molal volumes, V^∞, of $[M(edta)]^{2-}$ and $[M(hedta)(H_2O)]^-$ (M=Mn(II), Co(II), Ni(II), Cu(II), and Zn(II) and H_3hedta=*N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic acid) and two free ligands, $edta^{4-}$ and $hedta^{3-}$, have been determined from density measurements at 25 °C. From the results for V^∞, the volume changes for the complex formation of $[M(edta)]^{2-}$ and $[M(hedta)(H_2O)]^-$, ΔV^∞, were estimated. The values of ΔV^∞ for $[M(edta)]^{2-}$ (32.8 to 45.8 $cm^3 mol^{-1}$) and for $[M(hedta)(H_2O)]^-$ (25.2 to 36.5 $cm^3 mol^{-1}$) were large, positive ones, and a linear relationship between ΔV^∞ and ΔS was observed for these metal chelate ions.

The ethylenediaminetetraacetate ion, $edta^{4-}$, is well known as a chelating reagent and is capable of acting as a sexidentate ligand. The stereochemistries of various edta metal chelates have been established in the solid state by means of X-ray studies.[1] However, the structures of the edta chelates in aqueous solutions remain ambiguous, though they have been investigated by a variety of methods.[2-10] A previous study has shown that the partial molal volumes, V^∞, and volume changes for the complex formation, ΔV^∞, are useful in studying the solute-solvent interactions and complex-formation reactions of the metal chelate electrolytes.[11] The volume changes on complexation must be interpreted not only in terms of the simple electrostatic theory, but also by paying attention to the complex structural and solvation changes. Therefore, it seems of interest to compare the ΔV^∞ of $[M(edta)]^{2-}$ with that of $[M(phen)_3]^{2+}$.[11] The former has anionic and hydrophilic ligands, but the latter has neutral and hydrophobic ones.

However, the V^∞ and ΔV^∞ for the edta chelates have not been reported except for $[Ni(edta)]^{2-}$.[12] In this study, the partial molal volumes of $[M(edta)]^{2-}$ and $[M(hedta)(H_2O)]^-$ are determined, and the volume changes of complex formation are estimated.

Experimental

Materials. The edta chelates, $Na_2[Mn(edta)]\cdot 4H_2O$, $Na_2[Co(edta)]\cdot 3.5H_2O$, $Na_2[Ni(edta)]\cdot 3H_2O$, $Na_2[Cu(edta)]\cdot 3H_2O$, and $Na_2[Zn(edta)]\cdot 3.5H_2O$, were obtained from Nakarai Chemicals, Ltd., and were recrystallized twice from an water–ethanol mixture according to the literature method.[13] The hedta chelate electrolytes, $K[Mn(hedta)(H_2O)]\cdot 3H_2O$, $K[Co(hedta)(H_2O)]\cdot 1.5H_2O$, $K[Ni(hedta)(H_2O)]\cdot 1.5H_2O$, $K[Cu(hedta)(H_2O)]\cdot 1.5H_2O$, and $K[Zn(hedta)(H_2O)]\cdot 1.5H_2O$, were prepared by the following manner, similar to that used for the edta chelates.[13]

N-(2-Hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic acid (27.8 g, 0.1 mol) was slowly stirred into a mixture of a calculated amount of basic metal carbonate or cobalt acetate and water (50 ml). The slurry was warmed to 90 °C, after which stirring was continued for 30 min. Then, $KHCO_3$ (10 g or 30 g for the Co-chelate) was added slowly to the reaction mixture, and stirring was continued for a further 10 min at 90 °C. Absolute ethanol was vigorous stirred into the resulting solution, after which it was warmed almost to the boiling point, until the precipitate began to form. The solution was then cooled in an ice bath. The resulting precipitate was filtered and washed with ethanol and ether. The crude product was recrystallized twice from the water–ethanol mixture. The recrystallized metal chelate was placed in a desiccator over silica gel.

The purities of all the products obtained here were checked by analysis.

The metal chelate electrolytes were dried *in vacuo* for one week at 90 °C before use. The tetra sodium salt of edta and the tri sodium salt of hedta (Nakarai Chemicals, Ltd.) were used without further purification and were dehydrated *in vacuo* to a constant weight at 110 °C. All the solutions were prepared by weight with deionized and distilled water.

Apparatus. The densities were measured at 25 °C with a digital density meter (Shibayama Scientific Co., Ltd., Model SSD-200) described in a previous paper.[11] The temperature of the thermostated bath was set at ±0.03 °C and regulated to ±0.002 °C.

Results

The apparent molal volumes, ϕ_v, of the metal chelate electrolytes were calculated from the density data using this equation:

$$\phi_v = \frac{M}{d} + \frac{1000(d^\circ - d)}{m\, d\, d^\circ}, \quad (1)$$

where M is the molecular weight of the metal chelate, m is the the molality, and d° and d are the densities of the solvent and the solution respectively. The partial molal volumes at infinite dilution, V^∞, were obtained by means of the Redlich-Mayer equation:[14]

$$\phi_v - S_v C^{1/2} = V^\infty + b_v C, \quad (2)$$

where S_v is the theoretical Debye-Hückel limiting slope (1.868 and 9.706 $cm^3 dm^{3/2} mol^{-3/2}$ for 1:1 and 1:2 electrolytes respectively), C is the molar concentration, and b_v is the empirical constant. In Figs. 1 and 2, the plots of the $\phi_v - S_v C^{1/2}$ of the edta and hedta chelates against C are shown. The V^∞ and b_v values obtained by the least-squares method are shown in Table 1. The standard deviations of the fits are mostly less than 0.1 $cm^3 mol^{-1}$.

The ϕ_v of sodium salts of edta and hedta can not be directly determined from the densities of their aque-

$S_v = 9.706\,cm^3\,dm^{3/2}\,mol^{-3/2}$.

ous solutions because of the partial hydrolysis. Therefore, the stock solutions of the hypothetical solutes, $Na_4edta \cdot NaOH$ and $Na_3hedta \cdot NaOH$, were made up by mixing the anhydrous salts, stoichiometric amounts of the standard aqueous NaOH solution (0.3 mol dm^{-3}), and pure water. In this case, the pH values of the mixed solutions were around 12, and $edta^{4-}$ or $hedta^{3-}$ was assumed to be predominantly present from the pK_a values. The ϕ_v values, which were caluculated by introducing the molecular weight of the hypothetical solutes, fit the equation well over the present range of concentrations (0.01—0.1 mol dm^{-3}):

$$\phi_v = V^\infty + A_v C^{1/2} + B_v C, \quad (3)$$

where A_v and B_v are the fitting parameters. The parameters of Eq. 3, as determined by the least-squares method, are given in Table 1. The standard deviations of the fits are 0.2 $cm^3\,mol^{-1}$. The V^∞ values for Na_4 edta and Na_3 hedta are obtained by the subtraction of the V^∞ value for NaOH according to additivity rule.

The volume changes at infinite dilution, ΔV^∞, on the complex formation of:

$$[M(H_2O)_6]^{2+} + edta^{4-} \longrightarrow [M(edta)]^{2-} + 6H_2O, \quad (4)$$

$$[M(H_2O)_6]^{2+} + hedta^{3-} \longrightarrow [M(hedta)(H_2O)]^- + 5H_2O, \quad (5)$$

may be estimated from the V^∞ values of the reactants and the products according to the relationships for the edta chelates:

$$\Delta V^\infty = V^\infty([M(edta)]^{2-}) + 6V^*(H_2O) - V^\infty([M(H_2O)_6]^{2+}) - V^\infty(edta^{4-}), \quad (6)$$

and for the hedta chelates:

$$\Delta V^\infty = V^\infty([M(hedta)(H_2O)]^-) + 5V^*(H_2O) - V^\infty([M(H_2O)_6]^{2+}) - V^\infty(hedta^{3-}), \quad (7)$$

where $V^\infty([M(edta)]^{2-})$, $V^\infty([M(hedta)(H_2O)]^-)$, $V^\infty([M(H_2O)_6]^{2+})$, $V^\infty(edta^{4-})$, and $V^\infty(hedta^{3-})$ are the partial molal volumes of the species described in parentheses and $V^*(H_2O)$ is that of pure water. The V^∞ values of the hexaaqua-metal ions can be estimated by means

of this relation:[11,15]

$$V^{\infty}([M(H_2O)_6]^{2+}) = V^{\infty}(M^{2+}) + 6V^{*}(H_2O), \quad (8)$$

where $V^{\infty}(M^{2+})$ is the partial molal volume of the transition metal cation, which is generally obtained in the literature. The $V^{\infty}(M^{2+})$ values were estimated from the literature values for $Mn(ClO_4)_2$, $Co(ClO_4)_2$, $Ni(ClO_4)_2$, $Cu(ClO_4)_2$, and $Zn(ClO_4)_2$ using the additivity principle with $V^{\infty}(ClO_4^-)=49.5\,cm^3\,mol^{-1}$.[16,17] The ionic partial molal volumes of $[M(edta)]^{2-}$, $[M(hedta)(H_2O)]^-$ and the free ligands are given in Table 2; they were obtained using $V^{\infty}(Na^+)=-6.6$, $V^{\infty}(K^+)=3.6$, and $V^{\infty}(OH^-)=1.4\,cm^3\,mol^{-1}$.[17]

Discussion

The values of V^{∞} found for the bivalent metal edta chelates vary from 175.9 $cm^3\,mol^{-1}$ for $[Mn(edta)]^{2-}$ to 181.2 $cm^3\,mol^{-1}$ for $[Cu(edta)]^{2-}$; therefore, they do not significantly differ from each other. The same phenomenon is found in the case of the V^{∞} values of the hedta chelate ions, which vary from 181.2 $cm^3\,mol^{-1}$ for $[Ni(hedta)(H_2O)]^-$ to 187.3 $cm^3\,mol^{-1}$ for $[Cu(hedta)(H_2O)]^-$. These V^{∞} values are almost the same as those of the free ligands. The same facts were found for $[M(phen)_3]^{2+}$, which were about 4 to 6% smaller than three times the V^{∞} values of the free 1,10-phenanthroline.[11]

The estimated ΔV^{∞} values for the complex formation of $[M(edta)]^{2-}$ are in this order:

$$[Mn(edta)]^{2-} < [Co(edta)]^{2-} < [Ni(edta)]^{2-} < [Cu(edta)]^{2-} > [Zn(edta)]^{2-}.$$

This order is the same as in the Irving-Wiliams series. The ΔV^{∞} values for $[M(hedta)(H_2O)]^-$ are in a sequence similar to that of the edta chelates. In any case, the ΔV^{∞} values for $[M(edta)]^{2-}$ and $[M(hedta)(H_2O)]^-$ are $\Delta V^{\infty}([M(edta)]^{2-}) > \Delta V^{\infty}([(M(hedta)(H_2O)]^-]$, where M^{2+} is the same central metal ion. Furthermore, the formation of Mn(II) chelate ions of edta and hedta is accompanied by a markedly small ΔV^{∞} value in comparison with those of the other metal chelate ions. This can be attributed to the larger V^{∞} value of the high-spin d^5 Mn(II) aqua ion. For the other aqua ions, the V^{∞} are not so different and the ΔV^{∞} values of these edta and hedta chelates are almost the same.

The resultant ΔV^{∞} values for the edta and hedta chelates have markedly large positive values in comparison with the ΔV^{∞} values of the other complex formation reactions and ion-pair formation reactions. These large positive ΔV^{∞} values may be due to the large amount of water molecules released from the electrostricted solvation spheres of the reactants by the partial neutralization of the charges.

The volume changes in the ion-pair formation may serve as a reference for the volume change in the neutralization of the charges. For the inner-sphere ion-pair formation of $CaSO_4$, the ΔV^{∞} value has been reported to be 25.2 $cm^3\,mol^{-1}$,[18] which is similar in magnitude to the ΔV^{∞} values of the hedta chelates. However, the ΔV^{∞} values for the transition metal sulfate ion-pairs are fairly smaller, varying from 7.4 $cm^3\,mol^{-1}$ for $MnSO_4$ to 11.4 $cm^3\,mol^{-1}$ for $CuSO_4$.[19] For these ion-pairs, the amount of the inner-sphere ion-pair is estimated to be about 20%; therefore, the electrostricted solvation spheres of the constituent ions are not completely lost upon these ion-pairing processes.[19]

A positive contribution to the ΔV^{∞} values of edta and hedta can also be expected from the delocalization of the charge on the large metal chelate ion. This contribution becomes large when the ligand is a large hydrophobic one such as 1,10-phenanthroline. Previously, the formation of $[M(phen)_3]^{2+}$ has been reported.[11] In this system, the neutralization of the charge is not included, though the ΔV^{∞} values (*ca.* 20 $cm^3\,mol^{-1}$) except for $[Fe(phen)_3]^{2+}$ are comparable to that of an inner-

sphere ion pairing such as $CaSO_4$.[11]

A comparison of the ΔV^∞ values of the edta and hedta chelates with those of the bivalent metal carboxylato-complex formation reactions would be more instructive. For the 1:1 complex formation of Cu^{2+} with the unidentate carboxylate anions, acetate and propionate, the volume changes in the dilute solutions, ΔV, have been reported to be 13 $cm^3 mol^{-1}$ at 30 °C.[20] Furthermore, the ΔV values for the 1:1 complex of Cu^{2+} with the bidentate dicarboxylates, malonate, tartrate and maleate, are rather larger (27, 29, and 28 $cm^3 mol^{-1}$ respectively at 30 °C); these values are twice the ΔV values produced by the formation of Cu(II)-monocarboxylato complexes.[20] Therefore, it is of interest to compare the ΔV value for the edta chelate with that of the hedta chelate of the same central metal cation. The ΔV^∞ value for the latter is about three fourths that of the former; the ΔV^∞ values of these chelates are also in proportion to the number of carboxylate groups in the ligands. This means that the great part of the large positive ΔV^∞ values for the edta and the hedta chelates is responsible for the coordination of the carboxylate groups to the metal ions, even though the contributions of the nitrogen donor atoms to the ΔV^∞ can not be estimated. However, they are assumed to be smaller than those of the carboxylate groups. For example, the ΔV for Cu(II)-glycinato and Cu(II)-alaninato complexes are reported to be 14 and 15 $cm^3 mol^{-1}$ respectively at 30 °C, and for these systems the volume changes responsible for the coordinated nitrogen donor atoms are estimated to be 1—3 $cm^3 mol^{-1}$.[20]

The complex formation reactions of edta and hedta with the bivalent transition metal cations are characterized by large positive volume and entropy changes. As is shown in Fig. 3, a linear relationship between the ΔS value at an ionic strength of 0.1 mol dm^{-3} and ΔV^∞ value for the complexation of edta and hedta is observed within the limits of experimental error. Such large values for ΔS and ΔV^∞ are related, in large part, to the electrostriction effects: *i.e.*, the neutralization effect by the coordination of the acetate groups to the metal ions and the reduction of the electrostriction by the delocalization of the residual charges on the large metal chelate ions.[12] The lower ΔS and ΔV^∞ values for the hedta chelates than for the edta chelates suggest that the 2-hydroxyethyl group is not bonded to the metal ion and that fewer molecules of water are released on the complexation of the hedta chelates.

Smaller ΔS values for the edta and hedta chelates of Mn(II) than those of the analogous chelates are also found in the same manner as with ΔV^∞. The edta chelate of Mn(II) has been shown to have a seven-coordinated structure, with one water molecule.[6,9] This may be one of the reasons why the formation of the Mn(II)-edta chelate ion is accompanied by smaller ΔS and ΔV^∞ values, for at least one water molecule remains in the electronic field of the central metal cation. Therefore, it may be considered that the smaller ΔS and

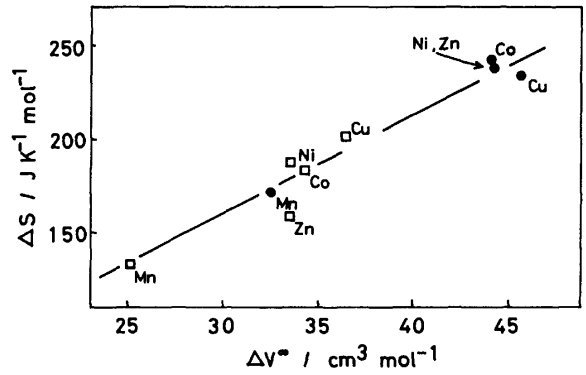

Fig. 3. Relationship between ΔV^∞ and ΔS at 25 °C.
●: $[M(edta)]^{2-}$, □: $[M(hedta)(H_2O)]^-$.

ΔV^∞ values of the Mn(II)-edta chelate than those of the other edta chelates are due to the different coordination geometry and the larger ionic size of the Mn(II) aqua ion. In the case of Mn(II)-hedta, its structure is not known; however, the present result may be supposed to indicate that the Mn(II)-hedta chelate has the same seven-coordinated structure as the Mn(II)-edta chelate, except for the two coordinated water molecules.

Many authors have concluded, on the basis of various methods of studies, that the edta chelates of Co(II), Ni(II), Cu(II), and Zn(II) in aqueous solutions are dynamic equilibrium mixtures between the dominant sexidentate form and the quinquedentate form, which contains one water molecule and a free carboxylate group.[2-10] If that is the case, the V^∞ values of the edta chelates may be written as:

$$V^\infty = \alpha V^\infty_{\mathrm{I}} + (1-\alpha)V^\infty_{\mathrm{II}} - (1-\alpha)V^*(H_2O), \quad (9)$$

where the V^∞_{I} and α are the partial molal volume and the fraction of the edta chelate in the sexidentate form and where V^∞_{II} is the partial molal volume in the quinquedentate form or the seven-coordinated form for the Mn(II)-edta chelate respectively. Therefore, the ΔV^∞ values for the edta chelates are expressed as:

$$\Delta V^\infty = V^\infty_{\mathrm{I}} + (1-\alpha)V^\infty_{\mathrm{II}} + (5+\alpha)V^*(H_2O) - V^\infty([M(H_2O)_6]^{2+}) - V^\infty(edta^{4-}). \quad (10)$$

The substitution of Eq. 9 into Eq. 10 leads to the same result as Eq. 6. The α's were estimated in the range from 60 to 80% for the edta complexes of Co(II), Ni(II), Cu(II), and Zn(II),[3,9,10] and the volume change between the quinquedentate form and the sexidentate form ($\Delta V^\infty_{\mathrm{II}\to\mathrm{I}} = V^\infty_{\mathrm{I}} + V^*(H_2O) - V^\infty_{\mathrm{II}}$) is calculated to be 4.9 $cm^3 mol^{-1}$ for the Co(II)-edta chelate.[10] When one substitutes these values into Eq. 10, the V^∞_{I} and V^∞_{II} values can be estimated separately. Such a treatment indicates that the dynamic equilibrium between the sexidentate form and the quinquedentate form of the edta chelate should have only a small effect on ΔV^∞, which is estimated to be 1—2 $cm^3 mol^{-1}$. The ΔV^∞ values for the edta chelates, except for Mn(II)-edta, are, unfortunately, not so effective in determining the structures of the edta chelates in aqueous solutions.

However, the large differences between the ΔV^{∞} values for the edta and the hedta chelate and the rather small volume change between the quinquedentate form and the sexidentate form of the edta chelate may be ascribed to the fact that the uncoordinated carboxylate group of the edta chelate in the quinquedentate form has already been situated in the second coordination sphere of the central metal cation and weakly interacts with it. This figure, except for the case of the Mn(II)–edta chelate, does not conflict with the results of the recent work on the structures of the edta chelates in aqueous solutions.

The author wishes to thank Professor Yuroku Yamamoto of Hiroshima University for his kind advice and encouragement throughout the present work. The author is also grateful to Dr. Manabu Yamamoto for his useful discussions. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 59740294 from the Ministry of Education, Science and Culture.

An X-Ray Diffraction Study on the Structures of Mono(glycinato)zinc(II) and Tris(glycinato)zincate(II) Complexes in Aqueous Solution

Kazuhiko Ozutsumi and Hitoshi Ohtaki*
Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227
(Received January 5, 1985)

The structure of zinc(II) complexes with glycinate ion in solution was investigated by the X-ray diffraction method. The measurements were performed at 20 °C for the solutions with the C_{gly}/C_{Zn} mole ratios of 1.49 (solution A) and 5.09 (solution B), where C_i denotes the total concentration of species i. From the analysis of the radial distribution curve of solution A, in which comparable amounts of the hexaaqua- and mono(glycinato)-zinc(II) complexes existed, it was found that the mono(glycinato)zinc(II) complex combined with four water molecules at the distance of (2.12±0.01) Å. The Zn-OH_2 bond length within the complex was longer than that within the hexaaquazinc(II) ion (2.08 Å). The Zn-O and Zn-N distances, where O and N denote oxygen and nitrogen atoms within the glycinate ion in the $[Zn(gly)(OH_2)_4]^+$ complex, were both (2.12±0.02) Å. Thus the mono(glycinato)zinc(II) complex had a regular octahedral structure. The nonbonding Zn···C distance was found to be (2.84±0.02) Å. The X-ray diffraction data of solution B, which contained the $[Zn(gly)_3]^-$ ion as a predominant species, showed that the tris(glycinato)zincate(II) complex had a regular octahedral structure with the both Zn-O and Zn-N bond distances of (2.12±0.01) Å. The nonbonding Zn···C(COO), Zn···C(CH_2), and Zn···O(O=C) lengths were (2.87±0.03) Å, (2.93±0.03) Å, and (4.10±0.04) Å, respectively. The solubility of the bis(glycinato)zinc(II) complex was so low that the structural determination of the complex by the present X-ray diffraction method was not possible.

Zinc(II) ion often changes the structure in the course of ligand substitution reactions. The hexaaquazinc-(II) ion has been reported to be regular octahedral in perchlorate, sulfate and nitrate solutions.[1,2] The Zn-OH_2 bond distance was found to be 2.08 Å in the former two solutions[1] and 2.093 Å in the latter.[2]

Yamaguchi and Ohtaki[3] found that the tetraamminezinc(II) complex has no water molecules in the first coordination shell and thus the tetraamminezinc(II) complex has a regular tetrahedral structure with the Zn-N bond length of 2.03 Å. The triamminemonochlorozinc(II) complex found in a dilute ammoniacal solution has a distorted tetrahedral structure. The Zn-N and Zn-Cl bond distances were determined to be 2.00 Å and 2.30 Å, respectively.

The structure of the bis(ethylenediamine)zinc(II) ion is a regular tetrahedron with the Zn-N bond length of 2.131 Å, although the structure of the tris(ethylenediamine)zinc(II) complex is a regular octahedron with a longer Zn-N bond distance of 2.276 Å.[4] Thus the coordination number of zinc(II) ion changed from 6 to 4 in the course of the formation of the ammine complexes, while the coordination number of zinc(II) ion within the ethylenediamine complexes varied from 6 within the hexaaquazinc(II) ion to 4 within the bis-(ethylenediamine)zinc(II) and then again to 6 within the tris(ethylenediamine)zinc(II) complex.

Structural changes in complex formation reactions with increasing number of ligands coordinated were found in Zn(II)-chloro[5] and Zn(II)-bromo complexes[6] in solution.

In previous studies[7,8] we determined the structures of the mono- and tris(glycinato) complexes of nickel-(II) and copper(II) ions in aqueous solutions by the X-ray diffraction method. In the present work we have attempted to determine the structure of glycinato-zinc-(II) complexes in a series of structural study of chelate complexes of transition metals in solution.

Many crystallographic data are available for amino carboxylato complexes. Though zinc(II) ion plays an important role in biochemical reactions as copper(II) ion does, less structural information on the zinc(II)-amino carboxylato complexes has been presented than that on the copper(II) complexes. The structure of the bis(glycinato)zinc(II) complex has been determined to be octahedral with two more carbonyl oxygen atoms within glycinate ions coordinated to adjacent zinc(II) ion in crystal.[9] However, structures of other complexes of zinc(II) ion with glycine have not been known even in crystal due to difficulty in preparation of stable single crystals of the mono- and tris(glycinato) complexes of zinc(II) ion. Therefore, we studied the structure of the mono(glycinato)zinc(II) and tris(glycinato)-zincate(II) complexes in aqueous solution. To find a structural change, if it occurs, of the complexes with changing number of the ligand is another aim of this investigation. The structure of the bis(glycinato)zinc-(II) complex in solution was not determinable by the X-ray diffraction method due to its low solubility in water.

Raman spectroscopic measurements have been carried out as a supplement to the structural determination of the complexes.

Experimental

Preparation and Analysis of Sample Solutions. All chemicals used were of reagent grade. Two test solutions were prepared in the similar way to that reported in previous papers.[7,8] *Solution A*, which contained the mono(glycinato)-zinc(II) complex as a predominant species, was prepared by dissolving crystals of the bis(glycinato)zinc(II) to a zinc(II) nitrate solution. In order to prevent hydrolysis of zinc(II) ion, a small amount of glycine was added to this solution. *Solution B*, in which the tris(glycinato)zincate(II) com-

density/g cm^{-3}	1.294	1.312

plex was formed as a main species, was prepared by mixing the bis(glycinato)zinc(II) and sodium glycinate in water.

Bis(glycinato)zinc(II) was prepared by mixing powder of zinc(II) oxide and glycine in boiling water and then recrystallized from a sodium glycinate solution. Sodium glycinate was obtained by the same manner previously reported.[7] Zinc(II) nitrate and glycine were recrystallized from water.

The total concentration of zinc(II) ions (C_{Zn}) in the sample solutions was determined by EDTA titration and gravimetry as $ZnNH_4PO_4$. The results of the two independent methods agreed each other within 0.2%. The total glycine concentration (C_{gly}) was determined by the Kjeldahl method. The concentrations of nitrate ions in solution A and sodium ions in solution B were evaluated by the material balance of ions in the solutions. Densities of the test solutions were measured pycnometrically. The composition of the solutions is listed in Table 1.

X-Ray Scattering Measurements. X-Ray scattering measurements were performed with a JEOL θ—θ diffractometer by using Mo $K\alpha$ radiation (λ=0.7107 Å). The observed range of scattering angle (2θ) was from 2° to 140°. Times required to acummulate 120000 counts at each angle were recorded. The method of measurements and data treatments were described in previous papers.[1,8,10] Calculations were carried out by using KURVLR[11] and NLPLSQ[12] programs with the computer at the Tokyo Institute of Technology and partly with the computer at the Institute for Molecular Science in Okazaki.

Raman Spectroscopic Measurements. Raman spectra for the sample solutions were measured with a JEOL laser Raman spectrophotometer JRS-SI with the use of the 5145 Å excited line of Ar^+ laser.

Results and Discussion

According to the stability constants of zinc(II)–glycine complexes,[13] solution A contains comparable amounts of the hexaaqua- and mono(glycinato)zinc(II) complexes and a small amount of the bis(glycinato)zinc(II) complex. However, the concentration of the bis(glycinato)zinc(II) is so small that the formation of the complex was neglected in the course of the analysis of the X-ray scattering data. In solution B almost all of the zinc(II) ions are expected to form the tris(glycinato)zincate(II) complex, since the C_{gly}/C_{Zn} mole ratio is 5.09.

The observed $s \cdot i(s)$ and $D(r)$ curves for solutions A and B are shown in Figs. 1 and 2, respectively.

The parameter values for the intramolecular structure within glycinate ion, as well as those within water molecule and nitrate ion, used for the computation of the X-ray scattering data are the same as those described in a previous paper.[7] Numbering of the atoms within the glycinate ion coordinated to the

(d) The theoretical peaks for Zn–OH_2, Zn–O_1, Zn–N, Zn···$C_{1,2}$, N···O, and O···O pairs within the mono-complex. The chain, dashed and dotted lines indicate the residual curves after subtracting the theoretical peaks in (b), (c), and (d), respectively.

zinc(II) ion is given in Fig. 3.

Solution A. In the $D(r)$ (Fig. 2A) and $D(r)-4\pi r^2\rho_0$ (Fig. 4a) curves, where ρ_0 represents the average scattering density in the stoichiometric volume V per zinc atom of the solution, we see four peaks at about 1.3, 2.2, 2.9, and 4.2 Å. The small and broad peak around 1.3 Å is owing to the O–H bonds within water molecules, the C–H, N–H, C_1–C_2, C_2–N, C_1⋍O_1, and C_1⋍O_2 bonds within glycinate ions and the N–O bonds within nitrate ions. The second peak appearing at 2.2 Å is mainly ascribed to the Zn–OH_2 bonds within the hexaaquazinc(II) ion and the Zn–OH_2, Zn–O_1, and Zn–N bonds within the mono(glycinato)zinc(II) complex. Nonbonding C_2···O_1, C_2···O_2, C_1···N, and O_1···O_2 interactions within glycinate ions and O···O contacts within nitrate ions also contribute, in part, to the peak. The third peak at about 2.9 Å is composed of peaks owing to nonbonding Zn···C_1 and Zn···C_2 interactions within the mono(glycinato)zinc(II) ion and interactions between ligand atoms in the first coordination sphere within the complexes, as well as the O···O contacts of the bulk water. In the fourth peak at 4.2 Å various longer range interactions, which will not be taken into account in the present analysis, may be included.

In order to evaluate the structure parameters of the mono(glycinato)zinc(II) complex, we firstly subtracted the theoretical peaks of the known interactions within water molecules, glycinate and nitrate ions from the observed radial distribution curve. The residual curve obtained (chain line in Fig. 4a) showed the peak at about 2.1 Å and the peak was well interpreted in terms of the octahedral configuration of six oxygen and nitrogen atoms around all zinc atoms in the solution, independent of the concentration ratio of the $[Zn(OH_2)_6]^{2+}$ to $[Zn(gly)]^+$ complexes. Since the Zn–O and Zn–N bonds were practically indistinguishable by the X-ray analysis, the result indicated that the mono(glycinato)zinc(II) complex should have six ligand atoms in the first coordination shell. Thus, we concluded that the $[Zn(gly)]^+$ complex has an octahedral structure combined with one glycinate ion and additional four water molecules.

The structure parameters of the mono(glycinato)zinc(II) complex were refined by using a least-squares method for the $s\cdot i(s)$ data over the range $s>5$ Å^{-1}. In order to avoid the introduction of errors by neglecting long-range interactions, the lower limit of the s-value was changed from 5.0 to 7.0 Å^{-1}. The concentration ratio of the $[Zn(OH_2)_6]^{2+}$ to $[Zn(gly)(OH_2)_4]^+$ complexes was assumed to be 40:60 in the present stage of the calculation. The parameter values first guessed from the analysis of the radial distribution curve of the mono(glycinato)zinc(II) ion were refined by the least-squares procedure at the fixed composition of the solution. The structural parameters of the hexaaquazinc(II) ion and the O···O contacts of bulk water were taken from the works by Ohtaki *et al.*[1] and by Narten[14] and were fixed at the literature values during the calculation. Since the lengths of the Zn–O_1 and Zn–N bonds were not determinable separately with a reasonable accuracy, we assumed that the Zn–O_1 and Zn–N bonds had the same structure parameters. The results obtained were listed in Table 2. We also tested another assumption for initial values inserted in the least-squares calculation. A tetrahedral coordination around the Zn(II) ion within the mono(glycinato)zinc(II) complex was assumed and the number of the Zn–OH_2 bond was set to be 2. When the refinement was carried out by floating the number of the Zn–OH_2

Table 2. Results of the least-squares refinements of solution A. Parameter values refined were bond distances (r/Å), temperature factors (b/Å^2) and frequency factors (n). The values in parentheses represent standard deviation

Interaction	Parameter	A-I (s>5.0 Å^{-1})	A-II (s>6.0 Å^{-1})	A-III (s>7.0 Å^{-1})

	b	0.010(2)	0.009(2)	0.007(2)

a) The values were kept constant during the calculation.

bonds at fixed frequency factor of the $Zn-O_1$ and Zn–N bonds, the number of the $Zn-OH_2$ bonds reached nearly 4 in the course of the calculation. Thus the octahedral structure of the mono(glycinato)zinc(II) complex was confirmed by the least-squares calculation. The $Zn-OH_2$ bond length was determined to be 2.12 Å and the distance of the $Zn-O_1$ and Zn–N bonds was also evaluated to be 2.12 Å.

Since we assumed that the $Zn-O_1$ and Zn–N bonds had the same structure parameters in the least-squares calculation described above, a possibility of the different lengths of the $Zn-O_1$ and Zn–N bonds was not well excluded. At the next step of calculation we examined assumptions of various lengths of the $Zn-O_1$ and Zn–N bonds. The residual radial distribution curve ascribed to the Zn–O and Zn–N bonds was extracted from the second peak of the distribution curve in Fig. 2A by subtracting intramolecular interactions of water molecules, glycinate and nitrate ions (Fig. 5). The curve consisted of peaks attributed to the interactions between Zn(II) ion and donor atoms within the complex around 2.1 Å and longer-range interatomic interactions at r>2.5 Å. The peak at 2.1 Å was drawn by assuming that it was a symmetrical Gaussian curve.

Calculations were carried out in order to minimize the error-square sum defined by Eq. 1 for various sets of the temperature factors of the $Zn-OH_2$ bond, lengths of the $Zn-O_1$ and Zn–N bonds and the concentration ratio of $[Zn(OH_2)_6]^{2+}$ to $[Zn(gly)(OH_2)_4]^+$.

$$U = \sum w\{D(r)^{2nd}_{calcd} - D(r)^{2nd}_{obsd}\}^2 \quad (1)$$

In Eq. 1, $D(r)^{2nd}$ represents the second peak extracted from the original radial distribution curve by the procedure described above. w is given as $\exp(-\alpha\cdot\Delta l^2)$, where $\Delta l = r_o - r$ and r_o denotes the r-value at the center of the peak. In this case we assumed that the r_o value was 2.11 Å and the value α was evaluated from the half-width of the second peak. In the course of the calculation the lengths of the $Zn-O_1$ and Zn–N bonds as well as

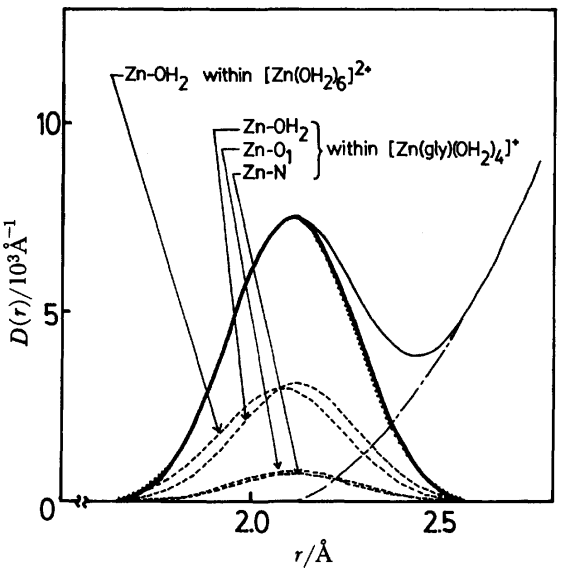

Fig. 5. The second peak of the radial distribution curve for solution A. The thin and thick solid lines show the experimental and extracted $D(r)$ curves, respectively, and the chain line indicates the residual curve after extraction. The theoretical peak shapes owing to the $Zn-OH_2$ bonds within the $[Zn(OH_2)_6]^{2+}$ ion, and the $Zn-OH_2$, $Zn-O_1$, and Zn–N bonds within the $[Zn(gly)(OH_2)_4]^+$ complex are shown by dashed lines. The dotted line represents the peak by summing peak shapes shown by dashed lines.

the concentration ratio of $[Zn(OH_2)_6]^{2+}$ to $[Zn(gly)(OH_2)_4]^+$, were stepwise changed. In addition, the temperature factor of the $Zn-OH_2$ bond within the mono(glycinato)zinc(II) complex was varied from 0.003 Å^2 to 0.005 Å^2. On the other hand, we fixed the values of the structure parameters of the $[Zn(OH_2)_6]^{2+}$ complex at the literature values,[1] as well as the length of the $Zn-OH_2$ bond within the mono(glycinato)zinc(II) complex at 2.12 Å and the temperature factor of the $Zn-O_1$ and Zn–N bonds at 0.003 Å^2.

At the temperature factor of 0.003 Å^2 for the $Zn-OH_2$ bond within the mono(glycinato)zinc(II) complex, a

TABLE 3. RESULTS OF THE ANALYSIS OF THE SECOND PEAK IN THE $D(r)$ CURVE OF SOLUTION A. ERROR-SQUARE SUMS ($U\times10^{-4}$/Å^{-2}) WERE CALCULATED ACCORDING TO Eq. 1. THE Zn–OH_2 BOND DISTANCE AND ALL TEMPERATURE FACTORS WITHIN THE MONO-COMPLEX WERE KEPT CONSTANT AT 2.12 Å AND 0.003 Å^2, RESPECTIVELY, IN THE COURSE OF THE CALCULATION

		mole fraction			
	Zn^{2+} :	0.3	0.4	0.5	0.6
	$Zn(gly)^+$:	0.7	0.6	0.5	0.4
Bond distance r/Å		$U\times10^{-4}$/Å^{-2}			
Zn–O_1	2.08	11.2	8.9	17.2	36.2
Zn–N	2.16				
Zn–O_1	2.10	10.8	6.7	14.3	33.0
Zn–N	2.14				
Zn–O_1	2.12	10.3	*6.2*	13.0	31.2
Zn–N	2.12				

minimum error-square sum was obtained at each set of the lengths of Zn–O_1 and Zn–N bonds. When we changed the length of the Zn–O_1 and Zn–N bonds and the concentration ratio of $[Zn(OH_2)_6]^{2+}$ to $[Zn(gly)(OH_2)_4]^+$ at the value of 0.003Å^2 for the temperature factor of the Zn–OH_2 bond, the minimum error-square sum was obtained when we assumed that the Zn–O_1 and Zn–N bonds have the same distance of 2.12Å and the concentration ratio of the $[Zn(OH_2)_6]^{2+}$ to $[Zn(gly)(OH_2)_4]^+$ was approximately 40:60 in the test solution (Table 3). Figure 5 represents the shape of the calculated curve from the Zn–OH_2 bonds within the $[Zn(OH_2)_6]^{2+}$ ion and the Zn–OH_2, Zn–O_1, and Zn–N bonds within the $[Zn(gly)(OH_2)_4]^+$ complex. The curve fitted well the extracted peak shape. Thus we concluded that the $[Zn(gly)(OH_2)_4]^+$ complex is regular octahedral.

Solution B. The $(D(r)-4\pi r^2\rho_o)$ curve given in Fig. 6a shows four peaks around 1.3, 2.3, 2.9, and 4.2Å and a small hump at 3.4Å. The peak at 1.3Å was attributed to the O–H bonds within water molecules and the C–H, N–H, C_1–C_2, C_2–N, C_1⋯O_1, and C_1⋯O_2 bonds within glycinate ions. The second peak appearing at 2.3Å mainly consisted of the Zn–O_1 and Zn–N interactions within the tris(glycinato)zincate(II) complex. Nonbonding C_2⋯$O_{1,2}$, C_1⋯N, and O_1⋯O_2 interactions within glycinate ions and Na–O pairs within hydrated sodium ions were also included in the peak. The peak around 2.9Å was composed of peaks owing to the nonbonding Zn⋯$C_{1,2}$ pairs and the interactions between ligand atoms in the first coordination sphere within the tris(glycinato)zincate(II) complex. The O⋯O contacts of water molecules in the bulk also contributed to the peak. In the fourth peak at about 4.2Å nonbonding Zn⋯O_2 and other long range interactions were contained.

In order to estimate the structural parameters of the $[Zn(gly)_3]^-$ complex, the peak shapes owing to interactions among water molecules, glycinate and sodium ions should be subtracted from the radial distribution function. We assumed an octahedral hydration of a

(d) The theoretical peaks for O⋯O contacts within hydrated sodium ion and Zn⋯O_2, $C_{1,2}$⋯N, $C_{1,2}$⋯O_1 pairs within the tris-complex. The chain, dashed and dotted lines show the residual curves after subtracting the theoretical peaks in (b), (c), and (d), respectively.

sodium ion since there was a small hump at 3.4Å which might be ascribable to the O⋯O contacts within a hydrated sodium ion as was previously pointed out.[7] The peak remained at 2.12Å (chain line in Fig. 6a) must be attributed to the Zn–O_1 and Zn–N interactions within the tris(glycinato)zincate(II) complex. From the analysis of the peak shape the Zn–O_1 and Zn–N bonds were found to have the same length of 2.12Å and the temperature factor of the bonds was evaluated to be about 0.003Å^2. The peak area corresponded to the sum of the peak areas of six bonds of Zn–O_1 and Zn–N. Thus the structure of the tris(glycinato)zincate(II) complex was concluded to be regular octahedral. The distance of longer range interactions within the tris(glycinato)-zincate(II) complex were estimated by using a suitable structure model of chelating glycinate ions. Subtraction of the above peaks from the radial distribution curve led to a smooth background curve (dotted line in Fig. 6a) having no appreciable peak over the range $r<4$Å.

The structure parameters of the tris(glycinato)zin-

a) Temperature factors of these interactions were fixed at 0.006 Å^2. b) The values were kept constant during the calculation.

cate(II) complex were finally determined by a least-squares calculation for the $s\cdot i(s)$ curve over the range $s>4$Å^{-1}. The calculations were performed by inserting the values for each interatomic interaction evaluated by the analysis of the radial distribution function. Three types of calculations were carried out on slightly different assumptions. In the B-I type calculation all the parameter values listed in Table 4 were floated as independent variables. In the B-II treatment some interatomic distances were allowed to remain unchanged. On the B-III assumption, similar to the B-II treatment, the frequency factors of all atom pairs in the table were fixed at the given values. No significant difference was found in the bond lengths in the three calculations.

In the course of the calculation the existence of the *fac-* and *mer*-isomers of the tris(glycinato)zincate(II) complex was taken into consideration. However, the structural difference between the isomers was too small to improve the result by the introduction of the existence of the isomers.

Raman Spectra of Solutions A and B. Krishnan and Plane[15] reported Raman spectra for aqueous zinc(II) nitrate–glycine solutions in the pH range 2.0—7.0. From a Job plot with the total concentration of zinc(II) ion plus glycinate ion keeping approximately constant, the Zn–N stretching frequencies for the mono(glycinato)zinc(II), bis(glycinato)zinc(II) and tris(glycinato)zincate(II) complexes were assigned to be *ca.* 445, 430, and 425 cm^{-1}, respectively. In solution A of the present work (Fig. 7) the line at 441 cm^{-1} was assignable to the Zn–N stretching vibration for the mono(glycinato)zinc(II) complex. Other lines at 520, 580, and 920 cm^{-1} were attributable to the CO_2^- rocking, CO_2^- wagging and C–C stretching vibrations, respectively, within glycinate ion. The $\tilde{\nu}_4$-band of the

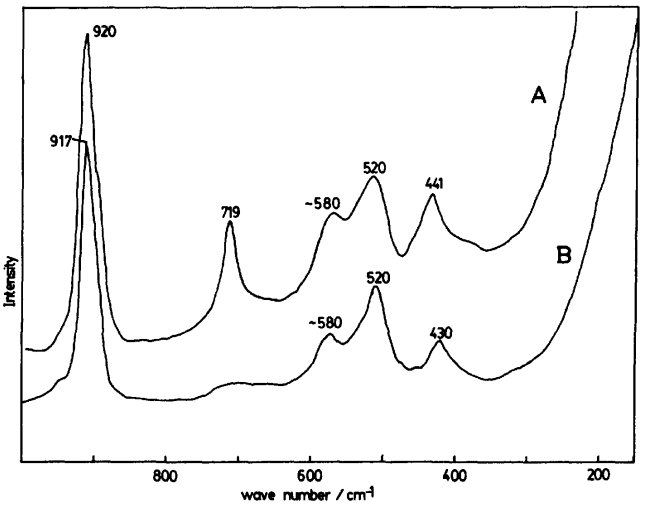

Fig. 7. Raman spectra of solutions A and B.

nitrate ion appeared at 720 cm^{-1}. In solution B we found a band ascribed to the Zn–N stretching for the tris(glycinato)zincate(II) complex at 430 cm^{-1}. Since solution B contained the tris(glycinato)zincate(II) complex as a main species, our result of the Zn–N frequency for the tris(glycinato)zincate(II) complex may be more reliable than that observed by Krishnan and Plane, because the concentration of the complex is sufficiently high in our solution. On the other hand the concentration of the tris-complex may be low under their experimental conditions where they kept the total concentration of zinc(II) and glycinate ions almost constant. The Raman spectra measured in the present work showed that the Zn–N stretching frequency was higher in the mono(glycinato)zinc(II) complex than in the tris(glycinato)zincate(II) ion, although the length of the Zn–N bond within the both complexes was practically

the same. The Zn–O and Zn–N bond lengths determined in the former complex may contain larger uncertainties than those in the latter do, because in the course of the structural analysis of the $[Zn(gly)(OH_2)_4]^+$ complex we have to evaluate lengths of three different kinds of bonds whilst the $[Zn(gly)_3]^-$ complex has bonds of two different kinds.

The mono(glycinato)zinc(II) and tris(glycinato)zincate(II) complexes in solution have a regular octahedral structure with the lengths between zinc(II) and ligand atoms of 2.12 Å. In crystal of the $[Zn(gly)_2]\cdot H_2O$[9] the equatorial square plane around the zinc(II) ion was occupied by chelating two glycinate ions and two apices of the distorted octahedron were filled with carbonyl oxygen atoms of glycinate ions combined with adjacent zinc(II) ions, though the bond distances between the Zn(II) ion and donor atoms were not determined. All the structures of the zinc(II)–glycinato complexes were octahedral and the metal-ligand bond lengths were practically indifferent in the complexes with varying numbers of the ligand coordinated, in contrast to the case of zinc(II)–ammine[3] and zinc(II)–ethylenediamine complexes.[4]

The work has been financially supported, in part, by the Grant-in-Aid for Scientific Research No. 57470054 from the Ministry of Education, Science and Culture. The financial aid by the Asahi Glass Foundation for Industrial Technology and the Japan Society for Promotion of Science is also acknowledged. A part of the computer calculations carried out in the present study has been performed at the Institute for Molecular Science in Okazaki.

The Stereoselective Retardation of the Alkaline Hydrolysis of Organic Esters by Binuclear Cu(II) Complexes with Cyclodextrins

Yoshihisa MATSUI* and Daisuke SUEMITSU
Department of Agricultural Chemistry, Shimane University, Nishikawatsu, Matsue 690
(Received November 21, 1984)

The alkaline hydrolysis of *p*-nitrophenyl acetate (*p*-NPA) in 1.0 mol dm^{-3} NaOH at 25 °C was almost completely retarded by the addition of a binuclear Cu(II) complex with α-cyclodextrin (Cu_2α-CD). The dissociation constant for an inclusion complex of Cu_2α-CD with *p*-NPA was determined to be 0.059 mmol dm^{-3}, which is about one 200th that for an inclusion complex of α-CD with *p*-NPA. The alkaline hydrolysis of *o*- and *m*-nitrophenyl acetates was also retarded by Cu_2α-CD, though the extent of retardation was much less than that for *p*-NPA. A binuclear Cu(II) complex with β-cyclodextrin (Cu_2β-CD) also caused a stereoselective deceleration of the alkaline hydrolysis of the esters. However, the stereoselectivity of Cu_2 β-CD was not so remarkable as that of Cu_2α-CD. Dissociation constants for inclusion complexes of Cu_2α-CD with several alcohols and other organic substrates were determined by the kinetic examination of the competitive inhibition effect of the substrates on the association of Cu_2α-CD with *p*-NPA. Cu_2α-CD formed stable inclusion complexes with such disk-like molecules as cyclohexanol, cycloheptanol, and *p*-nitrobenzyl alcohol. The geometry of a Cu_2α-CD-*p*-NPA inclusion complex was presumed on the basis of these results.

Copper(II) forms a binuclear complex (Cu_2CD) with cyclodextrin (CD) in an alkaline solution.[1] Although the structure of the complex has not been fully elucidated, it has been suggested that the two pairs of C2 and C3′ secondary hydroxyl groups of contiguous glucose units of CD are cross-linked by the $Cu(OH^-)_2$-Cu or $Cu(OH^-)(O^{2-})$Cu ion bridge (Fig. 1).[2]

The present work was undertaken to examine the binding and catalytic actions of this complex on organic substrates. The complex holds the CD cavity within which an organic molecule is included. The Cu(II) ions or the alkoxide ions of the complex may catalyze some reaction of an included molecule. Thus, it could be anticipated that the complex becomes a good model of metalloenzymes. The alkaline hydrolysis of nitrophenyl acetates (NPA) and the related esters was chosen as a test reaction in the present work, since the reaction has widely been used to examine the catalytic effects of CD itself[3-7] and modified CD's.[8-15] The catalytic property of the Cu_2CD complex has been reported only on the alkaline hydrolysis of a few organic phosphates[16] and monothiophosphates.[17]

Experimental

Materials. The α- and β-CD's commercially available were purified according to the directions of Cramer and Henglein.[18] Methyl α-D-glucopyranoside(MGP) of a reagent grade was used without further purification. $CuSO_4 \cdot 5H_2O$ of a reagent grade was recrystallized from water. The acetates (*o*-, *m*-, and *p*-NPA and 4-NNA) of *o*-, *m*-, and *p*-nitrophenols and 4-nitro-1-naphthol (*o*-, *m*-, and *p*-NP and 4-NN) were prepared by the reactions of the phenols and naphthol with acetic anhydride in pyridine at room temperature. The 4-NN (mp 164—166°, lit,[19] mp 164°) was prepared by the method of Hodgson and Kilner.[20] *p*-Nitrophenyl propionate (*p*-NPP) was prepared by the reaction of *p*-NP with propionyl chloride in pyridine. Mp 61—62°C. Alcohols such as 1-butanol, 1-pentanol, 2-methyl-2-propanol, 2,2-dimethyl-1-propanol, cyclohexanol, cycloheptanol, benzyl alcohol, and *p*-nitrobenzyl alcohol were commercially available and were used without further purification. *p*-Nitrobenzoic acid and methyl acetate commercially available were also used without further purification.

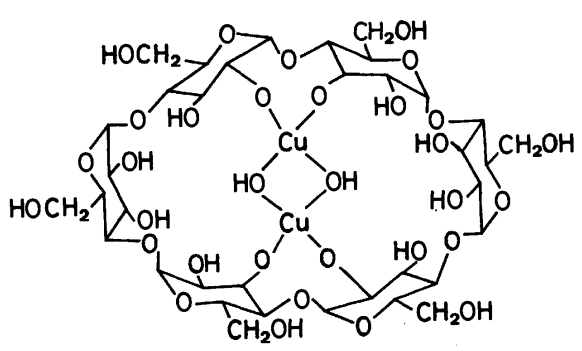

Fig. 1. A suggested structure of a Cu_2α-CD complex.

Kinetics. The rates of the alkaline hydrolyses of the esters were measured by following the appearance of the absorptions of the corresponding phenolate and naphtholate anions with an Union Giken stopped-flow reaction analyzer, Model RA-1100. A typical run is as follows. An alkaline CD solution was mixed with an aqueous $CuSO_4$ solution in such a way that the molar quantity of Cu in a resulting mixture was twice that of CD. The mixture was turbid and was shaken till it became clear, giving a Cu_2CD solution. The solution was rapidly mixed with an equal volume of an aqueous solution containing an organic ester at 25°C. The initial concentration of the ester in a reaction mixture and the wavelength at which the hydrolysis was followed are listed in Table 1. The change of absorbance with

time was treated according to the ordinary pseudo-first-order rate equation. The rate constants were calculated by the least-squares curve-fitting method with a microcomputer. All the reactions examined obeyed good first-order kinetics with regard to substrates irrespective of the absence or the presence of Cu_2CD in solution.

Determination of the Dissociation Constants and Rate Constants of Cu_2CD–Ester Complexes. As is illustrated in Fig. 2 for an example, the observed first-order rate constant (k_{obsd}) for each substrate approached a minimum value as the Cu_2CD concentration (c_0) increased. This saturation behavior suggests that the rate process involves the prior formation of an inclusion complex of Cu_2CD with a substrate. Upon the assumption of the formation of a 1:1 Cu_2CD–substrate complex, k_{obsd} is represented by the following equation if c_0 is much higher than the concentration of a substrate:[3]

$$k_{obsd} = \frac{K_d(k_{un}-k_{obsd})}{c_0} + k_c. \quad (1)$$

In this equation, K_d is the dissociation constant of an inclusion complex, and k_{un} and k_c, the rate constants for free and complexed substrates, respectively. The plot of k_{obsd} *vs.* $(k_{un}-k_{obsd})/c_0$ was virtually linear for each Cu_2CD–substrate system as is shown in Fig. 3. The values of K_d and k_c were calculated from the slope and intercept, respectively, of the straight line obtained by the use of the least-squares method.

Kinetic Determination of Dissociation Constants for Inclusion Complexes of $Cu_2\alpha$-CD with Alcohols and Other Organic Substrates. Dissociation constants (K_i) for inclusion complexes of $Cu_2\alpha$-CD with several alcohols and other organic substrates were determined by the kinetic examination of the competitive inhibition effect of the substrates on the association of $Cu_2\alpha$-CD with *p*-NPA in 1.0 mol dm^{-3} NaOH at 25 °C. An aqueous solution containing 0.06 mmol dm^{-3} *p*-NPA and varying amounts of an organic substrate was rapidly mixed with an equal volume of 2.0 mol dm^{-3} NaOH solution containing 3.0—5.0 mmol dm^{-3} $Cu_2\alpha$-CD at 25 °C. The k_{obsd} value for the alkaline hydrolysis of *p*-NPA in the presence of $Cu_2\alpha$-CD increased with increasing concentration (c_i) of the organic substrate. Relationships between k_{obsd} and c_i were analyzed by an equation derived by VanEtten, *et al.*:[3]

$$c_i = \frac{c_0 \cdot K_i}{K_d} \times \frac{k_{obsd}-k_c}{k_{un}-k_{obsd}} - K_i \quad (2)$$

Polarimetric Determination of Dissociation Constants for the Inclusion Complexes of CD or Cu_2CD with the p-*Nitrophenolate Ion.* The dissociation constant for the inclusion complex of CD or Cu_2CD with the *p*-NP anion was determined by a polarimetric examination of the effect of *p*-NP on the optical rotation of a CD or Cu_2CD solution at 25 °C. A Union Giken Model PM-101 polarimeter was used for the measurement. The optical rotation of the solution at λ=589 nm increased with the addition of *p*-NP. The K_d value was estimated using an ordinary Hildebrand-Benesi plot.

Results and Discussion

The effect of CD itself on the hydrolysis rates of *m*- and *p*-NPA had been examined in aqueous solutions (pH 10.0—10.6).[3] The present investigation was carried out in 1.0 mol dm^{-3} NaOH, since Cu(II) forms a stable 2:1 complex with CD in such a concentrated alkaline solution.[2] Table 2 shows the effects of CD and its Cu(II) complex on the hydrolysis rate of *p*-NPA at 25 °C. Although the hydrolysis was only slightly decelerated by the addition of α- or β-CD, the addition of $Cu_2\alpha$-CD or $Cu_2\beta$-CD markedly retarded the reaction. Among them, $Cu_2\alpha$-CD depressed the hydrolysis rate below one tenth the original rate. On the other hand, the

addition of a Cu(II) complex with MGP resulted in a slight acceleration of the hydrolysis. MGP forms a 1:1 complex with Cu(II) in an alkaline solution.[1] Thus, it is obvious that the marked retardation of the *p*-NPA cleavage by $Cu_2\alpha$-CD is not simply related to the direct action of the Cu(II) ion. The hydrolyses of *m*- and *o*-NPA and 4-NNA were also retarded by $Cu_2\alpha$-CD or $Cu_2\beta$-CD, though the extents of the retardation were not so large as that for a $Cu_2\alpha$-CD-*p*-NPA system. Interestingly, the hydrolysis of *p*-NPP was greatly retarded by $Cu_2\alpha$-CD to an extent similar to that of *p*-NPA.

The K_d and k_c values for these Cu_2CD-organic carboxylate systems were determined by the analysis of the relationships between k_{obsd} and the concentration (c_0) of Cu_2CD (Fig. 3). Table 3 gives the values obtained, together with those for Cu_2CD-organic phosphate and monothiophosphate systems reported previously.[16,17] These results indicate that $Cu_2\alpha$-CD causes a markedly stereoselective deceleration of the alkaline hydrolysis of organic carboxylates such as *o*-, *m*-, and *p*-NPA, *p*-NPP, and 4-NNA: The k_c/k_{un} value is virtually equal to zero for *p*-NPA and *p*-NPP, whereas it is 0.27 for *o*-NPA, 0.65 for *m*-NPA, and 0.88 for 4-NNA. Another remarkable stereoselectivity was observed for the binding of the esters to $Cu_2\alpha$-CD: The K_d value was determined to be 0.028 mmol dm^{-3} for *p*-NPP and 0.059 mmol dm^{-3} for *p*-NPA, these values being much smaller than those for *o*- and *m*-NPA and 4-NNA. According to VanEtten, *et al.*,[3] the K_d value for an α-CD-*p*-NPA system is equal to 12 mmol dm^{-3}, which is about 200 times that for a $Cu_2\alpha$-CD-*p*-NPA system. The K_d value for an α-CD-*m*-NPA system is 19 mmol dm^{-3} which is only 3 times that (6.3 mmol dm^{-3}) for a $Cu_2\alpha$-CD-*m*-NPA system. The binding site of $Cu_2\alpha$-CD may be significantly different in structure from that of uncomplexed α-CD.

$Cu_2\beta$-CD also caused a stereoselective deceleration of

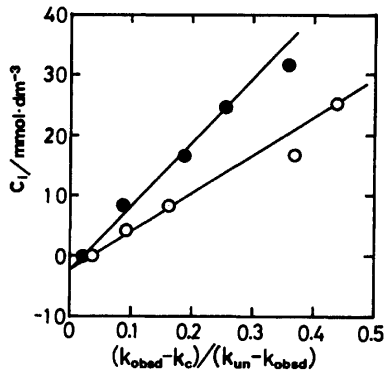

Fig. 4. Plots of c_i *vs.* $(k_{obsd}-k_c)/(k_{un}-k_{obsd})$ for a $Cu_2\alpha$-CD-*p*-NPA-cyclohexanol system in 1.0 mol dm^{-3} NaOH at 25 °C.
○: [$Cu_2\alpha$-CD]=1.5 mmol dm^{-3}, ●: [$Cu_2\alpha$-CD]=2.5 mmol dm^{-3}.

the alkaline hydrolysis of the carboxylates. However, the stereoselectivity of $Cu_2\beta$-CD is not so remarkable as that of $Cu_2\alpha$-CD with regard to both k_c/k_{un} and K_d. Furthermore, the retardation effect of $Cu_2\beta$-CD was less prominent in the carboxylates than in the phosphates and monothiophosphates. On the other hand, the binding and catalytic actions of $Cu_2\alpha$-CD on the phosphates and monothiophosphates are less stereoselective than those on the carboxylates. These results suggest that the binding and catalytic properties of Cu_2CD depend not only on the structures of the phenyl and acid moieties of the phenyl esters but also on the size of the CD ring.

In order to characterize the structure of the binding site of $Cu_2\alpha$-CD, dissociation constants (K_i) for inclusion complexes of $Cu_2\alpha$-CD with several alcohols and other organic molecules were determined by a kinetic examination of the competitive inhibition effect of the molecules on the association of $Cu_2\alpha$-CD with *p*-NPA in 1.0 mol dm^{-3} NaOH at 25 °C. Figure 4 shows the plots of c_i *vs.* $(k_{obsd}-k_c)/(k_{un}-k_{obsd})$, based on Eq. 2,

for a $Cu_2\alpha$-CD–cyclohexanol system at c_0=1.5 and 2.5 mmol dm^{-3}. The plots were virtually linear in both cases. The extrapolation of the straight lines to $(k_{obsd}-k_c)/(k_{un}-k_{obsd})=0$ gave virtually the same K_i value of 2.2 mmol dm^{-3}. As Eq. 2 suggests, the slopes of the straight lines are equal to $c_0 \cdot K_i/K_d$. The K_d values, thus estimated, were 0.052 mmol dm^{-3} in both cases. The value is very close to that directly determined (K_d=0.059 mmol dm^{-3}). Table 4 shows the K_i values obtained, together with the K_d value for a $Cu_2\alpha$-CD complex with the *p*-NP anion estimated by the polarimetric method. The K_d values for inclusion complexes of α-CD itself with these substances are also shown in the table for the sake of comparison.[21]

Although the K_d values for inclusion complexes of $Cu_2\alpha$-CD with *p*-NPA and *p*-NPP were very small, the K_i value for a $Cu_2\alpha$-CD complex with methyl acetate, as well as the K_d values for $Cu_2\alpha$-CD complexes with *o*- and *m*-NPA, was significantly large. It is obvious that the *p*-nitrophenyl moiety of *p*-NPA or *p*-NPP is essential for the strong binding of *p*-NPA or *p*-NPP to $Cu_2\alpha$-CD. This presumption is supported by the fact that the K_i value for a $Cu_2\alpha$-CD–*p*-nitrobenzyl alcohol system is considerably small (0.47 mmol dm^{-3}). However, the K_d or K_i values for a $Cu_2\alpha$-CD complex with the *p*-nitrophenolate or *p*-nitrobenzoate anion was not so small as the K_d value for a $Cu_2\alpha$-CD complex with *p*-NPA or *p*-NPP. $Cu_2\alpha$-CD holds two negative charges, and the inclusion of the *p*-nitrophenolate or *p*-nitrobenzoate anion within the $Cu_2\alpha$-CD cavity may be retarded by the electrostatic repulsive force. The K_i values for $Cu_2\alpha$-CD complexes with normal and branched alkanols such as 1-butanol, 1-pentanol, and 2-methyl-2-propanol were comparable to the corresponding K_d values for α-CD complexes with the alkanols. On the other hand, the K_i values for $Cu_2\alpha$-CD complexes with cycloalkanols such as cyclohexanol and cycloheptanol were considerably smaller than the corresponding K_d values for α-CD complexes with the cycloalkanols. It has been suggested that the macrocyclic ring of α-CD is distorted to the ellipsoidal form by the formation of a $Cu_2\alpha$-CD complex (Fig. 1),[2] whereas the ring is virtually regular hexagonal in α-CD inclusion complexes.[22,23] The ellipsoidal cavity of $Cu_2\alpha$-CD may be favorable for the inclusion of such disk-like molecules as cycloalkanols, *p*-nitrobenzyl alcohol, *p*-NPA, and *p*-NPP.

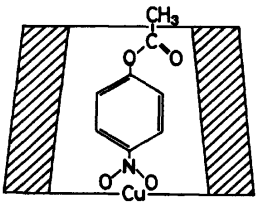

Fig. 5. The proposed geometry of *p*-NPA within the cavity of $Cu_2\alpha$-CD.

The geometry of the $Cu_2\alpha$-CD–*p*-NPA inclusion complex was presumed to be as is shown in Fig. 5 on the basis of the results described above. The substrate, *p*-NPA, may penetrate into the ellipsoidal cavity of $Cu_2\alpha$-CD so deeply that the maximum van der Waals contact with the cavity is attained. The coordination of the Cu(II) ion of $Cu_2\alpha$-CD to the nitro group of *p*-NPA may be possible to occur, resulting in the additional force for the strong binding of the substrate to $Cu_2\alpha$-CD. The carbonyl moiety of *p*-NPA may aloso be included within the cavity, so that the nucleophilic attack of the hydroxide ion on the carbonyl carbon is almost completely retarded by the steric hindrance of the α-CD macrocycle. In the cases of the organic phosphates and monothiophosphates, two methoxyl or two ethoxyl groups attached to the phosphorus atom may be too large to be included deeply within the cavity of $Cu_2\alpha$-CD. Then, the phosphorus atom is subject to the nucleophilic attack of the hydroxide ion from bulk solution. The *o*- and *m*-isomers of NPA may also be impossible to be deeply included within the $Cu_2\alpha$-CD cavity, owing to the steric hindrance of the substituents. $Cu_2\beta$-CD has a larger cavity in size than $Cu_2\alpha$-CD. Thus, *p*-NPA cannot fit the $Cu_2\beta$-CD cavity so closely as it fits the $Cu_2\alpha$-CD cavity, and the K_d and k_c/k_{un} values for a $Cu_2\beta$-CD–*p*-NPA system is much larger than those for a $Cu_2\alpha$-CD–*p*-NPA system. On the contrary, *o*- and *m*-NPA and 4-NNA as well as the organic phosphates and monothiophosphates may be more deeply included within the $Cu_2\beta$-CD cavity than within the $Cu_2\alpha$-CD cavity. Then, the k_c/k_{un} values for $Cu_2\beta$-CD complexes with these substrates are smaller than those for the corresponding $Cu_2\alpha$-CD complexes.

In conclusion, complex formation between Cu(II) and α-CD causes a large conformational change in the macrocycle of α-CD, which is responsible both for the markedly stereoselective binding of *p*-NPA and for the stereoselective retardation of the alkaline hydrolysis of

p-NPA by $Cu_2\alpha$-CD. Similar effects of metal ions on the conformation and binding and catalytic properties of enzymes have often been reported on metalloenzymes.[24,25] Thus, we can refer to the Cu_2CD complex as a good model of metalloenzymes.

Reactions of Tropone Tosylhydrazone Sodium Salt with Anthracene, 1,3-Diphenylisobenzofuran, and Phenylacetylene: [2+2] and [4+2] Type Cycloaddition Reactions of Cycloheptatrienylidene or 1,2,4,6-Cycloheptatetraene

(Received December 3, 1984)

The reaction of tropone tosylhydrazone sodium salt (**1**) with anthracene gave a [4+2]-type adduct and the reaction of **1** with 1,3-diphenylisobenzofuran afforded *endo*- and *exo*-[4+2]-type adducts as well as a heptafulvene derivative. The reaction of **1** with phenylacetylene yielded a [2+2]-type adduct, which rearranged into 2-phenylindene upon heating. The addition reactions are thought to proceed *via* the allene intermediate, 1,2,4,6-cycloheptatetraene, which is a valence-bond isomer of the carbene intermediate, cycloheptatrienylidene, initially generated by the pyrolysis of **1**. The photoreaction of adduct **3** with a high-pressure mercury lamp afforded a ring-closure product *via* the photobicyclization reaction of the cycloheptatriene moiety of the adduct. Thermal interconversions between the three products of the reaction of **1** with 1,3-diphenylisobenzofuran were investigated.

It is known that tropone tosylhydrazone sodium salt (**1**) generates the carbene, cycloheptatrienylidene (**3a**) accompanied by nitrogen gas and sodium *p*-toluenesulfinate (**2**) by pyrolysis or photolysis.[1] Cycloheptatrienylidene is recognized to be a nucleophilic singlet carbene, due to the contribution of a canonical formula (**3b**), which is stabilized by the 6 π-electrons aromatic system.[2] Actually, **3a** preferentially reacts with electron-deficient double bonds.[2] Recently, Jones *et al.* suggested the possibility of a valence-bond isomerization between the carbene **3a** and an allene, 1,2,4,6-cycloheptatetraene (**3c**), and proved experimentally that **3c** rearranged into **3a**.[3] However, the reverse isomerization, **3a** to **3c**, has never been found. We have pyrolyzed **1** in the presence of various olefins and we have evidence which suggests the isomerization of **3a** to **3c**. Here, we wish to report our findings.

Results

When **1** was allowed to react with anthracene (**4**) in anhydrous diglyme at 120 °C for 15 min, the [4+2]-type adduct **5** was afforded in a yield of 21%. The reaction of **1** with 1,3-diphenylisobenzofuran (**6**) under the identical conditions gave two [4+2]-type adducts, **7** and **8**, accompanied by the heptafulvene derivative **9**, in yields of 28, 3, and 4%, respectively. The analogous reaction of **1** with phenylacetylene (**10**) afforded a [2+2]-type adduct **11** and 2-phenyl-1*H*-indene (**12**)[4] in yields of 8 and 5%, respectively.

Compound **5** was thermally stable and was recovered quantitatively after heating at 150 °C for 40 h, but turned to polymeric materials upon heating at 180 °C for 20 h. No change was observed when **7** and **8** were kept at 120 °C for 15 min (the conditions of the pyrolysis of **1**), but upon heating at 130 °C for 25 h, **7** gave **8** and **9** in yields of 6 and 42%, respectively, as well as a 30% yield of recovered **7**. Under conditions analogous to the above, **8** afforded **7**, **9**, and recovered **8** in yields of 2, 20, and 68%, respectively. Upon heating at 120 °C for 1 h, **11** rearranged into **12** in a 55% yield. The red oil **9** was unstable and readily decomposed to a resinous material, but catalytic hydrogenation of **9** over palladium–charcoal resulted in the formation of a colorless oil **13** in 96% yield by absorbing 4 molar equivalents of hydrogen.

The irradiation of a methanol solution of **5** using a high-pressure mercury lamp afforded the ring-closure product **14** in a yield of 88%.

The structures of **5**, **7**, and **8** were deduced on the basis of their physical properties and confirmed by a comparison of these properties with those of analogous compounds.[5] The stereochemistries of **7** (*endo*-adduct) and **8** (*exo*-adduct) were deduced on the basis of the following arguments. According to Dreiding models, H_a of **8** (δ 2.60) and H_b of **7** (δ 4.75) are expected to appear in a higher field in the NMR spectra compared to H_a of **7** (δ 3.68) and H_b of **8** (δ 5.15), because of the diamagnetic anisotropic effects from the *o*-disubstituted benzene moiety. Furthermore, the chemical shifts of H_a of **7** (δ 3.68) and **8** (δ 2.60) are

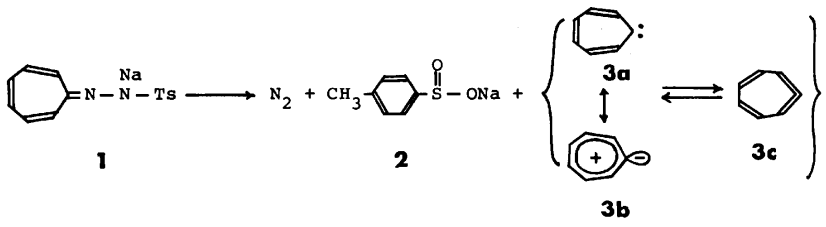

Fig. 1.

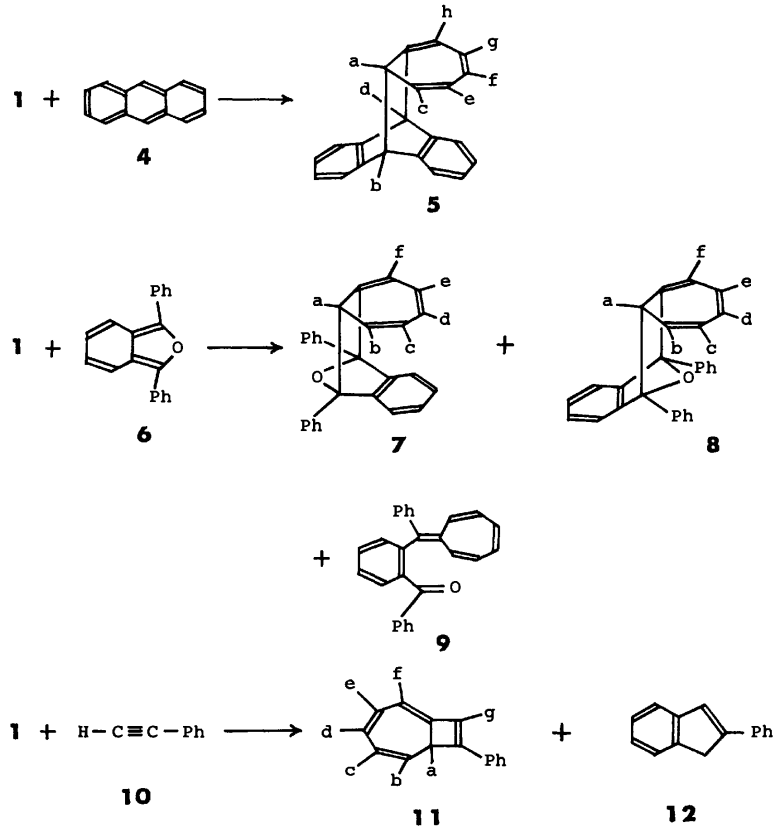

Fig. 2.

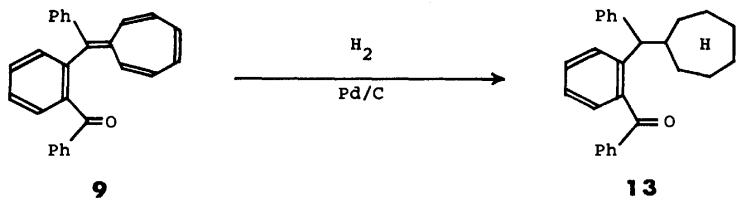

Fig. 3.

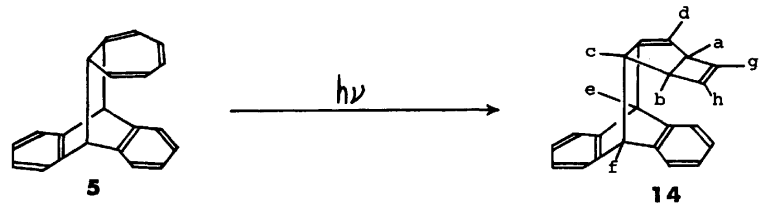

Fig. 4.

consistent with that of the bridge-head proton of the endo-adduct of **6** with cycloheptatriene (δ 3.88)[5d] and that of H_a of **5** (δ 2.46), respectively, indicating that each pair of protons is located in nearly the same chemical environment.

The structure of **9** was deduced mainly from its UV spectrum, which is characteristic of heptafulvene derivatives,[6] and its IR spectrum, which shows a carbonyl band in the same region as that of benzophenone. The absorbing of 4 molar equivalents of hydrogen by **9** to give a stable colorless oil **13** seems to support the structure of **9**.[6d]

The structure of the photoproduct **14** was deduced on the basis of the physical properties and confirmed by a comparison of the physical properties with those of the analogous compounds.[7]

Discussion

The mechanism for the formation of **9** from **7** and **8** initially involves the cleavage of the bond at 7-position of the cycloheptatriene moiety of **7** and **8** to give a tropylium cation (**15a**) or a tropylium radical intermediate (**15b**), which in turn affords **9** *via* an ether bond cleavage as shown in Fig. 5. The stability of the tropylium cation and/or the tropylium radical[8] and

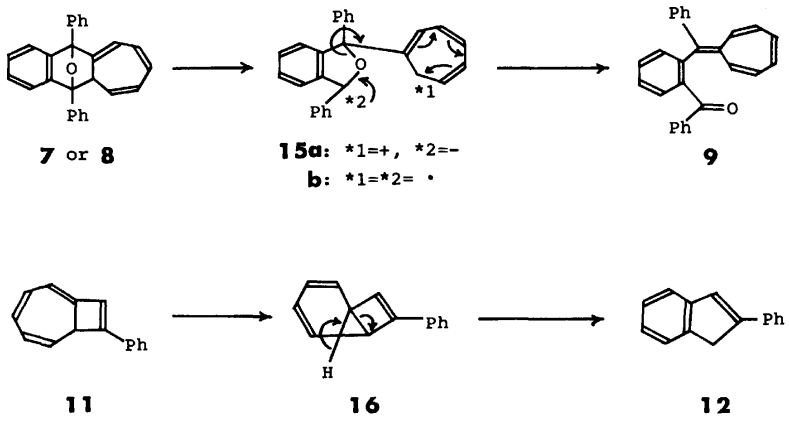

Fig. 5.

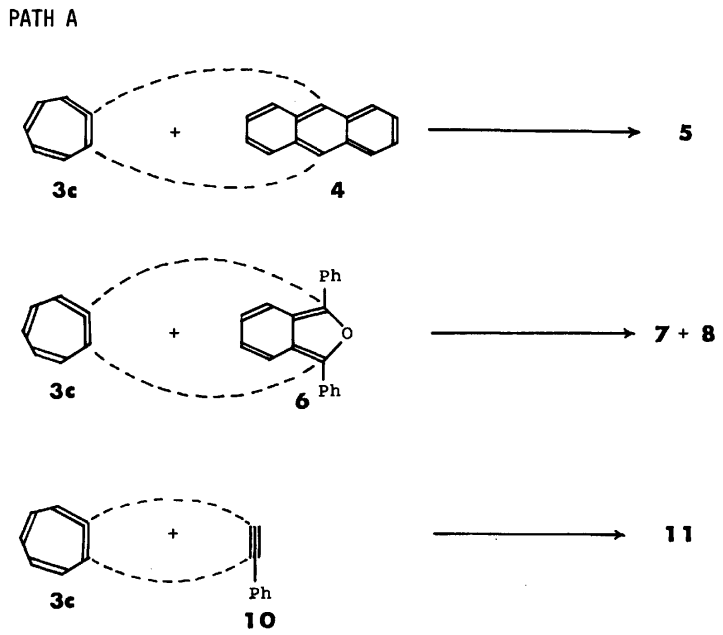

Fig. 6.

the formation of the stable benzophenone moiety can be regarded as the driving force for this reaction.

The isomerization mechanism of **11** to **12** may be explained as follows. The valence-bond isomerization of the cycloheptatriene moiety of **11** gives rise to the norcaradiene structure (**16**),[9] which rearranges to **12** *via* a hydrogen shift. The analogous reaction mechanism has been proposed for the formation of indane derivatives in the thermal reactions of spiro[2.6]nona-4,6,8-triene derivatives.[1b,7c,10] The photochemical formation of **14** proceeds *via* the well known 4 π-electrons photo-allowed disrotatory cyclization process.[7,11]

Two possible mechanisms may be considered for the reaction of **1** with **4**, **6**, and **10**. Pathway A involves an allene intermediate **3c** followed by a [4+2] or [2+2] addition reaction of the allenic double bond of **3c** with the appropriate moieties of **4**, **6**, and **10** to give the corresponding adducts. Pathway B involves the carbene intermediate **3a**, which reacts with **4**, **6**, and **10** to afford the tropylium cation intermediates **17a**, **15a**, and **18a**, respectively, or the tropylium radical intermediates **17b**, **15b**, and **18b**, respectively. Subsequent cyclization reactions of these intermediates lead to the formation of the corresponding products.

A closer examination into pathway B reveals two facts which do not adequately explain the observed products. First, intermediate **3a** is a nucleophilic carbene; therefore, the addition of this carbene to **4**, **6**, and **10** is not favored since these compounds do not contain any electron-defficient double bonds. Second, the yield of the *endo*-adduct **7** is higher than that of the *exo*-adduct **8**. According to Dreiding model, there is no obvious difference between the steric repulsions in the formation of **7** and **8** from**15**. On this basis, **7** and **8** are expected to be formed in an equal yield from **15**. The fairly large difference between the yield of **7** and **8** would suggest that the reaction does not proceed *via* **15**. On the other hand, several advantages are envisioned regarding pathway A. Compounds **4** and **6** are known to react readily as 4π-components

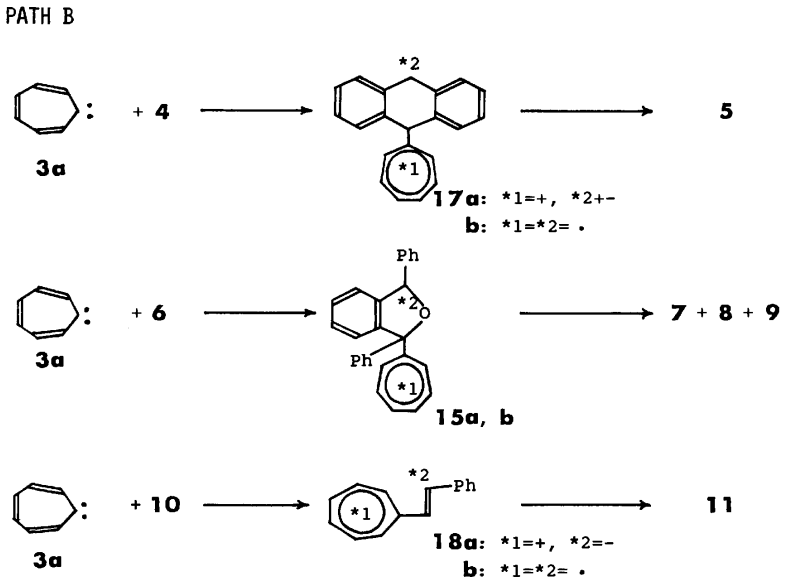

Fig. 7.

in [4+2]-type addition reactions.[12] Oda has reported that a cyclic conjugated allene derivative has been allowed to react with **6** to give *endo* and *exo* [4+2]-type adducts in a yield ratio of 5:1, without defining the stereochemistry of the adducts.[13] The major formation of the *endo*-adduct **7** can be explained as the result of the secondary orbital interaction in the transition state.[11]

As discussed above, it is difficult to decide whether the carbene intermediate **3a** or the allene intermediate **3c** is involved in the addition reactions, but a plausible pathway for the reaction would involve the allene intermediate **3c**. As for the reaction with **10**, pathway B seems to have still some possibility, because pathway A may involve a thermally forbidden [π2s+π2s] addition process.[14]

Experimental

The photoreactions were performed with a 400-W high-pressure mercury lamp, UVL-400P of Riko Kagaku Sangyo Ltd. under a nitrogen stream at room temperature. Thermal isomerizations were carried out in sealed ampoules. All melting points are uncorrected. UV and IR spectra were measured with the Hitachi 220A and DS-701G spectrometers, respectively. Mass spectra were measured with the Hitachi M-52 and JMS-DX300 spectrometers, and the NMR spectra were measured with a Hitachi R-20B or a Varian XL 200 spectrometer with tetramethylsilane as an internal standard. Wako Gel C-200 and activated alumina of Wako Pure Chemical Industries Ltd. were used for column chromatography. Wako Gel B5F was used for thin-layer chromatography.

Reaction of 1 with 4. A mixture of **1** (13.50 g, 46 mmol), **4** (25.00 g, 140 mmol) and anhydrous diglyme (120 ml) was heated at 120 °C for 15 min. After evolution of nitrogen gas had ceased (11, 97%), the gray powder of **2** (7.70 g, 95%) was removed by filtration. The filtrate was extracted with benzene, washed with water, and dried over anhydrous sodium sulfate. After filtration, the solvent was removed on a rotary evaporator to yield black crystals, which were recrystallized from benzene to give crystals of recovered **4** (21.29 g). The filtrate was chromatographed on silica gel to yield recovered **4** (0.85 g) by pet ether–benzene 9:1 and colorless crystals of **5** (2.57 g, 21%) by pet ether–benzene 8:2. The crystals of **5** were purified by recrystallization from benzene–ethanol. **5**: Mp 135—136 °C. Found: C, 93.80; H, 6.03%. Calcd for $C_{21}H_{16}$: C, 93.99; H, 6.01%. Mass *m/z* (rel intensity): 268 (M^+, 95), 191 (23), 178 (100). UV (EtOH): 276 nm (log ε, 3.53). IR (KBr): 3030, 1600, 1480 cm^{-1}. NMR ($CDCl_3$) δ=2.46 (m, H_a), 4.47 (d, H_b), 4.63 (dd, H_c), 4.78 (s, H_d), 5.86 (m, H_e), 6.20 (m, H_f, H_g, H_h), 7.0—7.5 (m, 8H, Ph). Coupling constants in Hz: J_{ab}=3, J_{ac}=5, J_{ce}=10, J_{ea}=2, J_{ef}=5.

Reaction of 1 with 6. A mixture of **1** (24.00 g, 80 mmol), **6** (43.00 g, 160 mmol) and anhydrous diglyme (200 ml) was heated at 120 °C for 15 min to evolve nitrogen gas (1.7 l, 96%). After separation of the gray powder of **2** (13.86 g, 96%) by filtration, the filtrate was treated, as usual, to yield a mixture of crystals and an oil. The crystals of recovered **6** (23.60 g) were separated by filtration and the filtrate was chromatographed on alumina to yield colorless crystals **7** (6.20 g) and mixed crystals of **7** and **8** (3.03 g) by pet ether–benzene 3:1 and a red oil **9** (1.15 g, 4%) by ether. The NMR spectrum of the mixed crystals showed that this mixture contained **7** and **8** in a ratio of 2:1. Thus, the yields of **7** and **8** were 8.22 g (28%) and 1.01 g (3%), respectively. Repeated recrystallization from benzene gave pure crystals of **7** and **8**. The red oil of **9** was further purified with thin-layer chromatography on silica gel using benzene as a developing solvent (R_f=0.60). **7**: Mp 189—190 °C. Found: C, 90.23; H, 5.43%. Calcd for $C_{27}H_{20}O$: C, 89.97; H, 5.59%. Mass *m/z* (rel intensity): 360 (M^+, 100), 255 (87), 105 (82). UV (EtOH): 278 nm (log ε, 3.44). IR (KBr): 3030, 1600, 1450 cm^{-1}. NMR ($CDCl_3$) δ=3.68 (m, H_a), 4.75 (dd, H_b), 5.85 (m, H_c), 6.13 (m, H_d), 6.20 (m, H_e, H_f), 7.0—7.8 (m, 14H, Ph). Coupling constants in Hz: J_{ab}=4, J_{ac}=2, J_{bc}=10, J_{cd}=5, J_{de}=11. **8**: Mp 177—178 °C. Found: C, 89.62; H, 5.59%. Calcd for $C_{27}H_{20}O$: C, 89.97; H, 5.59%. Mass *m/z* (rel intensity): 360 (M^+, 45), 255 (100), 105 (55). UV (EtOH): 278 nm (log ε, 3.67). IR (KBr): 3030, 1600, 1450 cm^{-1}. NMR ($CDCl_3$) δ=2.60 (m, H_a), 5.15 (dd, H_b), 6.05 (m, H_c), 6.32 (m, H_d), 6.43 (m, H_e, H_f), 7.0—7.8 (m, 14H, Ph).

Coupling constants in Hz: J_{ab}=4, J_{ac}=2, J_{bc}=10, J_{cd}=5, J_{de}=11. **9**: Found: C, 90.22; H, 5.61%. Calcd for $C_{27}H_{20}O$: C, 89.97; H, 5.59%. Mass *m/z* (rel intensity): 360 (M^+, 38), 209 (44), 152 (34), 105 (100). UV (EtOH): 248 nm (log ε, 4.32), 332 (3.93). IR (neat): 3030, 1670, 1600 cm^{-1}. NMR ($CDCl_3$) δ=5.3—6.5 (m, 6H), 7.0—7.4 (m, 14H, Ph).

Reaction of 1 with 10. A mixture of **1** (5.92 g, 20 mmol), **10** (10.20 g, 100 mmol), and anhydrous diglyme (50 ml) was heated at 120 °C for 15 min to evolve nitrogen gas (450 ml, 100%). After separation of the gray powder **2** (3.56 g, 100%), by filtration, the usual workup gave a black oil, which gave recovered **10** (7.69 g) by distillation under a reduced pressure (0.5 Torr†, bath temperature 75 °C). The residue was chromatographed on silica gel to give a tarry material (680 mg) by pet ether, which was thin layer chromatographed on silica gel using pet ether as a developing solvent to give crystals of **12** (207 mg, 5%, R_f=0.45, mp 167—168 °C, lit,[4] 166—167 °C) and a colorless oil of **11** (320 mg, 8%, R_f=0.40). **11**: Found *m/z* 192.0967. Calcd for $C_{15}H_{12}$: 192.0964. Mass *m/z* (rel intensity): 192 (100), 179 (11), 165 (20), 115 (14). UV (EtOH): 270 nm (log ε, 4.23). IR (neat): 3050, 2960, 1660 cm^{-1}. NMR ($CDCl_3$) δ=4.71 (m, H_a), 5.21 (m, H_b), 5.75 (m, H_c), 5.8—6.7 (m, H_d, H_e, H_f), 6.37 (d, H_g), 7.1—7.5 (m, 5H, Ph). Coupling constants in Hz: J_{ab}=4, J_{bc}=10, J_{ce}=5, J_{gf}=2.

Hydrogenation of 9. A solution of **9** (150 mg, 0.42 mmol) in benzene (15 ml) was hydrogenated with palladium-charcoal (30 mg) to absorb hydrogen gas (38 ml, 17 mmol). After filtration, the solvent was removed on a rotary evaporator to yield a colorless oil, which was thin-layer chromatographed on silica gel using benzene as a developing solvent to yield a colorless oil of **13** (146 mg, 96%, R_f=0.70). **13**: Found: C, 87.97; H, 7.43%. Calcd for $C_{27}H_{28}O$: C, 88.00; H, 7.66%. Mass *m/z* (rel intensity): 368 (M^+, 100), 309 (57), 270 (44), 165 (24). UV (EtOH): 250 nm (log ε, 4.31). IR (neat): 3030, 2950, 1673, 1600 cm^{-1}. NMR ($CDCl_3$) δ=1.3—2.4 (two broad peaks, 14H), 7.0—7.4 (m, 14H, Ph).

Thermal Isomerization of 7. A solution of **7** (80 mg) in benzene (0.3 ml) was kept at 130 °C for 25 h in a sealed ampoule. Thin-layer chromatography of the reaction mixture on silica gel using benzene as a developing solvent gave mixed crystals of **7** and **8** (30 mg, R_f=0.85) and a red oil of **9** (34 mg, 42%, R_f=0.60). The NMR spectrum of the mixed crystals showed that the crystals contained **7** and **8** in a ratio of 5:1; thus,the yields of **7** and **8** were 25 mg (30%) and 5 mg (6%), respectively.

Thermal Isomerization of 8. A solution of **8** (80 mg) in benzene (0.3 ml) was kept at 130 °C for 25 h. Thin-layer chromatography of the reaction mixture under the same conditions as above gave mixed crystals of **7** and **8** (56 mg) and a red oil of **9** (16 mg, 20%). The NMR spectrum showed that the mixed crystals contained the recovered **7** (54 mg, 68%) and **8** (2 mg, 2%).

Thermal Isomerization of 11. A solution of **11** (40 mg) in benzene (5 ml) was kept at 120 °C for 1 h. After evaporation of the solvent, the reaction mixture was thin-layer chromatographed on silica gel using pet ether as a developing solvent to yield crystals of **12** (22 mg, 55%, R_f=0.45).

Photoreaction of 5. A solution of **5** (100 mg) in methanol (200 ml) was irradiated with a high-presssure mercury lamp for 2 h. After evaporation of the solvent on a rotary evaporator, the residue was thin-layer chromatographed on silica gel using pet ether-benzene 8:2 as a developing solvent to yield a colorless oil of **14** (88 mg, 88%, R_f=0.80). **14**: Found: *m/z* 268.1227. Calcd for $C_{21}H_{16}$: *m/z* 268.1251. Mass *m/z* (rel intensity): 268 (14), 178 (100), 151 (7). UV (EtOH) 212 nm (sh, log ε, 4.45). IR (neat): 3030, 2980, 1460 cm^{-1}. NMR ($CDCl_3$) δ=2.76 (m, H_a), 3.10 (m, H_b), 4.19 (s, H_c), 4.35 (d, H_d), 5.54 (bs, H_e, H_f), 6.02 (d, H_g), 6.28 (d, H_h), 7.0—7.3 (m, 8H, Ph). Coupling constants in Hz: J_{ab}=4, J_{ad}=3, J_{gh}=3.

The authors are indebted to Professor Tadashi Sasaki of Nagoya University for his fruitful suggestions. This work was supported by a Scientific Research Grant from the Ministry of Education, Science, and Culture.

(Received December 6, 1984)

A new reducing agent was prepared from borane and amino alcohols. The reagent is very effective for chemoselective reduction of ketones in the presence of esters, oxime ethers, tertiary amides, nitriles, halides, and acyl chlorides. The polymeric reagent prepared from borane and polymer-supported amino alcohol was also prepared easily. Aldehydes are highly selectively reduced to primary alcohols in the presence of ketone with the polymeric reagent. Simple filtration separated cleanly the unchanged ketone from the polymeric reagent which gave, after hydrolysis, only primary alcohol as the product. The polymeric reagent was regenerated by treatment with borane and could be reused.

Borane reagents such as diborane, borane-tetrahydrofuran (THF), borane-dimethyl sulfide, alkylboranes, and amine-boranes are known to be effective reducing agents for a number of organic compounds.[1] Many attempts for the chemoselective reductions have been made using borane and its derivatives to get significant selectivities.[2-6] In previous papers,[7-9] we have shown that the borane complexes with chiral amino alcohols reduced prochiral ketones highly enantioselectively to give optically active alcohols with quantitative yields. In order to apply these novel borane-amino alcohol complexes to chemoselective reductions their reducing properties were investigated. Indeed a high chemoselectivity was realized in the reduction of ketones in the presence of many other functional groups by use of the reducing agents, easily prepared from commercially available amino alcohols and borane in THF. Polymer-supported amino alcohol-borane complexes were also examined to show an excellent selectivity in the reduction of aldehyde in the presence of ketone. Easy separation of the polymer-supported species from unreacted species present in the reaction mixture was performed by simple filtration. Easy recovery of the polymer-supported amino alcohol makes it possible to regenerate and reuse the reagent.

Results and Discussion

In the first place, the reducing agent prepared from 2-aminoethanol and borane was used to investigate its reducing properties. The molar ratio of borane to the amino alcohol affected the reactivity of the complex in the reduction of ketones. Acetophenone was reduced rapidly by the reagent prepared from 2:1 ratio of borane and 2-aminoethanol, whereas the reagent from 1:1 reacted slowly under the experimental conditions. Isopropylamine-borane and ethoxyborane did not also show so high reactivity. Surprisingly, the rate of ketone reduction by the reagent from 2:1 of borane and the amino alcohol was faster than borane itself as shown in Fig. 1. After treatment of 2-aminoethanol with two equimolar borane in THF, the excess of borane and solvent was evaporated off to give a white pasty solid which could also reduce acetophenone as rapidly as the non-evaporated reagent. In order to avoid the reduction by free borane, this highly-reactive, evaporated 2:1 complex was used for the selected organic compounds containing various functional groups. Results are summarized in Table 1. Carbonyl groups of aldehydes and ketones are rapidly and quantitatively reduced at room temperature in THF to give the primary and secondary alcohols, respectively. Epoxide ring of styrene oxide was cleaved with the complex at the more substituted position (anti-Markovnikov opening as a consequence of electrophilic attack). This high regioselectivity is the same as found for the conventional borane reduction. Unlike the ketone reductions, hydroboration of styrene with this complex was not so fast as with borane itself. The

regioselectivity was the same as borane, producing mainly 2-phenylethanol after oxidative treatment with alkaline hydrogen peroxide. The reduction of oxime ethers and tertiary amides proceeded slowly and smoothly to give the corresponding primary and tertiary amine respectively. Although this complex reacts with carboxylic acid to generate hydrogen, reduction did not occur under the experimental conditions. The use of more than two fold excess of the reagent allowed to reduce carboxylic acid to primary alcohol in good yield. It was observed that ester, nitrile, chloride, and acyl chloride are all inert toward the reagent. H. C. Brown *et al.*[10] already reported that the reactivity of borane with various functional groups decreases in the order; carboxylic acids>olefins>ketones>nitriles>epoxides>esters>acyl chlorides. Therefore, the amino alcohol-borane complex is quite different in the order of reactivity.

In view of the considerable attention focused in recent years on the use of polymer-supports to modify the reactivity and selectivity of various reagents,[11] we prepared polymer-supported amino alcohols (Scheme) which were treated with borane to give polymeric reducing agents. Polymer-supported amino alcohol-borane complex could also reduce ketones. Heterogeneous reactions by the use of cross-linked poly(styrene-divinylbenzene) copolymer as a polymer-support took place more slowly than those with the corresponding monomeric reagents. Complete reduction of acetophenone with a 2% cross-linked polymer-supported reagent required 50 h. The higher the degree of cross-linking, the slower is the reaction rate.

Chemoselective Reduction. By taking advantage of a high reactivity of this complex toward ketones, chemoselective reduction of ketones in the presence of ester was examined in THF at room temperature. 2-Aminoethanol-borane complex reduced acetophenone exclusively to give 1-phenylethanol within 30 min. No reduction of ethyl benzoate occured under these conditions. After usual work-up GLPC analysis showed only

two peaks of unreacted ethyl benzoate and 1-phenylethanol (Table 2). Polymer-supported amino alcohol–borane complexes (run 2,3) also gave the same result. As we expected from our previous results[12] the polymer-supported complex containing tertiary amine such as **1** required a longer reaction time to attain a quantitative reduction of ketone than the complex of secondary amine **2**. In addition to the successful chemoselective reduction, polymer-supported complex could be advantageously used to separate the reacted ketones from the unreactive esters by simple filtration. In other words, the ketone was selectively taken out of the mixture containing esters. This useful separation was realized only when the polymer-supported complex was used. We also examined the selective reduction of keto esters. Methyl acetoacetate and methyl benzoylformate were reduced chemoselectively to give only hydroxy esters. No diols were detected by ^{1}H-NMR or GLPC. Similarly, the inertness of organic halides toward the reagent allows the selective reduction of ketones in the presence of halo groups. Thus, chloroacetophenone and bromoacetophenone were selectively reduced to halohydrins which could be transformed to the synthetically useful epoxides. In the mixture of acetophenone and its oxime ether 2-aminoethanol–borane or polymer-supported complex reduced the ketone selectively (Table 3). Although a clear discrimination between acetophenone and *N*,*N*-dimethylbenzamide was difficult by 2-aminoethanol–borane complex because of its powerful reducing ability, polymer-supported complex from **1** and borane could reduce only acetophenone in the presence of *N*,*N*-dimethylbenzamide in 50 h (Table 4). The chemoselective reduction of aldehydes to primary alcohols in the presence of ketones was then examined with the complex. The chemoselectivity in the competitive reductions of benzaldehyde and acetophenone with several amino alcohol–borane complexes is illustrated in Table 5. In the case of the soluble amino alcohol–borane complexes (run 1, 2), its powerful reducing ability to the ketone carbonyl groups could not discriminate between aldehyde and ketone. On the other hand, the polymer-supported reagents could clearly discriminate between them. Degree of cross-linking of the polymer-support affects not only chemoselectivity but also reaction rate. Both reactivity and selectivity increased with decreasing degree of cross-linking (run 3—5). Separation of the aldehyde, reacted with polymer-supported complex, from the unreacted ketone was performed easily also in this case by simple filtration. Benzyl alcohol was obtained quantitatively after hydrolysis. The recovered polymer-supported amino alcohol could be reused for the reduction after the treatment with borane. In conclusion, the present study confirms the versatility of

8	**3**	2	54	5	0	100	80	20

the reagent has the unique reducing properties different from borane itself and the other hydrides. The complex showed an exceptionally powerful reducing ability toward the ketone carbonyl groups. This enabled the chemoselective reduction of ketone in the presence of other functional compounds such as esters, oximes, amides, nitriles; and halides. Its relatively easy availability should make this complex valuable for a variety of selective reductions. Furthermore, water-soluble amino alcohol made separation and isolation of organic products easy. Polymer-supported amino alcohol–borane complex also reduced ketones selectively. Aldehydes were distinguishable from ketones only when the polymer-supported complex was used as reducing agent. In addition to this highly chemoselective property, there are several advantages that polymer-supported complex makes the separation of the reacted substrate from the unreacted one easy by simple filtration and that it was easily recovered and reused.

Experimental

General. GLPC analyses were performed on a Yanaco G180 instrument with a stainless steel analytical column (3 m×3 mm) packed with PEG 20 M on Diasolid L. The products distributions were determined by their peak areas. ^{1}H-NMR spectra were measured on a JEOL JNM-PMX60 (60 MHz) spectrometer. IR spectra were measured on a JASCO A-3 instrument for nujol mulls. TLC was run on silica gel 60 F-254 pre-coated plates with chloroform as the mobile phase.

Materials. All reactions were carried out under an atmosphere of nitrogen. Tetrahydrofuran (THF) was heated under reflux over sodium metal and distilled from lithium aluminium hydride in a nitrogen atmosphere. Benzaldehyde, acetophenone, styrene oxide, ethyl benzoate, benzonitrile, benzyl chloride, methyl acetoacetate, methyl benzoylformate, and *N,N*-dimethylbenzamide were dried and distilled over calcium hydride. Benzoyl chloride, 2-aminoethanol, and 2-(methylamino)ethanol were purified by fractional distillation. α-Chloroacetophenone and α-bromoacetophenone were recrystallized from carbon tetrachloride and methanol, respectively. Acetophenone oxime O-benzyl ether was prepared by the methods of French and Harrison[13] and Karabatsos and Hsi[14] and purified by fractional distillation. Bp 145 °C/667 Pa. ^{1}H-NMR($CDCl_3$) δ=2.16 (3H, s), 5.16 (2H, s), 7.00—7.80 (10H, m). Borane–THF was prepared by the reaction of sodium borohydride with boron trifluoride–diethyl ether complex according to the procedure of Brown.[15] Ethoxyborane was prepared by the reaction of borane–THF with 1 equiv of ethanol. Isopropylamine–borane was prepared by the reaction of borane–THF with 1 equiv of isopropylamine. The purities of all reagents were checked by GLPC and ^{1}H-NMR spectroscopy. All materials described were stored under a nitrogen atmosphere prior to use. (*S*)-*N*-Benzylprolinol was prepared by the reaction of (*S*)-prolinol, which was obtained by the reaction of (*S*)-proline with $LiAlH_4$ in refluxing THF, with benzyl chloride in the presence of K_2CO_3 in refluxing toluene according to the method developed by Govindachari *et al.*[16] Bp 90—92 °C/27 Pa. $[\alpha]_D^{25}$ −59.9 °(*c* 1.0, $CHCl_3$). Polymer-supported (*S*)-prolinol (**1**) was prepared from 1,2, or 5% cross-linked chloromethylated polystyrene resin and (*S*)-prolinol according to the method previously reported.[12,17] Polymer-supported (*S*)-valinol (**2**) and polymer-supported 2-(methylamino)ethanol (**3**) were similarly prepared from chloromethylated polystyrene resin and (*S*)-valinol or 2-(aminomethyl)ethanol, respectively. The degree of ring substitution of polymer-supported amino alcohols is 40—70%.

Reduction of Acetophenone with the Reagent Prepared from 2-Aminoethanol and Borane in THF. To a solution of 2-aminoethanol (3 ml, 5 mmol) in dry THF was added borane–THF (5 ml, 10 mmol), initially at −78 °C and the mixture was warmed and kept at 30 °C overnight, followed by evaporation of the unchanged borane under reduced pressure (13 Pa) for 5 h. The reagent thus formed was allowed to desolve in THF (10 ml) under nitrogen. To this solution was added acetophenone (0.6 g, 5 mmol) with stirring, and the resulting mixture was stirred for 30 min at room temperature. After hydrolysis with 1 M† HCl, ether extract was washed with water, and then analyzed by GLPC (100% conversion). The crude product was distilled by bulb-to-bulb distillation to give 1-phenylethanol (0.56 g, 92% of isolated materials); it was characterized by IR and ^{1}H-NMR spectroscopies. Other

† 1 M=1 mol dm^{-3}.

substrates were reduced and analyzed by a similar procedure.

Chemoselective Reduction of Acetophenone in the Presence of Ethyl Benzoate. To a solution of the reagent prepared from aminoalcohol (5 mmol) and borane (10 mmol) in THF was added a mixture of acetophenone (0.6 g, 5 mmol) and ethyl benzoate (0.72 ml, 5 mmol) at 30 °C. After 30 min the reaction mixture was quenched with 1 M HCl. The ether extract of the organic layer was washed with water, and then analyzed by GLPC and ^{1}H-NMR which indicated the mixture to contain only 1-phenylethanol and unreacted ethyl benzoate.

Chemoselective Reduction of Acetophenone in the Presence of Benzonitrile. To a solution of the reagent prepared from 2-aminoethanol (5 mmol) and borane (10 mmol) in THF was added a mixture of acetophenone (0.6 g, 5 mmol) and benzonitrile (0.51 ml, 5 mmol) at 30 °C. After 30 min the reaction mixture was quenched with 1M HCl. The ether extract of the organic layer was washed with water, and then analyzed by GLPC and ^{1}H-NMR which indicated the mixture to contain only 1-phenylethanol and unreacted benzonitrile.

Chemoselective Reduction of Acetophenone in the Presence of Benzyl Chloride. To a solution of the reagent prepared from 2-aminoethanol (5 mmol) and borane (10 mmol) in THF was added a mixture of acetophenone (0.6 g, 5 mmol) and benzyl chloride (0.58 ml, 5 mmol) at 30 °C. After 30 min the reaction mixture was quenched with 1 M HCl. The ether extract of the organic layer was washed with water, and then analyzed by GLPC and ^{1}H-NMR which indicated the mixture to contain only 1-phenylethanol and unreacted benzyl chloride.

Chemoselective Reduction of Acetophenone in the Presence of Benzoyl Chloride. To a solution of the reagent prepared from 2-aminoethanol (5 mmol) and borane (10 mmol) in THF was added a mixture of acetophenone (0.6 g, 5 mmol) and benzoyl chloride (0.58 ml, 5 mmol) at 30 °C. After 30 min no acetophenone was detected by TLC (R_f=0.46) and benzoyl chloride was confirmed to remain by TLC (R_f=0.80). The reaction mixture was then hydrolyzed with 1 M HCl. The ether extract of organic layer was shaken with 1 M NaOH, washed with water, and then analyzed by GLPC which indicated 1-phenylethanol.

Chemoselective Reduction of α-Chloroacetophenone to Styrenechlorohydrin. To a solution of the reagent prepared from 2-aminoethanol (5 mmol) and borane (10 mmol) in THF was added α-chloroacetophenone (0.77 g, 5 mmol) in THF (5 ml) at 30 °C. After 30 min the reaction mixture was quenched with 1 M HCl. The ether extract of the organic layer was washed with water, dried ($MgSO_4$), and distilled (bulb-to-bulb) to give 2-chloro-1-phenylethan-1-ol (0.7 g, 90% of isolated material), it was characterized by ^{1}H-NMR spectroscopy. ^{1}H-NMR($CDCl_3$) δ=3.53 (2H, d), 4.40 (1H, s), 4.75 (1H, t), 7.18 (5H, m).

α-Bromoacetophenone was reduced to styrenebromohydrin in 88% yield by a similar procedure mentioned above.

Chemoselective Reduction of Methyl Acetoacetate to Methyl 3-Hydroxybutyrate. Methyl acetoacetate was converted to methyl 3-hydroxybutyrate (92% yield) by a similar procedure as mentioned above. It was characterized by ^{1}H-NMR spectroscopy. ^{1}H-NMR ($CDCl_3$) δ=1.24 (3H, d), 2.46 (2H, d), 3.70 (3H, s), 4.20 (1H, s).

Methyl benzoylformate was also converted to methyl mandelate in 85% yield, which was characterized by ^{1}H-NMR spectroscopy.

Chemoselective Reduction of Benzaldehyde in the Presence of Acetophenone with Polymer-supported Reagent. Polymer-supported reagent was prepared from polymer-bound (*S*)-prolinol (1% cross-linking, 60.8% ring substitution, 3.67 mmol/g, 2.72 g, 10 mmol) and borane (20 mmol) by the same method as monomeric one. To a THF suspension of the reagent was added a mixture of benzaldehyde (5 mmol) and acetophenone (5 mmol) at 30 °C. Reaction was checked by TLC. After 1 h the suspension was filtered carefully under a nitrogen atmosphere. Obtained polymer was hydrolyzed with 1 M HCl to give benzylalcohol alone, determined by GLPC and ^{1}H-NMR analyses. From the filtrate unreduced acetophenone was completely recovered.

Conformational Aspect of Indazole Adenine Dinucleotides in Aqueous Solution

Shuichi TONO-OKA,* Ichiro AZUMA, and Isao SEKIKAWA
Section of Chemistry, Institute of Immunological Science, Hokkaido University, Kita-ku, Sapporo 060
(Received December 18, 1984)

Conformational properties of various title compounds in aqueous solution were examined with the aid of 500 MHz ^{1}H-NMR spectroscopy. In particular, the signals of aromatic protons on both the indazole and adenine rings were shifted to higher fields without exception, compared with the corresponding signals in indazole and adenine mononucleotides. These observations, which can be explained as resulting from diamagnetic shielding effect of the indazole and adenine rings, indicate that the base pairs in the dinucleotides are closely stacked in parallel planes. On the other hand, the average conformation of riboses were deduced from $J_{1',2'}$-values as a proportion of $N \rightleftharpoons S$ equilibrium composition. Indazole riboses showed a roughly 50/50 equilibrium, whereas adenine riboses showed a small preference for the *N*-type conformer. Such a conformational state may be indispensable for taking up the strongly folded conformation between the base pairs in the dinucleotides, as judged by a somewhat favored *S*-type conformation of both riboses in the indazole- and adenine mononucleotides.

In studies of nucleoside and nucleotide compounds, the conformational analysis of the furanose rings is an important subject, because the difference in conformation of the compounds influences the biological activity. For that reason, nucleic acid-ribonucleosides components (adenosine, cytidine, uridine, *etc.*)[1,2] and some related compounds (alkylated, halogenated, aza, deaza analogs, *etc.*)[3-5] have been examined for molecular conformation with the aid of NMR spectroscopy. On the other hand, the stereochemistry in aqueous solution of pyridine dinucleotides has so far been studied in connection with coenzyme function. The conformational properties of two riboses, as well as the relative conformations of both the pyridine and adenine bases, were investigated with NAD and its alkylated analogs or the like.[6-9] Recently we have reported the synthesis and biochemical activity of some novel 2*H*-indazole dinucleotides.[10] The indazole dinucleotides, which contain a bicyclic base instead of pyridine one, are expected to adopt a different conformation in comparison with that of pyridine dinucleotides. This paper describes the conformational aspects of the indazole nucleotides in aqueous solution, comparing them with those of pyridine nucleotides, on the basis of the information obtained by high-frequency ^{1}H-NMR spectroscopy.

Experimental

Materials. The indazole adenine dinucleotides, indazole mononucleotides, and adenine mononucleotide (AMP) used for this study were prepared by an enzymic method in our laboratory.[10] Deuterium oxide (D_2O, 99.8%) and sodium 3-trimethylsilyl-1-propanesulfonate (DSS) were obtained from E. Merck, Darmstadt.

NMR Spectroscopy. ^{1}H-NMR measurements were performed in D_2O (pH 7) at a *ca.* 0.01 M (1 M=1 mol dm^{-3}) concentration of each sample, which was once lyophilized beforehand from D_2O, on a 500 MHz JEOL FX-500 spectrometer operating in a pulse Fourier-transform mode with quadrature detection. All spectra were obtained from accumulation of 64—128 free induction decays after each 45° pulse (5 μs) repeated every 4 s and were observed over a range of 5×10^3 Hz, corresponding to 32 K data points. Chemical shifts (δ-values) were measured in parts per million (ppm) downfield from DSS as an internal standard and estimated with an accuracy within ±0.001 ppm. Coupling constants were determined as an average value based on two measurements under the same conditions, and the precision was ±0.2 Hz. The residual HDO signal was suppressed by the gated decoupling method.[11]

Results and Discussion

Conformation between Indazole and Adenine Bases. NMR studies by Sarma *et al.*[7,8] have strongly indicated that both the oxidized and reduced pyridine dinucleotides exist in a folded conformation, in which the pyridine and adenine rings are stacked in parallel planes, rather than in an unfolded conformation. This conclusion has been derived from interpretation based on the following NMR spectral observations: All aromatic protons on both the pyridine and adenine rings, and anomeric protons are shifted to higher fields as compared with those in the NAD-constituting nicotinamide mononucleotide (NMN) and adenine

mononucleotide (AMP). The upfield resonances in the dinucleotide could be explained as resulting from diamagnetic shielding due to the mutual "ring-current effect" of the pyridine and adenine bases. Thus, the base pairs were found to be stacked in parallel planes. In connection with these studies based on the difference in chemical shifts, Freyne *et al.*[9] have also investigated 3-acetyl-5-alkylpyridine analogs of NAD and shown the occurrence of significant intramolecular interaction between the base pairs.

Various 2*H*-indazole adenine dinucleotides (**1**—**11**) which we have recently prepared[10] were examined for their chemical shifts of aromatic protons at pH 7 by 500 MHz ^{1}H-NMR spectroscopy. The chemical shift difference ($\Delta\delta$) of adenine and anomeric protons between each indazole dinucleotide and AMP are summarized in Table 1. All the resonances of H_2 ($\Delta\delta$ 0.25—0.34), H_8 ($\Delta\delta$ 0.26—0.44), and $C_1'H$ ($\Delta\delta$ 0.12—0.22) were shifted to higher fields compared with those in AMP. As for NAD, $\Delta\delta$-values of H_2, H_8, and $C_1'H$ in the adenine moiety have been estimated to be 0.15, 0.14, and 0.13 ppm, respectively.[6] These values are less than in indazole dinucleotides. On the other hand, the $\Delta\delta$-values of indazole protons between each indazole dinucleotide and the corresponding mononucleotide were also evaluated by a third order approximation (Table 2). It is apparent that, in the dinucleotide, all the aromatic signals are shifted remarkably to higher fields ($\Delta\delta$ 0.17—0.45) as observed for adenine protons. Furthermore, the substituent *O*-methyl and *N*-acetyl protons showed a slight upfield shift ($\approx$0.10 and $\approx$ 0.02 ppm, respectively). Previously Jardetzky and Wade-Jardetzky[6] have reported the $\Delta\delta$-values of pyridine signals between NAD and NMN (Table 3). One can see from Tables 2 and 3 that $\Delta\delta$-values between the indazole nucleotides are, on the whole, greater than those between the pyridine nucleotides. Thus, it was found that, in the indazole dinucleotides, the indazole and adenine rings suffer more diamagnetic shielding effect of each other than the pyridine and adenine base pairs in NAD. The enhancement of the anisotropic effect

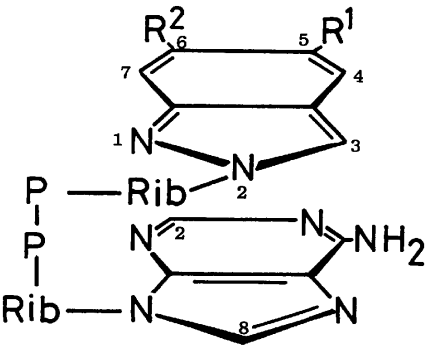

Fig. 1. Closely folded conformation for indazole dinucleotides.

seems to arise from the two-aromatic-ring system of indazole base, which may provide a wide shielding zone in the direction perpendicular to the ring plane.

These observations indicate that the base pairs in the indazole dinucleotide are more closely stacked in parallel planes as compared to those in the pyridine dinucleotide (Fig. 1).

Ribose Conformations. Altona and Sundaralingam[12] have introduced a comprehensible notation of furanose ring conformations based on the concept of pseudorotation: *N*-type conformers include the classical C(2')-*exo* and C(3')-*endo* conformations; *S*-type conformers include the classical C(2')-*endo* and C(3')-*exo* forms (Fig. 2). They have also shown that both conformers in dinucleotides as well as in mononucleotides in solution are present in a dynamic equilibrium. An equilibrium shift should bring about a change of average torsion angle between vicinal C–H bonds, and a coupling con-

stant for the vicinal protons can be expressed in terms of the dihedral torsion angle.[13] From a Dreiding model, one can see that the adoption of either of *N*- and *S*-type conformers induces no significant change of the vicinal torsion angle between C_2'–H and C_3'–H bonds. Thus, a practical and simple equation was proposed to deduce the conformational aspect of a ribose ring from the vicinal coupling constant, $J_{1',2'}$ or $J_{3',4'}$: $S(\%)=10\times J_{1',2'}$ or $10\times(10.1-J_{3',4'})$.[12]

Even in the 500 MHz NMR spectra of indazole dinucleotides, the signals of an indazole C_3'H and adenine C_3'H were overlapped each other to such an extent that a reasonable estimate of each $J_{3',4'}$ is impossible. As to the anomeric protons, which appeared as two clearly separate doublets, the two $J_{1',2'}$'s could be accurately determined. We, therefore, use the value of $J_{1',2'}$ to estimate equilibrium compositions of *N*- and *S*-type conformers. $J_{1',2'}$-values observed with indazole nucleotides are summarized in Table 4. In the dinucleotides, all indazole riboses show a greater $J_{1',2'}$-value, compared with adenine riboses, by 0.3—1.5 Hz. Upon conversion of the dinucleotides into mononucleotides, the coupling constant came to increase by 0.3—1.0 Hz in the indazole ribose and by 1.3—2.0 Hz in the adenine ribose, indicating a small change in conformation of respective ribose rings. Concerning pyridine dinucleotides, it has previously been reported[9] that pyridine $J_{1',2'}$-values were less than adenine ones by ≈0.5 Hz.

a) Calculated from the equation of Altona and Sundaralingam:[12] $S(\%)=10\times J_{1',2'}$. b) $N(\%)=100-S(\%)$. c) See the footnote b in Table 4.

The percentages of *N*-type conformer (100—*S*%) in the indazole nucleotides were calculated by taking the aforementioned equation (Table 5). In the dinucleotides, the adenine ribose showed a small preference for the *N*-type conformer, whereas the indazole ribose was observed to exist in a roughly 50/50 equilibrium between both conformers with a few exceptions. In the indazole mononucleotides, a slightly increased proportion of *S*-type form occurs in all cases. In the AMP ribose ($J_{1',2'}$=6.0 Hz), the percentage of *N*-type form (40%) decreased in favor of *S*-type form (60%). Such difference in ribose conformation of the dinucleotides compared with the mononucleotides may be closely correlated with the folded conformation between the indazole and adenine base pairs. The conformational deviation of ribose rings are probably necessary for the occurrence of enhanced intramolecular interaction between the base pairs, which would contribute to the stable conformation with a lower energy level for the whole molecule.

In a part of the previous paper of Freyne *et al.*[9] regarding the ribose conformation in pyridine dinucleotides, the percentage of *S*-type conformers has been based on $J_{3',4'}$-value. However, the method using $J_{3',4'}$ should be restricted to the case where $J_{1',2'}+J_{3',4'}=10.1$.[12] In their report, $J_{1',2'}$'s and $J_{3',4'}$'s for the pyridine ribose have been estimated to be 5.2—5.4 and 2.4—2.8 Hz, respectively. The sum of the two terms (*ca.* 8 Hz) may be too little to fit the equation. It can, therefore, be said that the *S* percentages (more than 70%) they have estimated are much greater than those actually to be expected.

The authors wish to thank Mr. M. Ikura (High-Resolution NMR Laboratory, Faculty of Science) for skillful measurement of ^{1}H-NMR spectra.

An Improved Preparation of the *p*-Tropoquinone Mono- and Diacetals by Thallium(III) Nitrate Oxidation of 2-Alkoxy-5-hydroxytropones

Hitoshi TAKESHITA,* Akira MORI, and Yasutoshi ISAYAMA†
Research Institute of Industrial Science, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816
†*Graduate School of Engineering Sciences, 39, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816*
(Received December 27, 1984)

The thallium(III) nitrate-oxidation of 2-alkoxy-5-hydroxytropones gave, in good yields, the mono- and diacetals of tropoquinones, which can be used for the introduction of oxygen functions to the seven-membered nucleus and preparation of the substituted tropoquinones. An improved synthesis of 4-methyl-*p*-tropoquinone or 4-methoxy-*p*-tropoquinone was accomplished.

We have previously synthesized a tropoquinone monoacetal, 7,7-ethylenedioxycyclohepta-2,5-diene-1,4-dione (**1**) by triethylamine-treatment and further manganese(IV) oxide oxidation of the endoperoxide of ethylenedioxytropone acetal (**2**) which can be prepared either by the dye-sensitized photooxidation of the corresponding tropone acetal (**3**) or by *p*-toluenesulfonic acid-catalyzed acetalization of the tropone endoperoxide (**4**).[1] Since **1** and its derivatives may behave as typical unsaturated ketones and are useful for the synthesis of various seven-membered derivatives, it is important and desirable to develop more effective routes to obtain the acetal derivatives.

The oxidation of 5-hydroxytropolone (**5**) with silver acetate,[2] which is a one-electron oxidizing agent, was already shown to form the derivatives of either *p*-tropoquinone (**6**) or 2,10-dihydroxydicyclohepta[*b*,*d*]-furan-3,9-dione (**7**) depending on the amounts of the oxidizing agent. Since the formation of **6** and **7** involved a common intermediate, the semiquinone radical, the yields of the derivatives of **7** should be improved by use of 5-hydroxy-2-methoxytropone (**8**) or its derivatives; unlike those from free 5-hydroxytropolones, the semiquinone radical derived from **8** is not convertible to **6**.[3] Taking these two points into account, it is predictable that the oxidation of **8** with an appropriate two-electron oxidizing agent in methanol may produce the acetal, 7,7-dimethoxy-2,5-cycloheptadiene-1,4-dione (**9**) but not **7**. Indeed, DDQ (2,3-dichloro-5,6-dicyano-*p*-benzoquinone) was effective for the purpose; as a preliminary study, we have employed it to obtain 4-methyl-*p*-tropoquinone (**10**).[4] Even more, thallium(III) nitrate (TTN)[5] seems to be a favorable choice, and **8** was accordingly oxidized in

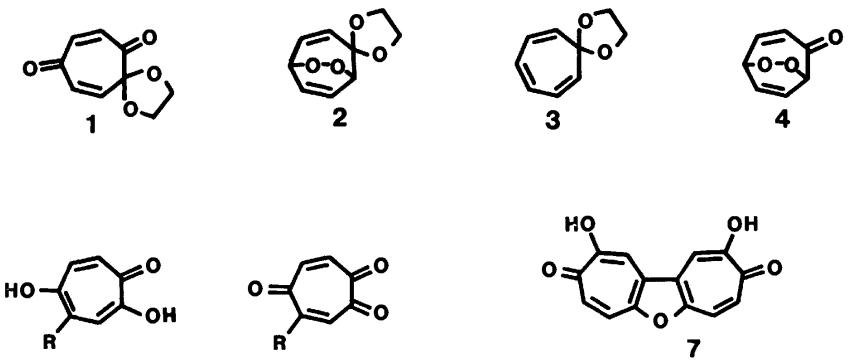

Chart 1.

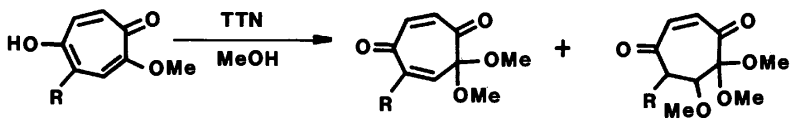


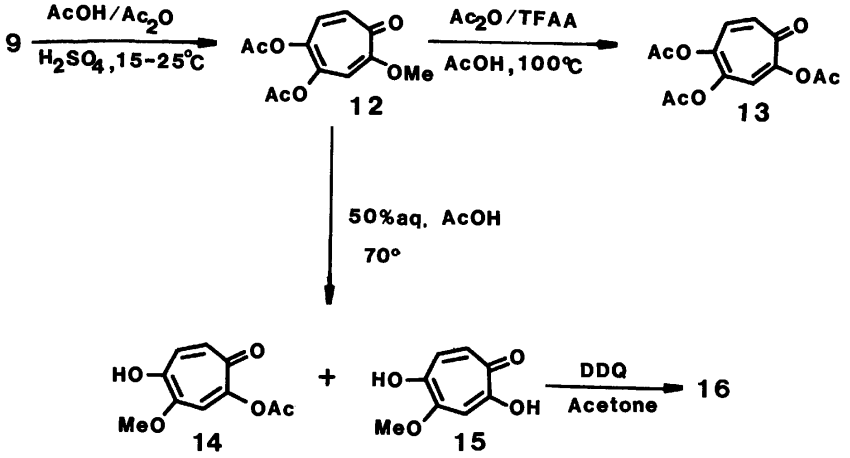
Scheme 1.

methanol at 15—25 °C for 4 h; the products obtained after brief work up were indeed **9**, a colorless oil, 90% yield, and its Michael type adduct, 5,5,6-trimethoxy-2-cycloheptene-1,4-dione (**11**), a colorless oil, 8% yield. On the other hand, prolonged treatment of **9** with TTN in methanol gave **11** in 77% yield. The position of the newly introduced methoxyl group was established by an aid of deuterio derivative of **8** (**8d**). Thus, heating of **8** in deuterium oxide yielded 5-hydroxy-2-methoxytropone-4-*d* (**8d**), whose ^{1}H NMR spectrum showed a disappearance of C-4 proton, δ=6.74.[6] The treatment of **8d** with TTN gave corresponding deuterio derivatives of **9** and **11** (**9d** and **11d**), 8% and 40% yields, respectively. The ^{1}H NMR spectrum of **11d** showed a diminishment of the signal at δ=2.87, together with change of splitting patterns of the proton signal (to d, J=4 Hz) at 3.95, ascribable to the proton on the carbon bearing the methoxyl group. Consequently, the position of the methoxyl group is C-6.

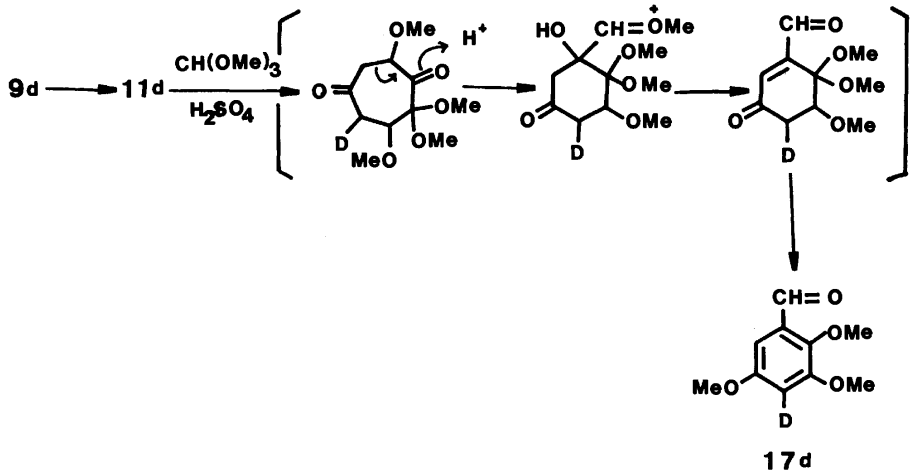
In parallel to this facile Michael reaction, the acetals smoothly underwent the Thiele-type addition reaction; *e.g.*, the brief treatment of **9** with a 1:1-mixture of acetic acid and acetic anhydride with a catalytic amount of sulfuric acid at 15—25 °C gave 4,5-diacetoxy-2-methoxytropone (**12**) in nearly quantitative yield.

The structure of **12** was obtained on the basis of the NMR spectral analysis as well as chemical derivations; thus, the further treatment of **12** with trifluoroacetic anhydride (TFAA) and acetic anhydride in acetic acid gave colorless crystalline triacetoxytropone (**13**). A mild hydrolysis of **12** with aqueous acetic acid afforded 2-acetoxy-5-hydroxy-4-methoxytropone (**14**) and 5-hydroxy-4-methoxytropolone (**15**), the latter of which was oxidized with DDQ to a derivative which must be 4-methoxy-*p*-tropoquinone (**16**): *i.e.*, the ^{1}H NMR spectrum of **16** revealed a 1H-singlet at δ=6.22, and a lack of the long-range coupling with other aromatic protons at 6.80 and 6.94, appearing as an AB pair (J=13 Hz), ruled out the possibility of the methoxyl group at C-3, whose singlet appeared at 3.90. Previously, the Thiele reaction of **6** itself was carried out by Hirama and Itô to form 2,4,7-triacetoxytropone in 7% yield by acetic anhydride and sulfuric acid;[7] the improvement of the yield of the present results was thus satisfactory and the site of the attack indicated the reaction should have been started by the protonation on the acetal oxygen.

Other than this, the attempted hydrolysis of **9** under modified conditions tends to cause a ring contraction to the benzenoid derivative; thus, the reaction of **9** or



Scheme 2.



Scheme 3.

11 with trimethoxymethane and sulfuric acid gave 2,3,5-trimethoxybenzaldehyde (**17**),[8] as the only identifiable product in 51 and 76% yields, respectively. Its formation mechanism, shown in Scheme 3, was verified by an aid of **9d**; the deuterium in **17d** was determined to be at C-4.

In general, a conversion of **5** to **6** has been achieved by the DDQ oxidation, however, sometimes there were experimental difficulties, *e.g.*, in order to prepare **10**, we have prepared 5-hydroxy-2-methoxy-4-methyltropone (**18**) by sequential reactions from **8**,[4] but every attempt to hydrolyze **18** to 5-hydroxy-4-methyltropolone (**19**) was unsuccessful. Alternatively, **18** was oxidized with DDQ in methanol to 7,7-dimethoxy-5-methyl-2,5-cycloheptadiene-1,4-dione (**20**), whose mild hydrolysis is known to afford the desired **10**.[4] For the formation of **20** from **18**, TTN was much superior than DDQ; the yield was 98%.

Furthermore, the TTN-oxidation of 5-hydroxy-2-(2-hydroxyethoxy)tropone (**21**) in methanol gave a crystalline diacetal, 4,5-dimethoxy-4,5-(ethylenedioxy)-2,6-cycloheptadien-1-one (**22**), 28%, and its monohemiacetal, the crystalline 4-hydroxy-5-methoxy derivative (**23**), 57%. The stereochemistry of **22** was shown to be trans on the basis of NMR observations of its dihydro derivative (**24**); *i.e.*, in the ^{1}H NMR spectrum, two methyl signals appeared separately, and the ^{13}C NMR spectrum exhibited all non-overlapped eleven signals. The **22** and **23** were also acetoxylated with acetic anhydride and sulfuric acid in acetic acid at room temperature for 3 h to 6-acetoxy-2,3-(ethylenedioxy)tropone (**25**)[9] through a rearrangement.

In conclusion, the present method provided a convenient entry to *p*-tropoquinone acetals, which are versatile intermediates for various functionalized troponoids. However, this method was not applicable to the free tropolone derivatives like 5-methoxytropolone; by the addition of TTN, the substrates precipitated out by salt formation, and prevented the oxidation to be taken place.

Some new aspects of the tropoquinone chemistry developed therefrom will be reported in future.

Experimental

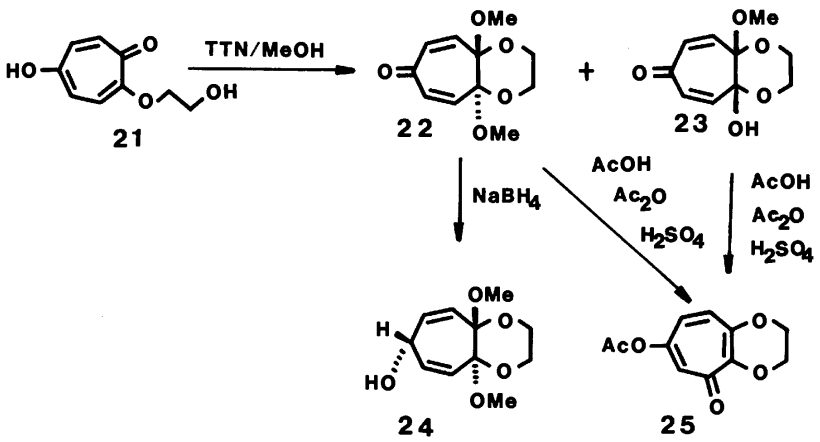
Elemental analyses were performed by Miss S. Hirashima at this Institute. The mps were measured by a Yanagimoto Micro-mp Apparatus and were uncorrected. The IR spectra were taken as KBr disks with a Jasco Model A 102 Spectrometer. The NMR spectra were measured in $CDCl_3$ solution, unless otherwise specified, by a JEOL FX 100 Model Spectrometer, and the chemical shifts were expressed in the δ unit from the internal Me_4Si. The mass spectra were measured on a JEOL 01SG-2 Model Spectrometer.

TTN-Oxidation of 5-Hydroxy-2-methoxytropone (8). a) An anhydrous MeOH solution (12 cm^3) of **8** (400 mg) was treated with TTN (1.17 g) at −20 °C, and the mixture was kept with stirring at 15—25 °C for 0.5 h. Silica-gel column chromatography of the mixture afforded a colorless oil, **9**, 430 mg (90%) [Found: M$^+$, 182.0574. Calcd for $C_9H_{10}O_4$: M$^+$, 182.0577. ^{1}H NMR δ=3.36 (6H, s), 6.25 (1H, dt, J=12, 1 Hz), 6.43 (1H, d, J=12 Hz), and 6.49 (2H, d, J=1 Hz). ^{13}C NMR δ= 50.7 (2C), 103.0, 133.5, 133.8, 136.7, 138.9, 190.8, and 192.7], and a colorless oil, **11**, 45 mg (8%) [Found: C, 55.77; H, 6.55%. Calcd for $C_{10}H_{14}O_5$: C, 56.07; H, 6.59%. ^{1}H NMR δ=2.87 (1H, dd, J=17, 3.8 Hz), 3.18 (1H, dd, J=17, 3.8 Hz), 3.18 (3H, s), 3.37 (3H, s), 3.40 (3H, s), 3.94 (1H, t, J=3.8 Hz), 6.34 (1H, d, J=13 Hz), and 6.54 (1H, d, J=13 Hz). ^{13}C NMR δ=43.4, 49.6, 50.9, 58.6, 75.5, 103.6, 133.4, 138.1, 193.4, and 197.3. $\lambda_{max}^{CHCl_3}$: 243 nm (ε=6900), 348 (1400). *m/z*: 182 (M$^+$−32), 75 (base peak)].

b) Prolonged treatment of the mixture of **8** (30 mg) and TTN (88 mg) in MeOH (0.5 cm^3) at 15—25 °C for 10 h and then at 50 °C for 2 h resulted in the formation of **11**, 33 mg (77%).

Preparation of Deuterio Derivative of 8 (8d). A mixture of **8** (1 g) and D_2O (10 cm^3) containing AcOH (50 mg) was heated at 90 °C for 23 h in a sealed tube. After cooling the mixture, yellow crystals (850 mg) [*m/z*, 152, 153, 154 (11:86:3). ^{1}H NMR (CD_3OD) δ=3.83 (3H, s), 6.5—6.8 (0.1H), 7.08 (1H, s), and 7.10 (2H, s)] obtained by filtration was identified to be **8d**.

TTN-Oxidation of 8d to 9d and 11d. An anhydrous MeOH solution (1 cm^3) of **8d** (50 mg) was treated with TTN (150 mg) under the same conditions to those of deuterium-free **8**. Silica-gel chromatography of the mixture afforded **9d**, 5 mg (8.5%) [*m/z*, 182, 183, 184 (18:76:6). ^{1}H NMR δ=3.30 (6H, s), 6.42 (1.2H, m), and 6.50 (1.8H, s)], and **11d**, 28 mg



Scheme 4.

(40%) [*m/z*, 183 (M^+-32), 182 (M^+-33), 75 (base peak). ^{1}H NMR δ=2.8—3.1 (1.2H, m), 3.18 (3H, s), 3.37 (3H, s), 3.41 (3H, s), 3.95 (1H, d, J=4 Hz), 6.34 (1H, d, J=13 Hz), and 6.51 (1H, dm, J=13 Hz)].

Reaction of **9** *with* Ac_2O *and* H_2SO_4. A mixture of **9** (50 mg), Ac_2O (0.3 cm^3), AcOH (0.3 cm^3), and H_2SO_4 (20 mg) was stirred at 15—25 °C for 0.5 h. Silica-gel column chromatography of the mixture afforded colorless needles, mp 116—117 °C, 46 mg (98%), **12** [Found: C, 57.14; H, 4.80%. Calcd for $C_{12}H_{12}O_6$: C, 57.03; H, 4.67%. ^{1}H NMR δ=2.28 (3H, s), 2.32 (3H, s), 3.80 (3H, s), 6.65 (1H, d, J=10.5 Hz), 6.70 (1H, s), and 6.91 (1H, d, J=10.5 Hz). ^{13}C NMR δ=20.4, 20.6, 56.5, 116.7, 121.0, 122.1, 148.2, 159.1, 168.2, 168.5, and 176.2. $\lambda_{max}^{CHCl_3}$: 247 nm (ε=38000), 257 (26000), 308 (5300)], and the recovered **9**, 16 mg.

Conversion of **9** *to 2,4,5-Triacetoxytropone (***13***).* A mixture of **9** (120 mg), Ac_2O (5 cm^3), TFAA (0.3 cm^3), and AcOH (60 mg) was heated at 100 °C for 4.5 h. The mixture was heated *in vacuo* to remove the solvents, and the residue chromatographed on a silica-gel column to give colorless needles, mp 121.5—123 °C, 23 mg (17%),[10] **13** [Found: C, 55.69; H, 4.31%. Calcd for $C_{13}H_{12}O_7$: C, 55.72; H, 4.32%. ^{1}H NMR δ=2.26 (6H, s), 2.32 (3H, s), 6.89 (1H, d, J=11.5 Hz), 7.06 (1H, s), and 7.11 (1H, d, J=11.5 Hz). ^{13}C NMR δ=20.4, 20.6, 20.8, 121.9, 123.5, 129.9, 146.5, 153.6, 153.8, 166.1, 167.2, 167.5, and 167.8].

Controlled Hydrolysis of **12** *to* **14** *and* **15**. A 50%-aqueous AcOH solution (3 cm^3) of **12** (1.2 g) was heated at 70 °C for 2 d. The mixture was heated *in vacuo* to remove the solvent, the residual mass was chromatographed on a silica-gel column to give colorless needles, mp 127—128 °C, 420 mg (42%), **14** [Found: C, 57.04; H, 4.83%. Calcd for $C_{10}H_{10}O_5$: C, 57.14; H, 4.80%. ^{1}H NMR δ=2.28 (3H, s), 3.86 (3H, s), 6.83 (1H, d, J=11 Hz), 6.93 (1H, s), and 6.96 (1H, d, J=11 Hz). ^{13}C NMR δ=20.3, 56.6, 109.1, 110.8, 126.6, 142.7, 161.1, 162.4, 168.9, and 175.6. $\lambda_{max}^{CHCl_3}$: 250 nm (ε=31500), 267 (15000), 325 (6400), 340 (4800), 355 (3600)], and pale yellow crystals, mp 209 °C, 250 mg (31%), **15** [Found: M^+, 168.0423. Calcd for $C_8H_8O_4$: 168.0423. ^{1}H NMR δ(CD_3OD)=4.14 (3H, s), 7.52 (1H, d, J=12 Hz), 7.64 (1H, d, J=12 Hz), and 7.67 (1H, s). ^{13}C NMR δ=58.2, 115.0, 125.5, 126.6, 158.1, 158.9, 161.6, and 165.3. λ_{max}^{MeOH}: 248 nm (ε=29600), 344 (11400). ν: 3100—2500, 1600, 1520, 1450—1400 cm^{-1}].

*Synthesis of 4-Methoxy-*p*-tropoquinone (***16***) from* **15**. An MeOH solution (2 cm^3) of **15** (50 mg) was mixed with DDQ (68 mg) and kept at 15—25 °C for 30 min. Silica-gel column chromatography of the mixture gave a yellow oil, 30 mg (61%), **16** [Found: M^+, 166.0267. Calcd for $C_8H_6O_4$ 166.0267. ^{13}C NMR δ=57.3, 108.8, 134.3, 137.6, 160.8, 181.5, 183.5, and 184.7].

The Reaction of **9** *with Trimethoxymethane and* H_2SO_4. A mixture of **9** (55 mg), $CH(OMe)_3$ (0.1 cm^3), MeOH (0.5 cm^3), and H_2SO_4 (30 mg) was kept at 15—25 °C for 1 h. Colorless crystals obtained, **17**, mp 62 °C, 30 mg (52%), was identified to be 2,3,5-trimethoxybenzaldehyde (lit,[8] mp 67 °C) [^{1}H NMR δ=3.80 (3H, s), 3.83 (3H, s), 3.85 (3H, s), 6.73 (1H, d, J=3 Hz), 6.83 (1H, d, J=3 Hz), and 10.38 (1H, s)].

The Reaction of **9d** *with Trimethoxymethane and* H_2SO_4. Similar to above, **9d** (75 mg) was treated in MeOH (1.5 cm^3) with $CH(OMe)_3$ (0.15 cm^3) and H_2SO_4 (50 mg) to give **17d**, 58 mg (72%) [^{1}H NMR δ=3.78 (3H, s), 3.85 (3H, s), 3.90 (3H, s), 6.72 (0.65H, d, J=3 Hz), 6.81 (0.65H, d, J=3 Hz), 6.81 (0.35H, s), and 10.32 (1H, s). *m/z*: 196, 197, 198 (68:29:3)].

The Reaction of **11** *with Trimethoxymethane and* H_2SO_4. Similarly, a mixture of **11** (40 mg), $CH(OMe)_3$ (0.1 cm^3), MeOH (2 cm^3), and H_2SO_4 (30 mg) was kept at 50 °C for 2 h. The product isolated was **17**, 28 mg (76%), identical in every respect to the sample prepared from **9**.

TTN-Oxidatin of **18** *in MeOH to 7,7-Dimethoxy-5-methyl-2,5-cycloheptadiene-1,4-dione (***20***).* An anhydrous MeOH solution (1.5 cm^3) of **18** (45 mg), prepared as previously,[4] was treated with TTN (120 mg) at −20 °C, and gradually raised the temperature to 20 °C within 1 h. The silica-gel chromatography of the mixture afforded **20**, 50 mg (93%).[4]

*TTN-Oxidation of 5-Hydroxy-2-(2-hydroxyethoxy)tropone (***21***) in MeOH.* To an anhydrous MeOH suspension (1.5 cm^3) of **21** (30 mg) which was prepared as previously,[1] TTN (73 mg) was added at −20 °C. After standing at 20 °C for 1 h, the mixture was chromatographed on a silica-gel column to give colorless crystals, mp 108—109 °C, 10.4 mg (28%), **22** [Found: C, 58.60; H, 6.22%. Calcd for $C_{11}H_{14}O_5$: C, 58.40; H, 6.24%. ^{1}H NMR δ=3.27 (6H, s), 3.8 (4H, m), 6.09 (2H, d, J=12.5 Hz), and 6.28 (2H, d, J=12.5 Hz). ^{13}C NMR δ=50.1 (2C), 58.8 (2C), 96.8 (2C), 131.3 (2C), 141.9 (2C), and 189.8], and colorless crystals, mp 123—124 °C, 20 mg (57%), **23** [Found: C, 56.46; H, 5.67%. Calcd for $C_{10}H_{12}O_5$: C, 56.60; H, 5.70%. ^{1}H NMR δ=3.29 (3H, s), 3.5—3.7 (2H, m), 3.9—4.5 (2H, m), 6.02 (1H, d, J=13 Hz), 6.14 (1H, d, J=13 Hz), 6.32 (1H, d, J=13 Hz), and 6.37 (1H, d, J=13 Hz). ^{13}C NMR δ=50.1, 58.6, 58.9, 93.5, 97.0, 129.9, 131.6, 142.2, 144.0, and 190.3].

NaBH$_4$*-Reduction of* **22** *to Dihydro Derivative (***24***).* An MeOH solution (2 cm^3) of **22** (30 mg) was mixed with $NaBH_4$ (12 mg) at 0 °C, and kept **1d** at 15—25 °C. Silica-gel column chromatography of the mixture afforded colorless needles, mp 105—107 °C, 17 mg (56%), **24**, [Found: M^+, 228.0991. Calcd for $C_{11}H_{16}O_5$: 228.0996. ^{1}H NMR δ=3.26 (3H, s), 3.30 (3H, s), 3.4—4.1 (4H, m), 4.90 (1H, qd, J=2.5, 2 Hz), 5.49 (1H, dd, J=11.5, 2.5 Hz), 5.50 (1H, dd, J=12.5, 2 Hz), 5.86 (1H, ddd, J=12.5, 2.5, 1.7 Hz), and 5.98 (1H, ddd, J=11.5, 2.5, 1.7 Hz). ^{13}C NMR δ=49.2, 49.3, 58.4, 58.6, 68.7, 95.3, 97.8, 127.3, 128.6, 134.1, and 136.8. ν: 3520 cm^{-1}].

Modified Thiele Reaction of **22** *to* **25**. A mixture of **22** (16 mg), Ac_2O (0.5 cm^3), AcOH (0.5 cm^3), and H_2SO_4 (30 mg) was kept at 15—25 °C for 3 h. After dilution with water, the mixture was extracted with ether. Silica-gel column chromatography of the extract gave a colorless oil, 10 mg (64%), **25** [Found: C, 59.31: H, 4.57%. Calcd for $C_{11}H_{10}O_5$: C, 59.46; H, 4.54%. ^{1}H NMR δ=2.26 (3H, s), 4.2—4.5 (4H, m), 6.53 (1H, dd, J=12.5, 2.8 Hz), 6.90 (1H, dd, J=12.5, 0.5 Hz), and 6.93 (1H, dd, J=2.8, 0.5 Hz), whose *ABC* system was deduced by simulation. ^{13}C NMR δ=21.0, 63.8, 64.0, 124.4, 129.3, 129.9, 147.5, 148.7, 154.6, 168.6, and 176.6].

The Synthesis of Internal Conjugated (*E*)-Enynyldialkylboranes and Their Applications to the Syntheses of Conjugated Alkynones, Conjugated (*E*)-Enynes, and Conjugated Enynes Bearing an Unsaturated Group on the Double Bond

Masayuki Hoshi, Yuzuru Masuda, and Akira Arase*
Department of Industrial Chemistry, Kitami Institute of Technology, Kitami 090
(Received December 27, 1984)

Internal conjugated (*E*)-enynyldialkylboranes were synthesized by successive reactions of 1-iodo-1-alkynes with dialkylboranes and 1-alkynyllithiums in 31—79% yields. (*E*)-Enynyldialkylboranes, thus obtained, gave regio- and/or stereospecifically defined corresponding conjugated alkynones by alkaline hydrogen peroxide oxidation, conjugated (*E*)-enynes by protonolysis with acetic acid, and conjugated enynes bearing an unsaturated group on the internal alkenyl carbon atom by bis(acetylacetonato)copper-catalyzed cross-coupling reaction with allyl bromide or 1-bromo-1-hexyne respectively.

The authors recently investigated a cross-coupling reaction of 1-halo-1-alkenyldialkylboranes with alkylmagnesium halides. Regio- and stereospecifically designed internal (*E*)-alkenyldialkylboranes, thus obtained, could be utilized for regio- and stereospecific syntheses of ketones,[1] (*E*)-alkenes[1] and trisubstituted ethylenes[2] (Scheme 1).

An introduction of an alkynyl group to the α-carbon atom of alkenyldialkylboranes by a similar cross-coupling reaction was highly attractive because organoboranes which had an enyne structure on boron atom were expected to have a wide variety of applications as intermediates.

Zweifel *et al.* have previously reported a formation of internal (*Z*)-enynyldialkylboranes by a controlled hydroboration of conjugated diynes with dialkylborane.[3] However, in view of regioselectivity, this

$$R^1C{\equiv}C\text{-}C{\equiv}CR^2 \xrightarrow{R_2BH} R^1CH{=}C(BR_2)\text{-}C{\equiv}CR^2 + R^1C{\equiv}C\text{-}C(BR_2){=}CHR^2$$

reaction is applicable only to such diynes in which two alkyl groups are of the same structure with each other because of ambiguity of the site of hydroboration.

On the contrary, in internal enynyldialkylboranes, which might be obtained by our cross-coupling reaction, the situation of boron–carbon bond was clearly defined and both alkyl groups on the unsaturated bond could be chosen arbitrarily to a certain extent. In addition, the configuration of the alkenyl moiety was expected to be *E*.

Results and Discussion

To find an appropriate procedure for the cross-coupling reaction, 1-bromo- or 1-iodo-1-hexyne was chosen as a starting material. It was hydroborated with dialkylborane and then treated with 1-hexynyl metal compound. As the hydroborating agent, dicyclohexylborane, bis(1,2-dimethylpropyl)borane and 9-borabicyclo[3.3.1]nonane (9-BBN) were examined, and as the 1-hexynyl metal compound, 1-hexynylmagnesium bromide and 1-hexynyllithium were examined respectively.

At the moment, we have no appropriate means to estimate the yield of the enynyldialkylborane (**2**), coupling product in Scheme 2, directly. However, it has been shown that alkenylboranes react readily with alkaline hydrogen peroxide to afford corresponding carbonyl derivatives.[4,5] Thus the yield of **2** was estimated from the amount of 7-dodecyn-6-one (**4a**) formed by alkaline hydrogen peroxide oxidation of the reaction mixture (Scheme 2).

In all cases examined, **4a** was formed in the yields ranging from 13% to 66%, based on the starting 1-halo-1-alkyne, indicating that **2** was formed at least in these yields. On the other hand, appreciable amount of cyclohexyl pentyl ketone or 2,3-dimethyl-4-nonanone (**5**) was formed in most cases, except for the case of 9-BBN, indicating that internal alkenyldialkylborane (**3**), whose one of the alkyl groups on the double bond was transfered from boron atom, (transfer product, in

Scheme 2), was also formed in the reaction.[6]

The best result was obtained when 1-iodo-1-hexyne was hydroborated with equimolar amount of bis(1,2-dimethylpropyl)borane in THF, and then treated with equimolar amount of 1-hexynyllithium in a mixture of hexane and THF, giving 66% yield of **4a** and 20% yield of **5** after the hydrogen peroxide oxidation. An addition of hexamethylphosphoric triamide (HMPT), as a co-solvent, showed a remarkable effect on the distribution of the products, increasing the amount of **4a** to 79% and decreasing the amount of **5** to 7%. Some of these results are shown in Table 1.

Coupling reactions of 1-iodo-1-alkenylbis(1,2-dimethylpropyl)boranes with some 1-alkynyllithiums

a) The protonolyses were carried out using 10 ml of acetic acid at room temperature for 5 h. b) Prepared from 10 mmol of 1-iodo-1-alkyne and 10 mmol of bis(1,2-dimethylpropyl)borane. c) Determined by GLC. d) See Ref. 8.

were examined in the same manner as described above. These results are shown in Table 2.

Not only in the case of unbranched alkynyllithiums but also in the case of a branched one, 3,3-dimethyl-1-butynyllithium, desired enynyldialkylboranes were formed in fairly good yields. These results suggest that the present reaction is generally applicable to the introduction of alkynyl group on the α-alkenyl carbon atom of the alkenyldialkylboranes. (Phenylethynyl)-lithium also gave the desired product, though the yield was somewhat poor.

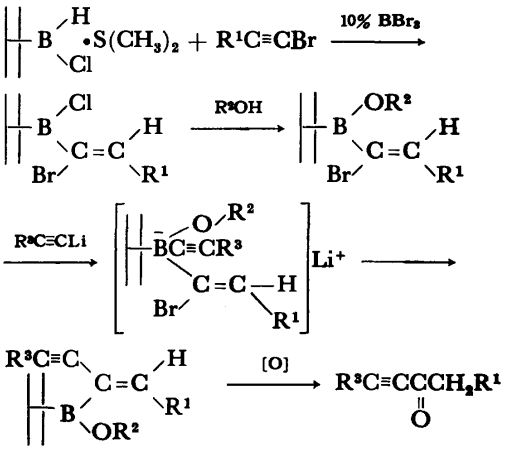
It has been shown that protonolysis of alkenylboranes with carboxylic acid provided corresponding alkenes in retention of configuration.[7] Accordingly, protonolysis of the internal enynyldialkylboranes should provide corresponding enynes, and thus examinations of the structure of these enynes should reveal the configuration of the alkenyl moiety of the internal enynyldialkylboranes.

As expected, conjugated enynes were obtained by the protonolysis of the reaction mixtures. For example, the reaction mixture, obtained by the successive reactions of 1-iodo-1-hexyne with bis(1,2-dimethylpropyl)borane and 1-hexynyllithium, was protonolyzed with acetic acid giving 76% yield of (*E*)-5-dodecen-7-yne (**6a**) and 7% yield of (*E*)-2,3-dimethyl-4-nonene (**7**) respectively (Scheme 3).

Examinations of these enynes by GLC using a glass capillary column and by ^1H NMR spectra revealed that they were isomerically pure. The *E* configuration was assigned for all of them by their absorptions of the alkenyl proton in IR spectra, near 965 cm^{-1}, and in ^1H NMR spectra, coupling constant, about 16 Hz. Thus, it was revealed that the coupling reaction occured in a complete inversion of configuration giving internal (*E*)-enynyldialkylboranes (Scheme 2). In the protonolysis reactions, a small amount of (*E*)-alkenes,[8] in which one of alkyl groups was transfered from the boron atom, was formed in nearly comparative yield to that of the corresponding alkanones appeared in Table 2. These results are shown in Table 3.

From the results shown in Tables 2 and 3, it is suggested that two reactions are involved in the present reaction. For example, both the coupling product **2** and the transfere product **3** are formed from borate complex (**1**) in a competitive manner.

The reactions, described above, are of interest as synthetic methods for conjugated alkynones and conjugated (*E*)-enynes using organoboranes. However, during the progress of our work, Brown *et al.* reported a synthesis of internal conjugated enynylborinic ester and its application to the synthesis of conjugated alkynones (61—63% yield).[9]



However, the internal (*E*)-enynyldialkylboranes obtained by our reaction seemed to be potential inter-

mediates in organic synthesis. Thus, we continued our program to find new applications using these internal enynyldialkylboranes.

The authors previously found that a cross-coupling reactions of internal (*E*)-alkenyldialkylboranes, prepared by the reaction of 1-halo-1-alkenyldialkylboranes with alkylmagnesium halides, with allyl bromide or 1-bromo-1-alkynes was effectively catalyzed by bis(acetylacetonato)copper, giving (*E*)-1,4-dienes or conjugated (*E*)-enynes.[2] An application of this reaction to the present internal (*E*)-enynyldialkylboranes was expected to provide conjugated enynes having a third unsaturated carbon–carbon bond.

As expected, such triply unsaturated hydrocarbons were obtained in the reactions and some of these results have been communicated briefly.[10] However the authors wish to report more detailed experimental results of the reactions. Because the reactions were carried out by relatively simple procedure and *in situ*, giving dienynes or endiynes in highly regio- and/or stereospecific manner, and, thus, they seemed synthetically interesting.

Preliminary experiments using the reaction mixture of **2** and **3**, obtained as described above, with allyl bromide revealed that this cross-coupling reaction was affected appreciably by the reaction conditions, such as the reaction temperature, the amount of catalyst, and the kind and the amount of alkali metal hydroxide added as the aqueous solution. The best result was obtained when the reaction mixture was treated with equimolar amount of allyl bromide at −15 °C in the presence of 5 mole% of bis(acetylacetonato)copper and equimolar amount of aqueous potassium hydroxide (Scheme 4).

6-Allyl-5-dodecen-7-yne (**8a**) was isolated from the worked-up reaction mixture by column chromatography in 70% yield, based on starting 1-iodo-1-hexyne. A comparison of δ value (5.82) of the conjugated alkenyl proton of **8** in ^{1}H NMR with that (5.55) of (*E*)-6-allyl-5-dodecen-7-yne (**10**) obtained by our previous work,[2] revealed that the reaction proceeded in retention of configuration. Thus, **8a** has *Z* configuration.

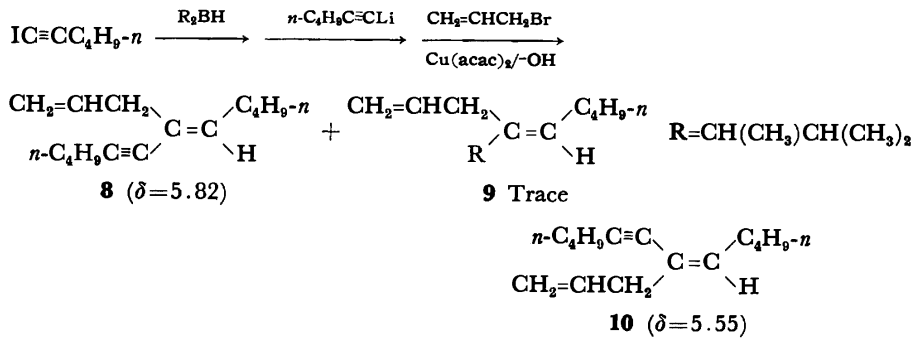
Similar results were also obtained with such (*E*)-enynyldialkylboranes, substituted by *t*-butyl or phenyl group at the triple bond, giving corresponding regio- and stereospecifically substituted enynes in fairly good yields.

A cross-coupling reaction of **2** with 1-bromo-1-hexyne was also carried out in similar reaction conditions (Scheme 5). In this case, aqueous sodium hydroxide was preferable to aqueous potassium hydroxide. 7-Pentylidene-5,8-tridecadiyne (**11a**) was formed almost uncontaminated by **12**. **11a** was isolated from the worked-up reaction mixture by column chromatography. Similar enediynes were obtained in the reactions of other internal (*E*)-enynyldialkylboranes with 1-bromo-1-alkynes.

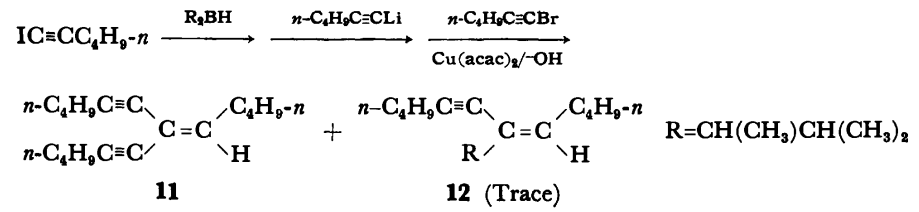
At present, we cannot reveal configurations of these enediynes from their spectral data or by direct comparisons with authentic samples. However, in bis(acetylacetonato)copper-catalyzed cross-coupling reactions of alkenyldialkylboranes with 1-halo-1-alkynes, 1-alkynyl groups were exclusively introduced to the α-carbon atom in retention of configuration.[2,11] Thus, these enediynes seem to be formed in retention of configuration.

These results are shown in Table 4.

Examinations of these triply unsaturated hydrocarbons by ^{1}H NMR and by GLC using a glass capillary column revealed that they were isomerically pure, indicating that the reaction proceeded in a stereospecific manner.



Scheme 4.



Scheme 5.

TABLE 4. YIELDS OF THE SUBSTITUTED ENYNES OBTAINED BY THE CROSS-COUPLING REACTIONS OF THE ENYNYL-BIS(1,2-DIMETHYLPROPYL)BORANES WITH ALLYL BROMIDE OR 1-BROMO-1-HEXYNE[a)]

a) The reactions were carried out in the presence of alkaline $Cu(acac)_2$. b) Prepared by the successive reactions of 10 mmol of 1-iodo-1-alkyne with 10 mmol of bis(1,2-dimethylpropyl)borane and 10 mmol of 1-alkynyllithium. c) Isolated by column chromatography using silica gel and based on starting 1-iodo-1-alkyne.

As appeared in Table 2, the internal (*E*)-enynyldialkylboranes, obtained in the present reaction, were always contaminated by a certain amount of corresponding internal (*E*)-alkenyldialkylboranes, (transfer product). In the cross-coupling reactions with allyl bromide or 1-bromo-1-hexyne, these contaminants should also provide corresponding coupling products, because in our previous work, the internal (*E*)-alkenyldialkylboranes provided corresponding enynes under similar reaction conditions.[2] However, fortunately, there have been detected only trace amount of such enynes in the present coupling reactions. For example, a mixture of about 7.9 mmol of **2** and 0.7 mmol of **3** provided 7 mmol of **8a** in the reaction with allyl bromide, and 4.9 mmol of **11a** in the reaction with 1-bromo-1-hexyne, almost uncontaminated by **9** and **12** respectively (Scheme 4 and Scheme 5).

These results may be attributed to the electronic character of the alkenyl moiety of organoboranes. That is, it is specurated that bis(acetylacetonato)copper can coordinate preferentially with the conjugated enynyl group on **2** to the enyl group on **3**, giving only the substituted enynes derived from **2**.

Some works, in which the alkenyl group of organoboranes were combined with the allyl or 1-alkynyl group giving doubly unsaturated hydrocarbons, have been reported.[2,11,13-15] However, in the present reaction, two unsaturated groups, one 1-alkynyl and one allyl groups or two 1-alkynyl groups, were introduced successively to the α-carbon atom of the alkenyl group of organoboranes in regio- and stereospecific manners. Thus, triply unsaturated hydrocarbons, which cannot easily be obtained by other methods, are synthesized in the present reaction.

Experimental

Instruments. IR spectra (film) were recorded by using a Hitachi 285 spectrometer. ^1H and ^{13}C sectra ($CDCl_3$, TMS) were run on a JNM-FX200S spectrometer. Mass spectra were recorded by using a Hitachi M-52 mass spectrometer.

Reagents. 2-Methyl-2-butene and cyclohexene were dried over lithium aluminium hydride and distilled under argon stream. Commercial 1-hexyne, 1-octyne and phenylacetylene were dried over Molecular Sieve 4A. 3,3-dimethyl-1-butyne was prepared by the method described in the literature,[16] and dried over Molecular Sieve 4A. 1-Iodo-1-hexyne,[17] 1-iodo-1-octyne,[17] and 1-bromo-1-hexyne[18] were prepared by the method described in the literatures, and they were dried over Molecular Sieve 4A. Bis(1,2-dimethylpropyl)borane and dicyclohexylborane in THF were prepared as described in the literature.[19] HMPT was distilled under argon stream after drying over calcium hydride and stored over Molecular Sieve 4A.

Representative Procedures. The Synthesis of 2 and Its Hydrogen Peroxide Oxidation. A 100-ml round-bottomed flask, equipped with a gas inlet for argon, a sample inlet with a serum cap and a magetic stirring bar, was flushed with argon. In the flask, 1-iodo-1-hexenylbis(1,2-dimethylpropyl)borane was prepared by the addition of 1.40 g of 2-methyl-2-butene (20 mmol) to BH_3 (10 mmol) in THF at −10 °C and the solution was stirred at 0 °C for 2 h. 2.08 g of 1-iodo-1-hexyne (10 mmol) was added slowly to the solution at −10 °C and the solution was stirred at 0 °C for 1 h, and then allowed to stand for additional 1 h to complete the reaction. Then 5 ml of anhydrous HMPT was added as the co-solvent and the solution was cooled to −78 °C immediately. To this solution, 1-hexynyllithium, prepared by the reaction of 0.82 g of 1-hexyne (10 mmol) in THF with butyllithium (10 mmol) in hexane, was added and the reaction mixture was maintained at −78 °C for 1 h. Then the solution was allowed to warm to room temperature and oxidized with alkaline hydrogen peroxide. The reaction mixture was extracted three times with diethyl ether, and the combined extracts were washed twice with NaCl-saturated water. Then it was dried over anhydrous magnesium sulfate. The solution was analyzed by GLC (5% FFAP, Diasolid M) using the internal standard method.

In the preparative reaction, the solvent was evaporated

off after the work-up and the residue was put on a column packed with silica gel (Wako gel Q-50). 1.3 g (72% yield) of 7-dodecyn-6-one, **4a**, was eluted with benzene. ^{1}H NMR δ=0.93 (t, J=7 Hz, 6H), 1.25—1.75 (m, 10H), 2.37 (t, J=7 Hz, 2H), and 2.52 (t, J=7 Hz, 2H);[20] ^{13}C NMR δ=13.50, 13.89, 18.63, 21.97, 22.40, 23.86, 29.75, 31.16, 45.51, 80.90 (C≡C), 94.21 (C≡C), and 188.62 (C=O); IR 2200 (C≡C) and 1680 (C=O) cm^{-1};[18] MS m/z 180 (M$^+$).

The Protonolysis of **2**. To the reaction mixture, obtained as described above, 10 ml of acetic acid was added at 0 °C, and the solution was stirred at room temperature for 5 h. 10 ml of water was added to the solution and the solution was extracted three times with hexane. The combined extracts were neutralized with aqueous sodium carbonate, washed twice with NaCl-saturated water and dried over anhydrous magnesium sulfate. The solution was analyzed by GLC (5% FFAP, Diasolid M) using the internal standard method. In the preparative reaction, the solvent was evaporated off after work-up and the residue was put on a column packed with silica gel (Wako gel Q-50). 1.1 g (76% yield) of (*E*)-5-dodecen-7-yne, **6a**, was isolated by elution with *n*-hexane. ^{1}H NMR δ=0.91 (m, 6H), 1.25—1.60 (m, 8H), 2.00—2.14 (m, 2H), 2.23—2.34 (m, 2H), 5.45 (dt, J=16 and 1.5 Hz, 1H), and 6.04 (dt, J=16 and 7 Hz, 1H);[21] ^{13}C NMR δ=13.65, 13.39, 19.07, 22.01, 22.18, 30.97 (2C), 32.67, 79.18 (C≡C), 88.64 (C≡C), 109.80 (-CH=) and 143.32 (-CH=); IR 2200 (C≡C) and 960 (⟋C=C⟍) cm^{-1};[19] MS m/z 164 (M$^+$).

The Cross-Coupling Reaction of **2** *with Allyl Bromide.* From the reaction mixture containing **2**, and **3**, obtained as described above, the solvents (THF and *n*-hexane) were removed under reduced pressure, and 10 ml of new THF was added. Then, 5 ml of aqueous 2 mol dm^{-3} solution of KOH was added at 0 °C and stirring was continued for 0.5 h at room temperature. The solution was cooled again to −15 °C, and 0.13 g of Cu(acac)$_2$ (0.5 mmol) was added under weak argon flow. Then the reaction mixture was warmed to room temperature, and stirring was maintained for 20 h. The solution was oxidized with alkaline hydrogen peroxide to decompose the residual organoboranes. The solution was extracted three times with diethyl ether. The combined extracts were washed twice with NaCl-saturated water and dried over anhydrous magnesium sulfate. The solvent was evaporated off and the residue was put on a column packed with silica gel (Wako gel Q-50). 1.43 g (70% yield) of (*Z*)-6-allyl-5-dodecen-7-yne, **8a**, was isolated by elution with *n*-hexane. ^{1}H NMR δ=0.91 (m, 6H), 1.25—1.55 (m, 8H), 1.95—2.15 (m,2H), 2.29 (t, J=6 Hz, 2H), 2.87 (d, J=6 Hz, 2H), 4.95—5.15 (m, 2H), 5.81 (t, J=7 Hz, 1H), and 5.75—5.90 (m, 1H); ^{13}C NMR δ=13.65, 13.94, 18.97, 21.97, 22.38, 27.92, 31.04, 31.45, 35.76, 82.39 (C≡C), 87.42 (C≡C), 115.42 (CH_2=), 120.87 (>C=), 135.51 (-CH=), and 137.27 (-CH=); IR 910 (CH_2=) cm^{-1}; MS m/z 204 (M$^+$).

The Cross-Coupling Reaction of **2** *with 1-Bromo-1-hexyne.* The reaction and the work-up procedures were the same as described above. 1.21 g (45% yield) of 7-pentylidene-5,8-tridecadiyne, **11a**, was isolated by elution with *n*-hexane. ^{1}H NMR δ=0.81—1.00 (m, 9H), 1.18—1.75 (m, 12H), 2.20—2.40 (m, 6H), and 6.14 (t, J=7 Hz, 1H); ^{13}C NMR δ=13.62, 13.87, 13.96, 19.00, 19.19, 21.97, 22.01, 22.33, 30.21, 30.33, 30.77 (2C), 76.72 (C≡C), 79.27 (C≡C), 86.84 (C≡C), 93.50 (C≡C), 105.81 (>C=), and 146.70 (-CH=); IR 2220 (C≡C) cm^{-1}; MS m/z 244 (M$^+$).

Analytical data of the other products are as follows.

*2,2-Dimethyl-3-decyn-5-one (**4b**)*: ^{1}H NMR δ=0.90 (t, J=7 Hz, 3H), 1.28 (s, 9H), 1.30—1.40 (m, 4H), 1.60—1.75 (m, 2H) and 2.51 (t, J=7 Hz, 2H); IR (film) 2210 (C≡C) and 1680 (C=O) cm^{-1}; MS m/z 180 (M$^+$).

*7-Tetradecyn-6-one (**4c**)*: ^{1}H NMR δ=0.90 (t, J=7 Hz, 6H), 1.25—1.75 (m, 14H), 2.36 (t, J=7 Hz, 2H), and 2.51 (t, J=7 Hz, 2H); IR 2200 (C≡C) and 1680 (C=O) cm^{-1}; MS m/z 208 (M$^+$).

*1-Phenyl-1-octyn-3-one (**4d**)*: ^{1}H NMR δ=0.91 (m, 3H), 1.25—1.40 (m, 4H), 1.65—1.80 (m, 2H), 2.64 (t, J=7 Hz, 2H), 7.35—7.45 (m, 3H), and 7.50—7.60 (m, 2H); IR 2190 (C≡C) and 1670 (C=O) cm^{-1}; MS m/z 200 (M$^+$).

*5-Tetradecyn-7-one (**4e**)*: ^{1}H NMR δ=0.93 (m, 6H), 1.25—1.75 (m, 14H), 2.37 (t, J=7 Hz, 2H), and 2.52 (t, J=7 Hz, 2H); IR 2210 (C≡C) and 1680 (C=O) cm^{-1}; MS m/z 208 (M$^+$).

*(E)-2,2-Dimethyl-5-decen-3-yne (**6b**)*: ^{1}H NMR δ=0.89 (t, J=7 Hz, 3H), 1.23 (s, 9H), 1.25—1.40 (m, 4H), 2.00—2.12 (m, 2H), 5.44 (dt, J=16 and 1.5 Hz, 1H), and 6.02 (dt, J=16 and 7 Hz, 1H); IR 2200 (C≡C) and 960 (⟋C=C⟍) cm^{-1}; MS m/z 164 (M$^+$).

*(E)-5-Tetradecen-7-yne (**6c**)*: ^{1}H NMR δ=0.89 (m, 6H), 1.25—1.60 (m, 12H), 2.00—2.15 (m, 2H), 2.20—2.35 (m, 2H), 5.44 (dt, J=16 and 1.5 Hz, 1H), and 6.03 (dt, J=16 and 7 Hz, 1H); IR 2220 (C≡C) and 960 (⟋C=C⟍) cm^{-1}; MS m/z 192 (M$^+$).

*(E)-1-Phenyl-3-octen-1-yne (**6d**)*: ^{1}H NMR δ=0.89 (t, J=7 Hz, 3H), 1.25—1.45 (m, 6H), 2.05—2.20 (m, 2H), 5.67 (dt, J=16 and 1.5 Hz, 1H), 6.22 (dt, J=16 and 7 Hz, 1H), 7.20—7.30 (m, 3H), and 7.35—7.45 (m, 2H); IR 2200 (C≡C) and 960 (⟋C=C⟍) cm^{-1}; MS m/z 184 (M$^+$).

*(E)-7-Tetradecen-5-yne (**6e**)*: ^{1}H NMR δ=0.91 (m, 6H), 1.20—1.60 (m, 12H), 2.00—2.10 (m, 2H), 2.20—2.35 (m, 2H), 5.44 (dt, J=16 and 1.5 Hz, 1H), and 6.03 (dt, J=16 and 7 Hz, 1H); IR 2210 (C≡C) and 960 (⟋C=C⟍) cm^{-1}; MS m/z 192 (M$^+$).

*(Z)-2,2-Dimethyl-5-allyl-5-dodecen-3-yne (**8a**)*: ^{1}H NMR δ=0.89 (m, 3H), 1.23 (s, 9H), 1.20—1.60 (m, 4H), 2.00—2.20 (m, 2H), 2.86 (d, J=6 Hz, 2H), 4.95—5.15 (m, 2H), 5.79 (t, J=7 Hz, 1H), and 5.70—5.95 (m, 1H); ^{13}C NMR δ=13.91, 22.38, 27.90, 30.87 (-C-), 31.21 (CH_3-, 3C), 31.45, 35.93, 80.71 (C≡C), 95.91 (C≡C), 115.32 (CH_2=), 120.92 (>C=), 135.56 (-CH=), and 136.75 (-CH=); IR 2220 (C≡C) and 910 (CH_2=) cm^{-1}; MS m/z 204 (M$^+$).

*(Z)-6-Allyl-5-tetradecen-7-yne (**8c**)*: ^{1}H NMR δ=0.89 (m, 6H), 1.20—1.60 (m, 12H), 2.00—2.15 (m, 2H), 2.28 (t, J=6 Hz, 2H), 2.87 (d, J=6 Hz, 2H), 4.95—5.20 (m, 2H), 5.81 (t, J=7 Hz, 1H), and 5.75—5.95 (m, 1H); ^{13}C NMR δ=13.94, 14.06, 19.31, 22.38, 22.60, 27.92, 28.56, 28.95, 31.40, 31.48, 35.76, 82.44 (C≡C), 87.50 (C≡C), 115.40 (CH_2=), 120.94 (>C=), 135.54 (-CH=), and 137.22 (-CH=); IR 910 (CH_2=) cm^{-1}; MS m/z 232 (M$^+$).

*(Z)-1-Phenyl-3-allyl-3-octen-1-yne (**8d**)*: ^{1}H NMR δ=0.91 (m, 3H), 1.20—1.60 (m, 4H), 2.05—2.25 (m, 2H), 2.98 (d, J=6 Hz, 2H), 4.95—5.25 (m, 2H), 5.75—6.15 (m, 1H), 6.03 (t, J=7 Hz, 1H), and 7.15—7.60 (m, 5H); ^{13}C NMR δ=13.94, 22.38, 28.14, 31.35, 35,47, 86.86 (C≡C), 91.56 (C≡C), 115.76 (CH_2=), 120.55 (>C=), 123.77 (>C=), 127.71 (-CH=), 128.19 (-CH=, 2C), 131.45 (-CH=, 2C), 135.22 (-CH=), and 139.30 (-CH=); IR 910 (CH_2=) cm^{-1}; MS m/z 224 (M$^+$).

*(Z)-7-Allyl-7-tetradecen-5-yne (**8e**)*: ^{1}H NMR δ=0.91 (m, 6H), 1.15—1.60 (m, 12H), 1.95—2.15 (m, 2H), 2.29 (t, J=6 Hz, 2H), 2.89 (d, J=6 Hz, 2H), 4.95—5.15 (m, 2H), 5.81 (t, J=7 Hz, 1H), and 5.70—5.95 (m, 1H); ^{13}C NMR δ=13.62, 14.08, 19.00, 21.97, 22.62, 28.22, 29.02, 29.29, 31.06, 31.72, 35.76, 82.41 (C≡C), 87.40 (C≡C), 115.37 (CH_2=), 120.89 (>C=), 135.51

(-CH=), and 137.27 (-CH=); IR 910 (CH_2=) cm^{-1}; MS *m/z* 232 (M^+).

Restricted Rotation Involving the Tetrahedral Carbon. LVI. NMR and Molecular Mechanics Studies on the Stereodynamics of 8,13-Dichloro-9-methoxy-1,4-dimethyltriptycene[1]

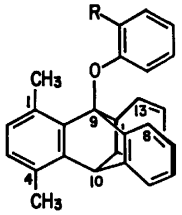
Gaku YAMAMOTO* and Michinori ŌKI
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received January 8, 1985)

The 400 MHz ^{1}H NMR spectrum of the title compound at −100 °C in dichloromethane revealed the presence of two isomers in a ratio of 88:12, which results from restricted rotation about the triptycyl-oxygen single bond. The major isomer was assigned to the *ap* rotamer on the basis of the low temperature ^{13}C NMR spectrum. Dynamic NMR studies gave the activation parameters for the $ap \rightarrow \pm sc$ conversion: $\Delta H^{\ddagger}=11.9\pm0.5$ kcal/mol (1 $cal_{th}=4.184$ J), $\Delta S^{\ddagger}=2.6\pm2.5$ eu, $\Delta G^{\ddagger}_{200K}=11.4$ kcal/mol. Results of molecular mechanics calculations on the compound are discussed.

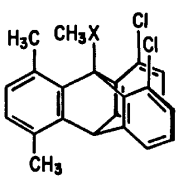
Abundant reports have appeared on dynamic NMR studies of restricted rotation about carbon–carbon single bonds including sp^3-sp^3, sp^3-sp^2, and sp^2-sp^2 combinations.[2] On the other hand, only a few examples have been reported on restricted rotation of carbon–oxygen bonds studied by NMR spectroscopy. In most cases, the bond in question is the one between an oxygen and an sp^2-hybridized carbon atoms, as in aryl esters,[3] diaryl ethers,[4] and most recently in chromium complexes of substituted anisoles.[5] While our interest is focused on rotational barriers which mainly originate from the differential steric effects in the ground and the transition states, several examples are known for another type of C(sp^2)–O rotational barriers which are mainly caused by destruction of conjugative stabilization.[6]

As for NMR studies on restricted rotation about sp^3-carbon-to-oxygen bonds, few reports have appeared. As far as we know, temperature dependence of ^{1}H NMR spectra of a quinone acetal, 4-ethoxy-2,3,5,6-tetramethylphenoxy dimer,[7] and more recently that of bis(9-anthrylmethyl) ether derivatives[8] have been reported. In both reports, mechanistic details of the dynamic process are not discussed, only the possible structure of the stable conformation being speculated.

We recently reported the preliminary results of dynamic NMR studies on the stereodynamics of 9-(2-alkylphenoxy)triptycenes (**1**).[9] Molecules of compounds **1** constitute a bevel gear system with a two-toothed and a three-toothed wheels in both static and dynamic sense: Correlated disrotation of the triptycyl–oxygen and aryl–oxygen bonds is observed by dynamic NMR spectroscopy. In this system, ground state conformations and the dynamic processes occurring are well defined.



1a: R = CH_3
1b: R = $CH(CH_3)_2$



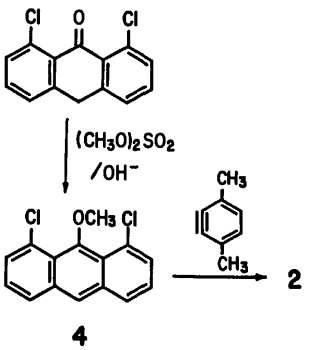
2: X = O
3: X = CH_2

We felt it essential to study a simpler and more fundamental system, 9-methoxytriptycenes, in order to get deeper insight into the general nature of rotational barriers of C–O bonds in comparison with those of C–C bonds. As a methyl group is considerably smaller than the aryl group in **1**, it seemed necessary to introduce substituents at three *peri*-positions (1, 8, and 13 positions) to obtain a sufficient steric congestion in the transition state for rotation so that the restricted rotation is observed by NMR spectroscopy. We therefore chose 8,13-dichloro-9-methoxy-1,4-dimethyltriptycene (**2**) as the target, taking also the synthetic ease into account.

In this article, we report on the dynamic NMR and molecular mechanics studies of **2** and discuss the results in comparison with those of the corresponding 9-ethyl derivative (**3**)[1] and of related compounds.

Results and Discussion

Synthesis. 1,8-Dichloroanthrone was methylated with dimethyl sulfate and alkali to give 1,8-dichloro-9-methoxyanthracene (**4**). Reaction of **4** with 3,6-dimethylbenzyne afforded **2** as colorless crystals with low solubility in common solvents.



4

NMR Spectra and Rotamer Equilibria. In the ^{1}H NMR spectrum of **2** at ambient temperature, three singlets are observed for the methyl groups reflecting fast internal rotation about the C_9–OCH_3 bond (Table 1). Of the two singlets ascribed to the aromatic methyl groups, the high-field one at δ 2.31 is unambiguously assigned to 4-methyl on the basis of nuclear Overhauser

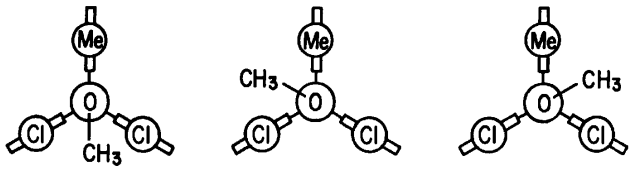
Table 1. ^{1}H NMR data of **2** in CD_2Cl_2 at 400 MHz[a)]

Temp °C	Pop %	1-CH_3	4-CH_3	OCH_3	10-H	Rotamer assigned
25		2.71_0	2.31_4	3.98_4	5.44_0	
−100	88	2.69_2	2.30_2	3.95_0	5.54_2	*ap*
	12	2.73_5	2.53_8	3.85_4	5.51_3	±*sc*
		(-0.04_3)	(-0.23_6)	(0.09_6)	(0.02_9)	

a) Data for aromatic protons are omitted; see Experimental. Chemical shifts are given in δ. In parentheses are chemical shift differences in ppm between the rotamers at −100 °C.

effect (NOE) experiments: Irradiation of this signal causes the intensity enhancement by *ca.* 20% of the signal at δ 5.44 ascribed to the bridgehead proton (10-H), while irradiation of the low-field methyl signal at δ 2.71 leaves the 10-H signal intact.

On lowering the temperature, each of the singlets broadens and splits into two unequally intense peaks. At −100 °C in dichloromethane-d_2, two sets of signals are observed indicating the presence of two isomers in a ratio of 88:12. It may be quite reasonable to assume that these isomers are rotamers about the C_9–OCH_3 bond, *ap* and ±*sc* (an equimolar mixture of +*sc* and −*sc*), but the rotamer assignment is not so straightforward from the ^{1}H NMR spectra, because the compound does not contain a prochiral group (*e.g.* $-CX_2Y$), which would definitely identify the chiral nature of the ±*sc* rotamer. The aromatic proton signals of the major rotamer appear rather simple, however, implying that it is *ap*.



ap +*sc* −*sc*

We expected that the unambiguous assignment of the rotamers could be made from the ^{13}C NMR spectrum at low temperature: The ±*sc* rotamer should give rise to eighteen different signals in the aromatic carbon region while the *ap* rotamer twelve peaks according to the molecular symmetry. Therefore we measured a 100 MHz ^{13}C NMR spectrum of **2** at −82 °C. Actually twelve large peaks assignable to the major isomer were observed in the region of δ 120—150 together with more than twelve small peaks derived from the minor isomer. This strongly suggests that the major isomer is *ap*, although all of the eighteen peaks are not detected for the minor isomer because of the overlap with the major peaks and the interference by noise peaks. The ^{13}C NMR data are given in Table 2 together with tentative assignments of the major peaks.

Predominance of the *ap* rotamer is reasonable on the basis of the generally accepted order of bulkiness of the *peri*-substituents, CH_3>Cl:[10] The methoxyl methyl group should be more comfortable when it is flanked by two Cl's than by CH_3 and Cl. Similar rotamer distribution was observed in the corresponding 9-ethyl compound (**3**), where the population of *ap* is 57% in chloroform-*d* at 35 °C.[1]

Table 2. ^{13}C NMR data of **2**[a)]

at 25 °C	at −82 °C major	at −82 °C minor	Tentative assignment
18.39 q	18.20	17.93	4-CH_3
20.24 q	20.05	19.15	1-CH_3

a) Obtained at 100.5 MHz in CD_2Cl_2. Chemical shifts of the aromatic carbons of the minor rotamer are not read. b) Shoulder. c) Not identified.

Inspection of Table 1 reveals an intriguing feature. The signals at −100 °C due to the 4-methyl group, which is remoter from the site of restricted rotation than 1-methyl, show a larger chemical shift difference (0.24 ppm) between the rotamers than those due to the latter (0.04 ppm). This seems quite unusual but the reason is not certain.

Dynamic NMR Studies and Rotational Barriers. Pairs of signals at low temperatures which are ascribed to the 1-methyl, 4-methyl, and methoxyl groups coalesce to single peaks at about −71, −62, and −50 °C, respectively, upon raising the temperature. While rigorous determination of the coalescence temperatures was not made, rate constants for the *ap*⇌±*sc* interconversion were obtained by simulating the three sets of signals at six temperatures between −81 and −56 °C. The data are given in Table 3 together with the activation parameters therefrom.

Comparison of the data with those of the carbon analog **3** reveals some interesting points. Generally, rotational barriers about C–O bonds are lower than those about the corresponding C–C bonds as typically illustrated by methanol *vs.* ethane (1.07 *vs.* 2.88 kcal/mol), and dimethyl ether *vs.* propane (2.7 *vs.* 3.4

TABLE 3. DYNAMIC NMR DATA OF **2** IN CD_2Cl_2 AT 400 MHz[a)]

$$ap \underset{k_{-1}}{\overset{2k_1}{\rightleftharpoons}} \pm sc \qquad K = 2k_1/k_{-1}$$

Temp	K	k_1	ΔG^*	ΔH^*	ΔS^*

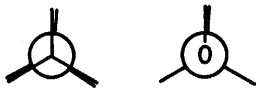
−70.9	0.156	2.0	11.40		
−65.9	0.163	4.6	11.35		
−60.8	0.176	9.7	11.33		
−55.7	0.176	18.5	11.33		

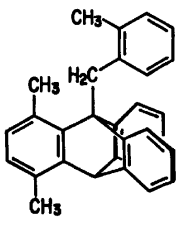
a) The parameters refer to the $ap \rightarrow \pm sc$ process.

kcal/mol).[11] This seems to be principally resulted from the fact that there are three eclipsing interactions in the transition state for C–C rotation, while only one for C–O rotation. As the lone pair electrons on oxygen are much smaller in their effective size than hydrogen or alkyl groups and highly polarizable, steric interaction



involving the lone pair electrons are considered to be negligible.

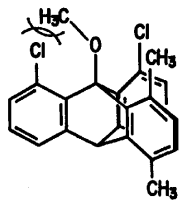
In this sense, the lower barrier in **2** than in **3** (ΔG^*=20.2 kcal/mol at 94 °C)[1] may be quite reasonable. However the larger barrier difference of about 9 kcal/mol is in striking contrast to the rather small difference found between **1a** and its carbon analog (**5**):[9,12] The gearing process in which the aryl group passes over the *peri*-methyl group has ΔG^* of 18.1 kcal/mol in **1a** and 20.0 kcal/mol in **5**.



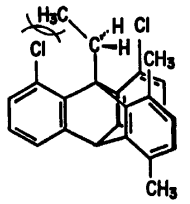
5

In order to understand this apparent discrepancy, secondary factors affecting the barrier difference should be considered. Among them, the difference in bond length between C–C and C–O would be the most important. In the following discussion, the effects of bond lengths in the transition states are considered, the other secondary factors being neglected. Effects of these factors as well as the bond lengths in the ground states are assumed to be smaller than in the transition states.

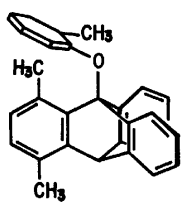
The probable transition states for the $ap \rightleftharpoons \pm sc$ interconversion in **2** and **3** are shown by **6** and **7**, respectively. Local steric interaction due to eclipsing of the β-methyl group in the 9-substituent and the *peri*-chloro group will not differ largely between **6** and **7**, because not only the C_9–O bond but also the O–CH_3 bond in **6** are shorter than the corresponding C–C bonds in **7**. Therefore the presence or absence of



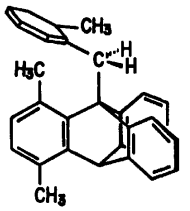
6



7



8



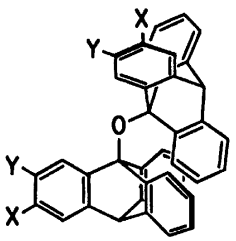
9

the eclipsing interaction between the α-hydrogen in the 9-substituent and the *peri*-chloro or *peri*-methyl group most effectively affects the transition state energy, resulting in the large barrier difference between **2** and **3**.

On the other hand, in the probable transition states (**8** and **9**) for the $ap \rightleftharpoons \pm sc$ gearing process in **1a** and **5**, respectively, the repulsive interaction between the *peri*-methyl and the aryl groups will be far severer in **8** than in **9**, because the C_9–O bond in **8** is shorter than the C_9–CH_2 bond in **9** while the difference between the Ar–O and Ar–CH_2 bond lengths does not seem to significantly affect this situation. Therefore the small barrier difference between **1a** and **5** may be understood by assuming that the sum of the eclipsing interactions between the aryl group and the *peri*-methyl group and those between the α-hydrogens and the *peri*-hydrogens in **9** do not largely exceed the eclipsing interaction between the aryl group and the *peri*-methyl group in **8**.

One may pose a possibility that the interconversion between the isomers might occur by configurational inversion at the oxygen atom by way of a transition state with a linear C–O–C arrangement, which is often called

a lateral shift, rather than internal rotation about the C–O bond. Although we do not have experimental evidence at hand for or against the hypothesis, there seems an indication against it. Kawada and Iwamura reported that the energy barrier to interconversion between the "phase isomers" in bis(9-triptycyl) ether derivatives (**10**) are 42—44 kcal/mol.[13] They rejected the lateral shift as the mechanism of the interconversion, and thus the inversion barrier at oxygen should be higher than these values in **10**, and there



10 X or Y = Cl

is no reason to assume that the inversion barrier in **2** is largely different from those in **10**.[14]

Molecular Mechanics Calculations. In order to confirm the rotamer assignment mentioned above by evaluating the relative energies of the rotamers and to have some insights into the molecular geometries of the rotamers, we performed molecular mechanics calculations on **2** and also on **3** for comparison, using the MM2 force field.[15] Several parameters were newly inputted in addition to those originally included in the program, which are given in the experimental section. Calculated total steric energies of the rotamers of **2** and **3** and their components are compiled in Table 4.

In both **2** and **3**, the *ap* rotamer is calculated to be more stable than ±*sc*, reproducing qualitatively the observation. The steric energy difference between the rotamers is fortuitously the same between **2** and **3**, but the component analysis shows that the contributing factors are different. In the oxygen compound **2**, the bending and torsion terms most contribute to the energy difference, both favoring the *ap* rotamer. In the methylene analog **3**, the torsion term strongly favors *ap*, while the van der Waals terms favor ±*sc*, partially compensating the contribution by torsion.

As the accurate values for the enthalpy and entropy differences between the rotamers could not be determined experimentally by the ^{1}H NMR studies, quantitative comparison between the experiment and the calculation is not straightforward. If it is assumed that the statistical factor of 2 for ±*sc* is the only contributor to the entropy difference, the populations of the *ap* rotamer are calculated from the steric energy difference of 1.18 kcal/mol to be 94% at −100 °C and 71% at 35 °C, which are compared with the observed values of 88% at −100 °C for **2** and 57% at 35 °C for **3**. Agreement seems fairly good.

The optimized geometries of *ap*-**2** and +*sc*-**2** are shown in Fig. 1. In both rotamers, the benzo bridge antiperiplanar to the *O*-methyl group is completely in a single plane together with the substituent(s) attached to it, and the benzo bridges flanking the *O*-methyl group and the *peri*-substituents attached to them bend away from the *O*-methyl group so as to relieve the steric congestion. No extraordinary bond lengths are found. The bonds connecting the benzo bridges to 9-C are somewhat longer (1.53—1.55 Å) than the normal sp^3-sp^2 carbon bond of 1.49 Å, and this feature is generally found in 9-substituted triptycene derivatives studied by X-ray crystallography.[16] The C_9–O–CH_3 angles are 113.7 and 113.4° in *ap*-**2** and ±*sc*-**2**, respectively, increasing by *ca.* 7° from the standard value of 106.8°.

In order to obtain the energy barrier to rotation about the C_9–OCH_3 bond in **2** by molecular mechanics calculations, dependence of the steric energy upon the dihedral angle C_{9a}–C_9–O–CH_3 was calculated by the "one-bond drive" technique. The transition state for the *ap*⇌±*sc* interconversion, in which the *O*-methyl group eclipses a *peri*-chlorine, was calculated to be 15.7 kcal/mol higher than the *ap* state. The calculated energy barrier is somewhat higher than the experimentally obtained one (11.9 kcal/mol). We must allow for the fact that highly strained transition states are usually difficult to be reproduced by using the parameters which are empirically determined so as to reproduce the energy and geometry of molecules in the ground state.

Table 4. Steric energies and their components by MM2[a]

	2			**3**		
	ap	±*sc*	Δ*E*	*ap*	±*sc*	Δ*E*
Total steric energy	30.87	32.05	−1.18	33.02	34.20	−1.18
Compression	3.44	3.46	−0.02	4.98	4.92	0.06
Bending	15.27	15.58	−0.31	17.14	17.18	−0.04
Stretch-bend	−0.27	−0.27	0.00	−0.26	−0.27	0.01
van der Waals						
1,4-	20.18	20.23	−0.05	19.63	19.52	0.11
other	−2.29	−2.33	0.04	1.28	0.83	0.45
Torsion	−7.41	−6.67	−0.74	−9.38	−7.66	−1.72
Dipole	1.95	2.05	−0.10	−0.37	−0.32	−0.05

a) in kcal/mol.

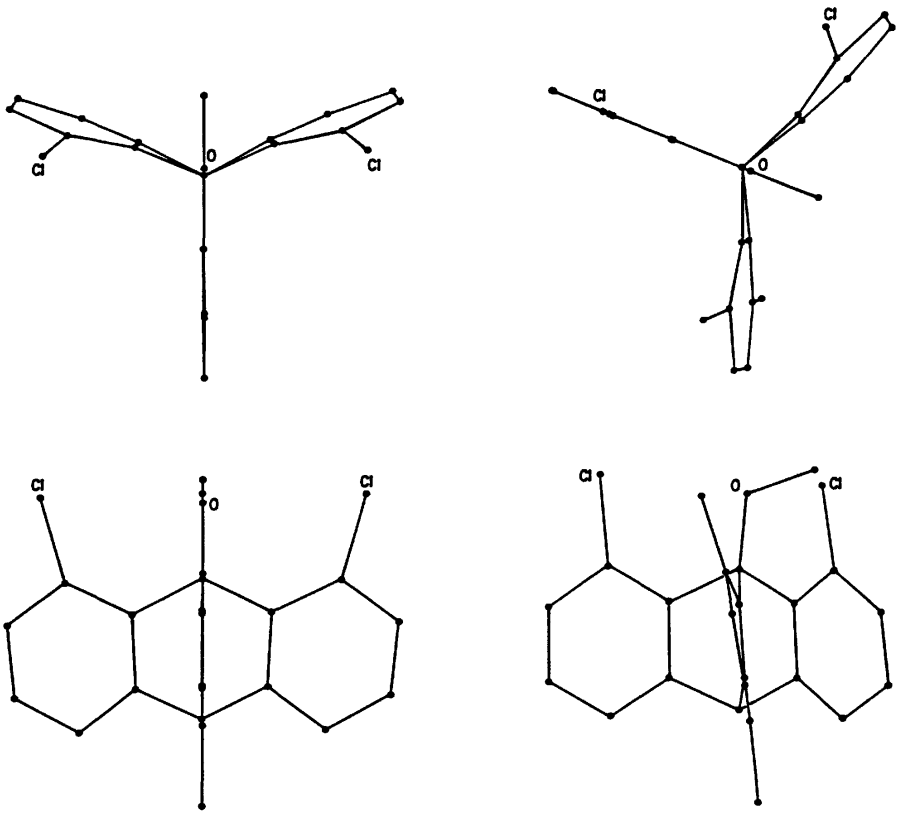


Fig. 1. The optimized geometries of *ap*-**2** and *+sc*-**2**. In each molecule, 9-C and 10-C are placed on the *z*-axis and 9a-C in the *xz* plane, and projections onto the *xy* (upper) and *yz* (lower) planes are shown. Hydrogens are not indicated.

The energy barrier to the direct $+sc \rightleftharpoons -sc$ interconversion, which is not experimentally obtained, was calculated to be 18.3 kcal/mol. As the *O*-methyl group eclipses the *peri*-methyl in the transition state, the higher barrier to this process than that to the $ap \rightleftharpoons \pm sc$ process may be reasonable.

More detailed and sophisticated molecular mechanics calculations on the potential surface of **2** are in progress and the results will be reported separately.

Experimental

1,8-Dichloro-9-methoxyanthracene (4). To a stirred solution of 2.63 g (10.0 mmol) of 1,8-dichloroanthrone[17] in 200 mL of ethanol was added alternately in small portions a solution of 3.0 g of sodium hydroxide in 15 mL of water, and 6.0 mL of dimethyl sulfate. The solid formed was collected by filtration, washed with water and then with methanol, and dried in air, affording 2.30 g (83%) of **4**, mp 170—172 °C (from tetrahydrofuran). Found: C, 64.72; H, 3.36; Cl, 25.57%. Calcd for $C_{15}H_{10}Cl_2O$: C, 65.01; H, 3.64; Cl, 25.58%. ^{1}H NMR ($CDCl_3$): δ=3.38 (3H, s), 7.2—8.2 (6H, m), 8.19 (1H, s).

8,13-Dichloro-9-methoxy-1,4-dimethyltriptycene (2). A solution of 3.30 g (20 mmol) of 3,6-dimethylanthranilic acid[18] in 30 mL of 1,2-dimethoxyethane was added dropwise in the course of 1 h to a boiling solution of 2.62 g (9.44 mmol) of **4** and 2 mL of isopentyl nitrite in 50 mL of dichloromethane. The mixture was heated under reflux for another 30 min and concentrated. The residue was chromatographed through an alumina column with benzene as the eluent. Recrystallization of the eluate from benzene gave 1.34 g (37%) of **2**, mp 279—281 °C. Found: C, 72.19; H, 4.59; Cl, 18.60%. Calcd for $C_{23}H_{18}Cl_2O$: C, 72.45; H, 4.76; Cl, 18.60%. The 400 MHz ^{1}H NMR spectrum of **2** at 25 °C in CD_2Cl_2 allows analysis of the aromatic proton signals: δ=6.635 and 6.669 (AB-q, J=7.8 Hz, 2,3-H_2), 7.061 (dd, J=7.1 and 7.9 Hz, 6,15-H_2), 7.081 (dd, J=1.2 and 7.9 Hz, 7,14-H_2), 7.312 (dd, J=1.2 and 7.1 Hz, 5,16-H_2).

Spectral Measurements. ^{1}H NMR spectra at ambient temperature were recorded on a Varian EM-390 spectrometer operating at 90.0 MHz. Variable temperature ^{1}H and ^{13}C NMR spectra were obtained on a JEOL GX-400 spectrometer operating at 399.65 and 100.53 MHz, respectively. Temperatures were read as digital outputs from the variable temperature accesory and are not corrected.

Computer Simulation. Theoretical spectra were obtained on a HITAC M-280H computer system at the Computer Center of the University of Tokyo (CCUT) using a modified version of the DNMR3 program by Binsch.[19] Three pairs of signals due to the 1-, 4-, and *O*-methyl groups were simulated at each temperature and the most consistent value of rate constant was chosen.

Molecular Mechanics Calculations. The calculations were performed on the HITAC M-280H system using the MM2 program in the CCUT Program Library (code name: Y4/TC/MM2). The force field in the program has been modified by Professor E. Ōsawa from the original program[15] in order that the four-fold torsional potential term (V_4) is considered. Any necessary modification of the calculation procedure accompanying the incorporation of the V_4 terms has been properly taken into account in the program. As

the force field does not contain the parameters concerning C_{arom}–Cl bonds, several parameters were newly added. For the compression and bending force constants, those obtained for tetrachloroethylene were used.[20] For the torsional parameters involving the aromatic chlorine, the corresponding hydrogen parameters in the program were diverted. New parameters are shown below together with modifications for C_{arom}–C_{arom} bonds. The atom type numbers represent as follows; 1: sp^3-carbon, 2: aromatic carbon, 5: hydrogen, 12: chlorine.

Compression	K_s/mdyn†/Å	l_0/Å
2 — 2	8.067	1.3937
2 —12	2.66	1.715

Bending	K_b/mdyn Å/rad^2	t_0/deg
2—2—12	0.400	120.0

Torsion	V_1	V_2	V_3	V_4/kcal/mol
1—2—2—12	0.0	16.4	0.0	−2.3
2—2—2—12	0.0	16.4	−1.06	−2.3
5—2—2—12	0.0	16.4	0.0	−2.3

The authors are grateful to Professor E. Ōsawa for helpful discussion on the molecular mechanics calculations, and to Dr. G. Izumi of Nippon Kayaku Co., Ltd. for the measurements of 400 MHz ^{1}H and 100 MHz ^{13}C NMR spectra.

† 1 dyn = 10^{-5} N.

Efficient Additions of an Electronically Stabilized Persistent Aminyl Radical to Conjugated Alkenes[1)]

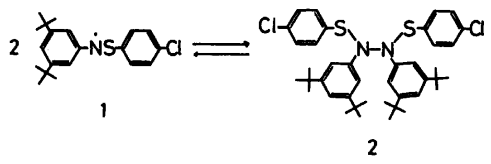
Yozo Miura,* Teruo Kunishi, and Masayoshi Kinoshita
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received January 9, 1985)

It has been found that an electronically stabilized persistent *N*-(4-chlorophenylthio)-3,5-di-*t*-butylphenylaminyl radical (**1**) adds to conjugated alkenes to afford 1:2 adducts of the alkenes and **1** in fair to excellent yields, along with small amounts of 1:1 adducts of the alkenes and **1**.

In contrast to the very large number of studies of the additions of carbon-centered free radicals to alkenes, reports in the literature concerning the additions of nitrogen-centered free radicals to alkenes are rare.[2-10)] Therefore, there is much less information regarding the additions of nitrogen-centered free radicals to alkenes, and the addition reactions are not yet well enough understood.

It has been reported that some aminyl radicals, including $\dot{N}H_2$ and dialkylamino radicals, add to alkenes to give 1:1 and 1:2 adducts of the alkenes and the radicals in low yields. For instance, the photolysis of a solution of tetramethyltetrazene and isopropenylbenzene in cyclohexane affords a 1:2 adduct of the alkene and the dimethylamino radical in a 10% yield, along with a minor formation of 1:1 adducts.[9)]

We have recently found that *N*-(4-chlorophenylthio)-3,5-di-*t*-butylphenylaminyl radical (**1**) adds to some conjugated alkenes to give 1:2 adducts of the alkenes and **1** in fair to excellent yields. Radical **1** is quite persistent, even in the presence of air, and can be isolated as the hydrazine-type dimer **2**, which, upon dissolution into ordinary solvents, dissociates into **1** with a relatively large dissociation constant.[11)] The efficient additions of such an electronically stabilized aminyl radical to conjugated alkenes are rather surprising and considerably interesting. We wish to report herein the products derived from the additions of **1** to conjugated alkenes; the mechanism of the formation of the adducts are also briefly described.



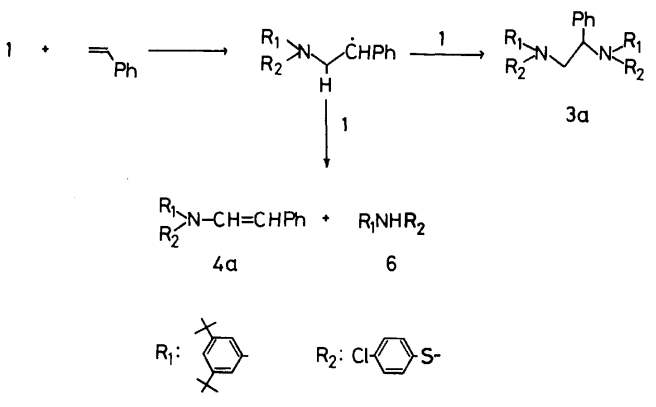
1 2

Results and Discussion

The reactions of **1** with alkenes were carried out in degassed benzene at 50 °C. When mixtures of **1** and alkenes (excess) were heated to 50 °C for 0.3—60 h, the dark blue color attributable to **1** disappeared almost completely, and the mixture became orange or red. The mixtures, after column chromatography, afforded 1:2 adducts of the alkenes and **1** in fair to excellent yields, along with small amounts of 1:1 adducts of alkenes and **1**. The results of the reactions are summarized in Table 1; the yields in the Table are averaged over at least three runs in most cases.

The reaction with styrene yielded, after heating for 14 h, two products (**3a** and **4a**) derived from styrene, along with **5** (11%) and **6** (41%), which do not contain the styrene moiety. Since the latter two products have been found to be formed *via* the self-decomposition of **1** (and **2**),[12)] considerable parts of the products seem to be generated by this reaction. In the former two products, **3a**, which is a 1:2 adduct of styrene and **1**, is the major product (31%), while the minor product, **4a**, which is a 1:1 adduct of styrene and **1**, is formed in a 12% yield. It is almost certain that these products are formed by the routes shown in Scheme 1. Furthermore, the predominant formation of **3a** shows that the intermediate radical, which is derived from the addition of **1** to styrene, is predominantly captured by another molecule of **1** to give **3a**, while hydrogen-atom abstraction from the intermediate radical, probably by **1**, is less important. Therefore, we believe that **1** is not highly active in hydrogen-atom abstraction.

The reaction with isopropenylbenzene afforded three products (**3b**, **4b**, and **7**) derived from the alkene, along with **5** (8.1%) and **6** (27%). The major product **3b**, which is formed in a 40% yield, is a 1:2 adduct of the alkene and **1**, much as in the case of styrene. On the other hand, two minor products, **4b** and **7**, are formed in 3.9 and 6.6% yields respectively. For the formation of **4b**, hydrogen-atom abstraction from the intermediate radical **8** is most likely. On the other hand, for the formation of **7** there are two possible routes: one is hydrogen-atom abstraction from the methyl group of **8**, and the second is first hydrogen-atom abstraction from



Scheme 1.

the methyl group of isopropenylbenzene, followed by the combination of the resultant intermediate radical with **1**. Although we can not determine unequivocally which route is predominant, we favor the former route, since **1** does not seem to be so active as to abstract a hydrogen atom from the methyl group of isopropenylbenzene.

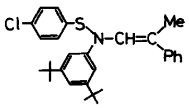
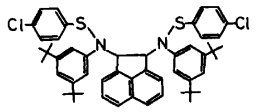
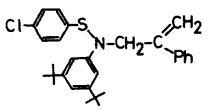
3b: X=Me, Y=Ph
3c: X=Y=Ph



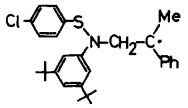
4b



3d



7

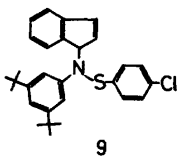


8

The reaction with 1,1-diphenylethylene afforded **3c** in an 88% yield, while the reaction with acenaphthylene gave **3d** in a 38% yield. In neither case could a 1:1 adduct corresponding to **4a** or **4b** be isolated from the reaction mixtures.

The reactions with 1-octene and (*E*)-1,2-diphenylethylene gave neither 1:2 nor 1:1 adducts; even when the mixture of **1** and the alkenes were heated at 50 °C for 60 h, the only products isolated were **5** and **6**.

The reaction with indene was complete within only 0.3 h and gave **9** in a 37% yield, instead of the corresponding 1:2 adduct. Although the TLC of the reaction mixture showed a spot suggesting the formation of trace amounts of the 1:2 adduct, it could not be isolated because they were only trace amounts. It is



9

most likely that this product is formed by the first abstraction of the allylic hydrogen of indene, probably by **1**, followed by combination of the resultant intermediate radical with **1**. Therefore, the hydrogen-atom abstraction is predominant over the addition of **1** to the double bond of indene; this is in accord with the highly reactive allylic hydrogens of indene.

As can be seen from Table 1, the total yields of the 1:1 and 1:2 adducts increase in the following order: 1-octene ≈(*E*)-1,2-diphenylethylene<acenaphthylene< styrene<isopropenylbenzene<1,1-diphenylethylene.

Table 1. Results of the reactions of **1** with alkenes[a—c]

Alkene[d]	Time[e] h	Products (%)[f]
1-Octene	60	g)
Styrene	14	**3a** (31), **4a** (12)
Isopropenylbenzene	11	**3b** (40), **4b** (3.9), **7** (6.6)
1,1-Diphenylethylene	7	**3c** (88)
(*E*)-1,2-Diphenylethylene	60	g)
Acenaphthylene	5	**3d** (38)
Indene	0.3	**9** (37)

a) Dimer **2**: 0.577 mmol. b) Temperature: 50 °C. c) Solvent: benzene 10 cm^3. d) Alkene: 7.7 mmol. e) Time required for the complete reaction of **1**. f) Isolated yield based on **1**. g) No formation of adducts was revealed by a TLC inspection of the reaction mixture.

This order is parallel to the stabilities of the intermediate radicals resulting from the addition of **1** to the alkenes. The only exception is (*E*)-1,2-diphenylethylene. In this case no formation of adducts can be reasonably explained in terms of the steric inhibition in the addition reaction.

Experimental

The melting point were taken on a Yanagimoto micro-melting point apparatus and are uncorrected. The IR spectra were run on a JASCO A-200 spectrometer as KBr pellets. The ^{1}H NMR spectra were measured with a JEOL PS-100 spectrometer, using TMS as the internal standard.

Styrene, isopropenylbenzene, 1,1-diphenylethylene, and indene were, after column chromatography on alumina (Merck art 1097; column size, 3×10 cm; eluant, hexane), distilled under reduced pressure prior to use, while acenaphthylene was purified by recrystallization (ethanol) and sublimation. *N,N'*-Bis(4-chlorophenylthio)-*N,N'*-bis(3,5-di-*t*-butylphenyl)hydrazine (**2**) was prepared by our previously reported method.[11]

General Procedure for Reactions of 1 with Alkenes. Dimer **2** (400 mg, 0.577 mmol), alkene (7.7 mmol), and benzene (10 cm^3) were placed in a glass tube, the content was degassed by three freeze-pump-thaw cycles, and the tube was sealed off from the vacuum system. The tube was then immersed in a water-bath heated to 50 °C, and the precipitate, **2**, in the solution was dissolved with occasional shaking. When the blue color of the reaction mixture had been changed to orange or red, the tube was broken and the mixture was evaporated under reduced pressure. Column chromatography of the residue on silica gel (Wako gel C-200, column size, 3×45 cm) at 3—5 °C gave products, **3**—**7** and **9**.

Reaction with Styrene. After being heated for 14 h, the reaction mixture (orange) was evaporated; subsequent column chromatography of the residue, with 1:7 benzene–hexane as the eluant, gave the following products: **5**, 30 mg (0.061 mmol), which was identified by its melting point [118—119 °C (from methanol) (lit,[12] 119—121 °C)] and by comparing its IR spectrum with that of an authentic sample. **4a**: 60 mg (0.13 mmol, 12%); colorless needles; mp 131—132 °C (from methanol); IR 2950—2850 (C–H of *t*-Bu) and 1640 cm^{-1} (vinyl); NMR ($CDCl_3$) δ=1.30 (s, *t*-Bu, 18H), 6.37 (d, J=15 Hz, vinylic, 1H), and 7.20—7.38 (m, aromatic, 12H, and vinylic, 1H). Found: C, 74.93; H, 7.05; N, 2.90%. Calcd

for $C_{28}H_{32}ClNS$: C, 74.72; H, 7.17; N, 3.11%. **3a**: 141 mg (0.177 mmol, 31%); colorless prisms; mp 179.5—180.5 °C (from methanol-benzene); NMR ($CDCl_3$) δ=1.13 and 1.23 (each s, *t*-Bu, 36H), 4.24 (dd, *J*=5 and 15 Hz, CHH-N, 1H), 4.52 (dd, *J*=7 and 15 Hz, CHH-N, 1H), 5.68 (dd, *J*=5 and 7 Hz, CH-N, 1H), and 6.76—7.29 (m, aromatic, 19H). Found: C, 72.16; H, 7.59; N, 3.64%. Calcd for $C_{48}H_{58}Cl_2N_2S_2$: C, 72.24; H, 7.33; N, 3.51%. **6**: 163 mg (0.468 mmol), which was identified by its melting point [151—152 °C (from hexane) (lit,[11] 150—151 °C)] and by comparing its IR spectrum with that of an authentic sample.

Reaction with Isopropenylbenzene. After being heated for 11 h, the reaction mixture (orange) was evaporated; subsequent column chromatography of the residue, with 1:7 benzene-hexane as the eluant, gave the following five products: **5**, 23 mg (0.047 mmol), which was identified by its melting point [118—119 °C (from methanol)(lit,[12] 119—121 °C] and by comparing its IR spectrum with that of an authentic sample. **4b**: 21 mg (0.045 mmol, 3.9%); colorless prisms; mp 96—97 °C (from methanol); IR 2950—2850 (C-H of *t*-Bu) and 1620 cm^{-1} (vinyl); NMR ($CDCl_3$) δ=1.28 (s, *t*-Bu, 18H), 1.97 (d, *J*=1.2 Hz, CH_3, 3H), 6.59 (q, *J*=1.2 Hz, vinylic, 1H), and 7.01—7.18 (m, aromatic, 12H). Found: C, 75.33; H, 7.29; N, 3.10%. Calcd for $C_{29}H_{34}ClNS$: C, 75.05; H, 7.38; N, 3.02%. **7**: 36 mg (0.078 mmol, 6.6%); colorless needles; mp 119—120 °C (from methanol); IR 2950—2850 (C-H of *t*-Bu) and 1630 cm^{-1} (vinyl); NMR ($CDCl_3$) δ=1.26 (s, *t*-Bu, 18H), 4.72 (s, CH_2, 2H), 5.22 (s, vinylic, 1H), 5.46 (s, vinylic, 1H), and 6.97—7.37 (m, aromatic, 12H). Found: C, 75.64; H, 7.51; N, 2.64%. Calcd for $C_{29}H_{34}ClNS$: C, 75.05; H, 7.38; N, 3.02%. **3b**: 186 mg (0.229 mmol, 40%); colorless prisms; mp 159—161 °C (from methanol-benzene); NMR (CCl_4) δ=1.12 and 1.20 (each s, *t*-Bu, 36H), 1.80 (s, CH_3, 3H), 4.31 (d, *J*=15 Hz, CHH-N, 1H), 4.56 (d, *J*=15 Hz, CHH-N, 1H), and 6.63—7.28 (m, aromatic, 19H). Found: C, 72.37; H, 7.37; N, 3.45%. Calcd for $C_{49}H_{60}Cl_2N_2S_2$: C, 72.47; H, 7.45; N, 3.45%. **6**: 108 mg (0.310 mmol), which was identified by its melting point [151—152 °C (from hexane) (lit,[11] 150—151 °C)] and by comparing its IR spectrum with that of an authentic sample.

Reaction with 1,1-Diphenylethylene. After being heated for 7 h, the reaction mixture (orange) was evaporated; subsequent column chromatography of the residue, with 1:5 benzene-hexane as the eluant, gave 445 mg (0.509 mmol, 88%) of **3c**: colorless needles; mp 116—117 °C (from methanol-benzene); NMR (CCl_4) δ=1.18 and 1.20 (each s, *t*-Bu, 36H), 4.62 (s, CH_2, 2H), and 6.46—7.50 (m, aromatic, 24H). Found: C, 74.05; H, 7.14; N, 3.31%. Calcd for $C_{54}H_{62}Cl_2N_2S_2$: C, 74.20; H, 7.15; N, 3.21%.

Reaction with Acenaphthylene. Afer being heated for 5 h, the reaction mixture (red) was evaporated; subsequent column chromatography of the residue, with 1:5 benzene-hexane as the eluant, gave 184 mg (0.217 mmol, 38%) of **3d**: colorless needles; mp 206—209 °C (decomp) (from methanol-benzene); NMR (CCl_4) δ=1.15 (s, *t*-Bu, 36H), 6.25 (s, CH, 2H), and 6.75—7.73 (m, aromatic, 20H). Found: C, 74.11; H, 6.88; N, 3.36%. Calcd for $C_{52}H_{58}Cl_2N_2S_2$: C, 73.82; H, 6.91; N, 3.31%.

Reaction with Indene. After being heated for 0.3 h, the reaction mixture (light orange) was evaporated; subsequent column chromatography of the residue, with 1:7 benzene-hexane as the eluant, gave 147 mg (0.423 mmol, 37%) of **9**: colorless needles; mp 149.5—150.5 °C (from methanol); NMR (CCl_4) δ=1.19 (s, *t*-Bu, 18H), 5.52 (dd, *J*=1.8 and 2.2 Hz, CH, 1H), 6.38 (dd, *J*=1.8 and 5.7 Hz, olefinic, 1H), 6.78 (dd, *J*=2.2 and 5.7 Hz, olefinic, 1H), and 6.84—7.40 (m, aromatic, 11H). Found: C, 75.13; H, 7.11; N, 3.27%. Calcd for $C_{29}H_{32}ClNS$: C, 75.37; H, 6.98; N, 3.03%..

Enantiodivergent Total Syntheses of Nanaomycins and Their Enantiomers, Kalafungins

Kuniaki TATSUTA,* Kohji AKIMOTO, Masahiko ANNAKA,
Yutaka OHNO, and Mitsuhiro KINOSHITA
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received January 10, 1985)

The first, enantiospecific total syntheses of pyranonaphthoquinone antibiotics, nanaomycins D and A, and their enantiomers, kalafungin and 4-deoxykalafunginic acid are described by an "enantiodivergent" strategy from a common optically active intermediate, (1*S*,3*RS*,4*S*)-3,4-dihydro-5,9,10-trimethoxy-1-methyl-1*H*-naphtho[2,3-*c*]pyran-3,4-diol, which has been derived from L-rhamnose *via* condensation of 4-methoxy-3-(phenylsulfonyl)-1(3*H*)-isobenzofuranone and methyl 3,4,6-trideoxy-α-L-*glycero*-hex-3-enopyranosid-2-ulose.

Nanaomycin D[1] (**1**), kalafungin[2] (**2**), granaticin[3] (**3**), medermycin[4] (**4**), and nanaomycin A[5] (**5**) are members of a growing family of pyranonaphthoquinone (benzoisochromanquinone) antibiotics (Chart 1), which have been shown to possess significant antimicrobial activities and potential antitumor activities.[6] Remarkably, nanaomycin D (**1**) and kalafungin (**2**) are enantiomers with each other, and both antipode systems have been found as major constituents of many kinds of pyranonaphthoquinone antibiotics such as **3** and

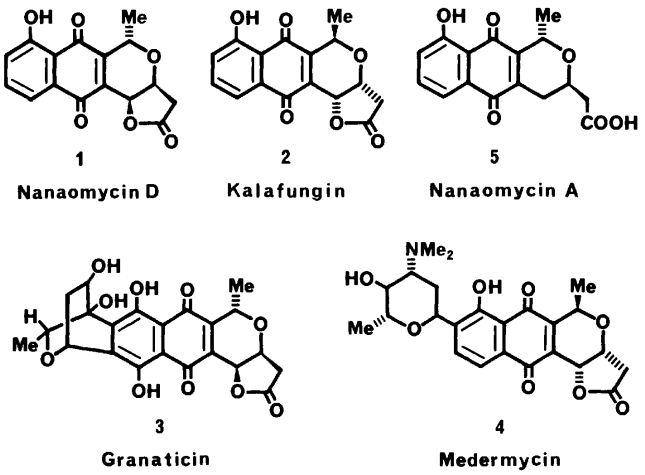

Chart 1.

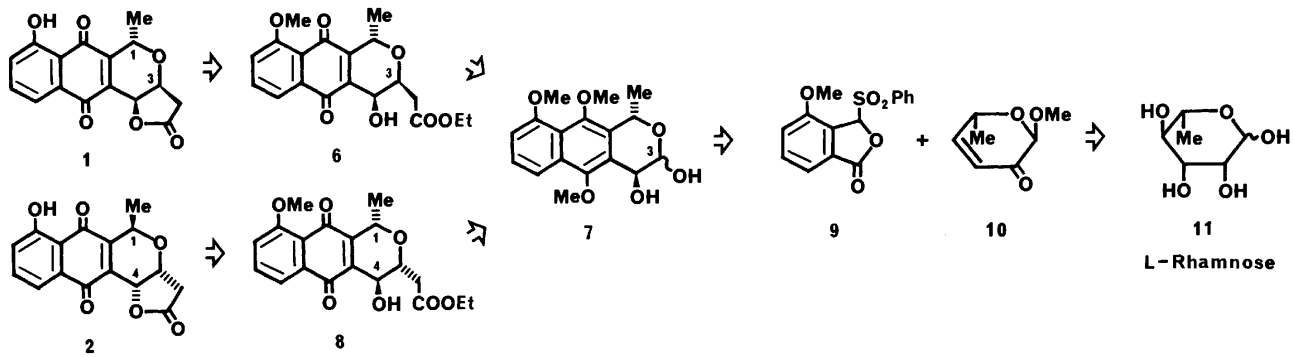
4. These unique structural features as well as the opportunities to develop synthetic strategies for the construction of more diverse analogs of these interesting antibiotics prompted the immense investigations of their syntheses.[7] No fewer than ten syntheses of racemic nanaomycin A (**5**), in particular, have been described with various strategies,[8] however, stereospecific syntheses of these kinds of optically active antibiotics have not been reported to date. Very recently, the first, total syntheses of natural nanaomycin D (**1**) and kalafungin (**2**) were disclosed in our laboratories.[9]

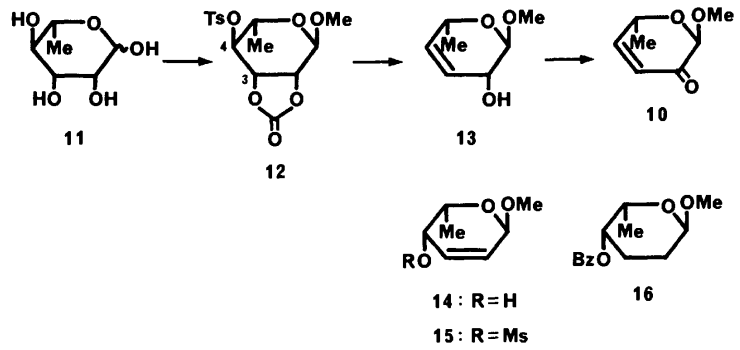
Described herein with full details are the first, enantiospecific total syntheses of nanaomycins D (**1**) and A (**5**), and their enantiomers, kalafungin (**2**) and 4-deoxykalafunginic acid (**5'**) from a common optically active intermediate **7** by the "enantiodivergent" strategy.[10]

The antithetic strategy relating both antipodes **1** and **2** to the starting material, L-rhamnose (**11**) is put forth in Scheme 1. The alcoholysis of the lactone moiety of **1** leads to the hydroxy ester **6**, which in turn leads to the hemiacetal **7** upon application of the indicated retro Michael cyclization and retro Wittig reaction at the C-3 position. On the other hand, the alcoholysis of **2** with the fascinating epimerization at the C-1 and C-4 positions leads to the other hydroxy ester **8**, which returns similarly to the key intermediate **7**. The common intermediate is expected to be derived from condensation of **9**[11] with **10**.

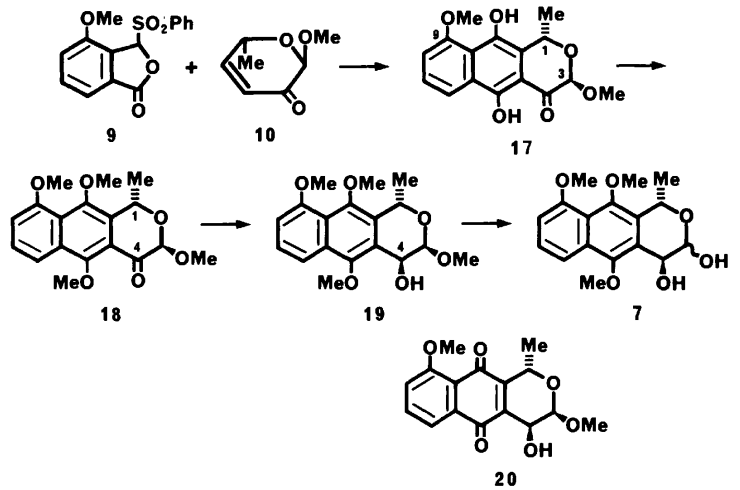
In the synthetic sense (Scheme 2), conversion of L-rhamnose (**11**) to methyl 3,4,6-trideoxy-α-L-*glycero*-hex-3-enopyranosid-2-ulose[12] (**10**) was initially achieved by the following practical procedure. Methyl α-L-rhamnoside, which was prepared from L-rhamnose (**11**), was converted into methyl 2,3-di-*O*-carbonyl-6-



Scheme 1.



Scheme 2.



Scheme 3.

deoxy-4-*O*-tosyl-α-L-mannoside (**12**) in an 80% overall yield by a one-pot reaction with trichloromethyl chloroformate and then tosyl chloride in pyridine. Treatment of **12** with zinc powder and sodium iodide in refluxing aqueous acetonitrile gave, presumably through the corresponding 3,4-epoxide[13] with removal of the carbonate-protecting group, a mixture of the desired unsaturated alcohol, methyl 3,4,6-trideoxy-α-L-*threo*-hex-3-enopyranoside[12] (**13**) and its migrated alcohol, methyl 2,3,6-trideoxy-α-L-*threo*-hex-2-enopyranoside (**14**) in 60 and 28% yields. Oxidation of **13** with pyridinium chlorochromate afforded the stable α,β-unsaturated ketone (**10**) in an 86% yield. The migrated alcohol **14** was efficiently recycled to **13** along with its C-2 epimeric alcohol in an 85% yield by mesylation to give methyl 2,3,6-trideoxy-4-*O*-mesyl-α-L-*threo*-hex-2-enopyranoside (**15**) followed by exposure to potassium carbonate in aqueous tetrahydrofuran to result in the S_N2' type solvolysis. The mixture thus obtained could be similarly converted into the desired ketone **10**. The stereochemistry of **14** was clarified by the ^{1}H NMR study of the corresponding benzoylated compound, methyl 4-*O*-benzoyl-2,3,6-trideoxy-α-L-*threo*-hexopyranoside (**16**), which existed in the $^1C_4$ conformation.

The other starting material, 4-methoxy-3-(phenylsulfonyl)-1(3*H*)-isobenzofuranone (**9**) was synthesized according to the Hauser's conditions.[11]

As shown in Scheme 3, condensation of **10** with the lithium *t*-butoxide generated anion of **9** gave, in an 80% yield, the hydroquinone, (1*S*,3*R*)-5,10-dihydroxy-3,9-dimethoxy-1-methyl-1*H*-naphtho[2,3-*c*]-pyran-4(3*H*)-one (**17**), which was treated with dimethyl sulfate to produce quantitatively (1*S*,3*R*)-3,5,9,10-tetramethoxy-1-methyl-1*H*-naphtho[2,3-*c*]pyran-4(3*H*)-one (**18**). Reduction of **18** with sodium borohydride afforded exclusively (1*S*,3*R*,4*S*)-3,4-dihydro-3,5,9,10-tetramethoxy-1-methyl-1*H*-naphtho[2,3-*c*]pyran-4-ol (**19**) in a 90% yield. The stereoselective hydride delivery is assisted in the desired sense by the *syn* stereodirecting influence of the pyrano oxygen atom[14] as partly depicted in Chart 2, where the C-3 *O*-methyl group would be oriented to be in axial by the anomeric effect[15] as commonly seen in carbohydrates. The (*S*)-con-

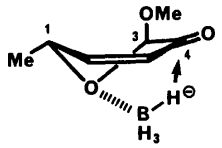


Chart 2.

figuration at the C-4 of **19** was confirmed by the ^{1}H NMR study of the following derivatives **21** ($J_{3,4}$= 3.0 Hz) and **22** ($J_{3,4}$=9.5 Hz), and the reasonable trans-

formation from **21** to **1**. Reaction of **19** with ammonium cerium(IV) nitrate[8b] gave the quinone, (1*S*,3*R*,4*S*)-3,4-dihydro-4-hydroxy-3,9-dimethoxy-1-methyl-1*H*-naphtho[2,3-*c*]pyran-5,10-dione (**20**), which was also derived directly from **17** by reduction with sodium borohydride followed by air oxidation. Acid hydrolysis of **20** gave the corresponding hemiacetal, which, however, was not a useful intermediate for the following Wittig reaction, because the reaction afforded several products in low yields. Then, **19** was hydrolyzed with dil. hydrochloric acid, giving quantitatively the key intermediate, (1*S*,3*RS*,4*S*)-3,4-dihydro-5,9,10-trimethoxy-1-methyl-1*H*-naphtho[2,3-*c*]pyran-3,4-diol (**7**) without epimerization at the C-1 and C-4. The hemiacetal **7** was submitted to Wittig reaction with ethoxycarbonylmethylenetriphenylphosphorane in refluxing toluene to give two products as expected:[8b,16] (1*S*,3*S*,4*S*)-3,4,11,12-tetrahydro-5,9,10-trimethoxy-1-methyl-1*H*-furo[3,2-*b*]-naphtho[2,3-*d*]pyran-12-one (**21**) and ethyl (1*S*,3*R*,4*S*)-3,4-dihydro-4-hydroxy-5,9,10-trimethoxy-1-methyl-1*H*-naphtho[2,3-*c*]pyran-3-acetate (**22**) in 53 and 41% yields, respectively (Scheme 4). The lactone **21** results from a two-step sequence including the intramolecular Michael cyclization of the intermediary Wittig α,β-unsaturated ester and concomitant lactonization of the resultant 3,4-*cis* hydroxy ester such as **6**. The other 3,4-*trans* hydroxy ester **22** results from the Michael cyclization without lactonization. The lactone **21** was treated with ammonium cerium(IV) nitrate[8b] to give, in a 92% yield, 9-*O*-methylnanaomycin D (**23**), which was equivalent to the structure **6**. The ^{1}H NMR spectrum of **23** has already been superimposable on that of nanaomycin D (**1**) except in the phenyl- and *O*-methyl-signals region. De-*O*-methylation of **23** was attempted with two known reagents, boron tribromide[8c] and aluminium chloride.[8b] Reaction with boron tribromide, however, furnished a mixture of nanaomycin D (**1**) and its brominated product, which were detected by thin-layer chromatography only with a solvent system of dichloromethane–chloroform. De-*O*-methylation with aluminium chloride provided (−)-nanaomycin D (**1**) in a 95% yield as a single product identical in all respects including antibacterial activity (Table 1) with an authentic sample of the natural antibiotic, thereby confirming the absolute structure.

On the other hand, the ester **22** was converted by the aforesaid cerium(IV) oxidative demethylation into ethyl (1*S*,3*R*,4*S*)-3,4,5,10-tetrahydro-4-hydroxy-9-methoxy-1-methyl-5,10-dioxo-1*H*-naphtho[2,3-*c*]pyran-3-acetate (**8**), which was treated with aluminium chloride to give ethyl (1*S*,3*R*,4*S*)-3,4,5,10-tetrahydro-4,9-dihydroxy-1-methyl-5,10-dioxo-1*H*-naphtho[2,3-*c*]-pyran-3-acetate (**24**) in an 84% overall yield. On the final stage, the favored epimerization of the C-1 and C-4 positions was realized by exposure to sulfuric acid[7a] in benzene along with some lactonization, followed by refluxing in toluene to complete the lactonization, affording, in a 92% yield, (+)-kalafungin (**2**) identical with an authentic sample of the natural antibiotic in all respects including antibacterial activity (Table 1). This stereocontrolled epimerization indicated that the C-3 stereochemistry was so vital for the subsequent development of the correct chirality at the C-1 and C-4 positions.

Hydrogenolysis of **1** and **2** furnished quantitatively nanaomycin A (**5**) and its enantiomer, 4-deoxykalafunginic acid (**5'**), respectively, the former of

which was identical with the natural antibiotic. Both compounds **5** and **5'** were readily recycled to **1** and **2**, respectively, by air oxidation.[1] Since compound **5'** has not been in the natural sources yet, these results suggest that, also in the biosynthesis, nanaomycin A (**5**) would be derived from nanaomycin D (**1**) by the appropriate reductase.[17]

The antibacterial activities (Table 1) of **1**, **2**, **5**, **5'**, **21**, **22**, **23**, and **24** revealed that the naphthoquinone and lactone portions were positively required for the appearance of stronger activities.

Thus, both antipodes of antibiotics, (−)-nanaomycins (**1** and **5**) and (+)-kalafungins (**2** and **5'**) have been synthesized from L-rhamnose (**11**) through a common key intermediate **7** in overall yields of approximately 18 and 13%, respectively, by the "enantiodivergent" strategy, which is promising for application to the syntheses of both optical antipodes of the other members of this important class of antibiotics.

Experimental

Melting points were determined on a micro hot-stage Yanaco MP-S3 and were uncorrected. IR spectra were recorded on a Hitachi Perkin-Elmer 225 spectrometer, UV spectra on JAS-CO UVIDEC-1 spectrometer, and ^{1}H-NMR spectra with TMS as internal standard on a Varian EM-390 (90 MHz) or a JEOL GX-400 (400 MHz) spectrometer. Optical rotations were measured on a JAS-CO DIP-360 photoelectric polarimeter. Silica gel TLC and column chromatography were performed on Merck TLC 60F-254 and Kieselgel 60, respectively. In general, organic solvents were purified and dried by the appropriate procedures, and evaporation and concentration were carried out under reduced pressure below 30 °C, unless otherwise noted.

The starting material, 4-methoxy-3-(phenylsulfonyl)-1(3*H*)-isobenzofuranone (**9**) was prepared according to the published procedure[11] and recrystallized from ethyl acetate–hexane to give needles: mp 189—191 °C.

Methyl 2,3-Di-O-carbonyl-6-deoxy-4-O-tosyl-α-L-mannoside (12). A) Through the Isolated 2,3-Carbonate: A solution of L-rhamnose monohydrate (**11**; 33.7 g) in methanol (169 ml) with 10% methanolic hydrogen chloride solution (2 ml) was refluxed for 72 h. After neutralization with $NaHCO_3$, the precipitated salt was filtered off and the filtrate was evaporated to a residue, which was dissolved in acetone (170 ml). After filtration, the filtrate was evaporated to give a crude solid of methyl α-L-rhamnoside (33 g).

To a stirred and ice-cooled solution of the crude solid (33 g) in pyridine (330 ml) was added dropwise trichloromethyl chloroformate (22.0 ml), and stirring was continued at room temperature for 1 h. After addition of water (7.3 ml), the mixture was evaporated and co-evaporated with toluene to give a residue, which was partitioned between ethyl acetate and a saturated aqueous $NaHCO_3$ solution. The combined organic layers were washed with a saturated aqueous NaCl solution, dried (Na_2SO_4), and evaporated to give a crude solid of the 2,3-carbonate (38 g). A part of the solid was recrystallized from ethyl acetate to afford plates of the 2,3-carbonate: mp 169—171 °C; $[\alpha]_D^{24}$ −59° (*c* 1.0, $CHCl_3$); IR (KBr) 1810 cm^{-1} (carbonate).

A solution of the crude solid (37.8 g) in pyridine (378 ml) was stirred with tosyl chloride (52.9 g) at 60 °C for 36 h. After addition of ethanol (16 ml), the mixture was evaporated to a residue, which was partitioned between ethyl acetate and a saturated aqueous $NaHCO_3$ solution. The combined organic layers were washed with a saturated aqueous NaCl solution, dried and evaporated to a residue, which was chromatographed on silica gel (1330 g) with 6:1 benzene–ethyl acetate to give a solid. Recrystallization from ethyl acetate–ether gave needles of **12** (53.0 g, 80% from **11**): R_f 0.72 (4:1 benzene–ethyl acetate); mp 99.5—101 °C; $[\alpha]_D^{24}$ +23° (*c* 1.0, $CHCl_3$); IR (KBr): 1816, 1792, and 1179 cm^{-1}; ^{1}H-NMR (90 MHz, $CDCl_3$): δ=1.38 (3H, d, Me, $J_{5,Me}$=6 Hz), 2.48 (3H, s, Me of Ts), 3.40 (3H, s, OMe), 3.86 (1H, dq, H-5, $J_{4,5}$=9.0 Hz), 4.23—4.72 (3H, m, H-2, 3, and 4), 4.93 (1H, s, H-1), 7.40 (2H, d, Ts, J_{AB}=9 Hz), 7.87 (2H, d, Ts).

Found: C, 50.02; H, 5.09; S, 8.90%. Calcd for $C_{15}H_{18}O_8S$: C, 50.27; H, 5.06; S, 8.95%.

B) Without Isolation of the 2,3-Carbonate: The crude methyl α-L-rhamnoside (49.9 g), which was prepared from L-rhamnose monohydrate (**11**; 50 g) as described above, was dissolved in pyridine (500 ml), and trichloromethyl chloroformate (32.1 ml) was added with cooling. After stirring at room temperature for 2 h, to the reaction mixture was added tosyl chloride (103 g), and stirring was continued at 80 °C for another 24 h. The resulting mixture was worked up as described above to give a solid of **12** (79.6 g, 81%), which was used for the next step.

Methyl 3,4,6-Trideoxy-α-L-threo-hex-3-enopyranoside (13) and Methyl 2,3,6-Trideoxy-α-L-threo-hex-2-enopyranoside (14). To a solution of **12** (70.1 g) in 95% aqueous acetonitrile (700 ml) were added NaI (235 g) and Zn powder (102 g), and the suspension was stirred under argon at 75 °C for 36 h and then cooled to room temperature. The suspension was filtered and the insoluble mass was washed with ethyl acetate. The filtrates and washings were combined, washed with 5% aqueous $Na_2S_2O_3$ solution, dried and evaporated at 85 °C under atmospheric pressure to give a residue. This was chromatographed on silica gel (1400 g) with 7:4 carbon tetrachloride–ethyl acetate to give **13** (16.9 g, 60%) and **14** (7.89 g, 28%) having the R_f-values of 0.26 and 0.20 (2:1 benzene–ethyl acetate), respectively.

13: Oil; bp 90 °C (933 Pa); $[\alpha]_D^{24}$ −206° (*c* 1.0, $CHCl_3$) [lit,[12] $[\alpha]_D^{20}$ −74° (*c* 1, $CHCl_3$)]; IR ($CHCl_3$): 1447, 1402, 1371, and 1345 cm^{-1}; ^{1}H-NMR (90 MHz, $CDCl_3$+D_2O): δ=1.29 (3H, d, Me, $J_{5,Me}$=6.5 Hz), 3.49 (3H, s, OMe), 3.76 (1H, broad s, H-2), 4.30 (1H, dq, H-5, $J_{4,5}$=1.5 Hz), 4.71 (1H, s, H-1), 5.90 (2H, apparently s, H-3 and 4, $J_{3,4}$=10.5 Hz).

14: Oil [bp 75 °C (400 Pa)], which, after distillation under reduced pressure, was changed to cottony crystals (mp 45—47 °C); $[\alpha]_D^{24}$ +123° (*c* 1.0, $CHCl_3$); IR (KBr): ≈1620, 1441, 1405, 1393, and 1386 cm^{-1}; ^{1}H-NMR (90 MHz, $CDCl_3$+D_2O): δ=1.30 (3H, d, Me, $J_{5,Me}$=6.5 Hz), 3.45 (3H, s, OMe), 3.55 (1H, sharp m, H-4, half-width of 10.5 Hz), 4.12 (1H, dq, H-5, $J_{4,5}$=2.2 Hz), 4.85 (1H, d, H-1, $J_{1,2}$=3 Hz), 5.88 (1H, dd, H-2, $J_{2,3}$=10.5 Hz), 6.20 (1H, dd, H-3, $J_{3,4}$=6 Hz).

Found: C, 58.06; H, 8.46%. Calcd for $C_7H_{12}O_3$: C, 58.32; H, 8.39%.

Methyl 2,3,6-Trideoxy-4-O-mesyl-α-L-threo-hex-2-enopyranoside (15). A solution of **14** (152 mg) in pyridine (3.0 ml) was stirred with mesyl chloride (0.10 ml) at room temperature for 30 min. After addition of ethanol (0.076 ml), the

mixture was evaporated to a residue, which was partitioned between ethyl acetate and water. The combined organic layers were evaporated to a residue, which was chromatographed on silica gel (10 g) with 5:1 benzene–ethyl acetate followed by recrystallization from ethyl acetate–hexane to give labile needles of **15** (222 mg, 95%): R_f 0.49 (2:1 benzene–ethyl acetate); mp 97—98 °C; $[\alpha]_D^{24}$ +168° (*c* 1.0, $CHCl_3$); IR (KBr): ≈1630 (olefin), and 1179 cm^{-1} (SO_2); ^{1}H-NMR (90 MHz, $CDCl_3$): δ=1.37 (3H, d, Me-5, $J_{5,Me}$=6.5 Hz), 3.06 (3H, s, Ms), 3.45 (3H, s, OMe), 4.26 (1H, dq, H-5, $J_{4,5}$=2.5 Hz), 4.65—4.80 (1H, sharp m, H-4, half-width of 8.0 Hz), 4.92 (1H, d, H-1, $J_{1,2}$=2.0 Hz), 5.95—6.32 (2H, m, H-2 and 3).

Found: C, 43.60; H, 6.08%. Calcd for $C_8H_{13}O_5S$: C, 43.43; H, 5.92%.

*Methyl 4-O-Benzoyl-2,3,6-trideoxy-α-*L*-*threo*-hexopyranoside (16).* A solution of **14** (1.10 g) in pyridine (22.2 ml) was stirred with benzoyl chloride (1.8 ml) at room temperature for 45 min. After addition of ethanol (1 ml), the mixture was evaporated to a residue, which was partitioned between ethyl acetate and a saturated aqueous NaCl solution. The combined organic layers were evaporated to a residue, which was chromatographed on silica gel (95 g) with 10:1 hexane–ethyl acetate to give a syrup of the benzoate (1.73 g, 90.8%): R_f 0.33 (10:1 hexane–ethyl acetate).

A solution of the syrup (235 mg) in ethanol (2.4 ml) was shaken with 5% palladium–carbon and 3-atm hydrogen at room temperature for 12 h, filtered and evaporated to a residue. This was chromatographed on silica gel (23 g) with 10:1 hexane–ethyl acetate to give a syrup of **16** (188 mg, 80%): R_f 0.35 (10:1 hexane–ethyl acetate); $[\alpha]_D^{24}$ −65° (*c* 1.0, $CHCl_3$); IR (neat): 1721, 1605, 1588, 1493, and 1455 cm^{-1}; ^{1}H-NMR (400 MHz, $CDCl_3$): δ=1.195 (3H, d, Me-5, $J_{5,Me}$=6.5 Hz), 1.61 (1H, dddd, H-2eq, $J_{1,2eq}$=2 Hz, $J_{2ax,2eq}$=13.5 Hz, $J_{2eq,3ax}$=4.5 Hz, $J_{2eq,3eq}$=2.5 Hz), 1.92 (1H, ddt, H-3eq, $J_{2ax,3eq}$=4 Hz, $J_{3ax,3eq}$= 13.5 Hz, $J_{2eq,3eq}$=$J_{3eq,4}$=2.5 Hz), 2.02 (1H, tt, H-2ax, $J_{1,2ax}$=4 Hz, $J_{2ax,3ax}$=13.5 Hz), 2.155 (1H, ddt, H-3ax, $J_{3ax,4}$=2.5 Hz), 3.41 (3H, s, OMe), 4.11 (1H, dq, H-5, $J_{4,5}$=1.5 Hz), 4.81 (1H, dd, H-1), 5.06 (1H, sharp m, H-4), 7.46 (2H, t, Bz, *J*=6.85 Hz), 7.57 (1H, t, Bz), and 8.12 (2H, d, Bz).

Found: C, 67.15; H, 7.18%. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%.

*Methyl 3,4,6-Trideoxy-α-*L*-*glycero*-hex-3-enopyranosid-2-ulose (10).* *A) From 13*: To a stirred and ice-cooled solution of **13** (487 mg) in dry dichloromethane (9.75 ml) were added Molecular Sieves 3A powder (1.02 g) and pyridinium chlorochromate (1.46 g), and stirring was continued at room temperature for 30 min. The mixture was diluted with ether and passed through a silica-gel column (12 g) with 1:1 chloroform–ether to give eluates containing **10**. The eluates were evaporated at 75 °C under atmospheric pressure, leaving a pale yellow syrup of **10** (0.41 g, 86%), which was used for the next step: R_f 0.72 (2:1 benzene–ethyl acetate).

An analytically pure sample was obtained by distillation under reduced pressure: bp 74 °C (666 Pa); $[\alpha]_D^{24}$ −58° (*c* 1.0, $CHCl_3$)[lit,[12] $[\alpha]_D^{20}$ −93° (*c* 1, MeOH)]; IR (neat) 1762, 1705, 1618, 1450 1390, and 1378 cm^{-1}; ^{1}H-NMR (90 MHz, $CDCl_3$) δ=1.40 (3H, d, Me, $J_{5,Me}$=7.5 Hz), 3.55 (3H, s, OMe), 4.69 (1H, ddq, H-5, $J_{3,5}$=2.5 Hz, $J_{4,5}$=1.5 Hz), 4.73 (1H, s, H-1), 6.06 (1H, dd, H-3, $J_{3,4}$=10.5 Hz), 6.91 (1H, dd, H-4).

Found: C, 58.84; H, 7.26%. Calcd for $C_7H_{10}O_3$: C, 59.15; H, 7.09%.

B) From 15: A solution of **15** (83.3 mg) in 50% aqueous tetrahydrofuran (0.83 ml) was stirred with K_2CO_3 (156 mg) at 50 °C for 9 h. The mixture was partitioned between ethyl acetate and a saturated aqueous NaCl solution, and the combined organic layers were dried and evaporated at 80 °C under atmospheric pressure to give a residue. This was chromatographed on silica gel (3 g) with 2:1 benzene–ethyl acetate to give, after removal of the solvent under atmospheric pressure, a syrup (48.8 mg) containing **13** and its C-2 epimer.

The syrup was oxidized by the procedure described in the preparation (A) to give a syrup of **10** (40 mg, 72% from **15**).

*(1S,3R)-5,10-Dihydroxy-3,9-dimethoxy-1-methyl-1*H*-naphtho-[2,3-c]pyran-4(3*H*)-one (17).* A solution of lithium *t*-butoxide (7.23 mmol) was initially prepared by adding butyllithium (4.50 ml of 1.6 M† solution, 7.23 mmol) to *t*-butyl alcohol (0.75 ml, 7.93 mmol) in tetrahydrofuran (6.85 ml) at 0 °C under argon. This solution was cooled to −78 °C, and **9** (805 mg, 2.65 mmol) was added in one portion with stirring to generate a slurry of the anion. After 15 min, to the stirred slurry was added a solution of **10** (341 mg, 2.40 mmol) in tetrahydrofuran (1.40 ml) at −78 °C, and stirring was continued at this temperature for 15 min and then at room temperature for 3 h under argon. The reaction mixture was partitioned between ethyl acetate and a saturated aqueous NH_4Cl solution, and the combined organic layers were dried and evaporated to a residue. This was chromatographed on silica gel (14 g) with 5:1 hexane–ethyl acetate followed by recrystallization from ethyl acetate to give yellow needles of **17** (580 mg, 80%): R_f 0.34 (4:1 hexane–acetone); mp 123—125 °C; $[\alpha]_D^{24}$ −304° (*c* 1.0, $CHCl_3$); IR (KBr): 1647, 1631, 1610, and 1588 cm^{-1}; UV (MeOH) λ (ε) 221 (24400), 265 (22800), 268 (23400), 321 (2800), 329 (3210), 386 (2440), and 431 nm (5420); ^{1}H-NMR (90 MHz, $CDCl_3$): δ=1.73 (3H, d, Me-1, $J_{1,Me}$=6.5 Hz), 3.60 (3H, s, OMe-3), 4.09 (3H, s, OMe-9), 5.08 (1H, s, H-3), 5.40 (1H, q, H-1), 7.02 and 8.07 (each 1H, dd, H-6 and 8, *J*=8 and 1.5 Hz), 7.40 (1H, t, H-7, *J*=8 Hz), 9.20 and 12.32 (each 1H, s, OH-5 and 10, *vice versa*).

Found: C, 63.44; H, 5.55%. Calcd for $C_{16}H_{16}O_6$: C, 63.15; H, 5.30%.

*(1S,3R)-3,5,9,10-Tetramethoxy-1-methyl-1*H*-naphtho[2,3-c]-pyran-4(3*H*)-one (18).* A solution of **17** (1.10 g) in acetone (22 ml) was stirred with dimethyl sulfate (1.20 ml) and K_2CO_3 (1.75 g) at 40 °C for 12 h. After further addition of dimethyl sulfate (0.60 ml) and K_2CO_3 (874 mg), stirring was continued at 40 °C for another 12 h. The reaction mixture was partitioned between ethyl acetate and a saturated aqueous $NaHCO_3$ solution, and the combined organic layers were washed with a saturated aqueous NaCl solution, dried and evaporated to give a yellow syrup of **18** (1.2 g), which was used for the next step.

An analytically pure sample was obtained by a silica-gel column chromatography with 9:1 benzene–ethyl acetate to give a yellow syrup: R_f 0.32 (4:1 hexane–acetone); $[\alpha]_D^{24}$ −154° (*c* 1.0, $CHCl_3$); IR ($CHCl_3$): 1701, 1603, 1578, 1569, and 1449 cm^{-1}; UV (MeOH) λ (ε) 221 (24500), 262 (26100), 295 (3860), 305 (4030), 320 (3540), 379 (3190), and 385 nm (Infl., 3450); ^{1}H-NMR (90 MHz, $CDCl_3$): δ=1.69 (3H, d, Me-1, $J_{1,Me}$=6.5 Hz), 3.55 (3H, s, OMe-3), 3.84 (3H, s, OMe), 4.04 (6H, s, OMe ×2), 4.94 (1H, s, H-3), 5.41 (1H, q, H-1), 7.02 and 7.98 (each 1H, d, H-6 and 8, *J*=8 Hz), 7.46 (1H, t, H-7).

Found: C, 64.80; H, 6.15%. Calcd for $C_{18}H_{20}O_6$: C, 65.05; H, 6.07%.

† 1 M=1 mol dm^{-3}.

naphtho[2,3-c]pyran-4-ol (19). A crude sample of **18** (1.20 g) was stirred with $NaBH_4$ (164 mg) in methanol (36 ml) at room temperature for 5 min. The reaction mixture was neutralized with Amberlite CG-50 (H type), filtered and then evaporated to a residue, which was chromatographed on silica gel (50 g) with 1:1 hexane–ethyl acetate followed by recrystallization from ethyl acetate–hexane to afford pale yellow cubics of **19** (1.06 g, 88% from **17**): R_f 0.48 (4:1 benzene–acetone); mp 176—177.5 °C (changed at 168 °C); $[\alpha]_D^{24}$ −97° (*c* 1.0, $CHCl_3$); IR (KBr): 1596, 1572, 1500, 1462, 1448, 1368, and 1266 cm^{-1}; UV (MeOH) λ (ε) 235 (53800), 293 (5620), 307 (7180), 322 (6000), and 337 nm (4740); ^{1}H-NMR (400 MHz, $CDCl_3$): δ=1.67 (3H, d, Me-1, $J_{1,Me}$=7.0 Hz), 3.28 (1H, d, OH-4, $J_{4,OH}$=4.0 Hz), 3.62 (3H, s, OMe-3), 3.82, 4.01 and 4.04 (each 3H, s, OMe×3), 4.95 (1H, d, H-3, $J_{3,4}$= 2.0 Hz), 5.07 (1H, dd, H-4), 5.44 (1H, q, H-1), 6.88 and 7.70 (each 1H, d, H-6 and 8, J=8 Hz), and 7.40 (1H, t, H-7).

Found: C, 64.43; H, 6.52%. Cacd for $C_{18}H_{22}O_6$: C, 64.66; H, 6.63%.

(1S,3R,4S)-3,4-Dihydro-4-hydroxy-3,9-dimethoxy-1-methyl-1H-naphtho[2,3-c]pyran-5,10-dione (20). A) From 19: A solution of **19** (33.5 mg) in acetonitrile (1 ml) was stirred with an aqueous solution (0.48 ml) of ammonium cerium(IV) nitrate (120 mg) at room temperature for 10 min. The reaction mixture was partitioned between ethyl acetate and water, and the combined organic layers were washed with a saturated aqueous NaCl solution, dried and evaporated to a residue. This was chromatographed on silica gel (1.5 g) with 1:1 hexane–ethyl acetate to give a yellow syrup of **20** (28 mg, 91%): R_f 0.19 (2:1 benzen–ethyl acetate); $[\alpha]_D^{24}$−248° (*c* 0.95, $CHCl_3$); IR ($CHCl_3$): 1665, 1660, 1656, 1590, and 1579 cm^{-1}; UV (MeOH) λ (ε) 211 (24500), 248 (14600), 261 (13900), 265 (Infl., 12900), 331 (2480), 385 (Infl., 3830), and 407 nm (4070); ^{1}H-NMR (90 MHz, $CDCl_3$+D_2O): δ=1.50 (3H, d, Me-1, $J_{1,Me}$= 6.5 Hz), 3.53 (3H, s, OMe-3), 3.97 (3H, s, OMe-9), 4.80—5.05 (3H, m, H-1, 3 and 4), 7.20—7.80 (3H, m, H-6,7 and 8).

Found: C, 63.42; H, 5.44%. Calcd for $C_{16}H_{16}O_6$: C, 63.15; H, 5.30%.

B) From 17: An ice-cooled solution of **17** (28 mg) in methanol (0.56 ml) was stirred with $NaBH_4$ (4.2 mg) for 3 min and then neutralized with Amberlite CG-50 (H type). After filtration, the filtrate was vigorously stirred under atmosphere at room temperature for 12 h and evaporated to a residue, which showed two spots having R_f-values of 0.19 and 0.30 on TLC with 2:1 benzene–ethyl acetate. The R_f 0.19-substance was identical with the aforesaid product **20**. Although the R_f 0.30-substance seemed to be the C-4 epimeric alcohol, it was not further investigated.

(1S,3RS,4S)-3,4-Dihydro-5,9,10-trimethoxy-1-methyl-1H-naphtho[2,3-c]pyran-3,4-diol (7). A sample of **19** (516 mg) was dissolved in a mixture of 0.5 M HCl (20.6 ml) and acetic acid (4.1 ml), and the solution was kept at 75 °C for 2 h. After neutralization with a saturated aqueous $NaHCO_3$ solution, the resulting mixture was extracted with ethyl acetate. The extracts were washed with a saturated aqueous NaCl solution, dried and evaporated to a residue, which was chromatographed on silica gel (20 g) with 3:1 benzene–acetone to give a yellow syrup of **7** (477 mg, 97%): R_f 0.22 (4:1 benzene–acetone); $[\alpha]_D^{24}$ −34° (*c* 1.0, $CHCl_3$); IR ($CHCl_3$); 1597, 1573, 1496, 1450, 1372, and 1339 cm^{-1}; UV (MeOH) λ (ε) 235 (61100), 265 (Infl., 940), 297 (6410), 307 (7920), 322 (6640), 337 (5190), 385 nm (Infl., 313); ^{1}H-NMR (90 MHz, $CDCl_3$+D_2O) δ=1.67 (3H, d, Me-1, $J_{1,Me}$=6.5 Hz), 3.81, 4.02 and 4.05 (each 3H, s, OMe ×3), 4.90 (1H, sharp d, H-4, $J_{3,4}\cong$1 Hz), 5.30 (1H, sharp d, H-3), 5.48 (1H, q, H-1), 6.90 and 7.72 (each 1H, d, H-6 and 8, J=7.5 Hz), 7.41 (1H, t, H-7).

Found: C, 63.44; H, 6.56%. Calcd for $C_{17}H_{20}O_6$: C, 63.74; H, 6.29%.

(1S,3S,4S)-3,4,11,12-Tetrahydro-5,9,10-trimethoxy-1-methyl-1H-furo[3,2-b]naphtho[2,3-d]pyran-12-one (21) and Ethyl (1S,3R,4S)-3,4-dihydro-4-hydroxy-5,9,10-trimethoxy-1-methyl-1H-naphtho-[2,3-c]pyran-3-acetate (22). To a solution of **7** (160 mg) in toluene (4.83 ml) was added ethoxycarbonylmethylenetriphenylphosphorane (526 mg), and the mixture was refluxed at 105 °C for 30 h and then evaporated to a residue. This was chromatographed on silica gel (10 g) with 7:1 benzene–ethyl acetate to give **21** (91.6 mg, 53%) and **22** (80.0 mg, 41%) having the R_f-values of 0.44 and 0.57 (3:1 benzene–ethyl acetate), respectively.

21: Pale yellow cubics from ethyl acetate–benzene; mp 232—234 °C (changed at 214 °C); $[\alpha]_D^{24}$ −279° (*c* 1.0, $CHCl_3$); IR (KBr): ≈1790, 1591, 1571, 1448, and 1338 cm^{-1}; UV (MeOH) λ (ε) 215 (22300), 235 (45500), 264 (Infl., 2570), 293 (4570), 309 (5860), 324 (4510), and 340 nm (4060); ^{1}H-NMR (400 MHz, $CDCl_3$): δ=1.57 (3H, d, Me-1, $J_{1,Me}$=7.0 Hz), 2.71 (1H, d, H-11, $J_{11,11'}$=17.5 Hz, $J_{3,11}$=0 Hz), 2.99 (1H, dd, H-11′, $J_{3,11'}$=5.0 Hz), 3.85, 4.03 and 4.07 (each 3H, s, OMe ×3), 4.75 (1H, dd, H-3, $J_{3,4}$=3.0 Hz), 5.37 (1H, q, H-1), 5.58 (1H, d, H-4), 6.93 and 7.72 (each 1H, d, H-6 and 8, J=8.0 Hz), 7.43 (1H, t, H-7).

Found: C, 66.20; H, 5.87%. Calcd for $C_{19}H_{20}O_6$: C, 66.27; H, 5.85%.

22: Yellow syrup; $[\alpha]_D^{24}$ −25° (*c* 1.0, $CHCl_3$); IR ($CHCl_3$): ≈1726, 1591, 1567, 1366, and 1335 cm^{-1}; UV (MeOH) λ (ε) 236 (57400), 265 (Infl., 1550), 296 (6130), 308 (7540), 322 (6220), and 337 nm (4670); ^{1}H-NMR (400 MHz, $CDCl_3$): δ=1.30 (3H, t, Me of Et, J=7.0 Hz), 1.64 (3H, d, Me-1, $J_{1,Me}$=6.5 Hz), 2.63 (1H, dd, H-11, $J_{11,11'}$=15.5 Hz, $J_{3,11}$=9.5 Hz), 3.07 (1H, dd, H-11′, $J_{3,11'}$= 3.5 Hz), 3.78 (3H, s, OMe), 3.92 (1H, dt, H-3, $J_{3,4}$=9.5 Hz), 4.00 and 4.01 (each 3H, s, OMe ×2), 4.221 and 4.224 (each 1H, q, CH_2 of Et), 4.77 (1H, d, OH-4, $J_{4,OH}$=1.0 Hz), 4.86 (1H, broad d, H-4), 5.19 (1H, q, H-1), 6.88 and 7.64 (each 1H, d, H-6 and 8, J=8.0 Hz), and 7.40 (1H, t, H-7).

Found: C, 64.31; H, 6.66%. Calcd for $C_{21}H_{26}O_7$: C, 64.60; H, 6.71%.

9-O-Methylnanaomycin D (23). A solution of **21** (205 mg) in acetonitrile (4.1 ml) was stirred with an aqueous solution (2.6 ml) of ammonium cerium(IV) nitrate (653 mg) at room temperature for 15 min. The reaction mixture was partitioned between ethyl acetate and water, and the combined organic layers were washed with a saturated aqueous NaCl solution, dried and evaporated to a residue. This was chromatographed on silica gel (15 g) with 3:1 benzene–ethyl acetate followed by recrystallization from ethyl acetate–petr. ether to give orange needles of **23** (171 mg, 92%): R_f 0.21 (3:1 benzene–ethyl acetate); mp 214—216 °C (dec.); $[\alpha]_D^{24}$ −65° (*c* 0.5, $CHCl_3$); IR (KBr): ≈1786, ≈1658, and 1585 cm^{-1}; UV (MeOH) λ (ε) 212 (21700), 252 (12400), 265 (Infl., 9600), 386 (3390), and 403 nm (3560); ^{1}H-NMR (90 MHz, $CDCl_3$): δ= 1.56 (3H, d, Me-1, $J_{1,Me}$=6.5 Hz), 2.65 (1H, d, H-11, $J_{11,11'}$= 18 Hz, $J_{3,11}$=0 Hz), 2.96 (1H, dd, H-11′, $J_{3,11'}$=5.0 Hz), 4.05 (3H, s, OMe), 4.69 (1H, dd, H-3, $J_{3,4}$=3 Hz), 5.08 (1H, q, H-1), 5.27 (1H, d, H-4), 7.3—7.9 (3H, m, H-6, 7 and 8).

Found: C, 65.12; H, 4.55%. Calcd for $C_{17}H_{14}O_6$: C, 64.97; H, 4.49%.

Nanaomycin D (1). To a stirred and ice-cooled solution

of **23** (19 mg) in dichloromethane (0.95 ml) was added $AlCl_3$ (190 mg), and stirring was continued at room temperature for 30 min. The reaction mixture was partitioned between chloroform and water, and the combined organic layers were washed with a saturated aqueous NaCl solution, dried and evaporated to a solid, which was recrystallized from ethyl acetate–petr. ether to give dark red rods and/or needles of **1** (17.2 mg, 95%).

An analytically pure sample was obtained by purification on PLC with 3:1 dichloromethane–chloroform followed by recrystallization from ethyl acetate–petr. ether to afford red rods of **1**, which changed into orange needles after a day: R_f 0.41 (3:1 benzene–ethyl acetate); R_f 0.55 (12:4:1 CH_2Cl_2–$CHCl_3$–acetone); red rods: mp 171—173 °C (lit,[1] mp 170—173 °C); orange needles: mp 196—203 °C; $[\alpha]_D^{24}$ −163° (*c* 0.44, $CHCl_3$); IR (KBr): ≈1778, 1766, 1760, 1668, 1651, 1629, and 1452 cm^{-1}; UV (MeOH) λ (ε) 212 (36400), 258 (11200), 265 (Infl., 10200), 385 (Infl., 2890), and 427 nm (4420); ^{1}H-NMR (400 MHz, $CDCl_3$): δ=1.57 (3H, d, Me-1, $J_{1,Me}$=7.0 Hz), 2.71 (1H, d, H-11, $J_{11,11'}$=18 Hz, $J_{3,11}$=0 Hz), 2.97 (1H, dd, H-11′, $J_{3,11'}$=5.0 Hz), 4.69 (1H, dd, H-3, $J_{3,4}$=3.0 Hz), 5.09 (1H, q, H-1), 5.26 (1H, d, H-4), 7.31 and 7.71 (each 1H, dd, H-6 and 8, *J*=8.0 and 2.0 Hz), 7.68 (1H, t, H-7, *J*=8.0 Hz), 11.84 (1H, s, OH-9).

Its IR, UV, and ^{1}H-NMR spectra, and antibacterial activity (Table 1) were identical with those of an authentic sample of the natural antibiotic.

Found: C, 64.14; H, 4.02%. Calcd for $C_{16}H_{12}O_6$: C, 64.00; H, 4.03%.

Ethyl (1S,3R,4S)-3,4,5,10-Tetrahydro-4-hydroxy-9-methoxy-1-methyl-5,10-dioxo-1H-naphtho[2,3-c]pyran-3-acetate (8). A sample of **22** (271 mg) was treated by the procedure described in the preparation of **23** and then worked up to give an orange syrup of **8** (220 mg, 88%): R_f 0.34 (3:1 benzene–ethyl acetate); $[\alpha]_D^{24}$ −269° (*c* 0.5, $CHCl_3$); IR ($CHCl_3$): 1730, 1656, 1626, 1590, 1471, and 1450 cm^{-1}; UV (MeOH) λ (ε) 211 (22000), 247 (13000), 267 (Infl., 11500), 332 (2150), 385 (Infl., 3670), and 396 nm (3520); ^{1}H-NMR (400 Hz, $CDCl_3$): δ=1.28 (3H, t, Me of Et, *J*=7.0 Hz), 1.49 (3H, d, Me-1, $J_{1,Me}$=6.5 Hz), 2.57 (1H, dd, H-11, $J_{3,11}$=9.0 Hz, $J_{11,11'}$=16 Hz), 2.98 (1H, dd, H-11′, $J_{3,11'}$=3.0 Hz), 3.85 (1H, dt, H-3, $J_{3,4}$=9.0 Hz), 4.01 (3H, s, OMe), 4.12 (1H, d, OH-4, $J_{4,OH}$=1.0 Hz), 4.196 and 4.204 (each 1H, q, CH_2 of Et), 4.61 (1H, ddd, H-4, $J_{1,4}$=2.0 Hz), 4.89 (1H, dq, H-1), 7.31 and 7.73 (each 1H, d, H-6 and 8, *J*=8 Hz), and 7.67 (1H, t, H-7).

Found: C, 63.06; H, 5.65%. Calcd for $C_{19}H_{20}O_7$: C, 63.33; H, 5.59%.

Ethyl (1S,3R,4S)-3,4,5,10-Tetrahydro-4,9-dihydroxy-1-methyl-5,10-dioxo-1H-naphtho[2,3-c]pyran-3-acetate (24). A sample of **8** (22.9 mg) was treated by the procedure described in the preparation of **1** and then worked up to give orange crystals of **24** (20.9 mg, 95%): R_f 0.65 (3:1 benzene–ethyl acetate); mp 100—102 °C; $[\alpha]_D^{24}$ −433° (*c* 0.5, $CHCl_3$); IR (KBr): 1728, 1634, 1612, 1572, and 1460 cm^{-1}; UV (MeOH) λ (ε) 213 (28000), 250 (8550), 257 (8640), 264 (Infl., 8250), 272 (9280), 385 (Infl., 2860), and 420 nm (3800); ^{1}H-NMR (90 MHz, $CDCl_3$): δ=1.29 (3H, t, Me of Et, *J*=7.0 Hz), 1.52 (3H, d, Me-1, $J_{1,Me}$=6.5 Hz), 2.54 (1H, dd, H-11, $J_{3,11}$=9.0 Hz, $J_{11,11'}$=16 Hz), 2.98 (1H, dd, H-11′, $J_{3,11'}$=3.0 Hz), 3.85 (1H, dt, H-3, $J_{3,4}$= 9.0 Hz), 3.99 (1H, d, OH-4, $J_{4,OH}$=1 Hz), 4.20 (2H, q, CH_2 of Et, *J*=7.0 Hz), 4.64 (1H, dull d, H-4), 4.87 (1H, dq, H-1, $J_{1,4}$=2.5 Hz), 7.2—7.7 (3H, m, H-6, 7 and 8).

Found: C, 62.21; H, 5.04%. Calcd for $C_{18}H_{18}O_7$: C, 62.42; H, 5.24%.

Kalafungin (2). To a stirred and ice-cooled solution of **24** (16.5 mg) in benzene (0.34 ml) was added conc. H_2SO_4 (0.11 ml), and stirring was continued at room temperature for 30 min. After cooling to 5 °C, the reaction mixture was partitioned between ice-cooled ethyl acetate and water. The combined organic layers were washed sequentially with saturated aqueous $NaHCO_3$ and NaCl solutions under ice-cooling, dried and evaporated to a residue, which showed two spots having R_f-values of 0.55 and 0.32 on TLC (12:4:1 CH_2Cl_2–$CHCl_3$–acetone; **24** R_f 0.70). Their R_f-values were identical with those of kalafungin (**2**) and ethyl kalafunginate, the latter of which was derived from kalafungin according to the published procedure.[2b]

The residue was dissolved in toluene (0.4 ml), and the resulting solution refluxed at 105 °C for 7 h and then evaporated to a solid, which was recrystallized from ethyl acetate–petr. ether to give red rods of **2** (13.1 mg, 92%).

An analytically pure sample was obtained by purification on PLC with 3:1 dichloromethane–chloroform followed by recrystallization from ethyl acetate–petr. ether to afford red rods of **2**: R_f 0.41 (3:1 benzene–ethyl acetate); R_f 0.55 (12:4:1 CH_2Cl_2–$CHCl_3$–acetone); mp 171—173 °C; $[\alpha]_D^{24}$ +160° (*c* 0.30, $CHCl_3$)[lit,[2] mp 163—166 °C; $[\alpha]_D^{25}$+159° (*c* 1, $CHCl_3$)].

Its IR, UV, and ^{1}H-NMR spectra, and TLC-behavior were identical with those of the aforesaid nanaomycin D (**1**), and also with those of an authentic sample of the natural kalafungin (**2**). The antibacterial activity was also identical with those of the natural antibiotic as shown in Table 1.

Found: C, 64.19; H, 4.06%. Calcd for $C_{16}H_{12}O_6$: C, 64.00; H, 4.03%.

Nanaomycin A (5). A solution of **1** (16 mg) in ethanol (3 ml) was shaken with platinum oxide and 3-atm hydrogen at room temperature for 1 h, filtered and evaporated to give orange crystals of **5** (15.7 mg, 98%).

An analytically pure sample was obtained by purification on PLC with 3:2 benzene–acetone followed by recrystallization from ethanol to give orange needles of **5**: R_f 0.20 (3:1 benzene–acetone; **1**: R_f 0.68); mp 179—181 °C (lit,[5] mp 178—180 °C); $[\alpha]_D^{20}$ −21° (*c* 0.4, $CHCl_3$); IR ($CHCl_3$): 1714, 1663, 1645, 1620, and 1576 cm^{-1}; UV (MeOH) λ (ε) 248 (11800), 273 (14400), 385 (Infl., 3760), and 420 nm (5450); ^{1}H-NMR (90 MHz, $CDCl_3$): δ=1.58 (3H, Me, $J_{1,Me}$=7 Hz), 2.33 (1H, ddd, H-4, $J_{1,4}$=2 Hz, $J_{3,4}$=10 Hz, $J_{4,4'}$=19 Hz), 2.72 (2H, d, CH_2-11, *J*=6.5 Hz), 2.87 (1H, dd, H-4′, $J_{3,4'}$=3 Hz), 4.34 (1H, m, H-3), 5.04 (1H, dq, H-1), 7.2—7.7 (3H, m, H-6,7, and 8), 8.8 (1H, broad signal, COOH), 12.03 (1H, s, OH-9).

Its IR, UV and ^{1}H-NMR spectra were identical with the published data of the natural antibiotic.[5]

Found: C, 63.54; H, 4.56%. Calcd for $C_{16}H_{14}O_6$: C, 63.57; H, 4.66%.

4-Deoxykalafunginic Acid (Enantiomer of Nanaomycin A) (5′). A sample of **2** (15 mg) was hydrogenated by the procedure described in the preparation of **5** to give orange crystals of **5′** (14.5 mg, 97%), which was purified to afford needles: R_f 0.20 (3:1 benzene–acetone); mp 179—181 °C; $[\alpha]_D^{20}$ +21° (*c* 0.4, $CHCl_3$).

Its IR, UV, and ^{1}H-NMR spectra and TLC-behavior were identical with those of nanaomycin A (**5**).

Found: C, 63.44; H, 4.49%. Calcd for $C_{16}H_{14}O_6$: C, 63.57; H, 4.66%.

We are grateful to Prof. Sumio Umezawa, Institute of

Bioorganic Chemistry, and Prof. Hamao Umezawa, Institute of Microbial Chemistry, for their generous support of our program. We also thank Prof. Satoshi Ōmura, Kitasato University and the Kitasato Institute, and Dr. Hiroshi Naganawa, Institute of Microbial Chemistry, for their generous gifts of natural nanaomycin D and kalafungin, and indebted to Mr. Saburo Nakada for elemental analyses.

(Received November 19, 1984)

Dechlorination of polychlorobenzenes over Fe_3O_4 was investigated by a pulse micro-reactor technique. Dechlorinations of various polychlorobenzenes in hexane and cyclohexane were carried out in the gas phase at the temperatures ranging from 498 to 623 K. In the presence of such hydrogen donating solvents, dechlorination was shown to proceed almost exclusively. The relative rates of dechlorination were measured by gas chromatography. It was found that the solvents used to dissolve polychlorobenzenes plays a role of a hydrogen donor in this reaction. The different rates among unequivalent chlorine atoms in a molecule were interpreted by the effect of steric acceleration caused by the neighboring chlorine atom(s). The reaction will probably proceed *via* hydrogenolytic cleavage of C-Cl bonds.

Recently, environmental contamination with polyhalogenated aromatic compounds has been a serious problem in many countries. For the first time, poisoning caused by polychlorinated biphenyls attracted the public attention, which stimulated the investigations on physical and biological properties, as well as chemical reactions, of other polyhalogenated aromatics.[1] Considerably large number of researches concerning their occurrence in environment, hazard, toxicity, and metabolism were reported.[2] And dehalogenation of polyhalogenated aromatic compounds have been investigated rather extensively in the view point of their detoxication. In this respect, several photochemical dehalogenation procedures have been reported in this decade.[3,4] However, the chemical behaviors of polyhalobenzenes have not been studied so extensively as polychlorobiphenyls.

In our previous reports, thermal decomposition of tribromobenzenes[5] and photochemical dehalogenation of polyhalobenzenes in hexane solution[6] were surveyed and their mechanism was discussed. From these experiments, the reactivities of halogen (Cl or Br) atoms occupying different positions were interpreted in terms of steric acceleration. In this paper, the authors wish to report an efficient method for the dechlorination of polychlorobenzenes by Fe_3O_4 in the presence of hexane or cyclohexane.

Experimental

Materials. Triiron tetraoxide (Fe_3O_4) was prepared by hydrolyzing a 1:1 (molar ratio) mixture of iron(II) and iron(III) chlorides with urea in aqueous solution. Under these conditions, fine particles of Fe_3O_4 were produced, their average size being determined to be 8.0 nm in diameter from the line broadening of the powder X-ray diffraction lines.

Some of polychlorobenzenes used in this investigation were prepared by a combination of direct halogenation and nitration followed by reduction and the Sandmeyer reaction (replacement by Cl) of appropriately halogenated benzenes and anilines. Commercially available materials were used after purification by distillation or by chromatography. All of polychlorobenzenes were identified by their melting and/or boiling points and by spectral properties.

Reactions. Dechlorination of polychlorobenzenes over Fe_3O_4 was carried out in a stream of helium as a carrier gas by use of a pulse micro-reactor technique in combination with gas chromatography for analysis.[7] The products and the residual reactant were determined quantitatively by means of gas chromatography. Gas chromatographic analyses were carried out on a Shimadzu GC-4B PFT apparatus equipped with a PEG 20 M column (glass, 3 mm×2 m). Details of the apparatus for the reactions were described in our previous paper.[8] The hexane or cyclohexane solution of polychlorobenzene was injected in portions (each 1.0 μl) to the reaction chamber containing 550 mg of Fe_3O_4.

Results and Discussion

Dehalogenation Activity and Activation of Fe_3O_4 by Hydrogen Donating Solvents. Newly prepared Fe_3O_4 is inactive towards dechlorination of polychlorobenzenes. For this reason, a pretreatment procedure was contrived in order to activate the new Fe_3O_4. While we are investigating the dechlorination in hexane solution, the treatment by hexane was shown to be effective for the activation of Fe_3O_4 by chance. And the dechlorination proceeded smoothly when a hexane solution of polychlorobenzene was injected to the reaction column containing pretreated Fe_3O_4. By the further examination with various solvents, Fe_3O_4 was shown to be activated by the pretreatment with hydrogen donating solvents, such as hexane, cyclohexane, and tetraline. Reactivity of Fe_3O_4 towards dehalogenation was influenced considerably by the nature and the amount of the hydrogen donor used for the pretreatment.[9]

Figure 1 shows the reactivity of Fe_3O_4 as a function of the amount of hexane used for the pretreatment. In this figure, the ordinate is scaled by an arbitrary unit proportional to the amount of the dechlorination product of 1,2,3-trichlorobenzene used as a probe for the reactivity towards dechlorination. In the process of the pretreatment, hydrogen was thought to be supplied to the surface of Fe_3O_4 from the hydrogen donating solvent. The hydrogen uptake of Fe_3O_4 was proven by the fact that a small amount of benzene was detected

†On leave from Department of Chemistry, Jilin University, Chanchun, People's Republic of China.

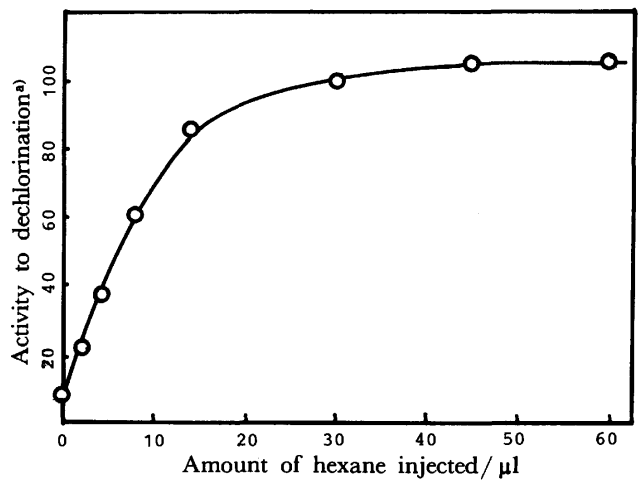

Fig. 1. Effect of the amount of hexane used for the pretreatment on the activity of Fe_3O_4 at 623 K (Amount of Fe_3O_4; 13.8 mg.

during the pretreatment of Fe_3O_4 by cyclohexane at 623 K. Since gaseous hydrogen reduces Fe_3O_4 to metallic iron under similar conditions,[10] the surface of Fe_3O_4 might be partly be reduced to Fe(0) during the pretreatment. In the case shown in Fig. 1, the Fe_3O_4 system seemed to have reached to an equilibrium after the pretreatment by 60 μl of hexane (as can be deduced from the plateau of the reactivity *vs.* the amount of hydrogen donor curve in this figure). The pretreated Fe_3O_4 showed the diffraction lines of original Fe_3O_4 in its powder X-ray spectrum, however.

Fe_3O_4 could be activated more effectively by use of a hydrogen donor stronger than hexane. Thus, Fe_3O_4 activated by 1,2,3,4-tetrahydronaphthalene (tetraline) is more reactive towards dechlorination. Naphthalene was detected as a product on passing tetraline over Fe_3O_4, rendering another support for the dehydrogenation on the surface of Fe_3O_4. On the other hand, benzene is little effective for the activation, and Fe_3O_4 shows no activity even after passing a considerable amount of benzene over the newly prepared Fe_3O_4. During the process of pretreatment by hydrogen donor, the color of Fe_3O_4 powder changed from dark brown to dark grey getting still darker after used for dechlorination.

Dechlorination of Polychlorobenzenes over Fe_3O_4. The dechlorination was carried out at first with the hexane solution of polychlorobenzene at 623 K, where the vaporized solvent played a part of hydrogen donor in the reaction, by use of the fine powder of Fe_3O_4 (550 mg) prepared as described in the experimental section and pretreated by 500 μl of hexane. Further pretreatment did not improve the activity to a measurable extent. The results are summarized in Table 1.

We have already correlated the migrating ability of the halogen atoms of polyhalobenzenes with the steric and the electronic factors during the Jacobsen type rearrangement[11] and also during the photo-dehalo-

genation.[6] In connection with these previous studies, we have paid much attention on the effect of the number and the positions of chlorine atoms on their reactivities, *i. e.*, the ease of removal. In this series of experiments with Fe_3O_4, the polychlorobenzene tends to be more reactive in the following order: 1,3,5-trichloro<1,4-dichloro<1,3-dichloro<monochloro<1,2,4-trichloro<1,2-dichloro<1,2,3,5-tetrachloro<1,2,3-trichloro<1,2,3,4-tetrachloro<pentachloro<hexachloro derivative. In general, the dechlorination becomes easy with the increase in the steric hindrance caused by the neighboring chlorine atoms and also by the buttressing effect[12] of the next neighbor chlorine atoms. Additional isolated halogen atom(s) on the ring tend to deactivate the dechlorination reaction as evidenced by the first four compounds of the above sequence. In other words, hexachlorobenzene is the most reactive, and the reactivity decreases in the following order: Polychlorobenzene having five adjacent Cl atoms> that having four adjacent Cl atoms>those having three adjacent Cl atoms>those having two adjacent Cl atoms>those having isolated Cl atom(s) only. For example, 1,2,3-trichlorobenzene is the most reactive and 1,3,5-trichloro derivative the least reactive among isomeric trichlorobenzenes. When compared intramolecularly, the most crowded chlorine atom tends to be eliminated most easily. Thus the dechlorination of 1,2,3-trichlorobenzene gives *m*-dichlorobenzene most predominantly by the elimination of the most hindered 2-chlorine atom. Similarly, 1,2,4-trichlorobenzene is the most predominant product by the dechlorination of 1,2,3,4-tetrachlorobenzene. The results are very similar to the photochemical dechlorination of polychlorobenzenes in hexane.[6] Hydrogen chloride was not detected as a gaseous product in any runs carried out over the newly pretreated Fe_3O_4.[9] When cyclohexane was used as a solvent, nearly the same results as in hexane were obtained.

Dechlorinations of trichlorobenzene isomers dissolved in hexane and cyclohexane were carried out over Fe_3O_4 in the temperature range of 498—623 K in order to examine the dependence on temperature. The temperature affected the products of the reaction in a very similar way when hexane and cyclohexane solutions were dechlorinated. Thus, only the results on their hexane solutions are illustrated in Fig. 2 as a typical example. In these runs, Fe_3O_4 was again pretreated by 500 μl of cyclohexane. The difference in the reactivity among the positional isomers is mainly determined by the circumstances of chlorine atoms in the molecule. At higher temperatures, chlorobenzene was also formed. Although in a low yield, 1,2,3-trichlorobenzene was found as a product of the reaction over Fe_3O_4 of 1,2,4-trichlorobenzene carried out at lower temperatures (Fig, 2(b)). Formation of the more crowded isomer is especially interesting. It can be a product of intramolecular rearrangement on which we have discussed previously with tribromobenzenes.[11] However,

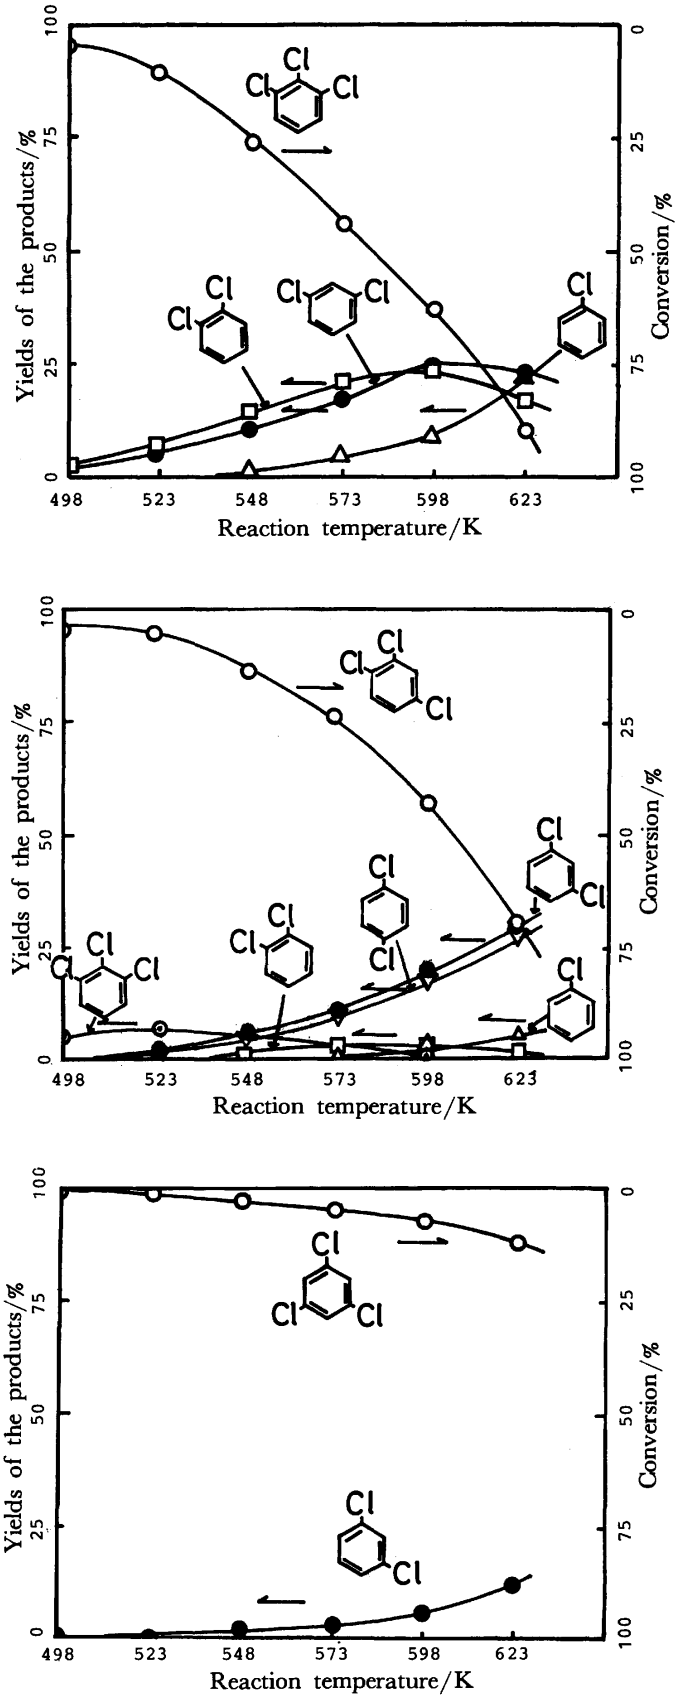

Fig. 2. Temperature dependence of the dechlorination products of isomeric trichlorobenzenes (on 550 mg of Fe_3O_4 pretreated with 500 μl of hexane). (a) 1,2,3-Trichlorobenzene, (b) 1,2,4-trichlorobenzene, and (c) 1,3,5-trichlorobenzene.

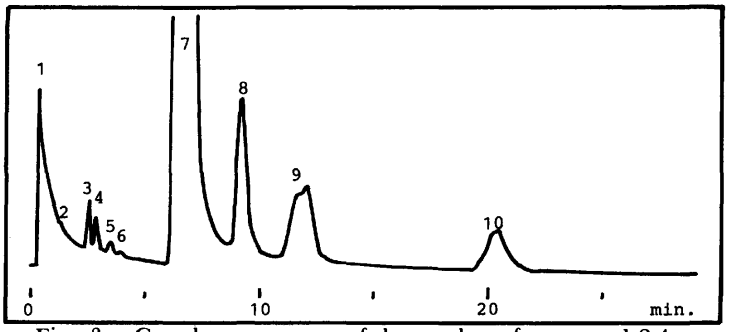

Fig. 3. Gas chromatogram of the products from neat 1,2,4-trichlorobenzene passed over Fe_3O_4 without pretreatment at 623 K. The numbers in this figure correspond to those of the products in Table 2.

further investigation is necessary to conclude the mechanism of its formation.

The dechlorination did not proceed when the benzene solution was injected, probably because benzene is a poor hydrogen donor in this reaction.

Dechlorination carried out by injecting neat polychorobenzene (chlorobenzene, *o*-dichlorobenzene, *m*-dichlorobenzene, and 1,2,4-trichlorobenzene) over pretreated Fe_3O_4 gave dechlorination products only in extremely low yields (Table 2). Alternatively, isomerized and highly substituted polychlorobenzenes were also detected as products. As an example, the gas chromatogram of the products from 1,2,4-trichlorobenzene is shown in Fig. 3. They might be formed secondarily by the substitution reactions by free chlorine atom (free radical) which is generated primarily by the cleavage of C–Cl bond, because the pattern of the substitution is rather random and suggestive of free radical reactions. The results resemble to those of the thermal decomposition of polybromobenzenes.[5)]

In conclution, the following scheme can explain the overall reactions: (i) Hydrogen is supplied from hydrogen donor (solvent) prior to the dechlorination. (ii) Cleavage of C–Cl bond proceeds by the catalysis of Fe_3O_4 forming polychlorophenyl free radical. (iii) Generated free radical receives hydrogen very promptly from a hydrogen donor molecule or from the surface of partly hydrogenated Fe_3O_4. Another path alternative to (ii) and (iii) is also possible, in which (ii′) C–Cl bond is hydrogenolytically cleaved on the surface of the partly reduced Fe_3O_4 containing hydrogen. Chlorine atom formed in the second stage ((ii) or (ii′)) might be bound rather tightly on the surface. Formation of iron chloride is probable but not detected by any means (powder X-ray, surface IR, *etc.*). At present there is no decessive evidence to differentiate the two alternative mechanism.

The authors are grateful to Miss Harue Okada for her assistance to this investigation.

9) Repeated injection of the sample causes a gradual decrease in the dechlorination activity of Fe_3O_4. The activity tends to be constant after several (5 to 7) times of injection. Fe_3O_4 in this state still retains about 60% of initial activity. The decreased activity could be regained partly (60 to 70%) by injecting sufficient hexane as a hydrogen donor, some chlorinated hydrocarbons being released from the Fe_3O_4 powder during the process.

(Received November 22, 1984)

Azomethine proton chemical shifts were measured for series of *N*-benzylideneanilines; $C_6H_5CH{=}NC_6H_4X$-4, 4-$YC_6H_4CH{=}NC_6H_5$, 4-$NMe_2C_6H_4CH{=}NC_6H_4X$-4, 4-$YC_6H_4CH{=}NC_6H_4NMe_2$-4, 4-$NO_2C_6H_4CH{=}NC_6H_4X$-4, 4-$YC_6H_4CH{=}NC_6H_4NO_2$-4, and 4-$YC_6H_4CH{=}NC_6H_3(CH_3)_2$-2,6. It was found that for *N*-benzylideneanilines carrying the variable substituents X on the anilino benzene ring the azomethine protons undergo upfield shifts with increasing electron-withdrawing property of X, whereas those for *N*-benzylideneanilines carrying the variable substituents Y on the benzylidene benzene ring exhibited expected lowfield shifts with increasing electron-withdrawing property of Y. ^{13}C-H coupling constants for azomethine carbon-hydrogen bonds ($J(^{13}C$-H)) were also measured for several derivatives of 4-$NO_2C_6H_4CH{=}NC_6H_4X$-4, 4-$YC_6H_4CH{=}NC_6H_4NO_2$-4, and 4-$YC_6H_4CH{=}NC_6H_3(CH_3)_2$-2,6. In contrast with the substituent effects on the azomethine proton chemical shifts, the coupling constant increases with increasing electron-withdrawing property of the substituent X or Y, regardless of the position of the substituents, indicating that a through-bond electronic effect of the substituent is a predominant factor to determine the magnitude of the coupling constant. These results show that the anomalous substituent effects on the azomethine proton chemical shifts are a general phenomenon in *N*-benzylideneanilines which carry variable substituents on the anilino benzene ring, and support our previous proposition that the anomaly is likely to originate primarily from the change of molecular conformation of these *N*-benzylideneanilines in solution.

Although inverse substituent effects on the azomethine proton chemical shifts in *N*-benzylideneanilines (for example, 4-NO_2 substitution on the anilino benzene ring (ring A) causes an upfield shift of the azomethine proton) have been reported by several groups,[1] only a few systematic studies have been made to elucidate the anomalos substituent effects.[1e,1f,2] In a previous paper, we have suggested that the anomalous effect of the 4-NO_2 group is likely to originate primarily from the change of molecular conformation (twist angle θ_N) induced by the 4-NO_2 substitution.[3] We have also reported the ^{13}C-NMR spectra of a wide variety of *N*-benzylideneanilines, and demonstrated, on the basis of nonadditivity of the multiple substituent effects on the azomethine carbon chemical shifts, that in disubstituted derivatives such as 4-$NO_2C_6H_4$-$CH{=}NC_6H_4X$-4, and 4-$YC_6H_4CH{=}NC_6H_4NMe_2$-4 the twist angle θ_N may be a function of electronic properties of the substituents X and Y.[4] It is therefore of interest to investigate the substituent effects on the azomethine proton chemical shifts for *N*-benzylideneanilines with a variety of substituents.

In the present study, the azomethine proton chemical shifts have been measured for six series of *N*-benzylideneanilines, **1**—**6**. (Scheme 2). In order to assist understanding the nature of the substituent effects on the azomethine proton chemical shifts, ^{13}C-H coupling constants for the azomethine carbon-hydrogen bonds

for some of the derivatives of **7**, which may be regarded as model compounds taking considerably twisted conformations.[5,6]

First, the results on the anomalous substituent effects on the azomethine proton chemical shifts are presented and the origin of the anomaly will be discussed. Second, efficiency of transmission of the substituent effects will also be briefly discussed on the basis of the results of the coupling constants. The present results support our previous proposition that coformational changes with substituents will be an important factor to cause the anomalous substituent effects on the azomethine proton chemical shifts in *N*-benzylideneanilines.

Results

Azomethine Proton Chemical Shifts. *N*-Benzylideneanilines, **1**—**4**, were prepared and their azomethine proton chemical shifts were measured under the conditions corresponding to infinite dilution using $CDCl_3$ as a solvent. The results are summarized in Table 1.

Examination of Table 1 indicates that for *N*-benzylideneanilines, **2**, **4**, and **6**, which carry the variable substituents Y on the benzylidene benzene ring (ring B), their azomethine proton chemical shifts tend to undergo downfield shifts with increasing the electron-withdrawing property of substituents Y to give normal substituent effects. In a striking contrast, those of **1**, **3**, and **5**, in which the variable substituents X are on the anilino benzene ring (ring A), exhibit anomalous upfield shifts with increasing electron-withdrawing property of the substituents X (inverse substituent effects). Careful inspection of Table 1 also reveals that the azomethine proton chemical shifts in **5** remain roughly constant independent of the electron-withdrawing groups such as CO_2Et, CN, and NO_2. These trends can well be seen in Figs. 1—3 in which the chemical shifts are plotted against Hammett σ constants.[7] The ρ values and correlation coefficients are shown in Table 2 in which a positive sign in the ρ values refers to the inverse substituent effect and a negative sign refers to the normal substituent effett. Table 3 depicts 4-NO_2 and 4-NMe_2 group-induced shifts of the azomethine proton chemical shifts in going from **2** to **6**, and to **4**, respectively.

^{13}C-H Coupling Constants. The $J(^{13}C$-H) values were also measured for the series of **5**, **6**, and **7**, and are also shown in Table 1 together with those of **1** and

4	−0.13	0.976
5	+0.06	0.886
5[b)]	+0.09	0.991
6[c)]	−0.15	0.956

a) Regression analyses were carried out with relative values ($\delta_H-\delta_X$ or $\delta_H-\delta_Y$) of the chemical shifts. b) The chemical shifts of **5h**, **5i**, and **5j** were omitted in the regression analysis. c) The chemical shift of **6f** was omitted in the regression analysis.

2 reported by Inamoto *et al.*[1d)] As shown in Table 1, the $J(^{13}C-H)$ values for all the series studied increase with increasing electron-withdrawing property of the substituents X or Y regardless of the positions of the substituents, which is in sharp contrast with the results of the azomethine proton chemical shifts. It is also clear that the $J(^{13}C-H)$ values of the disubstituted derivatives

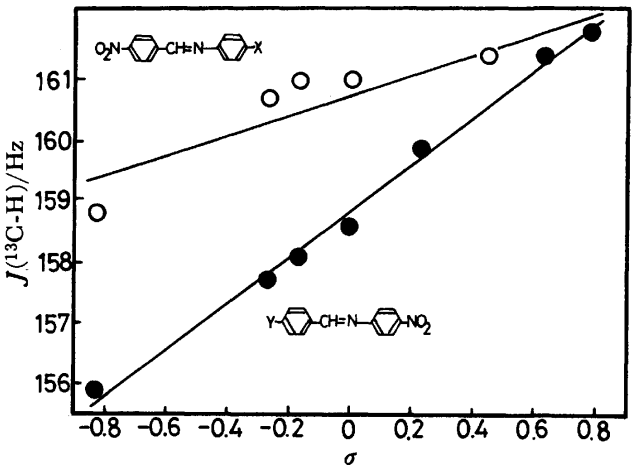

Fig. 4. Plot of $J(^{13}C-H)$ *vs.* Hammett σ Constants in **5** and **6**.

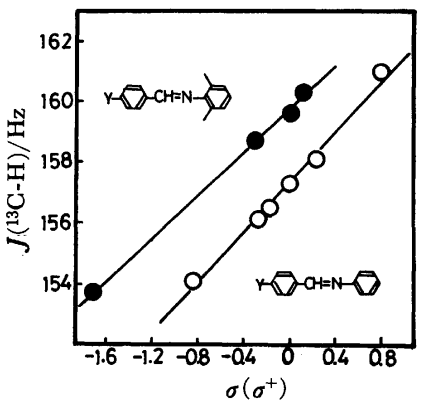

Fig. 5. Plot of $J(^{13}C-H)$ *vs.* Hammett σ^+ and σ Constants in **7** and **2**, respectively.

5 and **6** are greater than those of the monosubstituted derivatives **1** and **2**, respectively. Comparison of the $J(^{13}C-H)$ values between **2** and **7** indicates that replacement of two hydrogen atoms by the 2,6-dimethyl groups on the ring A usually increases the $J(^{13}C-H)$ values. Plots of the $J(^{13}C-H)$ values of **5**, **6**, and **7** against Hammett σ or σ^+ constants result in linear relationships as shown in Figs. 4 and 5. In Fig. 5, the Hammett plot is also shown for **2** for the sake of comparison. The ρ values and correlation coefficients are listed in Table 4.

Discussion

Inverse Substituent Effects on the Azomethine Proton

Chemical Shifts. As previously found by other workers,[1] the inverse substituent effect on the azomethine proton chemical shifts in **1** was also observed in the present study. Furthermore, the anomalous effects of the 4-substituents were shown to be a general phenomenon since the inverse substituent effects were also found for **3** and **5** which respectively carry 4′-NMe_2 and 4′-NO_2. The anomalous substituent effects in **1**, **3**, and **5** become more clear when we compare them with the substituent effects on the $J(^{13}C-H)$ values and the azomethine carbon chemical shifts. The comparison reveals that a principal controlling factor of the azomethine proton chemical shifts is different from that of the $J(^{13}C-H)$ values and the azomethine carbon chemical shifts. For example, the azomethine carbon chemical shifts of **5a**, **5d**,and **5j** are reported 151.46 (ppm/TMS in $CDCl_3$), 157.38, and 159.89, respectively, indicating that the azomethine carbon chemical shifts suffer substituent electronic effects.[4] The $J(^{13}C-H)$ values for the same series are, as shown in Table 1, 158.8 (Hz), 161.0, and 161.8, respectively. It is well known that the $^{13}C-H$ coupling constant is a function of *s* character of the C–H bond.[8] The above trend clearly indicates that the *s* character of the azomethine carbon–hydrogen bonds increases with increasing electron-withdrawing properties of the substituents X in **5**. These expected changes of the azomethine carbon chemical shifts and the $J(^{13}C-H)$ values indicate that through-bond electronic effects of the substituents X are important to determine the mode of the substituent effects on the $J(^{13}C-H)$ values and the azomethine carbon chemical shifts, whereas the azomethine proton chemical shifts will be governed by some other effects induced by the substituents. This does not mean that the through-bond electronic effect is absent as a controlling factor of the azomethine proton chemical shifts; it is hidden under the other effects. It has been once suggested[9] that the anomalous substituent effect of 4-NMe_2 group, for example, could be ascribed to dominance of the inductive effect over the resonance effect because it was then thought that *N*-benzylideneanilines take generally twisted conformations in solution regardless of the substituents on them. However, the present study clearly indicates that this view is not sufficient to explain the inverse substituent effects since the azomethine carbon chemical shifts and the $J(^{13}C-H)$ values suffer the normal substituent electronic effects, which indicates that the azomethine protons must also suffer (though not observed) similar substituent effects.

The present findings are consistent with our previous proposition that the inverse substituent effect may arise primarily from the change of the twist angle θ_N which subsequently changes the contribution of the paramagnetic deshielding effect of the ring A exerted on the azomethine proton. Actually, it is strongly suggested by Zollinger[10] and Kubota[11] that **5a** will take a nearly planar confromation in solution. Our previous NMR study also supports the view,[4] and furthermore, implies that the twist angle θ_N may decrease in going from X=NO_2 to NMe_2 in **5**. Under these circumstances, the paramagnetic deshielding effect of the ring A will greatly increase to result in the anomalous lowfield shift in **5a**, compared with, for example, **5j**. Since the azomethine carbon chemical shift as well as the $J(^{13}C-H)$ undergoes, as described above, the expected change upon the introduction of the electron-releasing groups, the electron density on the azomethine carbon must increase and the *s* character of the azomethine carbon–hydrogen bond must decrease in going from **5j** to **5a**. This should lead to upfield shift of the azomethine proton in going from **5j** to **5a**. The observed low field shift with increasing electron-donating property of the substituents X strongly suggests that change of the chemical shift caused by the paramagnetic deshielding effect (caused by the change of the twist angle θ_N) is larger than that by the through-bond electronic effect of the substituent X.

Comments should also be made on the findings that a better correlation of the azomethine proton chemical shifts with Hammett σ constants (correlation coefficient 0.991) was found when the electron-withdrawing groups (4-CO_2Et, 4-CN, and 4-NO_2) were excluded in the regression analysis, and that the chemical shifts almost remain constant for the derivatives bearing these substituents. In a previous paper,[4] we reported that the correlation coefficients for the azomethine carbon chemical shifts *vs.* Hammett σ and σ^+ constants in **5** are 0.978 and 0.999, respectively. As shown in Table 4, that for the $J(^{13}C-H)$ *vs.* Hammett σ constants is 0.928. Based on these values, the linearity of the azomethine proton chemical shifts with Hammett σ constants should also be similarly good with a *negative* ρ value if they suffer only the substituent electronic effects. The good correlation with a *positive* ρ value could imply that the paramagnetic deshielding effect (and hence the twist angle θ_N) is linearly changed with the substituent electronic effects.

The small variations of the chemical shifts in **5h**, **5j**, and **5i** could be interpreted in terms of combined effects of 4′-NO_2 group and minor conformational changes among these derivatives. Thus, the 4′-NO_2 group decreases electron density on the C–H bond so that the second electron-withdrawing group such as 4-CN and 4-NO_2 is not very effective to cause significant change of the chemical shift. Also if the twist angles θ_N among these derivatives are similar to each other, the ring current effects exerted on the azomethine proton may also be similar to each other to give roughly the same chemical shifts. It is not unreasonable to assume that the twist angles θ_N among **5h**, **5j**, and **5i** do not differ as much as they do among the derivatives bearing the electron-releasing groups such as 4-NMe_2 and 4-OCH_3, since through-conjugative interaction between the 4′-NO_2 and the 4-substituent, which is important to determine the twist angle θ_N for **5a** and **5b**,[4,10,11] is absent in **5h**, **5j**,

and **5i**. Probably, small changes of the chemical shifts caused by the 4′-NO_2 and those by the minor conformational changes will be cancelled by each other to give the observed chemical shifts.

The anomalous substituent effects in **1** and **3** can also be explained similarly. As shown in the previous paper,[4] azomethine carbon chemical shift in **3** suffers normal substituent effect. Although the $J(^{13}C\text{–}H)$ values are not available for all the compounds of **3**, those of **3d** and **3i** are 151.4 (Hz) and 155.9, respectively. These trends indicate, as discussed above, that the through-bond electronic effect of the substituents X is of primary importance for both NMR constants. On taking into account that 4-NMe_2[10] and 4-NO_2[3–6] substitutions tend to decrease and increase the twist angle θ_N, respectively, it is not unreasonable to consider that the inverse substituent effects in **3** may also arise primarily from the change of molecular conformation (twist angle θ_N) induced by the substituents.

The anomaly dicussed above may also be ascertained by comparison of the azomethine proton chemical shifts between **2** and **6**, and **2** and **4**. The comparison makes it clear that the 4-NO_2 and 4-NMe_2 substitution almost always generate the anomalous up- and low-field shifts, respectively, regardless of the nature of the substituents on the ring B.

Finally, it is worth noting that the anomalous substituent effect on the azomethine proton chemical shifts should not be simply ascribed to the twisted conformations of *N*-benzylideneanilines. Difference in conformation among the substituted *N*-benzylideneanilines should be taken into account to get a deeper understanding on it.[2]

J(¹³C–H) and Transmission of the Substituent Effects. We used in the previous section the results on the $J(^{13}C\text{–}H)$ values to get a deeper understanding on the origin of the anomalous substituent effects on the azomethine proton chemical shifts. It is also of interest to discuss the $J(^{13}C\text{–}H)$ values of **7**, and the efficiency of transmission of the substituent effects on the basis of the $J(^{13}C\text{–}H)$ values of **5**, **6**, and **7**.

Comparison of the $J(^{13}C\text{–}H)$ values between **2** and **7** is of particular interest. Since a methyl group is moderately electron-donating, the *s* character of the azomethine carbon–hydrogen bond would decrease from **2** to **7** to give rise to a larger $J(^{13}C\text{–}H)$ in **2** than in **7**. However, the reverse situation was found except Y=NMe_2. These results can well be explained in terms of considerably twisted conformations of **7**; introduction of the 2,6-dimethyl groups on the ring A forces the aromatic ring to be highly twisted, and the twisting is accompanied by enhancement of *N*-lone pair delocalization to the ring A, as shown in Scheme 3. Contribution of the canonical structure A must cause an increased *s* character of the azomethine carbon-hydrogen bond giving rise to the larger coupling constants in **7** than in **2**. The pronounced effect of the dimethylamino group to decrease the coupling

7	6.48	0.988	σ
7	3.57	0.999	σ^+

a) Ref. 1d.

constant indicates the efficient electron donation as shown in the canonical structure B. This finding is an alternative support for the enhanced *N*-lone pair delocalization in **7**, as shown earlier by Kobayashi.[12] The scheme is also consistent with a more enhanced transmission of the substituent effects in **7** than in **2** (see below).

The efficiency of transmission of substituent effects can be evaluated by the ρ values. As shown in Table 4, the ρ value for **7** (6.48) is larger than that for **2** (4.45). This shows that substituent effect is better transmitted in **7** than in **2**, and can be explained in terms of the development of positive charge on the azomethine carbons in **7**, as shown in the Scheme 3. Better correlation of the $J(^{13}C\text{–}H)$ values with Hammett σ^+ constants than with σ constants in **7** is also consistent with the scheme.

Concerning **5** and **6**, the ρ value was found to be larger in **6** than in **5**. This can be interpreted in terms of the through-bond substituent effect on the coupling constants as discussed in the previous section; the azomethine carbon–hydrogen bond in **6** is one bond closer to the substituent Y than to X in **5**.[1d]

Conclusion

Substituent effects on the azomethine proton chemical shifts for several series of mono- and disubstituted *N*-benzylideneanilines were examined. The inverse substituent effects were found to be a general phenomenon for *N*-benzylideneanilines carrying variable substituents at the 4-position of the anilino benzene ring regardless of the nature of the 4-substituents on the benzylidene benzene ring. On the basis of the results on similar substituent effects on the azomethine carbon chemical shifts and the $^{13}C\text{–}H$ coupling constants for the azomethinecarbon–hydrogen bonds together with available data on the molecular conformations of *N*-

benzylideneanilines, a concept of conformational change with substituents was invoked to account for the anomalous substituent effects.

Experimental

Materials. Most of the derivatives of **1**—**7** are available from a previous work.[4] Other compounds were similarly prepared, and identified by comparison of the physical and spectroscopic data with those of authentic samples.

Measurements of the Azomethine Proton Chemical Shifts. All measurements were run on a JEOL MH-100 spectrometer at room temperature (probe temperature was *ca.* 27°C). The solvent was spectral grade $CDCl_3$. Each solution was prepared by dissolving each sample in $CDCl_3$ containing 1% tetramethylsilane as an internal reference. An aliquot of each solution was taken for further dilution. In most cases, we have examined the chemical shifts in two or three concentrations; however, no appreciable dilution shifts were observed at the concentrations below 0.07 mol dm^{-3}. The chemical shifts were obtained at each concentration as the mean of at least three scans, in most cases, four scans. Sample concentrations were *ca.* 0.03—0.07 mol dm^{-3}.

Measurements of the ^{13}C-H Coupling Constants. The ^{13}C-H coupling constants were taken from a JEOL FX-60 spectrometer in $CDCl_3$ by the gated decoupling technique. Because of low solubility, the measurements of **5b**—**5j** and **6b**—**6j** were run at 40°C of the probe temperature. Other measurements were run at room temperature.[13]

Anodic Oxidation of Cyclohexanone on Lead Dioxide Electrode in Aqueous Sulfuric Acid Solution

Atsutaka KUNAI,* Kazuhito HATOH, Yoshinobu HIRANO, Junji HARADA, and Kazuo SASAKI
Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Shitami, Saijo-cho, Higashi-Hiroshima 724
(Received December 3, 1984)

The electrolytic behavior of cyclohexanone was examined by potentiometry with rotating disk electrode as well as by product analyses. The reaction was activation controlled and the reaction orders were first with respect to cyclohexanone and zero for proton. Cyclohexanone reacted by approximately 6 electrons to give adipic acid mainly which accumulated proportionally to the electricity consumed. Changes in temperature, proton concentration, and current density resulted in only minor effects on the reaction. In neutral solution, however, the oxidation was suppressed and oxygen evolution dominated. Other electrode materials such as Pt, graphite, RuO_2, and PtO_2 were inactive. The chemical oxidation with PbO_2 itself did not occur. From these facts, reaction mechanism was discussed.

It is well known that lead dioxide electrode is effective to the anodic oxidation of certain organic compounds. Especially, the oxidation of aromatic compounds, such as benzene, toluene, or phenol, with lead dioxide electrode leads to the formation of *p*-benzoquinone in good yields, and therefore, this reaction has been investigated by many workers from the industrial and mechanistic points of view.[1-13] The reason is, however, still left uncertain why PbO_2 electrode is actually effective to the oxidation of aromatic compounds.

This electrode is known to be active also to the oxidation of a certain alicyclic ketone such as cyclohexanone, but the formation of different products has been reported by Yokoyama,[14] Pyrrone,[15] and Sugawara and Sato.[16] At present time, no quantitative information is shown yet about the electrochemical behavior of PbO_2 electrode toward aliphatic ketones, in views of the special reactivity of this electrode, the product selectivity, or the reaction mechanism.

In this study, we should like to discuss in detail the basic behavior of PbO_2 in the presence of aliphatic ketones. For this purpose, cyclohexanone was chosen as the representative of the ketones and its oxidation behavior was compared with that of benzene. The main object was placed on studying the effectiveness of this particular electrode and evaluating the active species on PbO_2 as well as clarifying product selectivity.

Experimental

Cyclohexanone was reagent grade which was distilled and checked by GLC before use. All the other chemicals were analytical grade and were used as purchased.

All the electrochemical measurements were made using a Nichia Keiki NPG 1070E potentiostat. For preparative electrolysis, a Kikusui Denki PAD 110-1.5L regulated DC power supply was used. Proton concentration of the solutions was determined by a Toa Dempa MH-7B pH meter. All the potential values cited in this paper were those referred to Hg/Hg_2SO_4 electrode in 0.5 M† sulfuric acid. The reaction products were analyzed by Hitachi 665 high pressure liquid and 163 gas chromatographs.

The rotating disk electrode was prepared by filling a Pb rod of 5 mm in diameter into the center of a teflon holder, and the surface of the electrode was shaved planarly with a lathe and polished with cellulose fiber paper. The PbO_2 film was coated on the cleaned Pb surface by first stepping the electrode potential to 1.70 V for 25 min and to 1.10 V for another 20 min. The PbO_2 film was freshly prepared before each series of the experiments and the current values were determined after ten min of polarization.

For macro-scale electrolysis, a Pb plate of 5×6 cm in size was used as the anode which was pretreated before use in a similar manner as described above. An anolyte of 150 cm^3 in volume containing 0.34 M cyclohexanone was polarized under controlled current conditions in a divided cell. A small quantity of the sample was taken up in each interval and analyzed by HPLC using Merck Lichrosorb RP-18 (particle size 10 μm, 4×125 mm) as the column and a mixed solvent of acetonitrile (20%) and phosphate buffer solution of pH 3.5 (80%) as the eluent. The amounts were determined at 220 nm for adipic acid and at 280 nm for both cyclohexanone and 2-cyclohexenone.

For analysis of lactones, the electrolyzed solution was continuously extracted with ether and the concentrated extract was subjected to GLC analysis using PEG 20 M and KG 2 as columns and diethyl phthalate as the internal standard material. In some experiments, carboxylic acids were analyzed after the treatment with methanolic BF_3 solution. The products, 5-hexanolide, 4-hexanolide, and methyl esters of adipic, 5-oxohexanoic, glutaric, and succinic acids were isolated by preparative GLC and their spectrometric properties were compared with those of authentic samples.

Electrolyses were made also using other electrode materials, platinum, graphite, PtO_2, and RuO_2. The latter two electrodes were prepared by thermally depositing the metal oxide layer on Ti plates in the usual way.[17,18]

Results and Discussion

1. Current-potential Curves. Typical polarization curves obtained with the rotating disk electrode at 1500 rpm†† are shown in Fig. 1. In 0.5 M sulfuric acid solution, an apparent Tafel slope of 125 mV was observed and the current was independent of rotating velocity. On addition of cyclohexanone, the anodic current increased in the wide range of the potential

† M=mol dm^{-3}.

†† rpm=120 π rad s^{-1}.

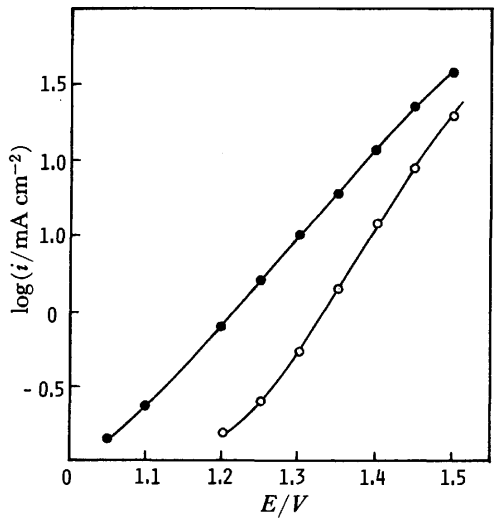

Fig. 1. Polarization curve for rotating PbO_2 electrode in 0.5 M H_2SO_4 (ω=1500 rpm), (O) in the absence and (●) in the presence of cyclohexanone (100 mM).

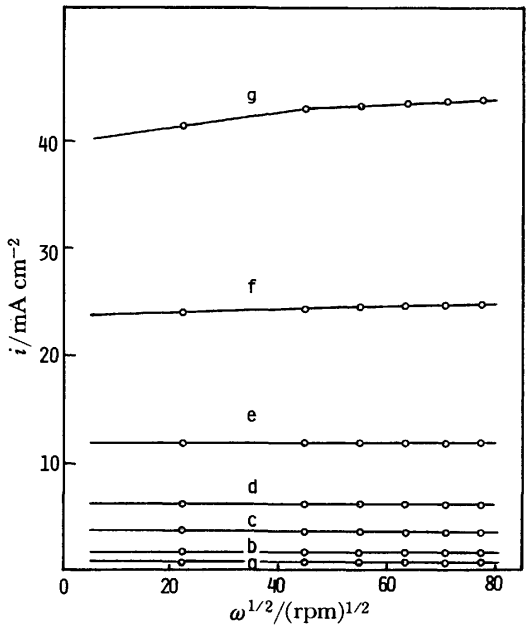

Fig. 2. Variation of total oxidation current as a function of $\omega^{1/2}$ at potentials of (a) 1.20, (b) 1.25, (c) 1.30, (d) 1.35, (e) 1.40, (f) 1.45, and (g) 1.50 V.

studied, and the Tafel region was observed in the potential range between 1.15 and 1.40 V.

The effect of rotating velocity on the current in the cyclohexanone solution is shown in Fig. 2. At the potential lower than 1.4 V, the anodic current was completely independent of rotating velocity. Although a slight influence of diffusion controlled process was observed at higher potential than 1.45 V, the oxidation of cyclohexanone on this electrode seemed to be essentially reaction controlled.

Figure 3 shows the effect of the concentration of cyclohexanone on the current at a rate of 1500 rpm. The plot of the currents against the concentrations within 200 mM exhibited a good linearity at each po-

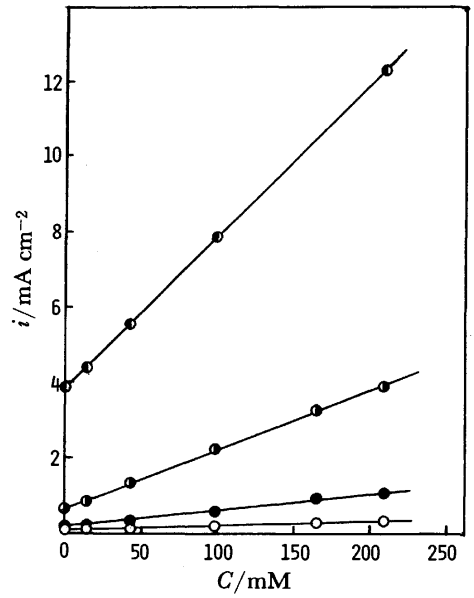

Fig. 3. Variation of total oxidation current as a function of cyclohexanone concentration, at potentials of (O) 1.10, (●) 1.20, (◑) 1.30, and (◐) 1.40 V (ω= 1500 rpm).

tential applied, 1.1, 1.2, 1.3, and 1.4 V, respectively. The extrapolated intercept of each line coincided with the value of the back ground current of the base solution. This indicates that there is no appreciable change in residual current even in the presence of high concentration of cyclohexanone. This is a marked difference from the case of benzene solution reported by Clarke *et al.*,[9] where oxygen evolution was substantially suppressed.

2. Reaction Order. The mass transport study (Fig. 2) and product analysis (section 3) clearly demonstrate that both diffusion and electrode potential little affect the reaction. The main reaction is the formation of adipic acid:

$$C_6H_{10}O + 3H_2O \longrightarrow C_6H_{10}O_4 + 6H^+ + 6e.$$

In general, activation controlled process can be expressed by the form of Eq. 1 for the anodic reaction:

$$i = nFk[C]^p\,[H^+]^q \exp(\alpha nFE/RT), \qquad (1)$$

where [C] is the concentration of cyclohexanone, E the electrode potential applied, and i the current. In this case, the current i should be the net oxidation current i_{net}, which is the difference between observed and residual currents. The reaction orders p with respect to cyclohexanone and q for proton should be, therefore, conveniently obtained from Eq. 2.

$$\log i_{net} = p\log[C] + q\log[H^+] + (\alpha nF/RT)E + \text{constant}. \qquad (2)$$

For the determination of p, i_{net} at 1500 rpm was plotted against log[C] in 0.5 M sulfuric acid solutions, where the concentration of proton was assumed to be constant (Fig. 4). The slopes of the log i_{net} *vs.* log[C] satis-

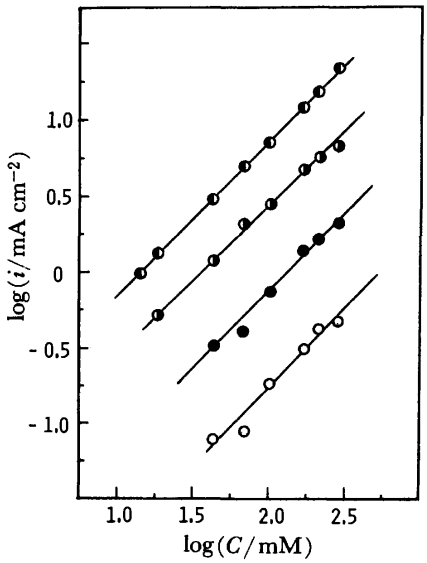

Fig. 4. Logarithmic plots of net oxidation current *vs.* cyclohexanone concentration obtained at potentials of (○) 1.10, (●) 1.20, (◑) 1.30, and (◐) 1.40 V (ω=1500 rpm).

fied good linearities and were exactly 1.0 at each potential applied, 1.1, 1.2, 1.3, and 1.4 V, respectively. This means that the oxidation of cyclohexanone is first order with respect to cyclohexanone.

For evaluating the participation of proton to the anodic process, we prepared a series of sulfate solutions within the pH range of 1 to 2.5, where the total concentration of the sulfate was adjusted to be 0.5 M.

We examined the relation of pH and logarithmic current of i_{net} under constant potential conditions, 1.3 V, where the concentration of cyclohexanone and the potential were kept unchanged. As shown in Fig. 5, the net oxidation current was unaffected by pH and the reaction order for proton was concluded to be zero.

3. Product Analysis. As a typical run, a solution of 0.34 M cyclohexanone in 0.5 M sulfuric acid was electrolyzed on PbO_2 anode under the constant current conditions (2 A dm^{-2}, 10 °C).

Product Isolation: The electrolyzed solution was extracted with ether. The concentrated extract was distilled *in vacuo*. The initial fraction consisted of mostly cyclohexanone recovered and the second fraction contained two products, 5-hexanolide (δ-lactone) and 4-hexanolide (γ-lactone), which were isolated by preparative GLC.

The nonvolatile residue showed strong IR absorption bands of carboxyl groups. Isolation of carboxylic acids was first tried by preparative LC (reverse phase), but complete identification was failed because of poor separation. The acids were, therefore, isolated as their methyl esters after the treatment with methanolic BF_3 solution. By preparative GLC, the esters of adipic, 5-oxohexanoic, glutaric, and succinic acids were isolated.

GLC Analysis: After passing 1.2 F mol^{-1} of the electricity,[†††] products were extracted with ether and analyzed by GLC. Taking an average over nine individual experiments, we estimated that the conversion rate of cyclohexanone was 155 mmol F^{-1} where approximately 6.5 electrons were necessary for a molecule that disappeared (Table 1). The chemical selectivity of δ- and γ-lactones were 25 and 4%, respectively. Traces of 2-cyclohexenone were detected.

In another run, the extract was esterified and analyzed by GLC (Table 2). The main product, adipic acid, was detected only in 7—8% of selectivity by this method because of, presumably, poor extraction efficiency of the dicarboxylic acids.

HPLC Analysis: The changes in concentration of cyclohexanone and carboxylic acids were monitored by reverse phase HPLC in the time course of the electrolysis. Cyclohexanone disappeared linearly at a rate of 150 mmol F^{-1} and, instead, a distinctive peak corresponding to adipic acid increased. The accumulation of this material was proportional to the quantities of electricity consumed. Supposing that this peak consisted of solely adipic acid, we obtained the accumulation rate to be 80.8 mmol F^{-1}. If this is the case, the chemical selectivity and the current efficiency for adipic acid reach to 54 and 49%, respectively. Other acids identified before seemed to be rather minor by HPLC analysis. The linear accumulation of adipic acid clearly shows that adipic acid is not formed by reoxidation of some solution phase products, such as lactones, but formed directly from cyclohexanone on the electrode.

These results were little affected by temperature, concentration of sulfuric acid, or current density which

[†††] F=96480C.

Table 1. GLC analysis of lactones

Electricity consumed	Cyclohexanone reacted		δ-Lactone		γ-Lactone		Total	
	Amount	Conv.	Amount	Select.	Amount	Select.	Amount	Select.

Electrolytic conditions were the same as those described in Table 2.
a) The solution contains 0.1 M Na_2SO_4.

were changed in the range of 0—20 °C, 0.5—6.0 M, or 0.5—4.0 A dm^{-2}, respectively (Table 3).

Effect of pH: When the electrolyses were done in phosphate buffer solutions containing 0.1 M sodium sulfate, the oxidation of cyclohexanone also occurred. Its reactivity, however, markedly decreased with the increase of pH (Table 4). At higher pH's, the chemical selectivity and the current efficiency of adipic acid were considerably suppressed, but the chemical selectivity of lactones did not much changed.

Comparison of Electrode Materials: In order to evaluate the effectiveness of PbO_2 as the electrode material for the oxidation of cyclohexanone, we studied the behaviors of other electrode materials. The polarization curves obtained with the stationary Pt and graphite electrodes were compared in the absence and presence of cyclohexanone. On addition of cyclohexanone, the total currents were rather suppressed over the potential range measured.

The macro-scale electrolyses with these electrodes

TABLE 5. COMPARISON OF ELECTRODE MATERIALS

Electrode	Cyclohexanone reacted/mmol F^{-1}	Adipic acid mmol F^{-1}	δ-Lactone mmol F^{-1}	γ-Lactone mmol F^{-1}	Cyclohexenone mmol F^{-1}
PbO_2	150	81	22	5.9	2.4
Bare Pt	17.3	—	Trace	Trace	0.4
Graphite	40	8.9	Trace	Trace	1.2
PtO_2/Ti	10.7	—	—	—	0.4
RuO_2/Ti	17.4	—	—	—	—

Electrolytic conditions were the same as those described in Table 2.

were carried out under similar conditions as described before. The reactivity of cyclohexanone was, as expected by the polarization curves, extremely small and substantial oxygen evolution occurred. We also tried to use PtO_2 and RuO_2 electrodes, but cyclohexanone was not oxidized on these electrodes (Table 5).

4. Reaction Mechanism. First, we briefly summarize the results for the oxidation of cyclohexanone on PbO_2 elcctrode. As discussed in *product analysis* study, PbO_2 shows particularly high oxidation ability toward cyclohexanone, but other electrode materials, such as Pt, graphite, RuO_2, and PtO_2, are almost inactive. At lower pH's, cyclohexanone consumes *ca.* 6 electrons on PbO_2 to afford adipic acid with 50—65% of the current efficiencies. Other products, such as lower carboxylic acids and lactones, are minor. Such results are almost unchanged with the increase of the acid concentrations. Furthermore, adipic acid is formed as the primary electrode product on PbO_2 surface, where ε-lactone is not the intermediate. All of these facts have not been clarified in earlier reports.[14-16]

By examination of *current-potential curves*, it is also confirmed that the velocity of the reaction is affected only by the cyclohexanone concentrations obeying first order law, but not by mass transport and proton concentrations.

The effect of pH on the reaction seems, however, drastic at higher pH's. In neutral solutions, only the oxygen evolution occurs. These phenomena are undoubtedly due to the properties of PbO_2 itself and independent of organic substrates, because similar observations have been reported in the cases of benzene[9] and thiophen.[21] This means that the reaction is governed only by the active state of PbO_2, *i.e.* β-PbO_2 in acidic media, [19] but not by acid-catalyzed enol formation. We now consider the relation of the reaction and β-PbO_2 in detail.

Many reports have been published for β-PbO_2 in views of preparation, structure, and chemical properties. Beta-lead dioxide is formed in acidic media by either oxidation of Pb(II) ion or, more conveniently, anodization of Pb itself. This material is thermodynamically an unstable form of Pb(IV) and therefore highly active, which oxidizes even water slowly to leave Pb(II) and oxygen.[19,20]

Here it should be worth noting the work reported by Clarke *et al.*[9] who discussed the oxidation of benzene on PbO_2 electrode in detail. They excluded the possibilities of the direct electron transfer to the electrode[8] and the hydroxylation reaction with adsorbed atomic oxygen[2,3] because of, mainly, highly selective formation of *p*-benzoquinone at low electrode potentials as well as completely unsimilar reactivity of other electrode materials such as Pt and graphite. Instead, they proposed the homogeneous phase reaction between benzene and PbO_2 followed by the electrochemical regeneration of PbO_2, where the former step was rate determining and the concentration of PbO_2 was a potential dependent term. The evidence for this mechanism was the fact that *p*-benzoquinone and maleic acid were formed chemically by shaking the benzene emulsion in the presence of PbO_2 powder for 24 h.

Their assumption should be understood in the following aspects. Namely, PbO_2 is practically insoluble in moderately acidic solutions such as 0.5 M sulfuric acid. The solubility is reported as $\log[Pb^{4+}]=-8.26-4pH$, if free from complexing agents.[20] Such a situation seems unfavorable to the homogeneous reaction proposed. Suppose that the homogeneous reaction with PbO_2 occurs, probably as a form of Pb^{4+} in the bulk solution, it might be expected that the subsequently formed low valent Pb, *i.e.*, hardly soluble $PbSO_4$, deposits into the solution in the course of the electrolysis. Such phenomena were, however, not found in our cases, the oxidation of cyclohexanone.

Another thinkable possibility is that the oxidation with Pb(IV) occurs only in the limited region of diffusion double layer and the low valent Pb does not diffuse away into the bulk solution. If this is the case, the surface of the electrode will be covered finally with the low valent Pb salt resulting in the marked decrease in the electrode potential unless the electrode is externally anodized.

Taking these mechanisms into consideration, we carried out additional experiments. A very thin layer of β-PbO_2 was electro-deposited on Pt surface (0.34 μmol cm^{-2}) and the chemical durability of this electrode was examined by measuring the change in the open circuit potentials both in the presence and absence of cyclohexanone. In typical runs, the potential of this electrode, *ca.* 900 mV, was unchanged in the base solution for 60 min and then felt down rapidly. When some depolarizing materials such as form-

aldehyde or phenol were present in the solution, the duration time of this electrode was definitely shortened. On addition of cyclohexanone, however, the duration time was not changed at all. These facts may indicate that the chemical oxidation in the above manner is, even if occurs, extremely slow compared to the oxidation of the solvent water itself, in the case of cyclohexanone.

From all of the experimental results, one should deduce a clear conclusion that cyclohexanone is oxidized directly on the electrode but not oxidized chemically in the manner of the mediation with the lead(IV)/lead(II) couple. The simplest explanation is, of course, the occurrence of the direct electron transfer to the electrode inducing the subsequent chemical and electrochemical reactions, in which the rate determining step is activation controlled. As a result, adipic acid is formed directly on the electrode surface. This mechanism seems to satisfy most experimental results except for the particular effectiveness of PbO_2 compared to other electrode materials.

Alternative explanation is the participation of a particular surface species formed on the PbO_2 electrode. Lead dioxide has a large oxygen overvoltage, which may cause the accumulation of precursors of O_2 evolution in high concentration. The probable candidate for the reactive species is adsorbed hydroxyl radical.[10,21] Hydroxyl radical is highly reactive and electrophilic species. For example, it adds to benzene ($k=3.5\times10^9$ $M^{-1}s^{-1}$) to give hydroxycyclohexadienyl radical or abstracts α-hydrogen from acetone ($k=6\times10^7$ $M^{-1}s^{-1}$).[22] If this is applicable to our case, the abstraction of hydrogen from cyclohexanone should be rate determining step. Once organic radicals are formed on the electrode surface, they are trapped immediately with another oxygen species and/or oxidized electrodically to give other organic species in turn, leading to the final formation of stable products, such as adipic acid.

In summary, we should point out again at the present time that the anodic oxidation of cyclohexanone on PbO_2 may be accounted for by direct electron-transfer mechanism or, alternatively, by the reaction of hydroxyl radical formed on the electrode surface.

Syntheses of Benzilic Acids through Electrochemical Reductive Carboxylation of Benzophenones in the Presence of Carbon Dioxide

Yoshikazu IKEDA* and Eiichiro MANDA
National Chemical Laboratory for Industry, Tsukuba 305
(Received December 14, 1984)

Reaction conditions for the electrochemical synthesis of benzilic acid (**2a**) under the atmosphere of carbon dioxide was investigated from the preparative points of view. The highest yield of **2a** (86%) was obtained under the following conditions; cathode: mercury, electricity passed: 2.3 F/mol, constant current density: 2.5 mA/cm^2, benzophenone (**1a**) (8.2×10^{-3}mol), electrolyte(KI, 1.7×10^{-2}mol) in DMF (50 ml). This method and conditions were applied to the syntheses of twelve benzilic acids (**2b—2m**) and yielded acids in the range of 10—92%. The yields were strongly depended on the electronic effect of substituents and benzilic acids were not obtained when the ring substituent was NO_2, OH, or Br group.

There are many reports on the production of carboxylic acids by bubbling CO_2 during reduction processes through catholytes containing organic materials. Among these, Wawzoneck *et al.*[1] have shown that benzophenone(**1a**) and acetophenone could be carboxylated to form benzilic acid (**2a**) and 2-hydroxy-2-phenylpropionic acid, respectively, during the course of mechanistic investigation on the reduction process of aromatic ketones. The yields of these acids were 54 and 6%, but the synthetic aspects of this reaction were not investigated.

We recently reported[2] that the electrochemical carboxylation reaction of 4-isobutylacetophenone in *N,N*-dimethylformamide (DMF) gave significant amounts of 2-hydroxy-2-(4-isobutylphenyl)propionic acid by a modification of the method of Wawzoneck for the synthetic application of organic electrochemistry. As an extension of this work, we report here a preparative electrochemical syntheses of benzilic acids from benzophenones in high yields under controlled conditions.

Experimental

All the melting points were measured on a Yanagimoto micromelting point apparatus and were uncorrected. IR spectra were recorded on a JASCO A-302 grating spectrometer in KBr. NMR spectra were measured on a Hitachi R-24 high resolution spectrometer (90 MHz) in $CDCl_3$ using TMS as an internal standard. Elemental analyses were performed by Microanalysis Laboratory of the Physical and Chemical Research Institute.

Materials. DMF was dried over anhydrous potassium carbonate for several days and distilled prior to use. Acetonitrile was refluxed and distilled from phosphorus pentaoxide and calcium hydride. Reagent grade lithium, sodium, potassium, rubidium, cesium and tetrabutylammonium iodide were used as supporting electrolytes without further purification. Benzophenones used were also reagent grade and were recrystallized from ethanol. Carbon dioxide used was 99.99% pure.

Electrolysis Apparatus. Preparative electrolysis experiments were carried out by using a Hokuto Denko HA-105 potentio-galvanostat equipped with a Hokuto Denko HF-201 coulometer. The electrolysis cell was a 200 ml H type vessel divided (3.6 cm dia.) with a sintered glass diaphragm. The cathode compartment was fitted with a glass bubbler tube placed very close to the cathode surface for introduction of CO_2.

General Electrolysis Procedure. All compounds listed in Table 2 were synthesized and isolated by using the procedures described in detail for the typical example below. A typical electrolysis procedure is as follows.

Preparative Scale Electroreduction of Benzophenones in the Presence of CO_2, the Synthesis of **2a**. A mercury pool (surface area 10.2 cm^2) was used as the cathode and the anode was a platinum plate (4.0 cm^2). 50 ml of DMF containing 14.2 g of KI was placed in each compartment. **1a** (1.5 g, 8.2×10^{-3} mol) was then added to the cathode compartment and CO_2 was passed through the catholyte for 60 min before the beginning of electrolysis. Catholyte was stirred magnetically and electrolysis was carried out under a fine stream of CO_2. The catholyte slowly turned opaque pale grayish with the progress of the electrolysis. After 2.3 F/mol of electricity was passed with a constant current of 2.5 mA/cm^2, the contents of the catholyte was poured into a separatory funnel. The mercury was taken off and DMF was removed under reduced pressure by a rotary evaporator. The residue was taken up in 150 ml of ether and the residue remaining after removal of the ether was dissolved in 100 ml of water and filtered. The filtrate was acidified with concentrated hydrochloric acid to yield white precipitates, which were collected by filtration, washed thoroughly with water, and dried *in vacuo*. Recrystallization from ethanol gave a pure compound of **2a**. Yield and physical properties are listed in Table 2.

Results and Discussion

At first, the synthesis of **2a** by electrochemical reduction of **1a** in the presence of CO_2 was investigated. Mercury pool cathode in DMF containing 8.6×10^{-3} mol of KI was used in a divided cell. Electricity passed was 2.0 F/mol of **1a** at a constant current of 2.5 mA/cm^2. The products and yields obtained in this system were essentially identical with those obtained previously.[1] **2a** was not obtained under the same conditions using undivided cell.

In order to optimize the yield of **2a**, the following experiments were carried out to investigate the influence of supporting electrolyte, solvent, concentrations of substrate and supporting electrolyte, amount of

TABLE 1. EFFECT OF SUPPORTING ELECTROLYTES AND SOLVENTS ON THE ELECTROCHEMICAL CARBOXYLATION OF **1a**[a]

Entry	Supporting electrolyte	Solvent	Yield of **2a**[b] %
1	LiI	DMF	4
2		CH_3CN	c)
3	NaI	DMF	29
4		CH_3CN	8

8		CH_3CN	c)
9	CsI	DMF	46
10		CH_3CN	c)
11	Bu_4NI	DMF	33
12		CH_3CN	30

a) Catholyte: **1a**(4.7 mmol) in 50 ml of DMF containing of 16 mmol of supporting electrolyte. Mercury pool was used as a cathode. Constant current density, 2.5 mA/cm². Electricity, 2.0 F/mol. Temperature, *ca.* 20°C. b) Isolated yield, based on **1a**. c) It can not be determined, because supporting electrolyte did not solved entirely in CH_3CN.

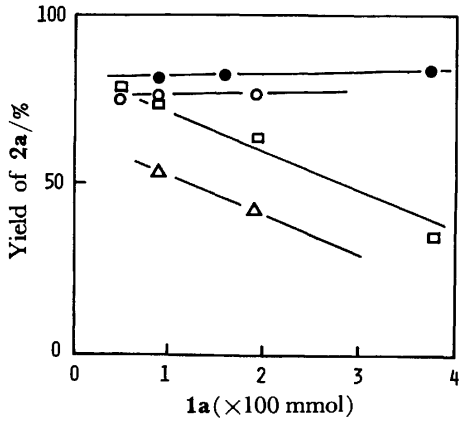

Fig. 1. The influence of the concentration of **1a** on the yield of **2a** under various concentration of KI as a supporting electrolyte.
Concentration of KI: -●-: 85.5 mmol, -○-: 47.0 mmol, -□-: 16.0 mmol, -△-: 8.0 mmol.
Divided cell, mercury cathode, 2.0 F/mol, constant current density (2.5 mA/cm²), solvent dry DMF (50 ml).

electricity, and cathode material. The influence of supporting electrolyte and solvent is shown in Table 1. Under similar experimental conditions, the maximum yield was obtained with KI-DMF system and effect of solvent was larger for alkali metal supporting electrolyte than for tetraalkylanmonium salt such as *n*-Bu_4NI, but remarkable improvement of the yield was not realized under these conditions.

The most significant effect was observed with the concentration of KI and the molar ratio of substrate to KI in KI-DMF system as shown in Fig. 1. The best yield (80%) was obtained when 10 moles of KI per mole of **1a** was used at high concentration of electrolyte, but further increase of the molar ratio showed no effect. In addition, the amount of electricity affected the yield of **2a**. The yield rose upon increasing the amount of electricity up to about 2.5 F/mol and then gradually decreased with excess faraday per mole of **1a**. However, an increase of the amount of polymeric materials as by-products, which were reported in earlier studies,[1] was not observed in the reaction products from the electrolysis of the excess faraday. These observations seem to suggest that good yields are attained by the inhibition of the migration *via* diffusion of a substrate caused by a high potential gradient at low concentration of supporting electrolyte (KI) and prolonged reaction time during the passage of larger amount of electricity.

The influence of cathode materials was found to be none under the same conditions. The employment of graphite plate cathode instead of mercury decreased the yield of **2a** to 14%. In the case of cadmium, platinum, nickel, copper and zinc cathode, a similar electrolysis of **1a** resulted in the formation of tarry materials predominantly and **2a** could not be isolated. On the basis of these experimental results, the current density of 2.5 mA/cm², 2.3 F/mol of electricity, DMF as solvent, KI as supporting electrolyte and highly concentrated solution of KI which KI is 10 times or more to the concentration of **1a** were selected as the most suitable synthetic conditions for the electrochemical carboxylation of **1a**. The carboxylic acid, **2a**, could be isolated in 86% yield under the above conditions.

On the other hand, **2a** has been synthesized *via* the reductive carboxylation of **1a** by using alkali metal[3] or radical anion of arylpyridine sodium,[4] benzilic acid rearrangement,[5] solvolytic reaction of diphenylketene,[6] and the reaction of benzoyl cyanide and imines.[7] The reported yields are in the range from 55 to 88% and these methods are very tedious compared with the present method.

This method is proved to be useful by the syntheses of substituted benzilic acids which cannot be easily synthesized by conventional methods.[8-11] The synthesis of twelve benzilic acids (**2b—2m**), affording relatively high yield, were carried out under the optimum conditions for the preparative synthesis of **2a**. The application to the syntheses of 4-bromo-, 4-nitro-, 4-hydroxy- and 4-(dimethylamino)benzilic acids were unsuccessful in the reaction system under the conditions employed by us. Resulting benzilic acids are summarized in Table 2 together with some previously reported data for comparison. Present method also indicates superiority in isolated yield over the previously reported one on the synthesis of substituted benzilic acids, as shown in the case of **2i**. All the methylated compounds (**2b—2g**) showed high yields in the range of 81—83% yield except the case of **2g**. Methoxy compounds (**2h—2i**) were obtained in the range of 64—75% yield. In a series of halogen compounds (**2j—2l**), **2k** was obtained in the yield of 92%. It is noteworthy that C-Cl bond cleavage[12] which resulted in a normal

a) Catholyte: benzophenones(8.2 mmol) in 50 ml of DMF containing 85.5 mmol of KI, Hg pool cathode, A constant current(2.5 mA/cm^2, 2.3 F/mol) was applied. b) Although NMR signals of OH and COOH in benzilic acids were not ascertained clearly, other signals of phenyl and alkyl displayed proper assignment. The proportions of integration of protons were consistent with the structure of benzilic acids when were integrated as involving two protons of OH and COOH in the phenyl signal. c) The products obtained were identified by a comparison of their physical and IR-spectral data with the literature data. d) Value in parentheses refers to yield of literature data. e) Electrolyzed were carried out with 2.4 mmol of 4,4′-dichlorobenzophenone and 85.5 mmol of KI in 50 ml of DMF. f) Yield has not been described. g) In Ref. 3, 4, 6, and 7. h) In Ref. 8. i) In Ref. 3 and 8. j) In Ref. 3 and 9. k) In Ref. 3, 8, and 10. l) In Ref. 10. m) In Ref. 4, 8, and 11.

electrochemical reduction of 4-chlorobenzophenone in DMF did not occur in our reaction system. In contrast, 4-bromobenzophenone gave **2a** in 30% yield, which resulted from the reductive cleavage of C–Br bond.[12] Also, **2j** was obtained in 88% yield. A syntheticaly useful intermediate for tick insecticide, **21**, was obtained in the yield of 73% when the reaction was carried out at low concentration of 4,4′-dichlorobenzophenone becauce of its low solubility in DMF. Likewise, **2m** was obtained in 92% yield. These results show that the yields are generally affected by electric effects of substituents. Steric effect is not observed for **2b—2d** in a series of methylated compounds. In the case of 4-nitrobenzophenone, the reduction of nitro group took place and the isolated product was 4,4′-dibenzoylazobenzene[13] (60%). 4-Dimethylamino- and 4-hydroxybenzophenone mainly provided tarry products.

The reduction potentials of the first reduction wave of methoxy-, unsubstituted and 4,4′-dichlorobenzophenones were −1.68, −1.63, and −1.52 V *vs.* Ag/AgCl by polarographic measurements in the presence of CO_2. The relationship between Hammett's substituent con-

stants and the reduction potentials is in accord with the result reported with benzophenones.[14] On the assumption that the reduction potentials correspond to the current density, we tried to improve the yield of **2h**, **2g**, and **2l** by changing the current density as shown in Fig. 2. The yield of **2h** increased from 73% to 95% by increasing a current density from 2.5 mA/cm² to 5.0 mA/cm². In a similar manner the yield of **2g** also increased to 25% but, this value was not so good as expected. The yield of **2l**, which is expected to increase at lower current density, could not be improved by changing the current density above or even below 2.5 mA/cm². In addition, similar treatment for the syntheses of 4-bromo- and 4-hydroxybenzilic acid could not produce benzilic acids. Thus it became evident that the influence of the working reduction potential on the product yields is relatively small compared to that of the electronic effect of substituents.

Although it is not completely understood as yet whether the mechanism of the electrochemical carboxylation of aromatic carbonyl compounds proceed through ECEC or EECC path such as successive electrochemical(E) and chemical(C) reaction, it is obvious that the reaction begins with the formation of a ketyl radical by one-electron reduction of a substrate.[15] The electron distributions of a ketyl radical are shown in Fig. 3, and structure A may be predominant when R is electron-withdrawing and structure B may be predominant when R is electron-donating. Thus, benzilic acid may be obtained easily from the substrate having electron-withdrawing substituents *via* successive carboxylation, electrochemical reduction and protonation. In contrast, the substrates having electron-donating substituents have the possibility of radical reactions such as coupling or polymerization, and the yield of benzilic acids may go down. When the substituent moiety is more reactive than carbonyl moiety in the reaction system, the obtained products are not corresponding benzilic acids but some other products as are shown in 4-bromo, 4-nitro, 4-hydroxy, and 4-dimethylamino derivatives.

In conclusion, we found suitable reaction conditions for the synthesis of **2a** through the electrochemical reduction of **1a** in the presence of CO_2 in view of preparative points. This method and conditions were successfully applied to the syntheses of some substituted benzilic acids. The results also showed that the electrochemical carboxylation is easily affected by the electronic effects of substituent together with the reduction potential of substrate.

We wish to thank Dr. Chizuko Nishihara of our institute for the measurement of polarography.

Structure-Taste Relationships of Aspartyl Tetrapeptide Esters

Yasuo ARIYOSHI
Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki-ku, Kawasaki 210
(Received January 10, 1985)

A series of fourteen analogues of L-α-Asp-Gly-Gly-Gly-OMe has been synthesized in relation to structural features of sweet peptides. The rule in the structure-taste relationships of tripeptides barely applies to the aspartyl tetrapeptide esters. In order for the aspartyl tetrapeptide esters to be sweet, the second amino acid must have a D-configuration and a small, compact alkyl side chain. However, the sweetness was accompanied by a bitter or astringent taste. Moreover, some of the tetrapeptides were not sweet but bitter, though they satisfied the requirements for sweet peptides. With increasing length of a peptide, it becomes difficult to fit the deep receptor pocket.

It has been suggested that sweet compounds have the AH-B-X[1](γ)[2] system in a molecule as a glucophore. In an attempt to elucidate structure-taste relationships, a large number of analogues of L-α-Asp-L-Phe-OMe[3] have been synthesized by several groups.[4-15] In previous papers,[16-18] the tastes of aspartyl dipeptides have been rationalized through projection formulas. In the structures (Ia and II), a small alkyl group (S or R^2) has been considered to participate in binding with the receptor through a hydrophobic interaction. The carboxyl and amino groups serve as a proton acceptor and a proton donor, respectively, in the hydrogen bonding with the receptor. The hydrophilic-hydrophobic balance in a molecule is another important factor. Space-filling properties are also important, since the receptor site seems to be in the shape of a deep pocket.[17] As described above, peptides with limited structures have shown sweetness, whereas various hydrophobic peptides are bitter. It has been known that peptides can be classified as bitter or nonbitter depending upon the magnitude of the hydrophobicity of their side chains.[19]

Another interesting problem is to examine whether the above rule for bitter peptides can be applied to tetrapeptides with a possible sweet structure in their molecules.

Synthesis

Synthesis of Boc-dipeptide esters and the removal of the Boc group were carried out according to the method described in a previous paper.[18] The protected tripeptides in Table 1 were prepared by condensation of the appropriate dipeptide ester with a Boc-amino acid *N*-hydroxysuccinimide ester. The Boc group of the tripeptide esters was removed with *p*-toluenesulfonic acid (TosOH) in methanol.[20] The protected tetrapeptides in Table 2 were prepared by condensation of *N*-benzyloxycarbonyl-L-aspartic acid β-benzyl α-succinimido ester (Z-L-Asp(OBzl)-ONSu[18]) with the appropriate tetrapeptide ester. The desired tetrapeptide esters in Table 3 were obtained by deprotection of the benzyloxycarbonyl and benzyl groups from the protected tetrapeptides in Table 2 by hydrogenation over Pd/C.

Results and Discussion

In order to evaluate the contributions of the side chains of each amino acid, the substituents R^1—R^6 of III (Fig. 3) were systematically modified. The results are summarized in Table 4. In order for aspartyl tripeptides to be sweet, the second amino acid must

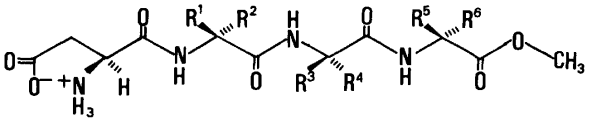
have a D-configuration and a small alkyl side chain.[18] Therefore, in systematic structural variation of the tetrapeptides (III), a small alkyl group was introduced at R^2 so as to meet the sweet structure (II). An L-antipode was introduced for the third amino acid, because the modification of tripeptides showed that an L-configuration of the third amino acid was required for a potent sweet taste.



III

Fig. 3. L-α-Aspartyl tetrapeptide esters.

As the first step, L-α-Asp-Gly-Gly-Gly-OMe (**29**) was synthesized. The peptide (**29**) was tasteless. The first candidate for sweet tetrapeptides was L-α-Asp-D-Ala-L-Ala-L-Ala-OMe (**30**). As expected, it was slightly sweet, 0.5 times as sweet as sucrose (Table 4). Replacement of a methyl group at R^5 of **30** by an isopropyl or isobutyl group gave L-α-Asp-D-Ala-L-Ala-L-Val-OMe (**31**) and L-α-Asp-D-Ala-L-Ala-L-Leu-OMe (**32**), respectively, which were weakly bitter. Replacement of a methyl group at R^4 of **30** by an isopropyl group gave a sweet peptide, L-α-Asp-D-Ala-L-Val-L-Ala-OMe (**33**). When a methyl group at R^5 of **33** was replaced by an isopropyl group, the resulting peptide, L-α-Asp-D-Ala-L-Val-L-Val-OMe (**34**), was bitter

Next, the second D-Ala was replaced by D-Val. The resulting peptides were faintly sweet (**35**), weakly bitter (**36** and **38**), and sweet-bitter (**37**).

Finally, the required configuration (R^1=H; R^2= small alkyl group) at the second amino acid was confirmed by synthesizing several tetrapeptides having an opposite configuration at this chiral center (**39**—**42**). All of them were devoid of sweetness. Thus, the requirement was confirmed.

In conclusion, the rule in the structure-taste relationships of tripeptides barely applies to the sweet tetrapeptides. However, the sweetness was accompanied by a bitter or astringent taste. Moreover, some of the tetrapeptides were not sweet but bitter, though they satisfied the requirements for the sweet peptides. The taste of aspartyl tetrapeptide esters tends to follow Ney's rule for bitter peptides. With increasing length of a peptide, it becomes difficult to fit the narrow receptor pocket. This may be a major reason that some of the tetrapeptides were not sweet but bitter, though they satisfied the requirements for sweet peptides. A similar result has been obtained in the modification of tripeptides,[18] in which the sweetness potencies significantly fell off when sweet dipeptides have been lengthen to tripeptides. Accordingly, the results obtained for the tetrapeptides, in conjunction with the results of di-[16] and tripeptides,[18] support that the receptor site is in the shape of a deep pocket with the binding site inside it.[17]

Experimental

All melting points were taken on a Yanagimoto capillary melting point apparatus Model MP-21 and are uncorrected. Optical rotations were measured on a JASCO DIP-140 digital polarimeter with a 10-cm water-jacketed cell at 25 °C and a 1% concentration. TLC was performed on precoated silica gel $60F_{254}$ plates (E. Merck) and spots were detected with ninhydrin or I_2 vapor. All compounds were essentially homogeneous on TLC. Sweetness potency was not evaluated by the panel method due to the small quantities available. In general, a panel evaluation needs a large quantity of sample. The yield, after purification, of each peptide (Table 3) was less than 0.8 g. The quantity of tetrapeptides obtained here was insufficient for the panel evaluation. Therefore, sweetness evaluation was carried out by the author by matching a threshold concentration of each compound with that of sucrose. Test solutions of the tetrapeptides were prepared at several concentrations. A series of the solutions was tasted up and down. Thus, it was possible to reproducibly determine the concentration which matched a 0.6% aqueous solution of sucrose. Therefore, it has been considered that the sweetness potencies in Table 4 are reproducible and reliable

enough to discuss the functions of a small hydrophobic group.

Materials. Boc-amino acids were purchased from Peptide Institute Inc. Esters of Gly and L-Val were synthesized in our laboratory. Z-L-Asp(OBzl)-OH and esters of L-Ala and L-Leu were purchased from Kokusan Chemical Works Ltd.

Protected Tripeptide Esters (1—14). A typical run (**6** in Table 1) was as follows: To a solution of Boc-L-Val-L-Val-OMe[21] (2.31 g, 7 mmol) in 20 ml of methanol was added TosOH·H_2O (1.60 g, 8.4 mmol). The mixture was stirred at 30°C for 5 h. The solvent was evaporated under reduced pressure at a bath temperature of 50°C to give H-L-Val-L-Val-OMe·TosOH as an oily residue. The oil was dissolved in 40 ml of chloroform and cooled in an ice-bath. To this solution was added triethylamine (Et_3N, 0.85 g, 8.4 mmol), followed by Boc-D-Ala-ONSu (1.72 g, 7 mmol) with stirring. The mixture was stirred at room temperature for 3 h and then kept standing overnight. The reaction mixture was washed successively with water, a 10% citric acid solution, a 5% sodium hydrogencarbonate solution and water, and then concentrated under reduced pressure to leave an oily product. The oil was crystallized from ethyl acetate–hexane to give Boc-D-Ala-L-Val-L-Val-OMe (**6**) as needles. Recrystallization was carried out from the same solvent. The data are given in Table 1.

Protected Tetrapeptide Esters (15—28). A typical run (**20** in Table 2) was as follows: To a solution of Boc-D-Ala-L-Val-L-Val-OMe (**6**, 1.73 g, 4.3 mmol) in 20 ml of methanol was added TosOH·H_2O (1.00 g, 5.3 mmol). The mixture was stirred at 30°C for 5 h. The solvent was evaporated under reduced pressure at a bath temperature of 50°C to give H-D-Ala-L-Val-L-Val-OMe·TosOH as a solid residue. The residue was dissolved in 30 ml of chloroform and cooled in an ice-bath. To this solution was added Et_3N (0.53 g, 5.3 mmol), followed by Z-L-Asp(OBzl)-ONSu[18] (1.82 g, 4 mmol) with stirring. The mxiture was stirred for 3 h and then kept standing overnight. The reaction mixture was washed successively with water, 1 M HCl (1 M=1 mol dm^{-3}), a 5% sodium hydrogencarbonate solution and water, and then concentrated under reduced pressure to leave an oily product. The oil was crystallized from ethyl acetate–hexane to give Z-L-Asp(OBzl)-D-Ala-L-Val-L-Val-OMe (**20**) as needles. Recrystallization was carried out from the same solvent. The data are given in Table 2.

Tetrapeptide Esters (29—42). A typical run (**34** in Table 3) was as follows: Z-L-Asp(OBzl)-D-Ala-L-Val-L-Val-OMe (**20**, 1.60 g) was dissolved in a mixture of acetic acid (40 ml) and water (10 ml), and hydrogenated in the presence of 5% Pd/C (0.45 g) with stirring at atmospheric pressure and room temperature for 5 h. The reaction mixture was filtered and the filtrate was concentrated to dryness under reduced pressure. The residue was dissolved in water and the solvent was evaporated under reduced pressure to remove the trace amount of remaining acetic acid. The procedure was repeated four times. The crystalline residue thus obtained was recrystallized from water to give 0.80 g (67.8%) of L-α-Asp-D-Ala-L-Val-L-Val-OMe·$3H_2O$ (**34**) as needles. The data are given in Table 3.

The Ability of an α-Aminoisobutyric Acid Residue to Promote Helical Folding in Oligopeptides[1)]

Mitsuaki NARITA,* Kazunori ISHIKAWA, Hiroki SUGASAWA, and Masamitsu DOI
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei 184
(Received January 11, 1985)

In order to investigate the ability of an Aib residue to promote helical folding in oligopeptides, oligo(Leu)s containing an Aib residue were prepared by stepwise elongation and fragment condensation methods. The peptides prepared were the following: Boc-Aib-Leu$_n$-OBzl (n=3—6 and 9), Boc-Leu$_n$-Aib-OBzl (n=3—6 and 9), Boc-Leu$_3$-Aib-Leu$_3$-OBzl, Boc-Leu$_4$-Aib-Leu$_4$-OBzl, Boc-Leu$_8$-Aib-Leu$_4$-OBzl, Boc-Leu$_4$-Aib-Leu$_8$-OBzl, and Boc-Leu$_8$-Aib-Leu$_8$-OBzl. The IR absorption conformational analyses of Boc-Aib-Leu$_n$-OBzl (n=3—6) in dichloromethane have shown the occurrence of incipient helical structures (α- or 3_{10}-helixes) formed by one, two, three, and so forth $i \rightarrow i$—4 or $i \rightarrow i$—3 hydrogen-bonding patterns. All the peptides except Boc-Aib-Leu$_9$-OBzl and Boc-Leu$_n$-Aib-OBzl (n=6 and 9) have also shown helical structures (α- or 3_{10}-helixes), indicating the great ability of an Aib residue to promote helical folding in peptides. This is in remarkable contrast with the fact that homologous oligo(Leu) counterparts have β-sheet structures. The solubility properties of the peptides were in good agreement with those speculated from their conformations. The initiation and stabilization mechanism of helical folding in peptides has been illustrated schematically and attributed to the restriction of the values of the backbone dihedral angles ϕ and ψ of an Aib residue due to steric hindrance, followed by the restriction of the values of ϕ and ψ of other amino acid residues due to hydrogen bonds initiated by the Aib residue. The great ability of an Aib residue to promote helical folding in peptides also suggests that the restriction of the values of the backbone dihedral angles ϕ and ψ (right-handed α-helix: ϕ=−57°, ψ=−47°) of an amino acid residue in peptide chains is one of important initiation mechanisms of α-helical folding in natural proteins. The implication of the new findings for the study of proteins containing Aib residues is presented on the basis of the stabilizing efficacy of Aib residues on helical regions of proteins.

Aib-rich peptide fragments are often found in membrane-channel-forming polypeptides like alamethicin[2—4)] and suzukacillin,[5)] and are well recognized to have 3_{10}- and α-helical structures.[6)] The wide occurrence of Aib residues in microbial, particularly in the peptaibophols, has been attributed to their role in constraining the peptide backbones. In a previous paper,[7)] we have demonstrated the usefulness of a novel strategy for solubility improvement in helical oligopeptides based on the restriction of the values of the backbone dihedral angles ϕ and ψ of Aib residues, and the results have been attributed to the ability of the Aib residue to promote helical folding in the peptide. We have also shown that the properties described there for an Aib residue have important implications for the study of proteins and that the introduction of a few Aib residues in place of Ala residues in helical regions of proteins offers the prospect for creating novel proteins not found in nature. In this relation, it is very interesting to investigate how many Leu residues in model oligo(Leu)s are constrained in helical folding by the introduction of an Aib residue at N- or C-terminal or at a central portion.

On the other hand, the investigation on the initiation mechanism of α-helical folding in proteins is one of the upmost interesting problems for understanding the mechanism of protein folding and the prediction of folding from amino acid sequence. Helical folding in Boc-Leu$_n$-Aib-OBzl (n=3 and 4) in the previous study[7)] apparently suggests that the restriction of the values of ϕ and ψ of an amino acid residue is one of the important mechanisms for the initiation of helical folding in proteins.

In this paper, we report syntheses and conformations of model oligo(Leu)s containing an Aib residue and the ability of Aib residues to promote helical folding in oligopeptides.

Experimental

General. The uncorrected capillary melting points will be reported. Analytical instruments and conditions were described in the previous paper.[7)]

General Procedure for the Stepwise Elongation Using DCC Activation. The preparation of Boc-Leu$_n$-OBzl (n=3—6) was described in a previous paper.[8)] The preparation of Boc-Aib-Leu$_n$-OBzl and Boc-Leu$_n$-Aib-OBzl (n=3—6) is essentially the same with that of Boc-Leu$_n$-OBzl. The preparation of Boc-Leu$_n$-Aib-OBzl (n=3 and 4) was actually described in the previous paper.[7)]

General Procedure for Removal of the Boc Group. A Boc-peptide Bzl ester (10 mmol) in 3 M[†] HCl/AcOEt (70 ml) was stirred in an ice-chilled bath for 1.5 h, and the mixture was concentrated *in vacuo*. The residue was used for a subsequent coupling reaction without further purification.

General Procedure for Removal of the Bzl Group. A Boc-peptide Bzl ester (7 mmol) was hydrogenated overnight at atmospheric pressure in a mixture of acetic acid and methanol (1/4, v/v) (100 ml) using 10% Pd/C (10 wt%) as a catalyst. After removal of Pd/C by filtration, the filtrate was concentrated *in vacuo*. The residue was triturated with water and purified by recrystallization from appropriate solvents (mainly aqueous ethanol).

General Procedure for Fragment Condensation Using DCC Activation in the Presence of HOBt. DCC (1.1 equiv) was added to an ice-chilled stirred mixture of a carboxyl component (1.1 equiv), HOBt (1.2 equiv), and an amino component (5 mmol) (obtained by treatment of the HCl salt with an equivalent NMM) in dichloromethane (100 ml). The reaction mixture was stirred in an ice-chilled bath for

[†] 1 M=1 mol dm^{-3}.

3 h, at room temperature overnight, and then filtered. The filtrate was washed with 10% citric acid, 5% sodium hydrogencarbonate, and water, dried over sodium sulfate, and concentrated *in vacuo*. The residue was purified by recrystallization from appropriate solvents shown in Table 1. The coupling reaction for the peptide **12** was performed in a mixture of dichloromethane and DMF (3/2, v/v) in an ice-chilled bath for 3 h and then at room temperature for 2 d, and that for the peptide **10**, in NMP on the same reaction conditions.

Results

Syntheses of Oligo(Leu)s Containing an Aib Residue. Oligo(Leu)s containing an Aib residue were prepared by stepwise elongation and fragment condensation methods. The synthetic scheme is shown below. Boc-Aib-Leu$_n$-OBzl (n=3—6: **1—4**) and Boc-Leu$_n$-Aib-OBzl (n=3—6: **6—9**) were prepared by a stepwise elongation, starting with H-Leu-OBzl and H-Aib-OBzl as amino components, respectively. The synthetic procedure was essentially the same with that described before.[7,8] Removal of the Bzl group from the peptides **6** and **7** was performed by hydrogenolyses using Pd/C as a catalyst and the products **6'** and **7'** were used as carboxyl components in subsequent fragment condensations for the preparation of Boc-Leu$_3$-Aib-Leu$_3$-OBzl (**11**) and Boc-Leu$_4$-Aib-Leu$_4$-OBzl (**12**), respectively. Boc-Aib-Leu$_9$-OBzl (**5**) and Boc-Leu$_9$-Aib-OBzl (**10**) were similarly prepared by fragment condensations of Boc-Aib-Leu$_6$-OH with H-Leu$_3$-OBzl, and of Boc-Leu$_3$-OH with H-Leu$_6$-Aib-OBzl, respectively. Boc-Leu$_8$-Aib-Leu$_4$-OBzl (**13**), Boc-Leu$_4$-Aib-Leu$_8$-OBzl (**14**), and Boc-Leu$_8$-Aib-Leu$_8$-OBzl (**15**) were also prepared by fragment condensations of Boc-Leu$_4$-OH with H-Leu$_4$-Aib-Leu$_4$-OBzl, of Boc-Leu$_4$-Aib-Leu$_4$-OH with H-Leu$_4$-OBzl, and of Boc-Leu$_4$-OH with H-Leu$_4$-Aib-Leu$_8$-OBzl, respectively. Through the preparation in the scheme, the fragment condensations were performed in high yields using DCC activation in the presence of HOBt, and were monitored by HPLC on a gel filtration column. Liberation of the amino groups from Boc-peptide Bzl esters was carried out by treatment with 3 M HCl/AcOEt followed by treatment with NMM. Removal of the Bzl groups from

other peptides was also performed by hydrogenolyses using Pd/C as a catalyst. Homogeneity of the peptides except the peptides **5** and **10** was easily ascertained as the peptides had a single peak on HPLC. The synthetic results and physical properties of the peptides are assembled in Table 1, and data of elemental and amino acid analyses of the peptides, in Table 2. The analytical data are in good agreement with the calculated values.

IR Absorption Conformational Analyses of the Peptides 1—15 in Dichloromethane. As a method of phase transformation of peptides from solution to a solid state greatly influences their solid-state conformational properties at critical size for development of helical structures,[9] the ability of an Aib residue to promote helical folding in oligo(Leu)s was examined in dichloromethane using IR absorption spectroscopies. Due to low solubility of the peptides **5**, **9**, and **10** in dichloromethane, these IR spectra were measured in the solid state for nujor mulls. The results in the most important spectral regions for the conformational assignments (3600—3200 cm^{-1}, amide A; 1700—1600 cm^{-1}, amide I) are listed in Table 3. As representative examples, the IR spectra of the peptides **1**—**4** are presented in Fig. 1. Those of the peptides **11**, **12**, and **15** are also shown in Fig. 2. All the peptides in solution show strong bands at 3340—3320 cm^{-1} in the amide A region and strong bands at 1673—1659 cm^{-1} in the amide I region, indicating helical structures.[10] Weak or medium-intensity bands at 3430—3420 cm^{-1} of the peptides are assigned to the free urethane and amide NH groups,[11] while the strong bands at 3340—3320 cm^{-1} to the intramolecular hydrogen-bonded NH groups (α-helix: $i \rightarrow i$—4, C_{13} or 3_{10}-helix: $i \rightarrow i$—3, C_{10}).[11] The latter absorption shifts to lower frequencies with increasing peptide chain length. In addition, the ratio of the intensity of the band of the hydrogen-bonded NH group to free NH group (A_H/A_F) increases regularly with increasing peptide chain length. The same tendency has been observed in the study of IR absorption spectra in deuteriochloroform in the 3480—3300 cm^{-1} frequency range of Z-(Aib)$_n$-O-*t*-Bu (n=3—5).[11b)]

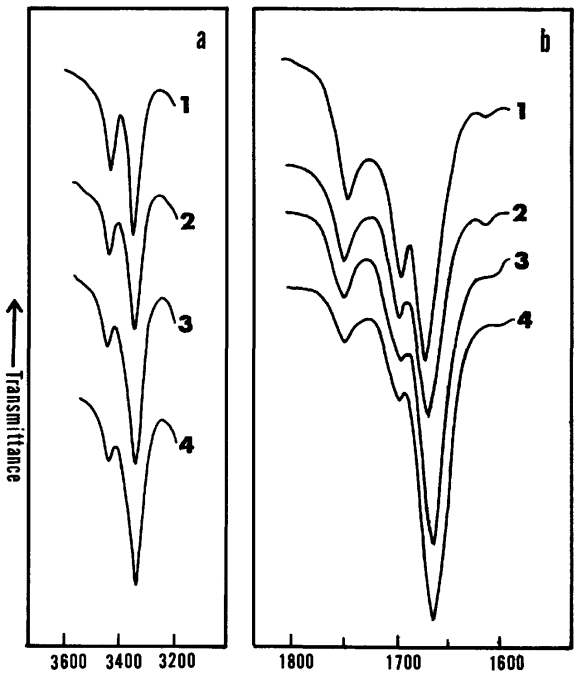

Fig. 1. IR absorption spectra of the peptides **1**—**4**. a: The amide A region; b: the amide I region.

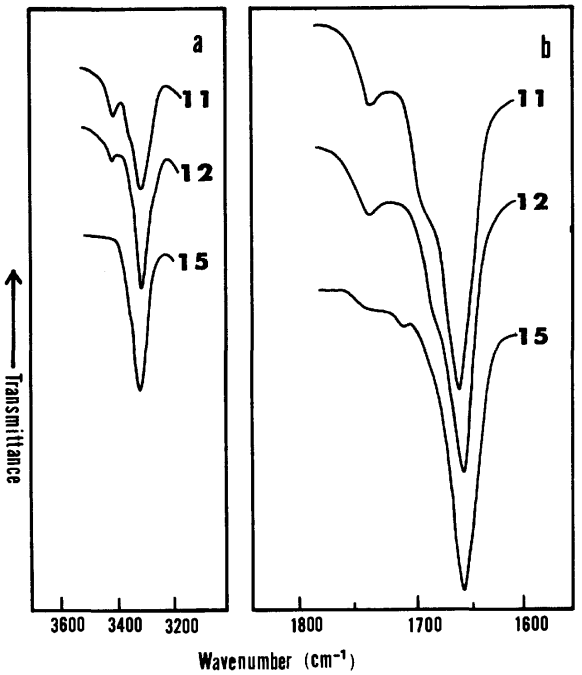

Fig. 2. IR absorption spectra of the peptides **11**, **12**, and **15**. a: The amide A region; b: the amide I region.

On the other hand, the solid-state conformations of the insoluble peptides **5**, **9**, and **10** are predominantly antiparallel β-sheet structures, judging from strong bands at 3280—3265 cm^{-1} in the amide A region and medium-intensity bands at 1692—1693 cm^{-1} and strong bands at 1630—1627 cm^{-1} in the amide I region,[10] accompanied with medium-intensity shoulders at 1660—1640 cm^{-1}, which was assigned to helical or coiled conformations.[10]

Solubility Properties. The relationship between solubilities and conformations of protected peptides has well documented and the severe insolubility of protected peptides in organic solvents results from their β-sheet aggregation.[7,8,12-14] The solubility data of the peptides **1**—**15** in various organic solvents are assembled in Table 4. The results are in agreement with those speculated from the conformations.

Discussion

The great ability of an Aib residue to promote helical folding in model oligo(Leu)s is clearly demonstrated by the IR absorption conformational analyses of the peptides **1**—**15**. The helical conformations of the peptides **1**—**4**, **6**—**8**, and **11**—**14** in dichloromethane are in remarkable contrast with the β-sheet

structures of the homologous oligo(Leu) counterparts.[7,15-17] Each Aib residue of these peptides apparently stabilizes helical folding in the peptides to great extent. For example, in Fig. 2, the ratio of the intensity of the amide A bands of the hydrogen-bonded NH groups to free NH groups increases regularly from the tetrapeptide **1** to the heptapeptide **4**, indicating helical propagation together with increasing peptide chain length. This is illustrated schematically in Fig. 3, where α-helical structures ($i \rightarrow i$—4 hydrogen-bonding patterns) are adopted as an example.[18] The initiation and propagation of helical structures of the peptides **1**—**4** is apparently attributed to the restriction of the Aib residue to conformations in the helical region ($\phi = \pm 60 \pm 20$, $\psi = \pm 30 \pm 20$) due to its steric hindrance,[19,20] followed by the restriction of the values of ϕ and ψ of other Leu residues due to hydrogen bonds initiated by the Aib residue. It is suggested that the restriction of the values of ϕ and ψ of an amino acid residue is one of the important mechanisms for the initiation of helical folding in proteins. Thus, we characterize this route for helical formation in protein folding as an initiation mechanism by the restriction of the values of the ϕ and ψ of an amino acid residue. The analogous idea of helix initiation was proposed by Blagdon and Goodman,[21] and characterized as terminal initiation mechanism by polar groups and by turns.

In Fig. 3, the urethane carbonyl groups of the peptides **1**—**4** participate in the 5→1 hydrogen-bonding. A shift of the frequencies of the urethane carbonyl groups to 1700—1690 cm^{-1} (Table 3) apparently supports the involvement of the carbonyl groups in the hydrogen bond.[22] In Fig. 3a, the amide carbonyl groups of the peptide **1** do not participate in a hydrogen bond, and this is supported by the observation that the peptide **1** has a strong band at 1672 cm^{-1} in the amide I region (Table 3). The α-helical structure of the peptide **1** in Fig. 3a, however, implies the restriction of the values of ϕ and ψ of the three Leu residues. The carbonyl absorption in the peptides **1**—**4** shifts to lower frequencies together with the NH absorption of the intramolecular hydrogen-bonding NH groups (Table 3), indicating propagation of helical structures with increasing peptide chain length as shown in Fig. 3. This observation is very close to the results that the X-ray diffraction and IR absorption conformational analyses of Z-$(Aib)_n$-OH (n=3—5) in the solid state have shown the occurrence of incipient 3_{10}-helixes, formed by one, two, and three type III (or type III′) β turns, respectively.[11b] In solvents of low polarity, the IR absorption data of Z-$(Aib)_n$-OH (n=3—5) were also in favor of the same intramolecular hydrogen-bonded forms as found in the solid state.[11b] The peptides **1**—**4**, however, could not be obtained as crystalline materials having helical structures, because α-helical→β conformational transformation took place during phase transformation of the peptides from solution to the solid state. Figure 4 presents the α- and 3_{10}-helical structures of the peptide **12** as an example. The α-helix in Fig. 4a appears to be more stable than the 3_{10}-helix in Fig. 4b, judging from the angles of hydrogen bonds, although it is well recognized that Aib-rich peptides favor 3_{10}-helixes.[2-6] The peptide **5** is soluble in a reaction mixture of dichloromethane during the coupling reaction, but it becomes less soluble as shown in Table 4 after obtaining as a crystalline material. The solubility data of the peptide **5** are in good agreement with the ones speculated from the β-sheet conformation.

The IR data of the peptides **6**—**8** in Table 3 also indicate that the helical structures correspond to those of the peptides **1**—**3** (Fig. 3a—c), respectively. In the peptides **6**—**10**, however, only the value of the backbone dihedral angle of ϕ of the Aib residues is restricted. Difference in helical stability between the peptides **4** and **9** appears to be illustrated by no participation of the ester group of the Aib residue of the peptide **9** in helical folding, while the Boc group bound to the Aib residue of the peptide **4** participates in helical folding. Thus, the peptides **9** and **10** are predominantly in favor of antiparallel β-sheet structures, and are less soluble in organic solvents (Table 4).

The peptides **9**—**15** are regarded to be produced by the hybridization, through an Aib residue, of the peptides having an Aib residue at C-terminal ends with those at N-terminal ends. The IR data in Table 3 clearly indicate that helical structures of the peptides **11**—**15** are efficiently stabilized by the hybridization of the

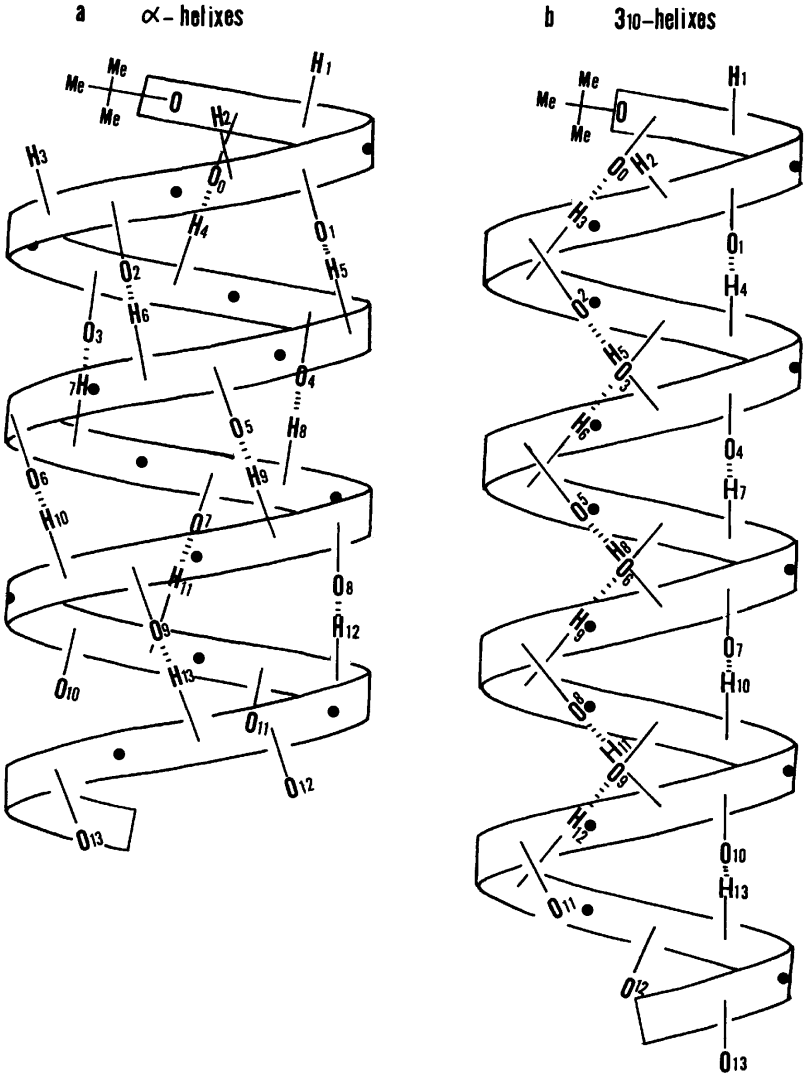

Fig. 4. α- and 3_{10}-helical structures of the peptide **12**.

corresponding two peptides. For example, the hybridization, through the Aib residue, of the peptide **1** with the peptide **6** and of the peptide **2** with the peptide **7** produces three additional hydrogen bonds in the peptides **11** and **12**, and strongly stabilizes the helical structure. This is illustrated schematically in Fig. 5, where α-helical structures are also postulated as an example. Difference in helical stability among the peptides **5**, **10**, and **13**—**15** is apparently resulted from the additional hydrogen bonds in the peptides **13**—**15**.

In this study the strategy for solubility improvement in protected peptides based on the restricted values of the backbone dihedral angles ϕ and ψ of an Aib residue[7] was also successfully applied to the model oligo(Leu)s. The solubility data of the peptides **1**—**15** directly reflect their conformations (Tables 3 and 4). The high solubility of the peptides **4** and **11**—**14** is in remarkable contrast with the observation that their homologous oligo(Leu) counterparts are barely soluble or insoluble in various organic solvents.[7,8]

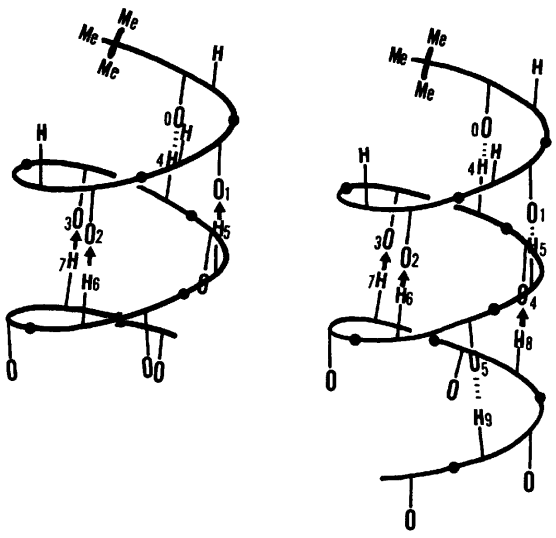

Fig. 5. Stabilization of α-helical structures of the peptides **11** and **12**. Three additional hydrogen bonds are shown by the arrow (→).

Conclusions

The great ability of an Aib residue to promote helical folding in peptides is clearly demonstrated using model oligo(Leu)s. The results make clear that the restriction of the values of the backbone dihedral angles ϕ and ψ of an amino acid residue is one of initiation mechanisms of helical folding in peptides, suggesting it to be one of important initiation mechanisms of α-helical folding in natural proteins. The stabilizing efficacy of an Aib residue on helical structures is also attributed to the restriction of the values of the backbone dihedral angles ϕ and ψ of the Aib residue, followed by the restriction of the values of those of other amino acid residues through hydrogen bonds initiated by the Aib residue. The properties of an Aib residue for stabilizing helical structures have innovative implications for the study of proteins. For example, replacement of a few Ala residue with Aib residue in helical regions of enzymes offers the prospect for creating novel enzymes, having thermostable properties and a wide range of pH optimum. The techniques offer the potential for altering protein function in ways not possible by any other method, just as mentioned in protein engineering pioneered by genetic technology.[24]

Effective Cleavage of 7-Alkoxytricyclo[6.4.0.0^{2,7}]dodecan-3-one System

Tsutomu KOJIMA, Yoshinobu INOUYE, and Hiroshi KAKISAWA*
Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305
(Received January 14, 1985)

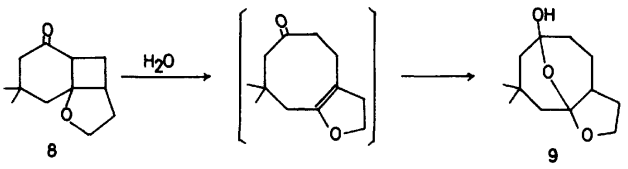
Several effective methods for the cleavage of the cyclobutane ring in 7-alkoxytricyclo[6.4.0.0^{2,7}]dodecan-3-one system are described. These involve reactions with hydriodic acid, with trimethylsilyl trifluoromethanesulfonate, and with KOH in H_2O–DMSO *via* a lactone derivative.

Among various naturally occuring materials, taxane (**1**)[1] and ophiobolane (**2**)[2] are interesting from a synthetic view point, for they have a unique carbon skeleton, that of an 8-membered ring condensed with a 6- or 5-membered ring.

In the course of our synthetic study to the taxane skeleton, the combination of regio- and stereo-controlled intramolecular enone-olefin cycloaddition with subsequent cyclobutane cleavage[3] has been employed as a key reaction. We described previously that the irradiation of 5,5-dimethyl-3-(3-methyl-2-cyclohexenylmethoxy)-2-cyclohexenone afforded a cyclobutane derivative **3**.[4] The remaining problem was how to cleave the cyclobutane ring to a bicyclo[6.4.0]dodecane derivative. In the present study, we will report several effective methods for the cleavage of the cyclobutane system.

The starting cyclobutane **6** was prepared from **3** *via* reaction sequences in Scheme 1. Allylation of the photocycloadduct **3** afforded a mixture of 2-allyl ketones **5** and an enol ether **4**; the mixture on heating underwent a Claisen rearrangement, providing a stereoisomeric mixture of **5a** (73%) and **5b** (9%). The stereochemistry of the allyl group in **5a** was confirmed by the pseudocontact shifts on the addition of Eu-FOD to the alcohol **7a** (see Experimental). The allyl group of **5a** was hydrogenated over PtO_2 to afford the 2-propyl ketone **6**.

In 1973, Tamura and co-workers reported that the photoadduct **8** could be cleaved into a cyclooctane derivative **9** in 53% yield by refluxing **8** in water.[5]



8 9

Scheme 2.

However, a similar attempt with **6** was unsuccessful. A more drastic conditions such as refluxing with aqueous hydriodic acid was required and, in this case, a fused 8-membered ring derivative **10** was obtained in 70% yield. The structure of **10** was confirmed by spectroscopic evidence. Besides the carbonyl group (1705 cm^{-1} in IR and δ 214.5 in ^{13}CNMR), an enol ether group is recognized in ^{13}CNMR spectrum at δ 115.6 and 145.4. The disappearance of eight-carbon signals in ^{13}CNMR spectrum suggests the conforma-

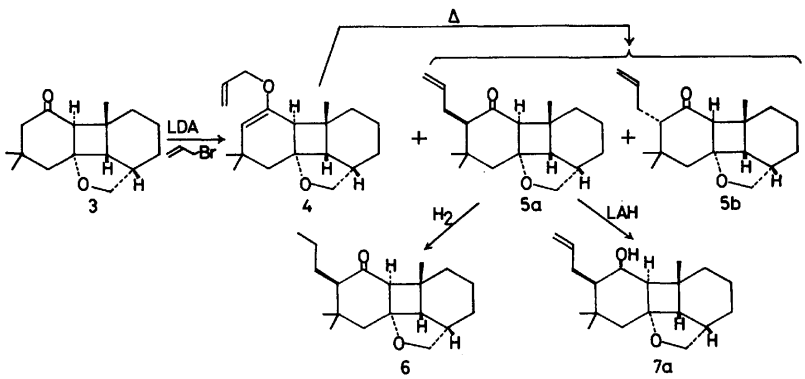
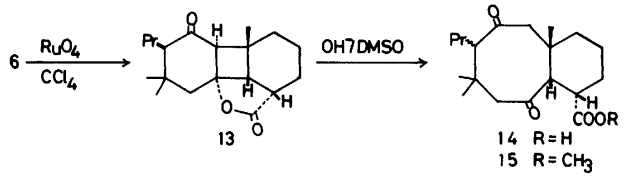


Scheme 1.

tional mobility of the cyclooctane ring.

In searching for milder conditions, we found that trimethylsilyl trifluoromethanesulfonate (TMSOTf)[6] would be effectively employed for the cleavage of the cyclobutane system under neutral conditions. Treatment of the ketone **6** with freshly prepared TMSOTf in purified carbon tetrachloride under an argon atmosphere gave a ring-opened compound **11** in 84% yield, accompanied by a small amount of a simple enol silyl ether **12** (11%) and recovered starting material **6** (5%). In ^{1}H NMR spectrum of **11**, the methylene protons attached to oxygen appear at δ 3.80 (1H, dd, J=9 and 3 Hz) and 4.23 (1H, t, J=9 Hz), and a vinyl proton at 4.53 (1H, s); four vinylic carbons are recognized in ^{13}C NMR spectrum at δ 115.2 (d), 115.9 (s), 145.1 (s), and 152.2 (s). The enol silyl ether **11** was quantitatively converted into the ketone **10** on aqueous hydrochloric acid in THF. This is the first example of the cleavage of the cyclobutane ring by means of TMSOTf.

An alternative procedure for the preparation of an 8-membered ring system *via* a lactone **13** is as follows.



Scheme 4.

The oxidation of **6** was successful by using a stoichiometric amount of RuO_4[7] in purified carbon tetrachloride for only several minutes at room temperature. The γ-lactone **13** (1765 cm^{-1} in IR) was obtained in 86% yield. Saponification of **13** in DMSO gave a diketo acid **14** in 80% yield. The ^{13}C NMR spectrum of the methyl ester **15** (214.2, C=O; 213.6, C=O; 176.0, ester) and mass spectrum [m/z 336 (M^+), 321 (M^+—CH_3), and 305 (M^+—OCH_3)] indicate that the cyclobutane ring is cleaved to an cyclooctane ring system.

In summary, the preparation of the fused 8-membered ring system can now be achieved not only under acidic or basic but also under neutral conditions.

Experimental

All the melting points are uncorrected. IR spectra were recorded on a Hitachi 215 grating spectrophotometer. ^{1}H NMR spectra were measured on JEOL MH-100 and LMN-FX90Q spectrometers and ^{13}C NMR on a JEOL LMN-FX90Q, using TMS as the internal standard. Mass spectra were obtained on a Hitachi RMU-6MG analyzer. High resolution mass spectra were performed at Nippon Roche Research Center, Kamakura.

4-Allyl-1,5,5-trimethyl-8-oxatetracyclo[8.3.1.0^{2,7}.0^{7,14}]tetradecan-3-one (5). To 5 ml of a dry THF solution of lithium diisopropylamide (LDA, 8.75 mmol), were added 5 ml of hexamethylphosphoric triamide (HMPA) at −78 °C and then 424 mg (1.71 mmol) of 1,5,5-trimethyl-8-oxatetracyclo-[8.3.1.0^{2,7}.0^{7,14}]tetradecan-3-one (**3**)[4] in 3 ml of dry THF. The mixture was stirred for 30 min, then allyl bromide was added at a once and the whole allowed to warm to room temperature. After 3 h, the mixture was poured into a saturated ammonium chloride solution, and extracted with ether. The ether layer was washed with water and brine, and dried over anhyd Na_2SO_4. Evaporation of the solvent gave an oil. Flash-chromatography on silica gel (elution with hexane-ethyl acetate=30:1—20:1) afforded 432 mg of an enol ether **4** and 88 mg of a mixture of **5a** and **5b**.

4: IR (CCl_4) 1650, 1145, 1050, 990, and 920 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.06 (3H, s), 1.08 (6H, s), 1.78 (2H, s), 2.75 (1H, br s), 3.75 (1H, t, J=9 Hz), 4.04 (1H, t, J=9 Hz), 4.13 (2H, m), 4.55 (1H, s), and 5.0—6.3 (3H, m); MS m/z 288 (M^+).

The enol ether **4** was heated in a sealed tube at 195 °C for 2 h. The combined mixture of **5a** and **5b** was flash-chromatographed on silica gel (elution with hexane-ethyl acetate=100:1—20:1) to give 359 mg of **5a** (73%) as crystals and 44 mg of **5b** (9%) as an oil.

5a: mp 70—71 °C (pentane); IR (CCl_4) 1685, 1635, 1170, 1040, 990, and 905 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.82 (3H, s), 1.05 (3H, s), 1.08 (3H, s), 1.94 (2H, AB center, J=16 Hz), 2.4 (2H, m), 2.74 (1H, s), 3.63 (1H, dd, J=10 and 9 Hz), 3.93 (1H, t, J=9 Hz), 4.7—4.9 (2H, m), and 5.6—6.1 (1H, m); MS m/z 288 (M^+, 2%) and 109 (100%).

Found: C, 79.09; H, 9.83%. Calcd for $C_{19}H_{28}O_2$: C, 79.12; H, 9.78%.

5b: oil; IR (CCl_4) 1710, 1045, 995, and 915 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.83 (3H, s), 1.17 (3H, s), 1.20 (3H, s), 2.74 (1H, br s), 3.76 (1H, t, J=9 Hz), 4.09 (1H, t, J=9 Hz), and 4.8—6.0 (3H, m); MS m/z 288 (M^+, 4%) and 109 (100%).

4-Allyl-1,5,5-trimethyl-8-oxatetracyclo[8.3.1.0^{2,7}.0^{7,14}]tetradecan-3-ol (7a). To a suspension of 20 mg of lithium aluminum hydride in 1 ml of dry THF, was added 21 mg of **5a** in 0.5 ml of dry THF at 0 °C. The mixture was stirred at that temperature for 15 min and then at room temperature for 30 min. Work up as usual and flash chromatography on silica gel with hexane-ethyl acetate (10:1) gave **7a** (71%) and **7b** (28%).

7a: mp 93—94 °C (hexane, 0 °C); IR (CCl_4) 3600, 1045, 980, and 920 cm^{-1}; ^{1}H NMR (CCl_4) δ (the Δ values show the pseudocontact shift upon the addition of 0.23 equiv of Eu-FOD)=0.76 (3H, s, Δ0.44), 0.95 (3H, s, Δ0.44), 1.27 (3H, s, Δ0.98), 2.65 (1H, br d, J=9 Hz, Δ2.57), 3.60 (1H, t, J=9 Hz, Δ0.30), 3.80 (1H, t, J=9 Hz, Δ2.34), 3.89 (1H, t, J=9 Hz, Δ0.29), and 4.8—6.2 (3H, m).

Found: C, 78.60; H, 10.41%. Calcd for $C_{19}H_{30}O_2$: C, 78.57; H, 10.42%.

7b (an epimeric alcohol of **7a**): oil; IR (CCl_4) 3300br, 1050, 1000, and 920 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.91 (3H, s), 0.92 (3H, s), 1.02 (3H, s), 3.62 (1H, br d, J=5 Hz), 3.70 (1H, t, J=9 Hz), 3.93 (1H, t, J=9 Hz), and 4.8—6.0 (3H, m).

4-Propyl-1,5,5-trimethyl-8-oxatetracyclo[8.3.1.0^{2,7}.0^{7,14}]tetradecan-3-one (6). An ethanolic solution (5 ml) of **5a** (25 mg) was hydrogenated over PtO_2 under hydrogen at ordinary pressure. After 2 h, the catalysts were removed by filtration and the filtrate was evaporated to give an oil. Chromatography on silica gel with chloroform afforded 22 mg (88%) of **6**.

6: mp 63—64 °C (methanol, −20 °C); IR ($CHCl_3$) 1690 sh and 1685 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.75 (3H, s), 0.83 (3H, t, J=6.5 Hz), 0.98 (3H, s), 1.05 (3H, s), 1.94 (1H, d, J=15 Hz), 2.00 (1H, d, J=10 Hz), 2.06 (1H, d, J=15 Hz), 2.46 (1H, m), 2.79 (1H, br s), 3.65 (1H, t, J=9 Hz), and 3.98 (1H, t, J=9 Hz); ^{13}C NMR ($CDCl_3$) δ=14.3 (q), 16.2 (t), 22.4 (t), 22.9 (t),24.1

(t), 26.3 (q), 26.7 (q), 29.6 (q), 32.0 (s), 33.7(d), 35.8 (t), 36.4 (s), 49.2 (t), 50.6 (d), 51.6 (d), 61.4(d), 71.1 (t), 82.0 (s), and 212.9 (s); MS *m/z* 290 (M^+, 4%) and 109 (100%).

Found: C, 78.55; H, 10.44%. Calcd for $C_{19}H_{30}O_2$: C, 78.57; H, 10.42%.

11-Propyl-8,12,12-trimethyl-2-oxatricyclo[6.5.1.0^{4,14}]tetradec-1(14)-en-10-one (10). *Procedure A*: To a vigorously stirred suspension of **6** (10 mg) in 5 ml of water, 5 drops of hydriodic acid were added, and the mixture was refluxed for 4 h. The products were extracted in ether and chromatographed on silica gel with chloroform–hexane (2:1—3:1) to give a ketone **10** (7 mg, 70%) as crystals.

10: mp 68—70°C; IR (CCl_4) 1705, 1685, 1460, 1365, and 1206 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.76 (6H, s), 1.00 (3H, s), 2.0—4.0 (several broad signals), and 4.27 (1H, t, J=9 Hz); ^{13}C NMR ($CDCl_3$) δ (sharp signals only at)=14.6, 21.6, 22.2, 28.6, 36.8, 41.0, 42.7, 73.3, 115.6, 145.4, and 214.5.

Found: *m/z* 290.2245. Calcd for $C_{19}H_{30}O_2$: M 290.2247.

Procedure B: To a solution of **11** (7 mg, see below) in 5 ml of THF, were added 2 drops of a 10% hydrochloric acid. The solution was stirred for 2 h at room temperature. The whole was poured into water, extracted with ether, and the ether extract was dried over anhyd $MgSO_4$. Evaporation of the solvent gave the ketone **10** (6 mg, 100%).

11-Propyl-8,12,12-trimethyl-10-trimethylsiloxy-2-oxatricyclo-[6.5.1.0^{4,14}]tetradeca-1(14),9-diene (11). In a 5 ml flask, containing a solution of the ketone **6** (20 mg, 7×10^{-2} mmol) in 0.5 ml of dry CCl_4 (washed with concd H_2SO_4, dil KOH, H_2O, dried over P_2O_5; fractionally distilled) and a spinning bar, was added 27 mg (2.4×10^{-1} mmol) of triethylamine. After stirring for 5 min, was added drop by drop 47 mg (2.1×10^{-1} mmol) of TMSOTf at 0°C, under a dry argon atmosphere. The whole was allowed to warm to room temperature and stirred for 24 h. If some of the starting ketone **6** still remained 1 mol equivalents of Et_3N and TMSOTf were added to the solution, and the whole was again stirred over night. The resulting solution was passed through a short silica-gel column with CH_2Cl_2 to remove triethylammonium triflate. The crude products, obtained by evaporation of the solvent, were chromatographed on silica gel (with hexane–benzene=5:1) to give an 8-membered enol trimethylsilyl ether **11** (22 mg, 84%) as crystals, a simple enol trimethylsilyl ether **12** (3 mg, 11%), and **6** (1 mg, 5%).

11: IR (CCl_4) 1670, 1635, 1365, 1245, 1200, and 1120 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.19 (9H, s), 0.83 (3H, s), 0.88 (3H, s), 1.23 (3H, s), 3.80 (1H, dd, J=9 and 3 Hz), 4.23 (1H, t, J=9 Hz), and 4.53 (1H, s); ^{13}C NMR ($CDCl_3$) δ=0.4 (q, ×3), 14.9 (q), 21.9 (t, ×2), 24.3 (q), 25.4 (q), 26.3 (q), 27.5 (t), 34.8 (s, ×2), 40.8 (t), 43.3 (d), 44.0 (t), 48.1 (d), 72.3 (t), 115.7 (d), 115.9 (s), 145.1 (s), and 152.7 (s); MS *m/z* 362 (M^+, 8%) and 347 ($M^+ - CH_3$, 100%).

12: oil; IR (CCl_4) 1665 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.15 (9H, s), 0.89 (3H, t, J=7 Hz), 1.05 (6H, s), 1.55 (3H, s), 2.57 (1H, br s), 3.90 (1H, t, J=9 Hz), and 4.20 (1H, t, J=9 Hz); MS *m/z* 362 (M^+, 15%) and 347 ($M^+ - CH_3$, 100%).

4-Propyl-1,5,5-trimethyl-8-oxatetracyclo[8.3.1.0^{2,7}.0^{7,14}]tetradecane-3,9-dione (13). To a solution of the ketone **6** (40 mg) in 10 ml of purified CCl_4 (see above), was added drop by drop a solution of RuO_4 (Mitsuwa Kagaku Yakuhin Co. Ltd., Osaka, Japan; 61% activity, 38 mg) in 5 ml of pure CCl_4. The whole was stirred for 10 min. The remained RuO_4 was reduced to RuO_2 by addition of several drops of 2-propanol. RuO_2 was removed through a silica-gel column by elution with CH_2Cl_2 and the eluates were evaporated to give a crude γ-lactone **13** (36 mg, 86%) as crystals. This material was decomposed during recrystallization and, therefore, an analytical sample was obtained by sublimation (110°C, 400 pa).

13: mp 152—153°C; IR($CHCl_3$) 1765, 1695, and 1185 cm^{-1}; ^1H NMR($CDCl_3$) δ=0.87 (3H, s), 0.91 (3H, t, J=6.6 Hz), 1.08 (3H, s), 1.14 (3H, s), 2.12 (2H, AB center), 2.42 (1H, dd, J=12 and 1 Hz), 2.80 (1H, br s), and 2.92 (1H, dm, J=12 Hz); ^{13}C NMR ($CDCl_3$) δ=79.6 (C-O), 180.5 (-COO-), and 211.1 (-CO-).

Found: C, 74.92; H, 9.27%. Calcd for $C_{19}H_{28}O_3$: C, 74.96; H, 9.27%.

Methyl 4-propyl-1,5,5-trimethyl-3,7-dioxobicyclo[6.4.0]dodecane-9-carboxylate (15). The γ-lactone **13** (7 mg) was dissolved in 2 ml of DMSO and 2 ml of a 10% KOH solution was added at room temperature under an argon atmosphere. After gently refluxed for 3 h, the mixture was allowed to cool to room temperature. The whole was poured into 10 ml of ice-water, washed with benzene and then acidified with 1 M† HCl. The solution was extracted with ether. Evaporation of the solvent gave crude carboxylic acid **14** (7 mg) as crystals. A pure sample was obtained by chromatography on silica gel (with CH_2Cl_2–acetone=100:1—20:1).

14: mp 190.5—191°C; IR ($CHCl_3$) 3500—2500br and 1695 cm^{-1}; ^1H NMR($CDCl_3$) δ=0.92 (3H, s), 0.98 (9H, s), and 1.97—3.12 (7H, m).

To a solution of the crude acid **14** in 20 ml of ether, was added drop by drop an ethereal solution of diazomethane at 0°C. The whole was stirred for 30 min at that temperature, and evaporated to give a crude oil. Chromatography of the oil on silica gel (CH_2Cl_2) gave a pure methyl ester **15** (5 mg, 92%; 72% overall yield from **13**).

15: oil; IR ($CHCl_3$) 1715 and 1695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.95 (s, 3H), 1.01 (s, 6H), 2.10 and 2.78 (AB, J=12.1 Hz), 2.23 and 3.10 (AB, J=12.7 Hz), 1.9—3.3 (3H, m), and 3.58 (3H, s); ^{13}C NMR ($CDCl_3$) δ=14.3 (q), 17.3 (q), 20.1 (q), 20.6 (t), 21.6 (t), 29.5 (t), 30.7 (t), 31.9 (q), 39.4 (s), 39.5 (s), 41.5 (t), 43.1 (d), 51.9 (q), 59.2 (t, ×2), 61.8 (d), 64.6 (d), 176.0 (s), 213.6 (s), and 214.2 (s).

Found: *m/z* 336.2295. Calcd for $C_{20}H_{32}O_4$: M 336.2302.

The Solution Chemistry of Organotin Compounds. III. A Thermodynamic Study of the Molecular Interaction of Me_2SnCl_2 with Lewis Bases by Means of Nuclear Magnetic Resonance Spectroscopy

Hideaki FUJIWARA,* Fumihiko SAKAI, Yoshihiro MIKAWA, and Yoshio SASAKI
Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamada-Oka, Suita, Osaka 565
(Received December 14, 1984)

Molecular interaction of Me_2SnCl_2 with Lewis bases has been investigated by measuring the concentration and temperature dependence of NMR coupling constant $^2J(^{119}Sn,H)$. It is found that 1:1 and 1(acid):2(base) complexes are formed concurrently in solution. Association constants and coupling constants in these complexes are determined at different temperatures, leading to the enthalpies ΔH° and entropies ΔS° for the relevant molecular interaction. The coupling constants are temperature independent and a merit of using this constant as a diagnostic tool has been proven. The E and C parameter treatment of ΔH°_{AB} has given reasonable E_A and C_A values for Me_2SnCl_2. Entropies ΔS° are also estimated in gas phase on the basis of molecular theory for the third-law entropy, and the contribution from solvation is shown important in the solution of $CHCl_2CHCl_2$.

Thermodynamic parameters are essential for the discussion of molecular interactions, being independent on the method of investigation and measuring conditions such as concentration and temperature unless there is a special reason to the contrary. Under this idea much effort has been devoted to determine these parameters as accurately as possible, and quite a lot of data have been collected for different interacting systems.[1] Hitherto, several useful equations have been established empirically from these data, especially from the enthalpies. That is, the E and C parameter treatment has been proposed by Drago[2] stating that $-\Delta H^\circ_{AB}=E_AE_B+C_AC_B$, while Gutman[3] proposed the donor number which is equal to $-\Delta H^\circ$ for the complex formation of bases with $SbCl_5$ in CH_2ClCH_2Cl. Such studies are important not only for the understanding of solution-chemical behavior of each compound treated but also for that of the nature of molecular interactions generally.

In this series of our study, organotin compounds which are of wide industrial and agricultural use are taken up as a model compound, and the molecular interaction is studied from the stand point of solution equilibria and thermodynamics. The authors have investigated the substituent effect in the complex formation of $MeSnCl_3$ with substituted pyridines, and derived and discussed the thermodynamic parameters in relation to the position of substituent in the Me_2SnCl_2 plus picoline systems.[4,5] In the present study acidic character of Me_2SnCl_2 is examined on the complex formation with typical Lewis bases, *N,N*-dimethylformamide (DMF), dimethyl sulfoxide (DMSO), hexamethylphosphoric triamide (HMPA), and γ-picoline *N*-oxide (PINO).[6] NMR coupling constant $^2J(^{119}Sn, H)$ is measured in an inert solvent $CHCl_2CHCl_2$, and enthalpies and entropies of the molecular interaction are determined from variable temperature experiments. The results are discussed in relation to the empirical treatment of the enthalpies and to the molecular theory of the third-law entropies.

Experimental

NMR coupling constant was measured with a Hitachi R-22 NMR spectrometer at 90 MHz. Variable temperature experiments were carried out in the conventional way. The sample temperature was measured by a copper-constantan thermocouple immersed in the solvent in a separate sample tube. Temperature variation was less than ±0.3 °C during the measurement of all samples at a given temperature. ^{119}Sn satellite position was measured by a YHP5315A frequency counter within an error of 0.05 Hz under internal mode of NMR lock.

All distillations and sample handling were done in dry boxes in order to prevent moisture contamination. $CHCl_2$-$CHCl_2$ and DMSO were dried over CaH_2, and DMF, HMPA, and PINO were over BaO, and then they were distilled under reduced pressure after decantation. Me_2SnCl_2 (Tokyo Kasei Co.) was sublimed at about 60 °C. In the Job experiment, total concentration of acid and base was held constant at about 0.15 mol dm^{-3} and the molar ratio was varied. In the concentration and temperature dependence study, molarity of Me_2SnCl_2 was held constant at a value as low as possible, *ca.* 0.025 mol dm^{-3}.

Calculations were done on a NEAC S-900 and S-1000 computers at the Computer Center in Osaka University. The program CONDEP[5,7] was used for the equilibrium analysis. Linear equations were solved by a least squares method to obtain E_A and C_A parameters of Me_2SnCl_2, making use of a Library Program TLELSD transferred from the Computer Center in Tohoku University. ΔH° and ΔS° were obtained by a linear regression analysis of van't Hoff plot, together with their error limits.

Results

Stoichiometry of the complexes formed in solution was first tested by the Job plot. An example is shown in Fig. 1 for the PINO system typically. The curve reaches its maximum at a molar ratio larger than 0.5 and contribution of an 1(acid):2(base) complex is suggested besides the 1:1 complex. In the other systems the plots show maximum at the molar ratio 0.5, and only the 1:1 is supported from this experiment. The NMR parameter $^2J(^{119}Sn, H)$ reflects well the order and degree of coordination around Sn atom and is less subject to the other subsidiary solvent effect. An example of the concentration and temperature dependence is shown in Fig. 2 for the system of DMSO. In the Me_2SnCl_2 plus DMSO system, concentration dependence of $^2J(^{119}Sn,$

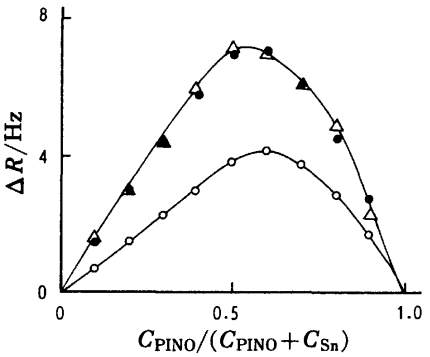

Fig. 1. Job plots for the system of Me_2SnCl_2 plus PINO at 34.1 °C. In the abscissa plotted are the molar ratio times variation in the NMR parameter, *e.g.*, $R_{acid}\cdot\Delta J$ for $^2J(^{119}Sn,H)$ where $\Delta J=J_{obsd}-J_{free}$. $\delta_H(SnCH_3)$ decreases on addition of the base and $R_{acid}\cdot(-\Delta\delta)$ is plotted.
R_{acid}=molar ratio of the acid. NMR parameters observed are: ●; $^2J(^{119}Sn,H)$, ○; $\delta_H(SnCH_3)$, △; $\delta_H(PINO,CH_3)$.
Total molarity of the acid and base is 0.18 mol dm^{-3} in $CHCl_2CHCl_2$.

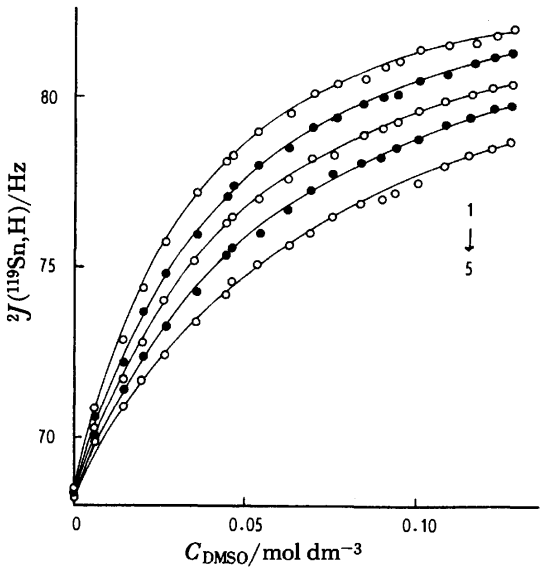

Fig. 2. Concentration and temperature dependence of $^2J(^{119}Sn,H)$ in the Me_2SnCl_2 plus DMSO system in $CHCl_2CHCl_2$.
Molarity of Me_2SnCl_2=0.025 mol dm^{-3}. Measurement temperatures are 34.1, 43.3, 51.4, 59.4, and 68.7 °C for curves 1 to 5.

H) is reproduced well within the experimental error by assuming only the 1:1 complex. This fact, together with the result of Job plot, indicates negligible contribution from 1:2 complex in solution treated here. In Table 1 analysis of the concentration dependence assuming only the 1:1 complex is compared with that assuming both 1:1 and 1:2 complexes. Standard deviation σ between the observed and the simulated coupling constants decreases only very slightly even if 1:2 complex is incorporated and one more adjustable parameter K_2 is introduced. K_2 is, if incorporated, very

II	A+B=AB	58.5±1.8	84.0±0.1	0.089
III[b]	A+B=AB	64.9±1.8	83.6±0.1	0.087

a) J_{AB_2} is set to 112.4 Hz. b) Lower half of the concentration range of DMSO is used for calculation.

small and its temperature dependence is scattered, indicating negligible contribution of the 1:2 complex. Calculations are also compared for the 1:1 complex formation in Table 1 using the total and the lower half of the concentration range of DMSO. The parameters are almost unchanged in these two calculations, supporting the model assumed. The results from the lower half of the concentration range are adopted below, because ten data points are usually sufficient for the simulation of two parameters, K_1 and J_{AB}, and because contribution of the 1:2 complex becomes much smaller with lowering the concentration of DMSO if it presents at all. Calculation of this DMSO system is summarized in Table 2. The error in each parameter is an estimation from the program or reproducibility in repeated experiments whichever is larger. When dissolved in neat DMSO, Me_2SnCl_2 is expected to form the 1:2 complex predominantly as evidenced by the J value of 112.4 Hz which is much larger than those of the free tin compound (68 Hz) and of the 1:1 complex (84 Hz). However, experiments with higher concentration of DMSO complex in $CHCl_2CHCl_2$ were prevented by the insufficient solubility.

Method of analysis of the Me_2SnCl_2 plus DMF system is similar to that of the DMSO system. When 1:2 complex was taken into account, K_2 value estimated was very small, sometimes even negative at higher temperatures. Therefore, only 1:1 complex is assumed. Calculation is also summarized in Table 2. It is worth noting that J_{AB} calculated is constant throughout the temperature range studied in common with above DMSO system. It is usual that chemical shift of complex exhibits quite large temperature dependence: this value needs be determined at each temperature and is not easily compared when derived at different temperatures or by different investigators. The temperature independency found in this study for the coupling constant indicates an intrinsic merit of using this constant as an observable.

Although 1:2 complex is not suggested from the Job plot in the Me_2SnCl_2 plus HMPA system, its formation is inevitable for the interpretation of the concentration dependence. Systematic errors appear between the observed and the recalculated J values, varying systematically with the concentration of HMPA. These errors are improved satisfactorily by incorporating the 1:2 complex, and the K_2 values change consistently

with the measurement temperature. The 4-parameter calculation including J_{AB_2} in adjustable parameters, however, proved unreliable because reproducibility of the two parameters K_2 and J_{AB_2} breaks down on repeated experiments. A small amount of 1:2 complex formed in solution seems responsible for this difficulty. This resembles to the Me_2SnCl_2 plus pyridine system,[7] but differs from the case in reference[4] where four parameters are simulated successfully in calculation. For this reason, calculation was done with the three adjustable parameters, fixing J_{AB_2} at a value in neat base.

It is clear from the Job plot that 1:2 complex is formed in solution for the Me_2SnCl_2 plus PINO system (Fig. 1). The 4-parameter calculation including J_{AB_2} was tested, but it gave rather scattered value of J_{AB_2}(104.6—108.3 Hz) at different temperatures and the van't Hoff plot of K_1 and K_2 deviated much from a linear line. Therefore, 3-parameter calculation was adopted for this case.

Discussion

Thermodynamic parameters of the complex formation are derived from van't Hoff plot of K_1 and K_2 obtained above (Fig. 3 and Table 3). Enthalpy-entropy compensation relation holds approximately (Fig. 4). A linear relation is also seen between ΔH°_{AB} and ΔJ_{AB} except for PINO (Fig. 5), as is often observed in a similar case.[8] This line will go through the origin in the Figure because ΔH° should be zero when ΔJ=0. NMR coupling constants are usually interrelated with the s-character of chemical bonds. Under this concept the break down of the ΔH—ΔJ proportionality for PINO will be interpreted as due to the different type of the complex suggested from IR study.[9] The E and C parameter treatment of ΔH°_{AB} proposed by Drago and Wayland[2] gives values of E_A=13.30 and C_A=5.48

0.0296[2] or E_A=6.25, C_A=0.60[10]), indicating enhanced acidity of Me_2SnCl_2.

On the contrary to enthalpies, entropy data have been overlooked frequently in the discussion of thermodynamic aspects of interacting systems. However, important informations are included in entropies, especially concerning the molecular (internal) motions and solvation of molecules. The entropy change on complex formation of A+B=AB can be equalized to the difference in the thermodynamic third-law entropies of the components, *i.e.*, $\Delta S^\circ_{AB,calcd}=S^\circ_{AB}-(S^\circ_A+S^\circ_B)$, the latters being calculated from molecular theory of thermodynamic functions.[11] This $\Delta S^\circ_{AB,calcd}$ is considered to correspond to the gas-phase value of ΔS°. Experimental entropies are compared with thus calculated ones in Table 4 where translational and rotational parts of entropy are used for calculation and the vibrational one is not included considering almost similar contributions from the starting compounds and the product.

The observed entropies are seen to be about 1/3 of the expected (calculated) values. Where does such a discrepancy come from? Some new chemical bonds are formed on complex formation, but contributions to the vibrational entropy from such bonds are very small (in the order of a few JK^{-1}mol^{-1}). Some internal motion will become restricted on complex formation, but such contribution is also small. In contrast, solvation by $CHCl_2CHCl_2$ is expected nontrivial. Its protons are known to have an acidic character, forming weak hydrogen bonding with base, and also it possesses polarity to solvate by means of electrostatic attraction. If, as a model calculation, $CHCl_2CHCl_2$ is assumed to solvate to a base molecule and the reaction proceeds in such a way as A+BS→AB+S, $\Delta S^\circ_{AB,calcd}$ is reduced in great deal in absolute value and −16 JK^{-1}mol^{-1} is obtained for the DMSO system. That is, the experimental value may be said correspond to the solvation number of 0.7. Similar number of 0.6—0.7 are reached for other systems studied here. Such calculation is only a model calculation, but it may be said soundly that the solvation as above contribute more (twice, roughly) to the entropy changes in $CHCl_2CHCl_2$ than the net entropy change in gas phase. It is well known that entropy changes in aqueous solutions become positive for ionic reactions such as protonation of bases, metal complex formation, or ion-pair formation, because of the release of water molecules on reaction. In the present case solvation does not take such a drastic role and the entropies remain negative, although the solvation takes a major part of the entropies observed.

^{119}Sn Mössbauer study of ^{60}Co-γ ray and thermal neutron irradiated potassium germanate glasses containing a small amount of SnO_2 has been performed to investigate the structural change of the glasses. The γ- and the thermal neutron-irradiation results in a disappearance of the distinct composition dependence of the Mössbauer parameters (quadrupole splitting and linewidth) observed before the irradiation. DTA measurement of the irradiated glasses also reveals drastic decreases in glass transition temperature (T_g) amounting to 20—120 °C and a simultaneous disappearance of the distinct composition dependence of T_g observed before the irradiation. This suggests a disruption of the chemical bond between germanium and oxygen atoms constituting GeO_6 units. On the other hand, Mössbauer measurement at lower temperatures reveals that a parameter of intermolecular force constant (θ^2M) obtained from the temperature dependence of the absorption area undergoes little change by the irradiations. This suggests that the irradiations bring about little changes in the ionic bond and the interatomic distance between tin and oxygen atoms, and that the irradiated germanate glasses can still be regarded as polymers from the lattice vibrational point of view.

Abnormal composition dependence of the physical properties of germanate glasses, *i.e.*, germanate anomaly has so far been found on density and refractive index,[1-3] viscosity,[4] and glass transition temperature (T_g).[4,5] Viscosity- and T_g-composition curves show maxima at the compositions of 17[4] and 15—16[5] mol% alkali oxides, respectively. The decrease in these physical properties in the higher alkali oxide content region was tentatively attributed to the formation of nonbridging oxygen (NBO) atoms, because it was expected that viscosity and T_g are well correlated with the cohesiveness and depolymerization of the glasses, respectively. The presence of NBO in germanate glasses was confirmed by Verweij and Buster[6] by means of Raman spectroscopy, and furthermore the fraction of NBO was obtained by Smets and Lommen[7] by means of X-ray photoelectron spectroscopy (XPS). In the Raman and XPS studies, the formation of NBO was concluded to start at an alkali oxide concentration of 18 mol%.

Mössbauer spectroscopy of ^{57}Fe has also been utilized for the structural studies of several kinds of glasses such as borate,[8-10] borosilicate,[11,12] phosphate,[13,14] and borophosphate[15] glasses. In ^{119}Sn Mössbauer study of germanate glasses[16] by the authors, the formation of NBO was concluded to start when the alkali oxide (K_2O) content is higher than about 16 mol%. The result was also supported by distinct composition dependences of T_g and parameter of intermolecular force constant (θ^2M) obtained from the temperature dependence of the Mössbauer absorption area. Structural studies of glasses by means of ^{119}Sn Mössbauer spectroscopy have also been performed on borate[17-20] and silicate[17,21,22] glasses, in which most Sn^{4+} species proved to be present in octahedral environment.

The present study was performed to elucidate the effects of γ- and thermal neutron-irradiation on germanate glasses by means of ^{119}Sn Mössbauer spectroscopy and DTA, because it was expected that the irradiation effects, if present, should depend upon the local structural change of the glasses based on the change in composition.

Experimental

Experimental procedures for the preparation of glass samples and for the Mössbauer and DTA measurements are already reported in our previous paper.[16] Gamma-ray irradiation of the germanate glasses denoted by $xK_2O\cdot(100-x)GeO_2\cdot 2SnO_2$ was performed in the ^{60}Co-γ ray irradiation facility of Kyushu University, with a dose rate of 5.9×10^5 R h^{-1} for 170 h at the ambient temperature (*ca.* 40 °C). Thermal neutron irradiation was carried out in the reactor of Atomic Energy Research Institute of Rikkyo University, with a flux of 5×10^{11} n cm^{-2} s^{-1} for 6 h at the ambient temperature. The γ-ray dose rate in the reactor is estimated to be 1×10^6 R h^{-1}. During the irradiation, each glass sample was kept in a sealed polyethylene bag filled with dry nitrogen gas, and the bag was placed in a glass tube or polyethylene capsule filled with dry nitrogen gas and silica gel to protect the sample from the atmospheric moisture.

Results and Discussion

Mössbauer spectra for the potassium germanate glasses irradiated with γ-rays of 10^8 R or thermal neutrons of 10^{16} n cm^{-2} consist apparently of a single absorption peak, which can be analyzed into a quadrupole doublet just like in the case of germanate glasses before the irradiation.[16] Change in the isomer shift of ^{119}Sn with K_2O content of the glasses is shown in Fig. 1, in which a broken line refers to the result obtained before the irradiation.[16] These isomer shift values correspond to the tetravalent ionic species (Sn^{4+}) with octahedral symmetry,[23] and the Sn^{4+} ion is considered to be present as a network modifier at an interstitial site of the network composed of GeO_4 and GeO_6 units.[16] It is seen from Fig. 1 that the isomer

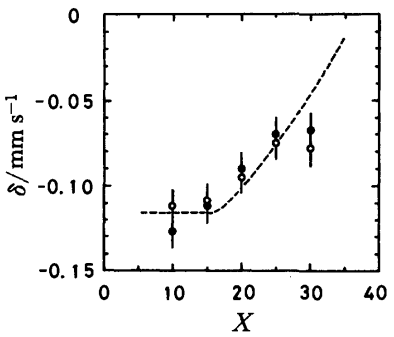

Fig. 1. Variation of the isomer shift of ^{119}Sn with K_2O content. (○): γ-Ray irrad., (●): thermal neutron irrad. The broken line refers to that of unirradiated glasses.

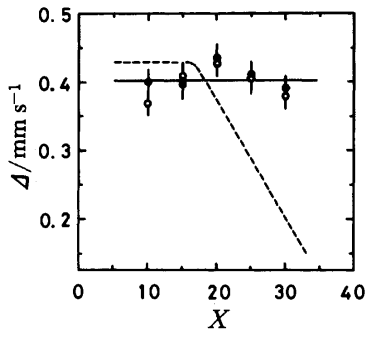

Fig. 2. Variation of the quadrupole splitting of Sn^{4+} with K_2O content. (○): γ-Ray irrad., (●): thermal neutron irrad. The broken line refers to that of unirradiated glasses.

shifts show little change by the γ- and the thermal neutron-irradiation, although only a small decrease is observed in the germanate glass with the alkali oxide content of x=30. The result shown in Fig. 1 is similar to the results of phosphate[14] and borophosphate[15] glasses in which both the isomer shift and quadrupole splitting show little change by the ^{60}Co-γ ray irradiations of 10^6 and 10^8 R. These results may be correlated with the structural role of Mössbauer nucleus, *i.e.*, both the iron (Fe^{2+} and Fe^{3+}) and tin (Sn^{4+}) play a role of network modifier which is present at an interstitial site of three-dimensional network in the case of phosphate,[13,14] borophosphate,[15] and germanate[16] glasses. On the other hand, the role of tin in borate and borosilicate glasses is reported to be a network former which is present at a substitutional site of tetrahedral boron or silicon atoms.[8,11] Irradiations of borate[9,24-26] and borosilicate[27] glasses with ^{60}Co-γ rays and thermal neutrons are reported to result in a decrease in isomer shift or an increase in the fraction of Fe^{2+} produced by the irradiation.

Change in the quadrupole splitting of Sn^{4+} in the germanate glasses irradiated with γ-rays and thermal neutrons is shown in Fig. 2, in which a broken line refers to the result obtained before the irradiation.[16] It is surprising that a drastic change in the quadrupole splitting observed before the irradiation disappears almost completely by the γ-ray (10^8 R) and thermal neutron (10^{16} n cm^{-2}) irradiations. This is very interesting and also quite different from the results of phosphate[14] and borophosphate[15] glasses in which little change in quadrupole splitting and linewidth was observed by ^{60}Co-γ ray irradiation. Irradiation of borate[9,24-26] and borosilicate[27] glasses with γ-rays or thermal neutrons is also reported to produce little change in the quadrupole splitting. The result of Fig. 2 therefore suggests that the irradiation brings about a structural change which has not been observed in the oxide glasses such as borate, borosilicate, and phosphate glasses. It is noteworthy that the quadrupole splitting values for the irradiated glasses are identical with those for the unirradiated germanate glasses with the alkali oxide content lower than 16 mol%. This means a disappearance of the structural role of NBO which has been concluded to be present only in GeO_4 units and causes an increase in the symmetry around Sn^{4+} ions.[16] Two possible explanations are given to the disappearance of the structural role of NBO in the irradiated glasses of which alkali oxide content is higher than 16 mol%, *i.e.*, one is a displacement of NBO from the neighboring site of Sn^{4+} to other site, and the other is a generation of a positive hole on an NBO atom. The former explanation, however, seems to be improbable because a displacement of NBO will bring about a change in the coordination number of tin (IV) and because such a change will be somewhat reflected in isomer shift. (Change in the coordination number of Sn^{4+} from 6 to 5 or 4 will result in an increase in the isomer shift of ^{119}Sn.) The latter explanation, *i.e.*, a generation of a positive hole on an electronegative NBO atom ($-O^-$) seems to be probable because the resultant oxygen atom is equivalent to a bridging oxygen from the electronical point of view. Therefore, the decreased symmetry around Sn^{4+} caused by the γ- and the thermal neutron-irradiaion is ascribed to a disappeared anionic character of NBO. This will result in a decreased Coulombic attraction between Sn^{4+} and NBO, and then a decrease in the symmetry around tin will be observed.

As is shown with a broken line in Fig. 3, a gradual and drastic increase in the linewidth (FWHM) has been observed for the unirradiated glasses with the alkali oxide content higher than 17 or 18 mol%. The increase in the linewidth has been attributed to the increased disorder brought about by NBO which is present at the neighboring site of Sn^{4+}.[19] It is obvious from Fig. 3 that γ- and thermal neutron-irradiation also results in a disappearance of the drastic increase in the linewidth caused by NBO. The disappearance of the drastic increase in the linewidth in the alkali oxide content region higher than 17—18 mol% is also concluded to be due to the disappeared structural role of NBO, because the magnitude of linewidth observed for the irradiated glasses is identical with that for the unirradiated glasses with the alkali oxide content lower than 17 mol%, just like the case of quadrupole splitting described above.

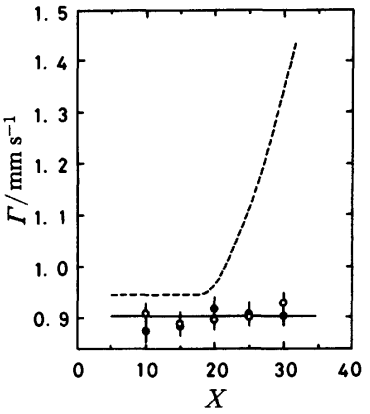

Fig. 3. Variation of the linewidth of Sn^{4+} with K_2O content.
(○): γ-Ray irrad., (●): thermal neutron irrad.
The broken line refers to that of unirradiated glasses.

The decrease in the linewidth is therefore explained by a rearrangement of oxygen atoms around Sn^{4+} as a result of the generation of a positive hole on an NBO atom, although no other experimental proof to support this idea has been obtained in the present study.

It is expected that some structural change, if present, will affect the physical properties such as T_g and viscosity. DTA measurement of the γ-ray irradiated germanate glasses was then carried out. This is shown in Fig. 4. It is noted that the irradiation gives rise to the decreases in T_g amounting to 20—120°C and a simultaneous disappearance of the distinct composition dependence of T_g observed before the irradiation. The composition dependence of T_g observed in the unirradiated glasses reflects, as described in our previous paper,[16] the formations of GeO_6 units and NBO in GeO_4 units in the alkali oxide content region lower than 16 mol% and in the range of 16—30 mol%, respectively. The decrease in the T_g brought about by the irradiation is ascribed to the disruption of the chemical bond between germanium and oxygen atoms constituting GeO_6 units, because the increase in T_g in the unirradiated glasses has been attributed to the formation of GeO_6 units.[16] This irradiation-effect seems not to affect the Mössbauer parameters such as isomer shift, quadrupole splitting, and linewidth, probably because the germanium or oxygen atoms in a GeO_6 unit of which chemical bond is disrupted by the irradiation are not present in the first or second coordination sphere of Mössbauer nucleus (^{119}Sn). (It is considered that a tin atom is interposed between two GeO_4 units to take an octahedral symmetry, and that a GeO_6 unit may be located at a site farther than the GeO_4 units.)

Mössbauer measurements at lower temperatures were also carried out to elucidate the extent of the irradiation-induced disruption of the chemical bond between germanium and oxygen constituting GeO_6 units, because a parameter of intermolecular force constant (θ^2M) obtained from the temperature dependence

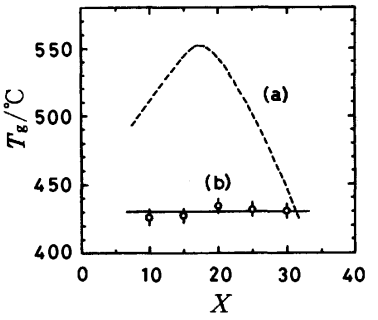

Fig. 4. Variation of the glass transition temperature (T_g) with K_2O content. (a): Unirrad., (b): γ-Ray irrad.

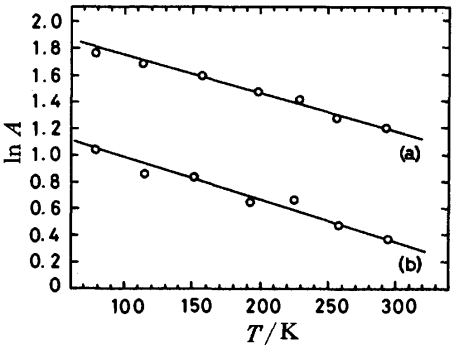

Fig. 5. Plots of the absorption area of $20K_2O \cdot 80GeO_2 \cdot 2SnO_2$ glass against temperature. (a): γ-Ray irrad., (b): thermal neutron irrad.

of the Mössbauer absorption area is known to give much information on the degree of polymerization and molecular association.[16,28] In the θ^2M value, M is the mass of Mössbauer nucleus and θ indicates Debye temperature. The correlation between θ and the maximum lattice vibration frequency ν_{max} for overall the glass matrix is expressed as $k\theta=h\nu_{max}$ where k is Boltzmann constant and h is Planck constant. The θ^2M value can be correlated with the Mössbauer recoil-free fraction f by using a Debye approximation,[23,29] and is expressed as

$$\theta^2M = \frac{3E^2}{kc^2}\left(\frac{-\mathrm{d}\ln f}{\mathrm{d}T}\right)^{-1}, \quad (1)$$

where E is Mössbauer transition energy and c is the velocity of light. Figure 5 shows the results of the Mössbauer measurements of $20K_2O \cdot 80GeO_2 \cdot 2SnO_2$ glass at lower temperatures, in which natural logarithm of the absorption area ($\ln A$) is plotted against measuring temperature T because $\ln f$ can be approximated by $\ln A$ when a very thin sample is used and the absorption is not saturated. It is seen from Fig. 5 that the absorption area for the thermal neutron irradiated germanate glass is more than one order smaller than that for the γ-ray irradiated glass. This means, as is generally known, that the thermal neutron irradiation results in a more drastic structural change in the network structure than the γ-ray irradiation. The decreased absorption area also suggests that the irradiations result in a disruption of the chemical bonds

in the germanate glass, because the recoil-free fraction is closely concerned with the rigidity of the matrix in which Mössbauer nucleus is incorporated. The disruption of the chemical bonds caused by the irradiations, if present, may also affect the θ^2M value for the germanate glass. These values being estimated from Eq.1 by dividing the value of $3E^2/kc^2$, *i.e.*, 2.13×10^4 in the case of 23.9 keV ^{119}Sn, with the slope of the individual straight line are 7.3×10^6 and 6.7×10^6 for the γ-ray and the thermal neutron irradiated germanate glasses, respectively. It is noted that the θ^2M value is 7.0×10^6 in the case of the $20K_2O\cdot80GeO_2\cdot2SnO_2$ glass before the irradiation.[16] Considering the magnitude of the error of θ^2M, *i.e.*, ±0.1—0.2, these results suggest that the γ- and the thermal neutron-irradiation results in little effect on the intermolecular force between two independent GeO_4 units which are connected with each other with the aid of a network modifier such as K^+ and Sn^{4+}. The irradiations are therefore concluded to bring about little change in the ionic bond between tin and the neighboring oxygen atoms constituting GeO_4 units, as is also concluded from the result of isomer shift shown in Fig. 1. The interatomic distance between tin and the neighboring oxygen atoms is also concluded to be unchanged, because the change in the isomer shift is reported to be closely correlated with the interatomic distance between Mössbauer atom and the neighboring atom.[30] This is well consistent with the unchanged θ^2M values observed for the irradiated glasses, because θ^2M value is also known to be closely affected by the degree of packing around Mössbauer nucleus besides the degree of polymerization. In the irradiated germanate glasses, recoil energy and the recoil momentum of Mössbauer γ-rays will therefore be transferred in almost the same way as do those in the unirradiated glasses. In other words, the irradiated germanate glasses studied in the present paper can still be regarded as polymers from the lattice vibrational point of view, although the chemical bond between germanium and oxygen constituting GeO_6 units is considered to be fairly disrupted.

The authors are indebted to Prof. Sumio Sakka of Kyoto University for his useful suggestion on the structure of germanate glasses. They are also indebted to Prof. Hirotoshi Sano of Tokyo Metropolitan University for his useful discussion. The authors are grateful to Profs. Teruaki Nagahara and Tatsuo Matsuura of Rikkyo University for their kind help in the thermal neutron irradiations, and also to Mr. Kiyoshi Matsumoto of Kyushu University for his kind help in the ^{60}Co-γ ray irradiations.

(Received January 21, 1985)

Complex formation equilibria between copper(II) and chloride ions have been studied by calorimetry and spectrophotometry in acetonitrile(AN) containing 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$ as a constant ionic medium at 25°C. Both calorimetric and spectrophotometric titration curves could be well explained in terms of formation of a series of four mononuclear complexes, $[CuCl_n]^{(2-n)+}$ (n=1—4), and formation constants, enthalpies and entropies of formation of the complexes were determined. Stepwise enthalpies ΔH_n° (n=1—4) were all negative, the ΔH_4° value being especially largely negative. On the other hand, the stepwise entropy ΔS_n° was largely positive for n=1—3, but largely negative for n=4. The result suggested that solvation of the $[CuCl_3]^-$ complex was extremely weak in AN and that release of solvent molecules from $[CuCl_3]^-$ was not so significant that the enthalpy and entropy of formation of $[CuCl_4]^{2-}$ were mainly attributable to those of desolvation of Cl^- followed by a bond formation between the $[CuCl_3]^-$ complex and the chloride ion. The $[CuCl_4]^{2-}$ complex might have no solvent molecules in the primary coordination sphere of the metal ion within the complex in AN. Enthalpies of solution of anhydrous $CuCl_2$ crystals were measured in AN and *N,N*-dimethylformamide(DMF) in order to evaluate enthalpies of transfer ΔH_t° of Cu^{2+} from water to the aprotic solvents. The ΔH_t° values well correlated with Gutmann's donor number of the solvents. The enthalpies of transfer ΔH_t° of $[CuCl_n]^{(2-n)+}$ (n=0—4) from AN to DMF were evaluated, and the enthalpy values monotonously increased with n. The $\Delta H_t^\circ(CuCl_4^{2-})$ value was only slightly positive as well as $\Delta H_t^\circ(Cl^-)$, and the result also suggested that the metal ion within the complex was not primarily solvated with solvent molecules in both AN and DMF. Electronic spectra of individual copper(II) chloride complexes were determined in AN.

In a previous paper,[1] we discussed about complex formation equilibria between copper(II) and chloride ions in *N,N*-dimethylformamide (DMF) studied by calorimetry and spectrophotometry.

It has already been pointed out that the formation of copper(II) chloride complexes is enhanced in aprotic solvents with either weaker (acetonitrile[2] and propylene carbonate[3]) or stronger (dimethyl sulfoxide[3] and DMF[4]) donicity than water.[5] According to Ahrland,[6] it can be explained in terms of difference in solvation of chloride ion between aprotic solvents and water. Solvation of chloride ion is more favorable in water owing to hydrogen-bonding with water molecules than in aprotic solvents.

Formation constants of copper(II) chloride complexes are largely different among aprotic solvents. Since the acceptor property of acetonitrile (AN) (the acceptor number (A_N)=19.3) is not largely different from that of DMF (A_N=16.0),[7] more favorable formation of copper(II) chloride complexes in AN than in DMF may be ascribed to weaker solvation of copper(II) ion with the former solvent (the donor number (D_N)=14.1) than with the latter (D_N=26.6).[7] Although the formation constants of copper(II) chloride complexes have been determined in AN,[2] no values of enthalpies and entropies of formation of the complexes have been reported.

In the present work, we investigated complex formation equilibria between copper(II) and chloride ions in acetonitrile by means of calorimetry and spectrophotometry as employed in a previous study[1] and determined formation constants, enthalpies and entropies of formation of the complexes. Enthalpies of solution of anhydrous $CuCl_2$ crystals were measured in AN and DMF in order to elucidate solvation phenomena of each complex species. Enthalpies of transfer of Cu^{2+} from water to the aprotic solvents were first evaluated, and then, enthalpies of transfer of individual copper(II) chloride complexes from AN to DMF were evaluated from the enthalpies of formation of the copper(II) chloride complexes obtained in both AN and DMF[1] and the enthalpies of transfer of Cu^{2+} and Cl^- from AN to DMF.

Electronic spectra of individual copper(II) chloride complexes were determined in AN and were compared with those determined in DMF, which suggested the difference in structures of the solvated neutral $[CuCl_2]$ complex in AN and DMF.

Experimental

Reagents. *Copper(II) perchlorate acetonitrile solution* was prepared according to Hathaway and Underhill[8] by the reaction of metallic copper with nitrosyl perchlorate, $Cu+2NOClO_4=Cu(ClO_4)_2+2NO$, in acetonitrile under a reduced pressure. Nitrosyl perchlorate was prepared by passing nitrogen oxides, which was obtained by dropwise adding concentrated nitric acid to sodium nitrate crystals, into 70% perchloric acid, and nitrosyl perchlorate thus obtained were filtered and then sucked under a dry atmosphere. About 10 g of nitrosyl perchlorate thus prepared was repeatedly washed with acetonitrile on a glass filter with a P_2O_5 guard-tube and finally a free-flowing powder was obtained. The dry nitrosyl perchlorate was reacted with metallic copper in *ca.* 100 cm^3 of dry acetonitrile within a round-bottle flask, which was evacuated through a P_2O_5 guard-tube with a

water pump. The reaction was continued for several hours and then the solution was filtered under a nitrogen atmosphere through a G4 glass filter to remove residual nitrosyl perchlorate and copper metals. The concentration of copper(II) perchlorate in the stock solution was determined electrogravimetrically.

Tetraethylammonium perchlorate and *tetraethylammonium chloride* of reagent grade were used without further purification and dried at 100 °C in a vacuum oven. Impurities of halide ions in the tetraethylammonium perchlorate was negligibly small because no precipitate of silver halide was found by titrating the aqueous solution of the salt with a silver nitrate solution.

Acetonitrile was dried with calcium hydride, and then distilled under an atmospheric pressure and stored over 4A 1/16 molecular sieves in a bottle closed with a P_2O_5 guard-tube. The residual water determined by a Karl-Fisher test was less than 50 ppm.

All test solutions were prepared in a dry box over P_2O_5 under an atmosphere of dried nitrogen gas.

Measurements. All calorimetric and spectrophotometric titrations were carried out in acetonitrile containing 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$ as a constant ionic medium.

Calorimetric measurements were carried out in a thermostated bath controlled at (25.000±0.007) °C placed in a room thermostated at (25.0±0.2) °C. A 100 cm^3 of copper(II) perchlorate solution was first placed in a Dewar vessel, which was filled with nitrogen gas and prevented from moisture with a P_2O_5 guard-tube, and then titrated with a 0.1 mol dm^{-3} $(C_2H_5)_4NCl$ solution. The heat of dilution of chloride ions was separately determined by titrating a 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$ solution without copper(II) perchlorate with the $(C_2H_5)_4NCl$ solution, and was 0.065 J cm^{-3} per the addition of a unit volume of the titrant. A heat of reaction evolved at each point of titration was ranged 0—5 J with certainty ±0.05 J. Calorimetric measurements were carried out by using a fully automatic on-line system as described elsewhere.[9]

Enthalpies of solution of anhydrous $CuCl_2$ crystals in a solvent were measured by using an MPS-11 calorimeter (Tokyo Riko, Tokyo) equipped with a PC-8801 computer (NEC, Tokyo) by breaking an ampoule containing a given amount of the salt in 50 cm^3 of the solvent without any ionic medium in a tefron vessel. Detailed procedure of measurement and analysis of heat evolved were described previously.[10]

Spectrophotometric measurements were carried out in acetonitrile solutions with a flow cell of a light-pass length of 0.5 cm which was connected with a titration vessel through tefron and glass tubes. A 15 cm^3 of $Cu(ClO_4)_2$ acetonitrile solution was placed in a vessel under a nitrogen atmosphere and then titrated with a 0.1 mol dm^{-3} $(C_2H_5)_4NCl$ solution. Electronic spectra were measured with a HITACHI 340 spectrophotometer (Hitachi, Tokyo) equipped with a JEC 6 electronic computer (JEOL) which recorded data at selected wavelengths at every 2 nm in the range 240—520 nm. The formation constants of copper(II) chloride complexes were determined spectrophotometrically by using absorbances obtained at 10 different wavelengths, 254, 278, 294, 304, 310, 330, 406, 420, 460, and 480 nm.

Analysis of Calorimetric and Spectrophotometric Data. A heat q_i evolved at a titration point i is represented by using formation constants β_n and overall enthalpies $\Delta H^\circ_{\beta n}$ of formation of $[CuCl_n]^{(2-n)+}$ complexes as follows:

$$q_i = -(V_i\sum_n \beta_n \Delta H^\circ_{\beta n} m_i x_i^n - V_{i-1}\sum_n \beta_n \Delta H^\circ_{\beta n} m_{i-1} x_{i-1}^n), \quad (1)$$

where V denotes the volume of the test solution, and m and x stand for concentrations of free copper(II) and chloride ions, respectively, which are related to their total concentrations C_M and C_X according to the mass-balance Eqs. 2 and 3:

$$C_M = m_i + \sum_n \beta_n m_i x_i^n, \quad (2)$$

$$C_X = x_i + \sum_n n\beta_n m_i x_i^n. \quad (3)$$

The formation constants and enthalpies were determined by minimizing the error-square sum, $U=\sum_i (q_{i,obsd} - q_{i,calcd})^2$ by using the program KALORI.[11]

Absorbance A_{ij} at a titration point i and a selected wavelength λ_j is represented by Eq. 4 by using formation constants and molar extinction coefficients $\varepsilon_n(\lambda_i)$ of the $[CuCl_n]^{(2-n)+}$ complexes.

$$A_{ij} = \sum_n \varepsilon_n(\lambda_j)\beta_n m_i x_i^n \quad (\beta_0 = 1). \quad (4)$$

The formation constants and molar extinction coefficients were determined by minimizing the error-square sum, $U=\sum_i\sum_j (A_{ij,obsd} - A_{ij,calcd})^2$, by using the program SPEC.

Results and Discussion

Calorimetric titration curves obtained in acetonitrile (AN) are depicted in Fig. 1. The enthalpy ΔH/kJ mol^{-1} of reaction per a unit mole addition of chloride ions at each titration point was plotted against the ratio C_X/C_M, where C_X and C_M denote the total cocentrations of chloride and copper(II) ions, respectively, in a solution. As seen in Fig. 1, remarkable changes in ΔH were observed at C_X/C_M=1 and 3, which indicate the formation of a series of four copper(II) chloride complexes having significantly different enthalpies of formation between $[CuCl]^+$ and $[CuCl_2]$ and between $[CuCl_3]^-$ and $[CuCl_4]^{2-}$, but inappreciable different ones between $[CuCl_2]$ and $[CuCl_3]^-$. Therefore, calorimetric data obtained were analyzed by assuming the formation of $[CuCl_n]^{(2-n)+}$ (n=1—4) by the least-squares method

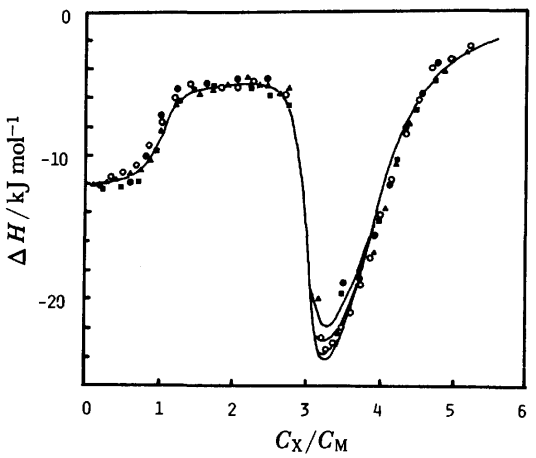

Fig. 1. Calorimetric titration curves of copper(II) chloride acetonitrile solutions containing 0.1 mol dm^{-2} $(C_2H_5)_4NClO_4$. Initial concentrations of copper(II) perchlorate (C_M/mmol dm^{-3}): 16.06 (○), 11.66 (▲), 9.67 (●), and 6.282 (■). The solid lines were calculated by using the constants in Table 1.

a) Least-squares sum, b) The number of data points. The values in parentheses refer to standard deviations.

to determine both formation constants and enthalpies of formation of the complexes. The theoretical curves calculated by using the constants thus optimized are illustrated by the solid lines in Fig. 1, and they well reproduced the experimental curves over the whole range of C_X/C_M examined. The formation constants and enthalpies of formation of the copper(II) chloride complexes finally obtained are summarized in Table 1. The formation constants determined by spectrophotometry are also listed in Table 1. $\Delta H^\circ_{\beta n}$ values given in the column of "Spectrophotometry" in Table 1 were those estimated by inserting the formation constants thus evaluated from the spectrophotometric data to the calorimetric data in Fig. 1. A reasonable agreement was obtained between the formation constants and enthalpies of formation determined by calorimetry and spectrophotometry, although standard deviations for each constant determined by calorimetry were not well evaluated.

Formation of Copper(II) Chloride Complexes in AN. Thermodynamic quantities, $\log(K_n/mol^{-1}dm^3)$, ΔG°_n/kJ mol^{-1}, ΔH°_n/kJ mol^{-1} and ΔS°_n/J $K^{-1}mol^{-1}$, for the stepwise reaction, $CuCl_{n-1}^{(3-n)+}+Cl^-=CuCl_n^{(2-n)+}$ (n=1—4), in the 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$ AN solution are summarized in Table 2, together with those in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solution.[1)]

Formation of the copper(II) chloride complexes was more favorable in AN than in DMF, as visualized in Fig. 2 by the distribution curves of the complexes in the solvents. The more enhanced formation of the complexes in AN than in DMF was mainly owing to the more negative enthalpy values in the former solvent than in the latter, since the entropy values of formation of the complexes were not largely different at each consecutive step n=1—3 in these solvents, and the formation of the $[CuCl_4]^{2-}$ complex was entropically less favorable in the former solvent than in the latter. The favorable enthalpies of formation of copper(II) chloride complexes in AN than in DMF may be ascribed to weaker solvation of the metal ion in the former

solvent, as is expected from the smaller donor number of AN.[7)] The difference in solvation of copper(II) ions in AN and DMF will be discussed in the following section.

The ΔH°_4 value was much more negative than other ΔH°_n (n=1—3) values in AN, the trend being more significant in AN than in DMF. Formation of a complex in a solution is accompanied by desolvation of both metal ion and ligand. Since the desolvation reactions are endothermic, the stronger the solvation of metal ion, the less negative enthalpy of formation of a complex would result. Therefore, the largely negative

ΔH_4° value than the ΔH_n° (n=1—3) values should be ascribed to the difference in solvation between $[CuCl_3]^-$ and $[CuCl_n]^{(2-n)+}$ (n=0—2) in AN, because the metal-ligand bond within a complex is usually weaker in a complex formed at a higher consecutive step. The metal-solvent interactions within $[CuCl_3]^-$ may be much weaker than those within $[CuCl_n]^{(2-n)+}$ (n=0—2) in AN, and thus, a relatively less energy for removing solvent molecules from the coordination sphere of the $[CuCl_3]^-$ complex might be needed in the course of formation of $[CuCl_4]^{2-}$.

As described in a previous paper,[1] a largely positive ΔS_n° (n=1—3) value indicated that desolvation of solvent molecules also played an important role in the course of the formation of $[CuCl_n]^{(2-n)+}$ in AN. On the other hand, a negative ΔS_4° value suggested that desolvation of the $[CuCl_3]^-$ complex did not play an essential role, and thus, the complex might not be strongly solvated. Thus, we concluded that the $[CuCl_4]^{2-}$ complex may practically have no solvent molecules in the primary coordination sphere of the metal ion within the complex in AN.

Enthalpies of Transfer of Cu^{2+}. Enthalpies of transfer of Cu^{2+} from water to AN and to DMF were determined by measuring enthalpies of solution of anhydrous $CuCl_2$ crystals in the solvents. Copper(II) chloride dissolved was expected to be completely dissociated into copper(II) and chloride ions in water,[5,10] but it was mostly associated in AN and in DMF.

Enthalpies of solution of $CuCl_2$ crystals for the following processes were determined in AN and DMF:

$$CuCl_2(c) = Cu^{2+}(s) + 2Cl^-(s);\ \Delta H_s^\circ(Cu^{2+}, 2Cl^-), \quad (5)$$

$$CuCl_2(c) = CuCl_2(s);\ \Delta H_s^\circ(CuCl_2), \quad (6)$$

by measuring the enthalpy of solution $\Delta H_{s,obsd}^\circ$ and by using Eqs. 7 and 8:

$$\Delta H_s^\circ(Cu^{2+}, 2Cl^-) = \Delta H_{s,obsd}^\circ - \sum_n \alpha_n \Delta H_{\beta n}^\circ, \quad (7)$$

$$\Delta H_s^\circ(CuCl_2) = \Delta H_s^\circ(Cu^{2+}, 2Cl^-) - \Delta H_{\beta 2}^\circ, \quad (8)$$

where c and s stand for crystalline and solution states, respectively, and α_n denotes the mole fraction of the $[CuCl_n]^{(2-n)+}$ complex. The α_n values were calculated in each measurement by knowing the formation constants of the copper(II) chloride complexes and the total concentration of $CuCl_2$ in a solvent. The results are listed in Table 3.

The enthalpy of transfer $\Delta H_t^\circ(Cu^{2+}, 2Cl^-)$ from water to another solvent (S) was represented as the sum of enthalpies of transfer of each ionic component as follows:

$$\Delta H_t^\circ(Cu^{2+}, 2Cl^-) = \Delta H_{s,S}^\circ(Cu^{2+}, 2Cl^-) - \Delta H_{s,W}^\circ(Cu^{2+}, 2Cl^-), \quad (9)$$

$$= \Delta H_t^\circ(Cu^{2+}) + 2\Delta H_t^\circ(Cl^-). \quad (10)$$

The $\Delta H_t^\circ(Cl^-)$ values from water to AN and to DMF have been reported by Cox *et al.*[12] on the basis of the extrathermodynamic assumption, $\Delta H_t^\circ(Ph_4As^+) = \Delta H_t^\circ(BPh_4^-)$, and thus, the $\Delta H_t^\circ(Cu^{2+})$ values from water to the aprotic solvents were calculated by subtracting the contribution of Cl^- ions from $\Delta H_t^\circ(Cu^{2+}, 2Cl^-)$. The results are also given in Table 3. The $\Delta H_t^\circ(Cu^{2+})$ values thus obtained were plotted against the donor number[7] of the solvents in Fig. 3, which showed a very good linear relationship. Figure 3 indicates that copper(II) ion is more strongly solvated in DMF than in water, and much more than in AN.

The $\Delta H_t^\circ(Cu^{2+})$ value from water to AN obtained was 18.9 kJ mol^{-1}, which was more positive than the value (11.5 kJ mol^{-1}) obtained by Libuś *et al.*[13] by employing a thermodynamic cycle different from that employed in the present work.

Enthalpies of Transfer of $[CuCl_n]^{(2-n)+}$ from AN to DMF. The differences in overall enthalpies of formation of the copper(II) chloride complexes in AN and in DMF are related to enthalpies of transfer of species pertaining to the complex formation reactions as follows:

$$\Delta H_{\beta n}^\circ(DMF) - \Delta H_{\beta n}^\circ(AN) = \Delta H_t^\circ(CuCl_n^{(2-n)+}) - \Delta H_t^\circ(Cu^{2+}) - n\Delta H_t^\circ(Cl^-). \quad (11)$$

a) $\Delta\Delta G_n^\circ=\Delta G_n^\circ(DMF)-\Delta G_n^\circ(AN)$, $\Delta\Delta H_n^\circ=\Delta H_n^\circ(DMF)-\Delta H_n^\circ(AN)$, $\Delta\Delta S_n^\circ=\Delta S_n^\circ(DMF)-\Delta S_n^\circ(AN)$, for the reaction, $CuCl_{n-1}^{(3-n)+}+Cl^-=CuCl_n^{(2-n)+}$ (n=1—4). b) Ref. 15. c) Ref. 12.

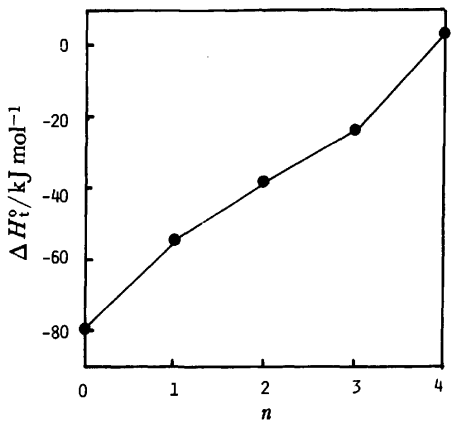

Fig. 4. Enthalpies of transfer of the $[CuCl_n]^{(2-n)+}$ (n=0—4) complexes plotted against n, the number of chloride ions bound per metal ion within a complex.

The $\Delta H_t^\circ(CuCl_n^{(2-n)+})$ value can be calculated, since all the values in Eq. 11 except for $\Delta H_t^\circ(CuCl_n^{(2-n)+})$ have been determined. The $\Delta H_t^\circ(CuCl_n^{(2-n)+})$ (n=1—4) values thus calculated are summarized in Table 4, and are also plotted against n in Fig. 4.

Although the absolute values of formal charges of the $[CuCl_n]^{(2-n)+}$ (n=0—4) complexes vary with n from 2 (n=0) to 0 (n=2) and then again 2 (n=4), the $\Delta H_t^\circ(CuCl_n^{(2-n)+})$ values monotonously changed with n from the $\Delta H_t^\circ(Cu^{2+})$ value of −79.7 kJ mol^{-1} to the $\Delta H_t^\circ(CuCl_4^{2-})$ value of 4.1 kJ mol^{-1}. Since the relative dielectric constant of AN (36.0) is not different from that of DMF (36.7), it is obvious that simple electrostatic theories (such as Born's equation and its derivatives with respect to temperature) are not applicable to explain the change in enthalpies of transfer of the complexes between the solvents. Such a monotonous variation of ΔH_t° values has also been observed for enthalpies of transfer of mercury(II) halide complexes $[HgX_n]^{(2-n)+}$ (n=1—4) from dimethyl sulfoxide to pyridine,[14] the solvents having largely different dielectric constants.

Accordingly, the enthalpy of transfer of $[CuCl_n]^{(2-n)+}$ from AN to DMF should be ascribed to different solvation of the both metal and ligand ions within the complex between the solvents. It is expected that solvation of Cl^- ion within $[CuCl_n]^{(2-n)+}$ may not be significantly different between AN and DMF, since the $\Delta H_t^\circ(Cl^-)$ value from AN to DMF is only slightly positive. The enthalpy of transfer of $[CuCl_n]^{(2-n)+}$ should thus be mainly attributed to the difference in solvation of the metal ion within the complex in the solvents.

The $\Delta H_t^\circ(CuCl_n^{(2-n)+})$ (n=1—3) values from AN to DMF were negative as well as $\Delta H_t^\circ(Cu^{2+})$, indicating that the metal ion within $[CuCl_n]^{(2-n)+}$ (n=1—3) was more strongly solvated with DMF than with AN. The ΔH_t° values increased in the sequence $[CuCl]^+<[CuCl_2]<[CuCl_3]^-$, which may be due, probably, to the decrease in the solvation number of the complexes with an increase in the number of chloride ions within the complexes, although the numbers of solvent molecules coordinating to the metal ion within the complexes have not been known.

The $\Delta H_t^\circ(CuCl_4^{2-})$ value was only slightly positive as well as $\Delta H_t^\circ(Cl^-)$, indicating that the metal ion within the complex was probably not primarily solvated with solvent molecules in both AN and DMF, and thus, the enthalpy of transfer of the $[CuCl_4]^{2-}$ complex was mainly determined by the change in solvation of chloride ions within the complex between the solvents.

Gibbs Energies and Entropies of Transfer of $[CuCl_n]^{(2-n)+}$ from AN to DMF. The Gibbs energy of transfer ΔG_t° of Cu^{2+} has been reported by Coetzee and Istone[15] to be 59.4 and −18.0 kJ mol^{-1} from water to AN and to DMF, respectively, and thus, the $\Delta G_t^\circ(Cu^{2+})$ value from AN to DMF is −77.4 kJ mol^{-1}. The $\Delta G_t^\circ(Cl^-)$ value has also been reported to be 3.7 kJ mol^{-1} from AN to DMF.[12]

By using the ΔG_t° values of copper(II) and chloride ions from AN to DMF, we calculated the Gibbs energies of transfer of $[CuCl_n]^{(2-n)+}$ (n=1—4) by the same procedure as used for evaluation of ΔH_t° of the complexes in a previous section.

The entropies of transfer ΔS_t° of $[CuCl_n]^{(2-n)+}$ (n=1—4) from AN to DMF could thus be calculated from the Gibbs energies and enthalpies of transfer of the complexes. The results are summarized in Table 4.

All the $[CuCl_n]^{(2-n)+}$ (n=1—4) complexes were more stable in DMF than in AN, as indicated by negative ΔG_t° values of the complexes, which were predominantly contributed by the enthalpy term except for the $[CuCl_4]^{2-}$ complex. As to the $[CuCl_4]^{2-}$ complex, the largely positive ΔS_t° value led to the negative ΔG_t° value, the ΔH_t° value being even slightly positive.

However, the reason why the $\Delta S_t^\circ(CuCl_4^{2-})$ value was so largely positive compared with the $\Delta S_t^\circ(CuCl_n^{(2-n)+})$ (n=1—3) values still remained unknown.

Electronic Spectra of Copper(II) Chloride Complexes. Electronic spectra of copper(II) chloride solutions at various concentrations of chloride ions were measured in the 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$ AN solution. Each spectrum obtained was resolved into spectra of individual copper(II) chloride complexes by knowing the formation constants of the copper(II) chloride complexes in the solution. Molar extinction coefficients of individual copper(II) chloride complexes at various wavelengths thus obtained in the 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$ AN solution are depicted in Fig. 5.

The absorption maxima of the individual copper(II) chloride complexes obtained in AN are given in Table 5, together with those obtained in DMF.[1] An absorption maximum of $[CuCl]^+$ was found at slightly longer wavelength by *ca.* 35 nm in AN than in DMF. Remarkably different spectra were observed for the $[CuCl_2]$ complex between AN and DMF. Three absorption maxima of the complex were found at *ca.* 255, 308, and 406 nm in AN, while only one absorption maximum was found at *ca.* 265 nm in DMF. The $[CuCl_3]^-$ complex showed three absorption maxima at almost the same wavelengths as those of $[CuCl_2]$ in AN, but only two maxima were found in DMF within the wavelength region examined here. The absorption spectrum of the $[CuCl_4]^{2-}$ complex with two absorption maxima at *ca.* 290 and 405 nm in AN was very similar to that in DMF.

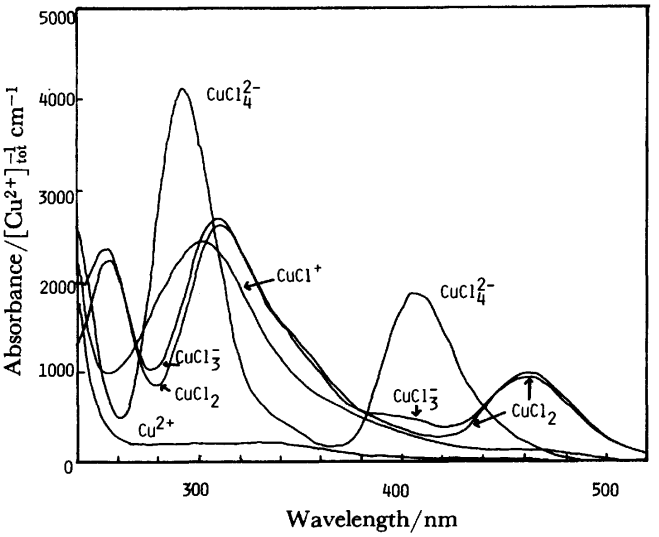

Fig. 5. Molar extinction coefficients of individual copper(II) chloride complexes at various wavelengths in the 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$ AN solution.

$[CuCl_3]^-$	255	
	308	300
	460	440
$[CuCl_4]^{2-}$	290	296
	405	410

a) Ref. 1 in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solution.

It has been indicated from thermodynamic quantities of formation and of transfer of $[CuCl_4]^{2-}$ in previous sections that the complex may have no solvent molecules in the primary coordination sphere of the metal ion within the complex. The structure of the $[CuCl_4]^{2-}$ complex in AN should be the same as that in DMF,[1] as indicated by the similar absorption spectra in both the solvents.

According to Fergusson,[16] as mentioned in a previous paper,[1] the presence of an absorption maximum between 435 and 455 nm of a copper(II) chloride complex was indicative of the D_{2d} form of the complex. Therefore, it is plausible that the $[CuCl_2]$ and $[CuCl_3]^-$ complexes have the D_{2d} form in AN, since their spectra have an absorption maximum at *ca.* 460 nm. On the other hand, the $[CuCl_2]$ complex in DMF has no maximum in the wavelength region 400—500 nm, and thus, the different solvate structures of the $[CuCl_2]$ complex in AN and in DMF were expected.

The work has been supported by the Grant-in-Aid for Scientific Research No. 59540386 from the Ministry of Education, Science and Culture.

Dialkylcarbamato Complexes of Ni(II), Zn(II), and Cd(II)-Tetraazacycloalkanes Obtained from CO_2-Uptake, and X-Ray Structure of (Diethylcarbamato)((7*RS*,14*RS*)-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane)nickel(II) Perchlorate

Haruko Ito† and Tasuku Ito*

Department of Applied Molecular Science, Institute for Molecular Science, Okazaki National Research Institutes, Okazaki 444

(Received January 23, 1985)

Nickel(II), zinc(II), and cadmium(II) complexes of certain tetraazacycloalkanes (L), $[M(L)](ClO_4)_2$, take up CO_2 as $R_2NCO_2^-$ to give carbamato complexes, $[M(O_2CNR_2)(L)]^+$, where L=(7*RS*,14*RS*)-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane (L^1) for $M=Ni^{2+}$, and L=1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (L^2) for $M=Ni^{2+}$, Zn^{2+}, and Cd^{2+}. The resulting complexes have been characterized by means of IR, and NMR or electronic spectroscopy. X-Ray analysis of $[Ni(O_2CN(C_2H_5)_2)(L^1)]ClO_4$ (monoclinic C2/c, a=15.842(3), b=13.675(3), c=13.753(2) Å, β=109.94(1)°) shows that it is a discrete six-coordinate complex with *cis*-NiO_2N_4 geometry, and the carbamato ligand is bidentate. Desired carbamato complexes were hardly obtained with $[M(L)]^{2+}$ containing tetraaza macrocyclic ligand which favors square-planar coordination. All the data indicate that carbamate ions chelate the metals, and thus use of tetraazacycloalkanes which fold readily is essential for this type of CO_2 uptake.

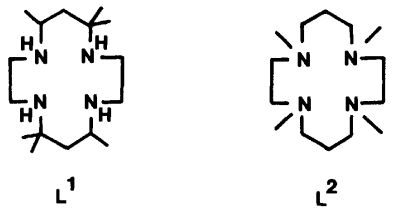
Considerable attention has been paid to the reaction of CO_2 with transition metal complexes in connection with the fixation and utilization of CO_2. We found that zinc(II)[1] and nickel(II)[2] complexes having certain tetraazacycloalkanes (L) take up CO_2 in basic alcohol solution as monoalkyl carbonate to give $[M(O_2COR)(L)]^+$. The reaction increases the coordination number of metal ion from four to five or six, as described below,

$$[M(L)]^{2+} + CO_2 + ROH + B \longrightarrow [M(O_2COR)(L)]^+ + HB^+$$

where B is base such as triethylamine or alkoxide. The starting complex, $[M(L)]^{2+}$, is of the square-planar type. In case of coordination of $ROCO_2^-$, geometry of $[M(L)]^{2+}$ changes to an octahedral or a trigonal bipyramidal type, giving rise to reactive vacant sites. Such a coordinately unsaturated nature of the $[M(L)]^{2+}$ complex is an important factor for the facile up-take reaction of the $ROCO_2^-$ ligand.

In the present study, similar reactions of certain nickel(II), zinc(II), and cadmium(II)-tetraazacycloalkane, in which CO_2 is taken up as carbamate ligand, $R_2NCO_2^-$, have been studied. The formation of free carbamate ion by the reaction of CO_2 with dialkylamine has been well characterized.[3] The tetraazacycloalkane ligand (L) used are (7*RS*,14*RS*)-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane (L^1) or 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (L^2). They are known to fold readily to afford five or six-coordinate complexes.

Carbamato complexes reported so far are obtained either by CO_2 insertion to metal-imido bond[3-5] or by ligand-exchange reaction with the carbamato ligand which has been produced in solution.[6-11] In this sence, the present reactions are of a unique type.



L^1 L^2

Experimental

Materials. α-$[Ni(L^1)](ClO_4)_2$,[12] $[Ni(O_2COCH_3)(L^2)](ClO_4)$,[2] $[Zn(O_2COH)(L^2)](ClO_4)$,[13] $[Zn(O_2COCH_3)(L^2)](ClO_4)$,[1] $[Cd(O_2COH)(L^2)](ClO_4)$,[13] and $[Cd(O_2COCH_3)(L^2)](ClO_4)$[13] were prepared according to the literature. The macrocyclic ligand L^2 was purchased from Strem Chemicals, Inc.

$[Ni(O_2CN(C_2H_5)_2)(L^1)](ClO_4)$ (1). CO_2 was bubbled through a suspended mixture of acetonitrile (10 cm^3) and 1.08 g (2 mmol) of α-$[Ni(L^1)](ClO_4)_2$ for a few minutes. The violet solids of α-$[Ni(L^1)(CH_3CN)_2](ClO_4)_2$ were immediately dissolved upon addition of 0.29 g (4 mmol) of diethylamine to give blue violet solution. Continuous bubbling of CO_2 resulted in the formation of violet crystals. The mixture was kept in a freezer (−10 °C) overnight. Violet crystals (0.85 g) were recrystallized from acetonitrile. Yield: 76%.

$[Ni(O_2CNR_2)(L^1)](ClO_4)$, R=$CH_3$ (2), n-C_3H_7 *(3), and* n-C_4H_9 *(4).* These complexes were prepared in a similar way, except that chloroform was used as solvent in the case of dimethylamine.

$[Ni(O_2CN(C_2H_5)_2)(L^2)](ClO_4)$ (5). CO_2 was bubbled through chloroform solution containing 0.48 g (1 mmol) of $[Ni(O_2COCH_3)(L^2)](ClO_4)$ and 0.15 g (2 m mol) of diethylamine. The color of the solution changed from green to emerald green. CO_2 was bubbled for a minute, and diethyl ether (5 cm^3) was added. Keeping the solution at −10 °C overnight, emerald green solids (0.47 g) were obtained and recrystallized from $CHCl_3$-ether. Yield 88%.

$[Ni(O_2CN(CH_3)_2)(L^2)](ClO_4)$ (6). This compound was prepared in the same way as **5** with use of dimethylamine.

$[Zn(O_2CNR_2)(L^2)](ClO_4)$, R=$CH_3$ (7), and C_2H_5 (8).

† Present address: Department of Chemistry, Aichi Kyoiku University, Kariya 448.

These were obtained either from $[Zn(O_2COCH_3)(L^2)](ClO_4)$ or $[Zn(O_2COH)(L^2)](ClO_4)$ in a similar way. To 3 cm^3 of chloroform solution containing 0.50 g of $[Zn(O_2COCH_3)(L^2)](ClO_4)$ (1 mmol), 0.073 g (1 m mol) of diethylamine was added. After 15 min, 10 cm^3 of diethylether was added and a white precipitate (0.38 g) of $[Zn(O_2CN(C_2H_5)_2)(L^2)](ClO_4)$ was obtained. Yield 70%.

$[Cd(O_2CNR_2)(L^2)](ClO_4)$, R=$CH_3$ (9), and C_2H_5 (10). These complexes were also prepared either from $[Cd(O_2COCH_3)(L^2)](ClO_4)$ or $[Cd(O_2COH)(L^2)](ClO_4)$ in a way similar to those for the corresponding zinc(II) complexes.

Elemental analyses of all the complexes prepared in this study were consistent with $[M(O_2CNR_2)(L)](ClO_4)$.

Measurements. The electronic and infrared spectra were recorded on a Hitachi 340 spectrophotometer and on a Jasco IR-810 infrared spectrophotometer, respectively. ^1H and ^{13}C NMR spectra were obtained on a Jeol FX-100 at 100 MHz and a Jeol GX-400 at 100 MHz, respectively. About 0.1 mmole of the sample was dissolved in 0.7 cm^{-3} of $CDCl_3$ for each NMR measurement.

X-Ray Analysis. A single crystal of $[Ni(O_2CN(C_2H_5)_2)(L^1)](ClO_4)$ with approximate dimensions 0.34×0.20×0.20 mm was used for X-ray study. Diffraction data were obtained on a Rigaku AFC-5 diffractometer with graphite monochromatized Mo $K\alpha$ radiation. Intensities were corrected for Lorentz and polarization factors. Crystal data are: monoclinic, C2/c, a=15.842(3), b=13.675(3), c=13.753(2) Å, β=109.94(1)°, V=2800.7(9) $Å^3$, Z=4, D_m=1.33, D_x=1.33 g cm^{-3}, μ(Mo $K\alpha$)=0.83 mm^{-1}. The structure was solved by the heavy atom method and refined by block-diagonal least-squares method. The weighting scheme, $w=[\sigma_{count}^2+(0.015|F_o|)^2]^{-1}$, was employed. All the hydrogen atoms except for methyl hydrogens of carbamate ion were located by the difference Fourier syntheses. Hydrogens for the methyl groups were located at calculated positions. In the final refinement, all the hydrogen atoms were included with the isotropic temperature factors. The final R indicies were R=0.048 and R_w=0.055 for 2193 independent reflections with $|F_o|>3\sigma(F_o)$.[14]

Calculations were carried out on the HITAC M-200H computer at the Computer Center of the Institute for Molecular Science with the Universal Crystallographic Computation Program System, UNICS III.[15]

Results and Discussion

Synthesis. There are two routes, (A) and (B) for the preparation of the carbamato complexes, $[M(O_2CNR_2)(L)]^+$.

$$(A)\quad [M(L)]^{2+} + CO_2 + 2R_2NH \longrightarrow [M(O_2CNR_2)(L)]^+ + NH_2R_2^+,$$

$$(B)\quad [M(O_2CX)(L)]^+ + R_2NH \longrightarrow [M(O_2CNR_2)(L)]^+ + HX,$$

where $X=CH_3O^-$ or OH^-. The complexes, $[Ni(O_2CNR_2)(L^1)](ClO_4)$, were obtained easily through route (A). The reaction proceeds *via* the following mechanism.

$$2NHR_2 + CO_2 \rightleftharpoons (NH_2R_2)(O_2CNR_2),$$

$$\alpha\text{-}[Ni(L^1)](ClO_4)_2 + (NH_2R_2)(O_2CNR_2) \longrightarrow [Ni(O_2CNR_2)(L^1)](ClO_4) + NH_2R_2ClO_4.$$

In the case of L^2 complexes, carbamato complexes were obtained easily and cleanly *via* route (B) from corresponding hydrogencarbonato or monomethyl carbonato complexes. The formation may occur *via* the following scheme.

$$[M(O_2CX)(L^2)]^+ \rightleftharpoons [M(L^2)]^{2+} + CO_2 + X^-,$$

$$[M(L^2)]^{2+} + CO_2 + X^- + NHR_2 \longrightarrow [M(O_2CNR_2)(L^2)]^+ + HX.$$

As to the preparation of $[Ni(O_2CNR_2)(L^1)]^+$, it may be worthwhile to point out the following facts. The complex, $[Ni(L^1)]^{2+}$, is known to exist as three isomeric α-, β-, and γ-forms.[12,16] Of these three isomers, only the α-isomer reacts readily with a bidentate ligand such as oxalate,[12] acetylacetonate,[16] acetate,[17] or tartrate[18] to form *cis*-type six-coordinate complexes with the macrocyclic ligand folded. Thermodynamically most stable isomer is of the β-type, and the α-isomer isomerizes in neutral or at much faster rate in basic media to the β-isomer. Therefore, it is necessary to add dialkylamine after CO_2 is bubbled thoroughly into the solution containing α-$[Ni(L^1)](ClO_4)_2$, when the carbamato complex is synthesized through route (A). Desired carbamato complexes were hardly obtained in the case of β-$[Ni(L^1)](ClO_4)_2$, $[Ni(meso\text{-}Me_6[14]aneN_4)](ClO_4)_2$, or $[Ni([14]aneN_4)](ClO_4)_2$, where the macrocyclic ligands take the conformation that can not fold (*meso*-$Me_6[14]aneN_4$=(7*SR*,14*RS*)-form of L^1 and $[14]aneN_4$=1,4,8,11-tetraazacyclotetradecane).

Infrared Spectra. Infrared spectra of nickel(II) and cadmium(II) complexes show strong ν_{CN} bands in the range of 1500—1520 cm^{-1}, while the corresponding absorptions of the zinc(II) complexes appear around 1580—1585 cm^{-1} (Tables 1 and 2). These frequency values of nickel(II) and cadmium(II) complexes are similar to the value of structurally determined compound **1**. Therefore, the carbamato ligands coordinate to the metals in bidente fashion. However, the values of zinc(II) complexes are somewhat higher than those of nickel(II) and cadmium(II) complexes, although they are in the normal range of bidentate carbamato ligands.[4] Rather high frequency values of zinc(II) complexes might be indicative of unsymmetric chelation of carbamate ion, since the frequency values are close to the value (ν_{CO}=1592 cm^{-1}) of $[Cd(O_2COH)(L^2)](ClO_4)$ in which two Cd-O bonds are nonequivalent and bond lengths differ by 0.152 Å.[13] Nonequivalent Zn-O bonds have also been found in six-coordinate $[Zn(O_2NC(CH_3)_2)(L^2)](ClO_4)$.[19]

Electronic Spectra of Nickel(II) Complexes. The electronic absorption spectra of nickel(II) complexes consist of three d-d bands corresponding to six-coordinate nickel(II) (Table 1). The absorption peaks of $[Ni(O_2CNR_2)(L^1)](ClO_4)$ are very close to those observed for NiL^1 complexes with *cis*-NiN_4O_2 chromophore, $[\{Ni(L^1)\}_2(d\text{-tart})(H_2O)](ClO_4)_2$,[18] and $[Ni(H_2O)_2(L^1)]Cl_2$.[20] The absorption spectra of $[Ni(O_2CNR_2)(L^2)](ClO_4)$ are quite similar to that of structurally

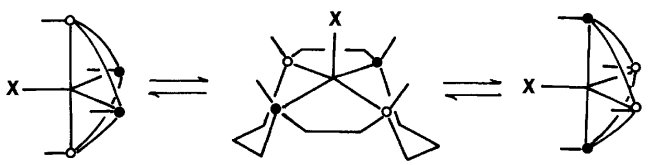
characterized $[Ni(O_2NCH(CH_3))(L^2)](ClO_4)$, the coordination geometry of which is of the *cis*-NiN_4O_2 type.[19] The X-ray analysis of the latter complex revealed that the *N*-methyl orientation is of the three-up-one-down type in terms of Bosnich's notation.[21] The same *N*-methyl orientation may be assigned to the present $[Ni(O_2CNR_2)(L^2)]^+$ complexes from the following observations as well as the absorption data. Both $[Ni(O_2CNR_2)(L^2)](ClO_4)$ and $[Ni(O_2NCH(CH_3))(L^2)](ClO_4)$ show a single ligand field band at 502 nm in dilute perchloric acid solution, where they decompose to square-planar four coordinate species, $[Ni(L^2)]^{2+}$. On the other hand, the ligand field absorption of the complex, $[Ni(L^2)](ClO_4)_2$, prepared from nickel(II) perchlorate and L^2 (the four-up form),[22] and of the complex prepared from *N*-methylation of the two-up-two-down form of $[Ni([14]aneN_4)]^{2+}$,[23] occurs at 514 and 493 nm, respectively, in the same solvent.

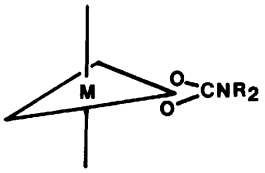
NMR Spectra. ^1H and ^{13}C NMR spectral data for $[Zn(O_2CNR_2)(L^2)](ClO_4)$ and $[Cd(O_2CNR_2)(L^2)](ClO_4)$ are given in Table 2. Spectral patterns, chemical shifts, and relative intensity relations are consistent, in all respects, with $[M(O_2CNR_2)(L^2)]^+$. In all the compounds studied, two alkyl groups of the carbamato ligand are pairwise equivalent. Interestingly, the ligand L^2 shows only four sharp signals in ^{13}C NMR spectra at room temperature, that is, one-forth of the ligand is magnetically independent on ^{13}C NMR time scale. When the temperature is lowered, a sharp singlet due to the central carbon of the six-membered chelate ring and signals of the carbamato ligand remained unchanged even at 217 K but the remaining three absorptions of L^2 broaden and finally each splits into two signals. Figure 1 shows such an example for $[Cd(O_2CN(CH_3)_2)(L^2)](ClO_4)$. The spectral pattern at 217



trigonal bipyramidal square pyramidal trigonal bipyramidal

K indicates that the complex adopts C_2 symmetry. A very similar temperature dependence was also observed for $[Zn(O_2CN(CH_3)_2)(L^2)](ClO_4)$ in $CDCl_3$. This observation can be interpreted by the dynamic process shown above, as characterized well for $[ZnX(L^2)]^+$, where X is Cl^- or NCS^-,[24] and $[Cd(L^2)](NO_3)_2$.[25] The activation parameters of the dynamic processes were obtained by full line-shape analyses with use of DNMR3 program.[26] The results were $\Delta H^*=34\pm3$ and 33 ± 4 kJ mol^{-1}, and $\Delta S^*=-63\pm13$ and -61 ± 20 J deg^{-1} mol^{-1}, for zinc(II) and cadmium(II) complex respectively. The similarity of the activation parameters of both zinc(II) and cadmium(II) supports the same dynamic process.[25]

Although the infrared data indicate the formation of six-coordinate complex with the chelated carbamato ligand, the occurrence of the dynamic process suggests that the coordination geometry about the metal can be taken as the trigonal bipyramidal type. The two donor oxygens of the carbamato ligand occupy an apex of the trigonal bipyramid as shown below. In



fact, X-ray structural analyses of $[Zn(O_2NC(CH_3)_2)(L^2)](ClO_4)$,[19] $[Cd(O_2COH)(L^2)](ClO_4)$,[13] and $[Cd(NO_3)(L^3)]_2[Cd(NO_3)_4]$,[27] where L^3 denotes 1,5,9,13-tetramethyl-1,5,9,13-tetraazacyclohexadecane, revealed that their coordination geometries are very similar to the structure shown above and are described better as pseudo trigonal bipyramidal. At the low temperature, the dynamic process is frozen and the complex is considered to have the trigonal bipyramidal geometry with C_2 symmetry, where the carbamato ligand chelates the metal symmetrically through two oxygen atoms.[28] In the NMR studies of the L^2 complexes of zinc(II) and cadmium(II), there were no indications for the presence of the three-up-one-down form found for the

corresponding nickel(II) complexes.

X-Ray Structure. The crystal structure of $[Ni(O_2CN(C_2H_5)_2)(L^1)](ClO_4)$ has been determined by X-ray analysis. Atomic parameters and relevant bond lengths and angles are given in Tables 3 and 4, respectively. Figure 2 shows an ORTEP view of the complex cation along with the atom numbering scheme.

Three types of coordination bonding modes are known for carbamato ligand:[4-11] (1) unidentate, (2) bidentate chelate, and (3) bridging. The present X-ray analysis revealed that the carbamato ligand adopts the type (2) structure.

The complex has crystallographic C_2 symmetry, the C_2-axis passing through Ni, C(L) and N(L) atoms. The metal-donor atom set, NiN_4O_2, is a distorted octahedron as is seen from the bond angles about Ni (Table 4). The Ni–N distances within NiN_2O_2 plane are slightly shorter than those of the axial Ni–N bonds. The C(L)–N(L) bond is shortened to 1.351(6)Å evidently through the influence of the $-CO_2^-$ group and has partial double bond character. The bond angles around C(L) and N(L) are approximately 120°, and the NiO_2CNC_2 moiety is planar within experimental error.

As has often been found for other carbamato complexes, methyl groups of the carbamato ligand have large thermal parameters due to the disordered orientation of the ethyl groups.[8] Short distances, N(L)–Cl(L)= 1.44(1) and Cl(L)–C2(L)=1.45(1)Å arise likely from such a situation.

All the present results including IR, NMR, electronic spectral and X-ray data indicate that the carbamato complexes obtained in this study have coordination geometry of *cis*-MO_2N_4 type. The desired carbamato complexes $[M(O_2CNR_2)(L)]^+$ were obtained with the tetraazacycloalkanes such as L^1 and L^2 which are known to fold readily, whereas tetraaza macrocyclic ligands which favor square-planar coordination did not work nicely. From these results, it is concluded that use of macrocyclic ligands of the former type is essential for the $R_2NCO_2^-$ uptake reaction by $[M(L)]^{2+}$ complexes. It is in contrast to the case of monoalkyl carbonato complex, $[M(O_2COR)(L)]^+$, formed similarly upon CO_2 uptake in basic alcohol.[1,2]

For the formation of $[M(O_2CNR_2)(L)]^+$ as well as $[M(O_2COR)(L)]^+$ unsaturated coordination of the starting complex $[M(L)]^{2+}$ is very important. Nickel(II), zinc(II) and cadmium(II) fulfill the required coordination behavior and work nicely.

The present study was supported by Grant-in-Aid for Scientific Research No. 58470039 from the Ministry of Education, Science and Culture.

Formation of Blocking Contacts at *p*-Type Porphyrin/ITO or Electrolyte Junctions

Kazuo YAMASHITA,* Yutaka HARIMA, and Yuhei MATSUMURA
Department of Environmental Science, Faculty of Integrated Arts and Sciences, Hiroshima University, Hiroshima 730
(Received December 25, 1984)

Energetics of ITO/*p*-type porphyrin/electrolyte interfaces are discussed on the basis of photoelectrochemical and photovoltaic measurements. When sensitized by a layer of 5,10,15,20-tetraphenylporphyrinatomagnesium(II)(MgTPP), the indium-tin oxide (ITO) electrode acts as only a photocathode in an aqueous electrolyte solution. However, the ITO electrode modified with a film of ZnTPP, CuTPP or H_2TPP having oxidation potential more positive than that of MgTPP acts as not only a photocathode but also a photoanode, depending on the electrode potential and the direction of irradiation on the ITO/porphyrin electrode. The cathodic component in the photocurrents is attributed to the downward band-bending in a space charge layer at the porphyrin/electrolyte (blocking) contact and the anodic component to that at the ITO/porphyrin (blocking) contact. The upward band-bending, on the contrary, is found inefficient in producing charge carriers, because the accumulation layer is conducting (ohmic) for majority carriers (holes). The porphyrin/electrolyte junction shows certain similarities to an ITO or metal/porphyrin (semiconductor) junction. However, it should be noted that a Helmholtz double layer exists at the porphyrin/electrolyte interface. The results are rationalized from the energy levels of the porphyrin films, ITO and the redox couple solutions with due regard to the orientation of water dipoles at the porphyrin surface.

A recent interest in the dye sensitization research has centered on modelling the primary energy conversion processes in photosynthesis and on the application to conversion of solar energy into electrical and/or chemical energy.[1] The organization of dye and substrate can be varied over a wide range and can therefore be optimized with respect to the quantum efficiency of the sensitization effect. Hence, organic materials such as phthalocyanines,[2-6] merocyanines[7-10] and porphyrins[11-19] have received much attention as the promising sensitizers.

Previously we have demonstrated that the most efficient photoelectrochemical cells based on synthetic *p*-type porphyrin films on Al reach power conversion efficiencies of 1% and generate photovoltages greater than 1 V.[11,20] The dark- and photo-electrochemical properties of the cells are attributed to the MIS Schottky barrier consisting of Al-Al_xO_y-porphyrin, where conduction and valence band (CB and VB) edges of the porphyrin bend downwards under short-circuit conditions. Furthermore we have noted that a blocking contact is not formed at a *p*-type porphyrin/Ag or Pt junction. Some workers, however, have shown different views from ours.[14-16] For instance, they have attributed the cathodic photocurrents at the irradiated Pt/*p*-type porphyrin electrodes to the formation of blocking contacts at the Pt/porphyrin junctions and described that the upward band-bending in a space charge layer at the porphyrin/Pt interface is effective in producing charge carriers.

In order to build more efficient devices using porphyrin films as sensitizers it is necessary and important to solve the inconsistency and to obtain a consensus. This paper represents the energetics of ITO/*p*-type porphyrin/electrolyte interfaces and clarifies the conditions under which a blocking or an ohmic contact is formed at the junction.

Experimental

Metal-free porphyrin [5,10,15,20-tetraphenylporphyrin (H_2TPP)] and its metal derivatives (MgTPP, ZnTPP, and CuTPP) were purchased from Strem Chemicals and were purified by chromatography (Woelm alumina grade I) followed by recrystallization. These porphyrins have been characterized as *p*-type organic semiconductors.[11,14,19] *p*-Benzoquinone (BQ) from Katayama Chemicals was used after sublimation. Other chemicals used were of reagent grade. An indium-tin oxide (ITO) film was used as substrate for the porphyrin electrode because of the superiority of light-transparency and the metallic property.[21,22] An ITO film was produced on a piece of cleaned slide glass (Matsunami No. 0) by means of a Tokuda CFS-8EP closed field sputtering apparatus. O_2 partial pressure of 1.3×10^{-2} Pa and Ar partial pressure of 6.7×10^{-1} Pa were employed for fabrication of the ITO electrode. The thickness of ITO films was about 100 nm. The electric resistance was about a few hundreds ohm/square and the transparency larger than 80% in the visible region of the solar spectrum. Films of the porphyrins (100—300 nm thick) and metals (Au, Ag, and Al, *ca.* 10 nm thick) were prepared by sublimation and evaporation at pressure 10^{-4} Pa, respectively. The porphyrin-coated ITO or metal electrode was insulated from the electrolyte with epoxy resin except for the portion to be exposed to light. The photoelectrochemical measurements of the porphyrin electrodes were carried out using a two or three electrode system. For potentiostatic steady-state measurements a coiled platinum wire was used as the auxiliary electrode and a saturated calomel electrode (SCE) served as the reference. Unless otherwise stated, dissolved oxygen in solution was removed by bubbling Ar gas. A custom-built potentiostat was used to obtain the steady-state current-potential curves. Voltages and currents produced by the cells were measured with a Takeda TR 8651 electrometer. Applied voltages were provided by a Takeda TR 6141 voltage supply and monitored with a Takeda TR 6855 digital multimeter. The light source consisted of a 45 W tungsten-halogen lamp and a Baush-Lomb Cat. No. 33-86-76 monochromator. An Ushio

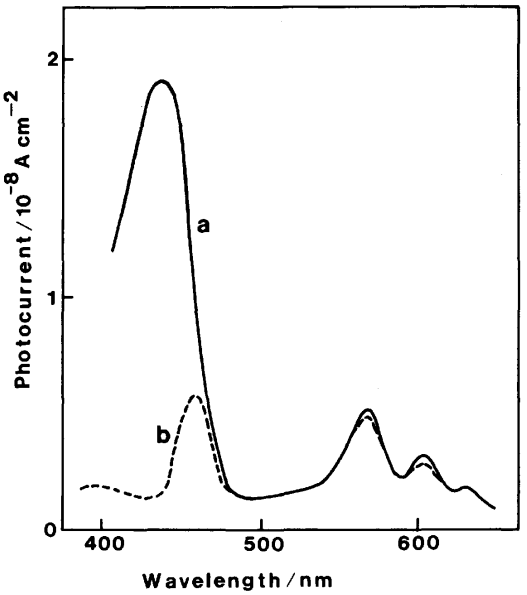

Fig. 1. Action spectra of short-circuit photocurrents of the ITO/MgTPP (*ca.* 200 nm thick)/HQ-BQ, phosphate buffer/Pt cell. (a) and (b) are obtained by irradiation of the MgTPP/electrolyte and ITO/MgTPP junctions.

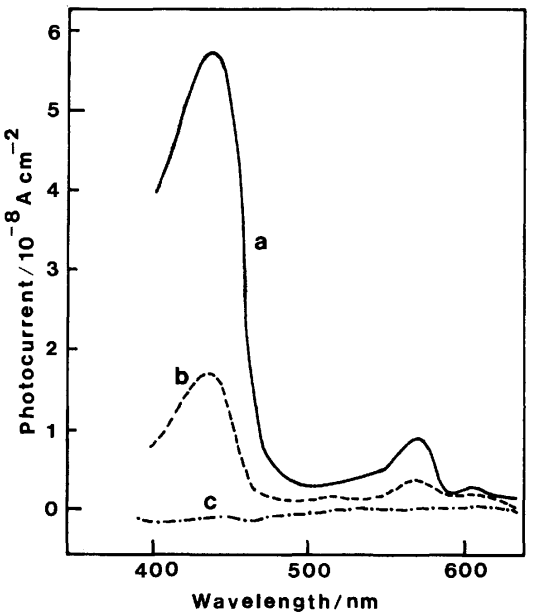

Fig. 2. Voltage dependence of the photocurrent action spectrum for the ITO/MgTPP/HQ-BQ/Pt cell. (a), (b), and (c) are obtained by irradiation of the MgTPP/electrolyte junction at voltages of −0.21 V, 0 V and +0.2 V, being applied to the ITO electrode.

500 W xenon lamp was also used as light source with a Toshiba KL-43 interference filter. Light intensity was measured with a calibrated Eppley thermopile of 16 junctions. Optical absorption spectra were recorded on a Shimadzu UV-240 spectrometer. All measurements were carried out at room temperature.

Results and Discussion

Figure 1 shows action spectra of short-circuit photocurrents for the ITO/MgTPP/electrolyte/Pt cell. The electrolyte was a phosphate buffer [0.025 M (1 M=1 mol dm^{-3}) KH_2PO_4, 0.025 M Na_2HPO_4 and 0.1 M KCl: pH 6.87], containing 1 mM hydroquinone (HQ) and 1 mM BQ. Curves (a) and (b) were obtained by irradiation of the MgTPP/electrolyte and ITO/MgTPP interfaces, respectively. The photocurrents have been normalized in such a way that the intensity of the incident light on the interface between MgTPP and ITO or electrolyte is constant (about 30 μW cm^{-2}) in consideration of the absorption of light with ITO or the electrolyte and the reflection at the glass/ITO or electrolyte interface. The photocurrents flowed from Pt to ITO through the MgTPP/electrolyte interface regardless of the wavelength and the direction of irradiation. Taking account of this and the finding that the action spectrum (a) resembles the optical absorption spectrum of a MgTPP film, the difference in shape between the action spectra (a) and (b) is attributable to an optical filtering effect of the MgTPP phase.[8] Namely it shows that the photocurrent is generated *via* the excited states of the porphyrin and that only the light absorbed near the blocking (electrolyte) contact is effective in producing charge carriers.[23,24] This was confirmed by the voltage dependence of the photocurrent action spectrum obtained under irradiation of the MgTPP/electrolyte interface (Fig. 2). When a negative bias voltage was applied to the ITO electrode, the cathodic photocurrent was strikingly enhanced. On the contrary, when a positive voltage was applied the photocurrent was reduced to zero.

In case of the ITO electrode modified with ZnTPP, which is uneasily oxidized in comparison with MgTPP, there was a wavelength region of around the peak of a Soret band (440 nm) of the ZnTPP film, where small anodic photocurrents were observed by irradiation of the ITO/ZnTPP interface under short-circuit conditions (Table 1). This shows the existence of a small Schottky barrier (blocking contact) at the ITO/ZnTPP junction and coincides with the dark current-voltage characteristics of the ITO/ZnTPP/Ag cell (Fig. 3). The observed rectification effect is due to the blocking contact at the ITO/ZnTPP junction, since the ZnTPP/Ag junction has been found an ohmic contact.[11,12]

For ITO electrodes modified with films of CuTPP and H_2TPP with oxidation potentials more positive than those of MgTPP and ZnTPP, both cathodic and anodic photocurrents were clearly observed, depending on the direction of irradiation on the ITO/porphyrin electrodes (Table 1). This indicates that blocking contacts are formed at both junctions of the porphyrin with ITO and the electrolyte and thus the ITO/porphyrin electrodes act as photocathodes and also as photoanodes. The observation of the anodic photocurrents seemingly depends on the oxidation potentials of the porphyrins.

Figure 4 illustrates energy levels of ITO, redox agents and porphyrin films studied. The free energy

TABLE 1. SUMMARY OF THE PHOTORESPONSE OF THE PORPHYRIN FILMS ON ITO IN THE ITO/PORPHYRIN/HQ–BQ, PHOSPHATE BUFFER/Pt CELL

Porphyrin	λ_{max}[a]/nm	$h\nu$→ITO/porphyrin	porphyrin/electrolyte←$h\nu$	$E_{1/2}$[b]/V *vs.* SCE
MgTPP	445	~	—[c]	0.61
Zn TPP	440	+[c]	—	0.78
Cu TPP	430	++	—	0.96
H_2 TPP	445	++	—	1.04

a) Peak of a Soret band of a porphyrin solid film, at which irradiation is carried out. b) Oxidation at Pt in CH_2Cl_2 with 0.1 M tetrabutylammonium perchlorate. c) Plus and minus signs denote anodic and cathodic photocurrents, respectively. Double plus and minus signs mean stronger photoresponse.

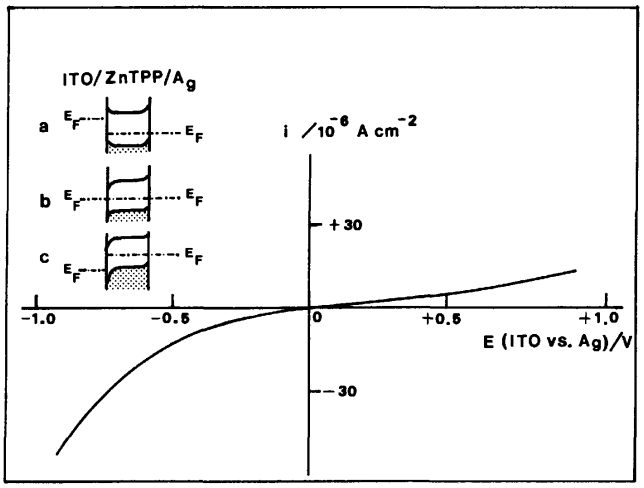

Fig. 3. Dark current-voltage curve for the ITO/ZnTPP/Ag cell. The inset shows the band-bending at the ITO/ZnTPP/Ag contact at (a) negative, (b) zero and (c) positive bias voltages.

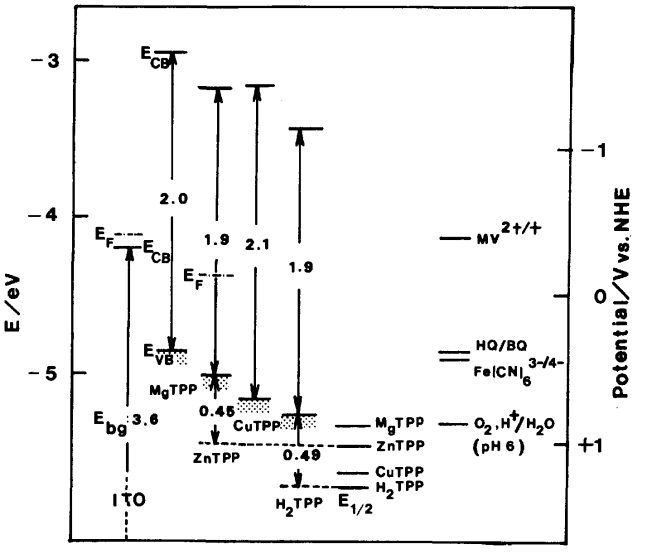

Fig. 4. Energy levels of ITO, porphyrin films and redox systems.

of electrons in a semiconductor or a metal is characterized by the Fermi level (E_F). The Fermi level in ITO lies just above the CB edge because of degeneracy of the *n*-type semiconductor. Hence, the electric behavior of ITO is similar to that of a metal. The E_F in a ZnTPP film has been found slightly closer to the VB, *viz.* E_{VB}=−5.0 eV, E_F=−4.3 eV and E_{CB}=−3.0 eV from the vacuum level.[14] The E_{VB} for a H_2TPP film is located at 5.2 eV below the vacuum level.[25] The values of E_{VB} of MgTPP and CuTPP films were estimated from the first ring oxidation potentials ($E_{1/2}$) obtained for the porphyrins in nonaqueous solutions assuming that the VB edges were situated at potentials 0.47 V higher than the oxidation potentials.[6] The energy difference of 0.47 eV was the average for experimental results (0.45 eV for ZnTPP and 0.49 eV for H_2TPP). The Fermi levels for MgTPP, CuTPP, and H_2TPP films might be about 0.7 eV higher than their respective VB edges as observed for ZnTPP film. The values of optical band gaps for the porphyrins were estimated from the spectral properties of the porphyrin films.

If a porphyrin film, whose Fermi level lies below that for ITO, is brought into contact with ITO, the Fermi levels will be equilibrated by electron transfer from the ITO to the porphyrin. This results in the formation of a space charge layer in the porphyrin, while counter charge remains very close to the interface in the ITO layer. Thus a blocking contact is formed at the ITO/porphyrin junction, where the CB and VB edges bend downwards, and leads to the production of anodic photocurrents. The anodic photocurrent at the irradiated ITO/porphyrin electrode depended upon the relative position of the Fermi levels of ITO and the porphyrin. For example, no distinct anodic photocurrent is observed by irradiation of the ITO/MgTPP electrode (Table 1), because the Fermi levels of ITO and MgTPP are almost the same. For a film of ZnTPP, CuTPP or H_2TPP having oxidation potential more positive than that of MgTPP, the Fermi level lies below that of ITO and the blocking contact must be formed at the ITO/porphyrin junction. In effect, the anodic photocurrents were observed. An upward band-bending, in principle, may be produced at a contact of ITO with a *p*-type porphyrin, of which Fermi level lies above that of ITO. However, such a contact should be ohmic for majority carriers (holes), unless surface states exist. This may be inferred from the finding that no obvious cathodic photocurrent is observed for the ITO/ZnTPP/Ag cell at negative bias voltages applied to the ITO electrode, where the upward band-bending is formed as shown in the inset of Fig. 3.

The Fermi level in an electrolyte solution corresponds to the redox potential of a redox couple in-

volved in the electrolyte.[26] Apparently, judging from the positions of the Fermi levels for the porphyrin films studied and the redox potential of the HQ/BQ couple (Fig. 4), the porphyrin/electrolyte contacts are supposed to be ohmic because the Fermi levels of the porphyrins lie above the redox potential of the HQ/BQ couple and at equilibrium upward band-bendings are produced at the porphyrin/electrolyte junctions. However, actually the cathodic photocurrents are observed by irradiation of the porphyrin/electrolyte interfaces. In view of the fact the photoelectric behaviors of the ITO/porphyrin contacts can reasonably be explained in terms of the energy diagram of Fig. 4, the inconsistency between the prediction and the experimental result reminds us of two plausible reasons. One is an existence of surface states at the porphyrin/electrolyte interface, which causes Fermi level pinning[27] and the other is that the energy levels of the porphyrin films in aqueous solution might be different from those *in vacuo*.

At first, we consider a few points about the possibility of the Fermi level pinning at the porphyrin/electrolyte interface. The positions of the Fermi level and band edges at the surface of the porphyrin contacting the electrolyte can be estimated from measurement of the flat-band potential (E_{fb}). Figure 5 illustrates the steady-state photocurrent-potential curves for the ITO/ZnTPP electrode in aqueous electrolyte solutions. Without oxdizing agents, only small photocurrents were observed over the potential range of −0.5 V to +1.0 V *vs.* SCE under irradiation of the ZnTPP/electrolyte interface at 430 nm [curve (a)]. In this case, the ZnTPP film used was so thick (*ca.* 200 nm) that the light hardly reached the ITO/ZnTPP interface through the porphyrin phase. The cathodic photocurrents obtained by irradiation of the ZnTPP/electrolyte interface were enhanced by the addition of oxidizing agents such as O_2, $[Fe(CN)_6]^{3-}$, BQ, methylviologen (MV^{2+}), 2,3-dichloro-5,6-dicyano-*p*-benzoquinone and $Cr_2O_7^{2-}$. The onset potential (E_{op}) of about +0.5 V *vs.* SCE was almost independent of the oxidizing species except for MV^{2+} and of pH in the range 5.5—9.0. It is well known that the surface states formed at inorganic semiconductors sometimes bring about the Fermi level pinning, which results in an output photovoltage independent of the redox potential of an electrolyte.[27] However, this may be not the case for the porphyrin electrode since the E_{op} of the ZnTPP electrode is found independent of the kind of the oxidizing species ranging in potential from +0.2 V to +0.7 V *vs.* NHE as described above. In other words, the band edges of the porphyrin films are fixed at the porphyrin/electrolyte interfaces.[28]

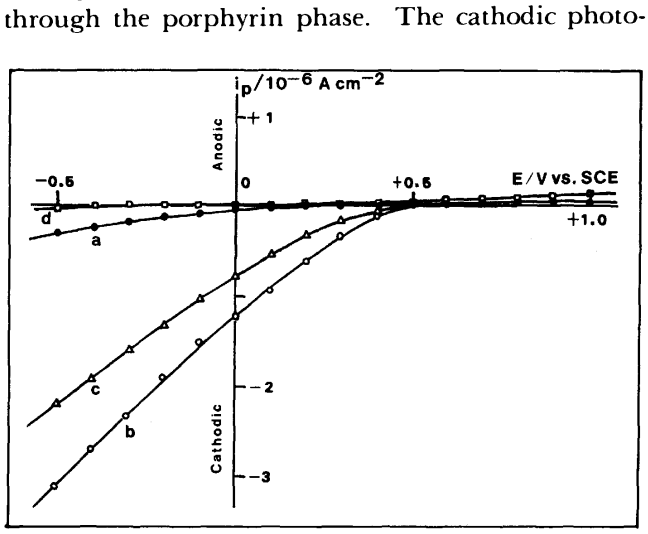

Fig. 5. Potential dependence of the steady-state photocurrent for the ITO/ZnTPP electrode. (a), (b) and (c) are obtained by irradiation of the ZnTPP/electrolyte junction, and (d) obtained by irradiation of the ITO/ZnTPP junction. (a): acetate buffer (1 M CH_3COOH and 1 M CH_3COONa, pH 4.7); (b): in (a) +0.2 mM O_2; (c) and (d): 0.1 M KCl+0.2 mM O_2.

Secondly, we discuss the difference in energy levels of the porphyrin films *in vacuo* and in aqueous electrolyte solution. The E_{op} of about +0.5 V is probably near the flat-band potential at the ZnTPP/electrolyte interface, from which the Fermi level of the ZnTPP film in the aqueous electrolyte solution is estimated to be about 0.9 eV lower than that (−4.3 eV) *in vacuo*. The contribution of the Helmholtz double layer, especially an inner Helmholtz layer, should be taken into consideration to account for the energy difference. In view of similarity between the E_{fb} for a semiconductor and the zero charge potential (E_{pzc}) for a metal, surface potential due to orientaion of water dipoles at the porphyrin is one of the plausible factors responsible for the energy difference. According to Trasatti,[29] the relationship between E_{pzc} and work function (ϕ) for a metal is written in the following form, $E_{pzc}=\phi-4.61-0.40\ \alpha$, where α is defined as the degree of orientation of water at the metal. The maximum surface potential of −0.40 V indicates that the dipole of water points the negative end (oxygen) towards the metal and forms an angle of about 34° with the metal surface. A surface potential of about 0.75 V corresponds to the perpendicular dipoles. On these bases, it may be possible to ascribe a part of the potential difference of +0.9 V to the surface potential due to the orientation of water dipoles at the porphyrin electrode. We note that in this case a water molecule must be oriented with the positive end (hydrogen) toward the porphyrin.

When the ITO/ZnTPP interface was irradiated in solution containing oxidizing agents, no evident photocurrent was observed [curve (d) in Fig. 5]. However, in the presence of reducing agents such as HQ and $[Fe(CN)_6]^{4-}$ instead of the oxidizing agents the ITO/ZnTPP electrode exhibited anodic photocurrents at potentials more positive than about −0.1 V *vs.* SCE (Fig. 6).

On these bases, the energy diagram of the ITO/ZnTPP/electrolyte interfaces is represented as shown in Fig. 7. At this time we should note the fact that the band edges are fixed at the porphyrin surfaces. It is

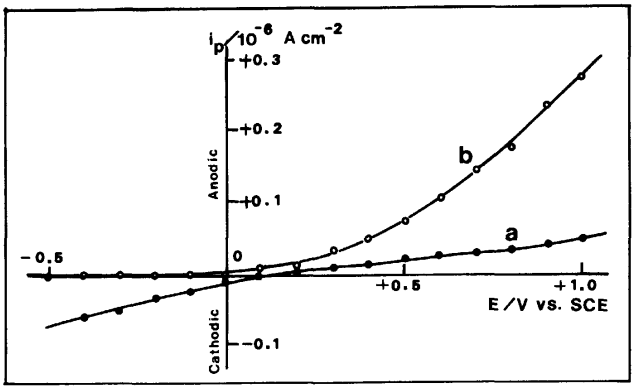

Fig. 6. Potential dependence of the steady-state photocurrent for the ITO/ZnTPP electrode in 0.5 mM $[Fe(CN)_6]^{4-}$ and 0.1 M KCl. (a) and (b) are obtained by irradiation of the ZnTPP/electrolyte and ITO/ZnTPP junctions, respectively.

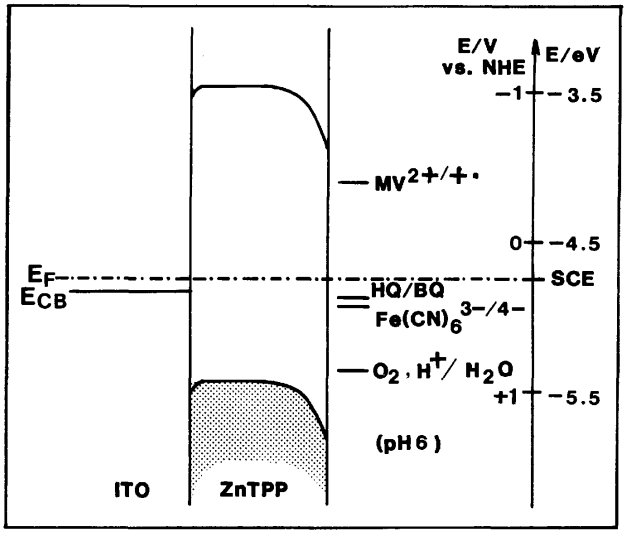

Fig. 7. Band model for the ITO/ZnTPP/electrolyte contacts at 0 V *vs.* SCE.

of great interest that photoelectrochemical reduction of methylviologen (MV^{2+}) occurs even near the flat-band potential, because such a *p*-type porphyrin electrode can be used as a photocathode for reduction of H_2O to produce H_2. The redox potential of HQ/BQ is negative so that at equilibrium the downward band-bending is produced at the ZnTPP/electrolyte interface, which brings about the cathodic photocurrent under short-circuit conditions (Fig. 8). This is in good agreement with the result for the photoelectrochemical cell with ZnTPP (Table 1). Similarly the steady-state photocurrent-potential curves of the ITO/H_2TPP electrode are understood (Fig. 9). The E_{op} for the cathodic photocurrent was negative a little more than that for the ZnTPP electrode. By all accounts it is deduced that the cathodic photocurrents observed at the Pt/ZnTPP electrode[14-16] might be due to the ZnTPP/electrolyte (blocking) contact and not to the Pt/ZnTPP contact.

This work was supported in part by the Grant-in-Aid for Energy Research (No. 59040051) from the Ministry of Education, Science and Culture.

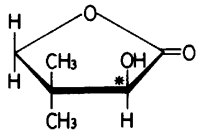
Intermolecular Hydrogen Bonding of Enantiomers of Pantolactone Studied by Infrared and ^{1}H-NMR Spectroscopy

Yoshihiko NAKAO, Hiromu SUGETA,* and Yoshimasa KYOGOKU
Institute for Protein Research, Osaka University, Suita, Osaka 565
(Received December 6, 1984)

Intermolecular associations of the enantiomers of pantolactone in carbon tetrachloride solution have been studied by infrared and ^{1}H-NMR spectroscopic methods. The spectroscopic data have been analyzed by the least squares method to obtain the association constants and thermodynamic parameters. It was found that pantolactone takes a cyclic dimer structure by dint of hydrogen bonding. The association constant for homochiral dimerization was obtained to be 8.9 mol^{-1} dm^3 at 26°C and the enthalpy and entropy changes were −35 kJ mol^{-1} and −97 J K^{-1} mol^{-1}, respectively. The association constant for heterochiral dimerization is just twice as large as that for homochiral dimerization, that is, no selective association exists between enantiomers.

In a previous study a general method for analyzing spectrophotometric data of a multicomponent equilibrium system has been developed.[1] The method was applied to the analysis of intermolecular hydrogen bond system of pantolactone **1** in carbon tetrachloride solution. Some spectroscopic measurements of pantolactone have been made, infrared spectra by Kuhnert-Brandstätter and Friedl[2] and Raman and ^{1}H-NMR spectra by Johnson *et al*,[3] but no quantitative analysis on intermolecular hydrogen bonding has yet been worked out. In the present work the infrared and ^{1}H-NMR studies of pantolactone were undertaken for elucidating the association mode and obtaining the association constants and thermodynamic parameters of the intermolecular hydrogen bonding. Pantolactone is an optically active molecule and a stereoselective association between enantiomers is possible. In order to elucidate this problem the quantitative analysis of the concentration dependence of the OH proton chemical shift was made on the solutions of the pure enantiomer (L-pantolactone), racemic mixture (DL-pantolactone), and the mixture of the enantiomers (D- and L-pantolactones) at different ratios.



1

Experimental

Materials and Methods. Enantiomers of pantolactone (dihydro-3-hydroxy-4,4-dimethyl-2(3*H*)-furanone) were purchased from Tokyo Kasei Co. and purified by sublimation *in vacuo*. Spectroscopic grade carbon tetrachloride was dried over molecular sieves of 3A and was used as the solvent.

Infrared spectra were measured on a JASCO A-3 infrared spectrophotometer interfaced to a personal computer (NEC PC-9801). The concentration dependences of the absorption intensities in the O–H and C=O stretching regions were measured in the concentration range from 0.08 to 0.003 M (1 M=1 mol dm^{-3}) at 26°C. The temperature dependence of the absorption intensities of the O–H stretching vibrations was measured at several temperatures from 20 to 58°C. The Raman spectra of L-pantolactone in CCl_4 solution (0.08 M) were measured on a JEOL-400D Raman spectrometer.

^{1}H-NMR spectra were measured mainly on a JEOL FX-200 spectrometer operated at 200 MHz and in part on a JEOL GX-500 spectrometer at 500 MHz locked on deuterium of 5 vol% cyclohexane-d_{12} in CCl_4 solvent at 30°C. Chemical shifts were measured relative to the ^{1}H resonance of internal tetramethylsilane. Solutions were prepared in the concentration range from 0.07 to 0.0005 M for pure L-enantiomer, and from 0.2 to 0.01 M for racemic mixture (DL-pantolactone). The measurements for the solutions of different mole ratio of D- and L-enantiomers were performed at the total concentration of 0.07 M.

Procedure for Analysis. The self association of pure enantiomer (D- or L-pantolactone) is expressed for n merization by

$$nX \rightleftharpoons X_n, \quad K_n = [X_n]/[X]^n, \tag{1}$$

where X stands for D or L, [X] and [X_n] are the concentrations of monomer and n-mer, respectively, and K_n is the association constant for n merization of pure enantiomer.

In the solution of mixture of D- and L-enantiomers the following equilibrium was assumed,

$$\begin{aligned} &2D \rightleftharpoons D_2, \quad 2L \rightleftharpoons L_2, \\ &\quad K_2 = K_{DD} = K_{LL} = [D_2]/[D]^2 = [L_2]/[L]^2, \\ &D + L \rightleftharpoons DL, \\ &\quad K_{DL} = [DL]/[D][L], \end{aligned} \tag{2}$$

where $K_2(=K_{DD}=K_{LL})$ and K_{DL} are the association constants for dimerization of pure enantiomer and for hetero-association of D- and L-enantiomers, respectively. [D] and [D_2] ([L] and [L_2]) are concentrations of monomer and dimer of the D- (L-) enantiomer and [DL] is the concentration of heteroassociate DL between D- and L-enantiomers.

The absorbances A for the solution containing n absorbing components are expressed by the sum of absorptions of n components,

$$A_\nu = l \sum_{i=1}^{n} E_{\nu i} C_i(K), \tag{3}$$

where A_ν is the absorbance at the wave number ν, l is the path length, $E_{\nu i}$ is the molar absorption coefficient at the wave number ν of the i-th absorbing component, and C_i is the concentration of the i-th component which is a function of the association constant K. The association constants and molar absorption coefficients were determined from the observed absorbance data by the method of least squares as

described previously.[1]

The chemical shifts (Δ) of the OH proton of pantolactone in the chemical equilibrium system (2) are expressed by

$$\Delta_D = \delta_D P_D + \delta_{DD} P_{DD} + \delta_{DL} P_{DL}(D),$$
$$\Delta_L = \delta_L P_L + \delta_{LL} P_{LL} + \delta_{DL} P_{DL}(L), \quad (4)$$

where Δ_D and Δ_L are observed chemical shifts for the D- and L-enantiomers, $\delta_D(=\delta_L)$, $\delta_{DD}(=\delta_{LL})$ and δ_{DL} are the intrinsic chemical shifts for the D- (or L-) monomer, homo-dimer D_2 (or L_2) and hetero-associate DL, respectively. P_i is the fraction of the i species given by

$$P_D = [D]/([D] + 2[D_2] + [DL]),$$
$$P_{DD} = 2[D_2]/([D] + 2[D_2] + [DL]),$$
$$P_{DL}(D) = [DL]/([D] + 2[D_2] + [DL]), \quad (5)$$

and P_L, P_{LL} and $P_{DL}(L)$ are given similarly. The association constants K_2 and K_{DL} and limiting shifts δ_D, δ_{DD}, and δ_{DL} were determined by the least squares method[1] with reference to the observed chemical shifts.

Results and Discussion

Infrared Spectra. The concentration dependences of absorption bands of the O-H and C=O stretching vibrations of L-pantolactone in CCl_4 solutions at 26°C are shown in Figs. 1 and 2, respectively. The broad band at 3460 cm^{-1} which is enhanced with concentration can readily be assigned to the intermolecularly hydrogen-bonded O-H stretching vibration, while the band at 3570 cm^{-1} enhanced with dilution can be assigned to the O-H stretching vibration of the monomer species. The observation of an isosbestic point at 3550 cm^{-1} suggests that the chemical equilibrium between two components would be predominant in this system. The temperature dependence of absorption intensities in the O-H stretching region was measured (data are not shown). No absorption band above 3600 cm^{-1} was recognized even at high temperature of 70 °C in the dilute solution. It is known that the hydrogen bond free O-H stretching band appears at the wave number above 3600 cm^{-1}.[4] Therefore it suggests that pantolactone exists exclusively in intra- and/or intermolecular hydrogen bonded forms. In the C=O stretching region the main peak at 1795 cm^{-1} is enhanced while the shoulders at 1780 and 1765 cm^{-1} diminish with dilution. Then the band at 1795 cm^{-1} is assigned to the C=O stretching vibration of the monomer species, while the shoulders at 1780 and 1765 cm^{-1} are assigned to the bands of intermolecularly hydrogen-bonded species.

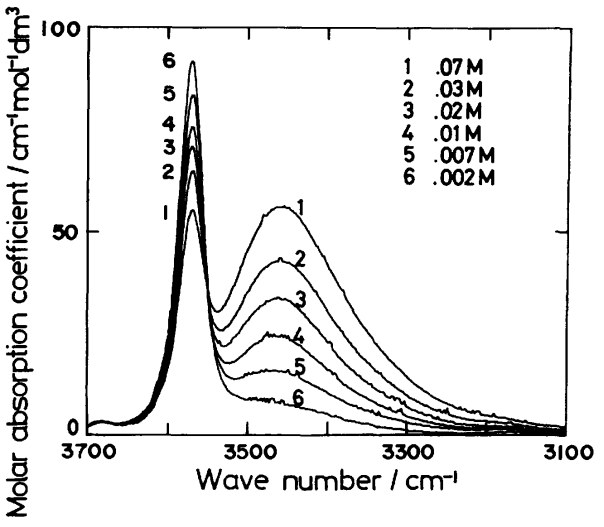


Fig. 1. Concentration dependence of the infrared spectra in the O-H stretching region of L-pantolactone in CCl_4 solutions at 26°C.

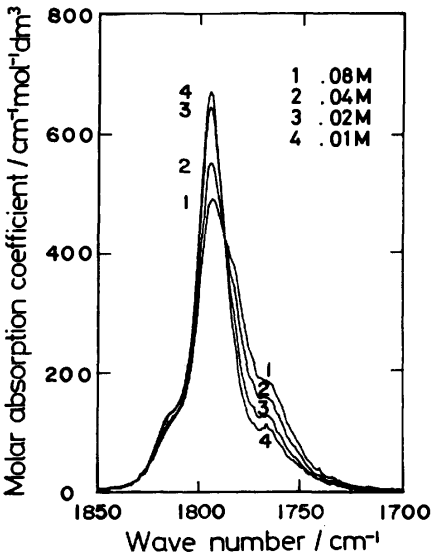

Fig. 2. Concentration dependence of the infrared spectra in the C=O stretching region of L-pantolactone in CCl_4 solutions at 26°C.

^{1}H-NMR Spectra. In ^{1}H-NMR spectrum of L-pantolactone two methyl groups give rise to the separate signals at δ 1.0 and 1.2 and methylene protons give rise to the AB quartet at δ 3.9 because of the existence of an asymmetric carbon atom. These methyl and methylene chemical shifts are independent of the concentration. The resonance lines of hydroxyl and methine protons are spin-spin coupled with each other and exhibit concentration dependence. Their chemical shifts vary from δ 3.5 to 2.2 and from δ 4.03 to 3.92, respectively, and the spin-spin coupling constant $^3J_{HCOH}$ changes from 3.7 to 2.3 Hz with the change in concentration from 0.07 to 0.0005 M.

In Fig. 3 is shown the mole ratio dependence of ^{1}H-NMR spectra for the solutions of the total concentration 0.07 M of the mixture of D- and L-enantiomers. The hydroxyl and methine proton signals are observed at δ 3.48 and 4.03 for the pure L-enantiomer solution of 0.07 M (Fig. 3(a)), but at δ 3.40 and 4.01 for the racemic solution (L:D=1:1) (Fig. 3(f)). At the mole ratios of $0<D/L<1$, the chemical shifts monotonously change between the extreme values (Fig. 4) and the peak areas are proportional to the mole ratio of enantiomers.[5-9]

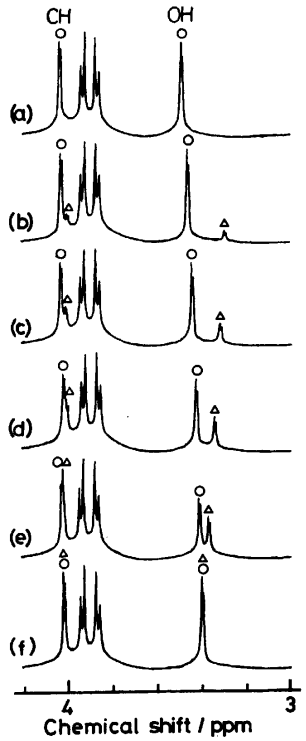

Fig. 3. 500 MHz proton magnetic resonance spectra of CCl_4 solutions of the total concentration 0.07 M of D- and L-pantolactone at 30 °C. The resonance lines of L- and D-enantiomers are denoted with the circles (O) and triangles (Δ), respectively. Enantiomeric compositions *D*:*L* are: (a) 0:1; (b) 1:9; (c) 2:8; (d) 3:7; (e) 4:6; (f) 5:5.

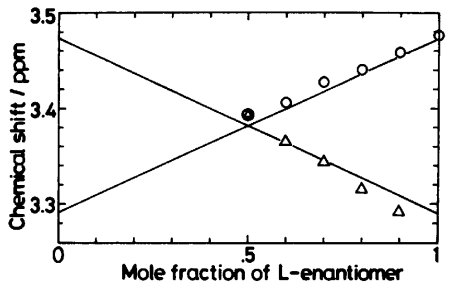

Fig. 4. The observed and calculated chemical shifts of the OH proton resonance against the mole fraction of L-enantiomer in the solutions of the total concentration 0.07 M of D- and L-pantolactone. The solid lines (—) are calculated, and the circles (O) and triangles (Δ) are observed for L- and D-enantiomers, respectively.

Homochiral Association. The concentration dependences of infrared absorption intensities in the O–H and C=O stretching regions of L-pantolactone were analyzed on the basis of the monomer-dimer equilibrium model by the method of the least squares.[1] The association constants for homochiral association were obtained as K_{LL}=8.9±0.6 and 9.8±0.8 M^{-1} at 26 °C from the spectral analyses in the O–H and C=O stretching regions, respectively. The calculated molar absorption coefficients of monomer and dimer species are shown in Figs. 5 and 6, in which those of dimer species

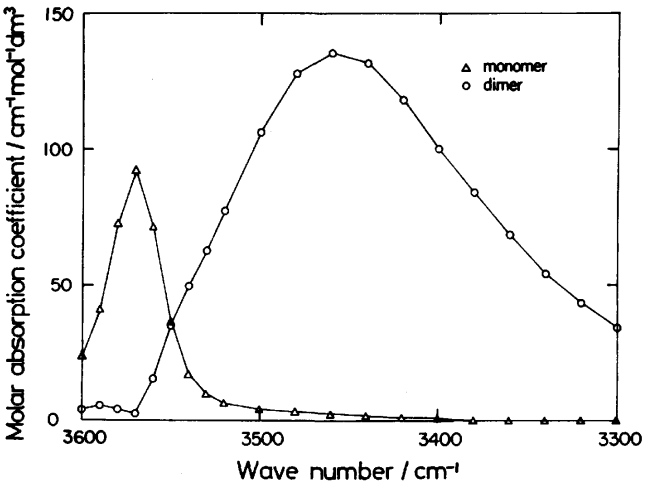

Fig. 5. Molar absorption coefficients for monomer (Δ) and dimer (O) species of L-pantolactone in the O–H stretching region at 26 °C.

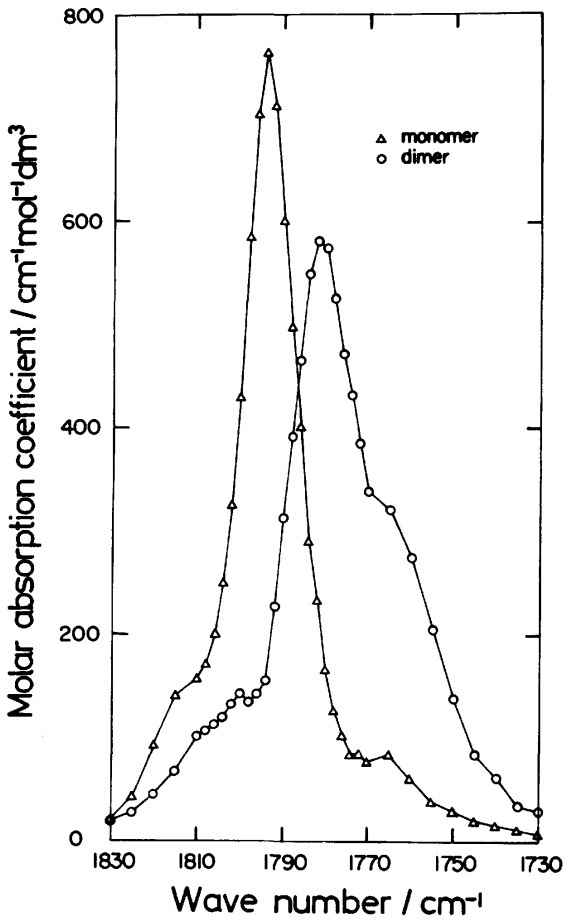

Fig. 6. Molar absorption coefficients for monomer (Δ) and dimer (O) species of L-pantolactone in the C=O stretching region at 26 °C.

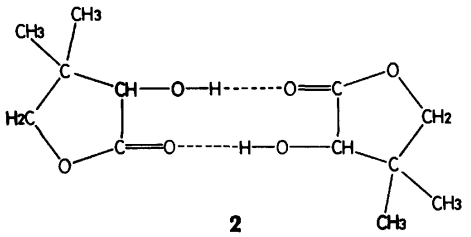
are given in values per monomer unit. The observed spectra could be reproduced by using the coefficients with root-mean-squares deviations of 0.66 and 4.2 molar absorption units in the O–H and C=O stretching regions, respectively. The monomer-trimer model

was also applied to the analysis but the agreement between the observed and calculated spectra was poor as compared with the monomer-dimer model. The least squares treatment on the monomer-dimer-trimer model could not give convergence. Therefore the dimerization would be predominant in the concentration range employed.

In the C=O stretching region the band at 1780 cm^{-1} can be observed, at most, as a shoulder even in the saturated solution as shown in Fig. 2. However, the quantitative analysis employed in this study clearly indicates that dimer species has a main peak at 1780 cm^{-1} and a shoulder at 1765 cm^{-1} as seen in Fig. 6. All the bands in the C=O stretching region were polarized in Raman scattering. Accordingly, the band at 1780 cm^{-1} could be assigned to the C=O stretching vibration of the dimer species and the shoulder at 1765 cm^{-1} might be an overtone or a combination band enhanced by a Fermi (anharmonic) resonance. The low frequency shift from 1795 to 1780 cm^{-1} of the C=O stretching suggests that the C=O groups are the proton acceptor sites of the intermolecular hydrogen bond.[10,11] In the calculated molar absorption spectra in Fig. 5, the dimer species exhibits only a broad band centered at 3460 cm^{-1} due to the intermolecular hydrogen bond but does not show any O-H stretching band free from hydrogen bonding. Therefore all the OH groups in the dimer species are responsible for intermolecular hydrogen bonding. It is consequently concluded that pantolactone takes a cyclic dimer structure as shown in **2**.



2

The dimer model is further supported by the analysis of the concentration dependence of the OH proton chemical shift in ^{1}H-NMR. The calculations of the least squares fitting[1] were carried out on the basis of several association models. The monomer-dimer model gives a better fit between the observed and calculated data as shown in Fig. 7.

The concentration dependence of the absorption intensities in the O-H stretching region was examined at various temperatures. The results were summarized in Table 1. The dimer model was not inferior to the other models as well. From the van't Hoff plot the enthalpy and entropy changes for dimerization were obtained as ΔH=−35±2 kJ mol^{-1} (−18±2 kJ mol^{-1} per hydrogen bond) and ΔS=−97±4 J K^{-1} mol^{-1}, respectively. The thermodynamic parameters obtained in the present study may be compared with those for the cyclic dimerization of carboxylic acids in CCl_4 solutions which

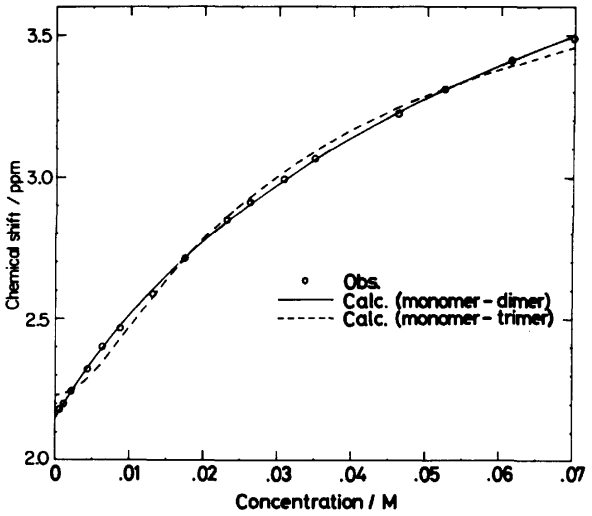


Fig. 7. Concentration dependence of the observed (O) and calculated OH proton chemical shifts of L-pantolactone in CCl_4 solutions at 30 °C. The solid (—) and broken (---) lines are calculated curves on the basis of the monomer-dimer and monomer-trimer models, respectively.

Table 1. Association constants of L-pantolactone at various temperatures

Temperature T/°C	Association constants K_2/M^{-1} O-H stretching	C=O stretching
20	11.6±0.7	
26	8.9±0.6	9.8±0.8
30	7.6±0.5	
40	5.3±0.5	
49	3.3±0.4	
58	2.3±0.3	

have been reported as ΔH=−12 to −23 kJ mol^{-1} and ΔS=−30 to −66 J K^{-1} mol^{-1} per hydrogen bond.[12] No absorption band of hydrogen-bond free O-H stretching above 3600 cm^{-1} could be observed even at 70 °C in the dilute solution (0.003 M). Therefore the monomer species would be stabilized at least by 6 kJ mol^{-1} by dint of an intramolecular hydrogen bond.

Heterochiral Association. Figure 8 shows the concentration dependences of the OH proton chemical shifts for the solutions of L-pantolactone (pure enantiomer) and DL-pantolactone (L:D=1:1). One can clearly recognize the differences between the chemical shifts for the pure enantiomer and racemic solutions in the high concentrations. It suggests that the association constant and/or limiting chemical shift for the heterochiral dimer would be different from those for the homochiral dimer.

In the pure enantiomer solution (*e.g.* L-pantolactone) of the stoichiometrical concentration, C=[L]+2[L_2], the concentration of dimer is given from Eq. 2 by

$$[\text{dimer}] = [L_2] = K_{LL}[L]^2 = K_2[\text{monomer}]^2. \quad (6)$$

In the racemic solution (DL-pantolactone) the total concentration of D- and L-pantolactone, C', is given by

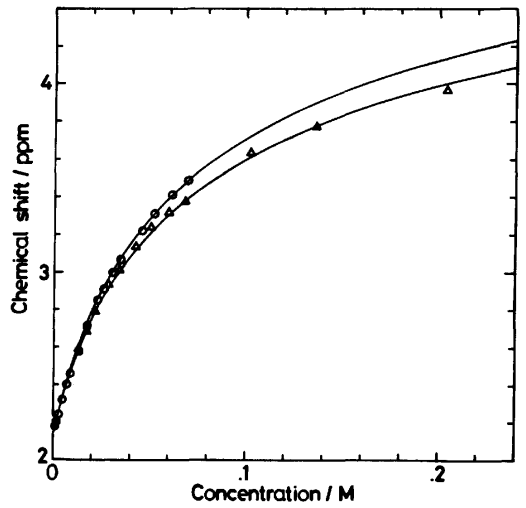

Fig. 8. Concentration dependence of the observed and calculated (solid line) OH proton chemical shifts of pantolactone in CCl_4 solutions at 30°C. The observed shifts are denoted with O and Δ for L- and DL-pantolactone, respectively.

$$C' = [D] + [L] + 2[D_2] + 2[L_2] + 2[DL] = 2[L] + 4[L_2] + 2[DL], \quad (7)$$

and the concentration of dimer species in the racemic solution is given as

$$\begin{aligned}[\text{dimer}] &= [D_2] + [L_2] + [DL] \\ &= K_2([D]^2 + [L]^2) + K_{DL}[D][L] \\ &= \frac{1}{4}(2K_2 + K_{DL})([D] + [L])^2 \\ &\quad + \frac{1}{4}(2K_2 - K_{DL})([D] - [L])^2 \\ &= \frac{1}{4}(2K_2 + K_{DL})[\text{monomer}]^2, \end{aligned} \quad (8)$$

where the relations in the racemic solution, [D]=[L] and [monomer]=[D]+[L], were employed. From the comparison of Eqs. 6 and 8, if the relation of $K_{DL}=2K_2$ ($=2K_{LL}$) holds, the degree of dimer formation in the racemic solution may be regarded to be the same as that in the solution of the pure enantiomer.

In order to elucidate the difference between the homo- and hetero-chiral associations in pantolactone the simultaneous analysis of the concentration dependence of the OH proton chemical shifts was undertaken for the solutions of pure enantiomer (L-pantolactone), racemic mixture (DL-pantolactone), and different mole ratios of D- and L-enantiomers with the total concentration of 0.07 M. The results were summarized in Table 2. The calculated chemical shifts are in good agreement with the observed data as shown in Figs. 4 and 8. It turns out that the association constant for heterochiral dimerization, K_{DL}, is just twice as large as that for homochiral dimerization, K_2 ($=K_{LL}$), that is, no selective association exists between enantiomers. It is consequently concluded that the difference between the chemical shifts of the solutions of pure enantiomer and racemic mixture can be ascribed to the dissimilarity between the limiting chemical shifts of homo- and hetero-chiral dimers.

Table 2. Association constants and limiting chemical shifts at 30°C

K_{LL}	6.9±0.4 M^{-1}
K_{DL}	13.8±0.4 M^{-1}
δ_L	2.132±0.008
δ_{LL}	5.74±0.08
δ_{DL}	5.25±0.05

Infrared Spectrum of Dichloroborane Produced by CO_2 Laser Enhanced Reaction

Kuk-Haeng LEE,† Harutoshi TAKEO, Shigeo KONDO,* and Chi MATSUMURA
National Chemical Laboratory for Industry, Tsukuba
Research Center, Yatabe, Ibaraki 305
(Received February 7, 1985)

Infrared spectra of $HBCl_2$ and $DBCl_2$ produced by a TEA CO_2 laser enhanced reaction of BCl_3 and H_2/D_2 have been observed by an FT-IR spectrometer at a resolution of 0.12 cm^{-1}. A detailed analysis has been carried out for the ν_1 band of $HBCl_2$ to obtain the precise molecular parameters, and they are compared with the microwave data. The fundamental frequencies other than the ν_3 band have all been determined. These frequency data combined with the results of an *ab initio* MO calculation have yielded the general symmetry force field through a least squares method. Some characteristic features on the CO_2 laser reaction of BCl_3 and H_2 are also discussed.

Infrared spectra of dichloroborane have been observed by several investigators.[1-7] However, very few analyses of the vibration-rotation bands of this molecule have been reported. Lynds and Bass[6,7] observed the ν_1 and ν_6 bands of dichloroborane with a low resolution using a conventional grating spectrometer, and determined the molecular structure from the observed values of the rotational constants $(A-\bar{B})$.[6] These authors and Dewames[8] calculated the fundamental frequencies of $HBCl_2$ assuming a force field which is similar to that of BCl_3. This was done only to make assignments of the observed bands. Mandirola and Westerkamp also calculated the fundamental frequencies of this molecule assuming appropriate values of the force constants.[9] However, there have been no attempts to determine the force field of this molecule. Quite recently Sugie *et al.*[10] studied the microwave spectra of this molecule. They obtained the rotational constants of $H^{11}B^{35}Cl_2$, $H^{10}B^{35}Cl_2$, $H^{11}B^{35}Cl^{37}Cl$, and $D^{11}B^{35}Cl_2$, and determined the precise structural parameters.

In Ref. 1—7, $HBCl_2$ was produced by heating a mixture of BCl_3 and H_2 in the presence of catalysts, where various compounds such as B_2H_6, B_2H_5Cl, *etc.* besides $HBCl_2$ and HCl were produced. Recently this reaction has been investigated by the use of CO_2 laser photolysis since the strong degenerate stretching band of BCl_3 coincides with a laser band of CO_2.[11-16] Rockwood and Hudson[16] found that the reaction of BCl_3 with H_2 by the irradiation of pulsed CO_2 laser yields only $HBCl_2$ and HCl as final products, the fact being in contrast with the case of thermal reaction. They also found that the efficiency of the reaction is as high as 122 (10.6 μ) photons per $HBCl_2$ molecule.

The purpose of the present study is to observe the vibration-rotation bands of $HBCl_2$ and $DBCl_2$ with relatively high resolution to determine the spectroscopic constants. The study also aims to determine the molecular force field from the observed frequency data. An *ab initio* MO method was used to calculate the force constants, which compensated the insufficient observed data. In connection with the preparation of sample, a CO_2 laser enhanced reaction between BCl_3 and H_2 was investigated.

Experimental

H_2 and D_2 gases were purchased from Showa Denko Co. and BCl_3 gas from Takachiho Chemical Co. These samples were used without further purification. The BCl_3/H_2 and BCl_3/D_2 gas mixtures were irradiated with a CO_2 laser beam in a glass reaction vessel of 13 cm in length and 3.2 cm in diameter fitted with KBr windows. Grease was not used in the vacuum sampling system to avoid contamination. A Pirani vacuum gauge and an MKS Baratron capacitance manometer were used to measure the pressures. A Lumonics model TEA-101-2 pulsed CO_2 laser was used to irradiate the sample. Burn patterns were made in thermal paper to check the distribution of the laser radiation. The laser power was measured with a Lumonics model 20D pyroelectric detector. The laser power was changed by placing an infrared absorption cell filled with an appropriate amount of BCl_3 gas before the reaction cell. The reaction was monitored by the absorbance of infrared spectrum taken after the irradiation with the laser shots.

The vibration-rotation spectra were measured with a Nicolet 7199 FT-IR spectrometer equipped with a Ge coated KBr beam splitter and a water cooled Glober source. All the spectra were observed at a resolution of 0.12 cm^{-1}. Since no attempt was made to separate and purify the sample of $HBCl_2$, absorption bands of BCl_3 and HCl/DCl were also observed.

Results and Discussion

Observed Spectra. Since the ν_1, ν_2, and ν_3 modes belong to A_1 species, they should give B-type bands. The ν_1 band which is associated with the B–H stretching mode showed a symmetrical band contour as shown in Fig. 1. In a prolate symmetric top approximation, the frequencies of the Q branch peaks are given by

$$\nu_0^{sub} = \nu_0 + (1\pm 2K)(A'-\bar{B}') + \{(A'-A'')-(\bar{B}'-\bar{B}'')\}K^2 \mp D_k(2K^2\mp 2K+1)(2K+1), \quad (1)$$

where the single and double primes refer to the upper and lower states, respectively. D_k is a centrifugal distortion constant. $\bar{B}$ is an average of B and C rotational constants. The observed frequencies of $H^{11}BCl_2$ were

†Present address: Department of Chemistry, College of Education, Jeonbug National University, Jeonju, Republic of Korea.

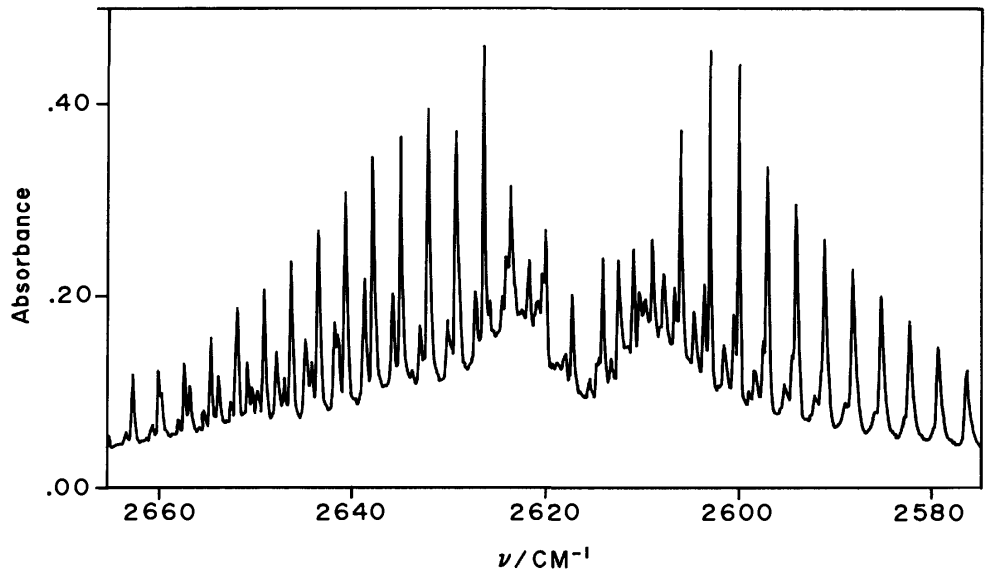

Fig. 1. Spectrum of ν_1 band of $H^{11}BCl_2$.

used for a least squares method by using Eq. 1 leading to the following;

$$\nu_1^{sub} = 2616.25 + 1.4580(1\pm 2K) - 0.00352(K^2) \mp 0.0000479(2K^2\mp 2K+1)(2K+1). \quad (2)$$

Since the band center area is overlapped by the hot bands as well as by the absorption of various isotopic species, the lines of small K values were not included in the calculation. Thus, the band center of ν_1 was determined as 2616.25 cm^{-1} for ^{11}B species. For ^{10}B species, the assignment was made so that the resulting values of the rotational constants agree well with the microwave values,[10] and the band center was determined as 2628.00 cm^{-1}. No assignment was made for the hot bands. The resulting values of the spectroscopic constants for this band are summarized in Table 1. The rotational constants are in good agreement with the microwave values shown in Table 2.[10] This fact con-

a) Ref. 10.

firms that the observed ν_1 spectrum is definitely due to $HBCl_2$ molecule.

The ν_2 band is due to the symmetric BCl stretching mode. The band center was determined as 734.62 cm^{-1} for $H^{11}B^{35}Cl_2$ species from the analysis of the vibration-rotation band, while for $H^{10}BCl_2$ species, assignment was not made, because the band center area was disturbed by the ν_4 band in addition to the hot bands. The ν_3 band, which is expected to be in the far-ir region, could not be detected.

The out-of-plane bending mode of this molecule gives a C-type band ν_4. For this band each rotational fine structure was observed as a doublet due to isotopic species of $HB^{35}Cl^{37}Cl$ whose abundance is *ca.* two thirds of $HB^{35}Cl_2$. The band centers were determined as 785.92 and 785.73 cm^{-1} for $H^{11}B^{35}Cl_2$ and $H^{11}B^{35}Cl^{37}Cl$, respectively. For ^{10}B species, the band center was determined only for $H^{10}B^{35}Cl_2$ species as 798.70 cm^{-1}.

The B_2 vibrational modes give A-type bands, which have a similar appearance to that of a parallel band of symmetric top molecule. The ν_5 B–Cl asymmetric stretching band was found at 1091.1 cm^{-1} for $H^{11}BCl_2$ and 1108.0 cm^{-1} for $H^{10}BCl_2$. The B–H in-plane deformation band, ν_6, was observed at 895.4 cm^{-1} for $H^{11}BCl_2$ and 916.5 cm^{-1} for $H^{10}BCl_2$. The ν_5 and ν_6 bands have conspicuously strong intensities compared with the other bands. The ν_6 band center area of $H^{11}BCl_2$ was slightly different in its shape from that of ν_5. From this fact, a large difference of the rotational constant A between the upper and lower states of ν_6 is expected. The observed frequency data for $HBCl_2$ are summarized in Table 3.

For $DBCl_2$ molecule, two bands were observed with about equal intensities in the BD streching band region. This is because the ν_1 and $2\nu_5$ bands are in Fermi resonance with each other. A slightly stronger one was tentatively assigned to the ν_1 band. Thus, the ν_1 band center for $D^{11}BCl_2$ was determined as 1979.94 cm^{-1}. This band is strongly disturbed also by the DCl rotation-vibration lines and by the hot bands. The ν_2 band center of $D^{11}BCl_2$ is completely obscured by the ν_6 band. The ν_3 band which is expected to be in the far-ir region could not be detected for $DBCl_2$, either.

The band center of the out-of-plane mode, ν_4, was found to be 647.21 cm^{-1} for $D^{11}BCl_2$ and 662.60 cm^{-1} for $D^{10}BCl_2$. As shown in Fig. 2, the splittings due to $DB^{35}Cl^{37}Cl$ species were also observed and its band center was determined as 646.99 cm^{-1}.

The B–Cl asymmetric stretching band, ν_5, was found at 975.20 cm^{-1} for $D^{11}BCl_2$. However, the band region for $D^{10}BCl_2$ was heavily overlapped by the ν_3 band of BCl_3, and we could not observe the band shape clearly. The B–D in-plane deformation band, ν_6, of $D^{11}BCl_2$ located at about 723 cm^{-1} is disturbed by the ν_2 band. Therefore, it was difficult to determine the band center precisely; the value given above is an approximate one. The observed date of $DBCl_2$ are also summarized in Table 3.

Force Constants. A normal coordiate calculation was carried out by the convensional GF method developed by Wilson *et al.*[17] In Fig. 3, the internal coordinates of $HBCl_2$ are illustrated. The out-of-plane coordinate, γ, is the angle between the BH bond and the ClBCl plane. The symmetry coordinates are given in terms of the internal coordinates as listed in Table 4. The adjustment of force constants was

made by using a standard least squares method such as developed by Shimanouchi *et al.*,[18] where, in each repeating cycle of the refinement procedure, the corrections to the force constants, $\Delta\boldsymbol{P}$, were made by solving the following normal equation;

$$\boldsymbol{J}'\boldsymbol{W}\boldsymbol{J}\Delta\boldsymbol{P}=\boldsymbol{J}'\boldsymbol{W}\Delta\boldsymbol{\nu} \quad (3)$$

where $\boldsymbol{J}$ denotes the Jacobian matrix, $\boldsymbol{W}$ the weight vector for the observed frequencies, and $\Delta\boldsymbol{\nu}$ the frequency error vector.

For B_1 and B_2 species, the number of the data was enough to determine all force constants uniquely and the results of the least-squares calculation are shown in Table 5. However, for A_1 species the number of the data was not enough to determine all six force constants uniquely. Then, in order to make predictions of the harmonic force field, an *ab initio* MO calculation was carried out. The calculation was made with the Pople's 4-31G* basis set by using the HONDOG computer program.[19] After geometry optimization was carried out by the gradient method,[20] the harmonic force field $\boldsymbol{F}_x$ was calculated. The $\boldsymbol{F}_x$ was transformed to a symmetry coordinates expression to give the $\boldsymbol{F}_s$ matrix. The harmonc force field of $HBCl_2$ thus obtained is shown in the second column of Table 5. These force constants were found to reproduce the observed fundamental frequencies fairly well as is clearly seen in Table 3. The agreement is markedly improved if the calculated frequencies are multiplied by an arbitrary factor of 0.9. This means that a factor of 0.81 should be used for the calculated force constants to fit them to the observed. Therefore, in order to determine the force constants for A_1 block from the

observed frequencies, the values of F_{12}, F_{13}, F_{23}, and F_{33} were constrained to the *ab initio* values multiplied by a factor of 0.81. The resulting values of the force constants are listed in Table 5. The calculated values of the fundamental frequencies from these force constants are also compared with the observed in Table 3.

CO_2 Laser Reaction of BCl_3 with H_2. As to the laser induced reaction used in the present study, a few characteristic features were noticed. For example, when the partial pressure of BCl_3 was less than 1 Torr†, we did not observe any appreciable changes in the infrared spectrum of the sample even after the 1000 shots of laser irradiation with fluence of 1.27 J/cm²/pulse, *i.e.* neither any absorption due to $HBCl_2$ nor any appreciable intensity change in BCl_3 bands was observed. However, the reaction did take place when the laser power density was increased by focusing the beam with an optical lens. When the sample pressures were raised to 5 Torr of BCl_3 and 5 Torr of H_2, the reaction became very rapid and it reached equilibrium after only 10 laser shots as shown in Fig. 4. This means that the threshold laser fluence for the reaction of BCl_3 with H_2 strongly depends on the pressure of BCl_3. It is concluded from this experiment that the average number of photons absorbed per molecule per pulse also depends on the pressure of the sample. This conclusion is demonstrated in Fig. 5, where non-linear dependence of the laser absorption on the BCl_3 sample pressure is clearly shown. The plotted data were obtained by taking the ratios of the laser power measured before and after the laser beam passes through the sample cell. In Fig. 5, the result of similar measurements for SiF_4 gas by P(42) CO_2 laser line is also shown for comparison. In both cases, non-linearity of the relationship between the absorbance and gas pressure is clearly demonstrated. Since almost the same absorption coefficients are obtained for the different laser fluences, the non-linearity may not be caused by the largeness of laser power. The most likely explanation of this phenomenon is that the pressure broadening of the BCl_3 absorption line is necessary to absorb the CO_2 laser efficiently. The very low absorption coefficient of the laser at low pressure probably causes the existence

† 1 Torr≈133.322 Pa.

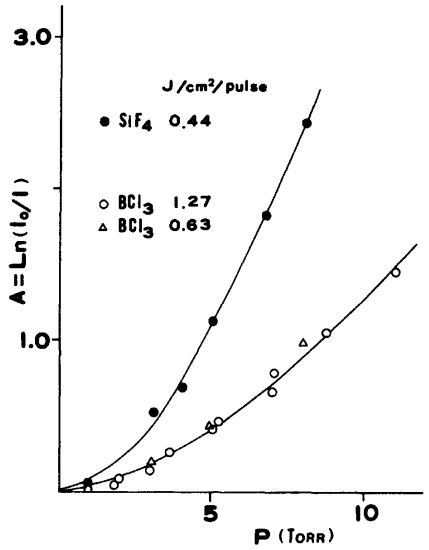

Fig. 5. Non-linear relationship between the absorbance and partial pressure for laser beam absorption by BCl_3 and SiF_4.

of the power threshold for the laser induced reaction between BCl_3 and H_2. The fact that the equilibrium mixture of BCl_3 and $BHCl_2$ is obtained as shown in Fig. 4 suggests that this reaction is almost thermal.

As described previously, the laser induced reaction between BCl_3 and H_2 does not produce B_2H_5Cl, although the external heating does. One reason may be that the catalyst is not used in the laser reaction and, therefore, the reaction occurs purely in the gas phase. Another possible reason is that the reaction products are cooled very rapidly in the pulsed laser reaction. This frozens the high temperature state so that the by-product such as B_2H_5Cl which is not stable at elevated temperatures cannot be produced.

One of the authors (KHL) wishes to express his gratitude to Japan International Cooperation Agency for providing the opportunity to carry out the present study.

To elucidate the physical meaning of the structure-activity relationship of alkanes, correlation coefficients between 24 thermodynamic properties of hexane, heptane, octane, and nonane isomers and four different topological indices were calculated. These properties were classified into five different types depending on the signs and magnitudes of their correlation coefficients with the two indices, Z and p_3. It is interpreted that Z and p_3, respectively, represent the dynamical and static features of the topological properties of molecules. The merit of correlation pattern recognition is demonstrated.

There have been proposed a number of empirical formulas relating various properties of chemical substances with their structural parameters, such as the topological index.[1-18] Although the term topological index was proposed first by one of the present authors for the Z-index defined below,[7,19] recently it is used as a common name given to a group of indices for characterizing certain aspects of the topological skeleton of a molecule obtained according to the specified algorithm.[8,10,20-24] Given a good structure-activity relationship for a certain property or a set of properties, two different directions are open for further studies, namely, predictable (or practical) and interpretable (or conceptual) ones.[13] A majority of QSAR (quantitative structure-activity relationship) studies aim the former goal by using as many parameters as possible for attaining accurate predictions.[1,8,9] On the other hand, toward the latter goal, continuing attempts have been undertaken to unveil the physical or microscopic meaning of various magic parameters, the topological indices.[4,7] Thermodynamic properties of saturated hydrocarbons seem to be the best probe for this study, since their isomeric differences seem to be governed mainly by the topological structure of the carbon atom skeleton, and a number of experimental data of good quality are available.[25]

The present authors have shown that the boiling point and entropy of saturated hydrocarbons are correlated fairly well with the Z index and many empirical rules on these properties can be derived by assuming linear relationships between Z and these properties.[7,14-16]

The pioneering works by Wiener[2] and Platt[3] established that almost all the thermodynamic properties can be correlated well with the combination of two different topological indices, *e.g.*, Wiener's path number w and polarity number p or p_3. Randić and Wilkins[13,17] chose another set of parameters, p_2 and p_3, for graph-theoretical ordering of the hydrocarbon isomers to analyze the molecular property correlation, where p_2 is the number of paths of length two, or the so-called Gordon-Scantlebury index, N_2.[18] It is interesting to note that similar two-parameter dependency of thermodynamic properties is observed in a systematic factor analysis by Cramer[12] for a larger group of substances of considerable diversity from helium to anthracene and from alkanes to amides. He claims that his two parameters B and C respectively represent molecular cohesiveness and molecular bulkiness.

What is then the best set of two parameters representing the different topological aspects of branching and cyclization? They should also be as orthogonal as possible to each other, and their physical meaning should be clear or at least interpretable. For this purpose those simple, say, interger topological indices, Z, w, p_2, and p_3, which have been introduced above are desirable. In this paper we have studied the correlation between the twenty four thermodynamic properties of saturated hydrocarbons and the individual and various combinations of these topological indices. The properties studied were found to be well classified into several types depending on the mixing-phase of the correlation coefficients with respect to the two parameters, Z and p_3. Attempts to get the physical interpretation of the two-parameter dependency of these properties are being under way.

I. Topological Indices

Definitions. The carbon atom skeleton of a (saturated) hydrocarbon molecule can be expressed as a non-directed graph G composed of lines (C–C bonds) and N points (C atoms), whose adjacency relation is to be expressed by an $N\times N$ adjacency matrix $\boldsymbol{A}$ with elements $a_{ij}=1$ and 0, respectively, for the bonding and non-bonding ij pairs of points. The distance matrix $\boldsymbol{D}$ is defined as the $N\times N$ matrix with elements d_{ij} as the number of shortest path from point i to j. The half sum of the off-diagonal matrix elements of $\boldsymbol{D}$ is defined as w.[2,7] One half of the number of $d_{ij}=2$ elements in $\boldsymbol{D}$ is defined as p_2 or N_2 (Gordon-Scantlebury index),[18] while that of $d_{ij}=3$ as p_3 or p.[2] The non-adjacent number $p(G,k)$ for G is defined as the number of ways for choosing k disjoint lines from G.[7] The total number of $p(G,k)$ is defined as Z_G (topological index or Z-index).[7] As shown in Fig. 1 we can

a) These numbers are used in Figs. 3—8. b) Platt's nomenclature.[3] c) The definitions of these indices are given in the text.

easily enumerate these topological indices with 2,2,4-trimethylpentane as an example. In Table 1 are tabulated the Z, w, p_2, and p_3 values for all the haxane, heptane, and octane isomers.[26,27]

Correlation among Z, w, p_2, and p_3. In Table 2 the correlation coefficients among the four different topological indices for eighteen octane isomers are given. It is evident that p_3 is the least correlated with other three indices. Among them w has rather large $|\rho|$ value of 0.79 with p_3. They are far from being orthogonal to each other. The index p_2 also has relatively large $|\rho|$ values both with Z and w, and is not a good candidate for an element of an orthogonal pair of indices.

Table 2. Correlation coefficients among the various topological indices for the eighteen octane isomers

	Z	w	p_3	p_2
Z	1			
w	0.761	1		
p_3	−0.257	−0.787	1	
p_2	−0.936	−0.903	0.543	1

On the other hand, the pair of Z and p_3 is found to be the most orthogonal to each other, whereas the $|\rho|$ value for the pair of Z and p_2 is the largest, though negative. As shown in Table 3 correlations among these indices were also calculated for other isomer sets with N=6, 7, and 9, and also for their cumulative sets (given in parentheses). Correlation patterns are found to be all the same for each isomer set.

Some of the above correlation patterns can be explained by the graph-theoretical properties of these indices. By definition w includes both p_2 and p_3 as its components. As seen in Table 2 the $|\rho|$ values among these three parameters are very large and thus one cannot choose any two of them as a good orthogonal pair of indices, although Randić and Wilkins classified the thermodynamic and some other physical properties according to their correlation patterns with respect to p_2 and p_3.[13] The value of p_2 increases by 1 and 2, respectively, for each tertiary and quarternary branching, just in the opposite direction for the case of the components of Z. Namely, p(G,2), an element of Z, decreases by 1 and 3, respectively, for each tertiary and quarternary branching.[7] On the other hand, the values of Z and p_3 forming a good orthogonal pair are derived from different countings, *i.e.*, Z from disjoint line selection and p_3 from distant point-pair selection.

It is to be noted that even for the orthogonal pair of Z and p_3, their correlation coefficients get dramatically large if more than two isomer sets with different carbon numbers are combined as shown in the parentheses in Table 3. Also for the pair of Z and w the correlation coefficient gets as large as 0.94 even in the cumulative set up to octanes. One can expect ρ=1 for the correlation between many different molecular quantities such as heat of formation and just the number of carbon atoms if an infinitely large number of hydrocarbons are taken! It is not necessarily true for the structure-activity correlation study that the larger the better.

Then in the following discussion we will mainly be

Table 3. Correlation coefficients among the various topological indices for hexane to nonane isomers

No. of Carbon	No. of Isomer	$Z-p_3$	$w-p_3$	$Z-w$	p_3-p_2

a) Number of carbon atoms. b) Only this property is correlated with $-Z$. c) A5 is heat of combustion, which has the same correlation coefficients as heat of formation. d) Data are not available for several isomers. e) C4 is specific refraction, which has the same correlation coefficients as molal refraction.

concerned with the correlation between the thermodynamic properties of isomeric hydrocarbons and the two topological indices Z and p ($=p_3$).

II. Structure-Activity Correlation

Thermodynamic Properties. From the American Petroleum Institute (API) Research Project 44[25] twenty four thermodynamic properties were chosen for five hexane, nine heptane, and eighteen octane isomers as listed in Table 4. For some of the selected cases the values of thirty five nonane isomers were also analyzed. The type symbol, such as A or B, is tentatively assigned to each property according to the discussion in the later part of this paper.[28] The correlation coefficients between these quantities and Z and p_3 were calculated as shown in Table 4. For some of the properties the data of a few isomers are missing, but no serious problem arose in comparing and discussing all the correlation coefficients given in Table 4 without further statistical correction.

Classification of Thermodynamic Properties. By looking at the patterns of the numbers in each row of Table 4, one may notice that they can roughly be grouped into four. Namely, the nine type A properties have large (0.7—1.0) positive $\rho(Z)$. However, as for $\rho(p_3)$ some of them have an appreciably large value as large as −0.6 and are assigned as type A', while the rest of them have very small $|\rho(p_3)|$ values. Type B properties have large (0.8—1.0) positive $\rho(p_3)$ values, while type C large (−0.9—−1.0) negative $\rho(p_3)$'s. The $\rho(Z)$ values of both type B and C properties are very small. For other properties in Table 4 , both the $\rho(Z)$ and $\rho(p_3)$ values are medium to small. However, if one looks at these figures more carefully, they may be grouped into two. To make these groupings more clear the ρ values of N=6, 7, and 8 isomers for each property were tentatively averaged with weights of 1, 2, and 4, respectively, to give $\bar{\rho}(Z)$ and $\bar{\rho}(p_3)$ in Table 4. Then

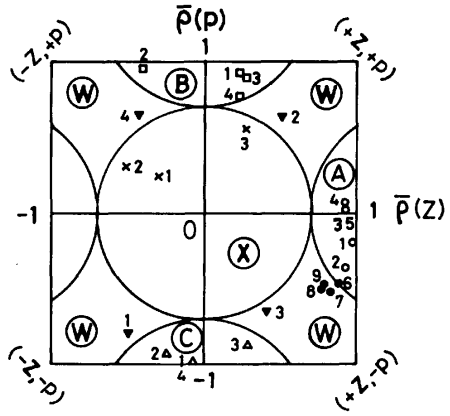

Fig. 2. Plot of $(\bar{\rho}(Z),\bar{\rho}(p_3))$ for the various thermodynamic properties averaged over hexane, heptane, and octane isomers.
○: type A, ●: type A′, □: type B, △: type C, ▼: type W, ×: type X.
The numbers near the points refer to the property numbers given in Table 4, where the $\bar{\rho}(Z)$ and $\bar{\rho}(p_3)$ values are also given.

it was found that for the entries other than types A, B, and C the correlation coefficients of $|\bar{\rho}(Z)|$ and $|\bar{\rho}(p_3)|$ are smaller than 0.5 and 0.8, respectively. Again they are divided into types W and X depending that the $|\rho(p_3)|$ value is larger or smaller than 0.6. Both the $|\rho(Z)|$ and $\rho(p_3)$ values for type X properties are smaller than 0.6.

Next the $\bar{\rho}(Z)$ and $\bar{\rho}(p_3)$ values for the twenty four properties were plotted in the rectangular coordinate plane as in Fig. 2. A pair of $(\bar{\rho}(Z), \bar{\rho}(p_3))$ is then found to be a good index for characterizing the nature of the topological factors on which the specified property depends. Namely, all the five entries of type A (boiling point, entropy, and heats of vaporization, formation, and combustion) fall into the far right arc in Fig. 2, whereas the four entries of type B (density of liquid, critical pressure, refractive index, and pressure coefficient of vaporization) and three of type C (molal refraction, specific refraction, molal volume, and refractivity intercept), are, respectively, encircled in the top and bottom arcs. Notice that by this plot all the four entries of type A′ (cryoscopic constant, heat of fusion, entropies of vaporization and fusion) get close to each other and are clearly distinct from W3 (critical volume). This supports our tentative grouping of the thermodynamic properties. Although the distance between the four A′ entries and A2 (entropy) is rather small, the latter discussion will differentiate them. It is interesting to note that all the four entries of type W (specific dispersion, critical temperature, critical volume, and cirtical density) find their respective places at the four corners showing all the possible different combinations of the modes of $\bar{\rho}(Z)$ and $\bar{\rho}(p_3)$ but are clearly distinct from the three properties of type X (melting point, critical pV/RT, and free energy of formation). It is interesting to note that these four entries are distinctively classified by Randić and Wilkins by the different combinations of the signs of the correlation with p_2 and p_3.[13] Their argument is based on the relative trends of the correlation patterns, while our criterion is based on the quantitative features of the correlation.[29]

Thus we can affirmatively classify the thermodynamic properties of alkanes into the following groups and select their typical entries as follows:

Type A: Heat of vaporization:
large $\rho(Z)$ and small $|\rho(p_3)|$

Type B: Density of liquid:
large $\rho(p_3)$ and small $|\rho(Z)|$

Type C: Molal refraction:
large $-\rho(p_3)$ and small $|\rho(Z)|$

Type W: Specific dispersion:
medium $|\rho(Z)|$ and $|\rho(p_3)|$

Type X: Melting point:
small $|\rho(Z)|$ and $|\rho(p_3)|$

However, there still remains a question if the pair of Z and p_3 parameters are the best combination for this sort of classification. To check this point the correlation coefficients of the above-mentioned five typical properties for the other parameters, w and p_2, were calculated and compared with the results for Z and p_3 in Table 5, where the $|\rho|$ values larger than 0.9 is printed in bold face. From this Table it is difficult to select such a useful pair of indices other than the pair of Z and p_3 that is capable of characterizing each type of properties. No $|\rho|$ value except for that of p_2 for Type A exceeds 0.9 suggesting inappropriateness of parameter p_2 for this purpose.

This conclusion is different from the criterion taken by Randić and Wilkins, who claim the effectiveness of the classification of the physical properties by the combination of p_2 and p_3.[30]

In Table 5 are also given important data for the $\rho(Z)$ and $\rho(p_3)$ values of thirty five nonane isomers, whose features on the ρ values are essentially the same, revealing that our tentative classification would be valid for relatively large saturated hydrocarbons.

Pattern Recognition of Correlation. Having established the classification of the thermodynamic properties into five types, let us see the similarity of the correlation pattern among each type. Figures 3 and 4 give the plots of four of type A properties (A1—A4) of the heptane and octane isomers against Z. The isomers are arranged in the increasing order of Z. The Wiener's path number w is also plotted against Z. While for heptane isomers correlation is fairly good, it gets worse for octane giving zigzag patterns.

It is worthy of notice that the zigzag patterns in the left half region of octanes of boiling point (bp) and heat of formation $(-\Delta H_f)$ in Fig. 4 have an opposite trend to w but coincide with the corresponding patterns of type B plots in Fig. 6, where all the four curves of B1—B4 amazingly run in parallel with p_3 (See

a) Data taken from nine heptane isomers but seven for melting point. b) Data taken from eighteen octane isomers but fourteen for melting point. c) Data taken from thirty five nonane isomers but nineteen for melting point. d) Those figures whose absolute magnitudes exceed 0.9 are underlined.

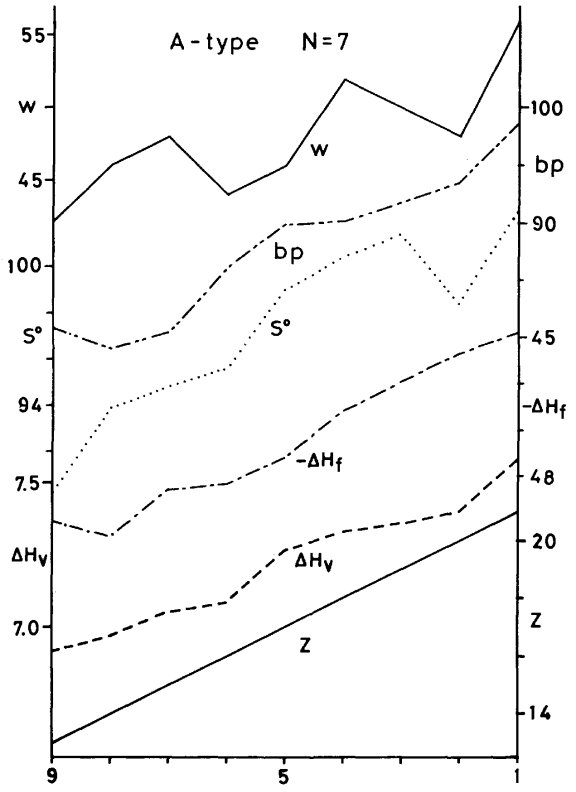

Fig. 3. Thermodynamic properties of heptanes. Type A. The numbers in the abscissa refer to the isomer numbers given in Table 1. The properties and their units are: A1, heat of vaporization (ΔH_v) in kcal·mol^{-1}; A2, entropy ($S°$) in cal·deg^{-1} mol^{-1}; A3, heat of formation ($-\Delta H_f$) in kcal·mol^{-1}; A4, boiling point (bp) in °C. (1 cal$_{th}$=4.184 J)

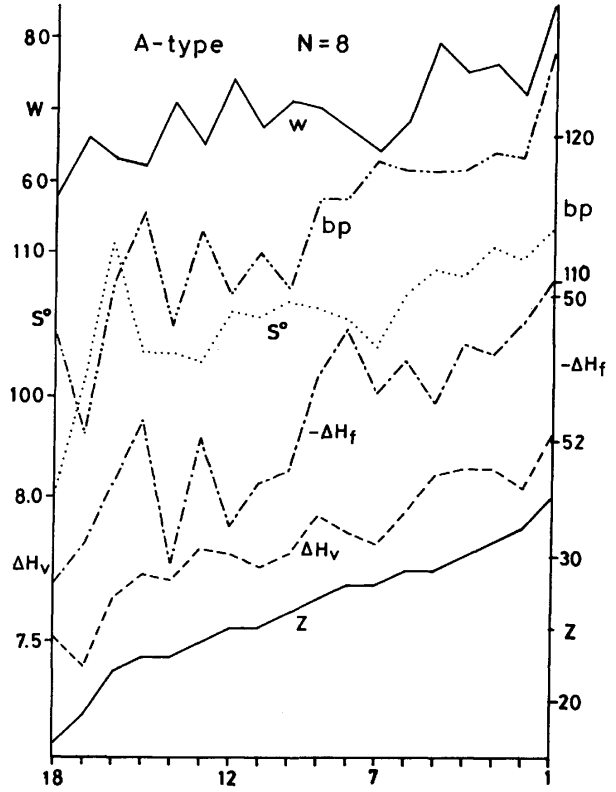

Fig. 4. Thermodynamic properties of octanes. Type A. See the footnotes of Fig. 3.

also Fig. 5 for type B properties of heptanes). Quite similarly type C properties show a good correlation with $1/p$ as demonstrated for C1—C3 in Figs. 7 and 8.

As have been shown in the above discussion the merits of drawing the correlation patterns like Figs. 3—8 lie not only in making certain of the classification of the structure-activity relationship but also in digging out the second variable hidden under the main correlation pattern. Further, if a good set of complementary indices like Z and p_3 are available, another correlation plot as Fig. 2 is found to be powerful for the analysis of structure-activity relationship.

Two-parameter Correlation. As has been inferred above, the p_3 character seems to be mixed in the correlation pattern of the boiling point against Z for octane isomers in Fig. 4. Then correlation coefficients were calculated between the A4 values of octane isomers and various in-phase linear combinations of Z and p_3. The optimum value was obtained to be $\rho(Z+p_3)=0.947$, which is to be compared with $\rho(Z)=0.888$ in Table 4.

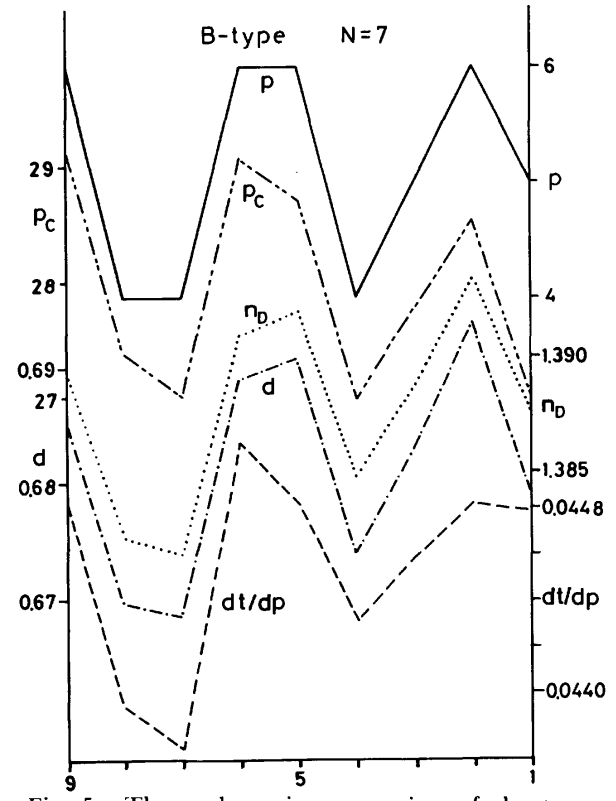

Fig. 5. Thermodynamic properties of heptanes. Type B. The numbers in the abscissa refer to the isomer numbers given in Table 1. The properties and their units are: B1, density of liquid (d^{25}) in g·ml^{-1}; B2, critical pressure (p_c) in atm.; B3, refractivity index (n_D); B4, pressure coefficient of vaporization (dt/dp) in °C·mmHg^{-1}. (1 mmHg= 133.322 Pa)

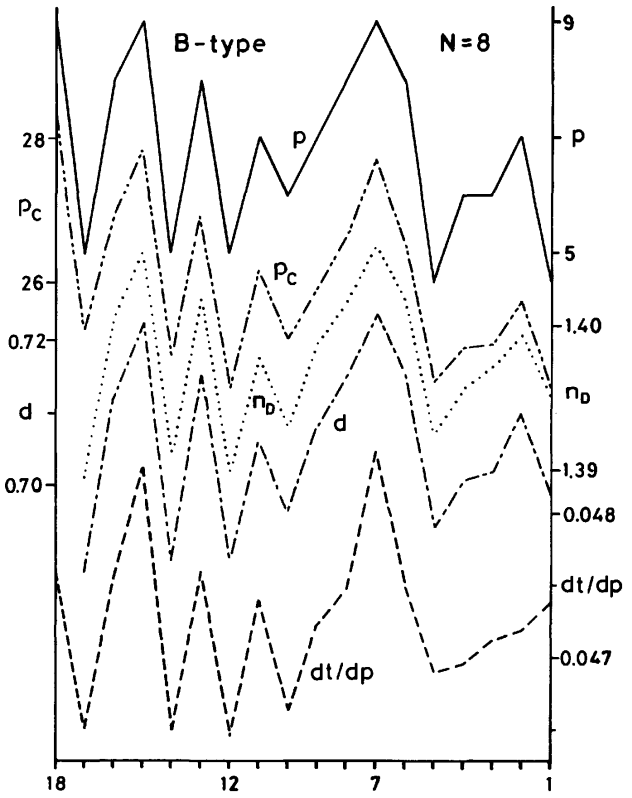

Fig. 6. Thermodynamic properties of octanes. Type B. See the footnotes of Fig. 5.

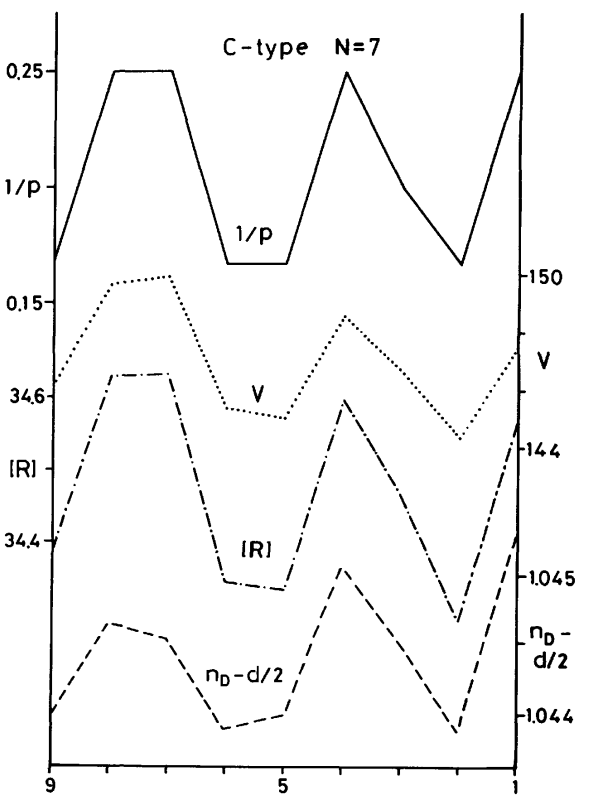

Fig. 7. Thermodynamic properties of heptanes. Type C. The numbers in the abscissa refer to the isomer numbers given in Table 1. The properties and their units are: C1, Molal refraction ([R]) in ml·mol^{-1}; C2, Molal volume (V) in ml·mol^{-1}; C3, Refractivity intercept ($n_D - d/2$).

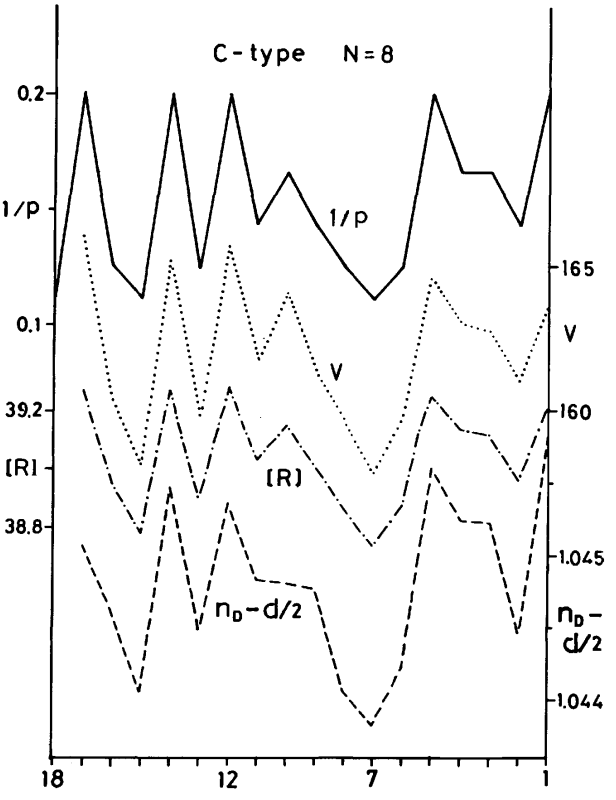

Fig. 8. Thermodynamic properties of octanes. Type C. See the footnotes of Fig. 7.

TABLE 6. EFFECT OF MIXING OF PARAMETERS Z AND p_3 ON THE CORRELATION COEFFICIENTS FOR SEVERAL THERMODYNAMIC PROPERTIES OF OCTANE ISOMERS

Property[a]	ρ (Z)[b]	ρ (p_3)[b]	$(\rho^2(Z)+\rho^2(p_3))^{1/2}$	Best ρ Value	Best ρ Combination

X3	−	+	0.829	0.826	p_3

a) See Table 4. b) Numerical values are given in Table 4.

Similar calculations were performed for the properties of types A', W, and X of octane isomers by varying the relative values of a and b for $\rho(aZ+bp_3)$. The results are given in Table 6, where the values of $|\rho|=(\rho^2(Z)+\rho^2(p_3))^{1/2}$ are also given. This quantity was found to be a good indicator for estimating the magnitude of the optimum value to be obtained with a mixing parameter $aZ+bp_3$. The value of $|\rho|$ itself does not have a definite meaning and thus sometimes may exceed unity. However, within each series of properties of types A, A', W, and X, good parallelism is observed between $|\rho|$ and the optimum $\rho(aZ+bp_3)$ value.

The fact that the four properties of type A' have the same optimum combination of Z and p_3 as $Z-2p_3$ corresponds to the clustering of the points for these properties in the $\rho(Z)-\rho(p_3)$ plot of Fig. 2.[31]

Note also that the signs of a and b giving the optimum value are correctly predicted by the corresponding signs of $\rho(Z)$ and $\rho(p_3)$. This is dramatically shown in the four properties of type W. All these entries are found in the four different quadrants in the $\rho(Z)-\rho(p_3)$ plot of Fig. 2. The above discussions support our tentative assignment of type W and A' properties. Among the four entries in type W, two of them (W1 and W2) achieved fair improvement in the ρ values, while the rest of them (W3 and W4) got only a little improvement. The optimum ρ values for the latter, however, are still larger than those for X1 and X2. If one looks at the data of octane isomers in Table 6, only X3 may be regrouped into type W having fairly large optimum ρ value. However, as evident in Table 4, for property X3, as well as X1, the fluctuation of the $\rho(Z)$ and $\rho(p_3)$ values is very large compared to other properties even to type W properties.

In this study only the optimum ρ value was sought for the mixing parameters of $aZ+bp_3$. Although there is a possibility to get a better result with $aZ+b/p_3$ or other combination of Z and p_3, the analysis has clarified the essential features of the two-parameter topological properties of saturated hydrocarbons.

Interpretation of Topological Factors. Then what do the two-parameter features in the structure-activity relationship mean? Among the four entries in type B properties, density of liquid d (B1) and refractive index n_D (B3) of alkanes are doubtlessly determined by the bulkiness of molecules. The fact that molal refraction $[R]$ (C1) and molal volume V (C2) of type C have large negative correlation with p_3 can also be explained by the bulkiness of molecules, since they are reciprocally related to density, respectively, as $[R]=M(n_D^2-1)/(n_D^2+2)d$ and $V=M/d$, where M is the molar mass. Since the specific refraction is expressed as $(n_D^2-1)/(n_D^2+2)d$, it should have quite the same correlation coefficients as molal refraction, and we did not include its values in Table 4. Refractive intercept $n_D-d/2$ (C3) belongs to type C but its physical meaning is left unclear.

Critical pressure (B2) is expressed as $p_c=a/27b^2$, where a and b are the constants in the van der Waals equation of state.[32] The parameters a and b are interpreted respectively to reflect intermolecular interaction and molecular size. If we assume that a is almost constant among the isomeric hydrocarbons, the critical pressure is inversely proportional to the square of b, or molecular size. Then the higher the density, the smaller the b value, leading to a parallelism between d and p_3. Similarly critical volume V_c (W3) and critical temperature T_c (W2) are related to a and b as $V_c=3b$ and $T_c=8a/27Rb$, leading to negative and positive correlation with p_3, respectively. Of course, critical density d_c (W4) is inversely proportional to V_c. Although T_c, V_c, and d_c belong to type W, the results of Table 6 show that all of them get larger ρ value if small amount of out-of-phase Z character is introduced into $\rho(aZ+bp_3)$. Thus no matter what mechanism is responsible for the good correlation between the path number p_3 and these p-related properties, the parameter p_3 surely can take account of the topological bulkiness factor. One may well call p_3 as the static

topological parameter, while the Z index as the dynamical topological parameter. The reason for the latter naming will be explained as follows.

We have shown in the previous paper[15] that the entropy $S°$ (A2) of alkanes is well correlated with the Z index except for sterically crowded and highly symmetrical molecules. The main factor in the parallelism between Z and $S°$ is due to the fact that the branching of alkanes decreases the Z value and also the freedom of rotation which eventually lowers $S°$.[33-35] Further, through the following relation

$$S° = \int_0^T C_p/T' \, dT'$$

and the Trouton's law, *i. e.*, bp (A4) is proportional to ΔH_v (A1), three of type A properties except heat of formation (A3) can be related to each other. All these properties are determined by the dynamical balance between the vigorous motion of molecules and intermolecular force. This picture is a little different from what the term cohesiveness means. Moreover, as the term molecular cohesiveness proposed by Cramer[12,17] seems to involve molecular packing and bulkiness to some extent, we prefer to say that the Z index takes account of the dynamical topological factor such as the rotational motion of molecules, and we may call Z as the dynamical topological parameter.

Deviation of the boiling point data from the Z-correlation as shown in Fig. 4 can be explained by the onset of stacking or bulkiness effect in the highly branched alkanes. A systematic study has not been done for viscosity, since a good set of data was not available. However, a preliminary study reveals that viscosity surely belongs to type W.

Now it is established that most of the thermodynamic properties, except type X properties as melting point (X1), are linear functions of two orthogonal topological parameters, namely, dynamical Z relating to the rotational degree of freedom and static p_3 governing the bulkiness of molecules. It is then deduced that the form of the linear function of a given property of hydrocarbons reflects how the two topological factors are competing in the molecular level. More detailed study, such as physical modelling and molecular dynamics type simulation calculation, can be proceeded further along the topological understanding obtained in this paper.

29) They actually did not obtain the correlation coefficients but observed the relative tendency of the physical properties against the increase of the parameters concerned.

30) According to Randić and Wilkins our W4 and B2 belong to the same (+,+) group. Their similar character can be shown as the proximity of their points in Fig. 2. This is also the case with the (+,−) group of W1 and C2, and (−,+) group of W2 and A5. This fact suggests the different criteria of the classification of the properties taken by us and by Randić and Wilkins.

31) Actually in Fig. 2, the plot is made for the $\bar{\rho}$ averaged over N=6—8, but as seen in Table 4, the corresponding signs of ρ values within types A′ and W are all the same for different N.

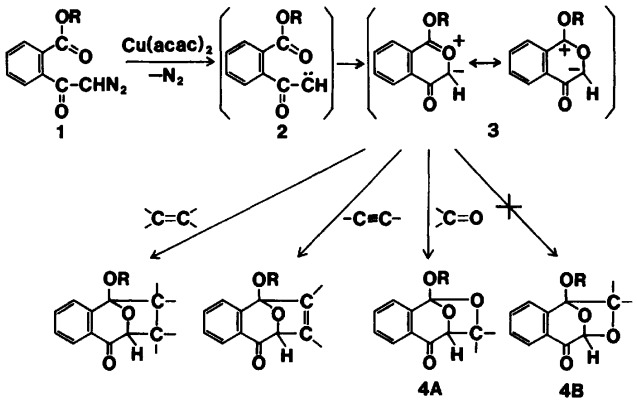
Formation and Reaction of Carbonyl Ylides. 1,3-Dipolar Cycloaddition of 2-Benzopyrylium-4-olates with Carbonyl Compounds

Toshikazu IBATA* and Jiro TOYODA
Institute of Chemistry, College of General Education, Osaka University, Toyonaka 560
(Received January 28, 1985)

Cyclic orthoester type 1,3-dipolar cycloadducts of 1-methoxy-2-benzopyrylium-4-olate with carbonyl compounds were obtained in high yields in the copper(II) acetylacetonate-catalyzed decomposition of *o*-methoxycarbonyl-α-diazoacetophenone in the presence of carbonyl compounds such as substituted benzaldehydes, acetaldehyde, propionaldehyde, isobutyraldehyde, pivalaldehyde, acetone, methyl ethyl ketone, methyl isopropyl ketone, 1,3-dichloroacetone, substituted acetophenones, benzoyl cyanides, cyclopentanone, cyclohexanone, 1-indanone, 9-fluorenone, anthrone, and anthraquinone. However, methyl *t*-butyl ketone, benzophenone, and xthanthone gave no adduct. Aldehydes and asymmetric ketones gave endo- and exo-adducts. The regiochemistry and stereochemistry of the adducts of aldehydes were determined on the basis of their coupling constants of methine protons. The reactions of *p*-methoxyphenyl *o*-diazoacetylbenzoate also gave similar 1,3-dipolar adducts. When carbonyl compounds of medium reactivity were used as a substrate, 2:1-adduct was obtained together with the 1:1-adduct. The formation of the 2:1-adduct was attributed to the competitive reaction of the corrsponding benzopyrylium-4-olate intermediate toward the carbonyl compounds and 1:1-adduct. The regiospecificity of the 1:1-cycloaddition was explained according to the frontier orbitals calculated by STO-3G method.

The initial work of the 1,3-dipolar cycloaddition of carbonyl ylide with carbonyl compounds was reported by Ullman and Milks in the photolysis of 2,3-epoxy-2,3-diphenyl-1-indenone.[1] However, only a few examples of the cycloaddition were reported in the literature.[2] The present authors have found the novel formation of carbonyl ylides of the type of 2-benzopyrylium-4-olate (**3**) by the intramolecular carbene–carbonyl reaction[3] and studied its 1,3-dipolar cycloaddition with acetylenic[4] and ethylenic compounds.[5] As an extension of this 1,3-dipolar cycloaddition, the authors have preliminarily reported the 1,3-dipolar cycloaddition of 1-methoxy-2-benzopyrylium-4-olate (**3a**:R=OCH_3) with benzaldehydes, propionaldehyde, acetophenones and fluorenone.[6] This paper deals with the application of the cycloaddition of (**3**) with various kinds of carbonyl compounds to understand the scope and limitation of the reaction for the synthesis of cyclic orthoesters. The regiochemistry and stereochemistry was also studied.



Results and Discussion

Reactions with Aldehydes. The $Cu(acac)_2$-catalyzed decomposition of *o*-methoxycarbonyl-α-diazoacetophenone (**1a**: R=OCH_3) in the presence of two molar equivalents of aromatic aldehydes gave each pair of isomeric adducts. For example, *p*-chlorobenzaldehyde gave two products of melting points at 135—137°C and 126—128°C. Results of elemental analysis and IR spectra showed that these are the isomeric adducts of **3a** and *p*-chlorobenzaldehyde having the same regiochemistry but different in configuration. The ^1H NMR coupling patterns of two methine protons of both adducts indicate that the cycloadducts have structures of orthoester as shown in formula **4A**. The higher melting product has doublet signals of methine protons at δ 5.08 and 5.53 with coupling constant J=6.0 Hz, which indicates the cis stereochemistry of two methine protons. Therefore, the substituent (**R′**) has *endo*-configuration as shown in formula **5**. The lower melting adduct has doublet siganls of methine protons at δ 4.78 and 4.86 with small coupling constant (J=1.3 Hz), which suggests the *exo*-structure (**6**) with trans configuration of two methine protons. The methine protons on C_5 (**Ha**) and C_6 (**Hb**) of the exo-adduct (**6c**) show its ^1H NMR signals at

a) Singlet signals. b) Signals of aromatic protons were omitted. c) The IR spectrum was not measured. d) The 2:1-adduct was obtained. e) Decomposed during column chromatography. f) J=6.5 Hz. g) J=6.5 Hz. h) δ=1.29 (dq, CH_2, J=6.9 and 7.2 Hz), 0.96 (t, CH_3, J=7.2 Hz). i) δ=1.76 (dq, CH_2, J=7.7 and 7.5 Hz), 1.07 (t, CH_3, J=7.5 Hz). j) δ=1.26 (d sep, CH, J=6.0 and 10.4 Hz), 0.90, 0.96 (d, CH_3, J=6.0 Hz). k) δ=1.95 (d sep, CH, J=6.5 and 10.4 Hz), 0.99, 1.06 (d, CH_3, J=6.5 Hz).

higher field than those of endo-adduct (**5c**). This may be attributed to shielding effect due to aryl (**R′**) and carbonyl groups located *syn* to each methine proton in the exo-adduct.

The assignment of the signals of methine protons (**Ha** and **Hb**) of the adducts (**5c** and **6c**) was determined on the basis of chemical shifts comparing with those of the adducts of aliphatic aldehydes. For example, endo-adduct of acetaldehyde has a doublet signal at δ 4.84 and a double quartet at δ 4.54 which were characterized to **Ha** and **Hb**, respectively. The exo-adduct also shows similar coupling pattern of methine protons (Table 1, Run k). The adducts of propionaldehyde and isobutyraldehyde were also identified similarly. In all of these adducts **Ha** showed a signal at lower field than that of **Hb**. The same tendency was observed in the adducts of aromatic aldehydes, and signals at δ 5.53 and 5.08 of the endo-adduct (**5c**) of *p*-chlorobenzaldehyde were assigned to **Ha** and **Hb**, respectively.

Other substituted benzaldehydes also gave similar results (Table 1, Run a—g). No adduct of the different regiochemistry as is shown by **4B** was obtained despite the detail inspection of the reaction mixture by column chromatography. The electron-attracting substituents on benzaldehyde such as *p*-NO_2 group tend to increase the yields of adducts in comparison with electron-releasing substituents (*p*-CH_3O). This means that the aldehydes with electron-attracting groups have high reactivity in this reaction system. However, these substituents do not show obvious effect on the stereoselectivity of the cycloaddition. Pivalaldehyde gave both endo- (**5n**) and exo-adduct (**6n**) in 11 and 57% respectively, reflecting the bulkyness of *t*-butyl group.

1-Methoxyphenyl *o*-diazoacetylbenzoate (**1b**:R=*p*-$CH_3OC_6H_4$) also gave similar results in the reaction with benzaldehydes. When *p*-anisaldehyde was used as a substrate, a 2:1-adduct (**7h**:R=R′=*p*-$CH_3OC_6H_4$) of **3b** and the aldehyde was obtained together with usual endo- and exo-1:1-adducts in the yields of 25, 35, and 21%, respectively. The 2:1-adduct has two singlet signals of methoxyl group at δ 3.47 (6H) and 3.73 (3H) and two doublets (δ 4.04, 4.65, J=1.5 Hz) and one singlet (δ 5.26) of methine protons besides multiplet signals of aromatic protons. The signals of the methine protons indicate the presence of two adjacent and one isolated methine protons. The coupling pattern of two dou-

a) Signals of aromatic protons were omitted. b) Isomer having phenyl moiety in endo. c) Isomer having phenyl moiety in exo.

blets is quite similar to that of exo-1:1-adduct (**6h**). Therefore, it is suggested that in the 2:1-adduct the *p*-methoxyphenyl group of the aldehyde origin has *exo* configuration, and that the 2:1-adduct is formed by the secondary cycloaddition of **3b** on exo-1:1-adduct (**6h**).

Reaction with Ketones. The decomposition of **1a** in acetone gave a similar adduct (**8a**) in 75% yield together with a 2:1-adduct (**10**: 12%) of **3a** and acetone. The adduct (**8a**) showed two singlet signals in its NMR spectrum at δ 1.55 and 1.11 which corresponded to the signals of the exo- (**6k**:δ 1.50) and endo-adduct (**5k**: δ 1.05) of acetaldehyde. Therefore, signals at δ 1.55 and 1.11 of **8a** were assigned to exo- and endo-methyl groups, respectively. Similar assignment was applied to the characterization of other methyl ketone adducts.

The NMR spectrum of the 2:1-adduct is quite similar to that of **8a** (Table 2). The spectroscopic data of the 2:1-adduct and the behavior of **3a** in the cycloaddition to carbonyl group noted above indicate that the 2:1-adduct is the secondary reaction product obtained by the cycloaddition of **3a** toward the carbonyl group of 1:1-adduct (**8a**), and is indicated by the structural formula **10**. The stereochemistry of the 2:1-adduct is not determined yet. Each of methyl ethyl ketone, methyl isopropyl ketone, substituted acetophenones and substituted benzoyl cyanides gave a pair of adducts different in the stereochemistry at C_6 (Table 2).

However, methyl *t*-butyl ketone and benzophenone did not give any adduct because of their low reactivity attributable to the steric hindrance or aromatic stabi-

lization. Cyclic ketones such as cyclopentanone, cyclohexanone, 1-indanone, 9-fluorenone, anthraquinone, and anthrone gave adducts of type **4A** (Table 3). Except 1-indanone, cyclic ketones gave single adducts because they were symmetric. 1-Indanone afforded two adducts in 1.3 and 6.8% yields which were identified as **Ph**-endo- and **Ph**-exo-adducts respectively on the basis of NMR data. The **Ph**-endo-adduct shows a signal of an aromatic proton of indanone moiety at δ 6.24 which may caused by the shielding effect of benzene ring of **3a** moiety. In the cyclic ketones used, aliphatic ketones were shown to have reactivities higher than those of aromatic ketones such as indanone, anthraquinone, and anthrone which were resonance stabilized. The exception was fluorenone, which gave an adduct in good yield in the reaction with **3a**. The adduct was confirmed to have the same structure with **4A** as the adducts of aldehydes and other ketones described above on the basis of ^{13}C NMR spectrum which showed a signal of nonaromatic quartanary carbon (C_1) at quite low field (δ 119.1). Another type of regioisomer (**4B**) may not give a signal of quarternary carbon in this region.

When the dipolarophilicity of the carbonyl compound was not so high, 2:1-adducts of the benzopyrylium-4-olates (**3**) with the dipolarophiles were also obtained along with 1:1-adducts as described above in the reaction with acetone. The details of the 2:1-adducts will be published elsewhere.

Frontier Orbital Explanation of the Regiospecificity and Reactivity of the Cycloaddition. The stereo-

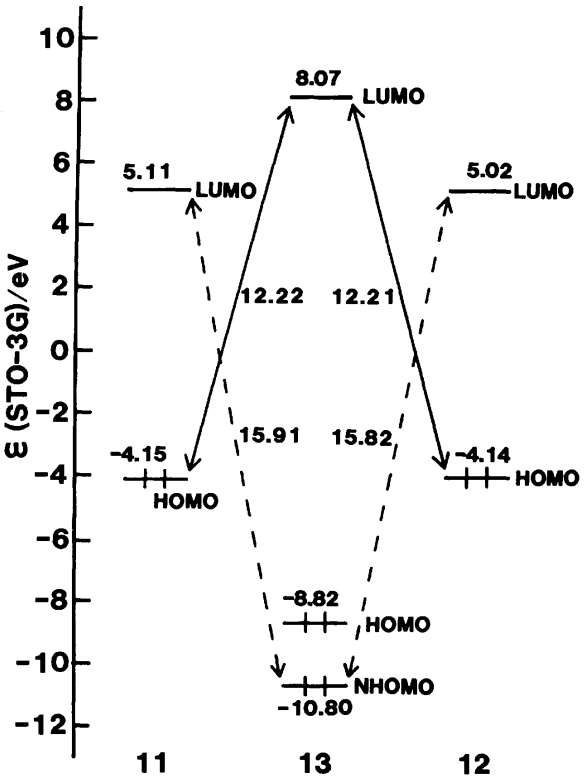

Fig. 1. HOMO and LUMO energy levels of carbonyl ylides (**11**, **12**) and acetone (**13**).

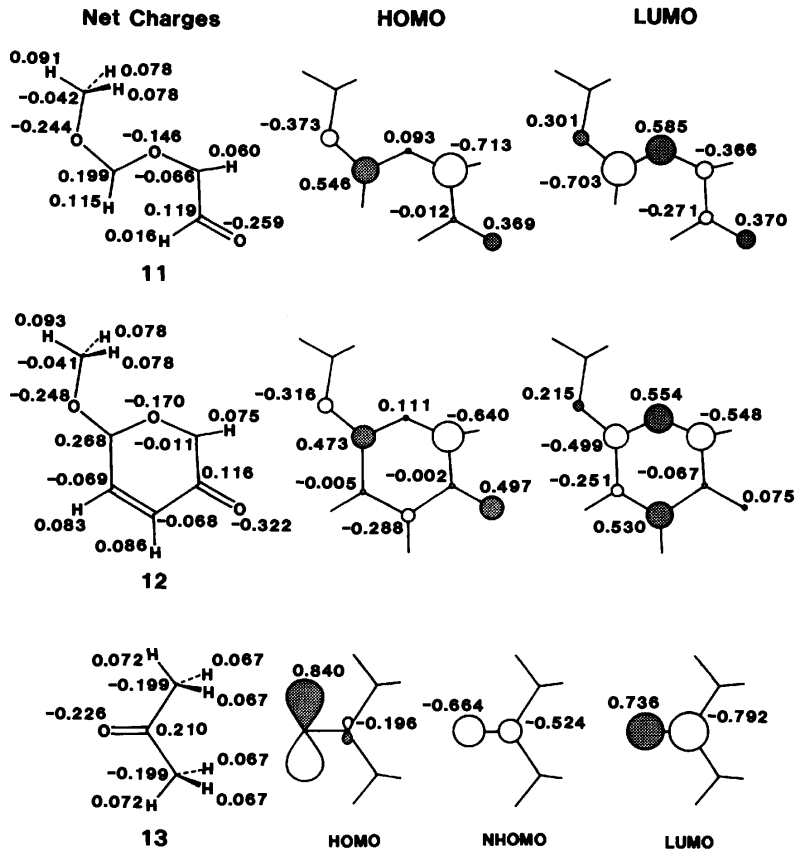

Fig. 2. Orbital coefficients of HOMO and LUMO of carbonyl ylide (**11**, **12**) and acetone (**13**).

specificity observed in the 1,3-dipolar cycloaddition of 2-benzopyrylium-4-olate (**3**) with cis- and trans-ethylenic dipolarophiles indicates that the reaction proceeds in the concerted process.[5] The regioselectivity and reactivity of the 1,3-dipolar cycloaddition has been explained by second-order perturbation expression.[7] Orbital energies and atomic orbital coefficients of carbonyl ylides and acetone were calculated by STO-3G level.[8] Instead of the complex carbonyl ylide like 1-methoxy-2-benzopyrylium-4-olate (**3a**) which has an electron-releasing methoxyl group on a carbonyl ylide carbon and an electron-attracting carbonyl group on another side, we chose 1-methoxy-3-formyl-carbonyl ylide (**11**) and 6-methoxypyrylium-3-olate (**12**) as model compounds. Energy levels of the two model carbonyl ylides (**11** and **12**) calculated are quite similar in their frontier orbitals. Frontier orbital energy levels of **11**, **12**, and acetone indicate that the cycloaddition is controled by the interaction of carbonyl ylide HOMO with carbonyl compound LUMO (Fig. 1).[9]

Atomic orbital coefficients of the frontier orbitals of carbonyl ylides (**11** and **12**) and acetone are shown in Fig. 2. The preferred orientation of the cycloaddition is that in which the atoms having larger terminal atomic coefficients of the interacting frontier orbitals are bonded. Therefore, oxygen atom of carbonyl compound bonded to carbon atom of carbonyl ylide attached by an electron-releasing group (OCH_3), to give an orthoester type adduct (**4A**), because these atoms have larger coefficients in carbonyl compound LUMO and carbonyl ylide HOMO, respectively. Dipole–dipole interaction between the carbonyl ylides, (methoxymethyleneoxonio)formylmethanide (**11**) and 6-methoxypyrylium-3-olate (**12**), and acetone shown in electron-density formula (Fig. 2) also supports the regiospecificity of the cycloaddition cited above.

Strong electron-attracting groups exert considerable

lowering effect on the LUMO of the carbonyl compounds, resulting in a small energy separation between the carbonyl ylide HOMO and carbonyl compound LUMO. This explains the high reactivity of carbonyl compounds having electron-attracting substituents such as *p*-nitroacetophenone, *p*-nitrobenzoyl cyanide and 1,3-dichloroacetone.

Experimental

All melting points were measured on a Yanagimoto Melting Point Apparatus and were not corrected. The IR spectra were taken on a Hitachi Spectrometer, model 260-10 and Perkin Elmer, model 983 in KBr mull. The ^{1}H NMR spectra were recorded on a Varian EM-390 Spectrometer in a $CDCl_3$ solution using TMS as an internal standard; ^{13}C NMR spectra were recorded on a Bruker AM-360. The chemical shifts were described in ppm downfield from TMS.

Materials. *o*-Methoxycarbonyl-α-diazoacetophenone (**1a**) was prepared by the procedure described in the previous paper.[4,5] *p*-Methoxyphenyl *o*-diazoacetylbenzoate (**1b**) was synthesized in 84% yield by the reaction of excess diazomethane with corresponding acid chloride: mp 67.5—68.8°C; IR (KBr) 3080 (CH), 2100 (diazo), 1730 (ester C=O), and 1610 cm^{-1} (diazoketone C=O); NMR ($CDCl_3$) δ=3.79 (s, OCH_3), 5.60 (s, CH), 6.88, 7.14 (ABq, arom), and 7.52—7.95 (m, arom). Found. C, 64.83; H, 4.07; N, 9.42%. Calcd for $C_{16}H_{12}O_4N_2$: C, 64.86; H, 4.08; N, 9.45%.

Aldehydes and ketones used were purified just before use by distillation or recrystallization of the commercial reagents.

General Procedure of the Decomposition of 1 in the Presence of Carbonyl Compounds. The Cu(acac)$_2$-catalyzed decomposition of **1** was carried out according to the procedure described in the previous paper:[4,5] a benzene solution of **1** was added drop by drop into a benzene solution of 2—10 molar equivalents of carbonyl compounds and catalytic amount of Cu(acac)$_2$ under reflux of benzene at 80°C. The reaction mixture was heated until no more N_2 was evolved (about one hour) and then separated by silica-gel column chromatography using benzene as the eluent.

The 2:1-adduct (**7h**) between **3b** and *p*-anisaldehyde: mp 245.5—247.0°C; IR (KBr) 1711 cm^{-1} (C=O); NMR ($CDCl_3$) δ=3.47 (s, OCH_3), 3.73 (s, OCH_3), 4.04 (d, CH, *J*=1.5 Hz), 4.65 (d, CH, *J*=1.5 Hz), 5.25 (s, CH), and 6.20—8.00 (m, 16H, Ar). Found: C, 71.85; H, 4.88%. Calcd for $C_{40}H_{32}O_{10}$: C, 71.42; H, 4.79%.

The 2:1-adduct (**10**) between **3a** and acetone: mp 184.2—185.0°C; IR(KBr) 1714 cm^{-1} (C=O); NMR ($CDCl_3$) δ=1.26 (s, CH_3), 1.51 (s, CH_3), 3.63 (s, OCH_3), 3.71 (s, OCH_3), 4.38 (s, CH), 5.26 (s, CH), and 6.19 (d, 1H, arom, *J*=8.1 Hz), 6.80—7.93 (m, 7H, arom). Found: C, 67.71; H, 5.47%. Calcd for $C_{23}H_{22}O_7$: C, 67.31; H, 5.40%.

The authors express their sincere thanks to Dr. Masami Sawada and Mr. Yoshio Takai of ISIR of Osaka University for measurements of ^{13}C NMR spectra and helpful discussions on the structural investigation of the adducts, and to Dr. Kizashi Yamaguchi of Faculty of Engineering Science, Osaka University for the MO calculations and fruitful discussions.

New Quassinoid Glucosides, Picrasinoside-A, -B, -C, -D, -E, -F, and -G and New Hemiacetals, Picrasinol-A and -B, from the Stem Bark of *Picrasma ailanthoides* PLANCHON[1)]

Masayoshi Okano,* Tomoyuki Fujita, Narihiko Fukamiya, and Takaaki Aratani
Interdisciplinary Studies of Natural Environment, Faculty of Integrated Arts and Sciences, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received January 31, 1985)

New quassinoid glucosides, picrasinoside-A, -B, -C, -D, -E, -F, and -G and new quassinoid hemiacetals, picrasinol-A and -B, were isolated from the stem bark of *Picrasma ailanthoides* PLANCHON, and their structures were established by spectral analyses and chemical transformations.

Since bruceantin[2)] isolated from the Ethiopian *Brucea antidysenterica* has been shown to have antitumor activity,[3)] quassinoids[4,5)] have been noted for their biological activity.[6–8)] Quassinoids of the Japanese *Picrasma ailanthoides* PLANCHON (=*P. quassioides BENNETT*) have been investigated in detail by Murae *et al.*[9–14)] and Hikino *et al.*[15)] and more than twenty quassinoides have been obtained. However, very few reports for quassinoid glycosides[16–18)] have been found. We were interested in quassinoid glycosides of *P. ailanthoides* and tried to isolate the glycosides from the stem bark of the plant. We wish to report on the isolation and structures of seven new quassinoid glycosides and two new quassinoid hemiacetals.

The half-dried stem bark of *P. ailanthoides* was continuously extracted with methanol and the extract was defatted by partition between hexane and water containing small amounts of methanol. The aqueous layer was further extracted with chloroform. The organic layer was evaporated to give a residue which was subjected to separation by silica-gel column chromatography, thin-layer chromatography (TLC), and high-performance liquid chromatography (HPLC) to afford seven new quassinoid glucosides, picrasinoside-A (**1**, 0.0024%), -B [**5**, 0.0042%), -C (**6**, 0.0062%), -D (**7**, 0.0011%), -E (**8**, 0.0022%), -F (**9**, 0.0006%), and -G (**10**, 0.0009%) and two new quassinoid hemiacetals, picrasinol-A (**11**, 0.032%) and -B (**12**, 0.029%), together with a known neoquassin (0.026%).[10)] Structures of new compounds and their derivatives are shown in Fig. 1. Physical (mp and specific rotation) and spectral (UV and IR) data of new compounds are shown in Table 1 and the ^{1}H NMR spectra of these compounds and their derivatives are shown in Table 2.

Picrasinoside-A (**1**) takes the form of colorless plates and has a bitter taste. A spectral examination (Tables 1 and 2) showed the presence of hydroxyl (IR 3350 cm^{-1}), lactone (IR 1735 (sh) and 1230 cm^{-1}), ketone (IR 1720 cm^{-1}), α,β-unsaturated ketone (IR 1680 cm^{-1}; UV 252 nm), a proton at the lactone terminus (^{1}H

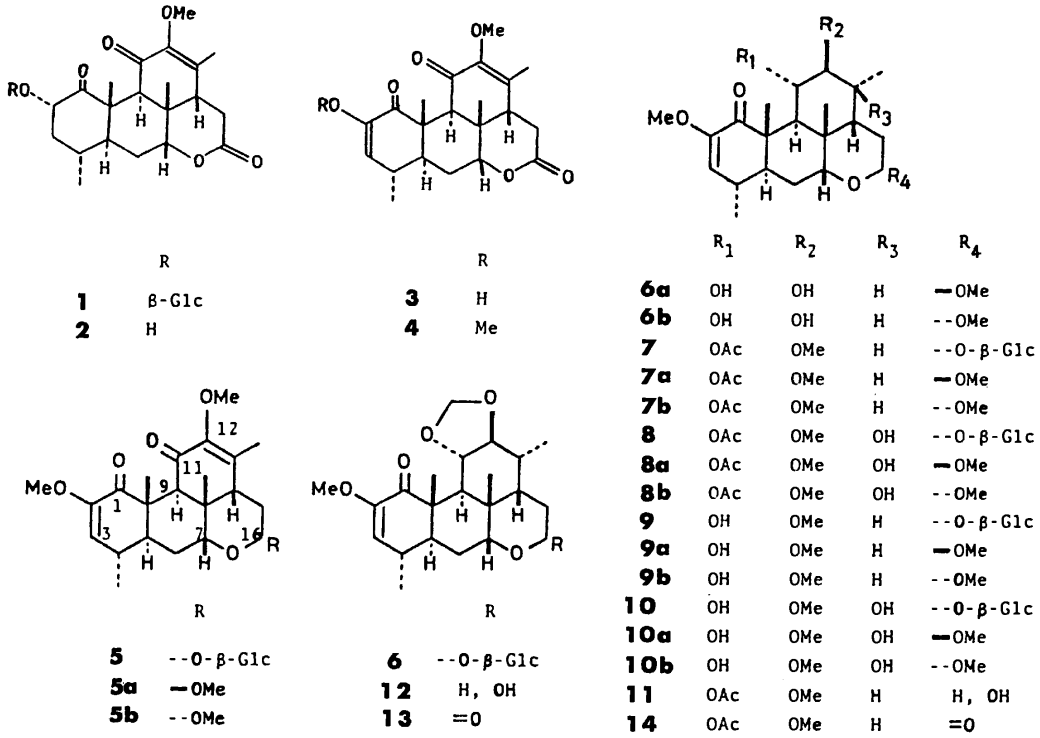

Fig. 1. Structures of quassinoid glucosides, hemiacetals, and their derivatives.

a) Not assigned. b) Signals due to the other isomer at C-16. c) Half width in Hz.

NMR δ 4.27, m), an anomeric proton at the glucose moiety (^{1}H NMR δ 4.6, m) two tertiary methyl groups, a secondary methyl group, and a methoxyl group (^{1}H NMR δ 1.15, s, δ 1.15, s, δ 0.91, d, and δ 3.61, s,

respectively). The FD mass spectrum of **1** ($C_{27}H_{38}O_{11}$, MW 538) showed a molecular ion at *m/z* 538 and a pseudo molecular ion at *m/z* 551 (M^++Na).

An acid hydrolysis of picrasinoside-A (**1**) gave picrasin B[15] (**2**,=nigakilactone I)[10] which was further converted to dehydropicrasin B (**3**)[15] and finally to quassin (**4**).[9] The sugar moiety was identified as D-glucose by a gas-chromatographic comparison of trimethylsilyl derivatives of the hydrolyzed product and authentic D-glucose. An enzyme hydrolysis of picrasinoside-A (**1**) using β-glucosidase also gave picrasin B (**2**) and D-glucose. From the above results, picrasinoside-A (**1**) was confirmed as 2α-*O*-β-glucopyranosylpicrasin B (=2α-*O*-β-glucopyranosylnigakilactone I).

Picrasinoside-B (**5**) takes also the form of colorless plates and has a bitter taste. The spectral data (Tables 1 and 2) showed the presence of hydroxyl (IR 3400 cm^{-1}), α,β-unsaturated ketones (IR 1690 and 1675 (sh) cm^{-1}; UV 255 nm), a proton at the hemiacetal terminus (^1H NMR δ 3.82, m), a proton at C-3 (^1H NMR δ 5.31, d), a proton at C-16 (^1H NMR δ 4.83, dd), an anomeric proton at the glucose moiety (^1H NMR δ 4.65, d), three tertiary methyl groups, a secondary methyl group, and two methoxyl groups (^1H NMR δ 1.06, s, δ 1.52, s, δ 1.85, s, δ 1.09, d, δ 3.56, s, and δ 3.63, s, respectively). The FAB mass spectrum of picrasinoside-B (**5**, $C_{18}H_{40}O_{11}$, MW 522) showed the pseudo molecular ion to be *m/z* 553 (M^++1).

An acid hydrolysis of picrasinoside-B (**5**) in methanol gave two compounds (**5a** and **5b**) and each compound (11:5) was isolated as a colorless amorphous powder by HPLC. Both compounds were characterized by the molecular formula $C_{23}H_{32}O_6$ (mass), a disappearance of the hydroxyl group (IR), and an appearance of a methoxyl group to the original compound (^1H NMR). These facts suggest that they are methanolysis products of picrasinoside-B (**5**). They were also obtained by heating neoquassin and methanol using sulfuric acid as a catalyst. ^1H NMR spectra reveal that the compound **5a** is 16β-*O*-methylneoquassin from an 16α-proton signal at δ 4.78 (dd, *J*=3,3) and the compound **5b** is 16α-*O*-methylneoquassin from an 16β-proton signal at δ 4.36 (dd, *J*=2.5, 9). Thus, picrasinoside-B (**5**) is confirmed as 16α-*O*-β-glucopyranosylneoquassin from an 16β-proton signal at δ 4.83 (dd, *J*=2.5, 6) and an 1′α-proton signal at δ 4.65 (d, *J*=7).

Picrasinol-B (**12**) forms as colorless needles and has a bitter taste. The spectral data showed the presence of hydroxyl (IR 3450 cm^{-1}), methylenedioxy (IR 2740 cm^{-1}; ^1H NMR δ 4.97, d and δ 5.15, d), α,β-unsaturated ketone IR 1710 cm^{-1}; UV 262 nm), a proton at the hemiacetal terminus (^1H NMR δ 3.94, m), a proton at C-3 (^1H NMR δ 5.21, d), a proton at C-16 (^1H NMR δ 4.69, bm and/or δ 5.35, m, tautomers), two tertiary methyl groups, two secondary methyl groups, and a methoxyl group (^1H NMR δ 1.14, s and/or δ 1.20, s, δ 1.38, s, δ 1.07, d and/or δ 1.04, d, δ 1.08, d and δ 3.55, s, respectively). The high-mass spectrum of **12** (M^+, *m/z* 392.21926) revealed the molecular to be $C_{22}H_{32}O_6$.

Picrasinol-B showed two peaks in HPLC and GC and it was positive against the silver mirror test. When each compound was isolated using a preparative HPLC and subjected to analytical HPLC, each sample showed the same chromatogram as the original one. This phenomenon shows that they are tautomers of hemiacetal. The reducing power of this substance depends upon the aldehyde as an intermediate. A Jones oxidation[19] of picrasinol-B (**12**) gave picrasin D (**13**)[15] as a colorless amorphous powder. From these results, the structure of picrasinol-B (**12**) was confirmed as shown in Fig. 1.

Picrasinoside-C (**6**) takes the form of colorless plates and exhibits a bitter taste. The spectral data indicated the presence of hydroxyl (IR 3400 cm^{-1}), a methylenedioxy group (IR 2740 (sh) cm^{-1}; ^1H NMR δ 4.96, d, and δ 5.13, d), an α,β-unsaturated ketone (IR 1700 cm^{-1}; UV 261 nm), a proton at the hemiacetal terminus (^1H NMR δ 3.82, m) a proton at C-3 (^1H NMR δ 5.24, d, a proton at C-16 (^1H NMR δ 4.73, dd), an anomeric proton at the glucose moiety (^1H NMR δ 4.61, d), two tertiary methyl groups, two secondary methyl groups, and a methoxyl group (^1H NMR δ 1.15, s, δ 1.38, s, δ 1.10, d, δ 1.12, d, δ 3.54, s, respectively). The FAB mass showed pseudo molecular ion at *m/z* 555 (M^++1).

An acid hydrolysis of picrasinoside-C (**6**) also gave two compounds (**6a** and **6b**); each compound (74:26) was isolated as a colorless amorphous powder by preparative HPLC. Both compounds were characterized by the molecular formula $C_{22}H_{34}O_6$ (mass), a disappearance of a methylenedioxy group (IR and ^1H NMR), and the appearance of a methoxyl group (^1H NMR). The disappearance of the methylenedioxy group depends upon the heating in sulfuric acid. Since picrasinol-B (**12**) and picrasin D (**13**)[15] also lost their methylenedioxy groups upon heating at 60 °C in dilute sulfuric acid to give nigakihemiacetal C[10] and nigakilactone A,[9] respectively. Hydrolyzed products (**6a** and **6b**) were obtained by heating picrasin B (**12**) in a mixture of dilute sulfuric acid and methanol at 60 °C. From these chemical transformations and chemical shifts at C-16, the hydrolyzed products (**6a** and **6b**) were revealed to be 16β-*O*-methylnigakihemiacetal C (=nigakihemiacetal F)[14] and 16α-*O*-methylnigakihemiacetal C, respectively. The sugar moiety was identified as D-glucose by a gas-chromatographic comparison of the trimethylsilyl derivative of the hydrolyzed product and authentic D-glucose. Thus, picrasinoside-C (**6**) was confirmed as 16α-*O*-β-glucopyranosylpicrasinol-B from an 16β-proton signal at δ 4.73 (dd, *J*=2.5, 5), an 1′α-proton signal at δ 4.61 (d, *J*=7), and the above results. Furthermore, an acid hydrolysis of picrasinoside-C in ethanol and 1-butanol gave, respectively, ethanolysis products and butanolysis products. The ^{13}C NMR spectrum of picrasinoside-C[20] also supports the structure as shown in Fig. 1.

Picrasinol-A (**11**) is a colorless amorphous powder and has a bitter taste. The spectral data showed the presence of hydroxyl (IR 3450 cm^{-1}), acetoxyl (IR 1730 and 1245 cm^{-1}; ^1H NMR δ 1.94, s), α,β-unsaturated ketone IR 1710 cm^{-1}; UV 261 nm), a proton at the hemiacetal terminus (^1H NMR δ 3.86, m), a proton at C-3 (^1H NMR δ 5.10, d), a proton at tertiary methyl groups, two secondary methyl groups, and two methoxyl groups (^1H NMR δ 1.14, s and/or δ 1.18, s, δ 1.21, s, δ 0.99, d, δ 1.06, d, δ 3.40, s, and δ 3.54, s, respectively. Picrasinol-A (**11**) showed the same behavior in the HPLC and silver-mirror test as those of picrasinol-B. A Jones oxidation[19] of picrasinol-A (**11**) gave nigakilactone-C (**14**)[9] as a colorless amorphous powder. From the above results, the structure of picrasinol-A (**11**) was confirmed as shown in Fig. 1.

Picrasinoside-D (**7**) takes the form of colorless plates and exhibits bitter taste. The spectral data reveal the presence of hydroxyl (IR 3400 cm^{-1}), acetoxyl (IR 1735 and 1245 cm^{-1}; ^1H NMR δ 1.94, s), α,β-unsaturated ketone (IR 1705 cm^{-1}; UV 262 nm), a proton at the hemiacetal terminus (^1H NMR δ 3.85, m), a proton at C-3 (^1H NMR δ 5.12, d), a proton at C-16 (^1H NMR δ 4.73, bm), an anomeric proton at the glucose moiety (^1H NMR δ 4.60, d), two tertiary methyl groups, two secondary methyl groups, and two methoxyl groups (^1H NMR δ 1.15, s, δ 1.23, s, δ 0.99, d, δ 1.06, d, δ 3.39, s, and δ 3.54, s, respectively). The spectral data was similar to that of picrasinol-A (**11**). The FD mass spectrum of picrasinoside-D (**7**) showed the molecular ion ($C_{30}H_{46}O_{12}$) at m/z 598.

An acid hydrolysis of picrasinoside-D (**7**) gave two compounds (**7a** and **7b**); each compound (8:3) was isolated as a colorless amorphous powder using a preparative HPLC. The two compounds (**7a** and **7b**) were also obtained by heating a mixture of picrasinol-A (**11**) and methanol using sulfuric acid as a catalyst. Therefore, they are considered as acetals of picrasinol-A (**11**). 16β-*O*-methyl derivatives (**5a** and **6a**) showed larger molecular ion intensity (90 and 54%) than that (21% and 26%) of 16α-isomers (**5a** and **6b**). Therefore, the products **7a** and **7b** should be 16β-*O*-methyl picrasinol-A (M^+, 1.9%) and 16α-*O*-methylpicrasinol-A (M^+, 0.8%), respectively. The sugar moiety was identified as D-glucose by the same method mentioned before. Picrasinoside-D (**7**) is thus confirmed as 16α-*O*-β-glucopyranosylpicrasinol-A from the above results and ^1H NMR signals of 16β-proton at δ 4.73 (half width 12 Hz) and 1′α-proton at δ 4.60 (d, J=7).

Picrasinoside-E (**8**) takes the form of colorless plates and has a bitter taste. The spectral data showed the presence of hydroxyl (IR 3400 cm^{-1}), acetoxyl (IR 1730 and 1250 cm^{-1}; ^1H NMR δ 1.96, s), an α,β-unsaturated ketone (IR 1705 cm^{-1}; UV 262 nm), a proton at the hemiacetal terminus (^1H NMR δ 3.87, m), a proton at C-3 (^1H NMR δ 5.13, d), a proton at C-16 (^1H NMR δ 4.72, bm), an anomeric proton at the glucose moiety (^1H NMR δ 4.60, d), three tertiary methyl groups, a secondary methyl group, and two methoxyl groups (^1H NMR δ 1.21, s, δ 1.23, s, δ 1.39, s, δ 1.07, d, δ 3.50, s, and δ 3.56, s, respectively). The spectral data were similar to that of nigakihemiacetal D.[12] The FD mass spectrum of picrasinoside-E (**8**, $C_{30}H_{46}O_{13}$, MW 614) showed the molecular ion at m/z 614.

An acid hydrolysis of picrasinoside-E (**8**) also gave two compounds (**8a** and **8b**); each compound (2:1) was isolated as a colorless amorphous powder using a preparative HPLC. Their mass spectra suggested that **8a** and **8b** are 16β-*O*-methylnigakihemiacetal D (M^+, 3.2%) and 16α-*O*-methylnigakihemiacetal D (M^+, 2.9%), respectively. **8a** and **8b** were converted into nigakihemiacetal D[12] by acid hydrolysis, which was identified by comparing its IR and MS spectra with those of the authentic one. The sugar moiety was identified as D-glucose in the same manner as described before. Picrasinoside-E (**8**) is, thus, confirmed as 16α-*O*-β-glucopyranosylnigakihemiacetal D from the above results and ^1H NMR signals of an 16β-proton at δ 4.72 (half width 12 Hz) and an 1′α-proton at δ 4.60 (d, J=8).

Picrasinoside-F (**9**) is also in the form of colorless plates and has a bitter taste. The spectral data showed the presence of hydroxyl (IR 3400 cm^{-1}), an α,β-unsaturated ketone (IR 1670 cm^{-1}; UV 271 nm), a proton at the hemiacetal terminus (^1H NMR δ 3.83, m), a proton at C-3 (^1H NMR δ 5.43, d), a proton at C-16 (^1H NMR δ 4.71, dd), an anomeric proton at the glucose moiety (^1H NMR δ 4.60, d), two tertiary methyl groups, two secondary methyl groups, and two methoxyl groups (^1H NMR δ 1.10, s, δ 1.42, s, δ 0.98, d, δ 1.10, d, δ 3.57, s, and δ 3.58, s, respectively). The FD mass spectrum of picrasinoside-F (**9**, $C_{28}H_{44}O_{11}$, MW 556) showed the molecular ion at m/z 556.

An acid hydrolysis of picrasinoside-F (**9**) gave two compounds (**9a** and **9b**); each one (7:3) was isolated as a colorless amorphous powder using a preparative HPLC. They were also obtained by deacetylation (alkaline hydrolysis) from **7a** and **7b**. Therefore, **9a** and **9b** should be 11-deacetoxyl-16β-*O*-methylpicrasinol-A and 11-deacetoxyl-16α-*O*-methylpicrasinol-A, respectively. The sugar moiety was identified as D-glucose in the same manner as described above. Thus, picrasinoside-F (**9**) is confirmed as 11-deacetyl-16α-*O*-β-glucopyranosylpicrasinol-A from the above results and ^1H NMR signals of an 16β-proton at δ 4.71 (dd, J=2.5, 6) and an 1′α-proton at δ 4.60 (d, J=7).

Picrasinoside-G (**10**) also takes the form of colorless plates and has a bitter taste. The spectral data showed the presence of hydroxyl (IR 3400 cm^{-1}), an α,β-unsaturated ketone (IR 1670 cm^{-1}; UV 271 nm), a proton at the hemiacetal terminus (^1H NMR δ 3.83, m), a proton at C-3 (^1H NMR δ 5.42, d), a proton at C-16 (^1H NMR δ 4.71, bm), an anomeric proton at the glucose moiety (^1H NMR δ 4.60, d), three tertiary methyl groups, a secondary methyl group, and two methoxyl groups (^1H NMR δ 1.19, s, δ 1.34, s, δ 1.44, s, δ 1.11, d,

δ 3.58, s, and δ 3.67, s, respectively). The spectral data was similar to that of nigakihemiacetal A.[10] The FD mass spectrum of picrasinoside-G (**10**, $C_{28}H_{44}O_{12}$, MW 572) showed the pseudo molecular ion at *m/z* 573 (M^++1).

An acid hydrolysis of picrasinoside-G (**10**) also gave two compounds (**10a** and **10b**) and each one (7:3) was isolated as a colorless amorphous powder using a preparative HPLC. They were also obtained by the deacetylation (alkaline hydrolysis) of **8a** and **8b**. Therefore, **10a** and **10b** were confirmed as 16β-*O*-methylnigakihemiacetal A and 16α-*O*-methylnigakihemiacetal A, respectively. This fact was supported by their mass spectra. The sugar moiety was identified as D-glucose by the same method as mentioned above. Thus, picrasinoside-G (**10**) is confirmed as 16α-*O*-β-glucopyranosylnigakihemiacetal A from the above results and the ^{1}H NMR signals of an 16β-proton at δ 4.71 (half width 12 Hz) and an 1′α-proton at δ 4.60 (d, J=7).

Thus, seven quassinoid glucosides, picrasinoside-A (**1**), -B (**5**), -C (**6**), -D (**7**), -E (**8**), -F (**9**), and -G (**10**) and two quassinoid hemiacetals, picrasinol-A (**11**) and -B (**12**) were newly isolated from the stem bark of *P. ailanthoides*, although Murae *et al.*[9-14] and Hikino *et al.*[15] had obtained eighteen quassinoids with a lactone moiety and six quassinoid hemiacetals from the stem of the plant. Among them, picrasinoside-A (**1**) and -B (**5**) were subjected to testing regarding the mean survival time (T/C%) in mice suffering from P 388 lymphocytic leukemia (test system: 3PS31); both compounds were inactive.[21] Cytotoxic and antileukemic activities in P 388 screen *in vitro* were also tested for picrasinoside-A (**1**), picrasin B (**2**), picrasinoside -B (**5**), and related compounds. The results will be reported elsewhere.[22]

Experimental

General Procedure. Melting points were determined on a MRK air-bath-type melting-point apparatus and were uncorrected. Specific rotations were obtained on a Yanagimoto OR-50 polarimeter (l=0.5 dm). Infrared (IR) and ultraviolet (UV) spectra were recorded, respectively, on a Hitachi 215 grating IR spectrometer and a Shimadzu 200-S UV spectrometer. Proton nuclear magnetic resonance (^{1}H NMR) spectra were determined on JEOL JNM-MH-60 II (60 MHz) and Hitachi R-22 (90 MHz) NMR spectrometers using tetramethylsilane as an internal standard in chloroform-*d* or pyridine-d_5. Chemical shifts and coupling constants were, respectively, shown in ppm and Hz. Mass spectra were determined on JEOL JMS-D100 (EI) and JEOL JMS-DX300 (EI and FD) instruments. Gas chromatography (GC) was performed on a Shimadzu GC-mini II gas chromatograph (2% OV-1). High-performance liquid chromatography (HPLC) was performed on a Waters ALC/GPC 206 liquid chromatograph using Radial PAK C_{18} and CN columns, and 441 UV and R401 RI detectors. Silica-gel (Merck, type 60), precoated silica-gel plates (Merck, 60 F-254, 0.25 mm), and silica gel (Merck, 60 HF-254+366) were used, respectively, for column chromatography, thin-layer chromatography (TLC), and the preparation of preparative TLC plates. The detection of components was accomplished either by the use of a UV lamp or by spraying 10% sulfuric acid solution, follwed by heating.

Plant Material and Extraction. Half-dried stem bark (3.1 kg) of *P. ailanthoides*, collected at Iwate prefecture in June of 1982, was extracted 3 times with methanol (30 l) at room temperature for 3 d. The methanol solutions were combined and the solvent was removed by evaporation until precipitates were found. The concentrated suspension was defatted with hexane (500 ml×5 times) and then extracted with chloroform (500 ml×5 times). The chloroform solutions were combined and concentrated to give a residue (40.5 g).

Separation. The residue (40.5 g) obtained by the chloroform extraction was subjected to column chromatographic separation (silica gel 1.7 kg), and eluted with chloroform–methanol (35:1, v/v, 17 l and then 8:1, v/v, 21 l); 27 fractions were collected. Each fraction was checked by TLC using two mixed solvents, ethyl acetate–ether (1:1, v/v) and chloroform–methanol–water (50:14:3, v/v, lower layer) to look for quassinoids and their glycosides which show UV absorption. As a result, fractions 19 (1.28 g) and 20 (1.14 g) were assumed to contain quassinoid glycosides, and fraction 7 (2.49 g) was considered to include their aglycons.

Isolation of Quassinoid Glycosides. Preparative TLC of fractions 19 and 20 using a mixed solvent of chloroform–methanol–water (50:14:3, v/v, lower layer) gave pale-yellow amorphous substances (715 and 642 mg, respectively), which showed strong UV absorption. The former (715 mg) showed three peaks with a shoulder in HPLC using Radial PAK C_{18} and a mixed solvent of water–methanol (3:2, v/v) and were subjected to preparative HPLC to afford picrasinoside-A (**1**, 74 mg), picrasinoside-G (**10**, 28 mg), picrasinoside-E (**8**, 68 mg), and picrasinoside-B (**5**, 111 mg), respectively. The latter (642 mg) showed four peaks with a shoulder in HPLC using Radial PAK C_{18} and a mixed solvent of water–methanol (11:9 v/v) and were subjected to preparative HPLC to give picrasinoside-F (**9**, 19 mg), picrasinoside-B (**5**, 19 mg), picrasinoside-D (**7**, 34 mg), and picrasinoside-C (**6**, 192 mg).

Acid Hydrolysis of Glycosides. Each glycoside (10—20 mg) was dissolved in methanol (4 ml) and then 1.5 M† sulfuric acid (2 ml) was added to the solution. The mixture was stirred at 60 °C (80 °C in case of picrasinoside-A) and the termination of hydrolysis was checked by TLC. After cooling, water (5 ml) was added to the reaction mixture, and the product (aglycon) was extracted with chloroform (5 ml×3 times). The extract was subjected to HPLC (radial PAK C_{18} or CN) to give pure aglycon. The water layer was neutralyzed with anion-exchange resins (Amberlite IRA-410), evaporated, and dried on P_2O_5 in a desiccator to give a residue (sugar). The residue was treated with 1-(trimethylsilyl)-imidazole at 90 °C for 1 h and then water was added to the reaction mixture to decompose the excess reagent. The reaction product was extracted with hexane (1 ml×3 times) and the hexane layer was washed with water (1 ml×3 times). The hexane solution was subjected to GC for an identification of the sugar moiety.

Enzyme Hydrolysis of Glycosides. Sixty mg of β-glucosidase (Boehringer Mannheim) was dissolved in a tris-(hydroxymethyl)methanamine–hydrochloric acid buffer solution (20 mM, pH 3.4, 3 ml) under cooling with ice-water. Each glycoside (3 mg) was suspended in a sodium acetate buffer solution (0.1 M, pH 5.0, 2 ml) and then a enzyme

† 1 M=1 mol dm^{-3}.

solution (0.1 ml) was added to the suspension. The mixture was stirred in a thermostat (25 °C). The termination of hydrolysis was checked by TLC. Aglycon and sugar were identified using the method as described above.

Isolation of Quassinoid Hemiacetals. A preparative TLC of fraction 7 using an ethyl acetate–diethyl ether (1:1, v/v) gave a pale-yellow amorphous substance (788 mg) which showed strong UV absorption. The substance showed six peaks in HPLC using Radial PAK CN and a mixed solvent of hexane–ethyl acetate (4:1, v/v), and was subjected to preparative HPLC to afford picrasinol-A (**11**, 152 mg) (corresponding to the first and the second peaks), picrasinol-B (**12**, 137 mg) (corresponding to the third and the fifth peaks), and neoquassin (123 mg) (corresponding to the fourth and the sixth peaks).

Methylation of Quassinoid Hemiacetals. A 1.5 M sulfuric acid–methanol (1:2, v/v) solution of each hemiacetal was stirred at 60 °C for 5 h and the methylated products were extracted with chloroform. The chloroform layer was washed with water and then the two products, methoxy isomers at C-16, were obtained by preparative HPLC (Radial PAK CN and a mixed solvent of hexane–ethyl acetate).

Jones Oxidation. A Jones reagent[19] (0.3 ml) was diluted with acetone (3 ml). The diluted oxidant was added to an acetone solution (1 ml) of a sample under cooling with ice-water. After the addition, the reaction mixture was stirred for 5 h and then a small amount of ethanol was added to the mixture to decompose the excess oxidant. Water (10 ml) was added to the mixture and the product was extracted with chloroform and purified by preparative HPLC (Radial PAK C_{18} and a mixed solvent of water–methanol).

Acid Hydrolysis of Picrasinoside-A (1). Picrasinoside-A (1, 19 mg) and 1.5 M sulfuric acid–methanol (1:2, v/v, 6 ml) was stirred at 80 °C for 24 h. Chloroform extraction and HPLC purification (Radial PAK C_{18}, water–methanol, 9:11, v/v) of the hydrolyzed product gave picrasin B[15] (**2**, nigakilactone I,[10] 10 mg): a colorless amorphous powder; mp 227—230 °C (lit,[15] 255—257 °C); Mass *m/z* 376 (M^+, $C_{21}H_{28}O_6$); IR ($CHCl_3$) 3500, 1735, 1720, 1680, 1640, and 1230 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ 0.90 (3H, d, J=6; $C_{(4)}$-CH_3), δ 1.16 and δ 1.42 (each 3H, s; $C_{(8)}$-CH_3 and $C_{(10)}$-CH_3), δ 1.89 (3H, s; $C_{(13)}$-CH_3), δ 3.27 (1H, s; $C_{(9)}$-H), δ 3.62 (3H, s; OCH_3), and δ 4.22 (1H, m; $C_{(7)}$-H). The water layer was treated to give a TMS derivative of the sugar. The derivative was analyzed by GC (OV-17, 2%, ID 2.6 mm, length 1.4 m, 140 °C, N_2 40 ml/min) which showed two peaks (t_R 12.5 and 21.2 min) and identified as the derivatives of α- and β-D-glucose by a comparison of the retention times with those of the authentic one.

Enzyme Hydrolysis of Picrasinoside-A (1). Picrasinoside-A (**1**, 3 mg) was suspended in a sodium acetate buffer solution (0.1 M, pH 5.0, 2 ml) and then the enzyme solution was added to the suspension. The mixture was stirred in a thermostat (25 °C) for 14 d. The aglycon was extracted with chloroform and identified as picrasin B by TLC, HPLC, GC, and GC-MS comparisons with those of the authentic one. Salts in the water layer were removed by treating with cation-exchange resins (Amberlite IR-120) and anion-exchange resins (Amberlite IRA-410). The water layer was dried and an obtained residue was converted into TMS derivatives of α- and β-D-glucose (identified by GC as described above).

Conversion of Picrasin B (2) into Quassin (4). Picrasin B (**2**, 9 mg) was oxidized with the Jones reagent as described above. A chloroform extraction of the reaction mixture and a purification by HPLC (C_{18}, water–methanol, 9:11, v/v) gave a colorless amorphous powder (**3**, dehydropicrasin B,[15] 5.8 mg): IR ($CHCl_3$) 3450, 1735, 1700, 1680, 1640, and 1230 cm^{-1}; Mass *m/z* 374 (M^+, $C_{21}H_{26}O_6$). Dehydropicrasin B (**3**, 5.3 mg) was further treated with a diazomethane–diethyl ether solution and the product was purified by HPLC (Radial PAK C_{18}, water–methanol, 9:11, v/v) to give colorless amorphous powder (**4**, quassin,[9] 1.7 mg): IR ($CHCl_3$) 1730, 1700, 1680, 1645, and 1640 cm^{-1}; Mass *m/z* 388 (M^+, $C_{22}H_{28}O_6$).

Conversion of Neoquassin into Quassin (4). Neoquassin (10 mg) isolated from *P. ailanthoides* was oxidized with the Jones reagent. A chloroform extraction of the reaction mixture and the purification by HPLC (Radial PAK C_{18}, water–methanol, 1:1, v/v) gave a colorless amorphous powder (**4**, quassin,[9] 8 mg): IR ($CHCl_3$) 1730, 1700, 1685, 1645, and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.09 (3H, d, J=7; $C_{(4)}$-CH_3), δ 1.17 (3H, s; $C_{(8)}$-CH_3), δ 1.54 (3H, s; $C_{(10)}$-CH_3), δ 1.85 (3H, s; $C_{(13)}$-CH_3), δ 2.99 (1H, s; $C_{(9)}$-H), δ 3.57 and δ 3.65 (each 3H, s; OCH_3), δ 4.32 (1H, m; $C_{(7)}$-H), δ 5.33 (1H, d, J=2; $C_{(3)}$-H); Mass *m/z* 388 (M^+, $C_{22}H_{28}O_6$).

Acid Hydrolysis of Picrasinoside-B (5). Picrasinoside-B (**2**, 35 mg) and 1.5 M sulfuric acid–methanol (1:2, v/v, 6 ml) were stirred at 60 °C for 5 h. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK CN, hexane–ethyl acetate, 4:1, v/v) to give two compounds as amorphous powders: 16β-*O*-methyl neoquassin (**5a**, 11 mg): IR ($CHCl_3$) 1690, 1680, and 1640 cm^{-1};. ^1H NMR (Table 2); Mass *m/z* (%) 404 (M^+, $C_{23}H_{32}O_6$; 90), 389(31), 372 (M^+—MeOH; 19), 357(13), 343(8), 329(29), 313(30), 302(33), 165(31), 154(7), 153(24), 152(100), 151(27), and 121(18) and 16α-*O*-methylneoquassin (**5b**, 5 mg): IR ($CHCl_3$) 1690, 1680, and 1640 cm^{-1}; ^1H NMR (Table 2); Mass *m/z* (%) 404 (M^+, $C_{23}H_{32}O_6$; 21), 389(4), 372 (M^+—MeOH; 79), 357(30), 343 (11), 329(42), 313(15), 302(100), 165(19), 154(4), 153(11), 152(39), 151(15), and 121(10). The water layer was treated in the same manner as described above and α- and β-D-glucose were identified.

Acid Hydrolysis of Picrasinoside-C (6). A mixture of picrasinoside-C (**6**, 20 mg) and 1.5 M sulfuric acid–methanol (1:2, v/v, 6 ml) was stirred at 60 °C for 5 h. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK CN, hexane–ethyl acetate, 7:3, v/v) to give two compounds as colorless amorphous powders: 16β-*O*-methylnigakihemiacetal C (=nigakihemiacetal F,[14] **6a**, 6.4 mg): IR ($CHCl_3$) 3420, 1680, and 1640 cm^{-1}; ^1H NMR (Table 2); Mass *m/z* (%) 394 (M^+, $C_{22}H_{34}O_6$; 54), 376 (M^+—H_2O; 86), 362 (M^+—MeOH; 18), 361(45), 344 (M^+—H_2O—MeOH; 36), 329(15), 316(48), 301(100), 257(46), 165(41), 154(27), 153(48), 152(52), 151(39), and 121(47) and 16α-*O*-methylnigakihemiacetal C (**6b**, 3.9 mg): IR ($CHCl_3$) 3410, 1680, and 1640 cm^{-1}; ^1H NMR (Table 2); Mass *m/z* (%) 394 (M^+, $C_{22}H_{34}O_6$; 26), 376 (M^+—H_2O; 11), 362 (M^+—MeOH; 35), 344 (M^+—H_2O—MeOH; 100), 329(39), 316(57), 301(83), 257(41), 165(45), 154(24), 153(46), 152(49), 151(25), and 121(46). The water layer was analyzed in the same manner as described above and α- and β-D-glucose were identified.

A mixture of picrasinoside-C (**6**, 5 mg) and 1.5 M sulfuric acid–ethanol (1:2, v/v, 3 ml) was stirred at 60 °C for 5 h. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK CN, hexane–ethyl acetate, 7:3, v/v) to give two compounds as colorless amorphous powders: 16β-*O*-ethyl nigakihemiacetal C (1.1 mg): Mass

m/z (%) 408 (M^+, $C_{23}H_{36}O_6$; 30), 390 (M^+-H_2O, 100), 375(69), 362(16), 344 ($M^+-H_2O-EtOH$; 47), 329(24), 316(25), 301(38), 251(30), 165(72), 154(52), 153(91), 152(100), 151(43), and 121(62) and 16α-*O*-ethylnigakihemiacetal C (0.5 mg): Mass *m/z* (%) 408 (M^+, $C_{23}H_{36}O_6$; 5), 390 (M^+-H_2O; 6), 375(4), 362(37), 344 ($M^+-H_2O-EtOH$; 100), 329(46), 316(30), 301(30), 251 (42), 165(49), 154(68), 152(63), 151(30), and 121(42).

A mixture of picrasinoside-C (**6**, 10 mg) and 1.5 M sulfuric acid-1-butanol (1:6, v/v, 3.5 ml) was stirred at 60 °C for 5 h. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK CN, hexane–ethyl acetate, 7:3, v/v) to give two compounds as colorless amorphous powders: 16β-*O*-butylnigakihemiacetal C (2.5 mg): Mass *m/z* (%) 436 (M^+, $C_{25}H_{40}O_6$; 20), 418 (M^+-H_2O; 84), 403(61), 363(48), 344 ($M^+-H_2O-BuOH$; 57), 329(26), 316(39), 301(48), 251(32), 165(73), 154(61), 153(100), 152(98), 151(47), and 121(62) and 16α-*O*-butylnigakihemiacetal C (1.8 mg): Mass *m/z* (%) 436 (M^+, $C_{25}H_{40}O_6$; 6), 418 (M^+-H_2O; 6), 403(5), 362(44), 344 ($M^+-H_2O-BuOH$; 100), 329(48), 316(43), 301(43), 251(55), 165(69), 154(44), 153(84), 152 (78), 151(35), and 121(57).

*Conversion of Picrasinol-B (**12**) into Picrasin D.* Picrasinol-B (**12**, 20 mg) was oxidized with the Jones reagent in the same manner as described above. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK CN, water–methanol, 1:1, v/v) to give colorless amorphous powders: (**13**, picrasin D,[15] 13 mg): IR ($CHCl_3$) 2740, 1725, 1705, 1640, and 1240 cm^{-1}; UV (EtOH) 262 nm (ε 3300); ^1H NMR (60 MHz, $CDCl_3$) δ 1.10 (6H, d, *J*= 7; $C_{(4)}$-CH_3 and $C_{(13)}$-CH_3), δ 1.27 and δ 1.42 (each 3H, s; $C_{(8)}$-CH_3 and $C_{(10)}$-CH_3), δ 3.57 (3H, s; OCH_3), δ 4.23 (1H, m; $C_{(7)}$-H), δ 5.04 and δ 5.20 (each 1H, d, *J*=1; -O-CH_2-O-), δ 5.27 (1H, d, *J*=2; $C_{(3)}$-H; Mass *m/z* 390 (M^+, $C_{22}H_{30}O_6$).

*Conversion of Picrasinol-B (**12**) into 16β-O-Methylnigakihemiacetal C (=nigakihemiacetal F, **6a**) and 16α-O-Methylnigakihemiacetal C (**6b**).* A mixture of picrasinol-B (**12**, 15 mg) and 1.5 M sulfuric acid–methanol (1:2, v/v, 6 ml) was stirred at 60 °C for 5 h. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK CN, hexane–ethyl acetate, 7:3, v/v) to give two compounds as colorless amorphous powders: 16β-*O*-methylnigakihemiacetal C (=nigakihemiacetal F,[14] **6a**) and 16α-*O*-methylnigakihemiacetal C (**6b**) whose spectral data coincided with those of the authentic one.

*Conversion of Picrasinoside-B (**12**) into Nigakihemiacetal C.* A mixture of picrasinol-B (**12**, 11 mg), acetone (0.1 ml), and 1.5 M sulfuric acid (2 ml) was stirred at 60 °C for 3 h. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK C_{18}, water–methanol, 1:1, v/v) to give a colorless amorphous powder (nigakihemiacetal C,[10] 7 mg): IR ($CHCl_3$) 3400, 1680, and 1640 cm^{-1}; Mass *m/z* 380 (M^+, $C_{21}H_{32}O_6$).

*Conversion of Picrasin D (**13**) into Nigakilactone A.* A mixture of picrasin D (**13**, 7 mg), which was obtained by the Jones oxidation of picrasinol-B (**12**), and 1.5 M sulfuric acid (2 ml) was stirred at 60 °C for 3 h. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK C_{18}, water–methanol, 1:1, v/v) to give a colorless amorphous powder (nigakilactone A,[9] 4 mg): IR ($CHCl_3$) 3400, 1680, and 1640 cm^{-1}; Mass *m/z* 378 (M^+, $C_{21}H_{30}O_6$).

*Acid Hydrolysis of Picrasinoside-D (**7**).* A mixture of picrasinoside-D (**7**, 9 mg) and 1.5 M sulfuric acid–methanol (1:2, v/v, 6 ml) was stirred at 60 °C for 5 h. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK CN, hexane–ethyl acetate, 9:1, v/v) to give two compounds as colorless amorphous powders: 16β-*O*-methylpicrasinol-A (**7a**, 4 mg): IR ($CHCl_3$) 1730, 1705, 1640, and 1245 cm^{-1}; Mass *m/z* (%) 450 (M^+, $C_{25}H_{38}O_7$; 1.9), 418 (M^+-MeOH; 15), 390 (M^+-AcOH; 20), 375(100), 372(18), 358 ($M^+-AcOH-MeOH$; 27), 344(18), 343 (43), 315(18), 299(27), 165(24), 154(14), 153(19), 152(17), 151 (16), and 121(18) and 16α-*O*-methylpicrasinol-A (**7b**, 1.5 mg): IR ($CHCl_3$) 1730, 1705, 1640, and 1245 cm^{-1}; Mass *m/z* (%) 450 (M^+, $C_{25}H_{38}O_7$; 0.8), 418 (M^+-MeOH; 2.4), 390(2.6), 386(56), 375(30), 372(3), 358 ($M^+-AcOH-MeOH$; 80), 344(100), 343 (73), 315(29), 299(52), 165(16), 154(9), 153(16), 152(15), 151 (12), and 121(16). The water layer was analyzed in the same manner as described above and α- and β-D-glucose were identified.

*Methylation of Picrasinol-A (**11**).* A mixture of picrasinol-A (**11**, 13 mg) and 1.5 M sulfuric acid–methanol (1:2, v/v, 6 ml) was stirred at 60 °C for 5 h. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK CN, hexane–ethyl acetate, 9:1, v/v) to give two compounds as colorless amorphous powders: 16β-*O*-methyl picrasinol-A (**7a**) and 16α-*O*-methylpicrasinol-A (**7b**). They were identified by spectral comparisons with those of the authentic one.

*Conversion of Picrasinol-A (**11**) into Nigakilactone C.*[9] Picrasinol-A (**11**, 14 mg) was oxidized with the Jones reagent in the same manner as described above. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK C_{18}, water–methanol, 1:1, v/v) to give a colorless amorphous powder (nigakilactone C,[9] 10 mg): mp 231—233 °C (lit,[9] 252.5—253 °C); IR ($CHCl_3$) 1735, 1730, 1705, 1640, and 1240 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$)δ 1.01 (3H, d, *J*=7; $C_{(13)}$-CH_3), δ 1.05 (3H, d, *J*=6; $C_{(4)}$-CH_3), δ 1.26 (6H, s, $C_{(8)}$-CH_3 and $C_{(10)}$-CH_3, δ 1.95 (3H, s, $OCOCH_3$), δ 3.41 and δ 3.54 (each 3H, s; OCH_3), δ 4.13 (1H, m; $C_{(7)}$-H, δ 5.10 (1H, d, *J*=2; $C_{(3)}$-H), and δ 5.18 (1H, dd, *J*=9, 11; $C_{(11)}$-H; Mass *m/z* 434 (M^+, $C_{24}H_{34}O_7$).

*Acid Hydrolysis of Picrasinoside-E (**8**).* A mixture of picrasinoside-E (**8**, 16 mg) and 1.5 M sulfuric acid–methanol (1:2, v/v, 6 ml) was stirred at 60 °C for 5 h. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK CN, hexane–ethyl acetate, 4:1, v/v) to give two compounds as amorphous powders: 16β-*O*-methylnigakihemiacetal D (**8a**, 3.6 mg: IR ($CHCl_3$) 3450, 1730, 1705, 1640, and 1245 cm^{-1}; Mass *m/z* (%) 466 (M^+, $C_{25}H_{38}O_8$; 3.2), 434 (M^+-MeOH; 22), 406 (M^+-AcOH; 43), 391(42), 375(48), 374 ($M^+-AcOH-MeOH$; 38), 359(100), 331(46), 313(30), 299(35), 165(51), 154(24), 153(53), 152(51), 151(36), and 121(34) and 16α-*O*-methylnigakihemiacetal D (**8b**, 3.2 mg): IR ($CHCl_3$) 3450, 1730, 1705, 1640, and 1245 cm^{-1}; Mass *m/z* (%) 466 (M^+, $C_{25}H_{38}O_8$; 2.9), 434 (M^+-MeOH; 26), 406 (M^+-AcOH; 37), 391(30), 375(51), 374 ($M^+-AcOH-MeOH$; 77), 359(89), 331(100), 313(48), 299(47), 165(67), 154(32), 153(69), 152(66), 151(45), and 121(47).

*Conversion of Compounds **8a** and **8b** into Nigakihemiacetal D.* A mixture of **8a** and **8b** (4 mg) and 1.5 M sulfuric acid (2 ml) was stirred at 60 °C for 3 h. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK CN, hexane–ethyl acetate, 4:1, v/v) to give a colorless amorphous powder (nigakihemiacetal D,[8] 2 mg): IR ($CHCl_3$) 3450, 1730, 1705, 1640, and 1245 cm^{-1}; Mass

m/z 452 (M^+, $C_{24}H_{36}O_8$).

Acid Hydrolysis of Picrasinoside-F (9). A mixture of picrasinoside-F (**9**, 4.2 mg) and 1.5 M sulfuric acid–methanol (1:2, v/v, 6 ml) was stirred at 60 °C for 5 h. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK CN, hexane–ethyl acetate, 4:1, v/v) to give two compounds as colorless amorphous powders: 11-deacetyl-16β-*O*-methylpicrasinol-A (**9a**, 1.1 mg): IR ($CHCl_3$) 3470, 1680, and 1645 cm^{-1}; Mass *m/z* (%) 408 (M^+, $C_{23}H_{36}O_6$; 7), 390 (M^+-H_2O; 2), 376 (M^+—MeOH; 78), 361(63), 358 (M^+-H_2O—MeOH; 13), 342 (100), 328(30), 313(27), 285(16), 217(51), 165(39), 154(25), 153(63), 152(47), 151(31), and 121(55) and 11-deacetyl-16α-*O*-methylpicrasinol-A (**9b**, 0.9 mg): IR ($CHCl_3$) 3470, 1680, and 1645 cm^{-1}; Mass *m/z* (%) 408 (M^+, $C_{23}H_{36}O_6$; 3), 390 (M^+-H_2O; 0.7), 376 (M^+—MeOH; 12), 361(5), 358 (M^+-H_2O—MeOH; 9), 344(52), 328 (100), 313(72), 285(25), 217(43), 165(24), 154(21), 153(41), 152 (32), 151(19), and 121(45). The water layer was analyzed in the same manner as described before and α- and β-D-glucose were identified.

Conversion of Compounds 7a and 7b into Compounds 9a and 9b. A mixture of **7a** and **7b** (*ca.* 4 mg) and 2% potassium hydroxide–ethanol (10 ml) was stirred at 80 °C for 2 h. The solvent was removed by distillation under reduced pressure from the reaction mixture to give a residue to which water (15 ml) was added and saturated with carbon dioxide gas for about 10 h. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK CN, hexane–ethyl acetate, 4:1, v/v) to give **9a** and **9b**. These were identified by spectral comparisons with authentic samples.

Acid Hydrolysis of Picrasinoside-G (10). A mixture of picrasinoside-G (**10**, 7 mg) and 1.5 M sulfuric acid–methanol (1:2, v/v, 6 ml) was stirred at 60 °C for 5 h. The reaction product was extracted with chloroform and subjected to preparative HPLC (Radial PAK CN, hexane–ethyl acetate, 17:3, v/v) to give two compounds as colorless amorphous powders: 16β-*O*-methylnigakihemiacetal A (**10a**, 3.1 mg): IR ($CHCl_3$) 3470, 1680, and 1645 cm^{-1}; Mass *m/z* (%) 424 (M^+, $C_{23}H_{36}O_7$; 9), 406 (M^+-H_2O; 45), 392 (M^+—MeOH; 22), 377 (32), 374 (M^+-H_2O—MeOH; 31), 359(17), 331(25), 304(37), 165(61), 154(50), 153(63), 152(77), 151(44), 127(100), and 121 (55) and 16α-*O*-methylnigakihemiacetal A (**10b**, 1.7 mg): IR ($CHCl_3$) 3470, 1680, and 1645 cm^{-1}; Mass *m/z* (%) 424 (M^+, $C_{23}H_{36}O_7$; 4.5), 406 (M^+-H_2O; 23), 392 (M^+—MeOH; 42), 377 (25), 374 (M^+-H_2O—MeOH; 71),359(25), 331(27), 304(26), 165(62), 154(41), 153(55), 152(74), 151(38), 127(100), and 121 (51). The water layer was analyzed in the same manner as described before and α- and β-D-glucose were identified.

Conversion of Compounds 8a and 8b into Compounds 10a and 10b. A mixture of **8a** and **8b** (*ca.* 2 mg) and 2% potassium hydroxide–ethanol (10 ml) was stirred at 80 °C for 2 h. The reaction mixture was treated in the same manner as described above and gave compounds **10a** and **10b**. These were identified by spectral comparisons with authentic samples.

Biological Activities of Picrasinoside-A (1) and -B (5). The mean survival time (*T/C*%) in mice suffering from P 388 lymphocytic leukemia (test system: 3PS31) was investigated by NCI (U.S.A.) for picrasinoside-A (**1**) and -B (**5**). The *T/C* values for picrasinoside-A (**1**) were 103, 107, and 103 at doses of 20.00, 10.00, and 5.00 mg/kg and those of picrasinoside-B (**5**) were 103, 94, and 96 at doses of 16.00, 8.00, and 4.00 mg/kg, respectively.[21]

The authors wish to thank Drs. Takashi Matsumoto and Sachihiko Imai of Hiroshima University for the ^1H NMR (90 MHz), Mr. Tomonaga Fujiwara of JEOL Co. Ltd. for the ^{13}C NMR (22.5 MHz), Dr. Tomei Oguri of Mitsubishiyuka Pharmaceutical Co. Ltd. for the FAB mass, and Miss Shigeko Miki of Meijiseika Kaisha Ltd. for the FD mass spectra.

Synthetic Studies of Rifamycins. VII.[1] A Facile Synthesis of the Aromatic Chromophore of Rifamycin S through a Rifamycin W Aromatic Segment

Masaya NAKATA, Shigeru WADA, Kuniaki TATSUTA, and Mitsuhiro KINOSHITA*
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received March 3, 1985)

The intact aromatic chromophore of rifamycin S, 7-amino-2,5-dihydroxy-2,4-dimethyl-naphtho[2,1-*b*]furan-1,6,9(2*H*)-trione, was synthesized through the rifamycin W aromatic segment, 1-[5,8-dimethoxy-2,4-bis-(methoxymethoxy)-3-methyl-6-nitro-1-naphthyl]-1-propanone which was prepared in 9 steps and 29.6% overall yield from 2,6-bis(benzyloxy)-3,5-dibromotoluene and furan.

In the preceding paper[1] of this series, we described a simple and convenient preparation of the nitronaphthalene derivative **1** which was demonstrated to be a promising aromatic segment for the total synthesis of rifamycin W (**2**)[2] by the successful aldol coupling with the aliphatic segment[3] of **2**. Although the methoxyl groups at C-2 and C-4 of **1** were quite stable during the elaboration[1] of **1** toward the total synthesis of **2**, the effective ether bond cleavage (de-*O*-methylation) on these methoxyl groups, that is indispensable at the final stage of the conquest of **2**, should naturally become the crucial problem. In this respect, we found that the new nitronaphthalene derivative **3**, which was expected to be a more promising aromatic segment for the rifamycin W synthesis,[4] was a synthetic intermediate suitable for the intact aromatic chromophore

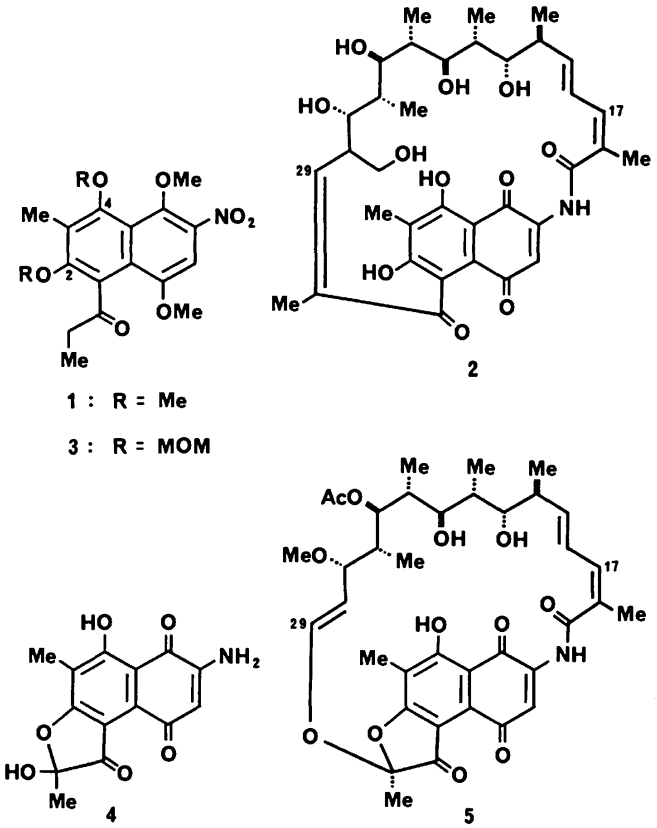

Fig. 1.

4[5] of rifamycin S (**5**). A synthesis of the aromatic segment of **5** has been reported by Kishi *et al.*[6] and an elegant and shorter synthesis of **4** has recently been reported by Kelly *et al.*[7] We now describe a facile synthesis of **4** through the new aromatic segment **3**.

The starting material, 2,6-bis(benzyloxy)-3,5-dibromotoluene (**7**), obtained in a 95% yield by benzylation of 3,5-dibromo-2,6-toluenediol (**6**),[8] was treated with 3.5 equimolar amounts of sodium amide and 30 equimolar amounts of furan in THF at 57 °C for 10 h to give the bromoepoxide **8** in a 97% yield. Lithiation of **8** with 1.2 equimolar amounts of butyllithium in

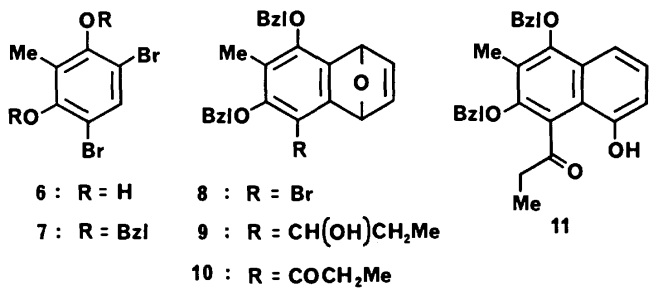

Fig. 2.

THF at −105 °C followed by treatment with 5 equimolar amounts of propanal afforded **9** in an 87% yield as an epimeric mixture. Oxidation of **9** with pyridinium chlorochromate (PCC) and subsequent treatment of the resulting epoxy ketone **10** with perchloric acid in THF at room temperature afforded the naphthol **11** in a 79% yield from **9** as a sole product. The structure shown for **11** was established by the following manner. The aforesaid lithiation of **8** followed by carboxylation afforded the naphthoic acid **12**. The ring-opening reaction of this epoxy acid by treatment with perchloric acid in THF proceeded very slowly at room temperature and was accompanied by de-

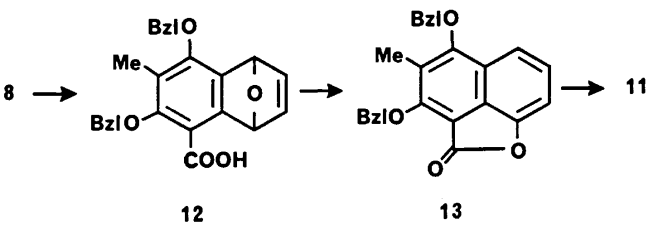

Fig. 3.

composition at elevated temperature. After many other unsuccessful results, the lactone **13** could be obtained in a 65% yield by treatment of **12** with 0.1 equimolar amounts of sulfuric acid in acetic anhydride. The reaction of **13** with equimolar amount of ethyllithium in ether afforded **11**. This sample of **11** proved to be identical with the specimen of **11** derived from **10** in all respects. To introduce a hydroxyl function at C-5 of **11**, **11** was subjected to oxidation using *N*-bromosuccinimide in aqueous acetic acid,[1,9] but only decomposition took place. Among various conditions studied, the oxidation of **11** using three equimolar amounts of thallium(III) nitrate[10] in methanol at 0°C proceeded smoothly to give the naphthoquinone **14** in an 82% yield. Catalytic hydrogena-

Fig. 4.

tion of **14** with hydrogen in the presence of Lindlar catalyst and pyridine in acetone afforded the air sensitive hydronaphthoquinone, which was immediately methylated with dimethyl sulfate and potassium carbonate to give **15** in a 74% yield. Conversion of the benzyl ether into the methoxymethyl ether was carried out by debenzylation of **15** followed by methoxymethylation of the resulting diol **16** to afford **17** in a 95% yield. Nitration of **17** with copper(II) nitrate[1,11] in acetic anhydride at −40°C afforded regiospecifically the nitronaphthalene **3** in a 77% yield. The structural elucidation of **3** was carried out as follows: cleavage of the methoxymethyl ether of **3** by treatment with 1 M† HCl in THF gave the diol **18**, which was methylated to give the tetramethoxynaphthalene proved to be identical with **1**[1] in all respects.

Conversion of **3** into the target chromophore **4** was achieved by the following procedure. Thus, reduction of **3** with hydrogen in the presence of 5% palladium on charcoal led to the amine **19**. To protect the amino group of **19**, the acid-labile protecting group was select-

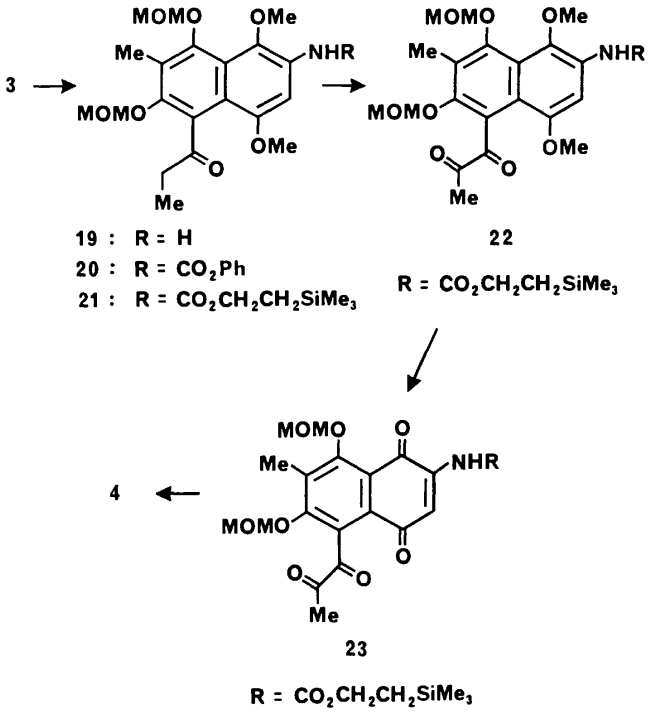

Fig. 5.

ed because acidic conditions were necessary for the formation of the furanone ring along with the removal of both the amino and the phenol protecting groups at the last stage in the synthesis of **4**. *t*-Buthoxycarbonyl group was first chosen but the corresponding carbamate was not obtained in a satisfactory yield. 2-(Trimethylsilyl)ethoxycarbonyl group afforded a good result, namely, the amine **19** was transformed by the Meyers' procedure[12] into the 2-(trimethylsilyl)ethyl carbamate **21** *via* the phenyl carbamate **20** in an 89% yield. Oxidation of **21** with oxygen[6,13] in the presence of 15 equimolar amounts of potassium *t*-butoxide in a mixture of *t*-butyl alcohol, dimethyl sulfoxide (DMSO), and 1,2-dimethoxyethane (DME) gave the α-diketone **22** in an 88% yield. In this reaction, only the starting material was recovered when DMSO was absent. Oxidative demethylation of **22** with ammonium cerium(IV) nitrate[14] in aqueous acetonitrile provided the naphthoquinone **23** in an 86% yield. Exposure of **23** to 100% trifluoroacetic acid[15] (TFA) at 0°C for 1.5 h gave the target aminonaphthoquinone **4** in a 93% yield. The spectral data (IR, UV, ^{1}H-NMR) of **4** were indistinguishable from those of naturally occurring **4**.[5]

Experimental

Melting points were determined on a micro hot-stage Yanaco MP-S3 and were uncorrected. IR spectra were recorded on a Hitachi Perkin-Elmer 225 spectrometer, UV spectra on JAS·CO UVIDEC-1 spectrometer, and ^{1}H-NMR

† 1 M=1 mol dm^{-3}.

spectra on Varian EM-390 spectrometer in $CDCl_3$ using TMS as internal standard. Silica gel TLC and column chromatography were performed on Merck TLC 60F-254 and Wakogel C-200, respectively. In general, evaporation of solvents was carried out under reduced pressure below 30°C.

2,6-Bis(benzyloxy)-3,5-dibromotoluene (7). To an ice-cold stirred suspension of **6** (1.00 g, 3.55 mmol) and potassium carbonate (1.23 g, 8.90 mmol) in dry acetone (10 ml), benzyl bromide (1.05 ml, 8.83 mmol) was added dropwise. After the addition was complete, the mixture was stirred at 60°C for 4 h and filtered with celite. The filter cake was washed with acetone and the combined filtrate and washings were evaporated. The residue was chromatographed on silica gel (82 g) with 25:1 hexane-ethyl acetate to afford **7** (1.56 g, 95%) as colorless crystals: mp 91.5—92.5°C (needles from ethyl acetate-methanol); R_f=0.34 (25:1 hexane-ethyl acetate); UV (EtOH) λ 214 nm (log ε 4.63); ^{1}H-NMR δ= 2.22 (3H, s, ArMe), 4.96 (4H, s, 2×OC<u>H</u>$_2$Ph), and 7.30—7.75 (11H, m, H-4 and 2×Ph).

Found: C, 54.32; H, 4.04; Br, 34.27%. Calcd for $C_{21}H_{18}O_2Br_2$: C, 54.57; H, 3.93; Br, 34.58%.

5,7-Bis(benzyloxy)-8-bromo-1,4-dihydro-6-methyl-1,4-epoxynaphthalene (8). To a solution of **7** (10.0 g, 21.6 mmol) in dry THF (70 ml) were added furan (47.0 ml, 646 mmol) and sodium amide (2.95 g, 75.6 mmol). After the mixture was stirred at 57°C for 10 h, the insoluble matter was filtered with celite and the filter cake was washed with ether. The combined filtrate and washings were evaporated and the residue was chromatographed on silica gel (240 g) with 50:1 toluene-ethyl acetate to give **8** (9.61 g, 99%) as a brown syrup. This syrup was treated with activated carbon in ether to afford a yollow-brown syrup (9.41 g, 97%) of **8**. An analytical sample (colorless syrup) was obtained after the additional column chromatography with 5:1 hexane-ethyl acetate: R_f= 0.13 (20:1 hexane-ethyl acetate); UV (EtOH) λ 218 nm (log ε 4.57); ^{1}H-NMR δ=2.14 (3H, s, ArMe), 4.88 and 5.05 (each 2H, each s, 2×OC<u>H</u>$_2$Ph), 5.79 and 5.93 (each 1H, each dd, H-1 and 4, J=1.0 and 2.0 Hz), 6.75 and 7.04 (each 1H, each dd, H-2 and 3, J=5.3 and 2.0 Hz), and 7.42 (10H, s, 2×Ph).

Found: C, 66.90; H, 4.82; Br, 18.02%. Calcd for $C_{25}H_{21}O_3Br$: C, 66.83; H, 4.71; Br, 17.78%.

1-[2,4-Bis(benzyloxy)-5,8-dihydro-3-methyl-5,8-epoxy-1-naphthyl]-1-propanol (9). To a stirred solution of **8** (9.41 g, 20.9 mmol) in dry THF (84 ml) at −105°C under argon was added 1.42 M butyllithium in hexane (17.7 ml, 25.1 mmol) over a period of 4 min. After being stirred at the same temperature for 6 min, propanal (7.55 ml, 105 mmol) was added to the mixture as soon as possible. The reaction mixture was stirred at the same temperature for 30 min and treated with a saturated aqueous NH_4Cl solution (80 ml). After being allowed to warm to room temperature, the resulting mixture was extracted with ether (100 ml×2), and the extract was washed with a saturated aqueous NaCl solution (70 ml), dried, and evaporated. The residue was chromatographed on silica gel (450 g) with 4:1 toluene-ethyl acetate to give **9** (7.80 g, 87%) as pale yellow-brown crystals. This sample showed two spots (R_f 0.32 and 0.21) on TLC with 15:1 chloroform-ethyl acetate. A part of this was separated by silica gel column chromatography with 15:1 chloroform-ethyl acetate to give colorless crystals of **9a** and **9b** with a ratio of 1.2:1:

9a, R_f=0.32 (15:1 chloroform-ethyl acetate), mp 107—108 °C (needles from chloroform-hexane); IR (KBr) 3410 cm^{-1}; UV (EtOH) λ (log ε) 222(4.51), 260 (sh, 3.34), and 295 nm (sh, 2.86); ^{1}H-NMR δ=0.95 (3H, t, CH$_2$<u>Me</u>, J=7.5 Hz), 1.60—2.00 (3H, m, OH and C<u>H</u>$_2$Me), 2.18 (3H, s, ArMe), 4.79 and 5.06 (each 2H, each s, 2×OC<u>H</u>$_2$Ph), 4.80—5.00 (1H, m, C<u>H</u>OH), 5.88 and 6.08 (each 1H, each dd, H-5 and 8, J=1.0 and 1.8 Hz), 6.74 and 6.98 (each 1H, each dd, H-6 and 7, J=1.8 and 5.6 Hz), and 7.44 (10H, s, 2×Ph).

Found: C, 78.35; H, 6.67%. Calcd for $C_{28}H_{28}O_4$: C, 78.48; H, 6.59%.

9b, R_f=0.21 (15:1 chloroform-ethyl acetate), mp 107—108 °C (needles from chloroform-hexane); IR (KBr) 3430 cm^{-1}; UV (EtOH) λ (log ε) 222(4.51), 260 (sh, 3.29), and 295 nm (sh, 2.81); ^{1}H-NMR δ=0.86 (3H, t, CH$_2$<u>Me</u>, J=7.5 Hz), 1.40—1.85 (3H, m, OH and C<u>H</u>$_2$Me), 2.18 (3H, s, ArMe), 4.79 and 5.06 (each 2H, each s, 2×OC<u>H</u>$_2$Ph), 4.80—5.00 (1H, m, C<u>H</u>OH), 5.88 and 6.25 (each 1H, each dd, H-5 and 8, J=1.0 and 1.8 Hz), 6.79 and 6.99 (each 1H, each dd, H-6 and 7, J=1.8 and 5.6 Hz), and 7.44 (10H, s, 2×Ph).

Found: C, 78.60; H, 6.70%. Calcd for $C_{28}H_{28}O_4$: C, 78.48; H, 6.59%.

1-[2,4-Bis(benzyloxy)-5,8-dihydro-3-methyl-5,8-epoxy-1-naphthyl]-1-propanone (10). To a stirred mixture of PCC (10.3 g, 47.8 mmol), molecular sieves 3A powder (15.9 g), and dry dichloromethane (40 ml) was added a solution of **9** (6.80 g, 15.9 mmol) in dry dichloromethane (34 ml) at room temperature. After being stirred at room temperature for 0.5 h, the reaction mixture was diluted with ether (75 ml) and the resulting suspension was transferred to a column filled with silica gel (130 g). The column was eluted with ether and the eluant was evaporated to give practically pure sample of **10** (6.70 g, 98%) as pale yellow crystals. An analytical sample was obtained after recrystallization from ethyl acetate-hexane: mp 112—114°C (colorless plates); R_f=0.45 (3:1 hexane-ethyl acetate) ; IR (KBr) 1663 cm^{-1}; UV (EtOH) λ (log ε) 212(4.39), and 247 nm (4.23) ; ^{1}H-NMR δ=1.08 (3H, t, CH$_2$-<u>Me</u>, J=7.0 Hz), 2.15 (3H, s, ArMe), 2.70—3.20 (2H, m, C<u>H</u>$_2$Me), 4.70 and 4.73 (each 1H, ABq, OC<u>H</u>$_2$Ph, J_{gem}=12.0 Hz), 5.11 and 5.21 (each 1H, ABq, OC<u>H</u>$_2$Ph, J_{gem}=12.0 Hz), 5.85 and 5.95 (each 1H, each br, H-5 and 8), 6.77 and 7.10 (each 1H, each dd, H-6 and 7, J=1.8 and 5.3 Hz), and 7.42 and 7.45 (each 5H, each s, 2×Ph).

Found: C, 78.58 ; H, 6.30%. Calcd for $C_{28}H_{26}O_4$; C, 78.85 ; H, 6.14%.

2,4-Bis(benzyloxy)-5,8-dihydro-3-methyl-5,8-epoxy-1-naphthalenecarboxylic Acid (12). To a stirred solution of **8** (960 mg, 2.14 mmol) in dry THF (8.55 ml) at −100°C under argon was added 1.39 M butyllithium in hexane (1.84 ml, 2.56 mmol). After being stirred at the same temperature for 30 min, CO_2 gas was bubbled through the reaction mixture for 20 min. The mixture was allowed to warm to 0°C and then acidified with 1 M HCl (30 ml). The mixture was extracted with ether and the extract was washed with a saturated aqueous NaCl solution, dried, and evaporated. The residue was chromatographed on silica gel (48 g) with 4:1:0.05 toluene-ethyl acetate-acetic acid to afford **12** (689 mg, 78%) as a brown syrup. This slightly impure syrup was crystallized from 1:4 acetone-hexane to afford colorless needles: mp 144—145 °C ; R_f=0.21 (4:1:0.05 toluene-ethyl acetate-acetic acid); IR (KBr) 1688 cm^{-1}; UV (EtOH) λ (log ε) 212(4.49), 233(4.47), and 297 nm (3.09); ^{1}H-NMR δ=2.21 (3H, s, ArMe), 4.91 (2H, s, OC<u>H</u>$_2$Ph), 5.15 and 5.30 (each 1H, ABq, OC<u>H</u>$_2$Ph, J_{gem}= 12.0 Hz), 6.02 and 6.53 (each 1H, each dd, H-5 and 8, J= 1.2 and 1.8 Hz), 6.78 and 7.12 (each 1H, each dd, H-6 and 7, $J_{6,7}$=5.7 Hz, J=1.8 Hz), and 7.45 (10H, s, 2×Ph).

Found: C, 75.48 ; H, 5.57%. Calcd for $C_{26}H_{22}O_5$: C, 75.35 ; H, 5.35%.

3,5-Bis(benzyloxy)-4-methyl-2H-naphtho[1,8-bc]furan-2-one (13). A 1.0 ml solution of 0.012 M concd H_2SO_4 in acetic anhydride was added to **12** (49.4 mg, 0.119 mmol) at 21 °C. The resulting white suspension was stirred for 10 min, and diluted with ether. The ether layer was washed with water (3 times) and a saturated aqueous NaCl solution, dried, and evaporated. The residue was chromatographed on silica gel (4.8 g) with 10:1 hexane-acetone to give **13** (30.5 mg, 65%) as colorless crystals. An analytical sample was obtained after recrystallization from chloroform-hexane: mp 136—137 °C (cottony crystals); R_f=0.23 (10:1 hexane-acetone); IR (KBr) 1754 cm^{-1}; UV (EtOH) λ (log ε) 220(4.50), 260(4.55), and 333 nm (4.04); ^{1}H-NMR δ=2.30 (3H, s, ArMe), 5.18 (2H, s, $OC\underline{H}_2Ph$), 6.00 (2H, s, $OC\underline{H}_2Ph$), 7.11 and 7.65 (each 1H, each d, H-6 and 8, J=7.2 Hz), and 7.30—7.60 (11H, m, 2×Ph and H-7).

Found: C, 78.50; H, 5.15%. Calcd for $C_{26}H_{20}O_4$: C, 78.77 ; H, 5.08%.

1-[2,4-Bis(benzyloxy)-8-hydroxy-3-methyl-1-naphthyl]-1-propanone (11). (a) To a solution of **10** (8.30 g, 19.5 mmol) in THF (140 ml), 60% $HClO_4$ (1.26 ml) was added. After being stirred at 25 °C for 35 h, the reaction mixture was diluted with ether (140 ml), washed with water (100 ml×3) and a saturated aqueous NaCl solution (100 ml×1), dried, and evaporated. The residue was recrystallized from THF (28 ml) and hexane (55 ml) at −25 °C overnight to afford **11** (3.21 g) as pale yellow-brown crystals. The mother liquor was evaporated and the residue was chromatographed on silica gel (250 g) with 8:1 toluene-ethyl acetate to afford additional **11** (3.53 g). The total amount was 6.74 g (81%). An analytical sample (colorless mossy crystals) was obtained after recrystallization (two times) from a mixture of chloroform and hexane: mp 188—190 °C (decomp); R_f=0.31 (8:1 toluene-ethyl acetate); IR (KBr) 3390 and 1675 cm^{-1} ;UV (0.01 M HCl-EtOH) λ (log ε) 221(4.77), 242(4.76), and 306 nm (4.00); ^{1}H-NMR δ=1.18 (3H, t, $CH_2\underline{Me}$, J=7.0 Hz), 2.39 (3H, s, ArMe), 2.94 (2H, q, $C\underline{H}_2Me$, J=7.0 Hz), 4.90 and 5.02 (each 2H, each s, 2× $OC\underline{H}_2Ph$), 6.28 (1H, s, OH), 6.81 and 7.71 (each 1H, each d, H-5 and 7, J=7.5 Hz), and 7.15—7.65 (11H, m, H-6 and 2× Ph).

Found: C, 78.60; H, 6.20%. Calcd for $C_{28}H_{26}O_4$; C, 78.85; H, 6.14%.

(b) To an ice-cold stirred suspension of **13** (30.4 mg, 0.0767 mmol) in dry ether (1.67 ml), 1.60 M ethyllithium in ether (0.0478 ml, 0.0765 mmol) was added dropwise. After being stirred at 0 °C for 1 h, a saturated aqueous NH_4Cl solution was added to the mixture. The mixture was extractred with ether and the extracts were washed with a saturated aqueous NaCl solution, dried, and evaporated. The residue was chromatographed on silica gel (3.2 g) with 8:1 toluene-ethyl acetate to give 8.5 mg (26%) of pale yellow-brown crystals and the unchanged starting lactone **13** (19.5 mg, 64% recovered). Recrystallization from chloroform-hexane gave slightly brown mossy crystals. This material was identical with **11** prepared from **10** in all respects (TLC, ^{1}H-NMR, IR, UV, mp).

5,7-Bis(benzyloxy)-6-methyl-8-propionyl-1,4-naphthalenedione (14). To an ice-cold stirred suspension of **11** (9.29 g, 21.8 mmol) in methanol (186 ml) a solution of thallium(III) nitrate trihydrate (29.0 g, 65.3 mmol) in methanol (145 ml) was added dropwise. The resulting mixture was stirred at 0 °C for 3 h and treated with ice-cold water (330 ml). The mixture was extrated with ethyl acetate (650 ml) and the extract was washed with a saturated aqueous $NaHCO_3$ solution, water, and a saturated aqueous NaCl solution successively, dried and evaporated. The residue was chromatographed on silica gel (480 g) with 13:1 toluene-ethyl acetate to afford **14** (7.90 g, 82%) as yellow crystals. An analytical sample was obtained after recrystallization (three times) from ethanol: mp 144.5—146 °C (yellow needles); R_f=0.54 (8:1 toluene-ethyl acetate); IR (KBr) 1698, 1665, and 1615 cm^{-1}; UV (EtOH) λ (log ε) 231(4.57), 253(4.35), and 363 nm (3.57); ^{1}H-NMR δ=1.25 (3H, t, $CH_2\underline{Me}$, J=7.2 Hz), 2.22 (3H, s, ArMe), 2.55—2.95 (2H, m, $C\underline{H}_2Me$), 4.83 and 4.97 (each 2H, br s and s, 2×$OC\underline{H}_2Ph$), 6.89 (2H, s, H-2 and 3), and 7.42 (10H, s, 2× Ph).

Found: C, 76.60 ; H, 5.66%. Calcd for $C_{28}H_{24}O_5$: C, 76.35 ; H, 5.49%.

1-[2,4-Bis(benzyloxy)-5,8-dimethoxy-3-methyl-1-naphthyl]-1-propanone (15). A mixture of **14** (5.00 g, 11.4 mmol), pyridine (6.89 ml, 85.2 mmol), Lindlar catalyst (1.50 g), and acetone (200 ml) was vigorously stirred at room temperature for 10 min under bulbling with H_2. The suspension was filtered with celite and the filter cake was washed with acetone under an argon atomosphere. To the combined filtrate and washings, dimethyl sulfate (10.7 ml, 113 mmol) and K_2CO_3 (7.84 g, 56.7 mmol) were added and vigorously stirred at room temperature for 41 h. To the resulting mixture dimethyl sulfate (10.7 ml, 113 mmol) and K_2CO_3 (7.84 g, 56.7 mmol) were added and stirring was continued for additional 52 h. The insoluble matter was filtered with celite and the filter cake was washed with acetone. The combined filtrate and washings were evaporatred and the residue was dissolved in ethyl acetate (300 ml). The solution was washed with water (100 ml) and a saturated aqueous NaCl solution (100 ml), dried, and evaporated. The residue was chromatographed on silica gel (300 g) with 17:1 toluene-ethyl acetate to give **15** (3.97 g, 74%) as pale green crystals. An analytical sample was obtained after recrystallization from chloroform-hexane: mp 118.7—119.5 °C (colorless needles); R_f= 0.35 (17:1 toluene-ethyl acetate); IR (KBr) 1708 cm^{-1}; UV (EtOH) λ (log ε) 222 (4.72), 249 (4.46), 327 (3.90), and 340 nm (3.86); ^{1}H-NMR δ=1.19 (3H, t, $CH_2\underline{Me}$, J=7.0 Hz), 2.36 (3H, s, ArMe), 2.83 (2H, dq, $C\underline{H}_2Me$, J_{gem}=7.0 Hz), 3.85 (6H, s, 2×OMe), 4.85 and 4.86 (each 1H, ABq, $OC\underline{H}_2Ph$, J_{gem}= 10.5 Hz), 4.92 (2H, s, $OC\underline{H}_2Ph$), 6.77 (2H, s, H-6 and 7), and 7.20—7.65 (10H, m, 2×Ph).

Found: C, 76.74; H, 6.52%. Calcd for $C_{30}H_{30}O_5$: C, 76.57; H, 6.43%.

1-(2,4-Dihydroxy-5,8-dimethoxy-3-methyl-1-naphthyl)-1-propanone (16). A solution of **15** (1.53 g, 3.25 mmol) in ethyl acetate (30 ml) was stirred with palladium black (in methanol) at 25 °C for 20 min under bubbling with H_2. The filtered solution was then evaporated to afford the crude **16** (944 mg, 100%) as yellow-brown crystals. This sample was pure enough for the next steps without further purification. A part of this was recrystallized from 1:3 ethyl acetate-hexane to give an analytical sample as yellow-green needles: mp 111—112 °C; R_f=0.40 (3:1 hexane-acetone); IR (KBr) 3305 and 1630 cm^{-1}; UV (0.01 M HCl-EtOH) λ (log ε) 232 (4.40), 272 (3.76), 315 (3.61), 347 (3.57), and 370 nm (3.41); ^{1}H-NMR δ=1.12 (3H, t, $CH_2\underline{Me}$, J=7.5 Hz), 2.21 (3H, s, ArMe), 2.35—2.80 (2H, m, $C\underline{H}_2Me$), 3.81 and 4.03 (each 3H, each s, 2×OMe), 6.67 and 6.73 (each 1H, ABq, H-6 and 7, J=9.0 Hz), and 10.26 and 10.73 (each 1H, s and br s, 2×OH).

Found: C, 65.95; H, 6.20%. Calcd for $C_{16}H_{18}O_5$: C, 66.19; H, 6.25%.

1-[5,8-Dimethoxy-2,4-bis(methoxymethoxy)-3-methyl-1-naphthyl]-1-propanone (17). To an ice-cold stirred solution of **16** (841 ml, 2.90 mmol) in dry THF (16.8 ml) was added sodium hydride (209 mg, 8.71 mmol) and the mixture was stirred at 20°C for 15 min, then cooled to 0°C. To this was added chloromethyl methyl ether (0.660 ml, 8.69 mmol) and the mixture was stirred at 20°C for 1 h. The resulting reaction mixture was poured into ice-water and the mixture was extracted with ether. The extract was washed with a saturated aqueous NaCl solution, dried and evaporated. The residue was chromatographed on silica gel (55 g) with 4:1 toluene–ethyl acetate to afford **17** (1.04 g, 95%) as a yellow-brown syrup. An analytical sample was obtained after recolumn chromatography with 3:1 hexane–acetone as a pale yellow syrup: R_f=0.23 (3:1 hexane–acetone); IR ($CHCl_3$) 1697 cm^{-1}; UV (EtOH) λ (log ε) 222 (4.62), 249 (4.40), 327 (3.88), and 340 nm (3.84); ^{1}H-NMR δ=1.20 (3H, t, $CH_2\underline{Me}$, J=7.5 Hz), 2.45 (3H, s, ArMe), 2.79 (2H, dq, $C\underline{H}_2Me$, J=7.5 and 9.0 Hz), 3.57, 3.63, 3.79, and 3.89 (each 3H, each s, 4×OMe), 4.96 and 5.05 (each 2H, *ca.* s and s, 2×OCH_2Ph), and 6.73 (2H, s, H-6 and 7).

Found: C, 63.20; H, 6.97%. Calcd for $C_{20}H_{26}O_7$: C, 63.48; H, 6.92%.

1-[5,8-Dimethoxy-2,4-bis(methoxymethoxy)-3-methyl-6-nitro-1-naphthyl]-1-propanone (3). To 10.0 ml of acetic anhydride, copper(II) nitrate trihydrate (1.00 g, 4.14 mmol) was added portionwise. The mixture was stirred at 30°C for 10 min and cooled to −40°C. To this mixture, a solution of **17** (1.43 g, 3.78 mmol) in acetic anhydride (14.3 ml) was added dropwise. After being stirred at −40°C for 1 h, ether (30 ml) and water (20 ml) were added to the mixture and the mixture was allowed to warm to room temperature. The organic layer was separated and the aqueous layer was extracted with ether (20 ml×2). The combined extracts were washed with a saturated aqueous NaCl solution (20 ml×3), dried, and evaporated. The residue was chromatographed on silica gel (80 g) with 10:1 toluene–ethyl acetate to afford **3** (1.26 g, 79%) as green crystals. This sample was treated with charcoal in ether to afford pure **3** (1.23 g, 77%) as yellow prisms: mp 89.5—90.5°C (hexane); R_f=0.30 (10:1 toluene–ethyl acetate); IR (KBr) 1715 cm^{-1}; UV (EtOH) λ (log ε) 233 (4.55), and 378 nm (3.58); ^{1}H-NMR δ=1.22 (3H, t, $CH_2\underline{Me}$, J=7.0 Hz), 2.49 (3H, s, ArMe), 2.79 (2H, dq, $C\underline{H}_2Me$, J_{gem}=7.0 Hz), 3.58 and 3.62 (each 3H, each s, 2×$CH_2O\underline{Me}$), 3.90 and 3.92 (each 3H, each s, 2×OMe), 4.97 and 5.03 (each 2H, each s, 2×OCH_2O), and 7.07 (1H, s, ArH).

Found: C, 56.45; H, 5.91; N, 3.18%. Calcd for $C_{20}H_{25}NO_9$: C, 56.73; H, 5.95; N, 3.31%.

Transformation of 3 into 1. A solution of **3** (13.9 mg, 0.0328 mmol) in THF (0.28 ml) and 1 M HCl (0.14 ml) was stirred at 23°C for 3 d. The reaction mixture was diluted with ethyl acetate, washed with water and a saturated aqueous NaCl solution, dried, and evaporated. The residual orange-yellow crystals of **18** [11.0 mg, 100%; R_f=0.49 (10:1 toluene–ethyl acetate); ^{1}H-NMR δ=1.14 (3H, t, $CH_2\underline{Me}$, J=7.5 Hz), 2.25 (3H, s, ArMe), 2.40—2.75 (2H, m, $C\underline{H}_2Me$), 3.95 and 4.11 (each 3H, each s, 2×OMe), 7.37 (1H, s, ArH), 10.30 and 10.58 (each 1H, each s, 2×OH)] was suspended in 0.22 ml of acetone and cooled to 0°C. To this were added dimethyl sulfate (0.0124 ml, 0.131 mmol) and K_2CO_3 (18.1 mg, 0.131 mmol). After being stirred at 20°C for 5 h, the mixture was filtered with celite and the filter cake was washed with acetone. The combined filtrate and washings were evaporated and the residue was chromatographed on silica gel (1.5 g) with 15:1 toluene–ethyl acetate to give yellow crystals (11.2 mg, 94% from **3**). This sample was identical with **1**[1] in all respects (^{1}H-NMR, IR, TLC, mp).

[1,4-Dimethoxy-6,8-bis(methoxymethoxy)-7-methyl-5-propionyl-2-naphthyl]carbamic Acid Phenyl Ester (20). A solution of **3** (500 mg, 1.18 mmol) in methanol (20 ml) was stirred with 5% Pd–C at 25°C for 20 min under bubbling with H_2. The filtered solution was then evaporated to afford the crude **19** (465 mg, 100%) as a yellow-brown syrup. To the ice-cold stirred solution of this syrup and dry pyridine (0.115 ml, 1.42 mmol) in dichloromethane (4.7 ml), phenyl chloroformate (0.178 ml, 1.42 mmol) was added dropwise and the mixture was stirred at 0°C for 1 h. Then the reaction was quenched by adding water, and the mixture was extracted with dichloromethane. The extract was washed with a saturated aqueous NaCl solution, dried, and evaporated. The residue was chromatographed on silica gel (61 g) with 6:1 toluene–ethyl acetate to give **20** (606 mg, 100%) as a pale yellow syrup. An analytical sample (colorless foam) was obtained after treatment with charcoal in ether and chromatographed again on silica gel with 20:1 chloroform–ethyl acetate: R_f=0.32 (6:1 toluene–ethyl acetate); IR ($CHCl_3$) 3412, 1745, and 1702 cm^{-1}; UV (EtOH) λ (log ε) 256 (4.84) and 318 nm (4.00); ^{1}H-NMR δ=1.20 (3H, t, $CH_2\underline{Me}$, J= 7.2 Hz), 2.46 (3H, s, ArMe), 2.78 (2H, dq, $C\underline{H}_2Me$, J_{gem}=7.2 Hz), 3.56, 3.61, 3.80, and 3.83 (each 3H, each s, 4×OMe), 4.92 and 4.98 (each 1H, ABq, OCH_2O, J_{gem}=7.5 Hz), 5.02 (2H, s, OCH_2O), 7.15—7.50 (5H, m, Ph), 7.80—8.00 (1H, br, NH), and 7.91 (1H, s, H-3).

(Received November 29, 1984)

Four cobalt(III) complexes of the [Co(L-quadridentate-*N,S,O*$_2$)(en)]$^+$ type were prepared; where L-quadridentate-*N,S,O*$_2$ denotes *S*-(carboxymethyl)-L-cysteinate(L-cmc), *S*-(2-carboxyethyl)-L-cysteinate(L-cec), *S*-(carboxymethyl)-L-homocysteinate(L-cmhc), or *S*-(2-carboxyethyl)-L-homocysteinate(L-cehc). Each complex was chromatographically separated into the quasi-enantiomeric isomers; *Λ*L-*trans*(*O*)-*S*(*S*) and *Λ*L-*cis*(*O*)-*R*(*S*) for the L-cmc, L-cmhc, and L-cehc complexes, and *Λ*L-*trans*(*O*)-*R*(*S*) and *Λ*L-*cis*(*O*)-*S*(*S*) for the L-cec one. These isomers were characterized from their absorption and ^{13}C NMR spectra. The sterically strained *Λ*L-*cis*(*O*) isomers exhibited some significant CD spectral behavior in the first d-d absorption band region. The CD spectra are discussed in relation to the sizes of the S-N and S-O chelate rings joining the chiral sulfur atom in the L-quadridentate-*N,S,O*$_2$ ligand.

In the previous papers,[1-3] we reported the stereochemical and spectrochemical properties of the cobalt(III) complexes with an L-quadridentate-*N*$_2$,*S,O* ligand, *S*-(2-aminoethyl)-L-homocysteinate (L-aehc), in which the sulfur atom is fixed by a five-membered terminal S-N and a six-membered medial S-N chelate rings. The L-quadridentate-*N,S,O*$_2$ ligand used in the present work is *S*-(carboxymethyl)-L-cysteinate (L-cmc), *S*-(2-carboxyethyl)-L-cysteinate (L-cec), *S*-(carboxymethyl)-L-homocysteinate (L-cmhc), and *S*-(2-carboxyethyl)-L-homocysteinate (L-cehc), and they are similar to L-aehc in the structure (Fig. 1). However, the L-quadridentate-*N,S,O*$_2$ ligand is different from L-aehc in the sizes of the chelate rings formed. Namely, when the L-quadridentate-*N,S,O*$_2$ ligand coordinates to the cobalt(III) ion, its terminal S-O (**A** ring in Fig. 1) and medial S-N (**B** ring) chelate rings joining the sulfur atom take the ring sizes as summarized in Table 1.

In this work, the [Co(L-quadridentate-*N,S, O*$_2$)(en)]$^+$-type complexes were prepared and chromatographically separated into two geometrical isomers, *Λ*L-*trans*(*O*) and *Λ*L-*cis*(*O*). All isomers were characterized from their absorption spectra. Of these isomers the coordinated sulfur atom of *Λ*L-*cis*(*O*)-[Co(L-cmhc or L-cehc)(en)]$^+$ is possible to take either configuration of *R*(*S*) and *S*(*S*), and these configurations were suggested on the basis of the ^{13}C NMR spectra. The CD spectral behaviors due to the difference in ring sizes of the chelates, S-N and S-O, were discussed in comparison with those of the L-aehc complexes.[1-3]

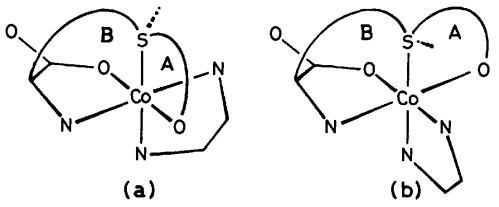

Fig. 1. Possible isomers of [Co(L-quadridentate-*N,S,O*$_2$)(en)]$^+$: (a) *Λ*L-*trans*(*O*) and (b) *Λ*L-*cis*(*O*).

TABLE 1. CHELATE RING SIZES OF **A** AND **B** RINGS IN Fig. 1

Ligand	**A** ring[a]	**B** ring[a]
L-cmc	5	5
L-cec	6	5
L-cmhc	5	6
L-cehc	6	6

a) **A** and **B** rings correspond to terminal S-O and medial S-N rings, respectively.

Experimental

Preparation of Ligands. 1) S-(Carboxymethyl)-L-homocysteine and S-(2-Carboxyethyl)-L-homocysteine: L-H$_2$*cmhc and L-H*$_2$*cehc.* These ligands were prepared by the method of Armstrong and Lewis.[4] Anal. for L-H$_2$cmhc ($C_6H_{11}NO_4S$) C, H, N. Anal. for L-H$_2$cehc ($C_7H_{13}NO_4S$) C, H, N. $[\alpha]_D^{24}$= +34.9° for L-H$_2$cmhc and $[\alpha]_D^{24}$=+44.4° for L-H$_2$cehc (*c* 1.0, 1 mol dm^{-3} HCl).

2) S-(2-Carboxyethyl)-L-cysteine: L-H$_2$*cec.* This ligand was prepared by a procedure similar to that used for (*R*)-2-(carboxymethylthio)propionic acid.[5] Anal. ($C_6H_{11}NO_4S$) C, H, N. $[\alpha]_D^{24}$=−14.8° (*c* 1.0, 1 mol dm^{-3} HCl).

3) S-(Carboxymethyl)-L-cysteine: L-H$_2$*cmc.* This ligand was supplied by the Aldrich Chemical Co. Ltd., and used without purification.

Preparation and Separation of Complexes. 4) {S-(Carboxymethyl)-L-homocysteinato}(ethylenediamine)cobalt(III) Chlolide: [Co(L-cmhc)(en)]Cl. A solution containing 2.0 g of L-H$_2$cmhc in 40 cm^3 of water was adjusted to pH 7 with a 1 mol dm^{-3} aqueous solution of sodium hydroxide. To this solution were added a solution containing 2.0 g of *trans*-[Co(Cl)$_2$(en)$_2$]Cl[6] in 10 cm^3 of water and 0.5 g of activated charcoal. The mixture was stirred at *ca.* 75 °C for 15 min, while the color of the solution changed from green to purple. After the solution had been cooled to room temperature, it was filtered and the filtrate was poured onto a column of Dowex 50W-X8 (200—400 mesh, Na^+ form, 2.0 cm×50 cm). After the column had been swept with water, the adsorbed band was eluted with a 0.05 mol dm^{-3} aqueous solution of NaCl. Two colored bands, red-violet (A-1) and red (A-2), were eluted in this order. It was found, from the absorption spectral measurements, that eluates A-1 and A-2 contained *trans*(*O*)- and *cis*(*O*)-[Co(L-cmhc)(en)]$^+$, respectively. Each eluate was concentrated to a small volume with a rotary evaporator below 25 °C and the deposited NaCl was filtered off. The filtrate was passed through a column of Sephadex G-10

(2.0 cm×150 cm) by elution with water and the eluate was concentrated again. After adding a small amount of ethanol, the solution was kept in a refrigerator. The crystals appeared were collected by filtration, and washed with ethanol and then ether. Isomer A-1 was obtained as flaky red-violet crystals and isomer A-2 as red needle ones. Found for A-1: C, 27.54; H, 5.07; N, 12.13%. Calcd for [Co(L-cmhc)(en)]Cl·0.25H_2O=$CoC_8H_{17}N_3O_4SCl$·0.25H_2O: C, 27.44; H, 5.04; N, 12.00%. Found for A-2: C, 26.54; H, 5.27; N, 11.68%. Calcd for [Co(L-cmhc)(en)]Cl·H_2O: C, 26.42; H, 5.27; N, 11.55%.

5) {S-(2-Carboxyethyl)-L-homocysteinato}(ethylenediamine)cobalt(III) Chloride: [Co(L-cehc)(en)]Cl. This complex was prepared and the isomers were chromatographically separated by the same procedure as for *4)*, using L-H_2cehc instead of L-H_2cmhc. Two colored bands, red-violet (B-1) and red (B-2), were eluted in this order, and eluates B-1 and B-2 contained *trans(O)*- and *cis(O)*-[Co(L-cehc)(en)]$^+$, respectively. Isomers B-1 and B-2 were obtained as red-violet flaky and red needle crystals, respectively. Found for B-1: C, 28.80; H, 5.47; N, 11.44%. Calcd for [Co(L-cehc)(en)]Cl·0.5H_2O=$CoC_9H_{19}N_3O_4SCl$·0.5H_2O: C, 29.31; H, 5.47; N, 11.48%. Found for B-2: C, 28.78; H, 5.65; N, 11.43%. Calcd for [Co(L-cehc)(en)]Cl·H_2O: C, 28.61; H, 5.61; N, 11.13%.

6) {S-(2-Carboxyethyl)-L-cysteinato}(ethylenediamine)cobalt(III) Chloride: [Co(L-cec)(en)]Cl. This complex was prepared and the isomers were chromatographically separated by the same procedure as for *4)*, using L-H_2cec instead of L-H_2cmhc. Two colored bands, red-violet (C-1) and red (C-2), were eluted in this order, and eluates C-1 and C-2 contained *trans(O)*- and *cis(O)*-[Co(L-cec)(en)]$^+$, respectively. Isomers C-1 and C-2 were also obtained as red-violet flaky and red needle crystals, respectively. Found for C-1: C, 26.50; H, 5.18; N, 11.75%. Calcd for [Co(L-cec)(en)]Cl·0.75H_2O=$CoC_8H_{17}N_3O_4$-SCl·0.75H_2O: C, 26.75; H, 5.19; N, 11.70%. Found for C-2: C, 25.08; H, 5.48; N, 11.21%. Calcd for [Co(L-cec)(en)]-Cl·1.75H_2O: C, 25.47; H, 5.48; N, 11.14%.

7) {S-(Carboxymethyl)-L-cysteinato}(ethylenediamine)cobalt(III) Chloride: [Co(L-cmc)(en)]Cl. This complex was also prepared and the isomers were chromatographically separated by the same procedure as for *4)*, using L-H_2cmc instead of L-H_2cmhc, except for adding activated charcoal. Two colored bands, red-violet (D-1) and red (D-2), were eluted in this order, and eluates D-1 and D-2 contained *trans(O)*- and *cis(O)*-[Co(L-cmc)(en)]$^+$, respectively. The yield of the slower eluted isomer (D-2) was very poor and this was obtained by repeating the preparation several times. Isomers D-1 and D-2 were also obtained as red-violet flaky and red needle crystals, respectively. Found for D-1: C, 24.07; H, 4.77; N, 12.24%. Calcd for [Co(L-cmc)(en)]Cl·0.75H_2O=$CoC_7H_{15}N_3O_4SCl$·0.75H_2O: C, 24.36; H, 4.82; N, 12.17%. Found for D-2: C, 24.83; H, 4.71; N, 12.52%. Calcd for [Co(L-cmc)(en)]Cl·0.25H_2O: C, 25.01; H, 4.65; N, 12.50%.

Measurements. The electronic absorption spectra were recorded with JASCO UVIDEC-1 and UVIDEC-610 spectrophotometers, and the CD spectra with a JASCO J-20 spectropolarimeter. All the measurements were carried out at room temperature.

The ^{13}C NMR spectra were recorded with a JEOL JNM-FX-100 NMR spectrometer at the probe temperature. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal reference.

Results and Discussion

Two quasi-enantiomeric geometrical isomers, ΛL-*trans(O)* and ΛL-*cis(O)*, are possible for the present [Co(L-quadridentate-*N,S,O*$_2$)(en)]$^+$-type complexes with L-cmc, L-cec, L-cmhc, and L-cehc (Fig. 1).[7] The ΛL-*trans(O)* isomers take the facial coordination with respect to the terminal S–O and medial S–N chelate rings joining the sulfur atom, while the ΛL-*cis(O)* isomers take the meridional one, where the terminal S–O and medial S–N chelate rings correspond to rings **A** and **B** in Fig. 1, respectively. The representative absorption spectra of [Co(L-quadridentate-*N,S,O*$_2$)(en)]$^+$ are shown in Fig. 2, and the data are summarized in Table 2. The eight isomers are classified into two groups based on the splittings of their first d-d absorption bands. One exhibits an explicit shoulder on the higher energy side of the major peak at 18.2—18.5×10^3 cm^{-1}, and the other a sharp band at 19.3—19.6×10^{3}cm^{-1}. Referring to the splitting of the first d-d absorption band of the [Co(N)$_3$(S)(O)$_2$]-type complexes,[1-3,8] the former group can be assigned as ΛL-*trans(O)* and the latter as ΛL-*cis(O)*. This assignment is consistent with that based on their ^{13}C NMR and CD spectra (*vide infra*). The terminal S–O and medial S–N chelate rings in [Co(L-quadridentate-*N,S,O*$_2$)(en)]$^+$ take the ring sizes as summarized in Table 1. As the ring size increases, the sulfur to metal charge transfer band at *ca.* 36×10^3 cm^{-1} for each of the ΛL-*trans(O)* and ΛL-*cis(O)* isomers shifts to lower energy in the following order: L-cmc>L-cmhc>L-cec>L-cehc (Table 2).

As shown in Fig. 3, the ^{13}C NMR spectra for [Co(L-quadridentate-*N,S,O*$_2$)(en)]$^+$ exhibit the resonance lines less than or equal to the numbers of the carbon

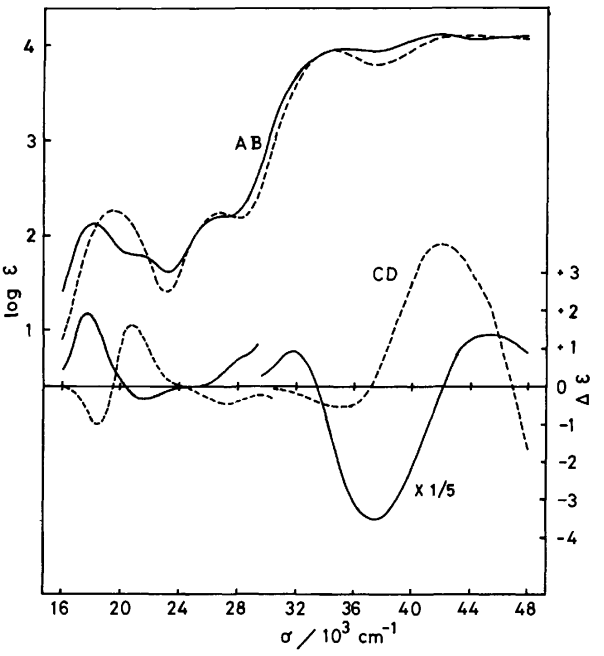

Fig. 2. Absorption and CD spectra of [Co(L-cehc)(en)]$^+$: ΛL-*trans(O)* (——) and ΛL-*cis(O)* (----).

TABLE 2. ABSORPTION AND CD SPECTRAL DATA OF [Co(quadridentate-N,S,O_2)(en)]$^+$

Complex	Absorption $\sigma/10^3\,cm^{-1}$ ($\varepsilon/mol^{-1}\,dm^3\,cm^{-1}$)	CD $\sigma/10^3\,cm^{-1}$ ($\Delta\varepsilon/mol^{-1}\,dm^3\,cm^{-1}$)

a) Sh denotes a shoulder.

atoms in the L-quadridentate-N,S,O_2 and en ligands. When the complexes take only *R(S)* or *S(S)* configuration[7] with respect to the chiral sulfur atom, the ^{13}CNMR spectra can be expected to show seven resonance lines for the L-cmc complex, eight ones for the L-cec and L-cmhc complexes, and nine ones for the L-cehc complex. While, when the complexes are a mixture of the *R(S)* and *S(S)* isomers and/or the other species such as [Co(L-cmc)(en)(H_2O)]$^+$ more multiple peaks can be expected for their ^{13}CNMR spectra. The present result suggests that each of the complexes takes either *R(S)* or *S(S)* configuration. According to the model constructions, the coordinated sulfur atoms of Δ_L-*cis(O)*-[Co(L-cmc)(en)]$^+$ and Δ_L-*trans(O)*-[Co(L-cec)(en)]$^+$ are limited to *R(S)* configuration, whereas those of Δ_L-*trans(O)*-[Co(L-cmc)(en)]$^+$, Δ_L-*cis(O)*-[Co(L-cec)(en)]$^+$, Δ_L-*trans(O)*-[Co(L-cmhc)(en)]$^+$, and Δ_L-*trans(O)*-[Co(L-cehc)(en)]$^+$ to *S(S)* configuration. In contrast to the above isomers, the coordinated sulfur atom of Δ_L-*cis(O)*-[Co(L-cmhc or L-cehc)(en)]$^+$ can take either configuration of *R(S)* and *S(S)*, depending on the conformation of the medial S–N chelate ring,[9] as in the case of the L-aehc complexes.[1-3] The Δ_L-*S(S)*- and Δ_L-*R(S)*-[Co(L-aehc)(en)]$^{2+}$ isomers exhibited a well defined

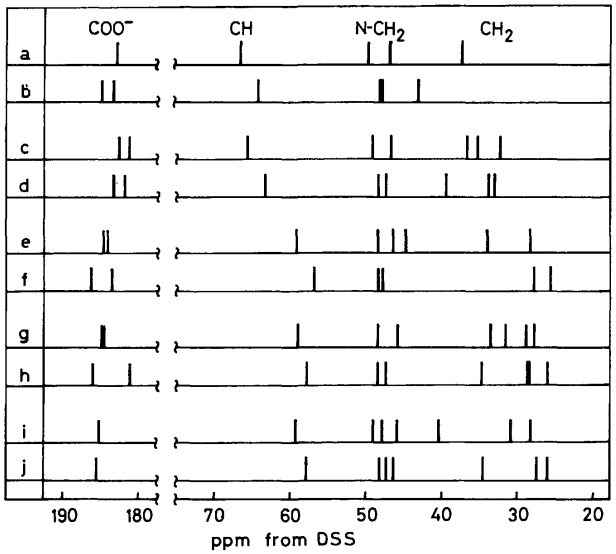

Fig. 3. The distribution of ^{13}C NMR chemical shifts of [Co(L)(en)]: L=L-cmc, a and b; L=L-cec, c and d; L=L-cmhc, e and f; L=L-cehc, g and h; and L=L-aehc, i and j. a, c, e, and g are Δ_L-*cis(O)* isomers, b, d, f, and h are Δ_L-*trans(O)* isomers, i is Δ_L isomer, and j is Λ_L isomer.

^{13}C NMR spectral relationship with regard to their β-methylene and the other carbon atom regions.[3] A similar relationship is also observed for the ^{13}C NMR spectra of the Λ_L-*trans(O)* and Δ_L-*cis(O)* isomers of each complex in the present work, especially in the methine carbon atom region (Fig. 3); namely, Λ_L-*trans(O)-S(S)* and Δ_L-*cis(O)-R(S)* for the L-cmc complex, Λ_L-*trans(O)-R(S)* and Δ_L-*cis(O)-S(S)* for the L-cec one, and Λ_L-*trans(O)-S(S)* and Δ_L-*cis(O)-R(S)* or -*S(S)* for the L-cmhc and L-cehc ones. Taking account of the shielding effect due to the two carboxyl groups[10,11] and the steric effect due to the interaction between the terminal S–O and medial S–N chelate rings, as in the L-aehc complexes,[3] the distribution of the chemical shifts for each of the methine, *N*-methylene, and carboxylate carbons in the L-quadridentate-*N,S,O*$_2$ and en ligands seems to depend on the direction of the terminal S–O chelate ring regardless of its chelate ring size. Thus, it is assumed that the Δ_L-*cis(O)* isomers of the L-cmhc and L-cehc complexes may take *R(S)* configuration.

Figure 2 shows the representative CD curves for [Co(L-quadridentate-*N,S,O*$_2$)(en)]$^+$, and the CD data are summarized in Table 2. The overall CD patterns for the L-cehc isomers are almost enantiomeric, although some deviations are observed in the region of 30—48×10^3 cm^{-1} (Fig. 2). A similar trend was also observed for the CD spectra of the isomers of each of the L-cmc, L-cec, and L-cmhc complexes (Table 2). In the first d-d absorption band region, the *trans(O)* and *cis(O)* isomers of the present complexes exhibit similar CD patterns to those of the Λ_L-*S(S)* and Δ_L-*R(S)* isomers of [Co(L-aehc)(L)] (L; ox, gly, en, and $(NH_3)_2$), respectively, whose CD patterns depend mainly on the coordination mode of the L-quadridentate-*N*$_2$*,S,O* ligand, L-aehc, regardless of the kind of ligand coordinating to the two remaining coordination sites.[1-3] These facts indicate that the *trans(O)* isomers take Λ_L coordination with respect to the configurational chirality of the coordinated L-quadridentate-*N,S,O*$_2$ ligand and the *cis(O)* isomers take Δ_L one, namely, Λ_L-*trans(O)* and Δ_L-*cis(O)*.

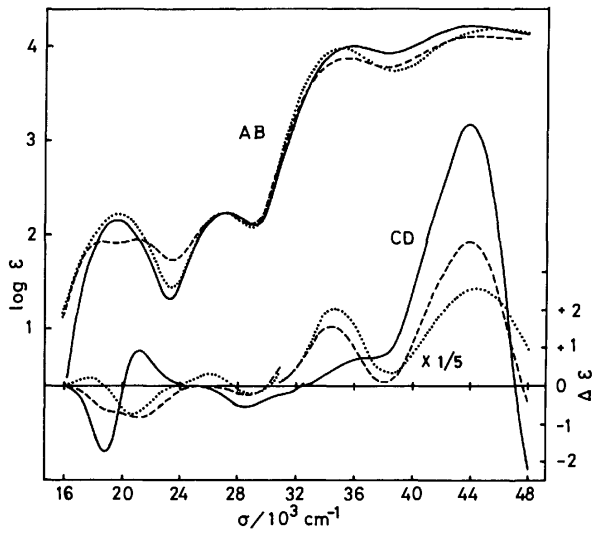

Fig. 4. Absorption and CD spectra of Δ_L-*cis(O)*-[Co(L-cmhc)(en)]$^+$ (——), Δ_L-*cis(O)*·*mer(N)*-[Co(L-aehc)(gly)]$^+$ (·····), and Δ_L-*trans(O)*·*mer(N)*-[Co(L-aehc)(gly)]$^+$ (----).

The absorption and CD spectra of Δ_L-*cis(O)-R(S)*-[Co(L-cmhc)(en)]$^+$, which has a quite similar framework and steric environment to the L-aehc complexes, are shown in Fig. 4, together with those of Δ_L-*cis(O)*·*mer(N)-R(S)*- and Δ_L-*trans(O)*·*mer(N)-R(S)*-[Co(L-aehc)(gly)]$^+$.[3] The Δ_L-*cis(O)-R(S)* L-cmhc isomer exhibits a more sharp first d-d absorption band than Δ_L-*cis(O)*·*mer(N)-R(S)*-[Co(L-aehc)(gly)]$^+$, indicating the *fac(N)* form (Fig. 4).[3] The Δ_L-*cis(O)-R(S)* L-cmhc isomer exhibits a different CD pattern in the first d-d absorption band region from Δ_L-*cis(O)*·*mer(N)-R(S)*- and Δ_L-*trans(O)*·*mer(N)-R(S)*-[Co(L-aehc)(gly)]$^+$, while Λ_L-*trans(O)-S(S)*-[Co(L-cmhc](en)]$^+$ and Λ_L-*cis(O)*·*mer(N)-S(S)*- and Λ_L-*cis(O)*·*fac(N)-S(S)*-[Co(L-aehc)(gly)]$^+$ exhibit similar CD patterns, (+) and (−) CD bands from lower energy.[1-3] These indicate that the CD pattern of the Δ_L-*cis(O)-R(S)*-[Co(L-cmhc)(en)]$^+$ isomer depends remarkably on the geometrical configuration with respect to the coordinated atom as in the case of the L-aehc complexes.[3] In the region of 32—48×10^3 cm^{-1}, it should be noted that the Δ_L-*R(S)* isomers commonly exhibit positive CD bands, suggesting that the configurational chirality due to the L-quadridentate ligand, Δ_L-*R(S)*, is mainly responsible for the CD pattern in this region, as in Δ_L-*R(S)*-[Co(L-aehc)(L)] (L; ox, gly, en, and $(NH_3)_2$).

The four Λ_L-*trans(O)* isomers of [Co(L-quadridentate-*N,S,O*$_2$)(en)]$^+$ exhibit some notable differences in CD intensity in the first d-d absorption band region. As shown in Fig. 5, the order of their CD intensities is L-

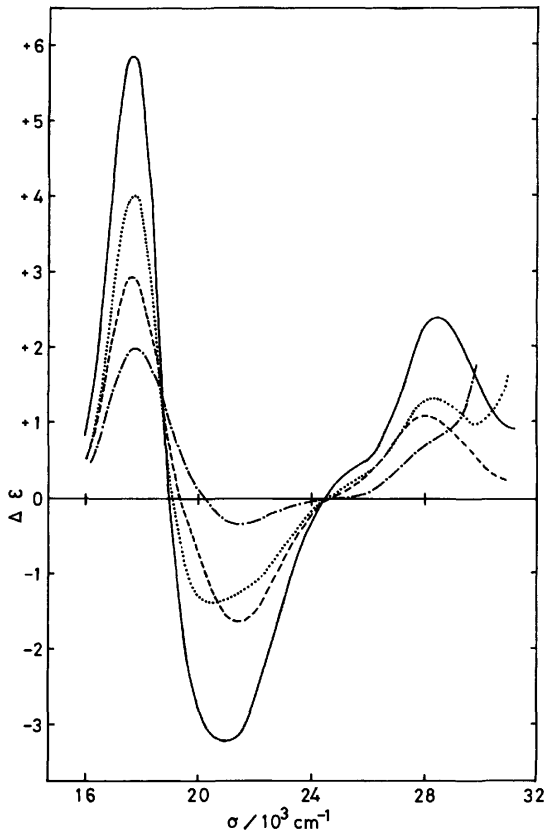

Fig. 5. CD spectra of Δ_L-*trans(O)*-[Co(L)(en)]$^+$: L=L-cmc (——), L-cmhc (·····), L-cec (----), and L-cehc (-·-·-·-).

cmc>L-cmhc>L-cec>L-cehc. This seems to be related to the ring sizes of the terminal S–O and medial S–N chelates. Namely, the L-cec and L-cehc isomers with the six-membered S–O chelate ring exhibit much weaker CD bands than the L-cmc and L-cmhc isomers with the five-membered one (Table 1). The L-cehc isomer taking the six-membered S–N chelate ring also exhibits more weak CD bands than the L-cec isomer taking the five-membered one (Table 1). A similar relationship was also observed for the L-cmc and L-cmhc isomers. The CD spectral change in intensity will be attributable to the rigidity of the chelate rings joining the chiral sulfur atom. In contrast to the Δ_L-*trans(O)* isomers, two types of the CD patterns are observed for the Δ_L-*cis(O)* isomers in the first d-d absorption band region (Fig. 6), namely, one is Δ_L-*cis(O)*-[Co(L-cmc or L-cec)(en)]$^+$ taking the medial five-membered S–N chelate ring and the other Δ_L-*cis(O)*-[Co(L-cmhc or L-cehc)(en)]$^+$ taking the six-membered one. The Δ_L-*cis(O)* isomer of [Co(L-cmhc or L-cehc)(en)]$^+$ exhibits an almost enantiomeric CD pattern to that of the corresponding Δ_L-*trans(O)* one, while the CD pattern for the Δ_L-*cis(O)* isomer of [Co(L-cmc or L-cec)(en)]$^+$ deviates significantly from that for the corresponding Δ_L-*trans(O)* one, as seen in Fig. 6. Of the four Δ_L-*cis(O)* isomers, the L-cmhc and L-cehc isomers are possible to take either configuration of *R(S)* or *S(S)* depending on the conformations

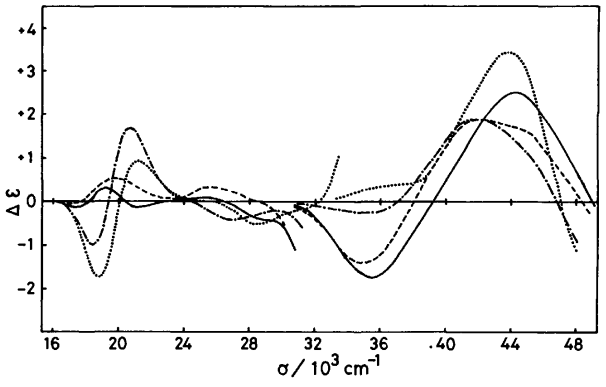

Fig. 6. CD spectra of Δ_L-*cis(O)*-[Co(L)(en)]$^+$: L=L-cmc (——), L-cmhc (·····), L-cec (----), and L-cehc (-·-·-·-).

(chair and skew-boat)[9] of the medial six-membered S–N chelate ring because of the flexible methioninate moiety.[1–3] From the good enantiomeric correspondence of the CD patterns of the two Δ_L-*cis(O)* isomers to the common CD pattern for the four Δ_L-*trans(O)*-[Co(L-quadridentate-N,S,O_2)(en)]$^+$ isomers, it is tentatively assigned that the Δ_L-*cis(O)* isomer of [Co(L-cmhc or L-cehc)(en)]$^+$ takes *R(S)* configuration in accordance with the assignment based on their ^{13}C NMR spectra. In the Δ_L-*cis(O)* isomer of [Co(L-cmc or L-cec)(en)]$^+$, on the other hand, the terminal S–O chelate ring is strongly strained because of the rigid cysteinate moiety. From this viewpoint, it may be assumed that the deviation in the CD pattern in the first d-d absorption band region is related to the flexibility around the chiral sulfur atom in the L-quadridentate-N,S,O_2 ligand.

Synthetic Inorganic Ion-exchange Materials. XXXX. Ion Exchange Properties of Tin(IV) Antimonate for Alkaline Earth and Transition Metal Ions and Its Application to Metal Separations

Mitsuo ABE* and Noboru FURUKI†

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, 2-12-1, Ookayama, Meguro-ku, Tokyo 152

(Received December 14, 1984)

Ion-exchange selectivities of alkaline earth and transition metal ions on tin(IV) antimonate cation exchanger were investigated in nitric acid media. The selectivity sequences were found to be; $Mg^{2+}<Ca^{2+}<Sr^{2+}<Ba^{2+}$ for alkaline earth metal ions and $Ni^{2+}<Mn^{2+}<Cd^{2+}<Co^{2+}<Cu^{2+}<Zn^{2+}$ for transition metal ions. The separation factors for neighboring pairs on the exchanger gave larger values than those on the ion-exchange resin of a strong acid type. The effective separations of Mg^{2+}-Ca^{2+}, Sr^{2+}-Ba^{2+}, and Na^{+}-Cs^{+}, Sr^{2+} have been achieved with a small column (5cm×0.5 cm i.d.).

The synthesis and ion-exchange properties of inorganic materials have been studied extensively by many workers.[1-4] Some inorganic ion-exchangers showed an excellent selectivity for a certain element or group of elements in the presence of large amounts of other components.

Phosphates of quadrivalent metals, such as zirconium and titanium, have been studied extensively by several workers.[5] Quadrivalent metal antimonate ion-exchangers were studied by Abe and Ito.[6] Tin(IV) and titanium(IV) antimonates (SnSbA and TiSbA) behaved as cation exchangers with relatively high capacities, and showed unusual selectivities for alkali metal ions in the order: $Na^{+}<K^{+}<Rb^{+}<Cs^{+}\ll Li^{+}$ on SnSbA,[7] and $Na^{+}<K^{+}<Rb^{+}<Li^{+}<Cs^{+}$ on TiSbA,[8] which are not included in Eisenman's selectivity series.[9] Thermal and chemical stabilities, and the selectivities of various metal antimonates for a number of metal ions have also been reported by Qureshi and co-workers.[10] The ion-exchange behavior of tin(IV) antimonate prepared by metathesis of $SnCl_4$ and $H[Sb(OH)_6]$, has been studied by Mathew and Tandon.[11] It has been known that the ion-exchange properties including the selectivities of inorganic ion-exchangers depend much on their preparative conditions. Especially, SnSbA with relatively high molar ratio of Sb/Sn up to 2.0 showed an excellent selectivity for lithium ions and could be applied to the removal of lithium ions from a large amount of sodium ions in solutions, such as seawater and hydrothermal water.[12]

This paper describes the ion-exchange properties of SnSbA for alkaline earth metal ions and its applications to chromatographic separations.

Experimental

Preparation of SnSbA. Suitable conditions were chosen so that the highest selectivity for lithium ions may be obtained.[7] The preparation procedure is as follows. A 62 cm^3 of liquid antimony(V) chloride was prehydrolyzed with an equal amount of demineralized water in order to prevent fractional precipitation of antimonic acid during the further procedures. The resultant 4 M (M=mol/dm^3) antimony (V) chloride solution was mixed with a 4 M tin(IV) chloride solution of 80 cm^3 at 80 °C. The mixed solution was hydrolyzed immediately in a 50-fold volume of demineralized water at 60 °C. The white precipitate obtained was kept in the mother solution at 60 °C overnight, then filtered and washed with water using a centrifuge (10000 min^{-1}) until the pH value of the supernatant solution was higher than 1.5. After drying at 60 °C, the product was ground and sieved to 100—200 mesh size. The collected samples were rewashed with water to remove adherent fine particle of SnSbA, and finally dried at 60 °C.

The characterization and identification of the SnSbA were carried out by powdered X-ray diffraction analysis with Ni-filtered Cu-$K\alpha$ radiation with a JEOL Model JDX-7, by IR spectra using a KBr technique with a Nihon Bunko Model 701G spectrometer, and by thermal analysis with a Rigaku Denki Thermoflex Model 8001.

Chemical Composition of the SnSbA. The composition was determined as reported previously.[7]

pH Titration Curves. The pH titration curve of the ion exchanger is one of its important characteristic properties. The character of the ion exchanging groups can be estimated from the pH titration curve as well as the ion-exchange capacity. A weighed amount (0.10 g) of the sample was immersed in 10.0 cm^3 of a mixed solution of varying ratio of $\{M(NO_3)_n+KOH\}$ or $\{M(NO_3)_n+HNO_3\}$ adjusted to an ionic strength of 0.1 with intermittent shaking at 30±0.5 °C. After the attainment of equilibrium, the pH of the supernatant solution was measured with a Toa model HM-5B pH meter. The amounts of the uptake of the metal ions were calculated from the difference in the metal ion concentration relative to the initial concentration in the solution.

Distribution Coefficient, K_d. The equilibrium K_d values of the metal ions were determined by a batch technique. The SnSbA was immersed in 10.0 cm^3 of a solution containing the metal ions of 10^{-4} M and nitric acid of different concentrations. The concentration of the metal ions in the exchanger and solution was deduced from the concentration relative to the initial concentration in the solution. The concentrations of metal ions were determined by flame photometry or atomic absorption spectrometry with a Varian Techtron 1100. The K_d values were calculated as follows:

$$K_d = \frac{\text{amount of metal ions in exchanger}}{\text{amount of metal ions in solution}} \times \frac{\text{cm}^3 \text{ of solution}}{\text{g of exchanger}}$$

†Present address: Mitsubishi Chem. Co. Ltd., Kurosaki, Yahata, Kita-kyushu 806.

Reagents. Antimony(V) chloride (>99.9% as metal, Yotsuhata Chemical Co. Ltd.) and tin(IV) chloride (Wako Chemical Co. Ltd.) were used without purification. The solutions of transition metal ions were prepared by dissolving the pure metals (>99.99%) in a nitric acid solution at a suitable concentration. Other reagents used were all of analytical grade.

Results and Discussion

Preparation of the SnSbA. The SnSbA obtained was identified by X-ray diffraction analysis, thermal analysis and IR spectra. The results showed a good agreement with those of our previous work.[7] The crystallite size of the SnSbA was found to be 41 Å by using the Scherrer's equation from a plane (110).[13]

Chemical Composition of the SnSbA. The Sb/Sn molar ratio in the SnSbA was found to be 1.88, which is similar to the previous results.[7]

The water content was determined from the weight loss of the heated sample at 950 °C, by assuming that the sample is finaly transformed to a mixture of α- and β-Sb_2O_4, and SnO_2 (cassiterite).[14]

The empirical formula of SnSbA can be given as;

$$SnO_2\ 0.94Sb_2O_5\ 4.95H_2O.$$

pH Titration Curves. A typical example of the pH titration curves is illustrated in Fig. 1. The pH titration curve of the SnSbA showed weak dibasic acid behavior, which is almost the same as reported in the previous work for alkali metal ions.[7] The uptake of strontium ions increased on increasing the pH of the solution, and is higher than that of lithium or potassium ions in the entire range studied. The ion-exchange sites in the SnSbA may be overlapping with different strength of the acidic sites. The uptakes of

lithium and potassium ions on the exchangers were consistent to the amount of hydrogen ions liberated from the exchangers (Fig. 1), indicating that the dissolution of the exchangers was negligible within experimental error.

Distribution Coefficient, K_d. The time dependence on adsorption of the different metal ions was studied in order to determine the equilibrium distribution coefficient (Fig. 2). The ion-exchange equilibrium of alkali metal ions-H^+ (except Li^+-H^+) on SnSbA was attained within 24 h, while that of Li^+-H^+ was about 10 d as reported previously. The reaction with alkaline

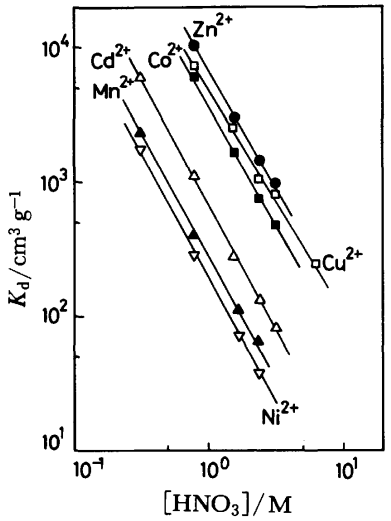

Fig. 3-b. Log-log plots of K_d values of transition metal ions on SnSbA *vs.* concentration of nitric acid. Initial concn. of metal ions; 10^{-4} M, exchanger; 0.250 g, total volume; 25.0 cm^3, temp; 30±0.5 °C.

earth or transition metal ion /H^+ was extremely slow, about 20—30 d being required for equilibrium.

The K_d values of alkali metal ions on the SnSbA showed almost the same values (except Li^+) as those on the sample (Sb/Sn ratio of 1.6) hydrolyzed at 100 °C, while the K_d values (2.2×10^4 in 0.1 M HCl) of Li^+ was lower than that (6.6×10^4) reported previously.[7] However, the selectivity sequence of alkali metal ions, $Na^+<K^+<Rb^+<Cs^+\ll Li^+$, agreed with the previous results.[7] The K_d values of alkaline earth and transition metal ions on a SnSbA are given in Figs. 3-a and 3-b, as log-log plots of K_d *vs.* $[HNO_3]$. The slope, d log K_d/d log $[HNO_3]$, was about −2, indicating ideal "1:2" ion-exchange reaction. The selectivity sequence showed: $Mg^{2+}<Ca^{2+}<Sr^{2+}<Ba^{2+}$, giving the same sequence of increasing crystal ionic radii of alkaline earth metals, as is obtained on organic ion-exchange resins of strong acid type. The K_d values and separation factors ($\alpha=K_{dB}/K_{dA}$), for a neigboring pair, are summarized in Table 1, where values from other ion-exchangers are shown for comparison. The sequence on the SnSbA is the same as that reported by Qureshi *et al.*[10] However, the separation factors for neigboring pairs of alkaline earth metal on the SnSbA are much larger than those obtained on strong acid type resins or the tin antimonate obtained by Qureshi *et al.*[10] The sequence, $Mg^{2+}<Ba^{2+}<Ca^{2+}<Sr^{2+}$, on tin antimonate prepared by Mathew and Tandon.[11] is the same as that obtained on the crystalline antimonic(V) acid which shows extremely high K_d values for Ca^{2+}, Sr^{2+} and Cd^{2+}.[14] The selectivity sequence for transition metal ions on the SnSbA, $Ni^{2+}<Mn^{2+}<Cd^{2+}<Co^{2+}<Cu^{2+}<Zn^{2+}$, is different from those on the tin antimontate prepared by Qureshi *et al.*[10] From data reported by Qureshi *et al.*, the slopes of d log K_d/d pH for transition metal ions, calculated by this author, do not show 2, even in a range of pH 0—1. In general, the K_d values also depend on the metal ion loading on the exchanger. The difference in the selectivity may be due to the difference of the loading and preparation of two exchangers. From data reported by Mathew and Tandon[11] and Qureshi *et al.*,[10] the extrapolated K_d values of bivalent metal ions to 1.0 M HNO_3 concentration were smaller

Column; 5.0 cm×0.5 cm i.d. (2.0 g of SnSbA), metal ion loading; 2.0 μmol for Na^+, and 0.2 μmol each for Sr^{2+} and Cs^+, flow rate; 0.2 $cm^3 min^{-1}$.

than those obtained on the SnSbA. This indicates that the number of the strongly acid sites in the SnSbA are larger than those in the tin antimonate prepared by Mathew and Tandon,[11] or Qureshi *et al.*[10]

Ion Exchange Separation. It is evident from studies of the separation factors on the SnSbA that some selective separation is feasible for various metal ions including alkali metal ions. Separations of Mg^{2+}–Ca^{2+} and Sr^{2+}–Ba^{2+} have been achieved by using a small column (5.0 cm×0.5 cm i.d.) containing 2.0 g of SnSbA with nitric acid solutions of different concentrations as eluents. The quantitative separations of Mg^{2+} from Ca^{2+} and of Sr^{2+} from Ba^{2+} were performed with 99—100% recovery with relatively short time (Fig. 4). From studies of the K_d values of alkali metal ions and bivalent metal ions, small amounts of Cs^+ and Sr^{2+} can be separated effectively from a relatively large amount of sodium. A satisfactory separation of Cs^+ and Sr^{2+} was performed from 10 fold (in mmol) of Na^+ with 98% recovery (Fig. 5).

The use of SnSbA is promising for the separation of radioactive ^{90}Sr and ^{137}Cs from natural water and seawater.

Syntheses and Properties of Oxomolybdenum(VI), -(V), and -(IV) Complexes with Ferrocenecarbodithioate

Masami NAKAMOTO, Koji TANAKA,† and Toshio TANAKA†*

Osaka Municipal Technical Research Institute, Morinomiya, Joto-ku, Osaka 536

†*Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565*

(Received December 19, 1984)

A series of ferrocenecarbodithioato-oxomolybdenum(VI), -(V), and -(IV) complexes, $Mo^{VI}O_2(S_2CC_5H_4Fe^{II}C_5H_5)_2$ (**1**), $Mo^{V}_2O_3(S_2CC_5H_4Fe^{II}C_5H_5)_4$ (**2**), and $Mo^{IV}O(S_2CC_5H_4Fe^{II}C_5H_5)_2$ (**3**) have been prepared. Complex **2** undergoes a disproportionation reaction in solution and exists as an equilibrium mixture with **1** and **3**. Cyclic voltammograms of **1** and **3** display two and three sets of quasi-reversible couples, respectively, arising from stepwise redox reactions of the molybdenum and iron sites. Electronic spectra revealed that the oxidized species $[Mo^{VI}O_2(S_2CC_5H_4Fe^{III}C_5H_5)_2]^{2+}$, $[Mo^{V}O(S_2CC_5H_4Fe^{II}C_5H_5)_2]^{+}$, and $[Mo^{V}O(S_2CC_5H_4Fe^{III}C_5H_5)_2]^{3+}$ generated electrochemically are considerably stable owing to the electron-donating ability of the ferrocenecarbodithioate ligand.

Molybdenum in high oxidation states is known to be an essential component in six well-characterized enzymes; nitrogenase, nitrate reductase, xanthine oxidase, aldehyde oxidase, and sulfite oxidase.[1] There exists a structural similarlity among the molybdenum sites of these enzymes except for nitrogenase.[2-4] Recent EXAFS studies on sulfite oxidase[3] and xanthine oxidase[4] suggest that molybdenum in those enzymes has one or two oxo ligands in sulfide-rich environments. These results have further stimulated the syntheses of a variety of oxomolybdenum complexes with sulfur-containing ligand as possible model compounds to molybdoenzymes.[5-8] Of the oxomolybdenum complexes with sulfur-containing ligands, which have been prepared so far, only the dithiocarbamate complexes have fully been characterized as a series of oxomolybdenum(VI), -(V), and -(IV) complexes.[9] Thus, the stabilization of oxomolybdenum complexes in the three oxidation states, (VI), (V), and (IV), may be resulted from the electron-donating ability of the dithiocarbamate ligand. Recently, we have briefly reported the syntheses of oxomolybdenum(VI) and -(V) complexes with ferrocenecarbodithioate,[10] which can stabilize the high oxidation states of molybdenum atoms. The present work reports the syntheses of a series of oxomolybdenum (VI), -(V), and -(IV) complexes with ferrocenecarbodithiocate, $Mo^{VI}O_2(S_2CC_5H_4Fe^{II}C_5H_5)_2$ (**1**), $Mo^{V}_2O_3(S_2CC_5H_4Fe^{II}C_5H_5)_4$ (**2**), and $Mo^{IV}O(S_2CC_5H_4Fe^{II}C_5H_5)_2$ (**3**), and their electrochemical properties.

Experimental

Materials and Methods. Dichlorodioxomolybdenum, $Mo^{VI}O_2Cl_2$,[11] and diethylammonium ferrocenecarbodithioate, $[Et_2NH_2][S_2CC_5H_4Fe^{II}C_5H_5]$[12] were prepared according to the literatures. All reactions and manipurations were carried out under nitrogen atmosphere and the solvents used for preparations and physical measurements were degassed by bubbling dry nitrogen for *ca.* 1 h or by distillation under nitrogen atmosphere prior to use.

Preparation of Complexes. Bis(ferrocenecarbodithioato)-dioxomolybdenum(VI), $Mo^{VI}O_2(S_2CC_5H_4Fe^{II}C_5H_5)_2$ (1). A methanol solution (20 cm³) of $Mo^{VI}O_2Cl_2$ (0.5 g, 2.5 mmol) was added dropwise to a stirred suspension of $[Et_2NH_2][S_2CC_5H_4Fe^{II}C_5H_5]$ (1.7 g, 5.0 mmol) in the same solvent (50 cm³) at −60 °C. The reaction mixture was stirred for further 2 h at the same temperature, followed by warming to 0 °C, which gave greenish blue precipitate. The precipitate was collected by filtration at 0 °C, washed with methanol (10 cm³×2 times), and dried *in vacuo*, 80% yield, mp>120 °C (dec). Anal. Calcd for $C_{22}H_{18}Fe_2MoO_2S_4$: C, 40.63; H, 2.79%. Found: C, 40.80; H, 2.99%. Molecular weight (MW) was measured in benzene cryoscopically: 628 (Calcd 650).

μ-Oxobis[bis(ferrocenecarbodithioato)oxomolybdenum(V)], $Mo^{V}_2O_3(S_2CC_5H_4Fe^{II}C_5H_5)_4$ (2). To a stirred aqueous solution (50 cm³) containing $Na_2Mo^{VI}O_4\cdot H_2O$ (1.2 g, 5.0 mmol) and $[Et_2NH_2][S_2CC_5H_4Fe^{II}C_5H_5]$ (3.4 g, 10 mmol) was added dropwise a 2 mol dm⁻³-HCl to adjust the pH of the solution to 5.5. The resulting dark blue precipitate was collected by filtration, washed with water and then diethyl ether, and dried *in vacuo*, 20% yield, mp>115 °C (dec). Anal. Calcd for $C_{44}H_{36}Fe_4Mo_2O_3S_8$: C, 41.14; H, 2.82%. Found: C, 41.49; H, 2.92%.

Bis(ferrocenecarbodithioato)oxomolybdenum(IV), $Mo^{IV}O(S_2CC_5H_4Fe^{II}C_5H_5)_2$ (3). A benzene solution (50 cm³) containing **1** (1.1 g, 1.7 mmol) and PPh_3 (0.47 g, 1.8 mmol) was refluxed for 2 h. After cooled to room temperature, the solution was evaporated to dryness under reduced pressures. The resulting solid was triturated with ethanol (20 cm³×2 times), collected by filtration, washed with diethyl ether (20 cm³×2 times), and dried *in vacuo*, which gave dark blue microcrystals, 88% yield, mp>180 °C (dec.). Anal. Calcd for $C_{22}H_{18}Fe_2MoOS_4$: C, 41.66; H, 2.86%. Found: C, 41.36; H, 3.03%. MW in benzene 620 (Calcd 634).

Physical Measurements. Infrared and electronic spectra were recorded on a Shimadzu IR-400 and a MPS-5000 spectrophotometer, respectively. ESR spectra were measured at 9.52 GHz with a JEOL ME-1X spectrometer. Electrochemical experiments were performed by using a Hokuto-Denko Model HA-501 potentiostat/galvanostat, a HB-104 function generater, and a HF-201 coulomb/amperehour meter. Cyclic voltammograms were recorded on a National VP-6422A X-Y recorder. Tetrabutylammonium perchlorate, $[n\text{-}Bu_4N][ClO_4]$, was used as a supporting electrolyte, and a saturated calomel electrode (SCE) was employed as a reference electrode. A platinum disk (0.20 cm²) and a platinum plate (1×1 cm²) were employed as working electrodes for the cyclic voltammetry and the controlled-potential electrolysis, respectively. The controlled-potential electrolysis was

performed at 110—180 mV more negative potentials than the cathodic peaks or more positive potentials than the anodic peaks of the complexes. Spectroelectrochemistry was accomplished by the use of an optically transparent thin-layer electrode (OTTLE) cell.[13]

Results and Discussion

Infrared Spectra in the Solid State and in Solution. The infrared spectrum of **1** in Nujol mull shows two strong ν(Mo=O) bands at 922 and 889 cm^{-1} (Table 1), which are compared with those of the corresponding dithiocarbamate complexes, $Mo^{VI}O_2(S_2CNR_2)_2$ (R=Me, Et, n-Pr, n-Bu; 912—905 and 877—875 cm^{-1}) with the two oxo ligands in *cis*-positions to each other in the octahedral configuration.[14] Complexes **2** and **3** in Nujol mulls exhibit the ν(Mo=O) bands at 940 and 960 cm^{-1}, respectively (Table 1); the former and the latter fall in the same region as the ν(Mo=O) frequencies of $Mo^{V}_2O_3(S_2CNR_2)_4$ (R=Me, Et, *i*-Pr; 943—938 cm^{-1})[15] and $Mo^{IV}O(S_2CNEt_2)_2$ (962 cm^{-1}), respectively, as well.[16] These results indicate that the ferrocenecarbodithioate ligand is coordinated to molybdenum in a bidentate manner and the present oxomolybdenum complexes **1**, **2**, and **3** may assume the geometries **A**, **B**, and **C**, respectively, which are similar to those of the corresponding dithiocarbamate complexes which have been revealed by the X-ray crystallographic analysis.[17]

The infrared spectrum of **2** in CH_2Br_2, however, displayed three ν(Mo=O) bands at 955, 920, and 885 cm^{-1}, the latter two of which are nearly the same frequencies as those of **1** in the same solvent. This is suggestive of the occurrence of the disproportionation reaction of **2** into **1** and **3** in solution (Eq. 1). Thus, the ν(Mo=O) bands arising from **2** and **3** may

$$Mo^{V}_2O_3(S_2CC_5H_4Fe^{II}C_5H_5)_4 \rightleftharpoons Mo^{VI}O_2(S_2CC_5H_4Fe^{II}C_5H_5)_2 + Mo^{IV}O(S_2CC_5H_4Fe^{II}C_5H_5)_2 \quad (1)$$

be overlapped with each other to appear as a broad one at 955 cm^{-1}. This is consistent with the fact that an equimolar mixture of **1** and **3** in CH_2Br_2 exhibited an infrared spectrum quite similar to **2** in the same solvent. Disproportionation equilibria of Eq. 1 have been reported for some μ-oxodimolybdenum complexes of the $Mo^{V}_2O_3L_4$ type (L=S_2CNR_2, S_2CSR, and S_2PPh_2) in solution[18,19] though only the dithiocarbamate complexes have so far been fully characterized throughout three different oxidation states of molybdenum, (VI), (V), and (IV).[16]

Electrochemistry. Figure 1 illustrates the cyclic voltammograms of **1**, **2**, and **3** in CH_2Cl_2. As shown in Fig. 1a, the cyclic voltammogram of **1** in CH_2Cl_2 shows two well resolved quasi-reversible waves ($E_{1/2}$=−0.89 and +0.77 V *vs.* SCE) and no wave associated with liberated ligands[20] has been observed within the potential range −2.0 to +2.0 V (*vs.* SCE). The controlled-potential electrolysis of **1** in CH_2Cl_2 at −1.05 and +0.95 V (*vs.* SCE, a little more negative or positive potential than $E_{1/2}$) have consumed 0.94 and 1.89 electrons, respectively, per one mole of **1**. This result indicates that **1** undergoes one electron reduction at $E_{1/2}$=−0.89 V (*vs.* SCE) to produce the $[Mo^{V}O_2(S_2CC_5H_4Fe^{II}C_5H_5)_2]^-$ species, and two ferrocenecarbodithioate ligands are both oxidized at the potential $E_{1/2}$=+0.77 V (*vs.* SCE) to give $[Mo^{VI}O_2(S_2CC_5H_4Fe^{III}C_5H_5)_2]^{2+}$. Thus, the redox processes of **1** can formally be expressed as Scheme 1.

A CH_2Cl_2 solution of **3** displays three discrete redox couples ($E_{1/2}$=−0.87, +0.60, and +0.98 *vs.* SCE) without any peaks due to liberated ligands, as depicted in Fig. 1c. The controlled-potential electrolysis at a little more negative or positive potential (−1.10, +0.80, and +1.25 V *vs.* SCE) than $E_{1/2}$ has consumed 1.02, 0.94, and 1.93 electrons, respectively, confirming that the cathodic peak at −0.92 V (*vs.* SCE) and the anodic one at +0.67 V (*vs.* SCE) are both one-electron processes, whereas the anodic peak at +1.12 V (*vs.* SCE) is a two-electron process. Thus, the redox couple at $E_{1/2}$=−0.87, +0.60, and +0.98 V (*vs.* SCE) may be assigned to the Mo(IV)/Mo(III), Mo(IV)/Mo(V), and Fe(II)/Fe(III) processes, respectively. The assignment for the redox couple at +0.60 V (*vs.* SCE) is consistent with the fact that an oxidized species generated by the electrolysis of **3** at +0.70 V (*vs.* SCE) in CH_2Cl_2 gives an ESR signal with g=2.007 at room temperature, as shown in Fig. 2. This g-value is quite normal for molybdenum(V) com-

Scheme 1.

plexes which exhibit a signal in the range g=1.905 (K_2MoOF_5)[21] to 2.011 ([$Mo(S_2C_2Ph_2)_3$]$^-$),[22] whereas the ferricenium radical cations display quite different g-values from 2.0 ($g_{\parallel}$=4.35—3.62 and $g_{\perp}$=1.62—1.77)[23,24]

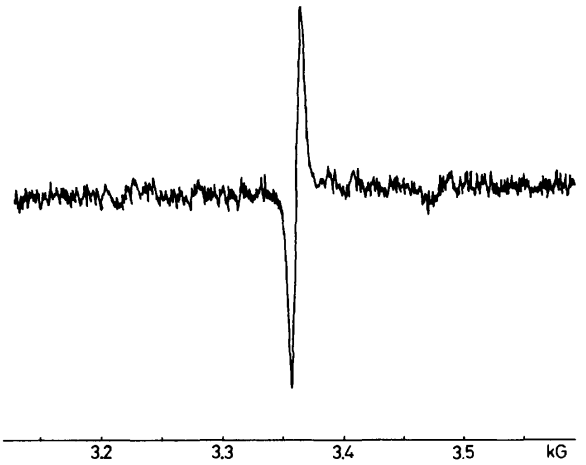

Fig. 2. Room temperature ESR spectrum of electrochemically generated $[Mo^{V}O(S_2CC_5H_4Fe^{II}C_5H_5)_2]^+$ in CH_2Cl_2 at 9.52 GHz.

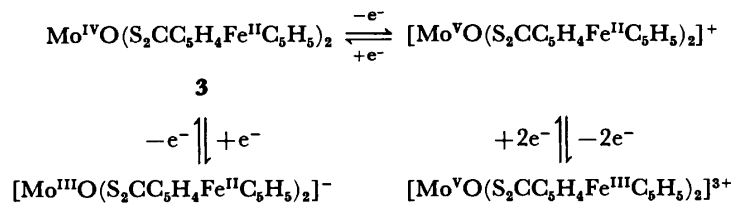
at low temperatures; no ESR signal of the radical cations has been detected above 78 K[25] owing to very short relaxation times T_1.[26] In addition, the assignment of the redox process Fe(II)/Fe(III) for the couple at $E_{1/2}$=+0.98 V (*vs.* SCE) is consistent with a two-electron process of the anodic peak at +1.12 V (*vs.* SCE), where the two iron atoms of both ferrocenecarbodithioate ligands undergo simultaneous one-electron oxidation at the same potential, as in the case of **1**. The redox reactions of **3** can, therefore, be expressed as Scheme 2. Thus, complex **1** and **3** are considerably stable toward the electrochemical redox reactions, probably because of a large polarizability of the ferrocenecarbodithioate ligand with π-electron systems. This is in marked contrast to the corresponding dithiocarbamate and trithiocarbonate complexes, $M^{VI}O_2L_2$ and $Mo^{IV}OL_2$ (L=S_2CNR_2, S_2CSR), whose electrochemical redox reactions are followed by rapid irreversible chemical reactions resulting from the dissociation of the dithio ligands.[9,27]

As described above, **2** partly disproportionates into **1** and **3** in solution. The cyclic voltammogram of **2** in CH_2Cl_2, therefore, is rather complicated, as seen in Fig. 1b. A pair of cathodic and anodic waves at E_c=−0.92 V and E_a=−0.82 V (*vs.* SCE) may be an overlap of the redox couples of both **1** and **3**, since these potentials are almost the same as that of either **1** or **3** existing alone (See Fig. 1a and 1c). Thus, the cathodic peak at E_c=−0.75 V (*vs.* SCE, Fig. 1b) may be assigned to the reduction of **2**, whereas the corresponding anodic peak is not observed. The anodic wave at +0.84 V (*vs.* SCE) (Fig. 1b) is assigned to the oxidation of **1**, and those at +0.67 and +1.12 V (*vs.* SCE) (Fig. 1b) to the oxidation of the molybdenum and ferrocenyl moieties of **3**, respectively, both of which are resulted from the disproportionation of **2** (Eq. 1). The broad cathodic wave at +0.72 V (*vs.* SCE) may, therefore, be assigned to the reduction of the both Fe^{3+} ions of $[Mo^{VI}O_2(S_2CC_5H_4Fe^{III}C_5H_5)_2]^{2+}$ and $[Mo^{V}O(S_2CC_5H_4Fe^{III}C_5H_5)_2]^{3+}$. The



Scheme 2.

remaining cathodic wave at +0.45 V (*vs.* SCE) may constitute a redox couple, Mo(IV)/Mo(V) of **3**, with the anodic wave at +0.67 V (*vs.* SCE). These assignments may be supported from the fact that the cyclic voltammogram of **2** obtained upon an anodic scan from 0 V to +2.0 V (*vs.* SCE) followed by a reverse one to 0 V (*vs.* SCE) gave three anodic and two cathodic waves with the same potentials as Fig. 1b.

Electronic Spectra. It has been reported that both dioxomolybdenum(VI) and oxomolybdenum(IV) complexes with dithio chelate ligands exhibit the absorption band due to a molybdenum-oxygen transition around 380 nm[16] and μ-oxodimolybdenum(V) complexes with the dithio chelates display another characteristic absorption band around 510 nm as well as the 380 nm band.[16] The electronic spectra of **1—3**, however, show two absorption bands around 350 and 600 nm and their appearances resemble one another, irrespective of the oxidation state of the molybdenum atom. On the other hand, the ferrocenecarbodithioate anion exhibits two strong absorptions due to π-π^* (308 nm) and n-π^* (525 nm) transitions of the thiocarbonyl group, both of which are known to shift to higher wavelengths on coordination to metal atoms.[12] Thus, the bands due to transitions resulting from Mo=O and Mo-O-Mo bonds in the present complexes may be concealed by the strong absorptions of the ferrocenyl chromophore.

Table 2 lists the absorption maxima and the extinction coefficients in the electronic spectra of **1—3**, together with those of the electrochemical oxidized species of **1** and **3**, obtained by using a OTTLE cell. The absorption bands at 350 and 600 nm of **1** were shifted to 330 and 540 nm, respectively, on the electrochemical reduction at −1.05 V (*vs.* SCE) in CH_2Cl_2. Similarly, the reduction of **3** at −1.10 V (*vs.* SCE) in CH_2Cl_2 caused the movement of the 355 and 605 nm bands to 320 and 530 nm, respectively. Upon reoxidation of the both resulting solutions at −0.70 V (*vs.* SCE), however, neither original spectrum of **1** nor that of **3** has been recovered, suggesting that $[Mo^{V}O_2(S_2CC_5H_4Fe^{II}C_5H_5)_2]^-$ and $[Mo^{III}O(S_2CC_5H_4Fe^{II}C_5H_5)_2]^-$ decompose on the coulometric electrolysis time scale. In accordance with this, several attempts to detect the ESR signals of these reduced species generated under the controlled-potential electrolysis at −1.10 V (*vs.* SCE) of **1** and **3** in CH_2Cl_2 have been unsuccessful.

On the other hand, the two absorption bands of **1** and **3** are shifted to higher wavelengths upon electrochemical oxidations (Compare Entries 1 with 2, and 4 with 5 and 6 in Table 2). This is consistent with the bathochromic shift of ferrocenyl derivatives with electron-attracting groups in the electronic spectra.[28] The oxidation of **1** at +0.95 V (*vs.* SCE) and the subsequent reduction at +0.60 V (*vs.* SCE) afforded the original electronic spectrum, suggesting that the oxidized species, $[Mo^{VI}O_2(S_2CC_5H_4Fe^{III}C_5H_5)_2]^{2+}$, is stable. Similarly, $[Mo^{V}O(S_2CC_5H_4Fe^{II}C_5H_5)_2]^+$ and $[Mo^{V}O(S_2CC_5H_4Fe^{III}C_5H_5)_2]^{3+}$ generated by the electrochemical oxidation of **3** at +0.80 and +1.25 V (*vs.* SCE), respectively, are stable, as confirmed from the fact that the electronic spectrum of **3** was recovered completely upon oxidation-reduction cycles. In contrast to the instability of the reduced species, the stability of electrochemically oxidized species of **1** and **3** may result from an electron-donating property of the ferrocenecarbodithioate ligand.

Liquid Crystal Materials with Sulfur Atoms Incorporated in the Principal Structure. IV. New Liquid Crystal Compounds; 2-(*p*-Substituted phenyl)-5-alkyl-1,3-oxathianes

Yuichiro HARAMOTO* and Hiroyoshi KAMOGAWA
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400
(Received January 25, 1985)

2-(*p*-Substituted phenyl)-5-alkyl-1,3-oxathianes, new liquid crystal compounds, were synthesized by the acetal-formation reaction of the corresponding aldehydes and 2-alkyl-3-mercapto-1-propanols. The mesomorphic behaviors of these 1,3-oxathiane compounds were compared with those of the corresponding 1,3-dithianes and 1,3-dioxanes. Some of 2-(*p*-cyanophenyl)-5-alkyl-1,3-oxathianes exhibit monotropic nematic liquid crystal phase at room temperature, whereas 2-(*p*-alkoxyphenyl)-5-alkyl-1,3-oxathianes tend hardly to exhibit liquid-crystal phase. These mesomorphic characters seem to originate in the molecular width and bending at the 1,3-oxathiane ring.

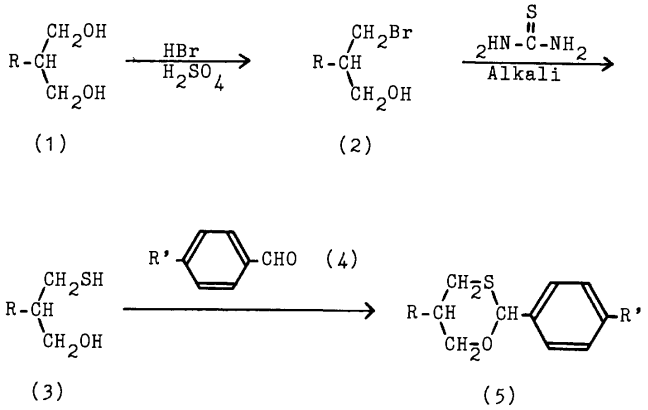
In recent years, 2,5-disubstituted 1,3-dithianes and several 2,5-disubstituted 1,3-oxathianes, new types of liquid-crystalline compounds, have been reported.[1-5] The present study relates to the synthesis and mesomorphic behavior of 2-(*p*-substituted phenyl)-5-alkyl-1,3-oxathianes having the systematically changed chain length of alkyl groups. The features concerning about appearance of mesophase of these 1,3-oxathianes were compared with those of the corresponding 1,3-dithianes and 1,3-dioxanes.

Results and Discussion

2-(*p*-Substituted phenyl)-5-alkyl-1,3-oxathianes were synthesized *via* the following route.

In step **1**→**2**, the reaction temperature must be kept between 70 and 75°C. At a temperature between 90 and 95°C, the main product was the disubstituted bromide contrary to the purpose. As compounds **3** were susceptible to oxidation, step **2**→**3** required nitrogen atmosphere. In **3**→**5**, both trans and cis isomers differing at C-5 position of the 1,3-oxathiane ring were produced.

Repeated recrystallizations were required to obtain the purified trans isomers. As trans and cis isomers



R: *n*-C_3H_7, *n*-C_4H_9, *n*-C_5H_{11}, *n*-C_6H_{13}, *n*-C_7H_{15}, *n*-C_8H_{17}.

R': OCH_3, OC_2H_5, $OC_3H_7^n$, $OC_4H_9^n$, $OC_5H_{11}^n$, CN.

Fig. 1.

exhibit C-2 proton signals of the 1,3-oxathiane ring in ^{1}H-NMR at δ 5.75 and 5.80 (R'=CN), respectively, the contamination of cis isomer can be detected by the examination of proton signals at δ 5.80.

The presence of 1,3-dithianes and 1,3-dioxanes can also be detected by the examination of C-2 proton signals at δ 5.10, and 5.30, respectively.

Absorptions of C2, C4, and C6 carbons of the 1,3-oxathiane ring in ^{13}C-NMR spectra, as determined by ^{1}H-complete decoupling (COM), ^{1}H-off resonance decoupling (OFR), and ^{1}H-selective decoupling (SEL) procedures, are located at δ 83.22, 34.84, and 75.55, respectively (R=C_8H_{17}, R'=CN). In ^{1}H-NMR, C4 proton signals are located at δ 3.4 (t), and 4.3 (m). The attribution of these two proton signals to the two protons attaching to C4 carbon of the 1,3-oxathiane ring derives from the fact that, in ^{1}H-selective decoupling of ^{13}C-NMR spectra, the peak of C2 carbon becomes more intense with irradiation of δ (3.4+4.3)/2, but indicates little change in both cases of irradiation of δ 3.4 and 4.3.

Measurements of mesomorphic ranges and assignments of the mesophases were carried out by means of a micro melting point apparatus equipped with polarizers. Mesomorphic ranges of the synthesized 2-(*p*-substituted phenyl)-5-alkyl-1,3 oxathianes and the corresponding 1,3-dithianes and 1,3-dioxanes are given in Table 1.

Transition temperatures of isotropic to nematic (T_{N-I}) for 2-(*p*-cyanophenyl)-5-alkyl-1,3-oxathianes were lower than those for the corresponding 1,3-dioxanes by about 20°C. It is known generally that the larger the molecular width, the lower the T_{N-I} is.[6] The width of 2-(*p*-cyanophenyl)-5-alkyl- 1,3-oxathianes is larger than that of the corresponding 1,3-dioxanes because of the presence of a large sulfur atom.

2-(*p*-Cyanophenyl)-5-alkyl-1,3-dithianes did not exhibit any liquid crystal phases. As molecular width of 2-(*p*-cyanophenyl)-5-alkyl-1,3-dithianes having two sulfur atoms are larger than those of 1,3-dioxane and 1,3-oxathiane compounds, they seem to be unable to exhibit a nematic phase.

As regards compounds having 2-(*p*-alkoxyphenyl)

a) C=crystal; N=nematic; I=isotropic. b) Cited from Ref. 2. c) Cited from Ref. 7.

group, compounds **5** seem hardly to exhibit liquid-crystal phases. Namely, the nematic phase is too unstable to exist over a wide range of temperature. Even with a long alkyl chain (R=C_8H_{17}), they did not exhibit smectic phase. The molecular widths in hetero rings increase in the order: 1,3-dioxane, 1,3-oxathiane, and 1,3-dithiane. Therefore, lateral molecular interactions of 1,3-oxathianes are larger than those of 1,3-dithianes from this point of view. 1,3-Oxathiane compounds, however, are bent at the 1,3-oxathiane ring due to the difference of atomic size between sulfur and oxygen.

2-(*p*-Cyanophenyl)-5-alkyl-1,3-oxathianes having an alkyl chain with odd carbon numbers tend to have somewhat higher values of T_{N-I} (R=C_5H_{11}, 19°C; R=C_7H_{15}, 30°C), whereas those having an alkyl chain of even carbon numbers tend to have somewhat lower values (R=C_6H_{13}, 17°C; R=C_8H_{17}, 26°C).

The principal features of the mesomorphic behavior of compounds **5** are (1), in *p*-cyanophenyl compounds, monotropic nematic liquid crystal phase is exhibited around ordinary room temperature, and (2), in *p*-alkoxyphenyl compounds, mesomorphic phases are hardly recognized, and even for the compounds having a long alkyl chain (C_8H_{17}), any smectic phases could not be observed.

Experimental

IR, ^{1}H-NHR, ^{13}C-NMR, and mass spectra were obtained with a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, a JNM-FX 90 Q FT-NMR spectrometer, and a Hitachi RMU-6MG spectrometer, respectively. Elemental analyses were carried out with a Perkin-Elmer 250 instrument. Mesomorphic phases and the transition temperatures were determined by means of both a Mitamura Riken micro melting-point apparatus equipped with polarizers and a Rigaku Denki D.S.C. CN8059L1, CN8208A2. The rate of cooling was fixed to 1°C/min.

2-Alkyl-3-bromo-1-propanol (2). To a solution of 48% HBr (50 g) and concd H_2SO_4 (15 g) cooled in an ice bath were added successively compound **1** (0.1 mol) and concd H_2SO_4 (25 g). The solution was kept at 70—75°C, for 18 h. The reaction mixture was then poured into ice water (200 g). The mixture was stirred and extracted twice with ether (each 400 ml). The extract was washed with cold 10% aq $NaHCO_3$ (100 ml), dried over anhyd. Na_2SO_4, and concentrated on a rotary evaporator at 30°C. The residue was distilled *in vacuo* to afford transparent liquid in a 40—50% yields.

Bp: 71—74°C/1—2 mmHg† (R=C_3H_7), 85—88°C/1—2 mmHg (R=C_4H_9), 93—95°C/1—2 mmHg (R=C_5H_{11}), 118—122°C/3—5 mmHg (R=C_6H_{13}), 104—107°C/1—2 mmHg (R=C_7H_{15}), 111—113°C/1—2 mmHg (R=C_8H_{17}). IR ($CHCl_3$) 3600 (OH), 2800—3000 (Alkyl) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ= 0.6—2.1 (m, R-CH), 2.3 (s, 1H, OH), 3.4—3.8 (m, 4H, CH_2-Br, CH_2-O).

2-Alkyl-3-mercapto-1-propanol (3). To a solution of thiourea (0.064 mol, 4.9 g) in triethylene glycol (8 ml) kept at 75°C was added compound **2** (0.016 mol) in a nitrogen atmosphere, followed by stirring at 75°C for 18 h. Tetraethylenepentamine (0.016 mol, 3.03 g) was then added, and the mixture was stirred at 75°C for 2 h under a nitrogen atomosphere. The reaction mixture was distilled *in vacuo* to afford transparent liquid in a 60—70% yields.

Bp: 90—92°C/1—2 mmHg (R=C_3H_7), 105—108°C/1—2 mmHg (R=C_4H_9), 128—135°C/1—2 mmHg (R=C_5H_{11}), 136—138°C/1—2 mmHg (R=C_6H_{13}), 138—140°C/1—2 mmHg (R=C_7H_{15}), 142—146°C/1—2 mmHg (R=C_8H_{17}). IR ($CHCl_3$) 3600 (OH), 2800—3000 (Alkyl) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ= 0.6—2.0 (m, R-CH, 2SH), 2.5—2.8 (m, 2H, -CH_2S), 3.3—3.9 (m, 3H, CH_2-OH).

2-(p-Substituted phenyl)-5-alkyl-1,3-oxathiane (5). To a solution of compound **3** (0.004 mol) and *p*-substituted benzaldehyde **4** (0.004 mol) in anhyd. $CHCl_3$ (200 ml) cooled in an ice bath were added $BF_3 \rightarrow (C_2HH_5)_2O$ (0.5 g) and molecular sieves (3A, 1/15; 3 g). The mixture was stirred at 0—5°C for 8 h and then at 20—25°C for 18 h. The solution was washed with 10% aq $NaHCO_3$ (400 ml), dried over anhyd. Na_2SO_4, and evaporated *in vacuo* at 40°C. The crude product was purified by recrystallizations from hexane, then if necessary, by centrifugal liquid chromatography.

2-(p-Alkoxyphenyl)-5-alkyl-1,3-oxathianes. IR ($CHCl_3$) 2800—3000 (Alkyl), 1600 (Ar), 1300 (Ether) cm^{-1}.

^{1}H-NMR ($CDCl_3$) Compounds **5-1**, **5-6**, and **5-17**: δ= 0.7—2.1 (m, R-CH), 2.7—3.0 (d, 2H, CH_2S), 3.4, 4.3 (t; 3.4, m; 4.3, 2H, CH_2O), 3.8 (s, 3H, OCH_3), 5.7 (s, 1H, $\overset{S}{\underset{O}{\rangle}}$CH), 6.8—7.6 (q, 4H, ArH). Compounds **5-2**, **5-4**, **5-7**, **5-9**, **5-13**, and **5-18**: δ=0.7—2.1 (m, R-CH, O-CH_2-CH_3), 2.7—3.0 (d, 2H, CH_2-S), 3.4, 4.3 (t; 3.4, m; 4.3, 2H, CH_2-O), 4.05 (q, 2H, O-CH_2-CH_3), 5.7 (s, 1H, $\overset{S}{\underset{O}{\rangle}}$CH), 6.7—7.6 (q, 4H, ArH). Others: δ=0.7—2.1 (m, R-CH, OCH_2-C_nH_{2n+1}), 2.7—3.0 (d, 2H, CH_2-S), 3.4, 4.3 (t; 3.4, m; 4.3, 2H, CH_2-O) 3.95 (t, 2H, -O-CH_2-C_nH_{2n+1}), 5.7 (s, 1H, $\overset{S}{\underset{O}{\rangle}}$CH-). 6.8—7.6 (q, 4H,

Determination of the Acid Strength Distribution of Manganese Dioxide by the Modified Indicator Method

Kazuo SUGIYAMA,* Yasushi NAKANO, Hiroshi MIURA, and Tsuneo MATSUDA
Department of Applied Chemistry, Faculty of Engineering, Saitama University, Shimo-ohkubo, Urawa 338
(Received October 30, 1984)

Synopsis. A new procedure for determining the distribution of acid and base centers of dark colored solids by the indicator method has been proposed. By this method weak acidic sites were found to be present on a manganese dioxide surface.

As a method for measuring the acidity of white colored solid samples such as silica-alumina, the fundamental titration procedure based on Johnson's method[1] is generally used. The acidity of colored solid samples, however, can not be measured by this method. In this case a modified procedure[2] such as the titration of the mixture of the sample and a white standard sample with known acidity is usually applied. By this modified method it is impossible to measure the acidity of black colored solids such as electrolyte manganese dioxide (EMD), because the color change of the Hammett indicator is difficult to observe.

On the EMD surface the presence of acidic sites should be predictable from the cation-exchange ability of its surface OH groups.[3,4] The understanding of the acidic properties on the EMD surface can help to improve the life of dry batteries.[5]

Recently we succeeded in determining the amounts of acid and basic areas on black colored solid samples by our modification of the indicator method. This paper describes this procedure and the distribution of the acidic sites on the EMD surface.

Experimental

Samples. EMD (type FM-H) was supplied by Toyo Soda Manufacturing Co. Ltd., and its particle size was 100—200 mesh (149—79 μ). Before the measurements it was preheated at 110—500 °C for 1 h in air. MnO was obtained by thermal decomposition of manganese carbonate at 500 °C in a stream of nitrogen. Silica-alumina (Catalysts & Chemicals Ind. Co. Ltd.; SiO_2 87%) dried at 110 °C and magnesium oxide (Wako Pure Chem. Co. Ltd.) calcined at 700 °C in air were used as a white standard probe with known acidity and basicity, respectively.

As shown in Fig. 1, a vessel developed by us is composed of a commercially available separate ground-glass Gooch crucible equipped with a cover on the head and a receiver (content volume 15 ml) on the bottom. The pore size of the glass filter is 20—30 μ (3G type).

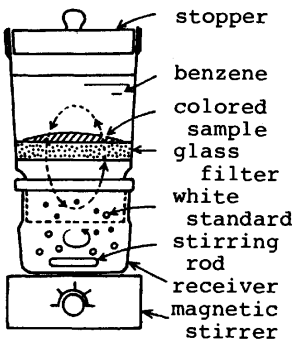

Fig. 1. The vessel to measure the acidic and basic properties of the dark colored solid samples.

Procedure. The standard probe of silica-alumina and a magnetic stirring rod are put into the receiver, to which the paired ground-glass Gooch crucible is attached. Dry benzene is poured into the crucible. When the inner pressure of the crucible is reduced by use of an aspirator, the vessel can be then degassed. The inner part of the vessel can then be easily filled with dry benzene. The known amount of preheated EMD is rapidly placed into the crucible in a stream of dry nitrogen. The weight of the EMD is about three times that of the silica-alumina. A few drops of Hammett indicator with the known pK_a is introduced into the EMD-benzene solution and stirred for 3 h, followed by standing for 12 h. At first 0.1 M† butylamine benzene solution equivalent to the amount of the acid in the silica-alumina is added to the crucible. Butylamine benzene solution is then added at 3-h intervals until the acidic color of the Hammett indicator on the silica-alumina is no longer observed. Stirring is continued all through the titration. A drop of 0.05 M trichloroacetic acid in benzene is added to ensure whether there is appreciable excess of butylamine at the end point or not.

Using benzoic acid instead of butylamine the basicity of dark colored samples can be determined in the same manner as described above.

Results and Discussion

In order to verify our method, the acidity of the white standard solid, silica-alumina, instead of black colored sample was first measured. The same results for the acidity were obtained by our method as for fundamental Johnson's method (Table 1). The silica-alumina, which has an acid strength distribution for the weak acidic sites, is suitable for the white standard probe to measure the acid amount of the EMD.

Our method showed a considerable amount of weak acidic sites were present on the EMD surface. The acid strength distribution of the EMD preheated at the various temperature were given in Table 1. A large amount of acid sites at $+6.8 \leqq H_o < +1.5$ was observed on the EMD surface preheated at 110 °C. When phenolphthalein ($pK_a = +9.3$) was used as a Hammett indicator, the basic sites could not be detected on the EMD surface. While the amount of basic sites at $H_o = +9.3$ on the MnO surface was 0.297 mmol/g.

Many OH groups are known to be present on the EMD surface.[5,6] The relation between the amount of surface OH groups determined by the KI method in *N,N*-dimethylformamide solvent[7] and the total acid amount on the EMD heat-treated at various temperature were shown in Fig. 2. Both the amounts of the surface OH groups and of the total acidic sites

† 1 M = 1 mol dm^{-3}.

Table 1. Acidic properties of electrolytic MnO_2

Sample	Calcinating temperature (°C)	Surface area (m^2/g)	Acid amount(mmol/g)			Total acid amount (mmol/g)
			$+1.5>H_o\geqq+3.3$	$+3.3>H_o\geqq+4.8$	$+4.8>H_o\geqq+6.8$	
MnO_2	110	33.2	0.006	0.072	0.023	0.101
MnO_2	200	28.5	0.005	0.046	0.037	0.088
MnO_2	300	16.3	0	0.019	0.064	0.083
MnO_2	500	12.9	0	0.015	0.025	0.040
SiO_2-Al_2O_3[a)]	110	302	0.142	0.339	0.384	0.865
SiO_2-Al_2O_3[b)]	110	302	0.144	0.333	0.381	0.858

a) By our modified method. b) By Johnson's method.

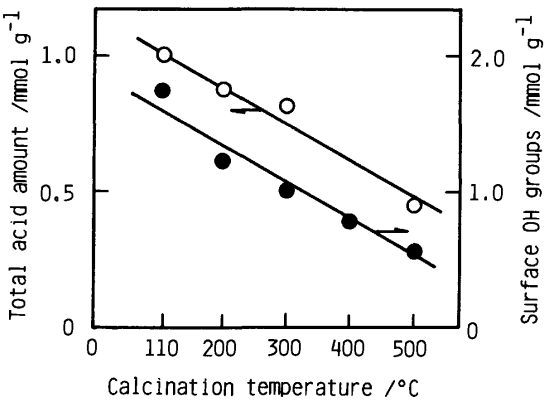

Fig. 2. Relation between both the amount of total acid and of surface OH groups on the electrolytic MnO_2 heat-treated at various temperatures.

decreased in nearly the same ratio as the pretreatment temperature was raised. These results suggest that the surface OH groups are the important factor associated with the acidic property of the EMD. The difference between the surface OH groups and the total acid amount should be expected to be either weak acid OH groups below the acid strength at H_o=+6.3 or the oxidation sites on the EMD. We propose to investigate the surface characterization for the acidic properties on the EMD in further detail.

Thus both the acidity and basicity of the dark colored solid samples can be measured satisfactorily by our method provided one selects suitable standard probes and indicators.

The Promotion Effect of Surface Hydroxyl on the Oxygen Adsorption over NiO, Fe_2O_3, and CuO

Yusaku TAKITA,* Yumie SAITO, Tetsuro TASHIRO, and Fumiaki HORI
Department of Environmental Chemistry and Engineering, Faculty of Engineering, Oita University, Dannoharu, Oita 870-11
(Received Nobember 9, 1984)

Synopsis. Oxygen TPD revealed that the adsorption of water vapor at 278 K promoted the desorption of the preadsorbed oxygen at 793→278 K over NiO and Fe_2O_3. Preadsorption of water vapor at 473 K brought about a marked enhancement over Fe_2O_3 and a slight increase over CuO in the adsorption of oxygen at 473→278 K.

It has been known that the addition of water vapor promoted the catalytic oxidations of methanol,[1] propene,[2] butene,[3] 2-butanone,[4] 2-methyl propenal (methacrolein),[5] toluene,[6] and the ammoxidation of propene.[7] It was proved that water or surface hydroxyl served as a reactant in the formation of alcoholic intermediate in several catalytic oxidations.[2,3,5] The promotion mechanism for other oxidations, however, is still not elucidated.

Water vapor is formed as by-product in almost all of catalytic oxidations of organic compounds and it will more or less affect the adsorption of reactants, products, and/or intermediates, so that it is of importance to know the behavior of oxygen adsorbate in the presence of water vapor for understanding of catalytic oxidations.

Recently, it has been reported that coadsorption of water vapor affected adsorption energy of oxygen on the metal oxide surfaces. Co_3O_4 gave a temperature programmed desorption (TPD) chromatogram of oxygen which composed of three kinds of oxygen adsorbate. The desorption peak with peak maximum temperature (T_m) at 365 K shifted to higher temperature by 50 K without loss of its amount when water vapor and oxygen were coadsorbed at 473→278 K.[8] Over Ag^+–SnO_2, a broad prateau above 610 K in oxygen TPD chromatogram was transformed into a sharp peak at 570 K by the coadsorption of water vapor.[9]

However it is still not known for other metal oxides. This paper deals with the behavior of oxygen adsorption in the presence of the adsorbate derived from water over the metal oxides.

The oxygen TPD chromatograms from NiO are shown in Fig. 1. The NiO sample after the treatment A (see Table 1) gave a chromatogram which consisted of a desorption peak with T_m=695 K and a shoulder peak at around 600 K (curve 1). This well agreed with that reported by Iwamoto *et al.*[10] Water adsorption at 294 K onto the NiO sample with oxygen adsorbate by the treatment A brought about drastic changes in its chromatogram of oxygen (curve 2): by the adsorption of 5.0 μmol/g water, a small α peak appeared at around 420 K and β peak became larger but γ peak decreased without shift of T_m. The amount of oxygen desorbed up to 793 K slightly increased from 7.92 to 8.89 μmol/g by the water coadsorption. Curve 3 is a chromatogram of water desorbed simultaneously with oxygen, which is composed of two peaks with T_m=490 K and >793 K. These peaks may arise from surface hydroxyl since the desorption temperatures are higher than the normal boiling point of water.

Fe_2O_3 showed two desorption peaks with T_m=620 K and 710 K (curve 1 in Fig. 2). Both α and β peaks shifted to lower temperatures and the latter peak was much enlarged by the adsorption of water at 278 K onto the sample preadsorbed with oxygen. The total amount of desorbed oxygen increased to about 1.4 times of that of dry surface. Curve 3 in Fig. 2 revealed that all of the water vapor was chemisorbed onto Fe_2O_3. In these experiments, no oxygen was supplied from gas phase during the adsorption of water vapor at 294 K. Therefore the increment of desorbed oxygen probably came from the oxygen which should be desorbed at >793 K from the dry surface.

Figure 3 shows the results of oxygen chemisorption onto the Fe_2O_3 surface preadsorbed with water vapor.

Table 1. Treatment of oxides

A:	Adsorption of oxygen (100 Torr*, 793 K, 30 min)	→	Cooling to r.t. (10 K/min)	→	Evacuation (r.t., 15 min)
B:	Treatment A	→	Adsorption of water vapor (2 Torr, 293 K, 30 min)	→	Evacuation (r.t., 15 min)
C:	Adsorption of oxygen (100 Torr, 473 K, 30 min)	→	Cooling to r.t. (10 K/min)	→	Evacuation (r.t., 15 min)
D:	Adsorption of water vapor (2 Torr, 473 K, 30 min)	→	Evacuation (473 K, 15 min)	→	Treatment C

* 1 Torr=133.322 Pa.

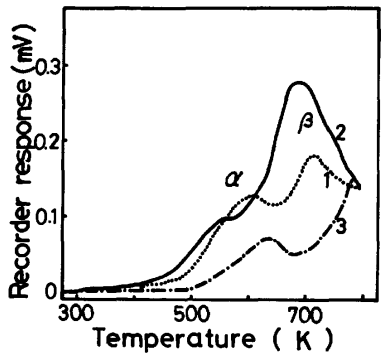

Fig. 2. TPD chromatograms from Fe_2O_3.
1: Oxygen, treatment A, 2: oxygen, treatment B, 3: water, treatment B.

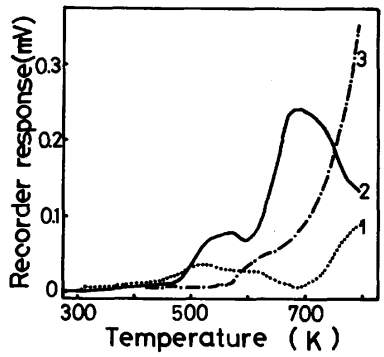

Fig. 3. TPD chromatograms from Fe_2O_3.
1: Oxygen, treatment C, 2: oxygen, treatment D, 3: water, treatment D.

In the oxygen adsorption on the dry surface at 473 K (the treatment C), only a small amount of oxygen could be chemisorbed and the chromatogram was composed of three desorption peaks with T_m=430 K, 610 K, and >793 K. The second peak (T_m=610 K) well coincided with that of α peak in curve 1 in Fig. 2. However, preadsorption of water at 473 K much promoted the adsorption of oxygen. The shape of curve 2 in Fig. 3 was much similar to that of curve 2 in Fig. 2, despite the differences in the adsorption temperature and procedure for water adsorption. The amount of desorbed oxygen was determined to be 2.35 μmol/g, which was 3.5 times larger than that of curve 1. It is noteworthy that this value exceeded the 2.06 μmol/g of oxygen adsorption at 793 K.

Assuming that surface concentration of iron(III) ion was about 10^{19} atom/m^2, surface coverages of adsorbed water and oxygen (tentatively presumed as dissociative adsorption) on the Fe_2O_3 sample after the treatment D were calculated to be 3.5 and 6.0%, respectively. Similarly, those for the NiO sample after the treatment B were 1.4 and 5.0%. Provided that all of the adsorbates are dispersed uniformly on the oxide surface, these values are too small for each adsorbate to interact with a neighboring another kind of adsorbate. So that it seems more likely that both species are adsorbed together onto some surface defects.

In the case of CuO, chromatogram of oxygen changed slightly by the preadsorption of water vapor with broadning of peak and shift of T_m to higher temperature by 25 K (curve 2 in Fig. 4).

Although most of surface hydroxyl may be desorbed

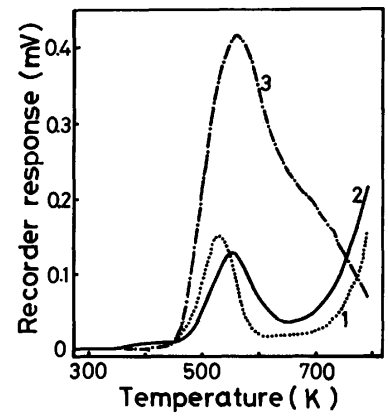

Fig. 4. TPD chromatograms from CuO.
1: Oxygen, treatment C, 2: oxygen, treatment D, 3: water, treatment D.

at higher reaction temperatures, a significant amount of surface hydroxyl may remain on the surface and modify the activity of oxygen adsorbate in the catalytic oxidation performed at moderate reaction temperatures. These phenomena may partly explain the promotion effect of water vapor in the catalytic oxidation of organic compounds.

Experimental

NiO, Fe_2O_3, and CuO were prepared by the thermal decomposition of $NiCO_3 \cdot 2Ni(OH)_2$, $Fe(NO_3)_2 \cdot 9H_2O$, and $CuCO_3 \cdot Cu(OH)_2 \cdot H_2O$ (Wako Pure Chem. Ind.) at 673 K for 4 h, followed by calcination at 823 K for 4 h in air. TPD apparatus used here was basically the same as that described in the literature.[11] Desorption chromatograms of water were obtained from the difference of the chromatograms recorded with two thermal conductivity detectors located at upper and at lower stream of the cold trap at 77 K for the removal of water vapor. The detector downstream gave chromatograms of oxygen.

UV and Visible Fluorescences of CF_3 Radicals Produced by the Two-photon Decomposition of CF_3Br and Their Radiative Lifetimes

Nobuaki WASHIDA,* Osamu HORIE,† and Karl H. BECKER†

Division of Atmospheric Environment, The National Institute for Environmental Studies, P. O. Tsukuba-gakuen, Ibaraki 305

†*Physikalische Chemie, FB9, Bergische Universität-gesamthochschule Wuppertal, Gaussstrasse 20, D-5600 Wuppertal, Federal Republic of Germany*

(Received December 5, 1984)

Synopsis. The UV and visible emission bands of the CF_3 radical were observed in the two-photon decomposition of CF_3Br using KrF excimer laser (248 nm) radiation. Very short radiative lifetimes (shorter than 40 and 50 ns for the UV and visible bands, respectively) were obtained.

Knowledge of the excited states of the CF_3 radical is important in both semiconductor-device fabrication[1] and regarding ozone depletion in the stratosphere.[2] Two emission bands of CF_3 radicals were observed in the UV (170—320 nm) and visible (400—750 nm) regions by the VUV (100—140 nm) photolysis of CF_3X molecules (X=H, Cl, Br) recently.[3] In the present study, the observation of the UV and visible emissions of CF_3, produced by the two-photon decomposition of CF_3Br, were investigated using KrF excimer laser light (248 nm). Also, measurements of the radiative lifetimes of both emission bands were attempted. Since both UV and visible emission bands of CF_3 were observed in the photolysis of CF_3Br by the Kr resonance line (123.6 nm) in the previous study, these emission bands can be produced by the two-photon photodecomposition of CF_3Br by the KrF excimer laser (248 nm).

$$CF_3Br + 2h\nu(248\text{ nm}) \longrightarrow CF_3^* + Br \qquad (1)$$

Further, if the radiative lifetimes of both bands are longer than the experimental response, these values can be obtained directly using a laser pulse.

The KrF excimer laser (Lamda Physik EMG 102) beam was focussed in a stainless steel fluorescence cell through a quartz lens. The emission was collected at a right angle to the laser beam (using an optical system consisting of three quartz lenses) and was dispersed with a 0.35-m monochromator (McPherson Model 270). Since fluorescence was measured in the UV and visible regions, two gratings (1200 grooves/mm) blazed at 250 and 500 nm were used. A glass filter (Schott Glaswerke, GG 475, transmission longer than 470 nm) was used in the measurement of the visible emission spectrum. Fluorescence signals were detected with a photomultiplier (EMI 9635 and 9558B for UV and visible, respectively) and processed by a boxcar integrator (PAR 162).

When laser light was focussed through a quartz lens in the CF_3Br gas, a very bright-yellow emission was visible from the cell. The measured UV emission band is shown in Fig. 1a. The pressure of CF_3Br in the cell was kept at 133 Pa and the gas was slowly pumped using a rotary pump. The discrete emission band observed in the region of 200—225 nm corresponds to the UV emission band of CF_3.[3] The spectral profile is quite similar to that observed previously and separations of the characteristic progression (shown by arrows, 1000—1050 cm^{-1}), correspond to the ν_1 mode of CF_3.[3] The emission appearing at 193 nm should originate from the resonance fluorescence of the excited carbon atoms,[4] $C(3^1P^0 \xrightarrow{193\text{ nm}} 2^1D)$, after the resonance absorption from $C(^1S)$, $C(3^1P^0 \xleftarrow{248\text{ nm}} 2^1S)$. The excited carbon atom, $C(^1S)$, might be produced during the multi-photon decomposition of CF_3Br. The strong emission band (starting at 220 nm) corresponds to the $CF(A^2\Sigma \rightarrow X^2\Pi)$ system.[5] Essentially, the UV emission band of CF_3 should extend to 300 nm, having a maximum at 240 nm. In the present experimental system, however, the emission band of the $CF(A \rightarrow X)$ system was too strong and the UV band of CF_3 can be identified only in the region from 200 to 220 nm. The strong emission band of the $CF_2(^1B_1 \rightarrow {}^1A_1)$ system was observed in the region from 250 to 350 nm and an unidentified strong emission band was present up to 450 nm.

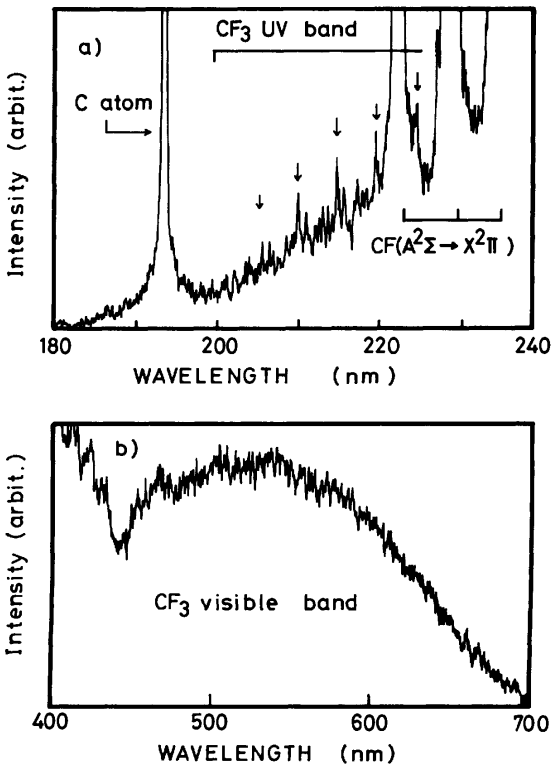

Fig. 1. Emission spectra of the UV (a) and visible (b) bands of CF_3 produced in the two-photon decomposition of CF_3Br by the KrF excimer laser (248 nm) radiation.

The observed visible emission-band spectrum is

shown in Fig. 1b. The continuous emission band (devoid of structure) in the region from 450 to 700 nm is also the same as that observed previously.[3] Since both UV and visible bands were observed, a two-photon decomposition of CF_3Br occured by Reaction (1), although other excited species (such as C, CF, and CF_2) were produced in this system.

The measurements of the radiative lifetimes were carried out at 210 nm for UV and 600 nm for the visible band (under 1 nm of spectral resolution). Fluorescence signals detected by photomultipliers were digitized by a transient digitizer (Tektronix R7912, 1 ns of time resolution) and processed by a minicomputer (DEC, LSI 11). Since the pulse of the KrF laser was 16 ns (fwhm) and the time response of the photomultipliers was about 25 ns (fwhm), radiative lifetimes could be obtained if the lifetime was longer than 50 ns (reliable value should be longer than 100 ns). The apparent radiative lifetimes measured at 27—667 Pa of CF_3Br were 30—40 ns for the UV band and 40—50 ns for the visible band. These lifetime values are shorter than the reliable instrumental time response. Therefore, it is concluded that radiative lifetimes for the UV and visible bands are shorter than 40 and 50 ns, respectively. No significant pressure dependence of the lifetime was observed for both measurements.

Very short radiative lifetimes were obtained for UV and visible band emissions of CF_3. Results are reasonable for the allowed transition of a polyatomic molecule. Using theoretical calculations[3] regarding the CF_3 electronic states, the UV band has been tentatively assigned to a Rydberg state (D_{3h} structure) emitting to the ground state ($2A'_1 \rightarrow 1A''_2$), while the visible band is thought, based on emission quenching experiments, to arise from transitions from the 1E' and/or $2A_2''$ Rydberg states (D_{3h}) to a repulsive state ($1A_1'$). The fluorescence quantum yields of the UV and visible band from the photolysis of CF_3Br at 124 nm were determined to be 1 and 5%, respectively.[3] It is possible that the predissociation occurs in both the upper states by the coupling of the potential curves of the lower electronic states. Short radiative lifetimes were obtained.

Recently, lifetime measurements regarding the UV and visible emission bands of CF_3 were carried out by two groups using synchrotron-radiation tequniques[6] and pulsed VUV laser (121 nm) radiation.[7] The former obtained fluorescence lifetimes of 14—17 ns for both the UV and visible bands and the later gave those of 15±3 and 18±3 ns for the UV- and the visible-band emissions, respectively.

Decomposition of Solid Potassium Nitrate by Incident 100 keV Ions†

Katsutoshi FURUKAWA and Shin-ichi OHNO*
Department of Chemistry, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11
(Received January 16, 1985)

Synopsis. Potassium nitrate was bombarded at 100 keV energy with ion beams extracted from a discharge of D_2, He, N_2, and O_2, and the yield for the formation of nitrite ion was determined: $G(NO_2^-)$=1.8, 1.8, 0.5, and 0.5, respectively. The results suggest that the reaction takes place *via* electronic excitations.

Whereas a lot is known about chemical reaction induced by ionizing radiations, very little information exists about chemical reaction induced by energetic particles having energies of 1 to 100 keV. Ions at keV energies have been used to initiate chemical reactions in gaseous methanol,[2,3] crystalline nitrate,[4] and condensed simple gases (H_2O, CH_4, CO).[5,6] The results in these low energy ion-impact experiments were interpreted as due to elastic collisions of incident ion with atoms leading to atomic displacements in the target molecules. Ions at higher energies lose energy more and more in inelastic collisions leading to electronic excitations of the molecule. Puglisi *et al.*, thus, studied chemical effects of elastic and inelastic collisions of 15—100 keV ions with benzene.[7]

In the present work, 100 keV ions were used to initiate the decomposition of potassium nitrate. Potassium nitrate was chosen because its radiolytic behavior toward ionizing radiations was well known: The only radiolytic products reported are nitrite ions and oxygen. The objectives of this work were to obtain the nitrite ion yields for 100 keV ions and to see the effect of the nature of bombarding ions on the decomposition yield.

Experimental

The sample to be irradiated was about 80 mg of polycrystalline potassium nitrate (Koso Chemical Co., Inc, Analytical Grade), pressed into a disk of the diameter of 10 mm, and mounted onto the sample holder by means of clamps. It was irradiated at ambient temperature in vacuum (*ca.* 10^{-5} Pa) with energetic ions. Ions were produced by discharge of D_2, He, N_2, and O_2 in a radio-frequency source,[8] extracted and accelerated at desired energies and were focussed through an aperture of 8 mmϕ onto the sample. The current density of the ion beam was measured by a Faraday cage and was 10 μA cm^{-2} throughout this work. Composition of the ionic species from each gas was analyzed magnetically; *i.e.*, D_2: D^+ (47%), D_2^+ (19%), and D_3^+ (34%); He: He^+ (99%); N_2: N^++N_2^{2+} (6%), N_2^+ (94%); and O_2: O^+ (17%), O_2^+ (82%), and O_3^+ (1%).

After irradiations, the samples were dissolved in water and the concentration of nitrite ions produced was determined spectrophotometrically[9] by adding 1-naphthylamine and sulfanilic acid. The molar absorption coefficient used was 35000 mol^{-1} dm^3 cm^{-1} at 520 nm.

†Chemical Reactions Induced by Energetic Particles. II.[1]

Results and Discussion

The yields of nitrite ion as a function of incident ion dose are shown in Fig. 1 for the bombardment with 100 keV ions. The rapid initial decomposition is followed by a decline in rate. At lower bombarding energies, *e.g.* 20, 50, and 80 keV, somewhat lower values for the initial yield were obtained, though the shape of the yield-dose curves remained unchanged.

From the initial slope of the curves in Fig. 1, the *G*-value for the formation of nitrite ions per 100 eV of the energy absorbed may be calculated. The results are included in Table 1, together with the $G(NO_2^-)$'s reported in the literature for other radiation sources.

On the other hand, we have calculated the electronic (S_e) and nuclear (S_n) stopping power of KNO_3 for these 100 keV ions according to the method of Lindhard *et al.*[10-12] The ratio S_e/S_n gives a relative amount of electronic and nuclear (elastic) energy deposition. Some relevant values of $S_e/(S_e+S_n)$ are included in Table 2. There may be seen a correlation between $G(NO_2^-)$ value and $S_e/(S_e+S_n)$ value. It should be remembered that ionizing radiations, *e.g.* α, β,

TABLE 1. COMPARISON OF $G(NO_2^-)$ FROM KNO_3 OBTAINED BY VARIOUS RADIATIONS.

i) This work (100 keV)

D^+,D_2^+,D_3^+	He^+	N_2^+	O^+,O_2^+
1.8±0.2	1.8±0.2	0.5±0.1	0.5±0.2

ii) Literature values

10 keV He^+	3.4 MeV α	1.5 MeV e^-	^{60}Co γ
1.54[4]	2.2[13]	1.48[14]	1.46[15]

Table 2. Some values of $S_e/(S_e+S_n)$ for the ions traversing KNO_3.

Energy/keV	Ion			
	D^+	He^+	N^+	O^+
100	1.0	0.99	—	—
50	0.99	0.97	0.67	0.58
20	0.98	0.91	0.42	0.39

*) It is assumed that a molecular ion traversing a solid decomposes into atomic fragments. Thus, in the calculation of stopping power, a 100 keV-N_2^+ ion, for example, is regarded as two 50 keV-N^+ ions.

and γ rays and protons, lose most of their energy by electronic excitations. Thus, it may be concluded that the energetic ion-induced decomposition of nitrate leading to the formation of nitrite is mainly through electronic excitations.

Moreover, it is interesting to compare the yield-dose curve for oxygen-ion bombardment with that for nitrogen-ion bombardment. As the concentration of oxygen increases due to implantation, the yield for nitrite ion diminishes. This fact suggests that a nitrate ion-reforming reaction from nitrite ion and oxygen-containing species take place:[13]

$$NO_2^- + 1/2\,O_2(O, O^+, O^-, O_2^-, \text{or } O_3) \longrightarrow NO_3^- \quad (1)$$

The yield-dose curve for deuterium ion should be compared to that for helium ion. The difference in yield at higher doses (shown in Fig. 1) may be ascribed to the elimination of the oxygen-containing species (Reaction 1) by the implanted deuterium ion.

In conclusion, it was found that electronic excitations play an important role in ion-induced decomposition of potassium nitrate and that the effect of different bombarding ion is to accelerate or decelerate the nitrate reforming thermal reaction.

Phosphorescence from Biacetyl and Benzophenone Surfaces by Collision with the T_1 State of Benzene

Shigeru OHSHIMA,† Tamotsu KONDOW,* and Kozo KUCHITSU

Synopsis. Benzene molecules in the lowest-excited triplet state, T_1, were allowed to collide with biacetyl and benzophenone surfaces, and phosphorescence from the surface due to energy transfer from the T_1 state of benzene was observed. The possibility of application of this method to detection of metastable species is discussed.

The T_1 state of benzene (3.5 eV [1]) is known to transmit its excitation energy efficiently to the T_1 state of biacetyl in the gas phase causing phosphorescence [2]. The quantum yields of gas-phase phosphorescence are reported to be 0.23 and 0.9, and the energies of the T_1 states are 2.53 and 3.0 eV for biacetyl [3] and benzophenone [4], respectively. This phenomenon can be extended to a gas-solid system by use of a phosphor surface, instead of a phosphor gas, as an energy acceptor. Since such an energy transfer occurs exclusively on the surface and is expected to depend on the spin multiplicity, observation of phosphorescence from the surface has potential applicability, for example, to detection of low-lying metastable states. In the present note, we report observation of phosphorescence from biacetyl and benzophenone surfaces in collision with metastable benzene molecules.
